The transformation of the *tripod* ligands **3** and **4**, which bear a CH_2OH group at the backbone, into the corresponding methyl ethers **5** and **6** followed the standard protocol (Scheme 2).[3i,7] None of the difficulties often observed in the etherification of analogous *tripod* ligands containing either three different P donors or P donors and Cp derived donor functions were encountered.[3i,4d,8] Analytical data of **5** and **6** are given in the Exp. Sect. and Tables 10, 12, and 14.

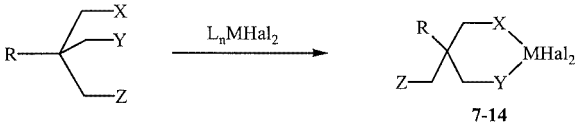
6a	PPh_2	pz	pz
6b	$PMes_2$	pz	pz

Scheme 2. Synthesis of *tripod* ligands **5** and **6**

Coordination Chemistry

Coordination derivatives, in which compounds **5** and **6** bind to $MHal_2$ (M = Ni^{II}, Pd^{II}, Pt^{II}) as bidentate ligands, are obtained by standard procedures (see Exp. Sect.), in some cases as single crystals suitable for X-ray analysis (Scheme 3, Table 1).



Scheme 3. Synthesis of coordination compounds **7**–**14**

Crystal structure analyses of metal complexes derived from the ligand **5a** were performed for compounds **7a**, **8**, and **9a** (Tables 2–4, 7, and Figures 1 and 2). All these compounds show a square-planar coordination around the metal centre. Ligand **5a** is observed to coordinate via its two PPh_2 donor groups exclusively while the pyrazole donor remains uncoordinated. The six-membered chelate cycle thus formed shows a half-chair conformation for **7a**, **8**, and **9a**. Figure 1 shows two examples. Within the chelate cycles showing a half-chair conformation (**7a/1**, **8**, **9a**) the CH_2OMe group occupies the axial position, with the more bulky CH_2pz group in the equatorial position throughout.

For **7a** two different crystal forms were obtained: one (**7a/1**·CH_2Cl_2) contains molecules with the chelate cycle in a half-chair conformation as well, and the other one (**7a/2**·0.5CH_2Cl_2) contains molecules in which the chelate cycle has a twist-boat conformation, showing that different conformations are accessible to the chelate cycles (Figure 2). These findings agree well with observations made on the chelate cycles in $[\{\kappa^2P\text{-}R_2PCH_2CH(OH)CH_2PR'_2\}Rh(\eta^4\text{-}cod)]^+PF_6^-$. For this type of diphosphane-containing chelate cycle a thorough analysis of the conformation hypersurface[9] as well as of the NMR dynamics[7,10] revealed a small energy difference between half-chair and twist-boat conformations of the chelate cycle. This agrees well with the fact that **7a** forms two different types of ring conformation in its crystals under standard crystallization conditions.

Ligands containing one phosphane and two pyrazole N donors are found to coordinate to nickel(II) by one phosphorus and one nitrogen donor (**11a**, **11c**, see Table 1) or by two pyrazole donors with the CH_2PR_2 group playing the

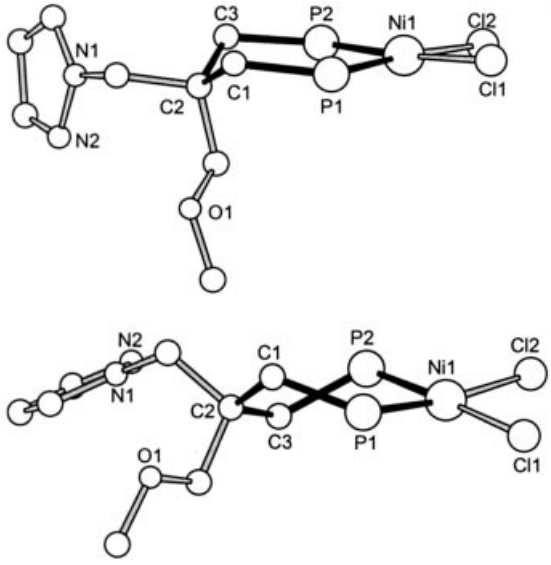

Figure 2. X-ray structure (without phenyl groups) of compound **7a/1** (top, half-chair conformation) and **7a/2** (bottom, twist-boat conformation)

role of a dangling arm (**13**, see Table 1). Figure 3 shows examples of the two coordination modes (*P*,*N* versus *N*,*N*). In addition to the ligands **6a** and **6b** two other *tripod* ligands containing a pz,pz donor set were used. Thus compounds **11c** and **14** (Table 1) are derived from ligands reported earlier.[5e] In each case the coordination geometry around nickel(II) is tetrahedral. Compounds **11a**−**c**, **13**, and **14** are paramagnetic − in contrast to compounds **7** and **8** with their square-planar nickel coordination.

Analytically pure **14** with its *tripod* ligand $CH_3C(CH_2pz)_3$[5e] crystallized as a conglomerate of different crystal forms, most of which were blue. Their structure corresponds to a tetrahedral coordination of the nickel atom as evidenced by crystallography (**14**, see Tables 1−4, 8). A few crystals were red-brown. Their quality was, however, insufficient for X-ray analysis. It is assumed that the difference in colour of these crystals is due to differing kinds of coordination, probably involving the formation of dinuclear entities with bromide acting as a bridging ligand. Thus, different chelate compounds containing $NiBr_2$ groups

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

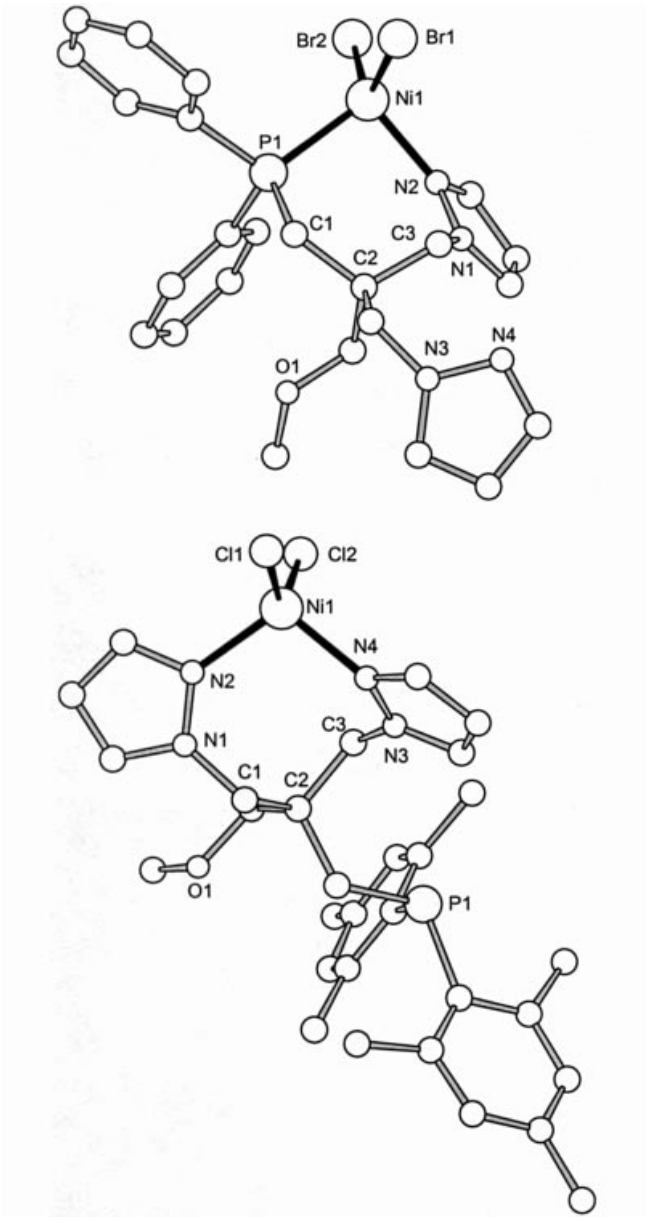

Figure 3. X-ray structure of compound **11a** (top) and **13** (bottom)

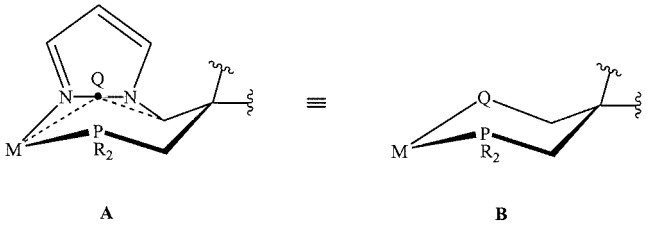
were prepared (**8**, **11a**, **11c**) in addition to **14**. The phenomenon could not be observed for **8** or **11a**. With **11c**, however, crystallization yielded violet crystals containing the tetrahedrally coordinated monomeric compound (analogous to **11a** depicted in Figure 3) and red-brown crystals containing the dinuclear species **15** (Figure 4). Both kinds of crystals were suitable for X-ray analysis. The nickel centres in **15** show idealized square-pyramidal coordination ($\tau = 0.16$, see Figure 4).[11]

With palladium(II) as the central metal ligand **6a** acts as a P,N ligand resulting in **12** (Table 1). However, the coordination around the palladium(II) atom is square-planar (Figure 5), in contrast to the tetrahedral coordination of nickel(II) (**11**) by the same ligand arrangement.

With each pyrazole group replacing a one-atom donor group (e.g. PR_2) of a six-membered chelate cycle, the number of atoms within the cycle increases by one, such that *P*,*N*-coordinated compounds (**11**, **12**) have seven-membered chelate cycles and *N*,*N*-coordinated compounds (**13**, **14**) contain eight-membered chelate cycles. Because the pyrazole ligands are coplanar with their substituents − with the carbon atom bonded to one of its nitrogen centres and the metal atom coordinated to the other − the conformation of the chelate cycles may be characterized by an idealized graph with a pseudo corner (Q) at the centre of the pyrazole N−N bond (Scheme 4).



Scheme 4. Idealized graph for chelate cycles containing pyrazole donors: **A**: original; **B**: idealization

This kind of idealization reduces the pyrazole-containing chelate cycles to six-membered cycles (**B**, Scheme 4), even though they actually have seven or eight atoms within the cycle (**A**, Scheme 4) . The observed conformations may therefore be characterized in the same way as for six-membered cycles.

Table 2 indicates the conformation of the chelate cycles observed in each case. The difference between the two classes − (i) twist-boat and (ii) chair or half-chair − is most clearly evident from the pseudo torsion angle 3−2−6−5 (Table 2). Chair or half-chair conformations have 2−3 and 6−5 bonds that are almost parallel. The respective torsion angles are close to zero (deviation from −1.9 to +12.9°, see Table 2). For twist-boat conformations these bonds cannot be parallel, of course, and the corresponding torsion angles are between 44.3 and 67.0° (for absolute values, see Table 2). These two classes are, of course, also differentiated by the sequence of sign changes of the torsion angles around the cycles (columns M−2−3−4 to 6−M−2−3 in Table 2). The different types of conformation listed in Table 2 do obviously not reflect the either square-planar or tetrahedral coordination of the metal centre since the same types of conformations are found for both coordination modes.

Table 3 shows that the nickel−ligand distances respond significantly to the kind of coordination. Ni−P distances of ca. 217 pm are found for compounds showing a square-planar coordination of the nickel atom (Table 3) and of ca. 230 pm for tetrahedrally coordinated nickel compounds (Table 3). Ni−N distances have only been measured for compounds with tetrahedrally coordinated nickel atoms, and are 198 pm, within a few standard deviations, in each case (Table 3). As expected, all nickel compounds that contain at least one nitrogen donor in their chelate cycle show tetrahedral nickel coordination. The Ni−Cl and Ni−Br distances are around 221 and 236 pm, respectively (Table 3),

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

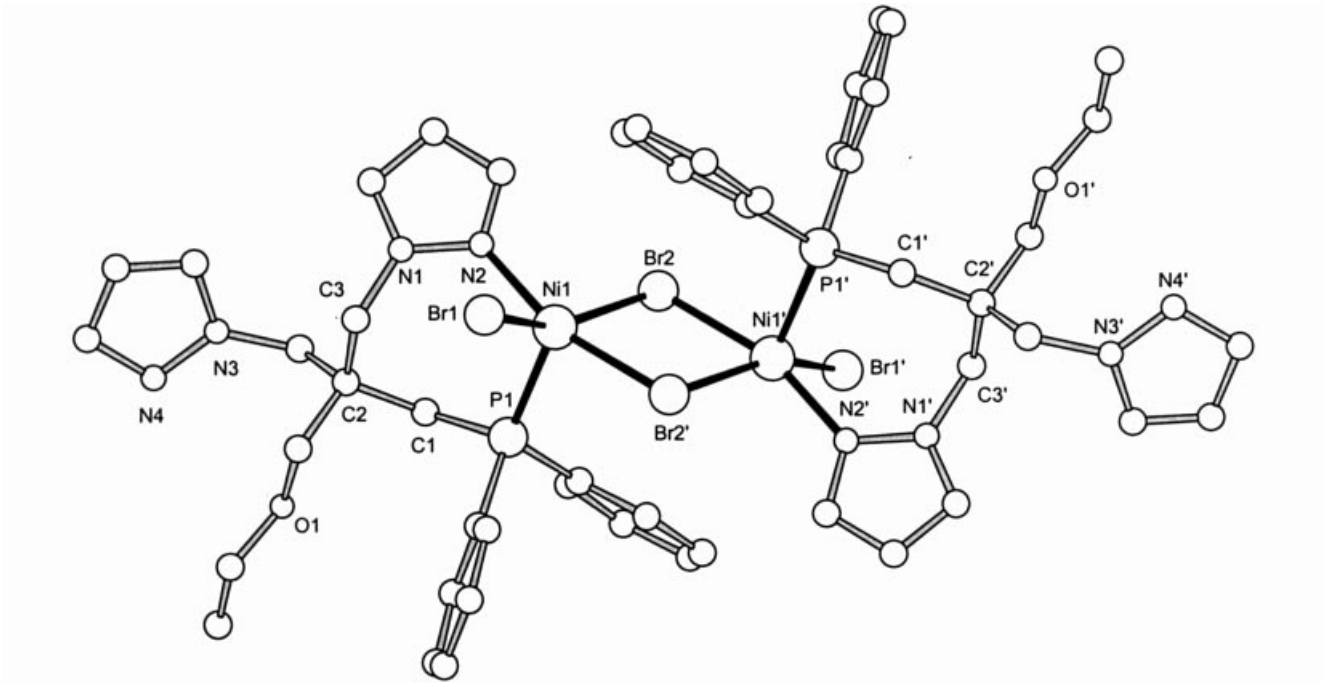


Figure 4. X-ray structure of the dinuclear nickel compound **15**; the compound is of crystallographic C_i symmetry

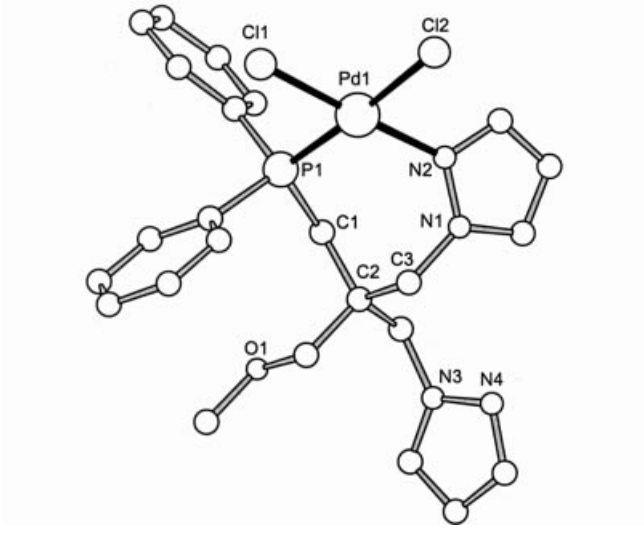

Figure 5. X-ray structure of compound **12**

with no detectable influence due to the kind of coordination geometry.

Compounds **9a** and **12** contain the palladium atom in a square-planar coordination with the chelate ligand coordinating via one N and one P donor (**12**). In **12** the Pd−Cl distances (Table 3) are influenced by their *trans* ligands, with the bond *trans* to the nitrogen donor [228.2(1) pm] being significantly shorter than that *trans* to the phosphorus donor [235.6(1) pm].

The Ni−P distance of the dinuclear compound **15** is 235.9 pm (Table 3, Figure 4), which is even longer than the Ni−P distances in compounds containing tetrahedrally coordinated nickel atoms. This corresponds to the apical position of the phosphorus donor in **15** (Figure 4). The Ni−Br distances are also longer than the Ni−Br distances observed in **8**, **11**, or **14** (Table 3). The shortest Ni−Br distance of **15** (245 pm) corresponds to the terminal Ni−Br bond. The bridging Ni−Br distances are still around 8 pm longer than this (Table 3). Consequently, all bonds are weakened by changing from tetra-coordination (**8**, **11**, and **14**) to penta-coordination (**15**). The fact that the monomeric arrangement in **11c** and the dimeric arrangement of the same compound in **15** are of almost equal energy is indicated by their co-crystallization as a conglomerate in the same experiment. The solubility of **11c** in CH_2Cl_2 is higher than that of **15**, such that attempts to dissolve red-brown **15** in CH_2Cl_2 led to violet solutions (Table 1) of **11c**.

The angles at the metal centre are in the ranges expected for square-planar and tetrahedral coordination (Table 4). In square-planar compounds the angles subtended by the coordinating atoms of the chelate ligands are somewhat larger than the ideal value of 90° (Table 4). For the tetrahedrally coordinated compounds these angles are smaller than expected for an ideal tetrahedron (109.4°, see Table 4). Deviation from this ideal value is greater for a P,N donor set (**11** and **12**, see Table 4) than for an N,N donor set (**13** and **14**, see Table 4).

NMR Dynamics

It is well known that L_2NiHal_2 (L = aryl phosphane) − even if square-planar in the solid state − may suffer distortions to tetrahedral arrangements at room temperature in solution such that no ^{31}P NMR signals are observed.[12]

When crystalline **7a**, which consists of crystals with the ligand in the chair conformation (**7a/1**) and crystals in twist-boat conformation (**7a/2**), is dissolved in CH_2Cl_2 no ^{31}P NMR signals are observed at room temperature. At −40°C a single sharp resonance is apparent, which broadens upon lowering the temperature further and gradually

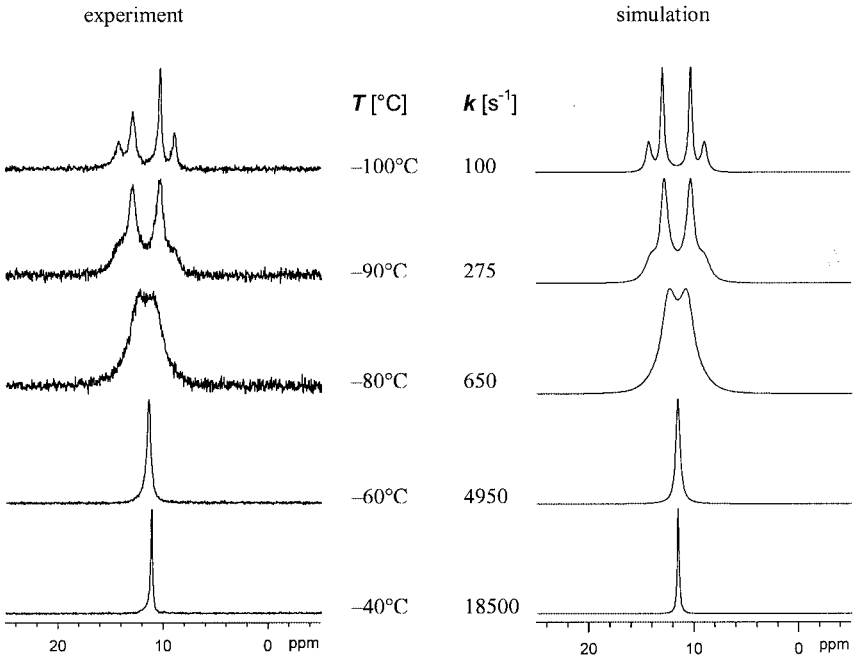

Figure 6. δ/λ isomerisation of **7a**; temperature dependence of the ^{31}P NMR spectra (81 MHz) of **7a** in CH_2Cl_2; experiment, simulation, and rate constants

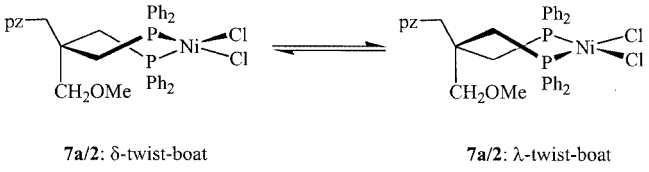
evolves into a pattern corresponding to two doublets with a coupling constant of $^2J_{PP}$ = 108 Hz (Figure 6). The underlying process is interpreted in terms of a δ/λ isomerisation of the chelate cycle (Scheme 5).



7a/2: δ-twist-boat **7a/2**: λ-twist-boat

Scheme 5. δ/λ isomerisation of the chelate cycle in **7a/2**

Due to the chiral conformation of the chelate cycle the two phosphorus nuclei within the cycle in a twist conformation are no longer equivalent. A pattern of two doublets is therefore expected for the ^{31}P NMR spectrum. The observed temperature dependence of the ^{31}P NMR spectra of **7a** can be neatly simulated[13] on the hypothesis of equilibrating δ- and λ-forms of the chelate cycle. Even though **7a** has also been obtained as crystals containing the chelate cycle in a chair conformation (**7a/1**) this conformation is not observed by NMR (temperature range below −40°C), which means that in solution the chair conformation has a higher energy than the twist-boat conformation. Figure 6 shows a comparison of the observed and the simulated ^{31}P NMR spectra of **7a**.

The rate constants for the δ/λ isomerisation of **7a** (Figure 6) give a linear Eyring plot with $\Delta G^{\neq}_{298}$ = 40.2±0.5 kJ/mol, $\Delta H^{\neq}$ = 28.1±0.9 kJ/mol and $\Delta S^{\neq}$ = −40.7±5.0 J/mol K. The coalescence temperature is 200 K (81.015 MHz), which results in $\Delta G^{\neq}_{200}$ = 37.0±0.8 kJ/mol, in fair agreement with the value taken from Eyring plot analysis ($\Delta G^{\neq}_{200}$ = 37.6±0.5 kJ/mol). The activation parameters for analogous processes, involving six-membered chelate cycles containing two phosphorus donors and a rhodium(I) centre, have recently been analysed in detail.[10] The activation enthalpies are somewhat higher (around 60 kJ/mol). The activation entropies are negative throughout, around −35 J/mol K. The ^{31}P NMR pattern observed for these rhodium chelate compounds is thus − mutatis mutandis − the same as the one observed for **7a**.[10] The main difference being that the ligands in the rhodium compounds are chiral while the ligand in **7a** is not.

Nickel compounds **7b** and **7c** contain two different PR_2 groups in the chelate cycle and their ligands are therefore chiral (Table 1). It was not possible to obtain crystals suitable for X-ray analysis of these compounds. With **7b** containing a PPh_2 donor and a P(*m*-Tol)$_2$ donor the limit of slow exchange could not be reached experimentally at the lowest achievable temperature in CH_2Cl_2 (−100°C for **7b**). With the more bulky $PMes_2$ donor group in the chelate cycle of **7c** (Table 1) a ^{31}P NMR spectrum close to the slow exchange limit was evident at −90°C. The solution could be undercooled to −110°C, at which point the slow exchange limit was reached. Above 0°C, where the high temperature limit is not yet reached, paramagnetic broadening starts to obscure individual resonances.

Throughout the temperature range −30 to −110°C a pattern with two doublets ($^2J_{PP}$ = 95 Hz) persists. A second structure, which appears as a broad singlet at −30°C, evolves into a pattern composed of a pair of two doublets with coupling constants of $^2J_{PP}$ = 98 and 101 Hz (Figure 7). This type of pattern is typical for the twist-boat conformation of a chiral chelate cycle.[10] The two doublets, which do not significantly change their appearance between

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

−30°C and −110°C (signals at the left- and right-hand side of the spectrum depicted in Figure 7), are ascribed to the chair conformation of the chelate cycle, which is in only slow exchange with the twist-boat conformation, such that the appearance of the signals is not affected by exchange processes (Scheme 6). The thermodynamic stability of the chair and the twist-boat forms of the chelate cycle is different: the signals corresponding to the chair conformation have a 4:1 integral ratio to the signals corresponding to the twist-boat conformation at −30°C, while this ratio is only 3:2 at −110°C.

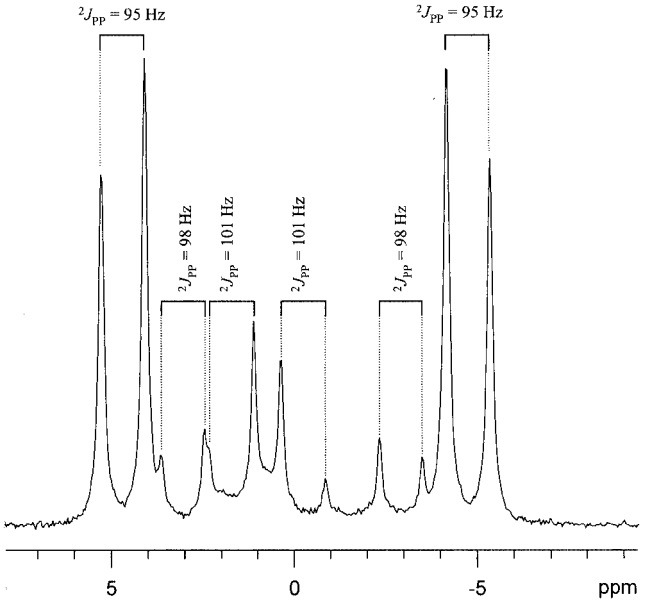


Figure 7. ^{31}P NMR spectrum of **7c** in CH_2Cl_2 at −110°C

The NMR data of **7b**−**7d** also clearly show that the ligands **5b**−**5d** bind by two phosphorus donors, with the CH_2pz group serving as a dangling arm. The structures of **7b**−**7d** are thus analogous to that of **7a** (Figure 2), which is known from crystallography (Tables 1−4). Interestingly, when the potential *tripod* ligands contain two pyrazole donors and one PR_2 donor (**6a**, **6b**) the preference for *P* coordination versus *N* coordination appears to depend on the bulkiness of the PR_2 ligand. While ligands containing one PPh_2 and two pyrazole donors show *P,N* coordination exclusively (**11a**, **11c**, **12**, **15**), ligand **6b** with a $PMes_2$,pz,pz donor set coordinates via the two pyrazole functions, with the CH_2PMes_2 group serving as a dangling arm in **13** (tetrahedral coordination). In **7c** where ligand **5c** offers a PPh_2, a $PMes_2$, and a pyrazole donor set the two phosphorus donors are bonded exclusively with the CH_2pz function playing the role of a dangling arm (square-planar coordination).

Temperature-dependent $^1H\{^{31}P\}$ NMR spectra of the palladium compound **12** (Figure 5) reveal a different type of dynamic exchange different to those already described. While the ^{31}P NMR signal of **12** is a singlet in the range −80 to 120°C the appearance of the proton spectrum changes drastically (Figure 8).

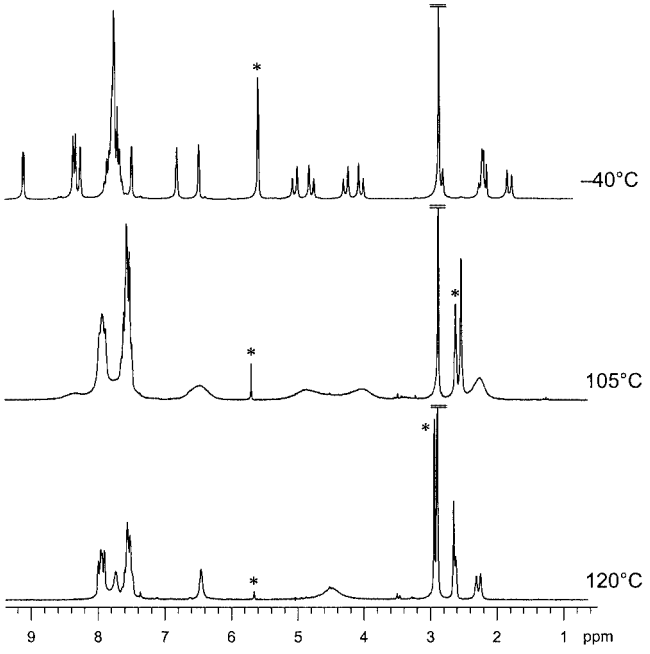

Figure 8. Variable-temperature $^1H\{^{31}P\}$ NMR spectra (200 MHz) of **12**; dynamic exchange is clearly apparent at δ ≈ 4.5 ppm and δ ≈ 6.5 ppm; spectra at 105 and 120°C were recorded in DMSO as solvent; at lower temperatures the solvent was CH_2Cl_2; asterisks designate solvent peaks

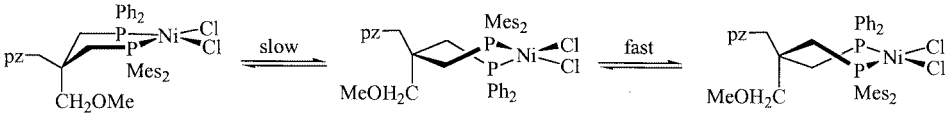
At −40°C a pattern of sharp signals is clearly evident, with all the resonances expected for **12** (Figure 8, Table 11). The signals corresponding to the coordinated CH_2pz arm and the noncoordinated one are clearly separated. The resonances of the coordinated pyrazole group are shifted downfield significantly (δ = 6.64, 8.98, 8.11), in contrast to the noncoordinated one (δ = 6.30, 7.33, 7.60). The methylene protons of the CH_2pz groups give rise to two doublets at δ = 3.79 and 4.02 ppm (noncoordinated) and 4.56 and 4.82 (coordinated), with similar coupling constants of about $^2J_{HH}$ = 14.5 Hz. At higher temperatures the corresponding signals coalesce. From the protons of the pyrazole groups (Table 11) only H4 (Scheme 13, Exp. Sect.) gives rise to a signal, which does not overlap with the signals of aromatic protons over the whole temperature range. Coalescence of signals of H4 for the coordinated and noncoordinated pro-



7c/1: half-chair **7c/2**: δ-twist-boat **7c/2**: λ-twist-boat

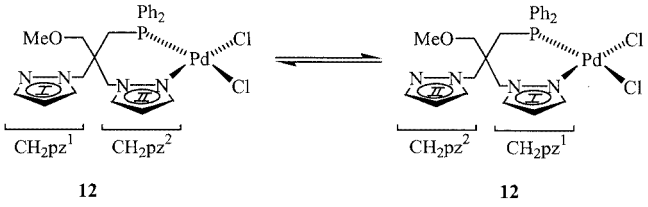
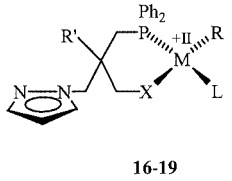
ton occurs at 105°C (k_c = 350 s^{-1}), corresponding to $\Delta G^{\neq}_{378}$ = 77.5±0.8 kJ/mol. The signals of the methylene group of the CH_2pz functions (coordinated and noncoordinated) are free from overlap with other signals over the whole temperature range. Coalescence is observed at 120°C (k_c = 150 s^{-1}), corresponding to $\Delta G^{\neq}_{403}$ = 80.0±0.8 kJ/mol. This kind of exchange phenomenon (Scheme 7) has not yet been observed for potential *tripod* ligands containing a P,N,N donor set.[5b]



Scheme 7. Dynamic exchange of the coordinated and noncoordinated CH_2pz function of **12** at higher temperatures

Substitution Products

All compounds **7**−**14** (Table 1) contain the chelate ligands bonded to an $MHal_2$ entity. Even though the metal−halide bond lengths are independent of the type of chelate ligand within each set of compounds (square-planar, tetrahedral, see Table 3), exchange of the halide ligands by other functions might well influence the binding mode of the chelate ligand. To analyse this potential influence derivatives **16**−**19** (Scheme 8, Table 5) were synthesized in which one or both of the halide functions are replaced by organic substituents.



Scheme 8. General structure of **16**−**19**

Compound **7a**, after activation with $TlPF_6$, reacts with C_3H_5MgBr to produce **16a·PF$_6$** in which the phosphorus donors of the chelate cycle are *trans* to an η^3-coordinated allylic system (Scheme 9). The palladium compound **16b·PF$_6$** was obtained by treating $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ with the ligand $EtOCH_2C(CH_2PPh_2)(CH_2pz)_2$[5e] and with KPF_6 as the halide-abstracting reagent (Scheme 9).

Direct, selective substitution of just one halide function in compounds of the type $[(chelate)M^{II}Hal_2]$ was, however, not successful. Substitution products $[(chelate)M^{II}RHal]$ were synthesized by starting from $[L_2M^{II}RHal]$ [L_2 = cod, $(PPh_3)_2$] by reaction with the *tripod* ligands.

Compound **17** was obtained from [*trans*-$(PPh_3)_2$Ni(Mes)Br] using **5a** as the chelating agent (Scheme 10).

Similarly, the palladium compound **18** was obtained by the reaction of [(η^4-cod)PdClMe] with **5a** (Scheme 11).

The structures of compounds **16a·PF$_6$**, **16b·PF$_6$**, and **18** (Figure 9, Tables 6 and 9) were analysed by crystallography. Suitable single crystals could not be obtained for **17**.

When, instead of **5a**, ligand **6a** − with its two pyrazole functions − was treated with [*trans*-$(PPh_3)_2$Ni(Mes)Br] the formation of **6a·Ni(Br)Mes** as an analogue of **17** (Scheme 10) was indicated by its ^{31}P NMR spectrum (a sin-

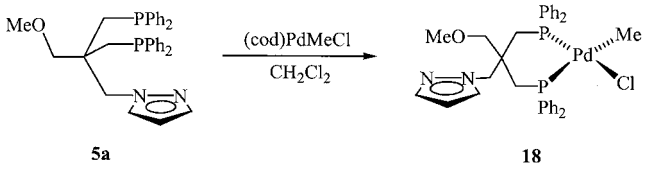

Scheme 11. Synthesis of compound **18**

glet at δ = 11.8 ppm). However, the compound could not be crystallized. Treatment of the reaction mixture with $TlPF_6$ resulted in the expected $Br^- \rightleftarrows PPh_3$ exchange to produce **19·PF$_6$** (Scheme 12), which could be characterized by X-ray analysis (Figure 10, Tables 6, 9).

The conformation of the chelate cycles (Table 6) in **16a**$^+$, **16b**$^+$, **18**, and **19**$^+$ is quantitatively similar to that described for [(chelate)$M^{II}Hal_2$] compounds (Table 2). In all four compounds the coordination around the metal atom is square-planar. The conformation of the chelate cycles (Table 6) corresponds to a chair (**16a**$^+$, **19**$^+$), a half-chair (**18**) and a twist-boat conformation (**16b**$^+$). The bond lengths between the chelate donor atoms and the metal atoms are very similar to the ones shown in Table 3. The M−C and M−Hal distances to the external ligands, as well as the valence angles at the metal centre, are all in the usual and normal range (Table 6). The only clear indication of a *trans* influence is observed for the M−P bonds in **18**. The N−P bond *trans* to the chloride ligand is not much different from the one observed in **12** (224.6 pm) with its P_2Cl_2 donor set (Table 3). The M−P distance *trans* to the methyl substituent in **18** is lengthened by the *trans* influence of the methyl group to 231.4 pm (Table 6). There is, however, some uncertainty with respect to the exact values of both distances, which may be larger than the calculated standard deviation (Table 6), due to the fact that crystals of **18** show some positional disorder between the chloride and the methyl substituents even though this disorder could be resolved by appropriate refinement (Table 9).

While the structure of the intermediate [**6a·Ni(Br)Mes**] formulated in the synthesis of **19·PF$_6$** may be − albeit indirectly − inferred from X-ray analysis of **19·PF$_6$** (see above) the structure of **17** [**5a·Ni(Br)Mes**] has to be inferred

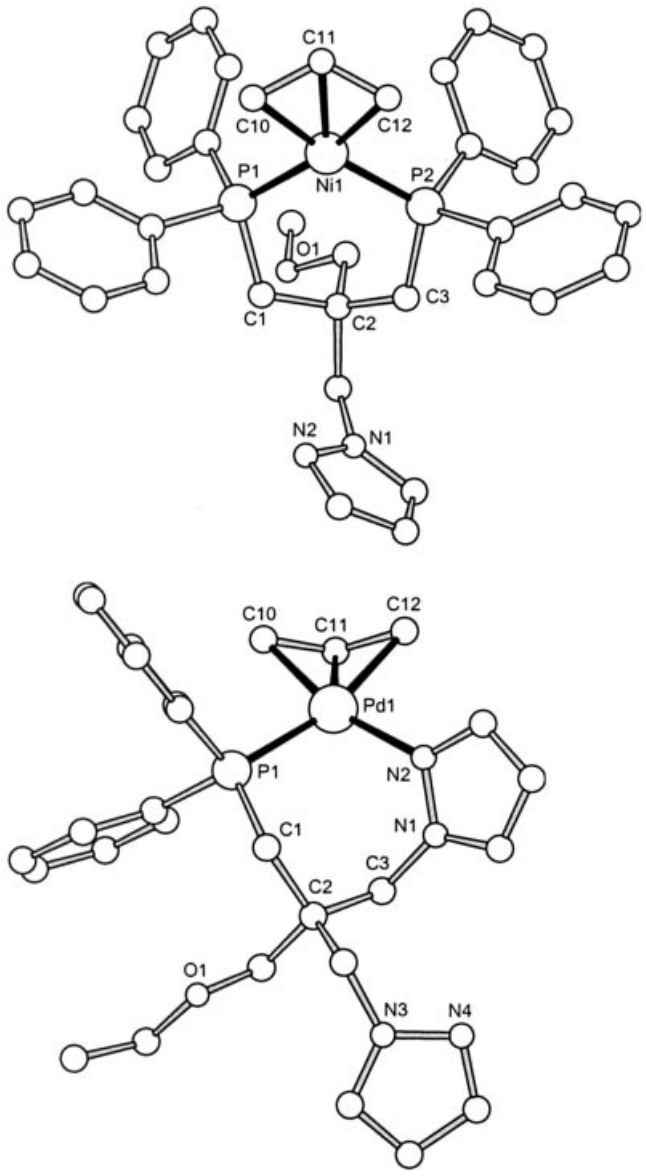

Figure 9. X-ray structure of the cation **16a**$^+$ (top) and **16b**$^+$ (bottom)

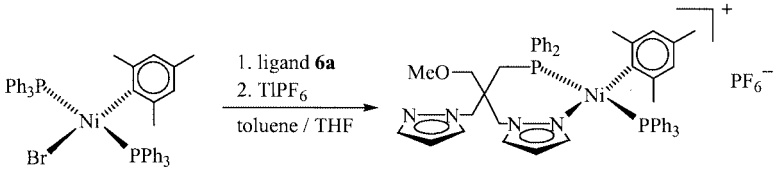
inter alia from NMR data. As expected for the diastereotopic phosphorus nuclei in **17** (the compound as a whole is chiral!) two doublets are observed in its ^{31}P NMR spectrum (see Exp. Sect. and remark therein). The diamagnetism of **17** proves the square-planar coordination of the nickel centre.

Even if the above results show that the conformation of the chelate cycles is not very much dependent on the kind



Scheme 12. Synthesis of **19·PF$_6$**

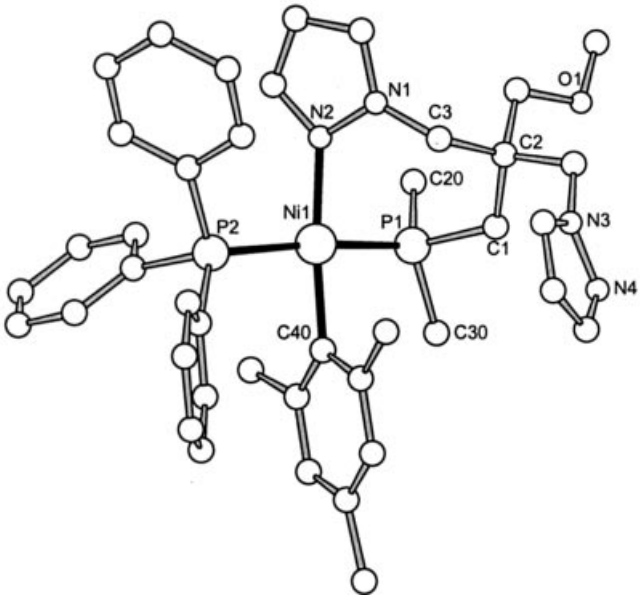


Figure 10. X-ray structure of the cation **19**$^+$ (for the sake of clarity, the phenyl groups of the *tripod* ligand are represented by their *ipso*-carbon atom only)

of co-ligands L in [(chelate)$M^{II}L_2$] there is a definite influence due to the kind of co-ligands on the type of coordination around a nickel(II) centre: ligand **6a** results in a tetrahedral coordination of the nickel atom with the $NiBr_2$ fragment (**11a**) while the same ligand coordinated to an $[Ni^{II}(PPh_3)(Mes)]^+$ fragment induces a square-planar coordination in **19**$^+$. The greater ligand field of PPh_3 and Mes (**19**$^+$) as compared with the two Br (**11a**) must be the reason for this.

Conclusion

1. The synthesis of *tripod* ligands $RCH_2C(CH_2PR_2)(CH_2pz)(CH_2X)$ with X being a phosphorus or a nitrogen donor has broad applicability.

2. These potential *tripod* ligands coordinate to d^8-metal ions (Ni^{II}, Pd^{II}, Pt^{II}) as bidentate chelate cycles, leaving the third group as a dangling arm. For ligands with a P,P,N donor set, coordination via the two phosphorus donors is generally observed. For ligands with a P,N,N donor set containing a bulky phosphorus donor (CH_2PMes_2), *N*,*N* coordination may be preferred over *P*,*N* coordination.

[a] Standard deviations in units of the least significant digit are given in each case. [b] A consistent numbering scheme for all the compounds as depicted below is used for the sake of easier comparison.

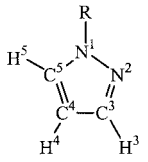
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3. For palladium(II) compounds derived from ligands containing a P,N,N donor set, dynamic exchange between coordinated and noncoordinated N donors is observed.

4. While palladium(II) and platinum(II) derivatives show a square-planar coordination throughout, the kind of coordination around the nickel atom (square-planar versus tetrahedral) depends on the donor set of the chelate ligand as well as on the kind of co-ligands.

Experimental Section

General Remarks: All manipulations involving phosphanes were carried out under argon by means of standard Schlenk techniques. All solvents were dried by standard methods[14] and distilled under argon. The solvents $CDCl_3$ and CD_2Cl_2 used for NMR spectroscopic measurements were degassed by three successive freeze-pump-thaw cycles and dried over molecular sieves (4 Å). NMR: Bruker Avance DPX 200 at 200.12 MHz (^{1}H); 50.323 MHz (^{13}C{^{1}H}); 81.015 MHz (^{31}P{^{1}H}); T = 303 K unless stated otherwise; chemical shifts (δ) in ppm with respect to $CDCl_3$ (^{1}H: δ = 7.27 ppm; ^{13}C: δ = 77.0 ppm) and CD_2Cl_2 (^{1}H: δ = 5.32 ppm; ^{13}C: δ = 53.5 ppm) as internal standards. ^{31}P chemical shifts (δ) in ppm with respect to 85% H_3PO_4 (^{31}P: δ = 0 ppm) as external standard. The NMR numbering scheme for the pyrazole cycle is shown in Scheme 13.[15] MS: Finnigan MAT 8230; EI (70 eV); FAB (xenon; matrix: 4-nitrobenzyl alcohol). UV/Vis: Perkin−Elmer Lambda 19. Elemental analyses: Microanalytical Laboratory of the Organisch-Chemisches Institut, University of Heidelberg.



Scheme 13. Numbering scheme of pyrazole as used for NMR data

Crystallographic Structure Determinations: Suitable crystals were taken directly from the mother liquor, immersed in perfluorinated polyether oil, and fixed to a glass capillary at 200 K. The measurements were carried out with a Siemens P4 four-circle diffractometer or with an Enraf−Nonius Kappa CCD diffractometer, using graphite-monochromated Mo-K_α radiation throughout. For the Siemens P4 diffractometer measurements the intensities of three check reflections (measured every 100 reflections) remained constant throughout the data collection, thus indicating crystal and electronic stability. The data collected with the Siemens P4 diffractometer were corrected as usual, including an experimental ab-

sorption correction. Data from the Enraf−Nonius Kappa CCD device were processed using the standard Nonius software.[16] The calculations were performed using the SHELXT PLUS software package. Structures were solved by direct methods with the SHELXS-97 program and refined with the SHELXL-97 program.[17] Graphical handling of the structural data during solution and refinement was performed with XMPA.[18] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Data relating to the structure determinations are collected in Tables 7, 8, and 9. Figures 1−5, 9, and 10 were prepared using WinRay-32.[19] CCDC-194026 to -194039 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Materials: Silica gel (Kieselgel 32−63 μm, ICN Biomedicals GmbH) used for chromatography was degassed at 1 mbar for 24 h and saturated with argon. A solution of *n*BuLi in hexane (2.5 M) was used for deprotonations. **1**,[1c] **2a**,[5e] **2c**,[5e] **3a**,[5e] **4a**,[5e] $EtOCH_2C(CH_2PPh_2)(CH_2pz)_2$,[5e] $CH_3C(CH_2pz)_3$,[5e] $HPPh_2$,[20] $HPMes_2$,[21] [*trans*-$(PPh_3)_2$Ni(Mes)Br],[22] and [(cod)PdClMe][23] were prepared according to or by adaptation of literature procedures. All other chemicals were obtained from commercial suppliers and used without further purification. Boiling range of the light petroleum ether used: 40−60°C. NMR and analytical data are collected in Tables 10−15.

Ligand Synthesis

Synthesis of 2b: Pyrrole (0.81 g, 12 mmol) was dissolved in THF (50 mL) and deprotonated at 0°C with 1 equiv. of KO*t*Bu (1.35 g, 12 mmol). After warming to 25°C, the solution was stirred for 30 min and then added at 0°C to a solution of **1** (2.59 g, 10 mmol) in THF (50 mL). The reaction was completed by refluxing for 4 h. In another flask, $HPPh_2$ (2.23 g, 12 mmol) was dissolved in THF (50 mL) and deprotonated at 0°C with 1 equiv. of KO*t*Bu (1.35 g, 12 mmol). After warming to 25°C and stirring for 30 min, the red potassium phosphide solution was added dropwise to the first reaction mixture, which was maintained at 0°C. After warming to 25°C and stirring for 10 h (the phosphide substitution was monitored by TLC), the then yellow solution was quenched by the addition of deoxygenated water (20 mL). The aqueous phase was extracted with diethyl ether (30 mL, 2×). The combined organic phases were washed with deoxygenated brine, dried with $MgSO_4$, filtered, and concentrated in vacuo. The resulting viscous oil was purified by column chromatography on silica gel by using petroleum ether/diethyl ether (1:1; R_f = 0.47) as eluent to obtain 1.84 g (5.5 mmol, 55%) of **2b** as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −26.9 (s, PPh_2) ppm. For further analytical data see Tables 10, 12, and 14.

General Procedure for the Synthesis of 3 and 4 The appropriately substituted oxetane **2** (1 equiv.) was dissolved in THF (50 mL). In a second flask, HPR_2 (1.2 equiv.) was dissolved in THF (50 mL) and deprotonated at 0°C with *n*BuLi (1.2 equiv.). After warming to 25°C and stirring for 30 min, the red lithium phosphide solution

was added dropwise to the oxetane solution at 0°C. The mixture was allowed to warm to 25°C, while the reaction progress was monitored by TLC. Upon completion (10 h stirring at 25°C), the reaction was quenched by the addition of deoxygenated water (50 mL). The aqueous phase was extracted with diethyl ether (30 mL, 2×). The combined organic phases were washed with deoxygenated brine, dried with $MgSO_4$, filtered, and concentrated in vacuo yielding the crude products as pale yellow oils. The crude product was purified by column chromatography on silica gel. **3b**: Starting material **2a** (2.02 g, 6.0 mmol). Eluent petroleum ether/diethyl ether (2:1; R_f = 0.24). Yield 1.90 g (3.45 mmol, 58%) as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −29.9 [d, $^4J_{PP}$ = 10 Hz, P(*m*-Tol)$_2$], −29.5 (d, $^4J_{PP}$ = 10 Hz, PPh$_2$) ppm. **3c**: Starting material **2a** (1.97 g, 5.85 mmol). Eluent petroleum ether/diethyl ether (1:1; R_f = 0.51). Yield 2.89 g (4.75 mmol, 81%) as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −35.9 (d, $^4J_{PP}$ = 16 Hz, PMes$_2$), −28.3 (d, $^4J_{PP}$ = 16 Hz, PPh$_2$). **3d**: Starting material **2a** (2.02 g, 6.0 mmol). Eluent petroleum ether/diethyl ether (3:1; R_f = 0.35). Yield 1.35 g (2.5 mmol, 42%) as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −29.9 (br. s, PPh$_2$), −18.5 [br. s, P(*c*-C_6H_{11})$_2$] ppm. **3e**: Starting material **2b** (670 mg, 2.0 mmol). Eluent petroleum ether/diethyl ether (2:1, R_f = 0.36). Yield 830 mg (1.6 mmol, 80%) as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −29.5 (s, PPh$_2$) ppm. **4b**: Starting material **2c** (1.75 g, 8.0 mmol). Eluent petroleum ether/diethyl ether (2:3; R_f = 0.35). Yield 2.65 g (5.4 mmol, 68%) as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −36.5 (s, PMes$_2$) ppm. For further analytical data see Tables 10, 12, and 14.

General Procedure for the Synthesis of 5 and 6: The substituted hydroxy compound **3** or **4** (1 equiv.), respectively, was dissolved in THF (50 mL) and the solution was cooled to 0°C. Addition of solid KO*t*Bu (2 equiv.) yielded a clear, pale yellow solution. After 5 min of stirring at 0°C, 2 equiv. of methyl iodide was added rapidly. Within a few minutes KI precipitated. The suspension was stirred for at 0°C 1 h (the methylation was monitored by TLC). The solvent was evaporated in vacuo at 0°C. The residue was dissolved in diethyl ether (30 mL) and the solution was filtered to remove potassium iodide. Removal of the solvent yielded the crude products as colourless oils. The crude product was purified by column chromatography on silica gel. **5a**: Starting material **3a** (1.77 g, 3.4 mmol). Eluent petroleum ether/diethyl ether (3:1; R_f = 0.36). Yield 1.41 g (2.6 mmol, 78%) as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −28.7 (s, PPh$_2$) ppm. **5b**: Starting material **3b** (1.60 g, 2.9 mmol). Eluent petroleum ether/diethyl ether (3:1; R_f = 0.36). Yield 1.31 g (2.3 mmol, 80%) as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −29.0 [d, $^4J_{PP}$ = 6 Hz, P(*m*-Tol)$_2$], −28.7 (d, $^4J_{PP}$ = 6 Hz, PPh$_2$) ppm. **5c**: Starting material **3c** (700 mg, 1.15 mmol). Eluent petroleum ether/diethyl ether (3:1; R_f = 0.43). Yield 615 mg (1.0 mmol, 87%) as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −35.8 (d, $^4J_{PP}$ = 6 Hz, PMes$_2$), −28.3 (d, $^4J_{PP}$ = 6 Hz, PPh$_2$). **5d**: Starting material **3e** (625 mg, 1.2 mmol). Eluent petroleum ether/diethyl ether (2:1; R_f = 0.65). Yield 560 mg (1.05 mmol, 87%) as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −29.2 (s, PPh$_2$) ppm. **6a**: Starting material **4a** (1.62 g, 4.0 mmol). Eluent petroleum ether/diethyl ether (2:1; R_f = 0.49). Yield 1.49 g (3.6 mmol, 89%) as a colourless, microcrystalline powder. ^{31}P

NMR ($CDCl_3$): δ = −28.6 (s, *P*Ph_2) ppm. **6b**: Starting material **4b** (1.95 g, 4.0 mmol). Eluent petroleum ether/diethyl ether (2:1; R_f = 0.65). Yield 1.65 g (3.3 mmol, 82%) as a colourless, microcrystalline powder. ^{31}P NMR ($CDCl_3$): δ = −36.6 (s, *P*Mes_2) ppm. For further analytical data see Tables 10, 12, and 14.

Coordination Chemistry

General Procedure for the Synthesis of 7a−d: A solution of the respective *tripod* ligand **5** (1.05 mmol) in ethanol (10 mL) was added rapidly to a solution of $NiCl_2·6H_2O$ (240 mg, 1.0 mmol) in ethanol (10 mL). The colour of the reaction mixture changed immediately to red and within a few minutes the nickel complexes precipitated. After stirring at 25°C for 1 h, the precipitate was filtered off, washed with 10-mL portions of diethyl ether (3×), and dried in vacuo. **7a**: Starting material **5a** (565 mg). Yield 540 mg (0.85 mmol, 85%) as an orange-coloured microcrystalline solid. Recrystallization from CH_2Cl_2/Et_2O afforded two different kinds of red crystals (**7a/1**·CH_2Cl_2 and **7a/2**·0.5CH_2Cl_2), both suitable for X-ray structure analysis. ^{31}P NMR (CD_2Cl_2, −30°C): δ = 11.2 (s, *P*Ph_2) ppm. ^{31}P NMR (CD_2Cl_2, −100°C): δ = 9.6 (d, $^2J_{PP}$ = 108 Hz, *P*Ph_2), 13.6 (d, $^2J_{PP}$ = 108 Hz, *P*Ph_2) ppm. **7b**: Starting material **5b** (590 mg). Yield 500 mg (0.72 mmol, 72%) as an orange-coloured, microcrystalline solid. ^{31}P NMR (CD_2Cl_2, −30°C): δ = 11.3 [br. s, *P*Ph_2, *P*(*m*-Tol)$_2$] ppm. ^{31}P NMR (CD_2Cl_2, −100°C): δ = 9.4 (d, $^2J_{PP}$ = 110 Hz), 12.1−15.0 (m) ppm. **7c**: Starting material **5c** (650 mg). Yield 710 mg (0.95 mmol, 95%) as a ruby-coloured, microcrystalline solid. ^1H NMR and ^{13}C NMR: due to dynamic processes, no sharp signals could be detected. ^{31}P NMR (CD_2Cl_2, −30°C): δ = −6.6 (d, $^2J_{PP}$ = 95 Hz, chair-*P*Mes_2), −0.5 (br. s, twist-*P*Mes_2, twist-*P*Ph_2), 2.2 (d, $^2J_{PP}$ = 95 Hz, chair-*P*Ph_2) ppm. ^{31}P NMR (CD_2Cl_2, −100°C): δ = −4.8 (d, $^2J_{PP}$ = 95 Hz, chair-*P*Mes_2), −3.0 (d, $^2J_{PP}$ = 98 Hz, twist-*P*Mes_2), −0.2 (d,

$^2J_{PP}$ = 101 Hz, twist-*P*Mes$_2$), 1.8 (d, $^2J_{PP}$ = 101 Hz, twist-*P*Ph$_2$), 3.1 (d, $^2J_{PP}$ = 98 Hz, twist-*P*Ph$_2$), 4.8 (d, $^2J_{PP}$ = 95 Hz, chair-*P*Ph$_2$) ppm, see Figure 7. **7d**: Starting material **5d** (560 mg). Yield 630 mg (0.95 mmol, 95%) as an orange-coloured, microcrystalline solid. ^{31}P NMR (CD_2Cl_2, −30°C): δ = 9.8 (s, *P*Ph$_2$) ppm. ^{31}P NMR (CD_2Cl_2, −100°C): δ = 10.4−10.8 (m, *P*Ph$_2$) ppm. For crystallographic data see Table 7; for further analytical data see Tables 11, 13, and 15.

General Procedure for the Synthesis of 8, 11a−c, 13, and 14: A solution of the respective *tripod* ligand **5** or **6** (1.05 mmol) in THF (20 mL) was added rapidly to a suspension of [(dme)$NiCl_2$] (220 mg, 1.0 mmol) or [(dme)$NiBr_2$] (310 mg, 1.0 mmol), respectively, in THF (20 mL). After stirring at 25°C for 12 h, all volatiles were removed in vacuo. The residual solid was washed with 10-mL portions of diethyl ether (3×) and dried in vacuo. **8**: Starting materials **5a** (565 mg) and [(dme)$NiBr_2$]. Yield 515 mg (0.68 mmol, 68%) as a red, microcrystalline solid. Recrystallization from CH_2Cl_2/Et_2O afforded red crystals suitable for X-ray structure analysis. ^{31}P NMR (CD_2Cl_2, −30°C): δ = 10.7 (s, *P*Ph$_2$) ppm. **11a**: Starting materials **6a** (440 mg) and [(dme)$NiBr_2$]. Yield 580 mg (0.91 mmol, 91%) as a blue-violet, microcrystalline solid. Recrystallization from CH_2Cl_2/Et_2O afforded blue-violet crystals suitable for X-ray structure analysis. UV/Vis (CH_2Cl_2): λ (ε) = 552 nm (200 $M^{-1}\cdot cm^{-1}$), 912 (110), 1007 (sh, 70). NMR: no NMR signals due to paramagnetism. **11b**: Starting materials **6a** (440 mg) and [(dme)$NiCl_2$]. Yield 485 mg (0.88 mmol, 88%) as a violet, microcrystalline solid. UV/Vis (CH_2Cl_2): λ (ε) = 527 nm (180 $M^{-1}\cdot cm^{-1}$), 890 (100), 997 (80). NMR: no NMR signals due to paramagnetism. **11c**: Starting materials $EtOCH_2C(CH_2PPh_2)(CH_2pz)_2$[5e] (455 mg) and [(dme)-$NiBr_2$]. Yield 525 mg (0.80 mmol, 80%) as a blue-violet, microcrystalline solid. Recrystallization from CH_2Cl_2/Et_2O afforded two different kinds of crystals, both suitable for X-ray structure analysis, which were identified as **11c**·0.5CH_2Cl_2 (blue-violet) and the dimer **15** (red-brown). UV/Vis (**11c**, CH_2Cl_2): λ (ε) = 550 nm (195 $M^{-1}\cdot cm^{-1}$), 913 (120), 1109 (sh, 50). NMR: no NMR signals due to paramagnetism. **13**: Starting materials **6b** (525 mg) and [(dme)$NiCl_2$]. Yield 495 mg (0.78 mmol, 78%) as a blue-violet, microcrystalline solid. Recrystallization from CH_2Cl_2/Et_2O afforded blue-violet crystals suitable for X-ray structure analysis. UV/Vis (CH_2Cl_2): λ (ε) = 520 nm (100 $M^{-1}\cdot cm^{-1}$), 579 (140), 974 (60). NMR: no NMR signals due to paramagnetism. **14**: Starting materials

[a] All signals are singlets unless otherwise stated; d = doublet; dd = doublet of doublet; t = triplet; m = multiplet. [b] Coupling constants in Hz. [c] See Scheme 13 for numbering scheme of the pyrazole.

$CH_3C(CH_2pz)_3$[5e] (285 mg) and [(dme)$NiBr_2$]. Yield 425 mg (0.87 mmol, 87%) as a blue, microcrystalline solid. Recrystallization from CH_2Cl_2/Et_2O afforded blue and red-brown crystals, but only the former were suitable for X-ray structure analysis. UV/Vis (CH_2Cl_2): λ (ε) = 550 nm (180 $M^{-1}\cdot cm^{-1}$), 600 (230), 1004 (90). NMR: no NMR signals due to paramagnetism. For crystallographic data see Tables 7 and 8; for further analytical data see Tables 11, 13, and 15.

General Procedure for the Synthesis of 9a, 9b, and 12: A solution of the respective *tripod* ligand **5** or **6** (0.5 mmol) in ethanol (15 mL) was added rapidly to a suspension of [(η^4-cod)$PdCl_2$] (145 mg, 0.5 mmol) in ethanol (10 mL). Within a few minutes the yellow reaction mixture was clearing up. After stirring at 25°C for 12 h, all volatiles were removed in vacuo. The residual solid was washed with portions of diethyl ether (10 mL, 3×) and dried in vacuo. **9a**: Starting material **5a** (270 mg). Yield 265 mg (0.37 mmol, 74%) as a colourless, microcrystalline solid. Recrystallization from CH_2Cl_2/Et_2O afforded colourless crystals suitable for X-ray structure analysis. ^{31}P NMR (CD_2Cl_2): δ = 15.8 (s, *P*Ph_2) ppm. ^{31}P NMR (CD_2Cl_2, −100°C): δ = 15.8 (d, $^2J_{PP}$ = 115 Hz, *P*Ph_2), 15.9 (d, $^2J_{PP}$ = 115 Hz, *P*Ph_2) ppm. **9b**: Starting material **5b** (280 mg). Yield 255 mg (0.34 mmol, 69%) as a pale yellow microcrystalline solid. ^{31}P NMR (CD_2Cl_2): δ = 15.8 [br. s, *P*Ph_2, *P*(*m*-Tol)$_2$] ppm. ^{31}P NMR (CD_2Cl_2, −100°C): δ = 14.9−15.8 (m), 16.6−17.1 (m) ppm. **12**: Starting material **6a** (210 mg). Yield 245 mg (0.41 mmol, 82%) as a yellow, microcrystalline solid. Recrystallization from CH_2Cl_2/Et_2O afforded yellow crystals suitable for X-ray structure analysis. ^{31}P NMR (CD_2Cl_2): δ = 9.8 (s, *P*Ph_2) ppm. For crystallographic data see Tables 7 and 8; for further analytical data see Tables 11, 13, and 15.

Synthesis of 10: A solution of the *tripod* ligand **5a** (135 mg, 0.25 mmol) in ethanol/THF (2:1; 15 mL) was added rapidly to a suspension of [*cis*-($CH_3CN)_2PtCl_2$] (85 mg, 0.25 mmol) in ethanol (10 mL). Within a few minutes the reaction mixture was clearing up and the platinum complex precipitated. After stirring at 25°C for 12 h, all volatiles were removed in vacuo. The residual solid was washed with portions of diethyl ether (10 mL, 3×) and dried in vacuo. Recrystallization from CH_2Cl_2/Et_2O afforded 150 mg (0.19 mmol, 75%) of **10** as colourless crystals. ^{31}P NMR (CD_2Cl_2): δ = −2.5 (s, with Pt satellites, $^1J_{PtP}$ = 1720 Hz, *P*Ph_2). ^{31}P NMR (CD_2Cl_2, −100°C): δ = −3.2 (d, $^2J_{PP}$ = 20 Hz, *P*Ph_2), −2.5 (d, $^2J_{PP}$ = 20 Hz, *P*Ph_2). For further analytical data, see Tables 11, 13, and 15.

Synthesis of 16a·PF_6: Solid $TlPF_6$ (2 equiv., 210 mg) was added, at 0°C, to a suspension of **7a** (200 mg, 0.3 mmol) in THF (50 mL) to

yield a white precipitate of TlCl. After stirring the reaction mixture at 0°C for 1 h, allylmagnesium bromide (0.35 mL of a 1 M solution in THF) was added dropwise. After stirring at 25°C for 10 h, the precipitate was filtered off through 2 cm of Kieselguhr and all volatiles were removed in vacuo. The orange-coloured residue was washed with portions of diethyl ether (10 mL, 2×) and then recrystallized from CH_2Cl_2/Et_2O to give 170 mg (0.22 mmol, 72%) of **16a·PF_6**·0.75CH_2Cl_2 as air-stable, yellow crystals suitable for X-ray structure analysis. ^{31}P NMR (CD_2Cl_2): δ = −144.0 (sept, $^1J_{PF}$ = 712 Hz, *P*F_6^-), 13.0 (s, *P*Ph_2) ppm. For crystallographic data see Table 9; for further analytical data see Tables 11, 13, and 15.

Synthesis of 16b·PF_6: A solution of the *tripod* ligand $EtOCH_2C(CH_2PPh_2)(CH_2pz)_2$[5e] (130 mg, 0.3 mmol) in EtOH (10 mL) was added rapidly to a suspension of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (55 mg, 0.15 mmol) in EtOH (10 mL). When a clear solution had formed (after about 30 min), solid KPF_6 (55 mg, 0.3 mmol) was added and within a few minutes the allyl complex precipitated. For complete precipitation the reaction mixture was cooled overnight to −30°C and afterwards filtered. The resultant grey residue was washed with portions of diethyl ether (10 mL, 2×), dried in vacuo, and recrystallized from CH_2Cl_2/Et_2O to give 140 mg (0.19 mmol, 64%) of **16b·PF_6** as air-stable, colourless crystals suitable for X-ray structure analysis. ^1H NMR and ^{13}C NMR: due to dynamic processes, no sharp signals could be detected. ^{31}P NMR (CD_2Cl_2): δ = −144.2 (sept, $^1J_{PF}$ = 710 Hz, *P*F_6^-), 11.5 (s, *P*Ph_2) ppm. For crystallographic data see Table 9; for further analytical data see Tables 11, 13, and 15.

Synthesis of 17: A solution of the *tripod* ligand **5a** (270 mg, 0.5 mmol) in toluene (15 mL) was added to a solution of [*trans*-$(PPh_3)_2Ni(Mes)Br$] (390 mg, 0.5 mmol) in toluene (15 mL). After stirring the orange-coloured reaction mixture at 25°C for 10 h, the solvent was removed in vacuo. The crude product was suspended in petroleum ether (20 mL). After filtration of the suspension, the residue was washed carefully with portions of petroleum ether

[a] $Br_{calcd.}$. [b] Br_{found}. [c] Calculated for **16a·PF$_6$**·0.75CH_2Cl_2. [d] Calculated for **19·PF$_6$**·0.35CH_2Cl_2.

(10 mL, 3×) to remove PPh_3, and dried in vacuo to give 285 mg (0.36 mmol, 72%) of **17** as a yellow, microcrystalline solid. ^{31}P NMR (CD_2Cl_2): δ = −8.0 (d, $^2J_{PP}$ = 41 Hz, *P*Ph_2 *trans* to Mes^-), 23.2 (d, $^2J_{PP}$ = 41 Hz, *P*Ph_2 *trans* to Br^-) ppm. For further analytical data see Tables 11, 13, and 15.

Synthesis of 18: A solution of the *tripod* ligand **5a** (270 mg, 0.5 mmol) in CH_2Cl_2 (15 mL) was added to a solution of [(η^4-cod)PdMeCl] (135 mg, 0.5 mmol) in CH_2Cl_2 (15 mL). After stirring the colourless reaction mixture at 25°C for 10 h, the solvent was removed in vacuo. The crude product was suspended in petroleum ether (20 mL). After filtration of the suspension, the resultant grey residue was washed with portions of petroleum ether (15 mL, 3×) and dried in vacuo. Recrystallization from CH_2Cl_2/Et_2O afforded 295 mg (0.43 mmol, 85%) of **18** as colourless crystals suitable for X-ray structure analysis. ^{31}P NMR (CD_2Cl_2): δ = −6.3 (d, $^2J_{PP}$ = 48 Hz, *P*Ph_2 *trans* to Me^-), 25.7 (d, $^2J_{PP}$ = 48 Hz, *P*Ph_2 *trans* to Cl^-) ppm. For crystallographic data see Table 9; for further analytical data see Tables 11, 13, and 15.

Synthesis of 19·PF$_6$: A solution of the *tripod* ligand **6a** (210 mg, 0.5 mmol) in toluene (15 mL) was added to a solution of [*trans*-(PPh_3)$_2$Ni(Mes)Br] (390 mg, 0.5 mmol) in toluene (15 mL). After stirring the orange-coloured reaction mixture at 25°C for 10 h, the solvent was removed in vacuo and the solid residue was dissolved in THF (30 mL). Solid $TlPF_6$ (175 mg, 0.5 mmol) was added and a precipitate of TlBr appeared immediately. The reaction mixture was stirred at 25°C for 3 h and then filtered through 2 cm of Kieselguhr to remove the $TlPF_6$. The solvent was removed in vacuo and the crude product was suspended in petroleum ether (20 mL). After filtration of the suspension, the residue was washed carefully with portions of petroleum ether (15 mL, 3×) to remove PPh_3, and dried in vacuo. Recrystallization from CH_2Cl_2/Et_2O afforded 250 mg (0.25 mmol, 50%) of **19·PF$_6$** as yellow crystals suitable for X-ray structure analysis. ^1H NMR and ^{13}C NMR: due to dynamic processes, no sharp signals could be detected. ^{31}P NMR (CD_2Cl_2): δ = −144.0 (sept, $^1J_{PF}$ = 712 Hz, *P*F_6^-), −5.8 (d, $^2J_{PP}$ = 272 Hz, *P*Ph_3), 7.9 (d, $^2J_{PP}$ = 280 Hz, *P*Ph_3), 19.4 (d, $^2J_{PP}$ = 280 Hz, *P*Ph_2), 21.7 (d, $^2J_{PP}$ = 272 Hz, *P*Ph_2) ppm. For this compound a ^{31}P NMR pattern of two doublets corresponding to the two P donors is expected. Instead, two such patterns are observed (δ = −5.8/21.7 and 7.9/19.4 ppm). The large coupling constants are in accord with a *trans* position of the two P donors in each case. There are obviously two isomers, and only the structure of the one characterized by X-ray crystallography is known. Attempts to isolate the other isomer have, so far, failed. For crystallographic data see Table 9; for further analytical data see Tables 11, 13, and 15.

Nickel(II) Compounds Derived from *tripod* Ligands: Efficient Catalysts for the Stereoselective Heterodimerization of Styrene and Propene

Ralf Faissner[a] and Gottfried Huttner*[a]

Dedicated to Professor Günter Helmchen[‡]

Keywords: Tripod ligands / Nickel / Catalysis / Heterodimerization

The *tripod* ligands $RCH_2C(CH_2X)(CH_2Y)(CH_2Z)$ form tetracoordinate compounds with $NiHal_2$. If two of the donor functions X, Y, Z are phosphanes, square-planar coordination is observed. In contrast, donor sets X,Y,Z = P,N,N or N,N,N form tetrahedral compounds, by *P,N* or *N,N* coordination, that are active in the catalysis of olefin oligomerization with MAO as a co-catalyst. These catalyst systems are also active in the stereoselective heterodimerization of olefins. The co-dimerization of styrene and propene by these systems leads to 4-phenyl-2-pentene almost exclusively, with regioselectivities up to 98% and (*E*)/(*Z*) ratios of up to 95:5, surpassing other reported catalysts for this process. The products of these catalytic transformations have been fully characterized by GC/MS techniques as well by isolation, NMR and MS characterization of the pure compounds.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Transition metal catalysed heterodimerization of olefins is a versatile method of carbon−carbon bond formation.[1,2] The co-dimerization of styrene and ethene has been much studied since its first report in 1965.[3] Many transition metals are active in this process[4,5] but catalysts containing nickel are the most active ones.[2,6,7] They could even be developed into systems that allow the enantioselective hydrovinylation of styrene.[7] Conversely, the long-standing problem of co-dimerizing styrene with propene[4a,5b,8] has only been partially solved.[7d,7e] The major prerequisite for an effective catalyst in this process appears to be a hemilabile co-ligand.[9]

Nickel(II) compounds containing P,N- or N,N-bonded chelate ligands are promising candidates as precatalysts in this type of reaction. The recent synthesis[10] of $(R'CH_2)(CH_2Z)C(CH_2\text{-}\kappa^1\text{-}X)(CH_2\text{-}\kappa^1\text{-}Y)NiHal_2$ compounds derived from potential *tripod* ligands $R'CH_2C(CH_2X)(CH_2Y)(CH_2Z)$ (R′ = H, OMe; X, Y, Z = PR_2, NR_2) has prompted the study of their catalytic properties as co-dimerization catalysts. The results of such a study are reported here.

[‡] As a late contribution to his 60th birthday.

Results and Discussion

The propensity of *tripod*-derived nickel(II) chelate compounds to act as precatalysts in styrene olefin co-dimerization was tested for compounds **1**−**5** (Scheme 1).

An initial check as to whether the compounds − when activated with MAO − lead to catalysts for ethene oligomerization[11] found that none of the compounds containing two phosphane donors in the chelate cycle (**5a**−**5d**) was active. However, compounds containing a P,N or an N,N donor set in the chelate cycle (**1**−**4**) are active as oligomerization catalysts. The ethene oligomers formed were soluble in toluene. GC/MS analysis of the toluene solution and of the gaseous phase revealed a broad distribution of oligomers up to an oligomerization degree around $n = 12$ with the expected decay of the respective yields with increasing degree of oligomerization (Scheme 2).

The oligomerization process is not stereoregular: instead of one single GC/MS peak at each oligomerization degree *n*, a pattern of overlapping peaks is observed, all of which correspond to the same mass number.

This first test with ethene as a substrate showed that compounds **1**−**4** − containing hemilabile P,N- and N,N-bonded chelates − are candidates as potential precatalysts of olefin co-dimerization. The next test therefore probed the activity of these compounds in the presence of MAO for propene dimerization.[12] The test was limited to **1a**, which was found to promote the dimerization of propene with more than 90% of the product being 2-methyl-1-pentene (Scheme 3). This product was isolated by distillation and

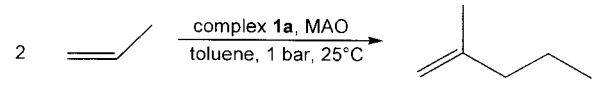
precatalyst = any of the compounds **1**-**4**

Scheme 2



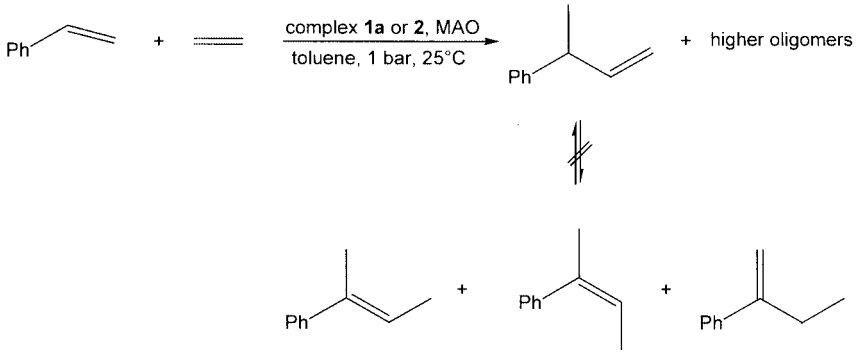
Scheme 3

identified unequivocally by 1D- and 2D-NMR spectroscopy (see Exp. Sect.).

This test shows that the catalytic process of dimerization is completely regioselective in this case.[13] Regioselectivity is an essential prerequisite for an effective heterodimerization catalyst. The next test was to analyse the potential catalytic dimerization of styrene and ethane with **1a** and **2** as precatalysts. The formation of heterodimers was observed in each case. From the many conceivable kinds of isomeric heterodimers only 3-phenyl-1-butene was formed (Scheme 4). The catalytic process was run until all styrene had been consumed (18 h, 0.1 mol % precatalyst). GC/MS analysis of the products showed that only around 30% of the products consisted of the dimer, while the rest were trimers or tetramers with all combinations of constituting olefins being present. However, no styrene dimer was observed.

These findings show that regioselective hydrovinylation of styrene is catalysed by the systems tested. They also demonstrate that the catalyst systems are too active since they activate the heterodimer for further C−C bond formation.

Consequently, the codimerization of *p*-chlorostyrene and ethene was analysed using **1a** and MAO as precatalyst system. This substituted styrene should be a less active olefin than styrene, such that the formation of oligomers containing more than one *p*-chlorostyrene moiety should be suppressed. It was observed that the catalyst system is still active with these components. The reaction is, however, much slower than with styrene, such that after 18 h (0.4 mol % precatalyst) only 45% of *p*-chlorostyrene had reacted. The almost exclusive product of this reaction is the heterodimeric compound 3-(*p*-chlorophenyl)-1-butene (Scheme 5). A very minor amount of a trimer composed of one *p*-chlorostyrene and two ethene moieties is formed. Thus, the



Scheme 4

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

selectivity of the catalyst system for the formation of heterodimers increases with decreasing activity of the olefinic partners.

All the above tests give credit to the idea that styrene and propene might be the proper choice of olefins to be co-dimerized by the above catalyst systems.

As a precatalyst for the heterodimerization of styrene and propene the system $[(\eta^3\text{-allyl})NiBr]_2/PPh_3/AgOTf$ has been described recently.[7e] This reaction was run in CH_2Cl_2 at −20 °C to give the co-dimerization products in more than 90% yield based on styrene.

A catalyst system composed of P,N or N,N chelate compounds **1**−**4** and MAO in toluene gives good yields of the desired dimers even at room temperature (see Scheme 6). The identity of the heterodimers was proved beyond doubt by their isolation, by distillation, and a combination of mass spectra, 1D- and 2D-NMR experiments (see Exp. Sect.).

The regioselectivity of this process − depending on the reaction conditions − is up to 98%, corresponding to the almost exclusive formation of 4-phenyl-2-pentene[14] (**A**, **B**) as the dimerization products. The (*E*) isomer is the predominant compound in each case, with (*E*)/(*Z*) ratios (**A**/**B**) between 89:11 and 95:5 depending on the catalyst and the reaction conditions. The observed regioselectivity (up to 98%) and stereoselectivities (up to 95:5) are higher than those reported for the $[(\eta^3\text{-allyl})NiBr]_2$ system (regioselectivity: 80%; stereoselectivity: 88:12).[7e]

The results of this analysis (Table 1) show that compounds that contain at least one nitrogen donor in the chelate cycle (Runs 1−10) are active as precatalysts, while none of the compounds that contain two phosphorus donors in their chelate cycle (Runs 11−14) show any activity.

The selectivity of the systems containing hemilabile P,N and N,N chelates (**1**−**4**) with respect to the formation of 4-phenyl-2-pentene (**A**, **B**) depends on the catalyst/substrate ratio (see Table 1). With 1.5 mol % of the catalyst (relative to styrene) up to 80% dimeric products are obtained. With lower catalyst/styrene ratios the yield of dimeric products decreases and is only around 20% for a ratio of 0.1 mol % (Table 1). The activities of the individual catalyst systems based on **1**−**4** are not too different in this process (Table 1).

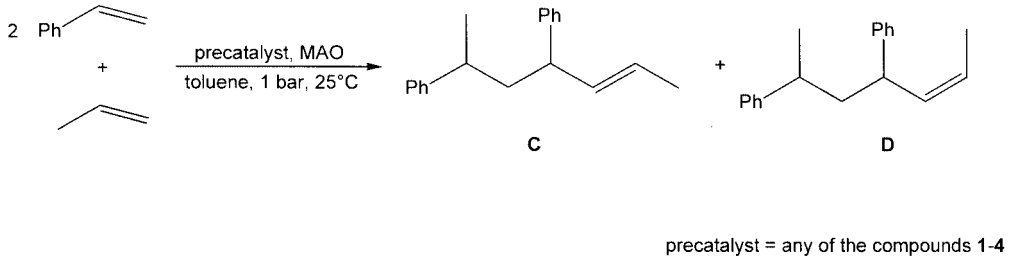


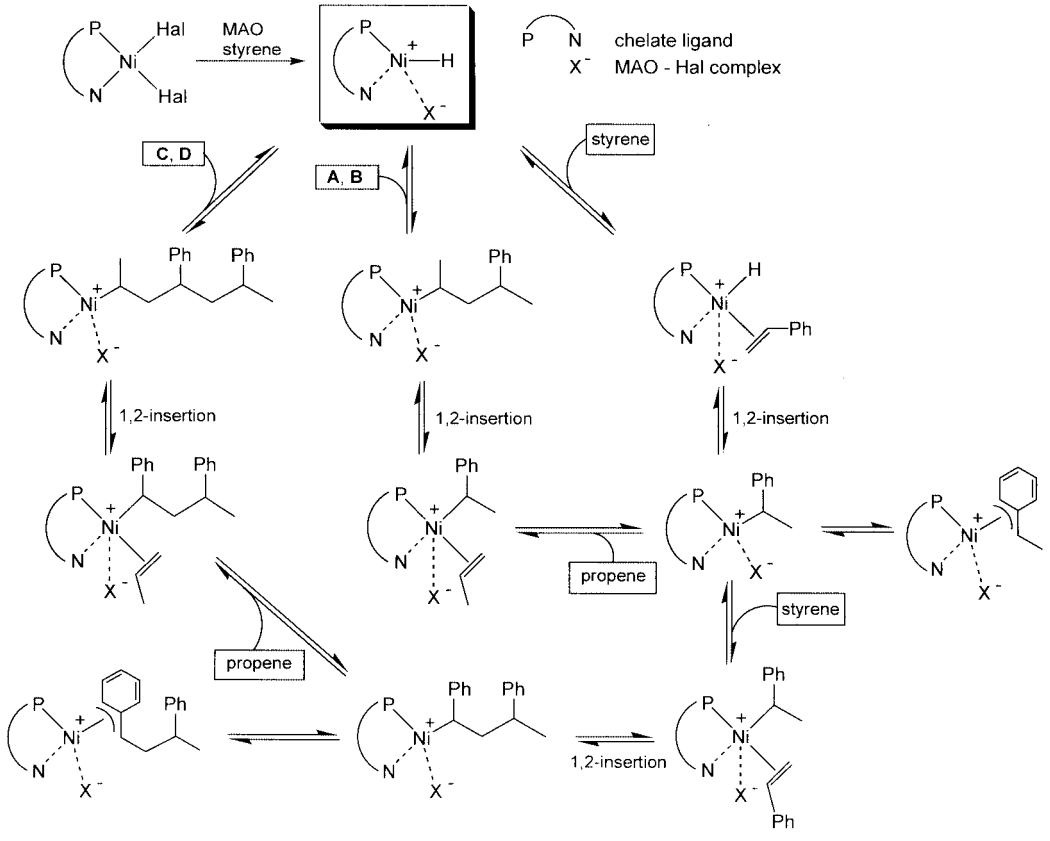
Scheme 7

Only **4**, which bears an Et_2N donor instead of a pyrazole donor (**1**−**3**), appears to be somewhat less reactive and less selective (Table 1). The reactivity of all systems is such that within 18 h styrene is quantitatively consumed, even if the molar ratio of catalyst/styrene is only 0.1 mol %.

In all experiments that lead to the catalytic formation of styrene/propene heterodimers (see Table 1), 4,6-diphenyl-2-heptene[15] is a by-product. This heterotrimer is composed of one propene and two styrene entities (**C**, **D**) (Scheme 7). The formation of **C** and **D** is completely regioselective. The (*E*)/(*Z*) ratio (**C**/**D**) is between 80:20 and 85:15 throughout, such that the reaction is also stereoselective in this respect. Both **C** and **D** were identified unequivocally by their isolation by distillation, and a combination of MS, 1D- and 2D-NMR experiments (see Exp. Sect.).

With "high" molar ratios of precatalyst/styrene (1.5 mol %), in addition to the trimer 4,6-diphenyl-2-heptene (**C**, **D**) other trimers composed of one styrene and two propene units are also formed, while with lower ratios (0.1−0.75 mol %) 4,6-diphenyl-2-heptene (**C**, **D**) is by far the predominant trimer (90−99%). The lowest percentage (65%) of **C** and **D** amongst these trimers was found with 1.5 mol % of **1b** as the precatalyst.

All the precatalysts **1**−**4** are paramagnetic nickel(II) compounds with a tetrahedral coordination around the metal atom. When the toluene solutions of these precatalysts are treated with MAO, these blue to violet tetrahedrally coordinated compounds turn red, which is characteristic of such diamagnetic square-planar nickel(II) compounds. This indicates that the substitution of the halide function by a methyl group occurs since the replacement of an Ni−Hal bond by an Ni−C bond in this type of compound leads to a transformation of tetrahedral into square-planar coordination due to the increased ligand field.[10b]



Scheme 8

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

All of the above observations may be rationalized by the mechanistic scheme shown in Scheme 8. In principle the scheme is similar to the accepted hypothesis concerning olefin oligomerization by nickel catalysts.[7a,7e] Activation of the precatalyst by MAO and its reaction with styrene leads to a coordinatively unsaturated cationic Ni−H species, which is able to add styrene. (The individual steps, which result in the activated Ni−H species, are shown in refs.[2,7a,7e]) Coordinative reactivity results from X^- being trapped by MAO and by the hemilability of the Ni−N coordination (dashed lines in Scheme 8). The usual sequence of insertion steps leads to 4-phenyl-2-pentene (**A**, **B**) when propene is added as the second olefin (inner circle of Scheme 8). When styrene is also added as the second olefin the sequence shown in the outer circle of Scheme 8 leads to the formation of 4,6-diphenyl-2-heptene (**C**, **D**) provided that propene is the third olefinic constituent taken up by the catalyst. The observed regioselectivity is in complete agreement with this scheme. All routes incorporate 1,2-insertions as crucial steps, from which the observed regioselectivity follows as a natural consequence.

Conclusion

The *tripod* ligands $RC(CH_2X)(CH_2Y)(CH_2Z)$ (X,Y,Z = P,N,N or N,N,N) coordinate to $NiHal_2$ in a bidentate mode, resulting in tetrahedral nickel(II) compounds that are active as precatalysts (co-catalyst: MAO) in the heterodimerization of styrene and propene. The current results indicate that the yield of dimeric products and the selectivity of the catalysts may be further increased by optimising the reaction conditions (i.e. styrene/precatalyst ratio, reaction temperature, solvent). The yield of dimeric products reached so far is up to 80% with regioselectivities of up to 98% and stereoselectivities of up to 95%.

Pyrazole as a nitrogen donor in *tripod* ligands has been found to promote this selectivity, while the third non-coordinated donor function, serving as a dangling arm, has no major influence on the catalytic activities. This finding should stimulate further experiments in which different groups at the dangling arm are introduced to either change the solubility of the precatalysts or to fix them on a support.

Experimental Section

General Remarks: All (hetero)dimerization reactions were carried out under moisture- and oxygen-free conditions by means of standard Schlenk techniques. The Schlenk flasks were equipped with a gas balloon. All solvents were dried by standard methods[16] and distilled under argon. Complexes **1**−**5** were prepared according to literature procedures.[10] Ethene, propene, styrene, *p*-chlorostyrene, MAO (10% solution in toluene), and dodecane were purchased from Aldrich and were used without further purification. NMR: Bruker Avance DPX 200 at 200.12 MHz (^{1}H); 50.323 MHz ($^{13}C\{^1H\}$); T = 303 K; chemical shifts (δ) in ppm with respect to $CDCl_3$ (^{1}H: δ = 7.27 ppm; ^{13}C: δ = 77.0 ppm) as internal standard. GC/MS: Agilent 6890 (GC) interfaced to an Agilent 5973N (MS) equipped with an HP-5MS capillary column (30 m long, 0.25 mm inner diameter) with helium as carrier gas. Yields of the products (Table 1) refer to dodecane as internal standard.

Typical Procedure for the (Hetero)dimerization Reaction: Styrene (500−2000 mg), precatalyst **1**−**4** (5.0−20.0 mg; 0.1−1.5 mol %), and dodecane (200 mg) as internal standard were dissolved in toluene (25 mL) at 25 °C. MAO (3.0 mL of a 10% solution in toluene) was then added to the reaction mixture, and the solution immediately turned from violet to red. Ethene or propene (1 bar), respectively, was then introduced into the catalyst solution and the resultant reaction mixture was stirred at 25 °C for 18 h under ethene or propene (1 bar), respectively. For GC/MS analysis the reaction mixture (0.5 mL) was quenched with a solution of half-concentrated HCl (20 mL) and diethyl ether (20 mL). The aqueous phase was extracted with diethyl ether (20 mL). The combined organic layers were washed with brine and dried with $MgSO_4$. For preparative isolation of the oligomerization products the same type of workup procedure was applied in an appropriately scaled-up version. After removing the solvent, the following products were isolated by Kugelrohr distillation:

2-Methyl-1-pentene: ^{1}H NMR ($CDCl_3$): δ = 1.04 (t, $^3J_{H,H}$ = 7.2 Hz, 3 H, CH_2CH_3), 1.51−1.62 (m, 2 H, CH_2CH_3), 1.75 (s, 3 H, $=CCH_3$), 2.10 (t, $^3J_{H,H}$ = 7.5 Hz, 2 H, $=CCH_2$), 4.80 (br. s, 2 H, $=CH_2$) ppm. ^{13}C NMR ($CDCl_3$): δ = 14.2 (s, CH_2CH_3), 20.5 (s, CH_2CH_3), 23.1 (s, $=CCH_3$), 40.4 (s, $=CCH_2$), 110.2 (s, $=CH_2$), 137.8 (s, $=C_q$) ppm. MS (EI): *m*/*z* (%) = 84 (34) [M^+], 69 (100) [$M^+ - CH_3$], 55 (13) [$M^+ - CH_2CH_3$]. B.p. 60 °C (1013 mbar).

3-Phenyl-1-butene: ^{1}H NMR ($CDCl_3$): δ = 1.37 (d, $^3J_{H,H}$ = 6.9 Hz, 3 H, CH_3), 3.45−3.61 (m, 1 H, PhC*H*), 5.01−5.09 (m, 2 H, $=CH_2$), 5.98−6.07 (m, 1 H, $=CH$), 7.19−7.30 (m, 5 H, aromat. *H*) ppm. ^{13}C NMR ($CDCl_3$): δ = 21.1 (s, CH_3), 43.7 (s, Ph*C*H), 113.3 (s, $=CH_2$), 125.9−145.5 (m, aromat. *C*), 143.8 (s, $=CH$) ppm. MS (EI): *m*/*z* (%) = 132 (25) [M^+], 117 (100) [$M^+ - CH_3$], 91 (25) [$C_7H_7^+$], 77 (18) [$C_6H_5^+$], 65 (10) [$C_5H_5^+$], 51 (22) [$C_4H_3^+$]. B.p. 30 °C (0.1 mbar).

(*E*)-4-Phenyl-2-pentene (A): ^{1}H NMR ($CDCl_3$): δ = 1.46 (d, $^3J_{H,H}$ = 7.1 Hz, 3 H, PhCHC*H*$_3$), 1.80 (d, $^3J_{H,H}$ = 6.2 Hz, 3 H, $=CHCH_3$), 3.54 (quint, $^3J_{H,H}$ = 6.9 Hz, 1 H, PhC*H*), 5.51−5.68 (m, 1 H, $CH_3CH=$), 5.76 (dd, $^3J_{H,H}$ = 6.8, $^3J_{H,H}$ = 15.2 Hz, 1 H, CHC*H*=), 7.24−7.44 (m, 5 H, aromat. *H*) ppm. ^{13}C NMR ($CDCl_3$): δ = 18.1 (s, $=CHCH_3$), 21.8 (s, PhCH*C*H$_3$), 42.9 (s, Ph*C*H), 124.0 (s, $CH_3CH=$), 126.3−128.7 (m, aromat. *C*), 136.8 (s, CH*C*H=) ppm. MS (EI): *m*/*z* (%) = 146 (22) [M^+], 131 (100) [$M^+ - CH_3$], 116 (14) [$M^+ - 2CH_3$], 91 (31) [$C_7H_7^+$], 77 (10) [$C_6H_5^+$]. B.p. 35−40 °C (0.1 mbar).

(*E*)-4,6-Diphenyl-2-heptene (C): ^{1}H NMR ($CDCl_3$): δ = 1.39 (d, $^3J_{H,H}$ = 7.0 Hz, 3 H, PhCHC*H*$_3$), 1.83 (d, $^3J_{H,H}$ = 6.3 Hz, 3 H, $=CHCH_3$), 2.01−2.21 (m, 2 H, CH_2), 2.87 (sext, 1 H, $^3J_{H,H}$ = 7.2 Hz, PhC*H*CH$_3$), 3.25 (q, $^3J_{H,H}$ = 7.6 Hz, 1 H, PhC*H*CH=), 5.55−5.61 (m, 1 H, $CH_3CH=$), 5.76 (dd, $^3J_{H,H}$ = 7.9, $^3J_{H,H}$ = 15.0 Hz, 1 H, PhCHC*H*=), 7.25−7.47 (m, 10 H, aromat. *H*) ppm. ^{13}C NMR ($CDCl_3$): δ = 18.2 (s, $=CHCH_3$), 23.0 (s, PhCH*C*H$_3$), 37.8 (s, Ph*C*HCH$_3$), 45.1 (s, CH_2), 47.1 (s, Ph*C*HCH=), 125.6 (s, $CH_3CH=$), 126.4−146.0 (m, aromat. *C*), 135.4 (s, PhCH*C*H=) ppm. MS (EI): *m*/*z* (%) = 250 (12) [M^+], 145 (10) [M^+ − PhCHCH$_3$], 131 (100) [$M^+ - PhCH(CH_3)CH_2$], 105 (35) [PhCHCH$_3^+$], 91 (38) [$C_7H_7^+$], 77 (10) [$C_6H_5^+$]. B.p. 215−220 °C (0.1 mbar).

The Aminolysis of Beryllium Dichloride with Diisopropylamine and Reactions of Some Aminoberyllium Chlorides[‡]

Heinrich Nöth*[a] and Dieter Schlosser[a]

Dedicated to Prof. Dr. D. Fenske on the occasion of his 60th birthday

Keywords: Adduct formation / Amines / Beryllium / N ligands / NMR spectroscopy

$BeCl_2$ is not aminolyzed by diisopropylamine. An excess of this amine reacts with $BeCl_2$ or $BeCl_2{\cdot}2OEt_2$ to give $BeCl_2{\cdot}HNiPr_2$ (**1**). This compound, on deprotonation with LiBu at low temperature, gives rise predominantly to dimers of $ClBe(NiPr_2)$ (**2**), together with $Be(NiPr_2)_2$ (**3**). Compound **2** adds diisopropylamine to give the adduct $ClBe(NiPr_2){\cdot}HNiPr_2$ (**4**), which provides **3** on treatment with LiBu. Compound **2** reacts with $LiBH_4$ to give dimeric iPr_2NBeBH_4 (**17**). The BH_4 group is μ^2-bonded to the Be centers, as shown by NMR spectroscopic data and an X-ray structure determination. Moreover, a number of dimeric organylberyllium diisopropylamides iPr_2NBeR have been prepared by treatment of **2** with LiR. In analogy, *tert*-butoxyberyllium diisopropylamide (**20**) has also been synthesized. Moreover, several 2,2,6,6-tetramethylpiperidinoberyllium and bis(trimethylsilyl)amino derivatives are reported. ^{9}Be NMR spectroscopic data of the new compounds are consistent with tricoordinated Be centers and dimeric units (MS, cryoscopy).

Introduction

The principles of the chemistry of beryllium−nitrogen compounds were explored particularly by Coates and coworkers, beginning in the 1950s.[2] Research focussed on dimethylamino derivatives, which in most cases proved to be dimeric (for $RBeNMe_2$; R = alkyl, aryl),[3] and the status of beryllium−nitrogen chemistry has been summarized by Lappert et al.[4] Unlike the trimeric $Be(NMe_2)_2$, and also $Be(NEt_2)_2$, which is dimeric, the silylamide $Be[N(SiMe_3)_2]_2$ proved to be monomeric.[5] Another monomeric beryllium bis(amide) is the 2,2,6,6-tetramethylpiperidino derivative $(tmp)_2Be$.[6] For $(iPr_2N)_2Be$, a monomer/dimer equilibrium in solution has been established.[6] Obviously, the steric requirements of the diisopropylamino group allow stabilization of both association states with a preference for the dimer in the solid, and it may therefore be expected that diisopropylamides of beryllium of type iPr_2NBeX should be monomeric for bulky groups X. In order to verify this we have been examining a number of beryllium amides of this kind.

Results

Reactions

So far, no systematic study of the aminolysis of beryllium dichloride has been performed.

Bis(dialkylamino)beryllium compounds are readily obtained from $BeCl_2{\cdot}2OEt_2$ and 2 equiv. of $LiNR_2$ as shown in Equation (1). This is the only known route to the sterically demanding monomeric bis(amides) $(tmp)_2Be$, $[t$Bu$(Me_3Si)N]_2Be$,[6] and $[(Me_3Si)_2N]_2Be$.[5] For sterically less bulky amine groups, one may also deprotonate adducts of secondary amines and beryllium dichloride with LiR [Equation (2)].[7] However, this route has not often been used. To date, most of the reported amine adducts of $BeCl_2$ have the composition $BeCl_2{\cdot}n$(amine) (n = 2−4).[8,9] In order to characterize the various steps from $BeCl_2$ to $(R_2N)_2Be$ we have studied the reaction between beryllium dichloride and diisopropylamine in more detail.

No adduct of $BeCl_2$ and $HNiPr_2$ has yet been described. The amine may not form a well-defined product, as has been found for the triethylamine adduct of $BeCl_2$.[9] We found that solid $BeCl_2$ does not react with an excess of $HNiPr_2$ at ambient temperature. Under reflux conditions, however, the crystals of $BeCl_2$ turned into a gray powder of composition $BeCl_2{\cdot}HNiPr_2$ (**1**) [Equation (3)]. This compound is more readily obtained by treatment of $BeCl_2{\cdot}2OEt_2$ with a large excess of diisopropylamine in diethyl ether solution. In this case the 1:1 adduct was formed

$$iPr_2NBeCl{\cdot}HNiPr_2 + LiBu \rightarrow BuH + LiCl + (iPr_2N)_2Be \quad (7)$$

as an oily product, which became solid on removal of all volatile substances in vacuo. An excess of the amine is therefore not able to deprotonate **1**. This was to be expected, because it is unlikely that the amine would be able to remove a proton from $BeCl_2{\cdot}HNiPr_2$, as the beryllium amide should be more basic than diisopropylamine. A stronger base, such as LiR, is therefore needed for deprotonation.

Astonishingly, the reaction between LiBu and **1** at ambient temperature provided not only iPr_2NBeCl (**2**), but also by-products such as iPr_2NBeBu and $(iPr_2N)_2Be$ (**3**). This latter compound was actually the main product. Moreover, **2** could not be separated from the other products by sublimation in vacuo. Obviously, **2** reacted more rapidly than **1** with LiBu, to give iPr_2NBeBu, and, moreover, a $BeNiPr_2$/LiBu exchange, resulting in the formation of $Li(iNPr_2)$, competes favorably with other reactions and provides an opportunity to generate **3**.

At present, the 1:1 reaction between $LiNiPr_2$ and $BeCl_2{\cdot}2OEt_2$ in diethyl ether at 0 °C is the best choice for the preparation of **2** [Equation (5)]. Some $iPr_2NBeOEt$ and $(iPr_2N)_2Be$ is also formed in this reaction, but the chloride **2** can be separated by sublimation. In contrast, neither ligand exchange between $BeCl_2$ and $(iPr_2N)_2Be$ in boiling benzene nor the reaction between $(iPr_2N)_2Be$ and $BeCl_2{\cdot}2OEt_2$ in boiling THF or toluene afford **2**.

Molecular mass values and spectroscopic data for **2** indicate that the compound is dimeric in solution, containing tricoordinated Be atoms. These should be able to act as Lewis acidic centers. It was therefore expected that **2** might add a Lewis base. In the context of aminolysis, the addition of diisopropylamine to **2** was studied. The existence of a compound $iPr_2NBeCl{\cdot}HNiPr_2$ (**4**) was indicated in the reaction between $BeCl_2$ and 2 equiv. of the amine in diethyl ether after addition of 1 equiv. of LiBu. Needles separated from the resulting solution, their NMR spectroscopic data being consistent with compound **4** in admixture with iPr_2NBeBu and **3**.

Actually, after 10−20 min, the ^1H NMR spectrum of the 1:1 mixture of **2** and $HNiPr_2$ showed only the components, and about 24 h were required until the new signals attained maximum intensity. These signals can be interpreted in terms of the equilibrium according to Equation (6). Heating of this mixture to 75 °C restored the original situation (i.e., only the signals for diisopropylamine and **2** were visible), and it again took more than 24 h at ambient temperature to reform the equilibrium situation, which in solution lies

to 75% on the side of the adduct **4**. Figure 1 depicts some NMR spectra to illustrate this kind of interaction.

As was to be expected, the adduct $ClBe(NiPr_2)\cdot HNiPr_2$ did not react further with an excess of the amine. However, it was deprotonated by LiBu at low temperature, as shown in Equation (7), to produce bis(diisopropylamino)beryllium (**3**).[6] At ambient temperature, iPr_2NBeBu is a by-product. Thus, *direct aminolysis* of $BeCl_2$ by diisopropylamine is not possible, most probably because the *Be*-bonded amino group is more basic than the amine itself.[10]

Similarly, it was expected that $BeCl_2\cdot 2OEt_2$ should react with *N*-lithio-2,2,6,6-tetramethylpiperidine [Li(tmp)] in a 1:1 ratio to give (tmp)BeCl (**5**). In hexane solution, however, the main product (was $(tmp)_2Be$ (**6**). On the other hand, when the reaction was performed at −78 °C in the presence of diethyl ether, a viscous oil was obtained, and this was analyzed by NMR spectroscopy as a mixture of **6** (15%) and (tmp)BeOEt (**7**, 85%). These components could not be separated by fractional distillation. Analogously, the 1:1 reaction between $BeCl_2$ and tBu(Me_3Si)NLi in diethyl ether afforded a mixture of [tBu(Me_3Si)N]$_2$Be (**8**), tBu(Me_3Si)NBeCl (**9**), and tBu(Me_3Si)$_2$NBeOEt (**10**). From this mixture the bis(amide) **8** was separated by distillation. However, when the reaction was started at −100 °C, compound **8** was not present, and **9** and **10** were obtained in a 1:1.8 ratio. Compound **9** was separated by fractional sublimation. Similar behavior was observed for the 1:1 reaction between $BeCl_2$ and $LiN(SiMe_3)_2$ in diethyl ether. At room temperature, only [$(Me_3Si)_2N]_2$Be (**11**) was obtained besides $BeCl_2\cdot 2OEt_2$. At −78 °C, a 1:4:2 mixture of **11**, (Me_3Si)$_2$NBeCl (**12**), and (Me_3Si)$_2$NBeOEt (**13**) resulted. When the reaction was started at −100 °C, however, only **12** and **13** were detected by NMR, and these two compounds could be separated by fractional sublimation.

Reactions of iPr_2NBeCl and other Aminoberyllium Chlorides

The aminoberyllium chlorides offer potential as reagents for the synthesis of other aminoberyllium compounds by nucleophilic substitution of the Cl atoms. $[iPr_2NBeCl]_2$ was used as a model compound for this kind of reaction. Treatment with LiBu in hexane gave a 68% yield of liquid iPr_2NBeBu (**14**), as shown in Equation (8).

$$[iPr_2NBeCl]_2 + 2\ LiBu \rightarrow [iPr_2NBeBu]_2 + 2\ LiCl \quad (8)$$

14

$$[iPr_2NBeCl]_2 + 2\ LitBu \rightarrow [iPr_2NBe(tBu)]_2 + 2\ LiCl \quad (9)$$

15

$$2\ tBuBeCl + 2\ LiNiPr_2 \rightarrow [iPr_2NBe(tBu)]_2 + 2\ LiCl \quad (10)$$

At 0 °C the reaction according to Equation (9) produced some gas, which may be due to elimination of isobutene and formation of the hydride $[iPr_2NBeH]_n$. However, workup by sublimation yielded compound **15** as a solid in 48% yield. The residue from the sublimation provided evidence for the formation of the hydride, because hydrogen was generated by hydrolysis with hydrochloric acid. When the reaction according to Equation (9) was performed at −78 °C the yield of **15** increased to 78%. This yield was also obtained in the reaction according to Equation (10).

In order to obtain information on the steric effect of the tmp group, $[tmpBeCl]_2$ was treated with LiBu and LitBu. The reaction between **5** and LiBu gave dimeric (tmp)BeBu (**16**) [Equation (11)]. This is a viscous oil, and its dimeric nature was determined by molecular mass measurement in cyclohexane. Temperature-dependent ^{9}Be NMR spectroscopy provided no evidence for a monomer/dimer equilibrium.

$$[(tmp)BeCl]_2 + 2\ LiBu \rightarrow [(tmp)BeBu]_2 + 2\ LiCl \quad (11)$$

16

$$[(tmp)BeCl]_2 + 2\ LitBu \rightarrow [(tmp)Be(tBu)]_2 + 2\ LiCl \quad (12)$$

$$[(tmp)BeCl]_2 + 2\ LitBu \rightarrow 2/n\ [(tmp)BeH]_n + LiCl + H_2C{=}CMe_2 \quad (13)$$

$$tBuBeCl\cdot OEt_2 + (tmp)Li \rightarrow (tmp)BeH + LiCl\cdot H_2C{=}CMe_2 \quad (14)$$

$$[iPr_2NBeCl]_2 + 2\ LiBH_4 \rightarrow [iPr_2NBeBH_4]_2 + 2\ LiCl \quad (15)$$

18

$$[iPr_2NBeCl]_2 + 2\ KOtBu \rightarrow [iPr_2NBeOtBu]_2 + 2\ KCl \quad (16)$$

19

$$[iPr_2NBeCl]_2 + 2\ py \rightarrow [iPr_2NBeCl\cdot py]_2 \quad (17)$$

20

$$[iPr_2NBeCl]_2 + 2\ EX_3 \rightarrow [iPr_2NBeCl\cdot EX_3]_2 \quad (18)$$

21 ($EX_3 = BCl_3$)

22 ($EX_3 = BBr_3$)

23 ($EX_3 = AlCl_3$)

When LitBu was allowed to react with $[(tmp)BeCl]_2$ in hexane according to Equation (12), gas evolution was noted. The ^{1}H and ^{13}C NMR spectra of the solution showed only very-low-intensity signals for a tBu group. When the reaction was performed at −78 °C, LiCl precipitated slowly [see Equation (13)]. On warming, gas evolution started at about 10 °C. When the reaction mixture obtained at −78 °C was subjected to NMR analysis, no signals for a *Be*-bonded tBu group could be observed. The ^{9}Be NMR signal found at $\delta = 11.9$ ppm ($h_{1/2} = 140$ Hz) shows the same shielding as for compound **16**, an indication of the formation of $[(tmp)Be(tBu)]_2$.

An attempt to prepare **17** by using monomeric tBuBeCl·OEt$_2$ as a starting material might have allowed a more straightforward substitution using (tmp)Li. Neither at 0 °C nor at −78 °C was this possible, however. Gas evolution was observed in both cases, and the filtrate from the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

suspension gave no evidence for the formation of **17** by NMR analysis. However, 1 equiv. of LiCl was formed, and the filtrate was virtually free of chloride. The yield of the crude material was 90% calculated for (tmp)BeH.[11] The reaction therefore has to be as shown in Equation (14).

Since ether cleavage has been observed in reactions between the aminoberyllium chlorides and $LiNR_2$ compounds in diethyl ether, resulting in ethoxy derivatives, we treated **2** with KO*t*Bu. The *tert*-butoxy derivative **19** was obtained in good yield, as shown in Equation (16) (see below for the structures of R_2NBeOR compounds).

Unlike the alkyl or alkoxy groups, which are usually unidentate substituents, the BH_4 group may be variously mono-, di-, or even tridentate. The reaction between **2** and $LiBH_4$ was therefore expected to give $iPr_2NBe(BH_4)$, which might be monomeric in the case of a structure such as $iPr_2NBe(\mu\text{-}H_3BH)$ but proved to be dimeric $[iPr_2NBeH_4]_2$ (**18**) as shown in Equation (15). However, analysis of the solution by ^{11}B NMR spectroscopy showed that the main product was iPr_2NBH_2, together with $(iPr_2N)_2BH$, $[iPr_2NB(H)Cl]_2$, and $Be(BH_4)_2$. Moreover, several ^9Be NMR signals were noted, but none could be reliably assigned. When the reaction according to Equation (15) was performed at −78 °C and the mixture was allowed to come to room temperature, however, crystals of **18** separated from a concentrated solution at −20 °C. The tetrahydroborate **18** is stable up to 85 °C, but very moisture-sensitive, although not spontaneously inflammable in contact with air. Its molecular structure was determined by X-ray crystallography.

While $[iPr_2NBeCl]_2$ should have Lewis-acidic properties, due to its tricoordinated Be atoms, only Lewis base behavior can be expected from its Cl atoms. Compound **2** reacts readily with pyridine (py) to form a deep red solution in hexane [Equation (17)]. The isolated product is $[iPr_2NBeCl{\cdot}py]_2$ (**20**), with tetracoordinate Be atoms as shown by ^9Be NMR spectroscopy ($\delta = 4.8$, $w_{1/2} = 1.5$ Hz). Triethylamine gave no stable adduct.[9] Surprisingly, **2** reacted with strong Lewis acids, provided they were strong chloride acceptors. Thus, 1:2 adducts $[iPr_2NBeCl]_2{\cdot}2ECl_3$ resulted from treatment of **2** with BCl_3, BBr_3, and $AlCl_3$ [Equation (18)]. One of the constitutions **A**−**C** would be expected for these adducts. Structure **A** can be ruled out, as the ^9Be NMR signal is typical of tetracoordinate Be. Structure **C** also does not have to be considered, primarily because two ^9Be NMR signals would be expected at low field for a tri- and a dicoordinated Be atom. The latter would have only an electron quadruplet, and the cation would certainly be a high-energy species. All NMR spectroscopic data, however, are in agreement with structure **B**, and we assume that the structure has C_{2v} symmetry.

C

Spectroscopic Data

Beryllium is a single-isotope element. Its nuclear spin is 3/2, and it has a favorable longitudinal relaxation time. Although its nuclear quadrupole moment of $5.2{\cdot}10^{-2}$ ($e{\cdot}10^{-24}$ cm^2) is about 70% that of ^{11}B, the linewidths of the signals may become rather broad for Be atoms residing in asymmetric environments. On the other hand, the sensitivity of the ^9Be nucleus is smaller than that of ^{11}B only by a factor of 10. Nevertheless, the nuclear properties of ^9Be are very favorable for use of ^9Be NMR as a tool for obtaining structural information. As has been shown previously, chemical shifts and linewidths depend not only on the substituents but also, to a large extent, on the coordination number of Be.[12] Table 1 summarizes the ^9Be chemical shifts and ^1H, ^{13}C, and ^{14} N NMR spectroscopic data for the compounds reported in this study.

Because of the low solubility of $Cl_2Be{\cdot}HNiPr_2$ in most solvents, all of its NMR spectroscopic data were collected at 60 °C in C_6D_6 solutions. The ^9Be NMR signal at δ = 5.84 ppm, and particularly its linewidth (see Table 1), shows that the compound contains tricoordinated Be atoms. No ^{14}N resonance could be recorded. The ammonium-type character of the coordinated amine is represented by a ^1H NMR signal for the NH group at δ = 5.05 ppm, 4.5 ppm downfield from the free amine. The proton signal for the CH group is also shifted downfield (δ = 1.97 ppm).

While the ^9Be chemical shifts and the linewidths of the aminoberyllium chlorides **2**, **5**, **9**, and **13** (see Table 1) are consistent with a coordination number of three for the Be atoms, the ^1H and the ^{13}C NMR signals are less strongly influenced than in compound **2**. Tetracoordination at ^{14}N is confirmed by chemical shifts in the range from δ = −120 to −140 ppm.[13]

Unexpectedly, only two ^1H NMR signals were observed for the 36 protons of dimeric (tmp)BeCl. The eight methyl groups are represented by a single sharp signal at δ = 1.30 ppm, contrasting with a broad, unresolved multiplet for the CH_2 groups. Again in contrast, four ^{13}C NMR signals were found. Assignment to the four equivalent C atoms (atoms C1/C5, C2/C4, C3, and Me) of the tmp units was possible with the aid of $^{13}C(^1H\text{-NOE})$ experiments. Dimeric (tmp)BeOEt provided similar NMR spectra, the ^{13}C NMR spectrum showed clearly resolved signals for the two magnetically equivalent ethoxy groups. Those of the tmp groups are at higher field than in tmpH, except for the atoms C1/C5, which are bonded to a tetracoordinated N atom. Almost the same chemical shifts as for Et_2O were noted for the EtO groups. This is further evidence that the EtO group does not bridge the Be atoms (i.e., of the three possible dimeric aminoberyllium ethoxide structures **D**−**F** only the symmetrical amino-bridged species were formed).

[a] $\delta^{14}N = -183$. [b] $\delta^{14}N = -280$. [c] $\delta^{14}N = -134$. [d] $\delta^{14}N = -112$.

The ^{9}Be nuclei of the alkylberyllium amides are strongly deshielded in relation to the aminoberyllium chlorides and ethoxides. This corresponds to similar shielding effects seen in aluminium chemistry.[14] Neither for (R$_2$NBeBu)$_2$ nor for [R$_2$NBe(tBu)]$_2$ were signals observed for the C atoms bound to Be. This phenomenon is due to short transversal relaxation times T_2, which result in line broadening, an effect well known in organoboron chemistry.[15] In the case of [iPr$_2$NBe(tBu)]$_2$, the NMR spectra show no change with temperature (20−80 °C). No partial monomerization is therefore observed up to 80 °C.

As indicated previously, compound (tmp)Be(tBu) is unstable and decomposes with gas evolution, most probably with formation of the hydride (tmp)BeH. Its ^{9}Be NMR spectrum should show a doublet due to $^1J(^9\text{Be}^1\text{H})$, but only a broad signal ($h_{1/2}$ = 140 Hz) at δ^9 Be = 11.9 ppm was observed. Both observations correspond to tricoordinated Be. Because a small coupling constant is to be expected for this compound, the linewidth may prevent detection of the coupling, as is the case with, for example, [(tmp)$_2$AlH]$_2$.[16] No $^1J(^9\text{Be}^1\text{H})$ coupling can be observed in the ^{1}H NMR spectrum of [iPr$_2$NBe(μ-H$_2$BH$_2$)]$_2$, while the ^{11}B resonance appears as a 1:4:6:4:1 quintuplet, showing that the four hydrogen atoms bonded to the B atoms are magnetically equivalent. This is typical for almost all metal tetrahydroborates and can be explained for covalent species by a rapid exchange between terminal and bridging positions.[17] In comparison with the shielding of the boron center in NaBH$_4$ [δ^{11}B = −41.7 ppm, $^1J(^{11}\text{B},^1\text{H})$ = 80.8 Hz[18]] or (Me$_3$Si)$_2$NMg(μ-H$_2$BH$_2$)·2THF [δ^{11}B = −39.1 ppm, $^1J(^{11}\text{B},^1\text{H})$ = 81.8 Hz][19] the boron nuclei in [iPr$_2$NBe(μ-H$_2$BH$_2$)]$_2$ are deshielded while the coupling constant remains the same.

IR spectroscopy, unlike NMR, did not prove to be very helpful for obtaining structural information. In case of the adduct BeCl$_2$·HNiPr$_2$, a sharp band at 3224 cm^{-1} corresponds to ν(NH), while the NH stretching band for the free amine is very broad, with a maximum at about 3250 cm^{-1}. A strong and sharp band at 555 cm^{-1} may be attributed to ν(BeCl$_2$). For the chlorides (R$_2$N−BeCl)$_2$ a strong band at 615±35 cm^{-1} is most likely due to ν(BeCl). We found no band characteristic for a Be−C stretching frequency, but the double-bridge bonding of the BH$_4$ group was readily noticeable by two bands for two bridging and two terminal hydrogen atoms (2500, 2430, 2120, 2090 cm^{-1}).

The NMR spectroscopic data of the Lewis acid adducts of **2** do not differ too much from the parent compound. Actually, there is also no pronounced difference in the ^{13}C chemical shifts for **2** and for diisopropylamine. The ammonium-type character of the diisopropylamino group is reflected in lowfield shifts for both the Me and the CH groups, while $^1J_{H,H}$ remains constant. The lowfield shifts observed for the BBr$_3$ adduct in relation to boron and aluminium trichloride adducts most probably reflects a paramagnetic downfield shift resulting from the bromine atoms. Moreover, one might have expected better shielding of the ^{9}Be nuclei in the EX$_3$ adducts of **3**. It is the smaller linewidth that points to the presence of tetracoordinated Be atoms. That the interaction between the halide atoms of the Lewis acids and the beryllium centers is weak can be seen from the ^{11}B and ^{27}Al chemical shifts. In case of the BCl$_3$ adduct the resonance is at higher field than that of BCl$_3$ but significantly deshielded with respect to free BCl$_4^-$ (δ^{11}B = 7 ppm)[20] while the ^{27}Al NMR signal of the AlCl$_3$ adduct is slightly better shielded than in the anion AlCl$_4^-$ (δ^{27}Al = 110 ppm).[21]

X-ray Structure of iPr$_2$NBeBH$_4$

Single crystals of iPr$_2$NBeBH$_4$ were obtained from a hexane solution at −20 °C. The compound crystallized in the monoclinic space group $P2_1/c$ with Z = 4 dimeric units. Figure 2 displays the molecular structure.

Molecular structure of $[i\mathrm{Pr_2NBeBH_4}]_2$; thermal ellipsoids are depicted on a 50% probability level; selected bonds lengths [A] and bond angles [°] (estimated standard deviations are represented in parentheses): Be1−N1 1.690(4), Be1−N2 1.703(4), Be2−N1 1.690(4), Be2−N2 1.697(4), Be1···B1 1.925(5), Be2···B2 1.950(5), Be1−H1a 1.50(3), Be1−H1b 1.53(3), B1−H1a 1.19(3), B1−H2a 1.23(3), B1−H3a 1.06(3), B1−H4a 1.11(3), B2−H1b 1.26(3), B2−H2b 1.25(3), B2−H3b 1.10(4), B1−H4b 1.06(4), N1−C1 1.513(4), N1−C4 1.504(4), N2−C7 1.520(5), N2−C10 1.486(4); N1−Be1−N2 99.9(2), N1−Be2−N2 100.1(2), Be1−N1−Be2 80.3(2), Be1−N2−Be2 79.7(2), H1a−Be1−H2a 78(2), H1b−Be2−H2b 80(2), H1a−B1−H2a 104(3), H1b−B2−H2b 100(2), H3a−B1−H4a 117(3), H3b−B2−H4b 112(3), C1−N1−C4 110.0(2), C7−N2−C10 110.9(2), Be1−N1−C1 117.7(2), Be1−N1−C4 113.3(2), Be2−N1−C1 116.0(2), Be2−N1−C4 117.0(2), Be2−N2−C7 111.2(3), Be2−N2−C10 120.1(3), Be1−N2 C10 121.2(3)

The central part of the molecule is an oblique four-membered Be_2N_2 ring with a comparatively short Be···Be distance of 2.179 Å, while the N···N distance is 2.697 Å. The Be−N bond lengths vary from 1.690(4) to 1.703(4) Å. Each Be atom is surrounded not only by two N atoms but also by two H atoms, with Be−H bond lengths of 1.46(3) and 1.53(3) Å. The Be−B distances are 1.938 and 1.942 Å, respectively.

As would be expected, the bridging hydrogen atoms show B−H bonds longer [av. 1.23(3) Å] than the terminal B−H bonds [1.17(3) Å]. The terminal H−B−H bond angles are more open [117(3)° at B1, 113(2)° at B2] than those of the bridging hydrogen atoms [104(2)° at B1, 100(2)° at B2]. The H−Be−H bond angles are more acute, with 78(2)° at Be1 and 80(2)° at Be2. It follows from the longer N···N distance in relation to the Be···Be distance that the bond angles at the N atoms are more acute [Be1−N1−Be2 80.3(3)°, Be1−N2−Be 2 79.7(2)°] than those at the Be atoms [N1−Be1−N2 99.9(2)°, N1−Be2−N2 100.1(2)°].

Discussion

Of the two possible routes to aminoberyllium chlorides considered, ligand exchange between $(R_2N)_2Be$ and $BeCl_2$ (or $BeCl_2{\cdot}2OEt_2$) was unsuccessful, unlike 1:1 reactions between $BeCl_2$ and $LiNR_2$ compounds [R_2N = N*i*Pr$_2$, tmp, N(SiMe$_3$*t*Bu)$_2$, N(SiMe$_3$)$_2$] in diethyl ether solution. Low temperatures are necessary to retard or suppress the formation of beryllium bis(amides), because the aminoberyllium chlorides formed react more rapidly than $BeCl_2$ with $LiNR_2$ at ambient temperature. However, the formation of ethoxyberyllium amides could not be prevented. This indicates that ether cleavage by $LiNR_2$ occurs to a considerable extent even at low temperature. All compounds of type R_2NBeX (X = R, Cl, EtO) are dimeric. Dimerization occurs through the N atoms, producing four-membered Be_2N_2 rings. No beryllates $Li[Be(NR_2)_nCl_mY_o]$ (Y = OEt; $n + m + o = 3$) could be detected in the diethyl ether solutions. Beryllates have been observed by Anderson and Coates[22] in reactions between $BeCl_2$ and $LiNMe_2$ in diethyl ether.

(tmp)Be(*t*Bu) could not be prepared, because it decomposes with gas evolution and presumably forms (tmp)BeH. This latter compound was, however, not obtained in a pure state. Isobutene elimination from *t*Bu−metal compounds is not unusual, as even Li*t*Bu itself decomposes into LiH and isobutene.[23]

Direct aminolysis of $BeCl_2$, either as the crystalline material or as $BeCl_2{\cdot}2OEt_2$, with diisopropylamine could not be achieved. The reactions stopped at the $BeCl_2{\cdot}HNiPr_2$ adduct stage. Obviously, the NH proton is not sufficiently acidic to react with additional amine to achieve aminolysis to either R_2NBeCl or $(R_2N)BeCl{\cdot}HNR_2$ (R = *i*Pr). This latter adduct is indeed formed, though only slowly, in the reaction between $(i\mathrm{Pr_2NBeCl})_2$ and diisopropylamine, but it readily disintegrates into the components in solution at higher temperatures. In this respect the aminolysis of $BeCl_2$ matches the aminolysis of $AlCl_3$ with secondary amines, which also stops at the adduct stage,[24] unlike the case of BCl_3, which is aminolyzed to give not only R_2NBCl_2 but also $(R_2N)_2BCl$ and even $B(NR_2)_3$ with many secondary amines.[25] The main reason for the lack of aminolysis of $BeCl_2$ and $AlCl_3$ is most probably that the amides formed have more strongly basic nitrogen centers than the amine itself, while in the boron case the basicity of the amino group is reduced due to B−N π-bonding. However, $BeCl_2{\cdot}HNiPr_2$ can be deprotonated with LiBu or $LiNR_2$ (i.e., with strong bases).

Experimental Section

General: All experiments were performed under anhydrous conditions with use of Schlenk techniques. Dinitrogen or argon were used as protecting gases. Anhydrous $BeCl_2$ was purchased from Aldrich and the amines from Fluka, while the LiR compounds were gifts from Chemetall GmbH (usually as 1.5 M solutions in hexane). The amines and the solvents used were dried in a conventional manner ($LiAlH_4$, CaH_2, P_2O_5). $BeCl_2$−diethyl ether was prepared from Be powder and HCl in diethyl ether.[26] All necessary safety measures were practiced in the experimental procedures, as Be compounds are toxic. After the experiments, the glassware was washed with conc. HCl and the solutions were collected in plastic flasks. These collected solutions were concentrated in vacuo using a rotary

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

evaporator. The oily or pasty residues were properly labeled and disposed as special waste.

Physical Measurements: Molecular masses were determined by cryoscopy in cyclohexane solutions or by mass spectrometry. NMR: JEOL 90 or Bruker WP200 instruments. ^{1}H (int. TMS, int. CD_2Cl_2, int. C_6D_6), ^{9}Be (1 M solution of $BeCl_2$ in 1 M HCl/D_2O), ^{13}C (int. TMS, int. $CDCl_3$, or int. $C_6D_{6'}$), ^{14}N (ext. 1 M solution of NH_4NO_3 in D_2O). MS: Atlas CH7. IR: Perkin-Elmer 235 spectrometer. Elemental analysis: Automatic C/H/N analyzer, chloride titration with a Metroohm instrument. M.p.: Mel-Temp. in capillaries.

X-ray Analysis: Siemens P4 diffractometer, Mo-K_α radiation, graphite monochromator, LT2 device. Data collection at −80 °C, data reduction with the program SAINT,[27] structure solution with SHELX79,[28] data refinement with SHELXTL. Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atom positions of the BH_4 group were taken from the difference Fourier map. These were freely refined with individual isotropic thermal parameters. H atoms of the isopropyl groups were placed in calculated positions and included in the final refinements as riding on their C atoms. Crystallographic data for **18** have been deposited with the Cambridge Crystallographic Data Center as supplementary publication CCDC-195196. Copies can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK; E-mail: deposit@ccdc.ac.uk.

Beryllium Dichloride−Diisopropylamine (1). a) Anhydrous crystalline $BeCl_2$ (1.50 g, 19 mmol) was covered with diisopropylamine (13.5 mL, 100 mmol) in a two-necked flask, and the mixture was kept at reflux for 3 h. During this time the crystals disappeared and turned into a gray mass. The solid was isolated by filtration, washed with pentane, and dried in vacuo. Yield: 2.40 g (100%) of **1**, m.p. 65 °C. NMR recorded at 70 °C: see Table 1. $C_6H_{14}BeCl_2N$ (180.12): calcd. C 39.79, H 8.37, Cl 39.14, N 7.74; found C 39.22, H 8.41, Cl 39.20, N 7.83. **b)** Diisopropylamine (12.5 mL, 90 mmol) was dissolved in diethyl ether (25 mL). A solution of $BeCl_2$ in diethyl ether (4.5 M, 10 mL, 45 mmol) was added dropwise to the stirred solution over 15 min. An oily phase formed. The mixture was kept at reflux for 1 h (this is not actually necessary). No crystals formed from the oily phase in a refrigerator within 24 h. All volatile components were then removed in vacuo. A gray mass was left behind, and this, after drying in vacuo, gave 18.12 g (99.5%) of **1**, m.p. 65 °C. NMR spectroscopic and analytical data are the same within standard errors as for the compound obtained by procedure a).

Deprotonation of $BeCl_2$·HN*i*Pr$_2$ with LiBu: Diisopropylamine (14.1 mL, 100 mmol) was added to $BeCl_2$ (7.99 g, 100 mmol) and the mixture was heated at reflux for 3 h. The resulting gray solid mass was then suspended in hexane (50 mL) and the stirred suspension was treated with a solution of LiBu in hexane (1.58 M, 66.7 mL, 100 mmol) over 2 h. The resulting suspension was kept at reflux for 2 h, insoluble material (4.9 g) was removed by filtration, and the solvent was removed from the filtrate in vacuo. An oily residue (17.5 g) remained. Half of the material was distilled. This afforded two fractions: fraction 1 (0.8 g), b.p. up to 60 °C/0.1 Torr; fraction 2 (5.67 g), b.p. 60−63 °C/0.1 Torr, showing three ^{9}Be NMR signals at δ = 9.9 (main product), 15.9, and 3.2 ppm. Redistillation of fraction 2 yielded 3.25 g of product with b.p. 61−62 °C/0.1 Torr. It showed the following NMR signals: δ^{1}H = 0.1 ppm (m), 0.87 (d, $^3J_{H,H}$ = 6.69 Hz), 1.04 (d, $^3J_{H,H}$ = 6.75 Hz), 1.21 (d, $^3J_{H,H}$ = 5.86 Hz), 1.52 (m), 2.9 (m), 3.7 (m). δ^{9}Be = 10.2 ppm with a shoulder at δ = 16 ppm. On standing, this fraction became partly crystalline. The crystals (0.72 g) were separated and washed with pentane. They showed a ^{1}H NMR spectrum fairly similar to that described above, with the most intense signal at δ = 1.21 ppm (d). δ^{9}Be = 1.7 and 15.4 ppm (broad, $h_{1/2}$ = 170 Hz). The chloride content of all fractions was very low by qualitative analysis. From comparison of NMR spectroscopic data, all fractions contained **3**, **14**, and small amounts of **2**. Several attempts to produce crystals from various solvents with the second part of the crude product failed at −20 and −78 °C.

Ligand Exchange between $BeCl_2$ and (*i*Pr$_2$N)$_2$Be: (*i*Pr$_2$N)$_2$Be (10.0 g, 48 mmol) and hexane (50 mL) were added to $BeCl_2$ (3.83 g, 48 mmol). The mixture was kept at reflux for 48 h. Hexane was removed from a sample in vacuo. The oily residue showed ^{1}H NMR signals at δ = 1.09 (d) and 2.92 ppm (sept) typical of **3**. Irradiation of the mixture by an Hg lamp in the presence or absence of hexane also did not induce any reaction; 3.87 g of $BeCl_2$ was recovered. Similarly, a mixture of (*i*Pr$_2$N)$_2$Be (3.14 g, 15 mmol) and $BeCl_2$·2OEt$_2$ (6 mL of a 2.5 M solution in ether) showed no reaction after being kept at reflux for 24 h, as evidenced by ^{9}Be NMR resonance [signals at δ = 12.7 ppm (amide) and δ = 1.15 ppm for beryllium chloride−diethyl ether].

(Diisopropylamino)beryllium Chloride (2). a) $BeCl_2$·2OEt$_2$ (16.8 mL of a 2.59 M solution in diethyl ether, 50 mmol) was diluted with diethyl ether (20 mL). A suspension of LiN*i*Pr$_2$ (37 mmol) in hexane (50 mL) was added with stirring over 2 h. Insoluble material was removed by filtration after 16 h, and the solvent was stripped off from the filtrate in vacuo. The oily residue was distilled (b.p. ca. 85 °C/0.1 Torr), and the distillate afforded colorless crystals of **2**, m.p. 72 °C. NMR: see Table 1. $C_6H_{14}BeClN$ (144.65): calcd. C 49.82, H 9.76, Cl 24.51, N 9.68; found C 48.65, H 9.78, Cl 23.93, N 9.65. Molecular mass: 286. **b)** The reaction was performed similarly at 0 °C (16.8 mL of a 2.98 M $BeCl_2$ solution in diethyl ether, 50 mmol, diluted with 25 mL of ether) with freshly prepared LiN*i*Pr$_2$ (50 mmol) in hexane (75 mL). Stirring at 0 °C for 3 h, and then at ambient temperature overnight gave LiCl (2.05 g, 97%), which was isolated from the suspension by filtration. The filtrate contained 7.42 g of a solid crude product. Its sublimation at 95 °C/0.005 Torr provided waxy crystals of **2**, m.p. 72 °C; yield 6.62 g (86%). MS: Correct isotope pattern for [M$^{+\cdot}$] (288). All other data are as stated under a).

(Diisopropylamino)beryllium Chloride−Diisopropylamine Adduct 4: $BeCl_2$ (2.05 g, 26 mmol) was allowed to react at reflux with diisopropylamine (7.45 mL, 53 mmol) for 2 h. Hexane (50 mL) was then added to the cooled (0 °C) suspension, followed by LiBu (1.56 M in hexane, 16.9 mL, 26 mmol). This produced a white suspension. After the mixture had been heated at reflux for 2 h, some crystals had separated on the walls of the flask. Insoluble material was then rapidly removed by filtration (1.11 g) and the filtrate was reduced to 30 mL in vacuo. Crystal settled from the filtrate at −20 °C. Yield 4.18 g (68%) of **4**; m.p. 65 °C with decomp. NMR: see Table 1. $C_{12}H_{29}BeClN_2$ (245.84): calcd. C 58.63, H 11.89, Cl 14.42, N 11.39; found C 59.19, H 12.43, Cl 14.33, N 10.75.

(2,2,6,6-Tetramethylpiperidino)beryllium Chloride (5): A diethyl ether solution of $BeCl_2$ (3.5 M, 13.3 mL) was diluted with diethyl ether (50 mL) and cooled to −100 °C. A suspension of (tmp)Li (7.36 g, 50 mmol) in pentane/hexane (1:1) was added dropwise with vigorous stirring over a period of 3 h. Stirring was continued for another 3 h, and the suspension was then allowed to come to room temperature overnight with continuous stirring. Insoluble material (2.08 g) was removed by filtration, and the solvents were stripped off from the filtrate in vacuo. A brownish solid (10.4 g) was left. This crude product showed the following NMR spectroscopic data:

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

δ^1H = 1.08 ppm (t), 1.16 (s), 3.9 [q, ^3J(H.H) = 7.08 Hz; (tmp)BeOEt, **7**], 1.30 (s), 1.64 [m, (tmp)BeCl, **5**], ratio of the singlets 2.2:1 (95% **5**, 5% **7**). δ^9Be = 9.4 ppm (**5**). Sublimation of the crude material at 110 °C/0.006 Torr yielded 6.84 g (74%) of **5**, m.p. 105−107 °C. NMR: see Table 1. $C_9H_{18}BeClN$ (184.74): calcd. C 58.31, H 9.84, Cl 19.19, N 7.89; found C 56.47, H 9.08, Cl 19.08, N 6.95. Molecular mass: 366. MS: 369 for [$M^{+\cdot}$] (correct isotopic pattern).

[*tert*-Butyl(trimethylsilyl)amino]beryllium Chloride (9): Analogously to the preparation of **5**, a diethyl ether solution of $BeCl_2$ (3.75 M, 13.3 mL, 50 mmol), diluted with diethyl ether (50 mL), was added at −100 °C to a suspension of $LiN(SiMe_3)CMe_3$ (6.66 g, 50 mmol) in pentane/hexane (1:1) (75 mL). Stirring was continued at −100 °C for 3 h and at −78 °Cfor 2 h. After the suspension had reached room temperature, the solid was filtered and the solvents were removed from the filtrate in vacuo. Residue: 8.43 g of a waxy solid. Sublimation at 125 °C/0.0049 Torr gave 3.4 g (36%) of **9**. NMR: see Table 1. $C_7H_{18}BeClNSi$ (188.81): cald. C 44.53, H 9.63, Cl 18.78, N 7.42; found C 43.92, H 9.05, Cl 18.54, N 6.86. Molecular mass: 375.

[Bis(trimethylsilyl)amino]beryllium Chloride (12) and Ethoxyberyllium Bis(trimethylsilyl)amide (13): This compound was prepared analogously to **9**, from $BeCl_2$ (25 mmol) in diethyl ether/pentane (1:1, 50 mL) and $LiN(SiMe_3)_2$ (4.18 g, 25 mmol) suspended in pentane/hexane (1:1, 50 mL) at −100 °C. After workup, 4.83 g of a slightly yellow, waxy solid was obtained, and this was shown by NMR analysis to be a 1:2.5 mixture of **12/13**. Fractional sublimation gave three fractions: a) at 110 °C/ 0.004 Torr, 1.24 g of compound **13**, m.p. 147−149 °C;NMR spectroscopic data see Table 1; b) at 110−117 °C/0.004 Torr, 2.18 g, this fraction was shown by NMR to be a mixture of **12** and **13**; c) 117 °C/0.004 Torr, 0.6 g of compound **12**, NMR: see Table 1. $C_6H_{18}BeClNSi_2$ (204.89): calcd. C 35.17, H 8.87, Cl 17.36, N 6.84; found C 34.23, H 8.25, Cl 17.21, N 6.23.

Butyl(diisopropylamino)beryllium (14): iPr$_2$NBeCl (3.18 g, 22 mmol) was dissolved in hexane (25 mL), and the solution was cooled to 0 °C. A solution of LiBu in hexane (1.56 M, 14.1 mL) was added dropwise, with stirring. The mixture was then kept at reflux for 1 h. After the solid material (LiCl) had been removed by filtration and the hexane had been distilled from the filtrate, the oily residue was distilled. Compound **14** had a b.p. of 78 °C/ 0.1 Torr. Yield 2.49 g (88%). NMR: see Table 1. $C_{10}H_{23}BeN$ (166.35): calcd. C 72.20, H 13.98, N 8.42; found C 71.08, H 12.41, N 7.95. Molecular mass: 426.

***tert*-Butyl(diisopropylamino)beryllium (15): a)** The compound was prepared as described for **14**, from iPr$_2$NBeCl(2.60 g, 18 mmol) in hexane (25 mL) and a solution of LitBu (1.50 M, 12 mL, 18 mmol), withstirring at ambient temperature for 3 h. Compound **15** showed a b.p. of 90 °C/0.005 Torr, Yield 1.44 g (48%), m.p. 84−86 °C. When the reaction was performed at −78 °C the yield rose to 78%. NMR spectroscopic data: see Table 1. $C_{10}H_{23}BeN$ (166.35): calcd. C 72.20, H 13.98, N 8.42; found C 69.58, H 13.05, N 7.93 (low C/H values due to insufficient protection against oxidation during the weighing process). Molecular mass: 331. **b)** tBuBeCl·OEt$_2$ (1.41 g, 8.0 mmol), dissolved in pentane (15 mL), was treated at −78 °C, with vigorous stirring, with a suspension of Li$N$$iPr_2$ (0.l86 g, 8 mmol) in pentane/hexane (1:1). After the mixture had been allowed to come to room temperature, the solid was removed by filtration and the solvents were removed in vacuo. The residue was distilled, b.p. 90 °C (oil bath)/0.005 Torr. Yield 1.01 g (76%) of **15**, m.p. 84−86 °C. NMR spectroscopic data are as found for compound **15** prepared by procedure a).

Butyl(2,2,6,6-tetramethylpiperidino)beryllium (16): (tmp)BeCl (2.03 g, 11 mmol) was dissolved in hexane (20 mL) and treated, whilst stirring, with LiBu (7.05 mL, 1.56 M solution in hexane diluted with 10 mL of hexane). The mixture was kept at reflux for 30 min. Insoluble material was removed by filtration and the solvents were removed in vacuo. The residue had a b.p. of 98−104 °C/ 0.006 Torr. Yield 1.32 g (58%) of **16**. NMR spectroscopic data: see Table 1. $C_{13}H_{27}BeN$ (206.42): calcd. C 75.67, H 13.21, N 6.79; found C 74.98, H 12.88, N 6.25. Molecular mass: 410.

Attempt to Prepare (tmp)Be(tBu) (17): a) (tmp)BeCl (2.77 g, 15 mmol) dissolved in pentane (40 mL) was cooled to −78 °C. A solution of LitBu (1.5 M, 10.0 mL, 15 mmol), diluted with pentane (15 mL), was then added with stirring over 3 h. After additional stirring for 2 h, the mixture was allowed to come to ambient temperature, whereupon vigorous gas evolution started at ca. 10 °C. Insoluble material was removed after stirring for additional 20 min, followed by stripping off of the solvents in vacuo. The residue (2.04 g), a yellowish, viscous oil, decomposed during attempted distillation. The residue was practically free of chloride. NMR (crude product): δ^1H = 1.01 ppm (s), 1.18 (s), 1.31 (s), 1.62 (m) in a ratio of 1.0:1.7:14.7:8.8. δ^{13}C = 18.55 ppm, 32.22, 32.76, 33.21, 34.37,

37.75. 39.87, 50.40, 52.21. δ^9Be = 11.9 ppm ($h_{1/2}$ = 145 Hz). **b)** *t*BuBeCl·OEt_2 (1.58 g, 9.00 mmol) was dissolved in pentane (20 mL) and the solution was cooled to −78 °C. A suspension of (tmp)Li (1.32 g, 9.00 mmol) in pentane/hexane (1:1) (20 mL) was added over 2 h. The solid that had formed was removed by filtration and the solvents were stripped off in vacuo. The NMR spectroscopic data are essentially the same as from experiment a), demonstrating that no single compound was produced [main product 90%; δ^1H = 1.31 ppm (s), 1.67 (m), by-products ca. 4 and 6%]. The product was essentially free of chloride.

(Diisopropylamino)beryllium Tetrahydroborate (18): A solution of $LiBH_4$ in diglyme (1.0 M, 5.8 mL, 5.8 mmol), to which diethyl ether (5 mL) had been added, was added to a solution of $(i\mathrm{Pr_2NBeCl})_2$ (0.83 g, 2.9 mmol) in diethyl ether (10 mL). After the addition, the mixture was kept at reflux for 1 h. Insoluble material was removed by filtration (G4), all solvents were stripped off in vacuo, and the residue was crystallized from pentane at −20 °C. Colorless, extremely moisture-sensitive crystals (0.54 g, 75%) were obtained, dec. at ca. 85 °C. NMR: see Table 1. IR: ν(BH): 2428, (st), 2405 (st), 2138 (st), 2068 (m) cm^{-1}. $C_{12}H_{36}B_2Be_2N_2$ (248.14): calcd. C 58.08, H 14.65, N 11.29; found C 56.46, H 9.53, N 10.59. The low H content seems to be due to insufficient protection of the compound during the weighing process. In addition, combustion occurred explosively. Molecular mass: 246.

***tert*-Butoxyberyllium Diisopropylamide (19):** $(i\mathrm{Pr_2NBeCl})_2$ (1.72 g, 5.94 mmol) was dissolved in hexane (30 mL) and treated with KO*t*Bu (1.47 g, 13.0 mmol) in hexane (15 mL). After the mixture had been heated at reflux for 30 min, the insoluble part was removed by filtration, the solvents were stripped off from the filtrate in vacuo, and the light brown residue was subjected to sublimation. Yield 1.70 g (78.5%) of **19** obtained at 150 °C/0.005 Torr, m.p. 138−139 °C. NMR: see Table 1. $C_{10}H_{23}BeNO$ (182.35): calcd. C 65.86, H 12.74, N 7.68; found C 63.47, H 11.65, N 7.08. Molecular mass: 359.

Adduct of (Diisopropylamino)beryllium Chloride and Boron Trichloride (21): $(i\mathrm{Pr_2NBeCl})_2$ (0.83 g, 2.9 mmol) was dissolved in dichloromethane (10 mL) and the solution was cooled to −78 °C. At this temperature, liquid BCl_3 (1 mL) was added and the mixture was stirred for 2 h. Excess BCl_3 and solvent were then removed in vacuo, and the dark brown solid residue was crystallized from pentane (3 mL). Yield 0.99 g (65%) of **22**, yellow solid, dec. at 132−140 °C. NMR: data see Table 2. $C_6H_{24}BBeCl_4N$ (261.83): calcd. C 27.52, H 4.89, Cl 54.16, N 5.35; found C 26.58, H 4.02, Cl 53.95, N 4.98.

Adduct of (Diisopropylamino)beryllium Chloride and Boron Tribromide (22): Analogously to the preparation of **22**, $(i\mathrm{Pr_2NBeCl})_2$ (0.62 g, 2.1 mmol) was treated with BBr_3 (0.47 mL, 5 mmol), dissolved in CH_2Cl_2. After removal of the dichloromethane from the solution, the dark brown residue was subjected to crystallization from pentane (9 mL) to give 0.98 g (58%) of dark brown **23**, dec. at 95−98 °C. NMR: see Table 2. $C_6H_{14}BBeBr_3ClN$ (395.18): calcd. C 18.23, H 3.58, N 3.55; found C 17.18, H 2.87, N 3.05; total halide contents: 0.41 mmol in 0.1 mol of compound **23**.

Adduct of (Diisopropylamino)beryllium Chloride and Aluminium Trichloride (23): Freshly sublimed $AlCl_3$ (0.69 g, 5.2 mmol) was added to a solution of $(i\mathrm{Pr_2NBeCl})_2$ (0.75 g, 2.6 mmol) in dichloromethane (10 mL). No reaction was observed after the mixture had been stirred for 1 h. After the mixture had been heated at reflux for 2 h, the $AlCl_3$ had dissolved. The solvent was then removed in vacuo and the yellow/brown solid was crystallized from pentane (8 mL). Yield: 0.89 g (62%) adduct as a light yellow solid, dec. at 115−117 °C. NMR: see Table 2. $C_6H_{14}AlBeCl_4N$ (278.04): calcd. C 25.92, H 5.09, N 5.04; found C 24.83, H 4.18, N 4.67.

Pyridine Adduct of (Diisopropylamino)beryllium Chloride (20): A solution of pyridine (0.70 mL, 6.6 mmol) in CH_2Cl_2 (5 mL) was added with stirring to a solution of $(i\mathrm{Pr_2NBeCl})_2$ (0.69 g, 3.3 mmol) in the same solvent (15 mL). A deep red solution formed. After 2 h, the solvent was removed in vacuo and the remaining brown solid was dissolved in pentane (5 mL). No crystals separated from this solution at −20 °C. On removal of the solvent a dark brown/red solid remained (1.48 g, 99%), dec. at 132−134 °C. NMR: see Table 2. $C_{11}H_{19}BeClN_2$ (223.78): calcd. C 59.04, H 8.58, Cl 15.84, N 12.52; found C 56.84, H 8.88, Cl 15.66, N 9.28.

Crystallographic Data and Structure Refinement Parameters for $(i\mathrm{Pr_2NBeBH_4})_2$: Empirical formula: $C_{12}H_{36}B_2Be_2N_2$, formula mass: 248.07, crystal color: colorless, crystal size: 0.32 × 0.30 × 0.42 mm, crystal system: monoclinic, space group: $P2_1/n$, unit cell dimensions: a = 7.813(2), b = 21.927(6), c = 10.437(4) Å, β = 93.60(3)°, V = 1784.5(9) $Å^3$, Z = 4, density (calcd.) = 0.923 g/cm^3, linear absorption coefficient: 0.46 cm^{-1}, F(000) = 559, wavelength: λ = 0.71073 Å, 2θ range for data collection: 3−46°, speed: 2.2−29.3 °/min, T = 18 °C, index ranges: h, k, $\pm l$, reflections collected: 2910, independent reflections: 2494, reflections observed (2.5σ): 1898, parameters refined: 273, R_i = 0.0281, structure solution: direct methods, R_1 = 0.0876, R_w = 0.080, largest residual electron density: 0.41 e/$Å^3$.

One-Step Preparation of [RuCp*(η⁶-arene)]⁺ Sandwich Complexes

Alexander Schmid,[a] Holger Piotrowski,[a] and Thomas Lindel*[a]

Keywords: Ruthenium / Sandwich complexes / NMR spectroscopy / Synthetic methods

In a single step, several variously functionalized [RuCp*(η⁶-arene)]⁺ sandwich complexes have been prepared starting from $RuCl_3 \cdot xH_2O$ in yields ranging from 35 to 80%, referring to ruthenium. The protocol covers the preparation of valuable [RuCp*]⁺-complexed amino acids. In comparative experiments starting from the oligomer $[RuCp^*Cl_2]_n$ and using methanol/methanolate as the reducing agent, the formation of undesired side products was observed, resulting from nucleophilic substitution at the *o*-chloroanisole complex and from methoxylation of the Cp* ligand.

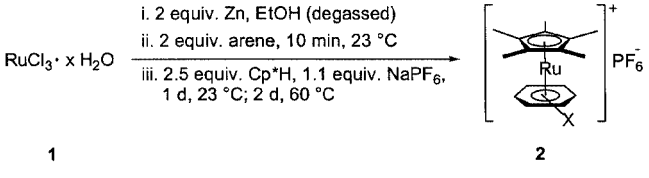
Introduction

Our program on the synthesis of oligomeric Ru-labelled diaryl ether peptoids[1] requires the availability of large quantities of various ruthenium sandwich complexes by a facile synthetic procedure. Radioactive labelling of peptoids[2] holds the promise to selectively bind and destroy tumour cells by combining the biological activity of biooligomers with the physical properties of metals. Ruthenium appears to be especially suitable because its radioactive isotopes cover half-lives ranging from three days to one year.[3] In this paper, we report a one-step procedure that provides large quantities of several [RuCp*]⁺ complexes, including some with amino acid ligands, to be used in bioorganometallic chemistry.

Pearson et al., Rich et al., and Matassa et al. have published pioneering work in the field of [RuCp]⁺-labelled peptoid diaryl ethers.[4] The [RuCp]⁺ complexation of the chloroarene precursors of the diaryl ethers follows a procedure based on the work of Gill and Mann.[5] Recently, the protocol was improved by Trost and Older,[6] but still needs four subsequent steps, starting from $RuCl_3 \cdot xH_2O$ (**1**). The situation may be simplified if [RuCp*]⁺ complexes are pursued instead (Cp* = pentamethylcyclopentadienyl). Kudinov et al. have obtained [RuCp*(η⁶-arene)]⁺ sandwich complexes from the reaction of $RuCl_3 \cdot xH_2O$ (**1**) with Cp*H and the three robust arenes benzene, toluene, and mesitylene in boiling alcohols as reducing agents.[7] The use of Zn — a milder reductant of the oligomer $[RuCp^*Cl_2]_n$ — in an overall two-step procedure was first reported by Chaudret et al.[8] In this paper we report a practically useful one-step procedure to [RuCp*(η⁶-arene)]⁺ sandwich complexes merging both approaches.

Results

Scheme 1 gives the reaction conditions we have developed. Upon addition of Zn (2 equiv.) to the ethanol solution of $RuCl_3 \cdot xH_2O$, a rapid colour change of the ethanolic solution from cherry red to dark blue occurred. Subsequently, the arene and Cp*H were added. The chosen stoichiometry gave the best yields. Table 1 gives 15 examples, 13 of which have been synthesised by the reported method. For comparison, only complexes **4**, **14** and **15** were obtained using methanol/methoxide as reducing agent, starting from the oligomer $[RuCp^*Cl_2]_n$.[14]



Scheme 1. One-step preparation of [RuCp*(η⁶-arene)]⁺ sandwich complexes

It was observed that the yield of the sandwich complexes **2** increased substantially with prolonged reaction times. While, for example, the reaction with acetophenone had proceeded to about 36% (referring to a Ru content of 37% in $RuCl_3 \cdot xH_2O$) after 10 minutes, a yield of 51% of the sandwich complex **11** was isolated after three days at 60 °C. Facile workup of the reaction mixture (Scheme 2) is very

important for practical applications and had to include the separation of non-polar by-products. The most convenient way was by partitioning of the column-filtered residue between water/methanol and *iso*-octane. Removal of inorganic salts was secured by exhaustive extraction of the crude product with dichloromethane. As reported by us for $[RuCp]^+$-complexed diaryl ether peptoids, aminopropyl-functionalised silica proved to be suitable for further purification of the cationic sandwich complexes by HPLC.[1]

Two new diastereomeric sandwich complexes (**13a**, **13b**) were obtained from (*E*)-ethyl cinnamate (entry 11), resulting from Diels–Alder cycloadditions of Cp*H to the olefinic double bond.[9] 2D NMR spectroscopic analysis (COSY, HSQC, HMBC) allowed the complete assignment of all chemical shifts to the diastereomers **13a** and **13b**. Since it was not possible to separate these diastereomers, even by HPLC, a NOESY spectrum of the mixture had to be the basis for the decision on which set of NMR signals belonged to which diastereomer. Complex **13a**, with the sandwich complex in the axial position of the norbornene system, shows a correlation between 7-H and 17-H while for the diastereomer **13b** a cross-peak between 8-H and 17-H is observed. For **13a** an X-ray analysis (Figure 1) confirmed its stereochemistry.

Figure 2 gives the crystal structure of the Cp*-monomethoxylated sandwich complex of ethyl benzene (**14**). Complex **14** was only formed by the oligomer route, and not in the direct preparation (entry 2).

We also prepared $[RuCp^*]^+$ complexes of amino acid esters (entries 14 and 15). The $[RuCp^*]^+$-complexed ethyl

Table 1. $[RuCp^*(\eta^6\text{-arene})]^+$ sandwich complexes obtained via the one-step procedure (Scheme 1, for entries 1–11, 14, 15) and via the oligomer route (entries 12, 13); the counterion is always hexafluorophosphate

ester **17** was formed directly from the acid (entry 15) when the reaction was carried out in ethanol. The esterification can be prevented if *tert*-butanol is used as a solvent instead.

Discussion

There are several multi-step routes to [RuCp*(η⁶-arene)]⁺ sandwich complexes. For the Cp analogues, a popular approach uses the reaction of $[RuCp(CH_3CN)_3]^+$ half-sandwich complexes with various arenes. The tris-acetonitrile complexes are air-sensitive and should be freshly prepared before use.[10] The availability[11] of the oligomer $[RuCp^*Cl_2]_n$ has opened several synthetic routes to [RuCp*(η⁶-arene)]⁺ sandwich complexes using $LiBEt_3H$,[12] Zn,[8,13] methanol/methoxide,[14] or various alcohols/K_2CO_3 [15] as reducing agents. However, the purity of the oligomer $[RuCp^*Cl_2]_n$ may vary and therefore have an unpredictable influence on the yields (55 to 80%) of the desired [RuCp*(η⁶-arene)]⁺ sandwich complexes.[11,16] The only characterised complex was obtained for $n = 2$ in a benchmark procedure, but this complex should not be stored for long periods.[17] As a by-product of the synthesis of the oligomer, decamethylruthenocene is formed in about 10−30% yield.[18] In addition, it has been reported that on prolonged standing the oligomer may transform into an entity with lower solubility which is less available for further conversion.[16b] As a consequence, it is desirable to avoid

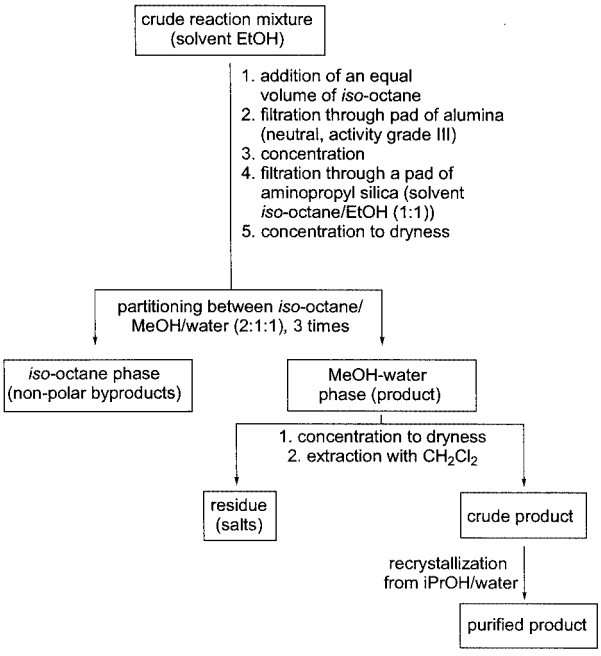

Scheme 2. Flow chart outlining the workup of the charged ruthenium complexes

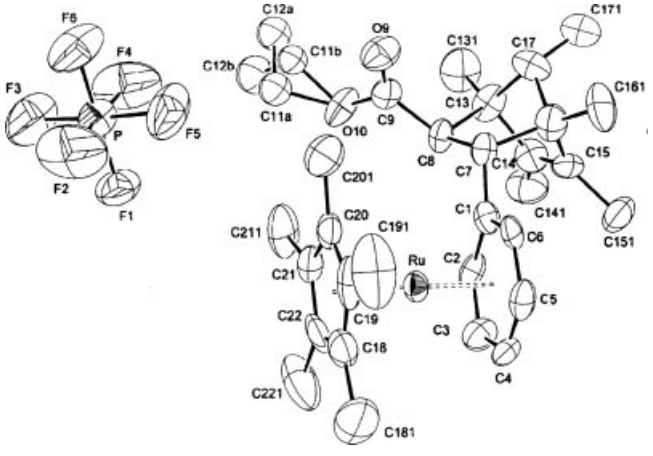

Figure 1. ORTEP plot of the Diels–Alder adduct **13a**; the atoms $C11_a$ and $C12_a$ (ethyl group) are disordered

the oligomer $[RuCp^*Cl_2]_n$ in the synthetic sequence. Koelle et al. circumvented that problem and synthesised alkoxoruthenium(II) complexes from the oligomer under mild conditions in quantitative yields. $[RuCp^*(Oalkyl)]_2$ is then reacted with two equivalents of arene to form the sandwich complex in yields ranging from 36% to 72%.[15,19] A pathway to $[RuCp^*(\eta^6\text{-arene})]^+$ sandwich complexes that does not begin with $RuCl_3 \cdot xH_2O$ (**1**) was pursued by Salzer and Ludi.[20] Ru^{II} triflate is reacted with a mixture of Cp*H and arene. The synthesis of $[Ru(H_2O)_6](OTf)_2$ is itself a three-step procedure including the distillation of the toxic RuO_4.[21]

The isolated yields obtained by our one-step procedure are similar to the more complicated protocols and vary from 35% (**5**, **10**) to 80% (**8**), relative to ruthenium (Table 1). At least partial reduction of $RuCl_3 \cdot xH_2O$ (**1**) prior to the addition of arene or Cp*H is indicated by the rapid colour change of the ethanolic solution from cherry red to dark blue. The excessive Zn may also act as a quencher of HCl after the subsequent reduction of the η^6-arene, Cp*H, and $NaPF_6$, as suggested by Salzer et al.[22] The $[RuCp^*]^+$ sandwich complexes of the electron-rich arenes **3**–**8** (entries 1–6) were prepared in order to establish the synthetic route. Compounds **3**, **6**, **8**, **10**, and **12** have been prepared before by other protocols.[23] The $[RuCp^*]^+$ sandwich complex **9** of *N*-Boc-protected *p*-chlorophenylethylamine (entry 7) is important for the synthesis of metal-complexed diaryl ether peptoids.[1] As for the correspondingly Boc-protected compounds **16** and **17**, the yield of compound **9** is very much improved if two equivalents of $NaHCO_3$ are added as a buffer before the addition of the arene. The Boc protecting groups would otherwise be cleaved off under the acidic conditions.

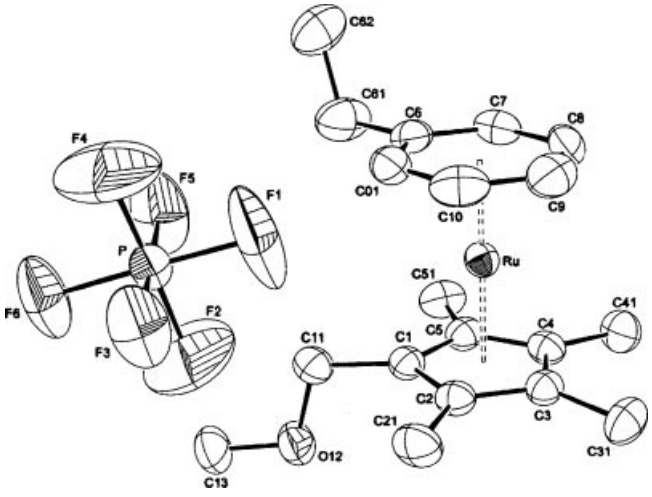

Figure 2. ORTEP plot of the methoxylated sandwich complex **14**

It was unclear if benzophenone (entry 8) would be complexed once or twice. Thus far, the doubly complexed sandwich complex of benzophenone has been obtained as by far the major product.[19] Our procedure provides the mono product **10** exclusively. The decrease in electron density in the uncomplexed phenyl group may prevent a second reaction. *p*-Toluenesulfonic acid (entry 10) cleanly gives the corresponding sandwich complex **12**.

Compared with our protocol (entries 2 and 3), difficulties were encountered when using methanol/methanolate as reducing agent of the oligomer $[RuCp^*Cl_2]_n$ ($n = 2$) (entries 12 and 13). Complexation of *o*-chloroanisole (entry 13) led to the dimethoxy sandwich complex **15** as the major product, with the desired chlorinated product formed in yields below 5%. Obviously, nucleophilic substitution is not suppressed under the reaction conditions. On the other hand, entry 3 demonstrates that the one-step procedure provides the desired *o*-chloroanisole complex **5**.

We discovered the monomethoxy sandwich **14** to be a side product (12%) when reacting ethylbenzene via the oligomer route (Scheme 3; Table 1, entry 12). An explanation could be the oxidation of the two Cp* ligands of the oligomer $[RuCp^*Cl_2]_n$ ($n = 2$) to two η^6-tetramethylfulvene li-

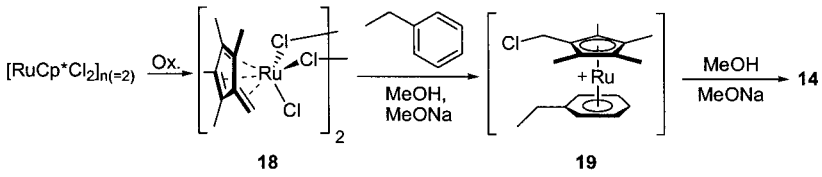

Scheme 3. Possible mechanism leading to the formation of the methoxylated sandwich complex **14** in methanol (explanation see text)

gands (Scheme 3). Upon treatment of **18** with carbon monoxide, Maitlis et al. have observed monochlorination of the Cp* ring.[24] In our case, ethylbenzene may take the role of carbon monoxide leading to the formation of the Cp*-chlorinated sandwich complex **19**. It has been reported that nucleophilic substitution by methoxide occurs readily.[24b]

In summary, this contribution presents, for the first time, a detailed study of the one-step preparation of [RuCp*(η⁶-arene)]⁺ sandwich complexes. Compounds **4**, **5**, **7**, **9**, **11**, **13a**, **13b**, **14**, **15**, **16**, and **17** have been prepared for the first time. The sandwich complexes **9**, **16** and **17** are used by us for applications in bioinorganic chemistry.[1] Very recently, Mann et al. used a similar protocol for the preparation of the trifluoromethylated complex [RuCp′(η⁶-benzene)]⁺PF_6^-, which was used as a starting point of the synthesis of other [RuCp′(η⁶-arene)]⁺ sandwich complexes.[25]

Experimental Section

General: All reactions were carried out under an argon atmosphere with distilled, non-anhydrous solvents. Yields refer to purified compounds. Reagents, of high commercial quality, were purchased from Aldrich, Acros, Merck and Fluka and were used without further purification. Reactions were controlled by thin-layer chromatography (0.25 mm E. Merck alumina plates NH_2 $F_{254}S$). TLCs were analysed under UV light (λ = 254 nm), followed by heating after treatment with 1,10-phenanthroline (2 M dipping solution in EtOH). E. Merck Al_2O_3 90 standardised (activity grade III, particle size 63−200 μm), E. Merck aminopropyl silica LiChroprep NH_2 (particle size 40−63 μm), and E. Merck silica 60 (particle size 40−63 μm) were used for preparative column chromatography. NMR spectra were recorded on a Varian VRX 400S spectrometer. The NMR shifts were calibrated using the solvent peak as internal reference and assigned on the basis of HSQC and HMBC experiments. All infrared spectra were recorded on an IFS 45 Bruker spectrometer. The UV/Vis spectra were recorded using a Omega 20 Bruins Instruments UV-spectrophotometer. High resolution fast atom bombardment (FAB) and electrospray ionization (ESI) mass spectra were recorded on a Finnigan MAT 95Q mass spectrometer. Only the three predominant isotopes are listed. Melting points were determined with a Electrothermal IA 9000 Series melting point microscope and are uncorrected.

General Procedure for the Preparation of the Ruthenium Sandwich Complexes: Zinc dust (2 equiv.) was added to a solution of $RuCl_3 \cdot xH_2O$ (35−40% Ru) in degassed EtOH (15 mL per mmol). After the solution had turned blue the arene (2 equiv.) was added and the mixture stirred for 10 min. In the case of the Boc-protected compounds **9**, **16**, and **17**, $NaHCO_3$ (2 equiv.) was added to the blue solution before the arene was added. 1,2,3,4,5-Pentamethylcyclopentadiene (2.5 equiv.) and $NaPF_6$ (1.1 equiv.) were added and the reaction mixture was stirred for 1 day at room temperature and for 2 days at 60 °C. *iso*-Octane (15 mL per mmol) was added and the mixture filtered through a pad of aluminium oxide. The filtrate was concentrated and filtered through a pad of aminopropyl silica [*iso*-octane/EtOH (1:1) as eluent]. After concentration of the filtrate to dryness, water (50 mL per mmol), *iso*-octane (100 mL per mmol) and MeOH (50 mL per mmol) were added. Further MeOH was added until the solution became clear. The *iso*-octane phase was separated and the polar phase was extracted with *iso*-octane (twice). The combined *iso*-octane phases were extracted with water/MeOH (1:1) and the polar phases were combined and concentrated to dryness. The product was extracted from the residue with dichloromethane (15 mL, three times) and recrystallised from water/isopropanol (addition of isopropanol to a boiling aqueous suspension).

Procedure for the Preparation of the Ruthenium Sandwich Complexes 4, 14, and 15 via the Methanol/Methoxide Route: The arene (2 equiv.) was added to a solution of [Cp*RuCl$_2$]$_2$ (1 equiv.) in MeOH (6.5 mL per mmol) and NaOMe (1 equiv.). The solution was stirred for 3 h under reflux. After addition of $NaPF_6$ (1.1 equiv.) and MeOH (15 mL per mmol) the mixture was filtered through a pad of aluminium oxide. The filtrate was concentrated and filtered through a pad of aminopropyl silica [*iso*-octane/EtOH (1:1) as eluent]. After concentration of the filtrate to dryness, water (50 mL per mmol), *iso*-octane (100 mL per mmol) and MeOH (50 mL per mmol) were added. Further MeOH was added until the solution became clear. The *iso*-octane phase was separated and the polar phase extracted with *iso*-octane (twice). The combined *iso*-octane phases were extracted with water/MeOH (1:1) and the polar phases were combined and concentrated to dryness. The product was extracted from the residue with dichloromethane (15 mL, three times) and recrystallised from water/*iso*-propanol (addition of *iso*-propanol to a boiling aqueous suspension).

(η⁶-1,2-Dimethoxybenzene)(η⁵-pentamethylcyclopentadienyl)-ruthenium Hexafluorophosphate (15). Colourless powder (66 mg, 20%); m.p. 342 °C (decomp.). ^{1}H NMR (400 MHz, [D$_6$]acetone): δ = 2.01 (s, 15 H, η⁵-CC*H*$_3$), 3.93 (s, 6 H, η⁶-C$_{ar}$OC*H*$_3$), 5.75 (m, 2 H, η⁶-C$_{ar}$*H*), 6.33 (m, 2 H, η⁶-C$_{ar}$*H*) ppm. ^{13}C NMR (100 MHz, [D$_6$]acetone): δ = 10.52 (η⁵-C*C*H$_3$), 57.68 (η⁶-C$_{ar}$O*C*H$_3$), 75.36 (η⁶-*C*$_{ar}$H), 83.86 (η⁶-*C*$_{ar}$H), 95.86 (η⁵-*C*CH$_3$), 124.44 (η⁶-*C*$_{ar}$OCH$_3$) ppm. For spectroscopic data of **4** see above.

Crystallographic Analysis: Single-crystal intensity data were collected from colourless crystals with a Stoe Imaging Plate Diffraction System **(13a)** or by use of an Enraf−Nonius Kappa CCD equipped with a rotating anode **(14)**. In both cases, graphite-monochromated Mo-K_α radiation (λ = 71.073 pm) was used and the measurement temperature was 200(2) K. A numerical absorption correction (XRed[26]) was applied to the data. All relevant information concerning the data collection are listed in Table 3. The structures were solved by direct methods (SIR97[27]) and refined using SHELXL-97 (full-matrix least-squares on F^2).[27,28] The hydrogen atoms were considered with a riding model. All other atoms were refined with anisotropic atomic displacement parameters, except a disordered ethyl group in **13a** which was refined isotropically.

Keywords: Cyclopentadienyl ligands / Electrochemistry / Electrospray-ionization mass spectrometry / Molybdenum / Oxo ligands

Complexes $[Cp^*_2Mo_2O_5]$ ($Cp^* = \eta^5$-C_5Me_5) and $[Cp^*_2Mo_2O_4]$ were investigated by combined on-line electrochemical (EC) reduction and electrospray-ionization mass spectrometry (ESI-MS) techniques in a trifluoroacetic acid buffered water/methanol solution. The reduction products at the larger negative potentials are identical for both compounds. The studies reveal the existence of a wide range of previously unknown di- and trinuclear Mo^V, Mo^{IV}, Mo^{III}, and mixed-valence complexes that were identified on the basis of their masses and characteristic isotope patterns. The structures of the initial compounds and the product of electroreduction with m/z = 713–729 were supported by in situ MS^n experiments that allowed the elucidation of the fragmentation pathway for the collision-induced dissociation.

Introduction

The development of the Electrospray-Ionization Mass Spectrometers (ESI-MS) by Yamashita and Fenn[1] has provided a very powerful technique for analyzing various charged inorganic,[2] organic[3] and organometallic species in solution.[4] Electrospray ionization at atmospheric pressure is a technique that makes use of an electrostatic sprayer to assist in the transfer of the ionic analytes that are initially present in solution into the gas phase.[5] In contrast to conventional ionization methods, which create undesirable fragment ions, the ESI technique usually gives simpler spectra.[6]

The on-line combination of electrochemistry with ESI-MS has been achieved in the last decade. Preparative electrochemistry, followed by ESI-MS analysis of the isolated products or products generated in situ, has been extensively explored by Bond et al.[7,8] Three other groups, those of Cole et al.,[9,10] Van Berkel et al.,[11,12] and Brajter-Toth et al.,[13] have used an electrochemical cell coupled on-line with mass spectrometry for the investigation of redox reactions.

In our previous publication, which focused only on the reductive process of compound $[Cp^*_2Mo_2O_5]$,[14] we have shown how, from an analytical point of view, various operating conditions may be optimized to minimize spurious reactions in the electrospray chamber and obtain spectra that reflect compositions in solution. The previous study was carried out in an acetic acid buffered solution and most of the resulting reduction products were found to incorporate the acetate ligand. A subsequent chemical reduction study allowed the isolation and structural characterization of $[Cp^*MoO(O_2CCH_3)]_2$, which is closely related to one of the species observed by EC-ESI-MS.[15] With the goal of generating more reactive aqua species, and to reach the lower oxidation states of Mo, we have expanded the previous study to solutions containing the stronger trifluoroacetic acid, whose conjugate base has a poorer coordinating ability than does the acetate ion. To verify the electroreduction pathway of the compound $[(C_5Me_5)_2Mo_2O_5]$, we have expanded the electroreduction experiments to the previously described[16–18] Mo^V compound, $[(C_5Me_5)_2Mo_2O_4]$.

Experiments on sequential product-ion fragmentations (MS^n) by collision-induced dissociation (CID) were performed to elucidate the gas-phase degradation pathway for the starting and product compounds. In general, low-energy CID is a powerful technique because of the simplicity and reliability of performing sequential ion fragmentation MS^n experiments. Collisions between analyte ions and the helium gas, which serves as a damping buffer gas in the ion trap, are used for analyte ion fragmentations and excitations. Collision-induced decomposition produces ionic and neutral species simultaneously in the ion trap. Only the

charged species, however, can be directly identified using conventional multistage mass spectrometry. The chemical structure of the neutral species can only be hypothesized on the basis of the most-favored fragmentation mechanisms. Valuable information on the molecular structures of organic compounds has also been acquired by ESI-MS^n, but very few investigations have been conducted with organometallic compounds.[19,20]

Results and Discussion

Positive-Mode ESI-MS Spectra of the Starting Compounds

The positive-mode ESI-MS spectra of the starting compounds are shown in Figure 1, frames A and B. The inserts show the characteristic isotopic patterns of mono-, di-, and trinuclear Mo fragments. For mononuclear Mo species, the isotopic envelope consists of seven lines with two gaps located between the first and second and the sixth and seventh lines, respectively. The isotopic envelope of a dinuclear Mo ion consists of 14 peaks and has a width of 16 *m*/*z* units, while that of a trinuclear Mo species has a width of 23 *m*/*z* units. The width of the isotopic envelope is an important characteristic in our MS^n fragmentation experiments for the perfect isolation of the whole set of the molecules with the same structure. We shall refer to the various species by the value of *m*/*z* of the full isotopic pattern in the isotopic distribution and compare it to the calculated distributions[21] for the molecular assignment.

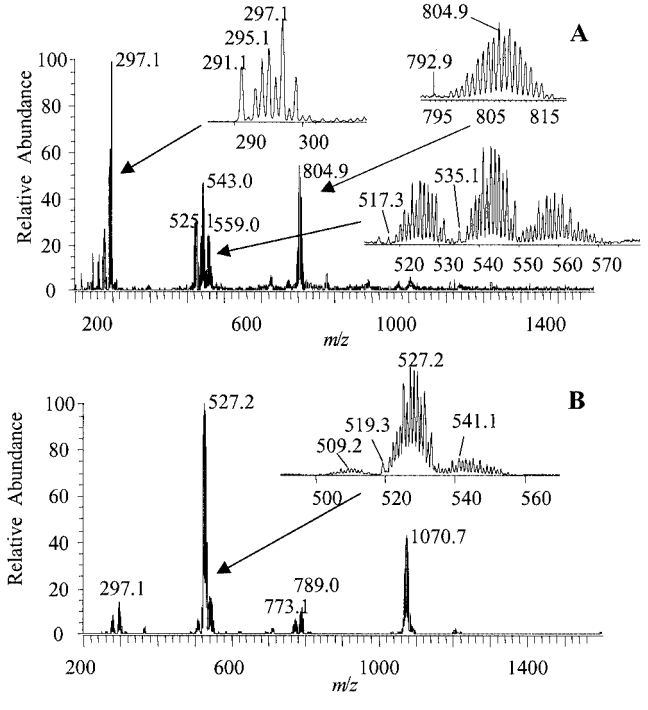

Figure 1. Positive-mode electrospray mass spectra in a mixture of 0.1 M CF_3COOH in H_2O/MeOH (1:1) (pH = 1.2) of (A) $[Cp^*_2Mo_2O_5]$ (0.1 mM) and (B) $[Cp^*_2Mo_2O_4]$ (0.1 mM)

Spectrum A was measured from a water/methanol solution of $[Cp^*_2Mo_2O_5]$ containing 0.1 M trifluoroacetic acid. It reveals three major regions of peaks, corresponding to mono-, di-, and trinuclear species, respectively. The ESI-MS spectrum of this compound in water/methanol containing 0.1 M ammonium acetate (pH = 4) has been described previously.[14] The lower pH (pH = 1.8) used in the present study changes the product distribution significantly in every region. The mononuclear region exhibits the $[Cp^*MoO_2]^+$ peak (*m*/*z* = 259−267) and the $[Cp^*MoO_3H_2]^+$ peak (*m*/*z* = 277−285) at approximately the same *relative* intensity as in the previous acetate buffer study. The strongest peak, however, corresponds to the methanol addition product, $[Cp^*MoO_2(MeOH)]^+$ (*m*/*z* = 291−299), which has only a very small intensity in the acetic buffer. The formation of adducts with solvent molecules in the ion trap is a well-known phenomenon.[22,23]

The main peak for dinuclear species corresponds to the protonated starting compound $[Cp^*_2Mo_2O_5H]^+$ (*m*/*z* = 535−551), as it was in the corresponding study in the acetic acid buffer.[14] The other most pronounced dinuclear peaks, corresponding to daughter ions formed in the ESI-MS chamber, had not been described previously, since their intensity was much lower when measured from the higher pH conditions. These dinuclear peaks increase in relative abundance with increasing temperatures of the heated capillary. The lighter set of peaks (*m*/*z* = 517−533) corresponds to the loss of one water molecule. This process must, of course, involve at least one of the Cp* methyl group's H atoms, leading to a tetramethylfulvene ligand. Therefore, the peak is assigned to complex $[Cp^*(C_4Me_4CH_2)Mo_2O_4]^+$. The methylene group of this ligand may be bonded to the molybdenum atom or to one of the oxygen atoms. The envelope at higher masses, on the other hand, results from the superposition of two envelopes, one (major) at *m*/*z* = 549−565 that is attributed to a MeOH adduct of the tetramethylfulvene complex just described, and one (minor) at *m*/*z* = 553−569 that probably results from the addition of water to the starting compound. The $[Cp^*_3Mo_3O_7]^+$ peak (*m*/*z* = 793−816) is the only relevant feature in the region of the trinuclear species.

The differences between Figure 1 and the corresponding spectrum from the experiment with the acetic acid buffer (see Figure 1 of ref.[14]) are consistent with our parallel speciation studies. We have shown that the complex $Cp^*MoO_2^+$ is the predominant species at pH < ca. 3, while a mixture of $[Cp^*MoO_2]^+$ and $[Cp^*MoO_3]^-$ {in equilibrium with $[Cp^*MoO_2(OH)]$ and $[Cp^*_2Mo_2O_5]$, depending on the H_2O/MeOH ratio} is present at a pH of ca. 4.[24] Indeed, the peaks corresponding to the dinuclear $[Cp^*_2Mo_2O_5]$ species are less abundant at the lower value of pH, while all those related to species $[Cp^*MoO_2]^+$ (mononuclear and trinuclear species) are comparatively more abundant. Indeed, the trinuclear species results from the addition of $[Cp^*MoO_2]^+$ to $[Cp^*_2Mo_2O_5]$ (vide infra).

The ESI-MS investigation of complex $[Cp^*_2Mo_2O_4]$, reported here for the first time, was carried out under the same conditions used for compound $[Cp^*_2Mo_2O_5]$, to allow comparisons to be made. The spectrum of the starting solution is shown in Frame B of Figure 1. The main peak corre-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sponds to the protonated starting compound, $[(C_5Me_5)_2Mo_2O_4H]^+$ (m/z = 519−535), and the second-most important component (m/z = 1058−1085) is assigned to the tetranuclear $[Cp^*_4Mo_4O_6(OH)_3]^+$ complex. The latter is formally obtained by dimerization of the starting compound and addition of a water molecule and a proton. Evidence for the existence of a tetranuclear species has been provided for the corresponding Cp system.[25] The spectrum shows fewer peaks relative to that of the pentaoxo analogue. This situation can result from either a simpler composition in solution (the speciation of this compound in methanol/water is yet unknown) or from a greater gas-phase stability and, therefore, a less pronounced collision-induced decomposition. Both compounds adopt a neutral molecular structure in organic solvents.[16,26] To further explore this point, we proceeded with a detailed investigation of the gas-phase stability and MS^n fragmentation pathways of the starting compounds.

Gas-Phase Stability of the Starting Compounds

Figure 2 shows the relative abundances of the peaks of the starting compound (m/z = 535−551 for $[Cp^*_2Mo_2O_5H]^+$ and m/z = 519−535 for $[Cp^*_2Mo_2O_4H]^+$) as a function of the applied collision energy during the collision-activated decomposition events in the ion-trap mass spectrometer. Both dissociation profiles lead to S-shaped curves. The half-wave collision energy ($E_{1/2}$) corresponds to the energy (in the percentage of the maximum tickling voltage) at which the relative abundance as a fraction of the total ion current of the starting ion is 0.5.[27−30] For the same charge state (+1), the larger the value of $E_{1/2}$ the more stable is the compound in the gas phase. As it is evident from Figure 2, the value of $E_{1/2}$ of $[Cp^*_2Mo_2O_4]$ is almost twice that of $[Cp^*_2Mo_2O_5]$, which underscores the greater gas-phase stability of the former compound. This difference can be rationalized rather easily on the basis of the known structural and bonding differences between the two compounds. While the tetraoxo Mo^V complex contains a direct metal−metal bond and two oxo bridges, the pentaoxo compound contains one oxo bridge and no metal−metal interactions.

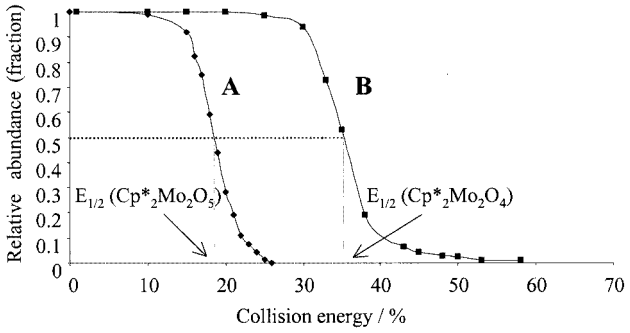

Figure 2. Dissociation profiles of the starting compounds {(A) $[Cp^*_2Mo_2O_5]$ and (B) $[Cp^*_2Mo_2O_4]$} in the same charge state as a function of increased collision energy in the ion trap; the solutions are as described in Figure 1

Fragmentation Pathways of the Starting Compounds

The dissociation profiles provided us with information about the stability of $[Cp^*_2Mo_2O_5]$ and $[Cp^*_2Mo_2O_4]$ complexes in the ion trap. An analysis of their degradation in the ion trap was carried out by their isolation therein, followed by the observation of their sequential multistep dissociations (MS^n experiments). The main results for $[Cp^*_2Mo_2O_5]$ and $[Cp^*_2Mo_2O_4]$ are shown in frames A and B of Figure 3, with the proposed fragmentation pathways in Schemes 1 and 2, respectively.

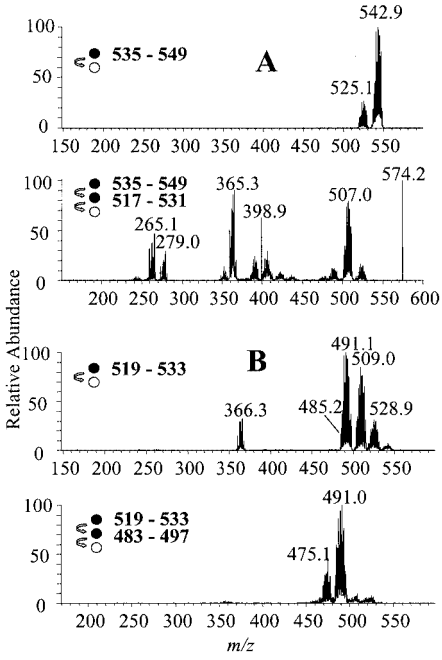

Figure 3. MS^n fragmentation pathways of compounds $[Cp^*_2Mo_2O_5]$ (A) and $[Cp^*_2Mo_2O_4]$ (B); the solutions are the same as those described in Figure 1

As concluded above from the dissociation profiles, $[Cp^*_2Mo_2O_5]$ is less stable than $[Cp^*_2Mo_2O_4]$ in the ion trap. The spectrum in Figure 3 (A) shows that the first CID step for the $[Cp^*_2Mo_2O_5H]^+$ ion generates only one daughter ion (m/z = 517−533) by loss of a water molecule. MS^3 fragmentation of this daughter ion leads to many products by further loss of water and of a neutral (fulvene)-dioxomolybdenum fragment. To the best of our knowledge, the C−H activation of a Cp* methyl group, that is associated to the elimination of a water molecule and to the transformation to a tetramethylfulvene ligand, has not been highlighted previously in an MS study. There is, however, at least one precedent in solution chemistry for compound $[\{Cp^*RuCl_2\}_2O]$.[31]

The main peaks are tentatively assigned in Scheme 1, although it is not possible to establish the particular methyl group that furnishes the hydrogen atoms. The m/z = 359−367 peak has the characteristic shape of a monomolybdenum species and is not observed at all in the regular ESI-MS. This compound would result from the elimination of a molybdic acid molecule with the abstraction of two H atoms from the Cp* methyl groups. This assignment is in

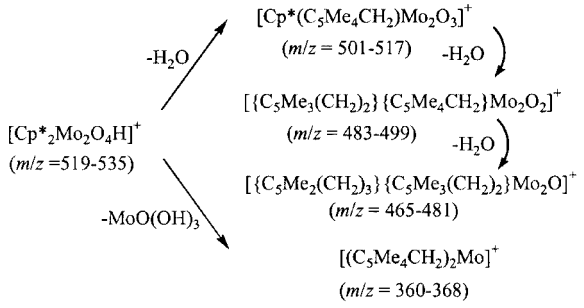

Scheme 2

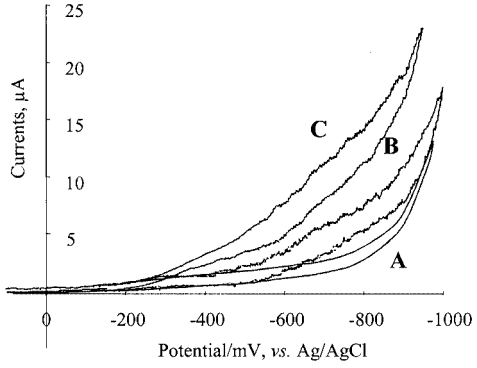

Figure 4. Cyclic voltammograms taken during the on-line combined EC/ESI-MS experiments. (a) blank solution; (b) 1.1 mM $[Cp^*_2Mo_2O_4]$; (c) 1.1 mM $[Cp^*_2Mo_2O_5]$, in H_2O/MeOH (1:1) containing CF_3COOH (0.1 M; pH = 1.2); scan rate: 0.5 mV/s

further agreement with related fragmentations of more reduced species, as will be shown later. We point out further that the exact structure of the proposed species containing two or more activated Me groups, e.g., $[(C_5Me_4CH_2)_2Mo]^+$ or $[\{C_5Me_2(CH_2)_3\}\{C_5Me_3(CH_2)_2\}Mo_2O]^+$, may implicate the formation of C−C or C−O bonds.

The CID of complex $[(C_5Me_5)_2Mo_2O_4]$ gives fewer peaks than its pentaoxo analogue. Most dinuclear peaks are related for the two compounds (16 fewer mass units corresponding to one oxygen atom). The main mononuclear peak (m/z = 360−369) is one mass unit higher than the main mononuclear peak derived from the pentaoxo solution, and, thus, the peak indicates that it is a one-electron-reduced form of it. The peak probably derives from the expulsion of a $MoO(OH)_3$ species from the parent dinuclear Mo^V complex, paralleling exactly the formation of the mononuclear species in Scheme 1.

Electrochemical Experiments

Figure 4 shows the voltammogram recorded in our flow-through electrochemical cell in parallel with the ESI-MS measurements. Curve A shows the background voltammogram, whereas curves B and C show the voltammograms of the $[Cp^*_2Mo_2O_4]$ and $[Cp^*_2Mo_2O_5]$ solutions, respectively. As the Mo concentration is identical for both solutions, any difference between curves B and C must be attributed to the difference in the oxidation state of the Mo atom in the starting compound. This assumption is supported by the volt-spectrogram of $[Cp^*_2Mo_2O_5]$ (vide infra), which clearly indicates that the electroreduction of $[Cp^*_2Mo_2O_5]$ proceeds through the formation of $[Cp^*_2Mo_2O_4]$.

The current−potential curves at the forward and backward scans are in parallel for both compounds and the heights are virtually independent of the scan rate over a rather wide range of scan rates (up to 100 $mV \cdot s^{-1}$). This observation means that the electrochemical reduction of both $[Cp^*_2Mo_2O_4]$ and $[Cp^*_2Mo_2O_5]$ is apparently controlled by an interfacial step rather than being limited by diffusion. In separate studies that are out of the scope of this paper, we have witnessed the formation of a polymer film on the electrode surface under the conditions of electroreduction. This phenomenon makes it impossible, solely on the basis of the voltammetric experiments, to elucidate the mechanisms of electroreduction of $[Cp^*_2Mo_2O_4]$ and $[Cp^*_2Mo_2O_5]$ and identify the electroreduction products.

Coupled Electrochemistry/ESI-MS Studies: Consumption of the Starting Species

The coupled EC/ESI-MS study was carried out with a slow (0.5 mV/s) linear potential sweep between 0 and −1 V, and then back again to 0 V, similar to the experiment described in our previous study.[14] Figure 5 shows the volt-spectrograms of the major mono-, di-, and trinuclear species. During the backward, anodic scan, the concentration profiles follow approximately the same pattern observed in

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

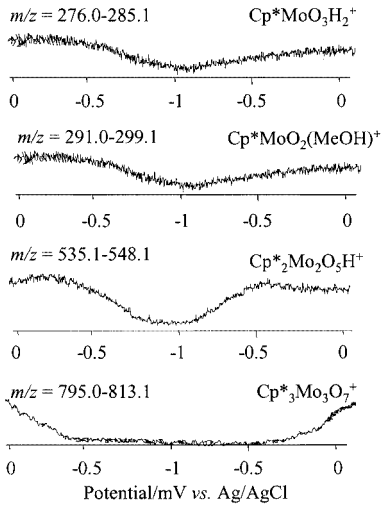

Figure 5. Dependence on potential of the relative abundance of the starting species during the coupled electrochemistry/ESI-MS of $[Cp^*_2Mo_2O_5]$; the experimental conditions are the same as those described in Figure 4

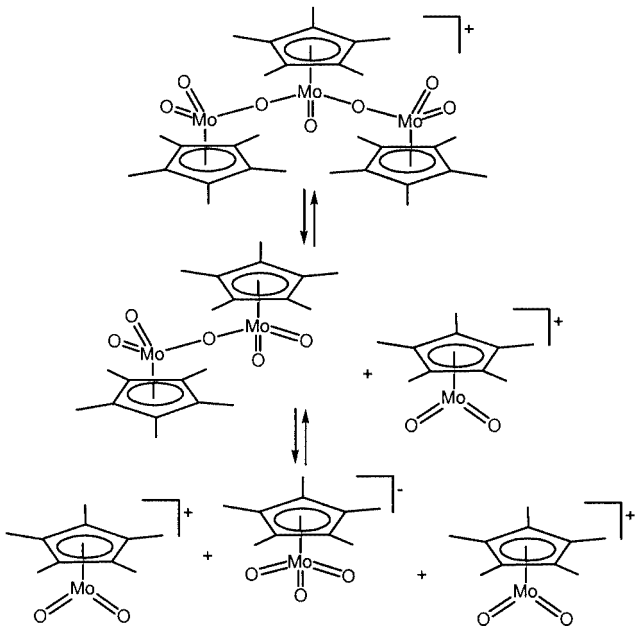

Scheme 8

the cathodic scan, indicating that the experiment is not polluted by film deposition processes.

The concentrations of both mononuclear species and of the dinuclear species start to decrease at a potential slightly less negative than $E = -0.5$ V. The trinuclear species, on the other hand, decreases in concentration much earlier, at $E \approx 0$ V, and reaches a minimum at $E = -0.5$ V. This result shows unambiguously that the trinuclear species must be present already in solution. If it had formed by a combination of $[Cp^*MoO_2^+]$ and $[Cp^*_2Mo_2O_5]$ in the spectrometer chamber only, its abundance would not decrease prior to that of either of the two other species. The reduction of the trinuclear species is thermodynamically easier than those of the mono- and dinuclear species, probably because of the metal−metal bond formation that is expected to accompany the process (vide infra). Since we have shown that a water-rich environment favors the spontaneous ionization of $[Cp^*_2Mo_2O_5]$ into $[Cp^*MoO_2]^+$ and $[Cp^*MoO_3]^-$, we propose equally that the trinuclear species is derived from the combination of $[Cp^*MoO_3^-]$ with two $[Cp^*MoO_2]^+$ ions, as shown in Scheme 3.

Electrochemical Formation of Reduced Dimer Compounds

Figure 6 shows the mass spectrum of the $[Cp^*_2Mo_2O_5]$ solution recorded at −1 V. Several new peaks, assigned to electroreduction products, are evident in this spectrum. Some of these peaks are associated with reduction products that are identical with, or related to, those observed previously under the same conditions in an acetic acid buffer (i.e., $[Cp^*_2Mo_2O_4H]^+$, $m/z = 519-535$). Other peaks, on the other hand, correspond to new species {i.e., $[Cp^*_2Mo_2(OH)(O_2CCF_3)_2]^+$, $m/z = 697-715$; $[Cp^*_2Mo_2O(OH)(O_2CF_3)_2]^+$, $m/z = 713-729$; $[Cp^*_2Mo_2O_3(O_2CCF_3)]^+$, $m/z = 615-633$}. The nature and the intensity/potential profiles of all electroreduction products obtained from the $[Cp^*_2Mo_2O_4]$ solution are identical with those derived from the pentaoxo solution. This observation indicates that all reduced products obtained from the pentaoxo solution are formed through the intermediacy of the tetraoxo complex.

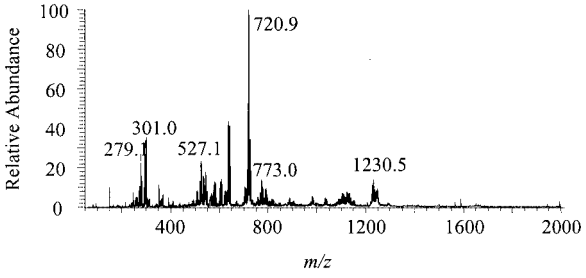

Figure 6. Positive-mode electrospray mass spectra in 0.28 mM CF_3COOH, H_2O/MeOH (1:1) (pH = 1.2) of $[Cp^*_2Mo_2O_5]$ (1.1 mM) after reduction ($E = -1$ V)

Figure 7 depicts volt-spectrograms of a few selected reduced dinuclear products, namely two $Mo^{V,V}_2$ species, $[Cp^*_2Mo_2O_4H]^+$ and $[Cp^*_2Mo_2O_3(O_2CCF_3)]^+$, a $Mo^{IV,IV}$ species, $[Cp^*_2Mo_2O(OH)(O_2CCF_3)_2]^+$, and a $Mo_2^{III,III}$ species, $[Cp^*_2Mo_2(OH)(O_2CCF_3)_2]^+$, together with their corresponding MS isotopic pattern and a tentatively assigned structure. Interestingly, the major electroreduction products observed in the current study are derived from subsequent two-electron addition processes, whereas the previous study in the acetic acid buffer also showed a dinuclear mixed-valence ($Mo^{IV,V}_2$) species. Mononuclear (acetato)Mo^V and -Mo^{IV} complexes were also evident in the previous study, but the corresponding trifluoroacetato species are not observed in the present investigation.

Another notable difference is that, whereas the observed $Mo^{V,V}_2$ products have the same stoichiometry under both

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

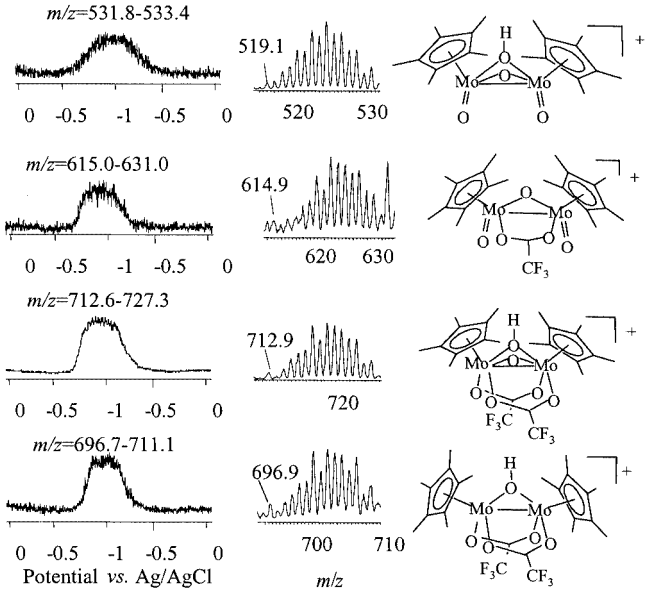

Figure 7. Dependence on potential of the relative abundance of the dinuclear species generated during the coupled electrochemistry/ESI-MS of $[Cp^*_2Mo_2O_5]$; left: volt-spectrograms with the range of *m/z* used for the integration. center: expanded isotopic pattern; right: tentative chemical structure; the experimental conditions are identical to those of Figure 5

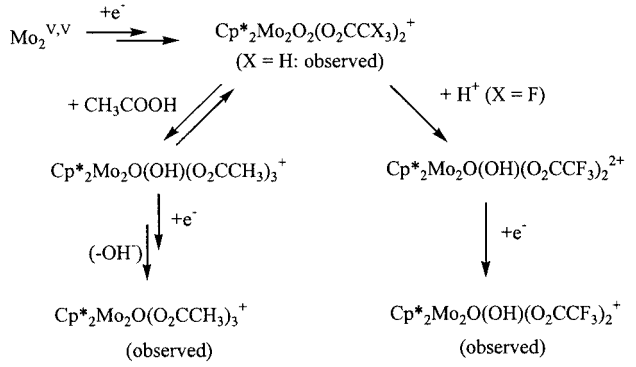

Scheme 4

conditions, the $Mo^{IV,IV}_2$ product is $[Cp^*_2Mo_2(O)(OH)(O_2CCF_3)_2]^+$ in the present study and $[Cp^*_2Mo_2O(O_2CCH_3)_3]^+$ in the previous acetate study. A peak for the corresponding $[Cp^*_2Mo_2O(O_2CCF_3)_3]^+$ ion is not observed in the present study. This result seems counterintuitive, because the stronger trifluoroacetic acid should be better suited to replace the hydroxo ligand. A possible, though somewhat speculative, interpretation relies on two fundamental differences between the two acids and the corresponding conjugate bases: while CF_3COOH is the stronger acid, CH_3COO^- is the better coordinating agent. Thus, reduction of the same $[Cp^*_2Mo_2O_3(O_2CCX_3)]^+$ ($Mo^{V,V}_2$; X = H, F) complex would lead to the same $[Cp^*_2Mo_2O_2(O_2CCX_3)_2]^+$ ($Mo^{IV,V}_2$) ion according to Scheme 4. This ion, however, would be observed only for the acetato system, because with the stronger acid (CF_3COOH) it would immediately be protonated. The CH_3COOH system could, on the other hand, lead to a triacetato species because of the stronger coordinating properties of the acetate ion. If this hypothesis holds true, each final $Mo^{IV,IV}_2$ product would be observed merely because the exchange process between hydroxide and (trifluoro)acetate, though thermodynamically favorable, is too slow under the present conditions. It is also worth mentioning that the neutral diacetato compound $[Cp^*_2Mo_2O_2(O_2CCH_3)_2]$ (i.e., a deprotonated version of the observed product for the trifluoroacetato system) has been isolated from a reductive chemical synthesis and characterized crystallographically.[15]

While electroreduction did not afford any dinuclear ions with oxidation states below IV when carried out in an acetic acid buffer, it also provides a $Mo^{III,III}_2$ complex in the presence of trifluoroacetic acid. This difference may again be attributed to the stronger acidity of CF_3COOH, which favors protonation of the oxo ligands and their elimination as water molecules.

The following approximate potential values for the appearance of every reduced dinuclear species may be measured on the volt-spectrograms in Figure 7: $[Cp^*_2Mo_2O_4H]^+$ ($Mo^{V,V}_2$), −0.55 V; $[Cp^*_2Mo_2O_3(O_2CCF_3)]^+$ ($Mo^{V,V}_2$), −0.60 V; $[Cp^*_2Mo_2(O)(OH)(O_2CCF_3)_2]^+$ ($Mo^{IV,IV}_2$), −0.68 V; $[Cp^*_2Mo_2O(O_2CCF_3)_2]^+$ ($Mo^{III,III}_2$), −0.76 V. A comparison of the onset reduction potentials with those observed in the previous acetate study is useful. The $[Cp^*_2Mo_2O_4H]^+$ product is not acid dependent. In both studies, the onset of this peak is at approximately the same potential as the onset for the $[Cp^*_2Mo_2O_5H]^+$ consumption and the two numerical values are quite similar (these numbers may be measured only with limited precision). The $[Cp^*_2Mo_2O_3(O_2CCF_3)]^+$ $Mo^{V,V}_2$ species starts to form at a more negative potential relative to the acetato analogue (−0.55 V). Further reduction to the $Mo^{IV,IV}_2$ species seems easier for the trifluoroacetato system, which is in agreement with expectations [cf. reduction at −0.74 and −0.78 V for the (acetato)$Mo^{IV,V}_2$ and -$Mo^{IV,IV}_2$ products, respectively]. Furthermore, reduction to the $Mo^{III,III}_2$ product starts at an even lower potential, while this process is not observed for the acetato system, as mentioned above.

Structural Elucidation of the Product at *m/z* = 713−729

The main product of the electroreductions of both $[Cp^*_2Mo_2O_5]$ and $[Cp^*_2Mo_2O_4]$, namely the $Mo^{IV,IV}_2$ ion interpreted as $[Cp^*_2Mo_2O(OH)(O_2CCF_3)_2]^+$, was the subject of more detailed MS^n studies. There are two reasons for choosing to study this product. First, we wanted to prove the general approach of our product identification. Second, we wanted to check whether any observed peaks are, in fact, attributable to daughter ions of this major peak, rather than to primary products of the electrochemical reduction.

Figure 8 shows the main results of the MS^n experiment. The spectrum shown in part A is produced from the isolation of the species at *m/z* = 713−729 and subsequent CID. There are four main daughter-ion products, the main

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

one being that with m/z = 599−615. In fact, the lighter products increase in subsequent MS^n experiments, while the heavier one (32 mass units higher) is obviously the solvent (methanol) adduct formed by gas-phase reactions in the ion trap.[28] This assignment is further supported by the next MS^n step. The product ion at m/z = 599−615 was isolated and subjected consequently to further collision activation (MS^3), giving the spectrum shown in Figure 8 (B). The further generation of the peak at m/z = 634−650 can be understood easily in terms of the formation of the solvent adduct. Additional fragmentation by CID (MS^4) of the product ion with m/z = 502−518 results in one main product with m/z = 485−501 and a mononuclear peak with m/z = 361−369 [see Figure 8 (C)].

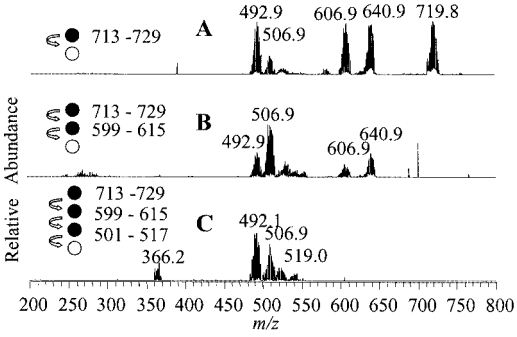

Figure 8. Structural elucidation by MS^n of the main product (m/z = 713−729) of the reduction of $[Cp^*_2Mo_2O_5]$ and $[Cp^*_2Mo_2O_4]$

The proposed product ion compositions and fragmentation pathways are shown in Scheme 5. The first fragment (m/z = 599−615) results from the loss of 114 units, which corresponds to the molecular weight of trifluoroacetic acid. Therefore, this fragment is still a dinuclear compound of Mo^{IV}. Under the conditions of the experiment (CID = 30% for every MS^n step), the next step of the fragmentation results in a prominent peak with the loss of 97 units, corresponding to a trifluoroacetyl group, and a minor peak with the loss of an additional 17 units (OH). The latter peak becomes the prominent one in the MS^4. Loss of the acetyl group results in a formal oxidation to a mixed-valence $Mo^{IV,V}_2$ ion that is not observed under the electroreduction conditions, whereas the subsequent loss of OH reforms a $Mo^{IV,IV}_2$ ion. The OH and MoO_2(OH) expulsion processes must involve one of the Cp* methyl group protons to yield a tetramethylfulvene ligand, as already observed above for the CID of the starting complexes. It is quite interesting to observe that, for the three fragmentation processes leading from dinuclear to mononuclear species with loss of a neutral inorganic Mo complex, the latter always corresponds to an oxide/hydroxide in the highest possible oxidation state; i.e., Mo^{VI} from $Mo^{VI,VI}_2$ (Scheme 1), Mo^{V} from $Mo^{V,V}_2$ (Scheme 2), and Mo^{V} from $Mo^{IV,V}_2$ (Scheme 5).

We conclude from Scheme 5 that the fragmentation pathway undertaken by the compound at m/z = 713−729 is similar to that of the starting compounds. It is noteworthy that the peaks at m/z = 485 and 361, generated by MS^4, are related to the fragments obtained from the Mo^{VI} precursor [m/z = 481 and 359, see Figure 3 (A)] and to those obtained from the Mo^{V} precursor [m/z = 483 and 360, see Figure 3 (B)]. Therefore, these mass values further support the notion that the ion at m/z = 713−729 corresponds to a $Mo^{IV,IV}_2$ complex.

Electrochemical Formation of Reduced Trinuclear Species

As can be seen by comparing Figures 1 and 6 there are prominent spectral changes in the trinuclear m/z region following the electrochemical reduction. Volt-spectrograms of the reduced trinuclear compounds are presented in Figure 9. Because of overlap between the isotopic envelopes of different trinuclear species, the volt-spectrogram integrations were carried out over limited ranges of m/z rather than over the entire envelope. The ranges used for the integrations are marked in the figure. As for the previous study with the acetic acid buffer, the envelope of the reduced trinuclear species is shifted by exactly 16 units to a lower value of m/z relative to its precursor complex $[Cp^*_3Mo_3O_7]^+$, suggesting its formulation is that of a proton-free hexaoxo species. In contrast to the previous study with the acetic acid buffer, on the other hand, further reduction occurs with successive steps of oxygen atom removal, resulting in the observation of $[Cp^*_3Mo_3O_6]^+$ ($Mo^{V,V,VI}_3$), $[Cp^*_3Mo_3O_5]^+$ ($Mo^{IV,V,V}_3$), and $[Cp^*_3Mo_3O_4]^+$ ($Mo^{IV,IV,IV}_3$). Once again, this behavior can be attributed to the stronger acidity of CF_3COOH. As for the dinuclear products discussed above, the formation of the trinuclear species in trifluoroacetic acid takes place through two-electron-transfer steps and the reduction potential becomes more negative as the oxidation state decreases. The onset potential values for the various reduced species, as measured from the volt-spectrograms in Figure 9 are, in order of decreasing number of oxygen atoms, −0.54, −0.61, and −0.75 V, repectively.

The structures assigned to various reduced species are only tentative and are drawn on the basis of the maximum symmetry principle. A $[(Cp^*Mo)_3(\mu\text{-}O)_6]$ core has been shown to exist in complex $[(Cp^*Mo)_3(\mu_2\text{-}OH)_n(\mu_2\text{-}O)_{6-n}]^{2+}$ (the value of n, probably 5, was not clearly established in the X-ray study)[32] and in related $[Cp^*_4Mo_5O_{11}]$ and $[Cp^*_6Mo_8O_{16}]$ clusters.[32,33] The oxidation state in these Mo_3O_6 cores, however, is lower ($Mo_3{}^{11+}-Mo_3{}^{14+}$). The dicapped $Mo_3(\mu_3\text{-}O)_2(\mu_2\text{-}O)_3$ unit is quite common in inorganic clusters, but has not been found as yet, to the best of our knowledge, for Cp*-substituted triangular clusters of any metal. Finally, the monocapped $Mo(\mu_3\text{-}O)(\mu_2\text{-}O)_3$ unit is also common for inorganic clusters. The first documented example containing half-sandwiched metal atoms comes from our own recent study of the chemical reduction of $[Cp^*_2Mo_2O_5]$ by zinc in methanol/water containing CF_3COOH.[34] The isolated compound contains the $[(Cp^*Mo)_3(\mu_3\text{-}O)(\mu_2\text{-}O)_3(\mu_2\text{-}O_2CCF_3)_3]^+$ ion, corresponding to a $Mo^{V,V,V}_3$ species.

No trinuclear species containing trifluoroacetate groups was detected in the present study, suggesting that this weakly coordinating anion has a high tendency to remain

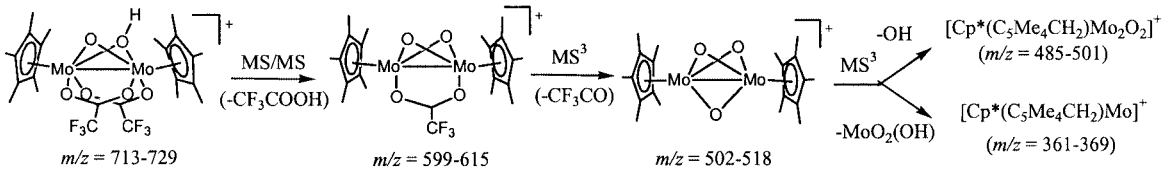

Scheme 5

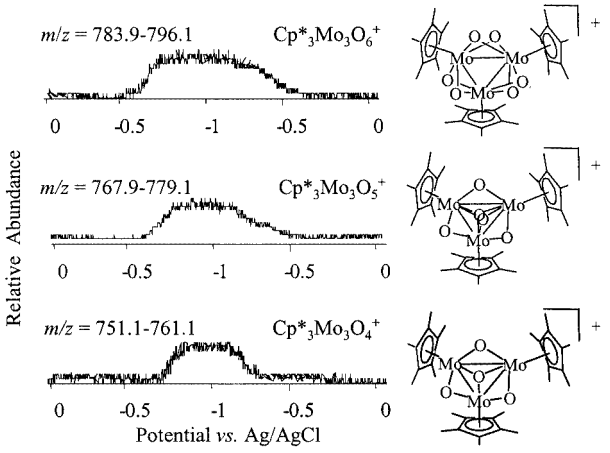

Figure 9. Volt-spectrograms of trimeric species generated during the coupled electrochemistry/ESI-MS of $[Cp^*_2Mo_2O_5]$, including the range of *m*/*z* used for the integration and the chemical formula; the experimental conditions are the same as those in Figure 4

dissociated in the highly dielectric aqueous medium. The isolation of the $[(Cp^*Mo)_3O_4(O_2CCF_3)_3]^+$ ion mentioned above, on the other hand, suggests the existence of a transient $[(Cp^*Mo)_3O_4]^{4+}$ species. Therefore, it is quite likely that a much wider variety of $[(Cp^*Mo)_3O_n]^{m+}$ derivatives may be isolated under different conditions of pH, solvent, and counterion. It is also likely that these complexes display very rich redox chemistry. Further synthetic studies are currently ongoing to test these hypotheses and to test the electrofunctionalization of organic substrates for possible catalytic applications.

Conclusion

The present study has provided new information on the nature of the $[Cp^*_2Mo_2O_5]$ in an aqueous medium and on electrochemical versatility of Cp*Mo species in water. Selected molecular structure assignments from values of *m*/*z* and isotopic distributions for Cp^*Mo^V and Cp^*Mo^{IV} reduction products where confirmed by MS^n fragmentation experiments in comparison with those of the Cp^*Mo^{VI} precursor. The study has shown that the lower pH conditions established by CF_3COOH provide access to a Cp^*Mo^{III} species, while reduction under acetic acid conditions went down as far as the oxidation state IV. The study has confirmed the robustness of the Cp*−Mo bond under aqueous conditions. Even at very low pH, there is no sign of the formation of species deriving from protonolysis of this bond. This feature, together with the proven rich redox chemistry of the system, holds promise for potential electrocatalytic applications in an aqueous environment.

Experimental Section

General Remarks: The starting compounds, $[(C_5Me_5)_2Mo_2O_5]$ and $[(C_5Me_5)_2Mo_2O_4]$, were prepared according to the literature procedure.[18] Unless otherwise stated, all solutions of test compounds were prepared in H_2O/MeOH mixture (1:1 by volume) containing 0.1 M CF_3COOH. CF_3COOH was purchased from Aldrich. HPLC-grade methanol was purchased from Baker. The water was triply distilled.

Electrospray Mass Spectrometry with an Ion Trap: A Finnigan (San Jose, USA) LCQ quadrupole ion-trap mass spectrometer equipped with an electrospray-ionization (ESI) interface was used for data acquisition. The ESI was operated in the positive-ion mode with a spray voltage of 4.5 kV, a capillary voltage of 3.5 V, and a source temperature of 120 °C. Mass spectra were obtained by scanning the mass analyzer from *m*/*z* = 100−2000 with a total of 5 microscans. The maximum injection time into the ion trap was 50 ms. The analyzer was operated at a background pressure of $2\cdot10^{-5}$ Torr. In all experiments, helium was introduced at an estimated pressure of 1 mTorr to improve the ion-trapping efficiency. The background helium also served as a collision gas during collision-activated decomposition events. The compounds were isolated in the ion trap with isolation width of 15 *m*/*z* units and were activated by using increased collision energy to obtain collision-energy-dissociation profiles.

Coupled Electrochemistry/Electrospray Mass Spectrometry: The electrochemical part of the experimental setup consisted of a PARC 273 potentiostat/galvanostat (Princeton, USA), connected to a specially designed flow-through electrochemical cell that has been described and characterized elsewhere.[35] The schematic of the electrochemical flow cell is shown in Figure 10. The working glassy-carbon-disk electrode (1) (Metrohm, Herisau, Switzerland), is placed on the bottom of the cell. Compartments of counter (2) and reference (3) electrodes were separated from the main flow of electrolyte by filters (Upchurch Scientific, Oak Harbor, WA, USA). Both electrodes were Ag/AgCl/1 M KCl. All reported potentials are given relative to the reference electrode. The analyte stream arrives on the working electrode surface through the outer tube (4) of the two coaxial system and the products of the electrode reaction are transferred to the mass spectrometer through the inner tube (5). The distance between the opening of the coaxial system and the working electrode was 50 μm. All tubes were from PEEK (Upchurch Scientific, Oak Harbor, WA, USA). The inner tube has an inner diameter of 125 μm, an outer diameter of 1.6 mm, and is 15 cm long. The flow of the solution was driven by a syringe pump.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The product stream was diluted with excess methanol. After mixing with methanol, the sample stream was delivered to the ESI interface by tubing that is 30 cm long, and has an inner diameter of 125 μm. The flow rate of the product stream was ca. 35 $\mu L \cdot min^{-1}$. The methanol flow in the auxiliary tubing was 30 $\mu L \cdot min^{-1}$. The reagent flow rate was set to 5 $\mu L \cdot min^{-1}$. The current cell design permitted us to measure mass spectra and linear sweep voltammograms simultaneously.

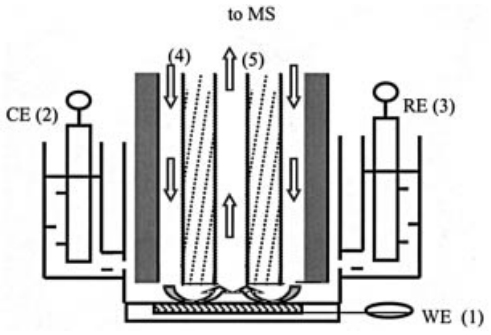

Figure 10. Scheme of the electrochemical cell used in this study: 1: working electrode (WE); 2: counter electrode (CE); 3: reference electrode (RE); 4: outer capillary (transfer line of reagents to working electrode); 5: inner capillary (transfer line of products to the ESI/MS)

Magnetic, ^{57}Fe Mössbauer, and IR Monitoring of the Thermal Spin Transition in a New Family of Iron(II) Spin-Transition Complexes

Arno F. Stassen,[a] Matthias Grunert,[b] Eva Dova,[c] Martin Müller,[d] Peter Weinberger,[d] Günter Wiesinger,[d] Henk Schenk,[c] Wolfgang Linert,[b] Jaap G. Haasnoot,*[a] and Jan Reedijk[a]

Keywords: Spin crossover / Iron / Tetrazole ligand / Mössbauer spectroscopy / Variable-temperature IR spectroscopy

A new family of iron(II) tetrafluoroborate and perchlorate spin-crossover compounds has been synthesised and is discussed. The iron(II) ion is surrounded by six 1-ethyltetrazole ligands, which are halogen-substituted on the C2 atom of the ethyl group. The spin-crossover temperatures $T_{1/2}$ are high compared to the unsubstituted (1-alkyltetrazole)iron(II) complexes. The shape of the spin-transition curve (i.e. γ_{HS} vs. T) varies largely over the different complexes and appears to be influenced neither by the crystal packing, nor by the electronic effects. The temperature-dependent spin-transition behaviour has been studied by magnetic susceptibility and by ^{57}Fe-Mössbauer spectroscopy. These data have been supported by temperature-dependent mid-range infrared spectroscopy: the thermally induced spin transition has been observed by direct monitoring of the aromatic C–H stretching frequency.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Among compounds featuring temperature-dependent spin transitions, the [Fe(1-alkyltetrazole)$_6$](anion)$_2$ compounds are probably the most studied complexes.[1−4] Methyl-, ethyl-, propyl- and isopropyltetrazole (*mtz*, *etz*, *ptz* and *iptz*) were used as ligands for iron(II) spin-crossover complexes[2] as early as 1982 by Franke et al. These complexes are special for several reasons, they were the first reported members of a family of spin-crossover complexes with monodentate ligands showing a strong cooperativity,[5] which led to the development of the model of the elastic interactions.[6] The synthesis of both the ligands and the complexes is straightforward and these iron(II) complexes are very stable compared to other iron(II) spin-crossover complexes. Finally, the spin-crossover behaviour among these four almost identical complexes differs strongly: the spin transition depends both on the ligand,[2] and the anion.[1,2,7]

Recently, the spin-crossover behaviour of a series of iron(II) complexes containing the new ligand 1-(2-chloroethyl)tetrazole (*teec*) was published.[8] These complexes show, depending on the anion and applied synthetic method, a wide variety of magnetic behaviour including transitions in two steps, residues of high-spin species at low temperature and a thermal hysteresis effect.

In order to study the influence of the size of the halogen atom in the 1-(2-haloethyl)tetrazole spin-crossover complexes, now also the fluorine- (*teef*), bromine- (*teeb*) and iodine-substituted (*teei*) ligands have also been synthesised. From donor-number calculations[9] and NMR spectroscopy[10] it is known that the electronic influence of the halogen atom on the electron density of the tetrazole ring is negligible. Therefore, the changes in ligand-field strength (and subsequently differences in spin-transition temperature $T_{1/2}$) should almost completely be caused by the crystal packing and not by electronic effects.

The ligands *teef*, *teeb* and *teei* have been used to synthesise iron(II) tetrafluoroborate and perchlorate complexes. The magnetic and spectral properties of these complexes have been studied to observe the influence of the ligand size on the thermal spin transition. Because of the potential explosive nature of perchlorate compounds, no Mössbauer or infrared measurements have been performed on the perchlorate complexes.

Results and Discussion

IR Spectroscopy of the Ligands

Mid-range FT-IR spectra of the undiluted complexes, and the ligands as KBr pellets have been recorded within the range of 4400−450 cm^{-1} at room temperature. For the interpretation of the spectra the observed data were compared with general tables in the compilation of Hesse et al.,[11] several publications of analogous tetrazole compounds,[12−20] as well as with the spectra of the starting products. One of the most prominent absorption features for the tetrazole ring is detected around 3140 cm^{-1} (stretching vibration ν_{C-H} at the tetrazole ring[12−14]). At about 1485 cm^{-1} the $\nu_{N2=N3}$ stretching vibration[15,16] appears, which also influences the $\nu_{N1=C5}$ as well as the $\nu_{N1=Calkyl}$ stretching vibration. The shifts of most of the bands of the tetrazole ring, caused by substitution of different halogen atoms, are not significant. An exception is the band which shifts due to a heavier halogen substituent from 1107 to 1096 cm^{-1} and belongs to the ν_{C5-N1} stretching vibration,[14] as well as the in-plane deformation of the C5−H1 bond (δ_{C5-H1}). An in-plane ring vibration[13,14] (δ_{ring2}) shifts in the same manner from 963 to 900 cm^{-1}. In the aliphatic part this trend can only be observed for the $\nu_{N1-Calkyl}$[11] stretching band (shift between 1363 and 1353 cm^{-1}) and for the deformation of the C−H2 bonds[11] (δ_{C-H2}). Table 1 gives an overview of the changes upon coordination, and lists other important IR bands.

IR Spectroscopy of the Complexes

In the iron(II) tetrafluoroborate complexes, two deformation vibrations[21] (δ_{B-F}) belonging to the tetrafluoroborate are identified. The only clearly visible, non-overlapping, deformation vibrations are at 533 and 522 cm^{-1} in the case of *teef*, *teec* and *teeb*, whereas in the compound with *teei* as ligand, a band at 515 cm^{-1} with a shoulder at 522 cm^{-1} appears. The B−F stretching vibration (ν_{B-F}) is responsible for the broad background between 1600 and 800 cm^{-1}. The maximum is located at about 1060 cm^{-1}.

Vibrations in the spectra measured at room temperature for the pure ligands and the iron(II) tetrafluoroborate complexes show differences of about −3 and +70 cm^{-1}, respectively. Interestingly, these shifts show different sensitivity: shifts of the aromatic and aliphatic C−H stretching differ between pure ligand and complex, e.g. ν_{C5-H} (between +1 and +9 cm^{-1}), δ_{C-H2} (between 0 and +19 cm^{-1}) and the broad aromatic overtone band (+33 to +67cm^{-1}). No strong influence is observed on these bands due to the variation of the halogen substituent. However, the bands associated with the tetrazole ring vibrations are influenced by the halogen substituent. With increasing halogen mass, the difference in frequency between the bands observed in the pure ligand and the iron(II) complex containing this ligand increases. The stretching vibration $\nu_{N2=N3}$ shifts upon coordination by +16 cm^{-1} for the fluorine-substituted compound, +17 cm^{-1} for the chlorine-, +26 cm^{-1} for the bromine- and +27 cm^{-1} for the iodine-substituted com-

pound. The asymmetric out-of-plane ring vibrations around 650 cm^{-1} are not significantly influenced at all. Figure 1 provides an illustration of the changes in the mid-range IR spectrum of the *teec* ligand compared to its iron(II) tetrafluoroborate complex at room temperature in the high-spin state and at 100 K in the low-spin state.

Due to the change of the spin state of iron(II) from LS to HS, the anti-bonding e_g-orbitals are populated, thus weakening the Fe−N4 bond. This weakening results in a bond-length expansion[20] of about 5−10%. The expansion can be detected as a shift in the far-infrared region, as has been shown in a similar case.[19] The structural changes around the iron centre also influence bond strengths in the ligand. The stretching vibrations in the tetrazole ring ($\nu_{N2=N3}$) and the C5−H stretching vibration of the tetrazole hydrogen atom (which is located close to the metal centre) are mostly influenced, but the stretching vibrations of the alkyl chain are also slightly affected. The asymmetric ring vibration (γ_{ring2}, γ_{ring3}) and the C−H2 deformation of the chain (δ_{C-H2}) are not significantly influenced.

Figure 2 shows that upon cooling, a thermal iron(II) spin transition takes place yielding new small bands. These new bands are associated with the low-spin state. The new stretching vibration ν_{C5-H}, due to the LS species, shifts with larger substituents (F, Cl, Br and I) to higher energies (3101, 3172, 3175 and 3176 cm^{-1}). Bands known from the high-spin spectra are also shifted, mainly to higher energies (e.g. ν_{C5-H} and δ_{C-H2}). A splitting of one of the bands ($\nu_{N2=N3}$) is also observed. This effect has also been detected in the complexes of *teeb* and *teei*.

The vibrational spectrum of $[Fe(teef)_6](BF_4)_2$ shows the shoulder of the ν_{C-H}(HS) band vanishing upon cooling. The newly arising ν_{C-H}(LS) shows a band splitting, which is observed at about 3100 cm^{-1} (see Figure 2). Furthermore, strong band splittings in the low-spin case are observed for the $\nu_{N2=N3}$ vibration, whereas for most of the other stretching vibrations this splitting is not very well pronounced.

Table 2 lists the vibrational frequencies of the iron(II) tetrafluoroborate complexes with *teef*, *teec*, *teeb* and *teei* at room temperature in the high-spin state and at about 100 K. At this temperature, in all four complexes, the majority of the iron(II) ions that undergo a thermal spin transition will be in the low-spin state (Figure 9, A).

Table 2. Mid IR bands of iron(II) $[Fe(L)_6](BF_4)_2$ with L = *teef*, *teec*, *teeb*, *teei* at room temperature and at about 100 K; frequencies in cm^{-1}; ν = stretching, δ = deformation or in-plane of the ring, γ = out-of-plane, italic numbers = significant changes during the spin conversion, bold = bands which are only observed in HS or LS state

Mössbauer Spectroscopy

teef

Representative spectra recorded at ambient and liquid helium temperatures and at a temperature within the spin transition regime are displayed in Figure 3. The substantial reduction of the absorption area due to the decreasing Lamb-Mössbauer factor upon increasing the temperature is obvious from this figure. This reduction indicates a significant weakening of the bond strength at higher temperatures and quite a low Debye temperature. On taking a closer look at the high-spin pattern (see Figure 4), a single doublet is insufficient to fit the data to a reasonable extent. This can only be performed successfully if the presence of two doublets with equal intensity is assumed. Due to the lack of resolution, however, a certain ambiguity remains concerning the exact absorption area, the error being estimated to lie around 10%. On cooling below ambient temperature the onset of the high-spin to low-spin transition can be detected at 160 K by the occurrence of a further subpattern exhibiting a significantly lower isomer shift and an almost collapsed quadrupole splitting (Table 3). Thus, the resolution of the low-spin state pattern is too poor to resolve the two species as observed in the high-spin case. The transition is found to be centred at about 140 K (Figure 5), which is in close agreement with the magnetic susceptibility results (vide infra). It is, however, an incomplete one, as at 4.2 K approximately 44% still remains in the high-spin state. The temperature dependence of the isomer shift (decreasing values on increasing the temperature) is mainly due to the second-order Doppler effect, with only a small contribution remaining from the change of the lattice dimensions depending on the temperature.

teeb

In the ^{57}Fe Mössbauer spectra of [Fe(*teeb*)$_6$](BF$_4$)$_2$ (see Figure 6 and Table 4), only one doublet is observed for the high-spin state. The transition to the low-spin state is gradual and complete, starting at about 210 K and being completed at about 110 K. The transition is centred at approximately 160 K, in agreement with the bulk magnetic data.

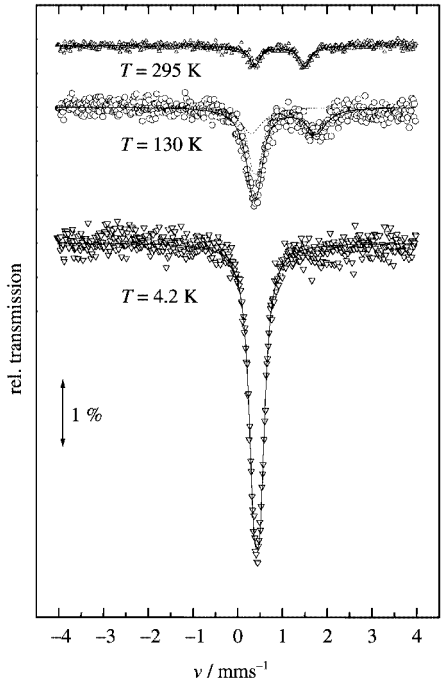

Figure 6. ^{57}Fe Mössbauer spectra recorded from [Fe(*teeb*)$_6$](BF$_4$)$_2$ at different temperatures; triangles and circles are experimental points, solid (broken) lines are computer fits as described in the text

teei

The spin transition observed from a ^{57}Fe Mössbauer spectrum of the compound [Fe(*teei*)$_6$](BF$_4$)$_2$ (see Figure 7, Table 5) is similar to the transition in [Fe(*teeb*)$_6$](BF$_4$)$_2$. The transition is gradual and complete and occurs between 160 and approximately 250 K. Again, only one doublet, associated with iron(II) high-spin species, is detected. The transition temperature as determined by Mössbauer spectroscopy is slightly below 200 K.

Figure 8 shows the spin-transition behaviour of all three compounds as obtained from ^{57}Fe Mössbauer spectroscopy; γ_{HS} can be directly calculated from the peak areas of the high-spin species (A_{HS}) and in the case of [Fe(*teef*)$_6$](BF$_4$)$_2$ from the combination of the peak areas A_{HS}' and A_{HS}''.

The isomer shift reflects the electron density at the Mössbauer nucleus. In the case of the high-spin state no significant influence of the individual ligand is observed. This is, however, not the case for the spectra arising from the low-spin state (Tables 3−5). The values obtained for [Fe(*teei*)$_6$](BF$_4$)$_2$ are considerably smaller than the others, indicating a larger (predominantly *s*-) electron density for this particular compound. For all three compounds under investigation the line width observed for both the high-spin and the low-spin pattern lies significantly beyond the value of the source (> 0.3 mm·s^{-1} compared to 0.22 mm·s^{-1}). This might be caused by slight inhomogeneities or defects in the sample disturbing the lattice periodicity.

Magnetic Susceptibility Measurements

In Figure 9, the fractions of the high-spin species vs. temperature (i.e. γ_{HS} vs. T) of all iron(II) spin-crossover complexes studied are shown. The compounds with tetrafluoroborate as the anion are plotted in graph A, the compounds with perchlorate as the anion are plotted in graph B.

teef

A significant difference is observed between the two magnetic susceptibility curves associated with the two complexes with *teef* as the ligand. The curve of the BF$_4$ complex shows a spin transition between 123 and 190 K with $T_{1/2}(1) = 137$ K and a second more gradual spin transition between 65 and 123 K with $T_{1/2}(2) = 108$ K. Each of these steps represent approximately one third of the iron(II) ions. One third of the ions do not undergo a temperature dependent spin transition, but remain in the high-spin state at all temperatures.

The curve of the magnetic susceptibility versus temperature for the perchlorate complex differs from the tetrafluoroborate complex, showing a one-step transition between 65 and 200 K with $T_{1/2} = 130$ K, thus featuring a higher spin-transition temperature than in the BF$_4$ complex. When the sample is cooled rapidly (cooling rate $>$ 50 K/min) a fraction of the iron(II) ions is trapped in the high-spin state. At approximately 55 K, this fraction transfers to the low-spin state, as depicted in Figure 9, B by a small decline of γ_{HS} between 55 and 65 K.

teeb

From magnetic susceptibility measurements of both the tetrafluoroborate and the perchlorate complexes the presence of only one magnetic site is concluded. Both compounds undergo an almost complete and gradual spin transition (over 90%) with transition temperatures of $T_{1/2} =$ 166 K for the tetrafluoroborate complex and $T_{1/2} = 150$ K for the perchlorate complex. In contrast to the *teec* com-

plexes[8] and to $[Fe(teef)_6](BF_4)_2$ the shape of the transition curves indicates that only one Fe site is present.

teei

In the magnetic susceptibility data of the *teei* compounds the transition curves of both the tetrafluoroborate and the perchlorate complex show a gradual transition. The transitions are 100% complete. The curves are steeper than those of the *teeb* complexes. It is also possible that in the $[Fe(teei)_6](ClO_4)_2$ compound two different magnetic sites are present, with an "inflection point" at 167.5 K. In the first derivative of the transition curve two maxima are visible at 150 and 195 K. The overall curve appears more gradual than the curve of the tetrafluoroborate compound.

Conclusion

In order to draw conclusions on the influence of the ligand, the results described in this paper are also compared with the equivalent *teec* complexes described previously.[8] The magnetic data of the crystallised *teec* compounds have been used for this purpose.

On summarising the two series of [(haloethyl)tetrazole]-iron(II) complexes, with BF_4^- and ClO_4^- as counterions several observations can be made (see Figure 9).

In both parts of Figure 9 (A and B) the sequence of the transition temperature of complexes with *teef*, *teeb* and *teei* as ligands corresponds with the size of the halogen atom. An increase in size correlates with an increase of the transition temperature. Because of the two-step transition in $[Fe(teec)_6](BF_4)_2$ and the partial transition in $[Fe(teec)_6](ClO_4)_2$ it is difficult to include these two in this order. What can be concluded is that the temperature range of the $[Fe(teec)_6](anion)_2$ samples is in the same range as that of the $[Fe(teeb)_6](anion)_2$ compounds, and between those of the *teef* and *teei* complexes.

In $[Fe(teef)_6](BF_4)_2$ a difference is observed between the spin transition obtained by Mössbauer spectroscopy and by magnetic susceptibility measurements. Both show a transition in approximately the same temperature range, but the fraction of iron(II) ions in the high-spin state at low temperature differs, with 44% high spin found by Mössbauer spectroscopy, and 35% by magnetic susceptibility. Ongoing structural measurements at low temperature will conclude whether a 1:2, or a 1:1, or no precise ratio at all, is found.[22]

Moreover, a splitting of the aromatic C−H bands in the $[Fe(teef)_6](BF_4)_2$ indicated the presence of different aromatic C−H vibrations, in other words in the same spin state, different tetrazole rings are present. Powder X-ray structure determination will have to be used to confirm whether the difference is caused by the presence of two

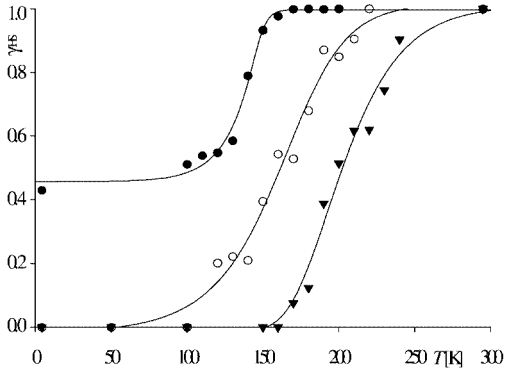

Figure 8. γ_{HS} (directly calculated from the relative absorption area of the high-spin species) vs. temperature derived from the ^{57}Fe Mössbauer spectra recorded from $[Fe(teef)_6](BF_4)$ (dots), $[Fe(teeb)_6](BF_4)$ (circles) and $[Fe(teei)_6](BF_4)_2$ (triangles); the sigmoidal lines are merely a guide to the eye

symmetrically non-equivalent tetrazole rings coordinated to the same iron(II) ion, or by two symmetrically non-equivalent iron(II) species. The last option is supported by the magnetic data and is proved independently by ^{57}Fe Mössbauer spectroscopy. In either case, the vibrational spectrum not only gives qualitative information about the spin-transition temperature $T_{1/2}$, but also about structural properties. This opens additional possibilities for the use of variable-temperature IR spectroscopy as a tool in the investigation of spin-crossover compounds.

The complexes with *teec* as ligand, $[Fe(teef)_6](BF_4)_2$ and $[Fe(teei)_6](ClO_4)_2$ all show a complicated spin-crossover behaviour, perhaps with the presence of two (or in the case of *teef* possibly even three) different sites. This spin-crossover behaviour is simpler in both the *teeb* compounds, perchlorate complex with *teef* ligands and the tetrafluoroborate complex with *teei* ligands, which all show gradual transitions without any steps.

Only in the complexes with *teeb* as the ligand is the influence of the counterion small (only a difference in transition temperature). In all other compounds the magnetic behaviour varies strongly from the tetrafluoroborate to the perchlorate complex. In the *teeb* complexes alone the transition curves shift to a slightly lower temperature when tetrafluoroborate is replaced by perchlorate. This behaviour has been observed before in mononuclear spin-crossover complexes.[23]

Structural analyses indicate that all compounds crystallise as iron(II) complexes with six (haloethyl)tetrazole ligands octahedrally surrounding each iron(II) centre.[22] At

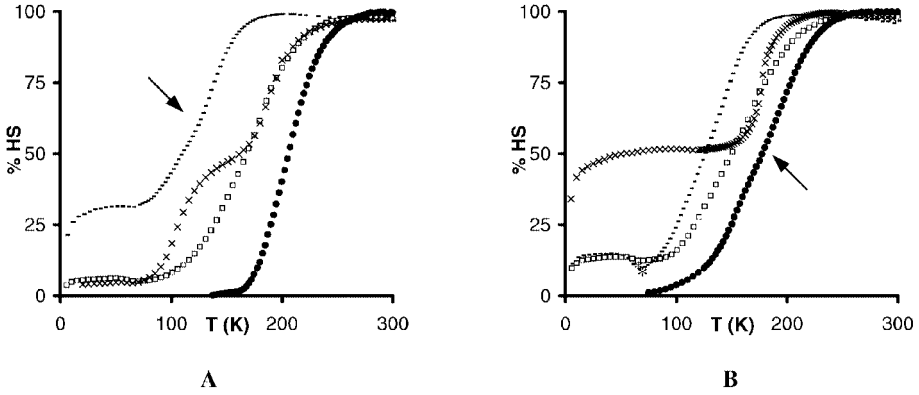

Figure 9. Transition curves of $[Fe(teex)_6](anion)_2$ with *teex* = *teef* (—), *teec* (×), *teeb* (squares), *teei* (dots); A) anion = BF_4^-, B) anion = ClO_4^- (for *teex* = *teec*, curves of the crystallised samples[8] are depicted); the arrows indicate the "bend" between two possible different transition curves, the * indicates the small step caused by thermal trapping in $[Fe(teef)_6](ClO_4)_2$

room temperature, all compounds studied by powder XRD appear to be isostructural to $[Fe(teec)_6](BF_4)_2$, with space group $P2_1/c$,[22] except for $[Fe(teef)_6](BF_4)_2$, which is triclinic in structure instead of monoclinic. Further studies will indicate whether or not the complex spin transition is caused by structural or thermodynamic properties.[22]

Variable-temperature mid-range infrared spectroscopy has been applied to supplement data obtained by magnetic susceptibility measurements and Mössbauer spectroscopy. As shown by a comparison of the spectra of the free ligands and the respective complexes, band shifts are indeed seen to originate from the different substituents used. But the thermally induced spin transition of the iron(II) coordination centres definitely has the strongest impact on the vibrational spectra. The direct observation of the bond-strength changes of the Fe−N bonds upon spin transition in the far IR region turns out to be difficult, mainly because of the coupling of intra-ligand vibrational modes with the Fe−N stretching vibration. Nevertheless, an indirect monitoring of the Fe−N bond strength changes can be achieved by variable-temperature mid-range IR spectroscopy. The focus of interest is the stretching vibration of the single hydrogen atom on the tetrazole ring. This aromatic C−H vibration can easily be distinguished from the aliphatic C−H vibrations of the alkyl substituents. It does not couple with other vibrations and is reasonably sensitive to the bond-strength change of the neighbouring Fe−N bond. Thus, with variable-temperature IR as a tool, it is possible to monitor the spin transition (in this case qualitative, but in other cases quantitative). In the case of a reasonably large band shift of this C−H band, which depends on the packing of the complex, a quantification of the respective peak intensities allows an independent determination of $T_{1/2}$.[23]

The influence of the substituent of the ethyl tail on the electron density of the tetrazole is virtually nonexistent. Therefore, the differences in the spin-transition behaviour should be caused entirely by the crystal packing. The iron−iron distance, and thereby the strength of the elastic interaction (larger when the relative volume change is larger), as well as the relative size of the anion compared to the cationic centre, seem to be the most important causes for the differences in the spin-transition behaviour. But no correlation has been observed between spin transition (i.e. γ_{HS} vs. T) on the one hand, and space group, anion and ligand size on the other. Therefore, it is not yet possible to predict the magnetic properties of a new spin-crossover compound with 1-alkyltetrazoles as ligands.

Experimental Section

General Remarks: Vibrational spectra were recorded with a Perkin−Elmer 16 PC mid-range FT-IR spectrometer using a Graseby-Specac thermostattable sample holder with a Graseby-Specac automatic temperature controller within the temperature range of 100−300 K. To accomplish a reasonable signal-to-noise ratio 64 scans have been summed. Magnetic susceptibility measurements (5−300 K) were carried out using a Quantum Design MPMS-5 5T SQUID magnetometer (measurements carried out at 0.1 T). The data were corrected for the magnetisation of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants.[25] C,H,N determinations were performed with a Perkin−Elmer 2400 Series II analyser. The ^{57}Fe Mössbauer spectra were recorded between 4.2 and 295 K using a conventional constant acceleration drive system. The source used was ^{57}Co in an Rh matrix with an activity of about 50 mCi. The data were analysed using a least-squares fitting program package under the assumption of a discrete superposition of Lorentzian lines. Since the high-spin and the low-spin pattern overlap to a certain extent, the errors of the hyperfine parameters, determined from the computer fit, i.e. isomer shift and quadrupole splitting, increase with decreasing absorption area of the given sub-spectrum from ± 0.01 mm·s^{-1} above 20% area to 0.05 mm·s^{-1} for an area of the order of a few percent. The isomer-shift values displayed in the tables are given relative to the source. If the values are to be compared with shifts relative to α-Fe, 0.12 mm·s^{-1} have to be added.

2-(1-Fluoroethyl)tetrazole (*teef*): This compound was obtained by refluxing a mixture of (1-fluoroethyl)amine hydrochloride (0.05 mol, 5.0 g) and sodium azide (0.01 mol, 6.5 g) in acetic acid (30 mL) and triethyl orthoformate (60 mL) for 8 h. The excess solvents were removed by evaporation. The product was extracted by treating the residue with 2-propanol and removing the insoluble salts (sodium chloride and unchanged sodium azide) by filtration. After further evaporation of the solvent, a yellow oil remained. The pure ligand was obtained by placing the $[Cu(teef)_2Br_2]_n$ complex in ethanol, dissolving this complex in water and extracting the *teef* ligand with dichloromethane. The yield is approximately 1.2 g (20%). ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 9.39 (s, CH), 4.88 (t, CH$_2$), 3.77 (t, CH$_2$) ppm. ^{13}C NMR (75 MHz, [D$_6$]DMSO): δ = 144.5 (CH), 48.7 (CH$_2$), 48.4 (CH$_2$) ppm.

2-(1-Bromoethyl)tetrazole (*teeb*): This compound was obtained by refluxing a mixture of (1-bromoethyl)amine hydrobromide (0.25 mol, 51 g) and sodium azide (0.3 mol, 22 g) in acetic acid (100 mL) and triethyl orthoformate (200 mL) for 6 h. After evaporation of the excess solvents and removal of the salts formed by filtration, the yellow oil obtained was dissolved in 2-propanol. After another subsequent filtration to remove the insoluble salts, *teeb* crystallised as a white solid after several weeks. The yield was approximately 0.9 g (20%). $C_3H_5BrN_4$ (177.0): calcd. C 20.4, H 3.0, N 31.7; found C 21.4, H 2.9, N 33.7. ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 9.47 (s, CH), 4.92 (t, CH$_2$), 3.98 (t, CH$_2$) ppm. ^{13}C NMR (75 MHz, [D$_6$]DMSO): δ = 144.4 (CH), 49.2 (CH$_2$), 42.8 (CH$_2$) ppm.

2-(1-Iodoethyl)tetrazole (*teei*): This compound was synthesised according to the Finkelstein reaction,[26,27] which involves substitution, starting from 2-(1-bromoethyl)tetrazole (*teeb*) and sodium iodide (1.5 equiv.). A 10% solution of *teeb* and sodium iodide in acetone was stirred under reflux conditions for over 2 h. At this stage, the bromide was substituted for iodide and the insoluble sodium bromide precipitated. After cooling, the solution was filtered to remove the insoluble sodium bromide and after removal of the solvent, the remaining oil was dissolved in water; *teei* was obtained by extraction with chloroform after removal of the solvent. The oil obtained slowly crystallised from 2-propanol. The yield was approximately 1 g (60%). ^{1}H NMR (250 MHz, [D$_6$]DMSO): δ = 9.45 (s, CH), 4.82 (t, CH$_2$), 3.66 (t, CH$_2$) ppm. ^{13}C NMR (68 MHz, [D$_6$]DMSO): δ = 144.4 (CH), 49.9 (CH$_2$), 3.26 (CH$_2$) ppm.

***WARNING:** Perchlorate salts are potentially explosive and when used should be treated as such!*

$[Fe(teef)_6](BF_4)_2$: This complex was prepared by dissolving $Fe(BF_4)_2{\cdot}6H_2O$ (1.0 mmol, 0.30 g) and *teef* (6.0 mmol, 0.70 g) in

Solvothermal Synthesis and Structure of Anhydrous Manganese(II) Formate, and Its Topotactic Dehydration from Manganese(II) Formate Dihydrate

Martin Viertelhaus,[a] Henning Henke,[a] Christopher E. Anson,[a] and Annie K. Powell*[a]

Dedicated to Professor Hartmut Bärnighausen on the occasion of his 70th birthday

Keywords: Manganese / Formates / Solvothermal synthesis / Solid-state reactions

Recrystallization of manganese(II) formate dihydrate from formic acid under solvothermal conditions results in single crystals of anhydrous manganese(II) formate $Mn(O_2CH)_2$, and the structure of this phase has been determined by X-ray diffraction. The same product can be obtained by solid-state dehydration of single crystals of manganese formate dihydrate, giving crystals that, although of poor quality, still allow for a single crystal structure determination. The structural relationship between the hydrated and anhydrous phases and the nature of the transformation have been determined. Given the nature of the rearrangement involved in the solid-state reaction, it is remarkable that a crystalline product is obtained. Magnetic measurements of the anhydrous manganese(II) formate show it to be a three-dimensional antiferromagnet.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Carboxylate-bridged polynuclear manganese complexes have been investigated for many years, particularly with regard to their magnetic properties. Examples include the oxo-centred trinuclear complexes[1] as well as $[Mn_{12}O_{12}(O_2CCH_3)_{16}(OH_2)_4]\cdot 4(H_2O)\cdot 2(CH_3CO_2H)$[2] and its related clusters synthesized with other carboxylic acids[3] which show the behaviour characteristic of "single molecule magnets". In addition to the interest in polynuclear clusters, much research on framework structures produced hydrothermally with carboxylates and related donors has been performed.[4] In this context and relevant to the work presented here the structures of anhydrous manganese acetate and manganese nitrate have only been determined relatively recently[5,6] whereas, for example, the structure of manganese carbonate[7] was determined in the early days of X-ray crystallography. In the course of our work on substitution of acetate ligands with formate, we have developed a new synthetic route to the preparation of crystalline anhydrous metal(II) formates.

With the exception of the strontium salt,[8] all the dihydrated metal(II) formates so far reported form an isomorphous series,[9] and isostructural mixed-metal formate dihydrates have also been described.[10] However, anhydrous diformates are only known for copper and cadmium formate.[11,12] These are synthesized at temperatures around 60−80 °C by slow evaporation of the solvent consisting of a mixture of water and formic acid. Other anhydrous formates are not available using this synthetic route.

Although scientific interest in metal(II) formate dihydrates has increased since they have been used as precursors for dehydrogenation catalysts,[13] very little is known about the structures of the anhydrous salts. With the knowledge of the synthesis and structures of the anhydrous formates, new types of metal oxide catalysts made from these formates are possible. With their increased density these anhydrous salts are more closely related to oxides than the dihydrates. The open framework structures of the precursors which are observed for other anhydrous formates (Mg, Fe, Co, Ni, Zn) are likely to influence the catalytic activity.

Even though metal formate dihydrates are model compounds for hydration/dehydration experiments and their decomposition properties have been well documented,[14] their dehydration products have only been characterized by X-ray powder diffraction (Mg,[15] Mn,[16] Fe,[17] Zn[18]), and their structures are not known. The dehydration of nickel and cobalt formate dihydrate only results in amorphous products.[19,20] However, the rehydration of the dehydrated product of manganese formate dihydrate has been reported and is reversible.[14a]

Using solvothermal conditions we have been able to synthesize a range of previously unreported anhydrous formates (Mg, Fe, Co, Ni, Mn, Zn) as crystalline products. We describe here the structure of anhydrous manganese(II) formate, as well as its formation by a remarkable solid-state dehydration reaction of the dihydrate.

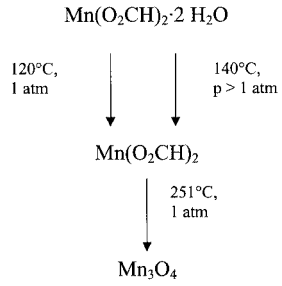
Results and Discussion

Recrystallisation of manganese(II) formate dihydrate (MnFD) from formic acid under solvothermal conditions yields pale pink needle-shaped crystals of anhydrous manganese(II) formate (MnFA), suitable for X-ray diffraction (Scheme 1). The structure was determined at 200 K, and crystallographic details are summarised in Table 3. Under ambient conditions the same product in polycrystalline form can be obtained from concentrated formic acid.[21]



Scheme 1

Anhydrous manganese formate crystallizes in the orthorhombic space group *Pnca* (no. 60) with lattice parameters $a = 5.8127(8)$, $b = 7.509(2)$ and $c = 9.492(1)$ Å and $Z = 4$ (see Table 3). Although MnFA crystallises with an orthorhombic unit cell, while MnFD is monoclinic, inspection of the unit cell parameters shows that two of the three cell lengths are rather close to *b* and *c* for MnFD (Table 3). Since it was soon apparent that the two structures are indeed related (vide infra), and that MnFA can also be obtained via a solid-state dehydration of MnFD, the structure of MnFA was determined in the non-standard setting *Pnca* of the space group *Pbcn* (no. 60) in order to permit consistent labelling of the unit cell axes between the two structures. As the reported structure of MnFD was determined at ambient temperature,[22] we redetermined the structure of MnFD at 200 K, in order to make meaningful comparisons between the two structures.

The asymmetric unit of MnFA contains one independent manganese cation on the special position 4*c* on the twofold axis and one formate group $HCOO^-$ on the general position 8*d*. The coordinating oxygen atoms of the formate ligand differ with respect to their linkage. While O(1) forms μ_2-oxygen-bridges between neighbouring manganese centres, O(2) is monocoordinate. The Mn is coordinated by four O(1) atoms, with the remaining two *cis*-positions occupied by O(2) atoms. This results in the formation of infinite chains of Mn centres linked by pairs of μ_2-oxygen-bridges along **a**, as shown in Figure 1. The coordination spheres around the Mn cations can be described in terms of chains of edge-sharing octahedra. These chains are organized in a manner similar to $ZrCl_4$,[23] in particular with regard to local symmetry elements, with the metal atoms on twofold

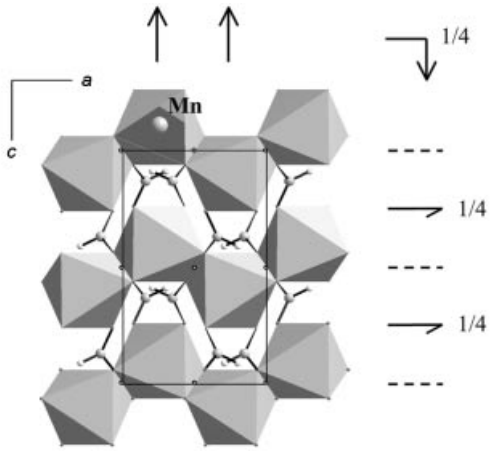


Figure 1. Projection of the structure of MnFA along *b* showing the edge-connected zig-zag chains of octahedrally coordinated Mn atoms; some of the symmetry elements of the space group *Pnca* (no. 60) are given as a help

axes and with inversion centres at the midpoint of the shared edges between octahedra. Similar chains are found in $TcCl_4$.[24] If the structure is viewed along the **a** axis, a rhomboidal network of Mn centres linked via *anti*,*anti*-bridging formate ligands is the characteristic motif (Figure 2). The Mn−O(1) distances in the μ_2-bridges are 2.231(2) and 2.210(2) Å, while the monocoordinate Mn−O(2^{II}) distance is 2.138(2) Å, shorter than in the bridges as might be expected. Bond lengths and angles are listed in Table 1.

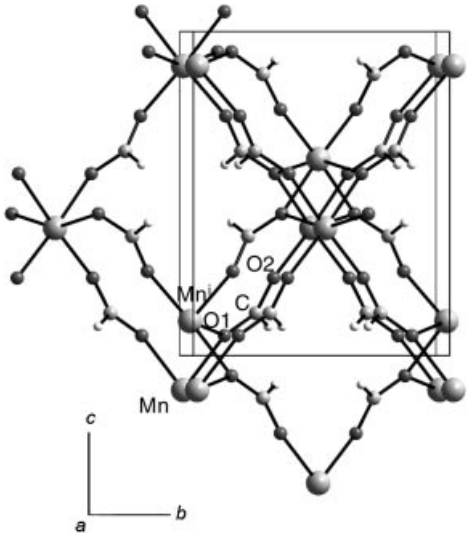

Figure 2. The network of formate groups connecting the manganese atoms of anhydrous MnFA. To aid the comparison with Figure 3 the drawing is slightly rotated with respect to *c*. Due to this rotation, all formate links at heights close to $x = 1/4$ and $x = 5/4$ appear doubled around the octahedrally coordinated manganese chain in the middle of the cell. With reference to Figure 3 the manganese atoms are shifted by 1/4 along *a* owing to the convention that a centre of inversion defines the origin. As a consequence Mn^i is related to Mn by $1 - x, -y, -z$.

Table 1. Bond lengths and angles of MnFA
Symmetry codes: (i) $1 - x, -y, -z$; (ii) $x, 1/2 - y, -1/2 + z$; (iii) $1/2 - x, 1/2 + y, 1/2 + z$; (iv) $1/2 - x, -1/2 + y, -1/2 + z$; (v) $-1/2 + x, y, -z$; (vi) $1/2 - x, -y, z$

Bond lengths [Å]		Bond angles [°]	
Mn−O(1)	2.231(1)	O(2^{iv})−Mn−O(2^{ii})	93.86(10)
Mn−O(1^{i})	2.210(2)	O(2^{iv})−Mn−O(1^{v})	90.80(7)
Mn−O(2^{ii})	2.138(2)	O(2^{iv})−Mn−O(1^{i})	104.27(7)
O(1)−C	1.269(3)	O(1^{i})−Mn−O(1^{v})	158.01(9)
O(2)−C	1.236(3)	O(2^{iv})−Mn−O(1)	176.95(6)
C−H	1.00(3)	O(2^{iv})−Mn−O(1^{vi})	88.86(7)
Mn···Mn(i)	3.539(1)	O(1)−Mn−O(1^{i})	74.29(7)
Mn···Mn(iii)	6.052(1)	O(1)−Mn−O(1^{v})	89.85(5)
Mn(i)···Mn(iii)	5.475(1)	O(1)−Mn−O(1^{vi})	88.45(9)

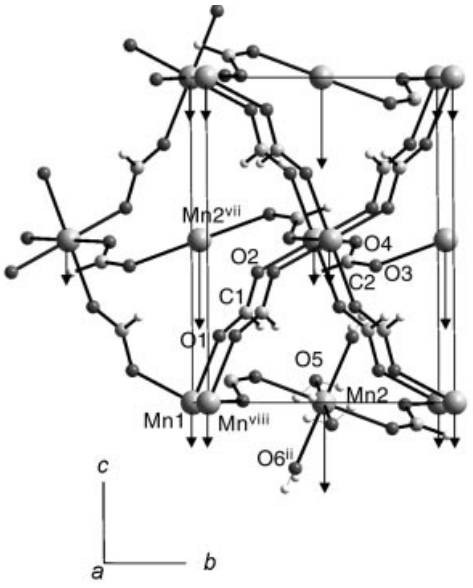

Figure 3. The structure of the dihydrate MnFD for comparison with Figure 2. Apart from the very similar formate-bridged network around atoms of type Mn(1) shown for layer heights close to $x = 0$ and additionally at $x = 1$ in most places, there are Mn(2)-centred loops linking the sheets at $x = 0$ and $x = 1$. Atom Mn(2) at $x = 1/2$ binds to four molecules of crystal water. Arrows indicate the relative moves necessary to reach the structure of MnFA. All equivalents of Mn(2) are shown with the water stripped off. Symmetry codes: (vii): $1 - x, -1/2 + y, 1/2 - z$, (viii): $1 + x, y, z$.

Differential thermal analysis (DTA) and thermogravimetry (TG) studies on MnFD in a nitrogen atmosphere show that the dehydration process takes place in the temperature range from 95 to 135 °C. A continuously decreasing sample mass is observed over this temperature range, with a mass loss of 19.3% (calculated value 19.9% for loss of two waters), and the appearance of an endothermic peak in the DTA curve. The decomposition of MnFA to Mn_3O_4 can be observed between 215 and 260 °C. During the mass loss of 37.4% (calcd. 38.0%) an exothermic peak can be seen in the DTA-curve (Scheme 1).

On dehydration of single crystals of MnFD at 120 °C, their plate-like habit is maintained, but they become off-white and opaque and are frequently cracked. This dehydration event clearly gives rise to a poorer quality sample with much larger spots on the image plate than for the solvothermal crystals. Thus, although the sample still appears to be a single crystal, it in fact consists of a collection of smaller crystallites which are, however, sufficiently aligned to allow for satisfactory structure determination and refinement. This showed that the dehydrated crystals had the identical structure to solvothermally-prepared MnFA, although as expected the final R-factors (Table 3) were higher than for the solvothermally prepared crystals.

A series of X-ray powder diffraction patterns measured during the course of dehydration shows the coexistence of both phases (MnFD and MnFA) (Figure 4). A similar heating experiment during which a sequence of orienting precession photographs was taken of a single crystal at 115 °C, also demonstrates the simultaneous presence of both phases within the same crystal specimen. The sharp diffraction spots of MnFD decrease in intensity while the more diffuse spots assigned to MnFA quickly become stronger. At 120 °C the slightly broadened (0*kl*) reflections of MnFA show clearly the systematic extinctions of the diagonal glide plane. Moreover, these observations give evidence that a fixed spatial relationship exists between the lattice of disappearing MnFD and freshly growing MnFA, indicating a topotactic transformation. Axes **b** and **c** retain their length approximately (see Table 3) and also their orientation within ±0.5°, whereas axis **a** undergoes changes both with regard to the angle of inclination (i.e. β of the monoclinic lattice decreases by over 7° to 90° in the orthorhombic phase) but also more drastically with regard to the shrinkage of the structure.

In contrast to MnFA, MnFD prepared under normal ambient conditions does not form needles, but plates with (100) as the dominant face. In accordance with the habit of the crystals the structure of MnFD consists of layers oriented parallel to the *bc*-plane. Figure 3, the corresponding section suitable for comparison with anhydrous MnFA (cf. Figure 2), shows that in MnFD nets of formate-bridged manganese atoms also exist in a variant similar to that of MnFA (see for instance O(1)−C(1)−O(2) coordinating Mn(1) plus all equivalent units at the same height of $x = 0$). Halfway along the x direction and exactly over the holes of the aforementioned network the other manganese species Mn(2) is surrounded by four water molecules in a planar arrangement. This coordination of Mn(2) is completed by two formate groups lying *trans* to each other (see the equivalent O(3)−C(2)−O(4) in Figure 3) forming crosslinks between the layers in $x = 0$ and $x = 1$. Thus the atom Mn(2) is part of a link extending from the upper left to the lower right of Figure 3.

Although the space group type of MnFD ($P12_1/c1$) is a subgroup of that of MnFA ($P2_1/n2_1/c2/a$), it is not possible that a simple displacive transition is taking place. Instead the mechanism has to be discontinuous due to the loss of the crystal water, causing a dramatic shrinkage of the unit cell along [100]. Whereas in the lower symmetry phase of the dihydrate Mn(1) and Mn(2) both lie on inversion centres, in *Pnca* they are grouped around the centres of inversion necessitating a rearrangement of the structure. The

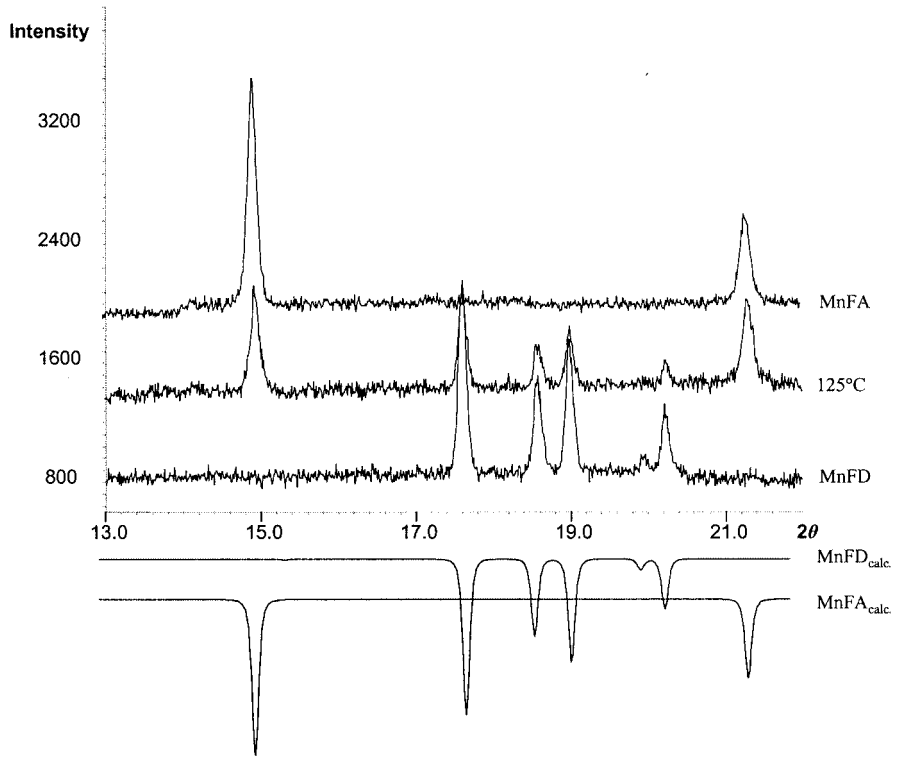

Figure 4. Heating powder diagrams with Cu-$K_{\alpha 1}$ radiation show the coexistence of MnFA and MnFD at an intermediate stage of the dehydration; for comparison the calculated patterns for MnFD and MnFA are given

shorter arrows of Figure 3 merely result from the convention that one of the centres of inversion in MnFA must be chosen to coincide with the origin of the unit cell. As indicated by the longer arrows of Figure 3 the topology of the anhydrous phase in Figure 2 is reproduced by virtue of a transverse move of Mn(2^{vii}) which brings it closer to Mn(1) and Mn(1^{viii}) in the upper and lower layer. The required relative shift in the **c**-direction amounts to ca. 2.77 Å. While in MnFD the distance between Mn(1) and Mn(2^{vii}) is 6.054(2) Å, and between Mn(1^{viii}) and Mn(2^{vii}) 6.917(2) Å, the distance between Mn and Mn^{i} in MnFA, is only 3.539(1) Å (see Table 1). These observations suggest an insertion mechanism on a local scale, which has the advantage that none of the existing bonds to formate groups need to be broken. With loss of the water ligands, the coordinatively-deficient Mn centres −OCHO−Mn(2)−OCHO− reorient themselves to gain additional coordination from formate oxygens O(1) and O(4), which as a consequence are now μ_2-bridging between Mn(1) and former Mn(2) centres, resulting in the zig-zag chains of crystallographically-equivalent Mn centres running along **a** in the structure of MnFA. This process requires a considerable contraction of the MnFD lattice in the **a**-direction amounting to ca. 2.98 Å.

It is remarkable that these large shifts are possible in a topotactical reaction without causing complete destruction of the crystal. As the broad reflections show the anhydrous phase consists of small domains. Their growth seems to start from numerous nucleation sites under the orienting influence of the parent phase MnFD. Similar observations have been reported for the dehydrations of brucite to periclase and of goethite to haematite and magnetite.[25]

Quite naturally nothing can be said by X-ray diffraction about the sequence of steps during the dehydration process. Here the topologies of MnFD and MnFA are simply compared leading to the conclusion that the reaction proceeds topotactically, such that the orientational relationship between both phases is preserved. Although the solid-state process is necessarily reconstructive, it seems to take place surprisingly smoothly.

The IR spectrum of MnFA is simpler than that of MnFD (Table 2); this is consistent with the two structures. Whereas in MnFD there are two inequivalent formate anions in the lattice, and several of the formate vibrational modes give rise to a pair of absorptions, there is only one independent anion in MnFA, and single bands are observed.

Full factor-group analyses for the two IR spectra predict three IR-active modes per formate "molecular" mode in the spectrum of MnFA, and four in the spectrum of MnFD. However, the numbers of observed bands is consistent with the simple molecular analysis.

In addition, there are no absorption bands from water in the MnFA spectrum. The IR spectrum for MnFA corresponds to the spectrum reported by Baraldi[26] for β-MnFA. Baraldi reported this β-MnFA as a metastable phase on the path towards α-MnFA which he identified only by IR spectroscopy. Since we do not observe this α-phase, we cannot say definitively which one is the thermodynamically more stable.

The magnetic behaviour of MnFD has been thoroughly studied.[28] The magnetic susceptibility measurements on MnFA show all the characteristics of a three-dimensional antiferromagnet (Figure 5). The χ^{-1} vs. T plot for temperatures higher than 10 K leads to a Curie temperature Θ of -13.2 K and a Curie constant C of 4.24 emu mol^{-1} K^{-1} which corresponds to the g-factor of 1.97. Every manganese atom has two nearest manganese neighbours along the μ_2-oxygen-bridged chain [3.539(1) Å] and eight further manganese neighbours linked by four *syn-anti* formate bridges [5.475(1) Å] and four *anti-anti* formate bridges [6.052(1) Å]. With its ten direct neighbours the antiferromagnetic coupling of -3.12 cm^{-1} per manganese atom corresponds to an average coupling of -0.31 cm^{-1} $\Theta = 1/3\ S(S+1)\ \Sigma\ J$ with $S = 5/2$ and $\Sigma\ J$ is the sum over all interaction constants for each Mn).

With reference to *J*-values, which are reported for Mn−O(R)−Mn ($J = -1$ to $-5\ cm^{-1}$)[29] and Mn−O−C(R)−O−Mn interactions ($J = -0.2$ to $-0.3\ cm^{-1}$)[30] we can predict that the interactions between manganese atoms within the μ_2-oxygen-bridged chain should be stronger than between adjacent chains. Although the interchain interactions are probably an order of magnitude weaker than the intrachain ones there are four times as many such interactions between the chains as along them, and these may therefore be significant with regard to the three-dimensional antiferromagnetic behaviour. These would require three *J* values and fitting the data in this way would have led to overparametrisation. Antiferromagnetic ordering starts at 8 K, and the spinflop field is 1.2(1) Ts.

Conclusion

We have shown that the crystal structure of anhydrous manganese(II) formate is topotactically related to the structure of manganese(II) formate dihydrate. It can be obtained either by solvothermal reaction or, surprisingly, by the topotactical dehydration of MnFD. Although the μ_2-oxygen-bridges in MnFA lead to one-dimensional chains of oxygen-bridged manganese atoms the additional interchain interactions via formate bridges result in a three-dimensional antiferromagnetic behaviour.

Experimental Section

MnFD was synthesized as reported previously.[16]

Synthesis of $Mn(O_2CH)_2$ (1): $Mn(O_2CH)_2$ was obtained by solvothermal reaction in a steel autoclave with a Teflon-insert of internal volume 10 mL. In a typical experiment $Mn(O_2CH)_2{\cdot}2H_2O$ (0.2 g, 1.1 mmol) was heated in 3 mL of formic acid to 140 °C. During the experiment (88 h) the CO_2 produced as a result of the decomposition of formic acid raises the pressure to such an extent, that in the initial experiment the lid of the Teflon-insert is punctured resulting in the evaporation of the remaining solvent. Subsequently these conditions were reproduced by slightly loosening the autoclave lids to act as a vent in order to avoid damage of the insert. A quantitative yield of needle-like pink crystals of MnFA was obtained. X-ray powder diffraction and TG experiments showed that the product was pure and contained no dihydrate.

X-ray Crystallography: Single-crystal data were measured on a Stoe IPDS image plate area detector diffractometer using graphite-monochromatised Mo-K_α radiation ($\lambda = 0.71073$ Å). Structures were solved by direct methods and refined by full-matrix least-squares against F^2 (all data) using the SHELXTL software package.[31] Non-hydrogen atoms were assigned anisotropic thermal parameters; hydrogen atoms were fully refined with isotropic temperature factors. CCDC-200199 and -200200 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Single-crystal photographs were taken on a Buerger precession camera from Huber (Mo radiation). The specimen was heated using a modified Enraf−Nonius FR 559 crystal heater,[32] with which the temperature of the crystal is maintained and controlled by a hot gas stream.

X-ray Powder Diffraction: The X-ray powder patterns were measured on a Stoe STADI P diffractometer using Cu-$K_{\alpha 1}$ radiation (Ge monochromator) and Debye−Scherrer geometry. The sample was placed in an open glass capillary and heated using a Stoe high-temperature attachment.

Thermal Analysis: The differential thermal analysis (DTA) and the thermogravimetry (TG) experiments were carried out using a Netzsch STA 409C system. Samples were heated in Al_2O_3 crucibles with a heating rate of $1\ K\ min^{-1}$ up to 600 °C under a nitrogen atmosphere with flow rate $30\ L\ h^{-1}$.

Susceptibility Measurement: Magnetic measurements were carried out with a Quantum-Design MPMS SQUID magnetometer. The powder sample was placed in a quartz tube and the susceptibility measured in the temperature range from 300 to 1.9 K.

IR Spectroscopy: FTIR spectra were measured using KBr pellets of the sample in the range from 4000 to $400\ cm^{-1}$ with a Perkin−Elmer Spectrum One spectrometer. For each spectrum four scans were measured at a resolution of $4\ cm^{-1}$.

Acknowledgments

We would like to thank PD Dr. Bernd Pilawa for help with the interpretation of the magnetic data.

Hybrid Organic/Inorganic Molecular Materials Formed by Tetrathiafulvalene Radicals and Magnetic Trimeric Clusters of Dimetallic Oxalate-Bridged Complexes: The Series $(TTF)_4\{M^{II}(H_2O)_2[M^{III}(ox)_3]_2\}\cdot nH_2O$ (M^{II} = Mn, Fe, Co, Ni, Cu and Zn; M^{III} = Cr and Fe; ox = $C_2O_4^{2-}$)

Eugenio Coronado,*[a] José Ramón Galán-Mascarós,[a] Carlos Giménez-Saiz,[a] Carlos J. Gómez-García,[a] and Catalina Ruiz-Pérez[b]

Keywords: Coordination chemistry / Hybrid materials / Magnetic properties / O ligands

The first examples of trimeric, dimetallic, pure oxalate-bridged complexes [ox = $(C_2O_4)^{2-}$] have been synthesized and characterized structurally and magnetically for the two new series of crystalline molecular assemblies formulated as $(TTF)_4\{M^{II}(H_2O)_2[M^{III}(ox)_3]_2\}\cdot nH_2O$ [for M^{III} = Cr; M^{II} = Mn (**1**), Fe (**2**), Co (**3**), Ni (**4**), Cu (**5**) and Zn (**6**); for M^{III} = Fe; M^{II} = Mn (**7**), Fe (**8**), Co (**9**), Ni (**10**) and Zn (**11**)]. Both series (Cr_2M and Fe_2M) are isostructural. The crystal structure of $(TTF)_4\{Mn(H_2O)_2[Cr(ox)_3]_2\}14H_2O$ (**1**) [monoclinic, space group *C*2/*c* (no. 15), *a* = 13.240(5) Å, *b* = 19.450(5) Å, *c* = 27.690(5) Å, β = 97.63(5)°, *V* = 7068(3) Å^3 and *Z* = 4] shows alternating layers of the organic radical TTF, arranged in an unprecedented one-dimensional κ-type phase formed by parallel chains of orthogonal dimers along the *a* axis, and layers of centrosymmetrical Cr–Mn–Cr trimers with oxalate bridges. The magnetic measurements show ferromagnetic coupling within the trimers for the Cr_2M series and antiferromagnetic for the Fe_2M series, giving rise to high-spin molecules in both cases [*S* = 11/2, 10/2, 9/2, 8/2 and 7/2 in compounds (**1**–**5**), respectively, and *S* = 5/2, 6/2, 7/2 and 8/2 in compounds (**7**–**10**), respectively]. These high-spin ground states are confirmed by magnetization measurements at 2 K. The ESR spectra of all compounds confirm the presence of the metals and a small amount of isolated TTF radical in all the samples, which is typical for these kinds of radical salts.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The discovery at the beginning of the 1990s of the ferromagnetic molecular material $\{NBu_4[CuCr(ox)_3]\}_x$ [ox = $(C_2O_4)^{2-}$], based on an oxalate-bridged two-dimensional dimetallic lattice,[1,2] has increased the interest in the oxalate ion as a bridging ligand to construct polynuclear complexes and extended lattices of transition metal ions of variable dimensionality in the search for new molecule-based magnets.[3,4] Thus, an extended family of two-dimensional dimetallic phases, formulated as $Bu_4N[M^{II}M^{III}(ox)_3]$ (M^{II} = Cr, Mn, Fe, Co, Ni and Cu; M^{III} = Cr, Fe and Ru),[5–11] has been obtained through the reaction of the chelate anions $[M^{III}(ox)_3]^{3-}$ with divalent first-row transition metal cations. These three series (M^{III} = Cr, Fe and Ru) behave as ferro- or ferrimagnets with critical temperatures ranging from 1.7 to 44 K, with the exception only of $Cr^{II}Cr^{III}$, which shows short-range antiferromagnetic interactions.[11]

Several attempts have been made to improve these transition temperatures. Substitution of the oxalate bridges by dithiooxalate (dto = $[C_2S_2O_2]^{2-}$) has led to the family of extended dimetallic assemblies of formula $Pr_4N[MCr(dto)_3]$ (M = Fe, Co, Ni and Zn).[12] Except for the Zn derivative, all the other members of this family behave as ferromagnets with T_c ranging from 8 to 23 K.

A more profound effect on the magnetic properties has been accomplished when mixtures of Cr^{III}, Fe^{III} and Ru^{III} were used for the construction of the anionic 2-D networks.[13] In this case, the competence of ferromagnetic $M^{II}-M^{III}$ (M^{III} = Cr and Ru) and antiferromagnetic $M^{II}-M^{III}$ (M^{III} = Fe) interactions within the magnetic layers increases the coercivity of these materials by at least one order of magnitude, and can be tuned depending on the metallic ratio in the solid. Thus, the series $[A][Fe^{II}Fe^{III}_xCr^{III}_{(1-x)}(ox)_3]$ presents a coercive field of 1.23 T for $x = 0.75 \pm 0.05$ with $A^+ = Bu_4N$ and 1.67 T for $x = 0.52 \pm 0.05$ with $A^+ = CoCp_2^*$.[14] This high coercive field can be increased up to 2.20 T in the series

$[A][Fe^{II}Ru^{III}_{x}Fe^{III}_{(1-x)}(ox)_3]$ for $x = 0.53$ with $A^+ = CoCp^*_2$.[15]

Another strategy consists of increasing the dimensionality of the lattice. Homo- and dimetallic chiral three-dimensional (3-D) oxalate-bridged networks ($[M^{II}_2(ox)_3]_n^{2n-}$ and $[M^{III}M^{I}(ox)_3]_n^{2n-}$) were prepared by using the triply chelated cations $[Z^{II}(bpy)_3]^{2+}$ and $[Z^{III}(bpy)_3]^{3+}$, where bpy is 2,2′-bipyridine.[3,16] Nevertheless, all these 3-D networks present antiferromagnetic exchange interactions, but no long-range order, except for two Co^{II} derivatives[17] (for the homometallic 3-D networks), or paramagnetic behaviors when M^{I} (alkali metal) isolates the magnetic M^{III} (Fe^{III} or Cr^{III}) metal ions in the network. More recently we have succeeded in preparing analogous dimetallic 3-D phases with a divalent (M^{II}) and a trivalent metal ion (Cr^{III}) connected through the oxalato bridges to give the anionic 3-D net of formula $[Cr^{III}M^{II}(ox)_3]_n^{n-}$.[18] These series contain the chiral $[Z^{II}(bpy)_3]^{2+}$ cation as counterion, which imposes the same overall chirality to the crystals. The series can be formulated as $[Z^{II}(bpy)_3](ClO_4)[Cr^{III}M^{II}(ox)_3]$ (Z^{II} = Ru, Fe, Co and Ni; M^{II} = Mn, Fe, Co, Ni, Cu and Zn). In this family of compounds we have also found, as in the related 2-D series, a ferromagnetic ordering, but at lower temperatures because of the weaker magnetic interactions between the metallic centers as a consequence of a loss of planarity in the oxalato bridge. It is noteworthy to mention that these series represent one of few examples of chiral magnets known to date.[19,20]

In addition to the possibility of modifying the magnetic polymeric structure, these magnetic systems allow us to use a novel approach to multiproperty materials. For instance, in all the cases where the 2-D oxalate-bridged networks are formed, the organic counterions (R_4X^+: X = N, P; R = *n*-alkyl or phenyl) are located between the anionic layers and determine the creation of the 2-D network and, at the same time, the interlayer separation. The idea of replacing these "inert" counterions by "electroactive" molecules, which could add a new property (magnetic, electrical or optical) to the material, can be used to prepare new multilayered materials presenting alternating layers and, thus, two alternating properties, resulting in coexistence or even synergy between them.

Our first attempt to construct magnetic-magnetic multilayered materials in this way was to prepare the series $[FeCp^*_2][M^{II}M^{III}(ox)_3]$ (M^{II} = Mn, Fe, Co, Ni and Cu; M^{III} = Cr and Fe), by using the paramagnetic ($S = 1/2$) decamethylferrocenium counterion.[21] The magnetic behavior of these series is roughly the same as that found for the tetrabutylammonium salts, indicating that the presence of paramagnetic units between the layers has no effect upon the magnetic ordering. The synthesis of optical-magnetic layered materials by using organic NLO-active cations, such as the $DAMS^+$ ion, has also been reported.[22] In this case, both properties are present in the material, but are completely independent from one another.

Maybe the most interesting possibility is that of preparing conducting-magnetic layered materials. In this direction, one of the most appealing possibilities is the radical cation of TTF derivatives, since TTF-type donors constitute the most widely used molecules in the synthesis of molecular conductors and superconductors.[23] In this context, the use of the organic donor bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF or ET) has already led to two important discoveries in molecular materials science: the first superconductor with paramagnetic metal ions, the radical salt $(BEDT\text{-}TTF)_4(H_3O)[Fe(ox)_3]$;[24,25] and the first molecular metallic ferromagnet $(BEDT\text{-}TTF)_3[MnCr(ox)_3]$ where layers of the organic radical BEDT-TTF alternate with the ferromagnetic layers $[MnCr(ox)_3]^-$.[26] In the latter case, a cooperative magnetic property (ferromagnetism in the oxalato layer) coexists for the first time with another cooperative property (the metallic behavior of the ET layer) in a molecule-based material.

According to this approach, but using the organic donor tetrathiafulvalene (TTF), we have synthesized a new series of molecular assemblies that combine oxalate-bridged dimetallic complexes and TTF donors. Here we report the synthesis, structure and magnetic charaterization of this new series of compounds that can be formulated as $TTF_4\{M^{II}(H_2O)_2[M^{III}(ox)_3]_2\}\cdot nH_2O$ (M^{III} = Cr and Fe; M^{II} = Mn, Fe, Co, Ni, Cu and Zn) and that constitute the first hybrid compounds based on dimetallic $M^{II}M^{III}$ oxalate complexes and TTF molecules.[27]

Results and Discussion

Structure of $TTF_4\{Mn(H_2O)_2[Cr(ox)_3]_2\}\cdot 14H_2O$ (1)

Although all members of both the Cr_2M^{II} (M^{II} = Mn, Fe, Co, Ni, Cu and Zn) and Fe_2M^{II} (M^{II} = Mn, Fe, Co, Ni and Zn) series are crystalline, single crystals suitable for X-ray structure determination were obtained only for the Cr_2Mn (**1**) and Fe_2Fe (**8**) compounds. According to their unit cells, both compounds appeared to be isostructural. Thus, the crystal structure was determined only for the Cr_2Mn compound, because of the better quality of the single crystals. The isostructurality of all the other members of both series was checked by X-ray powder diffraction, which showed an isomorphous pattern for each, and similar unit cells (see Supporting information). In the case of the Cr_2Cu compound, small differences observed in the X-ray powder pattern suggest that, although it is a compound analogous to the others, some small crystallographic differences must be present, in agreement with its magnetic properties (see below).

The structure of **1** consists of alternating layers of the organic donor tetrathiafulvalene (TTF) and the trimeric linear complex $\{Mn(H_2O)_2[Cr(ox)_3]_2\}^{4-}$ laying in the *ab* plane (Figure 1). The asymmetric unit is formed by a complete TTF molecule, two half-TTF molecules and half a trimer. There are, therefore, four TTF molecules per trimer. The centrosymmetric linear $Cr^{III}-Mn^{II}-Cr^{III}$ trimers are formed by two octahedral $[Cr(ox)_3]^{3-}$ entities connected via an Mn^{2+} ion (Figure 2). The Mn atom, which is located at an inversion center, is surrounded by two bis(bidentate) oxalate anions, one from each $[Cr(ox)_3]^{3-}$ unit, and com-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pletes its octahedral coordination with two water molecules in the axial positions. The $Mn-O_w$ distances for these two water molecules are shorter [Mn−O1 = 2.160(5) Å] than the $Mn-O_{ox}$ distances in the equatorial plane [Mn−O2 = 2.170(12) Å and Mn−O3 = 2.240(11) Å]. The long Mn−O3 distance produces a decrease in the chelate angle O2−Mn−O3, which is only 76.5(4)°. The two Cr^{III} atoms are made equivalent by the inversion center located on the Mn^{II} atom and they are surrounded by three bidentate oxalate groups, such as the $[Cr(ox)_3]^{3-}$ anion, sharing one of the oxalate groups with the central Mn atom. The Cr−O bond lengths [from 1.930(13) Å to 2.001(10) Å] are more homogeneous than those in the Mn^{II} environment. The average Cr−O distance (1.968Å) is very similar to those found for the free $[Cr(ox)_3]^{3-}$ anion in the K^+ and H_4N^+ salts (1.971 and 1.969, respectively),[28] indicating that the anion maintains its original geometry and size despite sharing one of the oxalate groups with the Mn^{2+} ion. In fact, the three O−Cr−O chelate angles between the two oxygen atoms of each oxalate group [81.4(4), 81.8(4) and 83.6(4)°] are very similar to those of the isolated anion [82.0(2), 82.1(2) and 82.4(2)°].[29]

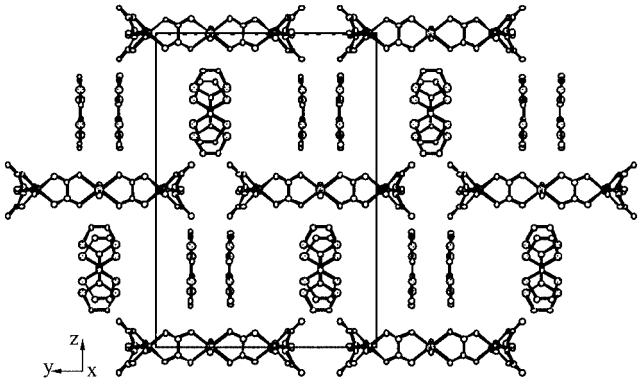

Figure 1. View of the unit cell of the salt $TTF_4\{Mn(H_2O)_2[Cr(C_2O_4)_3]_2\}$ (**1**) showing the alternating organic/inorganic layers in the *ab* plane

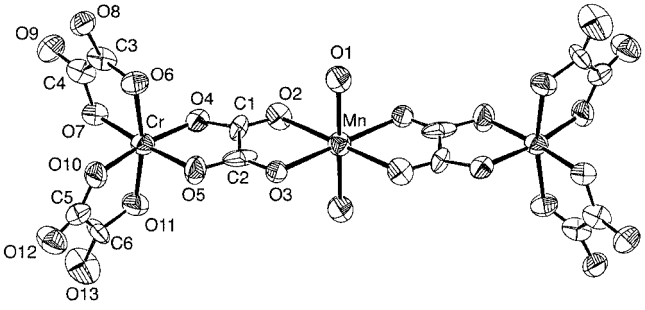

Figure 2. ORTEP representation (50% probability) of the $[Mn(H_2O)_2[Cr(C_2O_4)_3]_2]^{4-}$ anion showing the two $Cr(C_2O_4)_3$ units connected by the Mn ion

The dimetallic trimers form a 2-D framework wherein each trimer is connected by eight intermolecular hydrogen bonds [four O_w-O_{ox} distances of 2.740(11) Å and four of 2.760(12) Å] to its four nearest neighbors. These hydrogen bonds are formed between the water molecules coordinated to the Mn atom and one free oxygen atom from one of the terminal oxalate groups of the surrounding trimers (Figure 3). The dimetallic 2-D network can be described, therefore, as a pseudo-hexagonal lattice wherein each Mn^{II} atom is surrounded by six Cr^{III} atoms: two at 5.492(19) Å (the Mn−Cr intra-trimer distance) and four at 7.860(19) Å (the Mn−Cr inter-trimer distance) and each Cr^{III} atom is surrounded by three Cr^{III} ions [two at 6.740(19) Å and one at 8.480(19) Å] and three Mn^{II} ions [one at 5.490(19) Å and two at 7.860(19) Å].

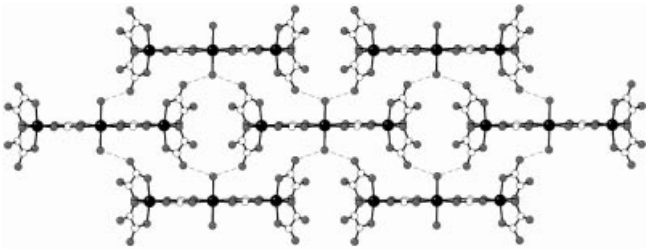

Figure 3. View of the anionic layer of the salt $TTF_4[Mn(H_2O)_2[Cr(C_2O_4)_3]_2]$ (**1**) showing the dimetallic trimers and the hydrogen bonds between them (dotted lines)

The organic layers are formed by three crystallographically independent TTF molecules, noted as **A**, **B** and **C**. These molecules form two types of eclipsed face-to-face dimers of TTF molecules (**A**−**A** and **B**−**C**) with short interplanar distances [3.410(14) and 3.370(14) Å, respectively]. The intradimer S−S distances are also very short [3.380(14) and 3.360(14) Å in the **A**−**A** and **B**−**C** dimers, respectively] and smaller than the sum of the van der Waals radii for two sulfur atoms (3.6 Å). There are two dimers (one **AA** and one **BC**) per anion. The dimers are disposed in an infinite chain formed by alternating orthogonal **AA** and **BC** dimers along the *a* axis (Figure 4). Inside the chain, both inter-dimer S−S distances also are short [3.540(13) and 3.560(14) Å for the **A**−**B** and **A**−**C** inter-dimer distances, respectively]. The neighboring chains are displaced in one dimer in such a way that the closest dimers of the neighboring chains are also orthogonal, giving rise to an infinite planar structure wherein each dimer is surrounded by four orthogonal dimers. This arrangement is similar to the so-called κ phase, which is the phase that has produced the highest number of organic superconductors in the TTF family, as well as those with the highest T_c.[23] Nevertheless, there are two features that make this κ phase original: one is that, to the best of our knowledge, this is the first time that such a phase has been observed for the donor TTF, and the other is that the intra- and inter-chain distances are not similar [the shortest inter-chain S···S distances are 6.560(19) and 6.580(19) Å, almost twice the shortest inter-dimer S···S distances inside the chains: 3.540(14) and 3.560(14) Å], whereas in the classical κ phases both distances are very close in value to one another. Thus, this

structure can be seen as a pseudo-κ or a one-dimensional-κ phase.

It is important to note that all the TTF molecules appear to be completely oxidized, according to the stoichiometry of the compound (4:1), and the charge of the anion (−4). Furthermore, the fact that these molecules are strongly dimerized, as discussed in this section, allows one to anticipate that the dimers will have no net spin from strong antiferromagnetic interactions between the unpaired electrons in each TTF molecule, and, therefore, all the magnetic contribution is expected to come from the inorganic lattice.

Magnetic Properties

(a) The Cr_2M Series

As can be seen in Figure 5, the product of the molar susceptibility and the temperature ($\chi_m T$, proportional to the square of μ_{eff}), plotted versus the temperature, shows a similar behavior for all the members of the Cr_2M family except for the Cu^{II} and Zn^{II} derivatives. Thus, compounds **1**−**4** exhibit, at room temperature, the Curie constant expected for magnetically diluted trimers Cr−M−Cr, with two independent Cr^{III} ions (S = 3/2) and an isolated M^{II} ion (with S = 5/2, 2, 3/2 and 1 for M^{II} = Mn, Fe, Co and Ni, respectively). Upon cooling, the value of the product $\chi_m T$ remains almost constant down to approx. 50 K. Below this temperature, the value of the product $\chi_m T$ increases with decreasing temperature, indicating the presence of ferromagnetic exchange interactions between the Cr^{III} and the M^{II} ions via the oxalate bridge. For the Fe^{II}, Co^{II} and Ni^{II} derivatives, the values of the products $\chi_m T$ reach maxima at approx. 3, 7 and 11 K, respectively and decrease below these temperatures. This feature is not observed in the Cr_2Mn derivative, with which no maximum is reached above 2 K. It is important to note that for the Ni^{II} derivative the increase in the value of $\chi_m T$ starts at higher temperatures and is more pronounced than for the other three derivatives, which suggests that the strongest ferromagnetic interaction occurs between the Cr^{III} and Ni^{II} ions. In all cases, the decrease in the value of the product $\chi_m T$ at very low temperature suggests the presence of a zero-field splitting of the metal ions and/or a predominant inter-trimer antiferromagnetic exchange interaction.

In the Cu^{II} and Zn^{II} derivatives of the Cr_2M series, the values of the products $\chi_m T$ at room temperature also show the Curie constants corresponding to magnetically diluted Cr−M−Cr trimers. In the Cu^{II} derivative, the value of the product $\chi_m T$, which is almost constant down to approx. 150 K, decreases smoothly below this temperature and then shows a sharper decrease below 40 K. The smooth decrease below 150 K suggests the presence of antiferromagnetic exchange interactions between the Cr^{III} and the Cu^{II} ions via the oxalate bridge, and the sharper decrease at lower temperatures indicates the presence of an extra contribution (zero-field splitting of the metal ions and/or inter-trimer antiferromagnetic exchange interactions). In the Cr_2Zn derivative, the value of the product $\chi_m T$ remains constant down to approx. 10 K, suggesting the typical paramagnetic behavior; below this temperature, a sharp decrease is observed.

The existence of antiferromagnetic exchange interactions between the Cr^{III} and the Cu^{II} ions via the oxalate bridge is surprising since a ferromagnetic coupling is expected for this pair. A possible reason is the existence of a different coordination geometry around the Cu^{II} ion, giving rise to a different structure, as indicated by the X-ray powder pattern (which is somewhat different to those of all the other members of both series). Thus, if we assume a quadrangular pyramidal structure, with the oxalate groups in the basal plane and a water molecule in the axial position, it is expected that the Cu^{II} ion should lie above the oxalate plane (as is usually found for this geometry), leading to a π-type interaction between the magnetic orbitals of the Cu^{II} ion and those of the oxalate group (see below) and, thus, to an antiferromagnetic coupling between both ions via the oxalate bridge. This idea is supported by EPR spectra (see below). It is also possible that there exists a 4 + 2 coordination, resulting from a shortening of the axial $Cu-O_w$ bond lengths and an elongation of two opposite equatorial $Cu-O_{ox}$ bonds, as a consequence of the pseudo-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Jahn−Teller effect. This tetragonal distortion has already been observed in similar oxalate-bridged Cr−Cu−Cr trimers, which also present antiferromagnetic exchange interactions.[29] The Zn^{II} derivative behaves as a paramagnet because the diamagnetism of the Zn^{II} ion isolates the Cr^{III} ions, giving rise to a temperature-independent magnetic moment. The sharp decrease at very low temperatures indicates the antiferromagnetic inter-trimer exchange interactions that have already been mentioned, which, at least in this case, must be due to the coupling between Cr^{III} ions of neighboring trimers.

The isothermal magnetization of this series at 2 K confirms the ferromagnetic nature of the $Cr-M^{II}$ coupling and can be reproduced satisfactorily with the Brillouin function for the expected S values, although with g values smaller than those obtained from the susceptibility data. This fact is not surprising because of the presence of antiferromagnetic inter-trimer interactions and/or zero-field splitting of the ions, which are effective at low temperatures.

(b) The Fe_2M Series

The magnetic behavior of the Fe_2M series is similar to that of the Cu^{II} derivative of the Cr_2M family; all members show the Curie constant at room temperature corresponding to magnetically diluted Fe−M−Fe trimers (S = 5/2 for Fe^{III} and S = 5/2, 2, 3/2, 1 and 0 for M = Mn^{II}, Fe^{II}, Co^{II}, Ni^{II} and Zn^{II}, respectively), but when cooling each sample the value of the product $\chi_m T$ smoothly decreases below 200 K (Figure 6). The decrease becomes sharper with decreasing temperature, but at low temperatures they all present a smoothening of the slope and almost reach a plateau. Nevertheless, before the magnetic moment reaches a real plateau, a new and sharper decrease is observed at lower temperatures. This behavior is observed for all the members of the Fe_2M family, except, of course, for the Zn^{II} derivative, and indicates the presence of antiferromagnetic intra-trimer exchange interactions between the Fe^{III} and the M^{II} ions. As a result of this antiferromagnetic interaction, the resulting spin of the $Fe^{III}-M^{II}-Fe^{III}$ trimers must be $2S_{Fe} - S_M$, i.e., S = 5/2, 3, 7/2 and 4 for the Fe_2Mn, Fe_2Fe, Fe_2Co and Fe_2Ni derivatives, respectively. The tendency to reach a plateau at low temperatures confirms that the spin ground state is non-zero. Nevertheless, the presence of antiferromagnetic inter-trimer exchange interactions and/or zero-field splitting of the metal ions precludes the clear observation of the plateau and produces the observed sharp decrease in the value of the product $\chi_m T$ at low temperatures.

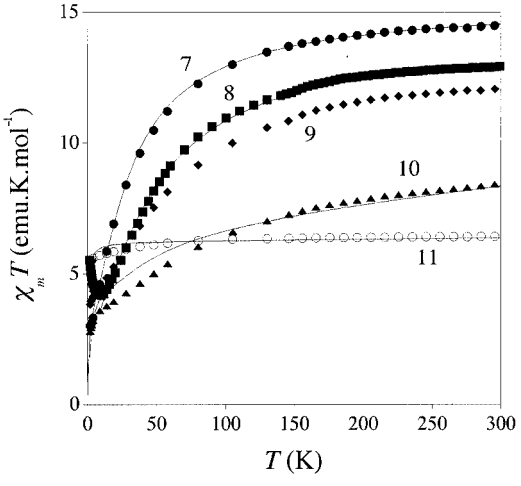

Figure 6. Plot of the value of the product $\chi_m T$ as a function of T for the Fe_2M series; M = Mn (**7**), Fe (**8**), Co (**9**), Ni (**10**) and Zn (**11**); solid lines represent the best fit to the model (see text)

As in the Cr_2M series, the isothermal magnetization of the Fe_2M series at 2 K confirms the antiferromagnetic nature of the $Fe-M^{II}$ coupling and it can be reproduced satisfactorily with the Brillouin function for the expected values of S. The values of g are also smaller than those obtained from the susceptibility data for the same reasons (vide supra).

According to the magnetic behaviors mentioned above, we have fitted the magnetic data of all compounds, except for M^{II} = Co and Zn, to a model of ferro- or antiferromagnetically coupled trimers with one exchange interaction (J) between the M^{III} and M^{II} ions (see Scheme 1).

Scheme 1

The exchange Hamiltonian can be expressed as: $H_{ex} = -2J\ (S_1{*}S_2 + S_2{*}S_3)$, where S_1, S_2 and S_3 are the spin states of the metallic ions of the trimers (see Scheme 1). We have assumed that the exchange integral is the same for both interactions inside the trimer as they are equivalent by symmetry.

By using the Kambé method,[30] we obtained an analytical expression of the energy levels as a function of J for all the spin states of the trimers, where $S^* = S_1 + S_3$ and $S_T = S^* + S_2$.

$$E_i = -J\,[S_T(S_T + 1) - S^*(S^* + 1) - S_2(S_2 + 1)] \quad (1)$$

Finally, the susceptibility is obtained with the Van Vleck equation [Equation (2)].

$$\chi_m T = \left(\frac{N g^2 \mu_B^2}{k_B}\right) \frac{\sum_i a_i \exp\left(\frac{-E_i}{k_B T}\right)}{\sum_i b_i \exp\left(\frac{-E_i}{k_B T}\right)} \quad (2)$$

The values of the coefficients a_i and b_i, as well as the energy E_i, as a function of J, for all the spin states of the trimers Cr_2M (M^{II} = Mn, Fe, Ni and Cu) and Fe_2M (M^{II} = Mn, Fe, Ni and Cu) are listed in the Supporting information.

The applied model reproduces the magnetic behavior of all the studied compounds very well (solid lines in Figures 5 and 6). For the Zn derivatives, in both families the magnetic behaviors correspond to those of isolated Cr^{III} or Fe^{III} ions

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

because of the isolating effect of the diamagnetic central Zn^{II} ion. Nevertheless, both compounds show a decrease in the value of the product $\chi_m T$ that can be reproduced well, modeled with the Curie−Weiss equation law [Equation (3)] using a weak antiferromagnetic inter-trimer interaction.

$$\chi_m = C/(T - \theta) \quad (3)$$

The magnetic parameters obtained with Equations (2) and (3) are displayed in Table 1. The ferromagnetic coupling found in the Cr_2M series is important for two reasons: first, because this ferromagnetic interaction leads to high-spin trimeric clusters comprising a large number of parallel unpaired electrons in the ground state (S = 11/2, 10/2, 9/2 and 8/2 for M^{II} = Mn, Fe, Co and Ni, respectively); second, because it confirms that the exchange interaction is ferromagnetic in oxalate-bridged $Cr^{III}-M^{II}$ systems. In fact, the exchange interactions obtained in our complexes (see Table 1) are in fair agreement with those reported in other oxalate-bridged dinuclear $Cr^{III}-M^{II}$ complexes where J values of 0.5 cm^{-1} (for M^{II} = Mn), 0.8 cm^{-1} (for M^{II} = Fe), 1.3 cm^{-1} (for M^{II} = Co), 2.7, 4.3 and 4.6 cm^{-1} (for M^{II} = Ni) and 2.2, 2.7 and 2.8 cm^{-1} (for M^{II} = Cu) have been reported.[1,31,32] Thus, our complexes provide additional experimental proof of the prediction of Okawa[3b] who suggested that Cr^{III} and M^{II} are ferromagnetically coupled in the 2-D lattice in the family of ferromagnets $Bu_4N[M^{II}Cr^{III}(ox)_3]$, and that the J value may be estimated assuming a linear relationship between the critical temperature and J (mean field approximation).[33] The J values estimated this way are 0.73, 1.76, 1.85, 3.55 and 2.90 cm^{-1} for M^{II} = Mn, Fe, Co, Ni and Cu, respectively, in relatively good agreement with the observed values for the exchange pair interactions in our Cr_2M trimers, except for the Cu derivative where a different structure must be considered.

Table 1. Magnetic parameters obtained with Equations (2) and (3) for the compounds of the series $(TTF)_4\{M^{II}(H_2O)_2[M^{III}(ox)_3]_2\}\cdot nH_2O$ (Cr_2M and Fe_2M series)

Compound	S	g	J [cm^{-1}]
Cr_2Mn (**1**)	11/2	1.917(2)	0.535(7)
Cr_2Fe (**2**)	10/2	1.885(6)	0.650(10)
Cr_2Co (**3**)	9/2	−	> 0
Cr_2Ni (**4**)	8/2	1.840(12)	3.40(3)
Cr_2Cu (**5**)	7/2	1.885(3)	−0.34(2)
Fe_2Mn (**7**)	5/2	2.208(2)	−1.49(7)
Fe_2Fe (**8**)	6/2	2.21(2)	−3.24(4)
Fe_2Co (**9**)	7/2	−	< 0
Fe_2Ni (**10**)	8/2	2.016(12)	−7.74(9)

Both the ferromagnetic coupling in the Cr_2M series and the antiferromagnetic one in the Fe_2M series can be explained easily by considering only the singly occupied molecular orbitals (SOMOs) of the interacting magnetic centers. Thus, the exchange interaction parameter $J_{MM'}$ can be expressed by the average of the individual interactions of the SOMOs (J_{ij}) as $J_{MM'} = (1/n_i n_j)\Sigma(J_{ij})$, where n_i and n_j are the number of unpaired electrons in the i and j SOMOs. Thus, in the Ni derivative of the Cr_2M series, all the possible exchange pathways are ferromagnetic because of orthogonality of the SOMOs of the Cr^{III} ion (of t_{2g} symmetry: d_{xy}, d_{xz} and d_{yx}) and those of the Ni^{II} ion ($d_{x^2-y^2}$ and d_{z^2}), which are all of e_g symmetry. In the other derivatives of the Cr_2M series (M = Co, Fe and Mn) there are SOMOs (of t_{2g} symmetry) that are not orthogonal to those of the Cr^{III} ion and contribute to the total value of $J_{MM'}$ with an antiferromagnetic term. As observed experimentally, this term is always smaller than the ferromagnetic one, since it decreases the value of $J_{MM'}$ for these three derivatives with respect to the Cr_2Ni derivative, maintaining the sign of the interaction.

Finally, in the Cr_2Cu derivative, the existence of the tetragonal distortion mentioned previously implies that the magnetic orbital of the Cu^{II} ion ($d_{x^2-y^2}$) is located in a plane perpendicular to the oxalate bridge and, consequently, it overlaps with the magnetic orbitals of the Cr^{III} ion, giving rise to the antiferromagnetic exchange interaction confirmed by the magnetic measurements. This distortion has been observed already in other oxalate-bridged complex of Cu^{II} and Cr^{III}.[29]

Unfortunately, the TTF entities must be completely ionized, as is deduced from the stoichiometry of four TTF units per $\{M^{II}(H_2O)_2[M^{III}(ox)_3]_2\}^{4-}$ anion, which precludes the existence of delocalized electrons in the organic sublattice, as confirmed by the EPR spectra of all the members of both series (see below) and by the very low electrical dc conductivity shown by the Cr_2Mn derivative ($\sigma = 2 \times 10^{-4}$ $S\cdot cm^{-1}$) and its high activation energy (approx. 200 meV).

The EPR spectra of both Zn derivatives are very similar to those of the precursor $[M^{III}(ox)_3]^{3-}$ anions; they show a single and large signal centered at $g \approx 3.7$ at any temperature from 300 to 4.5 K. The only difference between the Cr and Fe derivatives is the presence of a hyperfine structure in the spectrum of the Cr_2Zn compound because of the weak anisotropy of the Cr^{III} ion that gives rise to a zero-field splitting of the S = 3/2 ground spin state. We see in all the salts of both series a very weak signal at g = 2.0030−2.0060 with a linewidth of 18−22 G whose intensity increases with decreasing temperature. The weak intensity of this signal (two orders of magnitude weaker than the signal from the inorganic lattice) suggests that it corresponds to paramagnetic impurities coming from a small number of isolated TTF^+ radicals resulting from crystalline defects, and not to the localized electron of each TTF molecule, which confirms the results obtained from the static magnetic measurements that suggested that these entities must be strongly antiferromagnetically coupled, as expected from the strongly dimerized arrangement of the organic radicals, and do not contribute significantly to the total magnetic moment.

For the salts of the Cr_2M^{II} series, we can distinguish between those members containing an odd number of unpaired electrons in the inorganic sublattice (M^{II} = Mn, Co and Cu) and those containing an even number of unpaired electrons (M^{II} = Fe and Ni). In the first case, the EPR spectra at low temperatures show a strong signal for the three derivatives coming from the inorganic sublattice to-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gether with the weak signal of the isolated TTF^+ impurities (Figure 7). This last signal is weaker in the case of the Mn derivative, a situation that agrees with the fact that this derivative is the one that gives crystals of better quality. In the second case (M = Fe and Ni), the inorganic sublattice is EPR-silent and only at very low temperatures it is possible to observe a signal very similar to that observed in the Cr_2Zn derivative, which suggests that it may be attributed to a small fraction of isolated $[Cr(ox)_3]^{3-}$ impurities, more abundant in the Fe derivative.

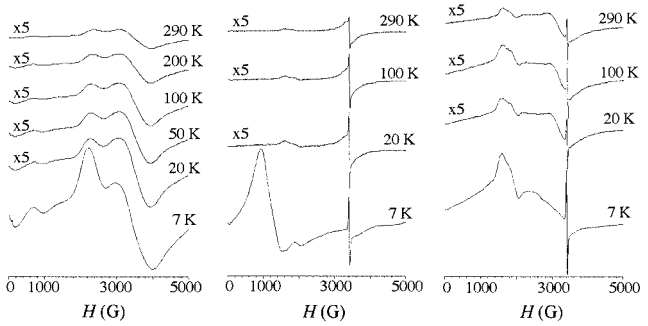

Figure 7. EPR spectra at different temperatures of the Cr_2Mn (**1**) (left), Cr_2Co (**3**) (center) and Cr_2Cu (**5**) (right) compounds

In the Fe_2M^{II} salts, we can also distinguish between the members containing an odd number of unpaired electrons in the trimer (M^{II} = Mn and Co) and those containing an even number of unpaired electrons (M^{II} = Fe and Ni). In this series, the behavior parallels that observed in the Cr_2M series; the Mn and Cu derivatives show, besides the TTF^+ signal, those signals of the anionic sublattice (Figure 8); the Fe and Ni derivatives are EPR-silent and only at very low temperatures do we observe a weak signal, very similar to that observed in the Fe_2Zn derivative, that may be attributed, as for the Cr_2M series, to a small fraction of isolated monomeric $[Fe(ox)_3]^{3-}$ impurities, which are also more abundant in the Fe derivative.

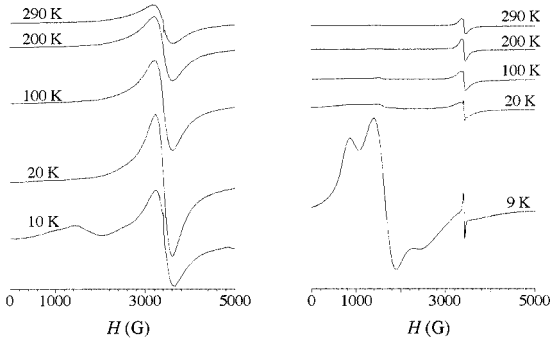

Figure 8. EPR spectra at different temperatures of the Fe_2Mn (**7**) (left) and Fe_2Co (**9**) (right) compounds

All these observations are in good agreement with the electronic structure proposed according to the magnetic measurements performed in these series.

Conclusion

In summary, we have presented a new family of organic/inorganic hybrids formed by trinuclear dimetallic oxalate complexes and TTF molecules that present different interesting properties. Indeed, these are the very first series of compounds that contain in their structure the organic donor TTF unit and dimetallic oxalate complexes.

From a structural point of view, both sublattices show unprecedented packing arrangements. It is the first time that a monodimensional pseudo-κ phase has been reported from orthogonal dimers of TTF molecules, while the inorganic layer is formed by dimetallic trimers formed exclusively by oxalate ligands without the presence of any other organic ligand blocking the possibility of polymerization. In this context, although no magnetic ordering is expected to occur in these kinds of lattices, they provide valuable information on the magnetic interactions between these metal ions, which should help us to understand the behavior of the extended magnetic lattices based on oxalate complexes. The predominant ferromagnetic interaction found in the $Cr^{III}-M^{II}-Cr^{III}$ trimeric clusters is especially remarkable since it stabilizes high-spin ground states (up to 11/2 for $FeCr_2$).

Experimental Section

General Remarks: All chemicals were of reagent grade and were used as purchased. Standard literature procedures were used to prepare the $K_3[M^{III}(ox)_3]\cdot 3H_2O$ (M^{III} = Cr and Fe) complexes.[34] The $(TTF)_3[BF_4]_2$ salt also was prepared according to a literature procedure.[35] Magnetic measurements were obtained using a Quantum Design MPMS-XL-5 SQUID magnetometer from polycrystalline samples held in gelatine capsules inside a plastic tube. The measured susceptibilities were corrected for core diamagnetism by using Pascal constants. All susceptibility measurements were performed at an applied field of 0.1 T on warming the samples from 2 to 300 K. The isothermal magnetization studies were performed at 2 K with applied magnetic fields up to 5 Tesla. EPR spectra for all the samples were performed on polycrystalline samples in quartz tubes from 300 to 4.2 K with a Bruker ER 200D spectrometer at 9.44 GHz equipped with a liquid Helium cryostat. For the Cr_2Mn compound, EPR spectra were recorded with a single crystal at different orientations and in a temperature range from 300 to 4.2 K with a Bruker ESP 300E spectrometer at 9.44 GHz equipped with a liquid helium cryostat. D.C. conductivity measurements were performed by the four-contacts method in two different crystals of the Cr_2Mn derivative because this salt produced the biggest single crystals. The contacts were pasted using silver paint and 10-μm diameter gold wires. The applied current (0.1−5 μA) was generated with a Keithley 224 current source and the potential was measured with a Keithley 199 microvoltimeter. The conductivity was measured on cooling and warming scans and no significant differences were observed. The cooling and warming rates were fixed at 1 K/

min using the cryostat of the SQUID susceptometer (Quantum Design MPMS-XL-5).

$(TTF)_4\{Mn(H_2O)_2[Cr(ox)_3]_2\}\cdot 14H_2O$ (1): Single crystals of compound **1** suitable for X-ray diffraction analysis were obtained by slow diffusion of an aqueous solution (15 mL) of $K_3[Cr(ox)_3]\cdot 3H_2O$ (12 mg, 0.025 mmol) and $MnCl_2\cdot 4H_2O$ (5 mg, 0.025 mmol) into a degassed acetonitrile solution (15 mL) of $(TTF)_3[BF_4]_2$ (10 mg, 0.013 mmol). After 5 d, small shiny black crystals were isolated by filtration, washed with acetonitrile, and air-dried at room temperature. $C_{36}H_{48}Cr_2MnO_{40}S_{16}$ (1792.74): calcd. C 24.12, H 2.70, Cr 5.80, Mn 3.06, S 28.62; found C 24.30, H 2.62, Cr 6.03, Mn 2.78, S 29.21.

$(TTF)_4\{Fe(H_2O)_2[Cr(ox)_3]_2\}\cdot nH_2O$ ($n \approx 4$) (2): $K_3[Cr(ox)_3]\cdot 3H_2O$ (122 mg, 0.25 mmol) was dissolved in distilled water (10 mL). An aqueous solution (10 mL) of $FeSO_4\cdot 7H_2O$ (70 mg, 0.25 mmol) was added at room temperature under argon. A solution of $(TTF)_3[BF_4]_2$ (100 mg, 0.13 mmol) in degassed acetonitrile (30 mL) was added dropwise to this mixture. After a few minutes, shiny black microcrystals were filtered off from this solution, washed with acetonitrile and dried at room temperature. Yield: 102 mg (65%). $C_{36}H_{28}Cr_2FeO_{30}S_{16}$ (1613.50): calcd. C 26.80, H 1.75, Cr 6.45, Fe 3.46, S 31.80; found C 27.48, H 1.56, Cr 6.22, Fe 3.67, S 31.69.

$(TTF)_4\{Co(H_2O)_2[Cr(ox)_3]_2\}\cdot nH_2O$ ($n \approx 8$) (3): Shiny black microcrystals of this compound were prepared as was **2**, but using $Co(NO_3)_2\cdot 6H_2O$ instead of $FeSO_4\cdot 7H_2O$. Yield: 97 mg (59%). $C_{36}H_{36}CoCr_2O_{34}S_{16}$ (1685.64): calcd. C 25.65, H 2.15, Co 3.32, Cr 6.17, S 30.44; found C 25.51, H 2.29, Co 3.40, Cr 6.38, S 30.99.

$(TTF)_4\{Ni(H_2O)_2[Cr(ox)_3]_2\}\cdot nH_2O$ ($n \approx 6$) (4): Shiny black microcrystals of this compound were prepared as was **2**, but using $NiCl_2\cdot 6H_2O$ instead of $FeSO_4\cdot 7H_2O$. Yield: 63 mg (39%). $C_{36}H_{32}Cr_2NiO_{32}S_{16}$ (1652.37): calcd. C 26.17, H 1.95, Cr 6.29, Ni 3.55, S 31.05; found C 26.29, H 1.90, Cr 6.10, Ni 3.48, S 31.09.

$(TTF)_4\{Cu(H_2O)_2[Cr(ox)_3]_2\}\cdot nH_2O$ ($n \approx 3$) (5): Shiny black microcrystals of this compound were prepared as was **2**, but using $CuCl_2\cdot 2H_2O$ instead of $FeSO_4\cdot 7H_2O$. Yield: 59 mg (38%). $C_{36}H_{26}Cr_2CuO_{29}S_{16}$ (1603.18): calcd. C 26.97, H 1.63, Cu 3.96, Cr 6.49, S 32.00; found C 27.02, H 1.69, Cu 3.95, Cr 6.38, S 31.93.

$(TTF)_4\{Zn(H_2O)_2[Cr(ox)_3]_2\}\cdot nH_2O$ ($n \approx 6$) (6): Shiny black microcrystals of this compound were prepared as was **2**, but using $Zn(NO_3)_2\cdot 6H_2O$ instead of $FeSO_4\cdot 7H_2O$. Yield: 68 mg (42%). $C_{36}H_{32}Cr_2O_{32}S_{16}Zn$ (1659.07): calcd. C 26.06, H 1.94, Cr 6.27, S 30.92, Zn 3.94; found C 26.70, H 1.98, Cr 6.30, S 31.12, Zn 3.86.

$(TTF)_4\{Mn(H_2O)_2[Fe(ox)_3]_2\}\cdot nH_2O$ ($n \approx 9$) (7): $K_3[Fe(ox)_3]\cdot 3H_2O$ (124 mg, 0.25 mmol) was dissolved in distilled water (10 mL). An aqueous solution (10 mL) of $MnCl_2\cdot 4H_2O$ (50 mg, 0.25 mmol) was added at room temperature under argon. A solution of $(TTF)_3[BF_4]_2$ (100 mg, 0.13 mmol) in degassed acetonitrile (30 mL) was added dropwise to this mixture. After a few minutes, from this solution shiny black microcrystals were filtered off, washed with acetonitrile and dried at room temperature. Yield: 123 mg (74%). $C_{36}H_{38}Fe_2MnO_{35}S_{16}$ (1710.37): calcd. C 25.28, H 2.24, Fe 6.53, Mn 3.21, S 30.00; found C 25.48, H 2.08, Fe 6.62, Mn 3.12, S 30.45.

$(TTF)_4\{Fe(H_2O)_2[Fe(ox)_3]_2\}\cdot nH_2O$ ($n \approx 5$) (8): Shiny black microcrystals of this compound were prepared as was **7**, but using $FeSO_4\cdot 7H_2O$ instead of $MnCl_2\cdot 4H_2O$. Yield: 109 mg (68%). $C_{36}H_{30}Fe_3O_{31}S_{16}$ (1639.21): calcd. C 26.38, H 1.84, Fe 10.22, S 31.30; found C 26.47, H 1.73, Fe 10.28, S 32.31. Single crystals suitable for X-ray diffraction analysis of **8** were obtained by slow diffusion of an aqueous solution (15 mL) of $K_3[Fe(ox)_3]\cdot 3H_2O$ (12 mg, 0.025 mmol) and $FeSO_4\cdot 7H_2O$ (7 mg, 0.025 mmol) into a degassed acetonitrile solution (15 mL) of $(TTF)_3[BF_4]_2$ (10 mg, 0.013 mmol). After 5 d, small shiny black crystals were isolated by filtration, washed with acetonitrile, and air-dried at room temperature.

$(TTF)_4\{Co(H_2O)_2[Fe(ox)_3]_2\}\cdot nH_2O$ ($n \approx 7$) (9): Shiny black microcrystals of this compound were prepared as was **7**, but using $Co(NO_3)_2\cdot 6H_2O$ instead of $MnCl_2\cdot 4H_2O$. Yield: 87 mg (53%). $C_{36}H_{34}CoFe_2O_{33}S_{16}$ (1675.33): calcd. C 25.81, H 2.05, Co 3.34, Fe 6.67, S 30.62; found C 26.00, H 1.97, Co 3.29, Fe 6.58, S 31.01.

$(TTF)_4\{Ni(H_2O)_2[Fe(ox)_3]_2\}\cdot nH_2O$ ($n \approx 9$) (10): Shiny black microcrystals of this compound were prepared as was **7**, but using $NiCl_2\cdot 6H_2O$ instead of $MnCl_2\cdot 4H_2O$. Yield: 59 mg (35%). $C_{36}H_{38}Fe_2NiO_{35}S_{16}$ (1714.12): calcd. C 25.23, H 2.23, Fe 6.52, Ni 3.42, S 29.93; found C 25.28, H 2.15, Fe 6.56, Ni 3.19, S 30.22.

$(TTF)_4\{Zn(H_2O)_2[Fe(ox)_3]_2\}\cdot nH_2O$ ($n \approx 7$) (11): Black shiny microcrystals of this compound were prepared as was **7**, but using $Zn(NO_3)_2\cdot 6H_2O$ instead of $MnCl_2\cdot 4H_2O$. Yield: 62 mg (38%). $C_{36}H_{34}Fe_2O_{33}S_{16}Zn$: (1684.79): calcd. C 25.66, H 2.03, Fe 6.63, S 30.45, Zn 3.88; found C 26.02, H 1.93, Fe 6.63, S 30.64, Zn 3.69.

X-ray Crystallographic Study: The crystal structure analysis was performed on a shiny black prismatic single crystal of the Cr_2Mn compound of approximate dimensions 0.15 × 0.10 × 0.20 mm. Relevant crystallographic data and structure determination parameters for the Cr_2Mn compound are given in Table 2. Cell parameters were obtained by the least-squares refinement method with 25 reflections. Intensity data were measured at room temperature with an Enraf−Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation with the ω-2θ method. The structure was solved by direct methods using the SIR97 program,[36] followed by Fourier synthesis and refined on F^2, for all but 348 reflections with very negative F^2 or flagged for potential systematic errors, using the SHELXL-93 program (G. M. Sheldrick, University of Göttingen). The atoms of the TTF unit do not have two components with different occupation factors. Refinement of the TTF molecules was carried out with a constraint-restraint model, restraining displacement components along the bond directions and each TTF molecule in one different refinement cycle. All non-hydrogen atoms were refined anisotropically except for the oxygen atoms of three water molecules (O26, O27 and O28) that were disordered and assigned site-occupation factors of 0.68 and refined

isotropically, giving $R(F) = 0.076$ and $R^2(F) = 0.212$ by using 2187 observed reflections with $I \geq 3\sigma(I)$. CCDC-182551 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]. The X-ray powder diffraction patterns were recorded with a Siemens D-500 powder diffractometer (Cu-K_α) in the 2Θ range of 2−60° (with steps of 0.02°, and a measuring time of 15 s). Experimental unit cells were obtained by indexation of the reflections in a monoclinic space group with the CELSIZ program (Unit Cell Refinement v1.1, XRDUtilities). Unit cell parameters are summarized in the Supporting information, see also the footnote on the first page of this article.

Synthesis of Oxalato-Bridged (Oxo)vanadium(IV) Dimers Using L-Ascorbic Acid as Oxalate Precursor: Structure and Magnetism of Two Systems

Bharat Baruah,[a] Vladimir O. Golub,[b] Charles J. O'Connor,[b] and Animesh Chakravorty*[a,c]

Keywords: Vanadium / Bridging ligands / Magnetic properties

The reaction of an aqueous solution of NH_4VO_3 with L-ascorbic acid and Et_4NBr has afforded $[Et_4N]_2[(VO)_2(C_2O_4)_3(H_2O)_2]\cdot 4H_2O$ (**3**). A similar reaction, in which malonic acid is also added, has furnished $[Et_4N]_2[(VO)_2(C_2O_4)(C_3H_2O_4)_2(H_2O)_2]\cdot 2H_2O$ (**4**). In these syntheses the oxalate ion is derived from L-ascorbic acid. In both the complexes the dinuclear anion is centrosymmetric. In **3** the metal atoms are displaced from the plane of the bridging oxalate anion by 0.05 Å, the corresponding displacement in **4** being 0.17 Å. The terminal oxalato chelate ring in **3** is roughly planar but the malonato chelate ring in **4** has a distorted boat conformation. The V−O distances in **4** are systematically shorter than the corresponding distances in **3** by 0.02−0.06 Å. The V···V distance within the dimer is 5.616(2) Å in **3** and 5.529(2) Å in **4**. The two uncoordinated water molecules in the asymmetric unit of **3** constitute a hydrogen-bonded dimer and the lattice consists of a supramolecular anionic assembly held by five different types of O···O hydrogen bonds. The anionic assembly in **4** involves three types of O···O hydrogen bonds. The Et_4N^+ cations reside between the anionic layers. The magnetic susceptibility data of both **3** and **4** fit excellently with the Heisenberg dimer model in the temperature interval 2−300 K. The species are antiferromagnetic and the *J* values are $-6.50\ cm^{-1}$ for **3** and $-6.25\ cm^{-1}$ for **4**. The two opposing factors — V−O(bridge) bond length and the displacement of the metal atom from the oxalate plane — appear to have more or less balanced each other resulting in virtually equal *J* values for the two complexes.

Introduction

There is a long-standing chemical interest in the interaction of metal ions with L-ascorbic acid.[1] Very few authentic metal ascorbates have, however, been isolated and characterized.[1−4] Our familiarity[5−8] with vanadate esters of polyols prompted us to scrutinize the use of L-ascorbic acid as a possible diol ligand towards vanadium. We have not succeeded in isolating vanadate esters of L-ascorbic acid but the study has furnished a new route for the synthesis of oxalato-bridged (oxo)vanadium dimers incorporating the moiety **1**. The structure and magnetism of two representative species are reported in the present work.

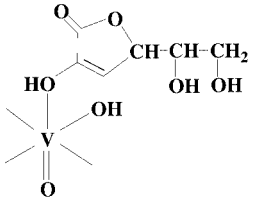
Results and Discussion

Synthesis

A rate study on the reaction of aqueous (oxo)vanadium(V) with L-ascorbic acid in strongly acidic media had suggested that a transient ascorbate complex is formed but it undergoes rapid redox transformation to (oxo)vanadium(IV) and dehydroascorbic acid.[9] In view of our diol work[5−8] the transient complex may have the bonding mode **2**.



2

We have also failed to isolate a stable vanadium complex of L-ascorbic acid by the reaction of vanadium salts with L-ascorbic acid under different conditions of stoichiometry, pH and temperature. On the other hand, treatment of an aqueous solution of ammonium metavanadate with L-ascorbic acid and Et_4NBr in the ratio 1:1.5:1 at 70 °C gave a dark-green solution from which blue crystals of **3** slowly

deposited in excellent yields. The mixed oxalato-malonato complex **4** was obtained by a similar procedure from ammonium metavanadate, L-ascorbic acid, malonic acid and Et_4NBr in the ratio 1:0.5:1:1.

$[Et_4N]_2[(VO)_2(C_2O_4)_3(H_2O)_2]\cdot 4H_2O$ (**3**)

$[Et_4N]_2[(VO)_2(C_2O_4)(C_3H_2O_4)_2(H_2O)_2]\cdot 2H_2O$ (**4**)

In the above syntheses, the oxalate ion is derived by oxidative/hydrolytic degradation [10−12] of L-ascorbic acid. As an in situ precursor of oxalic acid, L-ascorbic acid has recently found a use in the synthesis of oxalate complexes of metal ions;[13−15] we report here the first examples in the case of vanadium. Both **3** and **4** reported here are new compounds, although a few analogues of **3** synthesized from oxalic acid/oxalate are known.[16−18] Mononuclear oxalato chelates of (oxo)vanadium(IV) have been known for a long time.[19]

Characterization data are given in the Exp. Sect. The complexes display a V=O stretch near 980 cm^{-1} and multiple carboxylate vibrations in the region 800−1720 cm^{-1}. In aqueous solutions three ligand-field transitions occur in the visible region. Details are given in the Exp. Sect.

Structure

In both the complexes the dinuclear anion is centrosymmetric, the centre of inversion lying on the C−C bond of the bridging oxalato moiety. The asymmetric unit in each case corresponds to half the molecular formula. In **3** the Et_4N^+ cations lie in general positions while in **4** they lie on twofold axes passing through the nitrogen atoms. Views of the anions of **3** and **4** are shown in Figures 1 and 2, respectively. Selected bond parameters are listed in Table 1.

In **3** the $OV(C_2O_4)VO$ fragment defines a good plane of mean deviation 0.01 Å. In **4** the fragment is not quite planar (mean deviation 0.04 Å), the vanadium atoms being displaced by 0.17 Å above and below the nearly perfect plane of the oxalate anion (the corresponding displacement in **3** is only 0.05 Å). In **3** the terminal oxalato chelate rings are roughly planar (mean deviation 0.05 Å), the dihedral angle between them being 106.7°. In the $V(C_3H_2O_4)$ fragment of

4 the malonato chelate ring has a distorted boat shape (inset in Figure 2) in which the V and C4 atoms are displaced by 0.4 Å in the same direction from the plane of the O4, O5, C2, C3 atoms.

In the distorted octahedral VO_6 coordination spheres, the V−O(1) (oxo) and V−O(3) (*trans* to oxo) distances are shorter and longer, respectively, than the other distances in both **3** and **4**. The V−O distances in **4** are systematically shorter than the corresponding distances in **3** by 0.02−0.06

Å. The V···V distances within the dimer are 5.616(2) Å in **3** and 5.529(2) Å in **4**.

Hydrogen Bonding

The two uncoordinated water molecules (lattice water) in the asymmetric unit of **3** form a strongly hydrogen-bonded dimer, the O···O distance being 2.619(3) Å. The dimer is also involved in additional hydrogen bonding with coordinated and uncoordinated oxalato oxygen atoms and with the coordinated water molecule, which, in turn, is hydrogen-bonded to an uncoordinated oxalate oxygen atom. The lattice thus consists of a supramolecular anionic assembly held together by five different types of O···O hydrogen bonds (Table 2) as illustrated in Figure 3. The Et_4N^+ cations reside in between the anionic layers.

Table 2. Hydrogen bond lengths [Å] in **3** and **4**

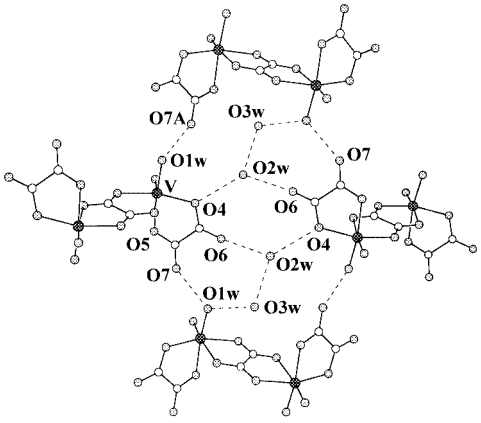

Figure 3. Hydrogen bonding in crystals of **3**

In the asymmetric unit of **4** there is only one lattice water, which is hydrogen-bonded to the coordinated water molecule and to an uncoordinated malonate oxygen atom. The coordinated water molecule is also hydrogen-bonded to an uncoordinated malonate oxygen atom. These three types of O···O hydrogen bonds generate the anionic assembly in the lattice of **4** (Figure 4, Table 2).

Magnetism

Magnetic data for **3** and **4** have been collected in the temperature range 2−300 K. Near perfect fits with the Heisenberg dimer model are attainable (Figures 5 and 6) using the parameters listed in Table 3. In both cases a susceptibility maximum occurs near 8 K and the compounds exhibit Curie−Weiss paramagnetism at high temperatures ($T >$ 50 K). The compounds are thus weakly antiferromagnetic and both the J values lie close to -6 cm^{-1}. The quality of

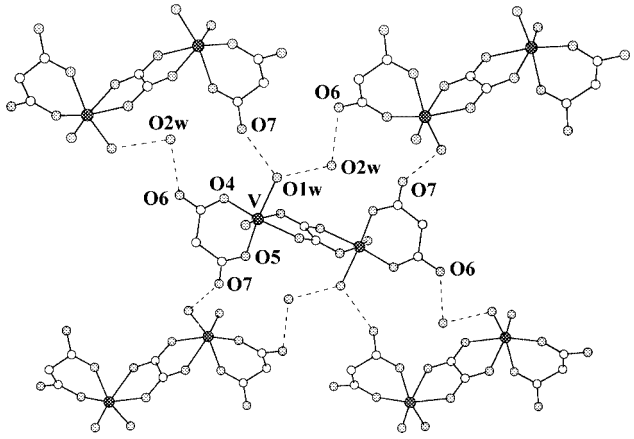

Figure 4. Hydrogen bonding in crystals of **4**

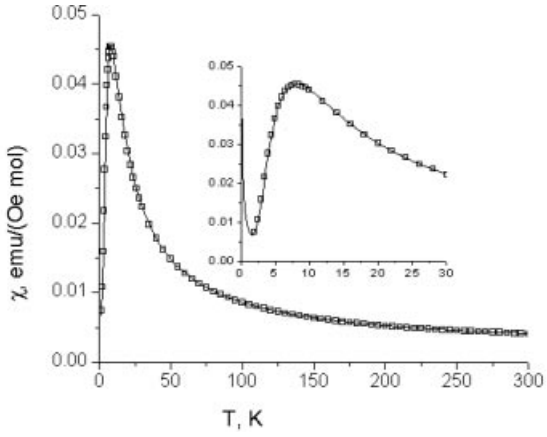

Figure 5. Variable-temperature magnetic susceptibility data of **3**; the solid line represents best fit to the dimer model

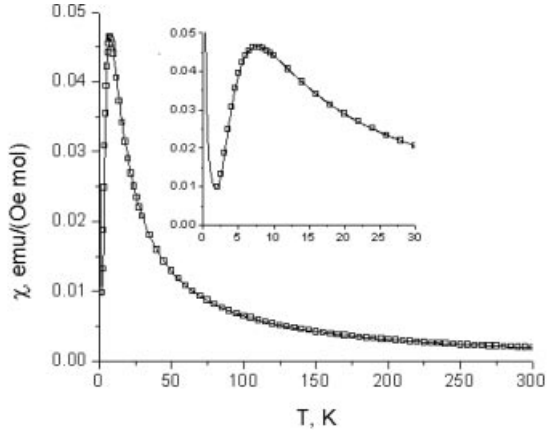

Figure 6. Variable-temperature magnetic susceptibility data of **4**; the solid line represents best fit to the dimer model

Table 3. Best-fit magnetic parameters

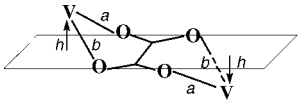
Compound	*g*	*J*	ρ	*tip*
3	1.93 ± 0.01	−6.50 ± 0.05	0.01 ± 0.002	0.0018 ± 0.00005
4	1.95 ± 0.01	−6.25 ± 0.05	0.02 ± 0.002	−0.0004 ± 0.00005

the fit to the dimer model indicates that, in spite of the extensive hydrogen bonding in the lattice, the interdimer magnetic interactions, if any, are small. Consistent[20] with the weak antiferromagnetism, polycrystalline samples of each compound display a virtually isotropic EPR signal at 77 K (**3**: $g = 1.969$; **4**: $g = 1.963$). No zero-field splitting or half-field signals are observed.

The (oxo)vanadium(IV) (d^1) magnetic orbital overlaps with the bridging oxygen orbitals only in the π-fashion as idealized in **5**. The resulting magnetic coupling in the dimer is expected to be relatively weak.[20] Compounds **3** and **4** provide a unique opportunity for qualitatively scrutinizing the effect of certain bond parameters (*a*, *b* and *h* as shown in **6**) on the strength of magnetic coupling.

5

The shorter V−O (bridge) lengths ($a = 2.009$ Å, $b = 2.218$ Å) in **4** compared to those ($a = 2.023$ Å, $b = 2.281$ Å) in **3** may be expected to result in a stronger exchange coupling in **4**. On the other hand, the metal atom is much more displaced from the plane of the bridging oxalate in **4** (0.17 Å) than in **3** (0.05 Å) and this is expected to diminish the exchange interaction in **4**. The two opposing factors appear to have more or less balanced each other and the net bridge-mediated coupling of the magnetic orbitals in the two compounds are virtually equal.



6

The present systems are somewhat stronger antiferromagnets than the two other structurally characterized compounds incorporating **1**: $[Ph_4P]_2[(VO)_2(C_2O_4)_3(H_2O)_2]\cdot 4H_2O$[17] ($J = -4.35$ cm^{-1}) and $[(VO)_2(C_2O_4)(H_2O)_6]Cl_2\cdot Bu_4NCl\cdot H_2O$[21] ($J = -3.85$ cm^{-1}). In $[(VO)_2(C_2O_4)(acac)_2(H_2O)_2]$[20] the value of J is -5.75 cm^{-1}, but its structure has not been determined.

Conclusion

Two oxalato-bridged (oxo)vanadium(IV) dimers **3** and **4** have been successfully assembled using L-ascorbic acid as an oxalate precursor. Structure determination has revealed significant differences in bond parameters of the $V(C_2O_4)V$ fragment in **3** and **4**. The V−O bond lengths follow the order **3** > **4** and the displacement of the metal atom from the bridging oxalate plane has the reverse order **4** > **3**. These inequalities act in opposite directions and the net antiferromagnetic coupling of the magnetic orbitals of the metal sites become virtually equal for **3** and **4** ($-J$ 6 cm^{-1}). Extensive hydrogen bonding is present in the lattice of both **3** and **4** but interdimer magnetic interactions are negligible.

Experimental Section

General: Ammonium metavanadate, L-ascorbic acid, malonic acid and tetraethylammonium bromide were obtained from S. D. Fine-Chem Ltd. All other chemicals and solvents were of analytical grade and were used as received. IR (KBr disk): Nicolet Magna IR 750 Series II spectrometer. UV/Vis: Shimadzu UVPC 1601 spectrometer. A Perkin−Elmer 2400 elemental analyzer was used for microanalysis (C,H,N).

$[Et_4N]_2[(VO)_2(C_2O_4)_3(H_2O)_2]\cdot 4H_2O$ (3): L-Ascorbic acid (0.113 g, 0.64 mmol) and tetraethylammonium bromide (0.09 g, 0.43 mmol) were added to a hot aqueous solution (20 mL) of NH_4VO_3 (0.05 g, 0.43 mmol). The solution was then stirred at 70 °C for 1 h. The dark-green solution thus obtained was further stirred at room temperature for 4 h and then left undisturbed exposed to air. After two weeks blue crystals were collected, washed with ethanol and air-dried. Yield: 0.28 g (84%). $C_{22}H_{52}N_2O_{20}V_2$ (766.5): calcd. C 34.47, H 6.84, N 3.66; found C 34.41, H 6.76, N 3.58. IR (KBr): $\tilde{\nu}$ = 984 (s, V=O), 1715, 1698 (s, C=O), 1658 (s, C=O), 1398, 1256 (s, C=O), 810 (m, O−C=O) cm^{-1}. UV/Vis (H_2O): λ_{max} (ε) = 595 sh (22), 783 (58), 960 sh nm (16 M^{-1}cm^{-1}).

$[Et_4N]_2[(VO)_2(C_2O_4)(C_3H_2O_4)_2(H_2O)_2]\cdot 2H_2O$ (4): L-Ascorbic acid (0.038 g, 0.22 mmol), malonic acid (0.045 g, 0.43 mmol) and tetraethylammonium bromide (0.09 g, 0.43 mmol) were added to a hot aqueous solution (20 mL) of NH_4VO_3 (0.05 g, 0.43 mmol). The blue solution thus obtained was treated as in the preparation of **3** furnishing blue crystals of **4**. Yield: 0.29 g (91%). $C_{24}H_{52}N_2O_{18}V_2$ (758.6): calcd. C 38.00, H 6.91, N 3.69; found C 37.91, H 6.96, N 3.56. IR (KBr): $\tilde{\nu}$: 975 (s, V=O), 1678, 1653 (s, C=O), 1589 (s, C=O), 1411, 1310 (s, C=O), 809 (m, O−C=O) cm^{-1}. UV/Vis (H_2O): λ_{max} (ε) =585 sh (19), 786 (65), 960 sh nm (13 M^{-1}cm^{-1}).

Crystal Structure Determination: Single crystals of complexes **3** and **4** were grown by slow evaporation of water from their aqueous solutions. Data were collected with a Nicolet R3m/V four-circle diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$Å) by the ω-scan technique in the range $3° \le 2\theta \le 47°$ for **3** and $3° \le 2\theta \le 50°$ for **4**. All data were corrected for Lorentz polarization, and an empirical absorption correction[22] was performed on each set of data on the basis of azimuthal scans

of six reflections. All calculations of data reduction, structure solution, and refinement were done with the programs of SHELXTL, Version 5.03.[23] The two structures were solved by direct methods and were refined by full-matrix least squares on F^2. All non-hydrogen atoms were refined anisotropically. All the hydrogen atoms in both the structures were included in calculated positions. Significant crystal data are listed in Table 4. CCDC-200295 (**3**) and -200296 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Magnetic Measurements: Magnetic data of polycrystalline samples (H = 1000 Oe) were recorded on 23.64 mg of **3** and 39.50 mg of **4** in the 2−300 K temperature range using a Quantum Design MPMS-5S SQUID Spectrometer. Calibration and operation procedures have been reported elsewhere.[24] The data were fitted to the Heisenberg dimer model of two S = 1/2 spins [Equation (1)] taking into account the presence of monomeric paramagnetic impurities (second term) and temperature-independent magnetism (third term), where χ is the magnetic susceptibility, T the temperature, g the g factor, J the exchange constant, *tip* is the temperature-independent contribution. The best-fit parameters are given in Table 3.

$$\chi = (1-\rho)\frac{N_A g^2 \mu_B{}^2}{k_B T}\,\frac{2\exp(\frac{2J}{k_B T})}{1+3\exp(\frac{2J}{k_B T})} + \rho\frac{N_A g^2 \mu_B{}^2}{2k_B T} + tip \qquad (1)$$

The X-band EPR spectra of polycrystalline samples were measured with a Varian E-109C spectrometer fitted with a liquid nitrogen Dewar vessel using the following settings: sweep width 5000G, power 30dB, modulation 100 kHz, sweep center 3200 G, sweep time 240 s.

Synthesis and Characterization of Mononuclear Amidogold(III) Complexes − Crystal Structure of $[Au(N_2C_{10}H_7(CMe_2C_6H_4)\text{-}6](NHC_6H_3Me_2\text{-}2,6)][PF_6]$ − Oxidation of 4-Methylaniline to Azotoluene

Maria Agostina Cinellu,*[a] Giovanni Minghetti,[a] Maria Vittoria Pinna,[a] Sergio Stoccoro,[a] Antonio Zucca,[a] and Mario Manassero[b]

Keywords: Gold / Nitrogen ligands / Metallacycles / Amido complexes / Amine oxidation

Mononuclear amidogold(III) complexes $[Au(C,N,N)(NRR')][PF_6]$ [C,N,N = $N_2C_{10}H_7(CMe_2C_6H_4)$-6, where $N_2C_{10}H_8$ = 2,2′-bipy; R = H, R′ = *p*-tolyl (**5**), *o*-xylyl (**6**), isobutyl (**7**), *sec*-butyl (**8**), R = R′ = Et (**9**)], $[Au(C,N)(AcO)(NHC_6H_4NO_2\text{-}4)]$ (**10**) [C,N = $NC_5H_4(CH_2C_6H_4)$-2, where NC_5H_5 = py] and $[Au(N,N)(NHC_6H_4NO_2\text{-}4)_2][PF_6]$ (**11**) (N,N = 2,2′-bipy), have been synthesized in fairly good yields by reaction of the hydroxo, methoxo, or acetato complexes **1**–**4** {$[Au(C,N,N)(OR)][PF_6]$ [R = H (**1**), Me (**2**)], $[Au(C,N)(AcO)_2]$ (**3**), $[Au(N,N)(OH)_2][PF_6]$ (**4**)} with amines. The structure of $[Au(C,N,N)(NHC_6H_3Me_2\text{-}2,6)][PF_6]$ (**6**) has been determined by X-ray diffraction. Reaction of the hydroxo complex **4** with $NH_2C_6H_4Me$-4 gives metallic gold, the protonated ligand $[N,NH][PF_6]$ and organic products, the main one being azotoluene.

Introduction

Amido complexes of late transition metals have attracted considerable interest[1] because of their involvement as intermediates in metal-catalyzed carbon−nitrogen bond-formation processes.[2] Isolation of such intermediates is often hampered by their high reactivity. Nevertheless several stable late transition metal amides have been synthesized and their structures in the solid state as well as their reactivity investigated.[3] While gold(III) (a d^8 metal ion) complexes with ammonia,[4] bidentate,[5] and terdentate[6] amines, and related amido complexes have been widely studied, mainly from a kinetic point of view, isolated complexes with simple amide ligands[7] are still scarcely represented.[8] This shortage of data[9] and a report on the intramolecular hydroamination of alkynes catalyzed by gold(III) salts[10] prompted us to investigate the reactivity of some gold(III) complexes with various amines.

Previously, we have described the synthesis, characterization, and reactivity of gold(III) cyclometallated derivatives $[Au(C,N,N)(Y)][PF_6]$ (C,N,N = 6-benzyl-2,2′-bipyridine) with various anionic ligands Y.[11] Among these, two stable amido complexes, $[Au(C,N,N)(NHC_6H_4NO_2\text{-}4)][PF_6]$ [C,N,N = $N_2C_{10}H_7(CHMeC_6H_4)$-6 and $N_2C_{10}H_7(CMe_2C_6H_4)$-6], could be obtained by σ-ligand metathesis of the corresponding methoxo complexes with *p*-nitroaniline.

Our study on amidogold(III) complexes has been extended to different amines and to different co-ligands to verify the effectiveness of the synthetic method and the influence of the ancillary ligand on the reactivity of the amidogold(III) complex. Here we show that a number of amidogold(III) complexes can be isolated with different co-ligands. The terdentate C,N,N ligand arising from 6-(1,1-dimethylbenzyl)-2,2′-bipyridine is the most effective in stabilizing different amido complexes, whereas the bidentate C,N and N,N ligands (deprotonated 2-benzylpyridine and 2,2′-bipyridine, respectively) could stabilize only the *p*-nitroanilide derivative. The gold complex $[Au(N,N)(OH)_2][PF_6]$[12] (**4**) can promote the oxidation of amines other than *p*-nitroaniline. With *p*-toluidine the main product is azotoluene.

The selective oxidation of aromatic amines under mild conditions is of current interest, as pointed out in a recent paper relevant to oxidation processes catalysed by an iron(III) complex.[13]

Results and Discussion

During previous studies on gold(III) chemistry we had found that several complexes, $[Au(C,N,N)Y]^+$, containing both gold−carbon and gold−heteroatom bonds are accessible by treatment of acetato, hydroxo, and methoxo com-

plexes with protic reagents at room temperature.[11] In particular, besides alkoxo, thiolato, and acetylide complexes, two stable gold amides have been synthesized by an exchange reaction of *p*-nitroaniline with [Au(C,N,N)(OMe)][PF_6] [C,N,N = $N_2C_{10}H_7(CHMeC_6H_4)$-6 and $N_2C_{10}H_7(CMe_2C_6H_4)$-6] in dichloromethane.[11]

New amidogold(III) complexes with three different ancillary ligands, all containing nitrogen donor atoms, have been obtained by the addition of different amines to hydroxo, methoxo, or acetato complexes under mild conditions that required excess amine to drive the equilibrium reaction to completion. The nature of the ancillary ligand dramatically affects the outcome of the reaction: with the terdentate cyclometallated ligand $N_2C_{10}H_7(CMe_2C_6H_4)$-6 both alkyl- and arylamides are obtained in fairly good yields (Scheme 1), whereas with the bidentate C,N ligand $NC_5H_4(CH_2C_6H_4)$-2 and the N,N ligand 2,2′-bipyridine only *p*-nitroanilide complexes have been isolated (Scheme 2). Addition of even large amounts of *p*-nitroaniline to complex **3** gives only substitution of one AcO group. Isolation of stable bis(amido) complexes other than the *p*-nitroaniline derivative, at least for complex **4**, is probably hampered by their high reactivity.

Alkylamido complexes **7**–**9** were obtained simply in a one-pot reaction in high yields, whereas arylamido complexes **5** and **6** required either the use of molecular sieves to trap water or further treatment of the crude mixture with excess amine (see Exp. Sect.). With complex **2** the trend observed suggests that the exchange reaction proceeds, at least in this case, by nucleophilic attack of the amine at the gold centre followed by proton transfer to the coordinated methoxide ligand and elimination of methanol. Reaction of the more basic amine $NHEt_2$ goes to completion within a few hours. For complexes **3** and **4** other mechanisms could be operative: thus, for the neutral complex **3** dissociation of the acetato group *trans* to the carbon atom can be envisaged. Coordination of the amine and successive deprotonation should follow to give the amido species.

Complexes **5**–**11** are air-stable compounds with relatively high melting points and good stability in solution: no decomposition was observed even for amides having β-hydrogen atoms (**7**–**9**). In the FAB mass spectra (positive ions) of compounds **5**, **6**, **8**, **9**, and **11** the molecular ions [M^+] ([M − H], for **8**) have been observed. In the spectrum of the isobutylamido derivative **7** the major peak (100% intensity) corresponds to the species [Au(C,N,N)(NBA − H)], which is probably formed by an exchange reaction of the nitrobenzyl alcohol (NBA) with the amido complex. Peaks corresponding to this species are also found in the mass spectra of the alkylamido complexes **8** and **9**. The neutral complex [Au(C,N)(OAc)($NHC_6H_4NO_2$-4)] (**10**) gives a medium-intensity peak, corresponding to [M − AcO], as is also observed for the starting bis(acetato) complex. Of the two possible geometrical isomers, *trans*-N(am)–Au–N(py) or *trans*-N(am)–Au–C (am = amide; py = pyridine), the IR and NMR spectra, taken together, support a *trans*-N–Au–N arrangement. Indeed the acetato group stretching vibrations are observed at values consistent with an acetato group *trans* to a carbon atom (see Exp. Sect.) and the chemical shift of the H^6 proton at a value similar to that found for the bis(acetato) complex. The high *trans* influence of the deprotonated amine,[6e] with respect to that of the pyridine nitrogen atom, is probably responsible for making thermodynamically stable the isomer with high *trans*-influencing ligands in mutually *cis* positions. Analogous results were found for the reaction of the dichloro complexes [Au(C,N)Cl_2] with excess PPh_3, where only one chloride ion was replaced to give [Au(C,N)(PPh_3)Cl]$^+$, having a *trans*-P–Au–N arrangement [C,N = $C_6H_4CH_2NMe_2$-2,[14a] $NC_5H_4(CRR'C_6H_4)$-2[14b]].

In the IR spectra, weak to medium $\tilde{\nu}$(N–H) absorptions are observed in the range 3200–3336 cm^{-1}. In the ^1H NMR spectra the N*H* resonance could be assigned due to exchange with D_2O. In complexes **5**–**8** the NH resonance is shifted downfield with respect to the free ligand with $\Delta\delta$ = 1.5, 1.5, 2, and 1.6 ppm, respectively. In complexes **7** and **8** H–N–C–H spin–spin coupling, not present in the free amines, is observed. H–N–C–H spin–spin coupling has been reported in amine solutions when either the nitrogen atom is weakly basic or the nitrogen lone pair is coordinated with a Lewis acid.[15] Thus, it appears that substi-

tution of a hydrogen ion with an [Au(C,N,N)] group lowers the basicity of the nitrogen atom of the amine.

Because the NHCHMeEt ligand in complex **8** has a stereogenic carbon atom β to the metal atom, the methylene protons are diastereotopic, giving rise to two sets of multiplets. Also, in complex **9** the two hydrogen atoms on each methylene group of the NEt_2 ligand are diastereotopic: the two signals are very broad at ambient temperature but a well-resolved ABX_3 pattern is observed at −20 °C. As reported previously for other N,N,C aurated derivatives,[11] the six-membered C,N ring is fluxional on the NMR time scale. Thus, one resonance alone is observed for the methyl protons on the benzylic carbon atom of complexes **5**−**9**: no significant variation is observed on lowering the temperature from 20 to −80 °C.

A diffraction study of suitable crystals of complex **6** revealed a structure that consists of $[Au(C,N,N)(NHC_6H_3Me_2\text{-}2,6)]^+$ cations and PF_6^- anions packed in a molar ratio 1:1 with normal van der Waals contacts. An ORTEP view of the cation with the atom labelling scheme is shown in Figure 1. Selected bond lengths and angles are reported in Table 1.

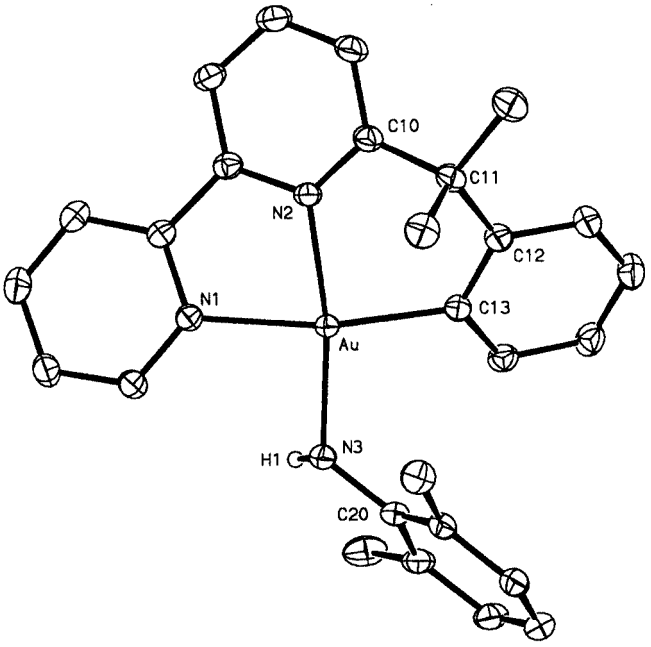

Figure 1. ORTEP view of the cation in compound **6**; ellipsoids are drawn at the 30% probability level

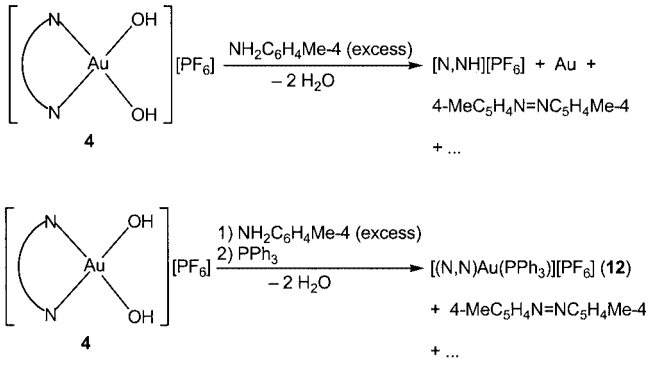
Table 1. Selected bond lengths [Å] and angles [°] with e.s.d.s in parentheses for the complex cation in compound **6**

Au−N(1)	2.128(2)	Au−N(2)	2.056(2)
Au−N(3)	2.015(2)	Au−C(13)	2.018(2)
N(3)−C(20)	1.401(3)	N(3)−H(1)	0.84(3)
N(1)−Au−N(2)	79.1(1)	N(1)−Au−N(3)	90.9(1)
N(1)−Au−C(13)	164.1(1)	N(2)−Au−N(3)	169.4(1)
N(2)−Au−C(13)	91.4(1)	N(3)−Au−C(13)	99.1(1)
Au−N(3)−C(20)	126.1(2)	Au−N(3)−H(1)	99(2)
C(20)−N(3)−H(1)	112(2)		

The gold atom in the cation displays a distorted square-planar coordination, with atoms Au(1), N(2), N(3), and C(13) essentially coplanar [maximum distances from their best plane being +0.005(2) Å for N(3) and −0.011(1) Å for Au], whereas atom N(1) is displaced by 0.484(2) Å out of the best plane. The distortion from the ideal square-planar geometry is probably due to the limited flexibility of the tridentate substituted bipyridine ligand. A similar distortion has been found in $[Au(C,N,N)Cl]^+$, which differs from the present one only in the substitution of the amido ligand with a chloride.[16] Bond lengths and angles in the present cation can be compared with those found in $[Au(C,N,N)Cl]^+$. Thus, the Au−N(1) and Au−C(13) bond lengths [2.128(2) and 2.018(2) Å, respectively] reported here are very similar to those in $[Au(C,N,N)Cl]^+$ [2.121(5) and 2.009(6) Å, respectively]. The slight elongation of the present Au−N(2) distance [2.056(2) Å] with respect to that of $[Au(C,N,N)Cl]^+$ [2.009(4) Å] indicates that the *trans* influence of the amide ligand is stronger than that of the chloride ligand. In the absence of suitable structural data[17] the Au(1)−N(3) bond length [2.015(2) Å] can be compared to the Pt−N distance found in *trans*-$[PtCl(NHC_6H_4I\text{-}4)(PEt_3)_2]$ [2.006(4) Å] and in a number of other (amido)Pt complexes (ref.[3l] and refs. therein). The six-membered metallacycle is in a boat conformation, with atoms N(2), C(10), C(12), and C(13) essentially coplanar, maximum deviations from their best plane being +0.025(2) and −0.025(2) Å for C(12) and C(10), respectively, whereas Au and C(11) lie 0.543(1) and 0.641(2) Å, respectively, above their best plane.

Reaction of complex **3** with amines other than *p*-nitroaniline led to mixtures of unidentified products and a small amount of gold. In contrast, complex **4** was quickly decomposed by the addition of amines and, with *p*-toluidine, it was possible to identify the main reaction products (Scheme 3). In addition to gold, which separated as a dark powder, 2,2′-bipyridine was recovered almost quantitatively (80%) as the salt $[N,NH][PF_6]$. Chromatography on silica gel of the organic fraction allowed us to isolate azotoluene (*trans* isomer) in 43% yield, based on the gold complex.



Scheme 3

The formation of azobenzene, as the main by-product, was observed in the oxidative carbonylation of amines cata-

lyzed by gold complexes, in particular when $HAuCl_4$ was employed in the reaction with aniline.[18] Azobenzene derivatives are also by-products in the $FeCl_2py_4^+$-catalyzed transformation of aromatic amines by H_2O_2,[13] as well as the main products of the ferrate oxidation of anilines, both in homogeneous[19] and in heterogeneous phases.[20] Different reaction mechanisms for the formation of azo compounds in the homogeneous phase have been claimed.[13,19]

In our case a bis(amido) intermediate can be envisaged for the formation of azotoluene. *N*,*N*′-Di-*p*-tolylhydrazine could form by N−N coupling of the bis(amido) complex $[Au(N,N)(NHC_6H_4Me_2\text{-}4)_2][PF_6]$, analogous to **11**, and then be oxidized to azotoluene.[21] This implies an unstable gold(I) intermediate $[Au(N,N)(solv)][PF_6]$ (solv = H_2O, MeCN). In an attempt to trap it, the reaction was carried out in the presence of PPh_3 (Scheme 3). Indeed, a gold(I) intermediate (**12**) was isolated, although not quantitatively, and identified as the known complex $[(N,N)Au(PPh_3)][PF_6]$.[22] The isolobal analogy between the cations $[(N,N)H]^+$ and $[(N,N)Au(PPh_3)]^+$ is notable.

Experimental Section

General: The gold complexes $[Au(C,N,N)Cl][PF_6]$ and $[Au(C,N)Cl_2]$ were obtained according to ref.[11] and ref.[14b], respectively. All the amines were used as received from commercial sources; the solvents were purified and dried according to standard methods. Celite (filter agent) and molecular sieves (4 Å) were purchased from Aldrich, and silica gel (70−230 mesh ASTM) from Merck. Elemental analyses were performed with a Perkin−Elmer Elemental Analyzer 240B by Mr. A. Canu (Dipartimento di Chimica, Università di Sassari). Conductivities were measured with a Philips PW 9505 conductimeter. Infrared spectra were recorded with a Perkin−Elmer 983 spectrophotometer; the values are given in cm^{-1}. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded with a Varian VXR 300 spectrometer operating at 299.9 and 121.4 MHz, respectively. Chemical shifts are given in ppm relative to internal TMS (^1H) or external H_3PO_4 (^{31}P). Mass spectra were obtained with a VG 7070 instrument operating under FAB conditions, with 3-nitrobenzyl alcohol (NBA) as supporting matrix or EI conditions. GC/MS analyses were conducted with a Hewlett-Packard G1800B Gas Chromatograph Electron Ionization Detector (GCD System).

[Au(C,N,N)(OH)][PF$_6$] (1): An aqueous solution of KOH (0.033 g, 0.59 mmol) was added to an aqueous suspension of $[Au(C,N,N)Cl][PF_6]$ (0.179 g, 0.27 mmol). The mixture was heated under reflux for 1 h whilst stirring and then filtered. The volume of the colourless filtrate was reduced in a rotary evaporator until crystallization was observed. The resultant white product was collected by filtration and dried in vacuo. Yield: 0.128 g (75%), m.p. 170 °C. $C_{19}H_{18}AuF_6N_2OP$ (632.32): calcd. C 36.09, H 2.87, N 4.43; found C 35.91, H 2.71, N 4.33. Λ_M ($5\cdot10^{-4}$ mol·dm^{-3}, Me_2CO) = 106 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. IR (Nujol): $\tilde{\nu}$ = 3360 m (broad) (OH), 1599 s, 1561 m, 1082 m, 1025 s, 846 vs (broad) cm^{-1}. ^1H NMR ([D$_6$]acetone): δ = 9.21 (dd, ^3J = 5.4, ^4J = 1.9 Hz, 1 H, H$^{6'}$), 8.92−7.18 (m, 10 H, other aromatics), 4.58 (s, 1 H, OH), 2.11 (s, 6 H, CH_3) ppm. MS (FAB$^+$): *m*/*z* (%) = 487 (100) [M$^+$], 470 (30) [Au(C,N,N)], 393 (10) [M − OH − C_6H_5], 273 (50) [C,N,N].

[Au(C,N,N)(OMe)][PF$_6$] (2): This was prepared according to ref.[11]

[Au(C,N)(AcO)$_2$] (3): Solid AcOAg (0.339 g, 2.03 mmol) was added to a suspension of $[Au(C,N)Cl_2]$ (0.401 g, 0.92 mmol) in acetone (20 mL). The resulting suspension was stirred at room temperature for 8 h and then filtered through Celite. Addition of diethyl ether to the concentrated solution afforded a creamy solid product. Recrystallization from chloroform/diethyl ether gave an analytical sample. Yield: 0.300 g (67%), m.p. 152 °C (dec.). $C_{16}H_{16}AuNO_4$ (483.30): calcd. C 39.76, H 3.34, N 2.90; found C 39.23, H 3.14, N 2.92. IR (Nujol): $\tilde{\nu}$ = 1668 vs and 1627 vs (C=O), 1568 m, 1307 vs and 1278 vs (C−O), 1042 m, 1031 m, 1007 m, 762 s, 704 m, 679 s cm^{-1}. ^1H NMR ($CDCl_3$): δ = 9.02 (d, ^3J = 5.1 Hz, 1 H, H^6), 8.03−7.01 (m, 7 H, other aromatic H), 4.38 (s, 2 H, CH_2), 2.11 (s, 3 H, Me), 2.04 (s, 3 H, Me) ppm. MS (FAB$^+$): *m*/*z* (%) = 533 (20) $[Au(C,N)_2]$, 424 (100) [M − CH_3CO_2].

[Au(N,N)(OH)$_2$][PF$_6$] (4): This was prepared according to ref.[12]

[Au(C,N,N)(NH-*p*-tol)][PF$_6$] (5). Method (a): Solid *p*-toluidine (0.064 g, 0.6 mmol) was added to a solution of **1** (0.126 g, 0.2 mmol) in dichloromethane (20 mL). The resulting red−orange solution was stirred at room temperature for 15 h in the presence of activated molecular sieves. The filtered solution was then concentrated to a small volume and diethyl ether added to give a red−orange solid product. Yield: 0.118 g (82%). **Method (b):** Solid *p*-toluidine (0.042 g, 0.39 mmol) was added to a solution of **2** (0.082 g, 0.13 mmol) in dichloromethane (15 mL). The resulting red−orange solution was stirred for 23 h at room temperature and then concentrated to a small volume. Addition of diethyl ether gave a red−orange precipitate of the equilibrium mixture (^1H NMR criterion) which was treated with excess *p*-toluidine in dichloromethane solution for 24 h to give complete conversion of **2**. Yield: 0.072 g (76%), m.p. 193−194 °C. $C_{26}H_{25}AuF_6N_3P$ (721.46): calcd. C 43.28, H 3.49, N 5.83; found C 42.80, H 3.35, N 5.61. Λ_M ($5\cdot10^{-4}$ mol·dm^{-3}, Me_2CO) = 120 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. IR (Nujol): $\tilde{\nu}$ = 3300 w (NH), 1600 s, 1560 m, 1500 s, 1250 s, 1160 m, 1100 m, 1070 m, 1040 m, 1025 vs, 846 vs (broad), 780 s, 640 w cm^{-1}. ^1H NMR (CD_2Cl_2): δ = 9.24 (dd, ^3J = 5.4, ^4J = 1.0 Hz, 1 H, H$^{6'}$), 8.66−7.06 (m, 10 H, other aromatic H), 6.97 (d, ^3J = 8.4 Hz, 2 H, H^{ortho}), 6.89 (d, ^3J = 8.4 Hz, 2 H, H^{meta}), 5.07 (s, 1 H, NH), 2.23 (s, 3 H, Me), 2.12 (s, 6 H, Me) ppm. MS (FAB$^+$): *m*/*z* (%) = 576 (100) [M$^+$], 470 (45) [Au(C,N,N)], 273 (40) [C,N,N].

[Au(C,N,N)(NH-*o*-xylyl)][PF$_6$] (6): Liquid *o*-xylidine (0.073 g, 0.6 mmol) was added to a solution of **1** (0.126 g, 0.2 mmol) in dichloromethane (20 mL). The resulting dark red solution was stirred at room temperature for 15 h in the presence of activated molecular sieves. The solution was then filtered and concentrated to a small volume and diethyl ether added to give a dark red solid product. Yield: 0.115 g (78%), m.p. 192 °C. $C_{27}H_{27}AuF_6N_3P$ (735.45): calcd. C 44.09, H 3.70, N 5.71%; found C 44.00, H 4.04, N 5.61. Λ_M ($5\cdot10^{-4}$ mol·dm^{-3}, Me_2CO) = 125 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. IR (Nujol): $\tilde{\nu}$ = 3300 w (NH), 1590 s, 1220 s, 1080 m, 1038 s, 1020s, 840 vs (broad), 770 vs, 640 m cm^{-1}. ^1H NMR (CD_2Cl_2): δ = 9.12 (d, ^3J = 5.4 Hz, 1 H, H$^{6'}$), 8.61−6.84 (m, 10 H, other aromatic H), 7.03. (d, ^3J = 7.3 Hz, 2 H, H^{meta}), 6.92 (t, ^3J = 7.3 Hz, 1 H, H^{para}), 5.04 (s, 1 H, NH), 2.31 [s, 6 H, 2 Me (xylydine)], 2.12 [s, 6 H, 2 Me (bipy)] ppm. MS (FAB$^+$): *m*/*z* (%) = 590 (100) [M$^+$], 470 (65) [Au(C,N,N)], 273 (30) [C,N,N]. Crystals suitable for a diffraction study were obtained by slow diffusion of diethyl ether into a dichloromethane solution of **6**.

[Au(C,N,N)(NH-*i*Bu)][PF$_6$] (7): Liquid isobutylamine (0.102 g, 1.4 mmol) was added to a solution of **2** (0.092 g, 0.14 mmol) in dichloromethane (15 mL). The resulting greenish solution was stirred at room temperature for 6 h and then concentrated to a

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

small volume. Addition of diethyl ether gave a greenish-yellow precipitate of the analytical sample. Yield: 0.095 g (97%), m.p. 153 °C. $C_{23}H_{27}AuF_6N_3P$ (687.45): calcd. C 40.18, H 3.96, N 6.11; found C 40.26, H 3.81, N 5.79. Λ_M ($5\cdot10^{-4}$ mol·dm^{-3}, Me_2CO) = 128 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. IR (Nujol): $\tilde{\nu}$ = 3300 w (NH), 1596 s, 1562 m, 1064 m, 1042 s, 850 vs (broad) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 9.25 (dd, ^3J = 5.4, ^4J = 1.0 Hz, 1 H, H$^{6'}$), 8.62−7.32 (m, 10 H, other aromatic H), 3.30 (t, $^3J_{HN-CH}$ = 9.0 Hz, 1 H, NH), 2.98 (dd, $^3J_{H,C-CH}$ = 6.6, $^3J_{H,C-NH}$ = 9.0 Hz, 2 H, CH_2), 2.09 (s, 6 H, Me), 1.96 (m, 1 H, CH), 1.10 (d, ^3J = 6.8, 6 H, Me) ppm. FAB$^+$: *m*/*z* (%) = 622 (100) [Au(C,N,N)(NBA − H)], 470 (35) [Au(C,N,N)], 273 (40) [C,N,N].

[Au(C,N,N)(NH-*s*Bu)][PF$_6$] (8): Liquid *sec*-butylamine (0.102 g, 1.4 mmol) was added to a solution of **2** (0.092 g, 0.14 mmol) in dichloromethane (15 mL). The resulting orange solution was stirred at room temperature for 23 h and then concentrated to a small volume. Addition of diethyl ether gave an orange precipitate of the analytical sample. Yield: 0.086 g (89%), m.p. 150 °C (dec.). $C_{23}H_{27}AuF_6N_3P$ (687.45): calcd. C 40.18, H 3.96, N 6.11; found C 40.06, H 3.72, N 5.83. Λ_M ($5\cdot10^{-4}$ mol·dm^{-3}, Me_2CO) = 126 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. IR (Nujol): $\tilde{\nu}$ = 3280 w (NH), 1590 s, 1520 m, 1080 s, 1040 s, 846 vs (broad) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 9.50 (dd, ^3J = 5.4, ^4J = 1.0 Hz, 1 H, H$^{6'}$), 8.58−7.27 (m, 10 H, other aromatics), 3.35 (d, $^3J_{HN-CH}$ = 4.0 Hz, 1 H, NH), 3.15 (m, 1 H, CH), 2.12 (s, 6 H, Me), 1.79 (m, 1 H, CH_AH$_B$), 1.64 (m, 1 H, CH$_A$$H_B$), 1.35 (d, ^3J = 6.3 Hz, 3 H, CH_3CH), 1.03 (t, ^3J = 7.3, 7.6 Hz, 3 H, CH_3CH$_2$) ppm. MS (FAB$^+$): *m*/*z* (%) = 622 (100) [Au(C,N,N)(NBA − H)], 541 (10) [M − H], 470 (40) [Au(C,N,N)], 273 (75) [C,N,N].

[Au(C,N,N)(NEt$_2$)][PF$_6$] (9): Liquid diethylamine (0.095 g, 1.3 mmol) was added to a solution of **2** (0.083 g, 0.13 mmol) in dichloromethane (15 mL). The resulting red solution was stirred at room temperature for 2 h then concentrated to a small volume. Addition of diethyl ether gave a dark orange precipitate of the analytical sample. Yield 0.086 g (96%), m.p. 160 °C. $C_{23}H_{27}AuF_6N_3P$ (687.45): calcd. C 40.18, H 3.96, N 6.11; found C 39.87, H 3.81, N 5.86. Λ_M ($5\cdot10^{-4}$ mol·dm^{-3}, Me_2CO) = 120 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. IR (Nujol): $\tilde{\nu}$ = 1595 s, 1576 m, 1082 s, 1021 s, 846 vs (broad) cm^{-1}. ^{1}H NMR (CD_2Cl_2, −20 °C): δ = 9.37 (d, ^3J = 4.8 Hz, 1 H, H$^{6'}$), 8.57−7.29 (m, 10 H, other aromatics), 3.04 (m, ^2J = 14.3 Hz, ^3J = 7.0 Hz, 2 H, CH_AH$_B$), 2.62 (m, ^2J = 14.3 Hz, ^3J = 7.0 Hz, 2 H, CH$_A$$H_B$), 2.12 (s, 6 H, Me), 1.24 (t, ^3J = 7.0 Hz, 6 H, CH_3−CH$_2$) ppm. MS (FAB): *m*/*z* (%) = 622 (37) [Au(C,N,N)(NBA − H)], 542 (82) [M$^+$], 470 (90) [Au(C,N,N)], 273 (64) [C,N,N].

[Au(C,N)(OAc)(NHC$_6$H$_4$NO$_2$-4)] (10): Solid *p*-nitroaniline (0.138 g, 1 mmol) was added to a solution of complex **3** (0.120 g, 0.25 mmol) in dichloromethane (20 mL); the resulting yellow solution was then stirred for 24 h at room temperature. During this period the solution turned red−orange. Addition of diethyl ether to the concentrated solution caused precipitation of the equilibrium mixture (^{1}H NMR criterion). The mixture was then subjected to the procedure described above until complete conversion of **3** occurred. Yield: 0.085 g (60%), m.p. 157 °C (dec.). $C_{20}H_{18}AuN_3O_4$ (561.37): calcd. C 42.79, H 3.23, N 7.49; found C 42.68, H 3.15, N 7.27. IR (Nujol): $\tilde{\nu}$ = 3330 m (N−H), 1624 s (C=O), 1583 vs (NO_2), 1299 vs (broad) (C−O) + (NO_2), 1182 s, 1111 vs, 834 m, 753 m cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 8.94 (d, ^3J = 5.6 Hz,1 H, H^6), 8.02−7.01 (m, 7 H, other aromatic H), 7.89 (d, ^3J = 9.3 Hz, 2 H, H^{meta}), 6.65 (d, ^3J = 9.3 Hz, 2 H, H^{ortho}), 4.75 (s, 1 H, NH), 4.38 (s, 2 H, CH_2), 2.00 (s, 3 H, Me) ppm. MS (FAB$^+$): *m*/*z* (%) = 533 (100) [Au(C,N)$_2$], 502 (68) [M − $MeCO_2$], 366 (40) [Au(C,N)].

[Au(N,N)(NHC$_6$H$_4$NO$_2$-4)$_2$][PF$_6$] (11): Solid *p*-nitroaniline (0.341 g, 2.44 mmol) was added to a solution of **4** (0.130 g, 0.24 mmol) in acetone (20 mL); the resulting yellow solution was stirred at room temperature for 53 h. During this period the solution turned deep red. Addition of diethyl ether to the concentrated solution gave a red product, which was washed with methanol to give an analytical sample. Yield: 0.037 g (20%), m.p. 163 °C. $C_{22}H_{18}AuF_6N_6O_4P$ (772.39): calcd. C 34.20, H 2.35, N 10.88; found C 33.98, H 2.22, N 10.45. Λ_M ($5\cdot10^{-4}$ mol·dm^{-3}, Me_2CO) = 120 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. IR (Nujol): $\tilde{\nu}$ = 3336 m (N−H), 1602 s, 1585 vs (NO_2), 1342 vs (broad) (NO_2), 1251 s, 1113 vs, 846 vs (broad) cm^{-1}. ^{1}H NMR ([D$_6$]acetone): δ = 9.35 (d, ^3J = 5.6 Hz, 2 H, H^6), 9.06 (d, ^3J = 7.6 Hz, 2 H, H^3), 8.79 (td, ^3J = 7.8, ^4J = 1.5 Hz, 2 H, H^4), 8.29 (t, ^3J = 7.1 Hz, 2 H, H^5), 7.78 (d, ^3J = 9.0 Hz, 4 H, H^{meta}), 7.10 (d, ^3J = 9.0 Hz, 4 H, H^{ortho}), 6.03 (s, 2 H, NH) ppm. MS (FAB$^+$): *m*/*z* (%) = 627 (20) [M$^+$], 490 (82) [M − NHC$_6$H$_4$NO$_2$-4], 353 [Au(N,N)].

Reaction of [Au(N,N)(OH)$_2$][PF$_6$] (4) with NH$_2$C$_6$H$_4$Me-4: Solid *p*-toluidine (0.098 g, 0.92 mmol) was added to a stirred solution of **4** (0.122 g, 0.23 mmol) in MeCN (20 mL); the resulting solution was stirred for 24 h at room temperature. During this period the solution turned dark red, and separation of a dark powder was observed. After filtration through Celite, the solution was concentrated to a small volume; subsequent addition of diethyl ether afforded a dirty white precipitate that was filtered off and identified as [N,NH][PF$_6$][23] (0.056 g, 80%). The mother liquor was concentrated to dryness to give a dark red solid, which was taken up with benzene and eluted through a column (15 × 1 cm) of silica gel. Removal of the solvent from the first eluate gave an orange crystalline product that was identified as *trans*-azotoluene. Yield: 0.021 g (43.4% with respect to complex **4**), m.p. 140 °C. MS (EI$^+$): *m*/*z* = 211 [MH$^+$], 119 [M − $C_6H_5CH_2$], 92 [C_6H_5Me]. ^{1}H NMR ($CDCl_3$): δ = 7.81 (d, ^3J = 8.1 Hz, 2 H), 7.30 (d, ^3J = 8.1 Hz, 2 H), 2.42 (s, 3 H, Me) ppm.

Reaction of [Au(N,N)(OH)$_2$][PF$_6$] (4) with NH$_2$C$_6$H$_4$Me-4 and PPh$_3$: A solution of PPh_3 (0.131 g, 0.5 mmol) in MeCN was added to a stirred solution of complex **4** (0.266 g, 0.5 mmol) and *p*-toluidine (0.214 g, 2 mmol) in MeCN (20 mL). The reaction mixture was stirred for 24 h at room temperature, filtered through Celite and concentrated to a small volume. Addition of diethyl ether afforded a dirty white product that was recrystallized from dichloromethane/diethyl ether to give an analytical sample, which was identified as [(N,N)Au(PPh_3)][PF$_6$] (**12**) (0.195 g, 51%), m.p. 195 °C (dec.). $C_{28}H_{23}AuF_6N_2P_2$ (760.39): calcd. C 44.22, H 3.05, N 3.68; found C 44.38, H 3.22, N 3.62. ^{1}H NMR (CD_2Cl_2): δ = 8.63 (d, ^3J = 4.1 Hz, 2 H, H^6), 8.33 (d, ^3J = 8.0 Hz, 2 H, H^3), 8.19 (t, ^3J = 7.3 Hz, 2 H, H^4), 7.72 (t, ^3J = 7.6 Hz, 2 H, H^5), 7.67−7.52 [m, 15 H, P(C$_6$$H_5$)$_3$] ppm. ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 31.3 (s, *P*Ph$_3$), −144.06 (sept, J_{P-F} = 711.1 Hz, *P*F$_6$) ppm. The mother liquor, containing organic products, was concentrated to dryness. The residue was then taken up with benzene and eluted through a column (20 × 1 cm) of silica gel. Removal of the solvent from the first eluate gave an orange crystalline product, which was identified as *trans*-azotoluene, yield 0.027 g (25.7%).

X-ray Data Collection and Structure Determination: Crystal data and other experimental details are summarized in Table 2. The diffraction experiment was carried out with a Bruker SMART CCD area-detector diffractometer at 223 K using Mo-K_α radiation (λ = 0.71073 Å) with a graphite crystal monochromator in the incident beam. Cell parameters and orientation matrix were obtained from the least-squares refinement of 141 reflections measured in three different sets of 15 frames each, in the range 3° < θ < 23°. At the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

end of data collection the first 50 frames, containing 325 reflections, were recollected to monitor crystal decay, which was not observed, so that no time-decay correction was needed. The collected frames were processed with the software SAINT,[24a] and an absorption correction was applied (SADABS)[24b] to the 19993 collected reflections, 7461 of which are unique, with R_{int} = 0.0307 ($R_{int} = \Sigma|F_o^2 - F_{mean}^2|/\Sigma F_o^2$). Calculations were performed with a Pentium III PC using the Personal Structure Determination Package,[25] and the physical constants tabulated therein. Scattering factors and anomalous dispersion corrections were taken from ref.[26] The structure was solved by direct methods (SHELXS 86)[27] and refined by full-matrix least squares using all reflections and minimizing the function $\Sigma w(F_o^2 - k|F_c|^2)^2$ (refinement on F^2). Anisotropic thermal factors were refined for all non-hydrogen atoms. The seven hydrogen atoms bonded to N(3) and to the two methyl groups of the 2,6-xylidine ligand were detected in the final Fourier maps and refined with fixed thermal parameters. The other hydrogen atoms were placed in their ideal positions (C−H = 0.97 Å, *B* 1.10 times that of the carbon atom to which they are attached) and not refined. In the final difference Fourier map the maximum residual was 0.96(13) e/Å^3 at 0.70 Å from Au. CCDC-189011 contains the atomic coordinates of the structure model, the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Crystal Engineering with Structurally Flexible 1,1′-Substituted Ferrocenes for Nonlinear Optical Materials

Dong Mok Shin,[a] In Su Lee,*[b] and Young Keun Chung*[a]

Keywords: Crystal engineering / Hydrogen bonds / Nonlinear optics / π-Interactions

Cocrystals derived from 1,1′-bis(ethenyl-4-pyridyl)ferrocene (**1**) and resorcinol/phloroglucinol and a crystal of 1,1′-bis-(ethenyl-4-quinolinyl)ferrocene (**5**) have been studied with the aim of engineering crystalline NLO materials. X-ray structure analyses revealed a NLO active *syn*-type molecular conformation of **1** and **5** via hydrogen bonding with resorcinol/phloroglucinol and π-π interaction between quinoline rings, respectively. For **5**, all molecular dipoles are aligned in the same direction and the SHG efficiency is about 4 times that of urea.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Crystal engineering, based on an understanding of physical phenomena such as charge transfer, electrostatic interaction, hydrogen bonding, van der Waals interaction, and π−π stacking, is a powerful technique for the production of functionalized solid materials with optimized properties.[1,2] It has been applied to various organometallic compounds.[3,4] Flexible π-bonds between metal and ligands produce highly variable organometallic structures (and packing modes), depending on the solid-state intra- and intermolecular nonbonding interactions.

Because of the significant electron-donating strength of the ferrocenyl group it is regarded as a good donor part of a donor−π-acceptor system for chromophores with high NLO responses.[5−10] Thus far, most efforts to synthesize NLO materials have concentrated on mono-acceptor conjugated ferrocenyl compounds, with little work on bis-substituted systems.[11] During an investigation into the preparation of chromophores with high NLO responses, we reported the crystal structures of 1,1′-bis(ethenyl-4-pyridyl)-ferrocene, **1**, and its cocrystals with 1,1′-binaphthol.[12] The two substituents on the cyclopentadienyl group of **1** adopt a typical 1,3′-orientation, i.e., in *anti*-fashion. Cocrystals of **1** with 1,1′-binaphthol in methanol and ethanol have the two substituents of the ferrocene at the 1- and 1′-positions, respectively. The use of optically pure 1,1′-binaphthol led to a noncentrosymmetric packing arrangement. Thus, the moiety **1** in cocrystals was quite flexible and its conformation appears to be sensitive to the hydrogen-bonding patterns with 1,1′-binaphthol molecules or incorporated solvent molecules. Consequently, we sought to establish a simple and transferable crystal engineering strategy for achieving the NLO active molecular conformation of the bis-substituted ferrocenyl molecule with readily available aromatic alcohols such as 1,3-dihydroxybenzene (resorcinol) and 1,3,5-trihydroxybenzene (phloroglucinol).[13,14] In addition, an analogue, 1,1′-bis(ethenyl-4-quinolyl)ferrocene, **5**, containing additional aromatic rings was synthesized to induce a π−π interaction between the aromatic rings, eventually leading to a *syn*-type molecular conformation. We report here the results of our investigation of the cocrystallization of **1** with resorcinol and phloroglucinol as well as the synthesis and crystal structure of **5**.

Results and Discussion

Cocrystallization of 1 with Resorcinol and Phloroglucinol: Crystal Structures of 2, 3, and 4

Resorcinol and phloroglucinol function as multifunctional hydrogen bond donors in the crystal engineering of one- or two-dimensional structures.[15,16]

When equimolar amounts of **1** and resorcinol were dissolved in THF and the resultant solution allowed to evaporate at room temperature, long block-shaped crystals of **2** were isolated in quantitative yield. X-ray crystallographic analysis reveals the formation of supramolecule **2** that contain **1** and resorcinol in the ratio 1:1 (Figure 1). A molecule of **1** and resorcinol are coupled via two hydrogen bonds between the pyridines of **1** and the hydroxy groups of **2**. The two cyclopentadienyl rings on **1** adopt an eclipsed con-

formation while the two substituents of **1** adopt a 1,1′ -orientation, i.e., a *syn*-fashion. For simultaneous hydrogen bonds with two widely separated oxygen atoms [O01−O02, 4.797(6) Å], the separation of the two pendant ligands smoothly increases from 3.398(7) (C11−C18) to 4.172(6) Å (N1−N2), which makes **1** appear to stretch its arms toward a resorcinol molecule. The two pyridine ring centers are 3.967 Å apart and the two ring planes make a torsion angle of 12.5(3)°. The phenyl ring of resorcinol in **2** is slightly inclined to make an angle of 64.1(2)°−83.8(2)° with the cyclopentadienyl rings and the pyridine rings of **1**. Compared with the symmetric molecular structure of free ligand **1**, the ferrocene fragment in **2** is largely deformed into an asymmetric structure, which is expected to have a nonzero molecular dipole moment. However, supramolecules **2** are packed in a centrosymmetric manner (space group: $P2_1/n$) and the net molecular dipole moments in the crystal should be zero.

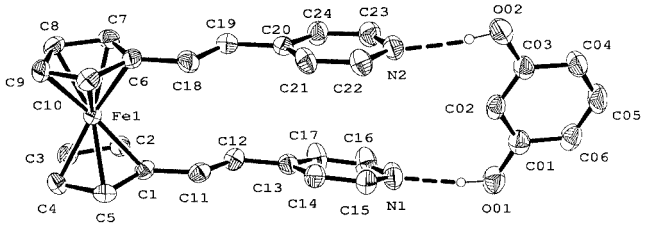

Figure 1. ORTEP drawing of **2** with 30% thermal ellipsoids

Cocrystallization of **1** with phloroglucinol was carried out in THF and EtOH, respectively. In THF at room temperature supramolecule **3** was formed, a unit of which consists of one molecule of **1**, one of phloroglucinol, and one solvent molecule of THF (Figure 2). The molecular structure of **1** (*syn*-type) and the hydrogen-bonding pattern are very similar to those in **2**. Of the three hydroxy groups of phloroglucinol, two make hydrogen bonds with pyridines of **1**, and the third is interconnected with a THF molecule. The conformation of phloroglucinol and the hydrogen bonds with the two pyridines are very similar to what is found in its cocrystal with 2,4-dimethylpyridine.[16] Supramolecules of **3** are packed in a centrosymmetric manner (Space group: $P2_1/n$) in the same way as **2**.

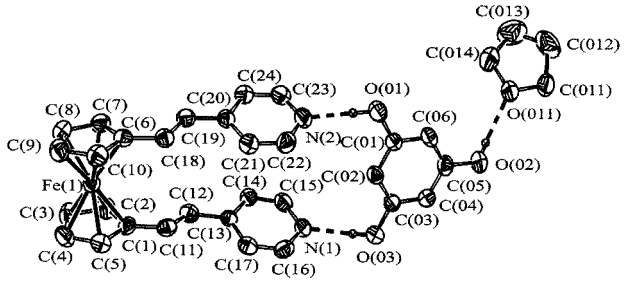

Figure 2. ORTEP drawing of **3** with 50% thermal ellipsoids

Cocrystallizion of **1** and phloroglucinol in EtOH at room temperature resulted in a supramolecule **4**, which consists of three components of **1**, phloroglucinol, and EtOH in the ratio 1:1:1. The crystal structure of **4** is a stair-like chain structure (Figure 3). A molecule of **1** in crystal **4** also makes double hydrogen bonds with a phloroglucinol molecule and shows a *syn*-type conformation, as it does in **2** and **3**. The incorporated EtOH molecule acts as a paste that connects components in the construction of a hydrogen-bonded supramolecular chain structure. It serves as a hydrogen donor to a phloroglucinol and also as a hydrogen acceptor to another phloroglucinol molecule. Every molecule of **1** within a supramolecular unit is fixed, facing the same direction, and their molecular dipole moments accumulate in a supramolecular unit. Crystal **4** belongs to the noncentrosymmetric space group, *Pc*. However, its asymmetric unit is composed of two triads of molecules with a pseudoinversion relation and two kinds of supramolecular chain face in opposite directions in a crystal (Figure 4). Therefore, the net dipole moment of the crystal **4** is expected to be close to zero.

Synthesis and Crystal Structure of 5

Compound **5**, an analogue of **1**, containing an additional aromatic ring for intramolecular stacking was prepared by treatment of 1,1′-ferrocenedicarboxaldehyde with the lithium carbanion of lepidine followed by protonation and dehydration (73% yield) (Scheme 1).

5

Scheme 1. Synthesis of **5**

Single crystals of **5** suitable for an X-ray study were grown by slow evaporation of an MeOH solution of **5**. Figure 5 shows a view of **5**, which belongs to the noncentrosymmetric space group, *Cc*.

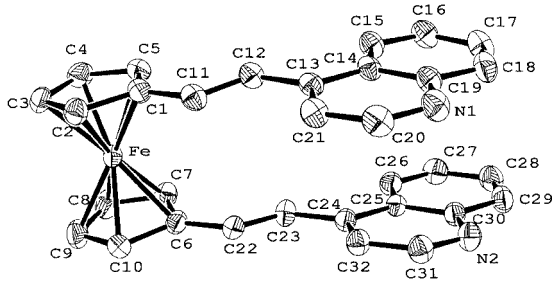

Figure 5. ORTEP drawing of **5** with 30% thermal ellipsoids

The molecular structure of **5** displays a polar conformation with a nonzero dipole moment. Two substituents of **5** adopt a 1,1′-orientation with an eclipsed conformation. The torsion angles of C(1)−C(11)−C(6)−C(22) and C(12)−C(13)−C(23)−C(24) are 8.6° and 8.0°, respectively, and the twist angle between two Cp rings is 7.5°. Two quinoline-bearing substituents lie on top of each other, indicating intramolecular stacking. The pyridine ring centers and the benzene ring centers are 3.657 and 3.876 Å apart, respectively. The tilt angle between two quinoline planes is 6.1(1)°, which quantitatively expresses the occurrence of π−π interactions between the two rings. Previously, Togni et al.[17] reported a similar eclipsed molecular structure for 1,1′-disubstituted ferrocene by virtue of the attractive interaction between two sulfur-containing fragments. However, in contrast to the highly tilted molecular structure in Togni's result, the Cp and quinoline rings of **5** are roughly coplanar with dihedral angles of 7.6(2)° and 11.2(2)°. A coplanar arrangement of Cp and substituents of **5** may allow maximum orbital mixing and effective electronic communication between an electron-donating ferrocene and electron-withdrawing quinoline groups, i.e., effective delocalization along the conjugated chains. Two N atoms of quinolines of **5** make contacts with quinoline and Cp rings in neighboring molecules (Figure 6). The CH···N distances of 2.59(4) and 2.78(4) Å and the C−H···N angles of 160(3)° and 167(3)° indicate weak C−H···N hydrogen-bonding interactions. The distances and angles fall in the range of reported interactions between $C(sp^2)$−H and N in a heterocyclic group.[18b−18d] Both intermolecular C−H···N interactions are arranged in almost the same direction and, eventually, cause all of the molecular dipoles in crystal **5** to align along the A axis (i.e., a polar crystal) (Figure 7). Such C−H···N interaction appears to be important in determining the crystal packing.[18]

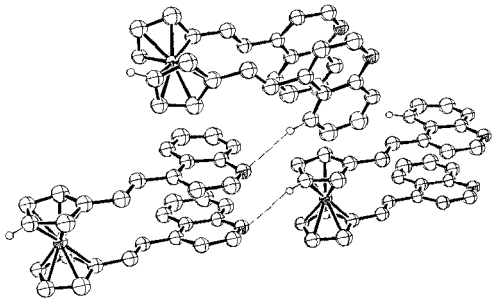

Figure 6. CH···N interactions of **5**

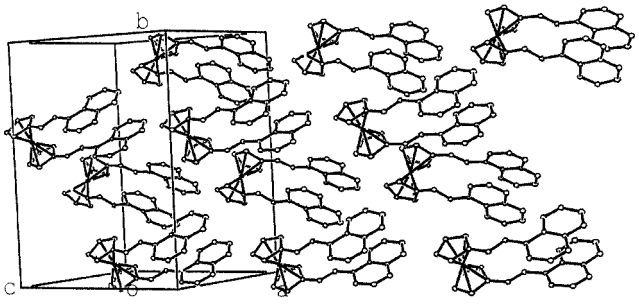

Figure 7. Cell packing diagram of **5**

Discussion

Ferrocenes adopt various conformations, depending on the magnitude of the rotational barrier, and are considered, in a sense, as nonrigid molecules that have a variable structure.[19] Free **1** crystallizes in the symmetric *anti*-conformation, which should possess a zero molecular dipole moment and hyperpolarizability.[12] However, in cocrystals of **2**, **3**, and **4**, the two substituents on the cyclopentadienyl groups of the ferrocene are situated at 1- and 1′-positions, and **1** shows a *syn*-type geometry. Resorcinol and phloroglucinol molecules act like molecular clips to create simultaneous double hydrogen bonds with a molecule of **1** and fix its conformation as a dipolar one − a prerequisite for a nonlinear optical molecule. Unlike the symmetric molecule of free **1**, asymmetric supramolecules of **2**, **3**, and **4** should possess nonzero molecular hyperpolarizabilities. However, the crystal arrangements of **2**, **3**, and **4** reveal an anti-parallel alignment of molecular dipoles, therefore no second-harmonic generations (SHG) are expected for the bulk materials. In the crystals **3** and **4**, solvent molecules of THF and EtOH are incorporated through hydrogen bonding with phloroglucinol. EtOH molecules of **4** serve as molecular

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pastes to construct a supramolecular chain and align all dipoles in a supramolecular unit in the same direction.

Compound **5** crystallizes in a dipolar *syn*-type conformation due to the significant π−π interaction between two pendent arms.[20] Moreover, an almost perfect dipole alignment is realized in crystal **5** through weak intermolecular C−H···N interactions. Thus, an effective SHG was expected. When Kurtz powder measurements were performed at 1.36 μm, **5** shows an SHG efficiency of about 4 times that of urea.[21] This is quite low compared with the highest bulk susceptibility (χ^2 up to 220 times the value for urea) reported for ferrocenyl derivatives,[10c] presumably due to the weak electron-accepting ability of the quinoline group.

Conclusion

We have demonstrated two crystal engineering approaches for achieving the NLO active molecular conformation of structurally flexible disubstituted ferrocenyl compounds. An X-ray crystal structure analysis of **5** shows that it crystallizes in a NLO active conformation. The efficiency of **5** in the second harmonic generation is 4 times that of urea. This is not a high value compared with the known bulk susceptibilities for ferrocenyl derivatives. We anticipate that the introduction of more electron-withdrawing groups into the skeleton of **5** will give more efficient NLO materials. Further related research will continue to be pursued.

Experimental Section

General Remarks: Resorcinol (Aldrich), phloroglucinol dihydrate (Aldrich), and lepidine (Lancaster) were used as received. The synthesis of **5** was carried out under nitrogen by using standard Schlenk techniques. Freshly distilled, dried, and oxygen-free solvents were used throughout. ^{1}H and ^{13}C NMR spectra were recorded with a Bruker 300 spectrometer. Elemental analysis was performed by the Analytical Center, College of Engineering, Seoul National University. High-resolution mass spectroscopy was carried out at the Korea Basic Science Institute (Daegu). 1,1′-Ferrocenedicarboxaldehyde and 1,1′-bis(ethenyl-4-pyridyl)ferrocene, **1**, were prepared according to published procedures.[22,23]

Cocrystallization of 1 with Resorcinol (Synthesis of 2): Compound **1** (20 mg, 0.051 mmol) and resorcinol (5.6 mg, 0.051 mmol) were dissolved in EtOH (5 mL). The resultant solution was allowed to evaporate at room temperature for 7 days. Long block-shaped crystals of **2** were isolated in quantitative yield. $C_{30}H_{26}FeN_2O_2$ (502.40): calcd. C 71.72, H 5.22, N 5.58; found C, 71.26, H 5.34, N 5.71.

Cocrystallization of 1 with Phloroglucinol (Syntheses of 3 and 4): Compound **1** (20 mg, 0.051 mmol) and phloroglucinol dihydrate (8.3 mg, 0.051 mmol) were dissolved in THF (5 mL). The resultant solution was allowed to evaporate at room temperature for about 7 days. Red needle-shaped crystals of **3** were then isolated in quantitative yield. $C_{34}H_{34}FeN_2O_4$ (590.50): calcd. C 69.16, H 5.80, N 4.74; found C, 68.99, H 5.46, N 4.83. Red cubic crystals of **4** were obtained quantitatively in the same way as **3**, using EtOH instead of THF as the reaction medium. $C_{32}H_{32}FeN_2O_4$ (564.46): calcd. C 69.16, H 5.80, N 4.74; found C, 68.99, H 5.46, N 4.83.

Synthesis of 5: Lepidine (1.2 mL, 9.1 mmol) was added at −78 °C to a solution of LDA (generated in situ by the reaction of diisopropylamine (1.3 mL, 9.3 mmol) in THF (30 mL) with *n*BuLi (4.0 mL, 10.0 mmol) at −78 °C). The resultant solution turned reddish during stirring at room temperature for 30 min. 1,1′-Ferrocenedicarboxaldehyde (0.66 g, 2.7 mmol) was then added at room temperature. This reaction mixture turned brownish as it was stirred at room temperature for 4 h, after which excess water (30 mL) and methylene dichloride (30 mL) were added. The methylene dichloride layer was collected, evaporated to dryness, and dissolved in pyridine (15 mL). The pyridine solution was cooled to 0 °C and excess $POCl_3$ (2 mL) was added dropwise. The resultant solution turned dark green during stirring at room temperature for 1 h, after

Crystal Structure Determinations of 2, 3, 4, and 5: Diffractions for **2**, **3**, and **4** were measured by an Enraf−Nonius CAD4 automated diffractometer. Unit cells were determined by centering 25 reflections in the appropriate 2θ range. Other relevant experimental details are listed in Table 1. The structures for **2**, **3**, and **4** were solved by direct methods using SHELXS-86 and refined by full-matrix least-squares with SHELXL-93.[24] For **5**, the diffraction data were collected on an Enraf−Nonius CCD single crystal X-ray diffractometer and the structure solved by direct methods using SHELXS-97 and refined against all F^2 data (SHELXS-97).[25] All non-hydrogen atoms were refined anisotropically. All hydrogen

atoms in **2**, **3**, and **5** and H(01*), H(02*), H(01), H(03), and H(01′) in **4** were found in the Fourier map and refined. The rest of the hydrogen atoms were located in ideal positions using a riding model with 1.2 times the equivalent isotropic temperature factors of the atoms to which they were attached. The absolute structures of **4** and **5** could not be defined as insufficient data were collected.

CCDC-196212 to -196215 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

SHG Measurements: The measurements of second harmonic generation (SHG) intensity were carried out by the Kurtz−Perry powder technique,[21] using a beam with $\lambda = 1.360$ μm and $I = 5$ MW/cm^2 generated by a BBO optical parametric oscillator pumped by a Nd:YAG laser. Samples were in the range 75−150 μm, and were 270 μm thick.

Ternary Mononuclear and Ferromagnetically Coupled Dinuclear Copper(II) Complexes of 1,10-Phenanthroline and *N*-Salicylidene-2-methoxyaniline that Show Supramolecular Self-Organization

Pattubala A. N. Reddy,[a] Munirathinam Nethaji,[a] and Akhil R. Chakravarty*[a]

Keywords: Copper / Magnetic properties / N ligands / Stacking interactions / Supramolecular chemistry

The ternary copper(II) complex [Cu(phen)(L)](ClO_4) (**1**) and dinuclear copper(II) complex [Cu_2(phen)$_3$(L)(O_2CMe)](ClO_4)$_2$ (**2**) have been prepared and characterized structurally by X-ray crystallography (HL: *N*-salicylidene-2-methoxyaniline; phen: 1,10-phenanthroline). The crystal structure of **1** displays a square-pyramidal [4+1] coordination geometry in which the basal plane has three nitrogen donor atoms and the phenolate oxygen atom of the Schiff base. The methoxy oxygen atom exhibits axial coordination in the CuN_3O_2 chromophore. Complex **2** has a dinuclear copper(II) core in which the Cu(phen)$_2^{2+}$ and Cu(phen)(L)$^+$ units are linked by an acetate ion showing equatorial/axial modes of bonding. In the bis(phen) unit, the basal plane has three nitrogen atoms and the acetate oxygen atom with one phen nitrogen atom occupying the axial site. In the mono(phen) unit, the basal plane has three nitrogen atoms and one phenolate oxygen atom. The acetate oxygen atom occupies the axial site. The equatorial/axial bridging mode of the acetate ion makes the dicopper(II) unit weakly ferromagnetic ($2J$ = +22 cm^{-1}) and the complex in CH_2Cl_2 glass at 77 K shows an axial EPR spectrum [$g_{\|}$ = 2.23 ($A_{\|}$ = 150 × 10^{-4} cm^{-1}); $g_{\perp}$ = 2.03] corresponding to a ΔM_s = ±1 transition and a half-field signal due to a ΔM_s = ±2 transition. Complex **1** displays an axial EPR spectrum with $g_{\|} > g_{\perp}$ indicating a $\{d_{x^2-y^2}\}^1$ ground state. The complexes show a d–d band near 650 nm and a charge-transfer band at ca. 415 nm in methanol. The complexes are redox-active and exhibit a Cu^{II}/Cu^{I} couple near 0.0 V versus SCE in DMF and CH_2Cl_2/0.1 M TBAP. Complex **1** is catalytically active in the oxidation of ascorbic acid by dioxygen in aqueous methanol. Complex **2** also shows similar catalytic activity, but the core is susceptible to cleavage under the reaction conditions. The complexes show π–π stacking interactions. Complex **1** forms a one-dimensional chain through intermolecular π–π stacking interactions involving phen and the phenolate ring of the Schiff base. Complex **2** displays intramolecular and intermolecular π–π stacking interactions involving phen ligands leading to the formation of a supramolecular tetrameric structure.

Introduction

Ternary copper(II) complexes of the type [CuL^1L^2]$^{n+}$, where L^1 and L^2 together form a square-pyramidal [4+1] coordination geometry with labile binding sites, are of biological relevance.[1−6] Ternary complexes have been used to model the active site structures and catalytic properties of several type-2 copper proteins.[7−17] It has been observed that the biological activities of such copper proteins often are dependent on the noncovalent interactions between aromatic moieties.[1] The complexes are related to the formation of the tyrosine phenoxyl Tyr272 radical in a stacking interaction with Trp290 in galactose oxidase and the involvement of trihydroxyphenylalanine (topa) quinone in amine oxidase.[18,19] Such weak interactions play a crucial role in bioinorganic chemistry toward stabilizing the tertiary structure of proteins, reactivity of the metalloenzymes, in the molecular recognition process and in nucleic acids chemistry.[20,21]

Sigel et al. have studied the stacking interactions of the aromatic rings in ternary complexes.[22] Such weak interactions have profound influence on the structure and function of the complexes.[1,21,22] The present work stems from our interest to prepare ternary copper(II) complexes using an *N*,*N*-donor, 1,10-phenanthroline (phen), and an *O*,*N*,*O*-donor Schiff base, *N*-salicylidene-2-methoxyaniline (HL), to study such noncovalent interactions. We have been able to prepare a mononuclear ternary copper(II) complex [Cu(phen)(L)](ClO_4) (**1**) that forms a 1D chain by intermolecular π−π interactions involving the phen and Schiff-base ligands. We have also prepared a ferromagnetically coupled acetato-bridged dicopper(II) complex [Cu_2(phen)$_3$(L)(O_2CMe)](ClO_4)$_2$ (**2**) that is stabilized by novel intramolecular π−π interactions involving two phen ligands belonging to two copper centers. Interestingly, complex **2** undergoes self-organization through intermolecular π−π interactions of two phen ligands belonging to two dimeric species to form an unusual discrete supramolecular tetrameric species. ein, we present the synthesis, crystal structure and properties of complexes **1** and **2**.

Results and Discussion

Synthesis and General Properties

The ternary monomeric complex **1** was prepared in high yield by a reaction of copper(II) perchlorate with 1,10-phenanthroline and the Schiff base (HL) in methanol. When the reaction of phen and HL is carried out with dimeric copper(II) acetate hydrate in methanol, followed by addition of sodium perchlorate, the major product is a dicopper(II) species of formulation $[Cu_2(phen)_3(L)(O_2CMe)](ClO_4)_2$ (**2**) along with **1** as a minor product. The complexes were characterized by analytical, spectral and single-crystal X-ray diffraction methods. The spectroscopic and magnetic data are given in Table 1.

The mononuclear complex **1** is one-electron paramagnetic. Magnetic susceptibility measurements in the range 30−302 K for the polycrystalline sample of **2** show weak ferromagnetic behavior of the complex. A theoretical fitting of the $\chi_M T$ vs. T plot gives a J value of +11 cm^{-1} with g = 2.17, $g1$ = 2.11 and ρ = 0.001 (Figure 1). Complexes **1** and **2** display axial X-band EPR spectra giving $g_{\parallel} > g_{\perp}$ indicating a $\{d_{x^2-y^2}\}^1$ ground state and a tetragonally distorted square-pyramidal geometry at the copper centers. Complex **2** in a CH_2Cl_2 glass at 77 K shows an additional signal at half-field corresponding to a $\Delta M_S = \pm 2$ transition indicating that it has dimeric nature and the triplet ground state (Figure 1).[23] This signal is, however, absent in a DMF glass at 77 K, possibly because of cleavage of the dimeric core. The complexes display a d−d band near 650 nm in methanol along with a charge-transfer band at ca. 415 nm.

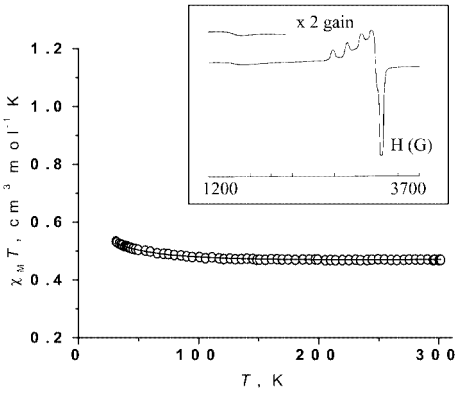

Figure 1. Plot of $\chi_M T$ vs. T for a polycrystalline sample of $[Cu_2(phen)_3(L)(O_2CMe)](ClO_4)_2$ (**2**) (circles); the solid line represents the best theoretical fit to the experimental data; an X-band EPR spectrum of **2** in a CH_2Cl_2 glass at 77 K is shown in the inset

Crystal Structures

Complexes **1** and **2** were characterized by single-crystal X-ray crystallography. Selected bond lengths and angles are given in Table 2. Perspective views of the molecules are shown in Figures 2 and 3. Complex **1** has a ternary structure consisting of a bidentate *N*,*N*-donor phen and tridentate *O*,*N*,*O*-donor Schiff base (L) bonded to the metal center in the cationic complex with a perchlorate counterion. While the basal plane is occupied by three nitrogen atoms and the phenolate oxygen atom, the methoxyl oxygen atom of the Schiff base shows axial bonding in the 4+1 coordination geometry with a CuN_3O_2 chromophore. The axial Cu−O bond length is 2.627(2) Å, which is similar to the metal-to-axial-tyrosinate-oxygen-atom distance of 2.69 Å in galactose oxidase.[18,24] The structure of **1** is distorted square-pyramidal, giving a trigonal distortion parameter (τ) value of 0.13.[25] In **1**, the torsion angle at the C=N (imine) moiety of the Schiff's base is 45.8°, which is similar to those angles observed in analogous complexes having axial sulfur ligation.[26] Complex **1** displays an intermolecular $\pi-\pi$ stacking interaction involving the phen and phenolate ring moieties with an interplanar distance of ca. 3.6 Å between the centroids of the rings that have essentially a parallel orientation (Figure 4).

The crystal structure of **2** displays a dicationic dicopper(II) complex crystallized with two perchlorate anions. The structure consists of two copper(II) centers, viz. $\{Cu(phen)_2^{2+}\}$ and $\{Cu(phen)(L)^{+}\}$, that are covalently

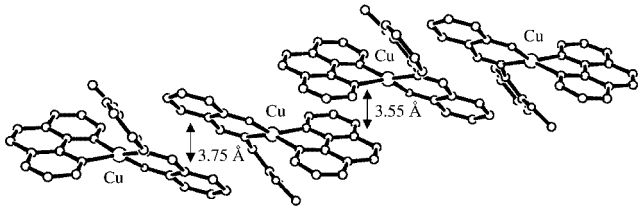

Figure 4. The intermolecular π−π stacking interaction in [Cu(phen)(L)](ClO_4) (**1**) involving phen ligands and phenolate rings to form a 1D chain

linked by an acetate ion showing a *syn*,*anti*-binding mode. The dimeric structure is stabilized by an intramolecular noncovalent π-stacking interaction involving two phen ligands belonging to two copper centers. An angle of 4.6° between the two phen planes indicates their near parallel orientation. A distance of 3.728 Å between the two centroids of the phen ligands suggests the significant stabilizing effect of the π−π interaction. Besides this interaction, two phen ligands belonging to two dimeric units are involved in an intermolecular π−π stacking interaction. This interaction leads to an association of two dimeric complexes into a discrete supramolecular tetrameric species (Figure 5). The Cu(1) center in **2** is bonded to one phen unit, the Schiff base and the bridging acetate ion. The Schiff base shows a bidentate chelating mode of bonding through the phenolate oxygen atom and the imine nitrogen atom. The methoxy oxygen atom essentially is nonbonded to the metal atom [Cu(1)···O(2), 2.966(6) Å]. The basal plane of Cu(1) comprises the phen unit and the Schiff-base ligand. The axial site is occupied by the acetate oxygen atom at a distance of 2.240(6) Å. The Cu(1) atom has a significantly distorted square-pyramidal [4+1] coordination geometry that gives a τ value of 0.45. The Cu(2) atom is bonded to one acetate and two phen ligands. The basal plane is occupied by three nitrogen atoms of the phen ligands and one oxygen atom of the acetate bridge. One nitrogen atom of a phen ligand occupies the axial site. The coordination geometry is axially

elongated distorted square-pyramidal (4+1) with a CuN_4O chromophore ($\tau = 0.4$).

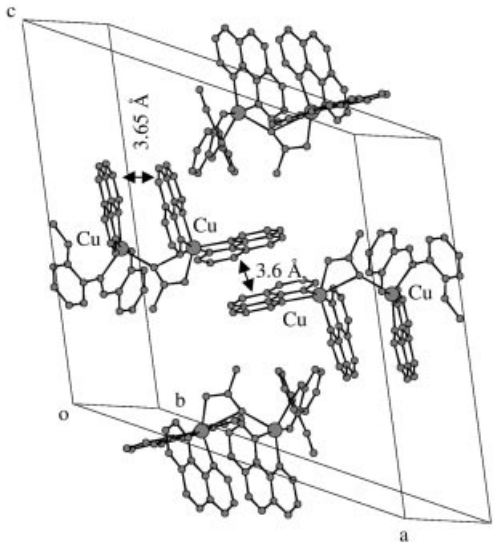

Figure 5. A unit-cell packing diagram showing the intra- and intermolecular π−π stacking interactions in $[Cu_2(phen)_3(L)(O_2CMe)](ClO_4)_2$ (**2**) to form the discrete supramolecular tetranuclear species; for clarity, the perchlorate anions are not shown

The Cu(1)−Cu(2) distance in **2** is 4.342(2) Å. The metal centers are linked by the acetate ion that shows an equatorial/axial mode of bonding. Such a binding mode involving the $d_{x^2-y^2}$ orbital of Cu(2) and the d_z^2 orbital of Cu(1) makes the metal centers essentially uncoupled because of the orthogonality of the orbitals. As a consequence, the magnetic exchange interaction in **2** becomes weakly ferromagnetic as is evidenced in the variable-temperature magnetic susceptibility studies and in the EPR spectrum in a CH_2Cl_2 glass at 77 K.[23,27] Complex **2** with two copper centers having different ligand environments and a weakly coupled dicopper(II) core has structural similarity to the dimeric sites of type-2 proteins, viz. dopamine β-hydroxylase and peptidylglycine α-hydroxylating monooxygenase.[3,28]

Redox and Catalytic Properties

The electron-transfer behavior of the complexes **1** and **2** was studied by cyclic voltammetry using a glassy-carbon working electrode. Selected data are given in Table 1 and voltammograms are shown in Figure 6. Complex **1** in CH_2Cl_2/0.1 M TBAP or DMF/0.1 M TBAP shows a cathodic peak near −0.25 V with an anodic counterpart at 0.34 V in CH_2Cl_2 and 0.13 V in DMF. The peaks are assignable to the Cu^{II}/Cu^{I} couple. The reduced ternary species [Cu(phen)(L)] is unstable as is evidenced from the i_{pc}/i_{pa} ratio of ca. 4.0.[29] The dimeric complex **2** displays a cathodic peak at −0.29 V with an anodic response at 0.35 V in CH_2Cl_2/0.1 M TBAP. Again, the i_{pc}/i_{pa} ratio of 14.0 indicates poor stability of the reduced species. The $E_{1/2}$ value of 0.03 V for the $Cu_2^{II}/Cu^{II}Cu^{I}$ couple compares well with that of **1**. The dimeric core was unstable in DMF/0.1 M TBAP solution. The DMF solution of **2** shows two cathodic peaks at −0.07 and −0.29 V with a broad anodic peak at 0.15 V. The cathodic peaks are assignable to the Cu^{II}/Cu^{I} couple of the $[Cu(phen)_2]^{2+}$ and $[Cu(phen)(L)]^{+}$ species.[30] It is likely that the weak axial bond of the acetate ion in **2** undergoes cleavage in a polar solvent such as DMF. Such a cleavage has been evidenced from the EPR spectrum of **2** showing no half-field signal in a DMF glass. Complex **2** also displays an irreversible cathodic peak at −0.89 V resulting from reduction of the Schiff's base.

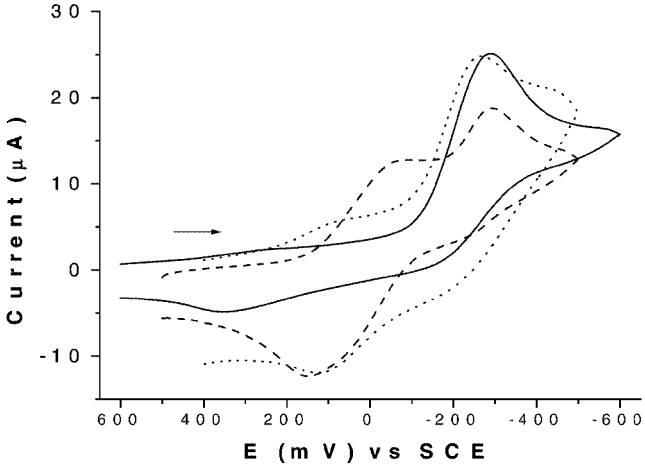

Figure 6. Cyclic voltammograms of $[Cu(phen)(L)](ClO_4)$ (**1**) in DMF/0.1 M TBAP (···), $[Cu_2(phen)_3(L)(O_2CMe)](ClO_4)_2$ (**2**) in DMF/0.1 M TBAP (---) and CH_2Cl_2/0.1 M TBAP (—) at 50 mV s^{-1}

Complex **1** reacts with ascorbic acid (H_2A) in aqueous methanol to form an unstable, brown copper(I) species, which on exposure to air converts to the parent complex. The catalytic cycle is effective at an H_2A/**1** molar ratio of 60:1. At higher concentrations of H_2A, a catalytically inactive oxalato species is formed. The formation of oxalic acid takes place from the oxidation of a dehydroascorbate species.[31] Complex **2** is also active in the oxidation of H_2A by dioxygen, but the complex is susceptible to cleavage in a polar reaction medium. The observed catalytic activity of **2** could be due to the formation of two catalytically active monomeric copper(II) species.

Conclusion

A ternary monomeric copper(II) complex having a tridentate *O*,*N*,*O*-donor Schiff base and bidentate *N*,*N*-donor phen unit was prepared and characterized structurally. The complex has a CuN_3O_2 square-pyramidal [4+1] coordination geometry with a methoxy oxygen atom as a weak axial ligand. A dicopper(II) complex was prepared and structurally characterized that has $Cu(phen)_2^{2+}$ and $Cu(phen)(L)^{+}$ units linked by an acetate ion showing equatorial/axial modes of bonding. Complex **2** has a ferromagnetically coupled dicopper(II) core. Crystal structures of the complexes **1** and **2** show intermolecular π−π stacking interactions. In addition, the dimeric complex **2** shows the presence of an intramolecular π−π stacking interaction involv-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing the phen ligands of two different metal centers having CuN_4O and CuN_3O_2 coordination environments. While complex **1** forms a 1D chain, the intermolecular interaction in **2** results in the aggregation of two dimeric units to form an unusual discrete supramolecular tetranuclear structure.

Experimental Section

Materials and Physical Measurements: Chemicals and reagents were obtained from commercial sources. Solvents were purified by standard procedures.[32] Salicylaldehyde was obtained from Aldrich. 2-Methoxyaniline and 1,10-phenanthroline were purchased from SD Fine Chemicals, Mumbai. Copper(II) acetate hydrate was from BDH (India). The Schiff-base ligand, *N*-salicylidene-2-methoxyaniline (HL) was prepared by a literature method.[33] The infrared, electronic and EPR spectra were recorded with Bruker Equinox 55, Hitachi U3000 and Varian E-109 X-band spectrometers, respectively. The elemental analysis was performed using a Heraeus CHN-O Rapid instrument. Magnetic susceptibility data of the polycrystalline samples were obtained from a George Associates Inc. Lewis-coil-force magnetometer system having Cahn balance and an APD closed-cycle cryostat. Diamagnetic corrections to the susceptibility data were made using Pascal's constants.[34] Variable-temperature magnetic susceptibility data for complex **2** in the 30−302 K range were corrected for temperature-independent paramagnetism ($N\alpha = 60 \times 10^{-6}$ cm^3 mol^{-1} per copper atom). The molar magnetic susceptibilities were fitted to the modified Bleaney−Bowers expression[35] based on the isotropic form of the Heisenberg−Dirac−van Vleck (HDvV) model with a spin Hamiltonian $H = -2JS_1S_2$ ($S_1 = S_2 = 1/2$ for d^9-d^9 configuration): $\chi_{Cu} = [Ng^2\beta^2/kT][3 + \exp(-2J/kT)]^{-1}(1 - \rho) + (Ng_1^2\beta^2/4kT)\rho + N\alpha$, where ρ is the fraction of monomeric impurity and $-2J$ is the singlet−triplet energy separation. The magnetic moments at various temperatures were calculated in μ_B units ($\mu_B \approx 9.274 \times 10^{-24}$ J T^{-1}). Electrochemical measurements were made at 25 °C with an EG&G PAR Model 253 Versastat Potentiostat/Galvanostat with electrochemical analysis software 270 for voltammetric work with a three-electrode setup comprising a glassy-carbon working electrode, a platinum-wire auxiliary electrode and a saturated calomel reference (SCE) electrode. The electrochemical data are uncorrected for junction potentials. Tetrabutylammonium perchlorate (TBAP) was used as a supporting electrolyte. Ferrocene was used as standard to monitor the reference electrode.

Syntheses

Preparation of [Cu(phen)(L)](ClO$_4$) (1) and [Cu$_2$(phen)$_3$(L)(O$_2$CMe)](ClO$_4$)$_2$ (2): The complexes were prepared as a mixture from a reaction of $Cu_2(O_2CMe)_4(H_2O)_2$ (0.2 g, 0.5 mmol) in methanol (5 mL) with phen (0.19 g, 1.0 mmol) whilst stirring for 0.5 h at 25 °C, followed by addition of the Schiff base (HL, 0.23 g, 1.0 mmol) in methanol (10 mL) and a methanolic solution of $NaClO_4$. On slow concentration, the reaction mixture gave large rhombohedral-shaped crystals of complex **2** (yield: ca. 60%) and thin plate-type

crystals of **1** (yield: ca. 20%). The crystals were separated manually and dried under vacuum over P_4O_{10}. $C_{26}H_{20}ClCuN_3O_6$ (569.5) (**1**): calcd. C 54.72, H 3.51, N 7.37; found C 54.78, H 3.68, N 7.32. $C_{52}H_{39}Cl_2Cu_2N_7O_{12}$ (1151.9) (**2**): calcd. C 54.16, H 3.38, N 8.51; found C 54.01, H 3.52, N 8.40. IR (KBr phase): $\tilde{\nu}$ = 3065 br, 1588 s, 1522 s, 1430 m, 1320 m, 1186 m, 1096 vs, 842 m, 778 m, 721 m, 618 w cm^{-1} for **1**; $\tilde{\nu}$ = 3434 br, 3065 m, 1614 s, 1442 m, 1329 m, 1242 m, 1150 m, 1087 vs, 843 m, 748 m, 620 w cm^{-1} for **2** (vs, very strong; s, strong; m, medium, w, weak; br, broad). Complex **1**, formed as a single product, was prepared from the reaction of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.37 g, 1.0 mmol) in methanol (10 mL) and phen (0.19 g, 1.0 mmol) in methanol (10 mL) followed by the addition of the Schiff base (HL, 0.23 g, 1.0 mmol) in methanol (5 mL). The mixture was stirred for 0.5 h at 25 °C. Removal of the solvent in a rotary evaporator gave **1** as a single product that was washed with water and diethyl ether before drying in vacuo over P_4O_{10} (yield: 70%). ***Caution!*** *Perchlorate salts are potentially explosive and should be handled in small quantities with suitable safety measures.*

X-ray Crystallographic Study: Intensity data for complex **1** in the triclinic crystal system were collected with an Enraf−Nonius CAD4 diffractometer fitted with a graphite-monochromated Mo-K_α radiation. The data were corrected for Lorentz, polarization and absorption effects.[36] The cell parameters and the intensity data for complex **2** were obtained from a Bruker SMART APEX CCD diffractometer, equipped with a fine-focus 1.75-kW sealed-tube Mo-K_α X-ray source, with increasing ω (width, 0.3° per frame) at a scan speed of 8 s/frame. The SMART software was used for data acquisition and the SAINT software for data extraction.[37] Absorption correction was done using SADABS.[38] The structures were solved and refined using SHELX programs.[39] The relations used for residuals are $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o)^2]\}^{1/2}$, $w = [\sigma^2(F_o)^2 + (AP)^2 + BP]^{-1}$, where $P = (F_o^2 + 2F_c^2)/3$ having A and B values of 0.0843 and 0.8796 for **1** and 0.1266 and 0.0000 for **2**. While complex **1** refined well without showing any significant disorder, the crystals of complex **2** diffracted poorly. The atoms belonging to the cationic complex of **2** and one perchlorate anion refined well. The other perchlorate anion in **2** showed positional disorders. This perchlorate anion was refined with two sets of five peaks having site occupancies of 0.7 and 0.3. The hydrogen atoms of **1** were located from the difference Fourier maps and were refined isotropically. The hydrogen atoms of **2** were generated and assigned isotropic thermal parameters, riding on their parent carbon atoms and used only for calculation of the F_o^2 structure factor. Selected crystal data for complexes **1** and **2** are given in Table 3. Perspective views of the complexes were obtained by ORTEP.[40] CCDC-192652 and -192653 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Crystal Structures and Third-Order Nonlinear Optical Properties of Two Novel Ferrocenyl Schiff-Base Complexes $[Ag(L)_2](NO_3)(MeOH)(EtOH)$ and $[HgI_2(L)]$ {L = 1,2-Bis[(ferrocen-l-ylmethylene)amino]ethane}

Hongwei Hou,*[a] Gang Li,[a] Yinglin Song,[b] Yaoting Fan,[a] Yu Zhu,[a] and Lu Zhu[a]

Keywords: Schiff bases / Silver / Mercury / Nonlinear optics

Two novel ferrocenyl complexes $[Ag(L)_2](NO_3)\cdot(MeOH)\cdot(EtOH)$ (**1**) and $[HgI_2(L)]$ (**2**) {L = 1,2-bis[(ferrocen-l-ylmethylene)amino]ethane} have been prepared and structurally characterized by means of X-ray single crystal diffraction. The central ion, silver(I) or mercury(II), has a distorted tetrahedral environment, the silver(I) ion coordinates with two L, and the mercury(II) ion binds one L and two iodine atoms. Their third-order nonlinear optical (NLO) properties were determined by Z-scan techniques in DMF solution. The results indicate that the two complexes exhibit very strong NLO absorption and strong self-focusing effects. The third-order NLO absorptive coefficients α_2 are 1.34×10^{-8} m W^{-1} for **1** and 3.1×10^{-9} m W^{-1} for **2**. The refractive indexes n_2 for the two complexes are 1.15×10^{-18} and 8.02×10^{-19} m^2 W^{-1}, respectively. The hyperpolarizability γ values are calculated to be 2.68×10^{-30} esu for **1** and 1.44×10^{-30} esu for **2**. The γ values are several orders of magnitude larger than those of the reported aryl and vinyl derivatives of ferrocene. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Ferrocene-containing compounds are currently receiving much attention due to their increasing role in the rapidly growing area of materials science. They have been used as homogeneous catalysts for various processes,[1] molecular sensors,[2] and molecular magnetic[3] and nonlinear optical materials.[4] In particular, several studies have been made on the nonlinear optical properties of ferrocene derivatives[4] since the first report that (*E*)-1-ferrocenyl-2-(*N*-methylpyridinium-4-yl)ethylene iodide and (*Z*)-1-ferrocenyl-2-(4-nitrophenyl)ethylene have large second harmonic generation efficiencies (220 and 62 times that of urea, respectively).[5]

Ferrocenyl Schiff bases as very important ferrocene derivatives have been studied in this context. Several groups have reported the NLO properties of various monoferrocenyl Schiff bases and bidentate diferrocenyl Schiff bases, but most have focused on second-order NLO properties of those compounds.[6−10] To the best of our knowledge, there are no reports on the third-order NLO properties of this type of compounds and the corresponding complexes.

Conversely, although the bidentate ferrocenyl Schiff base 1,2-bis[(ferrocen-l-ylmethylene)amino]ethane (L) has previously been prepared, its metal complexes are quite scarce due to its spontaneous hydrolytic degradation. However, a series of metal complexes with the parent amine of L, 1,2-bis[(ferrocenylmethyl)amino]ethane, have been obtained.[11−13] The only known complex containing L appears to be the $[ZnCl_2(L)]$ complex recently described by Li et al.[14] It is noteworthy that the syntheses of Ag- or Hg-containing ferrocenyl complexes are difficult, due mainly to the instability of Ag^I in solution and the poor solubility of Hg^{II} in ordinary solvents. To obtain Ag- or Hg-containing ferrocenyl compounds and find better third-order NLO materials, we utilized the reaction of L with Ag or Hg to synthesize two novel complexes, $[Ag(L)_2](NO_3)\cdot(MeOH)\cdot(EtOH)$ (**1**) and $[HgI_2(L)]$ (**2**), and further determined their third-order NLO properties using Z-scan techniques. The results reveal that both complexes have very strong third-order NLO absorptive and refractive properties in DMF solution. The hyperpolarizability γ values are calculated to be 2.68×10^{-30} esu and 1.44×10^{-30} esu for **1** and **2**, respectively.

Results and Discussion

Crystal Structure of $[Ag(L)_2](NO_3)(MeOH)(EtOH)$ (1)

The molecular structure of complex **1** was determined by single-crystal X-ray diffraction analysis. The asymmetric unit contains an $[Ag(L)_2]^+$ cation, one NO_3^- anion, and one crystallization molecule each of methanol and ethanol. The perspective view of the cation of **1** is illustrated in Figure 1.

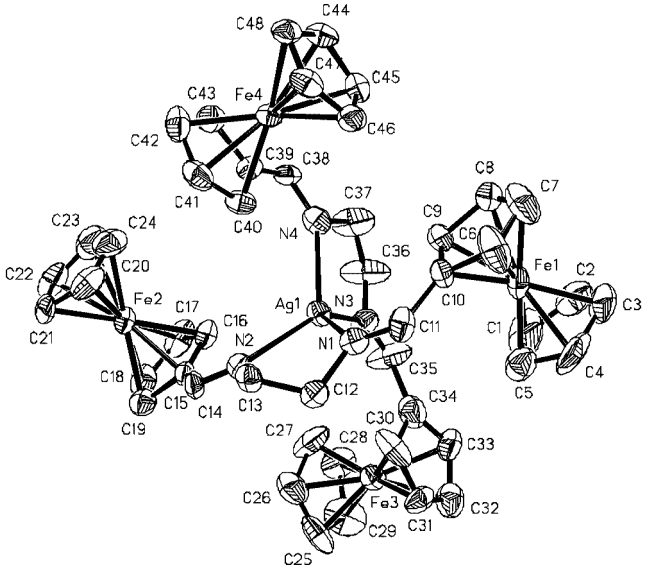

Figure 1. ORTEP drawing with atom-labeling scheme of the cation of $[Ag(L)_2](NO_3)\cdot(MeOH)\cdot(EtOH)$

The Ag^I ion is in a distorted tetrahedral environment with the four nitrogen atoms N1, N2, N3 and N4 of two L, which act as bidentate ligands. The Ag−N distances range from 2.277(8) to 2.397(8) Å. The angles N1−Ag1−N2 [77.7(3)°] and N3−Ag1−N4 [77.1(3)°] are acute, and are enforced by the ligand L. The other N−Ag1−N angles are in the range 125.2(3)−130.6(3)°. Hence, the average bond angle at Ag1 is 110.8°, while the dihedral angle between the planes [N1, Ag, N2] and [N3, Ag, N4] is 90.7°. Two five-membered rings, N1−C12−C13−N2−Ag1 and N3−C36−C37−N4−Ag1, adopt λ-conformations (the torsional angles of N1−C12−C13−N2 and N3−C36−C37−N4 are 63.7° and 26.0°, respectively). The geometry at the central Ag^I ion is, in fact, the same as that in the related compound $[Cu(L^1)_2]BF_4$ {L^1 = 1,2-bis[(ferrocen-1-ylmethylene)amino]benzene},[14] which is distorted by the bite of the ferrocenyl ligands.

The average $Fe-C_{ring}$ distance (2.014 Å) is close to that of the free ferrocene (2.04 Å). The average intra C−C bond length of cyclopentadienyl is 1.389 Å, which is shorter than that of the free ferrocene. The average C−C−C angle of 107.8(11)° is similar as those of reported compounds.[15] In each ferrocenyl moiety, the cyclopentadienyl rings are planar. The dihedral angle between the planes C15−C16−C17−C18−C19 and C20−C21−C22−C23−C24 at Fe2 is 3.5°, and is only 0.7° for the planes C39−C40−C41−C42−C43 and C44−C45−C46−C47−C48 at Fe4, but the other dihedral angles between the planes C6−C7−C8−C9−C10 and C1−C2−C3−C4−C5 at Fe1 and between the planes C30−C31−C32−C33−C34 and C25−C26−C27−C28−C29 at Fe3 are slightly larger at 6.6° and 7.6°, respectively. The ferrocenyl substituents on each ligand are *transoid*. The dihedral angles between the planes C6−C7−C8−C9−C10 and C10−C11−N1, C15−C16−C17−C18−C19 and C15−C14−N2, C39−C40−C41−C42−C43 and C39−C38−N4, and C30−C31−C32−C33−C34 and C34−C35−N3 are 4.2°, 14.6°, 26.3° and 10.6°, respectively, i.e., the ferrocenyl fragments are not coplanar with the L aldimine groups, unlike those in $[ZnCl_2(L)]$.[14] The intramolecular Ag1···Fe1, Ag1···Fe2, Ag1···Fe3, and Ag1···Fe4 distances are 4.772, 4.974, 4.813 and 5.011 Å, respectively, while the Fe1···Fe4, Fe1···Fe3, Fe2···Fe3, and Fe2···Fe4 distances are 6.634, 6.892, 7.153 and 6.977 Å, respectively.

The bond lengths and angles of the nitrate anion are as expected. The average N−O bond length is 1.132 Å, while the average intra-anion angle is 119.9°. The O2 and O3 atoms contribute to the packing by forming hydrogen bonds with crystallization molecules of methanol and ethanol, i.e. two hydrogen bonds arise from the interaction of the OH units in methanol and ethanol with O atoms of the nitrate anion (Figure 2).

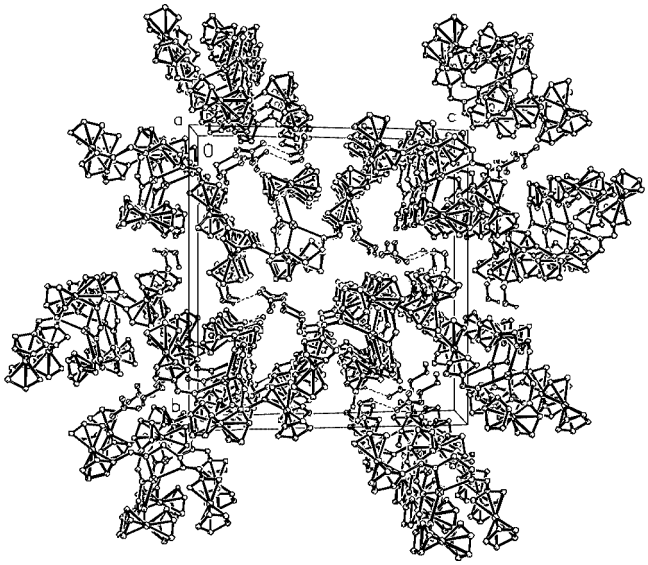

Figure 2. Crystal packing, viewed from the *a* axis, of $[Ag(L)_2](NO_3)\cdot(MeOH)\cdot(EtOH)$

Crystal Structure of $[HgI_2(L)]$ (2)

An X-ray diffraction analysis of **2** shows that a twofold axis exists in the molecular structure (Figure 3). The center Hg^{II} ion is coordinated by two nitrogen atoms of L and two iodine atoms, forming a distorted tetrahedral geometry, in contrast with the pseudo-tetrahedral zinc(II) center of $[ZnCl_2(L)]$.[14] The bond lengths of Hg−N and Hg−I are 2.392(6) and 2.6701(8) Å, respectively, which are close to

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

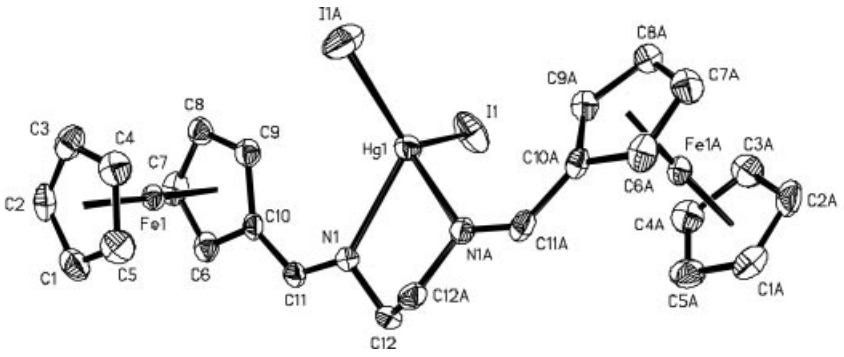

Figure 3. ORTEP drawing with atom-labeling scheme of $[HgI_2(L)]$

those of the reported coordination polymer $\{HgI_2[bpmp]_n\}$ [bpmp = *N*,*N*′-bis(4-pyridylmethyl)piperazine].[16] It is interesting that the acute N1−Hg1−N1A angle [74.5(3)°] was enforced by L as is the case for **1**. The widest bond angle around Hg1 is 128.29(4)°. Hence, the average bond angle at Hg^{II} is 107.5°, while the dihedral angle between the planes [Hg1, I1, I1A] and [Hg1, N1, N1A] is 76.7°. For $[ZnCl_2(L)]$ the reported N(1)−Zn(1)−N(2) bond angle is 84.3°, and the dihedral angle between [Zn(1), Cl(1), Cl(2)] and [Zn(1), N(1), N(2)] is 87.3°.

As with compound **1**, the ferrocenyl substituents are in a *transoid* arrangement and not coplanar with the L aldimine groups (the dihedral angle between the planes C6−C7−C8−C9−C10 and C10−C11−N1 is 11.0°). The cyclopentadienyl rings in each ferrocenyl fragment are planar and nearly parallel, with a dihedral angle of 2.2°. $Fe-C_{ring}$ distances range from 2.023(6) to 2.072(8) Å (average 2.04 Å) and intra-cyclopentadienyl C−C bond lengths lie in the range 1.400(12)−1.441(11) Å (average 1.42 Å); the C−C−C angles [average 108.0(5)°] of the ferrocenyl units are all similar to those reported in the literature.[15] The intermetallic distances Hg1···Fe1 and Fe1···Fe1A are 5.09 and 10.074 Å, respectively. The molecular packing is shown in Figure 4. The molecules are staggered, on viewing from the *c* axis, and the distance between neighboring Cp groups of different molecules is 3.622 Å, indicating π−π interactions. On the *ab* plane the molecules intercross.

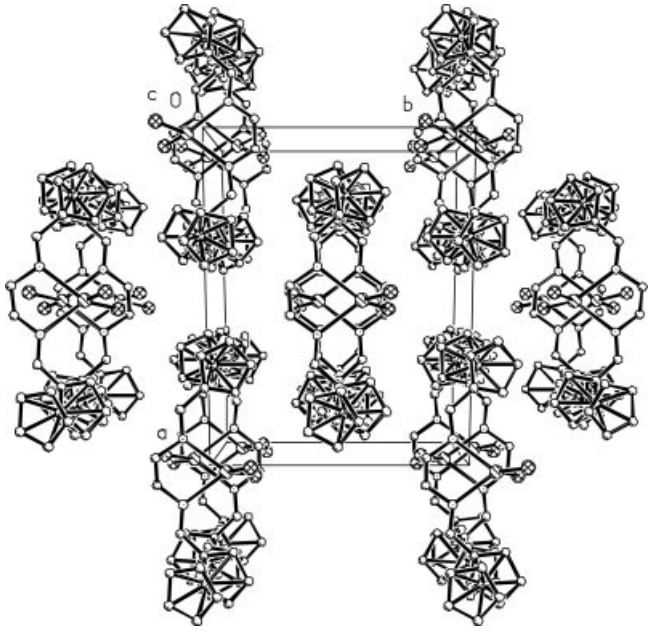

Figure 4. Crystal packing, viewed from the *c* axis, of $[HgI_2(L)]$

Spectroscopic Properties

The major IR peaks of the two compounds are consistent with the structural results. The characteristic IR bands of the ferrocenyl group at 3100 and 486 cm^{-1} due to ν(C−H) and ν(Fe−Cp) vibrations, respectively, are close to those of previously reported compounds.[11,15a] The imine stretching ν(C=N) shows a strong absorption at 1640 cm^{-1} in **1** and 1627 cm^{-1} in **2**. The strong absorption at 1384 cm^{-1} could be assigned to the N−O stretching mode of nitrate for **1**.

We found previously[17,18] that ferrocene exhibits two characteristic absorptions in the UV/Vis spectra at 440 nm (assigned to the $^1E_{1g}\leftarrow{}^1A_{1g}$ transition) and 325 nm (assigned to the $^1E_{2g}\leftarrow{}^1A_{1g}$ transition). Complexes **1** and **2** (in DMF) show three characteristic bands. The two absorptive peaks at 325 nm and 447 nm indicate a slight red-shift compared to free ferrocene. The effective bands at 275 nm of **1** and at 271 nm for **2** may be attributed to metal−ligand charge transfer (MLCT) transitions. Both compounds have a relatively low linear absorption, ranging from 500 to 1000 nm, promising low intensity loss and little temperature change due to photon absorption when light propagates in the materials.

The ^1H NMR spectra exhibit signals at δ = 8.49, 4.97, 4.53, 4.24−4.18, 3.72 ppm (for **1**) and 8.42, 4.83, 4.53, 4.30−4.27, 3.69 ppm (for **2**), which are similar to those of ligand L of δ = 8.19, 4.64, 4.36, 4.17, and 3.79 ppm.[12]

NLO Properties

The NLO determinations revealed that compounds **1** and **2** exhibit very strong nonlinear optical absorption and strong refractive effects.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

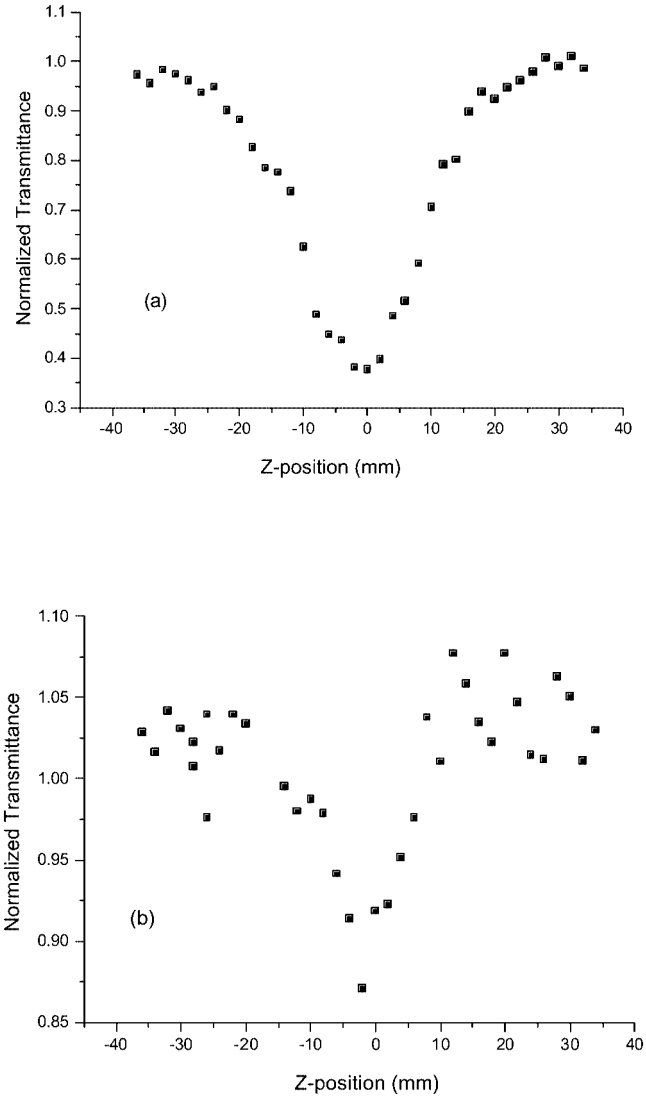

Figure 5. Data were collected under an open aperture configuration at 532 nm; (a; top) NLO absorptive behavior of $[Ag(L)_2](NO_3)\cdot(MeOH)\cdot(EtOH)$ in 8.5×10^{-4} mol·dm^{-3} DMF solution; (b; bottom) NLO absorptive behavior of $[HgI_2(L)]$ in 1.9×10^{-3} mol·dm^{-3} DMF solution

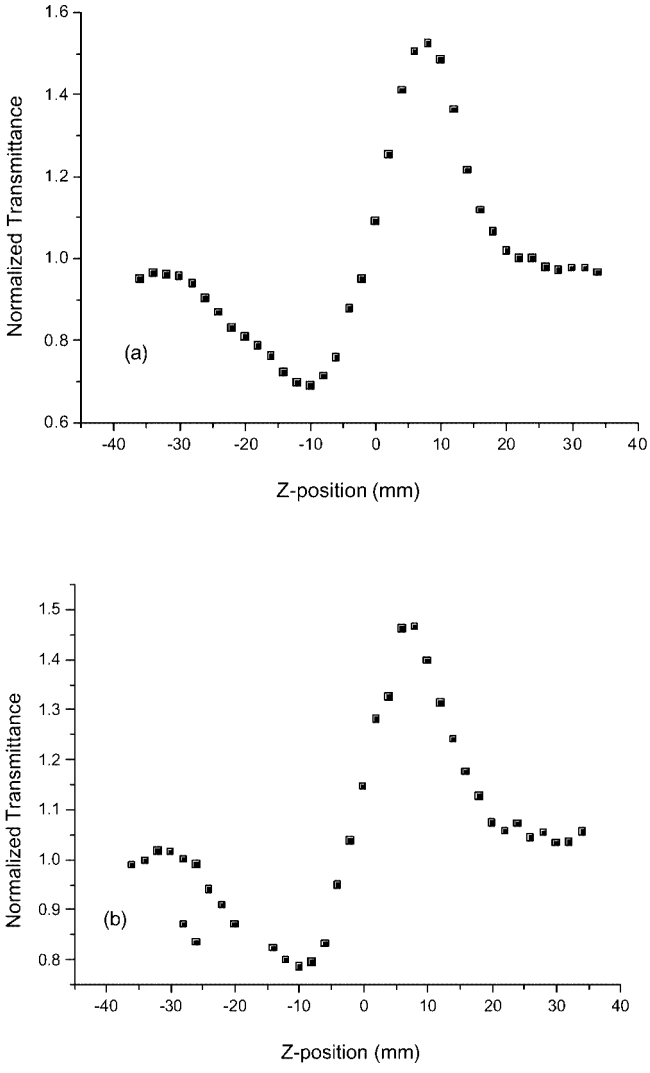

Figure 6. Data were assessed by dividing the normalized Z-scan data obtained under the closed aperture configuration by the normalized Z-scan data obtained under the open aperture configuration; self-focusing effects of (a; top) $[Ag(L)_2](NO_3)\cdot(MeOH)\cdot(EtOH)$ in 8.5×10^{-4} mol·dm^{-3} DMF solution at 532 nm and (b; bottom) $[HgI_2(L)]$ in 1.9×10^{-3}mol·dm^{-3} DMF solution at 532 nm

Figure 5(a and b) depict the NLO absorptive properties of complexes **1** and **2**, respectively. In Figure 5(a) the normalized transmittance drops to about 36% at the focus, showing that **1** has a strong NLO absorptive effect. The third-order NLO absorptive coefficient α_2 is 1.34×10^{-8} m W^{-1}. In Figure 5(b), the normalized transmittance of **2** drops to about 86% at the focus, and the corresponding α_2 value is 3.1×10^{-9} m W^{-1}. The NLO parameters of some known compounds are listed in Table 3, which shows that both **1** and **2** exhibit very strong NLO absorption, and that the α_2 values are larger than those of the reported compounds.[19−23]

Figure 6(a and b) give the NLO refractive effects of the two complexes; they have a similar positive sign for the refractive nonlinearity, which gives rise to self-focusing behavior. Figure 6(a) shows that the difference between valley-peak positions, $\Delta Z_{V\text{-}P}$, is 19 mm, and the difference between normalized transmittance values at valley and peak portions, $\Delta T_{V\text{-}P}$, is 0.86. The refractive index n_2 of **1** is calculated to be 1.15×10^{-18} m^2 W^{-1}. According to Figure 6(b), $\Delta Z_{V\text{-}P}$ and $\Delta T_{V\text{-}P}$ are 16 mm and 0.70, respectively, so that $n_2 = 8.02 \times 10^{-19}$ m^2 W^{-1} is obtained for **2**. Thus, both **1** and **2** have strong self-focusing behavior; similar refractive effects have been found for the clusters $MoCu_2OS_3(PPh_3)_3$, $WCu_2OS_3(PPh_3)_4$ and $W_2Ag_4S_8(AsPh_3)_4$.[20,23]

In accordance with the α_2 and n_2 values, the third-order susceptibility $\chi^{(3)}$ values can be calculated from $|\chi^{(3)}| = (|(9 \times 10^8 \varepsilon_0 n_0^2 c^2 \alpha_2)/2\nu|^2 + |c n_0^2 n_2/80\pi|^2)^{1/2}$. The $\chi^{(3)}$ values are 4.11×10^{-12} esu for **1** and 2.87×10^{-12} esu for **2**. From the discussions above, we can, reasonably, state that complexes **1** and **2** have similar NLO properties. Most high-performance NLO chromophores, organic polymers[24−30] and semiconductors[24−26] are neat materials. Impressive NLO values for ferrocenyl Schiff-base complexes are

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

achieved with a much diluted solution, and much superior NLO performance can be expected if the solubilities can be improved significantly. We can use the hyperpolarizability γ to represent the NLO properties of neat materials; $\gamma = \chi^{(3)}/NF^4$, where N is the number density of a ferrocenyl complex in the sample (in cm^{-3}), and $F^4 = 3$ is the local field correction factor. Thus γ for compounds **1** and **2** are calculated to be 2.68×10^{-30} and 1.44×10^{-30} esu, respectively.

Molecules possessing extensively conjugated π-electron systems exhibit large optical nonlinearities, especially third-order as described by the second hyperpolarizability, γ.[31] The γ values of aryl and vinyl of ferrocene increase strongly with the length of the conjugated π-electron system (ranging from $1.61 \pm 0.18 \times 10^{-35}$ to $1.550 \pm 0.270 \times 10^{-33}$ esu).[31] Compared with the ferrocene derivatives, the γ values of ferrocenyl complexes **1** and **2** are several orders of magnitude larger. A reasonable explanation for this is that the ferrocenyl Schiff-base ligands in the title complexes bearing extended conjugated systems can influence the optical nonlinearity, and the heavy transition metals (Ag, Hg and Fe) may contribute to the optical nonlinearity due to the tailorability of the metal−ferrocenyl ligand interactions. The γ values of our complexes are also similar to those of the ferrocenyl complexes 1,8-bis(ferrocenyl)octatetrayne[32] and NiL^2_2 and PdL^2_2 [L^2 = $FcC(CH_3)=N_2HCS_2CH_2C_6H_5$].[33] To our knowledge, there have been no reports on third-order NLO properties of diferrocenyl Schiff-base complexes. We believe that our explorations may provide a useful channel to seek new third-order NLO materials.

Experimental Section

General: All chemicals were of reagent-grade quality obtained from commercial sources and used without further purification. 1,2-Bis[(ferrocen-l-ylmethylene)amino]ethane (L) was prepared according to the literature method.[12] IR data were recorded with a Nicolet NEXUS 470-FTIR spectrophotometer with KBr pellets in the 400−4000 cm^{-1} region. UV/Vis spectra were performed with an HP 8453 spectrophotometer. Elemental analyses (C, H and N) were carried out with a Carlo−Erba1106 Elemental Analyzer. ^{1}H NMR spectra were recorded at room temperature with a Bruker DPX 400 spectrometer.

Synthesis of $[Ag(L)_2](NO_3)\cdot(MeOH)\cdot(EtOH)$ (1): A solution of L (90.3 mg, 0.20 mmol) in ethanol (3 mL) was added dropwise to a solution of $AgNO_3$ (17.0 mg, 0.10 mmol) in methanol (2 mL). The resulting solution was allowed to stand at room temperature in the dark. Dark-red crystals suitable for X-ray single crystals analysis were obtained over 24 h. Yield: 66.1 mg (61%). Crystals of **1** are unstable in the air. IR: $\tilde{\nu}$ = 2830 m, 1640 s, 1384 s, 1247 m, 1104 m, 1013 m, 819 m, 518 m, 510 m, 486 m cm^{-1}. $C_{51}H_{58}AgFe_4N_5O_5$ (1152.3): calcd. C 53.11, H 5.03, N 6.07; found C 52.45, H 4.80, N 6.21. ^{1}H NMR (400 MHz, DMSO): δ = 8.49 (s, 4 H, N=CH), 4.97 (s, 8 H, C_5H_4), 4.53 (s, 8 H, C_5H_4), 4.24−4.18 (s, 20 H, C_5H_5), 3.72(s, 8 H, CH_2).

Synthesis of $[HgI_2(L)]$ (2): L (90.3 mg, 0.20 mmol) in ethanol (3 mL) was slowly added to a solution of HgI_2 (45.60 mg; 0.1 mmol) in DMSO (2 mL) at room temperature. After allowing the resulting mixture to stand in the dark for 2 d, dark-red crystals of **2** suitable for X-ray structure determination were formed. Yield 52.2 mg (57%). **2** is air-stable. IR: $\tilde{\nu}$ = 1627 s, 1437 m, 1371 m, 1254 m, 1105 m, 1030 m, 820 m, 510 m, 487 m cm^{-1}. $C_{24}H_{24}HgFe_2N_2I_2$ (906.6): calcd. C 31.77, H 2.65, N 3.09; found C 32.04, H 2.78, N 2.93. ^{1}H NMR (400 MHz, DMSO): δ = 8.42 (s, 2 H, N=CH), 4.83 (s, 4 H, C_5H_4), 4.53 (s, 4 H, C_5H_4), 4.30−4.27 (s, 10 H, C_5H_5), 3.69(s, 4 H, CH_2).

X-ray Crystallographic Study: Crystal data and experimental details for compounds **1** and **2** are contained in Table 1. All measurements were made with a Rigaku RAXIS-IV imaging plate area detector with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). All data were collected at 291(2) K for **1** and 293(2) K for **2** using the ω-2θ scan technique and correction was applied for Lorenz polarization effects. A correction for secondary extinction was also applied. The two structures were solved by direct methods and ex-

panded using the Fourier technique. The non-hydrogen atoms were found by successive full-matrix least-squares refinement on F^2 and refined with anisotropic thermal parameters. Hydrogen atoms were included but not refined. All calculations were performed using the SHELX-97 crystallographic software package.[34] Selected bond lengths and bond angles are listed in Table 2. CCDC-178522 (**1**) and -178521 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

NLO Measurements: The third-order NLO properties were measured by the Z-scan technique[35] with a 532-nm laser pulse of 8 ns duration in a solution of 8.5×10^{-4} mol·dm^{-3} (for **1**) and 1.1×10^{-3} mol·dm^{-3} (for **2**) (the different concentrations are due to the different solubilities of the two complexes in DMF). The NLO absorption components were evaluated by a Z-scan experiment under an open-aperture configuration. Light transmittance (T) is a function of incident light irradiance $I_i(Z)$, nonlinear absorption [$\alpha_2 = \alpha_2(I_i)$], and linear absorption (α_0) as illustrated in Equations (1) and (2).[35b] The NLO absorption data of the two complexes can be well represented by Equations (1) and (2), where Z is the distance of the sample from the focal point; α_0 and α_2 are the linear and nonlinear absorption coefficients, respectively; L is the sample thickness (1 mm in this study); I_0 is the peak irradiation intensity at focus; $Z_0 = \pi\omega_0^2/\lambda$ where ω_0 is the spot radius of the laser beam at focus, and λ is the wavelength of the laser; r is the radial coordinate; t is the time; and t_0 is the pulse width.

$$T(Z) = \frac{1}{\sqrt{\pi}q(Z)} \int_{-\infty}^{+\infty} In[1+q(Z)]e^{-\tau^2} d\tau \quad (1)$$

$$q(Z) = \int_0^{\infty}\int_0^{\infty} \alpha_2 \frac{I_0}{1+(Z/Z_0)^2} e^{[-2(r/\omega_0)^2-(t/t_0)^2]} \frac{1-e^{-\alpha_0 L}}{\alpha_0} rdrdt \quad (2)$$

The NLO refractive effects were assessed by dividing the normalized Z-scan data obtained under the closed-aperture configuration by the normalized Z-scan data obtained under the open aperture configuration. An effective third-order NLO refractive index n_2 can then be derived by Equation (3), where $\Delta T_{V\text{-}P}$ and is the difference between normalized transmittance values at valley and peak positions; I is the peak irradiation intensity at focus. Table 3 gives the γ values of some reported NLO materials.

$$n_2 = \frac{\lambda\alpha_0}{0.812\pi I(1-e^{-\alpha_0 L})} \Delta T_{V-P} \quad (3)$$

Synthesis, Crystal Structure, and Electrical Properties of Novel Radical Cation Salts of Iodine-Substituted TTF-Derived Donors with the Nitroprusside Anion Exhibiting Strong -I···NC- Interactions

Kazumasa Ueda,*[a] Toyonari Sugimoto,[b] Christophe Faulmann,[a] and Patrick Cassoux[a]

Keywords: Cations / Radical ions / Fulvalenes / Conducting materials

Radical-cation salts of iodine-substituted TTF derivatives [diiodoethylenedithiotetrathiafulvalene (**1**) diiodoethylenedithiodiselenadithiafulvalene (**2**), or iodoethylenedithiotetrathiafulvalene (**3**)] with the $[Fe(CN)_5NO]^{2-}$ nitroprusside anion, namely, $\mathbf{1}_4$·$[Fe(CN)_5NO]$, $\mathbf{2}_4$·$[Fe(CN)_5NO]$ and $\mathbf{3}_3$·$[Fe(CN)_5NO]$, were synthesized by electrocrystallization from solutions of the appropriate TTF derivative in CH_2Cl_2 with bis(tetraphenylphosphonium)nitroprusside $[(PPh_4)_2\{Fe(CN)_5NO\}]$ as electrolyte. An X-ray structure analysis indicates that the crystal structures of $\mathbf{1}_4$·$[Fe(CN)_5NO]$ and $\mathbf{2}_4$·$[Fe(CN)_5NO]$ are very similar. In both cases, molecules **1** and **2** are stacked along the *c* direction, with their long molecular axis parallel to each other. By contrast, in $\mathbf{3}_3$·$[Fe(CN)_5NO]$, molecules **3** are stacked in triad units in which two of the molecules are arranged in a face-to-face fashion and the remaining molecule is arranged in a head-to-tail fashion with respect to its neighboring molecules. In all cases, several effective iodine-nitrogen contacts between donor molecules and $[Fe(CN)_5NO]^{2-}$ anions are observed. The room temperature electrical conductivities of $\mathbf{1}_4$·$[Fe(CN)_5NO]$, $\mathbf{2}_4$·$[Fe(CN)_5NO]$ and $\mathbf{3}_3$·$[Fe(CN)_5NO]$ are $<10^{-6}$, 2.2×10^{-2} and 5 S cm^{-1}, respectively. The temperature dependence of the electrical conductivity of $\mathbf{3}_3$·$[Fe(CN)_5NO]$ reveals semiconducting behavior with a small activation energy of 30 meV. The temperature dependence of the electrical conductivity of $\mathbf{2}_4$·$[Fe(CN)_5NO]$ also reveals a semiconducting behavior, but with two regimes: above 200 K the activation energy is 60 meV and becomes much smaller — 0.2 meV — below this temperature.

Introduction

Much current research is directed toward the formation of new molecular materials in which electrical conductivity coexists with other physical phenomena. One of the recent trends in this area is the combination of conducting and optical properties. In this area, the $[Fe(CN)_5NO]^{2-}$ anion ($[NP]^{2-}$) is of highest interest because it possesses extremely long-lived metastable states at low temperature that can be generated by laser irradiation.[1−6] It has been proposed that this electronic transition might be accompanied by possible changes in the geometry of the complex anion.[5] These changes may, in turn, affect the conducting properties of derived radical salts of organic donor molecules. In this context, the use of the $[NP]^{2-}$ anion and related transition metal mononitrosyl counteranions in radical cation salts of TTF- and TSF-derived donors (TTF = tetrathiafulvalene; TSF = tetraselenafulvalene) has been contemplated.[7−10] The existence of metastable states has indeed been detected in $(BEDT\text{-}TTF)_4$·$K[NP]_2$ [BEDT-TTF = bis(ethylenedithio)tetrathiafulvalene] and $(TTF)_7[NP]_2$ by DSC measurements,[10] but no effect of the above-mentioned changes of the geometry of the $[NP]^{2-}$ anion on the conducting behavior of these radical-cation salts has yet been observed. One, possibly more effective, approach for constructing novel photochromic organic conductors might consist of introducing a strong interaction between the donor molecules and the counteranions. In such systems, the changes in geometry of the excited states of the counteranions could affect the conducting properties more efficiently through stronger intermolecular interactions.

On the other hand, promoting a stronger interaction between the organic donor and the inorganic counteranions of radical salts is being investigated more and more for ensuring a better control of the molecular arrangement of these salts.[11−17] For example, radical salts of iodine-substituted TTF-derived donors such as diiodoethylenedithiotetrathiafulvalene (**1**) diiodoethylenedithiodiselenadithiafulvalene (**2**), or iodoethylenedithiotetrathiafulvalene (**3**) with cyano-group-containing anions such as $Ag[(CN)_2]^-$, $Pd[(CN)_4]^{2-}$, or with the $[Pd(mnt)_2]^{2-}$ anion (mnt = maleonitriledithiolate), have been synthesized and their crystal structures examined.[15−17] A PM3 MO calculation of **3** indicates a HOMO extended to the iodine atom. The largest

coefficient of the lowest unoccupied molecular orbital (LUMO) on the iodine atom suggests that it would be the driving force of the strong interactions with the cyano group. Extremely short I···N distances in the crystal structure of $\mathbf{3}_3$·[$Ag(CN)_4$], which are almost 20% shorter than the sum of the van der Waals radii (3.53 Å), arise from an interaction between the lone pair on the nitrogen atom and the p_π LUMO on the iodine atom.[15] In the crystal structure of $\mathbf{2}_4$·[$Pd(CN)_4$], reticulated donor···anion contacts were constructed using the strong and directional -I···NC- interaction.[16]

Combining both strategies, it was hoped that radical-cation salts of iodine-substituted organic donors and the $[NP]^{2-}$ anion could be organic conductors in which the existence of metastable states in the $[NP]^{2-}$ anion could affect the electrical conducting properties via possibly strong -I···NC- interaction.

Herein we report the synthesis, crystal structure and electrical conducting properties of novel radical-cation salts formed from the iodine-substituted donor molecules **1**, **2** and **3**, and the $[NP]^{2-}$ anion.

Results and Discussion

Synthesis

The iodine-substituted TTF-derived donors **1** and **3** were synthesized in accordance with the literature.[19] Compound **2** was synthesized by a modification of the method used for the preparation of **1** (see Exp. Sect.).

The salts $\mathbf{1}_4$·[$Fe(CN)_5NO$], $\mathbf{2}_4$·[$Fe(CN)_5NO$] and $\mathbf{3}_3$·[$Fe(CN)_5NO$], were synthesized by electro-crystallization from solutions of the appropriate iodine-substituted TTF-derived donors in CH_2Cl_2 with bis(tetraphenylphosphonium)nitroprusside [$(PPh_4)_2$·{$Fe(CN)_5NO$}] as electrolyte.

Crystal Structures

1_4·[NP] and 2_4·[NP]

These two compounds are isostructural. The asymmetric unit (Figure 1 and 2) contains two donor molecules and half an [NP] entity, with the Fe atom lying on a center of inversion.

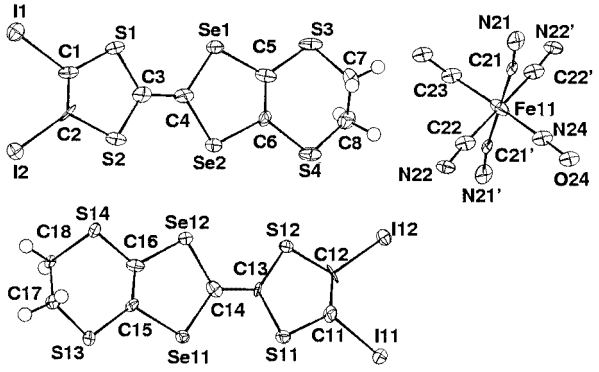

Figure 2. Atomic numbering scheme for $\mathbf{2}_4$·[NP]

Figure 3a and 3b show projections of the crystal structures of $\mathbf{1}_4$·[NP] and $\mathbf{2}_4$·[NP] down the *ab* plane. Their struc-

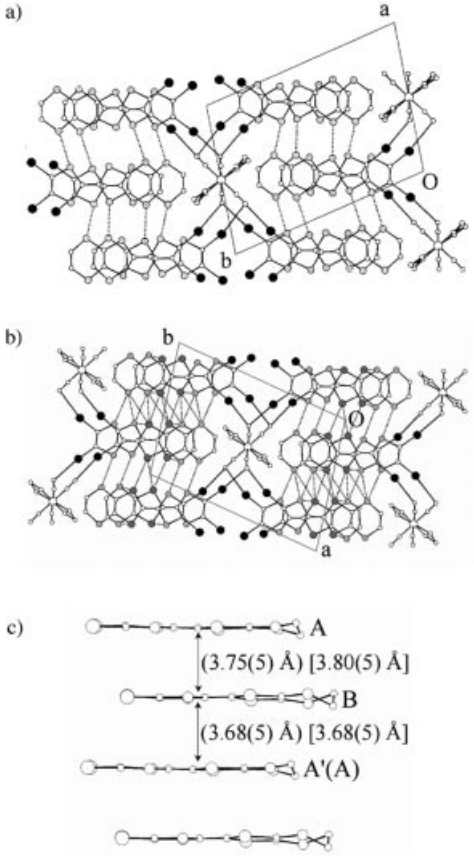

Figure 3. Projection down the *ab* plane for $\mathbf{1}_4$·[NP] (a) and $\mathbf{2}_4$·[NP] (b) and projection down the *bc* plane for both compounds (c). In Figure 3a and 3b, iodine, sulfur and selenium atoms are depicted with filled, light grey and dark grey circles, respectively. Thin dotted and solid lines show chalcogen-chalcogen and iodine-nitrogen intermolecular contacts, respectively

tures consist of sheets of adjacent columns of donor molecules in the *ac* plane alternating with layer of anions along the *b* direction (Figure 3a and 3b). The donor molecules stack along the *c* direction, with their long molecular axis parallel to each other (Figure 3c). The inter-planar distances are 3.78(3) and 3.65(3) Å for $\mathbf{1}_4$·[NP], and 3.72(5) and 3.76(5) Å for $\mathbf{2}_4$·[NP] i.e., rather longer than the "π-cloud thickness".[18]

Since the $[NP]^{2-}$ ions are located at a center of symmetry, there is a positional disorder in the NO^+ and CN^- ligands. Two kinds of overlapping mode [**A/B** and **B/A′(A)**] are observed in $\mathbf{1}_4$·[NP], as shown in Figure 4, as well as in $\mathbf{2}_4$·[NP] (not shown).

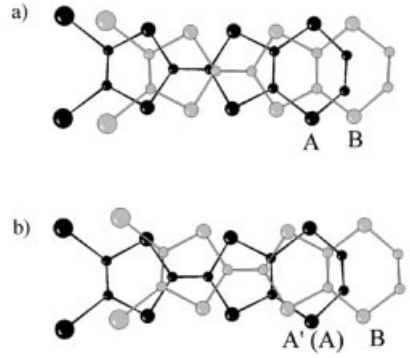

Figure 4. Modes of overlap of molecules **1** in $\mathbf{1}_4$·[NP]: (a) **A** and **B**, and (b) **B** and **A′(A)**

In both overlapping modes one molecule is stacked over the other molecule with a ring-over-bond type mode, since the molecules are slipped along their long axis.

Moreover, in $\mathbf{1}_4$·[NP], some effective side-by-side contacts are observed between donor molecules of adjacent columns. Indeed, interatomic distances rather shorter than the sum of the van der Waal's radii (3.70 Å) are observed between sulfur atoms of the ethylenedithio group and of the TTF moiety [S6···S11: 3.497(6); S2···S15: 3.536(6); S1···S16: 3.541(7); S14···S16: 3.601(8); S1···S5: 3.632(7) Å].

Even more importantly, several short contacts between the donor **1** and the $[NP]^{2-}$ anion through -I···NC- contacts are also observed, as indicated by several interatomic distances between iodine atoms of **1** and nitrogen atoms of the $[NP]^{2-}$ anion [I1···N22: 3.08(2); I2···N21: 3.11(1); I11···N22: 3.08(1); I12···N21: 3.25(2) Å], which are shorter than the sum (3.53 Å) of the van der Waals radii of the iodine and nitrogen atoms.

Due to the presence of Se atoms, $\mathbf{2}_4$·[NP] exhibits more contacts than $\mathbf{1}_4$·[NP]. The interaction between adjacent columns is accomplished through contacts between different sulfur atoms [S1···S1: 3.70(1); S2···S14: 3.59(1); S3···S11: 3.67(1); S4···S12: 3.55(1) and S11···S13: 3.66(1) Å], as well as between sulfur and selenium atoms [Se1···S3: 3.58(1) Å] and different selenium atoms [Se1···Se11: 3.67(1); Se2···Se2: 3.83(1); Se2···Se12: 3.67(1) and Se11···Se11: 3.77(1) Å], shorter than the sum of the corresponding van der Waals radii of the corresponding chalcogen atoms (3.70 Å for S···S, 3.80 Å for S···Se, and 3.90 for Se···Se). In addition, as for $\mathbf{1}_4$·[NP], several short interatomic distances [I1···N22: 3.25(3); I2···N21: 3.07(3); I11···N21: 3.07(3); I12···N22: 3.10(2) Å] are observed between the iodine atoms of **2** and nitrogen atoms of the $[NP]^{2-}$ anion.

$\mathbf{3}_3$·[NP]

The asymmetric unit (Figure 5) of $\mathbf{3}_3$·[NP] contains half an [NP] entity, with the Fe atom lying on a center of inversion, and two molecules of the donor **3**, among which one of the donor molecules (the one containing I11) has an occupancy of one half, since it is placed close to an inversion center.

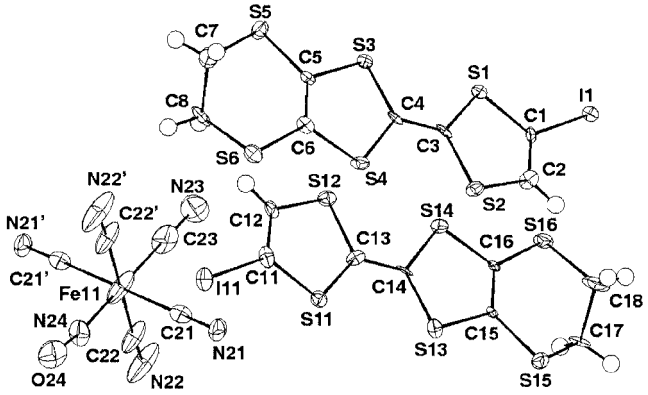

Figure 5. Atomic numbering scheme for $\mathbf{3}_3$·[NP]

Figure 6a and 6b shows the projections of the crystal structure down to the *bc* and *ab* planes. The structure consists of sheets of columns of **3** in the *ac* plane alternating with layers of $[NP]^{2-}$ anions along the *b* direction.

As shown in Figure 6b and 6c, the donor molecules **3** are stacked in a triad arrangement, ···**ABAABA**···. A **B** molecule is close to the center of symmetry, depicted as the gray circle, resulting in two orientations of the **B** molecule (**B** and **B′** generated by a symmetry operation of **B**) within a triad. Because of these two orientations of **B** molecules within the triad, there are two kinds of stacking mode: one of type **I** (shown at the top of Figure 6b and 6c), and the other of type **II** (shown at the bottom of Figure 6b and 6c). In the triad unit, two of the three molecules **3** (**A** and **B**) (type **I**), or **B′** and **A′′′** (type **II**) are arranged in a face-to-face fashion, whereas the remaining molecule (**A′** in type **I** and **A′′** in type **II**) is arranged in a head-to-tail fashion with respect to the **B** molecule (type **I**) or **B′** (type **II**). The inter-planar distances are 3.63(5) Å between the face-to-face molecules and 3.57(5) Å between the head-to-tail ones. The inter-planar distances are slightly longer than the "π-cloud thickness" (3.50 Å), but the [**A′/A"**] inter-planar distance between the triads is rather shorter [3.07(5) Å]. Figure 7a shows the overlap between the face-to-face molecules (**A** and **B** in mode **I**, or **B′** and **A′′′** in mode **II**). In this mode, **A** and **B** molecules are slipped transversally, resulting in a partial overlap of both molecules, but without any short S···S contacts.

In the head-to-tail mode (Figure 7b and **B/A′** or **A′′/B′** in Figure 6b and 6c), the molecules are slipped longitudinally,

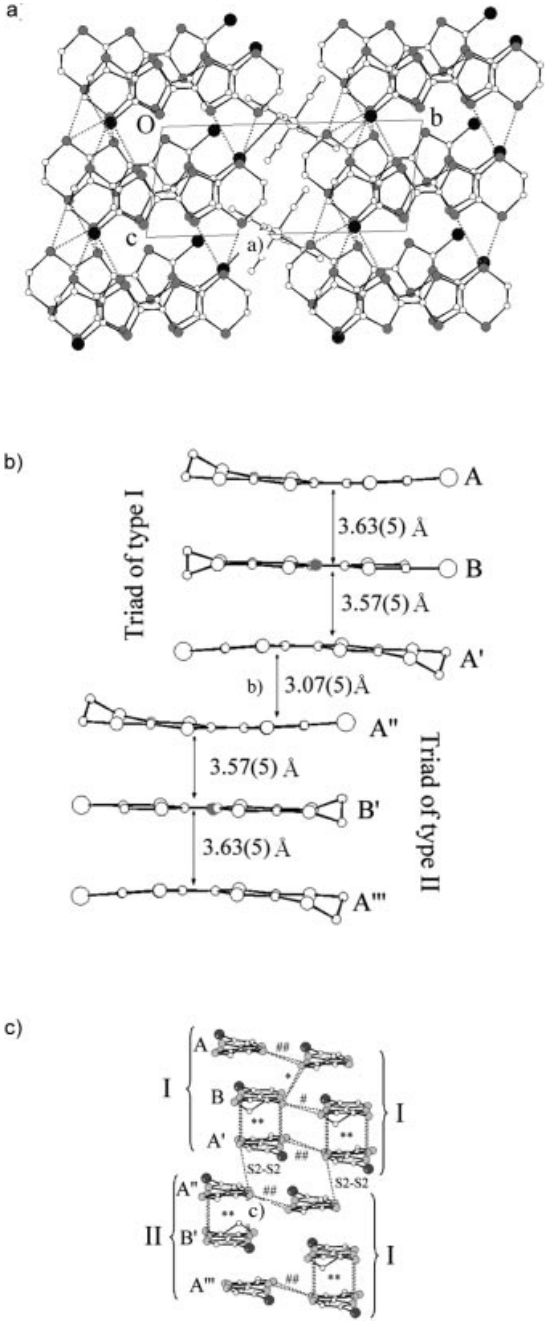

Figure 6. (a): Projection down the *bc* plane of $\mathbf{3}_3$·[NP]. Iodine and sulfur atoms are depicted with filled and grey circles, respectively. Dotted and solid lines show sulfur-sulfur and iodine-nitrogen contacts, respectively. (b): Projection down the *ab* plane showing the stacking modes of type **I** and **II** (the center of inversion is depicted as the grey circle). (c): Projection down the *ac* plane showing the S···S contacts between triads of type **I** and **II** (see text for the meaning of the symbols)

resulting in a ring-over-bond type overlap between these molecules. This configuration leads to several S···S contacts, depicted with the symbol ** in Figure 6c [S1···S14: 3.650(7); S2···S13: 3.43(3); S3···S12: 3.489(7) and S4···S11: 3.586(8) Å]. By contrast, the overlap between **A**′ and **A**′′ molecules belonging to different triads is minimal (one sulfur atom over a dithiacyclopentene ring; Figure 7c). **A**′ and **A**′′ are connected through one contact between the S2 atoms

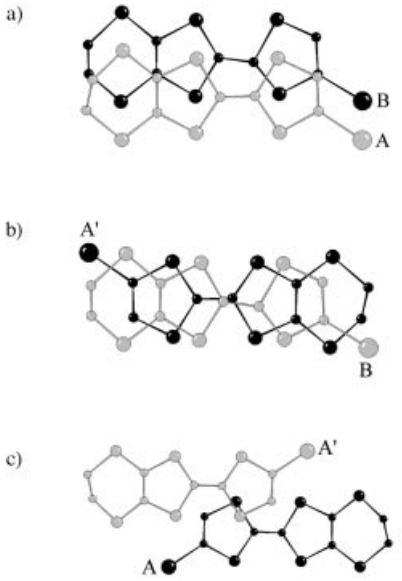

Figure 7. Modes of overlap in $\mathbf{3}_3$·[NP] between **A**/**B** (a), **B**/**A**′ (b), and **A**′/**A**′′ (c)

[3.502(4) Å]. Effective side-by-side contacts between sulfur atoms of adjacent triads are observed between **A** molecules [symbol ## in Figure 6c: S3···S6: 3.566(4); S5···S6: 3.427(5) Å], between **A** and **B** molecules [symbol * in Figure 6c: S3···S16: 3.551(7); S5···S16: 3.677(8) Å], and between **B** molecules when the adjacent triad is of the same nature [symbol # in Figure 6c: S13···S16: 3.49(1) and S15···S16: 3.37(1) Å]. Also, effective contacts between donor molecules and $[NP]^{2-}$ anions are observed, as indicated by short interatomic distances between the iodine atom of molecule **3** and nitrogen atoms of the $[NP]^{2-}$ anion [N21···I1: 2.93(1) and N22···I11: 3.51(2) Å].

In these three obtained salts, the I···N distances between the donor molecules and $[NP]^{2-}$ counterion are 8−18% shorter than the sum of the van der Waals radii of iodine and nitrogen atoms. These values indicate the existence of a strong interaction between the iodine atom of the donor molecules and a cyano group of the $[NP]^{2-}$ counterion. This strong interaction arises from an interaction between the lone pair on the nitrogen atom and the σ_p-LUMO on the iodine atom as is seen in the crystals of $\mathbf{3}_2$·$[Ag(CN)_2]$ and $\mathbf{2}_4$·$[Pd(CN)_4]$.[15,16]

Electrical Conductivity

The electrical conductivities of $\mathbf{1}_4$·[NP], $\mathbf{2}_4$·[NP] and $\mathbf{3}_3$·[NP] at room temperature are $<10^{-6}$, 2.2×10^{-2} and 5 S cm^{-1}, respectively. It should be noted that, although the structures of $\mathbf{2}_4$·[NP] and $\mathbf{1}_4$·[NP] are similar, the conductivity value determined for $\mathbf{2}_4$·[NP] is 10^4 times larger than that determined for $\mathbf{1}_4$·[NP]. This difference is likely to be due to the larger van der Waals radius of the selenium atom (2.00 Å), compared to that of the sulfur atom (1.85 Å), which induces interactions within the stack of $\mathbf{2}_4$·[NP] that are not observed in $\mathbf{1}_4$·[NP].

The temperature dependence of the resistivity was measured for $\mathbf{2}_4$·[NP] and $\mathbf{3}_3$·[NP] (Figure 8). In both cases the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

resistivity increases with decreasing temperatures, indicating a semiconducting behavior. In the case of $\mathbf{3}_3$·[NP], a small activation energy of 30 meV could be determined over the entire range (300−50 K) of temperatures. In contrast, two regimes are observed for $\mathbf{2}_4$·[NP]: from 293 K down to around 200 K the activation energy is 60 meV, and below 200 K a much smaller activation energy of 0.2 meV is found. The electrical conducting properties of these three salts can be readily understood by considering their crystal structures. The interplanar distances of **1** and **2** molecules in their columns are rather longer than the "π-cloud thickness". This means that the large interplanar distances between molecules suppress an effective overlap of the π-orbital of the donor molecules along the stacking direction. As a result of this unfavorable π-orbital interaction, these two salts have comparably low conducting behaviors. On the other hand, the semiconducting property of $\mathbf{3}_3$·[NP] can be reasonably understood by considering that the column structure is triadic and not uniform.

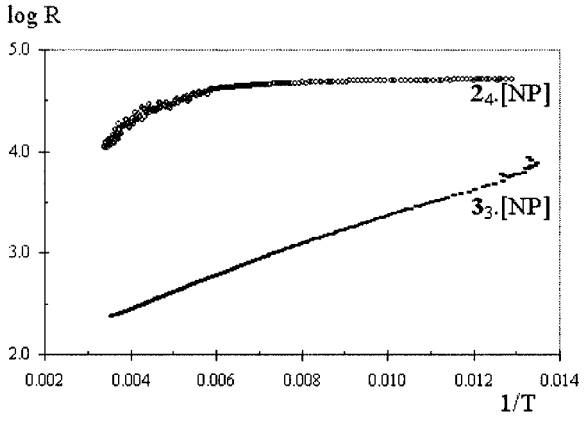

Figure 8. Temperature dependence of the resistance of single crystals of $\mathbf{2}_4$·[NP] (°) and $\mathbf{3}_3$·[NP] (−)

Conclusion

The synthesis, crystal structures and electrical conductivities of three new radical salts $\mathbf{1}_4$·[NP], $\mathbf{2}_4$·[NP] and $\mathbf{3}_3$·[NP] have been described. Both $\mathbf{2}_4$·[NP] and $\mathbf{3}_3$·[NP] are semiconductors, but two regimes, with a very low activation energy at low temperatures, are observed only for $\mathbf{2}_4$·[NP]. Although the structures of $\mathbf{2}_4$·[NP] and $\mathbf{1}_4$·[NP] are very similar, the only-sulfur containing $\mathbf{1}_4$·[NP] is an insulator with a room-temperature conductivity 10^4 times smaller than that of the sulfur-selenium containing $\mathbf{2}_4$·[NP].

The strategy of using iodine-substituted organic donors for promoting stronger donor-counteranion interaction actually led in the three salts studied here to effective contacts between the donor molecules and the $[NP]^{2-}$ anions. This is the first example in which donor molecules are connected with $[NP]^{2-}$ anions through strong and directional interactions of the -I···NC- type.

The detection of long-lived metastable states at low temperature generated by laser irradiation and conductivity measurements under irradiation remain to be carried out and are under progress.

Experimental Section

General Remarks: ^{1}H NMR spectra were recorded in $CDCl_3$ on a Bruker AC200 spectrometer. Chemical shifts are quoted relative to the residual solvent peak ($CDCl_3$: δ = 7.26 ppm). Mass spectra were recorded on a NERMAG R10-10 mass spectrometer operating in the DCI mode.

Synthesis of 2: Compound **2** was synthesized by a modification of the method used for the preparation of **1**.[19] A solution of 4,5-ethylenedithio-1,3-diselenol-2-one (217.9 mg, 0.7212 mmol) and 4,5-diiodo-2-thioxo-1,3-dithiole (556.8 mg) in toluene (20 mL) containing freshly distilled $P(OEt)_3$ (2.7 mL) was refluxed for 6 h. After removal of the solvent under reduced pressure a dark brown residue was obtained. This residue was purified by chromatography on silica gel using carbon disulfide (CS_2) as eluent to afford **2** (33.9 mg, 72% yield) which was recrystallized from CS_2/hexane. M.p. 173 °C. MS (DCI/NH_3): m/z = 643 [M^+] ^{1}H NMR ($CDCl_3/CS_2$): δ = 3.31 ppm.

Electrocrystallization of $\mathbf{1}_4$·[NP], $\mathbf{2}_4$·[NP] and $\mathbf{3}_3$·[NP]: Single crystals of $\mathbf{1}_4$·[NP], $\mathbf{2}_4$·[NP] and $\mathbf{3}_3$·[NP] were prepared by galvanostatic oxidation of the donor molecules (7.2 mg of **1** for $\mathbf{1}_4$·[NP], 9.1 mg of **2** for $\mathbf{2}_4$·[NP] and 3.8 mg of **3** for $\mathbf{3}_3$·[NP]) with $(Ph_4P)_2$[NP] (62 mg for $\mathbf{1}_4$·[NP] and $\mathbf{2}_4$·[NP], and 40 mg for $\mathbf{3}_3$·[NP]) as supporting electrolyte in CH_2Cl_2 (20 mL) under an argon atmosphere at 25 °C. A standard H-shaped cell and platinum-wire electrodes (1 mm diameter) were employed for the preparation of single crystals, applying constant currents (0.6 μA mg for $\mathbf{1}_4$·[NP] and $\mathbf{2}_4$·[NP], and 0.2 μA for $\mathbf{3}_3$·[NP]). Crystals were formed in the anode compartment, collected and washed with CH_2Cl_2: orange platelet-shaped crystals for $\mathbf{1}_4$·[NP], brown platelet-shaped crystals for $\mathbf{2}_4$·[NP], and black needle-shaped crystals for $\mathbf{3}_3$·[NP]. The composition of $\mathbf{1}_4$·[NP], $\mathbf{2}_4$·[NP] and $\mathbf{3}_3$·[NP] was determined by X-ray structure analyses.

X-ray Crystallographic Study: The X-ray diffraction data were collected at 180 K for $\mathbf{1}_4$·[NP] and $\mathbf{2}_4$·[NP], and 160 K for $\mathbf{3}_3$·[NP] on a STOE imaging plate diffractometer with graphite monochromated Mo-K_α radiation (λ= 0.71069 Å). Crystallographic data are gathered in Table 1.

The structures were solved by direct methods (SHELXS 97)[20] and refined on F_0^2 with full-matrix least-squares analysis. The calculations were carried out with the CRYSTALS[21] and WINGX[22] package programs running on a PC. For $\mathbf{1}_4$·[NP], the final cycle of least-squares refinement on F_0^2 for 5771 data and 367 parameters converged to $wR^2(F_0^2)$ = 0.231 for all data and to R = 0.075 for 3117 data with $I \geq 2\sigma(I)$. For $\mathbf{2}_4$·[NP], the final cycle of least-squares refinement on F_o^2 for 5888 data and 358 parameters converged to $wR^2(F_0^2)$ = 0.237 for all data and to R = 0.090 for 1915 data with $I \geq 2\sigma$ (I). For $\mathbf{3}_3$·[NP], the final cycle of least-squares refinement on F_o^2 for 3948 data and 349 parameters converged to $wR^2(F_0^2)$ = 0.181 for all data and to R = 0.072 for 3420 data with $I \geq 2\sigma(I)$. The drawings of the molecular structures were produced using CAMERON.[23] The atomic scattering factors were taken from International Tables for X-ray Crystallography.[24]

CCDC-193065−193067 ($\mathbf{1}_4$·[NP], $\mathbf{2}_4$·[NP]$\mathbf{3}_4$·[NP], respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Polymeric, Molecular, and Cation/Anion Arrangements in Chloro-, Bromo-, and Iododiruthenium(II,III) Carboxylate Compounds

M. Carmen Barral,[a] Rodrigo González-Prieto,[a] Reyes Jiménez-Aparicio,*[a] J. Luis Priego,[a] M. Rosario Torres,[b] and Francisco A. Urbanos[a]

Keywords: Carboxylate / Diruthenium / Metal−metal bonds / Multiple bonds / Ruthenium

The synthesis and characterization of the anhydrous compounds $[Ru_2X(\mu\text{-}O_2CR)_4]$ [R = CH_2CH_2OPh, X = Cl (**1a**), Br (**2a**), I (**3a**); R = $CMePh_2$, X = Br (**5a**), I (**6a**)] and of the solvated complexes $[Ru_2X(\mu\text{-}O_2CR)_4(H_2O)]$ [R = CH_2CH_2OPh, X = Cl (**1b**), I (**3b**); R = $CMePh_2$, X = Cl (**4b**), Br (**5b**), I (**6b**)] are described. Thermogravimetric analyses have been used to confirm the anhydrous or solvated natures of the complexes. The crystal structures of **1b·2MeOH**, **3b·0.5H$_2$O**, and **4b** have been investigated by X-ray diffraction and none of them shows the usual polymeric arrangement reported for tetracarboxylatodiruthenium(II,III) compounds. The structure of **3b·0.5H$_2$O** consists of cationic and anionic units, $[Ru_2(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)_2][Ru_2I_2(\mu\text{-}O_2CCH_2CH_2OPh)_4]$, and represents the first reported crystal structure of a tetracarboxylato(iodo)diruthenium(II,III) derivative. The structures **1b·2MeOH** and **4b** each show the presence of discrete dinuclear molecules. The crystal structure of $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ demonstrates that diruthenium compounds with the same halide and carboxylate ligands may adopt polymeric or discrete molecular dispositions. Magnetic susceptibility measurements of the complexes in the 2–300 K range have been carried out. Complex **2a** shows a strong antiferromagnetic coupling, consistent with the existence of linear chains in the solid state. The complexes $[Ru_2X(\mu\text{-}O_2CR)_4(H_2O)]$ show weak through-space antiferromagnetic coupling, in accordance with non-polymeric structures. The magnetic behaviour of **1a**, **3a**, **5a**, and **6a** suggests a mixture of arrangements.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Since the synthesis of $[Ru_2Cl(\mu\text{-}O_2CMe)_4]$ was first published,[1] numerous diruthenium(II,III) complexes of the formula $[Ru_2Cl(\mu\text{-}O_2CR)_4]$ (R = alkyl, aryl) have been described.[2−4] These complexes have attracted much attention, mainly due to interest in their electronic and magnetic properties.[2−4] More recently, many efforts have been devoted to the use of carboxylate complexes with metal−metal bonds as building blocks in the formation of supramolecular metallospecies.[5−8] In the $[Ru_2Cl(\mu\text{-}O_2CR)_4]$ compounds, the diruthenium atoms are strongly bonded by four bridging carboxylate ligands, with one axial position occupied by one chlorine atom. In the solid state, most of them have polymeric structures with chloride ligands bridging the dinuclear units to give zigzag chains.[9−15] A similar structure with linear chains with four carboxylate ligands has been found.[16−19] Discrete dinuclear molecules in which a neutral ligand is coordinated to one of the axial positions have also been described,[20−22] as has a unique example showing zigzag chains made up jointly of cationic and anionic units.[13] The different arrangements observed in the diruthenium complexes are collected in Scheme 1.

The influence of the carboxylate ligand on the polymeric or molecular nature of the diruthenium complexes has been investigated and seems to be related to the presence of branched chains in the carboxylate ligand.[21,22] Few bromo and iodo derivatives have been reported,[23,24] and the influence of the halogen axial ligand on the structure has not been studied. $[Ru_2Br(\mu\text{-}O_2CH)_4]$ is the sole example of this kind of compounds whose crystal structure has been reported.[23]

In this paper we investigate the possibility of obtaining both discrete molecules and polymeric species with the same carboxylate ligand. The ligands 3-phenoxypropionate and 2,2-diphenylpropionate have been used. The preparation of new chloro, bromo, and iodo derivatives has been carried out and the influence of the halogen axial ligand on the arrangement of the complexes explored.

Results and Discussion

Synthesis and Physicochemical Properties of the Compounds

The complex $[Ru_2Cl(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ (**1a**) was prepared by treatment of $[Ru_2Cl(\mu\text{-}O_2CMe)_4]$ with 3-phenoxypropionic acid in methanol/water (1:1). Two metathesis cycles were carried out to ensure the complete replacement of the acetate ligands. $AgBF_4$ was added to a solution of **1a** in THF in order to obtain $[Ru_2(\mu\text{-}O_2CCH_2CH_2OPh)_4(THF)_2]BF_4$, which was treated in ethanol with an aqueous solution of KBr to produce the precipitation of $[Ru_2Br(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ (**2a**). The synthesis of $[Ru_2I(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)]$ (**3b**) was carried out by using KI in place of KBr. The hydrate $[Ru_2Cl(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)]$ (**1b**) was obtained from a methanol solution of **1a**. The unsolvated $[Ru_2I(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ (**3a**) was prepared by prolonged heating of **3b** under vacuum. Attempts to obtain the analogous hydrated $[Ru_2Br(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)]$ gave the polymeric **2a** in all cases.

Treatment of $[Ru_2Cl(\mu\text{-}O_2CMe)_4]$ with 2,2-diphenylpropionic acid in methanol/water (1:1) produced $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (**4b**). The previously described compound $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4]$[18] crystallized when petroleum ether was added to a solution of **4b** in CH_2Cl_2. The complexes $[Ru_2X(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ [X = Br (**5b**), I (**6b**)] were obtained from $[Ru_2(\mu\text{-}O_2CCMePh_2)_4(THF)_2]BF_4$ and KBr or KI. The unsolvated **5a** and **6a** were prepared by heating **5b** and **6b**, respectively, under vacuum.

The cleavage of the polymeric chains of **1a**−**6a** by donor solvent molecules occurs in all cases except for that of the complex **2a**. The presence of coordinated water molecules in the complexes was inferred from analytical, IR, and thermogravimetric data.

Crystals of **1b·2MeOH** were formed by cooling of (−18 °C) methanol solutions of **1a** or **1b**. After several unsuccessful attempts to obtain crystals of the bromo and iodo derivatives, single crystals of **3b·0.5H$_2$O** suitable for an X-ray crystal structure analysis grew from a methanol solution containing $[Ru_2(\mu\text{-}O_2CCH_2CH_2OPh)_4]^+$ and I^- over 48 h. Single crystals of **4b** were obtained by the same procedure from a solution containing $[Ru_2(\mu\text{-}O_2CCMePh_2)_4]^+$ and Cl^-.

The chloro complexes are quite soluble in polar organic solvents such as methanol or THF, but insoluble in petroleum ether or toluene. The solubilities of complexes **1**−**6** in polar organic solvents decrease along the series Cl, Br, and I, the iodo derivatives being only partially soluble in these solvents. The conductivities of these compounds in methanol (ca. 10^{-4} M) indicate that they are 1:1 electrolytes in this solvent.[25] The process of dissolution of the polymeric complexes **1a** and **3a**−**6a** in donor solvents results in the cleavage of the chains, giving discrete dinuclear units. Thus, from MeOH/H_2O solutions, molecular $[Ru_2Cl(\mu\text{-}O_2CR)_4(H_2O)]$ complexes have been obtained.

Spectroscopic Properties

The IR spectra of all compounds show the pattern typical of bridging carboxylate ligands in the COO stretching region.[4] Other bands corresponding to the carboxylate ligands and attributable to CH or phenyl groups are also observed. The IR spectra of **1b** and **3b**−**6b** clearly show absorption bands due to the presence of water molecules.

The electronic spectra of all compounds in methanol are similar to those of other diruthenium(II,III) complexes,[2] showing two bands in the UV/Vis range at ca. 430 and ca. 290 nm and attributable to $\pi(RuO, Ru_2)\rightarrow\pi^*(Ru_2)$ and π(axial ligand)$\rightarrow\pi^*(Ru_2)$ transitions, respectively, as proposed by Norman et al.[26] and by Miskowski and Gray.[27] All complexes also absorb in the near infrared region at ca. 1000 nm, due to a $\delta\rightarrow\delta^*$ transition.[28]

Thermogravimetric Studies

The thermogravimetric curves of the hydrated complexes **1b** and **3b**−**6b** each show weight loss between 145 and 210 °C, corresponding to one water molecule per complex. The assumption that this water molecule is bonded to one axial position of the diruthenium complexes was confirmed by the crystal structure determinations of **1b·2MeOH**, **3b·0.5H$_2$O** and **4b**. In a further experiment, the thermal decomposition of each compound was interrupted after the release of the water molecule, and their IR spectra were identical to those of the corresponding $[Ru_2X(\mu\text{-}O_2CR)_4]$ species. Moreover, the anhydrous complexes do not display any weight loss before 250 °C. The loss of the halide ligand for **1a**, **2a**, **3b**, and **6b** is clearly observed in the 250−290 °C range, followed by the loss of the carboxylate groups in two steps. The thermogravimetric curves for the other compounds show that the release of the halide and of the first

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

two carboxylate ligands takes place at the same time. These data are in accordance with previous studies[29] on the thermal decomposition of pentakis(alkanoato)diruthenium(II,III) complexes.

Magnetic Properties

Magnetic measurements on compounds **1**−**6** at room temperature each show magnetic moments of 3.86−4.18 μ_B, corresponding to the presence of three unpaired electrons per dimer unit.[2] These magnetic moments are in accordance with the $\sigma^2\pi^4\delta^2(\pi^*\delta^*)^3$ ground-state configuration proposed by Norman et al.[26] In all complexes the molar susceptibility χ_M increases continuously with decreasing temperature (300−2 K), except for complexes **1a** and **2a**. The magnetic moment in all cases exhibits a pronounced decrease with temperature. This behaviour has been ascribed to a large zero-field splitting (ZFS) and some degree of antiferromagnetic coupling between the diruthenium units.[14,15,18,30−33] The model of Cukiernik et al.[14] was successfully used to fit the magnetic data of complexes **1b** and **3b**−**6b**. In this model, we used the isotropic *g* parameter instead of $g_\parallel$ and $g_\perp$ in order to reduce the number of parameters and to obtain more accurate values of *D* and *zJ*. Figure 1 shows the experimentally measured and calculated curves for complex **4b** by this model. Similar fits are obtained for the complexes **1b** and **3b**−**6b**.

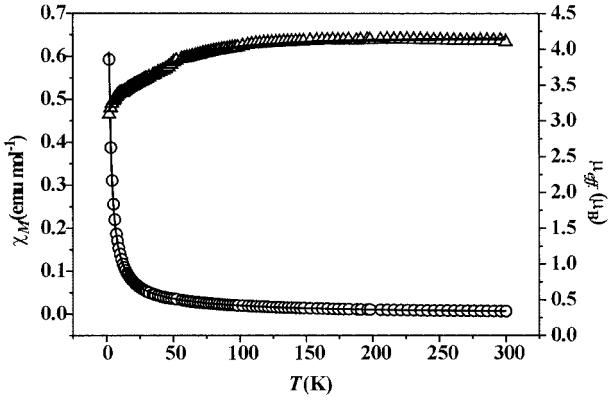

Figure 1. Temperature dependence of the molar susceptibility χ_M (circles) and $\mu_{eff.}$ (triangles) for complex **4b**; solid lines are the product of a least-squares fit to the model indicated in the text

Table 1 collects the calculated magnetic parameters (*g*, *D*, *zJ*, *TIP*, and *P*) for the complexes **1b**−**6b**, together with σ^2, which indicates the quality of the fits. All compounds show large zero-field splittings and low antiferromagnetic coupling values. The *D* values range from 50.60 to 64.72 cm^{-1}, similarly to those found previously for the analogous compounds.[8d,14,15,33−35] The molecular nature of the solvates **1b**−**6b** is in accordance with the low values (−0.04 to −1.33 cm^{-1}) of the antiferromagnetic coupling constants. Similar spin exchange by through-space pathways has recently observed in other molecular diruthenium complexes.[15]

Figure 2 displays the variation of the magnetic susceptibility with temperature for complex **2a**. A maximum is observed at 30 K. The paramagnetic tail and the turning point have been observed previously[18,33] in diruthenium(II,III) complexes with linear chain structures (Ru−Cl−Ru angle ca. 180°). In these cases strong antiferromagnetic coupling between the diruthenium(II,III) units through chlorine atoms gives rise to an inversion of the magnetic susceptibility curve and the approximation of the molecular field[14] cannot be used. Recently, we have developed a model[33] to fit this type of magnetic behaviour. A satisfactory agreement between experimentally measured and calculated curves of the molar susceptibility and the magnetic moment was obtained for complex **2a** (Figure 2) by use of this model.

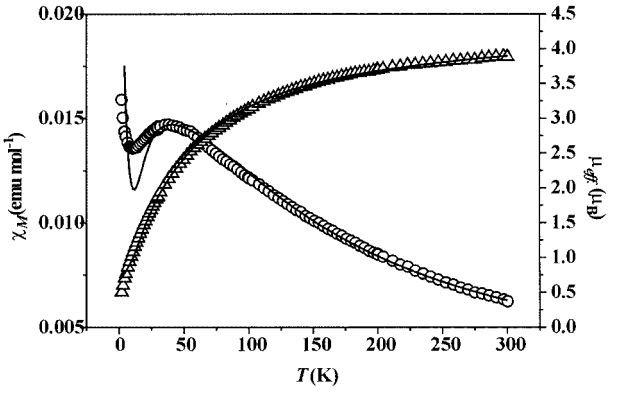

Figure 2. Temperature dependence of the molar susceptibility χ_M (circles) and $\mu_{eff.}$ (triangles) for complex **2a**; solid lines are the products of a least-squares fit to the model indicated in the text

The parameters obtained in the fit of the experimental data for complex **2a** are collected in Table 1. The *zJ* value calculated for complex **2a** is −9.08 cm^{-1}, analogous to those found[18,33] for $[Ru_2Cl(\mu\text{-}O_2CR)_4]$ [R = $CMePh_2$, CH_2CH_3, C(Me)=CHEt]. The high paramagnetic impurity value (3.3%), slightly higher than those observed

Table 1. Magnetic parameters obtained in the fits to the magnetic moment as a function of temperature

Compound	g	*D* [cm^{-1}]	*zJ* [cm^{-1}]	*TIP* [mL/mol]	*P* [%]	σ^2 [a]
1b	2.00	64.03	−1.33	1.49 10^{-3}	0.12	1.50 10^{-4}
2a	2.00	62.99	−9.08	8.31 10^{-4}	3.35	1.45 10^{-4}
3b	2.02	64.72	−0.04	7.90 10^{-4}	< 10^{-6}	6.85 10^{-6}
4b	2.15	50.60	−0.07	< 10^{-6}	0.01	3.00 10^{-5}
5b	2.09	62.80	−0.08	7.87 10^{-5}	< 10^{-4}	5.15 10^{-6}
6b	2.02	62.80	−0.20	6.41 10^{-4}	< 10^{-3}	3.33 10^{-5}

(1.7−2.7%) in the other linear chain compounds,[18,33] is probably due to the presence of the zigzag chain form in the solid.

In the variation of the magnetic susceptibility with temperature for complex **1a**, a maximum at 6 K and a shoulder at ca. 60 K are observed. These magnetic data cannot be fitted or the parameters obtained are anomalous. Since the elemental analysis and the spectroscopic and thermogravimetric data indicate that **1a** is a pure compound, the magnetic susceptibility data could indicate a mixture of two magnetically non-equivalent species. A similar mixture has been found previously[14] for the acetate complex.

As discussed above, the magnetic behaviour of complexes **3a**, **5a**, and **6a** cannot be fitted. These compounds were prepared by pumping the corresponding solvated complexes at 75 °C. If the anhydrous complexes have the usual polymeric structure through halogen bridging ligands, a rearrangement from the molecular to the polymeric structure must take place. In the solid state, however, this change could be difficult, and a mixture of arrays with different magnetic properties is possible. Complex **4b** may illustrate this behaviour. When this complex is heated to 75 °C under vacuum, the anhydrous $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4]$ is obtained. The variation of the magnetic susceptibility of this solid shows a maximum at the same temperature (67 K) as the maximum observed in the crystalline polymeric[18,33] $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4]$ (Figure 3), although the profile of the curves is different.

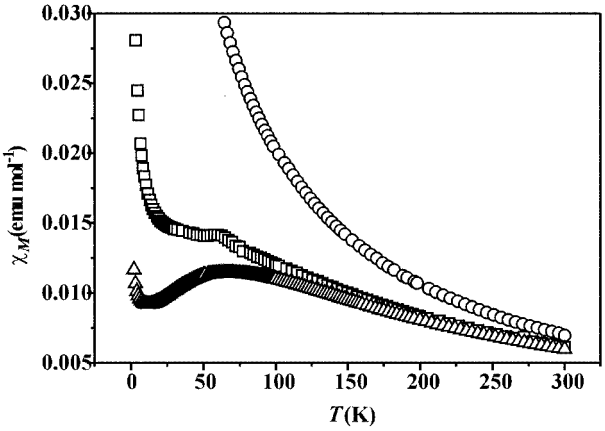

Figure 3. Temperature dependence of the molar susceptibility χ_M for complexes **4b** (circles), **4b** heated at 75 °C under vacuum (squares), and the polymeric $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4]$ (triangles)

Crystal Structure of $[Ru_2Cl(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)]\cdot 2MeOH$ (1b·2MeOH)

In the structure of **1b·2MeOH**, the asymmetric unit is composed of halves of two different crystallographically independent centrosymmetric molecules (A and B) with the inversion centre in the middle of the Ru−Ru bonds. A PLUTO view of the molecule (A) is shown in Figure 4. Table 2 gives selected bond lengths and angles of the complex. Each dinuclear unit of **1b·2MeOH** has two ruthenium atoms linked by four bridging 3-phenoxypropionoate ligands. Each axial position is shared by the O_{water} and Cl atoms with a 50% occupancy. The same situation has been found[21] for the complex $[Ru_2Cl(\mu\text{-}O_2CCMe_3)_4(H_2O)]$. The ruthenium atoms have a distorted octahedral coordination geometry. The distortion arises essentially from the longer $Ru-L_{axial}$ and Ru−Ru distances with respect to $Ru-O_{eq}$.

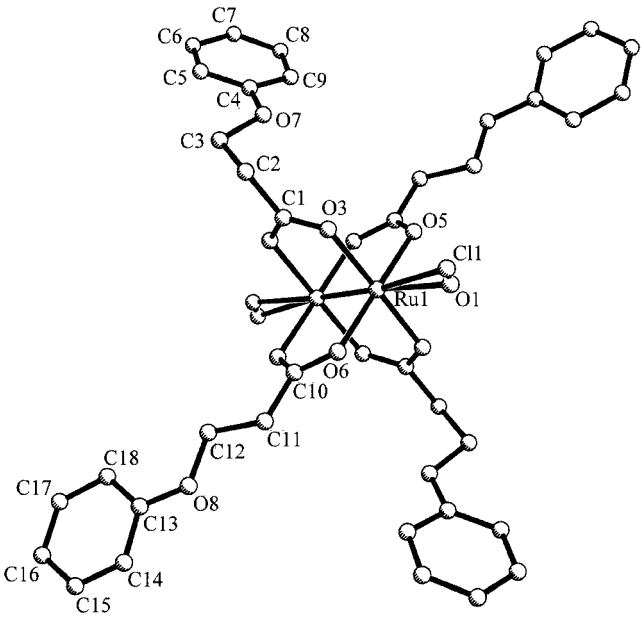

Figure 4. PLUTO view of the molecule (A) of the complex $[Ru_2Cl(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)]\cdot 2MeOH$ (**1b·2MeOH**); hydrogen atoms and MeOH molecules are omitted for clarity

The Ru−Ru distances in the two molecules are 2.278(2) and 2.280(2) Å. These distances are of the same order as those found in the other carboxylatodiruthenium(II,III) compounds.[2−4] The molecules are packed only by normal van der Waals forces.

The most important feature of these structures is their molecular nature. Only four crystal structures of molecular tetracarboxylato(chloro)diruthenium(II,III) complexes have been reported,[20−22] and their molecular natures have been attributed to the carboxylate bridges. The importance of the carboxylate ligands in the arrangement is illustrated by the structures of the compounds with O_2CCH_2OEt, O_2CCH_2OMe, and $O_2CCH_2CH_2OPh$. In the first case[13] a singular arrangement with formation of anionic, cationic, and polymeric units is formed. In the second case[15] a polymeric structure is observed, whereas in the last case a molecular arrangement is adopted.

Crystal Structure of $[Ru_2I(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)]\cdot 0.5H_2O$ (3b·0.5H$_2$O)

Crystals of **3b·0.5H$_2$O** were grown from a methanol solution containing $[Ru_2(\mu\text{-}O_2CCH_2CH_2OPh)_4]^+$ and I^-. The crystal structure determination shows packing of cationic $\{[Ru_2(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)_2]^+\}$ and anionic $\{[Ru_2I_2(\mu\text{-}O_2CCH_2CH_2OPh)_4]^-\}$ species, and water molecules. The asymmetric unit is composed of halves of the anion and the cation, with an inversion centre in the middle of the ruthenium−ruthenium bonds and half a molecule of

water of crystallization. A PLUTO view of the compound is shown in Figure 5.

Both ions contain a diruthenium(II,III) unit with four 3-phenoxypropionate moieties as bridging ligands. The cationic complexes have two axially coordinated water molecules, and the anions two iodide ligands. Compound **3b·0.5H$_2$O** could thus be formulated as $[Ru_2(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)_2][Ru_2I_2(\mu\text{-}O_2CCH_2CH_2OPh)_4]\cdot H_2O$.

There are only two known complexes in which both cationic and anionic units possess diruthenium cores:[13,36] $[Ru_2Cl(\mu\text{-}O_2CCH_2OEt)_4(H_2O)]$ and $[Ru_2(\mu\text{-}O_2CPh)_4(HSO_4)(EtOH)]$. Complex **3b·0.5H$_2$O** is the first tetracarboxylato(iodo)diruthenium complex whose crystal structure has been determined.

The Ru−Ru bond length in the cation unit [2.265(2) Å] is analogous to that found in complex **1b·2MeOH**, which is typical of these types of compounds.[4,37] In the anionic unit, however, the Ru−Ru distance is 2.310(2) Å. This bond is longer than those observed in the analogous chloro derivatives[13,16,38] $[Ru_2Cl_2(\mu\text{-}O_2CR)_4]^-$ (R = CH_2OEt, Me, H, C_6H_4-*p*-OMe) but shorter than the longest Ru−Ru distance [2.427(1) Å] found in the cation[39] $[Ru_2(\mu\text{-}O_2CMe)_4(PCy_3)_2]^+$ which has the very strong axial donor ligand PCy_3. The Ru−I bond length in the anionic unit [2.875(1) Å] is longer than any other Ru−L_{axial} bond in diruthenium complexes, including the compound[23] $[Ru_2Br(\mu\text{-}O_2CH)_4]$ [2.7170(8)−2.7313(9) Å]. This large Ru−I bond length is in accordance with the large size of the iodide ligand. The Ru−O_{axial} bond length in the cationic unit [2.271(7) Å] is similar to that found in other $[Ru_2(\mu\text{-}O_2CR)_4(H_2O)_2]^+$ cations.[8c,13,16,40,41]

Crystal Structure of $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (4b)

The molecular structure of **4b** is depicted in Figure 6, and selected bond lengths and angles are given in Table 2. This molecule has two Ru atoms linked by four 2,2-diphenylpropionate bridging ligands, with the axial positions occupied by one water molecule and one chloride ligand. Analogously to those described above for complex **1b·2MeOH**, the axial positions are shared by the O_{water} and Cl atoms with occupation factors of 50%. Although the hydrogen atoms of the axial water molecules were not located, the distances between the Cl and the O_{axial} atoms of the neighbouring molecule [3.04(1) Å] suggest hydrogen-bond interactions between them. Thus, the $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ molecules are packed, giving chains.

The molecular structure of complex **4b** contrasts with the polymeric structure reported[18] for $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4]$. In spite of their different arrangements in

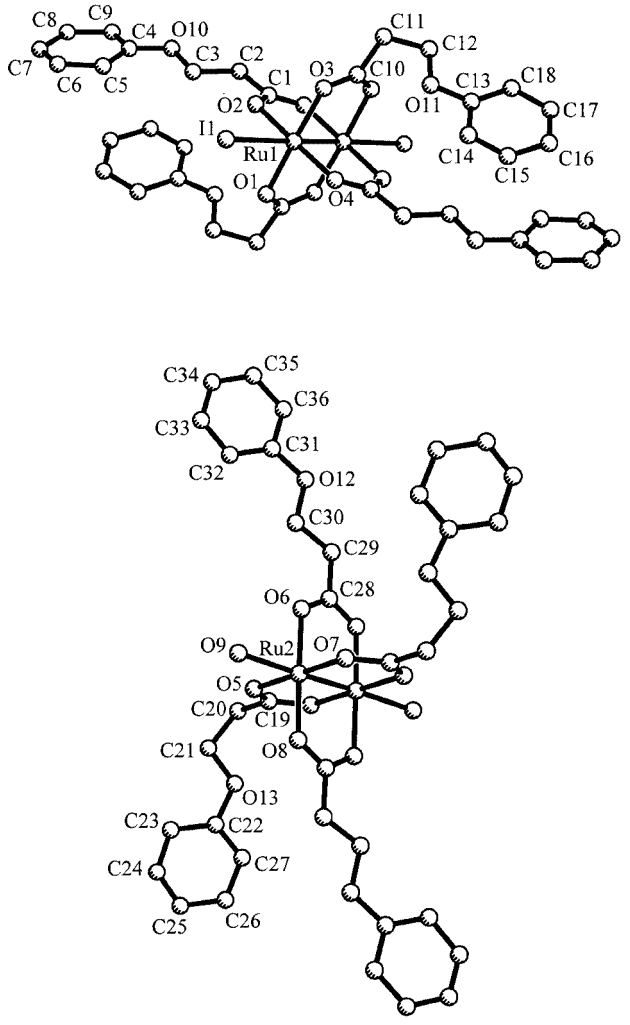

Figure 5. PLUTO view of $[Ru_2(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)_2][Ru_2I_2(\mu\text{-}O_2CCH_2CH_2OPh)_4]\cdot H_2O$ (**3b·0.5H$_2$O**); the water of hydration and hydrogen atoms have been omitted for clarity

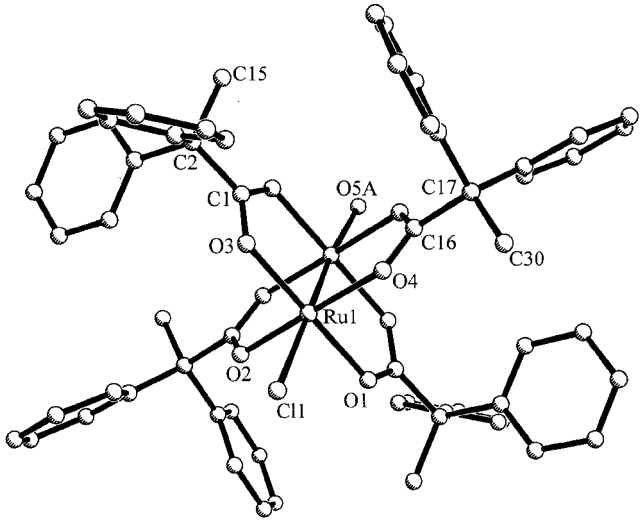

Figure 6. PLUTO view of $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (**4b**); hydrogen atoms are omitted for clarity

the solid state, all distances, including the Ru−Cl bond length, are very similar in both complexes.

The synthesis and X-ray analysis of the molecular $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ demonstrates that different arrays are possible with the same carboxylate ligand.

Conclusion

The crystal structure determination of two new molecular diruthenium(II,III) compounds indicates that the usual polymeric structure of the tetracarboxylato(chloro)diruthenium(II,III) complexes can be broken by neutral molecules, giving discrete dinuclear species. These results also confirm that small differences in the electronic or steric requirements of the carboxylate ligand can have important consequences in the arrangement in the solid state, as illustrated by the different arrays found in the complexes with the ligands O_2CCH_2OEt, O_2CCH_2OMe, and $O_2CCH_2CH_2OPh$.

The synthesis of derivatives with different halide ligands reveals that the nature of the axial ligand has a great influence on the arrangement in the solid state. Thus, the chloro complex with 3-phenoxypropionate ligands displays a molecular structure, whereas the iodo derivative shows a less usual cation/anion array.

Nevertheless, compound $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4]$ was known to have a polymeric structure while complex $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$, with the same halide and carboxylate ligands, has a molecular structure. There must therefore be other factors that play a role in the arrangement of the diruthenium(II,III) compounds. Efforts to study these factors and their influence on diruthenium chemistry are currently underway.

Experimental Section

General Remarks: All reactions were carried out under inert gases, by use of standard Schlenk techniques. Ruthenium trichloride and carboxylic acids were obtained from commercial sources. Solvents were used without previous purification. The complexes $[Ru_2Cl(\mu\text{-}O_2CR)_4]$ (R = $CMePh_2$, Me) were prepared by literature procedures.[18,42] IR spectra were recorded as KBr discs with a Nicolet Magna-FTIR 550 spectrophotometer. Elemental analysis of C and H were performed by the Microanalytical Service of Complutense University, Madrid. Electronic spectra in the range 200−2500 nm were recorded with a Cary 5G spectrophotometer in methanol solutions (10^{-4} M). The thermogravimetric analyses were carried out with a Perkin−Elmer Pyris 1 TGA thermogravimetric analyzer. The samples were heated up to 600 °C in platinum crucibles, with a heating rate of 5 °C min^{-1}, and purged in a nitrogen stream. The variable-temperature magnetic susceptibility data were measured with a Quantum Design MPMSXL SQUID (Superconducting Quantum Interference Device) susceptometer over a temperature range of 2−300 K. Each raw data field was corrected for the diamagnetic contribution of both the sample holder and the compound to the susceptibility. The molar diamagnetic corrections for the complexes were calculated on the basis of Pascal's constants. The fit of experimental data was carried out using the commercial MATLAB V.5.1.0.421 program.

Preparation of $[Ru_2Cl(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ (1a) and $[Ru_2Cl(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)]$ (1b): An excess of 3-phenoxypropionic acid (0.50 g, 3.00 mmol) was added to a solution (30 mL) of $Ru_2Cl(\mu\text{-}O_2CMe)_4$ (0.24 g, 0.50 mmol) in methanol/water (1:1, 24 mL). The reaction mixture was heated at reflux for 4 h, giving a red-brown solid. The solution was filtered, and the solid was washed with diethyl ether (3 × 20 mL) and again treated with fresh carboxylic acid (3.00 mmol) under the same conditions to ensure the complete replacement of the acetate ligands. The red-brown solid was isolated by filtration, washed again with diethyl ether, and dried under vacuum to give **1a**. A solution of the above red-brown solid in hot methanol (20 mL) was allowed to stand at room temperature and later at −18 °C, yielding red-brown crystals of **1b·2MeOH**. These crystals were dried under vacuum at room temperature to give **1b**.

$[Ru_2Cl(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ (1a): Yield: 0.34 g (75%). $C_{36}H_{36}ClO_{12}Ru_2$ (898.27): calcd. C 48.14, H 4.04; found C 48.32, H 4.04. IR (KBr): $\tilde{\nu}$ = 3061 w, 3040 w, 2933 w, 2892 w, 1599 m, 1587 m, 1529 m, 1497 s, 1460 vs, 1439 vs, 1418 s, 1317 m, 1244 s, 1225 s, 1039 m, 752 s, 703 m, 690 m cm^{-1}. UV/Vis (MeOH): $\lambda_{max.}$ (ε) = 297 (1653), 429 (786), 988 (18 $L{\cdot}mol^{-1}{\cdot}cm^{-1}$) nm. $\mu_{eff.}$ = 3.86 μ_B at room temperature.

$[Ru_2Cl(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)]$ (1b): Yield: 0.32 g (69%). $C_{36}H_{38}ClO_{13}Ru_2$ (916.29): calcd. C 47.19, H 4.18; found C 47.31, H 4.22. IR (KBr): $\tilde{\nu}$ = 3445 s, 3065 w, 3041 w, 2932 w, 1600 m, 1588 m, 1497 m, 1466 s, 1437 vs, 1243 s, 1041 m, 755 m, 693 m cm^{-1}. UV/Vis: identical to data of **1a**. $\mu_{eff.}$ = 3.98 μ_B at room temperature.

Preparation of $[Ru_2Br(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ (2a): Silver tetrafluoroborate (0.07 g, 0.35 mmol) was added to a solution of $[Ru_2Cl(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ (0.31 g, 0.35 mmol) in THF (30 mL). The reaction mixture was stirred for 24 h, giving a solid precipitate of AgCl and a brown solution. The precipitate was filtered through Celite and the solution was pumped to dryness. The solid was dissolved in ethanol (10 mL) and treated with an aqueous solution (10 mL) of KBr (0.42 g, 3.50 mmol), giving a dark brown precipitate, which was filtered, washed with water (3 × 20 mL) and dried under vacuum. Yield 0.24 g (72%). $C_{36}H_{36}BrO_{12}Ru_2$ (942.73): calcd. C 45.87, H 3.85; found C 45.77, H 3.86. IR (KBr): $\tilde{\nu}$ = 3060 w, 3041 w, 2930 w, 2888 w, 1599 s, 1587 s, 1470 vs, 1440 vs, 1419 s, 1243 vs, 1043 s, 753 s, 692 m cm^{-1}. UV/Vis (MeOH): $\lambda_{max.}$ (ε) = 291 (1857), 429 (829), 1004 (25 $L{\cdot}mol^{-1}{\cdot}cm^{-1}$) nm. $\mu_{eff.}$ = 3.88 μ_B at room temperature.

Preparation of $[Ru_2I(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ (3a) and $[Ru_2I(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)]$ (3b): The preparation was carried out as described above for **2a**, but with KI (0.58 g, 3.50 mmol) in place of KBr. The solid isolated by this procedure was characterized as **3b**. Complex **3a** was obtained after **3b** had been heated under vacuum at 75 °C for 24 h. Single crystals of **3b·0.5H$_2$O** were obtained by the following procedure: $[Ru_2Cl(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ (0.09 g, 0.10 mmol) was dissolved in methanol (15 mL) and treated with an aqueous solution of $AgNO_3$ (0.017 g, 0.10 mmol). The solution was filtered and treated with an excess of PPh_4I (0.26 g, 0.50 mmol). Crystals grew over 48 h.

$[Ru_2I(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ (3a): Yield 0.24 g (70%). $C_{36}H_{36}IO_{12}Ru_2$ (989.73): calcd. C 43.69, H 3.67; found C 43.58, H 3.62. IR (KBr): $\tilde{\nu}$ = 3066 w, 3040 w, 2936 w, 2889 w, 1599 m, 1588 m, 1496 m, 1466 s, 1437 vs, 1318 m, 1243 s, 1040 m, 756 m, 692 m cm^{-1}. UV/Vis (MeOH): $\lambda_{max.}$ (ε) = 288 (1836), 427 (748), 976 (19 $L{\cdot}mol^{-1}{\cdot}cm^{-1}$) nm. $\mu_{eff.}$ = 3.96 μ_B at room temperature.

$[Ru_2I(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)]$ (3b): Yield 0.25 g (70%). $C_{36}H_{38}IO_{13}Ru_2$ (1007.74): calcd. C 42.91, H 3.80; found C 42.78, H 3.75. IR (KBr): $\tilde{\nu}$ = 3431 m, 3066 w, 3040 w, 2936 w, 2889 w, 1599 m, 1588 m, 1496 m, 1466 s, 1437 v s, 1318 m, 1243 s, 1040 m, 756 m, 692 m cm^{-1}. UV/Vis: identical to data of **3a**. $\mu_{eff.}$ = 4.18 μ_B at room temperature.

Preparation of $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (4b): An excess of 2,2-diphenylpropionic acid (0.68 g, 3.00 mmol) was added to a solution (25 mL) of $Ru_2Cl(\mu\text{-}O_2CMe)_4$ (0.24 g, 0.50 mmol) in methanol/water (24 mL, 1:1). The reaction mixture was heated at reflux for 4 h, giving a red-brown solid. The solution was filtered, and the solid was washed with diethyl ether (2 × 10 mL) and dried under vacuum. Single crystals of **4b** were obtaining by the procedure described above for **3b·0.5H$_2$O**, with PPh_4Cl (0.19 g, 0.50 mmol) in place of PPh_4I.

$[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (4b): Yield 0.44 g (76%). $C_{60}H_{54}ClO_9Ru_2$ (1156.69): calcd. C 62.30, H 4.71; found C 62.20, H 4.69. IR (KBr): $\tilde{\nu}$ = 3446 w, 3141 w, 3057 w, 3021 w, 2994 w, 2941 w, 1598 w, 1494 m, 1464 s, 1436 s, 1394 vs, 1367 vs, 1029 m, 998 w, 760 m, 737 m, 731 m, 697 vs, 668 s cm^{-1}. UV/Vis (MeOH): $\lambda_{max.}$ (ε) = 287 (2962), 426 (818), 968 (21 $L{\cdot}mol^{-1}{\cdot}cm^{-1}$) nm. $\mu_{eff.}$ = 4.12 μ_B at room temperature.

Preparation of $[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4]$ (5a) and $[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (5b): The preparation was carried out similarly to that described for **2a**, with $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (0.40 g, 0.35 mmol). The brown solid was characterized as **5b**. Complex **5a** was obtained after **5b** had been heated under vacuum at 75 °C for 24 h.

$[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4]$ (5a): Yield 0.30 g (73%). $C_{60}H_{52}BrO_8Ru_2$ (1183.13): calcd. C 60.91, H 4.43; found C 60.80, H 4.39. IR (KBr): $\tilde{\nu}$ = 3088 w, 3058 w, 3031 w, 2984 w, 2940 w, 1599 w, 1494 m, 1466 m, 1440 m, 1392 vs, 1368 s, 1029 m, 751 m, 735 m, 698 s, 668 m cm^{-1}. UV/Vis (MeOH): $\lambda_{max.}$ (ε) = 330 (983), 425 (709), 944 (213 $L{\cdot}mol^{-1}{\cdot}cm^{-1}$) nm. $\mu_{eff.}$ = 4.13 μ_B at room temperature.

$[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (5b): Yield 0.31 g (73%). $C_{60}H_{54}BrO_9Ru_2$ (1201.14): calcd. C 60.00, H 4.53; found C 59.92, H 4.50. IR (KBr): $\tilde{\nu}$ = 3435 m, 3088 w, 3058 w, 3031 w, 2984 w, 2940 w, 1599 w, 1494 m, 1466 m, 1440 m, 1392 vs, 1368 s, 1029 m, 751 m, 735 m, 698 s, 668 m cm^{-1}. UV/Vis: identical to data of **5a**. $\mu_{eff.}$ = 4.06 μ_B at room temperature.

Preparation of $[Ru_2I(\mu\text{-}O_2CCMePh_2)_4]$ (6a) and $[Ru_2I(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (6b): The preparation was carried out as described previously for **3a** and **3b**, with $Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4(H_2O)$ (0.40 g, 0.35 mmol).

$[Ru_2I(\mu\text{-}O_2CCMePh_2)_4]$ (6a): Yield 0.29 g (67%). $C_{60}H_{52}IO_8Ru_2$ (1230.12): calcd. C 58.59, H 4.26; found C 58.51, H 4.22. IR (KBr): $\tilde{\nu}$ = 3088 w, 3059 w, 3024 w, 2983 w, 2940 w, 1582 w, 1494 m, 1467 m, 1440 m, 1392 vs, 1368 s, 1030 m, 752 w, 733 w, 698 s, 668 m cm^{-1}. UV/Vis (MeOH): $\lambda_{max.}$ (ε) = 328 (1160), 426 (820), 968 (25 $L{\cdot}mol^{-1}{\cdot}cm^{-1}$) nm. $\mu_{eff.}$ = 4.09 μ_B at room temperature.

$[Ru_2I(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (6b): Yield 0.29 g (67%). $C_{60}H_{54}IO_9Ru_2$ (1248.14): calcd. C 57.75, H 4.36; found C 57.65, H 4.32. IR (KBr): $\tilde{\nu}$ = 3436 m, 3088 w, 3059 w, 3024 w, 2983 w, 2940 w, 1582 w, 1494 m, 1467 m, 1440 m, 1392 vs, 1368 s, 1030 m, 752 w, 733 w, 698 s, 668 m cm^{-1}. UV/Vis: identical to data of **6a**. $\mu_{eff.}$ = 4.06 μ_B at room temperature.

summarised in Table 3. Representative crystals were mounted on a Bruker Smart-CCD diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation. For **1b·2MeOH**, data were collected over a quadrant of the reciprocal space by combination of two exposure sets. For **3b·0.5H$_2$O** and **4b**, data were collected over a hemisphere of the reciprocal space by combination of three exposures sets. The cell parameters were determined and refined by least-squares fitting of all reflections collected. The structures of **1b·2MeOH** and **3b·0.5H$_2$O** were solved by Patterson (Ru atoms, SHELXS)[43] and conventional Fourier techniques and refined by full-matrix, least-squares on F^2 (SHELXL).[44] The structure of **4b** was solved by direct methods and all calculations were performed with the aid of the SHELXS and SHELXL.[43,44] Final mixed refinement was undertaken with anisotropic thermal parameters for the non-hydrogen atoms, except for the solvent molecules, which were refined only isotropically. The hydrogen atoms were included with fixed isotropic contributions at their geometrically calculated positions, except for **1b·2MeOH** (the hydrogen atoms of the OH group of the methanol molecules, which were located in a Fourier synthesis and refined together with the oxygen atom) and for **3b·0.5H$_2$O** (the hydrogen atoms of the coordination water molecules were not found by Fourier synthesis or geometrically). For **1b·2MeOH** the positional disorder of Cl and O_{water} was resolved by refining with geometric restraints and a variable $Ru-O_{water}$ distance.[45] For **3b·0.5H$_2$O**, one residual peak was found in the last cycles of refinement, and was assigned as a solvent water molecule and refined isotropically as oxygen atom. It was not possible to locate the hydrogen atoms of this molecule. For **4b**, the refinement was carried out in both the centric ($P\bar{1}$) and noncentric ($P1$) space groups. In spite of having more refinable parameters in the acentric model the thermal parameters of several atoms became negative. Thus, the centric space group ($P\bar{1}$) was chosen. CCDC-199023 to -199025 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Photophysical and Energy-Transfer Properties of (Salen)zinc Complexes and Supramolecular Assemblies

Kathryn E. Splan,[a] Aaron M. Massari,[a] Gregory A. Morris,[a] Shih-Sheng Sun,[a] Eduardo Reina,[a] SonBinh T. Nguyen,[a] and Joseph T. Hupp*[a]

Keywords: Host-guest systems / Fluorescence / Supramolecular chemistry / Salen ligands

The absorption, emission, and energy-transfer properties of monomeric and supramolecular (salen)Zn complexes (square and rectangular assemblies) are reported. The monomeric complexes fluoresce in solution, displaying photophysical behavior similar to typical (porphyrin)zinc complexes. Rhenium coordination chemistry is used to assemble molecular rectangles and squares that largely retain the photophysical properties of the parent compounds. Host-guest assemblies obtained by binding a fifth (salen)Zn complex to a tetrakis-(salen) square are capable of efficient salen-to-salen electronic energy transfer. Energy transfer flow through these systems can be manipulated by modification of the salen building-block structure.

Introduction

(Salen)metal[1] complexes are most widely known for their ability to catalyze a broad range of chemical reactions, including the epoxidation of olefins, lactide polymerization, and the asymmetric ring-opening of epoxides.[2] While examining functionalized (salen)manganese complexes in the context of supramolecular assemblies for enantioselective epoxidation reactions we have found that the formation of supramolecular species, such as H-shaped trimeric assemblies and molecular squares featuring salen ligands as edges and transition metal ions as corners, can stabilize central or encapsulated (salen)metal complexes, substantially extending their lifetimes as functional catalysts.[3] In working with these complexes and assemblies, we were struck by their strong chromophoric character and wondered whether they might exhibit − by analogy to porphyrins and phthalocyanines − interesting, measurable photophysical properties. We report herein the properties and behavior of functionalized, photo-excited (salen)zinc species, both isolated complexes **1** and **2** and supramolecular assemblies **3**−**5**. We find that the (salen)zinc species are moderately fluorescent in solution at ambient temperature, exhibiting singlet excited-state lifetimes similar to those of common (porphyrin)zinc complexes[4] and displaying an ability in supramolecular assemblies to transfer energy between (salen)-metal subunits. While a few reports exist on the photophysical properties of flexible, metal-free salen ligands (primarily excited-state proton-transfer studies),[5] to the best of our knowledge no prior reports exist on the photophysical properties of (salen)metal complexes.

Results and Discussion

As indicated by the structures, pyridyl functionalities provide a basis for constructing supramolecular assemblies

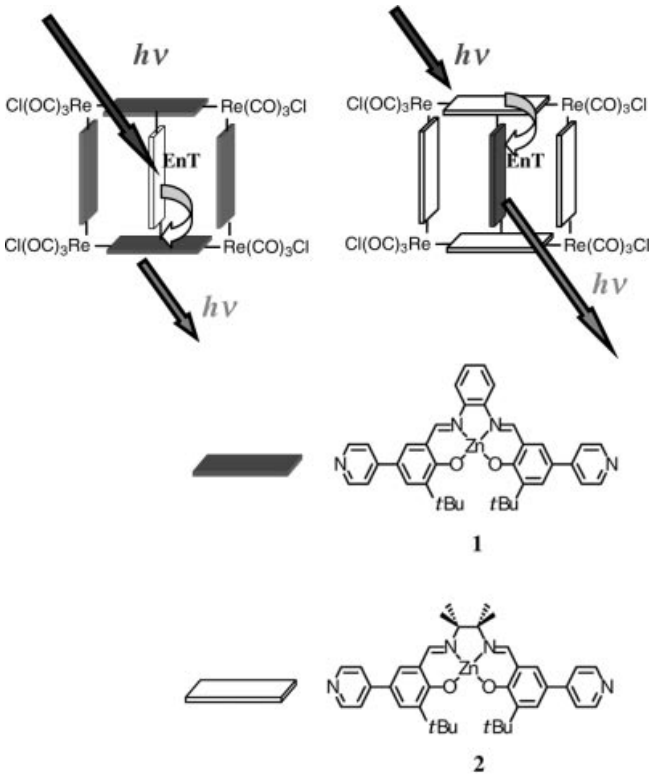

Scheme 1

using known rhenium(I) coordination chemistry.[6−8] The central zinc(II) ions rigidify the salen ligands, displace the hydroxylic protons whose transfer would otherwise dominate the photophysics,[9] and serve as axial ligation sites for reversible binding of Lewis basic groups, allowing for interior functionalization of **3** and **4**. In contrast to catalytically active metals such as manganese, chromium, and cobalt, however, the complexed zinc ions are electronically inactive in the compounds' ground and photo-excited states. Figure 1 shows the electronic absorption and emission spectra for **1** and **2** in tetrahydrofuran. The complexes are characterized by intense absorption in the near UV [ε(**1**) = 80000 $M^{-1}\cdot cm^{-1}$ and ε(**2**) = 52000 $M^{-1}cm^{-1}$] and in the blue region of the visible spectrum. These transitions increase in intensity and substantially red-shift upon zinc metallation when compared to the free-base derivatives of **1** and **2**, consistent with expanded conjugation over the entire ligand.[10] Semi-empirical electronic structure calculations (ZINDO-S, Hyperchem™ version 5.03) indicate predominantly $\pi\rightarrow\pi^*$ transitions for both compounds. The observed red shift for the phenyl-bridged complex **1** with respect to complex **2** is replicated qualitatively in the calculations and is consistent with expansion of the aromatic π-system in the emissive excited state of **1** versus **2**. Incorporation of **1** and **2** into molecular squares **3** and **4** results in only subtle changes in visible-region absorption characteristics (not shown), indicating little contribution from Re^I charge-transfer absorption.

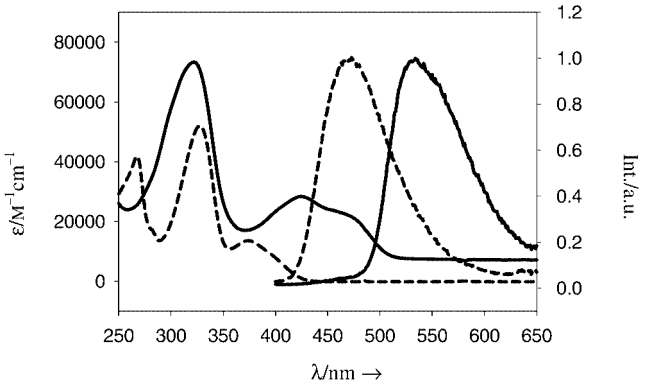

Figure 1. Absorption (left) and emission (right) spectra for **1** (—) and **2** (---) in THF

Table 1 summarizes the emission data collected for various (salen)zinc complexes. Briefly, the observed lifetimes and quantum yields of salen monomers **1** and **2** are similar to those typically seen for (porphyrin)zinc(II) complexes[4] and are consistent with singlet emission in competition with efficient singlet-to-triplet intersystem crossing. Extension of the study to supramolecular assemblies **3**−**5** (again see Table 1) shows that Re^I coordination induces slight emission blue shifts and causes a modest decrease in emission intensity and lifetime owing to enhanced intersystem crossing to non-emissive triplet states.[11] Interestingly, emission from **5** occurs from a singlet state that is about 3000 cm^{-1} *higher* in energy than the generally emissive metal-to-ligand charge-transfer (MLCT) excited states that characterizes most tricarbonylbis(imine)rhenium(I) complexes.[12] The MLCT states are typically long-lived and are nominally triplet states. That emission from these is not observed is likely indicative of an even lower energy for the salen-centered triplet state.

Table 1. Photophysical properties of salen complexes in THF

Compound	$\lambda_{em.\ max.}$ [nm]	φ_{fl}	τ_{fl} [ns]
1	532	0.11	0.63
2	471	0.19	1.15
3	526	0.073	0.62
4	460	0.039	0.50
5	454	0.031	0.36

Fluorescence titration of the salen square **3** with **2**, presumably to form a pentakis(salen) assembly,[13] yielded a binding constant of $9(\pm 3) \times 10^4$ M^{-1} in chloroform as solvent. As shown in Figure 2 (top), excitation at 400 nm, where both the square and the encapsulated salen absorb, results in fluorescence exclusively from the square. The increase in square emission intensity[14] and the absence of detectable emission from the encapsulated alkylsalen complex is indicative of efficient energy transfer (EnT) from the encapsulated salen to the surrounding square and is consistent with the good spectral overlap evidenced in Figure 1.[15] Based on the lifetimes of the component fluorophores the

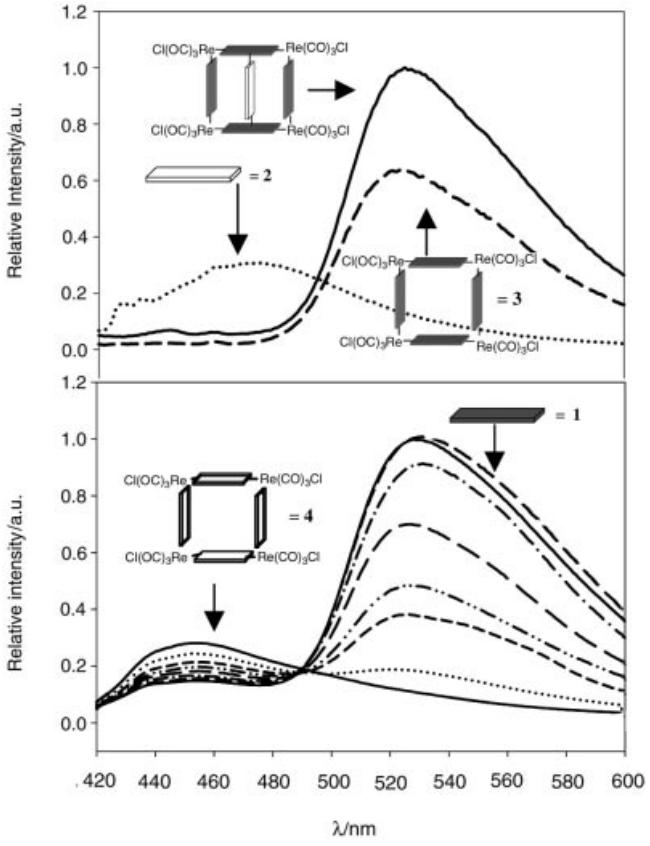

Figure 2. Top: emission spectra of 1 μM solutions of **2** (···), **3** (---), and an equimolar solution of **2** and **3** (—) in $CHCl_3$, based on 400 nm excitation; bottom: fluorescence titration of square **4** with **1**; sequential titrations show a quenching of square emission accompanied by an increase in guest salen emission

guest **2** to host **3** energy transfer rate constant is estimated as greater than 10^{-10} s^{-1}.

Based on the spectral overlap between compounds **1** and **2**, EnT should be observed from the alkylsalen complex (donor) to the phenyl complex (acceptor). Therefore, by reversing the back-bone functionalities of the salen building blocks the direction of energy transfer (EnT) can be controlled within the supramolecular assembly (Scheme 1). When **1** is added to square **4** (Figure 2, bottom) efficient energy transfer is observed. However, in contrast to the assembly described above in which the guest salen transfers energy to the host square, outside-to-inside EnT is observed, i.e. the salen walls act as antennae and transfer their energy to the encapsulated guest; see Scheme 1. A control experiment in which **4** was titrated with a derivative of **1** where the pyridyl moieties were replaced with non-binding *tert*-butyl groups underscores the importance of supramolecular assembly formation in facilitating rapid EnT. Neither quenching of the host square fluorescence nor sensitization of the candidate guest salen (*tert*-butylsalen) fluorescence was observed, consistent with the brevity of the host excited-state lifetime relative to diffusional encounter times.

To summarize, salen ligands, after complexation of Zn^{II}, display significant fluorescence and acquire roughly nanosecond singlet excited-state lifetimes. Substitution of alkyl groups by an arene on the salen backbone shifts the ligand's absorption spectrum well into the visible region. Square and rectangular supramolecular assemblies of salens, prepared by Re^{I} ligation of pendant pyridyl groups, also fluoresce at room temperature in solution, albeit with diminished quantum yields and lifetimes. Finally, electronic EnT is observed within pentakis(salen) assemblies. Modification of host and guest salen building blocks allows for manipulation of excitation energy flow through these systems.

Experimental Section

General: Monomeric salen complexes[16] **1** and **2** and dimetallic [{$(CO)_4Re$}$_2$BisBzIm] edges (BzIm = benzimidazolate)[7a,7b] were synthesized according to literature procedures. THF was dried with Na/benzophenone. All other chemicals and solvents were reagent grade and used as received. ^{1}H NMR spectra were recorded with a 400 MHz Varian Mercury spectrometer. FAB mass spectra were obtained in the Mass Spectrometry Laboratory, School of Chemical Sciences, University of Illinois or the Analytical Services Laboratory, Northwestern University.

3: Equimolar amounts of **1** (193 mg, 0.300 mmol) and $Re(CO)_5Cl$ (108 mg, 0.299 mmol) were refluxed in THF (100 mL) for 3 d under N_2. The reaction mixture was filtered and the initial dark precipitate was discarded. A yellow product (162 mg, 55%) was precipitated by concentrating the filtrate to 1/3 of its volume, adding hexanes, and cooling the solution to 0 °C. ^{1}H NMR (500 MHz, [D_6]DMSO): δ = 9.20 (br., 8 H), 8.59 (br., 8 H), 8.06 (br., 4 H), 7.94 (br., 4 H), 7.82 (br., 8 H), 7.71 (br., 4 H), 7.66 (br., 4 H), 7.43 (br., 8 H), 1.51 (s, 72 H) ppm. ^{13}C NMR (500 MHz, THF): δ = 197.7, 194.1, 175.4, 163.3, 154.3, 151.4, 144.6, 140.3, 135.1, 129.7, 128.4, 121.6, 121.0, 120.5, 116.7, 36.5, 30.1 ppm. FTIR (THF): ν_{CO} = 2024, 1913, 1885 cm^{-1}. $C_{164}H_{144}Cl_4N_{16}O_{20}Re_4Zn_4{\cdot}8H_2O$ (3951): calcd. C 49.85, H 4.08, N 5.67; found C, 50.22, H 4.29, N 5.30. FAB MS: calcd. *m*/*z* = 3807.2; found 3807.2.

4: A mixture of $Re(CO)_5Cl$ (50.0 mg, 0.138 mmol), **2** (90.0 mg, 0.138 mmol), and THF (50 mL) was heated to 60 °C for 40 h, during which time a yellow solid started to precipitate. The product was further precipitated by adding cold diethyl ether (excess) and was isolated by filtration to afford a yellowish powder. Yield 91% (120 mg). ^{1}H NMR (400 MHz, CD_3CN): δ = 8.55 (d, 16 H, *J* = 6.8 Hz), 8.49 (s, 8 H), 7.68 (s, 8 H), 7.66 (s, 8 H), 7.60 (d, 16 H, *J* = 6.8 Hz), 1.50 (s, 72 H), 1.27 (s, 48 H). LR FAB-MS: calcd. for $[M]^+$: *m*/*z* = 3839.5; found 3839.1. $C_{164}H_{176}Cl_4N_{16}O_{20}Re_4Zn_4{\cdot}4THF$ (4128): calcd. C 52.37, H 5.08, N 5.43; found C, 52.66, H 4.90, N 5.19.

5: Salen rectangle **5** was formed by allowing equimolar amounts of [{$(CO)_4Re$}$_2$BisBzIm] (103 mg, 0.125 mmol) and **2** (81.0 mg, 0.125 mmol) to react in refluxing THF (60 mL) under N_2 for2 d. The reaction mixture was cooled and concentrated to half of its volume. Upon addition of hexanes the desired product precipitated as a yellow powder in 69% yield (61.5 mg). ^{1}H NMR (500 MHz, 55 °C, [D_8]THF): δ = 8.42 (s, 4 H), 8.12 (br., 8 H), 7.81 (br., 8 H), 7.49 (s, 4 H), 7.43 (s, 4 H), 7.36 (br., 8 H), 7.31 (br., 8 H), 1.78 (s, 36 H), 1.41 (m, 24 H). FAB MS: calcd. for [M + H_2O]: *m*/*z* = 2855.6; found 2854.7.

[8] The identity of the supramolecular complexes **3** and **4** has been confirmed by combustion analysis and mass spectroscopic data. Combustion analysis establishes an Re/ligand ratio of 1:1, disproving the presence of metal or ligand terminated oligomers. Predominant peaks in the mass spectroscopic data correspond to tetramers, while peaks of higher and lower weight species are not observed. Additionally, square **3** has been characterized by pulsed-field gradient NMR spectroscopy (PFG NMR), a technique recently employed to establish the identity of supramolecular squares (vs. ligands and oligomers) by determining the diffusion coeffiecent of the species present: W. H. Otto, M. H. Keefe, K. E. Splan, J. T. Hupp, C. K. Larive, *Inorg. Chem.* **2002**, *41*, 6172−6174.

Iodoargentates and Cuprates Stabilized by Sulfonium Cations With Long Alkyl Chains

Heléne Paulsson,*[a] Malin Berggrund,[a] Andreas Fischer,[a] and Lars Kloo[a]

Keywords: Cations / Iodide / Copper / Silver / Crystal structure

$[DodMe_2S]_2AgI_3$ and $[DodMe_2S]Ag_2I_3$ were obtained from mixtures of dodecyldimethylsulfonium iodide and silver iodide in acetonitrile solution. $[DodMe_2S]_2AgI_3$ crystallizes in the orthorhombic crystal system, space group *Pbca* and contains trigonal planar anions AgI_3^{2-}, while $[DodMe_2S]Ag_2I_3$ crystallizes in the triclinic crystal system, space group $P\bar{1}$, and consists of polymeric anions $^1{}_\infty(Ag_2I_3)^-$. In both structures, the sulfonium cations form a layer of parallel and interpenetrating dodecyl chains with the sulfoniumdimethyl groups on both sides of the layer. $[DodMe_2S]_2CuI_3$ was obtained from dodecyldimethylsulfonium iodide and copper iodide mixtures and is isostructural with the corresponding silver compound.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Metal iodides and polyiodides are interesting and important materials that are useful in various electrochemical applications.[1−4] In our laboratory, many alkyl iodide and polyiodide compounds have been synthesized in sulfonium-based reaction media, which have emerged as efficient electrolytes in dye-sensitised nanostructured solar cells of the Grätzel type.[5−7] While iodometallates with symmetric cations, such as trimethylsulfonium and triethylsulfonium ions, have been prepared previously, sulfonium cations with long-chain substituents, such as dodecyl and hexadecyl groups, have not been investigated so far. $[DodMe_2S]I$ is the only compound known in this field that has been structurally characterized.[5] This is rather surprising since these long chains would introduce new properties into the materials, yielding compounds that may combine the polarity of a halometallate and the nonpolar properties of the alkyl groups.

Low-dimensional compounds, such as hybrid organic-inorganic layered solids, have been shown to combine conductivity and magnetism or optics and magnetism.[8−11] Several inorganic host networks with structural flexibility of the interlayer separation have been investigated and large organic anions (amphiphiles) been successfully inserted. These amphiphiles may be formed from long-chain alkyl compounds with charged, polar endings consisting of ammonium-, phosphonium- or sulfate-based complexes. The long-chain alkyl groups form mono- or bilayers, which are favourably close-packed.[12−15] In amphiphiles with polar sulfonium groups, the structure of the packed alkyl layers is preferably tilted. This has been observed in both hydroxide double salts and highly conducting, so called Longmuir−Blodgett films.[13−14]

The main purpose of this work is to investigate metal-iodide-doped long-chain alkyl sulfonium iodides, with and without additional iodine. One experimental difficulty that is inherent in these systems is imposed by the physical properties, such as very high viscosities, which makes it difficult to obtain crystals with a sufficiently high quality for structure determinations. This problem may be diminished, though, by use of organic solvents such as acetone or acetonitrile. From using systems of metal-iodide-doped asymmetric trialkylsulfonium iodides, we have obtained the new compounds $[DodMe_2S]_2AgI_3$, $[DodMe_2]Ag_2I_3$ and $[DodMe_2S]_2CuI_3$, whose structures are presented here.

Results and Discussion

Crystal Structure of $[DodMe_2S]_2CuI_3$ and $[DodMe_2S]_2AgI_3$

Both compounds are isostructural and crystallise in the orthorhombic crystal system, space group *Pbca*. The structures consist of dimethyldodecylsulfonium cations and approximately trigonal planar MI_3^{2-} anions (M = Ag, Cu). Figure 1 shows the arrangement of both structures in the unit cell. The cations are arranged in such a way that all dodecyl chains are zigzag shaped and run parallel to each other, thus forming laminar layers with the SMe_2 groups sticking out on both sides of the surfaces;[5] the MI_3^{2-} anions are found between the layers. The geometry of the MI_3 groups is almost trigonal planar with bond lengths between 2.523(2) and 2.561(2) Å in CuI_3^{2-}. In AgI_3^{2-} the

range of interatomic distances is between 2.703(2) and 2.757(2) Å. The angles between the metal-iodine bonds are between 115.7(1) and 123.9(1)° (Cu) and 114.20(6) and 125.55(2)° (Ag). Thus, the arrangement around the central metal atoms deviates significantly from the ideal trigonal geometry.

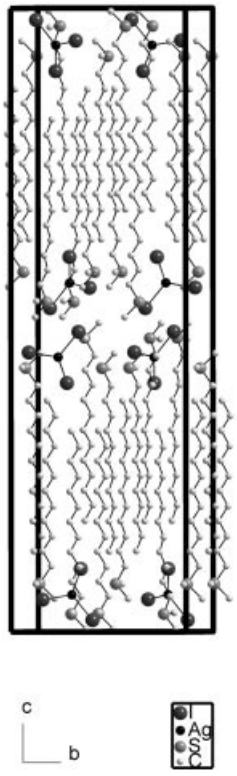

Figure 1. Structure of $[DodMe_2S]_2CuI_3$ and $[DodMe_2S]_2AgI_3$

While three-coordinate copper(I) appears frequently, this particular structural motif is not very common in the structural chemistry of discrete iodocuprates(I) and -argentates(I). So far, only one example of a compound containing AgI_3^{2-} anions has been published, namely in the structure of methyltriphenyl phosphonium triiodoargentate.[16] The geometry of the anion in this compound is in very good agreement with that in our study. In the case of iodocuprates, several examples of structures containing CuI_3 groups are known in compounds such as methyltriphenylphosphonium triiodocuprate[17] or cobaltocenium triiodocuprate.[18] Additionally, similar compounds for Cu^{II}, containing the CuX_3^- anion (X = Cl, Br), have been published recently.[19] The CuX_3^- conformation deviates from a perfect trigonal structure, as expected, due to potential Jahn-Teller instability. Also, due to the inherent instability of Cu^{II} in the presence of iodide, similar CuI_3^- ions are not known.

Crystal Structure of $[DodMe_2S]\ {}^1{}_\infty[Ag_2I_3]$

This compound crystallizes in the triclinic crystal system, space group $P\bar{1}$. It contains a polymeric structure consisting of one-dimensional, infinite Ag_2I_3 chains. These chains are made from two rows of edge-sharing AgI_4 tetrahedra, which are connected by common tetrahedron edges (Figure 2). The $Ag_2I_3^-$ anion is also present in the structures of $[NMe_4]Ag_2I_3$[20] and $CsAg_2I_3$.[21] Several iodocuprate(I) analogues are known, such as $CsCu_2I_3$ and RCu_2I_3 (R = *N*-methylpyridinium).[22–23]

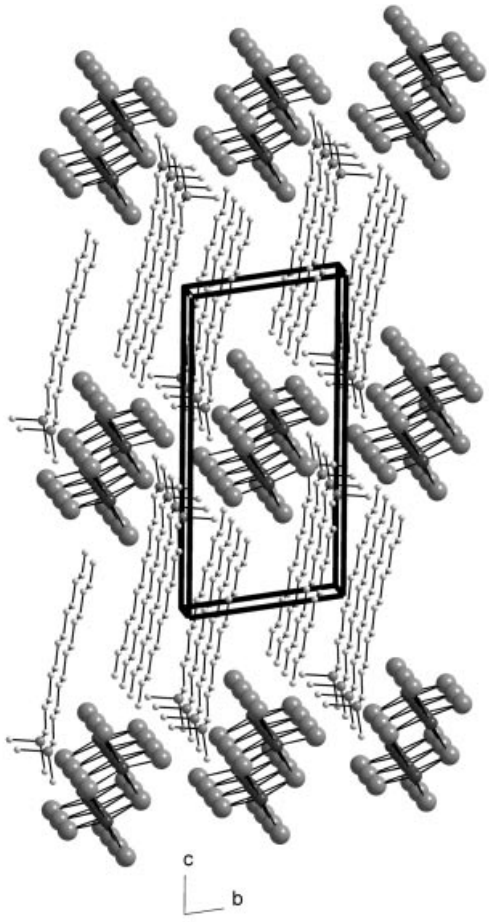

Figure 2. Structure of $[DodMe_2S]\ {}^1{}_\infty[Ag_2I_3]$

As in other polymeric anions of this type, the arrangement of the iodide ions around the silver ions is rather distorted. The I–Ag–I angles lie in a range of 100.0° to 119.7°, thus deviating significantly from the ideal tetrahedral coordination. The bond lengths illustrate the different nature of the two types of iodide ions that are present. Each I(1) connects four silver atoms and thus forms the corner of four common tetrahedra. The interatomic I(1)–Ag distances are therefore rather long (288.4–299.6 pm). I(2) and I(3) connect two silver ions and the distances between these iodide ions and the silver ions are in the range 279.7–283.0 pm.

Conclusions

Silver- and copper-iodide-containing dodecyldimethylsulfonium iodides are structurally stabilized by lamellar net-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

works formed by the long-chain dodecyl groups in $(DodMe_2S)^+$ cations, whereas the anionic building blocks may consist of either monomeric entities, such as AgI_3^{2-} and CuI_3^{2-}, or polymeric structures such as $Ag_2I_3^-$. The AgI_3^{2-} anions are preferably formed in the presence of elemental iodine. The structure of $[Ag^+(I^-)_3]^{2-}$ reveals that iodide ions obviously prefer silver ions to iodine molecules, since triiodide ions $(I_3)^-$ should otherwise be expected to form. Comparatively, thallium triiodide (TlI_3) has shown other properties since its crystal structure actually consists of Tl^+ and $(I_3)^-$ units.[5,24−25]

Experimental Section

General Remarks: The crystals for crystallographic analysis were grown as "hermits" in order to give maximum quality, and consequently the yield was not optimised. Bulk synthesis of the compounds typically produces a yield of about 70−80%. The purity of the products was checked by NMR and Raman spectroscopy as well as by a melting point determination.

Synthesis of $[DodMe_2S]_2CuI_3$ and $[DodMe_2S]_2AgI_3$: Crystals of $[DodMe_2S]_2CuI_3$ and $[DodMe_2S]_2AgI_3$ could be obtained by reacting dodecyldimethyl sulfonium iodide with the respective metal iodide in the sulfonium-to-metal-iodide proportion 1:0.3 and then dissolving the mixtures in an acetonitrile solution. The $[DodMe_2S]I$ used was synthesized by reacting equimolar amounts of dodecylmethyl sulfide and methyl iodide (see ref.[7]) Concerning the AgI_3-containing crystals, elemental iodine was also added in the sulfonium-to-iodine proportion 1:0.01. Upon slow evaporation of the solvent at room temperature, both compounds crystallized within a couple of days. In a typical synthesis, 10 mg of the respective mixture was dissolved in 0.1 mL acetonitrile and then left in an NMR tube for slow evaporation at room temperature yielding 6 mg (60%) of white or light yellow crystals.

Synthesis of $[DodMe_2S]Ag_2I_3$: White crystals of $[DodMe_2S]Ag_2I_3$ could be obtained from mixtures of $[DodMe_2S]I$ and silver iodide (AgI) in a similar way as mentioned above, though without any addition of iodine [yield: about 6 mg (60%)].

Crystal Structure Determination of $[DodMe_2S]_2CuI_3$ and $[DodMe_2S]_2AgI_3$: X-ray diffraction data for the crystals were collected using a Bruker Nonius KappaCCD diffractometer. Both compounds crystallise in the orthorhombic system. The space group *Pbca* could be unambiguously determined from the systematic absences. Numerical absorption corrections were applied[26] The positions of the Cu (Ag) and I atoms were determined by direct methods, and C and S atoms were localized in subsequent difference Fourier syntheses. Hydrogen atoms were placed at calculated positions and refined using a riding model. All parameters were refined against F^2. All non-hydrogen atoms were refined with anisotropic displacement parameters. Crystallographic details of the structure determinations are presented in Table 1.

Crystal Structure Determination of $[DodMe_2S]^1{}_\infty[Ag_2I_3]$: X-ray diffraction data were collected by using a Bruker Nonius KappaCCD diffractometer. The compound crystallises in the triclinic system; the space group $P\bar{1}$ could be confirmed during the structure determination. A numerical absorption correction was applied[26] The positions of Ag and I atoms were determined by direct methods,

COVER PICTURE

The cover picture shows the X-ray structure of an unprecedented supramolecular assembly comprising four porphyrins and six metal atoms (two Ru and four Zn); this very stable and symmetrical architecture was obtained by spontaneous self-assembly through four 4′-N(py)–Zn interactions of two equal bis(porphyrin)ruthenium self-complementary building blocks. The design of this and other robust and shape-persistent assemblies, obtained by coordination of *meso*-pyridylporphyrins to ruthenium, palladium and zinc centers, is comprehensively discussed in the microreview by E. Alessio et al. on p. 2371ff. NMR spectroscopy and X-ray crystallography were used jointly for the unambiguous characterization of the new species in solution and solid state, respectively. Very often the adducts of nanoscopic dimensions, in which the number, position, relative distance and orientation of the chromophores is well defined, were obtained through hierarchical supramolecular self-assembly: multi-porphyrin components were used as building blocks for the metal-mediated assembly of more elaborate architectures.

Discrete Supramolecular Assemblies of Porphyrins Mediated by Coordination Compounds

Elisabetta Iengo,[a][‡] Ennio Zangrando,[a] and Enzo Alessio*[a]

Keywords: Porphyrins / Supramolecular chemistry / Self-assembly / Ruthenium / Building blocks

Metal-driven self-assembly has emerged as a viable alternative to covalent synthesis in the construction of large and sophisticated multi-porphyrin architectures, whose complexity and function begin to approach the properties of naturally occurring systems. The design and preparation of robust and shape-persistent discrete assemblies, obtained by coordination of *meso*-pyridylporphyrins to ruthenium, palladium and zinc centers, is comprehensively discussed in this microreview, that covers research in this field carried out by the authors at the University of Trieste in the last few years. NMR spectroscopy and X-ray crystallography were used jointly for the unambiguous characterization of the new species in solution and solid state, respectively. Very often the adducts of nanoscopic dimensions, in which the number, position, relative distance and orientation of the chromophores is well defined, were obtained through hierarchical supramolecular self-assembly: multi-porphyrin components were used as building blocks for the metal-mediated assembly of more elaborate architectures.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

There is substantial interest in the construction of multiporphyrin assemblies which can mimic naturally occurring multichromophore aggregates,[1−4] thus generating potential electron- and/or energy-transfer molecular devices for advanced technological tasks.[5,6] Indeed, over the last few years, various molecular devices based on oligoporphyrins have been designed and prepared; these include photoinduced molecular switches, optoelectronic gates, fluorescence quenching sensors, photonic wires, and molecular elements for information storage essential for the miniaturization of electronic componentry and technology.[7]

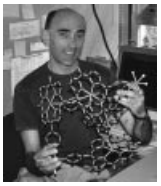
Elisabetta Iengo studied chemistry at the University of Trieste where she received her "Laurea" in 1998 and her PhD degree in 2002. In 1994 she spent a six-month period to the laboratories of Prof. P. J. Sadler, Birkbeck College, London (UK), within the Erasmus project. In 2002 she was awarded the prize for the best PhD thesis in Inorganic Chemistry by the Italian Chemical Society. She is currently a postdoctoral fellow in the laboratories of Dr. Jean-Pierre Sauvage, Université Louis Pasteur, Strasbourg (France). She is co-author of more than 25 publications in the fields of supramolecular chemistry and metal-based anticancer drugs.

Ennio Zangrando was born in Trieste (Italy). He received his degree in Chemistry at the University of Trieste in 1974 and some years later he joined the Department of Chemical Sciences at the same University as an Associate Researcher, prior to become Associate Professor of Inorganic Chemistry. In 1987−1988 he spent some months at the Laboratorium für chemisch-mineralogische Kristallographie of the Universität Bern with Professor H.-B. Bürgi. His research interest deal with X-ray crystallography, using conventional sources as well as synchrotron radiation. His work was dedicated to the structural properties of bio-inorganic complexes and has been extended in recent years to supramolecular chemistry.



Enzo Alessio was born in 1958 and studied chemistry at the University of Trieste where he received his "Laurea" in 1982 and his PhD degree in 1989. In 2000 he was appointed Associate Professor of Inorganic Chemistry at the same University. He spent one year as NATO-CNR fellow in the research group of Professor Luigi G. Marzilli at Emory University (Atlanta). In 1996 he was awarded with the Nasini Prize to young researchers by the Italian Chemical Society. He is co-author of more than 100 publications in the fields of coordination chemistry, metal-based anticancer drugs and supramolecular chemistry.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

Three-dimensional macrocyclic oligomers of metalloporphyrins are also being actively investigated as host molecules for homogeneous catalysis and selective molecular recognition that can result from the specific geometry of cavities defined by porphyrin planes.[8] Interestingly, some oligomeric porphyrins have been tested for photodynamic therapy of tumors and DNA cleavage.[9] Design strategies to develop solid-state multichromophore arrays of defined rigidity, dimensionality, porosity, and selectivity are also a part of active research.[10]

Conventional linear synthetic strategies to porphyrin arrays have generally proved quite limiting; they frequently involve many sequential steps, separation of statistical mixtures and extensive chromatographic purification, always resulting in a low product yield.[11]

Self-assembly has emerged as a viable alternative to covalent synthesis in the construction of large multi-component porphyrin architectures. Both coordination and multiple hydrogen bonds,[12] or their combination,[13] have been used as the source of the noncovalent bonding interactions.

Metal-Mediated Self-Assembly of Porphyrins

The metal-mediated self-assembly approach has recently allowed the design and preparation, in reasonable yield, of increasingly sophisticated supramolecular assemblies of porphyrins whose complexity and function begin to approach the properties of naturally occurring systems.[14]

Within this approach, porphyrins and metalloporphyrins can be exploited essentially in two ways as modules in the construction of discrete or polymeric ordered architectures:

(i) Metalloporphyrins can be *acceptor building blocks* (Figure 1) provided that the metal atom inside the porphyrin core has at least one axial site available for coordination. Oligomers, polymers, and dendrimers of axially connected metalloporphyrins can be designed through selection of the coordination geometry of metal atoms (usually either five- or six-coordinate) and the geometry of the polydentate bridging ligands.

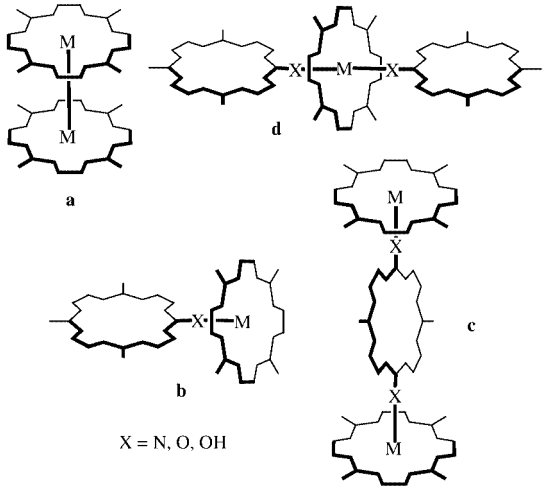


Figure 1. Some schematic examples of metalloporphyrins as acceptor building blocks in the construction of discrete supramolecular assemblies; the metal atom is five-coordinate in **a**−**c**, and six-coordinate in **d**; in **a** the thick line represents a generic bridging ligand; in **b**−**d** the axial ligands are porphyrins which bear X-donor substituents (X = N, O, OH) in peripheral (*meso*) positions

The number of coordination axial sites that can be exploited, their lability as well as the affinity toward different donor atoms can be fine-tuned by changing the nature and the oxidation state of the metal centers inserted into the porphyrin cores.[15] Metal−ligand bonds cover a range of energies depending on the nature of the metal and the ligand. The electronic structure (acidity of the metal center), and the access to the porphyrin core, can be designed by means of well-planned peripheral substitutions either at the β-pyrrole or *meso* position(s). For example, the zinc atom inside zinc−porphyrins prefers to adopt a five-coordinate square-pyramidal geometry and has a good affinity for nitrogen donor ligands. Many metalloporphyrin assemblies, obtained both in solution and as crystalline materials, are based on the zinc−porphyrin−N-heterocycle (pyridine, imidazole) interaction,[16] which is intrinsically weak (association constant, ca. 10^3 M^{-1}) and relatively labile.[14a] Stronger and more inert bonds to N-heterocycles are obtained with $Ru^{II}(CO)$−, $Os^{II}(CO)$−, or Rh^{III}-(halide)−porphyrins. Also in such cases, as with Zn−porphyrins, only one axial coordination site can be exploited for supramolecular construction because, even though the metal atom is six-coordinate, the carbonyl or halide ligands are very tightly bound and not easily displaced. On the other hand, Sn^{IV}−porphyrins adopt a six-coordinate geometry, prefer oxygen donor ligands, and exchange the axial ligands rather slowly.[15] Elegant examples of discrete self-assembled multi-metalloporphyrin arrays employing the mutually noninterfering coordination properties of Zn^{II}, Ru^{II}, and Sn^{IV} centers towards bifunctional ligands bearing pyridyl or carboxylic functionalities have been reported by the group of Sanders.[17]

Finally, the use of complexed ligands for axial coordination (i.e. metal-containing *donor* building blocks) allows for the introduction of further metal centers and thus leads to the construction of even more elaborate assemblies of porphyrins and metal functionalities.[18,19]

(ii) Porphyrins can behave as *donor building blocks*, provided that they have ligands appended to the periphery that can suitably coordinate to metal centers. Most of the examples reported in the literature take advantage of porphyrins elaborately decorated with covalently attached hydroxy or N-donor (imidazole, pyrazole, amine, pyridine) ligands usually at the *meso* positions. Within this framework, *meso*-pyridyl/phenylporphyrins (PyPs), or strictly related chromophores proved to be particularly versatile building blocks: PyPs can provide geometrically well-defined connections to as many as four metal centers by coordination of the pendant *meso*-pyridyl groups.

These two kinds of porphyrin modules, *acceptor* and *donor*, can be freely and rationally combined to build multiporphyrin self-assembling systems. When porphyrins bearing external coordination functionalities bind to other metalloporphyrins, assemblies of axially connected chromophores are generated (Figure 1).[20] Tailor-made

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

metalloporphyrins bearing nitrogen and oxygen donor functionalities have been designed that spontaneously self-assemble in discrete arrays by virtue of the independent coordination properties of Zn^{II}, Ru^{II}, Rh^{III} and Sn^{IV} centers.[21]

A particular case of self-assembly is self-coordination, which may occur in metalloporphyrins with matching appended donor ligands (i.e. modules possessing *acceptor* and *donor* features with reciprocal affinity). Most of the examples reported to date concern the one-point self-coordination of metalloporphyrins bearing one peripheral N-donor site, usually a pyridyl or imidazolyl moiety; with few exceptions,[22] the metal atom inside the porphyrin has only one axial coordination site available [e.g. Zn^{II} or Ru^{II}(CO)]. The nature of the resulting architectures, either discrete polycyclic structures or linear oligomers/polymers, depends mainly on the relative geometry of the porphyrin plane (acceptor site) and of the donor site (Figure 2).[23] Also the concentration plays a crucial role in determining the nature of the resulting species; in some cases a polymeric structure was found in the solid state, while spectroscopic evidence suggested that closed cyclic structures (macrocyclic oligomers) prevailed in solution, at least at NMR concentrations.[23a,24]

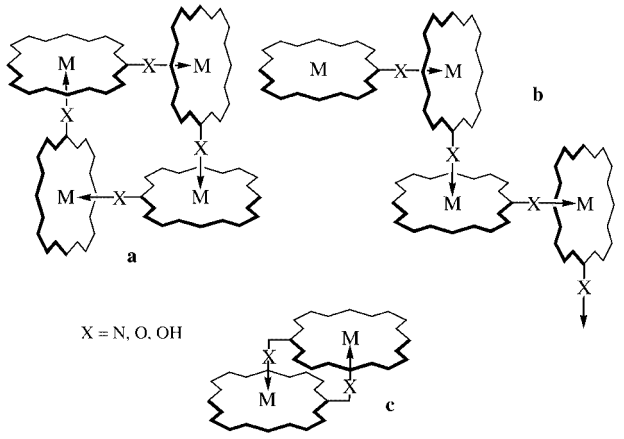

Figure 2. Schematic examples of supramolecular assemblies obtained by one-point self-coordination of metalloporphyrins which bear one X-donor substituent (X = N, O, OH) in the peripheral (*meso*) position; the nature of the resulting architectures, either discrete macrocyclic species (**a**, **c**) or linear stair-like oligomers/polymers (**b**), depends mainly on concentration and on the relative geometry of the metalloporphyrin plane (acceptor site) and of the donor site in the monomer

A convenient and extremely versatile synthetic strategy towards supramolecular assemblies of porphyrins exploits the formation of coordination bonds between donor sites on the porphyrins and external metal centers, that can either be naked ions or coordination compounds (Figure 3). In particular, when the design of three-dimensional structures or, in general, architectures containing cavities with precise size and shape is of interest, the use of coordination compounds as structural units has proved to be very efficient. A large and diverse number of transition-metal coordination geometries can be exploited in the construction of elaborate assemblies, giving access to different topologies rather difficult to obtain with the classical synthetic methods. Moreover, charge and polarity, as well as the introduction of additional functionalities, can be fine-tuned through the ancillary ligands.

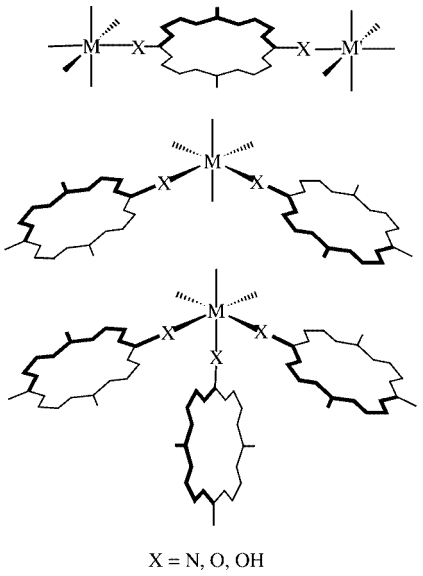

Figure 3. Some schematic examples of porphyrins connected through coordination compounds

Several polymeric structures of metal-coordinated porphyrins have been prepared as a result of exploring ways to construct three-dimensional channelled solids with different chemical architectures and potentially diverse catalytic activity.[10,25] However, as we are more interested in the construction of discrete assemblies endowed with particular properties and/or functions, as an example we describe here briefly the astonishing variety of 2D and 3D porphyrin assemblies obtained in less than a decade by the modular combination of PyPs (or related *meso*-substituted porphyrins) and square-planar Pt^{II} and Pd^{II} complexes with one or two available coordination sites.

Two-dimensional metallacycles of porphyrins, i.e. molecular squares, were obtained by treatment of *meso*-bis(4′-pyridyl)porphyrins (i.e. 4′-*cis*DPyP and 4′-*trans*DPyP) with the appropriate linear or angular metal fragments derived from *trans*-[$PdCl_2$(dmso)$_2$], *cis*-[$PtCl_2$(dmso)$_2$], and [Pt(dppp)$(OTf)_2$] or [Pd(dppp)$(OTf)_2$].[26] Depending on the geometries of the building blocks, the porphyrins can either sit on the corners (2+2 or 4+4 squares) or on the sides (4+4 squares) of the metallacycles; in this latter case the chromophores are actually oriented perpendicularly to the plane of the molecular square. With a similar synthetic approach, Drain and co-workers prepared more elaborate architectures, such as tessellated arrays of porphyrins.[27]

Three-dimensionality can be obtained by switching from 4′- to 3′-PyPs, in which the newly formed 3′-N(py)−M bond points out of the porphyrin plane. Reed, Boyd, and co-workers obtained a kinked bis(porphyrin)palladium complex by simple coordination of two 3′-MPyP units to

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the *trans*-$PdCl_2$ fragment.[28a] This jaw-like cleft has proved to be an efficient host for fullerene.[28b]

A more elaborate bis(porphyrin) host for fullerene, obtained by coordination of a covalent pyridylporphyrin dimer to [Pd(dppp)$(OTf)_2$], was recently reported by the group of Shinkai.[29] Interestingly, coordination to the bis(porphyrin) building block does not provide a receptor for C_{60}; coordination to the $Pd(dppp)^{2+}$ fragment interconverts the dimer from an *anti* to a *syn* conformation, thus creating a cavity for hosting fullerene.

The same group has described a molecular capsule self-assembled by coordination of two zinc−porphyrins to four $Pd(dppp)^{2+}$ fragments[30a] (and, more recently, also to chiral Pd fragments[30b]). Each porphyrin is substituted at *meso* positions with four rigid pyridylacetylene donor ligands oriented almost perpendicular to the plane of the chromophore; thus, coordination to the *cis* positions of the four bridging metal units leads to the two porphyrins being cofacial. The capsule was proved capable of selectively hosting a molecule of 4,4′-trimethylenebipyridine by two Zn−N interactions.

Fujita and co-workers, making use of a simple tetrapyridylporphyrin followed a similar approach. They reported a very elegant example of quantitative self-assembly of a porphyrin prism made up of three 3′-TPyP units and six $Pd(en)^{2+}$ fragments. The porphyrins behave as rigid molecular panels for the three-dimensional structure, while the six palladium complexes that clip them together sit at the apical positions, thus creating a large hydrophobic cavity, which should be capable of accommodating neutral organic molecules in aqueous solution.[31]

Finally, Reinhoudt and co-workers described the self-assembly of two porphyrin dendrimers, a pentamer and a nonamer. The central porphyrin is derivatized at the *meso* positions with four Pd centers; each of them can bind either one 4′-MPyP (pentamer) or a bis(4′-MPyP) building block (nonamer) by pyridyl coordination. These systems should be able to undergo energy transfer processes from the surface to the center of the assembly.[32]

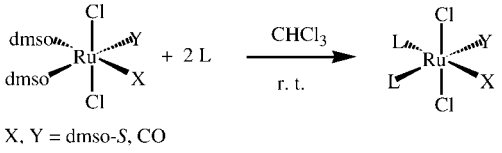
It should be noted that most of the above examples employed the $Pd(chel)^{2+}$ fragment as a connecting unit. It can easily be anticipated that the use of other metal fragments, e.g. with different geometry and/or number of coordination sites, might lead to an even larger variety of architectures. In our work, summarized in the following pages, we exploited the coordination chemistry of octahedral Ru complexes.

Ruthenium-Mediated Discrete Assemblies of Porphyrins

At the beginning of our investigation in this field, we prepared a series of oligomers of perpendicularly linked porphyrins by axial coordination of the 4′-pyridyl groups of 4′-PyPs to [Ru(TPP)(CO)(EtOH)].[33] Later, by using *meso*-3′-pyridylporphyrins (3′-PyPs) as building blocks instead of 4′-PyPs, we synthesized the canted analogs of selected perpendicular assemblies.[34] The synthesis, characterization and photophysical behavior of these adducts have been the subject of a recent review and will not be discussed here.[35] Rather, we will focus on the coordination-driven construction of discrete supramolecular assemblies employing 4′-pyridylporphyrins and neutral, octahedral, ruthenium coordination compounds. Compared to most previous examples, which used doubly charged square-planar metal fragments as structural units, our approach is likely to lead to neutral assemblies, thus providing greater solubility in organic solvents. Moreover, the two additional coordinated "spectator" ligands in each octahedral complex, besides being, in principle, useful extra spectroscopic handles for the characterization, might prove advantageous for a better fine-tuning of the properties of the metal and for further functionalization of the assemblies as well.

Coordination of 4′-Pyridylporphyrins to Ruthenium Complexes

In the past we established that the Ru^{II}−dmso complexes, *trans*-[$RuCl_2$(dmso-*S*)$_4$] (**1**),[36,37] *trans*,*cis*,*cis*-[$RuCl_2$(dmso-*O*)$_2$(CO)$_2$] (**2**),[38] and *trans*,*cis*,*cis*-[$RuCl_2$(dmso)$_3$(CO)] (**3**),[38] are suitable precursors for neutral *90° angular acceptor* building blocks, as they easily replace two *cis*-dmso ligands with heterocyclic N-donor ligands L (Scheme 1). The newly formed Ru−N bonds on the *trans*,*cis*,*cis*-[$RuCl_2$(X)(Y)] fragment (X, Y = dmso-*S*, CO) are both stable and inert.



Scheme 1

For example, reaction of **1** or **2** with 2 equiv. of monopyridylporphyrin, 4′-MPyP, under mild conditions (chloroform, room temperature) gave the 1:2 complexes *trans*,*cis*,*cis*-[$RuCl_2$(dmso-*S*)$_2$(4′-MPyP)$_2$] (**4**) and *trans*,*cis*,*cis*-[$RuCl_2(CO)_2$(4′-MPyP)$_2$] (**5**), respectively.

^{1}H NMR spectroscopy proved particularly useful for characterizing the new Ru−4′-PyP complexes. Coordination to Ru mainly affected the resonances of the pyridyl ring(s) of 4′-PyPs, causing downfield shifts [Δδ(H2,6) from 0.3 to 0.9 ppm, Δδ(H3,5) from 0.03 to 0.18 ppm]. The resonances of the pyrrole protons are particularly informative about the geometry of the porphyrin, while the dmso-*S* signals, when present, give information about the coordination environment. IR and $^{13}C\{^1H\}$ NMR spectroscopic data concerning the chloride, dmso, and carbonyl ligands provided further evidence for the unambiguous assignment of the product geometry. In general, all the adducts show UV/Vis spectra similar to those of the corresponding 4′-PyPs, except for minor bathochromic shifts of the Soret (ca. 10 nm) and Q-bands (from 2 to 6 nm) and small changes in their relative absorption intensities; these are consistent with the removal of electron density from the porphyrin π-system upon ruthenium−pyridine bond formation, as reported in similar cases.[26b,39]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In the ^{1}H NMR spectrum of the *cis*-disubstituted 4′-PyP species, such as *trans*,*cis*,*cis*-[$RuCl_2$(dmso-*S*)$_2$(4′-MPyP)$_2$] (**4**), we identified a signature that is quite characteristic of two mutually *cis*-coordinated pyridylporphyrins in free rotation about the metal−pyridyl axis: there are two sets of multiplets (1:2 ratio) for the phenyl protons (i.e. *o*H and *m*+*p*H) of the two *cis*-porphyrins (Figure 4). The signals of the major set, shifted upfield by about 0.2 ppm compared to those of the minor set, were assigned to the two phenyl rings *cis* to the pyridyl ring (positions 10 and 20). Such an upfield shift is caused by the rotation of the porphyrin about the Ru−pyridyl axis, which brings the phenyl rings at the 10 and 20 positions into the shielding cone of the adjacent porphyrin (Figure 5). The relatively small upfield shift suggests that the two porphyrins rotate freely and that the average time spent in the orientations inducing mutual shielding is rather short.

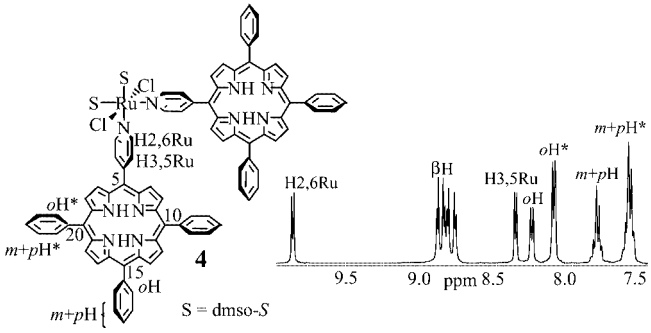


Figure 4. Downfield region of the ^{1}H NMR spectrum of *trans*,*cis*,*cis*-[$RuCl_2$(dmso-*S*)$_2$(4′-MPyP)$_2$] (**4**) in $CDCl_3$ (ppm); resonances of protons on phenyl rings at positions 10 and 20 are marked with an asterisk; see side drawing for detailed labeling scheme

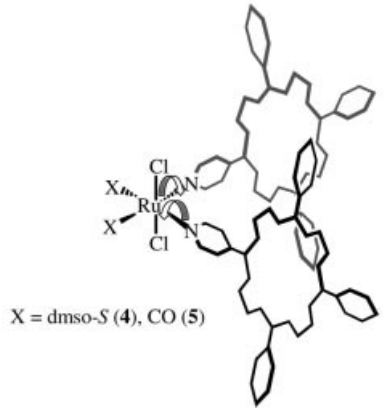

Figure 5. Schematic drawing of *trans*,*cis*,*cis*-[$RuCl_2$ (dmso-*S*)$_2$(4′-MPyP)$_2$] (**4**) and *trans*,*cis*,*cis*-[$RuCl_2(CO)_2$(4′-MPyP)$_2$] (**5**) showing that the phenyl rings at the *meso* positions 10 and 20 fall into the shielding cone of the *cis*-coordinated porphyrin

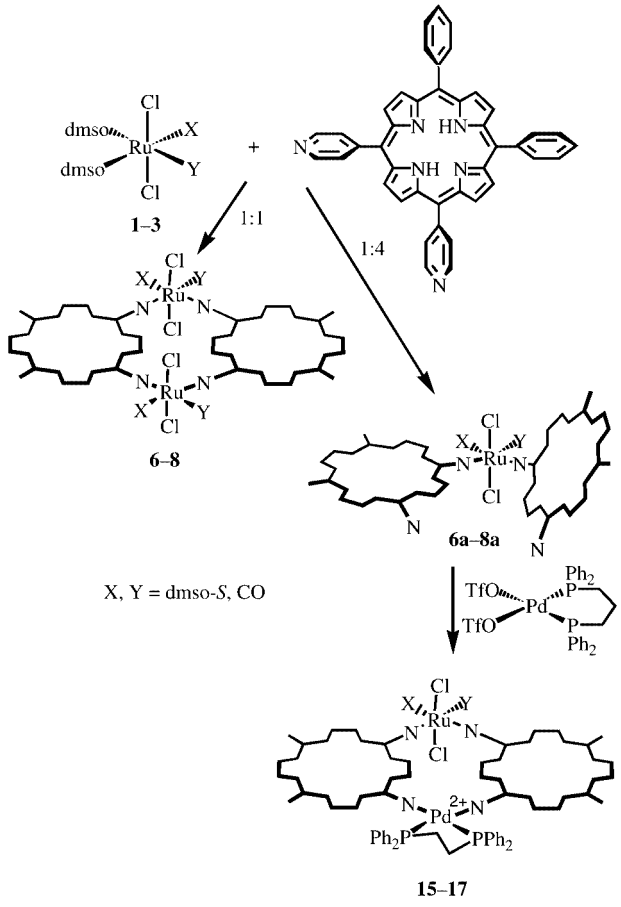

Scheme 2

As a logical extension of the synthetic results described above with 4′-MPyP, we then investigated the reaction of the *cis*-coordinating ruthenium precursors **1**−**3** with the angular porphyrin building block 4′-*cis*DPyP. We found that two different classes of products, namely molecular squares **6**−**8** and bis(pyridyl)porphyrin adducts **6a**−**8a**, are selectively formed depending on whether a stoichiometric amount (**6**−**8**) or an excess of 4′-*cis*DPyP (**6a**−**8a**) is used (Scheme 2). The two classes of products will be described separately.

Neutral Molecular Squares of Porphyrins Connected through Octahedral Ru^{II} Complexes[40]

Treatment of **1**−**3** with a stoichiometric amount of 4′-*cis*DPyP under mild conditions (chloroform, ambient temperature) led to the formation of the corresponding 2+2 homonuclear neutral squares of porphyrins of formula *trans*,*cis*,*cis*-[$RuCl_2$(X)(Y)(4′-*cis*DPyP)]$_2$ (X = Y = dmso-*S*: **6**; X = Y = CO: **7**; X = dmso-*S*, Y = CO: **8**) (Scheme 2).[40] These products were purified by column chromatography and fully characterized by means of NMR spectroscopy and FAB mass spectrometry. In general, the mobility of pyridylporphyrin adducts on silica gel is inversely related to the number of free 4′-N(py) sites. Thus, the most abundant and mobile product from each of the above reactions was

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

attributed to a metallacyclic species and some minor bands with lower mobilities to open-chain oligomers with unbound 4′-N(py) sites.

The ^{1}H NMR spectrum of **6**, that unambiguously established the metallacyclic nature (no signals for unbound pyridyl rings are present) and high symmetry (D_{2h}) of this species is reported in Figure 6.

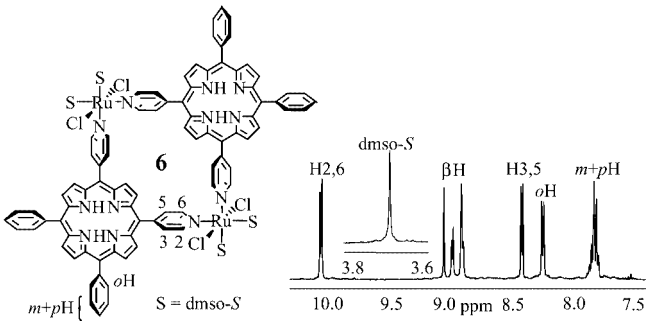

Figure 6. Schematic drawing of *trans,cis,cis*-[$RuCl_2$(dmso-*S*)$_2$(4′-*cis*DPyP)]$_2$ (**6**) with labeling scheme and its ^{1}H NMR spectrum (with the exception of the NH resonance) in $CDCl_3$ (ppm)

Contrary to what was found in the NMR spectra of **4** and **5**, the *o*H and the *m*+*p*H phenyl resonances of **6**−**8** are not each split into two multiplets, confirming that the chromophores are not free to rotate about the Ru−N bonds. The metallacycle *trans,cis,cis*-[$RuCl_2$(dmso-*S*)(CO)(4′-*cis*DPyP)]$_2$ (**8**) exists as an equimolar mixture of the two geometrical isomers **8′** and **8′′** (Figure 7); in one isomer (**8′**) the 4′-N(py) moieties of each porphyrin are *trans* to one CO and one dmso-*S* ligand, respectively, and the resulting metallacycle has a C_{2v} symmetry; in the other (**8"**), the two 4′-N(py) ligands of one 4′-*cis*DPyP are *trans* to CO, while those of the other are *trans* to dmso-*S* and the resulting molecular square has a C_{2h} symmetry. The two isomers could not be separated by column chromatography. Only the pyridyl protons of the two isomers have resolved resonances in the aromatic region of the NMR spectrum of the mixture of **8′** and **8′′**; all the other ^{1}H NMR resonances of **8′** and **8′′** overlap.

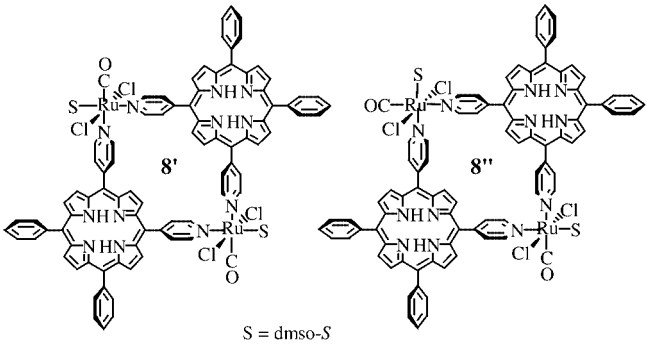

Figure 7. Schematic drawing of the two geometrical isomers of *trans,cis,cis*-[$RuCl_2$(dmso-*S*)(CO)(4′-*cis*DPyP)]$_2$, **8′** and **8′′**

The *trans,cis,cis*-[$RuCl_2$(dmso-*O*)$_2$(CO)$_2$] (**2**) precursor behaved somewhat differently from **1** and **3** and deserves further comment. The ^{1}H NMR spectrum of the crude reaction mixture between **2** and an equimolar amount of 4′-*cis*DPyP clearly indicated the presence of three major products with sharp and resolved resonances pertaining to cyclic symmetrical species, besides smaller amounts of open-chain oligomers with broad signals. The product with the largest mobility on silica gel, which is also the most abundant, was separated and purified by column chromatography and characterized as the molecular square *trans,cis,cis*-[$RuCl_2$(CO)$_2$(4′-*cis*DPyP)]$_2$ (**7**). A second product, namely **9**, which has an R_f value very similar to that of **7** on silica gel (0.67 versus 0.72 for **7**) was also obtained in its pure form after chromatography. The ^{1}H NMR spectrum of **9** has a pattern similar to that of **7**, thus establishing unambiguously its metallacyclic nature and high symmetry; it must be noted though that all signals of **9** are markedly upfield-shifted as compared to those of **7** (Figure 8).

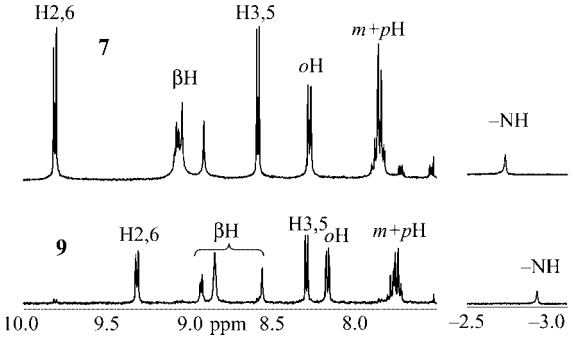

Figure 8. Comparison of the ^{1}H NMR spectra of the molecular square *trans,cis,cis*-[$RuCl_2$(CO)$_2$(4′-*cis*DPyP)]$_2$ (**7**, top) and of the "bowl-shaped" trinuclear metallacycle *trans,cis,cis*-[$RuCl_2$(CO)$_2$(4′-*cis*DPyP)]$_3$ (**9**, bottom)

According to FAB MS spectrometry compound **9** can be formulated as the trinuclear species [$RuCl_2$(CO)$_2$(4′-*cis*DPyP)]$_3$.[41] A triangular geometry in which three *cis*-coordinated 4′-*cis*DPyP units and three *trans,cis,cis*-[$RuCl_2$(CO)$_2$] fragments are coplanar would result in a very strained structure; more likely the two porphyrins coordinated to the same Ru fragment are not coplanar. A computer model showed that the result of the total energy minimization is a three-dimensional bowl-shaped architecture with a C_{3v} symmetry (Figure 9), with pairs of *cis*-porphyrins forming a ca. 90° dihedral angle to one another. Connection of each ruthenium atom to the center of the adjacent porphyrins yields a six-membered ring with a *chair*-like conformation. This model structure is in good agreement with the ^{1}H NMR spectroscopic data. The porphyrin units are mutually arranged so that each one lies partially in the shielding cone of the others, which may explain the upfield shifts observed for the porphyrin resonances in the ^{1}H NMR spectrum of **9** as compared to that of **7**.

The third product of the above reaction, **10**, has not been isolated in pure form thus far, having a mobility on silica very close to that of **9** (R_f = 0.65). From the ^{1}H NMR spectra of partially purified samples it is clear that **10** is a metallacycle, its pyridyl proton signals having chemical

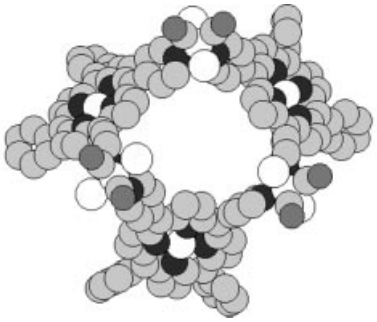

Figure 9. Computer-generated (Hyperchem) minimum energy model structure of the "bowl-shaped" trinuclear metallacycle *trans*,*cis*,*cis*-[$RuCl_2(CO)_2$(4′-*cis*DPyP)]$_3$ (**9**)

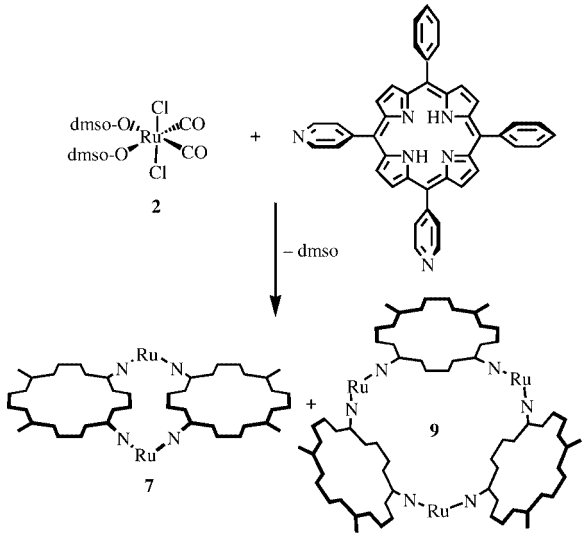
shifts in between those of **7** and **9**. Compound **10** could be either a conformational isomer of **9** or a porphyrin metallacycle with higher nuclearity (no mass spectrometric data are available for **10** as yet).

It must be stressed that no equilibration between these three products was observed; once isolated and redissolved they do not undergo any interconversion process and are indefinitely stable at ambient temperature. Therefore, the stoichiometric reaction between **2** and 4′-*cis*DPyP represents an example of a *combinatorial library* (Scheme 3). Most probably **7**, **9**, and **10** are kinetic products of the reaction. The fact that more than one cyclic geometry becomes accessible in this case is probably due to the presence of small ancillary ligands in the ruthenium fragments (X = Y = CO) which allow for the rotation of the *cis*-coordinated 4′-*cis*DPyP units around the $C_{meso}-C_{ring}$ bonds. This might not be the case for precursors **1** and **3**, in which rotation of the chromophores might be sterically disfavored by the bulkier dmso-*S* ligands.



Scheme 3

The electronic absorption spectra of metallacycles **6**–**9** are very similar to those of 4′-*cis*DPyP, apart from a small bathochromic shift for the Soret band (ca. 8 nm); the molar extinction coefficient per porphyrin in each square (ε/porphyrin for the Soret band) is substantially the same as that found for 4′-*cis*DPyP ($\varepsilon = 29 \times 10^4$ cm^{-1} M^{-1}). A detailed investigation of the photophysical properties of molecular squares **6** and **7**, in comparison to some acyclic reference compounds, was performed by the group of Scandola.[42] In all the adducts investigated the emitting singlet excited state is shorter-lived than in the parent pyridylporphyrin molecule. A nice correlation between the lifetime shortening and the number of metal centers attached to each chromophore was found by keeping the nature of the Ru fragment, peripherally bound to the pyridylporphyrin, constant. A likely explanation for the pyridylporphyrin singlet quenching in the adducts can be identified in the "heavy-atom effect" of the metal.

As a general comment we might add that, compared to the other neutral molecular squares of porphyrins, described by Hupp and co-workers,[39a,43] that feature octahedral *fac*-[$Re(CO)_3Cl$] corner units, our compounds have the advantage of being more symmetrical: the two axial ligands of the Re^I corners are different (one Cl and one CO), thus generating mixtures of isomers when connected in a square.

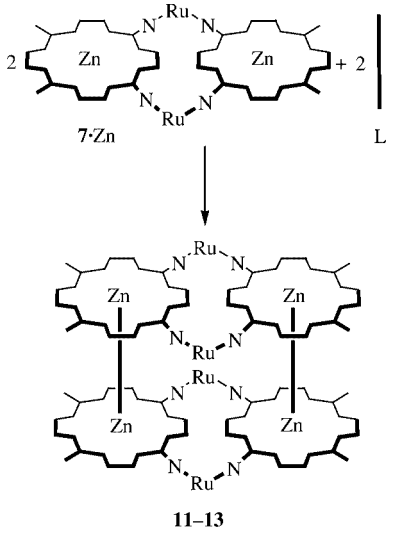
Self-Assembling of Higher Order Architectures by Axial Ligation of Molecular Squares of Metalloporphyrins

Treatment of molecular square **7** with excess zinc acetate in chloroform/methanol mixtures led to the isolation of the corresponding zinc adduct *trans*,*cis*,*cis*-[$RuCl_2(CO)_2$(Zn·4′-*cis*DPyP)]$_2$ (**7**·Zn). The same reaction was not pursued on **6** and **8** because, as previously reported by us for other Zn·PyP–Ru–dmso-*S* complexes, a self-assembling process is expected to occur between the oxygen atom of the dmso-*S* ligand of one molecule and the zinc center of another molecule that leads to a broadening of some NMR resonances.[36] The ^{1}H NMR spectrum of **7**·Zn is very similar to that of **7**, except for the absence of the –NH signal; the resonances are always sharp and the spectrum is concentration independent in the range between 0.1 and 10 mM (as was the case also for **6**–**9**), indicating that no aggregation occurs in chloroform solution.[40]

Owing to the preference of zinc–porphyrins for five-coordinate square-pyramidal geometry, **7**·Zn is a rigid two-dimensional building block with two axial *acceptor* sites. Thus, it can be treated with appropriate multidentate donor ligands for the construction of more elaborate supramolecular adducts. This is made possible by the inertness of the Ru–pyridyl bond, which provides kinetic stability to the molecular square **7**·Zn.

Using ^{1}H NMR spectroscopy we investigated the reactivity of **7**·Zn towards a series of linear ditopic N-donor ligands (L), namely 4,4′-bipy, 4′-*trans*DPyP, and 4′-*trans*DPyP-npm. We found that treatment of **7**·Zn with 1 equiv. of L leads selectively to the quantitative assembling of sandwich-like 2:2 supramolecular adducts of formula [(**7**·Zn)$_2$(μ-L)$_2$] (**11**–**13**; L = 4,4′-bipy: **11**; L = 4′-*trans*DPyP: **12**; L = 4′-*trans*DPyP-npm: **13**), consisting of two molecular squares connected face-to-face by two bridg-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 4

ing ligands which are axially bound to the zinc−porphyrins (Scheme 4).

The rigid frame of the molecular squares ensures that the bridging ligands are arranged at a fixed distance and with a well-defined mutual orientation. Symmetrical axial coordination of the bridging ligands to the squares was unambiguously established by the large upfield shift of all their resonances due to the combined ring currents of both porphyrins (which decreases gradually as the proton distance from the zinc−porphyrins increases). Unequivocal determination of the solution structures of **11**−**13** and complete assignment of their NMR resonances was achieved by 2D H-H COSY and EXSY experiments.

NMR spectroscopic evidence also indicated that in compounds [(**7**·Zn)$_2$(μ-4′-*trans*DPyP)$_2$] (**12**) and [(**7**·Zn)$_2$(μ-4′-*trans*DPyP-npm)$_2$] (**13**) the two bridging pyridylporphyrins maintain the cofacial orientation found in the solid state for **12** (see below). Thus **12** and **13**, which feature six porphyrins each, might be better defined as molecular boxes of porphyrins (Figure 10).

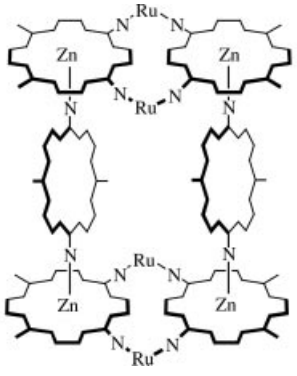


Figure 10. Schematic drawing of the molecular boxes of porphyrins **12** and **13**

Overall, the NMR spectroscopic features indicate that, at ambient temperature, the formation of [(**7**·Zn)$_2$(μ-L)$_2$] from **7**·Zn and L has an intermediate-to-slow rate on the NMR time-scale (relatively broad signals for L) and is a complete process (all-or-nothing process). Entropy considerations (no global conformational changes required owing to the rigidity of the building blocks) suggest that there must be considerable cooperativity between the addition of the first and of the second bridging ligand. Formation constants higher than 10^{18} M^{-2} were estimated in chloroform for compounds **11**−**13**. Accordingly, the NMR spectra of $CDCl_3$ solutions of both **11** and **12**, diluted to the limit of detection (ca 3×10^{-5} M), exclusively showed the resonances of the intact assemblies.

Single crystals of **11** and **12** suitable for X-ray investigations were obtained by slow diffusion of *n*-hexane into $CDCl_3$ solutions of each compound. The structural determination of compound **12** showed that the molecular sandwich architecture observed in solution is also found in the solid state (Figure 11). The distance between the two opposite molecular squares is ca. 19.5 Å. The two bridging 4′-*trans*DPyP ligands are slightly bowed inward and cofacial, at a distance of ca. 11.4 Å. The apical 4′-N(py) rings bound to the Zn ions are approximately perpendicular to the ZnN4 basal plane.

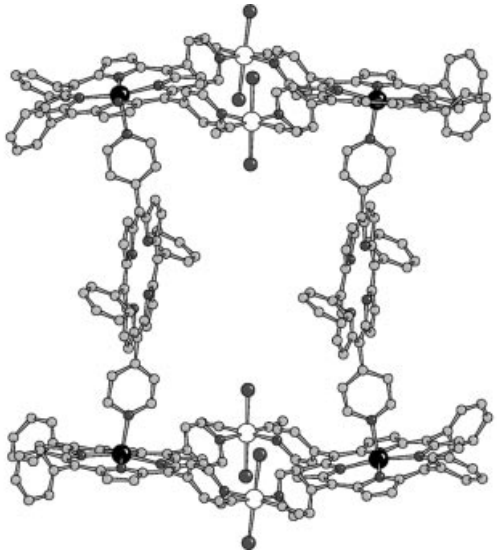

Figure 11. Perspective view of the solid-state structure of molecular box [(**7**·Zn)$_2$(μ-4′-*trans*DPyP)$_2$] (**12**); Ru atoms are represented by white spheres, Zn atoms by black spheres

To our surprise, the X-ray analysis of **11** showed that the solid-state architecture of this compound is different from that found in solution and consists of an infinite wire of **7**·Zn squares bridged by 4,4′-bipy ligands which are axially coordinated, alternatively, on the two opposite faces of each square, [(**7**·Zn)(μ-4,4′-bipy)]$_\infty$ (Figure 12). The polymeric chain structure found for **11** in the solid state is an unprecedented example of a molecular wire made of porphyrin metallacycles bridged by organic ligands. Two crystallographically different **7**·Zn macrocycles, *A* and *B*, alternate along the chain, forming a stair-like infinite structure featuring the (*ABA*)·(*ABA*) motive, with inversion centers lo-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

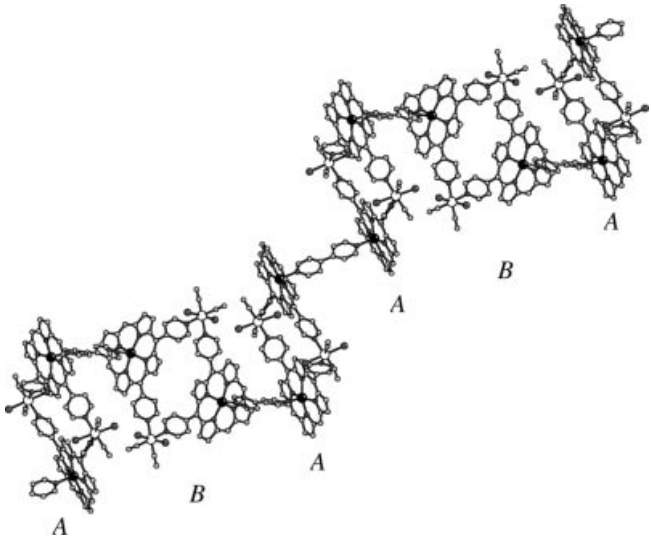

Figure 12. Solid-state structure of the one-dimensional polymeric compound $[(\mathbf{7}\cdot Zn)(\mu\text{-}4,4'\text{-bipy})]_\infty$ (**11**) composed of repeating *ABA* triplets (see text); Ru atoms are represented by white spheres, Zn atoms by black spheres

cated between two consecutive *ABA* triplets and in the center of units *B*.

In self-assembly processes, the equilibrium between discrete and polymeric species is dependent on concentration.[23a,24] The fact that in this case a polymer crystallizes out preferentially over sandwich **11**, even though this latter is the most favored assembly in solution in the range of concentrations examined (we had no spectroscopic evidence of polymeric or oligomeric material in solution), suggests that crystal packing forces must play a significant role in determining the solid-state structure.

In conclusion, we showed that molecular squares of porphyrins, after metallation, become suitable building blocks for the construction of more elaborate supramolecular arrays by axial coordination of bridging ligands. Although oligomers and polymers (molecular wires) of metalloporphyrins axially connected through bridging ligands have been described,[7a,23a,44] there are few examples concerning multiporphyrin systems. Anderson and co-workers extensively investigated the assembly of two flexible oligomers of covalently connected zinc−porphyrins through axial ligation of bridging N-donor ligands, thus obtaining 2D molecular ladder systems with increased inter-porphyrin conjugation.[45] To date, however, the stacking of 2D porphyrin macrocycles through axial ligation to yield 3D assemblies has been scarcely investigated; examples concerning the use of molecular squares of metalloporphyrins,[26a] and closely related systems such as molecular grids,[27] have been alluded to only briefly and are not well documented.

Compounds **12** and **13** are particularly stimulating for further investigation, as they can indeed be regarded as molecular boxes featuring two coplanar bridging pyridylporphyrins at a distance of about 11.4 Å. Even though cofacial bis(porphyrins) connected to one another by flexible or rigid organic bridges are well known,[46,47] systems in which the two porphyrins are not covalently linked are rather uncommon. A recent example of a porphyrin-based capsule constructed through Pd^{II}−pyridine bonds was reported by the group of Shinkai (see Introduction).[30] We are currently investigating the capability of **12** to behave as a host for the inclusion of guest molecules of appropriate shape and size through π-π interactions with the cofacial porphyrins.

Heterodimetallic Molecular Squares of Porphyrins

Treatment of **1**−**3** with excess 4′-*cis*DPyP under mild conditions led, after chromatographic purification, to the isolation of the bis(porphyrin) adducts *trans*,*cis*,*cis*-$[RuCl_2(X)(Y)(4'\text{-}cis\text{DPyP})_2]$ **6a**−**8a** in pure form (Scheme 2; X = Y = dmso-*S*: **6a**; X = Y = CO: **7a**; X = dmso-*S*, Y = CO: **8a**). Compounds **6a**−**8a** have one residual unbound 4′-N(py) ring on each of the two *cis*-coordinated 4′-*cis*DPyP units and are thus building blocks suited for two-point coordination.[48]

The nature and geometry of the products was established by ^1H and ^{13}C NMR spectroscopy. Signal integration (in **6a** and **8a**) revealed adduct stoichiometry, while H-H COSY spectra allowed unambiguous signal assignments.

Compounds **6a** and **7a** have C_{2v} symmetry, and thus the two porphyrins are equivalent. As observed before, coordination of 4′-*cis*DPyP to the ruthenium fragment induces downfield shifts for the H2,6 and H3,5 resonances of the 4′-N(py) ring involved in the new bond (position 5). Conversely, the resonances of the pyridyl and phenyl rings at positions 10 and 20, respectively, experience an upfield shift of ca. 0.2 ppm with respect to 4′-*cis*DPyP, which is characteristic of two mutually *cis*-pyridylporphyrins in free rotation about the metal−pyridyl axis, as already noted for monopyridylporphyrin derivatives **4** and **5** (see above). In **8a** the two 4′-*cis*DPyP units are inequivalent; the resonances of the two Ru−4′-N(py) rings are well resolved, whereas the other signals overlap.

Complexes **6a**−**8a** are indeed pre-programmed *donor* building blocks capable of chelating suitable 90° *acceptor* modules. As an example, we investigated their reactivity towards the bis(triflate) of $dpppPd^{II}$. ^1H NMR spectroscopy established that titration of $[Pd(dppp)(OTf)_2]$ into chloroform solutions of compounds **6a**−**8a** led readily to the quantitative formation of the corresponding heterodimetallic 2+2 molecular squares of formula $[Pd(dppp)\{trans,cis,cis\text{-}RuCl_2(X)(Y)(4'\text{-}cis\text{DPyP})_2\}](OTf)_2$ (**15**−**17**) (Scheme 2; X = Y = dmso-*S*: **15**; X = Y = CO: **16**; X = dmso-*S*, Y = CO: **17**). Chelation of the Pd−bis(phosphane) fragment by **6a**−**8a** induces characteristic shifts both in the ^1H NMR spectrum, which mainly concern the resonances of the previously unbound 4′-N(py) ring at position 10, and in the proton-decoupled ^{31}P NMR spectrum (upfield shift of ca. 10 ppm compared to $[Pd(dppp)(OTf)_2]$). The macrocycles were not affected by accidental excess of $[Pd(dppp)(OTf)_2]$ and no evidence of homometallic molecular squares was found. In solution squares **15** and **16** maintain the C_{2v} symmetry of the corresponding ruthenium precursor, and the two porphyrins at opposite corners are equivalent. The resonances of the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Pd−4′-N(py) rings are well resolved from those of the Ru−4′-N(py) rings. Macrocycle **17** lacks the orthogonal mirror plane containing the two metal atoms; hence the two porphyrin units are inequivalent.

Treatment of **7a** with excess zinc acetate led to *trans*,*cis*,*cis*-[$RuCl_2(CO)_2$(Zn·4′-*cis*DPyP)$_2$] (**7a**·Zn), which self-assembles spontaneously in solution (see below). Titration of [Pd(dppp)$(OTf)_2$] into a $CDCl_3$ solution of **7a**·Zn quantitatively yielded the corresponding molecular square [Pd(dppp){*trans*,*cis*,*cis*-$RuCl_2(CO)_2$(Zn·4′-*cis*DPyP)$_2$}]$(OTf)_2$ (**16**·Zn), which represents the first example of a heterotrimetallic molecular square of porphyrins.

The structure of molecular square **16**, with two 4′-*cis*DPyP moieties alternating with the Pd^{II} and Ru^{II} angular units, was established by X-ray single crystal analysis (Figure 13). At the time we published this result it was the first case in which data on the solid-state structure of a molecular square of porphyrins became available.

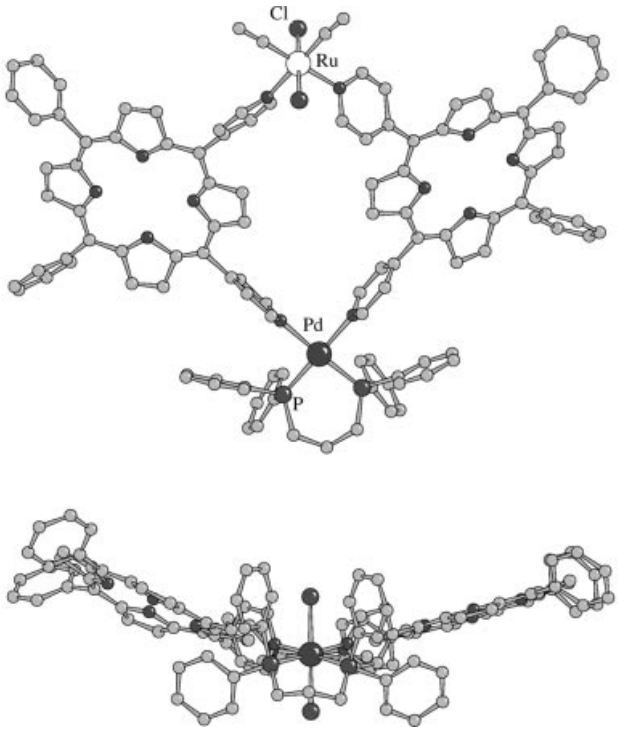

Figure 13. Two perspective views of the solid-state molecular structure of [Pd(dppp){*trans*,*cis*,*cis*-$RuCl_2(CO)_2$(4′-*cis*DPyP)$_2$}]$(OTf)_2$ (**16**); top: top-view; bottom: side-view along the Pd···Ru axis

In **16** the metal−porphyrin center distances are about 9.83 Å, and the diagonal Pd···Ru distance is ca. 14.0 Å; these dimensions are very similar to those found in ruthenium molecular square **7**·Zn (see above). Interestingly, the macrocycle exhibits in the solid state an arrangement with porphyrin least-squares planes that form a dihedral angle of 41.7(1)°, approximating a C_s symmetry (Figure 13).

In conclusion, we found that the reaction between 4′-*cis*DPyP and the ruthenium precursors **1**−**3** leads to different classes of products depending on the reagents ratio: either molecular squares **6**−**8** (1:1 ratio) or bis(pophyrin) complexes **6a**−**8a** (4:1 ratio). This experimental observation implies that the formation of such products is under kinetic control. This result might have been anticipated considering the inert nature of the Ru^{II}−4′-N(py) bond. It has been reported that when more labile metal centers are used as structural units, and thus the self-assembling reaction is under thermodynamic control, the most stable molecular square is the main reaction product regardless of the ratio of reagents being employed. Namely, when an excess of one of the two reagents is used, only the cyclometallated product (plus the unchanged building block) is obtained at the end of the reaction.[49]

In future, treatment of precursors **6a**−**8a** with other *angular* acceptor metal based units might be an efficient pathway to the construction of novel heterodimetallic 2+2 molecular squares of porphyrins, featuring metal ions of defined geometry and/or charge at opposite corners; specific reactions might be envisaged to derivatize these species selectively at either metal corner. Moreover, treatment of **6a**−**8a** with metal centers having different coordination numbers and geometries (for instance tetrahedral, or even octahedral naked ions) might lead to the formation of multiporphyrin−metal based assemblies in which the pairs of chromophores are locked with mutual orientations other than coplanar.

Two-Point Self-Coordination of the Dizinc(ii)−Bis(pyridylporphyrin)−Ruthenium Complex 7a·Zn

The bis(porphyrin)ruthenium complex *trans*,*cis*,*cis*-[$RuCl_2(CO)_2$(Zn·4′-*cis*DPyP)$_2$] (**7a**·Zn) described above is an unprecedented example of a metal-containing building block featuring two *donor* [the uncoordinated 4′-N(py) atoms] and two *acceptor* (the Zn atoms) sites, whose relative orientation depends on the torsion angles about the Ru−N bonds.[50]

^{1}H NMR spectroscopy indicates that **7a**·Zn self-assembles in $CDCl_3$ solution through 4′-N(py)−Zn interactions to yield selectively a single, highly symmetrical, discrete species (**7a**·Zn)$_n$, in which all donor and all acceptor sites of each **7a**·Zn unit are involved; accordingly (**7a**·Zn)$_n$ runs as a single spot on TLC plates and is significantly less polar than **7a**.

The single-crystal X-ray analysis of (**7a**·Zn)$_n$ established that the compound is actually a dinuclear species, (**7a**·Zn)$_2$, in which the four 4′-N(py) sites and the four Zn sites of the two **7a**·Zn units are mutually saturated (Figure 14).

The four porphyrins in (**7a**·Zn)$_2$ have a propeller-like arrangement, with a global S_4 symmetry (the improper rotation axis passes through the ruthenium atoms) and define a small internal cavity, partially occupied by two chloroform molecules. The adduct is a *meso* form derived from the combination of two **7a**·Zn units with opposite helical chirality. The Ru atoms, that display a distorted octahedral geometry, are ca. 19.6 Å apart; the four Zn ions, which have a square-pyramidal environment, occupy the vertices of a distorted tetrahedron (Figure 15). The distances between the carbonyl oxygen atoms of the two Ru ions (ca. 24.0 Å),

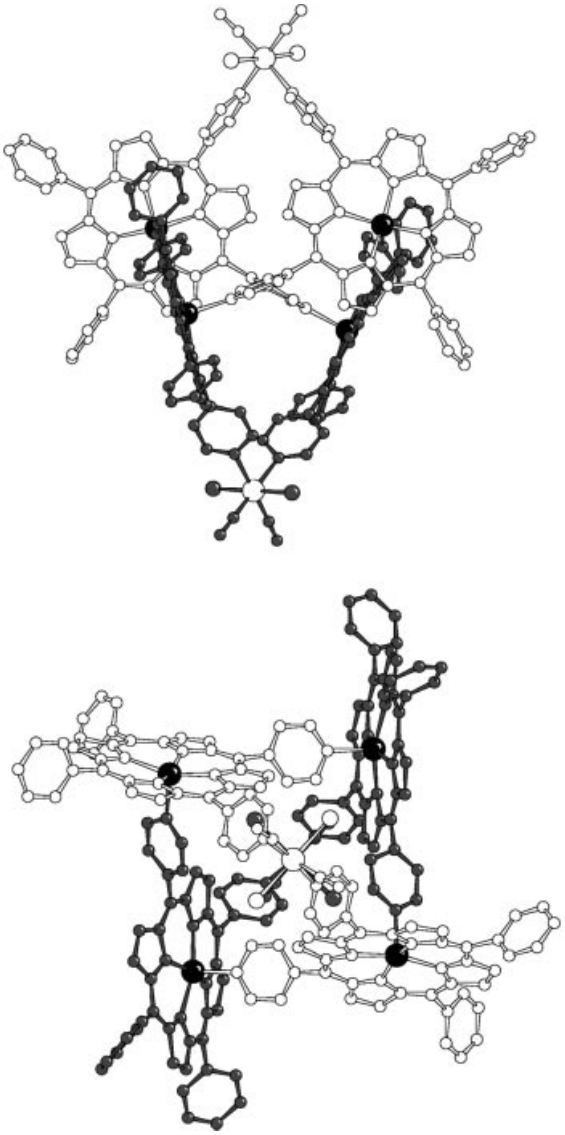

Figure 14. Two perspective views of the solid-state molecular structure of (**7a**·Zn)$_2$; the bottom view is along the S_4 axis; for clarity the two **7a**·Zn units have different shades; Ru atoms are represented by white spheres, Zn atoms by black spheres; adapted from ref.[50]

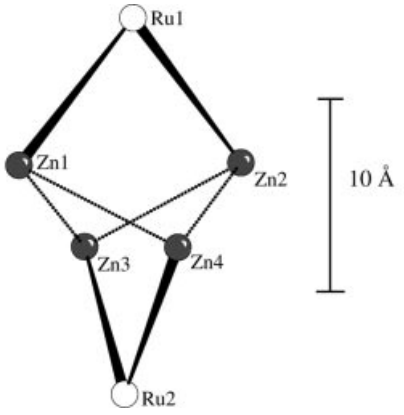

Figure 15. Disposition of the six metal ions in the solid-state molecular structure of (**7a**·Zn)$_2$; full lines represent each **7a**·Zn unit, while dotted lines represent the axial 4′-N(py)−Zn connections between porphyrins; the distorted tetrahedral arrangement of the four Zn ions is evident; the Zn···Zn distance in each **7a**·Zn unit averages to 12.463(4) Å, while the Zn···Zn distance between the two **7a**·Zn units is shorter [mean value of 9.830(4) Å]

are similar to those between the outermost phenyl carbon atoms and give a rough idea of the molecular size of (**7a**·Zn)$_2$.

The geometry of this highly symmetrical tetraporphyrin assembly in solution, determined by 1D and 2D H-H COSY and NOESY-EXSY NMR spectra, is essentially the same as that found in the solid state. The main NMR features of (**7a**·Zn)$_2$ (Figure 16) are the following: (i) All the porphyrins in (**7a**·Zn)$_2$ are equivalent to each other, because of C_2 and S_4 symmetry axes going through the two Ru atoms. (ii) All 4′-N(py) rings are bound either to Ru or to the Zn atom inside another porphyrin. Axial coordination to a Zn−porphyrin induces typical upfield shifts due to the anisotropic shielding cone of the porphyrin ring, in particular for the protons closest to Zn. All resonances are sharp at ambient temperature, with the exception of those of the pyridyl rings bound to Zn (because of the lability of Zn). (iii) Owing to the different coordination of the two 4′-N(py) rings on each 4′-*cis*DPyP unit of (**7a**·Zn)$_2$ (one bound to Ru and the other to Zn), each single porphyrin is in an asymmetric environment (Figure 16). In addition, each porphyrin has one side oriented towards the inside (*endo*) and the other towards the outside (*exo*) of the assembly; the *endo* protons (and those of the inner pyridyl rings in particular) are more shielded by the combined effects of the three porphyrins and therefore resonate more upfield than the corresponding *exo* protons. Thus, with the exception of the *meta*- and *para*-phenyl protons, each proton has its own well-resolved resonance. (iv) The two sides of each *meso* aromatic ring are exchanged by rotation around the $C_{meso}-C_{ring}$ bonds, which is slow on the NMR time-scale at room temperature. Finally, the ^{1}H NMR spectrum of a $CDCl_3$ solution of (**7a**·Zn)$_2$, diluted to the limit of detection (ca 3×10^{-5} M), exclusively showed the resonances of the intact adduct, indicating that the self-assembled structure is very stable. This finding agrees well with the high degree of cooperativity expected for the formation of (**7a**·Zn)$_2$.

Thus, **7a**·Zn is an unprecedented example of a metal-containing self-complementary building block that selectively recognizes itself through four 4′-N(py)−Zn interactions yielding a very stable and symmetrical dimeric species, (**7a**·Zn)$_2$, that features four porphyrins and six metal atoms (two Ru and four Zn).

To the best of our knowledge there are only two examples of systems assembled by two-point self-coordination. The group of Kobuke described that of a dizinc(II)−bis(imidazolyl)porphyrin dimer leading to a mixture of linear oligomers with potential application as optoelectronic materials.[51] Tsuda et al. have recently reported on the formation of a very stable cyclic supramolecular aggregate built as a result of many cooperative interactions from a *meso*−*meso*-linked Zn^{II}−bis(porphyrin) with pendant pyridyl groups.[52]

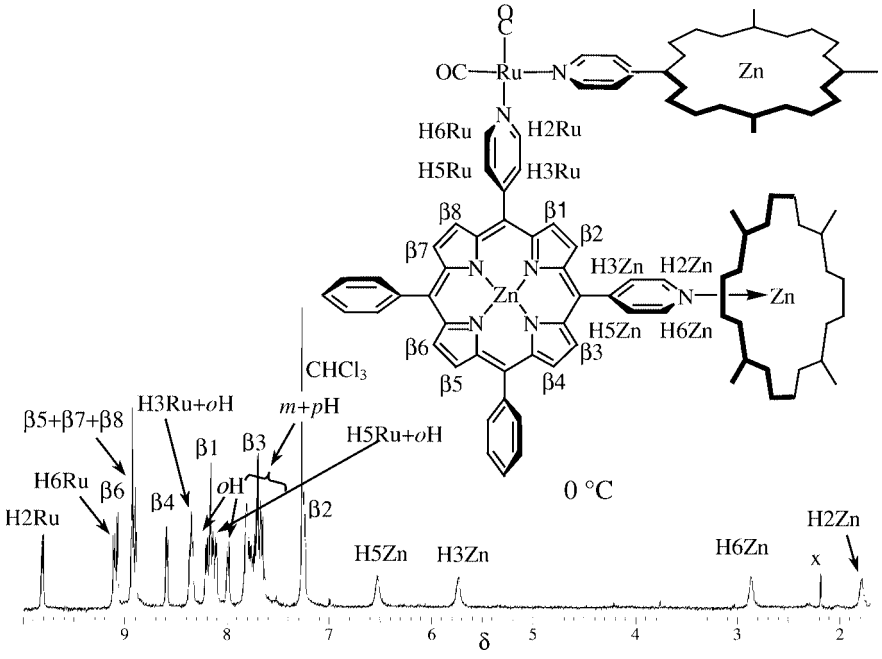

Figure 16. ^{1}H NMR spectra ($CDCl_3$) of (**7a**·Zn)$_2$ at 0 °C; an impurity is marked with x; for labeling scheme see the schematic drawing representing the coordination environment of each zincated porphyrin within (**7a**·Zn)$_2$ (top-view along the Cl−Ru−Cl bond system, Cl atoms omitted for clarity) reported on top of the spectrum

We are currently investigating the self-assembling properties of closely related building blocks featuring two donor and two acceptor binding sites. In particular, while maintaining the frame of the dizinc(II)−bis(pyridyl)porphyrin−ruthenium complex intact, we want to assess the effect of a change in the position of the N(py) atom (3′- instead of 4′-*cis*DPyP) or in the geometry of the bis(pyridyl)porphyrin (4′-*trans*DPyP instead of 4′-*cis*DPyP) on the nature of the self-assembled product. We also plan to assess the self-assembling behavior of complexes bearing three rather than two monocoordinated Zn−4′-*cis*DPyP ligands (that is three *donor* and three *acceptor* sites), either in *fac* or *mer* geometry.

Rational Design of a Ferromagnetic Trinuclear Copper(II) Complex with a Novel in-situ Synthesised Metalloligand

Ming-Liang Tong,*[a,b] Yin-Miao Wu,[a] Ye-Xiang Tong,[a] Xiao-Ming Chen,*[a] Ho-Chol Chang,[c] and Susumu Kitagawa*[c]

Keywords: Magnetic properties / Copper / N ligands / Nucleophilic addition

An interesting ferromagnetic linear trinuclear copper(II) compound containing an in-situ synthesised functional ligand has been rationally obtained and crystallographically characterised, confirming a new route to magnetic polynuclear clusters.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Multi-metal-centred complexes or metal-complex assemblies with highly ordered solid-state structures have attracted much attention in the past few decades.[1,2] In homometallic systems, either ferromagnetic or antiferromagnetic behaviours can occur depending on the bridging ligand shape, bridging angles, and other factors.[3] Although high spin multiplicities of the ground state, along with ferromagnetic behaviour, have been achieved by applying the concept of strict orthogonality[4] between two magnetic orbitals in designing molecules, the rational design and synthesis of novel metal clusters with large ground spin-states is still a challenging and central topic in the field of molecular magnetism. The development of new metalloligands,[2,5] which have been found to play an important role not only in mediating magnetic interactions but also in introducing a catalytic site in metal assembled complexes, is undoubtedly one of best methods for meeting this challenge. Recently, in our attempt to synthesise coordination polymers with metal(II) salts and sodium dicyanamide [Na(dca)],[6] an unexpected product, namely [Cu(dcaOMe)$_2$] (**1**) [dcaOMe = di(methoxycarbimido)aminato], was formed by an interesting in situ nucleophilic addition reaction of the ligand (Scheme 1). We speculated that a series of functional polydentate ligands may be designed and generated by using other nucleophiles with potential ligation sites instead of MeOH, and that these ligands may be used in the synthesis of homo- and heterometallic clusters. We report here the successful use of pyrazole to furnish an interesting ferromagnetically coupled linear trinuclear copper(II) compound [Cu_3(dcadpz)$_2$(pz)$_2$(ClO_4)$_2$](ClO_4)$_2$·H_2O [**2**; dcadpz = di(pyrazolecarbimido)aminato; pz = pyrazole], which contains an interesting metalloligand as a ferromagnetic coupler.

Results and Discussion

Single-crystal X-ray analysis revealed that **1** is a neutral planar Cu^{II} complex (Figure 1, top). The Cu^{II} atom is coordinated in a planar-square geometry to four nitrogen atoms from two dcaOMe ligands. The Cu1−N bond lengths are 1.939(2) and 1.946(2) Å. The dcaOMe ligand is apparently formed by the addition reaction of dca and MeOH. Although this product was synthesised by the addition of methanol and dicyanimide in the presence of zinc chloride, followed by the replacement of zinc by copper(II) using an ammoniacal solution of copper(II) sulfate,[7,8] no X-ray structural analysis had been done prior to our work.

Complex **2** is a symmetrical linear trinuclear copper(II) complex. The crystallographically asymmetric unit consists of 1.5 Cu^{II} centres, one dcadpz ligand, one pz ligand, two ClO_4^- ions and 0.5 disordered lattice water molecules (Figure 1, bottom). The central Cu1 atom is located at an inver-

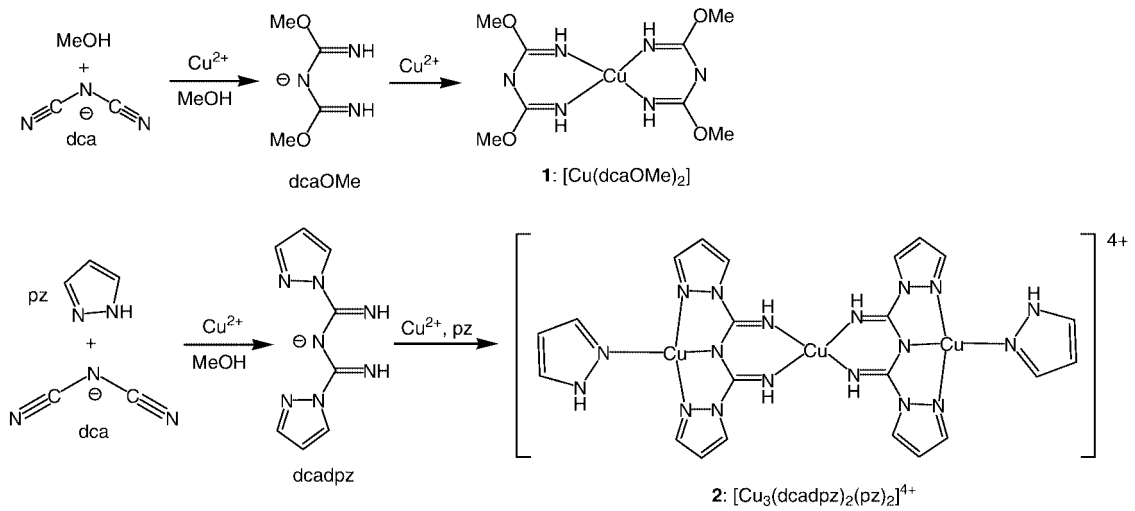

Scheme 1

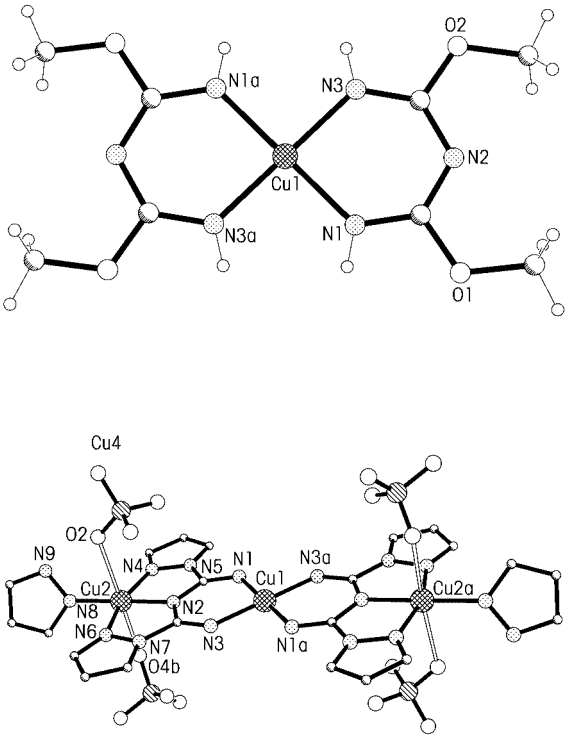

Figure 1. The coordination environment of the copper atoms in **1** (top) and **2** (bottom); selected bond lengths (Å): Cu(1)−N(1) 1.939(2), Cu(1)−N(3) 1.946(2) for **1**; Cu(1)−N(3) 1.949(4), Cu(1)−N(1) 1.955(4), Cu(2)−N(8) 1.957(4), Cu(2)−N(2) 1.958(4), Cu(2)−N(4) 1.976(4), Cu(2)−N(6) 1.980(4), Cu(2)−O(2) 2.518(5), Cu(2)−O(4b) 2.561(6) for **2**

sion centre and is coordinated in a perfectly square-planar geometry to four nitrogen atoms from two dcadpz ligands, with Cu1−N bond lengths of 1.949(4) and 1.955(4) Å, similar to those in **1**. Each of the terminal Cu2 atoms is coordinated in an elongated [4+2] distorted octahedral geometry with four nitrogen atoms in the equatorial positions [Cu2−N_{basal} bond lengths of 1.957(4)−1.980(4) Å], with three nitrogen atoms coming from a dcadpz ligand and the fourth from a monodendate pz ligand. The two oxygen atoms from two different perchlorate ions in the apical positions complete the octahedral geometry, with two long Cu2−O bond lengths of 2.518(5) and 2.561(6) Å. Each trinuclear Cu_3 unit is further connected to four adjacent Cu_3 units through quadruple μ-ClO_4^- bridges, resulting in a two-dimensional coordination layer (Figure 2). The uncoordinated ClO_4^- and the lattice water molecules are located between the layers and form hydrogen bonds with the imido groups, resulting in a three-dimensional network (Figure S1). It is interesting to note that the magnetic orbital of Cu1 is regarded as $d_{x^2-y^2}$ and is directed towards the four basal N atoms from the two dcadpz ligands, a situation similar to that found in the pioneering building block $[Cu(opba)]^{2-}$ [opba = *o*-phenylenebis(oxamato)].[2] The magnetic orbital of Cu2, mainly $d_{x^2-y^2}$, lies in the N_4(basal) plane and points towards the four basal donors.

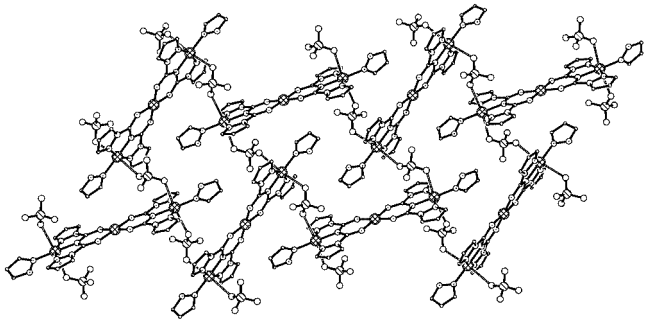

Figure 2. Perspective view of the 2D coordination layer along the *b* axis in **2**

The orientations of the magnetic orbits in **2** are verified by its magnetic behaviour. The value of the magnetic moment at room temperature is 3.25 μ_B per Cu_3 formula unit, consistent with three unpaired electrons per Cu_3 unit with $g = 2.17$. Upon lowering the temperature, the magnetic moment (μ_{eff}) gradually increases from 3.25 μ_B at 300 K to reach a maximum of 3.88 μ_B at 4.6 K (Figure 3), which is similar to the value (3.87 μ_B) of three ferromagnetically coupled Cu^{II} atoms. The plot of χ_M^{-1} versus T (50−300 K)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

obeys the Curie–Weiss Law [$\chi_M = C/(T - \theta)$] at 10 kOe with a Weiss constant, θ, of 1.74 K, and a Curie constant, C, of 1.30 $cm^3\ mol^{-1}$ K, indicating a significant ferromagnetic coupling between the three $S = 1/2$ spins within the Cu_3 unit through the dcadpz bridges. From the structural analysis, **2** is considered to consist of well-separated tri-copper(II) units connected by perchlorate ligands, with the closest Cu2···Cu2′ distance being 6.364 Å. The temperature dependence of μ_{eff} was analysed by an isolated three-spin model[1,9–11] ($H = -2J(S_{Cu2'}\cdot S_{Cu1} + S_{Cu1}\cdot S_{Cu2'})$] with MAGMUN4.0.[12] The best-fit parameters were $J = 7.18\ cm^{-1}$ with an averaged g value of 2.15. The three copper(II) ions are ferromagnetically coupled and each Cu_3 unit has a ground spin-multiplicity of 3/2, which is supported by the field dependence of the magnetization [Figure 3 (inset)], The $M(H)$ data show a linear behaviour from 0 to 20 kOe. The slope then starts to reduce and reaches a value of 2.92 Nβ at 50 kOe, which is very close to the saturated value of 3 Nβ per Cu_3 formula unit with $S = 3/2$. The existence of a ferromagnetic interaction in **2** apparently results from the spin orbital orthogonality: the central Cu atom is antisymmetric whereas the terminal Cu atom is symmetric, and hence the two $d_{x^2-y^2}$ orbitals are orthogonal to each other. This orthogonality is advantageous for ferromagnetic coupling. Magnetic susceptibility $\chi_M(T)$ and magnetization $M(H)$ measurements on single-phase polycrystalline samples of **1** were also performed to confirm the valence of the copper ion in **1**. The magnetic behaviour of **1** obeys the Curie–Weiss Law in the range 2–300 K with an effective magnetic moment of 1.81 μ_B at 300 K (Figure S2), consistent with the single unpaired electron of Cu^{II} in **1**.

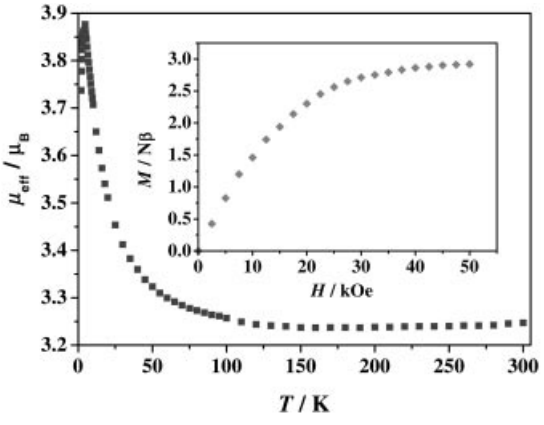

Figure 3. Temperature-dependent magnetic susceptibility plotted as μ_{eff} versus T and field-dependent magnetization plotted as M versus H (inset) at 2 K for a powdered sample of **2**

It is interesting to note that the neutral $Cu(dcadpz)_2$ metalloligand[13] features a planar structure and an intriguing functionality, possessing as it does three lone pairs on either side of the peripheral nitrogen atoms. Therefore, it may behave as a bis-bidentate ligand to connect two metal ions and may further act as a trinuclear building unit to generate low-dimensional coordination magnetic materials. In addition, it is characterised by its spin distribution. There is one unpaired electron arising from the central Cu^{2+} ion, and this electron occupies a $d_{x^2-y^2}$ orbital that is delocalised not only towards the nearest nitrogen atoms, but also towards the six peripheral donor atoms. Such a magnetic orbital interaction means that the $Cu(dcadpz)_2$ segment could be a very useful ferromagnetic coupler. Moreover, what interests us is that the metalloligand presented here can also be easily modified by adopting other starting materials instead of pyrazole. A new route for the synthesis of novel ferromagnetic couplers can therefore be anticipated that is quite different from another recently reported ferromagnetic coupler [$Cu(bptap)_2$], in which bptap was formed by the hydrolysis of tris(2-pyridyl)triazine in the presence of anhydrous $Cu(OAc)_2$ in absolute methanol.[11]

In summary, we provide here a rational strategy for the synthesis of an interesting polydentate ligand and its metal cluster by a simultaneous in-situ addition reaction of dicyanamide and pyrazole, followed by metal coordination. Investigation of this synthetic strategy towards other substituted pyrazole derivatives and the assembly of heteronuclear metal complexes constructed with this metalloligand is under way.

Experimental Section

Synthesis of 1 and 2: Purple crystals of **1** were synthesised by the reaction of $Cu(BF_4)_2\cdot 6H_2O$ (0.237 g, 1.0 mmol) and Na(dca) (0.089 g, 1.0 mmol) in MeOH at 50 °C in ca. 84% yield (0.136 g). The reaction of $Cu(ClO_4)_2\cdot 6H_2O$ (0.555 g, 1.5 mmol), Na(dca) (0.089 g, 1.0 mmol) and pyrazole (0.136 g, 2.0 mmol) in MeOH at 50 °C led to the formation of deep blue crystals of **2** in 78% yield (0.298 g).

1: $C_8H_{16}CuN_6O_4$ (323.8): calcd. C 29.72, H 4.99, N 26.01; found C 29.46, H 4.92, N 25.78

2: $C_{22}H_{26}Cl_4Cu_3N_{18}O_{17}$ (1147.0): calcd. C 23.10, H 2.29, N 22.06; found C 22.81, H 2.18, N 21.83. The IR spectra of **1** and **2** clearly indicate the absence of characteristic peaks for cyano groups, suggesting the transformation of cyano groups into carbimido groups during the reaction.

Crystal Structure Characterisation: X-ray diffraction data collection were carried out on a Bruker CCD diffractometer, using graphite-monochromated Mo-K_α radiation. All non-H atoms were refined anisotropically.

1: Purple crystals. $C_8H_{16}CuN_6O_4$, $M_r = 323.81$, monoclinic, space group $P2_1/n$ (no. 14), $a = 10.018(3)$, $b = 5.6635(14)$, $c = 11.632(3)$ Å, $\beta = 99.703(6)°$, $V = 650.6(3)$ Å^3, $Z = 2$, $D_c = 1.653\ g\ cm^{-3}$, $\mu = 17.00\ cm^{-1}$. Data collection ($4.01 \le 2\theta \le 26°$) was performed at 293 K on a Bruker CCD diffractometer (Mo-K_α, $\lambda = 0.71073$ Å). The structure was solved by direct methods and refined with full-matrix least-squares (SHELX-97),[14] giving a final R_1 value of 0.0400 for 98 parameters and 1032 unique reflections with $I \ge 2\sigma(I)$ and wR_2 of 0.1142 for all 1192 reflections.

2: Deep blue crystals, 293 K. $C_{22}H_{26}Cl_4Cu_3N_{18}O_{17}$, $M_r = 1147.03$, monoclinic, space group $P2_1/c$ (no. 14), $a = 9.362(6)$, $b = 12.469(7)$, $c = 17.570(8)$ Å, $b = 92.208(9)°$, $V = 2049.5(19)$ Å^3, $Z = 2$, $D_c = 1.859\ g\ cm^{-3}$, $\mu = 18.96\ cm^{-1}$. Final R_1 value of 0.0639 for 295 parameters and 3126 unique reflections with $I > 2\sigma(I)$ and wR_2 of 0.1895 for all 3991 reflections.

Assembly of Dicobalt(III) Complexes Incorporating Di-μ-thiophenolate Moieties

Armando Marin-Becerra,[a,b] Philip A. Stenson,[a] Jonathan McMaster,[a] Alexander J. Blake,[a] Claire Wilson,[a] and Martin Schröder*[a]

Keywords: Cobalt / Schiff-base ligand / Thiolate

The dinuclear $[Co^{III}Co^{III}]$ complexes $[Co_2(L^1)(\mu\text{-OAc})(OAc)(NH_3)](PF_6)_2$ and $[(Co_2(L^2)_2(\mu\text{-OAc})](PF_6)$, incorporating the rare $Co(\mu\text{-SR})_2Co$ moiety associated with Schiff-base co-ligands, are protected by bridging μ-OAc^- units situated within a domed cavity formed by the complexes; increasing the steric bulk of the ligand, as in $[L^3]^{2-}$, affords the mononuclear species $[Co(L^3)(OAc)]$.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Homo- and heterodimetallic complexes occur in a number of metalloenzymes, and increasing efforts have been directed towards the synthesis of compartmental macrocycles capable of mimicking their structural, spectroscopic and chemical properties.[1] Compartmental macrocyclic ligands derived from 2,6-dicarbonylphenols offer a stable framework for binding two metal cations in close proximity via a bridging phenolate, and may also be designed to incorporate unsymmetrical compartments and coordinating pendant groups.[1,2] We[3,4] and others[5,6] have developed synthetic strategies to thiophenolate macrocyclic analogues that stabilise the dinuclear dithiolate fragment within the macrocyclic core. The incorporation, however, of highly redox-active $Co^{II/III}$ centres into such coordination frameworks remains relatively rare.[7] We describe herein for the first time the synthesis and characterisation of two di-μ-thiolato dimetallic Co^{III} complexes, $[Co_2(L^1)(\mu\text{-OAc})(OAc)(NH_3)](PF_6)_2$ and $[Co_2(L^2)_2(\mu\text{-OAc})](PF_6)$, incorporating the macrocyclic ($[L^1]^{2-}$) and corresponding open-chain ($[L^2]^{2-}$) ligands, respectively. Interestingly and significantly, both complexes show novel coordination modes with very similar core structures at the metal centres. The complexes incorporate a pyramidal stereochemistry at the bridging thiolate donors, with the nonplanar, domed conformation of the ligand set affording a hydrophobic pocket for OAc^- binding.

Template reactions of Co^{II} and Co^{III} salts with 2,6-diformyl-4-methylthiophenol and 1,3-diaminopropane under a range of conditions generally do not afford the metal complexes in a pure, tractable form. Higher yields of up to 60% can be obtained, however, by transmetallation reactions of the analogous Zn^{II} complex. Thus, reaction of $[Zn_2(L^1)(OAc)](PF_6)$[3] with $Co(OAc)_2{\cdot}4H_2O$ in MeCN in the presence of NH_4PF_6 under aerobic conditions affords a red diamagnetic solid that precipitates from the reaction mixture. The IR spectrum of this product confirms the presence of both PF_6^- and OAc^- anions, with absorptions at 3353 and 3302 cm^{-1} indicating the presence of ammonia in the product. A broad signal (δ = 3.3−3.6 ppm), which exchanges with D_2O, in the ^1H NMR spectrum (CD_3CN) further supports the presence of coordinated NH_3. As the integral of this signal accounts for only one molecule of ammonia per macrocycle, the coordination at the two Co^{III} ions is, therefore, expected to be different. This hypothesis is supported by both ^1H and ^{13}C NMR spectroscopy, each of which shows two signals for the C(H)=N groups, at δ =

8.22 and 8.28 ppm and at δ = 168 and 171 ppm, respectively. Asymmetry is also observed for the $N-CH_2$ groups of the macrocyclic ligand. The ^1H NMR spectrum also confirms the presence of two nonequivalent acetate anions, with signals at δ = 0.77 and 2.03 ppm. The chemical shift for the former appears rather low, but such upfield shielding can occur when an acetate ion is located close to an aromatic ring current, as in calixarenes that bind guest molecules within a hydrophobic pocket.[8] Therefore, we interpret the upfield shift for the OAc^- signal as a strong indication that it is located within the macrocyclic hydrophobic pocket.

The solid-state structure of $[Co_2(L^1)(\mu\text{-OAc})(OAc)(NH_3)](PF_6)_2$ is entirely consistent with the structure proposed in solution. The molecular structure (Figure 1) shows two octahedral Co^{III} centres, each bound to the N_2S_2 donor set provided by the macrocyclic ligand and to a bridging acetate ion. The coordination sphere of one Co^{III} centre is completed by a monodentate acetate ion while the remaining site on the other centre is occupied by an NH_3 molecule. The macrocyclic ligand adopts a folded conformation, with the bridging acetate ion located within the cleft of the macrocycle. Because of its domed shape, the cleft can be de-

scribed by two dihedral angles, one between the two aromatic rings (97°), the other between the N_2S_2 planes (144)° (Figure 1). Cyclic voltammetry of $[Co_2L(\mu\text{-}OAc)(OAc)(NH_3)](PF_6)_2$ displays two reversible one-electron reductions (confirmed by coulometry) in MeCN (0.3 M $^nBu_4NPF_6$, C electrode, 293 K) at $E_{1/2} = -0.76$ and -0.96 V vs. Fc^+/Fc, assigned to the formation of $[Co^{III}Co^{II}]$ and $[Co^{II}Co^{II}]$ species, respectively.

Transmetallation of $[Zn(L^2)]$ with $Co(OAc)_2{\cdot}4H_2O$ in the presence of NH_4PF_6 affords a Co^{III} complex, the IR spectrum of which confirms the presence of both PF_6^- and OAc^- anions. ^1H NMR spectroscopy in CD_3CN indicates asymmetry in the complex and shows two signals for the C(H)=N groups at δ = 8.23 and 7.74 ppm, as well as two signals for the methyl groups at δ = 1.16 and 1.07 ppm. The signal belonging to the OAc^- anion can be observed at δ = 1.10 ppm and, as previously noted for $[Co_2L(\mu\text{-}OAc)(OAc)(NH_3)](PF_6)_2$, this upfield shift suggests the anion is exposed to an aromatic ring current.

The single-crystal X-ray structure of $[Co_2(L^2)_2(\mu\text{-}OAc)]PF_6$ (Figure 2) is in agreement with the spectroscopic data observed in solution, suggesting that the dinuclear structure is stable in solution, even in coordinating solvents such as MeCN. Although both metal ions exhibit the same coordination environment, the *cis* configuration adopted by the tetradentate ligand accounts for the various signals observed in the ^1H NMR spectrum. The overall structures of $[Co_2(L^2)_2(\mu\text{-}OAc)]PF_6$ and $[Co_2(L^1)(\mu\text{-}OAc)(OAc)(NH_3)](PF_6)_2$ are similar. The angle of the cleft defined by the aromatic rings is only 1° wider in the former and the N_2S_2 planes in $[Co_2(L^2)_2(\mu\text{-}OAc)]PF_6$ make an angle of 154°. As suggested by ^1H NMR spectroscopic data, an acetate anion is situated within this cleft. Cyclic voltammetry of $[Co_2(L^2)_2(\mu\text{-}OAc)]PF_6$ gives rise to only irreversible redox processes, reflecting the loss of redox stability on going from the macrocyclic chelate $[L^1]^{2-}$ to the polychelate $[L^2]^{2-}$, even though the resultant complexes have very similar coordination spheres.

Interestingly, reaction of $[Zn(L^3)]$ with $Co(AcO)_2{\cdot}4H_2O$ in $CHCl_3$ affords the corresponding *mononuclear* complex $[Co(L^3)(OAc)]$ (Figure 3), which shows octahedral coordination at Co^{III} with the OAc^- anion binding as a *cis*-chelate. The ligand $[L^3]^{2-}$ binds to the metal centre in a folded manner, the inherent steric hindrance of the ligand inhibiting the formation of dinuclear complex products. This observation is further confirmed by the formation of mononuclear complexes of $[L^3]^{2-}$ and related hindered ligands with square-planar Ni^{II}, Cu^{II} and Pd^{II}, and tetrahedral Zn^{II}.

Our current work seeks to examine the redox properties of these and related thiolate-bridged complexes and to develop new synthetic routes to heterodinuclear complexes.

For $Co^{III}Co^{III}$ complex: λ_{max} = 540 nm (ε = 1822 M^{-1} cm^{-1}), 430 (2933). For $Co^{III}Co^{II}$ complex: λ_{max} = 534 nm (ε = 1822 M^{-1} cm^{-1}).

Synthesis of $[Co_2(L^2)_2(\mu\text{-AcO})]PF_6$: A solution of $Co(AcO)_2{\cdot}4H_2O$ (0.027 g, 0.11 mmol) in MeOH (5 mL) was added to a solution of $[Zn(L^2)]$ (0.040 g, 0.1 mmol) in $CHCl_3$ (20 mL) The yellow solution immediately changed colour to become deep red and then slowly became ill-defined red-brown. After heating the resulting solution under reflux for 20 min, NH_4PF_6 (0.163 g, 1.0 mmol) in MeOH (5 mL) was added. After a few minutes, a brownish precipitate was obtained, which was washed with MeOH and diethyl ether (0.039 g, 80% yield). This product can be recrystallised from MeCN/diethyl ether. Single crystals suitable for X-ray analysis were obtained by this procedure. $C_{40}H_{43}Co_2F_6N_4O_2PS_4$ (1002.9): calcd. C 47.90, H 4.32, N 5.59; found C 47.86, H 4.22, N 5.57. MS (FAB^+, 3-NOBA): *m/z* = 399, 858; (ES^+): *m/z* = 857 $[(C_{19}H_{20}N_2S_2Co)_2CH_3CO_2]^+$, 399 $[C_{19}H_{20}N_2S_2Co]^+$. IR (KBr): $\tilde{\nu}$ = 3053 w, 2934 w, 2873 w, 1636 m, 1615 s, 1583 m, 1515 m, 1470 m, 1410 s, 1371 w, 1342 w, 1303 m, 1255 w, 1225 m, 1186 w, 1080 w, 1087 w, 1027 m, 839 vs, 679 w, 755 s cm^{-1}. ^1H NMR (CD_3CN): δ = 8.23 (s, 1 H, CH=N), 7.93 (d, *J* = 7.7 Hz, 1 H, Ar), 7.75 (s, 1 H, CH=N), 7.25−7.48 (m, 6 H, Ar), 7.18 (t, *J* = 7.4 Hz, 1 H, Ar), 5.01 (d, *J* = 11.1 Hz, 1 H, NCH_2), 4.47 (d, *J* = 11.5 Hz, 1 H, NCH_2), 3.59 (d, *J* = 11.1 Hz, 1 H, NCH_2), 3.11 (d, *J* = 11.5 Hz, 1 H, NCH_2), 1.16 (s, 3 H, CCH_3), 1.10 (s, 3 H, CO_2CH_3), 1.07 (s, 3 H, CCH_3).

Synthesis of $[Co(L^3)(AcO)]$: A solution of $Co(AcO)_2{\cdot}4H_2O$ (0.0271 g, 0.11 mmol) in MeOH (3 mL) was added to a solution of $[Zn(L^3)]$ (0.063 g, 0.1 mmol) in $CHCl_3$ (20 mL). The solution was stirred at 40 °C for 10 min, the resulting red-brown solution was concentrated to dryness and then the green residue was washed with MeOH and recrystallised from $CHCl_3$/diethyl ether (0.27 g, 40% yield). Single crystals were obtained by diffusion of ether into a $CHCl_3$ solution. $C_{37}H_{57}CoN_2O_3S_2$ (700.92): calcd. C 63.40, H 8.20, N 4.00; found C 63.43, H 7.90, N 4.01. MS (ES^+): *m/z* = 623 ($C_{35}H_{52}N_2S_2Co$ = $[Co(L^3)]^+$ requires 623). IR (KBr): $\tilde{\nu}$ = 2955 s, 2904 w, 2868 w, 1623 s, 1516 s, 1470 s, 1393 m, 1357 m, 1265 m, 1198 w, 1152 m, 1060 w, 947 m, 760 m, 681 m cm^{-1}. This compound is unstable towards oxidation, as the ligand can be oxidised when the compound is heated under reflux for longer periods of time in solvents such as ethyl acetate or chloroform. Thus, increases in *m/z* by 16 or 32 units indicate the gain of one or two atoms of oxygen [MS (ES^+): *m/z* = 639 and 655]. A deep-red colour in solution is associated with oxidation of the ligand.

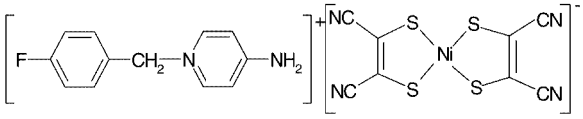
Keywords: Nickel / Maleonitriledithiolate / Crystal structure / Magnetic properties

An ion-pair complex $[FBzPyNH_2][Ni(mnt)_2]$ {$[FBzPyNH_2]^+$ = [1-(4′-fluorobenzyl)-4-amino]pyridinium and mnt^{2-} = maleonitriledithiolate} has been obtained by I_2 oxidation of the corresponding dianion complex. It forms a well-segregated stacking column structure in the solid state, and exhibits antiferromagnetic ordering below 2.5 K. It is the first complex in this series of complexes containing a maleonitriledithiolate dianion that exhibits metamagnetism.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Much effort has been devoted to the study of square-planar M(dithiolene)$_2$ complexes in the areas of conducting and magnetic materials, dyes, non-linear optics and catalysis.[1,2] Recently, we have employed a strategy of constructing one-dimensional molecule-based magnets based on ion-pair complexes containing $[M(mnt)]^-$ (M = Ni^{III}, Pt^{III}; mnt^{2-} = maleonitriledithiolate) anions with benzylpyridinium derivatives as counterions. Interestingly, varying the counterions led to a broader palette of complexes with markedly different magnetic-exchange properties, although they all have extremely similar molecular and stacking structures. Versatile magnetic properties such as ferromagnetic ordering at 2 K, unusual magnetic transitions from ferromagnetic coupling to diamagnetism or from paramagnetic to diamagnetic, or spin-Peierls-like transitions have been witnessed.[3] In order to further understand the magnetic coupling mechanism in this series of complexes, we should explore the relationship between stacking structures and magnetic properties systematically. Within this framework, we report the synthesis and crystal structure of an ion-pair complex [1-(4′-fluorobenzyl)-4-aminopyridinium]-$[Ni(mnt)_2]$ (Scheme 1), which has well-segregated stacking columns. A study of its magnetic properties shows antiferromagnetic ordering below 2.5 K and metamagnetic-like behavior.



Scheme 1. Molecular structure of **2**

Results and Discussion

$[FBzPyNH_2]_2[Ni(mnt)_2]$ (**1**) was prepared by the direct combination of $NiCl_2{\cdot}6H_2O$, Na_2mnt and [1-(4′-fluorobenzyl)-4-amino]pyridinium chloride in H_2O in a 1:2:2 molar ratio. The title complex **2** was prepared by I_2 oxidation of **1**,[4] and well-shaped single crystals were obtained by allowing Et_2O to diffuse into an MeCN solution of **2** for about a week. Figure S1 depicts the molecular structure of **2**. The coordination geometry of Ni^{III} is square planar with four sulfur donor atoms; the Ni−S bond lengths and S−Ni−S bond angles are in agreement with reported values.[3] The CN groups of the mnt^{2-} ligand are bent away from the plane defined by the Ni atom and four sulfur atoms. The deviation of the four terminal N atoms from the plane are 0.2926 Å, 0.3666 Å, 0.0802 Å and 0.1736 Å, respectively. In the $[FBzPyNH_2]^+$ cation, the dihedral angles between the C(15)−C(14)−N(5) reference plane and the aryl rings are 80.5° for the phenyl ring and 106.6° for the pyridine ring; these values are in line with previous results.[3] It should be noted that **2** possesses well-segregated stacking column along the *c*-axis (Figure 1a). Within an anion column, there exists a slipped nickel-over-sulfur con-

figuration of $[Ni(mnt)_2]^-$ anions and the Ni···Ni distances between adjacent anions are identical (3.991 Å); the nearest S···S, S···Ni contacts are 3.797 Å and 3.663 Å, respectively. These distances are larger than the sum of the van der Waals radii of the corresponding atoms. The closest Ni···Ni separation between anion chains is 14.32 Å, which is significantly larger than the Ni···Ni separation within a chain. Therefore, each $[Ni(mnt)_2]^-$ anion column can be considered as a one-dimensional (1-D) magnetic chain from the viewpoint of the crystal structure (Figure 1b). The $[FBzPyNH_2]^+$ cations orient themselves in the solid state. The pyridine rings of the neighboring cations are essentially parallel to each other with an identical center-center distance of 3.893 Å (Figure S2).

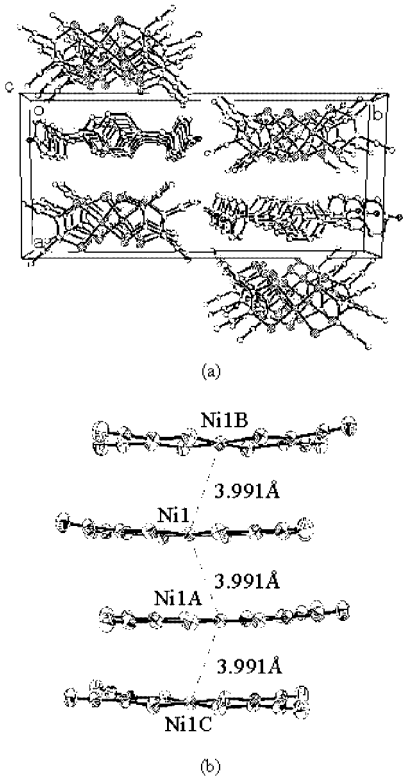

Figure 1. (a) Structure of anions and cations of **2** viewed along the *c*-axis; (b) side view of the 1-D anion chain of **2** (symmetry codes: A = x, 1.5 − y, 0.5 + z; B = x, 1.5 − y, −0.5 + z; C = x, y, z + 1)

The thermal variation of $\chi_m T$, measured at a field of 1 T, is shown in Figure 2. The observed $\chi_m T$ value at 308 K is 0.331 emu·K·mol^{-1}, slightly less than the theoretical value of 0.375 emu·K·mol^{-1} expected for a spin-only Ni^{III} ion with S = 1/2 and g = 2.0. Upon cooling down, the $\chi_m T$ values decreases smoothly and reaches a minimum of 0.223 emu·K·mol^{-1} at 24 K. This behaviour is characteristic of ferrimagnetic-like behavior. With a further decrease in temperature, the $\chi_m T$ values increase abruptly, reaching a maximum of 0.343 emu·K·mol^{-1} at 7.2 K, before decreasing again. The data above 24 K are best fit by the Bonner−Fisher model for a uniformly spaced chain of atoms with S = 1/2 spin.[5] Equation (1) for $H = -2JS_1 \cdot S_2$ [6] with $z = J/k_B T$.

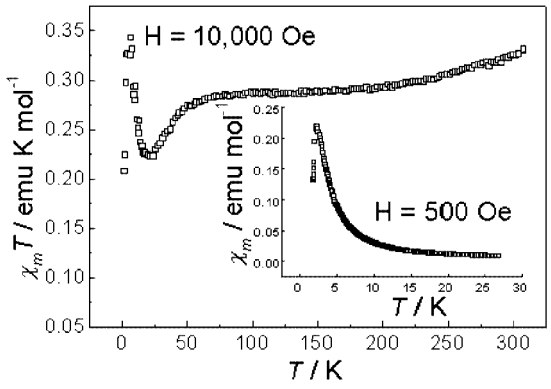

Figure 2. Temperature dependence of $\chi_m T$ for **2** measured at 10 KOe; inset: temperature dependence of χ_m for **2** measured at 500 Oe

$$\chi_m = \frac{Ng^2\mu_B^2}{k_B T} \frac{0.25 + 0.074975z + 0.075235z^2}{1.0 + 0.9931z + 0.172135z^2 + 0.757825z^3} \quad (1)$$

A fit of the data to Equation (1) gives $J = -6.8$ cm^{-1} and g = 2.0 (fixed), which suggests there exists weak antiferromagnetic coupling between adjacent S = 1/2 Ni^{III} spin carriers within the anion chain. The χ_m/T curve at 500 Oe field shows a sharp cusp at 2.5 K, suggesting a long-range antiferromagnetic (AF) ordering (inset of Figure 2). The M vs. H curve at 1.8 K exhibits a sigmoidal shape, indicating a metamagnetic-like behavior (Figure 3), which switches from an antiferromagnetic ground state to a ferrimagnetic-like state upon the application of a large enough field. At 1.8 K, the critical field is approximately 1000 Oe because the derivative dM/dH has an extremum (Figure S3). The saturation magnetization of **2** at 1.8 K (the higher applied magnetic field is 7 T) is 1310 emu·G·mol^{-1}, far from the theoretical saturation value of 5585 emu·G·mol^{-1}, which is usual in metamagnetic material if the temperature is not much lower than T_N.[7,8] The AF transition is further manifested by the in-phase signal (χ') of zero-field ac magnetic susceptibility, which has a maximum at about 2.5 K (T_N). No out-of-phase signal (χ'') could be detected and their is no frequency dependence, thus excluding any ferromagnetic

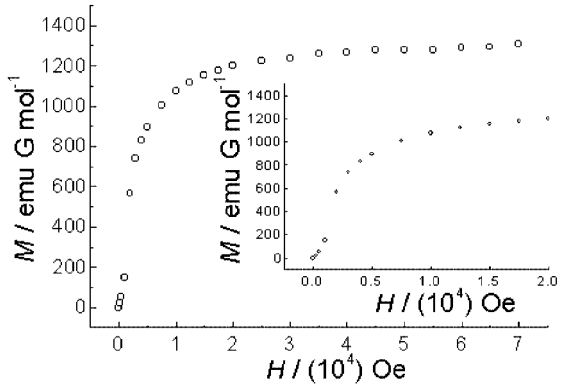

Figure 3. M-H curve of **2** measured at 1.8 K; inset: enlargement of the applied magnetic field range 0−20000 Oe

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

phase or spin-glass behavior (Figure S4). The FCM curves of **2** measured at lower fields (200 Oe and 1000 Oe) both show a maximum in χ_m at about 2.5 K (Figure S5), suggesting long-range magnetic ordering, whereas a higher field (5000 Oe) leads to the absence of the peak down to 2.0 K (inset of Figure S5).

Of all the commonly studied dithiolate systems, metamagnetism has been observed in some charge-transfer salts such as $[Fe(Cp^*)_2][Ni(edt)_2]$ (edt = ethylenedithiolate), $[Mn(Cp^*)_2][M(tfd)_2]$ [M = Ni, Pd, Pt; tfd = bis(trifluoromethyl)ethylenedithiolate].[7–9] For complexes containing the $[Ni(mnt)_2]^-$ anion, previous studies have shown that the magnetic coupling between $[Ni(mnt)_2]^-$ anions is very sensitive not only to intermolecular separation,[2a] but also to the degree of overlap of neighboring $[Ni(mnt)_2]^-$ anions.[10–12] Several shorter contact distances, such as Ni···Ni, Ni···S, S···S, S···N, S···C and C···N, play important roles in the superexchange pathway due to extensive electron delocalization in the $[Ni(mnt)_2]^-$ unit.[13] At very low temperature, superexchange and/or through-space intrachain antiferromagnetic couplings must be considered in order to yield a three-dimensional AF ordering state below 2.5 K.

In summary, a metamagnetic-like behavior is observed in the title complex, which, to the best of our knowledge, is the first example of metamagnetism in this series of complexes containing the maleonitriledithiolate dianion.

Experimental Section

All manipulations were carried out in air unless otherwise noted. Starting materials were purchased from Aldrich (4-fluorobenzyl chloride, 4-aminopyridine), and were used without further purification. [1-(4′-Fluorobenzyl)-4-amino]pyridinium chloride ($[FBzPyNH_2]Cl$) and disodium maleonitriledithiolate (Na_2mnt) were synthesized following the published procedures.[4]

$[FBzPyNH_2]_2[Ni(mnt)_2]$ (1): This compound was prepared by the direct combination of $NiCl_2·6H_2O$, Na_2mnt and $[FBzPyNH_2]Cl$ in H_2O in a 1:2:2 molar ratio. The red precipitate that formed was filtered off, washed with water and dried under vacuum. Yield: 93%. $C_{32}H_{24}F_2N_8NiS_4$ (745.5): calcd. C 51.55, H 3.24, N 15.03; found C 51.81, H 3.22, N 15.11. IR (KBr): ν(NH_2) 3420.3 cm^{-1}, 1657.4 vs; ν(CN) 2196.4 vs; ν(C=C) of mnt^{2-} 1485.3 s.

$[FBzPyNH_2][Ni(mnt)_2]$ (2): An MeCN solution (10 mL) of I_2 (150 mg, 0.59 mmol) was slowly added to an MeCN solution (20 mL) of $[FBzPyNH_2]_2[Ni(mnt)_2]$ (746 mg, 1.0 mmol), and stirred for 15 min. MeOH (90 mL) was then added, and the mixture allowed to stand overnight. The microcrystals formed were filtered off, washed with MeOH and dried in vacuo. Yield: 87%. $C_{20}H_{12}FN_6NiS_4$ (542.3): calcd. C 44.30, H 2.23, N 15.50; found C 44.52, H 2.22, N 15.42. IR: ν(NH_2) 3347.9 cm^{-1}, 1654.4 vs; ν(CN) 2206.7 vs; ν(C=C) of mnt^{2-} 1453.3 m. Good-shaped single crystals suitable for X-ray analysis were obtained by allowing Et_2O to diffuse into an MeCN solution of **2** for about a week.

X-ray Crystallography Study: $C_{20}H_{12}FN_6NiS_4$, M_r = 542.31, black, needle-shaped crystal, monoclinic, space group $P2_1/c$, a = 12.0041(17) Å, b = 26.095(4) Å, c = 7.4809(11) Å, β = 101.448(3)°, V = 2296.7(6) Å^3, Z = 4, D_c = 1.568 g cm^{-3}, μ(Mo-K_α) = 1.237 mm^{-1}, λ = 0.71073 Å, $-14 \le h \le 14$, $-31 \le k \le 22$, $-8 \le l \le 8$. A crystal of dimensions 0.20 × 0.15 × 0.10 mm^3 was selected for indexing and intensity data collection at 298 K. Data collection: *SMART* (Bruker, 1997). ω-Scans covering reciprocal space up to θ_{max} 24.99° with 99.8% completeness, total of 11370 reflections (4031 unique) with R_{int} = 0.1139. Structure solution SHELXL-97, full-matrix least-squares based on F^2 using SHELXL-97, final R = 0.058, wR = 0.154, GOF = 1.006. Final residual density was in the range −0.497 to 0.923 e·Å^{-3}.

CCDC-201344 (**2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information: ORTEP view, side view of cation chain, dM/dH vs. H plot, in-phase signal (χ') and FCM curve for **2**) is available (see footnote on the first page of this article.

Order−Disorder Transitions and Magnetic Behaviour in Lithium Ferrites $Li_{0.5+0.5x}Fe_{2.5-1.5x}Ti_xO_4$ (x = 1.28 and 1.50)

María Ángeles Arillo,[a] María Luisa López,[a] Carlos Pico,[a] María Luisa Veiga,*[a] Javier Campo,[b] José Luis Martínez,[c] and Alejandro Santrich-Badal[c]

Keywords: Lithium ferrites / Order−disorder phenomena / Spinels / Spin-glass behaviour

We report the structural characterization and magnetic behaviour of the spinels with general formula $Li_{0.5+0.5x}Fe_{2.5-1.5x}Ti_xO_4$, where x = 1.28 and 1.50. When the samples are cooled slowly, a 1:3 crystallographic order occurs, whereas a random disorder is observed when the samples are quenched. Neutron-powder-diffraction measurements were performed on the materials to characterize the structural transitions. Magnetic properties were studied by magnetic susceptibility (dc and ac), magnetisation and neutron-diffraction data and the results can be interpreted on the basis of a spin-glass behaviour.

Introduction

Lithium iron spinels, usually known as lithium ferrites, have been thoroughly studied materials because they are remarkably useful in many branches of technology.[1] The lithium ferrite $Li_{0.5}Fe_{2.5}O_4$ is known to occur in two crystalline forms.[2] Below 1008 K, there exists a 1:3 ordering of Li^+ and Fe^{3+} ions along the [110] directions of the unit cell, giving rise to the structural formula $(Fe)_T(Li_{0.5}Fe_{1.5})_OO_4$, in such a way that each lithium ion is followed by three iron cations that are all in octahedral coordination with oxygen ions. The remaining iron ions are located on the tetrahedral sites (space group $P4_332$).[3] Above 1000−1030 K, the 1:3 ordering is destroyed and the two types of cations are randomly distributed over the octahedral sites; the resulting phase is referred to as the disordered phase (space group $Fd3m$). By quenching rapidly from a high temperature, this latter phase can be retained indefinitely at room temperature or below.[4] The disordered $Li_{0.5}Fe_{2.5}O_4$ has an inverse spinel structure, with Fe^{3+} ions at tetrahedral 8*a* positions and Li^+ and Fe^{3+} ions distributed randomly over the 16*d* octahedral sites. The order−disorder transition in the lithium ferrite structure has been recorded by X-ray powder diffraction, and the relationship between the Wyckoff's positions of the $Fd3m$ and $P4_332$ states are as follows[5]:

$Fd3m \rightarrow P4_332$

$8a\ (8\ Fe^{3+}) \rightarrow 8c\ (8\ Fe^{3+})$

$16d\ (12\ Fe^{3+} + 4\ Li^+) \rightarrow 12d\ (12\ Fe^{3+}) + 4b\ (4Li^+)$

$32e\ (32\ O^{2-}) \rightarrow 24e\ (24\ O^{2-}) + 8c\ (8\ O^{2-})$

The magnetic properties of a spinel ferrite depend on their structural features, both of which are quite sensitive to the preparation conditions as well as to the amount and type of substitution. The most synthetically advantageous characteristic of spinel materials is that various ions can be placed at tetrahedral and octahedral sites within the structure, a situation that allows for control of their magnetic properties. In addition to ferromagnetism and antiferromagnetism (ferrimagnetism), another unique spin state − the so-called spin-glass (SG) state − can be assigned to spinel ferrites. The substitution of iron atoms by tetravalent titanium influences the above properties. Solid solutions of general formula $Li_{0.5+0.5x}Fe_{2.5-1.5x}Ti_xO_4$ ($0 \le x \le 1.67$) crystallise in the space groups $P4_332$ (in the ranges $0 \le x \le 0.4$ and $1.2 \le x \le 1.57$) and $Fd3m$ (in the ranges $0.4 \le x \le 1.2$ and $1.57 \le x \le 1.67$).[5,6] Several authors[6−9] have reported detailed studies using X-ray diffraction and Mössbauer spectroscopy for the structural resolution of this system in the range $1.1 \le x \le 1.67$, in agreement with the cation distribution proposed by Blasse[5] and White[10]. On the other hand, Dormann's group has proposed that this system shows local canted spin behaviour (LCS).[11−14] With increasing dilution of Fe atoms, the distribution of the canting angles enlarges and the average canting angle

increases at each site. As a consequence, the average magnitude of the transverse component S_t increases. Moreover, S_t becomes more widely distributed. A discrepancy exists, however, between the results of the Mössbauer spectra and the magnetic studies. An explanation can be found by considering the Rosencwaig canting model.[7] Scharner et al.[6] proposed order−disorder transitions for $x = 1.2$ and 1.57, but they did not suggest the possibility of canting in both positions.

The aim of the present work is to establish by means of neutron diffraction studies the behaviour of the phases, where $x = 1.28$ and 1.50, that are obtained by slowly cooling (SC) and rapid quenching (Q). The Rietveld refinement was used to solve the problem of the cation ordering in these phases, and additional magnetic measurements (ac and dc magnetic susceptibility and magnetisation curves) were performed to study the simultaneous substitution with nonmagnetic atoms in this series $Li_{0.5+0.5x}Fe_{2.5-1.5x}Ti_xO_4$.

Results and Discussion

Structural Features

Structural characterization at room temperature of the lithium ferrites with compositions $x = 1.28$ and 1.50 formed by slow cooling (SC) was carried out by neutron diffraction. The reflections were characteristic of a spinel structure in which some additional superstructural lines appear, and all these reflections were indexed satisfactorily on the basis of a cubic unit cell (Figure 1). Therefore, the SC samples exhibited cation ordering on the octahedral sites, resulting in a superstructure that could be refined in the $P4_332$ space group. We found, however, that a slight improvement in the fit was achieved by using a multiphase refinement using both the ordered ($P4_332$) and disordered ($Fd3m$) structures.[15,16] Rietveld analysis indicated that these samples are comprised of 94.9% superstructure (or ordered structure) and 5.1% disordered structure (for $x = 1.28$), and 82.3% superstructural component and 17.7% disordered component (for $x = 1.50$). Crystallographic data for both compounds obtained by Rietveld refinements are reported in Table 1 and the R-factors indicate a reliable structural model. The atomic coordinates are given in Table 2 and the most representative bond lengths are given in Table 3. These results suggest that the ordered structures have not been isolated as single phases under the present experimental conditions, although they are clearly in the majority, and this fact will certainly influence the magnetic behaviour of the materials.

At higher temperatures (1073 K for $x = 1.28$ and 973 K for $x = 1.50$), all the Bragg reflections were indexed on the basis of a cubic symmetry and the patterns were refined in the space group $Fd3m$. A good agreement between the calculated and observed patterns is shown in Figure 1. Therefore, the SC samples must undergo an order−disorder phase transition from the space group $P4_332$ to the space group $Fd3m$. Moreover, the neutron-diffraction pattern at 1073 K for $x = 1.50$ revealed the presence of an impurity,

tion of the most important interatomic distances are included in Table 5. On the other hand, for the samples obtained by quenching (Q), all the reflections can be indexed using the extinction laws of the space group *Fd3m*.[17,18] The resulting fits are shown in Figure 2 at 2 K (Figure 2, a) and 300 K (Figure 2, b). A summary of the structural parameters obtained in these refinements is given in Table 6 and 7.

The structure of SC samples were first reported by Blasse,[5] who described them as cation-ordered for x = 1.20 and x = 1.50. The 1:3 order on the octahedral sublattice is given by the lithium (4*b*) and titanium ions (12*d*), although the titanium sublattice contains some iron ions. Nevertheless, the Rietveld refinement of the neutron-diffraction data for our samples $(Li_{0.5x}Fe_{1-0.5x})_T(Li_{0.5}Fe_{1.5-x}Ti_x)_OO_4$ ob-

tained by SC show that the cation distribution is slightly different from that suggested by Blasse in that the octahedral (4*b*) sites are occupied by Li^+/Fe^{3+} cations and the 12*d* sites are occupied by Fe^{3+}/Ti^{4+} cations. These samples show a cation-ordered superstructure with a minority disordered phase that also has been obtained for $Li_{0.5}Fe_{2.5-x}Cr_xO_4$.[16] The ordered form is close to an inverse spinel (space group $P4_332$) in which the 12*d* sites are

occupied by iron and titanium ions giving rise to different M−O distances (Table 3, Table 5 and Table 7), whereas the Li^+/Fe^{3+} ions occupy the centre of regular octahedral 4*b* sites. The disordered form is an inverse spinel (space group *Fd*3*m*) in which the $Li^+/Fe^{3+}/Ti^{4+}$ atoms are distributed randomly over the regular octahedral sites, and the tetrahedral ones are occupied by Li^+/Fe^{3+} ions. Figure 3 illustrates these features in a fragment of the ordered (Figure 3, a) and disordered (Figure 3, b) structures. Finally, the values obtained in the refinement of the unit cell parameters for all samples reflect the abovementioned changes in the cationic site distribution resulting from an intracrystalline order−disorder process.[6]

Magnetic Behaviour

Figure 4 shows the dependence of the dc magnetic susceptibility of the title samples with temperature $\chi(T)$ in the range between 2 and 300 K measured at a field of 0.5 kOe. The $\chi(T)$ variation for the composition $x = 1.28$ (SC and Q) shows broad maxima at about 20 K and 17 K, respectively. The dc magnetic susceptibility decreases with temperature for the sample $x = 1.50$ (SC and Q). We observed that the magnetic susceptibility is remarkably smaller for the disordered samples than for the ordered ones, and this fact is consistent with a decrease of ordering. No Curie−Weiss behaviour was observed over the whole tem-

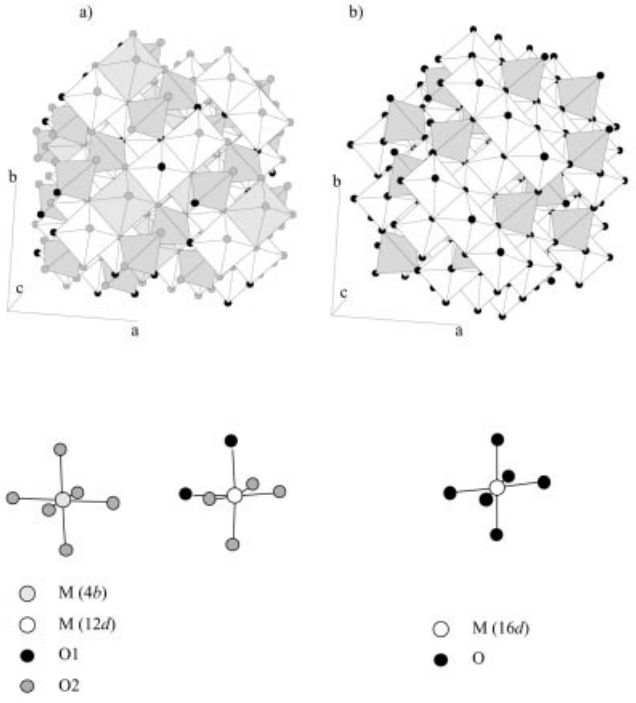

Figure 3. The structure of the $Li_{0.5+0.5x}Fe_{2.5-1.5x}Ti_xO_4$ spinels: a) ordered form (space group $P4_332$); b) disordered form (space group $Fd3m$)

perature range measured from the dc reciprocal susceptibility. The absence of a linear behaviour towards high temperature suggests that a ferrimagnetic transition is expected for a Curie temperature $T_C > 300$ K and, for example, these results are depicted in Figure 4 (part e) for the Q sample with $x = 1.28$ at $H = 1.5$ kOe.

Magnetisation measurements were performed in the temperature range $5 \leq T \leq 375$ K and some results are shown in Figure 5. We see that the magnetization increases with increasing applied field for each composition. In the present range of the magnetizing field, the magnetization does not show a saturation and it decreases slightly with increasing titanium content, in agreement with Néel's theorem of ferrimagnetism.[19] The individual magnetization in the A (tetrahedral) and B (octahedral) sites, M_A and M_B, of the two sublattices cannot be observed, but the net magnetization has been measured instead. Because the two magnetizations are oppositely directed, then $M = M_A - M_B$. The variation of magnetic moment with titanium content can be explained by assuming that, as the concentration of titanium ion increases, the relative number of Fe^{3+} ions decreases on both the A and B sites, but more on the B sites than on the A sites. This distribution is expected to disminish the A−B interactions, which in spinels, according to Néel's molecular field model, are stronger than A−A or B−B ones. Obviously, Ti^{4+} does not participate in any exchange interactions, but disminishes those resulting from the $Fe_A^{3+}-O-Fe_B^{3+}$ unit and the net effect is a decrease in the overall magnetization. Considering the spin-only moment for Fe^{3+} of 5 μ_B, the saturation moments have been estimated as being 0.3 μ_B and 1.05 μ_B for $x = 1.28$ and $x = 1.50$, respectively, but the values obtained at the highest fields (see Figure 5) are smaller than those expected from a collinear model. On the other hand, when the temperature is lowered, the magnetization curves below T_C show a clear ferromagnetic component with increasing importance. Such behaviour is evidence for a disordered spin-state (SG-like state) induced by disorder and frustration because of competing ferro- and antiferromagnetic exchange interactions.

As an example of the general behaviour, Figure 6 shows, for $x = 1.28$ (Q), the variation of the ac susceptibility with temperature ranging between 1.8 and 350 K at a magnetic field of 0.215 Oe for frequencies changing from 0.1 to 10 kHz. The susceptibility increases with increasing temperature, exhibiting a cusp, and then a marked decay. The cusp temperature is ca. 14−15 K, which is consistent with that observed in the dc measurement shown in Figure 4b. The inset of Figure 6 reflects that the cusp shows frequency dependence; it shifts to higher temperatures with increasing frequency and this feature is characteristic of the spin-glass behaviour stated above.

The spin-glass state occurs because of a combination of "randomness" and "frustration" in spin ordering, caused by the randomly mixed state of the ferromagnetic (spin-parallel) and antiferromagnetic (spin-antiparallel) spin interactions.[20] To obtain the spin-glass state in spinel ferrites, it is usual to substitute Fe^{3+} ions by nonmagnetic ions, such as Li^+ and Ti^{4+}, which results in the dilution of magnetic interactions (randomness) and the competition of exchange interactions (frustration). In this sense, Figure 7 shows a simplified model of the spin-glass phenomenon in a spinel ferrite AB_2O_4, in which the nearest neighbours of interacting metal ions bridged via the O^{2-} anion are shown. A denotes a tetrahedral site cation and B an octahedral one. In spinel oxides, the magnetic ions interact with each other through super-exchange antiferromagnetic interactions for which $|J_{AB}| >> |J_{BB}| > |J_{AA}|$ (J being the average value of the spin interactions). Thus, J_{AB} renders the undiluted spinel ferrimagnetism, with all A-site moments oriented antiparallel to all B-site moments, with BB and AA bonds remaining unsatisfied (left-hand side of Figure 7). After dilution of Fe^{3+} ions in the B sites by Li^+ and Ti^{4+} ions substitution, the magnetic order is broken and the frustration of certain moments occurs for BB and AA bonds (right-hand side of Figure 7).

To take into account the magnetic contribution to the Bragg diffraction peaks, the thermal evolution of the NPD patterns was acquired in the temperature ranges between 2−300 K, for $x = 1.28$ (SC) and 1.28 (Q), and 2−112 K, for $x = 1.50$ (Q), with $\lambda = 2.522$ Å and are shown in Figure 8a, 8b and 8c, respectively. Rietveld refinements in those temperature ranges were attempted, with and without a magnetic contribution, but the variation in intensity of the inner Bragg peaks — namely (111), (220), (311), (222), etc. — with the decrease in temperature was scarcely apparent, and this fact seems to indicate the absence of any magnetic long-range ordering (LRO) in these samples.[21]

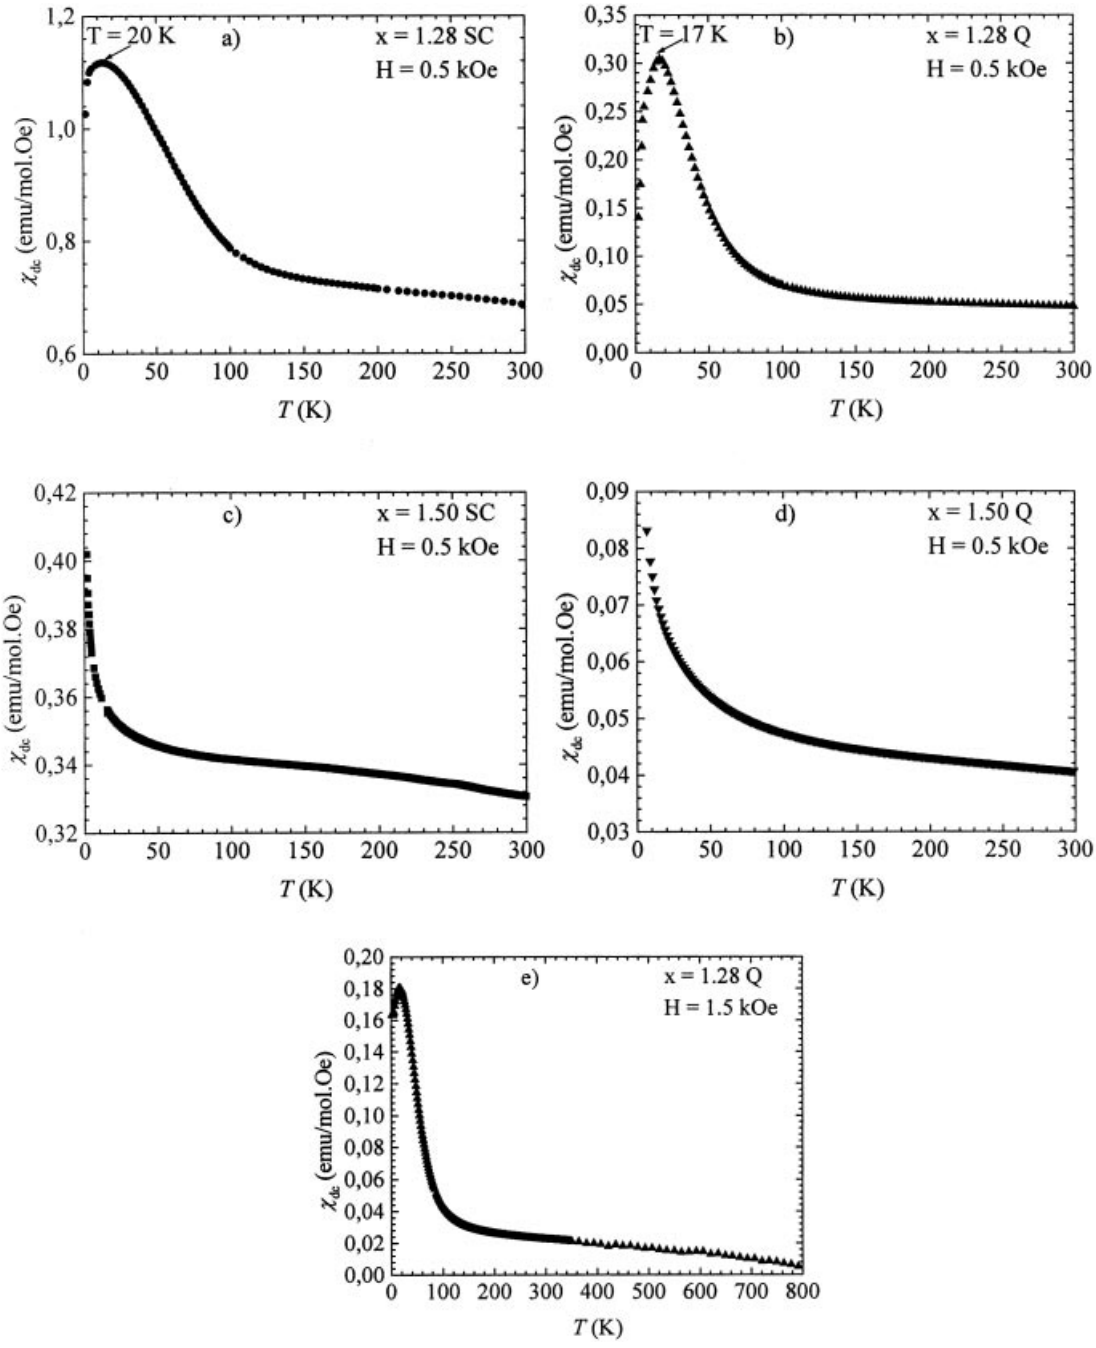

Figure 4. Variation of the dc magnetic susceptibility with temperature for $Li_{0.5+0.5x}Fe_{2.5-1.5x}Ti_xO_4$: $x = 1.28$ (SC and Q) and $x = 1.50$ (SC and Q). Applied field: 0.5kOe (a−d) and 1.5 kOe (e)

On the other hand, Figure 2 (part c) shows the variation of the (111) peak at 2 and 300 K for the sample $x = 1.28$ (Q), in which we see a slight increase in intensity at the lower temperature that seems to indicate a magnetic contribution. Moreover, it is noticeable that there is a considerable broadening of the (111) reflection, which suggests the presence of magnetic spin clusters.[22] Such a variation was not observed for our sample $x = 1.50$, from which the experimental data indicate a characteristic spin-glass behaviour.

Conclusions

Neutron-diffraction experiments were performed on lithium titanium ferrite $Li_{0.5+0.5x}Fe_{2.5-1.5x}Ti_xO_4$ ($x = 1.28$ and 1.50). The data show that the samples obtained by SC are ordered spinels of 1:3 type at octahedral sites, where Li^+ ions occupy octahedral (4*b*) and tetrahedral (8*c*) sites, Fe^{3+} cations are distributed over the octahedral (4*b* and 12*d*) and tetrahedral (8*c*) sites, and Ti^{4+} ions are exclusively located on octahedral (12*d*) sites. When the samples were quenched,

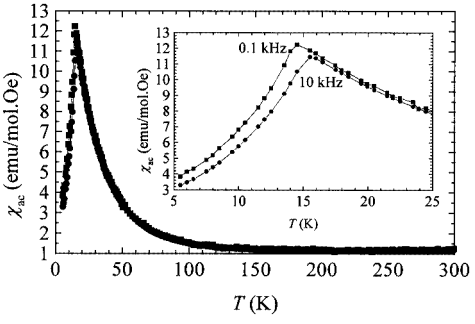

Figure 6. Real part of the ac magnetic susceptibility as a function of temperature from 1.8 to 350 K for $x = 1.28$ (Q) at $\nu = 0.1$ and 10 kHz, $H = 0.215$ Oe. Inset: temperature interval 5−25 K

the 1:3 ordering was destroyed and a change of symmetry occurred from $P4_332$ to $Fd3m$, so that the tetrahedral sites become occupied at random by Li^+/Fe^{3+} ions and the octahedral sites by $Li^+/Fe^{3+}/Ti^{4+}$ ions. Magnetic and neutron-diffraction measurements carried out on these samples confirm a spin-glass behaviour that is attributed to dilution of Fe^{3+} ions in the B sites by the substitution effect of Li^+ and Ti^{4+} ions. Therefore, magnetic order is broken and the

frustration of certain moments occurs for BB and AA interactions.

Experimental Section

Polycrystalline samples of $Li_{0.5+0.5x}Fe_{2.5-1.5x}Ti_xO_4$ (where x = 1.28 and 1.50) were prepared by the "liquid mix" technique[23] from powdered mixtures of Li_2CO_3, Fe_2O_3 and TiO_2 (all reactants were supplied by Merck, Germany) in stoichiometric ratios. The samples were obtained by two methods: slow cooling (SC, at 1073 K for a day) or rapid quenching (Q) from temperatures above 1073 K for 12 h (x = 1.28) and 973 K for 12 h (x = 1.50) to room temperature.

Neutron powder-diffraction data were obtained at different temperatures for the samples x = 1.28 (ordered and disordered phases) and x = 1.50 (ordered phase) on the D1A high-resolution powder diffractometer (λ = 1.9110 Å) at the Institute Laue-Langevin (Grenoble, France). The multidetector D1B powder diffractometer with a wavelength of 2.522 Å was used to obtain the thermal patterns in the temperature ranges 2−300 K for x = 1.28 (ordered and disordered phases) and 2−112 K for x = 1.50 (disordered phase). Diffraction patterns were analysed by the Rietveld[24] method and the Fullprof programme.[25]

The magnetic-susceptibility measurements were performed using a commercial superconducting quantum-interference-device magnetometer, Quantum Design Magnetic Properties Measurement System 5S, on powder samples in a temperature range from 1.8 to 300 K under an applied magnetic field of 0.215 Oe. The magnetic field isothermal variations up to 60 kOe were obtained with the aid of a Quantum Design Physical Properties Magnetic System, which allowed the experimental setting of highly homogeneous magnetic fields at specific temperatures.

Developing Remote Metal Binding Sites in Heteropolymolybdates[‡]

Pierre R. Marcoux,[a] Bernold Hasenknopf,*[a] Jacqueline Vaissermann,[a] and Pierre Gouzerh[a]

Keywords: Polyoxometalates / Molybdenum / N ligands / Coordination chemistry

Anderson-type polyoxomolybdates $[MMo_6O_{18}\{(OCH_2)_3CNH_2\}_2]^{3-}$ (M = Mn^{III}, Fe^{III}) were prepared and structurally characterized. The tris(alkoxo) ligands are bound to the central heteroatom via their oxygen atoms. The corresponding compounds with M = Ni^{II} or Zn^{II} are not accessible since these cations have a preference for the amino functionality. The pendant amino groups of the manganese-containing derivative react with pyridinecarbaldehydes to give the corresponding imines. This provides new mono- and bidentate binding sites for metal cations.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Organic moieties can be grafted onto polyoxometalates (POMs).[1] This provides an entry into the field of organic/inorganic hybrid compounds which combine the properties of the (oxo)metal cluster with those of the organic component.[2,3] Such functionalized POMs have been used in the preparation of polymers,[4−7] dendrimers,[8] and macroporous materials,[9] by covalently crosslinking the organic groups. Metallo-supramolecular chemistry can be used effectively for the construction of functional assemblies.[10−13] Both complete and lacunary POMs can act as ligands for a variety of metal cations,[14] and the resulting complexes have interesting electrical, optical, magnetic and catalytic properties.[15−21] The extra metal centers occasionally provide the way to the formation of 1-D[22,23] or 2-D[24] POM arrays. However, the complexation of metal ions at remote sites of organic ligands grafted on POMs is less common. Indeed the (ferrocenylimido)hexamolybdate reported by Maatta et al. was obtained by treating a ferrocenyl-substituted imido precursor with hexamolybdate.[25] More recently, Stein and co-workers obtained one-dimensional chains in the solid state by the coordination of Ag^I ions to $[Mo_{12}O_{46}(AsC_6H_4\text{-}4\text{-}NH_2)_4]^{4-}$.[26] To the best of our knowledge, complex formation in solution involving a ligand already bound to a polyoxometalate has not been reported in the literature.

Thus, our interest focused on the combination of POMs and other metals using organic ligands. This strategy is complementary to that involving the coordination of oxo ligands, in order to "bridge the gap between polyoxometalates and classic coordination compounds".[27] The organic molecules may display donor atoms other than oxygen, and their arrangement around the binding site may differ; thus, they provide the versatility to adjust to the chemical and geometrical preferences of the extra metal centers. Ideally, our approach would permit the selection of a specific ligand for a chosen metal ion, and to connect it to a chosen POM. The properties of the resulting assembly would be tuned by the individual optimization of the components.

The implementation of this concept requires the development of a flexible synthetic strategy. A key role is played by the organic linker between the POM and the remote coordination site. This molecule has to be bifunctional, with one side that can merge with a POM, and a reactive group on the other side to develop a coordination site. We chose tris(hydroxymethyl)aminomethane $[(HOCH_2)_3CNH_2$, TRIS] for this purpose since tris(alkoxo) moieties can be incorporated in Anderson,[28] Lindqvist,[29−31] Dawson[8,32] and other POMs,[32−34] while the free amino group can be used to create a new coordination site. The incorporation of TRIS into Anderson-type polyoxomolybdates was investigated first.

The Anderson structure $[H_x(M'O_6)M_6O_{18}]^{n-}$ (x = 0−6, n = 2−6) consists of a planar arrangement of six edge-sharing MO_6 (M = Mo, W) octahedra around a central heteroatom M′.[35−37] We have recently shown that two tris(hydroxymethyl)methane residues $RC(CH_2O)_3$ (R = CH_3, CH_2OH, CH_2NO_2) can cap both sides of the polyanion.[28] Two forms were found. In the first form − named δ for its approximate D_3 symmetry − the triol caps the central octahedron, while in the second form − named χ for its approximate C_{2v} symmetry − the triol caps a tetrahedral cavity. The central heteroatom can be a di- or trivalent transition metal cation, and we have prepared compounds with

Mn^{III}, Fe^{III}, Ni^{II} and Zn^{II} and the above-mentioned tris(hydroxymethyl)methane derivatives. Here, we present the results of the reactions with TRIS, and the derivatization of the pendant amino group. The protonated form of TRIS has been used as counterion for polyoxometalates.[38] It has been shown that amide and tertiary amine derivatives can be incorporated into the POM frameworks,[30,39] but to the best of our knowledge, TRIS itself has not been incorporated into the POMs yet. Difficulties with this compound have been linked to its role as a reductant.[39]

Results and Discussion

Grafting a Free Amino Group onto a POM

Treatment of $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$ with manganese(III) acetate in the presence of TRIS gave $[N(C_4H_9)_4]_3[MnMo_6O_{18}\{(OCH_2)_3CNH_2\}_2]$ (**1**) which was isolated as orange crystals in an 80% yield. The compound was characterized by single-crystal X-ray diffraction. Crystal structure data are summarized in Table 1. The overall molecular structure of the anion (Figure 1) is very similar to the analogous compounds previously reported.[28] Six edge-sharing MoO_6 octahedra are arranged around a central MnO_6 unit, forming the Anderson structure. The two

organic moieties cap both sides of the planar hexagon. All the alkoxo ligands are bound to the Mn^{III} ion; thus, the structure corresponds to the δ type. Selected bond lengths and angles are compiled in Table 2. It should be noted that the rigidity of the POM framework prevents the Mn^{III} ion from undergoing marked Jahn−Teller distortions: the coordination octahedron is only very slightly elongated.

The reaction of $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$ with iron(III) acetylacetonate in the presence of TRIS gave $[N(C_4H_9)_4]_3[FeMo_6O_{18}\{(OCH_2)_3CNH_2\}_2]$ (**2**) which was isolated as yellow crystals in a 50% yield. Structural analysis by X-ray diffraction of single crystals (Table 1) revealed the expected δ-type Anderson structure. Selected bond lengths and angles are compiled in Table 2.

IR spectra of compounds **1** and **2** (listed in the Exp. Sect.) are in agreement with the crystal structures.[28,40] It has to be pointed out that the IR spectra display a single, broad band at ca. 700 cm^{-1} which is assigned to the Mo−O−Mo bridges, in accordance with the δ structure. The IR spectra of the χ structure would present two bands in this region.[28]

The reactions of nickel(II) acetate or zinc(II) acetate with $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$ and TRIS did not yield the expected Anderson-type compound. This result is in contrast to other tris(hydroxymethyl)methane derivatives that do form the functionalized Anderson-type POM with a central Ni^{II} or Zn^{II} metal ion.[28] Therefore, we decided to vary the reaction conditions and to use a different source of molybdate. From the reaction of zinc(II) acetate with $[N(C_4H_9)_4]_2[Mo_2O_7]$ in the presence of TRIS, we isolated a compound with the molecular formula $[N(C_4H_9)_4]_2[Mo_2Zn_2O_6\{(OCH_2)_2C(NH_2)CH_2OH\}_2(CH_3CO_2)_2]$ (**3**) in a moderate yield (36%). Structural analysis by single-crystal X-ray diffraction (Table 1) revealed the molecular structure. Figure 2 shows a ball-and-stick representation of the anion. It has no internal symmetry. One of the two molybdenum atoms (Mo1) has a distorted octahedral environment, whereas the other Mo atom (Mo2) displays distorted tetrahedral coordination. Both molybdenum centers have two terminal oxo ligands. Mo1 shares three bridging alkoxo ligands with the zinc atoms, two with Zn1 and one with Zn2. A terminal alkoxo ligand completes its coordination sphere. Mo2 shares one bridging oxo ligand with each zinc atom. The two zinc atoms also have different environments. Zn1 has a distorted trigonal bipyramidal environment, whereas Zn2 displays distorted tetrahedral coordination. Each of the Zn atoms is bound to the amino functional group of a TRIS molecule and to a monodentate acetate ligand, and is connected by a μ-oxo ligand to the Mo2 center. The μ-alkoxo bridges formed with the octahedral molybdenum complete the coordination spheres. Thus, the two TRIS molecules are complexed by two oxygen atoms and a nitrogen atom, leaving one OH group of each TRIS free.

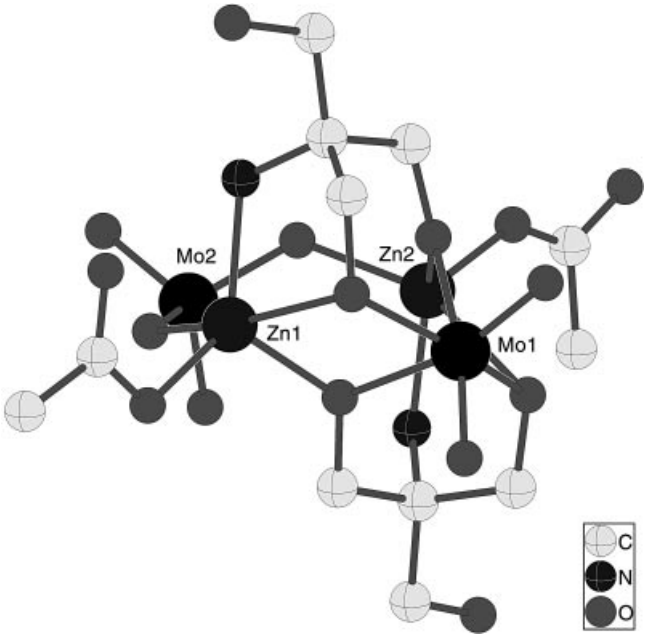

Figure 2. Ball-and-stick representation of the anion of **3**: $[Mo_2Zn_2O_6\{(OCH_2)C(NH_2)CH_2OH\}_2(CH_3CO_2)_2]^{2-}$; note the coordination of the amino groups to the zinc atoms

Compound **3** was also analyzed by solution NMR spectroscopy. In addition to the signals arising from the tetrabutylammonium cations and the acetate ligands, the ^1H NMR spectrum displays three broad signals of equal intensity which are assigned to the CH_2 groups of TRIS. In the ^{13}C NMR spectrum, the TRIS ligands give rise to four signals. This analysis does not exclude the fact that the structure of **3** is maintained in solution, with the overlap of some of the signals of the two TRIS molecules. Yet, it seems more likely

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that the spectra correspond to one or more compounds resulting from the fragmentation of **3**. The decomposition of **3** in solution is further supported by the appearance of some weak signals in the ^{13}C NMR spectrum.

Compound **3** is not suitable as a building block for hybrid molecular materials. However, it is important to point out that the amino group is coordinated to the zinc atom. Such a coordination mode may prohibit the formation of the Anderson structure, as it prevents the incorporation of the zinc atom into the (oxo)molybdenum framework. Based on the well-established HSAB concept,[41] it is not surprising that the soft Zn^{II} cation is bound to the nitrogen donor, whereas the hard Mo^{VI} center has a greater affinity towards the oxygen donors. The same factor is likely to play a role with the nickel(II) cation. Indeed, no Anderson-type compound was isolated from the reaction of nickel(II) acetate with $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$ in the presence of TRIS, and only ill-defined mixtures of compounds were obtained.

Developing Remote Binding Sites

The free amino groups of compounds **1** and **2** could serve as ligands for transition metal ions, and we are currently exploring this possibility. Furthermore, they can react with suitable organic substrates, thus developing different binding sites. With this perspective, we decided to form imines by reaction with aldehydes. Imine formation is known to proceed under conditions under which the functionalized POMs are stable.

Reaction of **1** with 2-pyridinecarbaldehyde afforded $[N(C_4H_9)_4]_3[MnMo_6O_{18}\{(OCH_2)_3CN{=}C(2\text{-}C_5H_4N)\}_2]$ (**4**) which was isolated in a 77% yield. The complex was characterized by single-crystal X-ray diffraction. Crystallographic data are compiled in Table 1, and the molecular structure of the complex anion is displayed in Figure 3. The polyoxomolybdate retains the Anderson structure of the parent compound **1**. Bond lengths and angles (Table 2) are very similar in both compounds. The 1,2-diimine functional group provides a new bidentate chelating site for transition metal ions, on each side of the polyanion.

Reaction of **1** with 4-pyridinecarbaldehyde proceeded in the same manner giving the corresponding compound $[N(C_4H_9)_4]_3[MnMo_6O_{18}\{(OCH_2)_3CN{=}C(4\text{-}C_5H_4N)\}_2]$ (**5**), in a 70% yield. IR and NMR spectroscopic studies show that compounds **4** and **5** are very similar. Beside the typical vibrational bands for the Anderson-type core, the IR spectra present a band for the imine functionality at 1643 and 1641 cm^{-1}, respectively. In the ^1H NMR spectra, all signals are broadened by the presence of the paramagnetic Mn^{III} center. The chemical shifts for the pyridine rings are in the normal range between $\delta = 7$ and 9 ppm (for details see Exp. Sect.), whereas the CH_2O groups are highly deshielded since they are closer to the Mn^{III} center. Nevertheless, they also reflect imine formation. The signals for the CH_2O groups are displayed at $\delta = 52.5$ and 53.9 ppm in compounds **4** and **5**, respectively, relative to $\delta = 61.1$ ppm in the free amino compound **1**.

Compounds **4** and **5** differ only in the nature of the pendant binding sites. Complex **5** only has monodentate binding sites, whereas complex **4** has two bidentate binding sites. This opens the way to vary complex formation of transition metals with respect to the type of metal ions bound and the stability of the complex formed. We are currently exploring these possibilities. Our first attempts to coordinate Cu^{II} or Pd^{II} complexes to the grafted ligands on compounds **4** and **5** gave very insoluble compounds. As our long-term goal is developing defined structures in solution, we are now modifying the ligand, and the transition metal complex.

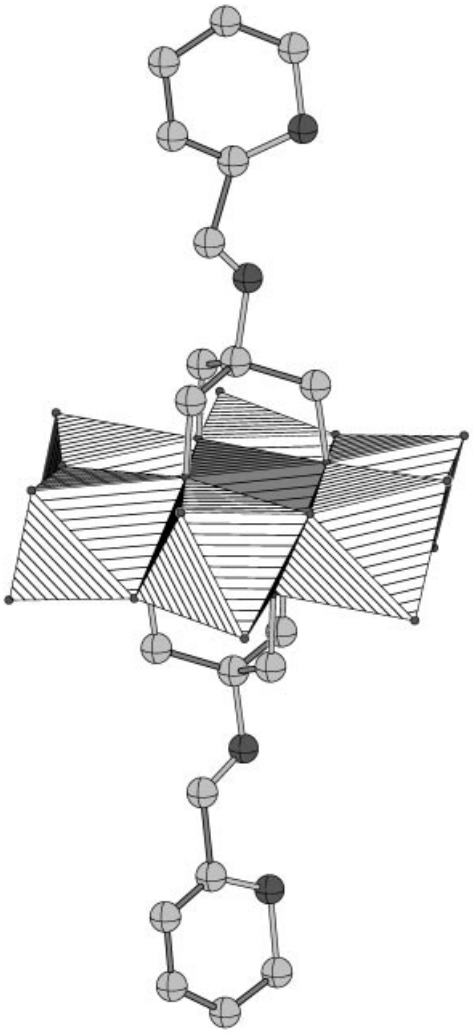

Figure 3. Structure of the anion of **4**: $[MnMo_6O_{18}\{(OCH_2)_3CN{=}C(2\text{-}C_5H_4N)\}_2]^{3-}$; a chelating binding site is displayed at both sides of the Anderson structure

Conclusion

We have shown the possibility of incorporating the TRIS ligand into a heteropolymolybdate. The self-assembly of such a functionalized POM arising from several metal ions (Mo^{VI}, Mn^{III}, Fe^{III}) and several ligands (oxo, alkoxo) is a highly complex process which relies on the molecular recognition of all the components. Their steric and electronic properties are complementary, thus allowing for the formation of the expected structure in high yields. The affinity of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Zn^{II} and Ni^{II} metal ions for nitrogen donors the preference of Mo^{VI} for oxo and alkoxo ligands are antagonistic, therefore disrupting the formation of the Anderson structure. As a result, mixtures of compounds are present in solutions of molybdate, TRIS and Zn^{II} or Ni^{II} cations. It was possible to isolate one compound (**3**) of such a mixture in the solid state. This compound contains tetra- and hexacoordinate molybdenum atoms with only O donor atoms, and tetra- and pentacoordinate zinc atoms with N and O ligands.

The grafted ligands on the POM can be modified by organic reactions.[42] The development of the binding sites presented here is only one aspect of this chemistry, and it is clear that other functionalities can be introduced in the same way. The advantage of this flexible approach is that the synthesis of the POM core and the introduction of a specific function are two distinct steps. We are exploring this field by separately modifying the POM (molybdates, vanadates, ...) and the function (metal binding, hydrogen bonding, targeting biological substances, ...).

Experimental Section

General Remarks: $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$[43] and $[N(C_4H_9)_4]_2[Mo_2O_7]$[44] were prepared by literature methods. All other chemicals, including solvents, were commercially available as reagent grade and used as received. Elemental analyses were performed by the "Service de microanalyse", Université Pierre et Marie Curie, Paris, France and by the "Service central d'analyse", CNRS, Vernaison, France.

Spectroscopy: NMR spectra (^1H, ^{13}C) were recorded with a Bruker AC300 spectrometer at 300 and 75.5 MHz, respectively, at 25 °C unless otherwise stated. Chemical shifts (δ) are expressed in ppm relative to Me_4Si, the high frequency direction being positive, with the residual solvent peak as standard. Assignment of signals is quoted with respect to numbering within the molecular fragments: "pyr" stands for the pyridine rings, "TBA" stands for the tetrabutylammonium cations. IR spectra were recorded using KBr pellets with a Bio-Rad FTS 165 spectrometer at 4 cm^{-1} resolution. Relative intensities are given after the wavenumber as vs = very strong, s = strong, m = medium, w = weak, sh = shoulder, br. = broad.

X-ray Crystal Structure Determination: Crystallographic data are summarized in Table 1. Data were recorded at room temperature with an Enraf−Nonius MACH3 diffractometer with graphite-monochromated Mo-K_α radiation. Unit cell dimensions with estimated standard deviations were obtained from least-squares refinements of the setting angles of 25 automatically centered reflections. Two standard reflections were monitored periodically. Some decay was observed (18, 38 and 22% for compounds **1**, **2** and **4**, respectively) and the data were scaled accordingly. Corrections were made for Lorentz and polarization effects and for absorption (based on Ψ scans for **1** and using DIFABS[45] for other compounds). Secondary extinction corrections were found necessary only for compound **2**. Computations were performed by using the PC version of CRYSTALS.[46] Atomic form factors for neutral atoms were taken from tabulated values.[47] Real and imaginary parts of anomalous dispersion were taken into account. The structures were solved by direct methods[48] and successive Fourier maps. For **1** and **2** non-hydrogen atoms were anisotropically refined except for the carbon atoms of the half cation contained in the asymmetric unit which presents some disorder, and for the oxygen atoms of the water molecules (compound **1**). Restraints were applied to the carbon−carbon distances in both cations and hydrogen atoms were not introduced. For **3** all non-hydrogen atoms were refined anisotropically. Application of restraints to one of the two acetate ligands was necessary. Hydrogen (C−H) atoms were introduced in calculated positions. For **4**, because of the few observed reflections only manganese, molybdenum and oxygen atoms were refined anisotropically. Restraints were applied to the carbon−carbon distances of the cations and no hydrogen atoms were introduced. In all cases least-squares refinements in full-matrix were carried out by minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where F_o and F_c are the observed and calculated structure factors. Models reached convergence with $R = \Sigma(||F_o| - |F_c||)/\Sigma wF_o$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o)^2]^{1/2}$, having values listed in Table 1. In the last stages of the refinement, each reflection was assigned a weight: $w = w'\{1 - [(|F_o| - |F_c|)/6\sigma|F_o|]^2\}^2$ with $w' = 1/\Sigma_r A_r T_r(X)$ with three coefficients for a Chebyshev series, for which $X = F_c/F_{c(max.)}$. In the final cycles, no parameter changed by more than 0.2σ (except for **2** where the value was 0.8σ due to the restraints applied to the acetate ligand) and the final difference Fourier maps were free of any significant residual density. CCDC-189392 (**1**), -189393 (**2**), -189394 (**3**) and -189395 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterization

$[N(C_4H_9)_4]_3[MnMo_6O_{18}\{(OCH_2)_3CNH_2\}_2]$ (1): A mixture of $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$ (8.00 g, 3.7 mmol), $Mn(CH_3COO)_3{\cdot}2H_2O$ (1.49 g, 5.6 mmol) and $(HOCH_2)_3CNH_2$ (1.56 g, 12.8 mmol) in 150 mL of acetonitrile was refluxed for 16 h. The orange solution was cooled to room temperature and filtered to remove a very fine black solid. The filtrate was exposed to ether vapor. After 2 h, a white precipitate was filtered off. The orange filtrate was again exposed to ether vapor for several days. Large orange crystals were obtained. They were isolated by filtration, washed with a small amount of acetonitrile and ether, and dried under vacuum. The crystal for X-ray analysis contained 2 H_2O. Yield: 7.42 g (80%). $C_{56}H_{124}MnMo_6N_5O_{24}$ (1882.21): calcd. C 35.74, H 6.64, Mo 30.58, Mn 2.92, N 3.72; found C 35.73, H 6.72, Mo 29.04, Mn 2.75, N 3.54. IR: $\tilde{\nu}_{max}$ = 3290 (ν_{as} NH, w), 2961 (ν CH, s), 2936 (ν CH, s), 2875 (ν CH, s), 1611 (w), 1480 (δ CH, s), 1384 (δ CH, m), 1348 (w), 1256 (w), 1151 (w), 1129 (w), 1108 (ν CO, m), 1040 (ν CO, s), 939 (ν Mo=O, s), 919 (ν Mo=O, s), 902 (ν Mo=O, s), 797 (w), 737 (w), 663 (ν Mo−O−Mo, vs), 563 (m), 520 (w), 461 (m), 413 (m), 368 (s), 321 (m), 282 (w) cm^{-1}. ^1H NMR ([D$_6$]DMSO): δ = 0.93 (t, ^3J = 7.3 Hz, 36 H, 4-H_{TBA}), 1.31 (m, 24 H, 3-H_{TBA}), 1.57 (m, 24 H, 2-H_{TBA}), 3.16 (m, 24 H, 1-H_{TBA}), 61.1 (s, 12 H, CH_2O) ppm.

$[N(C_4H_9)_4]_3[FeMo_6O_{18}\{(OCH_2)_3CNH_2\}_2]$ (2): A mixture of $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$ (1.08 g, 0.5 mmol), $[Fe(acac)_3]$ (265 mg, 0.75 mmol, acac = acetylacetonate) and $(HOCH_2)_3CNH_2$ (182 mg, 1.5 mmol) in 20 mL of acetonitrile was refluxed for 16 h. The red suspension was cooled to room temperature, and a yellow-orange solid was removed by filtration. The red filtrate was exposed to ether vapor. After 3 d, a microcrystalline solid was isolated by filtration. The compound was recrystallized from DMF to obtain analytically pure **2** with 2 equiv. of DMF. Yield: 615 mg (49%). Crystals suitable for X-ray diffraction were grown by slow ether diffusion into an acetonitrile solution. $C_{62}H_{138}FeMo_6N_7O_{26}$

(2029.31): calcd. C 36.70, H 6.85, Fe 2.75, Mo 28.37, N 4.83; found C 36.01, H 6.80, Fe 2.17, Mo 28.07, N 4.65. IR: $\tilde{\nu}_{max}$ = 2961 (ν CH, s), 2935 (ν CH, s), 2874 (ν CH, s), 1654 (w), 1482 (δ CH, m), 1382 (δ CH, w), 1153 (w), 1129 (w), 1041 (ν CO, s), 938 (ν Mo=O, vs), 920 (ν Mo=O, vs), 902 (ν Mo=O, vs), 802 (w), 665 (ν Mo−O−Mo, br., vs), 613 (w), 562 (m), 528 (w),487 (w), 450 (w), 410 (w), 367 (m), 324 (m), 278 (w) cm^{-1}. The paramagnetic nature of the compound prevents the recording of the NMR spectra.

$[N(C_4H_9)_4]_2[Mo_2Zn_2O_6\{(OCH_2)C(NH_2)CH_2OH\}_2(CH_3CO_2)_2]$ (3): A solution of $[N(C_4H_9)_4]_2[Mo_2O_7]$ (1.58 g, 2.0 mmol), $Zn(CH_3CO_2)_2$ (878 mg, 4.0 mmol) and $(HOCH_2)_3CNH_2$ (485 mg, 4.0 mmol) in 20 mL of acetonitrile was heated under reflux. After 20 min, the mixture became cloudy. After 16 h, the reaction mixture was filtered while hot. The filtrate was cooled to room temperature and exposed to ether vapor. Colorless crystals formed over a period of 2 months. They were isolated by filtration and dried under vacuum for analysis. Yield: 0.91 g (36%). The crystal used in the X-ray diffraction analysis was found to contain one equiv. of acetonitrile per polyanion. $C_{44}H_{96}Mo_2N_4O_{16}Zn_2$ (1259.91): calcd. C 41.95, H 7.68, N 4.45; found C 42.05, H 7.69, N 4.60. IR: $\tilde{\nu}_{max}$ = 2962 (ν CH, s), 2936 (ν CH, s), 2876 (ν CH, s), 2849 (s, sh), 2875 (w), 1615 (s), 1586 (s, sh), 1486 (δ CH, s), 1460 (δ CH, m), 1418 (m, sh), 1381 (δ CH, s), 1326 (m), 1278 (w), 1153 (m), 1104 (m, sh), 1088 (s, sh), 1075 (s), 1020 (ν CO, s), 972 (s), 939 (w, sh), 913 (ν Mo=O, vs), 890 (ν Mo=O, vs), 847 (ν Mo=O, vs), 825 (sh), 792 (sh), 739 (w), 671 (m), 662 (m), 615 (w), 561 (w), 525 (m), 449 (w), 421 (w), 336 (w), 330 (w), 292 (w) cm^{-1}. ^1H NMR ([D$_6$]DMSO, 80 °C): δ = 0.95 (t, ^3J = 7.0 Hz, 24 H, 4-H_{TBA}), 1.36 (m, 16 H, 3-H_{TBA}), 1.63 (m, 16 H, 2-H_{TBA}), 1.78 (s, 6 H, CH_3CO_2), 3.22 (m, 16 H, 1-H_{TBA}), 3.4−3.6 (br.), 3.9−4.05 (br.), 4.1−4.25 (br.), (ca. 4 H each) ppm. ^{13}C NMR ([D$_6$]DMSO, 80 °C): δ = 13.5 (C_{TBA}-4), 19.2 (C_{TBA}-3), 23.1 (C_{TBA}-2), 23.8 (CH_3COO), 56.7, 57.5 (C_{TBA}-1), 64.1, 70.8, 78.9, 176.1 (CH_3COO) ppm.

$[N(C_4H_9)_4]_3[MnMo_6O_{18}\{(OCH_2)_3CN{=}C(2\text{-}C_5H_4N)\}_2]$ (4): 2-Pyridinecarbaldehyde (330 μL, 3.5 mmol) and glacial acetic acid (10 μL, 0.17 mmol) were added to a boiling solution of **1** (3.00 g, 1.6 mmol) in 100 mL of methanol. After 10 min, an orange solid began to precipitate. The mixture was heated under reflux for further 3.5 h. After cooling to room temperature, a methanolic solution of $[N(C_4H_9)_4](OH)$ (c = 5.09·10^{-3} M, 34 mL, 0.17 mmol) was added and the orange precipitate was isolated by filtration, washed with methanol and dried under vacuum. Yield: 2.54 g (77%). Crystals suitable for X-ray diffraction were grown by slow ether diffusion into an acetonitrile solution. $C_{68}H_{130}MnMo_6N_7O_{24}$ (2060.40): calcd. C 39.64, H 6.36, N 4.76; found C 39.58, H 6.47, N 4.89. ^1H NMR ([D$_6$]DMSO, 80 °C): δ = 0.93 (t, ^3J = 7.6 Hz, 36 H, 4-H_{TBA}), 1.34 (m, 24 H, 3-H_{TBA}), 1.61 (m, 24 H, 2-H_{TBA}), 3.18 (m, 24 H, 1-H_{TBA}), 7.28 (2 H, 5-H_{pyr}), 7.84 (2 H, 4-H_{pyr}), 7.94 (2 H, 3-H_{pyr}), 8.24 (2 H, CH=N_{pyr}), 8.72 (2 H, 6-H_{pyr}), 52.5 (12 H, CH_2O) ppm. Heating is necessary for solubilization. The signals corresponding to protons on the anion are broadened due to the presence of Mn^{III}. ^{13}C NMR ([D$_6$]DMSO, 80 °C): δ = 12.82 (C_{TBA}-4), 18.79 (C_{TBA}-3), 22.78 (C_{TBA}-2), 57.71 (C_{TBA}-1), 121.6 (C_{pyr}-5), 125.7 (C_{pyr}-3), 135.8 (C_{pyr}-4), 148.0 (C_{pyr}-2), 151.6 (C_{pyr}-6), 198.0 (CH=N_{pyr}) ppm. IR: $\tilde{\nu}_{max}$ = 2961 (ν CH, s), 2936 (ν CH, s), 2875 (ν CH, s), 1643 (C=N, m), 1584 (Ar, w), 1567 (Ar, w), 1482 (δ CH, s), 1469 (δ CH, m), 1381 (δ CH, m), 1345 (w), 1262 (w), 1152 (w), 1095 (w), 1088 (w), 1026 (ν CO, s), 992 (w), 941 (ν Mo=O, s), 921 (ν Mo=O, s), 904 (ν Mo=O, s), 803 (w), 782 (w), 664 (ν Mo−O−Mo, vs), 592 (w), 562 (m), 463 (m), 410 (m), 366 (s), 321 (m), 260 (m) cm^{-1}.

$[N(C_4H_9)_4]_3[MnMo_6O_{18}\{(OCH_2)_3CN{=}C(4\text{-}C_5H_4N)\}_2]$ 5: The compound was obtained as an orange solid by the same procedure as for **4**. Compound **5** is more soluble than **4** in polar organic solvents. Yield: 2.23 g (70%). $C_{68}H_{130}MnMo_6N_7O_{24}$ (2060.40): calcd. C 39.64, H 6.36, N 4.76; found C 39.41, H 6.47, N 4.77. ^1H NMR (67 °C): δ = 0.98 (br., 36 H, 4-H_{TBA}), 1.41 (br., 24 H, 3-H_{TBA}), 1.66 (br., 24 H, 2-H_{TBA}), 3.17 (br., 24 H, 1-H_{TBA}), 7.56 (br., 4 H, 3-H_{pyr}, 6-H_{pyr}), 8.41 (br., 2 H, CH=N_{pyr}), 8.68 (br., 4 H, 4-H_{pyr}, 5-H_{pyr}), 53.9 (br., 12 H, CH_2O) ppm. ^{13}C NMR ([D$_6$]DMSO): δ = 13.60 (C_{TBA}-4), 19.33 (C_{TBA}-3), 23.07 (C_{TBA}-2), 57.50 (C_{TBA}-1), 123.6 (C_{pyr}-3, C_{pyr}-6), 136.1 (C_{pyr}-2), 149.4 (C_{pyr}-4, C_{pyr}-5), 197.6 (CH=N_{pyr}), 217.3 (CH_2O) ppm. IR: $\tilde{\nu}_{max}$ = 2961 (ν CH, s), 2935 (ν CH, s), 2874 (ν CH, s), 1641 (C=N, m), 1597 (Ar, m), 1559 (Ar, m), 1480 (δ CH, s), 1467 (δ CH, m), 1408 (m), 1381 (δ CH, m), 1348 (w), 1322 (w),1232 (w), 1170 (w), 1153 (w), 1094 (w), 1084 (w), 1026 (ν CO, s), 940 (ν Mo=O, s), 921 (ν Mo=O, s), 903 (ν Mo=O, s), 818 (w), 803 (w), 736 (w), 664 (ν Mo−O−Mo, vs), 563 (m), 521 (w), 465 (m), 410 (m), 367 (s), 322 (m) cm^{-1}.

Stereoisomer Discrimination Through π-Stacking Interactions in Spirocyclic Phosphazenes Bearing 2,2′-Dioxybiphenyl Units

Gabino A. Carriedo ,[a] Francisco J. Garcia-Alonso,[a] Jose L. García-Alvarez,[a] Giuseppe C. Pappalardo,*[b] Francesco Punzo,[b] and Patrizia Rossi[c]

Keywords: Phosphazenes / Pi interactions / Solid-state structure / Spiro compounds / Stereoisomer discrimination

The molecular structure of the 2,2′-dioxybiphenyl spirocyclic tetrachlorocyclotriphosphazene $[N_3P_3Cl_4(O_2C_{12}H_8)]$ (**3**) was determined by X-ray crystallography. The structure and conformation of **3** in the crystal are compared and discussed with respect to those of its analogues trispiro and dispiro derivatives, $[N_3P_3(O_2C_{12}H_8)_3]$ (**1**) and $[N_3P_3Cl_2(O_2C_{12}H_8)_2]$ (**2**), respectively. Both the (*R*) and (*S*) stereoisomers are present in the lattice of **3** as arranged in pairs (*R*)···(*S*) held together through sandwich-type π-stacking interactions of the (C7–C12)/(C7–C12)′ phenyl rings of the 2,2′-dioxybiphenyl groups. The polymer-like assembly of **2** was formed by interactions between the (*R*) and (*S*) portions of two *meso* molecules [in the sequence ···(*R*)···(*S*)···(*R*)···(*S*)···(*R*)···(*S*)···]. In this case, the pertinent phenyl rings involved in the noncovalent π-interactions assume a parallel-displaced configuration. To the best of our knowledge, no chiral discrimination in cyclic phosphazenes has been hitherto described, and the present findings provide the first evidence for the discrimination of stereoisomers in spirophosphazenes and the noncovalent forces that govern the chiral recognition in these systems. The energy of the π-stacking interaction increases with increasing number of 2,2′-dioxybiphenyl groups; i.e., on passing from **3** to **2**. In the case of molecule **1**, the discrimination of enantiomers does not take place at all because the π-stacking interaction becomes impossible because of steric hindrance.

Introduction

Many outstanding properties in materials science are expected to arise from phosphazenic macromolecules and nanosized assemblies of hexa(aryloxy)cyclotriphosphazenes acting as chiral responders and host molecules.[1−3] The spirocyclotriphosphazenes, bearing one to three dioxyaryl or other nucleophilic groups that cyclize to form rings with the phosphorus atoms,[4,5] are optimal candidates for such applications. They represent a unique class of highly tailorable host molecules,[6,7] and they have received much attention for the synthesis of new, high-molecular-weight spiropolyphosphazenes containing functionalized and optically active groups.[8,9] The basic research interest in the structural characterization of spirocyclotriphosphazenes stems from their ability to form inclusion adducts with polymers,[6] their ability, in some cases, to induce polymerization of a guest,[7] and, especially, their potential for stereoisomer discriminaton. The discrimination of enantiomers, frequently called chiral recognition,[10] is a very important concept[11] with applications in, inter alia, Langmuir−Blodgett film technology,[12] chromatographic separation of enantiomers,[13] asymmetric catalysis, and new materials.[14]

The spirocyclophosphazenes **1**, **2** and **3**, referred to as trispiro, dispiro and monospiro derivatives, respectively, have pairs of conformations that are rapidly interconverting in solution. Scheme 1 gives a schematic drawing of **1**−**3** showing the labeling of the atoms.

The molecular assembly of nanometer-sized particles in the bulk has been reported recently[15] by us for the 2,2′-dioxybinaphthyl trispirocyclic cyclotriphosphazene (+)-$[N_3P_3(O_2C_{20}H_{12})_3]$ using a combined experimental (energy-dispersive X-ray diffraction) and theoretical (molecular dynamics) approach. Previously, we reported the stereochemistry of the spirocyclophosphazenes **1**−**3** in solution.[16] Although the discrimination of enantiomers in general cannot be performed in the gas phase or in dilute solutions, it can be revealed in the solid state. A complete investigation, however, of the enantiomeric composition, and the interactions between enantiomers, in the crystal structures of **1**−**3** has not yet been undertaken.

As is the discrimination of any other pair of enantiomers, the types of nonbonding intermolecular forces that can be exploited are based on van der Waals, electrostatic, hydro-

gen-bonding, and π-stacking interactions. The latter interactions are very important in systems containing aromatic rings.[17,18]

In this work, the unanswered questions concerning the occurrence, the origins, the configurations and the strengths of the interactions between the enantiomers of spirophosphazenes **1**−**3** is addressed using X-ray diffraction analyses.

Previously reported X-ray structural analyses of spirocyclophosphazenes bearing 2,2′-dioxybiphenyl groups have concerned the trispiro compound[19] $[N_3P_3(O_2C_{12}H_8)_3]$ (**1**), the transannular and spiro-substituted derivatives 1,3- and 1,1-$[N_3P_3(OCH_2CF_3)_4(O_2C_{12}H_8)]$,[20] and the tetra- and difluoro-substituted analogues[21] of **1** and **2**, $[N_3P_3F_4(O_2C_{12}H_8)]$ and $[N_3P_3F_2(O_2C_{12}H_8)_2]$. Accordingly, we have compared the solid-state structure of **3** with that of **2** (as reported[22] by Dez et al.) and that of the 2,2′-dioxybiphenyl trispirocyclic cyclotriphosphazene **1** as reported[19] by Allcock et al. The goals of this paper are thus twofold: First to provide experimental information about the structure of **3** in the crystal and to compare it with those of **1** and **2**, and, secondly, to detect in **1**−**3** the factors that discriminate between stereoisomers, the operating noncovalent interactions and their relative strengths, and the resulting configurations.

Results and Discussion

X-ray Structure

An ORTEP view of compound **3** is shown in Figure 1. Bond lengths and angles of **3** are reported in Table 1. To make comparisons between structures, we consider the following aspects of the compounds in the solid state: (i) the conformation of the P_3N_3 plane, (ii) the conformation of the 2,2′-dioxybiphenyl moieties, and (iii) the intermolecular interactions. The three phosphorus and three nitrogen atoms deviate significantly from the P_3N_3 mean plane [the maximum deviation is 0.135(4) Å (N2)]. An analysis of the summary of agreement between chemically equivalent bonds and angles for **3** (Table 2) shows that: (i) the P−N distances have a noteworthy value of χ^2 because the bonds P2−N1 and P3−N3 are significantly shorter than the other four P−N bonds; (ii) the P−N−P and N−P−N angles also attain a high value of χ^2, since the angles P2−N2−P3 and N1−P1−N3 are smaller that the remaining P−N−P and N−P−N angles, respectively, which thus indicates a loss of planarity inside the P_3N_3 ring; (iii) the C−C−C angles are quite different, as is seen from the value of χ^2 for the C−C−C angle. The high value found for the angle N−P−O is due to the manner in which the biphenyl moieties are disposed with respect to the P_3N_3 ring.

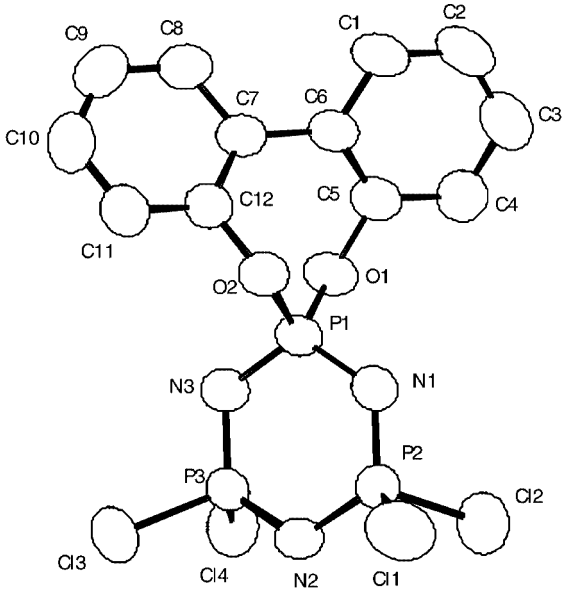

Figure 1. ORTEP view of **3**

For compound **2**, the reported[22] maximal deviations from the mean P_3N_3 planes are 0.007 and 0.054 Å for the two independent molecules **2(a)** and **2(b)**, respectively. In the case of compound **1**, the value of χ^2 found[19] for the P_3N_3 plane was 602.0, and a distortion of the P_3N_3 plane was also proposed. The analysis of the agreement between chemically equivalent bonds and angles for compound **2** attained a value of χ^2 for the C−C−C angle that is close to that found for **1** and **3**. Therefore, all the three compounds feature a significant distortion of the aromatic rings of the dioxybiphenyl moieties.

In compound **3** the dioxybiphenyl moiety is twisted by 48.19(4)° with respect to the P_3N_3 mean plane. This angle

is similar to those found for **1** and for the two independent molecules **2(a)** and **2(b)**.

According to the usual convention, a positive angle [(*R*) configuration] and a negative angle [(*S*) configuration] represent a clockwise and an anticlockwise twist, respectively, of the biphenyl axis from the mean ring plane when viewed from the phosphorus atom towards the biphenyl unit. For compound **2**, we found that the C1−C12 and C37−C48 biphenyl units have positive angles with the mean P_3N_3 plane, while the C13−C24 and C25−C36 planes have negative angles. In compound **1**, two of the three dioxybiphenyl moieties have a negative angle with the P_3N_3 plane while the other has a positive one. Allcock has suggested that such conformations of these groups are due to intermolecular repulsion interactions.[19]

Retrieving molecular structures deposited at the Cambridge Structural Database[23] that contain one or two (2,2′-dioxy-1,1′-biphenyl) groups bonded to a phosphorus atom shows that the angle between the aromatic rings of the 2,2′-dioxybiphenyl unit is in the range 35.6−58.5° with a mean value of 45.5°. This finding is in agreement with the value found in molecule **3** [40.8(1)°] as well as with those previously found[19,22] in **1** and **2**.

Table 2. Summary of agreement between chemically equivalent bonds [Å] and angles [°] for **3**

Bond or angle	No. of examples	Range [Å or °]	σ_{rms}	Mean	χ^2 [a]
P−N	6	1.544−1.604	0.004	1.574	144.44

C−C−C	12	116.9−123.1	0.5	120.0	190

[a] The value of χ^2 is the common statistical quantity, calculated to test the significance of a deviation from the mean. It is the sum of the squares of the deviations from the mean divided by root-mean square σ^2. [b] Aromatic C−C bonds within phenyl groups. [c] Biphenoxy C−C bonds.

Crystal Packing and Discrimination of Stereoisomers

The unit cell of **3** contains four molecules assembled in two pairs, each pair being made up of the two stereoisomers [(*R*) and (*S*)] held together by π-stacking interactions between their aromatic rings (Figure 2).

The configuration attained by such a bimolecular assembly in the crystal packing of **3** evidences that the (*R*)···(*S*) discrimination from molecule to molecule features effectively eclipsed sandwich-type π-interactions between the aromatic ring (C7−C12) and the (C7−C12)′ ring of a centrosymmetrically related molecule ($' = -x + 1, -y + 1, -z + 1$) (Figures 2 and 4). In this dimer-like assembly of **3**, the distances between the carbon atoms range from 3.605(7) to 3.993(8) Å (Table 3) and the interacting phenyl planes are perfectly superimposed and parallel.

In the case of **2**, the selective crystallization of the *meso* form from a mixture of all the possible stereoisomers in solution[16] can be accounted for by the diminuation of entropy resulting from the more ordered arrangement attained in the solid (Figure 3), and thus to more effective packing forces for the polymer-like chain assembly of the molecules in the crystal. The structure of the lattice of **2** shows that such an intermolecular polymer-like assembly arises from π-stacking interactions between one enantiomeric portion of a *meso* molecule that discriminates the opposite enantiomeric portion of the adjacent *meso* molecule. In particular, two aromatic rings of **2(a)** interact through two aromatic rings of two different **2(b)** molecules: unit

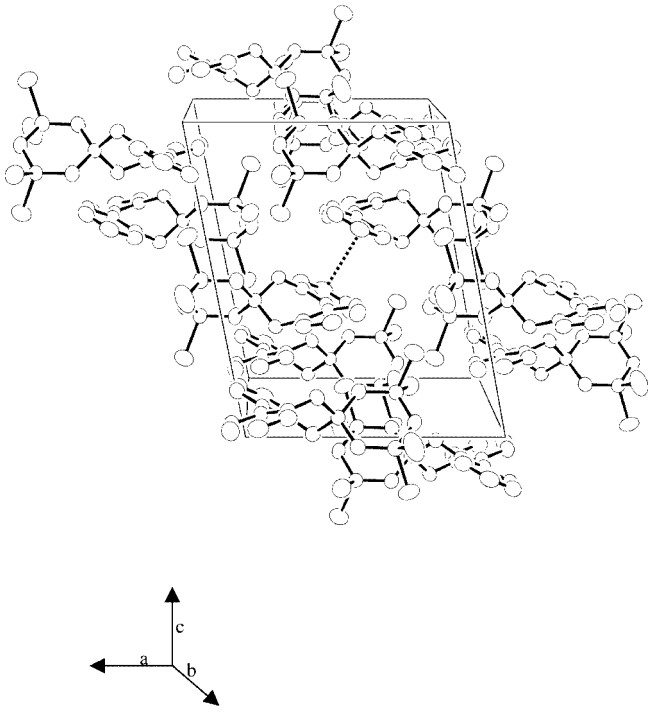

Figure 2. Crystal packing of **3**; the π-stacking interactions between the aromatic rings are denoted by dotted lines

Table 3. Selected intermolecular distances [Å] for molecules of **3** in the crystal

C7···C10′[a]	3.614(7)
C7···C11′	3.947(6)
C8···C10′	3.786(7)
C8···C11′	3.605(7)
C9···C11′	3.645(7)
C9···C12′	3.626(7)
C10···C11′	3.993(8)
C10···C12′	3.718(7)

[a] ′: $-x + 1, -y + 1, -z + 1$.

C7−C12 of **2(a)** interacts with unit C31−C36 of **2(b)**, and unit C13−C18 of **2(a)** interacts with unit C37′−C42′ of **2(b)** of a symmetry-related [$x + 0.5, y + 0.5, z$] molecule (Figure 3). The aromatic rings involved in these π-interactions assume a parallelly displaced configuration in which the (C7−C12)/(C31−C36), and (C13−C18)/(C37−C42)′ ring planes make angles of 4.6(3)° and 8.5(4)°, respectively (Figure 4). The distances of 3.78(2) and 3.85(3) Å between the planes (C7−C12)/(C31−C36) and (C13−C18)/(C37−C42)′, respectively, are similar to the value of 3.723(7) Å found for (C7−C12)/(C7−C12)′ in spirocyclophosphazene **3**.

In compound **3**, where only one 2,2′-dioxybiphenyl group is present, the sandwich-type π-stacking interaction between the rings responsible of the discrimination of enantiomers is stronger with respect to that in **2**. In compound **2**, the presence of two 2,2′-dioxybiphenyl moieties leads to the formation of a polymer-like structure through a parallelly displaced π-stacking interaction of the aromatic units of the dioxybiphenyl groups (Figure 4).

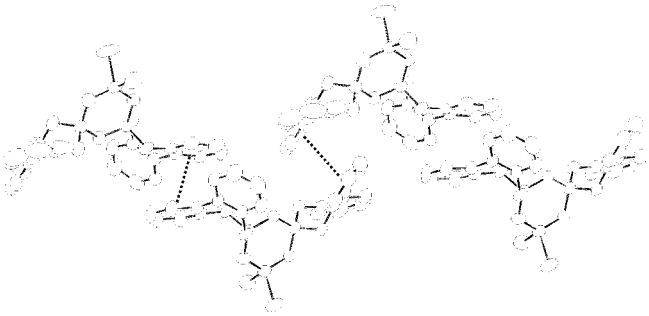

Figure 3. Molecular assembly of **2** (as obtained using the crystal coordinates available from ref.[22]); the chiral recognition (*R*)···(*S*) from molecule to molecule in the *meso* form is denoted by a dotted line

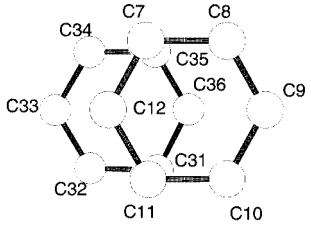

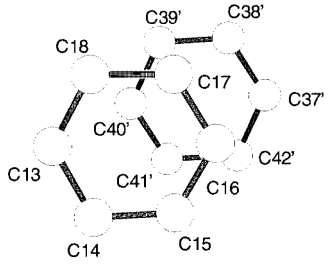

Figure 4. Sandwiched (**3**) and parallelly displaced (**2**) π-stacks of the aromatic units

In the case of compound **1**, in which the P_3N_3 ring bears three 2,2′-dioxybiphenyl groups, the intermolecular enantiomer discrimination does not operate. In fact, the molecules of **1** [(*SSR*) enantiomer] in the lattice[19] are not assembled with respect to each other in configurations that attain some π-stacking interactions, probably because of steric hindrance.

Conclusions

The 2,2′-dioxybiphenyl spirocyclic tetrachlorocyclotriphosphazene **3** was characterized crystallographically by X-ray analysis, and its structure is compared to that of the analogous derivatives **1** and **2**. Both the (*R*) and (*S*) stereoisomers are present in the unit cell of **3**. A twisting angle of ca. 48° between the dioxybiphenyl moiety and the P_3N_3 mean plane, and a significant distortion of the aromatic rings of the dioxybiphenyl moieties, are common features in the crystals of **1**−**3**.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The molecules of **3** in the crystal are assembled in pairs. Each pair is self-assembled in stacks of (*R*) and (*S*) stereoisomers. This structure results from attractive noncovalent π-stacking interactions (eclipsed sandwich configurations of the interacting aromatic units) between the dioxybiphenyl groups of two centrosymmetrically related molecules. A noncovalent π-stacking interaction (parallelly displaced configuration of the interacting aromatic units) between dioxybiphenyl groups was found to be effective also for molecules of **2** in its crystal. The ordered polymer-like assembly (Figure 3) in the solid state is determined by enantiomeric discrimination between the (*R*) and (*S*) molecular portions of the *meso* molecules of **2** in a sequential fashion [···(*R*)···(*S*)···(*R*)···(*S*)···(*R*)···(*S*)···]. The binding energy between the enantiomers on passing from the eclipsed sandwich configuration of the π-stacks in **3** to the parallelly displaced configuration of the π-stacks in **2** should be the same, and have a value of ca. 3 kcal·mol^{-1} suggested by recent findings for the benzene dimmer.[17] An analogous recognition of the stereoisomers is not present in the case of **1** because the nonbonded π-interactions between the possible stereoisomers (*RRR*/*SRR*/*RSS*/*RSR*/*SSR*/*SSS*) cannot take place because of steric hindrance.

Experimental Section

Sample Preparation: Compound **3** (m.p. 193 °C) was prepared as reported in the literature.[24] Crystals of **3** were obtained by slow diffusion of hexane into a dichloromethane solution and successive recrystallization from dichloromethane.

Crystal Structure Determination: The cell parameters and intensity data for **3** were obtained with a Siemens P4 diffractometer, using graphite-monochromated Cu-K_α radiation (λ = 1.54184 Å). Cell parameters were determined by least-squares fitting of 25 centered reflections. The intensities of three standard reflections were measured every 60 min to check the stability of the diffractometer and the decay of the crystal. Intensity data were corrected for Lorentz and polarization effects, and an absorption correction was applied once the structure was solved by using the Walker and Stuart method.[25] The structure was solved using the SIR-97 program[26] and subsequently refined by the full-matrix least-squares SHELX-97 program.[27] The hydrogen atoms were found in difference syntheses and their positions were refined as well as their isotropic displacement parameters. All the non-hydrogen atoms were refined anisotropically. Atomic scattering factors and anomalous dispersion corrections for all the atoms were taken from literature data.[28] Geometrical calculations were performed by the PARST97 routine.[29] The molecular plot was produced by the ORTEP program.[30] Crystal and structure refinement data are reported in Table 4. CCDC-197311 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Microstructural Characterisation of Two New One-Dimensional Members of the $(A_3NiMnO_6)_\alpha(A_3Mn_3O_9)_\beta$ Homologous Series (A = Ba, Sr)

María Hernando,[a] Khalid Boulahya,[a] Marina Parras,[a] Jose M. González-Calbet,*[a] and Ulises Amador[b]

Keywords: Electron diffraction / High-resolution electron microscopy / One-dimensional oxides / Twinned microstructure

Two new members of the one-dimensional $(A_3NiMnO_6)_\alpha(A_3Mn_3O_9)_\beta$ homologous series, with the compositions $(Sr_{0.75}Ba_{0.25})_5NiMn_3O_{12}$ and $Sr_9Ni_2Mn_5O_{21}$, have been synthesised. Their structures can each be described as a hexagonal array of infinite one-dimensional chains of face-sharing polyhedra, running parallel to the *c* axis and separated by the Sr/Ba cations. The structure of $(Sr_{0.75}Ba_{0.25})_5NiMn_3O_{12}$, which constitutes the ($\alpha = 3$, $\beta = 2$) member of the series, is made up of three face-sharing octahedra linked by one trigonal prism. For $Sr_9Ni_2Mn_5O_{21}$ ($\alpha = 2$, $\beta = 1$) the sequence of polyhedra along the chains corresponds to a motif consisting of two octahedra–one trigonal prism–three octahedra–one trigonal prism. The manganese atoms occupy the octahedral sites in both phases, while the Ni^{2+} cations are distributed in the trigonal-prismatic sites in a disordered way. Only a small fraction of these (close to 20%) is located at the centres of the trigonal prisms, 80% being displaced towards the rectangular faces of the polyhedra and giving rise to a square-planar-like coordination. Both oxides present twinned microstructures, as evidenced by SAED and HREM. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Growing interest has recently developed in a family of materials structurally related both to $A_3A'BO_6$ (K_4CdCl_6-type)[1] and to 2H-ABO_3 hexagonal perovskite.[2] In the former oxide, $A'O_6$ trigonal prisms (TP) and BO_6 octahedra (Oh) share triangular faces, in a 1:1 sequence, forming infinite polyhedra chains parallel to the *c* axis of a rhombohedral unit cell. The 2H-ABO_3 hexagonal perovskite is also composed of a hexagonal array of infinite chains, but the chains in this case are made up of face-sharing BO_6 octahedra. A large number of intermediate structures obtained by varying the number of octahedra between the trigonal prisms, maintaining the hexagonal array of the polyhedra one-dimensional chains have been described. In fact, all of these can be regarded as being formed by the ordered intergrowth of the structural units constituting the above structures. This building principle gives rise to the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ general formula, in which α and β denote the number of $A_3A'BO_6$ and 2H-ABO_3 structural blocks, respectively, in each term.[3]

A large number of oxides belonging to this family have been reported, due in part to the variety of elements that can be introduced into the oxygen framework. In this sense, the A cation usually corresponds to an alkaline earth metal, whilst the A′ and B sites can be occupied by many different metal atoms. In addition, the A′ and the B positions can be occupied by the same cation. Much of the work published on these materials has been performed on the A−(A′ = B)−O systems, in which A′ = B = Ni,[4,5] Co[6−8] and A = Ba, Sr, Ca. In the different stabilized members, Ni or Co seem to present both II and IV oxidation states.

When A′ = B = Mn, no one-dimensional hexagonal phases are known. In this sense it is worth noting that two-dimensional phases, also structurally related to 2H-$BaMnO_3$, have recently been reported. As an example, the compound $Ba_6Mn_5O_{16}$ [9] crystallizes in a laminar structure closely related to the 15-R polytype.[10] Note that Mn is only in the IV oxidation state. The same cationic relationship presents the one-dimensional $Ba_6Ni_5O_{15}$,[4] the ($\alpha = 3$, $\beta = 3$) member of the series, but Ni is now present both as Ni^{II} and as Ni^{IV}. According to this, one might think that one-dimensional oxides containing Mn as the sole metal in the polyhedra chains should be less stable, due to the low stability of Mn^{II} in a trigonal prism or in an octahedral environment. However, when A′ ≠ B = Mn, several one-dimensional phases in which Mn occupies the octahedral sites have been reported, whilst a metal of a different chemical nature, such as Zn,[11,12] Cu[13] or Ni,[14,16] is located in the TP. In the case of Ni, two phases have previously been reported: $Ca_3(Ni)_{TP}(Mn)_{Oh}O_6$ [14,15] and $Sr_4(Ni)_{TP}(Mn_2)_{Oh}O_9$,[16,17] corresponding to the ($\alpha = 3$, $\beta = 0$) and

($\alpha = 3$, $\beta = 1$) members of the series, respectively. In the former oxide, the polyhedra chains are made up of one octahedron and one trigonal prism sharing faces; in the latter, dimers of face-sharing octahedra are separated by one trigonal prism. In both cases, Mn ions, in the IV oxidation state, occupy the octahedral sites and Ni^{II} is situated in the TP positions. At this point it should be remarked that in some cases, such as in Ca_3NiMnO_6, the Ni atoms are located at the centres of the prisms, whereas in other cases, in $Sr_4Mn_2NiO_9$ for instance, approximately 80% of the Ni^{2+} ions are displaced towards one of the rectangular faces of the TP. This is fairly normal in Ni- or Cu-containing oxides such as Sr_3CuPtO_6,[18] $Sr_4Ni_3O_9$ [4] or $Sr_4CuIr_2O_9$.[19]

This paper reports the structural study of two new members, ($\alpha = 3$, $\beta = 2$) and ($\alpha = 2$, $\beta = 1$), of the $(A_3NiMnO_6)_\alpha(A_3Mn_3O_9)_\beta$ (A = Ba, Sr) series.

Results and Discussion

Chemical and Structural Characterization

Samples of nominal compositions $(Sr_{0.75}Ba_{0.25})_5NiMn_3O_{12}$ and $Sr_9Ni_2Mn_5O_{21}$ were confirmed to be single phases by X-ray diffraction (Figure 1). The average cationic ratios, determined by ICP, agree with the nominal compositions within experimental accuracy, the following metal

contents being obtained: Sr 35.88±0.9% (35.8%), Ba 17.7±0.4% (18.7%), Mn 17.8±0.4% (17.99%) and Ni 7.0±0.2% (6.5%) − in agreement with the nominal $Sr_{3.75}Ba_{1.25}NiMn_3O_{12}$ composition − and Sr 50.8±1.3% (51.99%), Mn 17.4±0.4% (18.1%) and Ni 7.84±0.2% (7.7%) − consistent with the $Sr_9Ni_2Mn_5O_{21}$ nominal composition. EDS analyses, performed on numerous crystallites with use of $SrMnO_3$ and $BaMnO_3$ as standards, confirm the above compositions.

Figure 1 (a) shows the X-ray diffraction pattern of $Sr_{3.75}Ba_{1.25}NiMn_3O_{12}$. The whole pattern can be indexed within a hexagonal unit cell of parameters $a = 0.97114(2)$ nm and $c = 2.03649(6)$ nm as corresponding to the ($\alpha = 3$, $\beta = 2$) member of the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ series. On the other hand, the corresponding XRD pattern of $Sr_9Ni_2Mn_5O_{21}$ is depicted in Figure 1 (b), all the peaks being indexed in a rhombohedral unit cell with $a = 0.96065(5)$ nm and $c = 3.5836(2)$ nm, in agreement with the structural characteristics of the ($\alpha = 2$, $\beta = 1$) term of the above one-dimensional family.

SAED and HREM

$(Sr_{0.75}Ba_{0.25})_5NiMn_3O_{12}$ ($\alpha = 3$, $\beta = 2$)

Microstructural characterization by SAED and HREM confirms the XRD results; the most relevant SAED patterns are shown in Figure 2 (a and b). All the maxima can be indexed in the hexagonal unit cell described above. The condition reflections are compatible with the $P\bar{3}c1$ space group previously proposed for isostructural $Sr_5Co_4O_{12}$.[7] In addition, the intensity distribution of the spots on the SAED pattern of Figure 2 (b) seems to indicate the presence of twinning in the crystals. Actually, Figure 2 (c) shows the same [1$\bar{2}$10] reciprocal plane corresponding to the untwinned isostructural oxide $Sr_5Co_4O_{12}$.[6] The intensity distribution of the spots corresponding to the (*h*0*i*2*h*) reflections is modulated. This feature is a general one in all one-dimensional oxides belonging to the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ series, the direction of the modulation always being perpendicular to the planes containing the metal atoms in the TP sites. When this SAED pattern is compared to that shown in Figure 2 (b), it can be observed that the modulated distribution of the intensity of the spots is apparent not only along the [*h*0*i*2*h*]* direction but also along the [$\bar{h}$0*i*2*h*]* direction. This is due to twinning of the crystals, as confirmed by HREM. Indeed, in the image taken along the [1$\bar{2}$10] zone axis, shown in Figure 3, two large identical domains, inclined towards one another around the *c* axis, are clearly observed. In both domains, *d* spacings of 0.83 and 1.01 nm − along the *c* and the *a* axes, respectively − are observed, such interplanar distances corresponding to d_{001} and d_{100} of the hexagonal unit cell described above. The contrast variation observed in both domains is characteristic of the $\alpha = 3$, $\beta = 2$ structure. In the magnification of one domain (Figure 3, b), it can be seen that, along the *c* axis, two bright dots alternate with three less intense dots. Such contrast variation can be attributed to the (Oh−Oh−Oh−TP) polyhedra sequence since, in all these one-dimensional oxides, the metal columns in the trigonal sites and the Sr/Ba atoms are imaged as bright dots. The calculated image (inset in Figure 3, b) agrees with the experimentally ascertained one for $\Delta t = 7.5$ and $\Delta f = -90$ nm.

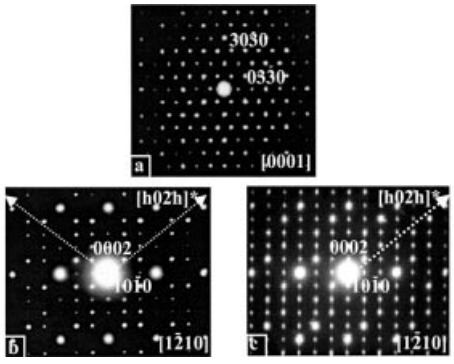

Figure 2. SAED patterns along the [0001] (a) and [1$\bar{2}$10] (b) zone axis corresponding to $(Sr_{0.75}Ba_{0.25})_5NiMn_3O_{12}$; (c) SAED pattern along the [1$\bar{2}$10] zone axis corresponding to $Sr_5Co_4O_{12}$

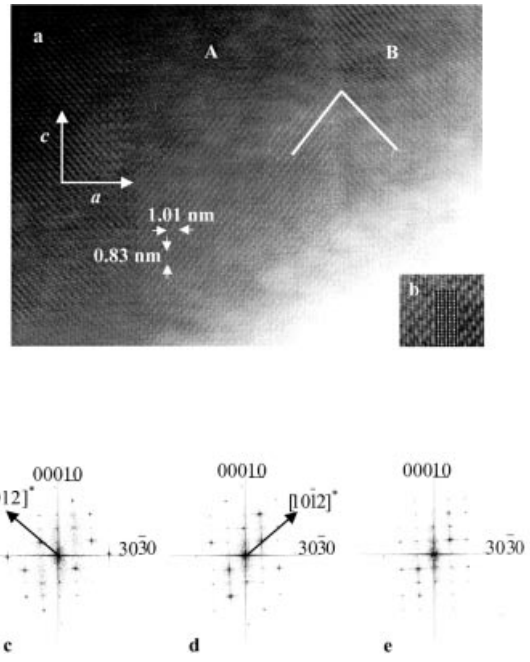

Figure 3. (a) HREM of $(Sr_{0.75}Ba_{0.25})_5NiMn_3O_{12}$ along [1$\bar{2}$10]; a twinned microstructure can clearly be seen; (b) magnification of one of the microdomains; calculated image is shown in the inset; optical Fourier transforms (FT) corresponding to domains marked with A (c) and B (d) in Figure 3a; (e) FT corresponding to the juxtaposition of both A and B domains

Optical Fourier Transforms of both domains, labelled A and B in Figure 3, are depicted in Figure 3 (c and d). Both patterns correspond to [1$\bar{2}$10]-oriented domains related to one another through a 90° rotation around *c**. Consequently, in the first domain, the intensity modulation is observed along the [*h*0*i*2*h*]* reciprocal direction whilst in the second domain the modulation is along the [$\bar{h}$0*i*2*h*]* one.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Juxtaposition of the two patterns (Figure 3, e) fits with the experimental one of Figure 2 (b).

$Sr_9Ni_2Mn_5O_{21}$ ($\alpha = 2$, $\beta = 1$)

Figure 4 (a) corresponds to the SAED pattern of the title sample along the [1$\bar{2}$10] zone axis. Once again, the features of this SAED suggest the presence of twinning in the crystal. Actually, Figure 4 (b) shows a typical [1$\bar{2}$10] reciprocal plane of an untwinned crystal of $(Sr_{0.6}Ca_{0.4})_9Co_7O_{21}$,[3] an ($\alpha = 2$, $\beta = 1$) term of the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ homologous series. Only the *hkl* reflections with $-h + k + l = 3n$ are observed, according to the rhombohedral symmetry of this phase (space group *R*3*c*). Note that the intensity distribution of the (*h*0*i*4*h*)* peaks is modulated in a similar way as in $(Sr_{0.75}Ba_{0.25})_5NiMn_3O_{12}$. Comparison between the SAED patterns shown in Figure 4 (a and b) highlights the presence of reflections forbidden for a rhombohedral symmetry in the pattern corresponding to $Sr_9Ni_2Mn_5O_{21}$. Moreover, the ($\bar{h}$0*i*4*h*) peaks are also present, and so a pseudo-trigonal symmetry results. This can be associated with the presence of twinning in the crystals, as confirmed by HREM. Actually, in the corresponding micrograph along the same zone (Figure 5, a), the presence of several domains tilted by 90° to each other around the *c* axis, is apparent. Each domain shows the structural features corresponding to this member of the series (see the magnification of one domain depicted in Figure 3, b). The simulated image (inset in Figure 3, b) agrees with the experimentally ascertained one for $\Delta t = 8.5$ and $\Delta f = -90$ nm. The optical Fourier transforms at the two sides of the twin plane are depicted in Figure 5 (c and d). In each domain, the modulation appears either along the [*h*0*i*4*h*]* or along the [$\bar{h}$0*i*4*h*] directions. Juxtaposition of the patterns (Figure 5, e) results in the experimental SAED shown in Figure 4 (a).

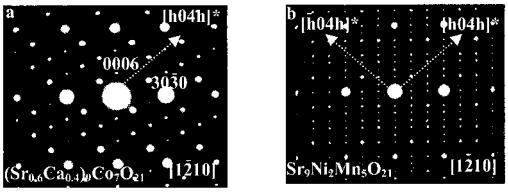

Figure 4. SAED patterns along the [1$\bar{2}$10] zone axis, corresponding to $Sr_9Ni_2Mn_5O_{21}$ (a) and $(Sr_{0.6}Ca_{0.4})_9Co_7O_{21}$ (b)

Structural Refinement

The fitting of experimental XRD patterns of the title compounds has been carried out by using as starting structural models those developed from SAED and HREM data. Thus, $Sr_{3.75}Ba_{1.25}Mn_3NiO_{12}$ consists of parallel chains made up of units of three face-sharing octahedra ($3O_h$) linked by a trigonal prism (TP), the sequence along a chain being: $-TP-3O_h-TP-3O_h-TP-3O_h-$. The structure of $Sr_9Mn_5Ni_2O_{21}$, on the other hand, is slightly more complex: the chains are made up of units of three face-sharing octahedra and units of two octahedra ($2O_h$) linked by trigonal prisms in a sequence: $-TP-3O_h-TP-2O_h-TP-3O_h-TP-2O_h-$.

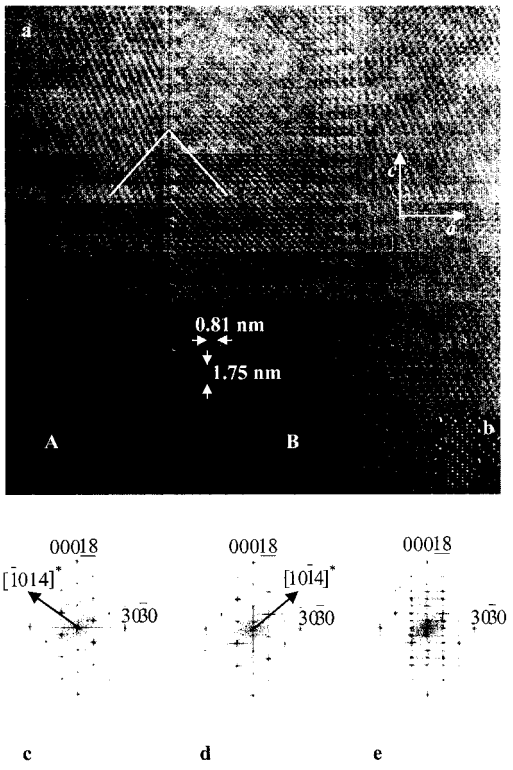

Figure 5. (a) HREM of $Sr_9Ni_2Mn_5O_{21}$ along [1$\bar{2}$10], a multitwinned microstructure can clearly be seen; (b) magnification of one of the microdomains shown in Figure 5 (a), calculated image is shown in the inset, optical Fourier transforms (FTs) corresponding to domains marked with A (c) and B (d) in Figure 5 (a); (e) FT corresponding to the juxtaposition of both A and B domains

On the basis of previous studies on similar systems,[14–17] we assume that the nickel ions are located in the prisms whereas the manganese atoms occupy the octahedra. It should be remarked that it is not possible to ascertain the actual occupation of both types of positions from XRD data. However, it was evident from the structural refinement that the atoms in the prisms are split into two positions. The atoms at the centre of the prisms are partially displaced towards the three square faces of the prisms, whereas the remaining atoms at the centres are displaced to one of the trigonal faces in some cases. This structural feature has very commonly been observed for nickel.[4,16,20]

Figure 1 (a and b) shows the result in graphic form of the fitting of the experimental X-ray diffraction pattern and the difference between observed and calculated data for $Sr_{3.75}Ba_{1.25}NiMn_3O_{12}$ and $Sr_9Ni_2Mn_5O_{21}$, respectively. The final structural parameters are collected in Tables 1 and 2, whereas Tables 3 and 4 show some selected interatomic distances. Figures 6 and 7 depict schematic representations of the structures of $Sr_{3.75}Ba_{1.25}NiMn_3O_{12}$ and $Sr_9Ni_2Mn_5O_{21}$, respectively.

As is well known, X-ray diffraction is not the best technique with which to study structural effects relating to light atoms such as oxygen in a "matrix" of metallic atoms, as is

Table 1. Final structural parameters of $(Sr_{0.75}Ba_{0.25})_5NiMn_3O_{12}$ [space group $P\bar{3}c$ (no. 165), a = 0.97114(2) nm, c = 2.03649(6) nm, V = 1.66334(7) nm^3, R_B = 0.070, R_{exp} = 0.058, R_{wp} = *0.18,* χ^2 = *10.1]*

the case of our materials. However, the refinements were stable and it was possible to refine the positions of the oxygen atoms, provided that the number of refined parameters was kept not too large, which is why we used the same temperature factor for various atoms in some cases. The metal−oxygen distances in Tables 3 and 4 should therefore be regarded with some caution, although the metallic coordination (i.e., the polyhedra defined by the closest oxygen atoms around a given metal atom) is undoubtedly correct, as are the metal−metal distances.

The crystal structure of $(Sr_{0.75}Ba_{0.25})_5NiMn_3O_{12}$ is made up of one-dimensional $[Mn_{3/4}Ni_{1/4}O_3]$ chains. The space between chains is occupied by the Ba/Sr metal atoms, coordinated to oxygen atoms at distances ranging between 2.3 and 2.99 Å. There are two crystallographically different types of chains (see Figure 6), one involving −Mn(2)−Mn(3)−Mn(5)−Ni(2)− cations and the other one composed of an −Mn(4)−Mn(1)−Ni(1)− cationic sequence. The octahedral environments of Mn(1), (2) and (5) are quite regular, with average M−O distances corresponding to 2.05, 2.01 and 2.04 Å, respectively. The octahedra

occupied by Mn(3) are less voluminous, with an average metal−oxygen distance of 1.80 Å. On the other hand, the Mn(4) atoms seem to be slightly displaced from the centres of the polyhedra, giving rise to distorted octahedra with average Mn(4)−O distance of 2.06 Å. A similar displacement of Mn has been reported in $Ba_6Mn_4ZnO_{15}$.[11] All the Mn−O distances in $(Sr_{0.75}Ba_{0.25})_5Mn_3NiO_{12}$ are similar to those previously reported in manganese-containing oxides. A particular feature of this structure is the Ni distribution in the TP sites. As can be seen in Table 1, most of the Ni cations (close to 80%) are displaced from the centres towards the square faces of the prisms. Only a small fraction (10%) of Ni(1), labelled as Ni1Pc in Tables 1 and 3, remains at the centres of the TP sites, with six equal Ni1Pc−O distances of 2.09 Å. The environments of the Ni2Pc atoms are less regular, since two different (but close) values of Ni2Pc−O distances are observed [$d_{average}$(Ni2Pc−O) = 2.11 Å]. These distances are very close to those found for Ni atoms in corresponding oxygen environments in Ca_3MnNiO_9 ($d_{average}$ = 2.145 Å)[14] and $Sr_4Ni_3O_9$ ($d_{average}$ = 2.09, 2.195 Å).[4] The remaining Ni1 and Ni2 (referred to as Ni1Pd and Ni2Pd in Table 1) are in square-planar coordination with average M−O distances of 1.95 and 1.97 Å, respectively; these values are also in agreement with Ni^{II}−O distances measured in comparable oxides with similar displacements of the Ni atoms, as in $Sr_4Ni_3O_9$ ($d_{average}$= 1.95, 2.07 Å) or $Sr_4NiMn_2O_9$ ($d_{average}$ = 2.02, 1.99 Å).[4,16] With regard to the M−M distances, the Mn−Mn ones range from 2.50 to 2.60 Å, characteristic of Mn^{IV}−Mn^{IV} in face-sharing octahedra. A similar value is obtained for the Ni1Pc−Mn distance (2.56 Å), but Ni2Pc is slightly displaced towards one of the triangular faces of the TP, giving rise to two very different distances to the neighbour Mn metal atoms. This feature has also been observed in $Sr_4NiMn_2O_9$.[16]

The structure of $Sr_9Ni_2Mn_5O_{21}$ also contains face-sharing [Mn/Ni]-polyhedra chains linked together by Sr−O bonds. The Sr cations are in nine- or tenfold coordination, at distances ranging from 2.38 to 3.00 Å. $Mn(1)O_6$ and $Mn(3)O_6$ define fairly regular octahedra, whereas Mn(2) is located in a distorted octahedron. All the Mn−O and all the Mn−Mn distances are consistent with previously reported bond lengths in comparable manganese oxides. With respect to the Ni environment, about 80% of the Ni atoms once again adopt square-like coordinations [$d_{average}$(NiPd−O) = 2.04 Å]. The remaining Ni atoms, lo-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cated in trigonal-prismatic coordinations, are each displaced from the centre towards a triangular face of the TP, giving rise to three short (1.96 Å) and three long (2.4 Å) NiPc−O distances. This displacement gives rise to a short Mn(2)−NiPc distance (2.30 Å), close to that found in $Sr_4NiMn_2O_9$ (2.32 Å).[16]

Conclusions

The structural refinement shows that the two new one-dimensional Mn/Ni oxides present the general structural features corresponding to the ($\alpha = 3$, $\beta = 2$) and the ($\alpha = 2$, $\beta = 1$) members of the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ series for the $(Sr_{0.75}Ba_{0.25})_5NiMn_3O_{12}$ and $Sr_9Ni_2Mn_5O_{12}$ compositions, respectively. The particular characteristic of each structure is the displacement of most of the Ni atoms from the centres of the trigonal prisms toward the square faces. On the other hand, both materials present twinned microstructures. The presence of twinning in this type of oxides is usually observed when some cationic disorder exists through the polyhedra chains. In this sense, when metal cations of different chemical natures are randomly distributed in the Oh and the TP sites, twinned one-dimensional oxides result. In the samples studied, $Sr_9Mn_5Ni_2O_{21}$ and $Sr_{3.75}Ba_{1.25}NiO_{12}Mn_3$, there is no disorder relative to the cationic distribution in the two different oxygen environments since Mn is located in the octahedra whereas Ni is occupying the trigonal prisms. However, the particular arrangement of the Ni atoms in the TP sites could induces a certain disorder at the Ni positions, most probably the origin of the multi-twinning in the crystals.

Experimental Section

Polycrystalline $Sr_{3.75}Ba_{1.25}NiMn_3O_{12}$ and $Sr_9Ni_2Mn_5O_{21}$ were synthesised by the ceramic procedure by heating stoichiometric amounts of ACO_3 (A = Sr, Ba) (Aldrich, 99.9+%), $MnCO_3$ (Aldrich, 99.9+%) and NiO (Aldrich, 99.99%) in air. The former was treated at 1200 °C for 3 days and the latter at 1050 °C for 6 days with intermediate grinding. In both cases the products were quenched to room temperature.

The average cationic composition was determined by Inductive Coupled Plasma (ICP) while the local composition in every crystal was established by X-ray Energy Dispersive Spectroscopy (EDS). A JEOL 2000 FX electron microscope equipped with an OXFORD ISIS 300-analyser system was employed for this purpose.

Powder X-ray diffraction (XRD) patterns were collected by use of Cu-K_α radiation at room temperature with a PHILIPS X'PERT diffractometer equipped with a graphite monochromator. The diffraction data were analysed by the Rietveld[21] method, by use of the Fullproff program.[22]

Selected Area Electron Diffraction (SAED) was carried out with a JEOL 2000FX electron microscope fitted with a double-tilting goniometer stage (±45°). High-Resolution Electron Microscopy (HREM) was performed with a JEOL 4000EX electron microscope fitted with a double-tilting goniometer stage (±25°). Simulated HREM images were calculated by the multislice method with the aid of the MacTempas software package.

Syntheses and Coordination Chemistry of Aminomethylphosphine Derivatives of Adenine

Qingzhi Zhang,[a] Guoxiong Hua,[a] Pravat Bhattacharyya,[a] Alexandra M. Z. Slawin,[a] and J. Derek Woollins*[a]

Keywords: Adenine / P ligands / Chelate complexes / Heterometallic complexes

Two aminomethylphosphane derivatives of adenine 9-(2-{bis[(diphenylphosphanyl)methyl]amino}ethyl)adenine (**La**) and 9-(3-{bis[(diphenylphosphanyl)methyl]amino}propyl)-adenine (**Lb**) were synthesised. Oxidation of **La** and **Lb** with H_2O_2, elemental sulfur or elemental selenium led to the corresponding oxidized products **4a/b**–**6a/b**. Both **La** and **Lb** behave as didentate ligands towards late transition metals. Reaction of **La** or **Lb** with [MX_2(cod)] (M = Pd, Pt; X = Cl, Me) gave chelate complexes **7a/b**–**10a/b**. Reaction of **La** or **Lb** with [AuCl(tht)] or [{RuCl(μ-Cl)(*p*-MeC_6H_4*i*Pr)}$_2$] gave the didentate bridging complexes **11a/b** and **12a**. All compounds have been fully characterised by microanalysis, IR, ^{1}H and ^{31}P{^{1}H} NMR spectroscopy, and EI/CI/FAB mass spectrometry. ^{1}H{^{31}P} NMR and ^{1}H-^{13}C correlation experiments were used to confirm the spectral assignments where necessary. Two compounds were structurally characterised by X-ray crystallographic analysis.

Introduction

Owing to their resemblance to the structure of adenosine and their broad-spectrum of antiviral or anticancer activity, adenine derivatives substituted at the 9-position constitute an important class of pharmacologically active compounds.[1] Among them 9-[2-(phosphonomethoxy)ethyl]adenine and its analogues have been extensively studied.[2,3] In bioinorganic chemistry, metal complexes capable of forming complementary hydrogen bonds occupy an increasingly important position in the development of biochemically active molecules. Houlton et al.[4] have prepared some interesting bifunctional complexes that combine the covalent bond-forming capabilities of the metal ion and a ligand surface capable of recognizing nucleotide bases by means of hydrogen bonding. The same group developed the concept of *directed metallation* and reported a series of nucleoside analogues in which the ribose group is replaced by a dimethylene/trimethylene tethered ethylenediamine [5−8] or 1,2-dithioethane.[9] Interaction of such chelate-tethered nucleoside analogues with metal ions gave interesting A−N^3-bound or A−C^8-bound mono- or polynuclear complexes. In an approach which combines the antitumour activities of diphosphanes and their gold complexes[10,11] and our experience in the synthesis coordination chemistry of P−C−N compounds,[12] we have incorporated the aminomethylphosphane unit into adenine through an aminodi/trimethylene linkage at the 9-position. The adenine analogues prepared in this way possess two functions: an excellent coordination tendency toward transition metals and the capacity for base-pair or complementary hydrogen-bonding interactions. Some enhanced biological activities are expected from the new combination of the bioactive adenine and aminophosphane as well as the corresponding complexes.

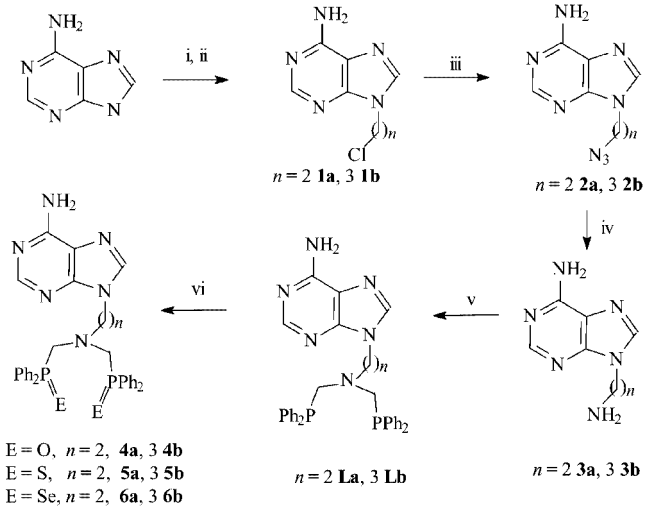
Results and Discussion

Preparation and Oxidation of La and Lb

Scheme 1 shows the synthesis of **La** and **Lb** and the corresponding oxidized compounds. Precursor **1a** was prepared using 1-bromo-2-chloroethane and the sodium salt of adenine, formed from adenine and sodium hydride in anhydrous DMF by a literature method,[13,14] while **1b** was prepared following a modified literature method using adenine and 1-bromo-3-chloropropane in the presence of anhydrous K_2CO_3 in anhydrous DMF, which proved to be milder than NaH and gave a higher yield of the target product.[15−17] Compounds **2**[18] and **3**[19] were also prepared according to the literature method, with slight modification.

Due to the low solubility of **3a** and **3b** in common organic solvents at room temperature, the condensation reactions with Ph_2PCH_2OH were carried out in refluxing acetonitrile. Monitoring by ^{31}P{^{1}H} NMR spectroscopy indicated that the reaction of **3a** or **3b** with a slight excess of Ph_2PCH_2OH (**3**: $Ph_2PCH_2OH \approx$ 1:2 molar ratio) gave **La**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim **DOI: 10.1002/ejic.200300037**



Scheme 1. Preparation and oxidation of **La** and **Lb**; i) NaH (60% in mineral oil) or K_2CO_3, anhydrous DMF, room temp.; ii) $ClCH_2CH_2Br$ or $ClCH_2CH_2CH_2Br$, room temp., 48 h; iii) NaN_3, DMF, 80 °C, 24 h; iv) H_2, 1 atm, Pd/C (10%), MeOH; v) Ph_2PCH_2OH, CH_3CN, reflux, overnight; vi) H_2O_2 (30%), 0 °C, THF, room temp., 2 h; or S_8/Se, THF, reflux, overnight

and **Lb** overnight. Workup by simple concentration and washing with Et_2O removes the excess Ph_2PCH_2OH, and recrystallisation from CH_3CN gave the air- and moisture-stable white solids **L** in good yields. The successful selectivity of N−C bond formation at the dangling alkylamino group rather than the aryl C^6-NH_2 at the purine ring can be attributed to the difference in basicities of the two primary amino groups. The alkylamino group at the 9-position is much more electron-rich than the amino group at the 6-position, whose lone pair is highly delocalised in the electron-withdrawing purine ring. Attempts to get 9-{2-[(diphenylphosphanyl)methylamino]ethyl}adenine and 9-{3-[(diphenylphosphanyl)methylamino]propyl}adenine by using a 1:1 molar ratio of reagents failed; double condensation always occurred under these conditions.

Oxidation of **La** and **Lb** with excess elemental sulfur or selenium in THF gave the corresponding sulfides and selenides. As shown by $^{31}P\{^1H\}$ NMR spectroscopy, however, there is always a trace of unidentified impurities ($\delta_P \approx 40.6$, 37.7 and 36.5 ppm for sulfides; $\delta_P \approx 27.0$ ppm for selenides) in the reaction mixture, implying that the P−C−N bond is not very robust under oxidation conditions. Attempts to get rid of the impurities were not successful by either chromatography or recrystallisation. Oxidation of **La** and **Lb** with aqueous H_2O_2 (30%) needs to be performed with caution. The oxidizing agent can only be used stoichiometrically or slightly in excess, otherwise oxidation at the N1 position of the purine ring occurs as described previously[20,21] and as observed in the mass spectrum. Even so, using our method there are still some unidentified impurities ($\delta_P \approx 30.9$, 27.0 and 26.0 ppm) in the reaction mixture that are very difficult to remove. Oxidation of **La** and **Lb** by air proved too slow to be useful as a preparative technique. Stirring a solution of **La** or **Lb** in THF in air at room temperature for four days only gives about 20% oxidation of the starting material.

Characterization of La, Lb and 1a/b−6a/b

La, **Lb** and compounds **1b, 2b, 3b, 4a/b−6a/b** were fully characterised by multinuclear NMR spectroscopy, EI/CI/FAB mass spectrometry, infrared spectrometry and microanalysis. All the compounds gave reasonable microanalysis results apart from **4a** and **4b**, which showed slightly lower carbon percentages than the calculated value due to the impurities described above. Their mass spectra show the molecular ions and the expected fragmentation pattern with appropriate isotope distributions. The sulfur and selenium species **5a/b−6a/b** show the $[M - S]^+$ and $[M - Se]^+$ fragment ions in their EIMS spectra. The corresponding $[M - O]^+$ ion was not observed for **4a/b**. In the IR spectra, all compounds display two broad medium intensity ν_{N-H} bands between 3349 and 3106 cm^{-1}. The strong N−H bending absorption of the NH_2 group and the stretching absorption of the C=N bond of the purine ring were observed at around 1655 cm^{-1} and 1598 cm^{-1}, respectively. Compounds **2a/b** show an $\nu_{N\equiv N}$ band at 2100 cm^{-1}. Compounds **4a** and **4b** display the $\nu_{P=O}$ absorption at ca. 1178 and 1176 cm^{-1}; the $\nu_{P=S}$ and $\nu_{P=Se}$ bands could not be assigned unambiguously for **5a/b** and **6a/b**.

The $^{31}P\{^1H\}$ NMR signals (Table 1 and 2) of **La/b** at around $\delta_P = -27$ ppm are similar to other bis[(diphenylphosphanyl)methyl]amine compounds.[22] The dichalcogenides **4a/b-6a/b** show signals shifted to higher frequency at ca. $\delta_P = 29$, 35 and 25 ppm compared with that of **La/b**. Interestingly, the $^{31}P\{^1H\}$ NMR spectra of the selenium species **6a/b** not only show a central singlet of 92% intensity with selenium satellites ($^1J_{P,Se} = 730$ Hz)[23] but also a small P−P coupling ($^4J_{P,P} = 9$ Hz) in the satellites. The latter is due to the inequivalence of the two phosphorus atoms arising from the $Ph_2P(Se)CH_2NCH_2P(^{77}Se)Ph_2$ isotopomer. Similar P−P couplings in the selenium satellites were also observed in $Ph_2P(Se)NHP(Se)Ph_2$ ($^2J_{P,P} = 29$ Hz)[24] and $Ph_2P(Se)OP(Se)Ph_2$ ($^2J_{P,P} = 44$ Hz).[25]

The ^1H NMR spectra of **1b**[14,26] and **3b**[27] in $[D_6]$DMSO or $[D_6]$DMSO + D_2O have been reported previously. In order to compare the NMR spectra of the precursors and the aminomethylphosphanes **La** and **Lb**, the same solvent should be employed. However, catalytic oxidation (with either catalyst or irradiation) of P^{III} compounds by DMSO has been reported[21,28−30] and we have also observed the gradual oxidation of some aminophosphane compounds in $[D_6]$DMSO during spectral acquisition, therefore the employment of $[D_6]$DMSO for **La** and **Lb** was precluded. For comparative purposes, in addition to the spectra in $[D_6]$DMSO, the ^1H NMR spectroscopic data of **1−3** in $CDCl_3$ containing a few drops of $[D_6]$DMSO were acquired. The data of **1a**, **2a** and **3a** will be reported elsewhere, and those of **1b**, **2b**, **3b** are listed in Table 3. In the ^1H NMR spectra the chemical shifts of the C^6-NH_2 group and one of the CH groups of the purine ring (C^2-H or C^8-H) vary with solvent ($[D_6]$DMSO, $CDCl_3$ or $CDCl_3$/$[D_6]$DMSO). On the other hand, in the $^{13}C\{^1H\}$ NMR

spectra, the resonance frequencies of the carbons (C^2, C^4, C^5, C^6 and C^8) of the purine ring of compounds **1−3** show little variation in different solvents. To assign the C^2−H and C^8−H protons unambiguously, ^1H-^{13}C heteronuclear correlation spectra (HMQC) were measured. It turned out that the C^8−H appears at lower frequency at around δ_H = 7.8 ppm in $CDCl_3$ or $CDCl_3$/[D_6]DMSO, while in [D_6]DMSO, it is close to the C^2−H resonance at around δ_H = 8.2 ppm. The C^6−NH_2 resonance in $CDCl_3$ or $CDCl_3$ + [D_6]DMSO is observed at around δ_H = 5.6 ppm, while in [D_6]DMSO it appears at around δ_H = 7.2 ppm.

Based on the above observation, we assign the higher frequency singlet at δ_H = 8.32−8.24 ppm to C^2−H and the lower one at δ_H = 7.10−7.88 ppm to C^8 in the ^1H NMR spectra of **La/b** and **4a/b−6a/b**. The ^1H-^{13}C heteronuclear correlation experiment confirmed the assignments. Like their precursors **1−3**, the broad singlet of C^6−NH_2 of **La**, **Lb** and **4−6** appears at around δ_H = 6 ppm. Among them, the resonance of C^6−NH_2 of the oxygen species **4a/b** appears at relatively higher frequency. The proton signals of the dangling chain of **La** and **4a/6a** are as easy to assign as their precursors **1a−3a**, which will be reported elsewhere, with the triplet of AdeC$H_2$$CH_2$ at higher frequency between δ_H = 4.48 and 4.05 ppm and the triplet of CH_2N(CH_2PPh_2) at lower frequency between δ_H = 3.61 and 3.42 ppm. For **Lb** and **4b/6b**, the triplet of AdeC$H_2$$CH_2$ between δ_H = 3.95 and 3.76 ppm and that of CH_2N(CH_2PPh_2) between δ_H = 3.09 and 2.79 ppm are at slightly lower frequency than in **La** and **4a/6a**, but still follow the tendency AdeC$H_2$$CH_2$ > CH_2N(CH_2PPh_2). The triplet of CH_2N(CH_2PPh_2) seems always less-well resolved and slightly broader than that of AdeC$H_2$$CH_2$, which may be attributed to the long-distance coupling of these methylene protons with phosphorus atoms. The AdeCH_2C$H_2$$CH_2$ signal in **Lb** and **4b−6b** appears as a well-resolved quintet at an even lower frequency, between δ_H = 1.87 and 1.69 ppm. The signal of C$H_2$$PPh_2$ of the above compounds appears between δ_H = 4.47 and 3.60 ppm as a doublet or

broad singlet arising from the two-bond or four-bond couplings of CH and phosphorus. This resonance can appear at a higher or lower frequency than, and sometimes even overlapped with, that of Ade$CH_2$$CH_2$.

In the $^{13}C\{^1H\}$ NMR spectra, **La/Lb** and their oxidized compounds show very similar purine ring carbon signals (Table 1 and 2) to their precursors and other reported adenine analogues.[31] However, as revealed by a ^1H-^{13}C heteronuclear correlation experiment, the ^{13}C signal of $CH_2NCH_2PPh_2$ is shifted to higher frequency between $\delta_C = 57.92$ and 53.13 ppm and appears as a triplet or broad singlet due to coupling with the phosphorus atoms, while the signal of AdeCH_2CH_2 remains as a singlet between $\delta_C = 42.58$ and 41.69 ppm. The CH_2PPh_2 signal, which appears as a doublet of doublets, doublet or broad singlet due to the $^1J_{P,C}$ and/or $^3J_{P,C}$ couplings, appears at the highest frequency in the alkyl region. **La** and **Lb** exhibit neat signals in the aromatic carbon region and the coupling constants $^nJ_{P,C}$ (n = 1, 2, 3) are available in Table 1 and 2. The coupling constants $^nJ_{P,C}$ (n = 1, 2, 3) in **4a/b-6a/b**, however, are very difficult to observe due to the trace impurities that cause small overlapping signals in the aromatic carbon resonance region in **4a/b-6a/b**.

Compound **2b** was also characterised by X-ray crystallography (Figure 1 and Table 4). Two typical types of hydrogen bonding for the purine system are observed between adjacent molecules (Figure 1, bottom), they are the Watson−Crick type between N(6)−H of one molecule and N(1) of a second molecule, [N(6)−H(6A)···N(1A), d(D···A) 3.056(4) Å, d(H···A) 2.10 Å, ∠(DHA) 164(2)°], and the

Coordination Chemistry of La/b with Late Transition Metals

As shown in Scheme 2, **La/b** are excellent didentate ligands towards late transition metals. Reaction of **La/b** with [MX$_2$(cod)] gave a series of didentate complexes **7a/b**−**10a/b**. Interaction of **La/b** with two molar equivalents of [AuCl(tht)] gave the didentate bridging bimetallic complexes **11a/b**. The reaction of **La** and [{RuCl$_2$(η^6-*p*-MeC$_6$H$_4$*i*Pr)}$_2$] also gave the bimetallic compound **12a**. All the complexes gave reasonable microanalyses. Their FAB-MS or ES-MS spectra show the expected molecular ion and fragmentation ions, with appropriate isotope distribution. In the IR spectra the anticipated medium intensity ν_{N-H} stretching band at around 3395−3314 cm^{-1} and 3186−3144 cm^{-1}, and the very strong ν_{N-H} bending and $\nu_{C=N}$ stretching at around 1637 cm^{-1} and 1596 cm^{-1}, respectively, were observed as in the free ligands and oxidized compounds. In the complexes, medium intensity ν_{M-Cl} vibrations were also observed at 329−246 cm^{-1}; the two bands in this region for complexes **7a/b**, **8a/b** are in agreement with the *cis*-geometry of the chelate complexes.

The ^{31}P{^{1}H} NMR spectra of **7a/b**−**10a/b** (Table 5) show high-frequency shifts relative to the free ligands. The platinum species gave more information because of the platinum satellites. In complexes **8a/b** and **9a/b** the large $^1J_{Pt,P}$ coupling (3416 Hz) and the relatively small $^1J_{Pt,P}$ coupling (ca. 1782 Hz) are typical of a phosphorus *trans* to a chloride and a methyl group, respectively, and are thus in agreement with the *cis*-geometry. Complex **10a/b** displays two doublets ($^2J_{P,P} \approx 22$ Hz) corresponding to the two inequivalent phosphorus atoms. The doublet at ca. δ_P = 4.0 ppm with a large $^1J_{Pt,P}$ coupling of ca. 4200 Hz was assigned to the phosphorus *trans* to chloride and the signal with a small $^1J_{Pt,P}$ of about 1640 Hz at ca. δ_P = 0.8 ppm to the phosphorus atoms *trans* to the methyl group.

The ^{1}H NMR spectra of the complexes in CD_2Cl_2 or $CDCl_3$ (Table 5) are generally similar to that of the free ligand **La/b**, the chemical shifts of C^2−H ($\delta_H \approx 8.2$ ppm) > C^8−H ($\delta_H \approx 7.0$ ppm) and that of AdeCH_2 ($\delta_H \approx 3.7$ ppm) > CH_2NCH$_2$P ($\delta_H \approx 3.0$ ppm). Like **La/b**, the chelate complexes show a doublets of doublet, a doublet or a broad singlet for CH_2P, arising from $^2J_{P,CH}$ and/or $^4J_{P,CH}$ coupling, between the signals of AdeCH_2 and CH_2NCH$_2$P, except complex **9b**, while the CH_2P signal in the bridging complexes **11a/b** and **12a** appears at higher frequency than that of AdeCH_2. The platinum complexes display satellites for both CH_2P and the coordinated CH_3 groups. The coupling constants $^3J_{PtCH} \approx 38$ Hz for the dichloride compounds **8a/b**, $^3J_{PtCH} \approx 15$ Hz for **9a/b**, and $^3J_{PtCH}$ = 45 and 15 Hz for **10a/b** were obtained unambiguously from the ^{1}H{^{31}P} NMR spectra. The doublet of doublets for CH_3 at δ_H = 0.33 and 0.49 ppm with satellites ($^2J_{Pt,CH}$ = 54 Hz) in **10a/b** can be easily interpreted as being due to the coupling of this group with the two inequivalent phosphorus atoms.

However, the two peaks at δ_H = 0.39 ppm with satellites ($^2J_{Pt,CH} \approx 68$ Hz) in **9a/b** are somewhat confusing. The $^1H\{^{31}P\}$ NMR spectra reveal that the signals are not from the inequivalent CH_3 groups but are a doublet ($^3J_{P,CH} \approx 2$ Hz) due to the coupling of the equivalent methyl groups with either a *trans* or a *cis* phosphorus atom; it is not clear why only one coupling is observed.

Slow diffusion of petroleum ether (b.p. 60−80 °C) into a solution of **10b** in CH_2Cl_2 gave colourless crystals suitable for X-ray analysis (Figure 2 and Table 6). Figure 2 (top) reveals a platinum coordinated in a square plane with a maximum deviation of 0.04 Å for the P(14)−P(15)−C(40A)−Cl(1A)−Pt(1) mean plane. The six-membered chelate ring is chair-like, with the N(13)−C(14)−C(15) plane heavily folded above (72°) and the P(14)−Pt(1)−P(15) plane slightly below (15°) the mean plane P(14)−P(15)−C(14)−C15) (mean deviation 0.03 Å). As shown in Figure 2 (bottom), both the Watson−Crick [N(6)−H(6A)···N(1A); d(D···A) 3.069(10) Å, d(H···A)

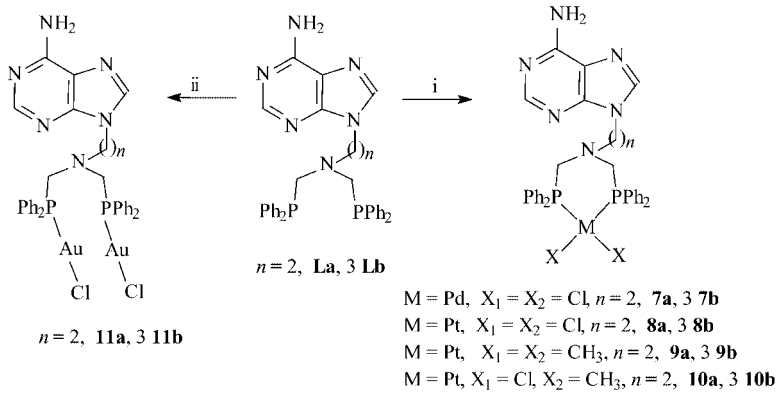

Scheme 2. Coordination of **La** and **Lb** to transition metals; i) $[MX_2(cod)]$ (M = Pd, Pt; X = Cl, CH_3), CH_2Cl_2, 2 h; ii) 2[AuCl(tht)], CH_2Cl_2, 2 h

2.12 Å, ∠(DHA) 164 (4)°] and Hoogsteen [N(6)−H(6B)···N(7B); d(D···A) 3.04(10) Å, d(H···A) 2.14 Å, νDHA 152(6)°] types of intermolecular hydrogen bonding between adjacent molecules are found in the crystal. A quarter molecule of solvate hexane was also observed. For clarity, the solvate molecule is omitted from the figure.

Conclusion

We report here two [(diphenylphosphanyl)methyl]amino analogues of adenosine **La/b** and their chalcogenide derivatives. **La** and **Lb** proved to be good didentate ligands towards late transition metals to give a series of didentate chelate complexes and didentate bridging complexes. All the compounds retain a free adenine moiety for complementary hydrogen bonding. Further studies on the interaction of these compounds with DNA and bioactivities are underway.

Experimental Section

General: All solvents and reagents were purchased from either Aldrich or Lancaster. Dichloromethane was heated to reflux over powdered calcium hydride and distilled under nitrogen. Diethyl ether and tetrahydrofuran were purified by reflux over sodium/benzophenone and distillation under nitrogen. Ligand preparations were performed under an oxygen-free nitrogen atmosphere using standard Schlenk techniques. Coordination reactions and workup were performed in dry solvents. Ph_2PCH_2OH,[32] $[MX_2(cod)]$ (M = Pd, Pt; X = Cl; cod = cycloocta-1,5-diene)[33] and [AuCl(tht)] (tht = tetrahydrothiophene)[34] were prepared following literature procedures.

Infrared spectra were recorded as KBr discs on a Perkin−Elmer system 2000 spectrometer. ^1H NMR spectra (300 MHz) were recorded on a Varian Gemini 2000 spectrometer, $^{31}P\{^1H\}$ NMR spectra at 121.4 MHz (referenced to external 85% H_3PO_4) and $^{13}C\{^1H\}$ NMR spectra at 67.9 MHz on a JEOL GSX 270 spectrometer, and $^1H\{^{31}P\}$ NMR and 2D NMR (^1H-^{13}C heteronuclear correlation experiment) on a Bruker Advance 300. Microanalyses were performed by the University Service within this Department and fast atom bombardment (FAB) or chemical ionization (CI) mass spectra by the EPSRC Mass Spectrometer Service (Swansea, UK). Precious metal salts were provided on loan by Johnson Matthey Plc.

9-(3-Chloropropyl)adenine (1b):[15−17] 1-Bromo-3-chloropropane was added to adenine (27 g, 199.8 mmol) and anhydrous K_2CO_3 in anhydrous DMF (300 mL). The mixture was stirred under an atmosphere of nitrogen for 4 days. The resultant suspension was filtered and the residue was washed with CH_2Cl_2 (3 × 30 cm^3). The combined filtrates were evaporated to dryness by rotary evaporation. The crude product was washed by water (600 cm^3) with sonication in an ultrasonic bath. Recrystallisation from ethanol (220 cm^3) gave 28.0 g of the white product. The mother liquor was concentrated and recrystallised three times to give three additional crops (5.92 g). Total yield: 33.92 g, 80.2%. $C_8H_{10}ClN_5$ (211.7): calcd. C 45.40, H 4.76, N 33.09; found C 45.79, H 4.54, N 33.34. IR (KBr disc): $\tilde{\nu}$ = 3289m cm^{-1}, 3114m, 1667vs, 1603vs. CIMS: *m/z* = 212 $[M + H]^+$, 176 $[M - Cl]^+$. EIMS: *m/z* = 211 $[M]^+$, 176 $[M - Cl]^+$, 148 $[M - CH_2CH_2Cl]^+$.

9-(3-Azidopropyl)adenine (2b):[18] Compound **1b** (20 g, 94.5 mmol) and sodium azide (18.4 g, 283 mmol) were mixed in DMF (150 cm^3). The mixture was stirred at 80 °C for 24 h, cooled to room temperature and then filtered. The solid was washed with CH_2Cl_2 (3 × 30 cm^3). The combined filtrates were vacuumed to almost dryness under rotary evaporation. The residue was taken up in H_2O (200 cm^3) with sonication. The crude product was filtered off and washed with water (3 × 30 cm^3). The combined aqueous layer was extracted with CH_2Cl_2 (3 × 600 cm^3). Removal of the solvent from the extracts led to another crop of crude product. The two crops of crude product were recrystallised from EtOH (300 cm^3) to gave 12.17 g of white solid. Further recrystallisation of the mother liquor gave another 3.90 g of product. Total yield: 16.07 g, 77.7%. $C_8H_{10}N_8$ (218.9): calcd. C 44.03, H 4.62, N 51.35; found C 44.13, H 4.44, N 52.06. IR (KBr disc): $\tilde{\nu}$ = 3302m cm^{-1}, 3140s, 2108vs, 1664vs, 1600vs. CIMS: *m/z* = 220 $[M + H]^+$, 219 $[M]^+$, 191 $[M - N_2]^+$, 163 $[M - CH_2N_3]^+$, 136 $[M - CH_2CH_2CH_2N_3]^+$.

9-(3-Aminopropyl)adenine (3b):[19] 9-(3-Azidoproyl)adenine (10 g, 5.76 mmol) was dissolved in methanol (700 cm^3). To this solution was added palladium on carbon (10%, 5.0 g) and hydrogen gas was bubbled in. Monitoring by TLC (SiO_2, CH_2Cl_2/ MeOH = 80:20) showed that the reaction was complete after about 22 h. The catalyst was removed by filtration through celite. Solvent removal from the filtrate by rotary evaporation gave the product as a white solid. Yield: 7.60 g, 83%. $C_8H_{12}N_6$ (192.2): calcd. C 49.99, H 6.29,

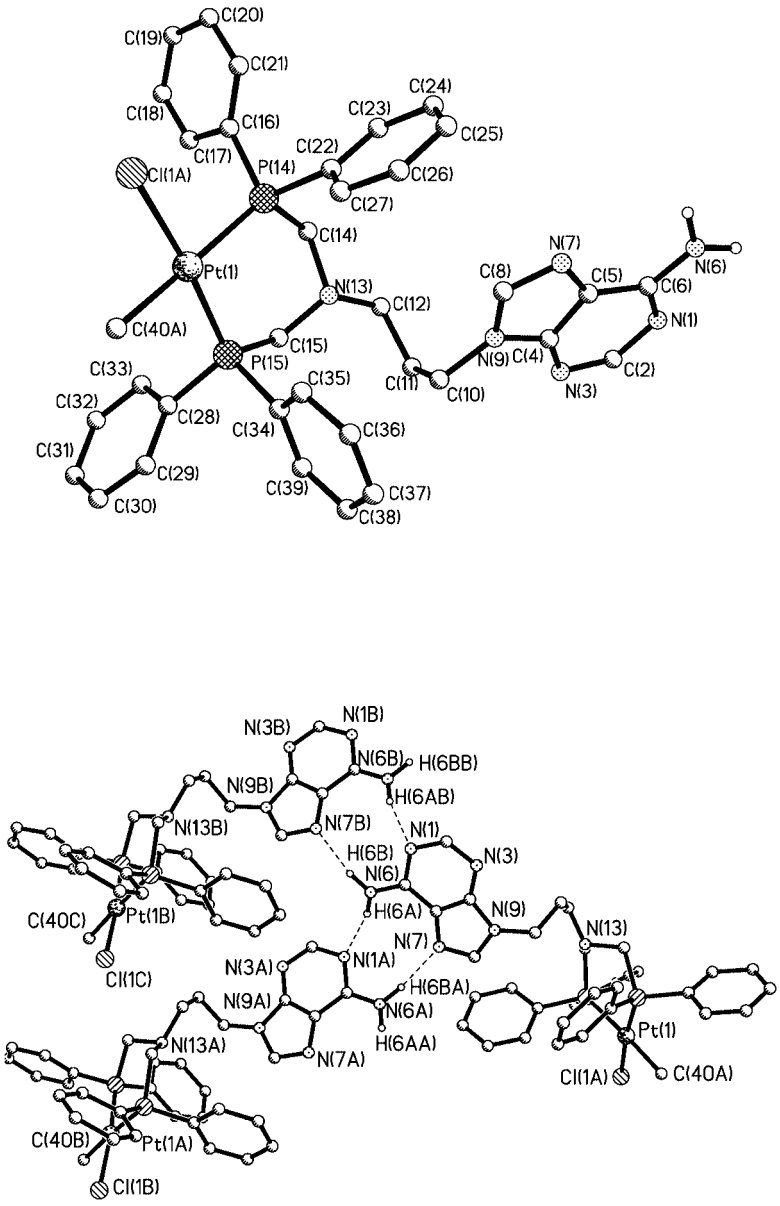

Figure 2. (top) Molecular structure of complex **10b**; (bottom) crystal structure of complex **10b** showing part of the hydrogen bonding

N 43.72; found C 49.37, H 6.28, N 42.73. IR (KBr disc): $\tilde{\nu}$ = 3349 m cm^{-1}, 3282s, 3112s, 1684vs, 1607vs. EIMS: *m*/*z* = 192 $[M]^+$.

9-(2-{Bis[(diphenylphosphanoyl)methyl]amino}ethyl)adenine (La): To a solution of 9-(2-aminoethyl)adenine (1.150 g, 6.45 mmol) in acetonitrile (150 cm^3) was added Ph_2PCH_2OH (2.79 g, 12.90 mmol). The mixture was refluxed overnight and then concentrated in vacuo until the solution became opaque (ca. 20 cm^3). Cooling in a fridge overnight led to the precipitation of the product. Subsequent filtration, and washing of the precipitate with cold acetonitrile (3 × 5 cm^3) and cold Et_2O (3 × 30 cm^3) gave the product as a white solid. Yield: 2.14 g, 57.9%. $C_{33}H_{32}N_6P_2$ (574.6): calcd. C 68.98, H 5.61, N 14.63; found C 67.54, H 5.47, N 13.90. IR (KBr disc): $\tilde{\nu}$ = 3315m cm^{-1}, 3136m, 1648vs, 1598vs, 742s, 696vs. ESMS$^+$: *m*/*z* = 613 $[M + K]^+$, 597 $[M + Na]^+$, 575 $[M + H]^+$.

9-(2-{Bis[(diphenylphosphanyl)methyl]amino}ethyl)adenine (4a): Aqueous hydrogen peroxide (92 μL, 811 μmol, 30%) was added to a solution of **La** (231 mg, 402 μmol) in THF (40 cm^3). The reaction mixture was stirred at 0−5 °C for 2 h, dried over molecular sieves and then passed through a short celite pad. The filtrate was concentrated to ca. 1 cm^3 by rotary evaporation. Et_2O (20 cm^3) was then added to precipitate the product, and filtration, washing with Et_2O (3 × 1 cm^3) and drying in vacuo gave a white solid. Yield: 222 mg, 92%. $C_{33}H_{32}N_6O_2P_2$ (606.6): calcd. C 65.34, H 5.32, N 13.85; found C 62.49, H 5.90, N 12.02. IR (KBr disc): $\tilde{\nu}$ = 3326m cm^{-1}, 3179m, 1648vs, 1599s, 1178vs, 718vs, 696vs. FABMS$^+$: *m*/*z* = 629 $[M + Na]^+$, 607 $[M + H]^+$.

9-(2-{Bis[(diphenylthiophosphanoyl)methyl]amino}ethyl)adenine (5a): Elemental sulfur (35 mg, 1.06 mmol) was added to a solution of **La** (300 mg, 522 μmol) in THF (20 cm^3). The reaction mixture was refluxed for 2 h and then concentrated to ca. 1 cm^3 by rotary evaporation. Et_2O (20 cm^3) was added to precipitate the product, and filtration, washing with Et_2O (3 × 1 cm^3) and drying in vacuo gave a white solid. Yield: 300 mg, 88%. $C_{33}H_{32}N_6P_2S_2$ (638.7): calcd. C 62.05, H 5.05, N 13.16; found C 59.76, H 5.09, N 14.41.

IR (KBr disc): $\tilde{\nu}$ = 3320m cm^{-1}, 3170w, 1638vs, 1597s, 705s, 692s. FABMS$^+$: *m*/*z* = 661 [M + Na]$^+$, 639 [M + H]$^+$.

9-(2-{Bis[(diphenylselenophosphanoyl)methyl]amino}ethyl)adenine (6a): Elemental selenium (55 mg, 696 μmol) was added to a solution of **La** (200 mg, 340 μmol) in THF (20 cm^3). The reaction mixture was refluxed for 2 h. After cooling, the mixture was passed through celite. The filtrate was concentrated to ca. 1 cm^3 by rotary evaporation. Et_2O (20 cm^3) was added to precipitate the product, and filtration, washing with Et_2O (3 × 1 cm^3) and drying in vacuo gave a white solid. Yield: 190 mg, 74.5%. $C_{33}H_{32}N_6P_2Se_2$ (732.5): calcd. C 54.11, H 4.40, N 11.47; found C 53.87, H 3.82, N 12.50. IR (KBr disc): $\tilde{\nu}$ = 3333m cm^{-1}, 3188m, 1654vs, 1595vs, 746m, 690s. FABMS$^+$: *m*/*z* = 757 [M + Na]$^+$, 735 [M + H]$^+$.

9-(3-{Bis[(diphenylphosphanoyl)methyl]amino}propyl)adenine (Lb): Ph_2PCH_2OH (3.566 g, 16.5 mmol) was added to a solution of 9-(2-aminoethyl)adenine (1.46 g, 7.60 mmol) in acetonitrile (300 cm^3). The mixture was refluxed overnight and then concentrated in vacuo to ca. 20 cm^3 until a white solid precipitated. The solvent was then pipetted off. The solid was washed with CH_3CN (2 × 20 cm^3) and Et_2O (2 × 50 cm^3). Drying in vacuo gave the product as a white solid. Yield: 3.25 g, 55%. $C_{34}H_{34}N_6P_2$ (588.6): calcd. C 69.38, H 5.82, N 14.28; found C 67.96, H 5.83, N 15.01. IR (KBr disc): $\tilde{\nu}$ = 3297m cm^{-1}, 3134m, 1667vs, 1599vs, 743s, 697vs. ESMS$^+$: *m*/*z* = 611 [M + Na]$^+$, 589 [M + H]$^+$.

9-(3-{Bis[(diphenylphosphanoyl)methyl]amino}propyl)adenine (4b): Aqueous hydrogen peroxide (77 μL, 679 μmol, 30%) was added to a solution of **Lb** (200 mg, 340 μmol) in THF (40 cm^3). The reaction mixture was stirred at 0−5 °C for 2 h, dried over molecular sieves and then passed through a short celite pad. The filtrate was concentrated to ca. 1 cm^3 by rotary evaporation. Et_2O (20 cm^3) was added to precipitate the product, and filtration, washing with Et_2O (3 × 1 cm^3) and drying in vacuo gave a white solid. Yield: 182 mg, 86%. $C_{34}H_{34}N_6O_2P_2$ (620.6): calcd. C 65.80, H 5.52, N 13.54; found C 62.87, H 5.94, N 11.42. IR (KBr disc): $\tilde{\nu}$ = 3324m cm^{-1}, 3180m, 1648vs, 1599vs, 1573m, 1176s, 718s, 695s. FABMS$^+$: *m*/*z* = 643 [M + Na]$^+$, 621 [M + H]$^+$.

9-(3-{Bis[(diphenylthiophosphanoyl)methyl]amino}propyl)adenine (5b): Elemental sulfur (22 mg, 688 μmol) was added to a solution of **Lb** (200 mg, 340 μmol) in THF (20 cm^3). The reaction mixture was refluxed for 2 h and concentrated to ca. 1 cm^3 by rotary evaporation. Et_2O (20 cm^3) was added to precipitate the product, and filtration, washing with Et_2O (3 × 1 cm^3) and drying in vacuo gave a white solid. Yield: 191 mg, 86%. $C_{34}H_{34}N_6P_2S_2$ (652.8): calcd. C 62.56, H 5.25, N 12.87; found C 60.77, H 4.71, N 13.70. IR (KBr disc): $\tilde{\nu}$ = 3315m cm^{-1}, 3173w, 1638vs, 1597vs, 705, 692s. FABMS$^+$: *m*/*z* = 675 [M + Na]$^+$, 653 [M + H]$^+$.

9-(3-{Bis[(diphenylselenophosphanoyl)methyl]amino}propyl)adenine (6b): Elemental selenium (54 mg, 684 μmol) was added to a solution of ligand **2** (200 mg, 340 μmol) in THF (20 cm^3). The reaction mixture was refluxed for 2 h and passed through a short celite pad. The filtrate was concentrated to ca. 1 cm^3 by rotary evaporation. Et_2O (20 cm^3) was added to precipitate the product, and filtration, washing with Et_2O (3 × 1 cm^3) and drying in vacuo gave a white solid. Yield: 176 mg, 69%. $C_{34}H_{34}N_6P_2Se_2$ (746.6): calcd. C 54.70, H 4.59, N 11.26; found C 54.31, H 4.46, N 11.67. IR (KBr disc): $\tilde{\nu}$ = 3312m cm^{-1}, 3162m, 1638vs, 1597s, 746m, 691vs. FABMS$^+$: *m*/*z* = 769 [M + Na]$^+$, 747 [M + H]$^+$.

[PdCl$_2$(La)] (7a): [PdCl$_2$(cod)] (48 mg, 169 μmol) was added to a solution of **La** (100 mg, 169 μmol) in CH_2Cl_2. The reaction mixture was stirred at room temperature for 2 h and then concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with light petroleum ether (3 × 1 cm^3) and Et_2O (3 × 1 cm^3) gave the product as a yellow solid. Yield: 102 mg, 80%. $C_{33}H_{32}Cl_2N_6P_2Pd$ (751.9): calcd. C 52.78, H 4.29, N 11.19; found C 54.71, H 5.00, N 9.81. IR (KBr disc): $\tilde{\nu}$ = 3387m cm^{-1}, 3203w, 1637vs, 1594s, 740s, 691s. ESMS$^+$: *m*/*z* = 790 [M + K]$^+$, 774 [M + Na]$^+$, 715 [M − HCl]$^+$, 697 [M − NH$_3$ − HCl]$^+$, 679 [M − HCl − Cl]$^+$.

[PdCl$_2$(Lb)] (7b): [PdCl$_2$(cod)] (69 mg, 242 μmol) was added to a solution of **Lb** (143 mg, 243 μmol) in CH_2Cl_2 (10 cm^3). A yellow precipitate appeared immediately. The reaction mixture was stirred at room temperature for 2 h and then concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with light petroleum ether (3 × 1 cm^3) and Et_2O (3 × 1 cm^3) gave the product as a yellow solid. Yield: 177 mg, 95%. $C_{34}H_{34}Cl_2N_6P_2Pd$ (765.9): calcd. C 53.32, H 4.47, N 10.97; found C 49.74, H 4.03, N 10.81. IR (KBr disc): $\tilde{\nu}$ = 3314m cm^{-1}, 3144m, 1637vs, 1603s, 737s, 670s, 305w, 291m. ESMS$^+$: *m*/*z* = 789 [M + Na]$^+$, 767 [M + H]$^+$, 729 [M − Cl]$^+$, 694 [M − HCl − Cl]$^+$.

[PtCl$_2$(La)] (8a): [PtCl$_2$(cod)] (65 mg, 171 μmol) was added to a solution of **La** (102 mg, 177 μmol) in CH_2Cl_2 (20 cm^3). The reaction mixture was stirred for 2 h and then concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with light petroleum ether (3 × 1 cm^3) and Et_2O (3 × 1 cm^3) gave the product as a white solid. Yield: 156 mg, 91%. $C_{33}H_{32}Cl_2N_6P_2Pt$ (840.6): calcd. C 47.15, H 3.84, N 10.00; found C 47.01, H 3.10, N 9.74. IR (KBr disc): $\tilde{\nu}$ = 3386m cm^{-1}, 3185w, 1637vs, 1596s, 741s, 692s, 313w, 286w. ESMS$^+$: *m*/*z* = 804 [M − HCl]$^+$.

[PtCl$_2$(Lb)] (8b): [PtCl$_2$(cod)] (78 mg, 208 μmol) was added to a solution of **Lb** (124 mg, 211 μmol) in CH_2Cl_2 (20 cm^3). A white precipitate appeared immediately. The reaction mixture was stirred for 2 h and then concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with light petroleum ether (3 × 1 cm^3) and Et_2O (3 × 1 cm^3) gave the product as a white solid. Yield: 166 mg, 93%. $C_{34}H_{34}Cl_2N_6P_2Pt$ (854.6): calcd. C 47.34, H 3.46, N

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

10.32; found C 47.78, H 4.01, N 9.83. IR (KBr disc): $\tilde{\nu}$ = 3338m cm^{-1}, 3163m, 1632vs, 1601s, 740s, 691vs, 314w, 292m. FABMS$^+$: m/z = 819 [M − Cl]$^+$, 783 [M − 2Cl]$^+$.

[Pt(CH$_3$)$_2$(La)] (9a): [Pt(CH$_3$)$_2$(cod)] (56 mg, 168 μmol) was added to a solution of **La** (100 mg, 174 μmol) in CH_2Cl_2 (10 cm^3). The reaction mixture was stirred for 2 h and then concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with light petroleum ether (3 × 1 cm^3) and Et_2O (3 × 1 cm^3) gave the product as a white solid. Yield: 124 mg, 62%. $C_{35}H_{38}N_6P_2Pt$ (799.8): calcd. C 52.56, H 4.79, N 10.51; found C 51.64, H 4.24, N 10.19. IR (KBr disc): $\tilde{\nu}$ = 3323m cm^{-1}, 3179w, 1638vs, 1594s, 737m, 696s. ESMS$^+$: m/z = 825 [M + Na]$^+$, 800 [M]$^+$, 783 [M − CH_3]$^+$.

[Pt(CH$_3$)$_2$(Lb)] (9b): [Pt(CH$_3$)$_2$(cod)] (77 mg, 234 μmol) was added to a solution of **Lb** (138 mg, 234 μmol) in CH_2Cl_2 (10 cm^3). The reaction mixture was stirred for 2 h and then concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with light petroleum ether (3 × 1 cm^3) and Et_2O (3 × 1 cm^3) gave the product as a white solid. Yield: 154 mg, 82%. $C_{36}H_{40}N_6P_2Pt$ (813.8): calcd. C 53.13, H 4.95, N 10.33; found C 52.41, H 4.52, N 10.66. IR (KBr disc): $\tilde{\nu}$ = 3328m cm^{-1}, 3163w, 1637vs, 1598s, 737m, 695vs. FABMS$^+$: m/z = 798 [M − CH_3]$^+$, 783 [M − H − 2CH_3]$^+$.

[PtCl(CH$_3$)(La)] (10a): [PtCl(CH$_3$)(cod)] (90 mg, 254 μmol) was added to a solution of **La** (147 mg, 254 μmol) in CH_2Cl_2 (20 cm^3). A white solid precipitated out gradually. The reaction mixture was stirred for 2 h and then concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with light petroleum ether (3 × 1 cm^3) and Et_2O (3 × 1 cm^3) gave the product as an off-white solid. Yield: 190 mg, 91%. $C_{34}H_{35}ClN_6P_2Pt$ (820.2): calcd. C 49.79, H 4.30, N 10.25; found C 51.18, H 4.13, N 9.86. IR (KBr disc): $\tilde{\nu}$ = 3320w cm^{-1}, 3163w, 1638vs, 1595s, 739s, 694vs. FABMS$^+$: m/z = 804 [M − CH_3]$^+$, 785 [M − Cl]$^+$.

[PtCl(CH$_3$)(Lb)] (10b): [PtCl(CH$_3$)(cod)] (70 mg, 230 μmol) was added to a solution of **Lb** (117 mg, 230 μmol) in CH_2Cl_2 (10 cm^3). A white solid precipitated out gradually. The reaction mixture was stirred for 2 h and then concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with light petroleum ether (3 × 1 cm^3) and Et_2O (3 × 1 cm^3) gave the product as an off-white solid. Yield: 149 mg, 91%. $C_{35}H_{37}ClN_6P_2Pt$ (834.2): calcd. C 50.39, H 4.47, N 10.07; found C 49.70, H 4.01, N 10.44. IR (KBr disc): $\tilde{\nu}$ = 3323m cm^{-1}, 3158m, 1636vs, 1600s, 738s, 694vs, 296m. FABMS$^+$: m/z = 798 [M − Cl]$^+$, 784 [M − Cl − CH_3]$^+$.

[(AuCl)$_2$(La)] (11a): [AuCl(tht)] (80 mg, 250 μmol) was added to a solution of **La** (74 mg, 129 μmol) in CH_2Cl_2 (10 cm^3). The reaction mixture was stirred for 2 h and a solid precipitated out after ca. 10 min. The resulting mixture was concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with Et_2O (3 × 1 cm^3) gave the product as a white solid. Yield: 124 mg, 96%. $C_{33}H_{32}Au_2Cl_2N_6P_2$ (1039.4): calcd. C 38.13, H 3.10, N 8.09; found C 38.14, H 2.53, N 8.25. IR (KBr disc): $\tilde{\nu}$ = 3321m cm^{-1}, 3181w, 1639vs, 1596vs, 744s, 692s, 329m. FAB$^+$: m/z = 1003 [M − Cl]$^+$, 967 [M − 2Cl − H]$^+$.

[(AuCl)$_2$(Lb)] (11b): [AuCl(tht)] (80 mg, 250 μmol) was added to a solution of **Lb** (75 mg, 127 μmol) in CH_2Cl_2 (10 cm^3). The reaction mixture was stirred for 2 h and a solid precipitated out after ca.10 - min. The resulting mixture was concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with Et_2O (3 × 1 cm^3) gave the product as a white solid. Yield: 120 mg, 92%. $C_{34}H_{34}Au_2Cl_2N_6P_2$ (1053.5): calcd. C 39.18, H 3.25, N 7.98; found C 38.76, H 3.08, N 7.98. IR (KBr disc): $\tilde{\nu}$ = 3317m cm^{-1}, 3161m, 1638vs, 1595s, 744s, 691vs, 326s. FABMS$^+$: m/z = 1017 [M − Cl]$^+$, 982 [M − 2 Cl − H]$^+$.

[RuCl$_2$(η^6-*p*-CH$_3$C$_6$H$_4$*i*Pr)(La)] (12a): [RuCl(μ-Cl)(*p*-CH$_3$-C$_6$H$_4$*i*Pr)]$_2$ (52 mg, 85 μmol) was added to a solution of **La** (50 mg, 87 μmol) in CH_2Cl_2 (20 cm^3). The reaction mixture was stirred for 2 h and then concentrated to ca. 0.5 cm^3. Addition of Et_2O (10 cm^3), filtration and washing with Et_2O (3 × 1 cm^3) gave the product as an orange solid. Yield: 85 mg, 83%. $C_{53}H_{60}Cl_4N_6P_2Ru_2$ (1187.0): calcd. C 53.63, H 5.09, N 7.08; found C 52.22, H 5.11, N 6.96. IR (KBr disc): $\tilde{\nu}$ = 3338m cm^{-1}, 3187w, 3054m, 1631vs, 1595s, 1474s, 1437s, 746s, 696vs. FABMS$^+$: m/z = 1188 [M + H]$^+$, 1212 [M + Na]$^+$.

Table 7. Details of the X-ray data collections and refinements for compounds **2b** and **10b**

Compound	**2b**	**10b**·1/4C_6H_{14}

Final *R*1, ω*R*2[$I > 2\sigma(I)$]	0.0456, 0.1036	0.0409, 0.0664

X-ray Crystallography: Table 7 lists details of data collections and refinements for **2b** and **10b**. Data were collected at room temperature using Mo-K_α radiation with a SMART system. Intensities were corrected for Lorentz-polarisation and for absorption. The structures were solved by the heavy-atom method or by direct methods. The positions of the hydrogen atoms were idealised. Refinements were by full-matrix least-squares based on F^2 using SHELXTL.[35] In complex **10b**, there is disorder of the chlorine and the methyl atoms attached to the platinum atom. The diagram in Figure 2 shows the major (70%) occupancy. CCDC-200672 (**2b**) and -200673 (**10b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We wish to thank the JREI for equipment grants, Johnson Matthey plc for the loan of precious metals and Dr. Andrew Houlton for his inspiration of this work. Qingzhi Zhang is indebted to St Andrews University for financial support. We are also grateful to Dr. Stephen M. Aucott and Mrs. Joanna Wheatley in this lab for the kind donation of [PtMe$_2$(cod)], [PtMeCl(cod)] and [AuCl(tht)] (tht = tetrahydrothiophene).

Keywords: Niobium / Allyl ligands / Hydride ligands / Insertion reactions / Isocyanide

The new allylniobocene complexes [NbCp′$_2$(η^3-CHRCHCHR′)] [Cp′ = η^5-$C_5H_4SiMe_3$; R = R′ = $SiMe_2tBu$ (**1**); R = H, R′ = $SiPh_3$ (**2**)] have been prepared and characterised. The molecular structure of **1** has been determined by X-ray diffraction studies, which confirm that the allyl ligand is η^3-bonded to the metal centre. The reactivity of the niobocene complexes **1**, **2,** [NbCp′$_2$H(η^2-CH_2=CH_2)] (**3**), and [NbCp′$_2$(η^3-CH_2CHCH_2)] (**4**) towards aliphatic, *t*BuNC, *n*BuNC, and aromatic, $CNC_6H_3Me_2$-2,6, isocyanide compounds has been studied. From these reactions the new alkylniobocene [NbCp′$_2$(CH_2CH_3)(CNR)] [R = *t*Bu (**5**), $C_6H_3Me_2$-2,6 (**6**), *n*Bu (**7**)], η^1-allylniobocene derivatives [NbCp′$_2$(η^1-$CH_2CHCHSiPh_3$)($CNC_6H_3Me_2$-2,6)] (**8**), and a family of the first neutral η^1-iminoacylniobocene complexes [NbCp′$_2$\{η^1-C(=NR)R′\}(CNR)] (R = $C_6H_3Me_2$-2,6, R′ = Et (**9**); R = *n*Bu, R′ = Et (**10**); R = $C_6H_3Me_2$-2,6, R′ = CH_2CH=$CHSiPh_3$ (**11**); R = $C_6H_3Me_2$-2,6, R′ = CH_2CH=CH_2 (**12**)] were prepared.

Introduction

The chemistry of η^3-allyl complexes of transition metals is well documented.[1] However there are only a relatively small number of η^3-allyl complexes of niobium and tantalum despite the synthesis of [Nb(η^5-C_5H_5)$_2$(η^3-C_3H_5)] being first reported in 1970.[2] This was followed by the preparation of [M(η^5-C_5H_5)$_2$R] (M = Nb, Ta; R = 1-methylallyl, 2-methylallyl).[3] Several related systems such as the metallacyclic (η^3-allyl)metallocene cations have also been published.[4] Nakamura et al. have also synthesised a family of allylniobocene complexes,[5] and more recently the allyltantalum complexes [Ta(=NR)(η^5-C_5Me_5)(η^1-CH_2CHCH_2)(η^3-CH_2CHCH_2)] (R = Si*t*Bu$_3$, 2,6-*i*PrC_6H_3) were reported.[6]

Our research group's contribution in this field describes the synthesis and reactivity of η^3-allyl, [NbCp′$_2$(η^3-C_3H_5)], and chelate azaallyl [NbCp′$_2$\{N($SiMe_3$)C(*t*Bu)CH_2\}], niobocene derivatives[7] and forms part of our ongoing studies in the use of unsaturated molecules in the synthesis of new families of niobium organometallic compounds.[8]

The behaviour of isocyanide molecules towards alkyl or aryl transition-metal compounds is well documented and insertion reactions are usually observed.[9] Varying the alkyl or aryl substituent of the isocyanide compound allows fine tuning of the electronic and steric properties of the metal complex. Isocyanides are able to bind to the metal through either or both the carbon and nitrogen atom. η^2-Coordination normally occurs at electron deficient metal centres and is characteristic for high valence early transition metal complexes.

Our well documented studies of the first insertion reaction of CO into the niobium−carbon bond of alkylniobocene complexes which give the corresponding η^1-acyl derivatives,[10] have led us to consider the insertion reactions of isocyanide compounds. The isolobal relationship between carbon monoxide and isocyanide compounds suggests that similar types of reactivity can be expected although isocyanides are generally regarded as better σ donors and weaker π acceptors than carbon monoxide.[11]

We report here the synthesis and characterisation of new allylniobocene complexes and their reactivity as well as that of olefin-hydride species towards aliphatic and aromatic isocyanide reagents. We also present the molecular structure of an η^3-allylniobocene complex, which to the best of our knowledge is only the second reported example.

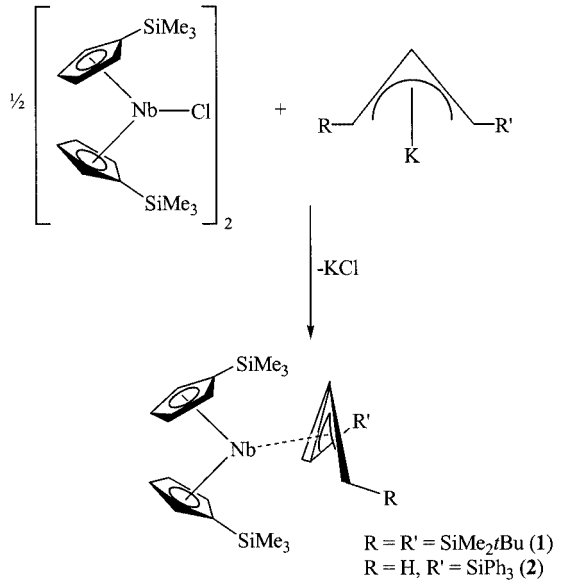
Results and Discussion

The eighteen-electron allyl complexes [NbCp′$_2$(η^3-CHRCHCHR′)] [Cp′ = η^5-$C_5H_4SiMe_3$; R = R′ = $SiMe_2tBu$ (**1**); R = H, R′ = $SiPh_3$ (**2**)] were prepared by the metathesis reaction of [{NbCp′$_2$Cl}$_2$] and the corresponding potassium salt [K(η^3-CHRCHCHR′)] (Scheme 1).



Scheme 1

Complexes **1** and **2** were characterised by NMR and mass spectroscopy (see Exp. Sect.). The ^{1}H NMR spectrum of **1** showed two sets of allylic proton signals, a doublet for the terminal allylic protons (two H_{anti}) and a triplet for the central allylic proton. Four signals were observed for the protons of the two cyclopentadienyl rings. The σ_v symmetry of **1** makes the protons 2-H, 5-H and 3-H, 4-H in each cyclopentadienyl ring equivalent (see Figure 1). The η^3-coordination of the allyl ligand results in the inequivalency of the two cyclopentadienyl rings and thus two sets of signals corresponding to the distinct cyclopentadienyl ligands were observed. In addition the two methyl groups of the allyl silyl substituents were found to be magnetically inequivalent and this was attributed to the greater restriction to rotation about the silicon−allyl−carbon bond of the allyl ligand.[12] The ^{13}C NMR spectrum observed was in accordance with the proposed structure (see Exp. Sect.).

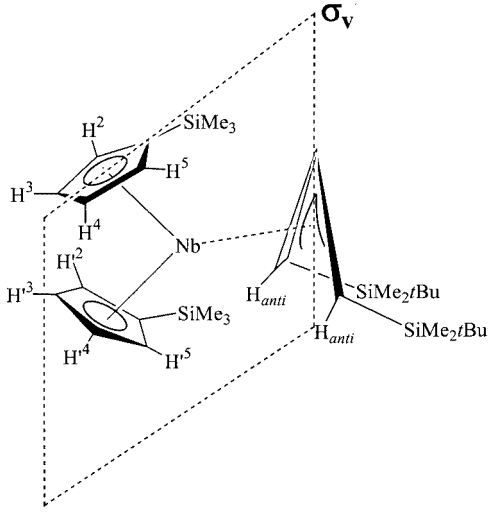


Figure 1. Proposed structure for [NbCp′$_2$(η^3-$tBuMe_2SiCHCHCH$-$SiMe_2tBu$)] (**1**)

The ^{1}H NMR spectrum of **2** showed eight signals for the protons of the cyclopentadienyl ligands and two singlets for the $SiMe_3$ ring substituents in accordance with an asymmetrical environment about the niobium centre. The inequivalence of the two cyclopentadienyl rings indicates an η^3 coordination of the allyl ligand (see Figure 2). Three sets of signals for the allylic group were observed, a doublet at $\delta = -0.09$ ppm assigned to the H_{anti} proton bonded to the silicon atom, a doublet of doublets at $\delta = 0.89$ ppm assigned to the H_{anti} of the unsubstituted terminal carbon and a multiplet at $\delta = 2.73$ ppm assigned to the central proton which overlaps with the signal assigned to the H_{syn} proton. The ^{13}C NMR spectrum observed was in accordance with the proposed structure (see Exp. Sect.).

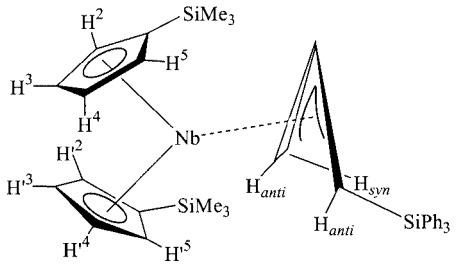

Figure 2. Proposed structure for [NbCp′$_2$(η^3-$CH_2CHCHSiPh_3$)] (**2**)

The molecular structure of **1** was established by single crystal X-ray diffraction and confirmed the η^3-coordination of the allyl ligand. The molecular structure and atom numbering scheme are shown in Figure 3. Selected bond lengths and angles for **1** are given in Table 1.

The structure of **1** shows the typical bent metallocene confirmation observed in niobocene complexes, with both cyclopentadienyl ligands bound to the metal in an η^5 mode. The environment of the niobium atom is completed by the η^3-allyl ligand. If the terminal carbon atoms of the allyl ligand are regarded as occupying two coordination sites, then the niobium metal centre can be considered as having a distorted tetrahedral geometry. The angle defined by Cent(1), Nb and Cent(2) is 131.48(1)°, by Cent(1), Nb and Cent(3) 113.13(2)°, and by Cent(2), Nb and Cent(3) 115.35(1)° [Cent(1) and Cent(2) are the centroids of the cyclopentadienyl ligands and Cent(3) is the centroid of the allyl ligand). The sum of these three angles is exactly 360° indicating that the vectors connecting the Nb atom with Cent(1), Cent(2) and Cent(3) are all in one plane.

Table 1. Selected bond lengths [Å] and angles [°] for **1**

Bond lengths		Bond angles	
av Nb(1)−C[Cent(1)][a][b]	2.398	Cent(1)−Nb(1)−Cent(2)	131.48(1)
av Nb(1)−C[Cent(2)][a][b]	2.429	Cent(1)−Nb(1)−Cent(3)	113.13(2)
Nb(1)−C(1)	2.395(4)	Cent(2)−Nb(1)−Cent(3)	115.35(1)
Nb(1)−C(2)	2.366(4)	C(2)−Nb(1)−C(1)	34.4(1)
Nb(1)−C(3)	2.377(5)	C(3)−Nb(1)−C(1)	64.2(2)
Si(1)−C(1)	1.869(5)	C(2)−C(1)−Si(1)	118.9(3)
Si(1)−C(10)	1.914(5)	C(2)−C(1)−Nb(1)	71.6(2)
Si(2)−C(3)	1.839(5)	Si(1)−C(1)−Nb(1)	137.9(2)
Si(2)−C(4)	1.904(6)	C(1)−C(2)−C(3)	127.3(4)
C(1)−C(2)	1.408(6)	C(1)−C(2)−Nb(1)	74.0(3)
C(2)−C(3)	1.421(6)	C(3)−C(2)−Nb(1)	73.0(3)
		C(2)−C(3)−Si(2)	124.1(4)
		C(2)−C(3)−Nb(1)	72.1(2)
		Si(2)−C(3)−Nb(1)	133.7(2)

[a] Cent(1), Cent(2) and Cent(3) are the centroids of C(21)−C(25), C(31)−C(35) and C(1)−C(3), respectively. [b] Refers to the average bond length between Nb(1) and the carbon atoms of the C_5 ring of the corresponding cyclopentadienyl moiety.

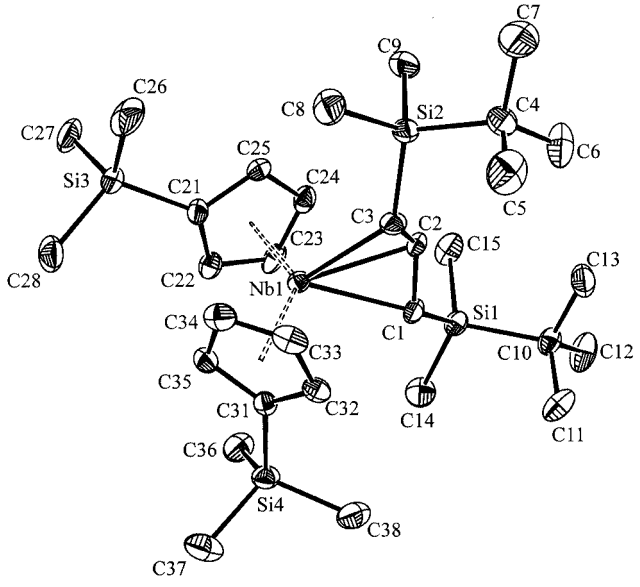

Figure 3. Molecular structure and atom-labelling scheme for [NbCp′$_2$(η^3-*t*BuMe$_2$SiCHCHCHSiMe$_2$*t*Bu)] (**1**), with thermal ellipsoids at 30% probability

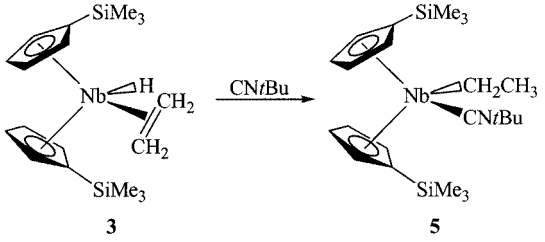
The allyl ligand assumes a planar *cis-syn* geometry and shows η^3-coordination to the metal centre. The carbon atoms of the allyl ligand are nearly planar with C−C distances of 1.408(6) Å and 1.421(6) Å, which are similar to the only other X-ray characterised allylniobocene complex, namely [Nb(η^5-C_5H_5)$_2$(η^3-C_3H_5)].[13] The plane of the allyl group in **1** is not perpendicular to the plane defined by Nb(1), C(2) and C(3) but at an angle of 116.0(4)°, typically tilted away from perpendicular to maximize orbital overlap. These structural features are consistent with a strong bonding interaction between the allyl nonbonding orbital and the empty metal orbital, and little back-bonding from the metal to the allyl.[13] The close structural similarity between the niobium derivatives **1**, and [Nb(η^5-C_5H_5)$_2$(η^3-C_3H_5)] (d^2 metal centre) with [Ti(η^5-C_5H_5)$_2$(η^3-C_3H_3-1,3-Me$_2$)][14] (d^1 metal centre) is also an indication that the metal-to-ligand back donation is negligible. The effect of alkyl substitution at the terminal carbons of the allyl ligand is reflected in the elongated Nb−C(1) and Nb−C(3) distances 2.395(4) Å and 2.377(5) Å, respectively. These values are greater than the Nb−C(2) distance [2.366(4) Å] and longer that observed in the unsubstituted allyl compound.[13]

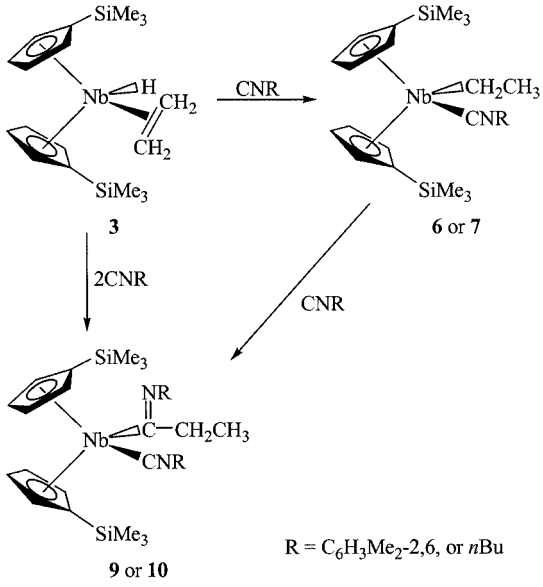
The reaction of the niobocene derivatives **1**, **2**, [NbCp′$_2$H(η^2-CH_2=CH_2)] (**3**)[10] and [NbCp′$_2$(η^3-CH_2CHCH_2)] (**4**)[7] with isocyanide compounds has been studied. The hydrido(ethylene)niobocene complex [NbCp′$_2$H(η^2-CH_2=CH_2)] (**3**) was found to react slowly at room temperature with *tert*-butyl isocyanide to give the ethyl isocyanide derivative [NbCp′$_2$(CH_2CH_3)(CN*t*Bu)] (**5**) in quantitative yield as a red oil (Scheme 2). The isocyanide ligand promotes the insertion of the olefin into the niobium−hydride bond and no further reaction was observed even when an excess of isocyanide was used or the reaction was carried out the at higher temperatures. Complex **5** was characterised spectroscopically. The most significant IR band for **5** corresponds to the isocyanide stretching mode ν(CN) at 2095 cm^{-1}. In the ^{13}C NMR spectrum of **5** the most interesting feature was the extremely low field resonance (δ = 270.0 ppm) which was observed for the metal-bonded isocyanide carbon. This resonance appears as a broad singlet due to the high relaxation time in the NMR time scale.[15]



Scheme 2

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In contrast with the behaviour observed in the synthesis of **5**, an equimolar amount of 2,6-dimethylphenyl isocyanide reacts at room temperature with **3** to give, initially the ethyl isocyanide derivative [NbCp′$_2$(CH$_2$CH$_3$)(CNC$_6$H$_3$Me$_2$-2,6)] (**6**) which evolves rapidly at room temperature with the insertion of a second equivalent of the isocyanide ligand into the niobium-carbon bond to yield the neutral iminoacyl compound [NbCp′$_2${η^1-C(=N−C$_6$H$_3$Me$_2$-2,6)(CH$_2$CH$_3$)}(CNC$_6$H$_3$Me$_2$-2,6)] (**9**) (Scheme 3). Compound **6** could not be isolated as a pure sample, but as part of a mixture containing, in addition, **3** and **9**. However, **9** could be prepared and isolated as a pure sample by the reaction of **3** with two equivalents of the isocyanide reagent.



Scheme 3

Compound **6** was characterised by ^{1}H NMR spectroscopy where typical resonances corresponding to the cyclopentadienyl, ethyl and isocyanide ligands were observed (see Exp. Sect.). Complex **9** showed in the IR spectrum a band corresponding to the stretching mode ν(CN) at 2021 cm^{-1} of the linear isocyanide ligand. The ν(C=N) stretching frequency corresponding to the η^1-iminoacyl ligand was observed at 1657 cm^{-1}.[16] NMR evidence supports the proposal that the iminoacyl ligand in this compound is coordinated in an η^1 fashion. The ^{1}H NMR resonance of the inserted methylene group of the ethyl ligand observed is displaced to lower field, δ = 2.35 ppm, with respect to that observed in **6**, δ = 0.81 ppm. In the ^{13}C NMR spectrum a low field resonance, δ = 218.2 ppm, was observed for the carbon of the terminal isocyanide ligand bonded to niobium. A second signal shifted to higher field, δ = 153.6 ppm, was assigned to the carbon of the η^1-iminoacyl ligand. The previously reported cationic iminoacylniobium derivatives [NbCp′$_2$X(η^2-C(=NPh)CHCHRPh)][17] (X = Cl, H, CH$_3$) showed the signal attributed to the η^2-iminoacyl carbon in the range δ = 213−219 ppm which was in accordance with the data reported for complexes of other early transition metals.[18] Adams and co-workers have shown that the η^2-iminoacyl carbon in [Mo(η^5-C$_5$H$_5$)(CO)$_2$(η^2-MeCNMe)] resonates approximately δ = 40 ppm downfield of the corresponding resonance in [Mo(η^5-C$_5$H$_5$)(CO)$_2${P(OMe)$_3$}(η^1-MeCNPh)].[19] Royo and co-workers have proposed a related η^1 iminoacyltantalum system as an intermediate in the synthesis of compounds containing imido-η^2-iminoacyl ligands [Ta(η^5-C$_5$Me$_5$)(=N*t*Bu)Cl{η^2-C[C(Me)=NR]=NR}] (R = C$_6$H$_3$Me$_2$-2,6).[20]

Further evolution of **9** to give the coupling of the isocyanide and the η^1-iminoacyl groups to produce metallacyclic compounds was not observed.[21]

The reaction of *n*-butyl isocyanide with **3** also gave a mixture of products, namely the alkyl compound [NbCp′$_2$(CH$_2$CH$_3$)(CN*n*Bu)] (**7**) and the iminoacyl complex [NbCp′$_2${η^1-C(=N*n*Bu)(CH$_2$CH$_3$)}(CN*n*Bu)] (**10**) (Scheme 3). With an excess of isocyanide further reactions gave a mixture of products which we were unable to identify. **7** was characterised by ^{1}H NMR spectroscopy where typical resonances corresponding to the cyclopentadienyl, ethyl and isocyanide ligands were observed (see Exp. Sect.). In the ^{1}H NMR spectrum a second set of signals corresponding to the cyclopentadienyl, ethyl, isocyanide and iminoacyl ligands were assigned to compound **10** (see Exp. Sect.).

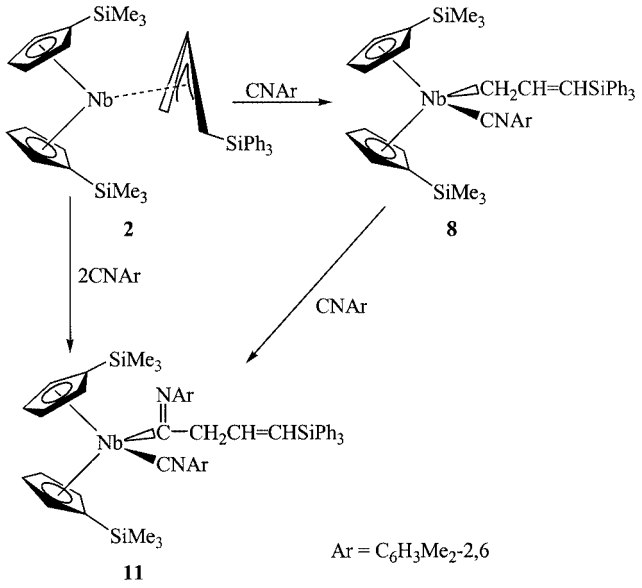
In the case of the allylniobocene derivatives, **1**, **2** and **4**, there was no reaction with *tert*-butyl isocyanide (even at 80 °C). Nevertheless the complexes rapidly reacted with *n*-butyl isocyanide although only to give mixtures of products which we were unable to identify.

Complex **1** did not react with 2,6-dimethylphenyl isocyanide at room temperature and at 80 °C the products from the reaction could not be identified. However, [NbCp′$_2$(η^3-CH$_2$CHCHSiPh$_3$)] (**2**) reacts with two equivalents of 2,6-dimethylphenyl isocyanide at room temperature to give initially the η^1-allyl isocyanide derivative [NbCp′$_2$(η^1-CH$_2$CH=CHSiPh$_3$)(CNC$_6$H$_3$Me$_2$-2,6)] (**8**) which undergoes an insertion reaction of further isocyanide to give the iminoacyl derivative [NbCp′$_2${η^1-C(=NC$_6$H$_3$Me$_2$-2,6)(CH$_2$CH=CHSiPh$_3$)}(CNC$_6$H$_3$Me$_2$-2,6)] (**11**) (Scheme 4).

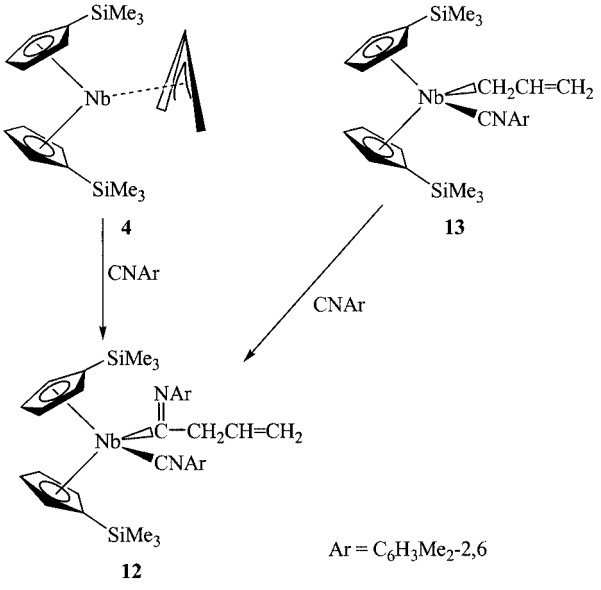
In contrast [NbCp′$_2$(η^3-CH$_2$CHCH$_2$)] (**4**) did not react with the aryl isocyanide at room temperature, and the reaction had to be carried out at 80 °C in order to obtain the corresponding η^1-iminoacyl compound [NbCp′$_2${η^1-C(=NC$_6$H$_3$Me$_2$-2,6)(CH$_2$CH=CH$_2$)}(CNC$_6$H$_3$Me$_2$-2,6)] (**12**) [Scheme (5)]. Under these conditions the corresponding intermediate η^1-allyl derivative [NbCp′$_2$(η^1-CH$_2$CH=CH$_2$)(CNC$_6$H$_3$Me$_2$-2,6)] (**13**) was not detected. However, we have previously reported its preparation by a distinctive synthetic route.[7] The reaction of **13** with an equimolar amount of aryl isocyanide gave the iminoacyl complex **12** (Scheme 5).

The complexes **8**, **11** and **12** were characterised by IR and NMR spectroscopy (see Exp. Sect.). ^{1}H NMR spectroscopy for these compounds showed that the two cyclopentadienyl ligands are equivalent indicating a σ_h symmetry plane in

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 4



Scheme 5

the molecule. The disappearance of the *anti* and *syn* protons signals of the starting complexes clearly shows the change of bonding mode of the allyl ligand from η^3 to η^1 in the final product. The η^1-allyl complexes exhibited, in the ^{1}H NMR spectra, for this group, three sets of signals corresponding to a doublet for the CH_2 bonded to the niobium or iminoacyl carbon atom, a multiplet, at ca. $\delta = 5.7$ ppm, for the central group CH and a multiplet, at ca. $\delta = 4.6$ ppm, for the terminal olefinic protons. One the more important features of the ^{1}H NMR spectra was the position of the resonance of the methylene group of the η^1-allyl system which was found to resonate at $\delta = 1.65$ ppm for **8** and $\delta = 1.39$ ppm for **13**, when this group is directly bonded to niobium. However, for **11** and **12** where the methylene group is bonded to the iminoacyl carbon atom, the corresponding signal was shifted downfield to $\delta = 3.54$ ppm and 3.26 ppm, respectively.

The IR spectrum for compounds **11** and **12** showed a band corresponding to the stretching mode ν(CN) at 2019 and 2029 cm^{-1}, respectively, corresponding to the isocyanide ligand coordinated to the metal atom. The ν(C=N) stretching frequencies for **11** and **12**, corresponding to the η^1-iminoacyl ligands appeared at 1659 and 1677 cm^{-1}, respectively.

In conclusion, two new allylniobocene complexes have been prepared and the X-ray structure (only the second reported example) for one of these compounds has been determined. η^1-Iminoacylniobocene complexes have been synthesised and characterised by spectroscopic techniques. NMR spectroscopy studies have allowed us to establish the ease of the different isocyanide molecules insertion reactions in the different niobium systems, and corresponds to the following order CN*n*Bu > $CNC_6H_3Me_2$-2,6 > CN*t*Bu for the isocyanide molecules and [$NbCp'_2H(\eta^2$-$CH_2{=}CH_2)$] (**3**) > [$NbCp'_2(\eta^3$-$CH_2CHCHSiPh_3)$] (**2**) > [$NbCp'_2(\eta^3$-$CH_2CHCH_2)$] (**4**), for the organometallic substrates.

Experimental Section

General Remarks: All reactions were performed using standard Schlenk tube techniques under dry nitrogen. Solvents were distilled from appropriate drying agents and degassed before used.

The compounds [$NbCp'_2H(\eta^2$-$CH_2{=}CH_2)$] (**3**),[10] [$NbCp'_2(\eta^3$-$CH_2CHCH_2)$] (**4**),[7] [$K(\eta^3$-CHRCHCHR′)] (R = R′ = $SiMe_2t$Bu; R = H, R′ = $SiPh_3$)[12] and [$NbCp'_2(\eta^1$-$CH_2CH{=}CH_2)$-($CNC_6H_3Me_2$-2,6)] (**13**)[7] were prepared as described earlier. *t*BuNC, *n*BuNC, $CNC_6H_3Me_2$-2,6 were purchased from Aldrich and Fluka and used directly. IR spectra were recorded with a Perkin−Elmer PE 883 IR spectrophotometer. ^{1}H and ^{13}C spectra were recorded with Varian FT-300 and Varian Gemini FT-200 spectrometers and referenced to the residual deuterated solvent. Microanalyses were carried out with a Perkin−Elmer 2400 microanalyzer.

Preparation of [$NbCp'_2(\eta^3$-*t*$BuMe_2SiCHCHCHSiMe_2t$Bu) (1): [$K(\eta^3$-*t*$BuMe_2SiCHCHCHSiMe_2t$Bu)] (0.30 g, 1.47 mmol) in THF (50 mL) was added at 0 °C to a solution of [{$NbCp'_2Cl$}$_2$] (0.20 g, 0.50 mmol) in THF (10 mL). The resulting mixture was warmed to room temperature and stirred for 12 h. Solvent was removed in vacuo and hexane (50 mL) added to the green solid. After filtration, all volatiles were removed, from the filtrate, under reduced pressure to yield a dark green solid of the title complex (0.27 g, 87%). X-ray quality crystals were obtained by recrystallisation from cold hexane. ^{1}H NMR (200 MHz, C_6D_6, 25 °C): $\delta = -0.05$, 0.34 (2s, each 12 H, 2 × CHSi*Me*$_2t$Bu), 0.04 (d, $^3J_{H,H} = 11.1$ Hz, 2 H, 2 × C*H*$SiMe_2t$Bu), 0.23, 0.24 (2s, each 9 H, 2 × C_5H_4Si*Me*$_3$), 1.17 (s, 18 H, 2 × $CHSiMe_2t$Bu), 3.02 [t, 1 H, *H*C(CHSiMe_2tBu)$_2$], 4.28, 4.54, 4.78, 4.89 (4m, each 2 H, 2 × C_5H_4) ppm. ^{13}C{^{1}H} NMR (50 MHz, C_6D_6, 25 °C): $\delta = -6.1$, −2.4 (CHSi*Me*$_2t$Bu), 0.5, 0.8

($C_5H_4SiMe_3$), 27.3, 33.7 ($CHSiMe_2tBu$), 39.9 [$CH(CHSiMe_2tBu)_2$], 96.0 [$CH(CHSiMe_2tBu)_2$], 85.6, 88.9, 94.3, 94.5, 101.6, 105.2 (C_5H_4) ppm. $C_{31}H_{59}NbSi_4$ (637.1): calcd. C 58.45, H 9.33; found C 58.29, H 9.25.

Preparation of [NbCp′$_2$(η^3-CH$_2$CHCHSiPh$_3$)] (2): The synthesis of **2** was carried out in an identical manner to that described for **1**. From [K(η^3-$CH_2CHCHSiPh_3$)] (0.31 g, 0.92 mmol) and [{NbCp′$_2$Cl}$_2$] (0.37 g, 0.46 mmol). Yield 0.47 g, 77%. ^{1}H NMR (200 MHz, C_6D_6, 25 °C): δ = −0.13 (d, 1 H, C*H*SiPh$_3$), 0.16, 0.32 (2s, each 9 H, 2 × $C_5H_4SiMe_3$), 1.15 (*anti*), 2.94 (*syn*) (2m, each 1 H, $CH_2CHCHSiPh_3$), 2.81, 3.39, 4.18, 4.38, 4.44, 4.59, 4.82, 5.51 (8m, each 1 H, 2 × C_5H_4), 7.27−8.10 (m, 15 H, Si*Ph*$_3$) ppm. ^{13}C{^{1}H} NMR (50 MHz, C_6D_6, 25 °C): δ = 0.1, 0.5 ($C_5H_4SiMe_3$) 21.8 ($CH_2CHCHSiPh_3$), 38.5 (*C*HSiPh$_3$), 88.1 ($CH_2CHCHSiPh_3$), 84.9, 87.0, 90.3, 93.2, 99.2, 100.1, 100.4, 100.7, 104.4, 105.3 (C_5H_4), 126.0−130.0 (Si*Ph*$_3$) ppm. $C_{37}H_{45}NbSi_3$ (666.9): calcd. C 66.63, H 6.80; found C 66.45, H 6.70.

Preparation of [NbCp′$_2$(CH$_2$CH$_3$)(CN*t*Bu)] (5): To a hexane solution (30 mL) of [NbCp′$_2$H(η^2-CH_2=CH_2)] (**3**) (0.28 g, 0.71 mmol) an equimolar amount of *tert*-butyl isocyanide (80 μL, 0.71 mmol) was added and the reaction mixture was stirred at room temperature for 16 h. The yellow solution gradually became red, and finally a red oily residue was obtained after removing the solvent. The red oily product was shown to be pure by NMR spectroscopy. At 60 °C the reaction takes place in 6 h. IR (KBr): ν_{CN} = 2095 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6, 25 °C): δ = 0.15 (s, 18 H, 2 × $C_5H_4SiMe_3$), 0.65 (q, $^3J_{H,H}$ = 7.6 Hz, 2 H, CH_2CH_3), 1.20 [s, 9 H, $CNC(CH_3)_3$], 1.33 (t, 3 H, CH_2CH_3), 4.63, 4.72, 5.04, 5.22 (4m, each 2 H, 2 × C_5H_4) ppm. ^{13}C{^{1}H} NMR (50 MHz, C_6D_6, 25 °C): δ = 0.6 ($C_5H_4SiMe_3$), 14.8 (CH_2CH_3), 23.6 (CH_2CH_3), 32.0 [$C(CH_3)_3$], 62.2 [$C(CH_3)_3$], 91.6, 95.6, 96.3, 102.5, 103.5 (C_5H_4), 270.0 (*C*N) ppm.

Preparation of [NbCp′$_2$(CH$_2$CH$_3$)(CNC$_6$H$_3$Me$_2$-2,6)] (6): To a deuterated benzene solution (1 mL) of [NbCp′$_2$H(η^2-CH_2=CH_2)] (**3**) (0.02 g, 0.05 mmol) in an NMR tube was added an excess of 2,6-dimethylphenyl isocyanide (0.01 g, 0.11 mmol). The reaction mixture was immediately monitored by ^{1}H NMR spectroscopy and a mixture of three compounds, the starting hydride-olefin compound **3** and the compounds **6** and **9**, in a 1:0.9:0.75 proportion, was identified. **6:** ^{1}H NMR (200 MHz, C_6D_6, 25 °C): δ = 0.16 (s, 18 H, 2 × $C_5H_4SiMe_3$), 0.81 (q, $^3J_{H,H}$ = 7.7 Hz, 2 H, CH_2CH_3), 1.45 (t, 3 H, CH_2CH_3), 1.64 (s, 6 H, $CNC_6H_3Me_2$), 3.71, 4.11, 5.13, 5.69 (4m, each 2 H, 2 × C_5H_4), 6.39−6.55 (m, 3 H, $CNC_6H_3Me_2$) ppm.

Preparation of [NbCp′$_2$(CH$_2$CH$_3$)(CN*n*Bu)] (7): The synthesis of **7** was carried out in an identical manner to that described for **6**. From [NbCp′$_2$H(η^2-CH_2=CH_2)] (**3**) (0.04 g, 0.10 mmol) and *n*-butyl isocyanide (11 μL, 0.10 mmol). A mixture of **3** and **7** in a 2:1 proportion was identified. **7:** ^{1}H NMR (200 MHz, C_6D_6, 25 °C): δ = 0.16 (s, 18 H, 2 × $C_5H_4SiMe_3$), 0.75 (m, 3 H, $CNCH_2CH_2CH_2CH_3$), 0.83 (q, $^3J_{H,H}$ = 7.7 Hz, 2 H, CH_2CH_3), 0.90 (m, 2 H, $CNCH_2CH_2CH_2CH_3$), 1.25 (m, 2 H, $CNCH_2CH_2CH_2CH_3$), 1.45 (t, 3 H, CH_2CH_3), 3.35 (m, 2 H, $CNCH_2CH_2CH_2CH_3$), 4.63, 4.69, 4.92, 5.17 (4m, each 2 H, 2 × C_5H_4) ppm.

Preparation of [NbCp′$_2$(η^1-CH$_2$CH=CHSiPh$_3$)(CNC$_6$H$_3$Me$_2$-2,6)] (8): The synthesis of **8** was carried out in an identical manner to that described for **6**. From [NbCp′$_2$(η^3-$CH_2CHCHSiPh_3$)] (**2**) (0.02 g, 0.03 mmol) and $CNC_6H_3Me_2$-2,6 (0.01 g, 0.09 mmol). ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.04 (s, 18 H, 2 × $C_5H_4SiMe_3$), 2.08 (s, 6 H, $CNC_6H_3Me_2$), 1.65 (d, 2 H, CH_2CH=$CHSiPh_3$), 4.70 (m, 2 H, CH_2CH=C*H*SiPh$_3$), 5.50 (m, 2 H, CH_2CH=$CHSiPh_3$), 4.60, 4.61, 4.89, 5.11, (4m, each 2 H, 2 × C_5H_4), 7.20−7.76 (m, 15 H, SiPh$_3$) ppm.

Preparation of [NbCp′$_2${η^1-C(=NC$_6$H$_3$Me$_2$-2,6)(CH$_2$CH$_3$)}(CNC$_6$H$_3$Me$_2$-2,6)] (9): The synthesis of **9** was carried out in an identical manner to that described for **5**. From [NbCp′$_2$H(η^2-CH_2=CH_2)] (**3**) (0.15 g, 0.39 mmol) and 2,6-dimethylphenyl isocyanide (0.10 g, 0.78 mmol). Yield 0.23 g, 90%. IR (KBr/Nujol): $\tilde{\nu}$ = 1657 ($\nu_{C=N}$, iminoacyl), 2021 (ν_{CN}, isocyanide) cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6, 25 °C): δ = 0.09 (s, 18 H, 2 × $C_5H_4SiMe_3$), 0.90 (t, $^3J_{H,H}$ = 7.6 Hz, 3 H, CH_2CH_3), 2.15 (s, 6 H, $CNC_6H_3Me_2$), 2.17 (s, 6 H, η^1-C{$NC_6H_3Me_2$}), 2.35 (q, 2 H, CH_2CH_3), 4.93, 5.25, 5.28, 5.49 (4m, each 2 H, 2 × C_5H_4), 6.39−6.55 (m, 6 H, 2 × $CNC_6H_3Me_2$) ppm. ^{13}C{^{1}H} NMR (50 MHz, C_6D_6, 25 °C): δ = 0.4 ($SiMe_3$), 11.2 (CH_2CH_3), 19.1 ($CNC_6H_3Me_2$), 19.9 (η^1-C{$NC_6H_3Me_2$}), 44.7 (CH_2CH_3), 91.8, 96.0, 98.2, 98.5, 105.0 (C_5H_4), 120.5−128.9 (η^1-C{N$C_6H_3Me_2$} and CN$C_6H_3Me_2$), 153.6 (η^1-*C*{$NC_6H_3Me_2$}), 218.2 ($CNC_6H_3Me_2$) ppm. $C_{36}H_{49}N_2NbSi_2$ (658.9): calcd. C 65.63, H 7.50, N 4.25; found C 65.50, H 7.42, N 4.25.

Preparation of [NbCp′$_2${η^1-C(=N*n*Bu)(CH$_2$CH$_3$)}(CN*n*Bu)] (10): The synthesis of **10** was carried out in an identical manner to that described for **6**. From [NbCp′$_2$H(η^2-CH_2=CH_2)] (**3**) (0.04 g, 0.10 mmol) and *n*-butyl isocyanide (22 μL, 0.20 mmol). IR (KBr/Nujol): $\tilde{\nu}$ = 1690 ($\nu_{C=N}$, iminoacyl), 2046 (ν_{CN}, isocyanide) cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6, 25 °C): δ = 0.26 (s, 18 H, 2 × $C_5H_4SiMe_3$), 0.96 (t, $^3J_{H,H}$ = 7.7 Hz, 3 H, CH_2CH_3), 0.81, 0.84 (2m, each 3 H, 2 × $CNCH_2CH_2CH_2CH_3$), 0.93, 0.97 (2m, each 2 H, 2 × $CNCH_2CH_2CH_2CH_3$), 1.30, 1.36 (2m, each 2 H, 2 × $CNCH_2CH_2CH_2CH_3$), 2.03 (q, 2 H, CH_2CH_3), 3.25, 3.30 (2m, each 2 H, 2 × $CNCH_2CH_2CH_2CH_3$), 3.38, 3.53, 5.06, 5.43 (4m, each 2 H, 2 × C_5H_4) ppm. ^{13}C{^{1}H} NMR (50 MHz, C_6D_6, 25 °C): δ = 1.3 ($C_5H_4SiMe_3$), 11.4 (CH_2CH_3), 13.5, 16.4, 25.3, 27.2, 34.2, 35.9, 60.4, 62.7 (*n*Bu), 49.5 (CH_2CH_3), 82.5, 93.6, 93.7, 94.7, 97.4 (C_5H_4), 162.6 (η^1-*C*{N*n*Bu}), 222.0 (*C*N*n*Bu) ppm. $C_{28}H_{49}N_2NbSi_2$ (562.8): calcd. C 59.76, H 8.78, N 4.98; found C 59.44, H 8.69, N 4.96.

Preparation of [NbCp′$_2${η^1-C(NC$_6$H$_3$Me$_2$-2,6)(CH$_2$CH=CHSiPh$_3$)}(CNC$_6$H$_3$Me$_2$-2,6)] (11): The synthesis of **11** was carried out in an identical manner to that described for **5**. From [NbCp′$_2$(η^3-$CH_2CHCHSiPh_3$)] (**2**) (0.11 g, 0.17 mmol) and 2,6-dimethylphenyl isocyanide (0.04 g, 0.34 mmol). Yield 0.13 g, 85%. IR (KBr/Nujol): $\tilde{\nu}$ = 1659 ($\nu_{C=N}$, iminoacyl), 2019 (ν_{CN}, isocyanide) cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6, 25 °C): δ = 0.08 (s, 18 H, 2 × $C_5H_4SiMe_3$), 2.06, 2.07 (2s, each 6 H, 2 × $CNC_6H_3Me_2$), 3.54 (d, 2 H, CH_2CH=$CHSiPh_3$), 4.61 (m, 1 H, CH_2CH=C*H*SiPh$_3$), 5.70 (m, 1 H, CH_2CH=$CHSiPh_3$), 4.82, 5.22, 5.28, 5.52 (4m, each 2 H, 2 × C_5H_4), 6.50−7.00 (m, 15 H, SiPh$_3$), 7.20−7.90 (m, 6 H, 2 × $CNC_6H_3Me_2$) ppm. ^{13}C{^{1}H} NMR (50 MHz, C_6D_6, 25 °C): δ = 0.4 ($C_5H_4SiMe_3$), 19.1 ($CNC_6H_3Me_2$), 20.0 (η^1-C{$NC_6H_3Me_2$}), 61.9 (CH_2CH=$CHSiPh_3$), 91.8, 95.3, 97.7, 98.0, 105.6 (C_5H_4), 120.8 (CH_2CH=*C*HSiPh$_3$), 121.6−129.8 (η^1-C{N$C_6H_3Me_2$}, CN$C_6H_3Me_2$ and Si*Ph*$_3$), 150.1 (CH_2CH=$CHSiPh_3$), 171.1 (η^1-*C*{$NC_6H_3Me_2$}), 228.0 ($CNC_6H_3Me_2$) ppm. $C_{55}H_{63}N_2NbSi_3$ (929.3): calcd. X-ray Crystal Structure Determination of [NbCp′$_2$(η^3-*t*BuMe$_2$Si-CHCHCHSiMe$_2$*t*Bu)] (1): The crystallographic data and experimental details are given in Table 2. Crystallographic reflections were collected at 230 K on a Nonius-Mach3 diffractometer equipped with graphite-monochromated radiation (λ = 0.71073 Å). Unit cell dimensions were obtained by least-squares fit of the 2θ values of 25 high-order reflections by using the Mach3 centring routines. The intensities of 8372 reflections were collected ($2 < \theta < 28$); of these only 5489 reflections obeyed the condition $I > 2\sigma(I)$. Data were corrected in the usual fashion for Lorentz and polarisation effects and absorption correction was not necessary. The structure was solved by direct methods (SIR92)[22] and refinement on F^2 was carried out by full-matrix least-squares analysis (SHELXL-97).[23] A number of cycles of refinement with isotropic thermal parameters, followed by difference synthesis, enabled location of all the non-hydrogen atoms. For the final cycles of refinement all non-hydrogen atoms were refined anisotropically, while the hydrogen atoms were included in calculated positions but non refined. CCDC-201888 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax:(internat.) +44−1223/336−033; Email: deposit@ccdc.cam.ac.uk].

Table 2. Crystal data and structure refinement for **1**

Empirical formula	$C_{31}H_{59}NbSi_4$
Molecular mass	637.05
Temperature	230(2) K
Wavelength	0.71073 Å
Crystal system, space group	Monoclinic, $P2_1/c$
Unit cell dimensions	a = 11.875(3) Å b = 25.236(3) Å, β = 107.57(2)° c = 12.701(2) Å
Volume	3628.6(12) Å^3
Z, calculated density	4, 1.166 g/cm^3
Absorption coefficient	4.81 cm^{-1}
F(000)	1368
Crystal size	0.3 × 0.2 × 0.2 mm
Limiting indices	$0 \le h \le 15$, $0 \le k \le 33$, $-14 \le l \le 14$
Reflections collected / unique	8372/8372 [R(int) = 0.0000]
Data/restraints/parameters	8372/0/337
Goodness-of-fit on F^2	1.014
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0424, $wR2$ = 0.1039
R indices (all data)	$R1$ = 0.0828, $wR2$ = 0.1734
Largest diff. peak and hole	0.551 and −0.741 e·Å^{-3}

The Reactivity of Primary and Secondary Amines, Secondary Phosphanes and N-Heterocyclic Carbenes towards Group-13 Metal(I) Halides

Robert J. Baker,[a] Helga Bettentrup,[a] and Cameron Jones*[a]

Keywords: Group-13 elements / Carbene ligands / Phosphanes / Sub-oxidation state

The reactions of a variety of primary and secondary amines and secondary phosphanes with "GaI" have been examined. In all cases disproportionation reactions occurred which led to the gallium(II) iodide complexes $[Ga_2I_4(L)_2]$ [L = $NCyH_2$, N*t*BuH_2, NCy_2H, PCy_2H or P*t*Bu$_2$H (Cy = cyclohexyl)]. All complexes have been crystallographically characterised and have been shown to be dimers possessing Ga–Ga bonds. The reaction of the sterically hindered N-heterocyclic carbene IPr [:CN(Ar)C_2H_2N(Ar) (Ar = C_6H_3iPr$_2$-2,6)] with "GaI" was also carried out and the novel salt $[Ga_2I_5(IPr)][IPrH]$ was formed in good yield and crystallographically characterised. Finally, the related reaction of the less hindered cyclic carbene IMe [:CN(Me)C_2Me$_2$N(Me)] with InCl gave a low yield of the crystallographically characterised salt [{InCl(IMe)}$_2$(μ-Cl)(μ-O)][Cl] which presumably forms due to the presence of adventitious oxygen in the reaction mixture.

Introduction

Over the past five years there has been a rapidly increasing interest in the chemistry of metastable aluminium(I) and gallium(I) halide complexes $[\{MX(L)\}_n]$ (**1**: M = Al or Ga; X = halide; L = ether, amine or phosphane). These have been invariably prepared by the co-condensation of the metal(I) halide with the donor solvent using a specially designed reactor, and several have been crystallographically characterised, for example $[Al_4Br_4(NEt_3)_4]$.[1] Studies of the reactivity of group-13 metal(I) halide complexes have provided an array of remarkable results, not least of which come from their use in the formation of polyhedral halide, such as $[Al_{22}Br_{20}(THF)_{12}]$, amide, such as $[Ga_{84}\{N(SiMe_3)_2\}_{20}]^{4-}$, alkyl, such as $[Ga_{19}\{C(SiMe_3)_3\}_6]^-$, and silyl, such as $[Ga_{26}\{Si(SiMe_3)_3\}_8]^{2-}$, metalloid clusters.[2] Attempts have been made to prepare **1**, with M = Ga and L = PEt_3 or PPh_3, from the reaction of PEt_3 or PPh_3 with "GaI".[3] These reactions, however, led to partial disproportionation and the facile formation of the gallium(II) iodide complexes $[Ga_2I_4(PR_3)_2]$ (R = Et or Ph), and the mixed oxidation state complex $[Ga_3I_5(PEt_3)_3]$, all of which were crystallographically characterised. It is noteworthy that only two other neutral gallium(II) iodide adducts $[Ga_2I_4(L)_2]$ (L = NEt_3 [4] or $AsEt_3$ [5]), which were prepared by alternative routes, have been structurally authenticated.

Surprisingly there are no known structurally characterised indium analogues of **1**. Recently, we attempted the preparation of such a compound using an N-heterocyclic carbene (NHC) as the donor ligand in a reaction with InBr. As in the aforementioned reactions of phosphanes with "GaI" this led to partial disproportionation and the formation of the indium(II) bromide complex $[In_2Br_4(IMes)_2]$ with IMes being the cyclic carbene :CN(Mes)C(H)C(H)N(Mes) (Mes = mesityl).[6] In the present study we have extended this work by examining the reactivity of several NHCs towards indium(I) and gallium(I) halides. In addition, the reactions of a variety of primary and secondary amines and secondary phosphanes with "GaI" have been carried out and these have led to the formation of the first crystallographically characterised complexes of the type $[Ga_2I_4(L)_2]$ (L = NR_2H, NRH_2, PR_2H).

Results and Discussion

Amine and Phosphane Reactions

In all reactions depicted in Scheme 1 "GaI" was prepared by sonicating gallium metal with 0.5 equiv. of I_2 in toluene at 50 °C according to the method of Green et al.[7] A toluene suspension of this material was treated with a variety of amines and phosphanes at −78 °C. Upon warming the reaction mixtures to room temperature gallium metal deposition was observed. The resulting suspensions were filtered and cooled to −30 °C affording moderate to high yields of the gallium(II) iodide adducts **2**−**6**. The mechanism of formation of these compounds presumably involves partial disproportionation of the "GaI" reagent upon treatment with the Lewis bases. All compounds are, however, quite stable at room temperature in both solution and the solid state and no further disproportionation to gallium(III) iodide complexes was observed.

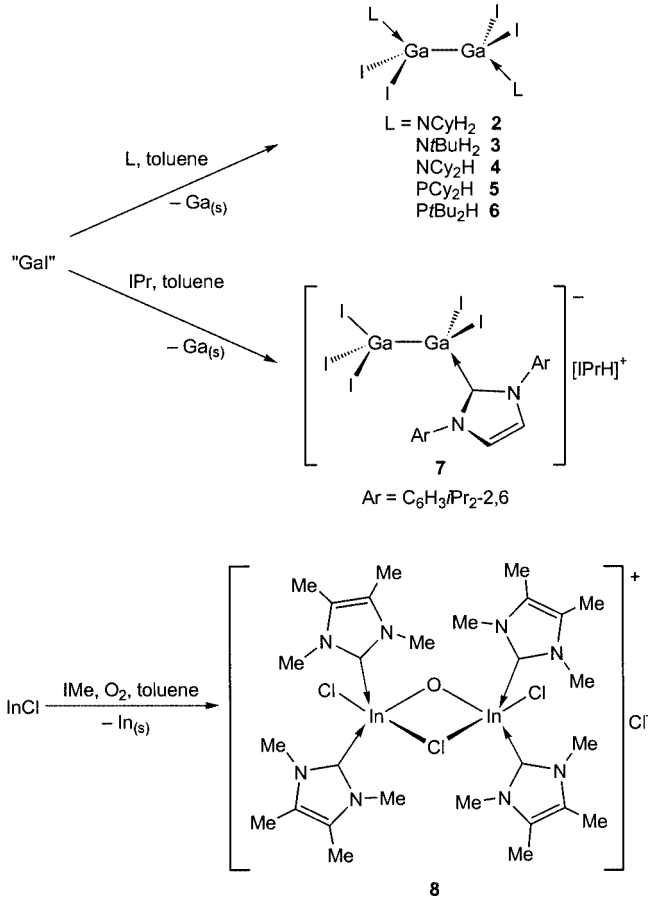

Scheme 1. Preparation of complexes **2**−**8**

The infrared spectra of all the amine complexes **2**−**4** display strong, broad N−H stretching absorptions in the expected region but the amine proton resonance was only observed in the ^{1}H NMR spectrum of **3**. The infrared spectra of **2**−**4** exhibit bands at 450, 453 and 409 cm^{-1} which have been assigned to Ga−N stretches from comparisons with related alkylgallium−amine adducts.[8] The infrared spectra of the secondary phosphane complexes **5** and **6** show P−H stretching bands at 2258 and 2353 cm^{-1}, respectively. In addition, their ^{31}P NMR spectra reveal doublet resonances with $^1J_{PH}$ coupling constants (**5**: 359 Hz; **6**: 351 Hz) of a significantly greater magnitude than those recorded for the free phosphanes (PCy_2H: 193 Hz; $PtBu_2H$: 198 Hz). A similar trend has been reported for secondary phosphane adducts of trialkylgallium compounds.[9] It should be noted that the reactions of several primary phosphanes, thiols and bulky alcohols with "GaI" were carried out but no tractable products could be obtained.

N-Heterocyclic Carbene Reactions

Due to the now well-known analogy between phosphanes and NHCs,[10] and given our previous preparation of [$In_2Br_4(IMes)_2$], it was thought worthwhile to examine the reactivity of a series of NHC ligands with "GaI". Unfortunately, success was only achieved with the reaction of the very hindered cyclic carbene IPr and "GaI" in toluene. Considerable gallium metal deposition was observed in this reaction and upon workup a good yield of the novel salt **7** resulted (Scheme 1). It is interesting that the nature of this product is different to that of the neutral complex [$In_2Br_4(IMes)_2$], but it seems likely that the imidazolium proton of the cation was abstracted from the solvent as this reaction is entirely reproducible in good yield, even when it is carried out under strictly anhydrous conditions. The fact that the anion of **7** contains only one coordinated carbene ligand, as opposed to the two cyclic carbene ligands in [$In_2Br_4(IMes)_2$], could be due to the greater bulk of the cylic carbene IPr and a lesser covalent radius of the metal atom in the former complex. It is also worth noting here that the formulation of "GaI" has been proposed to be $[Ga]_2[Ga_2I_6]$ based on Raman spectroscopic studies.[11] It is not inconceivable that the anion of **7** could be formed by displacement of one iodide ligand from the $[Ga_2I_6]^{2-}$ dianion of such a compound. The ^{1}H and ^{13}C NMR spectra of **7** show two sets of resonances which integrate in a 1:1 ratio and were assigned to the imidazolium cation and the cyclic carbene IPr coordinated to a gallium centre. The distinction between the two sets of resonances can be confidently made as the imidazolium cation has recently been structurally and spectroscopically characterised in the salt [IPrH][$InBr_4$].[12] The fact that sharp resonances were observed for both the imidazolium and carbene moieties over a range of temperatures suggests that the carbene ligand is strongly coordinated to the gallium centre and there is no carbene/imidazolium exchange occurring in this complex.

Reaction of the sterically less hindered cyclic carbene **:**CN(Me)C(Me)C(Me)N(Me) (IMe) with "GaI" also resulted in considerable gallium metal deposition, but only an inseparable mixture of unknown products formed. In contrast, the reaction of the same cyclic carbene with InCl afforded the unusual oxo-bridged dimer [{InCl(IMe)$_2$}$_2$(μ-Cl)(μ-O)][Cl] (**8**) in low yield (Scheme 1). This probably forms due to the presence of adventitious oxygen in the reaction mixture. Neither compound **8** nor any other product could be isolated or identified when the reaction was repeated under strictly anaerobic conditions. The spectroscopic data for **8** fully support its proposed structure; most notably an In−O stretch was observed at 335 cm^{-1} in its infrared spectrum. This is in good agreement with other examples in the literature.[13] No O−H stretching absorption could be seen in the same spectrum, which provides good evidence that there is no proton attached to the bridging oxygen centre.

Structural Studies

Crystals of **2**−**8** were grown from toluene solutions and the molecular structures of these compounds are depicted in Figures 1−7 (see also Tables 1 and 2). The five amine and phosphane complexes of Ga_2I_4, viz. **2**−**6**, display similar structural features in that their gallium centres all possess distorted tetrahedral environments and each

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[Ga_2I_4(L)_2]$ molecule exhibits a staggered conformation with respect to the Ga−Ga bond. A previous report has suggested that some geometrical parameters of complexes of the type $[Ga_2I_4(L)_2]$ can be used to gauge the relative Lewis basicity of the donor ligands L with respect to the Ga^{II} centres in these complexes.[3] Specifically, differences in gallium−gallium bond lengths and trends towards more sp^2-like geometries at the gallium centres, as evidenced by an increase in the I−Ga−I angle, were employed for this task. The complexes in the present study do not, however, appear to follow any trends (see Table 1). For example, the Ga−Ga bond lengths in **2**−**6** are all very similar [2.4243(9)−2.459 Å (av.)] despite incorporating a range of amine and phosphane ligands of variable basicity. In addition, the I−Ga−I angles in all complexes do not vary to any great degree. We believe, however, that a better indication of the degree of sp^2 character at each gallium centre can be gained from the sum of the I−Ga−I and Ga−Ga−I angles around them. In the five complexes studied here, these values range from 332.1 to 336.4°. Again, this range is too narrow to draw any firm conclusions on the basicity of the ligands involved. The Ga−P bond lengths in complexes **5** and **6** are similar to those in $[Ga_2I_4(PEt_3)_2]$ (2.413 Å) and $[Ga_2I_4(PPh_3)_2]$ (2.445 Å),[3] whilst the Ga−N distances in compounds **2**−**4** are close to those in the only known tertiary amine complex of gallium(II) iodide, namely $[Ga_2I_4(NEt_3)_2]$ (2.094 Å av.).[4]

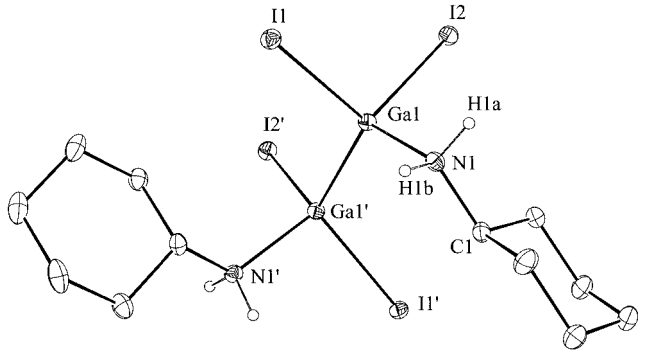

Figure 1. Molecular structure of **2**; symmetry operation: $' -x + 3/2, -y - 1/2, z$

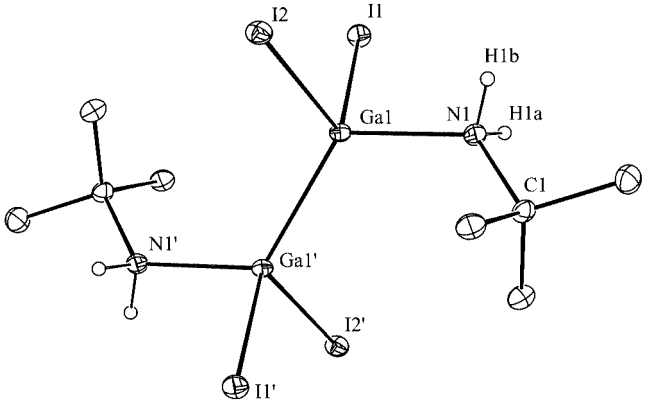

Figure 2. Molecular structure of **3**; symmetry operation: $' -x + 1, -y + 1, z$

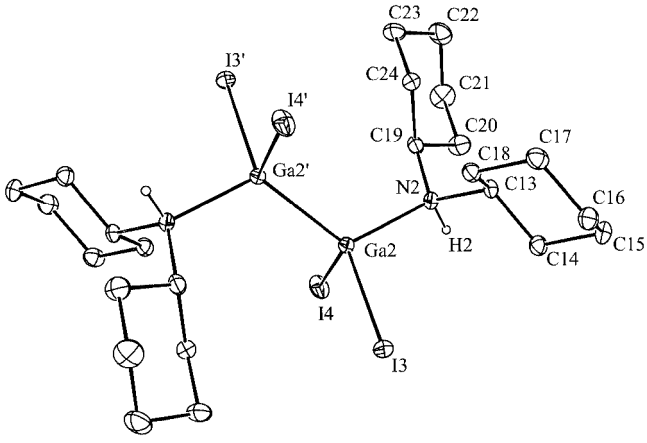

Figure 3. Molecular structure of **4**; symmetry operation: $' -x, -y + 1, -z$

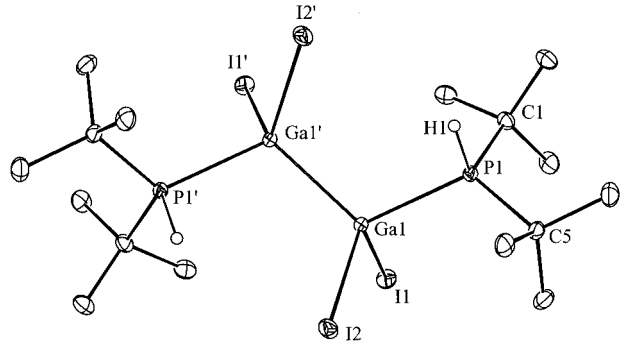

Figure 5. Molecular structure of **6**; symmetry operation: $' -x + 1, y, -z + 3/2$

The molecular structure of the anion of **7** is depicted in Figure 6. Both gallium centres have distorted tetrahedral coordination environments and the Ga−Ga distance [2.4739(12) Å] is slightly longer than any in **2**−**6**, and significantly longer than previously seen in the $[Ga_2I_6]^{2-}$ dianion, for example 2.413 Å in $[PPh_3H][Ga_2I_6]$.[14] All the Ga−I distances are similar to those in related systems, for example $[PPh_3H][Ga_2I_6]$, although the Ga−I bond lengths of the

ΣI−Ga−I and Ga−Ga−I	335.8	334.8	334.8 av.	336.4	332.1

GaI_3 fragment are slightly longer than those associated with the carbene-coordinated gallium centre. The metric parameters of the coordinated NHC ligand are similar to those seen in other group-13 complexes, such as $[InBr_3(IPr)]$,[12] and the Ga−C interaction is similar to those in NHC−Ga(III) complexes, cf. 2.077 Å (av.) in $[GaH_3\{CN(i\text{Pr})C_2Me_2N(i\text{Pr})\}]$.[15]

The crystal structure of the cationic component of **8** is shown in Figure 7. The indium atoms both have distorted trigonal-bipyramidal coordination environments whilst the four-membered In_2ClO ring is essentially flat (In−Cl−In−O torsion angle 0.7°). The average In−C bond of 2.227 Å is similar to that found in the complex $[InH_3(IMes)]$ [2.250(10) Å].[16] Interestingly, both the terminal and bridging In−Cl bonds (2.567 Å av. and 2.872 Å av., respectively) are considerably longer than the norms for such bonds (2.45 and 2.59 Å)[17] and indeed, the bridging Cl^- ligand can be thought of as only having an interaction with the indium centres. The acuteness of the In−Cl−In angle [78.54(5)°] adds weight to this proposal. This situation most likely arises from the fact that each indium centre is coordinated by two highly nucleophilic NHC ligands, which weaken the bonds from the other ligands to these metal centres.

Conclusions

In conclusion, we have shown that "GaI" reacts with a range of primary and secondary amine and secondary phosphane ligands to give adducts of the type $[Ga_2I_4(L)_2]$ (L = Lewis base), which are formed by disproportionation reactions. A range of these complexes have been crystallographically characterised, as have the products from the related reactions of N-heterocyclic carbenes with either "GaI" or InCl. We believe that complexes of the type **2**−**6**

have significant potential for use as precursors in the formation of heterocyclic and cage compounds containing low oxidation state Ga centres. To this end we are currently examining their reactivity towards a number of strong bases in the expectation that HI abstraction will occur. Our efforts in this area will be reported in a forthcoming publication.

Experimental Details

General Remarks: All manipulations were carried out using standard Schlenk and glove-box techniques under high-purity argon. Toluene was distilled from potassium whilst CH_2Cl_2 was distilled from CaH_2 then freeze/thaw-degassed prior to use. ^{1}H and ^{13}C NMR spectra were recorded with a Bruker DXP400 spectrometer and are referenced to the residual ^{1}H or ^{13}C resonances of the solvent used. ^{31}P NMR spectra were recorded with a Jeol Eclipse 300 spectrometer and are referenced to 85% H_3PO_4. APCI mass spectra were recorded using a VG Fisons Platform II instrument. FAB mass spectra were recorded by the EPSRC National Mass Spectrometric Service at Swansea University. IR spectra were recorded using a Nicolet 510 FT-IR spectrometer as Nujol mulls between CsI plates. Melting points were determined in sealed glass capillaries under argon and are uncorrected. Reproducible microanalyses were not obtained on any of the crystallographically characterised complexes because of the presence of solvent of crystallisation and/or the air-sensitive nature of these complexes. In all cases, however, the spectroscopic data pointed to the bulk materials having a purity of greater than 98%. "GaI'' was synthesised by a variation of the literature method[7] as were the cyclic carbenes IPr[18] and IMe.[19] All other chemicals were obtained commercially and used as received. Compounds **2**−**6** were prepared by the general procedure outlined below.

[$Ga_2I_4(NCyH_2)_2$] (2): GaI was synthesised by sonicating Ga (0.343 g, 4.92 mmol) and I_2 (0.62 g, 2.45 mmol) in toluene (10 mL) at 50 °C for approx. 2 h. The resulting green suspension was cooled to −78 °C and a solution of $NCyH_2$ (1.12 mL, 9.8 mmol) in toluene (5 mL) added to it over 5 min. The reaction mixture was warmed to room temperature and stirred for 12 h to give a brown solution and a precipitate of Ga metal. Filtration, concentration in vacuo and placement at −30 °C overnight yielded colourless crystals of **2** (0.38 g, 36%). M.p. 255−258 °C (dec). ^{1}H NMR (400 MHz, C_6D_6, 300 K): δ = 1.16 (m, 8 H, CH_2), 1.69 (m, 8 H, CH_2), 2.03 (m, 4 H, CH_2), 2.94 (m, 2 H, CH) ppm; NH_2 resonance not observed. ^{13}C NMR (100.6 MHz, C_6D_6, 300 K): δ = 35.6, 25.4, 24.9 (CH_2), 51.4 (CH) ppm. IR (Nujol): $\tilde{\nu}$ = 3427 (br.), 1940 (br.), 1463 (sh), 1377 (sh), 1260 (sh), 1087 (br.), 1017 (br.), 956 (m), 888 (w), 799 (s), 723 (m), 584 (w), 534 (w), 467 (m), 450 (m), 377 (br.), 331 (m). MS APCI: *m*/*z* (%) = 83 (100) [Cy^+], 100 (40) [$CyNH_3^+$], 268 (10) [Ga_2I^+].

[$Ga_2I_4(NtBuH_2)_2$] (3): Yield 48%. M.p. 161−164 °C (dec). ^{1}H NMR (400 MHz, C_6D_6, 300 K): δ = 1.17 (s, 18 H, *t*Bu), 8.52 (br., 4 H, NH_2) ppm. ^{13}C NMR (100.6 MHz, C_6D_6, 300 K): δ = 27.8 [$C(CH_3)_3$], 53.1 [$C(CH_3)_3$] ppm. IR (Nujol): $\tilde{\nu}$ = 3236 (sh), 3176 (sh), 1554 (sh), 1463 (s), 1374 (s), 1277 (m), 1257 (m), 1197 (w), 1163 (m), 1101 (br.), 1016 (w), 820 (m), 801 (m), 733 (m), 681 (m), 596 (br.), 453 (br.), 371 (w) cm^{-1}. MS FAB: *m*/*z* (%) = 57 (100) [tBu^+], 74 (24) [$tBuNH_3^+$].

[$Ga_2I_4(NCy_2H)_2$] (4): Yield 95%. M.p. 215−217 °C (dec). ^{1}H NMR (400 MHz, C_6D_6, 300 K): δ = 1.05 (m, 16 H, CH_2), 1.70 (m, 16 H, CH_2), 1.95 (m, 8 H, CH_2), 3.30 (m, 4 H, CH) ppm; NH resonance not observed. ^{13}C NMR (100.6 MHz, C_6D_6, 300 K): δ = 23.8, 23.9, 32.2 (CH_2), 57.7 (CH) ppm. IR (Nujol): $\tilde{\nu}$ = 3427 (w), 1453 (s), 1376 (s), 1260 (m), 1162 (w), 1122 (m), 1081 (s), 1028 (m), 960 (m), 916 (w), 895 (w), 800 (m), 715 (m), 409 (br.) cm^{-1} . MS FAB: *m*/*z* (%) = 182 (100) [Cy_2NH^+], 648 (8) [Ga_2I_2].

[$Ga_2I_4(PCy_2H)_2$] (5): Yield 41%. M.p. 78−81 °C (dec). ^{1}H NMR (400 MHz, C_6D_6, 300 K): δ = 1.10 (m, 16 H, CH_2), 1.62 (m, 16 H, CH_2), 2.09 (m, 8 H, CH_2), 2.59 (m, 4 H, CH), 4.45 (d, $^1J_{P-H}$ = 359 Hz, 2 H, PH) ppm. ^{13}C NMR (100.6 MHz, C_6D_6, 300 K): δ = 25.2 (d, $J_{P,C}$ = 13 Hz, CH_2), 27.1 (d, $^3J_{P,C}$ = 12 Hz, CH_2), 29.8 (d, $^4J_{P,C}$ = 8 Hz, CH_2), 32.2 (d, $^1J_{P,C}$ = 18 Hz, CH) ppm. ^{31}P{^{1}H} NMR (101.6 MHz, C_6D_6, 300 K): δ = −27.5 (s) ppm. IR (Nujol): $\tilde{\nu}$ = 2258 (m), 1448 (s), 1377 (s), 1349 (w), 1327 (w), 1295 (m), 1264 (m), 1202 (w), 1180 (w), 1117 (br.), 1002 (br.), 888 (m), 854 (w), 791 (m), 727 (w), 502 (br.), 381 (br.) cm^{-1} . MS FAB: *m*/*z* (%) = 197 (45) [$PCy_2H_2^+$]

[$Ga_2I_4(PtBu_2H)_2$] (6): Yield 54%. M.p. 137−140 °C (dec). ^{1}H NMR (400 MHz, C_6D_6, 300 K): δ = 1.26 (d, $^3J_{P-H}$ = 15 Hz, 36 H, *t*Bu);

4.92 (d, $^1J_{P-H}$ = 351 Hz, 2 H, PH) ppm. ^{13}C NMR (100.6 MHz, C_6D_6, 300 K): δ = 21.2 [C(CH_3)$_3$], 53.1 (d, $^1J_{P,C}$ = 10 Hz C(CH_3)$_3$] ppm. ^{31}P{^{1}H} NMR (101.6 MHz, C_6D_6, 300 K): δ = −9.04 (s) ppm. IR (Nujol): $\tilde{\nu}$ = 2353 (w), 1459 (s), 1376 (s), 1260 (m), 1162 (w), 1086 (m), 1021 (m), 936 (w), 870 (w), 803 (m), 727 (s), 694 (m), 555 (w), 462 (br.), 383 (br.), 323 (m) cm^{-1}. MS FAB: *m*/*z* (%) = 57 (100) [*t*Bu], 793 (4) [M$^+$ − PH*t*Bu$_2$].

[Ga_2I_5(IPr)][IPrH] (7): GaI was synthesised by sonicating Ga (0.125 g, 1.79 mmol) and I_2 (0.22 g, 0.88 mmol) in toluene (10 mL) at 50 °C for approx. 2 h. The resulting green suspension was cooled to −78 °C and a solution of the cyclic carbene IPr (0.69 g, 1.79 mmol) in toluene (20 mL) added to it over 5 min. The reaction mixture was warmed to room temperature and stirred for 12 h to give a brown solution and a precipitate of Ga metal. Filtration, concentration in vacuo and placement at −30 °C overnight yielded colourless crystals of **7** (0.36 g, 42%). M.p. 238−242 °C (dec). ^{1}H NMR (400 MHz, CD_2Cl_2, 300 K): δ = 1.10 (d, $^3J_{HH}$ = 7 Hz, 12 H, CH_3, cation), 1.21 (d, $^3J_{H,H}$ = 7 Hz, 12 H, CH_3, cation), 2.33 [sept, $^3J_{H,H}$ = 7 Hz, 4 H, CH(CH_3)$_2$, cation], 7.31 (d, $^3J_{H,H}$ = 8 Hz, 4 H, *m*-CH, cation), 7.54 (t, $^3J_{H,H}$ = 8 Hz, 2 H, *p*-CH, cation), 7.99 (s, 2 H, NC_2H_2N, cation), 8.42 (s, 1 H, NCHN, cation), 1.00 (d, $^3J_{H,H}$ = 7 Hz, 12 H, CH_3, anion), 1.36 (d, $^3J_{H,H}$ = 7 Hz, 12 H, CH_3, anion), 2.68 [sept, $^3J_{H,H}$ = 7 Hz, 4 H, CH(CH_3)$_2$, anion], 7.26 (d, $^3J_{H,H}$ = 8 Hz, 4 H, *m*-CH, anion), 7.40 (t, $^3J_{H,H}$ = 8 Hz, 2 H, *p*-CH, anion), 7.99 (s, 2 H, NC_2H_2N, anion) ppm. ^{13}C NMR (100.6 MHz, CD_2Cl_2, 300 K): δ = 23.7, 25.7 (CH_3, cation), 29.1 [C(CH_3)$_2$, cation], 124.9 (*p*-Ar, cation), 125.2 (*m*-Ar, cation), 132.4 (*o*-Ar, cation), 134.7 (*ipso*-Ar, cation), 145.1 (NCHN, cation), 145.7 (NC_2H_2N, cation), 23.9, 24.5 (CH_3, anion), 28.8 [CH(CH_3)$_2$, anion], 125.0 (*p*-Ar, anion), 127.0 (*m*-Ar, anion), 131.1 (*o*-Ar, anion), 136.1 (*ipso*-Ar, anion), 146.1 (NC_2H_2N, anion) ppm. IR (Nujol): $\tilde{\nu}$ = 2853 (br.), 1526 (m), 1455 (s), 1372 (s), 1260 (m), 1096 (s), 1055 (s), 1014 (s), 799 (s), 748 (m), 722 (m), 686 (w), 625 (w), 507 (w), 461 (w), 392 (br.), 305 (w), 289 (w), 245 (w) cm^{-1}. MS FAB: *m*/*z* (%) = 389 (100) [IPrH$^+$], 909 (61) [Ga_2I_3(IPr)$^+$]

[{InCl(IMe)$_2$}$_2$(μ-Cl)(μ-O)][Cl] (8): A solution of the cyclic carbene IMe (0.66 g, 5.31 mmol) in toluene (10 mL) was added to a suspension of InCl (0.40 g, 2.66 mmol) in toluene (10 mL) held at −78 °C. The reaction mixture was stirred for 4 h during which time indium metal deposition was observed. The resulting suspension was filtered and volatiles removed from the filtrate in vacuo. The yellow residue was extracted with CH_2Cl_2 (2 × 5 mL). Concentration to ca. 5 mL and the addition of toluene (2 mL) followed by placement at −30 °C overnight yielded colourless crystals of **8** (0.37 g, 16%). M.p. 155−158 °C (dec). ^{1}H NMR (400 MHz, CD_2Cl_2, 300 K): δ = 2.11 (s, 24 H, CMe), 3.64 (s, 24 H, NMe) ppm. ^{13}C NMR (100.6 MHz, CD_2Cl_2, 300 K): δ = 8.14 (s, CMe), 34.62 (s, NMe) ppm. IR (Nujol): $\tilde{\nu}$ = 2919 (s), 2852 (s), 1634 (m), 1598 (m), 1588 (m), 1470 (sh), 1372 (s), 1250 (sh), 1081 (s), 1034 (s), 891 (w), 850 (w), 799 (m), 727 (sh), 688 (sh), 563 (m), 533 (m), 461 (sh), 392 (br.), 335 (s), 289 (w) cm^{-1}. MS FAB: *m*/*z* (%) = 125 (100) [IMeH$^+$].

Structure Determinations: Crystals of **2**−**8** suitable for X-ray structural determination were mounted in silicone oil. Crystallographic measurements were made using a Nonius Kappa CCD diffractometer. The structures were solved by direct methods and refined on F^2 by full-matrix least squares (SHELX97)[20] using all unique data. All non-hydrogen atoms are anisotropic with H atoms included in calculated positions (riding model). The structure of **4** contains two crystallographically independent monomeric moieties in the asymmetric unit. The geometries of the dimeric units generated from these are not significantly different and thus the ORTEP diagram of only one is shown in Figure 3. The geometrical parameters for **4** in Table 1 are, however, an average of those in the two molecules. Crystal data, details of data collections and refinement are given in Table 2. The molecular structures of the complexes are depicted in Figures 1−7 and show thermal ellipsoids set at the 30% probability level. CCDC-203134 (**2**), -203135 (**3**), -203136 (**4**), -203137 (**5**), -203138 (**6**), -203139 (**7**) and -203140 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

A New Thioether-Based (N_2S_2)Copper(II/I) Complex Exhibiting a High Redox Potential

Stéphane Torelli,[a] Catherine Belle,*[a] Christian Philouze,[a] Jean-Louis Pierre,[a] Wassim Rammal,[a] and Eric Saint-Aman[b]

Keywords: S ligands / N ligands / Tripodal ligands / Copper / Redox chemistry

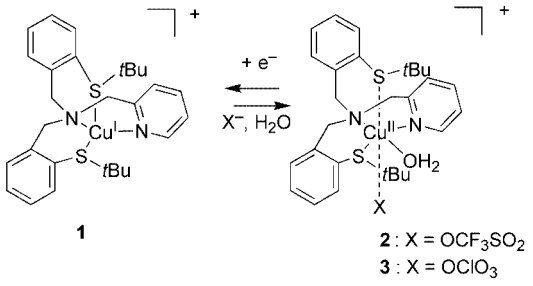
From the new ligand bis[2-(*tert*-butylthio)benzyl](2-pyridylmethyl)amine [$N_2(StBu)_2$], the corresponding complexes [$Cu^I\{N_2(StBu)_2\}$]CF_3SO_3 (**1**) and [$Cu^{II}\{N_2(StBu)_2\}$](H_2O)(CF_3SO_3)]CF_3SO_3 (**2**) were synthesized and characterized by X-ray crystallography. The Cu–S bonds are unusually shortened in **1** and elongated for the axial thioether in **2**. Redox studies show that **1** and **2** interconvert during the electron transfer with a high $Cu^{II/I}$ potential of 0.79 V vs. SCE in CH_2Cl_2.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Blue (type 1) copper proteins involved in electron-transfer processes have, in their active site, a single Cu atom bound to two histidine nitrogen atoms and to one cysteine thiolate group.[1,2] One additional axial thioether ligand (of methionine) is usually found in the coordination sphere of the copper ion (e.g plastocyanin[3] or azurin[4,5]). The positive $Cu^{II/I}$ redox potential, found in the range of 0.2−0.8 V vs. NHE,[1] has long held the interest of bioinorganic chemists. Model complexes, described by Kitajima[6] and more recently by Tolman,[7] present structural and spectroscopic features close to those of the type 1 site, but significant differences in electrochemical properties are observed. Synthetic copper complexes, for which both Cu^{II} and Cu^{I} structures are available, could provide information about the structure/redox properties relationships.[8−10]

We present herein the preparation and characterization, in both the Cu^{I} and Cu^{II} oxidation states, of a copper complex from a new tripodal N_2S_2 donor ligand (Scheme 1). The $Cu^{II/I}$ redox potential is as high as that found in blue copper proteins. We focused our attention on the role of the thioether ligand; few structurally characterized Cu^{II} and Cu^{I} complexes involving a long axial Cu−S(thioether) bond have been studied electrochemically.[11,12]



Scheme 1

Results and Discussion

By adding 1 equiv. of $Cu(CF_3SO_3)$, $Cu(CF_3SO_3)_2$ or $Cu(ClO_4)_2{\cdot}6H_2O$ to the ligand $N_2(StBu)_2$ {bis[2-(*tert*-butylthio)benzyl](2-pyridylmethyl)amine}, the Cu^{I} (**1**) and Cu^{II} (**2** and **3**) complexes were obtained (Scheme 1).

The X-ray structures of the cationic units are depicted in Figures 1 (for **1** and **2**) and 2 (for **3**). Selected bond lengths and angles are reported in Table 1.

The structure of **1** (Figure 1, A) shows a copper(I) center in a distorted tetrahedral geometry. The Cu−S distances in **1** are similar [Cu−S1 = 2.2421(7) Å and Cu−S2 = 2.2492(7) Å], although shorter than the usual $Cu^{I}-SR_2$ bond of 2.33(9) Å.[10]

The X-ray crystal structure of **2** reveals an elongated octahedral complex for the Cu^{II} redox state (Figure 1, B). Two nitrogen atoms, a thioether group and the water molecule are in the equatorial plane [a deviation of 0.007(3) Å from the mean plane for the copper atom is observed]. Two axial groups complete the octahedron: one S*t*Bu [Cu−S = 2.758(1) Å] and one oxygen atom of a CF_3SO_3 anion

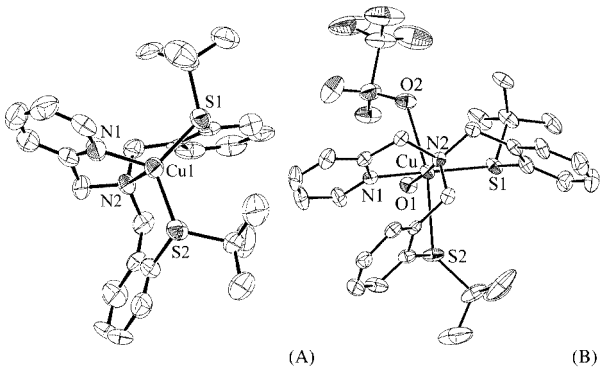

Figure 1. ORTEP view showing 50% displacement ellipsoids with partial atomic labeling for the cation (A) $[Cu^{I}(N_2(StBu)_2]^+$ of **1** and (B) $[Cu^{II}\{N_2(StBu)_2\}(H_2O)(CF_3SO_3)]^+$ of **2**; hydrogen atoms have been omitted for clarity

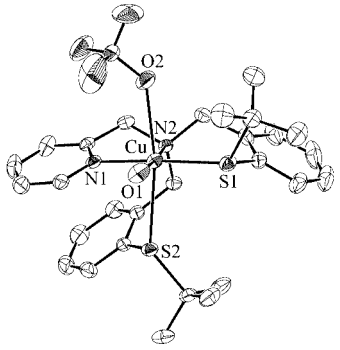

Figure 2. ORTEP view showing 50% displacement ellipsoid with partial atomic labeling for the cation $[Cu^{II}\{N_2(StBu)_2\}(H_2O)(ClO_4)]^+$ of **3**; hydrogen atoms have been omitted

[Cu−O = 2.457(3) Å] at semi-coordinating distances. Interestingly, **2** involves both an equatorial Cu−S(thioether) bond [2.354(1) Å], shorter than usual $Cu^{II}-SR_2$ bond lengths of 2.42 Å,[10] and one much longer axial Cu−S(thioether) bond [2.758(1) Å].

Complex **3** was obtained in a similar manner to complex **2** using $Cu(ClO_4)_2{\cdot}6H_2O$ as the metallic salt. The coordination sphere of the copper center in **3**, as in **2**, is described by an octahedral geometry (see Figure 2) with an oxygen atom of the perchlorate anion coordinated in an axial position. The structural data for the molecular entity **3** is close to that of **2** (see Table 1), except that the axial distances are longer in **3** [Cu−S*t*Bu = 2.822(1) Å and Cu−O = 2.546(3) Å] than in **2**.

Such an octahedral coordination with unequal Cu^{II}−S(thioether) bond lengths is unusual and has only been reported in complexes of non-tripodal ligands.[13,14]

The Cu−S distances in **2** (or **3**) can be compared to those found for the oxidized azurin,[4,5] characterized by two axial groups, an S(thioether) atom and a carbonyl oxygen atom of Gly45 in weak interaction with a copper(II) ion (near 3.1 Å). The equatorially bound S(thiolate) ligand (Cys) is 2.12 Å apart from the copper ion.

In CH_2Cl_2, the UV/Vis spectrum of **2** is characterized by a band at 345 nm ($\varepsilon \approx 2250\ M^{-1}{\cdot}cm^{-1}$) assigned to the S(thioether)→Cu^{II} LMCT band and a copper(II) d−d transition at 721 nm ($\varepsilon \approx 130\ M^{-1}{\cdot}cm^{-1}$).[15] In ethanolic solution, the LMCT band appears at 332 nm ($\varepsilon \approx 2180\ M^{-1}{\cdot}cm^{-1}$) and the d−d band is shifted up to 685 nm ($\varepsilon \approx 70\ M^{-1}{\cdot}cm^{-1}$). The changes observed in the UV/Vis spectra suggest the displacement of at least one ligand by a solvent molecule in the copper coordination sphere. In a frozen

solution of CH_2Cl_2/toluene (1:1) at 100 K, **2** displays a typical axial EPR spectrum (Figure 3, A), in agreement with the X-ray structure, with $g_{\|} = 2.19$, $g_{\perp} = 2.04$, $A_{\|} = 181 \times 10^{-4}$ cm^{-1}. In EtOH/toluene (1:1), two sets of overlapping signals centered at roughly $g_{1\|} = 2.17$, $A_{1\|} = 176 \times 10^{-4}$ cm^{-1} and $g_{2\|} = 2.29$, $A_{2\|} = 171 \times 10^{-4}$ cm^{-1} are observed (Figure 3, B). These features indicate that solvent molecules are involved in the coordination sphere of the metal center, giving rise to the formation of a mixture of complexes.

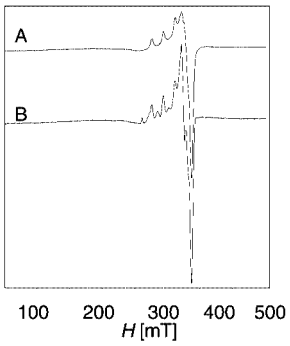

Figure 3. EPR spectrum at 100 K of **2**, at a microwave frequency of 9.419 GHz as a frozen solution, 3 mM in (A) CH_2Cl_2/toluene (1:1, v/v); (B) EtOH/toluene (1:1, v/v)

Thus, the electrochemical behaviors of **1** and **2** have been examined in coordinating solvents (MeOH or EtOH) and in a noncoordinating solvent (CH_2Cl_2) by CV and RDE experiments. In CH_2Cl_2 + TBAP (0.1 M) solution, the same CV features were found starting either from isolated **1** or from isolated **2**, i.e. compound **2** is the final product of the oxidation of **1** and vice versa (Scheme 1). The CV curve is characterized by a pair of peaks whose potentials depend strongly on the scan rate: their peak-to-peak separation increases from 0.21 V at 5 mVs^{-1} to 1.07 V at 5 Vs^{-1} (Figure 4). At low scan rates, E_{pa} and E_{pc} tend towards constant values of 0.41 V and 0.20 V vs. Fc/Fc$^+$. The RDE wave recorded in a CH_2Cl_2 solution of **1** is characterized by $E_{1/2} = 0.54$ V ($N = 600$ rpm).

Upon exhaustive potentiostatic electrolysis at 0.75 V (one exchanged electron), the RDE wave recorded in the resulting solution (Figure 4) matches well with that recorded in an electrolytic solution of **2**, $E_{1/2} = 0.14$ V ($N = 600$ rpm). Additionally, the UV/Vis features of both solutions are very close. The starting solution is fully restored upon further exhaustive reduction at −0.2 V. It can be seen that the anodic and cathodic $E_{1/2}$ values determined from RDE experiments performed in solution of **1** or **2** are different.

These results can be analyzed as the simple one-electron transfer depicted in Scheme 1. Simulations of the experimental CV curves allowed the determination of the apparent formal potential and the apparent heterogeneous electron-transfer rate constant of the overall mechanism: $E_{1/2} = 0.30 \pm 0.01$V and $k^0 = 2.0 \pm 0.9 \times 10^{-4}$ cm s^{-1}. The low value of k^0 suggests that the overall electrochemical mechanism involves coupled chemical reactions, i.e. the electron

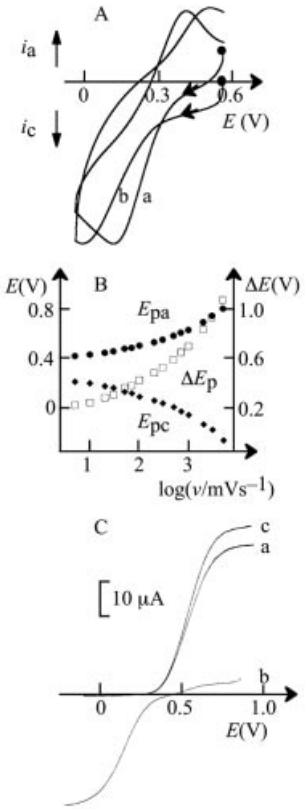

Figure 4. Voltammetric curves of **2** (A) and **1** (C), 1.2 mM, recorded in CH_2Cl_2 + TBAP (0.1 M), WE: glassy carbon ($\phi = 3$ mm), E vs. Fc/Fc$^+$; (A) CV at 0.03 (curve a) and 0.3 Vs^{-1} (curve b), normalized current vs. E; (B) anodic (E_{pa}), cathodic (E_{pc}) peak potential and peak-to-peak (ΔE_p) separation vs. scan rate; (C) RDE voltammetry, $N = 600$ rpm, initial (curve a), after oxidative electrolysis (0.8 exchanged electron, curve b), after re-reduction (curve c, the increase in the limiting current between curves a and c is due to a partial evaporation of CH_2Cl_2)

transfer implies changes in coordination and geometry during the redox cycle. The overall mechanism can thus be best described by the classic square scheme[2] in which the electron-transfer steps are followed by coordinate bond formations (or ruptures) accounting for the change in the coordination mode of the copper center according to its redox state, i.e. the electron transfer leads to an unstable intermediate which undergoes a fast rearrangement to yield the stable corresponding complex. Due to their very fast kinetics, the electroactivity of the intermediates could not be seen on the CV curves, the anodic and cathodic processes remaining electrochemically irreversible, even at high scan rate (10 Vs^{-1}). This precluded any precise determination of the kinetic constants by electrochemical simulations.

Intervention of a coupled chemical reaction is further confirmed by examining the electrochemical response of **1** or **2** in coordinating solvents. In an electrolytic EtOH solution of **2**, when scanning towards negative potentials (0.1 Vs^{-1}), the CV curve displays a main cathodic peak at $E_{pc} = 0.14$ V and a peak of low intensity at $E_{pc} = -0.15$ V. On the reverse scan, only one anodic peak is seen at $E_{pa} = 0.38$ V (Figure 5). After an exhaustive reduction/re-oxidation cy-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cle, the final CV curve displays the same signals but with different intensities (Figure 5). This results in an ill-behaved RDE wave for **2** characterized by an apparent $E_{1/2}$ = 0.23 V (N = 600 rpm), while a more resolved RDE wave for **1** is seen at apparent $E_{1/2}$ = 0.35 V (N = 600 rpm). It can be assumed that in coordinating solvents, solvent molecules are involved in the coordination sphere of the metal center giving rise to the formation of different complexes in equilibrium [as previously observed in UV/Vis and EPR spectra measured in ethanol (see above)].

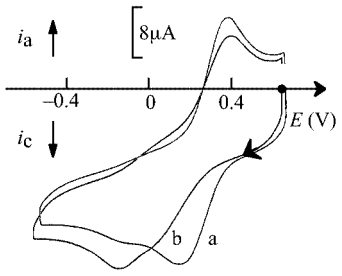

Figure 5. CV curves of **2**, 1.1 mM, recorded in EtOH + TBAP (0.1 M), WE: glassy carbon (ϕ = 3 mm), E vs. Fc/Fc^+, v = 0.1 Vs^{-1}; curve (a): initial; curve (b): after an oxidation/reduction cycle

Taking into account $E_{1/2}$ (Fc/Fc^+) = 0.49 V or 0.44 V vs. SCE, in CH_2Cl_2 or EtOH respectively, under our experimental conditions, the **1/2** electrochemical system presents a very high redox potential, similar to that of blue copper proteins (a value of 0.78 V vs. NHE is reported for fungal laccase).[16] As a consequence, whereas **1** is stable in CH_2Cl_2 or alcohol solution, **2** is partially reduced to the Cu^I state even in the presence of air (40% of Cu^{II} is reduced after 1 d in ethanol). High redox potential values have been reported for a few small $Cu^{II/I}$ molecular systems[17] but are rare for related copper systems involving tripodal ligands.[18,19] Compared to other redox couples involving tripodal N_2S_2 ligands, the **1/2** electrochemical system described herein displays a shift towards higher potentials by 0.2 V.[10]

Conclusion

The high redox potential of the **1/2** couple could result from a combination of: (i) the lower donating character of the aromatic thioether group compared to an aliphatic thioether group, (ii) the stabilization of the Cu^I redox state, as judged from the short Cu^I-SR_2 bonds, (iii) the long axial $Cu^{II}-SR_2$ bond leading to a weaker interaction, likely to be due to (iv) the geometric constraint afforded by the *t*Bu group. The present study may provide insights into the electron-transfer mechanism of the blue copper proteins. Further studies are in progress to understand the relationship between the subtle changes of the ligand and the deep changes induced in the redox properties of the related complexes.

Experimental Section

General: All chemicals were obtained from commercial sources and used as received. Solvents were purified by standard methods before use. ***Caution:*** Although no problems were encountered during the preparation of perchlorate salts, suitable care should be taken when handling such potentially hazardous compounds.

Spectrometry: Fast-atom bombardment (FAB) mass spectra in the positive mode were recorded with a Nermag R 1010C apparatus equipped with an M scan (Wallis) atom gun (8 kV, 20 mA). ESI mass spectra were obtained with a Bruker Esquire 3000 plus spectrometer with an ion trap. UV/Vis spectra were recorded using a Perkin−Elmer Lambda 2 spectrophotometer equipped with 1.0-cm matched quartz cells and operating in the range 200−900 nm; ε values are given in $M^{-1}\cdot cm^{-1}$. ^1H and ^{13}C NMR spectra were recorded with a Bruker Avance 300 spectrometer and a Bruker AC 200; chemical shifts (ppm) were referenced to residual solvent peaks. EPR spectra were recorded at 100 K with a Bruker ESP 300 spectrometer operating at 9.4 GHz (X-band), with 3 mM solutions.

Electrochemistry: Electrochemical experiments were carried out using a PAR model 273 potentiostat equipped with a Kipp-Zonen x-y recorder. All experiments were run at room temperature under argon. A standard three-electrode cell was used, with 0.1 M tetra-*n*-butylammonium perchlorate (TBAP) as supporting electrolyte. All potentials are referred to the regular Fc/Fc^+ redox couple used as internal reference. Vitreous carbon disc electrodes for cyclic voltammetry (CV) (5 mm diameter) and rotating disc electrode (RDE) (3 mm diameter) were polished with 1 μm diamond paste.

[2-(*tert*-Butylthio)benzyl](2-pyridylmethyl)amine: A solution of (2-pyridylmethyl)amine (477 μL, 4.54 mmol) in dry MeOH (10 mL) was added at room temperature to a solution of 2-(*tert*-butylthio)benzaldehyde (1 g, 5 mmol) in dry MeOH (100 mL) under Ar. After 3 h, $NaBH_4$ (455 mg, 11.5 mmol) was slowly added as a solid and the mixture stirred for an additional 2 h. After acidic treatment (HCl, 4 N), the solvent was removed under reduced pressure. The resulting product was dissolved in H_2O (50 mL) and extracted with CH_2Cl_2 to remove the excess of reduced aldehyde. The aqueous solution was then neutralized with saturated $NaHCO_3$ and extracted with CH_2Cl_2 (2 × 100 mL). The combined organic layers were washed with saturated NaCl, dried with Na_2SO_4 and concentrated under reduced pressure to give a brown oil. Yield: 1.2 g (91%). ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 8.51 (d, J = 4.8 Hz, 1 H, Py-*H*), 7.51−7.63 (m, 3 H, Py-*H*), 7.07−7.36 (m, 4 H, Ar-*H*), 4.11 (s, 2 H, NCH_2Ar), 3.92 (s, 2 H, NCH_2Py), 3.02 (s, 1 H, N*H*), 1.25 (s, 9 H, *t*Bu) ppm. ^{13}C NMR (50 MHz, $CDCl_3$, TMS): δ = 159.3, 148.9, 144.3, 138.5, 136.0, 131.8, 129.4, 128.8, 126.7, 122.0, 121.6, 54.0, 51.6, 46.9, 30.8 ppm. FAB+ MS: m/z = 286 [$M^+ + H^+$]. $C_{17}H_{21}N_2S$ (285): calcd. C 67.80, H 7.58, N 9.44, S 11.86; found C 68.00, H 7.74, N 9.78, S 11.19.

Bis[2-(*tert*-butylthio)benzyl](2-pyridylmethyl)amine [$N_2(StBu)_2$]: 2-(*tert*-Butylthio)benzaldehyde (847 mg, 4.23 mmol) and glacial acetic acid (878 μL, 15.36 mmol) were added to a solution of [2-(*tert*-butylthio)benzyl](2-pyridylmethyl)amine (1.1 g, 3.84 mmol) in dry MeOH (100 mL) under Ar. After 1 h, $NaBH_3CN$ (1.016 g, 15.36 mmol) was added and the mixture stirred overnight. Then, an acid treatment (HCl, 4 N) was performed and the solvent was removed under reduced pressure. The resulting product was dissolved in H_2O and extracted with CH_2Cl_2 to remove the excess of reduced aldehyde. The aqueous solution was neutralized with saturated $NaHCO_3$ and extracted with CH_2Cl_2 (2 × 100 mL). The combined organic layers were washed with saturated NaCl, dried

with Na_2SO_4 and concentrated under reduced pressure. Addition of pentane afforded the product as a pale beige powder. Yield: 1.2 g (68%), m.p. 95 °C. ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 8. 53 (d, *J* = 4.8 Hz, 1 H, Py-*H*), 7.50−7.60 (m, 3 H, Py-*H*), 7.07−7.36 (m, 8 H, Ar-*H*), 4.15 (s, 4 H, NCH_2Ar), 3.92 (s, 2 H, NCH_2Py), 1.25 (s, 18 H, *t*Bu) ppm. ^{13}C NMR (50 MHz, $CDCl_3$, TMS): δ = 160.6, 148.9, 145.0, 139.0, 136.5, 132.7, 129.1, 129.6, 126.6, 122.9, 121.9, 60.7, 57.0, 47.3, 31.3 ppm. FAB+ MS: *m*/*z* = 465 [M^+ + H^+]. $C_{28}H_{36}N_2S_2$ (464): calcd. C 71.86, H 7.88, N 5.92, S 13.68; found C 72.37, H 7.81, N 6.03, S 13.80.

[Cu^{I}{N$_2$(S*t*Bu)$_2$}](CF$_3$SO$_3$) (1): Copper(I) trifluoromethanesulfonate (0.230 g, 0.43 mmol, toluene complex) was added to a solution of N$_2$(S*t*Bu)$_2$ (0.2 g, 0.43 mmol) in CH_2Cl_2 (20 mL). The solution was stirred for 10 min and diethyl ether added (10 mL). After 24 h, **1** was obtained as a polycrystalline pale powder. Yield: 65% (0.188 g). Crystals of **1** suitable for X-ray crystallography were obtained by layering hexane onto a CH_2Cl_2 solution of **1**. ESI MS: *m*/*z* = 527 [N$_2$(S*t*Bu)$_2$ + 1 Cu^+]. ^{1}H NMR (300 MHz, CD_3CN, TMS): δ = 8. 68 (d, *J* = 4.7 Hz, 1 H, Py-*H*), 7.79 (t, *J* = 7.0 Hz, 1 H, Py-*H*), 7.81−7.37 (m, 5 H, Ar-*H* + Py-*H*), 7.27 (d, 1 H, Ar-*H*), 3.89 (s, 4 H, NCH_2Ar), 3.78 (s, 2 H, NCH_2Py), 1.17 (s, 18 H, *t*Bu) ppm.

[Cu^{II}{N$_2$(S*t*Bu)$_2$}(H$_2$O)(CF$_3$SO$_3$)](CF$_3$SO$_3$) (2): Copper(II) trifluoromethanesulfonate (0.155 g, 0.43 mmol) was added to a solution of **N$_2$(S*t*Bu)$_2$** (0.2 g, 0.43 mmol) in EtOH (20 mL). The solution was stirred for 10 min and diethyl ether added (10 mL). After 24 h at −20 °C, **2** was obtained as a polycrystalline blue powder. Yield: 70% (0.250 g). Crystals of **2** suitable for X-ray crystallography were obtained vapor diffusion of diethyl ether into an ethanol solution of **2**. FAB MS (NBA matrix): *m*/*z* = 678 [N$_2$(S*t*Bu)$_2$ + 1 Cu^{2+} − H_2O + 1 CF_3SO_3 + 1 H^+]. $C_{30}H_{38}CuF_6N_2O_7S_4$ (844): calcd. C 42.67, H 4.54, Cu 7.53, F 13.5, N 3.32, S 15.19; found C 42.31, H 4.56, Cu 7.31, N 3.31, S 15.85.

[Cu^{II}{N$_2$(S*t*Bu)$_2$}(H$_2$O)(ClO$_4$)](ClO$_4$) (3): Copper(II) perchlorate hexahydrate (0.271 g, 0.715 mmol) was added to a solution of **N$_2$(S*t*Bu)$_2$** (0.3 g, 0.65 mmol) in EtOH (20 mL). The solution was stirred for 10 min and diethyl ether/THF added (10 mL). After 24 h at −20 °C, **3** was obtained as a polycrystalline green-blue powder. Yield: 45% (0.218 g). Crystals of **3** suitable for X-ray crystallography were obtained by vapor diffusion of diethyl ether into an acetonitrile solution of **3**. FAB MS (NBA matrix): *m*/*z* = 628 [N$_2$(S*t*Bu)$_2$ + 1 Cu^{2+} − H_2O + 1 ClO_4 + 1 H^+]. UV/Vis (CH_2Cl_2): λ (ε) = 357 (4146), 706 nm (392 M^{-1}·cm^{-1}); (EtOH): λ = 338 (3954), 655 nm (149 M^{-1}·cm^{-1}). EPR (9.6 GHz, 100 K, 3 mM, CH_2Cl_2/toluene, 1:1): $g_\parallel$ = 2.22, $g_\perp$ = 2.06, $A_\parallel$ = 175 × 10^{-4} cm^{-1}; (EtOH/toluene, 1:1) main features at: $g_\parallel$ = 2.22, $g_\perp$ = 2.02, $A_\parallel$ = 170 × 10^{-4} cm^{-1}.

X-ray Crystallographic Studies: Crystal data and crystallographic experimental data for complexes **1**−**3** are listed in Table 2. In both structures, collected reflections were corrected for Lorentz and polarization effects but not for absorption. The structures were solved by direct methods and refined using the TEXSAN software package.[20] All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were generated in idealized positions, riding on the carrier atoms, with isotropic thermal parameters. CCDC-203164 (**1**), -203165 (**2**) and -203166 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Electrical Properties of the $Pr_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ System

María-Luisa Martínez-Sarrión,*[a] Lourdes Mestres,[a] Marta Herráiz,[a] Oscar Maqueda,[a] Nestor Fernández,[b] and Mario-Fidel García[c]

Keywords: Phase diagrams / Perovskite phases / Conducting materials

The stoichiometry, polymorphism, and electrical behaviour of the solid solutions $Pr_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ with perovskite-like structure have been studied. Data are given as a solid solution triangle, XRD patterns for two polymorphs T and O, the composition dependence of their parameters, and ionic conductivity plots. A region of perovskite-like solid solutions was obtained when the bismuth content in the general formula $Pr_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ was $y \leq 0.10$ and the lithium content was $0.033 \leq x \leq 0.133$. The compounds are mixed conductors. With increasing amounts of lithium the ionic conductivity first increased, reached a maximum for $x = 0.20$, with a conductivity at 25 °C of $6.639 \cdot 10^{-3}$ S·cm^{-1}, and then decreased.

Introduction

There has been much recent interest in the development of novel ionic conductors as solid electrolytes in lithium batteries.[1−12] Fast ionic conductors with the general formula $RE_{0.5+x}Li_{0.5-3x}TiO_3$, where RE = La, Pr, Nd, and Sm have been reported,[7−12] for which the maximum conductivity was for the La series ($1.1 \cdot 10^{-3}$ S·cm^{-1} for $x = 0.07$ at room temperature).[7] More recently the phase diagram, crystal chemistry, and ionic conductivity of the system $La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ have been reported.[13] The compounds of this system are ionic conductors whose conductivity increases as the amount of lithium increases, up to $x = 0.075$, but decreases when the amount of bismuth increases. The system with Bi needs less time in the thirst treatment at 1250 °C than a similar system without bismuth.[13]

We aimed to investigate the stoichiometry range, crystal chemistry, and electrical behaviour of materials of the general formula $Pr_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ and to establish the phase diagram at room temperature of the system $Pr_{0.67}TiO_3/Pr_{0.5}Li_{0.5}TiO_3/Bi_{0.5}Li_{0.5}TiO_3$. XRD patterns of perovskites with different Li and Bi contents have been analyzed and a study of the thermal treatment time with the content of Bi made. Finally, electrical conductivity data have been interpreted on the basis of the structural information deduced.

Results and Discussion

Phase Diagram

The triangle $Pr_{0.67}TiO_3/Pr_{0.5}Li_{0.5}TiO_3/Bi_{0.5}Li_{0.5}TiO_3$ in the system $Pr_6O_{11}/Li_2O/TiO_2/Bi_2O_3$ was chosen for detailed study since the $Pr_{0.67}TiO_3/Pr_{0.5}Li_{0.5}TiO_3$ join has been previously reported.[12] Thus, compositions of general formula $Pr_{0.5+x+y}Bi_yLi_{0.5-3x}TiO_3$ were synthesized as described in the Exp. Sect. The results of X-ray powder diffraction were then used to construct the composition diagram shown in Figure 1. ICP analysis confirmed the nominal composition, and these results were then used to construct the diagram.

Five distinct areas were found on this triangle: a region of perovskite-like solid solutions and three mixed-phase regions. Almost all of the superior part of the triangle (region C) was a mixture of the perovskite-like phase, $Bi_4Ti_3O_{12}$ (identified from PDF 73-2181) and an unknown phase (Figure 2, a). The region that was within the vertex $Pr_{0.5}Li_{0.5}TiO_3$ (region B) was a mixture of perovskite-like compound and peaks belonging to Li_2TiO_3, (identified from PDF 33-0831) (Figure 2, b), while the region close to the vertex $Pr_{0.67}TiO_3$ (region A) was a mixture of a perovskite-like phase and $Pr_4Ti_9O_{24}$ (identified from PDF 45-0265) (Figure 2, e). However, a perovskite-like solid solutions area (regions O and T) was also found between these three regions (Figure 2, c and d). No use was made of the previous results for $La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$[13] to study higher bismuth contents here (area D) as melting occurs because of the greater content of bismuth as Bi_2O_3, which melts at about 830 °C.

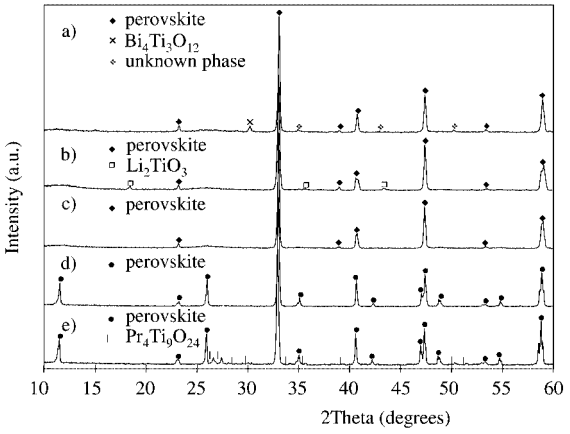

Figure 2. XRD patterns of the five regions on the composition triangle, showing both tetragonal (d) and orthorhombic (c) perovskite-like phases

Table 1 shows the X-ray powder diffraction data for $Pr_{0.57}Bi_{0.05}Li_{0.15}TiO_3$ (region T), which has a tetragonal perovskite-type structure. Table 2 shows the X-ray diffraction data for $Pr_{0.51}Bi_{0.05}Li_{0.325}TiO_3$ (region O), an orthorhombic perovskite-type structure. These two polymorphs are similar to those described in the $RE_{0.5+x}Li_{0.5-3x}TiO_3$ (RE = Pr, Nd) systems.[10,12]

Table 3 shows the X-ray diffraction data for $Pr_{0.58}Bi_{0.05}Li_{0.10}TiO_3$ (region A), containing reflections corresponding to a tetragonal perovskite-like structure and reflections corresponding to $Pr_4Ti_9O_{24}$. Table 4 shows the X-ray powder diffraction data for $Pr_{0.48}Bi_{0.025}Li_{0.5}TiO_3$ (region B) for which reflections corresponding to an orthorhombic perovskite-type structure and reflections corresponding to Li_2TiO_3 were observed. Finally, Table 5 shows X-ray powder diffraction data for $Pr_{0.43}Bi_{0.125}Li_{0.325}TiO_3$ (region C). In this region reflections corresponding to an orthorhombic perovskite-type structure, $Bi_4Ti_3O_{12}$, and an unknown phase were detected.

Perovskite-like phases mixed with titanium compounds are obtained in the areas A and B. In the area close to the

[a] Unknown phase.

vertex $Pr_{0.67}TiO_3$ (region A), $Pr_4Ti_9O_{24}$ is segregated along with the perovskite-like phase. On progressing towards the join $Pr_{0.67}TiO_3/Pr_{0.5}Li_{0.5}TiO_3$ the lithium content increases and Li_2TiO_3 is segregated along with the perovskite-like phase near the $Pr_{0.5}Li_{0.5}TiO_3$ vertex (region B).

The cell volume was obtained for two joins on the composition triangle (Figure 1). Along join 1 [$Pr_{0.45+x}Bi_{0.05}Li_{0.5-3x}TiO_3$] the lithium and praseodymium composition and the number of vacancies changed and the composition of bismuth was constant, while along join 2 [$Pr_{0.558-y}Bi_yLi_{0.325}TiO_3$] the number of vacancies and the amount of lithium was constant.

The cell volume was plotted against the amount of bismuth or lithium (Figure 3, a and b, respectively) and was found to increase smoothly as the bismuth content increased; conversely, it decreased smoothly with increasing lithium content. The bismuth, praseodymium, and lithium should be in equivalent 12-coordinated sites. Substitution of praseodymium by bismuth does not affect considerably the cell parameters due to their similar ionic radius. Therefore, the substitution of praseodymium by lithium leads to a reduction of the cell volume because the lithium ionic radius is smaller.

Electrical Measurements (AC)

DC conductivity measurements were carried out, but electronic conductivity was not found in these compounds.

AC measurements were carried out from 25 to 300 °C for compounds on join 1, $Pr_{0.45+x}Bi_{0.05}Li_{0.5-3x}TiO_3$ ($0.033 \leq x \leq 0.133$), and join 2, $Pr_{0.558-y}Bi_yLi_{0.325}TiO_3$ ($y \leq 0.10$). Two semicircles and a spike were observed in the impedance complex plane plots (Figure 4). The centers of the semicircles were clearly depressed below the baseline, indicating the kind of non-Debye response that has been detected in other ionic conductors.[14−16]

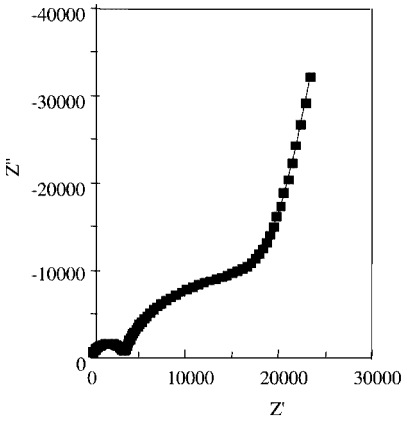

Figure 4. Impedance response at 155 °C for $Pr_{0.59}Bi_{0.01}Li_{0.325}TiO_3$

An equivalent circuit (Figure 5) with two RC elements and with CPE[16] (constant phase elements) for grain and

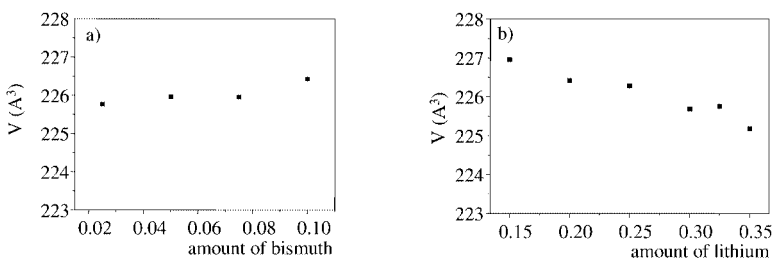

Figure 3. Cell volume with increasing concentration of a) bismuth and b) lithium

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

grain boundary response and an additional CPE element to model a low conductivity surface layer lithium ions was used to model the experimental data. All fitting used the Zview software package.[17] The first and second semicircles showed capacities of around 0.4 pF and 3 nF respectively, and are, therefore, related to bulk and grain boundaries. The spike had a capacitance around 30−60 nF, which is probably too small to be related to an electrode/sample double layer, but is probably linked to a low-conductivity layer on the pellet surface. Such a result has been reported for high Na^+ or Li^+ ion conductors[12−14] and attributed to the presence of an Na^+ or Li^+ free layer on the crystal surface.

Bulk ionic conductivity data from the impedance complex plane plots for compounds on joins $Pr_{0.45+x}Bi_{0.05}Li_{0.5-3x}TiO_3$ ($0.033 \leq x \leq 0.133$) and $Pr_{0.558-y}Bi_yLi_{0.325}TiO_3$ ($y \leq 0.10$) are shown in Arrhenius format in Figure 6 (a and b, respectively).

The variation in ionic conductivity with the increase of lithium concentration is quite large (Figure 7, a), while the activation energy is between 0.45 and 0.46 eV. No change in the conductivity mechanism can be supposed, but the increasing lithium concentration initially increases the concentration of carriers, thereby increasing the conductivity to a maximum at $x = 0.2$ with a conductivity at 25 °C of $6.639 \cdot 10^{-6}$ S·cm^{-1}. Further increases in the lithium concentration decreases the number of vacancies and the conductivity paths, with a corresponding decrease in conductivity. These results agree with earlier results for the La system,[13] which report a conduction mechanism based on the A-site vacancies.

Along the join $Pr_{0.558-y}Bi_yLi_{0.325}TiO_3$, where the amount of lithium remains constant, the conductivity decreases slightly when the amount of bismuth increases (Figure 7, b). However, substitution of Pr by Bi is not accompanied by a significant change in the cell volume of the perovskite, and so this behavior does not seem to be related to any change in the "bottleneck" size. However, it could be related to the lone-electron pair of bismuth.[18−19] The activation energy in this case was 0.45−0.46 eV.

Conclusions

A large range of single-phase solid solutions have been synthesized in the triangle $Pr_{0.67}TiO_3/Pr_{0.5}Li_{0.5}TiO_3/Bi_{0.5}Li_{0.5}TiO_3$. The phase diagram in the single-phase region showed the existence of two polymorphs with perovskite-like structures, labeled O and T. Polymorph O is an orthorhombic distortion of the simple cubic perovskite, while polymorph T is a tetragonal perovskite. Region A is a mixture of a perovskite-like phase and $Pr_4Ti_9O_{24}$. Region B is a mixture of a perovskite-like compound and Li_2TiO_3, and region C is a mixture of the perovskite-like phase, $Bi_4Ti_3O_{12}$ and an unknown phase.

The increase of bismuth concentration reduced the time for the third treatment and when $y \geq 0.075$ it is not necessary.

The cell volume decreased with increasing lithium content, but remained almost constant with increasing amounts of bismuth. This is attributable to the effect of ionic radii, which are similar for praseodymium and bismuth but shorter for lithium.

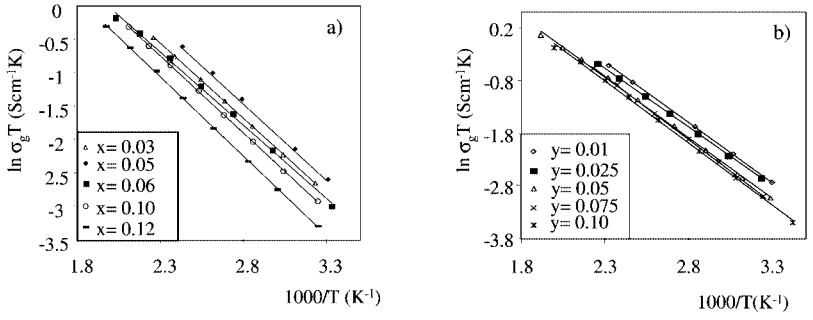

Figure 6. Arrhenius ionic conductivity plots for a) join 1 ($Pr_{0.45+x}Bi_{0.05}Li_{0.5-3x}TiO_3$) and b) join 2 ($Pr_{0.558-y}Bi_yLi_{0.325}TiO_3$)

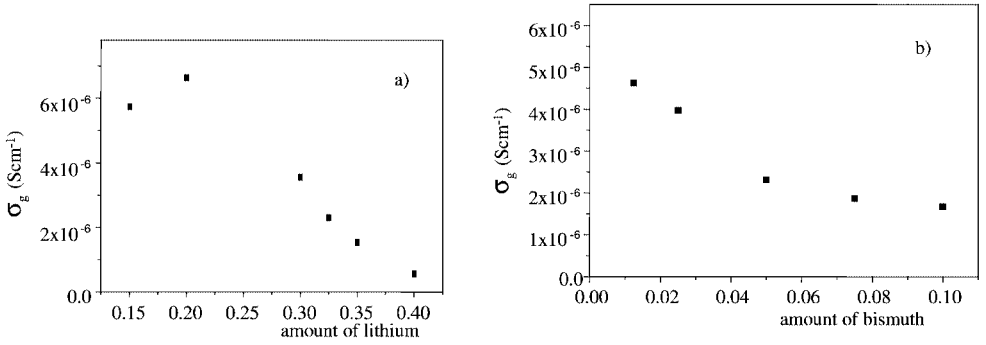

Figure 7. Plot of σ (bulk ionic conductivity) at room temperature vs. composition, a) in lithium along join 1 ($Pr_{0.45+x}Bi_{0.05}Li_{0.5-3x}TiO_3$) and b) in bismuth along join 2 ($Pr_{0.558-y}Bi_yLi_{0.325}TiO_3$)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

AC/DC measurements indicated that these compounds are ionic conductors. Li^+ ion conductivity increased with increasing lithium content up to $x = 0.2$ and subsequently decreased; the conductivity decreased slightly with increasing bismuth concentration.

The behaviour of the $Pr_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ system is similar to that of the $La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ system,[13] but, analogously to other systems of praseodymium, its ionic conductivity is lower than that of the corresponding lanthanum system.[3,5,20]

Experimental Section

Synthesis: Pr_6O_{11} (99.9%, Fluka), TiO_2 (99.9%, Aldrich), Bi_2O_3 (> 99%, J. T. Baker), and Li_2CO_3 (> 99%, Merck) were used as starting materials. Pr_6O_{11} and TiO_2 were dried overnight at 900 °C prior to weighing. Pretreated and untreated oxides were mixed in the desired proportions in an agate mortar with acetone, dried, and heated at 650 °C for 2 h to drive off CO_2. After grinding, samples were pressed into pellets, put into platinum vessels and covered with a powder of the same composition to avoid lithium loss during thermal treatment. The pellets were fired at 1100 °C for 12 h, giving green products that were reground, repelleted, and fired at 1200 °C for a further 12 h. A third treatment was carried out at 1250 °C, the required time depending on the Bi composition. Samples rich in Bi were found to need less time for the third treatment. Finally, the last treatment involved 4 h for samples with $y \leq 0.01$, 2 h for samples for $0.01 < y \leq 0.025$ and 1 h for samples of $0.025 < y \leq 0.05$. In samples with concentrations of bismuth of $y \geq 0.75$ no third treatment was necessary. After the third treatment, the samples were quenched in air to room temperature to stabilize the high-temperature phase.

X-ray Diffraction: The solid solution range, crystalline phase identification, and lattice parameters were obtained by powder X-ray diffraction with a Siemens D-500 diffractometer, in reflection mode, with a detector sensitive to the position and a secondary monochromator of quartz, using Cu-K_α radiation. Lattice parameters were obtained using a silicon internal standard.

ICP: Chemical analysis was performed by inductively coupled plasma (ICP) spectroscopy (Thermo Jarrel ASH Corporation, model Spectrometer Polyscan TM 61E) to determine the Li, Bi and Ti contents. The results indicated that the loss of lithium during firing was within the error range of the instrument; thus, the nominal composition is used here.

Electrical Measurements: DC conductivity measurements were carried out using an HP-34401A multimeter. AC measurements were performed with an HP 4192A Impedance Analyzer over the range $100\ Hz < f < 13\ MHz$, only in the single-phase region. Samples were pressed into pellets and sintered at 1250 °C for 1 h. Pellet sides were then sanded and painted with gold paste (Engelhard-Clal T-10112), which was fixed in a tubular furnace with a maximum temperature of 900 °C.

Neutral and Cationic [Bis(η¹-amidosilyl)-η⁵-cyclopentadienyl]titanium and -zirconium Complexes: Synthesis, X-ray Molecular Structures and DFT Calculations

Jesús Cano,[a] Pascual Royo,*[a] Heiko Jacobsen,[b][‡] Olivier Blacque,[b] Heinz Berke,[b] and Eberhardt Herdtweck[c]

Keywords: Cations / Cyclopentadienyl ligands / Density functional calculations / Nitrogen ligands / Titanium / Zirconium

Treatment of LiNH*t*Bu with THF solutions of $C_5H_4(SiMe_2Cl)_2$ gave $C_5H_4(SiMe_2NH$*t*$Bu)_2$ (**1**). Deprotonation of **1** with $M(NMe_2)_4$ (M = Ti, Zr) under different conditions provided the monocyclopentadienyl complexes $[M\{\eta^5\text{-}C_5H_3[SiMe_2(NH$*t*$Bu)]_2\}(NMe_2)_3]$ [M = Ti (**2**), Zr (**3**)] and the single (η-amidosilyl)cyclopentadienyl compounds $[M\{\eta^5\text{-}C_5H_3[SiMe_2(NH$*t*$Bu)][SiMe_2(\eta^1\text{-}N$*t*$Bu)]\}(NMe_2)_2]$ [M = Ti (**4**), Zr (**5**)]. The related dibenzyl compounds $[M\{\eta^5\text{-}C_5H_3[SiMe_2(NH$*t*$Bu)][SiMe_2(\eta^1\text{-}N$*t*$Bu)]\}(CH_2Ph)_2]$ [M = Ti (**6**), Zr (**7**)] resulted from treatment of **1** with $M(CH_2C_6H_5)_4$ (M = Ti, Zr). Further deprotonation of the amido complexes **4** and **5** and the benzyl complexes **6** and **7** by heating in toluene solution gave the bis(η-amidosilyl)cyclopentadienyl complexes $[M\{\eta^5\text{-}C_5H_3[SiMe_2(\eta^1\text{-}N$*t*$Bu)]_2\}(NMe_2)]$ [M = Ti (**8**), Zr (**9**)] and $[M\{\eta^5\text{-}C_5H_3[SiMe_2(\eta^1\text{-}N$*t*$Bu)]_2\}(CH_2Ph)]$ [M = Ti (**10**), Zr (**11**)], respectively. Treatment of the monobenzyl complexes **10** and **11** with $B(C_6F_5)_3$ yielded the cationic compounds $[M\{\eta^5\text{-}C_5H_3[SiMe_2(\eta^1\text{-}N$*t*$Bu)]_2\}]^+$ as $[(CH_2Ph)B(C_6F_5)_3]^-$ [M = Ti (**12**), Zr (**13**)] salts. All new compounds were characterized by NMR spectroscopy, and the crystal structures of **10** and **13** were studied by diffraction methods. DFT calculations for the neutral and cationic species are described and provide an explanation for the unusual η¹ coordination of a phenyl ring to a group-4 metal cation.

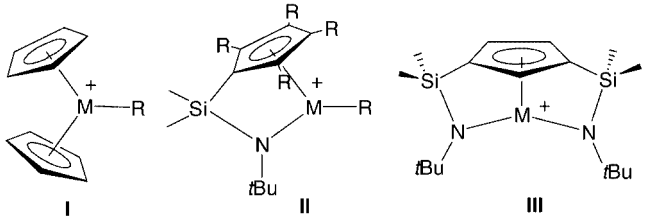
Introduction

The group-4 metallocenes $[MCp_2X_2]$[1] and cylopentadienylamido complexes $[M(\eta^5\text{-}C_5R_4\text{-}E\text{-}\eta^1\text{-}NR')X_2]$[2] are the two essential types of catalyst precursors for insertion polymerization of olefins based on the use of cyclopentadienyl ligands. After alkyl abstraction by a Lewis acid {MAO, $B(C_6F_5)_3$, $[CPh_3][B(C_6F_5)_4]$} the metallocene compounds generate the cationic, coordinatively unsaturated, 14-electron d^0 $[MCp_2R]^+$ species,[3] whereas the cyclopentadienylamido complexes provide the electronically more unsaturated 12-electron d^0 $[M(\eta^5\text{-}C_5R_4\text{-}E\text{-}\eta^1\text{-}NR')R']^+$ cations.[4] The technological applications[5] of these "constrained-geometry" catalysts are based not only on their electronic unsaturation, but also on their sterically open reactive sites, combined with rigidity of the molecular framework and thermal stability. These features facilitate the coordination of bulkier olefins, allowing the synthesis of various copolymers of ethylene with 1-hexene, 1-octene, styrene and other larger olefins.



Scheme 1. Types of metallocene and (cyclopentadienylsilyl)amido cations

Amido ligands are π-donors and in this respect resemble Cp ligands. Even if π-electrons are included, however, the formal electron count of a single group never reaches that of the Cp moiety. Replacement of one Cp by an amido group, as demonstrated in structures **I** and **II**, establishes a 12-electron cyclopentadienylamido complex[6] on the basis

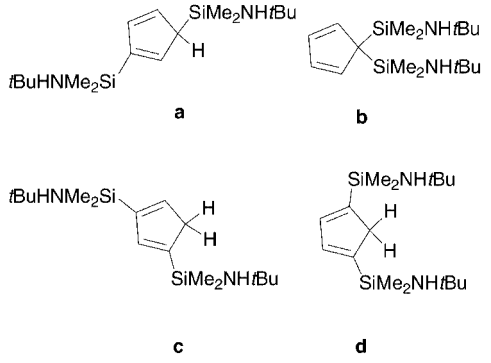
of a 14-electron metallocene species **I**. Structures of type **III** with two amido ligands would indeed have the formal electron count of **I**. Despite this, complexes **III** are special, since they do not bear an alkyl group ready for Ziegler−Natta-type insertion polymerizations. Nevertheless, we have reported[7] that they still have potential for polarized metal−olefin binding similar to, for instance, the 18-electron Cp_3M^+ series (M = Ti, Zr).[8] For this reason we decided to study the synthesis and chemical behaviour of [bis(amidosilyl)cyclopentadienyl]titanium and -zirconium complexes of type **III**.

Here we report the syntheses of monocyclopentadienyl [M{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)]$_2$}X_3], (amidosilyl)cyclopentadienyl [M{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)][$SiMe_2$(η^1-N*t*Bu)]}X_2] and bis(amidosilyl)cyclopentadienyl [M{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)$_2$}X] group-4 metal compounds and their cationic [M{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)$_2$}]$^+$ derivatives. The X-ray molecular structures of the neutral [Ti{η^5-C_5H_3[$SiMe_2$(η^1-N*t*Bu)]$_2$}(CH_2Ph)] and the cationic [Zr{η^5-C_5H_3[$SiMe_2$(η^1-N*t*Bu)]$_2$}]$^+$[($CH_2C_6H_5$)B(C_6F_5)$_3$]$^-$ complexes were determined by diffraction methods and DFT calculations were carried out for the neutral and cationic species.

Results and Discussion

The cyclopentadiene C_5H_4($SiMe_2$NH*t*Bu)$_2$ (**1**) was isolated as a yellow liquid by treatment of the reported bis(chlorosilyl)cyclopentadiene[9] with 2 equiv. of LiNH*t*Bu in THF and was characterized by ^{1}H and ^{13}C NMR spectroscopy as a mixture of isomers (Scheme 2). The ^{1}H NMR spectrum of **1** recorded at 20 °C indicated a mixture of isomers **a**, **b**, **c** and **d** in a molar ratio of 8:4:1.3:1.



Scheme 2. Isomers of C_5H_4($SiMe_2$NH*t*Bu)$_2$ observed by NMR spectroscopy

In comparison with other previously reported disilyl-substituted compounds C_5H_4(SiR_3)$_2$,[10] in which the 1,1-isomer (**b**; R = Me, Cl) is by far the major component, the steric hindrance caused by the bulkier substituents (R = NH*t*Bu) means that the 1,3-isomer (**a**; two broad Si*Me*$_2$ singlets) is the major component in the isomeric mixture of **1**, being more favourable than the 1,1-isomer (**b**; one broad Si*Me*$_2$ singlet), as shown in Scheme 2. The other two isomers (2,4- and 2,5-), with both silyl groups bound to sp^2 carbon atoms, were less abundant components. All of these isomers interconvert, probably through successive 1,2-shifts of the silyl groups,[10] and increasing temperatures increase the **a**/**b** ratio to 4:1 at 50 °C, 8:1 at 70 °C and more than 10:1 at temperatures higher than 80 °C. The broad signals observed for **1a** at 20 °C appeared as four singlets when the ^{1}H NMR spectrum was recorded at −40 °C.

The tetraamide M(NMe_2)$_4$[11] and tetrabenzyl M(CH_2Ph)$_4$[12] compounds (M = Ti, Zr) were used to deprotonate the cyclopentadiene compound **1**, which possesses three acidic protons, to generate the metal-coordinated cyclopentadienyl ligand.

Monocyclopentadienyl Compounds

Immediate deprotonation of the most acidic cyclopentadiene proton took place when a toluene solution of **1** was treated at room temperature with 1 equiv. of Zr(NMe_2)$_4$ to give the monocyclopentadienyl compound **3** (Scheme 3) as the unique reaction product after 1 h (100% NMR yield). When Ti(NMe_2)$_4$ was used, heating at 50 °C was required to complete the reaction, the analogous titanium derivative **2** being isolated. Compound **2** was isolated as a dark red oil in quantitative yield after removal of the toluene and extraction into hexanes. The related tribenzyltitanium and -zirconium derivatives could not be isolated when M(CH_2Ph)$_4$ was used[13] because further deprotonation to give the mono- and bis(silylamido) benzyl derivatives took place very easily at room temperature.

The different thermal conditions required to deprotonate the tribasic diaminocyclopentadiene **1** show that the deprotonation with irreversible toluene elimination by the tetrabenzyl compounds M(CH_2Ph)$_4$ is much easier than the reversible elimination of amine by the amido derivatives M(NMe_2)$_4$, and that the zirconium compounds are more easily deprotonated than the more crowded titanium analogues, in spite of their weaker Ti−C and Ti−N bonds.[14] In all reactions the first deprotonation involves the most acidic cyclopentadiene proton.

The ^{1}H NMR spectra of **2** and **3** in C_6D_6 each show equivalent silylamido groups with NH (δ = 1.04, 1.08 ppm), *t*Bu (δ = 1.16, 1.15 ppm), and diastereotopic $SiMe_2$ (δ = 0.41, 0.43 ppm; δ = 0.42, 0.44 ppm) resonances close to those observed for **1**. Additionally, they each show an A_2B spin system for the ring protons and one singlet for all three equivalent NMe_2 groups. The expected spectral features were also observed in the ^{13}C NMR spectra, which each show one downfield shifted ring C_{ipso} resonance (δ = 127.8, 127.2 ppm) and Δδ (δ C_{tert} − δ C_{Me}) values[15] (15.3 ppm and 15.4 ppm) consistent with the presence of uncoordinated $SiMe_2$−NH*t*Bu groups.

Single (Amidosilyl)cyclopentadienyl Compounds

When toluene or THF solutions of complex **3**, prepared at room temperature, were heated at 65 °C, complete transformation of **3** into **5** was observed after 3 h. Compound **5** was the only NMR-detectable product under these conditions, and it could be isolated as a brown solid and characterized by elemental analysis and NMR spec-

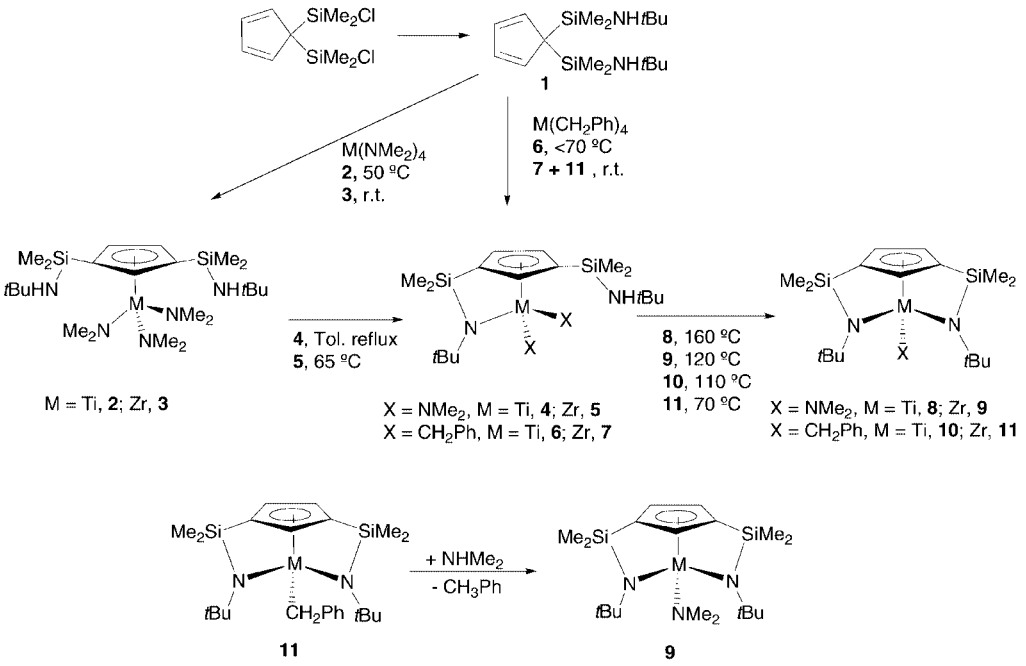

Scheme 3. Synthesis of cyclopentadienyl- and [(amidosilyl)- and bis(amidosilyl)cyclopentadienyl]titanium and -zirconium amide and benzyl complexes

troscopy. A similar transformation of **2** was achieved when a toluene solution of previously isolated **2** was heated at reflux for 5 h. The deprotonation of only one of the $SiMe_2NHtBu$ substituents with elimination of amine $NHMe_2$ occurred in a selective way to give pure **4**, which was isolated as a dark red oil and characterized by elemental analysis and NMR spectroscopy.

The related dibenzyl[*ansa*-(cyclopentadienylsilyl)amido]-titanium compound **6** was produced when a toluene solution of **1** and $Ti(CH_2Ph)_4$ was heated (below 70 °C) for 5 h. Higher temperatures could not be used, since further deprotonation would then occur, yielding small amounts of **8**. Under these conditions, **6** was the only reaction product that could be isolated, as a red-brown solid, and identified by elemental analysis and NMR spectroscopy. The third deprotonation could not be avoided when $Zr(CH_2Ph)_4$ was used, because deprotonation then occurs even at low temperature to give a mixture of **7** and other minor components. Because the products could not be separated, **7** was only characterized by NMR spectroscopy.

Coordination of the η⁵-cyclopentadienyl ligand increases the acidity of the NH*t*Bu amino protons [δ = 1.04 (**2**), 1.08 (**3**) ppm], and this is further increased after abstraction of the first amino hydrogen atom [δ = 0.86 (**4**), 0.85 (**5**) ppm]. For these reasons the reactions with the titanium reagents could be carried out selectively to give pure amido and benzyl compounds, whereas the tribenzyl compounds could not be isolated at room temperature.

The ^1H NMR spectra of the silylamido compounds **4**−**7** in C_6D_6 each show an ABC spin system for the three ring protons while the ^{13}C NMR spectra exhibit five resonances for the inequivalent ring carbon atoms, as expected for asymmetric molecules. Four resonances (^1H and ^{13}C) for the $SiMe_2$ moieties and two for the *t*Bu groups (^1H and ^{13}C), along with two ^{13}C resonances for their quaternary carbon atoms, are also observed for the two non-equivalent $SiMe_2NtBu$ and $SiMe_2NHtBu$ groups. Both can be easily distinguished by the different Δδ values[15] observed in the ^{13}C NMR spectra, which are smaller [15.5 (**4**), 15.7 (**5**), 16.0 (**6**, **7**) ppm] for uncoordinated NH*t*Bu groups than for bridging N*t*Bu groups [26.4 (**4**), 21.7 (**5**), 27.3 (**6**), 23.7 (**7**) ppm]. The amido complexes **4** and **5** also show two signals (^1H and ^{13}C) for non-equivalent NMe_2 ligands, whereas the benzyl derivatives **6** and **7** show four ^1H doublets and two ^{13}C resonances for diastereotopic methylene protons and carbon atoms of two non-equivalent benzyl ligands.

The chemical shifts observed in the ^1H and ^{13}C NMR spectra for all of the ring substituents of the analogous titanium and zirconium complexes show very slight differences, whereas resonances for the additional NMe_2 and CH_2Ph ligands appear at a lower field for the titanium than for the zirconium analogues. The *tert*-butyl ^1H and ^{13}C resonances of the coordinated amido ligand are shifted downfield with respect to a free NH*t*Bu group as a consequence of the π-donation to the metal centre, which is also consistent with a higher value of Δδ.

Bis(amidosilyl)cyclopentadienyl Compounds

Complete deprotonation of the uncoordinated $SiMe_2-NHtBu$ groups in the dibenzyl complexes **6** and **7** required heating of their toluene solutions under reflux or at 70 °C, respectively, to give the bis(silylamido) compounds **10**, isolated as orange crystals and **11**, isolated as a brown solid. Both complexes were identified by elemental analyses and NMR spectroscopy. Temperatures higher than reflux in toluene were required to achieve similar deprotonation

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the amido complexes **4** and **5**. The reaction was monitored by ^{1}H NMR spectroscopy with a C_6D_6 solution of **5** in a Teflon-valved NMR tube. Complete deprotonation was observed after 12 h of heating at 120 °C, giving the bis(silylamido) compound **9** as the only reaction product. This reaction was reversible, however, and when the solution was cooled to room temperature, **9** reacted in solution with the eliminated amine $NHMe_2$ to give the starting product **5** quantitatively, and so could not be isolated in this way. Nevertheless, pure **9** could be obtained at a preparative level when the same thermal treatment of **5** was carried out in a Teflon-valved Schlenk tube after addition of 1 equiv. of the monobenzylzirconium compound **11**, which reacts with amine in an irreversible reaction to give **9** with elimination of toluene (see Scheme 3). Similar deprotonation of the titanium compound **4** required heating at temperatures higher than 160 °C to afford the bis(silylamido)titanium derivative **8**. This transformation was not quantitative, although pure **8** could be easily recovered because the reaction was not reversible on cooling to room temperature. Compounds **8** and **9** were isolated as brown and yellow solids, respectively, and identified by NMR spectroscopy.

Formation of the bis(silylamido) compounds is more selective, as it requires heating at temperatures above 100 °C, except in the case of the benzylzirconium compound **11** (70 °C). For the same reason the formation of the amidozirconium compound **9** is reversible in the presence of free amine.

The ^{1}H and ^{13}C NMR spectra of these diamido compounds **8**−**11** in C_6D_6 are consistent with the presence of a plane of symmetry, making the two silylamido groups equivalent. They show one singlet (^{1}H) and two resonances (^{13}C) for the *t*Bu groups and two signals (^{1}H and ^{13}C) for the non-equivalent methyl groups of the $SiMe_2$ moiety. Additionally, they show an A_2B spin system for the ring protons and three signals for the ring carbon atoms, along with one resonance for the methyl (**8**, **9**) and methylene (**10**, **11**) protons and carbon atoms of the NMe_2 and CH_2Ph ligands, respectively. The $\Delta\delta$[15] values are larger than those observed for non-coordinated $SiMe_2NH$*t*Bu groups in monocyclopentadienyl (**2**, **3**) and single silylamido (**4**−**7**) compounds, but lower than those observed for the metal-coordinated $SiMe_2$-η^1-N*t*Bu groups in silylamido compounds (**4**−**7**).

Orange crystals of **10** suitable for X-ray diffraction studies were isolated after extraction into hexane and slow cooling. The molecular structure of **10** is shown in Figure 1, and selected bond lengths and angles are listed in Table 1.

The titanium atom is in a pseudo-tetrahedral environment defined by the methylene carbon atom of the benzyl ligand, the centroid of the cyclopentadienyl ring, and the two coordinated nitrogen atoms of the silylamido groups. This is the first example of a neutral compound with a tridentate cyclopentadienyl ligand tethered by two silylamido groups.

Complex **10** shows Ti−N distances slightly longer than those reported for related $[Ti\{\eta^5\text{-}C_5R_4SiMe_2(\eta^1\text{-}NR')\}X_2]$ compounds with only one silylamido ligand (1.907−1.919

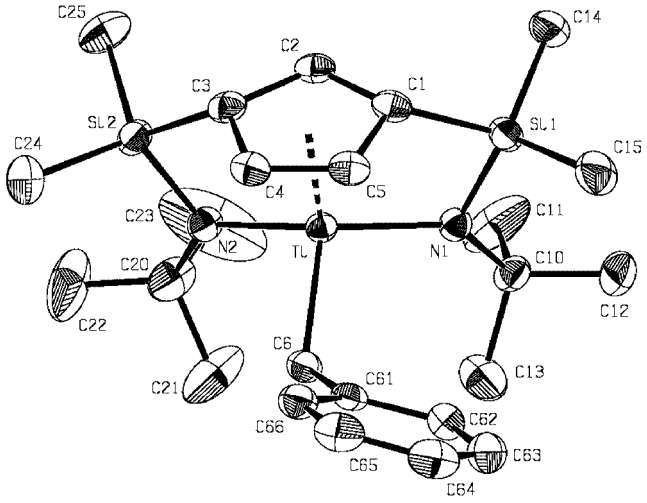

Figure 1. ORTEP drawing of the molecular structure of the major part of **10** in the solid state; thermal ellipsoids are drawn at the 50% probability level; the hydrogen atoms are omitted for clarity

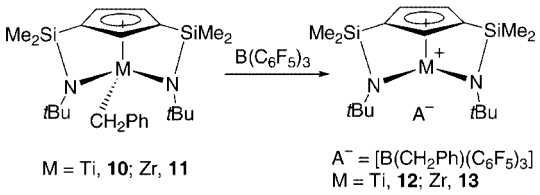
Å)[2h,4g,16,17,18] but similar to the distance (1.971Å)[19] reported for R = Me, R′ = *t*Bu, X_2 = 2 NMe_2 (see Table 2). This behaviour would be consistent with a weaker π-bonding contribution from the interaction between the nitrogen p_π orbital with the appropriate vacant metal d_π orbital due to the presence of a second amido group, which simultaneously increases the steric crowding and strain of the bicyclic structure. In contrast, the Si−N and Si−C distances observed for **10** are very close to those observed for all single silylamido compounds. The Ti−Cg distance is in the lower range found for singly bridged silylamido compounds. There is no deviation of the disilyl-substituted cyclopentadienyl ligand from η⁵-coordination, as deduced from the small differences in the Ti−C(ring) (2.347 Å average) and the C−C ring distances (1.419 Å average).

The amido nitrogen atom exhibits the expected planar disposition with sp^2 hybridization (the sum of bond angles around N is 360°) known for all structurally characterized silylamido complexes. The close Cg−C_{ring}−Si angles (147.3° average) account for the strain in these bicyclic compounds. In addition, the Cg−Ti−N angles are similar, whereas the Ti−N−Si angles are significantly narrower and the C1−Si1−N angles more open than those found in single silylamido compounds. This is also consistent with the differences observed in the bond lengths for a system in which the Si−N distances do not change whereas the Ti−N distances are longer. The N1−Ti−N2 angle is very open. The Ti−C6 distance is in the known range for benzyltitanium compounds.

The most significant structural feature of **10** is the orientation of the benzyl ligand, with its phenyl ring directed toward the cyclopentadienyl ring (see DFT calculations below). A similar orientation has also recently been observed for [Ti{1,3-[CH_2(2-C_4H_3N)]}$_2$(η⁵-C_5H_3)(NMe_2)].[20]

Cationic Compounds

Addition of C_6D_6 by vacuum transfer to a Teflon-valved NMR tube containing a mixture of $B(C_6F_5)_3$ and the benzyl compounds **10** or **11** in a 1:1 molar ratio immediately gave the partially soluble cationic species [M(η⁵-C_5H_3($SiMe_2$-η¹-N*t*Bu)$_2$]⁺, isolated as [$B(CH_2Ph)(C_6F_5)_3$]⁻ salts **12** and **13** as orange solids, which were identified by NMR spectroscopy and X-ray diffraction studies.



Scheme 4. Formation of cationic bis(amidosilyl)cyclopentadienyl complexes

The structures of the cations in C_6D_6 solutions were established by NMR studies. Their ^1H and ^{13}C NMR spectra are consistent with the C_s symmetry also observed for the neutral benzyl precursor compounds **10** and **11**. They each show one singlet (^1H) and two resonances (^{13}C) for the *t*Bu groups, two signals (^1H and ^{13}C) for non-equivalent methyl groups of the $SiMe_2$ groups, an A_2B spin system for the ring protons and three signals for the ring carbon atoms.

The $\Delta\delta$[15] values for the *t*Bu ^{13}C signals are slightly larger than those observed for corresponding neutral compounds. A surprising effect is observed when the ^{1}H and ^{13}C NMR spectra of the neutral benzyl precursor compounds **10**−**11** are compared with those of the corresponding cationic titanium and zirconium derivatives **12**−**13**: all of the NMR resonances for the cationic species are shifted upfield. It is also remarkable that this effect is particularly important for the ring CH proton located between the two silyl substituents. Furthermore, it is interesting to note that the ring C_{ipso} resonance is the signal at highest field for the neutral compounds whereas for the cationic derivatives it appears between the other two ring C resonances. This unexpected behaviour seems to be associated with the anisotropy of the benzyl ring exerted in the particular structure of these cationic species.

Orange crystals of **13**, appropriate for a single-crystal X-ray structure determination, were isolated from a C_6D_6 solution in the NMR tube. A perspective view of the molecular structure of **13** is shown in Figure 2, along with the non-hydrogen labelling scheme, and selected bond lengths and angles are listed in Table 1.

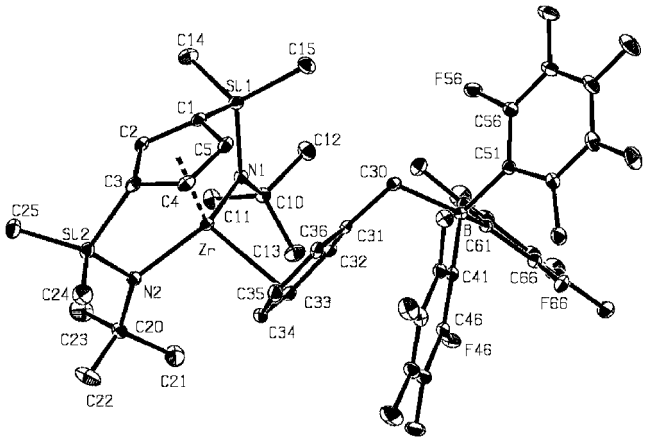

Figure 2. ORTEP drawing of the molecular structure of **13** in the solid state; thermal ellipsoids are drawn at the 10% probability level and hydrogen atoms are omitted for clarity

The pseudo-tetrahedral geometry about the Zr atom of **13** is defined by the centroid of the cyclopentadienyl ring and the two N-donors of the appended (dimethylsilyl)amido arms, with the remaining coordination site occupied by C(33) of the phenyl ring of the benzylborate anion. This disposition is very close to that observed for complex **12**[7] with the expected longer Zr−N and similar Si−N [1.773(5) Å; 1.788(5) Å for **12**] bonds. In comparison with those in the related neutral $[Zr\{(\eta^5\text{-}C_5R_4)SiMe_2(\eta^1\text{-}NR')\}X_2]$ compounds containing only one silylamido ligand, the Zr−N distances in **13** are similar,[21,22] but slightly shorter than the distances reported[19] for R = Me, R′ = *t*Bu, X_2 = 2 NMe_2. This behaviour is consistent with a similar π-bonding contribution from the two amido ligands to the more acidic zirconium cation. The Cg−Zr distance is significantly shorter than those observed in related single silylamido neutral complexes (see Table 2), indicating higher electron donation from the cyclopentadienyl ring.

The amido nitrogen atom exhibits the expected planar disposition with sp^2 hybridization (the sum of bond angles around N is 360°) known for all reported silylamido complexes. The constrained geometry of the $Cg-C_{ring}-Si-N-Zr$ cyclic systems is similar to that found for **12**. The ring C1 and C3 atoms, bearing the amidosilyl arms, are pyramidally distorted almost to the same extent, as shown by the sums of their bond angles (349.4° average) and by the $Cg-C_{ring}-Si$ angles (150.3° average). The angles at Si and N are in the range found for **12**, whereas the Cg−Zr−N angles (100.9° average) are significantly narrower than those observed in the related titanium cation **12** (106.65° average). This is consistent with the increased atomic radius of the Zr centre and is responsible for the slightly more constrained geometry shown by **13**.

The Zr−C33 bond [2.571(3) Å] is about 0.30 Å longer, whereas the distances to the neighbouring C32 and C34 atoms are about 0.8 Å longer than those observed for covalent Zr−C bonds, indicating an interaction of the empty hybrid metal orbital with the p_π orbital of the *meta*-C_{phenyl} atom of the borate anion.[23] The most significant feature of this structure is that the phenyl ring is oriented upward in the direction of the cyclopentadienyl ring, as also observed for the benzyl substituent in complex **10**.

Structure and Bonding of $[Ti\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}N\mathit{t}Bu)_2\}]^+$ Cations

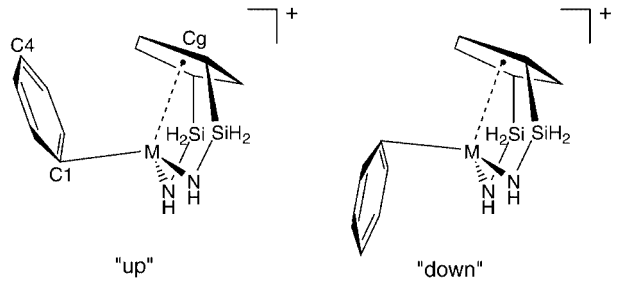
In this section we present density functional calculations performed on the model compound $[Ti\{\eta^5\text{-}C_5H_3(SiH_2\text{-}\eta^1\text{-}NH)_2\}]^+$ as well as on the real molecule $[Ti\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}N\mathit{t}Bu)_2\}]^+$. The calculations for the model system serve to establish characteristic patterns in chemical bonding for bis(amidosilyl)cyclopentadienyl compounds of Ti and Zr. As mentioned above, these compounds can reasonably be regarded as 14-electron species, due to inclusion of the amido π-electrons. In the light of our previous analysis,[8c] we can expect that the bonding of $[Ti\{\eta^5\text{-}C_5H_3(SiR_2\text{-}\eta^1\text{-}NR)_2\}]^+$ cations should be governed by electrostatic interaction and ligand-to-metal donation, whereas back-bonding should play an only minor role.

Bonding of the Model System $[Ti\{\eta^5\text{-}C_5H_3(SiH_2\text{-}\eta^1\text{-}NH)_2\}]^+$

We first performed DFT calculations on the species with aryl ligands, $[Ti\{\eta^5\text{-}C_5H_3(SiH_2\text{-}\eta^1\text{-}NH)_2\}]^+[\eta^x\text{-}C_6H_5R]$ (R = H, CH_3, $CH_2BF_3^-$; x = 1, 2). For benzene, we considered different "up" and "down" coordination modes, as indicated in Scheme 5. For η^1-coordination, "up" and "down" coordination modes are characterized by dihedral angles (C4−C1−M−Cg) close to 0 and 180°, respectively, C1 being the benzene carbon atom coordinating to the metal centre, and C4 being the benzene carbon atom in the position *para* to C1. Similarly, for η^2-coordination, dihedral angles (X4−X1−M−Cg) close to 0 and 180° characterize "up" and "down" coordination modes, X1 being the mid-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

point between the two coordinating benzene carbon atoms, and X4 being the midpoint of the two corresponding benzene carbon atoms in the *para* position.



Scheme 5. The "up" and "down" coordination modes of the solvated model cation $[Ti\{C_5H_3(SiH_2NH)_2\}]^+$

The optimized geometry of the naked cation $[Ti\{\eta^5\text{-}C_5H_3(SiH_2\text{-}\eta^1\text{-}NH)_2\}]^+$ and its main empty frontier molecular orbital are displayed in Figure 3. The HOMO of the aryl ligand, dominates the orbital interaction through donation to the empty d_z^2 orbital at the metal centre.

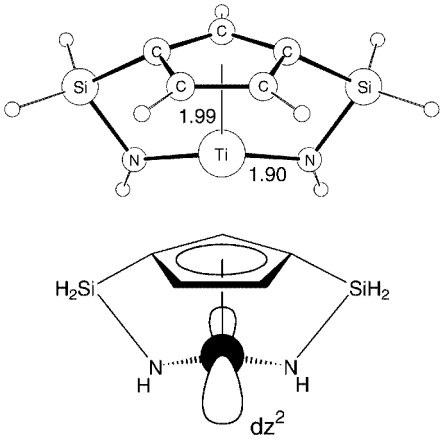


Figure 3. Optimized geometry for the model cation $[Ti\{C_5H_3(SiH_2NH)_2\}]^+$ and a main empty frontier MO

We recall from simple Hückel considerations that the HOMO of benzene consists of a set of degenerate e_{1g} orbitals, one of which is more likely to undergo η^1-type donation, whereas the other would induce a preference for η^2-coordination. For toluene, the degeneracy of the e_{1g} set is lifted, due to the antibonding hyperconjugation of the methyl group. In this case, the HOMO is most suited to η^1-coordination, having the largest orbital coefficient at the ring carbon atom in the position *para* to the methyl substituent.

The relative energies for various investigated complex geometries, together with optimized Ti−L bond lengths, are collected in Table 3. Relative energies are determined for groups of isomeric compounds, in which the energy of the isomer with the largest absolute value in total bonding energy is set to zero, and energies of isomers are reported with reference to the energy of the isomer at zero energy.

The energy differences are small, but significant. In particular, we note that η^1-coordination is favoured for the cationic complexes by about 10 kJ/mol. The small energy differences are accompanied by a fairly large change in the Ti−C bond length, of about 0.20 Å, indicating the subtle nature of this bonding interaction. The bond energies (*BE*s) of benzene and toluene amount to 89 kJ/mol and 100 kJ/mol, respectively.

Finally, complexes of the borate anion $C_6H_5CH_2BF_3^-$ are characterized by the Ti−C bonds, which are about 0.20 Å shorter than those in the related benzene or toluene complexes. Electrostatic interactions between the anionic ligand and the cationic metal fragment have a pronounced influence on the Ti−L bond strength. Again, η^1-coordination is favoured by 16 kJ/mol.

Complexes with the Cation $[Ti\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}NtBu)_2\}]^+$

We begin with the molecular geometry of $[Ti\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}N\mathit{t}Bu)_2\}\{\eta^1\text{-}C_6H_5CH_2B(C_6F_5)_3\}]$, which has also been established by crystal structure determination.[7] By our analysis, we can expect the following features for this compound. Firstly, the $[C_6H_5CH_2B(C_6F_5)_3]^-$ borate ligand should coordinate in η^1-fashion, being oriented upwards toward the site of the cyclopentadienyl ring. This structural feature is observed in the crystal structure of this compound. Furthermore, from simple Hückel orbital considerations, we expect that the coordinating ring carbon atom should be located *para* to the boron substituent. However, the solid-state structure reveals coordination through a *meta* carbon atom rather than one in the *para* position. We therefore optimized two representative geometries for both *meta* and *para* coordination, as shown in Figure 4.

For the *meta* coordination (Figure 4, a), inspection of the optimized geometries reveals the presence of short F···H distances ($d \approx 2.40$ Å), between the pentafluorophenyl rings and methyl groups of the metal fragment. For *para* coordi-

Table 3. Relative energies [kJ/mol] and metal-to-ligand bond lengths [Å] for coordination of the aryl double bond for various complexes of the type $[\{C_5H_3(SiH_2NH)_2\}Ti]^+[\eta^x\text{-}C_6H_5R]$ (R = H, CH_3, $CH_2BF_3^-$; x = 1, 2)

	R = H				R = Me		R = $CH_2BF_3^-$

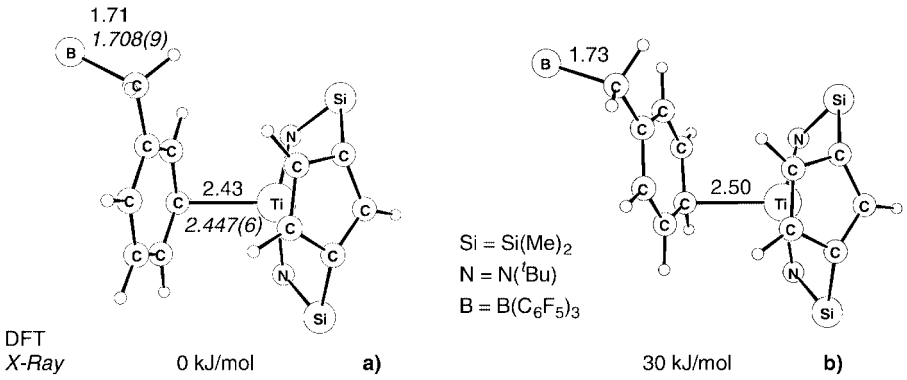

Figure 4. Relative energies and selected bond lengths for *meta* (a) and *para* coordination (b) of [Ti{η^5-C_5H_3($SiMe_2$N*t*Bu)$_2$}{η^1-$C_6H_5CH_2B(C_6F_5)_3$}]; comparison with X-ray analysis

nation (Figure 4, b), in contrast, no such short contacts can be found. The presence of such intramolecular hydrogen bonds might be the key point that explains why the *meta* geometry is energetically favoured by 30 kJ/mol. To produce further evidence for our argument, we also optimized *meta* and *para* geometries for [Ti{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)$_2$}(η^1-$C_6H_5CH_2BF_3$)]. As was to be expected, since no short F···H contacts can be achieved in this case, orbital interactions now favour the latter coordination mode by 13 kJ/mol.

We then optimized the molecular geometry of [Ti{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)$_2$}($CH_2C_6H_5$)], which is displayed in Figure 5. The geometry of the neutral benzyl complex again exhibits "up" coordination, with a typical Ti−C bond length of 2.19 Å. The optimized geometry is in good agreement with the crystal structure of this compound. The reaction energy (ΔE) for the formation of the benzyl complex from [Ti{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)$_2$}{η^1-$C_6H_5CH_2B(C_6F_5)_3$}], which involves the cleavage of a C−B bond, followed by a reorientation of the benzyl fragment, amounts to −15 kJ/mol. The latter compound is therefore stable for kinetic, but not for thermodynamic, reasons. One factor lending kinetic stability to the unusual η^1-adduct is the energy of preparation of the $B(C_6F_5)_3$ fragment, associated with the pyramidalization of the trigonal-planar-coordinated boron atom, which substantially increases the value for the C−B bond strength by the order of 80 kJ/mol.[8c]

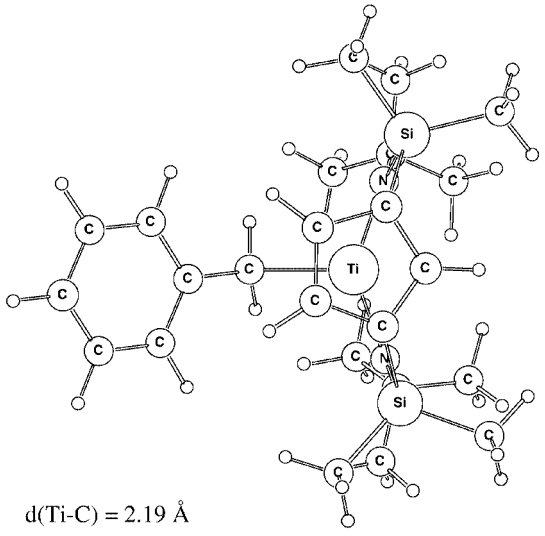

Figure 5. Optimized geometry of the benzyl complex [Ti{η^5-C_5H_3($SiMe_2$N*t*Bu)$_2$}($CH_2C_6H_5$)]

Conclusion

To conclude, we have synthesized a new type of [bis(η^1-amidosilyl)cyclopentadienyl]titanium and -zirconium complexes by direct deprotonation of the corresponding bis(aminosilyl)cyclopentadiene with metal tetraamide and tetrabenzyl derivatives under varying thermal conditions. The complexes obtained in this way may be classified into three categories: monocyclopentadienyl, *ansa*-(amidosilyl)cyclopentadienyl and bis[*ansa*-(amidosilyl)cyclopentadienyl] complexes. The first two categories show the structures and chemical behaviour expected for these well-known types of compounds. However, the bis[*ansa*-bis(amidosilyl)cyclopentadienyl] complexes are isolobal with previously reported tris(cyclopentadienyl) compounds and present reactivity pathways determined by the strong electrostatic character of the interactions, additionally facilitated by the unique accessible metal orbital. Treatment of the benzyl complexes with $B(C_6F_5)_3$ gave the cationic species, which were characterized by X-ray diffraction methods, indicating that the counter-ion is coordinated to the metal atom through a single interaction with the phenyl *m*-carbon atom of the benzyl borate anion.

Density functional calculations developed for the cationic complexes provide an explanation for their remarkable structural features, particularly the "up" (oriented toward the cyclopentadienyl ring) coordination of the benzyl group in the neutral benzyltitanium complex and of the ligand (solvent or counter-anion) bound in the cationic species.

Experimental Section

General Remarks: All experiments were carried out under argon by use either of a Vacuum Atmospheres glove box or of standard Schlenk techniques. Hydrocarbon solvents and THF were distilled from Na/benzophenone and stored under argon prior to use.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1,1-Bis(chlorodimethylsilyl)cyclopentadiene, $Ti(NMe_2)_4$,[11] $Zr(NMe_2)_4$,[11] $Ti(CH_2Ph)_4$,[12] $Zr(CH_2Ph)_4$[12] and $B(C_6F_5)_3$,[24] were prepared by previously reported methods. NMR spectra were recorded with Varian Unity FT 300 and Varian FT 500 Unity Plus instruments in Teflon-valved tubes at probe temperature (20 °C). ^1H and ^{13}C NMR chemical shifts were measured relative to the residual resonances of C_6D_6 used as solvent, but the chemical shifts are reported with respect to TMS. ^{19}F NMR chemical shifts are referenced to external $CFCl_3$. Coupling constants are reported in Hz. C, H and N analyses were carried out with a Perkin−Elmer 240 C analyzer.

$C_5H_4(SiMe_2NHtBu)_2$ (1): A solution of LiNH*t*Bu (1.61 g, 20.5 mmol) in THF (40 mL) was added at 0 °C to a solution of C_5H_4-1,1-$(SiMe_2Cl)_2$ (2.51 g, 10 mmol) in THF and the mixture was stirred for 12 h. The volatiles were removed under vacuum and the residue was extracted into hexane to give a mixture of isomers of **1** as a yellow liquid after removal of the solvent (2.92 g, 9.0 mmol, 90%). ^1H NMR (C_6D_6, 20 °C) of the major component (**1a**): δ = −0.05 (br. s, 6 H, $SiMe_2$), 0.21 (br. s, 6 H, $SiMe_2$), 1.12 (s, 9 H, NH*t*Bu), 1.17 (s, 9 H, NH*t*Bu), 3, 57 (m, 1 H, CpH), 6.50 (m, 1 H, C_5H_3), 6.71 (m, 2 H, C_5H_3) ppm. Component **1b**: δ = 0.09 (s, 12 H, $SiMe_2$), 1.15 (s, 18 H, NH*t*Bu), 6.53 (m, 2 H, C_5H_4), 6.78 (m, 2 H, C_5H_4) ppm.

[Ti{η⁵-C_5H_3-1,3-[$SiMe_2(NHtBu)]_2$}$(NMe_2)_3$] (2): A solution of $Ti(NMe_2)_4$ (0.65 g, 2.9 mmol) in toluene (70 mL) was cooled to 0 °C, and **1** (0.94 g, 2.9 mmol) was added by syringe. The resulting red solution was stirred at 50 °C for 5 h. When the evolution of gas had stopped, the solvent was removed under vacuum and the residue was extracted into pentane (70 mL). After filtration and removal of the solvent, complex **2** was isolated as a deep red oil (1.45 g, 2.8 mmol, 97%). ^1H NMR (C_6D_6, 20 °C): δ = 0.41 (s, 6 H, $SiMe_2$), 0.43 (s, 6 H, $SiMe_2$), 1.04 (s, 2 H, NH*t*Bu), 1.16 (s, 18 H, N*t*Bu), 3.13 (s, 18 H, NMe_2), 6.31 (d, 2 H, C_5H_3), 6.60 (t, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 2.9 ($SiMe_2$), 4.1 ($SiMe_2$), 34.0 (N*t*Bu), 49.3 ($NtBu_{tert}$), 50.3 (NMe_2), 119.9 (C_5H_3), 125.2 (C_5H_3), 127.8 (C_5H_{3ipso}) ppm. IR (Nujol): $\tilde{\nu}$ = 3383 (N−H) cm^{-1}. $C_{23}H_{53}N_5Si_2Ti$ (503.76): calcd. C 54.84, H 10.60, N 13.09; found C 54.17, H 10.23, N 12.82.

[Zr{η⁵-C_5H_3-1,3-[$SiMe_2(NHtBu)]_2$}$(NMe_2)_3$] (3): Compound **1** (0.05 g, 0.1 mmol) was added by syringe to a solution of $Zr(NMe_2)_4$ (0.041 g, 0.1 mmol) in C_6D_6 (0.6 mL). Complex **3** was immediately identified in the NMR spectrum as the unique product of the reaction. ^1H NMR (C_6D_6, 20 °C): δ = 0.42 (s, 6 H, $SiMe_2$), 0.44 (s, 6 H, $SiMe_2$), 1.08 (s, 2 H, NH*t*Bu), 1.15 (s, 18 H, N*t*Bu), 2.98 (s, 18 H, NMe_2), 6.50 (d, 2 H, C_5H_3), 6.78 (t, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 2.8 ($SiMe_2$), 3.5 ($SiMe_2$), 33.9 (N*t*Bu), 45.6 (NMe_2), 49.3 ($NtBu_{tert}$), 120.5 (C_5H_3), 127.0 (C_5H_3), 127.2 (C_5H_{3ipso}) ppm. Pure **3** was only observed in NMR-tube experiments, while solid samples were always contaminated by small amounts of **5**.

[Ti{η⁵-C_5H_3-1-[$SiMe_2(NHtBu)$]-3-[$SiMe_2(η^1$-N*t*Bu)}$(NMe_2)_2$] (4): A solution of $Ti(NMe_2)_4$ (2.00 g, 8.9 mmol) in toluene (70 mL) was cooled to 0 °C, and **1** (2.91 g, 8.9 mmol) was added by syringe. The resulting red solution was heated at reflux for 5 h. When the evolution of gas had stopped, the solvent was removed under vacuum and the residue was extracted into pentane (70 mL). After filtration and removal of the solvent, complex **4** was isolated as a deep red oil (4.10 g, 8.8 mmol, 98%). ^1H NMR (C_6D_6, 20 °C): δ = 0.35 (s, 3 H, $SiMe_2NHtBu$), 0.43 (s, 3 H, $SiMe_2NHtBu$), 0.50 (s, 3 H, $SiMe_2NtBu$), 0.54 (s, 3 H, $SiMe_2NtBu$), 0.86 (s, 1 H, NH*t*Bu), 1.12 (s, 9 H, NH*t*Bu), 1.28 (s, 9 H, N*t*Bu), 2.87 (s, 6 H, NMe_2), 3.05 (s, 6 H, NMe_2), 6.12 (m, 1 H, C_5H_3), 6.31 (m, 1 H, C_5H_3), 6.50 (m, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 2.1 ($SiMe_2$), 2.4 ($SiMe_2$), 2.4 ($SiMe_2$), 3.7 ($SiMe_2$), 34.1 (NH*t*Bu), 34.4 (N*t*Bu), 49.1 (NMe_2), 49.6 ($NHtBu_{tert}$), 50.4 (NMe_2), 60.8 ($NtBu_{tert}$), 109.1 (C_5H_{3ipso}), 121.2 (C_5H_3), 122.5 (C_5H_3), 123.7 (C_5H_3), 130.7 (C_5H_3) ppm. IR (Nujol): $\tilde{\nu}$ = 3385 (N−H) cm^{-1}. $C_{21}H_{46}N_4Si_2Ti$ (458.67): calcd. C 54.99, H 10.11, N 12.21; found C 54.67, H 9.97, N 12.04.

[Zr{η⁵-C_5H_3-1-[$SiMe_2(NHtBu)$]-3-[$SiMe_2(η^1$-N*t*Bu)]}$(NMe_2)_2$] (5): A solution of $Zr(NMe_2)_4$ (3.37 g, 12.6 mmol) in toluene (70 mL) was cooled to 0 °C, and **1** (4.09 g, 12.6 mmol) was added by syringe. The resulting yellow solution was warmed to 65 °C for 5 h. When the evolution of gas had stopped, the solvent was removed under vacuum and the residue was extracted into pentane (70 mL). After filtration and removal of the solvent, complex **5** was isolated as a light brown solid (6.19 g, 12.3 mmol, 98%). IR (Nujol): $\tilde{\nu}$ = 3384 (N−H) cm^{-1}. ^1H NMR (C_6D_6, 20 °C): δ = 0.35 (s, 3 H, $SiMe_2NHtBu$), 0.42 (s, 3 H, $SiMe_2NHtBu$), 0.57 (s, 3 H, $SiMe_2NtBu$), 0.59 (s, 3 H, $SiMe_2NtBu$), 0.85 (s, 1 H, NH*t*Bu), 1.11 (s, 9 H, NH*t*Bu), 1.27 (s, 9 H, N*t*Bu), 2.81 (s, 6 H, NMe_2), 2.82 (s, 6 H, NMe_2), 6.39 (m, 1 H, C_5H_3), 6.47 (m, 1 H, C_5H_3), 6.69 (m, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 2.3 ($SiMe_2$), 2.7 ($SiMe_2$), 2.8 ($SiMe_2$), 3.0 ($SiMe_2$), 33.9 (NH*t*Bu), 34.9 (N*t*Bu), 44.2 (NMe_2), 44.5 (NMe_2), 49.6 ($NHtBu_{tert}$), 56.6 ($NtBu_{tert}$), 111.4 (C_5H_{3ipso}), 122.6 (C_5H_3), 122.9 (C_5H_3); 124.7 (C_5H_3), 126.7 (C_5H_3) ppm. $C_{21}H_{46}N_4Si_2Zr$ (502.01): calcd. C 50.24, H 9.24, N 11.16; found C 49.73, H 9.05, N 11.45.

[Ti{η⁵-C_5H_3-1-[$SiMe_2(NHtBu)$]-3-[$SiMe_2(η^1$-N*t*Bu)]}$(CH_2Ph)_2$] (6): A solution of $Ti(CH_2Ph)_4$ (2.14 g, 5.2 mmol) in toluene (70 mL) was cooled to 0 °C, and **1** (1.69 gr, 5.2 mmol) was added by syringe. The resulting yellow solution was warmed to 70 °C for 5 h. When the evolution of gas had stopped, the solvent was removed under vacuum and the residue was extracted into pentane (70 mL). After filtration and removal of the solvent, complex **6** was isolated as a red-brown solid (2.86 g, 5.1 mmol, 98%). ^1H NMR (C_6D_6, 20 °C): δ = 0.21 (s, 3 H, $SiMe_2NHtBu$), 0.27 (s, 3 H, $SiMe_2NHtBu$), 0.37 (s, 3 H, $SiMe_2NtBu$), 0.38 (s, 3 H, $SiMe_2NtBu$), 0.72 (s, 1 H, NH*t*Bu), 1.06 (s, 9 H, NH*t*Bu), 1.44 (s, 9 H, N*t*Bu), 2.46 (d, *J* = 10.5 Hz, 1 H, CH_2Ph), 2.55 (d, *J* = 10.5 Hz, 1 H, CH_2Ph), 2.81 (d, *J* = 10.5 Hz, 1 H, CH_2Ph), 2.97 (d, *J* = 10.5 Hz, 1 H, CH_2Ph), 5.83 (m, 1 H, C_5H_3), 6.14 (m, 1 H, C_5H_3), 6.83 (m, 1 H, C_5H_3), 6.87−7.20 (m, 10 H, CH_2Ph) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 0.6 ($SiMe_2$), 1.5 ($SiMe_2$), 2.4 ($SiMe_2$), 2.9 ($SiMe_2$), 33.8 (NH*t*Bu), 34.2 (N*t*Bu), 49.8 ($NHtBu_{tert}$), 61.5 ($NtBu_{tert}$), 79.6 (CH_2Ph), 83.7 (CH_2Ph), 110.2 (C_5H_{3ipso}), 122.1 (C_5H_3), 122.5 (C_5H_3), 122.8 (C_5H_3), 123.0 (C_5H_3), 125.9 (C_6H_5), 126.8 (C_6H_5), 127.4 (C_6H_5), 128.5 (C_6H_5), 128.6 (C_6H_5), 128.7 (C_6H_5), 128.9 (C_6H_5), 129.8 (C_6H_5), 132.6 (C_6H_5), 149.6 (C_6H_{5ipso}), 150.1 (C_6H_{5ipso}) ppm. (s, 9 H, NH*t*Bu), 1.13 (s, 9 H, N*t*Bu), 1.66 (s, 1 H, CH_2Ph), 1.72 (s, 1 H, CH_2Ph), 2.12 (s, 1 H, CH_2Ph), 2.17 (s, 1 H, CH_2Ph), 6.21 (m, 1 H, C_5H_3), 6.35 (m, 1 H, C_5H_3), 6.60 (m, 1 H, C_5H_3), 6.90−7.30 (m, 10 H, C_6H_5) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 1.3 ($SiMe_2$), 2.0 ($SiMe_2$), 2.4 ($SiMe_2$), 2.5 ($SiMe_2$), 33.7 (NH*t*Bu), 33.8 (N*t*Bu), 49.7 (NH*t*Bu_{tert}), 54.9 (CH_2Ph), 57.5 (N*t*Bu_{tert}), 57.9 (CH_2Ph), 109.6 (C_5H_{3ipso}), 122.2 (C_5H_3), 122.5 (C_5H_3), 124.8 (C_5H_3), 125.6 (C_5H_3), 125.9 (C_6H_5), 126.4 (C_6H_5), 126.6 (C_6H_5), 127.8 (C_6H_5), 129.3 (C_6H_5), 129.6 (C_6H_5), 129.6 (C_6H_5), 129.8 (C_6H_5), 131.9 (C_6H_5), 145.8 (C_6H_{5ipso}), 146.2 (C_6H_{5ipso}) ppm.

[Ti{η⁵-C_5H_3-1,3-[$SiMe_2$(η¹-N*t*Bu)]$_2$}(NMe_2)] (8): When a C_6D_6 solution of the diamido complex **4** was heated at 160 °C for 12 h in a sealed NMR tube, a slow reaction took place with elimination of $NHMe_2$ to give **8**, identified by its ^1H and ^{13}C NMR spectra, together with the starting complex **4**. When the reaction mixture was cooled to room temperature, the reaction proved to be irreversible. ^1H NMR (C_6D_6, 20 °C): δ = 0.50 (s, 6 H, $SiMe_2$), 0.52 (s, 6 H, $SiMe_2$), 1.38 (s, 18 H, N*t*Bu), 2.83 (s, 6 H, NMe_2), 6.17 (d, 2 H, C_5H_3), 6.71 (t, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 2.7 ($SiMe_2$), 2.8 ($SiMe_2$), 35.2 (N*t*Bu), 51.3 (NMe_2), 59.3 (N*t*Bu_{tert}), 117.7 (C_5H_{3ipso}), 121.3 (C_5H_3), 131.9 (C_5H_3) ppm.

[Zr{η⁵-C_5H_3-1,3-[$SiMe_2$(η¹-N*t*Bu)]$_2$}(NMe_2)] (9). Method A: When a C_6D_6 solution of the diamido complex **5** was heated at 120 °C for 12 h in a sealed NMR tube, a slow reaction took place with elimination of $NHMe_2$ to give **9**, identified by its ^1H and ^{13}C NMR spectra. However, when the reaction mixture was cooled to room temperature, a reversible reaction with the free $NHMe_2$ present in solution once more yielded the starting complex **5**. **Method B:** A 1:1 molar ratio of the benzyl derivative **11** (1.46 g, 3.1 mmol) and the diamido derivative **5** (1.45 g, 3.1 mmol) in toluene was heated at 120 °C in a Teflon-valved Schlenk tube for 12 h. The solvent was removed under vacuum and the residue was extracted into pentane (50 mL). After filtration and removal of the solvent, complex **9** (1.32 g, 2.9 mmol, 94%) was isolated as a yellow solid. ^1H NMR (C_6D_6, 20 °C): δ = 0.51 (s, 6 H, $SiMe_2$), 0.55 (s, 6 H, $SiMe_2$), 1.31 (s, 18 H, N*t*Bu), 2.77 (s, 6 H, NMe_2), 6.34 (d, 2 H, C_5H_3), 6.78 (t, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 2.9 ($SiMe_2$), 3.0 ($SiMe_2$), 35.6 (N*t*Bu), 45.1 (NMe_2), 55.8 (N*t*Bu_{tert}), 117.7 (C_5H_{3ipso}) 119.8 (C_5H_3), 133.2 (C_5H_3) ppm. $C_{19}H_{39}N_3Si_2Zr$ (456.93): calcd. C 49.94, H 8.60, N 9.20; found C 50.28, H 8.31, N 8.86.

[Ti{η⁵-C_5H_3-1,3-[$SiMe_2$(η¹-N*t*Bu)]$_2$}(CH_2Ph)] (10): A solution of $Ti(CH_2Ph)_4$ (5.34 g, 12.9 mmol) in toluene (70 mL) was cooled to 0 °C, and **1** (4.21 g, 12.9 mmol) was added by syringe. The resulting deep red solution was warmed at 70 °C for 5 h. The solvent was removed under vacuum and the residue was extracted into pentane (70 mL). After filtration and removal of the solvent, complex **10** was isolated as a waxy, red solid, which was recrystallized from hexane to give orange crystals (5.88 g, 12.7 mmol, 98%). ^1H NMR (C_6D_6, 20 °C): δ = 0.39 (s, 6 H, $SiMe_2$), 0.40 (s, 6 H, $SiMe_2$), 1.42 (s, 18 H, N*t*Bu), 2.59 (s, 2 H, CH_2Ph), 6.12 (d, 2 H, C_5H_3), 6.39 (t, 1 H, C_5H_3), 6.89 (m, 1 H, C_6H_5), 6.95 (m, 2 H, C_6H_5), 7.22 (m, 2 H, C_6H_5) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 2.1 ($SiMe_2$), 2.2 ($SiMe_2$), 35.6 (N*t*Bu), 59.3 (N*t*Bu_{tert}), 69.6 (CH_2Ph), 117.7 (C_5H_{3ipso}), 121.5 (C_5H_3), 126.3 (C_5H_3), 128.5 (C_6H_5), 130.3 (C_6H_5), 132.6 (C_6H_5), 152.4 (C_6H_{5ipso}) ppm. $C_{24}H_{40}N_2Si_2Ti$ (460.63): calcd. C 62.58, H 8.75, N 6.08; found C 62.68, H 8.68, N 5.76.

[Zr{η⁵-C_5H_3-1,3-[$SiMe_2$(η¹-N*t*Bu)]$_2$}(CH_2Ph)] (11): A solution of $Zr(CH_2Ph)_4$ (2.93 g, 6.43 mmol) in toluene (70 mL) was cooled to 0 °C, and **1** (2.09 g, 6.43 mmol) was added by syringe. The resulting yellow solution was heated at reflux for 5 h. The solvent was removed under vacuum and the residue was extracted into pentane (70 mL). After filtration and removal of the solvent, complex **11** was isolated as a brown solid. (3.20 g, 6.34 mmol, 99%). ^1H NMR (C_6D_6, 20 °C): δ = 0.40 (s, 6 H, $SiMe_2$), 0.42 (s, 6 H, $SiMe_2$), 1.27 (s, 18 H, N*t*Bu), 2.12 (s, 2 H, CH_2Ph), 6.14 (d, 2 H, C_5H_3), 6.53 (t, 1 H, C_5H_3) 6.9−7.23 (m, 5 H, C_6H_5) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 2.4 ($SiMe_2$), δ = 2.4 ($SiMe_2$), 35.8 (N*t*Bu), 55.8 (CH_2Ph), 57.1 (N*t*Bu_{tert}), 116.5 (C_5H_{3ipso}), 120.7 (C_5H_3), 126.4 (C_5H_3), 128.5 (C_6H_5), 129.8 (C_6H_5), 132.7 (C_6H_5), 150.6 (C_6H_{5ipso}) ppm. $C_{24}H_{40}N_2Si_2Zr$ (503.97): calcd. C 57.20, H 8.00, N 5.56; found C 57.01, H 7.65, N 5.48.

[Ti{η⁵-C_5H_3-1,3-[$SiMe_2$(η¹-N*t*Bu)]$_2$}]⁺ [(CH_2Ph)B(C_6F_5)$_3$]⁻ (12): A toluene (20 mL) solution of the monobenzyl complex **10** (0.125 g, 0.25 mmol) was treated at room temperature with $B(C_6F_5)_3$ (0.126 g, 0.25 mmol), and the mixture was stirred for 30 min and cooled to −35 °C. The solvent was filtered off from the resulting insoluble residue, which was then dried under vacuum to give **12** (0.13 g, 60% yield) as an orange, crystalline solid. ^1H NMR (C_6D_6, 20 °C): δ = 0.19 (s, 6 H, $SiMe_2$), 0.38 (s, 6 H, $SiMe_2$), 1.12 (s, 18 H, N*t*Bu), 3.49 (s, 2 H, BCH_2), 5.03 (d, 2 H, C_5H_3), 5.86 (t, 1 H, C_5H_3), 6.21−7.10 (m, 5 H, C_6H_5) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 0.6 ($SiMe_2$), 1.4 ($SiMe_2$), 34.6 (N*t*Bu), 59.3 (N*t*Bu_{tert}), 122.1 (C_5H_{3ipso}) 126.1 (C_5H_3), 126.2 (C_5H_3), 128.3 (C_6H_5), 128.7 (C_6H_5), 132.9 (C_6H_5), 135.1 (C_6F_5), 140.1 (C_6F_5), 145.8 (C_6F_5), 150.9 (C_6F_5) ppm. ^{19}F NMR (300 MHz, C_6D_6, 20 °C, CCl_3F): δ = 132.1 (m, 2 F, *o*-C_6F_5), 163.7 (m, 1 F, *p*-C_6F_5), 167.3 (m, 2 F, *m*-C_6F_5) ppm. $C_{42}H_{40}BF_{15}N_2Si_2Ti$ (972.63): calcd. C 51.87, H 4.15, N 2.88; found C 51.98, H 4.04, N 3.08.

[Zr{η⁵-C_5H_3-1,3-[$SiMe_2$(η¹-N*t*Bu)]$_2$}]⁺ [(CH_2Ph)B(C_6F_5)$_3$]⁻ (13): A toluene (20 mL) solution of the monobenzyl complex **11** (0.116 g, 0.25 mmol) was treated with $B(C_6F_5)_3$ (0.126 g, 0.25 mmol) at room temperature and the mixture was stirred for 30 min and cooled to −35 °C. The solvent was filtered off from the resulting insoluble residue, which was then dried under vacuum to give **13** (0.21 g, 83% yield) as a dark brown oil. After recrystallization, a suitable orange monocrystal of **13** was separated for X-ray diffraction studies. ^1H NMR (C_6D_6, 20 °C): δ = 0.17 (s, 6 H, Si*Me*$_2$), 0.36 (s, 6 H, Si*Me*$_2$), 0.99 (s, 18 H, N*t*Bu), 3.42 (s, 2 H, BC*H*$_2$), 5.20 (d, 2 H, C_5H_3), 6.01 (t, 1 H, C_5H_3), 6.10 (m, 1 H, *p*-C_6H_5), 6.34 (m, 2 H, *m*-C_6H_5), 6.87 (m, 2 H, *o*-C_6H_5) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 1.5 (Si*Me*$_2$), 1.6 (Si*Me*$_2$), 34.8 (N*t*Bu), 58.6 (N*t*Bu_{tert}), 121.4 (C_5H_3), 123.5 (C_5H_{3ipso}), 127.4 (C_5H_3), 127.9 (C_6H_5), 128.1 (C_6H_5), 128.3 (C_6H_5), 136.5 (C_6F_5), 138.3 (C_6F_5), 147.8 (C_6F_5), 149.8 (C_6F_5), 162.0 (C_6H_{5ipso}) ppm. ^{19}F NMR (300 MHz, C_6D_6, 20 °C, CCl_3F): δ = 132.1 (m, 2 F, *o*-C_6F_5), 163.6 (m, 1 F, *p*-C_6F_5), 167.2 (m, 2 F, *m*-C_6F_5) ppm. $C_{42}H_{40}BF_{15}N_2Si_2Zr$ (1015.97): calcd. C 49.65, H 3.97, N 2.76; found C 50.51, H 3.71, N 3.35.

Crystal Structure Determination for Compound 10: Crystals of **10** were grown from a hexane solution. An orange fragment in perfluorinated ether was selected and transferred to a glass capillary, which was mounted in a cold N_2 stream. Preliminary examination and data collection were carried out with a Nonius KappaCCD device at the window of a rotating anode X-ray generator with use of graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), controlled by the Collect software package.[25] Collected images were processed by use of Denzo. The unit cell parameters were obtained by full-matrix, least-squares refinements of 4895 reflections.[26] A total number of 41477 reflections were integrated. After merging, 4739 reflections remained, and these were used for all further calculations. Absorption effects were corrected during the scaling procedure. The structure was solved by direct methods[27] and refined by standard difference Fourier techniques.[28] All non-hydrogen atoms of the asymmetric unit were refined with aniso-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tropic thermal displacement parameters. All hydrogen atoms were found in the difference Fourier map and refined freely with individual isotropic thermal displacement parameters, except for those located at a disordered *tert*-butyl group, which were placed in calculated positions (riding model). Full-matrix, least-squares refinements were carried out by minimization of $\Sigma w(F_o^2-F_c^2)^2$ by use of the SHELXL-97 weighting scheme and stopped at a maximum shift/err < 0.001.[28,29,30] One *tert*-butyl group in **10** appears to be disordered over two positions (73:27).

Crystal Structure Determination for Compound 13: Crystals of **13** were grown from a C_6D_6 solution. An orange plate in perfluorinated ether was selected and transferred to a glass capillary. Preliminary examination and data collection were carried out with a Nonius KappaCCD device at the window of a rotating anode X-ray generator by use of graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å), controlled by the Collect software package.[26] Collected images were processed by use of Denzo. The unit cell parameters were obtained by full-matrix, least-squares refinements of 8080 reflections.[27] A total number of 44162 reflections were integrated. After merging, 8099 reflections remained and were used for all further calculations. Absorption effects were corrected during the scaling procedure. The structure was solved by direct methods[27] and refined by standard difference Fourier techniques.[28] All non-hydrogen atoms of the asymmetric unit were refined with anisotropic thermal displacement parameters. All hydrogen atoms were found in the difference Fourier map and refined freely with individual isotropic thermal displacement parameters. Full-matrix, least-squares refinements were carried out by minimization of $\Sigma w(F_o^2-F_c^2)^2$ by use of the SHELXL-97 weighting scheme and stopped at a maximum shift/err < 0.001. A correction for extinction effects was applied.[28–30]

CCDC-200139 (**10**) and -200140 (**13**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details: Gradient corrected density functional calculations were carried out, with corrections for exchange and correlation according to Becke[31] and Perdew,[32] respectively (BP86). Geometries were optimized by use of the TURBOMOLE[33] program system within the framework of the RI-*J* approximation.[34] For the model systems, a triple-ζ valence basis plus polarization TZVP[35] was employed. For the geometry optimization of the real molecules, the main group elements were described by a split-valence basis set[36] with one set of polarization functions for the non-H atoms, and Ti was treated with the TZVP basis. For the determination of bond energies, final energies were obtained in a single-point calculation using the TZVP basis set for all atoms.

Synthesis, X-ray Crystallographic and ^{1}H NMR Spectroscopic Structural Studies on Cobalt(II) Complexes of Homoscorpionate, Heteroscorpionates and Chiral Tris(pyrazolyl)borates Obtained from 5(3)-*Iso*propyl-3(5)-phenylpyrazole and 3,5-Dimethylpyrazole[‡]

Tomasz Ruman,[a] Zbigniew Ciunik,[b] and Stanislaw Wołowiec*[a]

Keywords: Boron / Chirality / Cobalt / N ligands / NMR spectroscopy

Condensation of 5(3)-isopropyl-3(5)-phenylpyrazole with sodium borohydride led to a mixture of tris(pyrazolyl)borate ligands (Tp^x) – the homoscorpionate hydrotris(5-isopropyl-3-phenylpyrazolyl)borate and the heteroscorpionates hydro(3-isopropyl-5-phenylpyrazolyl)bis(5-isopropyl-3-phenylpyrazolyl)borate and hydrobis(3-isopropyl-5-phenylpyrazolyl)(5-isopropyl-3-phenylpyrazolyl)borate – that were converted into Tp^{x}Co(NCS) complexes. The molecular structures of pentacoordinate[hydrotris(5-isopropyl-3-phenylpyrazolyl)-borato](tetrahydrofuran)(thiocyanato)cobalt(II) (**1-THF**) and [hydrobis(3-isopropyl-5-phenylpyrazolyl)(5-isopropyl-3-phenylpyrazolyl)borato](tetrahydrofuran)(thiocyanato)-cobalt(II) (**3-THF**) were elucidated crystallographically. Hydro(3,5-dimethylpyrazolyl)bis(5-isopropyl-3-phenylpyrazolyl)borate was also obtained by condensation of 2.1 equiv. of 5(3)-isopropyl-3(5)-phenylpyrazole and 0.9 equiv. of 3,5-dimethylpyrazole with sodium borohydride, and it was converted into [hydro(3,5-dimethylpyrazolyl)bis(5-isopropyl-3-phenylpyrazolyl)borato](thiocyanato)cobalt(II) (**4**), which was characterized by X-ray crystallography. The latter was converted thermally under mild conditions (358 K in toluene) into [hydro(3,5-dimethylpyrazolyl)(3-isopropyl-5-phenylpyrazolyl)(5-isopropyl-3-phenylpyrazolyl)borato](thiocyanato)cobalt(II) (**9**) in 45% yield, as was concluded from the ^{1}H NMR spectrum of the post-reaction mixture. The dimer of **9** was obtained as single crystals from toluene/hexane and its structure was determined crystallographically. Two chiral Tp^x ligands of opposite boron-centered configurations are coordinated to cobalt(II) ions in a κ^3 fashion. The pentacoordinate metal ions are bridged head-to-tail by the thiocyanate anions. This chiral Tp^x ligand is the first example of a borate with fixed boron-centered chirality.

Introduction

Some 3(5)-R^1,5(3)-R^2-substituted pyrazoles (3-R^1,5-R^{2}pzH) form spontaneously both homo- and heteroscorpionate tris(pyrazolyl)borate anions when condensed with borohydride (BH_4^-).[1−10] The phenomenon was noticed originally by Trofimenko, who found that 3-isopropylpyrazole gave homoscorpionate tris(3-isopropylpyrazolyl)borate (Tp$^{i\mathrm{Pr}}$), which underwent thermal conversion in the Tp$^{i\mathrm{Pr}2}$Co complex into bis[hydrobis(3-isopropylpyrazolyl)-(5-isopropylpyrazolyl)borato]cobalt(II).[1] Metal-ion complexes of homoscorpionate Tp^x ligands have potentially C_{3v} symmetry when coordinated in a κ^3 manner, while the same type of coordination in case of heteroscorpionate Tp^x results in the formation of C_s local symmetry around the metal ion. Tp^x ligands of C_s symmetry form spontaneously from one pyrazole or by the use of two different pyrazoles. Hereafter, the latter species are named synthetic heteroscorpionates. Many synthetic heteroscorpionates have been prepared to date.[10−17] Recently, [hydro(3,5-dimethylpyrazolyl)bis(5-methyl-3-phenylpyrazolyl)borato](thiocyanato)-cobalt(II) was converted thermally into [hydro(3,5-dimethylpyrazolyl)(3-methyl-5-phenylpyrazolyl)(5-methyl-3-phenylpyrazolyl)borato](thiocyanato)cobalt(II) in ca. 30% yield upon heating the starting heteroscorpionate complex at 428 K in propylbenzene under reflux.[10] Encouraged by that result, we have replaced 5(3)-methyl-3(5)-phenylpyrazole with 5(3)-isopropyl-3(5)-phenylpyrazole to synthesize heteroscorpionates bearing 3- and 5-substituents of comparable size on the two pyrazolyl residues of Tp^x. We observed the ready formation of homo- and two heteroscorpionates when sodium borohydride was condensed with 3 equiv. of 5(3)-isopropyl-3(5)-phenylpyrazole. Three Tp^{x}Co(NCS) complexes were obtained and separated from this synthetic mixture, and two of them were characterized crystallographically. The ambivalent binding of 5(3)-isopro-

[‡] Complexes of Heteroscorpionate Trispyrazolylborate Ligands, VIII. Part VII: Ref.[17]

[a] Faculty of Chemistry, Rzeszów University of Technology, 6 Powstanców Warszawy Ave., 35-959 Rzeszów, Poland

pyl-3(5)-phenylpyrazole was then used for the thermal conversion in good yield under mild conditions of the synthetic heteroscorpionate in [hydro(3,5-dimethylpyrazolyl)bis(5-isopropyl-3-phenylpyrazolyl)borato](thiocyanato)cobalt(II) into its counterpart bearing a chiral Tp^x ligand.

Results and Discussion

Heteroscorpionate tris(pyrazolyl)borates formed spontaneously when the pyrazoles used to construct Tp^x were 3(5)-isopropylpyrazole,[1] 4-bromo-3(5)-isopropylpyrazole,[1,2] 3(5)-neopentylpyrazole,[3] 3(5)-mesitylpyrazole,[4] 5-methyl-3,4-diphenylpyrazole,[5] 3(5)-methylpyrazole,[6] 3(5)-phenylpyrazole,[7] 3(5)-cyclohexylpyrazole,[8] 4-bromo-3(5)-cyclohexylpyrazole,[8] (4*R*,7*R*)-7-isopropyl-4-methyl-4,5,6,7-tetrahydroindazole,[9] and 5(3)-methyl-3(5)-phenylpyrazole.[10] In the latter case, the sodium salt of heteroscorpionate Na[HB(3-Ph,5-Mepz)$_2$(3-Me,5-Phpz)] was separated from the homoscorpionate $NaTp^{Ph,Me}$ counterpart because of the good solubility of $NaTp^{Ph,Me}$ in hot heptane. Moreover, prolonged heating of sodium homoscorpionate in heptane under reflux caused considerable conversion of $NaTp^{Ph,Me}$ into sodium heteroscorpionate.[10,11] On the other hand, the heteroscorpionate Tp^x ligands were obtained by deliberate synthesis with the use of two different pyrazoles.[10−17]

Previously, we demonstrated that heating of [hydro(3,5-dimethylpyrazolyl)bis(5-methyl-3-phenylpyrazolyl)borato](thiocyanato)cobalt(II) {[HB(3-Ph,5-Mepz)$_2$(3,5-diMepz)]Co(NCS)} in propylbenzene at 428 K led to the formation of [hydro(3,5-dimethylpyrazolyl)(3-methyl-5-phenylpyrazolyl)(5-methyl-3-phenylpyrazolyl)borato](thiocyanato)cobalt(II) complex, containing a chiral Tp^x ligand, in ca. 30% yield.[14] The reaction was accompanied by formation of other products, namely [hydro(3,5-dimethylpyrazolyl)bis(3-methyl-5-phenylpyrazolyl)borato](thiocyanato)cobalt(II) and complexes later identified as $Tp^xCo(NCS)$ species containing Tp^x ligands of different composition resulting from cross-exchange of pyrazole units between the two Tp^x ligands.[11] These products form readily when thiocyanate in [HB(3-Ph,5-Mepz)$_2$(3,5-diMepz)]Co(NCS) is replaced with carboxylates, such as lactate, pyruvate, or 2-hydroxybutyrate.[11] This instability of Tp^x ligands containing the 3,5-dimethylpyrazolyl residue led to the formation of hydrobis(3,5-dimethylpyrazolyl)[5(3)-methyl-3(5)-phenylpyrazolyl]borate and even hydrotris(3,5-dimethylpyrazolyl)borate anions that are able to form bis(ligand) homo- and heteroleptic $Tp^xCoTp^{x\prime}$ complexes because of the low steric hindrance of the Tp^x ligands. Consequently, the dismutation of $Tp^xCo(OOCR)$ into $Tp^xCoTp^{x\prime}$ and $Co(OOCR)_2$ took place. To avoid the dismutation of $Tp^xCo(X)$ complexes, we have synthesized the Tp^x ligand composed of the 3(5)-isopropyl-5(3)-phenylpyrazole unit, with medium-sized substituents placed at both the 3- and 5-positions of the pyrazole unit. Thus, we have produced homo- and heteroscorpionate anionic ligands that are sterically more crowded in comparison with hydro(3,5-dimethylpyrazolyl)bis(5-methyl-3-phenylpyrazolyl)borate and have performed thermal conversion of the corresponding $Tp^xCo(NCS)$ complex into chiral Tp^x at lower temperature.

Spontaneously Formed Tp^x Heteroscorpionates Constructed of 5(3)-Isopropyl-3(5)-phenylpyrazole

Condensation of sodium borohydride with 5(3)-isopropyl-3(5)-phenylpyrazole and prolonged heating of the reaction mixture in heptane under reflux led to the formation of three Tp^x anions. These anions were bound into isolated $Tp^xCo(NCS)$ complexes − namely, [hydrotris(5-isopropyl-3-phenylpyrazolyl)borato](tetrahydrofuran)(thiocyanato)-cobalt(II) [$Tp^{Ph,iPr}$Co(NCS)(THF), **1-THF**], [hydro(3-isopropyl-5-phenylpyrazolyl)bis(5-isopropyl-3-phenylpyrazolyl)borato](thiocyanato)cobalt(II) {[HB(3-Ph,5-*i*Prpz)$_2$(3-*i*Pr,5-Phpz)]Co(NCS), **2**}, and [hydrobis(3-isopropyl-5-phenylpyrazolyl)(5-isopropyl-3-phenylpyrazolyl)-borato](tetrahydrofuran)(thiocyanato)cobalt(II) {[HB(3-*i*Pr,5-Phpz)$_2$(3-Ph,5-*i*Prpz)]Co(NCS)(THF), **3-THF**} − and two of them (**1-THF** and **3-THF**) were characterized by X-ray crystallography. Views of the molecules of **1-THF** and **3-THF** are presented in Figures 1 and 2, respectively.

Both Tp^x ligands are coordinated in a κ^3 manner to the central metal ion. The complexes are pentacoordinate, with a nitrogen atom donor of a thiocyanate unit and an oxygen atom of THF completing the coordination sphere. The cobalt-centered (β) and boron-centered (α) bite angles (measured disregarding the hydrogen atoms) in **1-THF** and **3-THF** are β = 75.6 and 86.4°, respectively, and α = 140.7 and 159.1°, respectively. We see that the Tp^x ligand in **3-THF** is much more relaxed. The release of the steric hindrance in the Tp^x ligand in **3-THF**, relative to that in **1-THF**, is probably the reason for the spontaneous transformation, even in the case of the sodium salt. On the other

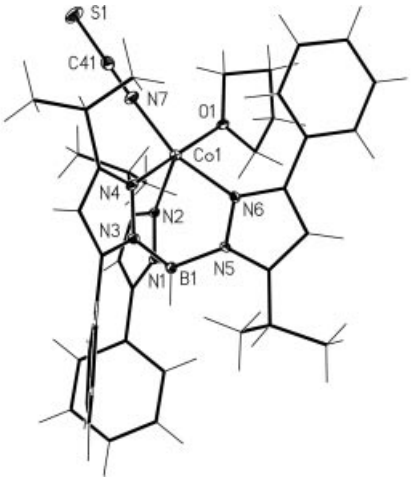

Figure 2. View of **3-THF**; selected bond lengths [Å] and angles [°]: Co(1)−N(7) 1.980(3), Co(1)−N(2) 2.056(3), Co(1)−N(4) 2.125(3), Co(1)−N(6) 2.067(2); Co(1)−O(1) 2.133(2), N(7)−Co(1)−N(2) 110.06(10), N(7)−Co(1)−N(4) 95.42(10), N(7)−Co(1)−N(6) 159.12(11), N(2)−Co(1)−N(4) 90.12(10), N(2)−Co(1)−N(6) 90.78(10), N(4)−Co(1)−N(6) 85.61(9), N(7)−Co(1)−O(1) 86.71(9), N(2)−Co(1)−O(1) 95.61(9), N(4)−Co(1)−O(1) 172.82(9), N(6)−Co(1)−O(1) 89.96(9)

hand, the boron−cobalt distance in **1-THF** is considerably shorter (3.07 Å) than that in **3-THF** (3.11 Å). The chemical shifts observed in the ^{1}H NMR spectra of **1**−**3** taken in [D$_4$]methanol corroborate strictly with those structural features (Figure 3).

The spectrum of **1-CD$_3$OD** is simple because of the effective C_{3v} symmetry of the complex and is composed of an upfield-shifted *o*-H(3-Ph) resonance at δ = −57.4 ppm, and a single downfield-shifted resonance at δ = 18.3 ppm for all of the 18 methyl group protons of the 5-*i*Pr substituent (Figure 3, trace A). The resonance of the methyl group protons of the 3-*i*Pr unit, which integrates to six protons at δ = −24.8 ppm in spectrum B, is diagnostic of **2-CD$_3$OD**. The methyl group protons of two 5-*i*Pr substituents show two separate signals at δ = 19.1 and 26.1 ppm because of diastereotopicity at the boron side of Tp^x in **2-CD$_3$OD**. The local chirality is caused by the fact that the 5-*i*Prpz residues are flanked by two different pyrazolyl moieties, i.e., the units 3-Ph,5-*i*Prpz and 3-*i*Pr,5-Phpz. The resonance of C*H*(3-*i*Prpz) is shifted upfield, as is that of *o*-H(3-Ph), which was anticipated on the basis of previous studies.[1,3,4,9−11,13−18] All other resonances − i.e., B-*H*, 4-H, and those of the 5-substituents − are shifted downfield (Figure 3, trace B). This feature is also observed for **3-CD$_3$OD** (Figure 3, trace C). In this case, the resonance of the methyl group protons of two 3-*i*Pr substituents are split into a doublet because of diastereotopicity at the cobalt side of Tp^x in **3-CD$_3$OD**. The chemical shift of C*H*$_3$(3-*i*Pr) is similar in both **2-CD$_3$OD** and **3-CD$_3$OD**.

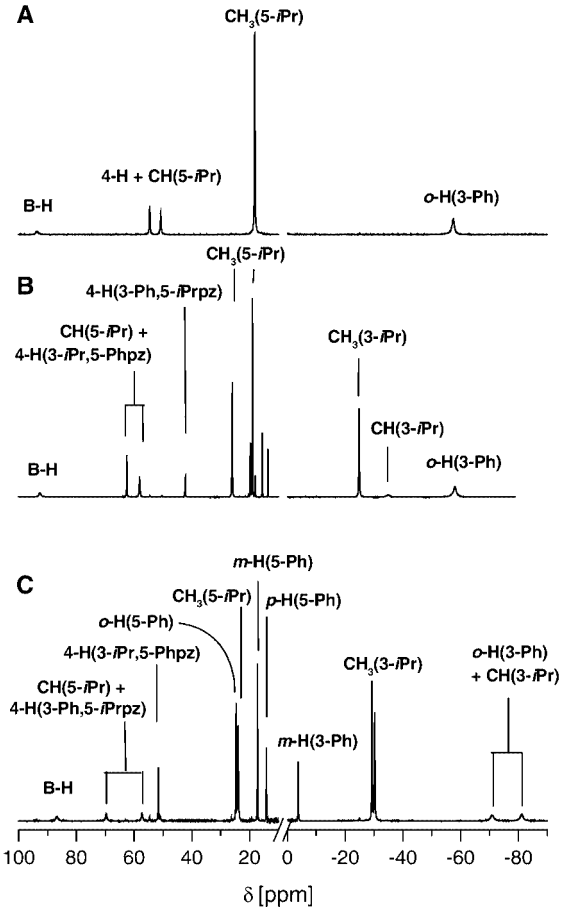

Figure 3. ^{1}H NMR spectra of **1-CD$_3$OD** (A), **2-CD$_3$OD** (B), and **3-CD$_3$OD** (C) in [D$_4$]methanol at 298 K; the 10−0-ppm region has been omitted for the sake of clarity.

Although the relationship between the solid-state structures of pentacoordinate ***n*-THF** complexes and ***n*-CD$_3$OD** counterparts (where ***n*** = **1** or **3**) is not straightforward, the correlation demonstrated by the data in Table 1 is remarkable.

Table 1. Relationship between structures and their ^{1}H NMR chemical shifts

Compound	Geometric factors[a]			Chemical shifts[b]			
	β [°]	α [°]	B···Co [Å]	δ(B-*H*) [ppm]	δ(C*H*,3-*i*Pr) [ppm]	δ(C*H*$_3$,3-*i*Pr) [ppm]	δ(*o*-H,3-Ph) [ppm]
1-CD$_3$OD	140.6	75.5	3.07	93.7	−	−	−57.4
2-CD$_3$OD[c]	−	−	−	92.7	−34.8	−24.8	−57.9
3-CD$_3$OD	159.0	86.4	3.11	86.7	−71.1	−29.8[d]	−81.2

[a] Data from X-ray crystallographic measurements for Tp^{x}Co(NCS)(THF) complexes, unless otherwise stated. [b] Measured in [D$_4$]methanol. [c] No X-ray crystallographic data available. [d] Averaged value for two separate resonances. [e] Geometric factors measured for tetracoordinate Tp^{x}Co(NCS) and pentacoordinate [Tp^{x}Co(NCS)]$_2$, respectively.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The correlation between the chemical shift of the B-*H* proton and the cobalt−boron distance is obvious; the longer the distance between the cobalt atom and the boron-attached hydrogen atom in an ***n*-THF** complex, the lower is the value of the chemical shift of the B-*H* proton in ***n*-CD_3OD**. A similar trend is found on the cobalt side of the Tp^x ligands; the mean distances between the C(*ortho*) atom of the 3-phenyl substituents and the cobalt ion in **1-THF** and **3-THF** are 3.52 and 3.46 Å, respectively, and, consequently, the chemical shifts of *o*-H(3-Ph) are δ = −57.4 and −81.2 ppm in **1-CD_3OD** and **3-CD_3OD**, respectively. A comparison of the bite angles in **1-THF** and **3-THF** indicates that steric crowding imposed by three 3-phenyl substituents around the cobalt ion in **1-CD_3OD** keeps the *o*-H(3-Ph) protons remote from the paramagnetic center, while the more relaxed surrounding of cobalt(II) in **3-CD_3OD** allows for the closer contact between the *o*-H(3-Ph) protons and the metal ion. Thus, the intermediate position of the resonances of the B-*H* and *o*-H(3-Ph) protons of **2-CD_3OD** is a rather expected result. The unexpected feature in the spectrum of **2-CD_3OD** is the considerably smaller chemical shift of the C-*H*(3-*i*Pr) proton in comparison with that in **3-CD_3OD**. This feature may be caused by the 3-*i*Pr substituent being pushed away by the two flanking 3-Ph substituents in the former complex. The ^1H NMR spectroscopic results obtained for the other two complexes described here will be discussed later.

Synthesis, Structure and Properties of [HB(3-Ph,5-*i*Prpz)$_2$-(3,5-diMepz)]Co(NCS) (4)

The ambivalent bonding of 3(5)-isopropyl-5(3)-phenylpyrazole to boron resulted in spontaneous formation of heteroscorpionates, which was demonstrated above. We did not intend to optimize the yield of the synthesis of the Tp^x ligands described. Instead, we have constructed the synthetic heteroscorpionate composed of two pyrazole units, i.e., two 3-Ph,5-*i*Prpz units and one 3,5-diMepz unit. The sodium salt of the Tp^x ligand was obtained as a pure product in good yield. We have assumed that the ligand remained unchanged during the synthesis of the [HB(3-Ph,5-*i*Prpz)$_2$(3,5-diMepz)]Co(NCS) complex, which was obtained by a standard procedure under mild conditions. During workup, we found that prolonged heating (12 h) of the complex in methanol was accompanied by formation of bis(ligand) complexes, similar to that found in the case of [HB(3-Ph,5-Mepz)$_2$(3,5-diMepz)]Co(NCS).[10,11] Examination by mass spectrometry of the white precipitate of side-products isolated from hot methanol indicated that a series of the following complexes were formed by cross-exchange of the pyrazolyl moieties: [HB(Ph,*i*Prpz)$_2$(3,5-diMepz)]$_2$Co [*m*/*z* (%) = 1014 (80)], [HB(Ph,*i*Prpz)$_2$(3,5-diMepz)]-[HB(Ph,*i*Prpz)(3,5-diMepz)$_2$]Co [*m*/*z* (%)= 923 (100)], [HB(Ph,*i*Prpz)(3,5-diMepz)$_2$]$_2$Co [*m*/*z* (%) = 832 (40)], [HB(Ph,*i*Prpz)(3,5-diMepz)$_2$][HB(3,5-diMepz)$_3$]Co [*m*/*z* (%) = 742 (10)], and [HB(3,5-diMepz)$_3$]$_2$Co [*m*/*z* (%) = 651 (40)]. The [HB(3-Ph,5-*i*Prpz)$_2$(3,5-diMepz)]Co(NCS) complex was much less prone, however, to undergo this conversion than was the [HB(3-Ph,5-Mepz)$_2$(3,5-diMepz)]Co(NCS) one.[11] Thus, we were able to isolate and grow crystals of **4** from the polar solvent THF. The molecular structure of **4** is presented in Figure 4. The cobalt is tetracoordinate in **4** despite the replacement of one pyrazolyl residue of medium steric demand (3-Ph,5-*i*Prpz in **1-THF**) by a sterically rather nondemanding one (3,5-diMepz). The cobalt-centered and boron-centered bite angles of the latter ligand in tetracoordinate **4** are slightly larger (141.3 and 77.6°, respectively) in comparison with those in **1-THF** (see Table 1). Nevertheless, the ligand is bound more tightly than are homo- and heteroscorpionate in **1-THF** and **3-THF**, respectively, which can be concluded from the relatively short cobalt−boron distance and the largest chemical shift of the B-*H* proton in **4-CD_3OD** (Table 1).

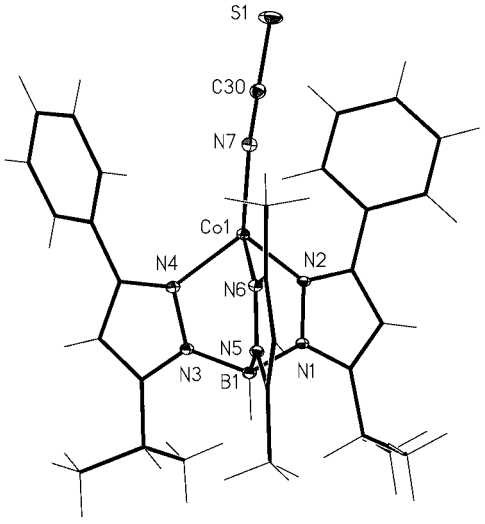

Figure 4. View of **4**; selected bond lengths [Å] and angles [°]: Co(1)−N(7) 1.9178(15), Co(1)−N(2) 2.0154(14), Co(1)−N(4) 2.0124(15), Co(1)−N(6) 2.0020(15); N(7)−Co(1)−N(2) 120.60(6), N(7)−Co(1)−N(4) 130.29(6), N(7)−Co(1)−N(6) 116.50(6), N(4)−Co(1)−N(2) 92.42(6), N(6)−Co(1)−N(2) 95.74(6), N(6)−Co(1)−N(4) 93.28(6)

Steric Demands of Tp^x Ligands in [HB(3-Ph,5-*i*Prpz)$_2$(3,5-diMepz)]CoTp (5), [HB(3-*i*Pr,5-Phpz)$_2$(3-Ph,5-*i*Prpz)]CoTp (6), [HB(3-Ph,5-*i*Prpz)$_2$(3-*i*Pr,5-Phpz)]CoTp (7), and $Tp^{Ph,iPr}$CoTp (8); Tp = Tris(pyrazolyl)borate

The presence of small- or medium-sized substituents at positions 3 and 5 of pyrazole units renders the $Tp^xCo(X)$ complexes able to coordinate Tp as the X unit in all of the compounds studied. Previously, it has been noted that the presence of merely one sterically demanding 3-*tert*-butyl or 3,5-di-*tert*-butylpyrazolyl residue precluded such a conversion.[13,10]

The comparison of the steric demands of Tp^x ligands has been made for their Tp^xCoTp complexes, which were generated in situ. The ^1H NMR spectra of pentacoordinate $Tp^xCo(NCS)(CD_3OD)$ complexes are shown in Figures 3 and 5 (A). The metathesis of the thiocyanate ion and the Tp unit occurred quantitatively without formation of Tp_2Co except in the case of $Tp^{Ph,iPr}Co(NCS)$. The Tp^x ligands of intermediate steric hindrance described here were expected to form stable hexacoordinate Tp^xCoTp com-

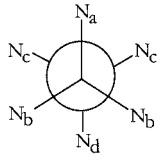
plexes, as was found in other cases.[1,3,5,9−11,13−17,20−25] The reactions between the thiocyanate-bearing starting complexes and KTp were monitored by ^{1}H NMR spectroscopy of [D$_4$]methanol solutions. The resulting spectra are presented in Figure 5 (B−E).

The ^{1}H NMR spectra of [HB(3-Ph,5-*i*Prpz)$_2$(3,5-diMepz)]CoTp, (**5**, trace B), [HB(3-Ph,5-*i*Prpz)(3-*i*Pr,5-Phpz)$_2$]CoTp (**6**, trace C), and [HB(3-*i*Pr,5-Phpz)(3-Ph,5-*i*Prpz)$_2$]CoTp (**7**, trace D) reveal that mutual rotation of the Tp and heteroscorpionate Tp^x ligands around the central metal ion at 298 K is slow on the timescale of the method; the resonances of the 3-H, 4-H, and 5-H protons of the Tp ligand appear as two signals with a ratio of intensities of 2:1. Other Tp^{x}CoTp complexes bearing Tp^x heteroscorpionates − [HB(3-Ph,5-Mepz)$_2$(3-Me,5-Phpz)]$^-$,[10] [HB(3-Ph,5-Mepz)$_2$(3,5-diMepz)]$^-$,[14] and [HB(3-Ph,5-Mepz)$_2$-(3,5-diEtpz)]$^-$,[24] − behave similarly.

Considering the chemical shifts of the 3-H and/or 5-H signals of the Tp ligand as a measure of the strength of the Co−N(Tp) bonds, we find that shorter Co−N(Tp) bonds are observed for those pyrazolyl(Tp) units that are flanked by the sterically less demanding pyrazolyl residues of Tp^x.

Thus, in the antiperiplanar isomer −



in which N$_a$ and N$_b$ stand for nitrogen donor atoms of the pz$_a$ and pz$_b$ units, respectively, of Tp and N$_c$ and N$_d$ are the nitrogen donor atoms of the pz$_c$ and pz$_d$ units, respectively, of heteroscorpionate Tp^x − the chemical shifts of the 3-H(pz$_a$,Tp) signals are higher in comparison with those of the 3-H(pz$_b$,Tp) signals when the 3-R substituents at pz$_c$ are smaller than the 3-R substituents at pz$_d$. This situation was found for **6**, in which pz$_c$ is 3-*i*Pr,5-Phpz, whereas pz$_d$ is 3-Ph,5-*i*Prpz (Table 2). In all other cases of Tp^{x}CoTp complexes (where Tp^x is the heteroscorpionate ligand), the pz$_c$ units are sterically more demanding, resulting in the 2:1 pattern observed for the resonances of the 3-H(Tp) and, 5-H(Tp) protons of pz$_b$ and pz$_a$, respectively, and the peaks with intensity of two hydrogen atoms are shifted more paramagnetically. For example, in **5** the two 3-Ph(pz$_c$,Tp^x) substituents are in a *synclinal* position with respect to the pz$_a$(Tp) unit. Thus, the pz$_a$(Tp) unit is bound more weakly in comparison to the two pz$_b$(Tp) units, which are flanked by *synclinal* 3-Ph,5-*i*Prpz and 3,5-diMepz units. Consistently, the isotropic shifts of 3-H(pz$_a$,Tp) and 5-H(pz$_a$,Tp) are smaller in comparison to those of 3-H(pz$_b$,Tp) and 5-H(pz$_b$,Tp) (Table 2).

Tp^x ligands with intermediate-sized 3- and 5-substituents weaken the bonding of Tp at the cobalt(II) center in Tp^{x}CoTp complexes, as is demonstrated by the hyperfine shift of the B-*H* signal being lower by 1.3−13.6 ppm (the average values of chemical shifts for Tp^x and Tp units are listed in column 5 of Table 2) in comparison with that in Tp$_2$Co. A more precise parameter is the shift of the 3-H and 5-H(Tp) signals (Δ_3 and Δ_5 in column 6). For Tp^{x}CoTp complexes with homoscorpionate Tp^x ligands, this weakening, composed of both steric and electronic effects (*trans*

effect) imposed by the 3−5-substituents, of the Tp^x ligands can be put into order: $Tp^{i\mathrm{Pr},4\mathrm{Br}} > Tp^{\mathrm{Ph},i\mathrm{Pr}} > Tp^{\mathrm{Ph,Me}} > Tp^{\mathrm{Cy},4\mathrm{Br}} > Tp^{\mathrm{Cy}}$.

Unfortunately, the crystallographic data are not available for those compounds, with one exception,[24] therefore a strict relationship between chemical shift observed in the ^{1}H NMR spectra and distances cannot be made. The difference between the effective size of the 3- and/or 5-substituents can be precisely derived, however, from the data of the heteroscorpionate Tp^xCoTp complexes based upon the differences between the chemical shifts of pairs of resonances of the 3-H proton and those of the 5-H(Tp) proton (SD_3 and SD_5, respectively, column 7 in Table 2). These resonances were assigned (Entries 7−14, Table 2) according to the symmetry of the studied species. Thus, the pairs of pyrazolyl residues resulting in differentiation of steric hindrance can be put in order: 3-Ph,5-*i*Prpz/3,5-diMepz > 3-Ph,5-Mepz/3,5-diMepz > 3-Ph,5-Mepz/3,5-diEtpz > 3-Ph,5-Mepz/3-Me,5-Phpz > 3-H,5-*i*Prpz/3-Me,5-Phpz > 3-H,5-*i*Prpz/3-Ph,5-*i*Prpz.

This comparison seems to be reliable. It shows, for instance, even a subtle difference in steric hindrance between 3,5-diMepz and 3,5-diEtpz (Entries 8 and 9), and the influence of steric hindrance imposed by 5-substituents, 5-Me vs. 5-*i*Pr (Entries 8 and 12) or 5-Me vs. 5-Ph (Entries 7 and 8).

Thermal Conversion of 4 into [HB(3-Ph,5-*i*Prpz)(3-*i*Pr,5-Phpz)(3,5-diMepz)]Co(NCS) (9)

Previously, we have demonstrated that [HB(3-Ph,5-Mepz)$_2$(3,5-diMepz)]Co(NCS) underwent conversion into chiral [HB(3-Me,5-Phpz)(3-Ph,5-Mepz)(3,5-diMepz)]-Co(NCS) in 30% yield when heated in propylbenzene for a prolonged time. That reaction was accompanied by the formation of [HB(3-Me,5-Phpz)$_2$(3,5-diMepz)]Co(NCS) and some other products − including bis(ligand) complexes $Tp^xCoTp^{x\prime}$ which were formed with Tp^x ligands of lower steric hindrance − obtained as a mixture.[10] These complexes also form as a result of scrambling of the pyrazolyl residues when the attempt was made to exchange the thiocyanate anion of [HB(3-Ph,5-Mepz)$_2$(3,5-diMepz)]Co(NCS) for carboxylate anions.[11] To avoid this kind of reactivity and to construct a ligand of higher steric demand, with the hope of leading to the thermal conversion under less dramatic conditions, we have replaced the 5-methyl-3-phenylpyrazolyl residue with the 5-isopropyl-3-phenylpyrazolyl one and converted the synthesized [HB(3-Ph,5-*i*Prpz)$_2$(3,5-diMepz)]Co(NCS) complex thermally. The reaction was monitored by ^{1}H NMR spectroscopy. Figure 6 presents the series of spectra taken for the [D$_8$]toluene solutions containing the starting complex and the species formed upon heating them. The ^{1}H NMR spectra of the Tp^xCo(NCS) complexes in this solvent are particularly easy to interpret because the low-field region of the spectra show exclusively the resonances of the 4-H protons of the 3,5-disubstituted Tp^x ligands. Thus, at 357 K the starting compound is represented by two resonances at δ = 60.7 and 53.1 ppm of 2:1 intensity ratio (Figure 6). Upon heating the starting complex at this temperature, three resonances for the 4-H protons, of 1:1:1 intensity ratio, appeared at δ = 62.3, 57.4, and 56.7 ppm, which were attributed to [HB(3-Ph,5-*i*Prpz)(3-*i*Pr,5-Ph)(3,5-diMepz)]Co(NCS) (**9**). The chiral complex was formed in 45% yield within 450 min (Figure 7). The formation of the chiral product was accompanied by formation of [HB(3-*i*Pr,5-Phpz)$_2$(3,5-diMepz)]Co(NCS) (see the resonances labeled as 10 in Figure 6) resulting from double borotropic shift in [HB(3-Ph,5-*i*Prpz)$_2$(3,5-diMepz)]Co(NCS). Although yet another product was formed under those condition, the yield of chiral product was much improved in comparison with the conversion performed for [HB(3-Ph,5-Mepz)$_2$(3,5-diMepz)]Co(NCS).[10]

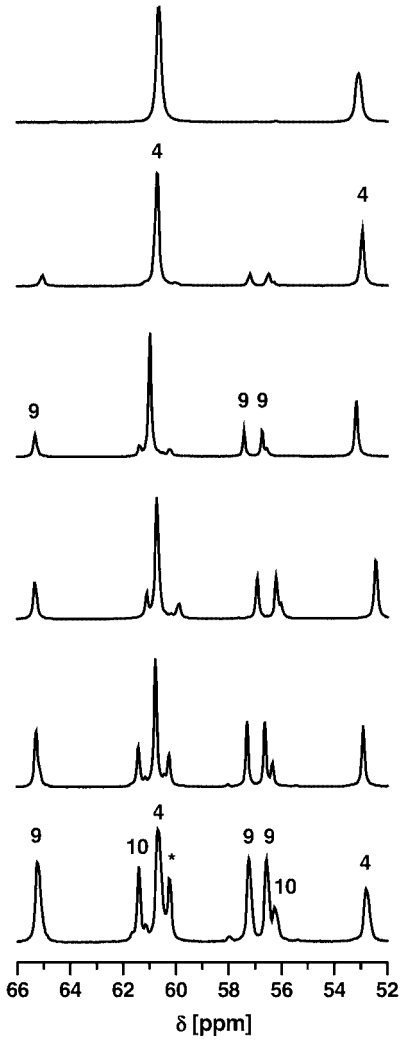

Figure 6. Selected fragments of the ^{1}H NMR spectra of the complexes formed during thermal conversion of [HB(3-Ph,5-*i*Prpz)$_2$(3,5-diMepz)]Co(NCS) (**4**) in [D$_8$]toluene; the resonances of the 4-H protons of the starting compound (trace A), [HB(3-Ph,5-*i*Prpz)(3-*i*Pr,5-Phpz)(3,5-diMepz)]Co(NCS) (**9**), [HB(3-*i*Pr,5-Phpz)$_2$(3,5-diMepz)]Co(NCS) (**10**), and unidentified side-product, are denoted by the arabic numerals 4, 9, and 10, and an asterisk, respectively

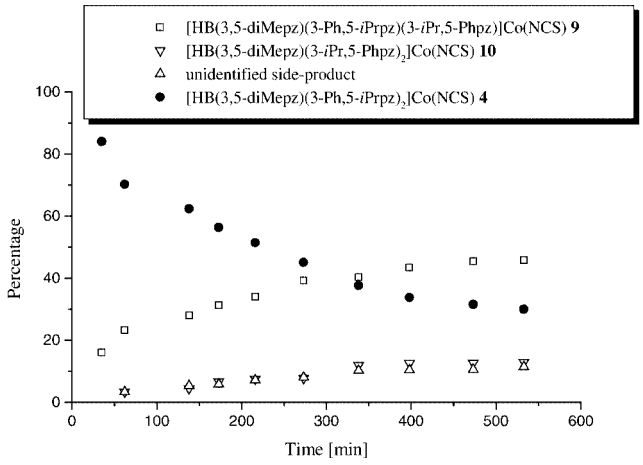

Figure 7. Percentage of the complexes formed during thermal conversion of **4** at 357 K in [D_8]toluene over the course of time

A large-scale procedure eventually gave pure **9**, which was obtained from the post-reaction mixture by fractional crystallization from toluene/heptane as a second crop of crystals. The structure of isolated dimeric compound $\mathbf{9_2}$ was determined crystallographically (Figure 8). Tp^x ligands impose intermediate steric hindrance and, therefore, the central cobalt(II) ion in **9** is pentacoordinate. Typically, the three coordination sites are occupied by the pyrazolyl nitrogen atoms, the thiocyanate nitrogen atom and, additionally, by the sulfur atom of a second thiocyanate anion that bridges to another cobalt(II) center in the dimeric complex. Two Tp^x ligands have opposite configuration at the chiral boron atom. Thus, the *meso* form of dimer of $\mathbf{9_2}$ was obtained in the solid state. The ^{1}H NMR spectrum of **9-CD_3OD** in [D_4]methanol is presented in Figure 9 (trace A). The upfield-shifted resonances belong to protons of the C-3 substituents − *o*-H(3-Ph) (δ = − 78.2 ppm), C*H*(3-*i*Pr) (δ = −70.2 ppm), 3-CH_3 (δ = −57.1 ppm), and diastereoisotopic CH_3(3-*i*Pr) (δ = −30.1, −28.1 ppm) − whereas the three resonances of the 4-H protons, and those belonging to the protons of the 5-substituent and the B-*H* unit, are shifted downfield. The conversion in situ of **9-CD_3OD** into Tp^xCoTp by simple titration of **9-CD_3OD** with KTp in [D_4]methanol produced the heteroleptic complex, which showed seven resonances, with intensity corresponding to one proton, of six 4-H (Tp^x and Tp) protons and one C*H*(5-*i*Pr) proton in the region of the spectrum between δ = 38 and 53 ppm (see inset in trace B). The diastereoisomers of Tp^xCo[OOCC(*S*)H(OH)CH_3] generated in situ by titration of **9-CD_3OD** with sodium (*S*)-lactate are present in solution in equal concentrations, as is concluded from the 1:1 intensity pattern of all the resonances of the two diastereoisomers in the ^{1}H NMR spectrum of

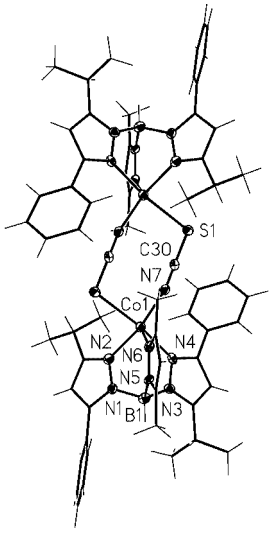

Figure 8. View of the dimer of **9**; selected bond lengths [Å] and angles [°]: Co(1)−N(7) 1.976(7), Co(1)−N(6) 2.031(6), Co(1)−N(2) 2.053(7), Co(1)−N(4) 2.142(7), Co(1)−S(1) 2.581(3); N(7)−Co(1)−N(6) 113.6(3), N(7)−Co(1)−N(2) 150.8(3), N(6)−Co(1)−N(2) 95.6(3), N(7)−Co(1)−N(4) 95.8(3), N(6)−Co(1)−N(4) 88.8(2), N(2)−Co(1)−N(4) 83.7(3), N(7)−Co(1)−S(1) 89.69(19), N(6)−Co(1)−S(1) 95.90(19), N(2)−Co(1)−S(1) 87.81(19), N(4)−Co(1)−S(1) 170.64(19)

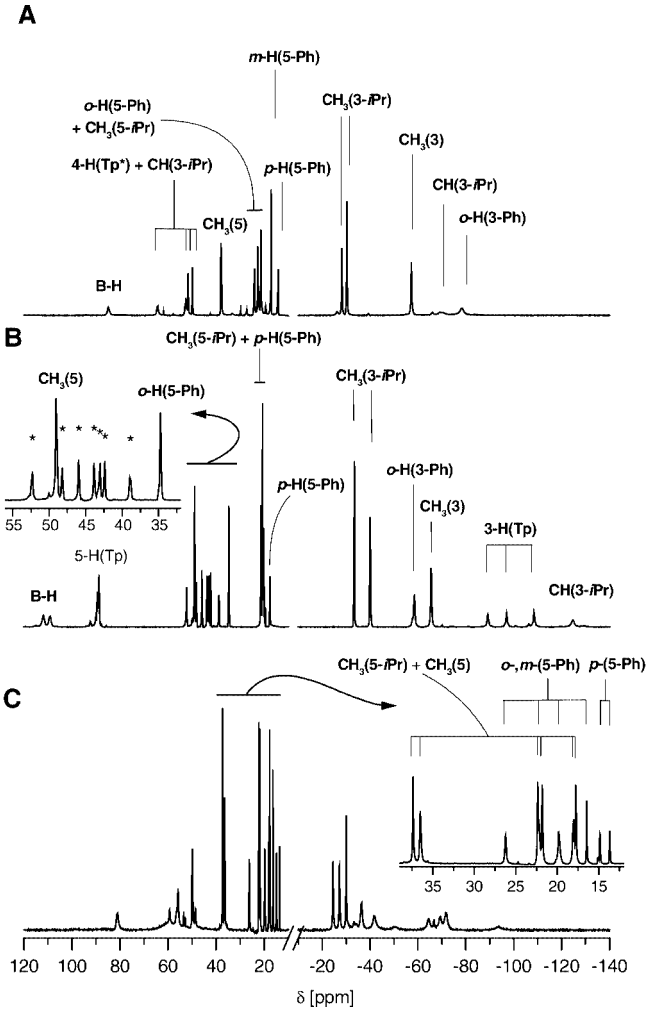

Figure 9. ^{1}H NMR spectra of [HB(3-Ph,5-*i*Prpz)(3-*i*Pr,5-Phpz)(3,5-diMepz)]Co(NCS)(CD_3OD) (A), [HB(3-Ph,5-*i*Prpz)(3-*i*Pr,5-Phpz)(3,5-diMepz)]CoTp (B), and [HB(3-Ph,5-*i*Prpz)(3-*i*Pr,5-Phpz)(3,5-diMepz)]Co(OOCCH(OH)CH_3] (C) in [D_4]methanol at 298 K; seven resonances of intensity corresponding to one hydrogen atom are labeled with asterisks in the inset of trace B and are attributed to the 4-H(Tp,Tp^x) and C*H*(5-*i*Pr) protons

$Tp^xCo[OOCC(S)H(OH)CH_3]$ presented as trace C. The bottom inset in Figure 9 shows the details of the 13−37-ppm region of the spectrum, in which we observe six methyl group resonances of the 3-CH_3 and CH_3(5-*i*Pr) groups and six *o*-, *m*-, and *p*-(5-Ph) resonances. The two diastereoisomers differ in energy and consequently have considerably different spectra. The spectrum remains unchanged over the course of time (24 h) indicating that rather little inversion of configuration at the boron atom takes place.

No tetracoordinate anionic borates with boron-centered chirality have been obtained to date. Tetrahedral (or nearly tetrahedral) neutral boron compounds with boron-centered chirality have been reported.[26−31] Several compounds of this type, with boron-centered chirality imposed by peripheral chiral substituents, have been structurally characterized.[28−31] Generally, separable enantiomers (diastereoisomers) of opposite boron-centered chirality interconvert rapidly at ambient temperatures ($\Delta G^{\ddagger}_{25}$ = 60−90 kJ/mol).[28−33] The chiral tripodal Tp^x ligand described in this report was designed as a chiral ancillary for facial Tp^xML_n complexes with catalytic activity. Currently, we are working on the isolation of the enantiomerically pure sodium salts of the chiral ligands and their thallium(I) complexes and the preparation of the catalytically active complexes of those ligands.

Experimental Section

Syntheses

5(3)-Isopropyl-3(5)-phenylpyrazole (3-Ph,5-*i*PrpzH): The 3(5)-Ph,5(3)-*i*PrpzH unit was synthesized from the corresponding diketone obtained by the general procedure of Swamer and Hauser.[19] Sodium hydride (19.2 g, 0.80 mol) was suspended in diethyl ether (100 mL) containing ethyl isobutyrate (106.8 mL, 92.6 g, 0.80 mol) under nitrogen in a 2-L three-neck round-bottom flask. The flask was later connected to a wet test-meter, condenser and a dropping funnel. The glass device was flushed with nitrogen. Acetophenone (46.6 mL, 47.86 g, 0.4 mol), dissolved in diethyl ether (100 mL), was added dropwise to the mixture. The reaction was initiated by gentle heating of the mixture. The progress of the reaction was monitored by measuring the volume of hydrogen gas evolved. The reaction was stopped after the evolution of hydrogen had ceased (8 L of gas was collected). Ice-cold water (300 mL) and hydrochloric acid were added to the reaction mixture. The diethyl ether phase was extracted with water (2 × 0.8 L) and the combined water extracts, which contained diketone, were left overnight to react with hydrazine monohydrate (20 mL 20.2 g, 0.4 mol). The solution turned orange and turbid. The pyrazole was extracted three times with diethyl ether (2 L). The solvent was evaporated in a rotary evaporator and the oily product was kept under reduced pressure overnight. Hexane (100 mL) was added to the crude product and the mixture was stirred at room temperature for 24 h. The light-yellow powder of 3(5)-Ph,5(3)-*i*PrpzH was collected and dried under high vacuum (8.8 g, 11.8%). ^{1}H NMR ($CDCl_3$): δ = 1.31 [d, J^3 = 6.7 Hz, 6 H,CH_3(*i*Pr)], 3.01 [sept, 1 H, CH(*i*Pr)], 6.36 (s, 1 H, 4-H), 7.3−7.8 (m, 5 H, *o*-, *m*-, *p*-phenyl), 8.5 (br. s, 1 H, NH) ppm. MS (ESI, positive polarization): *m*/*z* (%) = 186.3 (100) $[C_{12}H_{14}N_2]^+$.

Synthesis of Sodium Tris(pyrazolyl)borates

Sodium Hydrotris(5-isopropyl-3-phenylpyrazolyl)borate {Na[HB(3-Ph,5-*i*Prpz)$_3$]}, Sodium Hydro(3-isopropyl-5-methylpyrazolyl)bis(5-isopropyl-3-phenylpyrazolyl)borate, and Sodium Hydrobis(3-isopropyl-5-phenylpyrazolyl)(5-isopropyl-3-phenylpyrazolyl)borate: $NaBH_4$ (0.1389 g, 3.67 mmol) and 3-Ph,5-*i*PrpzH (2.0033 g, 10.77 mmol) in octadecane (40 mL) were heated with vigorous stirring in a 250-mL three-neck round-bottom flask equipped to a wet test-meter and condenser. The mixture was heated until 400 mL of hydrogen gas was evolved and then heating was continued for 40 min. Heptane (100 mL) was added to the solution after it had cooled to ca. 100 °C and then left overnight at room temperature. The solid was separated by filtration, washed with petroleum ether and dried under high vacuum. Yield 0.305 g (0.60 mmol, 16.3%). The mixture of sodium salts of Tp^x ligands was converted into $Tp^xCo(NCS)$ complexes as reported earlier[10] and was quantified as a mixture based upon the intensity of the integrals of the resonances in the ^{1}H NMR spectrum. The mixture comprised [HB(3-*i*Pr,5-Phpz)(3-Ph,5-*i*Prpz)$_2$]Co(NCS) (80.4%), [HB(3-*i*Pr,5-Phpz)$_2$(3-Ph,5-*i*Prpz)]Co(NCS) (10.8%), and [HB(3-Ph,5-*i*Prpz)$_3$]Co(NCS) (8.8%). The complexes were separated and identified by their ^{1}H NMR spectra (see below).

Synthesis and Separation of and [Hydrotris(5-isopropyl-3-phenylpyrazolyl)borato](thiocyanato)cobalt(II) [$Tp^{Ph,iPr}$Co(NCS)(THF), 1-THF], [Hydro(3-isopropyl-5-phenylpyrazolyl)bis(5-isopropyl-3-phenylpyrazolyl)borato](thiocyanato)cobalt(II) {[HB(3-Ph,5-*i*Prpz)$_2$(3-*i*Pr,5-Phpz)]Co(NCS), 2}, and [Hydrobis(3-isopropyl-5-phenylpyrazolyl)(5-isopropyl-3-phenylpyrazolyl)borato](thiocyanato)cobalt(II) {[HB(3-*i*Pr,5-Phpz)$_2$(3-Ph,5-*i*Prpz)]Co(NCS)(THF), 3-THF}: The complexes were synthesized as described previously[10] starting from $NaTp^x$ mixture (0.305 g, 0.52 mmol) and separated by fractional crystallization from THF/heptane at 4 °C. The blue, cube-shaped crystals of **1-THF** were collected as the first product (30 mg, 0.040 mmol, 7.7% yield), dark-blue needle-shaped crystals of **2-THF** (150 mg, 0.20 mmol, 38.5% yield) were obtained as the second crop and, finally, violet-blue crystals of analytically pure **3-THF** (38 mg, 0.050 mmol, 9.6% yield) were obtained. The crystals of **1-THF** and **3-THF** were examined by X-ray crystallography (Table 3), whereas all attempts to grow the crystals of **2-THF** gave crystalline material that was very sensitive to change of temperature, which precluded good-quality X-ray crystallographic measurement.

1-THF: $C_{41}H_{48}BCoN_7OS$ (756.66): calcd. C 65.08, H 6.39, N 12.96; found C 65.21, H 6.41, N 12.62. ^{1}H NMR (CD_3OD, 298 K): δ = −57.4 [6 H, *o*-H(3-Ph)], 3.7 [3 H, *p*-H(3-Ph)], 4.5 [6 H, *m*-H(3-Ph)], 18.3 [18 H, CH_3(5-*i*Pr)], 50.8 and 54.7 [3 H, CH(5-*i*Pr) and 3 H, 4-H(3-Ph,5-*i*Prpz)], 93.7 (B-H) ppm. IR (KBr): $\tilde{\nu}$ = 2588 (ν_{BH}), 2059 (ν_{NCS}) cm^{-1}.

2-THF: $C_{41}H_{48}N_7BCoOS$ (756.66): calcd. C 65.08, H 6.39, N 12.96; found C 65.12, H 6.23, N 12.48. ^{1}H NMR (CD_3OD, 298 K): δ = −57.9 [4 H, *o*-H(3-Ph)], −34.8 [1 H, CH(3-*i*Pr)], −24.8 [6 H, CH_3(3-*i*Pr)], 0.9 [2 H, *p*-H(3-Ph)], 1.2 [4 H, *m*-H(3-Ph)], 13.7 [1 H, *p*-H(5-Ph)], 15.8 [2 H, *m*-H(5-Ph)], 19.1 [6 H, CH_3(5-*i*Pr)], 19.8 [2 H, *o*-H(5-Ph)], 26.1 [6 H, CH_3(5-*i*Pr)], 42.4 [1 H, 4-H(3-*i*Pr,5-Phpz)], 58.2 and 62.6 [2 H, CH(5-*i*Pr) and 2 H, 4-H(3-Ph,5-*i*Prpz)], 92.7 (B-H) ppm. IR (KBr): $\tilde{\nu}$ = 2557 (ν_{BH}), 2062 (ν_{NCS}) cm^{-1}.

3-THF: $C_{41}H_{48}N_7BCoOS$ (756.66): calcd. C 65.08, H 6.39, N 12.96; found C 65.40, H 6.61, N 13.02. ^{1}H NMR (CD_3OD, 298 K): δ = −80.8, −70.8 [2 H, *o*-H(3-Ph) and 2 H, CH(3-*i*Pr)], −30.3, −29.4 [6 H, two diastereoisotopic CH_3(3-*i*Pr)], −3.8 [2 H, *m*-H(3-Ph)], 0.4 [1 H, *p*-H(3-Ph)], 14.2 [2 H, *p*-H(5-Ph)], 17.3 [4 H, *m*-H(5-Ph)], 23.9

[6 H, CH_3(5-*i*Pr)], 24.7 [4 H, *o*-H(5-Ph)], 51.6 [2 H, 4-H(3-*i*Pr,5-Phpz)], 57.2, 69.7 [1 H, CH(5-*i*Pr) and 1 H, 4-H(3-Ph,5-*i*Prpz)], 86.8 (B-H) ppm. IR (KBr): $\tilde{\nu}$ = 2597 (ν_{BH}), 2083 (ν_{NCS}) cm^{-1}.

Sodium Hydro(3,5-dimethylpyrazolyl)bis(5-isopropyl-3-phenylpyrazolyl)borate {Na[HB(3-Ph,5-*i*Prpz)$_2$(3,5-diMepz)]}: A mixture of $NaBH_4$ (0.2848 g, 7.53 mmol), 3-Ph,5-*i*PrpzH (2.9401 g, 15.81 mmol) and 3,5-diMepzH (0.6517 g, 6.78 mmol) in octadecane (40 mL) was heated with vigorous stirring in a 250-mL three-neck round-bottom flask equipped with a wet test-meter and condenser. The device was flushed with nitrogen before heating began. The temperature was increased gradually to the boiling point of octadecane (317 °C). Heating was continued until 630 mL of hydrogen gas was collected. Heptane (100 mL) was added to the solution after it had been cooled to ca. 100 °C and then the mixture was left overnight at 4 °C. The solid (0.6150 g, 16.4%) was separated by filtration at room temperature, washed with petroleum ether and then dried under high vacuum. From the heptane filtrate another sodium salt was recovered, i.e., sodium hydrotris(5-isopropyl-3-phenylpyrazolyl)borate (12%), which was synthesized also by a separate procedure (vide supra). ^{1}H NMR (CD_3OD, 298 K): δ = 1.53 [d, 12 H, CH_3(*i*Pr)], 2.19 [s, 6 H, 3- and 5-CH_3], 3.02 [sept, 2 H, CH(3-*i*Pr)], 5.91 [s, 1 H, 4-H(3,5-diMepz)], 6.43 [s, 2 H, 4-H(3-*i*Pr,5-Phpz)], 7.8−7.2 [10 H, m, *o*-, *m*-, and *p*-H(3-*i*Pr,5-Phpz)] ppm.

[Hydro(3,5-dimethylpyrazolyl)bis(5-isopropyl-3-phenylpyrazolyl)-borato](thiocyanato)cobalt(II) {[HB(3-Ph,5-*i*Prpz)$_2$(3,5-diMepz)]-Co(NCS), 4}: This complex was synthesized by adding Na[HB(3-Ph,5-*i*Prpz)$_2$(3,5-diMepz)] (110 mg, 0.22 mmol) in THF (5 mL) into an aqueous solution (50 mL) of 0.1 M $Co(NO_3)_2$ and 0.5 M KNCS. The resulting blue product was extracted into CH_2Cl_2 (100 mL), the organic layer was washed with water (2 × 100 mL), the CH_2Cl_2 was evaporated in a rotary evaporator. The solid residue was dissolved in THF (5 mL) and recrystallized by the co-diffusion of hexane (ca. 80 mL) at 4 °C. After two weeks, the product was collected as blue crystals (123 mg, 0.18 mmol, 82% yield). One of the crystals was analyzed crystallographically (Table 3).

4: $C_{30}H_{34}N_7BCoS$ (594.44): calcd. C 60.61, H 5.76, N 16.49; found C 60.42, H 5.61, N 16.40. ^{1}H NMR (CD_3OD, 298 K): δ = −69.6 [4 H, *o*-H(3-Ph)], −39.5 (3 H, 3-CH_3), 1.6 [4 H, *m*-H(3-Ph)], 2.8 [2 H, *p*-H(3-Ph)], 19.7 [6 H, CH_3(5-*i*Pr)], 24.7 [6 H, CH_3(5-*i*Pr)], 30.1 (3 H, 5-CH_3), 42.5 [1 H, 4-H(3,5-diMepz)], 58.7 [2 H, CH(5-*i*Pr)], 62.4 [2 H, 4-H(3-Ph,5-*i*Prpz)], 95.6 (1 H, BH) ppm. IR (KBr): $\tilde{\nu}$ = 2557 (ν_{BH}), 2064 (ν_{NCS}) cm^{-1}.

In Situ Conversions of Tp^{x}Co(NCS) into Tp^{x}CoTp Complexes: The complexes were converted into their Tp^{x}CoTp counterparts in [D_4]methanol on a micromolar scale by the stepwise addition of 1 M KTp in [D_4]methanol into the starting thiocyanate complex (ca. 6 mg), dissolved in [D_4]methanol (400 μL). The progress of reaction was monitored by ^{1}H NMR spectroscopy.

Thermal Conversion of 4 into [Hydro(3,5-dimethylpyrazolyl)(3-isopropyl-5-phenylpyrazolyl)(5-isopropyl-3-phenylpyrazolyl)borato]-(thiocyanato)cobalt(II) (9): Heteroscorpionate complex **4** (6.3 mg, 9.5 μmol) was dissolved in [D_8]toluene (450 μL) in an NMR tube, which was placed in the cavity of the NMR instrument and heated at 357 K for 23 h or at 377 K for 14 h. The progress of reaction was monitored by ^{1}H NMR spectroscopy. Large-scale conversion was performed with **4** (300 mg) in toluene (30 mL) at 357 K for 500 min. The resulting solution was layered with heptane and left to crystallize at room temperature. The first crop of crystals was identified as **4** by its ^{1}H NMR spectrum, while violet needles of **9_2** were obtained as the second crop (67 mg, 22% yield). The structure of **9_2** was determined crystallographically (Table 3).

9: $C_{30}H_{34}BCoN_7S$ (594.44): calcd. C 60.61, H 5.76, N 16.49; found C 60.63, H 5.80, N 16.59. ^{1}H NMR (CD_3OD, 298 K): δ = −78.2 [2 H, *o*-H(3-Ph)], −70.2 [1 H, CH(3-*i*Pr)], −57.2 (1 H, 3-CH_3), −30.1, −28.1 [3 H, 3 H, CH_3(3-*i*Pr)], −4.2 [2 H, *m*-H(3-Ph)], 0.8 [1 H, *p*-H(3-Ph)], 14.4 [1 H, *p*-H(5-Ph)], 17.4, [2 H, *m*-H(3-Ph)], 21.5, 22.8 [3 H, 3 H, CH_3(5-*i*Pr)], 24.3 [2 H, *o*-H(3-Ph)], 33.1 (3 H, 5-CH_3), 50.0, 51.9, 52.9 [1 H, 1 H, 1 H, 4-H(pz)], 64.7 [1 H, CH(5-*i*Pr)], 85.0 (1 H, BH) ppm. IR (KBr): $\tilde{\nu}$ = 2557 (ν_{BH}), 2121, 2058 (ν_{NCS}) cm^{-1}.

Methods: ^{1}H NMR spectra were obtained with a Bruker AMX300 spectrometer operating in the quadrature mode at 300 MHz. The residual peaks of deuterated solvents were used as internal standards. IR spectra were recorded with a Perkin−Elmer 1725X spectrophotometer. Elemental analyses were performed with an EA 1108 apparatus (Carbo Erba) at the Department of Organic Chemistry, Faculty of Chemistry, Rzeszów University of Technology. Mass spectra were obtained using a Finnigan MAT TSQ 700 spectrometer by the ESI method from chloroform with a 4.5-kV ionization potential and a capillary temperature of 250 °C. Crystal data are given in Table 1 together with refinement details. Measurements were performed at 293 K for **1-THF** and at 100 K for **3-THF**, **4** and $\mathbf{9_2}$ using an Oxford Cryosystem device with a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo-K_α radiation. The crystals were positioned at 65 mm from the CCD camera. 612 frames were measured at 0.75° intervals with a counting time of 10−15 s. Accurate cell parameters were determined and refined by least-squares fit of 2500−3800 of the strongest reflections. The data were corrected for Lorentz and polarization effects. No absorption correction was applied for **1-THF**, **3-THF** and **3**, and analytical absorption correction was applied for $\mathbf{9_2}$. Data reduction and analysis were carried out with the Oxford Diffraction (Poland) Sp. z o.o (formerly Kuma Diffraction Wroclaw, Poland) programs. Structures were solved by direct methods (program SHELXS-97)[34] and refined by the full-matrix least-squares method on all F^2 data using the SHELXL-97 programs.[35] Non-hydrogen atoms were refined with anisotropic displacement parameters; hydrogen atoms were included from geometry of molecules and Δρ maps but were not refined. CCDC-200532 (**1-THF**), -200533 (**3-THF**), -200534 (**4**) and -189010 ($\mathbf{9_2}$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Properties of Undoped and Ca-Doped $LaMnO_3$ − Non-Stoichiometry and Defect Structure

Mondher Yahia[a] and Habib Batis*[a]

Keywords: Non-stoichiometry / Perovskites / Preparation

Oxygen-excessive $LaMnO_{3+y}$ samples with $0.02 \leq y \leq 0.26$ have been prepared by thermal decomposition in air at 450 °C of a precursor obtained from an aqueous solution of lanthanum nitrate and manganese acetate (atomic ratio La/Mn = 1). The obtained solid is annealed at different temperatures from 700 to 1000 °C and under three oxygen pressures: 1.00, 0.21, and 10^{-4} atm. Samples with $0.14 \leq y \leq 0.26$ are simple-phased rhombohedral perovskites, the distortion of which decreases as the oxygen content (and Mn^{4+} content) increases. Samples with $0.02 \leq y \leq 0.09$, obtained under low oxygen pressure (10^{-4} atm), have orthorhombic symmetry. In this case, the order of lattice parameters $c/\sqrt{2} < a < b$, characteristic of O′-perovskites, is a consequence of the Jahn–Teller distortion of the oxide octahedron around the d^4 Mn^{4+} cation. The volume (V_f) per $LaMnO_{3+y}$ formula unit decreases regularly with increasing oxygen content (i.e., oxidation). Study has shown that the oxygen content is best described in terms of La and Mn vacancies, rather than of interstitial anions. Density measurements confirm the cation vacancy model involving equal amounts in La and Mn sublattices. The infrared spectra of $LaMnO_{3+y}$ samples have been interpreted in connection with the structures of these solids. Correlations have been established between the spectral evolution and the crystal distortion of these compounds. $La_{1-x}Ca_xMnO_{3\pm y}$ oxides with $0 < x \leq 1$ have been synthesised by the same route, at 700 °C and under an oxygen pressure of 0.21 atm. It is shown that a negative correlation exists between the calcium content *x* and the degree of non-stoichiometry: at low Ca content, the oxygen content is higher. The ability to form over-stoichiometric compounds in air decreases with increasing Ca content and mostly disappears at $x \geq 0.7$. Samples with $0.1 \leq x \leq 0.4$ are simple-phased rhombohedral perovskites with constant Mn^{3+}/Mn^{4+} ratios. Samples with $0.5 \leq x \leq 1$ have orthorhombic symmetry. In this case, a linear variation of the Mn^{4+} content as a function of the Ca content is observed. The defect structure of these compounds is described in terms of La and Mn vacancies when $0 < x \leq 0.7$ ($0 \leq y \leq 0.19$) and anion vacancies when $0.8 \leq x \leq 1$ ($-0.04 \leq y < 0$).

Introduction

Perovskite-type oxides can be represented as ABO_3, where B is a transition cation of the 3d, 4d, or 5d group and A is either a lanthanide (generally La, but sometimes Ce, Pr, or Nd) or an alkaline earth metal (Ca, Sr, or Ba). In the crystal structure, the A ion is coordinated by twelve oxygen ions, which in turn belong to eight BO_6 octahedrons sharing corners. The stability, derived primarily from the Madelung energy of the stacking of rigid BO_6 octahedrons, requires that B be a cation with a preference for octahedral coordination. The A ion occupying the large dodecahedral interstice has to have an appropriate size.[1−3]

They have been studied for their physical characteristics, such as ferroelectricity, piezoelectricity, magnetism, superconductivity at high temperature etc. During the last two decades they have been consistently proposed as alternative catalysts for reactions involving hydrogen, such as hydrogenolysis of hydrocarbons[4] as well as for reaction combustion of carbon monoxide and light hydrocarbons.[5−11]

The great variety of A and B ions able to take part in the structure, the possibility of changing the valence of the B ion by proper selection of A and also the partial substitution of cations to form compounds of formula $(AA')(BB')O_3$ make feasible the preparation of perovskites with very specific properties.

Lanthanum manganite oxides of formula $LaMnO_{3+y}$, exhibit non-stoichiometry on one or more sub-lattices.[12] The opinion is widely shared that the oxygen excess is partially compensated by the oxidation of Mn^{3+} (d^4) to Mn^{4+} (d^3) in the B sub-lattice. Consequently, it can be seen that the Jahn−Teller effect of Mn^{3+} ions, and hence the structure distortion, will decrease with increasing number of Mn^{4+} ions. In fact, there are two characteristic distortions that influence the perovskite structure of manganites. One consists of co-operative tilting of MnO_6 octahedrons. This kind of distortion is a consequence of the ionic radii and is common in perovskites with small central cations (Goldschmidt factor $t < 1$). The other kind of structure distortion is associated with the Jahn−Teller effect of Mn^{3+} ions, resulting

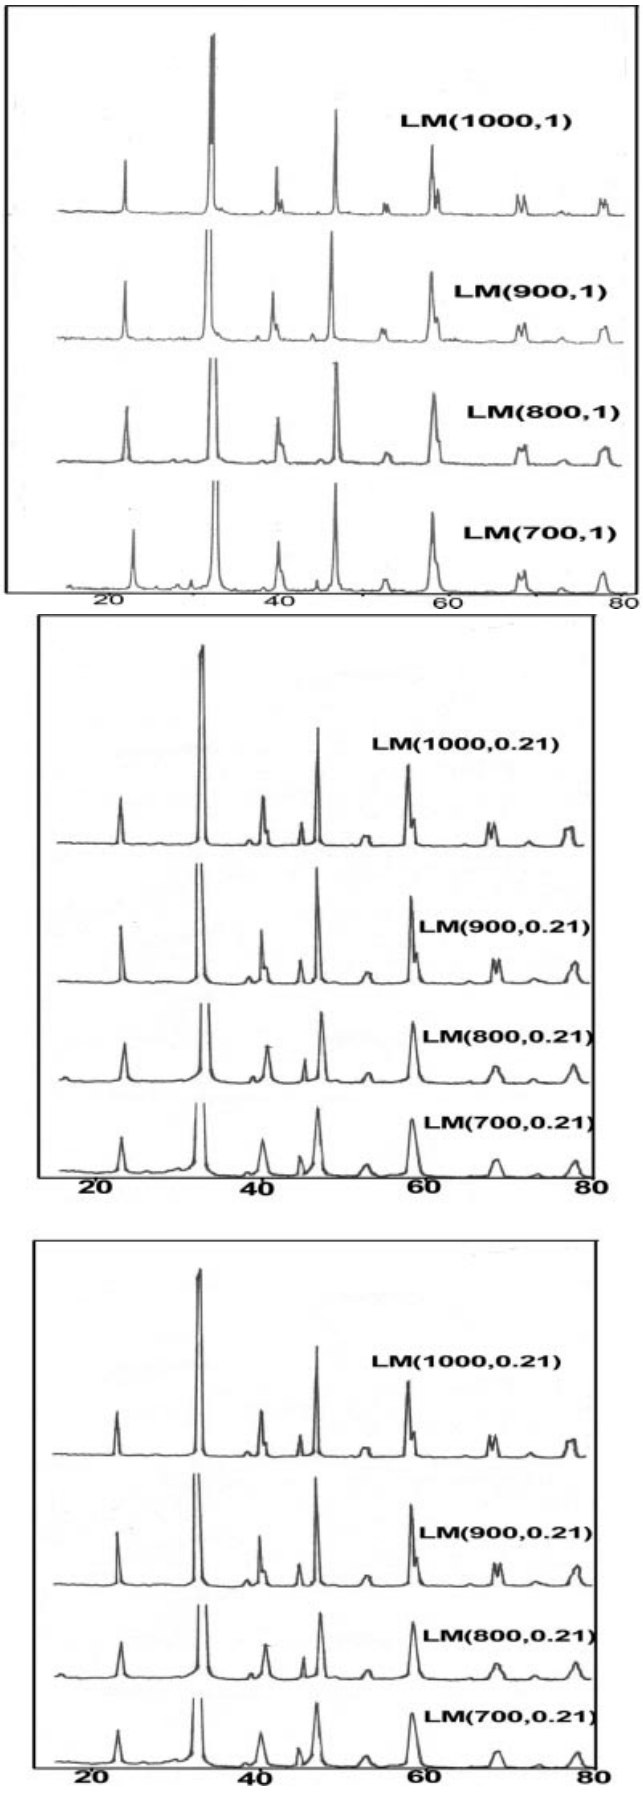

Figure 1. XRD diagrams of LM(*T*,*P*) samples

in the distortion of $Mn^{3+}O_6$ octahedrons and their co-operative ordering below a certain critical temperature. Despite the extensive literature on non-stoichiometric manganite perovskites, a detailed and systematic investigation over a wide range of y values to delineate the stability region of the homogeneous phase in the $LaMnO_{3+y}$ system is still lacking. As well as the non-stoichiometric $LaMnO_{3+y}$ family, Mn^{4+} ions can also be introduced into compounds of general formula $La_{1-x}C_xMnO_{3+y}$ by substitution of La^{3+} by a divalent ion (C = divalent cation, usually an alkaline earth). Such compounds have been extensively studied,[13−18] due to their potential for application as air electrodes in high-temperature solid oxide fuel cells. In the case of Sr-doped $LaMnO_3$, the range of concentration x is limited by the larger size of Sr^{2+} in relation to that of the La^{3+} ion. Given the importance of C content on the Mn^{3+}/Mn^{4+} ratio and therefore on the defect structure, it seems appropriate to consider the related system $La_{1-x}Ca_xMnO_{3\pm y}$ and to acquire knowledge of its defect structure over the whole range of concentrations ($0 \leq x \leq 1$).

The objectives of this study are:

(i) to prepare, by a simple and reproducible route, $LaMnO_{3+y}$ and $La_{1-x}Ca_xMnO_{3\pm y}$ compounds over a wide range of y and x values,

(ii) to determine their phase stabilities and oxygen non-stoichiometries,

(iii) to determine the best model for their defect chemistry,

(iiii) to study the effect of Mn^{4+} content on the frequency of Mn−O characteristic infrared absorption bands in undoped and in Ca-doped lanthanum manganites.

Results

1-LM(*T*,*P*) Oxides

The diffraction patterns of the LM(*T*,*P*) compounds were closely related to the patterns that would be expected of simple perovskite structures. Differences between the ideal

and observed patterns were the split reflections, implying distortions of the lattice from cubic symmetry (Figure 1). The XRD patterns of LM(T,0.21) and LM(T,1) oxides were refined in the space group $R\bar{3}c$, hexagonal description (Z = 6). Those of LM(T,10^{-4}) were refined in the *Pbnm* space group, orthorhombic description (Z = 4). The unit cell parameters determined after the refinement as well as the volume per unit formula (V_f) and oxygen contents (y) of the samples are listed in Table 1.

Mn−O distances were determined, taking those perovskites $LaNiO_3$[19] and $GdFeO_3$[20] exhibiting $R\bar{3}c$ and *Pbnm* space groups, respectively, as starting models. For $LaNiO_3$, La atoms are at 6a (0,0,$^1/_4$); Mn at 6b (0,0,0); and O at 18e (x,0,$^1/_4$) with $x \approx 0.547$. For $GdFeO_3$, La atoms are at 4c (x,y,$^1/_4$) with $x \approx 0.984$, $y \approx 0.063$; Mn at 4b (0,$^1/_2$,0); O1 at 4c with $x \approx 0.1005$, $y \approx 0.4672$ and O2 at 8d (x,y,z) with $x \approx 0.6957$, $y \approx 0.3016$, $z \approx 0.0506$.

Figure 2 shows the plot of unit formula volume (V_f) vs. y. A net decrease in the volume is observed as the oxygen content increases. This effect can be correlated with the increasing content of Mn^{4+} (= $2y$), which is smaller than Mn^{3+} [21] The presence of smaller cations in the B sublattice of the ABO_3 perovskite is responsible both for the reduction in unit cell volume and for the increase in the Goldschmidt tolerance factor[22] ($t = d_{A-O}/\sqrt{2}d_{B-O}$), hence the decrease of the rhombohedral distortion of the lattice. In contrast, for small y values (hence low Mn^{4+} concentrations), a more distorted structure is favoured, as observed for LM(T,10^{-4}) oxides, which show orthorhombic symmetry. In this case, the order of lattice parameters $c/\sqrt{2} < a < b$, characteristic of O′-perovskites,[3] is a consequence of the Jahn−Teller distortion of the oxide octahedron around the d^4 Mn^{3+} cation. A region of non-stoichiometry $0 < y < 0.15$ for $LaMnO_{3+y}$ was reported by Wold and Arnott,[23] with a change in symmetry (at room temperature) from orthorhombic to rhombohedral for an Mn^{4+} concentration greater than 21% ($LaMnO_{3.105}$), which closely agrees with our observation. The rhombohedral symmetry was observed even for the samples with the highest Mn^{4+} contents, as clearly shown by the characteristic splitting of the diffraction peaks (Figure 1). Moreover the rhombohedral angles of these samples are still considerably larger than 60° (which corresponds to cubic symmetry): α_r = 60.6°, for instance, for sample LM(700,1), with 52% Mn^{4+}. A sample of composition $LaMnO_{3.2}$ reported by Tofield and Scott[24] also showed a rhombohedral symmetry with an angle α_r = 60.3°.

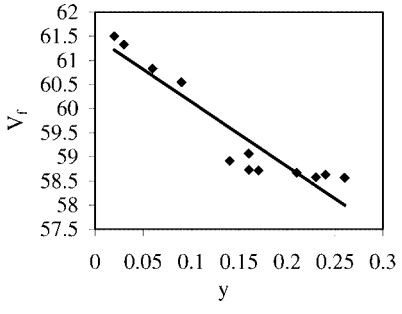

Figure 2. Variation of unit formula volume V_f with excess oxygen content y

To evaluate the nature of defects in LM(T,P) oxides, experimental density values were compared to those of five models of defect distribution in the lattice previously reported by Van Roosmalen et al.[25] For each of these models, the calculated density is defined by $d = M/N \cdot V_f$, where M is the molar mass of the formula unit, V_f is the formula unit volume, and N is the Avogadro constant. The variation of V_f as a function of y was derived from Figure 2. $V_f = (61.53 - 13.88 \cdot y)$ Å^3. The density calculated as a function of y for the five models, together with the experimentally determined densities obtained for LM(T,P) samples are reported in Table 2.

Table 2. Theoretical and experimentally determined density values [g·cm^{-3}] as a function of y

y	O_i[a]	V_{Mn}[b]	V_{La} and V_{Mn}[c]	V_{La}[d]	V_{La} and V_O[e]	ρ_{exp}
0.26	7.05	6.66	6.49	6.24	6.12	6.55(2)
0.24	7.01	6.65	6.49	6.26	6.08	6.54(2)
0.23	6.99	6.64	6.49	6.28	6.06	6.56(2)
0.21	6.94	6.64	6.49	6.30	6.02	6.54(2)
0.17	6.86	6.61	6.49	6.34	5.95	6.55(2)
0.16	6.84	6.60	6.49	6.35	5.93	6.55(2)
0.14	6.80	6.59	6.50	6.38	5.89	6.53(2)
0.09	6.70	6.57	6.50	6.43	5.80	6.53(2)
0.06	6.64	6.55	6.51	6.46	5.75	6.52(2)
0.03	6.58	6.54	6.52	6.49	5.70	6.53(2)
0.02	6.56	6.53	6.52	6.50	5.68	6.51(2)

[a] $LaMnO_3O_{i,y}$ (O interstitial). [b] $LaMn_{(3-2y/3)}O_3$ (Mn vacancies). [c] $La_{3/3+y}V_{La,y/3+y}Mn_{3/3+y}V_{Mn,y/3+y}O_3$ (La and Mn vacancies). [d] $La_{1-2y/3}V_{La,2y/3}MnO_3$ (La vacancies). [e] $La_{0.8}MnO_{2.7+y}$ (La and O vacancies).

From the agreement between the observed and calculated densities, it is obvious that an equal distribution of concentrations of Mn and La vacancies in cationic sub-lattices is the predominant defect model. The analysis results, which show an atomic ratio La/Mn = 1, are in good agreement with this proposed model.

[a] Average value of three Mn−O distances due to Jahn−Teller deformation. [b] r_{Mn} is the Mn site radius defined by: $r_{Mn} = [3\cdot(1 - y)]/(3 + y)\cdot r_{Mn^{3+}} + 6y/(3 + y)\cdot r_{Mn^{4+}} + y/(3 + y)\cdot r_V$, where r_V is the radius of a vacancy, taken equal to 0.60 Å[24] and $r_{Mn^{3+}} = 0.65$ Å; $r_{Mn^{4+}} = 0.54$ Å.

All samples showed similar types of IR spectra. As an example, Figure 3 shows the IR spectra of LM(T,0.21) samples. Two absorption bands, at 800−550 and 450−300 cm^{-1}, were observed in each spectrum. The higher frequency band extends from about 800 to 500 cm^{-1}. Its absorption maximum decreases progressively with increasing y values (Table 3). The lower frequency band extends from about 475 cm^{-1} to the limit of the available experimental range at about 300 cm^{-1}, with a centre at 380 cm^{-1}.

IR spectra of ABO_3 perovskite oxides have been studied by several workers.[26−29] In general, the ABO_3 perovskites show two prominent bands in the 1000−300 cm^{-1} spectral region. The assignment of absorption bands by factor group analysis in these oxides has not been as successful as in fluorides[29−32]; in an ABO_3 perovskite of cubic symmetry there should be three sets of triply degenerate infrared-active modes of symmetry F_{1u} and one inactive mode of symmetry F_{2u}. This F_{2u} mode, however, can become active through distortion of the crystal lattice from the ideal cubic structure. The perturbation needs only be slight and would of course split the degeneracies in all modes. Fair success has been obtained by considering the internal modes of the BO_3 octahedron and the external ones of the A−(BO_3) groups. In the discussion of the vibration nature of the BO_3 group, it is considered to be arranged as central B atom octahedrally surrounded by six O half-atoms. Nakagawa et al.[30] therefore assigned the ν_1 mode to the B−O stretching normal vibration where the motion is primarily that of a change in the length of the B−O bond. Two modes − ν_2 and ν_4 − were assigned to the B−O bending normal vibration, where the motion is that of a change in the O−B−O bond angle. Both the relative magnitude and the sign of the displacements will depend on the bond-force constants and relative masses of the atoms. Moreover, the frequency of these bands has been related to the strength of the metal−oxygen covalency.[26] A fourth mode − ν_3 − was assigned to the A−(BO_3) vibration. The stretching vibration would be expected to occur at frequencies higher than the bending vibration, from comparison of the change in potential energy due to repulsive forces between ions in the two normal vibrations.

Infrared absorption bands in the vicinities of 600 and 400 cm^{-1} were observed for the various manganites investigated. The higher frequency band ν_1 was assigned to the Mn−O stretching normal vibration and the lower band ν_2 to the Mn−O bending vibration. Detailed analysis of distorted $LaMnO_{3+y}$ spectra showed additional bands, probably due to systematic distortion from ideal cubic symmetry to the orthorhombic structure for LM(T,10^{-4}) and to the rhombohedral structure for LM(T,0.21) and LM(T,1), which would split degenerate modes to give additional distinct frequencies. Spectra are given in Figure 4 to illustrate the importance of cell deformation for the number, shape, and position of IR bands.

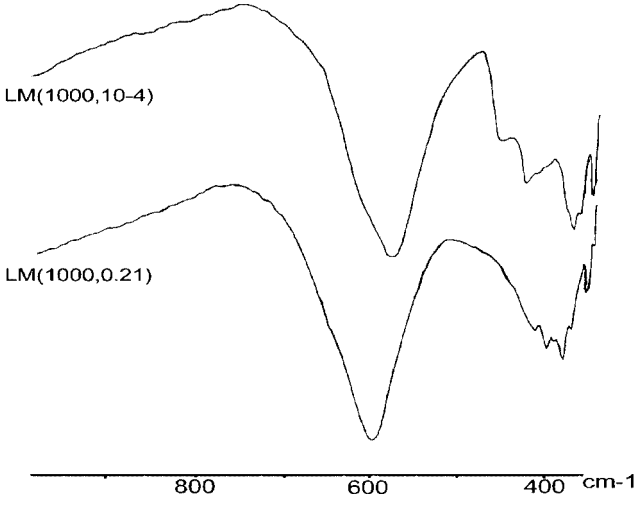

Figure 4. IR spectra of LM(1000,0.21) and LM(1000,10^{-4}) samples

Table 3 gives the vibrational frequencies of the M−O (ν_1) bond together with d_{Mn-O} distances as a function of non-stoichiometry y, which measures Mn^{4+} concentration in the MnO_3 sub-lattice. It can be seen that ν_1 decreases with decreasing y and increasing d_{Mn-O} distances.

2-LCMx(*T*,*P*) Oxides

All samples ($0 \leq x \leq 1$) were obtained after treatment under air at 700 °C. The diffraction patterns are given in Figure 5. X-ray powder diffraction patterns of all samples were completely indexed as the perovskite-type structure and showed the absence of simple oxides such as La_2O_3, Mn_2O_3, MnO_2, and CaO over the whole range of x values. The maximum incorporation rate seems to be influenced by the ionic radius of the substituted cation. Indeed, in the $LaMnO_3$ type of perovskite structure, the coordination number of La^{3+} ions is 12 with an ionic radius of 1.36 Å, and that of Ca^{2+} in the same site is 1.34 Å,[23] smaller than that of other alkaline metal ions such as Sr^{2+}. Thus, it is to

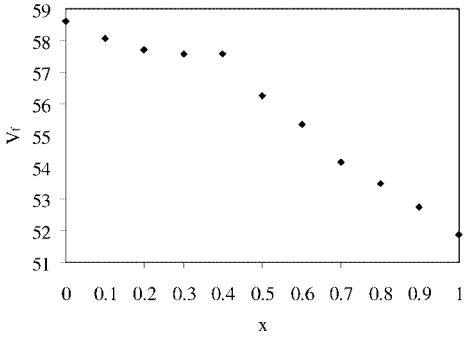

Figure 6. Variation of unit formula volume V_f with substitution level x

be expected that the limit of substitution of Ca^{2+} in $LaMnO_3$ should be much higher than that reported for Sr^{2+} ($x = 0.6$).

The influence of the calcium content on the perovskite-type structure is clearly shown by the evolution of the number and the profile of XRD peaks (Figure 5). For $0 \leq x < 0.5$, the XR diffraction diagrams are similar to those of LM(T,0.21) samples and so are indexed in the same space group (i.e., $R\bar{3}c$). For higher x values the splitting and broadening of XRD are indicative of lower symmetry. Therefore, for $0.5 \leq x \leq 1$, the diffraction patterns are indexed in space group *Pbnm*, orthorhombic description. The lattice parameter determined from XRD patterns of LCMx samples together with unit formula volume V_f, density, and atomic ratios are listed in Table 4.

Ca incorporation induces a cell contraction, as shown by the decrease in V_f when the substitution rate increases (Figure 6). Analysis results show that the atomic Ca/Mn ratio is almost equal to the theoretical value x while the O/Mn ratio decreases from 3.19 (for $x = 0.1$) to 2.96 (for $x = 1$). As in the case of $LaMnO_{3+y}$, experimental densities were determined for (La,Ca)$MnO_{3\pm y}$ and listed in Table 4.

The experimentally ascertained density value for each sample was compared to those of the previously discussed five models of defect distribution in the lattice. Two models were retained to describe the defect chemistry in

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(La,Ca)$MnO_{3\pm y}$. The first, Mn and La vacancies in equal concentrations, described the observed results well for $x \leq 0.7$. The second, with anion vacancies, described experimental results well for $x > 0.7$. Theoretical and experimental values are reported in Figure 7.

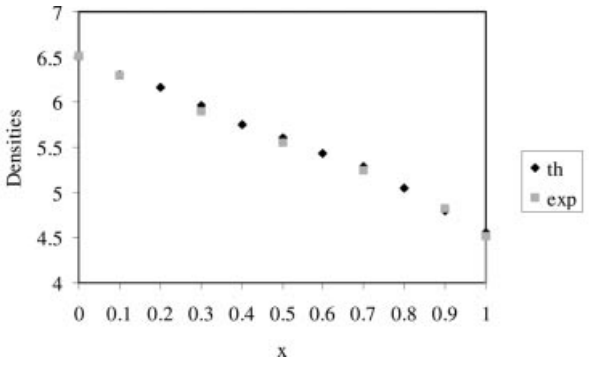

Figure 7. Theoretical (th) and experimentally determined (exp) densities of LCMx as a function of x

The oxygen non-stoichiometry y and the Mn^{4+} content are reported in Figure 8 as a function of Ca content x. The oxygen content y decreases with increasing x from $y = 0.24$ (for $x = 0$) to $y = -0.04$ (for $x = 1$). The Mn^{4+} concentration is constant for $0 \leq x \leq 0.4$ and increases almost linearly with increasing x for $0.5 \leq x \leq 1$.The maximum value, 0.92, for $x = 1$ shows that $CaMnO_{2.92}$ sample is in a reduced state. IR spectra of LCMx oxides (Figure 9) showed two absorption bands.

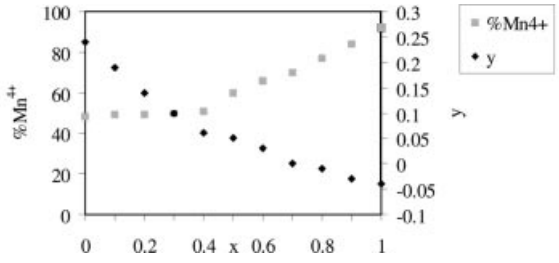

Figure 8. Variation of Mn^{4+} concentration and oxygen excess y with substitution level x in LCMx samples

The profiles of these bands changed with the substitution rate x. The higher frequency band, ν_1, was observed in the vicinity of 605 cm^{-1} for $x \leq 0.4$. For $0.5 \leq x \leq 1$, this band became asymmetric, with a high-frequency tail and extended from about 800 to 500 cm^{-1}. Its half-width increased from 90 to 180 cm^{-1}.The second band, of lower frequency, was initially centred at 380 cm^{-1} with shoulders at 392, 384, and 368 cm^{-1}. As x increased, this band broadened, shifted to somewhat higher frequencies and exhibited additional fine structure in the spectral range 350−520 cm^{-1}. For $x = 1$, the spectrum showed absorption bands in the 700−350 cm^{-1} region. In the spectral range of the ν_1 absorption mode, two bands were observed at 700 and 605 cm^{-1}. The lower frequency bands − at 514, 458, 421, 378, and 372 cm^{-1} − were in the spectral range of the ν_2 and

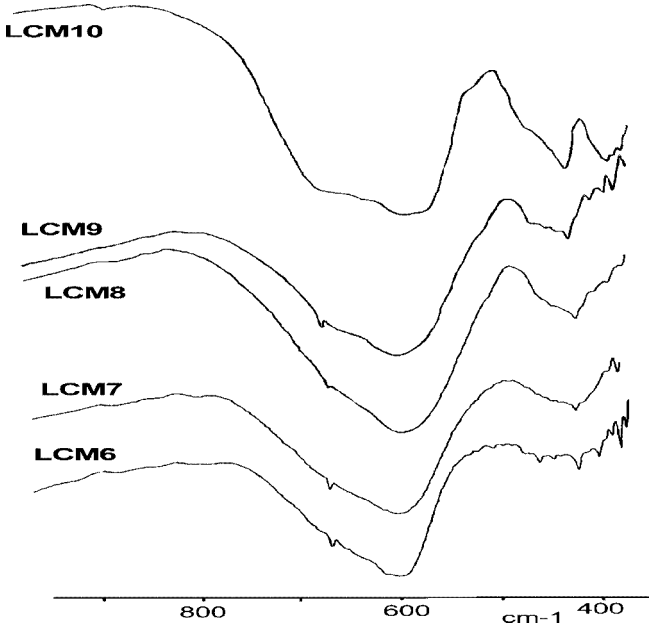

Figure 9. IR spectra of LCMx samples

ν_4 absorption modes of MnO_3 groups. Their splitting, in comparison to absorption bands in LCMx ($x \leq 0.4$) spectra, was indicative of an additional distortion of LCMx ($x \geq 0.5$) perovskite structures.

Discussion

$LaMnO_{3+y}$ oxides have been prepared as monophased perovskite structures from aqueous solutions of lanthanum nitrate $La(NO_3)_3{\cdot}6H_2O$ and manganese acetate $Mn(CH_3COO)_3$. The excess oxygen content y varied in a large range between 0.02 and 0.26. This was dependent of treatment, temperature and oxygen pressure. The y values thus decreased with increasing temperature and decreasing oxygen pressure. This tendency seemed to be confirmed under high oxygen pressures (200 atm) with a limiting y value of 0.31[33] Values comparable to $y = 0.26$ have been obtained by other preparation routes such as the sol-gel[34,35] and citrate methods[33] and calcination under an oxygen stream (1 atm).

XRD patterns showed a deviation from that of an ideal cubic structure. The splitting of peaks increased as the oxygen pressure of final treatment decreased. XRD patters were performed in the space group *Pbnm* ($Z = 4$), orthorhombic description for $y \leq 0.09$ ($[Mn^{4+}] \leq 18\%$), and in the space group $R\bar{3}c$ ($Z = 6$), rhombohedral description for $y \geq 0.14$ ($[Mn^{4+}] \geq 28\%$). The order, $c/\sqrt{2} < a < b$, of LM(T,10^{-4}) solids (orthorhombic structure), characteristic of O′-perovskites, is a consequence of the Jahn−Teller distortion of the oxide octahedron around the d^4 Mn^{3+} cation.[36] Long-range Jahn−Teller distortion is reduced when oxidation of some Mn^{3+} to Mn^{4+} occurs in $LaMnO_{3+y}$ with $y > 0.09$. There is a difference with the results ob-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tained by Hervieu et al.[37] and Verelest et al.,[34] who observed the formation of a cubic phase for $LaMnO_{3.165}$ oxide ($[Mn^{4+}] = 33\%$). In our case we observe rhombohedral symmetry even for the samples with higher Mn^{4+} contents, as clearly shown by the characteristic splitting of the diffraction peaks. Such splitting could be masked by a lack of crystallinity in the samples.

From the quoted cell parameters, we find the volume per unit formula V_f to decrease with increasing oxidation from 61.50 Å^3 for $y = 0.02$ ($[Mn^{4+}] = 4\%$) to 58.92 Å^3 for $y = 0.26$ ($[Mn^{4+}] = 52\%$). This tendency is also observed when oxidation to Mn^{4+} is partially compensated by the substitution of La^{3+} cations by Ca^{2+} in $La_{1-x}Ca_xMnO_{3\pm y}$ (Figure 10). In this case, V_f decreases to 51.86 Å^3 for $x = 1$. There is a good agreement between our V_f values and those reported in the literature for different oxygen stoichiometries, such as $LaMnO_{3.12}$[24] and $LaMnO_{3.158}$,[25] which interpolate well in Figure 10.

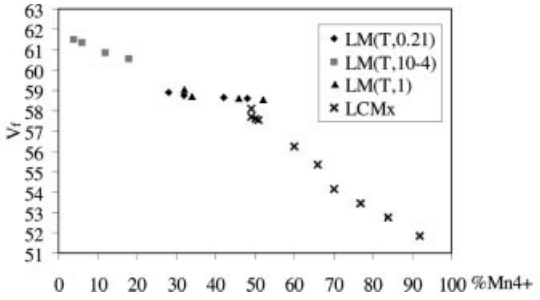

Figure 10. Variation of unit formula volume of LM and LCMx with Mn^{4+} content

The continuity in V_f vs. y variation between undoped and Ca-doped $LaMnO_3$ samples suggests that the symmetry of the manganite structure is largely determined by the concentration of Mn^{4+} ions. This is probably related to the mechanism of incorporation of the excess oxygen. The models involving vacancies either in cation or anion sublattices rather than oxygen interstitials were proposed as the predominant defects. This defect distribution in LM and LCMx solids, may be expressed by Kröger−Vink notations:[38]

LM samples:

$$LaMnO_3 + {}^{y}/_{2}\cdot O_2 \rightleftarrows LaV_{y/3}'''Mn_{1-2y}Mn_{2y}^{\circ}V_{y/3}'''O_{3+y};\quad [Mn^{4+}] = 2\cdot y$$

LCMx ($x \leq 0.7$) samples:

$$La_{1-x}Ca_x'Mn_{1-x}Mn_x^{\circ}O_3 + {}^{y}/_{2}\cdot O_2 \rightleftarrows La_{1-x}Ca_x'V_{y/3}'''Mn_{1-x-2y}Mn_{x+2y}^{\circ}V_{y/3}'''O_{3+y};\ [Mn^{4+}] = x + 2\cdot y$$

LCMx ($x \geq 0.7$) samples:

$$La_{1-x}Ca_x'Mn_{1-x}Mn_x^{\circ}O_3 \rightleftarrows La_{1-x}Ca_x'Mn_{1-x+2y}Mn_{x-2y}^{\circ}O_{3-y}V_y^{\circ\circ} + {}^{y}/_{2}\cdot O_2;\ [Mn^{4+}] = x - 2\cdot y$$

For LCMx samples, the Mn^{4+} content depends on the synthesis conditions as well as on the substitution level. As the temperature, oxygen pressure, and time of calcination were the same for all these samples, the $[Mn^{4+}]$ concentration plotted as a function of the Ca content should show a linear variation. This behaviour was observed for $x > 0.4$ (Figure 8). Fairly similar results for Sr-substituted manganite have been reported in the literature by many authors.[14−39] These authors showed that the concentration of Mn^{4+} was mostly determined by the substitution level of La^{3+} by Sr^{2+} rather than the synthesis conditions. For $0 \leq x \leq 0.4$, the Mn^{4+} content calculated from the substitution of lanthanum by calcium is different from that determined by chemical analysis, which indicated a deviation from the stoichiometry of lowly substituted LCMx compounds. Indeed, both the substitution level and the creation of cationic vacancies contribute to the determination of the Mn^{4+} concentration (see equations above). The results given in Figure 8 show that the ability to form over-stoichiometric compounds in air at 700 °C decreases with increasing calcium content and mostly disappears at $x = 0.7$. For $x > 0.7$, substoichiometric LCMx compounds were formed, their defect structures explained by the presence of anionic vacancies.

The structural modifications studied by XRD as a function of excess oxygen y and substitution level x were corroborated to IR investigations on the number and position of characteristic absorption bands. The observed band locations were explained in terms of an inverse relationship between atomic separation and vibrational frequency, and the band widths and splitting by the degree of degeneracy of the absorption mode and the resulting departure from cubic symmetry. $LaMnO_{3+y}$ ($y \geq 0.14$) and LCMx ($x \leq 0.4$) are rhombohedral, and the ν_1 band is narrower than this band in the orthorhombic materials [i.e., $LaMnO_{3+y}$ ($y \leq 0.09$) and LCMx ($x \geq 0.5$)].

The displacement of the ν_1 band to lower frequencies (Table 3) could be explained by consideration of the Mn−O bond order concept. Indeed, in the schematic energy level diagram of ABO_3 perovskites[40] the e_g electrons are in antibonding orbitals and so the bond order would decrease with an increase in the number of e_g electrons. This accounts for the observed decrease in the stretching frequency with increasing Mn^{3+} ($t_{2g}^3e_g^{*1}$) concentration (i.e. with decreasing y values). These results are in agreement with those reported for $LaBO_3$ oxides [B = Cr (d^3); Mn (d^4); Fe (d^5)] for which vibrational frequencies were in the order $\nu_{Cr-O} > \nu_{Mn-O} > \nu_{Fe-O}$.[41]

From the d_{Mn-O} values (Table 3) it can be seen that the increase in d_{Mn-O} together with the decrease in y induces a decrease in the vibrational frequency of the Mn−O bonds. This would be in agreement with a decrease in the bond force constant. Since the vibration ν_1 is primarily motion of oxygen ions, it is reasonable to expect that there should be little difference between Mn^{3+}−O and Mn^{4+}−O spectra. The Mn^{4+}−O frequency is slightly higher than that of Mn^{3+}−O because of the smaller lattice size and the fact that Mn^{4+} has a higher charge, thus increasing the Mn−O force constant. Moreover, the observed distances d_{Mn-O} were compared to the ionic radius sums $r_{Mn} + r_O$, where r_O is the ionic radius of the oxide ion (1.40 Å)[23] and r_{Mn} is the average ionic radius of the manganese site in the deficient structure [(c) in Table 1]. The differences between theoretical and observed distances (Δ) are included in

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 3. The negative Δ values probably reflect partial covalent bond character and this covalent character would be weaker for LM(T,10^{-4}) oxides.

The spectra of lowly substituted LCMx ($x \leq 0.4$) perovskites are similar to those of rhombohedral LM solids. The fair constancy of ν_1 band frequency in the vicinity of 605 cm^{-1} is in agreement with the constancy of the Mn^{3+}/Mn^{4+} ratio (Figure 8). These observations also show that a change in the cations in perovskite A sites from La, with a mass of 139, to Ca, with a mass of 40, has no effect on the internal stretching mode frequency of B−O bond. Consequently, it is reasonable that the spectral components associated with common structural elements, namely MnO_3 octahedra, of LM and LCMx with rhombohedral symmetry should be similar. However, the A−MnO_3 lattice vibration frequency, ν_3, which is beyond the range of the spectrometer, should necessarily be different. With increasing substitution level x, the deviation from ideal cubic symmetry increases together with the Mn^{4+} content in the Mn sub-lattice, resulting in a lattice shrinkage due to the smaller size of the tetravalent ion. Consequently, the degeneracy seems to be completely removed and the infrared absorption bands are split in some components.

Conclusion

$LaMnO_{3+y}$ and $La_{1-x}Ca_xMnO_{3\pm y}$ perovskites with wide ranges of y ($0.02 \leq y \leq 0.26$) and x values ($0 \leq x \leq 1$) have been obtained by thermal treatment of aqueous-decomposed precursors at different temperatures and under different oxygen pressures. The influence of oxygen excess content y and the substitution level x in lanthanum manganites over a wide range of concentrations on the Mn^{4+} content, the symmetry of the perovskite structure, the defect chemistry and the infrared absorption bands of the stretching and bending Mn−O bond has been studied. All samples showed a deviation from ideal cubic symmetry even for the highest Mn^{4+} contents. Their symmetries were described as rhombohedral for $LaMnO_{3+y}$ ($y \geq 0.14$) and $La_{1-x}Ca_xMnO_{3\pm y}$ ($x \leq 0.4$) and orthorhombic for $LaMnO_{3+y}$ ($y \leq 0.09$) and $La_{1-x}Ca_xMnO_{3\pm y}$ ($x \geq 0.5$). Through consideration of five limiting defect structure models, the situation with equal vacancies on both La and Mn sites was proposed for $LaMnO_{3+y}$ and $La_{1-x}Ca_xMnO_{3\pm y}$ ($x \leq 0.7$), while oxygen vacancies were favoured as the predominant defect in the oxygen deficient region [i.e. $La_{1-x}Ca_xMnO_{3\pm y}$ ($x > 0.7$)]. The linear decrease in the volume per unit formula of the Ca-doped and undoped lanthanum manganites as well as the absorption frequencies and profiles of infrared bands characteristic of Mn−O bond were correlated with the change in Mn^{4+} content.

The next question to be solved with these compounds is to evaluate the change in surface composition and its behaviour toward probe molecule adsorptions and catalytic activity in combustion reactions.

Experimental Section

$LaMnO_{3+y}$ and $La_{1-x}Ca_xMnO_{3\pm y}$ samples, with x ranging from 0.00 to 1.00, were prepared in polycrystalline form from aqueous solutions of lanthanum nitrate, manganese acetate (for $LaMnO_{3+y}$) and calcium nitrate (for $La_{1-x}Ca_xMnO_{3\pm y}$). The obtained solution, with La/Mn and La+Ca/Mn atomic ratios equal to 1, was stirred constantly for2 h. Upon removal of the excess solvent by heating at 70 °C in vacuo (17 Torr), a gel containing the metal in solid solution was formed. The gel was dried at 110 °C for 24 h and was then decomposed at 450 °C in air. This treatment enabled total elimination of organic and nitrate materials. The resulting black powder was heated at different temperatures ranging from 700 to 1000 °C and at three different partial oxygen pressures for $LaMnO_{3+y}$ and in air (P_{O_2} = 0.21 atm) at 700 °C for (La,Ca)$MnO_{3\pm y}$. Each solid was maintained at the desired temperature for 24 h. The sample was then rapidly cooled to room temperature.

Throughout this article, the formal notations of LM(T,P) and LCMx, respectively, are used. LM(T,P) corresponds to $LaMnO_{3+y}$ obtained at a temperature T (700, 800, 900, or 1000 °C) and oxygen pressure (10^{-4}, 0.21, or 1 atm) and LCMx corresponds to $La_{1-x}Ca_xMnO_{3\pm y}$ obtained at T = 700 °C and P = 0.21 atm.

X-ray powder diffraction (XRD) patterns were obtained with Cu-K_α radiation in a Kigaku goniometer. For unit cell determinations, the patterns were collected by step-scanning from 10 to 80° in 2θ, in increments of 0.05° and a counting of 4 s each step. Lattice constants were refined by the least-squares method with the aid of the SILEX program.

Infrared spectra were recorded with a Perkin−Elmer FT-IR Paragon 1000PC in the 2000−300 cm^{-1} spectral range. The substance (ca. 0.3 wt%) was mixed thoroughly with dry KBr and pressed into discs of 0.5 mm thickness and 10 mm in diameter.

The lanthanum, manganese, and calcium contents in the solids were determined by atomic absorption spectroscopy. The concentrations of Mn^{3+} and Mn^{4+} ions were determined by redox titration.[42,43]

The densities of the samples were obtained by determining the volume of a known amount of powder in a pycnometer by use of bromobenzene. The experiments were performed in a climate room with a temperature of 19−20 °C. About 4−5 g of powder was used for each measure.

Acknowledgments

We would like to thank Professor A. Belhadj Amara, Faculté des Sciences de Bizerte, for helpful discussion and experimental support. We are deeply indebted to Dr. F. B. Amor, Faculté des Sciences de Tunis, for performing the refinements of XRD patterns.

Physicochemical Characterization of P760, a New Macromolecular Contrast Agent with High Relaxivity[‡]

Luce Vander Elst,[a] Marc Port,[b] Isabelle Raynal,[b] Christian Simonot,[b] and Robert N. Muller*[a]

Keywords: Angiography / MRI contrast agents / NMRD / P760

P760-Gd, a hydrophilic derivative of DOTA-Gd with a molecular mass of 5.6 kDa, has been characterized in various media: aqueous solution, protein-containing solution, and Zn^{2+}-containing solution. Several investigations have been carried out, including the determination of the number of inner-sphere water molecules by laser-induced luminescence of the europium complex, water ^1H nuclear magnetic relaxation rates as a function of field strength, and ^{17}O relaxometry of water of the gadolinium complex, pulsed magnetic field gradient spin echo of proton, and ^2H transverse relaxation rates of the labeled lanthanum analogue. The large proton relaxivity of P760-Gd in water results from the long rotational correlation time of the hydrated complex ($\tau_R \approx 2$ ns at 310 K). As with DOTA-Gd, no significant Zn^{2+} transmetallation process was observed by proton relaxometry. Finally, analysis of the non-covalent binding of P760-Gd to serum proteins by proton relaxometry showed that P760-Gd does not interact with human serum albumin.

Introduction

Intensive research into the development of MR Blood Pool Agents (BPAs) has now been in progress for more than 10 years. Depending on their pharmacokinetic properties, these BPAs may be divided into three different classes: Low Diffusion Agents (LDAs), Rapid Clearance Blood Pool Agents (RCBPAs), and Slow Clearance Blood Pool Agents (SCBPAs).[1−3]

P760-Gd (Guerbet, Roissy − France) (Figure 1) is an original MR Contrast Agent belonging to the Low Diffusion Agent pharmacokinetic category. Indeed, because of its intermediate molecular size, P760-Gd can diffuse through the vascular endothelium, but at a much lower rate than a non-specific agent such as DOTA-Gd, whereas its renal excretion remains totally free.[1,3−5]

Very little concerning the physicochemical properties of this DOTA-Gd derivative has been reported. Its proton relaxivity at 20 MHz and 37 °C is quite large (24.7 s^{-1} mM^{-1}),[5] in good agreement with its large molecular size. In this work, an extensive in vitro physicochemical characterization of P760-Gd was performed. The number of inner-sphere water molecules q was evaluated by laser-induced luminescence of P760-Eu. The residence time τ_M of the coordinated water molecule was estimated by analysis of the temperature dependence of the water ^{17}O transverse relaxation of P760-Gd solution, whereas the rotational correlation time τ_R was calculated from the ^2H transverse relaxation rate of deuterated P760-La. The translational diffusion coefficient D, useful for calculation of the outer-sphere contribution to the relaxation rate and for the estimation of the molecular volume, was obtained by proton NMR on P760-La. The rate and magnitude of transmetallation by Zn^{2+} ions in aqueous phosphate solutions at pH = 7.0 was evaluated by proton relaxometry.

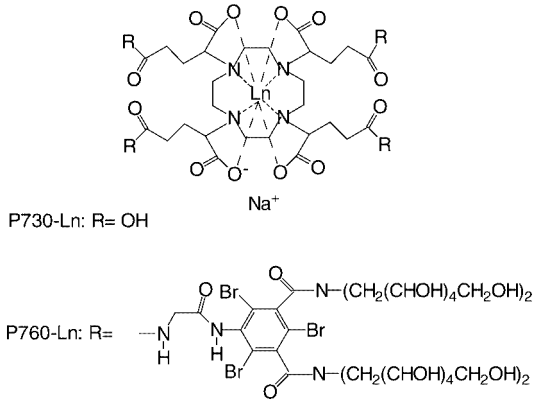

Figure 1. Chemical structures of P730 and P760

Finally, the proton T_1 Nuclear Magnetic Relaxation Dispersion (NMRD) curve of P760-Gd in water and its longitudinal proton relaxation rate in a 4% HSA solution were analyzed. In view of the clinical context of this kind of study, most of the data are reported at 310 K, physiological body temperature.

Results and Discussion

q Determination

Horrocks and Sudnick have shown that the differences in the decay rates of Eu^{3+} or Tb^{3+} luminescence in H_2O ($1/\tau_{H_2O(ms)}$) and D_2O ($1/\tau_{D_2O(ms)}$) solutions are related to the number of water molecules in the first coordination sphere [Equation (1)].[6] Recently, Beeby et al.[7] have refined the method, by consideration of the contributions from water molecules diffusing close to the Ln^{3+} complex and of other protons, exchangeable oscillators [Equation (2)]. The measured luminescence lifetimes of P760-Eu in H_2O and D_2O were 0.63 ms and 2.32 ms, respectively. The corresponding calculated *q* values are 1.16 by use of Horrock's equation or 1.03 according to Beeby et al., in good agreement with the expected value of 1.

$$q = 1.05\left(\frac{1}{\tau_{H_2O}} - \frac{1}{\tau_{D_2O}}\right) \quad (1)$$

$$q_{corr} = 1.2\left(\frac{1}{\tau_{H_2O}} - \frac{1}{\tau_{D_2O}} - 0.25\right) \quad (2)$$

τ_R Determination

The ^2H relaxation rates of diamagnetic compounds are predominantly functions of the interaction between the quadrupolar moment (Q) and the electric field gradient at the nucleus (q), and hence depend on the rotational correlation time τ_R. For small molecules, the extreme narrowing condition ($\omega_I^2\tau_R^2 << 1$) is fulfilled and R_1 and R_2 are equal. For larger molecules characterized by larger values of τ_R, $\omega_I^2\tau_R^2 \geq 1$ and consequently, $R_2 >> R_1$. At the magnetic field used for the ^2H NMR measurements (B_0 = 7.05 T), this situation occurs when $\tau_R \geq 1$ ns. At 310 K, the spectrum of the monodeuterated P760-La analogue shows a broad resonance ($\Delta\nu_{1/2}$ = 218 Hz) arising from the slowly rotating deuterium nuclei. The linewidth can thus be used to measure R_2 ($R_2 = \pi\,\Delta\nu_{1/2}$) and its dependence on the temperature. Values of τ_R calculated from R_2 by use of Equation (3) and a quadrupolar coupling constant e^2qQ/h equal to 170 kHz are 2.2 ns at 310 K and 3.3 ns at 298 K. In Equation (3), I is the nuclear spin and η is the asymmetry parameter of the field gradient. This latter parameter is negligible for deuterium nuclei involved in carbon−deuterium bonds.[8]

$$\frac{1}{T_2} = \frac{3}{400}\frac{2I+3}{I^2(2I-1)}\left(1+\frac{\eta^2}{3}\right)\left(\frac{e^2Qq}{\hbar}\right)^2\left[3\tau_R + \frac{5\tau_R}{1+\omega_I{}^2\tau_R{}^2} + \frac{2\tau_R}{1+4\omega_I{}^2\tau_R{}^2}\right] \quad (3)$$

A rough estimation of the τ_R value of P760-Gd has been made on the basis of the τ_R value of DOTA-Gd at 310 K (τ_R = 59 ps)[9] and the two molecular volumes [V^m(DOTA-Gd) = 0.38 nm^3 and V^m(P760-Gd) = 11.5 nm^3 obtained from photon correlation spectroscopy data[5]] from the relationship: $\tau_R^{P760\text{-}Gd} = \tau_R^{DOTA\text{-}Gd}$. V^m(P760-Gd)/V^m(DOTA-Gd) derived from the Stokes−Einstein equation [see Equation (4)] and by the assumption that the microviscosity factor f_R can be set to 1 either for DOTA-Gd or for P760-Gd. Such an estimation gives a value of 1.79 ns for P760-Gd, for a viscosity (η) of 0.69 mPa·s corresponding to a 1 mM solution.

$$\tau_R = \frac{\eta f_R V_m}{kT} \quad (4)$$

As the actual viscosity of the deuterated P760-La solution (28 mM) is equal to 1.32 mPa·s at 310 K, this value can be corrected by the viscosity factor, giving a τ_R value of 3.4 ns.

These calculations are somewhere imprecise, because the above molecular volumes calculated from the diffusion constant by the Stokes−Einstein−Debye model did not take the microviscosity factor (f_T) for the translational diffusion[10] into account [Equations (5) and (6), where r and r_s are the radius of the solute and solvent molecules, respectively]. If the microviscosity factors are included in the calculations, the calculated molecular volumes of DOTA-Gd and P760-Gd are 0.78 nm^3 and 14.4 nm^3, respectively

$$D = \frac{kT}{6\pi\eta f_T r} \quad (5)$$

$$f_T{}^{-1} = \frac{3r_s}{2r} + \frac{1}{\left(1+\frac{r_s}{r}\right)} \quad (6)$$

$$f_R{}^{-1} = 6\frac{r_s}{r} + \frac{1}{\left(1+\frac{r_s}{r}\right)^3} \quad (7)$$

By including the microviscosity factor for the rotational correlation time f_R [≈ 0.4 for DOTA-Gd and ≈ 0.68 for P760-Gd calculated by Equation (7)[10]], the estimated τ_R^{310} of P760-Gd by Equations (4) and (7) are 2 ns for a viscosity of 0.69 mPa·s (corresponding to a 1 mM solution) and 3.9 ns for a viscosity of 1.32 mPa·s (corresponding to a 28 mM solution), a value somewhat larger than that obtained from deuterium relaxation measurement. The activation energy for the rotation (E_R) was derived from the temperature dependence [Equation (8)] and was found to be equal to 32.3 kJ/mol, a value larger than those already reported for smaller complexes (Figure 2).[11−13]

$$\tau_R = \tau_R^{298}\, exp\left(\frac{E_R}{R}\left(\frac{1}{T} - \frac{1}{298.15}\right)\right) \quad (8)$$

τ_M Determination

The rate of exchange of the water molecule in the first coordination sphere of Gd^{3+} can be determined by analysis of the temperature dependence of the paramagnetic transverse relaxation rate ($R_2 = 1/T_2$) of the ^{17}O NMR signal of water in the gadolinium complex solution.[11−13] The temperature dependence of ^{17}O R_2 from 288 to 357 K was studied.

Analysis of the experimental data may be performed by use of two different hypotheses concerning the diamagnetic contribution, and theoretical fittings were performed for both, with or without quadrupolar contribution, providing four different solutions (Table 1). In the first approach, the reduced relaxation rate $\{1/T_2^R = 55.55\cdot(T_2\cdot q\cdot[\text{P760-Gd}])^{-1}\}$ was calculated by assuming that the diamagnetic contribution was that of pure water (closed circles, Figure 3). The fitting of the experimental data was then performed either with a model in which the transverse relaxation rate of the bound nuclei of ^{17}O ($1/T_2^M$) results mainly from scalar interaction with the gadolinium ion, as described in ref.[11] (2nd column of Table 1), or with a second model in which the quadrupolar contribution to $1/T_2^M$ was taken into account (3rd column of Table 1).

Both types of fittings allow for the determination of the following parameters:

(i) the hyperfine coupling constant between the oxygen-17 nucleus and the electronic spin of Gd^{3+} ($A/\hbar$),

(ii) the parameters related to the electronic relaxation times τ_{S1} and τ_{S2} (i.e., the correlation time for the modulation of the zero field splitting τ_V), the activation energy E_V for this process, and B which depends on the trace of the square of the zero field splitting tensor (Δ^2) and on the electron spin S $\{B = \Delta^2[4S(S + 1) - 3]/25\}$,

(iii) the parameters of the water exchange rate [i.e., the enthalpy ($\Delta H^{\neq}$) and the entropy ($\Delta S^{\neq}$) of activation],

(iv) when the quadrupolar contribution is taken into account, additional parameters describing this contribution are included [see Equation (3)]: the rotational correlation time τ_R and the activation energy for the rotation, which were fixed to the value estimated from the data obtained by ^{2}H NMR ($\tau_R^{298} = 3$ ns, $E_R = 32.3$ kJ/mol), as well as a term related to the quadrupolar coupling constant and the asymmetry parameter of ^{17}O set to the value of water $[(1 + \eta^2/3)^{1/2}(e^2qQ/h) = 7.58$ MHz].[13]

Table 1. Parameters obtained by the fittings of the ^{17}O NMR spectroscopic data

	Without quadrupolar contribution and with water diamagnetic contribution	With quadrupolar contribution and water diamagnetic contribution	Without quadrupolar contribution and with P760-La diamagnetic contribution	With quadrupolar contribution and P760-La diamagnetic contribution[a]

[a] Two sets of fitted parameters giving similarly good fits are reported.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In the second approach, the change in viscosity and the possible contribution of the oxygen atoms of water molecules interacting with the hydrophilic arms of P760-Gd were included in the diamagnetic contribution by measurement of the oxygen-17 transverse relaxation rate of water in a 19 mM solution of P760-La. From these data, a second set of reduced relaxation rates $1/T_2^R$ was obtained (open circles, Figure 3). On comparing the two $1/T_2^R$ sets, we observed a decrease in the reduced transverse relaxation rate over the whole temperature range, with a more pronounced effect at low temperature (Figure 3) when the P760-La diamagnetic contribution was taken into account. The fitting parameters with P760-La diamagnetic contribution, with or without quadrupolar contribution, are listed in Table 1 (4th and 5th columns). With the first approach, the results of the fitting show that the water residence time is short (about 100 ns at 310 K) and close to that reported for the parent compound DOTA-Gd at the same temperature.[13] The use of the appropriate diamagnetic contribution (2nd approach) gives slightly larger values of τ_M (average value of 128 ns).

It should be pointed out that the fitted values of the hyperfine coupling constant τ_V and B are interrelated and that similarly good fits can be obtained with two different sets of parameters, as shown in the last column of Table 1.

Determination of the Self-Diffusion Coefficient (D) by ^{1}H NMR

The aim of the measurement of D was twofold. Firstly, it is useful for estimation of the molecular radius [see Equation (5)], and secondly, the value of the relative diffusion coefficient ($D_{water} + D_{complex}$) is one of the parameters describing the outer-sphere contribution to the relaxation rate. The measurements were performed at four temperatures (293, 298, 303, and 310 K) and 4.7 T by the gradient spin echo method with selective saturation of the water resonance on a 3.3 mM P760-La solution in water; D was calculated from the variation in the intensity of the resonance at $\delta = 3.8$ ppm as a function of the applied gradient. To avoid interference between the signal arising from residual water, the intensities were measured with gradient strengths larger than 170 Gauss/cm. The obtained values are shown in Table 2. The value obtained at 293 K is in good agreement with the previously reported value of 1.5 10^{-10} m^2s^{-1} obtained by photon correlation spectroscopy.[5] Consequently, the radius calculated from the Debye−Stokes theory [Equation (5)] with f_T equal to 1 is 1.53 nm, a value slightly larger than that obtained by PCS ($r = 1.4$ nm). Refinement of the calculation by use of the translational microviscosity theory gives a value of 1.64 nm [Equation (6)]. This value corresponds to a τ_R^{310} of 2.1 ns ($\eta = 0.69$ mPa·s), consistent with the previous value of 2 ns found by deuterium transverse relaxation rates experiments.

Table 2. Diffusion coefficients measured on P760-La and water in a 3.3 mM solution at different temperatures

Temperature [K]	D of P760-La [10^{-10} m^2s^{-1}]	D of H_2O [10^{-10} m^2s^{-1}] in the P760-La solution
293	1.40	18.52
298	1.62	21.01
303	1.81	23.93
310	1.98	27.28

Transmetallation by Zn^{2+} Ions

Transmetallation of gadolinium complexes by Zn^{2+} ions induces a release of Gd^{3+} ions, which form insoluble phosphate complexes in the presence of phosphate ions; these released lanthanide ions no longer contribute to the proton paramagnetic relaxation rate of the solution. Subsequently, the water proton relaxation rate decreases during the transmetallation process and its evolution can be used to monitor the phenomenon quantitatively.[14] Under identical experimental conditions ($B_0 = 0.47$ T, $T = 310$ K, 2.5 mM of gadolinium complex, 2.5 mM of Zn^{2+} ions, and phosphate buffer pH = 7), no significant change in the paramagnetic relaxation rate was reported for the macrocyclic gadolinium complexes DOTA-Gd and HPDO3A-Gd {[10-(2-hydroxypropyl)-1,4,7-tris(methoxycarbonyl)-1,4,7,10-tetraazacyclododecane]gadolinium(III)} whereas R_1^p was about 57% of its initial value for DTPA-Gd and 22% for DTPA BMA-Gd after 1400 min, showing that significant transmetallation takes place for these open-chain gadolinium complexes. A similar experiment was performed with P760-Gd, but because of the large relaxivity of this complex at 20 MHz and to the limitations of the instrument, the concentrations of the gadolinium complex and of Zn^{2+} ions had to be reduced to 0.5 mM. As would be expected for a macrocyclic complex, the results show no significant evolution of the proton paramagnetic relaxation rate over a period of 1400 min and agree with the absence of transmetallation by Zn^{2+} ions (Figure 4).

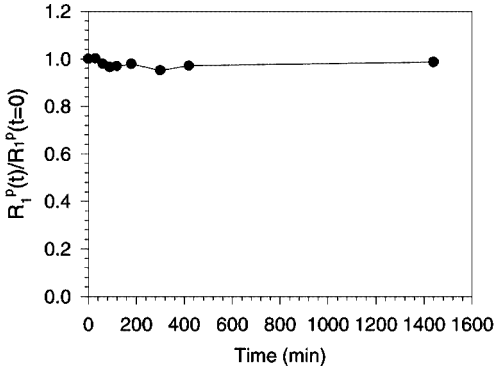

Figure 4. Evolution of the ratio $R_1^p(t)/R_1^p(t = 0)$ with time for a solution containing 0.5 mM of P760-Gd and $ZnCl_2$ at pH = 7.0 and 37 °C ($B_0 = 0.47$ T)

NMRD Fitting

The proton longitudinal relaxation rates were measured between 0.01 and 300 MHz on a 0.19 mM P760-Gd solution; the transverse relaxation rates were measured between 20 and 300 MHz. The calculated relaxivities (the relaxation rate enhancement afforded by 1 mmol/L of the gadolinium

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

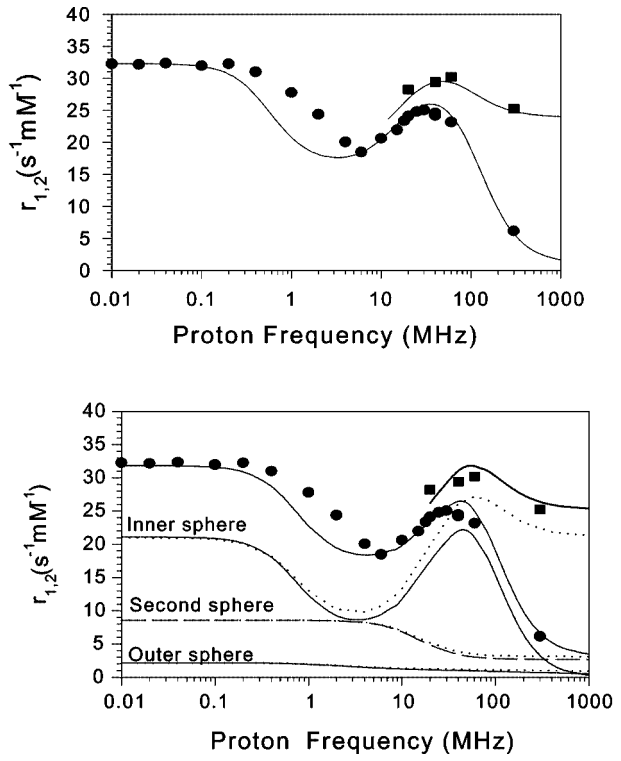

Figure 5. Proton NMRD data obtained at 310 K on a 0.19 mM solution (circles: r_1; squares: r_2; best fit); the top graph was obtained by use of the classical inner-sphere and outer-sphere theories with d = 0.36 nm, r = 0.31 nm, τ_{SO} = 740 ps, τ_V = 14 ps, τ_R = 1.8 ns, and τ_M = 320 ns; the bottom graph was obtained by use of the inner-sphere, outer-sphere, and second-sphere theory with d = 0.6 nm, r = 0.325 nm, τ_{SO} = 410 ps, τ_V = 13 ps, τ_R = 1.7 ns, τ_M = 170 ns, 25 water molecules in the second sphere at a distance of 0.4 nm and τ_{SS} = 15.6 ps

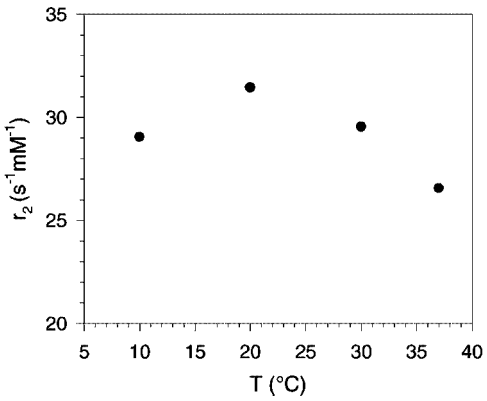

Figure 6. Proton transverse relaxivity of P760-Gd versus temperature at 7.05 T

complex) versus proton Larmor frequencies (proton NMRD curve) are shown on Figure 5.

In a first approach, ^{1}H NMRD curves were fitted according to the classical inner-sphere model described by Solomon[15] and Bloembergen[16] and to the outer-sphere model described by Freed.[17] In these fittings, q (the number of water molecules coordinated to the Gd^{3+} ion) was fixed to 1, r (the distance between the proton nuclei of the inner-sphere water molecule and the Gd^{3+}) was set to 0.31 nm, the relative diffusion constant D was set to the values obtained above by ^{1}H NMR spectroscopy (2.93 10^{-9} m^2s^{-1}), d (the distance of closest approach for the outer-sphere contribution) was set at 0.36 nm,[18,19] and the parameters describing the electronic relaxation times, τ_V and τ_{SO} (the electronic relaxation time at zero field), were optimized for the outer-sphere and the inner-sphere contributions simultaneously. Parameters τ_R and τ_M were allowed to fluctuate around the values obtained by ^{2}H and ^{17}O NMR spectroscopy. Satisfactory fits of the data could be obtained at low fields and at high fields with a τ_R value of 1.8 ns and a τ_M value of 320 ns (Figure 5, top graph). This latter value is significantly larger than that determined by ^{17}O NMR spectroscopy. The τ_{SO} and τ_V values are slightly larger than those reported for the parent compound DOTA-Gd (τ_{SO}^{310} = 480 ps and τ_V^{310} = 11 ps[13]). These discrepancies could be related to the fact that the simple model used to fit the ^{1}H NMRD curve is not appropriate to describe the behavior of slowly tumbling paramagnetic molecules[20] or to the presence of a second sphere of water molecules due to the hydrophilic nature of the P760-Gd complex. Such a second sphere, not included in this fitting of the proton NMRD data, can be taken into account (see below).

Data for r_2 were also obtained at 310 K and at magnetic fields ranging from 0.47 to 7.05 T (Figure 5). In addition, the temperature dependence of r_2 at 7.05 T was also studied (Figure 6). At this field, r_2 is predominantly determined by the inner-sphere interaction and so depends mainly on τ_R and τ_M [Equation (9)]. The data (Figure 6) suggest a situation of intermediate water exchange in the temperature range investigated with a limitation of r_2 by the water exchange.

$$r_2 \cong \frac{0.001}{55.55}\frac{1}{T_{2M} + \tau_M} \quad (9)$$

Values of (T_{2M} + τ_M) calculated from the experimental data [Equation (9)] range between 570 and 670 ns. Consequently, values of τ_M of the order of hundreds of nanoseconds and τ_R values greater than 1.3 ns would be expected. The theoretical fitting of r_2 NMRD data by the classical inner- and outer-sphere models[15–17] and the parameters obtained by the fitting of r_1 data agree very well with the experimental data.

In a second approach, the interactions between the gadolinium ion and water molecules in its second sphere were considered.[21] The hydrogen atoms of these water molecules are assumed to be at a distance of 0.4 nm, and the distance of closest approach was set to 0.6 nm because of the size of the complex. To obtain reasonable r_1 and r_2 fittings, the distance r had to be increased to 0.325 nm. With these settings, the experimental data could be fitted as shown in Figure 5 (bottom graph). The τ_R value (1.7 ns) is similar to that obtained above, but the value of τ_M (170 ns) is closer to that obtained by ^{17}O NMR spectroscopy. The τ_{SO} (410 ps) and τ_V (13 ps) values are similar to those reported for the parent compound DOTA-Gd. In this fitting, 25 water molecules

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are found in the second sphere and their interaction with the paramagnetic center is modulated by a correlation time (τ_{SS}) equal to 15.6 ps.

Interaction of P760-Gd with HSA and Blood Proteins

Proton relaxation measurements were performed at 20 MHz and at 37 °C on P760-Gd solutions (0.05−1.9 mM) in 4% non-defatted HSA. No significant change in the longitudinal proton relaxation rate was observed [R_1^p(water)/R_2^p(HSA, 4%) = 1.08 for a 1mM solution of P760-Gd], showing either that P760-Gd does not interact with HSA or that there is an interaction between P760-Gd and HSA but that the rotational correlation time of the paramagnetic center is not significantly modified by the binding. Similarly, longitudinal and transverse paramagnetic relaxation rates of 0.2 mM of P760-Gd in serum were only slightly increased (increase of 6% for R_1^p and 27% for R_2^p) at 310 K and 7.05 T, confirming the results discussed above.

Conclusion

The large longitudinal and transverse proton relaxivities ($r_1 \approx 25$ $s^{-1}mM^{-1}$ and $r_2 \approx 29.5$ $s^{-1}mM^{-1}$ at 310 K and 0.94 T) of P760-Gd are related to its large molecular weight (5.6 kDa), and consequently to its quite large rotational correlation time ($\tau_R \approx 2$ ns at 310 K). Like its parent complex DOTA-Gd, this original complex does not undergo transmetallation by zinc(II) ions and the residence time of its coordinated water molecule is of the order of a few hundred nanoseconds at 310 K. The r_1 relaxivity of P760-Gd is one of the highest reported in the literature for a gadolinium complex without any protein binding.[20] The proton relaxivity data clearly show that the expected benefits from the τ_R increase are not completely achieved because of the too slow water-exchange rate. For such types of complex, maximum r_1 and r_2 values of the order of 35 $s^{-1}mM^{-1}$ and 45 $s^{-1}mM^{-1}$, respectively, should be achievable at magnetic fields of 1.1−1.5 T, assuming a water residence time of about 20 ns.

Experimental Section

Chemical Synthesis

Synthesis of Ligand L (P730): Alkylation of cyclen with racemic dimethyl 2-bromoglutarate (K_2CO_3/CH_3CN/reflux) resulted in the formation of expected octamethyl ester. Base hydrolysis (6 M NaOH, 80 °C) afforded octacarboxylic acid ligand L (P730).[22]

Synthesis of L-Ln Complexes (Gd, Eu, La). P730-Ln: Lanthanide complexes were formed by heating of ligand L and Ln_2O_3 (Gd_2O_3, Eu_2O_3, La_2O_3) at pH = 5−6 in deionized water (80−100 °C, 1−24 h).

Synthesis of the Deuterated La Complex: Dry P730-La was heated at reflux in D_2O at pD = 3 (DCl) for 4 d. The solution was filtered and concentrated. After crystallization, the complex was isolated by filtration. Isotopic exchange assessed by mass spectrometry showed that the compound was monodeuterated on the α-carbon atom of the arm.

Synthesis of P760-Ln (Gd, Eu, La): A solution of L-Ln complex and polyhydroxylated aminotribromoisophthalic derivative R (4 equiv.) was mixed with 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide (EDCI). The reaction mixture was stirred at pH = 7 for 2 d (room temperature). The solution was ultrafiltered through a 3KDa membrane (FILTRON®). After removal of water by evaporation, the white solid was dried at reduced pressure.[5]

Chemicals: All commercial chemicals [$ZnCl_2$ (Merck) and Titrisol buffer pH 7.0 (Merck)] were used without further purification. Non-defatted human albumin (fraction V) was purchased from Sigma (Bornem, Belgium).

Viscosity: The viscosity of P760 Gd was measured with a Visco-Clock viscosimeter (SCHOTT − Germany) at 37 °C by the capillary standard procedure described in the European Pharmacopoeia, 3rd ed., **2001**, method number 2.2.9.

Luminescence Studies on the Eu Complexes: The Eu^{III} phosphorescence emission spectra were acquired with an LS-50B Perkin−Elmer spectrofluorimeter equipped with a pulsed Xenon lamp and a Hamamatsu R928 photomultiplier tube operating in time-resolved mode. Solutions of the Eu^{III} complex ($9.7\cdot10^{-3}$ M and $5.7\cdot10^{-3}$ M in H_2O and D_2O, respectively) were used in these experiments. Lifetimes (τ) were obtained by monitoring of the emission intensity at 616 nm resulting from pulsed excitation at 395 nm and 140 (H_2O) or 240 (D_2O) different delay times. Excitation and emission slit widths of 5 and 20 nm, respectively, were used and the gate time was 0.4 ms. The decays of the europium emitting state were fitted by use of an equation of the form $I(t) = I(0)\exp(-t/\tau)$, with the aid of a current software fitting procedure (Microsoft Excel®). High correlation coefficients were observed in each case (typically 0.9999). The number of water molecules (q) bound to the inner coordination sphere of the europium ion was quantified by use either of the relation proposed by Horrocks and Sudnick[6] [Equation (1)], in which τ is the lifetime (in ms) of the complex in H_2O and D_2O, or of the equation reported by Beeby et al.[7] [Equation (2)].

NMR: Proton Nuclear Magnetic Relaxation Dispersion (NMRD) profiles were recorded with a Field Cycling Relaxometer (Field Cycling Systems, Oradell, New Jersey, USA) working between 0.24 mT and 1.2 T on 0.6 mL solutions contained in 10 mm o.d. tubes. Proton relaxation rates were also measured at 0.235, 0.47, 0.94, and 1.5 T with Minispec PC-110, PC-120, PC-140, and mq-60 (Bruker, Karlsruhe, Germany). The additional relaxation rates at 7.05 T were obtained with a Bruker AMX 300 (Bruker, Karlsruhe, Germany) spectrometer. ^1H NMRD data were fitted according to the theoretical inner-sphere model described by Solomon[15] and Bloembergen[16] and to the outer-sphere contribution described by Freed.[17] Calculations were performed with previously described software.[23,24] Transmetallation by Zn^{II} ions was evaluated from the decrease in the water proton longitudinal relaxation rate at 310 K and 20 MHz (Bruker Minispec PC 120) of buffered solutions (pH = 7, phosphate buffer) containing 0.5 mM of the gadolinium complex and 0.5 mM of Zn^{II} according to the procedure described previously.[14] ^{17}O and ^2H NMR spectra were recorded on 2 mL samples (10 mm o.d. tubes) with a Bruker AMX 300 spectrometer (Bruker, Karlsruhe, Germany) with a broadband probe and a Bruker BVT 2000 unit for temperature control. ^{17}O transverse relaxation times of distilled water (pH = 6.5) were measured by use of a CPMG sequence and a subsequent two-parameter fit of the data points. The 90° and 180° pulse lengths were 25 μs and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

50 μs, respectively. The value for the ^{17}O T_2 of water in P760-Gd ([P760-Gd] = 19 mM, pH = 6.0−7.0) was obtained from linewidth measurement. All ^{17}O NMR spectra were proton-decoupled. The analyses of the ^{17}O data and of the transverse relaxation rates of deuterium were described elsewhere.[11] All T_1 measurements at 7.05 T (^1H, ^2H) were performed with the inversion recovery or fast inversion recovery Fourier transform technique and a subsequent three-parameter fit of the peak heights. Diffusion coefficients were measured with an Avance 200 spectrometer fitted with a thermostatted diffusion probe and the gradient spin echo sequence (25−30 gradient strengths ranging from 10 to 250 G/cm for water diffusion measurement or from 170 to 750 G/cm for P760-La diffusion measurement; gradient pulse duration: 1 ms, diffusion time: 6.05 ms, NA:1 for water or 8−32 for P760-La, TR: 8−10 s depending on the temperature). The sample (260 μL) was contained in a 5 mm o.d. tube. Thermostatting was guaranteed by the water flow inside the probe.

Acknowledgments

New Bis(mercaptoimidazolyl)(pyrazolyl)borate Ligands and Their Zinc Complex Chemistry

Mouhai Shu,[a] Rainer Walz,[a] Biao Wu,[a] Jan Seebacher,[a] and Heinrich Vahrenkamp*[a]

Keywords: Tripodal ligands / Zinc / Bioinorganic chemistry

Nine new tripodal NS_2 ligands of the bis(mercaptoimidazolyl)(pyrazolyl)borate type with varying 3-R-mercaptoimidazolyl moieties were prepared as their potassium salts. Treatment with zinc salts yielded the complex types L·Zn–Cl, L·Zn–I, L·Zn–ONO_2, L·Zn–$OClO_3$ and [L·Zn(imidazole)]ClO_4. Attempts at the formation of L·Zn–OH or cationic L·Zn complexes resulted in dismutation and formation of ZnL_2 complexes. Hydrolytic destruction yielded one [OZn_4(thiooimidazolate)$_6$] complex. The ZnS_2NO coordination which is present in the enzyme-substrate complex of alcohol dehydrogenase could be successfully modelled by an [L·Zn(C_2H_5OH)]$^+$ complex. The L·Zn–X complexes showed very low catalytic activity in the dehydrogenation of 2-propanol or the hydrogenation of *p*-nitrobenzaldehyde. The new compounds were identified by a total of 12 structure determinations.

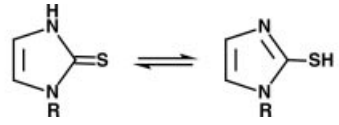
Introduction

The importance of tris(pyrazolyl)borate ligands for coordination chemistry can only be compared with that of cyclopentadienyl ligands in organometallic chemistry. This holds specifically for the classical or bioinorganic coordination chemistry of zinc[1,2] to which we have made contributions.[3] The advantage of these tripodal ligands is that they quite reliably support an N_3ZnX coordination motif which has given them then name "tetrahedral enforcers" and which has made them so valuable for the bioinorganic chemistry of zinc.[3,4]

The N_3Zn motif represents the attachment of a zinc ion to three histidine residues in a protein. Considering that cysteine is equally important for zinc binding in enzymes, one would like to have sulfur-containing tripodal ligands with qualities similar to those of the pyrazolylborates for a model complex chemistry. The accumulated experience with tripodal ligands containing thiolate functions has shown, however, that these are not suitable because the bridging tendency of the thiolates cannot be suppressed. In this context Reglinski's discovery of the tris(mercaptoimidazolyl)-borates[5] must be considered a breakthrough. As shown since by Reglinski himself[6,7] and his competitors,[8,9] including ourselves,[10] these tripods are very good "tetrahedral enforcers" and allow a fruitful biomimetic zinc model complex chemistry. The reason for this is the fact that their sulfur donors are "tame" thiolates with a low bridging tendency due to their thiol-thione tautomerism as depicted below.



Having the easily accessible tris(pyrazolyl)- and tris(mercaptoimidazolyl)borates available as N_3 and S_3 donors, we decided to aim at their combination in the form of N_2S and NS_2 donors. Specifically, the NS_2 tripods should be valuable as they allow us to mimic the $(NS_2)ZnX$ coordination in alcohol dehydrogenase. With this in mind both the research group of Parkin and ourselves set out to study the chemistry of the bis(mercaptoimidazolyl)(pyrazolyl)borates. Parkin has published the synthesis of one such ligand and some basic metal complex chemistry of it.[11–13] We have communicated the first correct structural model of the enzyme-substrate complex of alcohol dehydrogenase in the form of a $(NS_2)Zn(C_2H_5OH)$ complex.[14]

This paper summarises our recent work on bis(mercaptoimidazolyl)(pyrazolyl)borate ligands, their basic zinc complex chemistry and attempts to apply them for the modelling of the zinc enzyme alcohol dehydrogenase. Nine new ligands **L** were prepared and their zinc complexes identified by a total of twelve structure determinations.

Results and Discussion

Ligand Synthesis

From our work with tris(pyrazolyl)borates we have the experience that their biomimetic zinc complex chemistry requires a good encapsulation of the metal ion. This is achieved by bulky substituents at the 3-positions of the pyrazole rings. We applied this for the new NS_2 ligands **L** by incorporating 5-methyl-3-phenylpyrazole units in $\mathbf{L^1}$ to $\mathbf{L^8}$ and 3-*tert*-butyl-5-methylpyrazole in $\mathbf{L^9}$. Likewise, the thioimidazole units were made bulky with substituents at the outer nitrogen atoms, mostly with aromatic groups ($\mathbf{L^2}$ to $\mathbf{L^8}$), but also with methyl ($\mathbf{L^1}$) and *tert*-butyl ($\mathbf{L^9}$). Thus, all our NS_2 ligands are more bulky than the one with *N*-methylthioimidazole and unsubstituted pyrazole groups reported previously.[13]

The synthesis of the tripodal ligands **L** from KBH_4 and the nitrogen heterocycles is favoured by the fact that the thioimidazoles react more readily with KBH_4 than the pyrazoles. Thus, lower reaction temperatures are possible which ensures better yields and which allows us to run the preparations in a one-pot procedure. Mixtures of KBH_4, pyrazole and thioimidazole (1:1:2) were allowed to react in a melt at ca. 160 °C to form $\mathbf{L^1}$, $\mathbf{L^2}$, $\mathbf{L^5}$ and $\mathbf{L^9}$. Later it turned out that the preparations in boiling toluene gave better yields and cleaner products. Furthermore, a 10% excess of the pyrazole was found to improve the yield of ligand **L** considerably. Ligands $\mathbf{L^3}$, $\mathbf{L^4}$, $\mathbf{L^6}$, $\mathbf{L^7}$ and $\mathbf{L^8}$ were prepared this way. The isolated compounds K[**L**] are colourless powders which are somewhat air- and light-sensitive, sparingly soluble in aromatic hydrocarbons, and which decompose upon melting between 160 and 200 °C.

Simple Zinc Complexes

Like the tris(pyrazolyl)- and tris(mercaptoimidazolyl)-borates, the mixed ligands **L** easily form stable zinc halide complexes. This was applied for the products **1a**−**1f** by treating the corresponding ligands with the zinc halides.

$\mathbf{L^1}$•ZnCl	$\mathbf{L^2}$•ZnCl	$\mathbf{L^3}$•ZnCl
1a	**1b**	**1c**
$\mathbf{L^5}$•ZnCl	$\mathbf{L^6}$•ZnCl	$\mathbf{L^8}$•ZnCl
1d	**1e**	**1f**

The structures of **1c** and **1d** were determined, of which the one of **1c** is displayed here (Figure 1). There is very close agreement in terms of bond lengths and angles between **1c** and **1d**, and the coordination environment of the zinc ion also resembles that in the previously reported complex L·ZnI of a related NS_2 ligand.[11] The deviations from tetrahedral symmetry at the zinc ion are small. The largest bond angle is N−Zn−Cl, reflecting the steric hindrance between the phenyl substituent on the pyrazole and the Zn−Cl unit.

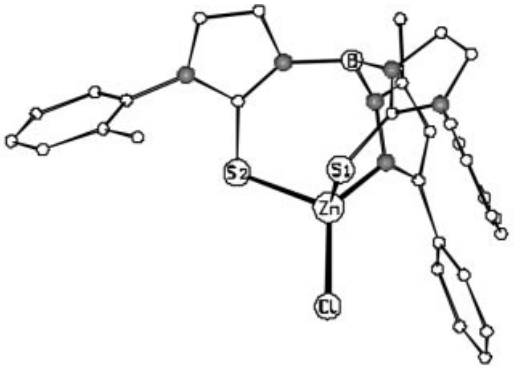

Figure 1. Molecular structure of complex **1c**; selected bond lengths [A] and angles [°]: Zn−Cl 2.201(1), Zn−S1 2.335(1), Zn−S2 2.329(1), Zn−N 2.041(2); Cl−Zn−S1 110.91(3), Cl−Zn−S2 109.11(3), Cl−Zn−N 120.09(6), S1−Zn−S2 107.60(3), S1−Zn−N 108.24(6), S2−Zn−N 99.82(6)

Other than the zinc halide and the zinc thiolate species,[15] the simple **L**·Zn complexes with anions of oxo acids turned out to be quite labile. Attempts to prepare acetates invariably led to the formation of ZnL_2 complexes (see below). The same was observed when trying to prepare nitrates. Only those ligands **L** with sterically demanding substituents, typically in the *ortho* positions of the aromatic rings, yielded nitrate complexes, of which **2a**−**2c** were isolated.

$\mathbf{L^3}$•$ZnONO_2$	$\mathbf{L^6}$•$ZnONO_2$	$\mathbf{L^8}$•$ZnONO_2$
2a	**2b**	**2c**

The structure determination of **2a** (Figure 2) proved the composition of the nitrate complexes and the semibidentate nature of the nitrate ligand. Again, the tetrahedral ligand environment is not seriously distorted, and again the N−Zn−O angle is unusually large due to steric hindrance. The semibidentate attachment of the nitrate coupled with its orientation with respect to the two sulfur donors makes the S1−Zn−O1 angle rather large and the S2−Zn−O1 angle rather small. In all these respects **2a** resembles the Zn−NO_3 complex of a related tris(mercaptoimidazolyl)borate ligand.[10]

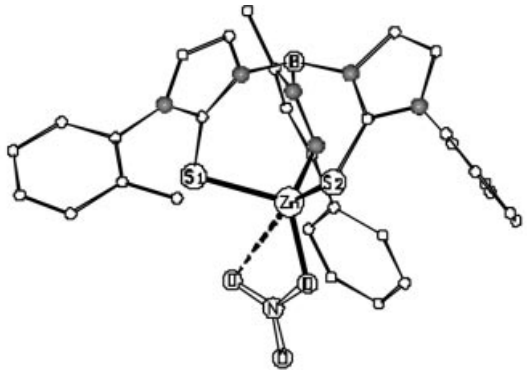

Figure 2. Molecular structure of complex **2a**; selected bond lengths [Å] and angles [°]: Zn−O1 1.965(5), Zn−O2 2.782(6), Zn−S1 2.307(2). Zn−S2 2.315(2), Zn−N 2.017(6); O1−Zn−S1 117.8(2), O1−Zn−S2 105.0(2), O1−Zn−N 115.3(2), S1−Zn−S2 108.6(1), S1−Zn−N 99.8(2), S2−Zn−N 110.2(2)

ZnL_2 Complexes

It has already been observed that the **L**·ZnX complexes of these NS_2 ligands are amenable to dismutation, with formation of the corresponding ZnL_2 complexes.[13] Our investigations were also plagued frequently by this tendency. Many attempts to prepare **L**·Zn complexes with hard coligands did not yield the desired **L**·ZnX species, but instead ZnL_2 and, presumably, ZnX_2. The reason for this is the highly preferred ZnS_4 coordination in the uncharged ZnL_2 molecules. In the following we describe those reactions that led to ZnL_2 species, even though we performed no designed (viz. trivial) synthesis of a ZnL_2 complex.

According to one of the goals of this work, namely the modelling of zinc enzymes, we intended to prepare $[L{\cdot}Zn{-}OH_2]^+$ or **L**·Zn−OH complexes. The most straightforward way to do this[3] is the reaction between a tripodal ligand **L** and hydrated zinc perchlorate, either directly or in combination with KOH. This was done here with L^1, L^5 and L^9. Although some evidence could be gathered for the formation of **L**·Zn−OH species (see below), they could not be isolated in a pure form, and the final products of the reactions were the ZnL_2 complexes **3a**, **3d** and **3f**. Also, as mentioned above, the **L**·Zn−OAc complexes were not stable enough to be isolated, and in the case of L^3 a clean dismutation yielded **3b**. Furthermore, the **L**·Zn−NO_3 complexes of those ligands **L** that are sterically less hindered, evaded their isolation by dismutation. In case of L^4 and L^7 this resulted in the isolation of pure **3c** and **3e**.

ZnL^1_2 **3a**	ZnL^3_2 **3b**	ZnL^4_2 **3c**
ZnL^5_2 **3d**	ZnL^7_2 **3e**	ZnL^9_2 **3f**

Structure determinations of **3a**, **3b**, **3c**, **3d** and **3f** revealed that in all cases the ligands **L** act as bidentate sulfur donors, i.e. the pyrazolyl arm of the tripod is uncoordinated. This corresponds to the observations made previously for similar ZnL_2 complexes[13] and for those derived from the tris(mercaptoimidazolyl)borates.[10] The molecular structures of **3a** and **3f** are shown as representative examples in Figures 3 and 4, respectively. In all complexes **3** the Zn−S bond lengths are in the range 2.33−2.40 Å, which is rather long but typical for this kind of ZnS_4 species.[10,13] The bond angles at the zinc ion show quite a range around the tetrahedral angle, the extremes being 89° in **3a** and 125° in **3c**.

Hydrolysis Products

During our attempts to prepare **L**·Zn−OH or $[L{\cdot}Zn]^+$ species by treating **L** with $Zn(ClO_4)_2$ it also became obvious that the (mercaptoimidazolyl)borates are not only more easily formed than the pyrazolylborates but also more easily hydrolysed. Thus, the acidic conditions brought about by dissolving hydrated zinc perchlorate in alcohols frequently led to the partial destruction of the ligands **L**, and free mercaptoimidazoles were found in the solutions. In three cases zinc complexes of the mercaptoimidazoles were the result of such hydrolytic cleavages.

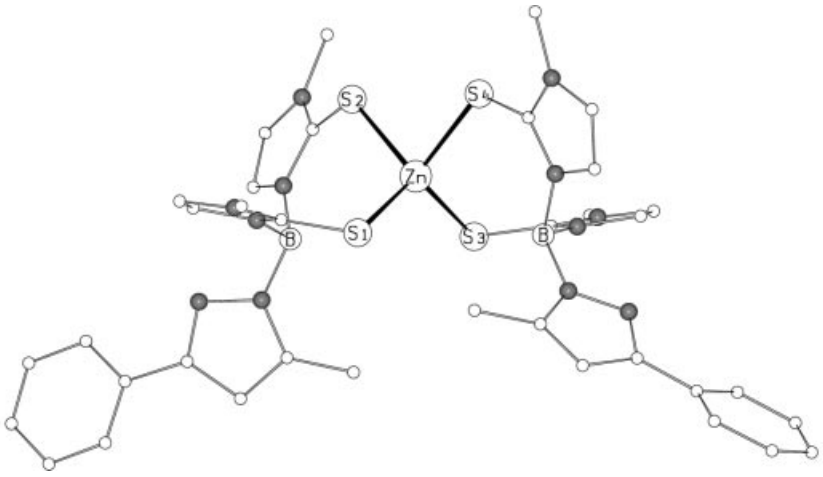

Figure 3. Molecular structure of **3a**; selected bond lengths [Å] and angles [°]: Zn−S1 2.336(2), Zn−S2 2.382(2), Zn−S3 2.346(2), Zn−S4 2.401(2); S1−Zn−S2 110.77(8), S1−Zn−S3 115.68(8), S1−Zn−S4 114.64(8), S2−Zn−S3 112.93(7), S2−Zn−S4 89.28(6), S3−Zn−S4 110.70(7)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

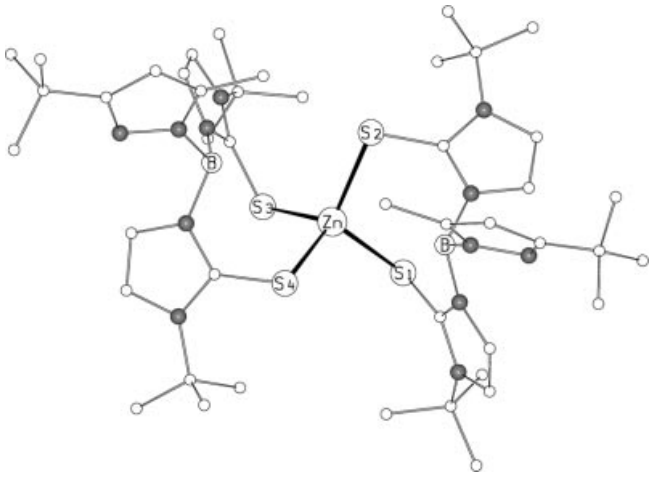

Figure 4. Molecular structure of **3f**; selected bond lengths [Å] and angles [°]: Zn−S1 2.359(2), Zn−S2 2.371(2), Zn−S3 2.368(2), Zn−S4 2.403(2); S1−Zn−S2 109.35(6), S1−Zn−S3 100.35(5), S1−Zn−S4 111.09(5), S2−Zn−S3 110.72(5), S2−Zn−S4 118.99(5), S3−Zn−S4 104.65(5)

In two of these cases the free mercaptoimidazole was incorporated as a coligand in the intended **L**·Zn complexes: $Zn(ClO_4)_2{\cdot}6H_2O$ and $\mathbf{L^3}$ yielded complex **4a**, and with $\mathbf{L^6}$ complex **4b** was formed. Both **4a** and **4b** were characterised by structure determinations. The structure of **4a** is shown in Figure 5. In **4a** and **4b** the tripod ligand is bound to the zinc ion in the normal fashion; the mercaptoimidazole is attached as a neutral molecule. Its bonding situation is that of a thioimidazoline, i.e. of a thiourea derivative. This is a very common situation in zinc complex chemistry, and the Zn−S bond length (2.33 Å in **4a**, 2.31 Å in **4b**) corresponds to expectation.[16] The deviations from tetrahedral symmetry at the zinc ion (smallest angle 99°, largest angle 123°) are in the same range as observed above.

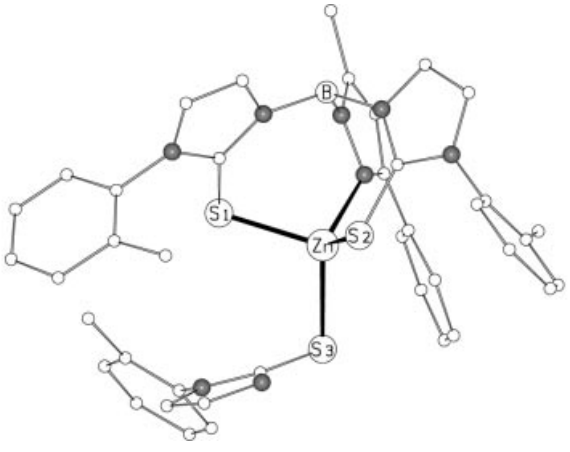

Figure 5. Molecular structure of **4a**; selected bond lengths [Å] and angles [°]: Zn−S1 2.323(2), Zn−S2 2.332(2), Zn−S3 2.326(2), Zn−N 2.027(5); N−Zn−S1 98.6(1), N−Zn−S2 105.6(1), N−Zn−S3 122.6(1), S1−Zn−S2 112.9(1), S1−Zn−S3 104.0(1), S2−Zn−S3 112.5(1)

$[\mathbf{L^3}{\cdot}Zn(N\text{-tolylthioimidazoline})]ClO_4$ **4a**

$[\mathbf{L^6}{\cdot}Zn(N\text{-cumylthioimidazoline})]ClO_4$ **4b**

In the case of $\mathbf{L^1}$ the hydrolytic destruction resulted in a zinc complex that bears only mercaptoimidazolate ligands. After addition of KOH to the reaction mixture, $[OZn_4(methimazolate)_6]$ (**5**) was obtained, another crystalline form of which has already been described.[17] Complex **5** is an analogue of $OZn_4(OAc)_6$,[18] i.e. a variant of the classical basic beryllium acetate structure with the six chelating N,S ligands spanning the edges of the Zn_4 tetrahedron. Figure 6 shows the structure of **5**, all details of which have already been discussed.[17]

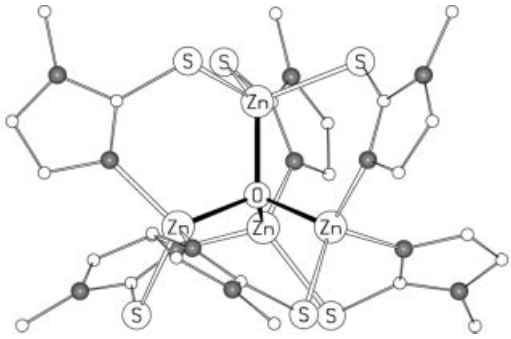

Figure 6. Molecular structure of **5**.; selected bond lengths [Å]: Zn−O 1.955(2), Zn−N 2.000(4), Zn−S 2.325(1) and 2.340(1)

Attempts at Enzyme Modelling

With the intention to prepare **L**·Zn−OH, **L**·Zn(H_2O) or $[\mathbf{L}{\cdot}Zn]^+$ complexes, i.e. functional models for the resting state of zinc enzymes, we performed a number of reactions between the ligands **L** and zinc salts of noncoordinating anions under varying pH conditions. So far, however, none of the intended species, which would be the starting point for modelling alcohol dehydrogenase chemistry, could be obtained in a pure form. However, in two cases evidence for the existence of a **L**·Zn−OH species could be gathered. Treatment of zinc perchlorate with $\mathbf{L^1}$ and KOH allowed the precipitation of a compound whose elemental analyses and spectra may be in agreement with its formulation as **6a**. Likewise, a species which may be formulated as **6b** was obtained with $\mathbf{L^2}$. Both compounds, however, show considerable amounts of impurities in their NMR spectra, and both could not be purified due to their lability toward hydrolysis or dismutation as described above.

$\mathbf{L^1}{\cdot}ZnOH$ **6a**

$\mathbf{L^2}{\cdot}ZnOH$ **6b**

Only with one ligand **L**, namely the *o*-methoxy-substituted $\mathbf{L^8}$, could stable complexes be prepared, which come close to containing naked $[\mathbf{L}{\cdot}Zn]^+$. Treatment with zinc perchlorate in methanol yielded **7**, and under the same conditions in ethanol **8** was obtained. The identification of **7** rests on its spectra. The presence of zinc-bound perchlorate is evident from the sharp and intense IR band at 1093

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cm^{-1}, in analogy to the structurally characterised [tris(mercaptoimidazolyl)borate]zinc perchlorate complex.[10] The ethanol complex **8** is a relative of two [tris(mercaptoimidazolyl)borate]zinc−alcohol complexes.[10,19]

$\mathbf{L^8}$•$ZnOClO_3$ $[\mathbf{L^8}$•$Zn(C_2H_5OH)]ClO_4$

7 **8**

The structure of **8** is shown in Figure 7. The ethanol ligand occupies the fourth coordination site of the zinc ion, the coordination geometry of which is tetrahedral to a good approximation. The Zn−O bond length is very similar to that in the nitrate complexes (see above), indicating a strong Zn−O(ethanol) bond. The ethanol ligand in the crystalline compound is connected by a hydrogen bond to a second ethanol molecule, which explains the absence of characteristic OH bands in the 3300−3700 cm^{-1} region in the IR spectrum. The molecular shape of **8** does not offer a convincing clue why it is just ligand $\mathbf{L^8}$ that makes complexes like **7** and **8** stable. Yet it is evident that the *o*-methoxy substituents enforce an orientation of the three phenyl groups that creates a bowl-like shape of the whole ligand, which may provide just enough stabilization of the Zn−EtOH unit in its interior.

Complex **8** is the first zinc complex in which an alcohol molecule is bound to a zinc ion with NS_2 ligation, creating a tetrahedral $ZnONS_2$ system. This bonding pattern reproduces the attachment of ethanol to the active centre of alcohol dehydrogenase.[20] In our preliminary communication on **8**[14] we have elaborated the close geometrical relation between the $ZnONS_2$ cores of **8** and of the enzyme structure of highest resolution. Hence, in terms of bioinorganic chemistry, the formation and structure of **8** are the most relevant result of this paper (Figure 7).

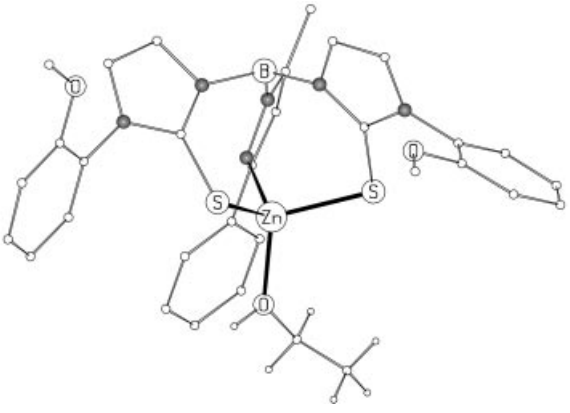

Figure 7. Molecular structure of **8**; selected bond lengths [Å] and angles [°]: Zn−O 1.970(3), Zn−S1 2.282(1), Zn−S2 2.314(1), Zn−N 2.012(3); O−Zn−S1 105.4(1), O−Zn−S2 109.8(1), O−Zn−N 116.9(1), S1−Zn−S2 113.2(1), S1−Zn−N 111.7(1), S2−Zn−N 100.2(1)

Having achieved structural modelling of alcohol dehydrogenase we also attempted functional modelling. As done before,[10,21,22] we used (benzyl)nicotinamide chloride ([BNA]Cl) as a mimic of NAD^+ and (dihydrobenzyl)nicotinamide (BNAH) as a mimic of NADH. For attempts at oxidation we used 2-propanol as an electron-rich alcohol and for attempts at reduction *p*-nitrobenzaldehyde as an electron-poor aldehyde. Thus, the model reactions were:

$$(CH_3)_2CHOH + BNA^+ \rightarrow (CH_3)_2CO + BNAH \quad (1)$$

$$p\text{-}O_2N\text{-}C_6H_4CHO + BNAH \rightarrow p\text{-}O_2N\text{-}C_6H_4CH_2OH + BNA^+ \quad (2)$$

It is known that reaction (1) does not proceed in the absence of a catalyst, but reaction (2) proceeds very slowly. Trying some of the **L**·Zn−X complexes described here we found that they show no or very low catalytic efficiency for both processes. The best results, obtained with complex **2a**, consisted in a 2−3% yield of acetone and traces of *p*-nitrobenzyl alcohol after 24 h of heating. These are the poorest results in our studies on the functional modelling of alcohol dehydrogenase, although the applied "catalysts" are the closest structural models of the enzyme. Conversely, the best catalytic results were obtained by us with zinc complexes whose structure has no resemblance at all with that of the enzyme.[22]

Conclusions

This work has shown that the tripodal NS_2 ligands **L** are easily accessible. They fill half of the gap between the analogous N_3 (i.e. pyrazolylborate) and S_3 (i.e. mercaptoimidazolylborate) ligands. Provided that the as-yet-unknown tripodal N_2S ligands of this type are also accessible, the door would be open for a complete set of comparative investigations of metal complexes with homologous tripodal N_3, N_2S, NS_2, and S_3 ligands. We intend to undertake this investigation with **L**·ZnX complexes, putting emphasis on enzyme model compounds.

The preliminary **L**·ZnX chemistry in this paper has revealed that the resulting complexes are not as inert as their tris(pyrazolylborate)·ZnX counterparts. One reason for this seems to be the high stability of the dismutation products ZnL_2 which comes from their ZnS_4 coordination in an uncharged complex. The other reason seems to be the geometrical disposition of the mercaptoimidazolyl moieties, which provides less encapsulation for the ZnX units than that of the pyrazolyl moieties, because their aromatic substituents point away from rather than enclosing the centre of the complexes. The relative stabilities of the **L**·ZnX complexes, however, give a clue on how to improve this situation: it seems that *ortho* substituents on the phenyl groups induce an orientation of them that creates a bowl-shaped environment around the ZnX units and hence the desired encapsulation.

The perchlorate complex **7** and the ethanol complex **8** are the best examples for this kind of stabilization. Complex **7** is as close as possible to being "naked" $[\mathbf{L}\cdot Zn]^+$, and **8** is the best model so far for the enzyme-substrate complex of alcohol dehydrogenase. Both **7** and **8** also demonstrate the subtle stability differences in these complexes of weakly bound ligands: perchlorate is a better ligand than methanol (**7** crystallises from methanol) but a weaker ligand than

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ethanol (**8** crystallises from ethanol). Thus **7** and **8** on one side show the way to improve the ligand design for making more stable **L**·Zn complexes of this type, on the other side they offer themselves as starting materials for a functional and possibly catalytic **L**·Zn chemistry.

Experimental Section

General: For general working and measuring procedures, see ref.[23] All procedures for the ligand syntheses were performed under an inert gas. 5-Methy-3-phenylpyrazole[24] and 3-*tert*-butyl-5-methylpyrazole[25] were prepared according to the published procedures. All *N*-substituted mercaptoimidazoles were prepared from the corresponding amino acetals $RNHCH_2CH(OEt)_2$ and HSCN according to an established procedure.[26,27] They were characterised by ^1H NMR spectroscopy in $CDCl_3$ as follows:

R = methyl: ^1H NMR ($CHCl_3$): δ = 3.66 ppm (s, 3 H, NMe), 6.59 (d, *J* = 2.0 Hz, 1 H, 4-H), 6.78 (d, *J* = 2.2 Hz, 1 H, 5-H). R = phenyl: ^1H NMR ($CHCl_3$): δ = 6.75 ppm (m, 2 H, 4-H, 5-H), 7.31−7.56 (m, 5 H, Ph). R = *o*-tolyl: ^1H NMR ($CHCl_3$): δ = 2.19 ppm (s, 3 H, Me), 6.66 (d, *J* = 2.4 Hz, 1 H, 4-H), 6.86 (d, *J* = 2.4 Hz, 1 H, 5-H), 7.00−7.43 (m, Ar). R = *p*-tolyl: ^1H NMR ($CHCl_3$): δ = 2.41 ppm (s, 3 H, Me), 6.80 (d, *J* = 1.6 Hz, 1 H, 4-H), 6.84 (d, *J* = 1.6 Hz, 1 H, 5-H), 7.28 (m, 2 H, Ar), 7.45 (m, 2 H, Ar). R = 2,4-xylyl: ^1H NMR ($CHCl_3$): δ = 2.16 ppm (s, 3 H, Me), 2.38 (s, 3 H, Me), 6.69 (d, *J* = 2.4 Hz, 1 H, 4-H), 6.81 (d, *J* = 2.4 Hz, 1 H, 5-H), 7.15 (m, 3 H, Ar), 7.26 (s, 1 H, Ar). R = *p*-cumyl: ^1H NMR ($CHCl_3$): δ = 1.28 ppm (d, *J* = 6.8 Hz, 6 H, Me), 2.97 (sept, *J* = 6.8 Hz, 1 H, CH), 6.80 (d, *J* = 2.4 Hz, 1 H, 4-H), 6.84 (d, *J* = 2.4 Hz, 1 H, 5-H), 7.34 (d, *J* = 6.6 Hz, 2 H, Ar), 7.50 (d, *J* = 6.6 Hz, 2 H, Ar). R = *p*-anisyl: ^1H NMR ($CHCl_3$): δ = 3.85 ppm (s, 3 H, OMe), 6.80 (d, *J* = 2.4 Hz, 1 H, 4-H), 6.98 (d, *J* = 2.2 Hz, 1 H, 5-H), 7.00 (d, *J* = 6.8 Hz, 2 H, Ar), 7.47 (d, *J* = 6.8 Hz, 2 H, Ar). R = *o*-anisyl: ^1H NMR ($CHCl_3$): δ = 3.74 ppm (s, 3 H, OMe), 6.81 (d, *J* = 2.1 Hz, 1 H, 4-H), 6.88 (d, *J* = 2.1 Hz, 1 H, 5-H), 6.98 (m, 2 H, Ar), 7.39 (m, 2 H, Ar). R = *tert*-butyl: ^1H NMR ($CHCl_3$): δ = 1.81 ppm (s, 9 H, *t*Bu), 6.67 (d, *J* = 2.4 Hz, 1 H, 4-H), 6.84 (d, *J* = 2.4 Hz, 1 H, 5-H).

Ligand Synthesis: All ligands **L** were prepared by thermal reaction between KBH_4, the pyrazole and the imidazole. Initially, the reactions were performed by melting the reagents (procedure A) which resulted in low yields and unsatisfactory purity of the products. Then it was found that the ligands **L** also form in boiling toluene (procedure B) which is the preferred procedure.

Procedure A: A 1:1 mixture of KBH_4 and the pyrazole was heated to 120 °C (thermometer immersed into the melt). The melt was stirred for 30 min. Then, 2 mol-equiv. of the mercaptoimidazole was added and the temperature raised slowly to 140 °C and kept at this temperature (30−60 min) until hydrogen evolution stopped. After cooling to room temp., the resulting solid was powdered and the raw product crystallised from ethanol at −30 °C.

Procedure B: A 1:1.1:2 mixture of KBH_4, the pyrazole and the imidazole was dried in vacuo at 60 °C for 2 h. 125 mL of dry toluene was added and the mixture refluxed for 4 days by heating with an oil bath (150 °C). Then, the volume of the solution was reduced in vacuo to 50 mL, and the mixture was poured into 200 mL of petroleum ether (boiling range 60−70 °C). The resulting precipitate was washed with a small amount of benzene and then with petroleum ether and dried in vacuo.

L^1: By procedure A from KBH_4 (1.70 g, 31.6 mmol), pyrazole (5.00 g, 31.6 mmol) and the imidazole (7.21 g, 63.2 mmol). Yield 4.10 g (30%); m.p. 200 °C (dec.). $C_{18}H_{20}BKN_6S_2$ (434.44): calcd. C 49.77, H 4.64, N 19.34; found C 48.59, H 4.90, N 17.60. ^1H NMR ($CDCl_3$): δ = 2.33 [s, 3 H, Me (pz)], 3.58 (s, 6 H, NMe), 6.30 [s, 1 H, H (pz)], 6.45 [d, *J* = 2.0 Hz, 2 H, H (im)], 6.63 [d, *J* = 2.0 Hz, 2 H, H (im)], 7.31 (m, 3 H, Ph), 7.51 (d, *J* = 7.4 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2392 m (BH) cm^{-1}.

L^2: By procedure A from KBH_4 (920 mg, 17.1 mmol), the pyrazole (2.70 g, 17.1 mmol) and the imidazole (6.03 g, 34.2 mmol). Yield 4.9 g (50%); m.p. 180 °C (dec.). $C_{28}H_{24}BKN_6S_2$ (558.58): calcd. C 60.21, H 4.33, N 15.05; found C 56.50, H 4.83, N 13.69. ^1H NMR ($CDCl_3$): δ = 2.29 [s, 3 H, Me (pz)], 6.29 [s, 2 H, H (pz)], 6.72 (d, *J* = 2.4 Hz, 2 H, H (im)], 6.75 [d, *J* = 2.4 Hz, 2 H, H (im)], 7.30−7.51 (m, 13 H, Ar), 7.53 (d, *J* = 7.4 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2483 m (BH) cm^{-1}.

L^3: By procedure B from KBH_4 (1.08 g, 20.0 mmol), the pyrazole (3.47 g, 22.0 mmol) and the imidazole (7.60 g, 40.0 mmol). Yield 10.1 g (86%); m.p. 205 °C (dec.). $C_{30}H_{28}BKN_6S_2$ (586.63): calcd. C 61.42, H 4.81, N 14.33, S 10.93; found C 61.36, H 5.12, N 14.23, S 10.47. ^1H NMR (CD_3OD): δ = 2.16 [s, 6 H, Me (tol)], 2.43 [s, 3 H, Me (pz)], 6.31 [s, 1 H, H (pz)], 6.59 [d, *J* = 2.2 Hz, 2 H, H (im)], 6.79 [d, *J* = 2.2 Hz, 2 H, H (im)], 7.27 (m, 8 H, Ar), 7.75 (d, *J* = 7.0 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2451 m (BH) cm^{-1}.

L^4: By procedure B from KBH_4 (1.08 g, 20.0 mmol), the pyrazole (3.47 g, 22.0 mmol) and the imidazole (7.60 g, 40.0 mmol). Yield 9.86 g (84%); m.p. 165 °C (dec.). $C_{30}H_{28}BKN_6S_2$ (586.63): calcd. C 61.42, H 4.81, N 14.33, S 10.93; found C 61.29, H 5.25, N 14.25, S 9.91. ^1H NMR (CD_3OD): δ = 2.37 [s, 6 H, Me (tol)], 2.42 [s, 3 H, Me (pz)], 6.30 [s, 1 H, H (pz)], 6.57 [d, *J* = 2.2 Hz, 2 H, H (im)], 6.92 [d, *J* = 2.2 Hz, 2 H, H (im)], 7.28 (m, 8 H, Ar), 7.45 [d, *J* = 8.2 Hz, 4 H, H (tol)], 7.74 (d, *J* = 7.0 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2482 m (BH) cm^{-1}.

L^5: By procedure A from KBH_4 (0.54 g, 10.0 mmol), the pyrazole (3.16 g, 20.0 mmol) and the imidazole (8.16 g, 40.0 mmol). Yield 0.74 g (12%); m.p. 185 °C (dec.). $C_{32}H_{32}BKN_6S_2$ (614.69): calcd. C 62.53, H 5.25, N 13.67; found C 58.72, H 5.31, N 12.33. ^1H NMR ($CDCl_3$): δ = 2.12 [s, 6 H, Me (xyl)], 2.34 [s, 6 H, Me (xyl)], 2.75 [s, 3 H, Me (pz)], 6.36 [s, 1 H, H (pz)], 6.54 [d, *J* = 2.0 Hz, 2 H, H (im)], 6.68 [d, *J* = 2.0 Hz, 2 H, H (im)], 7.04−7.15 (m, 6 H, xyl), 7.40−7.43 (m, 3 H, Ph), 7.69−7.75 (m, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2487 m (BH) cm^{-1}.

L^6: By procedure B from KBH_4 (1.08 g, 20.0 mmol), the pyrazole (3.47 g, 22.0 mmol) and the imidazole (8.72 g, 40.0 mmol). Yield 4.63 g (36%); m.p. 165 °C (dec.). $C_{34}H_{36}BKN_6S_2$ (642.74): calcd. C 63.54, H 5.65, N 13.08, S 9.98; found C 63.21, H 5.91, N 13.07, S 10.08. ^1H NMR (CD_3OD): δ = 1.22 [d, *J* = 6.8 Hz, 18 H, Me (*i*Pr)], 2.08 [s, 3 H, Me (pz)], 2.89 [sept, *J* = 6.8 Hz, 2 H, CH (*i*Pr)], 6.26 [s, 1 H, H (pz)], 6.37 [d, *J* = 2.2 Hz, 2 H, H (im)], 6.75 [d, *J* = 2.2 Hz, 2 H, H (im)], 7.24 (m, 8 H, Ar), 7.42 (d, *J* = 8.3 Hz, 4 H, Cum), 7.68 (d, *J* = 7.0 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2476 m (BH) cm^{-1}.

L^7: By procedure B from KBH_4 (0.54 g, 10.0 mmol), the pyrazole (1.74 g, 11.0 mmol) and the imidazole (4.12 g, 20.0 mmol). Yield 5.57 g (90%); m.p. 175 °C (dec.). $C_{30}H_{28}BKN_6O_2S_2$ (618.63): calcd. C 58.25, H 4.56, N 13.58, S 10.37; found C 57.68, H 4.42, N 13.20, S 10.13. ^1H NMR (CD_3OD): δ = 2.44 [s, 3 H, Me (pz)], 3.82 (s, 6 H, OMe), 6.29 [s, 1 H, H (pz)], 6.57 [d, *J* = 2.2 Hz, 2 H, H (im)], 6.90 [d, *J* = 2.2 Hz, 2 H, H (im)], 7.00 (d, *J* = 8.4 Hz, 4 H, C_6H_4),

7.31 (m, 3 H, Ph), 7.44 (d, J = 8.3 Hz, 4 H, C_6H_4), 7.72 (d, J = 7.0 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2486 m (BH) cm^{-1}.

L^8: By procedure B from KBH_4 (0.70 g, 13.0 mmol), the pyrazole (2.26 g, 14.3 mmol) and the imidazole (5.35 g, 26.0 mmol). Yield 6.79 g (85%); m.p. 185 °C (dec.). $C_{30}H_{28}BKN_6O_2S_2$ (618.63): calcd. C 58.25, H 4.56, N 13.58, S 10.37; found C 57.99, H 4.60, N 13.54, S 10.43. ^1H NMR ([D$_6$]DMSO): δ = 2.43 [s, 3 H, Me (pz)], 3.73 (s, 6 H, OMe), 6.24 [s, 1 H, H (pz)], 6.76 [d, J = 2.1 Hz, 2 H, H (im)], 6.82 [d, J = 2.1 Hz, 2 H, H (im)], 6.85−7.49 (m, 1 H, Ar), 7.74 (d, J = 7.1 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2441 w (BH) cm^{-1}.

L^9: By procedure A from (0.54 g, 10.0 mmol) of KBH_4, (3.00 g, 20.0 mmol) of the pyrazole and (6.24 g, 40.0 mmol) of the imidazole. Yield 0.51 g (10%), m.p. 160 °C (dec.). The product contained considerable amounts of impurities. ^1H NMR ([D$_6$]DMSO): δ = 1.18 [s, 9 H, *t*Bu (pz)], 1.73 [s, 18 H, *t*Bu (im)], 2.15 [s, 3 H, Me (pz)], 5.59 [s, 1 H, H (pz)], 6.26 [d, J = 2.0 Hz, 2 H, H (im)], 6.79 [d, J = 2.0 Hz, 2 H, H (im)] ppm. IR (KBr): $\tilde{\nu}$ = 2496m (BH) cm^{-1}.

Zinc Halide Complexes. General Procedure: A solution of the zinc halide in 10 mL of methanol was added dropwise, with stirring, to a solution of the ligand in 50 mL of dichloromethane. After 2 h of stirring, the solution was filtered, the filtrate reduced to half of its volume in vacuo and then cooled to −30 °C overnight. The resulting precipitate of the raw product was filtered off, washed with 1−2 mL of methanol and dried in vacuo. If necessary it was recrystallised from CH_2Cl_2/CH_3OH or CH_2Cl_2/CH_3CN. All **L**·ZnHal complexes were obtained as colourless powders.

1a: From **L^1** (200 mg, 0.46 mmol) and $ZnCl_2$ (63 mg, 0.46 mmol). Yield 57 mg (25%); m.p. 225 °C (dec.). $C_{18}H_{20}BClN_6S_2Zn$ (496.20): calcd. C 43.57, H 4.06, N 16.94; found C 42.86, H 4.13, N 16.32. ^1H NMR ($CDCl_3$): δ = 2.42 [s, 3 H, Me (pz)], 3.57 [s, 6 H, Me (im)], 6.22 [s, 1 H, H (pz)], 6.60 [d, J = 2.0 Hz, 2 H, H (im)], 7.15 [d, J = 2.0 Hz, 2 H, H (im)], 7.28 (m, 3 H, Ph), 7.74 (d, J = 7.4 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2503 m (BH) cm^{-1}.

1b: From **L^2** (300 mg, 0.52 mmol) and $ZnCl_2$ (71 mg, 0.52 mmol). Yield 156 mg (48%); m.p. 215 °C (dec.). $C_{28}H_{24}BClN_6S_2Zn$ (620.33): calcd. C 54.21, H 3.90, N 13.55; found C 54.68, H 4.05, N 13.57. ^1H NMR ($CDCl_3$): δ = 2.29 [s, 3 H, Me (pz)], 6.29 [s, 1 H, H (pz)], 6.75 [d, J = 2.4 Hz, 2 H, H (im)], 6.81 [d, J = 2.4 Hz, 2 H, H (im)], 7.30−7.51 (m, 13 H, Ar), 7.53 (d, J = 7.4 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2507 m (BH) cm^{-1}.

1c: From **L^3** (196 mg, 0.33 mmol) and $ZnCl_2$ (46 mg, 0.34 mmol). Yield 180 mg (84%); m.p. 270 °C (dec.). $C_{30}H_{28}BClN_6S_2Zn$ (648.38): calcd. C 55.57, H 4.35, N 12.96, S 9.89; found C 55.23, H 4.58, N 13.33, S 9.34. ^1H NMR ($CDCl_3$): δ = 2.06 [s, 3 H, Me^1 (tol)], 2.28 [s, 3 H, Me^2 (tol)], 2.49 [s, 3 H, Me (pz)], 6.39 [s, 1 H, H (pz)], 6.88 [s, 2 H, H (im)], 7.05 [s, 2 H, H (im)], 7.25−7.37 (m, 11 H, Ar), 7.53 (d, J = 7.2 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2559 w (BH) cm^{-1}.

1d: From **L^5** (614 mg, 1.00 mmol) and $ZnCl_2$ (136 mg, 1.00 mmol). Yield 0.25 mg (37%), m.p. 220 °C (dec.). $C_{32}H_{32}BClN_6S_2Zn$ (676.43): calcd. C 56.82, H 4.77, N 12.42; found C 56.99, H 4.70, N 12.36. ^1H NMR ($CDCl_3$): δ = 2.14 [s, 6 H, Me (xyl)], 2.37 [s, 6 H, Me (xyl)], 2.48 [s, 3 H, Me (pz)], 6.38 [s, 1 H, H (pz)], 6.83 [d, J = 2.0 Hz, 2 H, H (im)], 6.99 [d, J = 2.0 Hz, 2 H, H (im)], 7.00−7.17 (m, 6 H, xyl), 7.31−7.37 (m, 3 H, Ph), 7.53−7.58 (m, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2505 m (BH) cm^{-1}.

1e: From **L^6** (206 mg, 0.33 mmol) and $ZnCl_2$ (46 mg, 0.34 mmol). Yield 169 mg (67%), m.p. 240 °C (dec.). $C_{36}H_{40}BClN_6S_3Zn$ (764.60): calcd. C 56.55, H 5.27, N 10.99, S 12.58; found C 56.31, H 5.60, N 11.02, S 12.25. ^1H NMR ($CDCl_3$): δ = 1.26 [d, J = 7.0 Hz, 12 H, Me (*i*Pr)], 2.93 [sept, J = 7.0 Hz, 2 H, CH (*i*Pr)], 6.38 [s, 1 H, H (pz)], 7.01 [d, J = 2.0 Hz, 2 H, H (im)], 7.07 [d, J = 2.0 Hz, 2 H, H (im)], 7.28 (m, 8 H, Ar), 7.45 (m, 3 H, Ar), 7.62 (d, J = 7.4 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2512 w (BH) cm^{-1}.

1f: From **L^8** (301 mg, 0.49 mmol) and ZnI_2 (155 mg, 0.49 mmol). Yield 257 mg (69%), m.p. 230 °C (dec.). $C_{30}H_{28}BIN_6O_2S_2Zn·0.5(CH_2Cl_2)$ (771.83 +42.47): calcd. C 44.99, H 3.59, N 10.32, S 7.88; found C 45.79, H 3.95, N 10.75, S 8.25. ^1H NMR ($CDCl_3$): δ = 2.49 [s, 3 H, Me (pz)], 3.85 (s, 6 H, OMe), 5.32 (s, 1 H, CH_2Cl_2), 6.15 [s, 1 H, H (pz)], 6.91−7.95 [m, 15 H, H (im) + Ar] ppm. IR (KBr): $\tilde{\nu}$ = 2511 w (BH) cm^{-1}.

Zinc Nitrate Complexes

2a: A solution of **L_3** (196 mg, 0.33 mmol) in 5 mL of dichloromethane was added dropwise with stirring to a solution of $Zn(NO_3)_2·6H_2O$ (95 mg, 0.34 mmol) in 10 mL of methanol. After 4 h of stirring, the precipitate was filtered off. Recrystallisation from dichloromethane/acetonitrile yielded 158 mg (71%) of **2a**, m.p. 220 °C (dec.). $C_{30}H_{28}BN_7O_3S_2Zn$ (674.93): calcd. C 53.39, H 4.18, N 14.53, S 9.50; found C 53.29, H 4.29, N 14.42, S 9.30. ^1H NMR (CD_2Cl_2): δ = 1.96 [s, 3 H, Me^1 (tol)], 2.25 [s, 3 H, Me^2 (tol)], 2.53 [s, 3 H, Me (pz)], 6.46 [s, 1 H, H (pz)], 6.96 [d, J = 2.2 Hz, 2 H, H (im)], 7.08 [d, J = 2.2 Hz, 2 H, H (im)], 7.37 (m, 11 H, Ar), 7.52 (d, J = 6.0 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2479 w (BH), 1382 vs (NO_3), 1294 vs (NO_3) cm^{-1}.

2b: Like **2a** from **L^6** (214 mg, 0.33 mmol) and $Zn(NO_3)_2·6H_2O$ (95 mg, 0.34 mmol). Yield 169 mg (73%); m.p. 180 °C (dec.). $C_{34}H_{36}BN_7O_3S_2Zn$ (731.04): calcd. C 55.86, H 4.96, N 13.41, S 8.77; found C 56.26, H 5.46, N 12.87, S 8.01. ^1H NMR ($CDCl_3$): δ = 1.27 [d, J = 6.9 Hz, 12 H, Me (*i*Pr)], 2.96 [sept, J = 6.9 Hz, 2 H, CH (*i*Pr)], 6.40 [s, 1 H, H (pz)], 7.00 [s, 4 H, H (im)], 7.36 (s, 8 H, Cum), 7.38 (m, 3 H, Ph), 7.56 (d, J = 5.4 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2486 w (BH), 1373 s (NO_3), 1292 s (NO_3) cm^{-1}.

2c: Like **2a** from **L^8** (307 mg, 0.52 mmol) and $Zn(NO_3)_2·4H_2O$ (137 mg, 0.52 mmol). Yield 115 mg (31%), m.p. 215 °C (dec.). $C_{30}H_{28}BN_7O_5S_2Zn$ (706.93): calcd. C 50.97, H 3.99, N 13.87, S 9.07; found C 50.43, H 4.28, N 13.51, S 8.93. ^1H NMR ($CDCl_3$): δ = 2.44 [s, 3 H, Me (pz)], 3.75 (s, 6 H, OMe), 6.32 [s, 1 H, H (pz)], 6.86 [d, J = 2.2 Hz, 2 H, H (im)], 6.96 [d, J = 2.2 Hz, 2 H, H (im)], 7.10−7.48 (m, 11 H, Ar), 7.54−7.60 (m, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2489 w (BH), 1384 vs (NO_3), 1294 vs (NO_3) cm^{-1}.

ZnL_2 Complexes

3a: A solution of (171 mg, 0.46 mmol) of $Zn(ClO_4)_2·6H_2O$ in 20 mL of methanol was added with stirring to a solution of (200 mg, 0.46 mmol) of **L^1** in 50 mL of dichloromethane. After 30 min, powdered KOH (29 mg, 0.50 mmol) was added. After 20 h of stirring and filtration, the volume of the solution was reduced to one half in vacuo. Cooling to −4 °C overnight produced a colourless precipitate of **6a** (characterisation see below). Attempts to purify this product by dissolution in dichloromethane and slow concentration yielded, after 4 weeks, 18 mg (4%) of colourless crystalline **3a**; m.p. 230 °C (dec.). $C_{36}H_{40}B_2N_{12}S_4Zn·3H_2O$ (856.14 +54.02): calcd. C 47.51, H 5.09, N 18.47; found C 46.40, H 5.03, N 19.25. ^1H NMR ($CDCl_3$): δ = 1.49 (s, 6 H, H_2O), 2.38 [s, 6 H, Me (pz)], 3.43 [s, 12 H, Me (im)], 6.22 [s, 2 H, H (pz)], 6.67 [d, J = 2.0 Hz, 4 H, H (im)], 7.17 [d, J = 2.0 Hz, 4 H, H (im)], 7.31 (m, 6 H, Ph), 7.75 (d, J = 7.4 Hz, 4 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2500 m (BH) cm^{-1}.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3b: A solution of **L³** (196 mg, 0.33 mmol) in methanol (5 mL) was added dropwise with stirring to a solution of $Zn(CH_3COO)_2$ (62 mg, 0.34 mmol) in methanol (10 mL). After 4 h of stirring, the precipitate of raw **3b** was filtered off. Crystallisation from methanol/dichloromethane by slow concentration yielded 146 mg (76%) of **3b** as colourless crystals; m.p. 250 °C (dec.). $C_{60}H_{56}B_2N_{12}S_4Zn$ (1160.46): calcd. C 62.10, H 4.86, N 14.48, S 11.05; found C 61.90, H 4.90, N 14.56, S 11.27. ^{1}H NMR ($CDCl_3$): δ = 1.97 [s, 3 H, Me (tol)], 2.04 [s, 3 H, Me (tol)], 2.53 [s, 3 H, Me (pz)], 6.33 [s, 1 H, H (pz)], 6.59 [d, *J* = 2.0 Hz, 2 H, H (im)], 6.68 [d, *J* = 2.0 Hz, 2 H, H (im)], 7.18−7.41 (m, 11 H, Ar), 7.89 (d, *J* = 7.2 Hz, 2 H, Ph) ppm. IR (KBr): ṽ = 2521 m (BH) cm^{-1}.

3c: Like **3b** from **L⁴** (196 mg, 0.33 mmol) and $Zn(NO_3)_2{\cdot}6H_2O$ (95 mg, 0.34 mmol). Yield 159 mg (83%) of **3c** as colourless crystals; m.p. 240 °C (dec.). $C_{60}H_{56}B_2N_{12}S_4Zn$ (1160.46): calcd. C 62.10, H 4.86, N 14.48, S 11.05; found C 61.10, H 4.74, N 14.24, S 10.56. ^{1}H NMR ($CDCl_3$): δ = 2.43 [s, 6 H, Me (tol)], 2.75 [s, 3 H, Me (pz)], 6.38 [s, 1 H, H (pz)], 6.84 [d, *J* = 2.2 Hz, 2 H, H (im)], 6.94 [d, *J* = 2.2 Hz, 2 H, H (im)], 7.10−7.45 (m, 11 H, Ar), 7.74 (d, *J* = 7.2 Hz, 2 H, Ph) ppm. IR (KBr): ṽ = 2477 w (BH) cm^{-1}.

3d: A solution of $Zn(ClO_4)_2{\cdot}6H_2O$ (372 mg, 1.00 mmol) in methanol (10 mL) was slowly added dropwise with stirring to a solution of **L⁵** (614 mg, 1.00 mmol) in dichloromethane (10 mL). After 2 h of stirring, all volatiles were removed in vacuo. The residue was extracted with four 5-mL portions of dichloromethane. The combined extracts were concentrated to dryness and the residue dissolved in a minimum amount of benzene. Slow concentration produced a precipitate of crystalline solvated **3d**. Filtration and drying for 3 h in vacuo yielded 200 mg (32%) of **3d** as a colourless powder; m.p. 230 °C (dec.). $C_{64}H_{64}B_2N_{12}S_4Zn$ (1216.58): calcd. C 63.19, H 5.30, N 13.82; found C 63.26, H 5.66, N 12.80. ^{1}H NMR ($CDCl_3$): δ = 2.00 [s, 6 H, Me (xyl)], 2.21 [s, 6 H, Me (xyl)], 2.94 [s, 3 H, Me (pz)], 6.15 [s, 1 H, H (pz)], 6.25 [d, *J* = 2.0 Hz, 2 H, H (im)], 6.55 [d, *J* = 2.0 Hz, 2 H, H (im)], 6.79−7.00 (m, 6 H, xyl), 7.45−7.53 (m, 3 H, Ph), 8.32−8.35 (m, 2 H, Ph) ppm. IR (KBr): ṽ = 2513 m (BH) cm^{-1}.

3e: Like **3b** from **L⁷** (206 mg, 0.33 mmol) and $Zn(NO_3)_2{\cdot}6H_2O$ (95 mg, 0.34 mmol). Yield 127 mg (63%) of **3e** as colourless crystals; m.p. 245 °C (dec.). $C_{60}H_{56}B_2N_{12}O_4S_4Zn$ (1224.46): calcd. C 58.86, H 4.61, N 13.73, S 10.48; found C 58.54, H 4.83, N 13.52, S 10.12. ^{1}H NMR (CD_2Cl_2): δ = 2.75 [s, 3 H, Me (pz)], 3.83 (s, 6 H, OMe), 6.38 [s, 1 H, H (pz)], 6.83 [s, 2 H, H (im)], 6.96 (d, *J* = 8.4 Hz, 4 H, anisyl), 7.44 (d, *J* = 8.4 Hz, 4 H, anisyl), 7.46 (m, 3 H, Ph), 7.74 (d, *J* = 7.4 Hz, 2 H, Ph) ppm. IR (KBr): ṽ = 2488 m (BH) cm^{-1}.

3f: Like **3d** from $Zn(ClO_4)_2{\cdot}6H_2O$ (372 mg, 1.00 mmol) and **L⁹** (500 mg, 1.00 mmol). Recrystallisation from acetonitrile yielded 120 mg (24%) of **3f** as colourless crystals; m.p. 180 °C (dec.). $C_{44}H_{72}B_2N_{12}S_4Zn$ (984.40): calcd. C 53.69, H 7.37, N 17.07, S 13.03; found C 52.61, H 6.84, N 16.98, S 12.56. ^{1}H NMR (CD_2Cl_2): δ = 1.28 [s, 9 H, *t*Bu (pz)], 1.70 [s, 18 H, *t*Bu (im)], 2.44 [s, 3 H, Me (pz)], 5.78 [s, 1 H, H (pz)], 6.82 [d, *J* = 2.0 Hz, 2 H, H (im)], 6.87 [d, *J* = 2.2 Hz, 2 H, H (im)] ppm. IR (KBr): ṽ = 2520 m (BH) cm^{-1}.

Hydrolysis Products

4a: A solution of **L³** (196 mg, 0.33 mmol) in dichloromethane (5 mL) was added dropwise, with stirring, to a solution of $Zn(ClO_4)_2{\cdot}6H_2O$ (124 mg, 0.34 mmol) in ethanol (10 mL). After stirring for 24 h, all volatiles were removed in vacuo, the residue extracted with dichloromethane, filtered and the filtrate concentrated to dryness again. Recrystallisation from dichloromethane/ethanol yielded 110 mg (35%) of **4a** as colourless crystals; m.p. 210 °C (dec.). $C_{40}H_{38}BClN_8O_4S_3Zn$ (902.64): calcd. C 53.23, H 4.24, N 12.41, S 10.66; found C 51.94, H 4.36, N 11.95, S 10.02. ^{1}H NMR (CD_2Cl_2): δ = 1.78 [s, 3 H, Me (tol)], 1.96 [s, 3 H, Me (tol)], 2.12 [s, 3 H, Me (tol)], 2.49 [s, 3 H, Me (pz)], 6.40 [s, 1 H, H (pz)], 6.72 [s, 1 H, H (im)], 6.73 [d, *J* = 2.2 Hz, 1 H, H (im)], 6.80 [s, 1 H, H (im)], 6.84 [s, 1 H, H (im)], 7.00 [s, 2 H, H (im)], 7.10−7.39 (m, 17 H, Ar), 10.64 (s, 1 H, NH) ppm. IR (KBr): ṽ = 2463 w (BH) cm^{-1}.

4b: Like **4a** from **L⁶** (214 mg, 0.33 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (124 mg, 0.34 mmol). Yield 88 mg (27%) of **4b** as colourless crystals, m.p. 180 °C (dec.). $C_{46}H_{50}BClN_8O_4S_3Zn$ (986.80): calcd. C 55.99, H 5.11, N 11.36, S 9.75; found C 55.27, H 5.52, N 11.10, S 9.07. ^{1}H NMR ($CDCl_3$): δ = 1.28 [d, *J* = 7.0 Hz, 18 H, Me(*i*Pr)], 2.52 [s, 3 H, Me (pz)], 2.97 [sept, *J* = 7.0 Hz, 3 H, CH(*i*Pr)], 6.39 [s, 1 H, H (pz)], 6.83 [s, 1 H, H (im)], 6.94 [s, 1 H, H (im)], 6.99 [s, 2 H, H (im)], 7.14 [s, 2 H, H (im)], 7.29 (d, *J* = 8.0 Hz, 6 H, C_6H_4), 7.39 (m, 3 H, Ph), 7.43 (d, *J* = 8.0 Hz, 6 H, C_6H_4), 7.47 (d, *J* = 7.8 Hz, 2 H, Ph), 10.92 (s, 1 H, NH) ppm. IR (KBr): ṽ = 2468 w (BH) cm^{-1}.

5: A solution of **L¹** (350 mg, 0.80 mmol) in dichloromethane (50 mL) was added dropwise, with stirring, to a solution of $Zn(ClO_4)_2{\cdot}6H_2O$ (300 mg, 0.18 mmol) in methanol (100 mL). After 2 h of stirring, powdered KOH (46 mg, 0.80 mmol) was added and the mixture stirred for another 20 h. After filtration, the filtrate was concentrated to half its volume. Within a few weeks 74 mg (9%) of colourless crystalline **5**, m.p. 167 °C, was obtained. $C_{24}H_{30}N_{12}OS_6Zn_4{\cdot}6H_2O$ (956.50 + 108.06): calcd. C 27.08, H 3.98, N 15.79; found C 27.03, H 3.26, N 16.59. ^{1}H NMR ($CDCl_3$): δ = 1.51 (s, 2 H, H_2O), 3.49−3.69 (m, 3 H, Me), 6.78−7.10 (m, 2 H, H (im) ppm.

Enzyme Models

6a: The precipitate of **6a**, which is an intermediate in the formation of **3a** (see above), was dried in vacuo. 46 mg (21%) of raw **6a** remained as a colourless powder; m.p. 220 °C (dec.). $C_{18}H_{21}BN_6OS_2Zn$ (477.74): calcd. C 45.25, H 4.43, N 17.59, S 13.42; found C 43.44, H 4.16, N 17.56, S 12.66. ^{1}H NMR ($CDCl_3$): δ = 2.36 [s, 3 H, Me (pz)], 3.50 [s, 6 H, Me (im)], 6.22 [s, 1 H, H (pz)], 6.61 [d, *J* = 2.0 Hz, 2 H, H (im)], 7.14 [d, *J* = 2.0 Hz, 2 H, H (im)], 7.28 (m, 3 H, Ph), 7.77 (d, *J* = 7.4 Hz, 2 H, Ph) ppm. IR (KBr): ṽ = 3630 vw (OH), 2503 m (BH) cm^{-1}.

6b: A solution of $Zn(ClO_4)_2{\cdot}6H_2O$ (130 mg, 0.35 mmol) in methanol (20 mL) was added with stirring to a solution of **L²** (200 mg, 0.35 mmol) in dichloromethane (100 mL). After 30 min, powdered KOH (22 mg, 0.39 mmol) was added. After stirring for 20 h, the mixture was filtered and the filtrate reduced in vacuo to half its volume. Cooling to −30 °C for 3 days precipitated 96 mg (44%) of raw **6b** as colourless powder, m.p. 220 °C (dec.) which started decomposing upon attempts of further purification. $C_{28}H_{25}BN_6OS_2Zn$ (601.88): calcd. C 55.88, H 4.19, N 13.96, Zn 10.86; found C 54.68, H 4.05, N 13.57, Zn 10.71. ^{1}H NMR ($CDCl_3$): δ = 2.29 [s, 3 H, Me (pz)], 6.29 [s, 2 H, H (pz)], 6.73 [d, *J* = 2.4 Hz, 2 H, H (im)], 6.80 [d, *J* = 2.4 Hz, 2 H, H (im)], 7.30−7.51 (m, 13 H, Ar), 7.53 (d, *J* = 7.3 Hz, 2 H, Ph) ppm. IR (KBr): ṽ = 3650 w (OH), 2499 m (BH) cm^{-1}.

7: A solution of **L⁵** (665 mg, 1.08 mmol) and anhydrous methanol (60 mL) was slowly added dropwise, with stirring, to a solution of $Zn(ClO_4)_2{\cdot}6H_2O$ (400 mg, 1.08 mmol) in anhydrous methanol (60 mL). After stirring for 1 h, the precipitate was filtered off and the filtrate reduced to 80 mL in vacuo. The resulting precipitate

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was also filtered off and the filtrate concentrated to dryness. The residue was extracted with dichloromethane (14 mL). After filtration, the extract was concentrated to dryness and the residue dried in vacuo. 438 mg (55%) of **7** remained as a colourless powder; m.p. 230 °C (dec.). $C_{30}H_{28}BClN_6O_6S_2Zn$ (744.37): calcd. C 48.41, H 3.79, N 11.29, S 8.62; found C 48.57, H 4.30, N 11.28, S 8.43. ^{1}H NMR ($CDCl_3$): δ = 2.28 [s, 3 H, Me (pz)], 3.68 (s, 6 H, OMe), 6.49 [s, 1 H, H (pz)], 6.94−7.70 [m, 15 H, H (im), Ar], 7.93 [d, J = 7.2 Hz, 2 H, Ph] ppm. IR (KBr): $\tilde{\nu}$ = 2476 w (BH), 1179 vs, 1093 vs (ClO_4) cm^{-1}.

8: A solution of $\mathbf{L}^8$ (309 mg, 0.50 mmol) in anhydrous ethanol (25 mL) was slowly added dropwise, with stirring, to a solution of $Zn(ClO_4)_2{\cdot}6H_2O$ (186 mg, 0.50 mmol) in anhydrous ethanol (25 mL) and the mixture stirred for 15 h. After filtration, the volume was reduced to one half in vacuo and the resulting precipitate filtered off. Recrystallisation from anhydrous ethanol yielded 313 mg (71%) of **8** as colourless crystals, m.p. 200 °C (dec.). $C_{32}H_{34}BClN_6O_7S_2Zn{\cdot}C_2H_5OH$ (790.44 + 46.07): calcd. C 48.82, H 4.82, N 10.05, S 7.67; found C 47.75, H 4.87, N 9.74, S 7.33. ^{1}H NMR ($CDCl_3$): δ = 1.18 [t, J = 7.0 Hz, 6 H, CH_3 (Et)], 2.50 [s, 3

H, Me (pz)], 3.62 [dq, J = 7.0/5.2 Hz, 4 H, CH_2 (Et)], 3.82 (s, 6 H, OMe), 6.40 [s, 1 H, H (pz)], 6.94 [d, J = 2.1 Hz, 2 H, H (im)], 7.02 [d, J = 2.1 Hz, 2 H, H (im)], 7.03−7.48 (m, 11 H, Ar), 7.54−7.60 (m, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2499 w (BH), 1180 s, 1096 s, br. (ClO_4) cm^{-1}.

Catalytic Studies. Oxidation of 2-Propanol: 2a (33.8 mg, 0.05 mmol) and [BNA]Cl (12.5 mg, 0.05 mmol) were dissolved in [D_6]DMSO (2 mL). 2-Propanol (0.2 mL, 2.6 mmol) was added and the mixture stirred for 24 h at 100 °C in the dark. The oxidation reaction was monitored by recording the ^{1}H NMR signals of acetone at δ = 2.08 ppm and of the benzyl group of BNAH at δ = 4.30 ppm.

Reduction of *p*-Nitrobenzaldehyde: 2a (20.3 mg, 0.03 mmol), *p*-nitrobenzaldehyde (4.5 mg, 0.03 mmol) and BNAH (6.5 mg, 0.03 mmol) were dissolved in [D_6]DMSO (2 mL) and the mixture was stirred at 100 °C for 24 h. The reduction was monitored by recording the ^{1}H NMR signals of *p*-nitrobenzyl alcohol at δ = 4.25 ppm and of the benzyl group of BNA^+ at δ = 5.91 ppm.

Structure Determinations:[28] Crystals were obtained as described above. Diffraction data were recorded at 200 K (**2a**, **3c**, **3d**, **3f**, **4a**, **4b**, **5**, **8**) and at room temp. (**1c**, **1d**, **3a**, **3b**) with a Nonius CAD4 (**1d**, **3a**, **3d**, **5**) or a Bruker Smart CCD diffractometer (**1c**, **2a**, **3b**, **3c**, **3f**, **4a**, **4b**, **8**). Empirical absorption corrections were applied for **3b**, **3c**, **4a**, **4b** and **8**. The structures were solved with direct methods and refined anisotropically with the SHELX program suite.[29] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5-times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL.[30] Table 1 lists the crystallographic data.

Discrete Cyanide-Bridged Mixed-Valence Co/Fe Complexes: Outer-Sphere Redox Behaviour

Paul V. Bernhardt,[a] Fernando Bozoglian,[b] Brendan P. Macpherson,[a] Manuel Martínez,*[c] Gabriel González,[c] and Beatriz Sienra[b]

Keywords: Cobalt / Iron / Mixed-valence complexes / Redox processes

The outer-sphere redox behaviour of a series of $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ (L_n = *n*-membered pentadentate aza-macrocycle) complexes have been studied as a function of pH and oxidising agent. All the dinuclear complexes show a double protonation process at pH ≈ 2 that produces a shift in their UV/Vis spectra. Oxidation of the different non-protonated and diprotonated complexes has been carried out with peroxodisulfate, and of the non-protonated complexes also with trisoxalatocobaltate(III). The results are in agreement with predictions from the Marcus theory. The oxidation of $[Fe(phen)_3]^{3+}$ and $[IrCl_6]^{2-}$ is too fast to be measured, although for the latter the transient observation of the process has been achieved at pH = 0. The study of the kinetics of the outer-sphere redox process, with the $S_2O_8^{2-}$ and $[Co(ox)_3]^{3-}$ oxidants, has been carried out as a function of pH, temperature, and pressure. As a whole, the values found for the activation volumes, entropies, and enthalpies are in the following margins, for the diprotonated and non-protonated dinuclear complexes, respectively: $\Delta V^{\neq}$ from 11 to 13 and 15 to 20 $cm^3\ mol^{-1}$; $\Delta S^{\neq}$ from 110 to 30 and –60 to –90 $J\ K^{-1}\ mol^{-1}$; $\Delta H^{\neq}$ from 115 to 80 and 50 to 65 $kJ{\cdot}mol^{-1}$. The thermal activation parameters are clearly dominated by the electrostriction occurring on outer-sphere precursor formation, while the trends found for the values of the volume of activation indicate an important degree of tuning due to the charge distribution during the electron transfer process. The special arrangement on the amine ligands in the isomer *trans*-$[L_{14}Co^{III}NCFe^{II}(CN)_5]^-$ accounts for important differences in solvent-assisted hydrogen bonding occurring within the outer-sphere redox process, as has been established in redox reactions of similar compounds.

Introduction

Mixed-valence compounds have been of interest for a long time,[1] given the variable nature of valence localisation (or delocalisation) and the nature and tunability of their MMCT bands.[2] Their potential use as possible electrochromic materials for a variety of situations has already been established.[3,4] As a whole, their redox properties are of great importance, both for their applications and for an understanding of their electronic structure.[5] Despite all these facts, few redox studies on these types of complexes are available in the literature,[6] due primarily to the typically limited stability of the oxidized or reduced species involved in the process. Indeed, few well-characterised discrete (non-polymeric) mixed-valence complexes are known that exhibit redox bistability. In this respect the preparation of a family of well-characterised cyanide-bridged compounds has provided an ideal entry into this field.[7–9]

We have been involved in the study of a number of outer-sphere redox reactions of Co^{III} macrocyclic complexes with $[Fe(CN)_6]^{4-}$, where the importance of solvent reorganisation, in the process, proved to be crucial to differences in the derived thermal and baric activation parameters.[10] Furthermore, the existence of a tight outer-sphere complexation, prior to the rate-determining electron transfer, has been found to be a dominant factor, even in situations where ion-pairing seems very unlikely.[11,12] From these studies, the formation of a discrete Co^{III}/Fe^{II} species, produced by an inner-sphere redox process starting from the reduced Co^{II} macrocyclic complexes and the corresponding $[Fe(CN)_6]^{3-}$ ligand, similar to those detected for the classical CoEDTA/$Fe(CN)_6$ systems has been envisaged.[13] Further studies on these compounds have led us to the full characterisation of a series of molecular mixed-valence $Fe^{II}CNCo^{III}$ complexes with different macrocycles and geometries surrounding the Co^{III} centre.[7–9] During this period, a few redox studies on discrete dinuclear Fe/Ru mixed-valence compounds have appeared,[14,15] but neither the pH

Scheme 1

dependence of such reactions nor the use of transition metal complexes as redox partners has been examined. Furthermore, the stability and full characterisation of the complexes involved was not achieved in some cases.

In this paper we present a mechanistic study of the outer-sphere oxidation processes of the complexes indicated in Scheme 1 with a variety of oxidants such as $S_2O_8^{2-}$, $[Co(ox)_3]^{3-}$, $[IrCl_6]^{2-}$, and $[Fe(phen)_3]^{3+}$. In this case the full characterisation of the reduced and oxidised species has already been carried out; the temperature, pressure, and pH dependence of these reactions has also been investigated.

The differences in macrocycle size and its geometrical wrapping arrangement, are bound to produce important differences in both the electron transfer process and the encounter complex formation equilibrium. The reduction potential of the iron centre being affected by the nature of the wrapped cobalt ion, and the encounter complex affected by the external shape of the macrocycle attached to the cobalt atom.

Results and Discussion

Products

All the complexes have been prepared and characterised according to published procedures[7–9] and there are no aspects that merit special mention. The new *cis*-$[L_{13}Co^{III}NCFe^{II}(CN)_5]^-$ complex behaves as the already known derivatives with macrocycles of different sizes. Given the fact that the outer-sphere redox behaviour of these dinuclear complexes was to be studied under different acidity conditions, and that the $[Fe(CN)_6]^{4-}$ moiety of the molecule is likely to undergo protonation at low pH,[16] speciation of the dinuclear complexes as a function of pH has been carried out. Figure 1 (top) shows typical electronic spectral shifts obtained when the solution of the mixed valence complex is taken from a high to low pH. Despite the two sets of different shifts observed in the spectra, for all the complexes studied, the potentiometric titration indicated a double protonation process at pH $\approx$ 2 that could not be resolved in two different steps. The SPECFIT analysis[17] of the changes shown in Figure 1 (top), indicated the effective presence of two protonation steps with distinct electronic spectra (Figure 1, bottom). The estimated values of pK_{a1} and pK_{a2} are, however, too close for a reliable differentiation, and selecting a pH value that ensured the presence

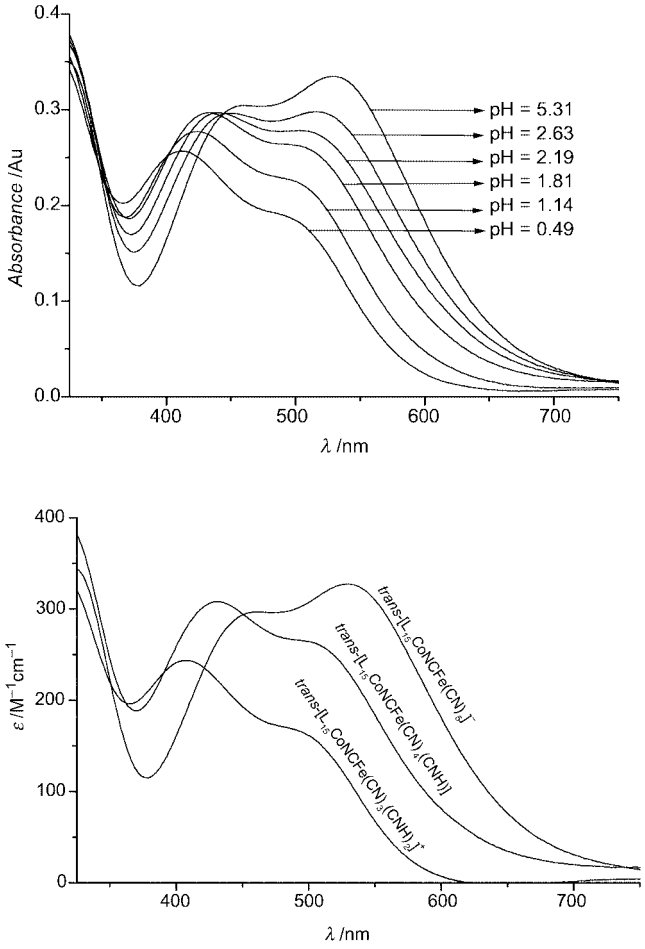

Figure 1. Top: UV/Vis spectral changes obtained for a solution 1×10^{-3} M of complex *trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_5]^-$ on changing the acidity conditions; bottom: SPECFIT estimation of the UV/Vis spectra of the *trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_5]^-$, *trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_4(CNH)]$, and *trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_3(CNH)_2]^+$ complexes for the same experiment (T = 298 K, I = 1.0 M $LiClO_4$)

of the monoprotonated complex, $[L_nCo^{III}NCFe^{II}(CN)_4(CNH)]$, as the main species in solution proved impossible.

As a result of this, the study has only been carried out on the complexes $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ and $[L_nCo^{III}NCFe^{II}(CN)_3(CNH)_2]^+$. Table 1 includes all the spectroscopic data and $p\beta_{12}$ values determined spectrophotometrically for the series of dinuclear complexes included in this study. The diprotonated species are less stable than the corresponding non-protonated ones, with respect to de-

composition into their Co^{III} and Fe^{II} parents; nevertheless, on neutralization of the resulting solution, a recombination of the two metal centres takes place to form the mixed-valence dinuclear complex.[10] This lesser stability is not surprising, taking into account the increase of positive charge density introduced onto the dinuclear complexes by the double protonation. We have investigated the Fe-centered oxidation processes of these complexes by cyclic voltammetry at pH = 0, where all the compounds are doubly protonated (Table 2).

[a] Versus NHE, average value for the anodic and cathodic cyclic voltammogram peaks.

A positive shift of ca. 130−165 mV is observed for all the systems when two of the terminal cyanide ions are protonated on the reduced dinuclear complexes, which is in line with the general rule of increasing reduction potential on increasing the positive charge of the reduced species.[18] The same sort of changes have been observed for the reduction potential of hexacyanoferrates measured at 1.0 M HCl,[19] or when the $\{L_nCo^{III}\}$ moiety is attached to one of the cyanide ligands.[7,8] As for the possible protonation sites of the $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ complexes, it is clear that they have to be at the axial and one of the equatorial positions of the $\{Fe(CN)_5\}$ fragment of the molecule. The protonation of two consecutive equatorial positions cannot be expected to have such similar pK_a values. In this respect the IR spectrum of protonated *cis*-$[L_{13}Co^{III}NCFe^{II}(CN)_3(CNH)_2]^+$ only shows the peak at 2120 cm^{-1} corresponding to the μ-CN and a rather broad band at 2055 cm^{-1}, which indicates the shifting to higher energies, as well as the loss in symmetry, due to protonation (Figure S1, Supporting Information, see also the footnote on the first page of this article).[20,21] In order for the integrity of the complex to be held, which prevents the formation of $Co_3[Fe^{III}(CN)_6]_2$, protonation of the amine groups of the macrocycle must not occur. The amine protons of the macrocycle are structurally (for any of the two possible conformations, *cis* or *trans*) too far away to prevent protonation of any of the equatorial cyanide groups on the iron centre. Furthermore the ^{13}C NMR spectrum of a sample of *trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_5]^-$ in 1.0 M $HClO_4$ (Figure S2, Supporting Information) agrees with the integrity of the Co^{III} moiety of the complex.

Redox Kinetics

It has already been qualitatively established that a well-behaved redox process is observed for the oxidation of the *trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_5]^-$ complex with the $S_2O_8^{2-}$ ion.[7] Despite its high standard potential (2010 mV), the electron transfer mechanism of the peroxodisulfate ion prevents the very fast reaction rate that would be expected,[22] producing a k_{ex} of ca. 10^{-18} M^{-1} s^{-1} by the direct application of the Marcus relationship.[23] Furthermore, no dependence on the pH is expected for the reduction potential in the acidity region used for this study. Given that some redox kinetics on dinuclear Ru/Fe mixed-valence compounds had already been studied with this oxidising agent,[24] the kinetics of the redox process between the $S_2O_8^{2-}$ ion and all the $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ systems have also been studied. Figure 2 shows the general kinetic behaviour found for these systems at varying $[S_2O_8^{2-}]$, temperature and pH; second-order rate constants extrapolated at 298 K, and thermal and pressure activation parameters are collected in Table 3.

The reaction of the four dinuclear complexes prepared with $[Fe(phen)_3]^{3+}$ has also been probed, in this case the high reduction potential at pH = 0 (1050 mV)[25,26] produces a redox reaction rate so fast that it cannot be measured even with a stopped-flow system. That is, the spectra measured at 1:1 concentration ratios and at 0.8 ms after mixing correspond exactly to the 1:1 mixture of $[Fe(phen)_3]^{2+}$ and $[L_nCo^{III}NCFe^{II}(CN)_5]^-$. In this case it seems clear that the reaction rate is extremely fast, as ex-

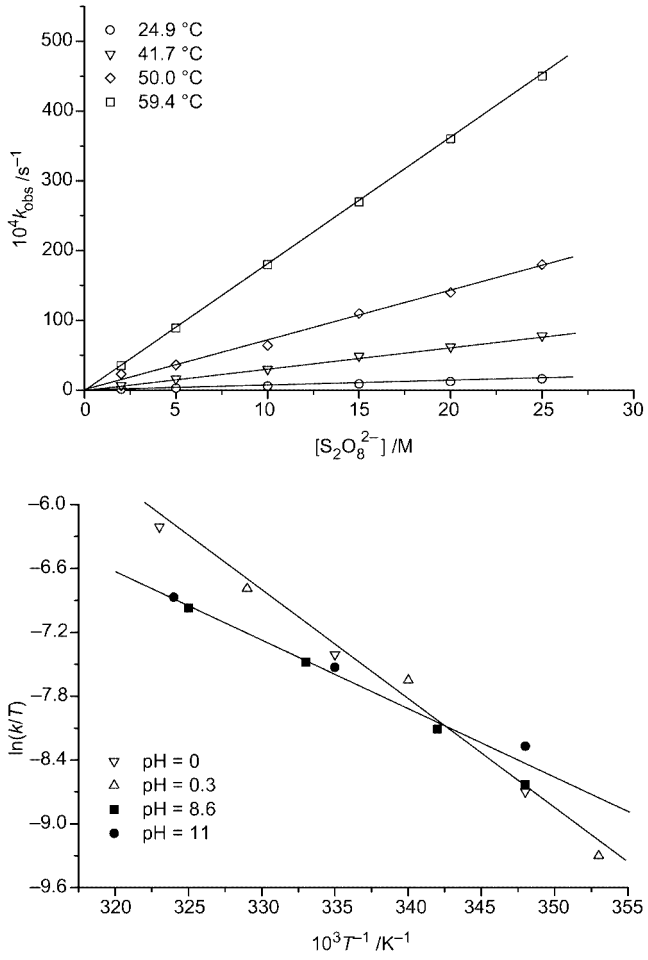

Figure 2. Top: plot of the values of the first-order rate constant, k_{obs}, for the $S_2O_8^{2-}$ oxidation of the *trans*-$[L_{14}Co^{III}NCFe^{II}(CN)_3(CNH)_2]^+$ complex at different temperatures; bottom: Eyring plot derived from the value of the second-order rate constant, k, for the *trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_5]^-$ (pH = 8.6 and 11) and *trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_3(CNH)_2]^+$ (pH = 0.0 and 0.3) plus $S_2O_8^{2-}$ systems (I = 1.0 M $LiClO_4$)

pected from the calculated value of E^0 = 275 mV and the validity of the Marcus relationship for these systems ($k_{ex}\{[Fe(phen)_3]^{3+/2+}\}$ = 1.3 × 10^7 M^{-1} s^{-1} and $k_{ex}\{[Fe(CN)_6]^{3-/4-}\}$ = 2.4 × 10^2 to 2 × 10^4 M^{-1} s^{-1}),[26,27] which produces an estimated cross reaction rate constant of 7.1 × 10^6 to 10 × 10^7 M^{-1} s^{-1} for the adiabatic redox process occurring on the iron moiety of the dinuclear complex.[28] The instability of $[Fe(phen)_3]^{3+}$ in solutions at higher pH prevented oxidation measurements on the non-protonated $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ complexes.

The reaction with $[IrCl_6]^{2-}$ was also tried, given the lower potential (892 mV),[29] as well as its independence of pH in the range used for this study. At pH = 0, the transient spectrum measured at 0.8 ms after mixing $[IrCl_6]^{2-}$ and $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ in a 1:1 ratio, effectively shows the presence of an Ir^{IV} oxidising agent which disappears in less than 0.05 s under these second-order conditions. This process could not be observed at pH = 5, where the initial spectrum after mixing corresponds exactly to a 1:1 mixture of the oxidised $[L_nCo^{III}NCFe^{III}(CN)_5]$ complexes and the Ir^{III} species. Taking into account that the redox reaction of $[Fe(CN)_6]^{4-}$ with $[IrCl_6]^{2-}$ has already been measured, and that the values found fit very well with the Marcus relationship,[30] the estimated values of $k_{ex}\{[L_nCoNCFe(CN)_5]^{0/-}\}$ for the different dinuclear systems cannot be smaller than that for the $[Fe(CN)_6]^{3-/4-}$ simple system. Taking into account that the reduction potential of $[Fe(CN)_6]^{3-/4-}$ at 1.0 M HCl is 688 mV;[19] if a nitrogen atom of one of the cyanide ligands of the hexacyanoferrate(II) has a proton, or an electron-withdrawing Co^{III} centre of the dinuclear complex attached, both the value of k_{ex} and that of E^0 seem to increase significantly.

Further inspection of the available oxidants with the appropriate potentials[26] indicated that $[Co(ox)_3]^{3-}$ should be an excellent partner for the process (570 mV[31] and $k_{ex}\{[Co(ox)_3]^{3-/4-}\}$ = 3 × 10^{-7} to 1.4 × 10^{-12} M^{-1} s^{-1}).[32,33] Consequently, the oxidation of the $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ species with tris(oxalato)cobaltate-

(III) at pH = 9 was carried out at different temperatures, concentrations, and pressures. Unfortunately, the stability of this complex is not very high and, although it could be used at pH = 9 by adding some EDTA to the solution medium to avoid precipitation of Co^{2+} salts, no studies could be carried out at pH = 0, where the decomposition of the tris(oxalato) complex was too fast when compared with the redox process studied. Figure 3 shows the general kinetic behaviour of the observed reaction rate constants under pseudo-first-order conditions. In this case, as seen in Figure 3, the kinetic behaviour is a bit more complex than with the $S_2O_8^{2-}$ oxidant, and a limiting outer-sphere (OS) precursor formation is observed according to $k_{obs} = (k_{et} \times K_{OS} \times [oxidant])/(1 + K_{OS} \times [oxidant])$. The value of k_{et} can be derived from the asymptotic limit of the plots. The temperature and pressure dependence of the derived rate constants produced the thermal and pressure activation parameters are shown in Table 3, together with the corresponding kinetic parameters extrapolated to 298 K.

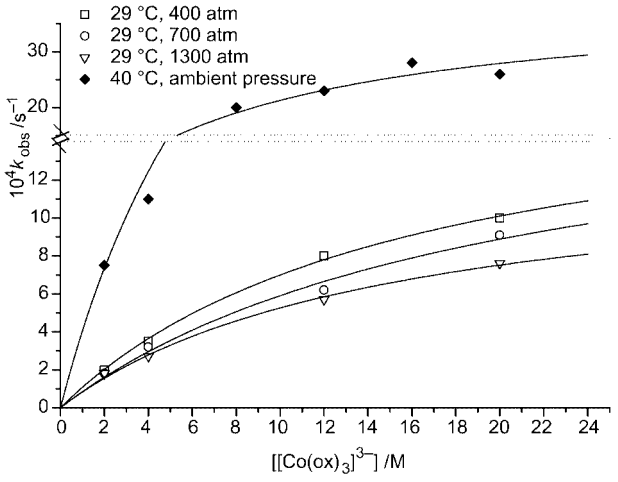

Figure 3. Plot of the values of the first-order rate constant, k_{obs}, for the $[Co(ox)_3]^{3-}$ oxidation of the *cis*-$[L_{13}Co^{III}NCFe^{II}(CN)_5]^-$ system at different temperatures and pressures and at pH = 9.0 (I = 1.0 M $LiClO_4$)

From a general point of view, the redox reaction with peroxodisulfate as oxidant seems to provide more information about the process studied, because it can be carried out at acidic, alkaline, or neutral pH (i.e. with the doubly protonated and non-protonated dinuclear complexes). A detailed observation of the activation parameters results in a clear differentiation between the non-protonated or diprotonated form of the dinuclear species, despite the minor differences found in k^{298}. Activation enthalpies are much higher for the diprotonated complexes and activation entropies are also more positive. These much more positive values for $\Delta S^{\neq}$ found for the $[L_nCo^{III}NCFe^{II}(CN)_3(CNH)_2]^+$ series of complexes, are indicative of the large differences in electrostriction on going from the reactants to the precursor outer-sphere complex involving the $SO_4^{(\cdot)}$ radical ({[1+] + [1−]} at low pH versus {[1−] + [1−]} for the non-protonated complex). These differences are compensated by larger values of $\Delta H^{\neq}$, producing the compensation plot shown in Figure 4, which is a clear indication of the constant reaction mechanism operating for these processes.

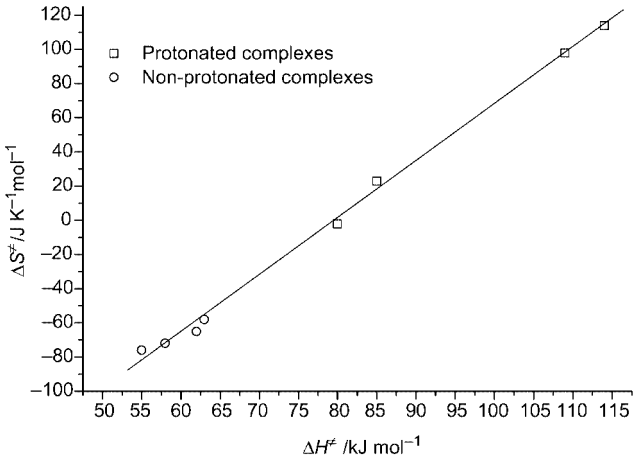

Figure 4. Compensation $\Delta H^{\neq}/\Delta S^{\neq}$ plot for the $S_2O_8^{2-}$ oxidation reactions studied for the *trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_5]^-$/*trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_3(CNH)_2]^+$ dinuclear complexes

Another surprising fact is that for the *trans*-arranged dinuclear complexes of the L_{14} and L_{15} macrocycles, the above-mentioned differences in the activation enthalpies and entropies decrease severely. Some ordering, relating to the geometrical arrangement of the macrocyclic ligand, in the transition state, or the precursor complex, must be responsible for the dramatic decrease of the $\Delta S^{\neq}$ values for the reaction with the protonated complex. The relative positions of a protonated equatorial CN group and the facing secondary amine protons of the macrocycle,[7−9] easily allow for a much more ordered positioning of the $SO_4^{(\cdot)-}$ radical in the outer sphere for the $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ complex, producing an important decrease in the $\Delta S^{\neq}$ values. If that is so, the general enthalpic demands for the transition state for the electron transfer on such a precursor are bound to be smaller as seen in the data for all the $[L_nCo^{III}NCFe^{II}(CN)_3(CNH)_2]^+$ complexes in reactions with the $S_2O_8^{2-}$ ion (Table 3).

As for the activation volumes, when the oxidation takes place on the non-protonated species the values determined for $\Delta V^{\neq}$ are more positive. Given that the electrostriction on going to the precursor outer-sphere complex would produce the opposite trend, as explained before, the sequence of values found for $\Delta V^{\neq}$ has to be dominated by the proper electrostriction effect occurring during the electron transfer process on the dinuclear species. At low pH the charge of the complex increases from [1+] to [2+] on electron transfer, while it decreases from [1−] to [0] for the non-protonated complex; consequently, the actual electron transfer process at low pH implies an increase on electrostriction with respect to a decrease at high pH. Nevertheless, the general important expansion observed, for all but the $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ complex, must originate in solvent-assisted hydrogen bonding within the precursor complex,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

producing an important ordered expansion.[34] This fact also explains the inherent ordering derived from the values of $\Delta S^{\neq}$ that were obtained for the $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ complex in reactions with the $S_2O_8^{2-}$ ion. This expansion/ordering combination must be much smaller for the protonated systems where solvent-assisted hydrogen bonding becomes less important.[10−12] For the $[L_n$-$Co^{III}NCFe^{II}(CN)_5]^-$ system, the values found for the activation entropy at low pH already indicated a unique behaviour of the system. If the possible explanation cited above, derived from the facing secondary amine protons of the macrocycle, is so, solvent assistance for the positioning of the $SO_4^{(\cdot)-}$ radical in the outer sphere of the protonated species should be even less important. As a consequence, the values of $\Delta V^{\neq}$ for those complexes with much less solvent-assisted hydrogen bonding takes place, would tend to the expected contraction values, both from electron transfer electrostriction (specially for the oxidation of the diprotonated species) and inner-sphere contributions.

With respect to the $[Co(ox)_3]^{3-}$ oxidation data in Table 3, the thermal activation parameters are similar to those obtained for the $S_2O_8^{2-}$ oxidation process, with the non-protonated $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ complexes. The fact that, in this case, the values determined for k^{298} correspond to the first-order rate constant (see Figure 3), only relates the activation parameters to the electron transfer process, the outer-sphere equilibrium constant being in the range 50−200 M^{-1}, which is similar to that found for similar systems.[10−12,27,35,36] The values determined for $\Delta H^{\neq}$ are practically the same as those found for the $S_2O_8^{2-}$ reaction, as expected given the small values associated with ΔH^0_{OS}, while those for $\Delta S^{\neq}$ are definitively more negative. Given the fact that no electrostriction related to the outer-sphere precursor complex formation is accounted for, and that no protonated species are present at this pH, the high degree of ordering approaching the transition state has to be related with the above-mentioned formation of solvent-assisted interactions during the electron transfer process. These types of interactions have also been held responsible for the behaviour of other systems,[37] and have explained the ordering/expansion effect detected in the previously discussed $[L_nCo^{III}NCFe^{II}(CN)_5]^-/S_2O_8^{2-}$ redox processes, where outer-sphere electrostriction is held to a minimum. In this respect, the values determined for the activation volumes are positive in all cases and are very similar to those determined for the reaction with the peroxodisulfate anion. Again, the value determined for the *trans*-$[L_{14}Co^{III}NCFe^{II}(CN)_5]^-$ complex is smaller than the rest, although it does not reach the extremely low values found for the peroxodisulfate reaction. Solvent assistance in outer-sphere complexation during electron transfer, can again be held responsible for the this decrease.

In conclusion, we have been able to completely characterise the solution redox behaviour of a complete family of discrete cyano-bridged mixed-valence Co^{III}/Fe^{II} complexes. Further studies are being carried out in order to increase the stabilisation of the Co^{II}/Fe^{II} oxidation state of the complex by tuning of the donor atoms in the macrocycle, which should allow for a wider accessibility of the redox systems.

Experimental Section

Products: All the dinuclear Co^{III}/Fe^{II} complexes have been prepared according to published procedures. The synthesis of *trans*- and *cis*-$[L_{14}Co^{III}NCFe^{II}(CN)_5]^-$ and *trans*-$[L_{15}Co^{III}NCFe^{II}(CN)_5]^-$ (isolated as their Na^+ salts) have been reported.[7−9] The analogue *cis*-$[L_{13}Co^{III}NCFe^{II}(CN)_5]^-$ has been prepared by the same procedure starting from *cis*-$[CoL_{13}Cl]^{2+}$.[38] Characterisation data for $Na[L_{13}$-$Co^{III}NCFe^{II}(CN)_5]$: $C_{16}H_{25}CoFeN_{11}Na\cdot 11H_2O$ (707.39): calcd. C 27.17, H 6.70, N 21.78; found C 27.2, H 8.6, N 22.2. ^{13}C NMR (62.9 MHz, D_2O): δ = 19.6, 49.0, 51.1, 51.9 (× 2), 53.5, 55.8, 56.4, 66.6, 175.0 (× 5), 191.0 ppm. IR (KBr disk): $\tilde{\nu}$ = 2040 (equatorial CN), 2072 (axial CN), 2115 (μ-CN) cm^{-1}. UV/Vis (H_2O): λ_{max} (ε) = 325 (367), 448 (390), 498 nm (380 $M^{-1}cm^{-1}$). Cyclic voltammogram $E_{1/2}$ (versus NHE; 1.0 M $LiClO_4$) = −543, 626 mV. The oxidants $[Co(ox)_3]^{3-}$ and $[Fe(phen)_3]^{3+}$ were prepared according to published procedures.[39−41] Other chemicals used were analytical grade, commercially available, and were used without further purification. All buffers were prepared according to well-established procedures.[42] The buffer concentration was set to 0.01 M, and final pH values were such that only one of the acid-base equilibrium species of each system was present in solution. Ionic strength was achieved by the addition of $LiClO_4$.

Acidity Constants: Potentiometric titrations (1.0 M, $HClO_4$) of the different dinuclear $[L_nCo^{III}NCFe^{II}(CN)_5]^-$ complexes were carried out in order to determine their acidity constants. The solutions were transferred to a 50 mL cell and thermostatted at 25 °C; addition of small amounts of standard 0.1 M NaOH produced successive e.m.f. readings on a Metrohm 713 pH meter (glass and Ag/AgCl reference electrodes). Argon was bubbled through the solution during the experiment to avoid the presence of CO_2. The general technique was the same as that described in the literature;[43] even though only one step was detected, the stoichiometry indicated a double deprotonation. Spectrophotometric titrations[44] of the complexes carried out with a Cary 50 instrument produced changes in the UV/Vis spectrum with pH (Figure 1, top) which indicated the presence of two distinct processes. Nevertheless, the pK_a values were too close to allow the selective formation of the monoprotonated complex,[18] and consequently only studies on the non-protonated and diprotonated species were carried out.

Electrochemistry: Electrochemical experiments were carried out with an EG&G PAR 263A instrument with a glassy carbon working electrode, a platinum wire secondary electrode and an Ag/AgCl reference electrode; solutions were degassed prior to the cyclic voltammetry experiment. Voltammograms of the complexes were carried out at 1×10^{-3} M complex concentration in water (1.0 M $LiClO_4$) and in 1.0 M $HClO_4$ in order to account for differences due to the protonation of the cyanide ligands.

Kinetics: The reactions were monitored by UV/Vis spectroscopy in the 800−300 nm range; runs with $t > 170$ s were recorded with an HP8452A instrument equipped with a thermostatted multicell transport; runs within the 7−170 s margin were recorded with an HP8452A or a J&M TIDAS instrument and using a High-Tech SFA-11 Rapid Kinetics Accessory. For the kinetic runs at elevated pressure, a previously described pressurizing system, and cylindrical or pillbox cell were used.[45,46] Observed rate constants were derived from absorbance/time traces at the wavelengths where a maximum increase or decrease of absorbance was observed; Table

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

S1 (Supporting Information) indicates all the obtained k_{obs} values for all the complexes studied as a function of the reducing and oxidising species, their concentration, pH, temperature, and pressure. No dependence of the observed rate constants on the selected wavelengths was detected, as generally expected for reactions where a good retention of isosbestic points is observed. The general kinetic technique was that previously described; in all cases pseudo-first-order conditions were maintained.[11,12] For reactions involving $[Co(ox)_3]^{3-}$, EDTA was added to the reaction medium to prevent the precipitation of the Co^{2+} reaction product.[10,47]

EPR Study of *o*-Semiquinone-Catecholate Cobalt Complexes with Bis(diphenylphosphanyl)ethane

Michael P. Bubnov,*[a] Irina A. Teplova,[a] Vladimir K. Cherkasov,[a] and Gleb A. Abakumov[a]

Keywords: Chelates / Cobalt / EPR spectroscopy / Quinones / Tautomerism

Three novel cobalt compounds with bis(diphenylphosphanyl)-ethane (dppe) and semiquinone and catecholate ligands were synthesized and investigated by EPR spectroscopy in solution. They are: [(dppe)Co(3,6-DBSQ)(Cat_{ox}^{Cl})] (**1**), [(dppe)Co(3,6-DBCat)(phen-SQ)] (**2**), and [(dppe)Co(3,6-DBSQ)$_2$] (**3**), where 3,6-DBSQ and 3,6-DBCat are the radical anion and dianion of 3,6-di-*tert*-butyl-*o*-benzoquinone, respectively, Cat_{ox}^{Cl} is the dianion of perchloroxanthrenequinone-2,3, and phen-SQ is the radical anion of phenanthrenequinone. According to the ratio of the redox potentials of the *o*-quinone fragments, **1** and **2** are mixed semiquinone-catecholate complexes, and the 3,6-di-*tert*-butyl-*o*-quinone fragment appears as a semiquinone in **1** and as a catecholate in **2**. Compound **3** exists as a mixture of redox isomers, namely semiquinone-catecholate and bis-semiquinone species.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

In 1980, Pierpont first observed a reversible intramolecular metal−ligand electron transfer of a cobalt bis-semiquinone complex in solution.[1]

$$[\alpha,\alpha'\text{-bpyCo}^{III}(3,5\text{-Cat})(3,5\text{-SQ})] \rightleftarrows [\alpha,\alpha'\text{-bpyCo}^{II}(3,5\text{-SQ})_2]$$

3,5-SQ and 3,5-Cat are the anion-radical and dianion of 3,5-di-*tert*-butyl-*o*-benzoquinone.

A similar equilibrium involving a two-electron transfer was described later[2] for the manganese complex [(py)$_2$Mn(3,5-DBCat)$_2$].

$$[(py)_2Mn(3,5\text{-DBCat})_2] \rightleftarrows [(py)_2Mn(3,5\text{-DBSQ})_2]$$

Reversible electron transfer, taking place in the solid state, was first observed by our group[3,4] in 1990 and by Hendrickson[5] in 1993. Further development of the understanding of reversible metal−ligand electron transfer in semiquinone metal complexes was dedicated to investigation of solid-phase transformations.[6−14]

Number of mono-semiquinone complexes of Rh,[15−18] Ir,[19] Cu,[20] and Ni[21] of general formula [L_nMSQ] demonstrate reversible electron transfer in solution (L_n is a neutral ligand for Rh, Ir, and Cu, or monovalent one for Ni). It has been shown that complexes exist in solution as an equilibrium mixture of redox isomers that interconvert rapidly (according to the EPR time scale) between one another. The equilibrium position and the rate of isomerization depend on the nature of the *o*-semiquinone, the neutral ligands, and the solvent. In all cases, decreasing the temperature shifts the equilibrium position towards the catecholate isomer.

All of the complexes [L_nM("Q")$_2$] that were investigated to date contain "Q" fragments that are derivatives of the same quinone and so their initial electronic ground state a priori is degenerate. The aim of this work was to obtain six-coordinate cobalt complexes containing different *o*-quinone fragments.

Most of publications listed above are dedicated to complexes containing nitrogen atom donors. We have not found in the literature any bis-quinone complexes with dppe. Moreover dppe contains two phosphorous atoms (^{31}P, I = 1/2, 100%), the hyperfine splitting of which in the EPR spectrum provides information regarding the spin distribution in complex molecules.

Results and Discussion

Cobalt compounds of types **1**−**3** can be obtained through oxidative addition reactions of the corresponding *o*-quinones to four-coordinate [(dppe)(3,6-di-*tert*-butylcatecholato)cobalt] [Equation (1)].

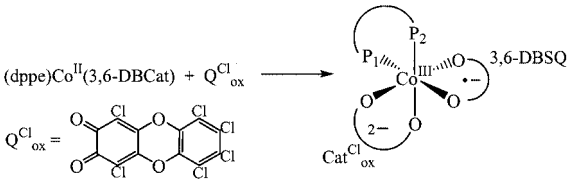
$$[L_nCo^{II}(Cat')] + Q'' \rightarrow [L_nCo^{III}(Cat')(SQ'')] \quad (1)$$

Stable paramagnetic adducts were studied by EPR spectroscopy in solution. The appearance of the EPR spectrum

[a] G. A. Razuvaev Institute of Organometallic Chemistry of RAS, 49 Tropinina str., Nizhny Novgorod, GSP-445, Russia 603950
Fax: (internat.) + 7-8312/661-497
E-mail: bmp@imoc.sinn.ru

of a particular product depends on the redox potential ratio of the quinone fragments. We have observed three situations.

The first takes place when additional quinone is quite a stronger acceptor than is 3,6-DBQ, which has formed the initial catecholate. We have used perchlorooxanthrenequinone-2,3 [Equation (2)].



(2)

The presented EPR spectrum (Figure 1) displays one unpaired electron localized on the 3,6-DBSQ fragment: $a_{H1(SQ)} = a_{H2(SQ)} = 0.30$ mT, $g_i = 2.0016 \pm 0.0005$. Perchloroxanthrenequinone receives two electrons and becomes a catecholate dianion. The cobalt atom is oxidized from the oxidation state +2 to +3. The different hyperfine coupling constants on the ^{31}P nuclei ($a_{P2} = 1.30$ mT, $a_{P1} = 0.30$ mT) reflect planar and apical positions of the corresponding nuclei with respect to the plane of the *o*-semiquinone.[22,23] The coupling constant on ^{59}Co ($a_{Co} = 1.00$ mT) are typical for octahedral *o*-semiquinone-catecholate complexes of cobalt(III) with one unpaired electron localized primarily (> 99% according to ref.[15]) on the semiquinone unit.[1] Thus, the result is a six-coordinate semiquinone-catecholate complex of low-spin cobalt(III).

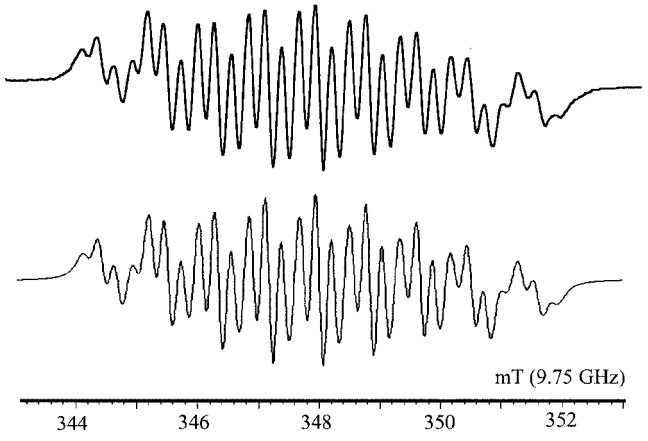


Figure 1. Room temperature x-band EPR spectrum (top) of [(dppe)Co(3,6-DBSQ)(Cat$^{Cl}_{ox}$)] (**1**) (toluene, 290 K) and (bottom) its simulation (EPR line width = 0.2 mT)

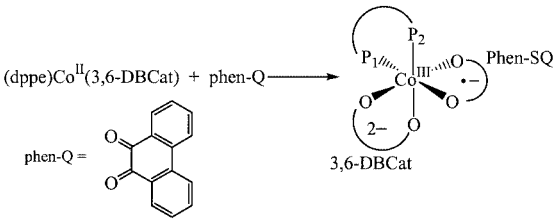
The second situation occurs when the additional quinone is a quite-weaker acceptor than is quinone, which has formed the initial catecholate; e.g., when it is phenanthrenequinone [Equation (3)].



(3)

The hyperfine coupling with protons of 3,6-DBSQ is absent ($g_{iso} = 2.0016 \pm 0.0005$, Figure 2). Only hyperfine coupling is observed with ^{59}Co and one $^{31}P_2$ ($a_{Co} \approx a_{P2} \approx 0.85$ mT). The interaction with the protons of phen-SQ and P_1 is unresolved because of a relatively large line width. The spectrum view changes slightly with temperature. Optimal resolution was achieved at 250 K. An acceptable simulation indicates an essentially larger line width than was observed in the case **1** (0.20 mT for **1** and 0.73 mT for **2**). Diminution of the ^{59}Co and ^{31}P coupling constants is expected. This feature is explained by lower acceptor properties of phen-Q relative to 3,6-DBQ.[24,25]

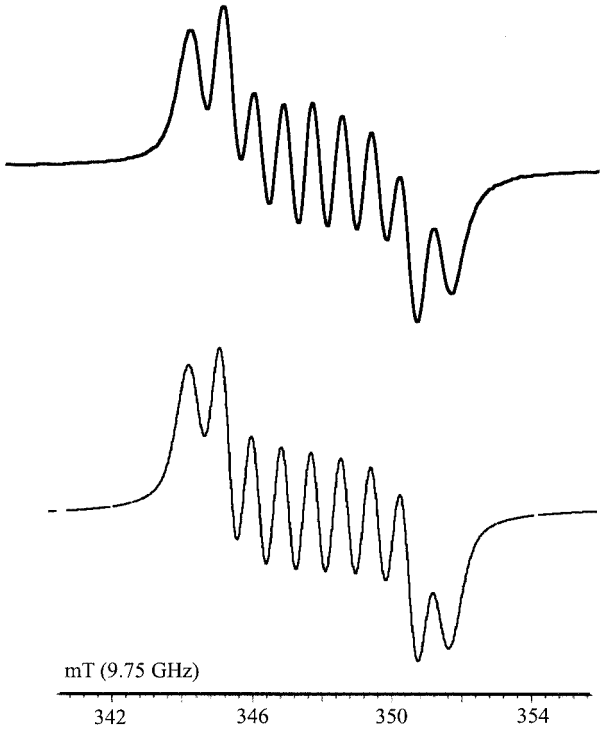


Figure 2. X-Band EPR spectrum (top) of [(dppe)Co(3,6-DBCat)(phen-SQ)] (**2**) (toluene, 250 K) and (bottom) its simulation (EPR line width = 0.73 mT)

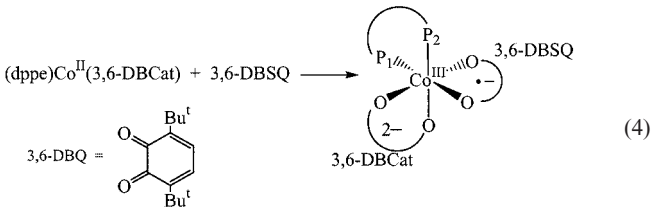
Thus, additional phenanthrenequinone accepts one electron and becomes a semiquinone, the cobalt(II) ion loses one electron and becomes a cobalt(III) ion, and the 3,6-DBSQ unit remains a catecholate. The resulting six-coordinate complex of cobalt(III) contains one unpaired electron localized on the phenanthrenesemiquinone and the 3,6-DBQ fragment in the catecholate form.

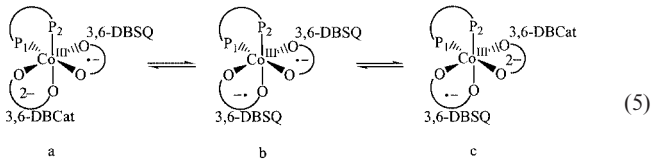
The third situation takes place when both the quinone fragments are the same [Equation (4)].

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



(4)

The EPR spectrum consists of one broad, unresolved line, the form and intensity of which depends on the temperature (g_{iso} = 2.0020±0.0005, Figure 3). No hyperfine structure is observed. A bearable simulation of the spectrum at 210 K indicates a line width of 5.0 mT. Based on literature data,[1,26] we propose that line broadening takes place because of the following equilibrium [Equation (5)]:



(5)

This equilibrium is a tautomeric interconversion of isomers **a** and **c** followed by a reversible electron transfer. It can occur though the intermediacy of a bis-semiquinone adduct of cobalt(II) (**b**). The presence of this intermediate containing at least three unpaired electrons could be the reason for the broadening and temperature dependence of the EPR spectrum.

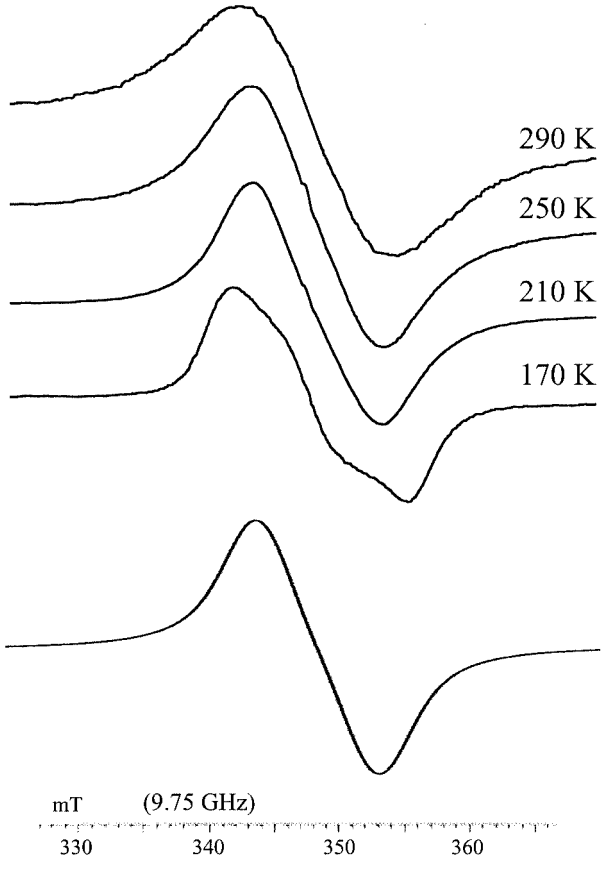


Figure 3. Temperature dependence of the x-band EPR spectrum (top) of [(dppe)Co(3,6-DBCat)(3,6-DBSQ)] (**3**) (g = 2.002±0.0005) and (bottom) its simulation at T = 210 K (a_{Co} = a_{P2} = 1.3 mT; line width = 5.0 mT).

One can imagine the EPR spectrum in the absence of this intermediate. In the case of slow interconversion (relative to the timescale of EPR spectroscopy) of **a** and **c**, the EPR spectrum should reflect, as was observed for 1, a hyperfine interaction with the cobalt nucleus of two different phosphorus atoms (one planar and one apical with respect to the plane of the semiquinone unit) and two protons of one semiquinone ring.

In the case of fast exchange, the EPR spectrum would show an interaction of the unpaired electron with the cobalt nucleus, the two different phosphorus atoms with equal constants, and the four protons of 3,6-DBSQ with one half-constant (≈ 0.15 mT).[27]

In the case of a medium rate of interconversion, i.e., when the lifetime of this intermediate is close to the characteristic time of EPR spectroscopy, an EPR spectrum presenting slow exchange phenomena will transform to depict fast exchange with an increase in temperature, according to known rules.[28] Only some components of the spectrum can undergo broadening.

Total EPR spectroscopic line broadening can take place in the case where one of the exchanging particles has a very broad (maybe infinite) line width and/or a very short lifetime. The particles **a** and **c** presented above have equal lifetimes because of their total identity; the EPR spectra corresponding to fast and slow exchange between them have already been described. A complex of cobalt(II) with two semiquinone units (particle **b**) having at least three unpaired electrons should display a very broad line. Interconversion of **a** to **c** passing through form **b** leads to lines broadening. However, the molar fraction of this cobalt(II) adduct appears to be relatively low because it is possible to observe the spectrum of **3** and its g factor is the same as it is in the cases of **1** and **2**.

In a publication describing a similar situation for complex [(α,α′-bpy)Rh(3,6-DBCat)(3,6-DBSQ)], EPR spectroscopic line broadening occurs upon warming it in solution as well as in the solid state at a very small high-spin fraction that cannot be detected by magnetic susceptibility.[26]

A very small impurity of a Co^{II} species seems to be present in the cases of the complexes **1** and **2**. This impurity might be the reason for the relatively large line widths. By comparing the EPR spectroscopic line widths of complexes **1** and **2** with the values of $E_{1/2}$ of the corresponding quinones [$E_{1/2}$(phen-Q) = −0.66 V, $E_{1/2}$(3,6-DBQ) = −0.39 V, $E_{1/2}(Q_{ox}^{Cl})$ = −0.03 V] it becomes clear why the EPR spectrum of **2** is poorly resolved in comparison with **1**. The difference between the values of $E_{1/2}$ of Q_{ox}^{Cl} and 3,6-DBQ (Δ ≈ 0.36 V) is larger than between 3,6-DBQ and phen-Q (Δ ≈ 0.27 V). Based on these general considerations it becomes clear that the energy separation between the Co^{III}(Cat′)(SQ′′) and Co^{II}(SQ′)(SQ′′) states is larger in the Q_{ox}^{Cl}−3,6-DBQ pair than in the 3,6-DBQ−phen-Q pair, and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

so the amount of an impurity of a Co^{II} species is, respectively, smaller. As a consequence, the line widths in the EPR spectrum of **1** are smaller than they are in the case of **2**. Of course, these comments are qualitative and approximate because they are based on the assumption that the first values of $E_{1/2}$ of quinones correlate with the second ones.

Complex **3** was isolated and characterized in the solid state. Moreover, it was obtained in another way [Equation (6)].

$$[Co(3,6\text{-DBSQ})_3] + dppe \rightarrow [(dppe)Co(3,6\text{-DBCat})(3,6\text{-DBSQ})] + 3,6\text{-DBQ} \quad (6)$$

A magnetic susceptibility investigation indicates a magnetic moment of ca. 1.76 μ_B, which corresponds to one unpaired electron per complex. The magnetic moment as a function of temperature remains constant down to ca. 10 K.

The EPR spectrum of **3** (powder), which displays one broad, unresolved line, is quite similar to those reported[26] to have been observed for [(α,α′-bpy)Rh(3,6-DBCat)(3,6-DBSQ)], and no temperature changes were detected. Thus, complex **3** appears to be a "Co^{III}(SQ)(Cat)" species in the solid state that lacks the "$Co^{II}(SQ)_2$" impurity.

Conclusion

Naturally, the charge on the quinone fragment − "3,6-DBQ" in complex [(dppe)Co("3,6-DBQ")("Q")] − depends on the redox potential of the neighboring quinone fragment "Q". If "Q" is a stronger acceptor, such as "Q^{Cl}_{ox}", then "3,6-DBQ" becomes a semiquinone unit, but if "Q" is a weaker acceptor ("phen-Q") then it remains a catecholate unit. When "Q" ligands are identical, the complex remains in the Co^{III}(Cat)(SQ) state, in general, but a very small impurity of a Co^{II} species essentially causes lines to broaden in the EPR spectrum. Complex [(dppe)Co(3,6-DBCat)(3,6-DBSQ)] in the solid state exists as a "Co^{III}-(Cat)(SQ)" species without any "$Co^{II}(SQ)_2$" impurity.

Experimental Section

General Remarks: EPR spectra were recorded on a Bruker ER 200D-SRC (X-band) spectrometer with an ER 4111 VT variable temperature unit. Coupling constants were determined with the help of a simulator (WINEPR SimFonia 1.25). All the operations with semiquinone and catecholate compounds were carried out under vacuum. Solvents were dried by standard procedures and degassed before use.

Phenanthrenequinone, dppe, $CoCl_2$, and solvents were obtained commercially. 3,6-DBQ,[29,30] perchloroxanthrenequinone-2,3[31] and $[Co(3,6\text{-DBSQ})_3]$[32] were obtained according to known procedures.

[Bis(diphenylphosphanyl)ethane](3,6-di-*tert*-butylcatecholato)cobalt: An evacuated ampoule containing 3,6-di-*tert*-butyl-*o*-quinone (0.22 g, 1.0 mmol) in THF (30 mL) and a large excess of thallium amalgam was shaken until the color of the suspension became bright yellow. The light suspension of thallium catecholate was carefully decanted to another evacuated ampoule. Thallium amalgam was carefully washed several times with THF (5 × 10 mL) until the solvent became colorless. (*Attention!* Thallium catecholate is extremely air sensitive.) Thallium catecholate was added to a mixture of dppe (0.4 g, 1 mmol) and $CoCl_2$ (0.13 g, 1.0 mmol) in THF (70 mL). The reaction mixture was heated under reflux for 1 h, and then the solvent was changed to toluene. The brown solution was filtered, partly evaporated, diluted with *n*-hexane, and then kept at −10 °C overnight. The resulting air-stable, brown, crystalline solid was filtered, washed with cold light petroleum, and then dried under vacuum. Yield 0.2 g (33%). IR (Nujol): $\tilde{\nu}$ = 515 s, 525 (C_3P skeleton vibrations); 735, 695 v.s. $\delta_\perp$ C−H (Ph); 1105 (ν_{P-C}); 1260, 1250 (ν_{C-O}, Cat); 940, 980, 1395, 1375, 1440 (3,6-DBCat) cm^{-1}. $C_{40}H_{44}CoO_2P_2$ (677.67) calcd. C 70.90, H 6.50, Co 8.71; found C 70.95, H 6.49, Co 8.75.

Sample Preparation: Equimolar amounts of [(dppe)Co(3,6-DBCat)] and the corresponding quinone were placed into a special ampoule for EPR spectroscopic investigations. The ampoule was evacuated and purified toluene was condensed inside.

[Bis(diphenylphosphanyl)ethane)(3,6-di-*tert*-butyl-*o*-benzosemiquinono)(3,6-di-*tert*-butylcatecholato)cobalt (3): Dppe (0.4 g, 1 mmol) in THF (50 mL) was added to $[Co(3,6\text{-DBSQ})_3]$ (0.716 g, 1.0 mmol) in THF (80 mL) and then the mixture was carefully warmed. The solvent was evaporated and the residue was washed with *n*-hexane (3 × 50 mL). The solid was dissolved in CH_2Cl_2, and then diluted with *n*-hexane. Slow evaporation led to a dark-blue microcrystalline solid, which was filtered, washed by cold light petroleum, and dried under vacuum. Yield: 0.5 g (ca. 50%). An additional crop of crystals was obtained after cooling the mother solution. IR (Nujol): $\tilde{\nu}$ = 480, 495, 535 (C_3P skeleton vibrations); 695 v.s., 740 m $\delta_\perp$ C−H (Ph); 1105 (ν_{P-C}); 1270, 1280 (ν_{C-O}, Cat); 1410 s (ν_{C-O}, SQ) cm^{-1}. $C_{54}H_{64}CoO_4P_2$ (897.98) calcd. C 72.24, H 7.13, Co 6.58; found C 72.32, H 7.18, Co 6.60.

Phosphadicarbaborane Analogues of Ferrocene: New Isomers of [*closo*-(η^5-C_5H_5)$FePC_2B_8H_{10}$]

Bohumil Štíbr,*[a] Josef Holub,[a] Mario Bakardjiev,[a] Ivan Pavlík,[b] Oleg L. Tok,[c] and Bernd Wrackmeyer[c]

Keywords: Sandwich complexes / Boranes / Isomerisation / Carbaboranes / NMR spectroscopy

Thermal isomerisation of the ferraphosphadicarbaborane [1-Cp-*closo*-1,2,4,5-$FePC_2B_8H_{10}$] (**1a**; Cp = η^5-$C_5H_5^-$) at elevated temperatures (180–350 °C) leads to the formation of three new isomeric complexes. These were characterized by multinuclear (^1H, ^{11}B, ^{31}P, and ^{13}C) NMR spectroscopy and mass spectrometry as [1-Cp-*closo*-1,2,3,8-$FePC_2B_8H_{10}$] (**1b**), [1-Cp-*closo*-1,10,2,4-$FePC_2B_8H_{10}$] (**1c**), and *closo*-[1,2,4,10-$FePC_2B_8H_{10}$] (**1d**). The formation of **1b** is accompanied by an unusual agglomeration of the P and C heteroatoms. Complexes **1b** and **1c** have also been isolated as side products from the direct reaction between *nido*-[7,8,9-$PC_2B_8H_{11}$] (**2**) and $[CpFe(CO)_2]_2$ in refluxing mesitylene, and **1a** and **1b** from the pyrolysis of [7-Fp-(η^1-*nido*-7,9,10-$PC_2B_8H_{10}$)] [**3**; Fp = $CpFe(CO)_2$] at 350 °C. NMR intercomparisons of all five [1-Cp-*closo*-$FePC_2B_8H_{10}$] isomers thus far isolated have been made.

Introduction

We have recently been interested in the synthesis and chemistry of the eleven-vertex *nido* phoshadicarbaboranes (phosphadicarbollides), which are analogues of tricarbollides.[1] In this field of boron cluster chemistry we have reported the synthesis of the two isomeric neutral compounds 7,8,11-$PC_2B_8H_{11}$ and 7,8,9-$PC_2B_8H_{11}$.[2,3] Deprotonation of these compounds gave the corresponding anions [7,8,11-$PC_2B_8H_{10}]^-$ and [7,8,9-$PC_2B_8H_{10}]^-$.[2,3] These anions can be regarded as Cp analogues as they are monoanionic and contain an open pentagonal face[1] capable of donating five electrons in an η^5-type coordination to metal fragments. This analogy was demonstrated just recently by the complexation of *nido*-7,8,9-$PC_2B_8H_{11}$ with $[CpFe(CO)_2]_2$ resulting ultimately in the synthesis of the first two representatives of the [1-Cp-*closo*-$FePC_2B_8H_{10}$] series (compounds **1a** and **1e**). These compounds are the first phosphadicarbaborane analogues of ferrocene. It was demonstrated that their formation proceeds via two isolable η^1-bonded, P-substituted complexes of general formula [Fp-*nido*-(η^1-$PC_2B_8H_{10}$)].[4] By analogy with dicarbollide[5] and tricarbollide complexes,[6] the complexes **1a** and **1e** were expected to undergo cluster rearrangement by migration of the heteroatomic CH and P cage units at higher temperatures to form further [1-Cp-*closo*-$FePC_2B_8H_{10}$] isomers. We report in this paper several variations of reactions from which we have isolated another three isomers of this constitution. The numbering system for the eleven-vertex *nido* and twelve-vertex *closo* skeletons used in this work is shown in structures **I** and **II**. These structures are presented in a simplified manner; unmarked vertices in the schemes stand for cluster BH units, while C and P denote CH and bare phosphorus vertices, respectively. For convenience, the Fe atom in structures of type **1** is numbered first, followed by P and C vertexes.

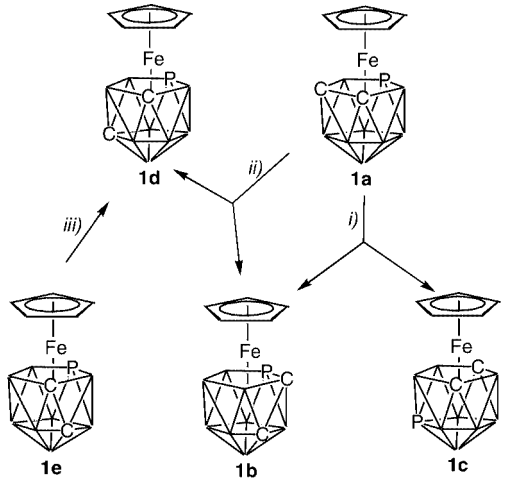
Results and Discussion

Syntheses

As shown in path i) of Scheme 1, prolonged heating of **1a** in mesitylene at reflux temperature produces the complexes [1-Cp-*closo*-1,2,3,8-$FePC_2B_8H_{10}$] (**1b**) and [1-Cp-*closo*-1,10,2,4-$FePC_2B_8H_{10}$] (**1c**) in yields of 15 and 13%, respectively. The conversion is, however, very slow and incomplete, and compound **1a** was recovered in 60% yield. The formation of **1b** from **1a** is very unusual as it is associated with the migration of one of the cage carbon atoms from the original *m*-position to the *o*-position with respect to the P center. Moreover, the second carbon atom is moved into the lower structural belt, to form a contiguous P−C−C string with a P−C bond in the pentagonal belt adjacent to the Fe center. The formation of **1c** from **1a** is associated with a migration of the P-vertex into an *m*-position with respect to the Fe center and *m*-separation of the C-vertices within the pentagon adjacent to the Fe atom to achieve a maximum space separation of the P and C vertices, a feature encountered in the isoelectronic [1-Cp-*closo*-1,2,4,10-$FeC_3B_8H_{11}$] tricarbollide series.[7] A different type of maximum separation of the C and P heteroatoms is encountered in the isomer [1-Cp-*closo*-1,2,4,10-$FePC_2B_8H_{10}$] (**1d**). As shown in path ii) of Scheme 1, this complex was isolated in a yield of 23%, together with the isomer **1b** (yield 52%), from thermal rearrangement of **1a** at 350 °C. The result of the **1a** → **1d** rearrangement is a movement of the one of the C vertexes into an *m*-position with respect to both C and P atoms in the lower belt near B(12). Moreover, isomer **1d** was additionally obtained in a yield of 51% by the thermolysis of **1e**[4] at 350 °C (see path iii of Scheme 1), the rearrangement being associated with a migration of one carbon vertex into or within the pentagonal belt connected to the B(12) atom.



Scheme 1. i) mesitylene, reflux, 3 hours. ii), iii) 350 °C, 2 hours

Complexes **1b** and **1c** can also be obtained directly from the phosphadicarbaborane **2** by treatment with $[CpFe(CO)_2]_2$ in refluxing mesitylene (two days). The main products isolated from this reaction were, however, the previously reported[4] compounds **1a** (yield 33%) and **3** (yield 28%); nevertheless, the reaction is accompanied by the formation of the isomeric complexes **1b** and **1c** (yields 10 and 7%, respectively). Alternatively, complex **1b** was also generated (yield 23%), together with compound **1a**[4] (yield 52%), by heating the *nido* compound **3**[4] at 350 °C in vacuo. It is obvious that complexes **1b** and **1c** in these experiments have been formed by rearrangement of **1a** as in path i) of Scheme 1. All the new isomeric complexes **1b**−**1d** are orange or dark orange compounds that are remarkably stable in air.

Structural Studies

Even though we were able to grow crystals of almost all new complexes of type **1**, the structural determinations of these species were unsuccessful owing to disorder problems encountered during structure solution. Nevertheless, the constitution of all new isomers **1b**−**1d** could be easily derived from multinuclear NMR (^1H, ^{11}B, ^{31}P, and ^{13}C) and two-dimensional [^{11}B-^{11}B]-COSY NMR measurements[8] combined with $^1H\{^{11}B(selective)\}$ experiments,[9] and the interpretation of the data led to complete assignments of all resonances to individual BH, CH, and P vertices. The mass spectra of compounds **1b**−**1d** exhibit the same molecular cut-off at $m/z = 275$, as expected for the identical molecular formulation. Some absorption bands in the IR spectra have been assigned to BH and CH vibrations.

The ^{11}B NMR spectra of all five isomers of general constitution **1** thus far isolated are depicted graphically in Figure 1 as simplified stick diagrams indicating the ^{11}B chemical shifts and relative intensities. The ^{11}B resonances fall within a relatively narrow span (ca. 20 ppm), which corresponds well to that of the isostructural [1-Cp-*closo*-$FeC_3B_8H_{11}$] compounds and their amino derivatives (also ca. 20 ppm).[1,7] The ^{11}B resonances of the BH units adjacent to the P vertex are generally either split into a doublet or at least broadened owing to unresolved ^{31}P-^{11}B scalar coupling. As shown in Figure 2, the ^{31}P resonances are very sensitive to structural changes among individual isomers of general formula **1**. The ^{31}P resonances of the isomers containing the Fe−P bond (**1a**, **1b**, **1d**, and **1e**) fall within a range of ca. $\delta = +20$ to -45 ppm, while the $^{31}P(10)$ resonance in **1c** is shifted to low frequency ($\delta^{31}_P = -166$ ppm), to a range typical of phosphorus in polyhedral boranes with a *closo* structure.[10] Therefore, the ^{31}P NMR signals at higher frequencies in the range of $\delta = +20$ to -55 ppm are a consequence of Fe−P bonding. As expected, the ^1H and $^{13}C\{^1H\}$ NMR chemical shifts associated with the Cp ring are not significantly affected by structural changes in the phosphadicarbaborane cage.

As shown in Figure 1, the ^{11}B NMR spectra of the C_s-symmetric isomers **1a**[4] and **1c** consist of 1:2:1:2:2 patterns of doublets, which is consistent with a plane of symmetry intersecting the Fe(1), B(or P)(10), and B(12) vertices. The spectra of **1a**[4] and **1c** are very similar to those of their tricarbollide congeners [1-Cp-*closo*-1,2,4,5-$FeC_3B_8H_{11}$] (**4a**)[11] and [1-Cp-*closo*-1,2,4,10-$FeC_3B_8H_{11}$] (**4b**),[7] except that the spectra of the ferraphosphadicarbollides are shifted

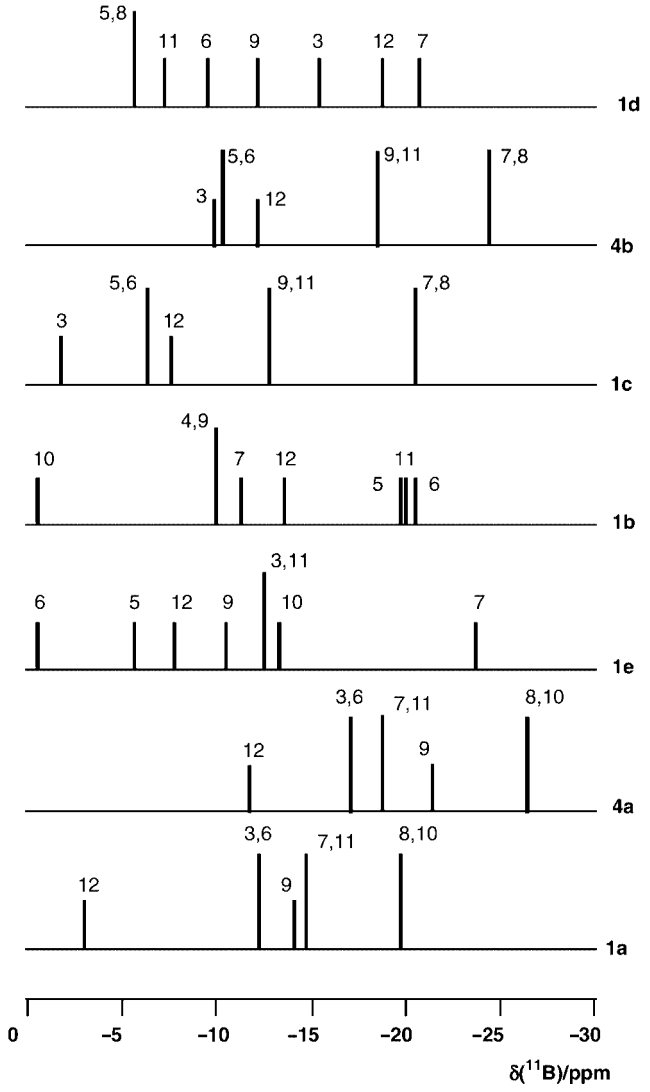

Figure 1. Simplified stick diagrams showing intercomparison of the ^{11}B NMR chemical shifts and relative intensities for all known ferraphosphadicarbollide [1-Cp-*closo*-$FePC_2B_8H_{10}$] (**1**) isomers with those for selected isostructural ferratricarbollides [1-Cp-*closo*-$FeC_3B_8H_{11}$] (**4**); data for **1a** and **1e** from ref.[4] and data for **4a** and **4b** from refs.[7,11]

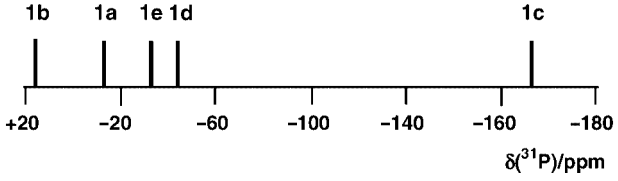

Figure 2. Stick representation of the ^{31}P NMR chemical shifts for all known ferraphosphadicarbollide [1-Cp-*closo*-$FePC_2B_8H_{10}$] (**1**) isomers; data for **1a** and **1e** from ref.[4]

downfield ($\Delta\delta$ = ca. 5 ppm). In agreement with the existence of the symmetry plane, the ^1H and $^{13}C\{^1H\}$ NMR spectra of **1c** show two singlet resonances of integral intensities 5:2, assigned to Cp and two equivalent CH(2,4) units, respectively. As expected for the asymmetric derivatives **1b**, **1d**, and **1e**,[4] their ^{11}B NMR spectra are characterized by eight different resonances some of which overlap. The ^1H and $^{13}C\{^1H\}$ NMR spectra of these asymmetrical isomers contain three resonances of relative areas 5:1:1 attributed to Cp and two different cage CH units. In the case of **1b**, which is a single isomer containing a P−C bond, one of the CH resonances shows distinct $^2J_{P,H}$ and $^1J_{P,C}$ doublet splittings.

Conclusions

We have demonstrated that another three structurally diverse isomers of general *closo* ferraphosphadicarbollide structure **1** can be isolated from various high-temperature reactions involving − directly or indirectly − the previously reported isomer **1a**.[4] There is no doubt that the separation of carbon atoms is not the only driving force responsible for the observed rearrangements, as the isomer **1b**, containing a contiguous P-C-C string, is formed as the main kinetic product. This fact is in sharp contrast to the rearrangements of the structurally related ferratricarbollide complexes[6,7] and to those of the [$CpCoC_2B_9H_{11}$] cobaltadicarbollides as well.[5] The isomerisations leading to **1b−1d** can be explained by the triangular-face rotation mechanism,[12] although the participation of other mechanisms (diamond-square-diamond,[13] pyramidal rotation,[14] and Lipscomb's hybrid[15]), cannot be excluded. It should also be noted that all the complexes isolated contain at least one heteroatom on the coordinating face and, in comparison with complexes of the [$CpCoC_2B_9H_{11}$] series,[5] no [$CpFePC_2B_8H_{10}$] isomer containing P or C heteroatoms in position 12 (*para* with respect to the Fe center) has been formed. These will probably be formed at temperatures higher than 400−500 °C; application of such severe conditions led to complete decomposition. The isomeric complexes of structure **1** are expected to undergo various substitution reactions either on the cluster atoms or the Cp ring, which might generate interesting substitution derivatives. Also, application of boron or carbon degradation reactions is expected to lead to other structurally interesting smaller-cage ferraphoshacarborane systems. These and related reactions aimed at establishing reactivity systemization within a series of phosphacarborane analogues of ferrocene are in progress.

Experimental Section

General Procedures: All reactions were carried out with use of standard vacuum or inert-atmosphere techniques as described by Shriver,[16] although some operations, such as column LC, were carried out in air. The starting compounds **1a**, **1e**, **2,** and **3** were prepared according to the literature.[3,4] Dichloromethane, hexane, and mesitylene (Fluka) were dried over CaH_2 and freshly distilled before use. Other chemicals were reagent or analytical grade and were used as purchased. Column chromatography was carried out using silica gel (Aldrich, 130−270 mesh) as the stationary phase. The purity of individual chromatographic fractions was checked by analytical TLC on Silufol (silica gel on aluminum foil; detection by iodine vapor, followed by 2% aqueous $AgNO_3$ spray). Melting points were measured in sealed capillaries under argon and are un-

corrected. Multinuclear (^{1}H, ^{11}B, ^{31}P, and ^{13}C) NMR and IR spectroscopy, and mass spectrometry have been performed essentially with the instrumentation described in other related papers from our laboratories.[4,17]

[1-Cp-1,2,3,8-FePC$_2$B$_8$H$_{10}$] (1b) and [1-Cp-1,10,2,4-FePC$_2$B$_8$H$_{10}$] (1c): a) A solution of compound **1a** (100 mg, 0.36 mmol) in mesitylene (20 mL) was heated under reflux for three days. Most of the mesitylene was removed by evaporation and the mixture was then worked up by repeated chromatography on a silica gel column (40 × 1.5 cm) using hexane as a mobile phase to collect three main fractions of R_f (hexane) 0.60, 0.50, and 0.43, from which complexes **1c** (13 mg, 13%), **1b** (15 mg, 15%), and the starting compound **1a** (60 mg, 60%) were isolated, respectively, by evaporation of the solvent and identified by ^{11}B NMR spectroscopy.

1c: R_f (hexane) 0.60. M.p. 80 °C. ^{1}H{^{11}B } NMR ($CDCl_3$): δ = 4.81 (s, 5 H, Cp), 3.14 (d, $^2J_{P,H}$ = 24 Hz, 2 H, $H_{5,6}$), 2.82 (d, $^2J_{P,H}$ = 23 Hz, 1 H, H_{12}), 2.50 (s, 2 H, $H_{2,4}$), 1.72 (s, 2 H, $H_{7,8}$), 1.70 (d, $^2J_{P,H}$ = 23 Hz, 2 H, $H_{9,11}$) ppm. ^{11}B NMR ($CDCl_3$): δ = −2.0 (d, $^1J_{B,H}$ = 166 Hz, 1 B, B_3), −6.4 (d, $^1J_{B,H}$ ≈ 160, $^1J_{B,P}$ = 35 Hz, 2 B, $B_{5,6}$), −7.5 (d, $^1J_{B,H}$ ≈ 160 Hz, 1 B, B_{12}), −15.4 (d, $^1J_{B,H}$ = 165 Hz, 2 B, $B_{9,11}$), −21.1 (d, $^1J_{B,H}$ = 161 Hz, 2 B, $B_{7,8}$) ppm. ^{31}P{^{1}H } NMR ($CDCl_3$): δ = −166.2 (s, 1 P, P_{10}) ppm. IR (KBr): $\tilde{\nu}$ = 2924 (CH), 2580 (BH) cm^{-1}. MS (70 eV, EI), *m/z* (%) = 275 (5) $[M]^+$, 273 (85) $[M - 2H]^+$. $C_7H_{15}B_8FeP$ (272.54): calcd. C 30.85, H 5.55; found C 30.98, H 5.70.

1b: R_f (hexane) 0.50. M.p. 180 °C. ^{1}H{^{11}B} NMR ($CDCl_3$): δ = 4.99 (s, 5 H, Cp), 4.21 (s, 1 H, $H_{4\ or\ 9}$), 3.46 (s, 1 H, H_8), 3.41 (s, 1 H, H_{10}), 2.29 (s, 1 H, $H_{4\ or\ 9}$), 2.23 (d, $^2J_{P,H}$ = 26 Hz, 1 H, H_7), 1.76 (s, 1 H, H_{12}), 1.52 (s, 1 H, H_5), 1.44 (d, $^2J_{P,H}$ = 26 Hz, 1 H, H_{11}), 1.94 (d, $^2J_{P,H}$ = 18 Hz, 1 H, H_3), 1.35 (d, $^2J_{P,H}$ = 15 Hz, 1 H, H_6) ppm. ^{11}B NMR ($CDCl_3$): δ = −0.9 (d, $^1J_{B,H}$ = 150 Hz, 1 B, B_{10}), −9.9 (d, $^1J_{B,H}$ ≈ 160 Hz, 2 B, $B_{4,9}$), −12.0 (d, $^1J_{B,H}$ = 162, $^1J_{B,P}$ = 36 Hz, 1 B, B_7), −13.7 (d, $^1J_{B,H}$ = 162 Hz, 1 B, B_{12}), −19.7 (d, $^1J_{B,H}$ = 162 Hz, 1 B, B_5), −20.0 (d, $^1J_{B,H}$ ≈ 160 Hz, 1 B, B_{11}), −21.6 (d, $^1J_{B,H}$ ≈ 160 Hz, 1 B, B_6) ppm. ^{13}C{^{1}H,^{11}B} NMR ($CDCl_3$): δ = 80.4 (s, 5 C, Cp), 58.6 (s, 1 C, C_8), 45.8 (s, $^1J_{C,P}$ = 74 Hz, 1 C, C_3) ppm. ^{31}P{^{1}H } NMR ($CDCl_3$): δ = 17.7 (s, 1 P, P_2) ppm. IR (KBr): $\tilde{\nu}$ = 2925 (CH), 2548 (BH) cm^{-1}. MS (70 eV, EI), *m/z* (%) = 275 (5) $[M]^+$, 273 (85) $[M - 2H]^+$. $C_7H_{15}B_8FeP$ (272.54): calcd. C 30.85, H 5.55; found C 31.20, H 5.73.

b) A solution of compound **2** (500 mg, 3.25 mmol) in mesitylene (20 mL) was treated with $[CpFe(CO)_2]_2$ (1500 mg, 4.23 mmol) and the mixture was heated under reflux for 24 h. Most of the mesitylene was removed by evaporation and the mixture was then worked up by repeated chromatography on a silica gel column (40 × 2.5 cm) using hexane as a mobile phase to isolate (ordered by decreasing R_f values) compounds **1c** (58 mg, 7%), **1b** (82 mg, 10%), **1a** (294 mg, 33%), and **3** (318 mg, 28%), which were identified by ^{11}B NMR spectroscopy.

c) Compound **3** (0.063 g, 0.19 mmol) was heated at 350 °C in an evacuated ampoule for 2 h. The melt was then cooled to ambient temperature and extracted with CH_2Cl_2 (2 × 10 mL). The extract was filtered, the solvents evaporated to dryness and the solid residue was separated by chromatography on silica gel in hexane. Two orange fractions of R_f = 0.50 and 0.43 were collected from which compounds **1b** (12 mg, 23%) and **1a**[4] (27 mg, 52%) were isolated, respectively, after evaporation of the solvents and drying in vacuo at ambient temperature and identified by ^{11}B NMR spectroscopy.

[1-Cp-1,2,4,10-FePC$_2$B$_8$H$_{10}$] 1d: a) Compound **1a** (100 mg, 0.36 mmol) was heated at 350 °C in an evacuated ampoule for 2 h. The melt was then cooled to ambient temperature and extracted with CH_2Cl_2 (2 × 10 mL). The extract was filtered, the solvents evaporated to dryness and the solid residue was separated by chromatography on silica gel in hexane. Two orange fractions of R_f = 0.60 and 0.50 were collected, from which compounds **1d** (12 mg, 23%) and **1b** (27 mg, 52%) were isolated, respectively, on evaporation of the solvents and drying in vacuo at ambient temperature.

1d: R_f (hexane) 0.60. M.p. 80 °C.^{1}H{^{11}B} NMR ($CDCl_3$): δ = 4.84 (s, 5 H, Cp), 3.53 (s, 1 H, $H_{5\ or\ 8}$), 3.27 (s, 1 H, $H_{5\ or\ 8}$), 2.99 (s, 1 H, $H_{4\ or\ 10}$), 2.81 (d, $^2J_{P,H}$ = 23 Hz, 1 H, H_{11}), 2.73 (s, 1 H, H_9), 2.36 (s, 1 H, $H_{4\ or\ 10}$), 1.91 (d, $^2J_{P,H}$ = 18 Hz, 1 H, H_3), 1.85 (s, 1 H, H_{12}), 1.84 (d, $^2J_{P,H}$ = 16 Hz, 1 H, H_6), 1.58 (d, $^2J_{P,H}$ = 22 Hz, 1 H, H_7) ppm. ^{11}B NMR ($CDCl_3$): δ = −6.4 (d, $^1J_{B,H}$ ≈ 160 Hz, 2 B, $B_{5,8}$), −7.3 (d, $^1J_{B,H}$ ≈ 160 Hz, 1 B, B_{11}), −8.6 (d, 1 B, B_6), −12.1 (d, $^1J_{B,H}$ = 169 Hz, 1 B, B_9), −15.7 (d, $^1J_{B,H}$ = 166, $^1J_{B,P}$ = 31 Hz, 1 B, B_3), −18.2 (d, $^1J_{B,H}$ = 161 Hz, 1 B, B_{12}), −21.1 (d, $^1J_{B,H}$ = 158 Hz, 1 B, B_7) ppm. ^{13}C{^{1}H } NMR ($CDCl_3$): δ = 79.8 (s, 5 C, Cp), 49.5 (s, 1 C, C_{10}), 46.5 (s, 1 C, C_4). ^{31}P{^{1}H } NMR ($CDCl_3$): δ = −41.3 (s, 1 P, P_2) ppm. IR (KBr): $\tilde{\nu}$ = 2924 (CH), 2580 (BH) cm^{-1}. MS (70 eV, EI), *m/z* (%) = 275 (5) $[M]^+$, 273 (100) $[M - 2H]^+$. $C_7H_{15}B_8FeP$ (272.54): calcd. C 30.85, H 5.55; found C 31.25, H 5.69.

b) Compound **1e** (20 mg, 0.07 mmol) was heated at 350 °C in an evacuated ampoule for 2 h. The melt was then cooled to ambient temperature and extracted with CH_2Cl_2 (2 × 5 mL). The extract was filtered, the solvents evaporated to dryness and the solid residue was separated by chromatography on silica gel in hexane to isolate the main orange band of R_f = 0.60, from which compound **1d** (10.2 mg, 51%) was isolated after evaporation of the solvents and drying in vacuo at ambient temperature; it was identified by NMR spectroscopy.

Iron Complexes Containing the Ligand *N*,*N*′-Bis(6-methyl-2-pyridylmethyl)-*N*,*N*′-bis(2-pyridylmethyl)ethane-1,2-diamine: Structural, Spectroscopic, and Electrochemical Studies, Reactivity with Hydrogen Peroxide and the Formation of a Low-Spin Fe−OOH Complex

Véronique Balland,[a] Frédéric Banse,*[a] Elodie Anxolabéhère-Mallart,*[a] Martine Nierlich,[b] and Jean-Jacques Girerd*[a]

Keywords: Iron / N ligands / Peroxo ligands / Bioinorganic chemistry

The ligand *N*,*N*′-bis(6-methyl-2-pyridylmethyl)-*N*,*N*′-bis(2-pyridylmethyl)ethane-1,2-diamine ($L_6^2$2M) has allowed to prepare the new Fe^{II} complex [($L_6^2$2M)$FeCl_2$] (**1**), and to compare its structural and spectroscopic characteristics with [($L_6^2$2M)FeCl]PF_6 (**2**). The molecular structure of **1**, resolved by X-ray diffraction, exhibits the ligand tetracoordinated with the two non-methylated pyridine rings coordinated. As shown by UV/Vis spectroscopy and cyclic voltammetry, upon dissolution in methanol or acetonitrile, one chloride ion is released and replaced by a pyridine group. Therefore, complexes **1** and **2** adopt identical structures in solution, i.e. [($L_6^2$2M)$FeCl^+$. However, upon oxidation complex **1** gives several ferric complexes with the ligand $L_6^2$2M pentacoordinated, or tetracoordinated with two chloride ions. This peculiar behaviour is due to the presence of chloride ions in solution in the case of **1**. Upon reaction with H_2O_2 in methanol, complex **2** leads to the formation of low-spin [($L_6^2$2M)$Fe^{III}(OOH)^{2+}$, whereas it is not observed in the case of **1**. Based on the presence or not of chloride ions in solution, a mechanism is proposed for the reactivity of complexes **1** and **2** toward H_2O_2.

Introduction

Dioxygen activation by biological iron-containing systems performing monooxygenation reactions is an attractive sequence since it has considerable scientific and commercial interests. Whatever the system considered, the intermediate responsible for the target reaction, i.e. oxidation of the substrate, is proposed to be a high-valent iron-oxygen species. For mononuclear as well as for dinuclear systems, the events can be schematically described by the same universal sequence: dioxygen reacts with the metal centre(s) in the ferrous state leading to a hydroperoxo ferric complex which then evolves to the high valent entity after O−O bond cleavage. Only in the case of methane monooxygenase (MMO), which contains a non-heme dinuclear active site, has a high valent entity (compound Q), formulated as $Fe^{IV}-(\mu\text{-}O)_2-Fe^{IV}$, been characterised.[1,2] In the case of mononuclear systems with either heme or non-heme active sites, the high valent Fe-oxygen species has not been directly observed, but rather proposed by analogy with compounds I and II of peroxidases which have been identified as Fe^{IV}=O entities.[3]

Evidence has been obtained for the existence of hydroperoxo species, which are the precursors of the fleeting high valent entities, in natural systems such as MMO(dinuclear)[4] and bleomycin (mononuclear),[5] and several synthetic models have also been prepared.[6] To date, no evidence for conversion of a hydroperoxo species to a high valent iron-oxo species in synthetic models has been obtained spectroscopically. However, the recent synthesis of a dinuclear $Fe^{IV}-(\mu\text{-}O)_2-Fe^{IV}$ complex from a mononuclear Fe^{III}-alkylperoxo species[7] shows that such a process may be viable.

In this paper we report the structure and characterisation of a new Fe^{II} complex [($L_6^2$2M)$FeCl_2$] containing the ligand *N*,*N*′-bis(6-methyl-2-pyridylmethyl)-*N*,*N*′-bis(2-pyridylmethyl)ethane-1,2-diamine ($L_6^2$2M). This ligand is a bulkier analogue of the ligand TPEN, which has been shown to give access to a low-spin Fe−OOH intermediate.[8] The behaviour of the new complex [($L_6^2$2M)$FeCl_2$] in solution is considered in detail and its reactivity with H_2O_2 is also presented. We have also investigated the reactivity of the complex [($L_6^2$2M)FeCl]PF_6, previously reported by Bernal et al.,[9] with H_2O_2, and report evidence for the formation of a low-spin Fe−OOH complex from this reaction.

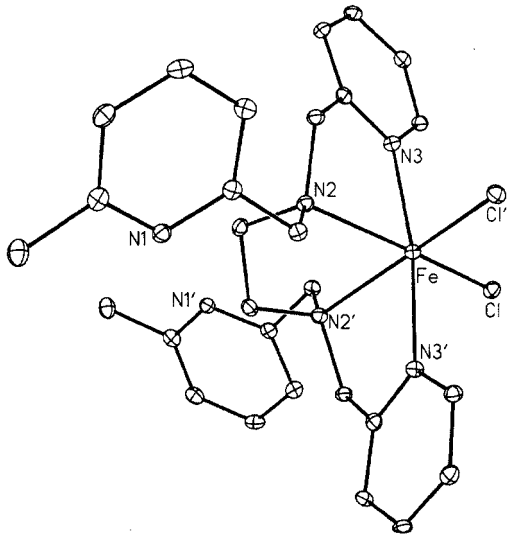

Figure 1. X-ray structure of the molecular complex $[(L_6^2 2M)FeCl_2]$ (**1**)

Results and Discussion

X-ray Crystal Structure

The structure of $[(L_6^2 2M)FeCl_2]$ (**1**) is presented in Figure 1. The Fe^{II} ion has a distorted octahedral geometry with two pyridine nitrogen atoms (N_3) in axial positions and two amino nitrogen atoms (N_2) in equatorial positions. The coordination sphere is completed by two chloride ligands in the equatorial plane.

The potentially hexadentate ligand $L_6^2 2M$ behaves here as a tetradentate ligand with the sterically hindered 6-methylpyridine groups not coordinating to the metal centre. This structure is analogous to those obtained for Fe complexes with tetradentate ligands derived from *N*,*N*′-bis(2-pyridylmethyl)ethane-1,2-diamine.[10−12]

A selection of structural data is reported in Table 1. The Fe−ligand bond lengths are characteristic of a high spin ferrous ion,[12] with the average bond length being 2.256 Å. As expected, the pyridine nitrogen atoms are closer to the Fe than the amino nitrogen atoms (cf. Table 1). The value of ca. 78° for the N_2-Fe-N_2 angle is typical of a five membered metallacycle.[13] Other angles between atoms in the Fe^{II} coordination sphere are also consistent with a strongly distorted octahedral geometry (cf. Table 1).

Table 1. Selected bond lengths and angles for $[(L_6^2 2M)FeCl_2]$ (**1**)

Bond lengths [Å]		Bond angles [°]	
Fe−N_2	2.320 (3)	N_2-Fe-N_2	78.18 (15)
Fe−N_3	2.192 (3)	N_3-Fe-N_3	170.90 (16)
Fe−Cl	2.4276 (10)	Cl−Fe−Cl	106.24 (5)

UV/Vis Spectroscopy

The electronic spectra of complexes $[(L_6^2 2M)FeCl_2]$ (**1**) and $[(L_6^2 2M)FeCl]PF_6$ (**2**) have been recorded in both acetonitrile and methanol, and the data are summarised in Table 2. The spectroscopic characteristics of both **1** and **2** are very similar in both solvents. In each case, the spectrum is dominated by an intense band in the UV corresponding to a pyridine π−π* transition (not reported in Table 2) and another at ca. 400 nm that is attributed to a Fe^{II}-to-pyridine MLCT transition. The ε values for the latter are characteristic of high-spin Fe^{II} systems.[14]

The fact that both $[(L_6^2 2M)FeCl_2]$ and $[(L_6^2 2M)FeCl]^+$ display similar spectra in solution suggests that they adopt a similar structure. Moreover, it is very likely that no solvent molecule is involved in the coordination sphere since the spectra obtained are identical in CH_3OH and CH_3CN.

The spectrum of $[(L_6^2 2M)FeCl_2]$ is different to that of $[(LBzl_2)FeCl_2]$ (cf. Table 2) and related complexes with a $[LFeCl_2]$ structure (L designates a tetradentate aminopyridine ligand).[12,16] These usually display a MLCT band at ca. 410 nm in acetonitrile. In contrast, $[(L_6^2 2M)FeCl_2]$ displays a MLCT band whose position and intensity are very similar to those observed for $[(L_6^2 2M)FeCl]PF_6$ (cf. Table 2) and similar complexes with three pyridines and an ethanediamine fragment.[8,9,14,15,17] The data reported for high spin Fe^{II} complexes with ethane-1,2-diamine/pyridine ligands show that the ε value of the MLCT band appears to correlate with the number of coordinated pyridines; for example, $\varepsilon \approx 1000\ M^{-1}cm^{-1}$ for complexes with two pyridines bound to Fe^{II} [12,16] while those with three pyridines bound to Fe^{II} [8,9,14,15,17] have $\varepsilon \approx 1600-2000\ M^{-1}cm^{-1}$.

It is also possible to compare the λ_{max} of the MLCT for *bis*-chloro complexes containing a tetradentate ligand ($\lambda_{max} \approx 410$ nm) with *mono*-chloro complexes containing a pentadentate ligand ($\lambda_{max} \approx 380$ nm). Substituting a π donor Cl^-, which destabilises the t_{2g} set of d orbitals, with a π accepting pyridine, which stabilises the t_{2g} set, will increase the gap between the t_{2g} metal orbitals and the pyri-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dine π* orbitals thus resulting in a shift of the λ_{max} of the MLCT to shorter wavelength.

Both the λ_{max} of ca. 380 nm and the ε value of 1700 $M^{-1}cm^{-1}$ obtained for $[(L_6^2 2M)FeCl_2]$ are thus consistent with a structure where three pyridines are coordinated to the metal. The neutral structure observed in the solid state by X-ray diffraction is therefore not maintained in CH_3CN or CH_3OH solution since a chloride ligand is displaced by one of the pendant pyridines.

Cyclic Voltammetry

The cyclic voltammograms of $[(L_6^2 2M)FeCl]PF_6$ and $[(L_6^2 2M)FeCl_2]$ recorded at 20 °C in acetonitrile are presented in Figure 2.

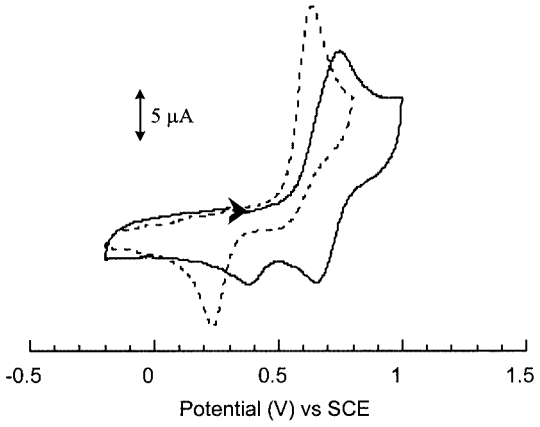

Figure 2. Cyclic voltammograms of $[(L_6^2 2M)Fe^{II}Cl]PF_6$ (**2**) (−) and $[(L_6^2 2M)Fe^{II}Cl_2]$ (**1**) (- - -) in acetonitrile at 20 °C

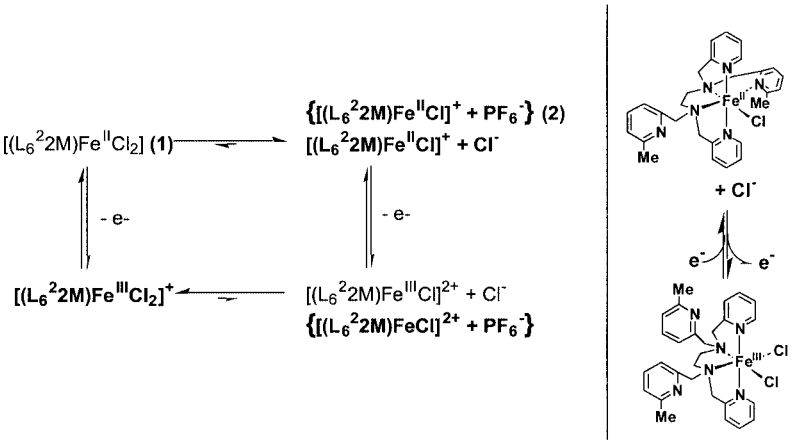
The cyclic voltammogram of $[(L_6^2 2M)FeCl]PF_6$ is analogous to the one previously reported by Bernal et al. for the same complex.[9] It exhibits one broad quasi-reversible wave with $E_{1/2}$ = 0.70 V (ΔE_p = 100 mV) and an extra cathodic wave at 0.38 V on the reverse scan. The broad quasi-reversible response corresponds to oxidation of $[(L_6^2 2M)Fe^{II}Cl]^+ \rightarrow [(L_6^2 2M)Fe^{III}Cl]^{2+}$. The second cathodic peak can be attributed to the reduction of a species obtained after rapid transformation of $[(L_6^2 2M)Fe^{III}Cl]^{2+}$ generated at the electrode. Indeed, the intensity of this last wave is decreased when the scan rate is increased. By analogy with the electrochemical behaviour of $[(L_5^3)Fe^{II}Cl]^+$ (L_5^3 = *N*-Methyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)propane-1,3-diamine) in CH_3OH[13] we propose that this transient complex can be formulated as $[(L_6^2 2M)Fe^{III}(OH)]^{2+}$, with the OH^- coming from residual water in the supporting electrolyte (see Exp. Sect.).

As depicted in Figure 2, $[(L_6^2 2M)FeCl_2]$ displays completely irreversible electrochemistry, with the anodic wave at E_{ox} = 0.63 V and a cathodic wave at 0.23 V. The oxidation potential of 0.63 V is close to that of $[(L_6^2 2M)Fe^{II}Cl]PF_6$ (E_{ox} = 0.75V; cf. Figure 2). This observation is in agreement with the conclusions drawn from the UV/Vis spectra (see above), i.e. formation of $[(L_6^2 2M)Fe^{II}Cl]^+$ from $[(L_6^2 2M)Fe^{II}Cl_2]$ in solution. Moreover, the one electron $Fe^{II} \rightarrow Fe^{III}$ oxidation observed for neutral $[LFeCl_2]$ complexes {L = *N*,*N*′-di-R-*N*,*N*′-bis(2-pyridylmethyl)ethane-1,2-diamine (R = H, Me, benzyl)} is usually reversible in acetonitrile, with $E_{1/2}$ values in the range 0.045−0.232 V vs. SCE,[10,12,18,19] significantly lower than the value of 0.63 V observed here. For example, the neutral complex $[L_4^2 Fe^{II}Cl_2]$ {L_4^2 = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-pyridylmethyl)-ethane-1,2-diamine} has $E_{1/2}$ = 0.18 V.[19] The value of 0.63 V indicates that neutral $[(L_6^2 2M)Fe^{II}Cl_2]$ rearranges to $[(L_6^2 2M)Fe^{II}Cl]Cl$ in acetonitrile, in agreement with UV/Vis spectroscopy studies. In contrast, the wave at 0.23 V on the reverse scan is characteristic of the reduction of the bis chloro complex $[(L_6^2 2M)Fe^{III}Cl_2]^+$.

The lower E_{ox} potential value for complex **1** (0.63 V) compared to complex **2** (0.75 V) suggests the existence of a rapid chemical reaction subsequent to the electron transfer (EC mechanism).[20] Variation of the scan rate between 50 and 500 mV/s had no influence on the shape of the voltammogram, indicating that even the fastest scan rate was in-



Scheme 1. Summary of electrochemical results for $[(L_6^2 2M)FeCl_2]$ (**1**) and $[(L_6^2 2M)FeCl]PF_6$ (**2**) in acetonitrile; species detected appear in bold characters; the second ferric complex detected in the cyclic voltammogram of **2** (see text) has been neglected here; the right part illustrates the EC mechanism observed for **1**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sufficiently rapid to allow observation of the fast chemical reaction following the electron transfer. From the above observations, we propose that this chemical reaction is the rapid complexation of the Fe^{III} species by free Cl^- ions, thus generating the $[(L_6^22M)Fe^{III}Cl_2]^+$ complex, in which the ligand is tetradentate with two pendant pyridines. Indeed the oxidation wave of free Cl^- is not observed even at 500 mV/s.

The results obtained from the electrochemical studies are summarised in Scheme 1. Dissolution of $[(L_6^22M)Fe^{II}Cl_2]$ (**1**) in acetonitrile immediately gives $[(L_6^22M)Fe^{II}Cl]^+$. When oxidised, this complex gives the unstable ferric analog which then interacts immediately with the free Cl^- to give $[(L_6^22M)Fe^{III}Cl_2]^+$ in which the ligand L_6^22M is tetradentate. This latter complex is reduced at 0.23V.

In the case of $[(L_6^22M)FeCl]PF_6$ (**2**), no extra Cl^- is available in solution to react with $[(L_6^22M)FeCl]^{2+}$ in which the L_6^22M ligand coordinates in a pentadentate fashion. As a matter of fact, this latter ferric complex is stable and can be easily detected. These electrochemical studies suggest that, although both complexes adopt the same structure at the ferrous level, they give different species on oxidation.

The electrochemical behaviour of these two complexes was also investigated in CH_3OH, and in both cases, the Fe^{II}/Fe^{III} system is completely irreversible. The complex $[(L_6^22M)Fe^{II}Cl]PF_6$ (**2**) reacts rapidly to form $[(L_6^22M)Fe^{III}(OCH_3)]^{2+}$ and $[(L_6^22M)Fe^{III}(OH)]^{2+}$. Such behaviour has already been observed for complexes with similar pentadentate ligands.[13,21] This indicates that the chloride ion is easily substituted in CH_3OH when the complex is in its ferric state. Following oxidation of $[(L_6^22M)Fe^{II}Cl_2]$ (**1**), the complexes $[(L_6^22M)Fe^{III}(OCH_3)]^{2+}$ and $[(L_6^22M)Fe^{III}(OH)]^{2+}$ are observed as for **2**. However, a third cathodic wave is detected at a lower potential (ca. 12 mV, see Supporting Information). By analogy with the study in CH_3CN, this latter wave is attributed to the reduction of $[(L_6^22M)Fe^{III}Cl_2]^+$. The chloride ions have such a high affinity for Fe^{III} even in CH_3OH that for $Cl^-/Fe = 2$, the bis-chloro-Fe^{III} complex is obtained.

Reactivity with H_2O_2

The reactivities of the complexes $[(L_6^22M)FeCl_2]$ and $[(L_6^22M)FeCl]PF_6$ with an excess of H_2O_2 was studied in CH_3OH by using a variety of techniques.

The reaction of H_2O_2 with $[(L_6^22M)FeCl]PF_6$ has previously been studied by Bernal et al. but no intermediate was clearly identified.[9] We present here a reinvestigation of this reaction. Addition of 100 equivalents of H_2O_2 to $[(L_6^22M)FeCl]PF_6$ in methanol at −40 °C resulted in the appearance of a low intensity band at 530 nm in the UV/Vis spectrum. This is attributed to a hydroperoxo-to-Fe^{III} charge transfer transition, with an energy similar to other low-spin $Fe^{III}-OOH$ species involving a ligand containing three pyridines coordinated to the metal.[6] The low intensity of the band indicates either a low conversion to Fe−OOH or a high instability of the hydroperoxo product. The maximum intensity is observed after ca. one hour (at −40 °C), which reflects a steady state for this intermediate, due to the large excess of H_2O_2. Similar behaviour was observed for $[(TPEN)FeCl]^+$ {TPEN = *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)ethane-1,2-diamine}, but a much more stable $Fe^{III}-OOH$ intermediate was obtained at room temperature.[8]

The EPR spectrum of the solution was recorded at 4 K. It exhibits several resonances that arise from more than one species (cf. Figure 3). A $g = 4.2$ signal is attributed to a high spin Fe^{III} degradation species (not shown in Figure 3).[22] Other resonances around $g = 2$ are characteristic of low-spin Fe^{III} complexes. Two sets of very close g values can be distinguished with $g_{max} = 2.2$ or 2.18; $g_{inter} = 2.12$ and 2.12; $g_{min} = 1.97$ or 1.96. Starting with the complex $[(L_6^22M)Fe(OH_2)](PF_6)_2$, Bernal et al. have observed identical values.[9] These sets of g values are characteristic of low-spin Fe^{III} in nearly axial symmetry, and are consistent with EPR data reported for low-spin $Fe^{III}-OOH$ entities.[6] For example, the Fe^{III} complex of the TPEN ligand exhibits g values of 2.22, 2.15, and 2.00.[8]

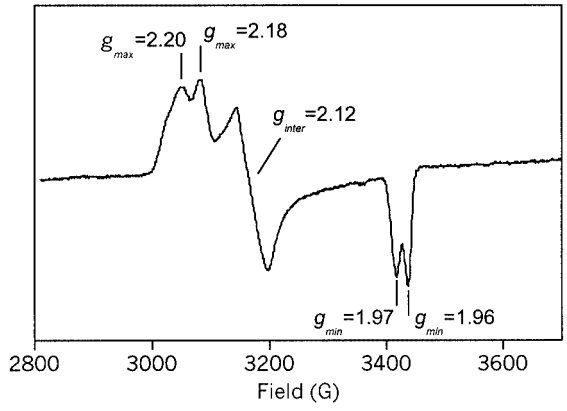


Figure 3. EPR spectrum of a mixture of $[(L_6^22M)Fe^{II}Cl]PF_6$ (**2**) and 100 equivalents of H_2O_2 in CH_3OH at 4 K

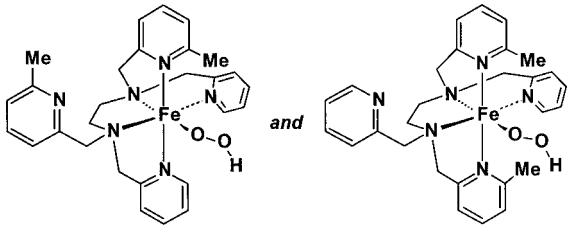
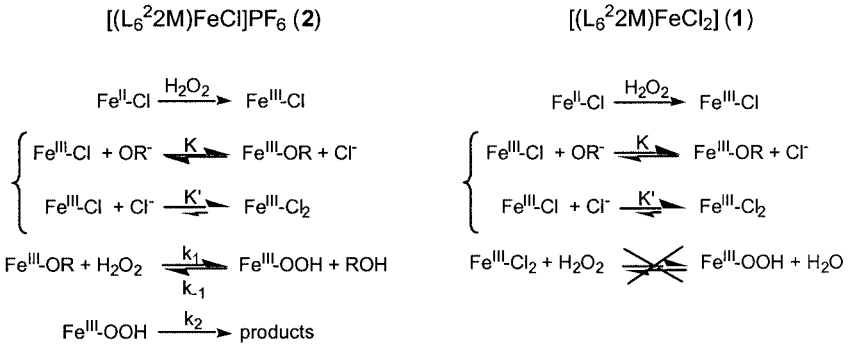
The simplest way to rationalise the presence of two close but different sets of g values is to propose two different coordination modes for the ligand L_6^22M. Indeed, the ratio of coordinated pyridines to coordinated methylated pyridines can be 1:2 or 2:1 when this ligand coordinates in a pentadentate fashion, as represented in Scheme 2.



Scheme 2. Proposed structures for the two low-spin intermediates of formula $[(L_6^22M)Fe(OOH)]^{2+}$

Starting with the complex $[(L_6^22M)FeCl_2]$ (**1**), no reaction intermediate was observed by UV/Vis spectroscopy at −40 °C even though it adopts a structure in solution ident-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3. Mechanism proposed for the reactivity toward H_2O_2 of complexes **1** and **2** (R=H or CH_3)

ical to that of complex **2** i.e. $[(L_6^22M)Fe^{II}Cl]^+$ (see above). The only difference between **1** and **2** is the presence of chloride ions in solution in the case of **1**. As shown by electrochemistry, oxidation of complex **1** leads to the formation of $[(L_6^22M)Fe^{III}Cl_2]^+$, in which the ligand coordinates in a tetradentate fashion. To the best of our knowledge, no reaction intermediate has ever been reported upon addition of H_2O_2 to a complex containing a linear tetracoordinate ligand.

The fact that $[(L_6^22M)FeCl]PF_6$ (**2**) but not $[(L_6^22M)FeCl_2]$ (**1**) has allowed to observe a low-spin mononuclear Fe−OOH intermediate, substantiates the mechanism we proposed for the formation of Fe−OOH intermediates.[13] In this paper, adjustment of kinetic data was made by considering very fast pre-equilibria to give a mononuclear Fe^{III} complex upon oxidation of the Fe^{II} precursor.[13] Here we propose that $[(L_6^22M)FeCl_2]$ is not able to give a mononuclear Fe−OOH complex since the ferric complex obtained contains the ligand L_6^22M bound in a tetradentate fashion following substitution of a pyridyl arm by a free chloride ion (cf. Scheme 3).

The statement that a mononuclear Fe−OOH is not obtained from complex **1** may not be rigorously true. Indeed, when complex **1** is oxidised in CH_3OH, it also gives the Fe^{III}−OH and Fe^{III}−OCH_3 complexes as in the case of **2**. These species are precursors of the Fe−OOH complex (cf. Scheme 3). However, since the conversion of **2** into the Fe−OOH is low as noted above, it will be even lower starting from complex **1**, and not observable under these experimental conditions.

Conclusion

We have synthesised two Fe^{II} complexes of the ligand L_6^22M. The crystal structure of neutral $[(L_6^22M)FeCl_2]$ (**1**) shows two chloride ions coordinated to the metal centre in *cis* positions and the potential hexadentate ligand coordinated in a tetradentate fashion. The complex $[(L_6^22M)FeCl]PF_6$ (**2**) contains the ligand bound in a pentacoordinate fashion, as revealed by UV/Vis and cyclic voltammetry. However, it probably exhibits two different coordination modes, with one pendant pyridine which may be either methylated or not methylated. Upon dissolution in acetonitrile or methanol, one chloride ion of $[(L_6^22M)FeCl_2]$ (**1**) is replaced by a nitrogen atom of a methylated pyridine group. Therefore, the two Fe^{II} complexes adopt similar structures in solution. Upon electrochemical oxidation in acetonitrile, $[(L_6^22M)FeCl]PF_6$ (**2**) gives its ferric analog whereas $[(L_6^22M)FeCl_2]$ (**1**) is subject to a fast EC mechanism to give $[(L_6^22M)Fe^{III}Cl_2]^+$ in which the ligand is tetracoordinate. When oxidised in MeOH, both **1** and **2** give $[(L_6^22M)Fe^{III}(OR)]^{2+}$ (R = H or CH_3), but a third complex, $[(L_6^22M)Fe^{III}Cl_2]^+$, is also observed for **1** with the ligand bound tetradentate.

These different structures at the Fe^{III} oxidation state are probably responsible for the different reactivities in the presence of H_2O_2. Two similar low-spin Fe^{III}−OOH intermediates have been characterised for $[(L_6^22M)FeCl]PF_6$ (**2**) upon reaction with H_2O_2 at −40 °C. These two Fe^{III}−OOH species very likely differ only in the number of coordinated methylated pyridines. The complexes reported here are unstable when compared to Fe^{III}−OOH complexes obtained with similar ligands. Compared to the parent ligand TPEN[8] the instability observed here may be related to the bulkiness of the L_6^22M ligand. Indeed it is likely that this ligand is not well adapted to the small Fe^{III} ion, due to steric congestion provided by the pyridine rings.

Starting from $[(L_6^22M)FeCl_2]$ (**1**) in MeOH, no intermediate could be detected under the same experimental conditions.

Although both Fe^{II} complexes have analogous structures in solution, their reactivities in the presence of H_2O_2 are different. This clearly establishes that the $Fe^{II} \rightarrow Fe^{III}$ oxidation is the first process occurring during the reaction between a ferrous complex and H_2O_2. The HOO^- ligand then reacts with the ferric complex obtained. The observations reported in this paper confirm the mechanism proposed to analyse the kinetic data of a similar low-spin Fe^{III}−OOH complex.[13]

Experimental Section

Materials: Starting materials were purchased from Acros. Solvents were purchased from Merck and used without further purification.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis of *N,N′*-bis(6-methyl-2-pyridylmethyl)-*N,N′*-bis(2-pyridylmethyl)ethane-1,2-diamine ($L_6^2$2M): This ligand was prepared following the method reported by Toftlund and Yde-Andersen.[23]

Synthesis of [($L_6^2$2M)$FeCl_2$] (1): This synthesis was performed by using Schlenk tubes and a vacuum-argon line. A solution of $L_6^2$2M (140 mg) in THF was added to a solution of $FeCl_2{\cdot}2H_2O$ (50 mg, 1.01 equiv.) in THF (10 mL) and a yellow powder rapidly precipitated. The reaction mixture was stirred for 30 minutes, the solvent was partially removed and the powder was isolated by filtration. Yield 86 mg (48%). Crystals suitable for structural determination were obtained by slow diffusion of *tert*-butyl methyl ether into an acetonitrile solution of the complex. Elemental analysis, found: C 58.43, H 5.30, Cl 12.47, N 14.15; calculated for $C_{28}H_{32}Cl_2FeN_6$ (579.4): C 58.12, H 5.58, Cl 12.1, N 14.53.

Synthesis of [($L_6^2$2M)FeCl]PF_6 (2): This synthesis was performed under an argon atmosphere as for complex **1** following the method reported by Bernal et al.[9] A methanol solution of $L_6^2$2M (515 mg) was added to a solution of $FeCl_2{\cdot}2H_2O$ (185 mg, 1 equiv.) in methanol (5 mL). The yellow solution was stirred for 15 minutes and $NaPF_6$ (200 mg, 2 equiv.) in methanol was then added. The majority of the solvent was removed and of to give a yellow powder. Yield 470 mg (50%). Elemental analysis, found: C 38.44, H 4.07, N 9.67; calculated for $C_{28}H_{32}N_6FeClPF_6{\cdot}NaPF_6{\cdot}H_2O$ (874.8): C 38.44, H 3.92, N 9.61.

Physical Measurements: Elemental analyses were performed by the Service Central d'Analyses du CNRS (Vernaison-France). UV/Vis spectra were recorded on a Varian Cary 300 Bio spectrophotometer at 20 °C with 1 cm quartz cuvettes. Stopped-flow experiments were performed with a Biologic SFM-300 equipped with a Julabo F 30C cryostat. Spectra were recorded in the range 200−1022 nm with a 0.5 cm optical path and a 50 μL cuvette. The delay after mixing is 3 ms. Cyclic Voltammograms were measured using an EGG PAR model M270 scanning potentiostat operating at scan rates of 10−1000 $mV{\cdot}s^{-1}$. Studies were carried out under an argon atmosphere in acetonitrile or methanol solutions using 0.2 M tBu_4NClO_4 (puriss grade, Fluka) as the supporting electrolyte, and 10^{-3} M of the complex. In order to minimise the amount of water contained in the system, the supporting electrolyte solution was dried over Al_2O_3 prior to use. The working electrode was a glassy carbon disk (0.32 cm^2) polished with 1 μm diamond paste. The reference electrode was Ag-$AgClO_4$ (0.3 V vs. SCE electrode) separated from the test solution by a salt bridge containing the solvent/supporting electrolyte, with a gold auxiliary electrode. All potentials are given vs. SCE electrode (0.241 V vs. NHE electrode).

Crystallographic Data Collection: The data were collected on a Nonius−Kappa-CCD area detector diffractometer by using graphite-monochromated Mo-K_α radiation. The lattice parameters were determined from ten images recorded with 2° -scans and later refined on all data. The data were recorded at 123 K. A 180° -range was scanned with 2° steps with a crystal to detector distance fixed at 30 mm. Data were corrected for Lorentz polarisation. The structure was solved by direct methods by using SHELXS[24] and refined by full-matrix least-squares on F^2 with anisotropic thermal parameters for all non H atoms using SHELXL-97.[25] H atoms were introduced at calculated positions as riding atoms with an isotropic displacement parameter equal to 1.2 (CH and CH_2) times that of the parent atom. The molecular plots were drawn by using SHELXTL.[26] All calculations were performed on a Silicon Graphics R10000 workstation. The crystal data and parameters for data collection are summarised in Table 3.

CCDC-199948 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information (see footnote on the first page of this article): Voltammograms of complexes (**1**) (- - -) and (**2**) (−) in CH_3OH at 20 °C.

COVER PICTURE

The cover picture shows the X-ray crystal structures of ruthenium and rhodium complexes of chiral 1,1′-bis(phosphetano)ferrocenes. These diphosphanes rank among the ligands inducing excellent enantioselectivities in rhodium-promoted hydrogenations of prochiral olefins. X-ray crystal structures of their metal complexes afford information about their coordinating behaviour and preferred conformations in catalytically active species. Details are discussed in the article by A. Marinetti et al. on p. 2583 ff.

Reactions of Dihydrogen(norbornadiene) Complexes

Guochen Jia,*[a] Zhenyang Lin,[a] and Chak Po Lau[b]

Keywords: Transition metals / Hydride ligands / Hydrogenations / Norbornadiene / Dihydrogen ligands

Dihydrogen(olefin) complexes have been proposed as active species in catalytic hydrogenation reactions. We have studied the hydrogen-transfer reactions of dihydrogen(olefin) complexes, especially those containing the norbornadiene (NBD) ligand, in order to address the following questions: (i) how the alignment of a H_2 ligand relative to an olefin ligand may affect their reactivity; (ii) in general, what is the detailed pathway for intramolecular hydrogen transfer from an H_2 ligand to an olefin ligand; and (iii) how will the hydrogen transfer reactions proceed in the presence of both an H_2 and a hydride ligand.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Over the last two decades, extensive studies have been carried out on dihydrogen transition metal complexes, especially on their syntheses and structural characterizations.[1,2] There has also been an interest in their reactivities and roles in catalysis.[3] Dihydrogen complexes of the types $[M(R)(H_2)L_n]$ and $[M(olefin)(H_2)L_n]$ have been proposed as intermediates in catalytic hydrogenation reactions.[4−7] As model complexes for reactions involving intramolecular hydrogen transfer from a coordinated dihydrogen ligand to the α-carbon atom of a σ-bonded carbon ligand, several dihydrogen complexes containing σ-bonded carbon ligands (e.g. alkynyl,[8] alkenyl,[9] and aryl[10]) have been synthesized in recent years. Intramolecular hydrogen transfer from a coordinated dihydrogen ligand to the α-carbon atom of the R

Guochen Jia (right) was born in China in 1962. He received his BSc degree in chemistry from the Wuhan University in 1983 and his PhD degree in 1989 from The Ohio State University in 1989 under the guidance of Professors Devon W. Meek and Andrew Wojcicki. After his postdoctoral stays with Professor Robert H. Morris at the University of Toronto and Professor Richard J. Puddephatt at the University of Western Ontario, he joined the Hong Kong University of Science and Technology as an assistant professor in 1992 and he is now an associate professor. His research interest includes transition-metal hydrides, vinylidenes, carbynes, metallabenzynes, carbon-rich organometallics, and homogeneous catalysis.

Zhenyang Lin (left) is now an associate professor at the chemistry department of the Hong Kong University of Science and Technology (HKUST). He received his BSc degree in chemistry from the Wuhan University of Geology in 1982 and his MPhil degree in 1985 from the Fujian Institute of Research on the Structure of Matter, Chinese Academy of Sciences. His doctoral research was carried out from October 1986 to August 1989 in the Inorganic Chemistry Laboratory of the University of Oxford under the supervision of Professor D. Michael P. Mingos. After his postdoctoral work with Professor Michael B. Hall at the Texas A&M University, he was appointed to an assistant professorship at HKUST in 1994. His research interest is in the area of theoretical/computational inorganic and organometallic chemistry.

Chak Po Lau (center) was born in Hong Kong and he received his undergraduate and graduate training in the United States. He earned his PhD under the guidance of the late Professor Carl H. Brubaker, Jr. at the Michigan State University in 1977. After his postdoctoral stay with the late Professor William E. Hatfield and Professor Maurice Brookhart at the UNC at Chapel Hill, he joined the Beijing Institute of Chemistry in China as an associated scientist. He returned to Hong Kong and became a lecturer at the then Hong Kong Polytechnic in 1983, and he is now Professor at the Department of Applied Biology & Chemical Technology of the Hong Kong Polytechnic University. His research interest includes homogeneous catalysis, transition-metal hydride chemistry, and hydrogen bond (dihydrogen bond) mediated chemical reactions.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

group in $[M(R)(H_2)L_n]$ has been demonstrated with well-defined dihydrogen complexes.[8–9]

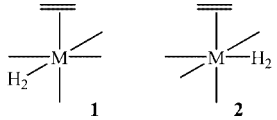
The current review is related to intramolecular hydrogen transfer reactions involving complexes of the type $[M(olefin)(H_2)L_n]$. The reactions are interesting because they are relevant to catalytic hydrogenation reactions. In addition, a detailed study on intramolecular hydrogen transfer from H_2 to olefin ligands may help to develop a field of chemistry based on the coupling of σ-bonds and unsaturated substrates.

In the past few years, we have tried to generate reactive dihydrogen(olefin) complexes in order to study the intramolecular hydrogen transfer from an H_2 ligand to olefin ligands. In particular, we wish to address the following questions.

(i) Structures **1** and **2** show two possible ways of arranging an H_2 ligand and an olefin ligand around a metal center if rotation of the olefin about the metal−olefin bond can effectively be restricted. With the restriction, the M−H_2 bond could be perpendicular to the olefin double bond (**1**) or parallel to the olefin double bond (**2**). The different arrangements of the H_2 ligand relative to the olefin ligand may affect the reactivity. This has been suggested by M. Poliakoff et al. when explaining the formation of norbornene (NBE) and nortricyclene in the photocatalytic hydrogenation of norbornadiene (NBD) using $[M(CO)_6]$.[11] We wish to see if similar reactions can also occur with other systems.

(ii) There are several possible pathways to transfer a dihydrogen ligand to an olefin ligand. For example, the dihydrogen ligand may undergo oxidative addition to give a dihydride intermediate before the hydrogen transfer; the hydrogen transfer reactions could proceed through a concerted mechanism (simultaneous transfer of the two hydrogen atoms to a double bond); or through a stepwise mechanism in which one of the hydrogen atoms from the coordinated H_2 is transferred to the olefin to give an alkyl(hydrido) complex, followed by reductive elimination. It is of interest to see which of the possible pathways is operative.

(iii) The presence of a hydride ligand in dihydrogen(olefin) complexes may affect the reactivity of the dihydrogen(olefin) complexes. It would be interesting to see how the hydrogen transfer reactions will proceed in the presence of both an H_2 and a hydrido ligand.



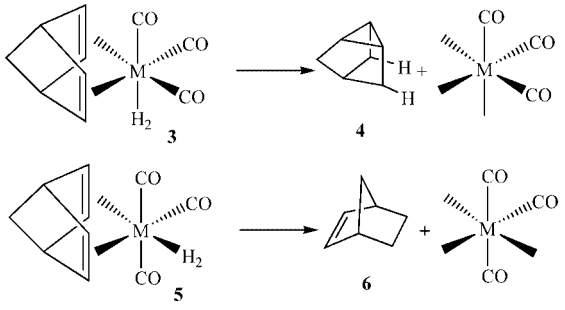
1 **2**

In this review, we will summarize the catalytic hydrogenation reactions involving dihydrogen(olefin) complexes and our recent work, aiming at addressing the above-mentioned questions.

Discussion

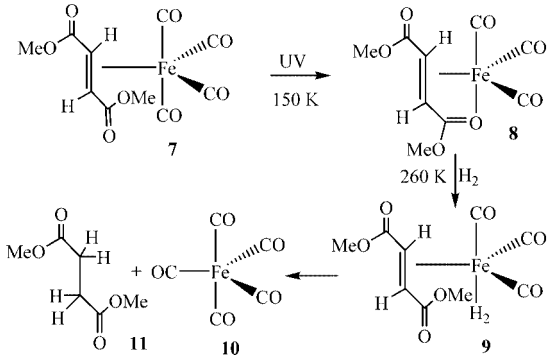
Dihydrogen(olefin) Complexes in Catalytic Hydrogenation

Catalytic hydrogenation reactions involving dihydrogen(olefin) complexes have been suggested for several systems. In some cases, the dihydrogen(olefin) intermediates have been detected. Complexes $[M(CO)_6]$ (M = Cr, Mo, and W)[11] are photocatalytically active for the hydrogenation of olefins. When norbornadiene is used as the substrate, the hydrogenation reactions give a mixture of norbornene and nortricyclene. After a detailed investigation by UV laser photolysis of $[M(CO)_6]$ and $[M(\eta^4\text{-NBD})(CO)_4]$ in the presence of H_2 and D_2, it was suggested that nortricyclene (**4**) is produced through the intermediates *fac*-$[M(H_2)(\eta^4\text{-NBD})(CO)_3]$ (**3**), while norbornene (**6**) is generated through the intermediates *mer*-$[M(H_2)(\eta^4\text{-NBD})(CO)_3]$ (**5**) (Scheme 1). Intramolecular hydrogen transfer within $[Cr(H_2)(\eta^4\text{-NBD})(CO)_3]$ is supported by the fact that the decay of the IR signals does not depend on the hydrogen pressure. Involvement of the dihydrogen intermediates in the hydrogenation reactions is also supported by an in situ NMR spectroscopic investigation of hydrogenation with parahydrogen.[12] A number of dihydrogen(olefin) complexes related to the catalytic system have been characterized by IR spectroscopy, e.g. *cis*-$[M(H_2)(\eta^2\text{-}C_2H_4)(CO)_4]$ (M = Cr, Mo, W), *mer*-$[M(H_2)(\eta^2\text{-}C_2H_4)_2(CO)_3]$ (M = Mo, W), *fac*-$[M(H_2)(\eta^4\text{-NBD})(CO)_3]$ (M = Cr, Mo, W), *mer*-$[M(H_2)(\eta^4\text{-NBD})(CO)_3]$ (M = Cr, Mo, W), and $[M(H_2)(\eta^2\text{-NBD})(CO)_4]$ (M = Mo, W).



Scheme 1

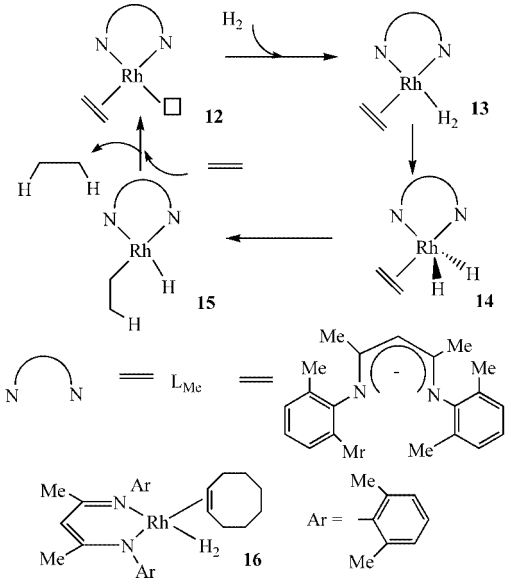
In a related study,[13] Poliakoff et al. studied the hydrogenation of dimethyl fumarate (DF) using $[Fe(CO)_4(\eta^2\text{-DF})]$ (**7**). When irradiated, **7** (in a polyethylene matrix) reacts with H_2 to give dimethyl succinate (**11**) and $[Fe(CO)_5]$ (**10**). The reaction sequence is shown in Scheme 2. The intermediates $[Fe(CO)_3(\eta^4\text{-DF})]$ (**8**) and $[Fe(CO)_3(H_2)(\eta^2\text{-DF})]$ (**9**) have been detected by FT-IR spectroscopy.



Scheme 2

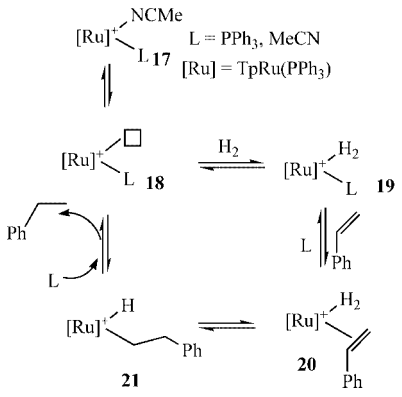
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Budzelaar et al. recently reported catalytic hydrogenation reactions using rhodium complexes, such as [L_{Me}Rh(CH_2=CH_2)$_2$], [L_{Me}Rh(COE)], and [L_{Me}Rh(COE)(CH_3CN)] [L_{Me} = (2,6-$C_6H_3Me_2$)NCMeCHCMeN(2,6-$C_6H_3Me_2$)].[14] The dihydrogen(olefin) complexes [Rh{(2,6-$C_6H_3Me_2$)-NCMeCHCMeN(2,6-$C_6H_3Me_2$)}(H_2)(olefin)] (**13**), which undergo oxidative addition reactions to give the dihydrido species **14**, were suggested as intermediates in the catalytic cycle, as shown in Scheme 3. The dihydrogen complex [Rh{(2,6-$C_6H_3Me_2$)NCMeCHCMeN(2,6-$C_6H_3Me_2$)}(H_2)-(COE)] (**16**) has been detected at low temperatures by NMR spectroscopy.



Scheme 3

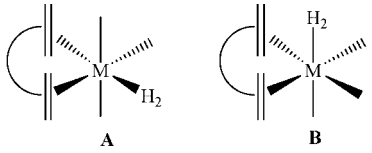
We have reported the catalytic hydrogenation of olefins using [Ru(Tp)(PPh_3)(L)(CH_3CN)]$^+$ (**17**) [Tp = hydrotris(1-pyrazolyl)borate; L = PPh_3, CH_3CN].[7] It was proposed that [Ru(Tp)(L)(H_2)(olefin)]$^+$ (**20**) is involved in the hydrogenation (Scheme 4), although the intermediate was not detected. It was suggested that the first hydrogen transfer might proceed through reactions analogous to the oxidative coupling of olefins.



Scheme 4

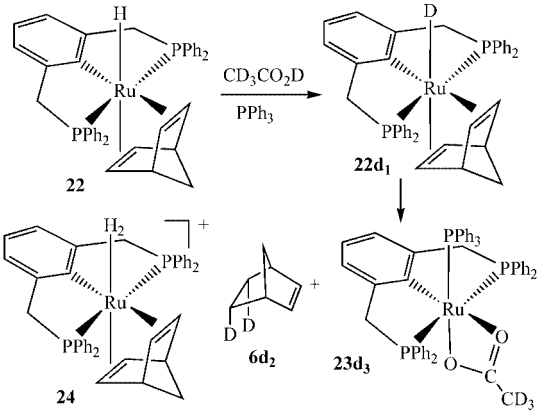
Modeling Reactions of Dihydrogen(olefin) Complexes

One of the main purposes of our work is to address how the relative arrangements of the H_2 and olefin ligands affect the hydrogen-transfer reactions. Structures **1** and **2** mentioned in the Introduction represent two ideal situations in which the olefin ligand has a specific orientational preference. However, monoolefin ligands do not necessarily show this kind of structural preference because the barriers of rotation about the metal-olefin bond are not prohibitively high.[15] Therefore, in our studies we have used diolefin ligands, such as NBD and COD, to restrict the rotation. Structures **A** and **B** show two possible structural isomers in which a diolefin ligand and an H_2 ligand are arranged in a *mer* and *fac* manner, respectively. Structure **A** models the structure of **1**, while structure **B** is closely related to structure **2**.



Complexes with a mer Arrangement of the H_2 and Diolefin Ligands

The protonation reactions of [RuH(NBD)(PCP)] (**22**) [PCP = 2,6-(PPh_2CH_2)$_2$$C_6H_3$] provide examples of studying the reactions of dihydrogen(olefin) complexes with a structural feature related to structure **1** (or **A**).[16] It was shown that protonation of complex **22** with excess CD_3CO_2D in the presence of PPh_3 gives [Ru(O_2CCD_3)(PPh_3)(PCP)] (**23d$_3$**) and partially deuterated (ca. 75% D in the *endo* positions) norbornene (see Scheme 5). The deuterium is only incorporated at the *endo* position of norbornene. In-situ NMR spectroscopic experiments revealed that Ru−H in **22** readily undergoes H/D exchange with CD_3CO_2D to give [RuD(NBD)(PCP)] (**22d$_1$**), and that the H/D exchange reaction is faster than the hydrogenation reaction.

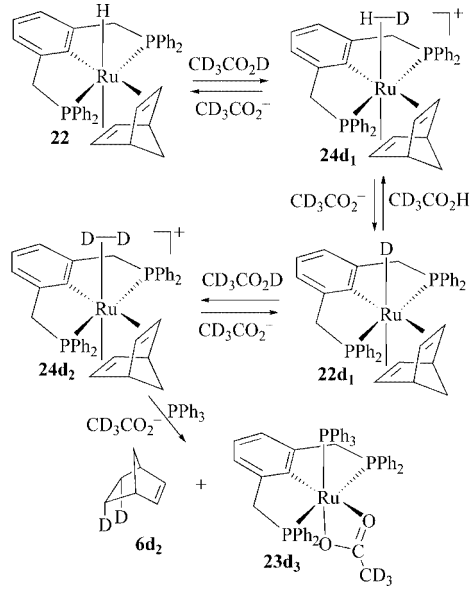


Scheme 5

Considering the fact that [RuH(H_2)(dppe)$_2$]$^+$ contains a dihydrogen ligand[17] and that norbornadiene (NBD) is less

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

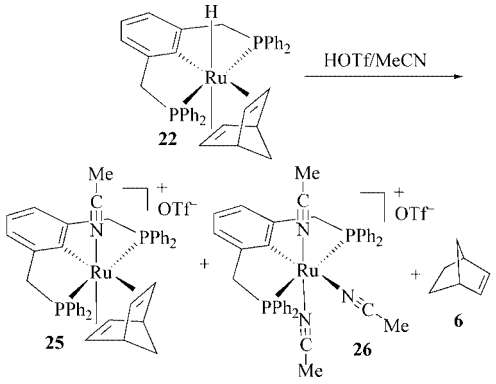
electron-donating than dppe, it was proposed that protonation of [RuH(NBD)(PCP)] (**22**) initially produces the dihydrogen complex $[Ru(H_2)(NBD)(PCP)]^+$ (**24**), which mediates the formation of norbornene and the H/D exchange reaction. A computational study[16] confirms that complex $[Ru(H_2)(NBD)\{2,6\text{-}(PH_2CH_2)_2C_6H_3\}]^+$ (**30**), a model complex of **24**, is indeed a typical octahedral dihydrogen complex, with a short H−H bond (0.868 Å). Scheme 6 shows the proposed mechanism for the H/D exchange reaction of **22** with CD_3CO_2D, and the formation of NBE in the protonation reactions with acetic acid. Reaction of **22** with CD_3CO_2D could produce the η^2-H−D complex $[Ru(HD)(NBD)(PCP)]^+$ (**24d$_1$**), which can then be deprotonated by $CD_3CO_2^-$ to give **22d$_1$**. The mechanism is similar to those proposed for the H/D exchange of $[W(D_2)(CO)_3(P\textit{i}Pr_3)_2]$ with H_2O,[18] and for the H/D exchange of $[Ru(Tp)(H_2)(PPh_3)_2]^+$ with D_2O.[7] Hydrogen transfer within $[Ru(H_2)(NBD)(PCP)]^+$ or its isotopomers would give NBE. For example, $[D_2]$NBE could be formed from $[Ru(D_2)(NBD)(PCP)]^+$ (**24d$_2$**) (Scheme 6). Such a proposition is consistent with the fact that protonation of **22** with CD_3CO_2D gave deuterated NBE in which the deuterium is at the *endo* positions of NBE.



Scheme 6

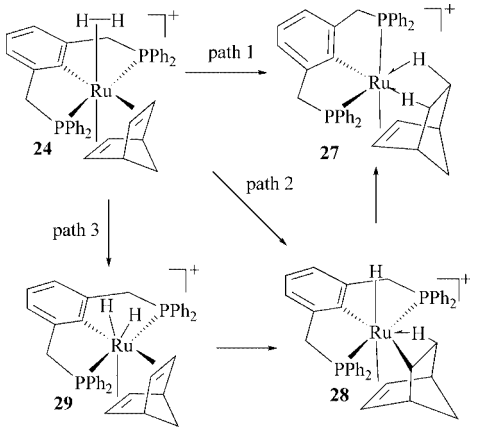
Protonation of **22** with HOTf in the presence of acetonitrile produces [Ru(MeCN)(NBD)(PCP)]OTf (**25**) and $[Ru(MeCN)_3(PCP)]$OTf (**26**), along with NBE (Scheme 7). Formation of [Ru(MeCN)(NBD)(PCP)]OTf (**25**) supports the proposition that protonation of **22** initially produces the dihydrogen complex **24**, as [Ru(MeCN)(NBD)(PCP)]OTf could be easily formed by displacement of the H_2 ligand in $[Ru(H_2)(NBD)(PCP)]$OTf using MeCN. Apparently, $[Ru(H_2)(NBD)(PCP)]$OTf also undergoes a hydrogen-transfer reaction in the presence of MeCN to give norbornene and $[Ru(MeCN)_3(PCP)]$OTf.

There are several possible reaction pathways for the hydrogenation of the NBD ligand in $[Ru(H_2)(NBD)$-



Scheme 7

$(PCP)]^+$. As shown in Scheme 8, the hydrogen transfer reactions could proceed by a concerted mechanism (simultaneous transfer of the two hydrogen atoms of the H_2 ligand to the double bond) (path 1); or through a stepwise mechanism in which one of the hydrogen atoms of coordinated H_2 is transferred to NBD to give the alkyl(hydrido) complex $[RuH(C_7H_9)(PCP)]^+$ (**28**), followed by reductive elimination (path 2); or via a dihydrido intermediate **29**, prior to hydrogen transfer (path 3).



Scheme 8

Density functional calculations at the B3LYP level of theory were performed to examine the favorable reaction pathway for the conversion of the model complex $[Ru(H_2)(NBD)\{2,6\text{-}(H_2PCH_2)_2C_6H_3\}]^+$ (**30**) to the assumed product $[Ru(NBE)\{2,6\text{-}(H_2PCH_2)_2C_6H_3\}]^+$ (**31**).[16] Here, **30** and **31** are the model complexes of **24** and **27** proposed in Scheme 8, respectively.

The results from the calculation[16] eliminate the oxidative addition product, the dihydrido complex **29**, as an intermediate. The dihydrido species was found to correspond to a transition state (see below). The results are understandable, since it is unlikely that a complex can have both a stable dihydrogen and a stable dihydrido form, without changing the geometry significantly (i.e. both forms correspond to a minimum on the potential energy surface). The calculations also eliminate the concerted pathway.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

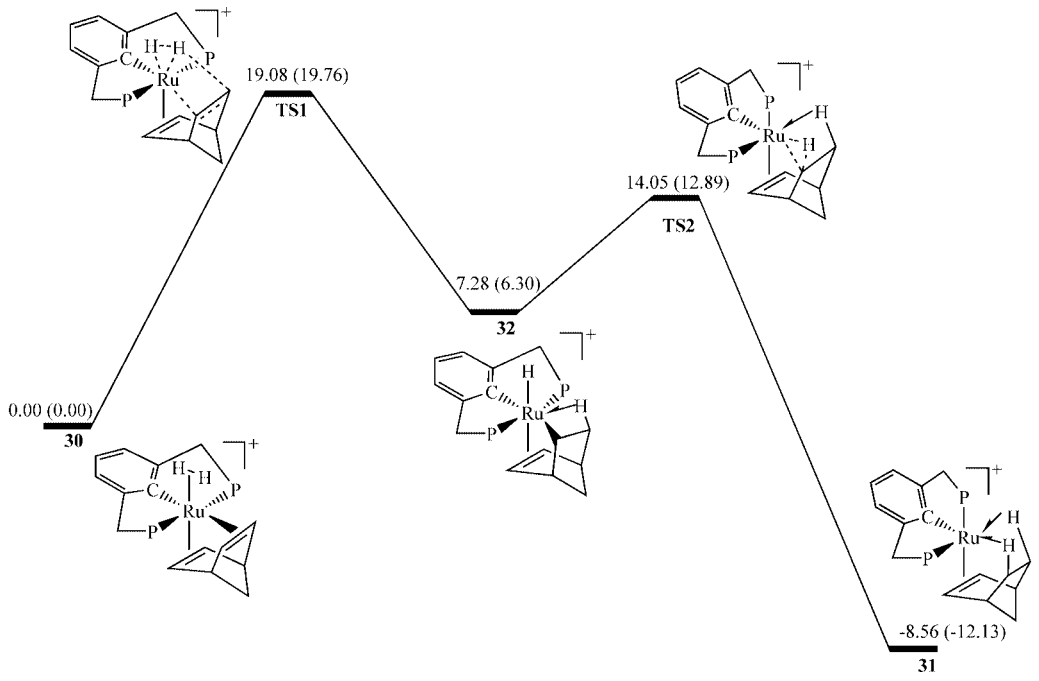


Figure 1. Schematic illustration of the reaction pathways of $[Ru(H_2)(NBD)(2,6\text{-}(PH_2CH_2)_2C_6H_3)]^+$, with calculated relative free energies [kcal/mol] and reaction energies [kcal/mol] (in parentheses), modified from ref.[16]

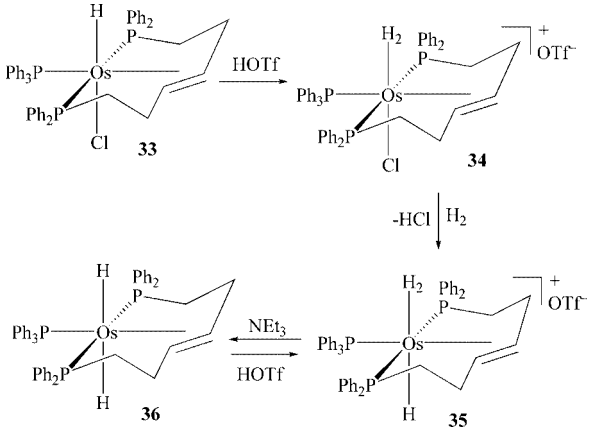
On the other hand, it was found that conversion of **24** to **27** through a stepwise process is feasible. Figure 1 shows the reaction steps for the conversion of **30** to **31** via **32** (the model complex of **28** proposed in Scheme 8), together with the relative free energies and reaction energies (in parentheses) calculated for all the species. The favorable stepwise mechanism involves two steps: one hydrogen atom of the coordinated H_2 ligand is transferred to NBD to form the pentagonal-bipyramidal intermediate **32** via the transition state **TS1**, with an energy barrier of 19.08 kcal/mol; the second hydrogen transfer then completes the hydrogenation of one of the two double bonds of NBD to form the NBE complex **31**, with a lower energy barrier of only 6.77 kcal/mol. As mentioned above, the first transition state (**TS1**) corresponds to a dihydrido species.

In another study on the reactivity of dihydrogen(olefin) complexes with a structural feature of **1** (or **A**), the protonation reaction of $[OsClH(PPh_3)\{Ph_2P(CH_2)_2CH{=}CH(CH_2)_2PPh_2\}]$ (**33**) has been investigated.[19] Protonation of **33** with HOTf produces the dihydrogen(olefin) complex $[OsCl(H_2)(PPh_3)\{Ph_2P(CH_2)_2CH{=}CH(CH_2)_2PPh_2\}]OTf$ (**34**), which has been characterized by NMR spectroscopy (Scheme 9).

Interestingly, the coordinated olefin double bond in **34** could not be hydrogenated, even when a solution of **34** in CD_2Cl_2 was stored under a H_2 (1 atm) for 1 d. Instead, the fluxional hydrido(dihydrogen) complex $[OsH(H_2)(PPh_3)\{Ph_2P(CH_2)_2CH{=}CH(CH_2)_2PPh_2\}]OTf$ (**35**) is slowly produced when **34** is exposed to H_2. Protonation of $[OsH_2(PPh_3)\{Ph_2P(CH_2)_2CH{=}CH(CH_2)_2PPh_2\}]$ (**36**) with HOTf also produces **35**. The coordinated olefin double bond in **35** could not be hydrogenated either.



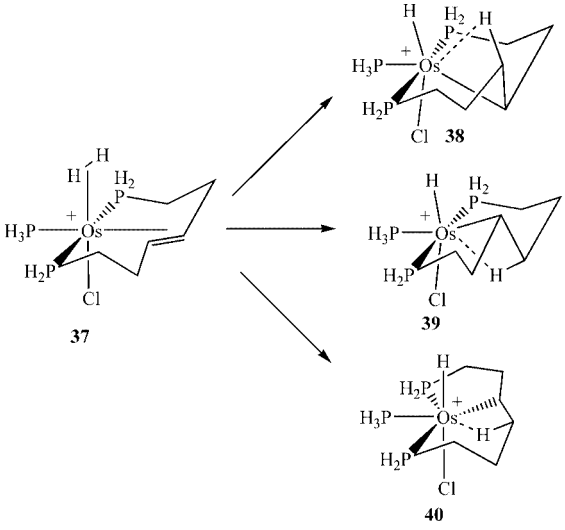
Scheme 9

These unexpected results were also examined by a computational study.[19] The calculated free energy change ($\Delta G°$) for the process, **37** + H_2 → $[OsCl(H_2)(PH_3)\{H_2P(CH_2)_6PH_2\}]^+$ (a model complex for the hydrogenated product of complex **34**), is ca. −1.0 kcal/mol, suggesting that the hydrogenation is thermodynamically feasible.

The computational study[19] found that the reaction was kinetically unfavorable, due to the constraint imposed by the $Ph_2P(CH_2)CH{=}CH(CH_2)_2PPh_2$ ligand. The reasons for the kinetically unfavorable reaction have been explained as follows. The optimized model complex $[OsCl(H_2)(PH_3)\{H_2P(CH_2)_2CH{=}CH(CH_2)_2PH_2\}]^+$ (**37**) contains an H_2 ligand with an H−H distance of 1.011 Å. The coordinated −HC=CH− unit is orientated in such a way that one olefinic carbon atom is closer to the η^2-H_2 ligand, while the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

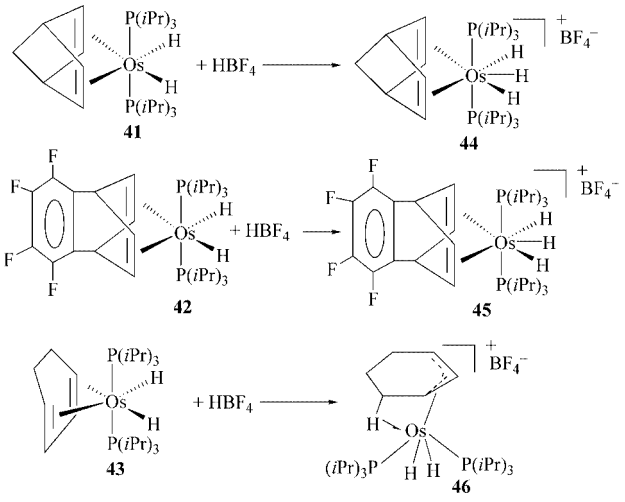
other is further away. The possible intermediates (Scheme 10), which can lead to the hydrogenation product by a reductive elimination step, are all inaccessible due to the conformational constraint imposed by the $Ph_2P(CH_2)_3CH(CH_2)_2PPh_2$ ligand. **38** does not correspond to a minimum on the potential energy surface. In addition, the separation of the hydrido and the bonded alkyl ligands prevents the reductive elimination, which leads to a hydrogenated product. The activation energy leading to **39** is calculated to be as high as 50 kcal/mol since the hydrogen-receiving carbon atom is further away from the η^2-H_2 ligand in the starting dihydrogen complex (**37**). Once again, **40** is not a local minimum as the five ligands in the pseudo-pentagonal-bipyramidal structure are all sterically bulky. The situation is different from the PCP system. The PCP ligand is more flexible in terms of its coordination arrangement, and can stabilize an intermediate (see Figure 1) in which both the agostic H−C and the bonded alkyl group are *cis* to the hydrido ligand, allowing further reductive elimination.



Scheme 10

The results discussed above suggest that whether an dihydrogen(olefin) complex in which an H_2 ligand is *cis* to both carbon atoms of an olefinic group (structure **1** or **A**) would undergo hydrogen transfer or not, depends on the structures of the intermediates formed after the first hydrogen transfer. If a relatively stable intermediate, in which the hydrido and the bonded alkyl ligands are *cis* to each other, is formed, reductive elimination, which forms a bond between the hydrido and bonded alkyl ligands, becomes feasible. However, when the ligand environment does not allow such an intermediate to form, reductive elimination is not possible, therefore no hydrogenation reactions will proceed.

In a related study, Esteruelas et al. reported the protonation reactions of $[OsH_2(diolefin)(P\mathit{i}Pr_3)_2]$ (diolefin = NBD: **41**; tetrafluorobenzobarrelene: **42**; and 1,3-hexadiene: **43**).[20] Protonation of **41** and **42** with HBF_4 does not lead to hydrogen-transfer products, but gives the trihydrido complexes **44** and **45**, respectively. Protonation of **43** with HBF_4 gives the cyclohexenyl complex **46** (Scheme 11).

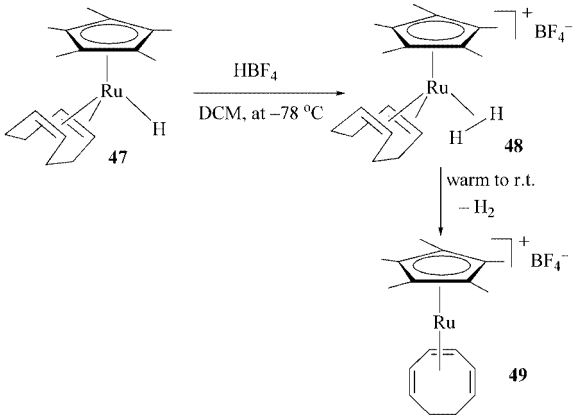


Scheme 11

Complexes with a fac Arrangement of the H_2 and Diolefin Ligands

The reactions of dihydrogen(olefin) complexes with a structural feature related to structure **2** (or **B**) have previously been suggested for *fac*-$[M(H_2)(\eta^4\text{-NBD})(CO)_3]$ (M = Cr, Mo, W).[11]

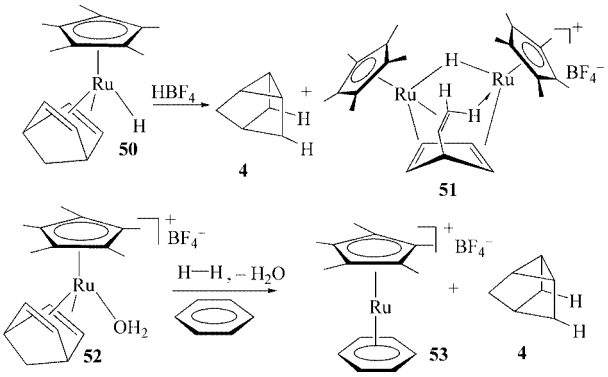
The protonation reactions of [Cp*RuH(diolefin)] have been studied in order to further model reactions of dihydrogen(olefin) complexes with a structural feature related to structure **2** (or **B**).[21] Protonation of [Cp*RuH(COD)] (**47**) at −76 °C with HBF_4 produces the thermally unstable dihydrogen(olefin) complex $[Cp^*Ru(H_2)(COD)]BF_4$ (**48**), which was characterized by NMR spectroscopy at low temperature.[21] On warming up to room temperature, complex **48** undergoes a dehydrogenation reaction to give [Cp*Ru(η^6-cyclooctatriene)]BF_4 (**49**), rather than a hydrogenation reaction (Scheme 12). The successful characterization of **48** suggests that a dihydrogen complex can be obtained through protonation of [Cp*RuH(diolefin)].



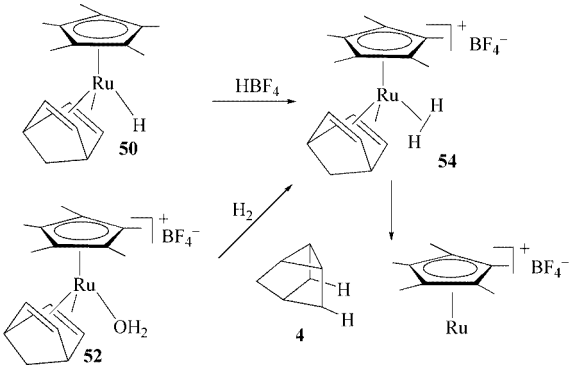
Scheme 12

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Protonation of [Cp*RuH(NBD)] (**50**) in dichloromethane produces nortricyclene (**4**) and the dimetallic complex **51**.[21] Nortricyclene is also formed, along with the η^6-benzene complex **53**, when a benzene solution of [Cp*Ru(H_2O)(NBD)]BF_4 (**52**) is exposed to H_2 (Scheme 13).[22] Since the complex [Cp*Ru(H_2)(COD)]$^+$ contains a dihydrogen ligand, it was proposed that the reaction of [Cp*Ru(H_2O)(NBD)]BF_4 with H_2, or protonation of [Cp* RuH(NBD)], initially gives the dihydrogen complex [Cp* Ru(H_2)(NBD)]BF_4 (**54**), which undergoes a hydrogen-transfer reaction to give nortricyclene (**4**) and a [Cp*Ru]$^+$ fragment (Scheme 14). In dichloromethane, the [Cp*Ru]$^+$ fragment reacts with **50** to give the dimetallic complex **51**. In benzene solution, the [Cp*Ru]$^+$ fragment is trapped with benzene producing complex **53**.



Scheme 13



Scheme 14

The detailed reaction steps were examined by a computational study.[22] Complex [CpRu(H_2)(NBD)]$^+$ (**55**), a model complex of **54**, was calculated to be a typical dihydrogen complex with an H−H distance of 0.854 Å. Once again, a stepwise mechanism was found to be responsible for the hydrogen-transfer reaction of the model complex **55**, to give **57**. The computed energy profiles for the reactions are illustrated in Figure 2. In the hydrogen transfer reaction, the first hydrogen atom is transferred from the η^2-H_2 ligand to one of the olefinic carbon atoms, leading to the formation of the hydrido intermediate **56**, which contains an agostic interaction. The hydrogen transfer reaction occurs with an energy barrier of 5.5 kcal/mol. The first transition state **TS3** corresponds to a dihydrido species. The energy barrier for the first hydrogen-transfer step is much less than that of the PCP system described above. It is understandable that reductive elimination to give NBE could not proceed from intermediate **56** as the hydrido ligand and the alkyl carbon atom are separated by a C−H agostic ligand. On the other hand, the hydrido ligand can transfer to the other olefinic functionality with a very small energy barrier. The reactions of H_2 with NBD, to give nortricyclene, are both kinetically and energetically very favorable.

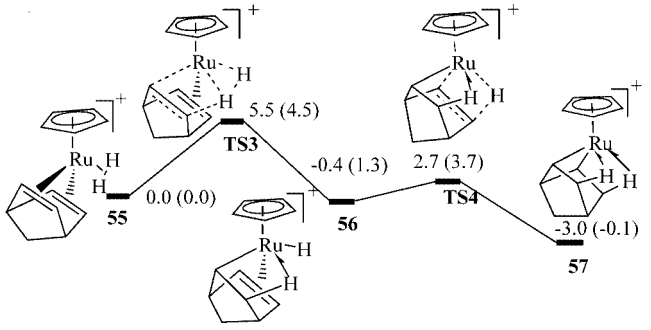


Figure 2. Schematic illustration of the reaction pathways of [CpRu(H_2)(NBD)]$^+$, with calculated relative free energies [kcal/mol] and reaction energies [kcal/mol] (in parentheses), modified from ref.[22]

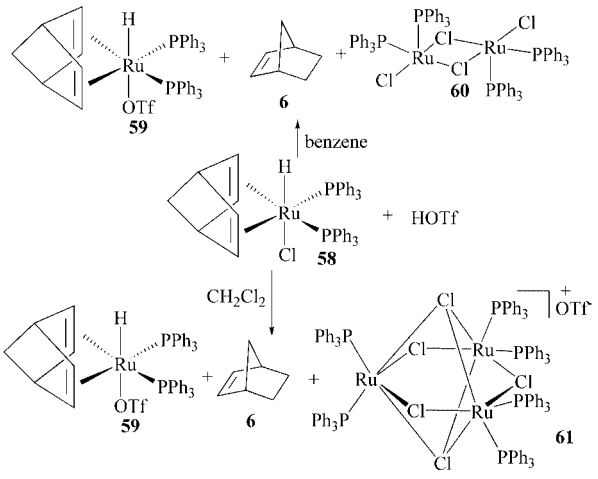
Reactions of dihydrogen(olefin) complexes with a structural feature related to **2** (or **B**) have also been studied through the protonation reactions of [RuH(Cl)(NBD)(PPh_3)$_2$].[23] Protonation of ruthenium complexes [RuH(X)L_4] {L_4 = (dppe)$_2$, X = Cl, Br;[24a,24b] L_4 = (dppp)$_2$, X = Cl;[24c] L_4 = (dcpe)$_2$, X = Cl;[24d] L_4 = (PPh_3)[2,6-(Ph_2PCH_2)$_2$$C_5H_3N$], X = Cl[25]} are known to give dihydrogen complexes of the type [M(X)(H_2)L_4]$^+$. Thus, it was expected that protonation of [MH(Cl)(NBD)(PPh_3)$_2$] could also produce the dihydrogen complex [MCl(H_2)(NBD)(PPh_3)$_2$]$^+$, which may undergo hydrogenation to produce nortricyclene, as in the case of *fac*-[M(H_2)(η^4-NBD)(CO)$_3$] (M = Cr, Mo, W)[11] and [Cp* Ru(H_2)(NBD)]$^+$.[21,22]

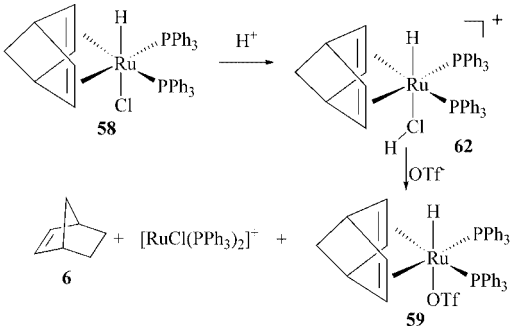
Interestingly, the expected hydrogenation product nortricyclene is not produced when [RuH(Cl)(NBD)(PPh_3)$_2$] (**58**) is protonated. Instead, protonation of **58** in C_6D_6 with a limiting amount of HOTf gives [RuH(OTf)(NBD)(PPh_3)$_2$] (**59**), norbornene (**6**) and [$RuCl_2$(PPh_3)$_2$]$_2$ (**60**) (Scheme 15). Protonation of **58** in dichloromethane with a limiting amount of HOTf gives [RuH(OTf)(NBD)(PPh_3)$_2$] (**59**), norbornene (**6**) and the unusual trimetallic complex [Ru_3Cl_5(PPh_3)$_6$]OTf (**61**). In these protonation reactions, the hydrido complex [RuH(OTf)(NBD)(PPh_3)$_2$] is presumably formed by protonation of the Cl ligand. The dimetallic complex [$RuCl_2$(PPh_3)$_2$]$_2$ (**60**) and the trimetallic complex [Ru_3Cl_5(PPh_3)$_6$]OTf (**61**) are presumably formed from the reaction of [RuCl(PPh_3)$_2$]$^+$ (generated whilst forming norbornene) with HCl {generated by protolysis of the chloride ligand of **58** to give [RuH(OTf)(NBD)(PPh_3)$_2$]}.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



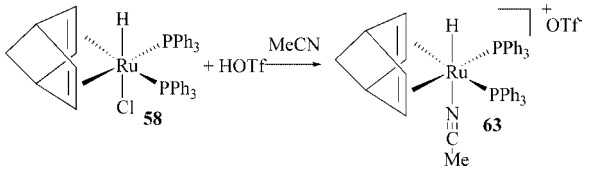
Scheme 15

In view of the fact that *fac*-[$M(H_2)(\eta^4$-NBD)$(CO)_3$] (M = Cr, Mo, W)[11] and [Cp*Ru(H_2)(NBD)]$^+$ [21,22] undergo hydrogen-transfer reactions to give nortricyclene, it was proposed that NBE may not be produced via the intermediate [RuCl(H_2)(NBD)$(PPh_3)_2]^+$. Instead, the formation of norbornene in the protonation reaction was thought to be related to the protonation of the chloro ligand (Scheme 16). Protonation of the chloro ligand could give the hydrogen chloride complex [RuH(HCl)(NBD)$(PPh_3)_2]^+$ (**62**), which can then undergo a hydrogen-transfer reaction to give NBE. A substitution reaction involving **62** would give [RuH(OTf)(NBD)$(PPh_3)_2$] (**59**). Protonation of halogeno ligands[26] has been observed during the protonation reactions of chloro(hydrido) complexes such as [PtHCl[P(tBu)$_2$Me]$_2$],[26] [$OsH_2Cl_2(P$*i*Pr$_3)_2$],[27a] and [OsH_2Cl(NO)(P*i*Pr$_3)_2$].[27b] Although well-characterized hydrogen halide complexes are still rare,[28] many alkyl halide complexes [M(XR)L_n][29] and halogeno complexes with an intra- or intermolecular MX···H interaction[30] have been reported.



Scheme 16

Protonation of the chloro ligand is supported by the following observations. [RuH(OTf)(NBD)$(PPh_3)_2$] was produced as one of the protonation products. In the presence of CH_3CN in C_6D_6 or CD_2Cl_2, [RuH(Cl)(NBD)$(PPh_3)_2$] (**58**) reacts rapidly with HOTf to give [RuH(CH_3CN)-(NBD)$(PPh_3)_2$]OTf (**63**) as the only product [Equation (1)].



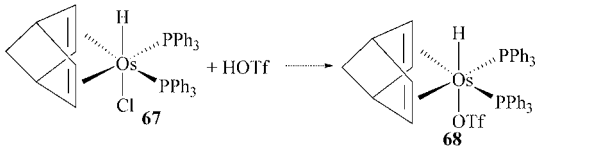
(1)

Involvement of the hydrogen chloride complex **62** in the formation of norbornene is consistent with the deuterium-labeling experiment, where protonation of [RuH(Cl)(NBD)$(PPh_3)_2$] with DOTf produced deuterated norbornene, in which the deuterium atom is at the *endo* position. This suggests that the deuterium atom is transferred to the olefin from the same side of the ruthenium center.

The feasibility of hydrogenation through the intermediate [RuH(HCl)(NBD)$(PPh_3)_2]^+$ was further supported by a computational study.[23] Calculations reveal that the model complex [RuH(HCl)(NBD)$(PH_3)_2]^+$ (**64**) is a reasonable species with a long Ru−Cl distance (2.838 Å) and that hydrogenation from the intermediate is both thermodynamically and kinetically favorable.

Figure 3 presents the energy profiles for the detailed reaction pathways starting from the hydrogen chloride complex **64** and the dihydrogen complex **64′**. The two starting complexes have comparable stability. The results from the calculation indicate that the reaction pathway starting from the hydrogen chloride complex **64** is both kinetically and thermodynamically more favorable than the pathway starting from the dihydrogen complex **64′**. The reaction pathway starting from the dihydrogen complex **64′** has to overcome two consecutive energy barriers, and gives the less stable precursor complex **66′** which leads to the formation of nortricyclene. One can conclude that the chloro ligand is indeed assisting the hydrogenation process by placing a hydrogen atom at a position proximal to the olefin ligand, through the HCl ligand. Clearly, the presence of the chloro ligand suppresses the formation of nortricyclene by the reaction starting from the dihydrogen complex.

In contrast to [RuH(Cl)(NBD)$(PPh_3)_2$], protonation of [OsH(Cl)(NBD)$(PPh_3)_2$] (**67**) with a limiting amount of HOTf in benzene or dichloromethane only produces [OsH-(OTf)(NBD)$(PPh_3)_2$] (**68**) [Equation (2)]. Neither norbornene, nor nortricyclene, were observed in the protonation reactions. The different reactivities of the Os and Ru complexes has been attributed to the stronger metal−olefin interaction in the osmium complex and therefore, the Os−NBD bonds remain intact in the reactions.



(2)

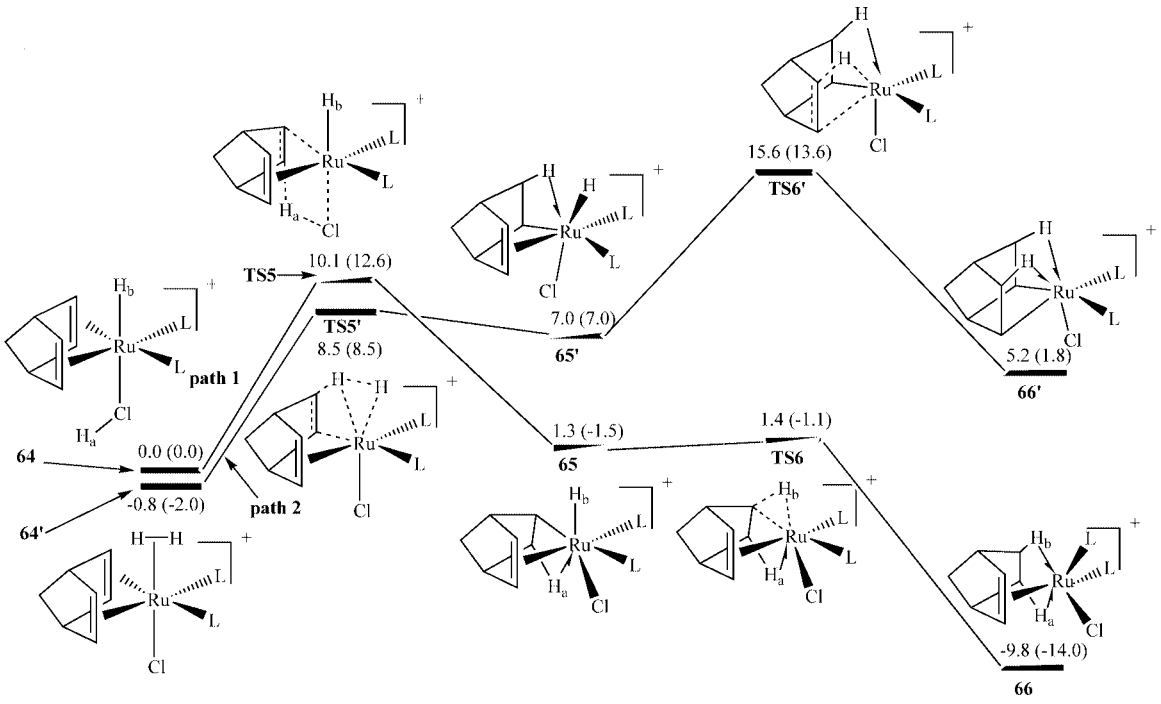


Figure 3. Schematic illustration of the reaction pathways of $[RuCl(H_2)(NBD)(PH_3)_2]^+$ and $[RuH(HCl)(NBD)(PH_3)_2]^+$, with calculated relative free energies [kcal/mol] and reaction energies [kcal/mol] (in parentheses), modified from ref.[23]

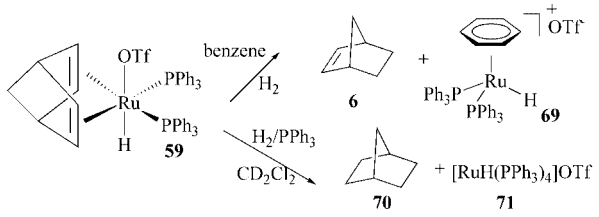
Dihydrogen(olefin) Complexes with an Additional Hydrido Functionality

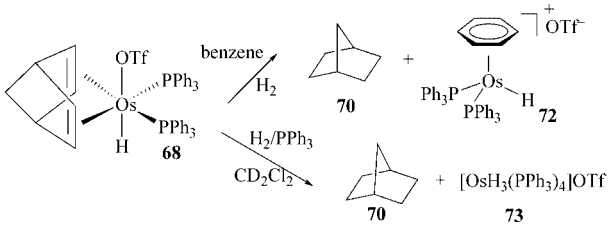
One might ask how the hydrogen transfer reaction will proceed in the presence of both H_2 and a hydrido ligand. Thus, the reactions of H_2 with $[MH(OTf)(NBD)(PPh_3)_2]$ (M = Ru, Os) have been carried out in order to answer the question.[31]

In benzene, complex $[RuH(OTf)(NBD)(PPh_3)_2]$ (**59**) reacts with H_2 to give norbornene (**6**) and the hydrido complex $[(\eta^6\text{-}C_6H_6)RuH(PPh_3)_2]OTf$ (**69**). In the presence of added PPh_3, complex **59** reacts with H_2 to give norbornane (**70**) and $[RuH(PPh_3)_4]OTf$ (**71**) (Scheme 17).



Scheme 17

The complex $[OsH(OTf)(NBD)(PPh_3)_2]$ (**68**) also reacts with H_2 in benzene to give norbornane (**70**) and the hydrido complex $[(\eta^6\text{-}C_6H_6)OsH(PPh_3)_2]OTf$ (**72**) (Scheme 18). In CD_2Cl_2 at room temperature, complex **68** reacts with H_2 in the presence of added PPh_3 to give norbornane and $[OsH_3(PPh_3)_4]^+$ (**73**).



Scheme 18

Since triflate is a weakly coordinating ligand that can readily be displaced under mild conditions,[32] and since a number of dihydrogen complexes of the type $[MH(H_2)(L_4)]^+$ (M = Ru, Os; L = phosphorus ligands) have previously been well characterized,[33] it was suggested that the first step of the reactions of $[MH(OTf)(NBD)(PPh_3)_2]$ with H_2 is to displace the triflate anion in $[MH(OTf)(NBD)(PPh_3)_2]$ with an H_2 molecule. This gives the dihydrogen complexes $[MH(H_2)(NBD)(PPh_3)_2]^+$ (M = Ru, Os), which lead to the hydrogenation of the NBD ligand. The norbornane is presumably formed by further hydrogenation of norbornene.

Density functional theory calculations[31] on the model complexes $[MH(H_2)(NBD)(PH_3)_2]^+$ (M = Ru, Os) confirm that complexes $[RuH(H_2)(NBD)(PH_3)_2]^+$ (**74**) and $[OsH(H_2)(NBD)(PH_3)_2]^+$ (**75**) are all typical dihydrogen complexes in which the nonclassical η^2-H_2 ligand is *trans* to the hydrido ligand and have short H−H distances of 0.793 and 0.831 Å, respectively. The related complex

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

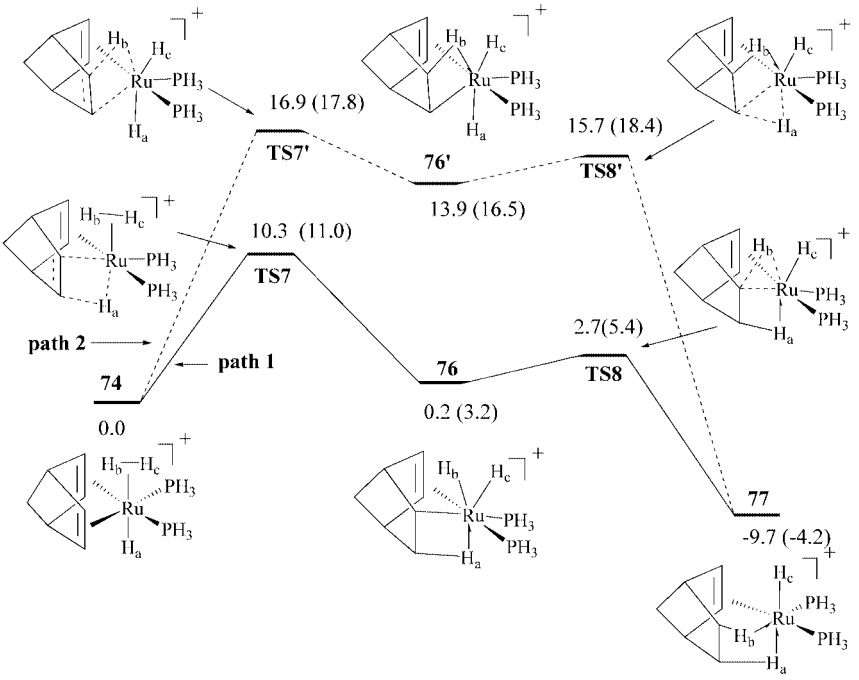


Figure 4. Schematic illustration of the reaction pathways of $[RuH(H_2)(NBD)(PH_3)_2]^+$, with calculated relative free energies [kcal/mol] and reaction energies [kcal/mol] (in parentheses), modified from ref.[31]

$[OsH_3(NBD)(P\mathit{i}Pr_3)_2]^+$, where the two phosphane groups are *trans* to each other, is known to adopt a trihydrido structure.[20]

There are two possible routes for the hydrogenation of the NBD ligands in the dihydrogen complexes $[MH(H_2)(NBD)(PPh_3)_2]^+$ (M = Ru, Os): the NBD ligand can be hydrogenated by transfer of the first hydrogen atom either from the hydrido or the dihydrogen ligand to the olefin ligand, followed by transfer of the second hydrogen atom to give norbornene.

The computational study[31] shows that the hydrogen transfer reactions of $[MH(H_2)(NBD)(PPh_3)_2]^+$, i.e. the conversion of the model complex $[RuH(H_2)(NBD)(PH_3)_2]^+$ (**74**) to $[RuH(NBE)(PH_3)_2]^+$ (NBE = norbornene) (**77**), favors a pathway (Path 1 in Figure 4) starting with the hydrogen transfer from the hydrido ligand (H_a), followed by the cleavage of the dihydrogen ligand to form a *cis*-dihydrido intermediate **76**. The second hydrogen atom is then transferred from one (H_b) of the two hydrido ligands to complete the hydrogenation, giving the coordinated NBE complex **77**.

The overall lower activation energies of Path 1 compared with those of Path 2 have been related to the structures of the transition states **TS7** and **TS7′**.[31] The first transition state **TS7** of Path 1 is a nonclassical complex with a slightly longer H_b-H_c distance (0.841 Å). However, the first transition state **TS7′** of Path 2 has a much longer H_b-H_c distance (1.387 Å), and typical Ru−hydrido distances, notably $Ru-H_a$ and $Ru-H_c$. The short Ru−H distances suggest that **TS7′** could be considered as a trihydrido species, with two hydrido ligands (H_a and H_c) *trans* (or nearly *trans*) to each other. This trihydrido structure, compared with that of **TS7**, has a relatively high energy because of the strong *trans* influence between H_a and H_c. The *trans* influence of a hydrido ligand weakens the metal−ligand interaction at the position *trans* to it, and thus destabilizes the system.[34]

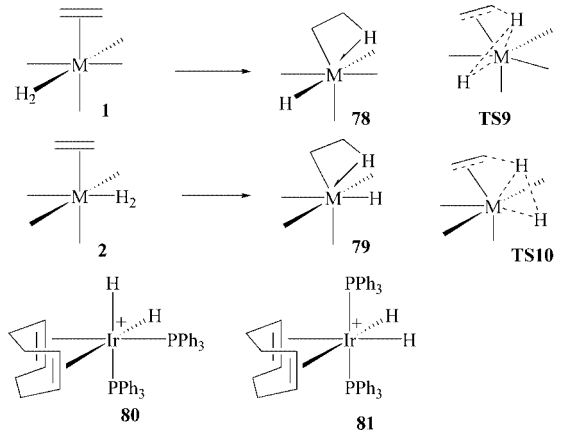
Conclusion

Dihydrogen(olefin) complexes have been proposed as active species in catalytic hydrogenation reactions. Hydrogen-transfer reactions of dihydrogen(olefin) complexes have been modeled with reactive dihydrogen(NBD) complexes, with different orientations of the olefin ligands relative to the H_2 ligand. They have also been studied by computational methods.

In the modeling reactions, the hydrogen transfer does not proceed through simultaneous transfer of the H_2 ligand to the olefin ligands, but through a stepwise pathway. Dihydrogen complexes in which the $M-(H_2)$ bond is perpendicular to the olefin double bond (**1**) can transfer the first hydrogen atom of an H_2 ligand to an olefin ligand, to give an alkyl(hydrido) intermediate (**78**) in which the hydrido ligand is *cis* to an alkyl bond (Scheme 19). The intermediate can then transfer the second hydrogen atom to the substrate by reductive elimination, to form a bond between the hydrido and the bonded alkyl ligands, thus giving the normal hydrogenated products. Dihydrogen complexes in which the $M-(H_2)$ bond is parallel to the olefin double bond (**2**) can transfer the first hydrogen atom of an H_2 ligand to an olefin ligand to give a alkyl(hydrido) intermediate (**79**) in which the hydrido ligand is separated from the alkyl bond by an agostic C−H bond. Reductive elimination from this inter-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mediate is difficult as the hydrido ligand and the alkyl carbon atom are separated by the C−H agostic ligand. Instead, the hydrido ligand can transfer to other olefin ligands, if present, and lead to other products. The reaction energy barrier for the first hydrogen transfer for complexes with a structural feature related to **2** is found to be smaller than that for complexes with a feature of structure **1**. The situation is similar to the insertion reactions of **80** and **81**, where **80** undergoes insertion reactions 40 times faster.[35]



Scheme 19

In the first proton-transfer step, the dihydrido species in most cases of our studies were found to be transition states (rather than intermediates) in which one of the hydrido ligands has a weak interaction with the receiving carbon atom. In the transition state, the olefinic double bond is also lengthened relative to that in the starting complex. These transition states are denoted **TS9** and **TS10**. The first step of the hydrogen transfer reaction is similar to the oxidative coupling of olefins or acetylenes, as illustrated by Equation (3), for the conversion of **82** to **83**.[36] An interesting question can be asked as to whether other σ-ligands (e.g. C−H, Si−H, B−H) can undergo similar reactions with unsaturated substrates, such as olefins, acetylenes and ketones.

(3)

The presence of other ligands may affect the hydrogen-transfer reactions. For example, in the hydrogen-transfer reactions of $[MH(H_2)(NBD)(PPh_3)_2]^+$ (M = Ru, Os), the first hydrogen transfer from the hydrido ligand is preferred over that from the dihydrogen ligand; in the protonation of $[RuHCl(NBD)(PPh_3)_2]$, the dihydrogen complex $[MCl(H_2)(NBD)(PPh_3)_2]^+$ is not involved in the hydrogenation.

This article discussed the hydrogen-transfer reactions of dihydrogen(olefin) complexes in which the olefin ligands have a specific orientational preference. The study showed that intramolecular hydrogen transfer from dihydrogen to olefin ligands is feasible for dihydrogen(olefin) complexes in which the $M-H_2$ bond is perpendicular to the olefin double bond or parallel to the olefin double bond. It is expected that hydrogen-transfer reactions should also occur for complexes in which the olefin can rotate "freely", although further work is needed to confirm this.

A Novel One-Dimensional Chain Complex Composed of Oxo-Centered Trinuclear Manganese Clusters

Jinkwon Kim,*[a] Jin Mook Lim,[b] and Youngkyu Do*[b]

Keywords: Magnetic properties / Manganese / Oxo ligands / Clusters

A new linear chain complex of oxo-centered trinuclear manganese clusters, $[\{Mn^{III}_2Mn^{II}O(O_2CCHCl_2)_6(H_2O)\}\{Mn(O_2CCHCl_2)_2(H_2O)_4\}]_n$ (**1**), has been synthesized by treatment of a mixture of $Mn(OAc)_2{\cdot}4H_2O$ and dichloroacetic acid in dichloromethane with $KMnO_4$. In this complex chains are formed by hydrogen bonding between carboxylate oxygens and coordinated water molecules, forming a two-dimensional structure. Antiferromagnetic coupling was observed by variable-temperature magnetic measurements.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

In the past few decades manganese chemistry has attracted much attention for the design of a new class of clusters for two reasons: first, to develop polynuclear manganese clusters as models for the water oxidation center of photosynthetic electron-transport chains in plants,[1] and second, to design new single-molecule magnets.[2] The first single-molecule magnetic behavior was observed in $[Mn_{12}O_{12}(OAc)_{16}(H_2O)_4]$ in 1993.[3] Single-molecule magnets (SMMs), as a prototype of nanomagnets, display an intramolecular magnetic hysteresis loop: each independent molecule in these materials possesses the ability to function as a magnetizable magnet owing to its intrinsic intramolecular properties rather than intermolecular interactions and long-range ordering.[4]

In the course of recent exploration of new manganese cluster complexes,[5] many oxo-centered trinuclear manganese carboxylate clusters with the common composition $[Mn_3O(O_2CR)_6L_3]$ have been synthesized and their physical properties studied extensively as model complexes for elucidating intramolecular electronic and magnetic interactions in clusters.[6−11] Furthermore, they have been used as a rich source of polynuclear complexes with a variety of interesting structural and physical properties.[12−14] Recently, we have focused our efforts on finding various synthetic routes to develop polynuclear manganese carboxylate clusters and were successful in synthesizing new Mn_6, Mn_8 and Mn_{18} clusters.[15,16] As part of our continuing interests to prepare new manganese clusters, we have studied the reaction of $Mn(OAc)_2{\cdot}4H_2O$ with $KMnO_4$ in the presence of an excess amount of dichloroacetic acid in dichloromethane. Herein, we report the synthesis and magnetic properties of an unprecedented linear-chain complex of oxo-centered trinuclear Mn clusters $[\{Mn^{III}_2Mn^{II}O(O_2CCHCl_2)_6(H_2O)\}\{Mn(O_2CCHCl_2)_2(H_2O)_4\}]_n$ (**1**).

Results and Discussion

The reaction mixture of $Mn(O_2CMe)_2{\cdot}4H_2O$ and dichloroacetic acid in dichloromethane solvent was treated with a fine powder of $KMnO_4$ with vigorous stirring to afford a dark brown solution. It is interesting to note that the same reaction in aqueous media gives $[Mn_{12}O_{12}(O_2CHCl_2)_{16}(H_2O)_4]$,[15] meaning that an aqueous medium provides a more acidic environment suitable for stabilizing higher oxidation state of manganese. Crystals suitable for X-ray crystallography were obtained by slow diffusion of *n*-pentane into a dichloromethane solution of **1**.

Complex **1** crystallizes in the monoclinic space group $P2_1/n$. The asymmetric unit of **1**, as depicted in Figure 1, consists of an oxo-centered trinuclear $[Mn_3(\mu_3\text{-}O)]^{6+}$ core and an $[Mn(H_2O)_4]^{2+}$ moiety. The manganese ions of the mixed-valent $[Mn^{II}Mn^{III}_2(\mu\text{-}O)]^{6+}$ core are bridged by six dichloroacetate ligands. The $[Mn(H_2O)_4]^{2+}$ moiety is bridged by Mn3 and the neighboring Mn1′ through dichloroacetates with a *syn-anti* conformation. One terminal water molecule is coordinated to Mn2 to give an octahedral geometry. On the basis of Jahn−Teller distortions and bond-valence sum calculations,[17,18] two manganese ions (Mn1 and Mn2) were assigned to Mn^{III}. The axial Mn1−O17 and Mn1−O13 bonds [1.830(5) and 1.951(5) Å, respectively] are shorter than the other equatorial bonds

[2.034(5)−2.096(5) Å] due to Jahn−Teller contraction, while the axial Mn2−O4 and Mn2−O7 bonds [2.124(6) and 2.244(6) Å, respectively] are rather longer than the other equatorial bonds [1.818(5)−1.989(5) Å] due to a Jahn−Teller elongation effect. The Mn^{II} ions (Mn3 and Mn4) have uniform Mn−O bond lengths [Mn3−O: 2.119(6)−2.179(5) Å; Mn4−O: 2.149(7)−2.220(6) Å]. The μ_3-O atom is essentially coplanar with the Mn_3 plane, with an O17−Mn_3 plane separation of only 0.002 Å. The oxo-bridged $Mn^{III}\cdots Mn^{III}$ distance of 3.224(2) Å is shorter than the oxo-bridged $Mn^{II}\cdots Mn^{III}$ distances of 3.401(2) and 3.467(2) Å, which are similar to a known $[Mn^{II}Mn^{III}_2(\mu\text{-}O)]^{6+}$ core.[8] The carboxylate-only bridged $Mn^{II}\cdots Mn^{II}$ distances are 4.893(2) Å and 4.899(2) Å. The adjacent chains are significantly associated via hydrogen bonding between the coordinated water molecule and the carboxylate oxygen atoms, as illustrated in Figure 2. The O···O distances of these hydrogen bonds are within the range 2.631(9)−3.067(9) Å. The interchain Mn···Mn distances of adjacent chains are 5.116 Å for Mn2···Mn2# ($-x$, $1-y$, $-z$) and 5.117 Å for Mn4···Mn4# ($1-x$, $-y$, $-z$), indicating significant magnetic interactions between the chains.

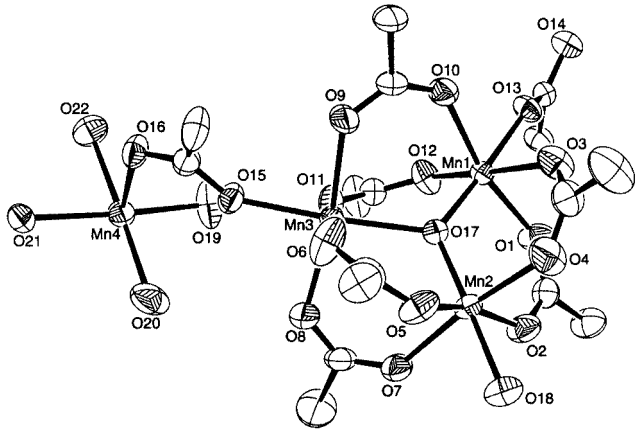

Figure 1. ORTEP diagram of **1** with atom numbering scheme; chlorine and hydrogen atoms are omitted for clarity; selected distances (A): Mn1···Mn2 3.224(2), Mn1···Mn3 3.467(2), Mn2···Mn3 3.401(2), Mn3···Mn4 4.899(2), Mn1··· Mn4# (x, $y-1$, z) 4.893(2)

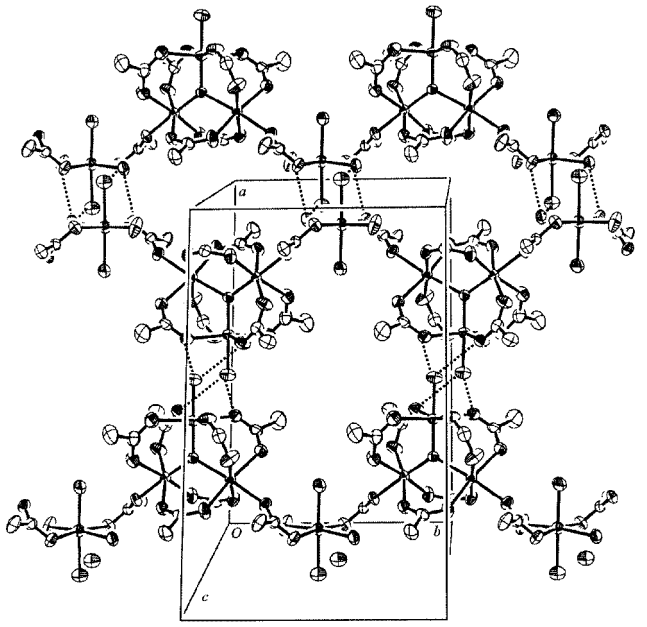

Figure 2. View down the *c*-axis showing the two-dimensional structure via interchain hydrogen bonding; chlorine atoms are omitted for clarity

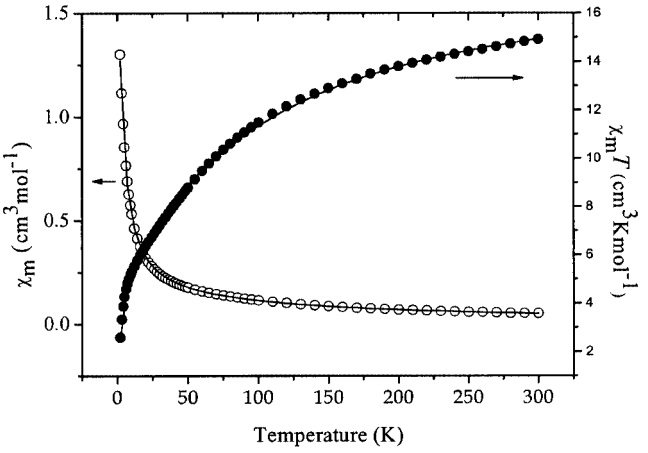

Figure 3. Temperature dependence of χ_{mol} (○) and χ_mT (·) at 500 Oe; the solid line represents the best fit of the data according to Equation (4)

Variable-temperature magnetic susceptibility data were measured for compound **1** from 2.0 to 300 K at 500 Oe. The resulting plot of χ_mT versus T for **1** is given in Figure 3. The χ_mT value is 14.9 $cm^3\cdot K\cdot mol^{-1}$ at 300 K, which is in good agreement with the spin-only value expected for high-spin, non-interacting $Mn^{II}_2Mn^{III}_2$ ions.

The spin Hamiltonian for the isotropic magnetic exchange interaction in a trinuclear Mn_3O unit is given in Equation (1).

$$\hat{H} = -2[J_{12}(\hat{S}_1\cdot\hat{S}_2) + J_{23}(\hat{S}_2\cdot\hat{S}_3) + J_{31}(\hat{S}_3\cdot\hat{S}_1)] \quad (1)$$

In complex **1**, there are two exchange parameters, $J = J_{12} = J_{31}$ for Mn^{II}-Mn^{III} interactions and $J' = J_{23}$ for the Mn^{III}-Mn^{III} interactions. The molar susceptibility is given by Equation (2) for the ground-state total spin of 1/2.[10] In this expression, the Weiss constant, θ, is introduced to roughly simulate interactions of paramagnetic species. Equation (3) represents the theoretical model for an $[Mn(H_2O)_4]^{2+}$ site. The intrachain exchange interaction of Mn^{II}-Mn^{II} might be quite weak, considering that the coupling constant has been estimated as only -0.20 cm^{-1} in a linear chain Mn^{II} complex bridged by a carboxylate ligand with a *syn-anti* bonding mode.[19] Furthermore, hydrogen-bond-mediated magnetic interactions between manganese ions are also weak.[20] Thus, based on these facts, the expected χ_mT value of **1** can be modeled with Equation (4).

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$\chi_{Mn_3O} = \frac{N\mu_B^2 g^2}{3k(T-\theta)} F(T;J,J') \quad (2)$$

$$\chi_{Mn} = \frac{N\mu_B^2 g^2}{3k(T-\theta)} S(S+1) \quad (3)$$

$$\chi_m = \chi_{Mn_3O} + \chi_{Mn} \quad (4)$$

The susceptibility data are fitted reasonably well by Equation (4), as shown in Figure 3. The fitting parameters are $J = -5.95$ cm^{-1}, $J' = -9.52$ cm^{-1}, $g = 2.16$, $\theta = -2.4$ K. The J, J', and g values are similar to the values for other mixed-valent $Mn^{II}Mn^{III}{}_2O$ complexes.[8] The θ value of −2.4 K implies that paramagnetic centers such as the $[Mn(H_2O)_4]^{2+}$ moiety and the Mn_3O units interact antiferromagnetically through intrachain bridging carboxylate bonds as well as interchain hydrogen bonds.

Experimental Section

General Remarks: All reagents and solvents were purchased from commercial sources and used as received. Elemental analysis was carried out by the Analytical Laboratory of the Korea Basic Science Institute, Seoul. Infrared spectra were recorded on a Perkin−Elmer 16 PC spectrophotometer. Variable-temperature magnetic susceptibility measurements were carried out on a crystalline sample of **1** in the 2−300 K temperature range using a Quantum Design MPMS*XL* susceptometer equipped with a 50 kG magnet at magnetic fields of 500 Oe. The correction for the diamagnetism of the complex was estimated from Pascal's constants, and the magnetic data were corrected for diamagnetic contributions of the sample holder.

Preparation of 1: $Mn(O_2CMe)_2{\cdot}4H_2O$ (2.02 g, 8.16 mmol) and dichloroacetic acid (12 mL) were dissolved in 8 mL of dichloromethane and treated with a fine powder of $KMnO_4$ (0.51 g, 3.2 mmol) with vigorous stirring to afford a dark brown solution. After filtration to remove insoluble impurities a large amount of pentane was added to give a dark brown solid. Dark brown single crystals for X-ray analysis were obtained by slow diffusion of pentane into a dichloromethane solution of **1** at room temperature. $C_{16}H_{18}Cl_{16}Mn_4O_{22}$ (1349.3): calcd. C 14.24, H 1.34; found C 14.18, H 1.35. IR (KBr): $\tilde{\nu}$ = 1677(vs), 1663(vs), 1623(vs), 1599(vs), 1396(vs), 1227(m), 956(w), 926(s), 781(m), 714(s), 676(s), 550(w) cm^{-1}.

X-ray Crystallographic Study: A dark brown crystal (0.30 × 0.30 × 0.20 mm^3) was selected and mounted on a glass fiber. Intensity data were collected on an Enraf−Nonius CAD4 Diffractometer equipped with monochromated Mo-K_α radiation (λ = 0.71073 Å). Unit-cell parameters were determined from a least-squares fit of 25 accurately centered reflections. These dimensions and other parameters, including conditions of data collection, are summarized in Table 1. Data were collected at 293 K in the ω/2θ scan mode. The absorption correction was performed by a semi-empirical psi-scan. The structure was solved by direct methods using the SHELXS-97 and refined with SHELXL-97 by full-matrix least-squares methods on F^2.[21] All non-hydrogen atoms were refined anisotropically, while the hydrogen atoms were included in their calculated positions. The C−H bond lengths were fixed and the U values were assigned based approximately on the U value of the attached atom. CCDC-207185 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

A Novel Three-Dimensional Metal-Organic Framework Constructed from Two-Dimensional Interpenetrating Layers Based on Trinuclear Cobalt Clusters: $[Co_3(btec)(C_2O_4)(H_2O)_2]_n$

Yang-Guang Li,[a] Na Hao,[a] En-Bo Wang,*[a,b] Ying Lu,[a] Chang-Wen Hu,[a] and Lin Xu[a]

Keywords: Hydrothermal synthesis / Carboxylate ligands / Cobalt / Coordination polymers / Magnetic properties

A novel coordination polymer $[Co_3(btec)(C_2O_4)(H_2O)_2]_n$ (**1**; btec = 1,2,4,5-benzenetetracarboxylate) has been hydrothermally synthesized and characterized by IR, XPS, XRPD, TG analysis and single-crystal X-ray diffraction. The structural analysis reveals that **1** exhibits a new three-dimensional metal-organic framework constructed from two-dimensional parallel interpenetrating networks based on trinuclear cobalt cluster building blocks. Such interpenetrating composite networks in **1** represent the first example in the {M-btec} (M = transition metal) system. Variable-temperature magnetic susceptibility measurements indicate an antiferromagnetic behavior in **1**.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The design and synthesis of infinite high-dimensional (especially two- and three-dimensional) metal-organic frameworks has attracted extensive interest in recent years, not only due to their intriguing structural motifs but also their potential applications in catalysis, molecular adsorption, and optical, electronic and magnetic materials.[1−2] Although it is not yet possible to prepare fully predictable metal-organic frameworks on the basis of rational design, recent exciting developments in coordination and organic chemistry provide great possibilities for the creative synthesis of desired novel frameworks.[3−5]

Among various metal-organic frameworks, the entangled structure, in which two or more infinite networks interpenetrate each other, is an attractive structural feature and has been widely researched.[6] In general there are two important factors for the formation of interpenetrating structures: one is that infinite networks contain large pores or cavities for interpenetration, and the other is that the individual 2-D networks should possess some appropriate elements of corrugation or undulation.[5] The use of long organic bridging ligands is often regarded as an effective strategy for the construction of such compounds.[7] In this aspect, organic aromatic polycarboxylate ligands, such as 1,4-benzenedicarboxylate and 1,3,5-benzenetricarboxylate, have been widely used in the construction of high-dimensional structures with large pores and/or undulated layers;[8] some interpenetrating frameworks have also been successfully prepared.[9] More recently, 1,2,4,5-benzenetetracarboxylate (btec) has proved to be a good candidate for assembling high dimensional metal-organic architectures owing to its two interesting structural features. In the first place, it contains multiple bridging moieties, which leads to a variety of connection modes with transitional metal centers and provides abundant structural motifs. Secondly, it can act both as a hydrogen-bond donor and as a hydrogen-bond acceptor due to the existence of protonated and/or deprotonated carboxyl groups.[10a] To date, a series of 2-D and 3-D metal-organic compounds in the {M-btec} (M = transition metal) system with large pores or undulated networks have been reported,[10] however, no interpenetrating structural feature in this system has hitherto been observed.

During our research on the hydrothermal synthesis of metal-organic frameworks in {M-btec} systems, another kind of organic bis-chelating oxalate ligand ($C_2O_4^{2-}$) has been introduced and a new coordination polymer, $[Co_3(btec)(C_2O_4)(H_2O)_2]_n$ (**1**), has been synthesized. Compound **1** exhibits a 3-D metal-organic framework consisting of 2-D interpenetrating networks on the basis of trinuclear cobalt cluster building blocks. To the best of our knowledge, compound **1** represents the first example in the {M-btec} system that possesses the interpenetrating structural feature. Furthermore, the btec ligand shows an unusual coordination mode linked with ten metal centers.

Results and Discussion

The hydrothermal reaction of an alkaline aqueous solution of $Co(C_2O_4)\cdot 2H_2O$, H_4btec and NaOH gives rise to

1 as purple block crystals. Single-crystal X-ray diffraction analysis revealed that **1** exhibits a novel 3-D metal-organic framework based on trinuclear cobalt cluster building blocks. The fundamental unit is shown in Figure 1. There are two crystallographically unique Co centers in the asymmetric unit, both displaying a distorted octahedral coordination geometry. The Co(1) center coordinates to four oxygen atoms of four different carboxylate groups, with $Co(1)-O_{(carboxyl)}$ distances in the range 1.9966(18)−2.0639(19) Å, and to two oxygen atoms of water molecules, with $Co(1)-O_{(water)}$ distances of 2.1991(19) Å. The O−Co(1)−O bond angles vary from 78.43(7)° to 180.00(14)°. The Co(2) center coordinates to three oxygen atoms of three different carboxylate groups [$Co(2)-O_{(carboxyl)}$ 2.0765(18)−2.1607(19) Å], two oxygen atoms of the oxalate ligand [$Co(2)-O_{(oxalate)}$ 2.0638(19)−2.131(2) Å] and one oxygen atom of a water molecule [$Co(2)-O_{(water)}$ 2.234(2) Å]. The O−Co(2)−O bond angles range from 75.71(7)° to 174.70(8)°. The three $\{CoO_6\}$ octahedra are connected together to form a linear trinuclear Co cluster in an edge-sharing mode. In addition, four carboxylate groups of the btec ligand exhibit two kinds of coordination modes with Co centers, as shown in Scheme 1. Two carboxylate groups act as a bidentate ligand, bridging two Co centers, while the other two exhibit an unusual bidentate bridging mode, linking three Co centers. Thus, one btec ligand is connected to ten Co centers, which has rarely been observed in previous reports.[10h] Furthermore, the oxalate groups ($C_2O_4^{2-}$) act as a bidentate bridging ligand to link trinuclear Co clusters into an interesting 1-D undulated chain. All these undulated chains are further connected by the btec ligands to form a 2-D grid-like network with large pores, as shown in Figure 2. The pore size is ca. 9.16 × 10.03 Å. The most important structural feature of **1** is that two such individual 2-D grid-like networks are self-entangled to form an interesting 2-D parallel interpenetrating layer (see Scheme 2 and Figure S1). To the best of our knowledge, no interpenetrating composite

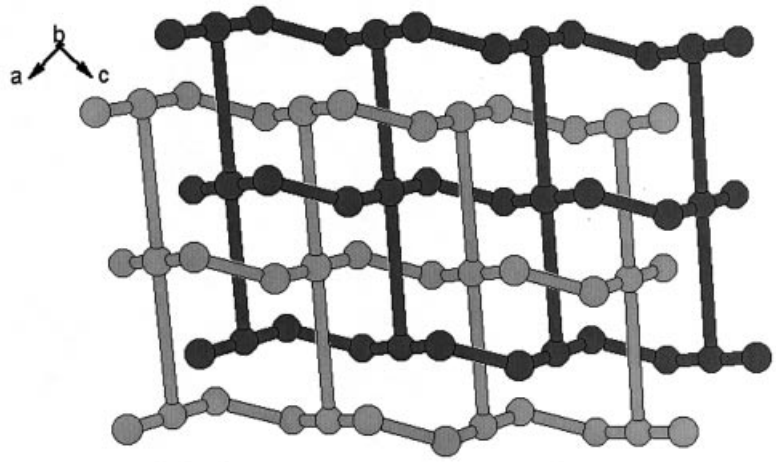

Scheme 2. Simplified schematic representation of the 2-D parallel interpenetrating network of **1** along the *b* axis

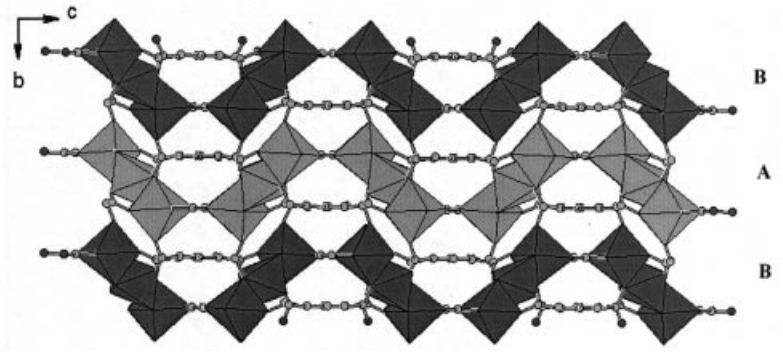

Figure 3. Polyhedral representation of the 3-D metal-organic framework of compound **1** viewed along the *a* axis; the light and dark colors represent two 2-D interpenetrating layers with different extending directions, respectively

network has hitherto been observed in the {M-btec} system. It is noteworthy that the presence of both large pores and an undulated element in the individual 2-D grid-like network provides the possibility of assembling interpenetrating architectures.

It is also interesting that these 2-D interpenetrating networks exhibit a wavelike layered structure along the *a* axis with each arched unit supported by the btec bridging ligand (see Figure 3). The adjacent 2-D interpenetrating layers extend perpendicular to each other in the *ac* plane and are alternately arranged in an ABAB mode along the *b* axis as shown in Figure 3. Thus, a 3-D metal-organic framework is formed by the connection of btec ligands (see Figure 3 and Figure S2).

The valence sum calculations of Co and O atoms are listed in Table S1. The bond-valence calculations (Co, 2.00) suggest all Co atoms are in the +2 oxidation state.[11] This result is also supported by an XPS measurement of the compound in the energy region of $Co2p^{1/2}$ and $Co2p^{3/2}$. The XPS spectrum (shown in Figure S3) gives one peak at 780.8 eV, attributable to Co^{2+}.[12] The O(1) atom has a bond-valence sum of 0.48, suggesting that it belongs to a coordinated water molecule. The O(2)−O(7) atoms have bond-valence sums of 1.90, 1.80, 1.92, 1.86, 1.85 and 1.81, respectively. These results indicate that all the oxygen atoms of the btec ligand and oxalate groups are deprotonated.[13] These results are consistent with the charge-balance considerations and alkaline synthetic conditions of compound **1**.

The variable-temperature magnetic susceptibility was measured from 2 K to 300 K at 5000 Oe for **1**. The magnetic data of **1** are displayed in Figure 4, plotted as the thermal variation of $\chi_m T$ and $1/\chi_m$. The $\chi_m T$ vs. T plot has a value of 9.32 emu·K·mol^{-1} at 300 K, and decreases continuously on cooling to a value of 0.54 emu·K·mol^{-1} at 2 K. The inverse susceptibility ($1/\chi_m$) plot as a function of temperature (T) is linear, closely following the Curie−Weiss law with C = 10.17 emu·K·mol^{-1}, corresponding to about one S = 3/2 spin per formula unit with g = 2.31 for Co^{II} centers. The effective magnetic moment per metal atom at 300 K, 4.47 μ_B, is in the range of experimentally observed values for high spin Co^{II} ions. The Weiss temperature, θ = −25.59 K, indicates that predominantly antiferromagnetic interactions exist between metallic Co^{II} centers. According to the structure of compound **1**, it could be presumed that the main magnetic interactions between the metal centers might happen in 1-D $\{Co_3(H_2O)_2(C_2O_4)\}$ chains, while the superexchange interactions between Co ions through the btec bridge can be ignored owing to the length of the btec ligands.[14]

The simulated and experimental XRPD patterns of compound **1** are shown in Figure S4. Their peak positions are

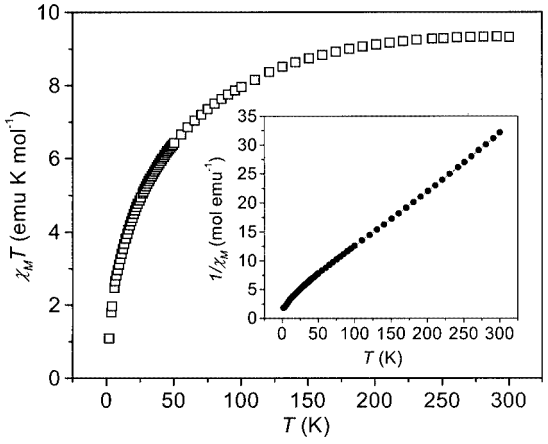

Figure 4. Thermal variation of $\chi_m T$ and $1/\chi_m$ for compound **1**

in good agreement with each other, indicating the phase purity of the products. The differences in intensity may be due to the preferred orientation of the powder samples. In the TG curve of compound **1** (see Figure S5), there is only one weight loss of 58.6% in the temperature range 200−450 °C, corresponding to the successive release of coordinated water, oxalate and btec ligands. Elemental analysis found that the brown residue might be CoO. The whole weight loss (58.6%) is in good agreement with the calculated value (59.2%).

Conclusion

In this work, a novel 3-D metal-organic framework $[Co_3(btec)(C_2O_4)(H_2O)_2]_n$ with 2-D parallel interpenetrating networks has been reported. Compound **1** is the first example in the {M-btec} system that possesses this interpenetrating structural feature. Both the large porous network and the undulated structural features are realized in the individual 2-D network (Figure 2) of **1** by the self-assembly of btec, $C_2O_4^{2-}$ and the linear trinuclear Co cluster building blocks, which provide great feasibility for the construction of interpenetrating network. The successful preparation of **1** indicates that metal-organic frameworks might be designed and synthesized according to specific structural features and inherent stereochemical and interactive information stored in the metal ions and organic ligands.[10a]

Experimental Section

Synthesis of 1: Compound **1** was synthesized from the reaction of $Co(C_2O_4)\cdot 2H_2O$ (0.091 g, 0.5 mmol), H_4btec (0.13 g, 0.5 mmol), NaOH (0.04 g, 1 mmol) and H_2O (8 mL, 444 mmol) in an 18 mL Teflon-lined autoclave under autogenous pressure at 160 °C for two days, followed by slow cooling (10 °C/h) to room temperature. The pH value of the reaction solution was ca. 8 and the final pH value was ca. 8.5. The product was washed with distilled water and air-dried at 50 °C. The product was of high quality in the form of purple block crystals (Yield: 0.079 g, 86% based on Co). $C_{12}H_6Co_3O_{14}$ (551.0): calcd. C 26.2, H 1.1, Co 32.1; found C 26.9, H 0.9, Co 31.9. Selected FT-IR data (KBr pellet): $\tilde{\nu}$ = 1638(s) cm^{-1}, 1589(s), 1509 (s), 1457(s), 1396(s), 1352(w), 1309(s), 1209(w), 1155(w), 1105(m), 915(s), 887(s), 836(s), 827(w), 808(w), 794(s), 763(w), 736(w), 698(w), 684(w), 635(w), 587(s), 535(s), 485 (s), 460 (w).

X-ray Crystallography: A purple crystal of **1** with dimensions of 0.578 ×0.378 × 0.258 mm^3 was glued onto a glass fiber. Data were collected on a Rigaku R-AXIS RAPID IP diffractometer with Mo-K_α monochromated radiation (λ = 0.71073 Å) at 93 K in the range of $2.12 < \theta < 27.12°$. An empirical absorption correction was applied.[15] The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2 with the SHELXL-97 software package.[16] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms on C atoms were located from difference electron-density maps. Crystal data: $C_{12}H_6Co_3O_{14}$, M_r = 550.96, orthorhombic, *Pbcn*, a = 7.0821(14), b = 12.557(3), c = 15.997(3) Å, $\alpha = \beta = \gamma = 90°$, U = 1422.6(5) Å^3, Z = 4, D_c = 2.572 gcm^{-3}, μ = 3.550 mm^{-1}, $F(000)$ = 1084, $R1$ = 0.0263, $wR2$ = 0.0831 and S = 1.065 for 1625 reflections with $I > 2\sigma(I)$ and 133 parameters ($R1$ = 0.0309, $wR2$ = 0.0845 for all 2988 data). CCDC-205531 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Introduction

Full-color electroluminescent displays require three color components — green, blue and red. Stable blue or red metal-organic coordination polymers useful in electroluminescent devices are still rare and challenging to prepare. However, organic polymers, such as poly(*p*-phenylene vinylene) and polythiophenes etc., permit color tuning through changes in their length, substitution, regioregularity, and degree of conjugation.[1] A common approach to control the emitted color of organic materials is to append fluorescent chromophores to a polymeric backbone or to blend dyes into inert polymeric matrices.[2] Similarly, the emission wavelength of most metal-organic complexes can be tuned or changed by adjusting the length or conjugation of ligand since fluorescent emission is mostly dominated by the coordinated ligand transition.[3,4] In addition, metal-organic fluorescent coordination polymers have many more advantages — such as high thermal stability, good mechanical properties and relatively high emitting intensity — over pure organic materials. These coordination polymers have thus attracted much attention recently.[5] The synthesis and rational design of suitable organic ligands is still a great challenge since the introduction of special physical properties can be achieved through conjugation of the ligand, combined with the crystal engineering strategy and hydro(solvo)thermal synthesis method.[6] Furthermore, 8-quinolinolate complexes of, for example, Al^{3+} and Be^{2+} and their derivatives have also attracted much attention due to their potential application for full-color, flat-panel displays.[7] To this end, the hydrolysis reactions of $Cd(ClO_4)_2 \cdot (6H_2O)$ with 4-[2-(2-pyridyl)ethenyl]benzonitrile (2-PEBN) and 2-[2-(4-cyanophenyl)ethenyl]-8-quinolinol (2-CEQH) under hydrothermal reaction conditions afford two different emitting color fluorescent coordination polymers, aquabis{4-[2-(2-pyridyl)ethenyl]benzoate}cadmium(II) (**1**) and 2-[2-(4-carboxylatophenyl)ethenyl]-8-quinolinolate(pyridine)cadmium(II) (**2**) (Scheme 1), respectively. Complexes **1** and **2** display strong blue and red fluorescent emission, respectively. Interestingly, both **1** and **2** have a 2-D grid framework containing a dimer as corner unit. To the best of our knowledge, **1** is the first example of a double-square grid while **2** also has an unusual herringbone-type network with a dimer as the connecting node. Herein we report their synthesis, solid-state structures and fluorescent properties.

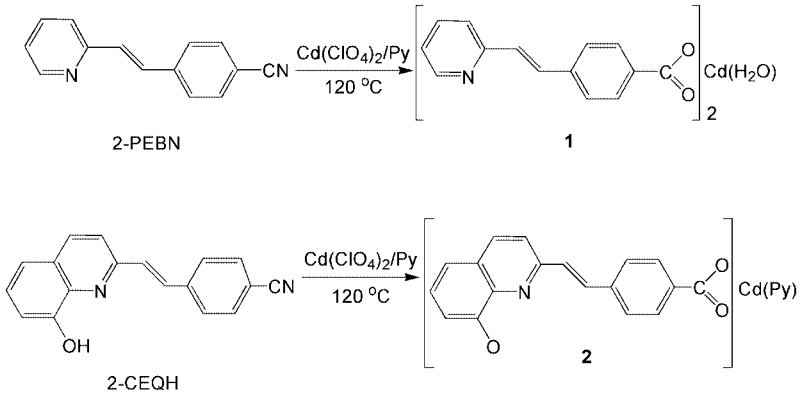
Results and Discussion

The coordination polymers **1** and **2** were prepared under hydrothermal reaction conditions from $Cd(ClO_4)_2 \cdot 6H_2O$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim **DOI: 10.1002/ejic.200300230**



Scheme 1

and 2-PEBN or 2-CEQH respectively. In these two reactions, the cyano groups were hydrolyzed into carboxylates to give 4-[2-(2-pyridyl)ethenyl]benzoate (2-PEBA) in **1** and 2-[2-(4-carboxylatephenyl)ethenyl]-8-quinolinolate (2-CEQA) in **2**. The presence of the carboxylates was confirmed by the presence of two very strong peaks at 1600 and 1380 cm^{-1} for **1** and 1582 and 1405 cm^{-1} for **2** in the IR spectra. No peak around 2100 cm^{-1} was found, suggesting that the cyano groups are no longer present in **1** and **2**. TGA analysis showed an onset temperature for **1** at 300 °C with a weight loss of 1.77%; **1** decomposes beyond 350 °C. This weight loss at 300 °C corresponds to the removal of one water molecule per formula unit (calcd. 1.58%) in **1**. An onset temperature of 280 °C was observed for **2**.

The two-dimensional polymeric structures of **1** and **2** were revealed by X-ray single-crystal diffraction. The local coordination environment around the Cd center in **1** can best be described as a slightly distorted octahedron (Figure 1) in which each Cd center coordinates to two N atoms, one O atom from the bridging water and three O atoms from three different 2-PEBA ligands. Thus there are two kinds of 2-PEBA ligands, with one acting as a tridentate spacer to link three Cd centers and the other as a bidentate spacer to bridge two Cd centers, resulting in the formation of a 2-D rectangular grid network (Figure 2a). A simplified network representation (Figure 2b) clearly shows that each net shares eight 2-PEBA ligands as a rhombic side and four dimers as a connecting node. Thus, **1** can be considered as a double-rectangular grid network with a dimer as connecting node. To the best of our knowledge, **1** is the first such network example in supramolecular motifs.[8,9]

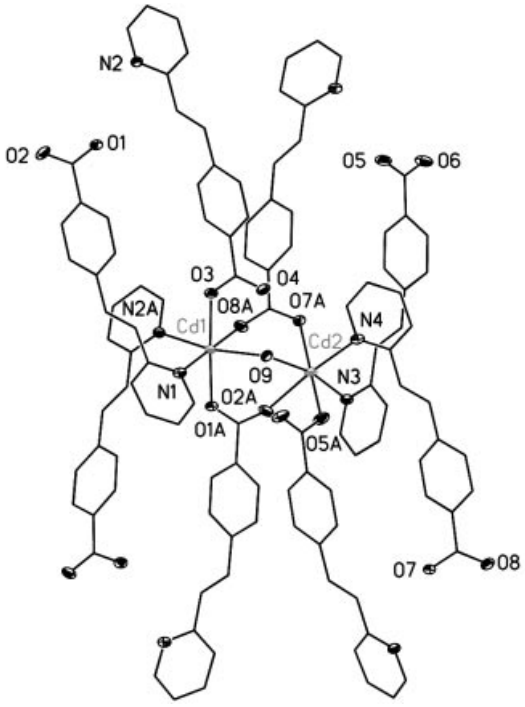


Figure 1. The asymmetric unit representation of **1** showing the local geometry around the Cd center; key bond lengths (Å): Cd1−O1A 2.213(2), Cd1−O3 2.253(2), Cd1−O8A 2.356(2), Cd1−O9 2.420(2), Cd1−N1 2.465(3), Cd1−N2A, 2.375(3), Cd2−O2A 2.389(3), Cd1−O5A 2.226(3), Cd1−O7A 2.211(2), Cd1−O9 2.413(2), Cd1−N3 2.374(3), Cd2−N4 2.461(3)

Like **1**, the local coordination geometry around each Cd center in **2** can also be described as a slightly distorted octahedron (Figure 3), in which each Cd center coordinates to two O atoms from a chelating, bridging 2-CEQA ligand and to two O atoms from the chelating carboxylate group of a different 2-CEQA ligand; the coordination sphere is completed by two N atoms, one from the chelating, bridging quinolinolate and one from pyridine. Thus, each 2-CEQA ligand acts as a pentadentate spacer to bridge three Cd centers, resulting in the formation of a 2-D rectangular grid network (Figure 4a). A simplified network representation of **2** (Figure 4b) clearly demonstrates that each rectangular grid shares four 2-CEQA ligands as a rhombic side and four dimers as connecting node resulting in the formation of a 2-D herringbone-type network. The structural feature in **2** is unusual as most supramolecular motifs with a herringbone net contain only one metal center as the connecting node.[8,9]

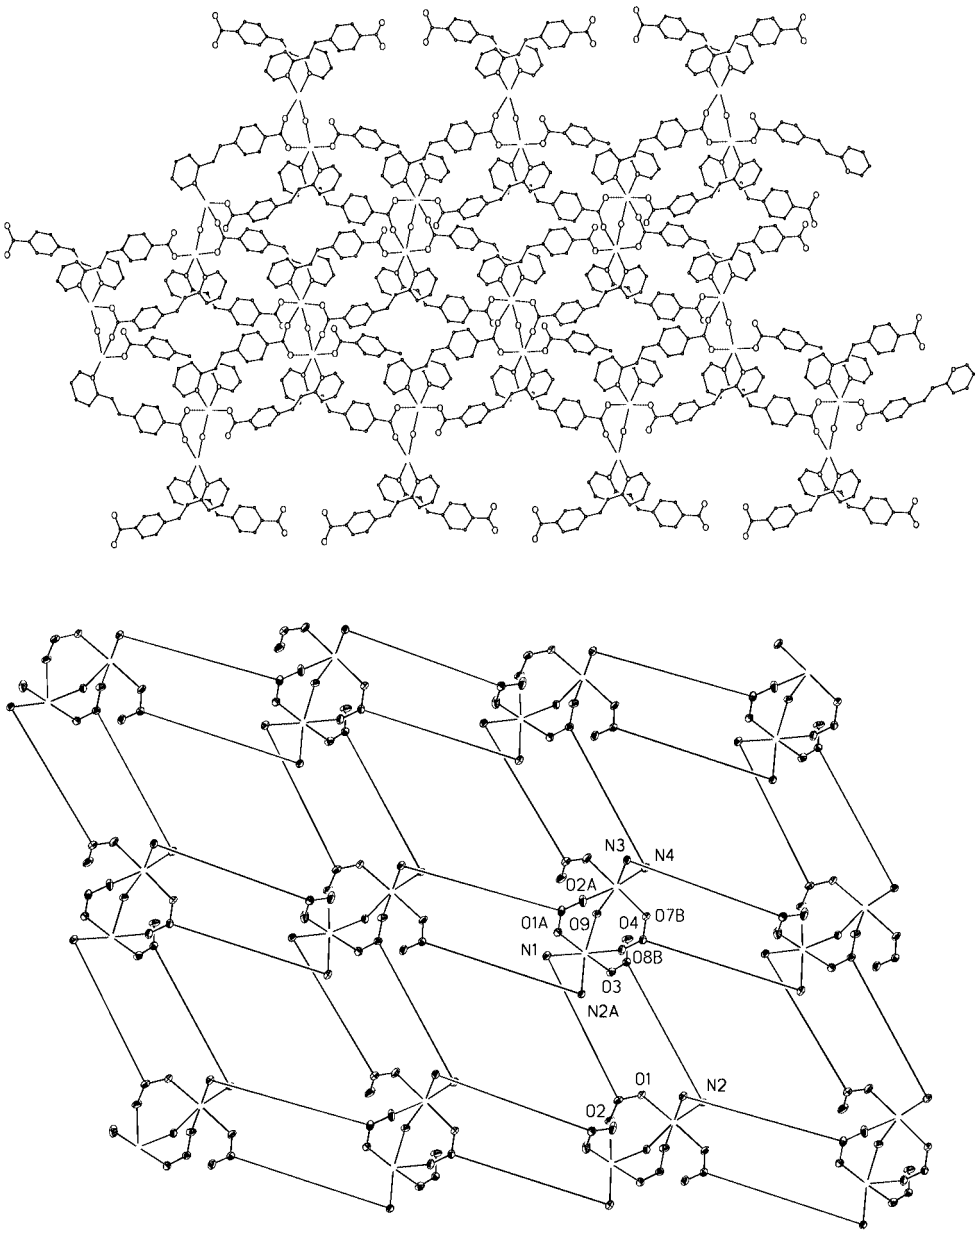

Figure 2. (a) 2-D grid network representation of **1**; (b) a simplified network representation of **1** in which the straight line is the 4-[2-(2-pyridyl)ethenyl]benzene group

The most important feature in the structures of **1** and **2** is that both have a 2-D condensed polymeric structure; this unique structure perhaps leads to significant enhancement of the fluorescent intensities, which are approximately two to three times larger than those of free 2-PEBA and 2-CEQA. These enhancements are perhaps a result of coordination of those ligands to Cd^{II}, which increases the ligands' conformational rigidity, thereby reducing the non-radiative decay of the intraligand $^1(\pi\text{-}\pi^*)$ excited state. Similar enhancement of the intraligand fluorescence has also been reported for $[Zn(terpyridine)_2]^{2+}$ and $[Zn(L)_2(OAc)_2]$ (L = *N*,*N*′-bisbenzyl-2,7-diamino-1,8-naphthyridine) [10] as well as $Zn(Norf)_2{\cdot}4(H_2O)$ (Norf = norfloxacin).[3] The solid-state diffuse reflectance UV/Vis spectra of **1** and **2** show two intense bands at 381 and 239 nm for **1** and 337 and 220 nm for **2**, which are assigned to intraligand π-π* transitions of 2-PEBA (388 and 246 nm) and 2-CEQA (338 and 215 nm). These bands match well with those in the excitation spectra of **1**, **2** and the free ligands (λ_{max} = 391 nm for 2-PEBA and λ_{max} = 348 nm for 2-CEQA). The emissions of **1** [λ_{max} = 418 nm, τ (lifetime) = 1.8 ns, Φ_{em} (quantum efficiency) ≈ 0.34; the short lifetime suggests that luminescence should be assigned to fluorescence] and **2** (λ_{max} = 600 nm, τ = 1.9 ns, Φ_{em} ≈ 0.46; Figure 5), are

[a] $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

neither MLCT (metal-to-ligand charge transfer) nor LMCT (ligand-to-metal charge transfer) in nature, and can be tentatively assigned to the intraligand fluorescent emission since a similar weak emission (2-PEBA for $\lambda_{max} = 420$ nm, $\tau = 1.0$ ns, $\Phi_{em} \approx 0.11$) and (2-CEQA for $\lambda_{max} = 604$ nm, $\tau = 1.0$ ns, $\Phi_{em} \approx 0.16$) is also observed for the free ligands. Thus, the emitting color of a Cd coordination polymer can be tuned by ligand conjugation. Due to the low solubility of compounds **1** and **2** in common solvents such as water, ethanol, benzene, chloroform, ethyl acetate, acetone and acetonitrile, a film can be prepared by the spin-coating method.

In conclusion, through tuning of ligand length and conjugation, complexes **1** and **2** display a strong fluorescent emission at different wavelengths, and may be used as excellent advanced materials for blue- or red-light-emitting diode devices. These polymeric structures show high thermal stability and their low solubility in most common solvents means that they could be used in LED devices.

Experimental Section

Synthesis of Cd(2-PEB)$_2$·(H$_2$O) (1): Hydrothermal treatment of $Cd(ClO_4)_2 \cdot 6H_2O$ (1.0 mmol), PEBN (2.0 mmol), pyridine (0.6 mL) and water (0.6 mL) for 2 days at 120 °C yielded pale-yellow, crystalline blocks of **1** with only one pure phase. The yield of **1** was about (0.313 g) 55% based on PEBN. $C_{56}H_{40}Cd_2N_4O_9$ (1137.8): calcd. C 59.07, H 3.52, N 4.92; found C, 59.07, H 3.45, N 5.03. IR (KBr): $\tilde{\nu} = 3400$ cm^{-1} (br., w), 3008 (w), 1600 (s), 1551 (m), 1480 (m), 1420 (w), 1380 (s), 1180 (w), 1160 (m), 1010 (w), 960 (m), 850 (w), 793 (m), 742 (w), 700 (w), 681 (w), 640 (w), 532 (w), 434 (w).

Synthesis of Cd(2-CEQA)(Py) (2): The procedure with 2-CEQB was similar to that for **1**. Yellow block crystals (one phase) of **2** were harvested in 0.312 g (65%) yield based on 2-CEQB. $C_{23}H_{16}CdN_2O_3$ (480.8): calcd. C 57.41, H 3.33, N 5.82; found C, 57.60, H 3.42, N 5.90. IR (KBr): $\tilde{\nu} = 3424$ cm^{-1} (br., w), 1583 (s), 1532 (s), 1504 (w), 1445 (s), 1405 (s), 1371 (sh, w), 1278 (w), 1101 (m), 1035 (w), 1010 (w), 958(w), 833 (w), 779 (w), 739 (w), 703 (w), 616 (w), 417 (w).

X-ray Crystallographic Determinations of 1 and 2: Data were collected at room temperature from epoxy-coated crystals mounted on a glass fiber. All measurements were made on a CCD Smart diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). Empirical absorption corrections were applied in each case. The relevant crystallographic data are presented in Table 1. The structure was solved by direct methods using the program SHELXTL (Sheldrick, 1997).[11] All the non-hydrogen atoms were located from the trial structure and then refined anisotropically with SHELXTL using full-matrix least-squares procedure. The hydrogen atom positions were fixed geometrically at calculated distances and allowed to ride on the parent carbon atoms. The final difference Fourier map was found to be featureless. CCDC-167840 (**1**) and CCDC-167841 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Two- and Three-Dimensional Frameworks Constructed From Bicapped Keggin Clusters

Li-Mei Duan,[a,b] Cheng-Ling Pan,[a] Ji-Qing Xu,*[a] Xiao-Bing Cui,[a] Feng-Tong Xie,[a] and Tie-Gang Wang[a]

Keywords: Polyoxometalates / Hydrothermal synthesis / Cluster compounds / Crystal structure

The novel two- and three-dimensional solid materials $[Cu(en)_2(H_2O)]\{PMo^{VI}_8V^{IV}_6O_{42}[Cu(en)_2][Cu_{0.5}(en)]_3\}\cdot 5.5H_2O$ and $H_3\{V^{V}Mo^{VI}_8V^{IV}_6O_{42}[Cu(en)_2]_4\}[MoO_4]_2\cdot 14H_2O$ (en = ethylenediamine) have been hydrothermally assembled and structurally characterized. Both networks are based on mixed Mo/V bicapped Keggin clusters interconnected through the transition metal complex moieties.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

The design and synthesis of framework materials linked by well-defined building blocks is still a challenge for the solid-state inorganic and material chemist. Polyoxometalates (POMs) have received considerable attention due to their diverse structures and unusual properties, with potential applications in fields such as catalysis, magnetism, optics and medicine.[1] Some POMs of the bicapped Keggin structure have been synthesized, such as discrete clusters $[V_{15}O_{42}]^{9-}$, $[PMo_{12}V_2O_{42}]^{5-}$ and $[PMo_8V_6O_{42}]^{5-}$,[2] the dimer cluster anions $[Mo_{16}V_{14}O_{84}]^{14-}$ [3] and one-dimensional chains connected through V−O−V bonds.[4] Our group has recently reported the first transition metal coordination compound supported on a metal-oxygen cluster with a bicapped Keggin structure.[5] There has recently been increasing interest in the assembly of higher-dimensional networks comprised of POM clusters and various bridging groups, either inorganic or organometallic. Typical compounds connected by metal cations include $[(CH_3)_4]_4Na_2H[\alpha\text{-}PW_{11}O_{39}]\cdot 8H_2O$,[6a] $[Gd(H_2O)_3]_3[GdMo_{12}O_{42}]\cdot 3H_2O$[6b] and a series of mixed-metal framework materials based on spherical $[V_{18}O_{42}(XO_4)]$ cages linked through $[M(H_2O)_4]$ groups (X: V, S; M: Fe, Co, Mn, Zn).[6c,6d] By introducing organic groups, some two-dimensional solid materials consisting of POMs and transition metal complexes have been assembled, such as $[\{Cu_3(4,7\text{-phen})_3\}_2\{Mo_{14}O_{45}\}]$, $[\{Cu(en)_2\}_2Mo_8O_{26}]$, $[Co(2,2'\text{-bpy})Mo_3O_{10}]$ and $[Co(en)_2][Co(bpy)_2]_2[PMo_8V_8O_{44}]\cdot 4.5H_2O$,[7] however, only a few three-dimensional compounds like $[\{Cu_2(triazolate)_2(H_2O)_2\}Mo_4O_{13}]$, $[Cu_2Mo_2O_8(4,4'\text{-bpy})]_n\cdot 4H_2O$ and $[\{Cu(1,2\text{-pn})_2\}_7\{V_{16}O_{38}(H_2O)\}_2]\cdot 4H_2O$[8] are known.

As a continuation of the hydrothermal synthesis of various polyoxometalates, we are trying to construct higher-dimensional frameworks from POM clusters through different bridging groups, especially transition metal complexes, and several compounds such as the two-dimensional $[\{Co(en)_2\}_2Sb_8V_{14}O_{42}(H_2O)]\cdot 6H_2O$ and $K\{V_{12}{}^{IV}V_6{}^{V}O_{42}Cl\text{-}[Ni(en)_2]_3\}\cdot 8H_2O$ have been assembled.[9] Here, we report the hydrothermal synthesis and structural characterization of two- and three-dimensional framework materials $[Cu(en)_2(H_2O)]\{PMo^{VI}_8V^{IV}_6O_{42}[Cu(en)_2][Cu_{0.5}(en)]_3\}\cdot 5.5H_2O$ (**1**) and $H_3\{V^{V}Mo^{VI}_8V^{IV}_6O_{42}[Cu(en)_2]_4\}[MoO_4]_2\cdot 14H_2O$ (**2**), both of which are based on the further condensation of the bicapped Keggin clusters $[XMo_8V_6O_{42}]^{7-}$ (X = P, V) through the linkage of $[Cu(en)_2]^{2+}$ bridging groups. To the best of our knowledge, no higher-dimensional networks constructed from bicapped Keggin clusters connected by transition metal coordination complexes have been reported until now.

The extended structure of compound **2** consists of $[(VO_4)Mo_8V_4O_{36}(VO)_2]^{7-}$ clusters, each of which is interconnected through eight $[Cu(en)_2]^{2+}$ bridging groups to eight other neighboring clusters via μ_2-O-Cu interactions, generating a three-dimensional network. The MoO_4^{2-} anions and water molecules occupy the cavities of the network solid. The structure of the cluster anion $[(VO_4)Mo_8V_4O_{36}(VO)_2]^{7-}$ in compound **2** is shown in Figure 1. The polyoxomolybdovanadate $[(VO_4)Mo_8V_4O_{36}(VO)_2]^{7-}$ has a reduced bicapped Keggin structure, which can be described as one Keggin core of $[VMo_8V_4O_{40}]^{11-}$ capped by two additional $\{VO\}^{2+}$ units. The vanadium atoms in compound **2** display three different coordination environments, including a disordered VO_4 tetrahedron at the center, distorted VO_6 octahedra as the sphere shell com-

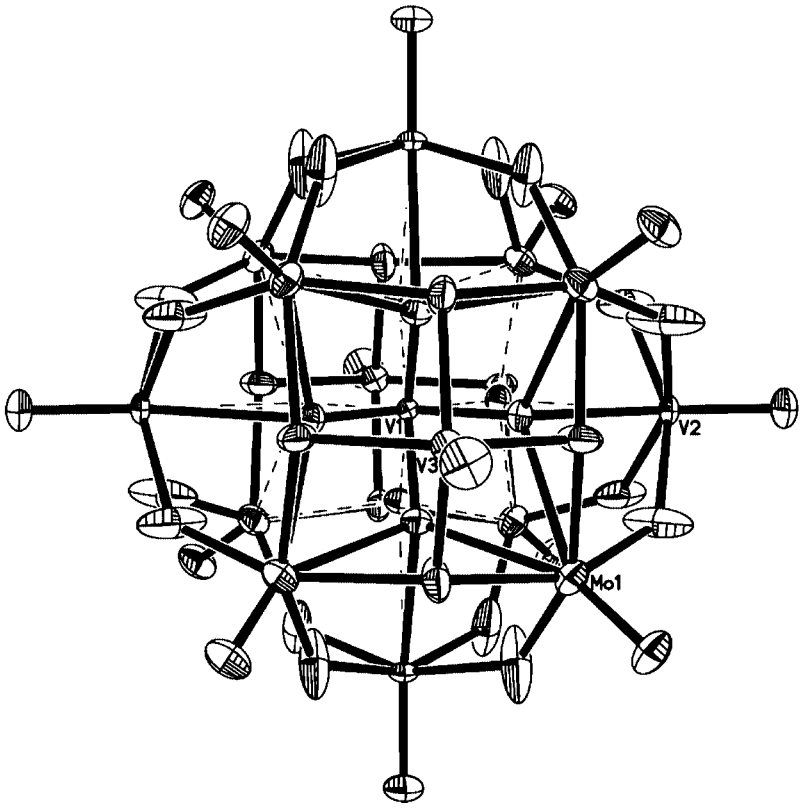

Figure 1. View of the $[V^{V}Mo^{VI}{}_{8}V_{6}{}^{IV}O_{42}]^{7-}$ cluster in compound **2**

position and VO_5 square pyramids at the capping positions. The central V(1) atom is located at the inversion center (0, 0, 0), which indicates that the central V(1) atom is surrounded by a cube of eight oxygen atoms with each oxygen site half-occupied. All the central V(1)−O distances are 1.689(10) Å, while the O−V(1)−O angles vary from 109.1(3)° to 110.2(7)°. The V(2)−O bond lengths in each VO_6 distorted octahedron vary as follows: 1.607(8) Å for terminal oxygens, 1.942(8)−1.945(7) Å for double or triply bridging oxygens and 2.418(10) Å for the oxygens of the central VO_4 tetrahedron. The V(3)−O distances in the VO_5 square pyramid are 1.633(12) Å for the capping terminal oxygens and 1.938(6) Å for the bridging oxygens. The Mo(1) atoms in the cluster have a distorted octahedral environment with the following Mo(1)−O distances: Mo(1)−$O_{terminal}$ 1.676(6) Å; Mo(1)−O_{bridge} 1.797(7)−2.065(10) Å and Mo(1)−O_{center} 2.412(10)−2.465(10) Å. The $MoO_4{}^{2-}$ ions contained in the cavities are slightly distorted tetrahedra with Mo(2)−O bond lengths 1.757(6) Å and O−Mo(2)−O angles of 107.3(4)° or 110.6(2)°.

As shown in Figure 2, all eight terminal oxo groups of the distorted MoO_6 octahedra in every $[(VO_4)Mo_8V_4O_{36}(VO)_2]^{7-}$ cluster are connected to a copper center, which, in turn, is coordinated to four nitrogen donors from two ethylenediamine molecules. The CuN_4 moiety of each $[Cu(en)_2]^{2+}$ group is rectangular, with Cu−N bond lengths of 2.007 and 2.008 Å, and N−Cu−N angles of 94.7(3)° and 85.3 (3)°. We may therefore describe the CuN_4O_2 unit as a highly distorted octahedron, with two axial Cu−O bonds being obviously elongated. Thus, each $[(VO_4)Mo_8V_4O_{36}(VO)_2]^{7-}$ cluster is connected to all of the adjacent ones through $[Cu(en)_2]^{2+}$ bridging groups in different directions via weak μ_2-O-Cu interactions, forming a

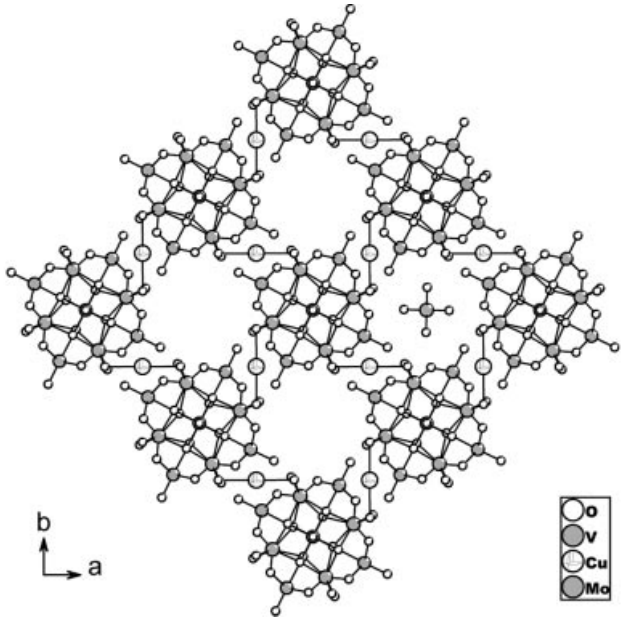

Figure 2. View of the three-dimensional framework structure of **2**, showing the clusters of $[V^{V}Mo^{VI}{}_{8}V_{6}{}^{IV}O_{42}]^{7-}$ interconnected through $[Cu(en)]^{2+}$ bridging groups; H_2O and en have been omitted for clarity

three-dimensional network. Usually, the lattice waters and/or some cations reside in the cavities, while in compound **2** the MoO_4^{2-} anions occupy the cavities of the three-dimensional network along with water molecules. Furthermore, this is the first example where MoO_4^{2-} ions are found together with bicapped Keggin $[(VO_4)Mo_8V_4O_{36}(VO)_2]^{7-}$ cluster anions.

The X-ray structure analysis of compound **1** reveals that the $[PMo^{VI}{}_8V^{IV}{}_6O_{42}]^{7-}$ cluster anion is similar to the polyoxoanion $[VMo^{VI}{}_8V^{IV}{}_6O_{42}]^{7-}$ of compound **2**. In comparison with other bicapped Keggin polyoxoanions, the unusual feature[5] of **1** is that the $[Cu(en)_2]^{2+}$ units along the *b* axis supported on the bicapped Keggin structure unit $[PMo_8V_6O_{42}]^{7-}$ are not bridging groups. The two-dimensional network structure of **1** (Figure 3) consists of $\{PMo_8V_6O_{42}\ [Cu(en)_2]\}$ cages, each of which is connected to three other neighboring cluster units via $[Cu(en)_2]^{2+}$ bridging groups with Cu−O distances of 2.498−2.880 Å. This generates a two-dimensional network composed of $[\{PMo_8V_6O_{42}[Cu(en)_2]\}\{Cu(en)_2\}\{PMo_8V_6O_{42}[Cu(en)_2]\}]_n$, which is wave-like along the crystallographic *a* axis. To the best of our knowledge, this is the first example of such a compound possessing an extended structure constructed from bicapped Keggin structure clusters.

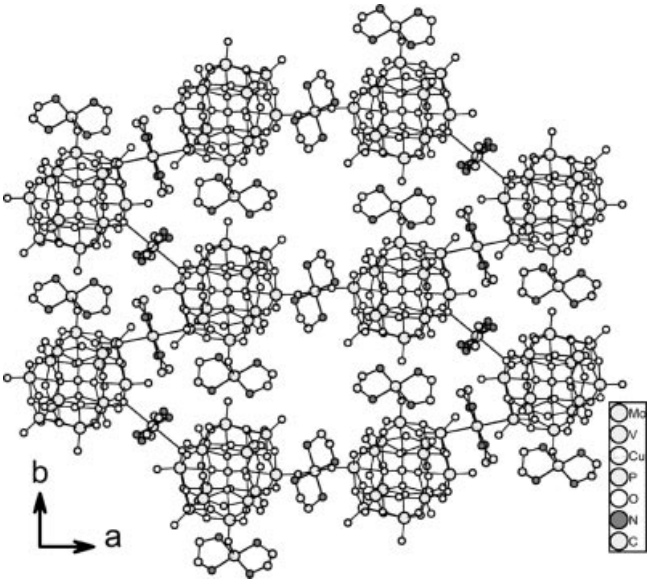

Figure 3. View of the two-dimensional network structure of **1**, showing the framework of $\{PMo_8V_6O_{42}[Cu(en)_2]\}$ clusters interconnected through $[Cu(en)_2]^{2+}$ bridging groups along the [001] direction

The assignments of oxidation states for the vanadium and molybdenum are consistent with their coordination geometries and are confirmed by valence sum calculations.[10] In compound **1**, the valence sums for the eight Mo atoms are 5.72, 5.74, 5.79, 5.85, 5.87, 5.83, 5.78 and 5.82, respectively, with an average value of 5.80; for the six V atoms the values are 3.96, 4.04, 4.12, 4.05, 4.12 and 4.07, respectively, with an average value of 4.06. The calculated values are 5.96 for Mo1, 6.04 for Mo2, 5.10 for the central V1 atom, 4.29 for V2 and 4.02 for the capping V3 atom in compound **2**. The room temperature ESR spectra of crystalline samples of compounds **1** and **2** display signals with $g = 1.976$ and $g = 2.055$, respectively, indicating the existence of V^{IV}. According to these ESR results, bond valence sum calculations, charge balance and elemental analyses, compounds **1** and **2** are formulated as $[Cu(en)_2(H_2O)]\{PMo^{VI}{}_8V^{IV}{}_6O_{42}[Cu(en)_2][Cu_{0.5}(en)]_3\}\cdot 5.5H_2O$ and $H_3\{V^{V}Mo^{VI}{}_8\ V^{IV}{}_6O_{42}[Cu(en)_2]_4\}[MoO_4]_2\cdot 14H_2O$, respectively.

In summary, we have synthesized the first two- and three-dimensional solid materials constructed from bicapped Keggin structure clusters and $[Cu(en)_2]^{2+}$ bridging groups. The successful design and synthesis of compounds **1** and **2** confirms once more that the further condensation of various POM clusters into higher-dimensional extended networks through the linkage of the transition metal complexes is feasible by controlling the synthesis conditions of the hydrothermal system. The formation of a particular product is usually restricted by various factors, and the rational synthesis of many kinds of compounds, including POMs and their polymers, is still difficult even under hydrothermal conditions. However, certain conditions are important for the assembly of higher-dimensional networks, such as the pH value of the reaction system, the species and metal-to-organic ligand ratio. For example, both compounds **1** and **2** were prepared with an en:Cu^{2+} molar ratio of less than 2, with the pH value ranging from 7 to 8. We have found that the formation of the $[Cu(en)_2]^{2+}$ complex supported on the polyoxomolybdovanadate or its polymer is very difficult when the en:Cu^{2+} molar ratio is greater than 3. Under particular synthetic conditions, certain types of targeted POMs or their polymers are reproducible and their structural type are roughly predictable, although the mechanism of the assembly remains elusive. Further systematic research is currently under way.

Experimental Section

Synthesis of 1: Compound **1** was synthesized as black block-shaped crystals by a hydrothermal method. A mixture of $CuCl_2\cdot 2H_2O$ (1.20 g), $Na_2MoO_4\cdot 2H_2O$ (1.6 g), NH_4VO_3 (0.8 g), en (0.6 mL), H_3PO_4 (0.5 mL, 50%) and distilled water (12 mL) at pH 7.0 was placed in a Teflon-lined reactor and heated at 170 °C for three days. After cooling to room temperature crystals of the title compound were isolated. $C_{14}H_{69}Cu_{3.5}Mo_8N_{14}O_{48.5}PV_6$ (2536.3): calcd. C 6.63, H 2.74, N 7.73; found C 6.74, H 2.65, N 7.58. The IR spectrum of **1** exhibits an intense band at 725 cm^{-1} attributed to ν(Mo-O, V-O), other bands at 1596, 1455, 1397, 1283, 1125 cm^{-1} that are characteristic of en, and bands at 1106, 1049 cm^{-1} attributed to ν(P-O).

Synthesis of 2: This compound was also synthesized by a hydrothermal method. A mixture of $CuAc_2\cdot H_2O$ (0.8 g), $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (1.2 g), V_2O_5 (0.6 g), KOH (0.2 g), en (0.3 mL) and water (20 mL) was sealed in a 30 cm^3 Teflon-lined reactor and kept at 180 °C for four days at a pH of about 7.0. The autoclave was then cooled to room temperature. Black block-shaped crystals of **2** suitable for an X-ray diffraction analysis were isolated and washed

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with water, then dried at ambient temperature. Compound **2** is stable in air and insoluble in water and common organic solvents. $C_{16}H_{92}Cu_4Mo_{10}N_{16}O_{64}V_7$ (3103.1): calcd. C 6.16, H 3.08, N 7.22; found C 6.28, H 3.21, N 7.09. The infrared spectrum of **2** exhibits strong absorption peaks at 954, 929 and 853, 760 cm^{-1} attributed to the ν(M=O) or ν(M-O-M) (M = Mo or V) bands. A series of bands at 1591, 1457, 1281, 1197, 1113 and 1055 cm^{-1} is attributed to the en groups.

Rhodium and Ruthenium Complexes of 1,1′-Bis(phosphetano)ferrocenes: Structural Characterisation and Catalytic Behaviour

Angela Marinetti,*[a] Francis Labrue,[a] Bénédicte Pons,[a] Sébastien Jus,[a] Louis Ricard,[b] and Jean-Pierre Genêt[a]

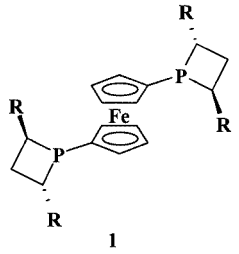
Keywords: Asymmetric catalysis / Hydrogenations / P ligands / Phosphetane / Rhodium / Ruthenium

The first structural characterisation of ruthenium and rhodium complexes of the 1,1′-bis(phosphetano)ferrocenes **1** (FerroTANEs) – namely [{(*S*,*S*)-*i*Pr-**1**}$RuCl_2Py_2$] and [{(*S*,*S*)-*i*Pr-**1**}Rh(COD)OTf] – is reported. X-ray data show that the ruthenium complex and the rhodium chelate complex both adopt δ conformations, as a result of the (*S*,*S*) configuration of the phosphetane moiety. The ruthenium complexes promote the catalytic hydrogenation of β-keto esters with moderate to high enantioselectivities. The behaviour of the rhodium complexes of **1** is compared with that of other phosphetane-based catalysts in the hydrogenation of methyl *N*-acetamidocinnamate.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The 1,1′-bis(phosphetano)ferrocenes **1** (FerroTANEs) rank among those ligands that induce excellent enantioselectivities in rhodium-promoted hydrogenations.[1] In particular, their practical utility has been demonstrated in the synthesis of amido succinates by asymmetric hydrogenation of itaconate derivatives.[2] In these reactions, ligands **1** perform better, in terms of efficiency and enantioselectivity, than other well known diphosphanes such as DuPHOS, DIPAMP or PHANEPHOS. Recently, their high efficiency in the catalytic hydrogenation of (*E*)-β-amino acid derivatives has also been established.[3] It thus seems that the combination of a conformationally constrained phosphetane ring with the relatively flexible ferrocene backbone represents a favourable structural feature for high catalytic efficiency. For comparison, the structurally analogous 1,1′-bis(phospholanyl)ferrocenes give only moderate to low enantioselectivities in hydrogenation reactions.[4]

Besides their good catalytic properties, the potential utility of diphosphanes **1** is also founded on their easy availability: diphosphanes **1** are easily accessible from fairly inexpensive chiral 1,3-diols and their structures and catalytic properties are easily and finely tuned by variation of the R groups at the α-positions of the phosphetane rings.



1

Following our initial report on the synthesis and preliminary catalytic screening of these ligands, we wish to disclose here the preparation and first structural characterisation of ruthenium and rhodium complexes of **1**, which are efficient catalyst precursors for hydrogenation reactions. Additional data on their catalytic properties is also reported.

Results and Discussion

Crystal Structures of the [(*S*,*S*-1c)$RuCl_2(Py)_2$] and [(COD)Rh(*S*,*S*-1c)OTf] Complexes

With regard to the excellent catalytic properties of the 1,1′-bis(phosphetano)ferrocenes **1**, it is highly interesting to investigate the coordinating behaviour of these new ligands towards catalytically active transition metals, as well as the structural features of their complexes. With this aim, we prepared the [{(*S*,*S*)-*i*Pr-**1**}$RuCl_2(Py)_2$] complex **2**, which is a potential precursor for hydrogenation catalysts. The synthesis of **2** was performed according to the Bergens procedure:[5] the reaction between **1** and the [(NBD)$RuCl_2Py_2$] complex (NBD = norbornadiene, Py = pyridine) at room temperature. Facile and quantitative displacement of the

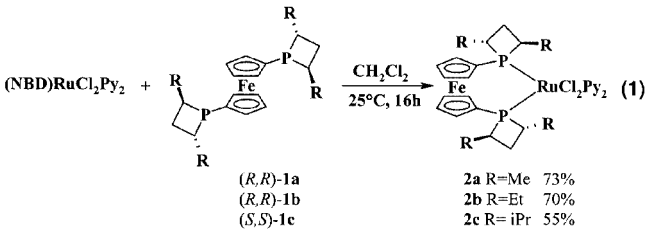
unsaturated ligand by the chelating diphosphane is observed, as shown in Equation (1).



The ruthenium complexes **2** are obtained in moderate to high yields after crystallisation from dichloromethane/pentane mixtures, as air-stable, orange, crystalline solids. NMR spectroscopy shows that complexes **2** have C_2-symmetrical structures, with equivalent phosphetane and also pyridine moieties. The ^{31}P NMR resonance of complexes **2** is shifted downfield with $\Delta\delta$ of 60−70 ppm relative to **1**, the less hindered complex **1a** undergoing the larger shift upon coordination.

The first structural characterisation of any 1,1′-bis(phosphetano)ferrocene−transition metal derivative has been performed on complex **2c**. An ORTEP drawing is shown in Figure 1, and selected bond lengths and angles are reported in Table 1.

Complex **2c** crystallises in the orthorhombic system, with one dichloromethane molecule per molecular unit. The ruthenium atom is approximately octahedral. The bis-equatorially coordinated diphosphane gives a P−Ru−P bite angle of 98.57(3)°, in good agreement with the expected value, as large deflections from the ideal 90° (metal natural bite angle) up to about 100° are usually observed in square-planar and octahedral complexes of dppf[6] and other 1,1′-bis(phosphanyl)ferrocenes.[7] The conformation of the Cp rings is staggered, with a torsion angle of 45.7°. The rotation of the cyclopentadienyl rings against each other, together with their tilt, produces a fairly large P−P distance of 3.51 Å (as compared with the Cp−Cp′ distances of 3.28 Å).

Table 1. Selected interatomic distances [Å] and angles [deg] for complex **2c**

Ru(1)−P(1)	2.321(1)	Ru(1)−Cl(2)	2.437(1)
Ru(1)−P(2)	2.319(1)	P(1)−C(1)	1.892(3)
Ru(1)−N(1)	2.231(3)	P(1)−C(3)	1.887(3)
Ru(1)−N(2)	2.170(3)	P(2)−C(11)	1.908(3)
Ru(1)−Cl(1)	2.425(1)	P(2)−C(9)	1.884(3)
P(1)−Ru(1)−P(2)	98.57(3)	C(1)−P(1)−C(3)	76.3(1)
N(1)−Ru(1)−N(2)	81.7(1)	C(4)−P(1)−Ru(1)	119.9(1)
P(1)−Ru(1)−N(1)	90.20(7)	C(11)−P(2)−C(12)	77.3(2)

The structural parameters of the phosphetane rings show standard values, with small intracyclic C−P−C angles of 76.3(1) and 77.3(2)°, respectively, and ring bending angles of 25.5 and 17.6°, respectively.

A significant structural feature of the complex is the δ conformation[8] adopted by the ferrocene backbone, which enforces a dissymmetric coordination of the phosphetane rings (see Figure 2): the C(3) and C(9) ring atoms, and the corresponding isopropyl substituents, are shifted away from the ruthenium coordination plane, in pseudoaxial positions, while the C(1) and C(11) atoms occupy pseudoequatorial positions. The corresponding dihedral angles between the P(1)−Ru−P(2) plane and the P−C axis are −93°

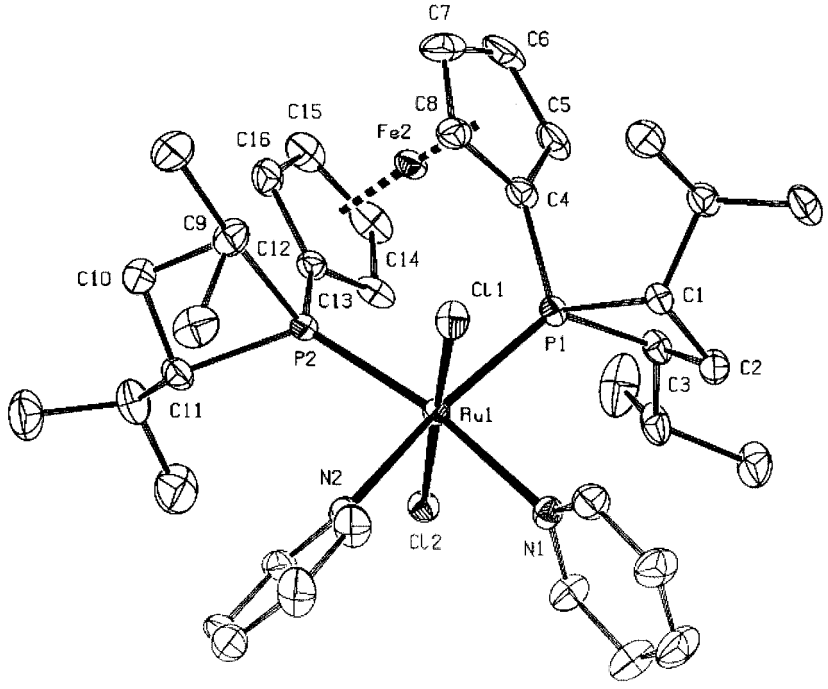


Figure 1. ORTEP drawing for the ruthenium complex **2c**

[P(1)−C(3)], 163° [P(1)−C(1)], −128° [P(2)−C(9)] and 141° [P(2)−C(11)]. The δ conformation of the ferrocene backbone therefore tends to minimise the steric hindrance between the isopropyl groups, which are oriented toward the metal, and the other ligands in the equatorial coordination plane of ruthenium. In a sense, this also balances the dissymmetry of the ruthenium environment created by the chiral phosphetane units and could decrease the asymmetric discrimination from these ligands somewhat.

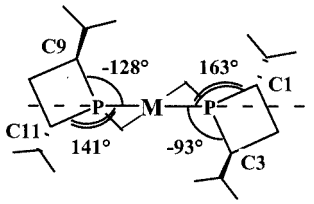

Figure 2. Coordination mode of the bis(phosphetano)ferrocene moiety in the ruthenium complex **2c**

A similar coordination mode is observed in the rhodium complex **3c**, containing the same ligand **1c**. An ORTEP drawing and selected bond angles and distances for complex **3c** are shown in Figure 3 and Table 2, respectively.

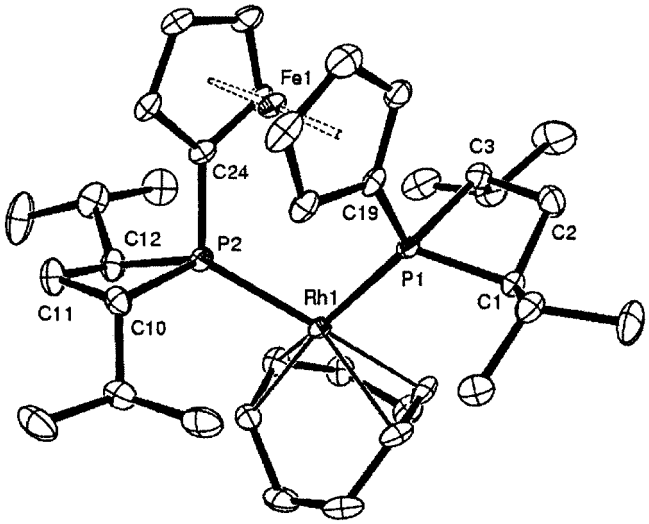

Figure 3. ORTEP drawing of the [(COD)Rh(**1c**)OTf] complex **3c**

Table 2. Selected interatomic distances [A°] and angles [deg] for complex **3c**

Rh(1)−P(1)	2.324(1)	C(1)−C(2)	1.570(5)
Rh(1)−P(2)	2.317(1)	C(2)−C(3)	1.554(6)
P(1)−C(1)	1.877(4)	P(2)−C(10)	1.885(3)
P(1)−C(3)	1.884(4)	P(2)−C(12)	1.869(4)
P(1)−C(19)	1.810(3)	P(2)−C(24)	1.813(3)
P(1)−Rh(1)−P(2)	96.90(3)	C(1)−P(1)−C(3)	78.1(2)
C(19)−P(1)−Rh(1)	121.5(1)	C(10)−P(2)−C(12)	77.9(2)

Phosphetane **1c** thus generally seems to favour δ conformations in its transition metal complexes, as a result of its (*S*,*S*) stereochemistry.

Ruthenium-Promoted Hydrogenations of β-Keto Esters

As shown by Bergens, many [(diphosphane)$RuCl_2Py_2$] complexes afford efficient hydrogenation catalysts after treatment with acids. This is also the case for complexes **2**: when activated by addition of four equivalents of HBr, these complexes catalyse the asymmetric hydrogenation of carbonyl derivatives. Methyl acetoacetate and ethyl isobutyrylacetate were selected as model substrates for the hydrogenation reactions (Table 3).

Under the conditions given (see Table 3), ligands **1a**−**c** display moderate to high enantioselectivities as a function of the phosphetane α-substituents: the enantiomeric excesses of the final β-hydroxy esters increase significantly with increasing steric hindrance of the ligand. Thus, for instance, *ee*s of 44%, 56%, and 80% were obtained in the hydrogenation of methyl acetoacetate with use of ligands **1a**, **1b**, and **1c**, respectively. The observed trend contrasts with the behaviour of the same ligands in rhodium-promoted hydrogenations of olefinic substrates, where the best enantioselectivities are attained with the 2,4-diethyl-substituted ligand.[2] This once again confirms the need for highly specific tuning of the ligand substituents for any given reaction.

Two other ruthenium catalyst precursors were evaluated under the above hydrogenation reactions: catalysts were formed in situ from **1a**−**c** and $[(C_6H_6)RuCl_2]_2$ or [(COD)-Ru(2-methylallyle)$_2$],[9] by known procedures. Selected results are given in Table 3. Both catalytic systems give activities and enantioselectivities either comparable to or somewhat lower than those obtained with complexes **2**. Thus, in our hands, complexes **2** were the most suitable catalyst precursors, being well defined, bench-stable and easy to handle.

The few catalytic tests above show that the 1,1′-bis(phosphetano)ferrocenes **1** afford moderate catalytic activities and quite high, albeit not magnificent, enantioselectivities in ruthenium-promoted hydrogenations of carbonyl derivatives. At first sight it seems that, in these reactions, ligands **1** will be not very competitive with other chiral ligands,[10] and especially with atropisomeric diphosphanes.[11] Of course, this cannot be regarded as a final settlement, as very few substrates, catalytic systems, and conditions have been evaluated. Fine tuning of the phosphetane substituents and/or of the reaction conditions could allow better achievements.

Rhodium-promoted Hydrogenations of Functionalised Olefins

The catalytic efficiency of 1,1′-bis(phosphetano)ferrocenes **1** in rhodium(I)-promoted hydrogenations of functionalised olefins has already been established.[1−3] The main purpose of this study was to gain insight into their behaviour in these reactions, in comparison with that of other phosphetane-based ligands, namely CnrPHOS[12] and BPE-4.[13]

[a] Reaction conditions: 1 mmol substrate, S/C = 100, MeOH (1 mL) as solvent, reaction time 24 h−48 h; (a) 50 °C; 10 bar H_2, (b) 50 °C; 80 bar H_2, (c) 80 °C, 10 bar.

More precisely, we examine here the enantioselectivity of the catalytic hydrogenation of dehydro amino acid derivatives, as a function of several experimental parameters. An analogous study on the CnrPHOS and BPE ligands highlighted, among other things, an unusually strong effect of the hydrogen pressure on the enantioselectivity, with higher *ee*s being obtained at higher pressures.[14] The preliminary data on this phenomenon were confirmed by the additional experiments shown in Table 4 and Figure 4. Methyl α-acetamidocinnamate **6** was hydrogenated, at various hydrogen pressures, in the presence of a rhodium catalyst generated in situ from $[Rh(COD)_2OTf]$ and (*S*,*S*)-CyBPE-4. Mechanical stirring was applied to ensure efficient adsorption of H_2 into the solution. For comparison, the *ee*s obtained with magnetic stirring are reported in entry 1 (from ref.[14]): mechanical stirring improves the enantioselectivity of reactions performed under otherwise identical conditions. This is probably related to more efficient and homogeneous dihydrogen exchange between gas and liquid phases.

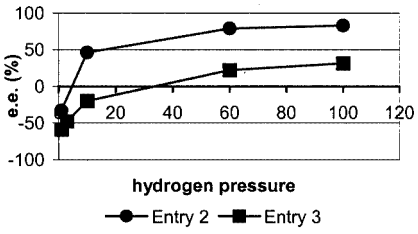

Figure 4. Plotting of data from Entries 2 and 3 in Table 4

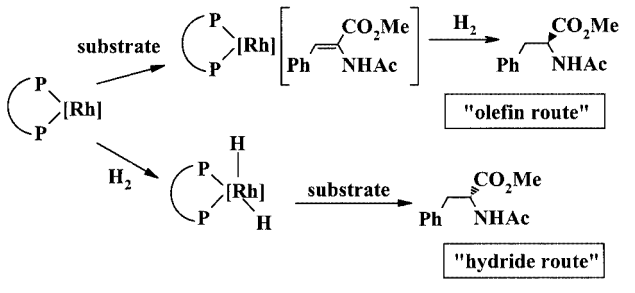
3	CH_2Cl_2	**59** (*S*)	48 (*S*)	20 (*S*)	22 (*R*)	31 (*R*)

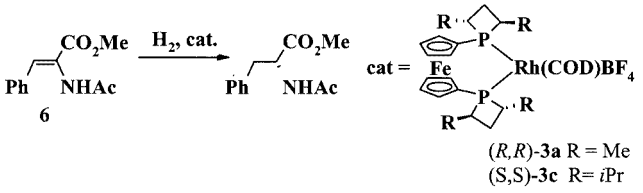
[a] From ref.[14] 1% catalyst, substrate concentration: 0.1 M, room temperature.

Two series of experiments were performed, in CH_2Cl_2 and in a C_6H_6/CH_2Cl_2 mixture (4:1). The expected significant effect of hydrogen pressure on stereoselectivity was observed in each case: increased hydrogen pressure clearly favours formation of the *R* enantiomer, while the *S* enantiomer predominates at low pressures. The enantioselectivity levels depend on the solvent used, higher *ee*s being attained in the benzene/dichloromethane mixtures. Mechanistic implications of analogous results have already been discussed in our preliminary communication. Most probably, the reversal of stereoselectivity should be related to some form of "tilting" over to a new reaction pathway which operates at



higher pressures. According to the most recent studies on rhodium-promoted enamide hydrogenation with electron-rich phosphanes,[15] competition between the "olefin" and the "hydride" mechanisms, operating at high pressure, seems to be a reasonable hypothesis.

After the above studies, we wondered whether the ferrocenyl-substituted phosphetanes **1** would or would not display analogous behaviour in rhodium-promoted hydrogenations. We therefore examined the pressure effect in the hydrogenation of the dehydroamino esters **6** with the preformed complexes **3** as the catalyst precursors.



From the data in Table 4 it appears that the pressure/enantioselectivity relationship for phosphetanes **1a** and **1c** does not follow the same trend as for Cy-BPE-4 and CnrPHOS: a slight decrease in the enantioselectivity is observed at higher pressure, both in dichloromethane/benzene mixtures and in methanol as solvents (see entries 1, 2, 5, and 6). This suggests that the pressure effect observed with Cy-BPE-4 and CnrPHOS cannot be assigned specifically to their phosphetane-type structures; their catalytic behaviour should be influenced by their whole structures. In particular, their electronic properties should be crucial, as it has been demonstrated that the stereochemical issue of the hydrogenation of dehydroamino acid derivatives is mainly governed by the electron-donating power of the diphosphane ligands.[14]

FerroTANEs **1** simply behave like other electron-rich diphosphanes such as DuPHOS[16] or BisP,[17] the (*S*,*S*)-configured ligand **1c** giving the expected (*R*)-configured product in good enantiomeric excesses. The enantiomeric excesses are then slightly modulated by hydrogen pressure, as well as by any other experimental conditions, in the usual manner.

Thus far, the best conditions for the hydrogenation of **6** are the following: phosphetane **1a** as the ligand, 1 bar of H_2 pressure, MeOH as the solvent, and a reaction temperature of about 50 °C. An enantiomeric excess of 96% is obtained.

The results in Table 5 also suggest that hydrogenation reactions with ligands **1a** and **1c** require slightly different optimal conditions. Fine tuning of the reaction conditions is thus required for each ligand-substrate couple in order to attain the highest selectivities, even within a single series of ligands.

When a different substrate is considered, optimisation is once again necessary, as variation of the experimental parameters has unpredictable effects on enantiomeric excesses. In the hydrogenation of methyl acetamidoacrylate with complex **3c**, for instance, we have observed that an increased H_2 pressure improves the enantioselectivity from 87%, under 1 bar pressure, to 94% under 5 bar (at room temperature, in MeOH; *R* enantiomer).

Table 5. Enantiomeric excesses of the catalytic hydrogenations promoted by complexes **3a** and **3c**; all experiments give the *R*-configured β-amino ester

				P(H_2)				
Entry	Solvent	Catalyst	T °C	1	5	10	30	50

6	MeOH		50	**96**	91			

The electron-rich character of P-ferrocenyl-substituted phosphetanes was ascertained by IR spectroscopy of the [Cl(CO)Rh{(*R*,*R*)-1-ferrocenyl-2,4-dimethylphosphetane}] complex **7a**.

The ν(CO) value for the ferrocenyl-substituted phosphetane complex **7a** appears at lower frequency than in the analogous *P*-phenylphosphetane complex **7c**, within the range expected for electron-rich phosphanes. For comparison, the ν(CO) values for analogous rhodium complexes of cyclic and acyclic phosphanes are reported in Table 6. The data in Table 6 also suggest that phosphetanes are poorer donating ligands than the corresponding phospholanes, as an effect of ring size.

Table 6. ν(CO) values for the [Cl(CO)RhL_2] complexes **7**

Complex		**7a**		**7b**	**7c**
L	PEt_3		$PhPEt_2$		
ν(CO) cm^{-1} (CH_2Cl_2)	1955[18]	1956	1962[18]	1963	1969

In summary, the hydrogenation reactions of dehydro amino acid derivatives promoted by rhodium complexes of the 1,1′-bis(phosphetano)ferrocenes **1** do not display the unusual pressure/enantioselectivity relationship shown by other C_2-symmetric bis(phosphetane) ligands. Ligands **1** behave like electron-rich diphosphanes and afford significantly high enantioselectivities under optimised experimental conditions.

Experimental Section

All reactions were performed under inert atmosphere (Ar) by use of Schlenk techniques. Solvents were purified according to standard

General Procedure for Hydrogenations Carried out with Complexes 2 as Catalyst Precursors: Hydrogenation experiments were carried out at a 1 mmol scale. The ruthenium complex **2** ($1\cdot10^{-2}$ mmol) was weighed into a small glass reactor fitted with a rubber septum and flushed with argon. Degassed MeOH (1 mL) and then a solution of HBr_{aq} in MeOH (0.16 M, 0.25 mL, 4 equivalents) were added with stirring at room temperature. After a few minutes, the substrate was introduced by syringe. The reaction vessel was placed in a stainless steel autoclave under argon. The argon atmosphere was replaced by hydrogen at the given pressure. The reaction was allowed to proceed for 24−48 h at the temperature given in Table 3. Conversion rates were determined by ^{1}H NMR spectroscopy. The enantiomeric excesses of the final alcohols were determined by chiral CG and the absolute configurations were assigned from the GC retention times by comparison with known samples. **Methyl 3-hydroxybutyrate**: Lipodex A, flow 1 mL·min^{-1}, initial temperature 35 °C (30 min), rate 1 °C·min^{-1}, final temperature 70 °C; retention times 45 (*S*) and 48 (*R*) min. **Ethyl 4-methyl-3-hydroxypentanoate**: Lipodex A, flow 1 mL·min^{-1}, initial temperature 50 °C (5 min),

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rate 0.5 °C·min^{-1}, final temperature 70 °C; retention times 48.6 (*S*) and 49.2 (*R*) min.

Preparation of other Catalyst Precursors: (a) According to ref.[9] [(cod)Ru(2-methylallyl)$_2$] (3.2 mg, 1·10^{-2} mmol) and FerroTANE **1** (1.1·10^{-2} mmol) were dissolved in acetone (1 mL) under argon. An HBr_{aq} solution (0.16 M in MeOH, 137 μL, 2.2 equivalents) was then added at room temperature, and the mixture was stirred for 30 min. The solvent was evaporated and the crude residue was taken up in degassed MeOH and used as the catalyst for the hydrogenation reactions (see Table 3). (b) The catalyst precursor was prepared at room temperature by mixing the [(benzene)$RuCl_2$]$_2$ complex (2.5 mg) with **1** in a 1:2 ratio, in CH_2Cl_2 at room temperature. After evaporation of the solvent, the crude residue was used as the catalyst precursor.

General Procedure for the Synthesis of the [(COD)Rh(1)OTf] Complexes 3: A dichloromethane solution of diphosphane **1** (0.2 mmol, 1 mL CH_2Cl_2) was added dropwise, at room temperature, to a solution of $(COD)_2RhOTf$ (93 mg, 0.2 mmol) in the same solvent (1 mL). After the mixture had been stirred for about 15 min, the solvent was removed and the residue was recrystallised either from a dichloromethane/ether mixture (for **3c**) or from a dichloromethane/pentane mixture (for **3a**) to afford a yellow-orange solid.

[(COD)Rh{1,1′-Bis[(*R*,*R*)-2,4-dimethyl-1-phosphetanyl]ferrocene}OTf] (3a): Yield 97 mg, 65%. ^{31}P NMR ($CDCl_3$): δ = 65 (d, $J_{P\text{-}Rh}$ = 147 Hz) ppm. ^{1}H NMR ($CDCl_3$): δ = 5.8 (br. m, 2 H, CH_{COD}), 5.15 (br. m, 2 H, CH_{COD}), 4.70 (s, 2 H, CH_{Cp}), 4.66 (s, 2 H, CH_{Cp}), 4.62 (s, 2 H, CH_{Cp}), 4.37 (s, 2 H, CH_{Cp}), 1.65 (dd, $^3J_{H\text{-}P}$ = 19.7, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 0.99 (dd, $^3J_{H\text{-}P}$ = 16.3, $^3J_{H,H}$ = 7.0 Hz, 6 H, CH_3) ppm.

[(COD)Rh{1,1′-Bis[(*S*,*S*)-2,4-diisopropyl-1-phosphetanyl]ferroceneOTf} (3c): Yield 120 mg, 70%. ^{31}P NMR ($CDCl_3$): δ = 47 (d, $J_{P\text{-}Rh}$ = 146 Hz). ^{1}H NMR ($CDCl_3$): δ = 5.56 (br. m, 2 H, CH_{COD}), 4.90 (br. m, 2 H, CH_{COD}), 4.80 (s, 2 H, CH_{Cp}), 4.60 (s, 4 H, CH_{Cp}), 4.37 (s, 2 H, CH_{Cp}), 2.2−2.8 (18H), 2.05 (q, *J* = 10.1 Hz, 2 H), 1.84 (d, $^3J_{H,H}$ = 6.5 Hz, 6 H, CH_3), 1.15 (d, $^3J_{H,H}$ = 6.1 Hz, 6 H, CH_3), 0.70 (d, $^3J_{H,H}$ = 6.3 Hz, 6 H, CH_3), 0.69 (d, $^3J_{H,H}$ = 5.5 Hz, 6 H, CH_3) ppm. $C_{37}H_{56}F_3FeO_3P_2RhS{\cdot}CH_2Cl_2$ (942.132): calcd. C 48.37, H 6.20; found C 49.80, H 6.56. For crystal data see Table 8.

The triflate anion (near −0.37, 0.10, 0.31) was highly disordered. Attempts to generate disorder (Shelxl FRAG and PART) all resulted in some non-positive thermal displacement parameters. Consequently, it was decided to account for its electron density by use of the Platon SQUEEZE function.

Rhodium-Promoted Hydrogenations of Methyl α-Acetamidocinnamate: The hydrogenation experiments described in Table 4 were performed in a Teflon-coated autoclave, with mechanical stirring. The rhodium catalyst was prepared at room temperature by mixing [$(COD)_2RhOTf$] (11.2 mg, 2.4·10^{-2} mmol) and (*S*,*S*)-Cy-BPE-4 (14.4 mg, 2.8·10^{-2} mmol) in CH_2Cl_2 (2 mL) for about 10 min. A degassed solution of the substrate (525 mg, 2.4 mmol) in 18 mL of solvent (CH_2Cl_2 or CH_2Cl_2/C_6H_6, 1:4 mixture) was then added and the system was pressurised with dihydrogen. The reaction time was about 24 h. The catalyst was removed by filtration through a short alumina column, with a cyclohexane/ethyl acetate mixture (1:1) as the eluent. Enantiomeric excesses were determined either by chiral HPLC or by chiral GC. The absolute configuration was assigned from the retention times by comparison with known samples. HPLC: Chiracel OD-H column, hexane/2-propanol (90:10), retention times: 11.5 min (*R*) and 14.8 min (*S*). GC: Chirasil-L-Val column, flow = 1 mL/min, *T* = 140 °C, retention times: 37 min (*R*), 39 min (*S*).

The same experimental procedure was applied to the hydrogenation reactions reported in Table 5. The preformed rhodium complexes **3a** and **3c** were used as the catalysts. Experiments were carried out at a 1 mmol scale, with a catalyst:substrate ratio of 5·10^{-3}.

Synthesis of the [Cl(CO)RhL_2] Complexes 7: 2,4-Dimethyl-1-ferrocenylphosphetane,[18] 2,4-dimethyl-1-phenylphosphetane,[19] and 2,5-dimethyl-1-phenylphospholane[20] were prepared as described previously. The rhodium complex [$ClRh(CO)_2]_2$ (20 mg, 5·10^{-2} mmol) and the phosphetane (or phospholane) ligand (20·10^{-2} mmol) were allowed to react in CH_2Cl_2 (2 mL) at room temperature for 15 min. ^{31}P NMR analysis of the crude reaction mixture in C_6D_6 showed quantitative formation of a single rhodium-phosphane complex. Complexes **7a**−**c** were characterised by NMR spectroscopy, without further purification. IR spectra of the crude complexes were recorded in CH_2Cl_2.

Synthesis and Structures of Compounds Based on Chalcocyanide Tetranuclear Rhenium Clusters: Bonding Cluster Complexes by diene-Bridged Cu^{II} Units

Yuri V. Mironov,[a,b] Olga A. Efremova,[b] Dmitry Yu. Naumov,[b] William S. Sheldrick,[a] and Vladimir E. Fedorov*[b]

Keywords: Rhenium / Clusters / Chalcogen / Copper / Solid-state structures

Six new tetrahedral chalcocyanide cluster compounds, $[\{Cu_2(dien)_3\}Re_4S_4(CN)_{12}]$ (**1**), $[\{Cu(dien)(NH_3)\}_2Re_4Se_4(CN)_{12}]\cdot 2.5H_2O$ (**2**), $[\{Cu_2(dien)_3\}Re_4Q_4(CN)_{12}]\cdot nH_2O$ (Q = Se (**3**), Te (**4**)] and $[K(H_2O)_2]_2[\{Cu_3(dien)_4\}\{Re_4Q_4(CN)_{12}\}_2]\cdot 8H_2O$ where Q = Se (**5**), Te (**6**) (dien = diethylenetriamine), have been synthesized by treating aqueous solutions of the salt-like cluster compounds $K_4Re_4Q_4(CN)_{12}\cdot nH_2O$ with solutions of copper(II) chloride in aqueous ammonia containing diethylenetriamine. All six compounds have been characterized by single-crystal X-ray diffraction analysis. Compound **1** has a chain-like polymeric structure; orthorhombic, space group $Pmn2_1$. Compound **2** has a molecular structure; triclinic, space group $P\bar{1}$. Compounds **3** and **4** are isostructural and also exhibit molecular structures; monoclinic, space group $P2_1/n$. Compounds **5** and **6** are isostructural and display a cross-bridged chain-like polymeric structure; triclinic, space group $P\bar{1}$.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Considerable recent research has been devoted to designing new polymeric compounds with extended structures based on rhenium cluster compounds.[1−4] Such compounds may have interesting catalytic, magnetic or zeolitic properties. The directional choice of cluster/ligand and cluster/cation combinations helps to control both the topology and the dimensionality of solids. A useful approach for this purpose consists of assembling two building blocks, which are often cluster complexes with terminal ligands that can act as bridges and transition metal complexes with vacant or readily substituted coordination sites. Typical examples are Re cluster chalcocyanide complexes with terminal CN ligands and aqua or amine transition metal complexes.[5−13] The next logical step in such investigations is to use polydentate ligands to block some of the available positions around the transition metal atom, so as to control the positions available for coordination with the CN ligands. The first examples of such complexes were published recently.[14] Here we present six complexes containing $[Re_4Q_4(CN)_{12}]^{4-}$ cluster anions and Cu^{II} cations, coordinated by dien ligands and bridging CN ligands of the cluster units. Our data demonstrate the significant dependence of the stoichiometry and structure of the product on the reaction conditions and internal ligands of the cluster unit. We have prepared one chain-like coordination polymer $[\{Cu_2(dien)_3\}_2Re_4S_4(CN)_{12}]$ (**1**) (dien = diethylenetriamine), three molecular complexes $[\{Cu(dien)(NH_3)\}_2Re_4Se_4(CN)_{12}]$ (**2**) and $[\{Cu_2(dien)_3\}Re_4Q_4(CN)_{12}]\cdot 8H_2O$ [Q = Se (**3**), Q = Te (**4**)], and two polymeric complexes $[K(H_2O)_2]_2[\{Cu_3(dien)_4\}\{Re_4Q_4(CN)_{12}\}_2]\cdot 8H_2O$ [Q = Se (**5**), Q = Te (**6**)]. One of the most interesting features of the polymeric complexes is their construction by dien-bridging of Cu^{II} atoms.

Results

Syntheses

The chain-like one-dimensional compound **1** was synthesized by treating an aqueous solution of the Re_4 thiocyanide cluster $K_4[Re_4S_4(CN)_{12}]$ with an ammonia solution of $CuCl_2$ and dien. Two molecular complexes, **2** and **3**, and the polymeric compound **5** were obtained in a similar manner using $K_4[Re_4Se_4(CN)_{12}]$ as a starting material. Analogously, the molecular complex **4** and the polymeric compound **6** were prepared using $K_4[Re_4Te_4(CN)_{12}]$ as a starting material. Thus, by performing the reactions with different ratios of the starting components, complexes with differing compositions and structures were obtained for cluster anions $[Re_4Q_4(CN)_{12}]^{4-}$ with the Q = Se and Te.

These investigations extend our earlier studies on the reactions of $K_4Re_4Te_4(CN)_{12}$ with aqua or ammine complexes of the transition metals, which yield cyano-bridged cluster complexes with differing dimensionalities. Transition

[b] Institute of Inorganic Chemistry of Russian Academy of Sciences, 3, Acad. Lavrentiev prospect, 630090 Novosibirsk, Russia

metal atoms in such complexes are coordinated by the N atoms of the cyanide ligands and by the N or O atoms, respectively, of ammonia and water molecules. Recent work[14] has shown that some of the coordination sites around the transition metal atom may effectively be blocked by bidentate ligands such as ethylenediamine.

Structures

All six compounds have been characterized by single-crystal X-ray diffraction. Compound **1** is polymeric, with the cluster anions $[Re_4S_4(CN)_{12}]^{4-}$ bridged by the cationic chains $[(dien)Cu-dien-Cu(dien)]^{4+}$ (Figure 1). The structure of the $[Re_4S_4(CN)_{12}]^{4-}$ anion is similar to that in the starting material and related compounds. It contains an Re_4S_4 cubane-like cluster core formed from a nearly regular Re_4 tetrahedron, with Re−Re and Re−(μ_3-S) distances in the ranges 2.739(2)−2.767(1) and 2.337(7)−2.434(7) Å, respectively. Each Re atom is further ligated by three cyano ligands. Each Cu atom in the cationic chain-like building blocks is coordinated in a square-pyramidal manner (*CN* = 5) by three N atoms of the tridentate dien, with Cu−N distances of 1.94(2)−2.03(2) Å, one N atom of the bridging dien, with a Cu−N length of 1.97(2) Å, and by one N atom of a CN^- ligand of the cluster anion with a Cu−N length of 2.20(2) Å.

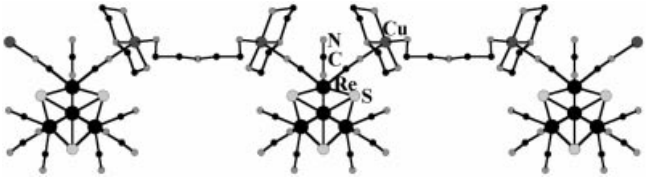

Figure 1. Chain fragment of the structure of compound **1**

In compound **2**, two $[Cu(dien)(NH_3)]^{2+}$ cations are coordinated to the N atoms of CN^- ligands of the $[Re_4Se_4(CN)_{12}]^{4-}$ anion (Figure 2). Each Cu atom is coordinated by the three N atoms of the dien ligand, with Cu−N distances of 2.01(1)−2.05(1) Å, one atom of an NH_3 ligand, with Cu−N distances of 1.99(1) and 2.03(1) Å, and by one N atom of a bridging CN^- ligand of the cluster anion with Cu−N distances of 2.38(1) and 2.19(1) Å. Once again the coordination number of each Cu is 5, and the copper atoms exhibit square-pyramidal coordination spheres with an axial cyanide nitrogen atom. Both $\{Cu(dien)(NH_3)\}^{2+}$ cations are coordinated to the same Re_4 cluster anion $[Re_4Se_4(CN)_{12}]^{4-}$. In the cluster anion the Re−Re and Re−(μ_3-S) distances are 2.792(1)−2.811(1) and 2.448(2)−2.470(2) Å, respectively, and are similar to that in the starting compound.

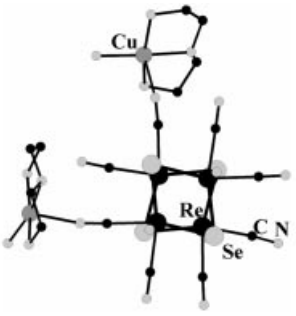

Figure 2. View of the $[\{Cu(dien)(NH_3)\}_2Re_4Se_4(CN)_{12}]$ molecule in compound **2**

Compounds $[\{Cu_2(dien)_3\}Re_4Q_4(CN)_{12}]\cdot nH_2O$ [Q = Se (**3**) and Te (**4**)] are isostructural. Their compositions are similar to that of **1**, but their structures are slightly different. Whereas compound **1** has a chain-like polymeric structure (Figure 1), **3** and **4** are molecular (Figure 3) and contain cluster anions $[Re_4Q_4(CN)_{12}]^{4-}$ (Q = Se, Te) and non-bridging cationic $[Cu_2(dien)_3]^{4+}$ units. In **1** both Cu atoms are crystallographically equivalent and coordinated to N atoms of CN^- ligands of different clusters. In **3** and **4** the Cu atoms exhibit different coordination environments. One Cu atom has a similar arrangement to the Cu atom in compound **1**; the second Cu atom is coordinated by three N atoms of one dien ligand and by two N atoms of another dien ligand, which bridges the two Cu atoms of the cationic unit through its third N atom. Thus, both Cu atoms in $[Cu_2(dien)_3]^{4+}$ cation are five-coordinate and, once again, have square-pyramidal coordination spheres.

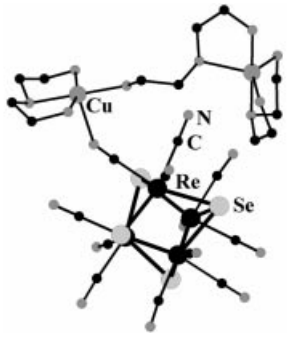

Figure 3. View of the $[\{Cu_2(dien)_3\}Re_4Se_4(CN)_{12}]$ molecule in compound **3**

$[K(H_2O)_2]_2[\{Cu_3(dien)_4\}\{Re_4Q_4(CN)_{12}\}_2]\cdot 8H_2O$ [Q = Se (**5**) and Te (**6**)] are also isostructural. The structures of the anionic components $[Re_4Q_4(CN)_{12}]^{4-}$ are similar to those in the starting materials and related compounds. The Re−Re distances are 2.8624(9)−2.8821(11) Å (**5**) and 2.798(1)−2.809(1) Å (**6**), and the Re−(μ_3-Q) distances are 2.624(1)−2.649(1) Å (**5**) and 2.457(2)−2.484(2) Å (**6**). The secondary building unit of this structure is provided by the molecular complex $[\{Cu_3(dien)_4\}\{Re_4Te_4(CN)_{12}\}_2]$ (Figure 4), in which two cluster anions $[Re_4Te_4(CN)_{12}]^{4-}$ are bridged by the cation $[Cu_3(dien)_4]^{6+}$, which can be described as [(dien)Cu−(dien)Cu(dien)−Cu(dien)]. There are two symmetry-equivalent Cu atoms, each coordinated by three N atoms of one dien ligand, one N atom of the bridging dien ligand, and by one N atom of a CN^- ligand of the $[Re_4Q_4(CN)_{12}]^{4-}$ anion [Cu−N distances are 2.009(9)−2.03(1), 2.011(9) and 2.376(9) Å for compound **5** and 2.03(1)−2.04(1), 2.04(1) and 2.38(1) Å for compound **6**]. The third Cu atom lies at the centre of this cation and is symmetrically coordinated by four N atoms of two bridg-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing dien ligands with Cu−N distances of 1.999(9)−2.086(8) Å (**5**) and 2.02(1)−2.099(9) Å (**6**) and at the same time by two additional *trans*-situated N atoms of CN^- ligands of two different anions (Figure 4). The opposite Cu−N distances are 2.579 Å for **5** and 2.581 Å for **6** and are slightly longer than the corresponding distances of five-coordinate Cu atoms. Thus, this Cu atom is octahedrally ($CN = 6$) coordinated and bridges the molecular units $[\{Cu_3(dien)_4\}\{Re_4Q_4(CN)_{12}\}_2]$ to construct the polymeric structure. The negative charge of this one-dimensional network is compensated by K^+ cations. N atoms of CN^- ligands coordinate to these cations as shown in Figure 5.

Figure 4. Anionic connectivity pattern in the crystal structure of compound **5**

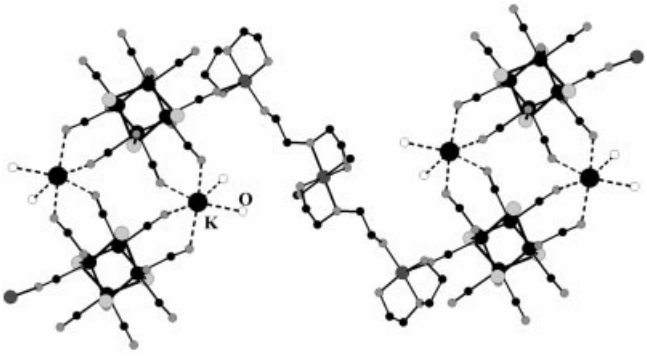

Figure 5. $[\{Cu_3(dien)_4\}\{Re_4Se_4(CN)_{12}\}_2]^{2-}$ secondary building unit in the crystal structure of compound **5** with associated potassium cations

In compounds **1**, **5** and **6** Cu atoms bridged by dien ligands are bonded to cluster anions, whereas in **3** and **4** the complex cation $\{Cu_2(dien)_3\}$ is coordinated to one cluster anion only (Figure 6). Such coordinations have not previously been observed in Cu complexes; in all known similar complexes three N atoms of the dien ligand are always coordinated to one Cu atom as, for example, in $[Cu(dien)]_3[Fe(CN)_6]_2 \cdot 6H_2O$.[15] There are only two known examples of metal compounds (both Ag-containing complexes) with bridging dien ligands.[16]

From the structure analyses we conclude that the coordination of copper atoms is very important: it determines not only the stoichiometry but also the main features of the crystal structure. Evidently, in solutions of these systems, which contain two competitive N-donor ligands, NH_3 and dien, some cationic complexes − monomeric $[Cu(NH_3)(dien)]^{2+}$, and oligomeric [(dien)Cu−(μ-dien)−Cu(dien)]$^{4+}$ and [(dien)Cu−(μ-dien)−Cu−(μ-dien)−Cu(dien)]$^{6+}$ are formed. The formation of oligomers can be explained by a deficiency of ligands in the coordination sphere of Cu^{2+} of simple complexes with stoichiometry [Cu(dien)] (dien has three N-donor atoms only). Copper atoms of similar complexes are unsaturated in their coordination and therefore tend to complete their environment by means of bond formation with other dien ligands. In the complexes **1**, **3**, **4** such interaction leads to oligomeric cations [(dien)Cu−(μ-dien)−Cu(dien)]$^{4+}$ where an additional μ-dien ligand becomes a bridged one. If the concentration of Cu^{2+} ions is decreased (as in the syntheses of **5** and **6**), oligomeric cations with two bridged μ-dien ligands, [(dien)Cu−(μ-dien)−Cu−(μ-dien)−Cu(dien)]$^{6+}$, are formed. However, the copper atoms in such oligomers are again unsaturated − a reason for further interaction with CN ligands of the cluster anions.

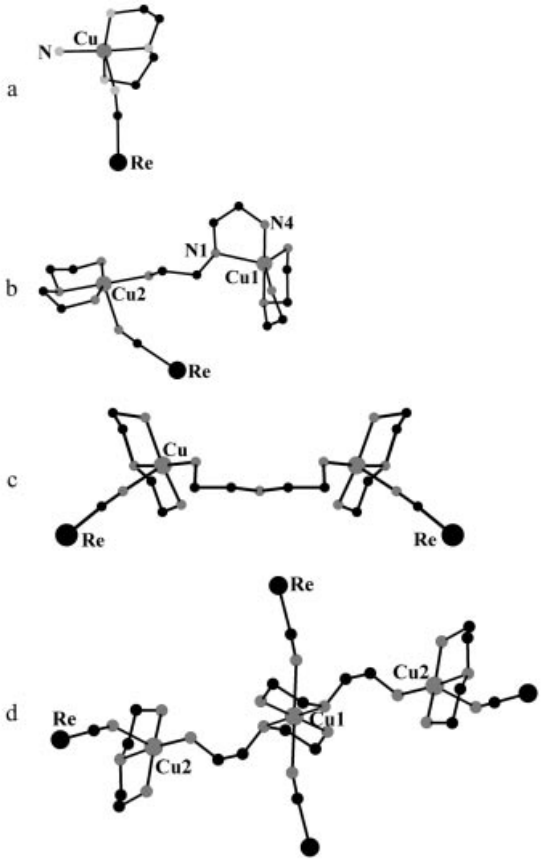

Figure 6. Ligand environment of Cu atoms: a (in **2**), b (in **3**, **4**), c (in **1**) and d (in **5**, **6**)

As expected, the ratio of reagents is an important experimental factor that affects the composition of the resultant compounds. For example, for a Cu/dien ratio near 1:1, complex **2** is formed. If the concentration of dien is increased, complexes **1**, **3**−**6** with higher dien contents are realized. It is of interest that, although in all these reactions the concentration of Cu^{2+} ions was sufficient to form complexes

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

containing only Cu^{2+} cations {the ratio $Cu^{2+}/[Re_4Q_4(CN)_{12}]^{4-} > 2$}, two compounds (**5** and **6**) were obtained that are crystallized with additional K^+ cations. This may be due to structural factors: these compounds contain longer oligomeric cations [(dien)Cu−(μ-dien)−Cu−(μ-dien)−Cu(dien)]$^{6+}$.

Comparison of complex **1** (Figure 6, c) with **3** and **4** (Figure 6, b) shows that the latter can be transformed into the structure of **1** by breaking the Cu1−N1(μ-dien) bond and then joining the CN group of the cluster complex to a vacated coordination site of the copper atom.

Experimental Section

Materials and Syntheses: All reagents were used as purchased. $[K_4Re_4Te_4(CN)_{12}]\cdot 5H_2O$ was synthesized by the reaction of $[Re_4Te_4(TeCl_2)_4Cl_8]$ with KCN in water.[17] Se and S analogues were synthesized by the reactions of $[Re_4Se_4(TeCl_2)_4Cl_8]$ and $[Re_4S_4(TeCl_2)_4Cl_8]$, respectively, with KCN as described for $[K_4Re_4Se_4(CN)_{12}]\cdot 6H_2O$.[12] $[Re_4Q_4(TeCl_2)_4Cl_8]$ (Q = Te, Se, S) were synthesized by the reaction of $ReCl_5$ with elemental Te or with a mixture of elemental Se or S with elemental Te.[18] FT-IR: Bruker IFS-85, Perkin−Elmer 1760X. Elemental analyses: Vario EL of Elementar Analysensysteme GmbH.

$[\{Cu_2(dien)_3\}Re_4S_4(CN)_{12}]$ (1): A solution of $CuCl_2$ (0.04 g) in concentrated aqueous ammonia (5 mL) was mixed with a solution of $[K_4Re_4S_4(CN)_{12}]\cdot 5H_2O$ (0.02 g) in water (5 mL). Diethylenetriamine (dien) (0.04 mL) was added to the reaction mixture and the resultant solution was kept for two weeks in a vessel covered by a watch glass. Dark red crystals that formed during this time were filtered off and dried on filter paper. Yield: 0.02 g (67%). $C_{24}H_{55}Cu_2N_{21}O_8Re_4S_4$ (2148.17): calcd. C 17.8, H 2.4, N 18.1, S 7.9; found C 17.5, H 2.9, N 17.9, S 7.6. IR (KBr): $\tilde{\nu}$ = 2180 (w), 2153 (s) [ν(CN)] cm^{-1}.

$[\{Cu(dien)(NH_3)\}_2Re_4Se_4(CN)_{12}]\cdot 2.5H_2O$ (2): A solution of $CuCl_2$ (0.030 g) in concentrated aqueous ammonia (2 mL) was mixed with a solution of $[K_4Re_4Se_4(CN)_{12}]\cdot 5H_2O$ (0.015 g) in water (2 mL); dien (0.02 mL) was added to the reaction mixture and the resultant solution was kept for two weeks in a vessel covered by a watch glass. Black crystals that formed during this time were filtered off and dried on filter paper. Yield: 0.014 g (82%). $C_{20}H_{37}Cu_2N_{20}O_{2.5}Re_4Se_4$ (1785.42): calcd. C 13.5, H 2.1, N 15.7; found C 13.4, H 2.0, N 15.7. IR (KBr): $\tilde{\nu}$ = 2145 cm^{-1}.

$[\{Cu_2(dien)_3\}Re_4Se_4(CN)_{12}]\cdot 8.25H_2O$ (3): A solution of $CuCl_2$ (0.020 g) in concentrated aqueous ammonia (2 mL) was mixed with a solution of $[K_4Re_4Se_4(CN)_{12}]\cdot 5H_2O$ (0.015 g) in water (2 mL); dien (0.04 mL) was added to the reaction mixture and the resultant solution was kept for one week in a vessel covered by a watch glass. Black needle-like crystals that formed during this time were filtered off and dried on filter paper. Yield: 0.012 g (67%). $C_{24}H_{55.5}Cu_2N_{21}O_{8.25}Re_4Se_4$ (1958.11): calcd. C 14.7, H 2.7, N 15.0; found C 15.0, H 2.5, N 15.2. IR (KBr): $\tilde{\nu}$ = 2142 [ν(CN)] cm^{-1}.

$[\{Cu_2(dien)_3\}Re_4Te_4(CN)_{12}]\cdot 8H_2O$ (4): A solution of $CuCl_2$ (0.015 g) in concentrated aqueous ammonia (2 mL) was mixed with a solution of $[K_4Re_4Te_4(CN)_{12}]\cdot 5H_2O$ (0.007 g) in water (2 mL); dien (0.04 mL) was added to the reaction mixture. The resultant solution was kept for two weeks in a vessel covered by a watch glass. Black needle-like crystals formed during this time were filtered off and dried on filter paper. Yield: 0.008 g (95%). $C_{24}H_{55}Cu_2N_{21}O_8Re_4Te_4$ (2148.17): calcd. C 13.4, H 2.6, N 13.7; found C 13.6, H 2.5, N 14.0. IR (KBr): $\tilde{\nu}$ = 2134 [ν(CN)] cm^{-1}.

$[K(H_2O)_2]_2[\{Cu_3(dien)_4\}\{Re_4Se_4(CN)_{12}\}_2]\cdot 8H_2O$ (5): A solution of $CuCl_2$ (0.005 g) and dien (0.04 mL) in concentrated aqueous ammonia (2 mL) was mixed with a solution of $[K_4Re_4Se_4(CN)_{12}]\cdot 5H_2O$ (0.015 g) in water (2 mL). The resultant solution was kept for two weeks in a vessel covered by a watch glass. Black crystals that formed during this time were filtered off and dried on filter paper. Yield: 0.013 g (76%). $C_{40}H_{76}Cu_3K_2N_{36}O_{12}Re_8Se_8$ (3643.47): calcd. C 13.2, H 2.1, N 13.8; found C 13.3, H 2.5, N 14.0. IR (KBr): $\tilde{\nu}$ = 2145 [ν(CN)] cm^{-1}.

$[K(H_2O)_2]_2[\{Cu_3(dien)_4\}\{Re_4Te_4(CN)_{12}\}_2]\cdot 8H_2O$ (6): A solution of $CuCl_2$ (0.005 g) in concentrated aqueous ammonia (2 mL) was mixed with a solution of $[K_4Re_4Te_4(CN)_{12}]\cdot 5H_2O$ (0.015 g) in water (2 mL); dien (0.04 mL) was added to the reaction mixture. The resultant solution was then kept for two weeks in a vessel covered by a watch glass. Black prismatic crystals that formed during this time were filtered off and dried on filter paper. Yield: 0.016 g (96%). $C_{40}H_{76}Cu_3K_2N_{36}O_{12}Re_8Te_8$ (4032.58): calcd. C 11.9, H 1.9, N 12.5; found C 12.0, H 1.9, N 13.6. IR (KBr): $\tilde{\nu}$ = 2136 [ν(CN)] cm^{-1}.

Crystallography: Single-crystal X-ray diffraction data were collected by standard techniques [Mo-K_α radiation (λ = 0.71073 Å), ω-scan mode] with Enraf-Nonius CAD4 (compound **1**) and Siemens P4 (compounds **2**−**6**) diffractometers under ambient conditions. Data were corrected for absorption with azimuthal scans. The structures were solved by direct methods and refined by least-squares methods against F^2. All non-hydrogen atoms were refined anisotropically taking into account all independent reflections. The positions of the hydrogen atoms of the dien groups were idealized; those of water molecules were not located. All calculations were carried out with an IBM PC using the SHELX-97 program package.[19,20]

1: Dark red prism, crystal dimensions 0.24 × 0.20 × 0.18 mm, orthorhombic, space group $Pmn2_1$, Z = 2, a = 15.272(2), b = 8.8743(9), c = 17.946(3) Å, V = 2432.2(6) Å^3, $\rho_{calcd.}$ = 2.215 g cm^{-1}, μ = 10.986 mm^{-1}, 4887 measured reflections, 4402 independent (R_{int} = 0.0387), $R(F)$ = 0.0392 for 2673 reflection with $F_{hkl} \geq 4\sigma(F_{hkl})$ and $R_w(F^2)$ = 0.0963 for all independent reflections. The absolute structure was established by use of the Flack parameter.

2: Black block, crystal dimension 0.22 × 0.22 × 0.65 mm, triclinic, space group $P\bar{1}$, Z = 2, a = 12.242(3), b = 12.969(4), c = 15.439(6) Å, α = 95.12(3), β = 110.38(3), γ = 114.02(2)°, V = 2020.8(11) Å^3, $\rho_{calcd.}$ = 2.934 g cm^{-1}, μ = 16.620 mm^{-1}, 7487 measured reflections, 7143 independent (R_{int} = 0.0503), $R(F)$ = 0.0465 for 5824 reflections with $F_{hkl} \geq 4\sigma(F_{hkl})$ and $R_w(F^2)$ = 0.1243 for all independent reflections.

3: Black needles, crystal dimensions 0.08 × 0.10 × 0.65 mm, monoclinic, space group $P2_1/n$, Z = 4, a = 13.839(3), b = 15.181(3), c = 24.015(4) Å, β = 95.78(2)°, V = 5019.7(17) Å^3, $\rho_{calcd.}$ = 2.798 g cm^{-1}, μ = 12.581 mm^{-1}, 10444 measured reflections, 8941 independent (R_{int} = 0.0589), $R(F)$ = 0.0613 for 5209 reflections with $F_{hkl} \geq 4\sigma(F_{hkl})$ and $R_w(F^2)$ = 0.1488 for all independent reflections.

4: Black needle, crystal dimensions 0.14 × 0.14 × 0.4 mm, monoclinic, space group $P2_1/n$, Z = 4, a = 13.844(3), b = 15.288(6), c = 24.194(6) Å, β = 95.287(13)°, V = 5099(2) Å^3, $\rho_{calcd.}$ = 2.591 g cm^{-1}, μ = 13.403 mm^{-1}, 9221 measured reflections, 8828 independent (R_{int} = 0.0463), $R(F)$ = 0.0499 for 5601 reflections with $F_{hkl} \geq 4\sigma(F_{hk})$ and $R_w(F^2)$ = 0.0952 for all independent reflections.

Iron(III) Chelation: Tuning of the pH Dependence by Mixed Ligands

Anne-Marie Albrecht-Gary,*[a] Sylvie Blanc,[a] Frederic Biaso,[b] Fabrice Thomas,[b] Paul Baret,[b] Gisele Gellon,[b] Jean-Louis Pierre,[b] and Guy Serratrice*[b]

Keywords: Tripodal ligands / Iron / Thermodynamics / UV/Vis spectroscopy / Siderophores

The iron(III) chelating properties of two heteropodands with 8-hydroxyquinoline and catechol binding groups were examined and compared to those of the corresponding homopodal analogues, O-TRENSOX and TRENCAMS. Like the parent homopodands, the two heteropodands are based on the TREN scaffold and the chelating units are connected by amide groups, TRENSOX2CAMS having two 8-hydroxyquinoline and one catechol arms and TRENSOXCAMS2 one 8-hydroxyquinoline and two catechol moieties. The aqueous coordination chemistry of these ligands was examined by potentiometric and spectrophotometric methods in combination with ^{1}H NMR spectroscopy. The respective pFe^{III} values showed a cooperative effect of the mixed chelating units. Moreover, the pFe^{III} dependence on pH showed that the mixed ligands exhibit a higher complexing ability than the parent ligands over the pH range 5–9 which is of biological relevance. This result could be of great interest for medical applications.

Introduction

Siderophores are iron chelating agents that are excreted by microorganisms to render iron soluble in the environment and favour the uptake of this metal. Iron chelation by some natural or synthetic chelators can be applied to human diseases characterised by iron overload. Although the coordination chemistry of a great number of water-soluble synthetic iron chelators has been described,[1] the pH dependence of the coordination abilities has not been thoroughly investigated. Most of the comparative data in the literature are allowed by the use of the pFe^{III} values (calculated for $[Fe^{III}]_{tot}$ = 1 μM, $[L]_{tot}$ = 10 μM at pH = 7.4) and, of course, pFe^{III} reflects only the complexing ability of a given ligand at physiological pH. Owing to the fact that pH can vary in a relatively large range between the different biological compartments, an understanding of the pH dependence of the pFe^{III} value may be a decisive criterion for the understanding of the in vivo behaviour of a given iron chelator. On the other hand, the design and the synthesis of iron chelators with high pFe^{III} values in a large range of pH, constitutes an interesting challenge for chemists. We previously reported the dependence of pFe^{III} on pH for two homopodands based on catechol and on 8-hydroxyquinoline bidentate units.[2,3] We showed that the tris(catechol) ligand TRENCAMS is a stronger ferric chelator than the tris(hydroxyquinolinate) analogue O-TRENSOX at pH values greater than 7 and that the opposite sequence is observed at pH values lower than 7. In order to obtain an efficient chelator of iron(III) over a large range of pH, we have synthesised mixed tripodal siderophores with both catechol and 8-hydroxyquinoline moieties. Recently, the synthesis of mixed tripodal ligands based on (i) two hydroxypiridinone and one catechol moieties, and (ii) two hydroxypiridinone and one 2-hydroxyisophtalamide groups has been published.[4] We report in this paper the synthesis, acid-base properties, and ferric complexation of two monotopic tripodal mixed ligands TRENSOX2CAMS (**L^1**) and TRENSOXCAMS2 (**L^2**; Figure 1). These molecules belong to a family of tripods with a tris(2-aminoethyl)amine group anchoring arms that bear bidentate coordination subunits (namely either a 5-sulfo-8-hydroxyquinoline-7-carbamoyl group or 5-sulfo-2,3-dihydroxybenzoyl unit). The ligands differ by the number of catecholylamide groups, none for ligand **L^0** (O-TRENSOX), one for ligand **L^1**, two for ligand **L^2** and three for ligand **L^3** (TRENCAMS; Figure 1). Combining potentiometric and absorption spectrophotometric titrations with ^{1}H NMR spectroscopy we were able to characterise in water the protonated and ferric species formed with ligands **L^1** and **L^2** over a large pH range.

Results and Discussion

Synthesis

The synthesis of the heterotripodal hexadentate ligands **L¹** and **L²** is presented in Figure 2. The two catecholate subunits of ligand **L²** were connected to the tripodal scaffold by direct condensation[5] of two equivalents of 2,3-dimethoxybenzoic chloride with one equivalent of tris(2-aminoethyl)amine (TREN) [path (a′)], then the oxinate subunit was grafted onto the free primary amine group by coupling with activated (CDI) 7-carboxy-8-hydroxyquinoline. The synthesis of **L¹** required protection of one arm of TREN with a trityl group [paths (a, b, c)]. Phenol groups were protected with benzyl groups (oxine) and methyl groups (catechol), respectively; deprotections were performed with BBr_3. Finally, regiospecific sulfonation in position 5 of both oxinate and catecholate subunits afforded the hydrosoluble ligands **L¹** and **L²**.

Acid-Base Properties of Ligands

The protonation constants of **L¹** and **L²** were determined by combination of potentiometric and spectrophotometric

titrations (see details in Exp. Sect.). Both ligands possess a total of ten protonable functions. However, protonation of the three sulfo groups that are moderately strong acids (log $K^H < 2$)[6] was not considered likely under our conditions. Seven stepwise protonation constants were determined for each ligand. The corresponding values and statistical errors are given in Table 1. Speciation diagrams are presented in Figures S1 and S2 of the supporting information.

Table 1. Assignment of the successive protonation constants of various heterotripodal ligands with 8-hydroxyquinoline and/or catechol subunits; solvent: water, $I = 0.10$ M ($NaClO_4$), $T = (25.0 \pm 0.2)$ °C; numbers in parentheses correspond to statistical errors (3σ) on the last digit

[a] Ref.[2] [b] Ref.[3] [c] Spectrophotometric determinations under basic conditions. [d] Average value for the three *meta* catechol OH groups.

The protonation constants of $\mathbf{L^1}$ were determined by potentiometry except for log $K_1^H = 11.5$ and log $K_7^H = 1.8$, which were determined spectrophotometrically. As for $\mathbf{L^2}$, the values in Table 1 represent averages of values determined by both methods, except for log $K_5^H = 6.56$ (determined by potentiometry) and log $K_1^H = 12.5$ (determined by spectrophotometry).

The protonation constants were attributed to $\mathbf{L^1}$ and $\mathbf{L^2}$ by comparison with the log K^H values of the ligand $\mathbf{L^0}$, bearing three hydroxyquinoline groups,[2] and with those of the tris(catecholate) ligand $\mathbf{L^3}$ [3] (Table 1). The highest protonation constants (11.5 for $\mathbf{L^1}$; 12.5 and 11.41 for $\mathbf{L^2}$) can be assigned to the *meta* hydroxyl groups of the sulfocatecholyl moieties. These values are in agreement with those reported under similar conditions for some sulfocatechol derivatives such as 1,2-dihydroxybenzene-4-sulfonic acid (log $K^H = 12.16$),[7] 1,2-dihydroxybenzene-3,5-disulfonic acid (Tiron; log $K^H = 12.5$)[8] or *N*,*N*-dimethyl-2,3-dihydroxy-5-sulfonatobenzamide (DMBS; log $K^H = 11.5$).[9] The values of the lowest protonation constants (1.8 and 2.89 for $\mathbf{L^1}$; 2.34 for $\mathbf{L^2}$) correspond to the pyridine nitrogen of the sulfohydroxyquinoline moieties. Compared to 8-hydroxyquinoline-5-sulfonic acid (log $K^H = 3.93$),[10] the protonation constants determined for $\mathbf{L^1}$ and $\mathbf{L^2}$ are two orders of magnitude lower. This could be explained by the electron-withdrawing effect of the carbonyl linker in position 7, which is similar to that of the nitro group in 7-nitro-8-hydroxyquinoline-5-sulfonic acid (log $K^H = 2.01$).[11] The hydroxyl protonation constant of 8-hydroxyquinoline-5-sulfonic acid[10] is equal to 8.42 and those of $\mathbf{L^0}$ vary between 7.44 and 8.62.[2] We attribute the values 8.78 and 7.85 for $\mathbf{L^1}$ and 7.93 for $\mathbf{L^2}$ to the protonation of the 8-hydroxyquinoline OH groups.

Based on the fact that the species $\mathbf{L^2}H_3$ and $\mathbf{L^2}H_4$ have the same absorption spectra, suggesting that protonation does not occur on a chromophore, the protonation constant log $K_5^H = 6.56$ was attributed to the tertiary amine nitrogen of $\mathbf{L^2}$ anchor. This was confirmed by the ^{1}H NMR titration of $\mathbf{L^2}$ which showed an inflection point at pD ≈ 6 and a significant upfield shift of the methylene protons, characteristic of the protonation of its closest acid-base site, i.e. the tertiary amine (Figure 3). Similarly for $\mathbf{L^1}$, the protonation constant log $K_4^H = 6.96$ was attributed to the tertiary amine.

The values of log K^H of the tertiary amine anchor determined for $\mathbf{L^1}$ and $\mathbf{L^2}$ are close to that of $\mathbf{L^0}$ (log $K^H = 6.36$).[2] They are, however, much lower than that of the tris(catechol) ligand $\mathbf{L^3}$ (log $K^H = 8.01$).[3] It has already been reported[12] that the protonation of this site is sensitive to the ability of the tertiary amine to form hydrogen bonds with substituents in the β-position of the TREN scaffold. Formation of a hydrogen bond between the lone electron pair of the tertiary amine nitrogen and the amide hydrogen

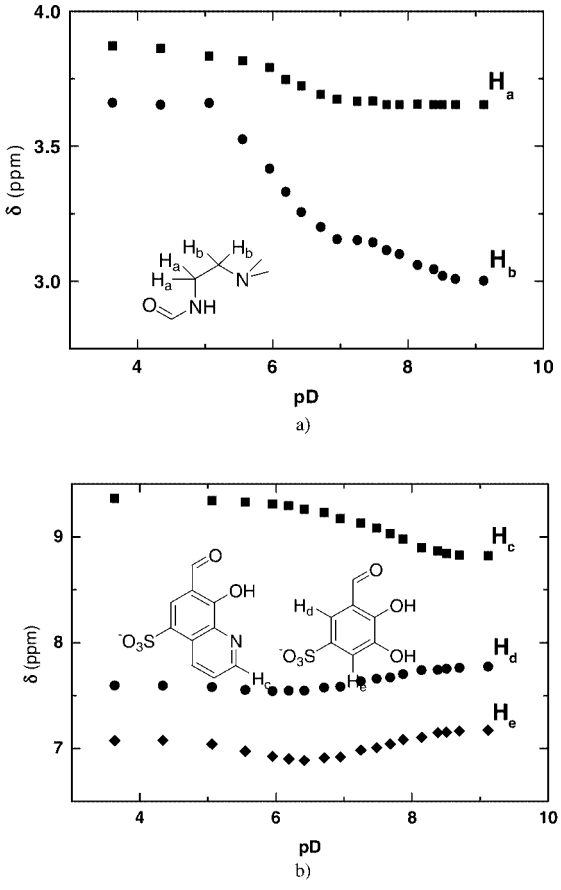

Figure 3. ^{1}H NMR chemical shift variation as a function of pD for the methylene (a) and aromatic (b) protons of $\mathbf{L^2}$; solvent: D_2O, $[\mathbf{L^2}] = 5$ mM

decreases strongly its basicity, providing a sufficient stabilisation of the deprotonated form of the amine, as observed with the tripodal ligands bearing 8-hydroxyquinoline groups.

The interactions of the amide linkers with the tertiary amine nitrogen can be further affected by the protonation state of the *ortho*-hydroxyl groups either of the 8-hydroxyquinoline or the catechol subunits. Indeed, the protonation of these sites could induce a different geometry around the TREN anchor, as suggested by the shoulder at pD = 7−8.5 in the curve H_b during the ^{1}H NMR titration of ligand **L²** (Figure 3). The isomer shift of the H_c as well as H_d and H_e (Figure 3) observed for **L²** increases from pD = 6.5 to 9 with an inflection point at pD = 7.5−8 in relation to the protonation of hydroxyl groups (log K^H = 7.35 and 7.93). This indicates that such a protonation is responsible for a conformational change around the amide-catechol axis, which induces a shift of the proton resonance.

The remaining protonation constants (7.35 and 5.55 for **L²** and 5.62 for **L¹**) are attributed to the catechol hydroxyl groups *ortho* with respect to the amide linker. These values are in agreement with those of other tripodal catecholylamide-type ligands.[13]

The calculated electronic spectra of protonated species of **L¹** and **L²** are given in Figure 4. The spectral properties of **L¹** and **L²** are qualitatively in agreement with those of other 8-hydroxyquinoline and/or catechol based ligands. Catechol derivatives show a $\pi \rightarrow \pi^*$ transitions in the UV region (300−400 nm) with the maximum of the absorption band shifting to longer wavelengths and the molar absorption coefficient increasing as the hydroxyl groups are deprotonated.[14] Similarly, 8-hydroxyquinoline-5-sulfonic acid displays spectral variations in this region upon protonation.[15] It should be noted that molar absorption coefficients of the heterotripodal ligands (≈2 × 10^4 M^{-1}·cm^{-1} at around 340 nm and ≈5−6 × 10^4 M^{-1}·cm^{-1} at around 270 nm for totally deprotonated **L¹** and **L²**) are higher than the value obtained by addition of molar absorption coefficients of simple 8-hydroxyquinolinate or catecholate ligands.[15,16]

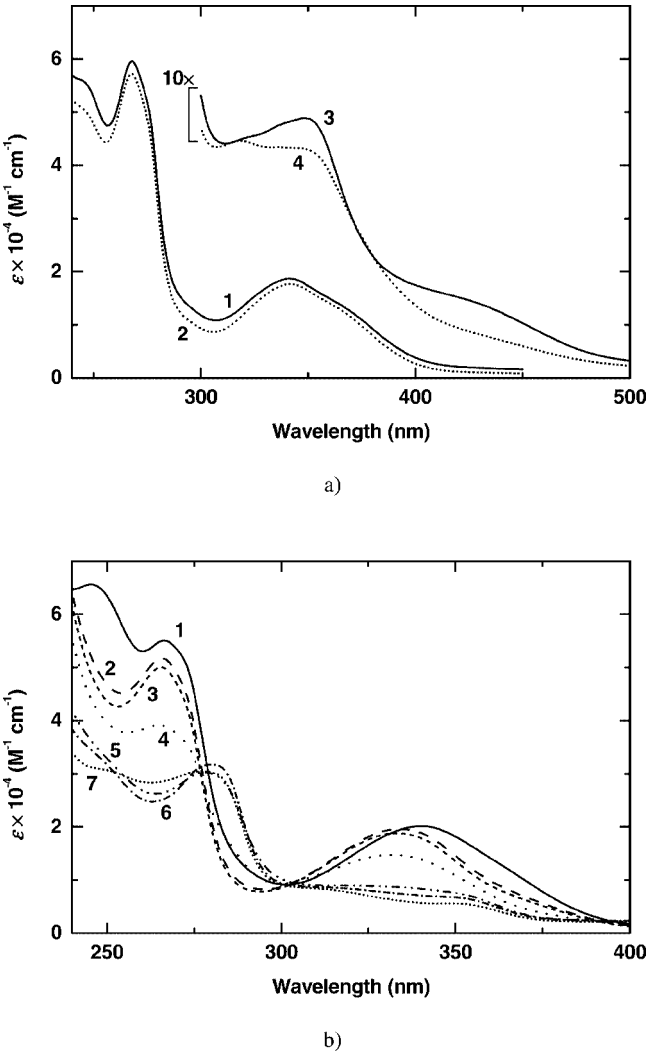

Figure 4. Calculated electronic spectra of the protonated species of heterotripodal ligands; solvent: water, I = 0.10 M ($NaClO_4$), T = (25.0 ± 0.2) °C: (a) ligand **L¹**: (1) $\mathbf{L^1H_7}$, (2) $\mathbf{L^1H_6}$, (3) $\mathbf{L^1H}$, (4) **L¹**; (b) ligand **L²**: (1) **L²**, (2) $\mathbf{L^2}$ H, (3) $\mathbf{L^2H_2}$, (4) $\mathbf{L^2H_3} \equiv \mathbf{L^2H_4}$, (5) $\mathbf{L^2H_5}$, (6) $\mathbf{L^2H_6}$, (7) $\mathbf{L^2H_7}$; charges are omitted for the sake of clarity

Characterisation of the Ferric Complexes

Both ligands are hexadentate and form only 1:1 ferric complexes. The potentiometric titration curves recorded for a 1:1 metal-to-ligand ratio (Figure 5) show a large pH jump at a = 7, indicating that all the ligand protons are released when the ferric ion is bound. Since both **L¹** and **L²** form ferric complexes totally at pH values less than 3 the global stability constant log β_{FeL} could not be determined from the potentiometric data.

The spectra obtained during the spectrophotometric titrations of ferric complexes of **L¹** and **L²** are shown in Figures S3 and S4. The absorbance data were refined with the Letagrop-Spefo[17,18] and Specfit[19−22] programs and provided values of global stability constants of ferric complexes of both **L¹** and **L²**. The spectrophotometric data obtained from the competition for ferric ion between **L²** and EDTA were treated with the Specfit program allowing the determination of the stability constant log β_{FeL}. All the results are summarised in Table 2.

The electronic spectra of de-, mono- and polyprotonated ferric complexes of **L¹** and **L²** calculated from the refinement of absorbance data are shown in Figure 6; speciation diagrams are presented in Figure 7.

The ferric complexes of catechol derivatives generally show a strong ligand-to-metal charge transfer (LMCT) band with a maximum at about 700 nm for mono(catecholate) species, at about 560 nm for bis(catecholate) species and finally at about 480 nm for tris(catecholate) complexes. The charge-transfer bands observed are due to electronic transitions from the highest valence orbitals of the ligand to the 3d orbitals of iron(III).[23] As the maximum moves to shorter wavelengths with increasing number of coordinating ligands the molar absorption coefficient increases. Electron-withdrawing substituents on the aromatic rings of the catechol moieties increase the molar absorption coefficient but have little effect on the wavelength of the maximum. Ferric

Figure 5. Potentiometric titration curves for the heterotripodal ligands and their ferric complexes; solvent: water, I = 0.10 M ($NaClO_4$), T = (25.0 ± 0.2) °C: (a) titration of $\mathbf{L^1}$ (1 mM): (1) free ligand, (2) 1:1 ferric complex; (b) titration of $\mathbf{L^2}$ (1 mM): (1) free ligand, (2) 1:1 ferric complex

complexes of 8-hydroxyquinoline-5-sulfonic acid are characterised by two absorption maxima in the visible region. The maximum at 443 nm is assigned to an LMCT band belonging to the phenolic oxygen, while the band at 595 nm is due to charge transfer from the pyridine nitrogen to the metal cation.[2] It should be noted that in common with $\mathbf{L^0}$ and $\mathbf{L^3}$, both $\mathbf{L^1}$ and $\mathbf{L^2}$ form protonated ferric complexes, indicating that the coordination sites of the complexes can be protonated without losing the ferric ion. This behaviour can be attributed to a change of catecholate or oxinate bonding mode to the salicylate mode (coordination with carbonyl and *o*-hydroxyl oxygens).

It is of interest to consider the different multiprotonated ferric complexes of $\mathbf{L^1}$ and $\mathbf{L^2}$ by examining their electronic spectra (Table 2) as this can provide information on the coordination modes and their successive deprotonation constants pK_{FeLH_n} (defined in Table 3). These values are calculated from the difference between the values of log β_{FeLH_n}

Table 2. Cumulative stability constants β_{FeLHn}, pFe^{III} values and UV/Vis spectral characteristics of ferric complexes formed with the tripodal ligands; solvent: water, I = 0.10 M ($NaClO_4$), T = (25.0 ± 0.2) °C; numbers in parentheses correspond to statistical errors (3σ) on the last digit; an incertitude of 5% is estimated for the molar absorption coefficients

	$Fe\mathbf{L^3}$	43.6(1)		488	5300

[a] $\beta_{FeLHn} = [FeLH_n]/([Fe^{III}] \times [L] \times [H^+]n)$. [b] Calculated for $[Fe^{III}]_{tot} = 10^{-6}$ M, $[L]_{tot} = 10^{-5}$ M, pH = 7.4. [c] * = shoulder. [d] Species have identical electronic spectra.

and are reported in Table 3 together with the values from tris(catecholate) and tris(8-hydroxyquinolinate) complexes for comparison. The deprotonation constants of ferric $\mathbf{L^1}$ and $\mathbf{L^2}$ complexes have been attributed by considering that the deprotonation of an 8-hydroxyquinoline group involved in the ferric coordination occurs at a pH much lower than that of the deprotonation of the catechol group. This is supported by the pK_{FeLH_n} values recently determined for tripodal ferric complexes containing a C-pivot scaffold with either an 8-hydroxyquinoline (ligand COX)[24] or a catechol subunit (ligand CacCAM).[25] In particular, the values of pK_{FeLH} (2.12 for Fe-COX and 6.59 for Fe-CacCAM) have been unambiguously attributed to the coordination of the third chelating arm.

The electronic spectrum of $Fe\mathbf{L^1}H_5$, which exhibits two shoulders at 440 nm (ε = 6940 $M^{-1}\cdot cm^{-1}$) and 540 nm (ε = 3680 $M^{-1}\cdot cm^{-1}$), is similar to that of the bis(salicylate) complex of $\mathbf{L^0}$ [2] involving a coordination with two 8-hydroxyquinoline arms of the ligand through the oxygen atoms of the carbonyl and hydroxyl groups. The spectrum of the $Fe\mathbf{L^1}H_3$ complex exhibits an absorption band at λ_{max} = 560 nm (ε = 3970 $M^{-1}\cdot cm^{-1}$), in agreement with the bis(oxinate) coordination. The oxygen and pyridine nitrogen atoms of two 8-hydroxyquinoline arms are involved in the coordination. The value $pK_{FeL^1H_5}$ = 2.4 ($Fe\mathbf{L^1}H_5/Fe\mathbf{L^1}H_3$ equilibrium) corresponds to the deprotonation of both 8-hydroxyquinoline nitrogens in a two-proton step. The small

b)

Figure 6. Calculated electronic spectra of the ferric complexes formed with the heterotripodal ligands; solvent: water, I = 0.10 M ($NaClO_4$), T = (25.0 ± 0.2) °C: (a) ferric $\mathbf{L^1}$ species: (1) Fe$\mathbf{L^1}$, (2) Fe$\mathbf{L^1}$H, (3) Fe$\mathbf{L^1}H_2$, (4) Fe$\mathbf{L^1}H_3$, (5) Fe$\mathbf{L^1}H_5$; (b) ferric $\mathbf{L^2}$ species: (1) Fe$\mathbf{L^2}$ ≡ Fe$\mathbf{L^2}$ H, (2) Fe$\mathbf{L^2}H_2$, (3) Fe$\mathbf{L^2}H_4$, (4) Fe$\mathbf{L^2}H_5$; charges are omitted for the sake of clarity

red-shift of λ_{max} to 580 nm for the formation of Fe$\mathbf{L^1}H_2$ without significant change of ε (3930 $M^{-1}\cdot cm^{-1}$) might be attributed to the deprotonation of the ammonium nitrogen. The value $pK_{FeL^1H_3}$ = 1.9 shows a strong stabilisation of the deprotonated tertiary amine nitrogen by intramolecular hydrogen bonds. The increase of ε to 4490 $M^{-1}\cdot cm^{-1}$ with the concomitant blue shift of λ_{max} to 560 nm for the formation of Fe$\mathbf{L^1}$H is in agreement with the coordination of the catechol arm in a salicylate mode. The last deprotonation equilibrium is accompanied with a spectral change (λ_{max} = 550 nm, ε = 4560 $M^{-1}\cdot cm^{-1}$) that is indicative of a shift to a catecholate coordination and formation of the Fe$\mathbf{L^1}$ species. It should be pointed out that the values of pK_{FeLH_2} and pK_{FeLH} (2.7 and 4.8) are significantly lower than those observed for tris(catecholate) complexes: 8.34 (two-proton step) and 5.5 for $\mathbf{L^3}$, and 4.1 and 5.74 for MECAMS[9] (Table 3), while the pK_a's of the free ligand are of the same order of magnitude.

[c] K_{FeLHn} = ([FeLH] × $[H]^4$)/[$FeLH_5$]. [d] K_{FeLHn} = ([$FeLH_{n-2}$] × $[H]^2$)/[$FeLH_n$]. [e] K_{FeLHn} = ([FeLH] × $[H]^3$)/[$FeLH_4$].

The spectral properties of the Fe$\mathbf{L^2}H_5$ species (ε = 4700 $M^{-1}\cdot cm^{-1}$ at λ_{max} = 409 nm and a shoulder at 520 nm with ε = 3260 $M^{-1}\cdot cm^{-1}$) are intermediate between the bis(salicylate) coordination of ferric $\mathbf{L^3}$ (two catechols)[3] and ferric $\mathbf{L^0}$ (two 8-hydroxyquinolines).[2] This confirms that $\mathbf{L^2}$ forms a bis(salicylate) complex with one catechol and one

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

8-hydroxyquinoline coordinated to the ferric ion. For the formation of Fe$\mathbf{L^2}H_4$ the λ_{max} is red-shifted to 573 nm, consistent with the change of coordination from a salicylate to an oxinate mode for the 8-hydroxyquinoline arm. There is only a slight change in ε (3530 $M^{-1}\cdot cm^{-1}$), indicating that iron is still coordinated by two arms. The value $pK_{FeL^2H_5}$ = 2.2 of the Fe$\mathbf{L^2}H_5$/ Fe$\mathbf{L^2}H_4$ equilibrium corresponds well to the pyridinium nitrogen deprotonation. The formation of the Fe$\mathbf{L^2}H_2$ and Fe$\mathbf{L^2}H$ species is accompanied by spectral shifts of λ_{max} from 573 nm to 542 nm and 525 nm, respectively, and an increase of ε to 4530 $M^{-1}\cdot cm^{-1}$ and 4820 $M^{-1}\cdot cm^{-1}$ is observed. The equilibrium between Fe$\mathbf{L^2}H_4$ and Fe$\mathbf{L^2}H_2$ ($pK_{FeL^2H_4}$ = 6.0) is attributed to the coordination of the third arm (catechol) in a salicylate mode and the change of coordination from salicylate to catecholate for the coordinated catechol arm. The equilibrium between Fe$\mathbf{L^2}H_2$ and Fe$\mathbf{L^2}H$ corresponds to the shift of bonding mode from salicylate to catecholate of the third catechol arm ($pK_{FeL^2H_2}$ = 3.0). As for Fe$\mathbf{L^1}$ complexes, the deprotonation of the catechol groups upon complexation occurs at lower pH than for tris(catechol) ligands cited above. The last equilibrium leading to Fe$\mathbf{L^2}$ species does not induce any spectral changes. It is likely that the deprotonation of the tertiary amine nitrogen is involved. The value of pK_{FeL^2H} = 3.4 is higher than the corresponding constant for ferric $\mathbf{L^1}$ complex ($pK_{FeL^1H_3}$ = 1.9).

pFe^{III} Values

Since the ligands are weak acids, proton competition occurs depending on their protonation constants and the pH. The pFe^{III} value (−log [Fe^{III}]) is thus a better measure of the relative efficiency of the ligands under given conditions of pH, $[Fe^{III}]_{tot}$ and $[L]_{tot}$. The pFe^{III} values have been calculated for pH values over the range 2−10 and are reported as the plot of pFe^{III} vs. pH presented in Figure 8, together with the plots calculated for $\mathbf{L^0}$ and $\mathbf{L^3}$.

The important result, as seen from Figure 8, is that the mixed ligands $\mathbf{L^1}$ and $\mathbf{L^2}$ are stronger iron chelating agents than $\mathbf{L^0}$ and $\mathbf{L^3}$ over the pH range 5−9. This shows that mixed ligands lead to enhanced affinity for the ferric ion at pH above 5 ($\mathbf{L^1}$) or 6 ($\mathbf{L^2}$) relative to ligands with three identical arms. This is related to the different basicities of the binding subunits. Catechol is more basic than 8-hydroxyquinoline, which leads to a stronger competition of protons with ferric ions for catechol ligands at low pH. Hence, 8-hydroxyquinoline is a better chelating agent at low pH, while catechol is a stronger chelator at high pH as observed for $\mathbf{L^0}$ [tris(8-hydroxyquinoline) ligand] and $\mathbf{L^3}$ [tris-(catechol) ligand]. Our results with $\mathbf{L^1}$ (one catechol group) and $\mathbf{L^2}$ (two catechol groups) show that a greater pK_a difference between the proton dissociation of the catechol in the free ligand and that of the same group in the complex is observed in comparison to other tripodal ligands containing only catechol groups (see Table 3). This suggests that the initial coordination of the 8-hydroxyquinoline arm with Fe^{III} favours proton loss of the free catechol and thus increases the affinity of this group for Fe^{III}. This can explain that the highest values for pFe^{III} are obtained with $\mathbf{L^1}$ and $\mathbf{L^2}$ over the pH range 5−9, which is biologically relevant, as shown by the plot in Figure 8. We have also reported in Table 2 the pFe^{III} values calculated under standard conditions (pH = 7.4, $[L]_{tot} = 10^{-5}$ M, $[Fe^{III}]_{tot} = 10^{-6}$ M) for $\mathbf{L^1}$ (31.6) and for $\mathbf{L^2}$ (32.3). These values are higher than those determined for $\mathbf{L^0}$ (29.5) and for $\mathbf{L^3}$ (29.6) and among the highest values determined for an iron sequestering agent.

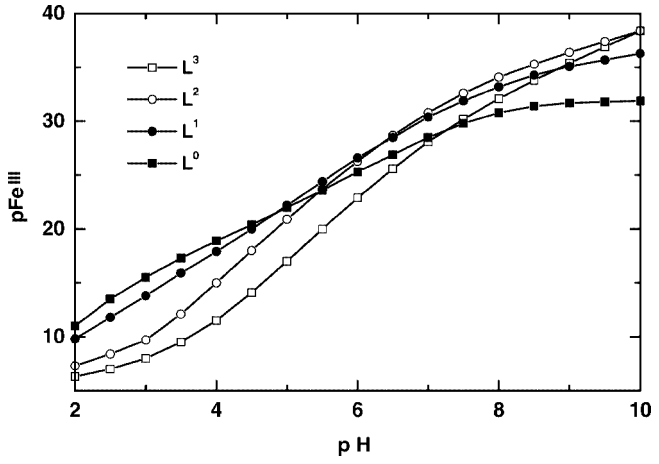

Figure 8. Plot of pFe versus pH for the tripodal ligands; calculated for $[L]_{tot} = 10^{-5}$ M and $[Fe^{III}]_{tot} = 10^{-6}$ M

Conclusion

Iron(III) complexation by two heterotripodal ligands $\mathbf{L^1}$ and $\mathbf{L^2}$ has been characterised. The results are compared to the parent homotripodal ligands allowing the study of the variation of the ligand properties from tris(8-hydroxyquinoline) to tris(catechol) ligand. The thermodynamic and spectroscopic study reveals that in the acidic medium the complex formation starts with two arms coordinating the ferric ion in the salicylate coordination mode. Both 8-hydroxyquinoline subunits are involved in the case of $\mathbf{L^1}$, and one 8-hydroxyquinoline and one catecholate subunit in the case of $\mathbf{L^2}$. This indicates that 8-hydroxyquinoline is a better ligand than catechol at low pH values. Despite the fact that catechol oxygens are better donors than the oxygen and nitrogen atoms of 8-hydroxyquinoline, the competition between H^+ and the metal cation "balances" the complexation efficiency. The striking feature of the mixed ligands is their higher complexing ability than that of the parent ligands over a range of biologically relevant pH values, and especially at neutral pH. This can be explained by the finely tuned complexation power of 8-hydroxyquinoline and catechol groups. It should be noted that the complexation efficiency of the tris(8-hydroxyquinoline) ligand $\mathbf{L^0}$ is less sensitive to pH than the tris(catechol) ligand $\mathbf{L^3}$ over the pH range 2−10. The results described in this work illustrate the great interest of the mixed ligands approach, which, via a synergistic action, leads to a more efficient iron complexing agent than the homopodate ligands.

Experimental Section

Materials and Equipment: Solvents were purified by standard techniques. The amine TREN was distilled from over CaH_2. All other compounds were of reagent grade and were used without further purification. Mass spectra were obtained on NERMAG R 10 10C or Thermo Finnigan Polaris Q or Bruker Esquire-LC 1.6n (electrospray) mass spectrometers. ^1H and ^{13}C NMR spectra were recorded in 5 mm tubes at 25 °C with Bruker AC 200 or WM 250 or Avance 300 spectrometers (δ ppm, TMS reference). Microanalyses were performed by the Central Service of CNRS, Solaise (France). Melting points were determined with a Büchi apparatus and are not corrected.

***N*¹,*N*¹-bis(2-aminoethyl)-*N*²-(trityl)-1,2-ethanediamine (2):** Under argon at room temperature, triphenylchloromethane (2.65 g, 9.5 mmol) in dry CH_2Cl_2 (150 mL) was added dropwise to a solution of tris(2-aminoethyl)amine (1; 5.56 g, 38 mmol) in CH_2Cl_2 (100 mL). The mixture was stirred overnight and then successively washed with 10% NaOH (ca. 100 mL) and brine. The organic phase was dried over sodium sulfate and concentrated under vacuum to give **2** as a yellowish solid (3.7 g, yield: 9.5 mmol, 100%). M.p. 63−65 °C. ^1H NMR (200 MHz, $CDCl_3$): δ = 7.5 (m, 6 H, ArH), 7.3−7.1 (m, 9 H, ArH), 2.9 (br. s, 5 H, NH), 2.7 (t, $^3J_{H,H}$ = 6 Hz, 4 H, CH_2), 2.6 (t, $^3J_{H,H}$ = 6 Hz, 2 H, CH_2), 2.4 (t, $^3J_{H,H}$ = 6 Hz, 4 H, CH_2), 2.2 (t, $^3J_{H,H}$ = 6 Hz, 2 H, CH_2) ppm. ^{13}C NMR (250 MHz, $CDCl_3$): δ = 146.1 (Cq), 128.5 (CH), 127.7 (CH), 126.1 (CH), 70.6 (Cq), 57.4 (CH_2), 55.0 (CH_2), 40.8 (CH_2), 39.9 (CH_2) ppm. MS (DCI, NH_3/isobutane): *m*/*z* = 389 $[M + H]^+$, 243 $[C_{19}H_{15}]^+$.

Compound 3a: Under a stream of argon in order to remove CO_2 as and when it is produced, a solution of 8-benzyloxy-7-carboxyquinoline (3.65 g, 13 mmol) in dry THF (150 mL) was treated with a solution of carbonyldiimidazole (CDI; 2.2 g, 13.6 mmol) in THF (40 mL), under reflux for 2 h. Tripod **2** (2.535 g, 6.5 mmol) in THF (50 mL) was then added dropwise and the mixture was stirred overnight under reflux. The solvent was evaporated off and CH_2Cl_2 was added to the residue. The solution was washed successively with saturated NH_4Cl and brine and then dried. Concentration afforded a dark oil which was chromatographed (silica, cyclohexane/CH_2Cl_2 gradient, then CH_2Cl_2/methanol 1 → 2%) to give **3a** as a yellow foam (3.7 g, 4 mmol, 62%). ^1H NMR (250 MHz, $CDCl_3$): δ = 8.95 (dd, $^3J_{H,H}$ = 1.6, 4.0 Hz, 2 H, ArH), 8.14 (m, 4 H, ArH), 8.07 (br. t, $^3J_{H,H}$ = 4.8 Hz, 2 H, NH amide), 7.6−7.0 (m, 29 H, ArH), 5.5 (s, 4 H, CH_2 benzyl), 3.2 (dt, $^3J_{H,H}$ = 6.3, 4.8 Hz, 4 H, CH_2), 2.47 (t, $^3J_{H,H}$ = 5.5 Hz, 2 H, CH_2), 2.21 (t, $^3J_{H,H}$ = 6.3, 4.8 Hz, 4 H, CH_2), 2.13 (t, $^3J_{H,H}$ = 5.3 Hz, 2 H, CH_2), 2.0 (br. s, 1 H, NH) ppm. ^{13}C NMR (250 MHz, $CDCl_3$): δ = 165.1 (CO), 153.8 (Cq), 149.5 (CH), 146.1 (Cq), 142.6 (Cq), 136.7 (Cq), 136.0 (CH), 131.3 (Cq), 128.8−128.5 (unresolved CH's), 127.6 (unresolved CH's), 126.0 (CH), 125.3 (Cq), 123.1 (CH), 122.3 (CH), 78.3 (CH_2), 70.7 (Cq), 53.9 (CH_2), 52.5 (CH_2), 40.5.(CH_2) ppm. MS (DCI, NH_3/isobutane): *m*/*z* = 911 $[MH]^+$, 243 $[C_{19}H_{15}]^+$; 91 $[C_7H_7]^+$. $C_{59}H_{54}N_6O_4$ (911.1): calcd. C 77.78, H 5.97, N 9.22; found C 77.40, H 5.92, N 9.31.

Compound 4a: Under argon at room temperature, a solution of **3a** (3.61 g, 4 mmol) in CH_2Cl_2 (100 mL) was stirred with CF_3CO_2H (3.7 g, 32 mmol) for 12 h. The mixture was treated with 10% NaOH, then washed with brine, dried and concentrated. Column chromatography (silica, CH_2Cl_2 then CH_2Cl_2/methanol 5%/isopropylamine 1%) afforded **4a** as a beige foam (2.15 g, 81%). ^1H NMR (300 MHz, $CDCl_3$, 22 °C, TMS): δ = 8.95 (dd, $^3J_{H,H}$ = 1.7, 4.1 Hz, 2 H, Hquin), 8.22 (br. t, $^3J_{H,H}$ = 5.6 Hz, 2 H, NH amide), 8.11 (dd, $^3J_{AB}$(H-H) = 1.7, 4.1 Hz, 2 H, Hquin), 7.97 (d, $^3J_{H,H}$ = 8.6 Hz, 2 H, Hquin), 7.5−7.3 (m, 14 H, ArH and Hquin), 5.5 (s, 4 H, CH_2 benzyl), 3.25 (dt, $^3J_{H,H}$ = 5.6, 6.4 Hz, 4 H, CH_2), 3.2 (br. t, 2 H, NH_2), 2.59 (m, 2 H, CH_2), 2.50 (m, 2 H, CH_2), 2.36 (t, ^{3}(H-H) = 6.4 Hz, 4 H, CH_2) ppm. ^{13}C NMR (300 MHz, $CDCl_3$): δ = 165.5 (CO), 153.7 (Cq), 149.6 (CH), 142.4 (Cq), 136.7 (Cq), 136.1 (CH), 131.3 (Cq), 128.9 (CH), 128.8 (CH), 128.7 (CH), 127.3 (CH), 125.3 (Cq), 123.2 (CH), 122.3 (CH), 78.5 (CH_2), 55.1 (CH_2), 53.5 (CH_2), 38.9(CH_2), 37.9(CH_2) ppm. MS (DCI, NH_3/isobutane): *m*/*z* = 669 $[M + H]^+$.

Compound 5a: 2,3-Dimethoxybenzoic acid (0.62 g, 3.4 mmol) was dissolved in $SOCl_2$ (15 mL) and the mixture was stirred overnight under argon. The solution was then evaporated to dryness to give 2,3-dimethoxybenzoic chloride (0.685 g). Compound **4a** (2.27 g, 3.4 mmol), triethylamine (0.35 g, 3.5 mmol) and dry CH_2Cl_2 (150 mL) were added and the mixture was stirred at room temperature under argon. The mixture was treated successively with 25% NaOH and brine and then dried and the solvent was evaporated off. Column chromatography (silica, CH_2Cl_2 then CH_2Cl_2/methanol 1 → 5%) gave **5a** as a white foam (1.665 g, 2 mmol, yield = 59%). ^1H NMR (250 MHz, CD Cl_3): δ = 8.94 (dd, $^3J_{H,H}$ = 1.6, 4.0 Hz, 2 H, Hquin), 8.2−8.1 (m, 7 H, Hquin + NH amide), 7.6−7.3 (m, 15 H, ArH), 7.01 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H, H catech.), 6.89 (dd, $^3J_{H,H}$ = 1.6, 6.4 Hz, 1 H, H catech.), 5.55 (s, 4 H, CH_2 benzyl), 3.80 (s, 3 H, OCH_3), 3.75 (s, 3 H, OCH_3), 3.41−3.25 (m, 6 H, CH_2), 2.6 (m, 2 H, CH_2), 2.4 (m, 4 H, CH_2) ppm. ^{13}C NMR (250 MHz, $CDCl_3$): δ = 165.2 (CO), 165.0 (CO), 153.8(Cq), 152.3 (Cq), 149.5 (CH), 147.4 (Cq), 142.4 (Cq), 136.7 (Cq), 135.9 (CH), 131.2 (Cq), 128.6 (unresolved CH's), 127.4 (CH), 126.8 (Cq), 125.0 (Cq), 123.9 (CH), 123.0 (CH), 122.4 (CH), 122.2 (CH), 114.9 CH), 78.3 (CH_2), 61.1 (CH_3), 55.7 (CH_3), 52.7 (CH_2), 52.4 (CH_2), 37.5 (CH_2), 37.2 (CH_2) ppm. MS (FAB, NBA matrix): *m*/*z* = 833 $[M + H]^+$, 541, 305 $[C_{19}H_{17}N_2O_2]^+$. $C_{49}H_{48}N_6O_7$ (832.9): calcd. C 70.66, H 5.81, N 10.09; found C 70.21, H 5.83, N 9.96.

Compound 6a: Under argon at 0 °C, BBr_3 (5.3 g, 21 mmol) in CH_2Cl_2 (30 mL) was added dropwise to a solution of **5a** (1.52 g, 1.8 mmol) in CH_2Cl_2 (250 mL). After stirring overnight at room temperature, the mixture was cooled to 0 °C and treated with methanol (50 mL). After 4 h the solution was concentrated and then repeatedly evaporated with methanol to remove the borate. The residue was treated with 4 N NaOH and extracted with CH_2Cl_2 to remove the impurities. The aqueous solution was acidified with 4 N HCl to give a beige precipitate which was washed with water and then dried under vacuum to give pure 6a (0.937 g, 1.5 mmol, 83%). ^1H NMR (300 MHz, DMSO): δ = 9.0−8.7 (m, 5 H, NH + ArH),8.3−8.1 (m, 2 H, ArH), 8.0 −7.8 (m, 2 H, ArH), 7.6−7.5 (m, 2 H, ArH), 7.3−7.1 (m, 4 H, ArH), 6.9−6.8 (m, 1 H, ArH), 3.5−3.3 (m, 6 H, CH_2), 2.8−2.7 (m, 6 H, CH_2) ppm. ^{13}C NMR (250 MHz, $CDCl_3$): δ = 169.6 (CO), 167.7 (CO), 156.7 (Cq), 151.2 (Cq), 149.4(Cq), 148.7 (CH), 146.2 (Cq), 139.1 (Cq), 135.9 (CH), 130.4 (Cq), 125.2 (CH), 118.5 (CH), 117.7 (CH), 117.6 (CH), 116.6 (CH), 112.8 (Cq), 52.9 (CH_2), 52.8 (CH_2), 37.3 (CH_2), 37.2 (CH_2) ppm. MS (DCI, NH_3/isobutane): *m*/*z* = 625 $[M + H]^+$.

Compound L¹: In portions, **6a** (0.7 g, 1.1 mmol) was added to oleum (SO_3/H_2SO_4; 15 mL) while stirring vigorously. After stirring overnight at room temperature, the mixture was carefully poured onto ice to give a beige precipitate. Filtration and washing with cold water gave the product, which was recrystallised from a minimum amount of water. The pure product (acidic form) was thoroughly dried under vacuum at 30 °C. A yellow powder was obtained (0.347 g, 0.4 mmol, 36.5%). ^1H NMR (300 MHz, D_2O/NaOD): δ = 8.65 (dd, $^3J_{H,H}$ = 1.6, 8.6 Hz, 2 H, Hquin), 8.56 (dd,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$^3J_{H,H}$ = 1.5, 4.1 Hz, 2 H, Hquin), 8.40 (s, 2 H, Hquin), 7.63 (d, $^3J_{H,H}$ = 2.5 Hz, 1 H, Hcatech.), 7.47 (dd, $^3J_{H,H}$ = 4.1, 8.6 Hz, 2 H, Hquin), 7.03 (d, $^3J_{H,H}$ = 2.6 Hz, 1 H, Hcatech.), 3.54 (m, 6 H, CH_2), 2.85 (m, 6 H, CH_2) ppm. ^{13}C NMR (300 MHz, D_2O-NaOD): δ = 171.3 (Cq), 170.7 (Cq), 170.2 (Cq), 161.3 (Cq), 148.9 (Cq), 147.4 (CH), 145.1 (Cq), 134.6 (CH), 129.1 (CH), 127.8 (Cq), 125.9 (Cq), 123.9 (CH), 119.6 (Cq), 119.0 (CH), 116.1 (Cq), 111.4 (Cq), 111.0 (CH), 53.2 (CH_2), 36.9 (CH_2) ppm. MS (Electrospray, methanol/water, +ve mode): *m/z* = 865 $[M + H]^+$. $C_{33}H_{32}N_6O_{16}S_3 \cdot 3.5H_2O$: calcd. C 42.72, H 4.24, N 9.06, S 10.37; found C 42.51, H 3.85, N 8.49, S 9.62.

Compound 4b: Under argon, a mixture of 2,3-dimethoxybenzoic acid (5.28 g, 29 mmol) and CDI (5.16 g, 31.9 mmol) in dry CH_2Cl_2 (350 mL) was refluxed for 1.5 h. A solution of TREN (2.11 g, 14.5 mmol) in CH_2Cl_2 (40 mL) was added dropwise and reflux was maintained overnight. The solution was filtered and washed with 4 N NaOH then brine. After drying over anhydrous Na_2SO_4, the solvent was eliminated to afford an oil. Chromatography (silica, CH_2Cl_2/methanol 1 → 8% and $iPrNH_2$ 1%) gave **4b** as a pale yellow oil (6.53 g, 13.7 mmol, 95%) pure enough for the following steps. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 8.22 (br. t, $^3J_{H,H}$ = 5 Hz, 2 H, NH), 7.61 (dd, $^3J_{H,H}$ = 1.6, 8 Hz, 2 H, ArH), 7.11 (t, $^3J_{H,H}$ = 8 Hz, 2 H, ArH), 7.01 (dd, $^3J_{H,H}$ = 1.6, 8 Hz, 4 H, ArH), 3.88 (s, 6 H, OCH_3), 3.87 (s, 6 H, OCH_3), 3.60 (dt, $^3J_{H,H}$ = 5.8, 6.2 Hz, 4 H, CH_2), 2.75 (m, 8 H, CH_2), 2.64 (m, 2 H, CH_2), 2.2 (br. s, 2 H, NH_2) ppm. ^{13}C NMR (200 MHz, $CDCl_3$): δ = 165.3 (CO), 152.3 (Cq), 147.2 (CH), 126.7 (Cq), 124.1 (CH), 122.3 (CH), 115.1 (CH), 61.1 (OCH_3), 57.0 (CH_2), 55.87 (OCH_3), 53.5 (CH_2), 39.7 (CH_2), 37.6 (CH_2) ppm. MS (DCI, NH_3/isobutane): *m/z* = 475 [M + H], 432, 280, 208, 182.

Compound 5b: Under argon a solution of 7-carboxy-8-hydroxyquinoline (2.30 g, 12 mmol) and CDI (2.27 g, 14 mmol) in dry THF (200 mL) was refluxed for 3 h. Compound **4b** (6 g, 12 mmol) in THF (80 mL) was added dropwise and the reflux was maintained during 12 h. The THF was evaporated off and the residue was dissolved CH_2Cl_2 and treated with NH_4Cl and brine. Drying and evaporation of the solvent afforded an orange foam which was chromatographed (silica, $iPrNH_2$ 1%, CH_2Cl_2, MeOH 1 → 5%) to give **4b** (5.8 g, 9 mmol, 75%) pure enough for the following step. ^{1}H NMR (20 MHz, CD Cl_3): δ = 8.82 (dd, $^3J_{H,H}$ = 1.6, 4.2 Hz, 1 H, Hquin), 8.19 (br. t, 3 H, NH), 8.11−8.02 (m, 1 H, Hquin),7.56−7.44 (m, 3 H, ArH + Hquin),7.27−6.86 (m, 6 H, ArH + Hquin), 3.83 (s, 6 H, 0 CH_3), 3.76 (s, 6 H, 0 CH_3), 3.65−3.56 (m, 6 H, CH_2), 2.94−2.82 (m, 6 H, CH_2) ppm. ^{13}C NMR (250 MHz, $CDCl_3$): δ = 167.2 (CO), 165.5 (CO), 154.4 (Cq), 152.2 (Cq), 148.1 (CH), 147.1 (Cq), 138.9 (Cq), 135.6 (Cq), 130.1 (Cq), 126.7 (Cq), 126.1 (CH), 124.0 (CH),122.8 (CH), 122.2 (CH), 116.7 (CH), 114.9 (CH), 112.8 (Cq), 61.1 ($COCH_3$), 55.7 ($COCH_3$), 53.7 (COH_2), 53.2 (CH_2), 37.8 (CH_2), 37.7 (CH_2) ppm.

Compound 6b: Under argon at 0 °C, BBr_3 (9.04 g, 36 mmol) in CH_2Cl_2 (30 mL) was added dropwise to a solution of **5b** (1.94 g, 3 mmol) in CH_2Cl_2 (300 mL). After stirring overnight at room temperature, the mixture was treated with methanol (50 mL) at 0 °C. The solution was concentrated and then repeatedly evaporated with methanol. The residue was treated with 4 N NaOH and extracted with CH_2Cl_2. The aqueous solution was then acidified to pH 7.6 with 4 N HCl to give a beige precipitate which was washed with water and dried under vacuum to give **6b** pure enough for the following step (1.65 g, 2.8 mmol, 93%). ^{1}H NMR (200 MHz, DMSO): δ = 8.9 (m, 1 H, Hquin), 8.7 (m, 3 H, NH), 8.32 (d, $^3J_{H,H}$ = 8.2 Hz, 1 H, Hquin), 7.94 (d, $^3J_{H,H}$ = 8.0 Hz, 1 H, Hquin), 7−6.3 (dd, $^3J_{H,H}$ = 4.80, 4 Hz, 1 H, Hquin), 7.37 (d, $^3J_{H,H}$ = 28.2 Hz, 1 H, Hquin.), 7.20 (d, $^3J_{H,H}$ = 7.4 Hz, 2 H, Hcat.), 6.84 (d, $^3J_{H,H}$ = 7.4 Hz, 2 H, Hcat.), 6.54 (t, $^3J_{H,H}$ = 7.4 Hz, 2 H, Hcat.), 3.42 (m, 6 H, CH_2), 2.77 (m, 6 H, CH_2) ppm. ^{13}C NMR (250 MHz, DMSO): δ = 169.7 (CO), 167.9 (CO), 156.4 (Cq), 149.4 (Cq), 149.0 (CH), 146.1 (Cq), 139.0 (Cq), 136.1 (CH), 130.5 (Cq), 125.3 (CH), 123.4 (CH), 118.8 (CH), 117.9 (CH), 117.3 (CH), 116.8 (CH), 115.1 (Cq), 112.7 (Cq), 52.6 (CH_2), 36.8 (CH_2) ppm. MS (DCI, NH_3/isobutane): *m/z* = 590 [M + H].

Compound L^2: In portions, **6b** (1.49 g, 2.5 mmol) was added to oleum (SO_3/H_2SO_4) (20 mL) while stirring vigorously. After stirring at room temperature for 12 h, the mixture was carefully poured onto ice to give a brown precipitate. Filtration and washing with cold water afforded the product, which was recrystallised from a minimum amount of water. The pure product (acidic form) was dried under vacuum at 30 °C. A yellowish powder was obtained (0.672 g, 0.8 mmol, 32%). ^{1}H NMR (250 MHz, D_2O/NaOD): δ = 8.48 (m, 1 H, Hquin), 8.48 (m, 1 H, Hquin), 8.23 (s, 1 H, Hquin), 7.30 (m, 1 H, Hquin), 7.14 (m, 2 H, Hcatech), 6.49 (m, 2 H, Hcatech), 3.30 (m, 6 H, CH_2), 2.62 (m, 6 H, CH_2) ppm. ^{13}C NMR (250 MHz, D_2O-NaOD): δ = 174.3 (Cq), 174.0 (Cq), 173.1 (Cq), 170.2 (Cq), 163.2 (Cq), 150.1 (CH), 147.8 (Cq), 137.0 (CH), 131.6 (CH), 130.3 (Cq), 128.6 (CH), 126.5 (Cq), 122.1 (Cq), 117.6 (Cq), 115.5 (CH), 115.4 (CH), 113.8 (Cq), 55.9 (CH_2), 39.3 (CH_2), 39.2 (CH_2) ppm. MS (Electrospray, methanol/water, +ve mode): *m/z* = 830 $[M + H]^+$, 750 $[M - SO_3]$. $C_{30}H_{31}N_5O_{17}S_3$ $5H_2O$: calcd. C 39.17, H 4.49; N 7.61; S 10.46; found C 39.29, H 4.59, N 7.64, S 9.65.

Potentiometric and Spectrophotometric Measurements: The solutions were prepared with boiled deionised water, de-oxygenated and flushed continuously with argon (purified by a Sigma Oxiclear cartridge) in order to exclude CO_2 and O_2. The ionic strength was maintained at 0.1 M with sodium perchlorate (Prolabo, Puriss or Merck, p.a.) and all measurements were carried out at (25.0 ± 0.2) °C. Perchloric acid (70%, Fluka; approx. 0.1 M) and sodium hydroxide (Normex, Carlo Erba; approx. 0.1 M) concentrations were determined respectively by titration of sodium tetraborate solution (purris. p. a., ACS, Fluka, approx. 0.1 M) in the presence of methyl red as indicator (Pointet Girard, France) and potassium hydrogenphthalate (purris. p. a., Fluka, approx. 0.1 M), with phenolphthalein as indicator (Prolabo, France). The ligands L^1 and L^2 were dissolved in aqueous 0.1 M $NaClO_4$ medium and their concentrations were calculated by weight. Stock iron(III) solutions [$Fe(ClO_4)_3 \cdot 9H_2O$, pract., Fluka or Aldrich; approx. 0.01 M], prepared under acidic conditions (0.1 M $HClO_4$), were back titrated with $Th(NO_3)_4 \cdot 5H_2O$ (Merck, approx. 0.1 M) in the presence of excess EDTA (Titrisol, Merck, approx. 0.1 M) and xylenol orange (Merck) as end-point indicator.[27] The concentration was also controlled spectrophotometrically by using the molar extinction coefficient[28] of 4160 $M^{-1} \cdot cm^{-1}$ at 240 nm in 0.1 M $HClO_4$. The acid in excess was evaluated by a potentiometric titration with standardised 0.1 M NaOH solution using quantitative formation of a complex with maltol (99%, Aldrich).[29] L^1 and L^2 ferric complexes were prepared by mixing adequate volumes of stock ferric perchlorate and stock ligand solutions. The free hydrogen concentrations were measured with a glass-Ag/AgCl combined electrode (Metrohm or Tacussel High Alkalinity, filled with 0.1 M NaCl and saturated with AgCl). The electrode was calibrated in order to read the pH according to the classical method (neutralisation of 0.1 M $HClO_4$ by 0.1 M NaOH).[30]

The potentiometric titrations were performed into a jacketed cell, thermostatted by the water flow of a Haake thermostat, using either a digital millivoltmeter (Tacussel Isis 20,000) with a piston-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fitted microburette (Gilmont) or an automatic titrator system (Metrohm, DMS Titrino 716) connected to an IBM Aptiva microcomputer. The titrations of the ligands ($[\mathbf{L}] \approx 10^{-3}$ M, $2.5 < pH < 10.5$ for $\mathbf{L^1}$ and $3.9 < pH < 9.8$ for $\mathbf{L^2}$) and of their iron(III) complexes ($[Fe^{III}]_{tot} = [\mathbf{L}]_{tot} \approx 10^{-3}$ M, $2.2 < pH < 11.0$ for $\mathbf{L^1}$ and $2.3 < pH < 8.9$ for $\mathbf{L^2}$) were carried out by addition of known volumes of standardised sodium hydroxide. The data obtained during the potentiometric titrations were fitted with the Superquad[31] or Hyperquad[32] software packages.

Spectrophotometric measurements were carried out on double-beam UV/Vis spectrophotometers, either Uvikon 941 (Kontron) or Perkin–Elmer (Lambda 2), equipped with a thermostatting cell holder (Perkin–Elmer PTP-1) and connected to an IBM PC 340 microcomputer for data acquisition (UV Winlab software, Perkin–Elmer). Absorption spectra of the free ligands ($[\mathbf{L}]_{tot} \approx 10^{-4}$ M, 240 nm $< \lambda <$ 400 nm, $2.5 < pH < 10.5$ for $\mathbf{L^1}$ and $2.6 < pH < 12.5$ for $\mathbf{L^2}$) and of their iron(III) species ($[\mathbf{L}]_{tot} = [Fe^{III}]_{tot} \approx 10^{-4}$ M, 400 nm $< \lambda <$ 800 nm, for $\mathbf{L^1}$ $2.5 < pH < 10.5$ and $1.0 < pH < 9.0$ for $\mathbf{L^2}$) were measured at different pH values using quartz spectrophotometric cells of 0.2 or 1 cm optical path length (Hellma) against 0.1 M aqueous $NaClO_4$ solution as a reference. Absorption spectra recorded as a function of pH for ferric complexes of $\mathbf{L^1}$ and $\mathbf{L^2}$ are given in the supporting information (Figures S3 and S4).

A batch competition titration between the ferric $\mathbf{L^2}$ complex and EDTA (99.5%, A.C.S. reagent, Aldrich) was carried out under conditions of $[\mathbf{L^2}]_{tot} = 5.4 \times 10^{-5}$ M, $[Fe^{III}]_{tot} = 4.5 \times 10^{-5}$ M, $[EDTA]_{tot} = 9.21 \times 10^{-4}$ M and the pH values adjusted with perchloric acid over the range 3.9 to 5.5 (in steps of 0.1 pH unit). The solution was equilibrated for two days and then the absorption spectra were recorded (400–800 nm).

The spectrophotometric data using absorbance values from 20 wavelengths (between 400 and 800 nm) were processed with both the Specfit[19–22] and Letagrop-Spefo[17,18] programs in order to calculate the thermodynamic constants of the absorbing species and their corresponding electronic spectra. The range of values for the residual-squares sum $[\Sigma(A_{exp} - A_{calcd.})^2]$ of the fits was over the range 10^{-2} to 10^{-3}. The calculated electronic spectra are presented in Figure 6.

NMR Titration: The proton NMR titration was carried out for $\mathbf{L^2}$ over the pD range 3.5–9.2 in order to attribute protonation constants to different protonable sites of the ligand. The ligand was dissolved in D_2O. The pD was adjusted with DCl or NaOD solutions. pH measurements were performed with a Tacussel PHN 850 apparatus equipped with a microelectrode Radiometer XC61. pD values were calculated according to $pD = pH_{meas} + 0.4$.[33]

Second-Order Nonlinear Optical Properties of Tetraaza-Coordinated Nickel(II) Complexes

Santo Di Bella*[a] and Ignazio Fragalà[a]

Keywords: Nickel / Nonlinear optics / Semiempirical calculations

In this contribution, we report the design and theoretical analysis, using the INDO/SCI-SOS quantum chemical formalism, of novel molecular architectures based on planar $[N_4]$-, (2-aminobenzylideneiminato)- and tetraazamacrocycle-coordinated nickel(II) complexes, having second-order nonlinear optical (NLO) properties. Calculations indicate that these molecules possess comparable, or even larger, second-order nonlinearity to the bis(salicylaldiminato)Ni^{II} Schiff-base analogues. The nonlinearity of substituted complexes is dominated by the nature and position of substituents on the tribenzo[*b*,*f*,*l*] and/or cyclotetradecine rings, and is determined by the relative directions of the ground- and excited-state dipole moments. Moreover, substitution with acceptor groups in the dibenzo[*b*,*l*] rings involves a significant octupolar contribution to optical nonlinearity.

Introduction

An intense research activity is currently associated with the synthesis and development of molecule-based second-order nonlinear optical (NLO) materials,[1] involving organic chromophores[2] and metal complexes.[3] The latter represent an emerging and growing class of materials by virtue of unique properties associated with the metal center. Various classes of transition metal complexes have been explored systematically, including organometallic and coordination complexes.[3]

Most second-order NLO metal complexes, as organic NLO chromophores, can be envisaged within a simple molecular scheme constituted by a donor−π-conjugate-bridge−acceptor (D−π−A) structure, in which an organometallic group selectively replaces the donor and/or the acceptor, or the bridge moieties.[3a] This requirement is because metal complexes possess intense, low-energy metal-to-ligand charge transfer (MLCT), ligand-to-metal charge transfer (LMCT), or intraligand charge transfer (ILCT) excitations. Therefore, they can behave effectively as donor and/or acceptor groups of the D−π−A system, or to be a constituent of the polarizable bridge.

Bis(salicylaldiminato)M^{II} (M = Co, Ni, Cu, Zn) Schiff-base complexes are prototypical examples of the latter case.[4,5] Complexation is accompanied by formation of geometrically constrained acentric, generally planar, structures. It always involves an enhancement of optical nonlinearity, compared to that of related free ligands and, in some cases, a "switching on" of the NLO response with resulting tunable hyperpolarizabilities, ranging from negative to positive β values.[6] Moreover, the nature of the metal deeply influences the nonlinearity.[7] The role of the metal centre in determining the NLO response in such structures is twofold, since it can act both as the donor and as the bridging moiety of the D−π−A system. Finally, the appropriate donor/acceptor substitution pattern results in an "in-plane" two-dimensional second-order nonlinearity.[8] Thus, bis(salicylaldiminato)M^{II} Schiff-base complexes represent suitable templates for second-order NLO molecular materials. Actually, starting from unsubstituted bis(salicylaldiminato)M^{II} Schiff-base complexes it is possible to design other molecular structures in which, instead of changing the donor or the acceptor substituents on the benzene rings, the donor atoms are changed.

In this paper, we report the design and a theoretical analysis, using the INDO/S-SOS quantum chemical formalism,[7a,9] of novel molecular architectures based on planar $[N_4]Ni^{II}$ complexes, having second-order NLO properties (Scheme 1). We demonstrate that these (2-aminobenzylideneiminato)- and tetraazamacrocycle-coordinated nickel(II) complexes represent suitable candidates for second-order NLO molecular materials.

Results and Discussion

Theoretical Method

Within the framework of the Sum-Over-excited-particle-hole-States (SOS) perturbation theory, the molecular quadratic hyperpolarizability, for instance the second harmonic

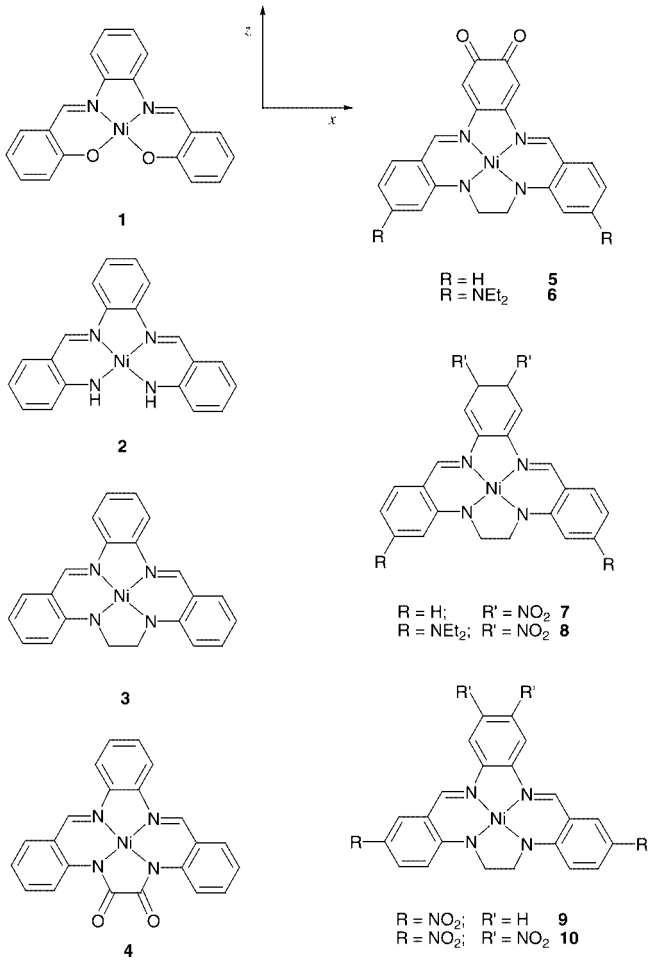

Scheme 1

generation, $\beta_{ijk}(2\omega; \omega, \omega)$, can be related exactly to all the excited states of the molecule in terms of energy, $\hbar\omega_{ge}$, transition dipole moment, r^{i}_{ge}, and dipole moment variation, $\Delta\mu^{i}_{ge} = r^{i}_{ee} - r^{i}_{gg}$, between ground ($g$) and excited ($n$) states.[10] The hyperpolarizability determined by a sum-over-states expression can be partitioned into two contributions,[9] the so-called two-level ($\beta_{ijk,2}$) terms and three-level ($\beta_{ijk,3}$) terms, such that: $\beta_{ijk}(2\omega; \omega, \omega) = \beta_{ijk,2} + \beta_{ijk,3}$. Each two-level component in the sum for $\beta_{ijk,2}$ contains only two states, the ground and one excited state, and is related to the product $r^{j}_{ge}r^{k}_{ge}\Delta\mu^{i}_{ge}$ (generic two-level term); the three-level contributions involve the ground state and two excited states, e, e', and are related to the product $r^{j}_{ge'}r^{i}_{e'e}r^{k}_{ge}$ (generic three-level term). For dipolar molecules, the molecular hyperpolarizability is generally related to the β_{μ} value, i.e., the vector component of the β_{ijk} tensor along the dipole moment direction, given by

$$\beta_{\mu} = \sum_{i=1}^{3} \frac{\mu_i \beta_i}{|\mu|}$$

where μ is the ground state dipole moment and $\beta_i = \beta_{iii} + 1/3\Sigma_{j\neq i}(\beta_{ijj} + \beta_{jij} + \beta_{jji})$. For most dipolar molecules, in which $\Delta\mu^{i}_{ge}$ and r^{i}_{ge} matrix elements are parallel to the dipolar i axis, the $\beta_{ijk,2}$ sum generally dominates the NLO response, resulting in 1D dipolar species with a single hyperpolarizability diagonal tensor component β_{iii}, so that $\beta_{\mu} \approx \beta_{iii}$. A further simplification of this approach can be made by restricting the "summation" to one excited state, the so-called "two-state" model,[11] in which: $\beta_{iii} \propto (r_{ge})^2\Delta\mu_{ge}/\hbar\omega_{ge}$. On the other hand, only nonzero, off-the-i-diagonal, dipole moment ($\Delta\mu^{j}_{ge}$, $j \neq i$) or transition dipole moment (r^{j}_{ge}, $j \neq i$) matrix elements, contribute to off-diagonal β_{ijk} hyperpolarizability tensor components. For dipolar molecules of C_{2v} symmetry, β has seven nonvanishing tensor components, five of which are independent. The nonzero components are β_{zzz}, $\beta_{xzx} = \beta_{xxz}$, β_{zxx}, $\beta_{yzy} = \beta_{yyz}$, β_{zyy}, where z is the C_2 axis. Since transition dipole moments perpendicular to the zx molecular plane are generally small, the components $\beta_{yzy} = \beta_{yyz}$, β_{zyy} are usually negligible. Thus, the parameter $u = \beta_{\text{off-diagonal}}/\beta_{zzz}$, where $\beta_{\text{off-diagonal}} = 1/3(\beta_{xzx} + \beta_{xxz} + \beta_{zxx})$, reflects the anisotropy of the in-plane optical nonlinearity.[12]

The all-valence INDO/S (Intermediate Neglect of Differential Overlap) model,[13] in connection with the SOS formalism,[10] was employed. Details of the computationally efficient ZINDO-SOS-based method for describing second-order molecular optical nonlinearities have been reported elsewhere.[7a,9] Standard parameters and basis functions were used.[13] In particular, the resonance integrals for the nickel atom were chosen to be $\beta_{sp} = -1$ eV and $\beta_d = -45$ eV.[13b] In the present approach, the closed-shell-restricted Hartree−Fock (RHF) formalism was adopted. The monoexcited configuration interaction (CIS) approximation was employed to describe the excited states. In all calculations, the lowest 250 energy transitions between SCF and CIS electronic configurations were chosen to undergo CI

mixing and were included in the SOS. This SOS truncation was found to be sufficient for complete convergence of the second-order response in all cases considered. Non-resonant hyperpolarizabilities were calculated within a perturbation series expansion employing the Ward definition,[10] the so-called phenomenological convention.[14] All calculations were performed using the ZINDO Version 3.5 program of the Cerius^2 package from Accelrys Inc.[15] on an SGI Origin3800 system. Metrical parameters of **1**−**10** used for INDO/S calculations were taken from fully optimized structures (at ZINDO/1 level) using the HyperChem package.[16] A C_{2v} planar structure of the bis(2-aminobenzylideneiminato) or the tetraazamacrocycle frameworks was always found in all cases presently considered.[17] Present optimised planar structures are consistent with available crystallographically derived planar structures of related complexes (vide infra). Moreover, optimized geometrical parameters (Supporting Information, see also the footnote on the first page of this article) are in favorable agreement with available experimental data (vide infra). In addition, INDO/S calculations were performed for representative free ligands **3a**, **6a**, **8a**, and **10a**, on the basis of their optimized structures (at ZINDO/1 level). Optimized structures of ligands **3a**−**10a** indicate a nonplanar structure of the tetraazamacrocycle framework, with C_2 symmetry. The computed ground state dipole moment and second-order NLO response for **1**−**10** and representative free ligands are collected in Table 1, while calculated low-energy CT transitions and analysis of relative two-level and three-level contributions to the static hyperpolarizability[18] are reported in Table 2.

Discussion

Bis(salicylaldiminato)M^{II} Schiff-base complexes have recently been developed as a new and versatile class of efficient second-order NLO materials.[4−8] The optical nonlinearity of the unsubstituted [Ni(salophen)] (**1**), has been related to a low-energy charge transfer (CT) transition, characterized as being principally $\pi \rightarrow \pi^*$ (HOMO → LUMO) in character, essentially involving the metal $3d_{xz}$,oxygen $2p_z$ and C=N orbitals.[6a] Therefore, the optical nonlinearity of M(salophen) complexes strongly depends on the nature of the (MN_2O_2) chelate and is tuned by the D/A substitution on the benzo rings.[6a,7,8] On this basis, it is expected that alternative chelate NLO structures could be envisaged on changing the donor atoms of the (salophen) template.

Substitution of the oxygen donor atoms of [M(salophen)] by NH groups results in the isoelectronic MN_4, bis(2-aminobenzylideneiminato) [M(abphen)] planar chelate. Some physicochemical properties of [M^{II}(abphen)] (M = Co, Ni, Cu) complexes have been previously reported.[19] These complexes presumably possess a planar structure,[19a] according to the present optimized planar structure of [Ni(abphen)] (**2**). On switching from **1** to **2**, theoretical data indicate a decrease of the ground state dipole moment, μ_g, which, analogously to **1**, is directed between the imino groups. Thus, the calculated smaller value of μ_g of **2** can be related to the less electron-withdrawing effect of NH groups compared to oxygen donor atoms. The calculated nonlinearity of **2** is similar to that of **1**, and can be related essentially to a single low-energy excited state, having a polarization parallel with respect to the molecular dipolar (*z*) axis. In fact, although the lowest state consists of an *x*-polarized transition, the associated low intensity (r^x_{ge} = 2.11 D) and CT character ($\Delta\mu_{ge}$ = −2.74 D) imply a negligible contribution to off-diagonal β_{ijk} tensors and, hence, to optical nonlinearity (Table 2). Thus, analogously to **1**, a single diagonal hyperpolarizability tensor component, β_{zzz}, parallel to the dipolar *z* axis of the molecule, mainly contributes to the NLO response (Table 1). Moreover, the slightly larger β_μ value of **2** can be related essentially to the calculated red-shift of the low-energy, *z*-polarized CT transition. A red-shift of the lowest electronic transitions also can be observed experimentally on comparing optical absorption spectra of **1**[6a] and **2**.[19a] Finally, calculated negative β values are a consequence of the negative dipole moment change between the ground and excited states, $\Delta\mu_{ge}$, associated with the β-determining CT transition (Table 2). While in the ground state the dipole moment is directed between the imine groups, in the excited state it has an opposite orientation, i.e., between the nitrogen donor atoms. Thus, [M(abphen)] complexes represent a new family of second-order NLO chromophores having an analogous nonlinearity to that of [M(salophen)] complexes.

A closely related structure to [M(abphen)] is offered by the macrocyclic M[14]N_4 complexes of the tribenzo[*b*,*f*,*l*][1,4,8,11]tetrazacyclotetradecine (TAD) ligand, which represents a versatile system readily accessible to a variety of substitutions, both in the tribenzo[*b*,*f*,*l*] as well as the cyclotetradecine rings.[20] First, we consider the prototypical unsubstituted planar Ni(TAD) complex **3**.[21] As expected, on passing from **2** to **3** we observe only minor changes as far as calculated linear and nonlinear optical features (Tables 1 and 2). In fact, analogously to **2**, μ_g is directed between the imino groups and negative values of $\Delta\mu_{ge}$ and β are predicted. The larger β values of **3** are a consequence of the red-shift of its lowest electronic transitions, as have also been observed experimentally.[20d] Again, these results indicate that M(TAD) complexes possess NLO characteristics like those of [M(salophen)] and [M(abphen)]. In view of their versatility to achieve substituted donor−acceptor derivatives, they represent attractive candidates for further theoretical investigations.

As the first example of an Ni(TAD)-substituted species, we consider the 12,13-dione complex **4**. Its 2,3,6,19-tetramethyl derivative,[22a] as well as a variety of substituted species,[22b,22c] has been synthesized and characterized previously. The calculated dipole moment of **4** is larger than the unsubstituted derivative **3**, because of the electron-withdrawing effect of the dioxo groups. However, its calculated nonlinearity is smaller than that of the unsubstituted complex **3** (Table 1). The presence of the 12,13-dioxo groups results in a blue-shift of the lowest electronic transitions,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with a consequent lower two-level contribution to optical nonlinearity (Table 2). Note that the calculated blue-shift of the lowest CT transitions on passing from **3** to **4** is in favorable agreement with that observed experimentally.[20d,22a,22c]

These results suggest that enhancement of nonlinearity in **3** necessarily implies that the acceptor substituents be on the benzo[*b*,*f*,*l*] rings. For this purpose we consider the 16,17-dione derivative **5**, whose related planar semiquinone has been synthesized and characterized previously.[20b] On switching from **3** to **5**, we observed a dramatic increase of the ground state dipole moment, which now has an opposite orientation, i.e., it is directed between the [1,4] nitrogen donor atoms of the TAD ring, thus involving positive values of $\Delta\mu_{ge}$, β_{ijk} and β_{μ} (Tables 1 and 2). Moreover, we predicted a significant larger optical nonlinearity, in terms of both static and dynamic hyperpolarizabilities. In a two-state picture, this situation is consistent with the calculated stronger (**3** vs. **5**) low-energy, *z*-polarized CT transition, strengthened by the larger charge delocalization over the benzo[*f*] ring in the excited state involved, because of the 16,17-dioxo substituents.

The optical nonlinearity of **5** is further enhanced by considering the donor 3,10-diethylamino substitution on the benzo[*b*,*l*] rings (**6**). This feature is due to the further strengthening of both the *z*- and *x*-polarized, lowest CT transitions. Moreover, the latter transition involves a very large $\Delta\mu_{ge}$ and is responsible for the appreciable calculated off-diagonal β_{ijk} tensors, thus resulting in a sizeable two-dimensional (2D) NLO character of **6** ($u = 0.24$) (Tables 1 and 2). Clearly, the two-state model is inadequate to describe the optical nonlinearity of such a system, since at least two states mainly contribute to the molecular hyperpolarizability.

Replacement of dioxo groups in **5** by two strong electron acceptors, such as nitro groups (**7**), does not result in an appreciable improvement in β_{μ}. Unlike **5**, however, the nitro derivative **7** possesses some 2D character, owing to the strengthening of the lowest-energy, *x*-polarized CT transition, as in **6**, and to the presence of an additional low-energy, *x*-polarized CT transition. Moreover, the off-diagonal β_{ijk} tensors have an opposite sign with respect the diagonal β_{zzz} one, with a resulting negative nonlinear anisotropy ($u = -0.22$). Negative off-diagonal β_{ijk} values for **7** are consequence of the larger negative contribution of three-level terms compared with two-level terms (Table 2).

The further donor substitution in **7** with two 9,16-diethylamino groups (**8**), leads to a one-dimensional character of the calculated optical nonlinearity, in spite of the existence, analogously to **7**, of two lowest-energy *x*-polarized CT transitions. In this case, however, both two-level and three-level contributions cancel each other, thus resulting in a single diagonal hyperpolarizability tensor component, β_{zzz}, and β_{μ} values similar to those of **6** (Table 2).

The 8,17-nitro substitution on the benzo[*b*,*l*] rings (**9**) offers the possibility to obtain an enhanced in-plane 2D character of the optical nonlinearity (Table 1). Actually, the calculated in-plane anisotropy for the dipolar complex **9** ($u = -0.5$) involves a significant octupolar contribution[12] to the optical nonlinearity. The negative in-plane anisotropy of **9** depends on off-diagonal β_{ijk} tensors, which have an opposite (positive) sign with respect to the diagonal (negative) β_{zzz} tensor (Table 2). Again, as in **7** and **8**, the presence of two low-energy *x*-polarized CT transitions leads to off-diagonal tensors dominated by the contribution of the three-level terms. In this case, however, the presence of 8,17-dinitro substituents on the benzo[*b*,*l*] rings implies that values of $\Delta\mu_{ge}$ associated with the two mentioned *x*-polarized CT transitions have opposite signs, resulting in a low two-level sum contribution. Thus, the calculated positive off-diagonal β_{ijk} values of **9** are a consequence of the larger positive contribution of three-level vs. two-level sums (Table 2). Note that, the 8,17-dinitrobenzo[*b*,*l*] ring substitution involves a blue-shift of the lowest calculated electronic transitions on passing from **3** to **9** (Table 2), according to observed changes in optical absorption maxima.[20c,20d]

The combination of **7** and **9** in the tetrasubstituted nitro derivative **10** is expected to involve an enhanced nonlinearity with negative in-plane anisotropy. Actually, compound **10** is characterized by the two lowest *x*-polarized CT transitions, in addition to the *z*-polarized CT transition, and results in an increased nonlinearity, relative to **9**, again with a significant octupolar contribution. Both diagonal and off-diagonal tensors are dominated by the three-level terms (Table 2).

The evaluation of NLO properties of related free ligands **3a**−**10a** allows a useful comparison to be made with complexes **3**−**10** (Tables 1 and 2). Their calculated optical nonlinearity is generally lower (ca. 60% for **3a**, **10a**; 20% for **6a**, **8a**) and parallels the two-dimensional character of related Ni^{II} complexes. The enhancement of the hyperpolarizability on switching from free ligands to Ni^{II} complexes, which is less evident for D/A-substituted species **6a** and **8a**, can be related to the involvement of metal 3d orbitals that leads to a larger charge delocalization over the planar macrocycle and, hence, to red-shifted, and sometimes stronger, CT transitions (Table 2). Therefore, the optical nonlinearity of the present donor−acceptor TAD derivatives is dominated by substituents on the tribenzo[*b*,*f*,*l*] rings. In these cases, the metal ion mostly acts as a bridge of the D−π−A system, as previously observed for donor−acceptor bis(salicylaldiminato)Ni^{II} complexes.[3a,4]

Conclusions

In this paper, we have demonstrated that starting from bis(salicylaldiminato)Ni^{II} Schiff'-base complexes it is possible to design alternative molecular NLO structures by changing the donor atoms of the (salophen) template. Thus, calculations on a series of novel molecular architectures, based on planar $[N_4]Ni^{II}$ complexes, indicate that these molecules possess comparable, or even larger, second-order nonlinearity to those of bis(salicylaldiminato)Ni^{II} Schiff-base analogues. The nonlinearity of substituted Ni(TAD)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complexes is dominated by the nature and position of substituents on the tribenzo[*b*,*f*,*l*] and/or cyclotetradecine rings, and is dictated by the relative magnitude and direction of the ground- and excited-state dipole moments. In particular, analogously to [Ni(salophen)] complexes, the donor substituents on the dibenzo[*b*,*l*] rings and the acceptors on the benzo[*f*] ring, involve larger nonlinearity. However, substitution with acceptor groups in the dibenzo[*b*,*l*] rings of the [Ni(TAD)] complex involves an enhanced octupolar β contribution with respect the dipolar one. This feature is a very interesting one with the perspective of designing polarization-independent materials for electro-optical applications.

NMR Investigation and Dynamic Behaviour of [2,2′-Bipyridylbis(pyridine)platinum(II)]$^{2+}$ and Related Cationic Complexes − Crystal Structure of $[Pt(bipy)(py)_2](PF_6)_2$

Enrico Rotondo,*[a] Giuseppe Bruschetta,[a] Giuseppe Bruno,[a] Archimede Rotondo,[a] Maria Letizia Di Pietro,[a] and Matteo Cusumano[a]

Keywords: Intercalations / N ligands / NMR spectroscopy / Platinum

Detailed ^{1}H and ^{13}C{^{1}H} NMR analysis has been carried out on complexes with the general formulae $[Pt(bipy)(n\text{-}Rpy)_2](PF_6)_2$ and $[Pt(4\text{-}Phbipy)(n\text{-}Rpy)_2](PF_6)_2$ [bipy = 2,2′-bipyridyl; 4-Phbipy = 4,4′-diphenyl-2,2′-dipyridyl; *n*-Rpy = pyridine or substituted pyridines]. The resonance assignments and X-ray structures of these complexes are important steps on our route to: (i) interpretation of the intercalative geometry on the basis of the magnetic changes produced on interaction with DNA, (ii) rational design of new intercalators. The X-ray structure of the parent complex $[Pt(bipy)(py)_2](PF_6)_2$ (py = pyridine) shows pyridine rings quasiperpendicular to the coordination plane. In solution, because of the hindered rotation about Pt–N bonds of *ortho*- and *meta*-monosubstituted pyridines, this arrangement leads to "head-to-head" *s-cis* C_s and "head-to-tail" *s-trans* C_2 rotamers in equilibrium. NMR line shape and ^{13}C relaxation time constant measurements were carried out in order to evaluate activation energies and anisotropic rotational motion of *n*-Rpy. In some of these complexes a second dynamic process could be frozen on the ^{13}C NMR timescale below 265 K. This lower activation energy process can reasonably be attributed to minimal bipyridyl torsion angle flipping driving a concerted molecular motion about the core of the four N-donors. Indeed, the X-ray structure of **1** proves distortion with a slight alternate up and down shift of the four nitrogen atoms about the coordination plane. Significantly, the fast rotation of unhindered pyridine rings does not allow NMR detection of this molecular distortion.

Introduction

Energy barriers for rotation about Pt−N bonds and the fluxional behaviour of rotational isomers of Pt^{II} square-planar complexes have attracted renewed interest in the last decade. These barriers are, in fact, important factors in stereocontrolled transition metal mediated self-assembly.[1] On the other hand, Pt−N(guanine) (or -adenine) rotational barriers can play key roles in inhibition of DNA duplication ensuing Pt^{II}−purine base inter- and intra-strand bond formation.[2] In the course of studies concerning the interactions of square-planar complexes and DNA[3] we have reported the intercalating properties of **7**.[4] Our attention was then attracted by complexes of general formulae $[Pt(bipy)(n\text{-}Rpy)_2](PF_6)_2$ and $[Pt(4\text{-}Phbipy)(n\text{-}Rpy)_2](PF_6)_2$ (**1**−**9**, Scheme 1).

Scheme 1

Indeed, the flat Pt(bipy) moiety is particularly well suited to intercalate DNA, whereas the rotational barriers of coordinated *n*-Rpy and phenyl substituents might either prevent or allow more extended intercalation, depending on the energy necessary to induce other aromatic rings to lay in the coordination plane.

Despite the popularity of such $[Pt(bipy)(n\text{-}Rpy)_2](PF_6)_2$ complexes, there are only a few NMR spectroscopic data concerning them. The aim of this paper is to provide NMR resonance assignments, together with dynamic and struc-

tural features of these molecules, in particular highlighting pyridine rotation about the Pt−N bond. These properties are fundamental for mapping of the complexes' intercalative geometries and for rational design of new intercalator families.

Results and Discussion

NMR Analysis

Tables 1 and 2 report selected ^{1}H and ^{13}C{^{1}H} NMR resonance frequencies of **1**−**9**. Peak assignments are supported by conventional 1D and 2D homo- and heteronuclear experiments. Unambiguous resonance assignments, as well as structural feature determinations, are obligatory steps in any NMR attempt to shed light on the DNA double helix intercalative geometries of these complexes.[5] All reported crystal structures of [Pt(bipy)(*n*-Rpy)$_2$]$^{2+}$ cations concordely showed orientations of the heteroaromatic pyridine rings quasiperpendicular to the coordination plane.[4,6] The X-ray structure of [Pt(bipy)(*n*-Rpy)$_2$](PF$_6$)$_2$ shown here confirms this arrangement, which forces the 6,6′-bipy protons to point toward the centre of the pyridine's ring current. NMR spectra consistently show a shift of the 6,6′-H(bipy) signals by about 1 ppm to lower frequency with respect to the analogous [Pt(bipy)(am)$_2$](PF$_6$)$_2$ (am = mono- and bidentate aliphatic amines) resonances.[7] The anisotropic diamagnetic shifts of 6,6′-bipy proton signals, monitored both for substituted and for unsubstituted pyridines, suggest that, in solution, the heteroaromatic rings preserve the quasiperpendicular orientation shown in the crystal structure. This preferred orientation does not, however, rule out the possibility of rotation. In order to obtain more clues relating to the capabilities of the aromatic rings in these molecules to rotate about the Pt−N bond, we measured and compared spin lattice relaxation time constants of selected ^{13}C atoms in **1**, **2**, **5** and **8**. Under decoupling conditions and for purely dipolar relaxations of aromatic C−H in the extreme narrowing limit, the Equation below applies.[8]

$$1/T_{1-DD} = \rho_{C\text{-}DD} = \tau_C [\gamma_H^2\gamma_C^2\eta^2/r^6]$$

If contributions of not directly attached protons are neglected and the C−H distance considered constant, relaxation time constants can be taken as a measure of the aromatic ring anisotropic spin diffusion. For aromatic ring carbon atoms bonded to fragments sufficiently large to be regarded as fixed matrices, diffusion preferentially occurs by rotation about the connection axis. This relatively fast motion slows down the relaxation rates of *ortho*- and *meta*-carbon atoms without altering the *para*-carbon atoms, the proton-attached dependent local fields of which are not affected by the rotation.[8,9] On this basis, the time constants (T_1) at room temperature are consistent with rotation of pyridine, *para*-substituted pyridine and phenyl rings, and hindered rotation of *meta*- and *ortho*-substituted pyridine rings (Table 3).

[a] No appreciable time constant differences found for the two rotamers.

For *ortho*- and *meta*-monosubstituted bis(pyridine) complexes the quasiperpendicular orientation implies the existence of "head-to-tail" *s-trans* and "head-to-head" *s-cis* rotamers of C_2 and C_s symmetry, respectively (two enantiomers can be envisaged for the C_2 molecules, owing to the chirality axes). The rates of these stereoisomer interconvertions depend on the lower activation energy path either

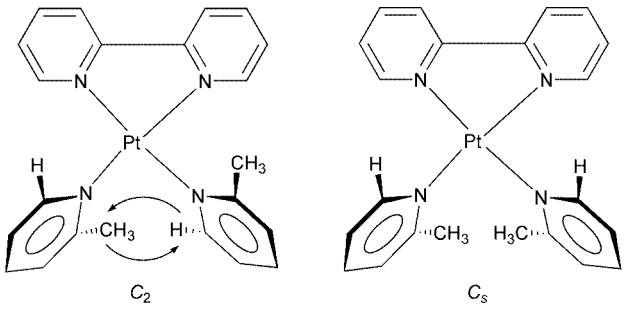
of a dissociative step involving Pt−N bond breaking, or of a single pyridine asynchronous rotation about the Pt−N bond. The NMR spectra of the monosubstituted pyridine complexes at 298 K show the resonances of the two rotamers in slow exchange on the NMR timescale. Signal integration showed approximately equal thermodynamic stability between rotamer couples. Resonance assignments (which rotamer is which) were made, when feasible, through positive NOEs between methyl (or aryl) groups and the opposite proton of the adjacent *cis*-pyridine (6-H for 2- and 5-H for 3-monosubstituted pyridines, respectively) observed for the C_s but not for the C_2 configurations (Scheme 2).



Scheme 2. Two-dimensional representation, symmetry and NOE contacts of the two rotamers of **2**

Pyridine-nitrogen, *ortho*-carbon and -proton resonances were used as probes for the conformational line shape analysis. The activation energy for rotamer interchange, calculated at coalescence, strongly differs as a function of the substituent position. We could not detect coalescence for 2-Mepy rotamers **2** even at 430 K in [D_6]DMSO ($\Delta G^{\neq} >$ 130 kJ), while 3-substituted pyridines **3**, **4** and **5**, in acetone, showed an activation energy of about 70 kJ (Table 4). The difference can be attributed to steric interactions between ligands differently hindering the pyridine crossing of coordination planes. The displacement of solvent molecules required by rotation, electronic effect of substituents on the Pt−N bond and, perhaps, stacking interactions between *cis*-pyridines may make contributions to these activation energies. These results are not consistent with a dissociative mechanism, which can also be ruled out on the basis of the permanence, above the coalescence temperatures, of ^{195}Pt satellites in the 2/6-py ^{1}H resonances.

Table 4. Activation energies for asynchronous rotation about the Pt−N bonds of monosubstituted bis(pyridine) complexes ($\Delta G^{\neq}_{(1)}$) and for molecular concerted distortion ($\Delta G^{\neq}_{(2)}$)

	$\Delta G^{\neq}_{(1)}$ [kJ·mol^{-1}]	$\Delta G^{\neq}_{(2)}$ [kJ·mol^{-1}]
2 (2-Me-py)	> 130	57 ± 2 (265 K)

5 (3-Ph-py)	71.6 ± 1 (323 K)	57 ± 2 (265 K)
3 (3-Me-py)	68.5 ± 1 (320 K)	57 ± 2 (265 K)

At 240 K, the ^{13}C{^{1}H} NMR spectrum of **3** showed the doubling of the C-2 and C-6 resonances as a consequence of a second dynamic process (Figure 1). At the same temperature, analogous carbon resonance splitting was observed for the other *ortho*- and *meta*-monosubstituted pyridine complexes. We suggest these splittings are due to freezing of square-planar-distorted conformations. As a matter of fact, the solid-state structure of **1** shows a small, propeller-like torsion of the bipyridyl rings about the C2−C2′ axis, displacing the N donors slightly out of the coordination plane. The X-ray structure also shows a "bumping" of bipy, constraining the pyridine's N3−Pt−N4 angle (about 80°). The 6,6′-H of slightly distorted bipy pushes the two opposite pyridines up and down the ring centre, respectively, causing a distortion of the ring planes by about 10° with respect to the perpendicular alignment. Steric crowding also forces the nitrogen donors of the Pt−N4 core alternatively up and down the mean coordination plane. Concerted bipy torsion angle flipping, pyridine ring windscreen-wiper rocking and up and down N-donors twisting about the mean coordination plane create a time-averaged planar symmetry for the bis(pyridine) complex. At low temperatures, freezing of the concerted flipping destroys the bipy averaged planarity, doubling the number of *ortho*- and *meta*-monosubstituted *s-trans* conformers. Indeed, the "frozen" C_2 propeller-like torsion of bipy generates two pairs of diastereomers from the two monosubstituted *s-trans* Δ and Λ enantiorotamers: namely ΔΔ′ and ΔΛ′ arising from the original Δ rotamer, and the corresponding enantiomers ΛΔ′ and ΛΛ′ from the original Λ rotamer (Scheme 3). On the other side, the *s-cis* rotamer is split into an enantiomer couple of C_1 symmetry, whose *cis*-pyridine nuclei resonate, in principle, at different frequencies. Significantly, only the C-2 and the C-6 pyridine nuclei, because of their preferential observation positions just on the top of the bipy moiety, double their resonances, indicating the molecular distortion freezing at low temperature.

In conclusion, variable-temperature spectra of rotamers show two different fluxional processes. We attribute the lower activation energy barrier to overall concerted flipping. The higher barrier must be due to asynchronous rotation of a single pyridine moiety about the Pt−N bond. In principle, simultaneous 180° rotation of the two heteroaromatic rings can physically not be distinguished from bipy flipping driving the concerted molecular motion. It is known, however,[10] that simultaneous rotation of both pyridines has a larger activation energy than the asynchronous single-ring rotation, so it seems reasonable to attribute the low fluxional activation energy to concerted flipping and the higher to the asynchronous rotation. No splitting of the resonances at low temperatures was observed for pyridine and *para*-substituted pyridine complexes **1**, **6**, **8** and **9**. This is consistent with low rotational barriers of these unhindered pyridines, which do not allow detection, at low temperatures, of bipy torsion freezing.

Discussion of Structure 1

Although **1** is the parent complex of an interesting class of metal species, the crystal structure, reported here with the PF_6^- counter ion, was not previously available. The

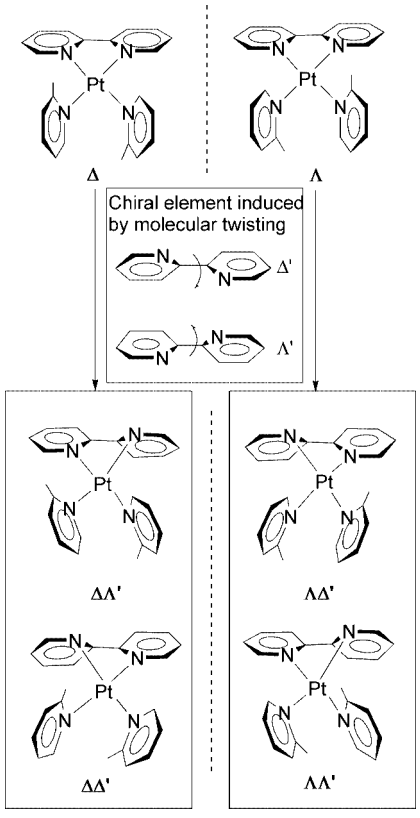

Scheme 3. Splitting due to the freezing of the C_2 twisting

complex crystallizes in the $P\bar{1}$ space group with one molecule in the asymmetric unit. The expected square-planar geometry is evident for the Pt coordination, whereas the anions show the usual octahedral conformation with just slight distortions (Figure 2 and Tables 5−7).

This square coordination plane is almost planar [max. deviation from the mean plane: N13 −0.0585(2) Å], though the bipyridyl short-bite strains the coordination angles and although the molecular symmetry is C_{2v}, the platinum atom is not able to occupy a special crystallographic position. The Pt−N distances are consistent with previously reported analogous crystal structures (Table 6).[3b,11,12]

The bipy plane almost overlaps the coordination plane [angle between mean planes: 3.69(8)°], while, as already observed in the cited papers,[3b,11,12] the pyridine aromatic rings are almost perpendicular to the coordination plane [angles between mean planes: 80.2(2)° and 80.8(1)°].

These moieties are not pointing directly toward the metal atom, which is slightly out from the pyridine averaged planes [0.196(1) and −0.323(1) Å]. This "clamp-like" closure may reasonably be due to the steric bumping of the pyridines against the bipy "wings", which is also consistent with the slightly greater corresponding strain detected for the palladium analogues.[13]

Other than the usual intermolecular hydrogen bonds, in which three fluorine atoms play the acceptor roles (see Tables), remarkable dipolar interactions take place between the fluorine and the metal atoms along the apical positions

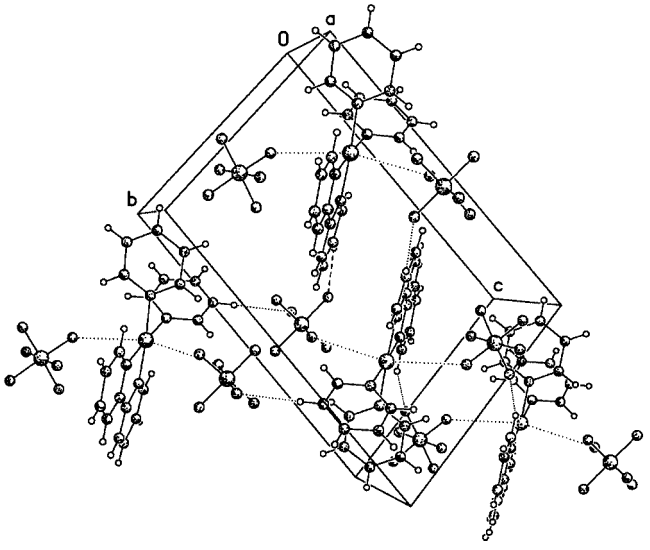

Figure 3. ORTEP view of the cell crystal packing for **1**

[Pt1···F5 3.298(5), Pt1···F8 3.338(5) Å]. These distances are shorter than those measured when pyridine is branched, probably because of steric hindrance.[3] Moreover, an intermolecular stacking interaction is present between the same ring of two bipyridyl moieties related by a symmetry inversion centre [distance between the two perfectly parallel planes: 3.339(1) Å].

All these attracting interactions produce three different types of dimeric aggregates in which the two units are related by an inversion centre and at least two pairs of interactions (see Figure 3).

Experimental Section

General: ^{1}H and $^{13}C\{^1H\}$ NMR spectra were recorded with a Bruker ARX 300 spectrometer, at 300.13 and 75.47 MHz, respectively. The ^{1}H NMR spectra were calibrated against the residual proton signals of the solvent as internal reference ([D$_6$]acetone: δ = 2.04 ppm), the $^{13}C\{^1H\}$ spectra were calibrated against the septuplet of the solvent ([D$_6$]acetone: δ = 29.80 ppm); $^{13}C\{^1H\}$ spin-lattice relaxation time constants were measured under N_2 by the "inversion recovery"[14] sequence.

Synthesis: The complexes were prepared by a previously described general procedure,[3,4] by heating of an aqueous suspension of [Pt(bipy)Cl$_2$] with an excess of the appropriate pyridine derivative at reflux. After dissolution of the solid, NH_4PF_6 was added and the resulting complexes [Pt(bipy)(*n*-Rpy)$_2$](PF$_6$)$_2$ precipitated as white or pale yellow substances, which were recrystallized from water/acetone. Elemental analyses were performed at the Microanalytical Laboratory of Redox snc (Milano).

[Pt(bipy)(py)$_2$](PF$_6$)$_2$ (1): ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 9.34 (dd, ^3J = 5.1, ^4J = 1.5 Hz, 4 H, 2-py, 6-py), 8.78 (d, ^3J = 8.2 Hz, 2 H, 3,3′-bipy), 8.59 (td, ^3J = 7.9, ^4J = 1.4 Hz, 2 H, 4,4′-bipy), 8.30 (tt, ^3J = 7.7, ^4J = 1.5 Hz, 2 H, 4-py), 8.01 (m, 2 H, 6,6′-bipy), 7.89 (m, 4 H, 3-py, 5-py), 7.81 (m, 2 H, 5,5′-bipy) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]acetone): δ = 157.6 (2 C, 2,2′-bipy), 153.4 (4 CH, 2-py, 6-py), 151.0 (2 CH, 6,6′-bipy), 143.7 (2 CH, 4,4′-bipy), 142.9 (2 CH, 4-py), 129.7 (2 CH, 5,5′-bipy), 129.6 (4 CH, 3-py, 5-py), 125.6 (2 CH, 3,3′-bipy) ppm. $C_{20}H_{18}F_{12}N_4P_2Pt$ (799): calcd. Crystal Structure Determination of 1: Crystals suitable for X-ray analysis were obtained by recrystallization from methanol solution. Diffraction data were collected from a colourless 0.58 × 0.46 × 0.32 mm irregular specimen at room temperature by use of a Siemens P4 automated four-circle single-crystal diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Lattice parameters were obtained from least-squares refinement of the setting angles of 42 and 39 reflections within 5.34° ≤ θ ≤ 17.50° range. 6822 reflections were measured by the fixed speed θ-2θ scan technique up to 2θ ≤ 55°. No crystal decay was evidenced by reference reflections monitored each 197 measurements. Intensities were evaluated by profile fitting of a 96-step peak scan among 2θ shells procedure[15] and then corrected for Lorentz polarization effects. Absorption correction was applied by Gaussian integration of the indexed crystal shape. Data collection, reduction and face-indexed absorption correction were performed with the aid of the XSCANS[16] and SHELXTL packages.[17] The structure was solved by the Patterson standard method in the SHELXS package,[18] and refined by minimization of the function $\Sigma w(F_o^2 - F_c^2)^2$ by the full-matrix, least-squares technique based on all independent F^2, by use of SHELXL-97.[19] All non-hydrogen atoms were treated as anisotropic. Hydrogen atoms were placed in idealized positions and all the isotropic thermal parameters were fixed to the best fitting value. An empirical extinction parameter was included in the last refinement cycles. The last difference map showed expected electron density residuals close to the metal atoms (max. and min. values: 1.558 and −1.396 e·Å^{-3}). The final geometrical calculations and drawings were carried out with the aid of the PARST program[20] and the XPW[21] utility of the Siemens package, respectively. CCDC-201345 (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Bis(2-aminobutanol)dichloroplatinum(II) Complexes and Their Singly and Doubly Ring-Closed Butanolato Species − Novel Prodrugs for Platinum-Based Antitumour Chemotherapy?

Markus Galanski,*[a] Christian Baumgartner,[a] Vladimir Arion,[a] and Bernhard K. Keppler[a]

Keywords: Antitumour agents / Bioinorganic chemistry / N,O ligands / Platinum

Cytotoxic hydroxyethyl-substituted (amine)platinum(II) and -(IV) complexes have recently attracted attention because of the ability of their hydroxyethyl groups to coordinate through the oxygen atom to the platinum centre during oxidation with hydrogen peroxide or through intramolecular ligand exchange reactions in dichloroplatinum(II) complexes. The last point in particular is of great interest, because the intramolecular attack of the hydroxy group dramatically influences the mode of action of platinum(II) compounds. On the other hand, there is also the chance to use such reactions specifically for the synthesis of novel anticancer platinum-based drugs for chemotherapy. We have therefore focused our chemistry program on the synthesis of dichloroplatinum(II) complexes that are in a position to form singly and, especially, doubly ring-closed alcoholato species and on investigation of their structures by X-ray crystallography. It was possible to determine the crystal structures of [Pt{(*R*)-(−)-HL}$_2$Cl$_2$], [Pt{(*S*)-(+)-HL}$_2$Cl$_2$], [Pt{(*R*)-(−)-HL}{(*S*)-(+)-HL}Cl$_2$], [Pt{(*S*)-(+)-HL}{(*S*)-(+)-L}Cl], [Pt{(*R*)-(−)-L}$_2$] and [Pt{(*S*)-(+)-L}$_2$] (HL = 2-aminobutanol-κ*N*, L = 2-aminobutanolato-κ^2*N*,*O*). The results obtained may represent the first step towards novel prodrugs for platinum-based antitumour chemotherapy.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Alongside the worldwide success of cisplatin [= *cis*-diamminedichloroplatinum(II)] and carboplatin [= *cis*-diammine(1,1-cyclobutanedicarboxylato)platinum(II)] which are routinely used in clinics against certain types of cancer,[1−5] the so-called third-generation platinum drug oxaliplatin {= [*trans*-(1*R*,2*R*)-cyclohexane-1,2-diamine]oxalatoplatinum(II) (Figure 1)} is also today in clinical use.[6]

In order to overcome the severe side-effects of platinum-based chemotherapy, to improve clinical effectiveness and to broaden the spectrum of activity, there is still a need for other platinum antitumour agents. During recent years, part of the research in this field has focused on platinum(II) and -(IV) complexes with peripheral functional groups. OH- and COOH-substituted ligands were especially of interest because of their potential to act as donors or acceptors for hydrogen bonds, which could play an important role in the binding of platinum compounds to DNA, the major target of platinum-based chemotherapy.[7] Moreover, these compounds were also used as starting materials for further derivatization,[8,9] with the aim of attaching suitable carrier molecules for drug targeting.[10,11]

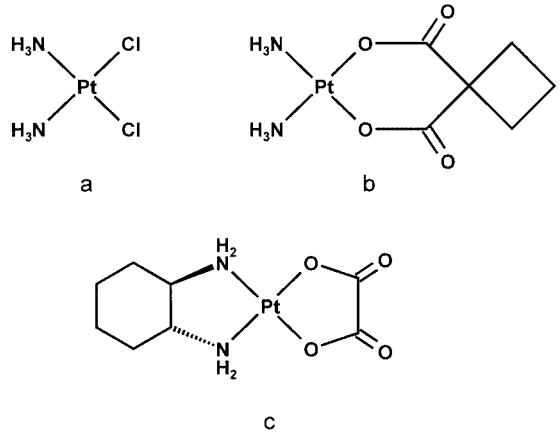

Figure 1. Platinum(II) complexes in clinical use: cisplatin (a), carboplatin (b) and oxaliplatin (c)

Hydroxyethyl residues have recently attracted attention because of their ability to coordinate to the platinum centre through the oxygen atom: (i) during oxidation with hydrogen peroxide[12] or (ii) through an intramolecular ligand exchange reaction in dichloroplatinum(II) complexes.[13]

In investigation of the binding of potentially cytotoxic platinum coordination compounds to nucleotides, the above intramolecular ligand exchange reaction might at first sight

be regarded as an undesirable side reaction of a competitive character, complicating the mechanism of action.[14−16] On the other hand, though, such reactions have also been used specifically for the synthesis of novel tumour-inhibiting platinum(IV) drugs.[17]

CZE-CE-MS studies have shown[18] that the binding behaviour of dichlorobis[(2-hydroxyethyl)amine]platinum(II) towards 5′-GMP is dramatically increased by a decrease in the pH from 7.4 to 6.0. This is of great interest in view of the lower pH values encountered in solid tumours and fits with a pH-dependent ring-closing/opening reaction of *N*-(hydroxyethyl)-substituted diaminedichloroplatinum(II) complexes.

The intramolecular ligand exchange reactions described above have been investigated by NMR spectroscopy but there was still a lack of structural information from X-ray crystallography. To fill this gap, and to develop new platinum-based antitumour drugs, we have focused on the synthesis and crystallisation of substituted dichlorobis[(2-hydroxyethyl)amine]platinum(II) complexes and especially their singly and doubly ring-closed species.

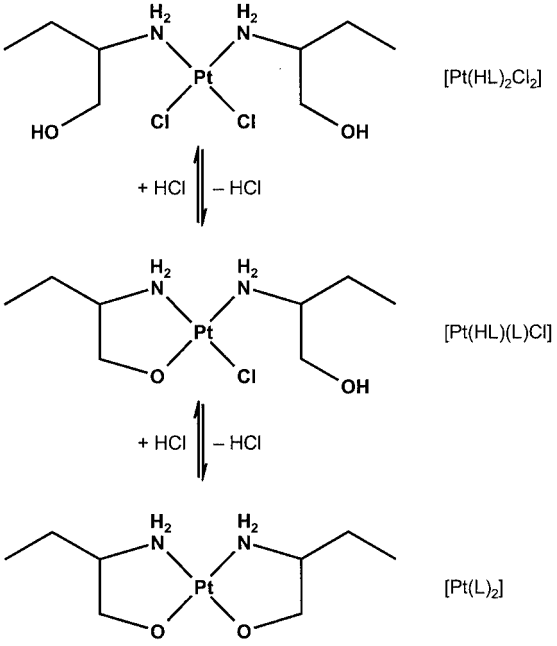

Figure 2. Intramolecular ligand exchange reactions resulting in singly ([Pt(HL)(L)Cl]) and doubly ([Pt(L)$_2$]) ring-closed species

Results and Discussion

Synthesis of the bis(2-aminobutanol)dichloroplatinum(II) complexes starts from potassium tetrachloroplatinate(II), K_2PtCl_4, which is converted in situ to the corresponding tetraiodoplatinate(II) by treatment with KI. After addition either of enantiomerically pure 2-aminobutanol or of the racemic mixture, the (2-aminobutanol)diidoplatinum(II) compounds are formed. Conversion of the diiodo to the dichloro complexes was performed by treatment of the diiodo compounds with silver nitrate, which afforded the diaminediaquaplatinum(II) species, and subsequent addition of KCl or HCl to provide the bis(2-aminobutanol)dichloroplatinum(II) complexes. Depending on pH, chloride ion concentration and crystallisation, either pure dichloroplatinum(II) complexes, [Pt(HL)$_2$Cl$_2$], or a mixture of [Pt(HL)$_2$Cl$_2$] and the singly ring-closed species [Pt(HL)(L)Cl] can be isolated (Figure 2). The doubly ring-closed coordination compound could not be detected during this synthetic pathway. The tailor-made synthesis of [Pt(L)$_2$] was achieved by (i) abstraction of the chloro ligands and (ii) by shifting the pH to values above 7 with a basic ion exchanger.

The purities of the synthesized complexes can best be judged by ^{1}H and ^{13}C NMR spectroscopy. In the case of the enantiomerically pure [Pt{(*S*)-(+)-HL}$_2$Cl$_2$] complex, six proton resonances are detected [δ = 0.86 (CH_3), 1.49 (CH$_3$CH_2), 1.70 (CH$_3$CH_2), 2.74 (C*H*), 3.60 (CH_2OH), 4.07 (CH_2OH) ppm]. Because of the asymmetrically substituted methine carbon atom, the two methylene groups show two sets of multiplets, in agreement with their diastereotopic character. Four different ^{13}C signals were found: atδ = 10.0 (*C*H$_3$), 24.6 (CH$_3$*C*H$_2$), 59.4 (*C*H) and 62.5 (*C*H$_2$OH) ppm. The corresponding resonances of the doubly ring-closed species were found to be atδ = 0.80 (CH_3), 1.34 (CH$_3$CH_2), 1.53 (CH$_3$CH_2), 2.48 (C*H*), 2.88 (CH_2O), 3.01 (CH_2O), 10.76 (*C*H$_3$), 22.90 (CH$_3$*C*H$_2$), 64.07 (*C*H) and 73.02 (*C*H$_2$O) ppm. Most indicative of the ring-closing reaction are the ^{1}H and ^{13}C chemical shifts of the methylene group next to the oxygen atom. In the chelating (*S*)-(+)-2-aminobutanolato ligands both of the singly and of the doubly ring-closed species, marked shifts of the ^{1}H resonances to higher field and downfield shifts of the ^{13}C signals in relation to the monodentate-coordinated (*S*)-(+)-2-aminobutanol can be seen.

During the synthesis it was possible to isolate crystals suitable for X-ray crystallographic studies. In the presence of hydrochloric acid, compound **1**, [Pt{(*R*)-(−)-HL}$_2$Cl$_2$], could be isolated as the dichloroplatinum(II) complex, whereas the structure of **2** {solution of [Pt{(*S*)-(+)-HL}$_2$Cl$_2$] in water and KCl} is made up of two different compounds − the dichloroplatinum(II) complex [Pt{(*S*)-(+)-HL}$_2$Cl$_2$] and the singly ring-closed species [Pt{(*S*)-(+)-HL}{(*S*)-(+)-L}Cl] − in a 1:1 ratio.

It was also possible to determine the structures of the corresponding doubly ring-closed enantiomerically pure bis(2-aminobutanolato)platinum(II) complexes **3** ([Pt{(*R*)-(−)-L}$_2$]) and **4** ([Pt{(*S*)-(+)-L}$_2$]) in the crystal.

Furthermore, the structure of **S1**, a 1:1 mixture of [Pt{(*R*)-(−)-HL}{(*S*)-(+)-HL}Cl$_2$] and [Pt{(*S*)-(+)-HL}$_2$Cl$_2$] isolated from the synthesis with a racemic mixture of 2-aminobutanol ligands, could also be resolved. Crystal data, data collection parameters and structure refinement details for **S1** are given in Table S4 of the Supporting Information, while the structure is shown in Figure S4.

Figure 3 summarises the results of the single-crystal X-ray structure of one of the two independent molecules of **1**, [Pt{(*R*)-(−)-HL}$_2$Cl$_2$]. The second independent molecule is shown in Figure S1 in the Supporting Information. The

platinum(II) atom has a square-planar coordination geometry. Two 2-aminobutanol ligands act as neutral monodentate ligands and bind to Pt^{II} through the terminal nitrogen atoms [Pt1−N1 2.057(5), Pt1−N2 2.035(6) Å]. These bond lengths are similar to Pt−N [2.042(4) Å] in $Pt^{II}Cl_2(EA)_2$ and shorter than Pt−N [2.070(3) Å] in $Pt^{IV}Cl_4(EA)_2\cdots H_2O$ (EA = ethanolamine).[19] In addition to two *cis*-disposed organic ligands, two chloride anions Cl1 and Cl2 are bound to Pt^{II} at 2.327(2) and 2.3139(19) Å, respectively. The bond lengths in the coordinated 2-aminobutanol ligands are in a normal range [O1−C1 1.402(10), O2−C5 1.435(9); C1−C2 1.550(13), C5−C6 1.516(10); C2−N1 1.489(9), C6−N2 1.512(9); C2−C3 1.516(9), C6−C7 1.490(9); C3−C4 1.533(13), C7−C8 1.548(11) Å]. Both coordinated NH_2 groups are involved in intramolecular hydrogen bonding (Figure 3) (N1-H1A···O2 with N1-H1A 0.90, H1A···O2 2.121, N1···O2 2.956 Å and N1-H1A···O2 153.77°; and N2-H2A···O1 with N2-H2A 0.90, H2A···O1 2.319, N2···O1 3.049 Å and N2-H2A···O1 138.21°). Both molecules are involved in a three-dimensional hydrogen-bonding network, the packing being dominated by O−H···O, N−H···O and N−H···Cl interactions. Detailed geometrical parameters for the intramolecular contacts in the second independent molecule of **1**, together with intermolecular contacts in **1**, are given in Table S1.

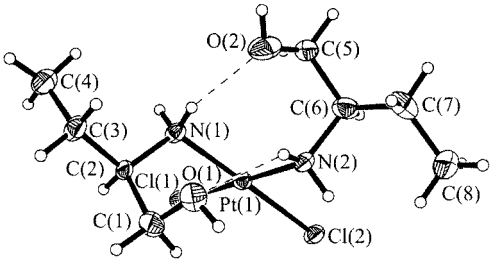

Figure 3. ORTEP diagram of one of the independent molecules of **1** with thermal ellipsoids at 50% probability

The structure of **2** is made up of two different molecules: [Pt{(*S*)-(+)-HL}$_2$Cl$_2$] (**I**) and [Pt{(*S*)-(+)-HL}{(*S*)-(+)-L}Cl] (**II**). There are four crystallographically independent molecules in the asymmetric unit: two (A and C) of composition I and two other ones (B and D) of composition II. In addition, molecule C was found to exist in the crystal as two conformers in ca. 0.4:0.6 ratio, differing slightly in the positions of the terminal ethyl groups (Figure S2). The molecular structures of **2-IA** and **2-IIB** are shown in Figures 4 and 5, respectively.

Two neutral 2-aminobutanol ligands act in monodentate fashion and coordinate to Pt^{II} through the terminal amino groups' N1 and N2 atoms in both molecules A and C. They each exhibit a square-planar coordination geometry around Pt, with two nitrogen atoms and two chloride ligands in a *cis* arrangement with average r.m.s. deviations of 0.03 and 0.02 Å, respectively. As in **2-IA** and **2-IC**, the coordination geometry around Pt^{II} in **2-IIB** and **2-IID** can be described as square-planar. The deviation of the coordinated atoms from their mean planes does not exceed 0.04 Å. One neutral 2-aminobutanol ligand acts in monodentate fashion and coordinates to Pt^{II} through N3 in **2-IIB** (Figure 5) and through N7 in **2-IID** (Figure S3), whereas another one, deprotonated at the OH group, chelates to the Pt atom through the N4/O4 (**2-IIB**) and N8/O8 (**2-IID**) atoms, giving a *cis* arrangement of amino groups. The fourth coordination place around Pt^{II} in molecules B and D is occupied by chloride anions Cl3 and Cl6, respectively. The chelate ring Pt2O4C13C14N4 in B has an envelope conformation.

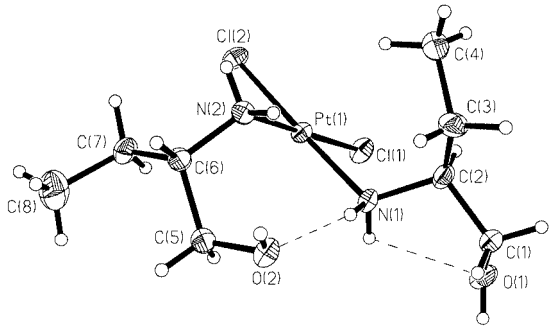

Figure 4. ORTEP diagram of **2-IA** with thermal ellipsoids at 50% probability

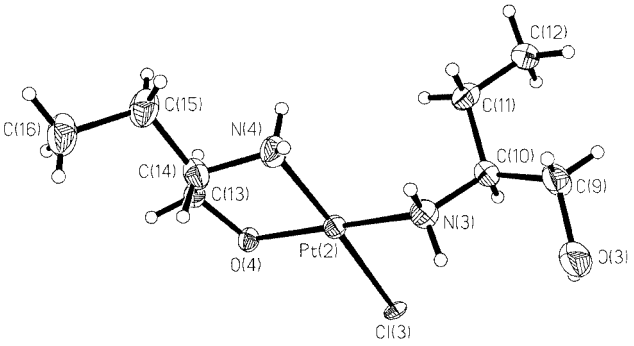

Figure 5. ORTEP diagram of **2-IIB** with thermal ellipsoids at 50% probability

The flap[20] atom protrudes from the plane of the coordinated atoms by 0.63 Å. In contrast, the Pt4O8C29C30N8 chelate ring has a distorted envelope conformation with a weak tendency towards a zigzag arrangement of C29 (+0.09 Å) and C30 (−0.54 Å) (Figure S3). The dihedral angles O4−C13−C14−N4 and O8−C29−C30−N8 compare well, at 48.1(7)° (B) and 50.7° (D). The bite angles, at 82.83(19) and 83.33(19)°, are also similar. The N3−C10 and N7−C26 bonds in the non-chelated ligands in B and D orient almost vertically to the planes of bound platinum atoms with corresponding angles Pt2−N3−C10 and Pt4−N7−C26 at 119.2(4) and 118.6(4)°. All asymmetric carbon atoms in **2** are (*S*)-chiral centres. The corresponding Pt−N, Pt−O and Pt−Cl bond lengths in molecules A, B, C and D as well as the bond lengths in the ligands are quoted in Tables 1 and 2.

Two intramolecular hydrogen bonds are observed between the amino group of one coordinated 2-aminobutanol ligand as donor and the hydroxy groups of both coordinated HL ligands as acceptors in A and C (Figures 4 and S1) (N1-H1A···O2 with N1−H1A 0.90, H1A···O2 2.070 Å and N1−H1A···O2 155.34°, and N1-H1B···O1 with N1−H1B 0.90, H1A···O2 2.390 Å and N1−H1A···O2 111.82° in A; and N5-H5A···O6 with N5−H5A 0.90, H5A···O6 1.958 Å and N5−H5A···O6 157.72°, and N5-H5B···O5 with N5−H5B 0.90, H5A···O6 2.382 Å and N5−H5A···O6 110.83° in C). All four molecules A, B, C and D are involved in a three-dimensional hydrogen-bonding network, the packing is dominated by O-H···O, N-H···O and N-H···Cl hydrogen-bonding interactions. Detailed geometrical parameters for the intermolecular contacts in **2** are listed in Table S2.

Both **3** {[Pt{(*R*)-(−)-L}$_2$]} and **4** {[Pt{(*S*)-(+)-L}$_2$]} crystallize in a non-centrosymmetric orthorhombic space group $P2_12_12$. The asymmetric units in **3** and **4** consist of one half of the complex molecule, related to the other by a twofold rotation axis lying in the molecule mean plane across the platinum atom. The results of X-ray crystal structure analyses of **3** and **4** are summarized in Figures 6 and 7.

In both enantiomers [C2 is an (*R*)-chiral centre in **3** and an (*S*)-chiral one in **4**] Pt^{II} has square-planar coordination with two mutually *cis*-arranged 2-aminobutanol ligands deprotonated at the OH group and chelated through NH_2 and O^-. None of the coordinated atoms protrudes from the corresponding least-squares mean plane by more than 0.002 Å for **3** and 0.004 Å for **4**. Two five-membered chelate rings, with bite angles of 83.31(13) and 83.32(9)° for **3** and **4**, respectively, are formed. A zigzag arrangement of the ligand atoms in the five-membered chelate rings alternately above and below the mean least-squares plane through PtN_2O_2 is observed in both complexes. Unlike in the case of $Pt^{IV}(Eta)_2Cl_2$,[21] the two chelate rings PtO1C1C2N1 and the symmetry-related one in the molecules of **3** and **4** are twisted in the opposite sense and their configurations can be described as δλ or λδ. The dihedral angles O1−C1−C2−N1 in **3** and **4**, which serve as measures of the deviation of the corresponding chelate rings from planarity, are −47.1(4) and 46.6(3)°, respectively. These values are similar to those in $Pt^{IV}(Eta)_2Cl_2$. The Pt−O1 and Pt−N1 bond lengths in **3** and **4** compare well, at 2.031(2) and 2.024(2) Å, and 2.029(4) and 2.018(3) Å, respectively. The distributions of electron density over the chelate rings are very similar for

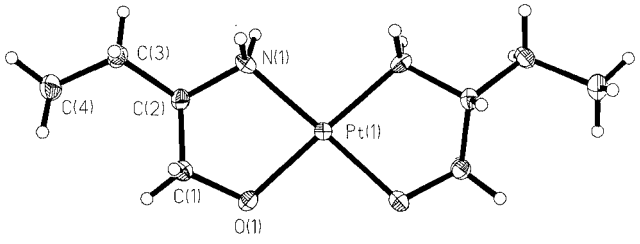

Figure 6. ORTEP diagram of **3** with thermal ellipsoids at 50% probability

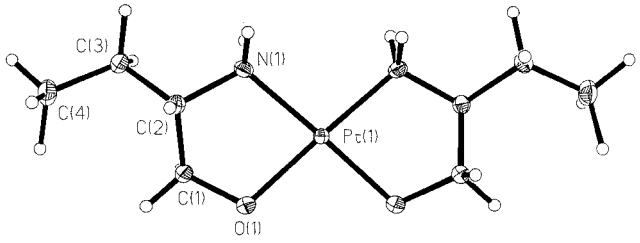

Figure 7. ORTEP diagram of **4** with thermal ellipsoids at 50% probability

the two enantiomers [O1−C1 at 1.433(5) and 1.434(3), C2−C3 at 1.523(6) and 1.527(4), C3−C4 at 1.524(6) and 1.520(4), N1−C2 at 1.509(5) and 1.500(4) Å for **3** and **4**, respectively].

The NH_2 and the deprotonated OH groups, together with the water molecules, are involved in intermolecular hydrogen bonding, forming a chain of tail-to-head-arranged $Pt^{II}L_2$ molecules (where HL = 2-aminobutanol), bridged by layers of hydrogen-bonded water molecules and running along the *c* axis, as shown for **3** in Figure 8.

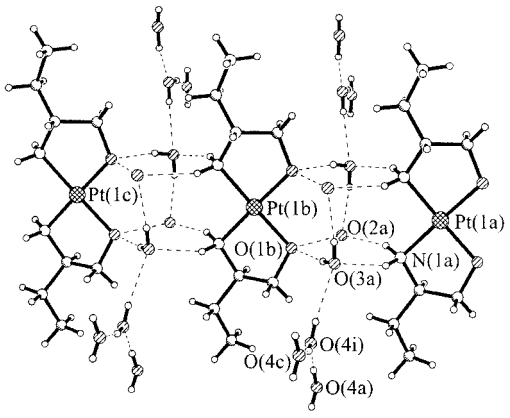

Figure 8. A portion of the crystal structure of **3** projected on the *ac* plane

Detailed geometrical parameters for the hydrogen bonds in **3** are quoted in Table S3. Another interesting feature is the stacked arrangement of $Pt^{II}L_2$ molecules, with a 4.2 Å intermolecular separation along the *b* axis (Figure 9). Very weak C−H···Pt intermolecular contacts with the C−H vector directed to the platinum atom (< C−H···Pt 176.5°) at ca. 3.1 Å are worth mentioning. At ca. 2.6 Å, they are significantly longer than the intramolecular contacts observed in other platinum(II) compounds with square-planar geometries.[22,23]

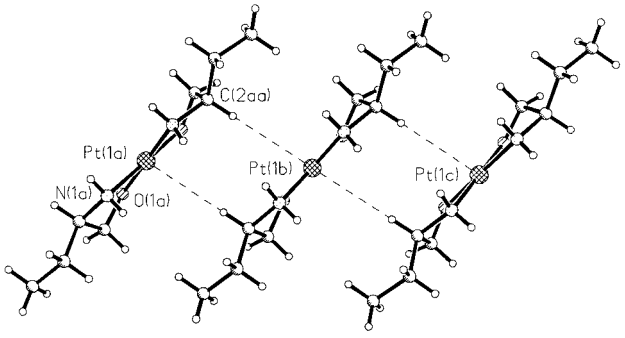

Figure 9. Portion of the crystal structure of **3**, showing stacking arrangement of $Pt^{II}L_2$ along the *b* axis

Conclusion

Cytotoxic hydroxyethyl-substituted amineplatinum(II) and -(IV) complexes have recently attracted attention because of: (i) the potential of their hydroxy groups to act as donors or acceptors of hydrogen bonds, thus influencing the mode of action, (ii) their use as starting materials for further derivatisation, and (iii) the ability of their hydroxyethyl groups to coordinate to the platinum centre through the oxygen atom during oxidation with hydrogen peroxide or through intramolecular ligand exchange reactions in dichloroplatinum(II) complexes.

The last point in particular is of great interest, because the intramolecular attack of the hydroxy group dramatically influences the mode of action of platinum(II) compounds, as was shown recently. Moreover, there is the chance to use such reactions specifically for the synthesis of novel anticancer platinum-based drugs for chemotherapy. We have therefore focused our chemistry program on the synthesis of dichloroplatinum(II) complexes that are in a position to form singly or − especially − doubly ring-closed alcoholato species and on investigation of their structures by X-ray crystallography.

The results obtained may represent the first step towards novel prodrugs for platinum-based antitumour chemotherapy.

Experimental Section

General Remarks: All chemicals were obtained from commercial suppliers and used as received. The ^1H and ^{13}C NMR spectra were recorded with a Bruker DPX 400 Ultrashield™ Magnet at 400.13 and 100.62 MHz. The elemental analyses were performed with a Perkin−Elmer 2400 CHN Elemental Analyser by the microlaboratory of the Institute of Physical Chemistry, University of Vienna.

(*SP*-4−2)-[Bis{(*R*)-(−)-2-aminobutanol}]diiodoplatinum(II): K_2PtCl_4 (3.621 g, 8.72 mmol) was dissolved in doubly distilled water (35 mL) and treated with KI (7.5 g, 45.18 mmol). The solution was stirred for 20 min at room temperature. A solution of (*R*)-(−)-2-aminobutanol (1.45 g, 16.27 mmol) in doubly distilled water (10 mL) was added dropwise to the brown suspension of tetraiodoplatinate. After the mixture had been stirred at room temperature for 5 h, $[Pt\{(R)\text{-}(-)\text{-}HL\}_2I_2]$ was obtained as a precipitate. After filtration, the yellow solid was washed twice with ice-cold water (10 mL). The product was dried over P_4O_{10}. $C_8H_{22}I_2N_2O_2Pt$ (627.18): calcd. C 15.32, H 3.54, N 4.47; found C 15.36, H 3.27 N 4.29. Yield: 2.722 g (50%).

(*SP*-4−2)-[Bis{(*S*)-(+)-2-aminobutanol}]diiodoplatinum(II): The synthetic procedure was the same as that used for $[Pt((R)\text{-}(-)\text{-}HL)_2I_2]$. $C_8H_{22}I_2N_2O_2Pt$ (627.18): calcd. C 15.32, H 3.54, N 4.47; found C 15.29, H 3.36, N 4.92. Yield: 3.4362 g (76%).

[Bis(2-aminobutanol)]diiodoplatinum(II): The synthetic procedure was the same as that used for $[Pt\{(R)\text{-}(-)\text{-}HL\}_2I_2]$. $C_8H_{22}I_2N_2O_2Pt$ (627.18): calcd. C 15.32, H 3.54, N 4.47; found C 15.02, H 3.30, N 4.25. Yield: 6.848 g (91%).

(*SP*-4−2)-[Bis{(*R*)-(−)-2-aminobutanol}]dichloroplatinum(II) (1): $[Pt\{(R)\text{-}(-)\text{-}HL\}_2I_2]$ (1.5 g, 2.39 mmol) was suspended in doubly distilled water (20 mL). $AgNO_3$ (0.772 g, 4.54 mmol) was added, and the mixture was stirred for 12 h at room temperature. AgI was removed by filtration. The slightly yellow filtrate was reduced to a volume of 10 mL, and concentrated HCl (1.4 mL, 16.38 mmol) was added. After 5 min, the dichloro complex began to crystallise as yellow needles. ^1H NMR (H_2O/D_2O, 9:1; 1 drop of $DCl_{conc.}$): δ = 0.74 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.28−1.67 (m, 4 H, CH_3CH_2),

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2.62 (m, 2 H, C*H*), 3.51 (m, 2 H, CH_2OH), 3.93 (m, 2 H, CH_2OH) ppm. ^{13}C NMR (H_2O/D_2O, 9:1; 1 drop of $DCl_{conc.}$): δ = 10.06 (2 C, *C*H_3), 24.66 (2 C, CH_3CH_2), 59.34 (2 C, *C*H), 62.49 (2 C, *C*H_2OH). $C_8H_{22}Cl_2N_2O_2Pt$ (444.27): calcd. C 21.63, H 4.99, N 6.31; found C 21.56, H 4.87, N 6.17. Yield: 0.55 g (41%).

(SP-4-2)-[Bis{(*S*)-(+)-2-aminobutanol}]dichloroplatinum(II) and (SP-4-3)-{(*S*)-(+)-2-aminobutanol}[{(*S*)-(+)-2-aminobutanolato}-κ*N*,*O*]chloroplatinum(II) (2): [Pt{(*S*)-(+)-HL}$_2$I$_2$] (1.8 g, 2.87 mmol) was suspended in doubly distilled water (20 mL). $AgNO_3$ (0.936 g, 5.51 mmol) was added to the mixture, which was stirred at room temperature for 12 h. AgI was filtered off, and KCl (0.53 g 7.11 mmol) was added to the slightly yellow filtrate. The colour of the filtrate turned to dark yellow; after 10 min, yellow needles began to crystallise. The mixture was stored at 4 °C for 3 h; 550 mg of a crystalline product could be collected. [Pt{(*S*)-(+)-HL}$_2$Cl$_2$]: ^{1}H,^{13}C-COSY NMR (H_2O/D_2O, 9:1): δ = 0.86/10.0 (*CH*$_3$), 1.49/24.6 (CH_3CH_2), 1.70/24.6 (CH_3CH_2), 2.74/59.4 (*CH*), 3.60/62.5 (CH_2OH), 4.07/62.5 (CH_2OH). [Pt{(*S*)-(+)-HL}{(*S*)-(+)-L}Cl], monodentate ligand: ^{1}H,^{13}C-COSY NMR (H_2O/D_2O, 9:1): δ = 0.86/10.0 (*CH*$_3$), 1.54/22.2 (CH_3CH_2), 1.67/22.2 (CH_3CH_2), 2.78/61.5 (*CH*), 3.60/62.4 (CH_2OH), 3.95/62.4 (CH_2OH). [Pt{(*S*)-(+)-HL}{(*S*)-(±)-L}Cl], bidentate ligand: ^{1}H,^{13}C-COSY NMR (H_2O/D_2O, 9:1): δ = 0.86/10.0 (*CH*$_3$), 1.54/22.2 (CH_3CH_2), 1.67/22.2 (CH_3CH_2), 2.56/60.4 (*CH*), 3.35/72.6 (CH_2OPt), 3.58/72.6 (CH_2OPt). $C_8H_{22}Cl_2N_2O_2Pt{\cdot}0.1C_8H_{20}ClN_2O_2Pt$ (485.05): calcd. C 21.79, Cl 15.35, H 5.01, N 6.35; Pt, 43.91; found C 21.50, Cl 15.35, H 4.84, N 6.84; Pt 43.96.

[Bis(2-aminobutanol)]dichloroplatinum(II) (S1): The synthetic procedure was the same as that used for [Pt{(*S*)-(+)-HL}$_2$Cl$_2$]. ^{1}H NMR (H_2O/D_2O, 9:1; [Pt(HL)$_2$Cl$_2$] and [Pt(HL)(L)Cl]): δ = 0.90 (t, $^3J_{H,H}$ = 7.5 Hz, CH_3), 1.42−1.81 (m, CH_3CH_2), 2.48−2.88 (m, C*H*), 3.32−4.14 (m, CH_2O) ppm. ^{13}C NMR (H_2O/D_2O, 9:1; [Pt(HL)$_2$Cl$_2$] and [Pt(HL)(L)Cl]): δ = 9.91, 9.95, 10.13, 10.15, 10.30 (*C*H_3), 22.37, 22.41, 24.49, 24.51, 24.70, 24.77 (CH_3CH_2), 59.51, 60.44, 60.48, 61.47, 61.54 (*C*H), 65.51, 62.58, 62.75 (*C*H_2OH), 72.64 (*C*H_2OPt). $C_8H_{22}Cl_2N_2O_2Pt$ (444.27): calcd. C 21.63, H 4.99, N 6.31; found C 21.72, H 4.79, N 6.25. Yield: 1.390 g (47%).

(*SP*-4-2)-[Bis{(*R*)-(−)-2-aminobutanolato}-κ^2*N*,*O*]platinum(II) (3): [Pt{(*R*)-(−)-HL}$_2$Cl$_2$] (0.3 g) was dissolved in doubly distilled water (10 mL) and treated with rinsed Amberlite IRA-400 (Cl^-) basic ion exchanger (20 mL). The suspension was stirred at room temperature for 24 h. The ion exchanger was filtered off and the colourless filtrate was concentrated to 1 mL under reduced pressure. The solution was stored over P_4O_{10} until colourless crystals had formed. ^{1}H NMR (H_2O/D_2O, 9:1): δ = 0.86 (t, $^3J_{H,H}$ = 7.6 Hz, 4 H, CH_3), 1.42 (m, 2 H, CH_3CH_2), 1.59 (m, 2 H, CH_3CH_2), 2.54 (m, 2 H, C*H*), 2.94 (m, 2 H, CH_2O), 3.06 (m, 2 H, CH_2O) ppm. ^{13}C NMR (H_2O/D_2O, 9:1): δ = 10.78 (2 C, *C*H_3), 22.89 (2 C, CH_3CH_2), 64.09 (2 C, *C*H), 73.01 (2 C, *C*H_2O).

(*SP*-4-2)-[Bis{(*S*)-(+)-2-aminobutanolato}-κ^2*N*,*O*]platinum(II) (4): The synthetic procedure was the same as that used for [Pt{(*R*)-(−)-L}$_2$]. ^{1}H NMR (H_2O/D_2O, 9:1): δ = 0.80 (t, $^3J_{H,H}$ = 7.3 Hz, 6 H, CH_3), 1.34 (m, 2 H, CH_3CH_2), 1.53 (m, 2 H, CH_3CH_2), 2.48 (m, 2 H, C*H*), 2.88 (m, 2 H, CH_2O), 3.01 (m, 2 H, CH_2O) ppm. ^{13}C NMR (H_2O/D_2O, 9:1): δ = 10.76 (s, 2 C, *C*H_3), 22.90 (s, 2 C, CH_3CH_2), 64.07 (s, 2 C, *C*H), 73.02 (s, 2 C, *C*H_2O).

[Bis(2-aminobutanolato)-κ^2*N*,*O*]platinum(II): The synthetic procedure was the same as that used for [Pt{(*R*)-(−)-L}$_2$]. ^{1}H NMR (H_2O/D_2O, 9:1): δ = 0.79 (t, $^3J_{H,H}$ = 7.3 Hz, 6 H, CH_3), 1.34 (m, 2 H, CH_3CH_2), 1.51 (m, 2 H, CH_3CH_2), 2.46 (m, 2 H, C*H*), 2.86 (m, 2 H, CH_2O), 3.00 (m, 2 H, CH_2O) ppm. ^{13}C NMR (H_2O/D_2O, 9:1): δ = 10.76 (2 C, *C*H_3), 22.90 (2 C, CH_3CH_2), 64.08 (2 C, *C*H), 72.90 (2 C, *C*H_2O). $C_8H_{20}N_2O_2Pt{\cdot}2H_2O$ (407.38): calcd. C 23.59, H 5.94, N 6.88; found C 23.86, H 5.54, N 6.60. Yield: 0.178 g (71%).

X-ray Crystallographic Study: X-ray diffraction measurements were performed with a Nonius Kappa CCD diffractometer at 120 K. Single crystals were positioned at 35, 40, 35, 35 and 30 mm from the detector and 496, 636, 597, 597 and 414 frames were measured, each for 25, 90, 50, 50 and 65 s over a 2, 1.5, 1.5, 1.5 and 2° scan for **1**−**4** and **S1**, respectively. The data were processed by use of Denzo-SMN software. Crystal data, data collection parameters, and structure refinement details for **1**−**4** are given in Table 3. Crystal data, data collection parameters, and structure refinement de-

tails for **S1** are given in Table S4 of the Supporting Information. The structures were solved by direct methods and refined by full-matrix, least-squares techniques. Non-hydrogen atoms were refined with anisotropic displacement parameters. H atoms were calculated and allowed to ride (**1**−**3** and **S1**) or located on difference Fourier maps (**4**) and isotropically refined, except for those attached to solvate O2 atoms in **3** and **4**, which were not included in the refinements. One of the 2-aminobutanol ligands in **S1** was found to be severely disordered, producing a very short C6−C7 bond and trigonal-planar geometry at C6. Splitting of the atoms C6, C7, C8 and O2 and refinement with a free variable, such that the combined S.O.F. summed to 1.0, resulted in two components with chemically reasonable geometries in a ca. 0.5:0.5 ratio. Both components were modelled by using appropriate SADI restraints to optimize the positions of C6X, C7X, C8X and O2X with respect to C6, C7, C8 and O2. Split atoms were also restrained to have similar anisotropic displacement parameters (ADPs). Redetermination of the structure in the chiral space group $P2_1$ resulted in a distorted geometry and large ADPs. Disorder modelling in one of the independent molecules in **2** required similar SADI restraints and equivalent anisotropic displacement parameters to be applied to the peripheral ethyl group. Two conformers in ca. 0.4:0.6 ratio resulted. Refinement of Flack parameters was useful in assigning the absolute configuration of **2**−**4**. In all these structures the contribution of the inverted enantiomer is negligible. Computer programs: SHELXS-97[24] (structure solution), SHELXL-97[25] (refinement), ORTEP[26] (molecular diagrams), Pentium II computer, scattering factors.[27] CCDC-201452 (**1**), -201455 (**2**), -201453 (**3**), -201454 (**4**) and -201456 (**S1**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The support of the FWF (Fonds zur Förderung der wissenschaftlichen Forschung) and COST is gratefully acknowledged. We are thankful to Dr. T. Weyhermüller for the discussion of X-ray data and his suggestions concerning the static disorder in S1 and to Dr. G. Giester for the collection of X-ray data.

Synthesis and Reactivity of Alkylzirconium Complexes Incorporating Asymmetrically Substituted *ansa* Ligands − X-ray Crystal Structure of [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3Me)$}$(CH_2Ph)Cl$]

Antonio Antiñolo,[a] Rafael Fernández-Galán,[a] Beatriz Gallego,[a] Antonio Otero,*[a] Sanjiv Prashar,[b] and Ana M. Rodríguez[c]

Keywords: Metallocenes / Zirconium / Insertion reactions / Isocyanides

The monoalkyl complexes [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3R)$}$(R')Cl$] [R = Me, R′ = CH_2Ph (**1**); R = Me, R′ = CH_2SiMe_3 (**2**); R = *i*Pr, R′ = CH_2Ph (**3**); R = *i*Pr, R′ = CH_2SiMe_3 (**4**); R = $SiMe_3$, R′ = CH_2Ph (**5**); R = $SiMe_3$, R′ = CH_2SiMe_3 (**6**)] have been synthesized by the reaction of the corresponding *ansa*-metallocene dichloride complex and 1 equiv of the alkyl Grignard reagent. Dialkyl complexes with large alkyl groups only formed for the zirconocene complex containing the *ansa* ligand $Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_4)$ and with the benzyl substituent giving [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_4)$}$(CH_2Ph)_2$] (**7**). When the alkyl substituent is CH_2SiMe_3 only the monoalkyl derivative, [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_4)$}$(CH_2SiMe_3)Cl$] (**8**), was formed. The insertion reaction of the isocyanide reagent $CNC_6H_3Me_2$-2,6 into the zirconium–carbon σ-bond of complexes **1**–**8** gave the corresponding η^2-iminoacyl compound [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3R)$}{η^2-R′C=$NC_6H_3Me_2$-2,6}Cl] [R = Me, R′ = CH_2Ph (**9**); R = Me, R′ = CH_2SiMe_3 (**10**); R = *i*Pr, R′ = CH_2Ph (**11**); R = *i*Pr, R′ = CH_2SiMe_3 (**12**); R = $SiMe_3$, R′ = CH_2Ph (**13**); R = $SiMe_3$, R′ = CH_2SiMe_3 (**14**); R = H, R′ = CH_2SiMe_3 (**16**)] and [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_4)$}{η^2-$PhCH_2C$=$NC_6H_3Me_2$-2,6}(CH_2Ph)] (**15**). The molecular structure of **1** has been determined by single-crystal X-ray diffraction studies.

Introduction

Zirconocene complexes are of considerable interest due to their synthetic and catalytic applications.[1] The relationship between the properties of different zirconocene catalysts and their molecular structures has been the subject of in-depth studies. The main emphasis of these studies has centred on the steric effects of various ring substituents and bridging units on the properties of the catalysts and their polymer products.[2] However, considerably less work has been carried out into the electronic effects that different ligands exert on the relative electron densities at the zirconium centre,[3] even though they will influence the reactivity of the catalysts.[4]

Although modifications of cyclopentadienyl ligands simultaneously change both the steric and electronic effects, a rational design of new olefin polymerization catalysts requires an approach in which the electron density at the metal atom and the shape of a coordination site can be predicted.[5] Recent studies have demonstrated that the incorporation of an *ansa* bridge may have a profound influence on the chemistry of metallocene systems.[6] The electrochemical properties of group-4 *ansa*-metallocene complexes have previously been reported[7] and indicate that a positive shift of E° occurs versus their non-*ansa* analogues. For example, the complex [Zr{$Me_2Si(\eta^5$-$C_5H_4)_2$}Cl_2] is reduced at a lesser negative potential than [$Zr(\eta^5$-$C_5H_5)_2Cl_2$] (by 0.1 V).[7a] Therefore it is well established that the electron density at the metal atom is modified by the alkyl group substituents of the cyclopentadienyl ligand. In methyl-substituted zirconocene dihalide complexes [$Zr(\eta^5$-$C_5H_{5-n}Me_n)_2Cl_2$] (n = 0−5) such trends were observed in shifts of electrochemical reduction potentials.[8] We have observed the same effect in our recently presented study on the electrochemistry of niobium(IV) dichloride complexes which contain the same *ansa* ligands as those discussed presently in this paper.[9]

Alkylzirconocene cations are currently of interest due to their role as single-site Ziegler−Natta olefin polymerization catalysis.[10] Common precursors to these cationic catalysts include dimethyl- and dibenzylzirconocenes which are stable species.[10,11]

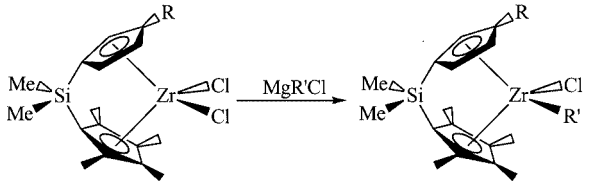
We recently developed a general synthesis of some $SiMe_2$-bridged asymmetric *ansa*-zirconocene complexes[12] and this series of highly active C_1-symmetric catalysts polymerize propylene with a high level of stereospecificity.[12b] Our research in this area is now focused on the elucidation of the mechanism of olefin polymerization as well as on the use of new types of metallocene complexes in stereoselective catalysis.[13]

In this paper we report our studies on the synthesis, characterization, and reactivity of new benzyl- and [(trimethylsilyl)methyl]zirconium derivatives containing asymmetric *ansa* ligands. Special attention is paid to the steric factors that govern the alkylation reactions due to the implication that this may have on the stereoselective mechanism in α-olefin polymerization.

Results and Discussion

The synthesis of the monoalkyl complexes, [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3R)$}(R′)Cl] [R = Me, R′ = CH_2Ph (**1**); R = Me, R′ = CH_2SiMe_3 (**2**); R = *i*Pr, R′ = CH_2Ph (**3**); R = *i*Pr, R′ = CH_2SiMe_3 (**4**); R = $SiMe_3$, R′ = CH_2Ph (**5**); R = $SiMe_3$, R′ = CH_2SiMe_3 (**6**)], was carried out by the reaction of 1 equiv. of the alkyl Grignard reagent with the corresponding *ansa*-metallocene dichloride derivative (Scheme 1).



R = Me, R' = CH_2Ph (**1**);
R = Me, R' = CH_2SiMe_3 (**2**);
R = *i*Pr, R' = CH_2Ph (**3**);
R = *i*Pr, R' = CH_2SiMe_3 (**4**);
R = $SiMe_3$, R' = CH_2Ph (**5**);
R = $SiMe_3$, R' = CH_2SiMe_3 (**6**)

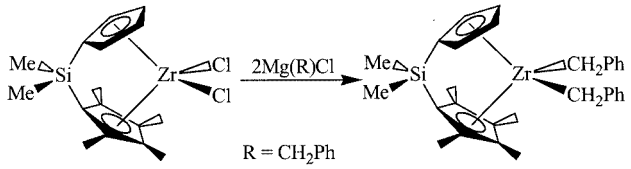
Scheme 1

The planar chirality exhibited by the *ansa*-zirconocene dichloride complexes, [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3R)$}Cl_2] (R = Me, *i*Pr, $SiMe_3$),[12] means that the two chloride positions are not equivalent. Thus, in the monoalkyl substitution reaction there exists the possibility of the formation of two stereoisomers. In all cases ^{1}H NMR spectroscopy revealed that only one of these isomers was present. In addition signals were observed for the nonequivalent methyl groups of the permethylated cyclopentadienyl moiety (4 singlets), the methyl groups of the $SiMe_2$ bridge (2 singlets), and the three protons of the monosubstituted cyclopentadienyl fragment (3 multiplets) (see Exp. Sect.). The methylene protons of the alkyl group (CH_2SiMe_3 or CH_2Ph) are diastereotopic due to the chiral nature of the metal centre and thus two doublets were observed in the ^{1}H NMR spectra of **1**−**6**. The signals corresponding to the differing alkyl groups (cyclopentadienyl- and metal-substituted) were also observed.

The corresponding dialkyl complexes were not obtained even when an excess of the alkylating reagent was used. This fact may be due to the bulky nature of the metal-bonded alkyl substituent or the presence of the β-alkyl substituent of the monosubstituted cyclopentadienyl moiety or indeed attributed to a combination of the two factors.

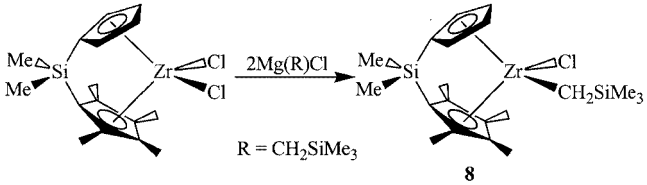
In the previously reported dimethyl complexes [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3R)$}Me_2] (R = H, Me, *i*Pr, $SiMe_3$), dialkyl substitution was shown to readily occur.[12b] The obvious reason for this reactivity can be attributed to the small size of the methyl group which allows the easy entry to the metal centre of two alkyl ligands which in addition also seem to be unaffected by the absence or presence of the β-cyclopentadienyl substituent.

For the *ansa*-zirconocene dichloride complex [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_4)$}Cl_2] (i.e. no β-substituent present) the alkylation reaction with the benzyl group gave the disubstituted derivative, [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_4)$}$(CH_2Ph)_2$] (**7**) (Scheme 2). This indicates that in the case of benzylation that the conditioning factor leading to mono- or disubstitution corresponds to the nature of β-substitution in the *ansa*-cyclopentadienyl ligand.



Scheme 2

When the same reaction was carried out but using $Mg(CH_2SiMe_3)Cl$ as the alkylating agent only the monoalkyl derivative, [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_4)$}(CH_2SiMe_3)Cl] (**8**), was isolated (Scheme 3). Therefore we can infer that for the bulkier CH_2SiMe_3 ligand, its voluminous nature (and not the substituent present in the cyclopentadienyl moiety) is the primary factor in the steric demands imposed on the final product.



Scheme 3

The syntheses of bis(CH_2SiMe_3) derivatives of non-*ansa*-zirconocene complexes, [Zr(η^5-$C_5H_4R)_2(CH_2SiMe_3)_2$] (R = H, Me, Et, *i*Pr, *t*Bu), have been reported.[14] However, the attempted preparation of the hafnium analogue with R = *t*Bu proved unsuccessful and gave only the monosubstituted derivative [Hf(η^5-C_5H_4tBu)$_2(CH_2SiMe_3)$Cl].[14a] In addition, when the size of the alkyl ligand was increased to $CH(SiMe_3)_2$, only the synthesis of the monoalkyl deriva-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tives, $[Zr(\eta^5\text{-}C_5H_4R)_2\{CH(SiMe_3)_2\}Cl]$ (R = H, Me, Et, *i*Pr, *t*Bu, $SiMe_3$), was possible.[15] It seems obvious therefore that steric constraints and not electronic effects are responsible for the substitution reaction behaviour. In the *ansa* complexes where there is no free rotation of the C_5 rings, their substituents are located in fixed positions and thus those located in the β-positions will always influence sterically the reactions at the metal centre. In addition, one can imagine that the flexibility of the cyclopentadienyl rings in non-*ansa* derivatives makes them less sensitive to steric factors than their more rigid *ansa*-metallocene analogues and this may explain why we only obtained the monoalkyl compound $[Zr\{Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_4)\}(CH_2SiMe_3)Cl]$ (**8**) and that dialkyl derivatives $[Zr(\eta^5\text{-}C_5H_4R)_2(CH_2SiMe_3)_2]$ (R = H, Me, Et, *i*Pr, *t*Bu)[15] could be readily formed for the non-*ansa* analogues.

For **7** and **8** ^{1}H NMR spectroscopy confirms the di- and monoalkyl substitution, respectively. The difference in symmetry of **7** (bis, C_s) and **8** (mono, C_1) is reflected in the ^{1}H NMR spectra. For the C_s symmetry in **7** only two signals were observed for the four protons of the unsubstituted cyclopentadienyl ring, two signals for the four methyl groups of the tetramethylcyclopentadienyl ring, one singlet for the two methyl groups of the *ansa*-$SiMe_2$ bridge, and one singlet for the methylene protons corresponding to the two benzyl ligands. For the C_1 symmetry in **8** four signals were observed for the four protons of the unsubstituted cyclopentadienyl ring, four signals for the four methyl groups of the tetramethylcyclopentadienyl ring, two singlets for the two methyl groups of the *ansa*-$SiMe_2$ bridge and two multiplets for the diastereoscopic methylene protons corresponding to the CH_2SiMe_3 ligand.

The molecular structure of **1** was established by single-crystal X-ray diffraction studies. The molecular structure and atomic numbering scheme are shown in Figure 1. Selected bond lengths and angles for **1** are given in Table 1.

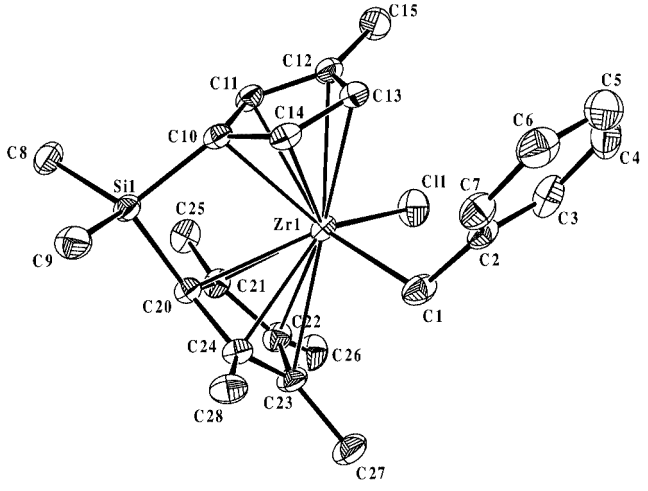


Figure 1. Molecular structure and atom-labeling scheme for $[Zr\{Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_3Me)\}(CH_2Ph)Cl]$ (**1**) with thermal ellipsoids at 30% probability

The structure of **1** shows the typical bent metallocene conformation observed in zirconocene dichloride complexes. The *ansa* ligand chelates the zirconium atom and both C_5 rings are bound to the metal atom in an η^5-mode. The environment of the zirconium atom is completed by a chlorine atom and the α-carbon atom of the benzyl group. The structure also reveals that the methyl substituent of the monosubstituted C_5 ring is orientated away from the benzyl group in a manner similar to that recently reported for imido *ansa*-niobocene complexes.[12a] The structural parameters of **1** are directly similar to those of its parent zirconocene dichloride complex $[Zr\{Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_3Me)\}Cl_2]$.[12a]

The migratory insertion of alkyl groups towards isocyanide ligands allows the introduction of iminoacyl groups which are present in different coordination modes. In fact, for high-valent oxophilic early transition metals, the iminoacyl group typically adopts an η^2-coordination mode through both the nitrogen and carbon atoms.[16] Similarly, an η^2-coordination mode is proposed for the iminoacyl ligand in **9**−**16** on the basis of IR and ^{13}C NMR spectroscopy which show the characteristic stretching vibration $\nu(C{=}N)$ at ca. 1600 cm^{-1} and iminoacyl quaternary carbon atom signal at $\delta \approx 250$ ppm, respectively. The ^1H NMR spectra of **9**−**16** in addition to the expected signals for the *ansa*-metallocene protons, gave signals corresponding to the iminoacyl alkyl group (see Exp. Sect.).

The iminoacyl group can position itself in two distinct conformations, the "proximal" or "N-outside" and the "distal" or "N-inside" configurations (see Figure 2). ^1H and ^{13}C NMR spectroscopic data indicate the presence of only one of the two possible conformations. Although it has been demonstrated that the N-outside isomer is the resulting initial kinetic iminoacyl product of the insertion reaction, most group-4 metal derivatives show the structure of the N-inside isomer which results from thermodynamic control.[17] For **9**−**16** the isolated product was observed not to evolve over time and therefore we tentatively propose that they are the products resulting from thermodynamic control and adopt the N-inside conformation.

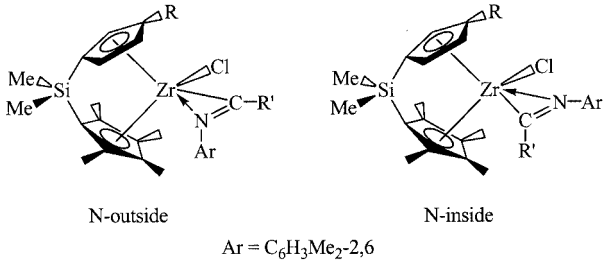

Figure 2. Two possible conformations for the (iminoacyl)metal complexes **9**−**16**

A second insertion was not observed even when stoichiometries other than 1:1 were tested.

Conclusions

In this paper we report our studies of the steric factors involved in the synthesis of alkylzirconocene complexes containing asymmetric *ansa* ligands. The preparation and characterization of mono- and dialkyl derivatives is described. The structural characterization of the monoalkyl complexes show the disposition of the β-alkyl substituent of the monosubstituted cyclopentadienyl moiety is such to orientate it away from the metal-bonded alkyl ligand. Insertion reactions with a bulky isocyanide, to give η^2-iminoacyl complexes, are also described.

Experimental Section

General Remarks: All reactions were performed using standard Schlenk tube techniques under dry nitrogen. Solvents were distilled from appropriate drying agents and degassed before use. Compounds [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3R)$}Cl_2] (R = H, Me, *i*Pr, $SiMe_3$) were prepared as described earlier.[12a] $Mg(CH_2Ph)Cl$, $Mg(CH_2SiMe_3)Cl$, and $CNC_6H_3Me_2$-2,6 were purchased from Aldrich and used directly. IR spectra were recorded with a Perkin−Elmer PE 883 IR spectrophotometer. ^1H and ^{13}C spectra were recorded with a Varian FT-300 spectrometer and referenced to the residual deuterated solvent. Microanalyses were carried out with a Perkin−Elmer 2400 microanalyzer.

Preparation of [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3Me)$}$(CH_2Ph)Cl$] (1): A 2 M solution of $Mg(CH_2Ph)Cl$ in THF (0.60 mL, 1.19 mmol) was added at −78 °C to a stirred solution of [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3Me)$}Cl_2] (0.50 g, 1.19 mmol) in THF (50 mL). The solution was allowed to warm to room temperature and stirred for 6 h. The solvent was removed in vacuo and the remaining solid extracted in hexane. A orange crystalline solid was obtained by concentrating and cooling (−30 °C) the solution (0.45 g, 79%). ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.19 and 0.28 (2 s, each 3 H, $SiMe_2$), 1.52, 1.58, 1.66, and 1.95 (4 s, each 3 H, C_5Me_4), 2.07 (s, 3 H, C_5H_3Me), 1.70 and 1.86 (2 d, $^2J_{H,H}$ = 18.9 Hz, each 1 H, CH_2Ph), 4.91, 5.06, and 5.47 (3 m, each 1 H, C_5H_3), 6.75−7.25 (m, 5 H, CH_2Ph) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = −0.5, −0.6 ($SiMe_2$), 11.2, 12.3, 14.6, 14.7 (C_5Me_4), 15.3 (C_5H_3Me), 38.2 (CH_2Ph), 102.1, 112.1, 113.9, 121.4, 134.9 (C_5H_3), 93.7, 121.9, 126.2, 131.1, 131.5 (C_5Me_4), 124.0, 126.9, 127.0, 128.5, 128.7, 153.6 (CH_2Ph) ppm. $C_{24}H_{31}ClSiZr$ (474.3): calcd. C 60.78, H 6.59; found C 60.59, H 6.54.

Preparation of [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3Me)$}$(CH_2SiMe_3)Cl$] (2): A 1 M solution of $Mg(CH_2SiMe_3)Cl$ in Et_2O (0.96 mL, 0.96 mmol) was added at −78 °C to a stirred solution of [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3Me)$}Cl_2] (0.40 g, 0.96 mmol) in THF (50 mL). The solution was allowed to warm to room temperature and stirred for 16 h. The resulting yellow solution was stirred under reflux for 2 h. The solvent was removed in vacuo and hexane added to the resulting solid. The mixture was filtered and the filtrate concentrated and cooled to −30 °C. The yellow solid that precipitated from the solution was isolated by filtration (0.37 g, 81%). ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.23 (s, 9 H, CH_2SiMe_3), 0.29 and 0.34 (2 s, each 3 H, $SiMe_2$), 1.48, 1.65, 1.92, and 2.00 (4 s, each 3 H, C_5Me_4), 2.30 (s, 3 H, C_5H_3Me), 1.77 and 1.91 (2 d, $^2J_{H,H}$ = 21.6 Hz, each 1 H, CH_2SiMe_3), 5.02, 5.09, and 6.60 (3 m, each 1 H, C_5H_3) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = −0.4, −0.7 ($SiMe_2$), 2.9 (CH_2SiMe_3), 12.2, 12.3, 14.5, 14.6 (C_5Me_4), 15.5 (C_5H_3Me), 42.1 (CH_2SiMe_3), 103.4, 111.4, 112.5, 122.8, 134.6 (C_5H_3), 93.7, 122.2, 122.5, 130.1, 131.6 (C_5Me_4) ppm. $C_{21}H_{35}ClSi_2Zr$ (470.4): calcd. C 53.62, H 7.50; found C 53.36, H 7.43.

Preparation of [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-C_5H_3*i*Pr)$}$(CH_2Ph)Cl$] (3): The synthesis of **3** was carried out in an identical manner to that of **1**: 2 M solution of $Mg(CH_2Ph)Cl$ in THF (0.38 mL, 0.76 mmol) and [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-C_5H_3*i*Pr)$}$Cl_2$] (0.34 g, 0.76 mmol). Yield 0.26 g, 69%. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.32 and 0.34 (2 s, each 3 H, $SiMe_2$), 1.03 and 1.07 (2 d, $^3J_{H,H}$ = 7.1 Hz, each 3 H, $HCMe_2$), 1.61, 1.67, 1.74, and 2.00 (4 s, each 3 H, C_5Me_4), 1.72 and 1.84 (2 d, $^2J_{H,H}$ = 17.2 Hz, each 1 H, CH_2Ph) 3.13 (sept, 1 H, $HCMe_2$), 5.05, 5.32, and 5.65 (3 m, each 1 H, C_5H_3), 6.88−7.33 (m, 5 H, CH_2Ph) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = −0.8, −0.3 ($SiMe_2$), 11.2, 12.4, 14.4, 14.8

Table 2. Crystal data and structure refinement for **1**

Empirical formula	$C_{24}H_{31}ClSiZr$
Formula mass	474.25
Temperature [K]	250(2)
Wavelength [Å]	0.71073
Crystal system, space group	triclinic, $P\bar{1}$
a [Å]	8.853(8)
b [Å]	11.134(3)
c [Å]	11.998(2)
α [°]	102.55(2)
β [°]	100.09(3)
γ [°]	90.23(4)
Volume [Å^3]	1135(1)
Z, calculated density [g/cm^3]	1, 1.387
Absorption coefficient [cm^{-1}]	6.61
F(000)	492
Crystal size [mm]	0.3 × 0.2 × 0.2
Limiting indices	$-11 \le h \le 11$ $-14 \le k \le 14$ $0 \le l \le 12$
Reflections collected/unique	5313/5057 [*R*(int) = 0.0366]
Data/restraints/parameters	5057/0/248
Goodness-of-fit on F^2	1.058
Final *R* indices [$I > 2\sigma(I)$]	*R*1 = 0.0338, *wR*2 = 0.0879
R indices (all data)	*R*1 = 0.0468, *wR*2 = 0.0975
Largest diff. peak and hole [e·Å^{-3}]	0.444 and −0.798

X-ray Crystal-Structure Determination of [Zr{$Me_2Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_3Me)$}$(CH_2Ph)Cl$] (1): Intensity data were collected with a NONIUS-MACH3 diffractometer equipped with a graphite monochromator and Mo-K_α radiation source (λ = 0.71073 Å) using an $\omega/2\theta$-scan technique. The final unit cell parameters were determined from 25 well-centered reflections and refined by least-squares methods. Data were corrected for Lorentz and polarization effects but not for absorption. The structure was solved by direct methods using the SHELXS computer program[18] and refined on F^2 by full-matrix least squares (SHELXL-97).[19] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in calculated positions and were refined with an overall isotropic temperature factor using a riding model. Weights were optimized in the final cycles. Crystallographic data are given in Table 2. CCDC-205931 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

New mono-dithiolene molybdenum(IV) complexes of *cis*-1,2-dicyano-1,2-ethylenedithiolato [$(mnt)^{2-}$] have been synthesized as models for molybdenum enzymes, with 4,4′-di-*tert*-butyl-2,2′-bipyridine (Bu_2bpy) and, *N*,*N*′-tetraethylethylenediamine (Et_4en) as ancillary ligands, and characterized by IR, UV/Vis, elemental analysis, ESI-mass and electrochemical techniques. The temperature-dependent ^1H NMR spectra, recorded in CD_3CN solution, indicated that [MoO(mnt)(Bu_2bpy)] (**1**) has a rigid structure but [MoO(mnt)(Et_4en)] (**2**) showed dynamic conformational inversion processes involving the chelating ethylenediamine unit. The complexes exhibited different reactivities toward molecular oxygen: **1** gave a single oxo-bridged dimolybdenum dimer complex [$Mo_2O_3(mnt)_2(Bu_2bpy)_2$] (**3**), while **2** did not react with O_2 and kept its mononuclear structure. Both complexes have almost the same redox potential for $Mo^{IV/V}$, and so the steric bulkiness and conformational dynamics were thought to cause this marked contrast. The obtained dimolybdenum complex **3** was also structurally characterized and investigated, and found to be a new dimolybdenum complex with one dithiolene per molybdenum. The crystal structure of the starting complex **4** was also reported. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Molybdenum enzymes are widely distributed in nature and participate in catalytic cycles in biological reactions of the earth's carbon, nitrogen, and sulfur.[1] Crystallographic and X-ray absorption spectroscopic studies have revealed that most of these enzymes have active sites containing mononuclear molybdenum(IV) or -(VI) complexes coordinated by pterin-dithiolene cofactor ligands:[2] Formate dehydrogenase and dimethyl sulfoxide reductase have two dithiolene ligands, while sulfite oxidase, xanthin oxidase and nitrate reductase have one dithiolene per molybdenum center. Holm and co-workers and Ueyama and co-workers have presented mono- and des-oxo molybdenum(IV), and di- and mono-oxo molybdenum(VI) complexes with bis-dithiolene and -dithiolate ligands, which can be regarded as model complexes of the former enzymes.[3] Although other molybdenum complexes with two dithiolene ligands have been characterized,[4] only a few molybdenum complexes that contain one dithiolene ligand. Nicholas et al. isolated the mono-oxo complex of [$Mo^{IV}O(mnt)(Ph_2PCH_2CH_2PPh_2)$]·$(CH_3)_2CO$ (mnt = *cis*-1,2-dicyano-1,2-ethylenedithiolate),[5] the first example of a structurally characterized molybdenum(IV) complex with mono-dithiolene ligands; however, its oxygen transfer properties were not elucidated. Enemark et al. reported several mono-dithiolene mono-oxo molybdenum complexes, [$Mo^{V}O(L)(3,5\text{-}Me_2Tp)$] (L = $C_6H_4S_2$, $C_7H_6S_2$, $C_2H_2S_2$, Me_2Tp = hydrotris(3,5-dimethylpyrazol-2-yl-borato),[6] in which the molybdenum centers were in a +5 oxidation state and their hexacoordinate structures provided no open site for substrate binding. More recently, Holm et al. have presented a series of mono-dithiolene molybdenum(V), -(VI) complexes, mono-oxo derivatives $[MoOCl_2(L)]^-$, $[MoO(2\text{-}Ads)_2(L)]^-$ [L: dithiolene = $S_2C_2Me_2$ (1,2-dimethyl-1,2-ethylenedithiolate), bdt (1,2-benzenedithiolate)], $[MoO(SC_6H_2\text{-}2,4,6\text{-}i Pr_3)_2(bdt)]^-$, $[MoOCl(SC_6H_2\text{-}2,4,6\text{-}i Pr_3)_2(bdt)]^-$, and di-oxo derivatives $[MoO_2(L1)(bdt)]^-$ (L1 = $OSiPh_3$, $SC_6H_2\text{-}2,4,6\text{-}i Pr_3$), as structural analogues for active sites of the sulfite oxidase enzyme family.[7] The mono-oxo molybdenum centers of these complexes also have an oxidation number of +5, as found in a resting form of native enzymes.

Here, we describe the synthesis and characterization of mono-dithiolene molybdenum(IV) complexes as new synthetic models for the active sites of sulfite oxidase, xanthin oxidase, and nitrate reductase. In addition to the mnt ligand, the ancillary ligands 4,4′-di-*tert*-butyl-2,2′-bipyridine (Bu_2bpy) provide σ-/π-bonding, and *N*,*N*′-tetraethylethylenediamine (Et_4en) give σ-donation character. Because most substrates in molybdenum enzyme reactions are neutral or negatively charged, the use of neutral Bu_2bpy and Et_4en

ligands offers different reactivities from those of previously reported model complexes having anionic ligands. Therefore, the present study offers new molybdenum models and also new insights into the reactivity of molybdenum enzymes.

Results and Discussion

Synthesis of Complexes

[MoO(mnt)(Bu_2bpy)] (**1**) was prepared by reacting [MoO_2Cl_2(Bu_2bpy)] (**4**) with Na_2mnt in CH_3OH. The IR spectrum of complex **1** shows strong absorptions at 2195 and 939 cm^{-1} assignable to ν(CN) of mnt and ν(Mo=O). Its ESI-mass signals centered at m/z = 561 in the presence of small amount of K^+ are consistent with the characteristic isotopic pattern of {[M] + K}$^+$. [MoO(mnt)(Et_4en)] (**2**) was obtained from the in situ reaction of MoO_2Cl_2 with Et_4en, and Na_2mnt in CH_3OH. The structure was similarly confirmed: IR: $\tilde{\nu}$ = 2194 and 906 cm^{-1}, ESI-mass m/z = 465 [M + K]$^+$. Elemental analysis data indicated that each complex had one oxo, one dithiolene, and one ancillary ligand (Figure 1). With Mo^{VI}, Na_2mnt, and ligands (1:1:1) the two complexes were obtained in 36 and 38% yield, respectively, suggesting that molybdenum(IV) formation is based on the reduction of molybdenum(VI) by the dithiolate of mnt^{2-}. In fact, the two-electron oxidized form of mnt^{2-}, $[(mnt)_2]^{2-}$ {$[C_2(CN)_2SS-SSC_2(CN)_2]^{2-}$}, was isolated from the filtrate (Figure S1 in the Supporting Information; see also the footnote on the first page of this article). Thus, we changed the ratio Mo^{VI}:Na_2mnt:ligands to 1:2:1, and improved the yield of [**1**] (56%). However, that of [**2**] was not improved under similar conditions and only a blue−green solution that was identical with $[Mo(mnt)_3]^{2-}$ was obtained.

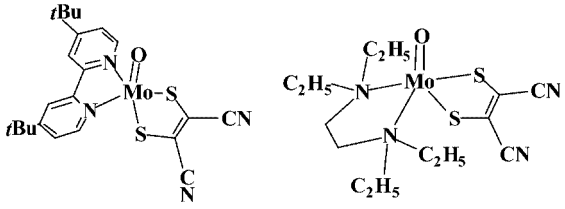

Figure 1. Structures of complexes **1** and **2**

Solution Structures of [MoO(Bu_2bpy)(mnt)] (1) and [MoO(Et_4en)(mnt)] (2): ^{1}H NMR Studies

Sharp ^{1}H NMR signals of [MoO(Bu_2bpy)(mnt)] (**1**) appeared in the region characteristic of diamagnetic molybdenum(IV)-d^2 complexes in CD_3CN: The signals for bipyridyl and butyl protons were observed at δ = 8.61, 8.44 and 7.68, and 1.42 ppm, respectively. Similarly, for [MoO(Et_4en)(mnt)] (**2**) the ^{1}H NMR spectrum supported a diamagnetic molybdenum(IV) complex structure, and showed temperature-dependent ^{1}H NMR behavior in CD_3CN (Figure 2).

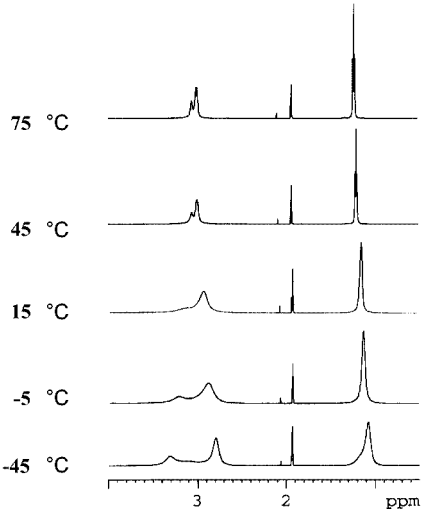

Figure 2. ^{1}H NMR spectra of [MoO(mnt)(Et_4en)] (**2**) in CD_3CN at various temperatures

At 75 °C, three signals appeared that were classified into two groups: Et and the C_2H_4 unit of ethylenediamine, based on their integration ratio. Methyl and methylene protons of the Et groups appeared at δ = 1.22 ppm (triplet) and δ = 3.00 ppm (broad doublet), while the C_2H_4 protons of ethylenediamine appeared as a broad singlet signal at δ = 3.05 ppm. These observations indicate that the four Et groups and two methylenes of C_2H_4 are equivalent within the ^{1}H NMR time scale. All the signals broadened as the temperature decreased from 75 to 15 °C. At lower temperatures, the broad signals for $CH_3-CH_2-$and for $-CH_2-CH_2-$ protons appeared at δ = 1.08, 2.79, and δ = 3.20 ppm, respectively, though the signals for methyl and ethylene protons were still observed as broad signals. Such temperature-dependent spectral changes could be as due to a conformational inversion between pseudo-gauche and -steric strain conformations of the chelating ethylenediamine unit (Scheme 1), since each chemical shift (ppm) also moved. Similar conformational inversion has been reported in dimolybdenum and ditungsten complexes with ethylenediamine, [$M_2(O)_2(\mu\text{-}O)_2(\mu\text{-}L)$] (M = Mo, W; L = edta (ethylenediaminetetraacetato), tpen (*N,N,N′,N′*-tetrakis(2-pyridylmethyl)ethylenediamine)).[8]

Reactivity of [MoO(Bu$_2$bpy)(mnt)] (1) and [MoO(Et$_4$en)(mnt)] (2)

Complex **1** shows interesting reactivity towards molecular oxygen in acetonitrile and acetone, giving the oxo-bridged dimolybdenum(V) complex $[Mo_2O_3(Bu_2bpy)_2(mnt)_2]$ (**3**), the structure of which was confirmed by X-ray crystallography (Figure 5). Although the molecular oxygen is not a substrate in native molybdenum enzymes, it is a good oxygen donor. The reaction showed a color change, from yellow to deep blue-gray (Figure 3, a). The peaks centered at 492 and 590 nm intensified and the final spectrum exhibited a similar shape to that of mono-oxo bridged $[Mo_2O_3(Bu_2bpy)_2(mnt)_2]$ (**3**) in CH_3CN, which was isolated independently as a crystalline powder. The ESI-MS spectrum recorded with the reaction solution is consistent with m/z = 1060 and the isotope pattern of dinuclear $[Mo_2O_3(Bu_2bpy)_2(mnt)_2]$ (**3**). Since comproportionation, $Mo^{IV} + Mo^{VI} \rightarrow 2\ Mo^{V}$, is common in molybdenum chemistry,[9] the air oxidation process of **1** leading to **3** can be noted as Equation (1), in which the di-oxo molybdenum(VI) complex is a transient species.

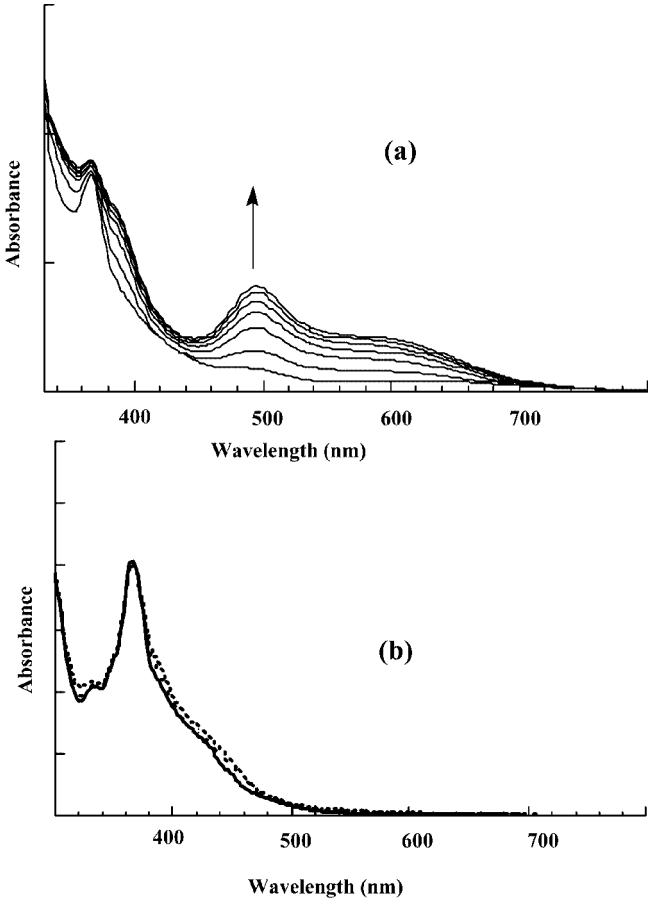

Figure 3. Spectral changes (every 5 h) of complexes **1** (a, 0.25 mM) and **2** (b, 0.25 mM) in acetonitrile (with exposure to air)

$$[MoO(Bubpy)(mnt)] + O_2 \rightarrow [MoO_2(Bubpy)(mnt)],$$
$$[MoO(Bubpy)(mnt)] + [MoO_2(Bubpy)(mnt)] \rightarrow [Mo_2O_3(Bu_2bpy)_2(mnt)_2] \quad (1)$$

In contrast, complex **2** did not react with molecular oxygen in CH_3CN (Figure 3, b). Although the redox potentials assigned to $Mo^{IV/V}$ for **1** and **2** were almost the same, 0.20 and 0.22 V vs. Ag/Ag^+, respectively, both complexes showed largely different reactivities toward molecular oxygen. The rigid molybdenum(IV)-porphyrin complex $[Mo^{IV}O(oep)]$ (oep = 2,3,7,8,12,13,17,18-octaethylporphyrinato) forms the dimerized $[\{Mo^{V}O(oep)\}_2(\mu\text{-}O)]$ via intermediate $[Mo^{VI}O(O_2)(oep)]$ upon treatment with O_2.[10] ^1H NMR studies indicate that complex **2** has a flexible ethylenediamine ligand, although complex **1** has a rigid bipyridyl ligand. Therefore, for the dimerization, an outer-sphere oxidation process is excluded but an inner-sphere oxidation process by O_2 may occur. Both the steric bulkiness of the four ethyl groups in **2**, and its dynamic behavior, prevent interaction of the molybdenum center in **2** with O_2 and so its reactivity differs from that of **1**. Xanthin oxidase, which has one dithiolane, prevents dimerization and retains a mononuclear molybdenum structure when exposed to molecular oxygen.[11] Thus, judging from the above described results, **2** rather than **1** may serve as an effective xanthine oxidase model. We have further demonstrated that the reactivity of the molybdenum-mono-dithiolene complexes, [MoO(mnt)], could be changed by varying the ancillary ligands.

Some of molybdenum(IV) mono-oxo bis(dithiolene) complexes react with trimethylamine N-oxide (Me_3NO) to give the corresponding molybdenum(VI) di-oxo complexes of $[MoO_2(dithiolene)_2]^{2-}$.[3f] When complexes **1** and **2** were treated with Me_3NO, electronic spectral changes were observed, but the corresponding molybdenum(VI) di-oxo complexes could not be isolated and their reaction could not be followed precisely (Figure 4).

Mo1−S2−C20	105.7(2)		

Complex **3** has a $[Mo_2O_3]$ neutral core, with each molybdenum center in a distorted octahedral geometry provided by two nitrogens of one Bu_2bpy, two sulfurs of one mnt, a terminal oxo group, and the bridging oxo group which occupies a crystallographic inversion center. Its $[Mo_2O_3]$ core is strictly *anti* planar, in which one molybdenum has an O2N2S2 donor set. The S1 atom is *trans* to the bridging oxygen O2; S2 is *trans* to N1; and N2 is *trans* to a terminal oxygen O1. Similar structures have been reported for $[Mo_2O_3(2\text{-}SC_5H_3N)_4]$,[12] $[Mo_2O_3(2\text{-}SC_5H_3N\text{-}3\text{-}SiNe_3)_4]$ (2-$SC_5H_3N_4$ = pyridine-2-thiolato),[13] $[Mo_2O_3(N,N'$-dimethyl-N,N'-bis(2-mercaptophenyl)ethylenediamine$)_2]$,[14] and $[Mo_2O_3(N,N'$-dimethyl-N,N'-bis(2-mercaptoethyl)ethylenediamine$)_2]$.[15] In these complexes, all nitrogen donors occupied *trans* positions to the oxygen donors, while the sulfur donors were *cis* to each other. In complex **3**, a somewhat longer Mo1−N2 bond length [2.327(4) Å] than that of Mo1−N1 [2.238(4) Å] was observed due to the *trans* influence of a strong Mo-dπ and terminal O−pπ interaction. A similar trend is found for Mo−S1 [2.464(1) Å] and Mo-S2 [2.394(1) Å] bond lengths. The $Mo-O_{terminal}$ [1.680(4) Å] and $Mo-O_{bridging}$ [1.8694(4) Å] distances are in the range found in the above example $[Mo_2O_3]$ complexes. Although some dinuclear molybdenum(v) complexes with one dithiolene per molybdenum center have been reported by Holm et al., their dimers have a di-oxo bridged Mo_2O_4 core of $[Mo_2O_2(\mu\text{-}O)_2(bdt)_2]^{2-}$.[7] Moreover, mono-dithiolene molybdenum(VI) $(Et_4N)_2\{Mo^{VI}O_2(Ph_3Si\text{-}bdt)\}_2(\mu\text{-}O)]$, having a dinuclear core bridged by one oxo group, has also been reported.[16] Since complex **3** has a mono-oxo bridged dimolybdenum(V) core, it is a new kind of mono-dithiolene dimolybdenum complex.

Experimental Section

Materials: The ligands Bu_2bpy and Na_2mnt were prepared as described in the literature.[17,18] Acetonitrile was dried with calcium hydride and distilled under dinitrogen. Methanol was dried over molecular sieves and also distilled under dinitrogen. THF was distilled from sodium/benzophenone. Tetrabutylammonium hexafluorophosphate ($TBAPF_6$) was recrystallized twice from hot ethanol. All other commercially available reagents were used as purchased. The preparation of complexes **1**−**3** was carried out under dinitrogen or argon.

Preparation of Complexes

[MoO(mnt)(Bu_2bpy)] (1): Na_2mnt (47 mg, 0.26 mmol) was added to a methanolic solution (10 mL) of $[MoO_2Cl_2(Bu_2bpy)]$ (**4**, see below) (60 mg, 0.13 mmol) and the solution was stirred for 1 day. After concentration of the solution to 3 mL, a yellow−brown microcrystalline powder, deposited upon addition of H_2O (1 mL), was collected by filtration and dried in vacuo. Yield 38 mg (56%). $C_{22}H_{24}MoN_4OS_2$ (520.53): calcd. C 50.76, H 4.65, N 10.76; found C 51.05, H 4.73, N 10.58. ESI-MS (acetonitrile): m/z = 561 $[M + K]^+$. IR (KBr): $\tilde{\nu}$ = 2195 [ν(C−N)], 939 cm^{-1} [ν(Mo=O)]. UV/Vis (acetonitrile): λ (ε, mol dm^3 cm^{-1}) = 607 (110), 492 (261), 369 (4090), 335 nm (2466). ^1H NMR ([D_3]acetonitrile, 25 °C): δ = 8.61 (d, 2 H), 8.44 (s, 2 H), 7.68 (d, 2 H), and 1.42 (s, 18 H) ppm. Redox potential (acetonitrile): $Mo^{V/IV}$, 0.20 V (reversible) vs. Ag/Ag^+.

[MoO(mnt)(Et_4en)] (2): MoO_2Cl_2 (99 mg, 0.5 mmol) was added to CH_3OH (10 mL) and then N,N'-tetraethylethylenediamine (102 μL, 0.5 mmol) was injected. After 15 min stirring, Na_2mnt (93 mg, 0.5 mmol) was gradually added to the solution. A yellow−orange microcrystalline powder then precipitated from the resulting red−brown solution, and was collected by filtration and dried in vacuo. Yield 81 mg (38%). $C_{14}H_{24}MoN_4OS_2$ (424.04): calcd. C 39.62, H 5.70, N 13.20; found C 39.91, H 5.56, N 12.98. ESI-MS (acetonitrile): m/z = 465 $[M + K]^+$. IR (KBr): $\tilde{\nu}$ = 2194 [ν(C−N)], 906 cm^{-1} [ν(Mo=O)]. UV/Vis (acetonitrile): λ (ε, mol dm^3 cm^{-1}) = 512 (512), 365 (7771), 331 nm (4167). ^1H NMR ([D_3]ace-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tonitrile, 25 °C.): δ = 3.05 (br., 4 H), 3.00 (d, 8 H), and 1.22 (t, 12 H) ppm. Redox potential (acetonitrile): $Mo^{V/IV}$, 0.20 V (reversible) vs. Ag/Ag^+.

$[Mo_2O_3(mnt)_2(Bu_2bpy)_2]$ (3). Method a: Na_2mnt (93 mg, 0.5 mmol) was added to a colorless acetone solution (10 mL) containing MoO_2Cl_2 (99 mg, 0.5 mmol) and Bu_2bpy (134 mg, 0.5 mmol). The resulting orange suspension was then stirred until a clear orange solution was obtained, which on exposure to air for 1 day gave black crystals of **3**. The crystals were collected by filtration and dried in air. Yield 115 mg (44%, based on two molybdenums).

Method b: Complex **1** (30 mg, 0.058 mmol) was dissolved in CH_3CN (10 mL) under argon to give a solution that upon exposure to air changed from yellow to blue-gray. Overnight, black−purple crystals then precipitated out of the solution, and were collected by filtration and dried in air. Yield 24 mg (78%). Precipitates obtained by methods a and b have the same IR and UV/Vis spectra.

$C_{44}H_{48}Mo_2N_8O_3S_4$ (1057.04): calcd. C 49.99, H 4.58, N 10.60; found C 50.21, H 4.54, N 10.55. ESI-MS (dimethylformamide): m/z = 1060 $[M]^-$. IR (KBr): $\tilde{\nu}$ = 2205 [ν(C−N)], 947 cm^{-1} [ν(Mo=O)]. Redox potential (dimethylformamide): $Mo^VMo^V/Mo^{IV}Mo^V$, −0.93 V (reversible) and −1.64 V (E_{pc}, irreversible) vs. Ag/Ag^+. UV/Vis (acetonitrile): λ (ε, mol dm^3 cm^{-1}) = 604 (sh) (663), 498 (1390), 342 nm (1060).

$[MoO_2Cl_2(Bu_2bpy)]$ (4): Bu_2bpy (134 mg, 0.5 mmol) was added to a freshly distilled THF solution (10 mL) containing MoO_2Cl_2 (99 mg, 0.5 mmol). The resulting colorless solution was evaporated to 2 mL to give a white microcrystalline powder, which was collected by filtration and dried in air. Yield 203 mg (87%). IR (KBr): $\tilde{\nu}$ = 939, 908 cm^{-1} [ν(Mo=O)]. ^1H NMR ([D_3]acetonitrile, 25 °C): δ = 9.46 (d, 2 H), 9.00 (s, 2 H), 8.07 (d, 2 H), 1.50 (s, 18 H) ppm.

X-ray Crystallographic Study: A single crystal of $[Mo_2O_3(Bu_2bpy)_2(mnt)_2]$ (**3**) was obtained upon standing for one day from the acetone solution, and a single crystal of $[MoO_2Cl_2(Bu_2bpy)]$ (**4**) was obtained by recrystallization from acetone solution. Each crystal was attached to the top of a glass fiber. X-ray data of complex **3** and **4** were then collected with graphitec-monochromated Mo-*Kα* radiation on a Rigaku/MSC Mercury CCD diffractometer at −100 °C and on a Rigaku AFC7R diffractometer at −50 °C, respectively. The structures were solved by direct methods (SIR, 92)[19] and expanded using Fourier techniques.[20] The non-hydrogen atoms of all complexes were refined anisotropically by the full-matrix least-squares method. All calculations were performed using TEXSAN.[21] Further crystallographic data are summarized in Table 2.

Complex **4** (see Supporting Information, Figure S2 and Table S1) has a distorted octahedral arrangement about the molybdenum atom, with two oxygen atoms in *cis* positions and the two chlorine atoms in *trans* positions. The bond lengths and angles around the molybdenum center are very similar to those of $[MoO_2Cl_2(4,4'$-dimethyl-2,2′-bipyridine)][22] and $[Mo_2O_2Cl_2(1,10$-phenanthroline)];[23] the structural arrangements are also the same in these complexes and **4**. It is noteworthy that **4** crystallized in a chiral space group $P2_12_12_1$, indicating that spontaneous resolution of complex occurred. Conversely, $[MoO_2Cl_2(4,4'$-dimethyl-2,2′-bipyridine)] crystallized in an achiral space group $P2_1/n$.

[a] $R = \Sigma(F_o^2 - F_c^2)/\Sigma F_o^2$. [b] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [c] $Rw = [(\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]]^{1/2}$. [d] $Rw = [(\Sigma w(F_o - F_c)^2/\Sigma w(Fo^2)^2]]^{1/2}$.

Other Measurements: Cyclic voltammetry was performed with a Hokuto HA-501 potentiostat and a Hokuto HB-105 function generator, equipped with a Graphtec WX2400 X-Y recorder, or a Hokuto HZ-3000. The working and counter electrodes were a glassy-carbon disk and a platinum wire, respectively. Cyclic voltammograms were recorded at 50 mV·s^{-1}. The sample solutions (ca. 1.0 mM) in 0.1 M $TBAPF_6$/acetonitrile were deoxygenated with a stream of dinitrogen gas. The reference electrode was Ag/Ag^+ and the half-wave potential of Fc^+/Fc [$E_{1/2}(Fc^{+/o})$] vs. Ag/Ag^+ was 0.015 V in CH_3CN. Electronic spectra were recorded with a Shimazu 2550 or HP 5254A spectrophotometer at 20 °C. IR spectra were recorded with a Perkin−Elmer Spectrum GX infrared spectrophotometer. ^1H NMR spectra were measured with a JEOL-Lambda 300 (300 MHz) or Bruker AVANCE 600 (600 MHz) spectrometer. ESI-MS was obtained with a PE SCIEX API300.

Supporting Information Available (see the footnote on the first page of this article): ORTEP drawings $(mnt)_2^{2-}$, the oxidized form of mnt^{2-}, (Figure S1) and complex **4** (Figure S2). Selected bond lengths and angles of complex **4** (Table S1).

New 1,3,4-Oxadiazolecopper(II) Derivatives Obtained from Thiosemicarbazone Complexes

Patricia Gómez-Saiz,[a] Javier García-Tojal,*[a] Miguel A. Maestro,[b] José Mahía,[b] Francisco J. Arnaiz,[a] Luis Lezama,[c] and Teófilo Rojo[c]

Keywords: Copper / Magnetic properties / Thiosemicarbazone complexes / Oxadiazole complexes / X-ray diffraction

Pyridine-2-carbaldehyde thiosemicarbazone and pyridine-2-carbaldehyde 4*N*-methyl thiosemicarbazone ligands (HL_I and HL_Imm respectively) undergo an oxidative cyclization when treated with bromate or iodate, leading to 2-amino-5-pyridin-2-yl-1,3,4-oxadiazole and 2-methylamino-5-pyridin-2-yl-1,3,4-oxadiazole (HL_{II} and HL_{II}mm). This reaction occurs either with free ligands or when coordinated to copper(II). Some of the starting ($[\{Cu(L_I mm)(NO_3)\}_2]$ (**3**), intermediate $Cu(L_I)(IO_3)\cdot(H_2O)$ (**1**), $[\{Cu(L_I)I\}_2]$ (**2**), $[\{Cu(L_I mm)Br\}_2]$ (**4**), and final compounds $[\{Cu(HL_{II})(H_2O)_3\}_2](SO_4)_2$ (**5**), $[\{Cu(HL_{II}mm)(H_2O)_2(SO_4)\}_2]\cdot 2H_2O$ (**6**), (HL_{II}) (**7**), $[HL_{II}mm]\cdot 3H_2O$ (**8**) have been isolated and characterized by elemental analyses, IR, UV-visible, NMR, and EPR spectroscopy. The structures of **2**, **3**, **4**, **5**, **6**, and **8**, solved by X-ray diffraction methods, contain dinuclear entities with either square-pyramidal (**2**, **3**, **4**) or octahedral (**5**, **6**) copper(II) ions. Structural and spectroscopic results suggest that ligand-to-metal charge transfer occurs in these compounds. The EPR spectra at 120 K exhibit rhombic (**1**, **3**, **4**), isotropic (**2**), and axial (**5**, **6**) signals. Magnetic measurements show antiferromagnetic couplings for **2**, **4**, **5**, and **6**. The susceptibility data were fitted by the Bleaney–Bowers equation for copper(II) dimers. The obtained J/k values are –20.20, –8.85, –2.75, and –2.78 K for **2**, **4**, **5**, and **6**, respectively. However, ferromagnetic intradimeric interactions are present in **3** (J/k = +9.90 K) together with antiferromagnetic interdimer coupling ($z'J'/k$ = –1.70 K). Magneto-structural studies show the influence of the non-thiosemicarbazone coligand in the magnetic behaviour of these complexes.

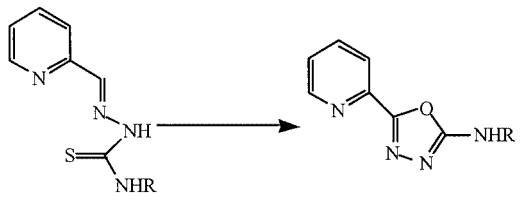
Introduction

Several copper(II) complexes of N-heterocyclic carbaldehyde thiosemicarbazones are of interest because they show a greater carcinostatic activity than the free thiosemicarbazone.[1–3] However, despite several proposals, the mechanism of their action in cells[4–13] is unclear. A deeper knowledge of their reactivity is essential to understand their interactions with biological molecules.

Among the reactions involving thiosemicarbazones, some published mechanisms of the oxidative cyclization give rise to thiadiazoles, thiadiazolines, pyrazolones, 1,2,4-triazoline-5-thiones, and other compounds.[14–16] Recently, we reported the oxidation of pyridine-2-carbaldehyde 4*N*-methyl-thiosemicarbazonatocopper(II) entities that led to the attainment of a copper(II) complex with the 2-methylamino-5-pyridin-2-yl-1,3,4-oxadiazole ligand, using potassium bromate as oxidant (see Scheme 1).[17] The singularity of this reaction lies not only in the fact that 1,3,4-oxadiazoles are obtained from a non−acylated substrate for the first time, but in the novel process of desulfurization of thiosemicarbazones that implies this oxidative cyclization. The usual methods of preparing oxadiazoles consist of the cyclization of substrates such as acyl thiosemicarbazides[18] or acyl thioureas[19,20] with a variety of oxidants.



Scheme 1

We present here the synthesis and spectroscopic studies of 8 new compounds, $[Cu(L_I)(IO_3)]\cdot(H_2O)$ (**1**), $[\{Cu(L_I)I\}_2]$ (**2**), $[\{Cu(L_I mm)(NO_3)\}_2]$ (**3**), $[\{Cu(L_I mm)Br\}_2]$ (**4**), $[\{Cu(HL_{II})(H_2O)_3\}_2](SO_4)_2$ (**5**), $[\{Cu(HL_{II}mm)(H_2O)_2$-

$(SO_4)\}_2]\cdot 2H_2O$ (**6**), (HL_{II}) (**7**), and (HL_{II}mm)$\cdot 3H_2O$ (**8**) (HL_I = pyridine-2-carbaldehyde thiosemicarbazone, HL_Imm = pyridine-2-carbaldehyde 4*N*-methylthiosemicarbazone, HL_{II} = 2-amino-5-pyridin-2-yl-1,3,4-oxadiazole and HL_{II}mm = 2-methylamino-5-pyridin-2-yl-1,3,4-oxadiazole), together with the structural characterization of six of them and the magnetic properties of **2**, **3**, **4**, **5**, and **6**. These compounds are reactants, products or intermediates in the oxidative cyclization process. A mechanism is proposed for the reaction.

Results and Discussion

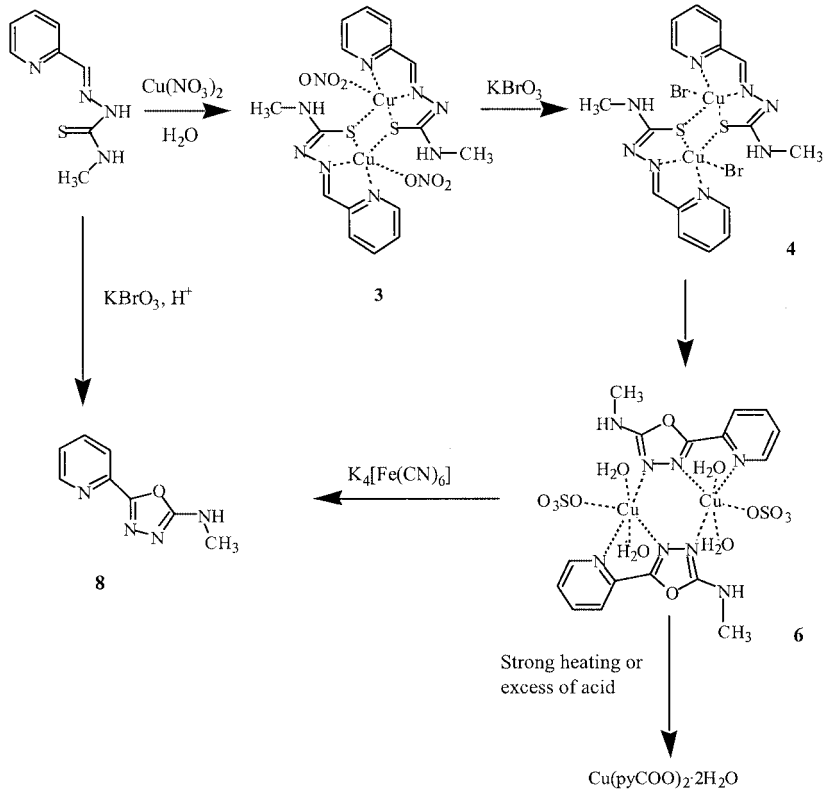
The Oxidation Process

The reactions involved in the oxidative attack of bromate on HL_Imm derivatives are summarized in Scheme 2.

The oxidative cyclization proceeds smoothly with the addition of bromate to a dark green aqueous solution of complex **3** adjusted to pH ≈ 6. After filtering off compound **4** the colour of the solution gradually becomes lighter. At the same time, the pH decreases to 3−4 and an irritant gas evolves from the reaction mixture, and single crystals of **6** are obtained after two days. The reaction is faster when small amounts of acid are added with slight heating. Excess acid and too much heat have led to brown solutions from which crystals of bis(pyridinecarboxylate)copper(II) were isolated.[17] Ligand **8** can be removed from **6** by the addition of $K_4[Fe(CN)_6]\cdot 3H_2O$ in ethanol. Furthermore, it can also be synthesized by direct oxidative cyclization of HL_Imm.

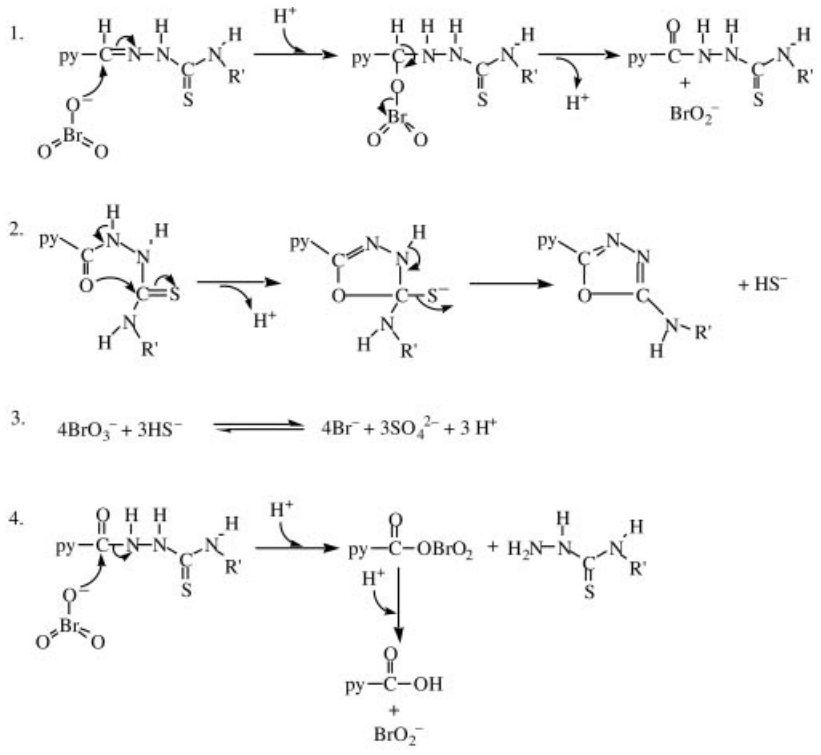
The oxidation of HL_I was developed in exactly the same way as for HL_Imm, and analogous compounds were identified. This procedure was also applied to a new ligand, HL_Idm (pyridine-2-carbaldehyde 4*N*,4′*N*-dimethylthiosemicarbazone), prepared following a published method.[21] However, no oxidation compounds could be isolated with either the thiosemicarbazone free ligand or the respective copper(II) complex as starting material, suggesting that steric effects can influence the oxidative cyclization.

The cyclization of the free ligands takes place either with bromate or iodate, requires pH ≈ 0−1 and yields similar results. For copper(II) complexes, oxidation with bromate occurs even at pH≈6, but no evidence of oxidative cyclization of thiosemicarbazone−copper(II) compounds was detected using iodate at pH≈6. This seems to accord with the reduction potentials: $E°$ (BrO_3^-/Br^-) = 1.15 V, $E°$ (IO_3^-/I^-) = 1.09 V. The reaction of a thiosemicarbazonatocopper(II) complex with bromate yields different products from those obtained with iodate. In fact, bromato thiosemicarbazonecopper(II) derivatives cannot be isolated. The use of acidic media gives rise to mixtures of compounds in both cases. Several attempts using chlorate as oxidant did not produce evidence of oxidative cyclization. This is surprising given its reduction potential [$E°$ (ClO_3^-/Cl^-) = 1.45 V at pH ≈ 0]; kinetic factors could account for this result.



Scheme 2

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3

From the experimental results we propose the two-step mechanism shown in Scheme 3 for the free ligand, and an analogous mechanism is proposed for the copper(II) complexes:

i) Formation of the Acylthiosemicarbazide

An initial nucleophilic attack of the bromate anion on the azomethinic carbon of the thiosemicarbazone ligand yields a new carbonyl group and bromite is released. The bromite can act as an oxidizing agent on other thiosemicarbazone ligands, giving rise to hypobromite ions. The successively reduced bromo derivatives from each oxidation step thus act as oxidants until the complete conversion of bromate into bromide.

Consequently, an acidic media should favor the beginning of the reaction, which is in good agreement with our experimental observations.

ii) Cyclization to 2-Amino-5-pyridin-2-yl-1,3,4-oxadiazole

In a second step, the acylthiosemicarbazide cyclizes to 2-amino-5-pyridin-2-yl-1,3,4-oxadiazole and, as a result, is desulfurized. This reorganization leads to a decrease in pH (in good agreement with experimental observations). The removal of the sulfur atom from the ligand, to give sulfate, could be due to concomitant inorganic processes such as those represented in reaction 3. Furthermore, the coupled reaction 3 shifts, to the right, reaction 2.

Further bromate attack on the acylic carbon would cleave the acylthiosemicarbazide, in competition with step ii). As a result, pyridine-2-carboxylic acid and other secondary products would be obtained (Scheme 3, reaction 4), which is in good agreement with the experimental results.

Since most published oxidation reactions leading to oxadiazoles take acylated compounds as reactants,[18−20] it seems highly probable that this intermediate is formed in a first step. Oxidative attacks similar to reaction 1 have been reported for the conversion of carbodiimide into urea using dimethyl sulfoxide as oxidant.[22,23] Furthermore, bromate derivatives oxidize primary alcohols to esters,[24] synthesize benzoxiodol-3-one starting from 2-iodobenzoic acid[25] and oxidize a keto group in the preparation of benzilic acid from benzoin.[26]

Conversely, cyclizations of open-chain compounds such as thioureas, thiosemicarbazides, semicarbazones or even thiosemicarbazones have been employed[19,27,28] to prepare ring-type molecules. These processes are an alternative to conventional organic synthesis, usually proceeding quickly and in only one step. The method we present here, starting from easily prepared thiosemicarbazonecopper(II) complexes, allows the preparation of 2-amino-1,3,4-oxadiazoles as the only product and requires, in some cases, less than an hour.

Structural Analysis

Crystal Structures of the Thiosemicarbazone Derivatives

The molecular structure of compound **2** is shown in Figure 1. Selected distances and angles are given in Table 1. The crystal contains $[Cu(L_I)I]$ entities, which stack through the sulfur atom of the thiosemicarbazone ligand to give the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

centrosymmetric [{Cu(L_I)I}$_2$] dimer. Each copper(II) ion has a distorted square-pyramidal topology ($\tau = 0.17$)[29] and is surrounded by one sulfur and two nitrogen atoms of one thiosemicarbazone ligand and the iodo ligand in the basal plane. The axial position is occupied by the sulfur atom of the symmetric [Cu(L_I)I] entity inside the dimer.

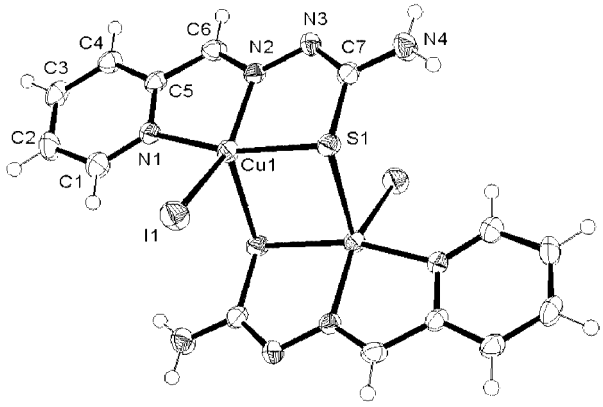


Figure 1. Molecular structure of **2** with thermal ellipsoids at 50% probability level

Table 1. Selected bond lengths [Å] and angles [°] for **2** and **4**

	2	**4**
Cu−N(1)	2.033(4)	2.034(4)

X−Cu−N(2)	152.9(1)	162.7(1)
Cu−S−Cu^i	85.80(4)	88.3(1)
S−Cu−S^i	94.20(4)	91.7(1)

[a] Symmetry transformations used to generate equivalent atoms: **2**: i = $-x+1, -y+1, -z+1$; ii = $-x+1, -y+2, -z+1$; **4**: i = $-x+1, -y+1, -z+2$; ii = $-x+1, -y, -z+2$.

The molecular structure of complex **3** has been described elsewhere[17] (see Figure 2).

Compound **4** consists of [Cu($L_I$mm)Br] entities linked through the sulfur atom of the thiosemicarbazone ligand, leading to dinuclear centrosymmetric [{Cu($L_I$mm)Br}$_2$] species. A perspective view of the dimer is shown in Figure 3, and selected bond lengths and angles are given in Table 1. Each copper(II) ion is 5-coordinate, with two nitrogens and the sulfur atom of the ligand and the bromo ligand at the basal positions, while the axial position is occupied by the sulfur atom of the symmetric thiosemicarbazonatocopper(II) entity. The calculated τ factor[29] is 0.02, which indicates that the copper(II) ions have close to the square-pyramidal topology.

Both thiosemicarbazones (HL_I and HL_Imm) can be considered as rigid and quasi-planar in these compounds. Considering the basal plane as that defined by the N(1)N(2)S donor set, the Cu and S^i atoms lie at 0.012 and 2.689 Å above it for **2**, 0.090 and 2.832 Å in complex **3**, and at 0.051 and 2.870 Å in complex **4**. The coligands [I, O(1), and Br for **2**, **3**, and **4** respectively] sit 1.158, 0.162, and 0.598 Å below the mentioned plane.

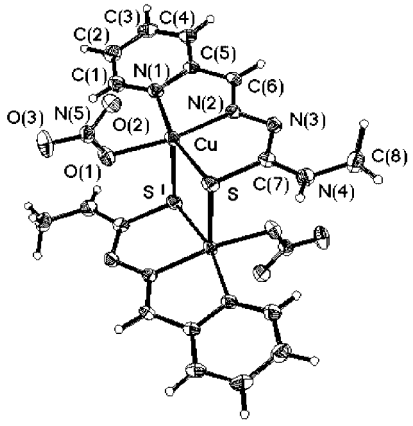

Figure 2. Molecular structure of **3** with thermal ellipsoids at 50% probability level

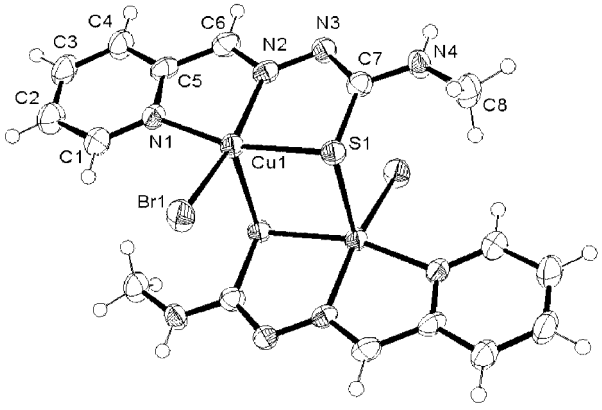

Figure 3. Molecular structure of **4** with thermal ellipsoids at 50% probability level

It is worth mentioning the presence of chains of dimers that stack along the *y* axis at distances that suggest the occurrence of π−π interactions. Thus, the minimum distances found are 3.32 Å [C(7)···C(3)^{ii}) in **2**, 3.38 Å [N(2)···C(5)^{ii}] in **3**, and 3.44 Å [N(3)···C(1)^{ii}] in complex **4**. In addition, π−π interactions occur along the *z* axis in compound **3**, with a minimum distance of 3.35 Å [C(3)···C(6)^{iv}, iv = $-x, -y+1, -z$]. The dimers are also interconnected by intermolecular hydrogen contacts (see Supporting Information, and also the footnote on the first page of this article).

Both thiosemicarbazones undergo conformational changes upon coordination. N(1) and N(2) are *anti* with respect to the C(5)−C(6) bond and atoms N(2) and S are *anti* with respect to the N(3)−C(7) linkage in the free ligands.[30,31] In both cases, they become *syn* after chelation. Furthermore, C(8) and S are *syn* in the free ligand as in **4**; but they are *anti* in complex **3**. This could be due to the steric hindrance induced by the size of the nitrato ligand.

Table 2. Selected structural differences between copper(II) complexes containing neutral and anionic HL_I or HL_Imm (Å, °) for **2**, **3**, and **4**

Compound	N(2)−N(3)−C(7)	S−C(7)−N(3)	S−C(7)−N(4)	Cu···N(3)	N(2)···C(7)
2	111.2(4)	124.9(4)	118.4(4)	2.99	2.23
3	111.5(2)	124.9(2)	116.8(2)	2.96	2.22
4	112.1(5)	124.6(5)	119.0(4)	2.96	2.22
HL range	116−118	121−122	121−123	2.89−2.90	2.28−2.32
L^- range	109−114	123−127	117−119	2.94−3.00	2.22−2.23

All C−C and C−N lengths are similar in the free and coordinated ligands except for those corresponding to the N(3)−C(7) and C(7)−S bonds, which are 1.358(4) and 1.698(3) Å and 1.369(2) and 1.649(2) Å for HL_I and HL_Imm, respectively.[30,31] The N(3)−C(7) and C(7)−S bond lengths decrease and increase, respectively, upon coordination, which has been related to the respective gain and loss in double-bond character upon complexation. The results summarized in Table 2 show that the selected parameters for **2**, **3**, and **4** are in good agreement with those expected for compounds containing HL_I or HL_Imm in anionic form.[32]

As can be seen, complexes **2**, **3** and **4** are made up of [Cu(L)X] units connected through the thioamide sulfur atom, giving rise to $\{Cu_2(\mu\text{-}SL)_2\}$ dimeric entities similar to other copper(II) derivatives of pyridine-2-carbaldehyde thiosemicarbazone.[33,34] A significant difference between compound **2** and the analogous chloro and bromo derivatives[34] is the short deviation of the copper(II) ion with respect to the basal plane in **2** (0.012 Å) compared with those for $[\{Cu(L_I)Cl\}_2]$ and $[\{Cu(L_I)Br\}_2]$ (around 0.2 Å).

Crystal Structures of the Oxadiazole Derivatives

A perspective view of the structure of complex **5** is shown in Figure 4. Selected interatomic dimensions are given in Table 3. The crystal structure consists of cationic dimeric $[\{Cu(HL_{II})(H_2O)_3\}_2]^{4+}$ entities and sulfate groups as counterions. Each copper(II) ion adopts a tetragonally distorted octahedral "4+2" geometry, being bonded to the oxygen atoms of three water molecules and to three nitrogen atoms: two belonging to one of the oxadiazoles and one to the ligand of the symmetric entity inside the dimer, which acts as a bridge between the two metal ions. The high thermal parameters in the sulfate ions cause disorder in some of the oxygen atom positions.

The molecular structure of **6** has been described previously;[17] the dimeric structure is shown in Figure 5.

In relation to the plane formed by the N(1)N(2)N(3) chelating set in **5** and **6**, the copper(II) atoms lie at 0.172 and 0.351 Å, respectively. In addition, the O(2S) and O(4) atoms are displaced by 0.159 and 0.866 Å, respectively, above the NNN plane.

The structure of **8**[17] consists of (HL_{II}mm) neutral units and three water molecules of crystallization which stabilizes the crystal lattice through a network of hydrogen bonds.

The oxadiazole ligands in these compounds contain two aromatic rings (pyridinic and oxadiazolic) whose planes are at 7.1, 6.3, and 7.4° with respect to each other (for, **5**, **6**, and **8**, respectively), indicating that complexation induces a higher planarity in the oxadiazole ligands. These values are in good agreement with those observed for [Cu(HL_{II}-

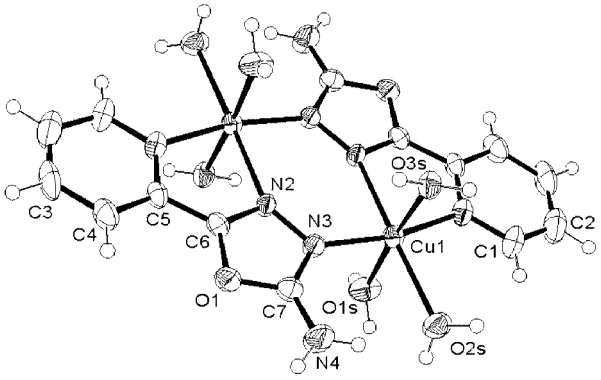

Figure 4. Molecular structure of the dimeric cationic entity of **5** with thermal ellipsoids at 50% probability level

$mm)_2(H_2O)_2](NO_3)_2$ and $[Cu(HL_{II}mm)(oxalate)(H_2O)]\cdot H_2O$ (1.8 and 0.3°, respectively).[35]

The bond lengths in these complexes are quite similar to those of the free ligand. However, the C(5)−C(6)−N(2) angle decreases upon coordination[17] (see Table 3). The N(3) and C(8) atoms are *syn* with respect to the C(7)−N(4) bond in the structure of $HL_{II}mm$ whereas in complex **6** they show an *anti* conformation. Taking into account that the above-mentioned $[Cu(HL_{II}mm)_2(H_2O)_2](NO_3)_2$ and $[Cu(HL_{II}mm)(oxalate)(H_2O)]\cdot H_2O$ complexes also display the *syn* conformation, this conformational change could be attributed to steric hindrance induced by the sulfato group.[35]

Several hydrogen bonds involving the water molecules and sulfate anions help stabilize the lattice in complexes **5** and **6**, leading to a sheet-like structure (see Supporting Information). The sheets are connected by π−π stacking interactions with a shortest interplanar atom···atom separation of C(4)···C(6)^{v} (3.45 Å, $v = -x + 2, -y, -z + 1$) and N(3)···C(3)^{vii} (3.378 Å, vii = $x-1, y, z$) for **5** and **6**, respectively. A peculiar view of the packing in complex **6** with alternating layers of dimers parallel to the (−1, 3, 0) and (−3, −9, 1) planes is shown in Figure 6.

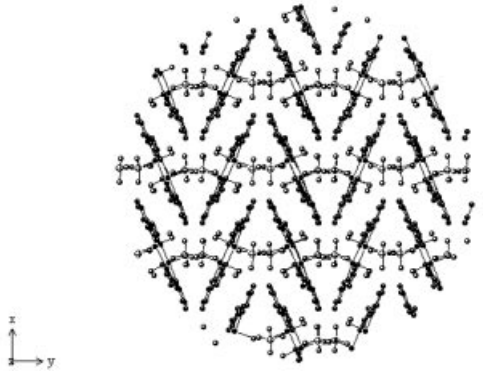

Figure 6. Arrow-like perspective of complex **6**

Analysis of the molecular packing of **8** suggests the lattice is stabilized by several hydrogen bonds, involving mainly the N(1), N(3) and N(4) atoms of the ligand and the lattice water (see Supporting Information). Pseudo-chains of coplanar molecules parallel to the (2, 6, −4) plane alternate with other chains of molecules parallel to the (−2, 6, 4) plane along the *y* axis (Figure 7). Each column is made up of sets of three molecules interconnected by π−π interactions (minimum distances 3.330 and 3.269 Å for C(6)···C(7)^{v} and C(7)···N(1)^{iii}, respectively). In addition, the molecules belonging to each column are linked through another hydrogen bond, which involves the N(4) and N(1) atoms.

Spectroscopic Studies

The IR spectrum of complex **1** exhibits absorptions at 808 and 735 cm^{-1} which can be assigned to the ν_1 and ν_3 vibrations of the halato group. Complex **3** shows strong bands at 1517, 1234, and 1023 cm^{-1} assignable to the ν_5, ν_1, and ν_2 modes of the monodentate nitrato ligand,[36] in good agreement with the structural results.

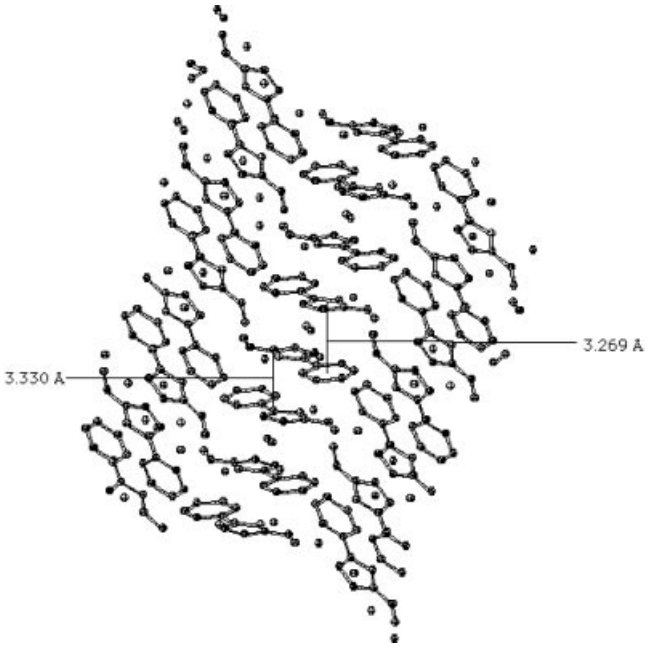

Figure 7. Pseudo-chains formed by the stackings of molecules in **8**

For **5** and **6** the 1300−900 cm^{-1} region displays many absorptions due to the coexistence of the oxadiazole and sulfate ligands, hampering definitive assignments. Nevertheless, the bands at 1095, 1065, and 640 cm^{-1} for complex **5** could be assigned to the ν_3 and ν_4 modes of the T_d sulfate. Conversely, **6** shows absorptions at: 1108(ν_3), 1050 (ν_3), 968 (ν_1), 645 (ν_4), 617 (ν_4), and 455 (ν_2) cm^{-1} that can be attributed to a monodentate-coordinated sulfate with C_{3v} symmetry.

The diffuse reflectance spectra of the thiosemicarbazone complexes are characterized by bands in the 210−245, 260−295, 380−415, and 460−500 nm regions, corresponding to intraligand (π→π*), (n→π*), LMCT $S\rightarrow Cu^{II}$, and $X\rightarrow Cu^{II}$ (X = N, O, Br, I), respectively[37−39] (see Table 4). The bands observed in solid samples in the 575−740 nm region are characteristic of d→d transitions for compounds exhibiting a square-pyramidal geometry with a $d_{x^2-y^2}$ ground state. A shoulder observed at 895 and 979 nm in the spectra of the nitrato and iodo derivatives is attributed to the distortion towards trigonal bipyramidal topology.

The UV−visible spectra of complexes **3** and **4** in aqueous solution are very similar (see Table 4) and differ significantly from their respective solid spectra, especially in the LMTC region, as also occurs with the spectra of complexes **1** and **2** in solution. This strongly suggests that $[Cu(L_Imm)(H_2O)_3]^+$ and $[Cu(L_I)(H_2O)_3]^+$, respectively, are present in aqueous solution. The band at 225 nm in the spectrum of complex **2** [and the analogous $Cu(L_Imm)I$] is also present in aqueous solutions of KI, being attributed to charge-transfer bands between the iodide ion and the solvent molecules.

The UV−visible spectra of the oxadiazole complexes **5** and **6** show absorptions in the 220−230, 260−285, and

330−500 nm regions which can be attributed to intraligand π→π*, n→π* and LMCT N/O→Cu^{II} transitions, respectively.[35] A very broad absorption at around 700 nm and a less intense shoulder in the 1100−1170 nm range are also observed, which are consistent with a copper(II) chromophore with a tetragonally distorted octahedral geometry.[40] These bands could be assigned to the $^2E_g \leftarrow {}^2B_{1g}$ and $^2A_{1g} \leftarrow {}^2B_{1g}$ transitions, respectively − in good agreement with the results reported for analogous triazole systems.[41] The solution spectra of complexes **5** and **6** are similar to those of the $[Cu(HL_{II}mm)_2(H_2O)_2](NO_3)_2$ complex. Furthermore, a study involving the latter has shown that some LMTC bands shift to higher energies in solution, overlapping with the intraligand absorptions.[35]

The *g* tensors for the powder X-band EPR spectra of the title complexes are shown in Table 5. The spectra of compounds **1**, **3**, and **4** are characteristic of a $d_{x^2-y^2}$ ground state for square-pyramidal copper(II) chromophores,[42] similar to those reported for other copper(II) thiosemicarbazone complexes.[33,34,43] Compound **2** exhibits a broad (≈ 200 G peak-to-peak) isotropic signal at room temperature in the $g = 2.074$ region. Upon lowering the temperature to 120 K the signal intensity increases but its shape does not change. The X-band EPR spectra of complexes **5** and **6** consist of an axial signal whose *g* values accord with a copper(II) ion in an elongated octahedral geometry.

Magnetic Behaviour

Plots of the molar susceptibility (χ_m), together with the $\chi_m T$ vs. *T* curves for compounds **2**, **3**, **4**, **5**, and **6** are given in Figures 8, 9, 10, 11, and 12, some of which show a shoulder around 60 K that is characteristic of O_2. The magnetic measurements all obey the Curie−Weiss law above 50 K. The Weiss temperatures are −9.46 (**2**), +2.87 (**3**), −5.75 (**4**), −1.76 (**5**), and −1.26 K (**6**). The C_m experimental values range from 0.40 to 0.44 $cm^3\cdot K\cdot mol^{-1}$ and the calculated μ_{eff} values at room temperature are 1.8 BM for

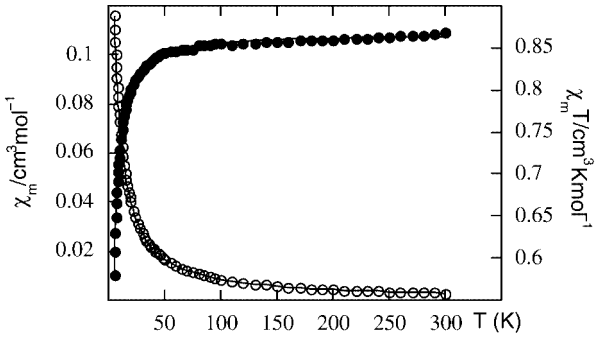

Figure 11. Thermal variation of the molar susceptibility (open circles) and $\chi_m T$ (black circles) for **5**. Solid lines represent the best fit

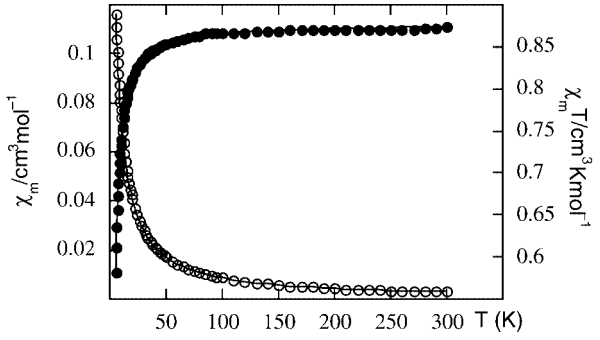

Figure 12. Thermal variation of the molar susceptibility (open circles) and $\chi_m T$ (black circles) for **6**. Solid lines represent the best fit

all compounds. The χ_m values increase with decreasing temperature for most complexes, reaching a maximum at 22.0 (0.008 cm^3·mol^{-1}, **2**), 11.0 (0.019 cm^3·mol^{-1}, **4**), 3.3 K (0.058 cm^3·mol^{-1}, theoretical values arising from the fit in **5**) and 3.4 K (0.058 cm^3·mol^{-1}, theoretical values arising from the fit in **6**). The $\chi_m T$ value continuously decreases on lowering the temperature, indicating the presence of antiferromagnetic interactions. However, compound **3** does not exhibit a maximum in the χ_m vs. T plot and $\chi_m T$ increases on lowering the temperature, which is characteristic of ferromagnetic behaviour.

Taking into account the dimeric nature of these complexes, we fitted the susceptibility data with the Bleaney−Bowers expression for copper(II) dinuclear compounds,[44] derived from the Heisenberg isotropic spin Hamiltonian ($H = -2J \cdot S1S2$), for two coupled $S = 1/2$ ions:

$$\chi = \frac{Ng^2\beta^2}{kT}\left(\frac{2}{3 + \exp(-2J/kT)}\right) + N\alpha \quad (1)$$

where $N\alpha$ = a temperature independent contribution, N is the Avogadro constant, β = Bohr magneton, and k = the Boltzmann constant. The best least-squares fit (solid line in Figures 8−12) is obtained with $J/k = -20.20$ K (-14.03 cm^{-1}, taking into account 5% paramagnetic impurities in **2**), -8.85 K (-6.14 cm^{-1}, **4**), -2.75 K (-1.91 cm^{-1}, **5**), and -2.78 K (-1.93 cm^{-1}, **6**). For **3**, the influence of intermolecular interactions must be considered in the fit treated in the molecular field approximation, and the values obtained are $J/k = +9.90$ K and $z'J' = -1.70$ K ($+6.88$ and -1.18 cm^{-1}, respectively). The g-values of 2.06, 2.11, 2.10, 2.15, and 2.16 for **2**, **3**, **4**, **5**, and **6**, respectively, are in good agreement with those obtained from EPR, 2.07 (**2**), 2.09 (**3**), 2.08 (**4**), 2.17 (**5**), and 2.15 (**6**). Taking into account the structural features, the existence of interdimeric magnetic interactions in these compounds should be considered. However, the fit was improved only for **3**, due to the opposite sign of the ferromagnetic intradimer vs. antiferromagnetic interdimer interactions. The data are given in Table 6 together with a summary of the J values for all copper(II) dinuclear derivatives of HL_I and HL_Imm described to date.

The strength of the magnetic interactions in the **2**, **3**, and **4** thiosemicarbazone derivatives suggests that the exchange propagation direction is in a different plane to that formed by the magnetic $d_{x^2-y^2}$ orbitals. These results agree well with the existence of an intradimer exchange coupling in the Cu_2S_2 units. However, the relatively intense antiferromagnetic coupling in **2** and the ferromagnetic interactions in **3** have not been observed before in the pyridine-2-carbaldehyde thiosemicarbazone−copper(II) system. Ferromagnetic interactions in other thiosemicarbazone−copper(II) systems have been referenced,[45] but, as far as we are aware, no magneto-structural studies have been carried out.

The results suggest that the nature of the coligands in the basal plane influences in the magnetic behaviour. Here, O-donor coligands show the smallest antiferromagnetic contributions to the J values. It has been established that the less electronegative is the donor atom in the basal plane the stronger the induced antiferromagnetic coupling is, due to a greater hybridization of the $d_{x^2-y^2}$ metal orbital towards the bridge.[46,47] Figure 13 shows a good accordance between the average J values and Pauling's electronegativity of the compounds in Table 6.

Conversely, the relationship between J and other structural parameters is not evident even for a given X-donor set. Several concomitant factors could be involved in the values of the exchange coupling constants for these compounds, such as the Cu···Cu intradimer distance, SP vs. BPT distortions around the copper(II) ion, deviation of the metal ion from the basal plane, deviation of the coligand from the basal plane, Cu−X apical distances, N(2)−Cu−S−Cu′/N(1)−Cu−O(1)−Cu′ dihedral angles which give a measurement of the shift of the [Cu(L)X] entities constituting the dimer, the influence of the thiosemicarbazone and coligands.

A qualitative study of the relationship between the magnetic exchange constant J and the square of the energy difference (Δ^2) between the two magnetic orbitals involved[48] required an extended Hückel molecular orbitals (EHMO) analysis.[49] Such EHMO calculations, using the crystallographic coordinates of the compounds following a procedure previously described,[50] gave a Δ^2 for **3** that is at least ten times smaller than those obtained for antiferro-

[a] Average value. [b] Crystal data not available.

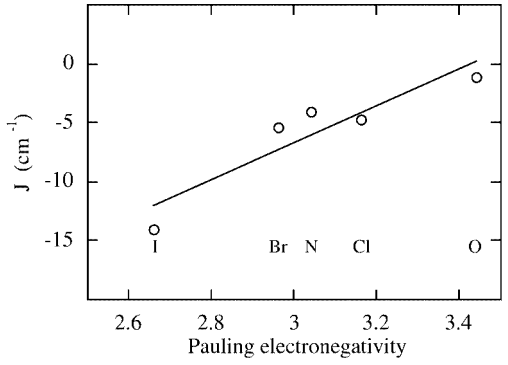

Figure 13. Plot of the average values of J (cm^{-1}) vs. the Pauling's electronegativities. The electronegativities are 3.44, 3.16, 3.04, 2.96, and 2.66 for O^-, Cl^-, N^-, Br^-, and I^- donors, respectively

magnetic derivatives in good accordance with its ferromagnetic behaviour. Unfortunately, the limitations of the EHMO calculations did not allow us to determine a perfect sequence for the J values. The most important disagreement involves Δ^2 for [{Cu(L_I)(NCS)}$_2$] and [{Cu(L_I)I}$_2$], but can be explained by taking into account that [{Cu(L_I)(NCS)}$_2$] is the only noncentrosymmetric compound in Table 6. Thus, it has been proposed that lowering the symmetry gives rise to a decrease in the antiferromagnetic contribution which is not reflected in the magnitude of Δ^2.[51,52]

The small values obtained for the magnetic exchange constant in **5** and **6** contrast with those reported for similar dimeric compounds containing copper(II) ions bridged through analogous diazole and triazole ligands.[41,53−56] This is consistent with the value of Δ gap in the EHMO analysis (0.099 eV for **5**), which is smaller than those reported for pyrazolate bridged compounds.[57,58] Such behaviour can be explained considering that the d_{z^2} orbitals lie in the O(4)−Cu−N(2) direction for compounds **5** and **6**, which involves the longest bond lengths and points to the oxadiazole bridges. The magnetic $d_{x^2-y^2}$ orbitals, however, are perpendicular to the exchange propagation direction.

Conclusion

HL_I and HL_Imm react with potassium bromate or iodate in an oxidative cyclization process that involves the elimination of sulfur and the attainment of the respective HL_{II} and HL_{II}mm ligands. This reaction also occurs when the copper(II) derivatives of these thiosemicarbazone ligands are used as reactants. The oxadiazole−copper(II) complexes so-formed maintain the dimeric nature of their thiosemicarbazonecopper(II) precursors. The planarity of the ligands gives rise to π−π stacking interactions that, along with the hydrogen bonding, stabilize the crystal packing. Weak antiferromagnetic intradimeric interactions are present in both thiosemicarbazone and oxadiazole−copper(II) systems. However, the nitrato derivative **3** shows ferromagnetic behaviour. The relative scarcity of pyridine-2-carbaldehyde thiosemicarbazone−copper(II) compounds, as well as the limitations of the semiempirical calculations developed, prevents good quantitative results. However, the influence of the electronegativity of the non-thiosemicarbazone basal donor atom seems to be clear.

Experimental Section

Materials: Thiosemicarbazides, pyridine-2-carbaldehyde, copper(II) sulfate pentahydrate, copper(II) nitrate trihydrate, potassium bromate and iodate, sodium bromide, potassium iodide, and potassium ferrocyanide trihydrate were purchased from commercial sources and used as received. Published methods with small modifications were used to synthesize HL_I,[59] HL_Imm,[31,60] Cu(L_I)(NO_3,[61] and [{Cu($L_I$mm)(NO_3)}$_2$].[17] All operations should be carried out in a fume cupboard.

Preparation of the Complexes

Synthesis of 1, 2, 5, and 7: Compound **1** was synthesized by the addition of solid potassium iodate (0.85 g, 4 mmol) to an aqueous solution of Cu(L_I)(NO_3) (0.30 g, 1 mmol) with continuous stirring. The pH of the reaction mixture was adjusted to 6.0 by addition of aqueous NaOH. A few minutes later, an abundant green precipitate appeared which was filtered off and dried (yield 0.30 g, 70%).

$C_7H_9CuIN_4O_4S$ (435.69): calcd. C 19.3, H 2.1, N 13.2, S 7.8; found C 19.3, H 2.1, N 12.9, S 7.4. The molar conductivity of $5\cdot10^{-4}$ M solutions in water (dimethylformamide) at 25 °C is Λ_M = 97.4 (immediate reaction to give **2**) $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. Selected IR bands ($cm^{-1}$, KBr): 3498 m, 3438 m, 3365 m, 3296 m, 3170 m, 1640 s, 1606 s, 1484 m, 1448 m, 1436 m, 1383 w, 1322 m, 1222 m, 1162 s,sh, 708 m, 781 s, 735 s.

Attempts to recrystallize **1** in water furnished good-quality crystals of a new thiosemicarbazonatocopper(II) derivative that was identified as **2** (0.05 g, 16% yield). $C_7H_7CuIN_4S$ (369.67): calcd. C 22.7, H 1.9, N 15.2, S 8.1; found. C 22.3, H 1.9, N 15.3, S 7.6. The molar conductivity of $5\cdot10^{-4}$ M solutions in water (dimethylformamide) at 25 °C is Λ_M = 123 (31.3) $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. Selected IR bands ($cm^{-1}$, KBr): 3423 s, 3279 m, 3135 m, 1625 s, 1600 s, 1480 s, 1446 vs, 1436 vs, 1226 m, 1166 s, 1155 m,sh, 909 m, 875 w, 778 m, 622 m, 469 m,b, 420 m.[62]

Aqueous solutions of $Cu(L_I)(NO_3)$ (0.30 g, 1 mmol) and potassium bromate (0.17 g, 1 mmol) were mixed with stirring. The pH of the reaction mixture was adjusted to 6 by addition of aqueous 5 M NaOH and maintained with stirring overnight at room temperature. A small amount of precipitate appeared, which was filtered off and washed with water and acetone. The product was identified as the $[\{Cu(L_I)(Br)\}_2]$ complex.[34] Bright green crystals of **5** were then obtained from the mother liquor after one week at room temperature (0.22 g, 58% yield). $C_{24}H_{24}Cu_2N_8O_{16}S_2$ (751.6): calcd. C 24.6, H 3.6, N 14.4, S 8.2; found. C 24.6, H 3.6, N 14.3, S 8.2. The molar conductivity of $5\cdot10^{-4}$ M solutions in water (dimethylformamide) at 25 °C is Λ_M = 227 (32.6) $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. Selected IR bands ($cm^{-1}$, KBr): 3381 m,b, 3077 m,b, 1684 s, 1577 m, 1518 m, 1493 m, 1441 m, 1350 m,sh, 1143 s,b, 1133 s, 1100−1000 s, 789 m, 751 m, 734 m, 619 m,b.

The HL_{II} ligand (**7**) was removed from complex **5** by the addition of $K_4[Fe(CN)_6]\cdot3H_2O$[17] (yield: 0.06 g, 45%). $C_8H_{14}N_4O_4$ (230.23): calcd. C 51.8, H 3.7, N 34.5; found. C 51.9, H 3.8, N 34.1. Selected IR bands (cm^{-1}, KBr): 3288 s, 3115 s, 1649 vs, 1588 vs,sh, 1562 s, 1460 vs, 1448 m, 1321 m, 1285 m, 1251 w, 1092 s, 1052 s, 1042 s, 786 m, 773 m, 742 s, 686 s, 620 m, 410 m. ^1H NMR (400 MHz; $[D_6]$DMSO, ppm): δ = 8.63 (dt, ^3J = 5 and 1.4 Hz, 1 H, H^1), 7.95 (d, ^3J 2 Hz, 1 H, H^4), 7.92 (m, 1 H, H^3), 7.47 (m, 1 H, H^2), 7.38 (s, 2 H, NH_2).

Ligand **7** can also be prepared by oxidative cyclization of HL_I in the absence of copper(II) as follows: solid potassium bromate (0.5 g, 3 mmol) was added to a suspension of the thiosemicarbazone in water (0.54 g, 3 mmol) acidified with H_2SO_4 to pH = 0−1. After a few minutes, the reaction mixture turned orange and a brown solid appeared. The suspension was filtered off and a solution of NaOH (5 M) was slowly added to the resulting clear solution to reach a pH ≈ 5 at 0 °C. After a further few minutes ligand **7** appeared as a white product which was washed with water and recrystallized from ethanol (yield 0.31 g, 45%).

Synthesis of 3, 4, 6, and 8: The oxidative cyclization procedure for HL_Imm is analogous to that described above for HL_I. The synthesis and characterization of complex **3** has been reported in the literature.[17]

Aqueous solutions of **3** (0.32 g, 0.5 mmol) and potassium bromate (0.17 g, 1 mmol) were allowed to react at pH 6 overnight. A green precipitate appeared that was filtered off, washed with water and acetone and dried. The product was identified as complex **4** (yield 0.03 g, 10%). $C_{16}H_{18}Br_2Cu_2N_8S_2$ (673.4): calcd. C 28.6, H 2.7, N 16.6, S 9.5; found. C 29.0, H 3.0, N 16.9, S 9.1. The molar conductivity of $5\cdot10^{-4}$ M solutions in water (dimethylformamide) at 25 °C is Λ_M = 118.2 (10) $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. Selected IR bands ($cm^{-1}$, KBr): 3219 m, 1593 s, 1570 m, 1534 s, 1472 s, 1357 vs,b, 1304 s, 1281 s, 1227 s, 1183 m, 1119 m, 1042 s, 898 w, 883 w, 862 w, 777 w, 607 m.[63]

After filtering complex **4**, the mother liquor was allowed to stand at room temperature, and after two days crystals of the complex **6** were obtained.[17]

The $HL_{II}mm$ ligand (**8**) can be obtained by analogous procedures to those described for **7**.[17,64−66]

Physical Measurements: Microanalyses were performed with a LECO CHNS-932 analyser. Conductivity measurements were made by a CRISON 522 conductimeter. Infrared spectra were obtained in the 400−4000 cm^{-1} region on a Nicolett Impact 410 FTIR spectrophotometer with samples prepared as KBr pellets. Reflectance spectra were carried out on a Cary 2415 spectrometer in the 200−2000 nm range. For UV-visible solution measurements, a Varian UV-VIS-NIR spectrophotometer was employed (200−900 nm). X-band EPR spectra were recorded on a Bruker EMX spectrometer, equipped with a standard Oxford continuous flow cryostat. Magnetic measurements of powdered samples were carried out in the range 5−300 K using a Quantum Design MPMS-7 Squid magnetometer. Diamagnetic corrections were estimated from Pascal tables.

X-ray Crystallographic Studies: Crystal data collections were carried out on a Bruker Smart CCD area detector equipped with a single crystal diffractometer. Absorption corrections were made using the SADABS program.[67] Direct methods (SHELXS-97)[68] were employed to solve the structures and then were refined by full-matrix least-squares method, using SHELXL-97.[69] All non-hydrogen atoms were assigned anisotropic thermal parameters. Hydrogen positions were determined by difference Fourier syntheses and introduced in calculations with a riding model. The scattering factors and anomalous dispersion coefficients were taken from International Tables of X-ray Crystallography.[70] Refinements were made on F_0^2 for all reflections. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre. The deposition numbers are CCDC−199599, −199600, and −199601 for compounds **2**, **4**, and **5**, respectively. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44−1223/336033; E-mail: deposit@ccdc.cam.ac.uk]. Crystallographic details for the crystal structures of compounds **2**, **4**, and **5** are shown in Table 7.

Supporting Information

Supporting information for this article (Hydrogen bond parameters (Å, °) for the six crystal structures) is available from the WWW under http://www.wiley-vch.de/home/eurjic or from the author.

Acknowledgments

We thank Dr. J. J. Delgado (SCAI, Universidad de Burgos, Spain) for the elemental analysis and Professor R. Olazcuaga and Dr. F. Guillen (CNRS, Pessac, France) for the reflectance measurements. This work has been carried out with the financial support of the Ministerio de Ciencia y Tecnología (BQU, 2002-00435) and the Junta de Castilla y León (BU15/03). P. G.-S. thanks the Universidad de Burgos for her Doctoral Fellowship.

[62] Compound **2** can be also obtained by addition of potassium iodide (0.166 g, 1 mmol) to an aqueous solution of $Cu(L_I)(NO_3)$ (0.30 g, 1 mmol) (yield 0.34 g, 93%).
[63] Compound **4** can be also prepared by mixing aqueous solutions of **3** (0.32 g, 0.5 mmol) and sodium bromide (0.1 g, 1 mmol) (yield 0.30 g, around 90%). Dark green crystals of **4** were obtained by slow reaction of **3** and sodium bromide in a diffusion device.
[64] The use of iodate as oxidizing agent in the cyclization of HL_Imm and HL_I gave the same results. However, the formation of iodine in the reaction forced us to make more separations to obtain the pure compounds and as a result the yield decreased.
[65] An analogous procedure carried out on complex **3** with iodate as oxidant yielded the $[Cu(L_I mm)(IO_3)]$ complex (yield 0.39 g, 90%) $C_8H_9CuIN_4O_3S$ (431.7): calcd. C 22.2, H 2.3, N 12.9, S 7.4; found C, 22.2, H 2.3, N 12.9, S 7.2. The molar conductivity of $5\cdot10^{-4}$ M solutions in water (dimethylformamide) at 25 °C is Λ_M = 73 (50) $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. Selected IR bands ($cm^{-1}$, KBr): 3220 m, 2979 w, 1597 s, 1572 s, 1538 vs, 1477 vs, 1355 vs, 1308 m, 1288 vs, 1225 s, 1180 s, 1178 m, 1116 s, 1097 m, 1038 m, 811 vs, 779 s, 751 vs, 732 vs, 720 vs, 608 m, 489 m. UV-visible bands in water, λ_{max} [nm] (ε, $M^{-1}\cdot cm^{-1}$): 287 (13000), 328 (13200), 385 (12000), 622 (170). EPR in the room temp.-to-120 K range (X-band, solid sample): g_1 = 2.195, g_2 = 2.054 and g_3 = 2.030. Likewise, the complex analogous to **2** was also synthesized and identified as $[Cu(L_I mm)I]$ (yield 0.33 g, 85%). $C_8H_9CuIN_4S$ (383.7): calcd. calcd. C 25.0, H 2.4, N 14.6, S 8.3; found C 25.0, H 2.4, N 14.8, S 7.8. The molar conductivity of $5\cdot10^{-4}$ M solutions in water (dimethylformamide) at 25 °C is Λ_M = 110 (41) $\Omega^{-1}cm^2mol^{-1}$. Selected IR bands (cm^{-1}, KBr): 3216 m, 3021 w, 2973 w, 1593 s, 1568 s, 1534 vs, 1472 s, 1354 vs, 1307 s, 1283 vs, 1225 s, 1178 s, 1118 s, 1099 m, 1039 s, 770 s, 603 w. UV-visible bands in water, λ_{max} [nm] (ε, $M^{-1}\cdot cm^{-1}$): 224 (25200), 287 (12300), 329 (12400), 386 (11250), 622 (150). EPR in the room temp.-to-120 K range (X-band, solid sample): $g_{\|}$ = 2.121 and $g_{\perp}$ = 2.038.
[66] Furthermore, complexes **5** and **6** were also prepared by adding $CuSO_4\cdot5H_2O$ to the acid, orange oxidizing solution of bromate and **7** or **8**, respectively, before the addition of NaOH.

Keywords: Osmium / Gold / Clusters / Electrochemistry / Carbonylations

Treatment of the mixture of $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ and $[AuPPh_3Cl]$ with excess triethylamine afforded three novel tetraosmium–gold mixed-metal clusters, $[Os_4Au_2(\mu\text{-}H)_2(CO)_{11}(PPh_3)_3]$ (**4**), $[Os_4Au_3(\mu\text{-}H)_3(CO)_{11}(PPh_3)_3]$ (**5**), and $[Os_4Au_4(\mu\text{-}H)_2(CO)_{11}(PPh_3)_4]$ (**6**) in moderate yields. Cluster $[Os_4Au(\mu\text{-}H)_3(CO)_{11}(NMe_3)(PPh_3)]$ (**2**) was also obtained in a similar reaction in the presence of trimethylamine *N*-oxide. They were fully characterized by different spectroscopic techniques, and the solid-state structures were established by X-ray analysis. These dimetallic clusters exhibit an osmium/gold ratio ranging from 1 to 4. Their electronic absorption properties, electrochemistry, and catalytic properties, as a result of the oxidative carbonylation of aniline, were investigated in terms of the Os/Au ratio.

Introduction

The chemistry of transition mixed-metal clusters containing (phosphane)gold units has been well established in the past decade.[1−14] The initial interest in these clusters stemmed from the perceived isolobal analogy between a hydride and a (phosphane)gold group.[15] This interest has continued to develop since they were found to be potential homogeneous dimetallic catalysts. The introduction of heterometallic metal−metal bonding into these clusters leads to an increase in the polarity of the molecule, which probably results in the enhancement of the catalytic activity. Examples of catalysis by mixed-metal clusters that contain (phosphane)gold groupings have been reported.[16−24] Previously, we reported that $[Os_4Au(\mu\text{-}H)_3(CO)_{12}(PPh_3)]$ (**1**) catalyzes the oxidative carbonylation of aniline to give methyl phenylcarbamate in methanol with good conversion and selectivity.[25] This paper reports in detail the syntheses and characterization of a series of novel tetraosmium−gold mixed-metal clusters with Os/Au ratios ranging from 1 to 4. A better understanding of the role of gold atoms in the dimetallic system has been developed through the study of their electronic absorption properties, electrochemistry, and catalytic properties.

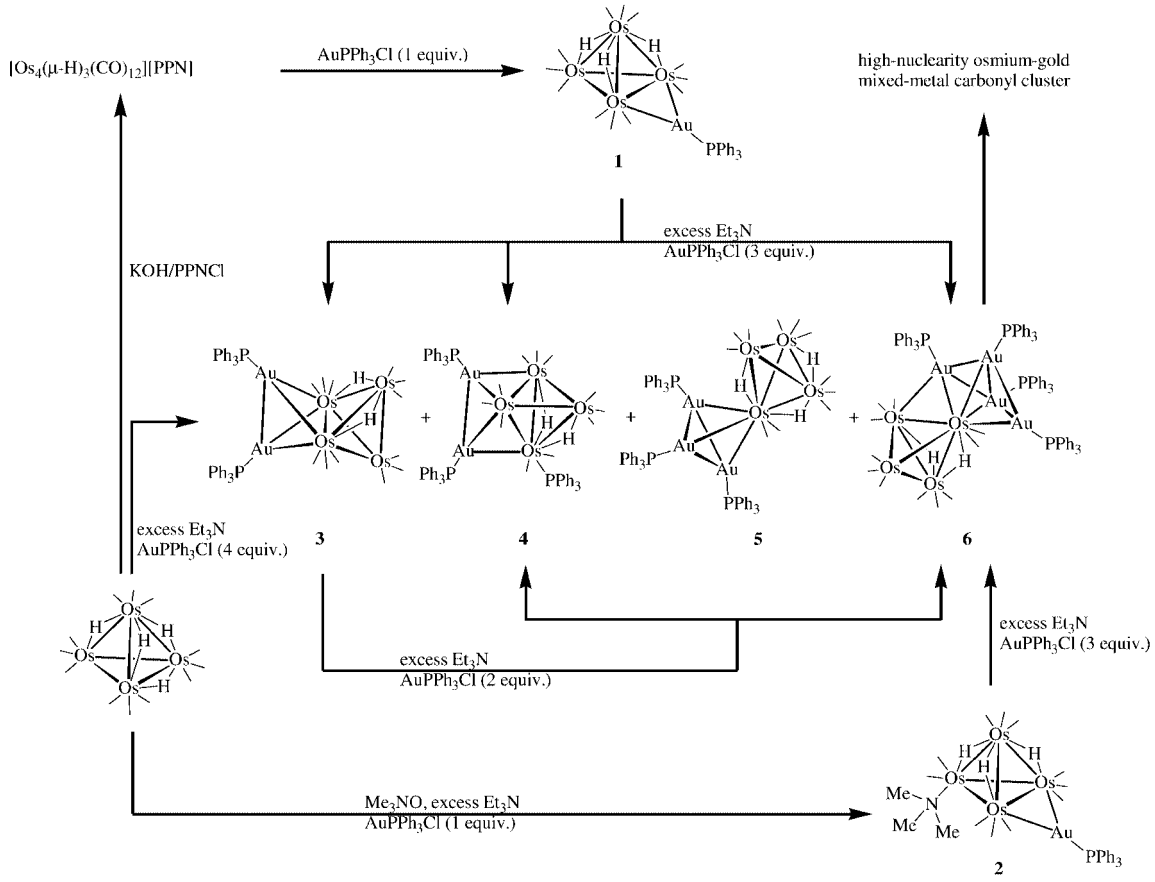
Results and Discussion

The preparation of **1**−**6** is summarized in Scheme 1. In fact, the synthesis and characterization of **1** and **3** were reported by Lewis in the 1980s,[26] and it is surprising that the high-nuclearity tetraosmium−gold mixed-metal clusters can also be isolated in a similar reaction with an excess amount of triethylamine. It appears that the protons in $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ were successively eliminated by Et_3N as $[Et_3NH]^+$, the vacant sites formed were then simultaneously filled up by $[AuPPh_3]^+$ to afford a series of osmium−gold mixed-metal clusters. The formation of gold clusters is also favorable in a reducing environment; as a result, the Au−Au bonds are formed in **3**−**6**. Nevertheless, further elimination of protons in **3**−**6** is improbable due to the limited reducing power of Et_3N. Recently, Raithby et al. have reported on the deprotonation of the cluster $[Os_4H(CO)_{12}(AuPR_3)_3]$ in the presence of $[AuPR_3]^+$ in an attempt to produce tetragold clusters, but met with little success. They alternatively used the chelated gold salt $[Au_2(Ph_2PCH_2PPh_2)Cl_2]$ to treat with the anion $[Os_4H_4(CO)_{11}]^{2-}$ and give $[Os_4(\mu\text{-}H)_2(CO)_{11}\{Au_2(dppm)\}_2]$.[27] The successful isolation of **5** and **6** proves that the deprotonation of (hydrido)osmium clusters in the presence of $[Au(PPh_3)]^+$ could be an efficient method for preparing the high-nuclearity osmium−gold mixed-metal clusters in a systematic manner.

These osmium−gold mixed-metal clusters were isolated with relatively small yields, even in the presence of excess $[AuPPh_3Cl]$, where the equilibrium between formation and decomposition of these mixed-metal clusters was established. Changing in stoichiometry of $[AuPPh_3Cl]$ has no significant effect on the product yields. This deprotonation reaction is also thought to be successive. Independent depro-



Scheme 1

tonation of all isolated compounds with an excess of the [$AuPPh_3Cl$] compound were studied (Scheme 1). This showed that **1**−**3** can be further converted into **4** or **6** in moderate yields. In addition, the deprotonation of **6** with an excess of [$AuPPh_3Cl$] gives an insoluble microcrystalline solid, which is believed to be a high-nuclearity osmium−gold mixed-metal carbonyl cluster with an Os/Au ratio of 3:2. The nature of this compound is still under active investigation.

Structural Characterization

The molecular structure of **2** is depicted in Figure 1. Four osmium atoms define a distorted tetrahedron. The Os(1)−Os(2) bond is symmetrically bridged by Au(1), with a bite angle Os(1)−Au(1)−Os(2) of 64.47(4)° and Os−Au bond lengths of 2.768(2) and 2.753(2) Å. The dihedral angle between the planes of Os(1)−Os(2)−Os(3) and Os(1)−Au(1)−Os(2) is 120.2° which is slightly larger than the corresponding value 109.5° that is observed in **1**.[25] The trimethylamine is terminally bonded to Os(3) with an Os(3)−N(1) distance of 2.24(2) Å which is similar to the value of 2.25(1) Å in $[Os_4(\mu\text{-}H)_4(CO)_{10}(NMe_3)\{\eta^1\text{-}NC_5H_4(N{=}N)C_6H_5\}]$.[28] The Os−Os bond lengths are observed in the range of 2.803(2)−3.009(2) Å, where the hydrido- or ligand-bridged Os−Os bonds are significantly elongated. The hydride ions bridging the Os(1)−Os(3) and Os(2)−Os(3) edges are chemically equivalent, which corresponds to the double integral hydride signal that is observed in the ^1H NMR spectrum of **2**.

The molecular structure of **4** is depicted in Figure 2, where the tetraosmium tetrahedron is terminally coordinated with eleven carbonyl ligands. Two {$AuPPh_3$} ligands bridge two adjacent Os−Os edges to form a distorted square pyramid [Au(1), Au(2), Os(1), Os(2), and Os(4)] which shares the plane Os(1)−Os(2)−Os(4) with the tetraosmium tetrahedron. A similar metal framework was observed in $[Os_4(CO)_{13}(AuPEt_3)_2]$.[29] The Au(1)−Au(2) bond [3.055(1) Å] is slightly shorter than the corresponding one in $[Os_4(CO)_{13}(AuPEt_3)_2]$ [3.128(1) Å], but is significantly longer than that in **3** [2.793(4) Å] where the two $AuPR_3$ groups bridge the same Os−Os edge.[26] An extra triphenylphosphane ligand is terminally bonded to Os(4), having an Os(4)−P(1) bond length of 2.362(6) Å. The gold− and osmium−triphenylphosphane protons give two multiplets with an integral ratio of 2:1 in the ^1H NMR spectrum of **4**. However, the P atoms of three different chemical environments in **4** give only one ^{31}P NMR signal. This is probably due to the fluxional behavior of the {$AuPPh_3$} ligand at room temperature on the NMR timescale which is frequently found in homo- and heteronuclear clusters.[30−32] Low-temperature ^{31}P NMR spectroscopy was carried out for **4** at 223 K and the signal resolved into two singlets with an intensity ratio of 2:1 (Figure 3). The formation of

osmium−triphenylphosphane may be due to a triphenylphosphane impurity in the starting material, a similar observation has been reported in the case of $[Os_3(CO)_8(PPh_3)\{Au(PPh_3)\}(2\text{-}NHC_5H_4N)]$.[33] However, the moderate yield of **4** implies that the Au−P bond cleavage probably occurs in the reaction, giving free triphenylphosphane ligands.

The ^1H NMR spectrum of **5** shows that one double doublet and two triplet peaks with an integral ratio of 2:1:2, which corresponds to the 45 phenyl protons, are observed in the aromatic region. The protons are differentiated into *ortho*-, *meta*-, and *para*-phenyl protons according to their coupling patterns and integral values. A broad signal is found in the hydride region; therefore, variable-temperature ^1H NMR spectroscopic studies were carried out for **5**. At 223 K, the broad signal was resolved into three sharp singlet peaks with equal integral values. The ^{31}P NMR spectrum of **5** exhibits a singlet peak attributable to the three equivalent $\{AuPPh_3\}$ ligands.

To the best of our knowledge, cluster **5** is the first example of a cluster with an Os_4Au_3 metal core. The X-ray analysis shows that the gold atoms are terminally coordinated to one of the vertices of the tetraosmium tetrahedron and bonded with each other by Au−Au bonds to form another tetrahedron [Au(1), Au(2), Au(3), and Os(1)] (Figure 4). The Au−Au bond lengths lie in the range of 2.796(3)−2.860(2) Å, which is significantly shorter than the values that were observed in **4**. The two tetrahedrons are fused together by sharing the central Os(1) atom, which has the highest metal−metal connectivity, with three Os−Os contacts and three Os−Au contacts. This kind of coordination mode is rare and significantly different from the metal core arrangement observed in $[Ru_4Au_3(\mu_3\text{-}H)(CO)_{12}(PPh_3)_3]$.[34] The dihedral angle between the planes Os(1)−Os(2)−Os(4) and Os(1)−Au(1)−Au(2) is 79.3°, while the angle of Au(3)−Os(1)−Os(3) is 148.0°. It seems that the tetrahedrons bend towards each other. In terms of electron counting, each Au atom is simply considered as a one-electron donor, and the tangential gold−gold interactions are ignored. Overall, the molecule of **5** has 60 cluster valence electrons, and is isoelectronic with $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ in the neutral oxidation state. It is surprising that **5** was not observed in the deprotonation reactions of **1**−**4**. It is reasonable to believe that the presence of the

bridging $\{AuPPh_3\}$ ligand in **1**−**4** probably makes the reaction unfavorable; an extra amount of energy is required to break the Os−Au bonds before the formation of **5**.

Cluster **6** exhibits aromatic ^1H NMR signals that are similar to those of **5**. Variable-temperature ^1H NMR studies were conducted for **6** at 223 K, the broad hydride peak was resolved into two sets of two sharp singlets, which correspond to the isomers of **6** in solution, named **6a** and **6b**, due to the disposition of hydrides. Three possible isomers of **6** are shown in Figure 5. It suggests that the ^1H NMR signal of the hydrido bridge on the Os*−Os bond is slightly different from the bridge on the Os−Os bond, where Os* is more electron-rich. The hydride ions of **6a** are most likely arranged in type C which gives relatively separated ^1H NMR signals at $\delta = -18.97$ and -14.52 ppm. Since the hydride signals of **6b** are relatively downfield and have a similar chemical shift, it is probably attributed to a type A isomer. Similarly, the fluxional behavior of $\{AuPPh_3\}$ ligands was also identified in the ^{31}P NMR spectrum of **6** at room temperature. The broad signal was resolved into eight singlet signals of equal intensity in the low-temperature ^{31}P NMR spectrum at 233 K, which is consistent with the existence of **6a** and **6b**.

The molecular structure of **6** is depicted in Figure 6. Similarly, the metal framework consists of a tetraosmium tetrahedron, and the Au(3) atom asymmetrically bridges the Os(1)−Os(2) edge. The other three gold atoms are terminally bonded to Os(1), and bonded with each other by Au−Au bonds to give a trigonal bipyramid that is defined by the atoms [Os(1), Au(1), Au(2), Au(3), and Au(4)]. The Au−Au bond lengths are observed in the range of 2.804(2)−3.069(2) Å, and are similar to the equivalent values observed in $[Os_4(\mu\text{-}H)_2(CO)_{11}\{Au_2(dppm)\}_2]$. As a result, the metal framework may be viewed as a tetrahedron fused with a trigonal bipyramid by sharing the Os(1) atom and connected by the Os(1)−Au(3) bond. The novel metal core geometry of **6** is significantly different from the arrangement observed in $[Os_4(\mu\text{-}H)_2(CO)_{11}Au_2(dppm)_2]$. The Os(1) atom has the highest metal−metal connectivity, with three Os−Os contacts and four Os−Au contacts. An overall of 60 cluster valence electrons is also observed in **6**.

Electrochemistry

The electrochemistry of **1**−**6** and the starting materials $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ and $[N(PPh_3)_2][Os_4(\mu\text{-}H)_3(CO)_{12}]$ were investigated in acetonitrile using cyclic voltammetry and controlled potential coulometry with tetrabutylammonium hexafluorophosphate (TBAHFP) as the supporting electrolyte. The results of the voltammetric and controlled potential coulometry experiments are summarized in Table 1.

The cyclic voltammogram of **1** contains two irreversible anodic waves with a large potential difference between the
