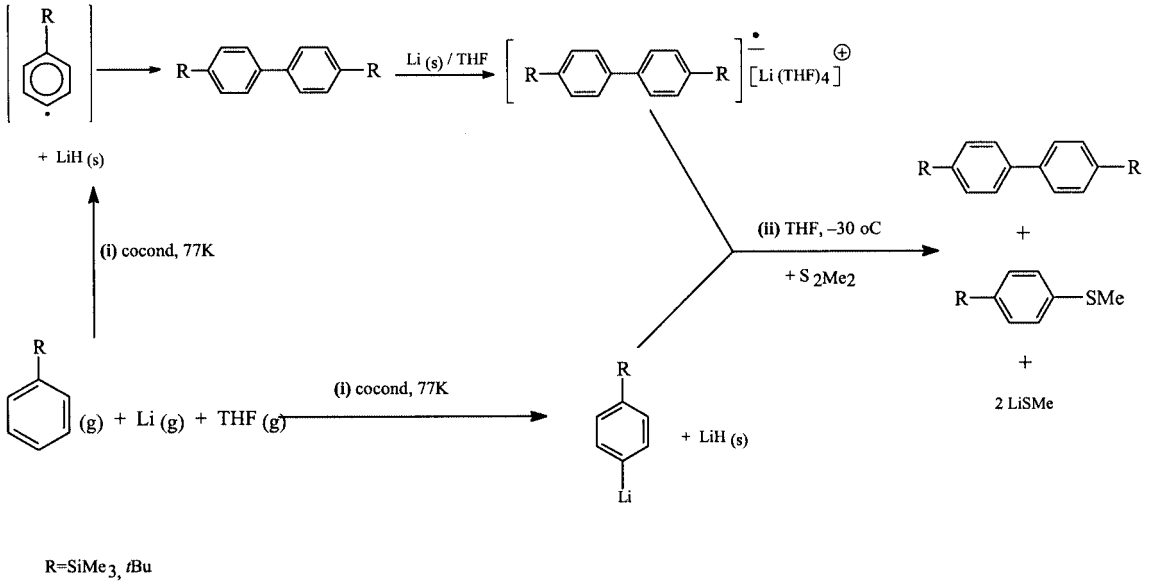
When the sulfur donor thioanisole was used, a different reaction occurred, resulting in a cleavage of the C−S bond instead of C−H bond activation. This time the major product was diphenyl disulfide as shown in Scheme 4. When the co-condensation product was washed with pentane, it yielded a white air-sensitive product. This was shown to be MeLi by treating it with benzaldehyde to produce 1-phenylethanol upon an aqueous work up (as outlined in Scheme 4). When the pentane solution was treated with chlorotrimethylsilane (Scheme 4), the lithiated product identified by NMR spectroscopy and GC MS measurements was shown to be trimethyl(phenylsulfanyl)silane.[19]

Changing the donor substituent to a nitrogen donor like *N*,*N*-dimethylaniline resulted in the formation of 2-(dimethylamino)phenyllithium as identified by NMR spectroscopy in a low yield of 1% as shown in Scheme 3. In the ^{13}C NMR spectrum in C_6D_6 an *ipso* carbon signal $\delta = 171.6$ ppm, in conjunction with the integration of the ^{1}H NMR peaks indicates a tetrameric structure with four coordinated THF molecules resulting in a species of the composition $Ar_4Li_4{\cdot}THF_4$. It was not possible to determine if the dimethylaniline group was intramolecularly coordinated to Li from the NMR spectroscopic data. The reaction of 2-(dimethylamino)phenyllithium with S_2Me_2 resulted in the formation of dimethyl[(2-methylsulfanyl)phenyl]amine, thus confirming that the regiochemistry is *ortho* to the NMe_2.[20,21]

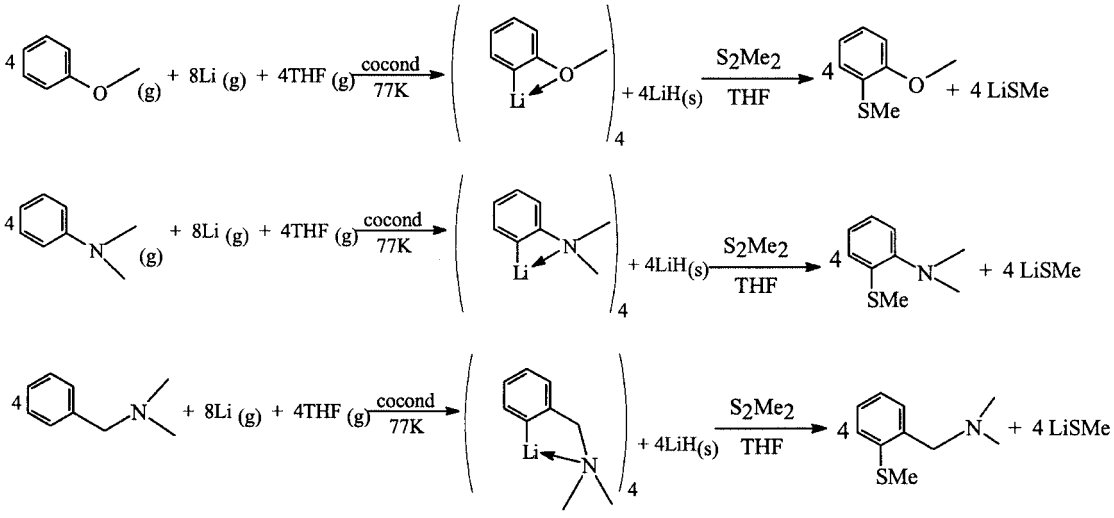
When *N*,*N*-benzylamine was co-condensed with lithium atoms and THF, it yielded a pyrophoric beige solid in 36% yield that was only sparingly soluble in aromatic solvents. NMR spectroscopy in C_6D_6 confirmed the *ortho* activation and the formation of 2-[(dimethylamino)methyl]phenyllithium.[21,22] Examination of the NMR spectroscopic data indicates a tetrameric structure of the composition Ar_4Li_4 in benzene, with no coordinated THF being present as outlined in Scheme 3. The reaction of 2-[(dimethylamino)methyl]phenyllithium with Me_2S_2 confirmed the regiochemistry as being *ortho* to the benzyl group. The isolated product was identified as dimethyl[2-(methylsulfanyl)benzyl]amine by GC-MS and NMR spectroscopic techniques as shown in Scheme 3.[23]

Theoretical Study

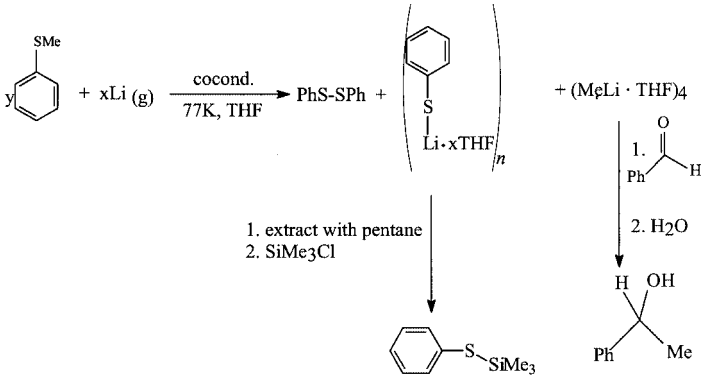
The previously reported mechanism for the reaction of lithium atoms with benzene was performed at the



Scheme 2. The reductive coupling of +I-substituted benzene derivatives by lithium atoms



Scheme 3. Reaction of donor-substituted aromatic compounds with lithium atoms in THF



Scheme 4. Co-condensation of lithium atoms with thioanisole in the presence of THF

Hartree−Fock level of theory.[9,10] We report here the recalculation of the key intermediates for this benzene co-condensation, using a DFT method, B3LYP, and the expansion of this mechanism to include other +I- and donor-substituted benzene derivatives. In the benzene system a similar trend is seen using the B3LYP/6-31G** method as was reported earlier.[9,10] The first step of the reaction, the formation of a π-complex (**1a**), resulted in a calculated reaction enthalpy of −8.2 kcal/mol. This is larger than the previously reported value (HF/6-31G**) of −5.9 kcal/mol.[10] The next step is a double electron transfer via the aromatic system, resulting in the insertion of the Li_2 cluster into the C−H bond (the formation of **1b**). This was calculated to be −15.8 kcal/mol. This is also larger than the previously calculated value of −8.0 kcal/mol.[10] These reaction enthalpies are outlined in Figure 2.

The calculated reaction enthalpies shown in Figure 2 for the intermediate species, from the reaction involving toluene with lithium atoms, agreed with the proposed mechanism reported earlier.[9,10] From these calculations it can be seen that the Li_2 cluster forms a π-complex (**1c**) with toluene resulting in a reaction enthalpy of −9.1 kcal/mol. This is larger than in the benzene experiment (−8.2 kcal/mol). The intermediate **1c** then undergoes a double electron transfer via the aromatic system in an exothermic step of −15.0 kcal/mol. However, this enthalpy is slightly lower in energy than that of the benzene system (−15.8 kcal/mol). In the resultant species **1d** the Li_2 cluster has inserted into the *para* C−H bond. When the CH_3 group of toluene was replaced by a *tert*-butyl group as in *tert*-butylbenzene, an identical series of reaction enthalpies was found.

When the aromatic compound is trimethyl(phenyl)silane, the energies for each step in the mechanism change slightly as described in Figure 2. For the first step, the coordination of the lithium cluster to the aromatic system to form the π-complex **1e**, the reaction enthalpy is −8.6 kcal/mol. This value is larger than it is in the benzene system but lower than it is for toluene or *tert*-butylbenzene. The second step, which is the formation of the insertion product **1f**, has a reaction enthalpy of −15.4 kcal/mol. This is larger than the reaction enthalpies for the benzene and toluene/*tert*-butylbenzene systems.

When *p*-xylene is used, the energies for each step in the mechanism also differ slightly compared to the previous cases. For the first step, the formation of **1i**, the reaction enthalpy (−9.8 kcal/mol) is the most exothermic of the +I-substituted benzene derivatives. The second step, the formation of **1j** is the lowest of the reaction enthalpies (−14.6 kcal/mol) of all the +I-substituted benzene derivatives.

When the substituent on the aromatic ring is a Lewis base (e.g. O, N, P, S donors) the reaction pathway is more complicated. Now there are two possibilities for coordination of the lithium cluster as shown in Figure 3. The first possibility is the formation of a π-complex (**2a**), as in the previous compounds (**1a**−**1j**). The second possibility is coordination of the Li_2 cluster to the donor moiety in an η^1-fashion (**2b**). When an oxygen donor is involved, e.g. anisole, the preferred pathway is via the η^1 complex. The energy difference between complex **2a** and **2b** is −2.6 kcal/mol, showing that the η^1 complex **2b** is more stable than the π-complex. As in the previous mechanism the next step is a double single-electron transfer step from the Li_2 cluster to the LUMO of the aromatic ring. However, for the anisole co-condensation this step has a larger reaction enthalpy of −24.7 kcal/mol, compared with the +I-substituted derivatives shown in Figure 2. In the η^1 species **2b** there is an agostic interaction between the *ortho* C−H bond and the coordinated Li_2 cluster, with an Li−H distance of 2.586 Å as detailed in Table 1. This explains the experimentally observed *ortho* activation of the C−H bond.

If the donor atom is changed from an oxygen to a nitrogen donor, for example *N*,*N*-dimethylbenzylamine as outlined in Figure 4, the formation energy for **3b**, the η^1-coordinated Li_2 species, is −15.5 kcal/mol, while for the π-com-

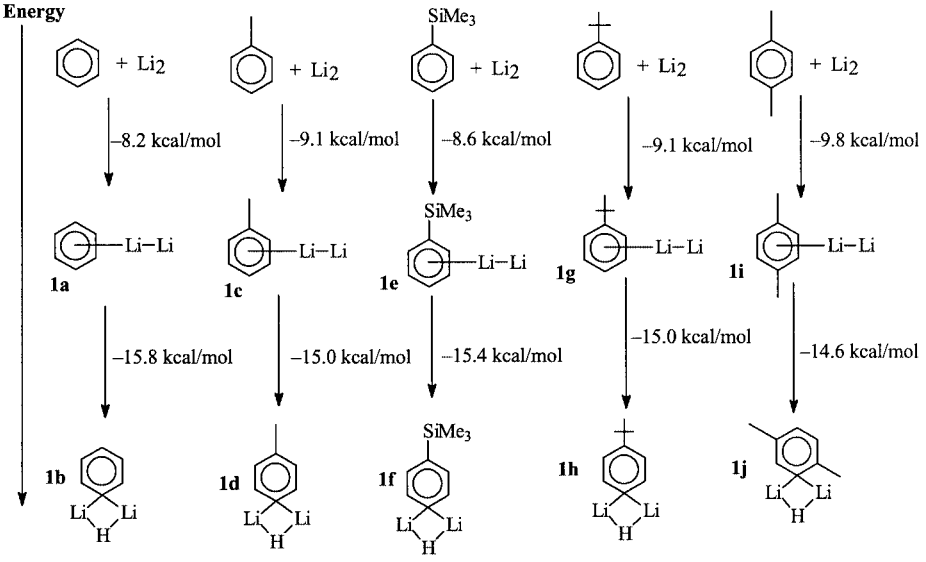


Figure 2. Calculated reaction enthalpies for +I-substituted benzene derivatives and Li_2

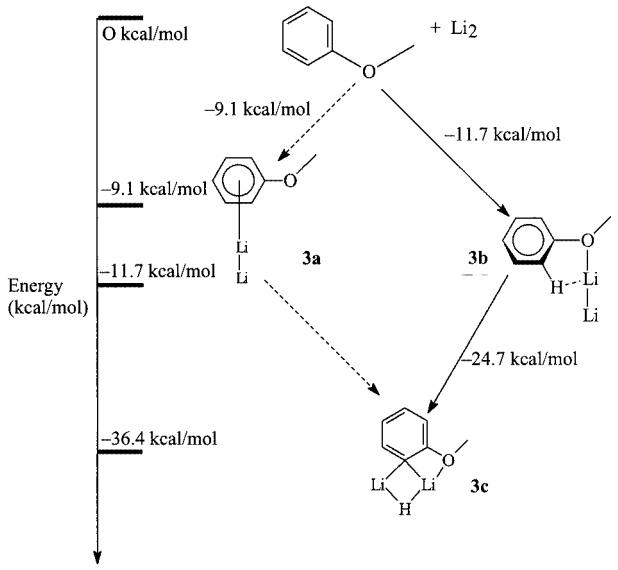

Figure 3. Calculated reaction mechanism for the co-condensation of lithium atoms with anisole

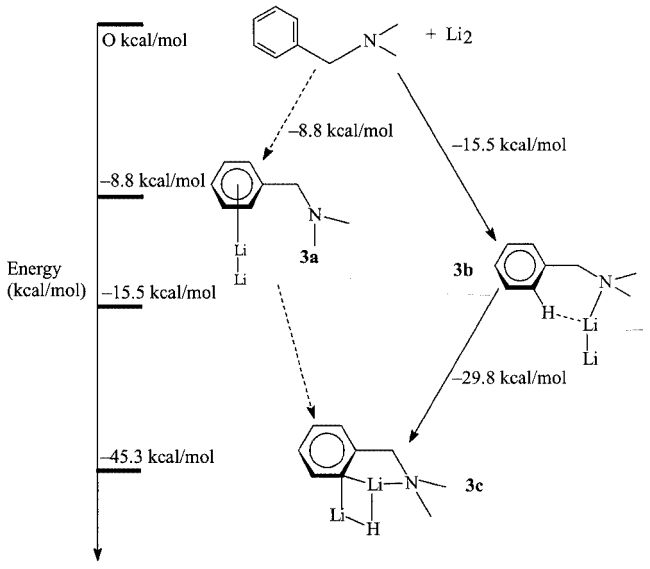

Figure 4. Calculated reaction mechanism for the co-condensation of lithium atoms with benzylamine

Table 1. Agostic H_{ortho}–Li interaction in η^1 complexes

	Li_a–H_{ortho} [Å]
Anisole	2.586
N,*N*-Dimethylaniline	2.777
N,*N*-Dimethylbenzylamine	2.669
Thioanisole	3.001
Dimethylphenylphosphane	3.109

plex **3a** the reaction enthalpy (−8.8 kcal/mol) is less exothermic. It is clear from this difference of −6.7 kcal/mol that the preferred pathway is by coordination to the donor moiety. As in the anisole case the energy for the insertion of the Li_2 cluster into the C−H bond (**3c**) is higher (at −23.1 kcal/mol) than via the π-complex types listed in Figure 2. In the calculated structure **3b** there is also an agostic-type interaction between the *ortho* C−H bond and the coordinated Li_2 cluster as detailed in Table 1. However, in this case the Li−H distance is longer (2.669 Å) than it is in the anisole species **2b** (2.586 Å).

A different preference is seen when the N-donor is *N*,*N*-dimethylaniline. In this reaction there is no clear preference between the η^1-coordination mode (**4b**) and the formation of a π-complex (**4a**) as shown in Figure 5. The difference in energy between these two species is small (−0.8 kcal/mol) and is in favour of an η^1 complex (**4b**). As in the previous two systems, there is an interaction between the *ortho* C−H bond and the coordinated Li_2 cluster **4b** with a long Li−H interaction of 2.777 Å compared to 2.586 Å in the anisole example **2b** (outlined in Table 1). The energy for the insertion into the *ortho* C−H bond of the aromatic ring is −21.9 kcal/mol, which is lower than it is in the other donor species (anisole and *N*,*N*-dimethylbenzylamine).

For soft donor atoms like phosphorus and sulfur, as defined by the Pearson concept, we see a different trend, outlined in Figure 6. When a similar theoretical study is performed on a phosphorus donor like dimethylphenylphosphane, the η^1-coordination mode (**5b**) is preferred over a π-complex (**5a**) with a calculated energy difference of −1.6 kcal/mol (shown in Figure 6). Unlike previous examples outlined above, there is no interaction between the *ortho* C−H bond and the coordinated Li_2 cluster as shown in Table 1. This can be seen from an extremely long Li−H distance of 3.109 Å. The reaction enthalpy for the insertion of the Li_2 into the C−H bond is −20.6 kcal/mol. This is smaller (compared to −21.9 kcal/mol and −24.7 kcal/mol

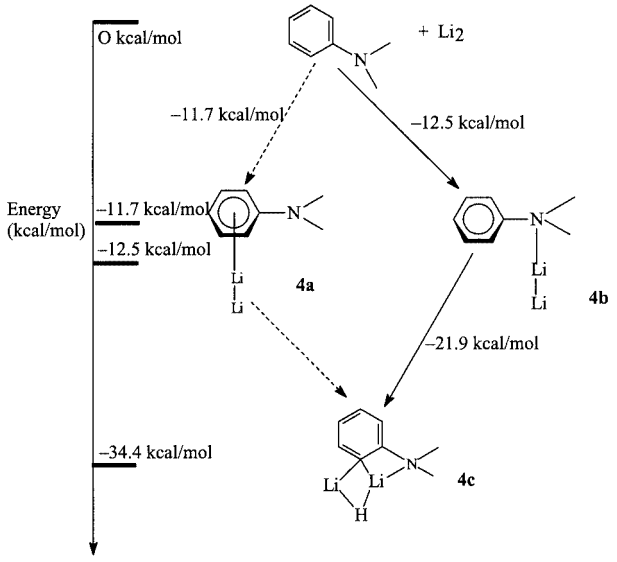

Figure 5. Calculated reaction mechanism for the co-condensation of lithium atoms with *N*,*N*-dimethylaniline

for the anisole system) than the other reaction enthalpies for this step.

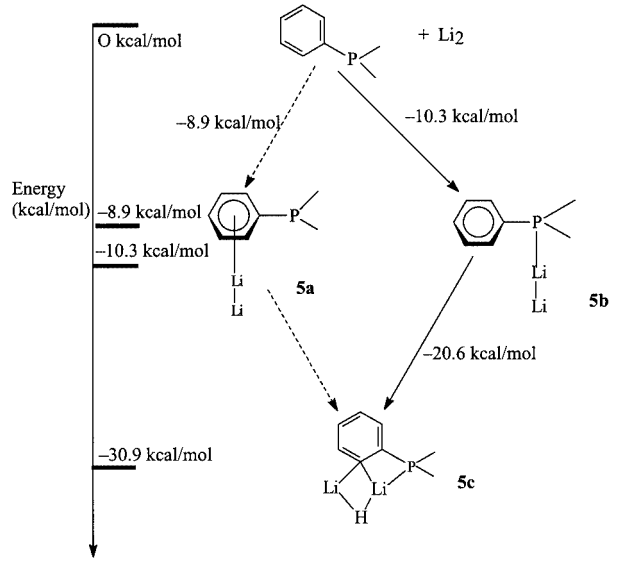

Figure 6. Calculated reaction mechanism for the co-condensation of lithium atoms with dimethylphenylphosphane

However, when the same calculation is performed on a sulfur donor like thioanisole, the situation changes. This time there is no favoured pathway, with the π-complex **6a** being just 0.1 kcal/mol lower in energy than the η^1-species **6b** as shown in Figure 7. Again there is no interaction between the *ortho* C−H bond and the η^1-coordinated Li_2 cluster. In this species the $Li-H_{agostic}$ distance is longer (3.001 Å) than it is in the corresponding η^1 complexes with oxygen and nitrogen donor substituents as outlined in Table 1. However the Li−S distance of 2.452 Å is significantly larger than in the anisole species (Li−O distance of 1.948 Å). This is a clear indication of weaker bonding due to the unfavourable hard/soft donor interaction. When a single electron is placed onto the free thioanisole there is a substantial elongation of the S−Me bond from 1.821 to 1.993 Å and the S−Ph bond length decreases from 1.785 to 1.739 Å. It was possible to predict the experimental observed C−S bond activation from this calculation.

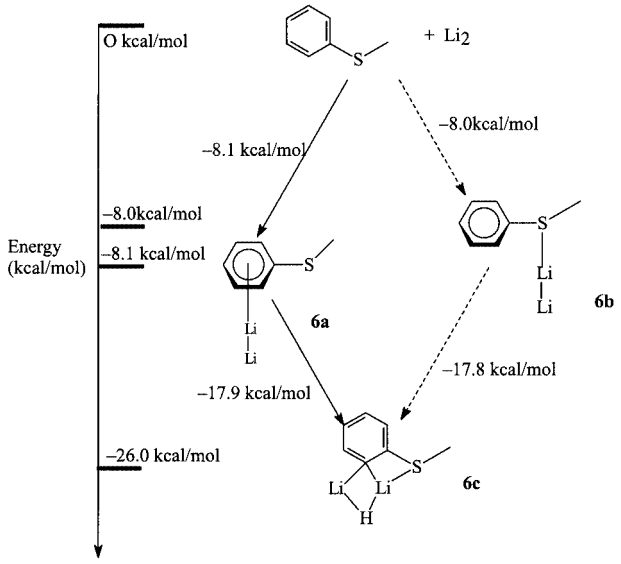

Figure 7. Calculated reaction mechanism for the co-condensation of lithium atoms with thioanisole

Discussion

Previous research in this area showed that toluene reacted with lithium atoms in the presence of THF under co-condensation conditions. The thermodynamic product benzyllithium was not formed; however, the isolated compound was identified as *p*-tolyllithium.[9,10] This interested us in the examination of the effect that other +I substituents have on the reaction. A delicate balance between +I enhancing complex formation ability and LUMO energy, allowing reductive cleavage of the aromatic C−H bond, is needed for successful C−H activation.

The electron-deficient Li_2 cluster **1** as shown in Scheme 5, will accept electron density from the aromatic system to form an unusual main group element π-complex (**2**). When the substituent on the aromatic ring donates electron density to the π-system (the +I effect), the interaction with the lithium cluster will strengthen. This can be observed by the decrease in the calculated Li−C and Li−Li bond lengths shown in Tables 2 and 3. For example in the case of toluene the Li−C distance decreases to 2.610 Å, while for mesitylene the Li−C distance is 2.591 Å compared with the longer Li−C of 2.626 Å for the benzene system. This means that there will be a stronger interaction between the aromatic rings of the +I-substituted benzene derivatives [for example xylene, *tert*-butylbenzene, mesitylene, and trimethyl(phenyl)silane] than benzene. However, the next mechanistic step is crucial. This involves the double single-elec-

Dimethylphenylphosphane	2.782	2.769	2.293	

tron transfer from the π-bonded Li_2 cluster **3** to the LUMO of the aromatic ring. The outcome of the reaction depends on how the substituents affect the LUMO, and not its +I ability. If the LUMO energy is increased in relation to toluene and benzene, as it is for mesitylene and xylene (as outlined in Table 4), it is impossible to place electron density into it, thereby preventing the reaction from occurring. This can be seen from the lack of reaction between lithium atoms and xylene or mesitylene (as described in Scheme 1). If the substituent lowers the LUMO energy, as for trimethyl(phenyl)silane and *tert*-butylbenzene (as shown in Table 4) the reaction will proceed quite readily. If the LUMO energy of the aromatic ring is lowered too much, a single electron reduction of the aromatic compound to its stable radical anion will occur instead of C−H bond activation.

Table 4. Calculated LUMO energies of selected reactants using B3LYP/6-31G**

	LUMO [eV]
N,*N*-Dimethylaniline	0.387
Mesitylene	0.261

Thioanisole	−0.041
Trimethyl(phenyl)silane	−0.180
4,4′-Di-*tert*-butylbiphenyl	−0.579
4,4′-Bis(trimethylsilanyl)biphenyl	−0.898

For the reaction of trimethyl(phenyl)silane with lithium atoms in the presence of THF, a reaction sequence different from the toluene co-condensation was observed. This is governed by the ability of the $SiMe_3$ group to stabilise an aromatic radical. The major product identified was 4,4′-bis-(trimethylsilanyl)biphenyl. This is the coupled product of the free phenyltrimethylsilyl radical. This indicates that a reduction of trimethyl(phenyl)silane occurs at 77 K, which then couples to form the substituted biphenyl derivative as outlined in Scheme 2. In this case the $SiMe_3$ substituent stabilises the radical long enough to allow it to form the coupled product 4,4′-bis(trimethylsilanyl)biphenyl. On warming in the MVS reactor, excess solid lithium reduces 4,4′-bis(trimethylsilanyl)biphenyl to its radical anion, in an analogous reaction to the reduction in solution of 4,4′-di-*tert*-butylbiphenyl by lithium metal.[14] From the calculated LUMO energies of these two biphenyl species (Table 4) a comparison can be made in relation to the ease of reduction of 4,4′-bis(trimethylsilanyl)biphenyl. The calculated LUMO energies for 4,4′-di-*tert*-butylbiphenyl is −0.579 eV, while 4,4′-bis(trimethylsilanyl)biphenyl has a lower LUMO energy of −0.898 eV. This shows that the reduction of 4,4′-bis(trimethylsilanyl)biphenyl by lithium metal can readily occur in THF solution.

However, a secondary C−H activated product was also identified. This was the *para*-lithiated aromatic 4-(trimethylsilyl)phenyllithium. It could not be identified in solution but treating this species with S_2Me_2 to form trimethyl[4-(methylsulfanyl)phenyl]silane, allowed a further full characterisation of the substitution pattern on the ring as outlined in Scheme 2.

The co-condensation of *tert*-butylbenzene and lithium atoms in the presence of THF was similar to the reaction involving trimethyl(phenyl)silane (as detailed in Scheme 2). The major product was found to be 4,4′-di-*tert*-butylbiphenyl. This is formed from the coupling of the *tert*-butylphenyl radical. On warming in the MVS machine it is believed that 4,4′-di-*tert*-butylbiphenyl is reduced by solid lithium metal to its radical anion. Because of this no direct NMR spectroscopy was attempted, instead the co-condensation product was treated with S_2Me_2. A minor product was observed to be *tert*-butyl-4-(methylsulfanyl)benzene, this corresponds to a secondary reaction occurring at 77 K, the activation of the *para* C−H bond of *tert*-butylbenzene.

When a Lewis base function is used, the +I inductive effect versus LUMO effect is no longer important, because the favoured donation mode to the Li_2 cluster is now via the η^1-coordination mode through the donor moiety as shown by a series of DFT calculations described in Figures 3−7. This mode of bonding is energetically favoured over the formation of a π-complex with the Li_2 cluster. Due to this change in the coordination mode, a change

in regiochemistry occurs, resulting in *ortho* C−H bond activation.

When an oxygen donor was used as in the case of anisole, the NMR spectroscopic data, which is in good agreement with the literature data,[16] showed an *ortho*-lithiated product. NMR spectroscopic data indicate a tetrameric structure of the composition Ar_4Li_4. In contrast to the benzene and toluene experiments reported previously,[9,10] the yield was increased to 30% from 12%, which is extremely high for an MVS experiment. As in the trimethyl(phenyl)silane co-condensation, treating it with dimethyl disulfide as outlined in Scheme 3, allowed a further characterisation of the lithiated product. This reaction confirms the *ortho* lithiation by the formation of 1-methoxy-2-(methylsulfanyl)benzene, which was identified from NMR spectroscopic data and GC MS data.[17,18]

When the oxygen donor substituent of anisole is changed to the softer sulfur atom as in thioanisole, a similar result was expected. However, no C−H bond activation was observed, instead NMR spectroscopic data indicated a cleavage of the S−Me bond. This resulted in the formation of the Ph−S˙ radical, which dimerises to form diphenyl disulfide. Secondary products were shown to be $(MeLi{\cdot}THF)_4$ and PhSLi·THF by derivatisation reactions and this is described in Scheme 4. This result is not unexpected since the S−Me bond strength of 69.4 kcal/mol is weaker than that of the C−H bond of 100 kcal/mol. The selectivity for the S−C sp^3 bond is due to its lower bond strength compared with the S−Ph sp^2 bond of 86.5 kcal/mol.[24]

When the donor substituent was a nitrogen donor as in *N*,*N*-dimethylaniline, the observed product was 2-(dimethylamino)phenyllithium (as outlined in Scheme 3). This reaction type is similar to the anisole case, but with a much lower yield of 1%. This is possibly due to the high LUMO energy (0.387 eV) of the *N*,*N*-dimethylaniline, as described in Table 4. This reaction is surprising since some +I-substituted aromatic compounds like mesitylene and xylenes, which have lower LUMO energies, do not react with lithium atoms. Presumably, the change in coordination mode to η^1 facilitates this reaction.

In an ether solution *N*,*N*-dimethylbenzylamine is known to react with BuLi to form 2-[(dimethylamino)methyl]phenyllithium. The factors controlling the selectivity are not well investigated.[20,21] It is reported as being tetrameric (Ar_4Li_4) in the solid state with the NMe_2 group intramoleculary coordinated to Li, while in THF solution it is dimeric with the composition $Ar_2Li_2{\cdot}4THF$. When benzylamine is co-condensed with lithium atoms and THF as outlined in Scheme 3, a pyrophoric beige solid is obtained in a larger yield (36%) than in the *N*,*N*-dimethylaniline experiment (1%). ^1H and ^{13}C NMR spectroscopic data show the presence of 2-[(dimethylamino)methyl]phenyllithium with no coordinated THF. This composition is in agreement with the published solid-state structure.[21] No activation was detected in the benzyl position. Confirmation of the regiochemistry was obtained as in previous co-condensations by the reaction with S_2Me_2.

Conclusion

Lithium atoms are able to activate +I- and donor-substituted benzene derivatives. In the case of +I-aromatic compounds like trimethyl(phenyl)silane and *tert*-butylbenzene, two products were observed, the major product was the coupled biphenyl and the minor product the C−H-activated *para*-lithiated aromatic compound. However, other +I benzene derivatives with higher LUMO energies than toluene, like xylenes and mesitylene, failed to react. It appears that this reaction type has a narrow range based on the LUMO energy of the aromatic compound. When donor substituted benzene derivatives like anisole, *N*,*N*-dimethylaniline, and *N*,*N*-benzylamine were co-condensed with lithium atoms in the presence of THF, *ortho* C−H bond activation was exclusively observed. This results from a mechanistic change from a π-bonded Li_2 cluster via the phenyl ring to a η^1-bonded Li_2 via the donor atom. For this reaction type, the LUMO energy is not as important as in the series of reactions using +I-substituted benzene derivatives. For the co-condensation of thioanisole with lithium atoms in THF, an activation of the C−S bond as well as a reductive coupling of thioanisole was observed.

Experimental Section

General: All experimental procedures were performed using standard Schlenk techniques under dry argon. THF, toluene, *m*-, *p*-xylene, anisole, and *tert*-butylbenzene were dried and distilled from sodium benzophenone ketyl under argon. Trimethyl(phenyl)silane, thioanisole, *N*,*N*-dimethylaniline, *N*,*N*-dimethylbenzylamine were dried and distilled from calcium dihydride under argon. All solvents were then degassed by three freeze-pump-thaw cycles. Celite was stored overnight in an oven at 120 °C and was dried under vacuum for 3 h before use. For each filtration layers of approximately 6 cm of Celite were used. ^1H and ^{13}C NMR spectra were obtained using either a Varian 300 MHz or a Varian 500 MHz NMR machine. All chemical shifts are reported in ppm and are referenced to TMS. The ^7Li NMR spectra in this study were obtained with a Jeol 300 MHz machine. The chemical shifts for the ^7Li NMR spectra are reported in ppm and are referenced to an internal standard of LiBr in D_2O. All GC MS samples were run as dichloromethane solutions using a Finnigan Trace GC MS, with an RTX-5MS 15-m column.

Typical Co-condensation Experiment: Lithium metal (0.53 g, 0.076 mol) was vapourised from an aluminium crucible protected by a stainless-steel inlet at around 800 °C over 90 min and co-condensed with a mixture of the aromatic compound (20 mL) and THF (80 mL, 1.12 mol). After removal of the solvent mixture, the residue was dissolved in dry toluene and the solution was filtered through Celite from the solid lithium hydride by-product and unreacted lithium metal. After removal of the toluene in vacuo a dark red solid was isolated and washed with dry pentane (20 mL). The lithiated aromatic compound was identified by ^1H and ^{13}C NMR spectroscopy.

Typical Derivatisation of the Lithiated Aromatic Compound with Me_2S_2: Dimethyl disulfide (0.3 mol/L) was added dropwise with vigorous stirring to a solution of of the lithiated aromatic compound (0.25 g) in THF (20 mL) at room temperature. The reaction

was thought to be complete when a colour change from red to yellow occurred. Water (10 mL) was added to this solution and the organic phase separated. The aqueous phase was washed three times with dichloromethane (10 mL). The combined organic extracts were dried with $MgSO_4$ and the solvent was then removed under reduced pressure, affording the derivatised compound as a brown oil. GC MS and ^1H and ^{13}C NMR spectroscopy were used to identify the product.

Theoretical Methods Used in this Study: With a view to determining the structures and reaction enthalpies of intermediates in the reaction mechanism, the application of theoretical methods has proven advantageous. For this purpose the program package used was GAUSSIAN 98[25] implemented on a DEC Alpha work station (500 MHz CPU/256 MB RAM) or an Origin 200 eight-processor cluster (SGI 180 MHz CPU/2 GB RAM). Ab-initio calculations were performed at the DFT level of theory (B3LYP) using the 6-31G** basis set for C, H, O, N, S, P, and Li. Harmonic vibrational frequencies, calculated at the same level, characterised stationary points and gave the zero-point energy. The difference in the sum of the electronic and the zero-point energies were interpreted as reaction enthalpies at 0 K. LUMO energies for each aromatic compound were obtained from geometry-optimised structures using B3LYP/6-31G**.

Macrocyclic Complexes of $[Ru(N\text{-}N)_2]^{2+}$ Units [N-N = 1,10 Phenanthroline or 4-(*p*-Anisyl)-1,10-Phenanthroline]: Synthesis and Photochemical Expulsion Studies

Anne-Chantal Laemmel,[a] Jean-Paul Collin,*[a] Jean-Pierre Sauvage,*[a] Gianluca Accorsi,[b] and Nicola Armaroli*[b]

Keywords: Ruthenium / Macrocycles / Receptors / Photochemistry / Molecular machines

Two ruthenium complexes $[Ru(phen)_2(m\text{-}36)]^{2+}$ and $[Ru(aphen)_2(m\text{-}36)]^{2+}$, indicated as **1** and **2** respectively, which contain a 36-membered macrocycle incorporating a sterically hindered bipyridine (m-36), and two 1,10-phenanthroline (phen) or 4-(*p*-anisyl)-1,10-phenanthroline (aphen) ligands, have been synthesised. Under light irradiation, as seen from the metal-to-ligand-charge-transfer (MLCT) bands of the visible spectral region, the $[Ru(phen)]_2^{2+}$ core of **1** and **2** is selectively expelled from the macrocycle to give the corresponding bis-acetonitrile derivative. This photochemical process was found to be notably less efficient than that observed in a simpler related complex $[Ru(phen)_2dmbp]^{2+}$ (dmbp = 6,6′dimethyl-2,2′-bipyridine), that lacks the macrocyclic motif. In the case of **1** thermal back reaction takes place quantitatively affording a completely reversible system. The isolation, by chromatographic techniques, of the axial-axial *cis*-$[(a,a)Ru(aphen)_2Cl_2]$ isomer, where the two aphen ligands bear two *p*-anisyl groups disposed trans to one another enabled the preparation of **2**. This type of complex undergoes a more complicated photochemical process, in fact, following the expected photolabilisation of the $[Ru(aphen)_2]^{2+}$ unit, photoisomerisation of the primary photo-product occurs and gives a statistical mixture of the three geometrical isomers: *cis*-$[(a,a)Ru(aphen)_2(CH_3CN)_2](PF_6)_2$, *cis*-$[(a,e)Ru(aphen)_2(CH_3CN)_2](PF_6)_2$ and *cis*-$[(e,e)Ru(aphen)_2(CH_3CN)_2](PF_6)_2$. This side-reaction precludes its use as rotaxane precursor suggesting that, for this purpose, a bis-phenanthroline ligand stabilising the ruthenium core is needed.

Introduction

The accessibility to rotaxanes and catenanes by strategies based on various template effects allowed their involvement in different research fields such as photo-induced energy and electron transfer or molecular machines.[1] The presence of mechanical bonds, an intrinsic property of such species, should confer good reversibility to systems designed for specific tasks related to large amplitude movements. The control of molecular motion for example is an essential function in artificial[2] as well as in biological systems[3] (ATPsynthase, myosin-actin, etc.).Very often, motions in the molecules or molecular assemblies have been triggered by chemical[4] or electrochemical signals.[5] Relatively few systems rely on *purely photonic* input.[6] We now report on a transition metal light-driven system based on dissociative photoexcited states. Ru^{II} complexes of the $[Ru(diimine)_3]^{2+}$ family (diimine = bidentate ligand) seem to be promising in building light-driven machines, since the use of a sterically hindered chelate (e.g. a 6,6′ substituted bipy) associated with a $[Ru(phen)_2]^{2+}$ core (phen = 1,10-phenanthroline) leads to the specific and quantitative photolabilisation of the chelate.[7] Indeed, excitation into the absorption bands of Ru^{II}-polyimine complexes corresponding to the singlet metal-to-ligand-charge-transfer transitions (^{1}MLCT) is followed by intersystem crossing to the lowest-lying triplet level (^{3}MLCT) which, by thermal redistribution, may populate upper-lying dissociative d-d metal centred (MC) states.[8] The MC/MLCT energy gap is small and the thermal deactivation of the ^{3}MLCT state is particularly effective when the ligand field is weakened by distortions due to the sterically hindering ligands. A recent communication described a system constituted by a $[Ru(phen)_2]^{2+}$-type fragment hosted in a macrocyclic receptor.[9] The present article extends this previous example to a possible rotaxane precursor and evidences the limitations brought by a competitive photoisomerisation reaction. Figure 1 displays the basis of the photochemical expulsion of the ruthenium unit from a macrocycle and its thermal back re-coordination.

Results and Discussion

The ruthenium complexes $[Ru(phen)_2(m\text{-}36)]^{2+}$ (**1**) and $[Ru(aphen)_2(m\text{-}36)]^{2+}$ (**2**) [see a) in Figure 2] in which a bipyridine unit is incorporated in a macrocycle have been synthesised as possible rotaxane precursors. Indeed, the re-

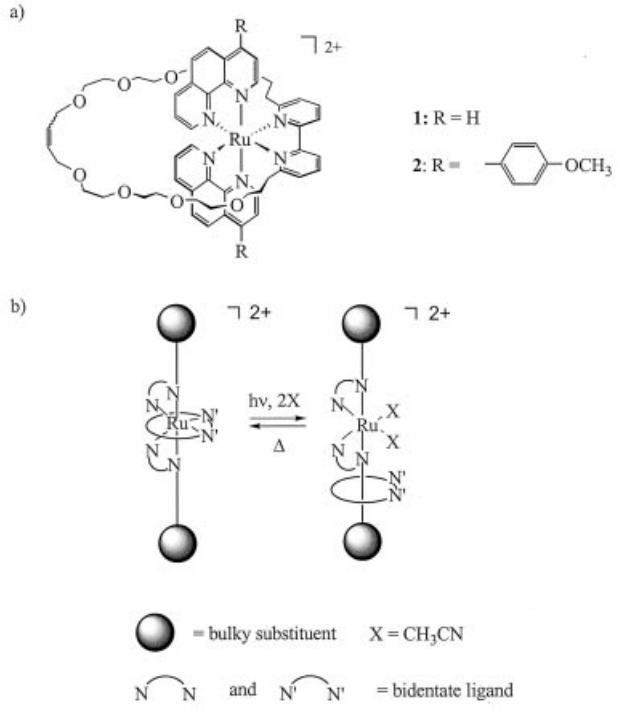

Figure 2. (a) Chemical structures of complexes **1** and **2**. (b) Possible photochemical reaction leading to a rotaxane if bulky stoppers are attached in the 4 positions

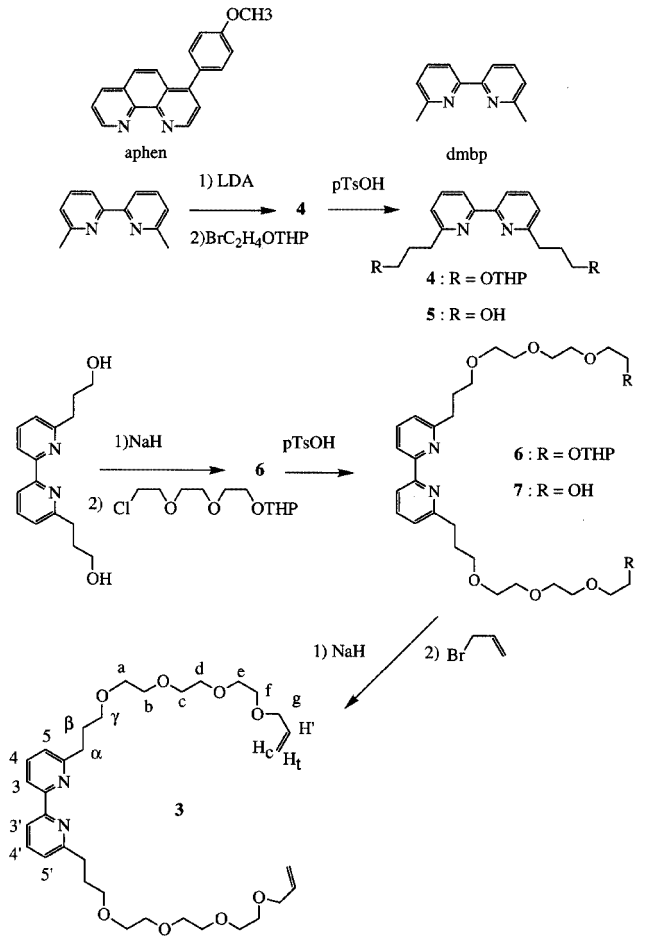
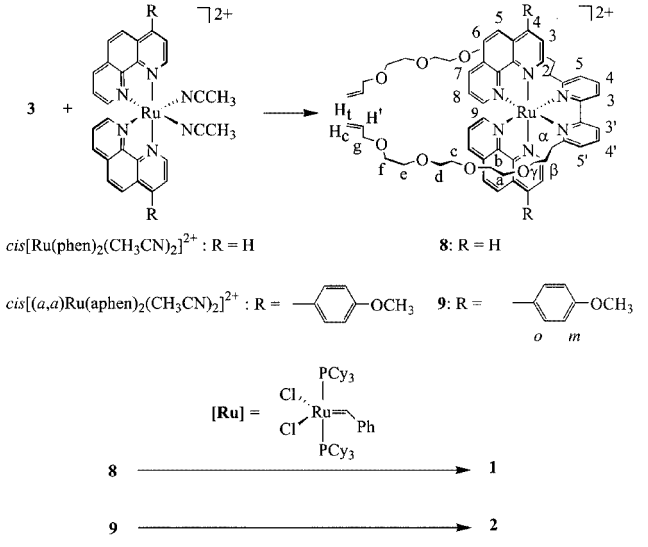
placement of the R group by bulky substituents and the photosubstitution of the bipyridine-based macrocycle by two molecules of solvent (CH_3CN) could lead to a real rotaxane as depicted in Figure 2, b). The synthesis of **1** and **2** is accomplished by applying the strategy of threading or clipping.

In this latter strategy the complexation of an appropriate bipyridine derivative bearing terminal olefins (**3**) precedes the closure of the macrocycle (Scheme 1 and 2).

The 2,2′-bipyridine ligand **3** substituted at its 6 and 6′ positions by two long chains terminated by olefinic groups was prepared in five steps from the 6,6′-dimethyl-2,2′-bipyridine (dmbp).[10] By deprotonation of dmbp with LDA in THF and reaction with two equivalents of THP-protected bromoethanol (THP = tetrahydropyran-2-yl) **4** was obtained in 63% yield. Deprotection of **4** afforded **5** in 70% yield. This alcohol was converted into **6** following the Williamson methodology (NaH/DME) by reaction with 2-{2-[2-(2-chloroethoxy)ethoxy)]ethoxy}tetrahydro-2*H*-pyran (53% yield). Deprotection with catalytic amounts of *para*-



Scheme 1



Scheme 2

toluenesulfonic acid (*p*TsOH) in ethanol led to the corresponding diol **7** in good yield (84%). The conversion of **7** to ligand **3** bearing terminal olefins was achieved with a large excess of allyl bromide in the presence of NaH in DME (75% yield).

It was recently shown that *cis*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$ is a more efficient starting material than the classical bis-chloro derivative *cis*-$[Ru(phen)_2Cl_2]$ for introducing a third chelate onto the ruthenium centre.[11] Good yields of **8** were obtained by heating a stoichiometric mixture of *cis*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$ [12] and **3** in ethylene glycol at 140 °C for 2 h. After column chromatography and anion exchange with PF_6^-, **8** was recovered as a red powder. The preparation of the analogous precursor **9** requires the isomeric form *cis*-$[(a,a)Ru(aphen)_2(CH_3CN)_2](PF_6)_2$ as the axle of the rotaxane (see b in Figure 2). It is itself obtained by solvolysis of the dichloride derivative *cis*-$[(a,a)Ru(aphen)_2Cl_2]$ (Figure 3).

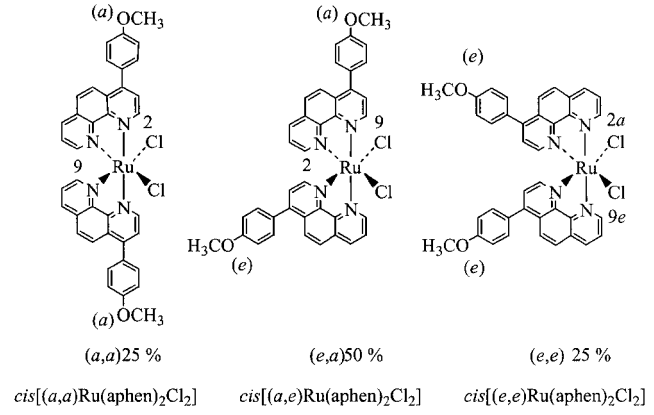


Figure 3. Schematic view of the isomeric complexes for the general species *cis*-$[Ru(aphen)_2Cl_2]^{2+}$ (*a* for axial, *e* for equatorial)

The use of an unsymmetrical ligand such as 4-(*p*-anisyl)-1,10-phenanthroline (aphen) is a challenging task since stereo- and geometric isomers are expected. The sequential addition of different bidentate polypyridyl ligands onto the ruthenium centre is actually described in the literature but several attempts following these methodologies failed.[13,14] Recently, $[Ru(CH_3CN)_4Cl_2]$ was used by von Zelewsky et al.[15] to prepare ruthenium bis-chloro complexes with a bis-bidentate ligand (chiragen). With this starting material and two equivalents of aphen a statistical mixture of three isomers as represented in Figure 3 was recovered in 46% yield. The separation of the geometric isomer *cis*-$[(a,a)Ru(aphen)_2Cl_2]$ from the mixture turned out to be possible on silica columns and on numerous acidic alumina columns with a yield of 87% being obtained. The identification of each isomer was made possible by analysing their ^1H NMR spectra (COSY and ROESY experiments). On heating the *cis*-$[(a,a)Ru(aphen)_2Cl_2]$ isomer in a CH_3CN/H_2O (50:50) mixture the bis-acetonitrile derivative *cis*-$[(a,a)Ru(aphen)_2(CH_3CN)_2]$ was isolated as a single isomer proving that no isomerisation occurs under these conditions. The reaction of ligand **7** with the complex *cis*-$[(a,a)Ru(aphen)_2(CH_3CN)_2](PF_6)_2$ gave the precursor complex **9** in 90% yield.

The cyclisation of the two terminal olefinic functions following the method developed by Grubbs et al.[16] (ring closing metathesis or RCM) turned out to be efficient. This method is compatible with a large variety of functions and has also been proved to be well suited to the synthesis of catenanes and molecular knots.[17] By using a relatively high concentration of the precursor complexes **8** and **9** (0.01 M, CH_2Cl_2 solution) and 7% of the ruthenium complex [Ru] (Scheme 2) as a catalyst the targeted complexes **1** and **2** were obtained in 67 and 45% yield, respectively. The progress of the cyclisation reactions can be monitored by the disappearance of the characteristic ^1H NMR signals of the terminal olefins and the concomitant appearance of signals corresponding to the cyclic olefin in its *cis* and *trans* isomeric forms. The electronic and mass spectra (FAB-MS) as well as the assignment of their ^1H NMR spectra (ROESY experiments) confirm the expected structures of **1** and **2**.

Upon irradiation at 404 nm (isosbestic point, see below) of an acetonitrile solution of **1**, a photochemical reaction is triggered that can be monitored by absorption and ^1H NMR spectroscopy. The starting 2.5×10^{-5} M red solution of **1** gradually changes its colour into yellow, as a consequence of the changes in position and intensity of the MLCT absorption bands. In particular, the band that peaked at 450 nm decreases with irradiation time and a new absorption band with a maximum at 380 nm grows (Figure 4).

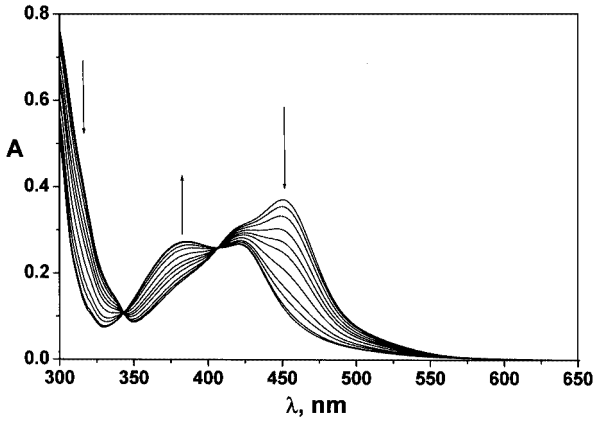

Figure 4. Changes in the electronic absorption spectra of a 2.5×10^{-5} M acetonitrile solution of **1** under irradiation with a 150 W xenon lamp at 404 nm. Spectra are recorded at t = 0, 2, 5, 10, 15, 20, 30, 45, 60, 90, 120 min of irradiation

Neat isosbestic points appear at 342 and 404 nm, emphasising the selectivity of the photochemical process and the final spectrum (Figure 4) is identical to that of the *cis*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$ species. Importantly, **1** is stable when kept in the dark for indefinite periods. The experimental data led us to conclude that an efficient photolabilisation of the $[Ru(phen)_2]^{2+}$ unit takes place, analogous with the results obtained for the simpler $[Ru(phen)_2(dmbp)]^{2+}$ complex.[7] Notably, in the case of **1**, under the same experimental conditions (150 W xenon lamp, λ_{exc} = 404 nm) the time required to complete the reaction (120 min) is longer than that for $[Ru(phen)_2(dmbp)]^{2+}$ (50 min), suggesting that the expulsion of the dmbp-containing macrocycle is kinetically less favoured than the loss of a plain dmbp ligand in $[Ru(phen)_2(dmbp)]^{2+}$, due to steric hindrance.

Experiments performed by ^{1}H NMR spectroscopy confirmed the above results. The spectrum obtained after irradiating an NMR tube containing **1** in CD_3CN corresponds to a mixture of *cis*-$[Ru(phen)_2(CD_3CN)_2]^{2+}$ and the free macrocycle m-36. Once again, the efficiency of this photochemical reaction is found to decrease in comparison with the previously studied system in which a $[Ru(phen)_2]^{2+}$ core is associated with dmbp.[7]

Complexes **1** and $[Ru(phen)_2dmbp]^{2+}$ are not luminescent at room temperature due to thermally induced deactivation of the potentially luminescent MLCT state via the upper lying MC level (possibly leading to photodissociation, see above). Lowering the temperature prevents this thermal deactivation process. Very intense, long-lived luminescence is observed at 77 K for both compounds (Table 1, Figure 5). *cis*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$ also exhibits intense MLCT luminescence at 77 K, and its maximum peak is substantially blue-shifted relative to **1** and $[Ru(phen)_2dmbp]^{2+}$.[18] Notably, after irradiation the emission spectra of **1** and $[Ru(phen)_2dmbp]^{2+}$ strongly resemble that of *cis*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$, revealing the presence of only a small residual amount (< 10%) of starting material (see spectral shoulder at 625 nm, Table 1). The excited state lifetime (3.0 μs) also strongly supports the view that photochemical induced expulsion of the bipy-type fragment has occurred, leading to the formation of a *cis*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$ coordination centre for both complexes.

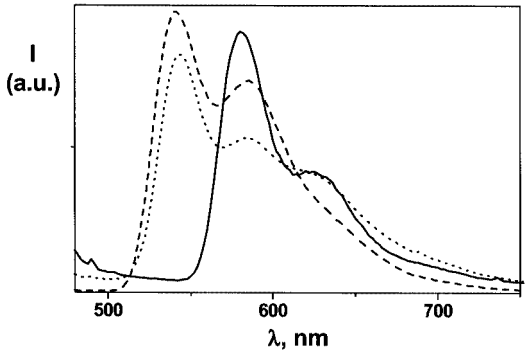

Figure 5. Emission spectra at 77 K of a CH_3CN rigid matrix of **1** before (full line, λ_{exc} = 449 nm) and after (dotted line, λ_{exc} = 420 nm) irradiation and of *cis*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$ (dashed line, λ_{exc} = 420 nm). O. D. = 0.5 for all samples at the excitation wavelength

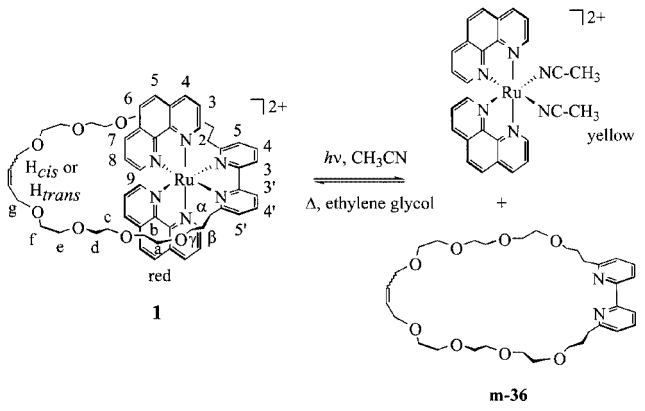
At 25 °C, quantum yields for photolabilisation are 0.020 ± 0.002 and 0.008 ± 0.001 in the case of $[Ru(phen)_2dmbp]^{2+}$ and **1,** respectively. Since the steric hindrance is more pronounced in **1** than in $[Ru(phen)_2dmbp]^{2+}$, it seems that some decoordination steps of the chelate unit are slower due to the presence of the macrocyclic chain. The cyclic nature of the complex is also expected to favour a *cis* conformation of the alkene group of the bipy-based macrocycle, making the stepwise decomplexation slightly more difficult than it is with its unconstrained analogue, dmbp.

After irradiation, it was possible to quantitatively recover complex **1** by refluxing the equimolar mixture of *cis*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$ and macrocycle m-36 in ethylene glycol for two hours. The principle of the photochemically driven motion and the thermal backward reaction is indicated in Scheme 3.



Scheme 3

The photochemical behaviour of complex **2** has also been studied under similar conditions as for complex **1**, i.e. with an efficiency similar to that observed for the same process in **1**. However, a careful examination of the area around the isosbestic point (417 nm) shows that some by-products were formed during the photoirradiation. By monitoring the photochemical reaction using ^{1}H NMR spectroscopy (CD_3CN, 500 MHz) the appearance of the free macrocycle is concomitant with the formation of the three isomeric forms of the complex *cis*-$[Ru(aphen)_2(CD_3CN)_2]^{2+}$ in the ratio 1(*a*,*a*)/2(*a*,*e*)/1(*e*,*e*). This experiment suggests that a photochemical isomerisation of the primary photo-product *cis*-[(*a*,*a*)$Ru(aphen)_2(CD_3CN)_2]^{2+}$ takes place at a similar or higher rate than that of the photosubstitution of the macrocycle m-36. A bis-phenanthroline ligand[19], that is able to stabilise the ruthenium core in a single isomeric form, is

Table 1. Luminescence Properties of the CH_3CN rigid matrix at 77 K

	$[Ru(phen)_2dmbp]^{2+}$ before irradiation	$[Ru(phen)_2dmbp]^{2+}$ after irradiation	**1** before irradiation	**1** after irradiation	$[Ru(phen)_2(CH_3CN)_2]^{2+}$

[a] Band maxima from uncorrected emission spectra, excitation wavelengths are the maxima of the room temperature MLCT absorption spectra, namely 450 nm for $[Ru(phen)_2dmbp]^{2+}$ and **1** before irradiation and 420 nm for these compounds after irradiation and $[Ru(phen)_2(CH_3CN)_2]^{2+}$. [b] Excited state lifetimes, λ_{exc} = 337 nm.

needed to circumvent this undesirable process. Preliminary experiments show that no photoisomerisation occurs when the phenanthroline ligands are linked by a *p*-xylyl bridge. We are currently working on a ruthenium complex that incorporates both this bis-phenanthroline ligand and a bipy-based macrocycle.

Experimental Section

Physical Measurements: ^{1}H NMR spectra were obtained with Bruker WP200 SY (200 MHz), Bruker AM 400 and ARX 500(400 and 500 MHz, respectively) spectrometers. Chemical shifts reported are referenced to Me_4Si as an internal standard. All the photochemical and photophysical experiments were carried out in acetonitrile (Carlo−Erba for spectroscopy). The absorption spectra were recorded with a Perkin−Elmer λ5 spectrophotometer. Emission spectra were obtained with a Spex Fluorolog II spectrofluorimeter (continuous 150-W Xe lamp), equipped with a Hamamatsu R-928 photomultiplier tube. Excited state lifetimes were determined with an IBH single photon counting spectrometer equipped with a thyratron gated nitrogen lamp working in the 4−30 kHz range (λ_{exc} = 337 nm, 0.5 ns time resolution); the detector was a red-sensitive (185−850 nm) Hamamatsu R-3237−01 photomultiplier tube.

Photochemical reactions were performed as follows: dilute solutions of the complexes (about 2.5×10^{-5} M), were put into 1 cm path spectrophotometric cuvettes and irradiated under continuous stirring with a 150 W xenon lamp (Osram XBOW/1) at 404 nm using slits of 2.5 mm (9.4 nm) at the entrance and exit of a Spex 1681 0.22M monochromator. At the end of the photoreaction, after removing CH_3CN under vacuum, the orange residue was dried under vacuum to give, quantitatively, the complex $[Ru(phen)_2(CH_3CN)_2]^{2+}$ and the macrocycle.

Quantum yields of the photoreaction at 436 nm were obtained by measuring the intensity of the light source with the "micro-version" of the ferric oxalate actinometer.[20]

Synthesis of Ligands and Complexes

Some ligands and complexes were prepared following literature procedures: 3-chloro-1-(*p*-methoxyphenyl)propanone,[21] 6,6′-dimethyl-2,2′-bipyridine (6,6′-dmbp),[10] *cis*-$[Ru(phen)_2(CH_3CN)_2](PF_6)_2$,[12] $[Ru(phen)_2(6,6'\text{-dmbp})](PF_6)_2$.[7] All charged species were isolated as PF_6^- salts. The solvents were distilled over the appropriate drying agents.

4-(*p*-Anisyl)-1,10-phenanthroline (aphen): In a three-neck round-bottomed flask equipped with a reflux condenser and a thermometer, a mixture of 8-aminoquinoline (20.0 g, 0.139 mol), arsenic pentoxide As_2O_5 (18.7 g, 0.081 mol), concentrated H_2SO_4 (30 mL) and H_2O (10 mL) was heated to 100 °C under strong magnetic stirring. 3-chloro-1-(*p*-methoxyphenyl)propanone (39.0 g, 0.197 mol) was then added rapidly. The reaction mixture was heated at reflux for 2.5 h, and then poured onto ice and made alkaline with concentrated aqueous 7 M KOH. After addition of CH_2Cl_2, the organic phase was separated, the aqueous layer was extracted 5 times with CH_2Cl_2 (500 mL) and the combined organic layers were washed with water (3 times), then dried over $MgSO_4$. The black oil was collected by filtration, washed with CH_2Cl_2 and was purified by repeated chromatography (silica, CH_2Cl_2, eluent: CH_2Cl_2/MeOH, 97:3; alumina, hexane/ether, 50:50, eluent: CH_2Cl_2/MeOH, 95:5; alumina, ether/EtOAc, 50:50, eluent: CH_2Cl_2/MeOH, 99:1) and recrystallised from ethyl acetate. A sand-brown powder was isolated (10.0 g, 0.035 mol) in 25% yield. Sand-brown powder (m.p. 138 °C). ^{1}H NMR (CD_2Cl_2, 200 MHz): δ = 9.14 (dd, *J* = 4.18 and 1.48 Hz, 1 H, 9-H), 9.12 (d, *J* = 4.42 Hz, 1 H, 2-H), 8.26 (dd, *J* = 7.99 and 1.85 Hz, 1 H, 7-H), 7.75 (d, *J* = 9.10 Hz, 1 H, 5-H), 7.68 (d, *J* = 9.10 Hz, 1 H, 6-H), 7.64 (dd*J* = 7.99 and 4.31 Hz, 1 H, 8-H,), 7.55 (d, *J* = 4.66 Hz, 1 H, 3-H), 7.49 (d, *J* = 8.84 Hz, 2 H, H_o), 7.09, *J* = 8.86 Hz(d, 2 H, H_m), 3.90 (s, 3 H, Me) ppm. $C_{19}H_{14}N_{20}$: calcd. C 79.70, H 4.93, N 9.78; found C 78.74, H 5.05, N 8.23.

6,6′-Bis(γ-tetrahydropyranylpropyl)-2,2′-bipyridine (4): A 1.64 M *n*BuLi (14.0 mL, 23.0 mmol) solution was added dropwise to a solution of diisopropylamine (3.4 mL, 24.3 mmol) in THF (21 mL), under argon. A degassed solution of 6,6′-dmbp (2.0 g, 10.8 mmol) in anhydrous THF (20 mL) was cooled to − 78 °C and the freshly prepared LDA solution was added via a cannula. The solution turned from yellow to blue-purple and was stirred for a further 2 h at − 78 °C, after which the temperature was allowed to rise to 5 °C. The deep red solution was once again cooled to − 78 °C. Meanwhile, a solution of tetrahydropyrannyl-2-bromoethyl-ethyl (4.7 g, 24.0 mmol) in anhydrous THF (5 mL) was cooled to − 78 °C and degassed. This solution was then transferred, under argon, to the solution of 6,6′-dmbp at − 78 °C and the mixture turned deep green. The solution was then stirred for 16 h at room temperature. The clear orange-brown solution was hydrolysed with water (80 mL) and turned yellow. After the solvent was removed and the residue treated with CH_2Cl_2, the organic layers were washed with water, dried over $MgSO_4$, and the solvent was evaporated. The resulting orange oil was purified by column chromatography on alumina (eluent: hexane/diethyl ether, 50:50). The product was obtained in 63% yield (3.0 g, 6.8 mmol). Yellow oil. ^{1}H NMR (CD_2Cl_2, 200 MHz): δ = 8.26 (dd, *J* = 7.87 Hz, 0.99 Hz, 2 H, 3,3′-H), 7.71 (t, *J* = 7.74 Hz, 2 H, 4,4′-H), 7.18 (dd, *J* = 7.60 and 0.99 Hz, 2 H, 5,5′-H), 4.57 (t, *J* = 3.44 Hz, 2 H, H_a), 3.80 (m, 4 H, H_e), 3.41 (m, 4 H, Hγ), 2.93 (t, *J* = 7.75 Hz, 4 H, H_α), 2.12 (m, 4 H, H_β), 1.59 (m, 12 H, $H_{b,c,d}$) ppm.

6,6′-Bis(γ-hydroxypropyl)-2,2′-bipyridine (5): The bipyridine derivative **4** (2.90 g, 6.61 mmol) was dissolved in 95% EtOH (45 mL) and heated to reflux. A spatula of *p*-toluenesulfonic acid (1.27 g, 6.54 mmol) was then added. The reaction was followed by TLC (SiO_2, eluent: CH_2Cl_2/5% MeOH) and the reflux was maintained for 4 h. Additional aliquots of acid (0.80 g, 4.12 mmol) were added and the solution was refluxed for a further 4 h. The ethanol was then removed and the residue was dissolved in a CH_2Cl_2/H_2O mixture. After neutralisation by an aqueous solution of K_2CO_3, the aqueous phase was extracted 3 times with CH_2Cl_2 and the organic layers were washed with water, dried over $MgSO_4$, filtered and the solvent evaporated. The crude mixture was purified by column chromatography on silica (eluent: CH_2Cl_2/MeOH, 94.5:5.5) to give the product (1.24 g, 4.55 mmol) in 69% yield. Yellow oil. ^{1}H NMR (CD_2Cl_2, 200 MHz): δ = 8.09 (dd, *J* = 7.75 Hz, 0.61 Hz, 2 H, 3,3′-H), 7.75 (t, *J* = 7.74 Hz, 2 H, 4,4′-H), 7.21 (dd, *J* = 7.75 Hz, 0.87 Hz, 2 H, 5,5′-H), 3.90 (br. s, 2 H, OH), 3.68 (t, *J* = 5.91 Hz, 4 H, H_γ), 3.01 (t, *J* = 6.89 Hz, 4 H, H_α), 2.01 (m, 4 H, H_β) ppm.

Bis-THP Derivative of 2,2′-Bipyridine (6): A degassed solution of **5** (1.19 g, 4.36 mmol) in DME (25 mL) was added dropwise at 0 °C under argon to a suspension of NaH (0.60 g, 13.7 mmol) in DME (50 mL) for 40 min, upon which the mixture turned white. The ice bath was removed and at room temperature a degassed solution of 2-[2-(chloroethoxy)ethoxy)]ethoxy}tetrahydro-2*H*-pyran (3.64 g, 14.40 mmol) in DME (35 mL) was added dropwise to the mixture which was then heated at 50 °C for 3 h after which the temperature

was increased and the reaction heated at reflux for 14 h. The reaction was monitored by TLC (Alumina, eluent: CH_2Cl_2/5% MeOH). More NaH (0.21 g, 4.80 mmol) and a solution of tetrahydropyrannyl derivative (2.00 g, 7.91 mmol) in DME (20 mL) was added. The reaction mixture was maintained under reflux under argon for a further 34 h, then it was cooled to 0 °C. Excess NaH was neutralised by the gradual addition of EtOH until no further evolution of gas was observed (12 mL overall). The solvent was then evaporated and the residue was dissolved in a 1:1 H_2O/CH_2Cl_2 mixture. The organic layer was separated, and the aqueous layer was extracted 4 times with CH_2Cl_2. The organic layers were combined, washed with water, dried over $MgSO_4$ and filtered. Following evaporation of the solvent, the orange oil was purified twice by column chromatography on alumina eluting with a CH_2Cl_2/MeOH mixture (98.7:1.3; 99.9:0.1). Pure **6** was isolated (0.65 g, 0.92 mmol) along with a mixture of the starting material and of the monosubstituted product (1.30 g) which was treated as follows. This mixture was added to a suspension of DMSO (10 mL) containing KOH powder (3.16 g, 47.60 mmol). To this orange-brown solution, tetrahydropyrannyl derivative (4.81 g, 19.04 mmol) was added and the stirring was maintained for 3.5 h.. The mixture was then heated at 50 °C for 35 min. After cooling and addition of H_2O/CH_2Cl_2, the organic phase was separated and the aqueous phase was extracted with $CHCl_3$ (twice, 150 mL) and also CH_2Cl_2 (twice, 150 mL). The combined organic layers were washed, dried over $MgSO_4$, filtered and the solvents evaporated. The crude oil was purified four times by column chromatography on alumina (CH_2Cl_2/MeOH, 98:0.2; 99.6:0.4) to give pure **7** (0.99 g, 1.41 mmol). The overall yield of **7** (1.64 g, 2.33 mmol) from the two reactions was 53%. Colourless oil. ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 8.23 (d, *J* = 7.51 Hz, 2 H, 3,3′-H), 7.68 (t, *J* = 7.75 Hz, 2 H, 4,4′-H), 7.14 (d, *J* = 7.62 Hz, 2 H, 5,5′-H), 4.62 (t, *J* = 3.32 Hz, 2 H, H_a), 3.84 (m, 4 H, H_e), 3.64 (m, 24 H, 6 × $-CH_2-CH_2-$), 3.55 (t, 4 H, H_γ), 2.92 (t, *J* = 7.63 Hz, 4 H, H_α), 2.11 (tt, 4 H, H_β), 1.90−1.30 (m, 12 H, 4 H_b, 4 H_c, 4 H_d) ppm.

2,2'-Bipyridine 7: 6 (1.62 g, 2.30 mmol) was heated to reflux in 95% EtOH (16 mL) and then *p*-toluenesulfonic acid (0.45 g, 2.30 mmol) was added. The reaction was followed by TLC (SiO_2; eluent: CH_2Cl_2/5% MeOH) and reflux was maintained for 27 h. After evaporation of the solvent, the residue was dissolved in a CH_2Cl_2/H_2O mixture and neutralised with an aqueous solution of $NaHCO_3$. The aqueous phase was extracted 3 times with CH_2Cl_2 and the organic layers were combined, washed with water, dried over $MgSO_4$ and the solvent was evaporated. **6** was isolated (1.03 g, 1.92 mmol) in 84% yield and was used without further purification (purity > 95% by NMR). Colourless oil. ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 8.23 (d, *J* = 7.25 Hz, 2 H, 3,3′-H), 7.69 (t, *J* = 7.75 Hz, 2 H, 4,4′-H), 7.15 (dd, *J* = 7.64 and 0.77 Hz, 2 H, 3,3′-H), 3.80−3.52 (m, 26 H, 2 × −OH, 6 × $-CH_2-CH_2-$), 3.56 (m, 4 H, H_γ), 2.92 (t, *J* = 7.63 Hz, 4 H, H_α), 2.12 (tt, 4 H, H_β) ppm.

3: In a degassed solution of **7** (1.03 g, 1.92 mmol) in DME (45 mL), NaH (0.93 g, 21.3 mmol) was added with a spatula and the mixture was heated to 50 °C. Allyl bromide (16 mL, 181.00 mmol) was then added via the cannula transfer technique. The reaction mixture was heated at reflux for 20 h and then monitored by TLC (Alumina; CH_2Cl_2/5% MeOH). The white solution was cooled to 0 °C and excess NaH was neutralised by adding small portions (3 mL) of absolute ethanol until there was no further evolution of gas. The solvent was then evaporated and the residue dissolved in a CH_2Cl_2/H_2O (1:1) mixture. The organic phase was separated and the aqueous phase was extracted 4 times with CH_2Cl_2. The organic phases were combined, washed with H_2O and dried over $MgSO_4$. After filtration of the solution and removal of the solvent, the oily residue was purified twice by column chromatography on alumina (eluent: CH_2Cl_2/MeOH, 99.5:0.5) to afford **3** (0.89 g, 1.44 mmol) in 75% yield. Pale yellow oil. ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 8.24 (d, *J* = 7.86 Hz, 2 H, 3,3′-H), 7.68 (t, *J* = 7.75 Hz, 2 H, 4,4′-H), 7.14 (dd, *J* = 7.62 and 0.98 Hz, 2 H, 5,5′-H), 5.91 (ddt, *J* = 17.22, 10.32 and 5.66 Hz, 2 H, H′), 5.26 (dtd, *J* = 17.10, 3.44 and 1.60 Hz, 2 H, H_t), 5.16 (m, *J* = 10.32, 1.72 and 1 Hz, 2 H_c), 4.01 (dt, *J* = 5.66 and 1.36 Hz, 4 H, H_g), 3.67−3.50 (m, 28 H, $H_{a,b,c,d,e,f}$, 4 H_γ), 2.92 (t, *J* = 7.50 Hz, 4 H, H_α), 2.11 (tt, *J* = 6.52 and 6.88 Hz, 4 H_β) ppm. FAB-MS for $C_{34}H_{52}N_2O_8$: *m*/*z* = 617.5 $[M + H]^+$, calcd. 617.4, 100%.

***cis*-[Ru(aphen)$_2$Cl$_2$]:** Following the complete dissolution of complex $[Ru(CH_3CN)_4Cl_2]$ (410.0 mg, 1.22 mmol) in a degassed solution of 1,2-dichloroethane (130 mL), the ligand aphen (684.0 mg, 2.39 mmol) was added and the orange-brown mixture was heated at reflux for 2 h. After evaporation of the solvent, the purple-brown residue was purified twice by flash chromatography on silica gel (Silica gel 60, 0.063−0.200 mm, Merck 7734) eluting with EtOH. The mixture of isomeric complexes *cis*-$[Ru(aphen)_2Cl_2]$ was obtained in 46% yield (412.5 mg, 0.55 mmol). The complexes obtained were purple in colour.

Separation of the Three Isomers of *cis*-[Ru(aphen)$_2$Cl$_2$]

The three isomers (460 mg, 0.620 mmol) were separated 13 times by flash chromatography on alumina (aluminium oxide 90, acidic, activity I, 0.063−0.200 mm, Merck 1078). The eluent was a mixture of CH_2Cl_2/MeOH (3%). The purple isomer **(*a*,*a*)**, which migrates as the first band, (100 mg, 0.134 mmol) was isolated as 87% of the theoretical yield (25%).

Isomer (*a*,*a*): ^{1}H NMR (CD_2Cl_2, 400 MHz): δ = 10.50 (d, *J* = 5.56 Hz, 2 H, 2-H), 8.23 (, *J* = 9.04 Hz d, 2 H, 5-H), 7.98 (d, *J* = 5.52 Hz, 2 H, 3-H), 7.97 (dd, *J* = 7.96 and 1.12 Hz, 2 H, 7-H), 7.93 (dd, *J* = 5.44 and 1.00 Hz, 2 H, 9-H), 7.88 (d, *J* = 9.28 Hz, 2 H, 6-H), 7.71 (d, *J* = 8.64 Hz, 4 H, H_o), 7.21 (d, *J* = 8.60 Hz, 4 H, H_m), 7.19 (m, 2 H, 8-H), 3.96 (s, 6 H, 2 Me) ppm. UV/Vis (CH_2Cl_2): λ = 553 (7400) nm. **Isomer (*a*,*e*):** ^{1}H NMR (CD_2Cl_2, 200 MHz): δ = 10.43 (m, 2 H, 2-H_a, 9-H_e), 8.43 (dd, *J* = 8.12 Hz, 1 H, 7-H_e), 8.23 (d, *J* = 9.10 Hz, 1 H, 5-H_a), 8.04 (dd, 2 H, 5-H_e, 6-H_e), 8.00−7.85 (m, 4 H, 3-H_a, 7-H_a, 9-H_a, 8-H_e), 7.86 (d, *J* = 9.10 Hz, 1 H, 6-H_a), 7.70 (d, *J* = 8.86 Hz, 2 H, $H_{o,a}$), 7.70 (m, 1 H, 2-H_e), 7.38 (d, *J* = 8.86 Hz, 2 H, $H_{o,e}$), 7.20 (d, *J* = 8.86 Hz, 2 H, $H_{m,a}$), 7.19 (m, 2 H, 8-H_a, 3-H_e), 7.04 (d, *J* = 8.86 Hz, 2 H, $H_{m,e}$), 3.95 (s, 3 H, Me a), 3.86 (s, 3 H, Me_e) ppm. UV/Vis (CH_2Cl_2): λ = 550 (9200) nm. **Isomer (*e*,*e*):** ^{1}H NMR (CD_2Cl_2, 400 MHz): δ = 10.48 (m, 2 × 9-H), 8.43 (d, *J* = 7.72 Hz, 2 H, 7-H), 8.06 (d,*J* = 8.80 Hz, 2 H, 6-H), 8.03 (, *J* = 9.16 Hz d, 2 H, 5-H), 8.01 (m, 2 H, 8-H), 7.71 (d, *J* = 8.80 Hz, 2 H, 2-H), 7.38 (dd, *J* = 8.44 Hz, 4 H, H_o), 7.20 (d, *J* = 8.80 Hz, 2 H, 3-H), 7.04 (d, *J* = 8.44 Hz, 4 H, H_m), 3.86 (s, 6 H, 2 Me) ppm. UV/Vis (CH_2Cl_2): λ = 547 (5800) nm.

***cis*-[(*a*,*a*)Ru(aphen)$_2$(CH$_3$CN)$_2$](PF$_6$)$_2$:** In a round bottomed flask, *cis*-[(*a*,*a*)Ru(aphen)$_2$Cl$_2$] (80 mg, 0.107 mmol) was heated at reflux under argon in a mixture of CH_3CN/H_2O 50:50 (12 mL) for 2.5 h. After cooling to room temperature, a saturated solution of aqueous KPF_6 (10 mL) and CH_3CN (5 mL) were added. The evaporation of the solvent caused a brown-orange solid to precipitate that was separated by filtration, washed with water and diethyl ether and then air-dried. *cis*-[(*a*,*a*)Ru(aphen)$_2$(CH$_3$CN)$_2$](PF$_6$)$_2$ was obtained in a yield of 45% (50 mg, 0.048 mmol). Brown-orange powder. ^{1}H NMR (CD_2Cl_2, 200 MHz): δ = 9.76 (d, *J* = 5.40 Hz, 2 H, 2-H), 8.38 (d, *J* = 9.10 Hz, 2 H, 5-H), 8.35 (dd, *J* = 8.36 Hz, 1.24 Hz, 2

H, 7-H), 8.20 (d, J = 5.42 Hz, 2 H, 3-H), 8.04 (d, J = 9.10 Hz, 2 H, 6-H), 7.87 (dd, J = 5.41 and 1.23 Hz, 2 H, 9-H), 7.76 (d, J = 8.84 Hz, 4 H, H_o), 7.50 (dd, J = 5.29 and 8.25 Hz, 2 H, 8-H), 7.25 (d, J = 8.60 Hz, 4 H, H_m), 3.97 (s, 6 H, 2 Me) ppm.

Compound 8: A stoichiometric mixture of *cis*-$[Ru(phen)_2(CH_3CN)_2](PF_6)_2$ (69.7 mg, 0.084 mmol) and **3** (51.8 mg, 0.084 mmol) was heated at 140 °C in degassed ethylene glycol (6 mL) for 2 h. After cooling to room temperature, water (8 mL) and then a saturated solution of aqueous KPF_6 (6 mL) were added. The precipitate obtained was collected by filtration and washed with water and diethyl ether. The crude product was purified by chromatography on silica gel eluting with an acetone/water/aqueous saturated KNO_3 (100:4:2) mixture. The cation was precipitated from the eluent by addition of an aqueous solution of KPF_6 and the resultant solid was filtered off to give **8** (86.2 mg, 0.063 mmol) in 75% yield. Red compound. ^{1}H NMR ([D$_6$]acetone, 200 MHz): δ = 8.94 (dd, J = 8.15 and 1.10 Hz, 2 H, 4-H), 8.74 (dd, J = 5.17 and 1.22 Hz, 2 H, 2-H), 8.67 (dd, J = 8.35 and 1.22 Hz, 2 H, 7-H), 8.63 (d, J = 8.86 Hz, 2 H, 3,3′-H), 8.47 (d, J = 8.86 Hz, 2 H, 5-H), 8.38 (d, J = 8.86 Hz, 2 H, 6-H), 8.10 (dd, J = 7.86 and 7.88 Hz, 2 H, 4,4′-H), 8.10 (dd, J = 5.23 and 8.24 Hz, 2 H, 3-H), 7.97 (dd, J = 5.40 and 1.23 Hz, 2 H, 9-H), 7.62 (dd, J = 5.28 and 8.24 Hz, 2 H, 8-H), 7.44 (dd, J = 7.87 and 0.99 Hz, 2 H, 5,5′-H), 5.82 (, J = 17.34, 10.44 and 5.23 Hz ddt, 2 H, H′), 5.18 (m, 2 H, H_t), 5.04 (m, 2 H, H_c), 3.88 (dt, J = 5.42 and 1.54 Hz, 4 H, H_g), 3.60−3.20 (m, 24 H, $H_{a,b,c,d,e,f}$), 3.20−1.00 (12 H, $H_{\alpha,\beta,\gamma}$) ppm.

$[Ru(phen)_2(m\text{-}36)](PF_6)_2$ (1): To a degassed Schlenk containing **8** (117.0 mg, 0.086 mmol) and the catalyst (Grubbs ruthenium(II) carbene: [Ru], (Scheme 2), 4.9 mg, 7% mol), freshly distilled and degassed CH_2Cl_2 (8.5 mL) was added via a cannula to obtain a 0.01 M solution. This mixture was stirred at room temperature for 18 h during which a syringe needle was periodically inserted into the reaction vessel to allow the ethylene gas to escape. The reaction was monitored by ^{1}H NMR spectroscopy. A further 7 mol percent of the catalyst was added and further solvent was added in order to maintain the desired concentration of the reaction mixture. The stirring was continued for 5 days. The solvent was then evaporated and the crude product was purified by chromatography on silica gel (eluent: acetone/H_2O/KNO_3, 100:5:2). Pure **1** was isolated (77.2 mg, 0.058 mmol) in 67% yield. Red compound. ^{1}H NMR ([D$_6$]acetone, 200 MHz): δ = 8.94 (dd, J = 8.36 and 1.24 Hz, 2 H, 4-H), 8.76 (dd, J = 5.41 and 1.23 Hz, 2 H, 2-H), 8.68 (dd, J = 8.37 and 1.23 Hz, 2 H, 7-H), 8.62 (d, J = 7.38 Hz, 2 H, 3,3′-H), 8.47 (d, J = 8.86 Hz, 2 H, 5-H), 8.38 (d, J = 8.86 Hz, 2 H, 6-H), 8.09 (dd, J = 8.12 and 7.14 Hz, 2 H, 4,4′-H), 8.09 (dd, 2 H, 3-H), 7.92 (dd, J = 5.29 and 1.11 Hz, 2 H, 9-H), 7.67 (dd, J = 5.42 and 8.12 Hz, 2 H, 8-H), 7.43 (d, J = 7.88 Hz, 2 H, 5,5′-H), 5.39 (m, 2 H, $H_{cis,}$ 75%), 5.31 (m, 2 H, $H_{trans,}$ 25%), 3.90−1.50 (m, 40 H, H_g, $H_{a,b,c,d,e,f}$, $H_{\alpha,\beta,\gamma}$) ppm. FAB-MS for $RuC_{56}H_{64}N_6O_8P_2F_{12}$: m/z = 1195.3 $[M - PF_6]^+$, calcd. 1195.3, 8%; 1049.3 $[M - 2\ PF_6 + e^-]^+$, calcd. 1050.3, 11%; 462.0 $[M - 2\ PF_6 - m_{36} + e^-]^+$, calcd. 462.0, 32%. UV/Vis (CH_3CN): 450 nm (9200).

9: A stoichiometric mixture of *cis*-[(*a*,*a*)Ru(aphen)$_2$(CH$_3$CN)$_2$](PF$_6$)$_2$ (50.0 mg, 0.048 mmol) and **3** (29.5 mg, 0.084 mmol) was heated at 140 °C in degassed ethylene glycol (7 mL) for 2.5 h. After cooling to room temperature, water (5 mL) and then a saturated solution of aqueous KPF_6 (10 mL) were added. The precipitate obtained was collected by filtration and washed with water and diethyl ether. The crude product **9** was isolated (68.8 mg, 0.044 mmol) and was used without further purification. Red compound. FAB-MS for $RuC_{72}H_{80}N_6O_{10}P_2F_{12}$: m/z = 1435.3 $[M - PF_6]^+$, calcd. 1435.4, 5%, 1289.4 $[M - 2\ PF_6 + e^-]^+$, calcd. 1290.5, 6%; 674.1 $[M - 2\ PF_{6-}$**3** $+ e^-]^+$, calcd. 674.1, 46%.

$[Ru(aphen)_2(m\text{-}36)](PF_6)_2$ (2): To a degassed Schlenk containing **9** (68.8 mg, 0.044 mmol) and the catalyst [Ru], 3 mg, 8% mol), freshly distilled and degassed CH_2Cl_2 (5 mL) was added via a cannula to obtain a 0.01 M solution. This mixture was stirred at room temperature for one day during which a syringe needle was periodically inserted into the reaction vessel to allow the escape of ethylene gas. A further 9 mol percent of the catalyst (3.5 mg) was added and after 4 days further solvent added in order to maintain the desired concentration of the reaction mixture. Further catalyst (5 mg, 14% mol) was added. The stirring was continued for 1 day (overall duration of reaction: 6 days). The solvent was then evaporated and addition of water (3 mL) and a saturated solution of aqueous KPF_6 (5 mL) allowed the precipitation of a crude product which was collected by filtration, washed with water and diethyl ether and was purified by chromatography (silica, eluent: acetone/H_2O/KNO_3, 100:7:0.7; alumina, eluent: toluene/CH_3CN 35:65; alumina, eluent: toluene/CH_3CN, 40:60). **2,** not completely pure, was isolated (30.4 mg, 0.020 mmol) in 45% yield. Preparative chromatography on silica (eluent: $CH_3CN/H_2O/KPF_6$, 100:10:2), performed twice, afforded pure **2**. Red compound. ^{1}H NMR (CD_3CN, 500 MHz): δ = 8.45 (dd, J = 8.25 and 1.15 Hz, 2 H, 7-H), 8.42 (dd, J = 5.55 Hz, 2 H, 2-H), 8.36 (d, J = 9.55 Hz, 2 H, 3,3′-H), 8.34 (d, J = 9.10 Hz, 2 H, 5-H), 8.16 (d, J = 9.25 Hz, 2 H, 6-H), 7.97 (dd, J = 7.85 and 8.15 Hz, 2 H, 4,4′-H), 7.80 (d, J = 5.55 Hz, 2 H, 3-H), 7.74 (dd, J = 5.32 and 1.17 Hz, 2 H, 9-H), 7.67 (d, J = 8.75 Hz, 4 H, H_o), 7.46 (dd, J = 5.37 and 8.17 Hz, 2 H, 8-H), 7.29 (d, J = 7.85 Hz, 2 H, 5,5′-H), 7.23 (d, J = 8.95 Hz, 4 H, H_m), 5.34 (m, 2 H, H_c), 5.21 (m, 2 H, H_t), 3.92 (s, 6 H, 2 OMe), 4.30−0.08 (m, 40 H, $H_{a,b,c,d,e,f,g,\alpha,\beta,\gamma}$) ppm. FAB-MS for $RuC_{70}H_{76}N_6O_{10}P_2F_{12}$: m/z = 1407.2 $[M - PF_6]^+$, calcd. 1407.4, 8%; 1262.3 $[M - 2\ PF_6 + e^-]^+$, calcd. 1262.4, 9%; 674.0 $[M - 2\ PF_6$ − m-36 $+ e^-]^+$, calcd. 674.1, 78%. UV/Vis (CH_3CN): λ = 457 (9700) nm.

Change in the Spin State of an Fe^{III} Center upon One N-to-O Switch in the Coordination of a 2,6-Pyridinedicarboxamido Unit: The Effect of Methyl Thioether and Methyl Ether Appendages at the Ligand Periphery

Todd C. Harrop,[a] Laurie A. Tyler,[a] Marilyn M. Olmstead,[b] and Pradip K. Mascharak*[a]

Keywords: Iron / N ligands / S ligands / Spin states / EPR spectroscopy

Two ligands bearing the 2,6-pyridinedicarboxamide unit, namely $PyPSMeH_2$ and $PyPOMeH_2$, have been used to prepare complexes of Fe^{III} which have been structurally characterised. The potentially pentadentate thioether ligand $PyPSMeH_2$ affords only the bis complex $(Et_4N)[Fe(PyPSMe)_2]$ (**1**), irrespective of the metal to ligand ratio, due to the weak affinity of the thioether groups for the Fe^{III} center. In $[Fe(PyPSMe)_2]^-$, the two $PyPSMe^{2-}$ ligands bind to the iron center in a *mer* fashion and steric crowding among the pendant thioether groups forces one of the four deprotonated carboxamido moieties to bind to the Fe^{III} center through the carbonyl oxygen, giving rise to an FeN_5O chromophore. The tridentate ligand $PyPOMeH_2$, in its deprotonated form, also gives rise to a bis complex, $(Et_4N)[Fe(PyPOMe)_2]$ (**2**), in which the two $PyPOMe^{2-}$ ligands bind to the iron center in a *mer* fashion. In this case, however, less steric crowding among the smaller pendant ether groups allows binding of all four carboxamido nitrogens to the Fe^{III} center in $[Fe(PyPOMe)_2]^-$ giving rise to an FeN_6 chromophore. This one N-to-O switch in donor atom makes the two complexes **1** and **2** very different. While complex **2** is low spin (g = 2.18, 1.94) much like the other reported Fe^{III} bis complexes with two ligated 2,6-pyridinedicarboxamido units, complex **1** is high spin (g = 4.3). The spin flip due to a switch in only one N or O donor atom in these two complexes is unprecedented. The two complexes also exhibit different stability towards water.

Introduction

In recent years, coordination of carboxamido nitrogen(s) to iron centers and the spectroscopic, redox and reactivity properties of the resulting complexes have received much interest following the discovery of iron$-N_{amido}$ (N_{amido} = carboxamido N) bonds in nitrogenase[1] and nitrile hydratase.[2,3] Initially, this type of coordination was thought to be highly unlikely since Fe^{III} rapidly precipitates out as its hydroxide at much lower pH values than that required for the deprotonation of carboxamido nitrogens.[4] During the past ten years, however, research by us,[5−10] and others[11−15] has demonstrated that coordination of carboxamido nitrogens to Fe^{III} centers can afford sufficiently stable and isolable complexes. Indeed, coordination of this group results in highly negative $E_{1/2}$ values (up to −1.10 V) indicating that carboxamido nitrogens provide significant stability to iron in the +3 oxidation state.[7] Furthermore, the majority of Fe^{III} complexes coordinated to one, two, or four carboxamido nitrogens contain low spin Fe^{III} centers.[7,8,9] In addition, it appears that Fe^{III} complexes with $Fe^{III}-N_{amido}$ bonds are resistant toward hydrolysis despite the common belief that the highly basic carboxamido nitrogens could be readily attacked by water. Collectively, these results indicate that carboxamido nitrogens have a high affinity for Fe^{III} centers and impart stability towards hydrolysis of the resultant complexes.

Coordination of designed ligands with built-in 2,6-pyridinedicarboxamido unit (Figure 1) to Fe^{III} centers has resulted in complexes with novel structures and properties.[5,6,9,11,15] Recent work in this laboratory has afforded a variety of Fe^{III} complexes based on this tridentate moiety in the first coordination sphere.[5,6,10] For example, coordination of the pentadentate ligand $POPyH_4$ to Fe^{III} (H represents dissociable amide protons) results in high-spin, seven-coordinate, pentagonal bipyramidal complexes with the entire ligand in the basal plane and with two exogenous axial ligands (structure i, Figure 2).[6] In contrast, the Fe^{III} complex of the similar pentadentate ligand $PyPSH_4$ is high spin, five-coordinate with a distorted trigonal bipyramidal geometry due to the steric bulk of the thiolato sulfur (structure ii, Figure 2).[10] It is interesting to note that the potentially pentadentate ligands Py_3PH_2 and $MePy_3PH_2$ invariably afford six-coordinate bis complexes in which the two ligands are coordinated to the Fe^{III} center through the 2,6-pyridinedicarboxamido moiety with *unbound* pendant

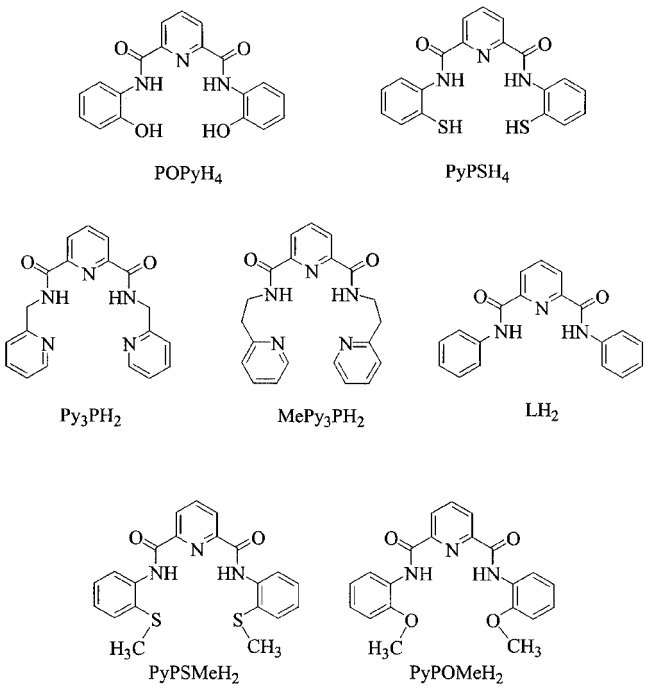

Figure 1. Ligands with the 2,6-pyridinedicarboxamide moiety (P stands for the peptide functionality in all abbreviations)

pyridine groups (structure iii, Figure 2).[5] The Fe^{III} centers in both of these complexes are low spin, much like the Fe^{III} complex of LH_2, namely $[FeL_2]^-$, reported by Mukherjee and co-workers.[11] The failure of the pendant pyridine units to bind to the Fe^{III} centers in these complexes is not related to any steric effect, since Py_3PH_2 gives rise to many $[Co(Py_3P)(L)]^{+/0}$ complexes.[16] We believe that formation of the bis complex $[Fe(Py_3P)_2]^-$ instead of $[Fe(Py_3P)(L)]^{+/0}$ with weak Fe^{III}-py interactions is a result of the high stability derived from coordination of four carboxamido nitrogens.

In order to elucidate the effect(s) of steric hindrance on the mode of coordination of carboxamido nitrogens to Fe^{III} centers and the spin-states of the resulting complexes, we have synthesized additional ligands with the 2,6-pyridinedicarboxamide moiety. The two designed ligands employed in this study are the potentially pentadentate ligand $PyPSMeH_2$ and the tridentate ligand $PyPOMeH_2$. Although $PyPSMeH_2$ is expected to bind to iron much like $PyPSH_4$, we report here that the deprotonated form, $PyPSMe^{2-}$, coordinates to Fe^{III} in a bis fashion irrespective of the ligand to Fe ratio and in the resulting complex, $(Et_4N)[Fe(PyPSMe)_2]$ (**1**), all the thioether groups remain unbound. Clearly, thioether sulfur (like pyridine nitrogen) is not a good donor for Fe^{III} and hence $PyPSMeH_2$ behaves like Py_3PH_2. It is also interesting to note that due to the steric repulsion among the pendant thioether groups in **1**, one of the carboxamido groups employs the carbonyl oxygen instead of the carboxamido nitrogen, as a donor atom, resulting in an FeN_5O chromophore. As a result of this N-to-O donor switch around the Fe^{III} center in **1**, the complex is high spin, which is in contrast to other similar bis complexes with two bound 2,6-pyridinedicarboxamido units (FeN_6 chromophore and all low spin).[5,11] In order to further substantiate our hypothesis that the steric repulsion among the pendant thioether groups in **1** is responsible for this N-to-O donor switch, we have also synthesized the bis Fe^{III} complex of the tridentate ligand $PyPOMeH_2$. The pendant ether groups in $(Et_4N)[Fe(PyPOMe)_2]$ (**2**) give rise to steric hindrance around the Fe^{III} center much like the crowding in **1**. As shown later, the structure of **2** is very similar to that of **1** except for the crucial fact that the extent of the steric repulsion among the pendant ether groups in **2** is slightly less than that among the pendant thioether groups in **1**. This allows the four carboxamido nitrogens of the two $PyPOMe^{2-}$ ligands to bind to the Fe^{III} center in **2**. Since there is no N-to-O switch, complex **2** is once again low spin much like $[FeL_2]^-$ and $[Fe(Py_3P)_2]^-$.

In this paper, we report (a) the syntheses of complexes **1** and **2**, (b) comparisons of the structures of **1** and **2** with other related Fe^{III} complexes with bound 2,6-pyridinedicarboxamide moieties, and (c) studies on spin-flip due to the N-to-O switch in **1** and **2**.

Results and Discussion

The potentially pentadentate ligand $PyPSMeH_2$ was synthesized by following a procedure previously reported by this group.[17] $PyPOMeH_2$ was prepared by reacting *o*-anisidine with 2,6-pyridinedicarbonyl dichloride (prepared from 2,6-pyridinedicarboxylic acid and thionyl chloride) in chloroform. Reaction of $(Et_4N)[FeCl_4]$ with $PyPSMe^{2-}$ in DMF

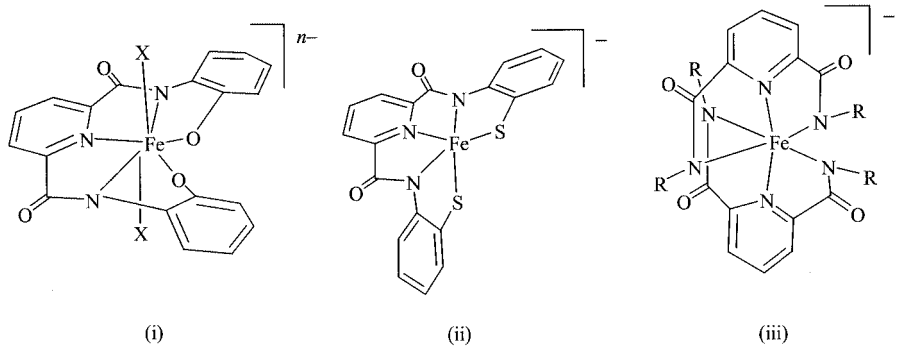

Figure 2. Different structures of Fe^{III} complexes of ligands with the 2,6-pyridinedicarboxamide moiety

afforded the red-brown Fe^{III} complex $(Et_4N)[Fe(PyPSMe)_2]$ (**1**) in good yield. It is important to note that the bis complex **1** is the only product isolated from this reaction irrespective of the ligand to Fe ratio. Thus when a 1:1 ligand to Fe ratio is used, only half of the iron is complexed by the ligand while the rest remains in solution in the form of $[FeCl_4]^-$. Clearly, the strong preference of the carboxamido nitrogens for Fe^{III}, and the weak affinity of the thioether sulfur for Fe^{III} lead to the formation of **1** as the sole product. The bright red complex $(Et_4N)[Fe(PyPOMe)_2]$ (**2**) was synthesized in high yield by reacting $(Et_4N)[FeCl_4]$ with two equivalents of $PyPOMeH_2$ and four equivalents of NaH (both relative to iron) in DMF.

Molecular Structure of $(Et_4N)[Fe(PyPSMe)_2]$ (1)

An X-ray crystallographic study of **1** (Table 1) revealed that the coordination geometry around the Fe^{III} center is distorted octahedral, with two $PyPSMe^{2-}$ units ligated in a *mer* fashion (Figure 3). Interestingly the $Fe^{III}N_5O$ chromophore consists of two pyridine nitrogens, three deprotonated carboxamido nitrogens, and the carbonyl oxygen of the fourth deprotonated carboxamido moiety. This observed mode of binding of the two $PyPSMe^{2-}$ ligands in **1** is not accidental and has also been noted in the corresponding Co^{III} complex $(Et_4N)[Co(PyPSMe)_2]$ (**3**).[17] The last carboxamido nitrogen moiety fails to bind through nitrogen due to the steric repulsion that builds up between the pendant thioether groups as an increasing number of carboxamido nitrogens become ligated to the M^{III} center. To the best of our knowledge, there is no other example of such an N-to-O donor switch in Fe^{III} complexes containing carboxamido group(s). A few examples of N-to-O linkage isomerization have been reported with ruthenium complexes[18] but these complexes contain neutral and not deprotonated carboxamide unit(s).

The $Fe^{III}-N_{amido}$ [av. 2.093(3) Å] and $Fe^{III}-N_{py}$ [av. 2.081(3) Å] bond lengths in **1** are significantly longer than those reported for similar Fe^{III} complexes containing *two* coordinated 2,6-pyridinedicarboxamido moieties in their primary coordination sphere.[5,11] A close examination of the literature reveals three bis complexes of Fe^{III} that contain the 2,6-pyridinedicarboxamido unit, namely $(Et_4N)[FeL_2]$,[11] $Na[Fe(Py_3P)_2]$,[5] and $Na[Fe(MePy_3P)_2]$.[5] All three complexes consist of an $Fe^{III}N_6$ chromophore with four deprotonated carboxamido nitrogens in the basal

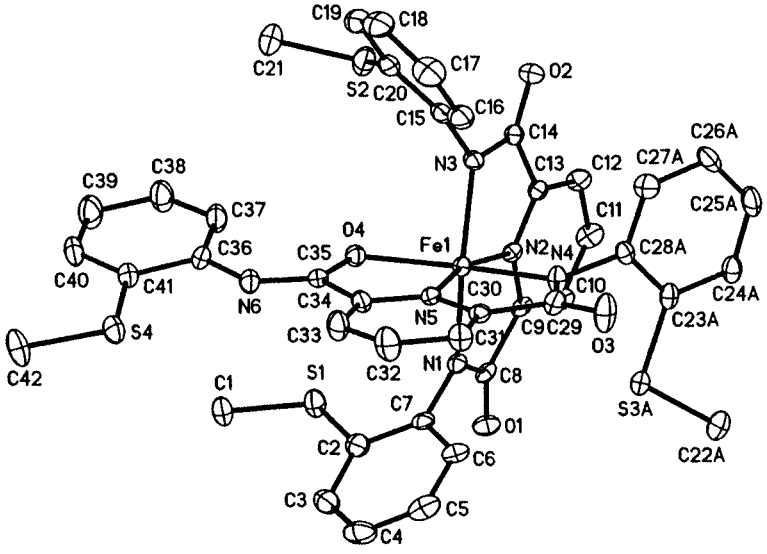

Figure 3. Thermal ellipsoid plot of $[Fe(PyPSMe)_2]^-$, the anion of **1** (at the 50% probability level); H atoms are omitted for the sake of clarity

plane and two axial pyridine donors. As a result of the strong ligand field of the carboxamido nitrogens, these Fe^{III} complexes are all low spin (vide infra) and exhibit shorter $Fe^{III}-N_{amido}$ [av. 1.961 Å] and $Fe^{III}-N_{py}$ [av. 1.877 Å] bond lengths.[5,11] Interestingly, the bond lengths of **1** compare well with those noted for high spin (vide infra) Fe^{III} complexes that contain *one* 2,6-pyridinedicarboxamido unit in the primary coordination sphere.[6,10,15] The C−O bond length of the O-bound carbonyl group [1.286(4) Å] is significantly longer than the C−O bond of the N-bound carbonyl groups [av. 1.236 Å] as a result of coordination of the carbonyl oxygen to the Fe^{III} center. Similarly, the C−N bond of the O-bound carboxamido unit [1.299(4) Å] is, as expected, shorter than the C−N bond of the N-bound carboxamido group [av. 1.336 Å] (Table 2).

Molecular Structure of $(Et_4N)[Fe(PyPOMe)_2]$ (2)

The coordination geometry around the Fe^{III} center in $[Fe(PyPOMe)_2]^-$ is distorted octahedral with two $PyPOMe^{2-}$ ligands coordinated in a *mer* fashion (Figure 4). Unlike **1**, complex **2** consists of an $Fe^{III}N_6$ chromophore with two axial pyridine nitrogens and *four* equatorial carboxamido nitrogens in its coordination sphere and hence resembles typical bis complexes with bound 2,6-pyridinedicarboxamido units such as $[Fe(Py_3P)_2]^-$. It is interesting to note that by simply decreasing the size of the pendant groups from SMe to OMe at the ligand periphery, a more sterically favorable situation can be created such that all six nitrogens are able to bind to the Fe^{III} center.

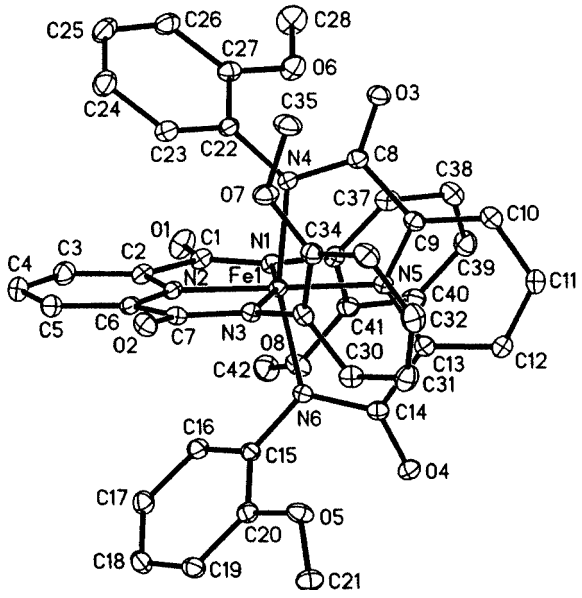

Figure 4. Thermal ellipsoid plot of $[Fe(PyPOMe)_2]^-$, the anion of **2** (at the 50% probability level); H atoms are omitted for the sake of clarity.

The $Fe^{III}-N_{amido}$ [av. 1.979(3) Å] and $Fe^{III}-N_{py}$ [av. 1.875(3) Å] bond lengths of **2** are similar to those noted in Fe^{III} complexes with FeN_6 chromophores arising from coordination of *two* 2,6-pyridinedicarboxamido units.[5,11] However, these bonds are consistently shorter than those in **1** due to the low spin nature of the Fe^{III} center in **2** (vide infra). Furthermore, the octahedral geometry of the N_6 framework in **2** is less distorted than that formed by the N_5O framework in **2**. For example, the $N_{py}-Fe-N_{py}$ and $N_{amido}-Fe-N_{amido}$ angles in **1** (166.85° and 147.56° respectively) are substantially smaller than the corresponding angles in **2** (178.14 ° and 162.23° respectively, Table 2).

Spectroscopic Properties

Coordination of $PyPSMe^{2-}$ and $PyPOMe^{2-}$ to the Fe^{III} centers is readily indicated by the IR spectra of the complexes. Ligation of the deprotonated carboxamido nitrogens to the metal centers results in a red-shift of the carbonyl stretching frequency (ν_{co}) from 1684 cm^{-1} (in both $PyPSMeH_2$ and $PyPOMeH_2$) to 1593 cm^{-1} in **1** and 1603 cm^{-1} in **2**. Also, the N−H stretching frequency of the free ligand (≈ 3200 cm^{-1} for both ligands) is absent in the IR spectra of the iron complexes confirming coordination of the ligands in their deprotonated forms.

The EPR spectrum of **1** in DMF glass at 80K confirms the high spin nature of the Fe^{III} center, displaying a strong signal at $g = 4.3$ (Figure 5). This is contrary to other bis Fe^{III} complexes with coordinated 2,6-pyridinedicarboxamido units.[5,11] The Fe^{III} centers in such complexes are exclusively low spin and exhibit axial EPR resonances with g values in the range of 2.19−1.94. This is also true for complex **2**. In the same DMF glass, complex **2** exhibits an axial EPR spectrum ($g = 2.18$, 1.94) typical of a low spin Fe^{III} center (Figure 5). The only difference between the two bis complexes **1** and **2** is the fact that in **1**, one of the four carboxamido moieties employs the carbonyl oxygen to bind the Fe^{III} center giving rise to an FeN_5O chromophore. This rather simple N-to-O switch in the donor set causes a spin flip and gives rise to the high spin complex **1**. In **2**, all six nitrogens from the two 2,6-pyridinedicarboxamido units are bonded to Fe^{III}, and the FeN_6 chromophore is low spin much like the other complexes of a similar kind.[5,11] To the best of our knowledge, change in the spin state due to only one N-to-O donor switch in otherwise similar complexes of Fe^{III} with carboxamide ligands has not been observed before. It appears that the $Fe-O_{carbonyl}$ interaction exerts a crucial effect on the strong ligand field of the carboxamido nitrogens in these species and just one such interaction can change the overall spin state of the complex. A similar trend in spin state has also been observed in other Fe^{III} complexes that contain $Fe-N_{amido}$ bonds in the presence of $Fe-O_{phen}$ bonds (where phen = phenolato oxygen).[8]

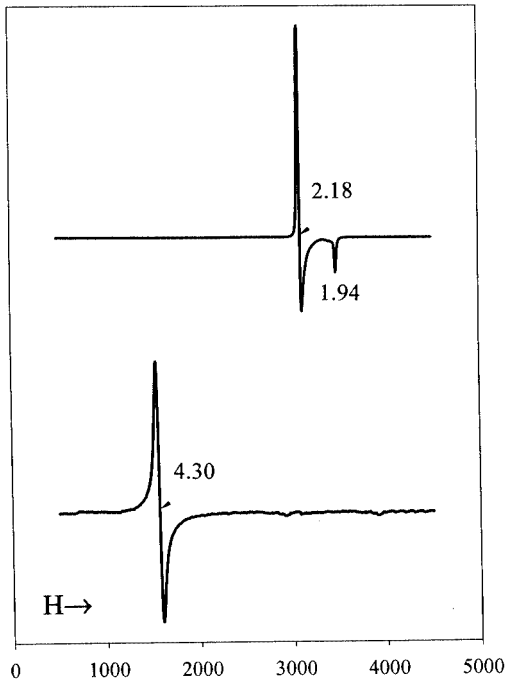

Figure 5. X-band EPR spectra of **1** (bottom panel) and **2** (top panel) in DMF glass at 80 K; instrument settings: microwave power 13 mW, microwave frequency 9.43 GHz, modulation frequency 100 KHz, modulation amplitude 2 G; selected g values are shown

Complexes **1** and **2** are soluble in a variety of solvents such as DMF and CH_3CN giving deep red-orange solutions. This color arises from strong ligand-to-metal charge transfer (LMCT) absorptions at 450 nm for **1** and 440 nm for **2** (both in DMF). Similar LMCT bands have been observed with analogous iron(III) complexes.[5,11] Although **1** is stable in aprotic solvents, it decomposes readily in water. The initial red solution loses its color within minutes and free $PyPSMeH_2$ precipitates from the solution as a white solid. This behavior contrasts sharply with that of other Fe^{III} complexes with FeN_6 chromophores, such as $Na[Fe(Py_3P)_2]$,[5] $Na[Fe(MePy_3P)_2]$,[5] and especially complex **2**. It is therefore evident that the O-bonded Fe^{III} complex **1** is inherently unstable, presumably due to its high spin nature.

Conclusion

In conclusion, we have synthesized and structurally characterized two new, six-coordinate Fe^{III} complexes that contain the 2,6-pyridinedicarboxamido unit. With the potentially pentadentate thioether ligand $PyPSMeH_2$, only the bis complex $(Et_4N)[Fe(PyPSMe)_2]$ (**1**) is obtained irrespective of the ligand to Fe ratio. This strongly suggests that *thioether sulfurs are not good donor groups for Fe^{III} in the presence of carboxamido groups.* On inspection of the few Fe^{III} complexes with bound thioether groups, it becomes evident that coordination of a thioether sulfur to Fe^{III} occurs only when the thioether group(s) exist between other strong donor groups on the ligand frame.[19−21] The steric repulsion among the pendant thioether groups in **1** gives rise to an FeN_5O coordination sphere in which one carbonyl oxygen binds to the Fe^{III} center. It appears that this subtle N-to-O switch in donor atom results in a high spin Fe^{III} center in **1**. In the case of the other Fe^{III} complex $(Et_4N)[Fe(PyPOMe)_2]$ (**2**), the smaller pendant ether groups allow coordination of all four carboxamido nitrogens resulting in a low spin complex with an FeN_6 chromophore. Collectively, these results indicate that the spin state of an Fe^{III} center coordinated by 2,6-pyridinedicarboxamido moieties can be influenced by simple addition of bulky groups to the ligand periphery. Further modifications to the 2,6-pyridinedicarboxamide ligand frame should enable the preparation of other Fe^{III} complexes with novel structural and spectroscopic properties. Such investigations are currently being performed in this laboratory.

Experimental Section

Physical Measurements: Infrared spectra were recorded with a Perkin−Elmer 1600 FTIR spectrophotometer. Absorption spectra were recorded on a Perkin−Elmer Lambda 9 spectrophotometer. ^1H and ^{13}C NMR spectra were recorded at 25 °C on a 500 MHz Varian Unity Plus spectrometer. EPR spectra at X-band frequencies were obtained at 80K with a Bruker ESP-300 spectrometer.

Materials and Methods: All manipulations were carried out using standard Schlenk techniques. 2,6-Pyridinedicarboxylic acid, 2-

(methylthio)aniline, *o*-anisidine, and sodium hydride were purchased from Aldrich and used without further purification. $(Et_4N)[FeCl_4]$[22] and $PyPSMeH_2$ [17] were synthesized by following published procedures. 2,6-Pyridinedicarbonyl dichloride was prepared by refluxing 2,6-pyridinedicarboxylic acid in neat thionyl chloride. All solvents were distilled from the appropriate drying agents prior to use: DMF from BaO, CH_3CN from CaH_2, THF from Na/benzophenone, Et_2O from Na, and $CHCl_3$ from $CaCl_2$.

Preparation of $PyPOMeH_2$: A solution of *o*-anisidine (3.79 g, 30 mmol) and Et_3N (5.00 g, 50 mmol) in $CHCl_3$ (40 mL) was slowly added to a solution of 2,6-pyridinedicarbonyl dichloride (3.11 g, 15 mmol) and Et_3N (5.00 g, 50 mmol) in $CHCl_3$ (50 mL) at 0 °C. The mixture was stirred at room temperature for 24 h. The resultant red solution was washed with aqueous $NaHCO_3$ and NaCl. The $CHCl_3$ layer was then dried over $MgSO_4$, filtered, and the solvent was removed by rotary evaporation to yield a red oil. The oil was triturated with Et_2O (25 mL) to yield a light brown solid (3.75 g, 65% yield). ^1H NMR (500 MHz, $CDCl_3$): δ = 3.95 (s, 6 H, OCH_3), 7.00 (d, 2 H, ArH), 7.10 (t, 2 H, ArH), 7.15 (t, 2 H, ArH), 8.14 (t, 1 H, ArH), 8.55 (d, 2 H, ArH), 8.61 (d, 2 H, ArH), 10.36 (s, 2 H, NH) ppm. ^{13}C NMR (500 MHz, $CDCl_3$): δ = 56.14 (OCH_3), 110.54 (ArC), 120.24 (ArC), 121.50 (ArC), 124.55 (ArC), 125.34 (ArC), 127.44 (ArC), 139.56 (ArC), 148.97 (ArC), 149.41 (ArC), 161.15 (C=O) ppm. Selected IR absorption bands (KBr pellet): $\tilde{\nu}$ = 3371 cm^{-1} (s, N−H), 3014 (w), 2979 (w), 1684 (vs, C=O), 1602 (s), 1536 (s), 1488 (s), 1461 (s), 1334 (m), 1291 (m), 1248 (s), 1220 (m), 1175 (w), 1138 (w), 1110 (m), 1070 (m), 1047 (m), 1029 (s), 1000 (w), 947 (w), 925 (w), 890 (w), 845 (w), 790 (w), 758 (w), 702 (w), 671 (s), 594 (w).

$(Et_4N)[Fe(PyPSMe)_2]$ (1): NaH (0.037 g, 1.54 mmol) was added to a solution of $PyPSMeH_2$ (0.310 g, 0.76 mmol) in DMF (15 mL) and the mixture was stirred until all the NaH had reacted. To the resultant yellow solution was added a solution of $(Et_4N)[FeCl_4]$ (0.120 g, 0.38 mmol) in DMF (2 mL). The resultant dark red solution was stirred for 2 h at 25 °C. The solvent was then removed under vacuum and the residue dissolved in CH_3CN (15 mL) and filtered to remove NaCl. Diethyl ether (7 mL) was added to the CH_3CN filtrate and the resulting solution was stored at −20 °C for 48 h. The dark red crystalline solid thus obtained was collected by filtration and dried under vacuum (0.190 g, 51% yield). Selected IR absorption bands: (KBr pellet): $\tilde{\nu}$ = 3049 cm^{-1} (w), 2983 (w), 2918 (w), 1593 (vs, ν_{CO}), 1461 (m), 1438 (w), 1377 (m), 1342 (w), 1144 (w), 1068 (w), 968 (w), 749 (w). Absorption spectrum in DMF: λ_{max} (ε, $M^{-1}\cdot cm^{-1}$) = 550 nm sh, 450 (7000), 365 (12 000).

$(Et_4N)[Fe(PyPOMe)_2]$ (2): $PyPOMeH_2$ (0.310 g, 0.82 mmol) was dissolved in DMF (10 mL) and to this was added solid NaH (0.046 g, 1.90 mmol). The mixture was stirred for 20 min and $(Et_4N)[FeCl_4]$ (0.140 g, 0.43 mmol) in DMF (2 mL) was then added. The resultant bright red solution was stirred at 25 °C for 2 h. The solvent was then removed in vacuo and the residue dissolved in CH_3CN (15 mL) and filtered to remove NaCl. To the CH_3CN filtrate was added Et_2O (5 mL) and THF (5 mL) and the solution was stored at −20 °C for three days. The bright red crystalline solid thus obtained was collected by filtration (0.290 g, 73% yield). Selected IR absorption bands: (KBr pellet): $\tilde{\nu}$ = 3072 cm^{-1} (w), 2989 (w), 2943 (w), 1603 (vs, C = O), 1578 (s), 1491 (s), 1458 (m), 1374 (m), 1249 (m), 1156 (w), 1112 (m), 1026 (m), 760 (m), 684 (w). Absorption spectrum in DMF: λ_{max} (ε, $M^{-1}\cdot cm^{-1}$) = 440 nm (6600), 305 (18 000).

X-ray Crystal Structure Analysis: Dark red/brown crystals of $(Et_4N)[Fe(PyPSMe)_2]\cdot 1.7CH_3CN\cdot Et_2O$ (**1**·$1.7CH_3CN\cdot Et_2O$) were grown from CH_3CN/Et_2O (3:1) at −20 °C. Bright red X-ray quality blocks of $(Et_4N)[Fe(PyPOMe)_2]\cdot 2H_2O$ (**2**·$2H_2O$) were grown from CH_3CN/Et_2O/THF (3:1:1) at −20 °C. Diffraction data for both complexes were collected at 90 K on a Bruker SMART 1000 diffractometer using Mo-K_α (0.71073 Å) radiation, and an absorption correction was applied in each case. The structures were solved by direct methods (SHELXS-97). In the structure of **1**·$1.7CH_3CN\cdot Et_2O$, there is disorder of one of the terminal groups of the ligand containing C22−S3−C28. This disorder has been omitted in Figure 3 for sake of clarity. Instrument parameters, crystal data, and data collection parameters for **1**·$1.7CH_3CN\cdot Et_2O$ and **2**·$2H_2O$ are summarized in Table 1. Selected bond lengths and angles are listed in Table 2.

CCDC-187840 (**1**·$1.7CH_3CN\cdot Et_2O$) and CCDC-187841 (**2**·$2H_2O$) contain the supplementary crystallographic data for this paper. These data may be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Studies on the Reduction of $[(C_5Me_5)_2Mo_2O_5]$ in Methanol/Water/Acetate Solutions by On-Line Electrochemical Flowcell and Electrospray Mass Spectrometry

Jenny Gun,*[a] Alexandre Modestov,[a] Ovadia Lev,[a] Dirk Saurenz,[b] Mikhail A. Vorotyntsev,[b] and Rinaldo Poli*[b]

Keywords: Cyclopentadienyl ligands / Electrochemistry / Mass spectrometry / Molybdenum / Oxo ligands

The complex $[Cp^*_2Mo_2O_5]$ ($Cp^* = \eta^5$-C_5Me_5) and its electrochemical reduction products in acetic acid/acetate-buffered (pH = 4.0) water/methanol solutions were investigated by combined electrochemical (EC) flowcell and on-line electrospray ionization mass spectrometry (ESI-MS). Mono-, di-, tri-, and tetranuclear organometallic molybdenum oxides were identified in the starting solution. The effect of the relevant ESI-MS parameters (ionic mode, heated capillary voltage, and heated capillary temperature) and of the concentration on the observed distribution of ions in the mass spectrometer was studied in order to minimize side reactions in the ESI chamber. It was verified that reduction in the ESI-MS is undetectable under open-circuit conditions. The on-line electrochemical study revealed the potential-dependent formation of previously unknown mono-, di-, tri-, and tetranuclear Mo^V, Mo^{IV}, and mixed-valence complexes. The compounds were identified by their characteristic isotope patterns and their ion trap MS^n fragmentations. The observed formation potentials reflect the higher stability of the multinuclear species relative to the mononuclear ones with the same oxidation state.

Introduction

The rapid development and eventual commercialization of Electrospray Ionization Mass Spectrometers (ESI-MS) in the 1980s and 1990s has opened the door to the determination of nonvolatile inorganic, organic, and organometallic compounds by mass spectrometry.[1,2] ESI-MS is an atmospheric-pressure technique that uses an electrostatic sprayer to transfer ionic solutes from the sample solution to the gas phase.[3,4] The ESI-MS technique is gradually becoming a valuable tool for the investigation of organometallic compounds in both protic and aprotic solvents[4] and has proven especially useful in combination with investigations of redox processes, particularly reduction processes.

Electrochemical methods are the method of choice for obtaining reduced organometallic compounds, since potential-dependent information can readily be obtained, reversibility is easily checked, and complexation by the chemical reducing agents or their by-products is minimized. Bond et al. have made extensive use of ESI-MS for the investigation of complex electrochemical transformations of organometallic compounds such as the reductions of *cis*-$[(Et_2\text{-dcbpy})_2RuX_2]$ (X = Cl^-, I^-, NCS^-, CN^-)[5] and 17-electron carbonyl(phosphane)rhenium(II) complexes.[6] These works are based on the combination of preparative electrochemistry and subsequent ESI-MS analysis. However, preparative electrochemistry suffers from several disadvantages. Firstly, considerable time is needed in order to achieve full conversion, thereby limiting the resolution of potential-dependent investigations. Secondly, the long reduction times often involve fouling of the electrode surface by polymeric by-products. Thirdly, the reduced compounds have ample time to participate in unwanted subsequent chemical reactions among themselves or with the oxidized forms. Fourthly, preparative electrochemistry monitored by ESI-MS studies involves considerable sample handling, which may result in oxygen penetration and impurity introduction.

The importance of flow-through electrochemical cells connected to a mass spectrometer and the instrumentation involved have recently been reviewed.[7] Cole et al.,[8,9] Bond et al.,[10] and Van Berkel et al.,[11,12] used different configurations of electrochemical cells coupled to on-line ESI mass spectrometers for the investigation of redox reactions. We have devised an on-line concentric electrochemical cell

connected to ESI-MS in which the counter-electrode and its products are separated from the reacting stream reaching the ESI-MS in order to isolate and protect the reduced compounds from the oxidized substances generated at the counter-electrode.

Oxygen-containing organomolybdenum complexes are especially intriguing since, in spite of their ability to attain a large number of oxidation states, relatively little is known about their speciation in protic solutions or about their electrochemistry. More information, on the other hand, is available on inorganic oxomolybdenum compounds, including ESI-MS speciation studies. Singly, doubly, and triply charged heteropoly- and isopolymolybdate anions were studied in organic and aqueous organic solutions,[13,14] though the reduction products of these compounds were not investigated by mass spectrometry. The subject of this study is the identification of the electrochemical reduction products of the complex $[Cp^*_2Mo_2O_5]$ in aqueous methanol solution. $[Cp^*_2Mo_2O_5]$ is a member of a relatively broad family of high-oxidation organometallic compounds, some of which have displayed some remarkable stoichiometric and/or catalytic chemical transformations. Although some of these molecules are stable in aqueous environments and have even been synthesized in water, their aqueous chemistry has rarely been investigated. In the particular case of $[Cp^*_2Mo_2O_5]$, while most studies have been carried out in organic solvents,[15−19] other contributions have restricted the use of aqueous media to some aspects of the synthetic procedure.[20−23] Some of us have recently reported an improved aqueous synthesis[24] of $[Cp^*_2Mo_2O_5]$ and a detailed investigation of its speciation in a $MeOH/H_2O$ mixture by conductivity studies.[25] An additional point of interest of this molybdenum system is the redox-richness of the metal. Exploration of the redox behavior of $[Cp^*_2Mo_2O_5]$ as a prototype compound may thus open up avenues for the development of new stoichiometric or catalytic redox chemistry.

Results and Discussion

(a) Studies of $[Cp^*_2Mo_2O_5]$ Solutions and Optimization of ESI-MS Conditions

The speciation of $[Cp^*_2Mo_2O_5]$ in water/methanol mixtures at various pH values is known from recent kinetic and conductivity studies in one of our laboratories.[25] The use of a mixed water/methanol medium was dictated by the insolubility of $[Cp^*_2Mo_2O_5]$ in pure water, while the hydrosoluble (but lipophobic) $[Cp^*MoO_3^-]$ ion is obtained under basic conditions. As a brief summary of the speciation studies, compound $[Cp^*_2Mo_2O_5]$ was found to exist as a dinuclear molecular species in organic solvents, but self-ionization to $[Cp^*MoO_2^+]$ and $[Cp^*MoO_3^-]$ occurs to a larger and larger extent as the water content in the solvent mixture increases. In 20% $MeOH/H_2O$, the compound behaves as a strong electrolyte, affording as the preponderant species $[Cp^*MoO_2^+]$ at pH < 2 and $[Cp^*MoO_3^-]$ at pH $>$ 5. Both species, plus a minor quantity of $[Cp^*MoO_2(OH)]$, are present at intermediate pH values.[25]

The first part of our investigation was devoted to ESI-MS studies of the reactant $[Cp^*_2Mo_2O_5]$ in order to find the analytical conditions that would most closely reflect its speciation in solution. It is worth noting in this respect that ESI-MS provides a sensitivity advantage over the previous analyses, which may have missed some less dominant species. On the other hand, even though ESI-MS is amongst the least intrusive mass spectrometric techniques,[26] the ionization process may nevertheless introduce fragmentation and rearrangement processes resulting in the observation of peaks of species that are not present in the solution. The experimental conditions must therefore be carefully optimized in order to minimize these phenomena. It is also important to verify that no redox process takes place in the ESI chamber in the absence of an applied electrochemical potential. For practical reasons, the ESI-MS studies were conducted in an $MeOH/H_2O$ (1:1) mixture containing a 0.1 M CH_3COONH_4/CH_3COOH buffer at pH = 4. Under these conditions, a substantial amount of dimolybdenum species (either the neutral $[Cp^*_2Mo_2O_5]$ or the tight ion pair $[Cp^*MoO_2^+]$,$[Cp^*MoO_3^-]$) is also present in solution.

Figure 1 compares ESI-MS analyses of a 0.1 mM solution of $[Cp^*_2Mo_2O_5]$ in positive (a) and negative (b) detection modes. The positive-mode ESI-MS spectrum exhibits four major isotopic patterns, corresponding to mono-, di-, tri-, and tetranuclear species, respectively. The mononuclear region shows two major species [see left insert in Figure 1 (a)], both exhibiting the characteristic, seven-peak isotopic pattern of a single Mo atom. The first species is characterized by an isotopic pattern at m/z = 259−267 and corresponds to the $[Cp^*MoO_2^+]$ cation, while the second one, starting 18 m/z units higher (m/z = 277−285), is attributable to the protonated hydroxo species $[Cp^*MoO_3H_2^+]$. While the former is a solution-borne species, the latter results from the protonation of $[Cp^*MoO_2(OH)]$ and $[Cp^*MoO_3^-]$ in the ESI chamber (its pK_a was estimated as ca. −2). Because of this protonation process, the ESI-MS fails to duplicate the known acid-base speciation.[25]

Two major species appear in the dimolybdenum region, both characterized by the expected isotopic distributions for species containing two Mo centers (see second insert of Figure 1 (a)]. The most abundant isotopic pattern is at m/z = 535−551, which corresponds to the protonated form of $[Cp^*_2Mo_2O_5]$. As stated above, this compound exists as a molecular species in organic solvents (including pure MeOH) but it partially dissociates in the presence of water. In an $MeOH/H_2O$ (1:1) mixture, as used in this study, the conductivity investigations showed that part of the dinuclear compound is undissociated. The observed peak can therefore be attributed to the combination of $[Cp^*_2Mo_2O_5]$ with protons originating from the ammonium buffer. The less abundant and lighter pattern (m/z = 517−533) in this region has 18 fewer m/z units than the previous one and is therefore attributable to a dehydrated form. Probably one of the Cp* protons is involved in the process leading to this species, thereby signaling ESI-MS fragmentation.[27,28]

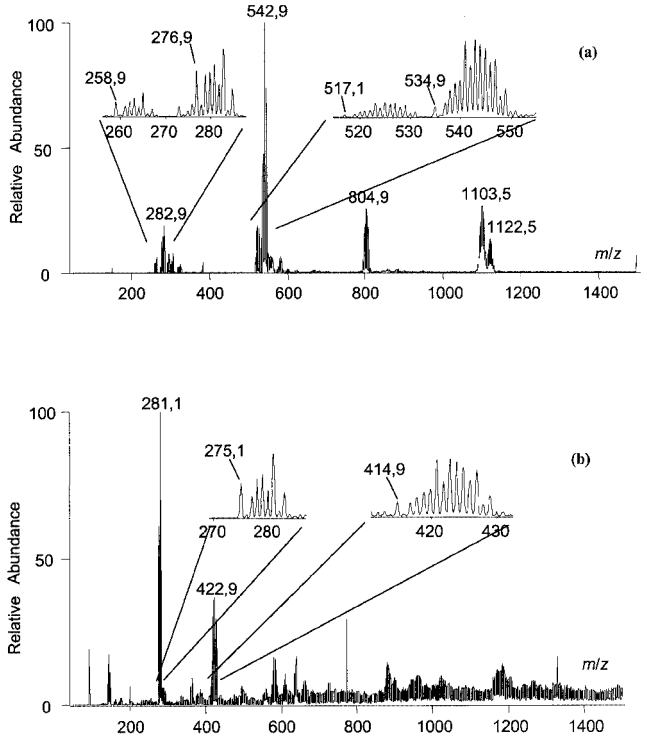

Figure 1. Electrospray mass spectra of a solution of $[Cp^*_2Mo_2O_5]$ (0.1 mM) in H_2O/MeOH (1:1) at pH = 4; heated capillary temperature = 100 °C; (a) positive mode; (b) negative mode; the largest *m/z* peaks are marked in the Figure and the first isotope in each isotopic pattern is marked in the inserts

The isotope patterns at *m/z* = 793−815 and 1090−1117 fit the calculated distributions of $[Cp^*_3Mo_3O_7^+]$ (slope = 1.0005, correlation coefficient R^2 = 0.999) and $[Cp^*_4Mo_4O_{11}H_3^+]$ (slope = 1.008, R^2 = 0.9998), respectively, very well.[29] Thus, both complexes still feature the metal atom in the oxidation state +6. It should be noted that a deviation of a single atomic mass unit (AMU), corresponding to a one-electron reduction process, can easily be distinguished by the isotope distribution fit. For example, curve-fitting of the isotope distribution of a hypothetical $[Cp^*_4Mo_4O_{11}H_4^+]$ to the observed isotope pattern for the tetranuclear species gives a slope of 1.004 but a correlation coefficient R^2 = 0.5451. Of course, the fitting of lower molecular weight molybdenum complexes to the observed patterns is even more sensitive to the assigned composition.

The negative mode spectrum of the same $[Cp^*_2Mo_2O_5]$ solution is given in Figure 1 (b). The major pattern at *m/z* = 275−283 corresponds to the deprotonated mononuclear species $[Cp^*MoO_3^-]$ (left insert). The second major distinguishable pattern (right insert, *m/z* = 415−431) is attributable to a species of formula $[Cp^*Mo_2O_6^-]$: the product of the replacement of one Cp^{*-} group with O^{2-}, a result of ESI-MS fragmentation. The negative mode spectrum also shows a much higher background current, relative to the positive mode spectrum, for *m/z* > 500. For these reasons, all further studies were conducted in the positive ion mode.

Two additional ESI-MS parameters were singled out for further optimization: the temperature of the heated capillary and the heated capillary voltage. Figure 2 (a) shows the ESI-MS spectrum recorded under the same conditions of Figure 2 (a), except that the heated capillary was maintained at 200 °C rather than at 100 °C. The differences between the two spectra confirm that the heated capillary temperature is a decisive factor in ESI-MS studies of our compounds. A comparison between the inserts of Figure 1 (a) and Figure 2 (a) reveals that $[CpMoO_3H_2^+]$ almost completely disappears at high temperatures, while the abundance of a new species with *m/z* = 273−281 (corresponding to $[CpMoO_3H_2^+ - 3\ H]$) − evidently resulting from a fragmentation process − increases. Furthermore, the daughter product with *m/z* = 517−533 in the dinuclear region becomes the preponderant species, while the original isotope pattern of the protonated dinuclear species $[Cp^*_2Mo_2O_5H^+]$ almost completely disappears. In addition,

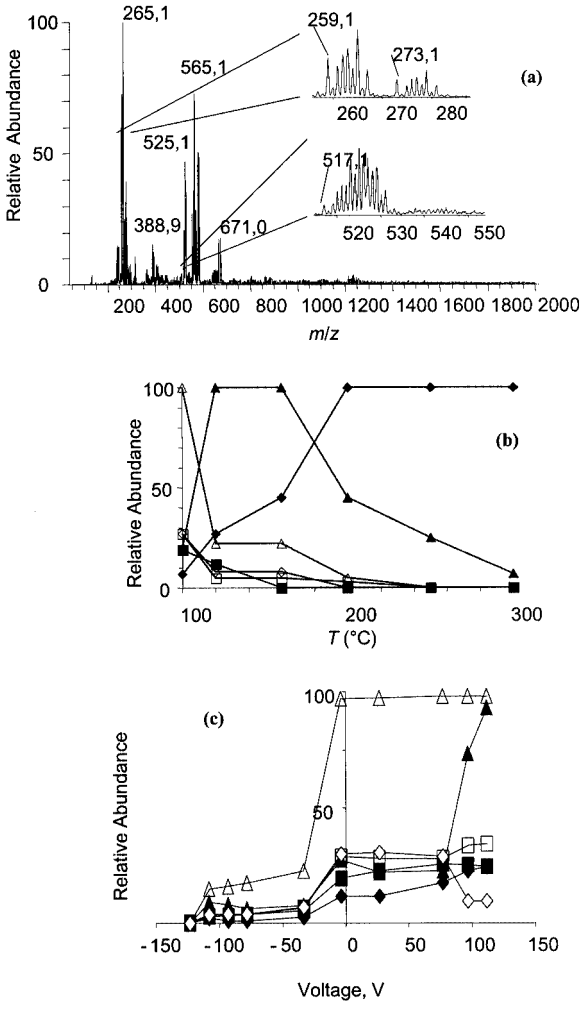

Figure 2. (a) Positive-mode electrospray mass spectra of a solution of $[Cp^*_2Mo_2O_5]$ (0.1 mM) in H_2O/MeOH (1:1) at pH = 4; heated capillary temperature = 200 °C; (b) and (c) evolution of the relative intensity of selected species {black diamonds: $[Cp^*MoO_2^+]$; black squares: $[Cp^*MoO_3H_2^+]$; black triangles: $[Cp^*_2Mo_2O_5H^+ - H_2O]$; white triangles: $[Cp^*_2Mo_2O_5H^+]$; white squares: $[Cp^*_3Mo_3O_7^+]$ species; white diamonds: $[Cp^*_4Mo_4O_{11}H_3^+]$} as a function of the heated capillary temperature (b) and heated capillary voltage (c)

other fragmentation products are also formed in relatively large proportions. Evidently, $[Cp^*_2Mo_2O_5]$ is cleaved at high temperatures.

The temperature dependence demonstrated in Figure 2 (a) is further elaborated upon in Figure 2 (b). The figure shows the dependence of several of the most abundant positive ion peaks as a function of the heated capillary temperature. Peak heights were normalized to the highest peak observed at the given heated capillary temperature. Under increased temperature conditions the abundance of the parent peak of the protonated $[Cp^*_2Mo_2O_5]$ decreases, while the abundance of the secondary peak of the dehydrated moiety goes through a maximum at 120−180 °C and then also decreases. The abundance of the monomeric form $[Cp^*MoO_2^+]$ increases monotonically with temperature, indicating a somewhat surprising thermal stability for this ion, whereas its relative abundance at 100 °C amounts to less than 10% of the dinuclear peak.

The relative abundances of the tri- and tetranuclear molybdenum species decrease steadily with the heated capillary temperature. This decrease suggests that the tri- and tetranuclear molybdenum species originate from the aqueous solution and that they were not generated by condensation reactions in the ESI chamber. Condensation reactions and dehydration should increase at higher temperatures, contrary to the tendency exhibited in Figure 2 (b). We thus believe that these compounds do exist in the solution, although they were not observed before by any other technique. These results directed our subsequent experiments to low source temperatures, set at 100 °C for detector sensitivity reasons.

The capillary voltage value was optimized (+25 V) during the automatic tuning process of our MS in order to give the highest sensitivity for the mass of $[Cp^*_2Mo_2O_5H^+]$. Since prior studies had pointed to the sensitivity of the observed spectra of organometallic complexes to the heated capillary voltage,[30] we carried out a set of tests in order to check the influence of this parameter in our case. The experiments showed that the spectra were not significantly changed as long as the heated capillary voltage remained within the −25 to +100 V range, see Figure 2 (c). It should be pointed out that no reduced molybdenum species were observed even when this potential was set as low as −100 V. Only for more negative cone voltages (< −110 V) did a reduction peak become observable (m/z = 777−799, attributable to $[Cp^*_3Mo_3{}^{V,V,VI}O_6^+]$).

The concentration dependence of the peak intensities for the five major species are shown in Figure 3. The relative abundances of the $[Cp^*MoO_3H_2^+]$ and $[Cp^*MoO_2^+]$ species are virtually concentration-independent, whereas those of all other species, including the dinuclear $[Cp^*_2Mo_2O_5H^+]$, increase with concentration. Given the established equilibrium in MeOH/H_2O solutions of various proportions between the dinuclear $[Cp^*_2Mo_2O_5]$ on one hand, and the separate ions $[Cp^*MoO_2^+]$ and $[Cp^*MoO_3^-]$ on the other, an increase of the relative abundance of dinuclear species with the concentration was to be expected. In principle, the observed increase in relative intensity with concentration for the trinuclear and tetranuclear peaks could be equally well explained by invoking similar solution equilibria. Since we have shown that a water-rich environment favors the spontaneous ionization of $[Cp^*_2Mo_2O_5]$ into $[Cp^*MoO_2^+]$ and $[Cp^*MoO_3^-]$, we propose that the trinuclear species derives from the combination of, for example, $[Cp^*MoO_3^-]$ with two $[Cp^*MoO_2^+]$ ions, as shown in Scheme 1.

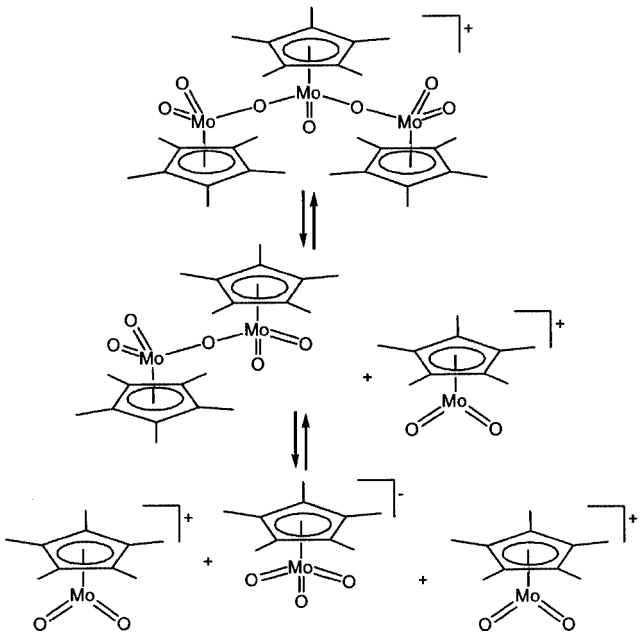

Scheme 1

A similar association process may occur for the tetranuclear species, although a simple breakdown into mononuclear charged components and a tentative structure for the assembled species cannot be as easily imagined as for the trinuclear species. It should further be remarked that these ionic association processes should be favored by the low polarity of the water/methanol (50:50) mixture. In the more polar (80:20) mixture, in which our previous speciation study was conducted,[25] no evidence for the presence of these ions was obtained, although the kinetics and conduc-

tivity may have been insensitive to the presence of small amounts of these species.

The choice of a buffer based on the ammonium cation rather than on other metal cations was dictated by the observation of complicating metal addition processes when the latter were used. For instance, Figure 4 shows the basic set of peaks of the dinuclear species in the presence of 1 M $LiBF_4$ (acidified to pH = 3.3 by acetic acid). Competitive protonation and formation of adducts with metal cations, the latter being preponderant, take place, and both adducts are discerned in the ESI-MS spectrum. The formation of metal ion adducts in preference to protonation in the ESI-MS chamber is a known phenomenon for neutral organometallic molecules.[31,32]

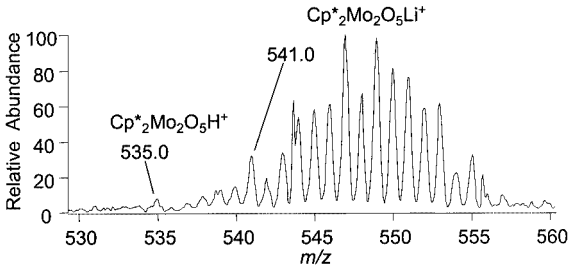

Figure 4. Detailed positive-mode electrospray mass spectra for a 0.1 mM solution of $[Cp^*_2Mo_2O_5]$ in H_2O/MeOH (1:1) in the presence 1 M $LiBF_4$ (pH = 3.3)

In addition to obtaining optimal ESI-MS parameters, two important interim conclusions could be reached on the basis of open-circuit studies of $[Cp^*_2Mo_2O_5]$ in methanol/water/acetate solutions. Firstly, condensation reactions do not occur to a large extent in the ESI chamber; the tri- and tetranuclear molybdenum species appear to be already present in solution. Secondly, reduced molybdenum compounds are not generated to any noticeable extent in the ESI-MS. This condition is a prerequisite for our further on-line electrochemical reduction/ESI-MS studies.

(b) On-Line Electrochemical Reduction/ESI-MS Study

Figure 5 (a) shows the background 3 mV/s voltammogram of an MeOH/H_2O (1:1) solution (acetic buffer, pH = 4) recorded in a regular three-compartment electrochemical cell with a glassy carbon working electrode. Curve (b) shows the voltammogram of a 1 mM solution of $[Cp^*_2Mo_2O_5]$. The reduction wave starts at approximately −0.45 V vs. saturated Ag/AgCl electrode. The current/potential curves at the forward and backward scans nearly coincide and the height of the reduction wave is virtually independent of the scan rate for a fairly wide range of scan rates (3−100 mV/s). The last two observations indicate that the electrochemical reduction of $[Cp^*_2Mo_2O_5]$ is controlled by an interfacial step and it is not diffusion-limited. A slope change at $E = -0.65$ V implies that an additional reduction step is switched on at this potential. It is quite obvious that identification of the electroreduction products solely on the basis of the voltammetric experiment is impossible.

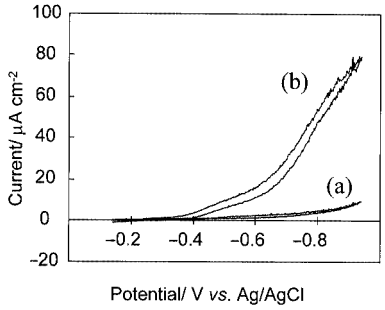

Figure 5. Voltammetry in 0.25 M NH_4Ac in H_2O/MeOH (1:1) at pH = 4 on a GC electrode; scan rate: 3 mV/s; (a) blank solution; (b) 1 mM $[Cp^*_2Mo_2O_5]$

Preparative electrolysis studies at −0.6, −0.7, and −0.8 V with a conventional 10-mm-diameter glassy carbon electrode showed a gradual decrease of the current after prolonged polarization (2 h) due to the formation of a thick oxide film on the electrode surface. This was accompanied by the accumulation of polymeric products in the solution, which increased the turbidity of the solution and could also be detected by ESI-MS studies. We thus preferred to direct our electrochemical studies towards the flow-through configuration because the shorter timescale of the experiment and the constant renewal of the electrolyzed solution insured the absence of contamination from slower secondary reactions.

The electrochemical investigations were therefore pursued in a combined on-line electrochemical cell/ESI-MS experimental setup (Figure 6). The flow configuration and the characteristics of this setup are described in full details elsewhere.[33] Briefly, the feed stream in this cell reaches the sample electrode through the outer annulus of a concentric dual capillary arrangement. The feed stream is split into an outer stream that diverges outwards and washes away the cell solution and an axial stream that flows inward through a 20-μm gap between the glassy carbon sample and the flat end of the dual capillary arrangement. The feed converges into an inner capillary transfer line that leads to the mass spectrometer. We preferred this type of setup over a regular tabular flow cell in order to avoid chemical interference due to the oxidation reactions on the counter-electrode. This configuration also minimizes ohmic potential drops in the cell. Note that, unlike regular flow-through electrochemical detectors that operate under mass-transport-limited conditions, we target a kinetically controlled reaction. Thus, by use of conventional flow-through cells, oxidized compounds generated at the counter-electrode will most probably escape electroreduction on the working electrode and will reach the transfer line to the mass spectrometer. This phenomenon may result either in the appearance of oxidized species in the MS or, even worse, in the occurrence of chemical reactions between the compounds generated at the counter-electrode and the working electrode. The flow cell of Figure 6 assures the confinement of the compounds gen-

erated at the counter-electrode away from the transfer line to the mass spectrometer.

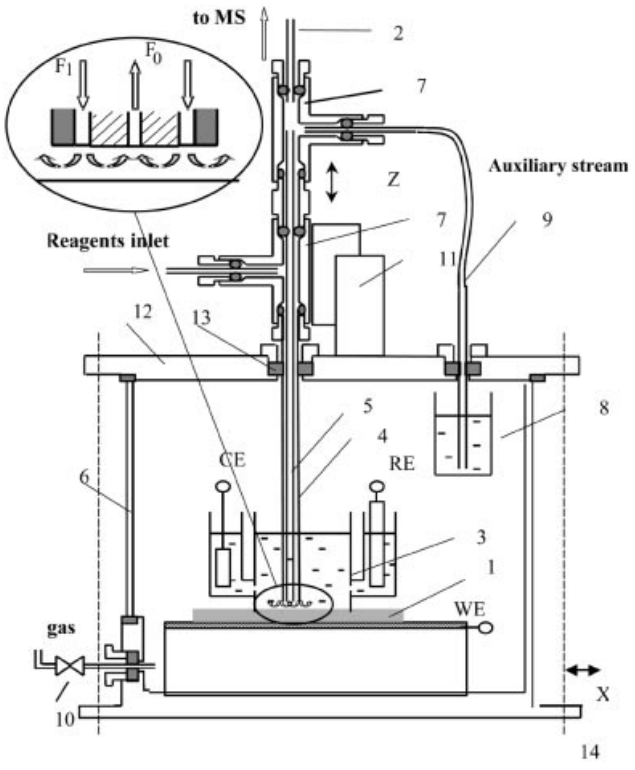

Figure 6. Scheme of the electrochemical cell used in this study; 1: working electrode; 2: transfer line to the ESI/MS; 3: three-compartment electrochemical glass cell; 4: outer capillary; 5: inner capillary; 6: pressure chamber; 7: T-junction; 8: auxiliary fluid beaker; 9: auxiliary capillary; 10: pressure regulator; 11: Z-translation stage; 12: pressure chamber cover; 13: rubber seal; 14: steel rod; insert: a scheme of the miniature flow cell formed at the bottom of the coaxial capillary setup; F_1 is the feed through the annulus of the coaxial capillary setup; F_0 is the product stream to the MS

Mass spectra are continuously recorded during the coupled EC/ESI-MS experiments, and so a three-dimensional domain of signal intensities as a function of *m*/*z* and time is generated. Projection of this space onto an *m*/*z* axis for a given time range gives a time-integrated traditional mass spectrum, while projection onto the time axis for a given *m*/*z* range gives the time evolution of the chosen species. Under potential ramp constraint, a potential-dependent generation or consumption of the specific compounds is obtained.

In order to translate the time-dependent relative abundances into potential-dependent curves it is necessary to measure the lag time in the transfer line from the electrochemical flowcell to the mass spectrometer and to estimate the degree of back-mixing (i.e. signal averaging) in the transfer line. These parameters were determined by application of a potential step to the GC working electrode between −0.35 and −0.9 V. According to the voltammetric curve (b) shown in Figure 5, the Mo species in the solution are exclusively in their oxidized state at $E = -0.35$ V, while reduction processes occur at $E = -0.9$. Figure 7 shows that the application of the potential step sharply decreases the concentration of $[Cp^*_2Mo_2O_5H^+]$. The intensity of the signal starts to decrease after a delay time of ca. 25 s. This seemingly corresponds to the retention time in the transfer line, in agreement with flow calculations. An additional 15-s interval is required to reach the half height of the concentration step change. The deviation of the MS response from a sharp step change is attributable to back-mixing in the transfer line and to the time constant of the ESI interface. Thus, the "lag time" of the instrument is approximately 40 s. The coupled EC/ESI-MS experiment with a continuous potential linear scan were therefore recorded under the quite slow scan rate conditions of 0.5 mV s^{-1}.

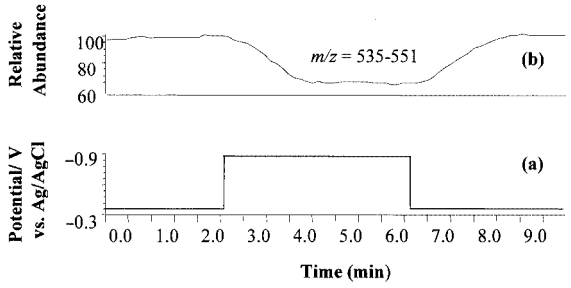

Figure 7. Response of the EC/ESI-MS (positive mode) to a potential step change of the GC electrode; feed stream: $[Cp^*_2Mo_2O_5]$ (1 mM) in 0.25 M NH_4Ac H_2O/MeOH (1:1) at pH = 4; (a) potential step function; (b) time trace of the $[Cp^*_2Mo_2O_5H^+]$ signal intensity, integrated over the given *m*/*z* range

Figure 8 shows the potential-dependent abundance of all major species present in solution under open-circuit conditions {i.e., the mononuclear $[Cp^*MoO_2^+]$ and $[Cp^*MoO_3H_2^+]$, the dinuclear $[Cp^*_2Mo_2O_5H^+]$, the trinuclear $[Cp^*_3Mo_3O_7^+]$ and the tetranuclear $[Cp^*_4Mo_4O_9(OH)_3^+]$; see Figure 1 (a)}, during the electroreduction process. The recorded signal was obtained by summing the relative abundances of all the peaks in each respective *m*/*z* range, covering the entire isotope envelope. The time axis of the product evolution curve was synchronized with the corresponding potential scale by the use of a 40 s delay time based on the potential step-change studies. During the backward, anodic scan, the concentration profiles essentially follow the same pattern as observed in the cathodic scan, indicating that the experiment is not significantly polluted by film-deposition processes. It is to be noted that all species start to be reduced at approximately the same potential. This would seem consistent with the presence of rapid equilibria between the various complexes, as proposed above, and with the selective reduction of only one of these species. However, it cannot be excluded that all the different species, or at least some of them, are reduced independently at approximately the same potential. A clarification of this point needs additional experiments under different concentration and pH conditions, which are in progress and will be reported in due course.

The mass spectrum measured at the switching potential (see Figure 9) reveals a set of new peaks corresponding to the different products of electrochemical reduction. New isotopic patterns corresponding to the formation of reduced

mononuclear, dinuclear, trinuclear, and tetranuclear species evolved at reduced potentials.

The potential-dependence of the MS intensities of the reduced molybdenum species are shown in Figure 10, together with their corresponding MS isotopic patterns and assigned structures. The last are based on the fit of the observed MS isotope patterns to the calculated isotope distributions. It should be noted that, although the molecular weight and Mo nuclearity are unambiguous, the assigned structures are only tentative. Alternative possibilities exist: species $[Cp^*_2Mo_2O_2(OAc)_2^+]$, for instance, may display two terminal oxo and two bridging acetato ligands, or two bridging oxo and two terminal (chelating) acetato ligands, or all ligands may be bridging, as shown in Figure 10. The chosen assignments are based on comparison with related examples from the literature. The closest analogues to the dinuclear complexes are half-sandwich sulfido and alkylsulfido species extensively investigated in the groups of Rakowski-Dubois and Pétillon.[34−36] No previous report of compounds in which the $[Cp^*_2Mo_2^{n+}]$ core is fully coordinated by hard, oxygen-based ligands seems to be available, the exceptions being the starting material $[Cp^*_2Mo_2O_5]$ and the corresponding Mo^V dimer $[Cp^*_2Mo_2O_4]$.[24,37,38] Related trinuclear [Cp*Mo] species of formula $[Cp^*_3Mo_3O_6H_n]^{2+}$ (n = 4, 5, 6), on the other hand, have previously been reported by Bottomley et al.[39] Amongst tetranuclear oxo clusters, the closest relationship is found with a Cp derivative, a red isomer of "$[CpMoO_2]$", the nuclearity of which was based solely on molecular weight determinations.[40] The more stable orange isomer has a dinuclear structure. A more reduced tetranuclear oxo cluster, $[Cp^*_4Mo_4O_7]$, formally a $Mo^{4.5+}$ species, has also previously been described.[41] No indication has been obtained, however, that the latter species is formed under our experimental conditions.

As shown in Figure 10 (central column), the isotopic envelopes of most identified species do not overlap with the other nearby isotopic patterns. An exception is the dinuclear complex $[Cp^*_2Mo_2O_4H^+]$ (m/z = 519−535), which overlaps with another species with m/z = 517−533, a daughter ion obviously deriving from hydrogen loss from the Cp* rings. The voltage-dependent intensity of the $[Cp^*_2Mo_2O_4H^+]$ species is obtained by integration of an m/z region where the overlap with the minor species is minimal (m/z = 532−534). Complex $[Cp^*MoO(OAc)^+]$ (m/z = 302−310) overlaps with another species with one fewer mass unit, indicating fragmentation with loss of hydrogen atoms. The envelope of the reduced trinuclear species is shifted to lower m/z by exactly 16 units from that of its precursor complex $[Cp^*_3Mo_3O_7^+]$, suggesting its formulation as a proton-free hexaoxo species.

The assignment of the chemical formulas for the reduced species is further supported by ion-trap MS^n fragmentation studies, the results being collected in Table 1. All MS^n studies were conducted with isolation widths corresponding to the whole range of the observed isotope patterns. The m/z = 302−310 monoacetate complex shows loss of acetic acid and formation of a methanol adduct in the MS^2. Similarly, the diacetate mononuclear complex (m/z = 345−353) exhibits loss of an acetic acid unit. The low stability of these low-weight mononuclear fragments did not allow further MS^3 fragmentation studies. The assignment of the m/z = 519−535 to a $[Cp^*_2Mo_2O_4H^+]$ species is supported by $MS^2/MS^3/MS^4$ subsequent fragmentations showing a consecutive series of single dehydrations. In addition, an MS^n study of separately synthesized $[Cp^*_2Mo_2O_4]$ revealed an identical fragmentation pathway. The assignment of m/z = 561−577 to a $[Cp^*_2Mo_2O_3(OAc)]$ species is supported by MS^2 fragmentation showing neutral losses of an acetyl fragment or water. The isotope pattern at m/z = 604−620 is assigned to $[Cp^*_2Mo_2O_2(OAc)_2^+]$ on the basis of the acetyl loss and dimer cleavage to give the $[Cp^*MoO_2(OAc)^+]$ and $[Cp^*MoO(OAc)_2^+]$ cationic fragments in the MS^2. The $[Cp^*_2Mo_2O(OAc)_3^+]$ complex (m/z = 647−663) gives rise to three different fragmentations at different collision ener-

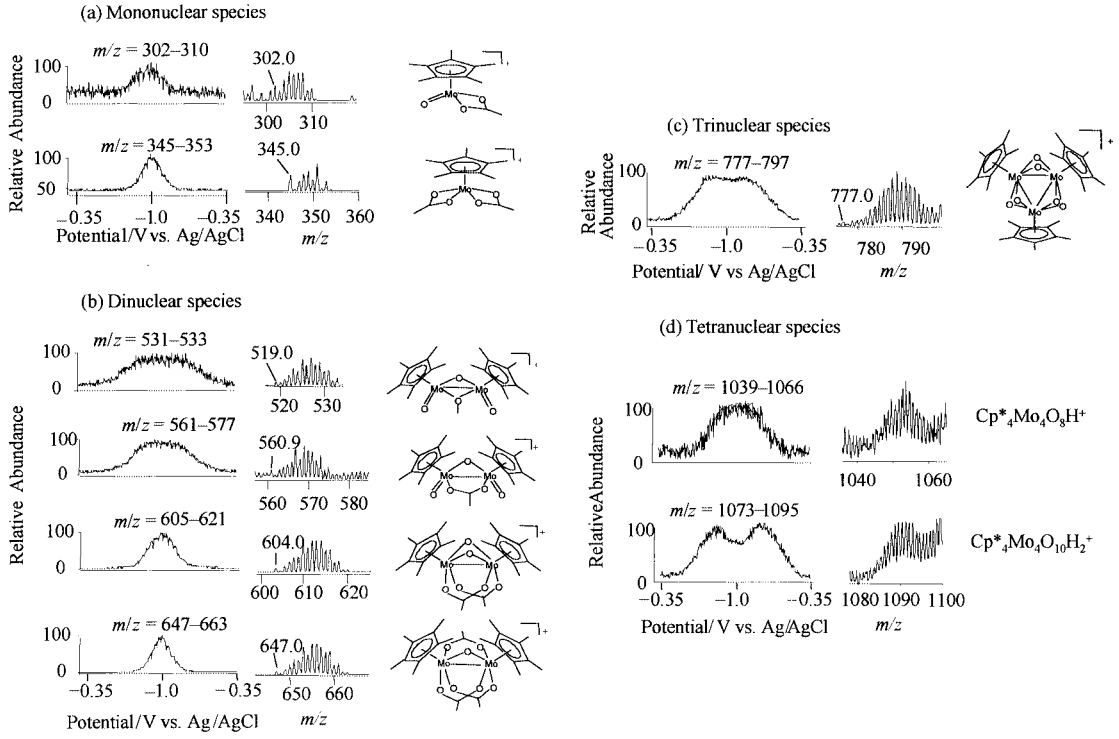

Figure 10. Potential dependence of the relative abundance of selected species generated during the coupled electrochemistry/ESI-MS of $[Cp^*_2Mo_2O_5]$; left: potential-dependent evolution of the integrated signal, the *m/z* range used for signal integration is specified above each curve; center: expanded isotopic pattern; right: proposed chemical structure; experimental conditions are as specified in Figure 7

gies, corresponding to loss of a one and two acetyl groups, and to dimer cleavage to give the mononuclear fragment $[Cp^*Mo(OAc)_2^+]$. Further MS^3 fragmentation of $[Cp^*Mo(OAc)_2^+$ reveals an additional acetyl loss. Finally, MS^4 fragmentation of $[Cp^*Mo(OAc)^+]$ reveals one oxygen atom loss.

The MS^n fragmentation of the trinuclear species is even more complicated. The primary species $[Cp^*_3Mo_3O_6^+]$ (m/z = 777−799) produces four fragments in the MS^2. The first two correspond to loss of $C_5Me_4CH_2$ and $C_5Me_4CH_2 + H_2O$, respectively, the third is a methanol adduct of the second, and the fourth corresponds to $[Cp_2Mo_2O_4^+]$, resulting from the loss of $[Cp^*MoO_2]$. It should be noted that the latter cleavage involves disruption of two oxo bridges and indeed it occurs at much higher collision energy than the first three processes. MS^3 fragmentation of the methanol adduct results in MeOH loss, and a subsequent MS^4 fragmentation reveals four ions corresponding to Cp* loss plus formation of three solvent adducts of the resulting fragment. MS^3 and MS^4 fragmentation of $[Cp^*_2Mo_2O_4^+]$ give rise to subsequent dehydration processes. No MS^n study of the reduced tetranuclear species could be carried out, because of the very low abundance of these peaks.

Table 2 presents the approximate potential values for the appearance of the various reduced species that may be measured in Figure 10. Analysis of these values enabled us to derive a certain number of conclusions: (i) for a given nuclearity, the potential becomes more negative as the oxidation state decreases, as one would expect, (ii) when comparing species of the same formal oxidation state, the dinuclear compounds are always obtained at a less negative potential than the mononuclear ones, while the tetranuclear $[Cp^*_4Mo_4O_8H^+]$ species is obtained at approximately the same potential (−0.52 V) as the dinuclear $[Cp^*_2Mo_2O_4H^+]$ species (−0.48 V), (iii) the latter complex is obtained at a less negative reduction potential than the other Mo^V dinuclear species containing an acetate ligand, and finally (iv) this potential nearly matches the potential at which the peaks of the starting complex start to disappear (Figure 8). The large deviation between the threshold formation potentials and the mid-intensity potential $E_{1/2}$ points to kinetically controlled formation reactions for all of the reduced molybdenum species. This is unfortunate, since it precludes direct evaluation of the corresponding thermodynamic formation parameters for these new compounds.

These combined observations may be interpreted as follows. The mononuclear products are likely to derive from the one-electron reduction of $[Cp^*MoO_2^+]$, affording a neutral radical. At more negative potentials, the latter species may be reduced further, possibly after a protonation stage. At each oxidation state level, two competing processes may occur: namely acetate/hydroxide exchange and dimerization (accompanied by the establishment of a metal−metal bond). For instance, the neutral Mo^V intermediate may dimerize to $[Cp^*_2Mo_2O_4]$, which is then detected by ESI-MS in its protonated form, or it may be protonated and the resulting $[Cp^*MoO(OH)^+]$ species may undergo a hydroxide/acetate exchange to produce the observed

$[Cp^*Mo^{V}O(OAc)^+]$	302–310	−0.76	−0.92

[a] E_{in} is defined as the potential corresponding to a 100% abundance increase over the background signal. $E_{1/2}$ = potential at which half of the maximum signal intensity is obtained.

$[Cp^*MoO(OAc)^+]$. The driving force of the rapid and irreversible metal–metal bond formation would account for the smaller reducing potential needed to generate an oligonuclear species relative to a mononuclear one at the same oxidation state level. It is also possible, however, that the higher nuclearity products are obtained by direct reduction of the higher nuclearity species present in solution. It can be noted that each one-electron reduction for the mononuclear and dinuclear species is formally accompanied by the replacement of one oxygen atom with an acetate group (corresponding to a mass increase of 43 units). The only exception to this substitution rule is the observation of two different compounds with the $Mo_2^{V,V}$ core and related to each other by the formal replacement of an OH with an acetate group. The spectrum in Figure 9 does not show any mononuclear species with a mass greater than the 345–353 envelope, nor dinuclear species with a mass greater than the 647.0–664.0 envelope. This suggests that no Mo species in oxidation states lower than +4 are produced under the experimental conditions chosen.

The major trinuclear product obtained under reducing conditions is an $Mo_3^{V,V,VI}$ species. On the other hand, the same basic structure was reported for the dicationic $Mo_3^{IV,IV,V}$, $Mo_3^{IV,IV,IV}$, and $Mo_3^{III,IV,IV}$ complexes $[Cp^*_3Mo_3O_6H_n^{2+}]$ (n = 4, 5, 6).[39] Although the isotope envelope simulation quite clearly indicates the nature of the major product, minor amounts of products of further reduction cannot be excluded. We did not observe any signals attributable to dicationic species. It is possible that the reduction potential range and the conditions used in this study do not allow access to the more reduced known trinuclear species, which were in fact previously obtained by zinc reduction of $[Cp^*MoO_2Cl]$ under non-aqueous conditions.[39]

As far as the tetranuclear reduction products are concerned, the $[Cp^*_4Mo_4O_8H]^+$ species may be related to the kinetic isomer previously identified for the Cp system when complex $[CpMoCl_4]$ is hydrolyzed, namely $[Cp_4Mo_4O_8]$.[40]

It is believed that this complex does not contain metal−metal bonds, whereas the dinuclear $[Cp_2Mo_2O_4]$ isomer does.[42] The formation of this tetranuclear compound from precursors that themselves are devoid of metal−metal interactions is therefore to be expected. The mixed-valence $[Cp^*_4Mo_4O_{10}H_2]^+$ species does not have any equivalent in the literature. The shape of the abundance vs. potential curve indicates that a direct reduction to other species, possibly the tetranuclear Mo^V cluster, becomes more favorable at more negative potentials.

As clearly shown by the cone voltage optimization study [Figure 2 (c)], the experimental conditions of the positive-mode electrospray process cannot, by themselves, induce an oxidation state decrease for the analyte. The reduced molybdenum products shown in Figure 10 must therefore originate from the electrochemical reactions in the electrochemical cell. The simple chemical composition of these species and the fact that they contain unfragmented acetate and pentamethylcyclopentadienyl ligands lead us to believe that they are all indeed solution-borne species.

Conclusion

The coupled EC/ESI-MS technique has proven to be a powerful analytical tool for the investigation of complex electrochemical transformations. At least six previously unreported species have been identified from the electroreduction of $[Cp^*_2Mo_2O_5]$, and the potential required for the generation of each one has been assessed. These species may be described as oxo- and/or acetate-stabilized $[Cp^*Mo^{n+}]$, $[Cp^*_2Mo_2^{n+}]$, $[Cp^*_3Mo_3^{n+}]$, and $[Cp^*_4Mo_4^{n+}]$ complexes. These species, as well as analogues with less coordinating anionic ligands, may be expected to result in new aqueous coordination chemistry, catalysis, and electrocatalysis. Indeed, a few dinuclear and trinuclear species related to those observed by this EC/ESI-MS investigation have been synthesized and isolated in one of our laboratories. These investigations are described in separate publications.[43,44]

Experimental Section

General Remarks: The starting compound was prepared by a literature procedure.[24] Unless otherwise stated, all solutions were prepared in H_2O/MeOH (1:1) containing CH_3COONH_4 (0.25 M) and buffered to pH = 4.0 by the addition of CH_3COOH. A lower concentration of MeOH in the spray solution resulted in significant losses of relative abundances. All reagents were purchased from Aldrich. Methanol was purchased from Baker and was of HPLC grade. The water was triple-distilled.

Electrospray Mass Spectrometry: A Finnigan (San Jose, USA) LCQ quadrupole ion trap mass spectrometer, equipped with an electrospray ionization (ESI) interface, was used for data acquisition. ESI was operated either in positive or in negative ion mode. In negative mode the tip of the capillary and the sampling cone were maintained at potentials of −3.5 kV (spray voltage) and −70 V (capillary voltage), respectively. In positive mode the spray voltage was at 3.6 kV and the capillary voltage was 25 V. The source temperature was the subject of a separate study. Mass spectra were acquired by scanning the mass analyzer from m/z = 100 to 2000 with five total microscans. The maximum injection time into the ion trap was 50 ms, and the sample injection flow rate was 5 μL min^{-1}. In all experiments, helium was introduced at an estimated pressure of 1 mTorr to improve the ion trapping efficiency. During MS^n experiments the compounds were isolated in the ion trap with isolation width of isotope pattern and activated by use of increased collision energy.

Electrochemical Investigations: A PARC 273 potentiostat/galvanostat (Princeton, USA) was used. A three-compartment electrochemical cell with a disk glassy-carbon working electrode (Metrohm, Herisau, Switzerland), platinum counter-electrode and Ag/AgCl (satd.) reference electrode (Metrohm) was used for the voltammetric studies.

Coupled Electrochemistry/Electrospray Mass Spectrometry: Figure 6 shows a scheme of the experimental setup used in this study; a detailed description of the electrochemical setup is given elsewhere.[33] The setup comprises a three-compartment electrochemical cell placed in a pressure chamber, a two coaxial capillary set, a micropositioning device, and a mass spectrometer equipped with an electrospray ionization (ESI) interface. The working glassy-carbon electrode (1) was pressed to the bottom opening of a three-compartment electrochemical cell (3). A Pt wire counter-electrode and Ag/AgCl (KCl satd.) reference electrodes were placed in the side compartments of the cell. All reported potentials are given relative to this reference electrode. The electrolyte in the cell was 0.25 M CH_3COONH_4 in H_2O/MeOH (1:1), buffered to pH = 4.0 by CH_3COOH. A $[Cp^*_2Mo_2O_5]$ solution (1 mM) in the same electrolyte was pumped through the annulus of the capillary set to the electrode. A coaxial capillary set (4, 5) was used to deliver the reagent solution to the electrode and to transfer the product stream to the interface of the mass spectrometer through the inner capillary. A syringe pump was used to deliver the feed stream to a T-junction (7) located outside the pressure chamber (6), from which the stream was directed through the annulus between the two capillaries to the electrode. The product stream (F_0) was pumped, following the interaction with the electrode, upward through the inner capillary (4) by the excess pressure in the pressure vessel. All capillaries were fused silica from SGE (Austin, USA). The inner capillary was 25 μm inner diameter, 285 μm outer diameter, 15 cm long. The product stream was diluted with excess methanol delivered from a glass beaker (8). The liquid flow rates and dilution ratio (product stream/methanol) were controlled by setting the pressure in the pressure vessel and choice of capillary length and inner diameter. The cell pressure was 2600 kPa. After mixing with the auxiliary liquid, the sample stream was delivered to the ESI interface of the mass spectrometer by a 30 cm long, 50 μm inner diameter capillary. The flow rate of the product stream was ca. 0.7 μL min^{-1}. The methanol flow in the auxiliary capillary was 14 μL min^{-1}. The reagent flow rate (F_1) was set to 4 μL min^{-1}.

New Monocyclopentadienyl Complexes of Tantalum(V) and Titanium(IV) with Chelating Pyrimidinethiolate and Oxypyridine Ligands − Molecular Structure of [Cp*$TaCl_3(SC_6H_7N_2)$]

Rosa Fandos,*[a] Carolina Hernández,[a] Antonio Otero,*[b] Ana Rodríguez,[c] María José Ruiz,[a] and Pilar Terreros[d]

Keywords: N ligands / S ligands / Tantalum / Titanium / Cyclopentadienyl ligands

New monocyclopentadienyl species of Ta^V, [Cp*TaL_3(XR)] (L = Cl, Me, X = O, S) bearing 4,6-dimethyl-2-pyrimidinethiolate (SR = $SC_6H_7N_2$) or 3-cyano-4,6-dimethyloxypyridine (OR = $OC_8H_7N_2$) ligands were prepared, namely [Cp*$TaCl_3(SC_6H_7N_2)$] (**1**), [Cp*$TaCl_3(OC_8H_7N_2)$] (**2**), [Cp*$TaMe_3(SC_6H_7N_2)$] (**3**). In addition, a bis(oxypyridine)titanium(IV) complex [Cp*$TiMe_2(OC_8H_7N_2)_2$] was isolated. The X-ray structure analysis of **1** revealed that the thiolate group is bonded to the metal center through the sulfur atom and one of the nitrogen atoms in an η^2-fashion. The reactivity of complex **3** with isocyanides (CNR), R = *t*Bu, Xyl (Xyl = 2,6-dimethylphenyl) was also studied showing differences depending on the nature of R group. The reaction with 2,6-dimethylphenyl isocyanide gives the azatantalacyclobutane complex [Cp*TaMe{XylN=CC(Me_2)NXyl}($SC_6H_7N_2$)] (**5**) as the final product, whereas in the reaction with *tert*-butyl isocyanide the η^2-imine-containing complex [Cp*Ta{*t*BuNC(Me_2)}($SC_6H_7N_2$)] (**6**) is proposed to be formed. The dynamic behavior of [Cp*$TaMe_3(SC_6H_7N_2)$] (**3**) was also studied by variable-temperature ^1H NMR spectroscopy.

Introduction

Ligand systems with two different donor atoms are attracting increasing interest in the chemistry of metal complexes. Under appropriate conditions, the remaining donor atom can coordinate reversibly to the metal center and eventually block a vacant coordination site.[1] In this field, complexes that incorporate pyridinethiolate and pyrimidinethiolate, as well as their alkoxide analogues, are interesting for their ability to chelate and bridge transition metal atoms, allowing access to both mono- and oligonuclear products. In addition, they contain functional groups that are common in crude oils and nucleic acids. The thiolate complexes are of particular interest in the field of bioinorganic chemistry due to their relevance to the structure, bonding and function of biologically active reaction centers such as nitrogenase or metalothioneins.[2,3]

Thiolate complexes also play an important role in different reactions, such as the desulfurization of organosulfur compounds [4,5] and metal-catalyzed synthetic reactions involving C−S bond cleavage and formation.[6] All of these features, as well as the propensity of sulfur to form M(μ-SR)M′ bridges, has led to the widespread use of sulfur-containing complexes as synthons for multinuclear transition metal complexes.[7]

Alkoxide and aryloxide ligands have been widely used to stabilize high oxidation states of early transition metals[8] and numerous studies have been reported concerning the catalytic activity of their complexes in alkene metathesis and, in particular, in alkene polymerization.[9]

A systematic study of the chemistry of mono- and bis(cyclopentadienyl) complexes of group-4 transition metals bearing chelating pyrimidinethiolate ligands and analogous oxygen derivatives has been carried out by our research group in recent years.[10] The interesting coordination modes and the reactivity observed along with the scarce number of reported examples of this kind of compounds[11] encouraged us to prepare analogous monocyclopentadienyl complexes of group-5 metals. In particular, this paper will focus on the synthesis, structural details and reactivity of

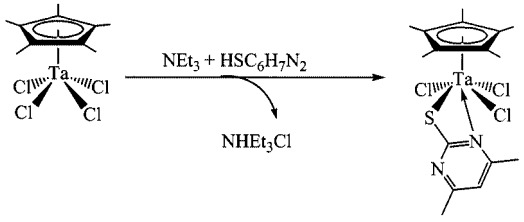
new monocyclopentadienyl complexes of tantalum(v) and titanium(iv) bearing chelating pyrimidinethiolate and oxypyridine ligands.

Results and Discussion

The reaction of [Cp*TaCl$_4$] (Cp* = η^5-C$_5$H$_5$) with 4,6-dimethyl-2-mercaptopyrimidine (HSR, R = C$_6$H$_7$N$_2$) in the presence of 1 equiv. of triethylamine proceeds at room temperature in toluene to yield the complex [Cp*TaCl$_3$(SR)] (**1**) [Equation (1)]. Attempts to perform the substitution of a second chlorine atom by a thiolate ligand were made under a wide variety of conditions but no further reaction was observed and in all cases the only isolated compound was **1**.



(1)

1

Complex **1** was isolated as an air-sensitive orange solid, soluble in toluene and THF and less soluble in pentane or Et$_2$O. It was characterized by ^{1}H and ^{13}C NMR and IR spectroscopy as well as by elemental analysis (see Exp. Sect.). The ^{1}H and ^{13}C NMR spectra indicate that the thiolate ligand is bonded to the metal atom in a bidentate fashion. For example, two resonances at δ = 1.71 and 2.88 ppm are present in the ^{1}H MNR spectrum for the two nonequivalent methyl groups of the thiolate ligand, in accordance with the proposed η^2-*S*,*N* coordination mode.

Crystals of **1**, suitable for an X-ray crystal structure determination, were obtained by slow diffusion of pentane into a saturated solution of the complex in toluene. Figure 1 shows an ORTEP diagram of the molecule; selected bond lengths and angles are given in Table 1.

The structure consists of discrete molecules separated by van der Waals distances. The tantalum atom is bonded to the cyclopentadienyl ring in an η^5-mode, to three chlorine atoms and to the thiolate ligand in the proposed chelate fashion. In this way, the coordination around the metal atom is pseudo-octahedral, with the tantalum atom 0.59 Å out of the plane defined by the S(1), Cl(1), Cl(2) and Cl(3) atoms. The nitrogen atom of the pyrimidinethiolate ligand is located *trans* to the Cp* group. The Ta(1)−S(1) bond length [2.456(2) Å] is as expected for tantalum(v) thiolate complexes[12] and the Ta(1)−N(1) bond [2.327(5) Å] is also in the normal range for pyridyltantalum(v) complexes.[13] Finally, the Ta(1)−S(1)−C(1) angle [84.6(2)°] is in accordance with others observed in this kind of complexes.[10,11]

When 3-cyano-2-hydroxy-4,6-dimethylpyridine was treated with [Cp*TaCl$_4$] in the presence of Et$_3$N in toluene at room temperature [Equation (2)] complex **2** was isolated

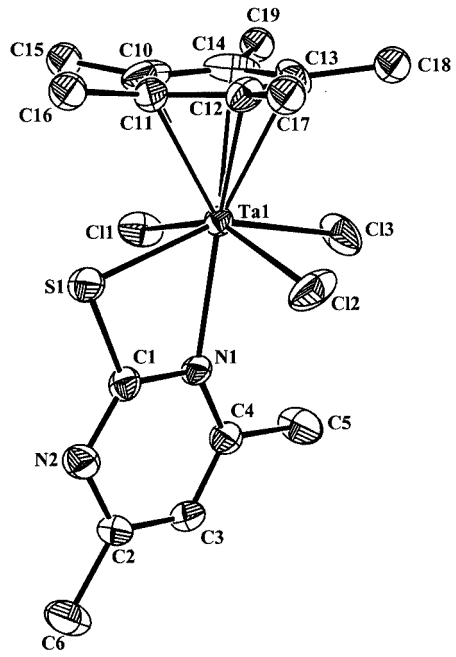


Figure 1. ORTEP drawing of complex **1** with the atomic labeling scheme; hydrogen atoms omitted for clarity; thermal ellipsoids are at the 30% level of probability

Table 1. Bond lengths [Å] and angles [°] for **1**

Ta(1)−N(1)	2.327(5)	N(1)−Ta(1)−Cl(1)	76.2(1)
Ta(1)−Cl(3)	2.393(2)	N(1)−Ta(1)−Cl(2)	76.3(2

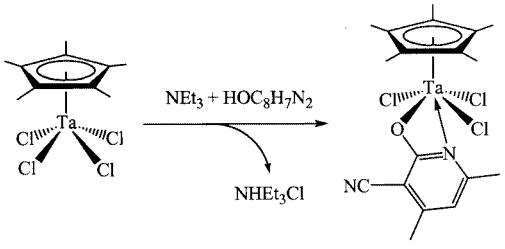
as a yellow, air-sensitive solid which was sparingly soluble in alkanes but soluble in toluene or THF.



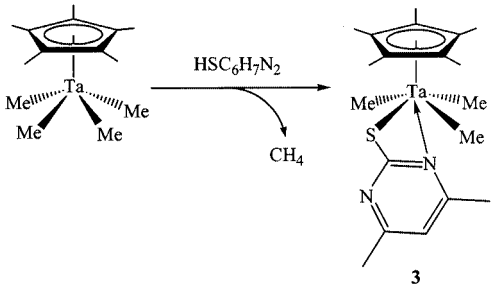
(2)

2

The ^{1}H and ^{13}C NMR spectra for **2** are analogous to those previously described for **1**. For example, the ^{1}H NMR spectrum exhibits two singlet resonances at δ = 1.52 and 2.49 ppm, attributable to the two nonequivalent methyl

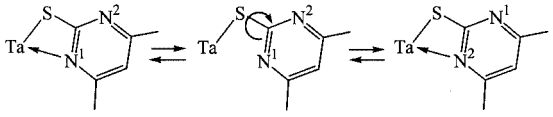
groups of the alkoxide ligand. By analogy with the situation for compound **1**, a bidentate coordination mode for the alkoxide ligand is proposed to be present in this complex.

Another general way to synthesize thiolate complexes is to carry out the protonolysis of metal−alkyl bonds with the corresponding thiol. In this way, the reaction of Cp^*TaMe_4 with 2-mercapto-4,6-dimethylpyrimidine at 80 °C in toluene yields $[Cp^*TaMe_3(SR)]$ (**3**) as an orange solid which is soluble in toluene and THF and scarcely soluble in pentane [Equation (3)]. As in the case of the chlorinated complex **1**, all attempts to increase the number of thiolate ligands around the metal atom were unsuccessful.



3 (3)

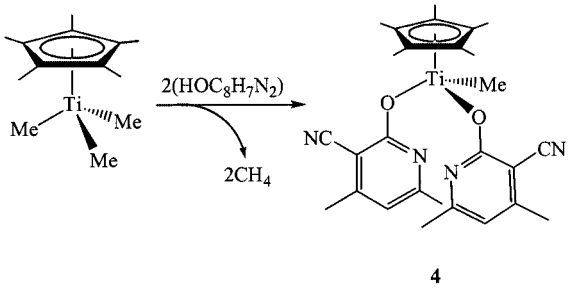
The ^{1}H NMR spectrum of **3** at room temperature shows a broad resonance at δ = 2.43 ppm that integrates for six protons and which is assigned to the methyl groups of the thiolate ligand. The broadness of the peak indicates a fluxional behavior through which both nitrogen atoms interchange their positions in the coordination sphere of the tantalum atom by rotation around the S−C bond (Scheme 1).



Scheme 1

In order to study this fluxional behavior a variable-temperature (VT) ^{1}H NMR experiment was carried out. At −40 °C the methyl groups are inequivalent and appear as two signals at δ = 2.74 and 2.04 ppm, indicating that rotation around the C−S bond is hindered for the thiolate ligand. When the temperature is raised, the peaks coalesce at −10 °C. The two site-exchange equations[14] and the coalescence temperature of 263 K can be used to estimate a value for $\Delta G^{\neq}$ of 12.0(2) kcal·mol^{-1} for the process. This value is in accordance with that previously found for analogous systems, i.e. $[Cp_2ZrMe(SR)]$ (SR = 4,6-dimethylpyrimidine-2-thiolate).[10a]

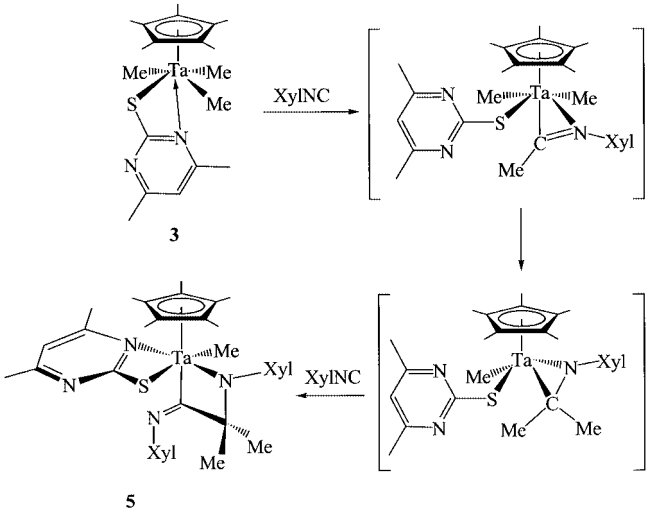
Complex **4** was synthesized in a similar way to **3**, by reaction of $[Cp^*TiMe_3]$ with 2 equiv. of 3-cyano-2-hydroxy-4,6-dimethylpyridine in toluene [Equation (4)].



4 (4)

This compound was isolated as a red solid which is soluble in toluene and THF but less soluble in pentane. The ^{1}H NMR spectrum shows a singlet at δ = 1.00 ppm, corresponding to the methyl group bonded to the titanium atom and a further singlet at δ = 1.77 ppm for the Cp* methyl groups. The pyridine ligands give rise to three signals, two of them at δ = 1.71 and 1.82 ppm are assigned to the methyl groups bonded to the pyridine rings, and the other, at δ = 5.46 ppm, corresponds to the aromatic proton. It can be inferred from these results that in complex **4** the two pyridine ligands are in the same chemical environment, and an η^1-*O* coordination is proposed for both ligands.

Finally, the reactivity of **3** toward isocyanide ligands has been considered. Compound **3** reacts readily in toluene at room temperature with 2,6-dimethylphenyl isocyanide in a 1:2 molar ratio to give the azatantalacyclobutane complex **5** containing an iminoacyl fragment (Scheme 2).



3 **5**

Scheme 2

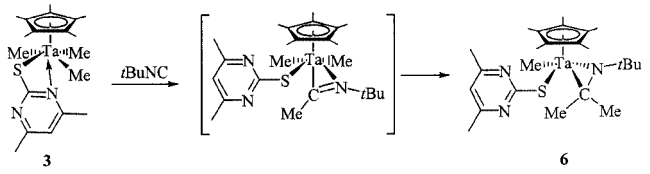
The ^{1}H NMR spectrum of compound **5** shows a singlet signal at δ = 1.39 ppm which is assigned to the Cp* protons and nine singlet signals between δ = 1.00 and 2.45 ppm, each of them integrating for three protons, corresponding to the methyl groups present in the molecule (see Exp. Sect.).

Furthermore, the ^{13}C NMR spectrum shows, among others, two signals at δ = 230.0 and 86.7 ppm, which we tentatively assign to an iminoacyl carbon atom and to the quaternary carbon atom of the Ta−N−C−C metallacycle.[15]

We propose (see Scheme 2) that, initially, complex **3** reacts with one molar equivalent of xylyl isocyanide by insertion into one Ta−Me bond to form an η^2-iminoacyl-containing complex. A second methyl migration would then occur, forming an η^2-imine-containing species. Finally, the insertion of a second isocyanide molecule into the newly formed Ta−C bond would lead to **5**.

Recently, we reported a mechanism for the reaction of xylyl isocyanide with $[Cp^*TaMe_2(SCH_2CH_2)_2O]$ in which the proposed η^2-imine intermediate was isolated .[16] Attempts to isolate this type of intermediate in the reaction of **3** were unsuccessful.

Furthermore, compound **3** reacts readily with *tert*-butyl isocyanide, at room temperature, in C_6D_6 on an NMR-tube scale, to give the η^2-imine complex **6** as the only detectable compound by ^1H NMR spectroscopy (Scheme 3). Isolation of **6** on a preparative scale with an acceptable level of purity was not possible.



Scheme 3

In contrast to the reactivity observed for complex **3** with xylyl isocyanide, no further reaction was observed when an excess of *tert*-butyl isocyanide was added.

The ^1H and ^{13}C NMR spectroscopic data point to an η^2-coordination of the imine ligand, while the thiolate would act as a monodentate ligand (see Exp. Sect.). The ^1H NMR spectroscopic data exhibit a singlet signal at $\delta = 0.04$ ppm corresponding to the methyl group bonded to the tantalum atom, a singlet at $\delta = 1.31$ ppm integrating for nine protons assignable to the *tert*-butyl group and a broad signal at $\delta = 1.79$ ppm due to the methyl groups of the thiolate ligand, indicating that a fluxional behavior similar to that described for **3** takes place. The methyl groups bonded to the quaternary carbon atom of the imine ligand appear as two singlets at $\delta = 1.66$ and 1.99 ppm, respectively. The ^{13}C NMR spectrum shows, as its outstanding feature, a signal at $\delta = 68.1$ ppm corresponding to the quaternary carbon atom of the imine ligand. The high-field shift of this resonance seems to confirm the η^2-coordination of the imine group.[17]

Conclusion

In this paper we report the synthesis of some new monocyclopentadienyl-containing tantalum(V) and titanium(IV) complexes with chelating pyrimidinethiolate and oxypyridine ligands. These compounds were prepared by halide or methyl displacement. The molecular structure of **1**, as determined by X-ray diffraction studies, shows a pseudo-octahedral geometry around the tantalum atom with the thiolate ligand chelating two coordination positions. This structural situation can be considered to also be present in the related tantalum complexes **2** and **3**, on the basis of spectroscopic data. We have also studied the reactivity of complex **3** with xylyl and *tert*-butyl isocyanides. With the first reagent the azatantalacyclobutane complex **5** was isolated, whereas with the second isocyanide the η^2-imine-containing complex **6** was obtained.

Experimental Section

General Remarks: The preparation and handling of the described compounds was performed with rigorous exclusion of air and moisture under nitrogen using standard vacuum line and Schlenk techniques. All solvents were dried and distilled under nitrogen. The following reagents were prepared by literature procedures: $[Cp^*TaCl_4]$[18] $[Cp^*TaMe_4]$[19] and $[Cp^*TiMe_3]$.[20] The commercially available compounds Cp*H, MeLi in diethyl ether, xylyl isocyanide, *tert*-butyl isocyanide, 2-mercapto-4,6-dimethylpyrimidine and 3-cyano-2-hydroxy-4,6-dimethylpyridine were used as received from Aldrich. ^1H and ^{13}C NMR spectra were recorded with a 200 Mercury Varian Fourier Transform spectrometer. Trace amounts of protonated solvents were used as reference, and chemical shifts are reported in units of ppm relative to $SiMe_4$. IR spectra were recorded in the region 4000−400 cm^{-1} with a Nicolet Magna-IR 550 spectrophotometer as Nujol mulls using PET cells.

$[Cp^*TaCl_3(SC_6H_7N_2)]$ (1): $HSC_6H_7N_2$ (0.136 g, 0.97 mmol) and Et_3N (0.140 mL, 0.97 mmol) were added to a solution of Cp^*TaCl_4 (0.446 g, 0.97 mmol) in 5 mL of toluene. The mixture was stirred at room temperature for 1 h. After filtration, the solid was washed twice with 5 mL of THF. The resulting solution was concentrated to dryness and the solid obtained was washed with diethyl ether to give an orange solid, which was characterized as **1** (0.425 g, 78%). IR (Nujol/PET): $\tilde{\nu} = 1591$ cm^{-1} (s), 1558 (w), 1520 (s), 1342 (m), 1271 (s), 1021 (m), 956 (w), 848 (m). ^1H NMR (200 MHz, C_6D_6): $\delta = 1.71$ (s, 3 H, CH_3), 2.24 (s, 15 H, Cp*), 2.88 (s, 3 H, CH_3), 5.67 (s, 1 H, CH pyrimidine) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = 13.0$ (Cp*), 23.7 (CH_3), 24.8 (CH_3), 119.6 (CH pyrimidine), 130.3 (Cp*), 165.5 ($C-CH_3$), 168.5 (CCH_3), 172.2 (CS) ppm. $C_{16}H_{22}N_2Cl_3STa$ (561.73): calcd. C 34.17, H 3.91, N 4.98; found C 34.17, H 3.90, N 5.09.

$[Cp^*TaCl_3(OC_8H_7N_2)]$ (2): $HOC_8H_7N_2$ (0.517 g, 3.49 mmol) and Et_3N (0.486 mL, 3.49 mmol) were added to a solution of $[Cp^*TaCl_4]$ (1.6 g, 3.49 mmol) in 25 mL of toluene. The mixture was stirred at room temperature for 2 h. After filtration, the resulting solution was concentrated to dryness and the solid obtained was washed with pentane to give a yellow solid, which was characterized as **2** (1.465 g, 74%). IR (Nujol/PET): $\tilde{\nu} = 2216$ cm^{-1} (s), 1666 (w), 1604 (ms), 1551 (s), 1304 (s), 1256 (m), 1026 (w), 651 (w), 570 (s). ^1H NMR (200 MHz, C_6D_6): $\delta = 1.52$ (s, 3 H, CH_3), 2.22 (s, 15 H, Cp*), 2.49 (s, 3 H, CH_3), 5.49 (s, 1 H, CH pyridine) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = 12.6$ (Cp*), 20.1 (CH_3), 22.1 (CH_3), 94.1 (*C*CN), 112.9 (CN), 118.7 (Cp*), 131.9 (CH pyridine), 155.9 (CCH_3), 157.3 (CCH_3), 168.3 (CO) ppm. $C_{18}H_{22}N_2Cl_3OTa$ (569.69): calcd. C 37.95, H 3.89, N 4.92; found C 38.14, H 3.75, N 4.66.

[Cp*TaMe$_3$(SC$_6$H$_7$N$_2$)] (3): Toluene (10 mL) was added to a mixture of Cp*TaMe$_4$ (0.379 g, 1.01 mmol) and HSC$_6$H$_7$N$_2$ (0.141 g, 1.01 mmol). The solution was heated slowly to 80 °C and stirred at this temperature for 1 h. After cooling, the mixture was filtered and the solvent removed. The oil obtained was washed with 10 mL of *n*-pentane to afford an orange solid (0.373 g, 75%) which was characterized as **3**. IR (Nujol/PET): $\tilde{\nu}$ = 1623 cm^{-1} (w), 1580 (s), 1532 (s), 1340 (s), 1274 (s), 1138 (m), 1026 (m) 955 (w) 844 (w), 814 (w). ^{1}H NMR (200 MHz, [D$_8$]toluene): δ = 0.23 (s, 6 H, CH$_3$Ta), 0.34 (s, 3 H, CH$_3$Ta), 2.04 (s, 15 H, Cp*), 2.43 (br. s, 6 H, CH$_3$ pyrimidine), 6.04 (s, 1 H, CH pyrimidine) ppm. ^{13}C{^{1}H} NMR (C$_6$D$_6$): δ = 11.6 (Cp*), 23.7 (CH$_3$, pyrimidine), 45.6 (CH$_3$Ta), 48.7 (CH$_3$Ta), 119.1 (CH pyrimidine), 120.5 (Cp*), 165.8 (*C*CH$_3$), 174.6 (CS) ppm. C$_{19}$H$_{31}$N$_2$STa (500.48): calcd. C 45.60, H 6.24, N 5.60; found C 45.39, H 5.82, N 5.61.

[Cp*TiMe(OC$_8$H$_7$N$_2$)$_2$] (4): Toluene (2 mL) was added to a mixture of [Cp*TiMe$_3$] (0.209 g, 0.92 mmol) and HOC$_8$H$_7$N$_2$ (0.271 g, 1.83 mmol). The solution was stirred at room temperature for 5 h and filtered. By addition of 4 mL of *n*-pentane and cooling to −30 °C a red solid (0.190 g, 42%) was obtained and characterized as **4**. IR (Nujol/PET): $\tilde{\nu}$ = 2218 cm^{-1} (s), 1560 (s), 1504 (s), 1221 (s), 1157 (m), 1098 (s), 783 (ms). ^{1}H NMR (200 MHz, C$_6$D$_6$): δ = 1.00 (s, 3 H, CH$_3$-Ti), 1.71 (s, 6 H, CH$_3$), 1.77 (s, 15 H, Cp*), 1.82 (s, 6 H, CH$_3$), 5.46 (s, 2 H, CH pyridine) ppm. ^{13}C{^{1}H} NMR (C$_6$D$_6$): δ = 11.9 (Cp*), 20.0 (CH$_3$), 20.9 (CH$_3$), 63.8 (CH$_3$Ti), 91.4 (*C*CN), 114.4 (CN), 115.0 (Cp*), 127.4 (CH pyridine), 155.1 (*C*CH$_3$), 157.5 (*C*CH$_3$), 171.0 (CO) ppm. C$_{27}$H$_{32}$N$_4$O$_2$Ti (492.44): calcd. C 65.85, H 6.55, N 11.38; found calcd. C 65.57, H 6.88, N 11.72.

[Cp*TaMe{XylN=CC(Me$_2$)NXyl}(SC$_6$H$_7$N$_2$)] (5): Toluene (5 mL) was added to a mixture of [Cp*TaMe$_3$(SC$_6$H$_7$N$_2$)] (0.132 g, 0.26 mmol) and XylN≡C (0.70 g, 0.53 mmol). The solution was stirred at room temperature for 30 min. After that, the mixture was filtered and the solvent removed. The oil obtained was washed with 5 mL of cool *n*-pentane to afford a yellow solid (0.110 g, 54%) which was characterized as **5**. IR (Nujol/PET): $\tilde{\nu}$ = 1666 cm^{-1} (w), 1633 (m), 1593 (s), 1553 (m). ^{1}H NMR (200 MHz, C$_6$D$_6$): δ = 1.00 (s, 3 H, CH$_3$-Ta), 1.29 (s, 3 H, CH$_3$), 1.39 (s, 15 H, Cp*), 1.44 (s, 3 H, CH$_3$), 1.76 (s, 3 H, CH$_3$), 1.94 (s, 3 H, CH$_3$), 2.11 (s, 3 H, CH$_3$), 2.15 (s, 3 H, CH$_3$), 2.40 (s, 3 H, CH$_3$), 2.45 (s, 3 H, CH$_3$), 5.64 (s, 1 H, CH pyrimidine), 6.57−6.82 (m, 6 H, Xyl) ppm. ^{13}C{^{1}H} NMR (C$_6$D$_6$): δ = 10.8 (Cp*), 19.6, 20.1, 21.8, 22.1, 22.3, 23.5, 23.8, 24.3 (CH$_3$), 39.8 (CH$_3$Ta), 86.7 (*C*Me$_2$), 116.9 (CH pyrimidine), 119.6 (Cp*), 119.6 (CH, Xyl), 125.0 (CH, Xyl), 127.1 (CH, Xyl), 127.9 (CH, Xyl), 128.4 (CH, Xyl), 128.6 (CH, Xyl) 136.4 (*C*CH$_3$, Xyl), 137.0 (*C*CH$_3$, Xyl), 146.9 (*C*N=C), 154.8 (CN), 164.9 (*C*CH$_3$, pyrimidine), 165.8 (*C*CH$_3$, pyrimidine), 176.7 (CS), 230.0 (C=N) ppm. C$_{37}$H$_{49}$N$_4$STa (762.83): calcd. C 58.26, H 6.47, N 7.34; found C 57.80, H 7.34, N 7.61.

[Cp*TaMe{*t*BuNC(Me$_2$)}(SC$_6$H$_7$N$_2$)] (6): *t*BuN≡C (7μL, 0.06 mmol) was added to a solution of Cp*TaMe$_3$(SC$_6$H$_7$N$_2$) (0.031 g, 0.06 mmol) in 0.7 mL of C$_6$D$_6$. The mixture was allowed to react at room temperature in an NMR tube during 10 min to yield the proposed complex **6** as only detectable compound. ^{1}H NMR (200 MHz, C$_6$D$_6$): δ = 0.04 (s, 3 H, CH$_3$Ta), 1.31 (s, 9 H, *t*Bu), 1.62 (s, 15 H, Cp*), 1.66 (s, 3 H, CH$_3$), 1.79 (br, 6 H, CH$_3$), 1.99 (s, 3 H, CH$_3$), 5.79 (s, 1 H, CH pyrimidine) ppm. ^{13}C{^{1}H} NMR (C$_6$D$_6$): δ = 11.4 (Cp*), 23.6 (CH$_3$ pyrimidine), 27.3, 32.8 (*C*H$_3$C=N), 31.5 (*t*Bu), 45.9 (CH$_3$Ta), 62.6 (*C*Me$_3$), 68.1 (*C*Me$_2$), 114.1 (CH pyrimidine), 116.3 (Cp*), 164.40 (*C*CH$_3$), 182.4 (CS) ppm.

Table 2. Crystal data and structure refinement for **1**

Empirical formula	C$_{16}$H$_{22}$Cl$_3$N$_2$STa
Formula mass	561.71
Temperature	293(2) K
Wavelength	0.71073 Å
Crystal system, space group	monoclinic, $P2_1/c$
Unit cell dimensions	a = 13.328(4) Å b = 8.596(3) Å, β = 90.74(3)° c = 17.224(2) Å
Volume	1973.1(9) Å^3
Z, calculated density	4, 1.891 Mg/m^3
Absorption coefficient	6.082 mm^{-1}
F(000)	1088
Crystal size	0.3 × 0.3 × 0.2 mm
θ range for data collection	2.37−27.97°
Limiting indices	$-17 \le h \le 17$, $0 \le k \le 11$, $0 \le l \le 22$
Reflections collected/unique	9175/4747 [R(int) = 0.0920]
Data/restraints/parameters	4747/0/213
Goodness-of-fit on F^2	1.052
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0351, $wR2$ = 0.0859
R indices (all data)	$R1$ = 0.0542, $wR2$ = 0.1060
Largest diff. peak and hole	1.297 and −2.295 e Å^{-3}

X-ray Crystallographic Study: The crystallographic data and experimental details are given in Table 2. Crystals of complex **1** suitable for an X-ray diffraction study were obtained by slow diffusion of pentane into a saturated solution of the complex in toluene. A prismatic crystal was selected, sealed in a Lindeman capillary under dry nitrogen and used for data collection. Accurate unit-cell parameters were determined by least-squares refinement of the setting angles of 25 randomly distributed and carefully centered reflections. The data collection was performed with a NONIUS-MACH3 diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) using an ω/2θ scan technique to a maximum value of 56°. Data were corrected for Lorentz and polarization effects. The structure was solved by direct methods (SIR92)[21] and refined first isotropically by full-matrix least squares using SHELXL-97[22] program and then anisotropically by blocked full-matrix least-squares techniques for all the non-hydrogen atoms. The hydrogen atoms were included in calculated positions and refined as "riding" on their parent carbon atoms. CCDC-189366 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Efficient Asymmetric Synthesis of Δ- and Λ-Enantiomers of (Bipyridyl)ruthenium Complexes and Crystallographic Analysis of Δ-Bis(2,2′-bipyridine)(2,2′-bipyridine-4,4′-dicarboxylato)ruthenium: Diastereoselective Homo- and Heterochiral Ion Pairing Revisited

Régis Caspar,[a] Hani Amouri,*[a] Michel Gruselle,[a] Christine Cordier,[b] Bernard Malézieux,[a] Raphäel Duval,[c] and Hubert Leveque[c]

Keywords: Ruthenium / Chiral resolution / Circular dichroism

Optically pure ruthenium complexes of the type Δ- or Λ-[Ru(bpy)$_2$(L–L)][PF$_6$]$_2$ [L–L = cmbpy = 4′-methyl-2,2′-bipyridine-4-carboxylic acid (**3a**, **b**); L–L = dcbpy = 2,2′-bipyridine-4,4′-dicarboxylic acid (**4a**, **b**)] were prepared and fully characterized. The Ru^{II} carboxylate complexes Δ- and Λ-[Ru(bpy)$_2$(dcabpy)] (**5a**, **b**) (dcabpy = 2,2′-bipyridine-4,4′-dicarboxylate) were resolved efficiently by chiral column chromatography and isolated in good yields. The Δ-[Ru(bpy)$_2$(dcabpy)] (**5a**) enantiomer was crystallized and its X-ray molecular structure determined. The enantiomeric nature and the absolute configuration of the tris(bipyridyl)ruthenium complexes were confirmed by NMR and circular dichroism studies. In addition, ion-pairing interactions between Δ-Trisphat (Δ-**1**, D_3 symmetry) and each enantiomer of the (monocarboxylic acid)Ru^{II} complex (**3a** and **3b**, C_1 symmetry) and the dicarboxylic acid complex (**4a** and **4b**, C_2 symmetry) were examined by NMR spectroscopy.

(© Wiley-VCH Verlag GmbH & Co KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Octahedral hexacoordinated ruthenium(II) complexes bearing 2,2′-bipyridine ligands (bpy) have received considerable attention because of their potential use as chiral building blocks for supramolecular assemblies,[1] or as chiral probes for biological molecules (polynucleotides, DNA).[2] In addition, they exhibit photoluminescence and electroluminescence properties, making them promising light-emitting devices.[3] More recently, efforts have been devoted to the study of the stereochemistry of these complexes as a result of the different interactions that may arise when enantiomeric forms (Δ or Λ) interact with a variety of substrates.[4,5a,5b]

We, and others, have been working in the area of stereoselective synthesis of tris(bpy)metal complexes with D_3 symmetry.[5] The determination of their enantiomeric purity by ^{1}H NMR spectroscopy has become an easy and routine task in the presence of the Trisphat anion (**1**) [Trisphat = tris(tetrachlorobenzenediolato)phosphate(v)],[6] which acts as a chiral shift reagent.[7] Further investigations carried out by Lacour have also shown that homochiral association (Δ,Δ) or (Λ,Λ) is favored over heterochiral association (Δ,Λ) in a solvent of low polarity and proceeds with high selectivity.[8] More recently Le Bozec, Lacour, and co-workers also found that homochiral ion-pairing is also favored for the tris(DEAS-bpy)ruthenium complex {DEAS-bpy = 4,4′-bis(diethylaminostyryl)-[2,2′]-bipyridine}.[9] Very recently, Kol and co-workers reported that octahedral mono(eilatin)ruthenium complexes form discrete dimers held by π-stacking interactions in both the solid state and in solution. In contrast to the results outlined above, heterochiral association (Δ,Λ) was found to be strongly favored.[10]

In order to investigate this ion-pairing phenomenon, we decided to prepare the optically pure dicationic (bipyridyl)-Ru^{II} complexes Δ- and Λ-[Ru(bpy)$_2$(cmbpy)][PF$_6$]$_2$ (**3a**, **b**; cmbpy = 4′-methyl-2,2′-bipyridine-4-carboxylic acid) and Δ- and Λ-[Ru(bpy)$_2$(dcbpy)][PF$_6$]$_2$ (**4a**, **b**; dcbpy = 2,2′-bipyridine-4,4′-dicarboxylic acid), with C_1 and C_2 symmetries, respectively. We anticipated that association of our model complexes with the Δ-Trisphat anion of D_3 symmetry should be the ideal probe to discriminate between homochiral and heterochiral ion-pairing association.

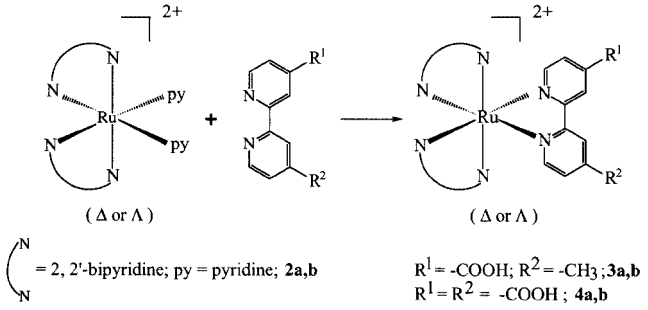
Supporting Information for this article is available on the WWW under http://www.eurjic.org or from the author.

In this paper we report the synthesis and complete characterization of **3a**, **3b**, **4a**, and **4b**. We also report the X-ray crystal structure of the optically pure Ru^{II} dicarboxylate complex Δ-[Ru(bpy)$_2$(dcabpy)] (**5a**; dcabpy = 2,2′-bipyridine-4,4′-dicarboxylate). The solution behavior and NMR studies of these resolved complexes in the presence of Δ-Trisphat are presented and discussed.

Results and Discussion

Synthesis of the (Bipyridyl)ruthenium Complexes 3a, b and 4a, b

The optically pure ruthenium complexes **3a** and **3b** were prepared in a single step by treatment of the resolved ruthenium complexes Δ- and Λ-[Ru(bpy)$_2$py$_2$][dibenzoyltartrate-*O*,*O*′] (**2a**, **b**)[11] with the appropriate chelating ligands in ethylene glycol/H_2O for several hours (Scheme 1). These compounds were obtained as red microcrystalline solids in good yields and were fully characterized (the synthesis of racemic **3** has been reported previously[2f]). The absolute configurations of **3a** and **3b** (Δ and Λ, respectively) were assigned by circular dichroism (see Figure 2).



Scheme 1. Preparation of ruthenium complexes **3a**, **3b**, **4a**, and **4b**

The dicarboxylic acid complexes **4a** and **4b** were obtained by two different methods. The first involves direct treatment of **2a** and **2b** with the dcabpy ligand following the synthetic procedure described above. However, several weeks were required to obtain resolved crystals of either **2a** or **2b**. A more convenient method was thus used, involving the preparation of racemic [Ru(bpy)$_2$(dcbpy)][Cl]$_2$ by treatment of Ru(bpy)$_2$Cl$_2$ with dcabpy in a refluxing 1:1 water/methanol mixture.[2g] [Ru(bpy)$_2$(dcbpy)][Cl$_6$]$_2$ was easily resolved using HPLC chromatography,[12] affording initially the related carboxylate derivatives **5a** and **5b** in almost quantitative yields (see Exp. Sect.), which on subsequent protonation and workup gave optically pure **4a** and **4b** (vide infra).

The IR spectra of **5a** and **5b** recorded as KBr disks supported the formation of the Ru^{II} carboxylate species with ν(CO) = 1617 cm^{-1}, and the structure of **5a** was confirmed by X-ray structural analysis.

X-ray Structure of Δ-[Ru(bpy)$_2$(dcabpy)] (5a)

Suitable crystals of **5a** were obtained by slow concentration of a saturated acetonitrile solution. Complex **5a** crystallizes in the chiral C_2 space group. Crystallographic data for **5a** are given in Table 2 (Exp. Sect.) and selected bond lengths and angles are given in Table 1. The structure shows a hexacoordinated Ru^{II} center complexed by one dcabpy and two bpy ligands, and confirms that the functionalized bipyridine ligand has two deprotonated carboxylate groups at the 4 and 4′ positions.

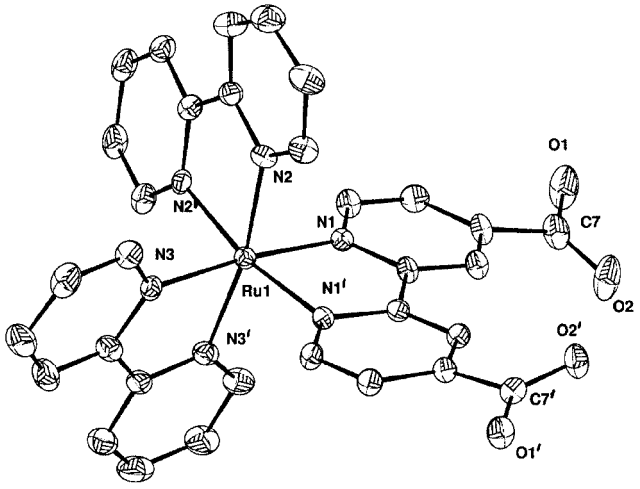

Figure 1. Molecular structure of **5a** with the atom numbering system; hydrogen atoms have been omitted for clarity

Figure 1 shows that the two carboxylate groups of the dcabpy ligand are coplanar with the substituted aromatic rings, suggesting an electronic delocalization throughout the conjugated π-systems. Although there has been a number of structural determinations of tris(bidentate ligand)ruthenium(II) complexes containing polypyridyl ligands,[13−15] the majority of these have involved racemic samples, and only a few structures confirming the absolute configuration of such complexes have been reported. Therefore our example is of interest, especially because several groups are currently interested in the polymetallic assembly involving optically pure ruthenium complexes as individual components.[1c] The absolute configurations of Δ and Λ for **5a** and **5b**, respectively, were also assigned by circular dichroism using the characteristic MLCT absorption band at λ_{max} = 295 nm (Figure 3). The $[\alpha]_D$ values of **5a** and **5b** were re-

corded in aqueous solution with $[\alpha]_D = -951$ ($c = 0.0063$, H_2O) for **5a** and $[\alpha]_D = +961$ ($c = 0.0083$, H_2O) for **5b**.

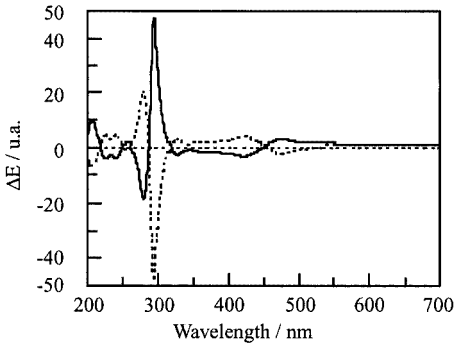

Figure 2. CD curves for **3a** (solid line) and **3b** (dotted line) in acetonitrile

We believe that the basic conditions used in the HPLC resolution (diethylamine/MeOH eluent) resulted in complete deprotonation of the acidic functions and led to the isolation of the deprotonated complexes **5a** and **5b**. The equilibrium between the carboxylate and carboxylic acid forms of the tris(bidentate ligand)ruthenium complexes can be monitored by ^{1}H NMR spectroscopy. Thus, addition of $HBF_4{\cdot}Et_2O$ to a racemic mixture of **5a** and **5b** in D_2O leads to significant changes in the ^{1}H NMR spectrum. For example, the signal corresponding to 3-H and 3′-H shifts downfield by 0.1 ppm. The spectrum of the starting material can be recovered by addition of excess triethylamine. Thus, starting from the pure enantiomers **5a** or **5b**, it is easy to obtain the related carboxylic acid complexes **4a** or **4b**.

Acidification of a solution of **5a** or **5b** in water (pH = 0.5, 1 M H_2SO_4), followed by addition of excess NH_4PF_6, leads to precipitation of **4a** or **4b**. These two enantiomers were characterized by elemental analyses, IR and ^{1}H NMR. It is noteworthy that the ν(CO) vibration in these complexes occurs at 1734 cm^{-1}, shifted by 117 cm^{-1} compared to the carboxylate starting materials. The circular dichroism curves for **4a** and **4b** (Figure 4) were recorded in CH_3CN solution, and show little change compared to those of the related starting carboxylates **5a** and **5b** (Figure 3). The $[\alpha]_D$ value for **4a** is −1058 ($c = 0.0152$, CH_3CN) and for **4b** is +1250 ($c = 0.0104$, CH_3CN).

Homo- and Heterochiral Ion-Pairing with Δ-Trisphat (Δ-1)

The determination of the enantiomeric purity of a variety of tris(bidentate ligand)Ru complexes by ^{1}H NMR techniques using the anion Δ-**1** as a chiral shift reagent has become a definitive and accurate method.[6] Thus, addition of Δ-**1** (D_3 symmetry) to D_3-symmetric ruthenium complexes causes a discrimination in the chemical shifts of the two enantiomeric forms. In fact several studies have suggested that the Δ−Δ homochiral ion-pairing interaction between the complex and Δ-**1** is stronger than that of the heterochiral triad based on geometrical criteria.[7,9]

We sought specific interactions between Δ-**1** and the ruthenium complexes of C_2 or C_1 symmetry in the hope that such complexes will act as appropriate probes to highlight this ion-pairing phenomenon; the results of these investigations are presented below.

i) C_2 Symmetry: Δ-Trisphat (Δ-1) and Δ- and Λ-[Ru(bpy)$_2$(dcbpy)][PF$_6$]$_2$ (4a, b)

Sequential addition of up to 5 equiv. of Δ-**1** to a racemic mixture of **4a** and **4b** in CD_2Cl_2/5%CD_3CN (v/v) was monitored by ^{1}H NMR spectroscopy at 293 K. Prior to addition of this chiral shift reagent, the ^{1}H NMR spectrum showed only one set of signals for the two magnetically equivalent enantiomers, in agreement with a C_2-symmetric topology. As shown in Figure 5, a splitting and a progressive chemical shift variation of specific signals are seen on successive addition of 0.5 equiv. aliquots of Δ-**1**. We attribute this result to the formation of a pair of diastereoisomers, **4a**−Δ-**1** and **4b**−Δ-**1**. The signals showing the largest changes in chemical shifts also broaden significantly. In order to discriminate between the two sets of signals ascribed to each diastereoisomeric pair, pure **4a** was added to the initial mixture. Full assignment of the ^{1}H NMR spectrum was achieved using standard 2D experiments (see Exp. Sect. and Supporting Information; see also footnote on the first page of this article).

The chemical shift variation upon addition of Δ-**1** is attributed to a fast exchange process between either Ru^{II} enantiomer (**4a**, **b**) and the ion-pair **4a**−Δ-**1** or **4b**−Δ-**1**, while the broad signals denote a slower dynamic phenomenon. These broad signals are assigned to the homochiral (Δ−Δ) ion-pair and these results therefore suggest that the interac-

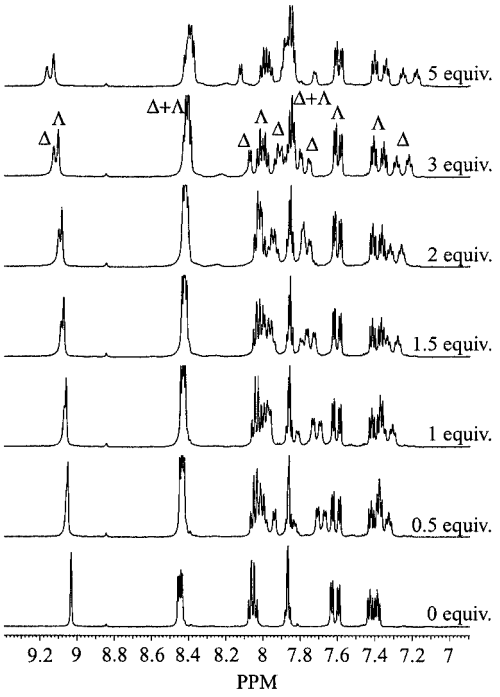

Figure 5. Section of the ^{1}H NMR spectra of racemic **4a**, **b** upon sequential addition of Δ-**1** from 0 to 5 equiv.; the symbols Δ and Λ, on the second trace from top, denote the diastereoisomers **4a**−Δ-**1** and **4b**−Δ-**1**, respectively

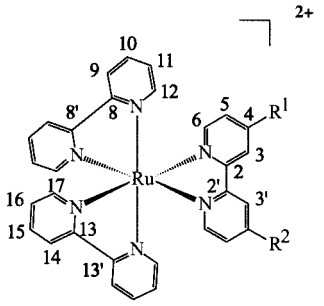
tions within the homochiral ion pair are stronger than those involved in the heterochiral ion pair. Moreover, the protons of the homochiral ion-pair exhibit the most pronounced shift of their resonance frequency upon addition of Δ-**1** (Figure 6 and Scheme 2). The resonance signals ascribed to the enantiomer **4a** are strongly spread out either upfield or downfield as a consequence of two concomitant effects; the intimate π-stacking with Δ-**1** and the coulombic attractions between the cationic metal center and the anionic phosphorus atom. The large shifts of the signals are clear evidence of the high vicinity of the octupoles within the homochiral association.



Scheme 2. Atom labelling for the NMR investigations

The heterochiral assembly is less favored, as suggested by the small variation in the chemical shifts of the signals of **4b**. We note that for this Λ−Δ ion-pair, only one C_2-related proton pair is shifted downfield, while the other proton signals remain unchanged or shift slightly upfield (Figure 6). From the ^{1}H NMR spectra, the retention of the twofold symmetry for both diastereoisomeric pairings is postulated. This suggests that in our model complex the pairing of one chiral object either with a homochiral species, or with a mirror-image partner, induces a decrease of symmetry for

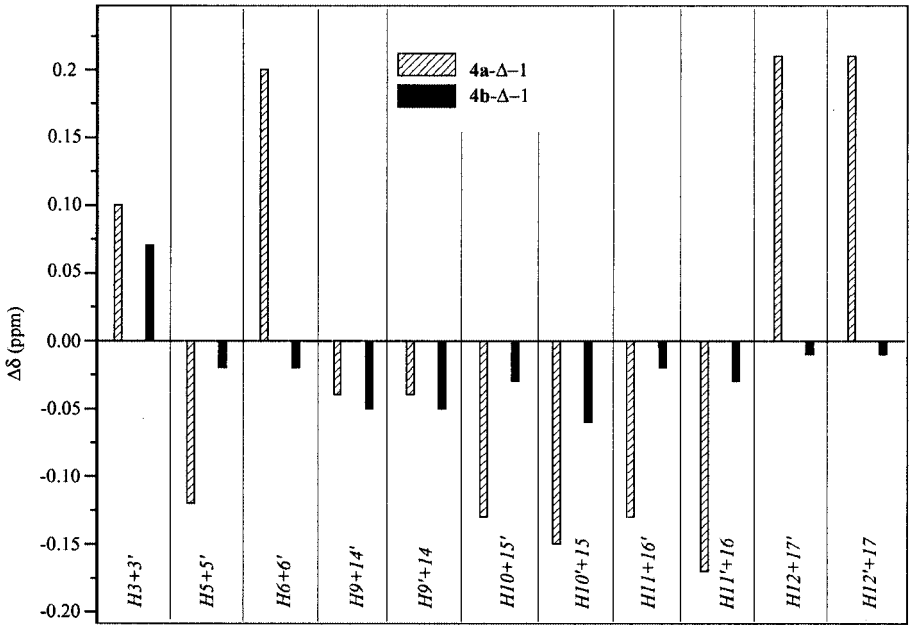


Figure 6. The differences, δ(**4a**−Δ-**1**) − δ(*rac*-**4a**, **b**) (white columns) and δ(**4b**−Δ-**1**) − δ(*rac*-**4a**, **b**) (black columns), point out the effect of Δ-Trisphat on the proton resonances; these values were measured in the presence of 3 equiv. of Δ-**1**

the whole supramolecular assembly i.e. C_2 symmetry in the latter case.

ii) C_1 Symmetry: Δ-Trisphat (Δ-1) and Δ- and Λ-[Ru(bpy)$_2$(cmbpy)][PF$_6$]$_2$ (3a, b)

We anticipated that both the homochiral (**3a**−Δ-**1**) and heterochiral (**3b**−Δ-**1**) ion-pairs should display the same NMR profile (i.e. the same number of signals). To avoid any complex NMR patterns, we studied the behavior of **3a** and **3b** separately in the presence of 4 equiv. of Δ-Trisphat in CD_2Cl_2/5%CD_3CN (v/v), and monitoring was performed by standard ^{1}H NMR techniques (see Exp. Sec. and Supporting Information). Our choice to run only one experiment in the presence of 4 equiv. of Δ-**1** is based on previous results that we obtained for **4a** and **4b**, where maximum separation of the signals of the enantiomers (Δδ) was achieved.

Surprisingly, the ^{1}H NMR spectrum of the homochiral ion-pair **3a**−Δ-**1** displays more signals than that of the heterochiral ion-pair **3b**−Δ-**1** (Figure 7). In the latter case the protons of the unsubstituted bipyridine ligands remain almost unchanged relative to the initial mixture (i.e. without chiral shift reagent) and this suggests that the ion-pairing interactions are weak.

In sharp contrast, the ^{1}H NMR spectrum of **3a**−Δ-**1** displays many signals, consistent with a C_1-symmetric ion-pair. Both the substituted and unsubstituted bipyridine ligands showed distinct signals (see Exp. Sect.) and we suggest this behavior is a result of a strong ion-pairing interaction in the homochiral self assembly **3a**−Δ-**1**. The NMR spectra of all samples remained unchanged over several weeks and we thus conclude that no enantiomeric conversion from **3a** to **3b** (i.e. the conversion from **3a**−Δ-**1** to **3b**−Δ-**1**) occurs. This observation suggests that these ruthenium complexes are configurationally rigid, in agreement with previous reports.[5d]

In summary, our NMR spectroscopic data suggest that the Δ−Δ homochiral ion-pairing interaction is stronger than that of the heterochiral triad. It appears that the initial geometry of the ionic partner is crucial in allowing an intimate association of the ions. The homosymmetry (D_3−D_3) criterion is not the sole defining parameter for the occurrence of ion-pairing; both D_3−C_2 and D_3−C_1 symmetries exhibit stable ion-pairs. These results represent the first investigation of ruthenium complexes with different symmetries.

Concluding Remarks

In this paper we have reported the synthesis of optically pure ruthenium complexes of the type Δ- or Λ-[Ru(bpy)$_2$(L−L)][PF$_6$]$_2$ [L−L = cmbpy = 4′-methyl-2,2′-bipyridine-4-carboxylic acid (**3a**, **b**); L−L = dcbpy = 2,2′-bipyridine-4,4′ dicarboxylic acid (**4a**, **b**)], including the X-ray crystal structure of the (dicarboxylato)ruthenium species Δ-[Ru(bpy)$_2$(dcabpy)] (**5a**). The enantiomeric nature and the absolute configuration of these tris(bidentate ligand)ruthenium complexes were confirmed by NMR and circular dichroism studies. NMR studies of **3a**, **3b**, **4a**, and **4b** in the presence of Δ-Trisphat (Δ-**1**) suggest that strong ion-pairing interactions are taking place, which favor a homochiral association (Δ−Δ), relative to the heterochiral ion pairing (Δ−Λ). We also note that the ^{1}H NMR spectrum of each ion-pair differs for each enantiomer, and depends on whether the cation possesses C_1 or C_2 symmetry. Further investigations are currently in progress with other ruthenium and osmium complexes.

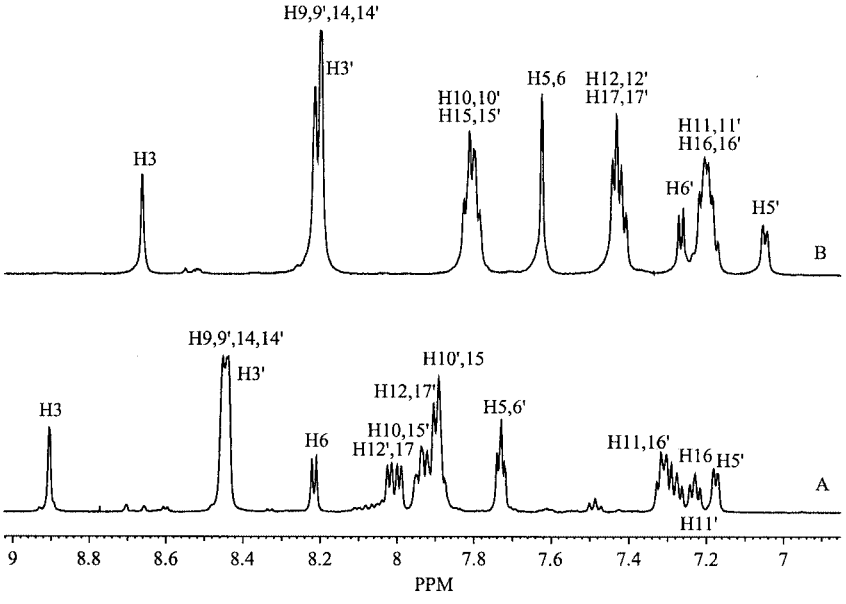

Figure 7. Section of the ^{1}H NMR spectra of **3a**−Δ-**1** (trace A) and **3b**−Δ-**1** (trace B), in the presence of 4 equiv. of Δ-**1**, showing the region of signals of aromatic protons

Experimental Section

General Procedures: All solvents used were reagent grade or better. Deuterated solvents were used as received. Commercially available reagents were used as received. The complexes Δ- and Λ-[Ru^{II}-$(bpy)_2(py)_2$][dibenzoyltartrate-*O*,*O*′],[11] [$Ru^{II}(bpy)_2(Cl)_2$],[16] and *rac*-[$Ru(bpy)_2(cmbpy)][PF_6]_2$ (**3a**,**b**),[2f] were prepared according to literature procedures. The ligand 2,2′-bipyridine-4,4′-dicarboxylate (dcbpy) was purchased from STREM Chemicals and used as received. ^1H NMR spectra were recorded with a Bruker AC-300 spectrometer and with a Bruker DRX-500 spectrometer, equipped with a Silicon Graphics workstation (vide infra). Chemical shifts are reported in ppm downfield from the tetramethylsilane signal and are referenced to the residual hydrogen signal of deuterated solvents (δ = 1.94 ppm, acetonitrile). IR spectra were recorded with a Bio-RAD IR-FT spectrophotometer as KBr disks in the 4000−250 cm^{-1} region. Specific rotations were measured at 20 °C, in a 1-dm cell using the sodium D-line of an Amber AA5 polarimeter. Circular dichroism spectra were measured using a Jasco model J-710 spectropolarimeter. HPLC was carried out using a CHIROSE-(R)C3 chiral column, (CHIRALSEP, La Frenaye, France) 50 mm diameter × 250 mm length, with methanol/diethylamine (100/0.1, v/v), as mobile phase; UV detection 275 nm. For a flow rate of 100 mL/min, retention times of 9.00 min for **5b** and 13.00 min for **5a** were observed. 60 mg of racemic mixture in 4 mL of acetonitrile was injected in each run.

Supporting Information: NMR spectra including complete assignments of the protons and carbon atoms of **3a**, **3b, 4a**, and **4b** (6 figures) are provided (see also footnote on the first page of this article).

Δ- or Λ-[$Ru(bpy)_2(cmbpy)][PF_6]_2$ (3a or 3b): Δ- or Λ-[$Ru^{II}(bpy)_2$-$(py)_2$][dibenzoyltartrate-*O*,*O*′] (390 mg, 419 μmol), cmbpy (220 mg, 1 mmol, 2.38 equiv.), sodium acetate (220 mg, 2.7 mmol, 5.65 equiv.), water (3 mL), and ethylene glycol (13 mL) were heated at 120 °C overnight, and the pH was then adjusted to 1 by addition of concentrated sulfuric acid. Water (30 mL) was added and the mixture was filtered to remove excess free ligand. The product was precipitated by addition of a saturated aqueous solution of NH_4PF_6, and filtration through a fine (porosity 5) glass frit gave a red powder. This was washed with water and dried under vacuum. Yield: 321 mg (85%). Spectroscopic data are similar to those reported for the racemic complexes.[2f]

***rac*-[$Ru(bpy)_2(dcbpy)][PF_6]_2$ (4a, b):** This product was prepared as described in the literature.[2h] Yield: 331 mg (85%). Selected IR data (KBr disk): $\tilde{\nu}$ = 1734 (C=O), 842 (P−F) cm^{-1}. ^1H NMR (300 MHz, CD_3CN): δ = 7.40 (qd, *J* = 5.7, *J*′ = 1.3 Hz, 4 H), 7.68 (dd, *J* = 6.5, *J*′ = 5.7 Hz, 4 H), 7.82 (dd, *J* = 5.7, *J*′ = 1.8 Hz, 2 H), 7.92 (d, *J* = 5.7 Hz, 2 H), 8.08 (qd, *J* = 7.5, *J*′ = 1.3 Hz, 4 H), 8.51 (dd, 4 H, *J* = 7.9, *J*′ = 2.6 Hz, 4 H), 9.11 (d, *J* = 0.9 Hz, 2 H) ppm. $^{13}C\{^1H\}$ NMR (500 MHz, CD_3CN): C (quaternary): δ = 163.97 (C=O), 157.45, 156.53, 156.41, 138.57; =CH: δ = 152.59, 152.49, 151.54, 151.30, 138.09, 137.98, 127.59, 127.52, 127.45, 126.52, 124.17, 123.74, 123.60. $C_{32}H_{24}F_{12}N_6O_4P_2Ru{\cdot}3H_2O$ (1001.66): calcd. C 38.37, H 3.02, N 8.39; found C 38.68, H 3.03, N 8.10.

Δ- or Λ-[$Ru(bpy)_2$ (dcbpy)][$PF_6]_2$ (4a or 4b): These complexes were prepared in a similar fashion to **3a** and **3b** using Δ- or Λ-[Ru^{II}-$(bpy)_2(py)_2$][tartrate] (200 mg 215 μmol), dcbpy (110 mg, 426 μmol, 1.98 equiv.), sodium acetate (110 mg, 1.34 mmol, 6.23 equiv.), water (3 mL), and ethylene glycol (13 mL). The compounds were obtained as purple powders. Yield: 140 mg (67%). Spectroscopic data are similar to those reported for the racemic compound (vide supra).

NMR Studies and Experimental Conditions: NMR samples were prepared by dissolving the solid Ru^{II} complexes in 500 μL of CD_2Cl_2 + 5 vol-% of CD_3CN ($c \approx 10^{-2}$ M for each sample). The spectra were recorded with a Bruker DRX-500 spectrometer, equipped with a Silicon Graphics workstation. A 5-mm broad-band probe with a shielded z-gradient was used. The temperature was monitored with a BCU 05 temperature unit and fixed at 293 K. Data were processed with Silicon Graphics stations using GIFA (version 4.3).[17,18] Proton spectra were obtained in 16 scans of 16 K data points over a 5.12 kHz spectral width. A presaturation (60 dB) of the solvent residual signal was performed. The free induction decays were processed using standard Fourier transformation. COSY 2D NMR spectra in the absolute mode were recorded using the standard pulse sequence with a presaturation (60 dB) of the solvent signal during the relaxation delay. This 2.0-s relaxation delay was introduced between the 48 transients of each increment. 320 FIDs with 2 K data points in F_2 over a 5.12 kHz spectral width were collected. Zero-fillings were added to increase the resolution in F_1. Before 2D Fourier transformation, a sine-bell window function was applied to both dimensions. The transformed data were then symmetrized. For the $^1H-^1H$ dipolar contact analyses, 2D ROESY experiments were preferred because of the molecular weight of the concerned ions for which NOEs are weakly positive or zero. The chosen ROESY sequence[19] introduces trim pulses (180_X, 180_{-X}, ...) used as spinlock to avoid TOCSY effects. The 180° pulses were calibrated for a 20 dB power. These experiments were acquired in the TPPI mode. Solvent signal suppression was achieved by a low power transmitter pulse of presaturation (45 dB) during the relaxation delay. 2D ROESY data were recorded with 2 K points in t_2 over 5.12 kHz and 400 points in t_1. A 2.0-s relaxation delay and a mixing time of 600 ms were used for the 32 scans of each FID. Zero-fillings were added in F_1. Shifted sinebell window functions were applied in both dimensions before the Fourier transformation. Baselines were corrected using a polynomial function if necessary.

Table 2. Crystal data and structure refinement for **5a**

Empirical formula	$C_{32}H_{36}N_6O_{11}Ru$
Formula mass	781.74

$Rw = [\Sigma w(\|\|F_o\| - \|F_c\|\|)^2/\Sigma wF_o^2]^{1/2}$	0.0615

X-ray Structure Determination: Data for **5a** (Table 2) were collected with an Enraf−Nonius CAD4 diffractometer, Mo-K_α radiation (λ = 0.71069 Å) collection range 2θ = 2−50°, crystal dimensions 0.25 × 0.30 × 0.35 mm. An empirical absorption correction (DIFABS)[20] was applied (T_{min} = 0.89, T_{max} = 1). The structure was solved by direct methods and subsequent difference Fourier syn-

theses, and refined by full-matrix least squares on *F* by using the programs of the PC version of CRYSTALS. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in a difference Fourier map and their coordinates were refined with an overall isotropic thermal parameter. CCDC-174554 (**5a**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

In-situ Energy-Dispersive X-ray Diffraction Studies of Crystal Growth and Compound Conversion Under Solvothermal Conditions

Lars Engelke,*[a] Michael Schaefer,[a] Felix Porsch,[b] and Wolfgang Bensch[a]

Keywords: X-ray diffraction / Cell design / Kinetics / Solvothermal synthesis / Thioantimonates

The results of in-situ energy-dispersive X-ray diffraction under solvothermal conditions performed on isostructural, layered thioantimonates $Mn_2Sb_2S_5$·L (L = amine) demonstrate the great potential of the method. When the synthesis was carried out at low temperatures with L being 1,3-diaminopropane (DAP), two crystalline intermediate phases were detected which then grew and disappeared when product growth started. Surprisingly, when *N*-methyl-1,3-diaminopropane (MDAP) was used, no crystalline intermediates could be detected and the induction time was significantly shorter than for DAP. For reactions up to 100 °C and for higher temperatures with $\alpha < 0.8$ (α is the extent of reaction), the crystallisation is predominantly controlled by nucleation. Further progress of crystallisation ($\alpha > 0.8$) leads to a change of the dominant process and a diffusion-controlled mechanism is observed. During the reaction with diethylenetriamine (DIEN), three crystalline intermediates were detected prior to product growth. The induction time is longer than for the other two compounds. The crystallisation seems to be diffusion-controlled and is faster than for the DAP and MDAP compounds. In a solution of DIEN, the crystalline phases $Mn_2Sb_2S_5$·L (L = DAP or MDAP) are transformed into the DIEN product under solvothermal conditions, and a rigorous analysis of the intensities of the reflections suggests a partial dissolution of the crystalline starting materials followed by crystallisation of the DIEN material.

Introduction

The synthesis of new and exciting porous materials is directly related to the application of solvo- and hydrothermal techniques. Under these conditions, primary building units like the TO_4 tetrahedra used to prepare zeolites, and organic molecules, which can act as structure-directing agents, are often stable. The final products are formed from these units and/or molecules by heterogeneous multicomponent reactions. Hydrothermal methods are widely applied in the preparation of open framework lattices such as zeolites, zeotypes, and metal-substituted zeolites.[1−4] Such porous materials are of great interest because of their use in a range of molecular recognition applications, as catalysts, absorption materials, and for ion-exchange reactions.[5−7] Due to the large technological potential of porous materials, most experiments are devoted to the preparation of new compounds with new and unprecedented properties. In order to understand solvothermal reactions and their mechanisms and to allow systematic developments of these materials, however, kinetic analyses by in-situ methods are necessary. Since the first study of a zeolite with in-situ energy-dispersive X-ray diffraction using synchrotron radiation (EDXRD) in 1992,[8] several reports of the results of such in-situ experiments have been published[5,9−15] (see also citations in ref.[11]). The in-situ powder diffraction method, as well as the latest developments in the technology required for such challenging experiments, was reviewed very recently by Walton and O'Hare.[16] The direct observation of crystallisation offers several advantages over conventional ex-situ techniques like angular-dispersive X-ray diffraction (ADXRD) and the advantages of in-situ methods are well documented in the literature.[5,11,16] Most of the experiments were performed on oxides and only a few studies were done on sulfides, i.e. on the compounds $(Me_4N)_2Sn_3S_7$·H_2O,[12,17] $(C_7H_{13}N)Mn_{0.25}Ge_{1.75}S_4$·$H_2O$,[18] and $Mn_2Sb_2S_5$·DAP.[19]

It must be kept in mind that the syntheses of chalcogenides or oxide phases under solvothermal conditions are multi-component heterogeneous reactions between liquid and solid components, and the chief difficulty of these reactions is the very large number of possible reaction variables. Changing one of these variables affects the pathway and kinetics of the reactions in ways which are not well understood. A systematic exploration of the effect on the synthesis of changing each variable can be a very time-consuming and inefficient process. In-situ EDXRD is a powerful method that allows the study of crystallisation kinetics under real-time conditions and the effect of altering one variable on crystallisation and product formation can be monitored easily. Furthermore, the occurrence and decay of

crystalline intermediate phases can be detected and monitored.

During the last few years we have prepared several new chalcogenides under solvothermal conditions.[20−29] The layered thioantimonates(III) $Mn_2Sb_2S_5$·L[20−22] [L = 1,3-diaminopropane (DAP), *N*-methyl-1,3-diaminopropane (MDAP), and diethylenetriamine (DIEN)] are of special interest because they are isostructural and can be prepared in the laboratory as phase-pure products under very similar reaction conditions. Therefore, the Mn−Sb−S−L systems are suitable for the study of the crystallisation kinetics as a function of the amine. The results of conversion experiments should give hints about the kinetic and thermodynamic stability of the different compounds.

In the present contribution we report the results of experiments carried out on the compounds $Mn_2Sb_2S_5$·MDAP and $Mn_2Sb_2S_5$·DIEN. In addition, the results of in-situ studies concerning the stability of the crystalline thioantimonates as well as their conversion are presented.

Results and Discussion

It is well documented that under solvothermal conditions several experimental variables strongly influence the product formation,[12,13,31−33] one of the most critical parameters being the reaction temperature. Bearing in mind that solvothermal crystallisation is a multicomponent heterogeneous reaction, it is clear that changing one parameter will influence other parameters in a way which is not well understood.

Prior to the in-situ EDXRD investigations, it was necessary to conduct the syntheses of $Mn_2Sb_2S_5$·L under dynamic conditions, i.e. stirring the mixtures during the reaction. Ex-situ experiments were performed to determine the stability of the crystalline thioantimonates in basic amine solutions. Interestingly, when diethylenetriamine (DIEN) was added to crystalline $Mn_2Sb_2S_5$·L (L = DAP or MDAP) phase-pure $Mn_2Sb_2S_5$·DIEN was always formed. These results obtained with the ex-situ experiments encouraged us to study the transformation of the crystalline starting materials with the in-situ EDXRD technique.

Studies of the Mn−Sb−S−DAP System

Very recently we reported the results of in-situ EDXRD experiments performed on the system Mn, Sb, S with DAP as amine.[19] The most important results of the experiments can be summarised as follows: The induction time t_0 depends strongly on the reaction temperature and increases from 15 min at 130 °C to about 60 min at 105 °C. The product growth is significantly accelerated at higher temperature. Analysis of the crystallisation kinetics showed that similar effects occur between 105 and 125 °C. The best agreement is obtained with a first-order reaction and/or a phase-boundary-controlled mechanism. With increasing α (α is the extent of reaction) the mechanism changes suggesting consecutive kinetics as the reaction proceeds. At 130 °C and α > 0.75 a three-dimensional, diffusion-controlled process dominates.

One of the surprising results was the observation of a crystalline precursor and a crystalline intermediate phase at reaction temperatures below 105 °C (Figure 1). The preliminary analysis provided evidence for a close correlation between the composition and structure of the intermediate and final products.[19] To trap the precursor and the intermediate, several experiments with different mixtures were conducted to isolate and characterise the two unknown crystalline phases. When a mixture of Mn, S, and DAP was heated to the desired temperature the first unknown phase formed; subsequent addition of antimony led to the product formation. Obviously, the precursor is an antimony-free phase composed of Mn, S, and DAP. Unfortunately, it was not possible to index the diffraction pattern of this precursor, but EDS and elemental analyses yielded an Mn/S/DAP ratio of 2:5:2. The second crystalline intermediate contains Sb, but its nature is still not clear. All attempts to quench the phase failed and it must be concluded that it is converted or destroyed during the cooling procedure and the workup of the mixture. Such a decomposition of a compound which is stable under the synthetic conditions is not surprising and similar observations have been made by other groups who have studied oxide systems by in-situ EDXRD.[13−16]

In-situ EDXRD Investigations of the Mn−Sb−S−MDAP and Mn−Sb−S−DIEN Systems

The experiments with MDAP and DIEN should show whether product formation with DAP, MDAP, and DIEN is identical or not. By comparing α with time for the three amines it is clear that product growth is significantly faster for MDAP than for DAP over the whole temperature range (see Figure 2). Between 85 and 120 °C the induction time t_0 is significantly shorter for MDAP (see Figure 3). The fastest growth was observed for DIEN but crystallisation needed the longest induction time. The DIEN reaction was therefore investigated in a temperature range from 110 to 170 °C.

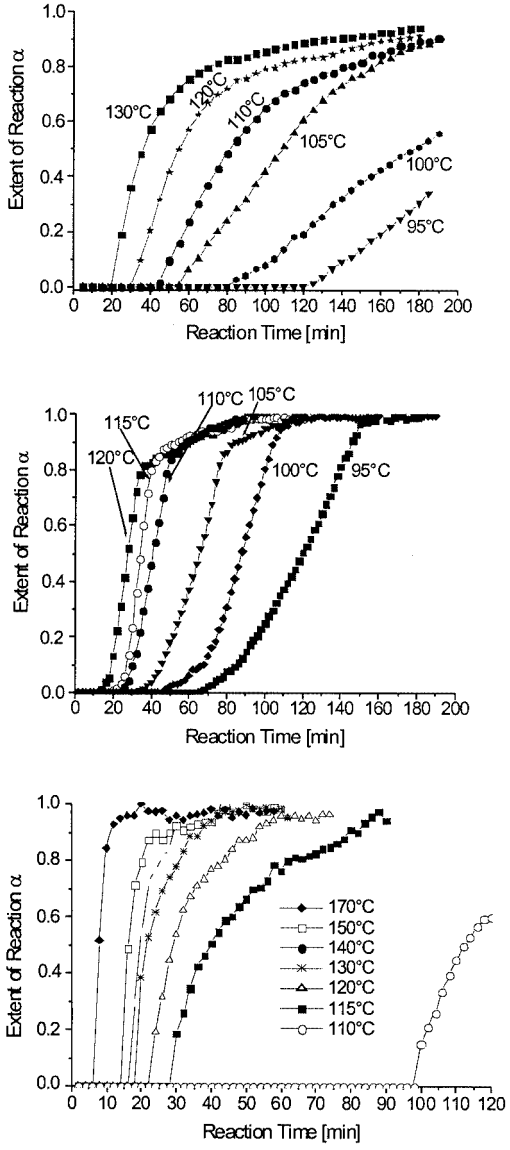

Figure 2. The extent of reaction (α) versus time for the (100) reflection of $Mn_2Sb_2S_5$·DAP (top), $Mn_2Sb_2S_5$·MDAP (centre) and $Mn_2Sb_2S_5$·DIEN (bottom) for different reaction temperatures

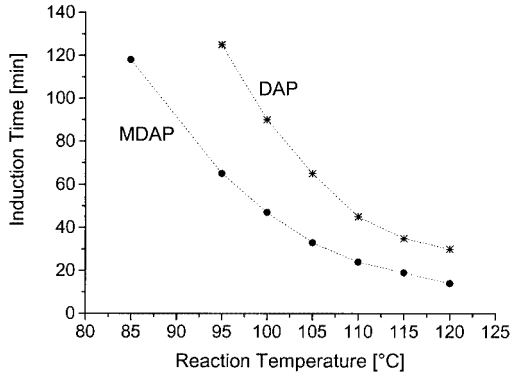

Figure 3. A comparison of the induction times t_0 for $Mn_2Sb_2S_5$·MDAP and $Mn_2Sb_2S_5$·DAP

In contrast to the experiments with DAP, no crystalline intermediate phases could be detected during the reaction with MDAP. All ex-situ and in-situ experiments to generate an analogue of the DAP precursor (see above) were unsuccessful. When using DIEN we observed a different pathway, as shown in Figure 4. First, an antimony-free precursor formed, as in the case of the DAP reaction. After a few minutes, the precursor disappeared, and this was followed by the occurrence of the first, short-lived, crystalline intermediate. A second crystalline compound was then seen which existed for a longer time. Finally, the product reflections of $Mn_2Sb_2S_5$·DIEN appeared.

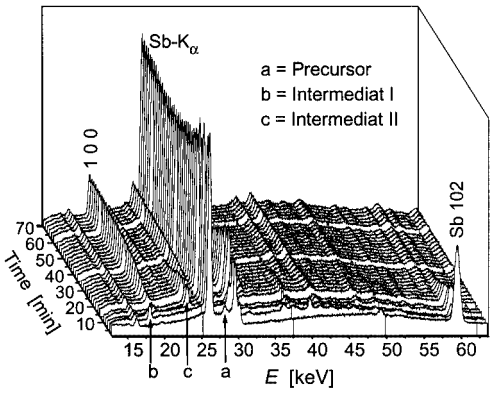

Figure 4. Time-resolved diffraction pattern of $Mn_2Sb_2S_5$·DIEN recorded at 130 °C; the most prominent reflections of the three crystalline intermediates are marked

These results suggest that in the early stages of the reactions, different consecutive and/or parallel mechanisms occur depending on the amine used. Analogous to the examinations of the DAP system,[19] kinetic studies were conducted with MDAP and DIEN. The spectra were collected every 120 s due to fast growth of the crystalline products. The intensity data were normalised with the Sb-K_α resonance and fitted to a theoretical expression relating α and time. The results were compared with expressions applied to solid-state kinetics. The general shapes of such expressions, represented graphically, are well documented.[13,34] The kinetic parameters were obtained by the Avrami−Erofeev expression $\alpha(t) = 1 - \exp[-(kt)^m]$ with α being the extent of reaction, m the reaction exponent and k [s^{-1}] the reaction rate coefficient.[35−37] The expression was then converted into the linear equation $\ln[-\ln(1-\alpha)] = m\cdot\ln(k) + m\cdot\ln(t)$ to analyse the product growth by a so-called Sharp−Hancock plot[34] plotting $\ln[-\ln(1-\alpha)]$ versus $\ln(t)$. Such a plot gives a straight line for that part of the reaction which follows the same mechanism. The reaction exponent m is obtained from the slope of the curve, whilst the rate constant k can be evaluated from the intercept with the y axis. The kinetic data obtained in this way for the MDAP reactions between 95 °C and 120 °C are listed in Table 1. For temperatures up to 100 °C a consistent mechanism was observed, being confirmed by the straight line through the points on the Sharp−Hancock plots (Figure 5, top). At higher temperatures two different regions can be

distinguished, with an inflexion point at $\alpha = 0.8$ (Figure 5, bottom). At $\alpha > 0.8$ a significantly lower reaction exponent m and a higher rate coefficient k were obtained. Due to the long induction times the DIEN data were collected between 110 and 170 °C (Table 2). After induction, the product growth is very fast. For larger α values the straight line in the Sharp−Hancock plots suggests a consistent mechanism.

Table 1. Kinetic data obtained by the analysis with Sharp−Hancock plots for crystallisation of $Mn_2Sb_2S_5$·MDAP; t_0 is the induction time, $t_{0.5}$ is the time when $\alpha = 0.5$

Reaction temp.	t_0 [s]	$t_{0.5}$ [s]	Rate constant k [s^{-1}]	Exponent (order) m
95 °C	3900	3300	$2.60(2)\cdot10^{-4}$	1.96(3)
100 °C	2800	2450	$3.69(7)\cdot10^{-4}$	3.13(6)
105 °C ($\alpha < 0.8$)	2000	1920	$4.40(6)\cdot10^{-4}$	1.97(3)
105 °C ($\alpha > 0.8$)			$7.01(8)\cdot10^{-4}$	1.07(6)
110 °C ($\alpha < 0.8$)	1350	1110	$7.75(5)\cdot10^{-4}$	2.27(4)
110 °C ($\alpha > 0.8$)			$1.36(9)\cdot10^{-3}$	0.78(6)
115 °C ($\alpha < 0.8$)	1100	970	$9.26(8)\cdot10^{-4}$	3.15(6)
115 °C ($\alpha > 0.8$)			$2.13(9)\cdot10^{-3}$	0.55(2)
120 °C ($\alpha < 0.8$)	800	850	$9.95(9)\cdot10^{-4}$	2.18(3)
120 °C ($\alpha > 0.8$)			$2.15(8)\cdot10^{-3}$	0.56(2)

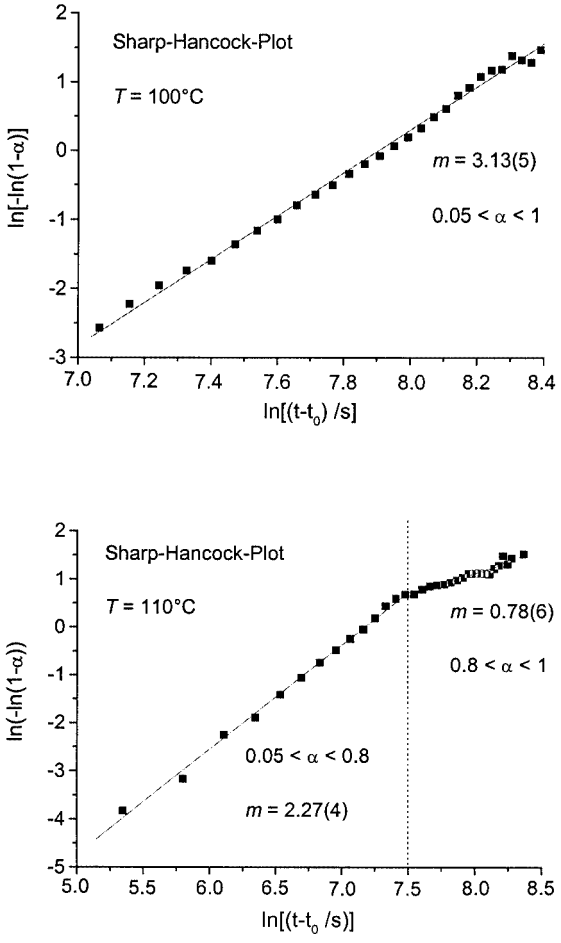

Figure 5. Sharp−Hancock plots of the data obtained for $Mn_2Sb_2S_5$·MDAP at 100 °C and 110 °C; experimental points are the solid squares and the lines represent the fits

Table 2. Kinetic data obtained by the analysis with Sharp−Hancock plots for the crystallisation of $Mn_2Sb_2S_5$·DIEN; t_0 is the induction time, $t_{0.5}$ is the time when $\alpha = 0.5$

Reaction temp.	t_0 [s]	$t_{0.5}$ [s]	Rate constant k [s^{-1}]	Exponent (order) m
110 °C ($\alpha < 0.6$)	5880	840	$7.64\cdot10^{-4}$	0.88(2)
110 °C ($\alpha > 0.6$)			$6.10\cdot10^{-4}$	0.44(2)
115 °C	1680	720	$8.86\cdot10^{-4}$	0.74(1)
120 °C	1320	440	$1.46\cdot10^{-3}$	0.87(2)
130 °C	1080	280	$2.79\cdot10^{-3}$	0.78(3)
140 °C	960	240	$5.38\cdot10^{-3}$	0.51(4)
150 °C	900	120	$7.84\cdot10^{-3}$	0.49(4)
160 °C	580	100	$8.87\cdot10^{-3}$	0.34(4)

To find a correct model for the crystallisation kinetics the data were plotted as $t/t_{0.5}$ versus α, with $t_{0.5}$ being the reaction time at $\alpha = 0.5$. Such a plot allows a direct comparison with the different models under consideration.[38] The different established models were compared with the experimental results (Table 3). For the temperatures up to 100 °C the $Mn_2Sb_2S_5$·MDAP crystallisation is predominately controlled by nucleation (Figure 6, top). This seems also to be the case for the reactions at higher temperatures with $\alpha < 0.8$. For the data with $\alpha > 0.8$ the curves are in reasonable agreement with a diffusion-controlled mechanism (D3) (Figure 6, bottom). It must be emphasised that such analyses are only approximations to the ideal borderline cases of the different models. Nevertheless, the data confirm that the crystallisation kinetics as well as the mechanisms are very different for the amines DAP and MDAP. The formation of $Mn_2Sb_2S_5$·DAP involves the formation and disappearance of two crystalline intermediates, and the crystallisation follows a phase-boundary-controlled mechanism. In contrast, for $Mn_2Sb_2S_5$·MDAP a nucleation-controlled growth without formation of any crystalline intermediate is observed. The proposed models are confirmed by the shapes of the α vs. time curves (Figure 2), which, as predicted by the theoretical models, are sigmoidal for nucleation-controlled mechanisms but not for phase-boundary-controlled models.[13] Interestingly, for the reaction with DIEN, different crystallisation kinetics are observed. Both, the shape of the curves and the $t/t_{0.5}$ data point to a diffusion-controlled mechanism. Due to the high rate constants the time resolution of 120 s is not adequate to determine low α values.

The activation energy of crystallisation was calculated by applying the Arrhenius equation $\ln(k) = \ln(A) - E_a/RT$. From the slope of an $\ln(k)$ versus $1/T$ plot, activation energies E_a of 65(5) kJ/mol (MDAP system) and 73(3) kJ/mol (DIEN system) were obtained. The values are in a range similar to those calculated for the crystallisation of the DAP compound as well as for usual zeolite compounds reported in the literature.[9,39] For the reactions with changing mechanisms the k values for $\alpha < 0.8$ were used.

Table 3. The rate equations for solid-state reactions reported in the literature

Growth model[38]	Rate equation f(α) = kt	m
Diffusion-controlled:		
$D_1(\alpha)$	$\alpha^2 = 0.25\ (t/t_{0.5})$	0.62
$D_2(\alpha)$	$(1-\alpha)\ln(1-\alpha)+\alpha = 0.1534\ (t/t_{0.5})$	0.57
$D_3(\alpha)$ [Jander]	$[1-(1-\alpha)^{1/3}]^2 = 0.0425\ (t/t_{0.5})$	0.54
$D_4(\alpha)$ [Ginstling−Brounshtein]	$1-2\alpha/3-(1-\alpha)^{2/3} = 0.0367\ (t/t_{0.5})$	0.57

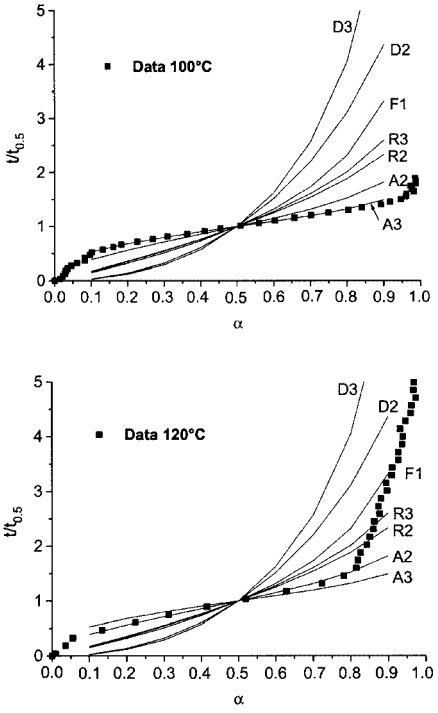

Figure 6. Comparison of the evolution of experimental $t/t_{0.5}$ data (T = 100 and 120 °C) as a function of α (black squares) with different kinetic models for $Mn_2Sb_2S_5$·MDAP; the letters with the numbers are the abbreviations of the different models listed in Table 2

Stability of Crystalline $Mn_2Sb_2S_5$·L Phases

In order to study the competition between the amines during product formation, 1:1 and 3:1 mixtures of two amines were examined and the reactions monitored. At the end of the reactions only one pure product containing only one amine was observed. The DAP/DIEN and MDAP/DIEN mixtures gave pure $Mn_2Sb_2S_5$·DIEN and for both mixtures the three crystalline phases were detected that were also seen using pure DIEN (see above). For DAP/MDAP mixtures the pure MDAP compound was formed, and even after 175 min no reflections of $Mn_2Sb_2S_5$·DAP were visible in the patterns. No hints were found for the appearance of the crystalline intermediate phases that were detected in the Mn−Sb−S−DAP system.

The conversion of the different isostructural phases which was observed with the ex-situ experiments was investigated in situ in the following way: The reactions with the amines DAP or MDAP, which gave the desired crystalline product, were monitored by in-situ EDXRD; after completion, 1 mL of a second amine was added to the product and spectra were recorded after 2 h at different temperatures to monitor possible changes in the starting material caused by the added amine.

After the addition of MDAP to the crystalline $Mn_2Sb_2S_5$·DAP product, no differences in the spectra could be detected even after 2 h at 120 °C (Figure 7). Very different results were obtained, however, when crystalline $Mn_2Sb_2S_5$·L (L = DAP or MDAP) products were treated with DIEN. The reaction between $Mn_2Sb_2S_5$·DAP and DIEN at 120 °C is relatively fast, and after about 45 min only reflections due to $Mn_2Sb_2S_5$·DIEN occurred in the pattern (Figure 8). The peak maximum of the (100) reflection shifts continuously from the position of $Mn_2Sb_2S_5$·DAP (18.74 keV) to that of $Mn_2Sb_2S_5$·DIEN (18.66 keV) as shown in Figure 9. The conversion of the DAP compound to the pure DIEN sample depends on the temperature, and the half-life was extended from about 10 min at 120 °C to 20 min at 110 °C.

Performing the experiments with crystalline $Mn_2Sb_2S_5$·MDAP resulted in the conversion into the DIEN product being slower. At 120 °C the appearance of reflections due to $Mn_2Sb_2S_5$·DIEN started after a few minutes but full conversion was not achieved for a further 2 h. Figure 10 shows the transformation of the MDAP to the DIEN phase. The temperature dependence is more pronounced than for DAP: The half-life has increased from 30 min at 120 °C to 120 min at 100 °C, and the completion requires several hours. These results suggest that $Mn_2Sb_2S_5$·DIEN is the most stable compound, followed by $Mn_2Sb_2S_5$·MDAP and $Mn_2Sb_2S_5$·DAP.

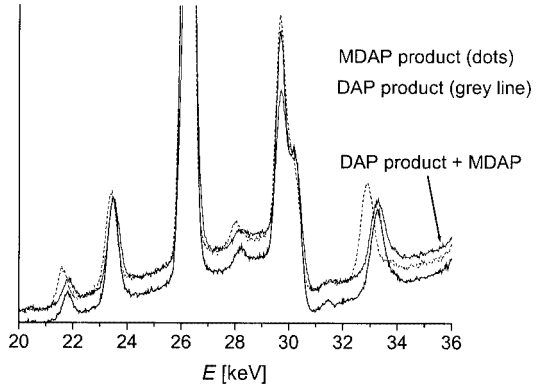

Figure 7. Comparison of the powder patterns of $Mn_2Sb_2S_5$·DAP and $Mn_2Sb_2S_5$·MDAP with the pattern measured after the reaction of $Mn_2Sb_2S_5$·DAP with a solution of MDAP

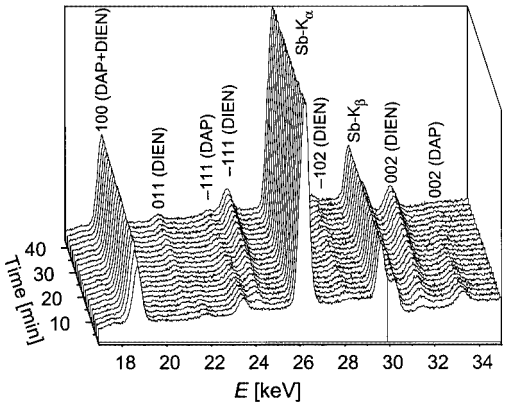

Figure 8. Time-resolved powder patterns collected during the conversion of $Mn_2Sb_2S_5$·DAP on adding DIEN at 120 °C; the indices of the reflections of the two phases are given

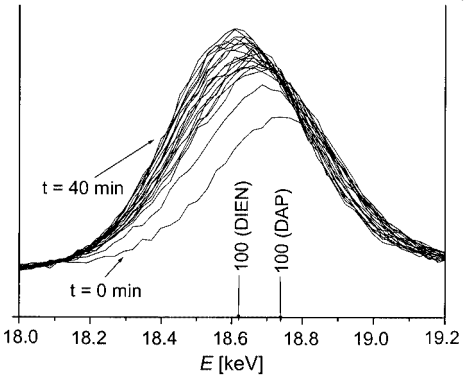

Figure 9. Subsequent shift of the position of the (100) reflection of $Mn_2Sb_2S_5$·DAP after DIEN addition

A quantitative evaluation of the change of MDAP into DIEN of the intensities of the (002) reflections at 100 and 120 °C is shown in Figure 11. Interestingly, the curves of the normalised intensities intersect at $\alpha \approx 0.5$ and several possibilities must be considered to explain this observation: i) direct solid-solid transformation, no amorphous intermediate, no dissolved phases involved in the process;

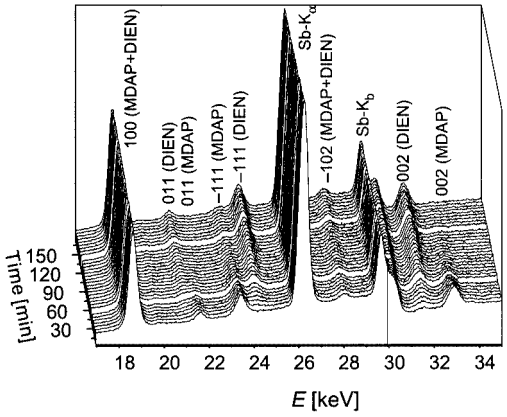

Figure 10. Time-resolved powder patterns collected during the conversion of $Mn_2Sb_2S_5$·MDAP applying DIEN at 120 °C; the indices of the reflections of the two phases are given

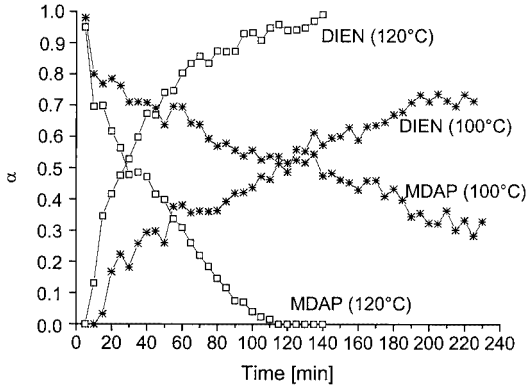

Figure 11. The evolution of the extent of reaction (α) for the (002) reflection of $Mn_2Sb_2S_5$·MDAP during the reaction with a DIEN solution monitored at 100 and 120 °C; note: the lines joining the symbols are only guides

ii) the first compound is completely converted into an amorphous phase, the product nucleates and crystallises subsequently;
iii) the first compound is completely dissolved and the product nucleates and crystallises from the solution;
iv) two completely separate processes for the formation of the first and the second product.

The decrease of the intensities of the DAP and MDAP compounds coincide with the occurrence of the reflections of the DIEN product. Therefore, explanation iv) can be immediately ruled out. Because the curves cross near $\alpha = 0.5$, a solid-solid transformation seems to be plausible, but partial dissolution or amorphisation of the starting material prior to crystallisation of the DIEN product cannot be excluded. A dissolution/amorphisation of a few percent of the DAP/MDAP starting material yields only minute changes in the intensities of the reflections.

It is highly likely that the transformation of the starting material compounds proceeds by one of the two mechanisms ii) or iii). To fully distinguish between these two possibilities other in-situ measurements are necessary. During

the syntheses of aluminophosphates intermediates were detected by in-situ NMR experiments. It is clear, however, that the Mn−Sb−S system is not suitable for such NMR investigations and other techniques such as in-situ Raman spectroscopy or in-situ XAS may provide the information necessary to understand what happens during the transformation of the intermediate into the final product. As demonstrated by Sankar[40,41] and Thomas[42] the combination of in-situ EDXRD and EXAFS is a powerful analytical tool for obtaining the missing information.

Conclusions

Despite the fact that $Mn_2Sb_2S_5$·DIEN, $Mn_2Sb_2S_5$·MDAP, and $Mn_2Sb_2S_5$·DAP are isostructural compounds, the mechanisms of formation are very different. For $Mn_2Sb_2S_5$·DAP crystallisation proceeds via two crystalline intermediates whereas for $Mn_2Sb_2S_5$·MDAP no hints for the formation of such intermediates were found. It is noteworthy that for the DIEN compound three crystalline precursors/intermediates could be detected. In addition, the data provide evidence that the crystallisation kinetics are different for the three compounds. For $Mn_2Sb_2S_5$·DAP, a first-order reaction or phase-boundary mechanism dominates at low temperatures, whereas at higher temperatures and $\alpha > 0.75$ a three-dimensional controlled process (D3) dominates. MDAP nucleation is the rate-limiting step in the low-temperature process and upon increasing the temperature the mechanism changes to D3 when $\alpha > 0.8$. Furthermore, the formation of $Mn_2Sb_2S_5$·MDAP requires shorter induction times than for the DAP analogue. The crystallisation of the DIEN compound proceeds by a diffusion-controlled mechanism after a significantly longer induction time.

The crystalline compounds $Mn_2Sb_2S_5$·DAP and $Mn_2Sb_2S_5$·MDAP are completely converted into the DIEN product suggesting that $Mn_2Sb_2S_5$·DIEN is the thermodynamically most stable compound of the isostructural samples. The difference in the stability between the DAP and MDAP compounds is too small for a transformation of DAP into MDAP. The rigorous analysis of the in-situ EDXRD data for the conversion of MDAP starting material into the DIEN product suggests that a small amount of $Mn_2Sb_2S_5$·MDAP is dissolved, followed by an immediate crystallisation of $Mn_2Sb_2S_5$·DIEN. It must be noted that the amount of the amine applied guarantees a 60-fold excess with respect to the elements Mn/Sb/S.

The results presented here clearly demonstrate that even for isostructural compounds the actual mechanism of formation is very different. Evidently, the amine used determines the mechanism of product crystallisation.

It is well documented that the reactions occurring in the heterogeneous mixture determine what type of compound nucleates and starts to crystallise. Because X-ray diffraction is "blind" with respect to the processes within the so-called induction period, future projects will focus on combined in-situ EXAFS/EDXRD experiments.

Experimental Section

The HASYLAB Beamline F3 receives white synchrotron radiation from a bending magnet with a critical energy of 16 keV and gives a positron beam energy of 4.5 GeV. An energy range from 13.5 to 65 keV can be observed with a maximum at about 20 keV. The diffracted beam is monitored by a nitrogen-cooled solid-state germanium detector. The detector angle was chosen so that all important Bragg reflections could be detected. The *d*-spacing range is given by $E = 6.199/(d \cdot \sin\theta)$. With a detector angle of approximately 1.96° the observable *d*-spacing range is 2.8 to 13.4 Å. Above 26 keV, the energy resolution $\Delta d/d$ is about 10^{-2}. The beam was collimated to 0.2 mm giving the best results.

The investigations were carried out in Teflon-lined autoclaves under autogenous pressure and isothermal conditions similar to those used for the ex-situ investigations in the laboratory. Because common steel autoclaves are not sufficiently permeable for synchrotron radiation, aluminium was used instead. Furthermore, the overall thickness of the wall of the autoclave was reduced from 2.5 mm to 1 mm. At the positions of beam inlet and outlet the wall thickness was machined down to 0.5 mm. The Teflon liner had an internal diameter of 10 mm, wall thickness of 1 mm, height of 94 mm and a capacity of 7 mL. A slightly different set-up for an in-situ cell was described by Evans et al.,[30] the smaller diameter should reduce absorption effects due to the pathway of the beam through the solution.

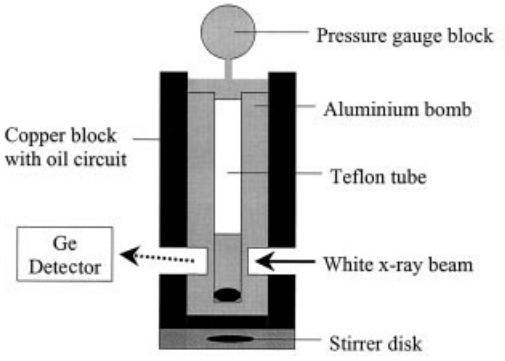

Figure 12. The experimental set-up used for the in-situ EDXRD experiments

The whole experimental set-up is shown in Figure 12 and the entire assembly was constructed according to the requirements of the desk of beamline F3 at HASYLAB in Hamburg. Time-resolved X-ray powder patterns with good counting statistics could be recorded with acquisition times of 300 s. A shorter acquisition time of 120 s was also used to obtain a higher resolution of induction times and reaction courses.

For the syntheses of $Mn_2Sb_2S_5$·L, elemental Mn (27.5 mg; 0.5 mmol), Sb (61.0 mg; 0.5 mmol), and S (40.0 mg; 1.25 mmol) were heated in a 70 % aqueous solution of the amines (2 mL) at temperatures ranging from 85 to 170 °C.

Formation of (σ-Alkenyl)- and (μ-Vinylidene)palladium and -platinum Complexes by Oxidative Addition of 4,4-Dichloro-1,1-diphenyl-2-azabuta-1,3-diene − The Molecular Structure of an Unusual Asymmetric (μ-Vinylidene)Pd−Pd Complex

Michael Knorr,*[a] Gérard Schmitt,*[a] Marek M. Kubicki,[b] and Estelle Vigier[b]

Keywords: Palladium / Vinylidene ligands / Platinum / Metal-metal interactions

4,4-Dichloro-1,1-diphenyl-2-azabuta-1,3-diene (**1**) oxidatively adds to $[Pd(PPh_3)_4]$ and $[Pt(C_2H_4)(PPh_3)_2]$ giving rise to the σ-alkenyl complexes *trans*-$[MCl\{[C(Cl)=C(H)–N=CPh_2]\}(PPh_3)_2]$ (**2a**: M = Pd; **2b**: M = Pt). When **1** is treated with $[Pd(PPh_3)_4]$ in a 1:2 ratio in refluxing toluene, the dimetallic μ-vinylidene complex $[(PPh_3)ClPd\{\mu\text{-}[C=C(H)–N=CPh_2]\}PdCl(PPh_3)_2]$ (**3**) is formed. In this fluxional compound, a PPh_3 ligands migrates in a reversible manner between the two Pd centers. Substitution of the PPh_3 ligands of **3** by 2 equiv. of $Ph_2PCH_2PPh_2$ affords the A-frame complex $[ClPd(\mu\text{-}dppm)_2\{\mu\text{-}[C=C(H)–N=CPh_2]\}PdCl]$ (**4**).

Introduction

Due to the eminent role of palladium in organometallic synthesis and homogenous catalysis, several methods for the formation of palladium−carbon bonds have been developed.[1] Among them, the oxidative addition of alkyl and aryl halides to Pd^0 complexes is common. It has been shown that vinyl chlorides may also oxidatively add to $[Pd(PPh_3)_4]$ giving rise to σ-alkenyl complexes of the type *trans*-$[PdCl\{[C(R)=CR_2]\}(PPh_3)_2]$.[2] In the course of our earlier studies in the field of organic 1,3-dipolar cycloaddition reactions, we prepared the new dichloro vinyl-like compound 4,4-dichloro-1,1-diphenyl-2-azabuta-1,3-diene (**1**).[3,4] This compound exhibits some promising features for coordination to inorganic and/or organometallic units as it bears a conjugated π-system and a potentially reactive C=N double bond. Furthermore, the basic iminium nitrogen atom may act as a potential donor for coordination of further metal centres to assemble (hetero)dimetallic systems. The group-10 late transition metal (Pd, Pt) complexes seem to be particularly good candidates for activation and coordination of this compound. We present here the first application of **1** in the organometallic chemistry of palladium and platinum.

Results and Discussion

Upon heating in toluene at 50 °C, complex **1** oxidatively adds to $[Pd(PPh_3)_4]$ to yield *trans*-$[PdCl\{[C(Cl)=C(H)-N=CPh_2]\}(PPh_3)_2]$ (**2a**) (Scheme 1). The expected

trans orientation of the two PPh_3 ligands follows from the $^{31}P\{^1H\}$ NMR spectrum, which displays a singlet at δ = 23.6 ppm. In order to obtain an unambiguous assignment of the stereochemistry of **2a**, the Pt analogue *trans*-[PtCl{[C(Cl)=C(H)−N=CPh_2]}$(PPh_3)_2$] (**2b**) was prepared by treating **1** in toluene with [Pt$(C_2H_4)(PPh_3)_2$] at 60 °C. The ^1H NMR spectrum of **2b** indicates that the regioisomer with the hydrogen atom on C-β in the *cis* position relative to the platinum atom is formed exclusively.[5] Since the chemical shifts for the olefinic hydrogen atom of **2a** (δ = 6.21 ppm) and **2b** [δ = 6.19 ppm, $^3J_{cis}$(Pt−H) = 27 Hz] are quite close, we suggest a (*Z*) configuration for these complexes.

When **1** is treated with [Pd$(PPh_3)_4$] in a 1:2 ratio in refluxing toluene, a two-centre, three-fragment oxidative addition of both vinylidene−chloride bonds across two Pd centers occurs affording the dimetallic μ-vinylidene complex [(PPh_3)ClPd{μ-[C=C(H)−N=CPh_2]}PdCl$(PPh_3)_2$] (**3**) in 49% yield {together with small amounts of **2a** and *trans*-[$PdCl_2(PPh_3)_2$]}. Suitable crystals of **3** for an X-ray diffraction study (Figure 1) were grown as red needles from a toluene/heptane solution. Surprisingly, this dimetallic complex possesses two different coordination spheres around each palladium atom; Pd(1) is ligated by P(1), P(2), and Cl(1), and the two Pd^{II} centers are bridged by C(1) in an slightly asymmetric manner [Pd(1)−C(1) 2.031(3), Pd(2)−C(1) 1.910(3) Å]. The close contact between Pd(1) and Pd(2) of 2.6785(3) Å is indicative of the existence of a metal−metal bond,[6,7] therefore Pd(1) may be described as five-coordinate. In contrast, Pd(2) is ligated with Cl(2) and only one phosphane ligand. To achieve the necessary 16-electron count, the metal−metal interaction is best described as a dative Pd1→Pd2 bond.

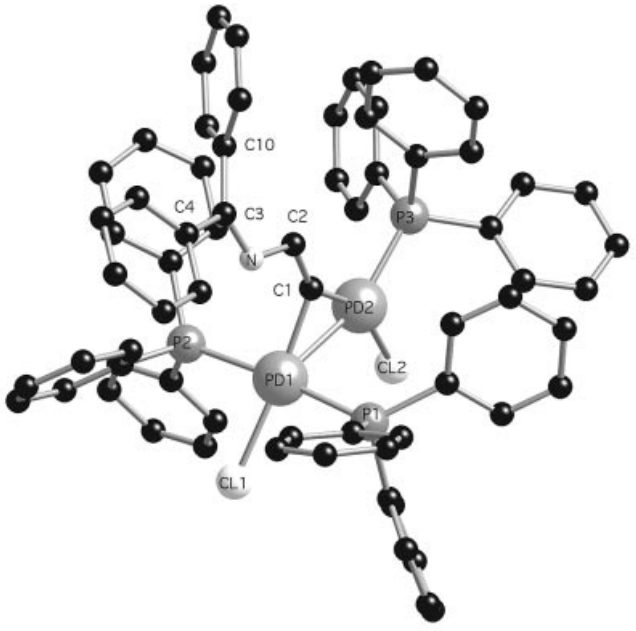

Figure 1. View of the crystal structure of **3**; selected bond lengths [Å] and angles [°]: Pd−Pd 2.6785(3), Pd(1)−P(1) 2.3375(9), Pd(1)−P(2) 2.3430(9), Pd(2)−P(3) 2.2399(9), Pd(1)−C(1) 2.031(3), Pd(2)−C(1) 1.910(3), Pd(1)−Cl(1) 2.3897(9), Pd(2)−Cl(2) 2.3887(9), C(1)−C(2) 1.339(4), N−C(2) 1.407(40), N−C(3) 1.302(4); Cl(1)−Pd(1)−C(1) 173.27(9), P(1)−Pd(1)−P(2) 174.82(3), P(1)−Pd(1)−C(1) 93.74(9), P(2)−Pd(1)−C(1) 91.28(9), P(3)−Pd(2)−C(1) 104.33(10), Pd(2)−C(1)−Pd(1) 85.58(13), C(1)−Pd(1)−Pd(2) 45.32(9), C(1)−Pd(2)−Pd(1) 49.10(10), C(1)−Pd(2)−Cl(2) 155.54(10), C(1)−C(2)−N 121.5(3)

To the best of our knowledge, no related Pd−Pd compound has been structurally characterized to date. However, the overall core structure in **3** is quite similar to that found in a platinum derivative [(PEt_3)BrPt{μ-[C=C(H)−Ph]}PtBr$(PEt_3)_2$].[8] Compound **3** is fluxional in solution, since a very broad singlet resonance at δ = 27.4 ppm is observed in the $^{31}P\{^1H\}$ NMR spectrum at 293 K, which sharpens upon heating to 323 K. At low temperature (223 K), the spectrum consists of distinct triplet and doublet resonances in a 1:2 ratio at δ = 34.0 and 24.8 ppm (see Figure 2). Addition of 2 equiv. of PPh_3 (at 293 K) to a sample of **3** has no influence on the chemical shift or shape of the resonance.

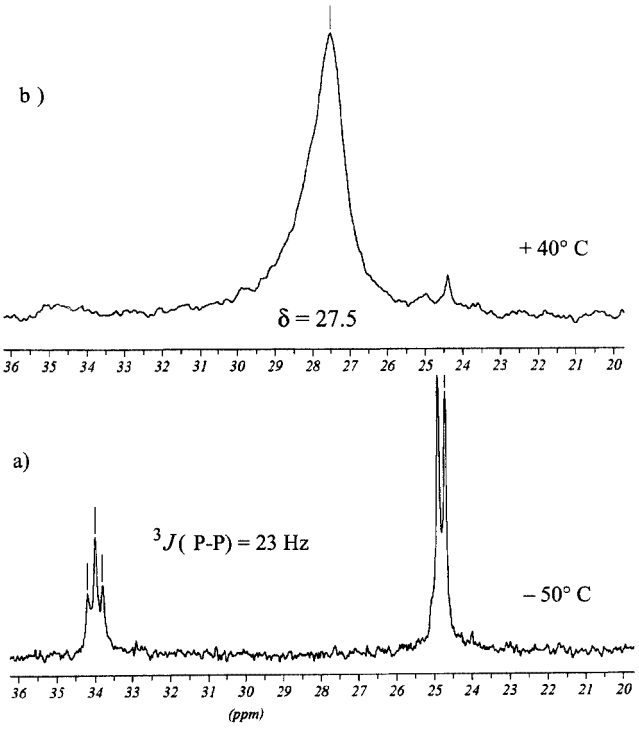

Figure 2. $^{31}P\{^1H\}$ NMR spectrum of **3** recorded in $CDCl_3$ at 223 K (a) and 313 K (b)

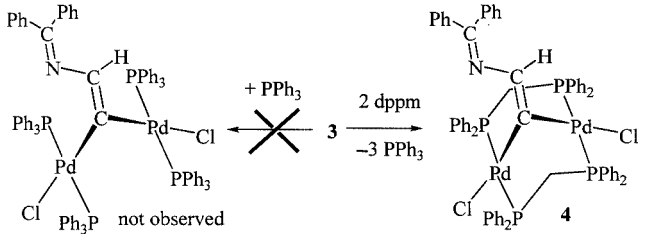
This fluxionality may be explained by a nondissociative intramolecular flipping[9a] of one PPh_3 ligand between Pd(1) and Pd(2) with concomitant switching of the vector of the dative bond, resulting in an averaged **3** ⇄ **3′** equilibrium on the NMR time scale. Note that this hypothesis involving the intermediacy of a μ-PPh_3 ligand is supported by the structural characterization of a stable Rh(μ-$PMe_3)_2$Rh complex.[9b,9c] Furthermore, a related reversible and nondissociative migration of a PR_3 ligand has been studied in detail very recently for the dimetallic system [{(η^5-C_5Me_5)Ru}$_2(PR_3)$(μ-H)$_2$].[9d] The ligation of Pd(2) by *just one* PPh_3 ligand is probably due to steric reasons. To avoid steric overcrowding by four bulky PPh_3 ligands in a mutual

trans arrangement on each Pd center, steric repulsion is minimized by dissociation of one of the four PPh_3 ligands, followed by an electronic *quasi* saturation of Pd(2) (up to 16 e^-) by formation of a dative Pd→Pd bond during formation of **3**. This hypothesis is corroborated by the observation that after addition of 2 equiv. of dppm, the three PPh_3 ligands are instantaneously replaced by two diphosphane ligands giving complex **4** quantitatively ($^{31}P\{^1H\}$ NMR monitoring, Scheme 2). As expected for an unsymmetrical dipalladium A-frame complex,[10−12] **4** displays an AA′BB′ pattern in the $^{31}P\{^1H\}$ NMR spectrum centered at δ = 16.3 ppm. This asymmetry may be explained by the coplanar orientation of the μ-azabutadiene unit with the Cl−Pd−C_μ−Pd−Cl array, thus rendering the two Pd environments nonequivalent.



Scheme 2

The potential of **1** and its derivatives as pincer ligands for cyclometallation and carbon−carbon coupling reactions as well for synthesis of other (hetero)dimetallic compounds is currently under investigation.[13]

Experimental Section

General: All reactions were performed in Schlenk-tube flasks under purified nitrogen. Solvents were dried and distilled under nitrogen before use: toluene and heptane from sodium, dichloromethane from P_4O_{10}. The ^1H, $^{31}P\{^1H\}$ NMR, and $^{195}Pt\{^1H\}$ NMR spectra were recorded with a Bruker Avance 300 MHz spectrometer (300.13, 121.49 MHz, and 64.52 MHz for ^1H, ^{31}P, and ^{195}Pt, respectively). Phosphorus chemical shifts are referenced to 85% H_3PO_4 in H_2O with downfield shifts reported as positive. ^{195}Pt chemical shifts are referenced to external K_2PtCl_4 in water with downfield chemical shifts reported as positive. All NMR spectra were recorded in $CDCl_3$.

Preparation of *trans*-[PdCl{[C(Cl)=C(H)−N=CPh$_2$]}(PPh$_3$)$_2$] (2a): Complex **1** (122 mg, 0.44 mmol) was added to a suspension of $[Pd(PPh_3)_4]$ (462 mg, 0.4 mmol) in toluene (15 mL) and the mixture warmed to 50 °C for 5 h. The resulting clear, orange solution was then concentrated to 8 mL, and layered with heptane. After keeping overnight in a refrigerator, **2a** crystallized. The yellow microcrystalline compound was rinsed with hexane (4 mL) and dried in vacuo. Yield: 66% (241 mg). ^1H NMR: δ = 6.21 (s, 1 H, C=CH), 6.49−7.86 (m, 40 H, phenyl) ppm. $^{31}P\{^1H\}$ NMR: δ = 23.6 (s) ppm. $C_{51}H_{41}Cl_2NP_2Pd$ (907.15): calcd. C 67.53, H 4.56, N 1.54; found C 67.98, H 4.56, N 1.90.

Preparation of *trans*-[PtCl{[C(Cl)=C(H)−N=CPh$_2$]}(PPh$_3$)$_2$] (2b): A mixture of $[Pt(C_2H_4)(PPh_3)_2]$ (750 mg, 1 mmol) and **1** (304 mg, 1.1 mmol) in toluene (20 mL) was heated to 60 °C for 14 h. The resulting clear yellowish solution was concentrated to ca. 10 mL and layered with heptane. After keeping at −25 °C, **2b** precipitated as an off-white, air-stable, microcrystalline solid, which was dried in vacuo. Yield: 79% (778 mg). ^1H NMR: δ = 6.19 [s, 1 H, C=CH, $^3J_{cis}$(Pt-H) = 27 Hz], 6.94−7.92 (m, 23 H, phenyl) ppm. $^{31}P\{^1H\}$ NMR: δ = 24.8 (s, $^1J_{Pt,P}$ = 3015 Hz). $^{195}Pt\{^1H\}$ NMR: δ = −2641 (t, $^1J_{Pt,P}$ = 3015 Hz) ppm. $C_{51}H_{41}Cl_2NP_2Pt$ (995.85.): calcd. C 61.51, H 4.15, N 1.41; found C 61.89, H 4.02, N 1.21.

Preparation of [(PPh$_3$)ClPd{μ-[C=C(H)−N=CPh$_2$]}PdCl(PPh$_3$)$_2$] (3): Complex **1** (55 mg, 0.2 mmol) was added to a suspension of $[Pd(PPh_3)_4]$ (462 mg, 0.4 mmol) in toluene (10 mL) and the mixture heated under reflux for 5 h. The solvent was then evaporated and the residue was washed with Et_2O (5 mL). The remaining solid was redissolved in warm toluene and layered with heptane. A mixture of red, air-stable, needle-shaped crystals of **3** and yellow crystals of **2a** and of *trans*-$[PdCl_2(PPh_3)_2]$ co-crystallized; they were separated manually. Yield: 49% (134 mg). ^1H NMR: δ = 6.30 (s, 1 H, C=CH), 6.32−7.98 (m, 55 H, phenyl) ppm. $^{31}P\{^1H\}$ NMR (223 K): δ = 24.8 (d, 2 P, $^3J_{P,P}$ = 23 Hz), 34.0 (t, 1 P, $^3J_{P,P}$ = 23 Hz) ppm. $C_{69}H_{56}Cl_2NP_3Pd_2{\cdot}C_7H_8$ (1367.99): calcd. C 66.73, H 4.72, N 1.02; found C 66.98, H 4.54, N 0.97.

Preparation of [ClPd(μ-dppm)$_2${μ-[C=C(H)−N=CPh$_2$]}PdCl] (4): To a solution of **3** (14 mg, 0.01 mmol) in CH_2Cl_2 (2 mL) was added dppm (8 mg, 0.021 mmol). The resulting orange solution was stirred for a further 10 min, and then the solvent was removed under reduced pressure. The residue was rinsed with Et_2O (2 mL) and than dried to afford orange, air-stable **4** in almost quantitative yield (12 mg). ^1H NMR: δ = 2.55 (m, 2 H, PCH_AP), 3.02 (m, 2 H, PCH_BP), 6.53 (m, 1 H, C=CH), 6.70−7.94 (m, 50 H, phenyl) ppm. $^1H\{^{31}P\}$ NMR: δ = 2.55 (d, 2 H, PCH_AP), 3.02 [d, 2 H, PCH_BP, $J(H_A\text{-}H_B)$ = 12.9 Hz], 6.53 (s, 1 H, C=CH), 6.70−7.94 (m, 50 H, phenyl) ppm. $^{31}P\{^1H\}$ NMR: δ = 16.3 (m, AA′BB′ pattern) ppm. $C_{65}H_{55}Cl_2NP_4Pd_2$ (1257.78): calcd. C 62.07, H 4.41, N 1.12; found C 61.68, H 4.24, N 0.96.

X-ray Crystal Structure Determination of 3·Toluene: A small (0.10 × 0.08 × 0.05 mm) irregularly shaped solvated (toluene) single crystal of **3** was mounted on a Nonius Kappa CCD diffractometer. The unit cell determination and intensity data collection were carried out with Mo-K_α radiation (λ = 0.71073 Å) at 120 K. The measured intensities were reduced with the DENZO program.[14] The structure was solved by both Patterson and direct methods using the routines incorporated in SHELXS-97.[15] The asymmetric unit contains one dinuclear complex and one toluene molecule. The model was further refined with SHELXL-97.[15]

Crystallographic Data: $C_{76}H_{64}Cl_2NP_3Pd_2$ (M = 1367.89): monoclinic, space group $P2_1/n$; a = 16.2461(2), b = 25.3368(3), c = 16.7569(2) Å, β = 108.934(1)°, V = 6524.34(14) Å^3, Z = 4, $\rho_{calcd.}$ = 1.393 g·cm^{-3}, $F(000)$ = 2792; 35364 measured reflections in the scan range 5.4° < 2θ < 61.0°, of which 18823 independent and 9156 observed with $I > 2\sigma(I)$ were used in the structure solution and refinement for 757 parameters; $R1 = \Sigma|F_o - F_c|/\Sigma|F_o|$ = 0.049 [$I > 2\sigma(I)$], $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma wF_o^4]^{1/2}$ = 0.101 (all data), S(GoF) = 0.929; anisotropic refinement for non-hydrogen atoms; hydrogen atoms in idealized (riding model) geometries. The highest residual electron-density peak in the differential Fourier map of 0.98 e·Å^{-3} is quasi-symmetrically located between the heavy palladium atoms (1.38 Å from Pd1 and 1.40 Å from Pd2). CCDC-185833 (**3**) contains the supplementary crystallographic data for

this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]. An ORTEP Plot of compound **3** (at the 50% probability level) and the SFC Eurochem 2002 abstract P2-41[13b] are available as Supporting Information.

Coordination Modes in a Tridentate NNS (Thiosemicarbazonato)copper(II) System Containing Oxygen-Donor Coligands − Structures of [{Cu(L)(X)}$_2$] (X = Formato, Propionato, Nitrito)

Patricia Gómez-Saiz,[a] Javier García-Tojal,*[a] Aránzazu Mendia,[a] Bruno Donnadieu,[b] Luis Lezama,[c] José Luis Pizarro,[d] Maria Isabel Arriortua,[d] and Teófilo Rojo[c]

Keywords: Copper / Magnetic properties / Stacking interactions / Thiosemicarbazone complexes

Complexes with the formula [{Cu(L)X}$_2$] [X = $HCOO^-$ (**1**), $CH_3CH_2COO^-$ (**2**), NO_2^- (**3**)], where HL = $C_7H_8N_4S$ (pyridine-2-carbaldehyde thiosemicarbazone), have been synthesised and characterised. Single-crystal X-ray diffraction studies show that the structures of these compounds consist of centrosymmetric dimers containing distorted square-pyramidal copper(II) ions. The metal centres are coordinated to the NNS atoms of the tridentate thiosemicarbazonato ligand and one oxygen atom of the X coligand in the basal position. These complexes mainly differ in the atom that occupies the apical position. The structures of compounds **1** and **3** are made up of {$Cu_2(\mu$–SL)$_2$} entities in which the sulfur atom of the tridentate ligand acts as a bridge occupying the apical position. Compound **2** contains a {$Cu_2(\mu$-OX)$_2$} species bridged through the oxygen atoms from both propionato ligands. The results demonstrate the influence of the size of the coligand on the structure of these complexes. Structural and spectroscopic results suggest the presence of relevant ligand-to-metal charge transfers in these compounds. The EPR spectra exhibit rhombic symmetry. Magnetic measurements show antiferromagnetic couplings. The susceptibility data were fitted using the Bleaney–Bowers equation for copper(II) dimers. The J/k values obtained are −4.0, −4.8 and −4.9 K for compounds **1**, **2** and **3**, respectively.

Introduction

In the last 30 years, thiosemicarbazones and their metal complexes have been extensively studied due to their relevant biological properties.[1] In particular, the copper(II) derivatives of pyridine-2-carbaldehyde thiosemicarbazone (HL = $C_7H_8N_4S$) have drawn much attention (see Scheme 1). This thiosemicarbazone ligand coordinates to the metal ions in both the anionic (L^-) and neutral (HL) forms. The anionic L^- form is usually present in [{Cu(L)X}$_2$] dimers. In these dinuclear compounds, the metal centres can either be bridged through the sulfur enethiolato atom (X = Cl, Br, NCS)[2,3] or the non-thiosemicarbazone coligands[4,5] (X = $CH_3CH_2COO^-$, Scheme 2). In recent work, we have tried to rationalise the structural,

spectroscopic and magnetic aspects of this system by means of comparative structural studies and approximate molecular orbital calculations.[6] Several structural differences between dinuclear S- and X-bridged complexes have been found. The presence of S-bridges is due to p + sp^2 hybridising of the thiolato sulfur atom. The results suggest that the electron density of the S p_z orbital in the S-bridged systems is less delocalised towards the thiosemicarbazone chain than that of the X-bridged complexes. The formation of complexes with the S-bridge as opposed to the X-bridge depends on the nature of the non-thiosemicarbazone ligands. However, the actual underlying reasons for the formation of S- over X-bridged systems are not clear to date.

In order to evaluate the influence of the size and the type of O-donor coligand in the structure of these compounds, we present the synthesis, crystal structure, spectroscopic and magnetic properties of the [{Cu(L)X}$_2$] [X = $HCOO^-$ (**1**), $CH_3CH_2COO^-$ (**2**), NO_2^- (**3**)] complexes. Approximate molecular orbital calculations of the extended Hückel type have been carried out in order to understand the magnetic features of these systems.

Results and Discussion

The pyridine-2-carbaldehyde thiosemicarbazone (HL) ligand and the [Cu(L)(NO_3)] complex used as starting materials were synthesised according to published methods with slight modifications.[7,8] Elemental analyses are consistent with the proposed stoichiometries. Crystallographic details are given in Table 1.

Discrete quasi-planar [Cu(L)(HCOO)] and [Cu(L)(NO_2)] entities form the crystal structures of compounds **1** and **3**, respectively, linked through the sulfur atom of the thiosemicarbazonato ligand, which leads to dinuclear centrosymmetric [{Cu(L)X}$_2$] species. The molecular structures are shown in Figures 1 and 2. Selected interatomic dimensions are given in Table 2. The copper(II) ions are five-coordinate with two nitrogen atoms and one sulfur atom from the thiosemicarbazonato ligand [Cu−N(1), N(2), S: 2.016(4), 1.976(4), 2.265(2), and 2.025(3), 1.974(3), 2.268(1) Å for **1** and **3**, respectively] and an oxygen atom from one of the formato/nitrito ligands [Cu−O(1) 1.956(4) and 1.964(3) Å] in the basal position. The axial position is occupied by the sulfur atom belonging to the thiosemicarbazonato ligand of

the adjacent [Cu(L)(X)] entity [Cu−S′ 2.820(2) and 2.918(2) Å for **1** and **3**, respectively]. The intramolecular Cu···Cu′ distance is 3.503(2) Å in **1** and 3.554(1) Å in **3**. The distortion of the coordination polyhedra from square-pyramidal (SP, $\tau = 0$) and trigonal-bipyramidal (TBP, $\tau = 1$) topologies have been analysed.[9] The τ values obtained were 0.06 (**1**) and 0.13 (**3**), which clearly indicates that the environment of the copper(II) ions is close to the SP topology.

The thiosemicarbazonato ligand exhibits high planarity. The dihedral angles formed by the least-squares planes of both the thiosemicarbazone molecules, inside the dimer, are about 2.4 and 1.5° for **1** and **3**, respectively.

The crystal structure of complex **2** consists of centrosymmetric $[\{Cu(L)(CH_3CH_2COO)\}_2]$ entities. A perspective view of the molecular structure is shown in Figure 3. Several distances and angles are shown in Table 2. Each copper(II) ion exhibits a five-coordinate geometry. It is coordinated by two nitrogen atoms and one sulfur atom of the thiosemicarbazonato ligand [Cu−N(1), N(2), S: 2.056(2), 1.966(2), 2.287(1) Å] and the oxygen O(1) atom of the propionato ligand at 1.951(2) Å, in the basal plane. The oxygen atom belonging to the thiosemicarbazonato ligand of the adjacent $[Cu(L)(CH_3CH_2COO)]$ entity [Cu−O(1)′ 2.387(2) Å] occupies the axial position. The intramolecular Cu···Cu′ distance is 3.460(2) Å. The distortion of the coordination polyhedron gives a value of $\tau = 0.19$ characteristic of a geometry close to that of SP.

The thiosemicarbazonato ligand is nearly planar in complex **2**. Both thiosemicarbazone molecules in the dimer are coplanar (dihedral angle about 0.0°).

As can be expected, the longest C−O/N−O bonds inside the coligands involve the O(1) atoms that are linked to the metal ions, for all three of the complexes.

Several hydrogen bonds are established in the lattice of these compounds in which the O(2), N(3) and N(4) atoms are involved (see Table 2). The presence of C−H···S linkages is also remarkable.

It is worth mentioning that the shortest distances between the pyridine plane and the thiosemicarbazone moiety of different molecules are 3.28 [C(3)···C(7)^{iv}], 3.31 [C(5)···N(2)^{iii}] and 3.37 Å [C(3)···C(7)^{v}] for **1**, **2** and **3**, re-

spectively. This suggests the existence of π-π stacking of the slipped packing type[10] as represented in Figure 4. These interactions have been evaluated,[11,12] and the results are shown in Table 3. The coordination of a metal ion to the nitrogen heteroatom of pyridines and other heterocycles enhances the electron-withdrawing effect through its positive charge, and hence the stability of the π-π interaction increases.[13,14] These kinds of interactions have been observed in other thiosemicarbazone systems.[15−18]

Complexation induces conformational changes in the ligand. Atoms N(1) and N(2) are *anti* with respect to the C(5)−C(6) bond in the free ligand;[19] however, they become *syn* after chelation. Furthermore, the N(2) and S atoms are *anti* with respect to the N(3)−C(7) bond in the free ligand[19] and also in the pyridinium $(H_2L)Cl{\cdot}H_2O$ cationic derivative,[20] but they are *syn* in the metal complexes. The C−C and C−N distances are similar to those found in the free ligand and its cationic form, except for the N(3)−C(7) and C(7)−S bond lengths, which are 1.358(4) and 1.698(3) Å, respectively, in the free ligand. This suggests that the double bond character of the N(3)−C(7) and C(7)−S bonds increases and decreases, respectively, in the complexed thiosemicarbazonato ligand. However, bond lengths are often in the range of the experimental error and other structural parameters such as some of the bond angles and non-contact distances are more appropriate to evaluate the anionic vs. neutral character of the ligand upon complexation.[6] The results summarised in Table 4 show that the distances and angles for the title complexes are in good agreement with those expected for compounds con-

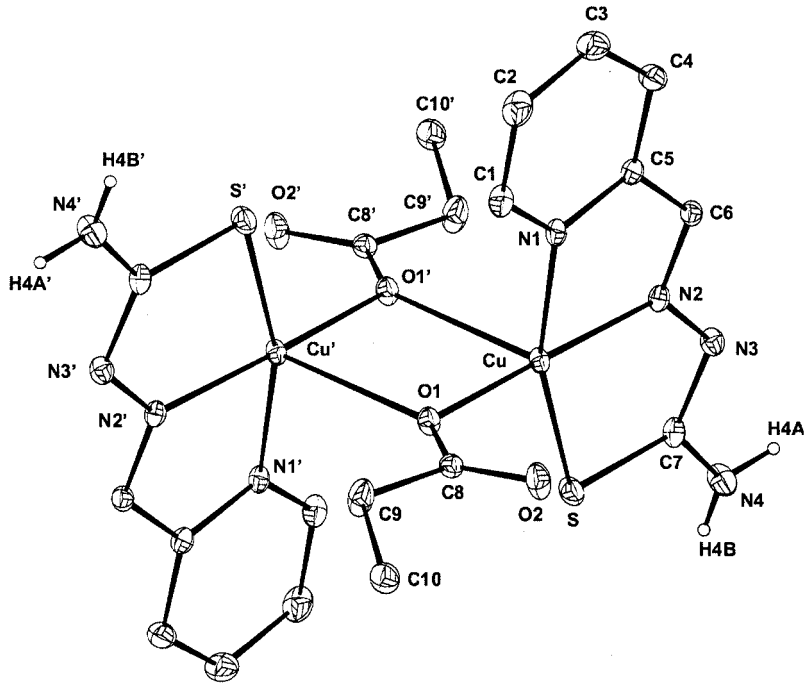

Figure 3. Molecular structure of **2** with thermal ellipsoids at 50% probability level

taining the pyridine-2-carbaldehyde thiosemicarbazone ligand in the anionic form.

The presence of μ-thiolato bridges between the metal centres in the iminothiolato systems such as heterocyclic thiosemicarbazone complexes is unusual,[21] although they have been found in other related thiosemicarbazone compounds.[2,3,17,22−28]

The existence of different infrared absorptions corresponding to the thioamide and pyridine substituents, together with the electron delocalisation through the thiosemicarbazone molecule, make the assignation of the bands in these compounds difficult. The intense bands around 1600 cm^{-1} can be attributed to the $\nu(C{=}N)_{azomethine}$, $\nu(C{=}N)_{pyridine}$ and $\delta(NH_2)$ modes. The strong band at 1525 cm^{-1} in the free ligand has been identified as corresponding to a thioamide I absorption, with high contribution of the $\delta(NH_2)$ and δ(NH) deformation modes. This band undergoes an increase in energy on complexation[29] and its intensity decreases in the compounds containing the deprotonated ligand. The thioamide IV band, which appears at 820 cm^{-1} in the free ligand, is absent in the copper(II) complexes. This is probably due to both a decrease in the double bond character of the C7−S bond and the change in the conformation of the N3−C7 bond on complexation.[3] Other absorptions observed in the 815−830 cm^{-1} region for **2** and **3** have been attributed to the coligand (see below). The bands at ca. 447 cm^{-1} have been assigned to the $\nu(Cu{-}N_{azomethine})$ vibration. These results indicate the presence of the thiosemicarbazonato ligand coordinated to the copper(II) ions through the $N_{pyridine}N_{azomethine}S$ chelating centres.

The very strong bands at 1616 and 1316 cm^{-1} in **1** have been attributed to the ν(C=O) and ν(C−O) absorptions of the formato ligand [the latter overlapped with a thioamide III absorption mainly due to δ(N−H) and ν(C−N) contributions of the thiosemicarbazone]. The Δ value [ν_a(COO) − ν_s(COO) in the free ion] is 300 cm^{-1} for **1**, which is greater than the value of 201 cm^{-1} observed for the ionic formate, in good agreement with the unidentate character of the coligand.[30] Unfortunately, the complexity of the spectrum of compound **2** only allows for the distinction of the strong band at 1603 cm^{-1}, due to the overlapped ν(C=O) and thioamide I absorptions [δ(N−H) and ν(C=N) contributions]. A weak band at 816 cm^{-1} appears in the infrared spectrum of **2** which is also present for the sodium propionate, and can be attributed to ν(C−C) vibration modes of the propionato ligand.

The infrared spectrum of compound **3** shows a shoulder at around 1408 cm^{-1} and two bands at 1125 and 826 cm^{-1}. These bands are attributed to the ν(N=O), ν(N−O) and δ(ONO) absorptions of the nitrito ligand.[31]

The reflectance spectra of the title compounds show bands in the 220−235, 260−270, 360−465 and 590−750 nm regions. These are assigned to $(\pi \rightarrow \pi^*)_{pyridine}$, $(n \rightarrow \pi^*)_{pyridine}$, $(n \rightarrow \pi^*)_{thiosemicarbazone}$, LMCT N/O/S → d and d → d transitions, respectively.[32,33]

The intense absorption observed in the 384−405 nm range is attributed to a S → Cu^{II} charge transfer transition.[3] The absorptions between 430−465 nm may be due to LMCT O/N → Cu^{II} transitions, as were observed in other related compounds.[34]

The maxima observed from the solid samples in the 595−650 nm region are characteristic of d → d transitions for compounds exhibiting a square pyramidal geometry with a $d_{x^2-y^2}$ ground state. These bands show unresolved shoulders obscured by the tails above 700 nm, which can be

attributed to a certain amount of distortion of the coordination polyhedra to trigonal bipyramidal, in these compounds.

The three compounds exhibit the same solution spectrum with bands at 280, 317 (sh), 382 and 629 nm (see Exp. Sect.), which is basically the same as that previously described for the acetato[35,36] and the nitrato derivatives.[3,5] This shows that the coligand has been removed from the coordination sphere indicating the possible existence of entities of type $[CuL(H_2O)_3]^+$ in aqueous solution, in good agreement with the close to 1:1 electrolyte character of these compounds in water.

The X-band EPR spectra of polycrystalline samples of the title complexes are shown in Figure 5. They all exhibit rhombic signals. The *g* values obtained are given in Table 5. These values are similar to those observed for other pyridine-2-carbaldehyde thiosemicarbazone derivatives containing copper(II) ions in distorted square-pyramidal topologies, with a $d_{x^2-y^2}$ ground state.[2,3,5,6] The O-bridged dimer is the most rhombic and has the largest value for g_1, which is in good accordance with the differences in the crystal structure.

The plot of the molar susceptibility (χ_m), together with the $\chi_m T$ vs. T curve for **1** is given in Figure 6. The results are very similar to those of complexes **2** and **3**. In all cases, the magnetic measurements obey the Curie−Weiss law at temperatures higher than 50 K. The Weiss temperatures are −2.72 (**1**), −3.29 (**2**) and −3.02 K (**3**). The C_m experimental value is approximately 0.41 $cm^3 \cdot K \cdot mol^{-1}$ and the calculated μ_{eff} values at room temperature are 1.80 BM for all of the compounds. The χ_m values increase with decreasing temperature, reaching a maximum at 5.0 [0.040 $cm^3\ mol^{-1}$ (**1**)], 6.0 [0.033 $cm^3\ mol^{-1}$ (**2**)] and 5.5 [0.033 $cm^3\ mol^{-1}$ (**3**)] K. The $\chi_m T$ value continuously decreases on lowering the temperature indicating the presence of antiferromagnetic interactions in these compounds.

Taking the dimeric nature of these complexes into account, we fitted the susceptibility data using the expression given by Bleaney−Bowers for copper(II) dinuclear compounds [Equation (1)],[37] derived from the Heisenberg isotropic spin Hamiltonian ($H = -2J\ S_1S_2$), for two coupled S = 1/2 ions; where $N\alpha = 60 \times 10^{-6}\ cm^3\ mol^{-1}$ per copper(II) ion, N = Avogadro number, β = Bohr magneton, and k = Boltzmann constant.

$$\chi = \frac{Ng^2\beta^2}{kT}\left(\frac{2}{3+\exp(-2J/kT)}\right) + N\alpha \qquad (1)$$

The best least-squares fit (solid line in Figure 6) is obtained from the parameters J/k = −4.0 K (−2.8 cm^{-1}), −4.8 (−3.3 cm^{-1}) and −4.9 K (−3.4 cm^{-1}). The *g* values are 2.09, 2.10 and 2.09 for the formato, propionato and nitrito complexes, respectively. These *g* values are in good agreement with those obtained from EPR spectroscopy, 2.083 (**1**), 2.091 (**2**) and 2.090 (**3**). Taking into account the structural features, the existence of interdimeric magnetic

interactions should be considered. However, an improvement in the fit was not observed.

The small values of the magnetic interactions suggest that the exchange propagation direction is in a different plane from that formed by the magnetic $d_{x^2-y^2}$ orbitals. These results are in good agreement with the existence of an intradimer exchange coupling in the Cu_2S_2 (**1**, **3**) and Cu_2O_2 (**2**) units.

It has been proposed[38] that the antiferromagnetic contribution to the magnetic exchange constant J for a dinuclear system with two unpaired electrons is proportional to the square of the energy difference (Δ^2) between the two molecular orbitals constructed from the $d_{x^2-y^2}$ magnetic orbitals. An Extended Hückel molecular orbital (EHMO) analysis has been carried out by means of the CACAO program[39] to give a qualitative explanation for the magnetic behaviour of these complexes. The EHMO calculations have been carried out using the crystallographic coordinates of the compounds followed by reorientation of the molecules to ensure a maximum overlap.[40] The data are given in Table 6. The results show a qualitative agreement between Δ^2 and the values of the exchange constant. Unfortunately, the limitations of the EHMO calculations do not allow a perfect sequence to be obtained for very similar J values (for instance, the value of Δ^2 for **3** should be slightly greater than that in **1**, but the opposite trend is observed).

The results obtained of the influence of the bridge angle and the bridge atom are not consistent with those of idealised dimers.[2,3] One of the factors to be considered is the nature of the terminal coligands placed in the basal plane. In our case, O-donor coligands show the smallest J values. In this sense, it has been established that the less electronegative the donor atom in the basal plane the stronger the induced antiferromagnetic coupling, due to a greater hybridisation of the $d_{x^2-y^2}$ metal orbital towards the bridge.[41,42] On the other hand, the relationship between J and the bridge angle could be clarified for a given X-donor set. Therefore, it seems that angles close to 90° tend to diminish the J value for compounds containing O-donor basal coligands. This is in good agreement with the results previously reported.[2] In any case, several concomitant factors could be involved in the values of the exchange coupling constants for these compounds [Cu···Cu intradimer distance, SP vs. BPT distortions around the copper(II) ion, deviation of the metal ion from the basal plane, deviation of the coligand from the basal plane, Cu−X apical distances, etc.]. The synthesis of new (pyridinecarbaldehyde thiosemicarbazonato)copper(II) complexes could lead to a better

Table 6. Comparison of the J, Δ^2 and bridging distance and angle values for (pyridine-2-carbaldehyde thiosemicarbazonato)copper(II) dinuclear complexes; the atoms are numbered according to the nomenclature used in the present work (*: average value)

evaluation of the parameters that influence their magnetic behaviour.

Conclusions

The structural features of these compounds suggest that the increment in the size of the coligand is the main factor that leads to an X- vs. an S-bridge in the [{CuX(L)}$_2$] systems. These results may serve to rationalise and predict the interactions of the [Cu(L)(H_2O)$_3$]$^+$ entities with biomolecules present in the physiological medium.

Magnetic susceptibility data indicate the presence of weak intradimer antiferromagnetic interactions in these complexes. This behaviour can be qualitatively described from an EHMO study on real molecules.

Experimental Section

Preparation of the Complexes: Thiosemicarbazide, pyridine-2-carbaldehyde, formic and propionic acids, sodium nitrite and copper(II) nitrate were purchased from Probus, Carlo Erba and Fluka. All the complexes were dried under vacuum. The pyridine-2-carbaldehyde thiosemicarbazone (HL) ligand and the [Cu(L)(NO_3)] complex were synthesised according to published methods with slight modifications.[5,7]

Synthesis of [{Cu(L)(HCOO)}$_2$] (1): Formic acid (0.23 g, 5 mmol) was slowly added to an aqueous solution of Cu(L)(NO_3) (0.152 g, 0.5 mmol). The pH of the solution was adjusted to 5.5 by the addition of NaOH (1 M). After 1 h, a dark green precipitate was filtered off, washed with water and acetone and dried. The yield was 0.105 g (73%). Crystals suitable for X-ray studies were obtained by diffusion of diethyl ether vapours into a solution of **1** in methanol. $C_{16}H_{16}Cu_2N_8O_4S_2$ (575.56): calcd. C 33.4, H 2.8, N 19.5, S 11.1; found C 33.3, H 2.8, N 19.4, S 12.0. Molar conductivity of $5 \cdot 10^{-4}$ M solutions in water (dimethylformamide) at 25 °C: Λ_M = 102 (4) Ω^{-1} cm^2 mol^{-1}. Selected IR bands (KBr): $\tilde{\nu}$ = 3290 (m), 3146 (m), 2829 (w), 1634 (s), 1616 (vs), 1602 (vs), 1585 (m, sh), 1559 (w), 1482 (s), 1444 (vs), 1432 (vs), 1381 (s), 1316 (vs), 1264 (m), 1219 (s), 1166 (vs), 1151 (m, sh), 922 (m), 880 (m), 783 (m), 766 (m), 746 (w), 732 (m), 624 (m, b), 449 (w), 416 (m) cm^{-1}. UV/Vis (reflectance spectrum on solid sample): λ_{max} (ε) = ca. 750 (vb, sh), 608 (vb), 463 (b, sh), 405, 267 (sh), 223 nm; (6×10^{-5} M water solution): λ_{max} (ε) = 628 (150), 382 (9600), 317 (10600), 280 (14600 M^{-1} cm^{-1}) nm.

Synthesis of [{Cu(L)(CH_3CH_2COO)}$_2$] (2): This compound was prepared according to an analogous procedure to that of **1** but replacing formic acid with propionic acid (0.37 g, 5 mmol). The bright green product obtained was filtered off, washed with water and acetone and dried. The yield was 0.137 g (87%). Good-quality green crystals were obtained from the mother liquor after some weeks. $C_{20}H_{24}Cu_2N_8O_4S_2$ (631.68): calcd. C 38.0, H 3.8, N 17.7, S 10.2; found C 37.8, H 3.8, N 17.6, S 9.7. Molar conductivity of $5 \cdot 10^{-4}$ M solutions in water (dimethylformamide) at 25 °C: Λ_M = 75 (2) Ω^{-1} cm^2 mol^{-1}. Selected IR bands (KBr): $\tilde{\nu}$ = 3442 (m), 3290 (m), 3106 (bs), 2974 (m), 1640 (s), 1603 (vs), 1585 (m, sh), 1560 (m), 1485 (m), 1443 (s, sh), 1430 (vs), 1380 (s, b), 1324 (b m), 1271 (s), 1233 (m), 1168 (s), 1153 (s), 931 (w), 880 (m), 816 (w), 764 (w), 738 (m), 630 (m), 449 (w), 415 (w) cm^{-1}. UV/Vis (reflectance spectrum on solid sample): λ_{max} = 649 (vb), 445 (b, sh), 384, 264, ca. 235 (b, sh) nm.

Synthesis of [{Cu(L)(NO_2)}$_2$] (3): Sodium nitrite (0.036 g, 0.5 mmol) was allowed to react with an aqueous solution of Cu(L)(NO_3) (0.152 g, 0.5 mmol). Several drops of NaOH (1 M) were added whilst stirring to reach pH ≈ 7. The green precipitate was filtered off, washed with water and acetone and dried. The yield was 0.105 g (73%). Dark green crystals suitable for X-ray studies were separated from the mother liquor by slow concentration at room temperature. $C_{14}H_{14}Cu_2N_{10}O_4S_2$ (577.56): calcd. C 29.1, H 2.4, N 24.3, S 11.1; found C 28.8, H 2.7, N 23.9, S 10.8. Molar conductivity of $5 \cdot 10^{-4}$ M solutions in water (dimethylformamide) at 25 °C: Λ_M = 123 (15) Ω^{-1} cm^2 mol^{-1}. Selected IR bands (KBr): $\tilde{\nu}$ = 3409 (m), 3280 m, 3148 (m), 2974 (m), 1627 (s), 1604 (s), 1585 (w), 1560 (w), 1482 (s), 1445 (vs), 1434 (vs), 1408 (s, sh), 1391 (vs), 1320 (m), 1268 (m), 1228 (s), 1169 (vs), 1125 (vs), 914 s, 878 (m), 826 (w), 775 (s), 743 (s, b), 732 (m, b), 626 (s), 447 (m), 415 (s) cm^{-1}. UV/Vis (reflectance spectrum on solid sample): λ_{max} = ca. 750 (vb, sh), 593 (vb), 463, 430 (sh), 396 (b), 269, 222 nm.

Physical Measurements: Microanalyses were performed with a LECO CHNS-932 analyser. Conductivity measurements were made with a CRISON 522 conductimeter. Infrared spectra were obtained with samples prepared as KBr pellets in the 400−4000 cm^{-1} region with a Nicolet Impact 410 FTIR spectrophotometer. Reflectance spectra were carried out with a Cary 2415 spectrometer in the range 200−2000 nm. For UV/Vis solution measurements, a Varian UV/Vis/NIR spectrophotometer was employed in the range 200−900 nm. X-band EPR spectra were recorded with a Bruker EMX spectrometer, equipped with a standard Oxford continuous-flow cryostat. Magnetic measurements of powdered samples were carried out in the temperature range 1.8−300 K using a Quantum Design MPMS-7 Squid magnetometer. Diamagnetic corrections were estimated from Pascal tables.

X-ray Crystallographic Studies: Data were collected at low temperature (T = 160 K) with an IPDS STOE diffractometer for **1** and an XCALIBUR-CCD OXFORD DIFFRACTION diffractometer for **2**, both equipped with a Nitrogen Cooler Device, an Enraf-Nonius CAD4 was used for **3**. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was employed in all cases. Semi-empirical absorption corrections: DIFABS[43] were applied on **1** and **2**, and a φ-scan method[44] on **3**. Structures were solved by Direct Methods using SIR92[45] (**1**, **2**) and (SHELXS-97)[46] (**3**), and refined by least-squares procedures on F^2 with the aid of SHELXL-97,[47] included in the package WinGX.[48] The Atomic Scattering Factors were taken from the International Tables for X-ray Crystallography.[49] All hydrogen atoms were located on difference Fourier maps, and refined by using a riding model with a common isotropic thermal parameter, except the H(1*n*), H(2*n*) hydrogen atoms connected to nitrogen atoms N(4) in **1** and **2**, which were isotropically refined. For the three compounds all non-hydrogen atoms were anisotropically refined. Drawings were performed by using the programs CAMERON[50] and ORTEP32[51] with 50% probability displacement ellipsoids for non-hydrogen atoms. CCDC-187690, -187691 and -187508 for compounds **1**, **2** and **3**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

Acknowledgments

We thank Dr. J. J. Delgado (SCAI, Universidad de Burgos, Spain) for the elemental analyses and Prof. R. Olazcuaga and Dr. F. Guillen (CNRS, Pessac, France) for the reflectance measurements. This work has been carried out with the financial support of the Basque Government (PI99/53). P. G.-S. thanks to the Universidad de Burgos for a Doctoral Fellowship.

DNA Cleavage by Copper Complexes of 2- and 3-Clip-Phen Derivatives

Marguerite Pitié,[a] Christophe Boldron,[a] Heinz Gornitzka,[b] Catherine Hemmert,[a] Bruno Donnadieu,[a] and Bernard Meunier*[a]

Keywords: Copper / DNA cleavage / Helical structures / Ligand design / N ligands

The DNA cleavage activity of copper complexes of phenanthroline has been increased by the use of "2-Clip-Phen" and "3-Clip-Phen" ligands containing two phenanthroline entities linked by a serinol bridge. In order to optimize DNA cleavage activity, two series of new Clip-Phen ligands (L) with two phenanthroline residues linked through their C-2 or C-3 carbon atoms by different bridges have been synthesized. The physicochemical properties and the DNA cleavage activities of the corresponding (Clip-Phen)copper complexes were investigated in the presence of a reductant and air. X-ray analyses of single crystals showed that the cupric complexes of Clip-Phen were able adopt dimeric double-helical geometries with L_2Cu_2 stoichiometries in the solid state. These complexes adopt different geometries and stoichiometries in solution, with monomeric LCu species predominant. The compounds with a bridge connected at C-2 are less active as DNA cleavage agents than complexes with the bridge at the C-3 positions. Copper complexes with a bridge containing three methylene units appear to give the best results in DNA cleavage experiments. This activity is increased in the case of 3-Clip-Phen·$CuCl_2$ by the presence of the primary amine function of the serinol bridge. This amine function is probably coordinated to the copper atom in the case of 2-Clip-Phen·$CuCl_2$, decreasing the reactivity toward DNA.

Introduction

1,10-Phenanthroline (Phen) is a well-known motif for the preparation of a large range of strongly chelating ligands for various metal ions. The complexing capability of this easily accessible ligand has been used to develop biomimetic models of metalloenzymes, to design analytical reagents, cleavers, or conformational probes for nucleic acids, or to prepare supramolecules for molecular recognition and self-assembling systems.[1−13]

Redox-active copper complexes of phenanthroline are efficient artificial nucleases.[13−15] This versatile ligand is able to chelate copper ions to give mono- or bis(Phen)-copper complexes in oxidation states +I or +II. These interact efficiently with double-stranded DNA from the minor groove, probably by partial intercalation.[20,21] In the presence of hydrogen peroxide the $(Phen)_2Cu^{I}$ complex mediates single-strand cleavage of double-stranded DNA by oxidative attacks at C-1′ and C-4′ of 2-deoxyribose units.[13,16−18] Hydrogen peroxide can be generated in close proximity to DNA by $(Phen)_2Cu^{II}$ itself in the presence of a reductant and molecular oxygen.

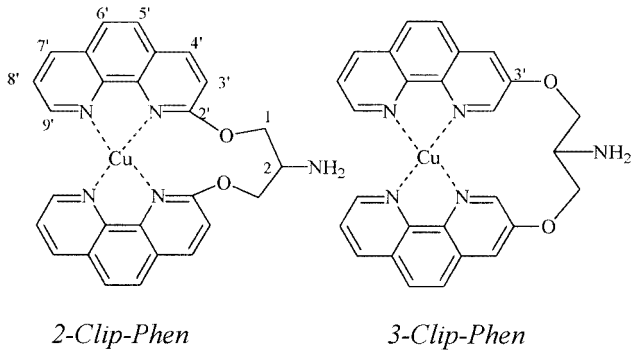
$(Phen)_2Cu^{I}$ is significantly more active than $(Phen)Cu^{I}$, but the association constant for the second phenanthroline ligand is only $10^{5.5}$ M^{-1}, too low for biological use at submicromolar concentrations of these complexes.[22] For this reason, we have recently prepared 2- and 3-Clip-Phen derivatives (Scheme 1) containing two Phen ligands linked through their 2′- or 3′-positions by a serinol bridge in order to favor the coordination of two Phen units around the same copper ion.[23,24] The oxidative nuclease activity of the copper complexes of these new ligands was found to be higher than with Phen itself; by a factor of 2 for 2-Clip-Phen, but by a factor of 60 for 3-Clip-Phen. The nuclease activity of 3-Clip-Phen·$CuCl_2$ is due to C-1′, C-4′, and C-5′ deoxyribose oxidations resulting from the cleavage interaction within the DNA minor groove.[25] 3-Clip-Phen·$CuCl_2$ itself appeared to be poorly sequence-selective, but the exogenous amine of its serinol bridge allowed the preparation of a conjugate with an analogue of distamycin (a minor groove binder that interacts selectively with five successive A·T base pairs) that appeared to be a sequence-selective DNA cleaver.[25,26] Conjugates of 2-Clip-Phen with the natural polyamine spermine (a minor groove binder)[27] or intercalators such as acridine derivatives[28] also exhibit enhanced nuclease activity.

Copper complexes of Clip-Phen have high DNA cleavage activity. This activity is preserved (and sometimes enhanced) when conjugated to a variety of vectors, which also retain their previous biological characteristics. This remarkable combination of properties opens wide perspectives for



Scheme 1. Structures of 2-Clip-Phen and 3-Clip-Phen; numbering corresponds to NMR assignments; the type of coordination with Cu attempted from the design of the ligands is shown

the use of Clip-phen derivatives. The compounds can be used as biological tools to study DNA structures, as new DNA footprinting agents or as potential antitumoral or antiviral agent mimics of iron bleomycin, a well-known antitumoral drug able to cleave the DNA of cancer cells.[29,30] In this context, Clip-Phen's properties of cell penetration and specificity for DNA might be modulated by the preparation of conjugates incorporating many different vectors.

The serinol bridge included in 2- and 3-Clip-Phen was initially chosen because of a number of different parameters: (i) its length was well adapted to favor "crab-pincer" copper complexes with two Phen entities of the same ligand chelating the same copper atom, (ii) its flexibility allowed the conformational changes that occur during Cu^{I}/Cu^{II} redox cycles, (iii) its amine function facilitated the synthesis of conjugates without modification of the Phen chelating entities, (iv) its C_2 symmetry axis avoided the formation of stereoisomers, and (v) its commercial accessibility. Both 2- and 3-Clip-Phen do, however, contain the same junction bridge even though the steric constraints in their copper complexes are not the same. On the other hand, a comparison of their physicochemical properties needs to be done.

Our interest in improving the efficiency of the Clip-Phen·Cu scission reagents prompted us to synthesize new Clip-Phen ligands with different short bridges between the two Phen entities in order to optimize the linker parameters (Figure 1). The length of the linker between C-2 or C-3 of the two Phen moieties was varied from two to five methylene units (ethyl-, propyl-, butyl-, or pentyl-Clip-Phen derivatives). Larger variations in the linker length were tested in the case of the 3-Clip-Phen series, on the assumption that that these ligands were sterically more constrained than the 2-Clip-Phen ones, in order to produce "crab-pincer" copper complexes. The influence of the primary amine of Clip-Phen on the nuclease activity was also studied, as was that of amide residues such as those included in conjugates with different vectors, by comparison with acetyl-Clip-Phen derivatives. In this work the geometry and the redox activity of these new copper complexes of phenanthroline have been analyzed under conditions similar to those used for DNA cleavage experiments. Determination of their respective DNA cleavage efficiency was performed. This study allows the parameters increasing the DNA cleavage activity of copper complexes of Clip-Phen to be clearly defined and provides information concerning the different types of complexes that can be generated in solution with the same ligand.

Figure 1. Structure of Clip-Phen derivatives **1**−**10** and general reaction pathways used for the preparation of Clip-Phen ligands

Results and Discussion

Preparation of the Ligands

The compounds **1**, **3**−**5**, and **7**−**10** were prepared by condensation of 1 equiv. of diol and 2 equiv. of halogenated phenanthroline (2-chloro or 3-bromo derivatives). Products substituted on C-2 of phenanthroline were obtained in good yields at 4 °C (70−80%). Products substituted at C-3, however, appeared to be more difficult to be prepared and were only obtained in poor yields (20−30%). As previously observed for the synthesis of 3-Clip-Phen (**5**), the low reactivity of 3-bromophenanthroline towards nucleophilic substitution necessitated a reaction temperature of 55 °C, and a proportion of the 3-BrPhen was lost due to a reduction process, giving back phenanthroline itself.[24] Ligands **2** and **6** were easily obtained by acetylation of 2- and 3-Clip-Phen, respectively (yield ca. 90%).

Characterization of the Copper Complexes

Ligands **1**−**10** were metallated with 1 equiv. of $CuCl_2$ in a DMF/methanol mixture and then precipitated with diethyl ether to produce polycrystalline green materials. We chose to use a copper chloride salt, since other DNA cleavage experiments have been carried out in the presence of NaCl in order to mimic physiological conditions. Analytical data are consistent with the formation of L/Cu^{II} 1:1 complexes,

but the coordination chemistry of the Clip-Phen family of ligands (L) with copper ions appeared to be more complicated than expected.

Crystal Structures

Copper complexes of Clip-Phen derivatives were unfortunately difficult to crystallize, and several attempts with 1 equiv. of different copper salts and various solvents were performed in order to obtain monocrystals of the copper complexes of **1**−**10** suitable for X-ray analysis. After several unsuccessful attempts, it was found to be possible to obtain suitable monocrystals of **1**·$Cu(BF_4)_2$, **3**·$CuCl_2$, **7**·$CuCl_2$, and also **1**·$ZnCl_2$ (Figures 2, 3, 4, and 5, respectively).

The $Cu(BF_4)_2$ complex of 2-Clip-Phen (**1**) crystallized on slow diffusion of CH_2Cl_2 into a solution of the complex, dissolved in a DMF/CH_3OH mixture, as a double-helical structure of general formula bis[(**1**)Cu][BF_4]$_2$ (Figure 2). Table 1 presents selected average bond lengths and angles of this complex. Each copper center shows the same coordination geometry and can be described as a distorted square-planar-pyramidal arrangement around the metal ion with the aliphatic amine and two phenanthroline residues (one from each Clip-Phen derivative ligand of the double helix). The equatorial positions are occupied by the aliphatic amine and three nitrogen atoms of the phenanthroline residues, with similar bond lengths of 2.02−2.05 Å. The axial bond length at 2.18 Å is longer. The phenanthroline nitrogen atom in the α-position to the bridge is equatorial. However, the angles in the crystal structure deviate from ideal values for a square-planar pyramid, although EPR results are in accordance with this geometry (see Exp. Sect. for these EPR values). Accordingly, the geometry could also be described as a distorted trigonal bipyramid with each nitrogen atom of a phenanthroline residue occupying one axial and one equatorial position.

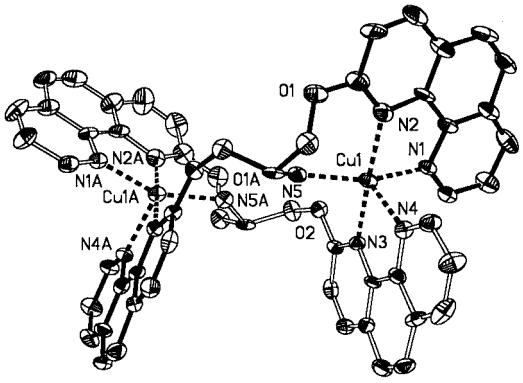

Figure 2. Crystal structure of bis[(**1**)Cu][BF_4]$_2$; hydrogen atoms, non-coordinated counter-ions, and solvent molecules are omitted for clarity

The double-helical motif of copper(II) complexes of Clip-Phen derivatives is also observed in the structures of **3**·$CuCl_2$ and **7**·$CuCl_2$, but with some major differences. The $CuCl_2$ complex of 2-ethyl-Clip-Phen (**3**) crystallizes in aqueous methanol as a double-helical structure of general formula [(**3**)CuCl]$_2$Cl$_2$ (Figure 3). Table 2 presents selected average bond lengths and angles of this complex. The coordination geometries are similar for each metal center and can be described as a distorted trigonal-bipyramidal arrangement with one chloride ion and two phenanthroline residues (one from each 2-ethyl-Clip-Phen ligand of the double-helix) around the copper atom. Each phenanthroline group occupies one axial and one equatorial position. The nitrogen atom in the α-position to the bridge is in an axial position for one phenanthroline residue and equatorial for the other. The third equatorial position is occupied by the chloride ion, with close Cu−Cl distances of 2.27 and 2.32 Å, respectively, for each copper center. Each coordinated chloride ion points in opposite direction of the double helix. The bond lengths between the copper atom and the phenanthroline nitrogen atoms are approximately 2.0 Å. The N−Cu−N angle formed by the nitrogen atoms of one phenanthroline residue and the central atom is smaller than the ideal value of 90° for a trigonal-bipyramid geometry, but the observed values of approximately 80° are typical for copper complexes of phenanthroline.[31] In addition, the axial Cu−N distances are always slightly compressed, consistently with other known trigonal-bipyramidal bis(phenanthroline)Cu^{II} crystal structures.[32]

Ligands **3** and **7** are isomers differing only in the position of the bridge − at C-2 or C-3 of the phenanthroline group in the cases of **3** and **7**, respectively. Figure 4 provides a view of the $CuCl_2$ complex of 3-ethyl-Clip-Phen (**7**). Because of the poor quality of the very small and weakly diffracting crystals, we were not able to refine the structure satisfactorily. Nevertheless, our model is good enough for discussion of the main features of this complex. Complex **7**·$CuCl_2$ crystallizes in a DMF/methanol (2:1) mixture in the form of a double-helical structure of general formula [(**7**)$CuCl]_2Cl_2$. In the case of [(**7**)$CuCl]_2Cl_2$ − as in that of [(**3**)$CuCl]_2Cl_2$ − the coordination geometries of each copper center are similar and are best described as a distorted trigonal-bipyramidal arrangement with one chloride ion and two phenanthroline residues (one from each ethyl-Clip-Phen ligand of the double-helix) around the copper atom. The main difference is the Cu···Cu distances, 11.00 Å in [(**7**)$CuCl]_2Cl_2$ and 6.48 Å in [(**3**)$CuCl]_2Cl_2$.

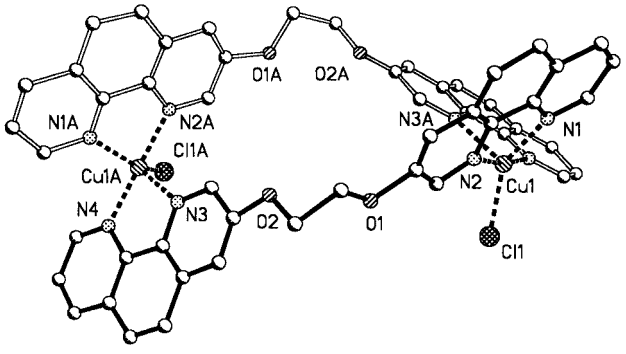

Figure 4. Complex of [(**7**)$CuCl]_2Cl_2$ in the crystalline solid state; hydrogen atoms, non-coordinated counter-ions, and solvent molecules are omitted for clarity

The double-helix units in all L_2Cu_2 copper complexes are chiral, but the three structures are in centrosymmetric space groups, which means that there is a racemic mixture of left- and right-turning helices present in the crystal.

Since copper(II) complexes of Clip-Phen derivatives are difficult to crystallize, we attempted to obtain more information on their geometry through the preparation of the corresponding zinc(II) complexes. We chose Zn^{II} since its coordination behavior and ionic radius are very close to those of Cu^{II} and because it − like Cu^{II} − forms penta- and hexadentate complexes, which could be isostructural to the Cu^{II} ones. Major differences, but also some interesting similarities, could be observed on comparison of the copper and zinc complexes of the same 2-Clip-Phen ligand **1**. Complex **1**·$ZnCl_2$ crystallizes in DMSO as a monomeric structure of general formula (**1**)$ZnCl_2$ (Figure 5). Table 3 presents selected average bond lengths and angles of this complex. The $P\bar{1}$ spatial group is centrosymmetric, in accordance with a racemic mixture in which the two enantiomers exits in the crystal in 1:1 proportions. As would be expected from the ionic radii of the divalent metal ions, the average of the Zn^{II}−N bonds is longer than those involving Cu^{II}. The coordination geometry is again best described as a distorted trigonal-bipyramidal arrangement around the metal atom, and the phenanthroline residue again occupies one axial and one equatorial position. Only one Phen residue of the ligand is coordinated; however; the other positions around the zinc(II) ion are occupied by two chloride ions in equatorial positions and the primary amine of the bridge in an axial one. The differences in geometry between **1**·$Cu(BF_4)_2$ and **1**·$ZnCl_2$ could easily be explained by the exchange of Cu^{II} by Zn^{II} and also the presence of chloride ions, which are better ligands than tetrafluoroborate, but in any case the coordination of the amine of the bridge of 2-Clip-Phen is strong and competes with the coordination of the second Phen residue of the ligand.

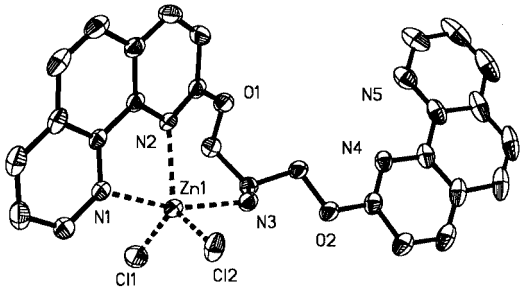

Figure 5. Crystal structure of (**1**)$ZnCl_2$; hydrogen atoms and solvent molecules are omitted for clarity

Mass Analysis

It is remarkable that, although we could legitimately assume that copper(II) complexes of Clip-Phen adopted a double-helical geometry with a copper/ligand stoichiometry of 2:2, these species were particularly difficult to observe by mass spectrometry (Figure 6). Electrospray mass spectra of the different complexes generally reflected a 1:1 copper/ligand stoichiometry. Analyses were conducted in a CH_3OH/H_2O 1:1 mixture, chosen because our DNA cleavages were performed in aqueous solution. High concentrations of $CuCl_2$ complexes (10^{-4} and 10^{-5} M) and different orifice voltages (50, 5, but also 0 V) were tested with the goal of promoting the observation of L_2Cu_2 complexes (see ref.[9]

and references therein for a discussion about these analytical conditions generally best used in order to promote the detection of double-helical structures by electrospray mass spectrometry). The 1:1 stoichiometry was confirmed by comparison with theoretical isotopic patterns, which could be analyzed unambiguously thanks to the presence of $^{63/65}Cu$ and $^{35/37}Cl$ isotopes, the *m*/*z* values being determined from the spacing between two isotope peaks.

The LCu^+ species was always observed, in agreement with the expected reduction of Cu^{II} in a mass spectrometer.[33] The monocationic species $LCu^{II}Cl$, however, was also clearly observed; LCu^{2+} species only being observed at lower activation voltages. The L_2Cu_2 species with or without chloride ion(s) or different charge states, though, were only observed − and only as minor products − for concentrated solutions with a low orifice voltage. It is reasonable to speculate that the dimeric species are poorly stable in solution and dissociate during analysis, or that they are absent or only present in small quantities in solution and are, in this last case, in equilibrium with monomeric LCu species in solution. No direct evidence for this last hypothesis was obtainable, but it seems reasonable since equilibria between monomeric and dimeric copper complexes of bis(phenanthroline) ligands have been observed previously, during the synthesis of a trefoil knot for example.[34] The geometries of monomeric species are probably similar to those of other previously described pincer-crab bis(phenanthroline)-copper complexes.[32]

It should be noted that different attempts were made to perform ^1H NMR analysis of cuprous complexes of **1**, **2**, **4**, or **5** (obtained by reduction of deaerated solutions of the cupric complexes in DMSO/H_2O mixtures by addition of ascorbate) or zinc complexes of the same ligands. The ^1H NMR spectra showed broader signals at room temperature, sharpening when the temperature increased, consistent with mixtures of species in rapid exchange on the NMR timescale (results not shown). Only the spectra of **1**·$ZnCl_2$ seem to be resolved at room temperature, but these also showed complex signals for the bridge protons, and irradiation experiments also confirmed the presence of different species in solution in this case (see the Exp. Sect. for these NMR spectroscopic data).

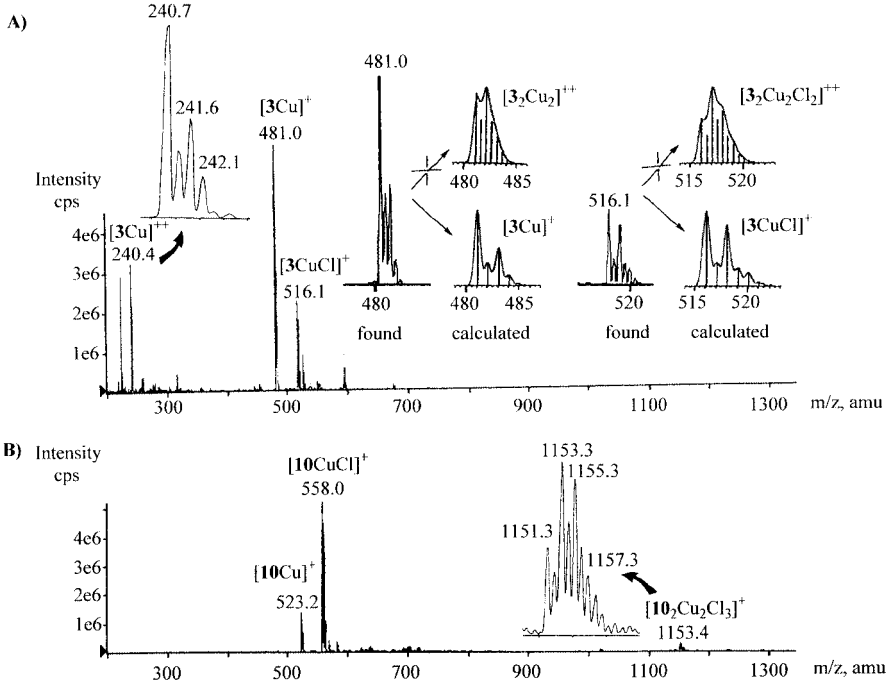

Figure 6. Typical examples of electrospray mass spectra analyses of copper(II) complexes of Clip-Phen derivatives in CH_3OH/H_2O (1:1): A) mass spectrum analysis of 2-ethyl-Clip-Phen·$CuCl_2$ (**3**·$CuCl_2$) (10^{-4} M, orifice voltage = 5 V); B) observation of traces of L_2Cu_2 species in the case of 3-pentyl-Clip-Phen·$CuCl_2$ (**10**·$CuCl_2$) (10^{-4} M, orifice voltage = 0 V)

It cannot be discounted that the copper complexes of Clip-Phen derivatives may adopt different geometries or stoichiometries in solution and that the relative proportions of these species could vary with the concentrations of the complexes (with the monomeric species being favored in dilute solutions, such as those used for DNA cleavage experiments).

As observed in the single-crystal analyses, L_2Cu_2 cupric complexes can form left- and right-turning double-helices. Cuprous and cupric LCu monomeric complexes, however, could form Λ and Δ enantiomers. Separations of these enantiomers have not been performed, but from model studies the two enantiomers probably have different DNA-binding modes. However, such studies are well behind the scope of this paper (for recent studies on DNA interaction with enantiomeric metal complexes, and metal helicates in particular, see refs.[35,36] and references therein).

EPR Data

Copper(II) complexes of the Clip-Phen derivatives were analyzed by electron spin resonance (Table 4). None of the complexes was magnetically sufficiently diluted to yield EPR spectra indicative of the solid-state geometry. X-EPR spectra of these green polycrystalline samples are best described as isotropical signals centered at $g = 2.12-2.14$ (except for **1**·$CuCl_2$ and **10**·$CuCl_2$, for which two g values were observed, reflecting axial symmetry). Superhyperfine coupling to nitrogen was not apparent but hyperfine coupling constants were obtained in DMF/CH_2Cl_2/CH_3OH (2:4:1) and H_2O/$C_2H_6O_2$ (1:2) glasses. Two g values were generally observed, in accordance with an axial symmetry of the g tensor, but different families of complexes could be observed.

The spectrum of the cupric complex of 2-ethyl-Clip-Phen (**3**·$CuCl_2$) was not well resolved in the two types of glasses tested, but the spectra of the cupric complexes of all the other compounds substituted at C-2 of the phenanthroline residues and in which the linker contained three carbon atoms (ligands **1**, **2**, and **4**) were well resolved. They had similar geometries in DMF/CH_2Cl_2/CH_3OH glass, since they exhibited similar EPR spectra consistent with a single configuration for a randomly oriented sample. The g and A values are in agreement with reported cases of trigonal-bipyramidal copper(II) complexes.[32] They exhibit two identifiable magnetic g values, together with the corresponding copper ($I = 3/2$) hyperfine splitting constants. The following values were observed: $g_{\|} = 2.20-2.23$, $A_{\|} = 100-110$ G, $g_{\perp} = 2.01$, $A_{\perp} = 78-90$ G. The parallel or perpendicular attribution of g values did not appear clearly in the spectra but was confirmed by integration of the corresponding signal area, the $g_{\|}$ area being, as expected, roughly twice that of the $g_{\perp}$ one. Crystallographic data obtained previously confirm that the complexes could adopt this trigonal-bipyramidal geometry. The fifth ligand might be a Cl^- or a water molecule, but the primary amine function can also play this role in the particular case of 2-Clip-Phen (**1**).

It is remarkable that these cupric complexes can adopt different geometries and that their geometries change in more polar media, as observed in H_2O/$C_2H_6O_2$ glasses. The resolution of the EPR spectra was poor, probably due to the presence of different conformations, but these spectra indicated that copper complexes of **1**, **2**, and **4** would be able to adopt geometries similar to those of cupric complexes of 3-Clip-Phen in water solution (the solvent used for DNA cleavage experiments).

The cupric complexes of 3-Clip-Phen derivatives **5**−**10** probably have poorer capabilities to change their geometries than the 2-Clip-Phen ones, since the EPR spectra for all these complexes are nearly superimposable in the two media tested. The spectra of **5**−**10**·$CuCl_2$ are consistent with a single configuration for a randomly oriented sample. They were in agreement with classical five- or six-coordinated copper(II) in a square-pyramidal or octahedral geometry with four equatorial ligands in a deformed square-planar geometry.[36] Two identifiable magnetic g values were observed, along with the corresponding copper ($I = 3/2$) hyp-

erfine splitting constants with the following values: $g_{\|}$ = 2.28, $A_{\|}$ = 150−158 G, $g_{\perp}$ = 2.07; $A_{\perp}$(Cu) was unobservable.

These results indicated that the EPR values of the complexes, and consequently their geometries, depend on the solvent and on the position of the bridge, at C-2 or C-3 of the phenanthroline entity. The length of the bridge, however, or the incorporation of substituents in this linker, in particular in the case of 3-Clip-Phen derivatives, had a limited influence on EPR spectra and probably also on the geometries of the cupric complexes.

Electrochemical Properties

The copper(II/I) redox potentials of the different copper complexes were compared in aqueous solution with KCl as supporting electrolyte, since nucleic acid cleavage experiments are performed in water in the presence of NaCl. The cyclic voltammograms consisted of only one oxidation and one reduction wave in all cases except for that of the copper complex of 3-pentyl-Clip-Phen (**10**·$CuCl_2$), for which the oxidation wave was not observable. As in the case of the EPR analyses, copper complexes of 2- and 3-Clip-Phen derivatives showed different behavior although the results were similar for all 2-Clip-Phen and all 3-Clip-Phen derivatives, respectively. Results are summarized in Table 5. $(Phen)_2CuCl_2$ was also used for comparison. $\Delta Ep = Ep_{ox} - Ep_{red}$ (= separation of its Cu^{II}/Cu^{I} couple) approached the 56/*n* mV separation expected for a reversible one-electron process. This one-electron metal-centered process has been confirmed for this complex previously, but also for 2-Clip-Phen·$CuCl_2$ by coulometry and EPR.[23]

Table 5. Comparison of cyclic voltammetry data for **1**−**10**·$CuCl_2$ complexes (1 mM in water); cyclic voltammetry measurements were carried out at 0.1 V/s with 0.1 M KCl as supporting electrolyte under argon and at room temperature; $\Delta Ep = Ep_{ox} - Ep_{red}$; SCE was used as a reference

The ΔEp separation for copper complexes of 2-Clip-Phen derivatives (**1**−**4**) ranges from 180 to 263 mV and is best described as quasi-reversible. In all cases, the reduction potentials of the copper complexes of 2-Clip-Phen derivatives were shifted to more positive values relative to the Cu^{II}/Cu^{I} couple of $(Phen)_2CuCl_2$, reflecting their more facile reduction and indicating that 2-Clip-Phen ligands stabilized the copper(I) state for their complexes. This phenomenon is well known in the cases of phenanthroline derivatives substituted on their C-2 and C-9 carbon atoms, in the α-position to the chelating nitrogen atom. They are known to stabilize the tetrahedral copper(I) complexes relative to copper(II) complexes, mostly through steric effects that inhibit the pentahedral or octahedral geometries favorable for copper(II).[3,4,7,22,38] In the case of 2-Clip-Phen derivatives only substituted at the C-2 position, however, this phenomenon was less important.

Further bulk electrolysis was performed with 2-Clip-Phen·$CuCl_2$ and **3**·$CuCl_2$, which form dimers in the crystals. This gave an *n* value of 1 for both. The observation of only one wave of oxidation and reduction and the observed *n* value were in accordance with the presence of monomeric species under the conditions used for electrolyses. The absence of two distinct redox states in cyclic voltammograms should not, however, be interpreted as definitive proof of monomeric species in solution, since double-helical dimeric structures can also exhibit a single redox state when both metal centers are strictly equivalent (as previously observed for some other copper dimetallic complexes[8,32,39,40]). Cyclic voltammetry was performed on the electrochemically reduced product, and again only one oxidation and one reduction wave were observed, with small differences in comparison with the cyclic voltammetry data of the oxidized form attributed to geometrical exchanges occurring between the +II and +I oxidation states. This reduced complex was then reoxidized electrochemically, and the cyclic voltammetry of the reoxidized form remained similar to that of the initial copper(II) complex, confirming the quasi-reversibility of the system (results not shown). Finally, it could be noted that the ΔEp increased when the scan rate increased in the case of 2-Clip-Phen·$CuCl_2$, this last result also being in accordance with a slow quasi-reversible system.

Surprisingly, the copper complexes of the 3-Clip-Phen derivatives (**5**−**10**) were only poorly electroactive. More strongly negative reduction potentials were observed than for $(Phen)_2CuCl_2$, which could reflect the greater stabilization of the copper(II) ion in these complexes with 3-Clip-Phen derivative ligands. However, the Cu^{II}/Cu^{I} reduction is quasi-irreversible for cupric complexes of **5**−**9** and seems to be irreversible for **10**·$CuCl_2$. The cupric complex of 3-pentyl-Clip-Phen (**10**) is in fact the most difficult of this series to reduce, but also the most irreversible (and is also the worst DNA cleaver in the 3-Clip-Phen series).

DNA Cleavage Activity

The DNA cleavage activities of the different (Clip-Phen)-copper complexes were compared. Relaxation of supercoiled circular ΦX174 DNA (form I) into relaxed (form II) and linear (form III) forms was used to quantify the relative cleavage efficiencies of the different complexes. Redox activity of the Cu^{II} complexes was initiated by the addition of 5 mM mercaptopropionic acid (MPA) in the presence of air. Control experiments clearly showed the necessity of the presence of copper complexes and a reductant for noticeable DNA cleavage (Table 7). Residual DNA cleavage was

observed in the case of 3-Clip-Phen (**5**) and for its cupric complex (the more active compound) without MPA. This was probably due to buffer impurities.

As previously observed for copper complexes of 2- and 3-Clip-Phen (**1** and **5**), DNA cleavage experiments performed in the presence of different concentrations of complexes showed that all compounds produced single-strand cleavages in DNA, since they transformed form I into form II. Form III resulted from multiple cleavage of form II and appeared only when full cleavage of form I was practically achieved. A smear corresponding to multifragmented DNA was also observed for higher DNA cleavage activities (results not shown).

All complexes were tested under the same experimental conditions (1 μM concentration for a reaction time of 1 h at 37 °C), in order to provide direct comparison of their DNA cleavage efficiencies. To facilitate this analysis, attempts to quantify the number *S* of single-strand cleavages per ΦX174 molecule were carried out according to refs.[41,42] This assumes random cleavage of the DNA target, as previously observed for **1**·$CuCl_2$ and **5**·$CuCl_2$.[25,27] Table 6 indicates that the relative DNA cleavage efficiencies of the different copper complexes were in the following order: **5**·$CuCl_2$ >> **6**·$CuCl_2$ > **8**·$CuCl_2$ > **7**·$CuCl_2$ ≈ **9**·$CuCl_2$ > **4**·$CuCl_2$ > **10**·$CuCl_2$ > **1**·$CuCl_2$ > **2**·$CuCl_2$ > **3**·$CuCl_2$. Comparison of the cleavage patterns of copper complexes of **1** versus **5**, **2** versus **6**, **3** versus **7**, and **4** versus **8** (*S* = 1.2 and 35, 0.8 and 21, 0.7 and 10, 6 and 15, respectively) clearly indicated that, for the same bridge, copper complexes of 3-Clip-Phen derivatives were always more active than their isomers with a junction at C-2 of the phenanthroline.

Differences between 2- and 3-Clip-Phen series also clearly appeared during electrochemical analyses of the different copper complexes (Table 5). All these data suggest that the lower DNA cleavage efficiency of copper complexes of 2-Clip-Phen derivatives might be correlated with their higher stabilization of cuprous species. It can be seen, however, that no correlation between the redox activity and the DNA cleavage efficiency within each series was observed. Other parameters such as steric or electrostatic constraints in the vicinity of the DNA target probably modulate the cleaving activities of the complexes.

The reactivities of the complexes are largely governed by the position of the bridge, at C-2 or C-3 of each phenanthroline residue. However, the length and the nature of this bridge also appeared to be significant for the DNA cleavage activity of these copper complexes. Hence, **4**·$CuCl_2$ of the 2-Clip-Phen series, for example, is a better DNA cleaver than **10**·$CuCl_2$ of the 3-Clip-Phen series.

Effect of the Length of the Bridge on the DNA Cleavage Efficiency

Comparison of cleavage patterns obtained with copper complexes of **3** and **4** on one hand and **7**−**10** on the other allowed the optimal length of the bridge for high DNA cleavage patterns to be determined, since these compounds differed only in the number of methylene units in the bridge.

Table 6 shows that for copper complexes of ethyl (**3**) and propyl (**4**) derivatives of 2-Clip-Phen, a small change due to the addition of one methylene unit to the bridge has a dramatic effect on DNA cleavage efficiency. For 1 μM of **3**·$CuCl_2$, 50% of DNA form I was present after 1 h of reac-

Table 6. Comparison of ΦX174 DNA cleavage efficiency of **1**−**10**·$CuCl_2$ complexes (1 μM in the presence of 5 mM MPA and air for 1 h at 37 °C); *S* corresponds to the average number of single-strand breaks per DNA molecule, assuming a random cleavage of the DNA target by the activated copper complexes

[a] For values less of 100%, the other part of DNA appeared as a smear on the gel.

tion. With $S = 0.7$, **3**·$CuCl_2$ has a rather poor DNA cleavage activity, just below that of $(Phen)_2$·$CuCl_2$ itself ($S = 0.9$). However, **4**·$CuCl_2$ appeared to be an efficient DNA cleaver under the same experimental conditions, converting nearly all supercoiled DNA not only into form II (95%), but also into form III (5%). With an S value estimated as 6, **4**·$CuCl_2$ appeared to be roughly ten times more active than **3**·$CuCl_2$. It is reasonable to propose that the poor DNA cleavage activity of **3**·$CuCl_2$, with the smallest bridge between the two phenanthroline residues, is due to steric constraints around the copper ion.

For copper complexes of ethyl (**7**), propyl (**8**), butyl (**9**), and pentyl (**10**) derivatives of 3-Clip-Phen ($S = 10$, 15, 10, and 2, respectively), variation by one methylene unit in the bridge had more limited effects. However, better DNA cleavage activity was obtained for **8**·$CuCl_2$, with three methylene units in the bridge, while, for a longer bridge such as in **10**·$CuCl_2$ (with five methylene units), the DNA cleavage efficiency significantly decreased. It is remarkable that 3-Clip-Phen (**5**) has the same bridge length as **8**. Thus, though serinol was chosen for reasons previously described, it also appears to have an optimal length to favor a high level of DNA cleavage activity.

Effect of the Nature of the Bridge on the DNA Cleavage Efficiency

Table 6 indicates that the nuclease activity of the copper complexes is also modulated by the chemical composition of the bridge. Three types of bridges of the previously observed optimized length were studied: unsubstituted ones [copper complexes of 2- and 3-propyl-Clip-Phen (**4** and **8**)], bridges including an amine residue such as in Clip-Phen [copper complexes of 2- and 3-Clip-Phen (**1** and **5**)], and bridges with an acetamido residue mimicking the amide junction used for the vectorization of Clip-Phen [copper complexes of 2- and 3-acetyl-Clip-Phen (**2** and **6**)].

Increases in DNA cleavage activity had previously been observed for copper complexes of conjugates of 2- or 3-Clip-Phen with DNA-binding molecules.[26−28] Acetylation of the amine residue of 2- and 3-Clip-Phen, however, resulted in a decrease in the DNA cleavage efficiency of their copper complexes by roughly 50%. This phenomenon was observed on comparison of the DNA cleavage activities of **1**·$CuCl_2$ and **5**·$CuCl_2$ ($S = 1.2$ and 35, respectively) with those of the corresponding acetylated derivatives **2**·$CuCl_2$ and **6**·$CuCl_2$ ($S = 0.8$ and 21, respectively). This difference was probably due not only to the steric effects of the bulkier amido group on the interaction with the DNA target, but also on the geometry changes during the Cu^I/Cu^{II} redox cycle. While this last proposal is not supported by the electrochemical data (Table 5), the phenomenon is probably enhanced in the case of a complex confined in the vicinity − or, more probably, in the floor − of the DNA minor groove, as suggested by DNA cleavage mechanism studies.[25] However, these phenomena were overcompensated by the increase of DNA affinity in conjugates with DNA binders, resulting in higher nuclease activities.

It is remarkable, though, that the amine on the bridge produced different effects on DNA cleavage for copper complexes of 2-Clip-Phen and 3-Clip-Phen derivatives. This phenomenon was clear on comparison of the DNA cleavage activities of **1**·$CuCl_2$ and **5**·$CuCl_2$ ($S = 1.2$ and 35, respectively) with those of their derivatives without the amine function **4**·$CuCl_2$ and **8**·$CuCl_2$ ($S = 6$ and 15, respectively). These data suggested that the presence of the amine decreased the DNA cleavage activity in the case of 2-Clip-Phen derivatives but increased it in the case of 3-Clip-Phen ones. Since the X-ray structures of the monocrystals of copper and zinc complexes of 2-Clip-Phen indicate that this amine could coordinate the metal ion, it is reasonable to propose that this type of coordination could also occur under DNA cleavage conditions. DNA cleavage results indicated that this coordination has an unfavorable effect on the DNA cleavage activity. However, geometrical constraints did not allow this type of coordination in the case of 3-Clip-Phen. It is reasonable to propose that, in the case of the copper complex of 3-Clip-Phen (**5**), the free amine residue could be protonated under the conditions used for DNA cleavage experiments, generating a cationic species with a higher affinity for the polyanionic DNA target, consequently increasing the DNA cleavage activity.

On the other hand, these last results indicate that the benefit of bridging on the C-2 carbon atom of Phen had previously been greatly underestimated, since data were obtained with the copper complex of 2-Clip-Phen (**1**), with the free primary amine function able to perturb the coordination sphere of the copper ion.

Conclusion

Different bis(phenanthroline) ligands were prepared in order not only to study their copper complexes but also to optimize the DNA cleavage activity of Clip-Phen derivatives. Physicochemical analysis showed that these copper complexes appear to be particularly versatile. As shown by structural analysis, the cupric complexes can adopt double-helical L_2Cu_2 geometries, but this type of geometry seems to be labile. The mass spectra results showed that the presence of monomeric structure L_1Cu_1 in solution could not be discounted. NMR studies showed that the complexes adopt different geometries, existing in equilibrium in solution. EPR analyses indicated that the geometries of the cupric complexes of 2-Clip-Phen derivatives could change with the composition of the solvent employed for their dilution. From electrochemical studies it also appears that all the ligands related to 2-Clip-Phen stabilize Cu^I more than their 3-Clip-Phen counterparts. Copper complexes of this latter ligand family appear to be surprisingly poorly redox-active.

DNA cleavage experiments allowed optimization of the bridge between the two phenanthroline residues of Clip-Phen to provide higher nuclease activity. The compounds with a bridge linked at C-3 were more active DNA cleavers than complexes with the bridge in the C-2 position. A tether length corresponding to three methylene units gave better

DNA cleavage activities, but incorporation of voluminous substituents within the linker could decrease the DNA cleavage efficiency. Surprisingly, the presence of an amine group in the bridge had different effects on DNA cleavage activity for the copper complexes of 2-Clip-Phen and of 3-Clip-Phen, and allowed the proposal that, in the case of 2-Clip-Phen·$CuCl_2$, this amine group could be coordinated to the copper ion under the DNA cleavage conditions.

Experimental Section

General Remarks: 2-Chloro-1,10-phenanthroline,[43] 3-bromo-1,10-phenanthroline,[44] 2-Clip-Phen (**1**),[23] 3-Clip-Phen (**5**),[24] 2-acetyl-Clip-Phen (**2**),[28] 3-propyl-Clip-Phen (**8**),[45] and 2-Clip-Phen·$CuCl_2$ (**1**·$CuCl_2$)[23] were synthesized by literature procedures. Proton NMR spectra were recorded with a Bruker 250 MHz instrument. The ESI-MS spectrometer was a Perkin−Elmer SCIEX API 365 used in positive mode; samples were introduced into the electrospray source with a Havard Apparatus syringe pump. UV/Vis spectra were recorded with a Hewlett Packard 8452A diode array spectrophotometer. EPR spectra were recorded with a Bruker ESP 300 in X Band, with an ER035 M gaussmeter (NMR probe) and an EIP 548 hyperfrequencemeter. Syntheses were monitored by thin layer silica chromatography (Macherey−Nagel Alugram Sil G/UV 254) eluted by CH_2Cl_2/methanol (9:1, v/v) to which 1% of concentrated aqueous ammonia (30%) had been added, and spots were viewed under UV light (violet spots at 254 nm). DMF was dried with 4 Å molecular sieves. Other commercially available reagents and solvents were purchased from standard chemical suppliers and used without further purification.

General Method for the Synthesis of 2-alkyl-Clip-Phen 3 and 4: 2-Chloro-1,10-phenanthroline (200 mg, 0.93 mmol) and the diol (ca. 0.46 mmol of ethylene glycol or 1,3-propanediol) were added to a suspension of sodium hydride (275 mg of a 60% suspension in mineral oil, 6.85 mmol) in 4 mL of dry DMF, cooled by an ice bath. After the mixture had been stirred for 24 h and allowed to warm to room temperature, the crude product was dissolved in 4 mL of ethanol before being precipitated with 40 mL of water. After filtration, the product was precipitated from 15 mL of hot methanol to give 2-alkyl-Clip-Phen.

2,2′-Ethane-1,2-dioxybis(1,10-phenanthroline) (2-ethyl-Clip-Phen, 3): Yield = 146 mg (75%) as white needles. ^{1}H NMR ($CDCl_3$): δ = 5.25 ppm (s, 4 H, 1-H), 7.21 (d, *J* = 8.7 Hz, 2 H, 3′-H), 7. 58 (dd, *J* = 8.1, 4.2 Hz, 2 H, 8′-H), 7.66 and 7.75 (AB, *J* = 8.7 Hz, 4 H, 5′-H and 6′-H), 8.12 (d, *J* = 8.7 Hz, 2 H, 4′-H), 8.23 (dd, *J* = 8.1, 1.8 Hz, 2 H, 7′-H), 9.18 (dd, *J* = 4.2, 1.8 Hz, 2 H, 9′-H). MS (CDI, NH_3): *m*/*z* (%) = 419 (100) [M + 1], 223 (67), 197 (65). UV/Vis (CH_3OH): λ (ε) = 228 nm (73600 $mol^{-1}·cm^{-1}$), 276 (52300), 292 (16400, sh), 316 (4000, sh), 332 (2300), 350 (1500). $C_{26}H_{18}N_4O_2$ (418): calcd. (+ 0.25 H_2O) C 73.86, H 4.41, N 13.25; found C 73.53, H 4.17, N 13.11.

2,2′-Propane-1,3-dioxybis(1,10-phenanthroline) (2-propyl-Clip-Phen, 4): Yield = 157 mg (78%) as a white powder. ^{1}H NMR (CD_2Cl_2): δ = 2.52 ppm (quint, *J* = 6.2 Hz, 2 H, 2-H), 4.93 (t, *J* = 6.2 Hz, 4 H, 1-H), 7.15 (d, *J* = 8.6 Hz, 2 H, 3′-H), 7. 59 (dd, *J* = 8.1, 4.2 Hz, 2 H, 8′-H), 7.68 and 7.76 (AB, *J* = 8.7 Hz, 4 H, 5′-H and 6′-H), 8.13 (d, *J* = 8.6 Hz, 2 H, 4′-H), 8.25 (dd, *J* = 8.1, 1.8 Hz, 2 H, 7′-H), 9.11 (dd, *J* = 4.2, 1.8 Hz, 2 H, 9′-H). MS (CDI, NH_3): *m*/*z* (%) = 433 (100) [M + 1], 235 (5), 197 (6). UV/Vis (CH_3OH): λ (ε) = 228 nm (67700 mol^{-1} cm^{-1}), 276 (48700), 292 (16400, sh), 314 (4400, sh), 332 (2300), 348 (1400). $C_{27}H_{20}N_4O_2$ (432): calcd. (+ 0.75 H_2O) C 72.74, H 4.85, N 12.56; found C 72.83, H 4.57, N 12.40.

General Method for the Synthesis of 3-Alkyl-Clip-Phen 7, 9, and 10: The appropriate diol (ca. 0.77 mmol of ethylene glycol, 1,4-butanediol, or 1,5-pentanediol) was added to a suspension of sodium hydride (156 mg of a 60% suspension in mineral oil, 3.9 mmol) in 7 mL of dry DMF. The mixture was stirred for 1 h at 55 °C, and then cooled to 4 °C with an ice bath. 3-Bromo-1,10-phenanthroline (400 mg, 1.54 mmol) was added, and the mixture was warmed at 55 °C overnight. After return to room temperature, 2 mL of ethanol was added, then 20 mL of water. The precipitate was filtered, dissolved in dichloromethane, and washed with a 5% solution of ammonia. The organic layer was concentrated and the product was crystallized from 3 mL of methanol before being dissolved in dichloromethane and precipitated with hexane to give pure 3-alkyl-Clip-Phen as white powder. *Warning:* The number of NaH equivalents should be optimized according to the intrinsic quality of reagents and solvents (ultrapure quality is preferred).

3,3′-Ethane-1,2-dioxybis(1,10-phenanthroline) (3-ethyl-Clip-Phen, 7): Yield = 74 mg (23%). ^{1}H NMR (CD_2Cl_2): δ = 4.67 ppm (s, 4 H, 1-H), 7.59 (dd, *J* = 4.4, 8.1 Hz, 2 H, 8′-H), 7.69 (d, *J* = 3.0 Hz, 2 H, 4′-H), 7.83 and 7.78 (AB, *J* = 8.9 Hz, 4 H, 5′-H and 6′-H), 8.25 (dd, *J* = 1.8, 8.1 Hz, 2 H, 7′-H), 8.93 (d, *J* = 3.0 Hz, 2 H, 2′-H), 9.09 (dd, *J* = 1.8, 4.4 Hz, 2 H, 9′-H). MS (CDI, NH_3): *m*/*z* (%) = 419 (100) [M + 1]. UV/Vis (CH_3OH): λ (ε) = 240 nm (69500 $mol^{-1}·cm^{-1}$),·272 (51700), 294 (27400, sh), 304 (17100, sh), 314 (8400, sh), 328 (5500), 342 (3600). $C_{26}H_{18}N_4O_2$ (418): calcd. (+ 0.5 CH_2Cl_2) C 69.06, H 4.15, N 12.16; found C 69.08, H 4.05, N 12.34.

3,3′-Butane-1,4-dioxybis(1,10-phenanthroline) (3-butyl-Clip-Phen, 9): Yield = 80 mg (23%). ^{1}H NMR (CD_2Cl_2): δ = 2.20 ppm (m, 4 H, 2-H), 4.30 (t, *J* = 5.4 Hz, 4 H, 1-H), 7.56 (dd, *J* = 4.2, 8.1 Hz, 2 H, 8′-H), 7.58 (d, *J* = 3.0 Hz, 2 H, 4′-H), 7.79 and 7.74 (AB, *J* = 8.9 Hz, 4 H, 5′-H and 6′-H), 8.23 (dd, *J* = 1.8, 8.1 Hz, 2 H, 7′-H), 8.87 (d, *J* = 3.0 Hz, 2 H, 2′-H), 9.08 (dd, *J* = 1.8, 4.2 Hz, 2 H, 9′-H). MS (CDI, NH_3): *m*/*z* (%) = 447 (100) [M + 1]. UV/Vis (CH_3OH): λ (ε) = 242 nm (72600 $mol^{-1}·cm^{-1}$), 272 (48200), 294 (24300, sh), 306 (14500, sh), 314 (7000, sh), 328 (5000), 344 (3300). $C_{28}H_{22}N_4O_2$ (446): calcd. (+ 0.1 CH_2Cl_2) C 74.18, H 4.92, N 12.31; found C 73.84, H 4.33, N 12.18.

3,3′-Pentane-1,5-dioxybis(1,10-phenanthroline) (3-pentyl-Clip-Phen, 10): Yield = 110 mg (31%). ^{1}H NMR (CD_2Cl_2): δ = 1.80 ppm (m, 2 H, 3-H), 1.99 (m, 4 H, 2-H), 4.20 (t, *J* = 6.3 Hz, 4 H, 1-H), 7.51−7.56 (m, 4 H, 4′-H and 8′-H), 7.79 and 7.74 (AB, *J* = 8.9 Hz, 4 H, 5′-H and 6′-H), 8.23 (dd, *J* = 1.8, 8.1 Hz, 2 H, 7′-H), 8.87 (d, *J* = 3.0 Hz, 2 H, 2′-H), 9.08 (dd, *J* = 1.8, 4.2 Hz, 2 H, 9′-H). MS (CDI, NH_3): *m*/*z* (%) = 461 (100) [M + 1]. UV/Vis (CH_3OH): λ (ε) = 240 nm (72400 $mol^{-1}·cm^{-1}$), 272 (51000), 294 (26600, sh), 304 (17000, sh), 314 (92000, sh), 328 (6000), 344 (4200). $C_{29}H_{24}N_4O_2$ (460): calcd. (+ 0.5 CH_2Cl_2 + 1.5 H_2O) C 66.85, H 5.32, N 10.57; found C 67.08, H 5.37, N 10.70.

2-Acetylamino-3,3′-propane-1,3-dioxybis(1,10-phenanthroline) (3-acetyl-Clip-Phen, 6): Acetic anhydride (50 μL, 50 mg, 0.49 mmol) was added to a solution of 3-Clip-Phen (50 mg, 0.11 mmol) in 2 mL of $CHCl_3$. The solution was stirred for 1 h at room temperature, 2 mL of water was then added, and the pH was adjusted to 9 with concentrated aqueous ammonia (30%). The organic layer was separated and washed twice with water, and the solvent was evaporated under vacuum to give **6** as a pale brown foam (50 mg, yield = 92%). ^{1}H NMR (CD_2Cl_2): δ = 2.16 ppm (s, 2 H, CH_3), 4.45 (m, 4 H, 1-H), 4.88 (m, 1 H, 2-H), 6.59 (d, *J* = 8.0 Hz, 1 H, NH), 7.55

(dd, J = 8.0, 4.4 Hz, 2 H, 8′-H), 7. 63 (d, J = 2.8 Hz, 2 H, 4′-H), 7.69 and 7.75 (AB, J = 8.7 Hz, 4 H, 5′-H and 6′-H), 8.19 (dd, J = 8.0, 1.7 Hz, 2 H, 7′-H), 8.90 (d, J = 2.8 Hz, 2 H, 2′-H), 9.11 (dd, J = 4.4, 1.7 Hz, 2 H, 9′-H). MS (CDI, NH_3): m/z (%) = 490 (81) [M + 1], 294 (100), 197 (60). UV/Vis (CH_3OH): λ (ε) = 240 nm (62700 $mol^{-1}\cdot cm^{-1}$), 272 (44500), 294 (22300, sh), 306 (12400, sh), 314 (6100, sh), 328 (4300), 342 (2700). $C_{29}H_{23}N_5O_3$ (489): calcd. (+ 0.4 $CHCl_3$) C 66.40, H 4.37, N 13.20; found C 66.19, H 4.51, N 13.22.

General Preparation of Copper Complexes (8·$CuCl_2$ exempted): $CuCl_2$ (1 equiv., previously dissolved at 58.7 mM concentration in DMF) was added to a solution of ligand (10 mg) in 1 mL of DMF/CH_3OH (1:1). After 1 h at room temperature, the complex was precipitated with 5 mL of diethyl ether overnight at −20 °C and then centrifuged for 10 min at 3000 rpm and washed twice with diethyl ether (2 × 6 mL) before being dried under vacuum.

Preparation of 8·$CuCl_2$: Solubility problems meant that the metallation of 3-propyl-Clip-Phen (**8**) was conducted under more dilute conditions than used for the General Preparation of the other copper complexes. A solution of $CuCl_2$ (23.1 μmol, 1 equiv.) in DMF was added over 2 h, as 5 aliquots of 100 μL, to a solution of 3-propyl-Clip-Phen (**8**, 10 mg, 23.1 μmol) in 23 mL of DMF (1 mM final concentration),. The mixture was stirred overnight and the volume was then reduced to 5 mL. The copper complex was precipitated with diethyl ether and centrifuged, the supernatant was removed, and the precipitate was washed twice with diethyl ether before being dried under vacuum.

2·$CuCl_2$: Treatment of **2** with $CuCl_2$ as described above on a 17.0 μmol scale afforded 11.4 mg (89%) of **2·$CuCl_2$** as a pale green powder. MS (ES, positive mode): m/z = 587 (monocation, M − Cl), 551 (cuprous complex). UV/Vis (H_2O): λ (ε) = 210 nm (59000 $mol^{-1}\cdot cm^{-1}$), 224 (66800), 276 (48400), 336 (2100, sh), 356 (1500, sh), 862 (160). $C_{29}H_{23}Cl_2CuN_5O_3$ (624): calcd. (+ 2.5 H_2O) C 52.07, H 4.21, N 10.47; found C 52.19, H 4.27, N 10.40.

3·$CuCl_2$: Treatment of **3** with $CuCl_2$ on a 23.1 μmol scale afforded 13.6 mg (98%) of **3·$CuCl_2$** as a pale green powder. MS (ES, positive mode): m/z = 516 (monocation, M − Cl), 481 (cuprous complex). UV/Vis (H_2O): λ (ε) = 208 nm (60500 $mol^{-1}\cdot cm^{-1}$), 218 (57300), 274 (38900), 340 (3300, sh), 356 (2600, sh), 825 (120). $C_{26}H_{18}Cl_2CuN_4O_2$ (553): calcd. (+ 2 H_2O) C 53.03, H 3.77, N 9.51; found C 53.11, H 4.20, N 9.48. Green crystals suitable for X-ray analysis were obtained by recrystallization of **3·$CuCl_2$** from hot methanol.

4·$CuCl_2$: Treatment of **4** with $CuCl_2$ on a 19.3 μmol scale afforded 12.2 mg (93%) of **4·$CuCl_2$** as a pale green powder. MS (ES, positive mode): m/z = 530 (monocation, M − Cl), 495 (cuprous complex). UV/Vis (H_2O): λ (ε) = 210 nm (61300 $mol^{-1}\cdot cm^{-1}$), 224 (69000), 274 (51300), 338 (2000, sh), 354 (1400, sh), 855 (160). $C_{27}H_{20}Cl_2CuN_4O_2$ (567): calcd. (+ 3.5 H_2O) C 51.48, H 4.32, N 8.89; found C 51.56, H 4.00, N 9.05.

5·$CuCl_2$: Treatment of **5** with $CuCl_2$ on a 20.3 μmol scale afforded 13.3 mg (93%) of **5·$CuCl_2$** as a green-brown powder. MS (ES, positive mode): m/z = 546 (monocation, M − Cl), 510 (cuprous complex). UV/Vis (H_2O): λ (ε) = 210 nm (51700 mol^{-1} cm^{-1}), 232 (56200), 280 (41100), 318 (10400, sh), 332 (7200, sh), 344 (3400, sh), 702 (70), 955 (40, sh). $C_{27}H_{21}Cl_2CuN_5O_2$ (582): calcd. (+ 4 H_2O) C 49.59, H 4.47, N 10.71; found C 49.64, H 4.10, N 10.85.

6·$CuCl_2$: Treatment of **6** with $CuCl_2$ on a 18.6 μmol scale afforded 11.4 mg (89%) of **6·$CuCl_2$** as a green-brown powder. MS (ES, positive mode): m/z = 587 (monocation, M − Cl), 552 (cuprous complex). UV/Vis (H_2O): λ (ε) = 208 nm (43000 mol^{-1} cm^{-1}), 230 (41900), 282 (31200), 316 (2100, sh), 330 (7400, sh), 344 (4000, sh), 693 (50), 900 (40, sh). $C_{29}H_{23}Cl_2CuN_5O_3$ (624): calcd. (+ 3.5 H_2O) C 50.70, H 4.40, N 10.19; found C 50.80, H 4.05, N 10.22.

7·$CuCl_2$: Treatment of **7** with $CuCl_2$ on a 23.8 μmol scale afforded 10.0 mg (76%) of **7·$CuCl_2$** as a green powder. MS (ES, positive mode): m/z = 516 (monocation, M − Cl), 481 (cuprous complex). UV/Vis (H_2O): λ (ε) = 208 nm (46900 mol^{-1} cm^{-1}), 232 (55700), 245 (50626, sh), 280 (45900), 320 (14700, sh), 332 (10300, sh), 346 (4300, sh), 700 (51). $C_{26}H_{18}Cl_2CuN_4O_2$ (553): calcd. (+ 0.1 H_2O) C 56.30, H 3.31, N 10.10; found C 56.39, H 3.50, N 9.98. Green crystals suitable for X-ray analysis were obtained from a DMF/methanol (2:1) solution of the complex after 3 d at −20 °C.

8·$CuCl_2$: Treatment of **8** with $CuCl_2$ on a 23.1 μmol scale afforded 10.3 mg (76%) of **8·$CuCl_2$** as a green powder. MS (ES, positive mode): m/z = 530 (monocation, M − Cl), 495 (cuprous complex). UV/Vis (H_2O): λ (ε) = 208 nm (49100 $mol^{-1}\cdot cm^{-1}$), 232 (54200), 245 (41900, sh), 280 (41100), 320 (14100, sh), 332 (11900, sh), 346 (4400, sh), 700 (59). $C_{27}H_{20}Cl_2CuN_4O_2$ (567): calcd. (+ 1.3 H_2O) C 54.93, H 3.86, N 9.49; found C 54.87, H 3.56, N 9.27.

9·$CuCl_2$: Treatment of **9** with $CuCl_2$ on a 22.3 μmol scale afforded 10.0 mg (74%) of **9·$CuCl_2$** as a green powder. MS (ES, positive mode): m/z = 544 (monocation, M − Cl), 509 (cuprous complex). UV/Vis (H_2O): λ (ε) = 208 nm (49000 $mol^{-1}\cdot cm^{-1}$), 232 (54600), 245 (43700, sh), 280 (40700), 320 (14100, sh), 332 (11800, sh), 346 (5100, sh), 720 (68). $C_{28}H_{22}Cl_2CuN_4O_2$ (581): calcd. (+ 1.5 H_2O) C 55.32, H 4.14, N 9.22; found C 55.09, H 4.02, N 9.48.

10·$CuCl_2$: Treatment of **10** with $CuCl_2$ on a 21.7 μmol scale afforded 10.3 mg (77%) of **10·$CuCl_2$** as a green powder. MS (ES, positive mode): m/z = 557 (monocation, M − Cl), 523 (cuprous complex). UV/Vis (H_2O): λ (ε) = 208 nm (48200 $mol^{-1}\cdot cm^{-1}$), 232 (50900), 245 (33700, sh), 280 (35900), 320 (12500, sh), 332 (11000, sh), 346 (5300, sh), 740 (71). $C_{29}H_{24}Cl_2CuN_4O_2$ (595): calcd. (+ 1.3 H_2O) C 56.33, H 4.34, N 9.06; found C 56.28, H 4.02, N 9.10.

Preparation of 1·$Cu(BF_4)_2$: $Cu(BF_4)_2\cdot 6\ H_2O$ (26.8 mg, 0.08 mmol) was added to 2-Clip-Phen (**1**, 50.6 mg, 0.11 mmol) dissolved in 600 μL of DMF/CH_3OH. The mixture was stirred for 1 h at room temperature, and green crystals of **1**·$Cu(BF_4)_2$ suitable for X-ray analysis were then obtained by slow diffusion of CH_2Cl_2 into the mixture. MS (ES, positive mode): m/z = 509 (monocharged monomer, **1**·Cu^+, major pick), 529 (monomer, **1**·$Cu^{++}F^-$), 1281 {monocharged dimer, $[(\mathbf{1})_2Cu_2][BF_4]_3$, minor pick}. $C_{27}H_{21}B_2CuF_8N_5O_2$ (685): calcd. (+ 1.5 H_2O) C 45.01, H 3.40, N 9.85; found C 44.91, H 3.38, N 9.60. EPR data: from solid state: $g_\perp$ = 2.09, $g_\parallel$ = 2.2; from a DMF/CH_2Cl_2/CH_3OH (2:4:1) glass (1 mM) at 100 K: $g_\perp$ = 2.09 ($A_\perp$ = 42 G, badly resolved), $g_\parallel$ = 2.24 ($A_\parallel$ = 67 G); from a H_2O/ethylene glycol (1:2) glass (1.1 mM) at 100 K: $g_\perp$ = 2.09, $g_\parallel$ = 2.27 ($A_\parallel$ = 75 G).

Preparation of 1·$ZnCl_2$: Compound **1** (10 mg, 22 μmol) was metallated with 1 equiv. of $ZnCl_2$ (3 mg, 22 μmol) in 0.5 mL of a CH_2Cl_2/CH_3OH (9:1) mixture. After 1 h at room temperature, the solvent was evaporated and the product was dissolved in 0.5 mL of [D_6]DMSO. White crystals suitable for X-ray analysis were obtained, directly in the NMR tube, after 2 d at room temperature. ^1H NMR ([D_6]DMSO): δ = 3.99 ppm (m, 1 H), 4.97 (dd, 2 H, 4.7 Hz and 12 Hz), [3.47 (d, J = 6.2 Hz), 3.99 (s) and 5.40 (br. d): 4 H in slow exchange on the NMR time scale as confirmed by selective irradiation of NMR signals], 7.29 (d, J = 8.7 Hz, 2 H, 3′-H), 7. 82 (dd, J = 7.9, 3.6 Hz, 2 H, 8′-H), 7.92 and 8.00 (AB, 4 H,

J = 8.8 Hz, 5′-H and 6′-H), 8.42 (d, J = 8.7 Hz, 2 H, 4′-H), 8.60 (br. d, 2 H, J = 7.9, 7′-H), 9.19 (br. d, 2 H, J = 3.6, 9′-H).

X-ray Crystallographic Study: Crystal data for all structures are presented in Table 7. Data for bis[(**1**)Cu][BF_4]$_2$ were collected at low temperature with a Stoe-IPDS diffractometer, and data for [(**3**)CuCl]$_2$Cl$_2$, [(**7**)CuCl]$_2$Cl$_2$, and (**1**)ZnCl$_2$ were collected at low temperatures with a Bruker-CCD with Mo-K_α (λ = 0.71073 Å). The structures were solved by direct methods by use of SIR92[46−47] {bis[(**1**)Cu][BF_4]$_2$} or SHELXS-97[48] {[(**3**)CuCl]$_2$Cl$_2$, [(**7**)CuCl]$_2$Cl$_2$, and (**1**)ZnCl$_2$} and refined with all data on F^2 by SHELXL-97.[49] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of the molecules were geometrically idealized and refined using a riding model. In all cases non-coordinated solvent molecules were refined anisotropically with the help of ADP and distances restraints. The fact that the very small crystals of [(**7**)CuCl]$_2$Cl$_2$ diffracted weakly and the presence of highly disordered solvent molecules do not permit the structure to be discussed in detail. We have limited the discussion to the main features of the complex. [(**7**)CuCl]$_2$Cl$_2$ crystallizes in the monoclinic space group $C2/c$ with the cell parameters: a = 26.020(11), b = 10.363(5), c = 29.498(13) Å and β = 114.20(1)°. Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre: CCDC-187474 {bis[(**1**)Cu][BF_4]$_2$}, -187475 {[(**3**)CuCl]$_2$Cl$_2$}, -187476 [(**1**)ZnCl$_2$]. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

Electrochemistry: Electrochemical measurements were carried with a custom-made potentiostat, using the interrupt method to minimize the uncompensated resistance (IR) drop.[50] Electrochemical experiments were performed at room temperature in an air-tight three-electrode cell connected to a vacuum argon/N_2 line. The reference electrode consisted of a saturated calomel electrode (SCE) separated from the solutions by a bridge compartment. The counter-electrode was a spiral of ca. 1 cm^2 apparent surface area, made of Pt wire 8 cm long and 0.5 mm in diameter. Cyclic voltammetry was conducted with a Pt (1 mm) working electrode in the potential range of −600 to +600 mV. The supporting electrolyte was KCl (Prolabo RP, Normapur) and was used as received. All solutions measured were 1 mM in complex and 0.1 M in supporting electrolyte. All experiments were conducted in water under argon. Stock solutions (2 mM) of ligand·$CuCl_2$ were prepared in water.

DNA Cleavage Experiments: The desired complex [4 μM, 5 μL, metallations carried out at 1 mM $CuCl_2$ concentration with 1 equiv. of ligand in DMF/water (1:1) for 4 h at room temperature before dilution of the complex with water to 4 μM] was added to ΦX174 (10 μL, 7 nM, 40 μM in bp) in sodium phosphate buffer (80 mM, pH = 7.2), NaCl (100 mM), and $MgCl_2$ (20 mM). After 30 min at room temperature, cleavage was initiated by addition of an aqueous solution of MPA (5 μL, 20 mM) and samples were incubated for 1 h at 37 °C. A solution of 7.5 μL of 50% (v/v) glycerol/40 mM Tris·Cl buffer (pH = 8)/0.05% bromophenol blue (w/v) was then added and samples were immediately loaded onto agarose gel (0.8%) containing 1 μg/mL of ethidium bromide. Electrophoresis was run at constant current (25 mA for 15 h) in TBE buffer. Bands were located by UV light (254 nm), photographed, and quantified by microdensity. The correction coefficient 1.47 was used for the decreased stainability of form I DNA vs. forms II and III.[41] When only forms I and II were present, the average number of single-strand scissions per DNA phage, S, was considered to be equal to

−ln(fraction of form I) according to a Poisson distribution. In case of the presence of the form III, the number of single-strand breaks per ΦX174 DNA molecule was calculated according to the equation: $I + II = \{1 - [S\cdot(2h + 1)/2L]\}^{S/2}$;[41,42] the (I + II) value is the percentage of form I and II, L is the number of DNA base pairs in ΦX174 (5386 bp), and h is the distance between nicks on opposite strands needed to produce a linear molecule. A value h = 16 bp previously proposed in ref.[42] was used since it allowed a good linearity of S as a function of the concentration of copper complexes of Clip-Phen derivatives.

Ground Spin State Variation in Carboxylate-Bridged Tetranuclear $[Fe_2Mn_2O_2]^{8+}$ Cores and a Comparison with Their $[Fe_4O_2]^{8+}$ and $[Mn_4O_2]^{8+}$ Congeners

Phalguni Chaudhuri,*[a] Eva Rentschler,[a] Frank Birkelbach,[a] Carsten Krebs,[a] Eckhard Bill,[a] Thomas Weyhermüller,[a] and Ulrich Flörke[b]

Keywords: Oxo ligands / Carboxylate ligands / Iron / Manganese / Magnetic properties / Tetranuclear complexes

Syntheses of ten new tetranuclear complexes containing the $[M_A(\mu_3\text{-}O)_2M_B]^{8+}$ butterfly core [$M_A = M_B = Fe^{III}$ (**1** and **2**), $M_A = M_B = Mn^{III}$ (**3** and **4**) and $M_A = Fe^{III}$, $M_B = Mn^{III}$ (**5**–**10**)] using 1,4,7-trimethyl-1,4,7-triazacyclononane (L) as the capping ligand, salicylaldoximato dianion ($salox^{2-}$) and six different carboxylate anions as bridging ligands, are described. The crystal structures of $[L_2Fe_2(\mu_3\text{-}O)_2(salox)_2(diphenylglycolate)_3Fe_2](ClO_4)$ (**1**), $[L_2Mn_2(\mu_3\text{-}O)_2(salox)_2(diphenylglycolate)_3Mn_2](ClO_4)$ (**3**), $[L_2Fe_2(\mu_3\text{-}O)_2(salox)_2(acetate)_3Mn_2](ClO_4)$ (**5**), $[L_2Fe_2(\mu_3\text{-}O)_2(salox)_2(diphenylglycolate)_3Mn_2](ClO_4)$ (**6**), and $[L_2Fe_2(\mu_3\text{-}O)_2(salox)_2(benzoate)_3Mn_2](ClO_4)$ (**8**) were determined by X-ray crystallography. The complexes are isostructural, with M^{III} ions disposed in a butterfly core where bridging between the M^{III} ions occurs via two μ_3-oxo anions. In complexes **5**, **6** and **8** the "wing-tip" positions of the butterfly are occupied by the LFe^{3+} units, whereas the "body" metal ions are d^4 high-spin Mn^{III} ions. Complexes **1**–**10** have been characterised by variable-temperature (2–290 K) magnetic susceptibility measurements (1 T) and by Mössbauer spectroscopy. A "2*J*" model has been applied to simulate the experimental μ_{eff} vs. *T* plots. Overall exchange interactions are antiferromagnetic in nature. Complexes with the Fe_4O_2 core (**1** and **2**) and the Mn_4O_2 core (**3** and **4**) possess an $S_t = 0$ and $S_t = 3$ ground state, respectively, regardless of the nature of the bridging carboxylate ligand. In contrast, changing the bridging carboxylates in the $[Fe_2Mn_2O_2]$ core from acetate (**5**) to diphenylglycolate (**6**), triphenyl acetate (**7**), benzoate (**8**), chloroacetate (**9**) and propionate (**10**), results in a variation of the ground state from $S_t = 1$ to $S_t = 3$, due to spin frustration of the "body" manganese centres. The spin-correlation diagram for the $Fe_2Mn_2O_2$ butterfly arrangement clearly demonstrates the ground state variation as a function of the ratio of two competing coupling interactions.

Introduction

Tetranuclear, oxide-bridged metal carboxylate assemblies are relevant to several areas including bioinorganic modelling and magnetochemistry. In the field of iron chemistry, the pursuit of model complexes for the iron proteins has yielded several interesting tetranuclear complexes[1–6] amongst other polynuclear iron complexes with unusual electronic structures.[7] The knowledge that in PSII the site of water oxidation is a tetranuclear manganese aggregate[8] in which four manganese atoms are essential for activity and appear to be in close proximity to one another, has augmented the search for tetranuclear manganese complexes. Thus, tetramanganese butterfly[6,9–12] complexes with the $[Mn_4O_2]^{8+}$ core have emerged as the most intensely studied oxide-bridged carboxylate clusters. Comparatively fewer studies of the butterfly $[Fe_4O_2]^{8+}$ core have been made, and there are relatively few studies of the analogous heterometallic butterfly complexes,[13,14] despite the fact that such studies might be more informative in comparison to those of homometal complexes. New exchange pathways can be expected for heteronuclear complexes,[15–18] where unusual sets of magnetic orbitals can be brought into close proximity.

There are several intriguing features associated with oxo-bridged carboxylate clusters. Firstly, these complexes can have unusual electronic structures and may serve as sources of fundamental information about exchange coupling in multinuclear assemblies. A second general reason to study polynuclear metal complexes is that they may be building blocks for molecular-based magnetic materials.[19] Because of their topology, molecules that have large numbers of unpaired electrons should serve as good starting points for constructing molecular magnetic materials. Even though the pairwise exchange interactions in these complexes are found almost always to be antiferromagnetic, spin frustration[20,21] in the general sense of the term, or more accurately, competing spin interactions, can result in polynuclear complexes having a relatively large number of unpaired

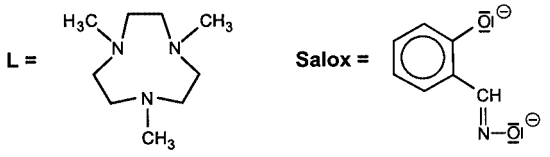
electrons in their ground states. Although spin frustration is a well-known magnetic phenomenon for extended lattices, its application to the magnetochemistry of discrete polynuclear complexes is not widely recognised. Competing spin interactions may give rise to unpredictable ground state spins and peculiar spin state spectra. Thus, the situation of ground state degeneracy induced by competing spin interactions is worth investigating.

We have been exploring the feasibility of using salicylaldoxime to influence the nuclearity and metal topology of metal carboxylate complexes. Although salicylaldoxime[22] has been known as a metal-chelating agent since 1930, reports on the ligating properties of salicylaldoxime towards trivalent transition metal ions are rare.[23,24] Our approach of using oximes as ligands has yielded several interesting 3d metal complexes with the cores $[M_A(oxime)_3M_B]^{n+}$,[24] $[M^{III}_3(\mu_3\text{-}O)(\mu_2\text{-}OPh)]^{6+}$ (M = Ti, V, Cr, Mn, Fe and Co),[25,26] $[M^{III}_6(\mu_3\text{-}O)_2(\mu_2\text{-}OOCR)_2]^{12+}$ (M = V, Cr, Mn, Fe)[27] and $[(M^{III}_A)_2(\mu_3\text{-}O)_2(M^{III}_B)_2]^{8+}$ ($M_A = M_B = Fe^{III}$;[4] $M_A = Cr^{III}$, $M_B = Fe^{III}$;[13] $M_A = Cr^{III}$, $M_B = Mn^{III}$).[14] In this paper we report the extension of our studies to complexes having tetranuclear cores, and include the preparation and characterisation of $[L_2Fe_4(\mu_3\text{-}O)_2(\mu_2\text{-}OOCC(OH)Ph_2]_3(salox)_2]\text{-}ClO_4$ (**1**), $[L_2Fe_4(\mu_3\text{-}O)_2(\mu_2\text{-}OOCCPh_3)_3(salox)_2]ClO_4$ (**2**), $[L_2Mn_4(\mu_3\text{-}O)_2(\mu_2\text{-}OOCC(OH)Ph_2]_3(salox)_2]ClO_4$ (**3**), $[L_2Mn_4(\mu_3\text{-}O)_2(\mu_2\text{-}OOCCPh_3)_3(salox)_2]ClO_4$ (**4**) and $[L_2Fe_2Mn_2(\mu_3\text{-}O)_2(\mu_2\text{-carboxylate})_3(salox)_2]ClO_4$ (**5**−**10**) [carboxylate = acetate (**5**), benzilate (diphenylglycolate) (**6**), triphenylacetate (**7**), benzoate (**8**), chloroacetate (**9**) and propionate (**10**)], where L is the cyclic amine 1,4,7-trimethyl-1,4,7-triazacyclononane and salox is the dianion of salicylaldoxime (H_2salox). Molecules **1**−**10** contain M^{III} ions disposed in a butterfly $[M_4O_2]^{8+}$ core, where bridging between the M^{III} ions occurs via two μ_3-oxo anions.



Results

Our previous investigations of the use of solvolysis reactivity of $[LFeCl_3]$[28] in the synthesis of homo- and heteropolynuclear complexes led us to anticipate compounds with a butterfly structure, in which the "body" metal ions differ from the "wing-tip" (Fe^{3+}) ions. The fact that the iron centres remain bonded to the macrocyclic ligand L during the formation of the polynuclear complexes was recognised and subsequently utilised as a synthetic strategy for building $Fe_2(O)_2Mn_2$ cores with Mn^{3+} as the "body" ions. Accordingly, the dark brown solution obtained from manganese(II) chloride, a carboxylic acid, salicylaldehyde oxime and triethylamine in methanol reacted with $[LFeCl_3]$ to afford, after addition of a perchlorate solution, dark brown crystals of $[L_2Fe_2(\mu_3\text{-}O)_2(\mu\text{-carboxylate})_3(salox)_2Mn_2]ClO_4$ in reasonable yield. Complex **5** was prepared by using Mn^{III} acetate.

The IR spectra of the tetranuclear complexes **1**−**10** exhibit, besides ligand and ClO_4 absorptions, a sharp medium-intensity band in the region 670−660 cm^{-1}, probably due to the ν_{asym} vibration of the four modes of the $FeMn_2(\mu_3\text{-}O)$ triangle.[29] The ν(CN) vibration is assigned to the medium-intensity band at ca. 1600 cm^{-1}. One of the characteristics in the IR spectra is a strong carboxyl stretching vibration found in the region 1550−1580 cm^{-1}. The complexes show a strong band, whose intensity is similar to that of ν(COO), at ca. 1090 cm^{-1} (antisymmetric stretch) and a sharp band at ca. 620 cm^{-1} (antisymmetric bend), indicative of uncoordinated perchlorate anions.

Interestingly, the mass spectra of complexes **1**−**7** differ widely. Although the all-iron complexes **1** and **2** show signals due to the respective monocations $[M^+]$ with the expected isotope distributions in the ESI positive mode, the manganese compound **3** does not show the corresponding molecular ion. However, in the case of the mixed-metal complexes **5**−**7**, mass spectrometry in the ESI-positive mode has proved to be a very useful tool for characterisation.

Structures of Complexs 1 and 3

Figure 1 shows a perspective view of the cation of **1**. Although this complex contains an $[Fe_4(\mu\text{-diphenylglycolate})_3(\mu_3\text{-oxo})_2]$ core very similar to that in the previously reported $[Fe_4(\mu\text{-acetato})_3(\mu_3\text{-oxo})_2]$ complex,[4] we have included the description of the structure of **1** in this paper to show that the OH groups of the diphenylglycolate ligands are not coordinated to the oxophilic Fe^{III} centres. It should also be noted that there are very few tetranuclear Fe^{III} complexes with the $[Fe_4O_2]^{8+}$ butterfly core reported

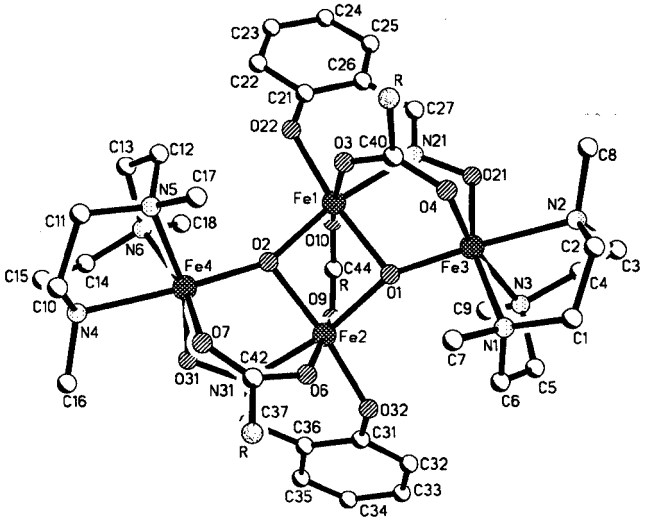


Figure 1. Structure of the monocation of complex **1**; the bridging diphenylglycolate (benzilate) anions are denoted by $RCOO^-$, i.e. "$Ph_2C(OH)$" has been replaced by "R" for clarity

in the literature.[1−6] The metal geometry of the cluster may be described as "butterfly" based on two edge-sharing $Fe_3(\mu_3\text{-O})$ triangular units, with the oxygen atoms O(1) (0.029 Å) and O(2) (0.004 Å) above the corresponding Fe_3 triangles. The Fe(1)···Fe(2) distance [2.841(2) Å] is at the low end of the range (2.829−3.108 Å) observed in other $[Fe_4O_2]$-containing compounds.[1−6] There are three types of independent Fe−O(oxo) distances, ranging from 1.872 to 1.988 Å, the two shortest being Fe(4)−O(2) [1.872(7) Å] and Fe(3)−O(1) [1.874(7) Å].

The dihedral angle between the planes Fe(1)Fe(2)Fe(3)O(1) and Fe(1)Fe(2)Fe(4)O(2) is 145.9°, which is slightly smaller than that in the corresponding acetate complex (153.9°). Selected bond lengths and angles for the $Fe_4(\mu_3\text{-O})_2$ core and for the rest of the cation are given in Table 1.

In addition to the two μ_3-oxo groups, there are three bridging carboxylate groups in the tetranuclear structure originating from the diphenylglycolate ion, one each between iron atom pairs Fe(4)Fe(2), Fe(1)Fe(2) and Fe(1)Fe(3). Additionally two N−O groups of the deprotonated salicylaldoximes are coordinated to iron atom pairs Fe(4)Fe(2) and Fe(3)Fe(1) through their oxygen and nitrogen donor atoms, respectively.

It should be noted that the enolic OH group of diphenylglycolic acid is not coordinated to any iron centre. It seems that the nonplanarity of the $[Fe_4O_2]^{8+}$ unit is a consequence of the bridging carboxylate (diphenylglycolate) groups. Specifically, the carboxylate-bridged iron atoms are apparently "pulled" closer to one another [Fe(1)···Fe(3) = 3.197(2) Å, Fe(2)···Fe(4) = 3.192(2) Å] than those without carboxylate bridging [Fe(1)···Fe(4) = 3.734(2) Å, Fe(2)···Fe(3) = 3.738(2) Å]. Just as there are two long and two short Fe···Fe separations, there are also two long [Fe(1)−O(1) = 1.988(6) Å, Fe(2)−O(2) = 1.981(7) Å] and two short [Fe(2)−O(1) = 1.949(7) Å, Fe(1)−O(2) = 1.949(7) Å] iron−μ_3-oxo bonds in the inner Fe(1)Fe(2)O(1)O(2) core.

Each iron atom is in a distorted octahedral environment, with Fe(1) and Fe(2) having an $FeNO_5$ and Fe(3) and Fe(4) an FeN_3O_3 coordination sphere, respectively. Fe−N and Fe−O bond lengths are typical of high-spin ferric complexes. The Fe−N bonds *trans* to the short Fe−μ_3-O bonds are noticeably longer than those *cis* to them, as observed

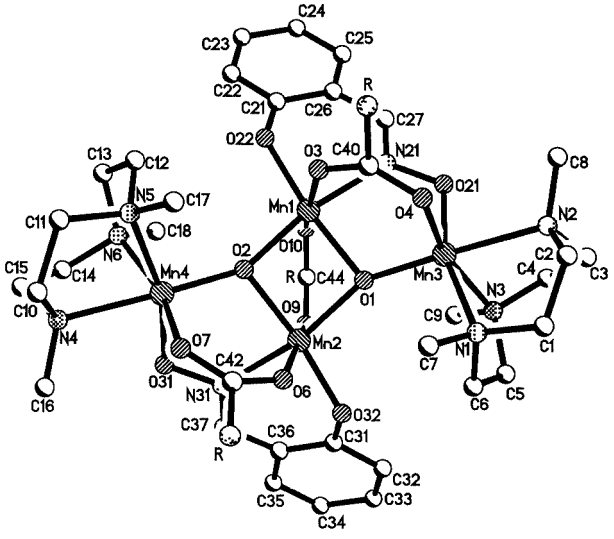

Figure 2. Perspective view of the cation of **3**; "$Ph_2C(OH)$" -units of the bridging diphenylglycolate (benzilate) anions are denoted only by "R" for the sake of clarity

earlier.[4] The structural parameters for **1** lie in the range reported for the other $[Fe_4O_2]^{8+}$ complexes.[1−6]

A perspective view of the cation of complex **3** is shown in Figure 2, and selected structural parameters are listed in Table 2. The cation, like that in **1**, possesses an M_4O_2 core which can be considered as two edge-sharing Mn_3O units, the metal dispositions being a butterfly structure with Mn(1) and Mn(2) occupying the "body" sites and Mn(3) and Mn(4) occupying "wing-tip" sites. Each body-wing-tip and body-body Mn_2 pair is bridged by a carboxylate group of the diphenylglycolate anion in its common *syn*,*syn* binding mode. The μ_3-O atoms O(1) and O(2) on each Mn_3 wing of the butterfly are 0.04 and 0.008 Å, respectively, above their Mn_3 least-squares planes. The dihedral angle between the planes comprising Mn(1)Mn(2)Mn(3)O(1) and Mn(1)Mn(2)Mn(4)O(2) is 145.8°, a value identical with that in the Fe_4O_2 core of **1**. The shortest Mn···Mn contact is 2.844(2) Å, between Mn(1) and Mn(2). The coordination spheres of "wing-tip" [Mn(4) and Mn(3)], and "body" [Mn(1) and Mn(2)] manganese ions are MnN_3O_3 and $MnNO_5$, respectively, in which the distortions along the axes O(3)Mn(1)O(10), O(6)Mn(2)O(9), N(2)Mn(3)O(1) and N(4)Mn(4)O(2) are as expected for Jahn−Teller-distorted high-spin d^4 ions in an octahedral geometry. The Mn−N and Mn−O bond lengths are consistent with a d^4 high-spin electronic configuration for the Mn^{III} centres. The essential features of the structure of the cation of **3** are very similar to those of **1.**

Structures of Complexes 5, 6 and 8

The molecular geometry and the atom-labelling scheme of the cation of **5** are shown in Figure 3. The structure consists of a discrete monocationic tetranuclear unit having a twofold rotation axis. Selected interatomic distances and angles are listed in Table 3. The cation possesses a "butterfly" $[Fe_2(\mu_3\text{-}O)_2Mn_2]$ core. Mn(1) and Mn(1a) occupy "body" positions, and Fe(1) and Fe(1a) occupy the "wing-tip" positions, with O(1) and O(1a) triply bridging each $FeMn_2$ wing. The structure can thus be considered as two edge-sharing $FeMn_2O$ triangular units with a dihedral angle of 145.1°. In contrast to the Mn_4O_2 complex **3**, O(1) lies significantly out (0.14 Å) of the $FeMn_2$ plane. In addition to the two μ_3-oxo groups, there are three bridging acetate groups in the tetranuclear structure, one each between the metal atom pairs Fe(1)Mn(1), Fe(1a)Mn(1a) and Mn(1)Mn(1a). Additionally, a salicylaldoximate dianion is

coordinated to Mn(1) through its phenolate oxygen atom O(3) and oxime nitrogen atom N(1), thus making Mn(1) six-coordinate. The X-ray structure clearly shows that the "body" metal ions are Jahn−Teller-distorted, high-spin d^4 Mn^{III} ions; the axially elongated sites are occupied by the carboxylate oxygen atoms of acetate, with Mn(1)−O(6) 2.160(2) Å, Mn(1)−O(5) 2.212(2) Å and O(5)−Mn(1)−O(6) 173.5°. Interestingly, the Mn(1)−O(1) distance [1.940(1) Å] is significantly shorter than the corresponding bond length in the analogous cation of **6**, but is similar to that in **8**.

The coordination geometry of the "wing-tip" ferric ion Fe(1) is distorted octahedral, with three nitrogen atoms from the facially coordinated tridentate macrocyclic amine (L) and three oxygen atoms [O(2) from the deprotonated oxime group, O(4) from the bridging acetate and O(1) from the μ_3-bridging oxo group], resulting in a *fac*-FeN_3O_3 coordination sphere. The Fe(1)−N(2) distance [2.279(2) Å] is significantly longer than the other Fe−N distances, due to the *trans* effect. The Fe−N (average 2.23 Å) and Fe−O (average 1.95 Å) distances are in agreement with a d^5 high-spin electronic configuration for the iron centres. The Fe(1)−μ_3-oxo distance [1.880(1) Å] is, as expected, the shortest amongst the metal−ligand bond lengths. The iron atom Fe(1) is displaced by 0.28 Å from the mean basal plane comprising N(3)N(4)O(2)O(4) toward the apical μ_3-oxygen atom O(1).

The structure of the cation of complex **6** is presented in Figure 4. The cation possesses an $Fe_2^{III}Mn_2^{III}(\mu_3\text{-}O)_2$ core very similar to those present in the Fe_4O_2 (**1**), Mn_4O_2 (**3**) and $Fe_2Mn_2O_2$ (**5** and **8**) core structures. The metal centres are thus disposed in a "butterfly" arrangement based on two edge-sharing $FeMn_2(\mu_3\text{-}O)$ triangular units, with the oxygen atoms O(1) and O(2) slightly above (0.07 Å) and below (0.02 Å) the Mn_2Fe triangle, as depicted below; note that the drawing is not meant to suggest a stepwise assembly process.

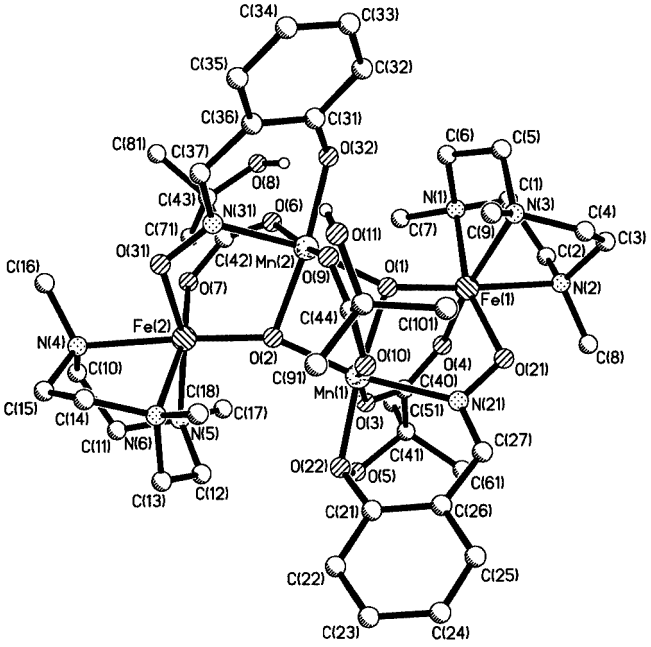

Figure 4. Structure of the tetranuclear monocation of **6**; phenyl rings (Ph) of the bridging diphenylglycolate (benzilate) $Ph_2C(OH)COO^-$ are denoted by C atoms

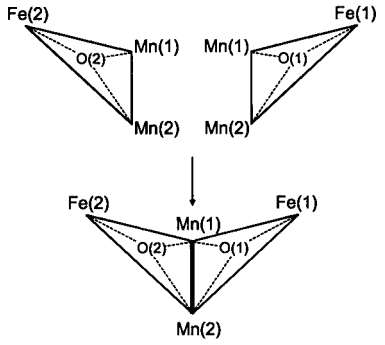

The dispositions of the μ_3-oxo groups are not completely symmetrical, but are consistent with all metal atoms being in the 3+ oxidation state. The dihedral angle between the planes Mn(1)Mn(2)Fe(2) and Mn(1)Mn(2)Fe(1) is 145.9°. Selected bond lengths and angles for the $Fe_2^{III}Mn_2^{III}O_2$ core and for the rest of the cation are given in Table 4. The "body" metal centres [Mn(1) and Mn(2)] show clear evidence of Jahn−Teller distortions, as expected for high-spin octahedral d^4 Mn^{III}, and the axially elongated sites are all occupied by carboxylate oxygen atoms of diphenylglycolic acid [O(3), O(10) for Mn(1) and O(6), O(9) for Mn(2)]. The hydroxy oxygen atoms of $(C_6H_5)_2C(OH)COO^-$ O(8), O(5) and O(11) are not coordinated to any of the metal centres. There are three types of independent Fe−O distances, ranging from 1.863(2) to 2.045(2) Å, with the shortest, as expected, being the Fe−μ_3-oxo distances Fe(1)−O(1) [1.863(2) Å] and Fe(2)−O(2) [1.876(2) Å]. The Fe−N distances *trans* to the μ_3-oxo groups [Fe(1)−N(2) = 2.268(3) Å, Fe(2)−N(4) = 2.270(2) Å] are longer than the other Fe−N distances, due to the *trans* effect. The coordination geometry of the "wing-tip" ferric ions, Fe(1) and Fe(2), is distorted octahedral, with three nitrogen atoms from the facially coordinated tridentate macrocyclic amine (L) and three oxygen atoms [O(31) or O(21) of the deprotonated oxime group, O(4) or O(7) of the bridging carboxylate and O(1) or O(2) of the μ_3-bridging oxo group] resulting in a *fac*-FeN_3O_3 coordination sphere. The Fe−N [average 2.20(6) Å] and Fe−O [average 1.95(6) Å] distances are similar to literature values[28] for high-spin Fe^{III} complexes with this macrocyclic amine. A deviation from the idealised octahedral geometry at the metal centre is found for the ligand L; the N−Fe−N angles range from 77.6 to 81.2°, whereas the O−Fe−O angles fall between 91.7 and 98.2°. The iron ions Fe(1) and Fe(2) are displaced by 0.28 Å from the mean basal planes comprising O(21)O(4)N(3)N(1) and N(5)N(6)O(7)O(31), respectively, toward the apical μ_3-oxygen atoms O(1) and O(2).

The "body" manganese ions, Mn(1) and Mn(2), are bridged by two oxo groups, O(2) and O(1). Each Mn is coordinated to three oxygen atoms [O(1), O(2) and phenolate O(22) or O(32)] and an imine nitrogen atom [N(21) or N(31)] of an oxime group in the basal plane. The carboxylate oxygen atoms O(3)/O(10) or O(6)/O(9) occupy the axially elongated apical positions. The Mn−N and Mn−O bond lengths are consistent with a d^4 high-spin electronic configuration for the Mn^{III} centres. The manganese centres Mn(1) and Mn(2) lie out of the best basal planes comprising Mn(1)N(21)O(22)O(1)O(2) and Mn(2)N(31)O(32)O(1)O(2) by 0.028 Å and 0.09 Å in the direction of the bridging O(3) or O(6), respectively.

The structure of **8**·2CH_3CN is very similar to that of **5** and **6** and hence only the core structure is shown in Fig-

ure 5. Table 5 gives selected bond lengths and angles for **8**. Remarkably, the Mn−O−Mn angles in **5**, **6** and **8** (93°) are nearly identical. On the other hand, the Mn−μ_3-O distances in **8** (average 1.92 Å) are shorter than those in **5** or **6** (average 1.94 Å), although the Fe−μ_3-O distances for **5**, **6** and **8** are nearly identical (average 1.88 Å). This difference in bond lengths presumably has significant effects on the ground state S_t values, as will be shown later.

Mössbauer Spectroscopy

The Mössbauer spectra of **1** (Figure 6, curve A) and **2** were recorded without an applied field at 80 K. Each spectrum is best fit to two equal-area doublets, whose isomer shifts (δ_{Fe}) and quadrupole splitting (ΔE_Q) values are listed in Table 6. The two doublets imply two Fe sites with different coordination spheres, in agreement with the molecular structure of **1**, and are thus assigned to the "body" and "wing-tip" pairs of Fe^{III} atoms. The isomer shift δ_{Fe} of 0.5 ± 0.05 mm/s is of the magnitude expected for the high-spin ferric state and is close to the values reported for similar compounds.[30] The ΔE_Q values for both sites in **1** and **2** reflect deviations from octahedral geometry, since the valence electron contribution to ΔE_Q is negligible for high-spin Fe^{III}. The two ΔE_Q values are significantly different, and larger than the 0.4−0.7 mm/s range observed for basic iron carboxylates.[31] By comparing the bond lengths for the NO_5 coordination sphere around Fe(1) and Fe(2) with those of the more symmetrical N_3O_3 coordination sphere about Fe(3) and Fe(4), the doublet with $\Delta E_Q \approx 1.37$ mm/s can be assigned to the "body" iron atoms Fe(1) and Fe(2), whereas the inner doublet is assignable to the "wing-tip" iron atoms Fe(3) and Fe(4). This assignment is also corroborated by the Mössbauer data for complexes **5**−**10**.

The powder-state Mössbauer spectrum of **6** at 80 K is displayed in Figure 6, curve B. Essentially similar spectra were obtained for the remaining complexes of the group. The δ_{Fe} and ΔE_Q values for **5**−**10** are listed in Table 6. Mössbauer results indicate a single quadrupole splitting, in accordance with only one type of iron coordination sphere in the solid-state structure, namely the "wing-tip" iron sites Fe(1) and Fe(2). The δ_{Fe} values of ca. 0.45 mm/s are consistent with a d^5 high-spin electron configuration for the iron centres Fe(1) and Fe(2) in complexes **5**−**10**. The isomer shift values are surprisingly constant within these complexes, and indicate that a change in the carboxylate group − with its varying electron-withdrawing power − has little effect upon the s-electron density at the iron nucleus. The ΔE_Q values (0.53−0.61 mm/s) for **5**−**10** lie within the 0.4−0.7 mm/s range found for basic iron carboxylates, and are similar to those for analogous structures with a dis-

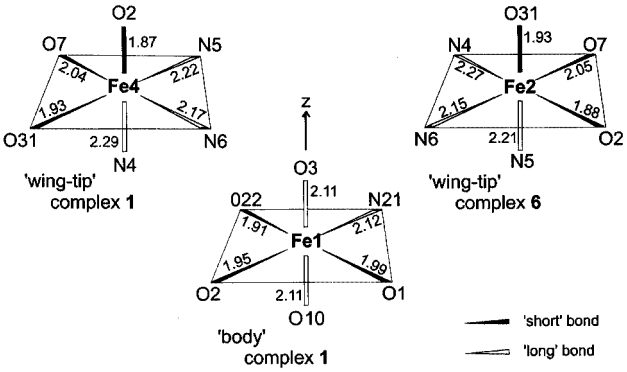
torted octahedral symmetry. Comparison of the Mössbauer data for **5**−**10** with those for **1** and **2** makes it clear that the "wing-tip positions in complexes **5**−**10** are occupied by Fe atoms in all cases, and hence the cyclic amine 1,4,7-trimethyl-1,4,7-triazacyclononane is coordinated to iron centres only.This is confirmed by the X-ray structures of **5**, **6** and **8**.

The remarkable difference in quadrupole splitting of the "wing-tip" and "body" iron sites in complexes **1**, **2** and **6** can be rationalised by comparing the distributions of bond lengths for the different coordination polyhedra. To this end, the iron−ligand bonds were classified into "short" and "long" bonds as sketched in Scheme 1.

It is striking that for the "wing-tip" iron atoms, the three shortest Fe−O bonds lie in a *fac* configuration, whereas for the "body" site, they have a *mer* arrangement. Thus, the "body" site can be regarded as a distorted octahedron with bond compression in the equatorial plane (if the *z* axis is taken in the O3−Fe1−O10 direction). Since large quadrupole splittings of high-spin Fe^{III} ($3d^5$ configuration) are the result of strong anisotropy in the covalent delocalisation of valence electrons, as suggested for the Fe−O−Fe unit in other systems,[32] we infer that the large electric field gradient for the "body" site [Fe(1) of complexes **1** and **2**] originates predominantly from strong covalency of the $d_{x^2-y^2}$ orbital and the resulting anisotropy in the distribution of valence electrons. In contrast, the short bonds in the "wing-tip" sites are distributed in a more balanced manner among the three major axes. In addition, the covalency due to the particularly short Fe4−O2 and Fe2−O2 bonds in compounds **1** and **6**, respectively, appears to be partly compensated for by a pronounced *trans* effect in the opposite bonds. Thus, the covalent delocalisation of 3d electrons seems to be more isotropic, as it affects both e_g orbitals. Since these orbitals, $d_{x^2-y^2}$ and d_{z^2}, have equally strong but opposite contributions to the total electric field gradient, the smaller quadrupole splittings observed for the "wing-tip" iron sites appears to be plausible.



Scheme 1

Magnetic Properties

The magnetic susceptibility data for polycrystalline samples of **1**−**10** were collected in the temperature range 2−290 K in an applied magnetic field of 1 T and are displayed in Figures 7−9 as plots of the effective magnetic moment (μ_{eff}) versus temperature (*T*). Table 7 summarises the intracluster exchange parameters, together with the observed spin ground states, and selected μ_{eff} values for **1**−**10** are listed in Table 8. The solid lines in Figures 7−9 repres-

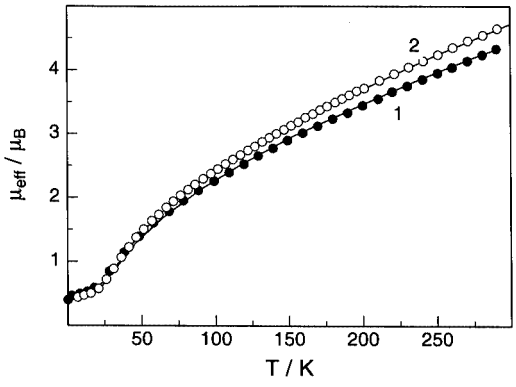


Figure 7. Temperature dependence of the magnetic moments of complexes **1** and **2**; the solid lines represent the best fit of data to the Heisenberg−Dirac−van Vleck model (see text)

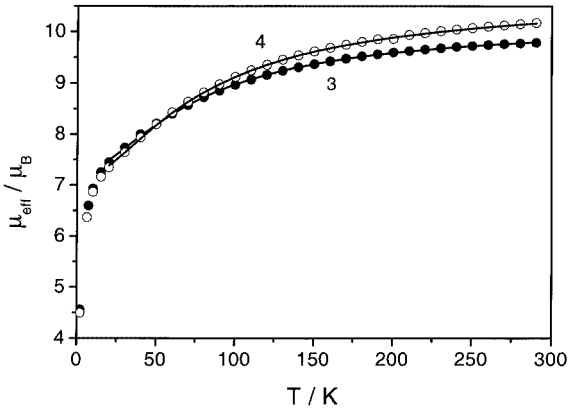

Figure 8. Plots of μ_{eff} vs. T for solid **3** and **4**; the solid lines are the best least-squares fits of the experimental data to the theoretical equation

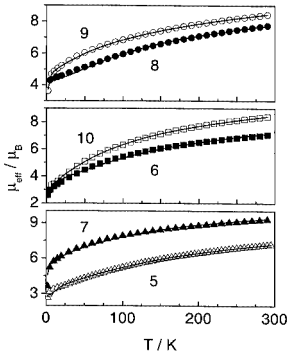

Figure 9. Temperature dependence of the magnetic moment, μ_{eff}, for **5**−**10**; the solid lines represent the simulation with the spin Hamiltonian (see text)

ent the simulations. The model used for the simulations involves two pairwise exchange interactions, J_{wb} for the wing-tip-body and J_{bb} for the body-body interactions. The oxide bridges have been shown to be more important mediators for the exchange interactions than the carboxylate bridges in the structurally related complexes $[Fe_4(\mu_3\text{-}O)_2]^{8+}$,[3,4] $[Mn_4(\mu_3\text{-}O)_2]^{8+}$,[9,35] $[Cr_4(\mu_3\text{-}O)_2]^{8+}$,[33] $[V_4(\mu_3\text{-}O)_2]^{8+}$,[34] $[Cr_2(\mu_3\text{-}O)_2Fe_2]^{8+}$ [13] and $[Cr_2(\mu_3\text{-}O)_2Mn_2]^{8+}$,[14] in which a similar "2J" model is able to adequately describe the magnetic behaviour of the tetranuclear complexes. Consequently, the other conceivable "3J" model has not been considered to avoid overparametrisation.

The resulting spin Hamiltonian used to describe the isotropic exchange interactions is given by

$\hat{H} = -2J_{wb}\ (\hat{S}_1 \bullet \hat{S}_3 + \hat{S}_2 \bullet \hat{S}_3 + \hat{S}_1 \bullet \hat{S}_4 + \hat{S}_2 \bullet \hat{S}_4) - 2J_{bb}(\hat{S}_1 \bullet \hat{S}_2)$

where S_i (i = 1, 2, 3, 4) = $^5/_2$ for **1** and **2**, S_i (i = 1, 2, 3, 4) = 2 for **3** and **4**, and $S_1 = S_2 = 2$; $S_3 = S_4 = {}^5/_2$ for **5**−**10**.

The magnetic moment for **1** and **2** decreases monotonically with decreasing temperature to an essentially diamag-

Table 8. Selected μ_{eff} values as a function of temperature for complexes **1**−**10**

Compound	Complex	μ_{eff}, μ_B (T [K])
1	Fe_4 benzilate	0.56 (2), 1.26 (40), 2.46 (110), 4.32 (290)

netic value of 0.55 μ_B for **1** at 2 K and 0.52 μ_B at 5 K for **2**; the residual nonzero moment is due primarily to an amount of a paramagnetic impurity PI (assumed $S = {}^5/_2$). Thus, the temperature-dependent behaviours of the magnetic moments of **1** and **2** clearly indicate an $S_t = 0$ electronic ground state, in agreement with previous observations[1−6] for other molecules of similar structure. The theoretical van Vleck equation used for simulation of the susceptibility data has been described earlier.[4]

The Zeeman interaction of the high-spin ferric ion in a $^6A_1$ ground state with practically no contribution from orbital angular momentum is isotropic and the observed g values are thus very close to the free-electron spin value of 2.0. Hence, we have used a fixed value of $g = 2.0$ for **1** and **2** during simulation. As the quality of the fit is negligibly dependent on J_{bb},[3,4] we have kept $J_{bb} = 0$. Previous work has shown that J_{bb} cannot be precisely determined from the susceptibility data in the temperature range ca 4−300 K for such complexes, but J_{wb} can be evaluated with reasonable accuracy.[3,4] Additionally, an error-surface plot for **1** as a function of J_{wb} and J_{bb} shows that, while the value of J_{wb} is well determined by the fitting procedure, the value of J_{bb} is not. The best fits are shown as solid lines in Figure 7 and the fitting parameters are $J_{wb} = -41.4$ cm^{-1}, $J_{bb} = 0$ (fixed), $g = 2.0$ (fixed) and PI = 0.008 for **1**, and $J_{wb} = -38.2$ cm^{-1}, $J_{bb} = 0$ (fixed), $g = 2.00$ (fixed) and PI = 0.009 for **2**. The J_{wb} values obtained compare closely with those previously determined by us for the Fe_4 acetate system[4], and also those reported in the literature.[3,6]

The effective magnetic moment of complexes **3** and **4** as a function of temperature is shown in Figure 8. The magnetic moment gradually decreases to 6.93 μ_B at 10 K for **3** and 6.87 μ_B at 10 K for **4**, whereupon the moment falls sharply to 4.56 μ_B for **3** and 4.50 μ_B for **4** by 2 K. Thus, the temperature-dependent behaviours of the magnetic moments of **3** and **4** suggest an $S_t = 3$ ground state. In both cases, only data for temperatures above 20 K were considered in the fit, to avoid complications at low temperature from zero-field splitting. The solid lines in Figure 8 represent the best fits with the following parameters: $J_{wb} = -0.47$ cm^{-1}, $J_{bb} = -7.73$ cm^{-1}, $g = 2.099$ (fixed) and $D = 0$ (fixed) for **3**, and $J_{wb} = -1.63$ cm^{-1}, $J_{bb} = -6.71$ cm^{-1}, $g = 2.215$ (fixed) and $D = 0$ cm^{-1} (fixed) for **4**. Field-dependent magnetisation measurements (not shown) at 2 K up to 6 T also confirm that the ground state for **3** is $S_t = 3$ [simulation with $S = 3.0$ (fixed), $g = 2.02$, $D = 4.13$ cm^{-1}]. The ground state is within 5 cm^{-1} of the first excited state with $S_t = 4$.

We note that the g values employed for the simulation are high for Mn^{III}. Nevertheless, they do not affect our conclusion that **3** and **4** have an $S_t = 3$ ground state. The ground state of $S_t = 3$ has been found for all carboxylate-bridged clusters with an $[Mn_4O_2]^{8+}$ core except one with a quintuply degenerate ground state.[35]

At 295 K the magnetic moment (μ_{eff}/molecule) for **5** is 7.16 μ_B, which is significantly lower than the value of $\mu_{eff} = 10.86$ μ_B expected for an uncoupled system containing two Fe^{III} ($S = {}^5/_2$) and two Mn^{III} ($S = 2$) ions. On lowering the temperature, μ_{eff} decreases monotonically until it reaches a value of $\mu_{eff} = 2.67$ μ_B at 2 K, indicating a ground state of $S_t = 1$ (Figure 9). A full-matrix diagonalisation approach including spin exchange ($-2J\ S_1 \cdot S_2$), Zeeman interactions, and single-ion zero-field interaction (DS_z^2), was employed to fit the data. The solid line in Figure 9 shows the good quality of the fit above $T = 15$ K with the following parameters:

$J_{FeMn} = J_{wb} = -25{\cdot}2$ cm^{-1}; $J_{MnMn} = J_{bb} = -35.1$ cm^{-1}; $D(Mn^{III}) = -0.38$ cm^{-1} and $g = 2.05$ (fixed). As it is difficult, if not impossible, to unambiguously determine the sign of D from powder magnetic susceptibility measurements, one should not put too much weight on the absolute value of D, although inclusion of D as a parameter slightly improved the quality of the fit. We addressed the point of global and local minima by consideration of the two-dimensional contour projection of the error surface. The error surface shows that the fitting procedure has correctly identified the global minimum and we conclude that **5** has an $S_t = 1$ ground state lying 22.3 cm^{-1} below the first excited state with $S_t = 2$. For a system of two high-spin Fe^{III} and two high-spin Mn^{III} ions disposed in a butterfly-type arrangement as found in complexes **5**−**10**, the overall spin degeneracy (900) is distributed over 110 levels with S_t values ranging from 0 to 9.

The effective magnetic moment (μ_{eff}/molecule) for **6** decreases monotonically with decreasing temperature from 7.05 μ_B at 290 K to 2.60 μ_B at 2 K (Figure 9). The two exchange coupling constants, J_{wb} and J_{bb}, were allowed to vary independently in the full-matrix diagonalisation program to optimise the agreement. A good fit was found with the following parameters: $J_{wb} = J_{FeMn} = -22.3$ cm^{-1}, $J_{bb} = J_{MnMn} = -31.6$ cm^{-1}, $g = 2.0$ (fixed) and $D = 0$ (fixed). The ground state of $S_t = 1$ for **6** lies about 14 cm^{-1} below the first excited state with $S_t = 2$.

A steady decrease of the magnetic moment with decreasing temperature is observed for **7**. The value of μ_{eff} at 2 K (3.63 μ_B) clearly indicates a different ground state than that for **5** or **6** with $S_t = 1$. The solid line in Figure 9 shows the good quality of the fit with the following parameters: $J_{wb} = J_{FeMn} = -5.5$ cm^{-1}; $J_{bb} = J_{MnMn} = -10.16$ cm^{-1}; $g = 2.00$ (fixed) and $D = 0$ (fixed). The relative error surface for fitting the magnetic data of **7** as a function of both J_{FeMn} and J_{MnMn}, representing a well-defined global minimum in the parameter space, has allowed us to estimate the error bars on the quoted J_{FeMn} and J_{MnMn} values as approximately ± 0.2 and ± 1.0 cm^{-1}, respectively. The ground state of $S_t = 2$ for **7** obtained from the exchange coupling constants is separated from the first excited state with $S_t = 3$ by an energy gap of only 5 cm^{-1}.

A good fit of the magnetic data for **8** yields $J_{wb} = J_{FeMn} = -19.38$ cm^{-1}, $J_{bb} = J_{MnMn} = -28.91$ cm^{-1}, $g = 2.09$ and $D = 0$ (Figure 9). The ground state of $S_t = 1$ for **8** is not well separated ($\Delta E \approx 1$ cm^{-1}) from the first excited state with $S_t = 2$.

The magnetic behaviour of **9** can be easily interpreted in terms of the competing influence of J_{wb} and J_{bb} upon spin coupling, yielding a ground state of $S_t = 2$. An excellent fit representing a well-defined global minimum for **9,** together

with the experimental magnetic moments, is shown in Figure 9. The parameters used for the least-squares fitting (fit shown as a solid line in Figure 9) are $J_{wb} = J_{FeMn} = -10.6$ cm^{-1}, $J_{bb} = J_{MnMn} = -17.8$ cm^{-1}, $g = 2.01$ (fixed) and $D = 2.07$ cm^{-1} (fixed). The relative error surface calculation has allowed us to estimate the error bars on the J_{FeMn} and J_{MnMn} values as approximately ± 0.6 cm^{-1} and ± 1.5 cm^{-1}, respectively. The relatively large uncertainties in the absolute magnitudes of J_{FeMn} and J_{MnMn} do not affect our conclusion that **9** has an $S_t = 2$ ground state lying 15.8 cm^{-1} below the first excited state of $S_t = 1$.

For **10**, a monotonous decrease of the magnetic moment with decreasing temperature, reaching a value of $\mu_{eff} = 2.72$ μ_B at 2 K, is observed. This clearly indicates a ground state with $S_t > 1$, which is attained by competing antiferromagnetic coupling between the wing-body ($J_{wb} = -14.4$ cm^{-1}) and the body-body ($J_{bb} = -19.4$ cm^{-1}) metal centres. The g value used for the simulation of the experimental data (data shown as squares in Figure 9) is $g = 2.13$. The solid line in Figure 9 is the simulation of the magnetic data with the abovementioned parameters. The evaluated lowest lying state of $S_t = 1$ lies 18 cm^{-1} below the second lowest state with $S_t = 2$.

Discussion

In the preceding section it has been experimentally established that **1** and **2**, with the Fe_4O_2 core, possess an $S_t = 0$ ground state. All thermally populated excited states are effectively only determined by J_{wb}, and the intrinsic character (i.e. antiparallel coupling) of the Fe(2)···Fe(1) interaction, $J_{bb} = J_{12}$, can be totally negated due to spin frustration,[20] making the J_{bb} interaction indeterminate in the $[Fe_4(\mu_3\text{-}O)_2]^{8+}$ core. On the other hand, **3** and **4**, with the Mn_4O_2 core, possess the ground state $S_t = 3$, irrespective of the nature of the bridging carboxylate, as has been found earlier.[9] In contrast, variation of the six bridging carboxylates from acetate (**5**), to benzilate (diphenylglycolate) (**6**), triphenyl acetate (**7**), benzoate (**8**), chloroacetate (**9**), and propionate (**10**), causes changes in the ground states for **5**−**10**, varying from $S_t = 1$ to 3, although the replacement of acetate in **5** by benzilate in **6** or benzoate in **8** has little structural effect within the $[Fe_2Mn_2O_2]^{8+}$ core, as is evident from the X-ray structures. These ground states have been confirmed by the field-dependent (0.5−6.5 T) magnetisation measurements. This indicates that *the "R" groups of the different carboxylic acids (RCOOH) might not be that innocent in mediating exchange interactions, as is commonly taken for granted.* The ground state does not represent the smallest spin state possible for the electronic d^n configuration when both interactions are antiferromagnetic. It is noteworthy in this respect that the ratio of competing coupling pathways, and not so much their absolute magnitudes, determines the electronic structures of these butterfly complexes. The ratio J_{MnMn}/J_{FeMn} varies from 1.39 for **5** (acetate), to 1.42 for **6** (benzilate), 1.85 for **7** (triphenyl acetate), 1.49 for **8** (benzoate), 1.68 for **9** (chloroacetate), and 1.35 for **10** (propionate). Figure 10 gives a selective spin-correlation diagram for the $Fe^{III}_2M^{III}_2(O)_2$ butterfly arrangement in which the energy (in units of J_{wb}) of a spin state denoted by (S_t, S_{Mn}, S_{Fe}) is plotted as a function of J_{bb}/J_{wb}. The correlation diagram clearly demonstrates the ground state variation as a function of the ratio of J_{bb}/J_{wb}, which is also consistent with the experimental findings for the different carboxylate bridging ligands within the heterometallic Fe_2Mn_2 core. As an example, the ground state $S_t = 3$ has component S_{Fe} and S_{Mn} values of 5 and 2, respectively. These values result from different relative orientations of $S_{Fe(3)}$, $S_{Fe(4)}$, $S_{Mn(1)}$, $S_{Mn(2)}$, which is represented below as an overall spin alignment due to spin frustration.

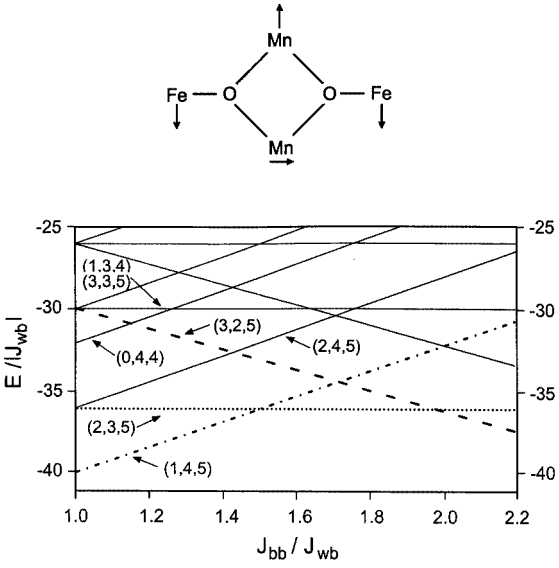

Figure 10. A selected energy-level diagram for the $[Fe_2Mn_2O_2]^{8+}$ core emphasising the ground state variation as a function of the ratio J_{bb}/J_{wb}; spin states are denoted by S_t, S_{Mn} and S_{Fe}, where $S_t = S_{Mn} + S_{Fe}$

Concluding Remarks

The results described in the present paper show that not only homometal tetranuclear metal clusters of Fe^{III} and Mn^{III} with a butterfly disposition, $[M_4(\mu_3\text{-}O)_2]^{8+}$, can be isolated, but also their mixed-metal analogues $[Fe^{III}_2M^{III}_2(\mu_3\text{-}O)_2]^{8+}$ are easily accessible. The tetranuclear cores are amenable to carboxylate bridging ligand variation but the structural parameters show insignificant variation. Although the spin ground states resulting from the exchange interactions within the $[Fe_4O_2]^{8+}$ and $[Mn_4O_2]^{8+}$ cores are little affected by the peripheral carboxylate ligands, variation of the six carboxylates (acetate, benzilate, triphenyl acetate, benzoate, chloroacetate propionate) causes significant changes in the electronic ground state structure ($S_t = 1-3$) of the $[Fe_2Mn_2O_2]^{8+}$ core. As the crystallographic data exclude steric effects as the cause of the ground state variation, the electronic (donor) properties seem to be responsible for the dependence of spin ground states on the nature of the bridging carboxylates. ably, spin coupling through carboxylate is not negligible, in contrast to the prevailing notion. Thus, future low molecular weight structural modelling of metalloproteins is expected to be guided by proper choice of the carboxylate ligands, in order to mimic the amino acids in the biomolecules.

The $[M_4O_2]^{8+}$ tetranuclear cores are structurally incongruent with currently known biological metal sites and hence might be irrelevant from a biological view point. However, being readily prepared and amenable to carboxylate variation, **5**−**10** have proven useful starting points to increase our knowledge on fine-tuning the spin properties of molecular aggregates. This fine-tuning is a result of spin frustration. Both the lowest and the intermediate spin ground states have been observed in the isostructural complexes **5**−**10** which vary only in the nature of their carboxylate bridging ligands. As is seen from Figure 10 "spin-frustration degeneracy" of the ground state leading to unusual electronic properties is expected for the $[Fe_2Mn_2O_2]^{8+}$ core if $J_{bb}/J_{wb} \approx 1.52$ and 2.0.

Experimental Section

General: ***CAUTION:*** Although we experienced no difficulties, the unpredictable behaviour of perchlorate salts necessitates extreme caution in their handling. The complex $LFeCl_3$ was prepared as described previously.[36] All other reagents were used as received. Elemental microanalyses were performed by the microanalytical laboratory Kolbe, Mülheim. Iron and manganese were determined spectrophotometrically by using pyridine-2,6-dicarboxylic acid as described in the literature.[37] Perchlorate ion was determined gravimetrically as tetraphenylarsonium perchlorate. Infrared spectra were measured as KBr disks with a Perkin−Elmer FT-IR spectrometer 2000. The magnetochemical measurements of the powdered samples were performed with a Quantum Design SQUID-Magnetometer, MPMS generally in a field of 1 T. The samples were put in gelatine capsules and the response function was measured four times for each of 32 measured temperature points. Diamagnetic contributions were estimated for each compound by making use of Pascal's constants. The Mössbauer spectrometer worked in the conventional constant-acceleration mode with a ^{57}Co/Rh source. Isomer shifts are given relative to α-Fe at room temperature.

X-ray Crystallography: The crystallographic data for **1**, **3**, **5**, **6** and **8** are summarised in Table 9. Graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) was used throughout. X-ray diffraction data were collected with a Siemens R3m/V diffractometer for **1** and **3**. Dark brown single crystals of **5**, **6** and **8** were fixed with perfluoropolyether on glass fibres and mounted on a Siemens SMART diffractometer equipped with a cryogenic nitrogen cold stream, and intensity data were collected at 100(2) K. Final cell constants were obtained from a least-squares fit of the setting angles of several thousand strong reflections. Intensity data were corrected for Lorentz and polarisation effects. An empirical absorption correction by Ψ scans was applied for **1** and **3**; intensity data of **5** and **8** were corrected for absorption using the program SADABS (G. M. Sheldrick, University of Göttingen, **1994**) giving maximum and minimum transmission factors of 0.928 and 0.736 for **5** and 0.853 and 0.768 for **8**. Intensities of **6** were left uncorrected. The Siemens ShelXTL, Vers. 5.0 (Siemens Industrial Automation, Inc., **1994**) software package was used for solution, refinement and artwork of the structures. Neutral atom scattering factors of the program were used. All structures were solved and refined by direct methods and difference Fourier techniques. Non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters. A crystallographic twofold axis passes through the central acetate bridge of the complex cation of **5** and the perchlorate anion is disordered since this axis is not coincident with the twofold axis of the ClO_4^- moiety. The disorder was satis-

factorily modelled by refining the complete anion slightly displaced from the axis with an occupation factor of 0.5. A phenyl group of a benzilate ligand in **6** was found to be disordered and therefore a split atom model was used. Two positions of the phenyl ring were refined with occupancies of 0.5 each. CCDC-187680 (**1**), -187681 (**3**), -187705 (**5**), -187706 (**6**) and -187707 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation of Complexes: Complexes **1** and **2** were prepared similarly by using a modified procedure for the corresponding acetate-bridged tetranuclear Fe^{III} compound.[4]

$[L_2Fe^{III}_4(salox)_2(\mu_3\text{-}O)_2(Ph_2C(OH)COO)_3]ClO_4$ (1): All operations were carried out under argon. $Fe(ClO_4)_2\cdot 6H_2O$ (0.30 g, 1 mmol), sodium diphenylglycolate (benzilate) (0.50 g, 2 mmol) and salicylaldoxime (0.27 g, 2 mmol) were added to vigorously stirred, degassed methanol (60 mL). The resulting suspension was stirred at room temperature for 1 h to yield a dark violet solution. This solution was charged with a solid sample of $[LFeCl_3]$[36] (0.33 g, 1 mmol), sodium diphenylglycolate (benzilate) (0.75 g, 3 mmol) and triethylamine (1 mL). The suspension was refluxed for 1 h and then filtered to remove some dark solid, identified as $[LFe^{III}(salox)_3Fe^{III}]$ by IR as described earlier.[24b] Sodium perchlorate monohydrate (0.4 g) was added to the filtrate and the red-brown solution was kept in air at ambient temperature. After 1 d, the red-brown crystals were filtered off and air-dried. Yield: 390 mg (47%). $C_{74}H_{85}ClFe_4N_8O_{19}$ (1648.35): calcd. C 53.89, H 5.19, N 6.79, Fe 13.54, ClO_4 6.03; found C 53.9, H 5.1, N 6.8, Fe 13.7, ClO_4 5.8. MS (ESI positive in CH_3CN/H_2O): *m/z* (%) = 1549 (100) $[M]^+$. IR (KBr): $\tilde{\nu}$ = 3472, 1600, 1569, 1157, 700, 669, 648, 638 cm^{-1}.

$[L_2Fe^{III}_4(salox)_2(\mu_3\text{-}O)_2(Ph_3CCOO)_3]ClO_4$ (2): Complex **2** was obtained similarly to complex **1** with sodium triphenylacetate used instead of sodium diphenylglycolate as the carboxylate source. Dark brown crystals were obtained. Yield: 410 mg (42%). $C_{92}H_{97}ClFe_4N_8O_{16}$ (1829.63): calcd. C 60.39, H 5.34, N 6.12, Fe 12.21, ClO_4 5.43; found C 58.4, H 5.4, N 6.0, Fe 12.3, ClO_4 5.5. MS (ESI positive in CH_3CN/H_2O): *m/z* (%) = 1730 (100) $[M]^+$. IR (KBr): $\tilde{\nu}$ = 1594, 1155, 1567, 699, 671, 652, 623 cm^{-1}.

$[L_2Mn^{III}_4(salox)_2(\mu_3\text{-}O)_2(Ph_2C(OH)COO)_3]ClO_4$ (3): Step 1: A suspension of diphenylglycolic acid (0.46 g, 2 mmol) and sodium hydroxide (0.08 g, 2 mmol) in water (30 mL) was stirred vigorously for 15 min. $MnCl_2\cdot 4H_2O$ (0.20 g, 1 mmol) was added and stirring was continued for a further 15 min. The precipitated solid was filtered off, washed thoroughly with water, and dried for 24 h under vacuum. Step 2: A suspension of the dried solid obtained from step 1 and salicylaldoxime (0.27 g, 2 mmol) in methanol (40 mL) containing triethylamine (1 mL) was refluxed in air for 0.5 h to obtain a dark green suspension. The green suspension was charged with $LMnCl_3$ [38] (0.33 g, 1 mmol) under argon and treated with triethylamine (0.5 mL). The resulting suspension was refluxed under argon for 0.5 h and then filtered to remove some green solid (presumably $[Mn(Hsalox)_3]$). Sodium perchlorate monohydrate (0.8 g) was added, and after 1−2 d the dark brown solution yielded deep brown crystals of **3**, which were collected by filtration and air-dried. Yield: 275 g (ca. 33%). $C_{74}H_{85}ClMn_4N_8O_{19}$ (1645.71): calcd. C 54.00, H 5.21, N 6.81, Mn 13.35, ClO_4 6.04; found C 53.8, H 5.1, N 6.8, Mn 13.1, ClO_4 5.9. IR (KBr): $\tilde{\nu}$ = 3472, 1617, 1592, 1574, 1158 cm^{-1}.

$[L_2Mn^{III}_4(salox)_2(\mu_3\text{-}O)_2(Ph_3CCOO)_3]ClO_4$ (4): Complex **4** was prepared similarly to **3** with triphenylacetic acid as the carboxylate source. Deep brown crystals were obtained in moderately good yield (45%). $C_{92}H_{97}ClMn_4N_8O_{16}$ (1825.99): calcd. C 60.51, H 5.35, N 6.14, Mn 12.03, ClO_4 5.45; found C 58.9, H 5.5, N 6.2, Mn 12.2, ClO_4 5.1. MS(ESI positive in CH_3CN): *m/z* (%) = 1727 (80) $[M]^+$, 1484 (100) $[M - L(Mn)(O)]^+$, 1439 (60) $[M - (C_6H_5)_3CCOO]^+$. IR (KBr): $\tilde{\nu}$ = 3441, 1587, 1541, 1152 cm^{-1}. Complex **4** was also prepared using CH_3CN as solvent.

$[L_2Fe^{III}_2(\mu_3\text{-}O)_2(salox)_2(\mu\text{-}OOC\cdot CH_3)_3Mn^{III}_2]ClO_4$ (5): "Basic manganese(III) acetate"[39] (0.27 g, 1 mmol) was added to a vigorously stirred solution of salicylaldoxime (0.135 g, 1 mmol) in methanol (60 mL). The resulting suspension was stirred at room temperature for 0.5 h to yield a dark brown solution which was then charged with a solid sample of $LFeCl_3$ (0.33 g, 1 mmol), sodium acetate (0.24 g, 3.0 mmol) and triethylamine (2 mL). The suspension was refluxed for 1 h and then filtered to remove some green solid (presumably $[Mn(Hsalox)_3]$). Sodium perchlorate monohydrate (0.4 g) was added to the clear solution and the red-brown solution was kept at ambient temperature in a closed vessel. After 12 h, the dark brown crystals were filtered off and air-dried. Yield: 400 mg (70%). $C_{38}H_{61}ClFe_2Mn_2N_8O_{16}$ (1142.98): calcd. C 39.93, H 5.38, N 9.80, Fe 9.77, Mn 9.61, ClO_4 8.70; found C 39.7, H 5.4, N 9.8, Fe 9.9, Mn 9.5, ClO_4 8.9. IR (KBr): $\tilde{\nu}$ = 1594, 1544, 1155, 755, 743, 663 cm^{-1}.

$[L_2Fe^{III}_2(\mu_3\text{-}O)_2(salox)_2(\mu\text{-}OOC\cdot C(OH)Ph_2]_3Mn^{III}_2]ClO_4$ (6): A solution containing $MnCl_2\cdot 4H_2O$ (0.20 g, 1 mmol), salicylaldoxime (0.27 g, 2 mmol) diphenylglycolic acid (0.63 g, 3 mmol) and triethylamine (1 mL) in methanol (60 mL) was heated to reflux for 0.5 h. $LFeCl_3$ (0.33 g, 1 mmol) and sodium diphenylglycolate (0.25 g, 1 mmol) were added to the resulting suspension. The mixture was refluxed for 1 h and then filtered to remove some green solid. The red-brown solution was kept at room temperature following addition of $NaClO_4\cdot H_2O$ (0.8 g). After 24 h, the deep brown crystals were filtered off and air-dried. Yield: 510 mg (ca. 62%). $C_{74}H_{85}ClFe_2Mn_2N_8O_{19}$ (1647.53): calcd. C 53.95, H 5.20, N 6.80, Fe 6.78, Mn 6.67, ClO_4 6.04; found C 53.80, H 5.1, N 6.8, Fe 6.5, Mn 6.4, ClO_4 5.5. MS (ESI positive in CH_3CN): *m/z* (%) = 1547 (100), 1548 (90) $[M]^+$. IR (KBr): $\tilde{\nu}$ = 3742, 1617, 1592, 1540, 1158, 704, 670, 638, 603 cm^{-1}.

$[L_2Fe^{III}_2(\mu_3\text{-}O)_2(salox)_2(\mu\text{-}OOC\cdot CPh_3)_3Mn^{III}_2]ClO_4$ (7), $[L_2Fe^{III}_2(\mu_3\text{-}O)_2(salox)_2(\mu\text{-}OOC\cdot Ph)_3Mn^{III}_2]ClO_4$ (8), $[L_2Fe^{III}_2(\mu_3\text{-}O)_2(salox)_2(\mu\text{-}OOCCH_2Cl)_3Mn^{III}_2]ClO_4$ (9), $[L_2Fe^{III}_2(\mu_3\text{-}O)_2(salox)_2(\mu\text{-}OOC\cdot CH_2CH_3)_3Mn^{III}_2]ClO_4$ (10): Complexes **7**−**10** were prepared according to the same protocol for **6** using triphenylacetic acid (**7**), benzoic acid (**8**), chloroacetic acid (**9**) or propionic acid (**10**) as the bridging carboxylate sources. Red-brown crystals were obtained with yields in the range 40−50%.

7: $C_{92}H_{97}ClFe_2Mn_2N_8O_{16}$ (1827.81): calcd. C 60.45, H 5.35, N 6.13, Fe 6.11, ClO_4 5.44; found C 58.9, H 5.4, N 6.3, Fe 6.0, Mn 6.01, ClO_4 5.8. MS (ESI positive in CH_3CN/H_2O): *m/z* (%) = 1727 (100) $[M]^+$. IR (KBr): $\tilde{\nu}$ = 1591, 1540, 701, 670, 645, 612 cm^{-1}.

8: $C_{53}H_{67}ClFe_2Mn_2N_8O_{16}$ (1329.18): calcd. C 47.89, H 5.08, N 8.43, Fe 8.40, Mn 8.27, ClO_4 7.48; found C 48.1, H 5.0, N 8.5, Fe, 8.4, Mn, 8.2, ClO_4 7.9. IR (KBr): $\tilde{\nu}$ = 1594, 1541, 1157, 738, 723, 663, 636 cm^{-1}.

9: $C_{38}H_{58}Cl_4Fe_2Mn_2N_8O_{16}$ (1246.30): calcd. C 36.62, H 4.69, N 8.99, Fe 8.96, Mn 8.82, ClO_4 8.00; found C 35.0, H 5.0, N 9.0, Fe 9.2, Mn 8.8, ClO_4 8.1. IR (KBr): $\tilde{\nu}$ = 1594, 1543, 1156, 757, 745, 663 cm^{-1}.

10: $C_{41}H_{67}ClFe_2Mn_2N_8O_{16}$ (1185.06): calcd. C 41.55, H 5.70, N 9.46, Fe, 9.43, Mn 9.27, ClO_4 8.39; found C 42.0, H 5.6, N 9.6, Fe 9.1, Mn 9.5, ClO_4 8.4. IR (KBr): $\tilde{\nu}$ = 1592, 1538, 1158, 704, 672, 640, 602 cm^{-1}.

Acknowledgments

This work was initiated in Bochum. Our thanks are due to Mrs. M. Hess, H. Schucht (Mülheim) and M. Winter (Bochum) for their technical assistance. Support from the Max Planck Society and Fonds der Chemischen Industrie is gratefully acknowledged.

Chiral Complexes of Rh^{I} Containing Binaphthalene-Core P,S-Heterobidentate Ligands − Synthesis, Characterization, and Catalytic Activity in Asymmetric Hydrogenation of α,β-Unsaturated Acids and Esters

Serafino Gladiali,*[a] Fabrizia Grepioni,[a] Serenella Medici,[a] Antonio Zucca,[a] Zoltán Berente,[b] and László Kollár[c]

Keywords: S ligands / P ligands / Rhodium / Asymmetric catalysis / Hydrogenations

The enantiopure complexes **3a** and **3b** $[Rh(NBD)(P,S)]^{+}BF_4^{-}$ [P,S = (*S*)-2-(diphenylphosphanyl)-2′-(methylthio)-1,1′-binaphthalene (**a**); (*S*)-2-(diphenylphosphanyl)-2′-(isopropylthio)-1,1′-binaphthalene (**b**)] have been prepared from $[Rh(NBD)(THF)_2]^{+}BF_4^{-}$ by reaction with a stoichiometric amount of the appropriate P,S-heterobidentate ligand. Single-crystal X-ray analysis of the *S*-methyl derivative shows that the seven-membered chelate ring is locked in a boat-like conformation with the methyl group in the equatorial position. Variable-temperature NMR measurements confirm that this conformation is maintained in solution and that the dynamic behaviour displayed by the complex is due to pseudo-rotation of the diolefin. Complexes **3** have been tested in the asymmetric hydrogenation of α,β-unsaturated acids and esters. Enantioselectivities of up to 60% *ee* have been recorded.

Introduction

The catalytic activity of transition metal complexes is largely dependent on the structure of the supporting ligands. The nature of the donor atoms is crucial because it affects substantially the electron density at the metal centre as well as the geometric properties of the corresponding complexes.

Owing to the presence of two donors of diverse ligating properties, bidentate P,X-heterodonor ligands, where the chelate coordination of a phosphanyl group (P) is supported by a different heteroatom (X), are sometimes endowed with a peculiar catalytic activity. Within the family of P,X-heterobidentate ligands, the P,S-pair deserves particular attention. When the sulfur atom is in a low oxidation state, as in sulfides, the softness of the S-donor is similar to that of the P-donor in a phosphane. Phosphanyl sulfides can be thus regarded as heterobidentate ligands that differ little in the ligating strength of the two donors. Consequently, such ligands are expected to have a fairly weak hemilabile character and to show a strong propensity towards chelate coordination to the metal atom.[1]

An additional interesting feature of the S-donor of a sulfide group is that upon coordination the S-centre becomes stereogenic. The stereochemistry at the S-binding site depends on the chiral backbone of the ligand and on the steric demand of the alkyl substituent at the S-centre. This results in the formation of diastereomeric complexes featuring either a matching or a mismatching combination of chiral elements; a fact that is expected to have a significant bearing on the use of these ligands in asymmetric catalysis.

Various chiral P,S-heterobidentate ligands have been reported recently. Phosphito sulfide derivatives based on the xylofuranose framework have been used in the Ir-catalysed asymmetric hydrogenation of itaconic acid (51% *ee*).[2] Glucopyranose-substituted phosphanyl sulfides are able to stabilize otherwise elusive Pd^0 complexes.[3]

Bis(phosphinite) ligands with a tetrahydrothiophene backbone have been synthesised and used in rhodium-catalysed enantioselective hydrogenation of methyl acetamidocinnamate. A tridentate coordination of the ligand, forming thioether-bridged dinuclear species, has been proposed.[4]

Novel P,S-bidentate ligands possessing an oxathiane ring condensed onto pulegone[5] or norbornane[6] moieties led to quite good enantioselectivity in the Co-catalysed asymmetric intramolecular Pauson−Khand reaction and in the Pd-catalysed asymmetric allylic substitution reaction, respectively.

Mixed phosphorus/sulfur ligands, where the thioether fragment is flanked by a diarylphosphinito[7] or a diaryl-

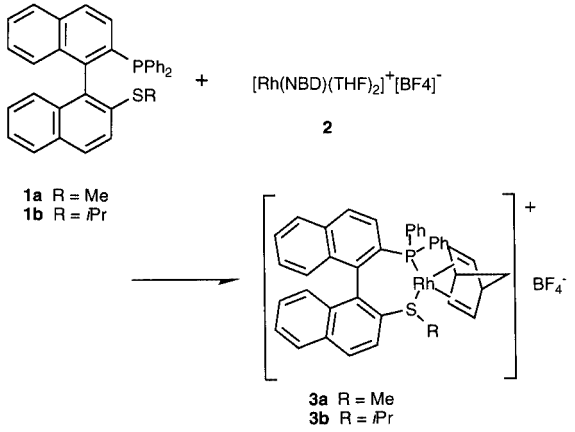
phosphanyl[8] unit supported on chiral 1,2-disubstituted aliphatic backbones, proved to be highly efficient in Pd-catalysed enantioselective allylic substitution and in Rh-catalysed hydrogenation, respectively.

Atropisomeric 1,1′-binaphthyl-templated diphosphanes such as BINAP are among the most efficient chiral ligands for asymmetric hydrogenation. Recently, we reported on the synthesis of BINAPS,[9] a heterobidentate version of BINAP in which one of the two diphenylphosphanyl substituents is replaced by an alkylthio group. BINAPS derivatives performed well in some Pd-catalysed asymmetric reactions, such as allylic alkylation[10] and hydrosilylation,[11] but were less satisfactory in Rh-catalysed processes such as hydroformylation and H-transfer reduction.[11]

We report here on further investigations into the preparation, dynamic behaviour and utilization in enantioselective hydrogenation of such BINAPS-based Rh complexes.

Results and Discussion

The required ligands (*S*)-**1a** and (*S*)-**1b** were synthesised in enantiopure form as reported previously.[11] The preparation of the enantiopure complexes **3a** and **3b** was accomplished as reported in Scheme 1 by treating the rhodium complex $[Rh(NBD)(THF)_2]^+BF_4^-$ (**2**) (NBD = 1,4-norbornadiene) with a stoichiometric amount of (*S*)-**1a** and (*S*)-**1b**, respectively. The required intermediate adduct **2** was prepared in situ from the corresponding chloro-bridged dimer $[Rh(NBD)Cl]_2$ and $AgBF_4$.[12] The isolated yields of the complexes **3a** and **3b** were in the range of 60−70%.



Scheme 1. Synthesis of complexes **3a** and **3b**

The molecular structure of the complex cation **3a** is depicted in Figure 1, together with the labelling scheme.

The Rh atom has a square-planar coordination geometry involving the double bonds of the norbornadiene ligand, the P atom and the stereogenic S-donor. The configuration at the newly created S-stereocentre is (*R*). The Rh−P and Rh−C bond lengths are comparable to those previously observed in $[Rh(NBD)(BINAP)]^+$.[13] The dihedral angle between the two naphthyl ligands (ca. 75°) is comparable to the 74.4° observed in the BINAP complex.

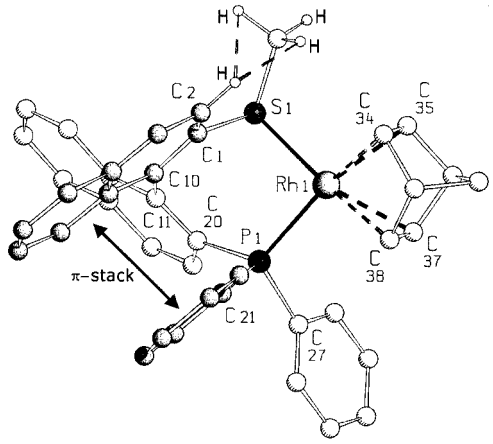


Figure 1. Ball-and-stick representation of the cationic complex in **3a**; selected structural parameters [Å]: Rh(1)−C(34) 2.200(5), Rh(1)−C(35) 2.216(5),Rh(1)−C(37) 2.181(5), Rh(1)−C(38) 2.144(6), Rh(1)−P(1) 3.290(1), Rh(1)−S(1) 2.343(1), P(1)−C(20) 1.838(4), S(1)−C(1) 1.793(4), C(34)−C(35) 1.385(7), C(37)−C(38) 1.356(9); the longest contacts involving H(2) and the H_{Me} atoms are shown by dotted lines; all remaining H atoms omitted for clarity

The H atom bound to C(2) is in close contact with the hydrogen atoms of the methyl group on the S atom; if free reorientation of the methyl group is assumed, the "dynamic" contacts between the H atoms range from 1.84 to 2.46 Å (assuming a normalised distance of 1.08 Å for the $C_{(by)}$−H group). One of the two extremes, with two equivalent $H_{CH}\cdots H_{Me}$ contacts of 2.46 Å, is shown in Figure 1.

Contrary to the BINAP complex, where the seven-membered chelate ring adopts a skew conformation in the solid state,[13] the seven-membered ring in **3a** adopts a boat-like conformation (see Figure 2), with the Rh(1), P(1), C(10), and C(1) atoms constituting the flat part of the boat (maximum deviation from the average plane 0.05 Å). The sulfur and C_{methyl} atom elevations from this plane are 1.21 and 1.28 Å, respectively; thus, the methyl group bound to the sulfur atom is in an equatorial position with respect to the ring.

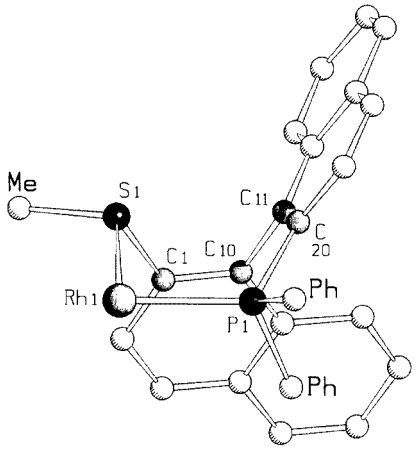

Figure 2. Boat-like conformation adopted by the seven-membered chelate ring in complex cation **3a**

Crystalline **3a** contains a stoichiometric amount of $CHCl_3$ solvent per formula unit. The H atom belonging to the solvent molecule interacts via bifurcated hydrogen bonding of the CH···F type with the BF_4^- anion (see Figure 3). The (C)H···F distances (after normalisation of the C−H distance to the neutron value of 1.08 Å) are 2.26(1) and 2.24(1) Å, and compare well with the shortest CH···F interactions observed for organometallic salts containing BF_4^- or PF_6^- anions.[14]

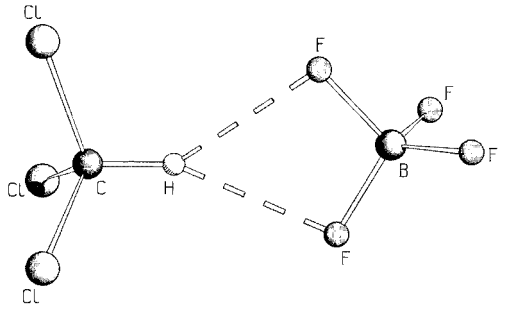

Figure 3. Bifurcated CH···F hydrogen bond interaction between the $CHCl_3$ solvent molecule and BF_4^-

One of the phenyl substituents bound to the phosphorus atom and the portion of the binaphthyl moiety bound to S(1) are arranged in a π-stacking fashion, with an average distance between the two mean planes of ca. 3.5 Å (see Figure 1).

In the ^1H NMR spectrum of **3a** ($CDCl_3$ solution) four lines, each one accounting for two protons, can be observed for the coordinated NBD at 303 K (Figure 4). The signals of the allylic (δ = 4.04 ppm) and the olefinic protons (δ = 4.40 and 4.67 ppm) are broad singlets, while the bridging methylene group resonates as a sharp singlet (δ = 1.50 ppm). When the temperature is lowered to 273 K, the olefinic protons' signal at δ = 4.67 ppm undergoes line broadening, becoming extremely broad at 258 K and practically disappearing at 243 K. The second olefinic signal at δ = 4.40 ppm also broadens, but at lower temperatures [ν(1/2) ≈ 20 Hz at 258 K], and practically disappears at 223 K. The allylic and the methylenic signals at δ = 4.04 and 1.50 ppm, respectively, are still observable even at 223 K [(ν(1/2) ≈ 40 Hz and 25 Hz, respectively]. From the NMR spectroscopic data it is apparent that a dynamic process is occurring in solution which averages the protons of the NBD ligand in the bound state.

The methyl peak appears at δ = 2.59 ppm as a sharp doublet (J = 1.5 Hz). This is due to ^3J(Rh,H) coupling as demonstrated by a selective $^1H\{^{31}P\}$ decoupling. The shape, chemical shift and coupling constant of this signal remain unchanged over the whole temperature range investigated (303−203 K), suggesting that in this interval no dissociation of the S-donor from the metal atom occurs. Irradiation of this peak causes a significant NOE enhancement of the signal at δ = 7.67 ppm which should be attributed to the naphthyl proton on the carbon atom adjacent to the *S*-substituted one. This is consistent with an equatorial location of the *S*-methyl group and confirms that the solid-state structure is preserved in solution.

The pattern of the aromatic protons undergoes some minor variation with temperature, but the isolated peaks remain sharp and the coupling constants are substantially unchanged.

The protons were assigned to the corresponding carbon atoms by a ^1H-^{13}C HSQC experiment. In the ^{13}C NMR spectrum all the carbon signals but those at δ = 81.61, 71.25, and 66.50 ppm show sharp lines. These were assigned to the olefinic and the methylenic carbon atoms of norbornadiene, respectively. Finally, the sharp doublet in the ^{31}P NMR spectrum [^1J(Rh,P) = 161.7 Hz] was not affected by the temperature variation.

The NOESY experiments show that the S−CH_3 group gives cross peaks with both olefinic signals at δ = 4.40 and 4.67 ppm. This tells us that the two vinylic protons of the same double bond of NBD are not averaged and provides further evidence for the equatorial position of the methyl group. If the methyl group were axial, only one of the two protons on the same double bond would give a cross peak (Figure 5).

The NOESY spectra also show close contacts between the naphthyl proton adjacent to the S atom (signal at δ = 7.67 ppm) and the olefinic proton of NBD (signal at δ = 4.67 ppm). Thus, the more deshielded olefinic signal could confidently be assigned to the olefinic proton H^a (H^d) located below the average plane of the chelate ring (Figure 5).

The olefinic protons (signals at δ = 4.40 and 4.67 ppm) also show contacts with the *ortho* protons of the two different phenyl substituents of the PPh_2 unit (signals at δ = 7.38 and 7.41 ppm).

These NMR experiments indicate that the dynamic process the complex experiences in solution results in averaging protons H^a with H^d and protons H^b with H^c (see Figure 5).

Dynamic behaviour of this type has been previously observed in cationic (diolefin)rhodium complexes with bidentate P,S- or P,N-ligands. This has been attributed to a mechanism involving Rh−S[15,16] or Rh−N[16] bond dissociation, followed by rotation around the remaining Rh−P bond and subsequent recombination of the dissociated bond.

Although the S-stereocentre might be labilised more readily than the P-centre, the present NMR evidence indicates that the sulfur atom remains tightly bound to the metal atom throughout. Chemical shift, coupling constant and sharpness of the signal of the *S*-methyl group remain unchanged over the temperature range investigated. No shift of the methyl group towards that of the free ligand is observed; such a shift would be expected if the sulfur donor were displaced from the metal atom. Furthermore, the doublet at δ = 6.01 ppm, regarded as diagnostic of the chelate coordination of the binaphthyl ligand, remains unchanged from 223 to 303 K.

All this evidence indicates that dissociation/inversion processes at the sulfur atom or conformational interconversions of the seven-membered ring do not take place. Instead, it appears that in solution both the chelate coordination of the P,S-ligand and the configurational integrity of

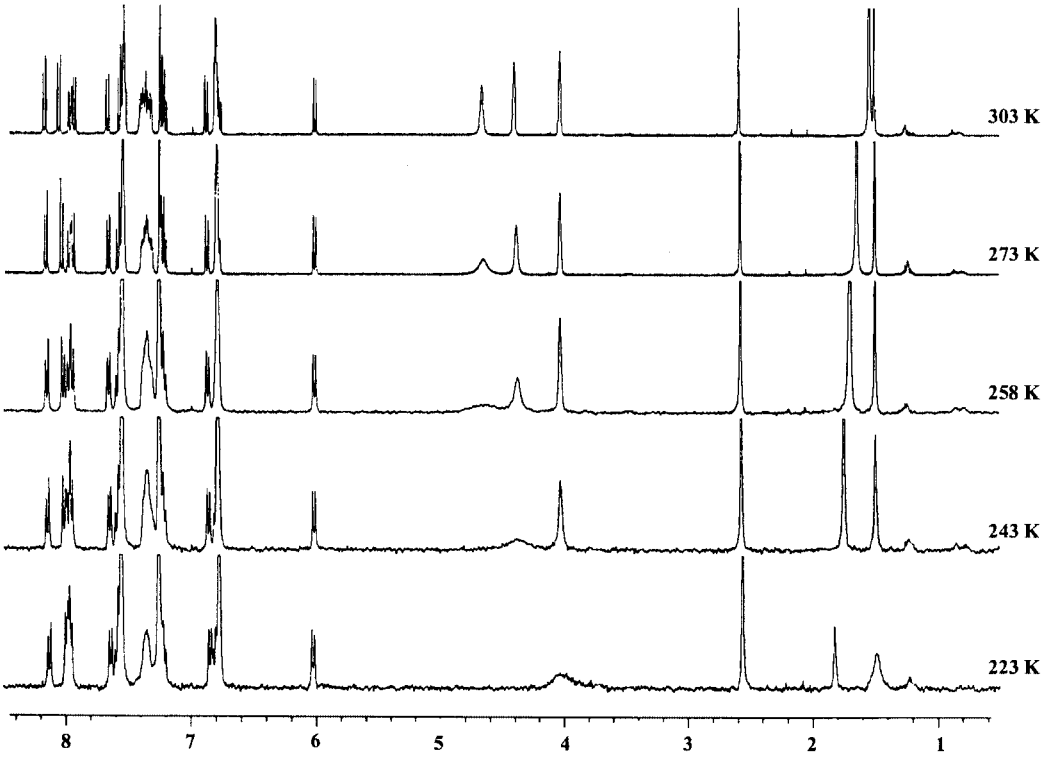

Figure 4. Variable-temperature ^1H NMR spectrum of **3a**

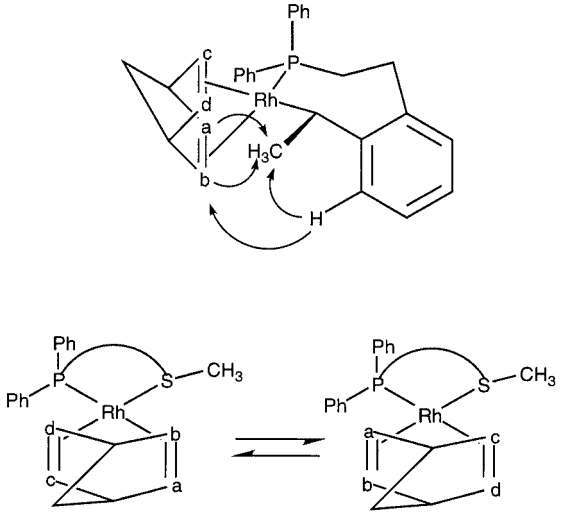

Figure 5. Representation of NOE contacts in **3a**

the S-stereocentre in the bound state are preserved over the temperature range investigated.

An alternative plausible mechanism involves a Barry pseudo-rotation promoted by coordination of a donor at the fifth position of the metal atom. Such a reaction path has been proposed previously for a (1,5-cycloctadiene)Rh complex containing 2-(diphenylphosphanyl)pyridine.[17] However, this possibility was not substantiated as the ^1H NMR spectra registered in $CDCl_3$ after addition of donor solvents such as THF, or in [D_6]acetone, show no significant change with respect to those registered in plain $CDCl_3$.

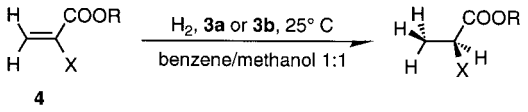
As it seems even more unlikely that the phosphorus atom is involved in a displacement/recombination process, the observed results should be ascribed to a dynamic process of the diolefin. This should proceed through an olefin pseudo-rotation, prompted by dissociation of one rhodium−olefin bond, followed by rotation through 180° around the remaining Rh−olefin bond and subsequent rebuilding of the chelate coordination of the diolefin. This conclusion fits better the experimental finding that the dynamic behaviour of the NBD protons is far more pronounced than that of the protons of the backbone of the P,S-ligand.

The isopropyl derivative **3b** shows in solution the same dynamic behaviour as **3a** as judged from the similar NMR pattern. The methylenic, allylic and olefinic protons of the norbornadiene ligand give rise to four broad singlets at δ = 1.49, 4.00, 4.48, and 4.61 ppm (2 H each), respectively. The signals of the diastereotopic methyl groups of the isopropyl group appear at δ = 1.18 and 1.28 ppm. The chelating coordination of **1b** is confirmed by the presence of the aromatic doublet at δ = 5.95 ppm.

Asymmetric Hydrogenation of α,β-Unsaturated Acids and Esters

Hydrogenation tests were performed on acrylic acid derivatives **4a**−**4c** (Scheme 2) at room temperature in methanol/benzene (1:1). A slight positive pressure of hydrogen was employed because at 1 bar the reaction was too sluggish. Even so, the catalytic activity of complexes **3a** and **3b** was rather low and fairly long reaction times were required

to attain a satisfactory conversion (Table 1). The two complexes exhibited comparable catalytic activity and both led to products of the same (*R*) configuration, although the methyl derivative **3a** was notably more efficient than the isopropyl counterpart **3b** and in all runs produced much higher *ee*s.



Scheme 2. Asymmetric hydrogenation of α,β-unsaturated carboxylic acids and esters **4a**−**4c**

Under our reaction conditions, the acid **4b** was hydrogenated with 49% *ee* by **3a**. This is basically the same *ee* obtained with the Rh complex with BINAPP′ [2-(Diphenylphosphanyl)-2′-(di-*o*-tolylphosphanyl)-1,1′-binaphthalene] (46% *ee*) and is much higher than the 13% *ee* we obtained with the corresponding Rh complex with BINAP.[18]

The improvement over the chelate diphosphane-based catalysts was more pronounced with the methyl ester **4a** where *ee*s obtained with BINAP (21%) and BINAPP′ (40%)[18] were outperformed by that obtained with complex **3a** (60%). This value is among the highest obtained in Rh-catalysed asymmetric hydrogenation using chiral P,S-heterodonor ligands. It is also close to that reported for the hydrogenation of the acid **4b** with a preformed [(*S*)-(BINAP)Rh(MeOH)$_2$]$^+$ClO$_4^-$ complex (67% *ee*).[19]

Both complexes **3a** and **3b** proved to be effective in hydrogenating dimethyl itaconate (**4c**), leading to high conversions (93 and 94%, respectively). Unfortunately, this activity was not matched by a high selectivity, and *ee*s were decidedly poor both with **3a** and **3b** (8% and 2% *ee*, respectively).

In all these experiments the prevailing enantiomer showed the (*R*) configuration, the same as obtained with (*S*)-BINAP and (*S*)-BINAPP′. Therefore, the stereochemistry of the hydrogenation of these substrates is basically driven by the handedness of the chiral backbone; the stereogenicity at the sulfur plays a minor, albeit cooperative role, in the transfer of the chiral information.

Further work is in progress to determine the effect of a substituent of higher steric demand on the sulfur atom, and whether this situation can be reversed by introducing a bulkier group such as *tert*-butyl on this donor centre.

Experimental Section

General: Some ^{1}H, ^{31}P, and ^{13}C NMR spectra, as well as NOESY measurements (mixing time = 500 ms) were carried out with a Varian VXR-S 300 instrument at 299.9 MHz, 121.4 MHz and 75.4 MHz, respectively. ^{1}H and ^{31}P variable-temperature measurements at 400 MHz and 161.9 MHz, respectively, as well as ^{1}H-^{13}C HSQC experiments were run with a Varian INOVA 400 WB spectrometer using a Highland VT unit. Chemical shifts, given in ppm, are referred to internal TMS (^{1}H and ^{13}C) or external 85% H_3PO_4 (^{31}P); coupling constants are in Hz. The two-dimensional experiments (NOESY and ^{1}H-^{13}C HSQC) were performed using standard pulse sequences. Solvents were dried and distilled under nitrogen before use. All the reactions were performed under argon. [Rh(NBD)Cl]$_2$ was purchased from Strem Chemicals and used without further purification. The ligands, (*S*)-2-(diphenylphosphanyl)-2′-(methylthio)-1,1′-binaphthalene (**1a**) and (*S*)-2-(diphenylphosphanyl)-2′-(isopropylthio)-1,1′-binaphthalene (**1b**), were prepared as previously reported.[11] The *ee*s of the samples from the catalytic runs were determined with a Hewlet Packard 5890A gas chromatograph fitted with a 25-m capillary column coated with diethyl *tert*-butylsilyl-β-cyclodextrin PS 086 (i.d. 0.25 mm), purchased from MEGA (Legnano, Italia), using He as the carrier (head pressure 60 kPa, split ratio 100).

Preparation of [(*S*)-2-(Diphenylphosphanyl)-2′-(methylthio)-1,1′-binaphthalene](2,5-norbornadiene)rhodium(i) Tetrafluoroborate (3a): $AgBF_4$ (39 mg, 0.2 mmol) was added to a solution of [Rh(NBD)Cl]$_2$ (48 mg, 0.1 mmol) in THF (10 mL). After stirring for 1 h, the mixture was filtered through Celite and (*S*)-2-(diphenylphosphanyl)-2′-(methylthio)-1,1′-binaphthalene (100 mg, 0.2 mmol) was added to the resulting yellow solution. A yellow solid precipitated immediately and was recovered by filtration. Yield 107 mg (70%). Crystals of **3a**$CHCl_3$ suitable for X-ray structure determination were obtained by slow concentration of a chloroform solution. ^{1}H NMR ($CDCl_3$ 298 K): δ = 1.50 [br. s, 2 H, CH_2 (NBD)], 2.59 (d, *J* = 1.5 Hz, 3 H, SCH_3), 4.04 [br. s, 2 H, allylic CH (NBD)], 4.40 and 4.67 [br. s, 2 × 2 H, olefinic CH (NBD)], 6.01 (d, *J* = 8.6 Hz, 1 H, Ar), 6.76−6.8 (m, 4 H, Ar), 6.88 (d, *J* = 8.6 Hz, 1 H, Ar), 7.20−7.26 (m, 2 H), 7.30−7.44 (m, 4 H),

Preparation of [(*S*)-2-(Diphenylphosphanyl)-2′-(isopropylthio)-1,1′-binaphthalene](2,5-norbornadiene)rhodium(i) Tetrafluoroborate (3b): Compound **3b** was obtained by the procedure described for **3a** except that after the addition of the ligand (*S*)-2-(diphenylphosphanyl)-2′-(isopropylthio)-1,1′-binaphthalene an orange solution was obtained. The solution was stirred for 1 h then concentrated. The orange precipitate formed after addition of pentane was recovered by filtration. Yield 99 mg (62%). ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.18 (d, J = 6.6 Hz, 3 H, CH_3), 1.28 (d, J = 6.6 Hz, 3 H, CH_3), 1.50 [s, 2 H, CH_2 (NBD)], 3.88 (sept, J = 6.6 Hz, 1 H, CH), 4.00 [s, 2 H, allylic CH (NBD)], 4.50 [s, 2 H, olefinic CH (NBD)], 4.6 [s, 2 H, olefinic CH (NBD)], 5.95 (d, J = 8.1 Hz, 1 H, Ar), 6.71−6.80 (m, 4 H, Ar), 6.94 (d, J = 8.4 Hz, 1 H, Ar), 7.21−7.58 (m, 11 H, Ar), 7.73 (d, J = 7.8 Hz, 1 H, Ar), 7.98 (m, 2 H, Ar), 8.14 (d, J = 8.7 Hz, 1 H, Ar), 8.27 (d, J = 8.7 Hz, 1 H, Ar) ppm. $^{31}P\{^{1}H\}$ NMR ($CDCl_3$, 298 K): δ = 26.8 [d, ^{1}J(Rh,P) = 161 Hz] ppm. $[\alpha]_D^{25}$ = −386 (c = 0.5, $CHCl_3$).

X-ray Structural Determination of 3a: X-ray diffraction data for **3a** were collected at 293 K with a Bruker diffractometer (SMART) (Mo-K_α radiation, λ = 0.71073 Å) and corrected for absorption. $C_{41}H_{32}BCl_3F_4PRhS$, M_r = 883.77, triclinic, space group $P\bar{1}$, a = 9.1724(7), b = 10.7757(7), c = 10.9453(8) Å, α = 68.456(2), β = 88.282(2), γ = 72.591(2)°, V = 956.2(1) Å^3, Z = 1, d_c = 1.535 g·cm^{-3}, μ = 0.802 mm^{-1}, F(000) = 446, 11681 reflections measured, refinement on F^2 (8621 independent reflections) for 446 parameters, $wR2$ (on F^2, all data) = 0.0906, $R1$ [on F, $I > 2\sigma(I)$] = 0.0358. The computer program SHELXL-97[20] was used for structure solution and refinement. All non-H atoms were treated anisotropically. The naphthyl moieties were refined as rigid groups. Hydrogen atoms were added in calculated positions and refined riding on their respective C atoms. For all molecular representations the graphic program SCHAKAL99[21] was used. Intermolecular interactions were calculated by means of the program PLATON.[22] CCDC-189656 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Activation of C−S Bonds in Organosulfur Compounds Containing α,β-Unsaturated Ketone Systems by Carbonylruthenium and -iron Complexes

Cecilio Alvarez-Toledano,[a] Esther Delgado,*[b] Bruno Donnadieu,[c] M. Angeles Gómez,[b] Elisa Hernández,[b] Gema Martín,[b] Fernando Ortega-Jiménez,[a] and Félix Zamora[b]

Keywords: Vinylidene ligands / Clusters / Iron / Carbonyl ligands / Ruthenium

Vinylidenetetraruthenium clusters have been obtained from the reactions between $[Ru_3(CO)_{12}]$ and $[CH_3C(O)CH=C(SCH_3)_2]$ or $[(C_5H_5)Fe\{C_5H_4CH=CHC(O)CH=C(SCH_2CH_2S)\}]$ by cleavage of the S–C sp^2 bonds in these ligands. An excess of $[CH_3C(O)CH=C(SCH_3)_2]$ afforded the dinuclear complex $[Ru_2(CO)_4(\mu\text{-}SCH_3)_2\{\eta^2\text{:}\kappa\text{-}C,O\text{-}C(SCH_3)CHC(O)CH_3\}_2]$, which was then converted into the vinylidene cluster $[Ru_4(CO)_{10}(\mu\text{-}SCH_3)_2\{\mu_4,\eta^3\text{:}\kappa\text{-}C,C,O\text{-}C{=}CHC(O)CH_3\}]$ in the presence of more of the carbonylruthenium complex. However, the carbonyliron complex led to the formation of the dinuclear compounds $[Fe_2(CO)_4(\mu\text{-}SCH_3)_2\{\eta^2\text{:}\kappa\text{-}C,O\text{-}(SCH_3)CHC(O)CH_3\}_2]$ and $[Fe_2(CO)_5\{\mu,\eta^4\text{:}\kappa\text{-}C,O,S,S\text{-}(SCH_2CH_2S)C{=}CHC(O)CH{=}CHC_5H_4\}Fe(C_5H_5)]$. All of the new complexes exhibit a pentametallacycle group as a consequence of the rupture of the S–C bonds, as well as the presence of the C(O)R substituent in these ligands. The compounds have been characterised by analytical and spectroscopic data and the crystal structures of some of them have been solved by X-ray diffraction.

Introduction

The chemistry of transition metals with organosulfur ligands is being widely developed due to its importance in a variety of applications such as hydrodesulfurisation processes, bioinorganic chemistry and synthetic procedures.[1] The activation of S−C bonds is known in the synthesis of sulfur cluster compounds.[2] We have previously reported[3] that the reaction between $Ru_3(CO)_{12}$ and $S(C{\equiv}CSiMe_3)_2$ affords two compounds $[Ru_3(CO)_9(\mu,\eta^2\text{-}SC{\equiv}CSiMe_3)(\mu_3,\eta^2\text{-}C{\equiv}CSiMe_3)]$ and $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}S)(\mu_4,\eta^2\text{-}C(SiMe_3)C(C{\equiv}CSiMe_3)]$ by cleavage of one or two of the S−C bonds in the sulfide ligand.

On the other hand, although clusters containing vinylidene ligands bonded to several metals have been considered as models in processes that imply the formation of hydrocarbons, as far as we know not many homopolynuclear derivatives have been prepared.[4]

Finally, in spite of the use of carbonyliron and -ruthenium compounds containing α,β-unsaturated ketone systems as precursors in organic syntheses,[5] there are few reports on the coordination chemistry of these multifunctional ligands with transition metals.[6]

Taking all of the above into account we are interested in exploring the chemistry of carbonylruthenium and -iron complexes and some organosulfur ligands, which have an α,β-unsaturated ketone group in common, in order to prepare some vinylidene clusters. Here, we report on the preparation of some dinuclear and cluster compounds containing pentametallacycle and thiolate groups. These compounds have been characterised by analytical and spectroscopic data and the structures of some of them have been confirmed by X-ray diffraction.

Results and Discussion

Treatment of $[Ru_3(CO)_{12}]$ and $[CH_3C(O)CH=C(SCH_3)_2]$ (1:1 stoichiometry) in the presence of $ONMe_3$ in toluene at 85 °C afforded the new compound $[Ru_4(CO)_{10}(\mu\text{-}SCH_3)_2\{\mu_4,\eta^3\text{:}\kappa\text{-}C,C,O\text{-}C{=}CHC(O)CH_3\}]$ (**1**) (Scheme 1) which was isolated in 35% yield as orange crystals after purification by column chromatography on silica gel, followed by recrystallisation from hexane at −20 °C. Compound **1** was characterised by analytical and spectroscopic data. The ν(CO) pattern in the carbonyl region is similar to that observed for the vinylidene derivatives $[Ru_4(CO)_{10}(\mu_4,\eta^2\text{-}C{=}CH\textit{i}Pr)(OR)(PPh_2)]$ (R = H, Et).[7] On the other hand, ^1H NMR resonances at δ = 4.50

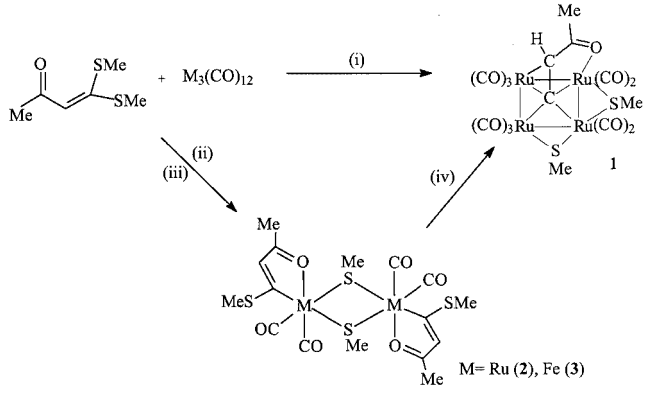
[C(O)CH=C], 2.70 and 2.20 (SCH_3) and 2.00 ppm [$C(O)CH_3$] are shifted in comparison with those of the ligand {δ = 6.02 [C(O)CH=C], 2.46 and 2.43 (SCH_3), 2.18 ppm [$C(O)CH_3$]}. A single-crystal X-ray diffraction study on compound **1** confirmed the formation of a vinylidenetetraruthenium compound by rupture of the two S−C bonds in the ligand. Examples of activation of the S−C bonds in the synthesis of clusters are known. Thus, the thioketene $C_6H_6Me_4C_2S$ derivative in its reaction with $[Os_3Pt(\mu\text{-}H)_2(CO)_{10}(PCy_3)]$ generates a heteronuclear compound bearing a terminal vinylidene ligand[8] and the triosmium cluster $[Os_3(CO)_9(\mu\text{-}H)(\mu\text{-}SPh)\{\mu_3,\eta^2\text{-}(CCH_2CH_2C)\}]$ has been isolated from cyclobutenyl thioether.[2a] We have also previously reported the synthesis of ruthenium clusters by thermolysis of $[Ru_3(CO)_{12}]$ and $S(C{\equiv}CSiMe_3)_2$.[3]



Scheme 1. (i) $ONMe_3$, toluene, 85 °C, 1:1 stoichiometry; (ii) $ONMe_3$, toluene, 85 °C, 3:1 stoichiometry; (iii) $ONMe_3$, THF, room temp., 1:1 stoichiometry; (iv) $[Ru_3(CO)_{12}]$, $ONMe_3$, toluene, 85 °C

Although several clusters with vinylidene ligands have been reported, as far as we know only a few examples of homotetrametallic compounds containing a μ_4-C=CRR′ or μ_4-C=CR_2 group have been described. Compounds $[Ru_4(CO)_{10}(\mu_4,\eta^2\text{-}C{=}CHiPr)(OR)(PPh_2)]$ (R = H, Et),[7] have been obtained in moderate yield by reaction of $[Ru_4(CO)_{11}(PPh_2C{\equiv}CR)]$ in wet THF, while the complexes $[Fe_4(CO)_{12}\{\mu_4,\eta^2\text{-}C{=}C(OMe)R\}]$ (R = OMe, Me)[9a] have been synthesised in high yield by methylation of the anionic clusters $[Fe_4(CO)_{12}\{CC(O)(OMe)\}]^-$ or $[Fe_4(CO)_{12}\{CC(O)(Me)\}]^-$, the former cluster being the precursor for $[Fe_4(CO)_{12}\{\mu_4,\eta^2\text{-}C{=}C(OMe)H\}]$.[9b] The reaction between $[Os_4(CO)_{12}(\mu_3\text{-}S)]$ and PhC≡CH affords the cluster $[Os_4(CO)_{12}(\mu_3\text{-}S)\{\mu_4,\eta^2\text{-}C{=}C(Ph)H\}]$.[9c] The known compound $[Ru_2(CO)_6(\mu\text{-}SCH_3)_2]$[10] was also obtained from this reaction in trace amounts along with compound **1**.

The same reaction, carried out with an excess of the ligand, yielded the new compound $[Ru_2(CO)_4(\mu\text{-}SCH_3)_2\{\eta^2{:}\kappa\text{-}C,O\text{-}C(SCH_3)CHC(O)CH_3\}_2]$ (**2**) in 45% yield. Compound **2** exists as a mixture of two isomers (*syn*/*anti*) in a 20:80 ratio, as determined from ^1H NMR spectroscopic data, that could be separated by chromatography. The major isomer gave suitable crystals for X-ray diffraction studies (Figure 2). The two IR bands observed at 2028, 1970 (*anti*) and 2044, 1988 cm^{-1} (*syn*) are expected for compounds of the type $[Ru(CO)_2L_2]_2$.[11] In the ^1H NMR spectrum, in addition to the resonance corresponding to the CH_3 group [δ = 2.12 (*anti*) and δ = 2.12 ppm (*syn*)], two more signals appear in this region at δ = 2.39 and 2.42 (*anti*), δ = 2.33 and 2.41 ppm (*syn*) that are indicative of the presence of two inequivalent SCH_3 groups. The FAB^+ mass spectrum of compound **2** reveals a molecular ion at *m*/*z* = 638 in agreement with this formulation. Conversion of the dinuclear compound **2** to the cluster **1** occurred on heating the former at 85 °C in toluene (Scheme 1).

The compound $[Ru_4(CO)_{10}(\mu\text{-}SCH_3)_2\{\mu_4,\eta^3{:}\kappa\text{-}C,C,O\text{-}C{=}CHC(O)CH_3\}]$ (**1**) contains two crystallographically independent molecules in the asymmetric unit. The discussion will be limited to only one of these molecules. An ORTEP illustration of compound **1** is given in Figure 1. Selected interatomic distances and angles are shown in Table 1.

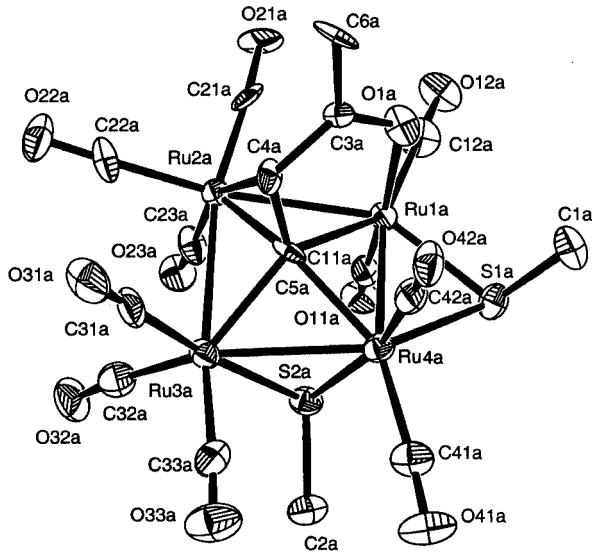


Figure 1. Molecular structure of compound **1**

Table 1. Selected distances [Å] and angles [°] for compound **1**

Ru(1)−Ru(2)	2.8306(14)	Ru(2)−C(5)	2.002(16)
Ru(2)−Ru(3)	2.923(2)	Ru(2)−C(4)	2.206(14)
Ru(1)−Ru(4)	2.7869(19)	Ru(3)−C(5)	2.137(13)
Ru(3)−Ru(4)	2.8009(14)	Ru(1)−C(5)	2.210(13)
Ru(1)−O(1)	2.108(10)	Ru(4)−C(5)	2.135(15)
Ru(1)−S(1)	2.368(4)	O(1)−C(3)	1.281(17)
Ru(3)−S(2)	2.403(4)	C(4)−C(5)	1.43(19)
Ru(4)−S(2)	2.424(4)	C(3)−C(4)	1.45(2)
Ru(4)−Ru(1)−Ru(2)	90.72(5)	C(3)−O(1)−Ru(1)	114.5(8)
Ru(4)−Ru(3)−Ru(2)	88.56(4)	O(1)−C(3)−C(4)	119.0(12)
Ru(1)−Ru(2)−Ru(3)	86.80(5)	C(3)−C(4)−C(5)	115.0(12)
Ru(1)−Ru(4)−Ru(3)	90.08(5)		

The four ruthenium atoms form a distorted rectangular geometry with three similar distances [Ru(1)−Ru(4) 2.7869(19), Ru(1)−Ru(2) 2.8306(14), Ru(3)−Ru(4) 2.8009(14) Å] and one that is slightly longer [Ru(2)−Ru(3) 2.923(2) Å] but still within the normal range found for other ruthenium clusters.[3,12] Although compounds

$[Ru_4(CO)_{10}(\mu_4,\eta^2\text{-}C{=}CH\textit{i}Pr)(OR)(PPh_2)]$ (R = H, Et)[7] and $[Fe_4(CO)_{12}\{\mu_4,\eta^2\text{-}C{=}C(OMe)R\}]$ (R = OMe, Me)[9a] show a butterfly geometry, a rhombus frame has been observed in the compound $[Os_4(CO)_{12}(\mu_3\text{-}S)\{\mu_4,\eta^2\text{-}C{=}C(Ph)H\}]$.[9c]

The breaking of two S−C sp^2 bonds in $[CH_3C(O)CH{=}C(SCH_3)_2]$ affords two methylthiolate ligands that are joined to three Ru atoms of the cluster framework. The remaining vinylidene group is coordinated to the four metal atoms at the C-α atom while the C-β atom is only attached to the Ru(2) atom. It is worth noting that the presence of the $C(O)CH_3$ group as a substituent on the C=CHR ligand allows the formation of a pentametallacycle. The cluster shell is completed by ten terminal carbonyl ligands. Most of the vinylidene tetranuclear cluster show a μ_4-η^2 coordination mode, such as has been observed in compound **1**. However, in the clusters $[Fe_4(CO)_{12}\{\mu_4,\eta^2\text{-}C{=}C(OMe)R\}]$ (R = OMe, Me)[9a] this ligand only acts towards the C-α atom.

The Ru−S distances [2.368(4), 2.335(4), 2.403(4) and 2.424(4) Å] are similar to the values reported for other thiolate-bridged complexes, $[Ru_3(CO)_9(\mu,\eta^2\text{-}SC{\equiv}CSiMe_3)(\mu_3,\eta^2\text{-}C{\equiv}CSiMe_3]$ [2.4353(7) and 2.4337(7) Å][3] and $[Ru_3(CO)_9(\mu\text{-}SEt)(\mu_3,\eta^2\text{-}C{\equiv}CPh)]$ [2.424(2) and 2.4116(2) Å].[13] The C(4)−C(5) distance [1.43(19) Å] for compound **1** is similar to those observed in $[Ru_4(CO)_{10}(\mu_4,\eta^2\text{-}C{=}CH\textit{i}Pr)(OH)(PPh_2)]$ [1.415 Å],[7] $[Ru_5(\mu\text{-}H)(\mu_4\text{-}\eta^2\text{-}C{=}CHPPh_2)(\mu\text{-}PPh_2)(CO)_{13}]$ [1.435(5) Å],[12] $[Ru_3H_2(\mu_3,\eta^2\text{-}C{=}C(CH_3)(C_6H_5)(CO)_9]$[14] [1.379(8) Å], and $[Os_4(CO)_{12}(\mu_3\text{-}S)\{\mu_4,\eta^2\text{-}C{=}C(Ph)H\}]$[9c] [1.446(16) Å]. The C(3)−O(1) distance of 1.281(17) Å is slightly longer than expected for a C=O bond [1.20 Å], which is indicative of the existence of a σ-bond between the oxygen atom of the ketone group and the Ru(1) atom.

This arrangement of the four Ru−Ru bonds is consistent with an electron count of 64 electrons achieved when the two methylthiolate ligands as well as the vinylidene $C{=}CHC(O)CH_3$ group each contribute six electrons.

The molecular structure of the *anti* isomer of $[Ru_2(CO)_4(\mu\text{-}SCH_3)_2\{\eta^2\text{:}\kappa\text{-}\textit{C},\textit{O}\text{-}C(SCH_3)CHC(O)CH_3\}_2]$ (**2**) is illustrated in Figure 2 and selected bond lengths and angles are given in Table 2. Compound **2** crystallises in the space group $P\bar{1}$ and is centrosymmetric. The cleavage of one $C{-}SCH_3$ bond in the disulfide ligand leads to the $C(SCH_3)CHC(O)CH_3$ group that acts as a three-electron donor making a pentaruthenacycle around each Ru atom. Both metal units are linked through two bridging methylthiolate ligands. The intramolecular distance between the ruthenium atoms [3.634(2) Å] suggests that there is no bonding interaction, while the Ru−S distances [2.4599(10) and 2.4352(11) Å] are slightly longer than those observed for compound **1**. The C(12)−Ru−S(1) [177.63(8)°] and C(1)−Ru−S′(1) [168.00(7)°] angles are indicative of a *cis* position for the two CO ligands. The equatorial plane of the octahedron seems to consist of the S(1), S′(1), C(1) and C(12) atoms. The remaining CO ligand and O(1) atom are located in the apical positions. The distances Ru−O(1) [2.1109(18) Å] and O(1)−C(3) [1.270(3) Å] are similar to those reported in the related compounds $[RuCl\{\textit{o}\text{-}C_6H_3CH_3C(O)C_6H_4CH_3\}(CO)(PMe_2Ph)]$,[15] $[RuCl\{\textit{o}\text{-}C_6H_4C(O)C_6H_4CH_3\}(CO)(PPh_3)]$,[16] and $[RuCl\{{=}C(CH_2Ph)OC(O)H\}(P\textit{i}Pr_3)]$.[17]

We have previously reported[6b] that the reaction of $[Fe_2(CO)_9]$ and $C_6H_5CH{=}CHC(O)CH{=}C(SCH_2CH_2S)$, in diethyl ether at room temperature, affords the compound $[Fe_2(CO)_5\{\mu,\eta^4\text{:}\kappa\text{-}\textit{C},\textit{O},\textit{S},\textit{S}\text{-}(SCH_2CH_2SC{=}CHC(O)CH{=}CHC_6H_5\}]$ by rupture of one S−C bond. On the other hand, taking into account that treatment of $Ru_3(CO)_{12}$ with $[CH_3C(O)CH{=}C(SCH_3)_2]$ yields the new cluster **1**, reported here, we were interested to know whether the use of $[Fe_3(CO)_{12}]$ instead of $[Fe_2(CO)_9]$, in the presence of $ONMe_3$ under mild conditions, leads to an iron cluster by reaction with $[CH_3C(O)CH{=}C(SCH_3)_2]$. Unfortunately, in this case, the reaction carried out by heating in toluene affords the expected vinylidene compound in trace amounts only, with $[Fe_2(CO)_6(\mu\text{-}SCH_3)_2]$ being the main product. However, the dinuclear compound $[Fe_2(CO)_4(\mu\text{-}SCH_3)_2\{\eta^2\text{:}\kappa\text{-}\textit{C},\textit{O}\text{-}C(SCH_3)CHC(O)CH_3\}_2]$ (**3**) was obtained at room temperature in THF in 25% yield (Scheme 1). The spectroscopic data are similar to those shown for compound **2**. In the FAB^+ mass spectrum peaks analogous to those observed in **2** corresponding to the molecular ion and the loss of CO groups were found.

Compound **3** was not converted into a vinylidene cluster on reaction with more carbonyliron compound, showing a

different behaviour from that observed in the analogous ruthenium case.

Following our research interest to synthesize vinylidene derivatives we decided to prepare [(C_5H_5)Fe{C_5H_4CH=CHC(O)CH=C(SCH_2CH_2S)}] (**4**), which is similar to the ligand studied before with an α,β-unsaturated ketone system. The presence of one more C=C bond in the chain as well as the active redox ferrocenyl group could lead to differences in its reactivity. Compound **4** was prepared according to the procedure described in the literature for other analogous compounds[19] and was characterised by analytical and spectroscopic techniques (see Exp. Sect.).

Treatment of [$Ru_3(CO)_{12}$] with [(C_5H_5)Fe{C_5H_4CH=CHC(O)CH=C(SCH_2CH_2S)}] in the presence of $ONMe_3$ in toluene at 85°C afforded the tetraruthenium compound [$Ru_4(CO)_{10}$(μ_4,η^3:κ-*C*,*C*,*O*-(C=CHC(O)CH=CHC_5H_4)Fe(C_5H_5)}] (**5**) (Scheme 2), as was inferred from the presence of the molecular ion peak in the FAB^+ mass spectrum (*m*/*z* = 1041) as well as from the analytical data. The ν(CO) pattern in the carbonyl region is similar to that observed for compound **1** and other related derivatives [$Ru_4(CO)_{10}$(μ_4,η^2-C=CH*i*Pr)(OR)(PPh_2)] (R = H, Et).[7] In the ^{1}H NMR spectrum resonances that appear at δ = 4.07 [C(O)CH=C] and 3.29, 2.42, 2.26 ppm [SCH_2CH_2S] are shifted in comparison with those of the ligand [δ = 6.77 ppm for C(O)CH=C; δ = 3.43, 3.35 ppm for SCH_2CH_2S]. It was found that the same chemical shift occurs as was observed in **1** for the [C(O)CH=C] resonance.

Finally, the reaction carried out between [$Fe_3(CO)_{12}$] and [(C_5H_5)Fe{C_5H_4CH=CHC(O)CH=C(SCH_2CH_2S)}] with $ONMe_3$ in THF at room temperature for 2 h yielded three compounds after chromatographic workup (Scheme 2). The first band, that appeared as traces from the column, gave an orange solid which was identified by IR and ^{1}H NMR spectroscopic data as the known compound [$Fe_2(CO)_6$(μ-SCH_2CH_2S)].[20] The second band afforded the main compound [$Fe(CO)_3${(C_5H_5)Fe{η^4:κ-(*C*=*C*,*C*=*O*)-C_5H_4CH=CHC(O)CH=C(SCH_2CH_2S)}}] (**6**) in 23% yield; its structure was confirmed by X-ray diffraction. A small amount of [$Fe_2(CO)_5$(μ,η^4:κ-*C*,*O*,*S*,*S*-SCH_2CH_2SC=CHC(O)CH=CHC_5H_4}Fe(C_5H_5)] (**7**) was obtained from the third band of the column. We have observed that if the reaction time is increased to 48 h, compound **7** is the main product of this reaction.

Compound **6** is formed by coordination of the $Fe(CO)_3$ fragment towards both the ketone group and the C=C bond of the ligand. The IR spectrum in the carbonyl region is similar to that found in the analogous compound [η^4-{(3*E*)-4-phenyl-1-(1,3-dithiolan-2-ylidene)butene-2-one}$Fe(CO)_3$] recently prepared by us.[6b] The ^{1}H NMR spectrum of compound **6** shows, as a prominent feature, two signals at δ = 5.71 and 3.38 ppm ($^3J_{H,H}$ = 8.7 Hz), corresponding to the protons of the coordinated CH=CHC(O) group which are shifted upfield with respect to the free ligand. A view of compound **6** with the atom numbering scheme is shown in Figure 3. Selected interatomic distances and angles are presented in Table 3. The coordination geometry of Fe(2) can be described as a distorted trigonal bipyramid with the atoms C(20), C(30) of the carbonyl groups and the C(2)−C(3) double bond in the equatorial positions, while the O(1) atom and the C(10) atom of the carbonyl group are located in the apical positions. The ferrocene unit is not affected much by the coordination of the $Fe(CO)_3$ moiety and the distances and angles are in the usual range found in many other ferrocene derivatives. The enone moiety and the 1,3-dithiolane ring shows only slight deviations from the analogous fragment present in [$Fe(CO)_3${η^4-H_5C_6CHCHC(O)CHC(SCH_2CH_2S)}].[6b] The comparison of the Fe−CO distance of the carbonyl group *trans* to the oxygen atom of the enone and the rest of the carbonyl groups suggests a *trans* influence.

Finally, the breaking of only one S−C bond in [(C_5H_5)Fe{(C_5H_4CH=CHC(O)CH=C(SCH_2CH_2S)}] generated [$Fe_2(CO)_5${μ,η^4-SCH_2CH_2SC=CHC(O)CH=CH-C_5H_4}Fe(C_5H_5)] (**7**). The analogous compound [{(3*E*)-4-phenyl-1-(1,3-dithiolan-2-ylidene)butene-2-one}$Fe_2(CO)_5$], whose structure has been confirmed by X-ray diffraction, was formed in a similar manner.[6b] The ν(CO) pattern is similar in both compounds. In the FAB^+ spectrum, a peak observed at *m*/*z* = 609 corresponding to the molecular ion

and the analytical data are in agreement with this formulation. The ^{1}H NMR spectrum exhibits two doublet resonances at δ = 7.12 and 6.47 ppm assigned to the uncoordinated double bond, with a value of $^3J_{H,H}$ = 15.7 Hz similar to that observed in compound **5**. Additionally a singlet signal that appears at δ = 2.35 ppm [C(O)CHC] is strongly shifted to a higher field than that observed in the free ligand (δ = 6.79 ppm). The compounds **6** and **7** are obtained in similar yield to those prepared by us using $[Fe_2(CO)_9]$ and analogous ligands.

Conclusion

Compounds $[CH_3C(O)CH{=}C(SCH_3)_2]$ and $[(C_5H_5)Fe\{C_5H_4CH{=}CHC(O)CH{=}C(SCH_2CH_2S)\}]$ act as precursors of vinylidene groups by activation of the two S−C bonds in their reactions with $[Ru_3(CO)_{12}]$ but not with $[Fe_3(CO)_{12}]$. This has allowed the formation of new homonuclear vinylideneruthenium clusters, which is important when one considers the scarcity of literature reports on these complexes.

The cleavage of only one S−C bond from $[CH_3C(O)CH{=}C(SCH_3)_2]$ as well as the presence of the ketone group led to the compounds $[M_2(CO)_4(\mu\text{-}SCH_3)_2\{\eta^2{:}\kappa\text{-}C,O\text{-}C(SCH_3)CHC(O)CH_3\}_2]$ (M = Ru, Fe) containing two metallacycles.

The presence of SCH_2CH_2S instead of two SCH_3 groups in the ligand $[(C_5H_5)Fe\{C_5H_4CH{=}CHC(O)CH{=}C(SCH_2CH_2S)\}]$ seems to drive the formation of the compound $[Fe_2(CO)_5\{\mu,\eta^4\text{-}SCH_2CH_2SC{=}CHC(O)CH{=}CHC_5H_4\}Fe(C_5H_5)]$.

Experimental Section

General Remarks: All reactions were carried out under argon using Schlenk techniques. Solvents were dried according to standard methods. IR spectra were recorded with a Perkin−Elmer 1650 FTIR spectrophotometer using NaCl cells. ^{1}H NMR spectra were recorded with a Bruker AMX-300 instrument in $CDCl_3$. Elemental analyses were performed with a Perkin−Elmer 240-B microanalyser. FAB mass spectra were carried out with a WG AutoSpec spectrometer, using 3-nitrobenzyl alcohol as the matrix. $[CH_3C(O)CH{=}C(SCH_3)_2]$[19] was synthesised according to literature methods.

Synthesis of $[Ru_4(CO)_{10}(\mu\text{-}SCH_3)_2\{\mu_4,\eta^3{:}\kappa\text{-}C,C,O\text{-}C{=}CHC(O)CH_3\}]$ (1): An excess of $ONMe_3$ (0.103 g, 1.38 mmol) was added to a solution of $[Ru_3(CO)_{12}]$ (0.300 g, 0.46 mmol) and $[CH_3C(O)CH{=}C(SCH_3)_2]$. (0.076 g, 0.46 mmol) in toluene (30 mL). The mixture was stirred at 85 °C for 24 h to give an orange-brown solution. The solvent was removed under vacuum, and the residue was chromatographed on silica gel 100. Elution with hexane afforded $[Ru_2(CO)_6(\mu\text{-}SMe)_2]$ in low yield. A second band using *n*-hexane/toluene (4:1) gave compound **1** as the main product (0.136 g, 35% yield). Crystals of **1** were obtained from *n*-hexane at −20 °C. IR (THF): $\tilde{\nu}$ = 2080 (m), 2044 (vs), 2026 (s), 2012 (s), 1986 (m), 1969 (sh), 1955 (w) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 4.50 [s, 1 H, C*H*C(O)], 2.70 (s, 3 H, SCH_3), 2.20 (s, 3 H, SCH_3), 2.00 [s, 3 H, C(O)CH_3] ppm. FAB$^+$: *m*/*z* = 846 [M$^+$], 818−566 [M$^+$ − *n* CO, *n* = 1−10]. $C_{16}H_{10}O_{11}Ru_4S_2$ (846.64): calcd. C 22.70, H 1.19; found C 22.83, H 1.44.

Synthesis of $[Ru_2(CO)_4(\mu\text{-}SCH_3)_2\{\eta^2{:}\kappa\text{-}C,O\text{-}C(SCH_3)CHC(O)CH_3\}_2]$ (2): $ONMe_3$ (0.092 g, 1.23 mmol) was added to a solution of $[Ru_3(CO)_{12}]$ (0.250 g, 0.39 mmol) and $[CH_3C(O)CH{=}C(SCH_3)_2]$ (0.200 g, 1.23 mmol) in toluene (30 mL). The mixture was stirred at 85 °C for 24 h. Removal of the solvent and chromatography on silica gel gave the first band of compound **1** in trace amounts, eluted with *n*-hexane/toluene (4:1). A second band using toluene/THF (5:1) afforded $[Ru_2(CO)_4(\mu\text{-}SCH_3)_2\{\eta^2{:}\kappa\text{-}C,O\text{-}C(SCH_3)CHC(O)CH_3\}_2]$ (**2**) as the main product (0.75 g, 45% yield). Crystals of **2** were obtained by diffusion of hexane in THF at 0 °C. IR (toluene): *anti* isomer: $\tilde{\nu}$ = 2028 (s), 1970 (s) cm^{-1}; *syn* isomer: $\tilde{\nu}$ = 2044 (s), 1988 (s) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 6.62 [s, 1 H, C*H*C(O)], 2.42 (s, 3 H, SCH_3, *anti* isomer), 2.41 (s, 3 H, SCH_3, *syn* isomer), 2.39 (s, 3 H, SCH_3, *anti* isomer), 2.39 (s, 3 H, SCH_3, *syn* isomer), 2.12 [s, 3 H, C(O)CH_3] ppm. FAB$^+$: *m*/*z* = 638 [M$^+$]. $C_{16}H_{20}O_6Ru_2S_4$ (638.71): calcd. C 30.11, H 3.13; found C 30.73, H 3.31.

Synthesis of $[Fe_2(CO)_4(\mu\text{-}SCH_3)_2\{\eta^2{:}\kappa\text{-}C,O\text{-}C(SCH_3)CH(CO)CH_3\}_2]$ (3): A solution of $[CH_3C(O)CH{=}C(SCH_3)_2]$ (0.068 g, 0.42 mmol) in THF (10 mL) was slowly added to a solution of $[Fe_3(CO)_{12}]$ (0.210 g, 0.42 mmol) and $ONMe_3$ (0.031 g, 0.42 mmol)

in THF. The resulting mixture was stirred at room temperature for 2.5 h. The solvent was then evaporated under vacuum to dryness and the residue chromatographed on silica gel 100. An orange band of $[Fe_2(CO)_6(\mu\text{-}SCH_3)_2]$ (trace) was obtained using *n*-hexane as the eluent. Further elution with *n*-hexane/THF (10:3) yielded a red band. The solvent was removed under vacuum and recrystallisation of the residue in THF/*n*-hexane at −20 °C yielded compound **3** (29 g, 25.9% yield). IR (THF): $\tilde{\nu}$ = 2017 (s), 1969 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 6.69 [s, 1 H, C*H*C(O)], 2.52 (s, 3 H, SCH_3), 2.35 (s, 3 H, SCH_3) 2.08 [s, 3 H, C(O)CH_3] ppm. FAB$^+$: *m*/*z* = 549.0 [M$^+$], 520.0 [M$^+$ − CO], 492.0 [M$^+$ − 2 CO], 436.0 [M$^+$ − 4 CO] ppm. $C_{16}Fe_2H_{20}O_6S_4$ (548.26): calcd. C 35.05; H 3.68; found C 34.88, H 3.62.

Synthesis of [(C$_5$H$_5$)Fe{C$_5$H$_4$CH=CHC(O)CH=C(SCH$_2$CH$_2$S)}] (4): This compound was prepared according to a procedure described for other analogous compounds.[17] Sodium hydroxide (0.125 g, 3.12 mmol) in EtOH (20 mL) was added to a solution of 1-(1,3-dithiolan-2-ylide)acetone (0.500 g, 3.12 mmol) in EtOH (30 mL). After 40 min of stirring, [(C$_5$H$_5$)Fe(C$_5$H$_5$CHO)] (0.067 g, 3.12 mmol) in EtOH (10 mL) was added. The mixture was stirred for 24 h affording a red precipitate. The solid compound was purified by column chromatography using *n*-hexane as the eluent (0.3 g, 27% yield). ^1H NMR ($CDCl_3$): δ = 7.52 [d, $^3J_{H,H}$ = 15.6 Hz, 1 H, *H*C=CHC(O)], 6.79 [s, 1 H, C(O)C*H*C], 6.39 [d, $^3J_{H,H}$ = 15.6 Hz, 1 H, HC=C*H*C(O)], 4.50 (t, $^3J_{H,H}$ = 1.8 Hz, 2 H, C_5H_4), 4.42 (t, $^3J_{H,H}$ = 1.8 Hz, 2 H, C_5H_4), 4.14 (s, 5 H, C_5H_5), 3.43 and 3.35 (m, 4 H, SCH_2CH_2S) ppm. FAB$^+$: *m*/*z* = 356 [M$^+$]. $C_{17}FeH_{16}OS_2$ (356.28): calcd. C 57.31; H 4.53; found C 56.90, H 4.59.

Reaction of Ru$_3$(CO)$_{12}$ and [(C$_5$H$_5$)Fe{C$_5$H$_4$CH=CHC(O)CH=C(SCH$_2$CH$_2$S)}]: The reaction was carried out according to the same procedure as for compound **1**, but leaving the reaction for 48 h. Chromatography on silica gel 100 afforded two compounds. Elution with hexane gave $[Ru_2(CO)_6(\mu\text{-}SCH_2CH_2S)]$ in a small amount, while hexane/toluene (5:3) gave the cherry-coloured compound **5** as the main product (0.100 g, 28% yield). IR (THF): $\tilde{\nu}$ = 2078 (m), 2045 (vs), 2028 (s), 2008 (s), 1974 (m) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 7.30 [d, $^3J_{H,H}$ = 15.5 Hz, 1 H, *CH*CH*C*(O)], 6.13 [d, $^3J_{H,H}$ = 15.5 Hz, 1 H, CH*CHC*(O)], 4.50 (m, 4 H, C_5H_4), 4.10 (s, 5 H, C_5H_5), 4.07 [s, 1 H, C(O)C*H*C], 3.29 (m, 2 H, SCH_2), 2.42 (m, 1 H, SCH_2), 2.26 (m, 1 H, SCH_2) ppm. FAB$^+$: *m*/*z* = 1041 [M$^+$], 985 [M$^+$ − 2 CO], 957 [M$^+$ − 3 CO], 901 [M$^+$ − 5 CO], 873 [M$^+$ − 6 CO], 789 [M$^+$ − 9 CO], 761 [M$^+$ − 10 CO]. $C_{27}FeH_{16}O_{11}Ru_4S_2$ (1040.66): calcd. C 31.16, H 1.55; found C 31.53, H 1.67.

Reaction of Fe$_3$(CO)$_{12}$ and [(C$_5$H$_5$)Fe{C$_5$H$_4$CH=CHC(O)CH=C(SCH$_2$CH$_2$S)}]: A solution of [(C$_5$H$_5$)Fe{C$_5$H$_4$CH=CHC(O)CH=C(SCH$_2$CH$_2$S)}] (0.156 g, 0.44 mmol) in THF (5 mL) was slowly added to a mixture of $[Fe_3(CO)_{12}]$ (0.220 g, 0.44 mmol) and $ONMe_3$ (0.033 g, 0.44 mmol) in the same solvent (15 mL). The resulting mixture was stirred at room temperature for 2 h. Then the solvent was evaporated under vacuum to dryness and the residue chromatographed on silica gel 100. Using *n*-hexane as the eluent, an orange band of $[Fe_2(CO)_6(\mu\text{-}SCH_2CH_2S)]$ (trace) was obtained. Further elution with a mixture of *n*-hexane/toluene (10:1) yielded a red band of **6** (0.050 g, 23.0% yield). Subsequent elution with *n*-hexane/toluene (1:2) gave a red-brown band of compound **7** in trace amounts. Applying the same procedure and increasing the reaction time to 48 h, compound **7** was obtained in a 17.8% yield.

6: IR (THF): $\tilde{\nu}$ = 2052 (s), 1990 (s), 1975 (s), 1604 (w) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 6.72 [s, 1 H, C(O)CHC], 5.71 [d, $^3J_{H,H}$ = 8.7 Hz, 1 H, *CH*CH*C*(O)], 4.42 (s, 1 H, C_5H_4), 4.20 (s, 2 H, C_5H_4), 4.16 (s, 1 H, C_5H_4), 4.13 (s, 5 H, C_5H_5), 3.38 [m, 5 H, SCH_2CH_2S and CHC*H*C(O)] ppm. FAB$^+$: *m*/*z* = 440 [M$^+$ − 2 CO], 412 [M$^+$ − 3 CO], 356 [M$^+$ − Fe − 3 CO]. $Fe_2S_2O_4C_{20}H_{16}$ (495.91): calcd. C 48.42, H 3.25; found C 48.12, H 3.61.

7: IR (THF): $\tilde{\nu}$ = 2052 (s), 2009 (vs), 1991 (s), 1975(sh), 1959 (w), 1946 (sh), 1647 (w) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 7.12 [d, $^3J_{H,H}$ = 15.7 Hz, 1 H, *CH*CH*C*(O)], 6.47 [d, $^3J_{H,H}$ = 15.7 Hz,1 H,CHC*H*C(O)], 4.45 (m, 2 H, C_5H_4), 4.34 (m, 2 H, C_5H_4), 4.15 (s,

X-ray Crystallographic Studies: For all the compounds data have been collected at low temperature with an STOE Imaging Plate Diffraction System (IPDS), equipped with an Oxford Cryosystems Cryostream Cooler Device and using a graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Crystal data and structure refinement parameters for compounds **1**, **2** and **6** are listed in Table 4. Final unit cell parameters have been obtained by using a least-squares refinement of a set of 5000 well-measured reflections, and crystal decay was monitored during data collection. No significant fluctuations of the intensity were observed. Structures were solved by Direct Methods using SIR92,[20] and subsequent difference Fourier maps refined by least-squares procedures on F^2 by using SHELXL-97[21] included in the package WINGX.[22] Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[23] All hydrogen atoms were located on a difference Fourier map and refined by using a riding model with an isotropic thermal parameter fixed at 20% higher than those of the carbon atoms to which they are connected. For all structures all non-hydrogen atoms were anisotropically refined and in the last cycles of refinement a weighting scheme was applied, where weights have been calculated from the following formula: $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. Drawings of the molecules were performed using the program ORTEP32[24] with 50% probability displacement ellipsoids for non-hydrogen atoms. The structure of compound **1** has been solved in the monoclinic cell (space group $P2_1$) with $\beta = 90°$ and may be emulated by an orthorhombic system of space group $P2_12_12$, all attempts to solve this structure in this system failed. We observed some characteristic warning signs of the presence of twinning in the data, notably a very low value for $E^2 - 1$ (= 0.63), lower than the expected value of 0.74 for the non-centrosymmetric case. Consequently, **1** was solved in the monoclinic system $P2_1$ by using the following twin law which allows to simultaneously refine general and racemic twinning: TWIN 1.00 0.00 0.00 0.00 − 1.00 0.00 0.00 0.00 − 1.00 −4. Application of this specific instruction led to a stable model which could be refined without any constraints or restraints and converged nicely. CCDC-183656 (**1**), -186787 (**2**), and -186357 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows the X-ray crystal structure of the complex [IrCl(Pigiphos)], where Pigiphos is a unique chiral tridentate ligand containing two ferrocenyl units. Enantiomerically pure triphosphanes are still quite rare and Pigiphos is particularly attractive because of its simple synthesis – one step from commercially available precursors. The study of the coordination chemistry of Pigiphos has shown that it can accomodate metal ions in essentially perfect square-planar geometries (Ni^{II}, Pd^{II}, Ph^{I}). In case of an ocatahedral coordination sphere it can adopt both a facial or an equatorial configuration (Ru^{II}). However, the present [IrCl(Pigiphos)] complex displays a severe deviation from the expected square-planar geometry and shows a dynamic behavior in solution. Synthesis, characterization, and reactivity of this and other Pigiphos complexes of Ir and Rh are presented in the article by P. Barbaro, A. Togni et al. on p. 601 ff.

Synthesis and Reactivity of Organoimido Complexes of Chromium

Wa-Hung Leung[a]

Keywords: Chromium / N ligands / Synthesis / Reactivity

Organoimido groups are excellent spectator ligands for high-valent organometallic compounds due to their strong π-donating capability. Of interest are imidochromium complexes that are used as catalysts for olefin polymerization. This microreview provides an overview of the organometallic chemistry of high-valent imidochromium complexes. Synthetic routes to alkyl- and arylimido complexes of chromium in oxidation states VI–IV will be presented. The reactivity of imidochromium complexes including imido group transfer and cycloaddition will be described. The use of imidochromium complexes as catalysts for regioselective ring opening of epoxides will be discussed.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

1. Introduction

Transition metal imido complexes have attracted much attention because of their proposed intermediacy in the industrially important ammoxidation of propylene,[1] and also due to their applications to organic transformations such as aziridination[2] and aminohydroxylation[3] of olefins, amidation of hydrocarbons,[2b] amination of silyl enol ethers,[4] hydroamination of unsaturated hydrocarbons,[5,6] imine metathesis,[7] and activation of alkane C−H bonds.[8] In addition, because of their high π-donor strength, organoimido groups (NR^{2-}; R = alkyl or aryl) prove to be excellent spectator ligands for high-valent organometallic complexes. Well-defined ring-opening metathesis polymerization[9] and ring-closing metathesis[10] catalysts based on Mo^{VI} imido alkylidene complexes have been developed, while the last decade has witnessed significant progress in the organometallic chemistry of high oxidation state (imido)Cr complexes, due in part to their catalytic activities toward olefin polymerization.[11,12] This microreview reviews the synthesis and reactivity of organoimido complexes of Cr in oxidation states VI−III. General reviews on organoimido complexes of transition metals have also appeared.[13−15]

2. Synthesis of Imidochromium Complexes

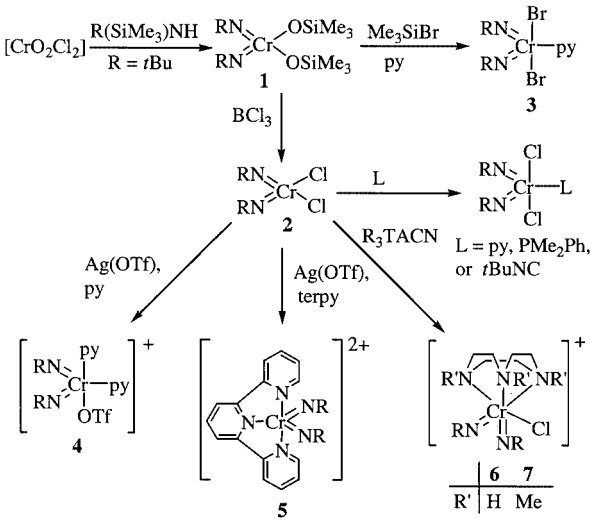
2.1. (Imido)Cr^{VI} Complexes

Nugent synthesized the first (organoimido)Cr^{VI} complex $[Cr(N\mathit{t}Bu)_2(OSiMe_3)_2]$ (**1**) by treatment of $[CrO_2Cl_2]$ with $\mathit{t}BuSiMe_3NH$.[16] Treatment of **1** with BCl_3 afforded the dichloride compound $[Cr(N\mathit{t}Bu)_2Cl_2]$ (**2**).[17] The bis(adamantyl)imido complex $[Cr(NAd)_2Cl_2]$ (Ad = 1-adamantyl) was synthesized similarly, from $[CrO_2Cl_2]$, $Ad(SiMe_3)NH$, and BCl_3,[18] while $[Cr(NR)_2Cl_2]$ reacted with donor ligands L to give monoadducts $[Cr(NR)_2Cl_2(L)]$ [R = tBu,[17] Ad;[18] L = pyridine (py), PMe_2Ph, and tBuNC]. The pyridine adduct $[Cr(N\mathit{t}Bu)_2Br_2(py)]$ (**3**) was also synthesized from **1** and Me_3SiBr in the presence of pyridine.[19] Treatment of **2** either with [Ag(OTf)] (OTf = triflate) or with

Wa-Hung Leung was born in Hong Kong in 1963. He obtained his Ph.D. degree from the University of Hong Kong in 1989 under the supervision of Prof. Chi-Ming Che. He was a Croucher Foundation postdoctoral fellow from 1989 to 1991 and joined Professor Geoffrey Wilkinson's research group in the Department of Chemistry, Imperial College, London, UK. He then joined the faculty of the Chemistry Department, the Hong Kong University of Science and Technology, where he is currently Associate Professor of Chemistry. He has been working in the field of synthetic inorganic and organometallic chemistry, and his research interests include metal−ligand multiple bonds, metal chalcogenide complexes, and organometallic complexes with O-donor ligands.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

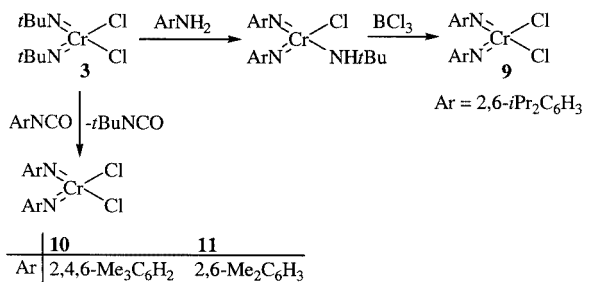
Ag(OAc) (OAc = acetate) afforded $[Cr(NtBu)_2(OTf)_2]$ and $[Cr(NtBu)_2(OAc)_2]$, respectively, while treatment of $[Cr(NtBu)_2(OTf)_2]$ with pyridine (py) or 2,2′:6′,2′′-terpyridine (terpy) gave cationic $[Cr(NtBu)_2(py)_2(CF_3SO_3)]^+$ (**4**)[17] or dicationic $[Cr(NtBu)_2(terpy)]^{2+}$ (**5**),[20] respectively. Treatment of **2** with R′$_3$TACN (TACN = 1,4,7-triazacyclononane) or KTp* [Tp* = hydrotris(3,5-dimethylpyrazol-1-yl)borate] afforded $[Cr(NtBu)_2(R'_3TACN)Cl]^+$ (**6**, R = H; **7**, R = Me)[21] and [Tp*Cr(N*t*Bu)$_2$Cl],[22] respectively (Scheme 1).



Scheme 1. Synthesis of bis(imido)Cr^{VI} complexes

Compound **2** afforded the bis(aryl oxide) compound $[Cr(NtBu)_2(OC_6H_3iPr_2\text{-}2,6)_2]$ (**8**) on treatment with NaO-$C_6H_3iPr_2$-2,6,[20] and $[Cr(NtBu)_2(NPPh_3)_2]$ on treatment with $LiNPPh_3$,[17] while with *t*BuNHLi it afforded $[Cr(NtBu)_2(NHtBu)_2]$, which was deprotonated with *n*BuLi to give the homoleptic (imido)Cr complex $[Li_2Cr(NtBu)_4]$. NMR spectroscopy suggested that $[Li_2Cr(NtBu)_4]$ has a structure similar to $[Li_2W(NtBu)_4]_2$, with terminal linear imido and bridging bent imido groups.[23]

The bis(arylimido)Cr^{VI} complex $[Cr(NC_6H_3iPr_2\text{-}2,6)_2(NHtBu)Cl]$ was prepared by imido group exchange between **2** and 2,6-$iPr_2C_6H_2NH_2$. Treatment of $[Cr(NC_6H_3iPr_2\text{-}2,6)_2(NHtBu)Cl]$ with BCl_3 afforded $[Cr(NC_6H_3iPr_2\text{-}2,6)_2Cl_2]$ (**9**).[24] Alternatively, $[Cr(NAr)_2Cl_2]$ (**10**, Ar = 2,4,6-$Me_3C_6H_2$; **11**, Ar = 2,6-$Me_2C_6H_3$) were synthesized from **2** and ArNCO through Wittig-like [2 + 2] exchange of imido groups[25] (Scheme 2).



Scheme 2. Synthesis of bis(arylimido)Cr^{VI} complexes

Interestingly, treatment of **2** with 2,6-$iPr_2C_6H_3NCO$ resulted in the formation of the Cr^{V} dimer $[Cr(\mu\text{-}NtBu)(N\text{-}C_6H_3iPr_2\text{-}2,6)Cl]_2$ rather than **9**.[24] Unlike **2**,[17] **3**,[18] and **9**,[26] which all formed monoadducts with donor ligands, **10** reacted with PMe_3 or py to yield six-coordinate $[Cr(NR)_2Cl_2(L)_2]$ (L = py, PMe_3).[25] Treatment of **10** with NaSR afforded the dithiolate compounds $[Cr(NC_6H_3Me_2\text{-}2,4,6)_2(SR)_2]$ (R = C_6F_5, 2,4,6-$Me_3C_6H_2$, 2,4,6-$iPr_3C_6H_2$),[25] while with 4 equiv. of ArNHLi (Ar = 2,4,6-$Me_3C_6H_2$), **10** gave $[Cr(NAr)(NHAr)(\mu\text{-}NAr)_2Li(OEt_2)_2]$ (**13**, Figure 1). The amido group in **12** could not be further deprotonated by *n*BuLi.[27]

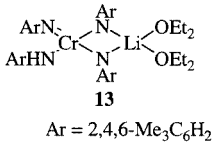


Figure 1. Structure of $[Cr(NAr)(NHAr)(\mu\text{-}NAr)_2Li(OEt_2)_2]$ (Ar = 2,4,6-$Me_3C_6H_2$)

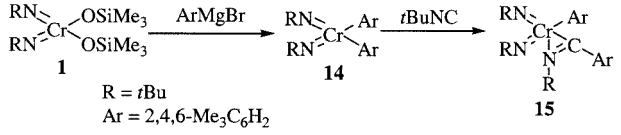
Similarly, treatment of **9** with 2,6-$iPr_2C_6H_3NHLi$ afforded $[Cr(NC_6H_3iPr_2\text{-}2,6)_2(NHC_6H_3iPr_2\text{-}2,6)Cl]$, which also resisted further deprotonation.[26]

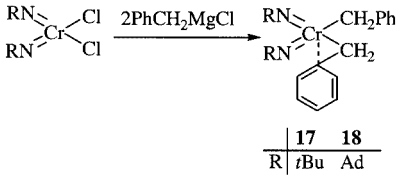
(Imido)Cr^{VI} Complexes Containing σ-Alkyl and Related Ligands

$[Cr(NtBu)_2(C_6H_2Me_3\text{-}2,4,6)_2]$ (**14**), the first isolated stable Cr^{VI} σ-aryl complex, was synthesized by alkylation of **1** with 2,4,6-$Me_3C_6H_2MgBr$. Similarly, alkylation of $[Cr(NR)_2Cl_2]$ with Li(fmes) [fmes = 2,4,6-$(CF_3)_3C_6H_2$] yielded $[Cr(NR)_2(fmes)_2]$ (R = *t*Bu, Ad).[18b] X-ray diffraction studies of $[Cr(NR)_2(fmes)_2]$ revealed pseudo-tetrahedral coordination of Cr, complemented by two secondary Cr···F interactions with the *ortho*-CF_3 groups of the fmes ligands. Treatment of **14** with *t*BuNC afforded the η^2-(iminoacyl) complex $[Cr(NtBu)_2(C_6H_2Me_3\text{-}2,4,6)(\eta^2\text{-}tBuN{=}CC_6H_2Me_3\text{-}2,4,6)]$ (**15**, Scheme 3).[28]



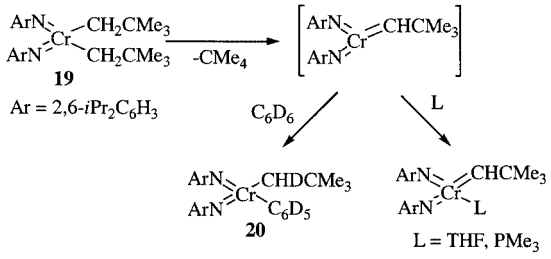
Scheme 3. Synthesis of $[Cr(NtBu)_2(C_6H_2Me_3\text{-}2,4,6)_2]$ and its reaction with *t*BuNC

Treatment of **2** or **3** with Me_3SiCH_2MgCl or $Zn(CH_2SiMe_3)_2$ gave $[Cr(NtBu)_2(CH_2SiMe_3)_2]$, isolated as an oil.[17,19] Alkylation of **3** with *o*-$C_6H_4[(CHSiMe_3)Li(TMEDA)]_2$ (TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) afforded crystalline $[Cr(NtBu)_2\{o\text{-}C_6H_4(CHSiMe_3)_2\}]$ (**16**).[19] Treatment of **3** with $Cp_2Mg(THF)_{2.5}$ (Cp = η^5-C_5H_5) afforded $[CpCr(NtBu)_2Br]$, which could be alkylated to give the monoalkyl compounds $[CpCr(NtBu)_2R]$ (R = Me, CH_2SiMe_3, CH_2CMe_3, CH_2CMe_2Ph).[19] Crystalline $[Cr(NR)_2(CH_2Ph)(\eta^2\text{-}CH_2Ph)]$ (**17**, R = *t*Bu;[29] **18**, R = Ad[18]) were isolated after alkylation of $[Cr(NR)_2Cl_2]$ with $PhCH_2MgCl$ (Scheme 4).



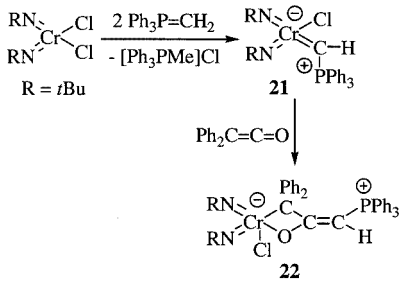
Scheme 4. Synthesis of dibenzylbis(imido)Cr^{VI} complexes

The Cr−C_α and Cr−C_{ipso} distances for the η^2-benzyl ligand in **17** are 207.1(2) and 235.7(2) pm, respectively.[28] The solid-state ^{13}C CP/MAS NMR spectrum of **17** displays two different resonance signals at δ = 157.9 and 124.4 ppm, assigned to the η^1- and η^2-*ipso*-phenyl carbon atoms, respectively.[29] Similarly, the dialkyl compounds $[Cr(NC_6H_3iPr_2\text{-}2,6)_2R_2]$ (R = CH_3, CH_2Ph, CH_2CMe_3)[30] and $[Cr(NC_6H_2Me_3\text{-}2,4,6)_2R_2]$ (R = CH_2Ph, CH_2CMe_3, CH_2CMe_2Ph)[25] have been prepared by alkylation of **9** and **10**, respectively, with RMgCl. In the solid state, $[Cr(NC_6H_3iPr_2\text{-}2,6)_2(CH_2CMe_3)_2]$ (**19**) shows weak α-agostic interactions between Cr and the methylene hydrogen atoms of the neopentyl ligands. Complex **19** reacted with C_6D_6 at room temperature to give $[Cr(NC_6H_3iPr_2\text{-}2,6)_2(CHDCMe_3)(C_6D_5)]$ (**20**) and $CHDCMe_3$, through an (alkylidene)Cr^{VI} intermediate that could be trapped by THF or PMe_3 to form adducts $[Cr(NC_6H_3iPr_2\text{-}2,6)_2(=CHCMe_3)L]$ (L = THF, PMe_3). The conversion of **19** into **20** was found to follow first-order kinetics, suggesting that the rate-determining step is the α-hydrogen elimination of **19** to give the transient three-coordinate alkylidene intermediate, which rapidly reacted with C_6D_6. Neither $[Cr(NC_6H_3iPr_2\text{-}2,6)_2(=CHCMe_3)L]$ nor base-free $[Cr(NC_6H_3iPr_2\text{-}2,6)_2(=CHCMe_3)]$ reacted with simple olefins (Scheme 5).[30]



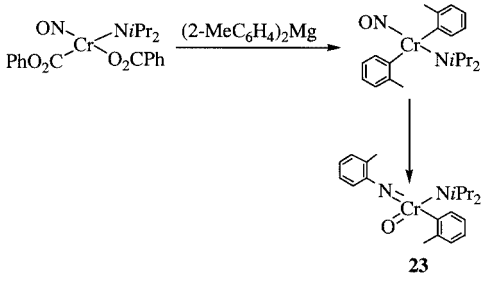
Scheme 5. Synthesis and C−H bond activation by an (alkylidene)Cr^{VI} complex

The (methylidene)(α-phosphonio) complex $[Cr(NtBu)_2Cl\{CH(PPh_3)\}]$ (**21**) was synthesized by transylidation of **2** with $Ph_3P{=}CH_2$. The NMR spectroscopic data for **21** ($\delta_{H\alpha}$ = 11.84 ppm; $\delta_{C\alpha}$ = 200.1 ppm) are characteristic for alkylidene complexes. The high barrier to rotation about the Cr−C bond [$\Delta G^{\ddagger}$(336 K) = 75 kJ·mol^{-1}] for **21** is indicative of the Cr=C double bond character. Treatment of **21** with $Ph_2C{=}C{=}O$ resulted in the nucleophilic attack of Cα on the ketene and the formation of the chromaoxetane $[Cr(NtBu)_2\{\eta^2\text{-}(O,C)\text{-}OC(CHPPh_3)CPh_2\}Cl]$ (**22**, Scheme 6).[31]



Scheme 6. Synthesis of (methylidene)(phosphanyl)Cr^{VI} complex and its reaction with ketene

Alkylation of $[Cr(NO)(NiPr_2)(O_2CPh)_2]$ with $(2\text{-}MeC_6H_4)_2Mg$ afforded the (imido)(oxo) compound $[Cr(O)(NC_6H_4Me\text{-}2)(NiPr_2)(C_6H_4Me\text{-}2)]$ (**23**), presumably through N−O cleavage in the intermediate $[Cr(NO)(C_6H_4Me\text{-}2)_2(NiPr_2)]$ (Scheme 7).[32]

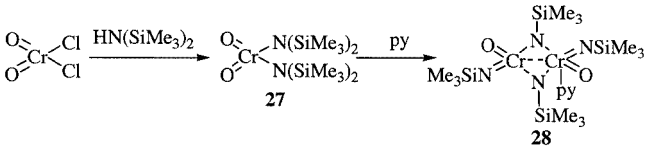


Scheme 7. Isolation of a mono(arylimido)Cr^{VI} complex from the alkylation of a (nitrosyl)Cr complex

2.2. (Imido)Cr^{V} Complexes

Treatment of $[CpCrCl_2]_2$ with $Me_3SiN{=}NSiMe_3$ gave the (silylimido)Cr^{V} complex $[CpCr(\mu\text{-}NSiMe_3)(NSiMe_3)]_2$ (**24**), which reacted with MeOH to yield the parent imido species $[CpCr(NH)(NSiMe_3)]_2$.[33] Reduction of **2** with cobaltocene gave dinuclear $[Cr(\mu\text{-}NtBu)(NtBu)Cl]_2$ (**25**).[17] Similarly, **9** reacted with LiCp or NaCp to give $[Cr(\mu\text{-}NC_6H_2iPr_2\text{-}2,6)(NC_6H_2iPr_2\text{-}2,6)Cl]_2$ (**26**).[26] Both **25** and **26** are diamagnetic, due to spin coupling through the imido bridges or Cr···Cr interaction [the Cr−Cr separation in **26** is 247.5(2) pm[26]].

Treatment of $[CrO_2Cl_2]$ with $(Me_3Si)_2NH$ afforded $[CrO_2\{N(SiMe_3)_2\}_2]$ (**27**), which reacted with pyridine to give the imido-bridged Cr^{V} dimer $[Cr_2(\mu\text{-}NSiMe_3)_2(NSiMe_3)_2(O)_2(py)]$ (**28**, Scheme 8).[34]

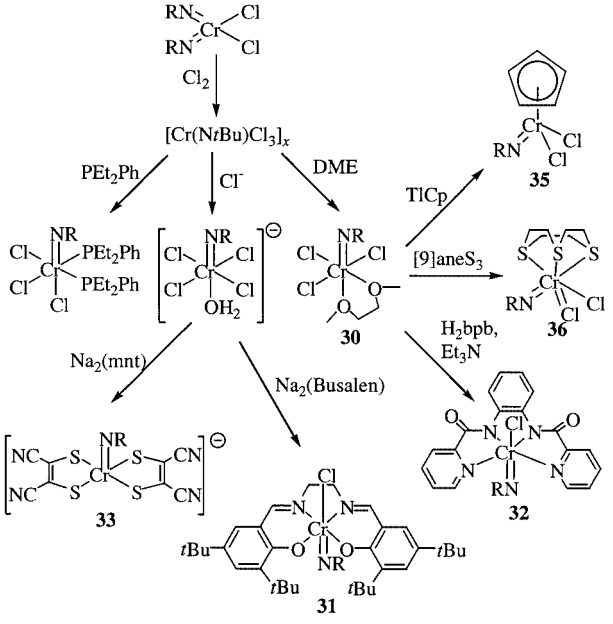


Scheme 8. Synthesis of a dinuclear (imido)(oxo)Cr^{V} complex

Treatment of **27** with *t*BuOH resulted in desilylation of the amido ligands and the formation of the (nitrido)Cr^{VI}

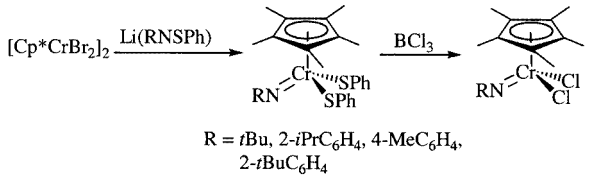
compound [Cr(N)(O*t*Bu)$_3$] (**29**). Complex **29** could also be prepared directly by addition of excess *t*BuOH to a reaction mixture of [NH$_4$]$_2$[Cr$_2$O$_7$], Me$_3$SiCl, HN(SiMe$_3$)$_2$, and Et$_3$N.[35]

Chlorination of **2** afforded mono(imido)Cr^{V} species [Cr(N*t*Bu)Cl$_3$]$_x$, which reacted with Lewis bases to give six-coordinate [Cr(N*t*Bu)Cl$_3$L$_2$] [L = PEt$_2$Ph, THF, py, 0.5DME (DME = 1,2-dimethoxyethane), 0.5bpy (bpy = 2,2′-bipyridine)].[36] Treatment of [Cr(N*t*Bu)Cl$_3$]$_x$ with CtCl in CH$_2$Cl$_2$ gave [Ct][Cr(N*t*Bu)Cl$_4$(H$_2$O)] {[Ct]$^+$ = [*n*Bu$_4$N]$^+$, [PPh$_4$]$^+$, or [N(PPh$_3$)$_2$]$^+$}.[36,37] Treatment of [Cr(N*t*Bu)Cl$_3$(DME)] (**30**) with H$_2$(bpb) [bis(2-pyridinecarboxamido)benzene] or with H$_2$(Busalen) [bis(2,4-di-*tert*-butylsalicylidene)diaminoethane] in the presence of a base afforded [Cr(N*t*Bu)(Busalen)Cl] (**31**)[37] and [Cr(N*t*Bu)(Cl)(bpb)] (**32**),[38] respectively. Treatment of [PPh$_4$][Cr(N*t*Bu)Cl$_4$(H$_2$O)] with Na$_2$(mnt) [mnt^{2-} = 1,2-maleonitriledithiolate(2−)] gave [PPh$_4$][Cr(N*t*Bu)(mnt)$_2$] (**33**)[36b] (Scheme 9), while treatment of **30** with NaO*t*Bu resulted in the isolation of [Cr(O*t*Bu)$_4$] together with [Cr(N*t*Bu)$_2$(O*t*Bu)$_2$], presumably through disproportionation of the trialkoxide intermediate [Cr(N*t*Bu)(OR)$_3$].[36b]



Scheme 9. Synthesis of mono(imido)Cr^{V} complexes

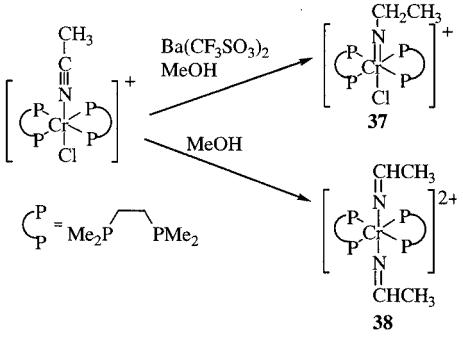
Treatment of **30** with NaL$_{OEt}$ (L$_{OEt^-}$ = [CpCo{P(O)(OEt)$_2$}$_3$]$^-$), TlCp (Cp = η^5-C$_5$H$_5$), or [9]aneS$_3$ gave [L$_{OEt}$Cr(N*t*Bu)Cl$_2$] (**34**), [CpCr(N*t*Bu)Cl$_2$] (**35**),[37] or [([9]ane[S$_3$])Cr(N*t*Bu)Cl$_2$]$^+$ (**36**),[39] respectively. Attempts to prepare (imido)(pentamethylcyclopentadienyl)Cr^{V} complexes from **30** and LiCp* or TlCp* (Cp* = η^5-C$_5$Me$_5$) were unsuccessful. Half-sandwich Cp*Cr^{V} imido complexes [Cp*Cr(NR)(SPh)$_2$] (R = *t*Bu, 2-*i*PrC$_6$H$_4$, 4-MeC$_6$H$_4$, 2-*t*BuC$_6$H$_4$) were prepared from [Cp*CrBr$_2$]$_2$ and Li(RNSPh).[40] Chlorination of [Cp*Cr(NR)(SPh)$_2$] with BCl$_3$ afforded [Cp*Cr(NR)Cl$_2$] (Scheme 10).[27]



Scheme 10. Synthesis of (imido)Cp*Cr^{V} complexes

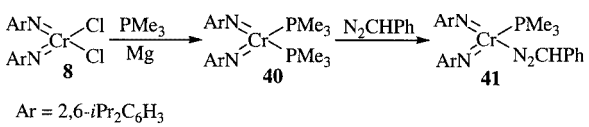
2.3. (Imido)Cr^{IV} and -Cr^{III} Complexes

Addition of a solution of Ba(CF$_3$SO$_3$)$_2$ in MeOH to [Cr(DMPE)$_2$(MeCN)Cl][BPh$_4$] [DMPE = 1,2-bis(dimethylphosphanyl)ethane] in MeCN afforded the (ethylimido)Cr^{IV} complex *trans*-[Cr(NEt)Cl(DMPE)$_2$]$^+$ (**37**). In contrast, addition of MeOH to [Cr(DMPE)$_2$(MeCN)Cl][BPh$_4$] in MeCN yielded the bis(ethylideneamido) complex *trans*-[Cr(N=CHMe)$_2$(DMPE)$_2$][BPh$_4$]$_2$ (**38**). It was proposed that the formation of complexes **37** and **38** involved hydride transfer from MeOH or methoxide to the carbon atom of the MeCN ligand (Scheme 11). Reduction of **30** with Na/Hg in the presence of DMPE gave [Cr(N*t*Bu)(DMPE)$_2$Cl]$^+$ (**39**).[36a] Complexes **37**−**39** are diamagnetic and show well-resolved ^{1}H NMR spectra in solution (Scheme 11).[41]



Scheme 11. Reaction between *trans*-[Cr(DMPE)$_2$(MeCN)Cl]$^+$ and MeOH

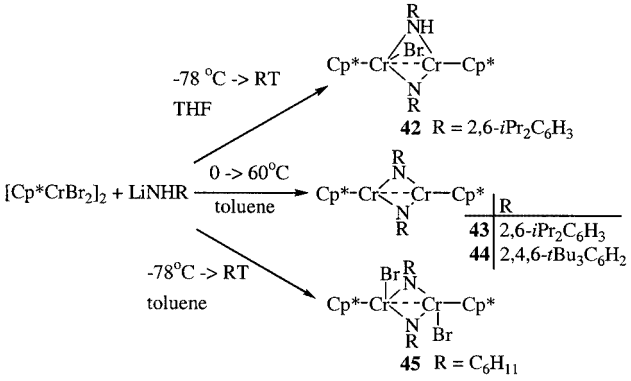
Heating of the dialkyl compounds [Cr(NC$_6$H$_2$Me$_3$-2,4,6)$_2$R$_2$] (R = CH$_2$Ph, CH$_2$CMe$_3$, CHCMe$_2$Ph) with PMe$_3$ in aromatic solvents afforded dinuclear (imido)Cr^{IV} complex [Cr(μ-NC$_6$H$_2$Me$_3$-2,4,6)(NC$_6$H$_2$Me$_3$-2,4,6)]$_2$.[25] Treatment of **10** with MgEtBr in the presence of PMe$_3$ resulted in the formation of [Cr$_2$(μ-NC$_6$H$_2$Me$_3$-2,4,6)$_2$(NC$_6$H$_2$Me$_3$-2,4,6)$_2$Br$_2$(PMe$_3$)],[25] while reduction of **9** with Mg in the presence of PMe$_3$ afforded [Cr(NC$_6$H$_3$*i*Pr$_2$-2,6)$_2$(PMe$_3$)$_2$] (**40**), which reacted with PhCHN$_2$ to give the diazoalkane compound [Cr(NC$_6$H$_3$*i*Pr$_2$-2,6)$_2$(PMe$_3$)(N$_2$CHPh)] (**41**, Scheme 12).[26]



Scheme 12. Preparation of bis(arylimido)Cr^{IV} complexes

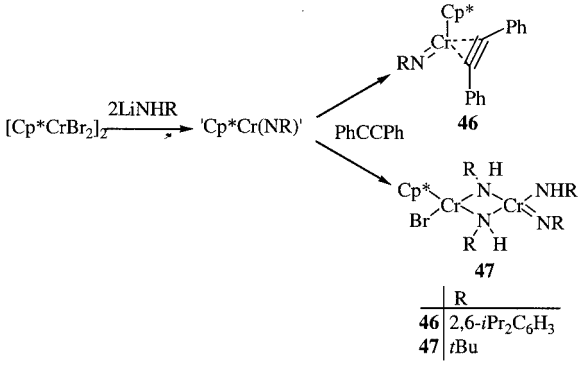
The (imido)Cr^{IV} porphyrins [$Cr(NC_6H_4X\text{-}4)(TPP)$] have been prepared from [Cr(TPP)] (TPP = tetraphenylporphyrin dianion) and aryl azides $4\text{-}XC_6H_4N_3$ (X = Me, Cl, I, MeO). Unlike the diamagnetic [Cr(O)(TPP)] and *trans*-$[Cr(NEt)Cl(DMPE)_2]^+$, [$Cr(NC_6H_4X\text{-}4)(TPP)$] are high spin, with measured μ_{eff} values of ca. 2.83 μ_B at 293 K. Treatment of [$Cr(TPP)(NC_6H_4Me\text{-}4)$] with [$V(O)(acac)_2$] (Hacac = 2,4-pentanedione) and [Fe(salen)(MeIm)] [salen = bis(salicylideneiminato)-1,2-diaminoethane, MeIm = 1-methylimidazole] afforded extremely moisture-sensitive imido-bridged dimetallic Cr−V and Cr−Fe species.[42]

The natures of the products of reactions between [Cp*$CrBr_2]_2$ and LiNHR were found to be dependent both upon the reactant used and upon the reaction conditions. Thus, treatment of [Cp*$CrBr_2]_2$ with 2,6-iPr$_2$C$_6$H$_3$NHLi in THF at −78 °C and subsequent rapid workup afforded dinuclear Cr^{III} complex [$(Cp^*Cr)_2(\mu\text{-}Br)(\mu\text{-}NHC_6H_3iPr_2\text{-}2,6)(\mu\text{-}NC_6H_3iPr_2\text{-}2,6)$] (**42**), which has a magnetic moment of 1.12 μ_B per Cr atom. The short Cr−Cr separation in **42** [264.7(5) and 265.1(5) pm)] is indicative of Cr···Cr interaction. On the other hand, addition of [Cp*$CrBr_2]_2$ to ArNHLi in toluene at 0 °C, followed by heating at 60 °C, gave the dinuclear (imido)Cr^{III} complexes [$Cp^*Cr(\mu\text{-}NAr)]_2$ (Ar = 2,6-iPr$_2$C$_6$H$_3$, **43**; 2,4,6-tBu$_3$C$_6$H$_2$, **44**). The Cr−Cr separations in **43** and **44** − of 259.1(1) and 256.4(1) pm, respectively − are indicative of Cr···Cr interaction. In contrast, treatment of [Cp*$CrBr_2]_2$ with $C_6H_{11}NHLi$ (C_6H_{11} = cyclohexyl) in toluene at −78 °C gave the paramagnetic dinuclear (imido)Cr^{IV} complex [$Cp^*CrBr(\mu\text{-}NC_6H_{11})]_2$ (**45**), presumably through 2 III → IV + II disproportionation (Scheme 13).[43]



Scheme 13. Reactions of [Cp*$CrBr_2]_2$ with RNHLi

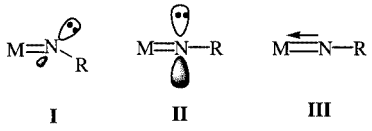
It seems likely that complexes **42**−**45** were formed by dimerization of the "Cp*Cr(NR)" intermediates that could be trapped by donor ligands. Thus, treatment of "Cp*$Cr(NC_6H_3iPr_2\text{-}2,6)$", prepared in situ from [Cp*$CrBr_2]_2$ and 2,6-iPr$_2$C$_6$H$_3$NHLi, with PhC≡CPh gave [Cp*$Cr(NC_6H_3iPr_2\text{-}2,6)(\eta^2\text{-}PhC{\equiv}CPh)$] (**46**). The C−C distance of the acetylene ligand in **46** is fairly long [129.5(5) pm], indicative of C=C double bond character, and so the Cr oxidation state for **46** could be assigned as either III or V. Complex **46** has a measured μ_{eff} of 2.20 μ_B at room temperature and showed an isotropic EPR signal at g = 2.007 with α_N = 3.7 G. In contrast, treatment of "Cp*Cr(NtBu)" (prepared in situ) with PhC≡CPh gave [Cp*CrBr(μ-NHtBu)$_2$Cr(NHtBu)(NtBu)] (**47**, Scheme 14).[43]



Scheme 14. Trapping of [Cp*Cr(NR)] intermediates by diphenylacetylene

3. Linear versus Bent Binding Modes of Imido Ligands

Imido groups bind to transition metal atoms either in linear or in bent fashion (Scheme 15). In general, linear imido ligands have M−N−C angles greater than 160°, whereas the bond angles for bent ones are less than 150°, although the dividing line between these two binding modes is not clear-cut. In valence bond description terms, the bent imido group − with sp^2-hybridized nitrogen atom − is regarded as a 4e donor (structure **I**). On the other hand, the linear imido group − with sp-hybridized nitrogen atom − can be either a 4e or a 6e donor, depending upon whether there are one or two M−N π bonds (structures **II** and **III**, respectively).[15]



Scheme 15. Valence bond description of linear and bent imido ligands[15]

The bent and linear binding modes for imido ligands have recently been investigated both theoretically[44−49] and experimentally.[50−55] Nitrogen NMR studies indicate that complexes possessing both linear and bent imido groups are fluxional in solution and that the energy barrier to bending of the M−N−C unit is relatively small,[51] consistently with the results of theoretical studies.[32,44,49] It appears that both electronic and steric factors affect the geometry of the imido ligands. Thus, while the observation of one bent imido ligand in [$Mo(NPh)_2(Et_2NCS_2)_2$] [Mo−N−C angle of

139.4(4)°; cf. 169.4(4)° for the linear one] has been interpreted in terms of the 18e rule,[53] the more bulky 2,6-diisopropylphenylimido analogue [Mo($NC_6H_3iPr_2$-2,6)$_2$(Et_2NCS_2)$_2$] possesses essentially linear imido groups [Mo−N−C angle of 169.9(2)°], presumably due to steric effects.[54]

The vast majority of (imido)Cr complexes so far isolated contain essentially linear imido ligands (type **III**). One of the imido ligands in **6** was found to be bent [Cr−N−C(imido) angle = 151.8(4)°], but this bending was attributed to crystal packing rather than electronic effects. It may be noted that both imido groups in the Mo analogue [Mo(TACN)(N*t*Bu)$_2$Cl][ClO_4] are essentially linear [Mo−N−C(imido) angles are 171.1(3) and 161.5(3)°].[22] An example of a strongly bent (imido)Cr complex is **23**, the Cr−N−C(imido) angle of which is 146.2(3)°. The bent Cr−N−C(imido) angle in **23** was explained in terms of π-conflict between the oxo and the imido groups. In order to investigate the origin of the bending of the Cr−N−C(imido) unit in **23**, DFT calculations were performed on a simplified model compound [Cr(NMe)(O)(N-Me_2)Me], which lacks the steric bulk present in **23**. It was found that the DFT-optimized geometry of [Cr(NMe)(O)(NMe_2)Me] satisfactorily reproduced the pertinent structural features in **23**. The calculated Cr−N−C(imido) angle of 149.0° is similar to that found in **23**, suggesting that electronic factors play a significant role in the distortion in **23**.[32]

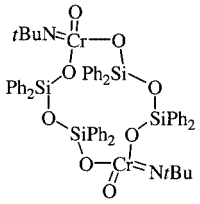
4. Electrochemistry of (Imido)Cr Complexes

The reduction couples observed in the range of −1.2 to −2.0 V vs. $Cp_2Fe^{+/0}$ for bis(imido)Cr^{VI} complexes have been attributed to metal-centered $Cr^{VI/V}$ reduction. For example, the diaryl compound **14** underwent 1e reduction in THF at $E_{1/2}$ = −1.31 V vs. Ag/AgCl (ca. −1.65 V vs. $Cp_2Fe^{+/0}$).[28] The $Cr^{VI/V}$ couple for the diaryl oxide compound **8** was found at −1.2 V vs. $Cp_2Fe^{+/0}$,[20] which is less negative than that for **14**, indicating that the σ-aryl moiety is a stronger donor than the aryl oxide. As would be expected, the $Cr^{VI/V}$ couple for dicationic **5** has a less negative $Cr^{VI/V}$ potential (−0.74 vs. $Cp_2Fe^{+/0}$).[20] Attempts to isolate bis(imido)Cr^{V} complexes by reduction of **5** or **14** with reducing agents were unsuccessful. For **6**, in addition to the Cr-centered reduction wave at −1.29 V vs. $Cp_2Fe^{+/0}$, a quasi-reversible oxidation couple was observed at 0.86 V and attributed to imido-centered oxidation. A similar oxidation potential (0.99 V) was found for the Mo analogue [Mo(TACN)(N*t*Bu)$_2$Cl]$^+$.[21] Cyclic voltammograms of (imido)Cr^{V} complexes showed irreversible reduction waves that were assigned to $Cr^{V/IV}$ reduction. For example, the $Cr^{V/IV}$ reduction for **31** was found at −0.71 V, which is more negative than that for the oxo analogue [Cr(O)(L)]$^+$ [L = 2,3-dimethyl-*N*,*N*′-bis(salicylidene)butane-2,3-diamine] (0.63 V vs. standard calomel electrode), reflecting the higher donor strength of imide relative to oxo.[37]

5. Reactivity of (Imido)Cr Complexes

5.1. Hydrolysis

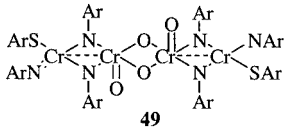
(Imido)Cr complexes are generally moisture-sensitive and readily hydrolyze to (oxo)Cr complexes. However, cationic bis(imido)Cr^{VI} complexes **5** and **6** are air-stable and inert to hydrolysis. Treatment of **1** with 1 equiv. of water in diethyl ether afforded the (imido)(oxo) complex [Cr(O)(N*t*Bu)($OSiMe_3$)$_2$], which reacted with PCl_5 to give [Cr(O)(N*t*Bu)Cl_2].[19] Treatment of **2** with [O(Ph_2SiOH)$_2$] in the presence of pyridine gave a dinuclear chromosiloxane complex [{Cr(O)(N*t*Bu)(OPh_2SiO)$_2$}$_2$] (**48**, Figure 2), the oxo group of which was presumably derived from the silanol.[56]



48

Figure 2. Structure of [{Cr(O)(N*t*Bu)(OPh_2SiO)$_2$}$_2$]

Treatment of [Cr(NAr)$_2$(SAr)$_2$] (Ar = 2,4,6-$Me_3C_6H_2$) with PMe_2Ph, followed by workup in the presence of adventitious oxygen, afforded an interesting tetranuclear (imido)(oxo)Cr cluster [Cr_4(μ-O)$_2$(μ-NAr)$_4$(O)$_2$(NAr)$_2$(SAr)$_2$] (**49**, Figure 3) in low yield.[57]



49

Ar = 2,4,6-$Me_3C_6H_2$

Figure 3. Structure of [Cr_4(μ-O)$_2$(μ-NAr)$_4$(O)$_2$(NAr)$_2$(SAr)$_2$] (Ar = 2,4,6-$Me_3C_6H_2$)

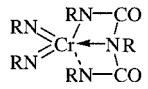
5.2. Cycloaddition

The [2 + 2] cycloaddition reactions between imido complexes and doubly bonded X=Y systems, presumably through four-membered metallacyclic intermediates (Scheme 16), are well documented.

Scheme 16. [2 + 2] cycloadditions between M=NR and X=Y

Treatment of **1** with PhCHO afforded the (imido)(oxo)-Cr^{VI} complex [Cr(N*t*Bu)(O)($OSiMe_3$)$_2$] and PhCH=N*t*Bu.[58] While **2** underwent cycloaddition and imido group exchange with aryl isocyanates ArNCO to give [Cr(NAr)$_2$$Cl_2$], no reactions were found between [Cr(NAr)$_2$$Cl_2$] and *t*BuNCO.[25] Treatment of

$[Cr(NtBu)_2\{N(SiMe_3)_2\}_2]$ with *t*BuNCO resulted in isocyanate insertion into the Cr−amide bond to give the *N*,*N*′,*N*′′-tri-*tert*-butylbiureto complex $[Cr(NtBu)_2\{(tBuNCO)_2NtBu\}]$ (**50**, Figure 4) rather than cycloaddition of Cr=N*t*Bu with isocyanate.[59]

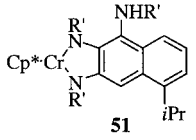


50

R = *t*Bu

Figure 4. Structure of $[Cr(NtBu)_2\{(tBuNCO)_2NtBu\}]$

Treatment of "Cp*Cr($NC_6H_3iPr_2$-2,6)" (prepared in situ) with 2,6-$Me_2C_6H_4NC$ resulted in coupling of the isocyanide with Cr=$NC_6H_3iPr_2$-2,6 and the formation of a Cp*Cr^{III} complex containing an *N*,*N*-bis(2,6-diisopropylphenyl)-4-isopropyl-1-(2,6-xylylamino)naphthaline-2,3-diamido ligand (**51**, Figure 5).[40]



51

R = 2,6-$iPr_2C_6H_3$, R′ = 2,6-$Me_2C_6H_3$

Figure 5. Structure of the product obtained on treatment of "Cp*Cr($NC_6H_3iPr_2$-2,6)" with 2,6-$Me_2C_6H_3NC$

Recent theoretical studies on olefin polymerization with bis(imido)Cr^{VI} catalysts revealed that the [2 + 2] cycloadditions between C=C and Cr=NR double bonds proceed with very low energy barriers. It was suggested that the resulting azachromacycles could be a starting point for further modification of the (alkyl)Cr^{VI} cations in the catalytic cycle.[12]

5.3. Imido Group Transfer

Organoimido complexes are less reactive than acylimido (M=NCOR) and tosylimido ($M=NSO_2R$) complexes toward imido group transfer. (Imido)Cr complexes undergo imido transfer with strong reducing agents such as tertiary phosphanes[20,36b,37,42] and isocyanides.[57,60] Imido transfer from (imido)Cr^{IV}−porphyrin compounds to benzaldehyde, CS_2, and styrene has also been reported,[42] and imido group transfer to phosphanes from (imido)Cr^{V} complexes was found to be catalyzed by light.[36,37] It was noted that the reactivity of (imido)Cr complexes toward imido transfer could be correlated with the electron deficiency at the Cr center.[20] Thus, while no reaction was found between the diaryl oxide compound **8** ($E_{1/2}$ = −1.2 V vs. $Cp_2Fe^{+/0}$) and PMe_3, dicationic **5** ($E_{1/2}$ = −0.74 V vs. $Cp_2Fe^{+/0}$) readily underwent imido transfer with tertiary phosphanes to give phosphanimines. Under pseudo-first-order conditions, the reaction between **5** and PMe_3 was found to follow biphasic kinetics, with $k_{obs1} \propto [PMe_3]$ and $k_{obs2} \propto [PMe_3]^2$. The kinetic data are consistent with a two-step mechanism as shown in Scheme 17.[20]

step 1

$$[Cr(NtBu)_2(terpy)]^{2+} + PMe_3 \xrightarrow{k_2} [Cr(NtBu)(terpy)]^{2+} + tBu{=}PMe_3$$

step 2

$$[Cr(NtBu)(terpy)]^{2+} + PMe_3 \overset{K}{\rightleftharpoons} [Cr(NtBu)(terpy)(PMe_3)]^{2+}$$

$$[Cr(NtBu)(terpy)(PMe_3)]^{2+} + PMe_3 \xrightarrow{k'} Cr(II) + tBuN{=}PMe_3$$

Scheme 17. Proposed mechanism for imido transfer from $[Cr(NtBu)(terpy)]^{2+}$ to PMe_3

For step 1, rate = k_2[Cr][PMe_3]. For step 2, at $K[PMe_3] >> 1$, rate = Kk'[Cr][PMe_3]^2 with $k_3 = kK'$. At 25 °C in acetonitrile solution, $k_2 = 0.48 \pm 0.10$ $M^{-1}\cdot s^{-1}$ and $k_3 = Kk' = 1.44 \pm 0.16$ $M^{-2}\cdot s^{-1}$.[20]

Treatment of $[Cr(NC_6H_2Me_3\text{-}2,4,6)_2(SC_6H_2Me_3\text{-}2,4,6)_2]$ with 2,6-$Me_2C_6H_3NC$ at reflux resulted in the formation of the mono(imido)Cr^{IV} complex $[Cr(NC_6H_2Me_3\text{-}2,4,6)(SC_6H_2Me_3\text{-}2,4,6)_2(CNC_6H_4Me_2\text{-}2,6)_2]$ and the carbodiimide 2,4,6-$Me_3C_6H_2N{=}C{=}NC_6H_3Me_2$-2,6. It seems likely that the imido transfer to the isocyanide occurred through a (η^2-carboimide)Cr intermediate.[57] Treatment of $[Cr(NC_6H_2Me_3\text{-}2,4,6)_2(SC_6F_5)_2]$ with 2,6-$Me_2C_6H_3NC$ resulted in the isolation of *mer*-$[Cr(SC_6F_5)_3(NCC_6H_2Me_2\text{-}2,6)_3]$ and *trans*-$[Cr(SC_6F_5)_2(NCC_6H_2Me_2\text{-}2,6)_4]$, together with other unidentified products.[60] No imido transfer was found between 2,6-$Me_2C_6H_3NC$ and either $[Cr(NC_6H_2iPr_3\text{-}2,4,6)(SC_6H_2Me_3\text{-}2,4,6)_2]$ or $[Mo(NAr)_2(SC_6H_3iPr_2\text{-}2,6)_2]$ (R = 2,4,6-$Me_3C_6H_2$ or 2,6-$iPr_2C_6H_3$), probably because of steric effects.[57][60]

5.4. Addition of Alkyl Group to Imido Ligand

Nugent and Harlow studied the addition of alkyl groups to coordinated imido groups in attempts to model the C−N formation step in ammoxidation of propylene. Thus, treatment of **1** with Ph_2Zn, followed by hydrolysis, afforded organic products including *tert*-butylaniline and biphenyl. It was believed that the former product was formed by the Cr-to-N migration of the phenyl ligand in a mono(phenyl)Cr^{VI} intermediate, whereas the latter product originated from reductive elimination of a diphenylCr^{VI} species.[61] Similarly, the reaction between **1** and benzyl radical, generated from toluene and dibenzyl peroxide, resulted in addition of benzyl radical to the imido nitrogen atom. Upon hydrolysis, *t*BuN=CHPh was produced, along with CO_2, bibenzyl, and methylbiphenyls.[1b] The (amido)Cr^{IV} species $[Cr\{N(C_6H_4\text{-}Me_3\text{-}2,4,6)(4\text{-}tBuC_6H_4)Cl\}_2(\mu\text{-}NC_6H_4Me_3\text{-}2,4,6)Cl]_2$, obtained from the alkylation of **9** with 4-$tBuC_6H_4CH_2MgCl$, has been isolated and characterized structurally.[25] No alkyl group migration was found for the alkylation of **1** with 2,4,6-$Me_3C_6H_2MgBr$, apparently because of the steric bulk of the mesityl group.[28] However, thermal decomposition of $[Cr(NtBu)_2\{C(O)C_6H_2Me_3\text{-}2,4,6\}_2]$, prepared by carbonylation of **14**, yielded 2,4,6-$Me_3C_6H_2C(O)NHtBu$, pre-

sumably through migration of the acyl group to the imido nitrogen atom.[28]

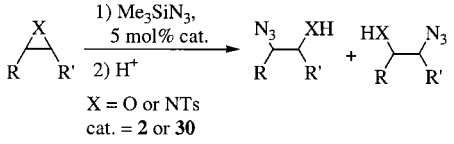
6. Reactions Catalyzed by (Imido)Cr Complexes

6.1. Olefin Polymerization

Chromium catalysts play important roles in the manufacture of polyolefins in industry. To this end, much effort has been devoted to the development of new, well-defined molecular chromium catalysts for olefin polymerization.[62] The catalytic activity of bis(imido)Cr^{VI} complexes and half-sandwich Group-5 CpM(NR) systems, which are isolobal with Group-4 metallocenes, toward olefin polymerization has been investigated.[11] Gibson and co-workers reported that **2** in conjunction with an activator such as MAO (methylaluminoxanes) and Et_2AlCl was capable of polymerization of ethylene to give poly(ethylene)s of high molecular weights with little branching. $[Mo(N\textit{t}Bu)_2Cl_2]$ was found to be a less active polymerization catalyst than the Cr congener.[11a] The dibenzyl compound $[Cr(N\textit{t}Bu)_2(CH_2Ph)_2]$ was able to polymerize ethylene in the presence of boron activators $[PhNMe_2H][B(C_6F_5)_4]$, $[CPh_3][B(C_6F_5)_4]$, and $B(C_6F_5)_3$ to give poly(ethylene)s of high molecular weights.[11c,29] Both $[Cr(NC_6H_4Me_2\text{-}2,6)_2Me_2]$ and $[Mo(NC_6H_4Me_2\text{-}2,6)_2Me_2]$ are active catalysts for polymerization of ethylene in the presence of $B(C_6F_5)_3$.[11c] Treatment of $[Cr(N\textit{t}Bu)_2(CH_2Ph)_2]$ with $[CPh_3][B(C_6F_5)_4]$ afforded an oily cationic species $[Cr(N\textit{t}Bu)_2(\eta^2\text{-}CH_2Ph)]^+$, which reacted with PMe_3 to give the monophosphane adduct. On the other hand, $[Cr(N\textit{t}Bu)_2(CH_2Ph)_2]$ reacted with $[PhNMe_2H][B(C_6F_5)_4]$ to yield a mixture of mono- and bis(dimethylaniline) adducts $[Cr(N\textit{t}Bu)_2(\eta^2\text{-}CH_2Ph)(NMe_2Ph)_n]^+$ (n = 1 or 2). Solutions containing $[Cr(N\textit{t}Bu)_2(\eta^2\text{-}CH_2Ph)]^+$ or $[Cr(N\textit{t}Bu)_2(\eta^2\text{-}CH_2Ph)(NMe_2Ph)_n]^+$ are capable of catalyzing ethylene polymerization in the absence of a co-catalyst.[11c] A recent theoretical study on $[Cr(NR)_2(C_3H_7)(C_2H_4)]^+$ (R = H, *t*Bu) revealed a facile reductive elimination involving β-hydrogen transfer from the alkyl chain, suggesting that the active species for the bis(imido)Cr^{VI}-based catalysts contain Cr in a lower oxidation state.[12b] Recently, Siemeling and co-workers reported that an *ansa*-bis(imido)Cr^{VI} complex $[(NCMe_2CH_2CH_2CMe_2N)Cr(CH_2Ph)(\eta^2\text{-}CH_2Ph)]$ (**52**), prepared from $[Cr(NCMe_2CH_2CH_2CMe_2N)Cl_2]$ and $PhCH_2MgCl$, and complex **17**, were capable of catalyzing polymerization of acrylonitrile in the absence of a co-catalyst to give poly(acrylonitrile)s with high molecular weights. Complexes **17** and **52** also catalyzed the copolymerization of acrylonitrile and methyl methacrylate.[63]

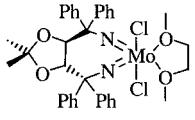
6.2. Ring-Opening of Epoxides and Aziridines

Coordinatively unsaturated imido complexes are good Lewis acid catalysts because of the presence of low-lying vacant metal d-orbitals, their high solubility in organic solvents, and their low tendency to dimerize or oligomerize in organic solvents. In view of this, the use of (imido)metal complexes as Lewis acid catalysts for ring-opening of epoxides and aziridines has been investigated. (Imido)Cr complexes **2** and **30** were capable of catalyzing ring-opening of epoxides[64] and tosylaziridines[65] with Me_3SiN_3 in good yield and with good regioselectivity (Scheme 18).



Scheme 18. Ring-opening of epoxides and aziridines catalyzed by (imido)Cr complexes

Treatment of styrene oxide (R = Ph, R′ =H) with Me_3SiN_3 and a catalytic amount of **2** exclusively gave 2-azido-1-phenylethanol, consistent with the Lewis acid mechanism for epoxide ring-opening. The catalytic activity of (imido)-metal complexes was found to decrease in the order **30** > **2** > $[Mo(N\textit{t}Bu)_2Cl_2]$.[64] It is believed that (azido)(imido)Cr complexes are the active intermediates for the Cr-mediated azidolysis of epoxides. Indeed, treatment of **2** with Me_3SiN_3 afforded dinuclear $[Cr(\mu\text{-}N_3)(N\textit{t}Bu)_2Cl]_2$, an active catalyst for epoxide ring-opening.[65] In an attempt to prepare a chiral (imido)Cr complex for asymmetric catalysis, **30** was treated with (*S*,*S*)-DIOP {(*S*,*S*)-4,5-[bis(diphenylphosphanyl)methyl]-2,2-dimethyl-1,3-dioxolane}. Unfortunately, dinuclear $[Cr(N\textit{t}Bu)Cl_3]_2${μ-(*S*,*S*)-DIOP} was isolated rather than mononuclear (*S*,*S*)-DIOP complex.[66] Recently, Sundermeyer and co-workers prepared a chiral Mo^{VI} complex with a C_2-symmetric bidentate diimido ligand $[TADDAMINat]^{4-}$ [TADDAMIN = (4*S*,5*S*)-2,2-dimethyl-α,α,α′,α′-tetraphenyl-1,3-dioxolane-4,5-diylbis(methanamine)]. [Mo(TADDAMINat)Cl_2(DME)] (**53**, Figure 6) has been used as a catalyst for the kinetic resolution of styrene oxide with Me_3SiN_3 and the asymmetric trimethylsilylcyanation of benzaldehyde. The enantioselectivities for the two reactions were 30 and 20% *ee*, respectively.[67]

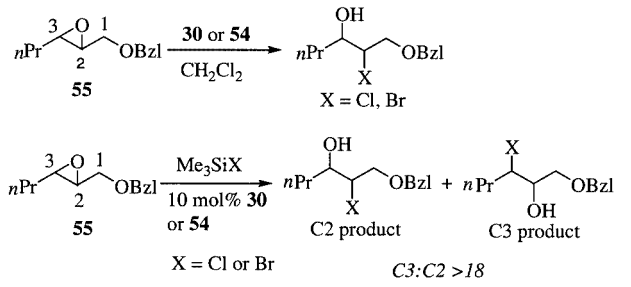


53

Figure 6. Structure of [Mo(TADDAMINat)Cl_2(DME)]

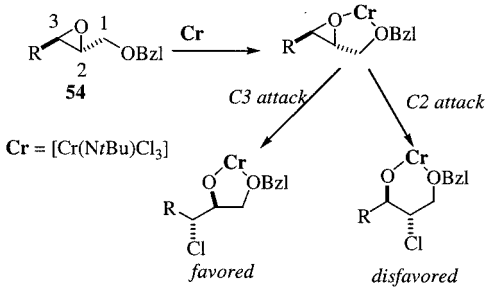
Because of the high affinities of (imido)Cr^{V} complexes for O-donor ligands, **30** and $[Cr(N\textit{t}Bu)Br_3(DME)]$ (**54**) were used to study the regioselectivity of ring-opening of disubstituted epoxides containing benzyloxy groups. Thus, treatment of **30** or **54** with disubstituted epoxide **55** afforded the corresponding 3-halohydrins in good yield and with good selectivity (C-3/C-2 > 49:1). The imido complexes **30** and **54** were also capable of catalyzing regioselective ring-opening of disubstituted epoxides with trimethylsilyl halide. Thus, treatment of epoxide **55** with trimethylsilyl halide in

the presence of a catalytic amount of **30** or **54** afforded the halohydrins with good C-3 selectivity (C-3/C-2 > 18, Scheme 19).[68]



Scheme 19. Cr-mediated regioselective ring-opening of benzyloxy epoxides

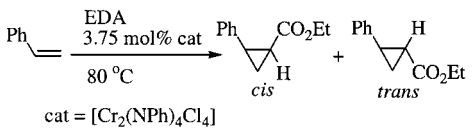
The observed C-3 selectivity for the ring-opening of **55** has been explained in terms of Cr chelation (Scheme 20). Nucleophilic attack at C-3 is preferred because of the higher stability of the five-membered metallacycle intermediate relative to the six-membered analogue.[68]



Scheme 20. Proposed mechanism for Cr-catalyzed regioselective ring-opening of disubstituted epoxides

6.3. Cyclopropanation of Olefins

Bis(imido)Cr^{VI} complexes $[Cr(\mu\text{-}NPh)(NPh)Cl_2]_2$ and $[Cr(NAr)_2Cl_2]$ (Ar = 2,6-$Cl_2C_6H_3$ or 2,6-$Br_2C_6H_3$) were found to catalyze cyclopropanation of substituted styrene on treatment with ethyl diazoacetate (EDA, Scheme 21). For example, treatment of styrene with EDA in the presence of ca. 4 mol % of $[Cr(\mu\text{-}NPh)(NPh)Cl_2]_2$ afforded the cyclopropane product in 90% yield with a *cis*/*trans* ratio of 0.65. Treatment of ethyl acrylate with EDA in the presence of the (imido)Cr catalyst afforded both cyclopropane and vinyl C−H insertion products.



Scheme 21. Cyclopropanation of styrene catalyzed by (imido)Cr complexes

The active intermediate for the Cr-catalyzed cyclopropanation was believed to be a Cr imido carbene species, possibly $[Cr(NPh)_2Cl_2(CHCO_2Et)]$. A competition experiment for the Cr-mediated carbene transfer showed that ethyl acrylate was consumed in preference to styrene, indicative of the nucleophilic character of the (carbene)Cr intermediate.[69]

7. Concluding Remarks

The successes obtained in isolation of stable (imido)Cr^{VI} and -Cr^{V} complexes and their organometallic derivatives demonstrate the significance of organoimido groups as stabilizing spectator ligands for organometallic compounds with highly oxidizing metal centers. In addition, owing to the steric bulk of organoimido ligands, coordinatively unsaturated $M(NR)_2$ and M(NR) complexes that are reactive toward unsaturated organic substrates can readily be synthesized. For example, d^0 Group-6 M(NR) and $M(NR)_2$ complexes have been found to be well-defined catalysts for olefin metathesis and polymerization, and have been used as Lewis acid catalysts for organic transformations. Recently, the imido chemistry has been extended to the right-hand side of the first transition series.[70−74] Notably, a new family of stable imido complexes of Mn in oxidation states VII−V has been synthesized by Danopoulos et al.[52,70] It may therefore be anticipated that compounds of Fe in less common oxidation states, such as Fe^{IV} and Fe^{V}, should be accessible if stabilized by organoimido ligands[72] and would exhibit novel organometallic chemistry.

Unexpected Effect of Cyclodextrins on Water-Soluble Rhodium Complexes[‡]

Laurent Caron,[a] Mickael Canipelle,[a] Sébastien Tilloy,[a] Hervé Bricout,[a] and Eric Monflier*[a]

Keywords: Rhodium / Phosphanes / Biphasic catalysis / Cyclodextrins / Molecular recognition

As shown by ^{31}P NMR spectroscopy, addition of β-cyclodextrin or randomly methylated β-cyclodextrin to an aqueous solution of $[HRh(CO)\{P(m\text{-}C_6H_4SO_3Na)_3\}_3]$ has no effect on the organometallic complex. In contrast, $[HRh(CO)\{(p\text{-}t\text{Bu}C_6H_4)P(m\text{-}C_6H_4SO_3Na)_2\}_3]$ can be partially converted in the presence of the same β-cyclodextrin derivatives into the hydroxy complex $[HORh(CO)\{(p\text{-}t\text{Bu}C_6H_4)P(m\text{-}C_6H_4SO_3Na)_2\}_2]$, under nitrogen, or to the hydrido complex $[HRh(CO)_2\{(p\text{-}t\text{Bu}C_6H_4)P(m\text{-}C_6H_4SO_3Na)_2\}_2]$ under carbon monoxide. This remarkable difference of behavior was attributed to the fact that the phosphane $(p\text{-}t\text{Bu}C_6H_4)P(m\text{-}C_6H_4SO_3Na)_2$ forms more stable inclusion complexes with the β-cyclodextrin derivatives than the phosphane $P(m\text{-}C_6H_4SO_3Na)_3$.

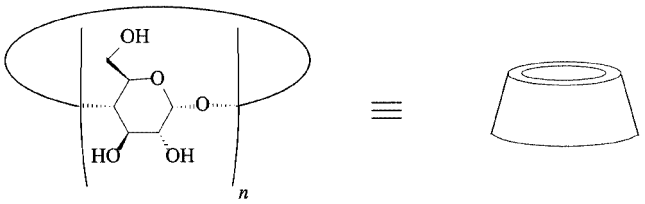
Introduction

In the course of our work on the use of cyclodextrins as mass-transfer promoters in aqueous-phase organometallic catalysis, we found that cyclodextrins (Scheme 1) form inclusion compounds with the water-soluble ligands used to dissolve the catalyst in the aqueous phase.[1,2] We have reported that tris(3-sodiosulfonatophenyl)phosphane [TPPTS; $P(m\text{-}C_6H_4SO_3Na)_3$],[3,4] diphenyl(3-sodiosulfonatophenyl)phosphane [TPPMS; $(C_6H_5)_2P(m\text{-}C_6H_4SO_3Na)$][5,6] and (4-*tert*-butylphenyl)bis(3-sodiosulfonatophenyl)phosphane [*t*BuTPPDS; $(p\text{-}t\text{Bu}C_6H_4)P(m\text{-}C_6H_4SO_3Na)_2$][7] are partially included in the hydrophobic cavity of the β-cyclodextrin derivatives. In the case of TPPMS and *t*BuTPPDS, it was also clearly demonstrated that the group included into the cavity is a non-sulfonated ring of the phosphane.



$n = 6$ α-cyclodextrin
$n = 7$ β-cyclodextrin
$n = 8$ γ-cyclodextrin

Scheme 1. Schematic representation of the shape of α-cyclodextrin ($n = 6$), β-cyclodextrin ($n = 7$) and γ-cyclodextrin ($n = 8$); the protons H-3 and H-5 are situated inside the host cavity, whereas protons H-1, H-2 and H-4 point outwards

Although we have assumed that these inclusion complexes can induce a decreased selectivity in the rhodium-catalyzed hydroformylation reaction by modifying the different equilibria between the catalytic species,[8] no spectroscopic evidence of an interaction of cyclodextrins with the catalysts has been obtained until now. In order to correct this, we have studied the influence of β-cyclodextrin (β-CD) or randomly methylated β-cyclodextrin (RAMEB) on two water-soluble, phosphane-modified rhodium hydroformylation catalysts by ^{31}P NMR spectroscopy. The water-soluble phosphanes used for this study were TPPTS and *t*BuTPPDS. These two phosphanes were chosen for their different affinity towards β-CD and RAMEB: the values of the association constants for the TPPTS/β-CD and *t*BuTPPDS/β-CD inclusion complexes were estimated to be 1,200 and 400,000 M^{-1} at 25 °C, respectively.[4,7] In the case of RAMEB, these values are lower and were estimated to be 1,000 and 250,000 M^{-1} at 25 °C for the TPPTS/RAMEB and *t*BuTPPDS/RAMEB inclusion complexes, respectively.[7,8]

Results and Discussion

Initial experiments were conducted with the complex $[HRh(CO)(TPPTS)_3]$ (**1**). As shown in Figure 1, the ^{31}P NMR spectrum of **1** (3 mM) exhibits, besides the minor resonance of the phosphane oxide impurity at $\delta = 35.7$ ppm, a characteristic sharp doublet at $\delta = 44.7$ ppm ($J_{Rh,P} = 156$ Hz).[9,10]

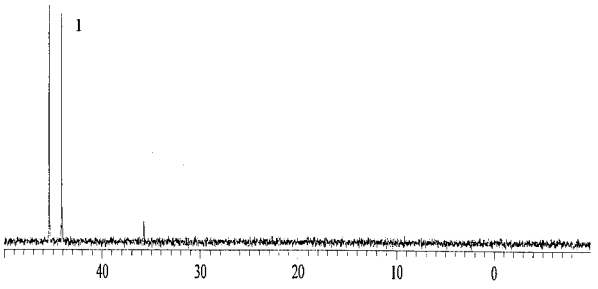

Figure 1. ^{31}P NMR spectrum of **1** (3 mM) at 27 °C in D_2O under nitrogen

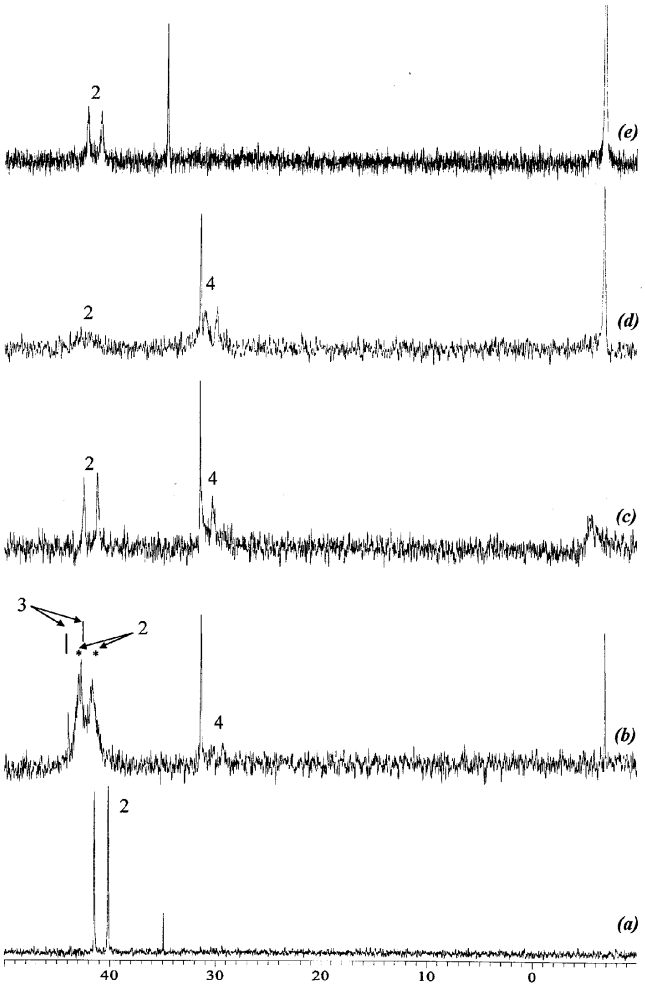

Figure 2. Effect of β-CD on complex **2**: (a) ^{31}P NMR spectrum of **2** (3 mM) in D_2O at 27 °C under nitrogen; (b) after addition of β-CD (9 mM) at 27 °C; (c) after 1 hour at 60 °C and recorded at 60 °C under nitrogen; (d) previous solution allowed to cool to 27 °C and recorded after 1 hour at 27 °C under nitrogen; (e) previous solution after addition of *t*BuTPPDS (9 mM) under 1 bar of hydrogen

When three equivalents of β-CD or RAMEB (9 mM) was added under nitrogen or carbon monoxide to an aqueous solution of **1**, no significant shift of any NMR signal was observed at different temperatures (20, 40 and 60 °C), suggesting that the cyclodextrin derivatives have no effect on the organometallic complex.

In the case of the complex [HRh(CO)(*t*BuTPPDS)$_3$] (**2**), addition of β-CD to the rhodium catalyst solution results in changes in the ^{31}P NMR spectrum. Indeed, the signal of **2** [δ = 40.8 ppm (d, $J_{Rh,P}$ = 155 Hz)] decreases significantly in intensity and three new signals are observed. The first signal at δ = −6.4 ppm is due to the *t*BuTPPDS/β-CD inclusion complex.[7] The second signal at δ = 43.2 ppm (d, $J_{Rh,P}$ = 155 Hz) and the third signal at δ = 30.4 ppm (d, $J_{Rh,P}$ = 131 Hz) were attributed to two new rhodium species **3** and **4** containing less than three phosphanes, as non-coordinated phosphane was observed at δ = −6.4 ppm (see Figure 2a and 2b).

Finally, it must be pointed out that the chemical shift difference for *t*BuTPPDS oxide (δ = 35 ppm without β-CD vs. δ = 31.4 ppm in the presence of β-CD) is due to the formation of an inclusion complex between β-CD and the phosphane oxide.[7]

Interestingly, when an aqueous solution of **2** was heated at 60 °C for one hour under nitrogen and the NMR spectra recorded at this temperature, the intensity of the signal of **4** increased significantly while the signal of **3** disappeared (Figure 2c). When the solution was allowed to cool to room temperature, only the signals of the *t*BuTPPDS/β-CD inclusion complex, **2** and **4** were observed (Figure 2d). The formation of **3** and **4** cannot be due to the temperature increase as no reaction occurred even at high temperature (80 °C) in the absence of cyclodextrins under the same experimental conditions.

As shown in Figure 3, addition of RAMEB to **2** under nitrogen also affects the ^{31}P NMR spectrum. However, only signals of **3** and the RAMEB-phosphane complex appear at room temperature; the formation of **4** requires heating of the complex solution to 60 °C (see Figure 3a−c).

As in the case of the β-CD, complex **3** disappears when the solution is warmed. It should be stressed that the chemical shift of *t*BuTPPDSO/RAMEB complex (δ = 30.1 ppm is lower than that of *t*BuTPPDSO/β-CD complex (δ = 31.4 ppm), probably owing to the affinity difference of phosphane oxide for each cyclodextrin. Interestingly, Figure 3c, 3d and 3e show that the proportion of different species does not change after heating or long reaction time (48 h), confirming that the transformation is complete, although not quantitative. Although the ^{31}P NMR spectra are not presented here, it is worth mentioning that it is possible to achieve the quantitative transformation of **2** into **4** by using a larger amount of RAMEB (20 mM) and high temperature (60 °C). Interestingly, when addition of RAMEB was carried out under carbon monoxide, the signal corresponding to the *t*BuTPPDS/RAMEB inclusion complex was always present but a sharp, new doublet was observed at δ = 37.1 ppm ($J_{Rh,P}$ = 139 Hz) (**5**; Figure 4).

Before discussing the nature of the new rhodium species observed in the presence of cyclodextrins under nitrogen or carbon monoxide, it must be pointed out that addition of methyl-α-D-glucopyranoside or an acyclic oligosaccharide composed of glucopyranose units such as maltose or maltoheptaose to **2** does not modify the NMR spectra of the rhodium complex and no new signal can be observed even

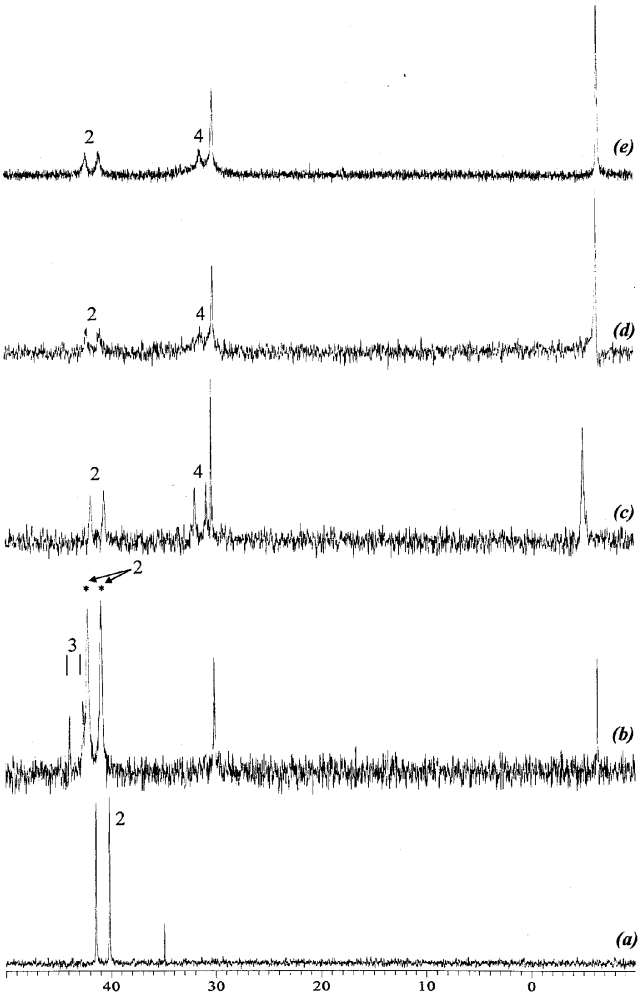

Figure 3. Effect of RAMEB on complex **2** under a nitrogen atmosphere: (a) ^{31}P NMR spectrum of **2** (3 mM) at 27 °C under nitrogen; (b) after addition of RAMEB (9 mM) at 27 °C; (c) after 1 hour at 60 °C and recorded at 60 °C under nitrogen; (d) previous solution allowed to cold to 27 °C and recorded after 1 hour at 27 °C under nitrogen; (e) previous solution recorded after 48 hours at 27 °C under nitrogen

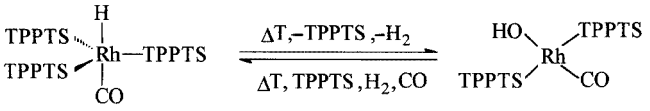
at 40 °C or 60 °C. These experiments prove without a shadow of a doubt that the phenomenon observed with β-CD and RAMEB cannot be attributed to a solvent effect but must be due to the complexing properties of the β-cyclodextrin derivatives. Methyl α-D-glucopyranoside or acyclic oligosaccharides have the same subunits as the cyclodextrins but do not possess a lipophilic cavity that can host an organic group.

The new rhodium species **4** and **5** were identified by comparison of their chemical shift and rhodium-phosphorus coupling constant values with those of known rhodium complexes.[10−15] In particular, we found that the spectroscopic data of **4** (δ = 30.4 ppm, $J_{Rh,P}$ = 131 Hz) are very similar to those of water-soluble hydroxy complexes {[HORh(CO)(TPPTS)$_2$]: δ = 31.8 ppm, $J_{Rh,P}$ = 129 Hz; [HORh(CO){P(C$_6$H$_5$)$_2$[CH$_2$CH(CH$_3$)(CO$_2$Na)]}$_2$]: δ = 27 ppm, $J_{Rh,P}$ = 130 Hz}.[13−5] As reported by Herrmann, the hydroxy complex [HORh(CO)(TPPTS)$_2$] can be obtained from [HRh(CO)(TPPTS)$_3$] by heating an aqueous solution of [HRh(CO)(TPPTS)$_3$] at reflux and can be quantitatively reconverted into [HRh(CO)(TPPTS)$_3$] under an H_2/CO atmosphere in the presence of an excess of TPPTS (Scheme 2).



Scheme 2. Equilibrium between [HRh(CO)(TPPTS$_3$] and [HORh(CO)(TPPTS)$_2$] as reported by Herrmann and coworkers[13,14]

Our assignment was fully supported by experiments conducted under H_2 atmosphere and in the presence of an excess of *t*BuTPPDS. Under these experimental conditions complex **4** can be converted into **2** as shown in Figure 2e.

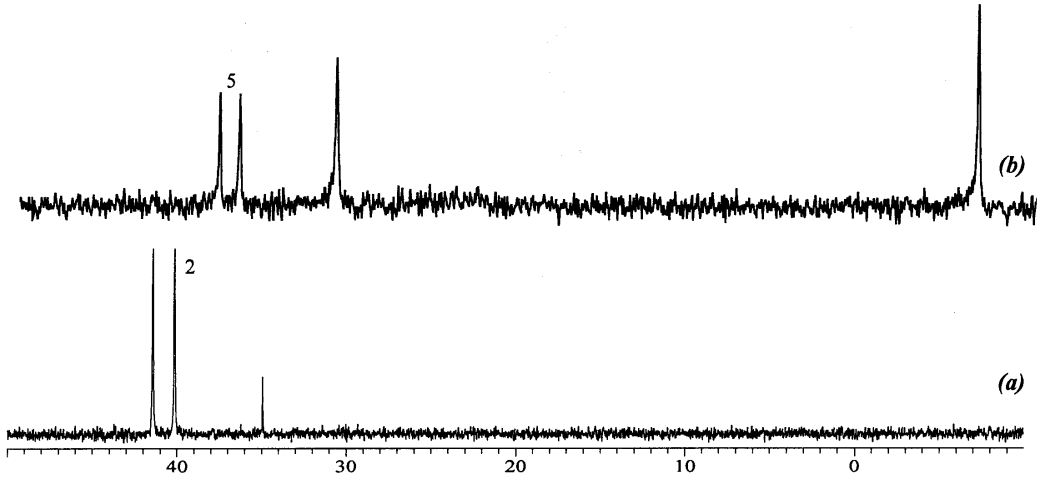


Figure 4. Effect of RAMEB on complex **2** under a carbon monoxide atmosphere: (a) spectrum of **2** (3 mM) in D_2O at 27 °C under carbon monoxide; (b) after addition of RAMEB (9 mM) at 27 °C under carbon monoxide

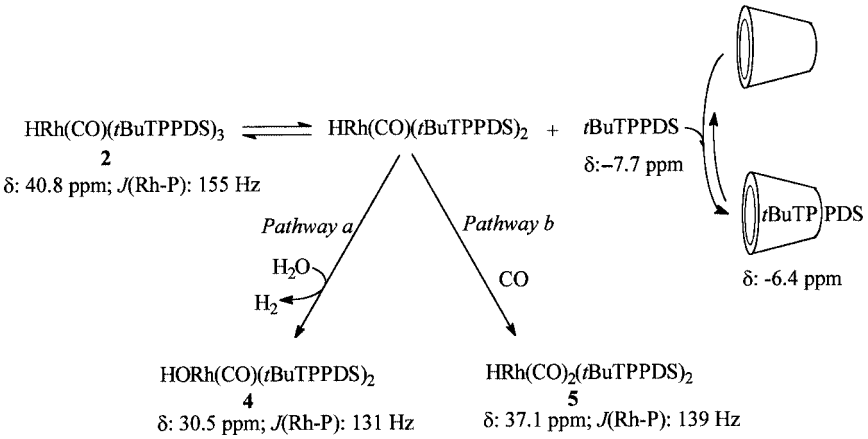

Scheme 3. Proposed mechanism for the formation of **4** and **5** from **2** in the presence of β-cyclodextrin derivatives

With respect to the rhodium species that forms under carbon monoxide, the spectroscopic data (δ = 37.1 ppm, $J_{Rh,P}$ = 139 Hz) are very similar to those of the hydrido complex [HRh(CO)$_2$[P(C$_6$H$_5$)$_3$]$_2$] (δ = 39.9 ppm, $J_{Rh,P}$ = 138 Hz), suggesting strongly that **5** is [HRh(CO)$_2$(*t*-BuTPPDS)$_2$].[16]

From a mechanistic point of view, the formation of an inclusion complex between the water-soluble phosphane and the cyclodextrin is probably the driving force of the reaction leading to the production of **4** (under nitrogen) or **5** (under carbon monoxide). Therefore the trapping of *t*BuTPPDS by the cyclodextrin can promote the dissociation of *t*BuTPPDS from **2** and, consequently, the formation of [HRh(CO)(*t*BuTPPDS)$_2$] as described in Scheme 3.

The complex [HRh(CO)(*t*BuTPPDS)$_2$] or its aqua form [HRh(H$_2$O)(CO)(*t*BuTPPDS)$_2$], either of which could be the unstable species **3**, would react with water (*pathway a* in Scheme 3) or a carbon monoxide molecule (*pathway b* in Scheme 3) to give rise to **4** and **5**, respectively. In the case of TPPTS, the affinity of cyclodextrin for the TPPTS is probably much too weak to observe an effect on the equilibrium described in Scheme 3, and therefore formation of the hydroxy or hydrido dicarbonyl complex is not promoted.

Conclusion

This work has clearly demonstrated that cyclodextrin can promote the formation of new species by trapping the ligand. This phenomenon is all the more important as the molecular recognition between the water-soluble ligand and the cyclodextrin is high. This finding is of interest for the development of transition metal chemistry in water because it could be used to generate easily coordinatively unsaturated organometallic complexes, which are catalytically active species in numerous reactions.

Experimental Section

General Remarks: The ^{31}P NMR spectra (121.49 MHz, referenced to external 85% H$_3$PO$_4$) were recorded on a Bruker DRX instrument. FTIR spectra were recorded on a Bruker IFS 55 spectrophotometer. D$_2$O (99.95% isotopic purity) was obtained from Merck. β-cyclodextrin (β-CD) and randomly methylated β-cyclodextrin (RAMEB) were purchased from Aldrich and dried carefully before use. The RAMEB used is a mixture of methylated-β-cyclodextrins, in which about fourteen of the twenty one hydroxy groups have been methylated. Tris(3-sodiosulfonatophenyl)phosphane [TPPTS; P(*m*-C$_6$H$_4$SO$_3$Na)$_3$] was synthesized as reported by Gärtner et al.[17] The purity of the TPPTS was carefully controlled. In particular, ^{31}P NMR spectroscopy indicated that the product was a mixture of the phosphane (ca. 98%) and its oxide (ca. 2%). The synthesis of (4-*tert*-butylphenyl)bis(3-sodiosulfonatophenyl)phosphane [*t*BuTPPDS; (*p*-*t*BuC$_6$H$_4$)P(*m*-C$_6$H$_4$SO$_3$Na)$_2$] was described in one of our previous publication.[18] The complex [HRh(CO)(TPPTS)$_3$] (**1**) was prepared by a modification of the literature method.[19]

[HRh(CO)(*t*BuTPPDS)$_3$] (2): [Rh(CO)$_2$(acac)] (100 mg) was introduced into a Schlenk tube and a *t*BuTPPDS solution (3.6 eq, 738 mg in 10 mL of degassed water) was added whilst stirring under CO/H$_2$ pressure (2 bar). After 6 hours, the crude reaction mixture was filtered and 20 mL of degassed dimethyl ethylene glycol ether was added to the solution. The pale green precipitate formed was collected by filtration, washed with dimethyl ethylene glycol ether and then dried under oil-pump vacuum: 535 mg, yield: 82%. ^{1}H NMR (300 MHz, D$_2$O, 25 °C): δ = −9.6 (q, $^2J_{H,P}$ = 13.1 Hz, 1 H, H-Rh), 1.26 (s, 27 H, *t*Bu), 7.17 (m, 18 H), 7.48 (br. s, 6 H), 7.67 (m, 12 H) ppm. ^{31}P{^{1}H} NMR (121.49 MHz, D$_2$O, 25 °C): δ = 40.8 (d, $^1J_{P,Rh}$ = 155 Hz, P) ppm. FTIR (KBr): $\tilde{\nu}$ = 2003 cm^{-1} (H-Rh), 1917 (CO).

Complexes of Rhodium(I) and Iridium(I) with the Chiral Tridentate Phosphane Pigiphos: Structure and Reactivity Studies

Lukas Hintermann,[a] Mauro Perseghini,[a] Pierluigi Barbaro,*[b] and Antonio Togni*[a]

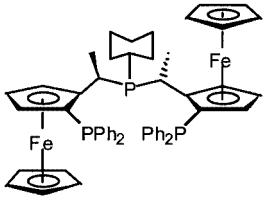
Keywords: Ferrocenyl ligands / Phosphanes / Iridium / Rhodium / Chiral ligands

The chiral ferrocenyltriphosphane Pigiphos [bis{(*S*)-1-[(*R*)-2-(diphenylphosphanyl)ferrocenyl]ethyl}cyclohexylphosphane] forms four-coordinate complexes with Ir^I and Rh^I. The tridentate ligand assumes different conformations in the derivatives [Rh(CO)(Pigiphos)]OTf (**4**) and [IrCl(Pigiphos)] (**1b**), the latter also showing a drastic deviation from the square-planar geometry. Reactivity studies have focussed on the more reactive **1b**. The HCl and O_2 adducts have been characterized in solution.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Chiral tridentate phosphanes and their transition metal complexes are rare.[1] We have previously described the chiral tridentate ferrocenylphosphane (*S*,*R*)-Pigiphos = bis{(*S*)-1-[(*R*)-2-(diphenylphosphanyl)ferrocenyl]ethyl}-cyclohexylphosphane (Scheme 1) and its complexes with palladium, nickel and ruthenium.[2] An element of design of Pigiphos is its simple synthetic accessibility (one step from commercially available materials),[2a] thus giving the possibility of varying the steric and electronic properties of the ligand according to a modular approach. Pigiphos forms two six-membered chelate rings when coordinating as a tridentate ligand and is thus best suited for both equatorial and facial arrangements around a transition metal atom, although partial hemilability cannot be excluded.



Scheme 1. (*S*,*R*)-Pigiphos

We were able to show that [*fac*-Ru{(*S*,*R*)-Pigiphos}$(CH_3CN)_3$]$(PF_6)_2$ is a catalyst for the enantioselective transfer-hydrogenation of *i*PrOH to acetophenone where *ee* values up to 71.7% could be obtained.[2b] Furthermore, cationic complexes of rhodium(III) and nickel(II) were prepared and their activity as acetalization catalysts was demonstrated.[2c] The synthesis of additional complexes with the unique Pigiphos ligand thus seemed worthwhile in order to explore its coordination chemistry and to find reactive complexes with possible application as catalysts.

The recent findings from our laboratory and from Tani's research group that highly reactive dinuclear iridium(I) complexes with chelating diphosphanes $[Ir_2Cl_2(PP)_2]$ (PP = Josiphos, Xyliphos, BINAP, bpbp) oxidatively add water[3,4] and methanol[4] pointed our attention towards low-valent group-9 species. It seemed that Pigiphos as an electron-rich tridentate ligand should give rise to similar reactivity.

In this paper we describe the synthesis of the reactive mononuclear complexes [RhCl{(*S*,*R*)-Pigiphos}] (**1a**) and [IrCl{(*R*,*S*)-Pigiphos}] (**1b**), and we report on several aspects of their coordination chemistry, including cationic solvento complexes, carbonyl complexes, and their reaction with molecular oxygen. The potential for oxidative addition of small molecules to the iridium(I) complex was investigated. X-ray structures have been determined for **1b** and for [Rh(CO){(*S*,*R*)-Pigiphos}]OTf (**4**)

Results and Discussion

Synthesis and Characterization of the Rh^I and Ir^I Complexes 1, 2, 4

Mononuclear, four-coordinate complexes of the general formula [MX(Pigiphos)]Y were prepared in good yields with M as Rh^I or Ir^I (Scheme 2). The neutral chloro complexes **1a** and **1b** were obtained by a ligand-exchange reaction using $[Rh_2Cl_2(COD)_2]$ or $[Rh_2Cl_2(C_2H_4)_4]$ and

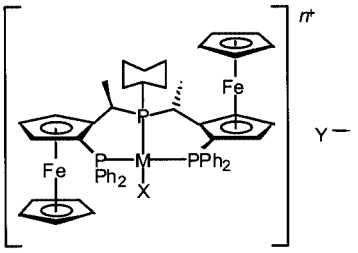
$[Ir_2Cl_2(COE)_4]$ (COE = cyclooctene) or $[IrCl(C_2H_4)_4]$, respectively. The cationic derivatives **2a**, **2b** and **4** were obtained by halogen abstraction from the corresponding chloro complexes, using a chloride scavenger.



M = Rh, X = Cl, *n* = 0 (**1a**)
M = Ir, X = Cl, *n* = 0 (**1b**)
M = Rh, X = CH_3CN, *n* = 1, Y = PF_6 (**2a**)
M = Ir, X = CH_3CN, *n* = 1, Y = PF_6 (**2b**)
M = Rh, X = CO, *n* = 1, Y = OTf (**4**)

Scheme 2. Sketch of the complexes **1**, **2**, **4**

With the exception of chlorinated solvents, all complexes are fairly stable in solution in deaerated, noncoordinating solvents. The solid-state IR spectra of the acetonitrile and carbonyl adducts [**2a**: ν(C−N) 2317 cm^{-1}; **4**: ν(C−O) 2020 cm^{-1}] show absorptions characteristic of coordinated CH_3CN[5−7] and CO[5,6,8] molecules. The $^{31}P\{^1H\}$ NMR spectroscopic data for the complexes are reported in Table 1, whereas selected ^1H NMR spectroscopic data are reported in the Exp. Sect.

The ^{31}P NMR spectral parameters are consistent with the presence of two diastereotopic ferrocenyl units with $^2J_{P_AP_B}$ coupling constants (from 131.8 to 287.0 Hz) indicative of *trans*-Ph_2P groups in each compound.[9] The complexes are slightly fluxional on the NMR time scale at room temperature, as shown by a moderate broadening of the $^{31}P\{^1H\}$ resonances. However, a slow-motion regime is attained by all compounds to give well-resolved patterns on lowering the temperature to 233−223 K. An analogous ^{31}P NMR behavior has been previously reported for the parent square-planar Pigiphos Pd^{II} and Ni^{II} complexes.[2a] These findings can be attributed to the presence of a conformational equilibrium within the six-membered chelate rings in the complexes. The dynamics of the process have been investigated in detail for complex **1b** (see below). In the rhodium complexes, the trend observed for the $^1J_{RhP}$ coupling constants can be rationalized on the basis of the *trans* influence of the coligands, which decreases in the order CyP ≈ CO > CH_3CN > Cl.[9b,10−12] Indeed, the $^1J_{RhP_A}$ and $^1J_{RhP_B}$ coupling constants of the two *trans*-Ph_2P phosphorus atoms are invariably smaller than the $^1J_{RhP}$ constant for the central CyP phosphorus atom. Consistently, this latter increases in going from **4** (121 Hz) to **2a** (163 Hz), to **1a** (173 Hz) (i.e. from *trans* to CO, CH_3CN, Cl).

The observed ^1H NMR spectral parameters, although in line with two diastereotopic ferrocenyl units, are rather routine and do not deserve any particular comment.

Solid-State Structure of 4

A single-crystal X-ray diffraction analysis carried out on **4** shows that the molecular structure consists of complex

cations $[Rh(CO)\{(S,R)\text{-Pigiphos}\}]^+$ and OTf^- anions. An ORTEP view of the cation is shown in Figure 1 while selected bond lengths and angles are reported in Table 2.

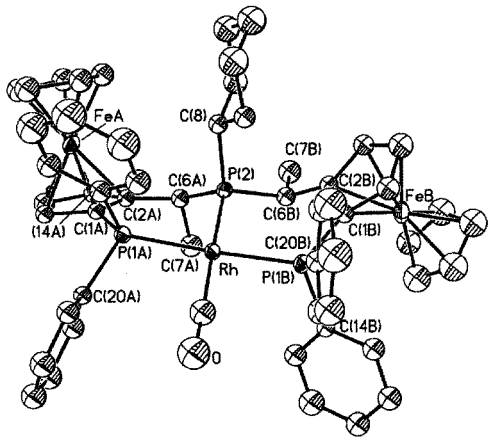

Figure 1. ORTEP drawing of the complex cation $[Rh(CO)\{(S,R)\text{-Pigiphos}\}]^+$ in **4**

The coordination around the metal center is approximately square-planar in which the carbonyl ligand and the CyP P(2) atom are mutually *trans*. The distortions from the idealized geometry are represented by the displacements of the Rh and C(26) atoms from the plane containing the three phosphorus atoms (−0.182 and −0.622 Å, respectively), as well as by the value of the bond angles at the metal (87.4−94.0°). However, considering the best idealized coordination plane of Rh (maximum deviations of the donor atoms 0.152 to −0.179 Å) one can observe that: (i) one of the unsubstituted Cp rings and the two methyl groups lie below this plane, whereas the second Cp ring and the cyclohexyl group are above, (ii) the four phenyl rings are pairwise above and below the plane, thus assuming an overall pseudo-C_2 symmetry, (iii) the couple of "C_2-symmetry-related" phenyl rings, identified by the C(14A) and C(14B) *ipso*-carbon atoms, face an observer lying on the C(26)−P(2) axis. Although both six-membered chelate rings adopt a distorted boat conformation in **4**, their geometry is markedly different. This is shown by the different relative positions of the two methyl groups [cf. the torsion angles C(1B)−C(2B)−C(6B)−C(7B) = −164.8(8)° and C(1A)−C(2A)−C(6A)−C(7A) = 95.7(11)°], as well as by the conformation of the two alkyl side chains [cf. the torsion angles C(1B)−C(2B)−C(6B)−P(2) = 62.7(10)° and C(1A)−C(2A)−C(6A)−P(2) = −26.4(13)°]. Furthermore, the P(1A) phenyl rings are closer to an axial/equatorial arrangement with respect to the coordination plane of Rh than those bonded to P(1B) [cf. the torsion angles C(26)−Rh−P(1A)−C(14A) = 90.3(7)°, C(26)−Rh−P(1A)−C(20A) = −22.3(7)°, C(26)−Rh−P(1B)−C(20B) = −59.1(7)°, C(26)−Rh−P(1B)−C(14B) = 56.7(7)°]. The Rh−C(26)−O angle (178.8°) as well as the C(26)−O (1.134 Å) and Rh−C(1) (1.849 Å) distances are in the range commonly observed for other square-planar (carbonyl)Rh^I complexes.[13,14] The overall conformation of the Pigiphos ligand in **4** closely resembles that already described for the square-planar cation complex $[PdCl\{(S,R)\text{-Pigiphos}\}]^+$.[2a]

Solid-State Structure of 1b·2(C_6H_6)

Compound **1b**·2(C_6H_6) was characterized by X-ray diffraction analysis. Selected bond lengths and angles are reported in Table 3. An ORTEP drawing is depicted in Figure 2.

Table 3. Selected bond lengths [Å] and angles [°] for $[IrCl\{(R,S)\text{-Pigiphos}\}]\cdot 2(C_6H_6)$

Ir−Cl	2.3997(17)	Ir−P(1A)	2.2714(16)
Ir−P(2)	2.2123(17)	Ir−P(1B)	2.2581(18)
Cl−Ir−P(2)	166.79(6)	P(1A)−Ir−P(1B)	154.29(6)
P(1A)−Ir−P(2)	90.73(7)	P(1B)−Ir−P(2)	95.82(7)
Cl−Ir−P(1A)	91.73(7)	Cl−Ir−P(1B)	87.53(7)

The coordination around Ir is approximately square-planar with the chlorine atom and the CyP(2) group *trans* to each other. However, the displacement of the iridium and chlorine atoms above the plane containing the three phosphorus atoms (0.450 and 1.462 Å, respectively) and the bond angles around the metal center (87.50−95.82°) show that the degree of distortion of this complex is larger than for the cation $[Rh(CO)\{(S,R)\text{-Pigiphos}\}]^+$ in **4**. In addition, the overall arrangement of the Pigiphos ligand is markedly different from that observed in **4** and in $[PdCl\{(S,R)\text{-Pigiphos}\}]^+$.[2a] Thus, both methyl groups are below the coordination plane, no pseudo-C_2 symmetry is shown by the phenylphosphanyl groups, and no specific axial/equatorial arrangement is adopted by the phenyl rings [cf. the torsion angles Cl−Ir−P(1B)−C(14B) = 65.7(3)°, Cl−Ir−P(1B)−C(20B) = −53.0(3)°, Cl−Ir−P(1A)−C(14A) = 71.3(3)°, Cl−Ir−P(1A)−C(20A) = −47.1(3)°]. The unusual

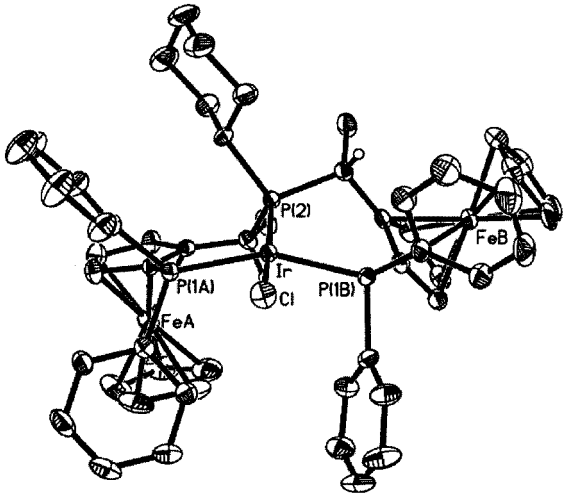

Figure 2. ORTEP view of the complex [IrCl{(*R*,*S*)-Pigiphos}] in **1b**·2(C_6H_6); solvent molecules are omitted for clarity

arrangement of Pigiphos in **1b** is inferred by the different conformation assumed by the two six-membered chelate rings; while the ring incorporating P(1A) can be described as an envelope with five atoms almost lying in a plane [with P(2) out of the plane], the one including P(1B) adopts a distorted boat conformation. It is worth noting that in most of the Josiphos-type ferrocenyldiphosphane complexes the six-membered chelate ring adopts a distorted boat conformation.[3,15,16]

$^{31}P\{^1H\}$ VT NMR Study of Complex 1b

A variable-temperature $^{31}P\{^1H\}$ NMR study was carried out on **1b**. Sections of the $^{31}P\{^1H\}$ NMR spectra of **1b** are shown in Figure 3.

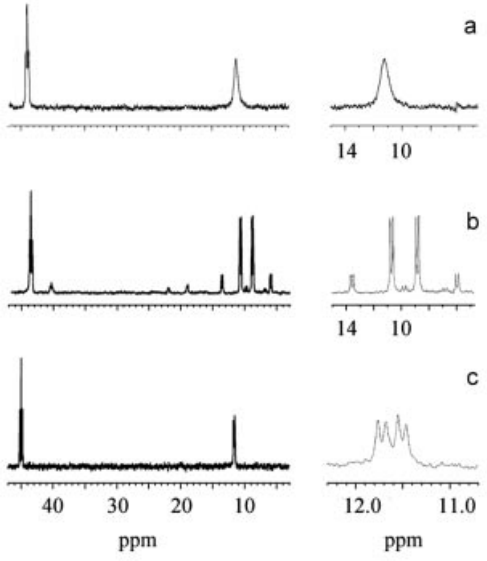

Figure 3. $^{31}P\{^1H\}$ NMR spectra of [IrCl{(*R*,*S*)-Pigiphos}] (**1**) (121.5 MHz, [D_8]toluene): (a) 21 °C, (b) −50 °C and (c) 80 °C

Compared to the parent rhodium complex **1a**, a greater fluxionality is observed for **1b** in room temperature solutions (see Table 1 and Figure 3 a). Indeed, only two resonances are observed at 21 °C, a broad triplet (δ = 44.02 ppm, J = 26 Hz) and a broad singlet (δ = 11.3 ppm), which can be attributed to the central CyP phosphorus atom and to the two terminal Ph_2P atoms, respectively. On lowering the temperature, the latter resonance splits to give a broad ABM spin system, as expected for two diastereotopic diphenylphosphanyl groups. Further cooling causes the signals to sharpen and a second ABM spin system to appear. The spectrum recorded at −50 °C is shown in Figure 3 b. Both sets of resonances (ca. 7:1 ratio, based on ^{31}P NMR integration) show signals characteristic of a central CyP phosphorus atom (major: δ = 43.5 ppm, $^2J_{PP}$ = 25 Hz; minor: δ = 40.3 ppm, $^2J_{PP}$ = 26 Hz) and *trans*-terminal diphenylphosphanyl groups (major: δ = 12.1 and 7.3 ppm, $^2J_{PP}$ = 351 Hz; minor: δ = 8.3 and 20.2 ppm, $^2J_{PP}$ = 358 Hz).[17] According to the solid-state structure, the two spin systems can be attributed to the presence of two isomers of **1b** differing in their conformation − either boat or envelope − of the two six-membered chelate rings. The signals due to the Ph_2P phosphorus atoms are much more differentiated in the minor than in the major isomer (Δδ = 11.9 ppm vs. Δδ = 4.8 ppm). This finding suggests that in the minor isomer the two PPh_2 groups are situated in a quite different chemical environment which results in comparatively unfavorable steric interactions. The observed variable temperature NMR pattern is consistent with an exchange equilibrium between the two isomers, most likely due to a ring-inversion mechanism. Similar ring-inversion processes have been observed previously for six-membered chelate rings in ferrocenyldiphosphane transition metal complexes.[3,15,16] The spectrum recorded at 80 °C is in line with the trend observed at lower temperature. Only one tightly coupled ABM system is found which accounts for the fast interconversion of the two conformers. The spectral parameters (CyP: δ = 44.83 ppm, $^2J_{PP}$ = 8.50 Hz; Ph_2P: δ = 12.02 and 11.19 ppm, $^2J_{PP}$ = 179.9 Hz)[17] indicate that at this temperature the complex attains a time-averaged preferred conformation in which the two terminal phenylphosphanyl groups are located in a similar chemical environment.

Synthesis and Characterization of the (Dioxygen)Rh^{III} and -Ir^{III} Adducts

The (dioxygen)Rh and -Ir adducts **3a** and **3b** were quantitatively obtained by exposure of a C_6H_6 solution of **1a** and **1b** to air, respectively. A color change from orange to yellow (**1a**) or deep red (**1b**) accompanied the O_2 uptake and the solid dioxygen complexes precipitated within a few minutes. The adducts **3** can be treated as formal six-coordinate (peroxo)Rh^{III} and -Ir^{III} complexes obtained by the oxidative addition of O_2 to the Rh^I and Ir^I centers,[18−24] in which an η^2-O_2 ligand is *trans* to the Ph_2P phosphorus atoms. This hypothesis is substantiated by the following experimental observations: (i) the solid-state IR spectra show an absorption characteristic for η^2-O_2 complexes (902 and 829 cm^{-1} ν(O−O) for **3a** and **3b**, respectively);[7,18,19,21−23,25] (ii) no residual paramagnetism is detected by magnetic susceptivity

measurement either in solution or in the solid state; (iii) the MALDI MS analysis carried out under oxygen-free conditions shows peaks consistent with O_2 uptake; (iv) the ^{31}P NMR spectra of **3a** and **3b** show a $^2J_{PP}$ coupling constant (17.2−22.4 Hz, Table 1) indicating a *cis* disposition of the phosphorus atoms and, therefore, a *fac* arrangement of the tridentate ligand; (v) consistent with the increased oxidation state of Rh, the $^1J_{RhP}$ coupling constant of the CyP phosphorus atom (122.1 Hz) in **3a** is smaller than the corresponding constant in the deoxygenated Rh^I complex **1a**;[2c,10,26] (vi) the $^1J_{RhP}$ coupling constant observed for the Ph_2P atoms in **3a** (134.8 Hz) is greater than that observed for the CyP phosphorus atom (122.1 Hz), thus indicating that the two diphenylphosphanyl groups experience a lower *trans* influence, as expected for a *trans*-oxygen donor as compared to a *trans* chloride donor.[12,27,28] The formation of η^2-O_2 complexes by addition of dioxygen to (polydentate phosphane)Rh^I and -Ir^I complexes has a number of precedents in the literature.[7,29−34] It is generally agreed that in the reaction of square-planar d^8 metal complexes with dioxygen to give peroxo adducts, the starting metal complex undergoes a geometrical distortion to allow a better overlap between the metal d orbitals and the π_g* orbital of dioxygen.[20,35,36] The observed *mer*-to-*fac* rearrangement of the Pigiphos ligand accompanying the conversion of **1** to **3** can be explained on this basis.

Oxidative Addition Reactions

The ability of **1b** to react with other small molecules to give the oxidative addition product was examined. In particular, the use of protic reagents with very different acid dissociation constants was investigated.

The reaction with an excess of HBF_4 in benzene solution was monitored by NMR spectroscopy. A quantitative conversion into the complex [IrClH{(*R*,*S*)-Pigiphos}]BF_4 (**5**) was shown and the product was characterized in situ by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy. The value of the $^2J_{PP}$ coupling constant (328 Hz) indicates a *trans* arrangement of the two terminal Ph_2P atoms and, therefore, a *mer* coordination of the tridentate ligand. An apical position can be assigned to the hydride observed in the ^1H NMR spectrum at $\delta = -32.15$ ppm on the basis of the low value of its $^2J_{PH}$ coupling (13.0 Hz).[9]

The reaction of **1b** with HCl gave the complex [$IrCl_2H$\{(*R*,*S*)-Pigiphos\}] (**6**), which was isolated in the solid state and completely characterized in solution by 2D NMR spectroscopy. All resonances were unequivocally attributed by 2D techniques. Once again, the $^{31}P\{^1H\}$ NMR spectroscopic data indicate a *mer* arrangement of the ligand ($^2J_{PP}$ = 440.1 Hz, Table 1). The $^2J_{HP}$ values (16.0 Hz) indicate a *cis* disposition of the hydride ligand [$\delta = -19.48$ (q) ppm] with respect to the phosphorus atoms.[9] An apical position of the hydride ligand can thus be anticipated. It only remained to be seen whether this proton is above or below the coordination plane of the iridium atom. A simple ^1H NOESY measurement addressed this point. The main NOE interactions observed for **6** are represented schematically in Figure 4.

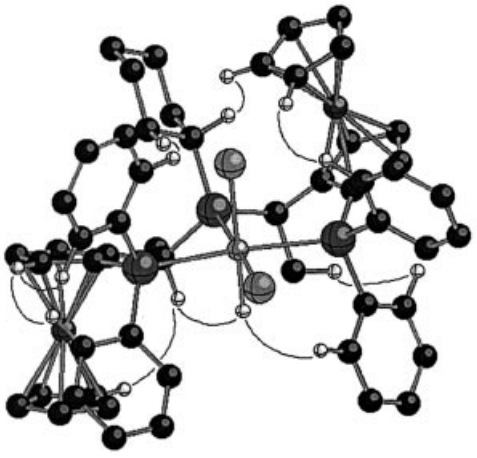

Figure 4. Significant NOEs observed for **6** (C_6D_6, 294 K, 400.13 MHz, drawing generated using the program Ball-and-Stick, see also Figure 5)

The dipolar interaction observed between the hydride atom and one of the α-methyl protons shows the hydride ligand to be located on the side of the plane opposite to that of the cyclohexyl group.

Reaction with methanol did not afford an oxidative addition product. The dihydrido complex [$IrClH_2$\{(*R*,*S*)-Pigiphos\}] (**7**) was obtained and isolated instead. The ^1H NMR spectrum of **7** shows resonances at $\delta = -21.5$ and -7.7 ppm for the two hydride ligands, respectively (see Exp. Sect.). Similar hydride resonances were previously reported for the product from the reaction of [$Ir_2Cl_2(COD)_2$] with tridentate phosphanes in the presence of ethanol/benzene mixtures.[37]

Conclusion

We have shown that Pigiphos behaves as a tridentate ligand with Rh^I and Ir^I forming tetracoordinate complexes. By virtue of a significant distortion of the ideal square-planar geometry, as observed in the solid state and as reflected by the dynamical behavior in solution, the Ir derivative **1b** displays a higher reactivity than **1a** (Rh).

Complex **1b** did not yield OH addition products. This can be explained by the inability of the sterically hindered complex **1b** to generate dinuclear bridged compounds, which seem to stabilize such oxidative addition products. A mononuclear compound would force the lone pairs of the oxygen atom into the electron-rich region of the complex, causing electronic repulsion. The high reactivity of **1b** is now under investigation in order to find possible applications as a catalyst precursor.

Experimental Section

General Remarks: All manipulations were performed under pure nitrogen or argon using standard Schlenk techniques unless other-

wise stated. Freshly distilled solvents were used throughout. Diethyl ether and THF were distilled from Na/benzophenone. Methanol, benzene, toluene, *n*-pentane and *n*-hexane were dried with sodium. CH_3CN was dried with CaH_2. (*S*,*R*)-PPFA and (*R*,*S*)-PPFA,[38] $[RhCl(COD)]_2$,[39] $[RhCl(C_2H_4)_2]_2$,[40] $[RhCl(CO)_2]_2$,[41] and $[IrCl(COE)_2]_2$ [42] were prepared as described previously. The ligands (*S*,*R*)-Pigiphos and (*R*,*S*)-Pigiphos were obtained in better yields (ca. 90%) than previously reported[2a] by using higher concentrations of the starting reagents. All the other chemicals were commercial products of reagent grade and were used as received. All solid compounds were collected on sintered glass frits before being dried in a stream of nitrogen. ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded with Bruker DPX 250, 300, 400 or Avance DRX-500 spectrometers. ^1H and ^{13}C chemical shifts are relative to tetramethylsilane as external reference or calibrated against solvent resonance. ^{31}P NMR shifts are referenced to external 85% H_3PO_4. The assignments of the signals resulted from ^1H homonuclear decoupling experiments, 2D ^1H COSY and proton-detected ^1H,^{13}C correlations using degassed nonspinning samples. 2D NMR spectra were recorded using pulse sequences suitable for phase-sensitive representations using TPPI. The ^1H,^{13}C correlations[43] were recorded using the standard HMQC sequence with no decoupling during acquisition. Standard pulse sequences were used for ^1H NOESY measurements.[44] Infrared spectra were recorded on Perkin−Elmer Paragon 1000 or 1600 FT-IR spectrometers using samples of KBr or mulled in Nujol between KBr plates. Mass spectrometry was carried out in inert matrices by the Analytical Service of the Organic Chemistry Laboratory, ETH Zürich. Intensities are given as percent relative to the largest peak. Microanalyses were performed by the Microelemental Analysis Service of the Organic Chemistry Laboratory, ETH Zürich. Merck silica gel 60, 230−400 mesh ASTM was used for column chromatography. Thin layer chromatography was performed with Macherey−Nagel Polygram SIL G/UV254 precoated plastic sheets.

[RhCl{(*S*,*R*)-Pigiphos}] (1a). (a): Solid $[Rh_2Cl_2(COD)_2]$ (0.05 g, 0.10 mmol) was added to a solution of (*S*,*R*)-Pigiphos (0.19 g, 0.21 mmol) in absolute ethanol (20 mL). The suspension was refluxed with stirring for 1.5 h causing the precipitation of an orange solid. After cooling the mixture to room temperature, the solid was filtered off and washed with *n*-hexane (20 mL) to give **1a** (0.17 g, 81%) as orange microcrystals. ^1H NMR (C_6D_6, 294 K, 500.13 MHz): δ = 3.69 (quint, $J_{HH} = J_{HP} = 6.9$ Hz, 1 H, C*H*′CH_3), 3.25 (dt, $J_{H,H} = 7.5$, $J_{HP} = 19.4$ Hz, 1 H, C*H*′′CH_3), 1.76 (t, 3 H, CH′C*H*$_3$), 1.80 (dd, $J_{HP} = 4.6$ Hz, 3 H, CH′′C*H*$_3$), 4.60 (s, 1 H, C_5H_3), 4.48 (s, 1 H, C_5H_3), 4.35 (s, 1 H, C_5H_3), 4.30 (s, 1 H, C_5H_3), 4.24 (s, 2 H, C_5H_3), 3.92 (s, 5 H, C_5H_5′), 3.67 (s, 5 H, C_5H_5") ppm. $C_{54}H_{55}ClFe_2P_3Rh$ (1047.01): calcd. C 61.95, H 5.29; found C 61.76, H 5.34. **(b):** Solid $[Rh_2Cl_2(C_2H_4)_4]$ (0.04 g, 0.10 mmol) was added to a solution of (*S*,*R*)-Pigiphos (0.19 g, 0.21 mmol) in benzene (20 mL). After stirring for 2 h at room temperature, the orange solution obtained was concentrated to ca. 10 mL under reduced pressure. Addition of *n*-hexane (10 mL) gave **1a** as an orange solid which was filtered off and washed with *n*-hexane (yield 0.10 g, 48%).

[IrCl{(*R*,*S*)-Pigiphos}] (1b): Solid $[Ir_2Cl_2(COE)_4]$ (COE = cyclooctene) (1.920 g, 2.143 mmol) was added to a solution of (*R*,*S*)-Pigiphos (3.897 g, 4.289 mmol) in THF (15 mL). After stirring for 2 h, the resulting dark brown solution was freed from undissolved material by decantation. Evaporation of the solvent under high vacuum for 3 h at 70 °C gave an orange crystalline mass. This material was triturated with *n*-hexane (30 mL), filtered, washed with *n*-pentane (50 mL) and dried under high vacuum to give 4.584 g of **1b** (94% yield) as a dark yellow powder. ^1H NMR ([D$_8$]toluene, 294 K, 400.13 MHz): δ = 8.15 (br. s, 2 H, *ortho*-Ph), 8.10−8.03 (m, 2 H, *ortho*-Ph), 8.03−7.96 (m, 2 H, *ortho*-Ph), 7.86−7.79 (m, 2 H, *ortho*-Ph), 7.18−6.98 (m, 12 H, Ph), 4.34−4.32 (m, 1 H, C_5H_3), 4.23 (br. s, 1 H, C_5H_3), 4.07−4.05 (m, 1 H, C_5H_3), 4.04−4.02 (m, 1 H, C_5H_3), 4.02−3.99 (m, 2 H, C_5H_3), 3.66 (s, 5 H, C_5H_5′), 3.64−3.59 (m, 1 H, C*H*′CH_3), 3.38 (s, 5 H, C_5H_5"), 3.14 (br. s, 1 H, C*H*"CH_3), 2.75 (br. q, $J = 11.0$ Hz, 1 H, CyH), 2.31−2.21 (m, 1 H, CyH), 1.84−1.75 (m, 1 H, CyH), 1.71−1.63 (m, 1 H, CyH), 1.58 (dd, $J = 7.0$, $J = 5.8$ Hz, 3 H, CH_3′), 1.54 (dd, $J = 4.0$, $J = 3.4$ Hz, 3 H, CH_3′′), 1.45−1.26 (m, 2 H, CyH), 1.23−1.16 (m, 3 H, CyH), 1.10−0.86 (m, 2 H, CyH) ppm. $^{13}C\{^1H\}$ NMR ([D$_8$]toluene, 294 K, 62.9 MHz): δ = 137.4, 137.1, 134.9, 134.4, 129.3, 129.2, 128.2, 126.9, 125.4, 99.8 (1 C, C_5H_3), 93.5 (1 C, C_5H_3), 75.3 (1 C, C_5H_3), 73.3 (1 C, C_5H_3), 70.7 (5C, C_5H_5′), 70.6 (5C, C_5H_5"), 69.2 (1 C, C_5H_3), 68.8 (1 C, C_5H_3), 68.1 (1 C, C_5H_3), 67.3 (1 C, C_5H_3), 38.9, (1 C, *C*HCH_3), 35.3 (1 C, α-CH-Cy), 30.3 (1 C, CH_2), 29.8 (1 C, CH_2), 28.0 (1 C, CH_2), 27.5 (1 C, CH_2), 27.2 (1 C, CH_2), 26.3 (1 C, *C*HCH_3), 23.0 (1 C, CH_3), 15.4 (1 C, CH_3) ppm. MS (MALDI): *m*/*z* (%) = 1101 (100) $[M - Cl]^+$, 1018 (22) $[M - Cl - Cy]^+$, 984 (14) $[M - Cl - FeCp]^+$, 919 (15), 902 (16), 838 (14), 804 (16), 725 (16), 711 (17), 634 (28). $C_{54}H_{55}ClFe_2IrP_3$ (1136.32): calcd. C 57.08, H 4.88, P 8.18; found C 57.34, H 5.02, P 8.44.

[Rh{(*S*,*R*)-Pigiphos}(CH$_3$CN)]PF$_6$ (2a): Solid $TlPF_6$ (0.03 g, 0.08 mmol) was added to a solution of **1a** (0.08 g, 0.08 mmol) in acetonitrile (7 mL) and the mixture was stirred for 10 min. After removal of TlCl by filtration, the orange solution obtained was concentrated to ca. half the volume under reduced pressure. Addition of diethyl ether (10 mL) caused the precipitation of an orange solid, which was separated, washed with diethyl ether (40 mL) and dried in vacuo to give 52 mg of **2a** (55% yield). ^1H NMR (CD_3COCD_3, 294 K, 500.13 MHz): δ = 3.68 (dt, $J_{H,H} = 6.8$, $J_{HP} = 19.3$ Hz, 1 H, C*H*′CH_3), 3.42 (quint, $J_{H,H} = J_{HP} = 7.3$ Hz, 1 H, C*H*"CH_3), 1.88 (dd, $J_{HP} = 13.8$ Hz, 3 H, CH′C*H*$_3$), 2.10 (dd, $J_{HP} = 10.4$ Hz, 3 H, CH"C*H*$_3$), 5.09 (s, 1 H, C_5H_3), 4.82 (s, 1 H, C_5H_3), 4.78 (q, 1 H, C_5H_3), 4.76 (s, 1 H, C_5H_3), 4.73 (t, 1 H, C_5H_3) 4.49 (s, 1 H, C_5H_3), 4.09 (s, 5 H, C_5H_5′), 3.87 (s, 5 H, C_5H_5"), 1.68 (s, 3 H, C*H*$_3$CN) ppm. ^{13}C NMR (CD_3COCD_3, 294 K, 125.76 MHz): δ = 1.82 (s, *C*H$_3$CN, $J_{C,H} = 134.4$ Hz) ppm. IR: $\tilde{\nu}$ = 2317 ν(C−N) cm^{-1}. $C_{56}H_{58}F_6Fe_2NP_4Rh$ (1197.57): calcd. C 56.17, H 4.88; found C 56.24, H 4.87.

[Ir{(*R*,*S*)-Pigiphos}(CH$_3$CN)]PF$_6$ (2b): $TlPF_6$ (0.36 g, 1.02 mmol) was added to a solution of **1b** (1.15 g, 1.01 mmol) in CH_3CN (10 mL). After stirring at room temperature for 4 d, the mixture obtained was filtered. Concentration to dryness yielded an orange resin which crystallized on standing. The solid material was powdered and dried under high vacuum (3 d at 50 °C) affording 1.3 g of **2b** (quantitative yield). ^1H NMR (CD_3CN, 294 K, 300.13 MHz): δ = 8.18−8.04 (m, 4 H, Ph), 7.56−7.37 (m, 11 H, Ph), 7.30−7.23 (m, 3 H, Ph), 6.99−6.90 (m, 2 H, Ph), 4.81 (br. s, 1 H, C_5H_3), 4.56−4.51 (m, 2 H, C_5H_3), 4.51−4.49 (m, 1 H, C_5H_3), 4.47 (br. t, 1 H, C_5H_3), 4.26 (br. s, 1 H, C_5H_3), 3.86 (s, 5 H, C_5H_5′), 3.67 (s, 5 H, C_5H_5"), 3.41 (dd, $J = 11.5$, $J = 6.8$ Hz, 1 H, C*H*′CH_3), 3.33 (dd, $J = 11.5$, $J = 7.7$ Hz, 1 H, C*H*"CH_3), 2.36 (br. q, $J = 11.0$ Hz, 1 H, CyH), 2.28 (br. d, $J = 14.0$ Hz, 1 H, CyH), 1.96 (s, 3 H, C*H*$_3$CN), 1.82 (dd, $J = 11.1$, $J = 7.3$ Hz, 3 H, C*H*$_3$′), 1.65 (dd, $J = 13.5$, $J = 6.9$ Hz, 3 H, C*H*$_3$′′), 1.78−1.56 (m, 3 H, CyH), 1.50 (br. d, $J = 11.0$ Hz, 1 H, CyH), 0.16−1.90 (m, 2 H, CyH), 0.68 (br. q, $J = 13.0$ Hz, 1 H, CyH), 0.50 (br. q, $J = 13.0$ Hz, 1 H, CyH), 0.31 (m, 1 H, CyH) ppm. $^{13}C\{^1H\}$ NMR (CD_3CN, 294 K, 62.9 MHz): δ = 121.3 (br. d, $J_{P,C} = 16.0$ Hz, 1 C, CD_3CN), 100.9 (br. d, $J_{P,C} = 21.0$ Hz 1 C, C_5H_3), 93.4 (dd, $J_{P,C} = 20.0$, $J_{P,C}$ =

5.0 Hz, 1 C, C_5H_3), 75.3 (t, $J_{P,C}$ = 3.0 Hz, 1 C, C_5H_3), 74.1 (t, $J_{P,C}$ = 3.0 Hz, 1 C, C_5H_3), 71.6 (s, 5 H, C_5H_5'), 71.3 (s, 5 H, C_5H_5"), 1.8 (s, 1 C, CH_3CN) ppm. $C_{56}H_{58}F_6Fe_2IrNP_4$ (1286.88): calcd. C 52.27, H 4.54, N 1.09; found C 51.78, H 5.00, N 1.04.

[RhCl(O$_2$){(*S*,*R*)-Pigiphos}] (3a): A solution of **1a** (0.05 g, 0.05 mmol) in benzene (5 mL) was stirred in air for 30 min. During this time, yellow microcrystals of **3a** precipitated. Subsequently, they were filtered off and washed with *n*-hexane. Yield: 47 mg (87%). ^{1}H NMR (C_6D_6, 294 K, 500.13 MHz): δ = 4.72 (dt, $J_{H,H}$ = 6.2, J_{HP} = 12.0 Hz 1 H, C*H*′CH$_3$), 3.61 (quint, 1 H, C*H*"CH$_3$, $J_{H,H}$ = J_{HP} = 5.2 Hz), 1.72 (dd, J_{HP} = 10.5 Hz, 3 H, CH′C*H*$_3$), 1.94 (dd, J_{HP} = 9.2 Hz, 3 H, CH"C*H*$_3$), 4.50 (s, 1 H, C_5H_3), 4.48 (s, 1 H, C_5H_3), 4.35 (s, 1 H, C_5H_3), 4.22 (s, 1 H, C_5H_3), 4.18 (s, 1 H, C_5H_3) 3.74 (s, 1 H, C_5H_3), 3.68 (s, 5 H, C_5H_5'), 3.47 (s, 5 H, C_5H_5") ppm. IR: $\tilde{\nu}$ = 902 ν(O−O) cm^{-1}. $C_{54}H_{55}ClFe_2O_2P_3Rh$ (1079.01): calcd. C 60.11, H 5.14; found C 60.33, H 5.01.

[IrCl(O$_2$){(*R*,*S*)-Pigiphos}] (3b): A solution of **1b** (15 mg, 13.2 μmol) in benzene (3 mL) was stirred in air for 5 min yielding **3** as a red precipitate. ^{1}H NMR ([D$_8$]toluene, 294 K, 300.13 MHz): δ = 8.87−8.73 (br. s, 2 H, *ortho*-Ph), 7.84−7.75 (m, 2 H, *ortho*-Ph), 7.69−7.61 (m, 2 H, *ortho*-Ph), 7.59−7.51 (m, 2 H, *ortho*-Ph), 4.26−4.23 (m, 1 H, C_5H_3), 4.22−4.20 (m, 1 H, C_5H_3), 4.13−4.10 (m, 2 H, C_5H_3), 3.95 (t, *J* = 2.4 Hz, 1 H, C_5H_3), 3.87 (t, *J* = 2.7 Hz, 1 H, C_5H_3), 3.41 (s, 5 H, C_5H_5'), 3.37 (s, 5 H, C_5H_5"), 1.67 (dd, *J* = 11.4, *J* = 7.2 Hz, 3 H, CH$_3$′), 1.45 (dd, *J* = 11.4, *J* = 7.2 Hz, 3 H, CH$_3$′′) ppm. MS (MALDI): *m*/*z* (%) = 1168 (20) [M]$^+$, 1152 (20) [M − O]$^+$, 1136.3 (100) [M − O$_2$]$^+$. IR (KBr): $\tilde{\nu}$ = 829 ν(O−O) cm^{-1}.$C_{54}H_{55}ClFe_2IrO_2P_3$ (1168.32): calcd. C 55.52, H 4.74; found C 55.71, H 4.91.

[Rh(CO){(*S*,*R*)-Pigiphos}]OTf (4): Solid [Rh$_2$Cl$_2$(CO)$_4$] (0.06 g, 0.15 mmol) was added to a solution of (*S*,*R*)-Pigiphos (0.30 g, 0.33 mmol) in acetone (10 mL). Solid AgOTf (0.08 g, 0.33 mmol) was added to the resulting solution and CO was bubbled through it for 10 min. The red solution obtained after filtration was concentrated to ca. half the volume under reduced pressure. Addition of *n*-pentane (15 mL) caused the formation of a red oil which crystallized on standing. The solid was washed with *n*-pentane and dried in vacuo to give 114 mg of **4** (64%). ^{1}H NMR (CD_3COCD_3, 294 K, 500.13 MHz): δ = 3.88 (dt, $J_{H,H}$ = 6.4, J_{HP} = 12.4 Hz, 1 H, C*H*′CH$_3$), 3.59 (quint, $J_{H,H}$ = J_{HP} = 7.4 Hz, 1 H, C*H*"CH$_3$), 1.84 (dd, J_{HP} = 14.1 Hz, 3 H, CH′C*H*$_3$), 2.14 (dd, J_{HP} = 11.0 Hz, 3 H, CH"C*H*$_3$), 5.23 (s, 1 H, C_5H_3), 4.96 (s, 1 H, C_5H_3), 4.90 (q, 1 H, C_5H_3), 4.86 (t, 1 H, C_5H_3), 4.81 (s, 1 H, C_5H_3) 4.56 (s, 1 H, C_5H_3), 4.16 (s, 5 H, C_5H_5'), 3.96 (s, 5 H, C_5H_5") ppm. X-ray Crystallographic Study: Crystals of **1b**·2(C_6H_6) were obtained by slow evaporation of the solvent from concentrated benzene/pentane solutions of **1b** under nitrogen. The X-ray diffraction analysis was performed with exclusion of air with a Siemens CCD SMART area detector system. Selected bond lengths and angles of **1b**·2(C_6H_6) are reported in Table 3. Crystals of **4** suitable for an X-ray diffraction analysis were obtained by recrystallization from acetone/*n*-pentane under a stream of nitrogen. X-ray data were collected at room temperature with an Enraf−Nonius CAD4 diffractometer. Selected bond lengths and angles for **4** are reported in Table 2. A summary of the most important crystal and data collection parameters is given in Table 4 for both compounds. CCDC-186457 (**1b**) and -186458 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to D. Broggini, H. Rüegger and D. Masi for technical assistance. We thank Patrick Dietemann, Laboratorium für Organische Chemie, ETH, for the graphite-assisted laser desorption/ionisation experiments which were performed with a home-built 2-m linear time-of-flight mass spectrometer. Thanks are also due to COST D24 Chemistry Action for financial support.

Preparation of Rhodium Catalysts Supported on Carbon Nanotubes by a Surface Mediated Organometallic Reaction

Roberto Giordano,[a] Philippe Serp,*[a] Philippe Kalck,[a] Yolande Kihn,[b] Joachim Schreiber,[c] Christiane Marhic,[c] and Jean-Luc Duvail[c]

Keywords: Nanotubes / Rhodium / Supported catalysts / Surface chemistry / Heterogeneous catalysis

The dimeric complex $[Rh_2Cl_2(CO)_4]$ was grafted to multi-walled carbon nanotubes (MWNTs) previously oxidised with nitric acid and then treated with sodium carbonate to produce carboxylate groups on their outer surface. The grafting mechanism involves bridge-splitting and substitution of -COO for Cl, as evidenced by the presence of NaCl in the samples. A further reduction/decomposition step under dihydrogen at 573 K afforded highly dispersed rhodium nanoparticles (≈1.5–2.5 nm). This novel rhodium-supported carbon material (Rh/MWNT-COONa) was tested as a catalyst for the hydrogenation of *trans*-cinnamaldehyde and the hydroformylation of hex-1-ene in the liquid phase: in both cases it was found to be very selective, toward C=C double-bond hydrogenation and the production of linear and branched aldehydes, respectively. A comparison was made between its catalytic activity and that of rhodium supported on pristine MWNTs and on nitric acid-oxidised MWNTs. We observed that these latter catalysts have larger particle sizes and lower activities, thus confirming the efficiency of our grafting procedure. Moreover, the better results obtained when using MWNT-COONa as support with respect to carboxylate-containing activated carbon also point to the important role played by the mesoporous nature of the carbon nanotube support, which can ameliorate transfer processes.

Introduction

Carbon materials are attractive supports in heterogeneous catalytic processes owing to their ability to be tailored to meet specific needs. Indeed, activated forms of carbon are currently employed as catalyst supports because of their high surface area, their stability at high temperatures under a nonoxidising atmosphere and the possibility of controlling both their porous structure and the chemical nature of their surface.[1,2] New forms of carbon have appeared during the last decade, showing novel interesting potentialities as supports.[3] Carbon nanofibres, also called graphite nanofibres, and carbon nanotubes, have so far been used successfully and shown to present, as final supported materials, catalytic properties superior to those of catalysts prepared on activated carbon, soot, or graphite.[2] Whilst carbon nanofibres consist of graphite sheets arranged in various orientations along the fibre axis — the most common structure being the one in which the planes are stacked up like a fishbone, with a lot of edges — both single-walled (SWNT)- and multi-walled (MWNT) carbon nanotubes show a concentric wall structure consisting of ordered graphite platelets. The morphology and the size of the above supports, especially since they present huge lengths vs. diameters, can play a significant role in catalytic applications owing to their ability to disperse the active phase. Their electronic properties are also of primary importance,[4] and their mechanical strength makes them resistant in view of recycling. A recent comparison between the interaction of transition metal atoms with carbon nanotube walls and with graphite indicates major differences in bonding sites, magnetic moments and charge-transfer direction.[5]

The most widely used technique to achieve the deposition of metals on the above materials is the incipient wetness impregnation one, in which the purified carrier is impregnated with a solution of the metal precursor, then dried, calcinated and/or reduced so as to obtain metal particles dispersed on the support.[3,6] Several studies have been performed on graphite-nanofibre-supported Fe-Cu,[7] Ni[8] or Pd[9] particles for catalytic hydrogenation. Graphite-nanofibre-supported rhodium catalysts were found to be active in ethene hydroformylation.[10] If we consider the use of carbon nanotubes, several examples are worth mentioning: Cu

nanoparticles were synthesised employing SWNTs as a template;[11] Ru/SWNTs[12] and alkali-promoted Ru/MWNTs[13] catalysts were prepared for hydrogenation reactions and for ammonia synthesis, respectively; Pd, Pt, Ag and Au nanoparticles were grown on SWNTs, and their size could be adjusted by changing the metal to carbon ratio;[14] Rh/MWNTs catalysts for propene hydroformylation were prepared by incipient wetness impregnation from benzene solutions of $[RhH(CO)(PPh_3)_3]$ on pristine nanotubes.[15]

Chemical treatment and/or modification of the surface of carbon nanotubes was found to be a useful tool for controlling their hydrophobic or hydrophilic character,[16] and studies carried out in order to accomplish the deposition of metals point to a strong interaction between metal atoms and the groups created by oxidation of the support surface.[17]

Thus, graphite nanofibre-supported iron Fischer–Tropsch catalysts have been prepared by three different methods on HNO_3-treated supports.[18] Important improvements toward the preparation of selective hydrogenation catalysts were achieved by supporting Pt on SWNTs oxidised in dilute HNO_3: the bonding between platinum and the carbon nanotube surface was presumably accomplished by ion-exchange on the carboxylic acid sites so formed.[19] Another example of such reactivity is the replacement of the proton of carboxylic groups with uranyl ions: XPS studies of oxidised nanotubes revealed that their surface is covered by carboxylic, carbonyl and hydroxyl groups, and, in particular, the presence of -COOH groups could be used to initiate nucleation on the support surface, leading to the selective covering of the outer surface by metallic species.[20] A Co/MWNTs system showing a good catalytic activity in dehydrogenation was prepared by oxidising MWNTs in boiling nitric acid prior to impregnation with a cobalt salt, followed by drying, calcination and reduction with H_2.[21]

Bimetallic Ru/Pt and Ru/Sn nanoparticles have been prepared from molecular heterobimetallic carbonyl clusters deposited on MWNTs previously treated with HNO_3.[22] A heterobimetallic precursor was also used to prepare Pt-Ru anode catalysts supported on oxidised and nonoxidised carbon nanofibres, SWNTs and MWNTs.[23] Coordination of Pd on HNO_3-treated carbon nanofibres[24] and of Pt on H_2SO_4/HNO_3-treated MWNTs has also been reported.[25]

A suitable technique to achieve the grafting of metal particles onto carbon nanotubes would therefore consist of functionalising the outer surface of the tubes and then performing a chemical reaction with a metal complex. This was initially accomplished by reacting Vaska's complex $[IrCl(CO)(PPh_3)_2]$ with a HNO_3-oxidised support: the tethering reaction occurs by coordination of iridium to the nanotubes through the oxygen atoms.[26]

Furthermore, a controlled chemical grafting of a metal species to the surface of carbon nanotubes would very likely result in a fine dispersion of metallic particles.

In this paper we describe a new technique that involves the organometallic reaction of the rhodium complex $[Rh_2Cl_2(CO)_4]$ with a modified MWNT surface bearing sodium carboxylate groups, which permits the production of highly dispersed Rh nanoparticles, after a decomposition/reduction step. We also report some preliminary results concerning the catalytic activity of these novel materials either in hydrogenation or hydroformylation reactions. Last but not least, the catalytic activity of these materials is compared to that observed when using rhodium-supported catalysts prepared by reacting $[Rh_2Cl_2(CO)_4]$ with pristine or HNO_3-treated MWNTs, as well as with activated carbon bearing sodium carboxylate groups.

Results and Discussion

Surface Modification of MWNTs

High purity samples of MWNTs were employed for this study (MWNTs 97%, the remaining 3% coming from iron nanoparticles encapsulated within the nanotubes and generated by the catalytic production process).[27] Typical TEM micrographs of this material are shown in Figure 1.

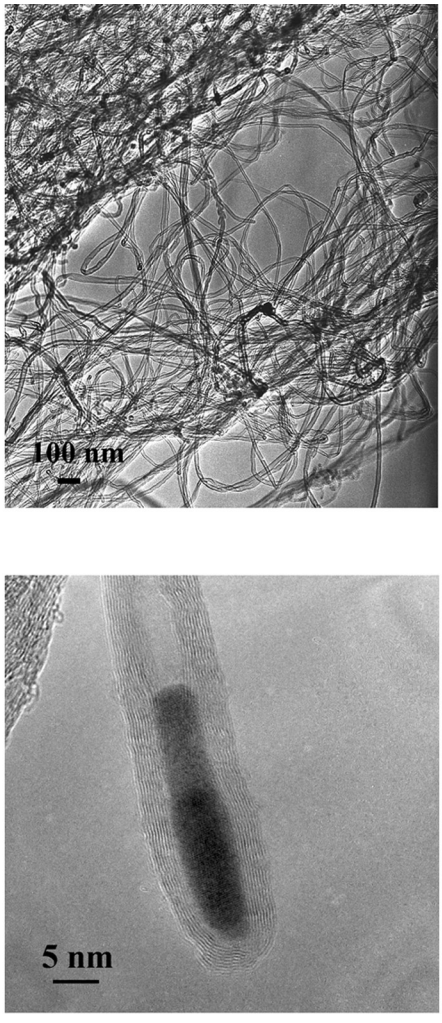

Figure 1. Typical TEM micrographs of pristine MWNTs

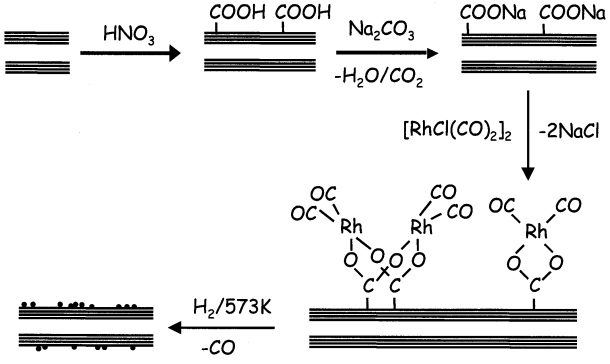
It consists of graphene layers (interlayer spacing d_{002} = 0.342 nm) arranged in a roughly parallel way with respect to the tube axis. Mean tube external and internal diameters

are 17 nm and 8 nm, respectively, which corresponds to about 13 walls. These nanotubes are characterised by a length of several micrometers and a specific surface area of about 180 $m^2 \cdot g^{-1}$, with no microporosity. Pores in aggregated MWNTs can be mainly divided into inner hollow cavities of small diameter (3−9 nm) and aggregated pores (15−25 nm) formed by interaction of isolated MWNTs.[28] From TEM observations it appears that one end of the tube is closed by graphene layers, the remaining iron carbide nanoparticles being located either at the tip of the tubes (see Figure 1) or in their inner cavities. Moreover, this material is highly hydrophobic since it does not present oxygen-containing groups, and therefore it should be unsuitable for supporting metallic nanoparticles.[29]

Thus, we envisaged to investigate the effect of chemical surface modifications on the feasibility of the grafting of the complex $[Rh_2Cl_2(CO)_4]$ and on the subsequent nanoparticle formation process by reductive treatment under H_2. Bridge-splitting and replacement reactions of rhodium carbonyl chloride dimer have been known for many years and often involve the use of silver carboxylate salts as reagents.[30] As it is well-known that oxidation of carbon nanotubes with nitric acid mainly generates carboxylic groups on the surface,[17b] we decided to investigate the possibility of synthesising the corresponding sodium carboxylates and hence of producing a true *nanotube salt*. Therefore the surface-mediated organometallic reaction depicted in Scheme 1 would be expected to occur on treatment with the dirhodium precursor, leading to a molecular dispersion of Rh carbonyl species and to a high dispersion of metallic particles after a further decomposition/reduction step (Scheme 1).



Scheme 1. Surface mediated organometallic reaction between $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ and MWNT-COONa

From TEM micrographs it appears that the morphology of MWNT-COOH and MWNT-COONa does not differ significantly from that of pristine tubes. Thus, under our experimental conditions the oxidation treatment performed causes only minor damage to the tips of the nanotubes (Figure 2). Raman spectra recorded either on pristine tubes or on oxidised samples clearly indicate that oxidation does not affect the degree of graphitisation of these materials (Figure 3). In both cases the graphite mode G-band and the defect mode D-band possess nearly the same intensities. Furthermore, a slight increase in the surface area is observed in the case of MWNT-COOH (S_{BET} = 200 $m^2 \cdot g^{-1}$).

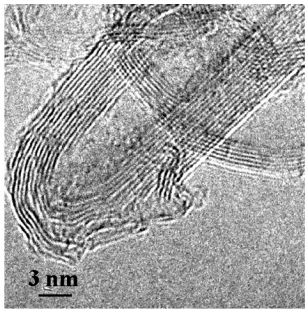


Figure 2. TEM micrograph of HNO_3-treated MWNTs

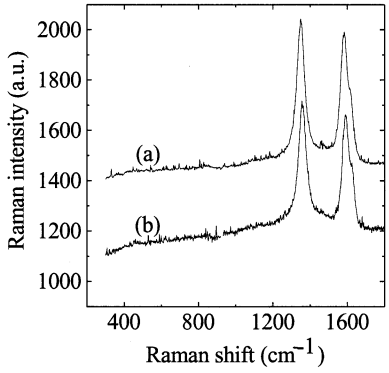

Figure 3. Raman spectra of: (a) pristine MWNTs and (b) MWNT-COOH

In order to examine the carbon environment on the surface, XPS analyses were performed on the different samples; the relevant data are given in Table 1.

Table 1. XPS data obtained from MWNT samples

Sample	Binding Energy[a] (eV)				S[b]	O[b]	C[b]	Na[b]
	530.9	532.1	533.2	534.2				
MWNT	55	45	–	–	0.14	0.81	99.05	–
MWNT-COOH	23	44	24	9	–	3.23	96.77	–
MWNT-COONa	25	49	–	14	–	5.29	93.04	1.67

[a] Values given as % of the total amount. [b] Atomic percentage.

The ratio of total oxygen to total carbon is a measure of the degree of surface oxidation, and reconstruction of the O1s peak gives additional information about the surface oxygen-containing groups. XPS spectra of all the modified MWNT samples show an increase of the oxygen content. The MWNT-COOH sample exhibits functionalities that contribute to the intensity of the O1s peaks located at 530.9 eV, 532.1 eV, 533.2 eV and 534.2 eV, in agreement with published data for activated carbon treated with nitric acid.[31] Hence, this type of treatment significantly increases

the amount of surface carboxylic groups. As for MWNT-COONa, a new peak appears at 535.4 eV, which can be attributed to the sodium carboxylate groups[32] (an XPS analysis performed on a CH_3COONa sample gave a value of 534.9 eV for -COONa). The presence of sodium was confirmed by the Na1s peak at 1071.5 eV.

The formation of sodium carboxylate groups on the outer surface of MWNTs makes this material highly hydrophilic, and it can easily be dispersed in water. Moreover, it is interesting to note that a small amount (ca, 5 mg·L^{-1}) of the so formed MWNT sodium salt is dissolved during washing with water, performed to remove the excess of sodium carbonate.

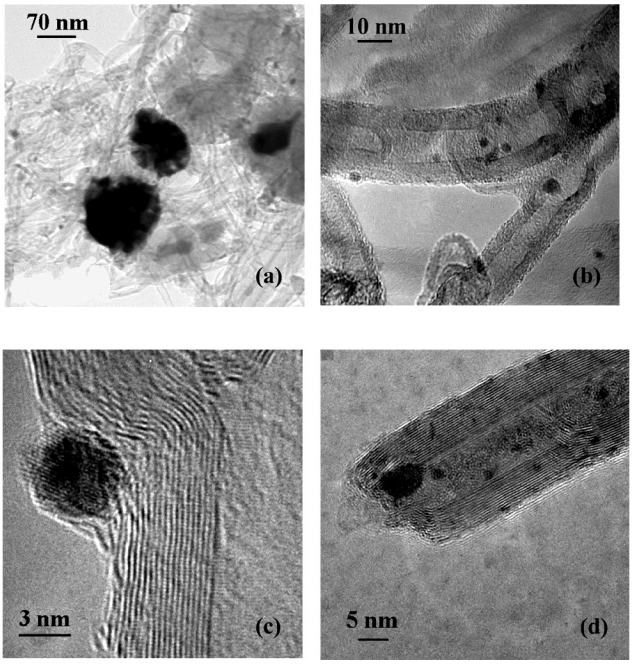

Figure 4. TEM micrographs of: (a) 1%Rh/MWNTs; (b) and (c) 1%Rh/MWNT-COOH; (d) 1%Rh/MWNT-COONa

Rh/MWNTs Catalyst Preparation by $[Rh_2Cl_2(CO)_4]$ Grafting

The grafting procedure described above involves the reaction between toluene solutions of $[Rh_2Cl_2(CO)_4]$ and various supports, namely MWNTs, MWNT-COOH, MWNT-COONa and C*-COONa. It is worth noting that with a loading of Rh equal to 1% w/w, whatever the carbon nanotube support employed, after impregnation and filtration the resulting solution is always colourless, pointing to a complete adsorption of the rhodium complex by some interaction between the complex and the MWNTs. IR spectra of these toluene solutions confirmed the absence of any detectable carbonyl bands due to rhodium species. Moreover, infrared and Raman spectra of all the solid samples obtained via the grafting procedure showed no bands attributable to the carbonyl ligands; this could very likely be due to the low rhodium loading (1−5% w/w), although the possibility of a decarbonylation reaction occurring during the grafting/drying procedure should also be considered. Furthermore, in the case of the reaction between $[Rh_2Cl_2(CO)_4]$ and MWNT-COONa, the observation by X-ray diffraction of the presence of NaCl in the samples coming from decomposition under dihydrogen clearly indicates the occurrence of the carboxylate group mediated grafting of the complex through bridge splitting.

After reductive decomposition at 573 K, careful rinsing with water to remove NaCl, and drying at 383 K under vacuum overnight, all of the samples were examined by TEM (Figure 4 and 5).

In the case of Rh/MWNTs the very large particle size distribution observed (particle size up to 100 nm has been measured) points to a weak interaction between the metal carbonyl precursor and the tube surface, which favours the migration and agglomeration of the rhodium(0) atoms deriving from the decomposition/reduction steps. As for Rh/MWNT-COOH, a better dispersion is obtained (mean particle size 2.5−5 nm), indicating that a reaction has occurred between the -COOH groups and the rhodium complex.

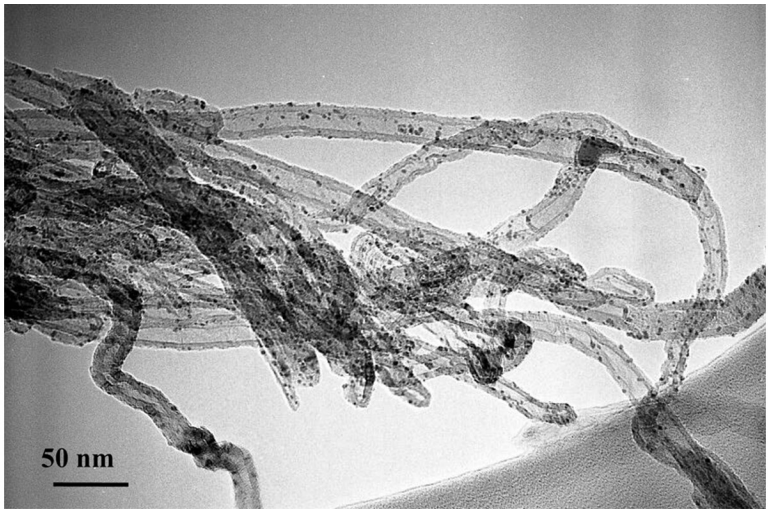

Figure 5. TEM micrographs of 9.5%Rh/MWNT-COONa

However, the results obtained with MWNT-COONa (mean particle size ≈1.5−2.5 nm) clearly show that the grafting to carboxylate groups is more efficient. Indeed, the reaction of surface carboxylate groups with the dirhodium precursor, which gives better results with respect to particle size and dispersion, is expected to be different from that of the carboxylic groups, owing to the higher nucleophilicity of the two oxygen atoms of the anionic -COO^- moiety and to the symmetric distribution of the charge (the hydrogen atom having been removed).

The MWNT sodium salt can hence be considered as a primary ligand that would be prone to react with the dirhodiumchlorocarbonyl dimeric complex to produce rhodium species grafted to the surface via splitting of the Cl bridges. Further decomposition under H_2 affords highly dispersed rhodium-supported particles even with metal loadings up to 9.5% w/w: a mean particle size of 3 nm has been measured in the case of 9.5% Rh/MWNT-COONa, with a very narrow (3 ± 2 nm) particle size distribution (see Figure 5).

Catalytic Experiments

In general, we have investigated liquid-phase catalytic reactions in order to determine whether the peculiar structures of MWNTs, and particularly their high mesoporosity, could improve transfer phenomena with respect to highly microporous activated carbons. Additionally, we were interested in the possibility of comparing surface-mediated organometallic synthesis methods to more classical impregnation techniques involving prior oxidation by nitric acid. Two reactions were studied: the hydrogenation of *trans*-cinnamaldehyde and the hydroformylation of hex-1-ene.

Prior to evaluating the catalytic activity of rhodium-supported catalysts, blank experiments were performed with MWNTs and MWNT-COOH in order to check the possible role of the remaining 3% w/w iron nanoparticles, encapsulated within the nanotubes, in the investigated catalytic systems. For MWNTs no activity was observed either in hydrogenation or in hydroformylation; in the case of MWNT-COOH a 1.7% conversion into hydrocinnamaldehyde was obtained, whilst no hydroformylation product could be detected. Indeed, iron nanoparticles of approx. 5 × 20 nm size, located either at the tip, or in inner cavities, of the nanotubes, are not accessible to the reactants in the case of MWNTs owing to the presence of graphene layers roughly perpendicular to the axis of MWNTs (bamboo-like structure), as shown on Figure 6. As depicted in Figure 2, the nitric acid treatment induces opening of the tip of the tubes, thus making iron particles reachable by the reactants. Since iron-based supported catalysts are known to be active in alkene hydrogenation,[33] it is very likely that the observed activity could actually be due to the presence of zero-valent iron and/or iron carbide particles.

Selective Hydrogenation of *trans*-Cinnamaldehyde

The catalytic results of liquid-phase hydrogenation of *trans*-cinnamaldehyde are depicted in Table 2.

One can observe that, except in the case of Rh/MWNTs, all these catalytic systems selectively afford hydrocinnamaldehyde through C=C double bond hydrogenation, irrespective of the Rh-supported carbon sample employed.

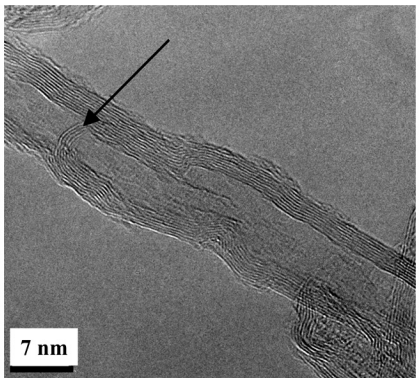

Figure 6. TEM micrograph showing graphene layers closing the inner cavity of a MWNT

Table 2. Catalytic hydrogenation of *trans*-cinnamaldehyde

Catalyst	Conv (%)	Activity[a]	Selectivity[b]

1% Rh/MWNT-COOH	5.3	26.8	100.0
1% Rh/MWNT-COONa	15.1	78.2	100.0
9.5% Rh/MWNT-COONa	23.2	11.4	100.0
1% Rh/C*-COONa	4.9	27.1	100.0
5% Pd/C*[c]	62.8	343.3	64.5[d]

[a] In g substrate transformed·g^{-1}_{Rh}·h^{-1} g^{-1}_{Rh}·h^{-1}. [b] % cinnamaldehyde. [c] A commercial 5% w/w Pd/C* (Johnson Matthey) was used for comparison purposes. [d] Hydrocinnamyl alcohol was the other product of the reaction.

The Rh/MWNTs samples, in accordance with TEM micrographs in which very large rhodium aggregates can be observed, possess no catalytic activity. In contrast, Rh/MWNT-COOH and Rh/MWNT-COONa are active and very selective catalysts for hydrocinnamaldehyde formation. If one compares the selectivity data, Rh-supported catalysts are more selective than a commercial Pd/C* catalyst, in that C=C double bond hydrogenation is the only reaction occurring under our experimental conditions.

As far as catalytic activity and conversion are concerned, it appears that the best method to support Rh particles on the MWNTs surface is indeed the grafting of the complex via surface-mediated organometallic synthesis, followed by reduction under H_2. The good performance of the thus-prepared catalysts can hence be attributed to the very small particle size obtained after the decomposition/reduction step and to the high purity of the metallic deposit. Higher conversion together with lower activity values for a 9.5% loading of rhodium on MWNTs could be attributed to the effect of the larger particle size observed. As for mass-transfer limitations, the complete absence of microporosity, together with a relatively high surface area, are crucial to a good catalytic activity. For instance, if we compare the Rh/MWNT-COONa catalyst to Rh/C*-COONa prepared ac-

cording to the same procedure, the former is three times more active.

Hydroformylation of Hex-1-ene

Liquid-phase hydroformylation runs were carried out with hex-1-ene under relatively mild conditions (2 MPa, 353 K) and afforded *n*-heptanal and 2-methylhexanal, together with 2-ethylpentanal. The presence of the last product is due to partial isomerization of the substrate to hex-2-ene, which has been observed in the reaction solutions by GC. Such a reaction pathway was previously observed under more drastic conditions (10 MPa, 423 K) on Rh/C* catalysts,[34] leading to C7 aldehyde, hexane and C7 alcohol formation. The catalytic results are shown in Table 3, and the selectivities to the products obtained are listed in Table 4.

It should be noted that the production of linear and branched aldehydes and a high linear/branched ratio (2.6) occur only with 1% Rh/MWNT-COOH, a sample characterised by large particle sizes and by the acidic character of the support. In this case no ethylpentanal and lower amounts of methylhexanal were detected. The most important feature of our catalytic system is the high conversion and activity values found for 1% Rh/MWNT-COONa and the selectivity of the reaction toward aldehyde formation, thus confirming, as for *trans*-cinnamaldehyde hydrogenation, the efficiency of our grafting method and the advantage of using carbon nanotubes as a support in liquid-phase catalytic reactions.

Table 3. Catalytic hydroformylation of hex-1-ene

Catalyst	Conv. (%)	Activity[a]	n/b ratio[b]
1% Rh/MWNT	–	–	–
1% Rh/MWNT-COOH	52.3	72.9	2.6
1% Rh/MWNT-COONa	75.8	197.6	1.2
9.5% Rh/MWNT-COONa	65.8	11.6	1.2
1%Rh/C*-COONa	66.1	105.6	1.2

[a] In g substrate transformed·g^{-1}_{Rh}·h^{-1} in g^{-1}_{Rh}·h^{-1}. [b] n = linear isomer; b = branched isomer.

Conclusion

Oxidation of the outer surface of multi-walled carbon nanotubes by nitric acid leads to the formation of carboxylic groups that can be used to anchor rhodium carbonyl moieties. Better results are obtained upon conversion of carboxylic into more reactive carboxylate groups. A further reduction step under dihydrogen affords highly dispersed (for instance 1.5−2.5 nm for a 1% w/w loading) rhodium nanoparticles even for rhodium loadings up to 9.5% w/w. These Rh-supported catalysts show interesting performances with respect to liquid-phase hydrogenation and hydroformylation reactions. Additionally, the nature of the MWNT support probably contributes to a better activity, presumably by ameliorating transfer processes with respect to what happens on classical activated carbons.

Experimental Section

General Remarks: Nitric acid (Prolabo, 52.5%), Na_2CO_3·$10H_2O$ (Acros Organics), toluene (Acros Organics, 99%), dioxane (SDS), *trans*-cinnamaldehyde (Aldrich, 98%) and hex-1-ene (Janssen, 97%) were used as received. H_2 and CO (Air Liquide, 99.99998 and 99.99%, respectively) were also used as received. The complex $[Rh_2Cl_2(CO)_4]$ was prepared according to a well established procedure.[36]

Carbon nanotubes were prepared by a catalytic CVD method[27] on an Fe/Al_2O_3 catalyst.[35] Dissolution of the alumina support and some of the iron was performed by acidic treatment (H_2SO_4, 98% Prolabo). Typical characterisation data for this material are given in Table 5.

Surface Modification of MWNTs

A mixture of 5 g of MWNTs in 150 mL of HNO_3 (52.5%) was refluxed for 3 hours at 403 K. Then the mixture was filtered and

Table 4. Product distribution for hex-1-ene hydroformylation (as selectivities, %)

Catalyst	2-Ethyl-pentanal	2-Methyl-hexanal	Heptanal
1% Rh/MWNT	–	–	–
1% Rh/MWNT-COOH	–	27.7	72.3
1% Rh/MWNT-COONa	12.6	39.8	47.6
9.5% Rh/MWNT-COONa	8.1	38.0	53.9
1%Rh/C*-COONa	7.3	37.4	55.3

Table 5. Main characteristics of pristine MWNTs

rinsed with deionized water until the pH of the water reached 7. The resulting material was dried overnight at 383 K in a thermostatted oven and crushed to a powder by a ball-milling process for 20 min.[37] This material is named MWNT-COOH.

The preparation of the corresponding nanotube sodium carboxylate salt (MWNT-COONa) was accomplished by treatment of a suspension of 5 g of MWNT-COOH in 100 mL of toluene with 200 mg of $Na_2CO_3 \cdot 10H_2O$ dissolved in 50 mL of H_2O. This suspension was stirred for 15 min, sonicated for 2 hours at 313 K and stirred again for 15 min at room temperature. The resulting mixture was then filtered through a Büchner funnel, and the material washed with deionized water to fully remove the excess of the sodium salt. Drying overnight in a thermostatted oven at 383 K afforded MWNT-COONa. Moreover, a C*-COONa sample was prepared for comparison purposes by the same procedure starting from a commercial activated carbon (Darco-G60, 100 mesh, $S_{BET} = 700\ m^2 \cdot g^{-1}$, Aldrich).

Surface Grafting of $[Rh_2Cl_2(CO)_4]$ and Production of Rh/MWNTs or Rh/C*-COONa: 100 mg of $[Rh_2Cl_2(CO)_4]$ was added to a suspension of 5.29 g of the carbon support in 100 mL of toluene, stirred for 3 hours at 333 K under nitrogen and then sonicated for 2 hours at room temperature. Filtration through a Büchner funnel, washing with *n*-hexane, drying in vacuo and crushing for 20 min resulted in the production of the rhodium grafted material. Activation of the supported complex was done under a continuous flow (250 sccm) of a N_2/H_2 gas mixture (80:20 v/v) for three hours at 573 K, then the samples were washed with water to remove the NaCl formed, dried overnight at 383 K and crushed to powder. The rhodium loading was so fixed at 1% w/w, if not otherwise specified in the text.

Evaluation of Catalyst Activity for trans-Cinnamaldehyde Hydrogenation and Hex-1-ene Hydroformylation: The selective hydrogenation of cinnamaldehyde was carried out at atmospheric pressure in a three-necked flask equipped with a reflux condenser and gas inlet. The mixture containing 100 mg of rhodium-supported catalyst, 2 mL of *trans*-cinnamaldehyde and 50 mL of dioxane was sonicated for 15 min at room temperature prior to each catalytic run; nitrogen gas at room temperature was bubbled through the liquid phase to purge the system, the temperature was raised to 353 K, then dihydrogen gas was let in. Each catalytic run lasted 4 h, during which time samples were taken at regular intervals for analysis.

The hydroformylation of hex-1-ene was performed in an autoclave under the following reaction conditions: 353 K, 2 MPa of CO/H_2 (1:1). A catalyst sample (100 mg) was dispersed in a mixture of 40 mL of toluene and 5 mL of hex-1-ene, sonicated in a Schlenk tube for 15 min and transferred under nitrogen into the autoclave, which was then pressurized and heated. At the end of the catalytic runs (24 h) the resulting mixture was cooled to room temperature, then filtered and analysed.

Analysis of the reaction products, both from hydrogenation and hydroformylation runs, was performed on a Carlo Erba HRGC 5160 gas-chromatograph equipped with a capillary column (DB-5 J&W Scientific, 30 m, i.d. O.32 μm, film O.25 μm); a Perkin−Elmer Q-Mass 910 GC-MS instrument (capillary column DB-1 J&W Scientific, E.I. 70 eV) was used to identify the hydrogenation or hydroformylation products and to confirm the nature of the by-products.

Characterisation of the Materials: TEM observations were made with a Hitachi HF2000 (200 kV) microscope equipped with a field emission gun, a cold cathode and a multiscan camera (Gatan) which allows the recording and manipulation of high-resolution images by means of Digital Micrograph software. The rhodium particle-size distributions were determined on the basis of TEM micrographs. Additional TEM observation were performed on a Phillips CM12 (120 kV voltage) electron microscope.

Raman spectra were recorded on a T64000 Jobin−Yvon spectrometer (4 cm^{-1} resolution) equipped with a Spectra Phisycs $Argon^+$ Laser; samples were excited at $\lambda = 514$ nm. X-ray photoelectron spectra were obtained on a VG ESCALAB MK II spectrometer. The measurements were carried out using unmonochromatized Mg-K_α radiation ($\lambda = 0.989$ nm) under a mean pressure of 6×10^{-11} kPa.

Acknowledgments

Special thanks to Dr B. Richard for technical assistance and to Mr J. Y. Mevellec for his help in Raman studies. We would like to thank also Engelhard-CLAL for a generous loan of $RhCl_3 \cdot 3H_2O$.

Syntheses, Crystal Structures, and Properties of Four Two-Dimensional Network Complexes with Multidentate Bis(Schiff Base) Ligands

Xing-Mei Ouyang,[a] Bao-Li Fei,[a] Taka-aki Okamura,[b] Hong-Wei Bu,[a] Wei-Yin Sun,*[a] Wen-Xia Tang,[a] and Norikazu Ueyama[b]

Keywords: Schiff bases / Silver / Cobalt / Crystal engineering

Four novel two-dimensional coordination polymers $[Ag_2(L1)_2](CF_3SO_3)_2{\cdot}H_2O$ (**1**), $[Ag_3(L1)_2](NO_3)_3{\cdot}H_2O$ (**2**), $[Co(L1)_2(SCN)_2]{\cdot}EtOH$ (**3**), and $[Co(L2)_2(SCN)_2]$ (**4**) were obtained by reactions of the bis(Schiff base) ligand 1,2-bis(4′-pyridylmethyleneamino)ethane (L1) with silver(I) trifluoromethanesulfonate, silver(I) nitrate, and cobalt(II) thiocyanate, and 1,2-bis(3′-pyridylmethyleneamino)ethane (L2) with cobalt(II) thiocyanate, respectively. In complex **1**, a 2D network structure was achieved by hydrogen bonding interactions between the two 1D chains, consisting of double-stranded helicates, through solvate water molecules. The 2D network of complex **2** was formed by the coordination to a two-coordinate silver(I) ion instead of hydrogen bonds as in complex **1**. Complex **3** contains molecular square units, which are occupied by disordered ethanol molecules. Complex **4** exhibits a classic square-grid network which is different from that of **3** due to the different terminal pyridyl groups in L1 (4-pyridyl) and L2 (3-pyridyl). These coordination polymers were characterized by X-ray crystallography, electrospray mass spectrometry, cyclic voltammetry and magnetic measurements. The results show a 2D network superstructural diversity by the fine-tuning of construction components.

Introduction

The construction of polymeric coordination complexes has developed rapidly in recent years owing to their structural topologies and interesting catalytic, electronic, magnetic and spectroscopic properties.[1] The "node-and-spacer" approach has been remarkably successful in constructing predictable network architectures, including zero-dimensional polyhedrons, and infinite one- (1D), two- (2D), and three-dimensional (3D) periodic nets.[2−7] In the case of 2D architectures, one would anticipate that the network would possess an inherent ability to include guest molecules. Square grid,[8] rectangular grid,[9] brick wall,[10] herringbone,[11] and bi-layer[12] networks have been reported and can be generated from commonly available metal moieties and linear "spacer" ligands. The square-grid is a simple and well-known 2D metal-organic network.[13] A series of square-grid networks has been obtained by the reaction of bipy spacer ligands with various transition metal ions such as Cd^{II}, Co^{II}, Ni^{II}, and Zn^{II}, with different crystal packing modes.[14] Other commonly used spacer ligands include cyano[15] and pyrazine moieties[16] and longer analogs of bipy.[17]

Although the node-and-spacer approach exerts significant effects on the construction of the network polymers, it can only successfully be applied to the self-assembly of rigid bidentate ligands and metal moieties. An assembly process containing multidentate ligands is usually very complicated and is influenced by various factors such as solvent system, templates, counterions, valences and the geometric needs of the metal ions and sometimes the ratio between the metal salt and the ligand.[18] Therefore it is still difficult at the present time to design and synthesize supermolecular architectures with predicted structures and properties when the number of donor atoms in the ligands is more than two.

To investigate the influence of the nature of multidentate ligands on the construction of 2D network polymers, the tetradentate bis(Schiff base) ligands 1,2-bis(4′-pyridyl)ethylenediamine (L1) and 1,2-bis(3′-pyridyl)ethylenediamine (L2; Scheme 1) − longer analogs of bipyridine − were em-

ployed as organic ligands. Self-assembly of these ligands with monovalent silver(I) and divalent cobalt(II) salts as the nodes was carried out.

Schiff bases are an important class of ligands in coordination chemistry and have been studied extensively[19] as they are selective and sensitive toward various metal ions. In our previous work we reported that the assembly of Schiff base ligand L1 with copper(I) salts produced two complexes $[Cu(L1)(CH_3CN)]NO_3$ and $[Cu(L1)(CH_3CN)]ClO_4$ with infinite zigzag chain-like structures;[20] two infinite 2D grid networks were obtained by assembly of reduced L1 ligand, 1,6-bis(4′-pyridyl)-2,5-diazahexane (L), with the same copper(I) salts.[22] This indicates the significant influence of the nature of the ligand on the construction of supramolecular architectures. In this paper, the reaction of L1 with silver(I) salts with different counteranions, is shown to produce two 2D coordination polymers $[Ag_2(L1)_2](CF_3SO_3)_2·H_2O$ (**1**) and $[Ag_3(L1)_2](NO_3)_3·H_2O$ (**2**) containing double-stranded helicates. In addition, the self-assembly of ligands L1 and L2 with $Co(SCN)_2$ produces two different 2D coordination complexes, $[Co(L1)_2](SCN)_2·EtOH$ (**3**) and $[Co(L2)_2](SCN)_2$ (**4**). These coordination complexes were characterized by X-ray crystal diffraction, electrospray mass spectrometry, cyclic voltammetry and magnetic measurements.

Results and Discussion

Crystal Structure Description

Complexes **1** and **2** have the same ligand and metal ion but different anions, while complexes **3** and **4** have different ligands. X-ray crystal structure analyses reveal that complexes **1**−**4** crystallize in different crystal systems with different symmetries, from triclinic to tetragonal. Details of the crystal parameters, data collection and refinement for complexes **1**−**4** are summarized in Table 4, and selected bond lengths and angles with their estimated standard deviations are listed in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] for **1**−**4**

Crystallographic analysis indicates that the asymmetric unit of complex **1** consists of two silver(I) ions, two L1 ligands, two $CF_3SO_3^-$ anions and one water molecule, as shown in Figure 1. It is interesting that the Ag^I atoms have two different coordination environments, which is not com-

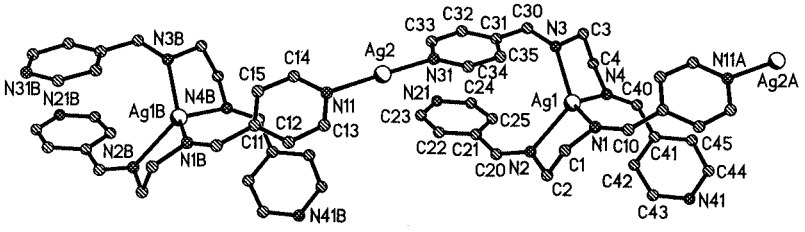

Figure 1. 1D chain structure of $[Ag_2(L1)_2](CF_3SO_3)_2·H_2O$ (**1**) with atom numbering scheme; anions, water molecules, and hydrogen atoms have been omitted for clarity

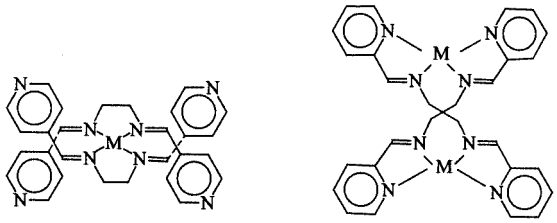
mon in metal complexes with open-chain bis(Schiff base) ligands. In the previously reported silver(I) complex with a flexible reduced bis(Schiff base) ligand, 1,7-bis(4′-pyridyl)-2,6-diazaheptane, the 2D brick-wall network consists of trigonal and linear silver(I) ions.[21] In complex **1**, four imine N atoms from two different L1 ligands bind to the Ag(1) atom to form a double-stranded helicate. The coordination geometry of the four-coordinate Ag(1) is distorted tetrahedral with N−Ag(1)−N coordination angles ranging from 74.68(8) to 135.86(8)° and an average Ag(1)−N bond length of 2.364(2) Å (Table 1). Similar Ag−N bond lengths have been reported for silver(I) complexes with the same AgN_4 binding site, for example $[Ag(L)]NO_3$ has an average Ag−N bond length of 2.360(3) Å.[22] The double-stranded helicates are further linked to the Ag(2) atom through the coordination of two pyridine N(11) and N(31) atoms, as illustrated in Figure 1. The N(31)−Ag(2)−N(11) angle of 171.42(9)° indicates that the Ag(2) has an almost linear coordination geometry with bond lengths of 2.176(2) and 2.185(2) Å. Therefore, each Ag(1) atom in **1** is coordinated by two different L1 ligands and, in turn, each L1 ligand connects two Ag^I ions. Such a coordination mode generates an infinite chain-like structure (Figure 1). The intermetallic distance between Ag(1) and Ag(2) is 7.39 Å. It has been reported that the bis(Schiff base) ligand obtained from pyridine-2-carbaldehye and 1,2-ethanediamine forms a dinuclear double-stranded helical complex with silver(I) tetrafluoroborate.[23,24] This helical complex shows remarkable differences to ours with respect to the coordination mode, as shown schematically in Scheme 2.



Scheme 2

It is noteworthy that one pyridine unit of each L1 ligand remains uncoordinated in complex **1**. This means that the N_4 donor ligand L1 actually serves as a tridentate ligand when it reacts with silver(I) trifluoromethanesulfonate. A similar phenomenon has been observed in the complex $[Cu(L1)(CH_3CN)]NO_3$ with a zigzag chain-like structure.[20] In this complex, one pyridine unit of the L1 ligand is also free from coordination; instead, one acetonitrile molecule coordinates to the copper center to complete the coordination sphere of the copper(I) ion.[20] The uncoordinated pyridine N atom in complex **1** forms an O−H···N hydrogen bond with a solvate water molecule. Each water molecule forms two such O−H···N hydrogen bonds between the two adjacent chains and links the 1D chains to give a 2D network structure as shown in Figure 2. The $CF_3SO_3^-$ anions located at the vacancy of the 2D network form four C−H···O hydrogen bonds. Each cavity contains two $CF_3SO_3^-$ anions. The hydrogen bonding data are summarized in Table 2.

When the self-assembly of ligand L1 with silver(I) nitrate was carried out under the same conditions as **1**, coordination polymer **2** with a similar 2D network structure was obtained. However, the asymmetric unit of complex **2** contains three Ag^I ions (rather than two as in **1**), two L1 ligands, three NO_3^- anions and one water molecule, as shown in Figure 3. The most important difference between **1** and **2** is that the four N atoms of the L1 ligand all participate in the coordination with silver(I) ions in complex **2**, while in **1** only three of the four N atoms coordinate to Ag (vide supra). The four-coordinate Ag(1) has a distorted tetrahedral geometry with coordination angles ranging from 73.90(11) to 138.71(13)° while Ag(2) [N(12)−Ag(2)−N(42) = 167.50(17)°] and Ag(3) [N(32)−Ag(3)−N(22) = 177.56(18)°] are both two-coordinate with an almost linear geometry in complex **2**. As illustrated in Figure 4, the 1D chains containing double-stranded helicates in **2** are connected by the coordination bonds of two-coordinate silver(I) ions with two pyridine ring N donors from two adjacent chains − instead of O−H···N hydrogen bonds as in complex **1** − into a 2D network structure. The NO_3^- anions located at the voids of the network form nine C−H···O hydrogen bonds as listed in Table 2. Each cavity contains three NO_3^- anions with the solvate water molecules located in the cavity between the two layers.

The different linkage mode from 1D chains to 2D network for complexes **1** and **2** may be explained by the different sizes of the $CF_3SO_3^-$ and NO_3^- anions which occupy the vacancies of the 2D network i.e. the size of the anion controls the vacancy size of the 2D networks. In the case of **1** (with the larger $CF_3SO_3^-$ anion) the vacancy has an Ag(2A)−Ag(2B) distance of 14.98 Å and an O(7A)−O(7B) distance of 14.36 Å (Figure 2), while in the case of **2** with the smaller NO_3^- anion, the corresponding distances are Ag(2)−Ag(2A) = Ag(3)−Ag(3B) = 14.09 Å (Figure 4). The distance between two pyridine N atoms [e.g. N(21B) and N(41A) in Figure 2] linked by one water molecule in complex **1** is 5.22 Å, which is longer than the distance of 4.29 Å between two pyridine N atoms [e.g. N(12) and N(42), N(22) and N(32) in Figure 4] coordinated by the two-coordinate silver(I) ion in complex **2**. This result shows that the counteranions have a large effect on the formation of network structures.

The Schiff-base ligand L1 and its reduced form L react with silver(I) nitrate to form the 2D network complex **2** and the 1D hinged-chain complex $[Ag(L)]NO_3$,[22] respectively. It is interesting that each ligand L1 in **2** has a "C" shape while the shape of L in $[Ag(L)]NO_3$ is "Z" due to the flexibility of the ligands. In addition, the imine N atoms and pyridyl N atoms are coordinated to four-coordinate and two-coordinate silver(I) ions, respectively, in **2** while in the case of $[Ag(L)]NO_3$, each silver(I) ion is coordinated by two

amine N atoms and two pyridyl N atoms from three different L ligands.[22] This suggests that a subtle change in the organic ligand may cause a large change in the assembly products.

In contrast to monovalent metal ions like Cu^I and Ag^I, which require a tetrahedral or linear coordination geometry, a divalent metal ion such as Co^{II} is usually six-coordinate with an octahedral geometry. After several attempts at reactions between the L1 ligand and Co^{II} salts with different anions, we succeeded in the isolation of a complex with the SCN^- anion, $[Co(L1)_2(SCN)_2] \cdot EtOH$ (**3**). The repeat unit of complex **3** is shown in Figure 5. The coordination sphere of the cobalt(II) ion is defined by four pyridine N donors of four different L1 ligands situated in the equatorial plane and two N donors of SCN^- anions at the axial positions, leading to a slightly distorted octahedral coordination environment. The two linear SCN^- anions are not perpendicular to the equatorial plane and the C(2)−N(2)−Co(1) and C(1)−N(1)−Co(1) angles are 147.3(3) and 161.2(3)°, respectively. The four equatorial Co−N bond lengths range from 2.159(3) to 2.191(3) Å and are longer than those of the two axial Co−N bonds [2.096(3) and 2.098(3) Å] (Table 1). Similar bond lengths and angles have been observed in a Co^{II} complex with the tetradentate Schiff-base ligand 1,3-bis(pyridine-2-carboxaldiamino)propane.[25] Surprisingly, the L1 ligand in **3** serves as a bidentate, not a tetradentate, ligand and connects two Co^{II} ions; the N atoms of the imine group do not participate in the coordination to the Co^{II} ion, as shown in Figure 6. The structure of complex **3** consists of many square units interconnected through L1 bridges into a 2D network. Each square unit is composed of two L1 spacers and two cobalt(II) ions and its cavity is occupied by a disordered ethanol molecule (Figure 6). It is obvious that the sheets of **2** have a corrugated and wavy network structure and are linked by C−H···N hydrogen bonds [Figure S1 (for Supporting Information see footnote on the first page of this article) and Table 2]. The disordered ethanol molecules are disposed between the layers by (ethanol) O−H···S and C−H···O (ethanol) hydrogen bonds (Table 2). Similar to the

extended analog of bipyridine, a metal-organic framework with larger cavity was constructed by reaction of the ligand L1 with the metal moiety.

In order to compare the structures of complexes obtained by reactions of $Co(SCN)_2$ with different ligands L1 and L2, a crystallographic analysis was carried out for complex **4**. It can be seen from Figure 7 that the coordination mode around the Co^{II} ion in complex **4** is similar to that in complex **3** (Figure 5); the N atoms of the imine groups also remain uncoordinated as in complex **3**. However, two SCN^- anions and the Co^{II} ion are in a line, i.e. the SCN^- anions are perpendicular to the equatorial plane in **4**. In addition, each Co^{II} ion is bridged by four L2 ligands to four adjacent Co^{II} centers, resulting in an infinite 2D square grid with dimensions of 11.34 × 11.34 Å (Figure 8, a), near to the value of 11 Å observed in the 1D ladder complex

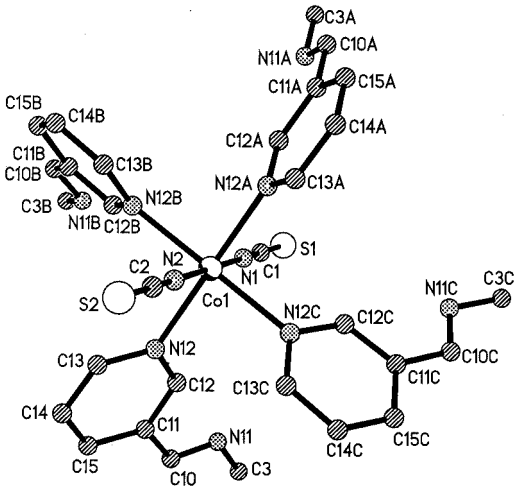

Figure 7. Coordination environment around the Co^{II} ion in the complex $[Co(L2)_2](SCN)_2$ (**4**) with atom numbering scheme; hydrogen atoms have been omitted for clarity

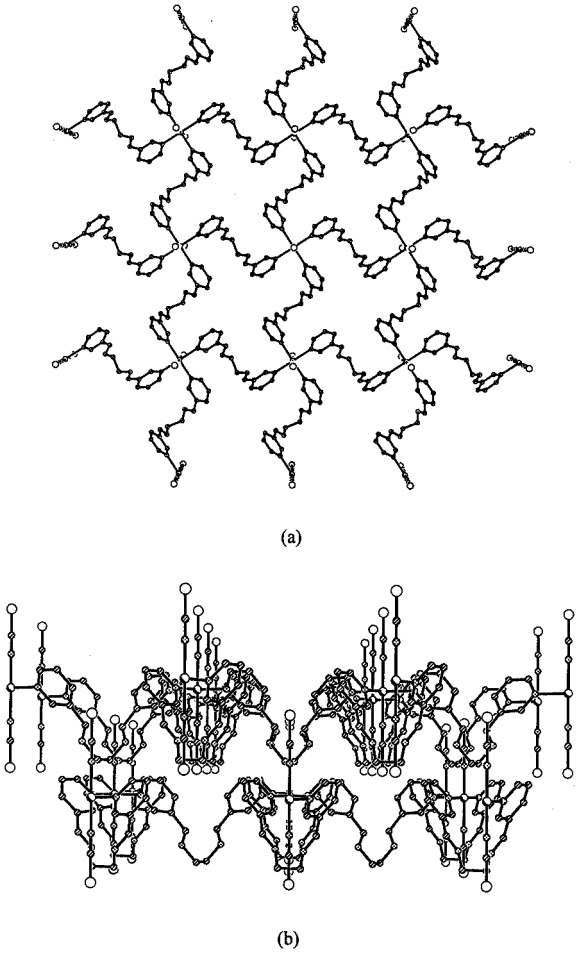

Figure 8. (a) Square-grid network of complex **4**; (b) packing diagram of two sheets in **4**

$[Co(bpy)_{1.5}(NO_3)_2]$.[26] The crystal packing diagram of **4**, shown in Figure 8, b, reveals that the 2D sheets repeat in an ---ABAB--- stacking sequence, with the Co atom of one layer located above the center of the grid of the adjacent layer. As a result, there is no open channel and no solvate molecules are found in complex **4**. Ligand L2 is different from L1 as it contains a 3-pyridyl group instead of a 4-pyridyl group and this change results in a completely different metal-organic framework. These results again demonstrate that the nature of the organic ligand plays an important role in the construction of supramolecular architectures.

Properties

Electrospray mass spectrometry (ES-MS) has recently been proved to be a powerful technique in the characterization of assemblies.[27] However, there are few reports on the application of ES-MS to self-assembled coordination polymers. Using this technique our group has successfully characterized coordination polymers and observed cationic mono-, di-, tri-, and tetranuclear metal species under ES-MS conditions.[22,28] Complexes **1**−**4** were also investigated by ES-MS and the spectroscopic data are summarized in Table 3. The ES-MS spectrum of the 2D coordination polymer **1** in acetonitrile solution is shown in Figure 9, a and gives a clear picture of the different species formed. Four main peaks at m/z = 345.2, 376.7, 583.0, and 615.0 are observed corresponding to the mononuclear species $[Ag(L1)]^+$ $[Ag(L1) + CH_3OH]^+$, $[Ag(L1)_2]^+$, and $[Ag(L1)_2 + CH_3OH]^+$ (methanol was used as the mobile phase), respectively. The other four peaks at 840.7, 872.9, 904.7, and 1162.5 originate from the dinuclear species (Table 3). All these assignments were confirmed by good agreement between the observed and calculated isotopic distributions. Figure 9, b shows a typical example of a comparison between the experimental and calculated isotope distributions for the peak at m/z = 872.9, corresponding to the dinuclear species $[Ag_2(L1)_2(CF_3SO_3) + CH_3OH]^+$. The observation of cationic species in the ES-MS spectrum confirms the coordination of L1 to the Ag^I atom under the ES-MS experimental conditions. Similar mono- and dinuclear species were also observed in the complexes **2**−**4** (Table 3). Observation of a peak at m/z = 715.9, corresponding to the $[Co(L1)_2H(SCN)_2 + C_2H_5OH + H_2O]^+$ species, confirms the presence of an ethanol molecule in complex **3**.

The complexes were further investigated by electrochemistry. The cyclic voltammograms for $[Co(L1)_2(SCN)_2]$·EtOH (**3**) and $[Co(L2)_2(SCN)_2]$ (**4**) are shown in Figure 10. It can be seen that the cobalt(II) complexes exhibit similar electrochemical behavior in the positive potential region. Irreversible anodic peaks were observed at +0.76 V for complex **3** and at +0.80 V for complex **4** vs. Ag/AgCl in acetonitrile. The known (Schiff base)cobalt complexes $[Co(DSALPTP)]_2[CoCl_4]$ [H_2DSALPTP = 1,3-bis(*o*-salicylaldiminophenylthio)propane] and [CoSalmbfn] [Salmbfn = bis(salicylaldehyde)methylene-*p*,*p*′-diphenylene] showed a similar irreversible oxidation of Co^{II} to Co^{III} at 0.75 and 0.80 V vs. Ag/AgCl, respectively.[29−31] The more positive oxidation potential of

complex **4** implies that it is more difficult to oxidize than complex **3** under the electrochemical conditions.

The temperature dependence of the magnetic susceptibility of complexes **3** and **4** was measured in the temperature range 75−300 K. It was found that the effective magnetic moment values for **3** and **4** were 5.05 μ_B and 4.85 μ_B ($\mu_B \approx 9.27\cdot10^{-24}$ J·T^{-1}), respectively, at 300 K. These values are within the expected range (4.3−5.2 μ_B) for isolated d^7 high-spin, six-coordinate Co^{II} complexes.[32] Upon lowering the temperature, the effective magnetic moment gradually decreased to 4.32 μ_B for **3** and 4.20 μ_B for **4**. These results indicate that there are only weak antiferromagnetic interactions between the metal centers due to the large Co···Co separations revealed by the crystal structures.

Conclusion

From the structure analysis of 2D networks **1** and **2**, it has been found that the anions play a key role in the construction of coordination polymers. In complex **1**, the large $CF_3SO_3^-$ anion lengthens the distances between the 1D chains, so that the formation of 2D network depends on the O−H···N hydrogen bonds formed between the chains and solvate water molecules. In complex **2**, with the small nitrate anion, a 2D structure is obtained by the coordination interactions between two-coordinate silver(I) ions and 1D chains. In addition variation of the terminal coordination group from 4-pydriyl to 3-pyridyl generates two completely different polymers **3** and **4**. These results indicate that a small change in the organic ligand has a significant effect on the self-assembly products.

The present study shows that the multidentate Schiff-base ligands L1 and L2 can offer a different number of N donors according to the coordination requirement of different transition metal ions. The ligand L1 is tridentate in complex **1** and tetradentate in complex **2**, while in the case of complexes **3** and **4**, both L1 and L2 act as bidentate ligands. This also suggests the complexity of multidentate ligands in the self-assembly process with metal salts.

Experimental Section

General: All commercially available chemicals were of reagent grade and used as received without further purification. L1 was prepared by a method reported previously.[20] Solvents were purified according to standard methods. Samples for C, H, N analyses were dried under vacuum and the analyses were performed with a Perkin−Elmer 240C elemental analyzer at the analysis center of Nanjing University. ^{1}H NMR spectra were measured with a Bruker DRX500 MHz NMR spectrometer at room temperature. Electrospray MS measurements were carried out with an LCQ System (Finnigan MAT, USA) using methanol as mobile phase. Variable-temperature magnetic susceptibilities (75−300 K) of complexes **3** and **4** were measured with a CHAN-2000 Faraday magnetometer. A diamagnetic correction was made with Pascal's constants for all the constituent atoms, and the magnetic moments were calculated by the equation $\mu_{eff} = 2.828(\chi_m)^{1/2}$. Cyclic voltammograms (CVs) were recorded with an EG&G M273 potentiostat/galvanostat system using a platinum working electrode, a platinum wire counter electrode and an Ag/AgCl reference electrode. The CV measurements were carried out in acetonitrile solution containing 0.1 M tetrabutylammonium perchlorate as supporting electrolyte at a scan rate of 100 mV·s^{-1}. Ferrocene was added at the end of the experiment and used as an internal reference.

Preparation of 1,2-Bis(3′-pyridylmethyleneamino)ethane (L2): 1,2-Ethanediamine (0.53 mL, 7.9 mmol) was dissolved in refluxing absolute methanol (30 mL) and pyridine-3-carbaldehyde (1.42 mL, 15.0 mmol) in absolute methanol (30 mL) was added slowly to give a clear yellowish solution. The mixture was refluxed for 3 h and stirred overnight at ambient temperature. The solvents were evaporated to give a yellow solid under reduced pressure. White needle-shaped crystals were obtained by recrystallization of the residue from methanol and deionized water. After washing with diethyl ether and drying under vacuum, 1.52 g of L2 was obtained with a yield of 85%. ES-MS: $m/z = 239.1$ [L2 + H]$^+$. $C_{14}H_{14}N_4$ (238.29): calcd. C 70.56, H 5.92, N 23.51; found C 70.39, H 5.81, N 23.75.

Synthesis of $[Ag_2(L1)_2](CF_3SO_3)_2·H_2O$ (1): All procedures for synthesis and recrystallization were carried out in the dark. A deionized aqueous solution (5 mL) of CF_3SO_3Ag (12.8 mg, 0.05 mmol)

was added dropwise to a stirred solution of L1 (11.9 mg, 0.05 mmol) in acetonitrile (5 mL) at room temperature. After filtration, the clear filtrate was allowed to stand at 5 °C for several days, and colorless crystals were collected (14.1 mg, 56%). Single crystals suitable for X-ray diffraction analysis were obtained by slow concentration of the filtrate at 5 °C. ^{1}H NMR (D_2O, 25 °C): δ = 3.98 (s, 4 H), 5.97 (s, 2 H), 7.81 (d, 4 H), 8.73 (d, 4 H) ppm. $C_{30}H_{30}Ag_2F_6N_8O_7S_2$ (1008.48): calcd. C 35.73, H 3.00, N 11.11; found C 35.77, H 3.05, N 11.05.

Synthesis of $[Ag_3(L1)_2](NO_3)_3·H_2O$ (2): The complex was prepared in a manner similar to that for **1** except that CF_3SO_3Ag was replaced by $AgNO_3$. Light-brown block single crystals were obtained (8.4 mg, 50%). $C_{28}H_{30}Ag_3N_{11}O_{10}$ (1004.24): calcd. C 33.49, H 3.01, N 15.34; found C 33.38, H 3.26, N 15.36.

Synthesis of $[Co(L1)_2(SCN)_2]·EtOH$ (3): This complex was prepared by the layering method. A solution of ligand L1 (11.9 mg, 0.05 mmol) in ethanol (5 mL) was added slowly and carefully to a layer of a solution of $Co(SCN)_2$ (11.5 mg, 0.05 mmol) in ethanol (3 mL) in a tube. Red-orange platelet single crystals suitable for X-ray diffraction analysis were obtained after standing for several days (12.6 mg, 72%). $C_{32}H_{34}CoN_{10}OS_2$ (697.74): calcd. C 55.08, H 4.91, N 20.07; found C 55.02, H 5.00, N 20.28.

Synthesis of $[Co(L2)_2(SCN)_2]$ (4): According to the preparation method of complex **3**, pink column single crystals suitable for X-ray diffraction analysis were obtained by reaction of the ligand L2 with $Co(SCN)_2$; yield 11.1 mg, 68%. $C_{30}H_{28}CoN_{10}S_2$ (651.67): calcd. C 55.29, H 4.33, N 21.49; found C 55.12, H 4.49, N 21.47.

X-ray Crystal Structure Analysis for Complexes 1−4: The intensity data for the complexes **1**−**4** (Table 4) were collected with a Rigaku RAXIS-RAPID Imaging Plate diffractometer at 200 K, using graphite-monochromated Mo-K_α radiation (λ = 0.7107 Å). The structures were solved by direct methods with SIR92[33] and expanded using Fourier techniques.[34] All data were refined anisotropically by the full-matrix least-squares method for non-hydrogen atoms. The hydrogen atom positions were generated geometrically except for those of the water molecules, which were found from difference maps. Disordered NO_3^- anions and ethanol molecules were observed in complex **2** and **3**, respectively, although the data collection was performed at low temperature (200 K). All calculations were carried out with an SGI workstation using the teXsan crystallographic software package of Molecular Structure corporation.[35] CCDC-189685 (**1**), -189686 (**2**), -189687 (**3**), and -189688 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Reactivity of $B(C_6F_5)_3$ with Oxovanadium(V) Complexes VOL_3 ($L = OCH_2CF_3$, NEt_2): Formation of the Organometallic Vanadium(V) Complex $[VO(\mu\text{-}OCH_2CF_3)(OCH_2CF_3)(C_6F_5)]_2$ and the Lewis Acid Adduct $[(Et_2N)_3VO{\cdot}B(C_6F_5)_3]$

Keywords: N ligands / O ligands / Boranes / Structure determination / Vanadium

Treatment of the oxovanadium(V) complex $[VO(OCH_2CF_3)_3]_2$ (**3**) with the Lewis acid $B(C_6F_5)_3$ leads to aryl/alkoxy group exchange and formation of the unexpected organometallic oxovanadium(V) $[VO(\mu\text{-}OCH_2CF_3)(OCH_2CF_3)(C_6F_5)]_2$ (**1**), while reaction of $B(C_6F_5)_3$ and $[VO(NEt_2)_3]$ produces the Lewis acid adduct $[(Et_2N)_3VO{\cdot}B(C_6F_5)_3]$ (**2**). The crystal structures of **1**, **2** and **3** were determined. ^{51}V NMR chemical shifts for complexes **1**–**3** and $[VO(NEt_2)_3]$ are discussed. A concentration-dependant monomer-dimer equilibrium for **3** is observed in solution.

Introduction

The reactivity and bonding of tris(pentafluorophenyl)-borane $B(C_6F_5)_3$ to transition metal complexes continues to be a field of intense interest in both fundamental and applied chemistry.[1] The Lewis acid properties of $B(C_6F_5)_3$ influence the reactivity greatly, and C−F···metal interactions or perfluoroaryl/alkyl exchange reactions have been observed.[2] More recently, the reactivity of tris(pentafluorophenyl)borane towards different oxo metal complexes M=O has been investigated and oxo-group adducts isolated, particularly $[(acac)_2VO{\cdot}B(C_6F_5)_3]$.[3] Additionally, a Lewis acid adduct derived from the coordination of an alkylaluminium complex to the terminal oxygen of the oxovanadium(V) complex $[VO(CH_2SiMe_3)_{3-x}(OSiPh_3)_x$ (x = 0−3)] was observed by multinuclear NMR spectroscopy (^{17}O, ^{51}V).[4]

We are interested in vanadium chemistry[5] and, among our recent work, we have identified a C−F···V interaction in vanada(IV)azirine complexes isolated from a new type of reaction between $[VCp_2]$ and the activated nitrile $RC{\equiv}N{\cdot}B(C_6F_5)_3$.[6] We have recently extended our study to the oxovanadium(V) complexes $[VO(NEt_2)_3]$[7] and $[VO(OCH_2CF_3)_3]$,[8] and have found that the reactivity of these complexes is influenced by the substituents L (L = NEt_2, OCH_2CF_3) attached to the vanadium center. In agreement with the ^1H NMR scale that we deduced from the chemical shift measurements of the mixed series $[VOL_2(O\textit{i}Pr)]$ or $[VOL(O\textit{i}Pr)_2]$, the relative Lewis acidity of $[VO(OCH_2CF_3)_3]$ toward $[VO(NEt_2)_3]$ can be inferred.[7−9]

Results and Discussion

Synthesis and Molecular Structures of $[VO(\mu\text{-}OCH_2CF_3)(OCH_2CF_3)(C_6F_5)]_2$ (1) and $[VO(OCH_2CF_3)_3]_2$ (3)

The reaction of $[VO(OCH_2CF_3)_3]_2$ (**3**) in pentane with $B(C_6F_5)_3$ gives the dimeric organometallic complex $[VO(\mu\text{-}OCH_2CF_3)(OCH_2CF_3)(C_6F_5)]_2$ (**1**), as shown in Equation (1). Complex **1** is the second example[10a] of an organometallic oxovanadium(V) to be fully characterized by an X-ray structure determination (Figure 1).

$$[VO(OCH_2CF_3)_3]_2 + 2B(C_6F_5)_3 \longrightarrow [VO(\mu\text{-}OCH_2CF_3)(OCH_2CF_3)(C_6F_5)]_2 \quad \text{(+ unidentified products)} \qquad (1)$$

The formation of this organometallic oxovanadium(V) complex is due to an exchange reaction between the $B(C_6F_5)_3$ and the fluoroalkoxy ligand OCH_2CF_3. Such an exchange is not unique and is already known in zirconium chemistry.[2a−2c] The distance of the vanadium atom to the basal plane O(2), C(11), O(3), O′(2) in **1** is 0.5476(19) Å. The molecular structure establishes that **1** is a complex with a five-coordinate distorted square pyramidal geometry with the three oxygen atoms and the C_{ipso} atom of the perfluorophenyl group occupying the basal site (79.6% on the Berry pseudorotation path between D_{3h} and C_{4v} [11]) for the vanadium center. The V−C distance [2.066(4) Å] is in the expected range for such a bond.[10] In order to compare the

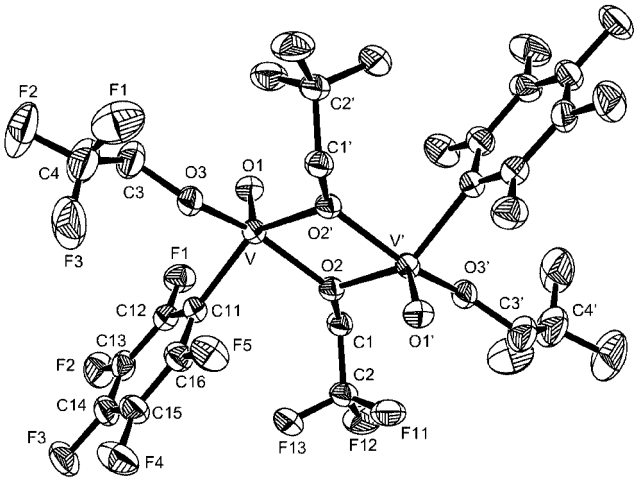

Figure 1. Molecular structure of **1** with selected bond lengths (Å) and angles (°), showing the labeling scheme; hydrogen atoms are omitted for clarity: V−C(11) 2.069(5), V−O(1) 1.569(4), V−O(2) 1.998(3), V−O(2)′ 1.995(3), V−O(3) 1.748(3); O(2)−V−O(2)′ 72.03(15), O(1)−V−O(3) 105.99(18), O(1)−V−C(11) 100.7(2), O(3)−V−C(11) 90.50(18), O(2)−V−C(11) 87.77(17), O(2)′−V−C(11) 141.13(18), V-[O(2)−V′ 107.97(15), V−O(2)−C(1) 126.4(3), V−O(3)−C(3) 134.8(3)

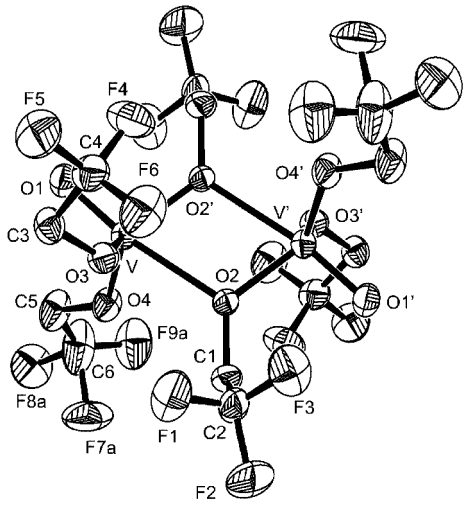

Figure 2. Molecular structure of **3** with selected bond lengths (Å) and angles (°), showing the labeling scheme; hydrogen atoms are omitted for clarity: V−O(1) 1.579(2), V−O(2) 2.297(2), V−O(3) 1.757(2), V−O(4) 1.771(2), V−O′(2) 1.843(2); V−O(2)−V′ 108.85(9), O(2)−V−O(2)′ 71.15(9), O(1)−V−O(2) 170.63(11), O(1)−V−O(2)′ 99.49(11), O(1)−V−O(3) 101.69(12), O(1)−V−O(4) 102.97(12), V−O(2)−C(1) 124.15(19), V′−O(2)−C(1) 126.3(2), V−O(3)−C(3) 131.0(2), V−O(4)−C(5) 129.9(3)

vanadium-oxygen bond lengths with the parent compound, a single-crystal X-ray diffraction study was performed on **3** (Figure 2). The vanadium centre is trigonal bipyramidal, as seen by the larger O(1)−V−O(2) angle of 170.6°, the sum of the O−V−O angles containing O(3), O(4) and O′(2) around the vanadium atom being 348.6° (18.7% on the Berry pseudorotation path[11]).

Both complexes **1** and **3** are centrosymmetric dimers in the solid state. A disymmetrical bridge V−O(R)−V is observed for **3**, and the average V−O bond length is similar to that in **1** (**1**: 1.997 Å (av); **3**: 1.843(2) Å, 2.296(3) Å]. The other V−OR (terminal) and V=O distances around the vanadium atom in **1** and **3** are essentially the same (**1**: 1.748(3) Å, 1.568(3) Å; **3**: 1.757(3) Å and 1.771(3) Å, 1.579(3) Å, respectively).

Although the V−O−C angle of the terminal OR group for **1** (134.8°) is similar to other V−O−C angles observed in different vanadium alkoxides ([$VO(OtBu)_3$]: 139.0° (av),[12] [$V(OiPr)_4]_2$: 126.27°, 134.67°, 140.27°,[13] [$VO(OSiPh_3)_3$]: V−O−Si (av) 155° [14]) the V−O−C angles of **3** are more acute (130.5° (av)), suggesting a poorer p_π-d_π overlap between the oxygen atoms and the vanadium center of **3**. It is worth noting that in a previous work published by one of us, a synthetic route for the preparation of the phenylvanadium(v) complexes [$PhVO(OiPr)_2$] and [PhVOCl(O*i*Pr)] was reported using LiPh or $HgPh_2$ as phenylating agents, although these vanadium complexes are unstable and decompose with time.[15] Attempts to prepare the phenyl analogue [$PhVO(OCH_2CF_3)_2$] by these routes were unsuccessful, in contrast to the easy formation of **1** using $B(C_6F_5)_3$ as an alkylating agent.

Synthesis and Molecular Structure of $[(Et_2N)_3VO{\cdot}B(C_6F_5)_3]$ (2)

Treatment of the more basic complex $[VO(NEt_2)_3]$ with $B(C_6F_5)_3$ gave the oxovanadium Lewis acid adduct compound $[(Et_2N)_3VO{\cdot}B(C_6F_5)_3]$ (**2**) as dark red crystals [Equation (2)].

$$[VO(NEt_2)_3] + B(C_6F_5)_3 \longrightarrow [(Et_2N)_3VO{\cdot}B(C_6F_5)_3] \quad (2)$$

The crystal structure of complex **2** (Figure 3) reveals the coordination of the Lewis acid $B(C_6F_5)_3$ to the V=O moiety. Both vanadium and boron atoms have a pseudo-tetrahedral structure (O−V−N and N−V−N average angles 113.3° and 105.4° respectively; O−B−C and C−B−C average angles 106.6° and 112.3°, respectively). The longer V=O distance of 1.6983(16) Å and the shorter B−O bond length [1.498(3) Å] indicate the reduction in bond order of the V=O moiety and the formation of a boron−oxygen single bond with a nearly linear V−O−B angle of 174.87 (15)°. It is worth noting that: i) the V−O bond length indicates the formation of a single V−O bond {cf. V−O (for terminal OR group) and V=O distances in $[VO(OR)_3]$: 1.753 Å (av), 1.790 Å and 1.595(2) Å and 1.591 Å (av) for R = *t*Bu and Me, respectively};[11] ii) the B−O bond length is shorter than that observed in $F_3B{\cdot}OPPh_3$ [1.516(3) Å][16] (for comparison, in $[(acac)_2VO{\cdot}B(C_6F_5)_3]$,[3a] V=O 1.648(1) Å, B−O 1.527(2) Å, V−O−B 168.9(1)°].

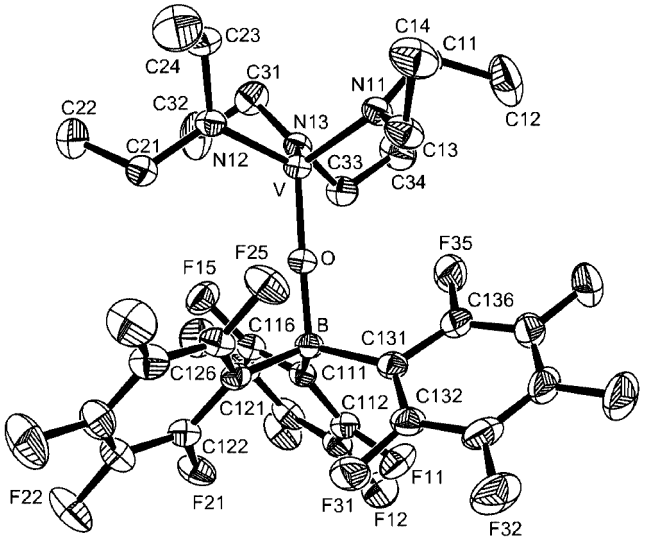

Figure 3. Molecular structure of **2** with selected bond lengths (Å) and angles (°), showing the labeling scheme; hydrogen atoms are omitted for clarity: V−O 1.6983(16), V−N(11) 1.8255(19), V−N(12) 1.8285(19), V−N(13) 1.8211(19), O−B 1.498(3); V−O−B 174.87(15), O−V-(N11) 104.03(9), O−V−N(12) 106.39(9), O−V−N(13) 112.97(8), O−B−C(111) 107.41(19), O−B−C(121) 105.49(18), O−B−C(131) 106.60(18).

^{1}H and ^{51}V NMR Spectroscopy

The ^{1}H NMR spectrum of **1** at room temperature shows a unique quadruplet resonance for the OCH_2CF_3 group (δ = 4.50 ppm), which reflects a rapid exchange of both terminal and bridging OR groups in solution. This persists at low temperature (in [D_8]toluene at −90 °C), indicating that the exchange is extremely rapid.[9] In contrast the ^{1}H NMR spectrum of **3** is concentration dependant, a well-known aspect of the monomer-dimer/polymer behavior in early transition metal alkoxides.[9,17] At low concentration, **3** is monomeric (δ = 4.56 ppm) whereas it dimerizes at higher concentration (δ = 4.95 ppm) showing an equilibrium between both forms in solution (see Exp. Sect.). The upfield shift of the methylene protons observed for **1** (δ = 4.50 ppm) relative to **3** (δ = 4.95 ppm) reflects the difference between an OR group which allows some π-donation and a purely electron-withdrawing σ-group (C_6F_5). The relative overall electron-withdrawing capability of both ligands (OCH_2CF_3 > C_6F_5) was deduced from these chemical shifts. Addition of one equivalent of $B(C_6F_5)_3$ to **1**, and monitoring of the reaction by ^{1}H and ^{19}F NMR spectroscopy for two days, confirmed that vanadium complex remains unchanged.

The ^{51}V NMR spectra for the series **1**, **2**, **3** and [$VO(NEt_2)_3$] were recorded in C_6D_6 solution at two different concentrations (see Exp. Sect.) to ensure that association phenomena do not interfere with the observed chemical shifts. We also verified that the synthesis of **2** gives only one compound in solution. For complex **1**, the preparative solution shows the peak assigned to the formation of **1** (isolated in high yield) and three other minor ^{51}V signals that could not be assigned. The two different ^{51}V NMR signals observed for **3** at low and high concentration (δ = −625 ppm and −570 ppm, respectively) confirm the above ^{1}H NMR results, i.e. a concentration-dependant monomer-dimer equilibrium. The values observed at δ = −481 ppm for the dimer **1** and δ = −570 ppm for dimer **3** show a deshielding effect for **1** due to the replacement of a fluoroalkoxy group with an alkyl perfluorophenyl group as a purely σ-bonding ligand. From the relative overall electron-withdrawing capability of both ligands already pointed out above, the ^{51}V chemical shifts of **1** and **3** follow an "inverse" halogen dependence, i.e. a shielding of the metal in the d^0 configuration upon increasing the electronegativity of the ligands attached to the coordination center.[18−21]

The ^{51}V chemical shifts for [$VO(NEt_2)_3$] and the borane adduct **2** (δ = −205 ppm and +57 ppm, respectively) are puzzling. If we consider that the sp^2 hybridization observed for the planar nitrogen atom of the NEt_2 ligands in **2** is unchanged in [$VO(NEt_2)_3$] before borane coordination (based on recent X-ray diffraction studies of different dialkylamido vanadium(IV) and vanadium(V) complexes recently carried out by our group[22] and others[23]) the observed deshielding shift could be attributed mainly to a decrease in electron density at the vanadium atom when the Lewis acid $B(C_6F_5)_3$ is attached to the oxygen atom. A similar consequence of poorer π-donation from O to V is also observed in the Lewis acid adducts [$VO(CH_2SiMe_3)_{3-x}(OSiPh_3)_x$ (x = 0−3)] with $Al(CH_2SiMe_3)_3$.[4b]

Conclusion

We have demonstrated that the reactivity of the Lewis acid $B(C_6F_5)_3$ with [VOL_3] is modulated by the electronic properties of the ligands L. The reaction with V=O is facilitated by the nucleophilic oxo group when L is an electron-donating dialkylamido group whereas formation of the organometallic complex **1** containing a V−C_6F_5 bond is promoted by an exchange reaction with $B(C_6F_5)_3$ when L is OCH_2CF_3 (an electron-withdrawing group). Potentially, this provides a suitable synthetic route for the development of new organometallic fluoroalkoxy complexes.

Experimental Section

General Remarks: All manipulations were carried out using standard Schlenk line or drybox techniques under an atmosphere of argon. Starting materials were purchased from Aldrich Inc. or Fluka Inc. and used without further purification. Solvents were refluxed and dried over appropriate drying agents under an atmosphere of argon, collected by distillation and stored in a drybox over activated 4-Å molecular sieves. Deuterated solvents were degassed and dried over activated 4-Å molecular sieves. NMR spectroscopic data were recorded using Bruker AMX-400, DPX-300 and AC-200 spectrometers, and referenced internally to residual protonated-solvent (^{1}H) resonances and are reported relative to tetramethylsilane (δ = 0 ppm). ^{19}F NMR (188.298 MHz) spectra were recorded on a Bruker AC-200 spectrometer (reference CF_3CO_2H). The AA′MM′X system in the ^{19}F NMR spectrum of compound **2** was simulated using the MestRe-C sofware package. ^{51}V NMR

(105.17 MHz) spectra were recorded on a Bruker AMX-400 spectrometer (reference $VOCl_3$ in C_6D_6: 9:1). Infrared spectra were prepared as KBr pellets under argon in a glove box and were recorded on a Perkin−Elmer Spectrum GX FT-IR spectrometer. Infrared data are quoted in wavenumbers (cm^{-1}). Elemental analyses were performed at the Laboratoire de Chimie de Coordination (Toulouse, France).

$[VO(NEt_2)_3]$ and **3** were prepared as described previously[7,8] and $B(C_6F_5)_3$ according to the literature.[24] Crystals of **3** were obtained by sublimation under vacuo (10^{-2} Torr) at 40 °C. The ^{51}V NMR spectrum of $[VO(NEt_2)_3]$ (EPR silent) was recorded in C_6D_6 at different ratios (9:1; 1:9) and found at δ = −205 ppm (we note that the value published by Rehder et al. for $[VO(NEt_2)_3]$ at δ = −389 ppm,[20] as a neat liquid, differs notably from our result). **$[VO(OCH_2CF_3)_3]$:** 2 experiments: a) 100 mg and b) 2 mg in 0.6 mL C_6D_6: a) ^1H NMR (C_6D_6): δ = 4.95 (q, $^3J_{H\text{-}F}$ = 8.3 Hz, CH_2) ppm. ^{19}F NMR (C_6D_6): δ = −0.8 (t, $^3J_{F\text{-}H}$ = 8.3 Hz, CF_3) ppm. ^{13}C NMR (C_6D_6): δ = 124.0 ($^1J_{C,F}$ = 279.3 Hz, CF_3), 80.6 ($^2J_{C,F}$ = 36.1 Hz, CH_2) ppm. ^{51}V NMR (C_6D_6): δ = −570. b) ^1H NMR (C_6D_6): δ = 4.55 (q, $^3J_{H\text{-}F}$ = 8.3 Hz, CH_2) ppm. ^{19}F NMR (C_6D_6): δ = −0.2 (t, $^3J_{F\text{-}H}$ = 8.3 Hz, CF_3) ppm. ^{51}V NMR (C_6D_6): δ = −625. $VO(NEt_2)_3$ ppm. ^1H NMR (C_6D_6): δ = 3.74 (q, ^3J = 6.9 Hz, CH_2), 1.25 (t, ^3J = 6.9 Hz, CH_3) ppm. ^{13}C NMR (C_6D_6): δ = 52.7 (CH_2), 16.5 (CH_3) ppm. ^{51}V NMR (C_6D_6): δ = −205 ppm.

$[VO(C_6F_5)(\mu\text{-}OCH_2CF_3)(OCH_2CF_3)]_2$ (1): A solution of $B(C_6F_5)_3$ (281 mg, 0.55 mmol) in pentane (4 mL) was added dropwise to a solution of $[VO(OCH_2CF_3)_3]$ (200 mg, 0.55 mmol) in pentane (3 mL) at room temperature. The reaction mixture was stirred for 2 h at room temperature and then cooled in the freezer overnight. Red crystals were filtered off, washed with pentane and dried under vacuum (152 mg, 64%). ^1H NMR (2 experiments at 5 mg and 60 mg in 0.6 mL C_6D_6 give same δ values): δ = 4.50 (q, $^3J_{H,F}$ = 8.0 Hz, CH_2CF_3). ^{13}C NMR (C_6D_6): δ = 149.2, 146.3, 145.2, 142.2, 138.8, 134.8 (C_6F_5) 123.5 (q, $^1J_{C,F}$ = 279.2 Hz, OCH_2CF_3), 79.4 (q, $^2J_{C,F}$ = 36.2 Hz, OCH_2CF_3) ppm. ^{19}F NMR (C_6D_6): δ = −0.2 (t, $^3J_{F,H}$ = 8.0 Hz, OCH_2CF_3), −40.7 (d, ^3J = 85.6 Hz, *o*-F, C_6F_5), −70.3 (t, ^3J = 11.3 Hz, *p*-F, C_6F_5), −84.2 (br. s, *m*-F, C_6F_5) ppm. ^{51}V NMR (C_6D_6) (2 experiments as for ^1H NMR): δ = −481 ppm. IR (KBr): $\tilde{\nu}$ = 2359 (m), 1636 (w), 1540 (s), 1510 (s), 1466 (m), 1359 (w), 1268 (s, br), 1182 (s, br), 1074 (s, br), 1035 (m, br), 962 (s), 839 (m), 746 (m), 669 (m), 581 (w), 497 (w). $C_{20}H_8F_{22}O_6V_2$: calcd. C 27.80, H 0.93; found C 27.80, H 0.85.The ^1H, ^{11}B and ^{51}V NMR spectra of the filtrate, after workup, show peaks for three minor unidentified species (^1H NMR: δ = 4.09, 3.86, 3.74 ppm. ^{11}B NMR: δ = 42, 27, 25 ppm. ^{51}V: δ = −531, −840, −885 ppm). Some of these high-field resonances could correspond to species where fluorines are attached directly to the vanadium atom.[20]

$[V(NEt_2)_3O{\cdot}B(C_6F_5)_3]$ (2): A solution of $B(C_6F_5)_3$ (362 mg, 0.70 mmol) in pentane (4 mL) was added dropwise to a solution of $[VO(NEt_2)_3]$ (200 mg, 0.70 mmol) in pentane (3 mL) at room temperature. After 4 days at room temperature, dark red crystals were filtered off, washed with pentane and dried under vacuum (122 mg, 22%). In another experiment, a solution of $B(C_6F_5)_3$ (15 mg, 0.03 mmol) in C_6D_6 (0.3 mL) was added to a solution of $[VO(NEt_2)_3]$ (8 mg, 0.03 mmol) in C_6D_6 (0.3 mL). The ^1H and ^{51}V NMR of the solution were identical to those of isolated **2** in the same solvent. ^1H NMR (C_6D_6): δ = 3.59 (q, ^3J = 7.0 Hz, 6 H, CH_2CH_3), 0.62 (t, ^3J = 7.0 Hz, 9 H, CH_2CH_3) ppm. ^{13}C NMR (C_6D_6): δ = 151.2, 147.5, 140.1, 138.5, 136.1 [$B(C_6F_5)_3$], 54.7 (CH_2CH_3), 14.6 (CH_2CH_3) ppm. ^{19}F NMR (C_6D_6): δ = −56.7 (AA′MM′X system, $^3J_{AM} = {}^3J_{A'M'}$ = −24.5, $^5J_{A'M} = {}^5J_{AM'}$ = 9.0 Hz, 2F, *o*-F, $B(C_6F_5)_3$], −82.9 (AA′MM′X system, $^3J_{M'X} = {}^3J_{MX}$ = −20.8 Hz, *p*-F, $B(C_6F_5)_3$], −88.7 (AA′MM′X system, $^3J_{AM} = {}^3J_{A'M'}$ = −24.5, $^5J_{A'M} = {}^5J_{AM'}$ = 9.0, $^4J_{MM'} = \pm$ 3.1 Hz, 2 F, *m*-F, $B(C_6F_5)_3$] ppm. ^{11}B NMR (C_6D_6): δ = 1.2. ^{51}V NMR (C_6D_6): δ = 57 ppm. IR (KBr): $\tilde{\nu}$ = 2983 (m), 2944 (m), 2360 (m), 2341 (m), 1643 (m), 1515 (s), 1458 (s, br), 1374 (m), 1358 (m), 1279 (m), 1182 (w), 1144 (m), 1096 (s, br), 972 (s, br), 909 (w), 848 (w), 793 (m), 771 (m), 738 (w), 676 (m), 626 (m), 613 (w), 574 (w), 478

X-ray Analysis of 1, 2 and 3: Data were collected at low temperature (T = 180 K) for the three compounds, on a IPDS STOE diffractometer equipped with an Oxford Cryosystems Cryostream Cooler Device and using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Final unit-cell parameters were obtained by means of a least-squares refinement of a set of well-defined reflections; crystal decay was monitored during data collection and no significant fluctuations of intensities were observed. The structures were solved by direct methods using SIR92,[25] refined by least-squares procedures on F^2 with the aid of SHELXL-97[26] included in the program package WinGX version 1.63.[27] The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[28] All hydrogens atoms were located on difference Fourier maps and refined using a riding model with an isotropic thermal parameter fixed at 20% higher than those of the carbons atoms to which they are connected. For **3** a disorder was located on the fluorine group: the fluorine atoms were found to be statistically disordered over two distinct orientations with an occupancy ratio of 55/45. Some restraints on interatomic C−F distances and F−C−F angles were imposed in order to reach a reasonable geometry and regularize the motion of the F atoms. For the three compounds all non-hydrogens atoms were refined anisotropically and, in the last cycles of refinement, a weighting scheme was used whose weights were calculated from the following formula: $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. For all structures the criteria for a satisfactory complete analysis were a ratio of rms shift to standard deviations of less than 0.1 and no significant residual electronic densities in the final differences maps. Drawings of molecules were performed with the program ORTEP32[29] with 50% probability displacement ellipsoids for non-hydrogen atoms. The crystallographic data of **1**, **2** and **3** are summarized in Table 1. CCDC-190469 (**1**) -190470 (**2**) and -190471 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Formation and Reactivity of a Tantalocene Trihydride Containing an Aminoethyl-Functionalised Ligand

Cyril Poulard,[a] Danièle Perrey,[a] Gilles Boni,*[a] Estelle Vigier,[a] Olivier Blacque,[a] Marek M. Kubicki,[a] and Claude Moïse[a]

Keywords: Cyclopentadienyl ligands / Metallocenes / Hydride ligands / Tantalum

The complex [Cp*{$C_5H_4(CH_2CH_2NMe_2)$}$TaCl_2$] (**1**) was synthesised by reaction of the lithium salt $LiC_5H_4(CH_2CH_2NMe_2)$ with the tantalum compound [Cp*$TaCl_3(PMe_3)$]. Reduction of **1** with $NaAl(H)_2(OCH_2CH_2OMe)_2$ leads to the trihydride derivative [Cp*{$C_5H_4(CH_2CH_2NMe_2)$}TaH_3] (**2**). The oxidation of **2** in THF with ferrocenium ion leads to a cationic dihydride intermediate [Cp*{$C_5H_4(CH_2CH_2NMe_2)$}TaH_2]PF_6 (**3**) with an intramolecular stabilization by the aminoethyl side-chain of the cyclopentadienyl ligand. The hemilabile character of the functionalised cyclopentadienyl ligand was checked by treating **3** with electron-donating ligands (e.g. phosphanes, sulfides, anions); in all cases, no displacement of the amino group was observed. When treated with HBF_4, **2** undergoes a loss of the hydride and the resulting cation can be isolated as a solvento adduct by carrying out the reaction in dimethyl sulfide. Acidolysis of **2** in the presence of an excess of trifluoroacetic acid affords the compound [Cp*{$C_5H_4(CH_2CH_2NHMe_2)$}$TaH(OCOCF_3)_2$](CF_3COO) (**5**). Microanalytical and NMR spectroscopic data for these complexes are given. The X-ray crystal structures are reported for [Cp*{$C_5H_4(CH_2CH_2NMe_2)$}TaH_2]PF_6 (**3**) and [Cp*{$C_5H_4(CH_2CH_2NHMe_2)$}$TaH(OCOCF_3)_2$](CF_3COO) (**5**).

Introduction

The cyclopentadienyl group has become one of the most important ligands in organo-transition-metal chemistry.[1] Variation in the ring substituents results in important changes in steric and electronic properties of this type of ligands.[2] In the last few years a wide range of functionalised cyclopentadienyl ligands, where a donor group (NR_2, OR, PR_2) is connected to the Cp ring by a suitable spacer, has been investigated.[3] Interest in such organometallic systems lies in the fact that the Cp ring binds strongly to the metal atom, whereas the donor atom interacts only when necessary. This concept of a hemilabile ligand has been used for the stabilisation of reactive intermediates and for catalytic processes.[4]

Following our studies on tantalocene complexes,[5] we have synthesised a new tantalocene dichloride and a trihydride incorporating the aminoethyl-functionalised cyclopentadienyl ligand [$C_5H_4(CH_2CH_2NMe_2)$]. The oxidation behaviour of the trihydride compound has been studied. It undergoes a loss of hydrogen atom upon reaction with ferrocenium ion leading to a cationic dihydride intermediate that is intramolecularly stabilized by the aminoethyl side-chain of the cyclopentadienyl ring.

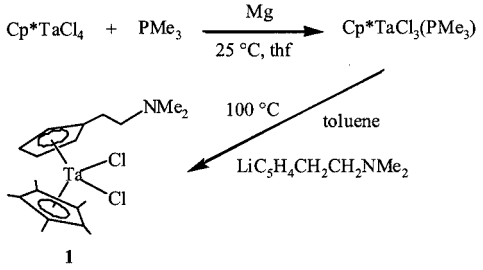
Results and Discussion

Synthesis of [Cp*{$C_5H_4(CH_2CH_2NMe_2)$}$TaCl_2$] (1) and [Cp*{$C_5H_4(CH_2CH_2NMe_2)$}TaH_3] (2)

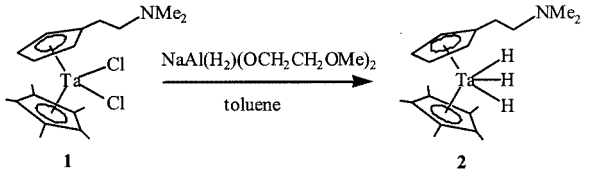
The synthesis of the tantalocene dichloride **1** was adapted from Bercaw's method[6] as outlined in Scheme 1. Complex **1** is isolated in good yield (80%) as a green solid soluble in halogenated solvents. It displays the eight-line ESR spectrum characteristic of bis(cyclopentadienyl)tantalum(IV) derivatives.



Scheme 1

Treatment of **1** with $NaAl(H)_2(OCH_2CH_2OMe)_2$ in toluene over a period of 3 h affords a red solution which, on hydrolysis, gives the trihydridometallocene **2** (Scheme 2). The ^1H NMR spectrum of **2** has the characteristic pattern of tantalocene trihydride:[7] a doublet ($\delta = -1.24$ ppm) and

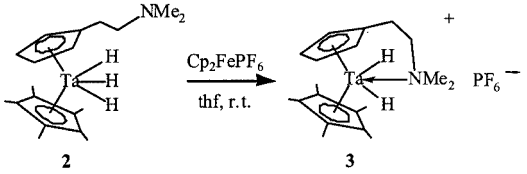
a triplet (δ = 0.46 ppm) ($^2J_{H,H}$ = 12.7 Hz) corresponding to the central and lateral hydride ions respectively.



Scheme 2

Formation and Stabilization of the Cationic Dihydride Species "[Cp*{$C_5H_4(CH_2CH_2NMe_2)$}TaH_2]$^+$"

It has been shown by our group that chemical oxidation of tantalocene trihydride [(η^5-tBuC_5H_4)$_2$TaH_3] by ferrocenium ion leads to the formation of the reactive species [(η^5-tBuC_5H_4)$_2$TaH_2]$^+$;[5c] this cationic intermediate can be stabilized and isolated as a solvento adduct when the reaction is carried out in a potentially coordinating solvent like dimethyl sulfide or tetrahydrothiophene. In contrast, when an amine is added to the reaction mixture, no stabilization is observed and no well-defined product could be isolated. In this context, it was interesting to oxidize the trihydride complex **2** and to test the intramolecular stabilization abilities of the pendant aminoethyl chain. Treatment of a THF solution of **2** with 1 equiv. of [Cp_2Fe]PF_6 at room temperature results in the formation of [Cp*{$C_5H_4(CH_2CH_2NMe_2)$}TaH_2]PF_6 (**3**) and ferrocene, while a vigorous gas evolution is observed (Scheme 3).



Scheme 3

The ^{1}H and ^{13}C NMR spectroscopic data for **3** show some remarkable differences compared with the data of **2**. The most significant change in the ^{1}H NMR spectra is the low-field shift for the signal of the methylene hydrogen atoms adjacent to the nitrogen atom of the side chain. While for complex **2** this signal is observed at δ = 2.67 ppm, the signal appears at δ = 3.20 ppm for **3**. In addition, the signals for the methyl group at the nitrogen atom are shifted downfield (Δδ = 0.57 ppm with respect to the tantalocene trihydride **2**). Corresponding downfield shifts for the signals of the methylene and methyl groups adjacent to the nitrogen atom are also observed in the ^{13}C NMR spectra. The signal for the NMe_2 group is shifted downfield by 32 ppm for complex **3** (δ = 77.9 ppm) relative to that in **2** (δ = 45.6 ppm). These NMR spectroscopic data agree with the intramolecular coordination of the amino group.[8] Moreover, the ^{1}H NMR spectrum of **3** displays one low-field singlet at δ = 6.71 ppm for the hydrido ligands (the value usually observed for cationic tantalocene species), suggesting their lateral positions and, consequently, the central position of the coordinated amino arm of the side chain. Such a description of the molecular structure of the cation in **3** has been confirmed by an X-ray diffraction study. The crystal structure of **3** is built up of discrete organometallic cations and PF_6 anions. The geometry of the cation is typical of bent tantalocenes (Ta^V, Figure 1). The intramolecular Ta−N bond of 2.430(3) Å observed in the cation corresponds well to the value expected for a single bond between the large metallic centre and the tertiary amine.

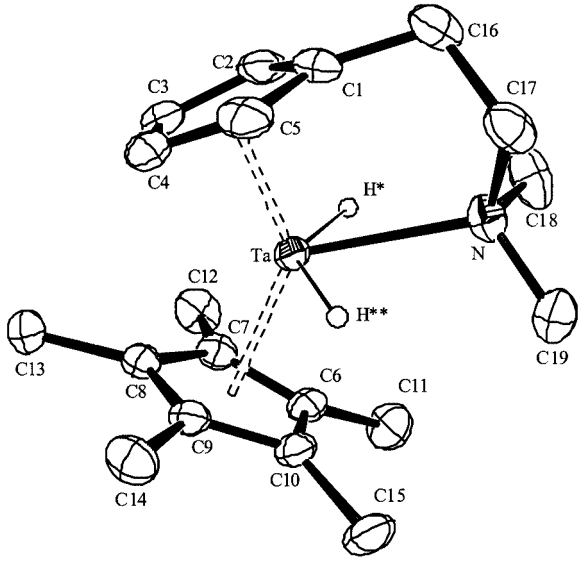


Figure 1. ORTEP drawing (50% probability displacement ellipsoids) of the cation in **3**; selected bond lengths [Å] and angles [°]: Ta−CP1 (geometrical centre of C1...C5 ring) 2.05, Ta−CP2 (geometrical centre of C6...C10 ring) 2.08, Ta−N 2.430(4), Ta−H* 1.71(5), Ta−H** 1.74(6); CP1−Ta−CP2 134.9, CP1−Ta−N 101.2, CP2−Ta−N 123.9, H*−Ta−H** 137(3), H*−Ta−N 67(2), H**−Ta−N 72(2)

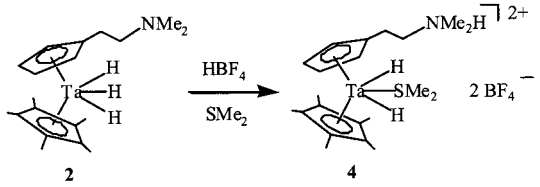
In order to check the hemilabile properties of the aminoethyl arm, complex **3** was treated with electron-donating species. When **3** is heated at 80 °C in toluene in the presence of a phosphane (PMe_3, PMe_2Ph, PPh_2H) or a sulfur donor (Me_2S) no reaction occurs and the starting material is recovered. Reactions with anions (BuLi, PPh_2Li) also failed and degradation products were obtained. Thus, the aminoethyl chain coordinates strongly to the tantalum atom and cannot be displaced.

However, an acidolysis-type reaction may generate the cationic species "[Cp*{$C_5H_4(CH_2CH_2NMe_2)$}TaH_2]$^+$".[5c] The addition of 2 equiv. of HBF_4·Et_2O to a dimethyl sulfide solution of **2** results, as expected, in the evolution of dihydrogen and the formation of the dicationic solvento adduct [Cp*{$C_5H_4(CH_2CH_2NHMe_2)$}TaH_2(SMe_2)](BF_4)$_2$ (**4**) (Scheme 4). The ^{1}H NMR spectrum of **4** shows two signals at δ = 5.36 and 5.89 ppm for the cyclopentadienyl protons together with one singlet at δ = 2.38 ppm for the two hydride ions, characteristic of a symmetrical structure. Deprotonation of the ammonium group with several different bases (NEt_3, NaOH, EtONa) was carried out. These reactions give degradation products and the displacement of the di-

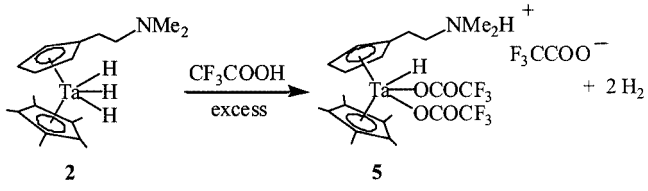
methyl sulfide ligand by the amino group could not be studied.



Scheme 4

Reaction of [Cp*{$C_5H_4(CH_2CH_2NMe_2)$}TaH_3] (2) with Carboxylic Acids

Complex **2** reacts rapidly with trifluoroacetic acid (4 equiv.) in toluene at room temperature leading to the protonation of the amino group and the formation of the tantalum(v) dicarboxylate complex **5** as a white solid, with evolution of dihydrogen (Scheme 5).



Scheme 5

The loss of two hydrido ligands is accompanied by the monodentate coordination of two carboxylate ions at the tantalum centre. As previously observed for the parent complex [$(\eta^5$-tBu$C_5H_4)_2TaH_3$],[5c] an excess of trifluoroacetic acid does not lead to the trisubstituted derivative. Complex **5** has been characterised by spectroscopic and analytical methods. Four signals are observed for the cyclopentadienyl protons in the ^{1}H NMR spectrum of **5** (δ = 4.99, 5.17, 6.06, 6.24 ppm), indicating an unsymmetrical structure due to the lateral position of the tantalocene hydride. The spectrum also contains a downfield singlet (δ = 12.58 ppm) for the residual hydride ion, consistent with the strong electron-withdrawing properties of the carboxylato ligands. In order to deprotonate the ammonium group, compound **5** was treated with MeLi, EtONa, or Et_3N. All attempts failed and no defined products were formed. X-ray diffraction experiment confirmed the proposed structure of the cation in **5** (Figure 2).

The asymmetric unit of the triclinic ($P\bar{1}$) unit cell of **5** contains one metal-containing cation, one trifluoroacetate anion and two chloroform solvent molecules. There is strong hydrogen bonding[9] between the ammonium end of the substituted cyclopentadienyl ligand and the anion [N···O5 = 2.732(4) Å]. The acetato ligands coordinated to Ta do not seem to participate in secondary interactions. For steric reasons their noncoordinated oxygen atoms (O2 and O4) lie on the less-hindered side of the C1...C5 ring.

Experimental Section

General: All manipulations were carried out under argon using standard Schlenk line techniques and conventional glass vessels. The solvents were dried with suitable reagents and freshly distilled under argon before use. [Cp*$TaCl_4$],[6] Li[$C_5H_4(CH_2CH_2NMe_2)$],[10] and ferrocenium salts[11] were prepared according to literature methods. NMR spectra were recorded with Bruker AC 200 or DRX 300 spectrometers for ^{1}H, ^{13}C, and ^{31}P NMR, with $SiMe_4$ and H_3PO_4 as references. Elemental analyses were performed with an EA 1108 CHNS-O FISONS Instruments apparatus.

[Cp*{$C_5H_4(CH_2CH_2NMe_2)$}$TaCl_2$] (1): Compound **1** was synthesised according to Bercaw's method reported for [Cp*$CpTaCl_2$][6] with minor modifications. [Cp*$TaCl_4$] (4.58 g, 10 mmol) was reduced with magnesium (0.12 g, 5 mmol) in THF

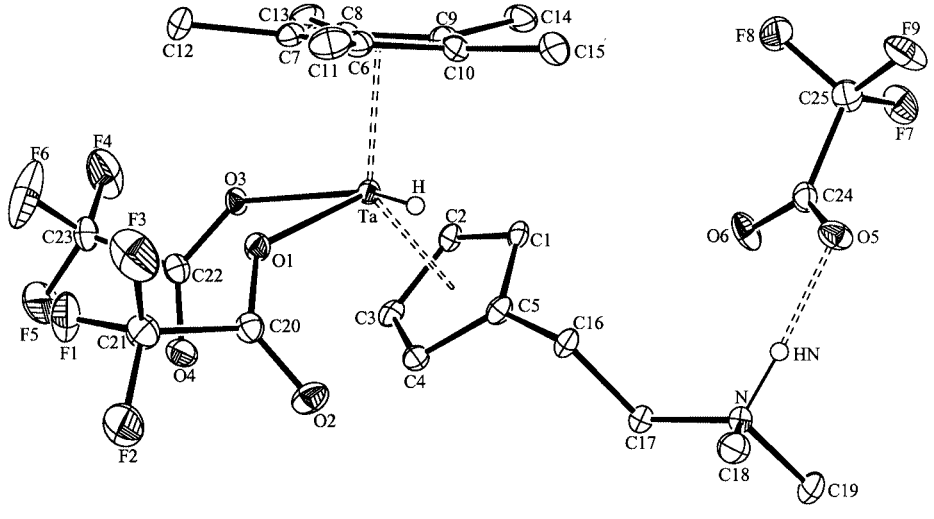


Figure 2. ORTEP drawing (30% probability displacement ellipsoids) of the cation in **5** showing the hydrogen bond between the ammonium group of the Cp ligand and the trifluoroacetate anion; selected bond lengths [Å] and angles [°]: Ta−CP1 (C1...C5 ring) 2.08, Ta−CP2 (C6...C10 ring) 2.095, Ta−H 1.48(4), Ta−O1 2.131(2), Ta−O3 2.162(2), CP1−Ta−CP2 132.8, H−Ta−O1 71(1), H−Ta−O3 143(1), O1−Ta−O3 72.2(1), N−HN 1.02(4), HN···O5 1.74(4), N···O5 2.732(4), N−HN···O5 166

(50 mL) in the presence of PMe_3 (0.76 g, 10 mmol). Removal of the solvent afforded a red residue which was treated with $Li[C_5H_4(CH_2CH_2NMe_2)]$ (1.43 g, 10 mmol) in toluene (50 mL) at 100 °C. After 12 h of stirring, extraction and crystallisation from acetone afforded the green paramagnetic product **1** (4.20 g, 80% yield). $C_{19}H_{29}Cl_2NTa$ (523.3): calcd. C 43.61, H 5.59, N 2.68; found C 44.16, H 5.74, N 2.47. The ESR spectrum in toluene showed an eight-line spectrum: g_{iso} = 1.9336; $A_{Ta,iso}$ = 103.54 G.

[Cp*{$C_5H_4CH_2CH_2NMe_2$)}TaH_3] (2): Complex **1** (2.62 g, 5 mmol) was reduced by $NaAlH_2(OCH_2CH_2OMe)_2$ (5 mL, 2 M in toluene, 10 mmol) in toluene (50 mL) at 0 °C. After 3 h of stirring, the brown-red solution was hydrolysed slowly with degassed water (10 mL). The organic layer was decanted and extracted. Evaporation of the solvent, followed by washing with pentane gave complex **2** (1.48 g, 65% yield). ^{1}H NMR (200 MHz, C_6D_6, 25 °C): δ = −1.24 (d, J = 12.7 Hz, 2 H), 0.46 (t, J = 12.7 Hz, 1 H), 1.99 (s, 15 H, Cp*), 2.06 (s, 6 H, NMe_2), 2.39 (t, J = 6.8 Hz, 2 H, CH_2), 2.67 (t, J = 6.8 Hz, 2 H, CH_2N), 4.53 (t, J = 2.4 Hz, 2 H, C_5H_4), 4.80 (t, J = 2.4 Hz, 2 H, C_5H_4) ppm. $^{13}C\{^1H\}$ NMR (50 MHz, C_6D_6, 25 °C): δ = 12.8 (CH_3 of Cp*), 29.3 (CH_2), 45.6 (NMe_2), 62.2 (CH_2N), 88.7 (ring C), 89.1 (ring C), 102.8 (ring Cp*), 113.8 (ring C) ppm. $C_{19}H_{32}NTa$ (455.42): calcd. C 50.11, H 7.08, N 3.08; found C 49.69, H 6.79, N 3.35.

[Cp*($C_5H_4CH_2CH_2NMe_2$)TaH_2][PF_6] (3): A solution of **2** (0.10 g, 0.22 mmol) in THF (10 mL) was treated at room temperature with $[Cp_2Fe][PF_6]$ (0.08 g, 0.22 mmol). The solution was stirred for an additional 0.5 h. During this time, a white precipitate formed; it was filtered off and washed with pentane. The crude reaction product was crystallised from chloroform (0.12 g, 90% yield). ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 2.11 (s, 15 H, Cp*), 2.56 (t, J = 2.6 Hz, 2 H, CH_2), 2.63 (s, 6 H, NMe_2), 3.20 (t, J = 2.6 Hz, 2 H, CH_2-N), 4.14 (t, J = 2.6 Hz, 2 H, C_5H_4), 6.71 (s, 2 H, Ta−H), 7.14 (t, J = 2.6 Hz, 2 H, C_5H_4) ppm. $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$, 25 °C): δ = 12.3 (CH_3 of Cp*), 24.1 (CH_2), 58.7 (CH_2), 77.9 (NMe_2), 93.3 (ring C), 100.2 (ring C), 111.6 (ring Cp*), 126.3 (ring C) ppm. $^{31}P\{^1H\}$ NMR (80 MHz, $CDCl_3$, 25 °C): δ = −153.8 (sept, J = 712 Hz) ppm. $C_{19}H_{31}F_6NPTa$ (599.38): calcd. C 38.07, H 5.21, N 2.34; found C 38.08, H 5.30, N 2.56.

[Cp*($C_5H_4CH_2CH_2NHMe_2$)TaH_2SMe_2][BF_4)$_2$ (4): A solution of **2** (0.105 g, 0.23 mmol) in dimethyl sulfide (10 mL) was treated at room temperature with 0.1 mL of HBF_4·Et_2O (54 wt% in Et_2O); the solution was stirred for an additional 0.5 h. After evaporation of the solvents, the crude solid was washed with diethyl ether and the complex was recrystallised from chloroform/pentane (2:1). Yield: 0.127 g (80%). ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 2.19 (s, 15 H, Cp*), 2.38 (s, 2 H, TaH), 2.70 (s, 6 H, SMe_2 or NMe_2),

[Cp*($C_5H_4CH_2CH_2NHMe_2$)TaH($OCOCF_3$)$_2$][CF_3COO] (5): A toluene (20 mL) solution of **2** (2.28 g, 5 mmol) was treated at room temperature with an excess of trifluoroacetic acid (0.176 g, 2 mmol). The colourless solution turned pale yellow, and gas evolution was observed. The solution was stirred for an additional 30 min, and the volatiles were then removed in vacuo. Recrystallisation from chloroform gave white crystals (3.17 g, 80% yield). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 2.10 (s, 15 H, Cp*), 2.82 (d, J = 23.5 Hz, 6 H, NMe_2), 3.23 (m, 2 H, CH_2), 3.89 (m, 2 H, CH_2), 4.99 (br. s, 1 H, C_5H_4), 5.17 (br. s, 1 H, C_5H_4), 6.06 (br. s, 1 H, C_5H_4), 6.24 (br. s, 1 H, C_5H_4), 12.58 (s, 2 H, TaH), 13.20 (s, 1 H, $HNMe_2$) ppm. $C_{25}H_{31}F_9NO_6Ta$ (793.46): calcd. C 37.84, H 3.94, N 1.77; found C 37.89, H 4.19, N 2.07.

X-ray Structure Analyses: Crystals of **3** and **5** suitable for X-ray studies were grown from acetone and chloroform solutions, respectively. The intensities were measured at room temperature (298 K) for **3** with an Enraf Nonius CAD4 and at 120 K for **5** with a Nonius Kappa CCD diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The measured intensities were reduced with MolEN of Enraf Nonius[12] for **3** and with the DENZO program[13] for **5**. The structures were solved by direct methods and Patterson syntheses with SHELXS-97. All models were further refined with full-matrix least-squares methods (SHELXL-97) based on $|F^2|$.[14] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrido ligands in both structures as well as the hydrogen atom of the ammonium group in **5** were located from difference Fourier maps and refined isotropically. Other hydrogen atoms were included in calculated positions and refined with a riding model. Crystallographic data and refinement parameters are gathered in Table 1. CCDC-190157 (**3**) and -190158 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Investigations on 1-Metallaindanes

Marcel Schreuder Goedheijt,[a] Tom Nijbacker,[b] Andrew D. Horton,[c] Franciscus J. J. de Kanter,[b] Otto S. Akkerman,[b] and Friedrich Bickelhaupt*[b]

Keywords: Metallacycles / Isomerization / Magnesium / Mercury / Zirconium

1-Mercuraindane (**6**) was prepared in three steps from 1-bromo-2-(2-bromoethyl)benzene (**3**) and converted into 1-magnesaindane (**1**) by reaction with magnesium. In solution, **6** was observed to occur in a remarkable dimer/trimer equilibrium, whereas **1** forms a dimer. From **1** and dichlorozirconocene, the 1-zirconaindane **2** was obtained, which reacted with $B(C_6F_5)_3$ to form the adduct **13**. According to spectroscopic data, **13** is formed by attack of the β-methylene carbon atom at the boron atom and has a zwitterionic structure with weak interactions between the zirconium ion and one of the *ortho*-fluorine atoms.

Introduction

Cyclic diorganylmagnesium compounds[1] often show interesting structural features.[2,3] One aspect is the relatively large C−Mg−C bond angle, which for normal diorganylmagnesium compounds of the general type R_2MgL_2 (L = ligand, mostly an ether) is around 120−130°. This leads to considerable strain if the two R groups are connected such that magnesium is incorporated into a small ring. As the carbon−magnesium bonds undergo a rapid exchange in ethereal solution, the strained monomers can easily escape from this situation and thus tend to form more stable dimers or higher aggregates in which the large bond angle can be accommodated free of strain; sometimes an equilibrium between two oligomers is established. For the sake of simplicity, the oligomers are indicated by the names of the *monomeric* parent units where appropriate; furthermore, magnesium is assumed to be tetracoordinate including two solvent molecules,[1−3] which in the present case is THF. We have previously reported the investigation of a number of such cyclic diorganylmagnesium compounds,[3,4] and wanted to extend this study to 1-magnesaindane (**1**) (Scheme 1).

A further reason for our interest in **1** was that it is a difunctional organomagnesium compound and as such is attractive for the preparation of other metallacycles such as the corresponding 1-zirconaindane **2**, which is potentially of interest as a precursor of a new class of single-site olefin polymerization catalysts.[5−7]

Scheme 1

Results and Discussion

Synthesis of Magnesaindane (1)

In order to obtain **1** in pure form, we decided to prepare it by transmetalation of the corresponding cyclic organomercury compound **6** with metallic magnesium, as shown in Scheme 2. For this purpose, the dibromide **3** was converted into **4**, which is the known[8] di-Grignard reagent corresponding to the diorganylmagnesium **1**. In an attempt to obtain **6** from **4** directly, we treated **4** with 1 mol-equiv. of mercury dibromide but, according to the ^{199}Hg NMR spectrum, a mixture of organomercury compounds was formed which could not be separated. However, **6** was obtained by reduction[9] of the corresponding organomercury halide **5** with stannous chloride in the presence of base. Reaction of **6** with metallic magnesium in THF furnished **1**, which was characterized spectroscopically by its ^1H and ^{13}C NMR spectrum (see Exp. Sect.) and chemically by reaction with deuterium oxide which gave [D_2]ethylbenzene (**7**) exclusively.

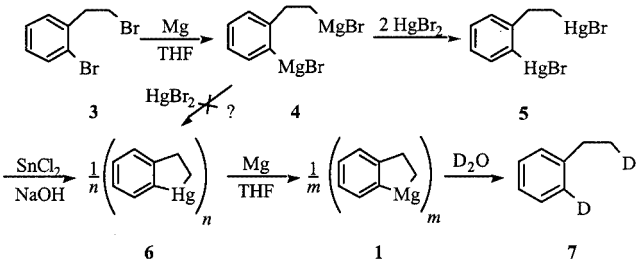
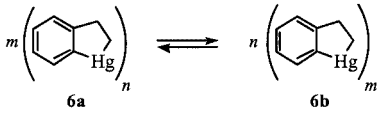


Scheme 2

Structure of 1-Mercuraindane (6)

Although initially **6** was only of interest as an intermediate for the preparation of **1**, it showed spectral features which led to a closer investigation. The ^{13}C NMR spectrum of pure **6** in $CDCl_3$ shows evidence for the occurrence of two species **6a** and **6b**, presumably differing in their degree of oligomerization. For instance, four methylene carbon resonances were observed (δ = 41.5 and 39.7 ppm for **6a**; δ = 41.7 and 38.4 ppm for **6b**) as well as eight resonances of aromatic carbon atoms and two of ^{199}Hg (δ = −273.2 ppm for **6a**; δ = −305.5 ppm for **6b**). The signal integral ratio of the benzylic methylene protons of **6a** and **6b** in the ^1H NMR spectrum was found to be concentration-dependent, which suggests an equilibrium between them in solution (Scheme 3). From ^1H NMR spectroscopic data (Table 1), the equilibrium constant at room temperature was determined. As, according to HRMS spectroscopy, **6** has a dimeric structure (m/z = 610.0642) in the gas phase, one of the species involved in solution is presumably a dimer. Assuming a dimer/trimer equilibrium, the equilibrium constant was found to be in the range of $K = 0.4 \pm 0.2$ L·mol^{-1}.



Scheme 3

Table 1. Data on the equilibrium of **6** at room temperature [in 0.5 mL of $CDCl_3$ at room temperature; determined from the ratio of the benzylic protons at δ = 3.36 ppm (**6a**) and 2.95 ppm (**6b**)]

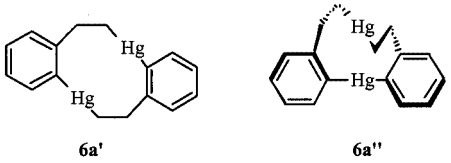
6[a]	[**6a**][b]	[**6b**][b]	K[c]
1.5	$8.8\cdot10^{-3}$	$5.8\cdot10^{-4}$	0.49
4.1	$2.4\cdot10^{-2}$	$2.8\cdot10^{-3}$	0.57
9.1	$5.2\cdot10^{-2}$	$7.6\cdot10^{-3}$	0.41
13.5	$7.6\cdot10^{-2}$	$1.2\cdot10^{-2}$	0.33
17.8	$1.0\cdot10^{-1}$	$1.7\cdot10^{-2}$	0.30
21.5	$1.2\cdot10^{-1}$	$2.1\cdot10^{-2}$	0.26
25.4	$1.4\cdot10^{-1}$	$2.7\cdot10^{-2}$	0.24
31.0	$1.7\cdot10^{-1}$	$3.3\cdot10^{-2}$	0.22

[a] In mg. [b] In mol·L^{-1} (**6a** as dimer, **6b** as trimer). [c] In L·mol^{-1}.

A dimer/trimer equilibrium is plausible since, in hypothetical monomeric **6**, the C−Hg−C angle would deviate too much from the ideal value of 180°, making the ensuing ring strain prohibitive. This is less so for a dimeric species **6a**, while a trimeric species **6b** is strain-free as concluded from CPK model studies. Species higher than a trimer are not formed since oligomerization is entropically unfavorable.

The establishment of such an equilibrium is unexpected because, in contrast to the kinetically highly labile carbon−magnesium bond, the carbon−mercury bond is usually stable under ordinary conditions. Redistribution reactions of bifunctional organomercury compounds have been reported, but only in the presence of a catalyst such as $AlCl_3$ [10] or an organomercury halide (RHgX).[10,11] For example, an equimolar mixture of Me_2Hg and Et_2Hg gives a random distribution of the three possible alkylmercury compounds, Me_2Hg, Et_2Hg and MeEtHg, upon standing at room temperature in the presence of $AlCl_3$, but after removal of the catalyst, MeEtHg can be distilled at 127 °C and is stable for months at room temperature.[10] The presence of an organomercury halide, such as **5**, as an impurity, which might act as a catalyst, was excluded by a negative halide test performed by evaporation of the solvent from a sample followed by treatment with HNO_3 and $AgNO_3$; a precipitate of AgCl was not observed.

To confirm the occurrence of an equilibrium for **6** and to estimate the exchange rates between both species, the magnetization-transfer NMR technique[12] was applied between 25 and 95 °C. Below 83 °C, no transfer was observed, which indicates that the establishment of the equilibrium is relatively slow at these temperatures. At 83 °C and 95 °C, the (pseudo-first-order) rates obtained for the equilibrium 3 **6a** $\rightleftarrows$ 2 **6b** were in the range of 0.1−1 s^{-1}. Thus, the exchange between the two oligomers is rather fast, and even at room temperature, one can estimate that it will be sufficient to allow establishment of the equilibrium. However, it is a remarkable process, and it remains unclear whether it is caused by inherent structural features or by some kind of undetected catalyst present in the system. Compound **6a** is probably dimeric (vide supra) and CPK models show that, of the two possible structures, **6a′** is less strained than **6a′′** due to the presence of the aryl−Hg−aryl arrangement in the latter (Scheme 4).



Scheme 4

Structure of 1 in Solution

The appreciable solubility of **1** in THF (ca. 0.1 M at room temperature) allowed investigations concerning its structure in solution. The degree of association was determined by the stationary isothermal distillation method,[13] which fur-

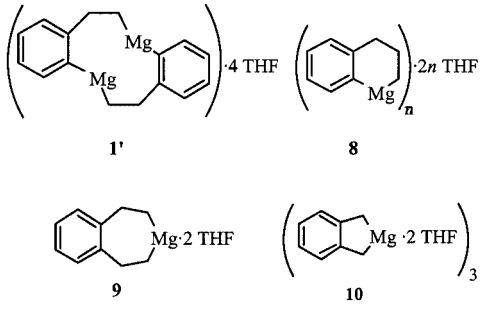
nished a concentration-independent degree of association of 2.08 (see Table 2).

Table 2. Degree of association of **1** in THF solution at 301 K[13]

[Mg][a]	S_{th}[b]	S_a[c]	i[d]
1.24	0.052	0.028	1.84
2.42	0.101	0.045	2.26
3.53	0.148	0.068	2.15
4.57	0.192	0.092	2.08
5.55	0.233	0.117	1.99
6.49	0.272	0.126	2.16

[a] [Mg] = Formal concentration of magnesium in mmol·g^{-1}. [b] S_{th} = Theoretical rate of evaporation (in mm·h^{-1}) = [Mg]·S_S, where S_S (in mm·h^{-1}·mmol^{-1}·L) = standard rate of evaporation found by calibration of the apparatus with triphenylmethane, S_S (301 K) = 0.0119 mm·h^{-1}·mmol^{-1}·L. [c] S_a = Apparent rate of evaporation in mm·h^{-1}. [d] Association number $i = S_{th}/S_a$.

The structure of two benzomagnesacycloalkanes in solution has been investigated by Freijee et al., who determined the degree of association in solution of the 1-magnesatetralin **8** and the tetrahydrobenzomagnesepin **9** (Scheme 5).[4] It was established that **8** was involved in a monomer/dimer equilibrium as its concentration-dependent degree of association was 1.26−1.49 in THF solution at room temperature, whereas the higher homologue **9** was completely monomeric. It was assumed that the higher ring strain in monomeric **8** (about 46 kJ·mol^{-1}) than in **9** (about 11 kJ·mol^{-1}) is largely responsible for the observed difference.



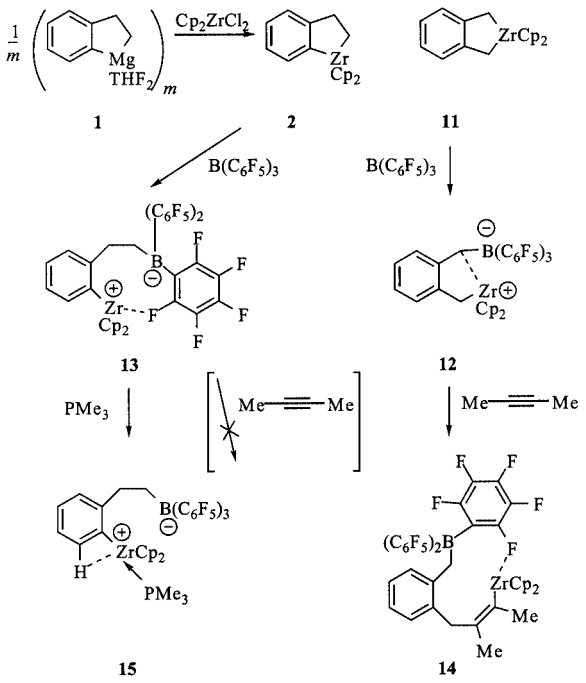
Scheme 5

The fact that **1** is completely dimeric in THF solution at room temperature is in line with the results obtained from **8** and **9** since ring strain in the hypothetical monomer of **1**, with magnesium in a five-membered ring, will be even higher than in monomeric **8**. As the trimer of **1** is not observed, we assume that entropy protects the system from further oligomerization as is also the case for other cyclic organomagnesium compounds.[3,4,14,15] Note, however, that the results presented so far pertain to the situation in solution where an equilibrium can be established; in the solid state, the degree of oligomerization may be different. Thus, Lappert et al. reported the crystal structure of 2-magnesaindane (**10**), the regioisomer of **1**, which turns out to be a trimer with a central fifteen-membered ring.[16] Unfortunately, data on the degree of oligomerization of **10** in solution are not available.

In analogy to other magnesacycles,[1−3] one may safely assume that the dimeric **1** has a ten-membered ring structure. As both the magnesium atom and the benzene ring prefer large bond angles (≥ 120°), the structure of **1′** as shown in Scheme 5 (which is analogous to **6a′**, Scheme 4), is suggested to be energetically more favorable than the alternative arrangement **1′′** (analogous to **6a"**) in which a C(Ar)−Mg−C(Ar) unit is present which probably would cause a higher ring strain in the molecule, as discussed for **6a**.

1,1-Dicyclopentadienyl-1-zirconaindane (2)

Having **1** available, it appeared to be an attractive starting material for the preparation of the 1-zirconaindane **2** which has previously been obtained by thermolysis of diphenylzirconocene in the presence of ethene.[17] It has been shown that the reaction of **11**, the 2-zircona analogue of **2**, with $B(C_6F_5)_3$ furnished the intramolecular ion pair **12** (Scheme 6).[5] It was therefore of interest to investigate the reaction of **2** with $B(C_6F_5)_3$ in order to generate the zwitterionic complex **13**. Study of the effect of anion−cation bonding interactions in **13** on the reactivity of unsaturated molecules was expected to improve our understanding of the factors influencing the activity of cationic metallocene catalysts in olefin polymerization.[18−22]



Scheme 6

Compound **2** was treated with 1 equiv. of $B(C_6F_5)_3$ in bromobenzene at −30 °C, and the product was isolated as a pale yellow powder in 81% yield by precipitation with *n*-pentane. Elemental analysis confirmed the composition of **13**. The ^{1}H NMR spectrum in $C_2D_2Cl_4$ shows a broad trip-

let signal at δ = 2.30 ppm which was assigned to the methylene protons next to the borate group; in the ^{13}C NMR spectrum, a signal at δ = 178.2 ppm indicates that the Zr−C(Ar) bond is still intact. Furthermore, the ^{19}F NMR spectrum ($C_2D_2Cl_4$, −25 °C) shows three resonances at δ = −134.8 (*o*-F), −160.1 (*p*-F), and −165.0 ppm (*m*-F). These data are in line with the presence of a tetracoordinate, negatively charged boron substituent[5] $[RB(C_6F_5)_3]^-$ in **13**. The presence of an anion−cation bonding interaction is indicated by the large value of Δδ(*m*,*p*-F) = 4.9 (Scheme 6).[23]

Solutions of **13** in tetrachloroethane are stable at room temperature for several hours. We ascribe this stabilization to intramolecular coordination of an *ortho*-fluoro substituent of one of the C_6F_5 groups to zirconium, as shown. This assumption was confirmed by variable-temperature ^{19}F NMR experiments in C_6D_5Br/[D_8]toluene. At −60 °C, the ^{19}F NMR spectrum shows eight resonances (Table 3) as expected when one of the C_6F_5 groups is coordinating to the zirconium atom and hence becomes rigid and unsymmetrical. One fluorine resonance is shielded to δ = −180.2 ppm, more than 50 ppm from the region typical for an *ortho*-fluorine nucleus in an $[RB(C_6F_5)_3]^-$ anion. A similar shielding (to δ = −190.3 ppm at −88 °C) was observed for one of the *ortho*-fluorine nuclei in the zirconoxyborane $Cp^*_2ZrOB(C_6F_5)_3$ in which the C−F···Zr interaction was proven by X-ray analysis;[24] more recently, a number of zwitterionic complexes with similar Zr···F bonding interactions have been spectroscopically and structurally characterized.[6,7] The ^{19}F resonances of **13** broaden above −50 °C, and at room temperature, only the initial three ^{19}F resonances are discernible. Note that, presumably for steric reasons, such a Zr···F interaction does not occur in **12**; instead, the X-ray structure reveals an interaction between the zirconium atom and the methylene group carrying the borate substituent.[5]

Table 3. ^{19}F NMR chemical shifts of **12** {in C_6D_5Br/[D_8]toluene at −60 °C (283.23 MHz; ref. $CF_3C_6H_5$ in C_6D_6: δ = −64 ppm)}

	F(2)[a]	F(3)[b]	F(4)[b]	F(5)[b]	F(6)[b]
Ring A	−180.2	−155.6	−156.3	−161.8	−123.3
Ring B, C	−131.5	−162.6	−157.5	−162.6	−131.5

[a] Fluorine positions are numbered clockwise, starting from the boron-substituted position.

The reactivity of **13** contrasts sharply with that of the related complex **12**. Whilst **12** inserts 2-butyne to furnish **14** (Scheme 6) and shows moderate catalytic activity in the polymerization of ethylene (about 20−40 times less active than simple cationic Group-4 catalysts[18,19]), **13** is inactive in both types of reactions. This may be partly due to the low intrinsic reactivity of the metal−aryl bond towards insertion as compared to metal−alkyl bonds.[25] Additionally, the fluorine−zirconium interaction in **13** (which is absent in **12**) hinders coordination of the substrate. Nevertheless, the fluorine−zirconium interaction in **13** is not strong enough to resist cleavage by PMe_3 in CD_2Cl_4 with formation of **15**. The yellow color of **13** disappeared, and **15** was isolated as an off-white solid in 96% yield by precipitation with *n*-pentane. The structure of **15** was assigned on the basis of the ^1H and ^{19}F NMR spectra. In particular, the small value of Δδ(*m*,*p*-F) = 3.0 ppm is consistent with the donor having displaced the anion−cation bonding interaction;[23] an aromatic proton signal at δ = 4.48 ppm strongly suggests an agostic Zr···H interaction.[26]

Conclusion

1-Magnesaindane (**1**) was obtained via the corresponding 1-mercuraindane (**6**) and found to occur as a dimeric ten-membered ring species in THF solution; in line with the behavior of other magnesacycles, this is due to an interplay between ring strain and entropy. In contrast, intermediate **6** forms a dimer/trimer equilibrium, which is remarkable as, at room temperature and in the absence of a catalyst, diorganomercury compounds usually do not establish equilibria by exchanging ligands.

The 1-zirconaindane **2** was obtained from **1** and dichlorozirconocene. It reacts with $B(C_6F_5)_3$ to form the adduct **13** which, according to spectroscopic data, has a zwitterionic structure with transannular interactions between the zirconium atom and one of the *ortho*-fluorine atoms. Although this interaction may contribute to the inertness towards insertion of the zirconium−aryl bond in **13**, it is kinetically unstable at room temperature and is easily cleaved by the Lewis base trimethylphoshane, which coordinates to the zirconium atom with formation of **15**.

Experimental Section

General: All manipulations involving organometallic compounds were carried out in fully sealed glassware using standard high vacuum techniques. Solvents were dried by distillation from liquid Na/K alloy after predrying with NaOH. Magnesium was sublimed twice before use. NMR spectra were measured with a Bruker AC 200 spectrometer (^1H NMR: 200 MHz. ^{13}C NMR: 50.3 MHz), a Varian VXR-300 spectrpmeter (^1H NMR: 300 MHz. ^{13}C NMR: 75.4 MHz, ^{31}P NMR: 121.6 MHz. ^{19}F NMR: 283.23 MHz), or a Bruker MSL 400 spectrometer (^1H NMR: 400.1 MHz. ^{199}Hg NMR: 71.6 MHz). GCMS analyses were performed with an HP 5890 GC/5970 MS combination, operating at 70 eV and equipped with a Chrompack BP1 (QSGE) 50 m/0.25 mm column. HRMS measurements were performed with a Finnigan MAT 90 mass spectrometer under EI conditions using a direct introducing interface for the introduction of air- and moisture-sensitive compounds. Elemental analyses were carried out at the Microanalytical Laboratory, Rijksuniversiteit Groningen, The Netherlands.

1-(Bromomercurio)-2-[2-(bromomercurio)ethyl]benzene (5): In a Schlenk vessel, 1-bromo-2-(2-bromoethyl)benzene (**3**)[8] (3.17 g, 12 mmol) in 20 mL of THF was slowly added during 5 h to a stirred suspension of magnesium (1.54 g, 64 mmol) in 60 mL of THF at room temperature. After the addition was complete, an

aliquot was hydrolyzed. Titration (HCl, EDTA)[27] showed an Mg^{2+}/OH^- ratio of 1.1:1 and 78% yield of 1-(bromomagnesio)-2-[2-(bromomagnesio)ethyl]benzene. Subsequently, mercury bromide (8.70 g, 24.2 mmol) in 30 mL of THF was added and the solution was stirred overnight, after which a grey suspension was obtained. After hydrolysis, the resulting suspension was filtered and the residue was washed twice with THF and H_2O and subsequently dried in vacuo to give **5** as a white powder. Yield: 6.0 g (75% based on **3**). ^{1}H NMR (200 MHz, [D$_6$]DMSO, ref. [D$_5$]DMSO: δ = 2.50 ppm; NOESY): δ = 7.47 (m, 1 H, 4-H), 7.30 (m, 1 H, 7-H), 7.21 (m, 2 H, 5,6-H), 3.00 (t, $^3J_{H,H}$ = 7.5 Hz, 2 H, $ArCH_2$), 2.06 (t, $^3J_{H,H}$ = 7.5 Hz, 2 H, CH_2Hg) ppm. ^{13}C NMR (50.3 MHz, [D$_6$]DMSO, ref. [D$_6$]DMSO: δ = 39.5 ppm): δ = 154.0 (br. s, C-1), 149.9 (s, C-2), 136.4 (dd, $^1J_{C,H}$ = 161.9, $^3J_{C,H}$ = 5.6 Hz, C-6), 128.1 (dd, $^1J_{C,H}$ = 159.6, $^3J_{C,H}$ = 7.8 Hz, C-4 or -5), 127.8 (dd, $^1J_{C,H}$ = 156.0, $^3J_{C,H}$ = 5.8 Hz, C-3), 125.5 (dd, $^1J_{C,H}$ = 159.6, $^3J_{C,H}$ = 7.0 Hz, C-4 or -5), 38.8 (t, $^1J_{C,H}$ = 126.1 Hz, $ArCH_2$), 35.2 (bt, $^1J_{C,H}$ = 139.8 Hz, CH_2Hg) ppm. ^{199}Hg NMR (71.6 MHz, DMSO, ref. Me_2Hg = 0): δ = −1107, −1231 ppm.

1-Mercuraindane (6): A solution of $SnCl_2{\cdot}2H_2O$ (5.42 g, 24 mmol) in 120 mL of 20% aqueous NaOH was slowly added over 5 h to a suspension of **5** (8.0 g, 12 mmol) in a mixture of 120 mL of 10% aqueous NaOH and 24 mL of $CHCl_3$ at room temperature.[9] After the addition was complete, a grey precipitate (Hg) was filtered off and the residue was extracted twice with $CHCl_3$. The combined organic phases were dried with $MgSO_4$ and the solvents evaporated to give **6** as a light-grey solid (3.46 g, 95%). **6:** M.p. 71 °C. HRMS: ($^{12}C_{16}H_{16}{}^{200}Hg^{202}Hg$): calcd. 610.0642; found 610.0642. C_8H_8Hg (304.74): calcd.C 31.53, H 2.65; found C 31.91, H 2.69. **6a:** ^{1}H NMR (200 MHz, $CDCl_3$, ref. $CHCl_3$: δ = 7.22 ppm): δ = 7.30−7.16 (m, 4 H, ArH), 3.36 (m, 2 H, $ArCH_2$), 1.73 (m, 2 H, CH_2Hg) ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$, ref. $CDCl_3$: δ = 76.8 ppm): δ = 180.1, C-7a), 153.2 (s, C-3a), 136.7 (dd, $^1J_{C,H}$ = 158, $^3J_{C,H}$ = 7 Hz, C-3), 130.4 (dd, $^1J_{C,H}$ = 156, $^3J_{C,H}$ = 6 Hz, C-6), 127.7 (dd, $^1J_{C,H}$ = 159, $^3J_{C,H}$ = 7 Hz, C-5), 125.5 (dd, $^1J_{C,H}$ = 159, $^3J_{C,H}$ = 7 Hz, C-4), 41.5 (t, $^1J_{C,H}$ = 131 Hz, C-3), 39.7 (t, $^1J_{C,H}$ = 125.5 Hz, C-2) ppm. ^{199}Hg NMR (71.6 MHz, $CDCl_3$, ref. Me_2Hg: δ = 0): δ = −237.2 ppm. **6b:** Due to the lower concentration of **6b** and to partial overlap of its NMR signals with those of **6a**, not all signals could be identified. ^{1}H NMR (200 MHz, $CDCl_3$, ref. $CHCl_3$: δ = 7.22 ppm): δ = 7.30−7.16 (undiscernible from those of **6a**, ArH), 2.95 (m, $ArCH_2$), 1.7 (shoulder on signal of **6a**, CH_2Hg) ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$, ref. $CDCl_3$: δ = 76.8 ppm): δ = 178.8, C-7a), 154.5 (C-3a), 136.9 (C-3), 129.2 (C-6), 128.4 (C-5), 125.8 (C-4), 41.7 (C-3), 38.7 (C-2) ppm. ^{199}Hg NMR (71.6 MHz, $CDCl_3$, ref. Me_2Hg: δ = 0): δ = −305.5. ppm.

1-Magnesaindane (1): Compound **6** (1.78 g, 5.9 mmol) and magnesium (2.5 g, 103 mmol) in 70 mL of THF were stirred for 4 d at 70 °C. A brown solution and a fine black precipitate were obtained. The excess magnesium and the black precipitate were removed by careful decantation. Crystallization by cooling a saturated THF solution gave **1** as colorless needles (4.1 mmol, 70% based on **6**; determined by titration[27]). Attempts to obtain crystals suitable for an X-ray crystal structure determination were not successful. ^{1}H NMR (400 MHz, [D$_8$]THF, ref. [D$_7$]THF: δ = 1.75 ppm): δ = 7.71 (d, $^3J_{H,H}$ = 6.4 Hz, 1 H), 6.73−6.86 (m, 3 H), 3.06 (t, $^3J_{H,H}$ = 7.2 Hz, 2 H, $ArCH_2$), 0.02 (t, $^3J_{H,H}$ = 7.2 Hz, 2 H, CH_2Mg) ppm. ^{13}C NMR (50.3 MHz, ref. [D$_8$]THF = 67.4): δ = 168.7 (bs), 167.2 (bs), 142.2 (d, $^1J_{C,H}$ = 149.3 Hz), 125.4 (d, $^1J_{C,H}$ = 154.5 Hz), 124.9 (d, $^1J_{C,H}$ = 150.3 Hz), 122.2 (d, $^1J_{C,H}$ = 153.6 Hz), 43.3 (t, $^1J_{C,H}$ = 119.3 Hz, C-3), 17.6 (t, $^1J_{C,H}$ = 108.6 Hz, C-2) ppm.

Reaction of 1 with Deuterium Oxide: An excess of D_2O was added at room temperature to a solution of **1** (about 0.1 mmol) in THF. Diethyl ether and water were added and the organic layer was dried ($MgSO_4$). By GCMS, only [D$_2$]ethylbenzene (**7**) was observed. GCMS: *m*/*z* (%) = 108 (100) $[M]^+$, 107 (18), 106 (6), 105 (7), 104 (6), 103 (2).

Formation of Zwitterion 13: The known complex **2**[17] was obtained from the reaction of **1** with Cp_2ZrCl_2. To a mixture of **2** (53.4 mg, 0.16 mmol) and $B(C_6F_5)_3$ (84.0 mg, 0.16 mmol), 1 mL of C_6H_5Br was added at −30 °C. Addition of 3 mL of *n*-pentane gave a light yellow microcrystalline solid. The supernatant was pipetted off and the precipitate was washed twice with *n*-pentane (3 mL) and dried at 25 °C in the glovebox (1 h) to yield **13** (108.9 mg, 81%) as a pale yellow solid. ^{1}H NMR (300 MHz, $C_2D_2Cl_4$, ref. C_2DHCl_4: δ = 5.91 ppm; −25 °C): δ = 6.83 (m, 3 H, ArH), 6.40 (s, 10 H, Cp), 6.32 (d, $^3J_{H,H}$ = 5.6 Hz, 1 H, ArH), 2.70 (bt, $^3J_{H,H}$ = 7.5 Hz, 2 H, $ArCH_2$), 2.30 (bm, 2 H, CH_2B) ppm. ^{13}C NMR (75.43 MHz, $C_2D_2Cl_4$, ref. $C_2D_2Cl_4$: δ = 74.35; −25 °C, cation signals only; those of the anion part were too broad for identification): δ = 178.2 (CZr), 152.2, 138.7, 129.4, 125.3, 124.8 (d, $^1J_{C,H}$ = 157.9 Hz), 116.5 (d, $^1J_{C,H}$ = 170.6 Hz, Cp), 37.8 (t, $^1J_{C,H}$ = 126.5 Hz, $ArCH_2$), 14.6 (CH_2B) ppm. ^{19}F NMR (283.23 MHz, $C_2D_2Cl_4$, ref. $CF_3C_6H_5$ in C_6D_6: δ = −64; −25 °C): δ = −134.8 (*o*-F), −160.1 (*p*-F), −165.0 (*m*-F) ppm. $C_{36}H_{18}F_{15}Zr$ (826.73): calcd. C 51.62, H 2.17; found C 52.02, H 2.37.

Reaction of 13 with PMe_3. Formation of Adduct 15: PMe_3 was added (0.046 mmol, 4.8 μL) to a solution of **13** (38.5 mg, 0.046 mmol) in 0.5 mL of $C_2D_2Cl_4$ and an immediate color change from yellow to almost colorless was observed. After addition of 1 mL of *n*-pentane, a light yellow precipitate was obtained, which was filtered off and washed twice with *n*-pentane (2 mL). Evaporation of the *n*-pentane solution in the glovebox gave **15** as an off-white solid (40.2 mg, 96%). ^{1}H NMR (300 MHz, $C_2D_2Cl_4$, ref. C_2DHCl_4: δ = 5.91; −25 °C): δ = 7.09 (d, $^3J_{H,H}$ = 7.1 Hz, 1 H, ArH), 6.92 (m, 2 H, ArH), 5.53 (s, 10 H, Cp), 4.48 (dd, $^3J_{H,H}$ = 10.4, $^4J_{H,H}$ = 7.0 Hz, 1 H, ArH···Zr), 2.06 (m, 2 H, $ArCH_2$), 1.35 (d, $^2J_{P,H}$ = 7.4 Hz, 9 H, PMe_3), 1.06 (m, 2 H, CH_2B) ppm. ^{19}F NMR (283.23 MHz, $C_2D_2Cl_4$, ref. $CF_3C_6H_5$ in C_6D_6: δ = −64 ppm; −25 °C): δ = −131.9 (*o*-F), −163.0 (*p*-F), −166.0 (*m*-F) ppm. ^{31}P{H} NMR (121.6 MHz, $C_2D_2Cl_4$, ref. PPh_3: δ = −6.0 ppm): δ = −15.8 ppm.

A Complex-Based Soft Template Route to PbSe Nanowires

Yuanfang Liu,*[a,b] Jinbo Cao,[a] Jinghui Zeng,[a] Cun Li,[a] Yitai Qian,[a] and Shuyuan Zhang[c]

Keywords: Nanostructures / Semiconductors / Luminescence / Carboxylate ligands

PbSe nanowires with an average size of 8 × 350 nm were synthesized by the reaction of $Pb(NO_3)_2$ and Se powder at 60 °C under ambient pressure. A mixture of arachidic acid (AA, n-$C_{19}H_{39}COOH$) and octadecylamine (ODA), which could form a complex with Pb^{2+}, was employed as a soft template to control the morphology of the resultant PbSe nanowires. The products were characterized by X-ray powder diffraction (XRD), X-ray photoelectron spectroscopy (XPS), and transmission electron microscopy. The photoluminescence (PL) spectrum of the PbSe nanowires is presented.

Introduction

Nanomaterials often display optical, electronic, and structural properties different from those of their bulk counterparts. Nanoparticles may adopt various shapes, which play a critical role in determining their basic properties.[1] To obtain a nanomaterial of a particular shape a variety of synthetic methods are needed not only to prepare the starting material but also to manipulate such materials to give desirable nanostructures.

One-dimensional (1D) nanostructures, such as nanorods, nanowires, and nanotubes, which serve as building blocks for many novel functional materials, are currently the focus of considerable interest.[2] So far, several significant synthetic methods, which include hard templates[3] (such as porous anodic alumina and carbon nanotubes), soft templates[4] (such as liquids and polymers), and hydrothermal routes[5] have been employed to prepare 1D nanostructures.

The study of PbSe 1D nanostructures is meaningful since PbSe can be used in IR sensors,[6] solar cells and infrared detectors,[7] and chemical sensors,[8] and is an important semiconductor owing to its large Bohr exciton radius, which can result in a strong confinement of the electron-hole pair.[9] However, there are only a few examples of the preparation of 1D PbSe nanostructures. These include: (i) synthesis of PbSe nanowires with an average size of 18 nm × 3 μm by the reaction of $PbCl_2$ and Se in ethylenediamine with KBH_4 as the reducing agent,[10] (ii) preparation in a monolayer of rod-like PbSe nanocrystals with a size of 10 × 100 nm,[3] and (iii) synthesis of PbSe nanorods with an average size of 60 × 700 nm through ultrasonic and γ-irradiation techniques in ethylenediamine.[11]

Soft templates have been demonstrated to be a very effective method for controlling the shapes of materials. Soft templates include liquid crystals,[12] monolayers,[13] polymers,[1] and surfactants.[14]

In this work, we obtained PbSe nanowires with an average size of 8 × 350 nm from a $CHCl_3$ solution of the surfactants arachidic acid (AA, n-$C_{19}H_{39}COOH$) and octadecylamine (ODA).

Results and Discussion

The XRD pattern of the PbSe nanowires isolated is shown in Figure 1. All peaks in Figure 1 could be indexed

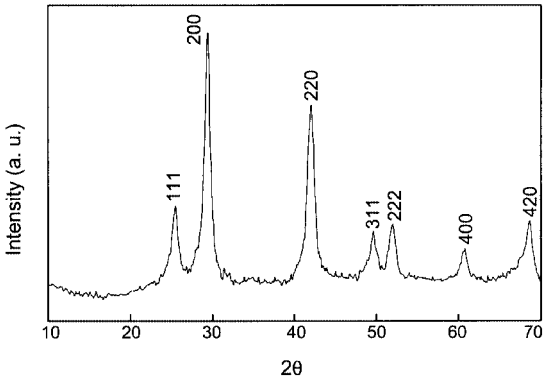

Figure 1. XRD pattern of prepared PbSe nanowires from AA/ODA (1:2)

as cubic PbSe. The calculated cell constant, a = 6.128 Å, is consistent with the reported value (a = 6.124 Å, JCPDS Card No.6-354). No peaks characteristic of impurities were observed. Given that the Debye−Scherrer calculations are approximate and more accurate for spherical particles, and that the PbSe has a curved nanowire morphology, the calculated average size of PbSe nanowires relies only on the TEM results.

XPS was further applied to determine the purity and composition of the product. The survey spectrum of PbSe nanowires is typical, and higher-resolution spectra of the Pb and Se regions of PbSe are shown in Figure 2. The survey spectrum of PbSe shows the presence of Pb and Se from the nanowires, and C and O from the surface of the material and from absorbed gaseous molecules. The strong peak observed in the Pb region at 137.2 eV is assigned to the (4f) Pb binding energy; the peak in the Se energy region is detected at 53.2 eV and is attributed to (3d) Se. No other peaks in the survey spectrum of PbSe were obvious. The (4f) Pb and (3d) Se peak areas quantified the content of Pb and Se and gave the atomic ratio of Pb to Se as 1:0.92, which is close to the literature value of 1:0.91.[10] Elemental analysis shows the atomic ratio of Pb/Se to be 1.003. This value is close to the stoichiometric ratio of PbSe (1) and the XRD results but is slightly different from that obtained by XPS. This is because XRD and elemental analysis are bulk-phase analyses while XPS gives only surface composition analysis. For nanoparticles, it is a common phenomenon, that surface composition is different from the corresponding bulk material, which is caused by the dangling bonds existing on the surface and segregation of a particular element to the surface of nanoparticles.[15,16]

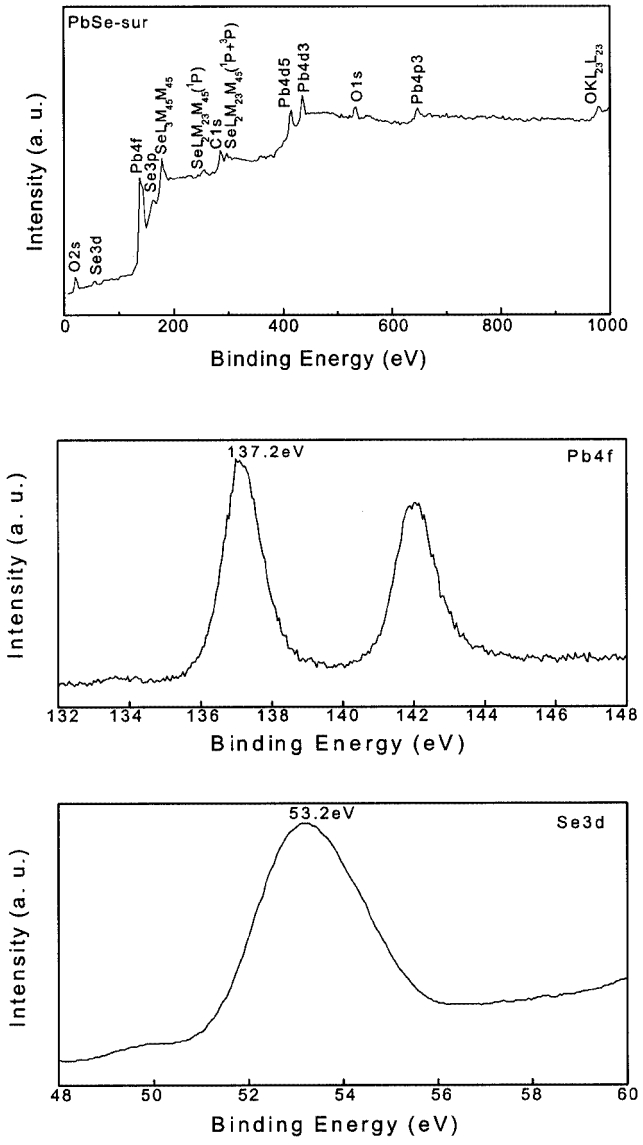

Figure 2. XPS analysis of as prepared PbSe nanowires from AA/ODA (1:2)

The morphology and size of the PbSe product were investigated by TEM, and the results are shown in Figure 3. The curved PbSe nanowires cross and overlap each other to form a net-like structure, and their average size is 8 × 350 nm (Figure 3, a). ED images of PbSe nanowires, shown in Figure 3, b, confirmed that the product is highly crystalline.

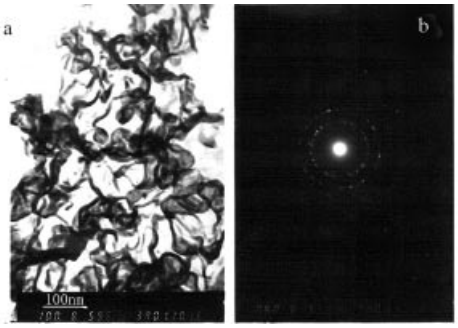

Figure 3. TEM and ED images of as prepared product from AA/ODA (1:2); (a) TEM of PbSe nanowires, (b) ED image of PbSe nanowires

To examine the quantum-confined effect of the product, the room-temperature photoluminescence (PL) spectrum of the PbSe nanowires, which were dispersed in alcohol, was recorded. To avoid the possible interference of trace AA and ODA, an alcohol solution of AA and ODA in a 2:1 ratio was used as reference. Figure 4 depicts the photoluminescence (PL) emission spectrum of the PbSe nanowires. Under photoluminescence excitation at 280 nm, the emitting peak is located at 359 nm with a 40 nm blue-shift compared with Guha's report.[9] The characteristic blue-shift of the PL spectrum of PbSe nanowires is attributed to their small diameter and larger aspect ratio.[17]

During formation of the PbSe nanowires, surfactants AA and ODA, in their various ratios, play an important role. When there is no surfactant and other conditions are identical, the PbSe obtained is a spherical nanoparticle. Mixtures of AA and ODA in varying ratios (0:1, 1:5, 1:1, 2:1, 5:1, and 1:0) were applied successively as a soft template keeping other conditions identical with those when AA/ODA = 1:2. The XRD patterns of the resultant products indicated that PbSe could indeed be formed in the mixtures of AA

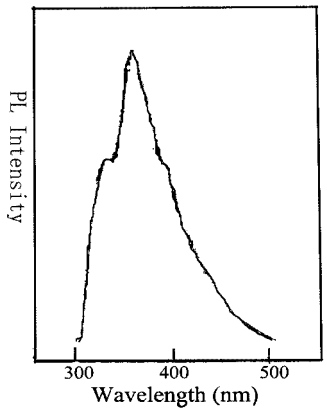

Figure 4. Photoluminescence (PL) spectrum of PbSe nanowires from AA/ODA (1:2)

and ODA. TEM images show the product yield of nanowires is clearly affected by the ratios of AA and ODA. When AA/ODA = 0:1, 1:5, 1:1, 2:1, or 5:1, nanorods and nanoparticles or hollow spheres consisting of nanoparticles are produced instead of nanowires. When the ratio of AA/ODA = 1:0, PbSe nanowires and a small amount of nanorods and nanoparticles are formed.

As regards the shape formation mechanism of PbSe nanowires, mixtures of AA and ODA have been employed before to prepare monolayers, which acted as a soft template to control the morphology of PbS and PbSe.[13] The shape of the PbS obtained is equilateral-triangular while that of PbSe is equilateral-triangular and rod-like. These results differ from those obtained in our experiments; presumably due to the different behavior and structure of AA/ODA as a solid-state monolayer compared to those of AA/ODA as a solution. In our experiment, the basicity of ODA which could promote conversion of RCOOH (AA) to $RCOO^-$.

It has been reported that Pb^{2+} can react with $RCOO^-$ to form lead carboxylate complexes with, for example, a three-dimensional polymer structure, a chain structure, or as monomers and dimers.[18,19] It can be concluded, therefore, that $RCOO^-$ in AA may act as a bidentate ligand to react with Pb^{2+} to form relatively stable complexes. According to the following experimental results, a three-dimensional polymer or chain structure was formed when $Pb(CH_3COO)_2$ reacted with AA in the presence of ODA. Lead carboxylate complexes of general formula $[Pb(C_{19}H_{39}COO)_2]_n$ were prepared as described in the Exp. Sect. IR spectroscopy indicates that the product has a similar IR spectrum to that of AA, except that the peaks at 1707.4 cm^{-1} [ν(C=O)], 2917.2 cm^{-1}, and 2848.8 cm^{-1} [ν(OH)] disappear, and new peaks at 1598.7 cm^{-1} [$\nu_{asym}(COO^-)$] and 1361 cm^{-1} [$\nu_{sym}(COO^-)$] appear. The values of $\nu_{asym}(COO^-)$ and $\nu_{sym}(COO^-)$ in the Pb^{2+}−AA complex are close to those in the Pb^{2+}−citric acid complex, which has a chain structure and bidentate carboxylic groups.[20] However, MALDI-TOF-MS results indicate no polymer was formed when the AA/ODA ratio was 0:1, 1:5, 1:1, 2:1, or 5:1. The MS of the Pb^{2+} complex formed when AA/ODA = 1:2, is as follows: calcd. for $\{[Pb(C_{19}H_{39}COO)_2]_{395}Na_2\}^{2+}$ 327738, found 327736.7; additional peaks: calcd. for $\{[Pb(C_{19}H_{39}COO)_2]_{10}Na_2\}^{2+}$ 8342, found 8344; calcd. for $[Pb(C_{19}H_{39}COO)_2Na_2]^{2+}$ 875.6, found 877.5.

All the above results confirm the formation of polymers of the Pb^{2+}−AA complex. From both literature reports[18,19] and these results, such $[Pb(C_{19}H_{39}COO)_2]_n$ systems may have a three-dimensional polymeric structure or a curved chain structure. In solution, Se^{2-}, which is produced in hydrazine,[21] attacks the complex. This attack can disrupt the bonds between the Pb and O atoms and promote gradual bond formation between Pb and Se. In the event of Pb−O bond cleavage, the Pb centre is ligated to Se and net-like PbSe nanowires are formed. Clearly, other carboxylic acids may be used as a soft template to prepare 1D nanomaterials. For example, Jiang et al.[2] prepared Ag nanowires with oleic acid as a soft template; Brase et al.[22] observed $BaSO_4$ nanowires in aqueous polymer solution, and pointed out that for nanowire formation, the polymer must have a high percentage of carboxy groups; Benton et al.[23] produced $BaSO_4$ nanofibers from polymaleate-based macromolecules with a high content of maleic acid as a modifier. All these results agree with our soft-template mechanism.

Efforts have also been made to prepare PbS 1D nanostructures with S replacing Se under identical conditions to those for the PbSe nanowires. The product obtained is a PbS nanorod. However, the nanorods are short and product yield is low. This result may be due to the different radii and coordination properties of S^{2-} and Se^{2-}.

Conclusion

In summary, a complex-based soft-template method has been developed to prepare PbSe nanowires in a mixture of AA and ODA at 60 °C under ambient atmosphere. The ratio of surfactants has a crucial influence on the rate of production of the PbSe nanowires. The optimum ratio of AA and ODA for preparing PbSe nanowires is 1:2. PbSe nanowires are formed because Pb^{2+} can react with AA to produce polymers of a Pb^{2+}−AA complex, which acts as a soft template. The soft-template mechanism provides a good example of the use of surfactants in the synthesis of 1D nanostructures. It is possible to replace AA by other carboxylic acid as a soft template for certain inorganic systems. The PL spectra of the PbSe nanowires show a strong confinement effect.

Experimental Section

General: Elemental analyses were carried out by gravimetric analysis combined with atomic emission spectroscopy using a Perkin−Elmer/6500 ICP-AES instrument. Microanalysis of C and H was carried out with a Perkin−Elmer 240C elemental analyzer. ^1H NMR spectra were recorded with a Bruker AM-200 spectrometer. MALDI-TOF-MS was performed with a Bruker Beflex III

mass spectrometer equipped with 1.25-m linear and 2.7-m reflection flight tubes and a 337-nm nitrogen laser. Angiotensin I (1269.5 Da) and adrenocorticotropic hormone (2466.7 Da) were used as external standards. The experiment was done at an accelerating potential of 20 kV. Sample solutions were prepared by dissolution of polymer, matrix (5-chlorosalicylic acid), and cationizing agent (CF_3COONa) in acetone. Typically, mixtures of 1.0 mL of a polymer solution (10 mg/ml) and 9.0 mL of a matrix solution (8.89 mg/ml) containing a cationizing agent (1.11 mg/ml) were prepared. Immediately after mixing, 1.0 μL portions of solution were deposited with a calibrated pipette onto the dimples of the sample slide and gently dried under air at room temperature. The plate was inserted into the apparatus under high vacuum (about 10^{-5} Pa). The X-ray powder diffraction (XRD) analysis was carried out with a Japan Rigaku D/max-γA X-ray diffractometer with graphite-monochromatized Cu-K_α radiation ($\lambda = 1.54178$ Å). X-ray photoelectron spectra (XPS) were collected with an ESCALAB MK II X-ray photoelectron spectrometer, using a monomochromatized Mg-K_α radiation as the X-ray excitation source. The binding energies are referenced to the (1s) C binding energy (284.6 eV) of the carbonaceous contaminant of the sample. Transmission electron microscopy (TEM) images were taken with a Hitachi H-800 transmission electron microscope. Infrared analyses were performed with KBr discs with a Magna IR-750 FT spectrometer in the range 400−4000 cm^{-1} at room temperature. Luminescence spectra were recorded with a Hitachi 850-fluorescence spectrophotometer.

Synthesis of PbSe Nanowires: In a typical procedure, AA and ODA in a 1:2 molar ratio (0.001 mol of AA and 0.002 mol of ODA) were dissolved in 100 mL of chloroform to form colloidal solutions of surfactants whilst stirring at 60 °C. A solution of 20 mL of absolute ethanol solution and 0.002 mol of $Pb(OAc)_2$ was added to the surfactants. A red solution of 0.002 mol of Se, 10 mL of 85% hydrazine, and 40 mL of absolute alcohol was added to the surfactant/metal salt mixture drop by drop to give an immediate black precipitate. After stirring at 60 °C for 0.5 h and standing for 1 h, the precipitate was filtered, and then washed successively with chloroform, absolute ethanol, and distilled water. Finally, the black product was dried under vacuum at 60 °C for 4 h.

Synthesis of the Lead Carboxylate Polymer: Similar to the preparation of PbSe nanowires, 0.001 mol of AA and 0.002 mol of ODA were dissolved in 100 mL of chloroform stirred at 60 °C to form a colloidal solution. A solution of 20 mL of absolute ethanol solution and 0.002 mol of $Pb(OAc)_2$ was added and after stirring at 60 °C for 0.5 h and standing for 1 h, the resultant white precipitate was filtered, then washed with chloroform, absolute ethanol, and distilled water. Finally, the white product was dried under vacuum at 60 °C for 4 h. ICP-AES for $[Pb(C_{19}H_{39}COO)_2]_n$: calcd. C 57.91, H 9.40, Pb 24.98; found C 57.58, H 9.82, Pb 24.88. ^1H NMR (C_6D_6): δ = 0.9 [3 H, $CH_3(CH_2)_{18}COO^-$], 1.27 [32 H, CH_3-$(CH_2)_{16}CH_2CH_2COO^-$], 1.65 [2 H, $CH_3(CH_2)_{16}CH_2CH_2COO^-$], 2.35 [2 H, $CH_3(CH_2)_{16}CH_2CH_2COO^-$] ppm. MALDI-TOF-MS: m/z = 344332.5, calcd. for $\{[Pb(C_{19}H_{39}COO)_2]_{415}Na_2\}^{2+}$ 344330; additional peaks at m/z = 322762.5, calcd. for $\{[Pb(C_{19}H_{39}COO)_2]_{389}Na_2\}^{2+}$ 322760.4 and m/z = 8344, calcd. for $\{[Pb(C_{19}H_{39}COO)_2]_{10}Na_2\}^{2+}$ = 8342.

Cobalt Chloride Complexes of N_3 and N_4 Donor Ligands

T. Martijn Kooistra,[a] Koen F. W. Hekking,[a] Quinten Knijnenburg,[a] Bas de Bruin,[a] Peter H. M. Budzelaar,[a] René de Gelder,[a] Jan M. M. Smits,[a] and Anton W. Gal*[a]

Keywords: Cobalt / N Ligands / Polymerisation

A number of cobalt(II) chloride complexes of pyridine/amine N_3 and N_4 donors have been prepared and structurally characterised. Even though they are paramagnetic, assignment of the ^{1}H NMR signals was possible in several cases. With the exception of tpa, which formed a cationic monochloride complex, all new complexes have *cis*-coordinated chlorides. Nevertheless, only the relatively rigid pyp ligands gave rise to (low) ethene polymerisation activity on activation with MAO.

Introduction

Cobalt complexes with nitrogen donor ligands have been used to mimic biological systems such as vitamin B-12 coenzyme.[1] They are also of interest in the context of dioxygen activation at transition metals.[2] Recently they have attracted attention as precatalysts for olefin polymerisation.[3] Typically, the precatalysts are the cobalt(II) chloride complexes of diiminepyridine (dip) ligands (see Figure 1). Structural characterisation of these complexes requires X-ray analysis because the paramagnetic Co^{II} centre complicates NMR studies. In the hope of obtaining some insight into the optimal coordination geometries for olefin polymerisation, we decided to study a range of flexible pyridine/amine complexes and compare these with the more rigid dip complexes. The ligands are of the picolylamine type and are multidentate, with amine (N_{am}) and pyridine (N_{py}) nitrogens (Figure 1).[4]

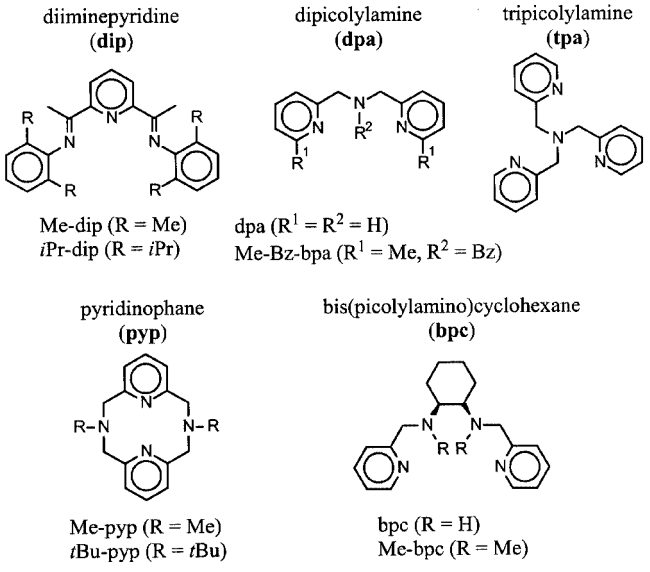

Figure 1. Pyridine/amine ligands used in this work; the dip ligand has been included for comparison

For polymerisation the two chlorides must be converted into an alkyl chain and a vacant coordination site *cis* to it. In five-coordinate complexes of dpa-type N_3 ligands, the small bite angles of the two five-membered chelate rings should disfavour equatorial coordination of all three nitrogens in a trigonal-bipyramidal coordination geometry; this leaves the *fac* and *mer* arrangements shown in Figure 2, both of which have a *cis* orientation of the remaining coordination sites (for the more rigid dip ligands, only the *mer* arrangement is accessible). Of the N_4 ligands, pyp is the least flexible one. In practice, it strongly prefers a *cis*-octahedral coordination geometry (Figure 2),[5] although other arrangements have been observed.[6,7] Six-coordinate complexes of tpa will also have a *cis*-octahedral structure; in addition, this ligands supports five-coordination, usually with an apical N_{am} donor (Figure 2). Finally, bpc-type ligands have been observed in three distinct coordination geometries shown in Figure 2: planar ("N4"), symmetric *cis*-octahedral ("N2/N2") and asymmetric *cis*-octahedral ("N3/N"). The different coordination geometries possible for the N_3 and N_4 donors also result in different patterns of N_{am} and N_{py} donors *trans* to the two sites potentially involved in polymerisation.

Results and Discussion

Synthesis

The N_3 and N_4 ligands used have all been reported previously.[8] Their $CoCl_2$ complexes were easily obtained by reaction with $CoCl_2 \cdot 6H_2O$ in the appropriate solvent.

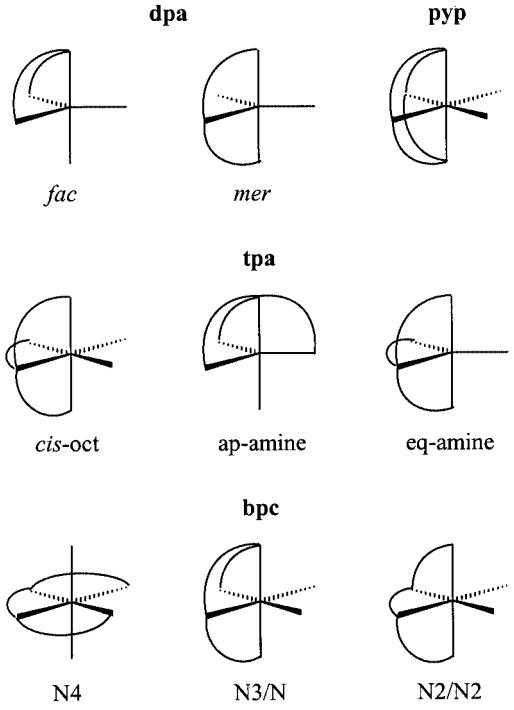

Figure 2. Coordination geometries of N_3 and N_4 ligands

Whereas most of the complexes are air stable, [(bpc)$CoCl_2$] (**5**) proved very sensitive to air and water. This complex was therefore synthesised by reaction of the ligand with dry $CoCl_2$ in anhydrous acetonitrile. The related complex [(Me-bpc)$CoCl_2$] (**6**) decomposes only very slowly in the presence of air and water.

Crystal Structures of N_4-Ligand Complexes

[(tpa)CoCl]$_2$$CoCl_4$

We expected to prepare an octahedral complex from tpa and $CoCl_2 \cdot 6H_2O$. However, X-ray analysis showed that the five-coordinate cation [(tpa)CoCl]$^+$ (**1**$^+$) had formed (Figure 3), with $CoCl_4^{2-}$ as the counterion. The unit cell contains two crystallographically independent cations **1**$^+$. Each of these has an almost C_3-symmetric trigonal-bipyramidal coordination geometry with N_{am} and Cl^- at the two axial positions. The Co^{II} centre is displaced approximately 0.5 Å from the equatorial N_3 plane in the direction of the chloride.

The structure of **1**$^+$ is very similar to that of the dicationic complex [(tpa)Co(MeCN)]$^{2+}$ (**2**) reported by Karlin.[9] The Co−N_{py} distances of **1**$^+$ and **2**$^{2+}$ are identical within experimental error. The Co−N_{am} distance for **1**$^+$ is longer than that for **2**$^{2+}$, as expected on the basis of the larger *trans*-influence of Cl^- compared to acetonitrile.

The structures of [(*t*Bu-pyp)$CoCl_2$] (**3**)[5d] and [(Me-pyp)-$CoCl_2$] (**4**)[5a] have been reported before. Both have a *cis*-octahedral coordination; the steric bulk of the *t*Bu substituents in **3** forces the ligand to twist, lowering the symmetry from C_{2v} (as observed in **4**) to C_2.

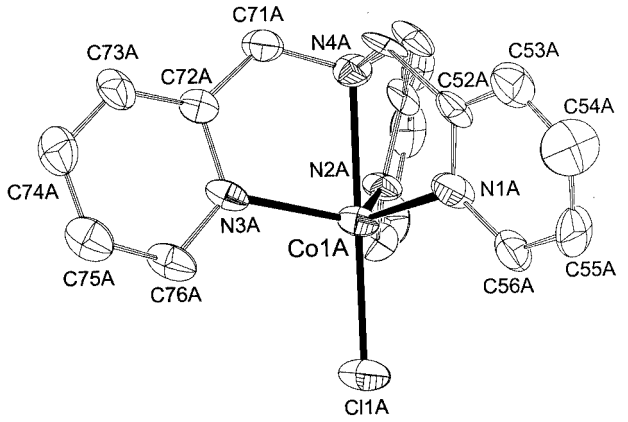

Figure 3. X-ray structure of one of the two independent cations **1**$^+$; selected bond lengths [Å] and angles [°]: Co1A−N1A 2.028(15), Co1A−N2A 2.038(14), Co1A−N3A 2.055(14), Co1A−N4A 2.240(14), Co1A−Cl1A 2.284(5), N1A−Co1A−N4A 76.3(6), N2A−Co1A−N4A 78.8(5), N3A−Co1A−N4A 76.7(5); corresponding values for the second cation: Co1B−N1B 2.072(15), Co1B−N2B 2.075(16), Co1B−N3B 2.055(14), Co1B−N4B 2.229(15), Co1B−Cl1B 2.280(6), N1B−Co1B−N4B 77.9(6), N2B−Co1B−N4B 76.2(6), N3B−Co1B−N4B 77.1(5); corresponding values for [(tpa)Co(MeCN)]$^{2+}$ (ref.[9]): Co−N1 2.041(3), Co−N2 2.037(3), Co−N3 2.053(3), Co−N4 2.177(3), Co−N5 2.046(3), N1−Co−N4 79.1(1), N2−Co−N4 78.9(1), N3−Co−N4 78.7(1)

[(bpc)$CoCl_2$] (5) and [(Me-bpc)$CoCl_2$] (6)

Both bpc complexes adopt a C_2-symmetric, *cis*-octahedral N2/N2 geometry (Figure 4). These two are the first examples of bis(picolylamino)ethylenediamine $CoCl_2$ complexes to be characterised by an X-ray structure determination. The structure of [(bpc)$CrCl_2$]$^+$ (an analogue of **5**) has been reported.[10] In addition, several metal dichloride com-

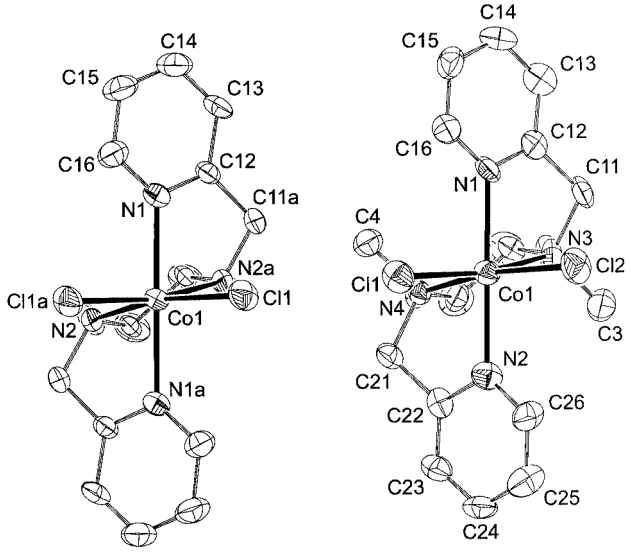

Figure 4. X-ray structures of **5** and **6**; selected bond lengths [Å] and angles [°] for **5**: Co1−N1 2.187(4), Co1−N2 2.205(4), Co1−Cl1 2.4187(14), N1−Co1−N1a 170.1(2), N2−Co1−N2a 79.8(2), Cl1−Co1−Cl1a 98.24(8) (atoms labeled a symmetry-related by $-x$, y, 1/2 − z); corresponding values for **6**: Co−N1 2.147(8), Co−N2 2.134(9), Co−N3 2.255(9), Co−N4 2.236(7), Co−Cl1 2.436(3), Co−Cl2 2.435(3), N1−Co−N2 173.1(4), N3−Co−N4 78.7(3), Cl1−Co−Cl2 98.24(13)

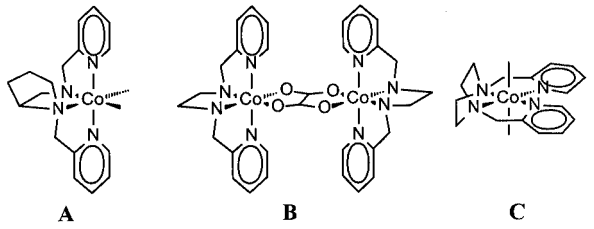
plexes of bis(picolylamino)ethylenediamine ligands lacking the cyclohexane ring have been structurally characterised.[11] A number of bpc and Me-bpc complexes of cobalt with counterions other than chloride have also been reported; all of these contain Co^{III}. Remarkably, all previously reported bpc cobalt complexes have the N3/N coordination geometry,[12] whereas the three Me-bpc cobalt complexes reported so far all have the N2/N2 arrangement.[13] Considering the wider class of bis(picolyl)ethylenediamine cobalt complexes, there are only a few examples of the N2/N2 arrangement: these include the more highly substituted system **A**[14] and the atypical, oxalato-bridged dimer **B**.[15]



Judging from these examples, the N3/N arrangement is preferred over N2/N2 by only a small margin; substituents at the backbone may cause increased steric hindrance at the "planar" N_{am} and so promote the more extensive folding of the N2/N2 geometry. The N2/N2 geometry found in the oxalato-bridged dimer might be caused by steric hindrance between the monomer units in the N3/N geometry. Finally, only a single example of the N4 arrangement has ever been reported,[16] and in that case (**C**, above) the geometry is probably enforced by the rigid ligand backbone.

Returning to our $CoCl_2$ complexes, it seems remarkable that even bpc adopts the N2/N2 structure here. We believe that the larger size of Co^{II} (compared to Co^{III}) disfavours formation of the N3/N structure and hence is responsible for shifting the balance towards N2/N2.

In contrast to **3**, where the two enantiomeric conformations of the ligand are only slightly different and will interconvert in solution, the chiral geometry in **5** and **6** is locked through the coordination of the two pyridyl groups. On going from **5** to **6**, the introduction of the N_{am} methyl substituent results in a longer $Co-N_{am}$ distance, which is compensated for by a strengthening of the $Co-N_{py}$ interaction. In addition, the two pyridyl fragments become more nearly orthogonal (angle between planes: 121° and 104°, respectively). The rather similar Co−Cl distances in complexes **3**−**6** indicate that the *trans*-influence of N_{am} and N_{py} on the chlorides is similar.

Crystal Structures of N_3-Ligand Complexes

[(Me−Bz−dpa)$CoCl_2$] (7)

Complex **7** (Figure 5) has a pseudo trigonal-bipyramidal coordination geometry, with the two axial positions occupied by the two N_{py} atoms. The rather similar crystal structure of [(Me-dpa)$NiBr_2$] has previously been reported.[17]

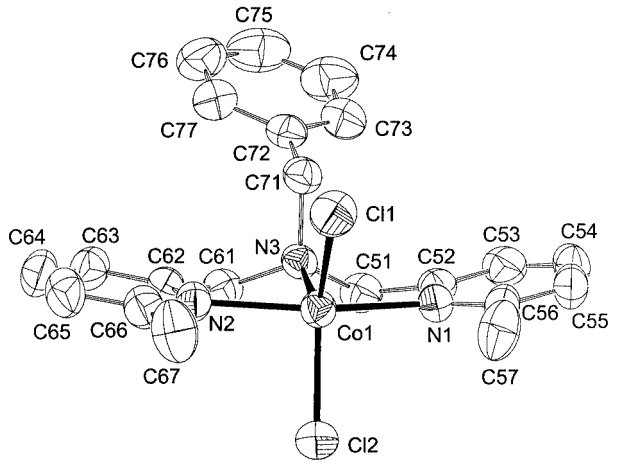


Figure 5. X-ray structure of **7**; selected bond lengths [Å] and angles [°]: Co−N1 2.178(2), Co−N2 2.182(2), Co−N3 2.124(2), Co−Cl1 2.2999(9), Co−Cl2 2.2784(9), N1−Co−N2 157.98(10), N3−Co−Cl1 111.33(6), N3−Co−Cl2 114.24(6), Cl1−Co−Cl2 134.41(4); corresponding values for (Me-dpa)$NiBr_2$ (ref.[17]): Ni−N1 2.042(10), Ni−N2 2.050(11), Ni−N3 2.007(14), Ni−Br1 2.473(3), Ni−Br2 2.494(3), N1−Ni−N2 163.6(5), N3−Ni−Br1 112.1(6), N3−Ni−Br2 98.7(5), Br1−Ni−Br2 149.2(1)

[(Me-dip)$CoCl_2$] (8)

Complex **8** (Figure 6) has a trigonal-bipyramidal geometry in the solid state, like its Fe analogue[18] and dpa complex **7**. In contrast, the $CoCl_2$ and $FeCl_2$ complexes of the isopropyl-substituted dip ligand have structures which are more nearly square pyramidal.[19] Apparently, the bulkier aryl groups promote this kind of distortion; a similar effect has been observed in a series of β-diiminate complexes.[20] In both dpa and dip complexes, the equatorial nitrogen is closer to the metal centre than the axial nitrogens. This effect is most pronounced for the dip complex, possibly due to geometric constraints of the ligand backbone.

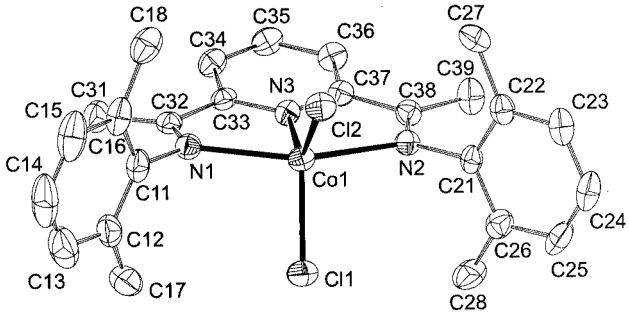

Figure 6. X-ray structure of **8**; selected bond lengths [Å] and angles [°]: Co−N1 2.247(2), Co−N2 2.265(2), Co−N3 2.0371(19), Co−Cl1 2.2578(7), Co−Cl2 2.2730(7), N1−Co−N2 150.42(7), N3−Co−Cl1 119.90(6), N3−Co−Cl2 127.14(6), Cl1−Co−Cl2 112.92(3); corresponding values for Fe analogue (ref.[18]): Fe−N1 2.271(6), Fe−N2 2.266(5), Fe−N3 2.110(6), Fe−Cl1 2.312(2), Fe−Cl2 2.278(2), N1−Fe−N2 145.5(2), N3−Fe−Cl1 118.9(2), N3−Fe−Cl2 131.3(2), Cl1−Fe−Cl2 109.9(1)

Five versus Six Coordination

The present work shows examples of both five- and six-coordinate structures. It seems that the ligand has a large influence on the preference for five- or six-coordination. The N_3 donor complexes **7** and **8** are naturally five-coordinate, but even the cobalt chloride complex of tpa prefers an ionic five-coordinate structure ($\mathbf{1}^+$). Five-coordination must be very favourable over six-coordination here (compared to pyp and bpc ligands) since even if a large excess of ligand is used, one-third of the cobalt is found as the counterion $[CoCl_4]^{2-}$ and free ligand remains. When NH_4PF_6 is then added to the reaction mixture, all cobalt is complexed by the ligand and the (presumably also five-coordinate) complex [**1**]PF_6 can be isolated. The other N_4 complexes all seem to prefer six-coordinate structures, although for complex **6** five-coordination in solution cannot be completely ruled out (see NMR section below). For **4** the coordination behaviour in solution has been described in the literature.[5a] Conductivity studies performed by Krüger showed that one chloride is exchanged for a coordinated solvent molecule in methanol, but only partial dissociation of one chloride takes place in acetonitrile. Although acetonitrile is generally considered to be a better ligand than methanol, methanol is very well suited for the solvation of chloride anions. This may be the driving force in the dissociation of chloride from **4**. The NMR spectrum of **3** shows a similar solvent dependence and suggests that this complex can also undergo chloride substitution in methanol. Clearly, complexes of pyp and bpc prefer six-coordination, although a chloride can sometimes be displaced by a polar solvent molecule. It is possible that five-coordination only occurs when the ligand can easily accommodate a trigonal-bipyramidal arrangement.

EPR Measurements

Six-coordinate [(*t*Bu-pyp)$CoCl_2$] (**3**) and five-coordinate [(Me-Bz-dpa)$CoCl_2$] (**7**) both have very broad X-band EPR spectra in the range $g = 2-6$, characteristic of high-spin ($S = 3/2$) cobalt(II) species with a large zero-field splitting ($D >> h\nu$). The EPR spectrum of **3** is shown in Figure 7.

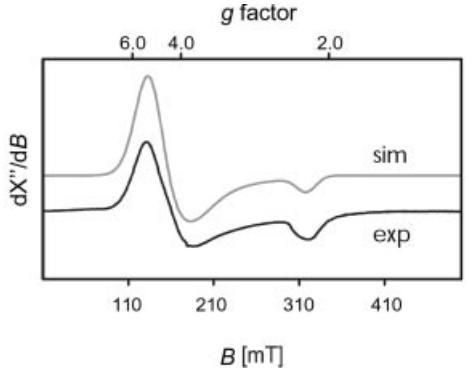

Figure 7. Experimental and simulated X-band EPR spectrum of **3**; experimental spectra in acetone/MeOH (2:3) at 6 K, 9.64 GHz. (attn. 55 dB, mod. 10 G)

Complex **3** reveals a nearly axial spectrum with no resolved hyperfine couplings, whereas the spectrum of **7** is rhombic and reveals hyperfine coupling with the cobalt nucleus at one of the *g*-tensors (Co, $I = 7/2$, 102 G). The apparent symmetry from the EPR spectra seems to correlate well with the cobalt coordination environments seen in the X-ray structures. The approximate real g values and *E*/*D* rhombicity factors derived from simulation of the experimental EPR spectra are $g_{11} = 2.17$, $g_{22} = g_{33} = 2.30$, $E/D = 0$ for complex **3** and $g_{11} = 2.03$, $g_{22} = 2.05$, $g_{33} = 2.20$, $E/D = 0.17$ for complex **7**. Apart from establishing the spin-state ($S = 3/2$) and the apparent coordination environment symmetry, these very broad EPR spectra are not very informative.

NMR Analysis

A complete interpretation of the paramagnetic ^1H NMR spectrum of $[(tpa)Co(CH_3CN)]^{2+}$ is presented in the report of Karlin,[9] and this helped us to assign all the peaks in the spectrum of $[(tpa)CoCl]^+$ ($\mathbf{1}^+$) on the basis of peak positions, linewidths and integrals. The signals from pyridine-H3, -H4, and -H5 are distinctly sharper than those of pyridine-H6 and the methylene protons. This seems to be the case for most pyridine-amine cobalt complexes studied here. Because the NMR shifts of [**1**]PF_6 and [**1**]$_2CoCl_4$ are identical, the same trigonal bipyramidal structure is assumed for both. Unfortunately, we did not succeed in growing X-ray quality crystals of [(dpa)$CoCl_2$] (**9**). However, its spectrum shows enough of a similarity to that of $[(tpa)CoCl]^+$ to allow a complete interpretation. For (Me−Bz−dpa)$CoCl_2$ (**7**), however, the extra signals from the benzyl substituent complicate the NMR spectrum too much to allow unambiguous assignments. Also, we observed no signals for the pyridine-H3 and -H5 protons between $\delta = 40$ and 60 ppm, although this is the most consistent feature of our NMR spectra. Since paramagnetic spectra are very sensitive to the environment at the metal centre, the large differences between the spectra of **7** and **9** may mean that these complexes do not have the same geometry. One possibility would be a switch to *fac* coordination of the dpa ligand in **9**. This would be inconsistent with the *decreased* tendency towards folding of bpc over Me-bpc discussed earlier. However, the two dpa complexes of Co that have been structurally characterised both have *fac*-coordinated dpa ligands.[21]

The ^1H NMR spectrum of [(bpc)$CoCl_2$] (**5**) could not be fully assigned, because all signals (apart from the NH) have approximately the same intensity and no distinct pattern could be discovered. The number of signals, however, agrees with the symmetrical structure observed in the solid state. [(Me-bpc)$CoCl_2$] (**6**) was never obtained as a single compound. A mixture of two products in a ratio of 10:6 or 10:4 was formed in the reaction of the ligand with $CoCl_2$ in CH_2Cl_2 and CH_3CN, respectively. ^1H NMR spectroscopy shows that *both* products produce twelve paramagnetic signals, the number expected for a symmetrically coordinated ligand (i.e. N4 or N2/N2, but *not* N3/N). Slow evaporation of an NMR sample resulted in crystallisation of one of the

products. This is probably the major product of the reaction, because both the crystal structure and the NMR spectrum resemble those of **5**, while the spectrum of the minor product shows no obvious similarities to that of **5**. Since the minor product also has a symmetrical ligand, one possibility would be the N4 structure, although this seems unlikely given that Co^{II} should have an even larger aversion to this arrangement than Co^{III}. Another possibility is that it is a cationic five-coordinate complex like $[(tpa)CoCl]^+$. A distinction between these two possibilities cannot be made at this stage. We were not able to obtain a ^{13}C NMR spectrum for any of the paramagnetic complexes.

Ethene Polymerisation

All the complexes except **8** were tested for polymerisation activity by treating them with 100 equivalents of MAO in chlorobenzene under an ethene atmosphere (7 and 35 bar). Most complexes did not exhibit any polymerisation activity at all, but pyp complexes **3** and **4** produced some polymer. The *tert*-butyl-substituted complex was particularly interesting as it remained active for a very long time (35 hours), resulting in an activity of 70 $g \cdot mol^{-1} \cdot h^{-1} \cdot bar^{-1}$. This is a factor of 7000 less than the reported cobalt-dip system under optimised conditions.[3a,3b] GPC analysis of the polymer formed at 35 bar showed that, besides a small amount of high molecular weight polyethene, the bulk of the "polymer" had a molecular weight of approximately 1000. It was difficult to optimise the pyp system because the complex seemed to decompose when a fresh batch of MAO was used for the polymerisation experiments.

It has been suggested that the dip-cobalt and -iron complexes used by Brookhart and Gibson polymerise ethene to high molecular weight polyethene because the large aryl substituents prevent associative displacement of the growing polymer chain. $[(Me\text{-}Bz\text{-}dpa)CoCl_2]$ (**7**) has nearly the same cobalt environment as precatalyst **8**, but lacks the steric bulk above and below the active site on cobalt. Indeed, **7** is not active in ethene polymerisation (nor is **9**). If this were caused by rapid chain transfer, formation of dimers would be expected. The fact that no ethene consumption was observed indicates that the lack of steric bulk is not the only obstruction for the reactivity of our N_3 complexes. Rather, it seems likely that the electronic properties of the ligand are also important. For example, $[(dip)CoCl_2]$ is apparently activated by reduction to a low-spin Co^{I} species, although the nature of the actual active species is still unclear.[22] Our pyridine-amine ligands are much weaker π-acceptors than dip ligands and are unlikely to stabilize the Co^{I} oxidation state, let alone induce the switch to a low-spin configuration. The main problem here is could be the *formation* of the active species, rather than the activity it would have once formed.

Conclusions

Analytically pure paramagnetic cobalt(II) complexes were easily synthesised by the reaction of $Co^{II}Cl_2$ with the appropriate N_3 or N_4 ligand. Most complexes are air-stable for at least a couple of days. Different modes of coordination became apparent from the obtained crystal structures. These were correlated with the ^1H NMR spectra of the complexes and helped in their interpretation. Variation of the solvent in the NMR experiments was informative for the behaviour in solution of the pyp complexes. The pyp ligands seemed to promote six-coordination, since even when a chloride dissociates in solution, a solvent molecule occupies the free coordination site. In contrast, tpa appears to favour five-coordination. The bpc complexes **5** and **6** are both six-coordinate in the solid state, but for **6** formation of a five-coordinate complex in solution cannot be excluded. Only two of the pyridine/amine complexes prepared (**3** and **4**) showed (low) activity in ethene polymerisation.

Experimental Section

General: All procedures were carried out under N_2 using standard Schlenk techniques unless specified otherwise. Acetonitrile, THF, dichloromethane and diethyl ether were distilled under nitrogen. Ethanol and methanol were deoxygenated by bubbling a stream of N_2 through the solvent for 15 minutes. For the synthesis of **5** and **6**, $CoCl_2 \cdot 6H_2O$ was dried for 4 hours at 150 °C before use. Ligands were prepared according to literature procedures.[8] All other chemicals are commercially available and were used without further purification. NMR measurements were performed on Bruker DPX200, AMX400, and AMX500 spectrometers. X-band EPR spectra were recorded on a Bruker ER 220 spectrometer. Samples were measured in acetone/MeOH (2:3) at 6−10 K. Simulations were performed with the program WEPR (F. Neese, University of Konstanz). Chemical shifts are listed in ppm with TMS as external reference (δ = 0 ppm). NMR signals for the NH protons of paramagnetic complexes were never observed. FAB^+- and ESI^+-MS spectra were recorded on a Finnigan MAT 900XL instrument.

$[(tpa)CoCl]_2[CoCl_4]$ ($[1]_2[CoCl_4]$): $CoCl_2 \cdot 6H_2O$ (205 mg, 0.86 mmol) was added to a solution of tpa (248 mg, 0.86 mmol; 1.0 equiv.) in 20 mL of ethanol. A blue solid precipitated almost immediately. After stirring for 1 hour at room temperature, the mixture was filtered. The solid was washed with diethyl ether and dried in vacuo; yield 0.19 g (66%). Crystals suitable for X-ray diffraction were grown by vapour diffusion of THF into a saturated acetonitrile solution. The blue product is air-stable as a solid and in solution. $C_{36}H_{36}Cl_6Co_3N_8$ (970.25): calcd C 44.56, H 3.74, N 11.55; found C 44.41, H 3.79, N 11.47. ^1H NMR (200 MHz, 298 K, ppm) CD_3OD: δ = 130.1 (3 H, py-*H6*), 108.0 (6 H, NCH_2), 58.2 (3 H, py-*H5*), 49.2 (3 H, py-*H3*), −1.7 (3 H, py-*H4*). CD_3CN: δ = 134.3 (3 H, py-*H6*), 107.3 (6 H, NCH_2), 60.8 (3 H, py-*H5*), 46.2 (3 H, py-*H3*), −3.5 (3 H, py-*H4*). FAB-MS: *m/z* = 803 $[(tpa)_2Co_2Cl_3]^+$, 384 $[M]^+$, 349 $[M - Cl]^+$, 291 $[M - CH_3Py]^+$, 256 $[M - Cl, - CH_3Py]^+$. ESI-MS: *m/z* = 384 $[M]^+$, 349 $[M - Cl]^+$.

$[(tpa)CoCl]PF_6$ ($[1]PF_6$): $CoCl_2 \cdot 6H_2O$ (330 mg, 1.39 mmol) was added to a solution of tpa (424 mg, 1.46 mmol; 1.05 equiv) in 25 mL of methanol. After addition of NH_4PF_6 (1.2 g, 7.2 mmol, 5.2 equiv.) a green microcrystalline solid precipitated. This solid was filtered off, washed three times with diethyl ether and dried under vacuum; yield 676 mg (92%). The product is air-stable as a solid and in solution. $C_{18}H_{18}ClCoF_6N_4P$ (529.72): calcd C 40.81, H 3.43, N 10.58; found C 40.64, H 3.42, N 10.44. ^1H NMR (200 MHz, 298 K, ppm): CD_3OD δ = 129.8 (3 H, py-*H6*), 107.6 (6 H, NCH_2),

57.91 (3 H, py-*H5*), 49.1 (3 H, py-*H3*), −1.44 (3 H, py-*H4*). CD_3CN: δ = 134.4 (3 H, py-*H6*), 107.1 (6 H, NCH_2), 60.8 (3 H, py-*H5*), 46.2 (3 H, py-*H3*), −3.6 (3 H, py-*H4*).

[(*t*Bu-pyp)$CoCl_2$] (3):[5d] $CoCl_2·6H_2O$ (172 mg, 0.72 mmol) was added to a warm solution (40 °C) of *t*Bu-pyp (256 mg, 0.72 mmol; 1.00 equiv.) in 35 mL of THF. After refluxing for 30 min a light-blue solid precipitated. The mixture was cooled to room temperature and filtered. The residue was washed twice with small portions of THF and dried under vacuum; yield 275 mg (79%). $C_{22}H_{32}Cl_2CoN_4$ (483.26): calcd C 54.78, H 6.69, N 11.62; found C 54.66, H 7.78, N 11.55. ^{1}H NMR (200 MHz, 298 K, ppm) CD_2Cl_2: δ = 81.4 (4 H, py-*H3*), 26.2 (2 H, py-*H4*), 3.1 (?), −9.4 (4 H, NCH_2), −35.8 (4 H, NCH_2), −43.5, −76.3 (*t*Bu?). CD_3OD: δ = 73.8 (4 H, py-*H3*), 28.3 (4 H, NCH_2), 18.8 (2 H, py-*H4*), −4.7 (4 H, NCH_2), −38.6 (*t*Bu). FAB-MS: *m*/*z* = 446 [M − Cl]$^+$, 411 [M − 2Cl]$^+$, 353 [M − 2Cl, − *t*BuH]$^+$.

[(Me-pyp)$CoCl_2$]·H_2O (4·H_2O): This compound was synthesised according to a literature procedure.[5a] ^{1}H NMR (200 MHz, 298 K, ppm) CD_2Cl_2: δ = 48.0 (4 H, NCH_2), 46.4 (4 H, py-*H3*), 24.0 (6 H, NCH_3), 14.2 (4 H, NCH_2), 7.2 (2 H, py-*H4*). CD_3OD: δ = 117.7 (6 H, NCH_3), 88.8 (4 H, NCH_2), 46.9 (4 H, py-*H3*), 31.5 (4 H, NCH_2).

[(bpc)$CoCl_2$] (5): A solution of dried $CoCl_2$ (106 mg, 0.82 mmol) in 10 mL of CH_3CN was added to a solution of bpc (239 mg, 0.81 mmol; 0.99 equiv.) in 7 mL of CH_3CN. The mixture immediately turned bright red. Evaporation of the solvent yielded a bright pink compound, which was washed twice with THF and dried under vacuum; yield 237 mg (68%). Single crystals suitable for X-ray diffraction were grown from a saturated CD_3CN solution. The product is highly air-sensitive as a solid and in solution. ^{1}H NMR (200 MHz, CD_3CN, 298 K, ppm): δ = 195.1 (2 H), 88.9 (2 H), 52.4 (2 H), 26.0 (2 H), 22.0 (4 H), 16.2 (2 H), 9.2 (2 H), 5.6 (2 H), 4.2 (2 H), 0.4 (2 H).

[(Me-bpc)$CoCl_2$] (6): Dried $CoCl_2$ (115 mg, 0.88 mmol) was added to a solution of Me-bpc (296 mg, 0.91 mmol; 1.03 equiv.) in 12 mL of CH_3CN. A purple solid precipitated immediately. After 2 hours the mixture was filtered and the dark pink residue was dried in vacuo; yield 244 mg (61%). Additional product precipitated from the mother liquor on standing at −20 °C. Crystals suitable for X-ray diffraction were obtained by slow evaporation of a CD_2Cl_2 solution. The product is air-stable as a solid and in solution, although it is very poorly soluble in most organic solvents. $C_{20}H_{28}Cl_2CoN_4$ (454.31): calcd C 52.88, H 6.21, N 12.33; found C 51.66, H 6.22, N 12.00. ^{1}H NMR (500 MHz, CD_2Cl_2, 298 K, ppm): δ = 164.9 (2H), 104.3 (2H), 102.6 (1.2 H), 89.4 (1.2 H), 83.0 (3.6 H, NCH_3), 61.1 (6 H, NCH_3), 51.8 (2 H), 47.5 (1.2 H), 29.7 (1.2 H), 24.7 (1.2 H), 24.4 (1.2 H), 23.9 (2H), 21.8 (0.8 H), 21.1 (2 H), 20.5 (2 H), 18.6 (2 H), 17.4 (1.2 H), 15.9 (1.2 H), 9.3 (1.2 H), 8.1 (2 H), 6.6 (2 H), 5.8 (2 H), 3.3 (1.2 H), −16.93 (2 H). FAB-MS: *m*/*z* = 418 [M − Cl]$^+$, 383 [M − 2Cl]$^+$.

[(Me-Bz-dpa)$CoCl_2$] (7): A solution of $CoCl_2·6H_2O$ (88 mg, 0.37 mmol) in 10 mL of acetonitrile was added to a solution of Me-Bz-dpa (111 mg, 0.35 mmol; 0.95 equiv.) in 5 mL of acetonitrile. The colour of the mixture immediately changed to blue/purple. After stirring for 7 hours at room temperature the volume was reduced by half under reduced pressure and a purple precipitate formed. The solid was collected by filtration, washed three times with diethyl ether and dried under vacuum; yield 85 mg (54%). The purple product is air-stable as a solid and in solution. Crystals of **7** suitable for X-ray diffraction were obtained by slow evaporation of an acetonitrile solution. **7**·CH_3CN, $C_{23}H_{26}Cl_2CoN_4$ (488.32): calcd C 56.57, H 5.37, N 11.47; found C 56.48, H 5.32, N 11.41. ^{1}H NMR (200 MHz, CD_3CN, 298 K, ppm): δ = 152.0 (2 H), 28.0 (2H), 15.6 (2 H), 14.6 (2 H), 14.2 (2 H), 12.1 (2 H), 7.7 (1 H, bz-*p*), −12.0 (2 H), −61.1 (6 H, py-CH_3). FAB-MS: *m*/*z* = 446 [M]$^+$, 411 [M − Cl]$^+$.

[(Me-dip)$CoCl_2$] (8):[3a] Me-dip (564 mg, 1.53 mmol) and $CoCl_2·6H_2O$ (363 mg, 1.53 mmol, 1.00 equiv.) were dissolved in 40 mL of THF. A colour change could be observed almost immediately and a green solid precipitated. After stirring for an additional hour at room temperature, this solid was filtered off, washed with THF (2×) and hexane (2×), and recrystallised from a layered methanol/hexane (1:1) solution, giving 266 mg (0.53 mmol, 35%) of the product as green air-stable crystals. ^{1}H NMR (200 MHz, 298 K, ppm) CD_2Cl_2: δ = 112.0 (2 H, py-*H3*), 36.1 (1 H, py-*H4*), 6.1 (4 H, Ar-*Hm*), −1.2 (6 H, N=C*Me*), −12.1 (2 H, Ar-*Hp*), −28.2 (12 H, Ar-*Me*). CD_3OD: δ = 111.9 (2 H, py-*H3*), 36.2 (1 H, py-*H4*), 6.2 (4 H, Ar-*Hm*), −1.1 (6 H, N=C*Me*), −12.0 (2 H, Ar-*Hp*), −28.1 (12 H, Ar-*Me*). FAB-MS: *m*/*z* = 463 [M − Cl]$^+$.

[(dpa)$CoCl_2$] (9): A solution of $CoCl_2·6H_2O$ (136 mg, 0.57 mmol) in 5 mL of ethanol was added to a solution of dpa (102 mg, 0.52 mmol; 0.91 equiv.) in 5 mL of ethanol. The colour of the mixture changed from light purple to dark-blue after stirring for 5 minutes at room temperature. After stirring for 16 hours at room temperature, the product was precipitated by adding diethyl ether. The mixture was filtered and the residue washed with diethyl ether and dried in vacuo; yield 73 mg (42%). The purple product is air-stable as a solid, however it decomposed in solution after being exposed to air for one day. ^{1}H NMR (200 MHz, 298 K, ppm) CD_3CN: δ = 126.1 (2 H, py-*H6*), 120.8 (2 H, NCH_2), 113.5 (2 H, NCH_2), 55.9 (2 H, py-*H5*), 44.0 (2 H, py-*H3*), −1.1 (2 H, py-*H4*). CD_2Cl_2: δ = 127.0 (2 H, py-*H6*), 113.6 (2 H, NCH_2), 110.3 (2 H, NCH_2), 55.7 (2 H, py-*H5*), 44.6 (2 H, py-*H3*), −0.80 (2 H, py-*H4*). $CDCl_3$: δ = 126.4 (2 H, py-*H6*), 112.9 (4 H, NCH_2), 55.1 (2 H, py-*H5*), 45.2 (2 H, py-*H3*), −0.7 (2 H, py-*H4*). FAB-MS: *m*/*z* = 293 [M − Cl]$^+$, 258 [M − 2Cl]$^+$.

Polymerisation Experiments: Chlorobenzene was distilled from a small amount of sodium. MAO was purchased as a solution in toluene (4.96% Al) and used as such. Polymerisation reactions under 7 bar of ethene were performed in a glass autoclave; reactions under 35 bar of ethene were done in a steel vessel (Hastelloy C).

A suspension of 33 μmol of the precatalyst in 10 mL of chlorobenzene was transferred under nitrogen into a 100 mL autoclave. Under nitrogen-flow 2 mL of MAO (100 equiv.) was transferred into a steel tube connected to the top of the pressure vessel. The complete system was put under ethylene pressure (7 or 35 bar), the MAO was added to the reaction mixture and the autoclave was closed. When ethylene consumption had stopped, or after about 6 hours if no reaction was observed, the autoclave was opened and the reaction mixture was neutralised by adding a mixture of methanol and aqueous HCl (5:1). The mixture was filtered and the polyethylene − if formed − was washed several times with methanol and dried under vacuum.

X-ray Structure Determinations: Single crystals were mounted in air on glass fibres. Intensity data were collected at room temperature on an Enraf−Nonius CAD4 diffractometer. Unit cell dimensions were determined from the angular setting of a limited number of reference reflections. Intensity data were corrected for Lorentz and polarisation effects, and for absorption using a semi-empirical ψ-scan correction.[23] Structures were solved by the program system DIRDIF[24] using the program PATTY[25] to locate all non-hydrogen atoms and refined with standard methods (refinement against

F^2 of all reflections) using SHELXL-97.[26] All non-hydrogen atoms were refined anisotropically; hydrogens were placed at calculated positions and refined isotropically in a riding mode, unless otherwise noted. Geometrical calculations (PLATON[27]) revealed neither unusual geometric features, nor unusual short intermolecular contacts, no higher symmetry and no (further) solvent-accessible areas. Details of the data collection and structure determinations are collected in Table 1.

CCDC-186122−186127 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Notes on Individual Structures

[1]$_2$[CoCl$_4$]: One molecule of water and one molecule of acetonitrile were located and refined (hydrogen atoms for the water molecule were not included in the refinement). Hydrogen atoms were placed at calculated positions and were subsequently refined freely. Some anisotropic thermal displacement parameters showed physically unacceptable values when determined using default least-squares refinement parameters. The SQUEEZE procedure[27] was used to account for the residual electron density in a solvent area of 50 Å^3, resulting in a total electron count for this void of 44 electrons in the unit cell. This electron density should probably also be attributed to water molecules. Next the DIFABS procedure[28] was used, lowering the anisotropic *R*-value from 8.3% to 7.9%, resulting in considerably improved anisotropic thermal displacement parameters. The DELU and SIMU options still had to be applied to all atoms, however, and the ISOR option specifically to N2A, C51A, C55A, C62A, C51B, C65B, C72B, C76B, and O1.

5: One molecule of acetonitrile was located and refined. The refinement was hampered by the severe deterioration of the crystal during the data collection. A correction of almost 50% for crystal decay was necessary during the data reduction process.

6: One molecule of water was located and refined; hydrogen atoms for this water molecule were not included in the refinement. Based solely on donor-acceptor distances hydrogen bonds could probably be formed between O1 and Cl1 and between O1 and Cl2.

[a] Excluding contents of a "void" of 165 Å^3; see text for details.

7: One molecule of acetonitrile was located and refined. Hydrogen atoms were refined freely.

8: Calculations[27] showed a void of 165 Å^3, containing 32 electrons, resulting in a large volume of about 35 Å^3 per atom. Hexane and methanol were used in the synthetic route but no reasonable guess could be made about the nature of the solvent moiety or moieties present, nor was it possible to assign any physically meaningful parameters to the electron density. Therefore the SQUEEZE procedure was applied to account for this electron density. As a consequence this electron density could not be taken into account while calculating the physical·molecular properties as given in Table 1.

Reactions of *cis*-2,3-Dimethylaziridine, 3-Pyrroline and Pyrrolidine with Me_3Al and Me_3Ga: Adducts and Dimeric Amides

Yuankui Zhang,[a,c] Peter H. M. Budzelaar,[a] Jan M. M. Smits,[a] René de Gelder,[a] Paul R. Hageman,[b] and Anton W. Gal*[a]

Keywords: Aluminium / Chemical vapour deposition / Gallium / Nitrides

The reactions of Me_3Al and Me_3Ga with *cis*-2,3-dimethylaziridine (**1**-H), 3-pyrroline (**2**-H) and pyrrolidine (**3**-H) have been investigated. At room temperature, monomeric adducts [Me_3M·LH] are obtained (M = Al, Ga; L = **1**–**3**). [Me_3Al·**1**-H] is the first example of a structurally characterized adduct of an aziridine and a group 13 metal. On heating in mesitylene, all adducts except [Me_3Ga·**2**-H] evolve methane to form the corresponding amides; the Ga complexes require somewhat higher temperatures for this reaction. In contrast to the unsubstituted aziridine derivatives (which are *trimers*), dimethylaziridine amides Me_2M-**1** are *dimers*, as shown by X-ray crystallography. NMR spectroscopic data suggest the occurrence of a *cis*-*trans* equilibrium for these dimers in solution. For the pyrroline and pyrrolidine derivatives, the X-ray structures suggested large changes in the C–C and C–N bond lengths on formation of the adducts and amides. However, DFT calculations reveal that these changes are artefacts, and that the real bond length changes are fairly modest.

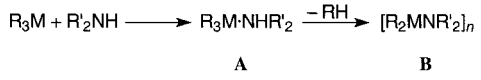
Introduction

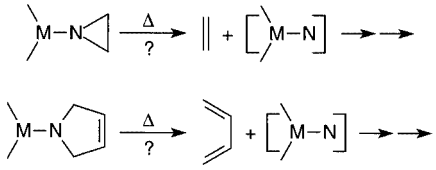
Compounds containing both a group 13 (Al, Ga) atom and nitrogen are of considerable interest, owing to their potential use as single-source precursors for the fabrication of aluminium/gallium nitrides. Two common types of single-source precursors are trialkylmetal−amine adducts **A** and their alkane elimination products **B**. A drawback of adducts **A** is that they dissociate relatively easily into their trialkylmetal and amine components. Amides **B** do not suffer from this problem, but they are invariably associated (into dimers or higher) and thus have a reduced volatility (Scheme 1).



Scheme 1

Despite these disadvantages, both types of compounds have been studied for their potential as MOCVD precursors. Aluminium amides and imides have been studied extensively,[1] and several Me_3Al−secondary amine adducts have been reported.[2] Gallium amides have been synthesized by hydrocarbon or salt elimination reactions[3] or by other means.[4] Several metallacyclic aluminium and gallium nitrogen compounds have also been reported.[5]

We were interested in preparing aluminium/gallium adducts or amides in which the amide could easily lose its hydrocarbon fragment through some kind of elimination reaction, potentially providing lower decomposition temperatures and/or reduced carbon contamination of the nitride formed. We chose the aziridinyl and 3-pyrrolinyl fragments, which should easily eliminate an alkene or a diene, respectively, as represented schematically in Scheme 2.



Scheme 2

Amides derived from the parent aziridine and Me_3Al[5b] and GaH_3 [23] have been reported. These have trimeric structures, however, and hence a vapour pressure too low for convenient MOCVD usage. We have studied the reactions of Me_3Al and Me_3Ga with *cis*-2,3-dimethylaziridine **1**-H, in the hope of obtaining more volatile amides. No Al

or Ga derivatives of 3-pyrroline (**2**-H) have yet been reported. Derivatives of the (presumably more stable) pyrrolidine (**3**-H) have been included here for comparison. Since **2**-H is expensive and the synthesis of the pure compound is cumbersome, we have also used a commercially available mixture of **2**-H and **3**-H (Scheme 3).

Scheme 3

Results and Discussion

Aziridine Adducts [Me_3M·1-H]

Treatment of Me_3M (M = Al, Ga) with dimethylaziridine in mesitylene at room temperature cleanly afforded the 1:1 Lewis acid-base adducts [Me_3M·**1**-H]. No further reaction to afford the amides occurred under these conditions. This is somewhat surprising, since Stucky reported that the reaction between Me_3Al and unsubstituted aziridine produced the amide $[Me_2AlNC_2H_4]_3$ directly, without formation of a detectable adduct ("solvated intermediate").[5b] Also, Trotter described the formation of $[H_2GaNC_2H_4]_3$ from GaH_3·NMe_3 and aziridine at room temperature, again without a detectable intermediate.[23] In our case, considerable heating (95 °C for Al, 155 °C for Ga) was required to induce methane elimination. It may be that the methyl substituents on the aziridine ring reduce its reactivity: in the adduct (see below), the amine proton is *cis* to the aziridine methyls, and is thus shielded by these groups as well as the bulky Me_3Al moiety. Another explanation might be that elimination is slower in the mesitylene solvent we use than in the neat aziridine employed by Stucky and Trotter.

As far as we are aware, [Me_3Al·**1**-H] is the first structurally characterized adduct of an aziridine with a group 13 metal (Al−Tl). Figure 1 shows the structure of the complex. The Me_3Al group is located *trans* to the aziridine methyl groups. The C−N ring bonds [1.493(3) Å av] appear to be slightly elongated with respect to those observed for unsubstituted aziridine [1.467(3) av.][15] and *cis*-2-methyl-3-phenylaziridine (1.475 av., no errors given),[16] whereas the differences in C−C bond lengths are small [1.472(2) vs. 1.462(3) and 1.486, respectively]. The most notable changes in the ^1H NMR spectrum on formation of the adduct are a low-field shift of the NH proton ($\Delta\delta$ = 0.33 ppm) and a high-field shift of the aziridine methyl groups ($\Delta\delta$ = −0.64 ppm).

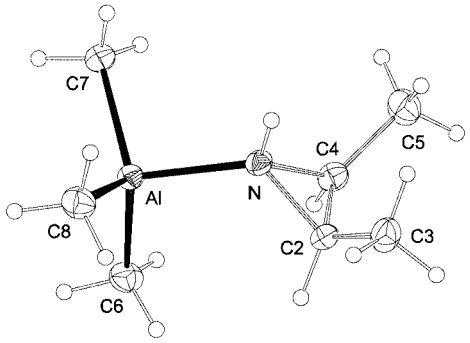

Figure 1. Molecular structure and atom numbering scheme for [Me_3Al·**1**-H]; selected bond lengths (Å): Al−C6 1.975(2), Al−C7 1.981(2), Al−C8 1.976(2), Al−N 1.977(2), N−C4 1.490(3), N−C2 1.495(2), C2−C4 1.472(3)

Aziridine Amides [Me_2M·**1**]$_2$

On heating in solution, the Al and Ga adducts both eliminate methane to give [Me_2Al·**1**]$_2$ and [Me_2Ga·**1**]$_2$, respectively. The amides, which are isostructural, crystallize as centrosymmetric dimers with a planar M_2N_2 ring; the aziridinyl and MMe_2 planes are nearly perpendicular to the M_2N_2 plane. Figure 2 shows the structure of the Al derivative. The bond lengths within the aziridinyl groups are virtually indistinguishable from those of adduct [Me_3Al·**1**-H]. These dimeric structures should be contrasted with the *trimeric* structures of the unsubstituted aziridinyl derivatives reported by Stucky,[5b] Trotter[23] and Müller,[5c] in which the six-membered M_3N_3 rings are markedly twisted. It seems likely that the added bulk of the methyl substituents in **1** is responsible for the lower degree of association, as it would result in steric hindrance between these methyl groups and the MMe_2 unit *cis* to it in any trimeric ring structure. Indeed, increased steric hindrance at aluminium instead of at the aziridine also results in the formation of dimers, as illustrated by the structure of $[(BH_4)_2AlNC_2H_4]_2$.[17]

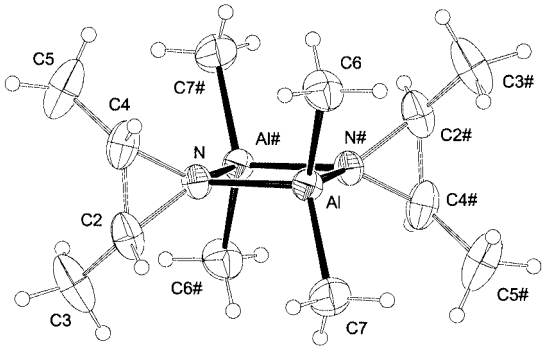

Figure 2. Molecular structure and atom numbering scheme for [Me_2Al-**1**]$_2$; selected bond lengths (Å): Al−C6 1.951(2), Al−C7 1.951(2), Al−N 1.938(2), Al−N# 1.929(2), N1−C4 1.489(2), N−C2 1.493(3), C2−C4 1.467(4); for the isostructural Ga complex: Ga−C6 1.955(8), Ga−C7 1.953(7), Ga−N 1.986(6), Ga−N# 2.000(5), N−C2 1.48(1), N−C4 1.49(1), C2−C4 1.47(1); # indicates symmetry-related atoms (−*x*, 1−*y*, 1−*z*)

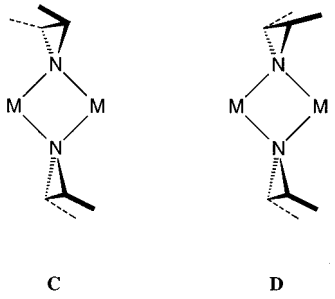
In the solid state, both amides have a *trans* arrangement of the aziridine moieties (structure **C**). In solution, we see two sets of signals for the aziridine CH and CH_3 groups in a roughly 1:1 ratio; this is particularly clear in the ^{13}C spectra [the CH_3(M) signals are broad and do not show a clear splitting]. This might indicate a dimer−trimer equilibrium, but in view of the concentration independence of this phe-

nomenon a more logical explanation would be a *cis-trans* equilibrium (e.g. **C** ⇄ **D**), apparently slow on the NMR timescale (Scheme 4).



Scheme 4

Pyrroline and Pyrrolidine Adducts, [Me_3M·2-H] and [Me_3M·3-H]

Treatment of Me_3M with **2**-H and **3**-H at room temperature in toluene afforded the 1:1 Lewis acid-base adducts [Me_3M·**2**-H] and [Me_3M·**3**-H]. No further reaction to afford the amides occurred under these conditions. A peak due to the NH group was observed in each ^1H NMR spectrum. Compared with those of free **2**-H and Me_3Al, the most notable changes in the ^1H NMR spectrum on formation of the adduct are a low-field shift of the NH proton ($\Delta\delta = 0.90$ ppm) and a high-field shift of the methyl groups of Me_3Al ($\Delta\delta = -0.17$ ppm). If a 2:1 mixture of **2-H** and **3**-H is used, the two adducts co-crystallize in approximately the same ratio as was present in solution. The crystal structures both of pure [Me_3Al·**2**-H] and of the [Me_3Al·**2-H**]/[Me_3Al·**3**-H] mixture were determined, and show only minor differences in bond lengths. Remarkably, pure [Me_3Al·**3**-H] and [Me_3Ga·**3**-H] crystallize in space groups different from those found for [Me_3Al·**2**-H] and the co-crystal. However, the molecular conformations are fairly similar for all these compounds. Figure 3 shows the structures of [Me_3Al·**2**-H] and [Me_3Al·**3**-H]. [Me_3Al·**3**-H] has been prepared before, by Krannich.[2a]

Pyrroline and Pyrrolidine Amides, [Me_2M-2]$_2$ and [Me_2M-3]$_2$

On heating in solution, the pyrroline and pyrrolidine adducts eliminate methane to give dimeric amides. Pyrroline appears to be a bit more reactive, and the Ga compounds require heating to higher temperatures than the Al compounds. Complex [Me_2Ga-**2**]$_2$ could not be prepared in this way, because disproportionation of the 3-pyrroline (to pyrrole, pyrrolidine and possibly 2-pyrroline) occurred at the temperature required for reaction. The other amides crystallize as dimers with planar or near-planar M_2N_2 rings, as shown in Figure 4 for [Me_2Al-**2**]$_2$ and in Figure 5 for [Me_2Ga-**3**]$_2$.

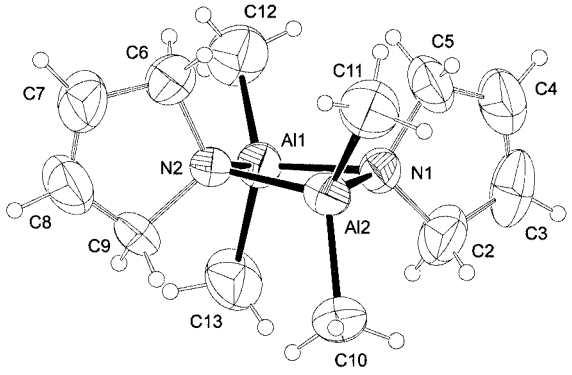


Figure 4. Structure of [Me_2Al-**2**]$_2$; selected bond lengths (Å): Al1−C12 1.94(2), Al1−C13 2.00(1), Al1−N1 1.98(1), Al1−N2 1.92(1), Al2−C10 1.93(1), Al2−C11 1.98(2), Al2−N1 1.94(1), Al2−N2 1.94(1), N1−C2 1.46(2), N1−C5 1.51(2), C3−C4 1.33(2), N2−C6 1.50(1), N2−C9 1.52(1), C7−C8 1.27(2)

Bond Length Changes Associated with Adduct and Amide Formation

The availability of several X-ray structures of adducts and amides makes it tempting to evaluate the bond length changes accompanying formation of these adducts and amides. One should, however, be careful in doing this for two reasons:

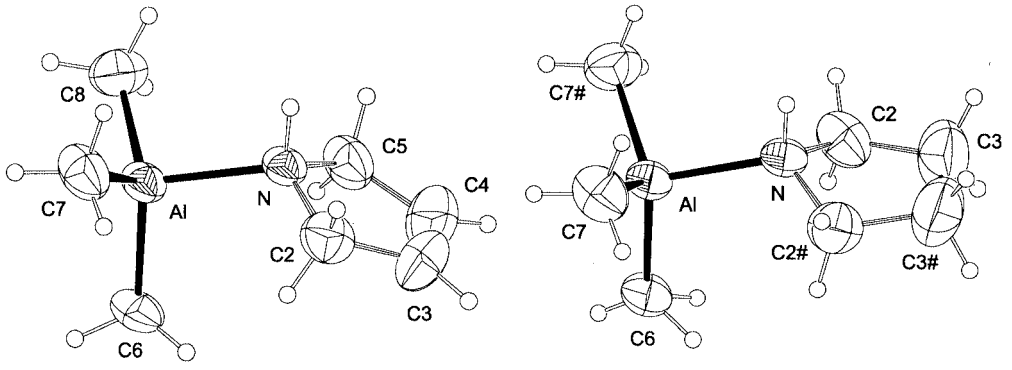

Figure 3. Structures of [Me_3Al·**2**-H] (left) and [Me_3Al·**3**-H] (right); selected bond lengths (Å) for [Me_3Al·**2**-H]: Al−C6 1.984(3), Al−C7 1.966(5), Al−C8 1.963(4), Al−N 1.999(3), N−C2 1.485(5), N−C5 1.495(5), C3−C4 1.264(8); for [Me_3Al·**3**-H]: Al−C6 1.977(4), Al−C7 1.967(3), Al−N 1.997(3), N−C2 1.468(4), C3−C3# 1.48(1) where # indicates symmetry−related atoms (x, 1/2−y, z); for [Me_3Ga·**3**-H] (refined in $P21$, i.e. not isostructural with [Me_3Al·**3**-H]): Ga−C6 2.00(1), Ga−C7 2.07(4), Ga−C8 1.91(4), Ga−N 2.11(1), N−C2 1.57(5), N−C5 1.38(5), C3−C4 1.53(3)

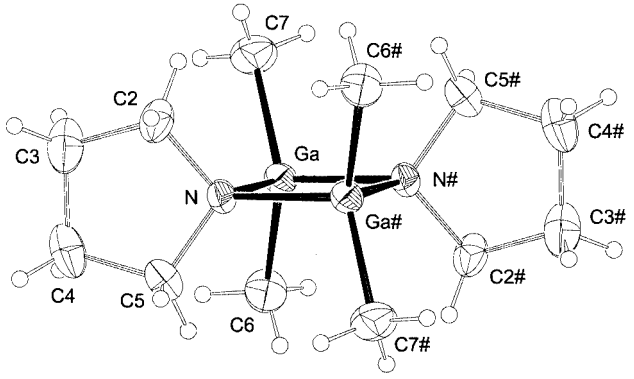

Figure 5. Structure of $[Me_2Ga\text{-}\mathbf{3}]_2$; selected bond lengths (Å): Ga−C7 1.969(6), Ga−C6 1.978(7), Ga−N# 2.017(5), Ga−N 2.028(5), N−C5 1.468(8), N−C2 1.482(7), C3−C4 1.512(12)

1. Bond length changes would be expected to be of the order of a few hundredths of an Å (i.e., not much larger than the error margins of X-ray structure determinations).
2. Many structures probably suffer from nonresolvable disorder problems, as we show further on. We find that the C−C and C−N bond lengths both of pyrrolines and of pyrrolidines often refine to unrealistically small values (see below). It is not clear a priori how strongly the other bond lengths in the molecule will be affected by such disorder problems.

To address these issues, we carried out geometry optimizations at the B3LYP/6-31G* level for all relevant Al species. The advantage of such theoretical results is that the *random* errors in bond lengths are much smaller (typically ≈ 0.001 Å) than found in X-ray structures. There are still significant *systematic* errors, but these should not strongly affect the bond length *changes* we are interested in. We first discuss the theoretical results (Table 1) and then compare them to the X-ray data (Table 2, Table 3).

For pyrrolidines and pyrrolines, complexation to $AlMe_3$ results in an elongation of the C−N bonds by about 0.02−0.03 Å. The adjacent C−C bonds are shortened by a much smaller amount (ca. 0.01 Å), and the distal C−C bond is not affected significantly. The same effects can be observed in the dimeric amides, and are even more pronounced there. For aziridine and dimethylaziridine, we find much smaller changes in the C−N and C−C bond lengths (≈ 0.01 Å at most). We tentatively interpret this as follows. The changes in C−N bond lengths for pyrrolidine and pyrroline derivatives are due to the changes in hybridization of the nitrogen atom, which becomes closer to sp^3 and hence uses a larger *p*-contribution for the C−N bonds. For the aziridines, however, the composition of the N hybrids used for forming the C−N bonds is nearly "fixed" by the small

CNC angle, so adduct or amide formation have little effect there. In agreement with this interpretation, the Al−C bonds of Me_3Al become longer on adduct formation by about 0.023 Å, *independent* of the nature of the amine.

To compare experimentally determined and calculated bond length changes, we need accurate reference bond lengths for our ligands. The structure of aziridine has been determined accurately.[18] For pyrroline, however, the only crystallographic data available is for two derivatives containing π-acceptor substituents at nitrogen.[19] The only available "non-disordered" X-ray structure for pyrrolidine available to date concerns a molecule intercalated in an aluminophosphate.[20] Relevant data are collected in Table 2. For pyrroline and in particular for pyrrolidine, the reported Cβ−Cβ bond lengths are too short. This indicates that these reference structures are already affected by some kind of disorder, which − in particular for the pyrrolidine intercalate − is unsurprising. Therefore, use of these reference bond lengths to assess bond length changes expected to be only a few hundredth of an Å is probably useless.

If we now compare the calculated and observed bond lengths for the adducts and amides (Table 3), we see that observed ring bond lengths are in general shorter, and in several cases − in particular for pyrrolidines and pyrrolines − *much* shorter. Several differences exceed the X-ray error limits, are larger than expected for any systematic errors in the B3LYP/6-31G* results, and are large enough to indicate unrealistic "observed" bond lengths (i.e., more than about 0.05 Å too short). A large in-plane libration amplitude for the whole ring might contribute for free pyrrolidine, but probably not for the adducts and amides. It thus seems likely that there are unresolved disorder problems in several of the structures.

Pyrrolidine rings are invariably puckered. The calculated puckering amplitudes[21] (Table 4) are consistently larger than the observed ones. This suggests the presence of disorder in the *orientation* of the puckering: any such disorder would result in a more nearly planar ring[22] as well as too short C−C and/or C−N bonds.

Table 4. Ring-puckering amplitudes for pyrroline and pyrrolidine rings

Compound	Ring puckering amplitude
C_4H_6N-NO X-ray[19a]	≈ 0
C_4H_6N-SSCTe(I)(C_4H_8) X-ray[19b]	≈ 0
2-H calcd.	0.156
[Me_3Al·**2**-H] X-ray	0.086
[Me_3Al· **2**-H] calcd.	0.198
[Me_2Al-**2**]$_2$ X-ray	≈0/0.133
[Me_2Al-**2**]$_2$ calcd.	0.226
3-H X-ray[17]	0.290
3-H calcd.	0.429
[Me_3Al·**3**-H] X-ray	0.292
Me_3Ga·**3**-H] X-ray	0.329
[Me_3Al·**3**-H] calcd.	0.367
[Me_2Ga-**3**]$_2$ X-ray	0.398
[***3***$_2$Al***3***]$_2$ X-ray[24]	0.374/0.384
[Me_2Al-**3**]$_2$ calcd.	0.421

Pyrroline rings have a near-planar $CH_2CH{=}CHCH_2$ fragment, but the ring may be folded somewhat along the $CH_2{-}CH_2$ line to produce an envelope-type conformation. Calculations predict that this happens both in free pyrroline and in its adduct and amide. Folding in the X-ray structure of adduct [Me_3Al·**2**-H] is smaller than predicted by calculations; the X-ray structure of amide [Me_2Al-**2**]$_2$ has two inequivalent rings, one of which is planar, while the other is distinctly folded. It seems likely that the potential for folding the ring is very flat, so that the actual structures are to a large degree determined by packing forces. Therefore, disordered structures can also be expected for pyrroline derivatives.

Clearly, in the presence of such disorder problems, little meaning can be attached even to those C−C and C−N bond lengths that look "reasonable". We thus conclude that a comparison of bond length changes on the basis of X-ray structures would be meaningless.

Decomposition Studies

All amides were tested under a variety of flow rates and substrate (Si) temperatures (up to 800 °C) in various configurations of a simplified MOCVD set-up. In several cases, dark-coloured deposits were observed. However, X-ray analysis of these deposits never gave any evidence for the formation of crystalline nitrides. We therefore decided to study the stability of the amides by DSC measurements.

The aziridine amides $[Me_2Al\text{-}\mathbf{1}]_2$ and $[Me_2Ga\text{-}\mathbf{1}]_2$ show an endothermic effect at their melting points (≈ 100 °C), a broad exotherm at 330−430 °C (Al) or 390−450 °C (Ga), and a very sharp endotherm at 450 °C (Al) or 470 °C (Ga). $[Me_2Al\text{-}\mathbf{2}]_2$ shows an endotherm at the melting point (≈ 64 °C) and a weak exotherm at 240−260 °C, followed by a sharp and large endotherm at 275 °C. Neither $[Me_2Al\text{-}\mathbf{3}]_2$ nor $[Me_2Ga\text{-}\mathbf{3}]_2$ show any such sharp endotherms up to the maximum temperature investigated (640 °C); weak effects were seen around 230 °C (ex), 300 °C (ex) and 330 °C (end) for Al, and around 300 °C (ex/end) for Ga. It thus appears that derivatives of **1** and **2** indeed undergo some kind of decomposition at a significantly lower temperature than those of saturated analogue **3**. However, we have not yet ascertained the nature of this decomposition.

Conclusions

The introduction of methyl substituents on aziridine has significant implications for its reaction behaviour with Me_3Al and Me_3Ga. In the first place, amide formation was slowed down so much that the amine *adducts* could be isolated and (for M = Al) crystallized. Secondly, the degree of association of the amides is reduced from 3 to 2, which might increase their volatility enough to allow their usage as MOCVD single-source precursors, although we have not yet been able to grow crystalline nitrides from them. Finally, the presence of the methyl groups allows observation of what are probably the *cis* and *trans* isomers of the amide dimer.

Adducts and amides for pyrroline and pyrrolidine could also be isolated. Comparison of calculated and observed bond lengths in the heterocyclic rings shows that the changes associated with complexation and amide formation are quite modest, and are completely swamped by random errors and hidden disorder in the X-ray structures.

Experimental Section

General Procedures: All manipulations of air- and moisture-sensitive compounds were performed under dry nitrogen by standard glove box and Schlenk techniques. Mesitylene, toluene and hexane were distilled over sodium/benzophenone under an atmosphere of nitrogen prior to use. *cis*-2,3-Dimethylaziridine (**1**-H) was prepared by the published procedure[6] and dried over KOH and distilled prior to use. 3-Pyrroline (**2**-H, 97% pure), pyrrolidine (**3**-H) and a 2:1 **2**-H/**3**-H mixture were purchased from Aldrich. Yields of crude adducts and amides (i.e. after evaporation of the solvent, as described below) were essentially quantitative (>95%) except for that of $[Me_2Ga\text{-}\mathbf{2}]_2$. Yields after crystallization were much lower (typically 10−25%) due to the high solubility of most complexes in the solvents used. ^1H and ^{13}C NMR spectroscopic data were collected for about 0.3 M C_6D_6 solutions at room temperature on Bruker DPX 200 and DPX 300 spectrometers. Elemental analyses were performed by the Analytical Laboratory of the Industriepark Kaiserau (Haus Heidbruch), 51789 Lindlar, Germany. Melting points were obtained with a Büchi B-545 melting point apparatus in silicon grease-sealed capillaries and are uncorrected. DSC measurements were performed on a Perkin−Elmer DSC7. In a glove box, samples (approximately 1.5 mg) were encapsulated in a 30μL sample vessel. This copper vessel fits closely into a stainless steel holder capable of withstanding 150 bar. DSC measurements covered the range of 30 °C to 650 °C, with a scanning rate of 20 °C/min.

Synthesis

[Me_3Al·1-H]: Compound **1**-H (3.5 mmol) was added slowly (0.5 h) at room temperature to a stirred solution of Me_3Al (0.25 g, 3.5 mmol) in mesitylene (4 mL) in a glove-box. After the reaction was complete, the Schlenk tube was taken out of the glove-box and the solvent was removed in vacuo at about 45 °C. The product, a white solid powder, was crystallized from toluene/hexane at about −20 °C. M.p. 75.7 °C. ^1H NMR: δ = −0.47 (s, 9 H, CH_3Al), 0.33 (d, 6 H, CH_3C), 0.87 (s, 1 H, N*H*), 1.81 (m, 2 H, C*H*) ppm. ^{13}C NMR: δ = −9.1 (br, *C*H_3Al), 11.1 (*C*H_3C), 34.7 (*C*H) ppm. $C_7H_{18}NAl$ (143.21): calcd. C 58.77, H 12.58, N 9.79, Al 18.86 found C 59.00, H 12.88, N 9.56, Al 18.56..

[Me_3Ga·1-H]: This compound was obtained in the same way as [Me_3Al·**1**-H], with Me_3Ga instead of Me_3Al. However, we did not succeed in crystallizing it. M.p. 45.7 °C. ^1H NMR: δ = −0.17 (s, 9 H, CH_3Ga), 0.40 (d, 6 H, CH_3C), 0.84 (s, 1 H, N*H*), 1.68 (m, 2 H, C*H*) ppm. ^{13}C NMR: δ = −6.3 (br, *C*H_3Ga), 11.5 (*C*H_3C), 33.4 (*C*H) ppm . $C_7H_{18}NGa$ (185.95): calcd. C 45.22, H 9.76, N 7.53, Ga 37.49; found C 44.98, H 9.52, N 7.48, Ga 37.26.

[Me_2Al-1]$_2$: *cis*-2,3-Dimethylaziridine (13.1 mmol) was added slowly (0.5 h) at room temperature to a stirred solution of Me_3Al (0.94 g, 13.1 mmol) in mesitylene (6 mL) in a glove-box. During the mixing, the solution warmed spontaneously. After it had cooled down to room temperature, the Schlenk tube was taken out of the glove-box. The solution was heated to 95 °C for 1 h, during which period evolution of gas (methane) was visible. After the solution had cooled, volatiles were removed in vacuo at 60 °C. The product, a white solid powder, was crystallized from toluene/hexane at about −20 °C. M.p. 94.7 °C. ^1H NMR: δ = −0.58 (s, 12 H, CH_3Al), 0.93−0.97 (m, 12 H, CH_3C), 2.04−2.09 (m, 4 H, C*H*) ppm. ^{13}C NMR: δ = −9.5 (br, *C*H_3Al), 14.2, 14.3 (*C*H_3C), 36.0, 36.4 (*C*H) ppm. $C_{12}H_{24}N_2Al_2$ (254.33): calcd. C 56.72, H 11.02, N 11.02, Al 21.24; found C 56.40, H 10.99, N 10.77, Al 21.47.

[Me_2Ga-1]$_2$: This compound was obtained in the same way as [Me_2Al-**1**]$_2$ (with Me_3Ga instead of Me_3Al), except that the solution was heated to 155 °C instead of 95 °C. The light-yellow product was crystallized from toluene/hexane at about −20 °C. M.p. 101.5 °C. ^1H NMR: δ = −0.22 (s, 12 H, CH_3Ga), 0.94−0.95 (m,

12 H, CH_3C), 1.89−1.95 (m, 4 H, CH) ppm. ^{13}C NMR: δ = −7.1 (*C*H_3Ga), 14.7, 14.8 (*C*H_3C), 34.3, 34.9 (*C*H) ppm. $C_{12}H_{24}N_2Ga_2$ (339.81): calcd. C 42.44, H 8.25, N 8.25, Ga 41.06; found C 42.30, H 8.23, N 8.27, Ga 40.92.

[Me_3Al·2-H]: Compound **2**-H (4 mmol) was added slowly (0.5 h) at room temperature to a stirred solution of Me_3Al (289 mg, 4 mmol) in toluene (1.0 mL) in a glove-box. After the reaction was complete, the Schlenk tube was taken out of the glove-box and put it in a refrigerator at about −20 °C for crystallization to take place. The formed crystals were transparent and light yellow. M.p. 65.5 °C. ^{1}H NMR: δ = −0.54 (s, 9 H, CH_3Al), 1. 86, (s, 1 H, NH), 3.51, (br. s, 4 H, CH_2), 5.44, (br. s, 2 H, CH) ppm. ^{13}C NMR: δ = −11.2 (*C*H_3Al), 55.4 (*C*H_2), 128.9 (*C*H) ppm. C_7H_{16}NAl (141.19): calcd. C 59.60, H 11.34, N 9.93, Al 19.13; found C 59.80, H 11.20, N 10.11, Al 19.32.

[Me_2Al-2]$_2$: Compound **2**-H (10 mmol) was added slowly (0.5 h) at room temperature to a stirred solution of Me_3Al (0.72 g, 10 mmol) in mesitylene (5 mL) in a glove-box. During the mixing, the solution warmed spontaneously. After it had cooled down to room temperature, the Schlenk tube was taken out of the glove-box. The solution was heated to 90 °C for 30 min, during which period evolution of gas (methane) was visible. After cooling the solution, volatiles were removed in vacuo at 40 °C. The transparent white product was crystallized from toluene/hexane at about −20 °C. M.p. 64.1 °C. ^{1}H NMR: δ = −0.53 (s, 12 H, CH_3Al), 3.51, (br. s, 8 H, CH_2), 5.43, (br. s, 4 H, CH) ppm. ^{13}C NMR: δ = −11.4 (*C*H_3Al), 55.4 (*C*H_2), 128.8 (*C*H) ppm. $C_{12}H_{24}N_2Al_2$ (250.30): calcd. C 57.63, H 9.60, N 11.20, Al 21.58; found C 57.33, H 9.58, N 10.98, Al 21.53.

[Me_3Al·3-H]: This compound was obtained in the same way as [Me_3Al·**2**-H], with use of **3**-H instead of **2**-H. The formed crystal was transparent and light yellow. M.p. 70.1 °C. ^{1}H NMR: δ = −0.52 (s, 9 H, CH_3Al), 0.89−0.96, (m, 4 H, β-CH_2), 1. 42, (s, 1 H, NH), 2.16−2.19 (m, 4 H, α-CH_2) ppm. ^{13}C NMR: δ = −9.6 (br, *C*H_3Al), 24.7 (β-*C*H_2), 46.4 (α-*C*H_2) ppm. C_7H_{18}NAl (143.21): calcd. C 58.77, H 12.58, N 9.79, Al 18.86; found C 58.44, H 12.42, N 9.67, Al 19.08.

[Me_2Al-3]$_2$: This compound was obtained in the same way as [Me_2Al-**2**]$_2$ (with use of **3**-H instead of **2**-H), except that the solution was heated at 125 °C for 1.5 h instead of at 90 °C for 30 min. The product was a light-white power. However, we did not succeed in crystallizing it. M.p. 59.3 °C. ^{1}H NMR: δ = −0.59 (s, 12 H, CH_3Al), 1.29−1.35, (m, 8 H, β-CH_2), 2.57−2.63 (m, 8 H, α-CH_2) ppm. ^{13}C NMR: δ = −11.9 (br, *C*H_3Al), 25.1 (β-*C*H_2), 49.7 (α-*C*H_2) ppm. $C_{12}H_{28}N_2Al_2$ (254.33): calcd. C 56.72, H 11.02, N 11.02, Al 21.24; found C 56.54, H 10.86, N 10.99, Al 20.98

Mixture (Cocrystal) of [Me_3Al·2-H] and [Me_3Al·3-H]: This compound was obtained in the same way as [Me_3Al·**2**-H], with the use of a 2:1 mixture of **2**-H/**3**-H. The product, a light-white solid powder, was crystallized from toluene/hexane at about −20 °C. M.p. 59.1 °C. ^{1}H and ^{13}C NMR spectra corresponded to a 2:1 mixture of [Me_3Al·**2**-H] and [Me_3Al·**3**-H] (see data given above). An NMR spectrum of a fragment of a large single crystal showed the same ratio of **2**-H/**3**-H as in the bulk mixture, demonstrating that the two compounds cocrystallize. Anal; found C 59.46, H 11.36, N 10.09, Al 19.31.

Mixture (Cocrystal) of [Me_2Al-2]$_2$ and [Me_2Al-3]$_2$: This compound was obtained in the same way as [Me_2Al-**2**]$_2$ (with the use of a 2:1 mixture of **2**-H/**3**-H), except that the solution was heated at 130 °C for 3 h instead of at 90 °C for 30 min. The product, a transparent light-white powder, was crystallized from toluene/hexane at about −20 °C. M.p. 65.8 °C. The ^{1}H and ^{13}C NMR spectra recorded at room temperature corresponded to a 2:1 mixture of [Me_2Al-**2**]$_2$ and [Me_2Al-**3**]$_2$ (see data given above) and did not show separate peaks for a mixed dimer. We do not know whether this means that the mixed dimer does not form or that exchange is rapid on the NMR timescale. Anal; found C 57.40, H 9.61, N 10.97, Al 21.72.

[Me_3Ga·2-H]: This compound was obtained in the same way as [Me_3Al·**2**-H], with the use of Me_3Ga instead of Me_3Al. The formed crystals were transparent light white. M.p. 35.5 °C. ^{1}H NMR: δ = −0.23 (s, 9 H, CH_3Ga), 1.51, (s, 1 H, NH), 2.96, (br. s, 4 H, CH_2), 5.05, (br. s, 2 H, CH) ppm. ^{13}C NMR: δ = −6.8 (*C*H_3Ga), 53.6 (*C*H_2), 126.8 (*C*H) ppm. C_7H_{16}NGa (183.93): calcd. C 45.71, H 8.77, N 7.62, Ga 37.91; found C 45.61, H 8.82, N 7.79, Ga 38.07.

Attempted Synthesis of [Me_2Ga-2]$_2$: Treatment of Me_3Ga with **2**-H to form [Me_2Ga-**2**]$_2$ was carried out similarly to that of Me_3Al with **2**-H. Heating to 155 °C was required for reaction. After evaporation of the solvent, a yellow-brown powder was left. ^{1}H NMR did not show any peaks attributable to the (protonated or deprotonated) pyrrolinyl group in the δ = 4 to 6 ppm range. Instead, broad singlets at δ = 6.29 and 6.85 ppm and several multiplets in the 0.9−2.8 ppm range were observed, which suggested that disproportionation to pyrrole and pyrrolidine and possibly isomerization to 2-pyrroline had occurred. No further attempts were made to separate or purify the products.

[Me_3Ga·3-H]: This compound was obtained in the same way as [Me_3Al·**3**-H] (with the use of Me_3Ga instead of Me_3Al). The formed crystal was cloudy and colourless. M.p. 48.3 °C (ref.[5e] 47 °C). ^{1}H NMR: δ = −0.18 (s, 9 H, CH_3Ga), 0.90−0.97, (m, 4 H, β-CH_2), 1. 15, (s, 1 H, NH), 2.12−2.15 (m, 4 H, α-CH_2) ppm. ^{13}C NMR: δ = −6.8 (br, *C*H_3Ga), 24.84 (s, β-*C*H_2), 46.7 (α-*C*H_2) ppm. C_7H_{18}NGa (185.95): calcd. C 45.25, H 9.69, N 7.54, Ga 37.53; found C 45.11, H 9.60, N 7.69, Ga 37.27.

[Me_2Ga-3]$_2$: This compound was obtained in the same way as [Me_2Al-**3**]$_2$ (with the use of Me_3Ga instead of Me_3Al), except that the solution was heated at 170 °C for 2.5 h instead of at 125 °C for 1.5 h. The product, a white solid, was crystallized from toluene at about −20 °C. M.p. 65.8 °C (ref.[5d], 74−75 °C; 64−67 °C[5a]). ^{1}H NMR: δ = −0.28 (s, 12 H, CH_3Ga), 1.29−1.36, (m, 8 H, β-CH_2), 2.59−2.65 (m, 8 H, α-CH_2) ppm. ^{13}C NMR: δ = −10.2 (*C*H-Ga), 24.9 (β-*C*H_2), 51.6 (α-*C*H_2) ppm. $C_{12}H_{28}N_2Ga_2$ (339.81): calcd. C 42.44, H 8.25, N 8.25, Ga 41.06; found C 42.27, H 8.06, N 8.34, Ga 40.87.

X-ray Crystal Structure Determinations

General: Crystals of these Al and Ga complexes were generally found to be soft. The crystal fragments sampled were cut from larger crystals, resulting in irregular shapes. Both factors may have contributed to the generally poor quality of the X-ray structure determinations (see below). Crystals were mounted in thin-walled glass capillaries under Ar. Data were collected on an Enraf−Nonius CAD4 diffractometer by use of graphite-monochromated Mo-K_α radiation (0.71073 Å). Details of all structure determinations are collected in Table 5 and Table 6. Since the glass capillaries prevented accurate description of the crystal shape, semi-empirical absorption corrections from ψ-scans[7] were applied. Structures were solved by use of the PATTY option[8] of the DIRDIF program system.[9] Refinements were carried out with the SHELXL-97 package.[10] All refinements were full-matrix, least-squares on *F*2. All non-hydrogen atoms were refined with anisotropic temperature factors. The hydrogen atoms were placed at cal-

culated positions, and refined isotropically in riding mode, unless noted otherwise (see below). Geometrical calculations[11] revealed neither unusual geometric features, nor unusual short intermolecular contacts. The calculations revealed no higher symmetry and no solvent-accessible areas. The structure drawings in Figure 1−5 show 30% thermal ellipsoids. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-187355 to -187364. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Notes on Individual Structures

[Me_3Al·1-H]: 1-H was refined freely.

[Me_3Al·2-H]: All hydrogen atoms refined freely.

[Me_3Al·2-H]/[Me_3Al·3-H] Cocrystal: 1-H was refined freely. The crystal structure determination was hampered by the poor crystal quality and more than average decay (up to 15%). No reliable data could be collected above 22° (resolution 0.95 Å).

[Me_3Al·3-H]: To test the presence of the mirror plane, a full least-squares refinement was performed in space group *P*21. Although the *R* factor was lower (0.0589), the standard deviations in bond angles and distances were significantly higher. Moreover, a statistical analysis of the intensities favours a centrosymmetric space group.

[Me_3Ga·3-H]: The crystal structure determination was hampered by the very poor crystal quality. No reliable data could be collected above 22° (resolution 0.95 Å). Because the semiempirical absorption correction by itself was not adequate, presumably due to the poor quality of the data and hence of the ψ-scans, an additional absorption correction was applied by use of the DIFABS procedure.[12] Even then it was necessary to use the ISOR option for N1 in the least-squares refinement to provide physically acceptable anisotropic thermal displacement parameters.

[Me_2Al-2]$_2$: The crystal structure determination was hampered by the extremely poor crystal quality. No reliable data could be collected above 21° (resolution 0.99 Å).

[Me_2Al-2]$_2$/[Me_2Al-3]$_2$ Cocrystal: The crystal structure determination was hampered by the very poor crystal quality. No reliable data could be collected above 23° (resolution 0.91 Å).

Calculations

All calculations were carried out with the GAMESS-UK package[13] by use of the B3LYP hybrid density functional[14] and the

Synthesis and Structures of Alkaline-Earth Metal Supersilanides: tBu$_3$SiMX and tBu$_3$Si−M−SitBu$_3$ (M = Be, Mg; X = Cl, Br)

Hans-Wolfram Lerner,*[a] Stefan Scholz,[a] Michael Bolte,[b][‡] Nils Wiberg,[c] Heinrich Nöth,[c][‡] and Ingo Krossing[c][‡]

Keywords: Silanes / Beryllium / Magnesium / X-ray structure analysis

The alkaline-earth metal silanides, (tBu$_3$Si)$_2$Be and (tBu$_3$Si)$_2$Mg, have been synthesized from the reaction of the sodium silanide tBu$_3$SiNa with BeCl$_2$ in Bu$_2$O and MgBr$_2$ in THF. The bissupersilylmagnesium THF adduct [(tBu$_3$Si)$_2$Mg(THF)$_2$] reacts with GaBr$_3$ in benzene at ambient temperature to form tBu$_3$SiGaBr$_2$ and tBu$_3$SiMgBr(THF). The structures of bissupersilyl silanides, (tBu$_3$Si)$_2$Be and (tBu$_3$Si)$_2$Mg(THF)$_2$, and the Grignard analogue, tBu$_3$SiMgBr(THF), have been determined by X-ray structure analysis.

Introduction

Silyl anions, which are conveniently accessible from silyl halides, are important and versatile organometallic reagents in synthesis. Various details of their molecular structures have, however, still not been fully elucidated and are therefore the subject of current investigations.[1] The best-studied class of silyl anions are the alkali metal silanides that feature monomeric,[2,3] dimeric,[2,3] and polymeric[4] arrangements as molecular units. Alkali metal silanides have not only become interesting for their molecular structures but have also attracted recent attention due to their synthetic utility. More recently, alkali metal tri-*tert*-butylsilanides (supersilanides), tBu$_3$SiM, have been used for the synthesis of new main group element clusters and compounds with elements in low coordination states. Accordingly, the reaction of sodium supersilanide with thallium(III) chloride produces the supersilylated thallium clusters [(tBu$_3$Si)$_6$Tl$_6$Cl$_2$] and [(tBu$_3$Si)$_4$Tl$_3$Cl],[5] and with [(Me$_3$Si)$_2$N]$_2$Sn leads to the tristannaallene, (tBu$_3$Si)$_2$Sn=Sn=Sn(SitBu$_3$)$_2$.[6]

In contrast to the well-established silanides with alkali metals, only a few alkaline-earth metal silanides are known. Information regarding the structure and reactivity of these molecules is thus still rather limited.[1,7]

We have therefore become interested in the synthesis of alkaline-earth metal silanides, tBu$_3$SiMX and tBu$_3$Si−M−SitBu$_3$, and in their respective structures.

Results and Discussion

Synthesis

Several routes to silyl anions are known. In this study of the synthesis of alkaline-earth metal supersilanides only the metathesis of MX$_2$ (M = Be, X = Cl; M = Mg, X = Br) with sodium supersilanide, tBu$_3$SiNa, has been employed. We expected that the Grignard analogous compound, tBu$_3$SiMX, should be produced by reaction of MX$_2$ with one equivalent of tBu$_3$SiNa, and that tBu$_3$Si−M−SitBu$_3$ should be obtained upon elimination of MX$_2$ from two molecules of tBu$_3$SiMX.

$$n\ t\mathrm{Bu_3SiNa} + n\ \mathrm{MX_2} \xrightarrow[-\,n\,\mathrm{NaX}]{} \underset{\mathbf{1}}{(t\mathrm{Bu_3SiMX})_n} \xrightarrow[-\,0.5\,n\,\mathrm{MX_2}]{} \underset{\mathbf{2}}{0.5\ n\ t\mathrm{Bu_3Si\text{-}M\text{-}Si}t\mathrm{Bu_3}} \quad (1)$$

1a: M = Be, X = Cl
1b: M = Mg, X = Br
2a: M = Be
2b: M = Mg

The compounds tBu$_3$Si−M−SitBu$_3$ (M = Be, Mg) were indeed formed by the addition of two equivalents of tBu$_3$SiNa to BeCl$_2$ in dibutyl ether or to a tetrahydrofuran solution of MgBr$_2$. The Grignard analogous compound, tBu$_3$SiMgBr, was prepared by mixing tetrahydrofuran solutions of MgBr$_2$ and tBu$_3$SiNa in a 1:1 molar ratio at −78 °C, but no crystals suitable for X-ray crystallography could be obtained from this solution. While tBu$_3$SiMgBr(THF)$_n$ was transformed in a similar manner to the

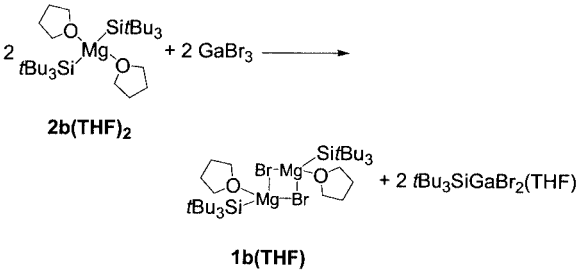
(2)

related hypersilyl compound $(Me_3Si)_3SiMgBr(THF)_2$[8] in non-donor solvents, as indicated in Equation (2), obtaining X-ray quality crystals from $tBu_3SiMgBr$ was very difficult.-

Tetrahydrofuran molecules could be eliminated by heating the solid adduct $(tBu_3Si)_2Mg(THF)_2$ in vacuo. From the resulting residue, uncomplexed $(tBu_3Si)_2Mg$ could be recovered quantitatively. When two equivalents of sodium supersilanide reacted with $BeCl_2$ in dibutyl ether only donor free $(tBu_3Si)_2Be$ was formed. The use of one equivalent of sodium supersilanide led to oligomeric $(tBu_3SiBeCl)_n$ which shows broad signals in the ^1H and ^{29}Si NMR spectrum.

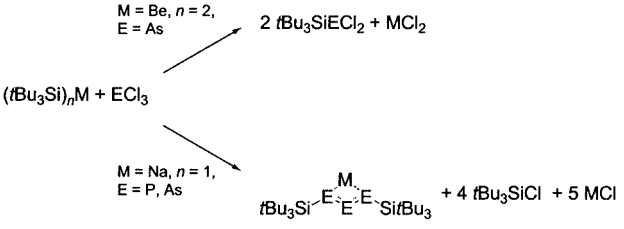


(3)

$GaBr_3$ reacts with $(tBu_3Si)_2Mg(THF)_2$ in benzene at ambient temperature to give the Grignard analogous compound, $tBu_3SiMgBr(THF)$, and $tBu_3SiGaBr_2(THF)$. X-ray quality crystals of $tBu_3SiMgBr(THF)$ were grown from this benzene solution.

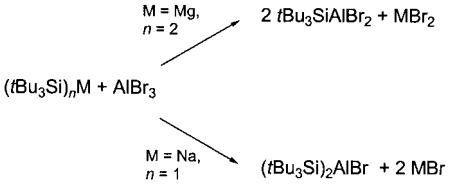
Reactivity

The supersilylated silanides of magnesium and beryllium are extremely sensitive to air and moisture. When a solution of $(tBu_3Si)_2Mg(THF)_2$ in benzene is treated with a small amount of water, the Mg^{2+} cation is substituted cleanly by two protons. When exposed to air, oxidation of $(tBu_3Si)_2Mg(THF)_2$ proceeds with the formation of superdisilane, $tBu_3Si-SitBu_3$, and $(tBu_3SiO)_2Mg$. Nucleophilic substitution reactions of alkali metal supersilanides with element halides EX_n often occur with the reduction of E and the formation of E–E bonds. As reported previously, the reaction of $tBu_3SiNa(THF)_2$ with ECl_3 (E = P, As) leads surprisingly to the sodium disupersilyltriphosphenide, $tBu_3Si(Na)P-P=PSitBu_3$, and the disupersilyltriarsenide, $tBu_3Si(Na)As-As=AsSitBu_3$, as shown in Equation (4).[9]



(4)

This result demonstrates the high reduction potential of alkali metal supersilanides. On the other hand, $(tBu_3Si)_2Be$ reacts with $AsCl_3$ to produce $tBu_3SiAsCl_2$ in high yield.



(5)

We have reported that the reaction of sodium supersilanide with triel halides, EX_3, does not depend on the starting material ratio (1:1 or 2:1) and always produces the disupersilylated compounds, $(tBu_3Si)_2EX$.[10] However, the reactions between $(tBu_3Si)_2Mg(THF)_2$ and EBr_3 (E = Al, Ga) take a different course, as depicted in Equations (3) and (5), and only the monosupersilylated compounds tBu_3SiEBr_2 (E = Al, Ga) are formed. $tBu_3SiAlBr_2$ could be isolated as its $MgBr_2$ adduct[10] and $tBu_3SiGaBr_2$ as its THF adduct.

Structures

Figure 1 shows the molecular structure of **2a**. Similar to the isoelectronic compound $(tBu_3Si)_2Zn$,[11] the Si–Be–Si unit is perfectly linear. The alkaline-earth metal silanide **2a** crystallizes in the triclinic space group $P\bar{1}$. The Be–Si distance of 2.1930(10) Å in the donor-free silanide **2a** is a little longer than the sum of the atomic radii (2.10 Å).[12]

The crystal structure of **2b(THF)$_2$** is shown in Figure 2; selected bond lengths and angles are listed in Table 1. X-ray-quality crystals of **2b(THF)$_2$** (orthorhombic, *Pbca*) were

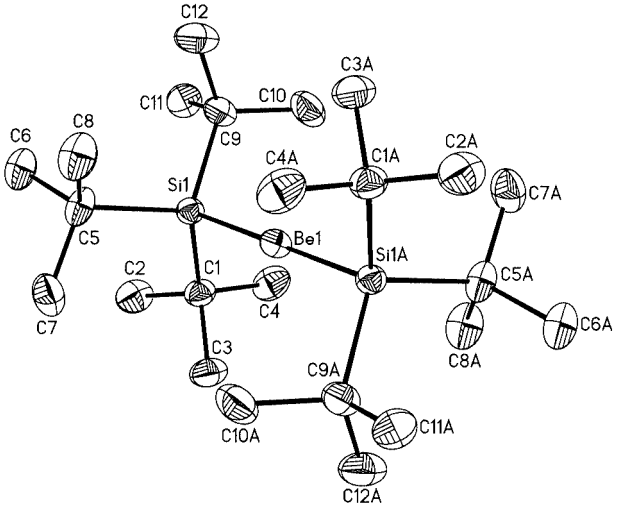


Figure 1. Thermal ellipsoid plot of **2a** showing the atom numbering scheme. The displacement ellipsoids are drawn at the 50% probability level

grown from pentane. Its Si−Mg−Si unit deviates from linearity [bond angle Si(1)−Mg−Si(2) = 132.82(4)°], due to interactions between Mg and two O atoms from tetrahydrofuran molecules. The distance between the Mg and Si atom is 2.777(2) Å. This distance is characteristic of a Mg−Si bond (sum of the atomic radii: 2.77 Å),[12] but is longer than in $(Me_3Si)_2Mg{\cdot}TMEDA$,[13] $(Me_3Si)_2Mg{\cdot}TMDAP$,[14] and $(Me_3Si)_2Mg{\cdot}DME$.[15]

Table 1. Selected bond lengths (average) [Å] and angles (average) [°] for **1b(THF)**, **2a**, and **2b(THF)$_2$**

	1b(THF)	**2a**	**2b(THF)$_2$**
M−Si	2.6075(11)	2.1930(10)	2.777(2)
C−C	1.543(4)	1.540(5)	1.531(12)
Si−C	1.963(3)	1.952(3)	1.973(7)
Mg−O	2.040(2)	−	2.153(2)
Si−M−Si	−	180	132.82(4)
C−Si−M	108.97(9)	107.34(10)	111.5(4)

Complex **1b(THF)** crystallizes with a molecule of benzene in the monoclinic space group *C*2/*c*, as shown in Figure 3. The central framework of the Grignard analogous compound **1b(THF)** forms a planar four-membered ring. The corners of this ring are alternately occupied by Mg and Br atoms [angle of **1b(THF)**: Br−Mg−Br 98.2(2)°, Mg−Si−Mg 81.4(2)°]. Apart from these two Br atoms, the Mg atom is surrounded by one Si atom and one molecule of tetrahydrofuran. Contrary to the Mg center in **1b(THF)**, the Mg atoms in $(Me_3Si)MgBr{\cdot}TMEDA$[13] and $(Me_3Si)_2Mg{\cdot}MeN(CH_2CH_2NMe_2)_2$[14] are pentacoordinate. Complex **1b(THF)** features two Mg−Si contacts with a Mg−Si distance of 2.6075(11) Å. However, the Mg−Si distances in **1b(THF)** are significantly shorter than in **2b(THF)$_2$**. The Mg−Br bond in **1b(THF)** has a length of 2.5929(9) Å. This distance is characteristic of a Mg−Br bond (sum of the ionic radii: 2.53 Å).[12]

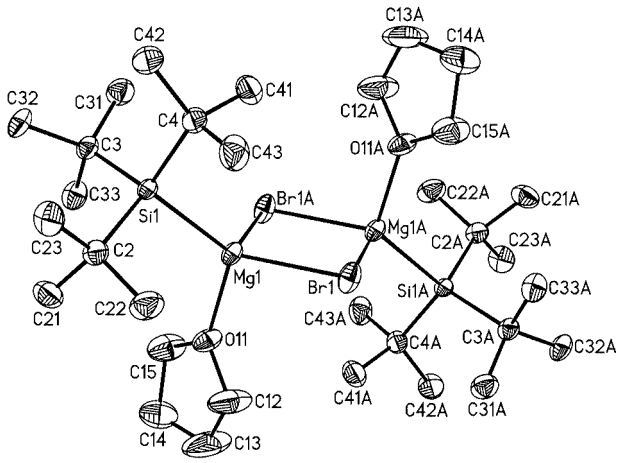

Figure 3. Thermal ellipsoid plot of **1b(THF)** showing the atom numbering scheme. The displacement ellipsoids are drawn at the 50% probability level

The disupersilylmagnesium compound **2b(THF)$_2$** shows an C−Si−C angle smaller than 110° [107.81(13)°], indicating a negatively polarized Si atom.[11]

Experimental Section

General Procedures: All experiments were carried out under dry argon or nitrogen with strict exclusion of air and moisture using standard Schlenk techniques. tBu$_3$SiNa[2] was prepared according to literature procedures. The solvents (benzene, heptane, toluene, tetrahydrofuran) were distilled from sodium/benzophenone prior to use.

The NMR spectra were recorded on a Jeol GSX 270 (^{1}H/^{13}C/^{29}Si: 270.17/67.94/53.67 MHz), a Jeol EX 400 (^{1}H/^{13}C/^{29}Si: 399.78/100.53/79.31 MHz), a Bruker AM 250 (^{1}H/^{13}C: 250.133/62.896 MHz), a Bruker DPX 250 (^{1}H/^{13}C/^{29}Si: 250.130/62.895/49.69 MHz) or a Bruker AMX 400 (^{1}H/^{29}Si: 400.130 MHz/79.495 MHz) spectrometer. The ^{29}Si NMR spectra were recorded using the INEPT pulse sequence with empirically optimized parameters for polarization transfer from the tBu substituents.

Caution! In view of the extreme toxicity of beryllium compounds, all experimental work was carried out in a well-ventilated fume cupboard used exclusively for this work. Any spillage of the beryllium solutions was washed out immediately. Established procedures for handling dangerous materials were followed rigorously in all phases of the synthetic work and measurements.

Synthesis of tBu$_3$SiBeCl [1a]: A solution of tBu$_3$SiNa(THF)$_n$ (0.146 g, 0.40 mmol) in 10 mL of tetrahydrofuran was added to a solution of $BeCl_2$ (0.093 g, 1.16 mmol) in 5 mL of tetrahydrofuran at ambient temperature. After concentrating the solution to 5 mL, **1a** was obtained as an air- and moisture-sensitive precipitate at −25 °C. Yield: 0. 101 g of **1a** (80%). ^{1}H NMR (C_6D_6, internal TMS): δ = 1.105 (s, 27 H, tBu$_3$Si) ppm. ^{13}C{^{1}H} NMR (C_6D_6, internal TMS): δ = 22.3 (s, *C*Me$_3$), 30.7 (s, C*Me$_3$*) ppm. ^{29}Si{^{1}H} NMR (C_6D_6, internal TMS): δ = 6.5 (s, SitBu$_3$) ppm.

Synthesis of tBu$_3$SiMgBr(THF)$_n$ [1b(THF)$_n$]: A solution of tBu$_3$SiNa(THF)$_n$ (0.792 g, 2.16 mmol) in 1.8 mL of tetrahydrofuran was added to a cooled solution (−78 °C) of $MgBr_2(THF)_4$ (0.403 g, 2.10 mmol) in 20 mL of tetrahydrofuran. After allowing the mix-

ture to attain ambient temperature and concentrating the solution to 10 mL, **1b(THF)$_n$** was obtained at −25 °C as air- and moisture-sensitive, colorless crystals. Yield: 0.482 g (0.82 mmol) of **1b(THF)$_n$** (39%). Decomposition at 144 °C. ^{1}H NMR ([D$_8$]THF internal TMS): δ = 1.056 (s, 27 H, *t*Bu$_3$Si) ppm. ^{13}C{^{1}H} NMR ([D$_8$]THF internal TMS): δ = 24.0 (s, *C*Me$_3$), 33.6 (s, C*Me$_3$*) ppm. ^{29}Si{^{1}H} NMR ([D$_8$]THF external TMS): δ = 26.4 (s, Si*t*Bu$_3$) ppm.

Remark: **1b(THF)$_n$** dissolved in [D$_6$]benzene transforms into **2b(THF)$_2$** (by ^{1}H and ^{29}Si NMR spectroscopy).

Synthesis of (*t*Bu$_3$Si)$_2$Be (2a): A slurry of BeCl$_2$ (0.154 g, 1.93 mmol) and *t*Bu$_3$SiNa(Bu$_2$O)$_2$ (1.40 g, 3.80 mmol) in 10 mL of heptane was stirred for two days at ambient temperature. The reaction mixture became colorless. The solid that formed was removed by filtration. Colorless crystals of **2a** were grown from the filtrate at −25 °C. Yield: 0.632 g (1.55 mmol) of **2a** (80%). m.p. 208−210 °C. ^{1}H NMR (C$_6$D$_6$, internal TMS): δ = 1.250 (s, 54 H, *t*Bu$_3$Si) ppm. ^{29}Si{^{1}H} NMR (C$_6$D$_6$, external TMS): δ = 6.9 (s, Si*t*Bu$_3$) ppm. X-ray structure analysis: see Figure 1.

Synthesis of (*t*Bu$_3$Si)$_2$Mg(THF)$_2$ [2b(THF)$_2$]: A solution of *t*Bu$_3$SiNa(THF)$_n$ (2.64 g, 7.20 mmol) in 6 mL of tetrahydrofuran was added to a cooled solution (−78 °C) of MgBr$_2$(THF)$_4$ (1.718 g, 3.63 mmol) in 20 mL of tetrahydrofuran. After allowing the mixture to attain ambient temperature, the solvent was removed in vacuo. The remaining residue was treated with 20 mL of heptane. After filtrating the insoluble material and concentrating the filtrate to 10 mL, **2b(THF)$_2$** was obtained at −25 °C as air- and moisture-sensitive colorless crystals, which were suitable for X-ray diffraction analysis (Figure 2). Yield: 1.402 g (2.48 mmol) of **2b(THF)$_2$** (68%). decomposition 116 °C. ^{1}H NMR (C$_6$D$_6$, internal TMS): δ = 1.328 (s, 54 H, *t*Bu$_3$Si), 1.269 (m, 8 H, CH$_2$), 3.566 (m, 8 H, OCH$_2$) ppm. ^{13}C{^{1}H} NMR (C$_6$D$_6$, internal TMS): δ = 24.1 (s, *C*Me$_3$), 33.5 (s, C*Me$_3$*), 24.7 (CH$_2$), 68.3 (OCH$_2$) ppm. ^{29}Si{^{1}H} NMR (C$_6$D$_6$, external TMS): δ = 31.2 (s, Si*t*Bu$_3$) ppm. C$_{32}$H$_{70}$Si$_2$O$_2$Mg (567.38): calcd. C 67.79, H 12.45; found C 62.15, H 11.40.

According to the ^{1}H and ^{29}Si NMR spectra solvent-free (*t*Bu$_3$Si)$_2$Mg was obtained quantitatively after (*t*Bu$_3$Si)$_2$Mg(THF)$_2$ (0.040 g, 0.07 mmol) was heated to 80 °C for 2 h in high vacuo. ^{1}H NMR (C$_6$D$_6$, internal TMS): δ = 1.380 (s, 54 H, *t*Bu$_3$Si) ppm. ^{29}Si{^{1}H} NMR (C$_6$D$_6$, external TMS): δ = 38.0 (s, Si*t*Bu$_3$) ppm.

Reaction of (*t*Bu$_3$Si)$_2$Be [2a] with AsCl$_3$: A solution of (*t*Bu$_3$Si)$_2$Be (0.054 g, 0.13 mmol) in 2 mL of heptane was added to a cooled solution (−78 °C) of AsCl$_3$ (0.42 g, 2.90 mmol) in 20 mL of tetrahydrofuran. After allowing the mixture to attain ambient temperature, all volatile compounds were removed in vacuo. The remaining residue was treated with 10 mL of heptane. After filtrating the insoluble material and removing the solvent in vacuo, *t*Bu$_3$SiAsCl$_2$ remained as an air- and moisture-sensitive colorless oil. Yield: 0.061 g (0.176 mmol) of *t*Bu$_3$SiAsCl$_2$ (68%). ^{1}H NMR

Reaction of (tBu$_3$Si)$_2$Mg(THF)$_2$ [2b(THF)$_2$] with GaBr$_3$: GaBr$_3$ (0.085 g, 0.274 mmol) was added to a solution of **2b(THF)$_2$** (0.150 g, 0.264 mmol) in 1.2 mL of C_6D_6. Colorless crystals of **1b(THF)**, tBu$_3$SiMgBr(THF)$_2$, grew from this benzene solution within one week at ambient temperature. These crystals were suitable for X-ray diffraction analysis (Figure 3). Yield: 0.084 g (0.194 mmol) of **1b(THF)** (73%). For NMR of **1b(THF)** see above. For the reaction of (tBu$_3$Si)$_2$Mg(THF)$_2$ (**2b**) with AlBr$_3$ see ref.[10]

The ^1H, ^{13}C, and ^{29}Si NMR spectra of the remaining benzene solution showed only the signals of tBu$_3$SiGaBr$_2$(THF).[10] After removing the solvent in vacuo, colorless tBu$_3$SiGaBr$_2$(THF) was obtained as a solid. ^1H NMR (C_6D_6, internal TMS): δ = 1.29 (s, 27 H, tBu$_3$Si), 1.42 (m, 8 H, CH_2), 3.62 (m, 8 H, OCH_2) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6, internal TMS): δ = 25.6 (s, CMe_3), 31.7 (s, CMe_3), 25.0 (CH_2), 68.2 (OCH_2) ppm. $^{29}Si\{^1H\}$ NMR (C_6D_6, external TMS): δ = 47.7 (s, SitBu$_3$) ppm.

Oxidation of (tBu$_3$Si)$_2$Mg(THF)$_2$ [2b(THF)$_2$]: N_2O (0.104 g, 0.61 mmol) was condensed into a solution of (tBu$_3$Si)$_2$Mg(THF)$_2$ (0.017 g, 0.027 mmol) in 1 mL of benzene. The supersiloxide (tBu$_3$SiO)$_2$Mg and N_2 were formed in quantitative yield (by ^1H, ^{13}C, and ^{29}Si NMR spectroscopy). Compound **2b** (0.2 mmol/1 mL of C_6D_6) reacts with dry air, forming superdisilane, tBu$_3$SiSitBu$_3$,[10] and (tBu$_3$SiO)$_2$Mg: ^1H NMR (C_6D_6, internal TMS): δ = 1.146 (s, 54 H, tBu$_3$Si) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6, internal TMS): δ = 22.1 (s, CMe_3), 30.8 (s, CMe_3) ppm. $^{29}Si\{^1H\}$ NMR (C_6D_6, external TMS): δ = −9.4 (s, SitBu$_3$) ppm.

X-ray Structure Determination: Data Collection (Table 2): Siemens CCD three-circle diffractometer, graphite-monochromated Mo-K_α radiation; empirical absorption correction using SADABS,[16] structure solution by direct methods,[17] structure refinement: full-matrix least-squares on F^2 with SHELXL-97.[17] Hydrogen atoms were placed at ideal positions and refined with fixed isotropic displacement parameters using a riding model. The Chelating Ligand 1,3-Bis(pyrazol-1′-yl)propane (Bpp) Enforces a Tetrahedral Geometry in Both Cu^{II} and Cu^{I} Species

Kristel Flinzner,[a] Arno F. Stassen,[a] Allison M. Mills,[b] Anthony L. Spek,[b] Jaap G. Haasnoot,*[a] and Jan Reedijk[a]

Keywords: N ligands / Copper / Crystal structures / Cyclic voltammetry

The ligand 1,3-bis(pyrazol-1′-yl)propane (bpp) has been prepared by reacting 1,3-dichloropropane with two equivalents of pyrazole. After reaction of bpp with copper(II) tetrafluoroborate, three different compounds were obtained, two with Cu^{II} and one with Cu^{I} as cation, depending on the preparative method. The formation of single crystals of these compounds was only observed when 1-(3-chloropropyl)pyrazole (ppc) was present in the solution. The single-crystal X-ray structures of $[Cu(bpp)_2](BF_4)_2$ and $[Cu(bpp)_2](BF_4)$ show that bpp acts as a didentate chelating ligand to form an uncommon eight-atom chelate ring with the copper ion. Two polymorphs of the Cu^{II} complex were characterized. In each of them, the metal atoms possess a distorted tetrahedral geometry. In the copper(I) complex the metal center is present in a less-distorted tetrahedral coordination sphere. The spectroscopic properties of the compounds are in agreement with the structural data. Cyclic voltammetry measurements showed a redox wave at 0.92 V vs. Ag/AgCl.

Introduction

Didentate ligands may either form chelates or bridges between two different metal ions depending on the number of atoms between the donor atoms. However, they frequently form chelates, coordinating to one metal ion in a chelate ring.[1] Chelate rings of different sizes have been the subject of intensive research in the past. For instance, five- to thirteen-membered rings are formed with 2,2′-bipyridine,[2] bis(2-benzimidazolyl)ethanes,[3,4] bis(2-benzimidazolyl)propanes[3,5,6] 1,3-bis(pyrazol-1′-yl)propane and derivatives[7] and 1,8-bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane.[8] Five-membered chelate rings are generally the most stable.[9]

The metal ion used also influences the stability of a complex. Although Cu^{I} is very unstable in protic solutions with respect to disproportionation [2 $Cu^{+}(aq) \rightarrow Cu^{2+}(aq) + Cu^{0}(s)$],[1] the Cu^{I} ion can be stabilized by coordination with ligands having a π-acceptor character.

Generally, Cu^{I} ions in coordination complexes have a (distorted) tetrahedral geometry. A few examples are complexes formed with bipyridine derivatives,[10] thiocyanate,[11] adiponitriles,[12] pyridines[13,14] and indole-containing ligands.[15] In rare cases, Cu^{I} can have other coordination environments, including linear,[1] trigonal,[1] and trigonal pyramidal.[16]

Cu^{II} ions in coordination complexes display several geometries; (distorted) octahedral,[17–19] distorted trigonal bipyramidal,[10] square pyramidal,[11] (distorted) square-planar[8,20] and (distorted) tetrahedral[4,5] complexes have been observed. However, because of the influence of the Jahn–Teller effect square-planar-based geometries are usually preferred[1] by four-coordinate Cu^{II}. Steric constraints are known to generate tetrahedral geometries. Coordination complexes of Cu^{II} and Cu^{I} sharing the same molecular formula and (distorted) tetrahedral geometry are therefore very rare. The previously reported[21] Cu^{II} and Cu^{I} compounds formed with the ligand 2,2′-bis(2-imidazolyl)biphenyl are examples of such complexes.

In this paper, Cu^{II} and Cu^{I} complexes with 1,3-bis(pyrazol-1′-yl)propane (bpp) that display similar (distorted) tetrahedral geometries are described. In these complexes, the bpp ligands act as didentate chelating ligands to form uncommon eight-atom chelate rings. In earlier work[7] metal complexes with the general formula $[M(bpp)X_2]$ (M = Cu^{2+}, Zn^{2+} or Co^{2+} and X = Cl^{-} or NO_3^{-}) have been reported.

The complexes described in this paper are the first containing two bpp ligands coordinated to one metal center. The best single crystals were grown from solutions of 1,3-bis(pyrazol-1′-yl)propane and Cu^{II} tetrafluoroborate, in which an excess of 1-(3-chloropropyl)pyrazole (ppc) was also present.

Two red polymorphic forms of the compound $[Cu(bpp)_2](BF_4)_2$ were obtained: orthorhombic α-$[Cu(bpp)_2](BF_4)_2$ (**1**) crystallized from ethanol, and triclinic β-$[Cu(bpp)_2](BF_4)_2$ (**2**) crystallized from methanol. In addi-

tion, the light yellow Cu^{I} complex $[Cu(bpp)_2](BF_4)$ (**3**) was isolated. This complex also formed from Cu^{II} tetrafluoroborate, upon standing, by auto-reduction.

The X-ray crystal structures of the two forms of $[Cu(bpp)_2](BF_4)_2$ and $[Cu(bpp)_2](BF_4)$ will be presented and discussed. Furthermore, the spectroscopic properties of $[Cu(bpp)_2](BF_4)$, and spectroscopic and magnetic properties of $[Cu(bpp)_2](BF_4)_2$ will be presented. Finally, the results of cyclic voltammetry measurements performed with $[Cu(bpp)_2](BF_4)_2$ will be discussed.

Results and Discussion

General Complex Synthesis

When crystallization attempts were performed with the ligand ppc, complexes containing the ligand bpp, which was present as a contamination in ppc, were isolated instead. These experiments were repeated using different Cu:bpp ratios and ppc in a large excess. In each case, independent of the Cu:bpp ratio, complexes in which Cu and bpp are present in a 1:2 ratio were formed. When crystallizations were performed without ppc, red solids formed which were shown by elemental analysis also to possess a Cu:bpp ratio of 1:2, as for the complexes formed in the presence of ppc. However, no single crystals could be obtained when ppc was not present in the solution. A possible reason for this is that ppc keeps the bpp complexes in solution longer, thus allowing slower crystallization and therefore the growth of high-quality single crystals. This theory is supported by the fact that the copper(I) complex $[Cu(bpp)_2](BF_4)$ does not form at all without the presence of ppc. Because the complex does not spend enough time in solution, formation by slow auto-reduction does not take place.

Molecular Structures of α-$[Cu(bpp)_2](BF_4)_2$ (1) and β-$[Cu(bpp)_2](BF_4)_2$ (2)

The Cu^{II} complex $[Cu(bpp)_2](BF_4)_2$ crystallizes in two polymorphs: orthorhombic α-$[Cu(bpp)_2](BF_4)_2$ (**1**), formed in ethanol, and triclinic β-$[Cu(bpp)_2](BF_4)_2$ (**2**), formed in methanol. The formation of **1** and **2** in different solvents is probably caused by a solvent effect. The presence of both polymorphs in the preparations is unlikely because several crystals were used for structure determination and each time only one polymorph was observed. Selected geometric parameters for **1** and **2** are listed in Table 1 and 2, respectively. The asymmetric unit of **1** contains one unique quarter of a cation with D_2 symmetry (Figure 1). In **2**, three independent cations are present in the asymmetric unit, all of which adopt similar conformations with approximate (noncrystallographic) D_2 symmetry (Figure 2). The cations in both structures are oriented such that one of their (pseudo) C_2-axes is parallel to a short a axis [**1**: a = 7.9532(1) Å; **2**: a = 7.9557(15) Å]. Translation-related cations are stacked into columns along the [100] direction (Figure 3). These columns, separated by the (disordered) BF_4^- anions, are arranged in different patterns in the two polymorphs. In **1**, all of the cations are parallel with their three C_2-axes aligned with the three cell axes, as required by the orthorhombic symmetry (Figure 4). In the triclinic polymorph **2**, the cations centered by Cu(2) and Cu(3) are nearly parallel and together with the BF_4^- anions they form two-column-wide layers within which the packing is similar to that in **1**. Columns of Cu(1)-centered cations, rotated by approximately 60° (about [100]) with respect to the other cations, fit efficiently between these layers (Figure 5). The higher calculated density of **2** (1.590 g cm^{-3}) in comparison to that of **1** (1.563 g cm^{-3}) reflects its more compact packing.

As shown in Figure 1 and 2, the Cu^{II} ions in both structures are each coordinated to two didentate bpp ligands via the N2 atoms of the pyrazole rings [**1**: Cu−N 1.948(3) Å; **2**: Cu−N 1.957(3)−1.982(3) Å], forming eight-membered

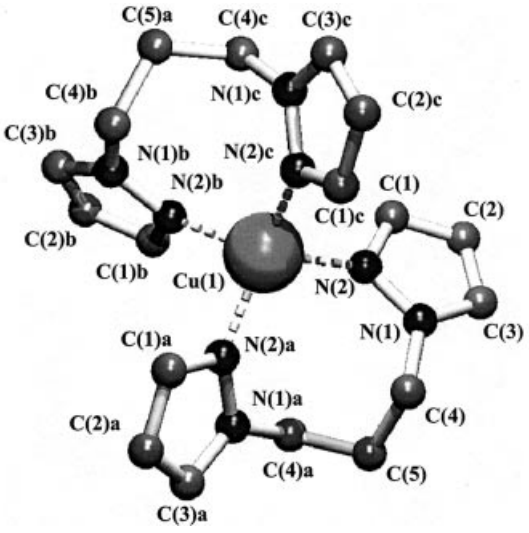

Figure 1. PLATON/POVRAY representation[27,28] of the molecular structure of the cation in α-$[Cu(bpp)_2](BF_4)_2$ (**1**); hydrogen atoms and counterions have been omitted for clarity

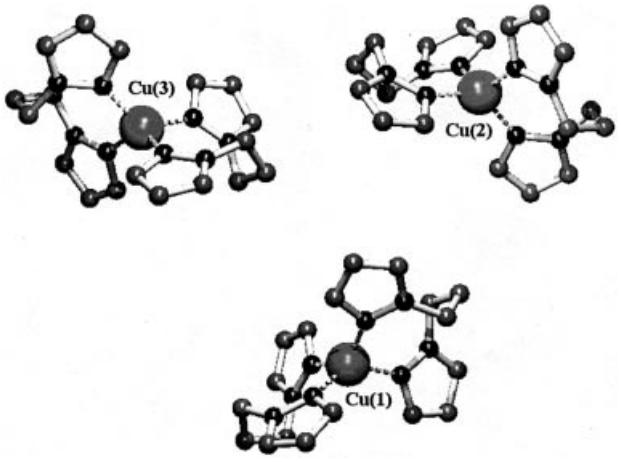

Figure 2. PLATON/POVRAY representation[27,28] of the molecular structure of the three independent cations in β-$[Cu(bpp)_2](BF_4)_2$ (**2**); hydrogen atoms and counterions have been omitted for clarity

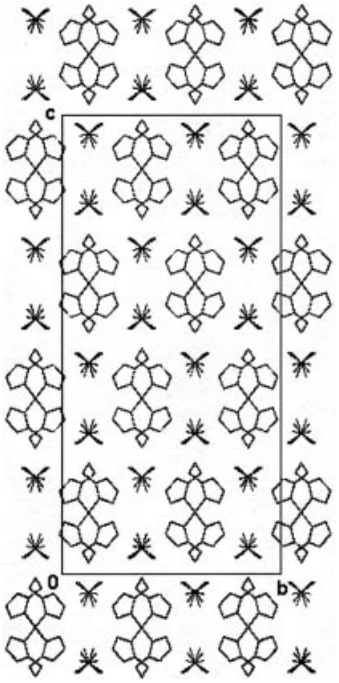

Figure 4. PLATON/POVRAY representation[27,28] of the crystal packing of α-$[Cu(bpp)_2](BF_4)_2$ (**1**), seen in a view down the *a* axis

chelate rings. The coordination geometry at the metal centers is distorted tetrahedral. Although the ligand bite angles are close to 109° [**1**: N−Cu−N 107.71(13)°; **2**: N−Cu−N 104.32(10)−105.76(10)°], the other N−Cu−N angles deviate by up to 18° (**1**) or 27° (**2**) from the ideal tetrahedral value. The dihedral angles between the N−Cu−N planes of the chelate rings in each complex cation [**1**: 66.8(2)°; **2**: 57.05(15)−62.30(15)°] also indicate a flattening of the CuN_4 tetrahedrons for which a value of 90° would be expected.

Molecular Structure of $[Cu(bpp)_2](BF_4)$ (3)

In the crystal structure of the Cu^I complex $[Cu(bpp)_2](BF_4)$ (**3**), the asymmetric unit contains one inde-

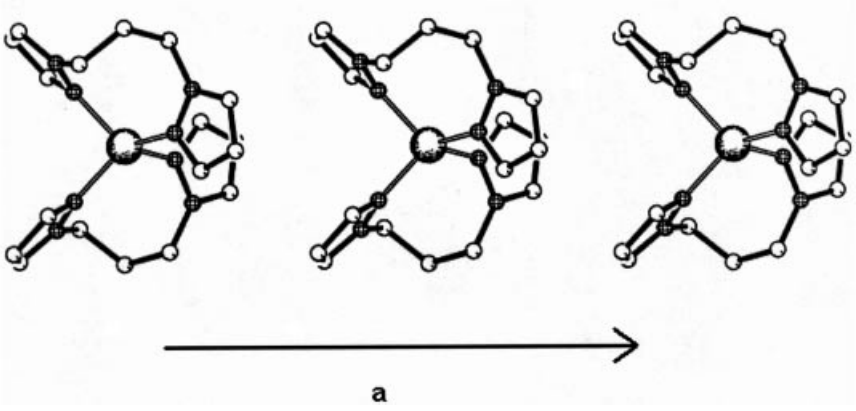

Figure 3. PLATON/POVRAY representation[27,28] of translation-related cations stacked into columns parallel to the *a* axis, in α-$[Cu(bpp)_2](BF_4)_2$ (**1**) and β-$[Cu(bpp)_2](BF_4)_2$ (**2**)

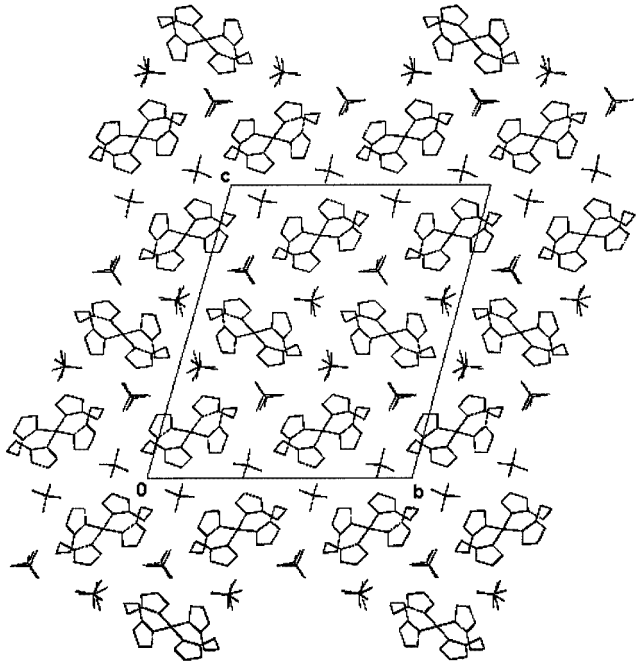

Figure 5. PLATON/POVRAY representation[27,28] of the crystal packing of β-[Cu(bpp)$_2$](BF$_4$)$_2$ (**2**), seen in a view down the *a* axis

pendent cation possessing (noncrystallographic) S_4-based symmetry, as shown in Figure 6. The relevant geometric parameters for **3** are given in Table 1. The Cu^{I} ion of **3** is coordinated to two bpp ligands, but at Cu−N distances of 2.0207(15)−2.0458(15) Å which, as expected, are longer than those found in the Cu^{II} complex. Similar Cu^{I}−N [2.029(6)−2.053(6) Å] and Cu^{II}−N [1.941(9)−1.977(8) Å] bond lengths have been reported for the nearly tetrahedral complexes [CuL$_2$](ClO$_4$) and [CuL$_2$](ClO$_4$)$_2$ [L = 2,2′-bis(2-imidazolyl)biphenyl].[21] In **3**, The Cu-centered coordination environment is a slightly distorted tetrahedron; the N−Cu−N angles range from 103.33(6)−114.18(6)°, and the dihedral angle between the N−Cu−N planes of the chelate rings is 89.58(9)°.

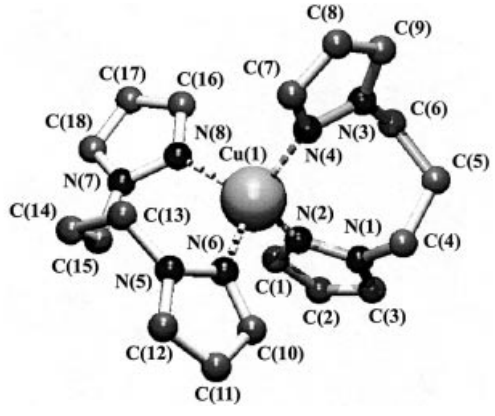

Figure 6. PLATON/POVRAY representation[27,28] of the molecular structure of the cation in [Cu(bpp)$_2$](BF$_4$) (**3**); hydrogen atoms and counterions have been omitted for clarity

Spectroscopic and Magnetic Properties

Ligand field spectra have been recorded for both [Cu(bpp)$_2$](BF$_4$)$_2$ and [Cu(bpp)$_2$](BF$_4$) in the solid state. The spectrum of α-[Cu(bpp)$_2$](BF$_4$)$_2$ (**1**) consists of broad signals at 39.2 × 10^3 cm^{-1} and 22.7 × 10^3 cm^{-1}, which are attributed to LMCT transitions. In the spectrum of β-[Cu(bpp)$_2$](BF$_4$)$_2$ (**2**), these signals are present at 40.2 × 10^3 cm^{-1} and 21.5 × 10^3 cm^{-1}. Furthermore, in the spectrum of **1** a weak signal is present at 14.5 × 10^3 cm^{-1}, in the normal range for d-d transitions in slightly distorted tetrahedrally coordinated Cu^{II} complexes.[7,22] This signal is not visible in the spectrum of **2**, where the LMCT transition dominates.

The diffuse reflectance spectrum of [Cu(bpp)$_2$](BF$_4$) consists of one broad signal at 37.9 × 10^3 cm^{-1}, with a shoulder at 25.0 × 10^3 cm^{-1}, which is ascribed to MLCT transitions. No d-d transition signals are present, as is expected for Cu^{I}.

The X-band EPR spectra of a polycrystalline powder of α-[Cu(bpp)$_2$](BF$_4$)$_2$ (**1**) were recorded at room temperature and 77 K. The resolution did not improve upon cooling to 77 K. The spectra show an axial $S = 1/2$ signal with g values that are normal for Cu^{II} in a slightly distorted tetrahedral environment: $g_{\perp} = 2.11$, $g_{//} = 2.32$ and $A_{//} = 13.0$ mT.[7] The spectrum of α-[Cu(bpp)$_2$](BF$_4$)$_2$ in a frozen solution of ethanol was also recorded. This spectrum shows g values that are similar to the g values of the powder spectra, which indicates that the complex is stable in solution. The same spectra were recorded for β-[Cu(bpp)$_2$](BF$_4$)$_2$ (**2**). These spectra show an axial $S = 1/2$ signal with $g_{\perp} = 2.13$, $g_{//} = 2.38$ and $A_{//} = 12.0$ mT.

Magnetic susceptibility measurements were also performed on [Cu(bpp)$_2$](BF$_4$)$_2$ to detect any possible magnetic exchange. A plot of χ^{-1} vs. T fits a straight line through zero, with a value of the Curie constant C of 0.44 cm^3·K·mol^{-1}, which corresponds to a μ_{eff} of 1.88.

Cyclic Voltammetry

The cyclic voltammogram of [Cu(bpp)$_2$](BF$_4$)$_2$ (Figure 7) shows an irreversible wave at 0.92 V vs. Ag/AgCl, ascribed to the couple Cu^{II}/Cu^{I} (E_{pc} at 0.83 V, E_{pa} at 1.01 V). At scan rates between 30−80 mV/s, $I_{pc}/I_{pa} = 1$ and $I_p/v^{1/2}$ is independent of v, but at higher and lower scan rates this reversibility is lost. In the Cu^{II} and Cu^{I} complexes with the ligand 2,2′-bis(2-imidazolyl)biphenyl mentioned above,[21] the Cu^{II}/Cu^{I} reduction wave occurs at 0.08 V vs. SCE (−0.052 V vs. Ag/AgCl) in acetonitrile.[23] Upon comparison, the reduction of [Cu(bpp)$_2$]$^{2+}$ to [Cu(bpp)$_2$]$^{+}$ takes place at an unusually high potential, confirming the high stability of the Cu^{I} complex [Cu(bpp)$_2$](BF$_4$), and also explaining the easy reduction of the Cu^{II} species in ethanol solution. Such a stabilisation of Cu^{I} by π-donor ligands such as azoles is well known. After reduction of Cu^{I} to Cu(0) at $E_{pc} = -0.55$ V, a stripping peak appears at $E_{pa} = -0.28$ V, as a result of the deposition of Cu(0) on the electrode surface. The Cu^{II}/Cu^{I} reduction wave becomes less prominent at scan rates higher and lower than 60 mV/s.

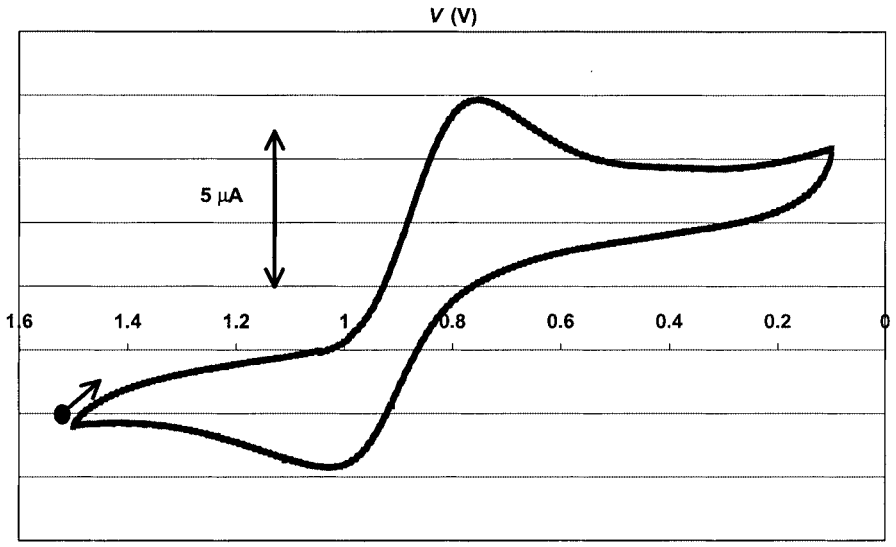

Figure 7. Cyclic voltammogram of $[Cu(bpp)_2](BF_4)_2$, in acetonitrile (10^{-3} M) at a scan rate of 60 mV/s

Conclusion

The ligand 1,3-bis(pyrazol-1′-yl)propane (bpp) has been synthesized from 1,3-dichloropropane and pyrazole. Attempts to obtain coordination complexes of bpp with both Cu^{II} and Cu^{I} succeeded. The complexes that were obtained are the first to contain copper ions surrounded by two — rather than only one — bpp ligands forming eight-atom chelate rings with the metal ion.[7] The best single crystals were grown from solutions of 1,3-bis(pyrazol-1′-yl)propane and Cu^{II} tetrafluoroborate, in which an excess of 1-(3-chloropropyl)pyrazole (ppc) was also present. A possible reason for this behavior is that the complexes stay in solution longer when ppc is present. The slower crystal growth yields higher quality single crystals. All attempts to obtain crystalline Cu^{II} complexes with only ppc were unsuccessful. The Cu^{II} ions in the two polymorphs of the $[Cu(bpp)_2](BF_4)_2$ complex are surrounded by a distorted tetrahedral coordination environment. This is remarkable because Cu^{II} has a strong preference for a square-planar geometry when it is surrounded by four monodentate ligands or two didentate ligands.[1] Tetrahedral geometries are much more common for Cu^{I} than for Cu^{II}. When the Cu^{II} complexes were found to be stable in a distorted tetrahedral geometry, it was expected that a tetrahedral Cu^{I} complex should also be stable, as is indeed the case. However, this complex was not expected to form from a Cu^{II} solution. The large redox potential for the copper ion in the complexes (0.92 V vs. Ag/AgCl) indicates the stability of the Cu^{I} complex.

Experimental Section

General Remarks

^{1}H NMR spectra were obtained with a Bruker 300 MHz spectrometer. X-band powder EPR spectra were obtained with a Jeol RE2x electron spin resonance spectrometer using DPPH (g = 2.0036) as a standard. FTIR spectra were obtained with a Perkin−Elmer Paragon 1000 FTIR spectrophotometer equipped with a Golden Gate ATR device, using the diffuse reflectance technique (4000−300 cm^{-1}, res. 4 cm^{-1}). Magnetic susceptibility measurements (2−300 K) were carried out using a Quantum Design MPMS-5 5T SQUID magnetometer (measurements carried out at 1000 Gauss). Data were corrected for the magnetization of the sample holder and for the sample diamagnetism, which was estimated from the Pascal constants.[24] Cyclic voltammetry measurements were performed with an Autolab PGSTAT 10 cyclic voltammeter, using a Pt working electrode, a Pt auxiliary electrode and a Ag/AgCl reference electrode in acetonitrile (10^{-3} M), with tetrabutylammonium hexafluorophosphate as electrolyte, at a scan rate of 60 mV/s. C, H, N determinations were performed with a Perkin−Elmer 2400 Series II analyzer.

Synthesis of the Ligands

1,3-Bis(pyrazol-1′-yl)propane (bpp; Figure 8) was prepared by adding 0.2 mol (13.6 g) of pyrazole and 0.4 mol (45.2 g) of 1,3-dichloropropane dissolved in 80 mL of toluene to a solution of 0.1 mol (4 g) of sodium hydroxide in 80 mL of water. After addition of 0.2 g of tetrabutylammonium bromide to increase the rate of charge transfer between the layers, the solution was refluxed at 100 °C for four days. The two layers were separated and the water layer was extracted with dichloromethane. All organic layers were combined, then dried with magnesium sulfate, and filtered. After evaporation of the solvents, the product was obtained as a yellow oil. The yield was 17% (2.99 g). ^{1}H NMR (300 MHz, $[D_6]$DMSO): δ = 7.70(d, a), 6.23 (dd, b), 7.44 (d, c), 4.07 (t, d), 2.17 (q, e).

1-(3-Chloropropyl)pyrazole (ppc) was prepared using the same procedure, but in this case only 0.1 mol (6.8 g) of pyrazole was added to the reaction mixture.

Synthesis of the Complexes

α-$[Cu(bpp)_2](BF_4)_2$ (1): This complex was obtained by adding a solution of 1.0 mmol (0.31 g) of $Cu(BF_4)_2{\cdot}4H_2O$ in 8 mL of ethanol to a solution of 1.0 mmol (0.15 g) of ppc and 0.1 mmol (0.02 g) of bpp in 8 mL ethanol. The compound crystallized from the green solution as red plates that were isolated by filtration and dried for several hours in air. $C_{18}H_{24}B_2CuF_8N_8$ (589.6): calcd. C 36.7, H 4.1, N 19.0; found C 36.7, H 4.3, N 19.0.

β-$[Cu(bpp)_2](BF_4)_2$ (2): This complex was obtained by adding a solution of 1.0 mmol (0.31 g) of $Cu(BF_4)_2{\cdot}4H_2O$ in 3 mL of methanol to a solution of 1.0 mmol (0.15 g) of ppc and 0.1 mmol (0.02 g) of bpp in 3 mL of methanol. The compound crystallized from the green solution as red plates that were isolated by filtration and dried for several hours in air. $C_{18}H_{24}B_2CuF_8N_8$ (589.6): calcd. C 36.7, H 4.1, N 19.0; found C 36.5, H 4.0, N 18.5.

$[Cu(bpp)_2](BF_4)$ (3): This complex was obtained by adding a solution of 1.0 mmol (0.31 g) of $Cu(BF_4)_2{\cdot}4H_2O$ in 12 mL of ethanol to a solution of 10.5 mmol (2.16 g) of ppc and 3.0 mmol (0.54 g) of bpp in 12 mL of ethanol. The resulting solution was heated to boiling and immediately filtered. After two weeks, colorless blocks crystallized from the green solution and these were isolated by filtration, then dried for several hours in air. $C_{18}H_{24}BCuF_4N_8$ (502.8): calcd. C 43.0, H 4.8, N 22.3; found C 42.7, H 5.0, N 22.5.

X-ray Crystallographic Study: Intensity data for each of the structures were collected on a Nonius KappaCCD diffractometer with rotating anode (Mo-K_α, λ = 0.71073 Å) at 150 K. Correction for absorption was considered unnecessary in all cases. The structures were solved by automated Patterson methods using DIRDIF99,[25] and refined on F^2 by least-squares procedures using SHELXL-97.[26] Structure validation and molecular graphics preparation were performed with the PLATON package.[27]

The BF_4^- anion in **1**, and four of the six independent anions in **2**, are disordered over two sets of atomic positions. All non-hydrogen atoms were refined with anisotropic displacement parameters, but the displacement parameters of the disordered atoms, as well as the ligand alkyl C atoms in complex **1**, were restrained to be approximately isotropic. Hydrogen atoms were constrained to idealized geometries and allowed to ride on their carrier atoms with an isotropic displacement parameter related to the equivalent displacement parameter of their carrier atoms. The BF_4^- anions were restrained to approximately tetrahedral geometries. Crystal data and further details of the data collections are given in Table 3.

CCDC-184550 (**1**), -184551 (**2**), and -184552 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html (or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

Acknowledgments

The work described in this paper has been supported by the Leiden University Study Group WFMO and has been performed under

the auspices of the Graduate Research School HRSMC, a joint activity of Leiden University and the two Universities in Amsterdam. This work has also been supported in part (A. L. S. & A. M. M.) by the Netherlands Foundation of Chemical Research (CW) with financial aid from the Netherlands Organization for Scientific Research (NWO). We are indebted to Jos van Brussel for performing the elemental analyses, to Annemarieke Schuitema for assistance with the EPR measurements and to Martijn Mulder and Elisabeth Bouwman for their help with the cyclic voltammetry measurements.

Synthesis and X-ray Structures of Tin(IV) and Lead(II) Complexes with Heterocyclic Thiones

Antonio Sousa-Pedrares,*[a] María I. Casanova,[a] José A. García-Vázquez,[a] María L. Durán,[a] Jaime Romero,[a] Antonio Sousa,*[a] Jack Silver,[b] and Philip J. Titler[b]

Keywords: Tin / Lead / N ligands / S ligands / Heterocycles

Tin(IV) and lead(II) complexes of 3-(trifluoromethyl)pyridine-2-thione (3-CF_3-pySH) and 5-(trifluoromethyl)pyridine-2-thione (5-CF_3-pySH) have been synthesised. The compounds [Sn(3-CF_3-pyS)$_4$] (1), [Sn(5-CF_3-pyS)$_4$] (2), [Pb(3-CF_3-pyS)$_2$] (3), and [Pb(5-CF_3-pyS)$_2$] (4) were obtained by addition of the appropriate ligand to a methanol solution of tin(II) chloride or lead acetate in the presence of triethylamine. The complex [Sn(5-CF_3-pyS)$_4$] was also prepared by electrochemical oxidation of a tin anode in a cell containing an acetonitrile solution of the ligand 5-(trifluoromethyl)pyridine-2-thione. The X-ray crystal structure of [Sn(3-CF_3-pyS)$_4$] reveals a dodecahedral coordination geometry around Sn^{IV}, with the four thionate ligands acting in a bidentate (N,S) manner. [Sn(5-CF_3-pyS)$_4$] also consists of monomeric neutral molecules with the tin(IV) atom in an octahedral geometry with two bidentate (N,S) ligands and two monodentate S ligands. The molecular structure of [Pb(3-CF_3-pyS)$_2$] shows the metal in a five-coordinate geometry with the stereochemically active lead(II) lone pair in an equatorial position of a trigonal bipyramid. Spectroscopic data for the complexes (IR, NMR, FAB, and Mössbauer spectra) are discussed and related to the structural information.

Introduction

Much of the interest in metal-sulfur chemistry results from the potential relevance of the resulting compounds to active sites in metalloenzymes and also to their ability to adopt various nuclearities of significant structural complexity.[1−3] However, in comparison with the coordination chemistry of transition metals, the chemistry of the main group metals with sulfur ligands remains much less developed.[4] In many cases, the interaction of toxic metals with biological systems involves bonding of the metal to the sulfydryl groups present in enzymes. Hence, an insight into the chemistry of main group thiolate compounds is important in terms of understanding the aforementioned interaction and for the design of detoxifying agents.[5,6] The generally poor solubility of group 14 metal/thiolate compounds makes it difficult to structurally characterise these systems and, for this reason, there is a lack of compounds whose structures have been determined by X-ray diffraction. Zubieta has determined the structures of [Sn(2-SC_5H_4N)$_4$][7] and [Sn(2-SC_5H_4N-3-$SiMe_3$)$_4$].[8] Curiously, while [Sn(2-SC_5H_4N)$_4$] has a distorted octahedral structure, the structure of [Sn(2-SC_5H_4N-3-$SiMe_3$)$_4$] is dodecahedral. This suggests that the nature and location of the substituents in the heterocyclic ring are important in determining the structure of the compound isolated. As a result of our continued interest in the coordination chemistry of thionate ligands, we decided to study the influence of the nature and location of substituents in the heterocyclic ring on the structure of the corresponding complexes. In particular, the work described here encompasses the synthesis and characterisation of tin(IV) and lead(II) complexes with 3-(trifluoromethyl)- and 5-(trifluoromethyl)pyridine-2-thionato ligands.

Results and Discussion

The reactions of 3-(trifluoromethyl)- and 5-(trifluoromethyl)pyridine-2-thione with $SnCl_2$ in methanol in the presence of triethylamine produce compounds whose microanalytical data correspond to SnL_4. On going from the tin precursor to the product, the metal atom is oxidised and so one possible reaction mechanism involves the formation of an initial tin(II) compound, which is subsequently oxidised in solution to tin(IV) in accordance with the following equations:

$$SnCl_2 + 2\ Et_3N + 2\ (R\text{-}pySH) \rightarrow [Sn(R\text{-}pyS)_2] + 2\ HEt_3NCl$$

$$[Sn(R\text{-}pyS)_2] + 2\ (R\text{-}pySH) \rightarrow [Sn(R\text{-}pyS)_4] + H_2$$

It is well-known that the electrochemical procedure for the synthesis of metal complexes produces compounds in which the metal is in a low oxidation state. For this reason,

we tried to ascertain whether tin(II) compounds with these ligands could be obtained using such a procedure. With this aim in mind, a solution of 5-(trifluoromethyl)pyridine-2-thione in acetonitrile was electrolysed using a tin plate as the anode. Once more, the microanalytical data and the X-ray structure (vide infra) for the resulting compound were consistent with the composition [Sn(5-CF_3-pyS)$_4$]. The electrochemical process has an efficiency value near to 0.5 mol·F^{-1} (E_f = 0.49). This means that the anode oxidation leads initially to a tin(II) species, which is then further oxidised to [SnL_4] in accordance with the following reaction sequence:

Cathode: 2 (5-CF_3pySH) + 2 e^- → 2 (5-CF_3pyS^-) + H_2

Anode: 2 (5-CF_3pyS^-) + Sn → [Sn(5-CF_3pyS)$_2$] + 2 e^-

[Sn(5-CF_3pyS)$_2$] + 2 (5-CF_3pySH) → [Sn(5-CF_3pyS)$_4$] + H_2

This behaviour has been observed in the synthesis of other Sn^{IV} complexes by electrochemical procedures.[9]

The lead(II) complexes were obtained in reasonable yields by stirring the corresponding ligand and lead acetate in solution in methanol in the presence of triethylamine. The formation of these lead complexes is believed to follow a similar scheme to that described above for [Sn(3-CF_3-pyS)$_4$]. However, in this case, the further oxidation step does not occur and the complexes have the general formula [PbL_2].

$Pb(CH_3COO)_2$ + 2 [Et_3N+ (R-pySH)] → [Pb(R-pyS)$_2$] + 2 HEt_3NCH_3COO

Crystallographic Studies

Structure of [Sn(3-CF_3-pyS)$_4$] (1)

Figure 1 shows the ORTEP drawing of the structure of [Sn(3-CF_3-pyS)$_4$] along with the numbering system used.

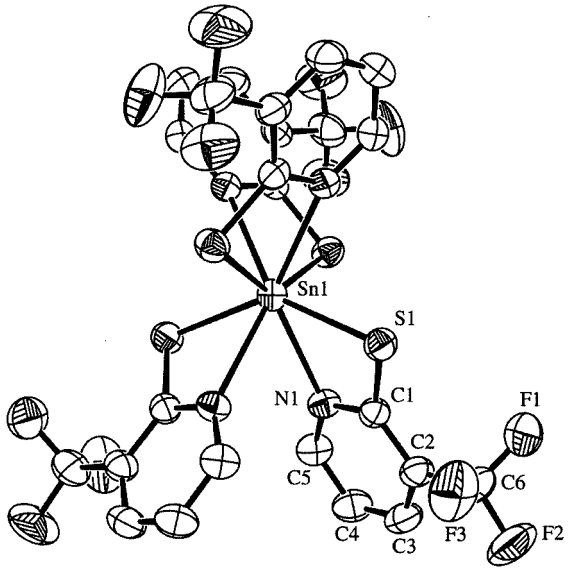

Figure 1. Molecular structure of [Sn(3-CF_3-pyS)$_4$]

The relevant bond lengths and bond angles are listed in Table 1.

The structure of **1** shows the tin atom to be coordinated by four bidentate (N,S) ligands. In this arrangement the metal atom is in an eight-coordinate environment. Comparison of the parameters found with values for the corresponding ideal geometry with the same coordination number shows that, in this case, the geometry is closer to a dodecahedron than to an antiprism.

The distortion of the dodecahedral geometry with regard to the regular geometry can be understood if we consider the regular dodecahedron as being the result of the interpenetration of two regular tetrahedra (Figure 2). In the complex under discussion, the four sulfur atoms are situated at the vertices of a distorted tetrahedron and the nitrogen atoms in the vertices of another distorted tetrahedron in an alternating manner.[10]

The main cause of distortion is the small bite of the chelate angle N−Sn−S at 61.72(5)°. Another factor that contributes to the distortion is the difference between the bond lengths Sn−N and Sn−S, which are 2.556(2) and 2.4935(8) Å, respectively. This causes the tetrahedron formed by the nitrogen atoms to be more distorted than the one formed by the sulfur atoms. In the tetrahedron formed by the sulfur atoms the values of the S−Sn−S angles are 97.322(12) and 138.17(3)°, while the N−Sn−N angles are 67.45(10) and 133.77(6)°, i.e. further from the theoretical value expected for a regular tetrahedron.

The four Sn−S bond lengths [2.4935(8) Å] are not very different from those found in other tin complexes with four-membered chelate rings such as, for example, [Sn(S_2CNEt_2)$_4$][11] and [Sn(S_2CNMe)$_4$],[12] or in the complex of tin with trisilylpyridine-2-thionate, [Sn(3-Me_3Si-pyS)$_4$], where the tin atom is also eight-coordinate in a dodecahedral geometry [average value 2.496(4) Å].[8]

The values of the Sn−N bond lengths are similar to those found in [Sn(3-Me_3Si-pyS)$_4$], average value 2.56(1) Å, but longer than the values found in [Sn(5-CF_3-pyS)$_4$], vide infra, where the tin atom is in a six-coordinate environment.

The pyridine rings are essentially planar and the S(1) atom lies approximately on the plane of the pyridine ring to which it is bound (maximum deviation 0.028 Å). The average S−C and C−N bond lengths [1.768(17) and 1.345(16) Å, respectively] are intermediate between the values found in free pyridine-2-thione [1.695(2) Å, 1.356(3) Å, respectively][13] and those in bis(3-*tert*-butyldimethylsilyl)-2-pyridyldisulfide[14] [average C−S: 1.794(3) Å; average N−C: 1.330(5) Å], suggesting that the ligand is coordinating in a way that is closer to the pyridine-2-thionato form than to the thione form.

Structure of [Sn(5-CF_3-pyS)$_4$] (2)

Figure 3 shows the ORTEP drawing of the structure of [Sn(5-CF_3-pyS)$_4$] along with the numbering system used. The relevant bond lengths and bond angles are listed in Table 2.

The geometry of [Sn(5-CF_3-pyS)$_4$] can be described as a severely distorted octahedron, with the tin atom coordin-

ated to two monodentate S thionato ligands and two bidentate (N,S) ligands.

The arrangement of the ligands is such that the sulfur atoms of the two monodentate thionate ligands are in a *cis* disposition with respect to one another and the sulfur atoms of the two bidentate ligands are in a *trans* disposition. The main cause of the distortion is the small bite of the bidentate thionato ligands [N−Sn−S angles of 64.6(9)° and 64.9(9)°]. This situation causes the angles defined by the two *trans* atoms and the tin atom [S(1)−Sn(1)−S(3) = 149.47(9), N(1)−Sn(1)−S(2) = 149.54(5), and N(3)−Sn(1)−S(4) = 148.02(5)°] to be very different from the expected values of 180° and, consequently, the angles formed by the tin and two *cis* atoms are also significantly different from 90° [64.09(9)−122.38(4)°].

The Sn−S distances are all slightly different and depend on whether the sulfur atom is provided by the bidentate ligand [2.4942(13) and 2.4921(13) Å] or by the monodentate ligand [2.4573(14) and 2.4618(13) Å]. The longest Sn−S distance is slightly shorter than those found in the tin complex with pyridine-2-thionate [Sn(pyS)$_4$][7] [average value 2.512(2) Å] but is very similar to those found in [Sn(3-CF_3-pyS)$_4$]. The distances between the tin atom and the sulfur atoms of the monodentate ligands [2.4573(14) and 2.4618(13) Å] are slightly shorter than those of [Sn(pyS)$_4$] [average value 2.469(2) Å].

The Sn−N bond lengths [2.384(4)−2.371(4) Å] are longer than the corresponding distances found in [Sn(pyS)$_4$] [2.332(5)−2.324(5) Å] but are shorter than those observed in the aforementioned eight-coordinate [Sn(3-CF_3-pyS)$_4$].

S(4)−Sn(1)−N(3)	149.54(10)	N(3)−C(13)−S(3)	113.1(3)
N(1)−Sn(1)−N(3)	76.28(13)	N(4)−C(19)−S(4)	117.9(4)
C(1)−S(1)−Sn(1)	84.2(2)		

This change in Sn−N bond length could be due to a change in the coordination number from six to eight.

The C−S bond lengths of the coordinated ligand range from 1.744(5) to 1.740(5) Å with an average value of 1.742 Å for the chelating ligands and 1.754(5)−1.751(5) Å for the monodentate ligands. Both distances are similar to those found in [Sn(3-CF_3-pyS)$_4$]. The C−N and C−C bond lengths of the ligands are as one would expect and do not warrant further discussion.

Each of the ligands is planar within experimental error, with the sulfur atoms of the bidentate ligands lying practically in the plane of the pyridine ring to which they are bound [by 0.032 Å for S(1) and 0.031 Å for S(3)]. In the case of the monodentate ligands the sulfur atoms lie out of the pyridine plane [by 0.082 Å for S(2) and 0.095 Å for S(4)].

It is worth noting that although compounds **1** and **2** have the same composition [SnL_4], their molecular structures are quite different. In the case of **1**, all of the ligands behave in a bidentate (S,N) manner and the Sn is in an eight-coordinate dodecahedral environment [SnS_4N_4]. Compound **2**, on the other hand, has two ligands that behave in a bidentate (S,N) way and another two that act in a monodentate S manner to give a six-coordinate octahedral geometry [SnS_4N_2] around the metal atom. The remarkable feature of this arrangement is that the more crowded structure is provided by the more sterically demanding ligand, 3-CF_3-pySH.

Structure of [Pb(3-CF_3-pyS)$_2$] (3)

The molecular structure of [Pb(3-CF_3-pyS)$_2$] is shown in Figure 4 together with the atom-labelling scheme. Selected bond lengths and angles are given in Table 3. The structure consists of discrete molecules without interactions between neighbours and with the lead atom coordinated by two bidentate (N,S) anionic 3-(trifluoromethyl)pyridine-2-thionato ligands. On the assumption that the lone pair on the lead atom is symmetrically placed with respect to the nitrogen and sulfur atoms, a value of 0.84 can be calculated for τ.[15] In this situation the environment around the lead atom is best described as a pseudo-trigonal bipyramid with a 16% distortion towards a square pyramid. In this case the nitro-

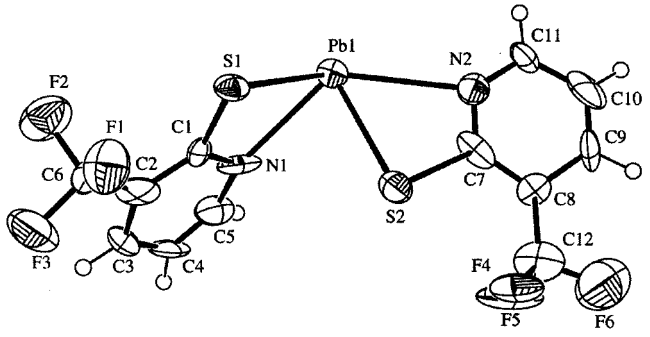

Figure 4. Molecular structure of [Pb(3-CF_3-pyS)$_2$]

S(1)−C(1)	1.72(3)	N(2)−C(11)	1.30(5)
N(1)−Pb(1)−S(1)	57.8(7)	C(1)−N(1)−C(5)	115(4)
S(2)−Pb(1)−N(2)	55.8(8)	C(1)−N(1)−Pb(1)	102.4(19)
S(1)−Pb(1)−N(2)	125.0(9)	C(5)−N(1)−Pb(1)	143(3)
S(2)−Pb(1)−N(1)	75.3(7)	C(7)−N(2)−C(11)	121(4)
S(1)−Pb(1)−S(2)	86.4(3)	C(7)−N(2)−Pb(1)	98(3)
N(1)−Pb(1)−N(2)	129.0(10)	C(11)−N(2)−Pb(1)	136(3)
C(1)−S(1)−Pb(1)	84.2(14)	N(1)−C(1)−S(1)	115(3)
C(7)−S(2)−Pb(1)	88.3(16)	N(2)−C(7)−S(2)	115(3)

gen atoms are in axial positions and the sulfur atoms and the lone pair in equatorial positions. This geometry is highly distorted with S−Pb−S and N−Pb−N bond angles of 86.4(3)° and 129.0(10)°, respectively. The bond angles between the axial nitrogen and sulfur atoms of the equatorial plane are in the range 55.8(8)−125.0(9)°, which is significantly different from the theoretical 90° for an ideal geometry. The main sources of distortion are the small value of the bond angle of the chelate ring [N−Pb−S = 55.8(8) and 57.8(7)°] and the effect of the active lone pair of the lead atom. The values of the bond angles among axial and equatorial positions, or in other words the angles S−Pb−N between atoms corresponding to different thionato ligands, are 75.3(7) and 125.0(9)°, again significantly different to the expected value of 90°.

The Pb−S bond lengths [2.883(1) and 2.707(11) Å] are longer than the Pb−S axial distance (2.696 Å) found in bis[6-(diethylcarbamoyl)-1-hydroxy-2(1*H*)-pyridine-2-thionato-*O*,*S*)lead(II)],[16] but are very close to the values of 2.737(7) and 2.782(8) Å in the trinuclear complex [Pb_3(3-$SiMe_3$-pyS)$_6$].[8]

Two different Pb−N bond lengths are observed in the compound [Pb(3-CF_3-pyS)$_2$]. The longest bond (2.793 Å) is similar to the distances observed for [Pb_3(3-$SiMe_3$-pyS)$_6$] [2.81(3) and 2.89(3) Å]. The other Pb−N bond length is significantly shorter at 2.59(3) Å, but is similar to the value of 2.59 Å found in other lead complexes with pyridine ligands.[17]

The structure of this compound differs markedly from that of [Pb(3-$SiMe_3$-pyS)$_2$], which shows a trinuclear structure with pentacoordinate metal atoms: two of the metals are coordinated by two nitrogen and three sulfur atoms in a distorted trigonal pyramidal environment and the third metal by the sulfur and nitrogen atoms of the two chelating ligands in a square pyramidal arrangement with the lead atom at the apex. Note that [Pb(3-$SiMe_3$-pyS)$_2$] has the more associated structure, despite the fact that contains a $SiMe_3$ group, which is considerably more bulky than the CF_3 group. Hence, in these cases steric hindrance is not a factor that determines the degree of association.

The pyridine rings of the ligands are essentially planar but the sulfur atoms lie out of the plane of the pyridine ring to which they are bound [by 0.077 Å for S(1) and 0.076 Å for S(2)]. The interplanar angle between these two ligands is 65.98°. The C−S bond lengths for the two ligands are also very different [C(1)−S(1) = 1.72(3) Å and 1.81(4) Å] but the average value of 1.765(4) Å is similar to those found in the complexes described above.

Spectroscopic Data

IR Spectra

The IR spectra of the complexes do not show bands assignable to ν(N−H), which in the free ligands appear at 3175 cm^{-1}. This suggests that deprotonation of the NH group has occurred during the synthesis and therefore that the ligand is coordinated in the thionato form. This conclusion is supported by the shift to smaller wavenumbers of the strong bands for ν(C=C) and ν(C=N), which appear at 1604−1545 and 1570−1512 cm^{-1} in the free ligands, on going from the free ligands to the complexes. In addition, the bands attributable to the ring breathing vibration at ca. 1000 and 630 cm^{-1} and the bands due to the C−H bending vibration at ca. 770 and 750 cm^{-1} are shifted to higher frequencies with respect to the free ligand. These shifts provide evidence that the nitrogen atom is bound to the metal atom.

NMR Spectra

The ^{1}H NMR spectra of the complexes do not show a signal for the NH proton, which appears as a broad singlet between δ = 13.0 and 14.0 ppm in the spectrum of the free ligand, thus demonstrating that in the complexes the ligands are deprotonated. The signals of all the hydrogen atoms of the pyridine ring are shifted to lower-field values in the complexes relative to the same signals in the spectra of the free ligands. The main change observed is the low-field shift of the signal due to the proton *ortho* to the nitrogen atom of the pyridine ring (δ = 9.18−8.14 ppm), demonstrating the coordination of the ligands to the metal atoms through the pyridine nitrogen.

It should be noted that in the case of [Sn(5-CF_3-pyS)$_4$], if the structure observed in the solid state is maintained in solution, two different types of ligands should be observed in the NMR spectrum. In particular, two different signals should be observed in the ^{1}H NMR spectrum for the proton *ortho* to the pyridine rings, two signals for C^2 and C^6 in the ^{13}C NMR spectrum, and two signals in the ^{19}F NMR spectrum. However, at room temperature only one signal is observed for each of these nuclei. This shows that the compound has a fluxional behaviour in solution. In order to investigate this possibility further, the spectrum was acquired at different temperatures down to −55 °C. Unfortunately, the spectrum does not change, showing that the fluxional exchange is too fast even at the lowest temperature compatible with the solvent used.

It is well-known that ^{119}Sn NMR spectroscopy is very sensitive to changes in the coordination number of tin(IV)[7] and can be used to determine the denticity of the ligands. The ^{119}Sn NMR spectrum of **2** in CD_3Cl at room temperature consists of a singlet at δ_{Sn} = −500.5 ppm. This value is similar to that of the hexacoordinate tin(IV) complex [Sn(pyS)$_4$], which also has a distorted octahedral [SnN_2S_4] environment with two ligands acting as monodentate S-bonded systems and another two as bidentate N,S bonded ligands.[7] The ^{119}Sn NMR spectrum of complex **1** shows a signal at δ_{Sn} = −662.6 ppm. The shift observed with respect to **2** is consistent with an increase in the coordination number from six to eight on going from **2** to **1**, and shows that the solid-state environment of **1** is maintained in solution.

Mass Spectra

The tin and lead complexes were also characterised by mass spectrometry using the positive ion FAB technique (*m*/*z*) in 3-nitrobenzyl alcohol (NBA) as matrix. The FAB spectrum of [Sn(3-CF_3-pyS)$_4$] shows the molecular ion

at m/z = 831, as well as peaks due to the fragments [Sn(3-CF_3-pyS)$_3$], [Sn(3-CF_3-pyS)$_2$], and [Sn(3-CF_3-pyS)] at m/z = 654, 475, and 298, produced by the loss of one, two, and three thionate ligands, respectively. The spectrum of the compound [Sn(5-CF_3-pyS)$_4$] does not show the molecular ion peak, but does show peaks associated with [Sn(5-CF_3-pyS)$_3$], [Sn(5-CF_3-pyS)$_2$], and [Sn(5-CF_3-pyS)] at m/z = 654 (100%), 475, and 298, respectively.

The FAB mass spectra of the lead compounds, [Pb(RpyS)$_2$] show, in all cases, the molecular ion peak at m/z = 563 along with a peak at m/z = 385, which is associated with [Pb(RpyS)] formed by loss of one thionate ligand. This evidence, together with the fact that the ^{19}F NMR spectra of both compounds are very similar, shows that [Pb(5-CF_3-pyS)$_2$] is a monomer with a structure similar to that of [Pb(3-CF_3-pyS)$_2$].

Mössbauer Spectroscopy

The ^{119}Sn Mössbauer data for compounds **1** and **2** appear in Table 4.

Table 4. ^{119}Sn Mössbauer Spectroscopic data recorded at 78 K

Compound[a]	δ [mm·s^{-1}]	ΔE_Q [mm·s^{-1}]	Γ[a] [mm·s^{-1}]
[Sn(3-CF_3-pyS)$_4$] (**1**)	0.93(1)	1.12(2)	1.16(3)
[Sn(5-CF_3-pyS)$_4$] (**2**)	0.98(1)	0.84(3)	1.14(6)

[a] Full width at half-mean height.

The *isomer shift* (δ) values are dependant on the *s*-electron density at the tin nucleus relative to a reference standard ($BaSnO_3$). As the *s*-electron density at the tin nucleus is measured relative to that in the valence shell of the atom, then factors that affect the latter must also affect the former. Therefore *p*-electron shielding and the polarity of the tin-ligand bonds,[18,19] together with their number, will affect δ.[20]

Clearly compound **1** has the smallest δ value, in keeping with the fact that it has eight ligands and these are relatively far from the Sn atom compared to those of compound **2**. Hence we would expect the environment to be "more ionic" and hence less s-electron density on the tin atom. The coordination number or stereochemistry at the tin also affects the δ value. When the coordination number of the tin atom increases, the concomitant increased involvement of the metal *5d* orbitals for bonding leads to a reduction in the *5s* electron density at the tin nucleus.[20,21]

The *quadrupole splitting* (ΔE_Q) arises from the interaction of the tin nucleus with the electric field gradient (EFG). If the tin atom has a perfectly symmetrical electronic environment ("cubic") then there is no EFG and only a single line is observed in the Mössbauer spectrum (as for $SnMe_4$).[21] Any deviation from a cubic electronic environment results in a doublet spectrum. As the EFG is the second derivative of the potential, its magnitude is inversely related to the cube of the distance of the charge from the nucleus. Therefore electron density on the Sn atom makes a larger contribution to ΔE_Q than that in the tin-ligand bonds. These latter are more important than charges on neighbouring atoms or ions.

Compound **1** has a ΔE_Q value of 1.12(2) mm·s^{-1} which is larger than that obtained for compound **2**. This means that the EFG in **1** is larger than that of **2**. This is in keeping with the distortion of the dodecahedral arrangement found in the structure of **1** and most probably arises from the imbalance of the electron density in the tin−ligand bonds, though the different polarity induced by the nitrogen and sulfur ligands must also play a role.

Compound **2** has a ΔE_Q value of 0.84(3) mm·s^{-1} which, although small, is substantial for an octahedral electronic environment. A perfect octahedral site would be expected to have zero splitting in a cubic structure. In this case it is in keeping with a highly distorted octahedral environment and is thus very compatible with the structure of compound **2**. It should be noted that these two Mössbauer spectra have low recoil-free fractions and hence were collected at 78 K only, whereas the crystal structures of **1** and **2** were recorded at room temperature. However at the very least it is shown here that the structures do not become symmetrical upon cooling to 78 K, and that in fact the Mössbauer spectra recorded at 78 K may reflect the room temperature structures.

Conclusions

The results discussed in this paper show that the structures of complexes of tin(IV) and lead(II) with derivatives of pyridine-2-thione depend on the nature and location of the substituents on the heterocyclic ring. Indeed, while [Sn(5-CF_3-pyS)$_4$] has an [SnN_2S_4] octahedral geometry around the metal atom, the structure of [Sn(3-CF_3-pyS)$_4$] shows the tin atom in an [SnN_4S_4] dodecahedral environment. On the other hand, while [Pb(3-CF_3-pyS)$_2$] and [Pb(5-CF_3-pyS)$_2$] are mononuclear compounds with the lead atom in a trigonal bipyramidal environment, [Pb(3-$SiMe_3$-pyS)$_2$] has a trimeric molecular structure. It appears that the factor responsible for this different behaviour is not of a steric nature, as the most sterically demanding ligands produce the structures with the higher coordination numbers. Further work is required to clarify this interesting phenomenon.

Experimental Section

Microanalysis were performed using a Carlo−Erba EA1108 microanalyser. Infrared spectra were recorded as compressed KBr discs by using an IR-FT Mattson model CYGNUS-100. Electron impact (EI) and fast atom bombardment (FAB) mass spectra were recorded on Hewlett−Packard HP5988A and Micromass Autospec spectrometers, respectively, with 3-nitrobenzyl alcohol as the matrix for the FAB spectra. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AMX300 using $CDCl_3$ as solvent and TMS as internal reference. ^{119}Sn NMR spectra were recorded on a Bruker AMX500 spectrometer using $CDCl_3$ as solvent and saturated $SnMe_4$ as a secondary reference. ^{19}F NMR spectra were recorded on a Bruker AMX300 spectrometer and referenced to $CFCl_3$. All Mössbauer

spectra were recorded at 78 K, with a ^{119m}Sn 23.875 keV γ source (370MBq, 10 mCi $CaSnO_3$ matrix, Wissel GmbH) mounted on the previously reported experimental setup.[22] All thiones and metal salts were commercial products and were used without further purification.

Preparations

All the complexes were prepared by reaction of a methanolic solution of the corresponding thione and triethylamine with a solution of the tin(II) or lead(II) salts in the same solvent. Tetrakis[5-(trifluoromethyl)pyridine-2-thiolato]tin(IV) was also prepared using an electrochemical procedure.[23]

[Sn(3-CF_3-pyS)$_4$] (1): $SnCl_2{\cdot}2H_2O$ (0.189 g, 0.84 mmol) was added to a solution of 3-(trifluoromethyl)pyridine-2-thione (0.30 g, 1.67 mmol) and dry triethylamine (0.25 mL, 1.84 mmol) in methanol (20 mL) with constant stirring at room temperature. The solution was evaporated to dryness and the solid was recrystallised from diethyl ether. Yield 38% (0.132 g). $C_{24}H_{12}F_{12}N_4S_4Sn$ (831.4): calcd. C 34.7, H 1.4, N 6.7; found C 34.8, H 1.2, N 6.8. IR (KBr): $\tilde{\nu}$ = 1584, 1563, 1485 cm^{-1} [ν(C=C), ν(C=N)py]. FAB MS: *m*/*z* (%) = 831.6 (1.1) [SnL_4], 654.0 (100) [SnL_3], 475 (9.5) [SnL_2], 298 (27.4) [SnL]. ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 8.15 (d, 1 H, py-H^6), 7.78 (d, 1 H, py-H^5), 7.01 (dt, 1 H, py-H^4) ppm. ^{13}C NMR ($CDCl_3$, 300 MHz): δ = 163.1 (py-C^2), 124.6 (py-C^3), 136.0 (py-C^4), 121.0 (py-C^5), 147.2 (py-C^6), 116.4 (CF_3) ppm. ^{19}F NMR ($CDCl_3$, 300 MHz): δ = −65.3 ppm. ^{119}Sn NMR ($CDCl_3$, 500 MHz): δ = −662.6 ppm.

[Sn(5-CF_3-pyS)$_4$] (2): (a) $SnCl_2{\cdot}2H_2O$ (0.189 g, 0.84 mmol) was added to a solution of 5-(trifluoromethyl)pyridine-2-thione (0.30 g, 1.67 mmol) and triethylamine (0.25 mL, 1.84 mmol) in methanol (20 mL) with constant stirring at room temperature. The reaction mixture was stirred for 4 hours and the resulting yellow solid was filtered off, washed with a small amount of diethyl ether, and dried under vacuum. Yield 47% (0.163 g). $C_{24}H_{12}F_{12}N_4S_4Sn$ (831.4): calcd. C 34.7, H 1.4, N 6.7, S 15.4; found C 34.9, H 1.5, N 6.7, S 15.3.

(b) A solution of 5-(trifluoromethyl)pyridine-2-thione (0.267 g, 1.49 mmol) in acetonitrile containing 20 mg of tetraethylammonium perchlorate was electrolysed using a tin rod as the anode and a platinum wire as the cathode. A current of 10 mA was applied during two hours, dissolving 43.39 mg of metal (E_f = 0.49 mol·F^{-1}). At the end of the electrolytic process the solution was evaporated to dryness and the solid recrystallised from diethyl ether. Yield 69% (0.213 g). $C_{24}H_{12}F_{12}N_4S_4Sn$ (831.4): calcd. C 34.7, H 1.4, N 6.7; found C 34.5, H 1.4, N 6.6. IR (KBr): $\tilde{\nu}$ = 1590, 1540, 1455 cm^{-1} [ν(C=C), ν(C=N)py]. FAB MS: *m*/*z* (%) = 654.0 (100) [SnL_3], 475 (3.5) [SnL_2], 298 (49.7) [SnL]. ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 9.18 (m, 1 H, py-H^6), 8.51 (m, 1 H, py-H^4), 7.79 (m, 1 H, py-H^3) ppm. ^{13}C NMR ($CDCl_3$, 300 MHz): δ = 167.9 (py-C^2), 128.6 (py-C^3), 134.6 (py-C^4), 125.0 (py-C^5), 142.4 (py-C^6), 121.4 (CF_3) ppm. ^{19}F NMR ($CDCl_3$, 300 MHz): δ = −62.7 ppm. ^{119}Sn NMR ($CDCl_3$, 500 MHz): δ = −500.5 ppm.

[Pb(3-CF_3-pyS)$_2$] (3): $Pb(OAc)_2{\cdot}3H_2O$ (0.21 g, 0.55 mmol) was added to a solution of 3-(trifluoromethyl)pyridine-2-thione (0.20 g, 1.11 mmol) and triethylamine (0.17 mL, 1.23 mmol) in methanol (20 mL) with constant stirring at room temperature. The reaction mixture was stirred for 5 hours and the resulting yellow precipitate was filtered off, washed with diethyl ether, and dried under vacuum. The product was recrystallised from diethyl ether. Yield 62% (0.195 g). $C_{12}H_6F_6N_2PbS_2$ (563.5): calcd. C 25.6, H 1.1, N 5.0; found C 25.3, H 1.0, N 4.8. IR (KBr): $\tilde{\nu}$ = 1583, 1558, 1442, 1402 cm^{-1} [ν(C=C), ν(C=N)py]. FAB MS: *m*/*z* (%) = 563.8 (4.4) [PbL_2], 385.8 (29.3) [PbL]. ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 8.75 (d, 1 H, py-H^6), 8.09 (dd, 1 H, py-H^5), 7.23 (dt, 1 H, py-H^4) ppm. ^{13}C NMR ($CDCl_3$, 300 MHz): δ = 169.9 (py-C^2), 128.0 (py-C^3), 134.6 (py-C^4), 121.7 (py-C^5), 148.4 (py-C^6), 115.6 (CF_3) ppm. ^{19}F NMR ($CDCl_3$, 300 MHz): δ = −48.8 ppm.

[Pb(5-CF_3-pyS)$_2$] (4): $Pb(OAc)_2{\cdot}3H_2O$ (0.21 g, 0.55 mmol) was added to a solution of 5-(trifluoromethyl)pyridine-2-thione (0.20 g, 1.11 mmol) and triethylamine (0.17 mL, 1.23 mmol) in methanol (20 mL) with constant stirring at room temperature. The reaction mixture was stirred for 5 hours and the resulting yellow precipitate was filtered off, washed with diethyl ether, and dried under vacuum. Yield 18% (0.057 g). $C_{12}H_6F_6N_2PbS_2$ (563.5): calcd. C 25.6, H 1.1, N 5.0; found C 25.6, H 1.2, N 5.2. IR (KBr): $\tilde{\nu}$ = 1603, 1547, 1460 cm^{-1} [ν(C=C), ν(C=N)py]. FAB MS: *m*/*z* (%) = 563.8 (0.5) [PbL_2], 385.8 (38.1) [PbL]. ^{1}H NMR ([D$_6$]DMSO, 300 MHz): δ = 8.38 (d, 1 H, py-H^6), 7.46 (dd, 1 H, py-H^4), 6.87 (dd, 1 H, py-H^3) ppm. ^{13}C NMR ($CDCl_3$, 300 MHz): δ = 176.9 (py-C^2), 131.9 (py-C^4), 130.3 (py-C^5), 142.1 (py-C^6), 117.6 (CF_3) ppm. ^{19}F NMR ($CDCl_3$, 300 MHz): δ = −56.2 ppm.

In the cases of compounds **1**, **2**, and **3**, X-ray quality crystals were obtained from saturated solutions of the complexes by slow evaporation of the solvents at room temperature.

X-ray Crystal Structure Determinations

Data Collection and Processing: X-ray data were collected on a Smart-CCD-1000 Bruker diffractometer for **1** and on an Enraf−Nonius CAD4 diffractometer for **2** and **3**: both fitted with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). The data were collected at 293 K for all structures. The ω-scan technique was employed to measure intensities in all crystals up to a maximum Bragg angle of 26.37° for **1**, 24.97° for **2**, and 28.04° for **3**. Decomposition of the crystals did not occur during data collection. Corrections were applied for Lorentz and polarisation effects and for absorption (μ = 1.195 mm^{-1} for **1**, 1.223 mm^{-1} for **2**, and 11.683 mm^{-1} for **3**).[24] A total of 14630 reflections for **1**, 4014 for **2**, and 3652 for **3** were collected, of which 1569 reflections in **1**, 3829 in **2**, and 3585 in **3** were unique [R_{int} = 0.0362 (**1**), 0.0148 (**2**), 0.0766 (**3**)] and, of these, 1261 (**1**), 3829 (**2**), and 1515 (**3**) satisfied the $I > 2\sigma(I)$ criterion of observability and were used in the subsequent analysis.

Structure Analysis and Refinement: The structures were solved by direct methods and missing atoms were located in the difference Fourier map and included in subsequent refinement cycles. The structures were refined by full-matrix least-squares refinement on F^2, using anisotropic displacement parameters for all non-hydrogen atoms. In all cases, hydrogen atoms were included using a riding model with C−H distances of 0.93−0.97 Å and fixed isotropic thermal parameters, except for **2**, where hydrogen atoms were located in the difference Fourier map and refined isotropically. A weighting scheme of the form $\omega = 1/\sigma^2(F)$ was introduced and the refinement proceeded smoothly to convergence with a maximum δ/σ = 0.000 when R = 0.0270, R_w = 0.0597 and GOF = 1.092 (goodness-of-fit) for 102 variables for **1**, maximum δ/σ = 0.001 when R = 0.0306, R_w = 0.0861 and GOF = 1.045 for 491 variables for **2** and δ/σ = 0.001 when R = 0.1145, R_w = 0.2843 and GOF = 1.049 for 208 variables for **3**. The residual analysis of the variance showed no special features and the maximum and minimum residual electron density peaks in the final difference map were, respectively, +0.24 and −0.23 e·$Å^{-3}$ in **1**, +0.64 and −0.45 e·$Å^{-3}$ in **2**, and +4.84 and −4.40 e·$Å^{-3}$ in **3**.

The crystallographic programs in SHELX97[25] were used for the structure solutions and refinement. Atomic scattering factors and anomalous-dispersion corrections for all atoms were taken from the International Tables for X-ray Crystallography.[26] Crystallographic data for these compounds are given in Table 5. Ortep3[27] drawings with the numbering scheme used are shown in Figures 1, 3, and 4.

CCDC-186656 (**1**), -186658 (**2**), and -186657 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Reactivity of the First η^6-Rhodium(I) and η^6-Iridium(I) Complexes of 2,6-Bis(trimethylsilyl)phosphinines

Marjolaine Doux,[a] Louis Ricard,[a] François Mathey,[a] Pascal Le Floch,*[a] and Nicolas Mézailles*[a]

Keywords: Phosphinines / P ligands / Pi interactions / Rhodium / Iridium

It has been shown that 2 equiv. of 2,3,5,6-tetraphenylphosphinine (**2**) react with $[Rh(COD)_2][BF_4]$ to yield the bis(η^1-phosphinine)Rh^I complex **6**, whose X-ray crystal structure is presented. On the other hand, 2,6-bis(trimethylsilyl)phosphinines **4** and **5** react with Rh^+ and Ir^+ precursors to yield the first (η^6-phosphinine)Rh^I and -Ir^I complexes **7**–**10**, and **11**–**12**, respectively. The X-ray crystal structure of complex **8** is presented. Reaction of these η^6-phosphinine complexes with water or ethanol yields the first (η^5-phosphacyclohexadienyl)Rh^I and -Ir^I complexes **13**–**17**, resulting from the formal 1,1-addition of RO^- and H^+. DFT calculations comparing isoelectronic (η^6-phosphinine)- and (η^6-benzene)Fe^0 and -Rh^I complexes allows the rationalization of the large difference in reactivity of these complexes.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The coordination chemistry of phosphinines has been studied for many years now. These ligands usually bind to electron-rich metal centers through the lone pair on the phosphorus atom.[1] Comparatively, fewer η^6 complexes have been synthesized with these ligands. The sandwich bis-η^6 complexes were usually synthesized by co-condensation techniques between the ligand (in large excess) and the vaporized metal(0) (Ti, V, Cr, Ho).[2] The Group-6 mono-η^6 complexes were synthesized either by starting with an η^1-coordinated phosphinine, or by a phosphinine bearing two bulky groups at the *ortho* positions.[3] The only Group-7 η^6 complex was obtained by photolysis of a mixed (carbonyl)(η^1-phosphinine) complex.[4] For Group 8, the zerovalent Fe complexes were obtained by Zenneck et al. in the mid 1990s,[5] and very recently we reported on the syntheses of [(η^6-phosphinine)RuCp*] complexes.[6] Most interestingly, [(η^6-phosphinine)Fe(COD)] complexes were found to be active in the cyclotrimerization of alkynes and in the synthesis of pyridine derivatives.[5a]

The [(η^6-arene)Rh]$^+$ complexes have been known for more than 30 years now and were first synthesized by Haines et al. in 1969.[7] Since then, a number of [(η^6-arene)Rh(L)(L′)]$^+$ have been isolated.[8] Among them, the zwitterionic complex [(η^6-$PhBPh_3$)Rh(COD)] appeared to be a versatile and effective catalyst for a number of carbonylation reactions[9] and for the silylformylation of alkynes.[10] More recently, analogous [(η^6-benzene)Ir]$^+$ complexes were obtained by Oro et al. on reduction of an [(η^6-benzene)$Ir(H)_2$]$^+$ complex by ethylene.[11]

Therefore, we were interested in developing a method leading to the first η^6-phosphinine complexes with Group-9 metal centers. We now wish to report on the syntheses of the [(η^6-phosphinine)M]$^+$ (M = Rh, Ir) complexes, and present DFT calculations comparing the isoelectronic (phosphinine)- and (benzene)Fe^0 and -Rh^I derivatives. Studies on their reactivity, leading to the first (η^5-phosphacyclohexadienyl)Rh^I and -Ir^I complexes are also presented.

Results and Discussion

The syntheses of (phosphinine)Fe^0 complexes relies on the co-condensation of Fe^0 with phosphinine and COD. Obviously, this method can not be duplicated to yield the

desired isoelectronic Rh^I and Ir^I complexes. Two different methods were thus devised. The first one, Method A, relies on the chloride abstraction of $[M(diene)Cl]_2$ (M = Rh, Ir; diene = COD, NBD) by $GaCl_3$ at low temperatures, followed by the coordination of the phosphinine. It is hoped that the phosphinine adopts a η^6-coordination mode. Method B relies on the classical displacement of one diene ligand from the $[Rh(diene)_2][BF_4]$ (diene = COD, NBD) precursor by phosphinine (Scheme 1).

Moreover, since the η^1 complexes are usually favored, it was necessary to study the different factors that lead to the η^6 complexes, namely the nature of the metal precursor and the substitution pattern of the ligand. In order to test the importance of this second factor, we chose four different phosphinines, **2**−**5**. Among these, two had not been previously reported (**2**−**3**) [Equation (1)].

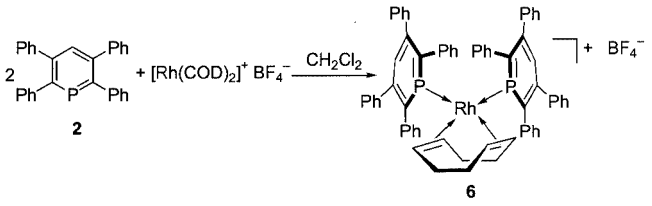
The phosphinines were synthesized according to the method developed several years ago in our laboratories.[12] This method relies on the high reactivity of the 1,3,2-diazaphosphinine **1** with alkynes. In a first step, **1** reacts with 1 equiv. of the first alkyne in a [4+2]/retro [4+2] sequence to produce a 1,2-monoazaphosphinine, which is not isolated, but whose complete formation is checked by ^{31}P NMR spectroscopy. This intermediate then reacts with the second alkyne, at higher temperature, in another [4+2]/retro [4+2] sequence to yield the desired phosphinine. The phosphinines are then easily purified by column chromatography. Phosphinines **2** and **3**, which are white solids, were fully characterized by usual NMR spectroscopic techniques and elemental analysis.

A first series of experiments showed that the 2,6-diphenyl derivatives only led to the formation of the bis(η^1) complex, irrespective of the method or the number of equivalents of phosphinine used, as indicated by ^{31}P NMR spectroscopy [Equation (2)]. Thus, 2 equiv. of the 2,3,5,6-tetraphenyl derivative **2** reacts with $[Rh(COD)_2]^+$ to quantitatively yield complex **6**.



(2)

This complex was fully characterized by usual NMR techniques as well as by elemental analysis. In the ^{31}P NMR spectrum, the complex is characterized by a doublet at δ = 175 ppm (coordination chemical shift $\Delta\delta$ = −33 ppm) and a large coupling constant $^1J_{Rh,P}$ of 166.5 Hz, clearly indicating the η^1-coordination mode.[1] This coordination mode was confirmed by the crystal structure analysis of **6**. An ORTEP drawing of **6** is presented in Figure 1, along with selected bond lengths and angles. As expected, the structure reveals a square-planar geometry around the rhodium center. The Rh−P bond lengths are 2.281 and 2.301 Å, and are typical, as are the C=C bond lengths within the ring (1.386−1.410 Å). The two C−P−C internal angles of the phosphinine ligands are 106.4 and 107.0°, and fall in the usual range for coordinated phosphinine. The C=C bond lengths of the COD moiety [1.353(7) and 1.388(7) Å] compare with those in the isoelectronic Fe^0 complex.[5a]

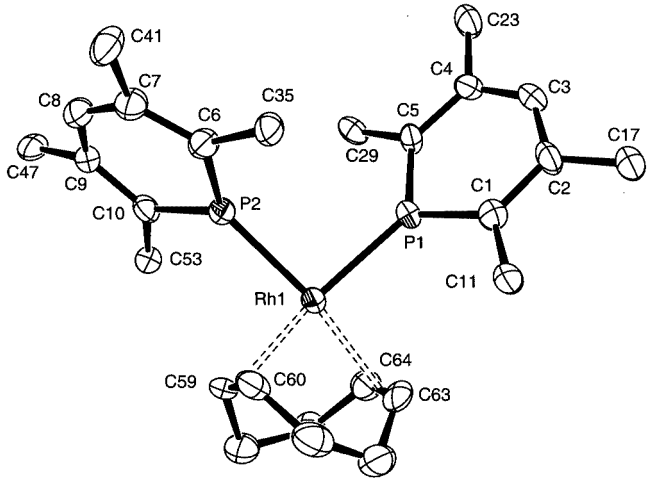


Figure 1. ORTEP view of complex **6**; ellipsoids are scaled to enclose 50% of the electron density; phenyl groups have been omitted for clarity; selected bond lengths [Å] and angles [°]; numbering is arbitrary and differs from the ones used in NMR spectra: Rh1−P1 2.301(1), P1−C1 1.738(5), P1−C5 1.738(5), C1−C2 1.407(6), C2−C3 1.386(7), C3−C4 1.391(7), C4−C5 1.410(6), Rh1−P2 2.281(1), P2−C6 1.721(5), P2−C10 1.740(5), C6−C7 1.397(7), C7−C8 1.388(7), C8−C9 1.396(7), C9−C10 1.405(6), C63−C64 1.353(7), C59−C60 1.388(7); C5−P1−C1 106.4(2), C6−P2−C10 107.0(2)

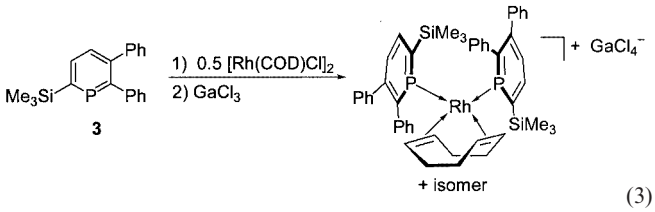
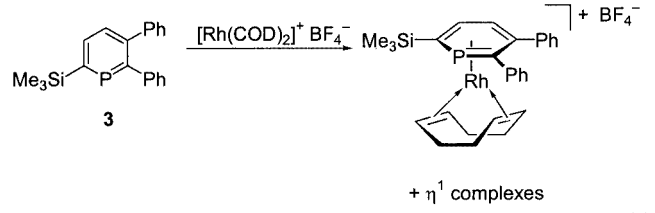
When a bulkier trimethylsilyl group replaces one phenyl group, such as in **3**, a different outcome is observed. In fact, the two methods yield different products. Method A leads to a mixture of two η^1 complexes as can be seen by ^{31}P

NMR spectroscopy, corresponding to different stereoisomers formed as a result of the bulkiness of the ligand which probably precludes their free rotation [Equation (3)].



(3)

However, when **3** was treated with $[Rh(COD)_2][BF_4]$ at room temperature for 4 h, the desired η^6 complex was formed [Equation (4)] as the major product (about 60% by ^{1}H NMR spectroscopy). The signal for the complex appears as a doublet which is strongly shifted to a higher field (δ = 84 ppm, $\Delta\delta$ = −124 ppm, $^1J_{Rh,P}$ = 6 Hz). The very small coupling constant between the phosphinine and the rhodium center is also very indicative of this type of coordination. Nevertheless, a mixture of the above-mentioned η^1 complexes (sets of doublets at $\delta \approx$ 190 ppm, $^1J_{Rh,P} \approx$ 160 Hz) was also formed during the reaction (about 40% by ^{1}H NMR spectroscopy).



(4)

Unfortunately, due to the large amount of by-products, the isolation of the pure η^6 complex was not achieved. In a third attempt, 2,6-bis(trimethylsilyl) derivatives were used. The two different methods depicted above led to the desired η^6 complexes [Equation (5)]. It appears then that two very bulky groups are needed to favor η^6-versus η^1 coordination. As can be seen with the syntheses of complexes **11** and **12**, this approach can be successfully extended to the Ir derivatives.

(5)

As can be predicted, the first method is faster and the reaction is completed between −78 °C and room temperature, whereas the second method requires a few hours of heating at 40 °C. The main NMR spectroscopic characteristics of the ligands and of these six complexes are summarized in Table 1.

As can be seen from the data, all the complexes are characterized by a strong shift of the signals in the ^{31}P NMR spectra ($\Delta\delta$ ranges from −150 to about −200 ppm). Unlike the η^1 coordination of phosphinines to Rh ($^1J_{Rh,P} \approx$ 160 Hz), the signals for complexes **7** and **8** appear as weakly coupled (small Rh-P coupling constant of 7.6 and 9.1 Hz, respectively), or as singlets for **9** and **10**. The signals for the iridium complexes **11** and **12** appear as singlets but at a much higher field than the Rh analogs ($\Delta\delta \approx$ −50 ppm). The strong shift of the signal for 4-H in the ^{1}H NMR spectra is also indicative of the η^6-coordination mode. This ranges from δ = 5.7 ppm in **7** to δ = 6.7 ppm in **9** (compared with δ = 7.1 ppm for **4**). In the ^{13}C NMR spectra, the most significant change on η^6-coordination is indicated by the chemical shift of the C-4 signal. In the Rh complexes, it appears as a doublet of doublets with $^3J_{C,P}$ of about 10 Hz (compared with $^3J_{C,P}$ = 20 Hz in the free ligand) and $^1J_{C,Rh}$ of about 2 Hz. The same $^3J_{C,P}$ value is observed in the Ir complexes **11** and **12**. The π coordination of the phosphinine was confirmed by two X-ray crystal analyses. Yellow crystals of **7** and **8** were obtained by slow diffusion of hexane into a CH_2Cl_2 solution of the complex. As the two structures are very similar, only the ORTEP plot of complex **8** is shown in Figure 2, together with selected bond lengths and bond angles. The ORTEP plot of complex **7** can be found in the Supporting Information (see footnote on the first page of this article).

The bonds between P and Rh are rather long [2.464(1) Å] compared with 2.279 and 2.304 Å in **6**. It should be noted that the bond between Rh and C3 (2.188 Å) is much shorter, by more than 0.18 Å, than the bonds between the rhodium atom and the other carbon atoms. Note that the atoms labeled C3 in the different crystal structures are named C-4 in the NMR discussions. A close inspection of the C−C bond lengths in these two complexes shows that what can be perceived as a minor change (Me or Ph substituents) can induce significant changes in the complexes. There are two long [C1−C2 (1.414 Å) and C4−C5 (1.420 Å)] bonds and two short [C2−C3 (1.409 Å) and C3−C4 (1.392 Å)] bonds in **7** (R = Me). The reverse is seen in **8** (R = Ph). The aromaticity of the phosphinine ring does not seem to be significantly perturbed by the coordination to the Rh center, as indicated by the typical bond lengths and angles. These values compare with those found in non-strained macrocycles recently synthesized.[13]

A study of the reactivity of the series of six η^6-phosphinine complexes was undertaken. First, the stability of the complexes towards water and ethanol was tested. All of the complexes were quantitatively converted, within minutes at room temperature and with 5 equiv. of water or ethanol, to the previously unknown (η^5-phosphacyclohexadienyl)rhodium and -iridium complexes (Scheme 2). As all the com-

plexes behave similarly, only three were fully characterized in their reaction with water, and two in their reaction with ethanol.

The most significant NMR spectroscopic data of the complexes **13**–**17** are collected in Table 2. In the ^{31}P NMR spectra of complexes **13** and **14**, the signals for both complexes appear as singlets at $\delta \approx -19.8$ and -16.2 ppm, respectively, despite the coordination to an Rh center. The reaction of **8** with ethanol yields complex **16** which displays a signal at a lower field ($\delta = -8.5$ ppm). The same trend is observed with the Ir complexes. For all of these complexes, when ^{31}P NMR spectroscopy is coupled with ^{1}H NMR spectroscopy, the singlets split into doublets, with very large $^{1}J_{H,P}$ coupling constants of 586 Hz (**13**) and 626 Hz (**17**). This proves the $R_2P(OR)H$ structure. When the ^{1}H NMR characteristics of these complexes are compared with the starting η^6-phosphinine complexes, it should be noted that the signal for 4-H is not significantly perturbed, showing that C-4 is still attached to the Rh center. This is also observed in the ^{13}C NMR spectra. In fact, the signals for C-4 and C-3,5 are only slightly shifted: $\delta = 91.8$ ppm and 125.9 ppm, respectively, in **13**, compared with $\delta = 97.1$ and 131.5 ppm, respectively, in **7**. However, the signal for C-2,6 is very significantly shifted in the new complexes: $\delta_{C\text{-}2,6}$ ranges from $\delta = 134.5$ ppm in **7** to $\delta = 69.7$ ppm in **13**. These data suggest the proposed new η^5-coordination mode. The crystal structures of **14**, **15** and **17** confirm this coordination mode. Suitable crystals were obtained by slow diffusion of hexane into THF solutions of the complexes. ORTEP views of **14** and **17** are presented in Figures 3 and 4, together with selected bond lengths and angles. The ORTEP view of complex **15** is very similar to that of **14**, and can be found in the Supporting Information.

From the three structures it can be seen that the phosphorus atom adopts a pyramid-type configuration. The η^5 coordination of the carbon part of the ring is also apparent. The presence of an $O-GaCl_3$ bond in **14** and **15** can be rationalized by the reaction of the transient P–OH with $GaCl_4^-$, which releases HCl [Equation (6)]. A similar type

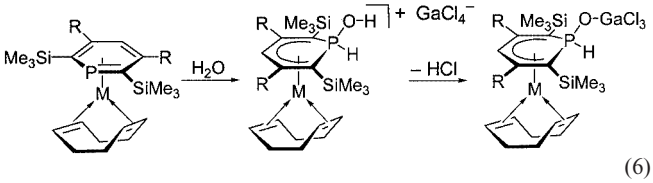
of reactivity has been observed between a [CpFe(η^6-phosphinine)][$AlCl_4^-$] complex and water.[14]



(6)

Apart from these features, the C−C and Rh−C bond lengths are very similar to those of the η^6 complexes. In the final products, a formal 1,1-addition of water or methanol takes place at the phosphorus atom. The mechanism most likely involves the reaction of the nucleophile at the electropositive phosphorus center, followed by the reaction of the electrophile. This type of mechanism has been reported by Dimroth in 1983 for the syntheses of tricarbonyl[η^5-(1λ^5-phosphinine)]metal(0) complexes (metal = Group-6 metal).[15]

Having tested the reactivity of the complexes towards protic sources, we then investigated the ease with which the diene moiety can be displaced. This factor is a prerequisite for the catalytic behavior of these complexes. Unfortunately, the reaction of the η^6 complexes with four-electron donor ligands, such as bipy or dppe, or even two-electron donor ligands, such as phosphanes, only led to the displacement of the phosphinine moiety within a few hours. In fact, this behavior is not unprecedented, and Valderrama et al. noted in 1982 that the arene ring in [Rh(C_6Me_6)($CO)_2$][PF_6] was very labile.[8g] It is not only displaced by bipy (instantaneously) but also by acetone or acetonitrile. In 2000, Werner et al. synthesized various [(η^6-arene)Rh(P*i*Pr$_3$)(η^2-COE)]$^+$ complexes with electron-rich and electron-poor arenes. They showed that both the alkene and the arene were displaced by ligands such as alkynes.[8m] Therefore, we tried to hydrogenate the diene moiety of these complexes under various pressures of H_2 in the presence of two-electron donors, hoping that hydrogenation would be faster than displacement of the phosphinine. Unfortunately, the typical solvent in which hydrogenation is fast (MeOH), destroys the η^6 coordination of the phosphinine, as shown above. In other solvents, the hydrogenation was not fast enough and displacement of the phosphinine always occurred.

The high sensitivity of the above-mentioned complexes towards nucleophilic attack prompted us to theoretically investigate, by DFT, the nature of the interaction between the

phosphinine ligand and the metal fragment. Considering the important difference in stability between cationic Group-9 complexes and their isoelectronic neutral iron(0) complexes synthesized by Zenneck et al., we extended our investigation to the η^6-Fe^0 species. Furthermore, in order to draw a comparison between phosphinines and arenes, the corresponding benzene derivatives were also studied. Therefore, a series of four complexes was studied: the $[Rh(\eta^6\text{-arene})(C_2H_4)_2]^+$ cationic species **I** (arene = C_6H_6) and **II** (arene = C_5H_5P), and the neutral species $[Fe(\eta^6\text{-arene})(C_2H_4)_2]$ **III** (arene = C_6H_6) and **IV** (arene = C_5H_5P) (Scheme 3).

[a] Binding energies are expressed in kcal/mol.

A first remark concerns the overall geometries of the calculated complexes that are analogous to that of the experimental structure. In each case, the D_2 (phosphinine complexes) and C_{2v} (benzene complexes) symmetries correspond to a minimum on the potential energy surface. Some discrepancies can be noted between the experimental and theoretical structures in the case of the (phosphinine)Fe and -Rh complexes; however, as mentioned above in the discussion of experimental structures of complexes **7** and **8**, the difference in the substitution pattern of the ring plays a very important role. Note that the nature of the olefin most likely plays a role in these distortions. The same can be said of the benzene complexes. Apart from this, all the coordinated ligands show a slightly inverse boat conformation (as noted in the structures of **7**−**9**). This distortion had already been observed in $[Rh(\eta^6\text{-arene})(olefin)L]$ complexes (L = 2e-donor ligand).

The most significant information is given by the NBO analysis,[16] which reveals that in rhodium complexes **I** and **II**, the arene ligands are electronically deficient (see Table 4). Thus, the sum of the NBO charges at the ligand reveals that +0.340 e has been transferred to the metallic fragment in **I**, and +0.423 e in the case of the phosphinine complex **II**. Most significant is the fact that in the coordinated phosphinine ligand, the phosphorus atom now bears a more important positive charge of +0.825, vs. +0.658 in the free ligand (calculated at the same level of theory). This simple comparison accounts for the higher reactivity of these η^6-ligated phosphinines towards nucleophilic attack. The NBO analysis also reveals that the Rh atom is more positively charged in the benzene complex **I** (+0.404) than in **II** (+0.274). In line with experimental observations (e.g. stability towards hydrolysis), the charge distribution pattern of the phosphinine ring is not significantly perturbed by coordination to the zero-valent $[Fe(C_2H_4)_2]$ fragment, and the NBO charges compare with those calculated for the free ligand. Thus, in complex **IV** the phosphorus atom bears a charge of +0.685, and the sum of the charges on all the atoms of the ring is close to zero (+0.035). Note that in **III** and **IV** a significant amount of electron-density has now been delocalized on the ethylene ligands, as shown by the sum of the charges (−0.204 in **III** and −0.160 in **IV**).

Interestingly, bond dissociation energies indicate that, although the bond strength of the ethylene ligands are quite similar in both types of complexes, benzene and phosphinine are more firmly bound to Fe in **III** and **IV**, than to Rh in **I** and **II**. This correlates very well with the experimental observations that shows that substitution of the ethylene ligands can occur in the case of Fe^0 complexes, but competes with that of the arene group in cationic Rh^I complexes. The bond dissociation energies are reported in Table 3. These data suggest that the contribution of the benzene and phosphinine ligands is nearly equivalent in these two types of complexes.

Therefore, to gain a deeper understanding of the arene−metal interactions in these complexes, a CDA analysis of **I**−**IV** was undertaken.[17] This method developed by Frenking and co-workers already proved to be a powerful tool in analyzing donor−acceptor interactions in terms of the common Dewar−Chatt−Duncansson (DCD) model concepts. The results given by the CDA analysis are summarized in Table 5. We did not limit our investigation to the arene ligands, and the analysis of the ethylene−metal interaction was also carried out. Care was taken to differentiate between the ethylene ligands in the phosphinine complexes **II** and **IV**, for obvious symmetry reasons.

A first important point concerns the residual term (Δ), which is important in analyzing the donor−acceptor interaction. In all cases, the values calculated are small and compare with those already reported in the literature for various ligands that were described following the DCD model. These values were found to be comparable for the ethylene

ligands in all the complexes studied; however, they were found to be higher for the two arene ligands in the iron complexes. This is consistent with the finding that the π-accepting capacity of both arenes is enhanced in the zero-valent iron complexes **III** and **IV**. As can be seen in Table 4, the $b/(b + d)$ ratio increases by about 10% on going from the rhodium to the iron complexes. Consequently, one may propose that an increase in the back donation (b) would increase covalency, and hence a larger absolute value for this residual term results. On examining the d/b and $b/(b + d)$ ratios, one can assume that in both types of complexes, the arenes essentially behave as π-donors, the percentage of π-acceptance [given by the $b/(d + b)$ ratio] does not exceed 29.73%. It also appears that absolute values of donation (d) are slightly greater in the case of the phosphinine complexes, but care must be taken since it should be emphasized that the absolute values of d and b are not important, only their ratios are relevant. In view of these results, it is obvious that the contribution of the phosphinine and benzene groups to the electronic exchange in the complex are relatively similar. On the other hand, the contribution of the ethylene ligands also appears to be comparable in both types of complexes, as shown by the $b/(d + b)$ ratio, which ranges from 36.25 to 40.23%, and the corresponding Wiberg bond indices, which vary from 1.41 to 1.45.

In conclusion, we have devised two different methods that allowed us to synthesize the first (η^6-phosphinine)Rh^I and -Ir^I complexes. The first studies of the reactivity of these complexes with ethanol or water quantitatively yielded the first (η^5-phosphacyclohexadienyl)Rh^I and -Ir^I complexes, which resulted from the formal 1,1-addition of RO^-, followed by H^+. DFT calculations allowed us to rationalize the large differences in reactivity between the (η^6-phosphinine or benzene)rhodium cationic complexes and the isoelectronic Fe^0 complexes. A study on the chemical reactivity of these complexes is underway in our laboratories.

Experimental Section

General: All reactions were routinely performed under argon or nitrogen by using Schlenk and glove-box techniques and dry deoxygenated solvents. Dry THF and hexane were obtained by distillation from Na/benzophenone, and dry $CDCl_3$ from P_2O_5. CD_2Cl_2 was dried and stored, like $CDCl_3$, overn 4 Å Linde molecular sieves. Nuclear magnetic resonance spectra were recorded with a

Bruker AC-200 SY spectrometer operating at 300.0 MHz for ^{1}H, 75.5 MHz for ^{13}C and 121.5 MHz for ^{31}P. Solvent peaks were used as internal references relative to Me_4Si for ^{1}H and ^{13}C chemical shifts (ppm); ^{31}P chemical shifts were relative to a 85% H_3PO_4 external reference. Coupling constants are given in Hz. The following abbreviations are used: s = singlet, d = doublet, t = triplet, m = multiplet, quint = quintuplet, v = virtual. IR data were collected with a Perkin−Elmer 297 spectrometer. Mass spectra were obtained at 70 eV with an HP 5989B spectrometer coupled to an HP 5980 chromatograph by the direct inlet method. Elemental analyses were performed by the "Service d'analyse du CNRS", at Gif sur Yvette, France. Diazaphosphinine **1**,[12a] phosphinines **4**,[18] **5**,[12a] $[Rh(COD)Cl]_2$,[19] $[Rh(NBD)Cl]_2$,[20] $[Ir(COD)Cl]_2$,[21] $[Rh(COD)_2][BF_4]$[8b,22] were prepared according to reported procedures.

Synthesis of 2,3,5,6-Tetraphenylphosphinine (2): 5 equiv. of diphenylacetylene (1.78 g, 10.0 mmol) were added to a solution of **1** (0.42 g, 2.0 mmol) in 8 mL of toluene. The mixture was then heated at 130 °C for 12 h. The completion of the reaction was checked by ^{31}P NMR spectroscopy. The solution was then cooled to room temperature, and the title product purified by column chromatography on silica gel. Excess diphenylacetylene was eluted first with hexane, and phosphinine **2** was then eluted with a mixture of hexane/toluene (80:20). Yield 55%, 440 mg. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 7.26−7.40 (m, 20 H, CH of Ph), 7.70 (d, $^4J_{H,P}$ = 3.6, 1 H, 4-H) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 127.5−130.9 (m, CH of Ph), 137.4 (d, $^3J_{C,P}$ = 12.5, C-4), 142.4 (d, $^2J_{C,P}$ = 24.5, C-α of Ph), 142.5 (s, C-α of Ph), 145.8 (d, $^2J_{C,P}$ = 10.9, C-3,5), 169.6 (d, $^1J_{C,P}$ = 54.8, C-2,6) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = 206.0 (s) ppm. $C_{29}H_{21}P$ (400.45): calcd. C 86.98, H 5.29; found C 86.97, H 5.44.

Synthesis of 5,6-Diphenyl-2-(trimethylsilyl)phosphinine (3): 1 equiv. of (trimethylsilyl)acetylene (0.20 g, 2.0 mmol) was added to a solution of **1** (0.42 g, 2.0 mmol) in 8 mL of toluene. The mixture was then heated at 60 °C for 12 h. The complete formation of the monoazaphosphinine was observed by ^{31}P NMR spectroscopy. 3 equiv. of diphenylacetylene (1.07 g, 6.0 mmol) were then added to the mixture, and the mixture was heated at 130 °C for 16 h. The solution was then cooled to room temperature and the title product purified by column chromatography. Excess diphenylacetylene was eluted first with hexane, and phosphinine **3** was then eluted with a mixture of hexane/toluene (80:20). **3** was recovered as a white solid after solvent evaporation. Yield 75%, 480 mg. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 0.32 (d, $^4J_{H,P}$ = 0.8, 9 H, $SiMe_3$), 7.02−7.16 (m, 10 H, CH of Ph), 7.45 (dd, $^4J_{H,P}$ = 3.0, $^2J_{H,H}$ = 8.1, 1 H, 4-H), 8.03 (dd, $^3J_{H,P}$ = 10.6, $^2J_{H,H}$ = 8.1, 1 H, 3-H) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 0.6 (d, $^3J_{C,P}$ = 5.7, $SiMe_3$), 127.2−131.3 (m, CH of Ph), 137.9 (d, $^3J_{C,P}$ = 12.5, C-4), 142.8 (s, C-α of Ph), 143.4 (d, $^2J_{C,P}$ = 23.6, C-α of Ph), 146.4 (d, $^2J_{C,P}$ = 10.3, C-3,5), 170.0 (d, $^1J_{C,P}$ = 62.3, C-2), 170.7 (d, $^1J_{C,P}$ = 77.1, C-6) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = 232.7 (s) ppm. $C_{20}H_{21}PSi$ (320.44): calcd. C 74.96, H 6.61; found C 75.27, H 6.25.

Synthesis of Complex 6: Phosphinine **2** (240 mg, 0.6 mmol) and $[Rh(COD)_2][BF_4]$ (121 mg, 0.3 mmol) were weighed in air and then placed under nitrogen in a Schlenk flask. CH_2Cl_2 (10 mL) was then added by syringe into the mixture, which was stirred for 2 h at 40 °C. The solvent was then evaporated under vacuum and the COD extracted with 2 mL of hexane. The solid was then dried under vacuum to yield pure **6** as a yellow powder. Yield 95%, 313 mg. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 1.97−2.01 (m, Σ*J* = 13, 8 H, CH_2 of COD), 4.00 (m, Σ*J* = 13, 4 H, CH of COD), 6.92−7.26 (m, 20 H, CH of C_6H_5), 7.50 (AXX′, vt, $\Sigma J_{H,P}$ = 7.5, 1 H, 4-H) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 25.8 (s, CH_2 of COD), 70.0 (s, CH of COD), 127.8 (s, CH of Ph), 128.3 (s, CH of Ph), 128.5 (s, CH of Ph), 128.6 (s, CH of Ph), 129.5 (s, CH of Ph), 132.2 (s, CH of Ph), 134.9 (AXX′, vt, $\Sigma J_{C,P}$ = 23, C-4), 138.9 (m, C-α of Ph), 140.5 (t, $^1J_{C,P}$ = 2.3, C-2,6), 150.5 (m, C of Ph) 161.5 (m, C-3,5) ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 175.15 (d, $^1J_{P,Rh}$ = 166.5) ppm. $C_{66}H_{54}P_2RhBF_4$ (1098.81): calcd. C 72.14, H 4.95; found C 72.43, H 5.15.

Synthesis of the η^6-Phosphinine Complexes. Method A: A solution of $GaCl_3$ (63.4 mg, 0.36 mmol) in CH_2Cl_2 was added by cannula into a mixture of $[M(diene)Cl]_2$ (0.15 mmol) and phosphinine (0.3 mmol) in CH_2Cl_2 at −78 °C. The resulting mixture was then stirred for 30 min at room temperature. The solid was then precipitated with hexane, filtered, and dried under vacuum yielding the title complex. **Method B:** CH_2Cl_2 (10 mL) was added to a mixture of $[Rh(diene)_2][BF_4]$ (0.3 mmol) and phosphinine (0.3 mmol). The solution was heated at 40 °C until the reaction was complete, as shown by ^{31}P NMR spectroscopy. After evaporation of the solvent under vacuum, the solid was washed with hexane and dried to yield the title complex.

Synthesis of Complex 7: 3,5-Dimethyl-2,6-bis(trimethylsilyl)phosphinine (**4**) (80 mg, 0.3 mmol) was used with Method A {$[Rh(COD)Cl]_2$ (74 mg, 0.15 mmol)} and Method B {$[Rh(COD)_2][BF_4]$ (121 mg, 0.3 mmol)}. Method A: yield 87%, 180 mg; Method B: yield 66%, 112 mg. Slow diffusion of hexane into a THF solution of the complex yielded X-ray quality crystals. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 0.49 (s, 18 H, $SiCH_3$), 2.20−2.28 (m, 8 H, CH_2 of COD), 2.64 (s, 6 H, CH_3), 4.70 (s, 4 H, CH of COD), 5.92 (s, 1 H, 4-H) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 1.2 (d, $^3J_{C,P}$ = 16.8, $SiCH_3$), 24.4 (s, CH_3), 32.0 (s, CH_2 of COD), 83.3 (d, $^1J_{C,Rh}$ = 11.6, CH of COD), 97.1 (dd, $^3J_{P,C}$ = 8.6, $^1J_{C,Rh}$ = 3.2, C-4), 131.5 (dd, $^2J_{C,P}$ = 2.8, $^1J_{C,Rh}$ = 1.7, C-3,5), 134.5 (dd, $^1J_{C,P}$ = 76.5, $^1J_{C,Rh}$ = 1.7, C-2,6) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = 101.42 (d, $^1J_{Rh,P}$ = 7.6) ppm. $C_{21}H_{37}BF_4PRhSi_2$ (566.37): calcd. C 44.53, H 6.58; found C 44.02, H 6.18.

Synthesis of Complex 8: 3,5-Diphenyl-2,6-bis(trimethylsilyl)phosphinine (**5**) (118 mg, 0.3 mmol) was used with Method A {$[Rh(COD)Cl]_2$ (74 mg, 0.15 mmol)} and Method B {$[Rh(COD)_2][BF_4]$ (122 mg, 0.3 mmol)}. Method A: yield 77%, 188 mg; Method B: yield 69%, 143 mg. Slow diffusion of hexane into a THF solution of the complex yielded yellow crystals suitable for X-ray analysis. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 0.26 (s, 18 H, $SiCH_3$), 2.34−2.37 (m, 4 H, CH_2 of COD), 2.39−2.53 (m, 4 H, CH_2 of COD), 4.85 (s, 4 H, CH of COD), 5.72 (d, $^4J_{H,P}$ = 1.3, 1 H, 4-H, 7.51−7.57 (m, 10 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 2.2 (dd, $^3J_{C,P}$ = 9.8, $^3J_{C,Rh}$ = 2.3, $SiCH_3$), 32.1 (s, CH_2 of COD), 84.8 (d, $^1J_{C,Rh}$ = 11.5, CH of COD), 94.1 (dd, $^3J_{C,P}$ = 10.4, $^1J_{C,Rh}$ = 3.5, C-4), 129.5−136.8 (s, Ph), 137.9 (s, C-3,5), 141.1 (d, $^1J_{C,P}$ = 104.5, C-2,6) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = 103.16 (d, $^1J_{Rh,P}$ = 9.1) ppm. $C_{31}H_{41}Cl_4GaPRhSi_2$ (815.24): calcd. C 45.67, H 5.07; found C 45.23, H 4.76.

Synthesis of Complex 9: 3,5-Dimethyl-2,6-bis(trimethylsilyl)phosphinine (**4**) (80 mg, 0.3 mmol) was used with Method A {$[Rh(NBD)Cl]_2$ (69 mg, 0.15 mmol)} and Method B {$[Rh(NBD)_2][BF_4]$ (112 mg, 0.3 mmol)}. Beige solid. Method A: yield 58%, 117 mg; Method B: yield 75%, 124 mg. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 0.46 (s, 18 H, $SiCH_3$), 1.34 (s, 2 H, CH_2 of NBD), 2.57 (s, 6 H, CH_3), 3.58 (s, 2 H, CH of NBD), 4.12

(m, ΣJ = 7.3, 4 H, CH of NBD), 6.68 (s, 1 H, 4-H) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 1.3 (d, $^3J_{C,P}$ = 9.7, $SiCH_3$), 24.7 (s, CH_3), 47.1 (d, $^2J_{C,Rh}$ = 2, CH of NBD), 48.3 (d, $^1J_{C,Rh}$ = 8.8, CH of NBD), 60.1 (d, $^3J_{C,Rh}$ = 4, CH_2 of NBD), 101.5 (dd, $^3J_{C,P}$ = 12.9, $^1J_{C,Rh}$ = 2.3, C-4), 127.9 (d, $^1J_{C,Rh}$ = 3.2, C-3,5), 130.3 (dd, $^1J_{C,P}$ = 101.2, $^1J_{C,Rh}$ = 3.0, C-2,6) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = 107.77 ppm. $C_{20}H_{33}BF_4PRhSi_2$ (550.33): calcd. C 43.65, H 6.04; found C 42.27, H 5.75.

Synthesis of Complex 10: 3,5-Diphenyl-2,6-bis(trimethylsilyl)phosphinine (**5**) (118 mg, 0.3 mmol) was used with Method A {$[Rh(NBD)Cl]_2$ (69.1 mg, 0.15 mmol)} and Method B {$[Rh(NBD)_2][BF_4]$ (112 mg, 0.3 mmol)}. Brown solid. Method A: yield 62%, 148 mg; Method B: yield 71%, 144 mg. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 0.18 (d, $^4J_{H,P}$ = 1.7, 18 H, $SiCH_3$), 1.49 (t, $^3J_{H,H}$ = 1.7, 2 H, CH_2 of NBD), 3.76 (t, $^3J_{H,H}$ = 1.7, 2 H, CH of NBD), 4.44 (m, ΣJ = 10, 4 H, CH of NBD), 6.6 (d, $^4J_{H,P}$ = 1.5, 1 H, 4-H), 7.35−7.52 (m, 10 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 2.3 (dd, $^3J_{C,P}$ = 9.3, $^3J_{C,Rh}$ = 3.1, $SiCH_3$), 46.9 (d, $^2J_{C,Rh}$ = 1.7, CH of NBD), 49.2 (d, $^1J_{C,Rh}$ = 8.7, CH of NBD), 61.1 (d, $^3J_{C,Rh}$ = 6.8, CH_2 of NBD), 100.7 (dd, $^3J_{C,P}$ = 12, $^1J_{C,Rh}$ = 2.3, C-4), 129.3−130.5 (s, Ph), 132.2 (d, $^1J_{C,P}$ = 104.6, $^1J_{C,Rh}$ = 2.3, C-2,6), 133.2 (dd, $^1J_{C,P}$ = 5.7, $^1J_{C,Rh}$ = 2.3, C-3,5) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = 116.57 ppm. $C_{30}H_{37}Cl_4GaPRhSi_2$ (799.20): calcd. C 45.09, H 4.67; found C 44.71, H 4.34.

Synthesis of Complex 11: 3,5-Dimethyl-2,6-bis(trimethylsilyl)phosphinine (**4**) (80 mg, 0.3 mmol) was used with Method A {$[Ir(COD)Cl]_2$ (101 mg, 0.15 mmol)}. Beige solid. Method A: yield 84%, 197 mg. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 0.46 (s, 18 H, $SiCH_3$), 2.15−2.18 (m, 8 H, CH_2 of COD), 2.69 (s, 3 H, CH_3), 4.55 (s, 4 H, CH of COD), 6.0 (s, 1 H, 4-H) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 0.5 (d, $^3J_{P,C}$ = 9.7, $SiCH_3$), 23.4 (d, $^3J_{P,C}$ = 2.4, CH_3), 32.8 (s, CH_2 of COD), 67.8 (s, CH of COD), 90.7 (d, $^3J_{P,C}$ = 10.3, C-4), 123.7 (d, $^1J_{P,C}$ = 102.1, C-2,6), 127.7 (d, $^2J_{P,C}$ = 5.4, C-3,5) ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 60.45 ppm. $C_{21}H_{37}Cl_4GaIrPSi_2$ (780.41): calcd. C 32.32, H 4.78; found C 31.95, H 4.31.

Synthesis of Complex 12: 3,5-Diphenyl-2,6-bis(trimethylsilyl)phosphinine (**5**) (118 mg, 0.3 mmol) was used with Method A {$[Ir(COD)Cl]_2$ (101 mg, 0.15 mmol)}. Brown solid. Method A: yield 79%, 215 mg. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 0.15 (s, 18 H, TMS), 2.17−2.21 (m, 8 H, CH_2 of COD), 4.70 (s, 4 H, CH of COD), 6.01(s, 1 H, 4-H), 7.34−7.48 (s, 10 H, H of Ph) ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 58.09 ppm.

Reactivity with H_2O: The same procedure was used for all the complexes: 5 equiv. of water were added to a CH_2Cl_2 solution of the complex. The solution instantaneously turned pale yellow and the ^{31}P NMR spectra showed the formation of a unique product. The solution was then concentrated to dryness and the title complex was obtained as a yellow solid. Yield 100%.

Synthesis of Complex 13: Complex **7** (70 mg, 0.1 mmol) was used. Yield 100%, 67 mg. Slow diffusion of hexane into a CH_2Cl_2 solution of the complex yielded X-ray quality crystals. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 0.46 (s, 18 H, $SiCH_3$), 2.06 (d, $J_{H,H}$ = 8.5, 4 H, CH_2 COD), 2.28 (s, 3 H, CH_3), 2.38 (d, $J_{H,H}$ = 14.8, 4 H, CH_2 of COD), 4.12 (s, 4 H, CH of COD), 5.04 (d, $^4J_{H,P}$ = 2.7, 1 H, 4-H), 6.69 (d, $^1J_{H,P}$ = 586, 1 H, PH) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 1.3 (m, $SiCH_3$), 24.23 (d, $^3J_{C,P}$ = 10.8, CH_3), 32.3 (s, CH_2 of COD), 69.7 (dd, $^1J_{C,P}$ = 59.4, $^1J_{C,Rh}$ = 3.6, C-2,6), 75.0 (d, $^1J_{C,Rh}$ = 12.5, CH of COD), 91.8 (dd, $^3J_{C,P}$ = 29,$^1J_{C,Rh}$ = 3.6, C-4), 125.9 (t, $^1J_{C,Rh}$ = $^3J_{C,P}$ = 3.6, C-3,5) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = −19.81 (d, $^1J_{P,H}$ = 586) ppm. $C_{21}H_{38}Cl_3GaOPRhSi_2$ (672.66): calcd. C 37.50, H 5.69; found C 37.21, H 5.25.

Synthesis of Complex 14: Complex **8** (73 mg, 0.09 mmol) was used. Yield 100%, 71 mg. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 0.20 (s, 18 H, $SiMe_3$), 2.16−2.45 (m, 8 H, CH_2 of COD), 4.48 (s, 4 H, CH of COD), 5.53 (d, $^4J_{H,P}$ = 3.4, 1 H, 4-H), 7.13 (d, $^1J_{H,P}$ = 581.2, 1 H, PH), 7.18−7.48 (m, 10 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 1.4 (d, $^3J_{C,P}$ = 3.0, $SiMe_3$), 31.5 (s, CH_2 of COD), 69.0 (dd, $^1J_{C,P}$ = 53.5, $^1J_{C,Rh}$ = 53.5, C-2,6), 75.9 (d, $^1J_{C,Rh}$ = 12.2, CH_2 of COD), 94.3 (dd, $^3J_{C,P}$ = 25.7, $^1J_{C,Rh}$ = 3.1, C-4), 128.5−129.7 (s, CH of Ph), 130.3 (t, $^1J_{C,Rh}$ = $^2J_{C,P}$ = 3.0, C-3), 139.7 (d, $^3J_{C,P}$ = 11.3, C-α of Ph) ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = −15.31 (d, $^1J_{P,H}$ = 581.2) ppm. $C_{31}H_{42}Cl_3GaOPRhSi_2$ (796.80): calcd. C 46.73, H 5.31; found C 46.32, H 4.97.

Synthesis of Complex 15: Complex **11** (100 mg, 0.13 mmol) was used. Yield 100%, 99 mg. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 0.39 (s, 18 H, $SiCH_3$), 1.96−2.22 (m, 8 H, CH_2 COD), 2.24 (s, 3 H, CH_3), 2.93 (d, $J_{H,H}$ = 14.8, 4 H, CH_2 of COD), 4.12 (s, 4 H, CH of COD), 5.99 (d, $^4J_{H,P}$ = 3.2, 1 H, 4-H), 6.77 (d, $^1J_{H,P}$ = 582.4, 1 H, PH) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 1.2 (d, $^3J_{C,P}$ = 3.4, $SiCH_3$), 22.7 (d, $^3J_{C,P}$ = 8.6, CH_3), 33.0 (s, CH_2 of COD), 51.5 (m, C-2,6), 58.6 (s, CH of COD), 98.6 (m, C-4), 112.0 (t, $^3J_{C,P}$ = 5.7, C-3,5) ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = −5.79 (d, $^1J_{P,H}$ = 582.4) ppm. $C_{21}H_{38}Cl_3GaIrOPSi_2$ (761.97): calcd. C 33.10, H 5.03; found C 32.88, H 4.65.

Reactivity with Ethanol: The same procedure was used for all the complexes: 5 equiv. of ethanol were added to a CH_2Cl_2 solution of the complex (100 mg). The solution instantaneously turned pale yellow and the ^{31}P NMR spectra showed the formation of a unique product. The solution was then concentrated to dryness and the title complex was obtained as a yellow solid. Yield 100%.

Synthesis of Complex 16: Complex **8** (73 mg, 0.09 mmol) was used. Yield 100%, 77.4 mg. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 0.20 (s, 18 H, $SiCH_3$), 1.39 (t, $^3J_{H,H}$ = 6.9, 3 H, CH_3 of EtO), 2.28 (d, J = 8.8, 4 H, CH_2 of COD), 2.31−2.49 (m, 4 H, CH_2 of COD), 3.75 (dq, $^3J_{H,P}$ = 14.9, $^3J_{H,H}$ = 6.9, 2 H, CH_2 of EtO), 4.63 (s, 4 H, CH of COD), 5.77 (d, $^4J_{H,P}$ = 3.0, 1 H, 4-H), 7.25 (d, $^4J_{H,P}$ = 621, 1 H, PH), 7.35−7.38 (m, 4 H, CH of Ph), 7.49−7.50 (m, 6 H, H of Ph) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 1.3 (m, $SiCH_3$), 15.0 (s, CH_3), 30.3 (s, CH_2 of COD), 62.2 (d, $^2J_{C,P}$ = 6.8, CH_2), 63.8 (dd, $^1J_{C,P}$ = 42.7, $^1J_{C,Rh}$ = 3, C-2,6), 79.0 (d, $^1J_{C,Rh}$ = 12.3, CH of COD), 92.0 (d, $^4J_{C,P}$ = 22.7, $^1J_{C,Rh}$ = 3.5, C-4), 129.4−129.6 (s, Ph), 133.1 (t, $^1J_{C,Rh}$ = $^3J_{C,P}$ = 2.9, C-3,5), 138.6 (d, $^2J_{C,P}$ = 11.9, Ph) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = −8.51 (d, $^1J_{P,H}$ = 621) ppm. $C_{33}H_{47}Cl_4GaOPRhSi_2$ (861.31): calcd. C 46.02, H 5.50; found C 45.71, H 5.19.

Synthesis of Complex 17: Complex **11** (100 mg, 0.13 mmol) was used. Yield 100%, 107 mg. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 0.41 (s, 18 H, $SiCH_3$), 1.24 (t, $^3J_{H,H}$ = 7, 3 H, CH_3), 2.13−2.16 (m, 8 H, CH_2 of COD), 2.41 (s, 3 H, CH_3), 3.49 (dq, $^3J_{H,P}$ = 15.2, $^3J_{H,H}$ = 7.1, 2 H, CH_2), 4.08 (s, 4 H, CH of COD), 6.42 (d, $^4J_{H,P}$ = 1.6, 1 H, 4-H), 6.90 (d, $^1J_{H,P}$ = 626, 1 H, PH) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 1.3 (s, $SiCH_3$), 16.3 (s, CH_3), 23.2 (d, $^3J_{C,P}$ = 9.4, CH_3), 33.3 (s, CH_2 of COD), 48.0 (d, $^1J_{C,P}$ = 45.6, C-2,6), 61.3 (s, CH of COD), 63,5 (d, $^2J_{P,C}$ = 6.5, CH_2), 98.9 (d, $^3J_{P,C}$ = 30.3, C-4), 114.5 (d, $^2J_{P,C}$ = 4.8, C-3,5) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = −1,82 (d, $^1J_{P,H}$ = 626) ppm. $C_{23}H_{43}Cl_4GaIrOPSi_2$ (826.48): calcd. C 33.42, H 5.24; found C 33.08, H 4.83.

Theoretical Methods: The geometries of complexes **I**−**IV** were optimized using the gradient-corrected density functional theory (DFT), using Becke's three-parameter hybrid method B3LYP.[16] The basis set used is identical to that used by Frenking and coworkers in many studies.[17] The basis set, which is known as "Basis Set II", incorporates the Hay and Wadt small-core relativistic effective core potential and double-ζ valence basis set (441/2111/*N*1) (N = 4, 3, 2 for first, second, and third transition metal rows, respectively) for transition metals, in conjunction with all-electron 6-31G(d) basis sets for the main-group elements, H, C, and P.[25] All optimized structures reported here have only positive eigenvalues of the Hessian matrix, i.e. they are minima on the potential energy surface. The charge distribution in the optimized structures was calculated with the NBO partitioning scheme. Inspection of the arenes (benzene or phosphinine) and ethylene−metal fragment donor−acceptor interactions was performed using the charge-decomposition analysis (CDA).[26] In the CDA method, the molecular orbitals (canonical, natural, or Kohn−Sham) of the complex are expressed in terms of MOs of appropriately chosen fragments. In the cases studied, the Kohn−Sham orbitals of the B3LYP/II calculations are formed in the CDA procedure as a linear combination of the MOs of the arene and those of the remaining fragment [M(C_2H_4)$_2$] (positively charged for M = Rh and neutral for M = Fe). The same approach was used for the analysis of the ethylene ligand, [M(arene)(C_2H_4)] (positively charged for M = Rh and neutral for M = Fe) being considered as the second fragment. In both cases, the arene and ethylene ligands, as well as the considered fragments were computed in the geometry of the complex. The orbital contributions are divided into four parts: (i) the mixing of the occupied MOs of the ligand and the unoccupied MOs of the metal fragment; this value (noted *d*) represents the donation ligand → [metal fragment]; (ii) the mixing of the unoccupied MOs of the ligand and the occupied MOs of the metal fragment; this value (noted *b*) accounts for the back donation [metal fragment] → ligand; (iii) the mixing of the occupied MOs of the ligand and the occupied MOs of the metal fragment; this term (noted <*r*>), which describes the repulsive polarization ligand ⇄ [metal fragment], is negative because electronic charge is removed from the overlapping area of the occupied orbitals; (iv) the residual term (Δ), which results from the mixing of the unoccupied MOs of the two respective fragments; usually, this term is very close to zero for closed-shell interactions. This value constitutes an important probe in determining whether the bonding studied can really be classified as a donor−acceptor interaction following the Dewar−Chatt−Duncansson model. Important deviations from Δ = 0 imply that the bond studied is more conventionally described as a normal covalent bond between two open-shell fragments. A more detailed presentation of the CDA method and the interpretation of the results can be found in the literature. CDA calculations were performed with the program CDA version 2.1. More details about the method and a discussion of its applications and results can be found in the literature. These calculations were performed with the Gaussian-98 program.[27]

X-ray Structure Determinations: Crystals of complexes **6**−**8**, **14**, **15**, **17** suitable for X-ray diffraction were obtained by slow diffusion of hexane into a dichloromethane solution of the complexes. Data were collected with a Nonius Kappa CCD diffractometer, using an Mo-K_α (λ = 0.71070 Å) X-ray source and a graphite monochromator. Experimental details are described in Tables 6 and 7. The crystal structures were solved using SIR 97[28] and SHELXL-97.[29] ORTEP drawings were made using ORTEP III for Windows.[30]

Compound **6** and **14** each contain a highly disordered CH_2Cl_2 molecule. They were accounted for by using the Platon SQUEEZE function. The structure of compound **6** calls for an additional comment. Both $GaCl_4$ anions present in the asymmetric unit appear to be disordered. When average positions are used, $R1$ converges to about 7.9%. The anion labeled GA1 has fewer problems than the second one, and the disorder could not be refined. For the anion labeled GA2, a model consisting of a major site, accounting for 70% of the electron-density, and a minor site (30% at GA2A) was refined. This model implies that the neighboring CH_2Cl_2 solvate is similarly disordered; not taking this into account results in apparent contacts of about 1.4 Å between the chlorine atoms of GA2A and the H atoms of the solvate. Compound **7** is twinned, twin operator [1 0 0 0 −1 0 0 0 −1], BASF = 0.41. CCDC-188543 (**6**), -188544 (**7**), -188545 (**8**), -188546 (**14**), -188547 (**15**), and -188548 (**17**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information Available: ORTEP drawings of complexes **7** and **15** (see footnote on the first page of this article).

Acknowledgments

The authors thank the CNRS and the Ecole Polytechnique for supporting this work.

Electrospray Behavior of Lacunary Keggin-Type Polyoxotungstates $[XW_{11}O_{39}]^{p-}$ (X = Si, P): Mass Spectrometric Evidence for a Concentration-Dependent Incorporation of an MO^{n+} ($M = W^{VI}$, Mo^{VI}, V^{V}) Unit into the Polyoxometalate Vacancy

Keywords: Polyoxometalates / Mass spectrometry / Tungsten / Speciation / Lacunary species

ESI-MS analysis provides a straightforward tool for the solution characterization of highly charged mono-lacunary Keggin-type polyoxotungstates α-$[XW_{11}O_{39}]^{p-}$ (X = Si, P; p = 8, 7). Doubly and triply charged quasi-molecular ion peaks were identified on the basis of both the theoretical simulation of the isotopic cluster distributions and the fragmentation modes observed with MS/MS technique. This approach allows the characterization of the inorganic polyanions transferred into the gas-phase with associated alkali metal cations (Li^+, Na^+). Indeed, the ESI-MS spectrum was found to be dependent on the counterion nature and on the initial concentration of the polyoxotungstate. While lithium salts at millimolar concentration represent the best choice for the analytical protocol, upon dilution the inorganic structure rearranges to a saturated Keggin dodecametalate complex. This phenomenon is induced by the electrospray ionization process and was exploited to produce gas-phase ions of monosubstituted species formed through incorporation of molybdenum and vanadium into the polyoxotungstate framework.

Introduction

Polyoxometalates (POM), are discrete metal−oxygen clusters of early transition metals in their highest oxidation state.[1] Their chemistry, dictated by their remarkable structural and electronic properties, is the subject of an intense interdisciplinary research activity in some major scientific areas, namely catalysis, materials science and medicine.[1−3]

An efficient approach to the synthesis of new polyoxometalate architectures is mainly based on lacunary POMs, i.e. species with defect structures.[1−3] Due to the presence of a structural "vacancy", lacunary species possess a reactive nucleophilic polyoxygenated site that can be readily functionalized, and because of this they have been used to provide (i) highly robust, all-inorganic ligands for catalytically active hetero-transition metal nuclei;[4,5] (ii) linking building units for the preparation of nanosized aggregates;[6,7] (iii) inorganic rigid templates that can be derivatized with organic or organometallic residues.[8−10]

The study of such reactive intermediates in terms of their intricate assembly equilibria, solution speciation and stability both in aqueous and in organic media is relevant to the success of the synthetic strategies mentioned above and therefore is receiving considerable attention.[11,12] In this respect, heteronuclear NMR spectroscopy has been the technique of choice to investigate the solution speciation and to identify the products. The main drawbacks inherent to such a technique are, however, the low sensitivity and the difficulties in structural assignments.[13,14]

Recently, electrospray mass spectrometry (ESI-MS) has been successfully employed for the inspection of different polynuclear metal complexes equilibrating in solution.[15,16] In these studies, ESI-MS has emerged as an effective tool for the investigation of rapidly exchanging systems, and has proved to be a powerful diagnostic alternative to NMR spectroscopy.[15−17]

ESI-MS has been underused in the analysis of polyoxoanion solutions, even though the soft ESI-mode allows the transfer of even large inorganic polyanions from solution to the gas phase.[18−20] In contrast, the Fast Atom Bombardment (FAB) ionization mode has been used very often for the characterization of POMs, providing information on their molecular mass and elemental composition. Such a technique, however, leads to extensive cationization and fragmentation of the POMs, and the necessary use of a matrix support often interferes with their solution chemistry.[21−24]

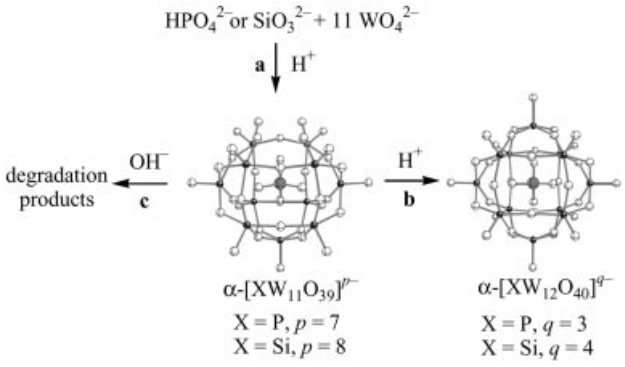
We describe here the straightforward ESI-MS analysis of aqueous solutions containing lacunary Keggin-type polyoxotungstates with general formula α-$[XW_{11}O_{39}]^{p-}$. The present paper indicates a rapid and efficient protocol for the solution characterization of these polyanions based on: (i) the simultaneous examination of the multiply charged ions generated from the polyelectrolyte; (ii) the theoretical simulation of the isotopic cluster distributions determined experimentally for such ions; (iii) the use of the tandem mass spectrometric technique[25] to evaluate the fragmentation modes of the complex. Our results also include the new observation that the electrospray behavior of the inorganic polyanion depends on the nature of the alkali metal counterion and on the polyelectrolyte concentration. Thus, lithium salts at millimolar concentrations were found to be the best choice for the analytical protocol, allowing a fast and unambiguous solution characterization of the polyanion in agreement with the NMR results.

Results and Discussion

Monovacant Keggin-type polyoxotungstates with formula α-$[XW_{11}O_{39}]^{p-}$ (X = P, Si) were readily prepared by stoichiometric acidification of $[WO_4]^{2-}$ in the presence of $[HPO_4]^-$ or $[SiO_3]^{2-}$ (Scheme 1, path a).[26] The defect nature and the purity of the polyoxotungstate formed in solution, obtained as lithium or sodium salt by ion-exchange chromatography, was checked by ^{29}Si, ^{31}P and ^{183}W NMR spectroscopy, this latter analysis giving a clean six-signal spectrum (C_s symmetry) in agreement with literature data.[26]



Scheme 1. Synthesis and hydrolytic stability of mono-lacunary α-Keggin polyoxotungstates with formula α-$[XW_{11}O_{39}]^{p-}$ (X = P, Si)

The solution integrity of the lacunary complex is pH-dependent: reconstitution of the T_d-symmetric, complete Keggin structure, α-$[XW_{12}O_{40}]^{q-}$, occurs readily upon further acidification (Scheme 1, path b), while addition of base leads to a progressive degradation of the structure producing lower order aggregates and eventually re-forming the original monomeric reagents (Scheme 1, path c).[1] The pH stability of the analyte is an important parameter to evaluate before the ESI-MS experiments. In fact, the electrospray process of aqueous solutions is known to produce a marked acidity increase in the nebulized droplets formed under ESI positive-ion mode, while, under ESI negative-ion mode, a considerable pH increase is obtained.[27]

Table 1 presents the negative-ion ESI-MS data collected for the lacunary polyoxotungstates α-$[PW_{11}O_{39}]^{7-}$ (Entries 1−5) and α-$[SiW_{11}O_{39}]^{8-}$ (Entries 6, 7), using water/methanol (1:1) as the mobile phase. In the case of α-$[PW_{11}O_{39}]^{7-}$, the electrospray behavior of both the lithium and sodium derivatives has been analyzed under analogous conditions (see Exp. Sect.). Table 1 also includes the results obtained for the reference monomer Li_2WO_4 (Entries 8, 9).

As a general feature, at millimolar concentrations the mass spectrum of the heteropolyanion is dominated by two peaks corresponding to the doubly and triply charged molecular ions (vide infra). Other ionic species, ascribable to an ES-induced decomposition, can be identified as the monocharged ions $[HWO_4]^-$, $[LiW_6O_{19}]^-$ and the analogous $[NaW_6O_{19}]^-$, observed at m/z = 249, 1415, 1431, respectively.

Both the charge state and the molecular composition of all the ions detected in the mass spectra have been assigned through examination of the experimental isotopic cluster distributions. This approach is exemplified in Figure 1 for the doubly and triply charged molecular species derived from $Li_7PW_{11}O_{39}$. In the mass spectrum of the latter (Table 1, Entry 1), the base peak is found at m/z = 1353 and features a double-charge signature with an isotopic separation of ca. 0.50 m/z units (Figure 1, part a), while the other diagnostic ion peak is found at m/z = 900 and displays the isotopic envelope spaced by ca. 0.33 m/z units, i.e. a triple charge (Figure 1, part b). Theoretical simulation of both the observed isotopic patterns allows the assignment the pertinent molecular formula, $[Li_4PW_{11}O_{39}^{3-} + H^+]^{2-}$ and $[Li_3PW_{11}O_{39}^{4-} + H^+]^{3-}$, with the highest peak of the calculated isotopic distributions located at m/z = 1353.00 and 899.67, respectively.

Such results indicate that the lithium salt $Li_7PW_{11}O_{39}$ is a suitable precursor for the ESI-MS analysis of the lacunary polyanion since both Li^+-for-H^+ exchange (cationization) and fragmentation are observed only to a small extent (see Table 1, Entry 1).

A more complicated spectrum is obtained in the case of the sodium salt (Table 1, Entry 4), whose ESI behavior shows a high degree of cationization and the formation of the non-lacunary derivative, indicated by peaks for $[NaPW_{12}O_{40}]^{2-}$ at m/z = 1450 and $[PW_{12}O_{40}]^{3-}$ at m/z = 959 with an overall relative intensity of 14%.

The first point at issue is very well represented in Figure 2, which shows the expanded spectrum of the sodium salt in the m/z range from 1340 to 1410. The simulated isotopic distributions agree with the presence of at least four doubly charged molecular ions whose compositions differ by the number of sodium and/or proton countercations as indicated by the general formula $[Na_xH_yPW_{11}O_{39}]^{2-}$.

The second aspect of the problem is the ESI-induced production of the W_{12}-containing species by inclusion of a formal WO^{4+} unit into the W_{11} precursor. Such a phenomenon may be ascribed to an intrinsic weakness of the vacant

Table 1. Counterion (Li^+, Na^+) and concentration effect on the ESI-MS data collected for lacunary polyoxotungstates α-$[XW_{11}O_{39}]^{p-}$ (X = P, Si) and for the monomeric precursor Li_2WO_4

[a] m/z values refer to the highest peak of the ion clusters. [b] % includes contribution of $[Na_5PW_{11}O_{39}]^{2-}$ (m/z = 1396), $[Na_4HPW_{11}O_{39}]^{2-}$ (m/z = 1385), $[Na_2H_3PW_{11}O_{39}]^{2-}$ (m/z = 1363), $[NaH_4PW_{11}O_{39}]^{2-}$ (m/z = 1352), see Figure 2. [c] % includes contribution of $[Na_4PW_{11}O_{39}]^{3-}$ (m/z = 923), $[Na_3HPW_{11}O_{39}]^{3-}$ (m/z = 916) and $[Na_2H_2PW_{11}O_{39}]^{3-}$ (m/z = 908). [d] Ions ascribable to potassium-containing species were also observed: $[Na_xK_ySiW_{11}O_{39}]^{2-}$ (m/z = 1415−1447) and $[NaK_4SiW_{11}O_{39}]^{3-}$ (m/z = 952).

polyoxometalate structure as its sodium salt. The importance of the nature of the countercation in determining the solution behavior of polyoxometalates in terms of their stability, spectroscopic response, selectivity of reactions and reaction rates has been documented in several literature reports.[26,28−31] In particular, the lithium form of the lacunary tungstophosphate anion has been indicated as the precursor of choice for high temperature hydrothermal synthesis due to its peculiar stability.[32,33] The ESI-MS results support this latter observation.

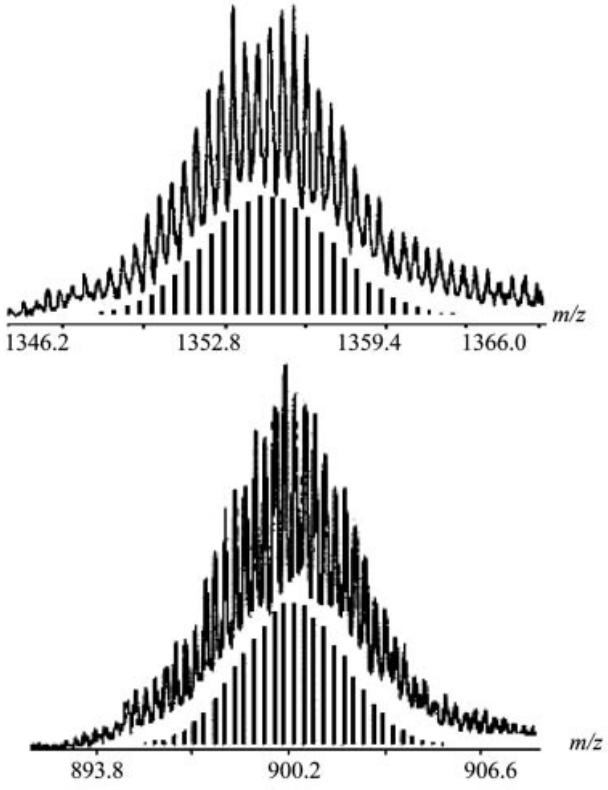

Figure 1. Experimental and calculated isotopic distribution for ion $[Li_4HPW_{11}O_{39}]^{2-}$ (m/z = 1353) and ion $[Li_3HPW_{11}O_{39}]^{3-}$ (m/z = 900)

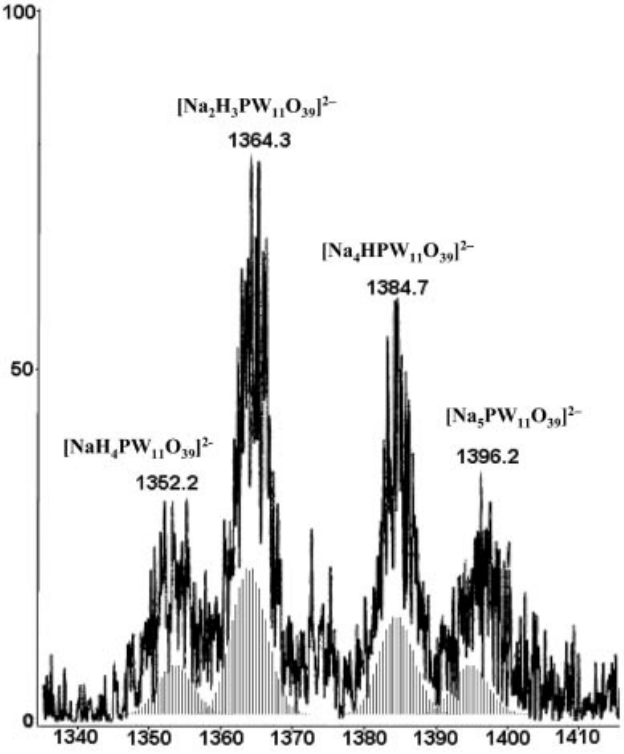

Figure 2. Experimental and calculated isotopic distributions of ions with general formula $[Na_xH_yPW_{11}O_{39}]^{2-}$ (m/z = 1352−1396)

In the negative-ion mode ESI-MS spectrum of the undecatungstosilicate species α-$[Li_8SiW_{11}O_{39}]$ (Table 1, Entry 6), the quasi-molecular ion peaks ($[Li_6SiW_{11}O_{39}]^{2-}$ at m/z = 1358 and $[Li_5SiW_{11}O_{39}]^{3-}$ at m/z = 903) are observed together with a 30% total intensity of the W_{12} anion ($[Li_2SiW_{12}O_{40}]^{2-}$ at m/z = 1444 and $[LiSiW_{12}O_{40}]^{3-}$ at m/z = 960). This evidence is consistent with the limited pH stability range registered in aqueous solution for this lacunary species.[1] The sodium salt (Table 1, Entry 7) again shows a more complicated spectrum.

The Collision Induced Dissociation (CID) of both saturated and lacunary derivatives has been analyzed for tungstophosphate anions as their lithium salts. MS/MS experiments performed on the doubly and triply charged precursors show the multiple loss of WO_3 fragments and oxygen atoms to yield di- or trivacant structures (W_{10}- or W_9-containing anions, respectively; Table 2). This behavior is known to dominate the gas-phase fragmentation of polyoxotungstates as generally observed under FAB-MS conditions.[21–24] As expected, due to the stability of the saturated complex, MS/MS experiments on the W_{12} species require high CID energy conditions of up to 3 V.

In order to optimize the ESI-MS protocol for these highly charged inorganic complexes, the spectra were recorded at different analyte concentrations (Table 1). Surprisingly, the spray of dilute solutions (initial polyanion concentration $\leq 10^{-5}$ M) yields different mass spectra. In particular, starting with the vacant W_{11} polyanion as its lithium or sodium salt (Table 1, Entries 3, 5), the peak corresponding to the saturated W_{12} anion becomes the dominant one. These results are in contrast to the NMR characterization of the species and with the ESI results achieved at higher concentrations. This ESI-MS behavior can be conveniently monitored by progressive dilution of the initially sprayed POM solution ($[Li_7PW_{11}O_{39}]_0 = 2 \times 10^{-3}$ M) with the mobile phase. The spectra recorded at different time intervals (Figure 3) show the evolution of the original W_{11} anion (ion peaks at m/z = 900 and 1353) to the W_{12} species (ion peaks at m/z = 959 and 1442).

The origin of the phenomenon can be discussed on the basis of the following control experiments: (i) the spray of an equimolar solution (2×10^{-3} M) of Li_2WO_4 and $Li_7PW_{11}O_{39}$ yields peaks ascribable only to the two reagents, with no trace of the W_{12} anion, thus indicating that no solution reaction is taking place under the conditions adopted; (ii) when these two ions are isolated within the instrument ion-trap, no gas-phase reaction is again observed; (iii) an aggregation process is also detected when sub-millimolar Li_2WO_4 solutions are sprayed (Table 1, Entries 8, 9), producing the hexatungstate complex, revealed as its dianion $[W_6O_{19}]^{2-}$ at m/z = 704 or in its monoprotonated form at m/z = 1409. This latter result is of particular interest in the study of the nucleation of polyoxometalate structures.

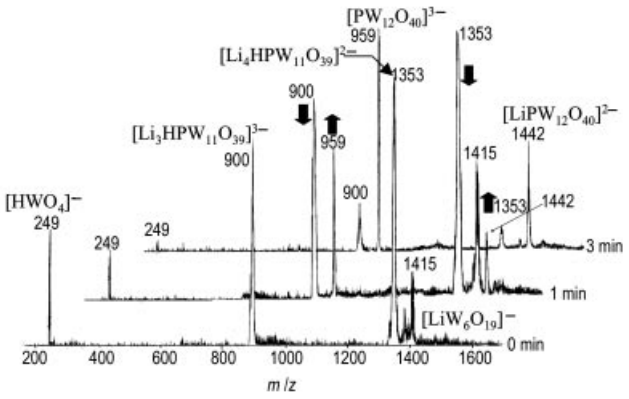

Figure 3. Evolution of the ESI-MS spectrum with time collected for α-$[Li_7PW_{11}O_{39}]$ (initial concentration of 2×10^{-3} M) upon progressive dilution

Considering the ESI process and the generation of POM-based gas-phase ions, the observed changes of ion charge and structure can be ascribed to the relief of coulombic stress as solvent is removed upon the transfer of the ions from the charged droplets to the gas phase.[27]

This might well be the driving force for the ESI-induced polyoxometalate aggregation in the incipient gas phase, producing species with lower charge or with a reduced charge density. However, the opportunity to detect structural rearrangement of the charged analytes should be related both to the composition and to the time of residency of the species within the charged droplets generated by the ESI process. It is then conceivable that at particularly high polyelectrolyte concentration the rapid droplet fission allows the minimization and eventual suppression of any side reactions.[34]

As the reconstitution of the W_{12} structure occurs very efficiently for the undecatungstate complex sprayed at sub-millimolar concentration, a set of experiments was designed to detect the inclusion of a hetero-transition metal based MO^{n+} unit within the lacunary site, under analogous ESI-

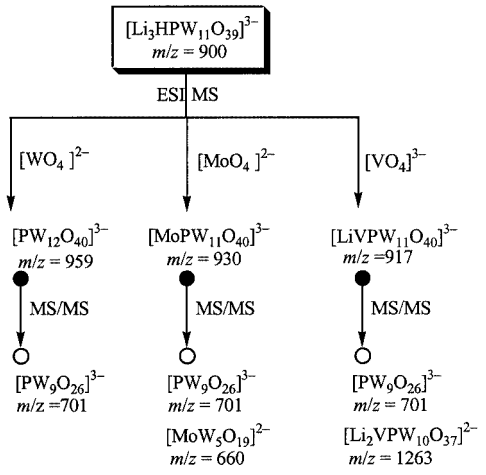

Scheme 2. Formation of the triply charged ions (*m*/*z*) in the ESI-MS spectrum of α-$[Li_7PW_{11}O_{39}]$ collected at sub-millimolar concentration (10^{-5} M) in the presence of stoichiometric $[MoO_4]^{2-}$ or $[VO_4]^{3-}$, showing the evolution to a dodecametalate structure as confirmed also by tandem MS/MS experiments

MS conditions (Scheme 2). To this aim, a solution of $Li_7PW_{11}O_{39}$ (10^{-5} M) was sprayed in the presence of equimolar amounts of molybdate and vanadate anions. Inspection of the triply charged *m*/*z* region (Scheme 2) gives a clear indication that the monosubstituted Keggin species forms by incorporation of either an Mo^{VI} or a V^{V} atom within the polyoxotungstate structure, yielding ion peaks at *m*/*z* = 930 ($[MoPW_{11}O_{40}]^{3-}$) and 917 ($[LiVPW_{11}O_{40}]^{3-}$).[35] This process competes, however, with the production of the dodecatungstate anion, by far the main process emerging in all the recorded spectra, where the ion peak at *m*/*z* = 959 appears always as the most intense one.[35] MS/MS experiments performed on the resulting $[Li_nMPW_{11}O_{40}]^{3-}$ (M = V^{V}, Mo^{VI}; *n* = 0, 1) anions yield fragments that are consistent with the expected Keggin structure (the peak at *m*/*z* = 701, identified as $[PW_9O_{26}]^{3-}$, is common to all the three dodecametallate structures)[19] and monosubstitution with the hetero-transition metal (see the lacunary fragments incorporating vanadium or molybdenum in Scheme 2).

The ESI-induced metalation of the lacunary undecatungstate establishes a new route to the gas-phase detection of the Mo and V monosubstituted species whose hydrolytic instability hampers the synthetic protocol.[36,37] As a matter of fact, the direct hydrothermal metalation (H_2O, 150 °C) of the lacunary precursor (2×10^{-3} M) in the presence of stoichiometric amounts of tungstate, molybdate or vanadate anions, in the first two cases does not lead to products, while in the latter case the disubstituted complex is formed. This conclusion has been reached by ESI-MS analysis of the reaction mixtures, showing, for the vanadium-containing system, the replacement of the reagent signals with two new ion peaks at *m*/*z* = 873 and 1313, attributed to $[LiHPV_2W_{10}O_{40}]^{3-}$ and $[Li_2HPV_2W_{10}O_{40}]^{2-}$, respectively.[38]

Conclusion

This study highlights the use of ESI-MS to address the solution structure of polyoxometalates. The results collected delineate a precise protocol for the straightforward characterization of highly charged mono-vacant undecatungsto complexes, thus providing a convenient alternative to heteronuclear NMR spectroscopy. Although extreme care is required to correlate the ESI-MS data with the content of the original solution, it has been shown that the ESI technique allows the isolation of discrete ion-paired structures whose stoichiometry, composition and gas-phase reactivity can be readily defined. Both the role of the counterion on the gas-phase transfer of polyoxometalate-based ion-pairs and the effect of the polyelectrolyte concentration in promoting an ESI-induced aggregation process are fundamental aspects that need further clarification.

Experimental Section

Materials: Monovacant Keggin-type polyoxotungstates with formula α-$[XW_{11}O_{39}]^{p-}$ (X = P, Si) were prepared by literature procedures[26] and characterized in solution by heteronuclear NMR spectroscopy as follows: **α-$[Li_7PW_{11}O_{39}]$:** ^{31}P NMR (162.00 MHz, D_2O, H_3PO_4 85%): δ = −11.2 ppm. ^{183}W NMR (16.67 MHz, H_2O, Na_2WO_4): δ = −98.0 (2 W), −98.6 (2 W), −103.3 (2 W), −121.0 (1 W), −132.0 (2 W) −151.8 (2 W) ppm. **α-$[Na_7PW_{11}O_{39}]$:** ^{183}W NMR (16.67 MHz, H_2O, Na_2WO_4): δ = −99.0 (2 W), −103.9 (2 W), −110.7 (2 W), −118.6 (1 W), −134.0 (2 W) −154.8 (2 W) ppm. **α-$[Na_8SiW_{11}O_{39}]$:** ^{29}Si NMR (79.50 MHz, D_2O, TMS): δ = −84.5 ppm. ^{183}W NMR (16.67 MHz, H_2O, Na_2WO_4): δ = −100.9 (2 W), −116.4 (2 W), −121.5 (1 W), −128.4 (2 W), −143.2 (2 W) −176.5 (2 W) ppm. **α-$[Li_8SiW_{11}O_{39}]$:** ^{183}W NMR (16.67 MHz, H_2O, Na_2WO_4): δ = −106.7 (2 W), −108.7 (2 W), −122.0 (2 W), −123.1 (1 W) −144.9 (2 W) −175.1 (2 W) ppm. All other reagents were obtained from commercial sources and used as received. HPLC grade solvents were generally used. Cation-exchange chromatography was performed on Amberlite IR 120 resin.

Methods: NMR spectra were obtained with a Bruker Avance DRX 400 instrument, equipped with a standard (^{31}P-^{109}Ag) 10-mm broadband probe which could be tuned below its specifications. Hydrothermal syntheses were performed in a closed reactor (HPR-1000/10S, Milestone) equipped with temperature and pressure control units and irradiated inside the cavity of an MW Ethos-1600 labstation (Milestone). ESI-MS full-scan mass spectra were performed with a Mariner Time-of-Flight Mass Spectrometer (Perspective Biosystem) and with a Finnigan LCQ instrument, obtaining comparable results. The *m*/*z* values refer to the highest peak of the ion clusters. All experiments were performed in negative mode by direct infusion with a syringe pump. Standard experimental conditions given for the LCQ instrument were as follows: sample concentration (10^{-3} to 10^{-5} M), mobile phase (H_2O/CH_3OH, 1:1) flow rate 8 μL min^{-1}, nebulizing gas N_2: 40 units flow rate, spray voltage −4.00 kV, capillary voltage −25 V, capillary temperature 150 °C, tube lenses offset, 30 V. The parameters related to octupoles and detector were those achieved by the automatic setup procedure. The tuning of the spray parameters i.e. flow rate (3−13 μL min^{-1}), nebulizing gas (20−70 units flow rate), negative spray voltage (2−4.50 kV), negative capillary voltage (3−28 V) and capillary temperature (70−160 °C) was investigated and did not

affect the spectra. The collision-induced decomposition of selected ions was obtained by applying a supplementary radio frequency voltage (tickling voltage) to the end-cap electrodes of the ion-trap in Finnigan LCQ instrument (resonance activation).

Hydrothermal Synthesis: α-$[Li_7PW_{11}O_{39}]$ (60 μmol) was dissolved in water (30 mL). The solution was then divided into three portions (10 mL each), in the presence of a stoichiometric amount of Li_2WO_4 (reaction 1), Na_2MoO_4 (reaction 2) or Na_3VO_4 (reaction 3). The reaction mixtures were then placed in three closed units of the multi-section microwave reactor system (HPR-1000/10S) inside the Microwave labstation and irradiated (ν = 2.45 GHz) according to the following parameters: initial power 300 W; initial time 4 min; $T_{max.}$ = 150 °C, final power 150 W, reaction time 5 min. ESI-MS analysis was used to monitor the reaction outcome. Reaction 1: MS (ESI-LCQ): *m/z* (%) = 249 (90) $[HWO_4]^-$, 900 (53) $[Li_3HPW_{11}O_{39}]^{3-}$, 1353 (100) $[Li_4HPW_{11}O_{39}]^{2-}$, 1415 (50) $[LiW_6O_{19}]^-$. Reaction 2: MS (ESI-LCQ): *m/z* (%) = 163 (100) $[HMoO_4]^-$, 249 (75) $[HWO_4]^-$, 900 (48) $[Li_3HPW_{11}O_{39}]^{3-}$, 1353 (70) $[Li_4HPW_{11}O_{39}]^{2-}$, 1415 (40) $[LiW_6O_{19}]^-$. Reaction 3: MS (ESI-LCQ): *m/z* (%) = 249 (100) $[HWO_4]^-$, 873 (45) $[LiHPV_2W_{10}O_{40}]^{3-}$, 959 (15) $[PW_{12}O_{40}]^{3-}$, 1313 (50) $[Li_2HPV_2W_{10}O_{40}]^{2-}$, 1324 (48) $[NaLi_2PV_2W_{10}O_{40}]^{2-}$, 1415 (10) $[LiW_6O_{19}]^-$.

[34] Tuning of the spray parameters, in the range indicated, did not affect the spectra: flow rate (3−13 μL min^{-1}), nebulizing gas (20−70 units flow rate), negative spray voltage (2−4.50 kV), negative capillary voltage (3−28 V), capillary temperature (70−160 °C).
[35] Doubly charged ions relative to monosubstituted polyoxotungstates were also revealed for molybdenum at *m/z* = 1399 ($[LiMoPW_{11}O_{40}]^{2-}$) and for vanadium at *m/z* = 1379 ($[Li_2VPW_{11}O_{40}]^{2-}$). Incorporation of vanadium was also confirmed by detection of an ion peak at *m/z* = 686 attributed to $[VPW_{11}O_{40}]^{4-}$. In all spectra the base peak was found at *m/z* = 959 $[PW_{12}O_{40}]^{3-}$.

Synthesis and Structure of Redox-Active Heterotetranuclear Molecular Polygons by Self-Assembly of Two Ferrocene-Bridged Bis(pyridines) with Two Transition Metals[‡]

Ekkehard Lindner,*[a] Ruifa Zong,[a] Klaus Eichele,[a] Ulrike Weisser,[a] and Markus Ströbele[a]

Keywords: Self-assembly / Nanostructures / Metal-metal interactions / N ligands / Nickel / Silver / Palladium

The macrocyclic complexes $[(\eta^5\text{-}C_5H_4C_2\text{-}4\text{-}py)_2Fe]_2Ni_2(NO_3)_4$ (**2**), $[(\eta^5\text{-}C_5H_4C_2\text{-}3\text{-}py)_2Fe]_2Ag_2(ClO_4)_2$ (**4**), and $[(\eta^5\text{-}C_5H_4C_2\text{-}3\text{-}py)_2Fe]_2Pd_2Cl_4$ (**5**) were obtained by reaction of $[Ni(H_2O)_6](NO_3)_2$, $AgClO_4$, and $PdCl_2(COD)$ with the ligands $(\eta^5\text{-}C_5H_4C_2\text{-}4\text{-}py)_2Fe$ (**1**) and $(\eta^5\text{-}C_5H_4C_2\text{-}3\text{-}py)_2Fe$ (**3**), respectively, under high dilution conditions (Scheme 1). The molecular motifs of **2**, **4**, and **5** were studied by single-crystal X-ray structural investigations. Elemental analyses and ^1H NMR and IR spectra were also used to confirm the structures. Compound **2** represents an unsymmetric paddlewheel, in which the centers of the four Cp rings define a nearly ideal rectangle with dimensions of 20.2 × 3.3 Å. In principle, macrocycles **4** and **5** can also be described as rectangles, however, due to the 3-positioned nitrogen donors with deformed edges (17.4 × 3.3 Å for **4**). In contrast to the offset packing of the molecules in **2**, the macrocycles in the crystal of **4** are aligned, with trapped acetonitrile molecules in between. The intra- and intermolecular Ag–Ag distances are 3.50 and 3.79 Å, respectively. Cyclovoltammetric studies reveal chemically reversible ferrocene-based redox reactions of **1**–**4**. Although no electronic communication was observed between the two identical ferrocene units, a weak through-bond electronic interaction between ferrocene and nickel, or silver, was established. In **2** a weak antiferromagnetic interaction between the nickel atoms was also found.

Introduction

A great number of bis(pyridine)-functionalized ligands with different angles between their binding sites have been rationally designed, synthesized, and treated with transition metal complexes to obtain two-dimensional macrocyclic molecular assemblies, such as molecular squares, triangles, and other polygons.[1,2] With the increasing multitude of motifs self-assembled from these nitrogen-functionalized building blocks, a library of such supramolecular architectures has been set up.[3] Stang and Fujita have made a huge contribution to this field, although they have mainly employed pre-constructed *cis*-ML_2 (M = Pd/Pt) units.[1–4] Both metals are electrochemically and magnetically inert. Hence, it is desirable to make accessible molecular polygons and polyhedra with magnetic and redox-active centers.[1,5] Although 1,1′-bis(diphenylphosphanyl)ferrocene (dppf) has been used to obtain redox-active molecular squares, the *syn*-dppf conformer is not part of the backbone.[1,6] A structurally characterized molecular square containing an *anti*-1,1′-ferrocenedicarboxylate moiety in its backbone was recently reported by Cotton et al.[4,5] Compared to systems assembled from non-ferrocene bridges, its electrochemical properties are rather unusual. The preparation of self-assembled structures that contain functionalized sites capable of showing interesting electronic, magnetic, and optical properties is still a big challenge.[1]

Linked metallocenes, in particular those with extended conjugated spacers, are redox-active and good candidates for the investigation of through-bond electronic communication.[7] Ideal models consist of two or more identical metallocene units as spectators.[7,8] It has been demonstrated that acetylene-bridged ferrocenes show third-order non-linear optical properties.[9] Furthermore, systems incorporating paramagnetic transition metal ions are good candidates for novel molecular-based magnetic materials.[10,11] Dinuclear molecules based on dinickel, dicopper, and dimanganese cores, with different magnetic coupling patterns, have drawn much attention in the last decade.[12–14] Here, we present the synthesis and structure of three redox-active tetranuclear supramolecular rectangles **2**, **4**, and **5**, each bearing two ferrocene subunits and two nickel(II), silver(I), and palladium(II) atoms, respectively, in their backbone.

Results and Discussion

Syntheses of the Macrocycles 2, 4, and 5

The macrocyclic motifs **2**, **4**, and **5** were obtained in 92−95% yields by mixing a solution of the nitrogen donor ligands 1,1′-bis(4- and 3-pyridylethynyl)ferrocene **1**[15] and **3**[15] in dichloromethane with a solution of $[Ni(OH_2)_6](NO_3)_2$, $AgClO_4$, or $PdCl_2(COD)$ in methanol, acetonitrile, or dichloromethane, respectively, under high-dilution conditions[16] at room temperature (Scheme 1). Elemental analyses are satisfactory and consistent with their proposed structures. While the red silver compound **4** is at least slightly soluble in polar organic media like acetonitrile, the red nickel complex **2** shows only a very low solubility in methanol and acetonitrile. Macrocycle **5** is insoluble in these solvents, but slightly soluble in dichloromethane and DMF. Complex **2** decomposes in DMF and DMSO.

Crystal Structures of 2, 4, and 5

To obtain detailed information about the structures of the nickel(II)-, silver(I)-, and palladium(II)-containing macrocyclic complexes **2**, **4**, and **5**, X-ray structural investigations were performed. Selected distances and angles are summarized in Tables 1 and 2, respectively, and the corresponding ORTEP plots with atom labeling are depicted in Figures 1 and 2. Both compounds **2** and **4** crystallize in the triclinic space group $P\bar{1}$ and each molecule has a center of symmetry. They crystallize with three CH_2Cl_2 and two CH_3CN solvent molecules, respectively.

Table 1. Selected distances [Å] and angles [°] for **2**·3CH_2Cl_2

Ni1−O1	2.081(2)	Ni1−Ni1A	3.39
Ni1−O1A	2.112(2)	Cp1 (cent.)−Cp2 (cent.)	3.31
Ni1−O4	2.120(2)	Fe1−Fe1A	20.18
Ni1−O5	2.079(2)	Cp1 (cent.)−Cp2A (cent.)	20.24
Ni1−N1	2.058(2)	Fe1−Ni1	10.20
Ni1−N2A	2.058(2)	Fe1−Ni1A	10.25
O2−H41A	2.49	O6−H41B	2.42
O3−H40B	2.55		
N1−Ni1−O1	91.58(9)	N2A−Ni1−O5	89.97(9)
N1−Ni1−O1A	92.42(9)	O1−Ni1−O4	115.06(9)
N1−Ni1−O4	89.37(9)	O1−Ni1−O1A	72.22(9)
N1−Ni1−O5	88.28(9)	O5−Ni1−O4	61.40(10)
N2A−Ni1−O1	90.00(9)	O5−Ni1−O1A	111.33(9)
N2A−Ni1−O1A	90.70(9)	N1−Ni1−N2A	176.81(9)
N2A−Ni1−O4	87.45(9)	Ni1−O1−Ni1A	107.79(9)

Both nickel atoms in **2** are octahedrally coordinated by two nitrogen and four oxygen donor functions, forming a *trans*-N_2O_4 coordination sphere. The two *trans*-located nitrogen atoms are equidistant from the nickel atom (2.05 Å), while the four Ni−O bonds have lengths of between 2.08

and 2.12 Å. However, the nickel-centered angles of the octahedron vary between 61 and 115°, indicating a considerably distorted geometry around the nickel atom.

Complex **2** is constructed of a dinickel core with two bridging ligands **1** [μ-η^1:η^1-**1**-*N*,*N*′] and four nitrate counterions. The nitrate ions are coordinated in two different modes to the nickel centers. Two of them function as μ_2-bridging ligands, whereas the other two are η^2-chelated. Within a ligand **1** in complex **2**, the N−N distance of 3.49 Å is significantly shorter than the corresponding average distance of 3.96 Å in the free ligand **1**,[17] in which the repulsion of the nitrogen lone pairs has to be considered.

Concerning the dinickel core, the structure of **2** can be designated as an unsymmetric paddlewheel consisting of the coordinated nitrate ions and two moieties of ligand **1**. The

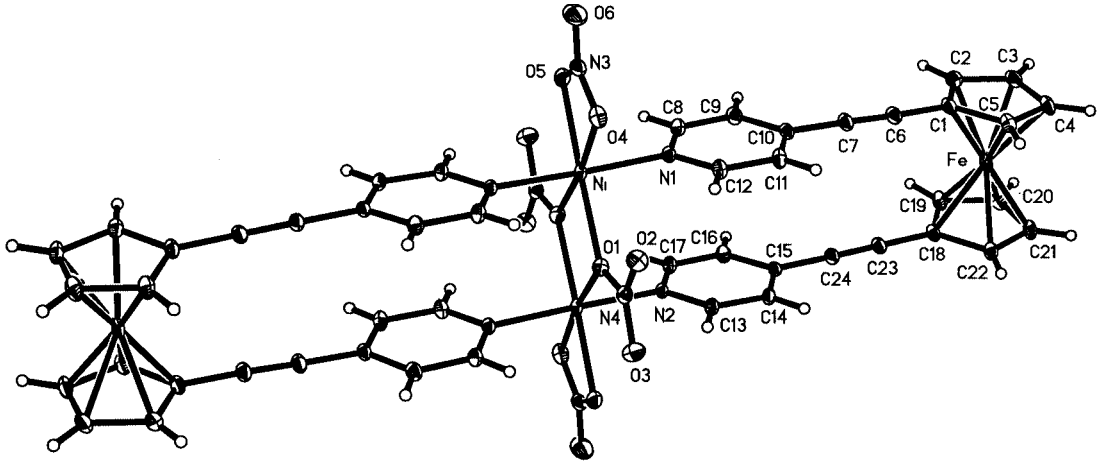

Figure 1. Molecular structure of **2**; ORTEP plot with thermal ellipsoids at 20% probability; solvent molecules are omitted for clarity; for bond lengths and angles see Table 1

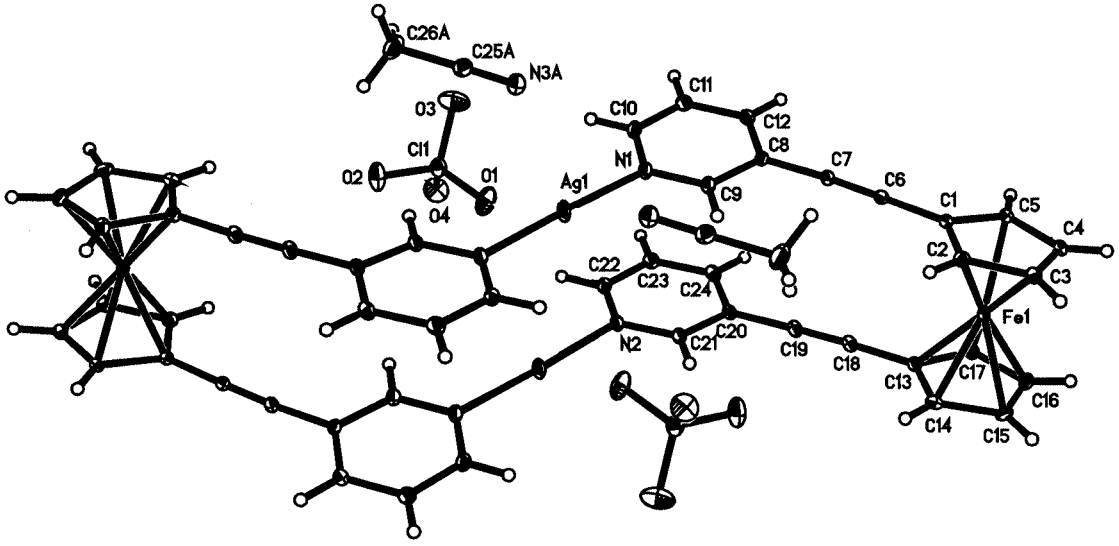

Figure 2. Molecular structure of **4**; ORTEP plot with thermal ellipsoids at 20% probability; for bond lengths and angles see Table 2

whole structure has the shape of a molecular rectangle in which the four Cp rings occupy the vertices, whereas the four metal atoms are located in the middle of the edges. The lengths of the edges are 3.31 and 20.24 Å, calculated from the center points of the cyclopentadienyl rings. Both nickel and iron atoms are separated by a distance of 3.39 and 20.18 Å, respectively. In this molecule the four metal atoms lie in a plane, creating almost a regular rhombus with lengths of 10.20 (Fe−Ni) and 10.25 Å (Fe−NiA) and angles of 19° (Ni−Fe−NiA) and 161° (Fe−Ni−FeA). One of the most important structural features of **2** is the coplanarity of the entire inorganic entity (nickel atoms and all four nitrates). The ferrocene units are positioned above and below this plane. In the solid state, molecules of **2** are offset positioned and separated by two crystallographically different kinds of dichloromethane molecules (Figure 3). Dichloromethane molecules of each kind are oriented head-to-head. Weak contacts (shown by dotted lines in Figure 3) between the solvent molecules and the macrocycles are found, as indicated by the non-bonding distances of 2.42, 2.49, and 2.55 Å for H(41B)−O(2), H(41A)−O(6), and H(40B)−O(3), respectively.

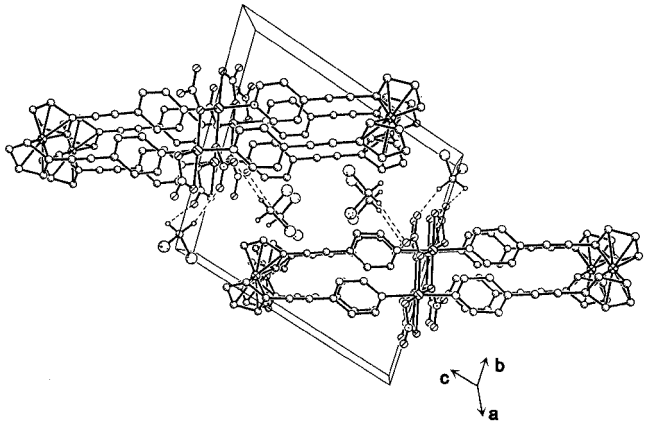

Figure 3. Molecular packing of **2** showing the head-to-head orientation of dichloromethane molecules, the offset arrangement of **2**, and the weak H···O contacts (dotted lines); aromatic protons are omitted for clarity

Due to the 3-position of the nitrogen donors in ligand **3**, the structure of the cation in **4** is somewhat different from that of **2**. The former forms a distorted rectangle defined by the central points of the four cyclopentadienyl rings (Figure 2). If a connecting line is drawn between these points, one pyridine ring is located in front of and the other one behind this line. The dimensions of the rectangle are 17.42 × 3.31 Å. All four transition metals (two silver and two iron atoms) lie in a plane and the Fe−Fe and Ag−Ag distances are 17.34 and 3.50 Å, respectively. The heteroatom distances (Ag−Fe) are 8.65 and 9.03 Å. Similar to complex **2**, the silver atom in **4** is nearly equidistant from the two coordinated pyridine N atoms [2.170(2) and 2.179(2) Å]. Only a slight deviation from a linear N−Ag−N arrangement is observed (178.1°). The two CpC_2py arms on each side of the macrocycle are not oriented exactly parallel, deviations with respect to Cp/py and py/py are 6.1/13.1 and 6.2°, respectively.

In the crystals of **4** (Figure 4), both perchlorate anions are positioned on opposite sides of the rectangular plane, but are not coordinated to silver(I). The macrocycles of **4** are layered and acetonitrile is located between these rectangular molecules. The molecules of **4** are held together along the *a* axis by interactions between the bifurcated acetonitrile molecules and the macrocycles as indicated by the remarkably short Ag−N distances of 2.705(2) and 2.891(2) Å compared to the corresponding sum of the van der Waals radii. The inter- (Ag_2N_2) and intramolecular (Ag_2O_2) planes deviate by an angle of 17.5°. Contrary to the offset packing of macrocycle **2**, the cationic macrocycle **4** is aligned along the *a* axis with intra- and intermolecular Ag−Ag distances of 3.50 and 3.79 Å, respectively.

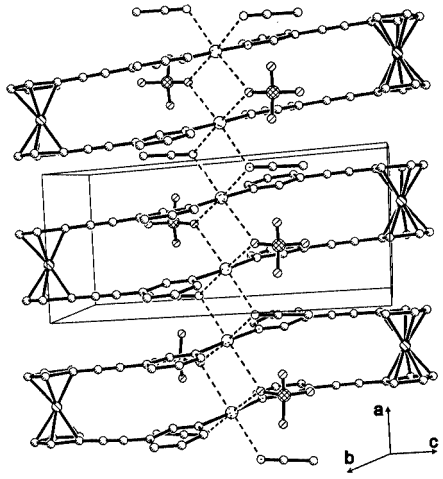

Figure 4. Molecular packing of **4** along the *a* axis presenting the parallel alignment of the silver ions and the other components as well as the weak Ag···O and Ag···N contacts (dotted lines); protons are omitted for clarity

Due to the low quality of the crystal of **5**, only a brief description is given.[18,19] The molecular structure of **5** is similar to that of **4**, and also has a center of symmetry. Each palladium atom is additionally coordinated by two *trans*-positioned chloride ions with $PdCl_2$ units about 45° to the pyridine rings.

^{1}H NMR and IR Spectroscopic Characterization of the Macrocycles 2, 4, and 5

Because of the low solubility only ^{1}H NMR spectra of the macrocycles **4** and **5** could be recorded; the nickel(II) complex **2** is paramagnetic. Upon complexation of ligand **3** to silver(I) (**4**) and palladium(II) (**5**) a slight downfield shift of the pyridine proton signals is observed. While only the resonance at δ = 7.05 ppm, which is assigned to 5-H of the pyridine ring in **3** (numbering scheme is given in Scheme 1), is markedly downfield shifted to δ = 7.20 ppm in the disilver complex **4**, all other protons of this entity remain unchanged. In the ^{1}H NMR spectrum of **5** the protons (2-H and 6-H) adjacent to the nitrogen atom give rise to a re-

markable downfield shift of 0.18 and 0.31 ppm, respectively. On the other hand, notable upfield shifts of 0.27 and 0.31 ppm are observed for 4-H and 5-H. The AA′XX′ pattern for the cyclopentadienyl rings in the spectra of **4** and **5** remains unchanged.

In the FT-IR spectra of **2**, **4**, and **5** the absorptions for the C=N and C≡C stretching vibrations are shifted (12−16 and 2−5 cm^{-1}, respectively) to somewhat higher wavenumbers relative to the free ligands **1** and **3**. This is consistent with the coordination of transition metals to nitrogen. Intense bands at 1289/1218 and 1095/1050 cm^{-1} are assigned to the stretching vibrations of the nitrate and perchlorate anions, respectively.

Electrochemical Investigation of 1−4

The redox properties of compounds **1**−**4** were investigated in acetonitrile; cyclic voltammetric data are listed in Table 3. The low solubility of the palladium complex **5** prevents any studies of its electrochemical behavior. Although the ferrocene-based redox reactions of **1**−**4** are chemically reversible in each case, their electrochemistry is somewhat different. While ligand **3** shows a diffusion-controlled one-electron transfer reaction, the response of ligand **1** is diffusion-controlled and dependent on the rate of electron transfer. Isomeric ligands **1** and **3** show different redox potentials, at 318 and 283 mV relative to that of ferrocene/ferrocenium, respectively. They are more difficult to oxidize than the unsubstituted parent ferrocene, which is due to the electron-withdrawing nature of the substituents on the Cp rings. However, the difference of 35 mV between **1** and **3** indicates the influence of the charge distribution on the transfer of this effect. Although both ferrocene subunits of complex **2** are oxidized at the same potential, it reveals a 32 mV positive shift relative to ligand **1**. This finding demonstrates a successful electron transfer from ferrocene to the nickel atoms, but no communication between the two ferrocene units.

Table 3. Cyclic voltammetric responses of compounds **1**−**4** in acetonitrile

Compound	$E_{1/2}$ [mV]	ΔE [mV]	i_{pa}/i_{pc}
Ferrocene	0	69	1.00
1	318	63	0.99
2	350	60	1.16[a]
3	283	71	0.96
4	273	70	1.04

[a] A background correction was not carried out because of the adsorption nature of this complex.

Compared to ligand **3** a negative shift of 10 mV was established for the disilver complex **4**. This effect is usually not expected and is probably due to the weak σ-electron acceptor and strong π-donor capabilities of silver(I).[20] As a result of this back bonding and/or the charge distribution

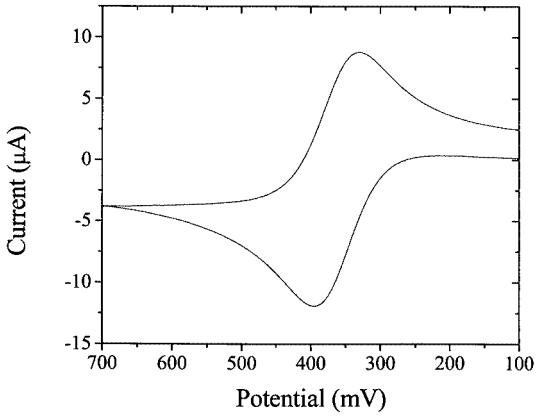

Figure 5. Cyclic voltammogram of **4** in acetonitrile/0.1 M tetrabutylammonium hexafluorophosphate; concentration of **4**: $1 \cdot 10^{-4}$ M, scan rate of 100 mV/s

order the ferrocene moieties are easily oxidized. Figure 5 shows the cyclic voltammogram of complex **4**, the electrochemical response of which is diffusion-controlled, whereas that of the dinickel complex **2** is more complicated due to its adsorption character.

For a possible electronic communication between the two ferrocene units the intramolecular iron−iron distances (**2**: 2.0 nm; **4**: 1.7 nm) are of importance. Because of the well-separated ferrocene building blocks the coulombic interaction (through-space electronic coupling) is negligible. On the other hand, the alignment of the molecular orbitals[21] and the extent of conjugation[7] could be a reason for through-bond electronic communication, as was observed in a conjugated alkyne-bridged rhenium(II) complex.[22] In spite of these favorable preconditions no electronic communication was found in complexes **2** and **4**.

Magnetic Investigation of Complex 2

The magnetic properties of the dinickel complex **2** were studied at 10 T in the temperature range between 300 and 5 K. Experimental data obtained for the molar susceptibility and the calculated effective magnetic moment are plotted in Figure 6. The general isotropic spin-Hamiltonian expression for the symmetrical dinickel compound is $\mathbf{H} = -J\mathbf{S_A}\cdot\mathbf{S_B}$ ($S_A = S_B = 1$), where J is the coupling constant between the two nickel(II) atoms. Although no maximum for χ_M in Figure 6 is found in the selected temperature range, a non-linear fit of the experimental data for the susceptibility per nickel dimer using published expressions[23] yields the following values: $g = 2.22 \pm 0.01$, $J = -17.37 \pm 0.24$ cm^{-1}, $D = 7.87 \pm 0.17$ cm^{-1}, and $p = 17.6 \pm 0.1\%$. The g value is reasonable for octahedrally coordinated nickel(II),[13] and the coupling constant reveals a weak, intramolecular, antiferromagnetic interaction between the nickel(II) atoms. This coupling for the bis(μ-oxo)-bridged dinickel(II) complex **2** (Ni−Ni distance of 3.39 Å) is more significant than that observed for other dinickel complexes in which two bridges consisting of two or more atoms are present and both nickel units are separated by distances of between 4.16 and 4.32 Å,[13] although it is cle-

arly weaker than that of cyano-bridged dinickel complexes.[12] Complex **2** also contains an uncoupled paramagnetic impurity which is a chain-like polymer or oligomer[24] which is formed even under high-dilution conditions. This could not be separated from **2** because both entities show very low solubility. The agreement factor $R = 9.8 \cdot 10^{-5}$ shows that the curve is well fitted.

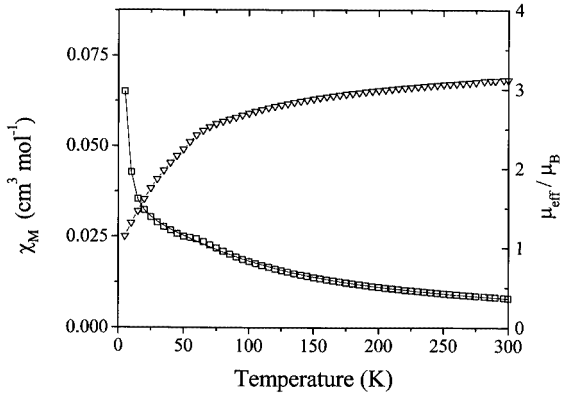

Figure 6. Temperature dependence of the magnetic susceptibility (squares, left scale) and effective magnetic moment (triangles, right scale) of **2**; the solid lines represent the best-fit curves

Conclusion

Functionalized heterotetranuclear regular and distorted rectangles bearing two redox-active ferrocene subunits and a pair of transition metal atoms each were made accessible by coordination-driven spontaneous self-assembly. Although silver is considerably bigger than nickel the separation between the two equal transition metal atoms in the dimetallic Ag_2 and Ni_2 cores is rather similar (3.50 vs. 3.39 Å). This behavior is mainly controlled by the kind of ligands employed (**1** or **3**). Due to the different positions of the nitrogen atoms in ligands **1** and **3**, the molecular structure of **2** is an ideal rectangle, whereas **4** and **5** are deformed rectangles. No long-range through-bond electronic communication was established in the macrocyclic complexes **2** and **4**. Two factors should mainly be responsible for this observation: (i) both ferrocene building blocks are separated by a distance of more than 1.7 nm, and are thus too far away to communicate, and (ii) the Ni_2 and Ag_2 cores fail to transmit the Cp−C≡C−py conjugation.[25] However, a weak influence of the Ni^{II} and Ag^{I} atoms on the redox potential of the ferrocene units has been established through the conjugated bonds in spite of a separation of 1 nm. In the case of the nickel(II) complex **2**, a weak antiferromagnetic interaction between the intramolecularly arranged nickel(II) atoms was found.

Experimental Section

General Remarks: All reactions and manipulations were carried out under argon by use of standard Schlenk techniques except otherwise noted. Acetonitrile and dichloromethane were dried with calcium hydride and distilled, degassed, and stored under argon. FT-IR data were obtained with a Bruker IFS 48 FT-IR spectrometer. The EI mass spectrum of ligand **3** was recorded with a Finnigan TSQ 70 (200°C) instrument. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded at 25 °C with a Bruker DRX 250 spectrometer operating at 250.13 and 62.90 MHz, respectively. ^1H and ^{13}C NMR chemical shifts are referenced to partially deuterated and deuterated solvent peaks, and are reported relative to TMS. Elemental analyses were carried out with an Elementar Vario EL analyzer. All electrochemical experiments were performed with a Bioanalytical CV-50W Voltammetric Analyzer (BAS, West Lafayette, IN, USA) controlled by a standard 80486 personal computer (control program version 2.0). For electroanalytical experiments a Metrohm platinum-tip electrode (Filderstadt, Germany) was applied as working electrode. The counter electrode was a platinum wire of 1 mm in diameter. A single-unit Haber-Luggin Ag^+/Ag double reference electrode was used. The resulting potential values are referenced to Ag/Ag^+ (0.01 M in CH_3CN/0.1 M Bu_4NPF_6). Ferrocene was used as an external standard. Its potential of 102.5 mV was determined by separate cyclic voltammetric experiments in the respective solvent, and all potentials in the present paper are reported relative to the fc/fc^+ standard. For cyclic voltammetry, a glass-tight full-glass three-electrode cell was used; its assembly for the experiments has been described previously.[26] The cell was purged with argon before it was filled with the electrolyte. Background curves were recorded before adding the substrate to the solution. These were later subtracted from the experimental data of the samples (excluding complex **2**). The automatic BAS CV-50 W *iR*-drop compensation facility was used for all experiments. Magnetic susceptibility of a powdered sample packed in a capsule was measured using a SQUID Quantum Design MPMS magnetometer at 10000 Gauss over the temperature range 5−300 K. All data were corrected for sample-holder contribution. The diamagnetism of the sample and paramagnetism of nickel(II) were represented by a parameter in the non-linear fit equation. This parameter was found to be $(5.4 \pm 1.4) \times 10^{-4}$ emu/mol. Compounds **1**,[15] **3**,[15] and $[PdCl_2(COD)]$[27] were synthesized according to literature methods. $AgClO_4$ and $Ni(NO_3)_2 \cdot 6H_2O$, were used as received without further treatment.

Complex 2: Solutions of nickel(II) nitrate hexahydrate (74 mg, 0.25 mmol) in methanol (50 mL) and of ligand **1**[15] (98 mg, 0.25 mmol) in dichloromethane (50 mL) were simultaneously added dropwise to a stirred mixture of dichloromethane and methanol (50/50 mL) within 4 h at room temperature. The resulting red mixture was stirred for 20 h at the same temperature. Then, the solvents were removed under vacuum. The red residue was washed with methanol (2 mL) and dichloromethane (5 mL) and dried in vacuo for 15 h. Yield 136 mg (92%), red solid, m.p. > 270°C. FT-IR (KBr, cm^{-1}): $\tilde{\nu}$ = 2207 s (C≡C), 1611 vs (C=N), 1289 s (NO_3^-), 1218 sh (NO_3^-). $C_{48}H_{32}Fe_2N_8Ni_2O_{12} \cdot 0.5CH_2Cl_2$ (1184.37): calcd. C 49.18, H 2.81, N 9.46; found C 49.12 H, 2.88 N 9.25.

Ligand 3: This ligand was prepared by a published method,[15] and further purified by recrystallization from dichloromethane and acetonitrile. Red crystals, m.p. 195°C. ^1H NMR (CD_2Cl_2, ppm): δ = 8.50 (dd, $^4J_{H,H}$ = 2.20, $^5J_{H,H}$ = 0.82 Hz, 4 H, 2-H, C_5H_4N), 8.35 (dd, $^3J_{H,H}$ = 4.87, $^4J_{H,H}$ = 1.73 Hz, 4 H, 6-H, C_5H_4N), 7.63 (ddd, $^3J_{H,H}$ = 7.91, $^4J_{H,H}$ = 1.92, $^4J_{H,H}$ = 1.92 Hz, 4 H, 4-H, C_5H_4N), 7.05 (ddd, $^3J_{H,H}$ = 7.91, $^4J_{H,H}$ = 4.87, $^5J_{H,H}$ = 0.82 Hz, 4 H, 5-H, C_5H_4N), 4.50 (m,[28] 8 H, C_4H_4C), 4.29 (m,[29] 8 H, C_4H_4C). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, ppm): δ = 152.17 (C-2), 148.23 (C-6), 138.11 (C-4), 123.24 (C-5), 121.10 (C-3), 90.55, 83.79 (C≡C), 73.38,

71.41 (C_4H_4C), 66.96 (C_4H_4C). MS (EI); *m/z*: 388.0 [M^+]. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 2206 s (C≡C), 1581 w (C=N). $C_{24}H_{16}FeN_2 \cdot 0.05CH_2Cl_2$ (392.50): calcd. C 73.60, H 4.13, N 7.14; found C 73.44, H 4.18, N 6.98.

Complex 4: Solutions of ligand **3** (42 mg, 0.108 mmol) in a mixture of acetonitrile/dichloromethane (25/2 mL) and of silver(I) perchlorate (23.5 mg, 0.114 mmol) in acetonitrile (20 mL) were simultaneously added dropwise to stirred dichloromethane (20 mL) at room temperature during a period of 2 h. After the addition, the mixture was stirred for 24 h at the same temperature followed by the removal of solvents under vacuum. The precipitate was filtered (P3) and washed with dichloromethane (3 mL) and finally dried in vacuo. ***WARNING:*** *This perchlorate complex is hazardous because of the possibility of explosion! Compound* ***4*** *exploded at about 220 °C during the measurement of the melting point! Special care should therefore be taken and only very small amounts of the sample should be handled!* Yield 64.5 mg (94%), red powder, m.p. > 220°C (*explosive!*). ^{1}H NMR (CD_3CN, ppm): δ = 8.49 (dd, $^4J_{H,H}$ = 2.20, $^5J_{H,H}$ = 0.71 Hz, 4 H, 2-H, C_5H_4N), 8.41 (dd, $^3J_{H,H}$ = 4.94, $^4J_{H,H}$ = 1.57 Hz, 4 H, 6-H, C_5H_4N), 7.64 (ddd, $^3J_{H,H}$ = 7.98, $^4J_{H,H}$ = 1.88, $^4J_{H,H}$ = 1.88 Hz, 4 H, 4-H, C_5H_4N), 7.20 (ddd, $^3J_{H,H}$ = 7.98, $^4J_{H,H}$ = 4.94, $^5J_{H,H}$ = 0.71 Hz, 4 H, 5-H, C_5H_4N), 4.50 (m,[28] 8 H, C_4H_4C), 4.29 (m,[29] 8 H, C_4H_4C). IR (KBr, cm^{-1}): $\tilde{\nu}$ = 2211 m (C≡C), 1593 w (C=N), 1095 vs, 1050 s (ClO_4^-). $C_{48}H_{32}Ag_2Cl_2Fe_2N_4O_8 \cdot CH_3CN \cdot 0.5\ CH_2Cl_2$ (1274.66): calcd. C 47.59, H 2.85, N 5.49; found C 47.30, H 2.83, N 5.30.

Complex 5: Solutions of ligand **3** (77 mg, 0.2 mmol) in dichloromethane (50 mL) and of [$PdCl_2$(COD)] (57 mg, 0.2 mmol) in dichloromethane (50 mL) were simultaneously added dropwise to stirred dichloromethane (50 mL) at room temperature during a period of 1 h. After the addition, the mixture was stirred for 20 h at the same temperature followed by the removal of solvents under vacuum. The precipitate was filtered and washed with dichloromethane (3 mL) and finally dried in vacuo. Yield 107 mg (95%), red powder, m.p. > 270 °C. ^{1}H NMR (CD_2Cl_2, ppm): δ = 8.68 (d, $^4J_{H,H}$ = 2.51 Hz, 4 H, 2-H, C_5H_4N), 8.66 (dd, $^3J_{H,H}$ = 6.08, $^4J_{H,H}$ = 1.30 Hz, 4 H, 6-H, C_5H_4N), 7.36 (ddd, $^3J_{H,H}$ = 7.96, $^4J_{H,H}$ = 1.90, $^4J_{H,H}$ = 1.90 Hz, 4 H, 4-H, C_5H_4N), 6.74 (ddd, $^3J_{H,H}$ = 7.96, $^4J_{H,H}$ = 6.08, $^5J_{H,H}$ = 0.67 Hz, 4 H, 5-H, C_5H_4N), 4.55 (m,[28] 8 H, C_4H_4C), 4.30 (m,[29] 8 H, C_4H_4C). IR (KBr, cm^{-1}): $\tilde{\nu}$ = 2209 s (C≡C), 1596 w (C=N), 1095 vs, 1050 s (ClO_4^-). $C_{48}H_{32}Cl_4Fe_2N_4Pd_2$ (1131.15): calcd. C 50.97, H 2.85, Cl 12.54, N 4.95; found C 50.58, H 2.68, Cl 12.57, N 4.83.

X-ray Crystallographic Study: Crystallographic and data collection information as well as a description of the structural analyses and refinements for complexes **2** and **4** are summarized in Table 4. Single crystals of **2** were obtained by slow diffusion of a solution of ligand **1** in dichloromethane into a solution of nickel(II) nitrate hexahydrate in methanol.[30] Suitable single crystals of **4** were obtained by slow diffusion of a solution of ligand **3** in dichloromethane into a solution of silver(I) perchlorate in acetonitrile. Crystals of **5** were obtained by slow diffusion of a [$PdCl_2$(COD)] solution

in dichloromethane into a dichloromethane solution of ligand **3** at room temperature. Each crystal was fixed on a glass fiber using perfluoropolyether RS 3000 and transferred to a Siemens P4 diffractometer (**2**, **4**) or a Stoe IPDS diffractometer (**5**) equipped with a graphite-monochromated Mo-K_α radiation unit. The lattice constants for both macrocycles **2** and **4** were determined by 50 precisely centered high-angle reflections. Intensities were collected by the ω-scan technique. An empirical absorption correction was performed in each case. The structures of **2** and **4** were solved by direct methods with SHELXTL V5.1 (NT version)[31] and refined by least-squares methods with the same program, with anisotropic thermal parameters for all non-hydrogen atoms. All hydrogen atoms were located in calculated positions (riding mode). In **2**, one of the dichloromethane molecules (near the corner of the unit cell in Figure 3) is disordered about the center of inversion. The largest peak and hole in the last difference synthesis were 1.175/−0.696 (**2**), and 0.520/−0.500 (**4**) e·Å^{-3}, respectively. The structure of **5** was solved by direct methods with SHELXS.[32] CCDC-190120 (**2**) and -190121 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Orientation- and Temperature-Dependent Rotational Behavior of Imidazole Ligands (L) in β-$[Ru(azpy)_2(L)_2](PF_6)_2$ Complexes

Aldrik H. Velders,[a][‡] Adoracion Gomez Quiroga,[a][‡‡] Jaap G. Haasnoot,[a] and Jan Reedijk*[a]

Keywords: Ruthenium / N ligands / NMR spectroscopy / Bioinorganic chemistry

The synthesis and characterization of the *cis* bifunctional coordinated ruthenium(II) complexes β-$[Ru(azpy)_2(MeIm)_2](PF_6)_2$ (β-MeIm) and β-$[Ru(azpy)_2(MeBim)_2](PF_6)_2$ (β-MeBim) (azpy = 2-phenylazopyridine, MeIm = 1-methylimidazole and MeBim = 1-methylbenzimidazole) is reported. In β-MeIm the two MeIm ligands can both freely rotate around the Ru–N axes on the NMR timescale. In β-MeBim the two MeBim ligands appear restricted in their rotation around the Ru–N axes, which becomes slow on the NMR timescale at low temperatures. In contrast to the analogous complexes α-$[Ru(azpy)_2(MeBim)_2](PF_6)_2$ and *cis*-$[Ru(bpy)_2(MeBim)_2](PF_6)_2$, only one atropisomer is observed for the two MeBim ligands in β-MeBim. The orientation of the MeBim ligands appears to correspond to an HT isomer which is similar to the orientation of the MeBim ligands in the most abundant atropisomer found in the related α-$[Ru(azpy)_2(MeBim)_2](PF_6)_2$. A stacking interaction between the phenyl ring of one azpy and one MeBim ligand is likely to stabilize the observed atropisomer of β-MeBim, and is such that the rotation of the phenyl ring of one of the two azpy ligands is restricted. At very low temperatures this rotation, or flipping of the phenyl ring between two identical positions, is in the slow-exchange range on the NMR timescale.

Introduction

Dichlorobis(azpy)ruthenium(II) isomers [azpy = 2-(phenylazo)pyridine] have gained interest because of the very different cytotoxicity they exhibit against a series of tumor cell lines, α-$[Ru(azpy)_2(Cl)_2]$ being very cytotoxic and β-$[Ru(azpy)_2(Cl)_2]$ only moderately so.[1] In a similar manner to platinum antitumor compounds, ruthenium complexes are thought to exhibit their cytotoxic activity through their coordination to biological target molecules like proteins or DNA.[2] Therefore, the differences in cytotoxicity found for the isomeric $[Ru(azpy)_2Cl_2]$ complexes might be very useful in the search for a structure-activity relationship (SAR) of antitumor-active ruthenium complexes. From steric aspects derived from the crystal structures[3,4] of α- and β-$[Ru(azpy)_2(Cl)_2]$ and *cis*-$[Ru(bpy)_2(Cl)_2]$, it was suggested that the potential *cis* binding sites in these three complexes are least accessible in the β isomer.[1,5] All three *cis*-$[Ru(LL')_2]$ moieties (LL′ = bpy or azpy) bind only monofunctionally to guanine derivatives.[5–7] Due to the absence of a C_2 axis, the β isomer has actually two different binding sites (see Figure 1), which both appear to be accessible for the binding of an oxopurine ligand; however, the bifunctional coordination of non-tethered purines appears impossible for this isomer.

Previously,[5,8,9] it has been described that the study of the coordination of ruthenium complexes to the lopsided heterocyclic ligand 1-methylbenzimidazole, MeBim, can provide information about the (steric) possibilities of a complex to bind in a *cis* bis(configuration) to the purines of DNA. In the present paper the binding of the lopsided imidazoles (L) 1-methylimidazole (MeIm) and MeBim (see Figure 2) to β-$[Ru(azpy)_2(NO_3)_2]$ is described and their ro-

Results and Discussion

The α- and β-isomers are generally accepted to be the most stable isomers of the bis(azpy)ruthenium(II) complexes.[11−13] However, in solution these two complexes can isomerize, as in fact is observed in the reaction of the isomeric complexes α- and β-[Ru(azpy)$_2$(NO$_3$)$_2$] with guanine derivatives under refluxing conditions in water.[5−7] In the synthesis of bis(adducts) of the type α-[Ru(azpy)$_2$(L)$_2$](PF$_6$)$_2$ no evidence for isomerisation has been found;[5,10] in the present synthesis of the β-isomer bis(adducts), no isomerized compounds were observed either. Apparently, once fully coordinated with nitrogen ligands the α- and β-bis(azpy)ruthenium complexes are stable to isomerisation, even under refluxing conditions in acetone/water.

Similar to the ^{1}H NMR spectra of the analogous complexes α-[Ru(azpy)$_2$(MeIm)$_2$](PF$_6$)$_2$ [5,10] and *cis*-[Ru(bpy)$_2$(MeIm)$_2$](PF$_6$)$_2$,[8,9] the β-MeIm complex shows a ^{1}H NMR spectrum with sharp signals, suggesting that the MeIm ligands are rotating rapidly on the NMR timescale (Figure 3). Also analogous to the bpy and α-azpy systems, the β-MeBim complex shows mainly broad peaks at room temperature, suggesting that the MeBim ligands are rotating at an intermediate speed on the NMR timescale. The possible

presence of rotameric structures in the β-MeBim complex requires a short introduction, which is given below.

For two *cis*-coordinated lopsided ligands on the ruthenium ion, the corresponding atoms can be on the same side (head-to-head, HH), or on opposite sides (head-to-tail, HT) of the ligand−metal−ligand plane.[14] As a lopsided ligand prefers not to orient in the same plane as another ligand,[15] four staggered orientations are possible. In a *cis* bifunctional octahedrally coordinated complex 16 possible atropisomers can be drawn.[5] It can be reasonably assumed that the bicyclic ligands will prefer an orientation with the longitudinal axis parallel to each other, and not orthogonal, therefore only the eight atropisomers depicted in Figure 4 have to be taken into account when identifying the atropisomers. In the complex *cis*-[Ru(bpy)$_2$(L)$_2$](PF$_6$)$_2$] the orientation of the imidazole ligands above the bpy ring system is not observed, diminishing the number of possible atropisomers.[8,9] The other four atropisomers, R5−R8, are not observed, the steric hindrance of the bpy rings most likely preventing the orientation of an MeBim unit above its ring system. It appears, however, that such an orientation cannot be excluded in α-[Ru(azpy)$_2$(L)$_2$](PF$_6$)$_2$ complexes.[5,10] The identification of the observed rotamers for bis(azpy)ruthenium complexes therefore requires a detailed investigation and consideration of all the eight atropisomers R1−R8. Most convenient for the identification of atropisomers in the α-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ system[5,10] is the fact that the C_2 symmetry in the α-[Ru(azpy)$_2$] moiety reduces the number of different rotamers from eight to six. Furthermore, four of the HT rotamers have C_2 symmetry, resulting in the two azpy and the two MeBim ligands being indistinguishable by ^{1}H NMR spectroscopy, which proves the presence of the HT isomers already from a 1D ^{1}H NMR spectrum. Due to the lack of C_2 symmetry in the β-[Ru(azpy)$_2$] moiety, all the eight atropisomers are different from each other, and each of them is expected to give different proton resonances for both azpy and both imidazole ligands.

β-[Ru(azpy)$_2$(MeIm)$_2$](PF$_6$)$_2$ (β-MeIm)

The ^{1}H NMR spectrum of β-MeIm at room temperature is shown in Figure 3. In the aromatic region, 20 resonances

are found, several of which overlap with other signals. With the use of COSY and NOESY data the complete assignment of all resonances has been done (Figure 3 and Table 1). One doublet and two triplet peaks with double intensity in the high-field region can immediately be attributed to the azpy *ortho* [H(*o*)], and *meta* [H(*m*)] protons of the phenyl ring, respectively, after which a COSY spectrum reveals the triplet at δ = 7.55 ppm to be attributed to H(*p*). The MeIm peaks were assigned starting from an NOESY spectrum in which the Me(i) resonances show interaction with the parent H(ii) as well as the H(v) proton resonances; the latter also shows a cross peak with H(iv). From a COSY spectrum, the four signals of the pyridine part of the azpy ligands could be correlated; on the basis of the ^3J coupling, the doublets at δ = 8.8 and 7.9 ppm were assigned to the H6 and H6′ resonances (≈ 6 Hz), whilst the doublet at δ = 9.0 ppm (≈ 9 Hz) was assigned to the two overlapping H3 and H3′ resonances. The peak assignment was further confirmed by the (weak) NOE cross-peaks observed between the H6 and the H6′ resonances, and the H(*o*) and H(*o*′) signals, as would be expected for the β-isomer.[5,7,16]

Table 1. Selection of ^{1}H NMR spectroscopic data (chemical shifts) of β-[Ru(azpy)$_2$(MeIm)$_2$](PF$_6$)$_2$, β-MeIm, and β-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$, β-MeBim, in [D$_6$]acetone at room temp. and at −95 °C, respectively

	H3	H6	H3′	H6′	H(ii)	H(iv)	H(ii′)	H(iv′)
β-MeIm	9.08	8.87	9.08	8.02	7.08	6.21	7.69	6.49
β-MeBim	9.35	7.82	9.35	8.87	8.02	5.3	7.76	6.35

On the basis of only the inter-azpy NOE interactions, it is impossible to attribute one of the two sets of pyridine- or one of the two sets of phenyl-ring proton resonances to a specific azpy ligand. Whereas the interligand NOE peaks of H6 with H(*o*) in a (non-C_2-symmetric) bis(adduct) of the α-isomer allow to distinguish between the azpy moieties, this is not the case for the β-isomer.[5,16] As the H6′ is oriented just above the pyridine ring of the other azpy ligand (Figure 5) a relatively strong shielding of this proton resonance is expected with respect to the H6 proton, and therefore the high-field doublet with a ^3J coupling of 6 Hz has been attributed to the H6′ proton, whilst the low-field doublet with a coupling of 6 Hz is assigned to H6. The

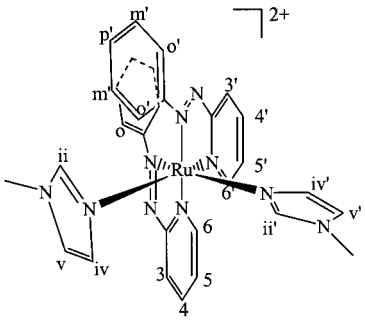

Figure 5. Structural representation and proton numbering scheme of β-[Ru(azpy)$_2$(MeIm)$_2$](PF$_6$)$_2$ (β-MeIm)

resonances of the two phenyl ring systems have been assigned on the basis of the interligand azpy-MeIm NOE interactions (vide infra).

The ^{1}H NMR spectrum of β-MeIm (Figure 3) shows two sets of azpy and two sets of imidazole signals. In theory, such a spectrum can either represent a complex in which both the MeIm ligands are rotating rapidly on the NMR timescale, or it can represent one of the eight atropisomers depicted in Figure 4. As the MeBim ligands in this complex show rotational behavior at room temp. (vide infra) it is reasonable to assume the smaller MeIm ligands do so, too. Upon lowering the temperature to −95 °C, the ^{1}H NMR spectrum of β-MeIm does not change significantly, indicating that at lower temperatures the MeIm ligands are still rotating rapidly on the NMR timescale. In the study with the *cis*-[Ru(bpy)$_2$(L)$_2$]$^{2+}$ [8,9] and α-[Ru(azpy)$_2$(L)$_2$]$^{2+}$ complexes[5,10] it is pointed out that the didentate heterocycles are spectator ligands, with the protons closest to the coordination sites functioning as probe protons that can be used to monitor the orientation and/or the rotation of the monodentate imidazole ligands L. The present results indicate that the H6/H6′ and the H(*o*)/H(*o*′) protons of the azpy ligand can also function as probe protons to monitor the orientation and rotational behavior of the *cis* bis(coordinated) ligands L. The NOESY spectrum of β-MeIm (Figure 6) shows that the azpy H6 proton interacts with the H(ii) and H(iv) protons of both MeIm ligands. These NOE peaks indicate that the MeIm ligands are rotating around their Ru−N axes on the NMR timescale, and this is further confirmed by the cross peaks between the two MeIm ligands: H(ii)-H(ii′), H(ii)−H(iv′), H(iv)−H(ii′) and H(ii)−H(iv′). The 2D ^{1}H NMR spectroscopic data clearly confirm, therefore, that the MeIm ligands are indeed rotating (fast) around their Ru−N(iii) axes.

β-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ (β-MeBim)

Variable-Temperature ^{1}H NMR Behavior

At room temperature broad peaks are observed in the ^{1}H NMR spectrum of β-MeBim (Figure 3). These are characteristic of a complex with different rotamers that are exchanging with each other on the NMR timescale. In the ^{1}H NMR spectrum of β-MeBim at higher temperatures, no (complete) sharpening of the signals is observed. On lowering the temperature, on the other hand, a sharp set of signals is observed (Figure 7). All the azpy protons resonances can be assigned from the COSY and NOESY spectra in a similar way to β-MeIm. The identification of the rotamers was made from the 2D NOE data and by evaluating the (de)shielding effects of the ligands on the other proton resonances; the rotational aspects of the ligands at different temperatures were determined from the ROESY data.

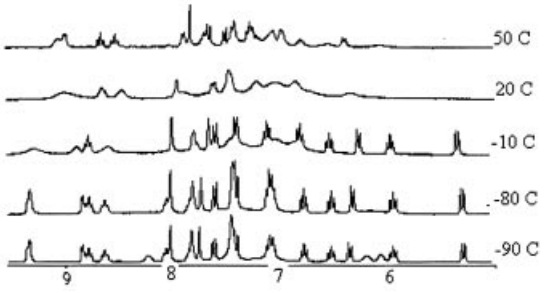

Figure 7. ^{1}H NMR spectra (δ scale in ppm) of β-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ at different temperatures; assignment of resonances in the low temperature spectrum is given in Table 1

Analogous to the discussion of the MeIm complex, for β-MeBim a theoretical total of 24 resonance signals in the aromatic region for the two azpy ligands and the two MeBim ligands could indicate the presence in solution of only one symmetric atropisomer, in slow exchange on the NMR timescale, or on the other hand it could indicate the average of a rotational system which is in fast exchange on the NMR timescale. For β-MeBim the ^{1}H NMR spectrum at room temperature shows broad peaks, suggesting that the presence of different atropisomers could possibly be observed at lower temperatures. The results obtained with the α-[Ru(azpy)$_2$(MeBim)$_2$]$^{2+}$ complex explicitly demonstrate[5,10] that one should take great care in interpreting the ^{1}H NMR spectroscopic data of rotational complexes, as a set of signals can indicate a system which has no rotating ligands on the NMR timescale, but can also indicate a system with fast moving ligands, which can freeze out into different atropisomers upon lowering the temperature. Furthermore, the sets of signals belonging to these "atropisomers" in slow exchange can sometimes represent the average signal of more possible atropisomers.[5,10] For β-MeBim, the spectrum at −95 °C is shown to represent one specific atropisomer (see next section), but the VT ^{1}H NMR spectroscopic data show one particular feature that should be treated in more detail. This regards the rotational behavior of the phenyl ring of one of the two azpy ligands, which, due to interaction with the lopsided ligands, becomes slow on the NMR timescale in the low-temperature region.

Orientations of the Two MeBim Ligands in β-MeBim

The orientation of the MeBim ligands in β-MeBim as observed at low temperatures was determined from the NOE data. As pointed out for the MeIm complex β-MeIm, the H(*o*) and H6 protons of the azpy ligands are found close to the imidazole ligands, and NOE interactions are most useful for determining the orientation of the MeBim ligands. Unfortunately, the H(*o*) resonances are very broad at the recording temperature and no NOE cross-peaks are observed. The most important NOE cross peaks observed for β-MeBim (Figure 8) are the H6−H(iv′) and the weak cross peaks between the H(ii) and H(iv′) resonances and H(iv) and H(ii′) resonances. These three cross peaks point to a conformer in which the imidazole H(ii) protons of both the benzimidazole ligands are oriented above the aza binding of their *fac*-coordinated azpy ligands (R5 in Figure 4; see Note added in proof). The six-membered ring of the MeBim ligand [H(iv)] is oriented in a face-to-face manner with the pyridine of the *mer*-coordinated azpy ligand, whilst the other MeBim ligand [H(iv′)] has its six-membered ring face-to-face with the phenyl ring of the *mer*-oriented azpy ligand. This HT atropisomer is different from the two HT atropisomers found for the *cis*-[Ru(bpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ system[8,9] in which none of the rotamers has the lopsided part of a MeBim ligand oriented above the didentate ligand. Interestingly, this rotamer is very similar to the most abundant (HT) atropisomer observed in the related α complex.[5,10]

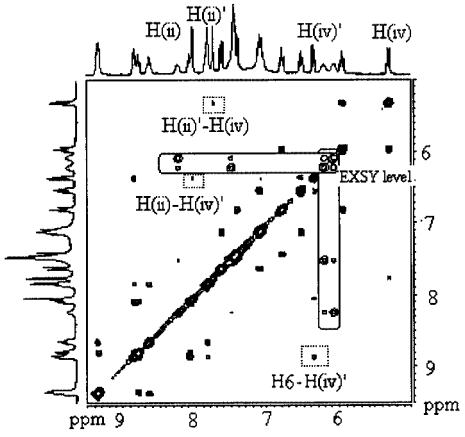

Figure 8. ROESY spectrum of β-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ (β-MeBim) in [D$_6$]acetone at −95 °C; NOE cross peaks are highlighted in the dotted areas (see Note added in proof)

It is most likely that the bulky, rotating phenyl rings of the two azpy ligands prevent the MeBim ligand from orienting in the direction of the two aromatic rings of the two azpy ligands (R1−R4).The orientation of the MeBim′ li-

gand with the six-membered ring above the azpy ligand is also not expected due to severe steric clashes (R7, R8). For the same reason atropisomer R6 is likely to be sterically disfavored. The remaining atropisomer, R5, has the MeBim ligands oriented in such a way that the imidazole ring protons are oriented close to the aza bond of the azpy ligands. Besides the steric effects preferring this orientation, an electronic effect is possibly also stabilizing the orientations of the MeBim ligands. Marzilli et al.[17] have pointed out that the orientation of imidazole ligands can partly be determined by the electrostatic interaction between the relatively positive NCHN δ^+ site of the imidazole ring with partly negative ligands like chloride ions. In β-MeBim there might be two such interactions between the imidazole ring of both MeBim ligands and the aza bond of the respectively *fac*-oriented azpy ligands.

In summary, taking into account that, for symmetry reasons the two HH rotamers in α-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ each represent two (identical) atropisomers, seven out of the eight possible orientations of the two MeBim ligands shown in Figure 4 are observed.[5,10] The isomeric complex β-MeBim, however, shows only one stable atropisomer, i.e. the HT isomer R5 (Figure 4).

From the discussion of the possible orientation of the non-tethered MeBim ligands in β-MeBim, it is concluded that only one stable atropisomer is to be expected. For the investigation of atropisomers in *cis*-[Ru(bpy)$_2$(L)$_2$](PF$_6$)$_2$ complexes, the mdbz ligand [bis(1-methyl-2-benzimidazolyl)-ethane] has been used to prepare the complex *cis*-[Ru(bpy)$_2$(mdbz)](PF$_6$)$_2$. In this mdbz complex, the two MeBim moieties are oriented as in the R1 atropisomer (A in the previous paper)[9] but are tethered, and therefore rotation of the imidazole ligands around the Ru−N axes cannot be expected and is indeed not observed. On reaction of β-[Ru(azpy)$_2$(NO$_3$)$_2$] with mdbz, however, no β-[Ru(azpy)$_2$(mdbz)](PF$_6$)$_2$ could be obtained at all. From a space-filling model of β-[Ru(azpy)$_2$(mdbz)](PF$_6$)$_2$, and from Figure 4, it is clear that the didentate ligand mdbz cannot coordinate in a bifunctional mode to the β-bis(azpy) isomer in such a way as to adopt the HT atropisomer R5, as the imidazole moieties in the R5 orientation are too distant. On the other hand, to adopt the HT orientation from atropisomer R1, one phenyl ring of the mdbz should be coordinated wedged in between the pyridine rings of the two azpy ligands. The "tail" part of the mdbz in β-[Ru(azpy)$_2$(mdbz)](PF$_6$)$_2$ should be wedged in between the phenyl rings of the two azpy ligands. In particular, the phenyl rings of the two azpy ligands are prevent the second benzimidazole moiety of the mdbz from coordinating to the ruthenium ion. (See the Supporting Information where the hypothetical structure of β-[Ru(azpy)$_2$(mdbz)](PF$_6$)$_2$ is drawn schematically.) This indicates that the (main) HT conformation in which the benzimidazole ligands coordinate to the *cis*-[Ru(bpy)$_2$] is not possible for the β-[Ru(azpy)$_2$] complex, and confirms the mdbz to be a good model ligand for an HT interaction in which the imidazole sites of the MeBim ligands are pointing towards each other.

(De)Shielding Effects

Because of the different (de)shielding effects caused by the different orientations of the MeBim ligands, the probe protons shift characteristically, as is nicely illustrated for the three main atropisomers found[5,10] in α-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ and the three atropisomers observed[8,9] in *cis*-[Ru(bpy)$_2$(MeBim)$_2$](PF$_6$)$_2$. In β-MeBim only one atropisomer is observed, and therefore the relative shifts of the probe protons in different atropisomers cannot be discussed. However, a few remarkable proton resonances do require further discussion.

The most upfield-shifted aromatic proton signal appears to be the H(iv) resonance at δ = 5.30 ppm. In the free ligand the H(iv) proton resonance is observed at δ = 7.6 ppm, and in the *cis*-[Ru(bpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ complex at δ = 7.1−7.2 ppm for the atropisomer R2/R3 and R4 (atropisomers B and C, respectively, as mentioned in the corresponding previous publications).[8,9] In the α-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ complex the most upfield-shifted H(iv) resonance signals are at δ = 6.1 and 6.2 ppm,[5,10] and belong to the least abundant atropisomer R6/R7. The exceptional upfield shift of H(iv) in β-MeBim can be nicely explained by the strong shielding effect of the proximate phenyl ring of the azpy ligand (see Figure 9).

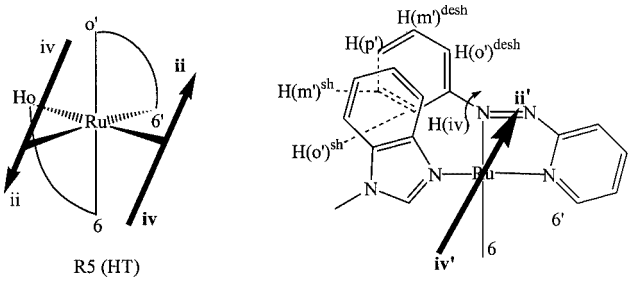

Figure 9. Schematic representation of the atropisomer R5 of β-MeBim (left) and projection along the MeBim′−Ru axis (right); the overlap and consequential mutual shielding effects of the six-membered rings of the azpy phenyl group and the MeBim ligand is visualized

It is most likely that some kind of stacking interaction is present, with H(iv) oriented just above the slowly flipping phenyl ring, which most of the time is oriented parallel and face-to-face with the MeBim six-membered ring. Consecutively, the two phenyl ring H(*o*) protons, once having become inequivalent due to the slow rotation of the ring around the C−N axis, are, in turn, expected to shift characteristically due to the shielding effect of the six-membered ring of the MeBim ligand. In fact, one resonance [δ = 6.1 ppm, H(*o*)^{sh}] is shifted strongly upfield whilst the other is deshielded [δ = 8.3 ppm, H(*o*)^{desh}] and shifted downfield. The H(*m*′) protons show a similar effect {δ = 6.3 [H(*m*′)^{sh}] and 7.6 ppm [H(*m*′)^{desh}]}, albeit with a frequency difference, $\Delta\nu$, less extreme than observed for the H(*o*) resonances (660 and 390 Hz, respectively).

From Figure 9 the mutual shielding effect of the azpy phenyl ring and the MeBim six-membered ring is evident. The H(*o*′)^{sh} signal is assigned to the proton which is oriented just above the shielding cone of the MeBim six-mem-

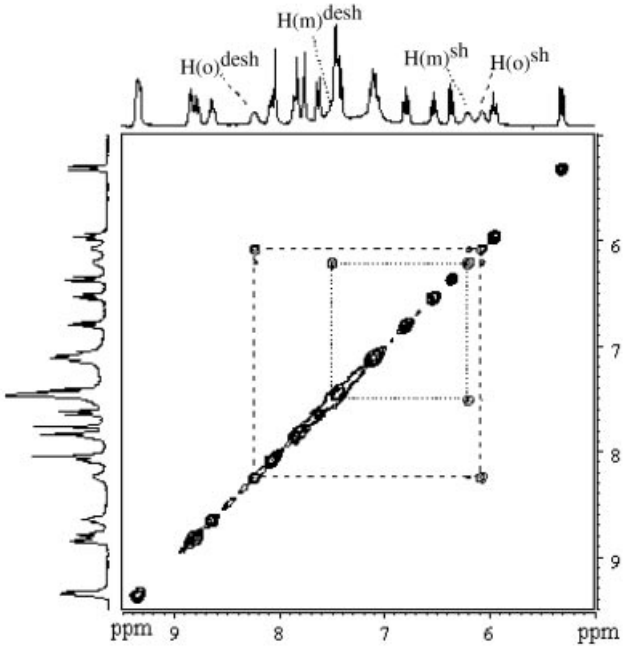

Figure 10. EXSY level of the ROESY spectrum of β-MeBim in [D$_6$]acetone at −95 °C; the H(*o′*) and H(*m′*) exchange peaks are indicated with dashed and dotted lines, respectively

bered ring, whilst the H(*o′*)^{desh} signal is attributed to the other H(*o′*) proton. NOE cross peaks between H(*o′*) and H(iv) would unambiguously confirm this orientation; however, none are observed. At −95 °C the phenyl ring is still flipping as can be concluded from the cross peaks observed in the EXSY level of a ROESY spectrum (Figure 10). The H(*o′*) resonance is too broad to detect any NOE interaction. However, all assignments and conclusions agree well with the results of the analogous 1,2-dimethylimidazole complex, in which the phenyl ring is rotating even more slowly on the NMR timescale than in the analogous MeBim complex, and the signals of the phenyl ring protons are sharper.[18]

Exchange Mechanism

The kinetics of exchanging systems can be studied by 1D and/or 2D NMR spectroscopic techniques. At higher temperatures a broadening of signals is observed for β-MeBim which might be due to rotational behavior of the MeBim ligands. The broadening of the peaks is not the result of interchanging rotamers present at low temperatures. The energy input upon increasing the temperature might allow the interconversion of the atropisomers R5 into (one of the) other atropisomers. In the highly symmetric system *cis*-[Ru(bpy)$_2$(4Pic)$_2$](PF$_6$)$_2$, in which the four rotamers present are all identical,[19] the thermodynamic parameters of the rotation of a heterocyclic six-ring ligand, 4-picoline, could be determined. The phenyl ring rotation in complex β-MeBim is observed to be relatively independent from the other rotational processes in the temperature range between −95 °C and −50 °C. However, close to the temperatures where the coalescence of the H(*o′*)^{desh} and H(*o′*)^{sh}, and the H(*m′*)^{desh} and H(*m′*)^{sh} signals are expected, the other signals of β-MeBim are also broadening, indicating that another rotational process is occurring. Besides the fact that the coalescence temperature of the phenyl ring protons is difficult to observe because of overlap with other signals, the occurrence of other dynamic processes in the same temperature region severely complicates the calculation of the thermodynamic parameters.

Conclusion

The synthesis and characterization of the bifunctional coordinated ruthenium(II) complexes β-[Ru(azpy)$_2$(L)$_2$](PF$_6$)$_2$ provides detailed information of the steric properties of the β-[Ru(azpy)$_2$] moiety. Both MeIm ligands in β-MeIm can rotate freely on the NMR timescale at all recording temperatures. The MeBim ligands in β-MeBim, in contrast to MeBim in the analogous complexes α-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ and *cis*-[Ru(bpy)$_2$(MeBim)$_2$](PF$_6$)$_2$, do not orient in different ways on the ruthenium ion at low recording temperatures, and only one atropisomer is observed. By using NMR techniques, including COSY and NOESY, the complete structural characterization of the conformation has been carried out, and the MeBim ligands appear to be oriented in an HT orientation similar to that found in the isomeric complex α-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$. An interesting observation is that the steric hindrance of the MeBim ligands is such that the rotation of the phenyl rings of one of the two azpy ligands is hindered. At very low temperatures the rotation is just at slow exchange on the NMR timescale, causing all five phenyl-ring protons to become inequivalent. This stacking interaction probably stabilizes the observed atropisomer.

The results for α-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ and β-[Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ might indicate that the cytotoxic effect of the α-[Ru(azpy)$_2$Cl$_2$] complex is not due to a (static) interaction with the DNA bases in an HT configuration, which is observed in the main atropisomer of all three complexes. The antitumor drug cisplatin coordinates in a *cis* bis(mode) to two neighboring guanine units in DNA, with the guanine units oriented in an HH conformation.[20] In the complex β-MeBim, neither of the two MeBim ligands appears to rotate around its Ru−N(iii) axis on the NMR timescale. The 1D and 2D VT ^{1}H NMR studies on complexes of the type *cis*-[Ru(Xpy)$_2$(L)$_2$]$^{2+}$ (with Xpy being a didentate ligand like bpy or azpy, and L an imidazole ligand) confirm clearly that complexes of the type *cis*-[Ru(Xpy)$_2$(L)$_2$]$^{2+}$ are sterically borderline cases in which bifunctional coordination of lopsided heterocycles depends on relatively small differences in the ligands or in their mutual orientations. The 1D and 2D VT ^{1}H NMR study presented here is an elaborate, but informative, method for determining such small differences in the steric properties of complexes of the type *cis*-[Ru(Xpy)$_2$]$^{2+}$. Whether the coordination and/or fluxional properties of heterocyclic ligands to *cis*-[Ru(Xpy)$_2$]$^{2+}$-type ruthenium complexes is indeed crucial for the biological activity of the complexes is a sub-

ject that should be investigated further with other *cis*-[Ru(Xpy)$_2$]$^{2+}$ complexes, as well as with in vitro DNA binding studies.

The current data prove that coordination of heterocyclic bicyclic ligands to bpy and azpy complexes differs significantly. The β-[Ru(azpy)$_2$]$^{2+}$ moiety is sterically less versatile than the *cis*-[Ru(bpy)$_2$]$^{2+}$ and α-[Ru(azpy)$_2$]$^{2+}$ moieties. Therefore, the β isomer, which is biologically not as active as the α isomer, shows a relatively reduced affinity regarding coordination to the heterocyclic ligands. Besides the orientation of DNA bases to platinum complexes, also the (ligand) rotational properties are accepted to be important factors influencing the antitumor properties.[20] If these differences in orientational and rotational behavior can indeed explain the differences in biological activity of *cis*-dichlororuthenium complexes, then a systematic, extensive investigation of a series of complexes of the type *cis*-[Ru(Xpy)$_2$] is of paramount importance.

Experimental Section

Materials and Physical Measurements: 1-Methylimidazole (MeIm, Aldrich) and 1-methylbenzimidazole (MeBim, Sigma) were used without further purification. Hydrated $RuCl_3$ was used as received from Johnson Matthey; azpy and β-[Ru(azpy)$_2$(Cl)$_2$]·$CHCl_3$ were prepared according to literature procedures.[11] For the purification of β-Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ neutral aluminum oxide (Alumina Woelm N Super I) was used. The complex β-[Ru(azpy)$_2$-(NO$_3$)$_2$]·$CHCl_3$ was prepared as described elsewhere.[5,7] NMR measurements were performed as described before[8,9] at 300.13 MHz with a Bruker 300 MHz DPX spectrometer, equipped with a Bruker B-VT1000 variable-temperature unit. Concentrations were in the 0.01 M region or below.

Syntheses

β-Ru(azpy)$_2$(MeIm)$_2$](PF$_6$)$_2$ (β-MeIm): β-[Ru(azpy)$_2$(NO$_3$)$_2$]·$CHCl_3$ (0.15 g, 0.21 mmol) was dissolved in a mixture of 10 mL of water and 4 mL of acetone and stirred at room temperature for 24 h. After addition of an excess of 1-methylimidazole (0.78 g, 9 mmol), the solution was refluxed for 3 h, and after addition of NH_4PF_6, β-MeIm was isolated by filtration. Recrystallization from ethanol/water, and from acetone/diethyl ether resulted in a purple microcrystalline material. Yield 0.10 g (54%). $C_{30}H_{30}F_{12}N_{10}P_2Ru$ (921.63): calcd. C 39.10, H 3.28, N 15.2; found C 38.5, H 3.18, N 14.7.

β-Ru(azpy)$_2$(MeBim)$_2$](PF$_6$)$_2$ (β-MeBim): β-[Ru(azpy)$_2$(NO$_3$)$_2$]·$CHCl_3$ (0.15 g, 0.21 mmol) was dissolved in a mixture of 10 mL of water and 4 mL of acetone and stirred at room temperature for 24 h. An excess of 1-methylbenzimidazole (1.19 g., 9 mmol) was added and the solute was refluxed for 3 h. The solid isolated after addition of NH_4PF_6 was recrystallized from ethanol/water and further purified by column chromatography with acetone/methanol (99:1) as eluent. Yield 0.060 g. (42%).^{1}H NMR spectroscopic data indicate the presence of a co-crystallized acetone molecule. $C_{38}H_{34}F_{12}N_{10}P_2Ru$·$(CH_3)_2CO$ (1079.83): calcd. C 45.6, H 3.73, N 12.9; found C 45.8, H 3.79, N 12.6.

Supporting Information: Schematic representation of the α and β isomers of Ru(azpy)$_2$L$_2$ species is given in Figure S1 (see also footnote on the first page of this article). A representation of the mdbz ligand and a hypothetical orientation of the mdbz ligand on the β-[Ru(azpy)$_2$] is given in Figures S2 and S3. The steric hindrance of the two phenyl rings of the two azpy ligands prevents the coordination of one of the MeBim moieties to the ruthenium ion.

Acknowledgments

One of the authors (J. R.) is indebted to Johnson−Matthey (Reading, UK) for their generous loan of $RuCl_3$·$3H_2O$. The support and sponsorship concerted by COST Action D8/0017/97 (Chemistry of Metals in Medicine) is kindly acknowledged. This research has also been financially supported by the Council for Chemical Sciences of the Netherlands Organisation for Scientific Research (CW-NWO). One of the authors (A. G. Q.) wants to thank the CICYT Spain (SAF00-0029).

Note added in proof (December 16, 2002): The assignment to this atropisomer is further confirmed by the observation of (very) weak NOE cross peaks from both H(ii) and H(ii)′ with the (overlapping) H3 and H3′ proton resonances (not visible in the present Figure 8).

New Molecular Charge-Transfer Salts of TM-TTF and BMDT-TTF with Thiocyanate and Selenocyanate Complex Anions [TMTTF = Tetramethyltetrathiafulvalene; BMDT-TTF = Bis(methylenedithio)tetrathiafulvalene]

Marta Mas-Torrent,[a] Scott S. Turner,[b] Klaus Wurst,[c] José Vidal-Gancedo,[a] Jaume Veciana,[a] Peter Day,*[b] and Concepció Rovira*[a]

Keywords: Charge transfer / Tetrathiafulvalene / Complex anions / Magnetic properties

Three new charge-transfer salts of tetrathiafulvalene (TTF)-based donors with thiocyanato- or selenocyanato-metal complex anions have been synthesised. The salts isolated were $[BMDT\text{-}TTF]_4[Cr(NCS)_6]$ (**1**), $[TM\text{-}TTF]_4[Cr(NCS)_6]\cdot 2CH_3CN$ (**2**) and $[TM\text{-}TTF]_4[Cr(NCSe)_6]\cdot 2CH_3CN$ (**3**) [BMDT-TTF = bis-(methylenedithio)tetrathiafulvalene and TM-TTF = tetramethyltetrathiafulvalene]. Single crystals of compound **1** crystallise in the monoclinic $C2/c$ space group with a = 37.286(3), b = 10.0539(6), c = 21.069(2) Å, β = 124.348(4)°, V = 6520.9(9) Å^3 and Z = 4. Compound **3** was also suitable for an X-ray diffraction study, however the anionic part, $[Cr(NCSe)_6]^-$ was highly disordered and the best solution gave a final R factor of 16.4%. A solution was found for the monoclinic space group $C2/m$ with a = 13.787(3), b = 19.507(3), c = 14.735(5) Å, β = 102.90(3)°, V = 3862.9(17) Å^3 and Z = 2. For compound **1** there are several S···S close atomic contacts between the donors and acceptors, but there is no discernible magnetic exchange between ions. Such an interaction was previously observed in related salts such as $[TTF][Cr(NCS)_4(phenanthroline)_2]$ and $[donor][M(NCS)_4(isoquinoline)_2]$ [M = Cr, Fe and donor = TTF, BEDT-TTF or TM-TTF (tetramethyltetrathiafulvalene)]. Compounds **1** to **3** are all paramagnetic semiconductors in which the magnetic susceptibility is dominated by the Cr-containing anions. The structure-function relationship, along with a comparison with related compounds, indicates that there is no long-range magnetic order because there are no π-stacking interactions between donor and acceptor; these types of interactions are seen in all of the bulk magnets of this type in which the donor spin is magnetically coupled to the anion.

Introduction

With the discovery of metallic properties in molecular organic compounds,[1] large efforts have been devoted to the development of new organic conductors based on π-electron donors. Tetrathiafulvalene (TTF) and its analogues have to date provided the largest number of organic metals and superconductors.[2] Until relatively recently interest in this class of compounds was focused on their transport properties, whereas current synthetic efforts are aimed towards bringing together combinations of physical properties. Since the majority of TTF-based salts consist of discrete layers of cationic and anionic components, it should be possible to prepare new molecular-based materials in which electrical, optical and magnetic properties can coexist, by including different properties into the different layers. Components with magnetic properties can be introduced by anionic complexes with paramagnetic centres.[3−8] Of special interest to us is to establish electrical transport, even superconductivity, in a crystal lattice containing localised magnetic moments.[3,4] With the aim of obtaining salts with long-range magnetic ordering, together with conductivity properties, some research groups have been using bimetallic complexes as counterions to the TTF-based molecule.[4,5b] Some of us recently embarked on a different approach that consists of promoting strong interactions between the cationic and anionic sub-lattices so the electronic systems in the different networks can be coupled to achieve interesting magnetic properties.[7] For example, we prepared a range of TTF-based salts with strong donor-acceptor interactions and subsequently long-range ferrimagnetic order.[7] This was achieved by using anions of the type $[Cr(NCS)_4(N\text{-donor})_x]^-$, where N-donor = 1,10′-phenanthroline (x = 1)

or isoquinoline ($x = 2$). The anions were designed to provide the opportunity for both π-stacking and close S···S contacts between the anion containing localised magnetic moments and the radical donor; the resulting ferrimagnetic compounds display both of these interactions. The question still remains, however, as to what role each of these interactions plays in promoting long-range magnetic ordering. Looking at this point we prepared salts using hexathiocyanato complexes, which can only have short S···S contacts between anions and cations. No magnetic order was observed.[8] However, the empirical conclusion that S···S contacts are less important than π-stacking for magnetic exchange interactions was preliminary, since other factors, such as the angle of overlap of S···S short contacts and the donor charge could, of course, be significant in promoting certain physical properties.

The purpose of the present work is to continue building a range of similar compounds for our investigation into the origin of the bulk ferrimagnetism found in this family of salts. We report on the synthesis and characterisation of novel charge-transfer salts based on TM-TTF (tetramethyltetrathiafulvalene) and BMDT-TTF [bis(methylenedithio)tetrathiafulvalene] with paramagnetic anions that can only provide S···S or S···Se interactions.[9]

Results and Discussion

Synthesis

The salts described here were synthesised by electrocrystallisation in conventional H-shaped electrocrystallisation cells with Pt electrodes. Black needle-shaped crystals of $[BMDT\text{-}TTF]_4[Cr(NCS)_6]$ (**1**) were obtained with BMDT-TTF as donor and $[C_9H_8N][Cr(NCS)_4(C_9H_7N)_2]$ [(C_9H_7N) = quinoline] as electrolyte in CH_2Cl_2 solution. The fact that the quinoline ligand is not present can only be explained by a ligand exchange during the electrocrystallisation due to the lability of the quinoline.[9] The isostructural salts $[TM\text{-}TTF]_4[Cr(NCS)_6]\cdot 2CH_3CN$ (**2**) and $[TM\text{-}TTF]_4[Cr(NCSe)_6]\cdot 2CH_3CN$ (**3**) were synthesised with TM-TTF as donor and the anions $[(C_2H_5)_4N]_3[Cr(NCS)_6]$ and $[(C_2H_5)_4N]_3[Cr(NCSe)_6]$, respectively, as electrolytes in a mixture of dichloromethane and acetonitrile.

Description of Crystal Structures

The collection data and crystal parameters for compounds **1** and **3** are given in Table 1. A standard ORTEP[13] diagram of the asymmetric unit of compound **1**, showing the atom numbering scheme and atoms as 50% thermal ellipsoids, is shown in Figure 1.

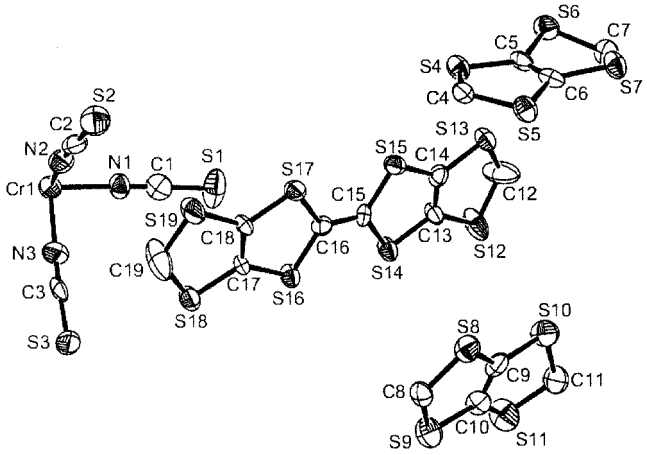

Figure 1. An ORTEP[13] diagram of the asymmetric unit of **1**, showing the atom numbering scheme and atoms as 50% thermal ellipsoids; the hydrogen atoms have been removed for clarity

As with many charge-transfer salts based on TTF-like donors the overall structure consists of alternating layers of cations and anions, as shown in Figure 2.

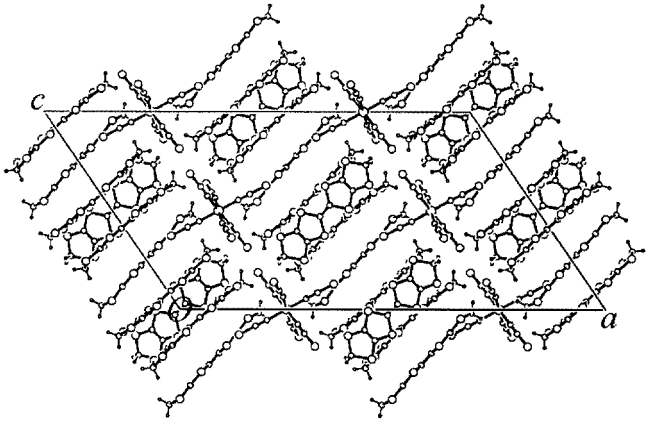

Figure 2. Unit cell diagram showing the overall molecular packing arrangement for **1**

Furthermore, in this salt the cationic BMDT-TTF layers are interpenetrated by two NCS ligands per anion. The packing arrangement for the donor molecules within each cationic layer in Figure 3 can be described in terms of two

types of rows. Row A, as marked in Figure 3, consists of a face-to-face BMDT-TTF dimer that alternates with a single donor molecule arranged perpendicular to the dimer. Row B, which lies between each type-A row, consists of single BMDT-TTF molecules that lie parallel to the dimers of row A, but are translated along the crystallographic *b* axis with respect to the dimers.

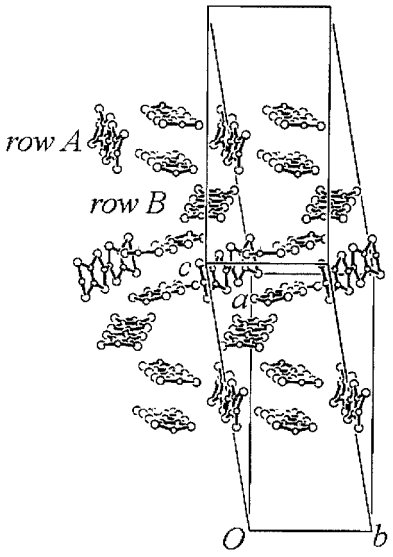

Figure 3. Packing motif of BMDT-TTF donors in compound **1**; the labels for rows A and B are described in the text

Furthermore, in successive instances of row A, the C=C central bonds of the donors are twisted by an angle of approximately 31° with respect to each other. Any close S···S intermolecular contacts are almost all in rows of type A and for the inter-dimer distances these range from 3.38 Å (S12···S6) to 3.50 Å (S15···S16). Between molecules of a dimer and the neighbouring perpendicular BMDT-TTF molecule in the same row they range from 3.43 Å (S14···S17) to 3.56 Å (S13···S4). There are only two close atomic contacts between rows A and B of 3.50 Å (S19···S10) and 3.57 Å (S17···S10). In addition there are a few atomic S···S contacts between the anions and cations even though an NCS ligand (with terminal S1) penetrates the cation layer. Each of these contacts is close to the sum of the van de Waals radii of two sulfur atoms, with values of 3.55, 3.57 and 3.60 Å for contacts S18···S3, S19···S2 and S7···S3, respectively. There are no significant atomic contacts between the anions, as the shortest distance between the terminal S atoms on neighbouring Cr complexes is just 4.06 Å.

For compound **3** the structure could only be refined to an *R* factor of 16%, mainly due to one-dimensional disorder of the anion layers and therefore this structure will not be discussed in detail. Nevertheless, the donor molecules are well ordered and are stacked along the *a* axis with intermolecular S···S distances of between 3.65 and 3.81 Å (Figure 4). The donor molecules between neighbouring stacks along the *c* axis have alternate distances due to the insertion of NCSe ligands. A simplified layout showing only Cr and Se atoms of the anionic layer, parallel to the crystallographic *ab* plane, is shown in Figure 5. The $CrSe_6$ units with filled bonds form a regular anionic sheet, although in this refinement all the positions have an occupancy factor of 0.5 except for the overlying Se(1) atoms along the *b* axis, which have a factor of 1.0. The one-dimensional disorder is caused by displacement of the regular layer with a half-lattice constant along the *a* direction.

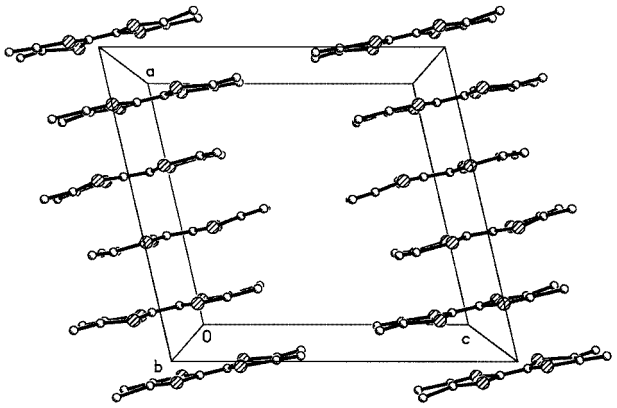

Figure 4. Packing motif of TM-TTF donors in compound **2** and **3**

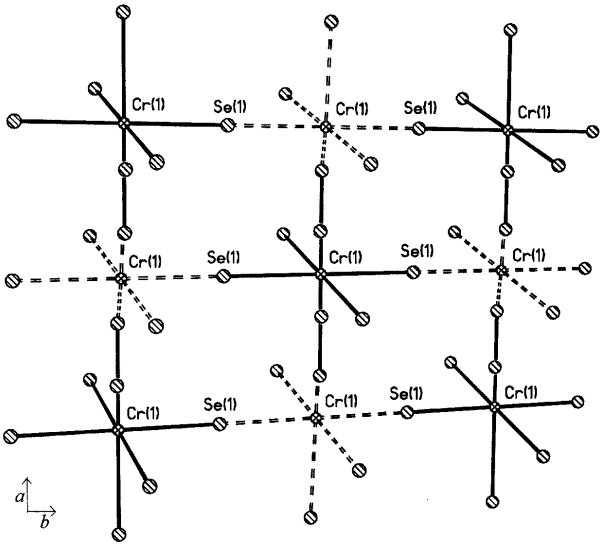

Figure 5. Two overlying $Cr(NCSe)_6^{3-}$ sheets showing one-dimensional disorder (see text)

Compound **2** crystallises in the same space group with nearly identical coordinates for all atoms and a similar one-dimensional disorder. The *R* value is about 18.5%, with unit cell parameters $a = 13.806(7)$, $b = 19.41(1)$, $c = 14.63(1)$ Å, $\beta = 103.03(4)°$ and $V = 3818.7(4)$ Å^3 at 223 K

Electrical Transport and Magnetic Properties

The conductivity behaviour for compound **1** was measured from 300 to 120 K. This compound shows a semiconducting behaviour with a modest room temperature conductivity (σ_{300K}) of 4×10^{-3} S cm^{-1} and an Arrhenius-like behaviour on decreasing the temperature with an activation energy (E_a) of 0.1 eV. For compound **2**, due to the crystal

morphology (elongated hexagonal plates), we were able to measure the electrical transport in three mutually perpendicular directions, although because of the small crystal size only two probe measurements were possible. For all three directions a plot of ln(resistance) vs. 1/T gave a straight line, i.e the Arrhenius behaviour of a semiconductor. Perpendicular to the plane of the plate $\sigma_{300K} = 2.26 \times 10^{-3}$ S cm^{-1} and $E_a = 0.05$ eV; in the plane of the plate, across the long direction of the elongated hexagon $\sigma_{300K} = 3.07 \times 10^{-3}$ S cm^{-1} and $E_a = 0.04$ eV; in the plane of the plate across the shorter direction $\sigma_{300K} = 6.02 \times 10^{-3}$ S cm^{-1} and $E_a = 0.04$ eV. For compound **3** it was only possible to measure along the needles long axis by standard four-probe methods and although a large σ_{300K} of 454.1 S cm^{-1} was found, the variation with temperature indicated semiconducting behaviour, with $E_a = 0.06$ eV (Figure 6).

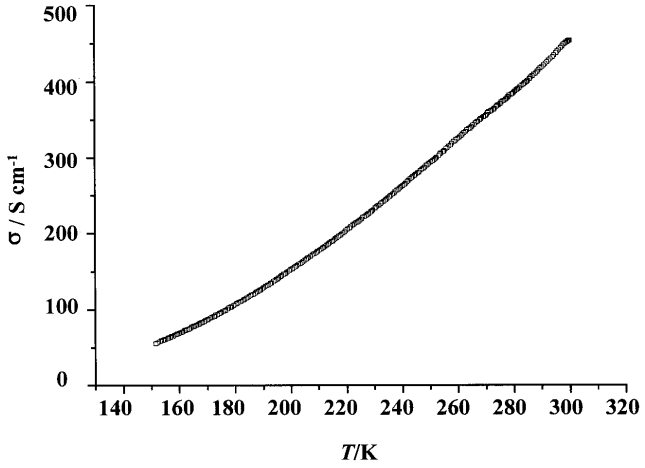

Figure 6. Plot of conductivity vs. temperature for compound **3**

The magnetic properties of **1** resemble a paramagnetic material in which the magnetic susceptibility is dominated by the metal complex. A plot of susceptibility vs. temperature was fitted well to the Curie−Weiss law and gave a Curie constant C of 2.49 emu K mol^{-1} and a small negative Weiss constant of $\theta = -1.1$ K. For compound **2** a similar fit gave C = 2.10 emu K mol^{-1} and $\theta = -0.05$ K; for compound **3** the values are C = 1.94 emu K mol^{-1} and $\theta = -0.28$ K. All of the salts gave a Curie constant greater than expected for a Cr^{III} spin 3/2 centre alone, for which a value of 1.875 emu K mol^{-1} is expected, indicating that the donor radical contributes to the measured susceptibility to some extent. The salts each show small negative Weiss values, which indicate that they all have a small number of short range antiferromagnetic interactions.

Spectroscopic Properties

The mixed-valence character of compounds **1**−**3** was confirmed by the presence of the characteristic broad A band in the IR and NIR-visible spectra, corresponding to the mixed-valence states of low-dimensional conducting organic solids, centred at 3300, 2400 and 2350 cm^{-1}, respectively.[14]

Since the size of the crystals for compound **1** was suitable, the degree of ionicity of the donor could be studied by Raman reflection spectrometry. It has been reported previously that there is an approximately linear dependence between the donor charge and the Raman-active C=C stretching frequencies in salts of the electron-donor molecule BEDT-TTF.[15] Raman spectra of the BMDT-TTF neutral donor shows two bands at 1501.9 and 1549.7 cm^{-1} in the C=C stretching region, while in salt **1** we can observe one band at 1438.6 cm^{-1}. Fitting this data to the equations used for BEDT-TTF, for salt **1** the donor charge was found to be 0.75, which is in agreement with the compound stoichiometry found by single crystal X-ray diffraction and elemental analysis. The Raman data further show that the charge is the same for each of the donor molecules, rather than being distributed unevenly.

EPR Spectroscopy

The EPR spectrum of **1** was carried out on a microcrystalline sample. One unique broad signal with a *g* factor of 2.0134 and a linewidth of 320 G was observed. Since no discrete signals were seen for the cation and anion this indicates that there is some electronic interaction between the spins of the different sites. The temperature dependence of the EPR signal for compound **1** was studied down to 108 K but no significant changes in its parameters were observed, revealing that there are no electronic phase-transitions down to this temperature. Compounds **2** and **3** both display a narrow EPR signal of 7.5 G with a *g* factor of 2.0076, which is consistent with the radical donor alone, and also show a very broad signal arising from the Cr^{III} spin, with a *g* factor of 1.8455. This shows that there are no electronic interactions between the anion and the radical donor. In order to examine the paramagnetic contribution of the donor network separately, the temperature dependence of the narrow signal was observed down to 4 K. The dependence of the double integral of this signal with temperature follows the Curie−Weiss law, with the rest of the signal parameters not changing to any significant extent.

Conclusions

We have described three new charge-transfer salts, including their synthesis and characterisation by magnetic susceptibility, electrical transport and spectroscopic measurements. One of the salts, $[BMDT\text{-}TTF]_4[Cr(NCS)_6]$ (**1**), was well characterised by single crystal X-ray diffraction. The remaining two compounds were found to be $[TM\text{-}TTF]_4[Cr(NCS)_6]\cdot 2CH_3CN$ and $[TM\text{-}TTF]_4[Cr(NCSe)_6]\cdot 2CH_3CN$. As observed in the crystal structure of **1** the only close atomic contacts between the anion and cation components are close S···S contacts at distances below the sum of the van de Waals radii of two sulfur atoms. It must also be assumed that the TM-TTF salts have either no anion to cation contacts or, more likely, they are also only those between chalcogenides. As a result each of the salts is a paramagnetic semiconductor, since there is no magnetic ex-

change between donor and acceptor molecules. Unlike the related salts based on $[Cr(NCS)_4$phenanthroline$]^-$ or $[Cr(NCS)_4(isoquinoline)_2]^-$ anions, which show magnetic exchange, the new salts have no mechanism for anion to cation π-stacking. At present we and others have made several salts, with different stoichiometries,[16] which only have close S···S or S···Se contacts between ions, and none of them show long range-magnetic order. Other salts have been made with other close contacts between ions, such as those involving halogens[17] or hydrogen bonding,[18] but so far only our approach with π-stacking has resulted in bulk magnetic materials with TTF-based donor-to-acceptor magnetic exchange. Therefore, our further efforts in this area will focus on the synthesis of TTF-based salts containing paramagnetic anions with aromatic ligands that can increase π-stacking interactions between the ions in an effort to increase magnetic critical temperatures beyond the current highest value of 8.9 K.

Experimental Section

Synthesis

The synthesis of BMDT-TTF was carried out as described previously.[10] TM-TTF was synthesised by a Wittig-type coupling with triethylamine as reported in the literature.[11] $[C_9H_8N][Cr(NCS)_4(C_9H_7N)_2]$, where C_9H_7N is quinoline, was prepared as described previously for the isoquinoline derivative,[7a] by a ligand-exchange reaction with Reinecke's salt, $NH_4[Cr(NCS)_4(NH_3)_2]$, on adding the corresponding nitrogen donor ligand and refluxing in ethanol overnight. $[(C_2H_5)_4N]_3[Cr(NCS)_6]$ and $[(C_2H_5)_4N]_3[Cr(NCSe)_6]$ were prepared by the published methods.[12]

Electrocrystallisation

The charge-transfer salts were synthesised by electrochemical crystallisation from freshly distilled dichloromethane or acetonitrile solutions (see below for details) in conventional H-shaped electrochemical cells with Pt electrodes at a constant temperature of 295(2) K over one week and at a constant current of 1 μA.

A suspension of $[C_9H_8N][Cr(NCS)_4(C_9H_7N)_2]$ (80 mg) in 50 mL of dichloromethane was prepared and, whilst stirring, 18-crown-6-ether was added slowly until the anion dissolved completely. Solid BMDT-TTF (10 mg) was placed on the anode arm and the remainder of the cell was filled with the solution of the Cr complex (total cell volume 60 mL). Black needle-shaped crystals suitable for X-ray diffraction were obtained and found to be $[BMDT\text{-}TTF]_4[Cr(NCS)_6]$ (**1**).

The compound $[(C_2H_5)_4N]_3[Cr(NCS)_6]$ or $[(C_2H_5)_4N]_3[Cr(NCSe)_6]$ (6 mg) was dissolved in 12 mL of a mixture of dichloromethane and acetonitrile (2:1 v/v). TM-TTF (3 mg) was placed in the anode compartment of the electrochemical cell and the remainder was filled with the solution of the anion (total cell volume 15 mL). The product salts are characterised as black elongated hexagonal plates of $[TM\text{-}TTF]_4[Cr(NCS)_6]$ $2CH_3CN$ (**2**) and thin dark needles of $[TM\text{-}TTF]_4[Cr(NCSe)_6]\cdot 2CH_3CN$ (**3**).

Physical Measurements

The magnetic measurements of polycrystalline and randomly orientated samples of **1**−**3**, held in gelatine capsules inside a plastic tube, were measured using a Quantum Design MPMS7 SQUID magnetometer. The core diamagnetism was estimated for each of the salts by using Pascal's constants.

Conductivity measurements were performed on an Oxford Instruments Maglab System 2000 with an electrical properties (EP) probe. Gold wires (0.0025 mm) were attached directly to the crystals using Au conductive paste, and then connected to the EP probe with an eight-pin integrated circuit plug, allowing simultaneous measurement of two samples by four-electrode techniques.

EPR spectra were obtained with a Bruker X-band ESP 300E spectrometer, equipped with a rectangular cavity, operating in the T102 mode. Spectra were recorded in the 2−400 K range using a Bruker variable-temperature unit and an Oxford Instruments EPR-900 cryostat, a field frequency lock ER 033M system and an NMR gaussmeter ER 035M.

Transmission spectra were measured for finely ground samples as a KBr pellet (about 1 wt.%) with a Nicolet 5ZDX interferometer with Fourier transform (400−4400 cm^{-1}) or a Varian Cary 5 spectrometer (3330−20000 cm^{-1}). The Raman spectrum of **1** was measured at room temperature on a Renishaw Ramascope System 1000 using a He-Ne laser (632.8 nm), a CCD detector, a slit width of 10 μm and a 10% neutral density filter.

X-ray diffraction data were collected at 223 K, on a Nonius Kappa CCD diffractometer with monochromatic Mo-K_α (λ = 0.71073 Å) radiation. Data were collected via φ and ω multiscans and reduced with the program DENZO-SMN without absorption correction. For compounds **2** and **3** several crystals were checked and four or five measurements were made with the best of them. Nevertheless, the refinement of the structures was not good due to one-dimensional disorder of the anionic lattice. This resulted in diffuse stripes being seen in the broad reflections of the diffraction images, which means that some diffuse scattering is included in the diffraction. Further problems with one-dimensional disorder lie in the variability of the diffraction, which usually produces extinction of some of the reflections and hence a change in the Bravais lattice could occur. Since the disorder only exists in the anionic part, the donor molecules are well ordered and the packing can be well established.

CCDC-179735 (**1**) and CCDC-179736 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Syntheses and Structures of Layered Copper(II) Diphosphonates with Mixed Ligands

Ping Yin,[a] Yang Peng,[a] Li-Min Zheng,*[a,b] Song Gao,[b] and Xin-Quan Xin[a]

Keywords: Organic-inorganic hybrid composites / Phosphonates / Copper / N ligands

This paper describes the syntheses and crystal structures of two new copper(II) diphosphonates with mixed ligands: $[Cu_3(hedpH)_2(4,4'\text{-bipy})(H_2O)_2]\cdot 2H_2O$ (**1**) and $[Cu_3(hedpH)_2(4,4'\text{-azpy})(H_2O)_2]\cdot 1.6H_2O$ (**2**) (hedp = 1-hydroxyethylidenediphosphonate, 4,4′-bipy = 4,4′-bipyridine, 4,4′-azpy = 4,4′-azobispyridine). Both adopt a two-dimensional layer structure containing neutral ladder-like chains of $\{Cu_3(hedpH)_2(H_2O)_2\}_n$ linked by 4,4′-bipy or 4,4′-azpy ligands. The adjacent layers are held together by strong hydrogen bonds, thus generating a three-dimensional network with rectangular shaped channels. The lattice water is found in these channels. The magnetic properties of compounds **1** and **2** have also been investigated.

Introduction

Research on metal phosphonates is undergoing rapid expansion because of their potential applications in the areas of sorption, ion exchange, catalysis, sensors, and nonlinear optics.[1−5] Many efforts have been devoted to the exploration of metal phosphonate materials with new structure types, especially open-framework structures.[6−10] Among the metal phosphonates reported so far, the number of copper phosphonates is still limited. Most of them were prepared by direct reactions of copper salts and phosphonic acids.[11−16] By introducing a second organic ligand, a few copper phosphonates with mixed ligands have been synthesised, including a dodecanuclear cage compound containing 3,5-dimethylpyrazole.[17−19] We are interested in both the structures and magnetic properties of copper diphosphonates based on 1-hydroxyethylidenediphosphonate [hedp, $CH_3C(OH)(PO_3)_2^{4-}$], and a series of compounds have been obtained using a template approach.[20] In order to construct open-framework structures of Cu-hedp compounds, we tried to introduce a second bridging ligand into the system, and compound $[Cu_4(hedp)_2(pz)(H_2O)_4]$, with a three-dimensional structure, was prepared successfully.[21] This compound also shows interesting metamagnetic properties. In this paper we report the syntheses and structures of two new layered copper phosphonates containing 4,4′-bipyridine (4,4′-bipy) or 4,4′-azobispyridine (4,4′-azpy) ligands.

Results and Discussion

Crystal Structures of 1−2

The structures of $[Cu_3(hedpH)_2(4,4'\text{-bipy})(H_2O)_2]\cdot 2H_2O$ (**1**) and $[Cu_3(hedpH)_2(4,4'\text{-azpy})(H_2O)_2]\cdot 1.6H_2O$ (**2**) were determined by X-ray crystallography. Crystallographic and refinement details are listed in Table 3, with selected bond lengths and angles in Table 1 for **1** and Table 2 for **2**. The fundamental building unit of **1** is shown in Figure 1, with the atomic labeling scheme. Apparently, there are two types

[a] Symmetry code: A, $-x + 1, -y, -z$; B, $x - 1, y, z$; C, $x + 1, y, z$.

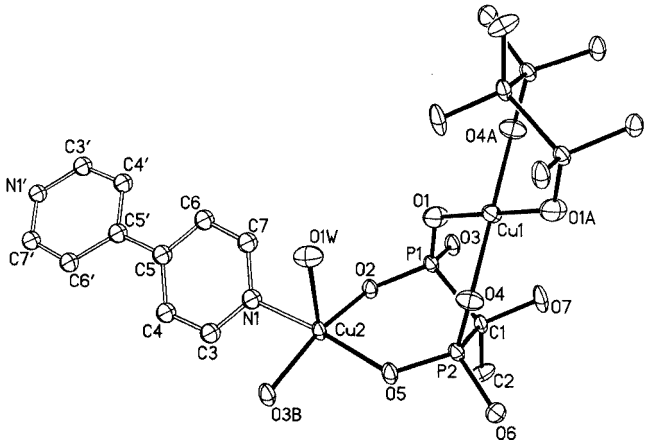

Figure 1. Building unit of **1** with the atomic labeling scheme (50% probability)

of copper atoms. The Cu(1) atom, sitting at an inversion center, has a square-planar environment. The four coordination sites are provided by two pairs of oxygens [O(1), O(4)] from two equivalent $hedpH^{3-}$ ligands. The Cu(2) atom resides in a general position, and bears a distorted square-pyramidal coordination geometry. The basal positions are filled with three phosphonate oxygens from two $hedpH^{3-}$ groups and one nitrogen atom from a 4,4′-bipyridine ligand. The largest deviation of the basal plane, defined by O(2), O(5), O(3B), and N(1), is 0.112(7) Å at O(3B). The Cu(2) atom lies out of this plane by 0.243(3) Å. The apical position is occupied by O(1w) from the water molecule. The Cu−O bond lengths are similar to those in other copper phosphonates, although the Cu(2)−O(1w) distance is slightly longer [2.192(4) Å]. The Cu(2)−N(1) bond length [av. 2.031(6) Å] is in agreement with that in $[\{Cu(dmp)(MeCN)\}_2(\mu\text{-}4,4'\text{-bipy})]^{2+}$ [2.070(4) Å].[22]

Each $hedpH^{3-}$ group in **1** serves as a bis-chelating ligand, and bridges the Cu(1) and Cu(2) atoms using four of its six phosphonate oxygens. One of the remaining two oxygen atoms, O(3), is further linked to the equivalent Cu(2) atom, forming an infinite chain along the [100] direction (Figure 2). The O(6) atom is protonated [P(2)−O(6) 1.562(4) Å]. The ladder-like chains are connected by 4,4′-bipy ligands, forming a zigzag layer in the (101) plane (Figures 2 and 3). These layers are held together by strong interlayer hydrogen bonds between the phosphonate ligands. The shortest inter-layer O···O distances are 2.594(5) and 2.757(5) Å for O(6)···O(7)^{i} and O(7)···O(5)^{ii}, respectively (symmetry code: i, $-x+1$, $-y+2$, $-z$; ii, $x+1$, y, z). Hence, a three-dimensional open network structure is constructed with rectangular channels generated along the *a* axis. The lattice water resides in these channels (Figure 3).

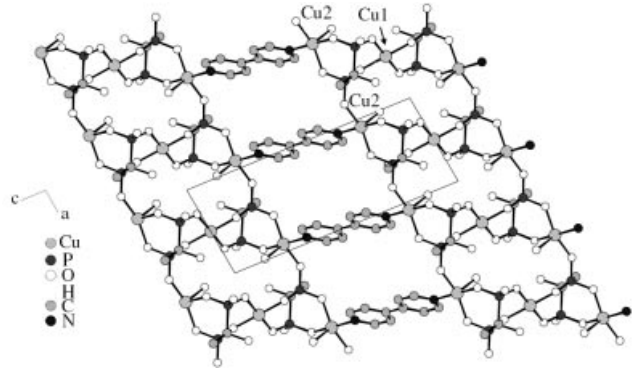

Figure 2. One layer of structure **1** viewed along the *b* axis; all the H atoms and half of the disordered 4,4′-bipy are omitted for clarity

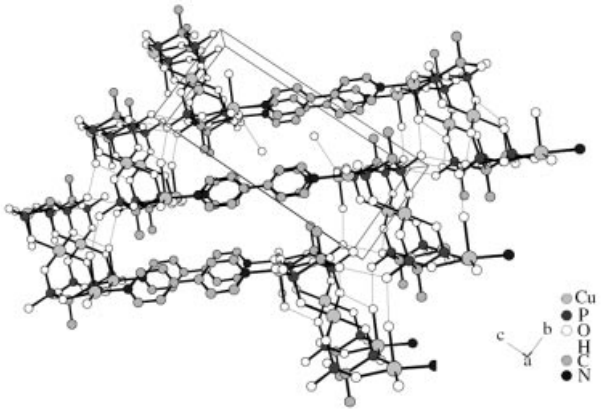

Figure 3. Structure of **1** packed along the *a* axis; all the H atoms and half of the disordered 4,4′-bipy are omitted for clarity

The structure of compound **2** is analogous to that of **1**, except that 4,4′-bipy is replaced by a longer bi-functional ligand 4,4′-azpy (Figure 4, Table 2). It also has a layer structure in which the ladder-like chains of $\{Cu_3(hedpH)_2(H_2O)_2\}$ are connected by 4,4′-azpy (Figure 5). As the ligand is arranged approximately along the [001] direction, the *c* axis in **2** (16.071 Å) is longer than that in **1** (15.469 Å). Strong interlayer hydrogen bonds are also observed.

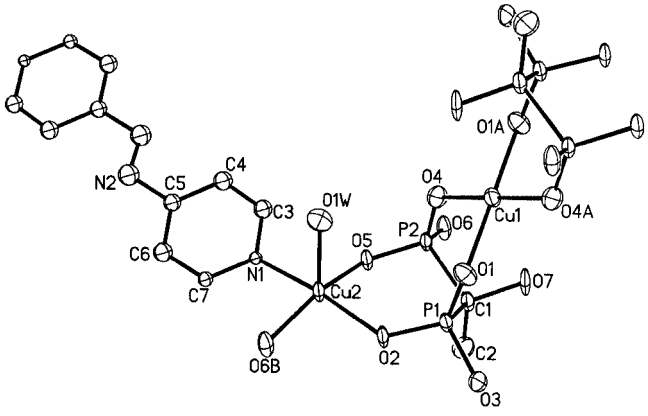

Figure 4. Building unit of **2** with the atomic labeling scheme (50% probability); all the H atoms and half of the disordered 4,4′-azpy are omitted for clarity

The layer structures of compounds **1** and **2** are different from that of $[Cu_4(hedp)_2(pz)(H_2O)_4]$,[21] where a three-dimensional open-framework structure is observed. Although all three contain similar layers built up from $\{Cu_3(hedp)_2(H_2O)_2\}$ double chains and bifunctional organic linkages, the contacts between the layers are completely different. In compounds **1** and **2**, it is mainly the hydrogen bonds between the phosphonate or hydroxy oxy-

gens of the $\{Cu_3(hedp)_2(H_2O)_2\}$ chains that connect the layers into a supramolecular network. In compound $[Cu_4(hedp)_2(pz)(H_2O)_4]$, however, the $\{Cu_3(hedp)_2(H_2O)_2\}$ chains from the neighboring layers are linked by CuO_4 units through corner-sharing of CPO_3 tetrahedra and CuO_4 planes, forming a unique open-framework structure. This structure can also be viewed as being composed of $\{Cu_4(hedp)_2(H_2O)_2\}$ layers and pz linkages. Furthermore, the phosphonate oxygens in compound $[Cu_4(hedp)_2(pz)(H_2O)_4]$ are all deprotonated, while in compounds **1** and **2** one oxygen is protonated in order to balance the overall charges and to stabilize the lattice through interlayer hydrogen bonds.

Magnetic Properties

Figure 6 shows the temperature-dependent magnetic susceptibility for **1** in the form of a $\chi_m T$ vs. T plot. The effective magnetic moment at 295 K, calculated from $\mu_{eff} = 2.828(\chi_m T)^{1/2}$, is 3.38 μ_B per Cu_3, in agreement with the calculated value (3.00 μ_B) for three isolated spin 1/2 nuclei. Upon cooling, $\chi_m T$ decreases continuously, and more steeply below 10 K towards zero, indicating a dominant antiferromagnetic interaction. The magnetic behavior of **2** is very similar to that of **1** (Figure 7).

Both compounds **1** and **2** have a layer structure made up of $\{Cu_3(hedp)_2(H_2O)_2\}$ chains and organic linkages. Between the layers, the magnetic interactions are very weak because the shortest Cu···Cu distance is 7.009 Å. The exchange coupling within the layer can be propagated either through the organic bridging ligand or through the O−P−O units. Considering that the Cu···Cu distances through the 4,4′-bipyridine and 4,4′-azobispyridine ligands are 11.165 (for **1**) and 13.087 Å (for **2**), the bulk magnetic behavior should be mainly attributed to the $\{Cu_3(hedp)_2(H_2O)_2\}$ chain. Within the double chain, the Cu(1)···Cu(2) distance through the O−P−O bridge is ca. 4.8 Å, and the Cu(2)···Cu(2) distance is ca. 6.2 Å (Figure 2). The exchange between Cu(1) and Cu(2) should be more efficient. The susceptibility data were thus analyzed by an expression based on a topological 1D ferrimagnet model.[23] This theoretical fitting was, however, unsuccessful. It is worth noting that, for a homometallic chain like $\{Cu_3(hedp)_2(H_2O)_2\}$, the odd number of magnetic centers should result in a ferrimagnetic behavior within the chain. The overall antiferromagnetic interactions observed in compounds **1** and **2** could be due to the dominant antiferromagnetic exchange couplings between the chains through the organic linkages and/or space at low temperature.

Conclusion

Two new copper(II) diphosphonates $[Cu_3(hedpH)_2(4,4'\text{-bipy})(H_2O)_2]\cdot 2H_2O$ (**1**) and $[Cu_3(hedpH)_2(4,4'\text{-azpy})(H_2O)_2]\cdot 1.6H_2O$ (**2**) have been reported in this paper. Their structures are two-dimensional with strong inter-layer hydrogen-bond interactions. Within the layer, the ladder-like chains of $\{Cu_3(hedpH)_2(H_2O)_2\}_n$ are linked by 4,4′-bipy or 4,4′-azpy ligands. The magnetic studies show that both compounds exhibit dominant antiferromagnetic interactions. The results demonstrate that novel metal phosphonates may be anticipated by combining with second organic ligands.

Experimental Section

Materials and Methods: The 50% aqueous solution of 1-hydroxyethylidenediphosphonic acid ($hedpH_4$) was purchased from Nanjing Shuguang Chemical Factory. All other starting materials were reagent grade and used as purchased. The elemental analyses were performed with a PE 240C elemental analyzer. The infrared spectra were recorded on a Nicolet 170SX FT-IR spectrometer with pressed KBr pellets. Thermal analyses were performed in nitrogen in the temperature range 20−600 °C with a heating rate of 5 °C/min on a TGA-DTA V1.1B TA Inst 2100. Variable-temperature magnetic susceptibility data were obtained on polycrystalline samples (27.9 mg for **1**, 27.5 mg for **2**) from 2 to ca. 300 K in a magnetic field of 10 kOe after zero-field cooling using a MagLab System 2000 magnetometer. Diamagnetic corrections were estimated from Pascal's constants.[24]

Synthesis of $[Cu_3(hedpH)_2(4,4'\text{-bipy})(H_2O)_2]\cdot 2H_2O$ (1): A mixture of $Cu(NO_3)_2\cdot 3H_2O$ (1 mmol, 0.2450 g), 4,4′-bipy (1 mmol, 0.1543 g), 50% $hedpH_4$ (2.5 mmol, 1 cm^3), 1 M NaOH (6 cm^3), and water (2 cm^3) with a pH of approximately 3 was transferred to a Teflon-lined autoclave (25 cm^3) and kept at 165 °C for 48 h. After slow cooling, blue plate-like crystals were obtained together with some yellow flocculent material. The blue crystals were isolated and their purity judged by a powder X-ray diffraction measurement. These crystals were further used for the structural determination and the physical property measurements. Yield: 22% based on Cu. $C_{14}H_{26}Cu_3N_2O_{18}P_4$: calcd. (found) C 20.73 (20.38), H 3.28 (3.18), N 2.85 (3.40). IR (KBr): $\tilde{\nu}$ = 3654 m, 3573 m, 3414 m, 3078 m, 2760 m, 1634 m, 1611 m, 1492 m, 1414 m, 1227 m, 1166 s, 1131 s, 1039 s, 940 s, 821 m, 674 m, 572 m, 444 m cm^{-1}.

When a molar ratio of Cu/4,4′-bipy/hedp/Na was 1:1:1.25:2 (pH ≈ 3), a similar hydrothermal reaction at 140 °C led to the same compound with a higher yield (58%). Thermal analysis of **1** showed two decomposition steps between 20 and 180 °C. The total observed weight loss (8.45%) is in agreement with the theoretical value (8.74%) for the removal of two lattices plus two coordinated water molecules.

Synthesis of $[Cu_3(hedpH)_2(4,4'\text{-azpy})(H_2O)_2]\cdot 1.6H_2O$ (2): A mixture of $Cu(NO_3)_2\cdot 3H_2O$ (1 mmol, 0.2440 g), 4,4′-azpy (1.1 mmol, 0.2081 g), 50% $hedpH_4$ (1.25 mmol, 0.5 cm^3), 1 M NaOH (2 cm^3), and water (6 cm^3) with a pH of approximately 3 was transferred to a Teflon-lined autoclave (25 cm^3) and kept at 140 °C for 48 h. After slow cooling, green crystals appeared as a single phase. Yield: 78% based on Cu. $C_{14}H_{27.2}Cu_3N_4O_{17.6}P_4$: calcd. (found) C 20.64 (19.81), H 3.19 (3.21), N 6.60 (6.61). IR (KBr): $\tilde{\nu}$ = 3575 m, 3413 m, 3093 m, 2771 m, 1605 m, 1484 w, 1421 m, 1166 s, 1130 s, 1039 s, 940 s, 827 m, 675 m, 574 s, 419 m cm^{-1}. Compound **2** can be obtained at pH = 1.6−3.6 with a Cu:hedp molar ratio of 1:2.5. Thermal analysis of **2** revealed that the total weight loss (7.14%) in the temperature range 30−160 °C corresponds to the release of 3.6 H_2O molecules (7.64%).

Crystallographic Studies: Single crystals of dimensions 0.30 × 0.30 × 0.20 mm for **1** and 0.40 × 0.05 × 0.05 mm for **2** were used for structure determinations (Table 3). Data corrections for compound **1** were made at room temperature on an Enraf−Nonius CAD-4 diffractometer equipped with graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å), operating in ω-2θ scanning mode. The unit cell parameters were obtained by least-squares refinement of 25 well-centred reflections. Intensity data were collected in the θ range 1.33−24.97°. Corrections for Lorentz and polarizaton factors were applied to the intensity values.

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. $wR_2=[\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

Data corrections for compound **2** were made at room temperature on a Bruker SMART APEX CCD diffractometer equipped with graphite-monochromatized Mo-K_α radiation (λ=0.71073 Å). A hemisphere of data was collected in the θ range 3.03−25.02° using a narrow-frame method with scan widths of 0.30° in ω and an exposure time of 20 s/frame. The data were integrated using the Siemens SAINT program,[25] with the intensities corrected for Lorentz factors, polarization, air absorption, and absorption due to variation in the path length through the detector faceplate. An empirical absorption correction was applied for both compounds.

The structures were solved by direct methods and refined on F^2 by a full-matrix least-squares procedure using SHELXL 97.[26] All the non-hydrogen atoms were refined anisotropically except the O atom of lattice water and the C and N atoms of 4,4′-bipy (for **1**) and 4,4′-azpy (for **2**). The latter are disordered and were refined isotropically. Hydrogen atoms were either put in calculated positions or found by Fourier syntheses, and were refined isotropically. The H atoms of lattice water were not located in either compound. In the final Fourier-difference map of **2** the deepest hole was −0.737 e·Å^3 and the highest peak 1.994 e·Å^3 [located near C(6); 1.729 Å]. The X-ray fluorescence spectrum measurement excludes the possible presence of Cl.

CCDC-184721 (**1**) and CCDC-184722 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or

from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Crystal Structures and Magnetism of a Series of Heptanuclear Rare-Earth-Centered Trigonal Prism Clusters

Qin-De Liu,[a] Jun-Ran Li,*[a] Song Gao,*[a] Bao-Qing Ma,[a] Hui-Zhong Kou,[a] Liang Ouyang,[a] Rui-Li Huang,[b] Xi-Xiang Zhang,[c] and Kai-Bei Yu[d]

Keywords: Copper / Lanthanides / N ligands / O ligands / Template synthesis / Magnetic properties

A series of heptanuclear rare-earth-centered trigonal prism clusters $[LnCu_6(\mu\text{-}OH)_3(HL)_2(L)_4]\cdot(ClO_4)_2\cdot 25H_2O$ (Ln = La–Ho and Y; H_2L = iminodiacetic acid) was synthesized and their crystal structures were determined by X-ray diffraction. The rare-earth center and the copper ions are bridged by three μ_3-OH and six μ_2-O moieties from the carboxyl groups of six different ligands. The rare earth ion is nine-coordinate and the coordination polyhedron is an unusual, highly symmetrical tricapped trigonal prism (C_{3h}). The cluster has an interesting, highly symmetrical eclipsed structure (C_{3h}) which utilizes the central rare earth cation as a template. The temperature-dependence of the magnetic susceptibility of the cluster series was investigated and was found to vary with the central rare-earth ions. The magnitude of the antiferromagnetic interaction constants J between Cu^{2+} ions in $[LaCu_6]$ and $[YCu_6]$ were compared and estimated to be –24 cm^{-1} and –7 cm^{-1}, respectively, indicating a significant effect of the central diamagnetic ions.

Introduction

Heteronuclear transition-metal and rare-earth mixed complexes are of great interest due to their interesting structures and magnetic properties.[1−9] These compounds are very important in understanding the nature of magnetic exchange interactions between rare-earth and transition-metal ions. Potential applications can be found for them in magnetic materials.[2−8] However, previous magnetic investigations of these complexes have mostly focused on the nature of Gd−Cu coupling. Up until now, reports on Ln−Cu complexes other than those of Gd have been rather scarce.[6,10−13] Whereas magnetostructural correlations have been established in some transition-metal complexes,[14−21] little is known about the same correlation in polynuclear complexes containing both rare-earth and transition-metal ions.

Host-guest interactions have proven to be of paramount importance for the template synthesis of large magnetic clusters,[22−25] and one expects to learn more on how the guests influence the magnetic coupling in the clusters. Schröder and co-workers reported some heteronuclear complexes obtained by template assembly of metal aggregates using imino-carboxylate ligands.[26] In that work, a tetradentate ligand was used to synthesize complexes that containd various metal ions as templates. Recently we reported the structures and magnetic properties of $[LaCu_6]$ and $[TbCu_6]$ clusters.[13] As an extension of that work, a series of heptanuclear lanthanide-centered trigonal prism clusters $[LnCu_6(\mu\text{-}OH)_3(HL)_2(L)_4]\cdot(ClO_4)_2\cdot 25H_2O$ (Ln = Ce−Gd, Dy−Ho and Y; H_2L = iminodiacetic acid), were obtained at a considerably higher pH value (approx. 6.0), and their magnetic behaviors were studied in the context of their structures.

Results and Discussion

IR Spectra

Using $[GdCu_6]$ as an example, the IR resonances of the carboxylate moiety, ν_{as}(OCO) and ν_s(OCO), in free (H_2L) and coordinated (HL) ligands were compared. After coordination to the metal centers, the ν_{as}(OCO) absorption was found to have blue-shifted 45 cm^{-1}, from a value of 1583cm^{-1} to 1628 cm^{-1}; the ν_s(OCO) absorption at 1397cm^{-1} shifted 35 cm^{-1} up to 1432 cm^{-1}, and 19 cm^{-1}

down to 1378 cm^{-1}. This shows that the two carboxyl groups of the ligand bound to the metal ions have two coordination modes.[26] The value of ν_s(C−N) in the complex shifted 92 cm^{-1} down to 1118 cm^{-1}. These results indicate that the carboxyl groups and the N atom of the ligand are all coordinated to metal ions. The IR spectra of the other [$LnCu_6$] complexes are very similar to that of [$GdCu_6$].

Thermal Analysis

The thermal behavior of all eleven complexes is similar. For example, the crystalline compound [$GdCu_6$] begins to lose part of its crystal lattice water molecules at a surprisingly low temperature (around 30 °C), and the water-loss rate reaches a maximum at ca 56 °C. The complex loses a total of nine water molecules in the temperature range 30.0−60.0 °C (loss of weight found: 8.1%; loss of weight calculated based on the loss of nine water molecules: 8.0%). The thermal analysis results are in accordance with the elemental analysis results for all eleven complexes. Elemental analysis data are given in Table 1.

Description of Structures

X-ray diffraction analyses indicate that these complexes are isomorphous. Among them the crystal structures of the [$LaCu_6$] and [$TbCu_6$] complexes have been reported.[13] As a typical example, the structural features of [$SmCu_6$] will be discussed briefly. Figure 1 shows an ORTEP view of this complex. The Sm^{3+} ion is nine-coordinate and the coordination polyhedron can be described as a tricapped trigonal prism, which is highly symmetrical. The observed geometries of nine-coordinate lanthanide ions are usually asymmetrical monocapped square antiprism[28,29] or distorted tricapped trigonal prism.[30−32] This kind of highly symmetrical coordination polyhedron (C_{3h}) is very unusual among 4f-3d and 4f coordination compounds. The Cu^{2+} ions in the complex are all five-coordinate, exhibiting a distorted tetragonal pyramidal geometry. Crystal data, details of data collection, and refinement are listed in Table 2. Crystal cell parameters of all the complexes are listed in Table 3 and important bond lengths and angles are given in Table 4.

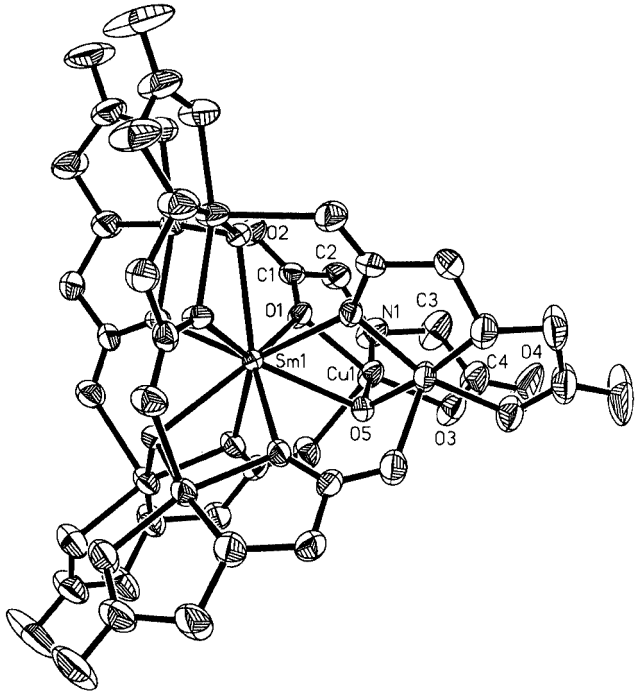

Figure 1. An ORTEP drawing of [$SmCu_6$]

The [$SmCu_6$] cluster consists of two parallel layers, with each layer being composed of three Cu^{2+}ions and three L's. The six Cu^{2+} ions form a trigonal prism (C_{3h}) with the Sm^{3+} ion located in the center (Figure 2). The Sm^{3+} ion lying between two layers is bridged to the six Cu^{2+} ions by three μ_3-OH groups and six μ_2-O atoms from six L's. Therefore, the two layers are connected by the nine-coordinate Sm^{3+} ion and three μ_3-OH groups. Each μ_3-OH is coordinated to the Sm^{3+} ion and two Cu^{2+} ions, one from each layer.

The structural features of the eleven complexes are practically the same, except that the volumes of the crystal cells are slightly different. This result shows that almost all the rare earth ions (except for Er, Tm, Yb, and Lu) can be centered in this type of [$LnCu_6$] complex. Crystals of these complexes were obtained at relatively high pH (approx. 6). Therefore, it can be considered that these complexes were assembled using a rare-earth cation as the template, and the process is also affected by the μ_3-bridged hydroxyl groups yielded from the slow hydrolysis of the rare earth ions while the pH value of the reaction mixture was adjusted with aqueous ammonia. From their crystal cell parameters (Table 3), we can see that the size of the trigonal prism cage formed by Cu^{2+} ions does not change much in the presence of different rare earth ions. This indicates that the radius of the template cation should be limited to within a certain range. Our failure to obtain complexes of Er, Tm, Yb and Lu similar to [$SmCu_6$] may be explained by the fact that the

radii of these ions are too small for them to be stably centered in the cage.

Magnetic Properties

The temperature dependence of the magnetic susceptibilities (χ_M) and of $\chi_M T$ for [$LaCu_6$], [$PrCu_6$], [$NdCu_6$], [$GdCu_6$], [$TbCu_6$], [$DyCu_6$], [$HoCu_6$], and [YCu_6] are shown in Figure 3 and Figure 4. The M···M (M = Ln or Cu) distances in some [$LnCu_6$] clusters are listed in Table 5.

It can be seen that the complexes exhibit different overall magnetic behaviors which seem to be dependent upon the different central rare earth ions within the [$LnCu_6$] complexes, even though all these complexes are isomorphous. Our previous results tells us that the magnetic interactions between the Cu^{2+} ions are antiferromagnetic in [$LaCu_6$], and there is a ferromagnetic coupling between the Tb^{3+} and Cu^{2+} ions in [$TbCu_6$].[13] The magnetic behavior of [$GdCu_6$], which shows an obvious ferromagnetic coupling between the Gd^{3+} and Cu^{2+} ions, is similar to that of [$TbCu_6$]. Referring to the structural data in Table 5, the M···M separations in [$GdCu_6$] are all very similar to those in [$TbCu_6$] (with a general difference of ca 0.01 Å). This may be an explanation for their similar magnetic behavior. For [$DyCu_6$], [$HoCu_6$], [$NdCu_6$], and [$PrCu_6$], the nature of the magnetic interactions between the Ln^{3+} and Cu^{2+} ions cannot be definitively defined because the magnetic behavior of these systems can be affected by many factors, such as the Ln−Ln, Cu−Cu, and Ln−Cu interactions, the

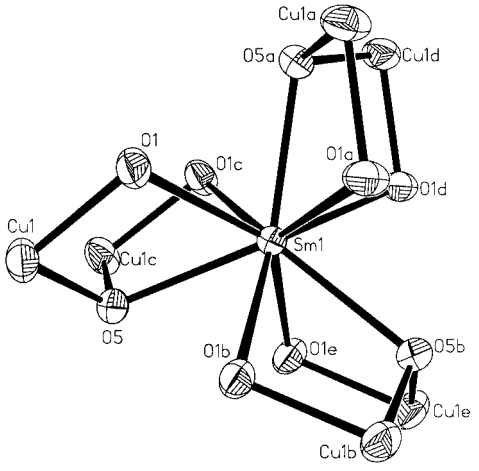

Figure 2. The trigonal prism cage formed by six Cu^{2+} and the bridges among Sm^{3+} and six Cu^{2+} (O5, O5C, O5E are from the three μ_3-OH; O1, O1A−O1E are from carboxyl groups of the six ligands)

ligand-field effects of the Ln^{3+} ion, and field saturation effects.

Figure 4 indicates that the interactions between the Cu^{2+} ions in [$LaCu_6$] and [YCu_6] are all antiferromagnetic in nature. However, the magnitudes of these antiferromagnetic interactions are different, and the J values are evaluated to

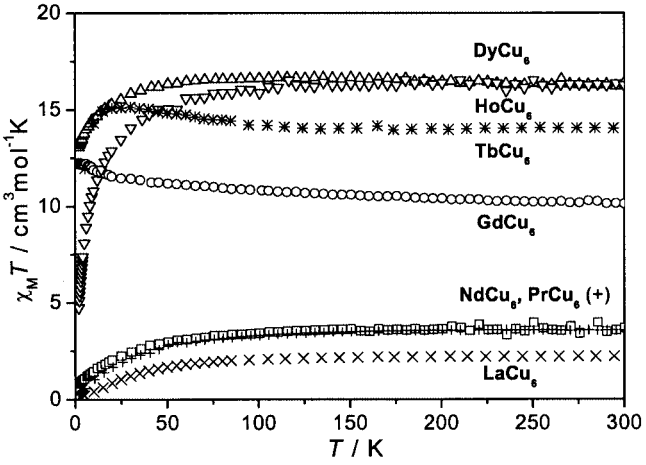

Figure 3. Plot of the magnetic susceptibilities (χ_M) and the $\chi_M T$ product vs. T for [$LaCu_6$], [$PrCu_6$], [$NdCu_6$], [$GdCu_6$], [$TbCu_6$], [$DyCu_6$], [$HoCu_6$]

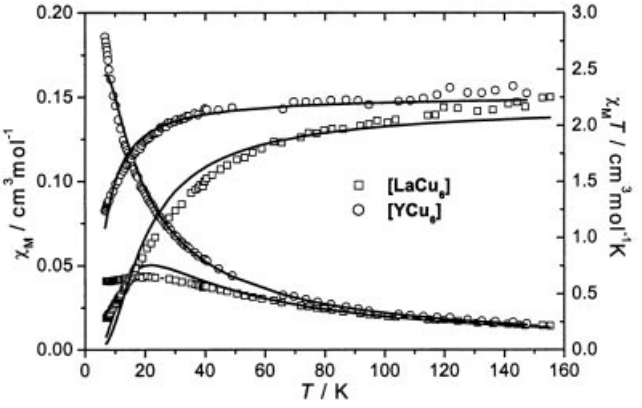

Figure 4. Plot of the magnetic susceptibilities (χ_M) and the $\chi_M T$ product vs. T for [$LaCu_6$] and [YCu_6]; solid lines show the best fit of the data

be $-24\ cm^{-1}$ and $-7\ cm^{-1}$ for [$LaCu_6$] and [YCu_6], respectively, using the same approach as previously[13] ($R = \Sigma(\chi_M T^{cal} - \chi_M T^{obs})^2/\Sigma(\chi_M T^{obs})^2 = 7.4 \times 10^{-3}$, and 9.7×10^{-4} for [$LaCu_6$] and [YCu_6], respectively). The difference in the J values shows the significant impact of the central diamagnetic ions, La^{3+} and Y^{3+}. Upon substitution of La^{3+} ion with Y^{3+} ion, the Cu···Cu distances decrease from 5.325 Å, 3.383 Å and 6.309 Å to 5.231 Å, 3.324 Å and 6.197 Å, the Ln···Cu distance deceases from 3.509 Å to 3.447 Å, and the Cu···O···Cu angle decreases from 120.7° to 118.4°. Therefore, the shorter ionic radius of Y^{3+} (1.075 Å), with respect to that of La^{3+} (1.216 Å), leads to a decrease in the size of the cage composed from the Cu^{2+} ions. The fact that the J value is larger in [$LaCu_6$] than in [YCu_6] reveals a dependency of J on the Cu···Cu separation and the Cu···O···Cu angle: smaller Cu···Cu separations and Cu···O···Cu angles lead to weaker antiferromagnetic exchange-coupling interactions between the Cu^{2+} ions for the systems in this paper. This result is consistent with the conclusion drawn previously,[17] showing that the direct overlap of metal orbitals plays a minor role, since it would enhance

Table 5. Selected M···M distances (Å) and Cu−O−Cu angles (deg)

	Cu···Cu (intra-layer)	Cu···Cu (inter-layer)	Ln···Cu	Cu−O−Cu
[$LaCu_6$]	5.325	3.383, 6.309	3.509	120.7
[$SmCu_6$]	5.271	3.337, 6.238	3.470	119.4
[$GdCu_6$]	5.258	3.331, 6.225	3.463	118.8
[$TbCu_6$]	5.245	3.319, 6.207	3.453	118.1

[YCu_6]	5.231	3.324, 6.197	3.447	118.4

antiferromagnetic coupling at shorter Cu···Cu separations. The encapsulated Ln^{3+} ion in the cage has a tuning effect on the magnetism of the core: the magnetic behavior is related to the ionic radius of the guest rare earth ion, which determines the exact geometry of the bridging ligands.

Conclusion

A series of highly symmetrical heptanuclear trigonal prism clusters, [$LnCu_6$], was assembled using rare earth cations as templates. The process is also affected by the μ_3-bridged hydroxyl groups. It was also shown that different central rare-earth ions in the cage significantly influence the magnetic behavior of these complexes.

Experimental Section

Physical Measurements: Elemental analysis was performed on a German Elementar Vario EL instrument. IR spectra were measured as KBr pellets with a Nicolet Magna-IR 750 spectrometer at 295 K. Thermal analyses were performed on a Du Pont 1090B thermal analyzer. Magnetic measurements were performed on a SQUID and an Oxford MagLab2000 System in the temperature range 2−300 K. Diamagnetic corrections were estimated on the basis of Pascal's constants. All starting materials were analytical reagents from Beijing Reagent Co. Sodium iminodiacetate (Na_2L) was obtained by the direct reaction of iminodiacetic acid with sodium hydroxide in an aqueous solution.

Preparations

$LnCu_6C_{24}H_{85}N_6Cl_2O_{60}$ (Ln =La−Ho and Y): All heptanuclear complexes (La−Ho,Y) were synthesized by first mixing copper perchlorate, the rare earth perchlorate and sodium iminodiacetate (1:1:1 mol ratio) in 10 cm^3 water under vigorous stirring, then carefully adjusting the pH value to about 6 with aqueous ammonia. The reaction mixture was left to stand at room temperature. After two days, deep-blue hexagonal prism crystals of $LnCu_6C_{24}H_{85}N_6Cl_2O_{60}$ (Ln = La−Ho and Y) were obtained and collected, with yields of ca 20%. Previous to the elemental analyses, the loosely bound waters of crystallization were eliminated by keeping the products at 60 °C until constant weights were reached. The results of elemental analysis are listed in Table 1. Similar crystals of the compounds with Ln = Er, Tm, Yb or Lu could not be obtained.

X-ray Crystallographic Study: All single-crystal X-ray experiments were performed on a Nonius CAD4 or Kappa CCD, or a Siemens P4 four-circle diffractometer. For example, with [$GdCu_6$], a crystal of dimensions 0.48 × 0.38 × 0.30 mm was mounted in a thin-walled capillary for the structure determination. Intensity data were collected on a Siemens P4 diffractometer with Mo-K_α radiation in the ω-scan mode. Lattice parameter were obtained from a least-squares refinement of 36 reflections in the range $6.22° \leq 2\theta \leq 33.14°$ and 2019 independent reflections were collected. Empirical absorption corrections were applied using the XPRED program. The structure was determined by direct methods and difference-Fourier syntheses, and refined by full-matrix least-squares using Siemens SHELXTL/PC system. The proton of the HL ligand in the complexes is assumed to have statistical distribution.

CCDC-135918 ($C_{24}H_{85}Cl_2Cu_6GdN_6O_{60}$), -135919 ($C_{24}H_{85}Cl_2Cu_6N_6O_{60}Sm$), -136464 ($C_{24}H_{85}Cl_2Cu_6HoN_6O_{60}$), and -170527 ($C_{24}H_{85}Cl_2Cu_6N_6O_{60}Y$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Spectroscopic and Structural Characterizations of Novel Water-Soluble Peroxo[polyaminocarboxylato bis(*N*-oxido)]niobate(v) Complexes

Daisy Bayot,[a] Bernard Tinant,[b] Benoît Mathieu,[b] Jean-Paul Declercq,[b] and Michel Devillers*[a]

Keywords: Niobium / Peroxo ligands / N,O ligands / NMR spectroscopy / IR spectroscopy

New water-soluble peroxo complexes of niobium(v) with polyaminocarboxylic acids (PAC) have been prepared and characterized by IR and NMR (^{1}H, ^{13}C, ^{15}N) spectroscopy, as well as by thermal analysis. The synthesis in presence of excess H_2O_2 leads to the oxidation of the nitrogen atoms of the PAC ligand into *N*-oxide groups. The compounds obtained correspond to the general formula $(A^I)_3[Nb(O_2)_2(LO_2)]\cdot xH_2O\cdot yH_2O_2$ [$A^I = NH_4^+$ or $CN_3H_6^+$ (gu) and L = edta, pdta] in which H_4LO_2 refers to the bis(*N*-oxide) derivative of the PAC ligand. The crystal structures of the guanidinium derivatives of the (edta)- and (pdta)Nb complexes have been determined, both showing an eight-coordinate Nb atom with two bidentate peroxo ligands and a quadridentate PAC bis(*N*-oxido) ligand, resulting in a distorted dodecahedral geometry. The structure of the guanidinium derivative of the edta bis(*N*-oxido) ligand is also described.

Introduction

Because multimetallic Nb-based oxides generate great interest as potential heterogeneous catalysts for several highly challenging industrial processes, like alkane oxidation or ammoxidation,[1−4] fundamental research on Nb coordination compounds that could be used as molecular precursors for the preparation of such catalysts, is definitely welcome. In particular, the aqueous chemistry of niobium is restricted to very few available precursors, some of them being poorly defined from the point of view of composition and molecular structure. Because peroxoniobium compounds are soluble in water, they are adequate candidates for that purpose. Several such complexes have already been described in the literature; they correspond either to homoleptic tetraperoxoniobates of general formula $(A^I)_3[Nb(O_2)_4]$ [$A^I = Na^+$, K^+, Rb^+, Cs^+, NH_4^+, and $CN_3H_6^+$ (guanidinium, gu^+)][5−7] or to heteroleptic carboxylato(peroxo) compounds such as $(A^I)_3[Nb(O_2)_3(L)]\cdot nH_2O$ ($A^I = K^+$ or NH_4^+ and L = tartrate, citrate, *o*-phenanthroline),[8−10] $(A^I)_3[Nb(O_2)_2(C_2O_4)_2]\cdot H_2O$ ($A^I = NH_4^+$ or $CN_3H_6^+$)[9,11] and $K[Nb(O_2)_2(L)_2]\cdot 3H_2O$ (L = 8-hydroxyquinolinate).[12] As far as the peroxo(polyaminocarboxylato) compounds are concerned, only a few studies have been reported and they are essentially restricted to the edta(peroxo) compound and its solution chemistry.[13,14] A bis(aqua)edta complex of Nb^{IV}, $[Nb(edta)(H_2O)_2]\cdot 2H_2O$, has also been described.[15]

Within the framework of the preparation of oxide materials, we have already reported on the use of carboxylato and carboxylato(peroxo)Nb complexes in the preparation of silica-dispersed Nb-Mo-O phases, by association with analogous Mo compounds.[9] The present work dedicates particular attention to new water-soluble peroxo(polyaminocarboxylato)Nb^V compounds corresponding to the general formula $(A^I)_3[Nb(O_2)_2(LO_2)]\cdot nH_2O\cdot nH_2O_2$ [$A^I = NH_4^+$ or guanidinium ($CN_3H_6^+$)]. Two different PAC ligands (L) have been selected: ethylenediaminetetraacetic acid (H_4edta) and propylenediaminetetraacetic acid (H_4pdta). There is so far only one report of *N*-oxide derivatives of polyaminocarboxylato complexes with some alkaline-earth and transition metal ions.[16] The present paper reports for the first time crystal structures of such compounds.

Results and Discussion

General Comments on the Synthetic Procedures

The peroxo(polyaminocarboxylato)Nb^V complexes were prepared by replacing peroxo groups by a PAC ligand of the tetraperoxoniobate anion $[Nb(O_2)_4]^{3-}$, formed in situ. The syntheses were adapted from the procedure used by Vuletic et al.[13] to obtain the ammonium edta(peroxo) complex. These syntheses were carried out in the presence of

excess hydrogen peroxide, which led to the direct formation of the *N*-oxide derivative of the PAC ligand. The PAC bis(*N*-oxido) ligands, H_4edtaO_2, and H_4pdtaO_2, were synthesized separately according to the procedure of Porter et al.[17] The peroxo(PAC)Nb^V complexes were also prepared starting from the pre-isolated reactants $(A^I)_3[Nb(O_2)_4]$ and $H_4LO_2{\cdot}nH_2O$ (with $A^I = NH_4^+$, gu^+ and L = edta, pdta) in aqueous media. Both synthetic pathways were shown to lead to the same compounds.

IR Spectroscopy

Table 1 lists the infrared bands assigned to the side-bonded peroxo ligands, the *N*-oxide groups and some representative vibrational modes of the coordinated PAC ligands for compounds **1**, **2a**, and **3**.

In addition to the bands arising from the PAC ligands, the IR spectra of the complexes systematically show two ν(O−O) bands of medium intensity in the range 855−875 cm^{-1}, assigned to a diperoxo species.[9,18] Other bands due to the presence of coordinated peroxo ligands also arise at ca. 550 and 650 cm^{-1} and correspond to ν_{as}[Nb(O_2)] and ν_s[Nb(O_2)], respectively. The asymmetric stretching frequency of the carboxylato groups bound to the niobium atom occurs in the spectra of the edta and pdta compounds as a broad band near 1600−1650 cm^{-1}. Coordination of the metal atom by these carboxylato groups is evidenced by the broadening of this ν_{as}(COO) band and by its significant shift in comparison with the free acid [ν_{as}(COO) at ca. 1700 cm^{-1}]. Finally, oxidation of the nitrogen atoms of the PAC ligand during the syntheses (excess H_2O_2 medium) is evidenced by the presence, in all IR spectra, of the ν(N−O) band at ca. 900 cm^{-1}. In the corresponding bis(*N*-oxide) derivative of the free ligand, $H_4edtaO_2{\cdot}1/2H_2O$ (**4a**) and $H_4pdtaO_2{\cdot}H_2O$ (**5**), this band appears at 890 and 909 cm^{-1}, respectively.

NMR Spectroscopy

Table 2 lists the ^{13}C and ^{15}N resonance lines occurring from compounds **1**, **3**, **4a**, **5**, and also from the commercial PAC ligands. The results obtained for the guanidinium edta compound **2a** are not reported because they are very similar to those obtained for the ammonium derivative.

Table 2. ^{13}C and ^{15}N NMR chemical shifts (δ, in ppm) for compounds **1**, **3**, **4a**, **5**, and commercial PAC ligands

Compound	^{13}C NMR[a]	^{15}N NMR[a]
1	57.4, 64.9, 70.8, 168.4, 169.9	121.2
3	19.3, 54.8, 66.6, 67.9, 168.8, 171.3	72.1, 128.1
4a/NaOD[b]	59.7, 67.5, 170.6	114.9
5/NaOD[b]	19.1, 64.9, 66.6, 171.4	123.6
H_4edta/NaOD[b]	50.9, 57.5, 176.9	38.5
H_4pdta/NaOD[b]	23.0, 53.2, 58.9, 179.3	53.1

[a] In D_2O. [b] H_4L and H_4LO_2 compounds are not soluble in D_2O at room temp. and were solubilized by adding an excess of NaOD.

Just like the IR spectra, the ^{15}N NMR spectra of the prepared complexes reveal the oxidation of the nitrogen atoms in the PAC ligand. The ^{15}N NMR spectrum of compound **1** displays one single line at δ = 121.2 ppm arising from the two identical nitrogen atoms in the ligand. This particularly high ^{15}N chemical shift confirms the formation of *N*-oxide groups by comparison with the values obtained for the species H_4edta and $H_4edtaO_2{\cdot}1/2H_2O$ (**4a**) (δ = 38.5 and 114.9 ppm, respectively). A similar effect of *N*-oxidation on ^{15}N chemical shifts was observed by Hadden et al. in alkaloid compounds.[19] In the ^{15}N NMR analysis of compound **3**, resonances occurring at δ = 72.1 and 128.1 ppm are assigned to the nitrogen atoms of the guanidinium counterions and the oxidized pdta ligand, respectively. In free H_4pdta and $H_4pdtaO_2{\cdot}H_2O$ (**5**), the related lines occur at δ = 53.1 and 123.6 ppm, respectively.

Information on the coordination mode of the bis(*N*-oxido) ligand is provided by ^{13}C NMR spectroscopy. The ^{13}C NMR spectrum of the anion $[Nb(O_2)_2(edtaO_2)]^{3-}$ shows three lines at δ = 57.4, 64.9, and 70.8 ppm, arising from the CH_2 groups of the edta ligand. These carbon atoms are clearly influenced by the complexation process. Whereas all four CH_2 moieties of the acetate groups occur as one single peak in the free ligand (δ = 50.9 ppm), they undergo a significant variation in chemical shift and are differentiated in the complex (δ = 57.4 and 64.9 ppm). Moreover, the CH_2 groups of the *N*-bound ethylene moiety are not differentiated (they appear as a single line as in H_4edta) but they are shifted from δ = 57.5 ppm in the free ligand to δ = 70.8 ppm in the complex. A similar value is observed for these carbon atoms in the free edta bis(*N*-oxido) ligand (**4a**;

δ = 67.5 ppm). This result confirms the presence of N−O groups in the complexed ligand. The signal corresponding to the quaternary carbon atoms of the carboxylato groups in the complex appears as two resonance signals rather than the single line found for the free ligand. The presence of two lines at δ = 168.4 and 169.9 ppm in the ^{13}C NMR spectrum implies that two carboxylato groups are coordinated to Nb and the other two remain free. The complete analysis of the ^{13}C NMR spectrum of compound **1** allows us to determine the coordination mode of the ligand to the niobium atom; the edta bis(*N*-oxide) is quadridentate, the four binding atoms being oxygen atoms of two of the carboxylate groups (each placed on a different N atom) and two *N*-oxide groups. A similar analysis based on the ^{13}C NMR spectrum obtained for compound **3** leads to the same conclusion about the coordination mode of the pdta bis(*N*-oxido) ligand.

X-ray Crystal Structures

The asymmetric part of the unit cell of **2b** consists of two $[Nb(O_2)_2(edtaO_2)]^{3-}$ anions, six guanidinium cations, six water molecules, and two hydrogen peroxide molecules. In **3**, only one half of the $[Nb(O_2)_2(pdtaO_2)]^{3-}$ entity is observed in the asymmetric part of the unit cell as a consequence of a crystallographic twofold axis passing through the Nb atom, the central carbon atom of the PAC ligand (C10) and the C and N atoms belonging to one guanidinium ion. In **4b**, only one half of the molecule is observed in the asymmetric part of the unit cell. Crystallographic data for **2b**, **3**, and **4b** are given in Table 4 and selected bond lengths for **2b** and **3** in Table 3.

Table 3. Selected bond lengths and maximum deviations from mean peroxo plane [Å] for both anionic moieties of **2b** and **3**

	2b		**3**
	Anion 1	Anion 2	
Distances			
Nb−O (carboxylate)	2.155(5)	2.147(5)	2.162(2)
	2.154(5)	2.140(5)	
Nb−O (*N*-oxide)	2.089(4)	2.087(5)	2.119(2)
	2.083(5)	2.074(4)	
Nb−O (peroxo)	1.966(5)	1.982(4)	1.973(2)
	1.968(5)	1.979(5)	1.988(2)
	1.977(5)	1.972(5)	
	1.992(5)	1.990(5)	
O−O (peroxo)	1.478(7)	1.485(7)	1.488(3)
	1.483(7)	1.475(7)	
N−O (*N*-oxide)	1.411(7)	1.414(7)	
	1.416(7)	1.407(7)	1.419(2)
Maximum deviation from mean plane through four O (peroxo)			
O (peroxo)	0.04	0.03	0.060
O (*N*-oxide)	2.72	2.75	2.75
	2.69	2.66	
O (carboxylate)	1.64	1.65	1.65
	1.78	1.78	
Nb	1.10	1.17	1.16

The crystal structures of complexes **2b** and **3** are similar in many ways. The bis(*N*-oxido) ligands, $edtaO_2$ and $pdtaO_2$, wrap around the Nb atom, essentially in the same manner. The quadridentate coordination mode of these ligands, deduced from the NMR analysis, is confirmed and, for each anion, coordination is completed by two bidentate peroxo groups. From this it is seen that the niobium atom exhibits an eightfold coordination as observed in all (peroxo)Nb compounds described so far in the literature.[5,6,9−12] Figures 1 and 2 show the molecular structure of the $[Nb(O_2)_2(edtaO_2)]^{3-}$ and $[Nb(O_2)_2(pdtaO_2)]^{3-}$ anions, respectively. The coordination polyhedron observed in both cases is identical to those reported for dioxalatodiperoxoNb^V compounds with different counterions.[9,11] The question of whether eightfold coordinated atoms display dodecahedral (DD) or square-antiprismatic (SAP) config-

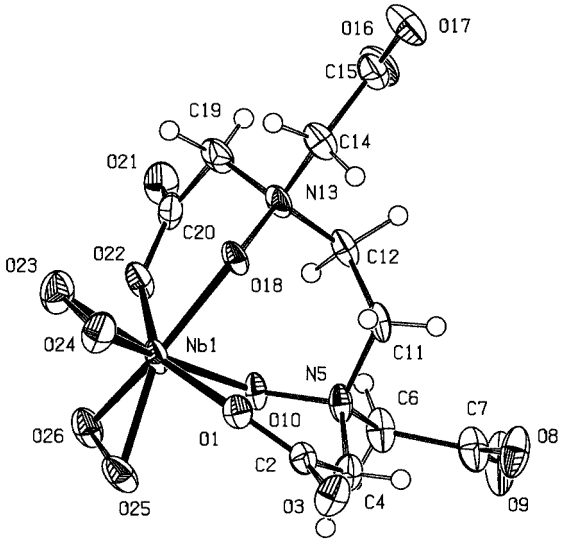

Figure 1. ORTEP plot of $[Nb(O_2)_2(edtaO_2)]^{3-}$ (50% probability)[24]

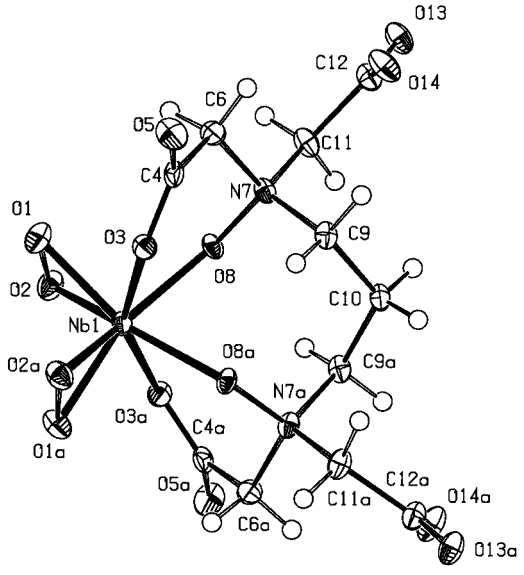

Figure 2. ORTEP plot of the molecular anion of $[Nb(O_2)_2(pdtaO_2)]^{3-}$ (50% probability)[24]

urations is not an obvious one to answer, and has been addressed from a theoretical point of view in the literature.[20] In relation to the fact that the energy balance between DD and SAP is very sensitive to small differences in electronic or steric effects, the obtention of intermediate configurations between them has also been discussed.[21] Theoretical considerations confirmed that "small-bite" ligands like O_2^{2-} definitely prefer the dodecahedral geometry,[20] as is observed in all peroxoniobate complexes described so far. In the present cases, the polyhedron may be described as a triangular dodecahedron that is rather distorted on one side. As indicated in Table 3, for the three anionic moieties encountered in these compounds, the four oxygen atoms of the peroxo groups are coplanar within experimental error. The maximum deviation from the best mean plane through these four O atoms is less than 0.06 Å. On the opposite side of the polyhedron, the four oxygen atoms of the PAC ligand are not coplanar. In all three anions described above, the oxygen atoms of the two carboxylate and the two *N*-oxide groups are observed with quite similar distances from the mean plane, of about 1.7 Å and 2.7 Å, respectively (see Table 3).

The mean Nb−O (*N*-oxide) bond length is 2.090(4) Å, a value which is larger than that observed in the related (hydroxyimino)niobium complex $(PPh_4)[Nb(hida)_2]$.[22] The other coordination distances are in the range of the values already reported.[6,9−11,22] The mean value for the Nb−O (carboxylato) distances is 2.152(5) Å and is slightly larger than the average of the sixteen values reported in the literature (2.095 Å). The Nb−O (peroxo) and (O−O) mean distances are 1.979(5) and 1.482(7) Å, respectively, and compare very well with the reported Nb−O distances (average over 36 values is 2.000 Å) and O−O distances (average over 14 values is 1.495 Å).[6,9−11,22] It is worth noting that, for both Nb complexes, the N−O (*N*-oxide) bond lengths range from 1.407(7) to 1.419(2) Å with a mean value of 1.413(5) Å. As expected, this value is slightly larger than the N−O distance observed in the free ligand [1.398(2) Å]. Moreover, as illustrated in Figure 3, which shows the molecular structure of the $[edtaO_2]^{4-}$ anion, there is a significant change of ligand conformation upon chelation. In the free anion, the N−O bands that are related by a symmetry center are in an "*anti*" orientation, pointing in opposite directions.

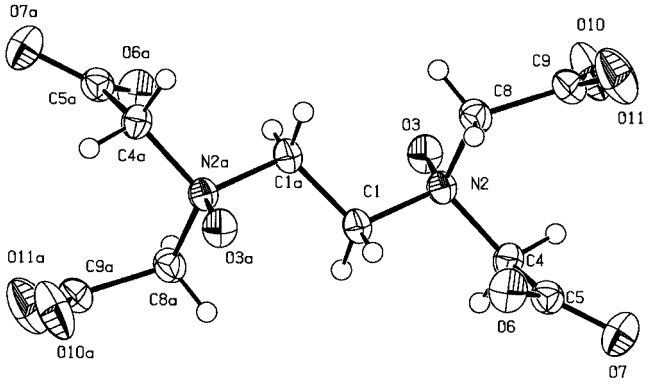

Figure 3. ORTEP plot of the molecular anion of $[edtaO_2]^{4-}$ (50% probability)[24]

For **2a**, the co-crystallized water and hydrogen peroxide molecules are involved in an intricate hydrogen bond network as illustrated in Figure 4. All the H-donors of the carboxylato groups and of the NH_2 groups of the guanidinium counterions participate in the network. There is no co-crystallized solvent molecule in crystals of **3** and **4b** but, in both structures, all carboxylate, peroxo, and amine groups are hydrogen-bonded.

Thermal Analyses

After dehydration, compound **1** undergoes a three-step degradation into Nb_2O_5 up to a final decomposition tem-

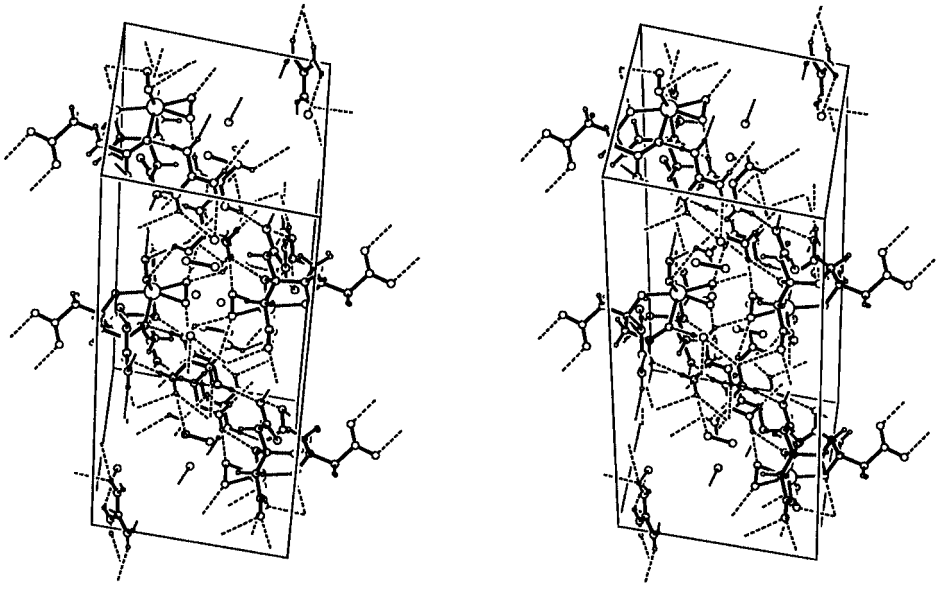

Figure 4. Stereoscopic view of the unit cell of **2b** showing the hydrogen bond network

perature of 620 °C. The thermal behavior of the guanidinium compounds **2a** and **3** is quite similar but their thermograms display an additional step, probably due to the counterion itself. The thermogravimetric analyses of the two edta(peroxo) compounds (**1** and **2a**) are illustrated in Figure 5.

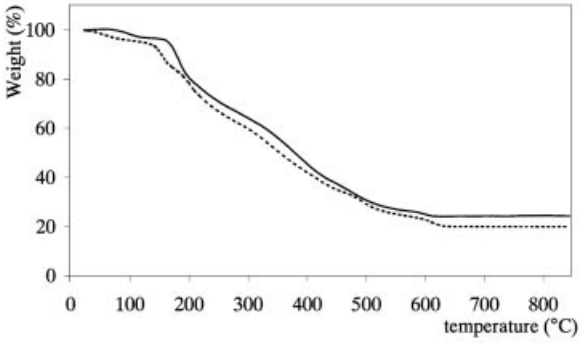

Figure 5. Thermogravimetric analyses of **1** (straight line) and **2a** (dashed line) in air (10 °C/min)

Conclusion

New niobium(v) complexes with *N*-oxide derivatives of polyaminocarboxylic acids have been prepared and characterized from the structural and spectroscopic point of view. Because these compounds exhibit a high solubility in water, they are ideal as precursors for Nb-based materials. The structures reported here are the first ones describing metal complexes with *N*-oxide derivatives of PAC ligands. The one-step synthesis of such compounds in the presence of hydrogen peroxide or their formation from the pre-isolated PAC (*N*-oxide)s opens new perspectives towards the obtention of PAC-type complexes with hard cations which, like Nb^{5+}, display a higher affinity towards oxygen than towards nitrogen.

Experimental Section

General: Ethylenediaminetetraacetic acid, H_4edta (Fluka), propylenediaminetetraacetic acid, H_4pdta (Fluka), and guanidinium carbonate, $(gu)_2CO_3$ (Aldrich), were commercial products and used as received. Niobic acid, $Nb_2O_5{\cdot}nH_2O$ was supplied by CBMM (Brazil). Hydrogen peroxide, H_2O_2 (35 wt-%, Acros), aqueous ammonia (25 wt-%), ethanol, and acetic acid were used without purification. Elemental analyses (C, H, N) were carried out at the University College of London. IR spectra in the 4000−400 cm^{-1} range were recorded with an FTS-135 Bio-RAD spectrometer, using KBr pellets containing ca 1 wt-% of the powder. ^1H, ^{13}C, and ^{15}N NMR spectra were measured in D_2O at 500, 125, and 50 MHz, respectively, with a Bruker Avance 500 MHz spectrometer equipped with a broad-band inverse probe. ^{15}N NMR spectra were recorded using the HMBC pulse sequence with a mixing time of 100 ms. Chemical shifts are expressed in ppm and are referenced to TMS for ^1H and ^{13}C (δ = 0 ppm) or nitromethane for ^{15}N (δ = 375 ppm).

$(NH_4)_3[Nb(O_2)_2(edtaO_2)]{\cdot}H_2O{\cdot}H_2O_2$ (1): A slurry of niobic acid (1 g, 6.36 mmol) in distilled water (20 mL) was treated with a 35 wt-% solution of H_2O_2 (20 mL) and ammonia (6 mL of a 25 wt-% solution). The cloudy solution was stirred for a few hours. When the solid was totally dissolved, H_4edta (1.86 g, 6.36 mmol) was added gradually, reaching pH = 5−5.5. The pale yellow solution was then gently heated for 10 min (T = 60 °C) and the solvents evaporated to a final volume of 20 mL under reduced pressure. The addition of ethanol (100 mL) yielded a white solid that was filtered off, washed with ethanol, and air-dried. Yield: 2.09 g (56%). $C_{10}H_{28}N_5NbO_{17}$ (583.16): calcd. C 20.57, H 4.80, N 12.00; found C 20.51, H 4.78, N 11.97. ^1H NMR (500 MHz, D_2O): δ = 3.88 (d, J = 16.5 Hz, 2 H), 4.06 (d, J = 16.0 Hz, 2 H), 4.37 (d, J = 16.5 Hz, 2 H), 4.42 (d, J = 14.0 Hz, 2 H), 4.76 (d, J = 13.5 Hz, 2 H), 5.04 (d, J = 16.5 Hz, 2 H) ppm. ^{13}C (125 MHz, D_2O) and ^{15}N (50 MHz, D_2O) NMR: see Table 2.

$(gu)_3[Nb(O_2)_2(edtaO_2)]{\cdot}2H_2O$ (2a): This guanidinium compound was prepared according to the same procedure as used for the ammonium derivative **1** but replacing ammonia by guanidinium carbonate, $(gu)_2CO_3$ (1.72 g, 9.55 mmol). The complex was isolated as a crystalline light-yellow solid. Yield: 2.78 g (63%). $C_{13}H_{34}N_{11}NbO_{16}$ (693.16): calcd. C 22.50, H 4.90, N 22.21; found C 22.36, H 5.02, N 22.03. The slow concentration at 5 °C of an aqueous concentrated solution yielded after several days small crystals suitable for structure determination by single-crystal X-ray diffraction and similar to compound **2a**, but containing additional water and hydrogen peroxide molecules $\{(gu)_3[Nb(O_2)_2(edtaO_2)]{\cdot}3H_2O{\cdot}H_2O_2$, **2b**$\}$.

$(gu)_3[Nb(O_2)_2(pdtaO_2)]$ (3): A slurry of niobic acid (1 g, 6.36 mmol) in distilled water (50 mL) was treated with a 35 wt-% solution of H_2O_2 (50 mL) and $(gu)_2CO_3$ (1.72 g, 9.55 mmol). When the solid was totally dissolved, H_4pdta (1.95 g, 6.36 mmol) was added, reaching pH = 6. The pale yellow solution was then gently heated for 10 min (T = 60 °C) and the solvents evaporated to a final volume of 50 mL under reduced pressure. Addition of ethanol (100 mL) produced, after a few minutes, a pale yellow crystalline solid that was filtered off, washed with ethanol, and air-dried. Yield: 3.01 g (71%). $C_{14}H_{32}N_{11}NbO_{14}$ (671.18): calcd. C 25.03, H 4.77, N 22.94; found C 25.20, H 4.69, N 22.76. ^1H NMR (500 MHz, D_2O): δ = 2.2−2.3 (m, 2 H), 3.94 (d, J = 16.5 Hz, 2 H), 3.99 (d, J = 13.0 Hz, 2 H), 4.19 (d, J = 16.5 Hz, 2 H), 4.83 (d, J = 13.0 Hz, 2 H), 4.86 (d, J = 16.5 Hz, 2 H) ppm. ^{13}C (125 MHz, D_2O) and ^{15}N (50 MHz, D_2O) NMR: see Table 2. The slow concentration at room temperature of an aqueous concentrated solution yielded after several days small yellow crystals of compound **3**.

$H_4edtaO_2{\cdot}1/2\ H_2O$ (4a): H_4edta (2 g, 6.84 mmol) was dispersed in glacial acetic acid (100 mL) and 35 wt-% solution of H_2O_2 (50 mL). The suspension was stirred for 72 h at room temperature. The white solid was then filtered off, washed with water and ethanol and finally air-dried. Yield: 1.81 g (79%). $C_{10}H_{16}N_2O_{10}{\cdot}1/2H_2O$ (333.25): calcd. C 36.00, H 5.10, N 8.40; found C 36.19, H 4.91, N 8.27. ^1H NMR (500 MHz, D_2O): δ = 4.09 (d, J = 15.5 Hz, 4 H), 4.19 (s, 4 H), 4.37 (d, J = 15.5 Hz, 4 H), 4.70 (s, H_2O) ppm. ^{13}C (125 MHz, D_2O) and ^{15}N (50 MHz, D_2O) NMR: see Table 2. Crystallization of a guanidinium derivative of the edta bis(*N*-oxido) ligand was obtained after neutralizing the carboxylic groups by guanidinium carbonate; **4a** (1 g, 3 mmol) was dissolved in distilled water (10 mL) and the addition of $(gu)_2CO_3$ (2.16 g, 12 mmol) yielded a clear solution that was allowed to concentrate at room temperature. After several days, large crystals of $(gu)_4edtaO_2$ (**4b**) had formed. $C_{14}H_{36}N_{14}O_{10}$ (560.57): calcd. C 29.98, H 6.07, N 34.98; found C 30.40, H 6.22, N 35.40.

$H_4pdtaO_2{\cdot}H_2O$ (5): This compound was prepared according to the same procedure as used for the edta derivative but replacing H_4edta

by H_4pdta (2 g, 6.53 mmol). Yield: 1.68 g (72%). $C_{11}H_{20}N_2O_{10}\cdot H_2O$ (356.25): calcd. C 37.05, H 5.61, N 7.86; found C 37.10, H 5.71, N 7.81. ^{1}H NMR (500 MHz, D_2O): δ = 2.41−2.51 (m, 2 H), 4.10 (t, J = 7.0 Hz, 4 H), 4.39 (d, J = 16.0 Hz, 4 H), 4.46 (d, J = 16.0 Hz, 4 H) ppm. ^{13}C (125 MHz, D_2O) and ^{15}N (50 MHz, D_2O) NMR: see Table 2.

X-ray Crystallography: The X-ray intensity data were measured at 100 K with an MAR345 image plate using Mo-K_α (λ = 0.71069 Å) radiation. Selected crystals of **2b** and **3** were mounted in inert oil and transferred to the cold gas stream for flash cooling. Data of **4b** were collected at room temperature. Crystal data and data collection parameters are summarized in Table 4. The unit cell parameters were refined using all the collected spots after the integration process. The three structures were solved by direct methods and refined by full-matrix least-squares on F^2 using SHELXL-97.[23] All the non-hydrogen atoms were refined anisotropically. For **2b** and **3**, the hydrogen atoms were calculated with AFIX and included in the refinement with a common isotropic temperature factor. The H atoms of the carboxylic groups, the water and hydrogen peroxide molecules were not localized. For **4b**, the H atoms were localized by Fourier difference synthesis. In compound **2b**, the asymmetric part of the unit cell concsists of two complex units related to each other by a pseudo translation symmetry. There is only one half of the ligand molecule and two guanidinium cations in the asymmetric part of the unit cell of **4b**; the midpoint of the central C1−C1a bond corresponds to a crystallographic center of symmetry. The details of the refinement and the final R indices are presented in Table 4. In **2b** and **3**, the largest peak in the final Fourier difference synthesis is located near an Nb atom. CCDC-187664 (**2b**), -187665 (**3**), and -192609 (**4b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Pyridine- and 3-/6-Methylpyridine-2-tellurolate Complexes of Palladium(II) and Platinum(II)

Sandip Dey,[a] Vimal K. Jain,*[a] Jaspreet Singh,[b] Veena Trehan,[b] Kuldip K. Bhasin,[b] and Babu Varghese[c]

Keywords: Palladium / Platinum / N ligands / Tellurium / NMR spectroscopy

The reaction of py_2Te_2 or $(3\text{-}MeC_5H_3N)_2Te_2$ with Na_2PdCl_4 in methanol yields an insoluble brown complex, $[PdCl(TeNC_5H_3R)]_n$ (R = H or Me). Several reactions of $pyTe^-$, $(3\text{-}MeC_5H_3N)Te^-$, or $(6\text{-}MeC_5H_3N)Te^-$ with various palladium(II) and platinum(II) complexes have been carried out. Complexes of the types $[MCl(Te\text{–}N)(PR_3)]$, $[Pt(Te\text{–}N)_2(dppe)]$, $[Pt(Te\text{–}N)_2(PPh_3)_2]$, and $[Pt_2(\mu\text{-}Te\text{–}N)_2(dppe)_2][BPh_4]_2$ [M = Pd or Pt; Te–N = pyTe, (3- or 6-MeC_5H_3N)Te] have been prepared and characterized by elemental analyses, UV/Vis, IR, and NMR (^1H, ^{31}P, ^{195}Pt) spectroscopy. The complexes $[MCl(Te\text{–}N)(PR_3)]$ show irreversible oxidation and reduction by CV in DMF. The molecular structure of $[PdCl\{Te(3\text{-}MeC_5H_3N)\}(PPh_3)]$ (**2c**) has been established by single-crystal X-ray diffraction analysis. The palladium atom is bound to the chelating 3-methylpyridinetellurolate ligand, a chlorine atom and a PPh_3 ligand. The pyrolysis of $[PdCl\{Te(3\text{-}MeC_5H_3N)\}(PR_3)]$ (PR_3 = PEt_3 or PPh_3) at 340 °C yields PdTe.

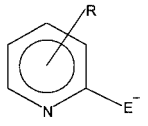
Introduction

The synthesis and characterization of metal chalcogenolates continues to be an area of considerable interest. Their emerging applications as single-source precursors for a low-temperature preparation of solid-state chalcogenide materials has further accelerated work in this area.[1–4] The area of metal chalcogenolates has been dominated by molecules containing the M–SR linkage.[5] In most cases, these molecules have been isolated as non-volatile insoluble (or sparingly soluble) polymers, thus making them inconvenient precursors for the preparation of metal chalcogenides. To suppress polymerization, several strategies have been explored. These include use of (a) a strongly coordinating ligand, such as tertiary phosphanes,[6,7] (b) a sterically demanding chalcogenolate ion,[8] (c) internally functionalized small-bite ligands.[9–13] One of the families of the latter class of ligands is the pyridine-2-chalcogenolate ion **I**. While the ligand chemistry of $C_5H_4NO^-$ [14] and $C_5H_4NS^-$ [15] has been well documented, the coordination chemistry of the pyridine-2-selenolate ion has been explored only recently by us[11,16] and others.[17–21] In contrast, metal complexes with pyridine-2-tellurolate are virtually non-existent, although py_2Te_2 has been known for some time.[22,23] Possibly, a rather tedious preparation ("difficult to reproduce"[22]) of py_2Te_2, the precursor for $C_5H_4NTe^-$, appears to be a limiting factor for its use as a ligand.



I

(E = O, S, Se, Te; R = H or Me)

Group-10 metal chalcogenides (M_xE_y; M = Pd or Pt; E = S, Se, Te) have found several applications in catalysis[24] (PdTe supported on carbon is employed industrially) and in the electronic industry.[25,26] Besides their wide structural diversity[5] and relevance in catalysis,[9,27,28] platinum-group metal chalcogenolates offer an attractive possibility of serving as precursors for the synthesis of metal chalcogenides.[12,29] In continuation of our program on the molecular design of platinum-group metal precursors, we have now synthesized bis(2-pyridyl) and bis(methyl-substituted 2-pyridyl) ditelluride, and have investigated the chemistry of their palladium and platinum complexes.

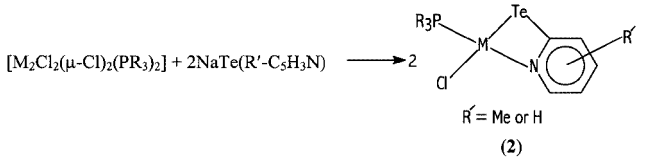
Results and Discussion

Synthesis and NMR Spectroscopic Data

A methanolic solution of Na_2PdCl_4 was treated with py_2Te_2 or $(3\text{-}MeC_5H_3N)_2Te_2$ at room temperature to give a brown insoluble product, $[PdCl\{Te(3\text{-}RC_5H_3N)\}]_n$ [R = H (**1a**) or Me (**1b**)]. The IR spectrum of **1b** exhibits a band at 281 cm^{-1} which is assigned to the terminal ν_{Pd-Cl} stretching. On treatment with tertiary phosphanes, the mononuclear complexes $[MCl\{Te(3\text{-}MeC_5H_3N)\}(PR_3)]$ are obtained. The latter complexes and their platinum analogues can readily be prepared by the reaction of $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ with 2 equiv. of $NaTe(RC_5H_3N)$ (R = H, 3-Me, or 6-Me) [(Scheme 1), prepared by the cleavage of the Te−Te bond in bis(2-pyridyl) ditelluride with $NaBH_4$ in methanol]. The reaction exclusively gives $[MCl\{Te(RC_5H_3N)\}(PR_3)]$ (**2**).



(2)

(M = Pd or Pt; PR_3 = PEt_3, $PnPr_3$, PMe_2Ph, $PMePh_2$, PPh_3, $Ptol_3$, PPh_2py)

Scheme 1

Similar reactions with pyO^- afford 2-pyridinolate-bridged dinuclear complexes, $[M_2Cl_2(\mu\text{-}OC_5H_4N)_2(PR_3)_2]$,[30] while in the reactions with pyS^-, both mono- and dinuclear complexes $[MCl(SC_5H_4N)(PR_3)]$ and $[M_2Cl_2(\mu\text{-}SC_5H_4N)_2(PR_3)_2]$ are formed, depending on the nature of the phosphane ligand.[31−35] In solution a dimer ⇄ monomer equilibrium is established, which is shifted to either side by subtle energetic factors. The reactions with $C_5H_4NSe^-$ preferentially yield mononuclear complexes, $[MCl(SeC_5H_4N)(PR_3)]$. However, dinuclear species are formed in small concentration (ca. 5%) in certain cases when trialkylphosphanes are used.[11] Clearly, as the Pd−E

[a] Recorded in $[D_6]$acetone; methyl resonance of the $3\text{-}MeC_5H_3N$ merged in the multiplet of $[D_6]$acetone. [b] Recorded in $CDCl_3$.

distance (Pd−O ≈ 2.10 Å; Pd−S ≈ 2.28 Å; Pd−Se ≈ 2.45 Å; Pd−Te ≈ 2.55 Å) increases with increasing size of the chalcogen atom, the Pd−N interaction of these small-bite ligands with a single metal center is facilitated.

The reaction of $PtCl_2$(dppe) with 2 equiv. of NaTe(3-MeC_5H_3N) yields the yellow mononuclear complex [Pt{Te(3-MeC_5H_3N)}$_2$(dppe)]. The NMR spectroscopic data (^{1}H, ^{31}P, and ^{195}Pt) are consistent with several organochalcogenolates, *cis*-[Pt(ER)$_2$(P−P)].[6,7,11−13] The reaction, performed in a 1:1 ratio in the presence of $NaBPh_4$, gives a cationic complex [Pt$_2$\{Te(3-MeC_5H_3N)\}$_2$(dppe)$_2$][BPh_4]$_2$. The ^{31}P and ^{195}Pt NMR spectra show two sets of resonances and doublets of doublets, respectively; a pattern which can be attributed to the non-equivalence of the phosphorus nuclei of the P−P ligand. Similar spectral features have been reported for [Pt$_2$(μ-$SeCH_2CH_2NMe_2$)$_2$(dppe)$_2$]$^{2+}$ [13] for which the existence of an asymmetric M−Se bridge has been suggested.

Treatment of $PtCl_2(PPh_3)_2$ with 2 equiv. of NaTe(3-MeC_5H_3N) affords [Pt{Te(3-MeC_5H_3N)}$_2$(PPh_3)$_2$]. The ^{31}P NMR spectrum of the complex exhibits a resonance at δ = 6.6 ppm, with ^1J(Pt−P) = 3725 Hz, together with a signal which is assigned to PPh_3 (δ = −4.5 ppm) (Table 1). A dynamic equilibrium between free PPh_3 and [M(EC_5H_4N)$_2$(PPh_3)] (M = Pd or Pt; E = S or Se)[11,16] has been reported earlier.

The ^{1}H NMR spectra of **2** show characteristic resonances for the ligand protons. The 6-H proton signal for the (3-MeC_5H_3N)Te ligand in the platinum complexes is flanked by ^{195}Pt satellites with ^3J(Pt-H) ≈ 40 Hz. The ^{31}P NMR spectra of these complexes display a single resonance indicating the formation of only one isomer. The magnitude of ^1J(^{195}Pt-^{31}P) in the platinum complexes suggests that the phosphane ligand is *trans* to the nitrogen atom of the chelating 2-pyridinetellurolate ligands,[11−13] and this is confirmed by the X-ray structural analysis. The ^{195}Pt NMR spectra (Table 2) show a doublet due to coupling with the single phosphorus nucleus. The ^{195}Pt resonance is considerably shielded relative to the signal for the corresponding 2-pyridineselenolate complexes.[11]

UV/Vis Spectroscopy

All these complexes are deeply colored crystalline solids. The UV/Vis spectra (Table 3) in dichloromethane show a well-separated relatively weak broad band in the visible region, and this is responsible for the deep colors observed for these complexes. The platinum complexes have an absorbance band at higher energies than that of the corresponding palladium analogues. For both the series of complexes (Pd or Pt), this band is hypsochromically shifted with increasing donor strength of the phosphane ligand. The DFT calculations of [MCl($TeCH_2CH_2NMe_2$)(PR_3)] (M = Pd or Pt) reveal a metal-mediated charge-transfer between coordinated ligands. The highest occupied molecular orbital (HOMO) is predominantly centered on the tellurolate ligand, whereas the lowest unoccupied molecular orbital (LUMO) is delocalized over the system, with significant phosphane contributions. The low-energy electronic transitions between the frontier orbitals give rise to the colors.[35]

Table 3. UV/Vis data for the 2-pyridinechalcogenolate complexes of [MCl{E(3-MeC_5H_3N)}(PR_3)] (M = Pd^{II} and Pt^{II}; E = Se, Te) in CH_2Cl_2

Cyclic Voltammetry

The complexes show irreversible oxidation and reduction in DMF/0.01 M Et_4NClO_4 (Table 4). The lower oxidation potential of the Pt/Te system indicates that the HOMO (Te) is destabilized relative to that of the corresponding Pd/Te system. Such behavior has been reported for [MCl($TeCH_2CH_2NMe_2$)(PR_3)] complexes.[35] It was difficult to oxidize the 2-pyridineselenolates [MCl(SeC_5H_4N)(PR_3)] (high oxidation potential values).

tion analysis. The ORTEP[36] plot with the atomic numbering scheme is shown in Figure 1, and the selected bond lengths and angles are given in Table 5. The molecule consists of a distorted square-planar palladium atom that is bound to the chelating 3-methyl-2-pyridinetellurolate ligand, a chlorine atom and a PPh_3 ligand. The neutral donors (N, P) are mutually *trans*, and as a consequence the chloride ion and the Te atom adopt a *trans* arrangement, a configuration that has been reported previously for selenolate and tellurolate complexes, [MCl(E−N)(PR_3)] (M = Pd or Pt; E−N = $SeCH_2CH_2NMe_2$, $TeCH_2CH_2NMe_2$).[12,13,35] The square plane of the palladium atom (defined by the N, Cl, P, Te atoms), the four-membered chelate ring [Pd, N, C(5), Te], and the pyridine ring are almost coplanar, with the interplanar angles varying between 3.68 and 6.68°. The Te atom lies 0.1 Å out of the plane defined by the Pd, N, Cl, and P atoms.

P−Pd−Te	100.67(4)	C(7)−P−C(19)	104.0(3)
Cl−Pd−Te	165.21(4)	C(13)−P−C(19)	103.0(3)

The various angles around the Pd atom differ significantly from [PdCl($TeCH_2CH_2NMe_2$)(PR_3)] (PR_3 = P*n*Pr_3, $PMePh_2$),[35] owing to the small bite of the four-membered (3-MeC_5H_3N)Te moiety. The Pd−Te distanceis slightly longer [2.5606(8) Å] than that observed for [PdCl($TeCH_2CH_2NMe_2$)(PR_3)] [PR_3 = P*n*Pr_3 2.5095(8) and $PMePh_2$ 2.5156(6) Å],[35] while the Pd−N distance [2.085(4) Å] is shorter than that reported for [PdCl($TeCH_2CH_2NMe_2$)(PR_3)].[35] These distances, as well as the Pd−Cl, Pd−P and Te−C bond lengths are not unusual.[33−35,37−40]

Thermal Behavior

Thermogravimetric analysis of [PdCl{Te(3-MeC_5H_3N)}(PPh_3)] (**2c**) was carried out under a dynamic argon pressure. The TG curve shows a one-step decomposition (290°C), leading to the formation of PdTe as inferred from the calculated weight loss. In order to prepare large quantities of the telluride, a substantial amount (100−350 mg) of the complexes (**2a**, **2c**) was heated in a furnace at 340°C for 2 h under a dynamic dry argon pressure. The weight loss and XRD pattern (Figure 2) of the residue obtained after decomposition in each case matches the product obtained from TG. The XRD patterns (Figure 2) of all these samples are in agreement with the standard pattern of PdTe[41] [analysis of the prepared PdTe: sample from **2a**: C 1.8, H < 0.2, N < 0.2; sample from **2c**: C < 0.2, H < 0.2, N < 0.2 (detection limit 0.2%)]. The scanning electron micrographs

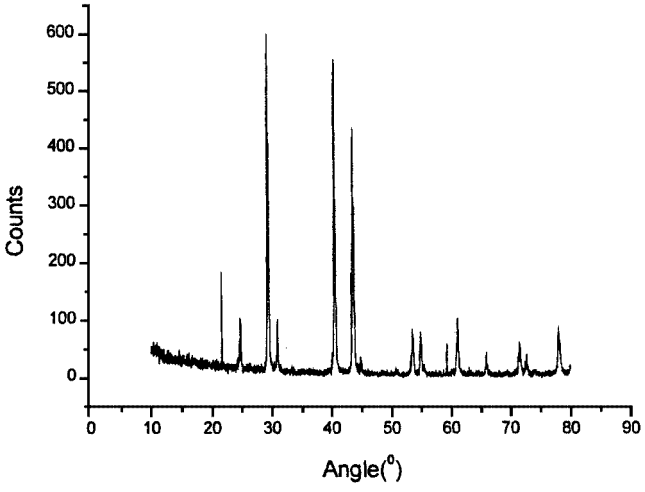

Figure 2. XRD pattern of PdTe obtained from [PdCl{Te(3-MeC_5H_3N)}(PPh_3)]

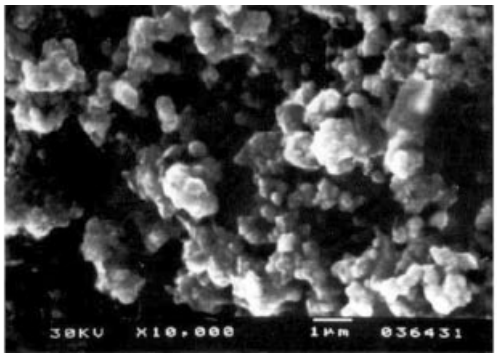

Figure 3. SEM picture of PdTe obtained from [PdCl{Te(3-MeC_5H_3N)}(PPh_3)]

(Figure 3) of PdTe obtained from **2c** taken at different resolutions show large aggregates of microcrystals.

Experimental Section

General: The complexes Na_2PdCl_4, $[PtCl_2(PPh_3)_2]$, $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ (M = Pd or Pt; PR_3 = PEt_3, $PnPr_3$, PMe_2Ph, $PMePh_2$, PPh_3), $[PtCl_2(dppe)]$,[42] py_2Te_2,[43a] (3-/6-$MeC_5H_3N)_2Te_2$,[43b] and the methyl-substituted 2-bromopyridines[44] were prepared according to literature methods. The phosphanes were obtained from Strem Chemicals (USA). All reactions were carried out under nitrogen, in dry and distilled analytical grade solvents. Microanalyses were carried out in the Analytical Chemistry Division of B.A.R.C. ^1H, $^{31}P\{^1H\}$, $^{125}Te\{^1H\}$, and $^{195}Pt\{^1H\}$ NMR spectra were recorded with a Bruker DPX-300 NMR spectrometer, operating at 300, 121.49, 94.86, and 64.52 MHz, respectively. Chemical shifts are relative to the internal chloroform peak (δ = 7.26 ppm) for ^1H, external 85% H_3PO_4 for ^{31}P, $Te(dtc)_2$ (dtc = Et_2NCS_2) for ^{125}Te, and $Na_2[PtCl_6]$ in D_2O for ^{195}Pt. A 90° pulse was used in every case. The IR spectra were recorded as Nujol mulls between CsI plates with a Bomen MB-102 FT-IR spectrometer. UV/Vis absorbance spectra were recorded with a JASCO V-530 spectrometer using quartz cuvettes with a diameter of 1 cm. Cyclic voltammetry was carried out at a scan rate of 100 $mV \cdot s^{-1}$ in DMF/0.01 M Et_4NClO_4, using a three-electrode configuration (glassy carbon electrode, platinum counter electrode, calomel reference electrode) and an Ecochemie potentiostat 100 with autolab software. The ferrocene/ferrocenium couple served as the external reference. Mass spectra were recorded with a VG-705 11-250J spectrometer at RSIC, Panjab University, Chandigarh. Thermogravimetric analysis (TGA) was carried out using a Setaram 92-16-18 instrument calibrated with $CaC_2O_4 \cdot H_2O$. The TG curves were recorded at a heating rate of 10 $°C \cdot min^{-1}$ under a flow of argon. X-ray powder diffraction was measured using Cu-K_α radiation. SEM photographs were taken using a JEOL JSM-T330A instrument.

Preparations

Preparation of Bis(3- and 6-methyl-2-pyridyl) Ditelluride: Sodium borohydride (4.0 g, 108 mmol) was added slowly under a flow of nitrogen to a suspension of tellurium powder (9.65 g, 76 mmol) in 2-ethoxyethanol. The resulting colorless solution was refluxed for 30 min and then cooled to room temperature; 3- or 6-methyl-substituted 2-bromopyridine (13.07 g, 76 mmol) was added and the resulting solution was refluxed until all the 2-bromopyridine was consumed (48−96 h). The progress of the reaction was monitored by TLC. The nitrogen flow was stopped and the mixture was subjected to oxidation in air. The solvent was removed under vacuum and the crude residue was washed with water, and extracted with diethyl ether (4 × 100 mL). The extract was dried with anhydrous sodium sulfate and the solvent removed using a rotary evaporator, leaving the crude ditelluride. This was purified by column chromatography (silica gel; hexane/ethyl acetate, 10:1).

Bis(3-methyl-2-pyridyl) Ditelluride {[(3-$MeC_5H_3N)Te]_2$}: Yield 52%, m.p. 125−128°C. $C_{12}H_{12}N_2Te_2$ (439.4): calcd. C 32.8, H 2.7, N 6.4; found C 32.6, H 2.42, N 6.18. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 297 (3260), 346 (sh, 1340), 412 (510) nm. ^1H NMR ($CDCl_3$): δ = 2.41 (s, Me), 6.96 (dd, *J* = 3.2, 5.0 Hz, 5-H), 7.25 (d, *J* = 4.6 Hz, 4-H); 8.20 (dd, *J* = 0.8, 3.5 Hz, 6-H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 24.4 (s, Me), 122.1 (C-4), 134.9 (C-5), 137.8 (C-2), 140.7 (C-3), 148.3 (C-6) ppm. $^{125}Te\{^1H\}$ NMR ($CDCl_3$): δ = −382.7 ppm. IR (KBr): $\tilde{\nu}$ = 3060, 2960, 2920, 1580, 1540, 1430, 1120, 1090, 1020, 840, 780, 660, 540 cm^{-1}. MS (EI): *m*/*z* (%) = 440 (7.33) [M (^{130}Te)]$^+$, 314 (14.51) [M − Te]$^+$, 216 (1.47) [M − MeC_5H_3NTe], 183 (76.62) [M − Te_2H]$^+$, 92 (100) [M − CH_3pyTe_2]$^+$.

Bis(6-methyl-2-pyridyl) Ditelluride: Yield 24%, m.p. 55−56°C. $C_{12}H_{12}N_2Te_2$ (439.4): calcd. C 32.8, H 2.7, N 6.4; found C 32.21, H 2.52, N 6.18. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 292 (sh, 8110), 386 (850) nm. ^1H NMR ($CDCl_3$): δ = 2.50 (s, Me), 6.85 (d, *J* = 5.0 Hz, 3-H), 7.25 (t, *J* = 5.0 Hz, 4-H), 7.84 (d, *J* = 5.0 Hz, 5-H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$) δ = 24.2 (s, Me), 121.0 (C-4), 128.0 (C-5), 134.9 (C-2), 137.0 (C-3), 158.9 (C-6) ppm. $^{125}Te\{^1H\}$ NMR ($CDCl_3$): δ = −426.4 ppm. IR (KBr): $\tilde{\nu}$ = 3042, 2916, 1571, 1429, 1376, 1242, 1163, 1083, 988, 826, 781, 655, 545 cm^{-1}. MS (EI): *m*/*z* (%) = 444 (5.5) [M (^{130}Te)]$^+$, 314 (6.5) [M − Te]$^+$, 216 (0.6) [M − MeC_5H_3NTe], 183 (30.9) [M − Te_2H]$^+$, 92 (100) [M − CH_3pyTe_2]$^+$.

[PdCl{Te(3-MeC_5H_3N)}]$_n$ (1b): A methanolic solution (10 mL) of Na_2PdCl_4 (342 mg, 1.16 mmol) was added to a methanolic solution (20 mL) of (3-$MeC_5H_3N)_2Te_2$ (256 mg, 0.58 mmol) while stirring at room temperature, whereupon a brown precipitate formed. Stirring was continued for 3 h. The brown precipitate was filtered, washed with methanol, water, acetone, and diethyl ether and dried in vacuo (yield: 235 mg, 56%). Complex **1a** was also prepared in a similar manner.

[PdCl{Te(3-MeC_5H_3N)}(PEt_3)] (2a): An acetone suspension (20 mL) of $[Pd_2Cl_2(\mu\text{-}Cl)_2(PEt_3)_2]$ (108 mg, 0.18 mmol) was added to a freshly prepared methanolic solution (5 mL) of NaTe(3-MeC_5H_3N) [prepared from (3-$MeC_5H_3N)_2Te_2$ (82 mg, 0.19 mmol) and $NaBH_4$ (15 mg, 0.39 mmol)], and the mixture was stirred for 4 h at room temperature. The solvents were evaporated in vacuo and the residue was extracted with acetone (3 × 8 mL). The solution was passed through a Florisil column. The blue solution was concentrated to 3 mL, a few drops of hexane were added, and the solution was kept at −5°C in a freezer giving blue-violet crystals (130 mg, 74%). Similarly, other palladium (**2b**, **2c**, **2f**) and platinum (**3a**−**3d**) complexes were prepared. The most important data are summarized in Table 6.

[PdCl{Te(3-MeC_5H_3N)}($Ptol_3$)] (2d): Solid $Ptol_3$ (tol = 4-MeC_6H_4) (26 mg, 0.09 mmol) was added to an acetone suspension (20 mL) of **1** (30 mg, 0.08 mmol), and the mixture was stirred for 1 h. The green solution was dried in vacuo and the residue was washed with hexane, diethyl ether and recrystallized from acetone/hexane to yield green crystals (38 mg, 68%). The complexes **2c** and **2e** were prepared in an analogous manner.

Table 6. Physical and analytical data for 3-methyl- and 6-methyl-2-pyridinetellurolate complexes of Pd^{II} and Pt^{II}

Complex	Color	Recrystallization solvent (yield [%])	M.p. [°C]	Analysis: found (calcd.) C	H	N

$[Pt\{Te(3\text{-}MeC_5H_3N)\}_2(dppe)]$ (**4a**)	yellow	CH_2Cl_2/hexane (64)	192	45.0 (44.2)	3.2 (3.5)	2.8 (2.7)
$[Pt\{Te(6\text{-}MeC_5H_3N)_2(dppe)]$ (**4b**)	yellow	acetone/hexane (56)	167	43.4 (44.2)	3.2 (3.5)	2.4 (2.7)
$[Pt\{Te(3\text{-}MeC_5H_3N)\}_2(PPh_3)_2]$ (**5**)	yellow	acetone/benzene (42)	168	49.3 (49.8)	2.5 (3.6)	2.1 (2.4)
$[Pt_2\{Te(3\text{-}MeC_5H_3N)\}_2(dppe)_2][BPh_4]_2$ (**6**)	yellow	acetone (60)	213	59.5 (59.4)	4.2 (4.4)	1.4 (1.2)

$[Pt\{Te(3\text{-}MeC_5H_3N)\}_2(dppe)]$ (4a): This compound was prepared analogously to **2a** by using $[PtCl_2(dppe)]$ (110 mg, 0.17 mmol) and $NaTe(3\text{-}MeC_5H_3N)$ [prepared from $(3\text{-}MeC_5H_3N)_2Te_2$ (73 mg, 0.17 mmol) and $NaBH_4$ (13 mg, 0.34 mmol)]. The yellow residue was recrystallized from a CH_2Cl_2/hexane mixture (yield: 109 mg, 64%). Complex **4b** was prepared in a similar manner.

$[Pt\{Te(3\text{-}MeC_5H_3N)\}_2(PPh_3)_2]$ (5): A benzene suspension of $[PtCl_2(PPh_3)_2]$ (154 mg, 0.19 mmol) was added to a freshly prepared methanolic solution (5 mL) of $NaTe(3\text{-}MeC_5H_3N)$ [prepared from $(3\text{-}MeC_5H_3N)_2Te_2$ (85 mg, 0.19 mmol) and $NaBH_4$ (15 mg, 0.39 mmol)], and the yellow-orange mixture was stirred for 4 h. The solvents were evaporated in vacuo and the residue was washed thoroughly with hexane, diethyl ether, and acetone and then extracted with benzene (3 × 8 mL). The solution was passed through a Florisil column and concentrated to 5 mL, a few drops of acetone were added, and the solution was kept at −5°C in a freezer, giving a yellow powder (95 mg, 42%).

$[Pt_2\{Te(3\text{-}MeC_5H_3N)\}_2(dppe)_2][BPh_4]_2$ (6): An acetone suspension (20 mL) of $[PCl_2(dppe)]$ (203 mg, 0.31 mmol) was added to a freshly prepared methanolic solution (5 mL) of $NaTe(3\text{-}MeC_5H_3N)$ [prepared from $(3\text{-}MeC_5H_3N)_2Te_2$ (68 mg, 0.16 mmol) and $NaBH_4$ (12 mg, 0.32 mmol)], while stirring. After 2 h, an acetone solution (8 mL) of $NaBPh_4$ (107 mg, 0.31 mmol) was added, while stirring was continued for 3 h. The solvents were evaporated under vacuum. The yellow residue was extracted with acetone (3 × 8 mL) and passed through a Florisil column. The solution was concentrated to 5 mL and yellow crystals were obtained (207 mg, 60%).

Crystallography: X-ray data on dark green crystals of $[PdCl\{Te(3\text{-}MeC_5H_3N)\}(PPh_3)]$ (**2c**) were collected at room temperature with an Enraf−Nonius CAD-4 diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), employing the ω-2θ scan technique. Crystal data are given in Table 7. The unit cell parameters were determined from 25 reflections measured by random search routine and indexed by the method of short vectors followed by least-squares refinement. The intensity data were corrected for Lorentz polarization and absorption effects. The structure was solved using the SHELXS86[45] and refined using the SHELXL97[46] computer programs. The non-hydrogen atoms were refined anisotropically. CCDC-181928 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 7. Crystallographic and structure refinement details for $[PdCl\{Te(3\text{-}MeC_5H_3N)\}(PPh_3)]$ (**2c**)

Empirical formula	$C_{24}H_{21}ClNPPdTe$
Formula mass	623.84
Crystal size [mm]	0.3×0.3×0.2
T [K]	293(2)
λ [Å]	0.71073
Crystal system	monoclinic
Space group	$P2_1/n$
Unit cell dimensions	
a [Å]	8.607(2)
b [Å]	11.088(3)
c [Å]	24.552(5)
β [°]	98.83(2)
V [Å^3]	2315.4(9)
$\rho_{calcd.}$ [Mg·m^{-3}]	1.790
Z	4
μ [mm^{-1}]	2.231
θ for data collection/°	2.02 to 24.96
Reflections collected/unique	4349/4059 [R_{int} = 0.03−0.01]
Refinement method	Full-matrix least-squares on F^2
Absorption correction	ψ scan
Data/restraints/parameters	4059/0/263
Goodness of fit on F^2	1.104
Final $R1$, wR_2 indices	0.0376, 0.0955
R_1, wR_2 (all data)	0.0563, 0.1265
Largest diff peak and hole [e·Å^{-3}]	0.944 and −1.058

Acknowledgments

We thank Dr. J. P. Mittal and Dr. P. Raj for encouragement of this work. We are grateful to Dr. M. Sudersan, Head, Analytical Chemistry Division, for providing microanalyses of the complexes. We are thankful to Mr. S. Nath of RC&CD and Mr. A. Satpati of ACD for recording the UV/Vis spectra and cyclic voltammograms.

Selective Synthesis of *N*-Methylanilinooligosilanes

Uwe Böhme,*[a] Betty Günther,[a] and Ben Rittmeister[a]

Keywords: Amides / Silanes / Disilanes / Aminosilanes / Stereochemistry

Defined crystalline amino-substituted organosilanes were prepared by reaction of *N*-methylaniline with 1,1,2,2-tetrachloro-1,2-dimethyldisilane. It is possible to selectively prepare mono-, di-, and triaminodisilanes depending on the reactant ratio. The X-ray structure analyses of 1,2-dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (**2**), 1-chloro-1,2-dimethyl-1,2,2-tris(*N*-methylanilino)disilane (**3**), and 1,2-dimethyl-1,1,2,2-tetrakis(*N*-methylanilino)disilane (**4**) were performed. The absolute structure of **2** was determined by crystallographic methods. Compound **2** is a useful reagent for preparing a variety of other aminoorganodisilanes like $[Me(PhMeN)_2Si]_2$ (**4**), $[FMe(PhMeN)Si]_2$ (**12**), [(PhCC)-Me(PhMeN)Si]$_2$ (**13**), $[(p\text{-}MeC_6H_4)Me(PhMeN)Si]_2$ (**14**), and $[(PhCH_2)Me(PhMeN)Si]_2$ (**15**). Other chloroorganooligosilanes also react with *N*-methylaniline to give PhMeN[Si-$Me_2]_2Cl$ (**5**), PhMeN$[SiMe_2]_2$NMePh (**6**), Cl$[SiMe_2]_3$NMePh (**7**), PhMeN$[SiMe_2]_3$NMePh (**8**), Cl$[SiMe_2]_4$NMePh (**9**), MeClSi[Si(NMePh)ClMe]$_2$ (**10**), and MeSi[Si(NMePh)-ClMe]$_3$ (**11**).

Introduction

Functionally substituted di- and oligosilanes are valuable building blocks for preparing organopolysilanes and silicon-containing materials.[1] A good method for preparing such compounds is the reductive coupling of chloroorganosilanes with alkaline metals[2] and subsequent cleavage of aromatic substituents with gaseous hydrogen chloride and $AlCl_3$[3] or trifluoromethylsulfonic acid.[4] The preparation of chloro(methyl)oligosilanes by halogen/methyl exchange using Me_3SiCl and $AlCl_3$ is another frequently used method.[5]

The reductive coupling of chloro(diethylamino)organosilanes is a convenient new way to prepare functionalized oligosilanes. The diethylamino group in the resulting oligosilanes can be replaced, under very mild conditions, by various reagents such as alcohols or hydrogen chloride. A number of amino(chloro)organooligosilanes have been prepared, but these are often oils and it is very difficult to separate pure compounds from the mixture of liquid products.[6,7] Some X-ray structures of amino(organo)oligosilanes without chlorine substituents are known.[8] Until now very little structural data on amino(chloro)organooligosilanes has been available.[9]

We have developed reliable synthetic pathways to a variety of crystalline amino(chloro)methyloligosilanes. A number of different aromatic diorganoamines were tested for their reactivity with 1,1,2,2-tetrachloro-1,2-dimethyldisilane.[9] The large flat aromatic groups should help to obtain crystalline products. The products obtained with *N*-methylaniline are soluble in aprotic organic solvents and are extremely crystalline.

Results and Discussion

The reaction of *N*-methylaniline with 1,1,2,2-tetrachloro-1,2-dimethyldisilane in the presence of excess NEt_3 gives mono-, di-, and triaminodisilanes depending on the reactant ratio. 1,1,2-Trichloro-2-(*N*-methylanilino)-1,2-dimethyldisilane (**1**) was obtained as a colorless oil. According to the ^{29}Si NMR spectrum, the product contains about 20% impurities, which were identified as **2** and 1,1,2,2-tetrachloro-1,2-dimethyldisilane. Because of these impurities we did not use this compound in further reactions. 1,2-Dichloro-1,2-bis(*N*-methylanilino)-1,2-dimethyldisilane (**2**) was isolated as an ivory-colored solid. The crude product contains traces of **3** and was recrystallized from a pentane/diethyl ether mixture (5:1); **3** was synthesized by the same experimental procedure and obtained as a white crystalline solid (Scheme 1).

The ^{29}Si NMR spectra of **2**, **3**, and **4** have some interesting features. The tetraamide **4** shows one signal at $\delta = -7.53$ ppm for the spectroscopically equivalent silicon atoms; **3** has two chemically and spectroscopically different silicon atoms. The (*R*) and (*S*) isomers have identical signals in the spectrum. Thus, two signals with an intensity ratio of 1:1 are observed at $\delta = -7.94$ and 6.27 ppm. The silicon atoms in **2** are chemically equivalent, and chiral. Two signals are expected, one for the racemate [(*R*,*R*) and (*S*,*S*) isomer] and one for the *meso* form and there are indeed two such signals at $\delta = 3.66$ and 1.37 ppm. The intensity ratio

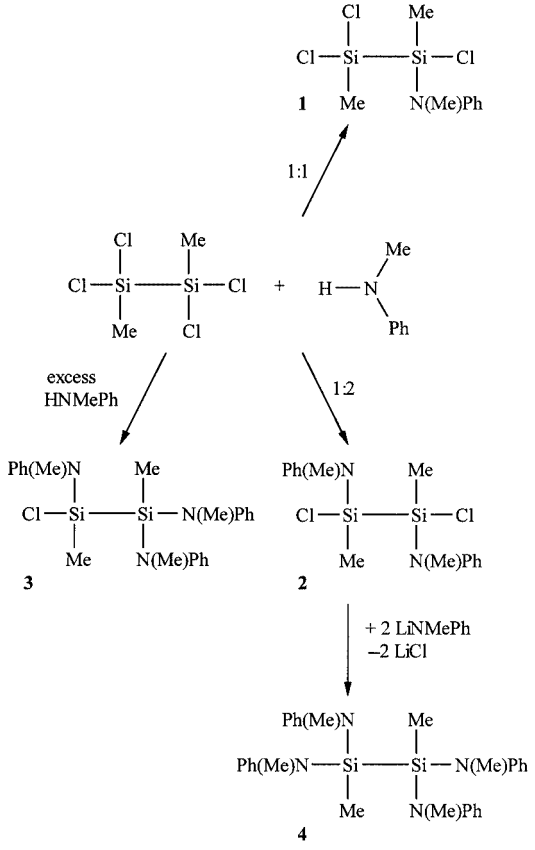


Scheme 1

of the two signals is always between 5:1 and 6:1. We assume that the main product is the racemate. It is rather unusual that one isomer is formed preferentially over another. Investigations concerning the isomerization of diastereomers of $(FArMeSi)_2$ have shown that a *rac*/*meso* mixture of 1:1 was obtained during the preparation process.[10] Detailed experiments regarding the isomerization processes of this compound have shown that the enrichment of the *meso* form proceeds by crystallization-induced asymmetric transformation (AT).[11]

We investigated the quantitative composition of the crude product of **2** by in situ NMR spectroscopy and found a relative intensity ratio of 5.5:1. In further experiments, we used NMR spectroscopy to monitor the course of the reaction for several weeks. We prepared two reaction batches, one with pentane and the other with DME as the solvent. In both experiments, we found no substantial change in the relative product composition! The relative product ratio was always between 5.5:1 and 6:1. Furthermore, samples of **2** can be dissolved and recrystallized without change in the composition of the diastereomers. In summary, we found no evidence for a crystallization-induced asymmetric transformation of **2**.

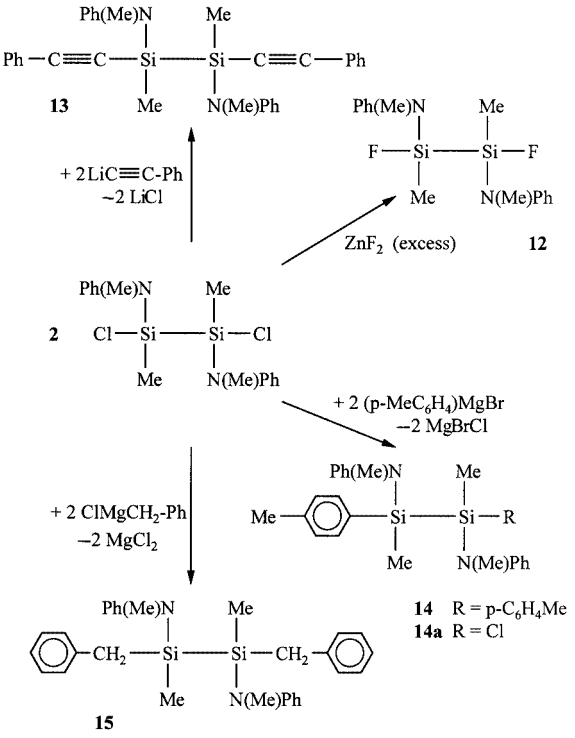
Quantum chemical calculations on the diastereomers of **2** show that the *rac* form has a substantially lower total energy. The energy difference between the (*R*,*R*) and the *meso* form is 18 kJ/mol at the B3LYP/6-31G* level of theory.[12] This suggests a preferred formation of the racemate during the synthesis of **2**.

In order to explore further the available range of *N*-methylanilinosilanes, we treated different oligomeric chloro(organo)silanes with *N*-methylaniline. It was possible to selectively obtain mono- and disubstituted aminosilanes (**5**, **7** and **6**, **8**) from $Cl[SiMe_2]_nCl$. The reactivity of the homologous α,ω-dichlorooligosilanes decreases with increasing chain length. Therefore, the tetrasilane $Cl[SiMe_2]_4Cl$ gave only the monosubstituted product $Cl[SiMe_2]_4NMePh$ (**9**). The branched chlorosilanes $MeClSi(SiCl_2Me)_2$ and $MeSi(SiCl_2Me)_3$ were prepared by disproportionation of 1,1,2,2-tetrachloro-1,2-dimethyldisilane.[13] The reaction of these compounds with *N*-methylaniline in different stoichiometric ratios gave product mixtures. We succeeded in obtaining defined reaction products only when an excess of *N*-methylaniline was used. One chlorine atom remains at each silicon atom and the products formed under these conditions were characterized as $MeClSi[Si(NMePh)ClMe]_2$ (**10**) and $MeSi[Si(NMePh)ClMe]_3$ (**11**). It was not possible to replace all the chlorine atoms in these chlorine-rich organosilanes with the *N*-methylanilido group. Although, it might be possible to replace the last chlorine atoms when using the corresponding lithium amide. The compounds **5**−**11** were characterized by NMR spectroscopy (see Exp. Sect.).

The reactivity of **2** and **3** was investigated: 1-chloro-1,2-dimethyl-1,2,2-tris(*N*-methylanilino)disilane (**3**) is rather inert with respect to nucleophilic reagents. The compound does not react with diorganoamines, such as $HNEt_2$ and Grignard reagents. The treatment of **3** with alkyllithium compounds yields mainly unchanged starting material. Aside from this, small amounts of reaction products were detected by NMR spectroscopy. It was not possible to isolate pure compounds by recrystallization of the product mixtures. ^{29}Si NMR spectroscopy identified one of the compounds in these mixtures as 1,2-dimethyl-1,1,2,2-tetrakis(*N*-methylanilino)disilane (**4**), which was also synthesized by an alternative method, see below; **4** was formed in these reactions, probably by transamination with the strong nucleophilic alkyllithium compound. The alkyllithium compound might form in situ lithium *N*-methylanilide which reacts with **3**.

In contrast to **3**, 1,2-dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (**2**) reacts with nucleophiles with the substitution of both chlorine atoms in a straightforward reaction (see Scheme 2). It was possible to prepare a variety of derivatives with different nucleophiles, such as lithium amides (**4**), zinc fluoride (**12**), alkynyllithium compounds (**13**), and Grignard reagents (**14** and **15**; see Scheme 2). Since the *N*-methylanilino group remains unaffected in these reactions, it acts as a valuable protecting group.

1,2-Difluoro-1,2-dimethyl-1,2-bis(*N*-methylanilino)-disilane (**12**) was prepared by the reaction of excess of ZnF_2 with **2**. The reaction between the dissolved amino(chloro)silane and the solid zinc fluoride took about 6 d. The progress of the reaction was monitored by NMR spectroscopy. A mixture of ClMe(PhMeN)SiSi(NMePh)MeF and



Scheme 2

$[FMe(PhMeN)Si]_2$ (**12**) was formed during the first 48 h. This mixture slowly converted to **12** in the presence of excess ZnF_2. Signals for the diastereomers of **12** (*rac* and *meso*) were observed in the reaction mixture but only one diastereomer was obtained after the workup procedure. This suggests that the solubility for both diastereomers is very different. It might also be caused by crystallization-induced asymmetric transformation.

$[(p\text{-}MeC_6H_4)Me(PhMeN)Si]_2$ (**14**) was obtained as a mixture with the monosubstituted product $(p\text{-}MeC_6H_4)$-Me(PhMeN)SiSi(NMePh)MeCl (**14a**) (ratio **14**/**14a** = 2:1). The reaction of **2** with excess *p*-tolylmagnesium bromide gave a slightly different product ratio of 2.2:1, but this synthesis did not enable pure **14** to be obtained. The compounds $[(PhCC)Me(PhMeN)Si]_2$ (**13**), $[(p\text{-}MeC_6H_4)$-$Me(PhMeN)Si]_2$ (**14**), and $[(PhCH_2)Me(PhMeN)Si]_2$ (**15**) were obtained as a mixture of diastereomers. Integration of the MeSi signals in the ^1H NMR spectra provides the relative ratio of *rac*/*meso* isomers; **13** and **15** have a ratio of about 1:1, and **14** a ratio of 1.5:1. This means that the substitution reactions with the organometallic reagents are not stereoselective.

Crystal and Molecular Structures

The solid-state structures of **2**−**4** were determined from the data obtained by X-ray diffraction. Details of the structure determinations and refinement are summarized in Table 3. The X-ray structure analyses confirm the structures of the compounds **2**−**4** as proposed in Scheme 1; **3** crystallizes in the space group $P2_1/n$ as a racemate and **4** crystallizes in the space group $P2_1/a$; **2** was obtained as separated pure enantiomorphic crystals that crystallize in the noncentrosymmetric space group $C222_1$. The structure of one crystalline modification was determined. Only the half-molecule, ClSi(NMePh)Me, is found in the asymmetric unit, so the unit cell only contains four molecules. The second part of the molecule is generated by symmetry elements. Three times more reflections were collected than normally necessary for an orthorhombic space group, in order to determine the absolute configuration through the anomalous scattering effect. Refinement of the Flack enantiopole parameter led to a value of ca. 0, thus confirming the absolute structure of the crystal.[14] The molecular structure of **2** is shown in Figure 1. The silicon atom has an (*R*) configuration. The fact that both silicon atoms have the same configuration means that, in the crystal under examination, the molecules have an (*R*,*R*) configuration. There are a number of chiral silicon compounds reported in the literature.[15,16] Diastereomers have mainly been prepared with one chiral silicon atom and one chiral organic group such as the (−)-menthoxy group. Only one diastereomeric dichlorodisilane with two chiral silicon atoms was found in the Cambridge Crystallographic Database.[17] The value of optical rotation was estimated to be $\alpha = 377°$ (20 °C, 302 nm, *n*-pentane) from a randomly chosen crystal of **2**.

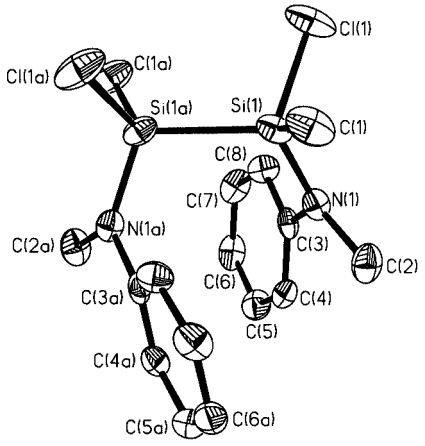


Figure 1. Molecular structure of 1,2-dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (**2**) with 50% thermal ellipsoids; hydrogen atoms are omitted for clarity

The compounds **2** (Figure 1), **3** (Figure 2), and **4** (Figure 3) are homologous amino(methyl)disilanes with an increasing number of *N*-methylanilino groups bonded to the silicon atoms. The increasing degree of substitution with *N*-methylanilino groups causes some changes in the molecular structure of these three compounds. The silicon−silicon bond length is 2.375 Å in **4**, which is an increase in length from that seen in **2**. The Si−N bonds in **4** (1.754 Å, average value) are also longer than those in **2** (1.718 Å) and **3** (1.740 Å). The Si−C bond is slightly shorter in **2** than it is in **3** and **4**. The torsion angle C−Si−Si−C has similar values for **2** (141.9°) and **3** (−130.4°);[18] **4** has a *transoid* conformation around this torsion angle which is 173.6°. All bond lengths are in the normal range for covalent bonds, the silicon

atoms are tetrahedrally coordinated and no significant intermolecular interactions are observed.

Conclusions

The ease of preparing a variety of structurally different linear and branched chloro(methyl)(*N*-methylanilino)oligosilanes was demonstrated throughout this work. We were able to show that the *N*-methylanilino group is a highly useful substituent for chloro(organo)silanes in two respects. First, it is possible to obtain crystalline amino(organo)disilanes with this substituent. Second, the *N*-methylanilino group acts as a protecting group in further substitution reactions. With this strategy we were able to prepare a variety of amino(organo)disilanes starting from 1,2-dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (**2**).

Experimental Section

General: All preparative work and handling of the samples was carried out under Ar using dry glassware and dry solvents. Pentane was freshly distilled from $LiAlH_4$. Triethylamine was refluxed over sodium/benzophenone until the color of the solution was violet, then freshly distilled prior to use. Zinc fluoride was dried 6 h in vacuo to remove all traces of moisture. Commercially available *N*-methylaniline was distilled prior to use from KOH pellets. 1,1,2,2-Tetrachloro-1,2-dimethyldisilane was prepared according to a well-known procedure.[19] Melting points were recorded in capillary tubes and are uncorrected. NMR spectra were recorded with a Bruker DPX 400 with $SiMe_4$ (TMS) as internal standard at 25 °C with 400.13 MHz for ^{1}H NMR, 100.62 MHz for ^{13}C NMR, and 79.49 MHz for ^{29}Si NMR spectroscopy. Signals are noted as s (singlet), d (doublet), t (triplet), q (quadruplet), m (multiplet), and dd (doublet, doublet). The Si-Si coupling constants have been calculated from the shift differences of the Si satellites in the ^{29}Si NMR spectrum. Elemental analyses were performed with a CHN-O-RAPID (Hanau). The carbon content values were lower than expected due to the formation of silicon carbide. GC-MS spectra were obtained with a 70 eV Hewlett Packard 5890 Series II/5971 Series GC/MS system.

1,1,2-Trichloro-1,2-dimethyl-2-(*N*-methylanilino)disilane (1): *N*-methylaniline (2.4 g, 23 mmol) was added to a solution of 1,1,2,2-tetrachloro-1,2-dimethyldisilane (5.2 g, 23 mmol) and triethylamine (4.7 g, 46 mmol) in pentane (200 mL). The mixture was stirred for 140 h at room temperature. A white precipitate formed after a few hours. The resulting suspension was filtered to remove the resulting Et_3NHCl. The solvent was removed in vacuo and the resulting oily product was dried in vacuo. The purity of the product was 80%, estimated by ^{29}Si NMR spectroscopy. About 15% 1,2-dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (**2**) and 5% 1,1,2,2-tetrachloro-1,2-dimethyldisilane were detected as impurities. NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.65 ppm (s, 3 H, MeSiClN), 0.77 (s, 3 H, $MeSiCl_2$), 3.07 (s, 3 H, MeN), 6.4−7.48 (m, 5 H, Ph). ^{13}C: δ = 1.29 ppm ($MeSiCl_2$), 6.61 (MeSiClN), 37.84 (MeN), 123.40, 123.85, 129.30 (*o*-, *m*-, *p*-Ph), 148.52 (*i*-Ph). ^{29}Si: δ = −0.6 ppm (MeSiClN), 21.4 ($MeSiCl_2$).

1,2-Dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (2): Triethylamine (14 mL, 10.1 g, 100 mmol) was added to a solution of 1,1,2,2-tetrachloro-1,2-dimethyldisilane (6.0 g, 26 mmol) in pentane (150 mL). *N*-Methylaniline (5.7 mL, 5.6 g, 52 mmol) was mixed

with pentane (60 mL) and added dropwise over a period of 1 h to the reaction mixture. The reaction mixture became warm, and a voluminous white precipitate formed. The suspension was stirred at room temperature for 10 h, and then the precipitate consisting of Et_3NHCl was removed by filtration. The volume of the filtrate was reduced in vacuo to ca. 100 mL and left overnight at 5 °C. A white precipitate formed that consisted mainly of Et_3NHCl. The precipitate was removed by filtration and the filtrate was concentrated to give **2** (6.4 g , 67% yield) as a crystalline product. The crude product contained traces of **3** and was recrystallized from a pentane/diethyl ether (5:1) mixture. Ivory-colored crystals (5.9 g, 61.5%) resulted with m.p. 38 °C. $[\alpha]_\lambda$ = 377° (0.165 g/100 mL *n*-pentane, 20 °C, 302 nm). NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.51 ppm (s, SiMe, *meso*), 0.77 (s, SiMe, *rac*), 2.67 (s, NMe, *rac*), 3.0 (s, NMe, *meso*), 6.83−7.23 (m, Ph). ^{13}C: δ = 3.08 ppm (SiMe, *meso*), 3.57 (SiMe, *rac*), 36.43 (NMe, *rac*), 37.86 (NMe, *meso*), 120.95, 122.19, 123.01, 123.10, 128.83, 129.0, 148.99, 149.18 (Ph). ^{29}Si: δ = 3.66 ppm (*rac*), 1.37 (*meso*). MS: *m*/*z* = 368 [M^+], 262 [M^+ − NMePh], 184 (98) [M^+ − NMePh − HCl], 149 (100%) [Si(NMePh)Me^+]. $C_{16}H_{22}Cl_2N_2Si_2$ (369.45): calcd. C 52.02, H 6.00, N 7.58; found calcd. C 51.89, H 6.08, N 7.54.

1-Chloro-1,2-dimethyl-1,2,2-tris(*N*-methylanilino)disilane (3): To synthesize compound **3**, the same approach was applied as described for **2** using 1,1,2,2-tetrachloro-1,2-dimethyldisilane (5.47 g, 24 mmol), triethylamine (16.7 mL, 12.1 g, 120 mmol) and *N*-methylaniline (13 mL, 12.8 g, 120 mmol). White crystals (7.6 g, 72% yield), m.p. 76 °C. NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.33 ppm (s, 3 H, SiMe), 0.72 (s, 3 H, SiMe), 2.52 (s, 3 H, NMe), 2.57 (s, 3 H, NMe), 2.91 (s, 3 H, NMe), 6.72−7.27 (m, 18 H, Ph). ^{13}C: δ = 1.47, 4.71 ppm (SiMe); 30.72, 34.50, 36.50 (NMe); 112.41, 117.09, 117.25, 118.67, 119.51, 120.06, 120.87, 121.07, 121.54, 128.57, 128.64, 128.83, 149.57, 149.66, 149.79 (Ph). ^{29}Si: δ = −7.94 ppm [SiMe(NMePh)$_2$], 6.27 [SiMe(NMePh)Cl], $^1J_{Si\text{-}Si}$ = 152 Hz. MS: *m*/*z* = 439 [M^+], 255 (100%) [Si(NMePh)$_2$$Me^+$], 226 [PhSi(NMePh)$Me^+$], 184 [ClSi(NMePh)$Me^+$]. $C_{23}H_{30}ClN_3Si_2$ (440.14): calcd. C 62.76, H 6.87, N 9.55; found calcd. C 62.24, H 7.53, N 9.24.

1,2-Dimethyl-1,1,2,2-tetrakis(*N*-methylanilino)disilane (4): A solution of lithium *N*-methylanilide (1.2 g, 10.3 mmol) in diethyl ether (20 mL) was added to a solution of 1,2-dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (1.4 g, 3.7 mmol) at 0 °C. A white precipitate was formed after 4 h. The solution was stirred for an additional 24 h at room temperature. Afterwards, the solvent was removed completely in vacuo. The remaining oily residue was extracted with diethyl ether and the resulting suspension was filtered. The solvent was partially removed in vacuo and the remaining solution was cooled to 5 °C to yield the product as a white crystalline solid. The product contained crystals that were suitable for X-ray structure analysis. Yield: 1.08 g (57.2%), m.p. 116−118 °C NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.48 ppm (s, 6 H), 2.74 (s, 12 H), 7.11−7.16 (m, 20 H). ^{13}C: δ = 2.31 ppm (MeSi), 36.09 (MeN), 119.18, 120.30, 129.19 (*o*-, *m*-, *p*-Ph), 150.4 (*i*-Ph). ^{29}Si: δ = −7.53 ppm. $C_{30}H_{38}N_4Si_2$ (510.54): calcd. C 70.52, H 7.50, N 10.98; found calcd. C 70.15, H 7.38, N 9.95.

1-Chloro-1,1,2,2-tetramethyl-2-(*N*-methylanilino)disilane (5) and 1,1,2,2-Tetramethyl-1,2-bis(*N*-methylanilino)disilane (6): A solution of *N*-methylaniline (15.0 g, 140 mmol) in pentane (50 mL) was added dropwise to a solution of 1,2-dichloro-1,1,2,2-tetramethyldisilane (8.5 g, 45 mmol) and triethylamine (14.2 g, 140 mmol) in pentane (100 mL). A voluminous white precipitate formed during this procedure. The suspension was stirred at reflux temperature for 28 h and for a further 60 h at room temperature. The suspension was then filtered, the solvent was removed in vacuo and the remaining residue was distilled under high vacuum to give **5** and **6** in separated fractions. 1st fraction, b.p. (0.025 Torr) 56−59 °C, 1-chloro-1,1,2,2-tetramethyl-2-(*N*-methylanilino)disilane (**5**); 2nd fraction, b.p. (0.025 Torr) 66−70 °C, 1-chloro-1,1,2,2-tetramethyl-2-(*N*-methylanilino)disilane (**5**); 3rd fraction, b.p. (0.025 Torr) 129−137 °C, 1,1,2,2-tetramethyl-1,2-bis(*N*-methylanilino)disilane (**6**). Compound **5**: Colorless oil, fractions 1 and 2 together are 3.6 g (31.1% yield, 98% purity). NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.40 ppm (s, 6 H, MeSiN), 0.46 (s, 6 H, MeSiCl), 2.93 (s, 3 H, MeN), 6.81−7.21 (m, 5 H, Ph). ^{13}C: δ = −0.30 ppm (MeSiCl), 2.95 (MeSiN), 35.81 (MeN), 117.85, 119.24, 128.86 (*o*-, *p*-, *m*-Ph), 150.98 (*i*-Ph). ^{29}Si: δ = −1.9 ppm (SiN), 20.9 (SiCl); $^1J_{Si\text{-}Si}$ = 106 Hz. Compound **6**: Pale yellow oil, yield: 3.8 g (25.7% yield, 87% purity). The product contains 13% of **5**. NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.34 ppm (s, 12 H, MeSi), 2.72 (s, 6 H, MeN), 6.71−7.16 (m, 10 H, Ph). ^{13}C: δ = 1.07 ppm (MeSi), 34.99 (MeN), 116.65, 117.99, 128.59 (*o*-, *p*-, *m*-Ph), 151.09 (*i*-Ph). ^{29}Si: δ = −1.9 ppm. MS: 164 (100%) [$Me_2SiNMePh^+$], 59 [Me_2SiH^+], 222 [$Me_4Si_2NMePh^+$], 328 [M^+].

General Procedure for Preparing the Chloro(methyl)oligosilanes 7−11: An excess of triethylamine (1.5 mol per mol of reactive chlorine) was added to a solution of the chloro(methyl)oligosilane (5 mmol) in 100 mL of pentane. The stoichiometric amount of *N*-methylaniline (see Table 2) was mixed with pentane and added dropwise to the reaction mixture. A voluminous white precipitate of triethylammonium chloride was formed. The suspension was stirred at room temperature for at least 10 h. The solvent and the excess triethylamine was distilled off at reduced pressure. The remaining solid was extracted with pentane and filtered. The solvent

Table 2. Reaction products of oligomeric chloro(methyl)oligosilanes with *N*-methylaniline in the presence of excess triethylamine

Chlorosilane	Ratio chlorosilane/HNMePh	Product
$Cl_2Si(Me)SiMeCl_2$	1:1	$Cl_2MeSiSi(NMePh)ClMe$ (**1**)
$Cl_2Si(M)eSiMeCl_2$	1:2	$[ClMe(PhMeN)Si]_2$ (**2**)

$Cl[SiMe_2]_3Cl$	1:1	$Cl[SiMe_2]_3NMePh$ (**7**)
$Cl[SiMe_2]_3Cl$	1:2	$PhMeN[SiMe_2]_3NMePh$ (**8**)
$Cl[SiMe_2]_4Cl$	1:2	$Cl[SiMe_2]_4NMePh$ (**9**)
$MeClSi(SiCl_2Me)_2$	excess HNMePh	$MeClSi[Si(NMePh)ClMe]_2$ (**10**)
$MeSi(SiCl_2Me)_3$	excess HNMePh	$MeSi[Si(NMePh)ClMe]_3$ (**11**)

was partially removed from the filtrate in a vacuum and the concentrated solution was left for several days at 5 °C; **9**, **10**, and **11** formed a white precipitate which was isolated by filtration and dried in vacuo; **7** and **8** did not crystallize and were therefore purified by vacuum distillation.

Cl[SiMe$_2$]$_3$NMePh (7): Colorless oil, yield: 340 mg (22%), b.p.$_{0.01Torr}$ 97 °C. NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.16 ppm (s, 6 H, (PhMeNSiMe$_2$Si*Me*$_2$), 0.28 (s, 6 H, (PhMeNSi*Me*$_2$SiMe$_2$), 0.59 (s, 6 H,ClSi*Me*$_2$), 2.79 (s, 6 H, Ph*Me*N), 6.83−7.24 (m, 5 H, Ph). ^{13}C: δ = −1.6 ppm (PhMeNSiMe$_2$Si*Me*$_2$), 0.8 (PhMeNSi*Me*$_2$-SiMe$_2$), 5.2 (ClSi*Me*$_2$), 37.3 (Ph*Me*N), 119.2.120.1.127.9, 149.8 (Ph). ^{29}Si: δ = 25.9 ppm, 2.4, −45.2.

PhMeN[SiMe$_2$]$_3$NMePh (8): Yellow oil, yield: 600 mg (31%), b.p.$_{0.01Torr}$ 128 °C. NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.16 ppm [s, 6 H, (PhMeNSiMe$_2$)$_2$Si*Me*$_2$], 0.28 [s, 12 H, (PhMeNSi*Me*$_2$)$_2$-SiMe$_2$], 2.82 (s, 6 H, Ph*Me*N), 6.76−7.19 (m, 10 H, Ph). ^{13}C: δ = −3.8 ppm [(PhMeNSiMe$_2$)$_2$Si*Me*$_2$], 0.7 [(PhMeNSi*Me*$_2$)$_2$SiMe$_2$], 35.6 (Ph*Me*N), 117.1, 118.1.128.6, 151.3 (Ph). ^{29}Si: δ = 3.0 ppm, −47.6; $^1J_{Si\text{-}Si}$ = 80 Hz.

Cl[SiMe$_2$]$_4$NMePh (9): Pale yellow oil, yield: 880 mg (47%). NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.23 ppm (s, 6 H, Si*Me*$_2$SiMe$_2$N-MePh), 0.34 (s, 6 H, ClSiMe$_2$Si*Me*$_2$), 0.42 (s, 6 H, Si*Me*$_2$NMePh), 0.61 (s, 6 H, ClSi*Me*$_2$), 2.92 (s, 3 H, N*Me*Ph), 6.96−7.31 (m, 5 H, Ph). ^{13}C: δ = 2.3 ppm (Si*Me*$_2$SiMe$_2$NMePh), 3.4 (ClSiMe$_2$Si*Me*$_2$), 3.9 (Si*Me*$_2$NMePh), 6.1 (ClSi*Me*$_2$), 36.3 (N*Me*Ph), 118.3, 122.4, 123.3, 148.7 (Ph). ^{29}Si: δ = 26.4, 3.3, −41.3, −43.9 ppm.

MeClSi[Si(NMePh)ClMe]$_2$ (10): Yellow oil, yield: 510 mg (23%). NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.37 ppm {s, 6 H, MeClSi[Si-(NMePh)Cl*Me*]$_2$}, 0.58 {s, 3 H, *Me*ClSi[Si(NMePh)ClMe]$_2$}, 2.73, 2.74, 2.82, 2.86, {s, 6 H, MeClSi[Si(N*Me*Ph)ClMe]$_2$}, 6.54−7.09 (m, 10 H, Ph). ^{13}C: δ = −0.8 ppm {*Me*ClSi[Si(NMePh)ClMe]$_2$}, 6.3 {MeClSi[Si(NMePh)Cl*Me*]$_2$}, 36.9, 37.1, 37.7, 37.9 {MeClSi[Si(N*Me*Ph)ClMe]$_2$, diastereomers}, 122.9, 123.6, 128.6, 128.7, 129.1, 129.3, 149.2 (Ph, diastereomers). ^{29}Si: δ = −4.3 ppm, 3.0; $^1J_{Si\text{-}Si}$ = 58 Hz.

MeSi[Si(NMePh)ClMe]$_3$ (11): Yellow oil, yield: 2.17 g (73%). NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.64 ppm, 0.5 {s, 9 H, MeSi-[Si(NMePh)Cl*Me*]$_3$, diastereomers}, 0.50 {s, 3 H, *Me*Si[Si-(NMePh)ClMe]$_3$, diastereomers}, 2.93, 2.96.2.97.3.01 {s, 9 H, MeSi[Si(N*Me*Ph)ClMe]$_3$, diastereomers} 6.99-7.26 (m, 15 H, Ph). ^{13}C: δ = −7.6 ppm, −7.4 {*Me*Si[Si(NMePh)ClMe]$_3$, diastereomers}, 5.2, 5.5 {MeSi[Si(NMePh)Cl*Me*]$_3$, diastereomers}, 38.1, 38.4, 38.7, 38.8 {MeSi[Si(N*Me*Ph)ClMe]$_3$, diastereomers}, 122.2, 122.5, 122.8.122.9, 123.0, 123.4, 128.9, 129.0, 148.8, 148.9, (Ph, diastereomers). ^{29}Si: δ = −73.3 ppm, −72.9, 12.45, 12.62, 12.76, 12.80 ($^1J_{Si\text{-}Si}$ = 88 Hz, diastereomers).

1,2-Difluoro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (12): A suspension of 1,2-dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)-disilane (**2**) (3.9 g, 10.6 mmol) and zinc fluoride (11.4 g, 110 mmol) in DME (50 mL) was stirred for 150 h at room temperature. Afterwards, the solvent was removed under reduced pressure. The remaining oily residue was extracted with pentane, filtered, and cooled to 5 °C. A white crystalline solid was formed. The product was isolated by filtration, washed with pentane, and dried in vacuo to yield 2.55 g (71.5%) white crystalline powder with m.p. 89−90 °C. NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.48 ppm (dd, 6 H, MeSi, $^3J_{H\text{-}F}$ = 3 Hz), 2.44 (d, 6 H, MeN), 6.72−7.23 (10 H, Ph). ^{13}C: δ = 0.43 ppm (MeSi), 43.13 (MeN), 118.16, 20.88, 128.88 (*o*-, *m*-, *p*-Ph), 149.41 (*i*-Ph). ^{29}Si: δ = 2.45 ppm (dd, $^1J_{Si\text{-}F}$ = 326, $^2J_{Si\text{-}F}$ = 63 Hz). $C_{16}H_{22}F_2N_2Si_2$ (336.54): calcd. C 57.10, H 6.59, N 8.32; found C 57.71, H 6.98, N 7.96.

1,2-Dimethyl-1,2-bis(*N*-methylanilino)-1,2-bis(phenylethynyl)-disilane (13): A solution of lithium phenylacetylide (0.17 g, 17.0 mmol) in diethyl ether (30 mL) was added dropwise to a solution of 1,2-dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (**2**) (3.15 g, 8.5 mmol) in DME (80 mL) at 0 °C. A white precipitate formed immediately. The suspension was stirred for an additional 24 h. The solvent was then removed under reduced pressure. The remaining oily residue was extracted with pentane, filtered and the clear filtrate was stored in the refrigerator. The cooling of the solution led to a phase separation. The solvent was removed completely in vacuo and the product was isolated as a pale yellow oil, yield: 2.72 g (64%). NMR ($CDCl_3$, 395 K, TMS) ^{1}H: δ = 0.65 ppm, 0.72 (6 H, MeSi, *rac*/*meso* = 1:1), 2.73, 2.90 (6 H, MeN, *rac*, *meso*); 6.76−7.47 (m, 10 H, Ph). ^{13}C: δ = 0.43 ppm (MeSi), 35.2, 35.7 (MeN, *rac*, *meso*), 91.3, 91.6 (SiC*C*Ph, *rac*, *meso*), 109.2 (Si*C*CPh), 116.7, 117.0, 128.1, 128.2, 128.48, 128.53, 128.6, 128.7, 131.8 (*o*-, *m*-, *p*-Ph, *rac*, *meso*), 122.2 (*i*-CC*Ph*), 150.0 (*i*-PhN). ^{29}Si: δ = −25.78, −25.82 ppm (*rac*, *meso*).

1,2-Dimethyl-1,2-bis(*N*-methylanilino)-1,2-bis(*p*-tolyl)disilane (14) and 1-Chloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)-2-(*p*-tolyl)disilane (14a): A solution of *p*-tolylmagnesium bromide (3.6 g, 18.6 mmol) in THF (20 mL) was added slowly to a solution of 1,2-dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (**2**) (3.4 g, 9.3 mmol) in DME (60 mL) at 0 °C. The resulting mixture was stirred for 24 h at room temperature. The solvent was removed completely in vacuo. The residue was extracted with a pentane/DME mixture (3:1). The resulting suspension was filtered and the solvent was partially removed in vacuo. The addition of a small amount diethyl ether and cooling to −16 °C gave a white precipitate, which was isolated by filtration and dried in vacuo. The product consisted of a mixture of **14** and **14a** in a product ratio of 2:1. It was not possible to separate both products by fractional crystallization. 1,2-Dimethyl-1,2-bis(*N*-methylanilino)-1,2-bis(*p*-tolyl)disilane (**14**): ^{29}Si NMR ($CDCl_3$, 25 °C, TMS): δ = −7.7 ppm, −7.5 (*rac*/*meso* = 1.5:1). 1-Chloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)-2-(*p*-tolyl)disilane (**14a**): ^{29}Si NMR ($CDCl_3$, 25 °C, TMS): δ = −9.6 ppm (MeSiTolN), 8.5 (MeSiClN); $^1J_{Si\text{-}Si}$ = 20 Hz (only one diastereomer was detected).

1,2-Dibenzyl-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (15): A solution of benzylmagnesium chloride (3.2 g, 21.2 mmol) in diethyl ether (17 mL) was added dropwise to a solution of 1,2-dichloro-1,2-dimethyl-1,2-bis(*N*-methylanilino)disilane (**2**) (3.9 g, 10.6 mmol) in DME (80 mL) at 0 °C. The solution was stirred for an additional 24 h. Afterwards, the solvent was removed under reduced pressure. The remaining residue was extracted with pentane, filtered and the solvent was partially removed in vacuo. Storage of the concentrated solution at −16 °C yielded a white precipitate which was separated by filtration, washed with cold pentane and dried in vacuo; yield: 1.8 g (35.4%), m.p. 98−100 °C. NMR ($CDCl_3$, 25 °C, TMS): ^{1}H: δ = 0.17 ppm, 0.25 (6 H, MeSi, *rac*/*meso* = 1:1), 2.10, 2.13, 2.64, 2.67 (4 H, CH_2Ph, *rac*, *meso*), 2.45, 2.54 (6 H, MeN, *rac*, *meso*), 6.68−7.21 (m, 10 H, Ph). ^{13}C: δ = −1.8 ppm, −1.4 (MeSi, *rac*, *meso*), 27.1, 27.5 (CH_2, *rac*, *meso*), 35.6 (MeN), 117.3, 117.5, 128.07, 128.12, 128.52, 128.58 (*o*-, *m*-, *p*-CH_2*Ph*, *rac*, *meso*), 118.6, 124.3, 128.8 (*o*-, *m*-, *p*-*Ph*N), 138.6 (*i*-CH_2*Ph*), 151.0 (*i*-PhN). ^{29}Si: δ = −3.4 ppm, −4.3 (*rac*, *meso*). $C_{30}H_{36}N_2Si_2$ (480.80): calcd. C 74.94, H 7.55, N 5.83; found C 74.35, H 7.48, N 5.46.

X-ray Crystal Structure Determinations: Suitable single crystals were mounted on glass fibers under paraffin oil and transferred to the diffractometer. Diffraction measurements were made with an Enraf−Nonius CAD-4 diffractometer. Further details on crystal data and structure determination are summarized in Table 3.

Synthesis, X-ray Structure and Properties of a Trinuclear Mixed-Valence Co^{III}-Co^{II}-Co^{III} Complex with Carboxamido N and Sulfinato S Donors

Mathieu Rat,[a] Rodolphe Alves de Sousa,[a] Alain Tomas,[b] Yves Frapart,[a] Jean-Pierre Tuchagues,[c] and Isabelle Artaud*[a]

Keywords: Cobalt / N ligands / S ligands / Enzyme models

Air oxidation of the six-coordinate $(Et_4N)_2[Co(N_2S_2)(CN)(CH_3CN)]$ complex derived from *N*,*N*′-(3-mercapto-3-methylbutyryl)-*o*-phenylenediamine results in the formation of the trinuclear mixed-valence complex $(Et_4N)_4\{Co^{II}[Co^{III}\{N_2(SO_2)_2\}(CN)(OH)]_2\}$ (**3**) where the thiolates have been oxidized to sulfinates. Its X-ray structure reveals a linear arrangement of cobalt ions with bridging hydroxides and sulfinates. All cobalt ions are in a distorted octahedral environment. The mixed-valence nature of this complex has been demonstrated by temperature-dependent magnetic susceptibility measurements and by EPR spectroscopy both in the solid state and in solution. These data are in agreement with a high-spin Co^{II}. The IR spectrum shows the typical vibrations of cyanide and sulfinate at 2130 cm^{-1} (ν_{CN}), 1175 ($\nu_{as/SO2}$) and 1030 cm^{-1} ($\nu_{s/SO2}$). Trapping of Co^{II} by chelex chromatography after treatment with aqueous HCl, or " in situ" in aqueous solution, yields six-coordinate low-spin complexes with two different axial ligands $Na_3[Co\{N_2(SO_2)_2\}(CN)(Cl)]$ (**5a**) and $(Et_4N)_2[Co\{N_2(SO_2)_2\}(CN)(H_2O)]$ (**5b**). The pK_a of the bound water molecule was estimated as 10.1 by pH-metric titration. While **3** and **5a** were inactive toward acetonitrile hydration, **5b** catalyzes acetamide formation at 50 °C and pH 4.7 and 7 with low efficiency.

Introduction

Nitrile hydratases (NHases) are at the centre of the industrial production of acrylamide. These bacterial enzymes, which catalyze the hydration of nitriles to amides, contain either a non-heme iron(III) or a non-corrinoid cobalt(III) centre. The crystal structure of a Co-type NHase produced from a *Pseudonocardia thermophila* species at 1.8 Å resolution has been reported recently.[1] The ligands to the cobalt atom are two peptide amide nitrogens and three sulfurs from cysteines. The two cysteines in the mean-plane *trans* to the amide nitrogens are oxidized to cysteine-sulfinic and cysteine-sulfenic acids. The apical ligands are one cysteine thiolate and a water molecule. As previously suggested,[2] the cobalt environment is very similar to the iron environment revealed by the X-ray structure of *Rhodococcus* Fe-type NHase crystallised in its NO inactivated form.[3] In this case, NO replaces H_2O as the sixth axial ligand. These results clearly show that the post-translational cysteine oxidations are general among NHases irrespective of whether they contain iron or cobalt at their active site

Most of the cobalt NHase mimics reported so far contain thiolates as sulfur donors; a few contain sulfinates and/or sulfenates.[4−7] One six-coordinate Co^{III} complex with two thiolato S-donors includes CN^- which can be replaced by H_2O at the sixth site.[4a] Most of the complexes containing oxidized thiolates as sulfur donors are six-coordinate and do not have a labile ligand that might be exchanged with H_2O or HO^-. Only one complex containing a sulfinate ligand is five-coordinate and has an open coordination site,[5] but the presence of an apical sulfinate prevents binding of any exogenous ligand at this open coordination site. Recently, we have prepared square planar $(Et_4N)[Co^{III}(N_2S_2)]$ complexes[7,8] containing, similarly to NHase, two carboxamido nitrogens *trans* to two thiolates, and we have described the conversion of the *S*-bound thiolates to *S*-bound sulfinates in the presence of *tert*-butyl isocyanide.[7] The resulting six-coordinate complex $(Et_4N)[Co^{III}(N_2(SO_2)_2](CN\textit{t}Bu)_2]$ has two isocyanide ligands tightly ligated to the cobalt centre. All attempts to exchange one isocyanide with another axial ligand have failed. This contrasts with the behaviour of the precursor square planar Co^{III} complex which has only a low affinity for isocyanide. In this report we show that this $[Co^{III}(N_2S_2)]$ complex interacts with cyanide yielding a six-coordinate complex with apically bonded cy-

anide and solvent molecule. Air oxidation of this complex affords a trinuclear Co^{III}-Co^{II}-Co^{III} species which has been crystallographically and spectroscopically characterised. The ligands at the Co^{III} centre are two nitrogens *trans* to two *S*-bound sulfinates in the mean plane and one cyanide and one hydroxide in the axial positions. Finally we describe its reactivity in solution and show that Co^{II} can be removed, yielding a six-coordinate Co^{III} complex.

Results and Discussion

The synthesis and spectroscopic characterisation of the square planar $(Et_4N)[Co^{III}(N_2S_2)]$ complex **1** (Scheme 1) has been described previously.[7] Its interaction with CN^- was monitored by UV/Vis spectroscopy under argon. While the electronic spectrum of complex **1** in acetonitrile exhibits an absorption at 695 nm, addition of a CH_3CN solution of Et_4NCN results in the progressive disappearance of this band and appearance of a new one at 820 nm. The conversion is complete after addition of one equivalent of CN^- per Co^{III} centre. Complex **2a** prepared in deaerated DMF and isolated by precipitation with diethyl ether corresponds to the formula $(Et_4N)_2[Co^{III}(N_2S_2)(CN)(DMF)]$. Its ^1H NMR spectrum in $[D_7]$DMF exhibits only signals between $\delta = 0$ and 10 ppm, indicating that **2** is a six-coordinate low spin Co^{III} complex. The non-equivalence of the CH_3 groups and of the CH_2 protons on either side of the N_2S_2 plane is in agreement with the binding of only one axial cyanide. The sixth position is occupied by a DMF molecule whose methyl resonances are clearly different from those of the free solvent. In the IR spectrum (KBr pellet), the ν_{CN} and ν_{CO} stretching bands corresponding to the axial CN^- and DMF are located at 2080 cm^{-1} and 1670 cm^{-1} respectively. In contrast to a related $[Co^{III}(N_2S_2)]$ complex with two aliphatic carboxamido N donors,[9] addition of cyanide in excess does not result in the formation of a dicyanide species. Consequently, whereas complex **1** can bind two isocyanide molecules, complex **2** binds only one cyanide ion and a solvent molecule such as DMF yielding, in both cases, a six-coordinate low spin Co^{III} complex.

Slow air oxidation of an acetonitrile solution of complex **1** with one equivalent of Et_4NCN (yielding **2b** with CH_3CN at the sixth site, Scheme 1) results in the precipitation of an orange powder, which was collected by filtration. Vapour diffusion of diethyl ether into a highly diluted CH_3CN solution of this species afforded crystals of complex **3** suitable for X-ray analysis. The crystal structure of complex **3** shown in Figure 1 reveals the formation of a linear tetra-

anionic trinuclear complex in which the thiolates of the tetradentate ligand have been oxidized to sulfinates. For crystal data of **3** see also Table 1. All three Co centres are in distorted coordination environments. The distortion from ideal octahedral geometry for each cobalt atom is due to restrictions imposed by the ligand, as evidenced by the bite angles [O(2)−Co(1)−O(7): 84.2°, O(4)−Co(1)−O(7): 85.6° and O(2)−Co(1)−O(4): 91.6° for Co(1) and N(1)−Co(2)−N(2): 82.1(1)° for Co(2)]. The terminal Co atoms are related by an inversion centre occupied by the central Co(1) atom. Each outer Co is surrounded by two carboxamido-N and two sulfinato-S donors, *trans* to the nitrogens in the equatorial plane, and by one cyanide and one hydroxide at the axial coordination sites [Co(2)−O(7)−Co(1): 116.2(1)°]. Co(2) lies 0.037(1) Å out of the best least-squares plane defined by S(1), S(2), N(1) and N(2) [maximum deviation of −0.008(1) Å for S(2)]. The Co(1)−Co(2) distance is 3.359 Å. The sulfinates and the hydroxide bridge the terminal and central cobalt ions, the latter being coordinated to the two bridging hydroxides and four oxygens from the four bridging sulfinates. Selected bond angles and distances are listed in Table 2. The Co-N distances are equivalent to those determined for complex **4**[7] (Scheme 1) and related complexes,[4−6] and for the Co-NHase active site.[1] They are in agreement with cobalt coordination to deprotonated amide nitrogens. The sulfur-to-Co bond lengths are about 0.025 Å shorter than in complex **4**.[7] O-coordination of the sulfinates to the central Co atom differentiates the two S−O bonds. The sulfur distances to the bonded oxygen atoms [S(1)−O(2), 1.488(3) Å; S(2)−O(4), 1.493(9) Å] are significantly longer than those to the non-coordinated oxygen atoms [S(1)−O(1) 1.4621 Å; S(2)−O(3) 1.4488 Å). The Co(1)−O(2)−S(1)−Co(2) and Co(1)−O(4)−S(2)−Co(2) bridges are slightly twisted with torsion angles of −0.4(2)° and +2.9(2)°, respectively. The Co(2)−CN and C−N distances fall within the range so far determined for other mono- or dicyanide Co^{III} complexes containing carboxamido nitrogens and pyridine nitrogens[10] or thiolates.[11]

The stoichiometry of four Et_4N cations per trinuclear cobalt cluster and the charge balance suggest a Co^{III}-Co^{II}-Co^{III} distribution of oxidation states. This hypothesis is supported by the length of the Co−OH bonds: as expected from the larger ionic radius of Co^{II} compared to Co^{III},[12] the Co(1)−O(7) bond length is noticeably longer than the Co(2)−O(7) one. Furthermore the *N*-amidate- bonded Co(2) centre is expected to be Co^{III} as in complex **4**.[7] Interestingly, the Co^{III}(2)−O(7) distance (1.94 Å) is shorter than the corresponding Co-O distance (2.58 Å) reported for Co-NHase.[1] This result supports the proposal of the Japanese group[1] that a water molecule, rather than a hydroxide ion, is coordinated to the Co centre of NHase.

In the CSD database,[13] we found few trinuclear cobalt complexes with a Co^{III}-Co^{II}-Co^{III} arrangement where the central Co^{II} is octahedrally coordinated to six oxygens.[14] Complex **3** is the first example of such a trinuclear complex containing bridging sulfinato groups.

Further characterisation of the trinuclear complex **3** has been performed both in the solid state and in solution.

Infrared Spectroscopy

Thiolate to sulfinate oxidation results in a shift of the ν_{CN} band from 2080 cm^{-1} in **2** to 2130 cm^{-1} in **3**. As previously discussed,[7] this shows that the cyanide is a weaker π-acceptor and a stronger σ-donor ligand in **3** than in **2**. In addition, comparison of the IR spectra of complexes **3** and **4** shows a decrease of the $\nu_{as}(SO_2)$ and $\nu_s(SO_2)$ from 1210 and 1070 cm^{-1} (**4**) to 1175 and 1030 cm^{-1} (**3**). This shift to lower energy associated with the shorter C−S distances found in the structure of **3** shows that the metal-to-ligand back donation is stronger in the N_2S_2 mean plane of **3** than in **4**.

Magnetic Properties

The temperature dependence of the magnetic susceptibility in the 300−2 K range is shown in Figure 2. The room temperature effective magnetic moment (μ_{eff} = 4.73 BM) lies in the 4.40−5.00 BM range corresponding to one high-spin cobalt(II) (S = 3/2).[15] It decreases slowly to 3.99 BM at 20 K and then drops to 3.63 BM at 4 K. This behaviour may be understood as arising from the combined effects of orbital degeneracy and zero-field splitting (ZFS). These magnetic data are very similar to those previously reported

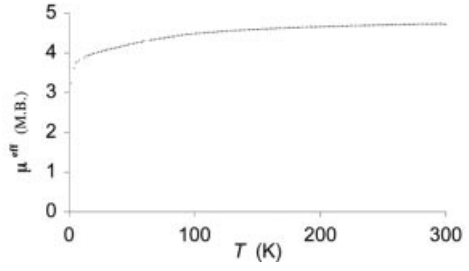

Figure 2. Temperature dependence of the effective magnetic moment for complex **3**

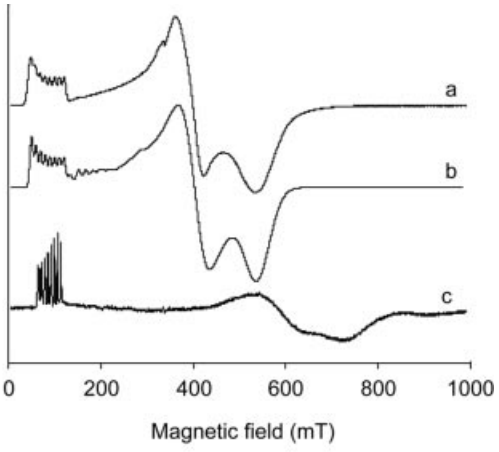

Figure 3. X-band EPR spectra of **3** at 10 K in the polycrystalline state (a) and in methanol solution (c); **3b**) simulation of spectrum **3a** using the Xsophe software package (g_x^{eff}=1.26, g_y^{eff}=1.71, g_z^{eff}= 7.91 and A_z = 10 mT, and linewidths Θ_x = 20.2 mT, Θ_Θ = 31.3 mT, Θ_Θ = 15.1 mT); experimental conditions: microwave frequency: 9.45 GHz, modulation frequency 100 kHz, modulation amplitude 1 mT, microwave power 20 mW

for a sulfito-bridged trinuclear cobalt complex,[14b] and confirm that complex **3** is in the mixed valence state Co^{III}(S = 0)-Co^{II}(S = 3/2)-Co^{III}(S = 0) as suggested by the X-ray structural analysis.

EPR Spectroscopy

The EPR spectrum of compound **3** as a polycrystalline powder recorded at 10 K is shown in Figure 3, part a. The simulation (Figure 3, part b) yields the effective *g* values g_x^{eff}=1.26, g_y^{eff}=1.71, g_z^{eff}=7.91 and a hyperfine splitting value A_z of 10 mT, which are characteristic of a single S = 3/2 Co^{II} ion. The eight-line hyperfine structure observed at g_z is due to the coupling between the electronic spin and the nuclear spin of Co^{II} (I = 7/2). The g^{eff} values can be analysed on the basis of the spin hamiltonian for an S = 3/2 centre:

$$\hat{H}_{eff} = \mu_b \vec{S}\,\bar{g}\,\vec{B} + D[\hat{S}^2_z - 1/3\,S(S+1) + E/D(\hat{S}^2_x - \hat{S}^2_y)] + \vec{S}\,\bar{A}\,\vec{I} \quad (1)$$

μ_b is the Bohr magneton, $\vec{B}$ is the external magnetic field, $\bar{g}$ the electronic tensor, $\bar{A}$ the hyperfine coupling tensor, and I the nuclear spin quantum number. *D* and *E*/*D* correspond to the zero-field splitting and rhombicity parameters, respectively. Such *g* values are due to a large axial distortion giving rise to a large zero-field splitting (10 $cm^{-1} \leq D \leq 30\ cm^{-1}$) and a large rhombicity ($E/D \geq 0.27$).[16,17] Finally, the EPR spectra of compound **3** in solution (*g* = 7.55, 1.15 and 0.9 in MeOH) (Figure 3, part c) and in the solid state (Figure 3, part a) are very similar. Therefore the same Co^{II} (S = 3/2, I = 7/2) formalism can be used to analyze the spectrum of compound **3** in solution. The signals broaden with temperature, and disappear above 30 K as expected for high-spin Co^{II} complex for which electron spin-lattice relaxation is very fast. It is very likely that the trinuclear structure determined in the solid state is retained in solution.

^{1}H NMR Spectroscopy

Complex **3** is paramagnetic as evidenced by its ^{1}H NMR spectrum in D_2O which extends over 70 ppm. The assignment of only six resonances to the $N_2(SO_2)_2$ ligand is consistent with the presence of an inversion centre in the overall structure and with the absence of a symmetry plane for the terminal Co^{III} centres. Consequently, the two signals at δ = −41 and +11.6 ppm were attributed to the methyl groups on the basis of the integration ratios. The four remaining signals, each accounting for two protons, were not assigned.

The purpose of the investigation reported below was to find proper conditions for removing the Co^{II} cation with the aim of recovering a six-coordinate Co^{III} mononuclear complex. In a first experiment, the trinuclear complex was treated with an excess of aqueous HCl solution and the resulting complex **5a** (Scheme 1) was purified over chelex chromatography, to retain the cobalt(II), and isolated as a powder after lyophilization. The characteristics of complex **5a** are consistent with the formation of a six-coordinate

Co^{III} complex with both cyanide and chloride axial ligands: (i) electrospray mass ionization (ESI^-) exhibits two peaks at 565.85 and 507.93 corresponding to the mass of the $\{(Na)_2[Co^{III}\{N_2(SO_2)_2\}(CN)(Cl)]\}^-$ and $\{(Na)[Co^{III}\{N_2(SO_2)_2\}(CN)]\}^-$ anions, respectively; (ii) elemental analysis corresponds to the formula $C_{19}H_{20}ClN_3O_6S_2Na_3Co\cdot 3NaCl\cdot 2H_2O$; (iii) IR spectroscopy shows a ν_{CN} vibration located at 2130 cm^{-1}; (iv) ^1H NMR spectroscopy is consistent with a low-spin six-coordinate Co^{III} with two different axial ligands. As expected, the methyl protons on both sides of the mean plane are non-equivalent, as are the protons of the CH_2 groups.

Using the same procedure, the corresponding aquo or hydroxo complex **5b** (Scheme1) was prepared upon stirring an aqueous (H_2O or D_2O) solution of **3** with chelex. However, **5b** could not be isolated in the solid state since it was destroyed during the lyophilisation step; it was characterised "in situ" in solution after filtration. Its ^1H NMR spectrum in D_2O is characteristic of a low-spin mononuclear Co^{III} species with two different axial ligands (CN^-/H_2O or CN^-/HO^-). The pK_a of the bound water molecule was determined by pH-metry. Titration of **5b** ($2.7\ 10^{-4}$ M) with aqueous HCl (10^{-3} M) reveals two acidic functions with pK_a values of 10.1 and 6.5 (Figure 4, part b). The former is attributed to the bound water in $[Co^{III}\{N_2(SO_2)_2\}(CN)(H_2O)]^{2-}$ and the latter to a bound HNC in $[Co^{III}\{N_2(SO_2)_2\}(HNC)(H_2O)]^-$. None of these p$K_a$ values can correspond to an amide coordinated in its protonated tautomer iminol form, since in complex **4**, which has two *tert*-butyl isocyanides at the axial sites, no protonation site was identified upon acidic titration (Figure 4, part a).

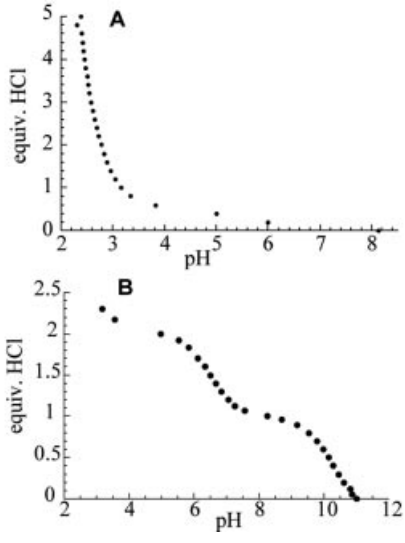

Figure 4. pH-metric titration of complex **4** a) and complex **5b** b) with aqueous HCl

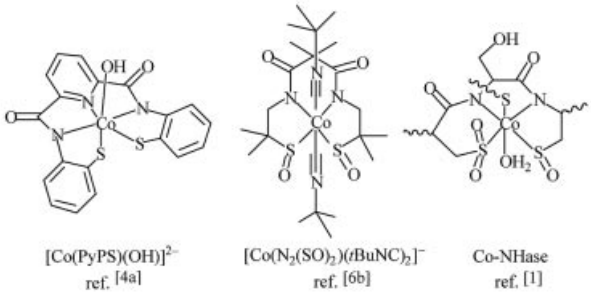
A more efficient way for preparing a more concentrated solution of **5b** "in situ" is to trap the Co^{II} cation with cyanide as $K_3[Co(CN)_6]$. This reaction was monitored by ^1H NMR spectroscopy. Progressive addition of six equivalents of KCN to a D_2O solution of **3** resulted in the formation of a low-spin species identical to **5b**. Finally the reactivity of complexes **3**, **5a**, **5b** (prepared as mentioned previously) was assayed toward acetonitrile hydration in buffered solution at pH 4.7, 7.3 and 10.3. The amide conversion was estimated by ^1H NMR spectroscopy after lyophilisation and dissolution of the residue in [D_6]DMSO. While the trinuclear and chloro complexes were inactive, amide formation corresponding to 7 and 14 turnovers of complex **5b** was determined after 24 h at 50 °C at pH 4.7 and 7, respectively. The catalyst was destroyed at higher pH. Under the same conditions, formation of amide was not detected either in the absence of complex **5b** or in the presence of the unique $K_3[Co(CN)_6]$ species. Two other mimics of NHase catalyze acetonitrile hydration with low efficiency (Scheme 2): a dithiolato hydroxo Co^{III} complex, $[Co(PyPS)(OH)]^{2-}$, prepared by Mascharak et al.[4a] and a di-sulfenato Co^{III} complex, $[Co\{N_2(SO)_2\}(t\text{BuNC})_2]^-$, described by Chottard et al.[6b] These two complexes, as well as **5b**, reproduce some of the structural features characteristic of the Co-NHase active site but not all of them. Accordingly, the presence of both a sulfenate and an aquo or hydroxo ligand seems to be required for a high activity.



Scheme 2. Schematic drawing of the two previously reported mimics of Co-NHase activity and of the Co-NHase active site

Conclusion

This work describes the first example of thiolate to sulfinate oxidation in a six-coordinate Co^{III} complex whose apical sites are occupied by a cyanide and a labile solvent molecule. This oxidation results in the formation of a new trinuclear mixed valence Co^{III}-Co^{II}-Co^{III} complex with bridging sulfinates which has been characterised both in the solid state and in solution. The terminal Co^{III} ions retain the environment of the starting Co^{III} compound but with S-bonded sulfinates and a hydroxide replacing the solvent molecule in the sixth coordination position. The high-spin Co^{II} is held by interactions with the six oxygens of the bridging hydroxides and sulfinates. The central Co^{II} ion is easily trapped by chelating agents, yielding the first example of a six-coordinate low-spin $[Co^{III}\{N_2(SO_2)_2\}(CN)(H_2O)](Et_4N)_2$ complex including an exchangeable coordination site able to bind Cl^-. Preliminary experiments show that the aquo complex catalyzes hydration of acetonitrile, although with a low efficiency.

Experimental Section

Complex 2: Et_4NCN (14.8 mg, 0.095 mmol) in deaerated CH_3CN was added to a deaerated DMF solution of $(Et_4N)[Co(N_2S_2)]$ **1** (50 mg, 0.095 mmol, 1 mL). The resulting brown mixture was stirred at room temp. for 5 min. Cooling to −20 °C and addition of cold Et_2O afforded complex **2** as a brown powder. The solid was dried under vacuum and stored in a glovebox. (35 mg, 45%). $C_{36}H_{67}CoN_6O_3S_2{\cdot}CH_3CN{\cdot}2H_2O$ (832.10): calcd. C 54.85, H 8.96, N 11.78; found C 55.06, H 9.36, N 11.99. UV/Vis (CH_3CN): λ_{max} (ε, $M^{-1}cm^{-1}$) = 232 (24000), 259 (21800), 470 (1100), 822 (800) nm. IR (KBr): $\tilde{\nu}$ = 2080 (ν_{CN}), 1620 (ν_{CO} DMF), 1545 (ν_{CO}) cm^{-1}. ^1H NMR (250 MHz, [D_7]DMF, 300 K): δ = 1.16 (s, 24 H, Me Et_4N), 1.25 (s, 6 H, Me), 1.43 (s, 6 H, Me), 2.23 (d, J = 12 Hz, 2 H, CH_2,), 2.66 (s, 3 H, Me DMF), 2.82 (s, 3 H, Me DMF), 2.98 (s,16 H, CH_2 Et_4N), 3.42 (d, J = 12 Hz, 2 H, CH_2), 6.36 (dd, 2 H, H_{ar}), 7.90 (s, HCO DMF), 8.52 (dd, 2 H, H_{ar}) ppm. MS (FAB^-): m/z (%) = 395 (100) $[Co(N_2S_2)]^-$.

Complex 3: Et_4NCN (60 mg, 0.4 mmol) was added to a CH_3CN solution of $(Et_4N)[Co(N_2S_2)]$ **1** (200 mg, 0.4 mmol, 4 mL). The resulting brown mixture was stirred under a dioxygen atmosphere at 4 °C for a week. An orange precipitate was collected (95 mg, 41%), washed with Et_2O and dried under vacuum. $C_{66}H_{122}Co_3N_{10}O_{14}S_4{\cdot}6H_2O{\cdot}CH_3CN$ (1733.97): calcd. C 47.10, H 7.96, N 8.89; found C 46.94, H 8.02, N 8.83. UV/Vis (H_2O): λ_{max} (ε, $M^{-1}cm^{-1}$) = 252 (33800), 279 (44300), 300 (sh), 460 (1400) nm. IR (KBr): $\tilde{\nu}$ = 2130 (ν_{CN}), 1540 (ν_{CO}), 1175 and 1030 (ν_{SO2}) cm^{-1}. ^1H NMR (250 MHz, D_2O): δ = 27 (2 H), 22 (2 H), 11.7 (6 H), 3.33 (32 H, CH_2 Et_4N), 1.55 (2 H), 1.50 (s, 48 H, Me Et_4N) −8 (2 H), −42.2 (6 H) ppm. MS(ESI^- in MeOH): m/z (%) = 242.5 (100) $[Co\{N_2(SO_2)_2\}(CN)]^{2-}$.

Complex 5a: A batch of **3** (50 mg, 0.029 mmol) was dissolved in 10 mL of 1 N HCl and stirred for 15 min. After lyophilisation, the residue was dissolved in methanol and loaded onto a Chelex 100 resin column. The first pink band eluted with methanol was collected. Addition of Et_2O afforded complex **5a** as a pink powder (20 mg, 42%) upon cooling. $C_{17}H_{20}CoN_3Na_3O_6S_2Cl{\cdot}3NaCl{\cdot}3H_2O$ (819.22): calcd. C 24.92, H 3.20, N 5.13; found C 25.18, H 3.27, N 5.22. UV/Vis (H_2O): λ_{max} (ε, $M^{-1}cm^{-1}$) = 250 (36700), 281 (51700), 302 (42800), 470 (1400) nm. IR (KBr): $\tilde{\nu}$ = 2130 (ν_{CN}), 1535 (ν_{CO}), 1175 and 1060 (ν_{SO2}) cm^{-1}. ^1H NMR (250 MHz, D_2O): δ = 1.30 (s, 6 H, Me), 1.42 (s, 6 H, Me), 2.43 (d, J = 17 Hz, 2 H CH_2), 2.91 (d, J = 17 Hz, 2 H, CH_2), 6.90 (dd, 2 H, H_{ar}), 7.42 (dd, 2 H, H_{ar}) ppm. MS (ESI^- in MeOH): m/z (%) = 507.93 (100) $\{(Na)[Co\{N_2(SO_2)_2\}(CN)]\}^-$, 565.83 (25) $\{(Na)_2[Co\{N_2(SO_2)_2\}(CN)(Cl)]\}^-$.

Crystal Structure Determination of 3: A brown crystal with dimensions 0.6 × 0.6 × 0.3 mm^3 was stuck on a glass fibre and mounted on a Stoe IPDS Imaging Plate Diffraction System (IPDS) equipped with an Oxford Cryosystems Cooler Device.[18] The final unit cell parameters were obtained by the least-squares refinement of 5000 reflections. Only statistical fluctuations were observed in the intensity monitors over the course of the data collection. Crystal data and data collection parameters are listed in Table 1. Corrections for Lorentz and polarisation effects were applied. The structure was solved by direct methods using SHELXS-97.[19] Refinement, based on F^2, was carried out by full-matrix least-squares with anisotropic thermal parameters for all non-hydrogen atoms using SHELXL-97.[20] All hydrogen atoms were located on a difference Fourier map and refined as riding models with isotropic parameters constrained to be 1.2-times the Ueq of the carrier atom. Least-squares refinements were carried out by minimising the function $\Sigma w(F_o^2 - F_c^2)^2$, where F_o and F_c are the observed and calculated structure factors. The weighting scheme used in the last refinement was $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. Models reached convergence with $R1 = \Sigma(||F_o| - |F_c||)/\Sigma(|F_o|)$ and $wR2 = \{\Sigma w(F_o^2 - F_c^2)^2/\Sigma w (F_o^2)^2\}^{1/2}$, having the values listed in Table 1. ORTEP-II was used to produced molecular graphics.[21] Fractional atomic coordinates, anisotropic thermal parameters for non-hydrogen atoms and atomic coordinates for H atoms have been deposited with the Cambridge Crystallographic Data Centre.
CCDC-182354 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Complex 5b: A D_2O solution of complex **3** (1.7 mg in 1 mL) was stirred with chelex (10 mg) resulting in the formation of **5b**. The supernatant was analysed by ^1H NMR spectroscopy. ^1H NMR (250 MHz, D_2O): δ = 1.34 (s, 3 H, Me), 1.46 (s, 3 H, Me), 2.48 (d, J = 17 Hz, 2 H, CH_2), 2.95 (d, J = 17 Hz, 2 H, CH_2), 6.95 (m, 2 H_{ar}), 7.78 (m, 2 H_{ar}) ppm.

pH-metric Titration of Complex 5b: 5 mL of an aqueous solution of complex **3** (3.5 mg) was stirred at room temp. with chelex (50 mg) for 3 hours. After filtration the resin was washed with water (2.5 mL) and the filtrate (**5b**: 2.7 10^{-4} M) was titrated with HCl (10^{-3} M).

Catalytic Assays: 50 μL of an aqueous solution of KCN (1.8 M, 90 μmoL) was added to 950 μL of an aqueous solution of **3** (26 mg, 15 μmoL) yielding a 3 10^{-3} M solution of **5b**. 100 μL was withdrawn and added to a mixture of 500 μL of a 0.1 M buffered solution (acetate pH 4.7, Hepes pH 7.3 and carbonate pH 10.3) and CH_3CN (100 μL). The mixture was heated to 50 °C for 48 H. After cooling and lyophilization, the residue was dissolved in [D_6]DMSO in the presence of trimethoxybenzene as an internal standard. The filtrate was analysed by ^1H NMR spectroscopy.

The Influence of Functional Group Orientation on the Structure of Zinc 1,1,4-Trimethylthiosemicarbazide Dicarboxylates: Probing the Limits of Crystal Engineering Strategies

Andrew D. Burrows,*[a] Ross W. Harrington,[a] Mary F. Mahon,[a] and Simon J. Teat[b]

Keywords: Zinc / Carboxylate ligands / Hydrogen bonds / Coordination polymers / Supramolecular chemistry

The reaction of $[Zn(tmtsc)_2](NO_3)_2$ [tmtsc = 1,1,4-trimethylthiosemicarbazide, $MeNHC(S)NHNMe_2$] with a range of sodium dicarboxylates has been shown to lie on the borderline between commonly used crystal engineering strategies. The products exhibit a wide range of structural diversity with the main driving force being the relative orientation of the carboxylate groups. Thus, fumarate leads to the hydrogen-bonded aggregate $[Zn(tmtsc)_2(OH_2)][fumarate]$ (**2**) in which cations and anions are linked by hydrogen bond donor-donor acceptor-acceptor (DD:AA) interactions, whereas isophthalate and (+)-camphorate lead to coordination polymers [Zn(tmtsc)(μ-isophthalate)] (**3a**) and [Zn(tmtsc)(μ-camphorate)] (**4**) with the metal centres linked by bridging dicarboxylate ligands. In the case of isophthalate, a hydrated product [Zn(tmtsc)(μ-isophthalate)]·H_2O (**3b**) was also characterised, although microanalysis and powder X-ray diffraction revealed this to be a minor product. Incorporation of water was shown to lead to a change in carboxylate coordination mode from η^1 in **3a** to η^2 in **3b**. Use of terephthalate leads to the compound $[\{Zn(tmtsc)(OH_2)\}_2(\mu\text{-terephthalate})]$-[terephthalate]·$2H_2O$ (**5**), in which half of the terephthalates bridge metal centres, to form dimers, and the remainder link the dimeric cations through DD:AA hydrogen bond interactions. Homophthalate leads to discrete dimers $[Zn(tmtsc)(\mu\text{-homophthalate})]_2$ (**6**), whereas acetylenedicarboxylate yields the unexpected compound $[Zn(tmtsc)_2(OH_2)][O_2CCH{=}CC(O)N(Me)C(=NNMe_2)S]_2{\cdot}H_2O$ (**7**) in which the dicarboxylate has reacted with tmtsc to give a 2-hydrazono-4-oxo-1,3-thiazolidineacetate, which is subsequently trapped in the solid state by DD:AA hydrogen bonding interactions with $[Zn(tmtsc)_2(OH_2)]^{2+}$. All products were characterised by single crystal X-ray crystallography, and the representational nature of these crystal structures to the bulk materials was confirmed by microanalysis and powder diffraction.

Introduction

Progress in the field of crystal engineering has largely arisen as a result of the identification and use of *supramolecular synthons*[1] − small units within molecules that are anticipated to interact with each other in a predictable manner. There are currently two main strategies adopted in crystal engineering, in which these supramolecular synthons are based either on metal-ligand interactions[2] or, alternatively, on intermolecular interactions such as hydrogen bonds,[3] and recently there have been reports using both of these approaches together.[4] We are particularly interested in the competitive interplay between the two strategies, and as a consequence have focussed our attention on systems in which both types of aggregation are possible.

As part of this study, we have shown that $[Zn(thiourea)_4]^{2+}$ cations react with dicarboxylates by displacing thiourea ligands to give polymers or dimers in which the zinc centres are linked by bridging dicarboxylates.[5,6] In contrast, under similar conditions $[M(tsc)_2]^{2+}$ (M = Zn, Ni; tsc = thiosemicarbazide) cations give ionic structures of the type $[M(tsc)_2][dicarboxylate]$ in which the cations and anions are linked together into tapes by hydrogen bonds.[5,7] Hence, changing the ligands on the metal centre from uni- to bidentate has been shown to alter the mode of supramolecular assembly and consequently the type of structure formed.

In this paper we report on the reactions of $[Zn(tmtsc)_2]^{2+}$ [tmtsc = 1,1,4-trimethylthiosemicarbazide, $MeNHC(S)NHNMe_2$] with a range of dicarboxylates. The presence of the tertiary amine group in the tmtsc ligand was expected to increase its lability relative to tsc,[8] and therefore enhance the possibility of ligand displacement from the metal coordination sphere. This has been borne out and, in contrast to the reactions with $[Zn(thiourea)_4]^{2+}$ or $[M(tsc)_2]^{2+}$, reactions with $[Zn(tmtsc)_2]^{2+}$ give a wide variety of structural types, with that observed from a particular reaction depending on the relative orientation of the carboxylate groups within the anion.

Results and Discussion

Synthesis

The complex $[Zn(tmtsc)_2](NO_3)_2$ was prepared from the reaction of zinc(II) nitrate with tmtsc in ethanol. Recrystallisation of the product from water gave single crystals of $[Zn(tmtsc)_2(OH_2)_2](NO_3)_2$ (**1**), the identity of which was confirmed crystallographically. Selected bond lengths and angles for **1** are given in Table 1.

Table 1. Selected bond lengths (Å) and angles (°) for compounds **1**, **3a**, **3b** and **6**

[a]	**1**	**3a**	**3b**	**6**

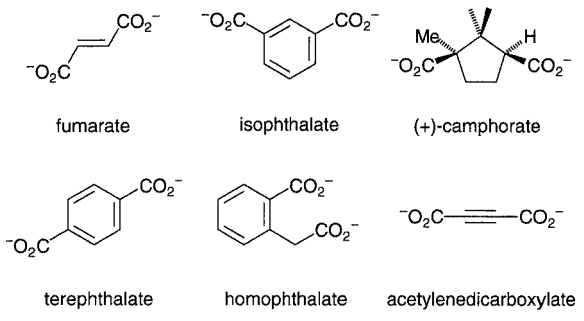
O(1)−Zn(1)−O′ [b]		116.13(17)	103.61(8)	137.90(8)

[a] Primed atoms generated by symmetry transformations $-x + {}^3/_2$, $y-{}^1/_2$, $z + {}^1/_2$ (**3a**), $-x + 1$, $y-{}^1/_2$, $-z + {}^1/_2$ (**3b**) and $-x + 1$, $-y + 1$, $-z$ (**6**). [b] O′ = O(3)′ for **3a**; O′ = O(4)′ for **3b** and **6**.

Reaction of $[Zn(tmtsc)_2](NO_3)_2$, in aqueous solution, with sodium salts of fumaric, (+)-camphoric, terephthalic, homophthalic and acetylenedicarboxylic acids gave compounds $[Zn(tmtsc)_2(OH_2)]$[fumarate] (**2**), [Zn(tmtsc)(μ-(+)camphorate)] (**4**), $[\{Zn(tmtsc)(OH_2)\}_2$(μ-terephthalate)][terephthalate]·$2H_2O$ (**5**), [Zn(tmtsc)(μ-homophthalate)]$_2$ (**6**) and $[Zn(tmtsc)_2(OH_2)][O_2CCH{=}CC(O)N(Me)C(=NNMe_2)S]_2{\cdot}H_2O$ (**7**), as the only isolated compounds in good yield. The analogous reaction with isophthalate gave two compounds, [Zn(tmtsc)(μ-isophthalate)] (**3a**) and [Zn(tmtsc)(μ-isophthalate)]·H_2O (**3b**), with the anhydrous complex **3a** the major product. The empirical formulae of compounds **2**, **3a**, **4**, **5**, **6** and **7** were confirmed by microanalyses, and the structures of all the compounds were determined by single crystal X-ray analyses. A comparison of the experimental powder diffraction data with that simulated from the single-crystal data confirmed that the crystal structures are representative of the bulk materials, with the experimental data for isophthalate consistent with **3a**. The dicarboxylates used are illustrated in Scheme 1.



Scheme 1. Structures of the dicarboxylates used

Supramolecular Structures of 2−7

The crystal structure of compound **2** consists of $[Zn(tmtsc)_2(OH_2)]^{2+}$ cations and fumarate anions. The coordination geometry around the zinc centre is distorted square pyramidal ($\tau = 0.39$),[9] with mutually *trans* tmtsc ligands. Selected bond lengths and angles are given in Table 2, and hydrogen bonding parameters are given in Table 3. Two hydrogen bonds between the parallel NH

groups on the tmtsc ligands and the two oxygen atoms of the carboxylate groups serve to link the cations and anions together into tapes (Figure 1). These hydrogen bond donor-donor acceptor-acceptor (DD:AA) interactions are similar to those observed in $[Zn(tsc)_2(OH_2)_2][terephthalate]\cdot 2H_2O$[5] and in nickel thiosemicarbazide dicarboxylates[7] [graph set[10] $R_2^2(8)$]. The cation···anion tapes in **2** are linked into sheets by O−H···O hydrogen bonds from the aqua ligands in a neighbouring plane to carboxylate oxygen atoms. Since the aqua ligands within each tape are all orientated in the same direction, these O−H···O hydrogen bonds ensure that the sheets exist as bilayers, with weaker C−H···O interactions linking these bilayers into the gross structure. Similar DD:AA interactions were observed between the tmtsc ligands and the nitrate anions in the structure of **1**. However, a mismatch in both the charge and shape of the ions guarantees that the DD:AA interactions do not lead to tape formation in the nitrate − instead, discrete $[Zn(tmtsc)_2(OH_2)_2](NO_3)_2$ units are linked only by O−H···O hydrogen bonds.

The crystal structures of compounds **3a** and **3b** reveal that, in contrast to **2**, both compounds are coordination polymers with isophthalates bridging between metal centres (Figure 2). In both structures each zinc(II) centre is coordinated to a tmtsc ligand and two isophthalate ligands; in **3b** included water molecules are also present in the lattice. Selected bond lengths and angles for both **3a** and **3b** are given in Table 1 and hydrogen bonding parameters are given in Table 3.

The coordination geometry around the zinc centre in compound **3a** is distorted tetrahedral with the carboxylates η^1-coordinated (Figure 2, top), as observed in [Zn(thiourea)$_2$(μ-dicarboxylate)] polymers.[6] Coordination of the carboxylates prevents the formation of DD:AA interactions, although hydrogen bonding is still present, linking the chains through two N−H···O interactions from the NH groups to a single carboxylate oxygen atom [graph set $R_2^1(6)$].

The presence of the lattice water molecule in compound **3b** leads to differences in the manner in which the chains are linked together (Figure 2, bottom). One of the NH groups hydrogen bonds to a carboxylate oxygen atom, whereas the other forms an N−H···O hydrogen bond to the included water molecule. Two O−H···O hydrogen bonds from the water to carboxylate oxygen atoms complete the hydrogen bonding, with one of these leading to the formation of $R_3^3(10)$ rings. Significant π−π interactions are also present, with the shortest C···C distance between isophthalate rings being 3.45 Å. In order to accommodate the hydrogen bonding in **3b** there is a change in the metal coordination geometry relative to that in **3a**, with both carboxylate groups unsymmetrically η^2-coordinated, thus affording distorted octahedral geometry at the metal centre. Consequently the longer Zn−O distances have been reduced from 2.838(5)

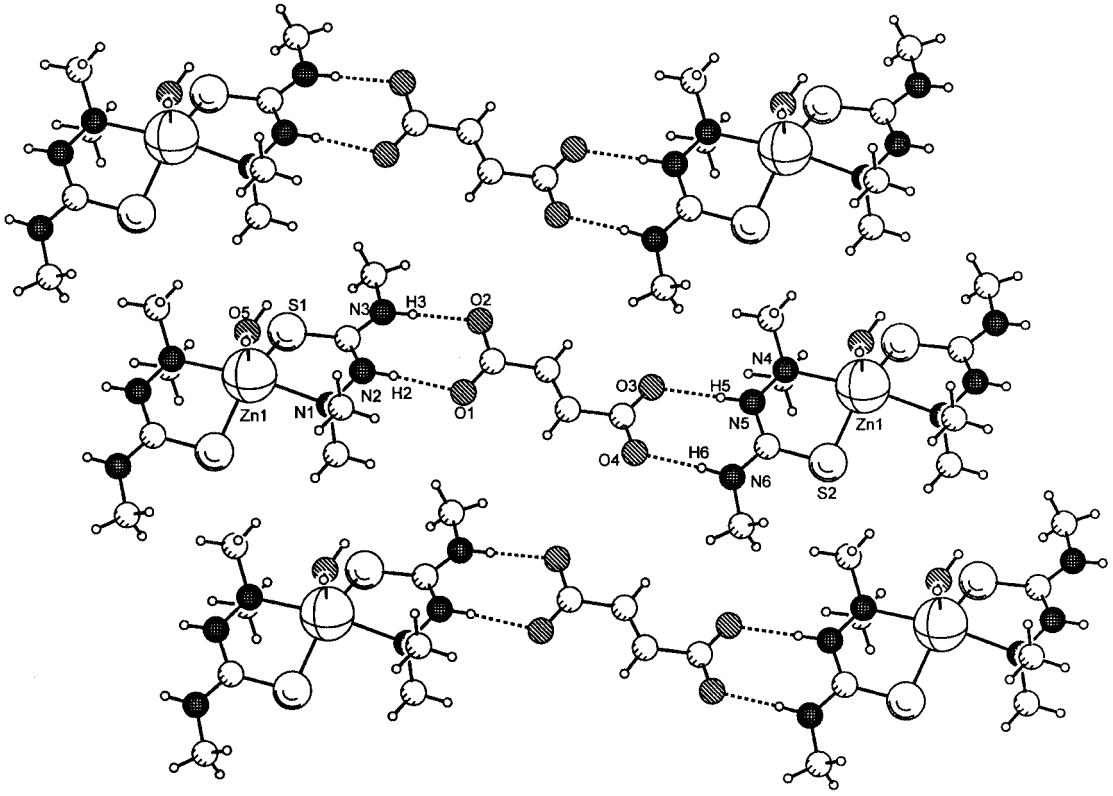

Figure 1. The solid state structure of $[Zn(tmtsc)_2(OH_2)][fumarate]$ (**2**)

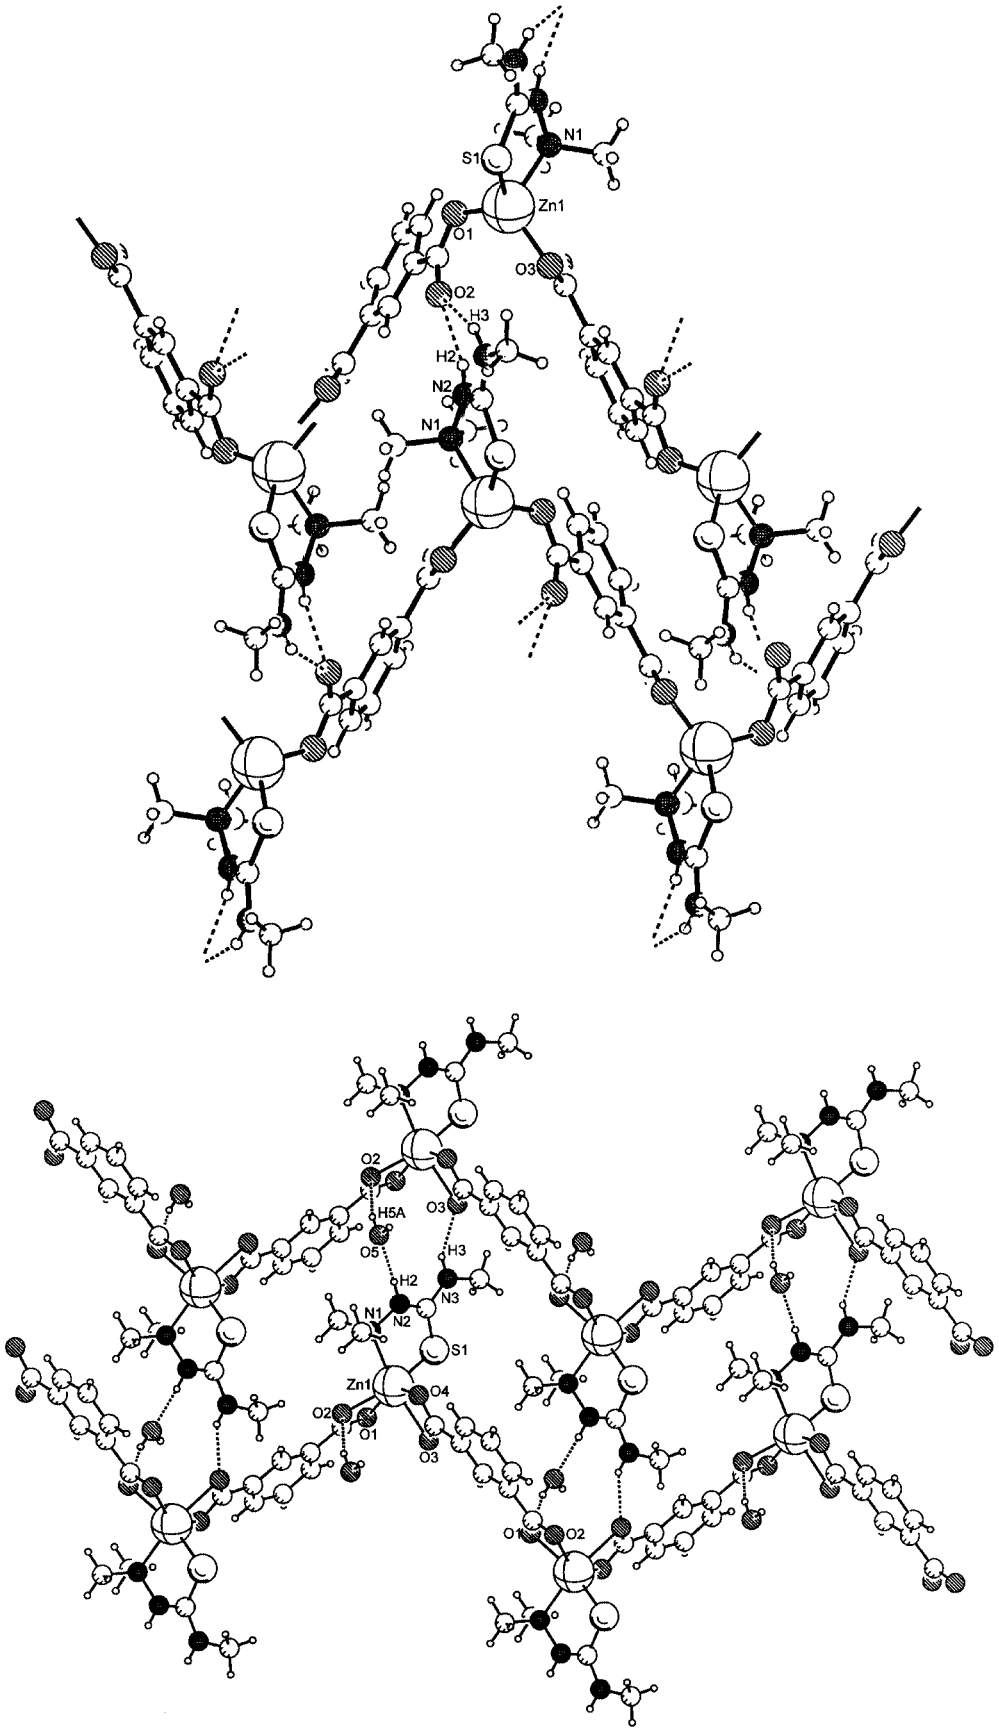

Figure 2. The solid state structures of (top) [Zn(tmtsc)(μ-isophthalate)] (**3a**) and (bottom) [Zn(tmtsc)(μ-isophthalate)]·H_2O (**3b**)

and 3.071(4) Å in **3a** to 2.334(2) and 2.343(2) Å in **3b** on incorporation of the water. The increase in coordination number has little effect on the Zn−S distance, but leads to a significant increase in the Zn−N bond length and a reduction of the tmtsc bite angle (Table 1).

Compound **4**, incorporating the (+)-camphorate dianion, also exists as a coordination polymer, with the (+)-camphorates linking the zinc centres. The asymmetric unit of this compound contains two independent Zn(tmtsc) groups and two independent (+)-camphorates. Both zinc centres are five-coordinate, with one carboxylate group bound η^1 and the other η^2. Selected bond lengths and angles are given in Table 4 and hydrogen bonding parameters are given in Table 3. The two independent (+)-camphorate dianions differ in that one contains two η^1-carboxylates whereas the other contains two η^2-carboxylates.

The structure of **4** differs from those for **3a** and **3b** by virtue of the manner in which the coordination polymers interact with each other. In **4** this is through two N−H···O hydrogen bonds from each of the tmtsc ligands, with the acceptors being oxygen atoms on separate carboxylate groups (Figure 3). One of these oxygen atoms is non-coordinated [O(2) or O(4)] whereas the other forms the longer Zn−O bond of an η^2-carboxylate [O(5) or O(8)]. This hydrogen bonding pattern is facilitated by a change in conformation of the tmtsc ligand. A rotation of 180° around the C−N(amino) bond means that the two NH groups within each ligand are no longer orientated in the same direction. Such a conformational change has been observed previously in the structure of *cis*-[Ni(4-Et-tsc)$_2$][terephthalate],[11] although in the nickel complex the *cis* orientation of the ligands results in the formation of a new DD face which is involved in hydrogen bonding. This does not happen for **4** however, and the loss of potential secondary interactions is compensated by the formation of four strong hydrogen bonds.

ated. Selected bond lengths and angles are given in Table 5 and hydrogen bonding parameters are given in Table 3. The cation in **5** can be regarded in hydrogen bonding terms as an "expanded" $[Zn(tmtsc)_2]^{2+}$ cation, since both contain the same number and relative orientation of NH groups. The cations and anions in **5** interact through two hydrogen bonds in a similar DD:AA manner to that observed in **2**, which overall serves to link the ions into tapes (Figure 4). These tapes are connected into sheets by hydrogen bonding to water molecules, although, in contrast to **2**, these involve both water included within the lattice and coordinated water ligands from tapes above and below the sheets. Since each cation contains two axial coordinated water molecules, pointing in opposite directions, the sheets are all linked in the same manner, which contrasts with the bilayers observed in **2**. The structure of **5** can be regarded as intermediate between those of **2** and **3**, as half the dicarboxylates link the metal centres together through coordinative bonds while the remaining half link the metal centres through hydrogen bonds to the coordinated tmtsc ligands. Despite the importance of dicarboxylates in crystal engineering this is, to the best of our knowledge, the first occasion a structure has been observed in which the anion fulfils both discrete coordination and hydrogen bonding roles.

The crystal structure of compound **6** consists of discrete $[Zn(tmtsc)(\mu\text{-homophthalate})]_2$ molecules (Figure 5), in which the two zinc centres are crystallographically equivalent, related through an inversion centre. Selected bond lengths and angles are given in Table 2, and hydrogen bonding parameters are given in Table 3. Each carboxylate group is unsymmetrically η^2-coordinated, though the Zn(1)−O(2) distance is long [2.540(2) Å]. This oxygen atom is involved in N−H···O hydrogen bonding (see below). The distorted octahedral coordination geometry around the metal centres is similar to that observed in **3b**. The dimeric structure of **6**

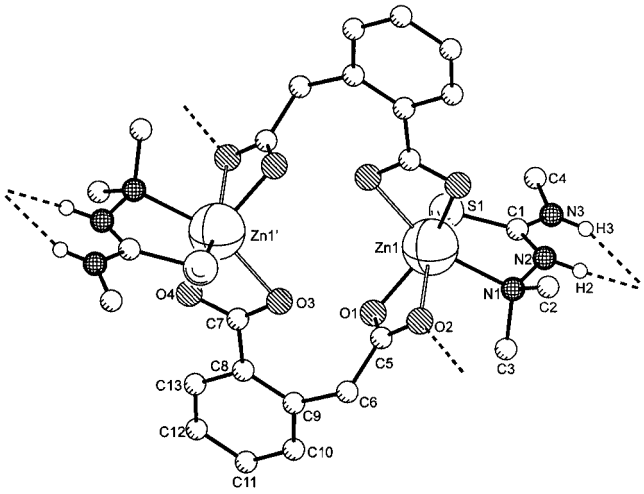

Figure 5. The molecular structure of $[Zn(tmtsc)(\mu\text{-homophthalate})]_2$ (**6**), with all carbon-bound hydrogen atoms omitted for clarity

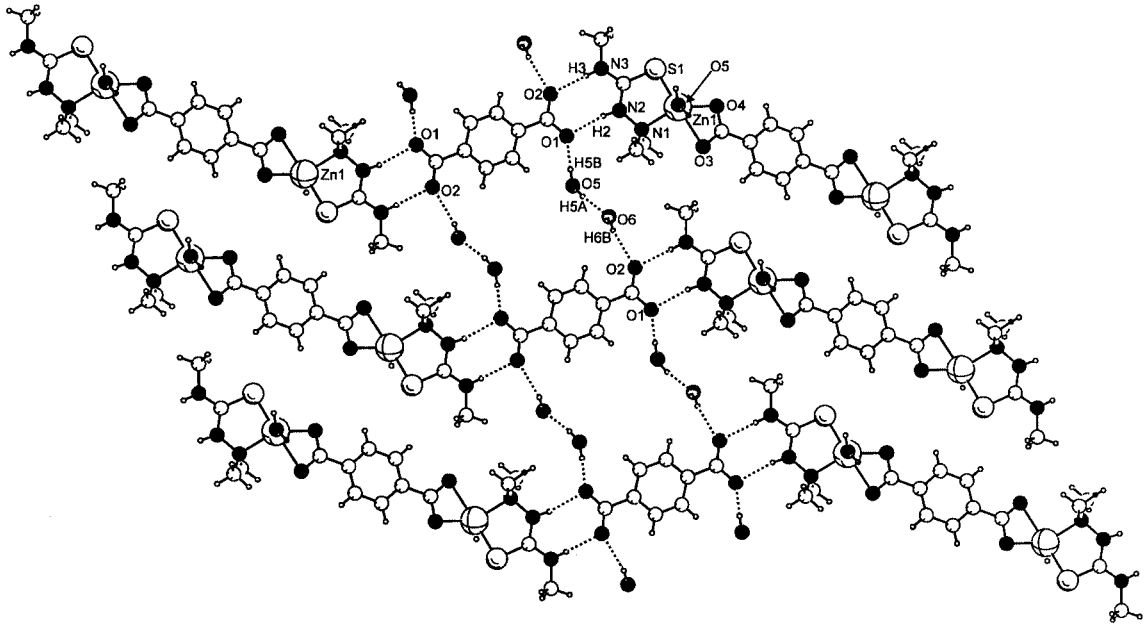

Figure 4. The solid state structure of $[\{Zn(tmtsc)(OH_2)\}_2(\mu\text{-terephthalate})][terephthalate]\cdot 2H_2O$ (**5**)

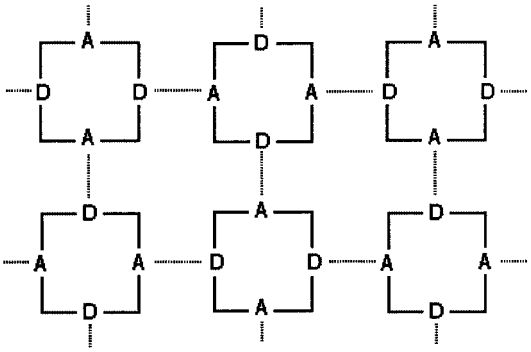
is similar to that previously observed in $[Zn\{SC(NH_2)_2\}_2(\mu\text{-homophthalate})]_2$ [6] strongly suggesting that dimer formation is driven by the relative orientation of the carboxylate groups in the homophthalate dianion. In contrast to **6**, $[Zn\{SC(NH_2)_2\}_2(\mu\text{-homophthalate})]_2$ contains η^1-coordinated carboxylate groups, with non-bonded Zn−O distances of 2.86(3) and 3.05(3) Å. The distances across the ring in **6**, as represented by the O(2)···O(2′) and O(3)···O(3′) separations, are 5.9 and 3.9 Å respectively, hence the dimers are somewhat flattened relative to those present in $[Zn\{SC(NH_2)_2\}_2(\mu\text{-homophthalate})]_2$ (O···O 5.3 and 4.9 Å).

Molecules of **6** are linked in the solid state through two N−H···O hydrogen bonds to a single carboxylate oxygen atom O(2), in an analogous manner to **3a** [graph set $R_2^1(6)$]. Each molecule provides hydrogen bond donors in one dimension and hydrogen bond acceptors in a second, as shown schematically in Figure 6 (top). These interactions therefore serve to link the molecules into sheets (Figure 6, bottom). Despite the presence of carboxylate oxygen atoms which are not involved in hydrogen bonding, there are no hydrogen bond interactions linking the sheets together.

The reaction between $[Zn(tmtsc)_2](NO_3)_2$ and acetylenedicarboxylate does not give a compound in which the dicarboxylate is incorporated, either as a ligand or as a hydrogen bonded anion. Instead, a reaction (Scheme 2) between acetylenedicarboxylate and a tmtsc molecule occurs to give a



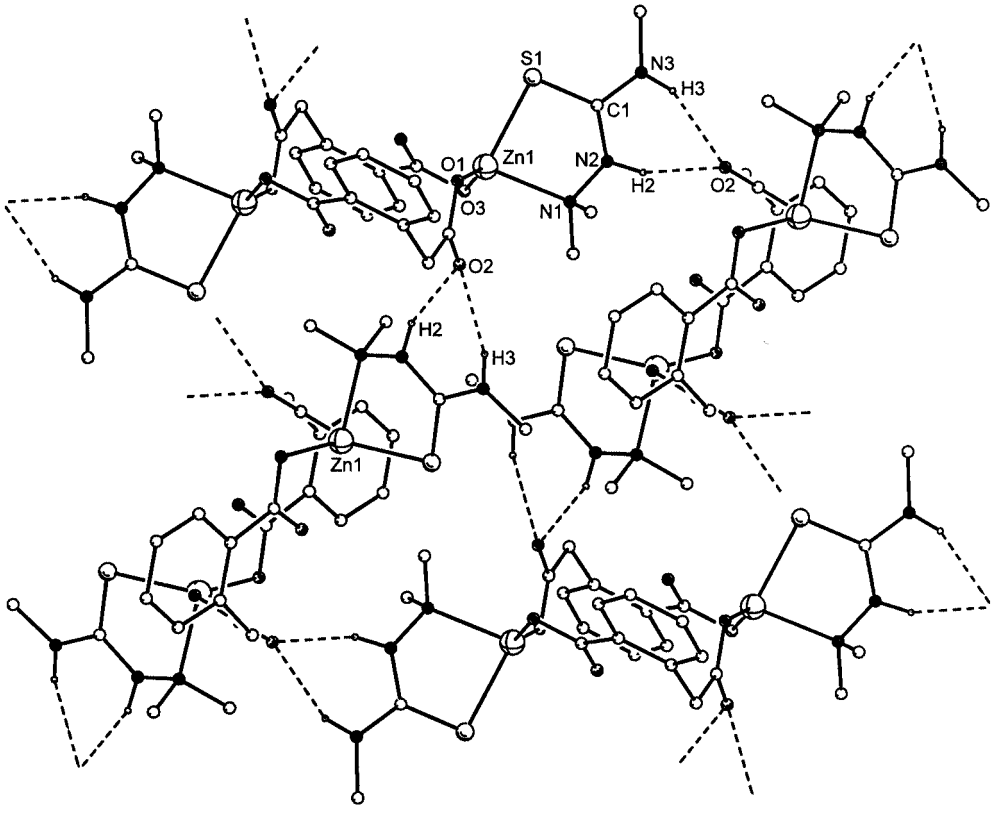


Figure 6. Intermolecular interactions present in $[Zn(tmtsc)(\mu\text{-homophthalate})]_2$ (**6**); (top) schematic representation of hydrogen bonded sheets; (bottom) part of the extended structure, with all carbon-bound hydrogen atoms omitted for clarity

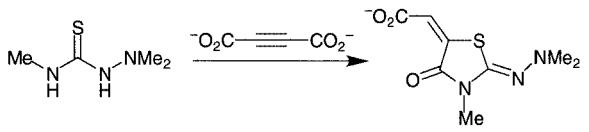

Scheme 2. Conversion of 1,1,4-trimethylthiosemicarbazide into the anion observed in compound **7**

2-hydrazono-4-oxo-1,3-thiazolidineacetate, which is itself incorporated into the structure as the anion. Thus the identity of **7**, as determined by the crystal structure, is $[Zn(tmtsc)_2(OH_2)][O_2CCH{=}CC(O)N(Me)C(=NNMe_2)S]_2{\cdot}H_2O$ (Figure 7). The $[Zn(tmtsc)_2(OH_2)]^{2+}$ cation has a distorted square pyramidal geometry ($\tau = 0.41$[9]) with the tmtsc ligands mutually *trans* as in **2** and **5**. Selected bond lengths and angles are given in Table 2, with hydrogen bond parameters given in Table 3. Reactions between thiosemicarbazides and acetylenedicarboxylic acid giving similar products have been reported previously,[12] and the observation of such a reaction here provides evidence of the lability of the tmtsc ligand on zinc, as is also evident from the structures of **3**−**6**.

The heterocyclic anion contains a carboxylate group, and these oxygen atoms are involved in DD:AA hydrogen bonds with the parallel NH groups of the tmtsc ligands. Thus the principal hydrogen bonding motif in **7** is the same as that in both **2** and **5**. However, the presence of only one carboxylate group per anion means that extended cation···anion tapes cannot be formed, and instead the available interactions afford only [cation][anion]$_2$ units as observed for **1**. These units are linked together into the gross structure of **7** *via* hydrogen bonds involving the coordinated and included water molecules, where the former acts as a hydrogen bond donor to both a carboxylate oxygen atom and the included water, and the latter acts as a hydrogen bond donor to a carboxylate oxygen atom and a nitrogen atom.

Discussion

Compounds **2**−**7** were all isolated in good yield as the sole products from the reactions between $[Zn(tmtsc)_2](NO_3)_2$ and a dicarboxylate under identical conditions. There is a wide structural diversity in the products ranging from coordination polymers (**3a**, **3b**, **4**) to hydrogen-bonded ionic aggregates (**2**) via an intermediate structure (**5**) in which half the anions are coordinated. This diversity confirms the initial premise concerning the lability of tmtsc lying between those of tsc and thiourea. The metal coordination number varies from 4 to 6, and is not a major factor in determining the supramolecular structure − this is witnessed by the zinc centres in the coordination polymers **3a**, **3b** and **4** having coordination numbers of 4, 6 and 5 respectively. The products observed are also not affected by changes in the stoichiometry of $[Zn(tmtsc)_2](NO_3)_2$ and dicarboxylate used in the reaction, nor do differences appear to be related to the basicity of the dicarboxylates or the pH of the reaction mixture. However, it is possible to rationalise the structural differences on the basis of the dicarboxylate shape, specifically the relative orientation of the two carboxylate groups.

Yaghi, O′Keeffe and co-workers have recently described the geometry of dicarboxylates in terms of three angles, θ, ψ and φ, and used these angular parameters to help in the design and preparation of porous metal-organic frameworks with predictable structures.[13] Starting from the planar terephthalate anion, θ represents bending in the centre of the anion with the two carboxylates remaining coplanar, ψ represents bending of the carboxylates towards each other, and φ represents the relative twisting of the planes of the carboxylate groups. For terephthalate and fumarate in the structures of **5** and **2**, θ and ψ are 180° and φ is close to zero, as the carboxylate groups are almost coplanar and orientated in opposite directions. These compounds consist of ionic structures based on cation···anion tapes, held together by DD:AA hydrogen bond interactions. This is consistent with previous structures containing these anions,[5,7] though the formation of **5**, in which half of the terephthalates are coordinated giving "extended" $[\{Zn(tmtsc)(OH_2)\}_2(\mu\text{-terephthalate})]^{2+}$ cations is somewhat unexpected, as the nickel compound $[Ni(tmtsc)_2(OH_2)_2]$[terephthalate] readily forms in a comparative reaction. The presence of the extended cation in **5** does prevent unfavourable interactions between the methyl groups on neighbouring tapes that would occur if simple $[Zn(tmtsc)_2]^{2+}$ cations were incorporated in the orientation

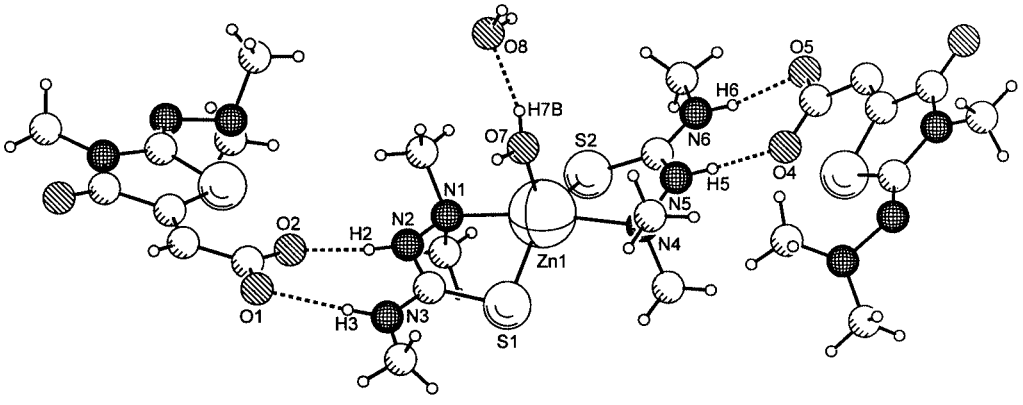

Figure 7. Part of the solid state structure of $[Zn(tmtsc)_2(OH_2)][O_2CCH{=}CC(O)N(Me)C(=NNMe_2)S]_2{\cdot}H_2O$ (**7**)

adopted. Despite possessing the same angular parameters, terephthalate and fumarate differ in the distance between the carboxylate groups and the fact that for fumarate these are not co-linear, there being a lateral displacement of 1.07 Å.

While isophthalate and camphorate are structurally very different, it is noteworthy that each possesses one of the angular parameters − θ for isophthalate and φ for camphorate − that has been reduced from the 180° value for terephthalate to 120°, and both of these dicarboxylates form coordination polymers with Zn(tmtsc) centres. While the carboxylate orientations in **3a**, **3b** and **4** do not preclude hydrogen bonded structures, they may reduce their likelihood since there are more limited ways in which the resultant zig-zag tapes would be able to pack.

The structures of **6** and $[Zn\{SC(NH_2)_2\}_2(\mu\text{-homophthalate})]_2$ reflect a clear propensity for homophthalate to form dimers, despite the dicarboxylates in these complexes adopting different coordination modes. In the $[Zn\{SC(NH_2)_2\}_2]^{2+}$ system this tendency is particularly marked since homophthalate is the only dicarboxylate out of 13 structurally characterised compounds not to form a coordination polymer. A search of the CSD[14] reveals no examples of homophthalate coordination polymers, and it is noticeable that dimerisation of Mo_2 units has also been observed with this dicarboxylate.[15]

The reaction between $[Zn(tmtsc)_2](NO_3)_2$ and acetylenedicarboxylate gave an unexpected product in **7**. The coupling reaction between tmtsc and acetylenedicarboxylate has generated a 2-hydrazono-4-oxo-1,3-thiazolidineacetate anion, and the structure of **7** illustrates the potential for trapping reaction products in hydrogen bonded networks through the use of species containing complementary hydrogen bonding groups.

Four of the seven carboxylate-containing structures reported in this paper contain water, either as a ligand (**2**), included in the lattice (**3b**), or both (**5** and **7**). The tmtsc ligand has only two hydrogen bond donors whereas a carboxylate group can accept four or even more hydrogen bonds. Therefore use of tmtsc as a ligand in these systems leads to a relative deficiency of hydrogen bond donors in the gross structure which can be overcome by inclusion of water. This solvent inclusion also affords greater flexibility in the relative orientations of hydrogen bonding groups.

Conclusions

In this paper we have demonstrated that a deceptively simple series of compounds − those resulting from the reaction between $[Zn(tmtsc)_2]^{2+}$ and a dicarboxylate − have widely differing structures, with the relative orientation of the carboxylate groups a major factor in determining the type of structure formed. The variety of structural types obtained from this reaction series contrasts with the products observed from analogous reactions using thiourea or thiosemicarbazide complexes. Thiourea is invariably displaced from $[Zn\{SC(NH_2)_2\}_4]^{2+}$ leading to coordination polymers or cyclic oligomers, all containing tetrahedral zinc centres, whereas thiosemicarbazide is generally retained on the metal leading to structures in which the ions are only associated through hydrogen bonds. The tmtsc ligand lies between these two extremes confirming our initial premise concerning its lability, and this places $[Zn(tmtsc)_2]^{2+}$ on the borderline between the two main strategies currently employed in crystal engineering. These observations are important in helping to define the limits of the different crystal engineering strategies.

Experimental Section

Microanalyses were carried out by Mr. Alan Carver (University of Bath Microanalytical Service). 1,1,4-Trimethylthiosemicarbazide (tmtsc) was prepared from the reaction of *N*,*N*-dimethylhydrazine with methyl isothiocyanate in diethyl ether.[16] Sodium dicarboxylates were either purchased from commercial sources and used directly (fumarate and terephthalate) or prepared from the appropriate dicarboxylic acid and either sodium hydroxide or sodium hydrogen carbonate.

Synthesis of $[Zn(tmtsc)_2](NO_3)_2$: 1,1,4-Trimethylthiosemicarbazide (0.448 g, 3.36 mmol) in ethanol (10 cm^3) was added to zinc nitrate hexahydrate (0.500 g, 1.68 mmol) in ethanol (10 cm^3) and the solution stirred for 1 h. The volume of the solution was reduced to 5 cm^3 in vacuo, and the colourless crystals that precipitated overnight were separated by filtration. Yield 0.75 g (98%). On recrystallisation from water, crystals of $[Zn(tmtsc)_2(OH_2)_2](NO_3)_2$ (**1**) were obtained.

Synthesis of 2: Aqueous solutions of sodium fumarate (35 mg, 0.22 mmol) and $[Zn(tmtsc)_2](NO_3)_2$ (100 mg, 0.22 mmol) were mixed. After approximately 24 hours colourless crystals formed, and these were isolated by filtration. Yield 80 mg (79%). $C_{12}H_{26}N_6O_5S_2Zn$ (463.9): calcd. C 31.1, N 18.1, H 5.65; found C 31.3, N 18.1, H 5.71.

Synthesis of 3a and 3b: As for **2** using sodium isophthalate (53 mg, 0.25 mmol) and $[Zn(tmtsc)_2](NO_3)_2$ (115 mg, 0.25 mmol). Yield 81 mg (88%). $C_{12}H_{15}N_3O_4SZn$ (362.7): calcd. C 39.7, N 11.6, H 4.17; found C 39.6, N 11.5, H 4.22

Synthesis of 4: As for **2** using sodium (1*R*,3*S*)-(+)-camphorate (54 mg, 0.22 mmol) and $[Zn(tmtsc)_2](NO_3)_2$ (100 mg, 0.22 mmol). Yield 56 mg (64%). $C_{14}H_{25}N_3O_4SZn$ (396.8) calcd. C 42.4, N 10.6, H 6.35; found C 42.1, N 10.6, H 6.28.

Synthesis of 5: As for **2** using sodium terephthalate (46 mg, 0.22 mmol) and $[Zn(tmtsc)_2](NO_3)_2$ (100 mg, 0.22 mmol). Yield 63 mg (72%). $C_{24}H_{38}N_6O_{12}S_2Zn_2$ (797.5): calcd. C 36.2, N 10.5, H 4.80; found C 36.5, N 10.4, H 4.79.

Synthesis of 6: As for **2** using sodium homophthalate (49 mg, 0.22 mmol) and $[Zn(tmtsc)_2](NO_3)_2$ (100 mg, 0.22 mmol). Yield 59 mg (71%). $C_{26}H_{34}N_6O_8S_2Zn_2$ (753.5): calcd. C 41.5, N 11.2, H 4.55; found C 41.2, N 10.9, H 4.48.

Synthesis of 7: As for **2** using sodium acetylenedicarboxylate (35 mg, 0.22 mmol) and $[Zn(tmtsc)_2](NO_3)_2$ (100 mg, 0.22 mmol). Yellow crystals. Yield 74 mg (82% based on tmtsc).

$C_{24}H_{46}N_{12}O_8S_4Zn$ (824.3): calcd. C 35.0, N 20.4, H 5.62; found C 34.7, N 20.1, H 5.59.

The syntheses of **2**–**7** were repeated on a smaller scale in more dilute solutions in order to obtain crystals of suitable quality for the single-crystal X-ray analyses.

For compounds **2**, **3b**, **5** and **7**, data were collected on an Enraf–Nonius CAD4 automatic four-circle diffractometer and for compounds **1**, **4** and **6** data were collected on a Nonius Kappa CCD diffractometer, in all cases using Mo-K_α radiation (graphite monochromated) with λ = 0.71069 Å for **2**, **3b**, **5** and **7** and 0.71070 Å for **1**, **4** and **6**. Due to small crystal size, data for compound **3a** were collected at Station 9.8 at the SRS, Daresbury using synchrotron radiation (silicon 111 monochromated) with λ = 0.68980 Å. Crystallographic data are presented in Table 6. Lorentz and polarisation corrections were applied in all analyses and extinction coefficients were applied for compounds **2**, **3a**, **3b** and **4**. Absorption corrections (SORTAV[17]) were applied to the data for **1**, **4** and **6**. The structures were solved by direct methods (SHELXS-86[18] or SHELXS-97) with full-matrix least-squares (SHELXL-97[19]) refinement based on F^2. Non-hydrogen atoms were treated anisotropically. Hydrogen atoms were refined in calculated positions where relevant on carbon atoms, whereas the NH and OH hydrogen atoms were located and refined at a fixed distance of 0.89 Å from the parent atom throughout. CCDC 191738–191745 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44–1223/336–033; Email: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows yellow crystals and red melt of tellurium(II) dimethanethiolate, $Te(SCH_3)_2$, together with its molecular structure in the solid state and the light-induced deposition of elemental tellurium on glass, from a solution of $Te(SCH_3)_2$. In the solid state, $Te(SCH_3)_2$ exhibits a *cis* conformation of the methyl groups with respect to the TeS_2 plane, an unprecedented case for nonfunctionalized organotrichalcogenides. For $Te(SR)_2$ (R = Me, Et, *i*Pr, *t*Bu) Te–S bonding and Te···S intermolecular distances are correlated, as are ^{125}Te NMR chemical shifts and the ionization energies of the corresponding thiols. Results are rationalized in terms of σ- and π-type $n_p(S)$-σ*(Te–S) orbital interactions. Details are presented in the article by H. Fleischer et al. on p. 815ff.

The Strained η^2-N_{Amido}−$N_{Pyridine}$ Coordination of Aminopyridinato Ligands

Rhett Kempe*[a,b][‡]

Dedicated to Prof. Dr. Uwe Rosenthal

Keywords: N ligands / Catalysis / Coordination modes / Lanthanides / Transition metals

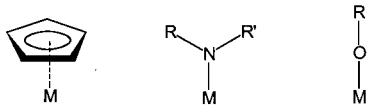
This review gives an account of the syntheses and structures of group-3 (including lanthanides), -4 and -5 metal complexes stabilised by strained η^2-coordinated aminopyridinato ligands. Reactivity studies and catalytic applications of the coordination compounds are discussed.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

General Remarks

Considerable efforts are being expended in organometallic chemistry on modifying the reactivity of metal−carbon bonds through choice of appropriate coligands. The information thus obtained is now being extensively used in, for example, homogeneous catalysis.[1] Coligands such as the cyclopentadienyl (Cp) fragment and phosphanes (Scheme 1) have hitherto played the dominant role as anionic and neutral donor functions, respectively.[2]



Scheme 1. The three most important ligand types for the stabilisation of early transition metal ions in medium to high oxidation states (R, R′ = alkyl, aryl or silyl)

In addition to these classic examples for the control of complex reactivity, exhaustive efforts over the last decade have been devoted to the development of novel ligands. As well as Cp ligands (Scheme 1, left), alkoxy (right) and amido ligands[3] (centre) have proven to be suitable for the stabilisation of early, electron-poor transition metal ions in medium to high oxidation states. Of these two alternatives, the amido ligand is especially interesting since it offers a

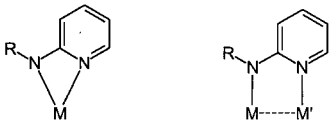
Rhett Kempe was born in Dresden in 1964. He studied chemistry at the Universität Leipzig including research stays in Jena (Prof. D. Walther) and Stuttgart (Prof. H.-G. von Schnering) and received his PhD degree (organonickel chemistry) under the supervision of Prof. J. Sieler (1989). During a DAAD postdoctoral research fellowship at MIT (1992/1993) with Prof. R. R. Schrock he became interested in N_2 activation. After a period at the MPI für Kohlenforschung in Mülheim (1993/1994) he began to study for his habilitation in the Max-Planck-Gesellschaft Group "Complex Catalysis" led by Prof. U. Rosenthal. The habilitation (metal−amido chemistry) followed at the Universität Rostock in 1998. He worked as a group leader in the Institut für Organische Katalyseforschung Rostock (IfOK) for two years and moved in 2000/2001 as a visiting scientist to the University of Melbourne (Prof. R. Robson's group). He became a Professor of Inorganic Chemistry at the University of Oldenburg in 2001 and was appointed to a Chair of Inorganic Chemistry at the University of Bayreuth in 2002. His research interests include the development of novel catalyst systems and he is working at the interface between coordination chemistry and homogeneous catalysis. He is an author of more than 170 publications and was awarded the Karl-Winnacker-Stipendium (1998) and the Heisenberg-Stipendium (2000).

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

greater variety in ligand and complex design because of the possibility for double substitution at the donor atom.

The foundations of amido transition metal chemistry were laid in the 1960s and 1970s and are associated with names such as Bürger, Wannagat, Bradley, and Lappert. The motivation for these investigations was mainly the exploration of the reactivity of metal−amido bonds in comparison to the metal−carbon bond. Disappointingly, the metal−amido bond is kinetically inert and thermodynamically more stable than the corresponding metal−carbon bond, and thus synthetically far less interesting. Today in metal−amido chemistry the stable metal−amido bond is exploited to produce well-defined reaction centres in transition metal complexes. In this way the reactivity of the resulting compounds can be specifically tailored.[4]

Aminopyridinato ligands (Scheme 2) are an important class of amido ligands and are derived from deprotonated 2-aminopyridines.[5]

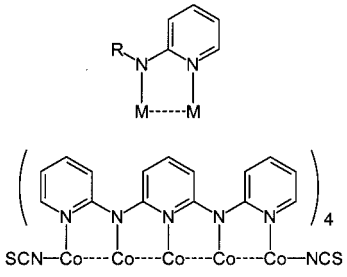


Scheme 2. Binding modes of aminopyridinato ligands (R = alkyl, aryl or silyl; M = transition metal, M′ = late transition metal)

They are interesting due to the flexibility of their binding modes. This microreview encompasses the early transition metal coordination chemistry of aminopyridinato ligands as well as the reactivity of their complexes.

Di- and Multimetallic Compounds

In addition to early transition metal coordination chemistry, deprotonated 2-aminopyridine ligands have been used to stabilise di- and multimetallic compounds (Scheme 3).[6]

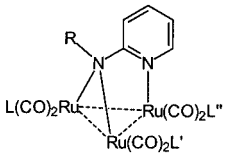


Scheme 3. Dimetallic complexes (top) and an example of a multinuclear cobalt compound (bottom) stabilised by deprotonated 2-aminopyridine ligands (R = H, alkyl or aryl; M = Ag, Cd, Co, Cr, Cu, Ir, Mo, Ni, Os, Pd, Pt, Rh, Ru, W and Zn)

Such complexes have been extensively described for Co,[7] Cr,[8] Cu,[7a,7b,9], Mo,[8a,10] Ni,[7e,9b,11] Rh,[12] and Ru[12i,13] and are known for Ag,[9e,9i,14] Cd,[15] Ir,[16] Os,[17] Pd,[18] Pt,[18] W,[8a,10d,19] and Zn.[9e,20]

Cluster Chemistry

The syntheses and reactivities of Ru[21] and Os[22] cluster compounds coordinated by deprotonated 2-aminopyridines (Scheme 4) have been reported.



Scheme 4. Examples of cluster compounds stabilised by deprotonated 2-aminopyridines (R = H, alkyl or aryl, L, L′, L′′ = additional ligand, for instance CO, PPh_3 or alkyne)

Main-Group Metal Complexes

The structural variety of aminopyridinato main-group metal complexes[23,60] makes their coordination chemistry a fascinating field and must be mentioned in any discussion of such ligands. This chemistry, as well as that of the multimetallic and cluster compounds, are not reviewed in this article.

Early Work and Contributions to the Renaissance of (Amido)metal Chemistry

The first strained η^2-coordinated aminopyridinato complex (Scheme 2, left) was published by Cotton et al.,[24] and only a few compounds[9e,25,26] had been investigated prior to 1996. The first early transition metal complex, a vanadium compound, was published by Gambarotta et al. in 1991.[26] Four years later, aminopyridinato ligands started to become extensively used to stabilise early transition metal ions in medium or high oxidation states. These studies can be seen in the context of the renaissance of metal−amido chemistry[4] which was initiated by the search for alternatives to the well-known Cp ligands. An interest in these systems soon grew due to the unique chemistry of these ligands, which is mainly a result of the close proximity of the amido and pyridine functions. In addition, these ligands may be easily derivatised to fine-tune metal complex reactivity.

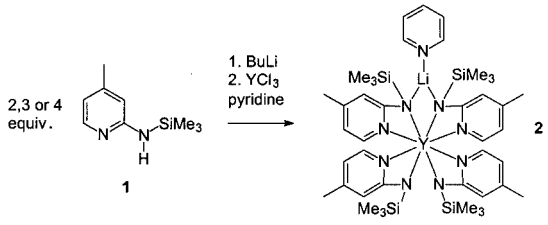
Lanthanide Chemistry Including Sc and Y

The steric bulk of aminopyridinato ligands is rather small in comparison to the related cyclopentadienyl ligands[27] and the closely related silyl-substituted amidinates.[28,29] Therefore the chemistry of aminopyridinato ligands differs dramatically from these two types in cases such as group-3 or lanthanide chemistry where steric bulk is important for the stabilisation of reactive transition metal complexes.[30]

Simple Aminopyridinato Ligands and Their Transfer Reactions

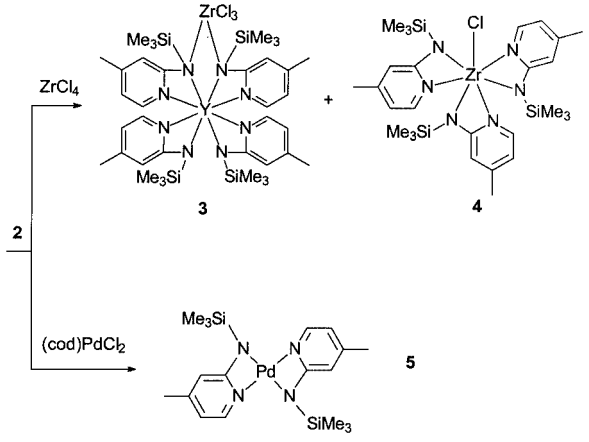
The reactions of deprotonated aminopyridines such as **1** (Scheme 5) with lanthanide trihalides gave the ate complexes such as **2**.[31] Monochloro compounds were formed

if 2 equiv. of cyclopentadienyl ligands[32] or silyl-substituted amidinates[33,28,29] were used instead of **1**.



Scheme 5. Synthesis of extensively N-coordinated ate complexes

Compound **2** can be considered as a sterically demanding lithium amide and was thus expected to react with transition metal chlorides. The reaction with $ZrCl_4$ and [(cod)$PdCl_2$] (COD = 1,5-cyclooctadiene) afforded the aminopyridinato complexes **4** and **5**, respectively (Scheme 6). The isolation of **3**, a Y−Zr dimetallic complex, indicates that such reactions proceed via heterodimetallic intermediates. Complex **5** is a rare example of a homoleptic (amido)-palladium compound.[34] In addition to the ligand transfer method, **5** was also synthesised by a salt elimination reaction at low temperature in THF (THF = tetrahydrofuran).[31] Since lanthanide ate complexes react with late metal chlorides, such salt metathesis reactions might be the key to the synthesis of heterodimetallic compounds combining lanthanides and group-8 to -10 metals. The ligand transfer reaction must be avoided in order to stabilise intermediates such as **3**.

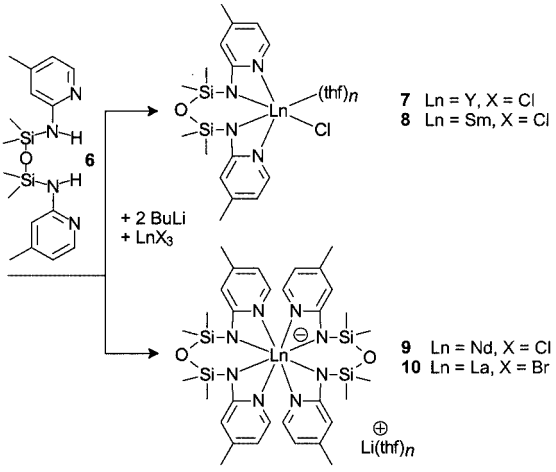


Scheme 6. Ligand transfer reactions

Bis(aminopyridinato) Ligand Complexes

Some of the limitations of simple aminopyridinato ligands can be overcome by using bis(aminopyridinato) ligands such as deprotonated **6**.

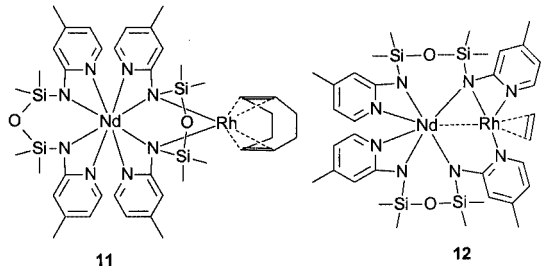
Reaction of bis(lithiated) **6** (generated in situ) with $LnCl_3$ gave different products depending on the size of the lanthanide ion. For Ln = Y and Sm, the monochloro complexes **7** and **8** were formed (Scheme 7). These could be further functionalised with $LiCH(SiMe_3)_2$, $(C_4H_9)_4NBH_4$ and $NaBH_4$ to give the corresponding bis[$CH(SiMe_3)_2$] and bis(BH_4) ate complexes.[35] Similar reactions as used to synthesise **7** and **8** afforded **9** and **10** for the larger Nd and La ions (Scheme 7). The aminopyridinato ate complex **10** was investigated as an initiator in the ring opening polymerisation of ε-caprolactone and δ-valerolactone, with particular interest focusing on the relationship between the monomer/initiator ratio and the molecular weight of the polyester, as well as the production of high molecular weight products. In both cases an almost linear relationship between the monomer/initiator ratio and the molecular weight was observed.[35] The high efficiency of the system was shown by carrying out the polymerisation in neat ε-caprolactone at room temperature. A solid polyester block (300000 g/mol, M_w/M_n = 2.3) was formed after 3 min. Ring-opening polymerisation of lactones is a useful method to produce biodegradable aliphatic polyesters,[36] and well-defined polymers of this type have possible applications as surgical sutures and in drug delivery systems.[37] The production of polymers with a well-defined molecular weight as well as a narrow molecular weight distribution is needed for such applications, since the polymer decomposition process depends on the length of the polymer chains.



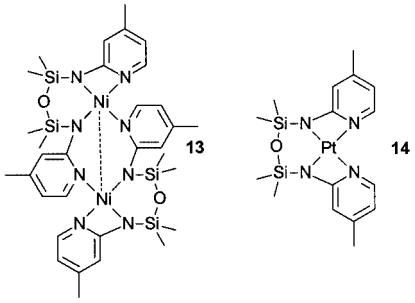
Scheme 7. Synthesis of bis(aminopyridinato) complexes

The reaction of **9** with [(cod)$RhCl]_2$ and $[(C_2H_4)_2RhCl]_2$ gave rise to the dimetallic compounds **11** and **12**, respectively (Scheme 8).[38] Both compounds are rare examples of early late heterobimetallics (ELHB) in which lanthanides and group-9 metals are combined. Investigations of the nature of the interactions between the two metals are underway.[39] The very short distance between Nd and Rh in **12** is consistent with a direct metal−metal bond, the only other example being the Lu−Ru bond in $[Cp_2(THF)Lu-RuCp(CO)_2]$ [2.955(2) Å].[40]

The reaction of **9** or **10** with [(dme)$NiCl_2$] and [(cod)$PtCl_2$] (DME = dimethoxyethane) gave the dimeric nickel complex **13** and a mononuclear platinum complex **14** (Scheme 9).[41] Both compounds are rare examples of late metal amido complexes.

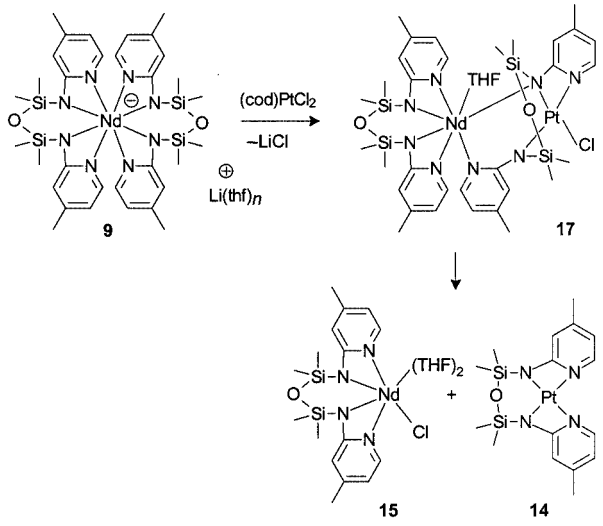


Scheme 8. Nd−Rh dimetallic complexes; Nd−Rh distances are 3.2283(15) Å for **11** and 2.9744(15) Å for **12**



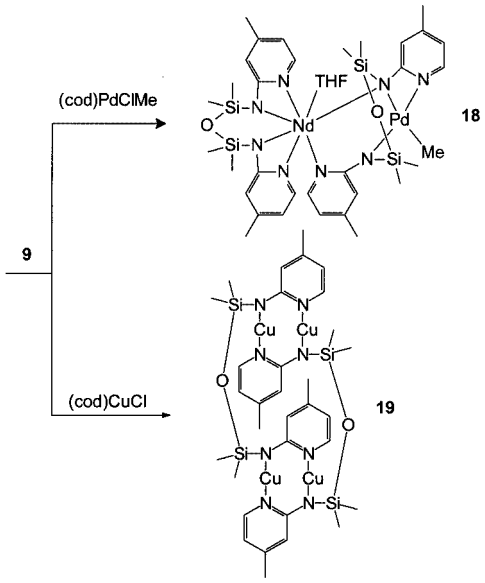
Scheme 9. Synthesis of **13** and **14** by ligand transfer

The mechanism shown in Scheme 10 was proposed for the synthesis of **14**. The neodymium ate complex **9** reacts with [(cod)$PtCl_2$] and the heterodimetallic intermediate **17** is formed. Transient **17** decomposes to give **14** and **15**. In addition to **14**, the monochloro complex **15** and LiCl were also isolated as by-products.



Scheme 10. Proposed mechanism for the formation of **14**

The reaction of **9** with [(cod)PdClMe][42] afforded the dimetallic compound **18** which can be considered as a model compound for the intermediate **17**. If **9** or **10** were treated with [(cod)$PdCl_2$] the formation of Pd black was observed. Ligand transfer also gave the tetrameric copper complex **19** (Scheme 11).



Scheme 11. Synthesis of **18** and **19**

The compounds **13**, **14** and **19** are rare examples of group-10 and -11 amido complexes.[43,44] Activation of **13** with $EtAlCl_2$ (Al/Ni = 150) in hexane at room temperature generated an efficient ethylene oligomerisation catalyst. The obtained oligoethylenes contained mainly internal double bonds (Schulz−Flory distribution, TOF = 2400 h^{-1}). When $Et_3Al_2Cl_3$ was used as a co-catalyst and CH_2Cl_2 as the solvent, highly branched oligomers with a very narrow molecular weight distribution [M_n = 230 g/mol (relative to polystyrene standards), M_w/M_n = 1.14] were produced. According to NMR investigations, the oligomers are identical with results recently published by Sen et al. The catalyst system based on **13** has significantly higher activity.[45]

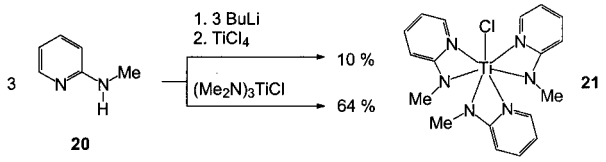
The ligand transfer reactions that led to **5**, **13**, **14** and **19** can be explained in terms of modification of the reactivity of the corresponding lithium amides by coordination at the lanthanide centres. Thus, the reduction potential is lowered but the lithium amides are still active enough to react with transition metal chlorides. Unstable Ln−Ni, Ln−Pt and Ln−Cu heterodimetallic complexes can be assumed as intermediates in the ligand transfer reactions. These intermediates are important for the formation of the polycyclic and multinuclear structures of the resulting complexes such as **13** and **19**.

Bis(aminopyridinato) ligands are useful to prepare heterodimetallic compounds with metal−metal distances smaller then 3 Å. The nature of possible interactions between the lanthanides and the group-9 or -10 metals is not yet clear. Unfortunately, the synthesis of ate complexes using deprotonated **6** is limited to larger Ln ions, and the ligand transfer could only be avoided for selected examples of group-9 and -10 metals. Ligand variations might be the key to overcome these restrictions, as was shown by the recent use of (aminopyridinato)(Cp) ligands.[46]

Titanium, Zirconium and Hafnium

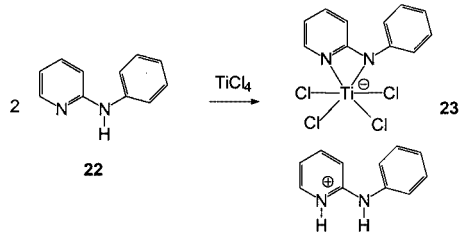
Titanium and Zirconium Complexes that Contain Alkyl-, Aryl- and Silyl-Substituted Ap (Ap = Aminopyridinato) Ligands

The exploration of group-4 metal coordination chemistry of selected aminopyridinato ligands began in 1996.[47,48] The investigators were interested in replacing Cp ligands with special amido-type ligands and studying the reactivities of the resulting complexes. It was emphasised that traditional synthesis protocols such as salt metathesis failed in the case of titanium. For instance, the lithiation of the preligand **20** with BuLi and subsequent reaction with $TiCl_4$ or $[TiCl_4(THF)_2]$ afforded **21** in only very low yield (Scheme 12).



Scheme 12. Synthesis of **21** by salt metathesis and amine elimination

The poor yield was thought to be due to reduction of the titanium centre by the lithiated Ap ligands. Two solutions were found, namely "direct synthesis" (Scheme 13) and amine elimination (Scheme 12). Direct synthesis involves treatment of an alkyl- or aryl-substituted aminopyridine (for instance **22**) with $TiCl_4$ in either boiling toluene or without solvent at temperatures above 100 °C.

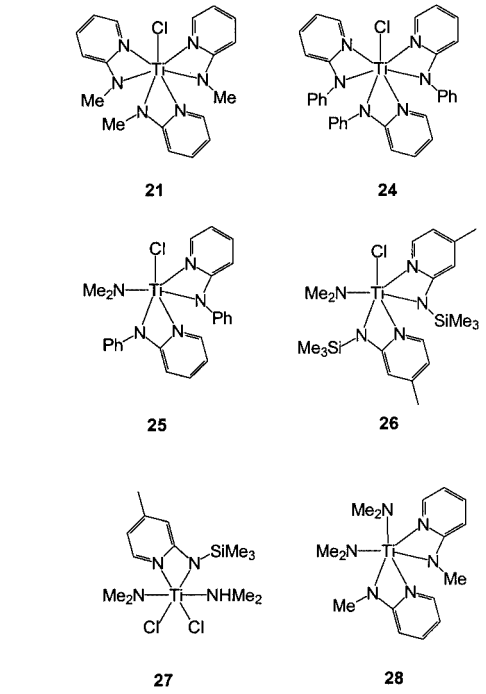


Scheme 13. "Direct synthesis": reaction of an aminopyridine with $TiCl_4$

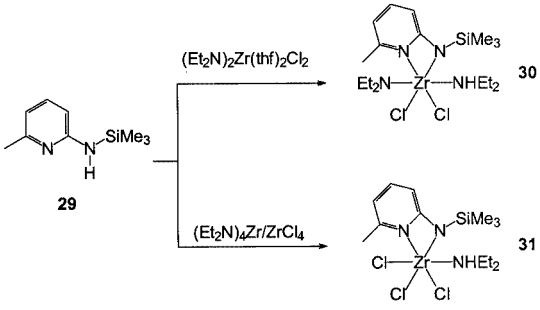
Amine elimination has been useful for the synthesis of many titanium complexes. The reaction of **1**, **20** and **22** with $(Me_2N)_3TiCl$[49] or $(Me_2N)_2TiCl_2$ [49] afforded **21**, **24**, **25**, **26**[48] and **27**.[50] Reaction of **20** with $(Me_2N)_4Ti$ gave **28**.[51]

Compound **27** showed very high[52] activities for the polymerisation of propene and 1-butene if activated with MAO, triisobutylaluminium/$B(C_6F_5)_3$ or ethylaluminium sesquichloride.[50] Remarkably the corresponding zirconium complex **30** (Scheme 15) was inactive. Compound **30** is accessible by amine elimination starting from $[(Et_2N)_2Zr(THF)_2Cl_2]$[53] and **29**.

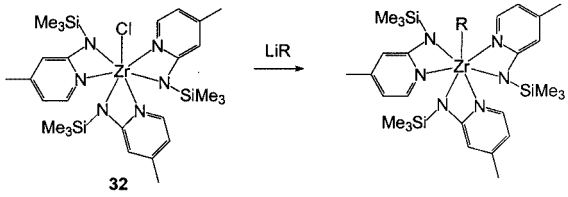
The use of in situ-generated mixed (amido)(chloro)zirconium complexes instead of the well-defined starting material $(Et_2N)_2Zr(THF)_2Cl_2$ leads to by-products such as **31**.[54] Besides amine elimination and salt metathesis, "direct synthesis" has proven to be efficient for the synthesis of zirconium complexes. In situ lithiation of **1** and subsequent reaction with $ZrCl_4$ gave **32**.[55] The propeller-like arrangement of the three Ap ligands in **32** provides a sterically well-protected reactive pocket. This allows the stabilisation of a variety of alkyl-,[55] aryl-,[55,56] alkynyl-[55,57] and butadiynylzirconium[58] complexes (Scheme 16).



Scheme 14. Ap titanium complexes by amine elimination starting from $(Me_2N)_3TiCl$, $(Me_2N)_2TiCl_2$ and $(Me_2N)_4Ti$

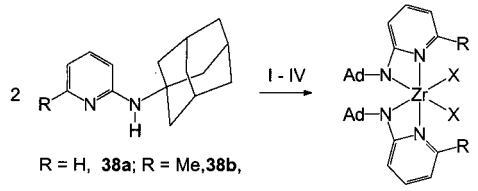


Scheme 15. Synthesis of **30** and **31**



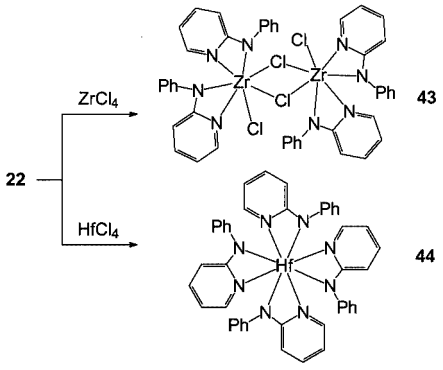
Scheme 16. Synthesis of alkyl-, aryl-, alkynyl- and butadiynylzirconium complexes [R = Me (**33**), Ph (**34**), C≡CPh (**35**), C≡CSiMe$_3$ (**36**), C≡CC≡CSiMe$_3$ (**37**)]

Better control of the zirconium/ligand stoichiometry and structures of bis(aminopyridinato) complexes is possible by introduction of sterically demanding alkyl substituents (e.g. adamantyl) on the ligands. Scott et al. reported the synthesis and structure of bis(Ap)zirconium complexes by salt metathesis, amine and alkyl elimination reactions (Scheme 17).[59]



Scheme 17. Synthesis of bis(aminopyridinato)zirconium complexes [I: 2 BuLi, $ZrCl_4$; II: $(Me_2N)_4Zr$; III: $(PhCH_2)_4Zr$; IV: (*tert*-butyl$CH_2)_4Zr$; **39a/39b** R = H/Me, X = Cl; **40a/40b** R = H/Me, X = NMe_2; **41a/41b** R = H/Me, X = CH_2Ph; **42a/42b** R = H/Me, X = CH_2-*tert*-butyl]

The activation of **39a** with MAO afforded a catalyst that showed moderate[52] activity in ethylene polymerisation. A bis(aminopyridinato) complex of zirconium has been described previously. Polamo et al. reported the "direct synthesis" of **43** by treating **22** with $ZrCl_4$.[60] A similar reaction of **22** with $HfCl_4$ gave the homoleptic complex **4** (Scheme 18).[61] This work shows that the "direct synthesis" is not a consistent method and does not allow control of the metal/ligand stoichiometry.

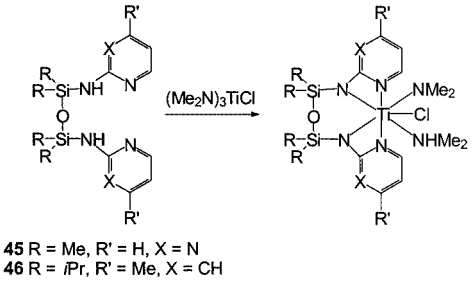


Scheme 18. Synthesis of **43** and **44**

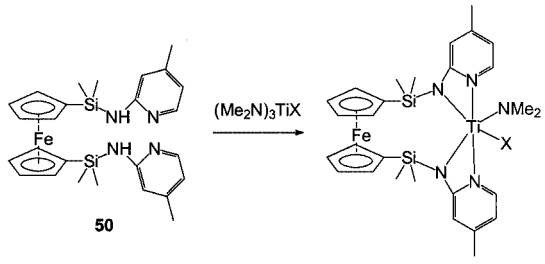
Bis(aminopyridinato)titanium Complexes

As mentioned above (see group-3 and lanthanide chemistry) two aminopyridine moieties may be easily connected and this leads to better tuned reactive sites of the corresponding transition metal complexes. The reaction of the siloxane-bridged bis(aminopyridine) **6**, **45** and **46** with $(Me_2N)_3TiCl$ yielded mixed (amido)(chloro) complexes **47**−**49** (Scheme 19).[62]

Olefin polymerisation studies of **47**−**49** have been carried out. Activation of the complexes with MAO gave rise to low[52] activities in ethylene polymerisation and no activity was observed for higher olefins. Structural studies of the precatalysts showed planar coordination of the bis(aminopyridinato) ligands and the ligands thus "cut" the complexes into two parts. This results in a separation of the coordination site of the growing alkyl chain and the coordination site for olefins during the polymerisation process. Such a separation leads to a high insertion barrier and a correspondingly slow polymerisation process. In addition to siloxane bridges, a ferrocene moiety was also introduced as a connector.[63] The reaction of **50** with $(Me_2N)_4Ti$ and $(Me_2N)_3TiCl$ afforded the heterodimetallic complexes **51** and **52** (Scheme 20).



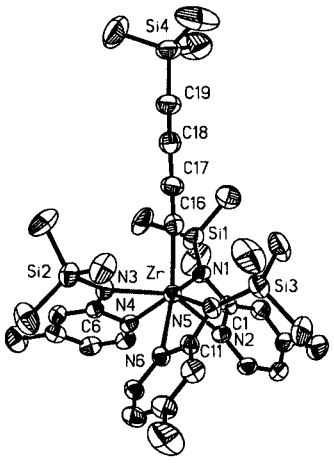
Scheme 19. Synthesis of the bis(aminopyridinato)titanium complexes **47** (R = Me, R′ = Me, X = CH), **48** (R = Me, R′ = H, X = N) and **49** (R = *i*Pr, R′ = Me, X = CH)



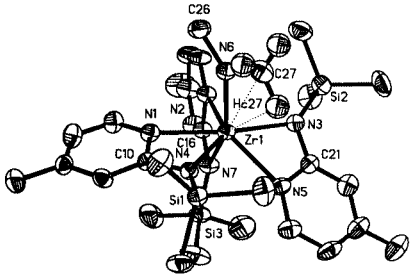
Scheme 20. Synthesis of heterodimetallic complexes **51** (X = NMe_2) and **52** (X = Cl)

Ligand/Substrate Communication

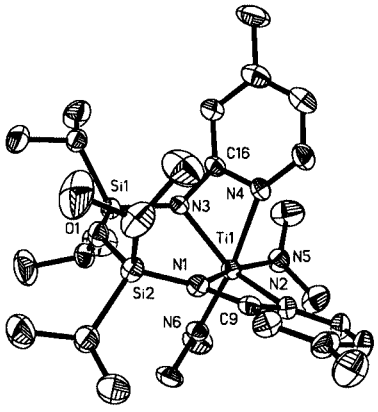
Ligand/substrate communication (steric repulsion between a ligand core and an ancillary coordinated substrate as well as electronic interactions of both via the metal centre) is a fundamental component of all metal-mediated transformation reactions, especially catalysis. While the design of a reactive metal centre is well understood in many cases,[1] understanding of the opposite influence, how substrate binding changes the coordination mode of a certain ligand core, is poor. Owing to the high flexibility of the binding modes of aminopyridinato ligands, their corresponding metal complexes may act as model systems to study ligand substrate communication because the ligands are sensitive to the steric and electronic requirements of the ancillary coordinated substrates. Comparison of the σ-butadiynylzirconium complex **37** with the dimethylamido compound **53** and the *ansa*-(aminopyridinato)titanium complexes accommodating dimethylamido (**54**) and ε-caprolactamato moieties (**55**) shows how the flexible Ap ligands can meet substrate requirements.[58] Molecular structures of the aforementioned compounds are shown in Scheme 21.



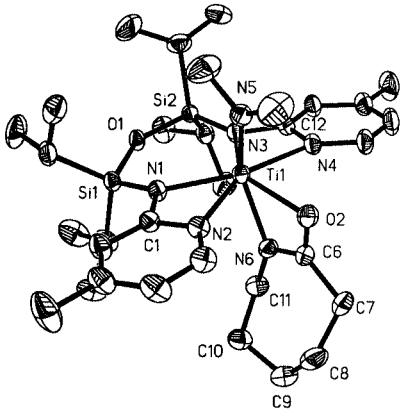
37



53



54



55

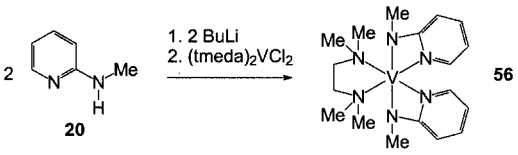
Scheme 21. Crystal structures of **37**, **53**, **54** and **55**

The propeller-like arrangement of the three aminopyridinato ligands in **37** may cause a kinetic stabilisation. The zirconium−carbon bond is sterically shielded by the three bulky trimethylsilyl groups of the ligands. This coordination mode seems to be favoured with regard to electronic considerations and is accomplished as long as the steric demand of the ancillary coordinated substrate does not dictate a rearrangement. If the substrate is sterically demanding like the dimethylamido moiety (see complex **53**), the aminopyridinato-coordinated metal centre easily alters its coordination mode. This alteration is facilitated by the extraordinary flexibility of the ligand system. It opens up a large coordination site to provide sufficient space even for an agostic interaction of the methyl group of the dimethylamido moiety. Such an interaction is proposed as an intermediate in the early transition metal catalysed aminomethylation of non-activated olefins.[64] An adaptation of the coordination mode of the ligand core can also be observed by comparing **54** and **55**. Compound **54** is a six-coordinate complex, and in order to achieve an octahedral coordination geometry the aminopyridinato ligand must become twisted. Thus, two different binding modes of the ligand core can be observed. The coordination number must be raised from six to seven to bind the caprolactamato ligand, and the pyridine moiety situated "out of plane" in **54** is turned "in the plane" in **55** to offer the additional coordination site. The ligand thus becomes planar. In addition to the geometric rearrangement, the binding mode of the formerly "out-of-plane" ligand arm is switched to the delocalised form[65] (almost equal Ti−N bond lengths). Steric and electronic changes are necessary to meet the requirements of the caprolactamato moiety.

The Vanadium Triad

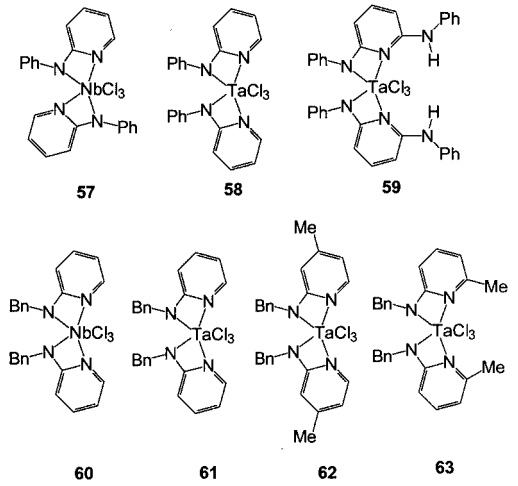
Niobium and Tantalum Complexes and Their Application in Polymerisation Reactions

The first well-characterised early transition metal aminopyridinato complex was reported by Gambarotta et al.[26] The reaction of $[(tmeda)_2VCl_2]$ (tmeda = tetramethylethylenediamine) with in situ lithiated **20** gave **56** (Scheme 22).



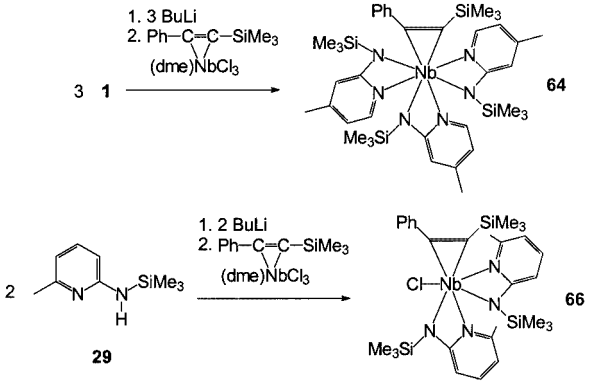
Scheme 22. Synthesis of **56**

A more detailed investigation of the group-5 metal coordination chemistry was started by Polamo et al. He applied the "direct synthesis" method to prepare a variety of niobium and tantalum complexes in high oxidation states (Scheme 23).[60,66−68]



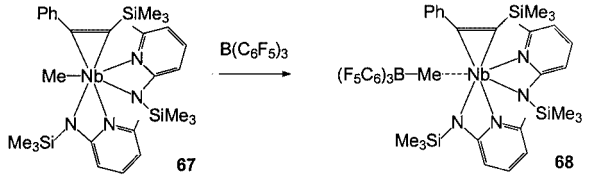
Scheme 23. Trichloro complexes of Nb and Ta prepared by "direct synthesis"

The syntheses of **57**−**59** were carried out in toluene and the compounds **60**−**63** were generated "solvent-free" using molten preligands (aminopyridines) as solvent. All compounds have been characterised by X-ray crystallography and adopt a pentagonal-bipyramidal molecular structure in the solid state. Very high[52] ethylene polymerisation activities were observed for **59** and **61** if the complexes were activated with MAO.[69] The catalyst system based on **61** gave up to 5000 $kg_{PE}/(mol_{Ta}h)$ and that based on **59** up to 23900 $kg_{PE}/(mol_{Ta}h)$. Experiments were carried out for 7 min, with longer polymerisation times leading to dramatically reduced activities. While the exact nature of the catalysts is not known, some analogy to group-4 metallocene chemistry can be drawn,[70] and mechanistic studies on high oxidation state (alkyne)bis(aminopyridinato)niobium complexes underline this analogy.[71] Treatment of $[(dme)NbCl_3(PhC{\equiv}CSiMe_3)]$[72] with 3 equiv. of in situ lithiated **1** gave the orange-red alkylniobium complex **64** (Scheme 24). The niobacyclopropene ring in **64** is extremely stable and does not react with ketones, styrene oxide, alkynes and olefins. This converses the high reactivity for the (alkyne)metallocene complexes of the titanium triad.[73]



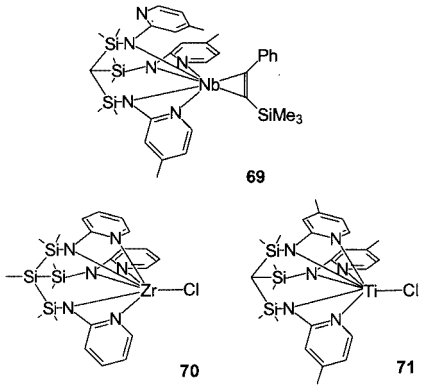
Scheme 24. (Alkyne)niobium complexes

Complexes containing two amido ligands are accessible by using the sterically more demanding deprotonated **29** (Scheme 24). The otherwise analogous reaction (first line in Scheme 24) led to **66**. NMR spectra of **66** indicated a dynamic behaviour which could be explained by alkyne rotation, with the barrier to rotation being $\Delta G^{\neq} = 80$ kJ/mol. The reaction of **66** with MeLi led to **67**, a methyl complex where the methyl group could be partially abstracted by $B(C_6F_5)_3$ (Scheme 25).



Scheme 25. Partial abstraction of a methyl group by $B(C_6F_5)_3$

Complex **68** is a zwitterionic compound and a single component ethylene polymerisation catalyst. The partial abstraction of the methyl group and the structural parameters of **68** are similar to what has been observed for group-4 metallocenes.[74] Thus, an analogy in terms of the generation of ethylene polymerisation catalysts can be drawn between high oxidation state group-5 metal Ap compounds and group-4 metallocenes. The synthetic procedure described in Scheme 24 could also be used to synthesise the niobium alkyne **69**.[75] Complex **69** polymerised acetylene without the formation of benzene as a by-product. The first metal complex of a tris(aminopyridinato) ligand (**70**) was reported by Gade et al.[76] Complexes of such ligands are rarely described (see **69**, **70** and **71** in Scheme 26).

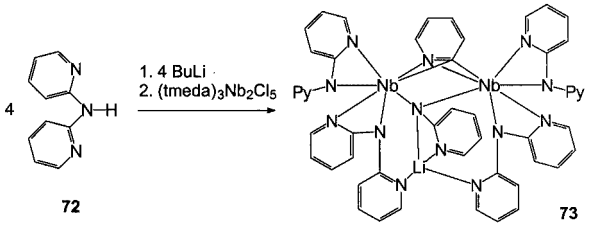


Scheme 26. Complexes stabilised by tris(aminopyridinato) ligands

Complex **71** was synthesised by amine elimination. Owing to the steric crowding in **69**, one of the three pyridine moieties does not coordinate to the niobium centre, in contrast to the hexadentate coordination of **71**. Tris(aminopyridinato) ligands are variable in their denticity, a phenomenon which is characteristic of many Ap compounds during substrate binding and release, but seldom observed in molecular structures determined by X-ray crystallography.

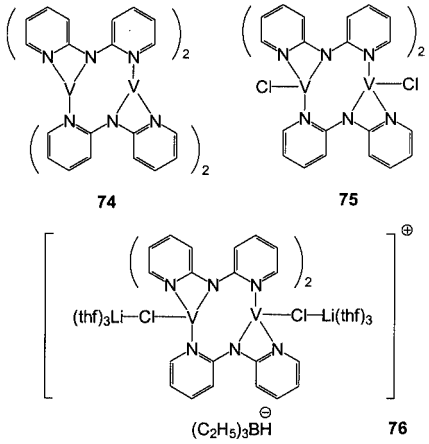
Low Oxidation State Chemistry

Oxidative addition of C−X bonds (X = N, P, O, S, halogen) performed by transition metal complexes is an area of research which is of interest not only from a fundamental point of view, but also because of the many possible applications of such reactions. Aminopyridinato ligands can either stabilise reactive group-5 metal complexes in low oxidation states or be involved in bond cleavage processes. Compound **56** (Scheme 22) is an example of a group-5 complex in a low oxidation state. The reaction which led to **56** proceeded as expected and no C−X bond activation was observed. C−N bond cleavage took place if $(tmeda)_3Nb_2Cl_5$ was treated with the lithium salt of **72** (Scheme 27).[77]



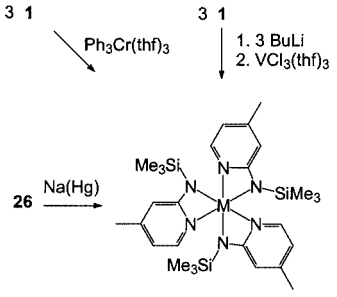
Scheme 27. C−N bond cleavage of an aminopyridinato moiety

The reaction of "$VCl_2{\cdot}n$THF" [generated in situ by the reduction of $VCl_3(THF)_3$ with $NaB(C_2H_5)_3H$] and lithiated **72** yielded **74** if a mixture of THF and toluene was used as solvent at reflux temperature. A similar reaction carried out in THF at 0 °C gave **76**. C−Cl bond cleavage was observed during the reaction of **76** with CH_2Cl_2. Compound **75** was the product of this transformation (Scheme 28).[78]



Scheme 28. Products of the reaction of "$VCl_2{\cdot}n$THF" with lithiated **72**

Complexes shown in Scheme 27 and Scheme 28 are dinuclear compounds. Deprotonated **72** acts as a tridentate ligand and its linear arrangement of the three N donor functions does not stabilise mononuclear complexes. A mononuclear homoleptic tris(aminopyridinato)vanadium complex was synthesised from lithiated **1** (in situ) and $[VCl_3(THF)_3]$ (Scheme 29).[79]



Scheme 29. Mononuclear tris(aminopyridinato)M^{III} complexes (**77**: M = V; **78**: M = Ti; **79**: M = Cr)

Compound **79** is a rare example of an aminopyridinato group-6 metal complex in which the Ap ligands coordinate in a strained η^2-fashion.[25,80]

Conclusions and Outlook

Aminopyridinato ligands can coordinate a variety of early transition metal complexes in the strained η^2-fashion. This binding mode initiates a special reactivity. Thus, it has become possible to stabilise heterodinuclear compounds with unusual metal−metal combinations including short metal−metal distances as well as highly active olefin polymerisation catalysts. The exploration of the catalytic and stoichiometric reactivity of many of the complexes synthesised so far was started only recently and a lot of exiting "chemistry" can be expected in the near future, covering

fields like small molecule activation, homogenous catalysis and the synthesis and reactivity of multinuclear complexes.

Acknowledgments

Financial support of our own work from the Deutsche Forschungsgemeinschaft (KE, 756/2-1, KE 756/3-1), the Fonds der Chemischen Industrie, the Max-Planck-Gesellschaft, the Karl-Winnacker-Stiftung, the IfOK Rostock, and the Carl von Ossietzky Universität Oldenburg is gratefully acknowledged. Cyclodextrin-Encapsulated Iron Catalysts for the Polymerization of Ethylene

Dominique Armspach,*[a] Dominique Matt,*[a] Frédéric Peruch,*[b] and Pierre Lutz*[b]

Keywords: Cyclodextrins / Polymerization / Iron / N ligands / Cavitands

The synthesis and characterization of dichloroiron(II) complexes of tridentate nitrogen ligands based on 2,6-bis(imino)-pyridine-capped α- and β-cyclodextrin derivatives are described and their propensity to act as ethylene polymerization catalysts reported.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Although dominated by the very active Group 4 metallocenes catalysts for a long time,[1] the field of catalytic polymerization has recently been rejuvenated by Brookhart[2] and Gibson's seminal works[3,4] on the use of late transition metal complexes in olefin polymerization. Beside systems containing the α-diimine ligand framework,[5] nitrogen-containing tridentate complexes of iron and cobalt based on the 2,6-bis(iminoaryl)pyridine fragment are amongst the most studied because of their ability to promote the formation of linear polyethylene very efficiently.[6] Steric bulk control around the metal center is a prerequisite not only for forming the neutral trigonal-pyramidal MCl_2 catalyst precursor at the expense of the inactive octahedral cationic $[(N,N,N)_2Fe]^{2+}$ complex,[7] but also for tuning the molecular weight of the polymer produced.[4] So far, the control of the steric environment at the metal has been achieved by changing the size of the aryl (Ar) and imino carbon (R) substituents of the 2,6-bis(iminoaryl)pyridine moiety. An alternative would be to encapsulate the metal fragment in molecular cavities of various sizes. Here we describe the synthesis of methylated α- and β-cyclodextrin (CD) derivatives[8] rigidly capped with a 2,6-bis(imino)pyridyl fragment and the activity of their iron complexes in ethylene polymerization.

Results and Discussion

The ligands **4a** and **4b** used in this study were prepared by condensing 2,6-diformylpyridine with diamines **3a**[9] and **3b**, respectively (Scheme 1). The latter was synthesized in two steps from the known dimesylate **1**[10] according to a procedure adapted from that used for preparing diamine **3a**. The cyclisation of both diamines proceeded smoothly in dilute MeCN solution in the presence of molecular sieves (4 Å) with only small amounts of oligomeric material being produced during the reaction. The latter was removed by simple recrystallisation from $CHCl_3$/pentane so that the pure capped CDs **4a** and **4b** could be obtained in 46 and 64% yields, respectively. As shown by ^1H NMR and ^{13}C NMR spectroscopy, the C_2 symmetry of diamine **3a** is retained upon cyclisation. In addition, it is unlikely that the macrocyclic structures of both **4a** and **4b** are strongly distorted by the presence of the relatively short and rigid capping unit as the signals of the anomeric protons all fall in a narrow chemical shift region ($\Delta\delta < 0.17$ ppm).[9] This observation was confirmed by a single-crystal X-ray diffraction study on ligand **4a** (Figure 1). The structure of the latter reveals an almost perfectly round shape for the C_2-symmetrical CD framework, with all the glucose units in the standard $^4C_1$ conformation. Interestingly, the atoms of the bridging unit lie almost in the same plane, the N(1)−C(27)−C(28)−N(2) torsion angle being 4.5°. This particular feature is a result of the presence of a single water molecule located in the middle of the cavity, which is hydrogen-bonded to two opposing imine nitrogen atoms. A distance of 3.00(2) Å can be calculated between the imine nitrogen N(1)/N(1A) atoms and the encapsulated water oxygen O_w, while the N(1)−O_w−N(1A) angle has a value of 106.5°. In keeping with the C_2 symmetry of the ligand, the plane defined by the water and the 2,6-diformylpyridyl atoms is perpendicular to the average plane defined by the six glucosidic O-4 atoms. Clearly, the three nitrogen atoms are well positioned to coordinate a metal fragment inside the CD cavity. As expected, treatment of ligands **4a/4b** with $FeCl_2$ afforded the desired complexes **5a/5b** in good yields. Both compounds could be univocally identified by mic-

roanalysis and FAB-MS measurements, the latter showing an intense peak for the $[M-Cl]^+$ ion in each case. ^{1}H NMR spectroscopy also proved to be useful even though both complexes are paramagnetic. In particular, the C_2 symmetry of **5a** could be confirmed by the presence of eight signals of equal intensity, corresponding to 16 CD methoxy groups, in its ^{1}H NMR spectrum. Although similar Fe^{II}-aldimines are reported to be green-brown,[4] **5a/5b** turned out to be deep blue. This difference in color probably results from the fact that the coordinating unit no longer consists of a 2,6-bis(imino*aryl*)pyridine fragment but, for the first time, of a 2,6-bis(imino*alkyl*)pyridine one. We anticipated that the **5a/5b**-promoted ethylene polymerization might be influenced by this modification, which undoubtedly alters the electronic nature of the Fe^{II} complexes.

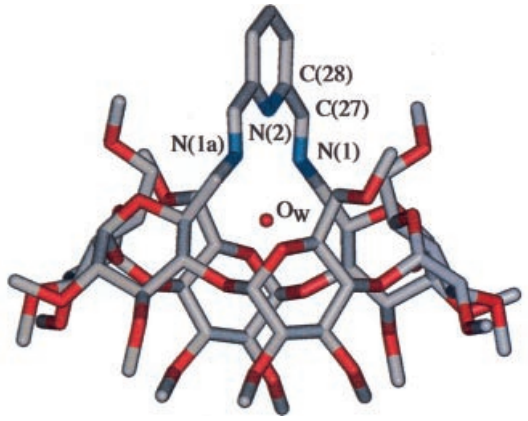

Figure 1. Molecular structure of ligand **5a** (sticks); "O_w" stands for the oxygen atom of the entrapped water molecule

The results of ethylene polymerization are collected in Table 1. Procatalyst **5a**, after activation with a large excess of MAO (methylaluminoxane), proved to be almost inactive. With a maximum TOF value of 125 h^{-1}, **5b**, which possesses a larger cavity, is much more active and produces linear polyethylene, as expected. However, **5b** is still about 1000 times less active than the comparable iron-aldimine system **6**.[3] The presence of a CD cavity tightly wrapped around the metal center may inhibit the chain growing process to the extent that the small α-CD host does not allow any polymerization at all even if **5a** is activated by MAO, as revealed by the change of color from blue to orange. Moreover, **5b** requires larger amounts of MAO than usual to reach the maximum activity (Al/Fe > 2000 equiv.), which means that access to the metal center by MAO may be also hindered to a certain extent. It is also possible that the numerous primary face ether oxygen atoms interact unfavorably with the MAO-generated iron(III) cationic active species,[11] thus reducing the overall rate of polymerization. In terms of molecular weight, melting temperatures and crystallinity, the polyethylene generated by **5b** compares well

Table 1. Results of ethylene polymerization runs using precatalysts **5a** and **5b**

Run	Precatalyst (μmol)	Activator[a] (mmol/equiv.)	T (°C)	T (h)	Yield (mg)	TOF[b] (mol/mol·h)	T_f (°C)	χ_c	M_n (g·mol^{-1})	M_w (g·mol^{-1})	IP

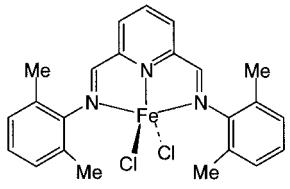
with that obtained with the classical system **6**. Clearly, the β-CD cavity in **5b** provides adequate steric protection of the active site for the polymer chain to reach an appreciable length, although at the expense of activity.



6

We have demonstrated that encapsulation of the metal center in molecular cavities like cyclodextrins is a viable alternative to the active site steric protection provided by substituted aryl rings in 2,6-bis(imino)pyridyl-based ethylene polymerization catalysts. The activity and the potential of the latter may be further improved by using large capped calixarenes, which contain only a limited number of oxygen atoms and provide plenty of space for the chain growth to take place. Investigation of these alternative systems is currently underway.

Experimental Section

General: All manipulations were performed under dry nitrogen using purified solvents. Pyridine dicarboxaldehyde,[12] dimesylate **1**,[10] and diamine **3a**[9] were synthesized according to literature procedures. MAO 10-wt% (Aldrich) was used either as received or as a white powder which was obtained after evaporation of the solvent (60 °C, 3 h). This treatment reduces the amount of residual trimethylaluminium to ca. 3%. The synthesis of compound **3b** starts with the preparation of intermediate **2b**.

Diazide 2b: Dry sodium azide (0.550 g, 8.50 mmol) was added to a solution of **1** (0.650 g, 0.42 mmol) in dry DMF (75 mL). The reaction mixture was stirred under N_2 at 65 °C for 18 h, cooled to room temperature, and then poured into ice-water (200 mL). The aqueous solution was extracted with diethyl ether (4 × 100 mL) and the organic extract washed with water (200 mL) before being dried ($MgSO_4$) and the solvents evaporated to dryness to afford **2** (0.610 g, 100%) as a colorless solid. m.p. 188–190 °C. ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 3.38 (s, 9 H, CH_3O-6), 3.40 (s, 6 H, CH_3O-6), 3.50 (s, 3 H, OCH_3), 3.51 (s, 9 H, OCH_3), 3.52 (s, 9 H, OCH_3), 3.63 (s, 12 H, OCH_3), 3.64 (s, 3 H, OCH_3), 3.65 (s, 3 H, OCH_3), 3.66 (s, 3 H, OCH_3), 3.15–3.98 (42 H, H-2, H-3, H-4, H-5, H-6), 5.06 (d, ^3J = 3.9 Hz, 1 H, H-1), 5.07 (d, ^3J = 4.1 Hz, 1 H, H-1), 5.12 (d, ^3J = 3.7 Hz, 5 H, H-1) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, $CDCl_3$, 25 °C): δ = 51.9 [×2] (CH_2N_3), 58.3 [×3], 58.4, 58.5 [×2], 58.6, 58.8 [×5], 61.1 [×3], 61.2 and 61.4 [×3] (OCH_3), 70.6, 70.7 [×2], and 70.8 [×4] (C-5), 70.9, 71.2, and 71.5 [×3] (C-6^{B,C,E,F,G}), 80.0 [×4], 80.1 [×2], 81.3 [×3], 81.5, 81.6 [×5], 81.8 [×4], and 81.9 [×2] (C-2, C-3, C-4), 98.2 [×2], 98.8, 98.9, 99.0, and 99.1 [×2] (C-1) ppm. $C_{61}H_{106}N_6O_{33}$ (1451.54): calcd. C 50.48, H 7.36, N 5.79; found C 50.75, H 7.54, N 5.57.

Diamine 3b: Triphenylphosphane (0.610 g, 2.32 mmol) was added to a solution of diazide **2** (0.550 g, 0.39 mmol) in dioxane (6 mL) under N_2. The clear solution was stirred for 1 h at room temperature before adding conc. aqueous NH_4OH solution (1.6 mL) dropwise. After overnight stirring, the reaction mixture was poured into water (200 mL) and the pH of the resulting suspension adjusted to 4 with HCl before being extracted with toluene (5 × 50 mL). The aqueous phase was then made alkaline by adding 2 M NaOH (50 mL) and the compound subsequently extracted with CH_2Cl_2 (5 × 50 mL). The CH_2Cl_2 extract was dried ($MgSO_4$) before being evaporated to dryness. Recrystallisation from heptane afforded **3b** (0.46 g, 84%) as colorless fluffy solid. ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 1.56 (br. s, 4 H, NH_2), 3.37 (s, 9 H, CH_3O-6), 3.38 (s, 6 H, CH_3O-6), 3.49 (s, 6 H, OCH_3), 3.50 (s, 9 H, OCH_3), 3.53 (s, 6 H, OCH_3), 3.58 (s, 3 H, OCH_3), 3.62 (s, 3 H, OCH_3), 3.63 (s, 3 H, OCH_3), 3.64 (s, 6 H, OCH_3), 3.65 (s, 3 H, OCH_3), 3.67 (s, 3 H, OCH_3), 3.02–3.90 (42 H, H-2, H-3, H-4, H-5, H-6), 5.04–5.11 (5 H, H-1), 5.19 (d, ^3J = 3.7 Hz, 2 H, H-1) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, $CDCl_3$, 25 °C): δ = 42.3 and 42.4 (CH_3N), 57.7, 57.9 [×2], 58.0, 58.2, 58.7 [×3], 58.8 [×2], 58.9 [×2], 60.7 [×2], 61.2 [×2], 61.3 and 61.4 [×2] (OCH_3), 66.7 [×2], 70.9 [×2], and 71.2 (C-6^{B,C,E,F,G}), 70.9 [×5] and 71.3 [×2] (C-5), 79.4, 79.5, 80.1, 80.3 [×3], 80.5, 81.4 [×4], 81.5 [×5], 81.6 [×2], 81.7, 82.4 and 82.8 (C-2, C-3, C-4), 98.4 [×2], 98.6, 98.8 [×2], and 99.2 [×2] (C-1) ppm. $C_{61}H_{110}N_2O_{33}·2H_2O$ (1399.55 + 36.03): calcd. C 51.04, H 8.00, N 1.95; found C 51.16, H 8.03, N 1.85.

Ligand 4a: A solution of diamine **3a** (1.000 g, 0.84 mmol) in CH_3CN (50 mL) and a solution of 2,6-diformylpyridine (0.113 g, 0.84 mmol) in CH_3CN (50 mL) were added simultaneously to a vigorously stirred suspension of molecular sieves (4 Å) in CH_3CN (20 mL) in 1 h at room temperature. The reaction mixture was then

stirred for 1 h at room temperature before being filtered through Celite. Removal of the solvent in vacuo afforded a colorless solid which was recrystallized from $CHCl_3$/pentane to afford pure **4a** (0.500 g, 46%) as a colorless solid. m.p. 200 °C (dec.). ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 3.03 (s, 6 H, CH_3O-6), 3.18 (s, 6 H, CH_3O-6), 3.44 (s, 6 H, OCH_3), 3.48 (s, 6 H, OCH_3), 3.51 (s, 6 H, OCH_3), 3.64 (s, 12 H, OCH_3), 3.71 (s, 6 H, OCH_3), 2.88−4.77 (36 H, H-2, H-3, H-4, H-5, H-6), 4.95 (d, ^3J = 3.4 Hz, 2 H, H-1), 5.00 (d, ^3J = 3.2 Hz, 2 H, H-1), 5.09 (d, ^3J = 3.4 Hz, 2 H, H-1), 7.51 (d, ^3J = 7.3 Hz, 2 H, H_{pyr}-3,5), 7.96 (t, ^3J = 7.6 Hz, 1 H, H_{pyr}-4), 8.41 (br. m, 2 H, CH=N) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, $CDCl_3$, 25 °C): δ = 57.3, 57.6, 58.0, 58.8, 61.5, 61.8 [×2] and 62.0 (OCH_3), 62.8 (CH_2N), 70.1 and 70.8 (C-6^{B,C,E,F}), 70.3, 70.6 and 72.5 (C-5), 80.4, 81.2 [×2], 81.8, 82.0, 82.5 [×2], 82.6 and 85.3 (C-2, C-3, C-4), 99.2, 99.7 and 100.1 (C-1), 125.9 (C_{pyr}-3,5), 137.9 (C_{pyr}-4), 153.2 (C_{pyr}-2,6), 159.8 (C=N) ppm. MS (FAB): *m*/*z* (%) = 1294.6 (95) [M^+ + H], 1316.6 (25) [M^+ + Na]. $C_{59}H_{95}N_3O_{28}$ (1294.43): calcd. C 54.75, H 7.40, N 3.25; found C 54.71, H 7.69, N 3.14.

Ligand 4b: The previously described procedure was used to prepare **4b** from diamine **3b** (0.450 g, 0.32 mmol) and 2,6-diformylpyridine (0.044 g, 0.32 mmol). Addition of pentane to a solution of crude **4b** in $CHCl_3$ resulted in the precipitation of higher oligomers that were eliminated by filtration. The filtrate was then evaporated to dryness to afford pure **4b** as a colorless amorphous solid (0.300 g, 64%). m.p. 200 °C (dec.). ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 3.04 (s, 3 H, OCH_3), 3.10 (s, 3 H, OCH_3), 3.30 (s, 6 H, OCH_3), 3.31 (s, 3 H, OCH_3), 3.44 (s, 3 H, OCH_3), 3.47 (s, 9 H, OCH_3), 3.49 (s, 3 H, OCH_3), 3.53 (s, 3 H, OCH_3), 3.58 (s, 3 H, OCH_3), 3.63 (s, 9 H, OCH_3), 3.65 (s, 3 H, OCH_3), 3.67 (s, 3 H, OCH_3), 3.68 (s, 3 H, OCH_3), 3.74 (s, 3 H, OCH_3), 2.85−4.73 (42 H, H-2, H-3, H-4, H-5, H-6), 4.90 (d, ^3J = 3.7 Hz, 1 H, H-1), 4.97 (d, ^3J = 3.4 Hz, 1 H, H-1), 5.02 (d, ^3J = 3.7 Hz, 1 H, H-1), 5.05 (d, ^3J = 3.7 Hz, 2 H, H-1), 5.17 (d, ^3J = 3.9 Hz, 2 H, H-1), 7.51 (d, ^3J = 6.4 Hz, 1 H, H_{pyr}-3 or H_{pyr}-5), 7.62 (t, ^3J = 7.6 Hz, 1 H, H_{pyr}-4), 7.99 (d, ^3J = 6.6 Hz, 1 H, H_{pyr}-3 or H_{pyr}-5), 8.49 (br. s, 2 H, CH=N) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, $CDCl_3$, 25 °C): δ = 57.2, 57.3, 58.0, 58.1 [×3], 58.4 [×2], 58.8 [×3], 59.3, 60.0, 60.6, 60.7, 61.6 [×3], 61.7, 61.9 and 62.0 (OCH_3), 64.9 [×2] (CH_2N), 69.4, 70.1 [×2], and 70.5 [×2] (C-6^{B,C,E,F,G}), 70.2, 70.5, 70.7 [×2], 71.0, 71.3 and 73.6 (C-5), 80.9 [×2], 81.0, 81.2 [×2], 81.3, 81.4 [×3], 81.7 [×2], 81.8 [×2], 81.9, 82.0 [×2], 82.2, 82.4, 82.9, 83.0 and 83.1 (C-2, C-3, C-4), 98.4, 98.6, 99.1, 99.3, 99.6, 99.8 and 100.2 (C-1), 121.7 and 125.0 (C_{pyr}-3,5), 136.9 (C_{pyr}-4), 152.7 and 155.3 (C_{pyr}-2,6), 159.4 and 164.5 (C=N) ppm. $C_{68}H_{111}N_3O_{33}$ (1498.64): calcd. C 54.50, H 7.47, N 2.80; found C 54.62, H 7.70, N 2.71.

Complex 5a: A solution of **4a** (0.400 g, 0.31 mmol) in degassed *n*-butanol (3 mL) was added dropwise to a solution of anhydrous $FeCl_2$ (0.039 g, 0.31 mmol) in *n*-butanol (5 mL) at 80 °C. The resulting blue solution was stirred at 80 °C for 30 min before being cooled to room temperature. The reaction mixture was evaporated almost to dryness whereupon diisopropyl ether (30 mL) was added to precipitate the product as a blue powder, which was subsequently filtered, washed with diethyl ether (3 × 10 mL), and dried to afford 0.280 g of **4** (64%). ^{1}H NMR (400.1 MHz, $CDCl_3$, 25 °C): δ = −44 to +32 (44 H, H-1, H-2, H-3, H-4, H-5, H-6, C*H*=N), −10.19 (6 H, OCH_3), −7.81 (6 H, OCH_3), 1.36 (6 H, OCH_3), 3.88 (6 H, OCH_3), 4.68 (6 H, OCH_3), 6.23 (6 H, OCH_3), 8.98 (6 H, OCH_3), 9.27 (6 H, OCH_3), 46.87 (1 H, H_{pyr}-4), 66.95 (2 H, H_{pyr}-3,5) ppm. MS (FAB): *m*/*z* (%) = 1387.7 (100) [M^+ − Cl]. $C_{59}H_{95}Cl_2FeN_3O_{28}$ (1421.17): calcd. C 49.86, H 6.74, N 2.96; found C 49.76, H 6.64, N 2.81.

Complex 5b: The previously described procedure was used to prepare **5b** from ligand **4b** (0.260 g, 0.17 mmol) and anhydrous $FeCl_2$ (0.022 g, 0.17 mmol) in 5 mL of degassed *n*-butanol. Complex **5b** was obtained as a blue microcrystalline solid in 61% yield (0.170 g). ^{1}H NMR (400.1 MHz, $CDCl_3$, 25 °C): δ = −43.4 to +50.7 (51 H, H-1, H-2, H-3, H-4, H-5, H-6, C*H*=N), −15.24 (3 H, OCH_3), −0.98 (3 H, OCH_3), −0.80 (3 H, OCH_3), 0.14 (3 H, OCH_3), 0.24 (3 H, OCH_3), 0.38 (3 H, OCH_3), 0.78 (3 H, OCH_3), 1.24 (3 H, OCH_3), 1.32 (3 H, OCH_3), 1.42 (3 H, OCH_3), 2.37 (3 H, OCH_3), 3.71 (3 H, OCH_3), 4.67 (3 H, OCH_3), 4.85 (3 H, OCH_3), 5.45 (3 H, OCH_3), 6.38 (3 H, OCH_3), 8.56 (3 H, OCH_3), 9.41 (3 H, OCH_3), 13.03 (3 H, OCH_3), 44.96 (1 H, H_{pyr}-4), 54.15 (1 H, H_{pyr}-3 or H_{pyr}-5), 62.33 (1 H, H_{pyr}-3 or H_{pyr}-5) ppm. MS (FAB): *m*/*z* (%) = 1623.7 (70) [M^+], 1588.7 (100) [M^+ − Cl]. $C_{68}H_{111}Cl_2FeN_3O_{33}$ (1625.39): calcd. C 50.25, H 6.88, N 2.59; found C 50.46, H 7.06, N 2.56.

Crystal Data for 4a: $C_{59}H_{95}N_3O_{28}{\cdot}H_2O{\cdot}5CHCl_3$, M_r = 1909.32, orthorhombic, space group $P2_12_12$, a = 25.3628(2), b =18.2041(3), c = 9.6156(6) Å, V = 4439.6(3) Å^3, Z = 2 (the ligand has crystallographic C_2 symmetry), ρ = 1.43 g·cm^{-3}, Mo-K_α radiation (λ = 0.71073 Å), μ = 0.321 mm^{-1}. Data were collected on a Kappa CCD Enraf−Nonius system at 173 K. The structure was solved by direct methods and refined on F_0^2 by full-matrix least-squares. All non-hydrogen atoms were refined anisotropically. The absolute structure was determined by refining Flack's x parameter. $R1$ = 0.065 and $\omega R2$ = 0.075 for 3478 data with $I > 3\sigma(I)$.
CCDC-192556 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Polymerization Procedure: The polymerization reactions were carried out in a Büchi miniclave (200 mL). In a typical procedure, a Schlenk flask was charged with the complex (7 mmol) and toluene (10 mL). The solution was injected into the autoclave together with additional toluene (10 mL) whereupon MAO was introduced. The autoclave was then pressurized with ethene. After completion of the reaction (see reaction conditions in Table 1), acidified ethanol (30 mL) was added to the reaction mixture. Further precipitation was achieved by adding more ethanol. The white polymer was dried under vacuum at 50 °C for 12 h.

Acknowledgments

The authors thank Mrs. S. Zehnacker (Strasbourg) for DSC measurements, and Prof. H. Cramail and E. Ibarboure (Laboratoire de Chimie des Polymères Organiques de Bordeaux) for HT SEC measurements. We also thank the University Louis Pasteur for financial support (projet exceptionnel 2001).

Ti^{IV} Complexes with Novel, Chiral, Tridentate Amido-Amidinate or Monoanionic, Didentate Amidinate Ligands

Jian-Feng Li,[a] Shu-Ping Huang,*[a] Lin-Hong Weng,[b] and Dian-Sheng Liu*[a]

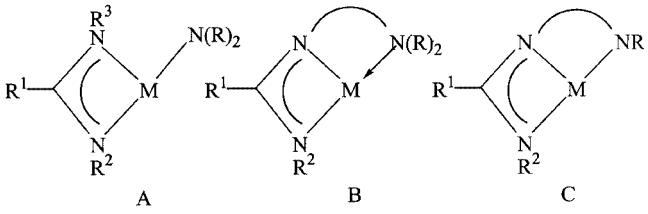
Keywords: Titanium / N ligands / Coordination modes / Rearrangement / Elimination

Reaction of LiL or a new type of dianionic ligand Li_2L (**2**) {H_2L = (1*R*,2*R*)-(−)-1-[N(H)C(Ph)N(SiMe$_3$)]-2-[N(H)SiMe$_3$]-C_6H_{10}} with $TiCl_2(OiPr)_2$ yielded the novel complexes [TiCl(L)(O*i*Pr)$_2$] (**1**) and [Ti(L)(O*i*Pr)$_2$] (**3**), respectively. Treatment of Na_2L' {H_2L' = (1*R*,2*R*)-(−)-1,2-[N(H)C(Ph)N-(SiMe$_3$)]$_2C_6H_{10}$} with $Ti(OiPr)_2Cl_2$ unexpectedly gave **3** via a unusual rearrangement/elimination reaction; The structure of complex **3** shows both an η^3-π bond and σ-bonds to the central metal. This is a new coordination model and is obtained for the first time for this type of amido-amidinate complex.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

There has been an intense interest in organometallic complexes with amidinate ligands as these ligands have proven to be very versatile due to the ease of adapting their properties to the steric and electronic requirements of the metal centre simply by changing the substitution at the terminal nitrogen atoms.[1,2] For group 4 transition metals, amidinates have been used as ancillary ligands in olefin polymerization catalysis.[3,4] Recently, several groups have reported the introduction of an additional electron-donor amine or pyridine functionality thus forming six-electron-donor, three-coordinate ligands that are close analogues of Cp ligands.[5−9] This system may be sub-divided into models **A**−**C** (see Scheme 1): (**A**) a mixed ligand with the amine group and amidinate attached to the central metal via η^3-π and σ bonds {e.g. Ge[$C_6H_{11}NC(CMe_3)NC_6H_{11}]_2$};[10] (**B**) a linked amido-amidinate ligand with the tertiary amine functionality as a pendant group on the amidinate framework and the nitrogen of the amine bonding through a lone pair of electrons {e.g. [Al{N(SiMe$_3$)C(Ph)N(CH$_2$)$_3$NMe$_2$}Cl$_2$];[9] (**C**) a linked amido-amidinate ligand but with η^3-π- and σ-bonds both to the central metal — a new type of ligand that we have developed.

Recently, we reported a fully characterized chiral amidinate ligand of type **B** (LiL) {HL = (1*R*,2*R*)-(−)-1-[N(H)C(Ph)N(SiMe$_3$)]-2-[N(H)SiMe$_3$]C_6H_{10}} containing a pendant amine group.[11−13] To apply our preceding work in transition element chemistry and explore the ligand geometry and bonding modes, we report here the synthesis of



Scheme 1. Three ligand models

[TiCl(L)(O*i*Pr)$_2$] (**1**) from LiL, and, for the first time, a new, chiral, dianionic tridentate amido-amidinate ligand (Li_2L; **2**), similar to type **C** and its corresponding titanium compound [Ti(L)(O*i*Pr)$_2$] (**3**). The crystallographic studies and comparison of the complexes **1** and **3** show several noteworthy features.

Treatment of LiL with one equivalent of $TiCl_2(OiPr)_2$ gave the mixed-ligand monochloride complex [TiCl(L)(O-*i*Pr)$_2$] (**1**; Scheme 2). A second deprotonation of LiL with *n*BuLi gave white crystals of Li_2L (**2**) in high yield (80%). Reaction of **2** with $TiCl_2(OiPr)_2$ afforded yellow, crystalline [Ti(L)(O*i*Pr)$_2$] (**3**), in marked contrast to the didentate amidinate product **1**.

Interestingly, treatment of Na_2L' {H_2L' = [(1*R*,2*R*)-(−)-1,2-[N(H)C(Ph)N(SiMe$_3$)]$_2C_6H_{10}$]} (derived from the lithium compound by reaction with *t*BuNa and synthesized in a manner analogous to that employed for the preparation of benzamidinates[6,9,11]) with $TiCl_2(OiPr)_2$ also gave compound **3**, probably via an unusual rearrangement/elimination reaction (Scheme 3)[14] that is actually the reverse reaction of the addition reaction. A similar reaction was reported by Richeson in which the treatment of two equivalents of Li[N(SiMe$_3$)C(*t*Bu)N(SiMe$_3$)] with $SnCl_2$ or $GeCl_2$ gave mixed amido-amidinate complexes of type **A** and loss

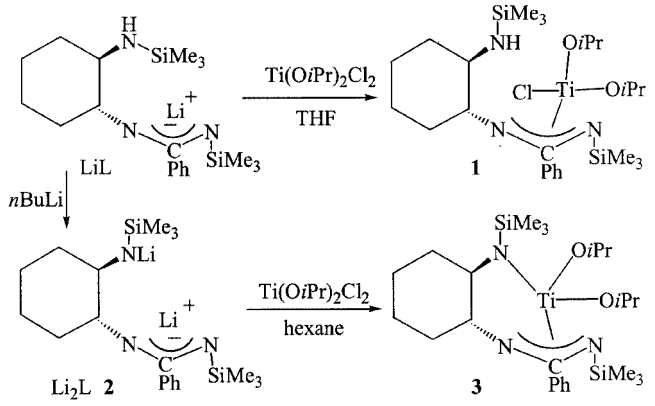
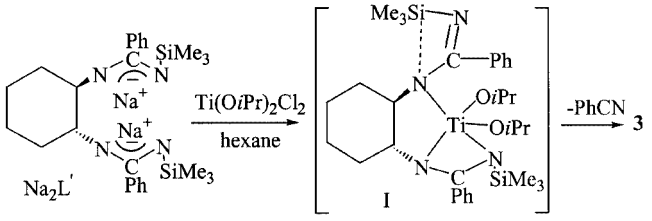


Scheme 2. Synthesis of complexes **1**−**3**

of *t*BuCN.[15] Their investigation showed that the lithium reagent rearranges to form the amido complex, with a 1,3 trimethylsilyl group migration and elimination of *t*BuCN, upon dissolution in Et_2O, prior to reaction with the metal chloride. In our case, from the ^1H and ^{13}C NMR spectroscopic data of [Na_2L'] there was no such rearrangement/elimination in hexane, and treatment of [Li_2L'] with $ZrCl_4$ gave a linked bis(amidinate) complex [$Zr(L')Cl_2(THF)$] without loss of PhCN (as confirmed by X-ray diffraction).[16] Thus, treatment of [Na_2L'] with $TiCl_2(OiPr)_2$ is likely to proceed via a transition state such as intermediate **I** in Scheme 3, and then lead directly to an amido-amidinate titanium complex of type **C** by an intramolecular rearrangement/elimination of $SiMe_3$/PhCN. The driving force for this reaction might be the steric effects of the isopropoxy groups attached to the Ti atom.



Scheme 3. Reaction of [Na_2L'] with $TiCl_2(OiPr)_2$

The structures of complexes **1**−**3** were determined by X-ray diffraction and elemental analysis; ^1H and ^{13}C NMR spectroscopy also gave satisfactory results. The molecular structure of **1** is shown in Figure 1. The ligand is doubly coordinated to the central metal atom with Ti−N bond lengths of 2.128(3) and 2.078(4) Å. The benzamidinate ligands form four-membered rings that are almost coplanar with the titanium atom [torsion angle N(5)−C(10)−N(6)−Ti(1) = 9.27°]. The dihedral angle between the benzyl moiety and N5−N6−Ti1 is almost vertical (95.4°), with the two isopropyl groups placed above/below the N5−N6−Ti1 plane.

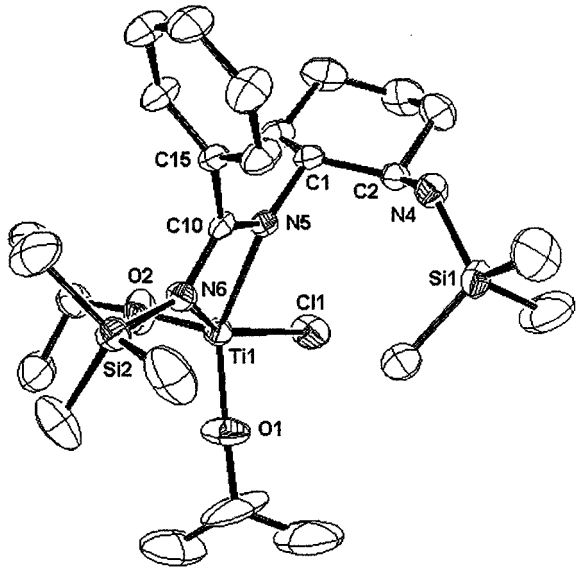


Figure 1. ORTEP view of **1** with thermal ellipsoids at 50% probability level (for one of the two independent molecules in the unit cell); all hydrogen omitted for clarity; selected bond lengths (Å) and angles (deg): N5−Ti1 2.128(3), N6−Ti1 2.078(4), C10−Ti1 2.521(4); N5−C10−N6 112.7(4), N5−Ti1−N6 63.51(13), N5−C1−C2 110.5(3), C1−C2−N4 111.8(4), C1−N5−Ti1 143.1(3)

The molecular structure of **2** is shown in Figure 2. Dimeric aggregation is observed and built around a nearly planar Li_4 ring. However, the coordination number of the Li atoms is different — two are four-coordinate and the other two are three- and two-coordinate — and the Li−Li distances range from 2.415(13) to 2.641(13) Å. Two of the five-membered Li−N−C−C−N rings adopt an envelope conformation.

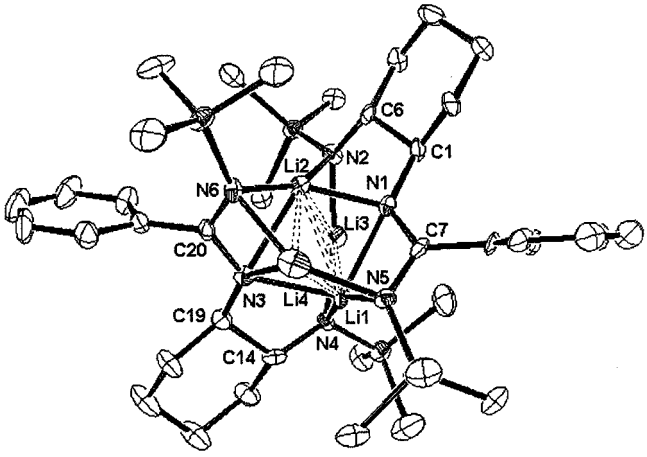

Figure 2. ORTEP view of **2** with thermal ellipsoids at 30% probability level; all hydrogen atoms omitted for clarity; selected bond lengths (Å) and angles (deg): Li1−N1 2.225(10), Li1−N4 1.982(10), Li1−N5 2.039(10), Li1−N3 2.133(9); N1−C7−N5 117.6(5), N6−C20−N3 116.0(5)

The crystal structure determination of **3** confirmed the tridentate nature and the chelating bonding mode of the

linked amido-amidinate ligand (Figure 3). The ligand adopts an approximately meridional coordination mode with the amidinate attached to the metal in an η^3-fashion [two Ti−N bonds of 2.087(2) and 2.127(3) Å; Ti−C = 2.492(3) Å] and the amido group by a σ-bond [Ti−N = 1.972(2) Å], a distinct difference from complexes of type **B**, which have a coordinated lone pair of electrons and obvious differences in bond lengths.[8]

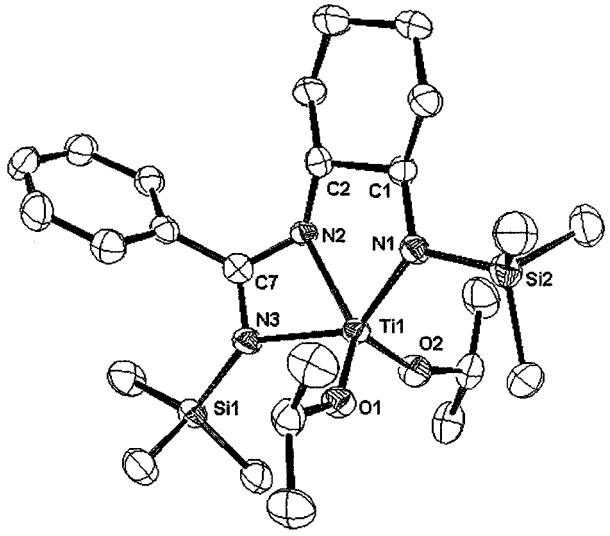

Figure 3. ORTEP view of **3** with thermal ellipsoids at 50% probability level; all hydrogen omitted for clarity; selected bond lengths (Å) and angles (deg): N1−Ti1 1.972(2), N2−Ti1 2.087(2), N3−Ti1 2.127(3), Ti1−C7 2.492(3); C2−C1−N1 108.9(2), C1−C2−N2 103.0(2), C2−N2−Ti1 116.79(18), N2−C7−N3 111.1(3), O1−Ti1−O2 108.82(10)

A comparison of the geometry in **3** with the parent complex **1** shows that the ligand responds to the tethering in the following way: The titanium atom in **3** links to N1 and N2 forming a five-membered ring and thus gives a rigid, bicyclic core with the cyclohexane. This behavior restricts the angles C2−C1−N1 [108.9(2)°] and C1−C2−N2 [103.0(2)°] [the same angles in **1** are 111.8(4) and 110.5(3)°]. As a result of this coordination sphere, the C2−N2−Ti1 angle [116.79(18)°] in **3** is dramatically smaller than the C1−N5−Ti1 angle in **1** [143.1(3)°]. The bond between Ti and the pendant amido group also greatly weakens the *trans* nature of the ligand, with the N1−C1−C2−N2 torsion angle in **3** being −42.68 (1)° [62.71(42)° in **1**].

Experimental Section

General: All manipulations were carried out under argon, using standard high-vacuum, Schlenk techniques. Deuterated solvents (C_6D_6, $CDCl_3$) were dried over Na/K alloy and vacuum transferred before use. Hexane, Et_2O and THF were distilled from over Na or Na/K alloy before use; chlorinated solvents were distilled from over activated molecular sieves (3 Å) or CaH_2. Benzonitrile was redistilled and dried over activated molecular sieves (4 Å) before use. ^{1}H (300 MHz) and ^{13}C (75.47 MHz) NMR spectra were recorded on a Bruker DRX-300 spectrometer at ambient temperature. Element analyses were performed by the Analysis Center of Shanxi University.

Preparation of [(1*R*,2*R*)-(−)-1-{NC(Ph)N(SiMe$_3$)}-2-{N(H)SiMe$_3$}-C$_6$H$_{10}$][TiCl(O*i*Pr)$_2$]: White solid $TiCl_2(OiPr)_2$ (0.28 g, 1.12 mmol) was added at −78 °C to a solution of LiL (0.41 g, 1.12 mmol) in 20 mL of THF. The mixture was warmed to room temperature slowly and stirred for 12 h. Subsequently, the solvent was removed in vacuo and the residual yellow solid was extracted with hexane (15 mL). The extract was concentrated to ca. 5 mL and cooled to −10 °C for two days, yielding 0.49 g (79%) of pale-yellow, crystalline **1**. ^{1}H NMR ($CDCl_3$): δ = −0.12 [s, 9 H, NSi(C*H*$_3$)$_3$], 0.06 [s, 9 H, NSi(C*H*$_3$)$_3$], 0.72 (m, 1 H, C*H*), 0.92 (m, 1 H, C*H*), 1.33 (m, 12 H, 2 × OCHC$_2$*H*$_6$), 1.48 (m, 2H C*H*), 1.57 (m, 2 H, C*H*), 1.77 (m, 1 H, C*H*), 2.18 (m, 1 H, C*H*), 2.53 (m, 1 H, C*H*), 3.17 (m, 1 H, C*H*), 4.81 (m, 2 H, 2 × OC*H*C$_2$H$_6$), 7.19 (m, 2 H, Ph), 7.39 (m, 3 H, Ph) ppm. ^{13}C NMR ($CDCl_3$): δ = 2.4 [s, (*C*H$_3$)$_3$], 2.5 [s, (*C*H$_3$)$_3$], 26.4 (s, OCH*C*$_2$H$_6$), 26.5 (s, OCH*C*$_2$H$_6$), 33.9 (s, NCC*C*), 38.9 (s, NCC*C*), 54.8 (s, NC*C*), 66.8 (s, CN), 78.2 (s, CN), 83.4 (s, O*C*HC$_2$H$_6$), 83.6 (s, O*C*HC$_2$H$_6$), 129.2 (s, *C*$_5$H$_5$), 130.0 (s, *C*$_5$H$_5$), 136.0 (s, *C*C$_5$H$_5$), 181.2 (s, *C*Ph) ppm. $C_{25}H_{48}ClN_3O_2Si_2Ti$ (562.19): calcd. C 53.41, H 8.61, N 7.47; found C 53.45, H 8.68, N 7.28.

Preparation of Li$_2$L (2): *n*BuLi (2.98 mL, 2.22 M in hexane) was added carefully to a solution of LiL (2.436 g, 6.63 mmol) in hexane (50 mL) by syringe at 0 °C. The mixture was warmed to ambient temperature slowly and stirred overnight. The clear, pale-yellow solution was concentrated to ca. 15 mL, to give colorless, pillar-like, crystalline **2** (1.98 g, 80%). ^{1}H NMR ([D$_6$]benzene): δ = 0.06 [s, 9 H, NSi(C*H*$_3$)$_3$], 0.59 [s, 9 H, NSi(C*H*$_3$)$_3$], 0.85 (m, 1 H, C*H*),1.19 (m, 1 H, C*H*), 1.44 (m, 4 H, C*H*), 1.65 (m, 1 H, C*H*), 1.90 (m, 1 H, C*H*), 3.08 (m, 1 H, C*H*), 3.30 (m, 1 H, C*H*), 7.22 (m, 2 H, Ph), 7.43 (m, 3 H, Ph) ppm. ^{13}C NMR ([D$_6$]benzene): δ = 2.8 [s, (*C*H$_3$)$_3$], 5.3 [s, (*C*H$_3$)$_3$], 26.3 (s, NCC*C*), 27.1 (s, NCC*C*), 35.1 (s, NC*C*), 40.6 (s, NC*C*), 65.1 (s, CN), 67.5 (s, CN), 128.1−128.7 (m, *C*$_5$H$_5$), 141.5 (s, *C*C$_5$H$_5$), 180.4 (s, *C*Ph) ppm. $C_{19}H_{33}Li_2N_3Si_2$ (373.55): calcd. C 61.09, H 8.90, N 11.25; found C 61.23, H 9.11, N 11.01.

Preparation of [(1*R*,2*R*)-(−)-1-{NC(Ph)N(SiMe$_3$)}-2-(NSiMe$_3$)-C$_6$H$_{10}$][Ti(O*i*Pr)$_2$]: $TiCl_2(OiPr)_2$ (0.28 g, 1.17 mmol) was added at 0 °C to a solution of Li_2L (**2**; 0.44 g, 1.17 mmol) in 25 mL of hexane. The mixture was warmed to room temperature and stirred overnight. Then, the yellow solution was filtered and reduced to ca.10 mL. Cooling to −20 °C for 5 days yielded 0.47 g (76%) of yellow crystalline **3**. ^{1}H NMR ($CDCl_3$): δ = −0.12 [s, 9 H, NSi(C*H*$_3$)$_3$], 0.24 [s, 9 H, NSi(C*H*$_3$)$_3$], 0.98 (m, 2 H, C*H*), 1.33 (m, 12 H, 2×OCHC$_2$*H*$_6$), 1.57 (m, 4 H, C*H*), 1.80 (m, 1 H, C*H*), 1.96 (m, 1 H, C*H*), 2.81 (m, 1 H, C*H*), 3.57 (m, 1 H, C*H*), 4.66 (m, 2 H, 2 × OC*H*C$_2$H$_6$), 7.28 (m, 2 H, Ph), 7.40 (m, 3 H, Ph) ppm. ^{13}C NMR ($CDCl_3$): δ = 2.1 [s, (*C*H$_3$)$_3$], 4.3 [s, (*C*H$_3$)$_3$], 25.3 (s, NCC*C*), 26.2 (s, NCC*C*), 27.0 (s, OCH(*C*H$_3$)CH$_3$], 27.1 (s, OCH(CH$_3$)*C*H$_3$], 27.5 (s, OCH(*C*H$_3$)CH$_3$], 27.6 (s, OCH(*C*H$_3$)CH$_3$], 34.7 (s, NC*C*), 36.4 (s, NC*C*), 71.0 (s, CN), 71.3 (s, CN), 76.1 (s, O*C*HC$_2$H$_6$), 76.7 (s, O*C*HC$_2$H$_6$), 137.4 (s, *C*C$_5$H$_5$), 178.4 (s, *C*Ph) ppm. $C_{25}H_{47}N_3O_2Si_2Ti$ (525.74): calcd. C 57.12, H 9.01, N 7.99; found C 57.30, H 9.23, N 7.63.

Crystal Structure Analysis of 1−3: Bruker SMART APEX diffractometer/CCD area detector, Mo-K_α radiation (λ = 0.71073 Å). Crystal data for **1**: $C_{25}H_{48}ClN_3O_2Si_2Ti$, M = 562.19, orthorhombic, space group $P2_12_12_1$, a = 11.1529(15) Å, b = 13.5196(18) Å, c = 43.770(6) Å, α = 90.00°, V = 6599.7(15) Å^3, Z = 8, $D_{calcd.}$ = 1.130 g/cm^3, T = 180(2) K, scan type ω, μ = 0.436 mm^{-1}, 27252 measured reflections, 11565 independent reflections (R_{int} =

Tellurium(II) Dialkanethiolates: $n_p(S)$-σ*(Te−S′) Orbital Interactions Determine the ^{125}Te NMR Chemical Shift, and the Molecular and Crystal Structure

Holger Fleischer,*[a] Norbert W. Mitzel,[b] and Dieter Schollmeyer[c]

Keywords: NMR spectroscopy / Noncovalent interactions / Solid-state structures / Sulfur / Tellurium

Tellurium(II) dimethanethiolate, $Te(SMe)_2$, and tellurium(II) diethanethiolate, $Te(SEt)_2$, were synthesized by reaction of TeO_2 and $Te(OiPr)_4$ with HSMe and HSEt, respectively. In the solid state, $Te(SMe)_2$ exhibits a *cis*-conformation of the methyl groups with respect to the TeS_2 plane – an unprecedented situation for nonfunctionalized organotrichalcogenides – whereas $Te(SEt)_2$ shows a *trans*-conformation. Ab initio calculations performed for $Te(SMe)_2$ and $Te(SEt)_2$ show that the *cis*- and *trans*-conformers represent minima on the potential energy surface and are stabilized by intramolecular π-type n(S)-σ*(Te–S′) orbital interactions. In the solid state, the molecules of each compound are associated through two centrosymmetric Te_2S_2 units with two of their neighbors, resulting in tetracoordinate Te atoms with distorted trapezoidal configurations. While the intermolecular Te···S distance increases in the sequence R = Me < Et < *i*Pr < *t*Bu, the length of the covalent Te–S bond decreases in the same order, a result attributed to intermolecular σ-type $n_p(S)$-σ*(Te–S′) orbital interactions. The ^{125}Te NMR chemical shift of $Te(SR)_2$ largely depends on R (R = Me, Et, *i*Pr, *t*Bu) and shows a nearly linear correlation with the first ionization energy of the corresponding thiol HSR. Ab initio calculations of the ^{125}Te NMR shifts for the model compound $Te(SH)_2$ (C_2 symmetry) reveal that it also depends strongly on the HSTeS torsion angle. These results can be explained by a model in which π-type $n_p(S)$-σ*(Te–S′) and $n_p(Te)$-σ*(S–H) orbital interactions determine the paramagnetic shielding of the tellurium nucleus.

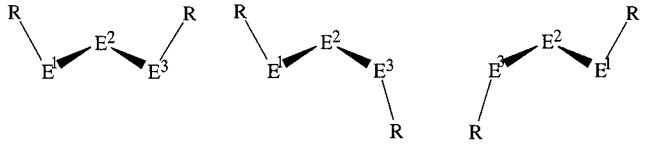
Introduction

In nearly every case known so far, noncyclic diorganotrichalcogenides, $RE^1E^2E^3R$ (see Scheme 1), exhibit a helical structure, as is the case in hexagonal selenium or tellurium, i.e. both R groups are *trans* with respect to the $E^1E^2E^3$ plane.[1−5] Spectroscopic and quantum chemical investigations have clearly demonstrated that trisulfane, HSSSH, can exist as both the *cis*- and *trans*-conformer. Due to the small steric demand of the hydrogen atoms, their energies differ by only 1 kJ·mol^{-1} in favor of the *trans*-conformer.[6,7]



Scheme 1. Structural formulae of the organotrichalcogenides with *cis*- (left) and two enantiomeric *trans*- (middle and right) conformations (R = organic group, E^1, E^2, E^3 = S, Se, Te)

Tellurium(II) dithiolates, $Te(SR)_2$, are thermally and photochemically unstable with respect to decomposition to elemental tellurium and disulfide, RSSR, but their kinetic stability depends very much on R.[3,8] This class of compounds is thus a source of elemental tellurium, whose release and deposition on surfaces can be controlled by thermal energy and irradiation. Recent ab initio studies have shown that the kinetic stability is due to the conformation of the CSTeS unit, which, in turn, is likely to be a consequence of π-type $n_p(S^1)$-σ*(Te−S^2) orbital interactions.[8] The motivation of the present research was to synthesize sterically noncrowded tellurium(II) dithiolates, $Te(SR)_2$, and to investigate their stability, physical properties and structural features.

Results and Discussion

Synthesis

$Te(SMe)_2$ and $Te(SEt)_2$ were prepared by reductive elimination from Te^{IV} compounds according to Equations (1) and (2):

$$TeO_2 + 4\ MeSH \rightarrow Te(SMe)_2 + (SMe)_2 + 2\ H_2O \quad (1)$$

$$Te(O\mathit{i}Pr)_4 + 4\ EtSH \rightarrow Te(SEt)_2 + (SEt)_2 + 4\ HO\mathit{i}Pr \quad (2)$$

Both compounds form yellow crystals giving dark red liquids on melting. They are stable towards air and water, but, like other tellurium(II) dithiolates,[4] are thermodynamically unstable towards decomposition to Te and the respective disulfides. They are kinetically much less stable than $Te(S\mathit{i}Pr)_2$ and $Te(S\mathit{t}Bu)_2$ and, within a few hours, the walls of glass flasks containing one of the compounds at room temperature are covered by a thin, mirror-like film of tellurium. $Te(SMe)_2$ and $Te(SEt)_2$ are also very sensitive to light, and in order to minimize decomposition the compounds were kept in the dark at −40 °C.

Like $Te(S\mathit{i}Pr)_2$ and $Te(S\mathit{t}Bu)_2$, $Te(SMe)_2$ and $Te(SEt)_2$ exchange their thiolate ligands with thiols and other tellurium(II) dithiolates.[4] On the other hand, cryoscopic measurements hint at $Te(SMe)_2$ being monomeric in cyclohexane solution, which means that intermolecular associations are rather weak (vide infra).

NMR Spectroscopy

In contrast to the compounds $Te(OR)_4$, whose ^{125}Te NMR chemical shifts vary only slightly with R, $\delta[^{125}Te(SR)_2]$ depends strongly on R, as can be seen from the data given in Table 1. A major influence of inductive electronic effects or of through-space shielding of the groups R on $\delta(^{125}Te)$ can hence be excluded, since in these cases, the four ligands in $Te(OR)_4$ should have a stronger effect than the two ligands in $Te(SR)_2$. Thus, $\delta[^{125}Te(SR)_2]$ must largely be determined by stereoelectronic effects and should therefore depend on the C−S−Te−S torsion angle. Indeed, ab initio NMR calculations performed in the present study for the model compound $Te(SH)_2$ (C_2 symmetry) revealed a strong dependence of $\delta(^{125}Te)$ on τ(H−S−Te−S), while $\delta[^{125}Te(OH)_4]$ (C_2 symmetry) varies only slightly with $\tau(HO^{eq}TeO^{eq})$ (see Figure 1 and Table 2). For $Te(SH)_2$, the shielding of the ^{125}Te nucleus is at its maximum, i.e. $\delta(^{125}Te)$ is a minimum, if τ(H−S−Te−S) = 90°.[12] Figure 2 shows the nearly linear correlation between $\delta[^{125}Te(SR)_2]$ and the first ionization energy of the corresponding thiol. A theoretical model for these results is presented in terms of natural orbitals and their interaction;[12,13] the relevant data are given in Table 2. The chemical shift of the heavier elements is mainly determined by the paramagnetic contribution to the nuclear shielding, σ_p. In terms of the MO concept, σ_p is proportional to the reciprocal of the energy difference, ΔE, between the highest occupied and the lowest unoccupied MO to which the AOs of the atom considered make a substantial contribution.[14] Hence, the bigger ΔE, the smaller is σ_p and the more the signal is shifted to high field. In terms of localized natural bond orbitals (NBO), the HOMO is mainly represented by the n_p(Te) orbital and the LUMO by the symmetric combination of both σ*(Te−S) orbitals. Nevertheless, a second-order perturbation analysis revealed significant n_p(Te)-σ*(S−H) and n_p(S)-σ*(Te−S′) orbital interactions. According to second-order perturbation theory, the energy of n_p(Te), and thus of the HOMO, is lowered and the energy of σ*(Te−S), and thus of the LUMO, is raised by these interactions. The data given in Table 2 confirm that E_{HOMO} correlates with $E[n_p(Te)\text{-}\sigma^*(S-H)]$ and E_{LUMO} with $E[n_p(S)\text{-}\sigma^*(Te-S')]$. Hence, the energies of HOMO and LUMO also show a strong dependence on τ(HSTeS) and support the model that their difference is essential for $\delta(^{125}Te)$. With Koopman's theorem,[15] the dependence of $\delta(^{125}Te)$ on the first ionization energy of the corresponding thiol can be rationalized. According to this theorem, the first ionization energy of a molecule is equal to the negative energy of its HOMO, i.e. n_{3p}(S) in the case of the thiols. Second-order perturbation theory predicts an increased $n_p(S)\text{-}\sigma^*(Te-S')$ interaction if $E[n_{3p}(S)]$ is raised and hence IE(HSR) is lowered. This has the effect that E_{LUMO} and ΔE are increased and thus $\delta(^{125}Te)$ is decreased, in accordance with the results presented in Figure 1 and 2.[16]

Table 1. ^{125}Te NMR chemical shifts of tellurium(II) dialkanethiolates and tellurium(IV) tetraalkoxides, calculated values are given in parentheses[9]

	R = Me	R = Et	R = *i*Pr	R = *t*Bu
$Te(SR)_2$	1419 (1376) [a]	1184 (1319)[a]	1026 [b]	907 (883) [a,b]
$Te(OR)_4$	1519 (792) [a] [c]	1503 [d]	1538 [c]	–

[a] Calculated value for conformer with C_2 symmetry. [b] Value from reference.[4] [c] Value from reference.[10] [d] Value from reference.[11]

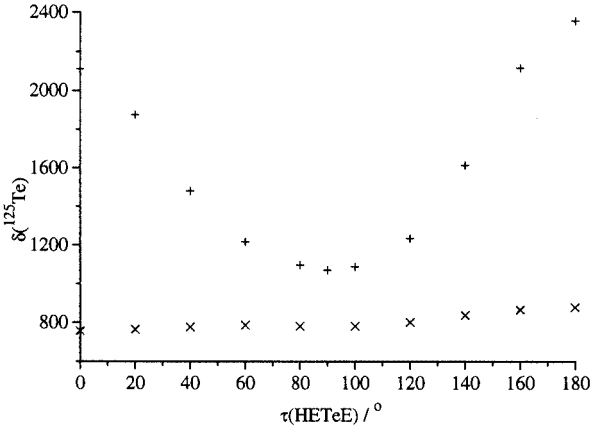

Figure 1. HF/3−21G(d) calculated ^{125}Te NMR chemical shifts of $Te(SH)_2$ (+, C_2 symmetry, MP2/LANL2DZP optimized geometry) and $Te(OH)_4$ (*x*, C_2 symmetry, MP2/LANL2DZP optimized geometry) vs. the H−E−Te−E torsion angle (E = S for $Te(SH)_2$ and $E = O^{eq}$ for $Te(OH)_4$)[9]

The temperature dependence of $\delta(^{125}Te)$ of $Te(SMe)_2$ and $Te(S\mathit{t}Bu)_2$, which is presented in Table 3, can also be interpreted in terms of this model. A rise in temperature will lead to an increased torsional vibration around the Te−S bonds. Since electronic energy and $\delta[^{125}Te(SR)_2]$ exhibit minima for values of τ(X−S−Te−S) close to 90° (X = H, C; see Figure 1 and Figure 6 (b) further down. See also ref.[4]), thermally induced torsional vibrations will increasingly populate angles outside 90° and hence cause an increase in $\delta(^{125}Te)$.

Molecular and Crystal Structures

The single crystal X-ray structure of $Te(SMe)_2$ (see Figure 3, a) shows this compound to exhibit a *cis*-conformation in the solid state. It is thus different from $Te(SEt)_2$ (see Figure 4, a), $Te(SiPr)_2$, $Te(StBu)_2$ and the isovalence electronic compound $S(OCH_3)_2$, which crystallize as *trans*-conformers.[4,17] Since the energy differences between *cis*- and *trans*-conformers are similar for $Te(SMe)_2$ and $Te(SEt)_2$ (vide infra), packing effects in the crystal are seen to stabilize the *cis*-conformer in one and the *trans*-conformer in the other case. Each $Te(SMe)_2$ and each $Te(SEt)_2$ molecule forms two Te···S bonds to each of its two nearest neighbors, leading to $(TeS_2)_n$ chains in which each Te atom exhibits a distorted trapezoidal coordination (see Figure 3 and 4). In $Te(SEt)_2$, neighboring molecules in these chains exhibit enantiomeric *trans*-conformations. The average intermolecular Te···S distances and the Te−S bond lengths in $Te(SR)_2$ (R = Me, Et, *i*Pr, *t*Bu) correlate with each other, as can be seen in Figure 5: the shorter the intermolecular Te···S distances are, the longer the Te−S bonds become. This corresponds to the correlation of S−S bond lengths with intramolecular S···S distances in 6a-thiathiophthene derivatives.[18] Comparison of the MP2/LANL2DZP optimized structural parameters of monomeric *cis*-$Te(SMe)_2$ with the middle unit of [*cis*-$Te(SMe)_2]_3$ also reveals that Te···S interactions increase the Te−S bond lengths and narrow the S−Te−S angle (see Table 4). This structure correlation leads to the assumption that a σ*(Te−S) orbital is involved

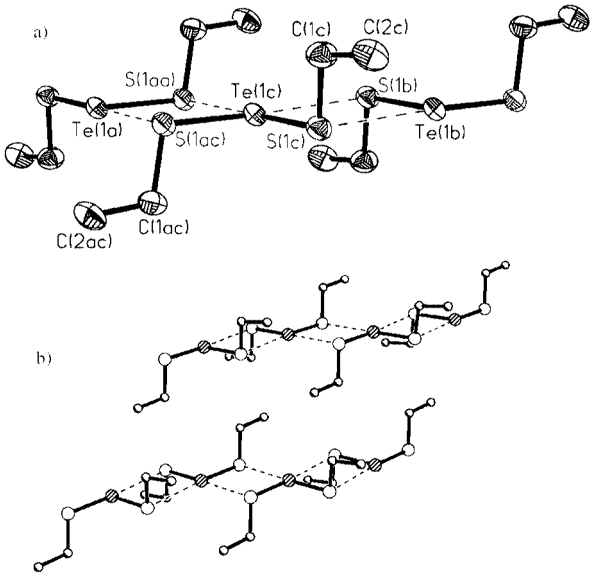

Figure 4. (a) Molecular structure and intermolecular association of $Te(SEt)_2$ in the solid state; displacement ellipsoids are at the 50% probability level; (b) packing of chains of $[trans\text{-}Te(SEt)_2]_n$ in the solid state; hydrogen atoms are omitted for clarity

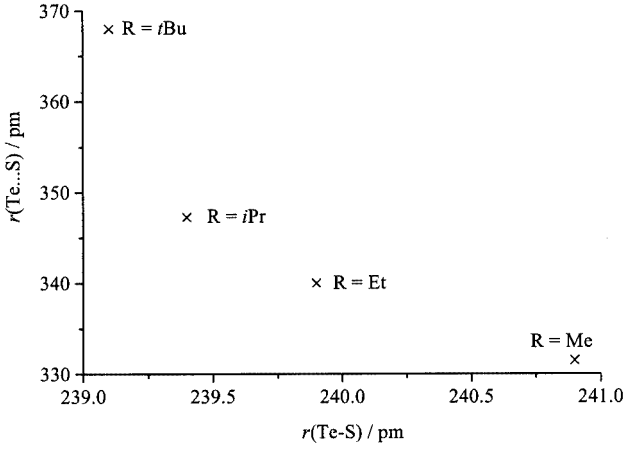

Figure 5. Intermolecular Te···S distances vs. Te−S bond lengths in the solid state structures of $Te(SR)_2$ (R = Me, Et, *i*Pr, *t*Bu); data for $Te(SiPr)_2$ and $Te(StBu)_2$ are taken from reference[4]

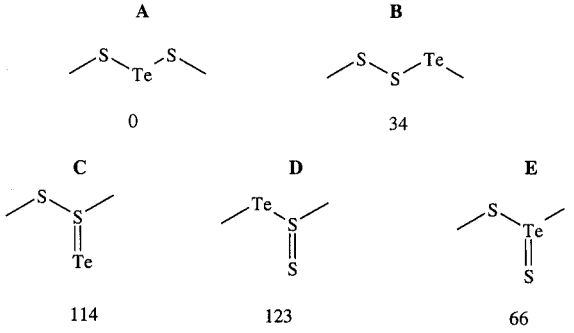
in the formation of the Te···S bond. An analysis of the bonding situation in the $Te(SMe)_2$ trimer in terms of natural bond orbitals shows that apart from π-type intramolecular $n_p(S)$-σ*(Te−S′) interactions (69 kJ·mol^{-1}), σ-type intermolecular $n_p(S)$-σ*(Te−S′) interactions (61 kJ·mol^{-1}) are also present. While the former are important for the Te−S bonds, the latter are essential for the Te···S interaction. These σ-type intermolecular $n_p(S)$-σ*(Te−S′) interactions explain the lengthening of the Te−S bond (transfer of electron density into an antibonding orbital) as well as the narrowing of the S−Te−S angle (reduced intramolecular repulsion of the S atoms).

Ab initio Thermochemistry

There are several constitutional isomers of $Te(SMe)_2$, some of which are given in Scheme 2 together with their calculated (MP2/LANL2DZP) relative standard enthalpies. Each of these isomers represents a minimum on the potential energy surface. The *trans*-conformers are given for isomers A and B. In isomers D and E, the Te−C and S−C bond vectors are nearly orthogonal to each other. Isomer A exhibits the lowest standard enthalpy of the entire group, hence $Te(SMe)_2$ is not only the kinetically favored product of the reaction of Te^{IV} compounds with HSMe, but is also thermodynamically more stable than the other constitutional isomers. Isomers A and B, which contain only divalent chalcogen atoms, are more stable than C−E, where one tetravalent chalcogen atom is present. Among the latter, E, which possesses a tetravalent Te atom, is more stable than C and D, which contain tetravalent S atoms. Regarding the relative stabilities of A and B, a comparison with ab initio calculations of the constitutional isomers of HSOSH is of interest.[19] Due to the larger energy of the O−H bond com-



Scheme 2. Different constitutional isomers of $Te(SMe)_2$ (A) and their MP2/LANL2DZP calculated relative standard enthalpies, ΔH^{298} (kJ·mol^{-1})

pared to that of the S−H bond, the HOSSH isomer is significantly more stable than the HSOSH form. For $Te(SMe)_2$, an analogous case is assumed regarding the energies of the S−C and the Te−C bond.

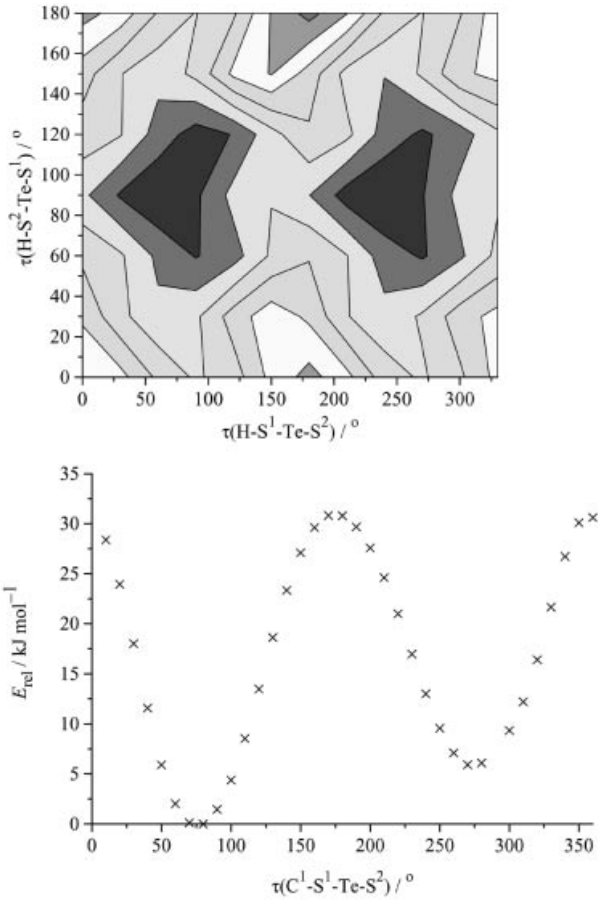

Figure 6. (a) MP2/LANL2DZP electronic energy of $Te(SH)_2$ as a function of both STeSH torsion angles; dark regions correspond to low energies and light regions to high energies; (b) MP2/LANL2DZP electronic energy of $Te(SMe)_2$ as a function of the $C^1-S^1-Te-S^2$ torsion angle; the $C^2-S^2-Te-S^1$ torsion angle was optimized freely and adopted values between 75 and 90°

As can be seen from Figure 6, part a, the model compound $Te(SH)_2$ forms stable *cis*- and *trans*-conformers. The electronic energy of *trans*-$Te(SH)_2$ [left minimum in Figure 6, part a)] is only about 1 kJ·mol^{-1} smaller than that of *cis*-$Te(SH)_2$. The C_{2v} symmetric conformation with $H-S^1-Te-S^2 = H-S^2-Te-S^1 = 180°$ represents a second-order saddle point on the potential energy surface.

Ab initio studies revealed that $Te(SMe)_2$ and $Te(SEt)_2$ also form stable *cis*- and *trans*-conformers. The electronic energies of *trans*-$Te(SMe)_2$ and *trans*-$Te(SEt)_2$ are lower than those of *cis*-$Te(SMe)_2$ and *cis*-$Te(SEt)_2$ by 6 and 5 kJ·mol^{-1}, respectively. The potential energy of $Te(SMe)_2$ as a function of one C−S−Te−S torsion angle is depicted in Figure 6, part b). The barrier between *cis*- and *trans*-$Te(SMe)_2$ amounts to about 30 kJ·mol^{-1} and should thus allow for a rapid interconversion of the two conformers at ambient temperatures.

Conclusion

Characteristic structural and ^{125}Te NMR spectroscopic features of tellurium(II) dialkanethiolates, $Te(SR)_2$, can be explained by intra- and intermolecular $n_p(S)$-σ*(Te−S′) orbital interactions. Since this orbital interaction varies significantly with the C−S−Te−S- torsion angle, the ^{125}Te NMR chemical shift of $Te(SR)_2$ shows a strong dependence on the molecular conformation. While intramolecular $n_p(S)$-σ*(Te−S′) interactions are responsible for molecular conformations, intermolecular $n_p(S)$-σ*(Te−S′) interactions play an essential role in determining the structure in the solid state. Since the orbital energies depend on the ligand, the electronic features of the tellurium atom in $Te(SR)_2$, and hence the reactivity of the compound, can be controlled by changing the nature of the alkyl group R.

Experimental Section

General Procedures: All procedures were carried out under an inert gas atmosphere or in vacuo. Solvents were purified according to standard procedures. If possible, exposure of $Te(SMe)_2$ and $Te(SEt)_2$ to daylight was avoided. Due to their thermal instability, both compounds were stored at −40 °C.

NMR: Bruker DRX 400. IR: Mattson Galaxy 2030 FTIR, resolution 4 cm^{-1}. MS: Finnigan MAT 8230. CHS analysis: Elemental Vario EL2.

$Te(SCH_3)_2$: Liquid methanethiol ($HSCH_3$; 20 mL; ρ(0 °C) = 0.87 g·mL^{-1}, 0.36 mol) was slowly transferred in the gas phase with a stream of argon into an ice-cooled suspension of tellurium dioxide (14.30 g, 89.6 mmol) in methanol (100 mL) and hydrochloric acid (0.5 mL, 37%). During the course of the reaction, the suspension at first became yellow before turning black due to precipitation of elemental tellurium. Subsequently, the solvent and all volatile reaction products were removed from the reaction mixture by low temperature distillation under reduced pressure. The crude product was extracted with petroleum ether several times and, from the combined extracts, yellow crystals of $Te(SCH_3)_2$ precipitated at −40 °C. Yield: 13.92 g (70.5%). M.p. 5 °C. $C_2H_6S_2Te$ (221.79): calcd. C 10.83, H 2.73, S 28.91; found C 10.37, H 2.35, S 27.63. MS(70 eV, EI): *m/z* (%) = 223.6 (36.4) [M^+], 176.7 (27.2) [$TeSCH_3^+$], 93.9 (100.0) [$H_3CSSCH_3^+$] ppm. ^1H NMR (400.000 MHz, C_6D_6, 25 °C, TMS): δ = 2.86 ppm. $^{13}C\{^1H\}$ NMR (100.577 MHz, C_6D_6, 25 °C, TMS): δ = 22.7 ppm. $^{125}Te\{^1H\}$ NMR (126.387 MHz, C_6D_6, 25 °C, $Te(CH_3)_2$]: δ = 1419 ppm. IR (liq., CsI): $\tilde{\nu}$ = 2981 [s, $\nu_s(CH_3)$], 2908 [vs, $\nu_{as}(CH_3)$], 2836 [m, $\nu(CH_3)$], 2815 (s, 1st overtone of 1419), 1419 [vs, $\delta(CH_3)$], 1303 [vs, $\delta(CH_3)$], 950 [vs, $\rho(CH_3)$], 688 [m, $\nu_{as}(S-C)$], 351 [s, $\nu_{as}(TeS_2)$], 331 [s, $\nu_s(TeS_2)$] cm^{-1}.

$Te(SCH_2CH_3)_2$: Tellurium(IV) tetraisopropoxide [$Te(OiPr)_4$; 1.18 g, 3.2 mmol) dissolved in petroleum ether (10 mL) was slowly added to a stirred solution of ethanethiol ($HSCH_2CH_3$; 0.82 g, 13.2 mmol) in petroleum ether (10 mL) at −78 °C. During this procedure the initally colorless solution turned yellow. Subsequently, the solvent and all volatile compounds were distilled in vacuo and the remaining yellow solid was dissolved in petroleum ether. From this solution yellow crystals of $Te(SCH_2CH_3)_2$ precipitated at −40 °C which were dried in vacuo. Yield: 0.76 g (95.0%). M. p. 18−20 °C. $C_4H_{10}S_2Te$ (249.84): calcd. C 19.23, H 4.03, S 25.66; found C 19.25, H 4.01, S 25.57. MS (70 eV, EI): *m/z* (%) = 251.9 (58.8)

Crystal Structure Determination: Diffraction experiments for $Te(SMe)_2$ were performed on a Nonius-Turbo-CAD4 diffractometer. Its crystal structure was solved by direct methods and structural refinement against F^2 (SHELXTL 5.01).[22]

Diffraction experiments for $Te(SEt)_2$ were performed on a BRUKER Nonius CCD diffractometer. Its crystal structure was solved by direct methods and structural refinement was F^2 (SHELXL 97).[23] Details of the crystal structure determination of $Te(SMe)_2$ and $Te(SEt)_2$, as well as their crystal data, are given in Table 5.

CCDC-170962 and CCDC-191964 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre,12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44)1223−336−033; or E-mail: deposit@ccdc.cam.ac.uk).

Theoretical Methods: Quantum chemical ab initio investigations were performed with the Gaussian 94 and Gaussian 98 program packages.[24,25] Optimization of molecular geometries, calculation of vibrational frequencies and an analysis of the electronic structure in terms of natural orbitals [12,13] was performed at the MP2 level, with an effective core double-zeta valence basis set,[26] augmented by appropriate polarization functions for Te, S (with exponents according to Höllwarth et al. [27]), and C (exponent 0.75), the basis set being designated as LANL2DZP. Applied symmetry restrictions are given in the text. Calculated vibrational frequencies, scaled by a factor 0.96, were used to assign the IR signals. NMR shielding tensors were calculated according to the GIAO method[28] by using density functional theory (B3LYP) [29] and the IGLO-II basis set,[30] together with an MP2/LANL2DZP optimized molecular geometry.

Acknowledgments

We thank Prof. Dr. M. Kaupp (Universität Würzburg) for his support concerning the calculation of NMR shifts.

[1] Out of 34 solid-state molecular structures with noncyclic $CE^1E^2E^3C$ units found in the Cambridge crystallographic data base, $S(S_2COCH_3)$ and $Se(S_2COCH_3)$ are the only examples exhibiting a *cis*-conformation (see ref.[2]).

[9] Since no relativistic effects were included in the calculation of the nuclear shielding constants, there are considerable differences between calculated and experimental ^{125}Te NMR chemical shifts. It was previously shown (Y. Ruiz-Morales, G. Schreckenbach, T. Ziegler, *J. Phys. Chem. A* **1997**, *101*, 4121−4127) that calculations neglecting the spin-orbit-induced contributions to nuclear shielding still give ^{125}Te chemical shifts which are in good agreement with experimental values. In the present case, the experimentally observed trends of $\delta[^{125}Te(SR)_2]$ with R are at least well reproduced.

Synthesis of Tetrahemispheraplexes with Ammonium, Alkylammonium or Alkaline Metal Ions as Exohedral Guests via Self-Assembly or Guest Exchange[‡]

Rolf W. Saalfrank,*[a] Bernhard Demleitner,[a] Horst Glaser,[a] Harald Maid,[a] Stefan Reihs,[a] Walter Bauer,[a] Monica Maluenga,[a] Frank Hampel,[a] Markus Teichert,[b] and Harald Krautscheid[c]

Dedicated to Prof. Dr. Horst Kisch on the occasion of his 60th birthday

Keywords: Cage compounds / Supramolecular chemistry / Magnesium / Host-guest chemistry

To study the interplay between the steric demand of the guest and the space available at the host, we have prepared the tetraammonium complexes $\{(NH_4)_4 \cap [Mg_4(L^{1/2})_6]\}$ **1**, tetrakis(methylammonium) complexes $\{(Me\text{-}NH_3)_4 \cap [Mg_4(L^{1/2})_6]\}$ **2**, tetrakis(ethylammonium) complex $\{(Et\text{-}NH_3)_4 \cap [Mg_4(L^1)_6]\}$ **3**, and mixed sodium tris(ethylammonium) complex $\{Na(Et\text{-}NH_3)_3 \cap [Mg_4(L^2)_6]\}$ **4**. The tetrahemispheraplexes **1**–**4** were available in one-pot syntheses. The tetrakis(alkylammonium) clusters $\{(R^1\text{–}NH_3)_4 \cap [Mg_4(L^1)_6]\}$ **5** and the mixed diammonium-bis(*p*-methoxybenzylammonium) cluster $\{(NH_4)_2(R^2\text{–}NH_3)_2 \cap [Mg_4(L^1)_6]\}$ **6**, however, were prepared by exchange of the ammonium ions of **1a** by alkylammonium ions. Similarly, exchange of the four ammonium ions of **1b** by alkaline metal cations afforded the tetraalkaline metal tetrahemispheraplexes $\{M_4 \cap [Mg_4(L^2)_6]\}$ **7**.

Introduction

Following the considerable progress made towards predicting ordered supramolecular assemblies on the basis of coordinative metal/ligand bonds,[1] great attention is being paid to the role guest molecules play in the self-assembly of metal/ligand clusters. The inner voids of supramolecular metal/ligand cages are possible sites for encapsulated anionic,[2] electronically neutral[3] and cationic species.[4] Kinetic data for the equilibria of guest exchange reactions have been determined.[5] In special cases, the nature of the encapsulated guest was shown to be the crucial factor for the nuclearity of the compound formed.[6] However, there are far fewer examples of host/guest interactions at the surface of supramolecular coordination polygons.[7–9] The synthesis of novel tetrahemispheraplexes that contain alkylammonium and alkaline-metal cations has been achieved by an advanced one-pot procedure or by host/guest exchange reactions and is subject of this paper.

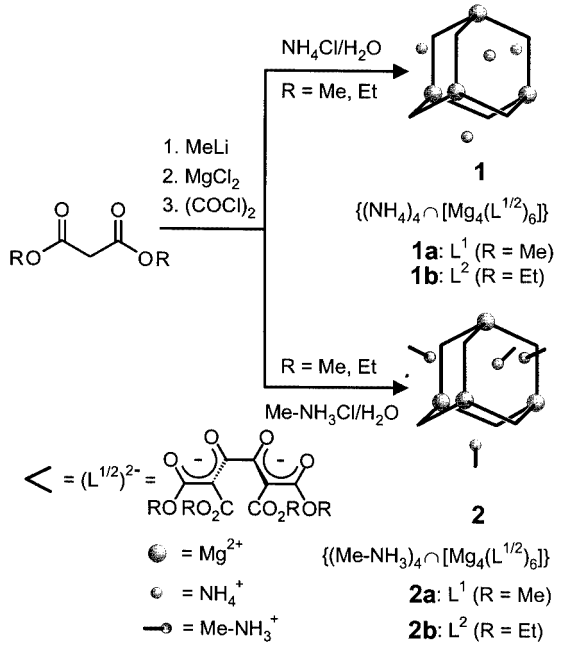
Results and Discussion

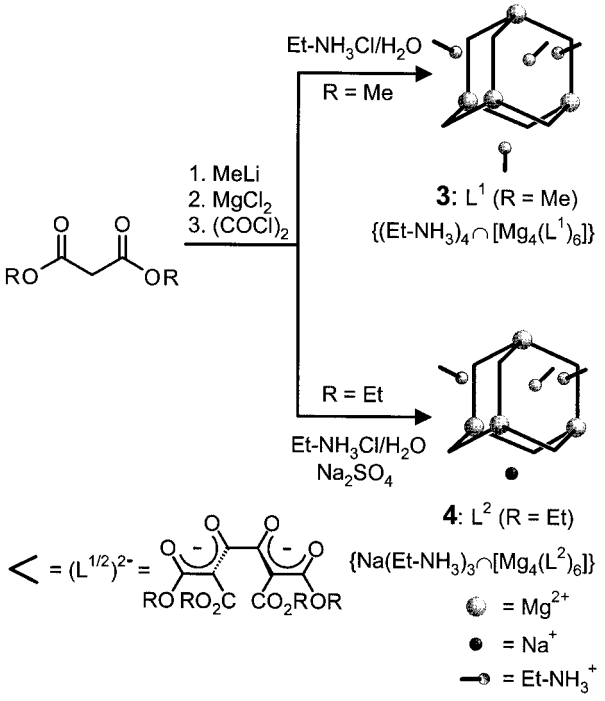
One-Pot Syntheses of Tetraammonium Complexes 1 and Tetrakis(methylammonium) Complexes 2

We have previously reported the gram-scale synthesis of tetraammonium tetramagnesium chelate complexes $\{(NH_4)_4 \cap [Mg_4(L^{1/2})_6]\}$ **1a**,**b** in high yields by deprotonation of dialkyl malonates with methyllithium in tetrahydrofuran, subsequent addition of magnesium chloride and oxalyl chloride followed by workup with aqueous ammonium chloride solution (Scheme 1).[8] The doubly bidentate bridging ligands $(L^{1/2})^{2-}$ (R = Me, Et) are formally obtained by template coupling of two malonate monoanions with oxalyl chloride and spontaneous double deprotonation of the bisenol intermediates. Replacement of the aqueous ammonium chloride solution of this one-pot reaction by a solution of methylammonium chloride yielded the corresponding tetrahemispheraplexes $\{(Me\text{−}NH_3)_4 \cap [Mg_4(L^{1/2})_6]\}$ **2a,b** (Scheme 1).

The NMR spectra of the tetrahemispheraplexes **1** and **2** are surprisingly simple. For example, despite there being four stereogenic metal centers and six C_2-symmetric ligands, the ^{13}C NMR spectrum of **2a** displays only six signals, representing the atropisomeric ligands, and only one for the four exohedrally bonded methylammonium ions. The low number of signals is explained by approximate molecular T symmetry of **2a** (characterised by three C_2 and four C_3 axes). To further support the proposed structure of



Scheme 1. Synthesis of tetraammonium tetrahemispheraplexes **1** and tetrakis(methylammonium) tetrahemispheraplexes **2**



Scheme 2. Synthesis of tetrakis(ethylammonium) tetrahemispheraplex **3** and mixed sodium tris(ethylammonium) tetrahemispheraplex **4**

2a, we carried out a single crystal X-ray structure determination.[11−13] According to this analysis, **2a** crystallises in the monoclinic space group $P2_1/c$ with four molecules per unit cell. The four magnesium cations of the tetraanionic core $[Mg_4(L^1)_6]^{4-}$of tetrahemispheraplex **2a** frame the corners of an idealised tetrahedron and are linked along each of the six edges by doubly bidentate tetramethyl-2,3-dioxobutane-1,1,4,4-tetracarboxylato(2^-) bridges. Consequently, each of the four magnesium ions is octahedrally coordinated by six oxygen donors. Charge compensation of $[Mg_4(L^1)_6]^{4-}$ is achieved by a set of four methylammonium counterions, which are hydrogen bonded to the oxygen donors of the triangular faces of the tetraanionic core to give **2a**. The crystals of **2a** consist of a racemic mixture of homochiral stereoisomers with (Δ,Δ,Δ,Δ)-*fac* or (Λ,Λ,Λ,Λ)-*fac* configuration at the magnesium centers and with six atropisomeric ligands each, twisted clockwise or counter-clockwise.

One-Pot Synthesis of Tetrakis(ethylammonium) Complex 3 and Mixed Sodium Tris(ethylammonium) Complex 4

To study the effect of the steric demand of the ligands $(L^{1/2})^{2-}$ (R = Me, Et) on the packing density at the surfaces of the tetraanionic $[Mg_4(L^{1/2})_6]^{4-}$ cores, unlike the synthesis of **2**, an aqueous *ethyl*ammonium instead of an *methyl*ammonium chloride solution was used for workup. Starting from *dimethyl* malonate, tetrakis(ethylammonium) complex $\{(Et-NH_3)_4\cap[Mg_4(L^1)_6]\}$ **3** was formed, whereas sodium tris(ethylammonium) complex $\{Na(Et-NH_3)_3\cap[Mg_4(L^2)_6]\}$ **4** was isolated with *diethyl* malonate as starting material and the reaction mixture dried over sodium sulfate (Scheme 2).

The NMR spectra of **3**, as with **1** and **2**, originate from the molecular T symmetry of the tetrahemispheraplex in solution. However, the ^1H and ^{13}C NMR spectra of **4** were more complex. Two signals in the ^{13}C NMR spectrum confirm magnetically equivalent exohedral ethylammonium guests. Integration of the ^1H NMR signals provide an ethylammonium-to-ligand ratio of 1:2, indicating that only three of the four triangular faces of the compound are occupied by ethylammonium ions. Compared to the higher symmetric analogue **3**, the ^{13}C NMR spectrum of C_3-symmetric **4** displayed a total of 32 signals due to two sets of three C_1-symmetric ligands $(L^2)^{2-}$ (R = Et). The structure proposed for **4** is further supported by a single crystal X-ray structure determination,[11−13] which shows that $\{Na(Et-NH_3)_3\cap[Mg_4(L^2)_6]\}\cdot 2H_2O$ **4** crystallises in the monoclinic space group $P2_1/n$ with four molecules per unit cell. The crystals of **4** consist of a racemic mixture of homochiral stereoisomers with a (Δ,Δ,Δ,Δ)-*fac* or (Λ,Λ,Λ,Λ)-*fac* configuration at the metal centers and with two sets of three atropisomeric ligands each, twisted clockwise or counter-clockwise. Unlike to the tetrahedral core $[Mg_4(L^1)_6]^{4-}$ of **2a**, in **4** the $[Mg_4(L^2)_6]^{4-}$ framework is stretched along the C_3 axis. This results in an overall trigonal pyramidal scaffold for **4**. Each of the three isosceles triangular faces of the pyramid are occupied by one ethylammonium ion hydrogen bonded to three oxygen donors of the adjacent ligands. Charge compensation of the resulting $\{(Et-NH_3)_3\cap[Mg_4(L^2)_6]\}^-$ framework is achieved by the sterically less demanding sodium ion, which is coordinated by two carbonyl oxygen donors of each of the three ligands,

establishing the basic equilateral triangle. The sodium coordination sphere is completed by two water molecules. Remarkably, one water molecule is located *in* the void and the other one *outside* the trigonal pyramid (Figure 1).[10]

Exchange of Ammonium Ions of 1a,b by Alkylammonium Ions to give the Tetrakis(alkylammonium) Clusters 5 and the Mixed Diammonium-bis(*p*-methoxybenzylammonium) Cluster 6

To tune the physical and chemical properties of the spherical surface of $\{(NH_4)_4 \cap [Mg_4(L^1)_6]\}$ **1a** we extended the *direct method* described above by replacing the four ammonium ions with *n*-alkylammonium ions. The exchange of the ammonium ions in **1a** (R = Me) for *n*-alkylammonium ions to form the tetrakis(alkylammonium) tetrahemispheraplexes $\{(R^1-NH_3)_4 \cap [Mg_4(L^1)_6]\}$ **5** is achieved by addition of *n*-alkylamines R^1-NH_2 in excess. Ammonia is liberated during this exchange process.[9,14] The NMR spectra of **5** are consistent with the predicted structures (see the Exp. section for data).

However, when **1a** (R = Me) was allowed to react with an excess of bulky *p*-methoxybenzylamine R^2-NH_2, only two ammonium ions were exchanged by *p*-methoxybenzylammonium groups to give diammonium bis(*p*-methoxybenzylammonium) tetrahemispheraplex $\{(NH_4)_2(R^2-NH_3)_2 \cap [Mg_4(L^1)_6]\}$ **6** (Scheme 3).

The ^1H and ^{13}C NMR spectra of **6** were rather complex. Six signals in the ^{13}C NMR spectrum confirmed magnetically equivalent exohedral *p*-methoxybenzylammonium guests. Integration of the ^1H NMR signals provided a *p*-methoxybenzylammonium-to-ligand ratio of 1:3, indicating that only two of the four triangular faces of **6** are occupied by *p*-methoxybenzylammonium ions. Whereas the ^{13}C NMR spectrum for the *T*-symmetric precursor **1a** shows six signals, that of the C_2 symmetric core of **6** displays 36 signals. In **6**, the ligands are subdivided into four types: two different C_2-symmetric ligands and two sets of two identical C_1-symmetric ligands. Accordingly, thirteen discrete singlets are expected, representing the methoxy groups of the ligands and the guests; twelve (two signals are superimposed) were recorded.

A single crystal X-ray structure determination of **6**[11−13,15] is consistent with the proposal that **6** crystallises in the monoclinic space group *P*2/*c* with four molecules per unit cell. A common feature of **1a**, **5** and **6** is the tetrahedral module $[Mg_4(L^1)_6]^{4-}$. However, they differ markedly due to their exohedral guests. In **6**, charge compensation is achieved by two ammonium and two *p*-methoxybenzylammonium counterions, which are hydrogen-bonded to the

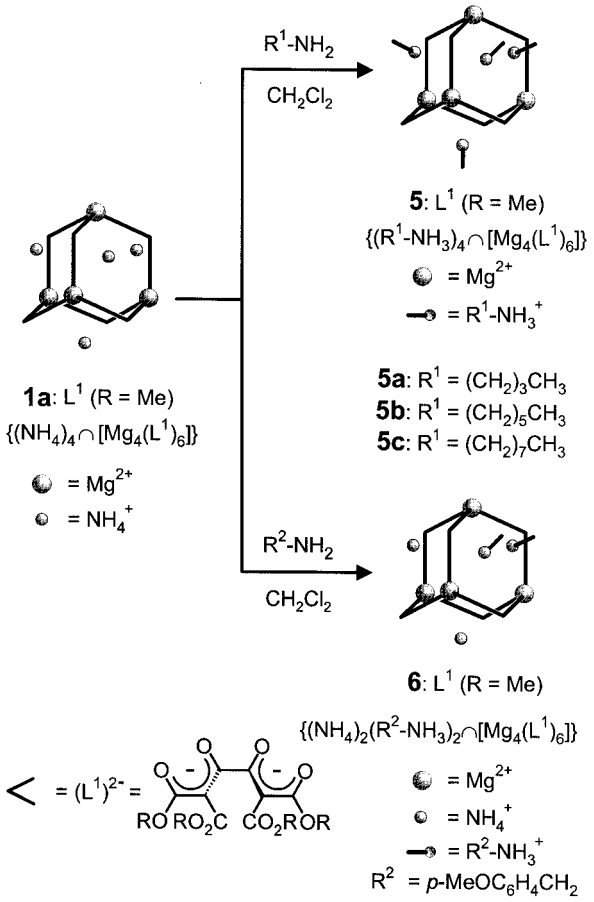
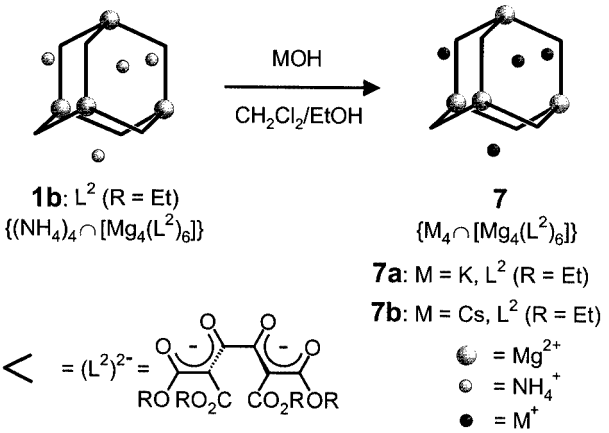


Scheme 3. Ammonium ion exchange of **1a**: Synthesis of tetrakis(alkylammonium) tetrahemispheraplexes **5** and diammonium-bis(*p*-methoxybenzylammonium) tetrahemispheraplex **6**



Scheme 4. Ammonium ion exchange of **1b**: Synthesis of tetraalkaline metal tetrahemispheraplexes **7**

oxygen donors of the ligands of the triangular faces (Figure 2).[10]

Exchange of the Four Ammonium Ions of 1b by Alkaline Cations to Give the Tetraalkaline Metal Complexes 7

Reaction of a solution of tetraammonium tetrahemispheraplex **1b** in dichloromethane with a solution of potassium or caesium hydroxide in dichloromethane/ethanol afforded the alkaline metal complexes $\{M_4 \cap [Mg_4(L^2)_6]\}$ **7** [(M = K, Cs; L^2 (R = Et)] in excellent yields (Scheme 4).

The NMR spectra of the tetrahemispheraplexes $\{M_4 \cap [Mg_4(L^2)_6]\}$ **7a**,**b** are principally identical to those of **1b**, except for the missing ^{1}H NMR signals characteristic of the ammonium protons of **1b**. According to a single crystal X-ray structure determination, $\{K_4 \cap [Mg_4(L^2)_6]\} \cdot 4H_2O$ **7a** crystallises in the monoclinic space group $P2_1$ with two molecules per unit cell.[11–13] Charge compensation of the tetrahedral $[Mg_4(L^2)_6]^{4-}$ core is achieved by a set of four potassium counterions. The idealised structure of **7a** consists of four fused [15]metalla-crown-6 systems that encapsulate one potassium cation, each (Figure 3, top).[10] However, careful consideration revealed different coordination spheres at the potassium ions. Remarkably, the coordination number at the most symmetrically ligated potassium cation is eight. Its coordination sphere is composed of six carbonyl oxygen donors, one oxygen donor of a water molecule at the periphery and one oxygen donor of a water molecule encapsulated in the void of the tetrahedron (Figure 3, bottom). As with **1b**, the crystals of **7a** consist of a racemic mixture of homochiral stereoisomers.

Conclusions

The present study has shown that the space available at the surface of the self-assembled tetrahedral tetraanionic cores $[Mg_4(L^{1/2})_6]\}^{4-}$ depends on the steric demand of the ligands $(L^{1/2})^{2-}$. Whereas $[Mg_4(L^1)_6]\}^{4-}$ (L^1: R = Me) is able to host four Et–NH_3^+ cations, the more crowded $[Mg_4(L^2)_6]\}^{4-}$ (L^2: R = Et) is apt to only host four of the smaller NH_4^+-, Me–NH_3^+- or alkaline metal cations. However, tetrahemispheraplexes of $[Mg_4(L^2)_6]\}^{4-}$ (L^2: R = Et) with Et–NH_3^+ are conceivable in combination with the smaller Na^+ cation, and of $[Mg_4(L^1)_6]\}^{4-}$ (L^1: R = Me) with *p*-$MeOC_6H_4CH_2$–NH_3^+ together with NH_4^+ cations. In $\{(NH_4)_4 \cap [Mg_4(L^2)_6]\}$ **1b** the four ammonium ions could be exchanged by potassium or caesium ions.

Experimental Section

General Methods: NMR spectra were recorded on a JEOL EX 400 and on a JEOL ALPHA 500 in $CDCl_3$ solutions. The residual solvent signal (δ = 7.27 ppm) was used as an internal standard. IR spectra were performed on a Bruker IFS 25 spectrometer. Elemental analyses were carried out on an EA 1110 CHNS-Microautomat.

Materials: All reagents and solvents employed were commercially available, high-grade purity materials (Fluka, Aldrich), used as supplied.

General Procedure. Direct Synthesis: A methyllithium solution (18.75 mL, 1.6 M in diethyl ether, 30 mmol) diluted with dry THF (10 mL) was added dropwise to a solution of dialkyl malonate (30 mmol) in dry THF (50 mL) (N_2, −78 °C) over 30 min. After stirring for 1 h, $MgCl_2$ (2.86 g, 30.0 mmol) was added and 1 h later a solution of oxalyl chloride (0.95 g, 7.5 mmol) in dry THF (20 mL)

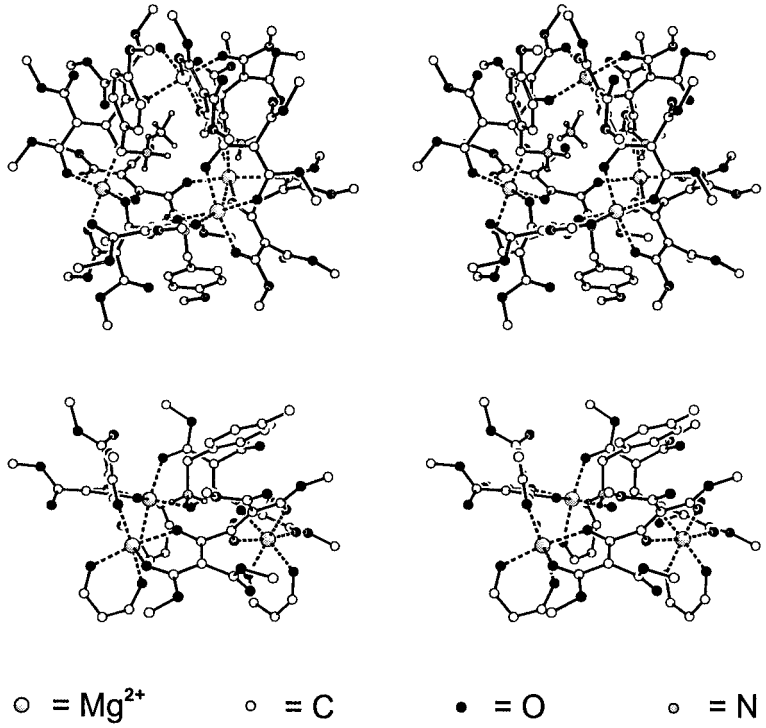


Figure 2. (Stereo view): Top: Structure of $\{(NH_4)_2(R^2-NH_3)_2\cap[Mg_4(L^1)_6]\}$ **6** (L^1: R = Me; R^2 = *p*-$MeOC_6H_4CH_2$) in the crystal. Bottom: Selected tetrahedral face hosting *p*-methoxybenzylammonium. Solvent molecules and hydrogen atoms except ammonium hydrogens are not depicted for clarity

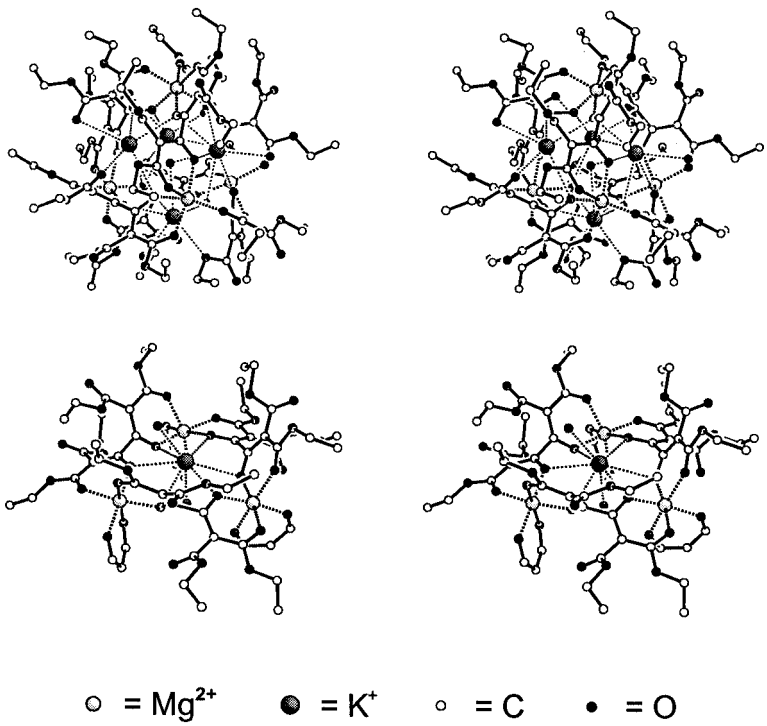

Figure 3. (Stereo view): Top: Structure of $\{K_4\cap[Mg_4(L^2)_6]\}$ **7a** (L^2: R = Et) in the crystal. Bottom: Selected tetrahedral face highlighting its metalla-coronate character. Solvent molecules and hydrogen atoms are not depicted for clarity

was added dropwise into the suspension within 2 h. The mixture was then allowed to warm to 20 °C during 18 h and the resulting yellow solution treated for 5 min with 10% aqueous alkyl ammonium chloride (50 mL). The two layers present were separated, the aqueous layer was extracted three times with chloroform (50 mL), and the combined organic phases were dried over anhydrous sodium sulfate. The solvent was removed in vacuo and the remaining yellow oil was diluted in chloroform (5 mL). The reaction product was crystallised by addition of isohexane (50 mL).

Compound 1a: Yield: 2.23 g (86%) colourless powder; m.p. 181 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.57, 3.78 (each s, 72 H, 24 OCH_3), 7.30 ppm (br. s, 16 H, 4 NH_4^+). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 51.39, 52.05 (24 OCH_3), 94.29 (12 =C), 167.97, 170.82 (24 C=O, ester), 184.25 ppm (12 C=O, keto). IR ($CHBr_3$): $\tilde{\nu}$ = 3180 (NH), 1680 (C=O), 1630 cm^{-1} (C=C). $C_{72}H_{88}Mg_4N_4O_{60}$ (2066.71): calcd. C 41.84, H 4.29, N 2.71; found C 41.29, H 4.63, N 2.66.

Compound 1b: See ref.[8]

Compound 2a: Yield: 1.80 g (68%) colourless microcrystals; m.p. 161 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.20 (s, 12 H, 4 CH_3), 3.55, 3.81 (each s, 72 H, 24 OCH_3), 8.09 ppm (br. s, 12 H, 4 NH_3^+). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 25.92 (4 CH_3), 51.26, 52.26 (24 OCH_3), 94.56 (12 =C), 167.30, 170.88 (24 C=O, ester), 184.34 ppm (12C=O, keto). IR ($CHBr_3$): $\tilde{\nu}$ = 1710 (C=O), 1640 cm^{-1} (C=C). $C_{76}H_{96}Mg_4N_4O_{60}$ (2122.82): calcd. C 43.00, H 4.56, N 2.64; found C 42.64, H 4.68, N 2.43.

Compound 2b: Yield: 1.65 g (54%) colourless powder; m.p. 202 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.15, 1.27 (each t, *J* = 7.08 Hz, 72 H, 24 CH_3), 2.25 (br. s, 12 H, 4 NCH_3), 3.95, 4.06, 4.18, 4.29 (each m, 48 H, 24 $OCH^{A/B}$), 8.16 ppm (br. s, 12 H, 4 NH_3^+). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 14.03, 14.08 (24 CH_3), 26.00 (4 NCH_3), 59.76, 60.73 (24 OCH_2), 95.40 (12 =C), 166.71, 170.59 (24 C=O, ester), 184.24 ppm (12 C=O, keto). IR ($CHBr_3$): $\tilde{\nu}$ = 1700 (C=O), 1640 cm^{-1} (C=C). $C_{100}H_{144}Mg_4N_4O_{60}$ (2459.46): calcd. C 48.84, H 5.90, N 2.28; found C 48.94, H 5.90, N 2.23.

Compound 3: Yield: 1.25 g (46%) colourless powder; m.p. 182 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.89 (t, *J* = 7.08 Hz, 12 H, 4 CH_3), 2.65, 2.82 (each br. m, 8 H, 4 $NCH^{A/B}$), 3.56, 3.78 (each s, 72 H, 36 OCH_3), 7.67 ppm (br. s, 12 H, 4 NH_3^+). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 11.80 (4 CH_3), 36.50 (4 NCH_2), 51.26, 52.01 (24 OCH_3), 95.15 (12 =C), 167.39, 170.80 (24 C=O, ester), 184.56 ppm (12 C=O, keto). IR ($CHBr_3$): $\tilde{\nu}$ = 1730 (C=O), 1650 cm^{-1} (C=C). $C_{80}H_{104}Mg_4N_4O_{60}$ (2178.95): calcd. C 44.10, H 4.81, N 2.57; found C 42.84, H 4.64, N 1.80.

Compound 4: Yield: 2.83 g (91%) colourless prisms, from dichloromethane/isohexane; m.p. 186 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.92 (t, *J* = 7.4 Hz, 9 H, 3 CH_3), 1.08−1.27 (m, 72 H, 24 CH_3), 2.61, 2.81 (each br. m, 6 H, 3 $NCH^{A/B}$), 3.85−4.31 (m, 48 H, 24 OCH_2), 7.50 ppm (br. s, 9 H, 3 NH_3^+). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 11.91 (3 CH_3), 13.67, 13.83, 13.93, 13.98, 14.19, 14.22, 14.36, two superimposed signals (24 CH_3), 36.12 (3 NCH_2), 59.74, 59.88, 60.09, 60.12, 60.20, 60.42, 60.55, 60.60 (24 OCH_2), 94.38, 94.91, 95.09, 95.59 (12 =C), 167.07, 167.27, 167.56, 168.99, 170.34, 170.58, 170.76, two superimposed signals (24 C=O, ester), 184.54, 184.74, 185.23, 185.67 ppm (12 C=O, keto); When the NMR spectra of C_3-symmetric **4** were carried out in $CD_3CN/CDCl_3$ instead of $CDCl_3$ alone, the spectra of **4** revealed molecular *T* symmetry due to the core $[Mg_4(L^2)_6]^{4-}$. This is explained by fast exchange of Na^+ and $[H_3NC_2H_5]^+$. ^{1}H NMR (400 MHz, $CDCl_3/CD_3CN$): δ = 0.92 (t, *J* = 7.4 Hz, 9 H, 3 CH_3); 1.13, 1.22 (t, *J* = 7.1 Hz, 72 H, 24 CH_3); 2.22, 2.70 (each br. s, 6 H, 3 CH_2); 3.88, 3.99, 4.09, 4.17 (each m, 48 H, 24 OCH_2); 7.51 (br. s, 9 H, 3 NH_3^+) ppm. ^{13}C NMR (100.5 MHz, $CDCl_3/CD_3CN$): δ = 12.26 (3 CH_3); 14.26, 14.48 (24 CH_3); 36.75 (3 NCH_2); 60.45, 61.06 (24 OCH_2); 95.71 (12 =C); 167.95, 171.28 (24 C=O, ester); 185.56 (12 C=O, keto). IR ($CHBr_3$): $\tilde{\nu}$ = 1700 (C=O), 1640 cm^{-1} (C=C). $C_{102}H_{144}Mg_4N_3NaO_{60}$ (2492.47): calcd. C 49.15, H 5.82, N 1.69; found C 48.09, H 6.02, N 1.60.

General Procedure. Ammonium/Alkylammonium Cation-Exchange: A solution of the corresponding primary amine (5 mmol, 1 mmol for **6**) in dichloromethane (5 mL) was added dropwise to a solution of the corresponding tetrahemispheraplex **1a** (1.03 g, 0.5 mmol) in dichloromethane (50 mL) over 5 min. The mixture was then stirred for 20 min (5 min for **6**) at 0 °C. Subsequently, the volatile components were removed in vacuo and the resulting colourless solid was washed three times with hexane (30 mL), dried and crystallised from dichloromethane/diethyl ether.

Compound 5a: Yield: 0.49 g (43%) colourless powder; m.p. 186 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.65 (t, *J* = 7.1 Hz, 12 H, 4 CH_3), 0.93, 1.30 (each m, 16 H, 8 CH_2), 2.47, 2.73 (each br. m, 8 H, 4 $NCH^{A/B}$), 3.56, 3.79 (each s, 72 H, 24 CH_3), 7.68 ppm (br. s, 12 H, 4 NH_3^+). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 12.89 (4 CH_3), 20.00, 28.18 (8 CH_2), 41.58 (4 NCH_2), 51.15, 51.93 (24 OCH_3), 95.36 (12 =C), 167.16, 170.78 (24 C=O, ester), 184.38 ppm (12 C=O, keto). IR ($CHBr_3$): $\tilde{\nu}$ = 1720 (C=O), 1650 cm^{-1} (C=C). $C_{88}H_{120}Mg_4N_4O_{60}$ (2291.17): calcd. C 46.13, H 5.28, N 2.45; found C 46.06, H 5.56, N 2.51.

Compound 5b: Yield: 0.47 g (49%) colourless powder; m.p. 194 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.79 (t, *J* = 7.3 Hz, 12 H, 4 CH_3), 0.89, 0.98, 1.12, 1.30 (each m, 32 H, 16 CH_2), 2.45, 2.74 (each br. m, 8 H, 4 $NCH^{A/B}$), 3.55, 3.78 (each s, 72 H, 24 CH_3), 7.70 ppm (br. s, 12 H, 4 NH_3^+). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 13.88 (4 CH_3), 22.06, 25.99, 26.34, 30.61 (16 CH_2), 41.50 (4 NCH_2), 51.16, 51.95 (24 OCH_3), 95.26 (12 =C), 167.18, 170.78 (24 C=O, ester), 184.30 ppm (12 C=O, keto). IR ($CHBr_3$): $\tilde{\nu}$ = 1725 (C=O), 1640 cm^{-1} (C=C). $C_{96}H_{136}Mg_4N_4O_{60}$ (2403.36): calcd. C 47.98, H 5.70, N 2.33; found C 48.07, H 6.13, N 2.22.

Compound 5c: Yield: 0.48 g (38%) colourless powder; m.p. 187 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.86 (t, *J* = 7.1 Hz, 12 H, 4 CH_3), 0.98, 1.00, 1.13, 1.15, 1.24, 1.26 (each m, 48 H, 24 CH_2), 2.45, 2.73 (each br. m, 8 H, 4 $NCH^{A/B}$), 3.55, 3.78 (each s, 72 H, 24 CH_3), 7.69 ppm (br. s, 12 H, 4 NH_3^+). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 14.12 (4 CH_3), 22.51, 26.25, 26.89, 28.59, 28.99, 31.86 (24 CH_2), 41.56 (4 NCH_2), 51.21, 51.98 (24 OCH_3), 95.35 (12 =C), 167.22, 170.82 (24 C=O, ester), 184.36 ppm (12 C=O, keto). IR ($CHBr_3$): $\tilde{\nu}$ = 1720 (C=O), 1645 cm^{-1} (C=C). $C_{104}H_{152}Mg_4N_4O_{60}$ (2515.57): calcd. C 49.66, H 6.09, N 2.23; found C 49.26, H 6.54, N 2.41.

Compound 6: Yield: 0.73 g (63%) colourless microcrystals; m.p. 182 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.43, 3.50, 3.51, 3.55, 3.56, 3.64, 3.67, 3.71, 3.72, 3.77, 3.79, 3.87, two times two superimposed signals (each s, 80 H, 26 OCH_3, 2 CH^A), 4.06 (br. m, 2 H, 2 CH^B, the corresponding H^A was identified by HETCOR), 6.55 (d, *J* = 8.6 Hz, 4 H, Ar-H), 6.96 (d, *J* = 8.6 Hz, 4 H, 4 Ar-H), 7.03 (br. s, 8 H, 2 NH_4^+), 8.05 (br. s, 6 H, 2 NH_3^+). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 43.66 (2 CH_2), 50.47, 50.86, 51.29, 51.32, 51.62, 51.70, 51.75, 51.98, 52.09, three times two superimposed signals (24 OCH_3), 54.86 (2 OCH_3), 94.05, 94.32, 94.45, 95.22, 95.25, two superimposed signals (12 =C), 113.56 (4 Ar-CH), 124.41 (2 Ar-C), 131.05 (4 Ar-CH), 159.71 (2 Ar-C), 166.18, 166.73, 166.99, 168.09, 169.54, 169.58, 170.35, 170.39, 170.67, 170.87, 170.93, 171.09 (24 C=O, ester), 183.83, 184.10, 184.22, 184.36, 185.33, 185.44 (12 C=O, keto); When the NMR spectra of C_2-symmetric **6** were recorded in $CD_3CN/CDCl_3$ instead of $CDCl_3$ alone, the spectra of **6** revealed molecular *T* symmetry due to the core $[Mg_4(L^1)_6]^{4-}$. This is explained by fast exchange of $[NH_4]^+$ and $[H_3NCH_2C_6H_4OMe]^+$. At lower temperatures, the NMR signals characteristic of C_2-symmetric **6** reappeared. ^{1}H NMR (500 MHz, $CDCl_3/CD_3CN$): δ = 3.44 (s, 36 H, 12 CH_3);

IR ($CHBr_3$): $\tilde{\nu}$ = 1710 (C=O), 1640 cm^{-1} (C=C). $C_{88}H_{104}Mg_4N_4O_{62}$ (2307.01): calcd. C 45.82, H 4.54, N 2.43; found C 46.25, H 4.71, N 2.41.

General Procedure. Ammonium/Alkali Cation-Exchange: A solution of potassium hydroxide or caesium hydroxide hydrate (1.7 mmol) in a dichloromethane/ethanol mixture (1:1, 12 mL) was added dropwise to a solution of tetrahemispheraplex **1b** (0.96 g, 0.4 mmol) in dichloromethane (12 mL) over a period of 10 min. The mixture was stirred for 48 h at room temperature and concentrated to ca. 10 mL. The products were then obtained by addition of a mixture of diethyl ether/hexane (1:1, 100 mL), filtered off, washed three times with hexane and dried in vacuo.

Compound 7a: Yield: 0.94 g (94%) colourless microcrystals; m.p. >250 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.94, 0.98 (each t, J = 7.0 Hz, 72 H, 24 CH_3), 3.55, 3.78, 4.11, 4.24 (each m, 48 H, 24 $OCH^{A/B}$). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 13.79, 14.02 (24 CH_3), 60.01, 60.23 (24 OCH_2), 93.99 (12 =C), 166.61, 170.14 (24 C=O, ester), 185.38 ppm (12 C=O, keto). IR ($CHBr_3$): $\tilde{\nu}$ = 1640 (C=O), 1480 cm^{-1} (C=C). $C_{96}H_{120}K_4Mg_4O_{60}$ (2487.60): calcd. C 46.35, H 4.86; found C 45.32, H 5.23.

Compound 7b: Yield: 1.03 g (91%) colourless microcrystals; m.p. 224 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.17, 1.21 (each t, J = 7.2 Hz, 72 H, 24 CH_3), 3.93, 3.98, 4.05, 4.14 (each m, 48 H, 24 $CH^{A/B}$). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 13.90, 14.14 (24 CH_3), 60.03, 60.24 (24 OCH_2), 94.00 (12 =C), 168.88, 170.14 (24 C=O, ester), 185.30 ppm (12 C=O, keto). IR ($CHBr_3$): $\tilde{\nu}$ = 1640 (C=O), 1480 cm^{-1} (C=C). $C_{96}H_{120}Cs_4Mg_4O_{60}$ (2862.82): calcd. C 40.28, H 4.22; found C 41.57, H 4.41.

para-Functionalized NCN-Pincer Palladium(II) Complexes: Synthesis, Catalysis and DFT Calculations

Harm P. Dijkstra,[a] Martijn Q. Slagt,[a] Aidan McDonald,[a] Cornelis A. Kruithof,[a] Robert Kreiter,[a] Allison M. Mills,[b] Martin Lutz,[b] Anthony L. Spek,[b][‡] Wim Klopper,[c][‡‡] Gerard P. M. van Klink,[a] and Gerard van Koten*[a]

Keywords: Density functional calculations / Homogeneous catalysis / Substituent effects / Supported catalysts / Synthesis design

Several *para*-substituted NCN-pincer palladium(II) complexes (**1a**–**g** and **6a**–**g**) {NCN = $[C_6H_3(CH_2NMe_2)_2$-2,6$]^-$, *para* = 4-position} have been prepared and the electronic influences of the *para* substituents were studied in catalysis as well as by DFT calculations (B3LYP/LANL2DZ). From DFT calculations, it was found that the *para* substituent exerts only a minor effect on the partial charge, investigated by means of the Mulliken population analysis, at the palladium(II) center. Also, when the *para*-functionalized, cationic NCN–Pd^{II} complexes **6a**–**g** were applied as Lewis acid catalysts in the double Michael reaction between methyl vinyl ketone and ethyl α-cyanoacetate, only small differences in the activities of the various catalysts were observed. These results, when translated to immobilized multipincer catalysts, imply that various *para* functionalities can be used for immobilization of the pincer–metal complexes without affecting the catalytic activity of the individual sites. The application of a number of shape-persistent nanosize $(NCN–Pd^{II})_n$ complexes (**7**, $n = 3$; **8**, $n = 3$; **9**, $n = 8$; **10**, $n = 12$) as homogeneous catalysts in the same Michael reaction, confirmed this expectation. For complexes **7**, **8** and **9**, the catalytic activity per Pd^{II} center was found to be the same as for the monopincer analogs. Only dodecakis(NCN–Pd^{II}) complex **10** showed an almost threefold enhancement in catalytic activity per Pd^{II} center, which is ascribed to the high catalyst concentration at the periphery of this material.

Introduction

Metalated pincer complexes (see Figure 1) have been successfully applied as homogeneous catalysts in organic transformations.[1] Advantageous to the pincer system is the ease of alteration of several functionalities, allowing fine-tuning of these pincer complexes for the desired application.[2] The donor substituents Y can be varied easily, giving access to NCN- (Y = NR'_2), PCP- (Y = PR'_2) and SCS-type (Y = SR′) pincer ligands. As a result, metal centers such as palladium, platinum, nickel, iridium, ruthenium and rhodium can nowadays be introduced into the various pincer ligands thereby allowing application of pincer catalysts in a broad range of catalytic reactions.[2] Furthermore, chirality can be introduced into the pincer catalysts by the benzylic substituent R′′ and/or the donor group Y, opening the possibility for asymmetric catalysis.[3] In addition, the electronic as well as the steric environment of the metal center can be fine-tuned by variation of the substituent Y and/or the R′ groups attached to Y. A recent study illustrated the influence of the donor substituent Y on the catalytic activity of cationic YCY−Pd^{II} complexes in a double Michael reaction.[4] It was found that NCN-type catalysts were superior to SCS- and PCP-type catalysts, while also small effects on the catalytic activity were observed when different types of N-donor groups were used. Finally, the *para* substituent R (Figure 1) can also be used to influence the electron density at the metal center. An illustrative example of the *para* substituent influence on the reactivity of a pincer−metal catalyst was reported by Van de Kuil et al., in which various *para*-substituted NCN−Ni^{II} catalysts were studied in the Kharasch addition reaction.[1d,5] Electron-donating and -withdrawing substituents were found to have a significant effect on the Ni^{II}/Ni^{III} oxidation potential, the crucial step in the catalytic cycle of the Kharasch addition.

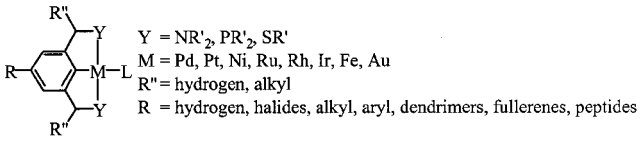

Figure 1. The metalated pincer system

Immobilization of pincer catalysts on soluble or solid supports in order to prepare recyclable catalysts has been intensively studied in recent years.[1e,6] It was demonstrated that the *para* position (R, Figure 1) is excellent for anchoring these pincer complexes to support materials. In particular, we studied shape-persistent multi(YCY−metal) complexes as homogeneous catalysts as well as their application in a nanofiltration membrane reactor in order to enhance total turnover numbers of the catalysts by recycling.[4,7,8] In this field of research, it is desirable to be able to use diverse functionalities at the *para* position of the pincer complex for anchoring purposes. In order to estimate beforehand any uncontrolled influences by these functionalities on the catalytic properties of the pincer−metal moieties, we set out to study the electronic influence of *para* substituents on the catalytic activity of pincer systems in organic transformations. Since (NCN−Pd^{II}) complexes were already found to be very active as homogeneous Lewis acid catalysts in the double Michael reaction between methyl vinyl ketone (MVK) and ethyl α-cyanoacetate[4] and because the conditions nicely meet the requirements for the commercially available nanofiltration membranes,[9] we decided to use this reaction for our catalyst screening. A number of *para*-functionalized, cationic NCN−Pd^{II} complexes [Figure 2, X = $OH_2(BF_4)$] were prepared and applied as Lewis acid catalysts in the double Michael reaction. We also performed density functional theory (DFT) calculations on these systems in order to gain insight in the electronic influence of the *para* substituent on the Pd^{II} center. Furthermore, palladated shape-persistent multi(NCN-pincer) complexes, in which the pincer moiety is anchored to the various supports by different *para* functionalities, were also included in this study.

Results and Discussion

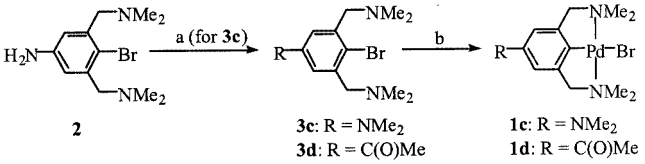
Synthesis of *para*-Substituted NCN−Pd^{II} Complexes

para-Substituted NCN-pincer complexes **1a**−**g** were selected for this study (Figure 2). Complexes **1a** (X = Br),[10] **1b** (X = Br)[11] and **1g** (X = Cl)[12] were prepared according

	1a	1b	1c	1d	1e	1f	1g
R	H	NO_2	NMe_2	C(O)Me	OCH_2Ph	Ph	$SiMe_3$

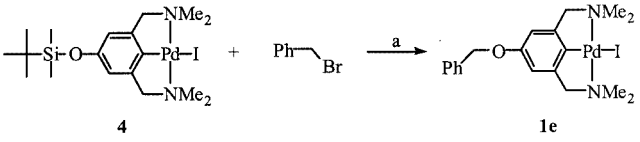
Figure 2. A series of *para*-substituted NCN-pincer palladium(II) complexes

to literature procedures. Palladium(II) complex **1c** (X = Br) was prepared in two steps (Scheme 1). Treatment of *para*-amino pincer derivative **2**[13] with formaldehyde and formic acid, yielded the desired ligand **3c** in 62% yield. Treatment of **3c** with $Pd_2(dba)_3$·$CHCl_3$ in benzene, afforded NCN−palladium(II) complex **1c** (Scheme 1). The *para*-acetyl-substituted NCN-pincer complex **1d** (X = Br) was prepared according to the same palladation procedure, starting from the previously prepared ligand precursor **3d**[13] (Scheme 1).



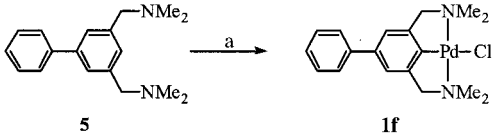
Scheme 1. a) Formaldehyde, formic acid, room temp., 3 h; b) [$Pd_2(dba)_3$]·$CHCl_3$, C_6H_6, room temp., 18 h

para-Benzyloxy pincer complex **1e** (X = I) was synthesized according to a procedure recently developed for the synthesis of nanosize multipincer complexes.[7b] Treatment of a mixture of the *para*-(*tert*-butyldimethylsilyl)-protected phenolic pincer **4**, benzyl bromide, potassium carbonate and 18-crown-6 with tetrabutylammonium fluoride in acetone, resulted in the formation of **1e** in 80% yield (Scheme 2). Note that the metal ion is already present during the introduction step of the *para* substituent, showing the versatility and strength of the pincer system.[14]



Scheme 2. a) Bu_4NF, K_2CO_3, 18-crown-6, acetone, room temp., 18 h

para-Phenyl pincer complex **1f** (X = Cl) was synthesized from *para*-phenyl-substituted NCN ligand precursor **5**[15] by a lithiation/transpalladation procedure (Scheme 3), affording **1f** in 83% yield.

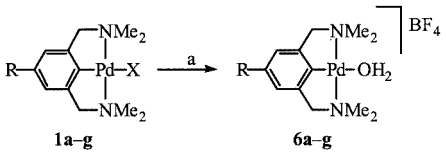


Scheme 3. a) *n*BuLi, hexanes, −80 °C → room temp., 4 h, followed by [$PdCl_2$(cod)], Et_2O, room temp., 2 h

Noteworthy is that three different methods were used to arrive at *para*-substituted NCN−Pd^{II} complexes: i) an oxidative addition reaction (**1a**−**1d**), ii) a lithiation/transmetalation reaction (**1f** and **1g**), and iii) the introduction of the *para* substituent with the metal ion already present in the pincer ligand (**1e**). These examples illustrate the wide variety of reactions which can be used to prepare functionalized pincer−metal complexes. Especially for the synthesis of multi(YCY−metal) complexes, having a variety of

methods available to construct the multimetallic material is considered of great importance.[4,7]

The neutral NCN−Pd^{II} complexes **1a**−**g** were readily converted into the corresponding cationic species **6a**−**g**, the Lewis acid catalyst precursors for the double Michael reaction, by treatment with silver tetrafluoroborate in wet acetone (Scheme 4).[16]



1a–g **6a–g**

Scheme 4. a) $AgBF_4$, wet acetone, room temp., 1 h

Crystals suitable for X-ray crystal structure determination were obtained for neutral NCN−palladium complexes **1c** and **1d** [Figure 3, parts a) and b), respectively]. The molecular structures comprise square-planar palladium(II) centers ligated by a terdentate η^3-coordinating NCN ligand and a bromine ligand *trans* to the aryl ring of the pincer ligand. Table 1 summarizes a number of representative interatomic bond lengths and angles of **1c** and **1d**. The crystal structure of **1d** contains two independent molecules, of which only one is shown in Figure 3. The two molecules differ only slightly in the conformation of the acetyl substituent with respect to the pincer−palladium fragment. In both **1c** and **1d**, the *para* substituents are almost in the same plane with the pincer aryl ring, as can be concluded from the dihedral angles given in Table 1. This coplanarity is commonly observed in the crystal structures of molecules containing an Me_2N−aryl or MeC(O)−aryl moiety.[17] Furthermore, as indicated by the small differences in the Pd−Br distances [**1b**: Pd−Br = 2.5516(3) Å],[11] the different *para* substituents have only minor influences on the electron density of the palladium center.

Density Functional Theory (DFT) Calculations

To further investigate the electronic influences of the *para* substituents on the Lewis acidity of the palladium(II) center, DFT calculations were performed on cationic catalyst precursors **6a**−**g**. Recently, similar calculations on substituted

[a] By means of Mulliken population analysis. [b] Hammett parameters for the various *para*-substituents obtained from Exner.[20]

NCN−Pt^{II} complexes demonstrated that the calculated structures correlated well with the experimental observations.[11b] In addition, the calculated Mulliken charge at the Pt^{II} centers showed a linear relationship with the chemical shifts of the Pt nuclei in the ^{195}Pt NMR spectra of the various complexes as well as with the σ_p Hammett parameter of the various *para* substituents.[11b] The DFT method B3LYP/LANL2DZ[18] as implemented in Gaussian 98[19] was used to calculate the partial charge, by means of Mulliken population analysis, at the palladium(II) centers of *para*-substituted catalyst precursors **6a**−**g**. Table 2 summarizes a number of selected data which were obtained from these calculations and also displays the Hammett parameter (σ_p) of the various *para* substituents.

Both from the Mulliken charge at the Pd^{II} centers and from the Pd−OH_2 and Pd−C_{ipso}(aryl) distances, it becomes clear that the *para* substituent R has only a minor electronic influence on the palladium(II) center, and thus on its Lewis acidity. Nevertheless, the complexes with the highest Mulliken charge at the Pd^{II} center (**6b** and **6d**, most electron-withdrawing substituents) have the shortest calculated Pd−O distances, while complex **6c** (most electron-donating substituent) possessing the lowest Mulliken charge at the Pd^{II} center displays the largest Pd−O distance (Table 2). In addition, plotting the Hammett parameter (σ_p) against the calculated Mulliken charge at the Pd^{II} centers of **6a**−**g**, clearly demonstrates the expected trend (Figure 4). Although, the linear fit is rather poor (in particular **6b** shows a significant deviation), this result indicates that DFT calculations can be used to predict the relative electronic influence of substituents on catalytically active metal centers.

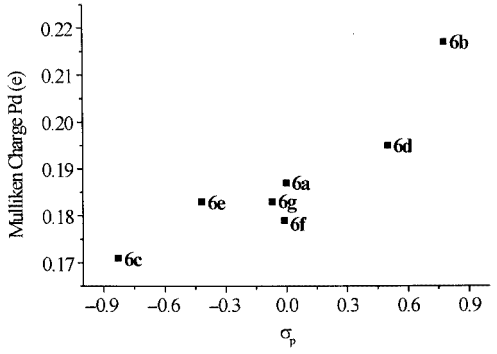

Figure 4. Linear relationship between Hammett parameter (σ_p) of the *para* substituents and Mulliken charge at the Pd centers

Catalysis Using *para*-Substituted NCN−Pd^{II} Catalysts

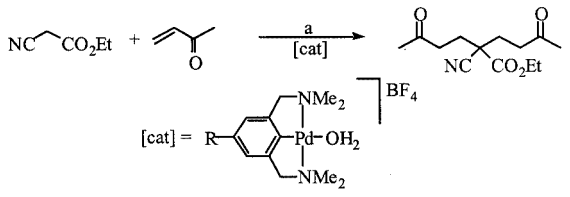
Cationic NCN−Pd^{II}−aqua complexes **6a**−**g** were applied as homogeneous Lewis acid catalysts in the double Michael reaction between methyl vinyl ketone (MVK) and ethyl α-cyanoacetate (Scheme 5). The results are summarized in Table 3.[21] In all cases 0.5 mol % [Pd^{II}] centers was used. From the $k_{obsd.}$ found for the various catalysts, it is apparent once again that the *para* substituents exert only a small influence on the catalytic activity of the Pd^{II} centers for this particular reaction. Only **6c** (R = Me_2N, Table 3) displays a significantly lower activity in this reaction as compared to the other catalysts.

Table 3. Catalytic results of **6a**−**g** in the double Michael reaction

Catalyst	*p*-R	$k_{obsd.}$ [$\times 10^{-4}$ s^{-1}][a]	$t_{1/2}$ [min][b]
6a	H	2.8	41
6b	NO_2	2.2	53
6c	NMe_2	1.3	89
6d	C(O)Me	2.3	50
6e	OCH_2Ph	2.4	48
6f	Ph	2.7	43
6g	$SiMe_3$	2.6	44

[a] Determined by ^1H NMR spectroscopy by comparison of the integration of the α-CH_2 protons of ethyl α-cyanoacetate to the combined integration of the ethyl ester CH_2 protons of the reactant and product. First-order reactions CN (CN = ethyl α-cyanoacetate); rate constant *k* was determined by plotting $-\ln([CN]/[CN]_0)$ versus time [s]. [b] $t_{1/2} = \ln 2/(k \times 60)$.

Comparison of the experimentally obtained catalytic data with the theoretical data reveals that there is no linear relationship between the observed rate constants ($k_{obsd.}$, Table 3) and the calculated Mulliken charges at the Pd^{II} centers of **6a**−**g** (Table 2). Plotting the Hammett σ_p parameters of the various *para* substituents against the log-



Scheme 5. Double Michael reaction between MVK and ethyl α-cyanoacetate; a) iPr_2NEt (10 mol %), [cat] (0.5 mol %), CH_2Cl_2, room temp.

($k_{obsd.}$) values of **6a**−**g** resulted in a curved function passing through a maximum (Figure 5). This type of behavior has previously been observed for reactions in which a reversible step is followed by an irreversible step.[22] Apparently, the *para* substituents alter the relative magnitude of the rate constants of the individual mechanistic steps and thus change the rate-determining step. In the double Michael reaction, a reversible step − deprotonation of the α-CH_2 group of ethyl α-cyanoacetate − is followed by an irreversible step − the 1,4-addition of the ethyl α-cyanoacetate anion to MVK. Thus, changing the *para* substituent from an electron-withdrawing to an electron-donating group can shift the rate-determining step from the deprotonation step to the nucleophilic 1,4-addition step. From the catalytic data presented in Table 3, it seems that the *p*-NMe_2 substituent has the largest influence, as the activity of **6c** was found to be considerably lower than that of the other catalytic species. Further research to elucidate this change in the rate-determining step is currently under investigation.

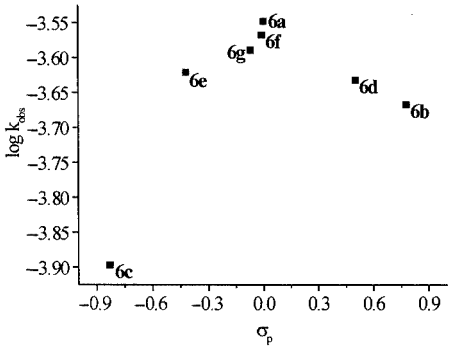


Figure 5. Hammett σ_p parameter versus log($k_{obsd.}$) of **6a**−**g**

Catalysis Using Multi(NCN−Pd^{II}) Catalysts

Previously, we reported the synthesis of shape-persistent multi(NCN−Pd^{II}) catalyst precursors **7**−**10** (Figure 6).[23] These complexes were also applied as homogeneous catalysts in the double Michael reaction between MVK and ethyl α-cyanoacetate (Scheme 5). The catalytic results are

8	2.6	44
9	2.1	55
10	8.1	14

[a] Determined by ^{1}H NMR spectroscopy by comparison of the integration of the α-CH_2 protons of ethyl α-cyanoacetate to the combined integration of the ethyl ester CH_2 protons of the reactant and product. First-order reactions CN (CN = ethyl α-cyanoacetate); rate constant k was determined by plotting $-\ln[CN/[CN]_0)$ versus time [s]. [b] $t_{1/2} = \ln 2/(k \times 60)$.

summarized in Table 4. In all cases, 0.5 mol % [Pd^{II}] centers was used and the $k_{obsd.}$ values for the various multimetallic systems were determined per palladium(II) center.

The catalysis results obtained for the tris(NCN−Pd^{II}) catalyst **7** (Table 4) were reported previously.[4] Compared to the catalytic activity of the reference monometallic catalyst **6a** (R = H, Table 3), it becomes clear that the catalytic activities per palladium(II) center for multi(NCN−Pd^{II}) catalysts **7**−**9** (Table 4) are similar, indicating that all palladium(II) centers in **7**−**9** act as independent catalytic sites. This is an important result; it implies an efficient use of all catalytic sites during catalysis. In addition, it once again underlines that the (Lewis acid) catalytic activity depends little on the *para* functionality of the pincer moiety, which is in agreement with the results obtained for the monometallic *para*-substituted NCN−Pd^{II} catalysts (Table 3). Interestingly, the dodecakis(NCN−Pd^{II}) catalyst **10** shows an almost threefold increase in catalytic activity per Pd^{II} center (Table 4) as compared to reference **6a** (R = H, Table 3). This increase in catalytic activity does not originate from the influence of the *para* substituent, since no increase in catalytic activity was observed for **6e** (R = OCH_2Ph, Table 3) and **9** (Table 4), both possessing the same *para* substituent as **10**. Molecular modeling studies of the isostructural platinum analogs of **9** and **10**,[7b] respectively, already indicated that on average the metal sites are in closer proximity to each other in the case of **10**, suggesting cooperative effects between the Pd^{II} centers during catalysis. Another possible explanation is that large aggregates of **10**, induced by the polar organometallic periphery, assemble in solution, resulting in the formation of polar micro-environments and thereby enhancing the catalytic transformations. This aggregate formation would be more difficult for **9** due to its spherical geometry.

Conclusions

A series of *para*-substituted NCN−Pd^{II} complexes was synthesized and the electronic influence of the *para* substituents on the Lewis-acidic palladium(II) centers was investigated by means of catalysis and DFT calculations. The application of these complexes as homogeneous Lewis acid catalysts in the double Michael reaction between MVK and ethyl α-cyanoacetate, clearly showed that in general the *para* substituents only slightly affect the catalytic activity of the Pd^{II} centers. Only the use of the *para*-(dimethylamino) substituent (**6c**) resulted in a considerable decrease in the catalytic activity. These results were confirmed by DFT calculations, which revealed that the *para* substituents have only minor influences on the partial charge (expressed by the Mulliken population) and thus on the Lewis acidity of the palladium(II) centers. In addition, several shape-persistent multi(NCN−Pd^{II}) complexes were applied as Lewis acid catalysts in the double Michael reaction. The catalysis results of **7**−**9** showed that all catalytic sites act as independent catalysts; the activities per Pd^{II} center were similar to the activities found for the mononuclear catalysts. Surprisingly, the dodecakis(NCN−Pd^{II}) system **10** exhibited a threefold increase in catalytic activity, probably due to cooperativity between metalated pincer groups at the periphery of **10**. Retention measurements with the isostructural platinum analogs of **7**−**10** in a nanofiltration membrane reactor have already shown that these shape-persistent complexes are very efficiently retained by nanofiltration membranes.[7b] Currently, these shape-persistent nanosize complexes are being further explored as homogeneous catalysts in a nanofiltration membrane reactor under continuously operating conditions.

Experimental Section

General: Solvents were purified and dried according to standard procedures, stored under nitrogen and freshly distilled prior to use. NMR solvents were purchased and used without further purification. Compounds **1a**,[10] **1b**,[11] **1g**,[12] **2**,[1d] **3d**,[5] **4**,[7b] **5**,[15] **6a**,[16] and [$PdCl_2$(cod)][24] were prepared according to literature procedures. All other reagents were purchased and used without further purification. NMR spectra were recorded with a Varian 300 spectrometer (^{1}H NMR: 300.1 MHz. ^{13}C NMR: 75.5 MHz. ^{31}P NMR: 121.5 MHz) or a Varian Gemini 200 spectrometer (^{1}H NMR: 200.1 MHz. ^{13}C NMR: 50.3 MHz. ^{31}P NMR: 81.0 MHz). Microanalyses were determined by Dornis and Kolbe, Mikroanalytisches Laboratorium, Mülheim a. d. Ruhr, Germany.

3c: Arylamine **2** (0.20 g, 0.68 mmol) was dissolved in a mixture of formaldehyde (10 mL) and formic acid (10 mL) and this mixture was stirred at room temperature for 3 h. Subsequently, 1 M NaOH (aq) was added to this solution until pH = 11 was reached. The aqueous layer was extracted with CH_2Cl_2 (3 × 20 mL) and the combined organic layers were dried with $MgSO_4$. After evaporation of all volatiles, hexanes (20 mL) were added and the resulting mixture was filtered and the solvents were evaporated to dryness, leaving a slightly brown solid. This product was used without further purification. Yield: 0.13 g (62%). ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 2.30 (s, 12 H, NCH_3), 2.95 (s, 6 H, *p*-NCH_3), 3.50 (s, 4 H, CH_2), 6.74 (s, 2 H, Ar*H*) ppm. ^{13}C NMR ($CDCl_3$, 75 MHz): δ = 40.95, 45.98, 64.49, 114.15, 123.66, 138.77, 149.59 ppm.

1c: [Pd_2(dba)$_3$]·$CHCl_3$ (0.33 g, 0.32 mmol) in benzene (10 mL) was added to a solution of **3c** (0.20 g, 0.64 mmol) in benzene (10 mL) and this solution was stirred at room temperature for 3 h. Subsequently, all volatiles were evaporated, CH_2Cl_2 (15 mL) was added and the resulting solution was filtered through Celite. The Celite layer was washed with CH_2Cl_2 (2 × 5 mL). The combined filtrates

were concentrated to ca. 5 mL and upon addition of Et_2O (10 mL) the product precipitated from the yellow solution. Light-brown crystals suitable for a crystal structure determination were obtained by slow diffusion of pentane into a concentrated solution of **1c** in CH_2Cl_2. Yield: 0.13 g (50%). ^1H NMR ($CDCl_3$, 200 MHz): δ = 2.86 (s, 6 H, *p*-NCH_3), 2.96 (s, 12 H, NCH_3), 3.95 (s, 4 H, CH_2), 6.26 (s, 2 H, Ar*H*) ppm. ^{13}C NMR ($CDCl_3$, 75 MHz): δ = 41.55, 53.96, 75.05, 105.28, 144.53, 145.67, 149.53 ppm. $C_{14}H_{24}BrN_3Pd$ (420.69): calcd. C 39.97, H 5.75, N 9.99; found C 39.78, H 5.67, N 9.92.

1d: Synthesis as described for **1c**, using **3d** (0.20 g, 0.64 mmol) and $Pd_2(dba)_3{\cdot}CHCl_3$ (0.33 g, 0.32 mmol) in benzene (10 mL). Orange/brown crystals of **1d** suitable for a crystal structure determination were obtained by slow concentration in air of a concentrated solution of **1d** in CH_2Cl_2. Yield: 0.18 g (67%). ^1H NMR ($CDCl_3$, 200 MHz): δ = 2.52 [s, 3 H, C(O)CH_3], 2.99 (s, 12 H, NCH_3), 4.05 (s, 4 H, NCH_2), 7.41 (s, 2 H, Ar*H*) ppm. ^{13}C NMR ($CDCl_3$, 75 MHz): δ = 26.80, 54.09, 74.66, 120.22, 134.75, 145.45, 197.92 ppm. $C_{14}H_{21}BrN_2OPd$ (419.66): calcd. C 40.07, H 5.04, N 6.68; found C 40.26, H 5.11, N 6.56.

1e: Tetrabutylammonium fluoride (1 M in THF) (0.54 mL, 0.54 mmol) was added to a mixture of **4** (0.30 g, 0.54 mmol), benzyl bromide (0.10 mL, 0.83 mmol), K_2CO_3 (0.38 g, 2.7 mmol) and 18-crown-6 (13 mg, 0.05 mmol) in acetone (15 mL). This mixture was stirred at room temperature for 5 h. Subsequently, all volatiles were evaporated, CH_2Cl_2 (15 mL) was added and the resulting mixture was filtered. The filtrate was reduced to 5 mL and upon addition of Et_2O (10 mL) the product precipitated as an off-white solid. Slow diffusion of Et_2O into a concentrated solution of **1e** in CH_2Cl_2, afforded analytically pure **1e** as a white powder. Yield: 0.17 g (59%). ^1H NMR ($CDCl_3$, 300 MHz): δ = 2.98 (s, 12 H, NCH_3), 3.97 (s, 4 H, NCH_2), 4.98 (s, 2 H, OCH_2), 6.49 (s, 2 H, Ar*H*), 7.30−7.42 (m, 5 H, Ar*H*) ppm. ^{13}C NMR ($CDCl_3$, 75 MHz): δ = 54.01, 73.66, 74.80, 107.25, 127.65, 128.22, 128.84, 137.32, 145.86, 157.48 ppm. $C_{19}H_{25}IN_2OPd$ (530.74): calcd. C 43.00, H 4.75, N 5.28; found C 43.15, H 4.80, N 5.24.

1f: *n*BuLi (2.3 mL, 3.7 mmol) was added to a solution of **5** (1.0 g, 3.7 mmol) in dry hexanes (20 mL) at −80 °C. After the addition was completed, the temperature was allowed to rise to room temperature and stirring was continued for 4 h. Subsequently, this solution was added to a suspension of [$PdCl_2$(cod)] (1.1 g, 3.7 mmol) in Et_2O at room temperature and the resulting mixture was stirred for an additional 3 h. The solvents were evaporated to dryness and the residue was extracted with CH_2Cl_2 (10 mL). The organic layer was filtered through Celite and the filtrate was reduced to ca. 3 mL. Addition of Et_2O resulted in the formation of a white precipitate which was collected and dried in vacuo. Analytically pure **1f** was obtained by slow diffusion of Et_2O into a concentrated solution of **1f** in CH_2Cl_2, affording colorless needles of **1f**. Yield: 1.2 g (78%). ^1H NMR ($CDCl_3$, 200 MHz): δ = 2.97 (s, 12 H, NCH_3), 4.05 (s, 4 H, NCH_2), 7.00 (s, 2 H, Ar*H*), 7.30−7.51 (m, 5 H, Ar*H*) ppm. ^{13}C NMR ($CDCl_3$, 75 MHz): δ = 53.38 (C_{ipso} signal not observed), 75.03, 119.00, 127.16, 128.99, 138.51, 141.84, 145.65, 156.09 ppm. $C_{18}H_{23}ClN_2Pd$ (409.27): calcd. C 52.83, H 5.66, N 6.84; found C 52.65, H 5.75, N 6.73.

General Procedure for the Synthesis of 6a−g: $AgBF_4$ (97.3 mg, 0.50 mmol) in wet acetone (1 mL) was added to a solution of **1a−g** (0.50 mmol) in acetone (10 mL) and the resulting solution was stirred at room temperature for 1 h. The mixture was filtered through Celite and the filtrate was concentrated to ca. 3 mL. Upon slow addition of Et_2O (5 mL), the product precipitated as an off-white solid. After isolation, the product was analyzed by ^1H NMR spectroscopy and immediately used in the catalytic experiments.

6a:[16] Yield: 0.17 g (86%). ^1H NMR ([D_6]acetone, 300 MHz): δ = 2.87 (s, 12 H, NCH_3), 4.11 (s, 4 H, NCH_2), 6.84 (d, $^3J_{H,H}$ = 7.5 Hz, 2 H, Ar*H*), 7.02 (t, $^3J_{H,H}$ = 7.5 Hz, 1 H, Ar*H*) ppm. ^{13}C NMR ([D_6]acetone, 75 MHz): δ = 51.72, 73.32, 120.42, 125.48, 145.68, 150.49 ppm.

6b: Yield: 0.17 g (78%). ^1H NMR ([D_6]acetone, 300 MHz): δ = 2.92 (s, 12 H, NCH_3), 4.34 (s, 4 H, NCH_2), 7.79 (s, 2 H, Ar*H*) ppm. ^{13}C NMR ([D_6]acetone, 75 MHz): δ = 51.93, 73.08, 115.81, 146.80, 146.90, 161.97 ppm.

6c: Yield: 0.15 g (67%). ^1H NMR ([D_6]acetone, 200 MHz): δ = 2.81 (s, 6 H, *p*-NCH_3), 2.83 (s, 12 H, NCH_3), 4.08 (s, 4 H, NCH_2), 6.38 (s, 2 H, Ar*H*) ppm.

6d: Yield: 0.21 g (93%). ^1H NMR ([D_6]acetone, 300 MHz): δ = 2.49 [s, 3 H, C(O)CH_3], 2.94 (s, 12 H, NCH_3), 4.22 (s, 4 H, NCH_2), 7.50 (s, 2 H, Ar*H*) ppm. ^{13}C NMR ([D_6]acetone, 75 MHz): δ = 26.02, 52.42, 73.66, 120.42, 135.78, 146.80, 162.29, 197.02 ppm.

6e: Yield: 0.24 g (95%). ^1H NMR ([D_6]acetone, 300 MHz): δ = 2.85 (s, 12 H, NCH_3), 4.13 (s, 4 H, NCH_2), 5.04 (s, 2 H, OCH_2), 6.63 (s, 2 H, Ar*H*), 7.32−7.46 (m, 5 H, Ar*H*) ppm. ^{13}C NMR ([D_6]acetone, 75 MHz): δ = 52.01, 70.13, 73.49, 107.80, 127.71, 127.95, 128.61, 137.83, 146.11, 158.28 ppm.

6f: Yield: 0.22 g (93%). ^1H NMR ([D_6]acetone, 300 MHz): δ = 2.89 (s, 12 H, NCH_3), 4.25 (s, 4 H, NCH_2), 7.18 (s, 2 H, Ar*H*), 7.29−7.60 (m, 5 H, Ar*H*) ppm. ^{13}C NMR ([D_6]acetone, 75 MHz): δ = 51.93, 73.45, 119.29, 129.06, 126.94, 127.24, 139.08, 141.54, 146.13, 150.31 ppm.

6g: Yield: 0.22 g (91%). ^1H NMR ([D_6]acetone, 200 MHz): δ = 0.21 (s, 9 H, SiCH_3), 2.85 (s, 12 H, NCH_3), 4.16 (s, 4 H, NCH_2), 7.03 (s, 2 H, Ar*H*) ppm. ^{13}C NMR ([D_6]acetone, 75 MHz): δ = −1.48, 51.84, 73.45, 125.07, 136.92, 145.30, 152.75 ppm.

Catalysis in the Double Michael Reaction Between MVK and Ethyl α-Cyanoacetate. A Typical Experiment. Ethyl α-cyanoacetate (0.17 mL, 1.6 mmol), methyl vinyl ketone (0.40 mL, 4.8 mmol), ethyldiisopropylamine (28 μL, 0.16 mmol) and **6a** (3.2 mg, 8 μmol, 0.5 mol % [Pd]) were mixed in CH_2Cl_2 (5 mL) and stirred at room temperature. The reaction mixture was sampled (100 μL) at regular intervals and the samples worked up by evaporating solvent and methyl vinyl ketone with a gentle stream of nitrogen. The conversions were determined by ^1H NMR spectroscopy. Conversions obtained were confirmed by GC analysis of the reaction mixture. In all cases, the product was isolated by bulb-to-bulb distillation. For all reactions, yields were found to be between 85 and 100%.

Crystal Structure Determinations: Intensities were measured with a Nonius KappaCCD diffractometer with rotating anode (Mo-K_α, λ = 0.71073 Å) at a temperature of 150 K. The structure was solved with automated Patterson methods using the program DIRDIF97,[25] and refined with the program SHELXL-97[26] against F^2 of all reflections up to a resolution of $(\sin/\lambda)_{max}$ = 0.65 $Å^{-1}$. Non-hydrogen atoms were refined freely with anisotropic displacement parameters. Hydrogen atoms were refined as rigid groups. The drawings, structure calculations, and checking for higher symmetry was performed with the program PLATON.[27]

Compound 1c: $C_{14}H_{24}BrN_3Pd$, M = 420.67, orange plate, 0.24 × 0.24 × 0.09 mm, monoclinic, $P2_1/c$ (no. 14), a = 9.1973(1) Å, b = 11.1707(2) Å, c = 16.4736(3) Å, β = 108.3990(8)°, V = 1605.98(4) $Å^3$, Z = 4, ρ = 1.740 g cm^{-3}. The absorption correction was per-

formed with PLATON[27] (routine DELABS, μ = 3.64 mm^{-1}, 0.49−0.72 transmission). 17563 measured reflections, 3671 unique reflections (R_{int} = 0.0508), 2999 observed reflections [$I > 2\sigma(I)$]. 178 refined parameters, 0 restraints. *R* (obsd. refl.): *R*1 = 0.0254, *wR*2 = 0.0517. *R* (all data): *R*1 = 0.0387, *wR*2 = 0.0549. *S* = 1.039. CCDC-187019 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Compound 1d: $C_{14}H_{21}BrN_2OPd$, *M* = 419.64, yellow plate, 0.12 × 0.12 × 0.05 mm, monoclinic, $P2_1/c$ (no. 14), *a* = 17.1168(3) Å, *b* = 15.1078(3) Å, *c* = 12.4777(3) Å, β = 107.1925(12)°, *V* = 3082.52(11) $Å^3$, *Z* = 8, ρ = 1.808 g cm^{-3}. The absorption correction was performed with PLATON[27] (routine MULABS, μ = 3.79 mm^{-1}, 0.68−0.82 transmission). 26887 measured reflections, 7047 unique reflections (R_{int} = 0.0729), 5091 observed reflections [$I > 2\sigma(I)$]. 353 refined parameters, 0 restraints. *R* (obsd. refl.): *R*1 = 0.0456, *wR*2 = 0.0931. *R* (all data): *R*1 = 0.0748, *wR*2 = 0.1034. *S* = 1.012. CCDC-187020 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[18] The DFT-B3LYP/LANL2DZ method uses density functional theory combined with effective core potentials. The basis set used for palladium is the Los Alamos National Laboratory set (LANL) for effective core potentials (ECP) of double ζ type, consisting of a small core ECP with 3s and 3p orbitals in the valence space. The functional form used is the B3LYP, and the relativistic correlations for heavy atoms are considered in the ECP.

Investigation of the Ligand Exchange Behavior of Square-Planar Nickel(II) Complexes by X-ray Absorption Spectroscopy and X-ray Diffraction

Martin P. Feth,*[a] Axel Klein,*[b] and Helmut Bertagnolli[a]

Keywords: Nickel / Ligand exchange / EXAFS spectroscopy / XANES / X-ray diffraction

The local structure of nickel and bromine in three square-planar nickel(II) complexes [(2,2′-bipyridyl)(bromo)(mesityl)-nickel(II)] (**1**), [(bromo)(*N*,*N*-diisopropyl-1,2-ethanediimine)-(mesityl)nickel(II)] (**2**), [(bromo)(mesityl)bis(triphenylphosphane)nickel(II) (**3**)] and their ligand exchange behavior towards several solvents has been determined by means of X-ray Absorption Near Edge Spectroscopy (XANES), Extended X-ray Absorption Fine Structure Spectroscopy (EXAFS), X-ray Diffraction (XRD), multinuclear NMR and UV/Vis spectroscopy. Several square-planar and octahedral nickel(II) complexes were prepared and spectroscopically characterized as reference compounds. The exchange behavior strongly depends on the nature of the incoming donor ligand (solvent molecule). In some cases the substitution of one or more ligands was accompanied by conservation of the square-planar geometry. In other solvents the geometry changed from square-planar to octahedral. The structural information obtained is important to the further development of such nickel(II) complexes as catalysts for various applications.

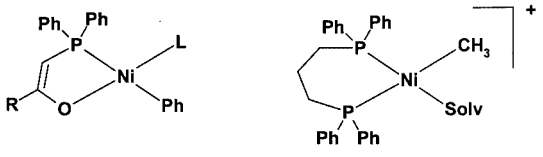
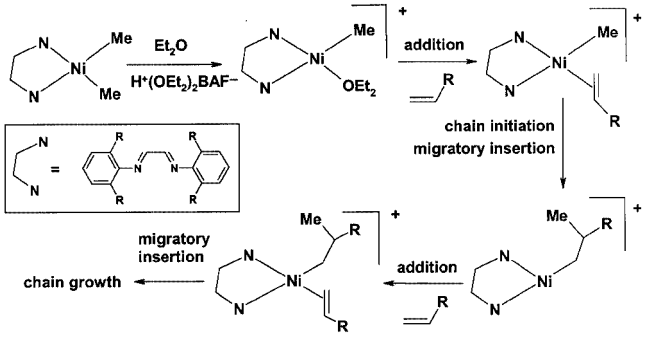
Introduction

Organonickel(II) complexes are widely used in organometallic catalysis. One of the first benchmarks was the (phosphane)nickel complexes used in the Shell Higher Olefin Process (SHOP)[1−7] (Scheme 1).



Scheme 1. Nickel catalysts for the oligomerization of olefins in the Shell Higher Olefin Process (SHOP) (**A**)[2−5] (left) or for copolymerization of ethene with CO (**B**)[6,7] (right)

A crucial requirement for these two systems to act as catalysts is that they contain a labile ligand (L or Solv) − as exhibited by the highly reactive catalysts for olefin polymerization developed over the last decade, mainly by Brookhart [1,2,8−14]. The active catalyst species are prepared from dialkylnickel precursor complexes as shown in Scheme 2.



Scheme 2. (α-Diimine)nickel complexes (diimine = 1,4-diazabutadiene) as catalysts for the polymerization of olefins;[2] preparation of the active catalyst species (top) and elemental steps in polymerization catalysis (bottom); BAF = perfluorinated tetraarylborates

Recently, we have investigated organonickel complexes of the type [(diimine)Ni(R)X] (R = alkyl or aryl; X = Cl or Br) to develop an alternative route to catalytically active species. We originally intended to abstract X by the addition of silver salts or related reagents; however, in polar solvents the complexes already showed a considerable degree of dissociation into the ionic species $[(diimine)Ni(R)(Solv)]^+$ and X^-, depending on X, the polarity of the solvent and the bulkiness of the R group [2,8,9,11−13]. With X = Cl the complexes are more inert towards X-dissociation but are very sensitive to hydrolysis. Complexes with X = Br are much more reactive towards dissociation but are quite inert towards water. Alkyl derivatives (R = alkyl) are very reactive to both dissociation and water whereas aryl complexes are relatively stable.[15,16] Dissociation can be enormously accel-

erated by electrochemical reduction of the starting complexes. The rapid loss of Br^- after reduction to the radical anionic species $[(diimine)Ni(R)Br]^{\cdot -}$ can only be slowed to a measurable rate for the very bulky mesityl group and at quite low temperatures.[17−20] The dissociation reactions yield species which should be quite reactive in the catalytic polymerization of olefins. However, we first wanted to examine in detail the structural aspects of these ligand exchange reactions (X^- to Solv) and to determine whether, in these media, further ligand exchange reactions occur that would lead to the replacement of the diimine ligand. To our astonishment this question has never been investigated thoroughly in mechanistic studies of olefin polymerization or related reactions.[1,6,7,9,11,21] In the nonpolar media used for the reactions and the applied excesses of ligand there is no need to consider ligand loss. However, if the reactions are to be extended to highly polar solvents with donor capabilities, or the ligand appears to be the "cost-determining step" and should not be used in excess, the partial or total loss of the chelate ligand (here the diimine) has to be considered, since it might influence the catalytic mechanism. We therefore investigated the ligand exchange reactions of the complexes [(diimine)Ni(Mes)Br] and also *trans*-$[(PPh_3)_2Ni(Mes)Br]$. The latter is not only the starting complex for the preparation of the *cis*-configured diimine complexes but shows the same dissociation lability and has been the subject of a related kinetic study.[22] Also it was previously used to catalyze the co-dimerization of butadiene and ethylene.[23] The combination of the bulky R group and the good leaving group Br^- renders these systems very suitable for a detailed mechanistic study since the timescale of the reactions lie in the range of minutes to hours. From the available diimine complexes we have chosen two different types: 2,2′-bipyridine (bpy), a classical aromatic diimine ligand, and *N*,*N*-diisopropyl-1,4-diazabutadiene (*i*Pr-DAB), a "Brookhart"-type ligand (see Scheme 2) developed some five decades ago.[24−27] in addition to the standard spectroscopic techniques (multinuclear NMR or UV/Vis absorption spectroscopy) we have made great use of EXAFS spectroscopy to investigate the ligand exchange reactions. For studies were crystalline samples are not available or of isotropic (X-ray amorphous) media like solutions, or powders, EXAFS is a powerful tool to elucidate the coordination sphere of such catalytically relevant species.[28−31] We used EXAFS spectroscopy at the nickel *K*-edge as well as on the bromine *K*-edge to investigate ligand exchange reactions in these complexes in solution as well as on separately prepared and isolated samples of possible intermediates. Molecular structures determined by XRD from single crystals helped to adjust reasonable fitting models. Investigation of the XANES region of an X-ray absorption spectra is also a powerful tool for the determination of the geometry of the first coordination shell and the oxidation state of an absorbing atom.[32,33] Emphasis can be given to the so-called pre-edge peaks (short: pre-peaks), which are related to electric dipole transitions from inner shells to unfilled bound states, e.g. 1s → 3d. These pre-peaks are very sensitive to geometrical changes in the first coordination shell of the absorbing atom. The symmetry of the first shell determines if certain pre-peaks appear in the spectrum or are symmetrically forbidden. For the square-planar Ni^{II} complexes the XANES investigations focus on the pre-peaks assigned to the 1s → 3d and 1s → $4p_z$ transitions.[34,35]

Results and Discussion

UV/Vis Absorption and Multinuclear NMR Spectroscopy in Solution

The bright colors of the compounds under investigation can be used to monitor their reactions. The complexes [(diimine)Ni(Mes)Br] show characteristic solvatochromic absorptions in the visible region[18,21,36,37] and dissolving them in non- to moderately coordinating solvents, such as toluene, CH_2Cl_2, THF, acetone, propylene carbonate (PC) and *N*,*N*-dimethylformamide (DMF), leads only to the expected solvatochromic shift. Solutions with pyridine or acetonitrile as solvent, however, show markedly blue-shifted absorption maxima within a few seconds {as shown for [(bpy)Ni(Mes)Br] in Figure 1}. These rapid reactions are followed by slower ones and the observed absorption bands were again shifted to higher energies. For the reaction of [(bpy)Ni(Mes)Br] in MeCN the rate of the first reaction was determined as $k = 0.324(6)\ M^{-1}\ s^{-1}$, assuming a first-order mechanism. We assign this to the dissociation of the bromide ligand and substitution by MeCN. The second reaction is much slower [$k = 0.0041(3)\ M^{-1}\ s^{-1}$] and is assigned to the replacement of the chelate ligand. This is deduced from the corresponding reaction in pyridine solution, where the rate constant is comparable [$k = 0.0029(3)\ M^{-1}\ s^{-1}$] and the resulting absorptions are coincident with those of the pyridine complex $[(py)_3NiMes]^+$ (see Exp. Sect.).

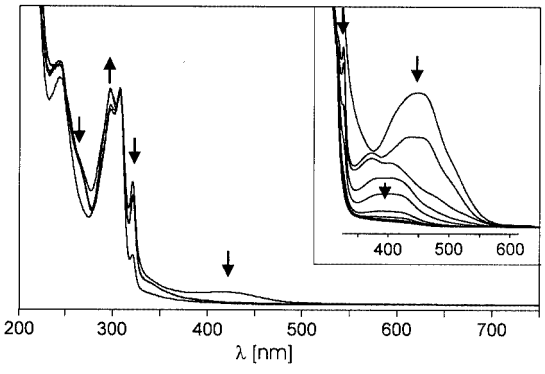

Figure 1. UV/Vis absorption spectra of [(bpy)Ni(Mes)Br] in acetonitrile (MeCN), immediately after dissolution and 3, 4.5 and 21 h later; insert: 20 s, 60 s, 180 s, 360 s, 540 s, and 720 s after dissolution

^1H NMR spectroscopy gives no sign of (partial) dissociation of the chelate ligand in the first minutes after dissolving, thus supporting the assumed reaction sequence. Subsequently, several reaction products appear that cannot be assigned unambiguously. After a prolonged reaction (several days) only in the case of pyridine we could clearly identify $[(py)_3Ni(Mes)]^+$ and the free ligand. In MeCN

numerous soluble products are found, along with insoluble green material.

The complex $[(PPh_3)_2Ni(Mes)Br]$ exhibits, in solvents such as toluene, CH_2Cl_2 or acetone, a solvent-invariant, weak long-wavelength absorption band with a maximum around 450 nm.[22] In pyridine solution a reaction occurs that can be monitored by a decrease of this band and the appearance of the blue-shifted maximum at around 410 nm. After this relatively fast reaction [$k(1) = 0.284(9)$ м$^{-1}$ s^{-1}], a second slower reaction follows with $k(2) = 0.0061(5)$ м$^{-1}$ s^{-1}. The reactions were confirmed by ^{1}H and ^{31}P NMR spectroscopy as identical to those of the diimine complexes.[11]. The ^{31}P NMR signal at $\delta = 20.2$ ppm for the starting complex is replaced by a singlet at $\delta = 27$ ppm that can be assigned to *trans*-$[(PPh_3)_2Ni(Mes)(py)]^+$ (see Exp. Sect.). Finally, after 36 h, only free PPh_3 ($\delta = -5$ ppm) is detected in solution. The ^{1}H NMR spectrum confirms the formation of $[(py)_3Ni(Mes)]^+$. In THF solution the reaction seems to stop after the first sequence and the resulting ^{31}P signal at $\delta = 29$ ppm is assigned to the solvent-coordinated species $[(PPh_3)_2Ni(Mes)(THF)]^+$. For a ligand-exchange reaction using thiocyanate (SCN^-) Martinez and Muller derived a two-term rate law, with $k_s = 5.2 \pm 0.6 \times 10^{-2}$ mol^{-1} s^{-1}, for the exchange of bromide versus the acetone solvent and $k_{an} = 3.0 \pm 0.4 \times 10^{-1}$ mol^{-1} s^{-1} for the subsequent replacement of acetone by SCN^-. On varying R in $[(PPh_3)_2Ni(R)Br]$ from C_6H_4Cl to C_6Cl_5 the k_{an} value lies in the range 43 to 6.6×10^{-4} with mesityl occupying an intermediate position.[22] Our experiments (see also EXAFS) confirm that even weakly coordinating solvents such as acetone or THF can replace bromide to form $[(PPh_3)_2Ni(Mes)(Solv)]^+$, which is in sharp contrast to the behavior of [(bpy)Ni(Mes)Br]. This is due to the strong *trans* effect of the mesityl ligand. Since our substitution reactions on $[(PPh_3)_2Ni(Mes)Br]$ were performed in neat pyridine or other media that are potential ligands, we fitted our kinetic data according to a first-order rate law, thus deviating from the established two-term rate law.[22] Our $k(1)$ value agrees excellently with the k_{an} measured by Martinez and Muller, indicating that SCN^- and pyridine are of comparable σ-donor capability. In acetonitrile the first rapid reaction leads to a green solution. Inspection of the absorption spectrum shows weak long-wavelength absorptions at 1228 nm (8143 cm^{-1}; $\varepsilon = 40$ м$^{-1}$·cm^{-1}) and 630 nm (15873 cm^{-1}; $\varepsilon = 160$ м$^{-1}$·cm^{-1}; with a shoulder at 681 nm). The latter is responsible for the observed green color. In the UV region, shoulders at 431 nm (23202 cm^{-1}) and 419 nm (23877 cm^{-1}) are discernible and the spectrum is dominated by an intense band at 267 nm (37450 cm^{-1}; $\varepsilon = 23000$ м$^{-1}$cm^{-1}). The long-wavelength bands are quite weak and typical for ligand field transitions of nickel(II) complexes.[38,39] We assume a tetrahedral coordination of the ligands in $[(PPh_3)_2Ni(Mes)(MeCN)]^+$, the product of the first substitution reaction. An octahedral coordination was excluded because of the bulkiness of the Mes and PPh_3 ligands. The corresponding absorptions were assigned to $\nu_1 = {}^3T_2(F) \rightarrow {}^3T_1(F)$; $\nu_2 = {}^3A_2(F) \rightarrow {}^3T_1(F)$ and $\nu_3 = {}^3T_1(P) \rightarrow {}^3T_1(F)$. Such transitions are usually more intense than those of octahedral species and exhibit splitting due to spin-orbit coupling. The ^{31}P NMR spectra of such green solutions show the presence of a singlet at $\delta = 21.7$ ppm. In addition, two further singlets at $\delta = 20.3$ ppm (starting complex) and $\delta = 19.3$ ppm (1/20 intensity of the $\delta = 21.7$ ppm signal) are observed whereas free PPh_3 is not found. The ^{1}H NMR spectra confirm the presence of several species, but line broadening precludes further assignments.. Apart from different degrees of substitution, an equilibrium between tetrahedral and square-planar conformations of an individual species might account for the complicated behavior, as has been described for $[(PEtPh_2)_2NiBr_2]$.[40,41] As tetrahedral nickel(II) species should be paramagnetic ($S = 1$), which might explain the poor NMR spectroscopic data, an ESR investigation of these species is planned.

Structural Studies on the [(bpy)Ni(Mes)Br] System

Crystal Structure

The crystal structure of [(bpy)Ni(Mes)Br]·THF (Figure 2) shows two very similar, but independent, molecules in the unit cell. Both structures exhibit the expected square-planar environment of the nickel atoms, with only slight tetrahedral distortions [N(11)−Ni(1)−N(12) towards C(11)−Ni(1)−Br(1) of 8.6° or 12.1°, respectively].

The bond lengths of **1** and **2** are very similar and lie in the expected range.[17,42,43] However, while the interplanar angle between the two pyridine moieties is negligible for **1** (1.9°) it is appreciable for **2** (10.5°). A further distortion for **2** concerns the C(21)−Ni(2)−N(22) angle of 170.4(3), which deviates markedly from the idealized 180°. For **1** we found 176.2(3)°. Both molecules are similar to the recently described dimesityl complex $[(bpy)Ni(Mes)_2]$.[17] The distortion of the coordination plane in $[(bpy)Ni(Mes)_2]$ is very much like that in **2** (12.4°) whereas the pyridine interplanar angle (3.2°) is close to that of **1**. Many other molecular parameters are very similar for these three structures, with the notable exception of the Ni−N distance *trans* to the Br ligand, which is markedly shorter than the others in agreement with the expected *trans* influence.

XANES Investigations

In the XANES spectra of the square-planar Ni^{II} at the Ni *K*-edge complexes two pre-edge peaks can be observed [Figure 3 (a)]. The pre-peak at about 8333 eV can be assigned to a $1s \rightarrow 3d$ electron transition, while the second peak, which occurs at about 8337 eV, is due to a $1s \rightarrow 4p_z$ transition.[34,35] In octahedral Ni^{II} complexes the $1s \rightarrow 3d$ transition as well as the $1s \rightarrow 4p_z$ transition are forbidden; however, the small orbital mixing by lower symmetry gives some probability for the $1s \rightarrow 3d$ transition. Thus, in octahedral complexes the $1s \rightarrow 4p_z$ pre-peak at 8337 eV is absent and the $1s \rightarrow 3d$ pre-peak shows a much smaller intensity than in square-planar complexes [34,35,44]. Therefore octahedral and square-planar complexes can be distinguished by the presence or absence of the $1s \rightarrow 4p_z$ transition.

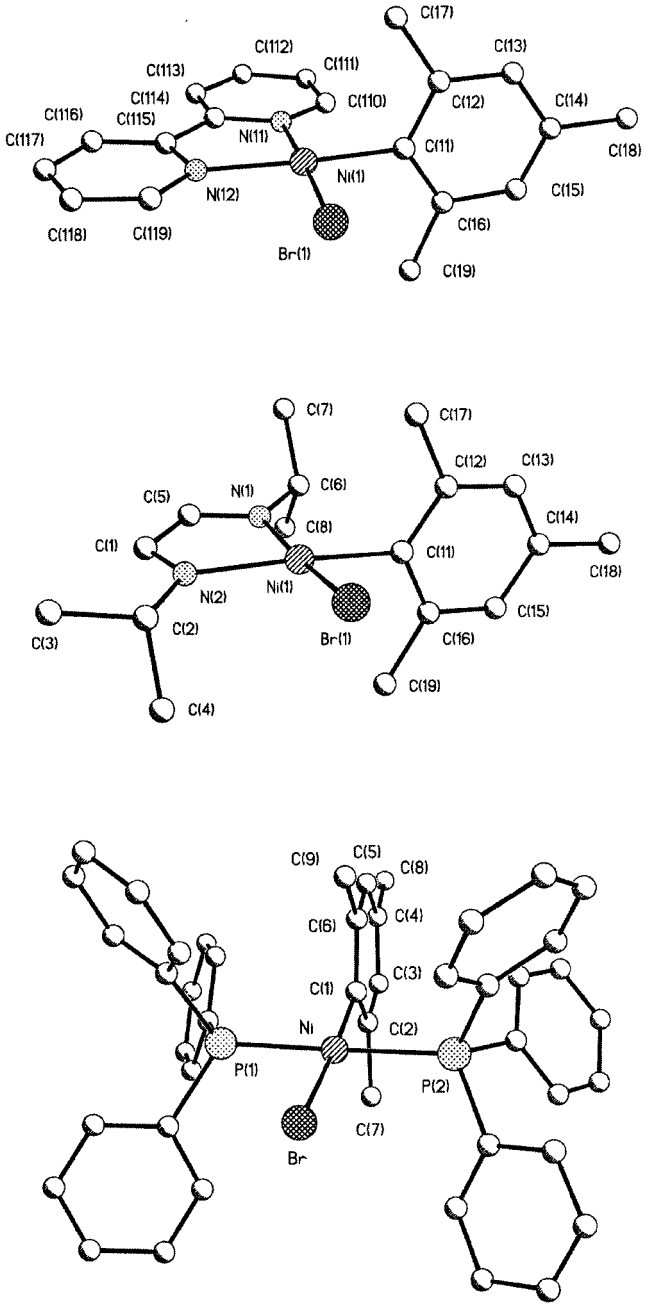

Figure 2. Molecular structure of the investigated Ni^{II} complexes: [(bpy)Ni(Mes)Br] (**1**) (top), [(*i*Pr-DAB)Ni(Mes)Br] (**2**) (center) and $[(PPh_3)_2Ni(Mes)Br]$ (**3**) (bottom)

In Figure 3 (a) the pre-edge and XANES region at the Ni *K*-edge of the solid complex **1** is shown in comparison with its solutions in pyridine and acetonitrile. As an octahedral reference compound the XANES spectra of $[(1,10\text{-phenanthroline})_2NiBr_2]$ is also shown. In the pure, solid square-planar complex (solid line) the typical two pre-peaks for the $1s \rightarrow 3d$ and $1s \rightarrow 4p_z$ transitions are clearly visible. The solution in pyridine (dotted line) also shows these two pre-peaks; thus the local structure around the Ni atoms remains in a square-planar geometry. The XANES spectra of the dissolved complex **1** in THF, collidine, or acetone also reveal retention of the square-planar geometry.

In contrast to the pyridine solution the XANES region of **1** in acetonitrile solution shows only the weak pre-peak of the $1s \rightarrow 3d$ transition, similar to the XANES region of the octahedral reference complex $[(phen)_2NiBr_2]$. This clearly hints that the complex has changed from a square-planar to an octahedral structure. The same behavior was observed for other nitriles (benzonitrile or butyronitrile), in alcohols, e.g. methanol in Figure 3 (b), and a mixture of acetone and water (molar ratio 1:1.23).

Figure 3 (b) the XANES region of [(bpy)Ni(Mes)(OMe)] shows two pre-peaks, indicating a square-planar geometry. This compound was obtained from the reaction of [(bpy)-Ni(Mes)Br] with sodium methoxide in THF (see Exp. Sect.). The same species was observed upon prolonged reaction of [(bpy)Ni(Mes)Br] in methoxide solutions. Retention of the square-planar geometry, even in the presence of a large excess of methoxide, indicates that formation of the octahedral species requires the acid protons of the solvent. Presumably the loss of the shielding mesityl ligand is the crucial step.

Figure 3 (c) shows the XANES spectra of the solid products of [(bpy)Ni(Mes)Br] in several linear primary and secondary alcohols after 16 h reaction. In methanol only the $1s \rightarrow 3d$ transition can be seen; thus, it can be concluded that the Ni^{II} complex has completely changed its geometry from square-planar to octahedral. In other alcohols after the same reaction time, the $1s \rightarrow 4p_z$ transition is still observable, but the signal is significantly weaker than that of the pure complex. This can be explained by a mixture of square-planar and octahedral species in the investigated reaction products. The highest $1s \rightarrow 4p_z$ signal is observed in 2-butanol and the signal decreases in the sequence 2-butanol, 2-propanol, 1-propanol, ethanol and methanol. Thus, the reaction rate decreases with increasing carbon-chain length and is higher in primary alcohols. This is also in agreement with the sequence of the acidity constants of the corresponding alcohols.[45–47]

EXAFS Investigations

The obtained structural parameters of the system [(bpy)-Ni(Mes)Br] system, determined by EXAFS at the Ni *K*- and Br *K*-edge, are summarized in Table 1. Table 2 presents results from the EXAFS fitting procedure of several octahedral and square-planar reference compounds, also measured at the Ni *K*- and Br *K*-edge.

Figure 4 shows the k^3-weighted experimental and Fourier-transformed (FT) EXAFS function of the solid complex **1** in comparison with its solutions in THF and pyridine at the Ni *K*-edge.

The fit of the Ni *K*-edge EXAFS spectrum of the solid complex was performed with three different coordination shells. The first shell at about 1.9 Å consists of the two coordinating nitrogen atoms of the bipyridine ligand and the carbon atom of the mesityl ligand. Because of the similar distances of these backscatterers [XRD: $r(Ni-C_{Mes})$ = 1.896 Å, $r(Ni-N_{bpy,1})$ = 1.896 Å, $r(Ni-N_{bpy,2})$ = 1.984 Å], they cannot be fitted separately and thus were fitted as one

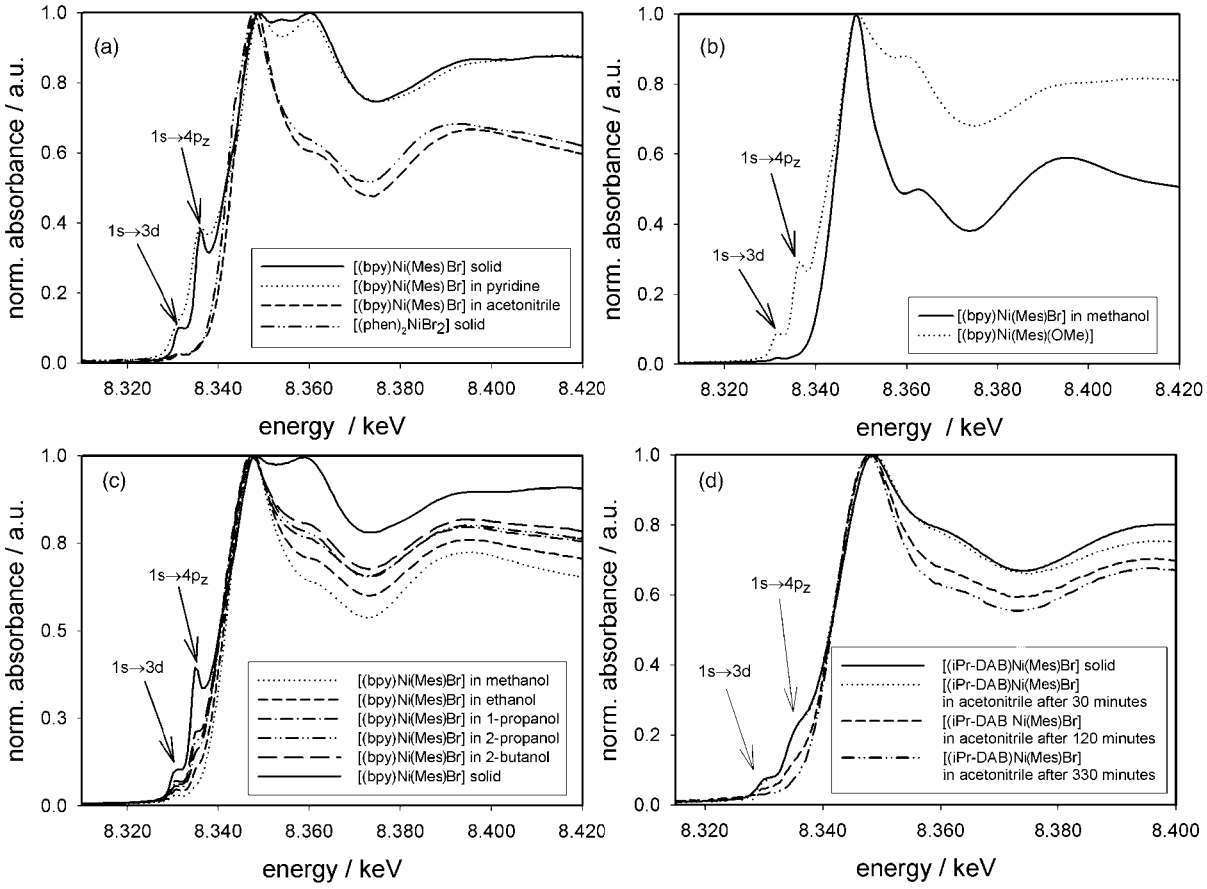

Figure 3. (a) Comparison of the Ni *K*-edge XANES regions of solid [(bpy)Ni(Mes)Br] and its solutions in pyridine and acetonitrile with solid $[(phen)_2NiBr_2]$; (b) comparison of the Ni *K*-edge XANES regions of the solid products of [(bpy)Ni(Mes)Br] in methanol after 48 h reaction with [(bpy)Ni(Mes)Br] + MeONa in THF; (c) comparison of the Ni *K*-edge XANES regions of the solid products of [(bpy)Ni-(Mes)Br] in methanol, ethanol, 1-propanol, 2-propanol and 2-butanol after 16 h reaction; (d) comparison of the Ni *K*-edge XANES regions of solid [(*i*Pr-DAB)Ni(Mes)Br] and its solution in acetonitrile over time

shell with nitrogen amplitude- and phase-functions. The determined distance of 1.92 Å as well as the coordination number of 3.1 is in good agreement with the average value of 1.93 Å known from XRD. The bromine backscatterer was found at 2.30 Å with a coordination number of 1.0. These values are in very good agreement with those found from the Br *K*-edge EXAFS spectrum [N = 0.9, r(Ni−Br) = 2.30 Å] and from the single-crystal XRD experiment (2.30 Å). The third coordination shell was fitted with carbon backscatterers and led to an Ni−C distance of 2.81 Å and a coordination number of 5.6. Possible candidates for these carbon backscatterers are the C(12) and C(16) atom of the mesityl ligand and the C(114), C(115) and C(110) atoms of the bipyridine ligand. This is also in agreement with the relatively high Debye−Waller factor of this shell (σ = 0.110 Å), which is a consequence of the distance distribution of the backscatterers from 2.77 to 2.91 Å. As the observed coordination numbers of the fitted three shells are in good agreement with the expected values, multiple scattering does not seem to play a significant role. Therefore the definition of multiple scattering units is unnecessary.

As can be seen from Figure 4 (a and b), there are only negligible differences between the spectra of the solid complex and its solution in THF. The Ni *K*-edge EXAFS spectra of [(bpy)Ni(Mes)Br] solutions in acetone, THF, or collidine yielded almost identical structural parameters to those found for the solid complex (Table 1). Thus, in these solvents, the complex does not undergo structural changes. This is consistent with observations from the Ni XANES region. In pyridine, however, upon dissolving the initial red complex the solution immediately turned yellow. Fourier-transform of the experimental EXAFS spectrum of the pyridine solution [Figure 4 (b)] shows, in comparison with the solid complex, a higher intensity for the peak at about 1.9 Å and the loss of bromine atom signal at ca. 2.3 Å. Fitting the EXAFS function revealed an increase in the coordination number of the first coordination shell from 3 to 4, with an average distance of 1.88 Å. Bromine backscatterers did not contribute to the EXAFS function. As the XANES region of the pyridine solution shows the typical pre-peaks for a square-planar geometry around the Ni atoms, it can be concluded that the bromine atom has been substituted in an associative process by a pyridine solvent molecule. To determine whether the bipyridine ligand has also been replaced by pyridine, several pyridine derivatives of [(bpy)Ni(Mes)Br] have been synthesized and characterized by EXAFS, and ^{1}H and ^{13}C NMR spectroscopy. The results of the EXAFS experiments on these reference compounds at the Ni *K*- and Br *K*-edge are reported

in Table 2. Comparison of the experimental EXAFS functions in Figure 4 (c and d) shows that the complex in pyridine solution is not identical to [(bpy)Ni(Mes)(py)]NO_3, but exhibits a very similar spectrum to $[(py)_3$Ni(Mes)]Br. In [(bpy)Ni(Mes)(py)] two different Ni−C_{Mes}/N and Ni−N distances for the first coordination sphere were observed at 1.93 Å (*N* = 3.1) and 2.11 Å (*N* = 1.4), possibly due to the rigidity of the bipyridine ligand, which endeavors to keep a chelate bite angle of 82−83°. In $[(py)_3$Ni(Mes)]Br the first coordination sphere was fitted, as well as the pyridine solution, with only one shell at 1.90 Å (*N* = 4.2). In $[(py)_2$Ni(Mes)Br] the Ni−C_{Mes}/*N* distance of 1.88 Å (*N* = 3.2) agrees with those found in $[(py)_3$Ni(Mes)]Br and the pyridine solution. The quite long Ni−Br−distance in $[(py)_2$Ni(Mes)Br] of 2.40 Å is a consequence of a *trans* orientation of the mesityl and the bromide ligand.

In agreement with the other spectroscopic results we conclude that, in pyridine, [(bpy)Ni(Mes)Br] undergoes a ligand exchange reaction in which the bromide and bipyridine ligands are replaced, but the geometry of the first coordination shell around the nickel atom remains square-planar. The stability of [(bpy)Ni(Mes)Br] in collidine is due to the bulky nature of both the collidine and mesityl ligands, which prevents associative substitution.

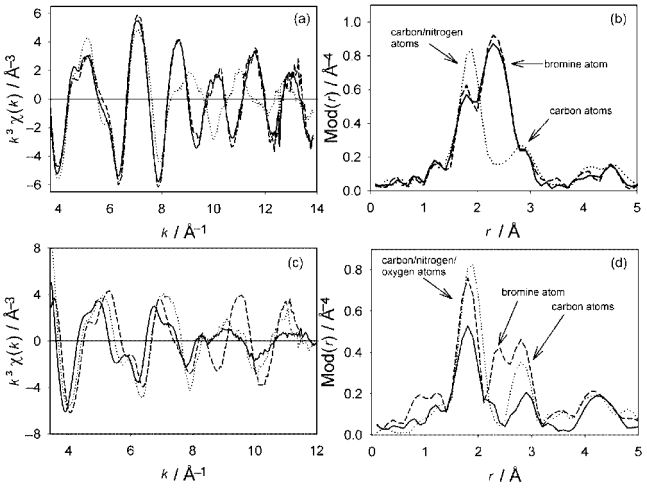

Figure 4. Comparison of the experimental $k^3\ \chi(k)$ functions (a) and their Fourier transforms (b) of solid [(bpy)Ni(Mes)Br] (solid line) with its solutions in THF (dashed line) or pyridine (dotted line) (Ni *K*-edge); comparison of the experimental $k^3\ \chi(k)$ functions (c) and their Fourier transforms (d) of solid [(bpy)Ni(Mes)(py)]NO_3 (solid line), [$(py)_3$Ni(Mes)]Br (dotted line) with solid [$(py)_2$Ni-(Mes)Br] (dashed line) (Ni *K*-edge)

From the XANES spectra it is evident that, in nitriles, alcohols and mixtures of acetone and water, the complex changes from square-planar to octahedral. The solubility of the complex in nitriles and alcohols is sufficient to carry out XANES experiments in transmission mode. For EXAFS investigations, however, the quality of the spectra obtained in solution was not satisfactory. Therefore the reaction mixtures were concentrated to dryness and the EXAFS measurements performed on the solid reaction products. In all the above-mentioned cases an octahedral coordination of the Ni atom was confirmed by EXAFS.

The distance of the first coordination shell from the metal ion is in all cases higher than in the square-planar complexes and consistent with the $Ni-N_{Phen}$ distance of 2.05 Å found in the octahedral reference compound [(1,10-phenanthroline)$_2$NiBr$_2$] (see Table 2).

Figure 5 shows the EXAFS spectra and the Fourier transforms of the products of the reaction of **1** in methanol after 2 or 48 h reaction, respectively, measured at the Ni *K*-edge [Figure 5 (a and b)] and Br *K*-edge [Figure 5 (c and d)]. The bromine FT-EXAFS spectrum of the product after 2 h of reaction in methanol [Figure 5 (b)] still shows a significant, but weak, contribution of nickel backscatterers to the signal. The fit of the EXAFS function led to a coordination number of 0.3, thus revealing that the reaction product after 2 h is still a mixture of bromide-containing square-planar and octahedral species. The EXAFS spectrum at the Ni *K*-edge of the product after 48 h reaction in methanol [Figure 5 (a)] was fitted with three coordination shells. The first coordination shell was fitted with oxygen backscatterers at 2.06 Å and proved the sixfold coordination of the nickel atom ($N = 6.5 \pm 0.6$). The very intense signal at about 3 Å in the FT EXAFS spectrum [Figure 5 (b)] is due to C backscatterers at 2.95 Å ($N = 6.2$) and Ni backscatterers at 3.09 Å ($N = 3.5$). These structural parameters fit the reported crystal structure of a (methanol)Ni^{II} complex.[48] In addition to the EXAFS investigations, the ^{1}H NMR spectrum of the [D_6]acetone extract of the prod-

uct obtained after 48 h showed the presence of uncoordinated bipyridine and mesitylene. Thus, in methanol, complete ligand exchange of all ligands (bromide, bipyridine and mesityl) against methanol molecules has taken place. That the Ni atoms in the methanolic product are only surrounded by oxygen atoms can be shown by comparison of the EXAFS spectra of solid $Ni(OH)_2$ with the product. In $Ni(OH)_2$ the Ni atoms are surrounded by six oxygen atoms at a similar distance (2.07 Å), as in the methanolic product. Furthermore, $Ni(OH)_2$ reveals an Ni−Ni distance (3.12 Å) that is almost identical with the one found in the methanolic product. The EXAFS spectrum and the FT of $Ni(OH)_2$ have been added to Figure 5 (a and b). The intensity of the first signal in the FT of both compounds is almost identical, which can be correlated with the same number and type of backscatterers in these compounds. The signal of the Ni backscatterers at 3.12 Å in $Ni(OH)_2$ is higher due to the higher coordination number of 6 in $Ni(OH)_2$.[49]

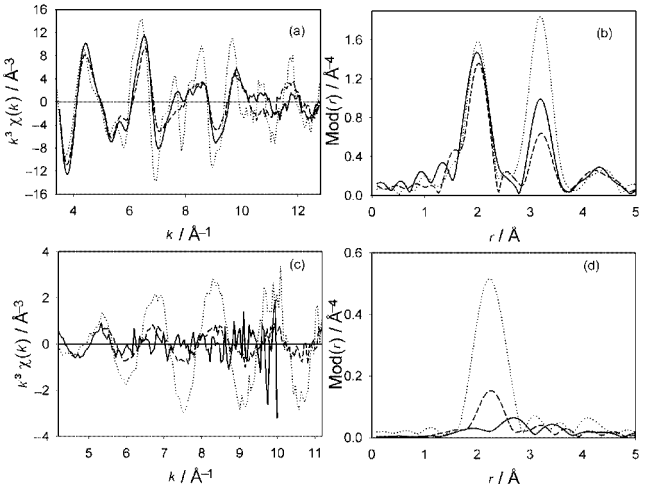

Figure 5. Comparison of the experimental k^3 $\chi(k)$ functions (a) and their Fourier transforms (b) of the isolated solid product of [(bpy)Ni(Mes)Br] in methanol after 2 h reaction (dashed line) and after 48 h reaction (solid line) with solid $Ni(OH)_2$ (dotted line) (Ni *K*-edge); comparison of the experimental k^3 $\chi(k)$ functions (c) and their Fourier transforms (d) of solid [(bpy)Ni(Mes)Br] (dotted line) with the isolated solid products of [(bpy)Ni(Mes)Br] in methanol after 2 h reaction (dashed line) and after 48 h reaction (solid line) (Br *K*-edge)

In the EXAFS function of the solid product of [(bpy)Ni(Mes)Br] in acetonitrile after 3 h reaction [Figure 6 (a)] the contribution of Ni backscatterers was similar to that of the product of the methanol solution. The structural parameters determined from the Ni *K*-edge EXAFS spectrum agree quite well to the acetonitrile complex $[Ni(CH_3CN)_6]SbF_6$,[50] in which the acetonitrile molecules have a bridging position between the Ni atoms. ^1H NMR experiments on the acetonitrile product have proved the splitting of the bpy and the mesityl ligand (as mesitylene), the latter seems to be a pre-requisite to the formation of octahedral species.

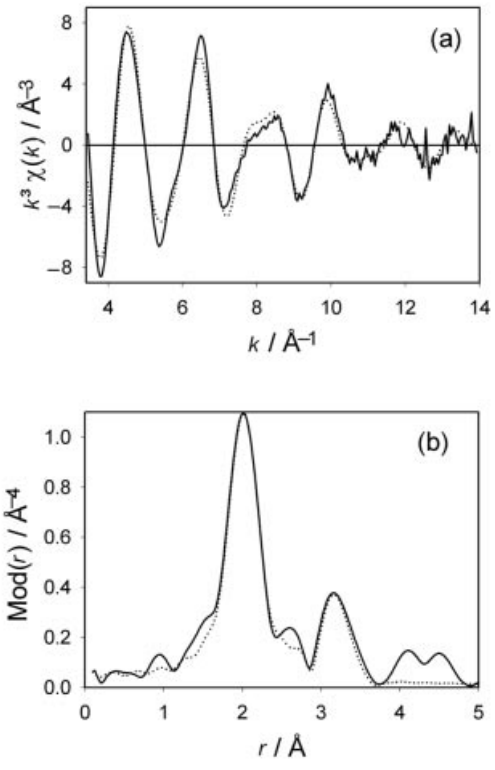

Figure 6. Experimental (solid line) and calculated (dotted line) k^3 $\chi(k)$ function (a) and their Fourier transform (b) of the isolated solid product of [(bpy)Ni(Mes)Br] acetonitrile after 3 h reaction (Ni *K*-edge)

Structural Studies on the [(*i*Pr-DAB)Ni(Mes)Br] System

Crystal Structure

In the crystal structure of [(*i*Pr-DAB)Ni(Mes)Br] (Figure 2) no intermolecular interactions other than van der Waals were found. The structure was solved with a disorder on one of the two isopropyl substituents. The two positions were found to be occupied in a 60:40% ratio. However, this has no impact on the square-planar coordination sphere of the nickel atom. Deviation towards the tetrahedron is only 9.3° and the angle C(11)−Ni(1)−N(2) deviates by 6.6° from the ideal 180°, thus resembling the less distorted molecule 1 of [(bpy)Ni(Mes)Br]·THF. The *trans* influence has a marked effect on the Ni−N bond lengths as Ni−N *trans* to the strong donor mesityl is about 100 pm longer than *trans* to Br. As expected, to reduce the inter-ligand interactions the isopropyl substituents point away from the coordination sphere.[51−53] Nevertheless, they might also shield the nickel center, along with the methyl substituents of the mesityl ligand,[17] as the distances of the two groups from the Ni atom are similar, ca. 3.5 Å and ca. 3.1 Å, respectively.

XANES Investigations

In Figure 3 (d) the XANES spectra of solid [(*i*Pr-DAB)-Ni(Mes)Br] and its solution in acetonitrile in dependence

of time are shown. The spectrum of the solid complex shows the typical two pre-peaks for square-planar Ni^{II} complexes. The acetonitrile solution after 30 min reaction also shows these two pre-peaks, which means that most of the Ni atoms have retained their square-planar geometry. After 120 min, the signal of the $1s \rightarrow 4p_z$ transition is significantly weaker, strongly indicating a change from square-planar to octahedral for the Ni atoms. After 330 min, the signal of the $1s \rightarrow 4p_z$ transition has vanished. Obviously, the geometry change was completed within 330 min, which is in good agreement with the rate constants determined by UV/Vis in the acetonitrile solution of [(bpy)Ni(Mes)Br].

EXAFS Investigations

The structural parameters of the [(*i*Pr-DAB)Ni(Mes)Br] system determined from the Ni *K*-edge and Br *K*-edge are summarized in Table 3. The obtained structural data of the pure, solid complex are in good agreement with those found from the single-crystal analysis. The experimental and calculated EXAFS functions and the FT (Ni *K*-edge) of the pure, solid complex can be seen in Figure 7 (a and b). To examine if [(*i*Pr-DAB)Ni(Mes)Br] shows a similar ligand exchange behavior to [(bpy)Ni(Mes)Br], a solution of the complex in acetonitrile was monitored by EXAFS spectroscopy. Because of the low solubility of the complex in acetonitrile the spectra were of low quality. Therefore the EXAFS functions were fitted with only one coordination shell, in the *k*-range of 2.8−8 $Å^{-1}$ [Figure 7 (c)], and showed that the coordination number of the first coordination shell increased from 3.1 nitrogen backscatterers after 30 min to 6.0 nitrogen backscatterers after 330 min. The determined average distance of 2.13 Å for the first coordination shell after 330 min is 0.07 Å higher than in the solid product of [(bpy)Ni(Mes)Br] in acetonitrile due to a higher mobility of the coordinated solvent molecules in the liquid state. From these experiments there is no evidence of an additional shielding of the nickel atom by the *i*Pr-DAB ligand compared to bpy.

Structural Studies on the $[(PPh_3)_2Ni(Mes)Br]$ System

Crystal Structure

As with the two diimine complexes the crystal structure of $[(PPh_3)_2Ni(Mes)Br]$ (Figure 2) reveals no significant intermolecular interaction. The coordination plane is nearly perfect, with only the Br ligand being slightly bent (by 3.8°) so that the Br−Ni−C1 angle is 176.2°. Concurrently, the angle P(1)−Ni−P(2) of 183.95° is larger than the ideal 180°. The mesityl ligand is oriented perfectly orthogonal to the coordination plane in contrast to the diimine complexes where tilt angles around 70° are found for the mesityl ligand. The molecular structure is thus similar to that of the related molecule $[(PMe_3)_2Ni(Ph)Br]$.[54] The Ni−P distances [2.214(2) Å and 2.202(2) Å] and the Ni−C(1) distance

[1.891(6) Å] in the latter are slightly shorter than can be explained by the bulkiness of the PPh_3 ligand. A marked difference lies in the orientation of the PR_3 ligands. The *trans*-oriented PPh_3 ligands show a nearly eclipsed conformation, whereas the PMe_3 ligands are staggered. Viewing the PPh_3 complex along an axis that parallels P(1)−Ni−P(2) one can see a graphite-like interaction of each one of the phenyl substituents with the nickel-bound mesityl ligand. This interaction might account for the eclipsed conformation, which probably leads to the steric repulsion of the phosphane ligands.

XANES Investigations

The XANES spectra of solid $[(PPh_3)_2Ni(Mes)Br]$ and its solid products formed by dissolving in acetonitrile, pyridine and collidine are shown in Figure 8. In all cases the 1s → $4p_z$ transition is clearly visible, identifying the complex and its solution products as square-planar. The 1s → 3d transition in all investigated complexes was very weak.

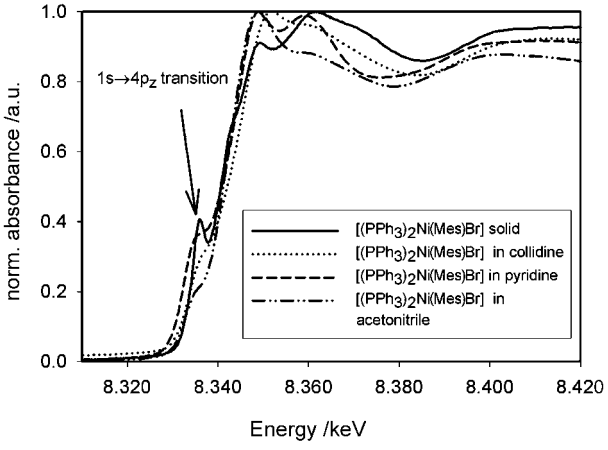

Figure 8. Comparison of the Ni *K*-edge XANES regions of solid $[(PPh_3)_2Ni(Mes)Br]$ with the solid products formed after 3 h in pyridine, collidine and acetonitrile

EXAFS Investigations

The solid $[(PPh_3)_2Ni(Mes)Br]$ was investigated at Ni *K*- and Br *K*-edge. The obtained structural parameters are summarized in Table 4. To fit the EXAFS function at the Ni *K*-edge three coordination shells were necessary. The determined values for the Ni−C_{Mes}, Ni−P and Ni−Br distances, as well as the coordination numbers of each shell, are in good agreement with the single-crystal experiment. EXAFS experiments on the solid products of $[(PPh_3)_2Ni(Mes)Br]$ in acetonitrile, pyridine and collidine after 3 h reaction are shown in Figure 9 (a and b). In all cases Br backscatterers did not contribute to the EXAFS functions. In contrast to the [(bpy)Ni(Mes)Br] and [(*i*Pr-DAB)Ni(Mes)Br] systems no geometrical change towards octahedral was observed in acetonitrile or THF solution. In the solid products of $[(PPh_3)_2Ni(Mes)Br]$ in acetonitrile or THF the coordination number of the first coordination shell is in total 4 (2 C/N + 2 P or 2 C/O + 2 P). The preservation of

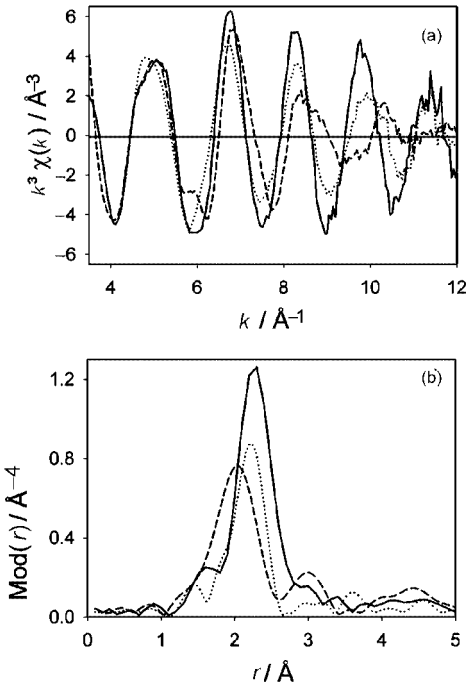

Figure 9. Comparison of the experimental $k^3\,\chi(k)$ functions (a) and their Fourier transforms (b) of solid $[(PPh_3)_2Ni(Mes)Br]$ (solid line) with the solid products of $[(PPh_3)_2Ni(Mes)Br]$ in acetonitrile (dotted line) or pyridine (dashed line)

the square-planar geometry can again be explained by the shielding mesityl ligand that prevents the formation of octahedral species. However, as to why in acetonitrile or THF solution the mesityl ligand is not split off as observed for the diimine complexes we can so far only speculate. Perhaps the steric hindrance of the bulky triphenylphosphane ligands prevents the hydrolysis reaction. Abstraction of the bromide ligand was also observed in the product obtained from the collidine solution. The $Ni-C_{Mes}/N_{Col}$ distance, however, is 0.07 Å shorter than in the acetonitrile product, since collidine is a better σ-donor ligand than acetonitrile.

It is noteworthy that [(bpy)Ni(Mes)Br] is stable in collidine solution, whereas for $[(PPh_3)_2Ni(Mes)Br]$ substitution of the bromide ligand was observed. Obviously, the bromide is a better leaving group in $[(PPh_3)_2Ni(Mes)Br]$ than in [(bpy)Ni(Mes)Br]. In pyridine solution the bromide ligand is replaced by the solvent as in the above-mentioned cases. Furthermore, substitution of one of the triphenylphosphane ligands was concluded from the increase in coordination number in the carbon/nitrogen shell from 1.2 in the pure complex to 3.1 in the pyridine solution and the decrease in the phosphorus coordination from 2.3 to 0.9.

Conclusion

A combined spectroscopic (multinuclear NMR, absorption) and structural investigation using XRD, XANES and EXAFS was successfully applied to monitor the ligand exchange behavior of three square-planar mesitylnickel(II) complexes, *cis*-[(diimine)Ni(Mes)Br] (diimine = 2,2′-bipyridine or *N*,*N*-diisopropyl-1,2-ethanediimine), and *trans*-$[(PPh_3)_2Ni(Mes)Br]$. The chosen system with bromide as the leaving ligand, the mesityl ligand as a strong donor and effective shielding group, as well as the *cis* (diimine ligands) and *trans* (PPh_3) variation of the complexes conformation has allowed us to draw some important conclusions.

The replacement of bromide is strongly accelerated when oriented *trans* to the strong donor ligand mesityl, which can be observed from the rapid splitting off of bromide from *trans*-[$(PPh_3)_2$Ni(Mes)Br] in weakly coordinating solvents such as acetone or THF in which the diimine complexes are stable. While further ligand exchange has never been reported for such complexes we have found that upon prolonged reaction times the diimine ligands or PPh_3 were also replaced by the solvent molecules, which is of great importance regarding the catalytic activity of such molecules. The rates of these reaction are smaller by orders of magnitude but this has to be viewed against the backdrop of long-term stability. In protic media such as alcohols the mesityl ligand is split off and, after the loss of this shielding group, octahedral nickel species are formed. Interestingly this is also valid for nitriles. The change in geometry from square-planar to octahedral can be readily monitored by XANES. Since the formation of such saturated octahedral species is concomitant with the breakdown of catalytic activity a successfully operating catalyst system has to contain a stable shielding unit. In the successfully applied systems by Brookhart and others this is provided by the diimine ligand, e.g. bulky R-DAB ligands with R = 2-6-dialkylated aryl substituents. However, we found that the diimine ligands can also be cleaved. Therefore, new long-term stable systems need to take account of the potential loss of the diimine ligand. In further studies we aim to develop catalytic systems with such long-term stability and apply them under real catalytic conditions.

Experimental Section

Preparations: All preparations were carried out under argon. The synthesis of the complexes [$(PPh_3)_2$Ni(Mes)Br] and [(bpy)Ni(Mes)Br] has been recently described.[17] All solvents were obtained from commercial sources and used as received. The alcohols and acetonitrile used were anhydrous. The other solvents were of spectroscopic grade.

Synthesis of [(*i*Pr-DAB)Ni(Mes)Br]: *i*Pr-DAB (250 mg, 1.78 mmol) was added to a vigorously stirred suspension of [$(PPh_3)_2$Ni(Mes)Br] (250 mg, 0.32 mmol) in 500 mL of *n*-pentane. After a few minutes, the yellow solid dissolved and at the same time a violet voluminous solid precipitated. After stirring for 4 h, the solid was filtered off, washed with pentane, recrystallized from CH_2Cl_2/*n*-heptane (1:8) and dried in vacuo to yield dark violet microcrystals. Yield: 112 mg (82%). $C_{17}H_{27}BrN_2Ni$ (398.03): calcd. C 57.07, H 6.59, N 31.60; found C 56.55, H 6.29, N 32.09. ^{1}H NMR ([D$_6$]acetone): δ = 8.55 (s, 1 H, H_{imine}), 8.43 (s, 1 H, H_{imine}), 6.42 (s, 2 H, *m*-H), 3.26 (m, 2 H, HC*i*Pr), 2.97 (s, 6 H, *o*-CH_3), 2.21 (s, 3 H, *p*-CH_3), 2.03 (d, 12 H, H_3C*i*Pr) ppm.

Synthesis of [(bpy)Ni(Mes)(OMe)]: Fine-cut sodium (100 mg, 4.35 mmol) was added to a mixture of 50 mL of THF and 10 mL of methanol. After all of the sodium had dissolved and reacted, [(bpy)Ni(Mes)Br] (400 mg, 0.97 mmol) was added to this solution. The red color of the starting material immediately turned to violet. After stirring for 3 h, the reaction solvents were evaporated to dryness and the residue extracted with 5 × 10 mL of CH_2Cl_2. The resultant Bordeaux colored solution was carefully filtered and then concentrated to dryness. Recrystallization from CH_2Cl_2/*n*-heptane (1:1) gave red-violet microcrystals. Yield: 290 mg (82%). $C_{20}H_{22}N_2NiO$ (365.12): calcd. C 65.79, H 6.07, N 7.67; found C 65.55, H 6.02, N 7.59. ^{1}H NMR ([D$_6$]acetone): δ = 9.0 [s (broad), 1 H, bpy-6], 8.31 (d, 1 H, bpy-3), 8.20 (d, 1 H, bpy-3′), 8.20 (dt, 1 H, bpy-4), 8.04 (dt, 1 H, bpy-4′), 7.71 (ddd, 1 H, bpy-5), 7.56 [s (broad), 1 H, bpy-6′), 7.21 (ddd, 1 H, bpy-5′), 6.57 (s, 2 H, *m*-H), 3.28 (s, 3 H, OCH_3), 3.07 (s, 6 H, *o*-CH_3), 2.20 (s, 3 H, *p*-CH_3) ppm. ^{13}C NMR ([D$_6$]acetone): δ = 156.4, 153.1, 151.5, 148.4, 148.3, 143.5, 139.6, 137.7, 127.3, 126.5, 132.8, 126.1, 122.4, 121.35, 69.1 (OCH_3), 25.8 (*o*-CH_3), 20.8 (*p*-CH_3) ppm.

Synthesis of [(bpy)Ni(Mes)(py)](NO$_3$): [(bpy)Ni(Mes)Br] (203 mg, 0.49 mmol) was dissolved in a mixture of 50 mL of acetone/acetonitrile (3:1) and thallium nitrate ($TlNO_3$) (133 mg, 0.5 mmol) and pyridine (40 mg, 0.5 mmol) were added to the red solution. $TlNO_3$ slowly dissolved while the reaction proceeded. After 5 h of stirring, the solution was orange-yellow and a greenish precipitate had formed that was carefully filtered off, and the filtrate was then concentrated to dryness. After washing the residue with 5 × 10 mL of diethyl ether, a bright yellow amorphous solid was obtained. Yield: 209 mg (90%). $C_{24}H_{24}N_4NiO_3$ (475.19): calcd. C 60.66, H 5.09, N 11.79; found C 60.36, H 5.01, N 11.68%. Due to the insolubility of the compound in common organic solvents no NMR spectra were obtained.

Synthesis of [(py)$_3$Ni(Mes)]Br: [(bpy)Ni(Mes)Br] (240 mg, 0.58 mmol) was dissolved in pyridine (30 mL) and stirred for 24 h. The volume was then reduced to 1/3 and *n*-octane (30 mL) added. The resultant yellow solution was stored at −30 °C overnight during which time a microcrystalline solid precipitated. After filtration, this solid was washed with *n*-pentane. Yield: 192 mg (67%). From the mother liquor further yellow material was isolated. However, this turned out to be a mixture of products. $C_{24}H_{26}BrN_3Ni$ (495.1): calcd. C 58.22, H 5.29, N 8.49; found C 58.18, H 5.21, N 8.44. ^{1}H NMR ([D$_6$]acetone): δ = 8.91 (d, 4 H, py-2,6), 8.18 (d, 2 H, py-2,6), 7.75 (t, 2 H, py-4), 7.46 (t, 1 H, py-4), 7.32 (dd, 4 H, py-3,5), 7.00 (dd, 2 H, py-3,5), 6.41 (d, 2 H, *m*-H), 3.45 (s, 6 H, *o*-CH_3), 2.21 (s, 3 H, *p*-CH_3) ppm. UV/Vis (pyridine): λ = 420 nm (ε = 320 M^{-1} cm^{-1}), 396 (sh, 320), 363 (1000), 323 (sh, 710).

Synthesis of *trans*-[(py)$_2$Ni(Mes)Br]: [$(PPh_3)_2$Ni(Mes)Br] (180 mg, 0.23 mmol) was dissolved in toluene (20 mL) and pyridine (80 mg, 1 mmol) was added to this red solution. After a few minutes, when the solution had turned yellow, the volume was reduced to 1/2. During storing of the solution at −20 °C overnight, yellow microcrystals had formed. Filtration and subsequent washing with *n*-pentane yielded a first crop (46 mg, 48%). The material that was further isolated from the mother liquor turned out to be a mixture including compounds of higher and lower degrees of substitution. $C_{14}H_{21}BrN_2Ni$ (416): calcd. C 54.86, H 5.09, N 6.73; found C 54.81, H 5.06, N 6.70. ^{1}H NMR ([D$_6$]acetone): δ = 8.96 (d, 4 H, py-2,6), 7.68 (t, 2 H, py-4), 7.20 (dd, 4 H, py-3,5), 6.33 (s, 2 H, *m*-H), 3.44 (s, 6 H, *o*-CH_3), 2.16 (s, 3 H, *p*-CH_3) ppm.

Synthesis of [(phen)$_2$NiBr$_2$]: [$NiBr_2$] (236 mg, 1.08 mmol) was added to DMF (10 mL) and dissolved on heating to 100 °C. Upon addition of 1,10-phenanthroline (390 mg, 2.16 mmol), the initially brownish solution turned green. On cooling to ambient temperature, a green solid precipitated that was collected by filtration, washed with diethyl ether and recrystallized from ethanol/diethyl ether (4:1). Yield: 562 mg (90%). $C_{24}H_{16}Br_2N_4Ni$ (578.93): calcd. C 49.79, H 2.79, N 9.68; found C 49.63, H 2.71, N 9.61. UV/Vis (MeCN): λ = 1055 nm (ε = 61 M^{-1} cm^{-1}), 631 nm (82), 326 (1040), 268 (26600), 226 (17860).

XANES and EXAFS Measurements: XANES and EXAFS measurements were performed at beamlines X1.1 (RÖMO II) and E4 at the Hamburger Synchrotronstrahlungslabor des Deutschen Elektronensynchrotrons (HASYLAB at DESY, Hamburg, Germany), at beamline 2−3 at the Stanford Synchrotron Radiation Laboratory (SSRL) at SLAC (Stanford, USA) and at beamline KMC-2 at the Berliner Elektronenspeicherring-Gesellschaft für Synchrotronstrahlung m.b.H. (BESSY II, Berlin, Germany). For measurements at the Ni *K*-edge (8332.8 eV) an Si(111) double crystal monochromator was used and at the Br *K*-edge (13474.0 eV) a Si(311) double crystal monochromator was used at SSRL and at DESY respectively. At BESSY a SiGe(220) double crystal (0.5% Ge/cm) monochromator was used for the nickel and the bromine *K*-edge. The synchrotron beam current was between 80 and 100 mA at HASYLAB (positron energy 4.45 GeV), between 100 and 250 mA at BESSY (electron energy 1.7 GeV) and between 80 and 100 mA at the SSRL (electron energy 1.7 GeV). The tilt of the second monochromator crystal was set to 40% harmonic rejection. The energy resolution was estimated to be about 0.7−1.0 eV for the Ni *K*-edge and 4.0 eV for the Br *K*-edge. Energy calibration was performed with the corresponding metal foils in the case of nickel, and with lead metal foil (Pb L_{III}-edge) in the case of bromine. The spectra were collected under ambient conditions at 25 °C in transmission mode with ion chambers. All ion chambers were filled with nitrogen for measurements at the Ni *K*-edge, and the second and third chamber filled with argon for measurements at the Br *K*-edge. The solid-state samples were embedded in a polyethylene matrix and pressed into pellets. Solutions of the complexes were measured in a specially designed transmission sample cell for liquids. The concentration of all samples was adjusted to yield an absorption jump of $\mu \approx 1.5$. Data evaluation started with removal of the background absorption from the experimental absorption spectrum by subtraction of a Victoreen-type polynomial. The background-subtracted spectrum was then convoluted with a series of increasingly broader Gauss functions and the common intersection point of the convoluted spectra was taken as energy E_0.[55,56] To determine the smooth part of the spectrum, corrected for pre-edge absorption, a piecewise polynomial was adjusted in such a way that the low-*R* components of the resulting Fourier transform were minimal. After division of the background subtracted spectrum by its smooth part, the photon energy was converted into photoelectron wave numbers *k*. The resulting EXAFS function was weighted with k^3. Data analysis in *k* space was performed according to the curved wave multiple scattering formalism of the program EXCURV92 with XALPHA phase- and amplitude-functions.[57] The mean free path of the scattered electrons was calculated from the imaginary part of the potential (VPI was set to −4.00) and an overall energy shift (ΔE_0) was assumed. The Amplitude Reduction Factor (AFAC) was set to a value of 0.8 in the case of both the Ni *K*-edge and Br *K*-edge.

NMR and UV/Vis Spectroscopy: ^{1}H, ^{13}C and ^{31}P NMR spectra were recorded with a Bruker AC 250 spectrometer. UV/Vis absorption spectra were recorded with a Bruins Instruments Omega 10 spectrometer. Kinetic data were fitted using a monoexponential decay assuming a first-order mechanism.

X-ray Crystallography: For compounds **1**−**3** data collection was performed at $T = 173(2)$ K with a Siemens P4 diffractometer using Mo-K_α radiation ($\lambda = 0.71073$ Å). The structures were solved by the Patterson method using the SHELXTL-PLUS package [58] and refinement was carried out with SHELXL-97 employing full-matrix least-squares methods on F^2 [59] with $F_o^2 \geq 3\sigma(F_o^2)$. Empirical absorption ($\psi$ scans) correction was performed for all three complexes. All non-hydrogen atoms were treated anisotropically, and hydrogen atoms were included by using appropriate riding models. CCDC-194378, -194379 and -194380 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank HASYLAB at DESY (Hamburg, Germany), the SSRL at SLAC (Stanford, USA) and BESSY (Berlin, Germany) for providing synchrotron radiation. The SSRL is operated by the U.S. Department of Energy, Office of Basic Energy Science. The authors would like to also thank Prof. Dr. Alexei Erko and Dr. Martin Fieber-Erdmann (BESSY GmbH, Berlin, Germany) for support during the beam times.

Regiospecific Cyclometalation of Diphenyl(2-substituted phenyl)phosphane with Methyltetrakis(trimethylphosphane)cobalt(I)

Hans-Friedrich Klein,*[a] Robert Beck,[a] Ulrich Flörke,[b] and Hans-Jürgen Haupt[b]

Keywords: Orthometalation / Cobalt / Coordination chemistry / Structure elucidation / Steric control

The pre-chelate molecules 2-(diphenylphosphanyl)-*N*,*N*-dimethylaniline, [2-(diphenylphosphanyl)benzyl]dimethylamine, 1-(diphenylphosphanyl)-2-ethylbenzene, 1-(diphenylphosphanyl)-2-isopropylbenzene, and 2-(diphenylphosphanyl)benzonitrile, in a reaction with [CoMe(PMe_3)$_4$], eliminate methane to afford the selectively 6-*ortho*-metalated complexes **1**–**5** that contain four-membered metallacycles. The molecular structure of **3** shows a tbp-coordinated cobalt atom, with axial C and PMe_3 donor groups. Metalation in the aliphatic side-chain occurs with 2-(diphenylphosphanyl)toluene, giving complex **6** that contains a five-membered metallacycle. Benzyldiphenylphosphane is selectively *ortho*-metalated in the benzyl group, affording **7**. As shown by the molecular structures, complex **7** is a true ligand isomer of **6**. Substitution of a trimethylphosphane group in compounds **4** and **6** by ethene gives the pentacoordinate complexes **8** and **9**, respectively. The ethene ligand is π-coordinated in the equatorial plane of a trigonal bipyramid. Under 1 bar of CO, complex **6** forms monocarbonyl complex **10**. Carbonylation of complexes **3** and **4** proceeds by insertion of CO into the Co–C bond under ring expansion, affording the aroylcobalt complexes **11** and **12**, respectively. Complex **6** reacts with iodomethane in an oxidative substitution reaction yielding a structurally characterized octahedral complex *mer*-**13**, which eliminates a methyl group in THF at 20 °C to form a pentacoordinate cobalt(II) complex **14**. Complex **3** oxidatively adds iodomethane in a stereoselective *cis* addition to give the cobalt(III) complex *mer*-**15**, which retains its four-membered metallacycle and the $CoCH_3$ group.

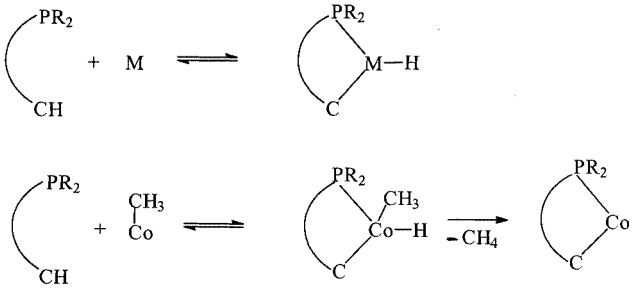
Introduction

Cyclometalation reactions are among the oldest C−H-activation processes, and those involving phenylphosphanes are well known in electron-rich complexes of the late transition metals.[1] In many cases cyclometalation has been shown to be a reversible reaction involving an oxidative-addition and a reductive-elimination step (Scheme 1).

A residual methylmetal function can utilize the new hydrido ligand in an alternative reductive elimination reaction and can also stabilize three-membered Zr−N−C rings.[2] With [CoMe(PMe_3)$_4$], the subsequent elimination of methane, which proceeds at −70 °C, renders the formation of a metallacycle practically irreversible, since methane does not react in the same manner as dihydrogen at 20 °C in a hydrogenolytic cleavage reaction.[3] Given a selective course of such cyclometalation reactions, we do not expect the kinetically favored product complex to undergo equilibration of possible isomers. We have recently found an unusually high selectivity in the reaction of [CoMe(PMe_3)$_4$] with 2-(diphenylphosphanyl)-*N*,*N*-dimethylaniline,[4] and report here on our investigation of substituent effects on the selectivity of cyclometalation reactions. Our strategy was firstly to generate gradual steric and electronic changes in the vicinity of the anchoring PPh_2 group in order to favor attack at the available four sites in the unsubstituted phenyl groups, and secondly to provide 2-substituents that would favor an attack at the side-chain. Investigation of molecular structures with respect to ring size and bite-angle of chelating ligands are warranted because these parameters have



Scheme 1. Reversible and irreversible cyclometalation reactions

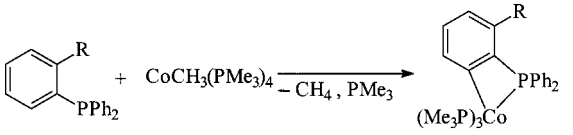
been shown in homogeneous catalysis to be among the most sensitive steering devices within the metal coordination sphere.[5]

Results and Discussion

a) The $ArNMe_2 \rightarrow ArCH_2NMe_2 \rightarrow ArCH_2Me \rightarrow ArCHMe_2$ Line

A side-chain in one of the six *ortho* positions of triphenylphosphane containing an N-donor function and activated aliphatic C−H bonds was provided in the pre-chelate molecules 2-(diphenylphosphanyl)-*N*,*N*-dimethylaniline, [2-(diphenylphosphanyl)benzyl]dimethylamine, 1-(diphenylphosphanyl)-2-ethylbenzene, and 1-(diphenylphosphanyl)-2-isopropylbenzene. Reactions with $[CoMe(PMe_3)_4]$ proceeded at −70 °C in THF [Equation (1)], and afforded the selectively *ortho*-metalated complexes **1**,[4] and **2**−**4**.



(1)

1: R = NMe_2
2: R = CH_2NMe_2
3: R = CH_2CH_3
4: R = $CH(CH_3)_2$
5: R = CN

The ^{31}P NMR spectra at 233 K most clearly show three resonances with chemical shifts and a coupling pattern which are characteristic of an *ortho*-metalated tris(trimethylphosphane)cobalt complex.[3] As no other signals are detected, the absence of possible isomers in solution (< ca. 2%) is demonstrated in all four compounds.

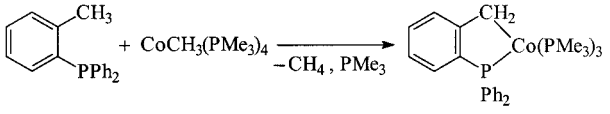
The dominant feature in the molecular structure of **3** is a four-membered cobaltacycle (Figure 1), in which the chelating ligand spans the C-axial and P-equatorial positions of a trigonal bipyramid. The small bite-angle [C12−Co−P1 = 71.02(15)°], which falls just outside the range of Rh and Ir complexes (67−69°),[6] causes bending between the axial positions [C12−Co−P4 = 166.25(15)°]. Bond lengths and angles do not substantially deviate from those in the unsubstituted molecule.[3]

b) The $ArNMe_2 \rightarrow ArCH_2Me \rightarrow ArCN$ Line

Electron-donating dimethylamino and ethyl groups were replaced by the strong electron-accepting cyano group. However, reaction of $[CoMe(PMe_3)_4]$ with 2-(diphenylphosphanyl)benzonitrile followed the same route as in Equation (1), affording **5** as a single *ortho*-metalated isomer. The ^{31}P NMR spectrum at 233 K closely resembles those of **1**−**4**. Thus, there is little chance for the electronic steering of the *ortho*-metalation reaction.

c) The $ArOH \rightarrow ArNH_2 \rightarrow ArCH_3$ Line

The isoelectronic donor functions of the pre-chelate systems in 2-(diphenylphosphanyl)phenol or 2-(diphenylphosphanyl)aniline were compared with the P,C-donor group in 2-(diphenylphosphanyl)toluene. Reaction of this type of weak C−H acid with $[CoMe(PMe_3)_4]$ at −70 °C produces methane [Equation (2)].



(2)

6

From a red-brown solution in pentane, complex **6** is obtained as black prismatic crystals. In the ^1H NMR spectrum at 296 K, a broad resonance at δ = 1.80 ppm (2 H) containing multiple phosphorus coupling is assigned to a $CoCH_2$ group. Doublet and pseudotriplet PCH_3 resonances with intensity ratios of 1:2 also indicate little ligand mobility. Complex **6** remains pentacoordinate, which differs from the rapidly exchanging trimethylphosphane from [P,O]-chelate and [P,N]-chelate systems on the NMR time scale. However, the ^{31}P NMR chemical shifts at 233 K are found in similar positions to those of the [P,N] and [P,O] complexes, and are in no way related to those in complexes **1**−**4**.

Therefore, a selective attack appears to be directed at the *ortho*-methyl group to form a five-membered metallacycle, which is known to form with platinum.[7] The molecular structure (Figure 2) is entirely consistent with the configuration of **6** derived from the solution data. A cobalt atom is centered in a trigonal bipyramid with axial CH_2 and PMe_3 groups and a five-membered metallacycle occupying C-axial and P-equatorial positions with a narrow bite-angle [C10−Co−P1 = 77.77(17)°] and considerable ring bending

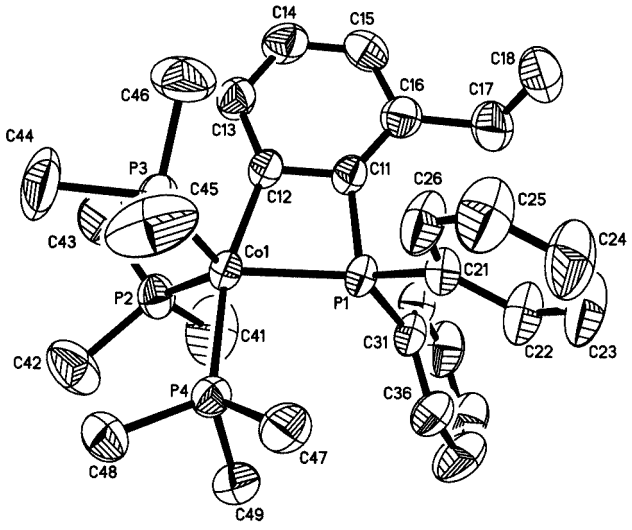


Figure 1. Molecular structure of **3** (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C12 1.984(5), Co−P1 2.2103(14), Co−P2 2.1639(17), Co−P3 2.1691(17), Co−P4 2.1857(17), P1−C11 1.796(6), C11−C12 1.401(7); C12−Co−P1 71.02(15), C12−Co−P2 90.96(16), C12−Co−P3 90.89(15), C12−Co−P4 166.25(15), P1−Co−P2 119.25(7), P1−Co−P3 121.97(7), P1−Co−P4 95.23(6), P2−Co−P3 115.56(7), P2−Co−P4 95.79(7), P3−Co−P4 96.95(7)

(sum of internal angles = 518.8°). The Co−C10 distance [2.080(5) Å] is within the range of Co−C(sp^3) bonds (2.03−2.15 Å),[8] and Co−P distances are typical and appear unaffected by the *trans* influence of the distant CH_2 group. We note here an unexpected and complete switching of the cyclometalation reaction on changing from a 2-methyl to a 2-ethyl group.

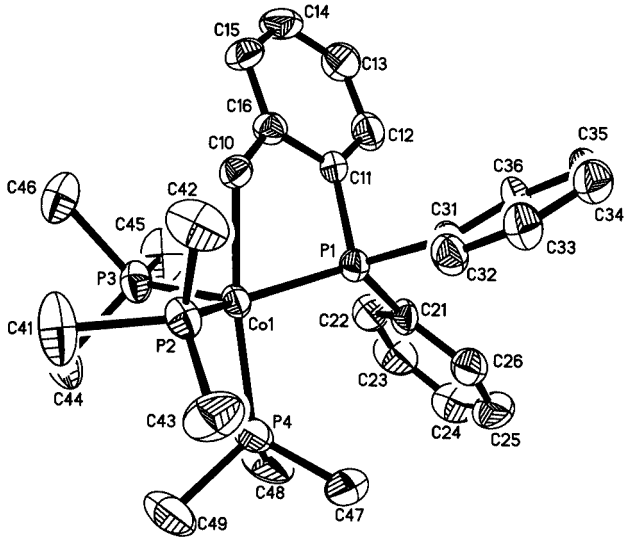

Figure 2. Molecular structure of **6** (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C10 2.080(5), Co−P1 2.1646(18), Co−P2 2.206(2), Co−P3 2.186(2), Co−P4 2.180(2), P1−C11 1.827(7), C10−C16 1.494(8), C11−C16 1.399(8); C10−Co−P1 77.77(17), C10−Co−P2 87.15(17), C10−Co−P3 88.10(18), C10−Co−P4 172.48(18), P1−Co−P2 132.14(8), P1−Co−P3 114.22(8), P1−Co−P4 95.86(7), P2−Co−P3 110.29(7), P2−Co−P4 94.36(8), P3−Co−P4 98.26(8)

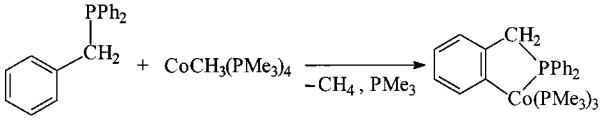
Formation of a five-membered cobaltacycle with reversed ring positions of $Co(PMe_3)_3$ and PPh_2 groups can be expected from a reaction of $[CoMe(PMe_3)_4]$ with benzyldiphenylphosphane [Equation (3)].



(3)

7

When the reactants are combined at −70 °C, the color changes to red-brown and the evolution of gas commences. Eventually, red crystals of **7**, which are air-sensitive and decompose under argon above 75 °C, were obtained from pentane. The ^{31}P NMR spectrum contains a doublet of triplets (δ = 63 ppm, PPh_2) and two doublets of doublets (δ = −4 and 22 ppm, PMe_3), with couplings that suggest a five-membered cobaltacycle in the C(axial)/P(equatorial) positions of a trigonal bipyramid. The expected configuration is observed in the molecular structure of **7** (Figure 3).

All bond lengths in **7** are similar to those in the ligand isomer **6** (Figure 2). In particular, the distance [Co−C11 = 2.011(4) Å] falls in the range reported for Co−C(sp^2) bonds

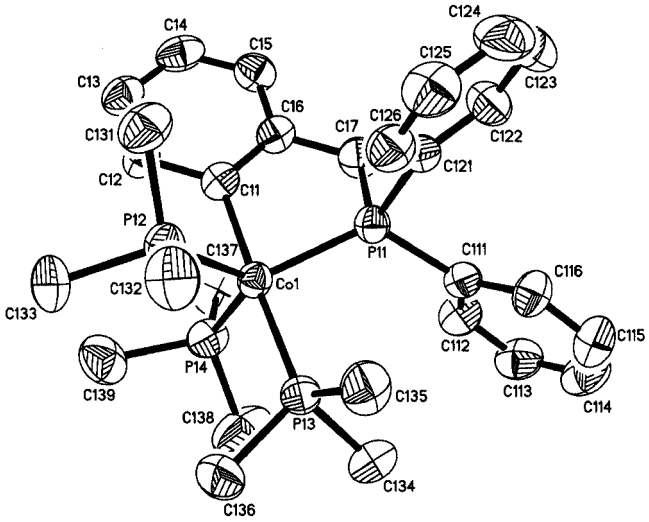


Figure 3. Molecular structure of **7** (molecule A) (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C11 2.011(4), Co−P11 2.1625(12), Co−P12 2.2197(13), Co−P13 2.1994(12), Co−P14 2.1833(13), P11−C17 1.830(4), C16−C17 1.501(5), C11−C16 1.415(6); C11−Co−P11 83.08(12), C11−Co−P12 88.51(12), C11−Co−P13 177.17(12), C11−Co−P14 84.22(12), P11−Co−P12 120.47(5), P11−Co−P13 94.83(5), P11−Co−P14 119.37(5), P12−Co−P13 94.21(5), P12−Co−P14 118.13(5), P13−Co−P14 95.19(5), Co−C11−C16 120.6(3), C11−C16−C17 118.0(4), C16−C17−P11 106.2(3)

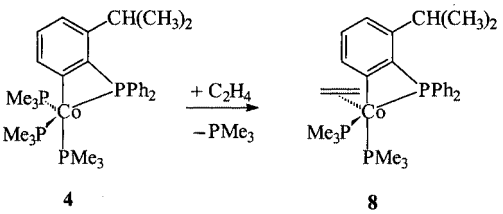
(1.97−2.01 Å).[8,9] The approximation to an ideal tbp geometry is better in **7**, and the sum of the internal angles in the cobaltacycle (532.7°) is closer to planarity (540°) than in **6** (518.8°).

d) Reactions with Ethene

π-Olefin coordination in aryl(trimethylphosphane)cobalt(I) complexes is an expected phenomenon.[4] The steric limitations of pentacoordination will be modified by the angular strain of the four- and five-membered metallacycles on the preferred equatorial binding site. A spontaneous substitution reaction is not feasible with complex **4**. When complex **4** is kept at 100 °C for 3 h under vacuum, a vacant coordination site is formed by dissociation of 1 mol-equiv. of trimethylphosphane that is necessary for subsequent coordination of olefin to occur [Equation (4)].



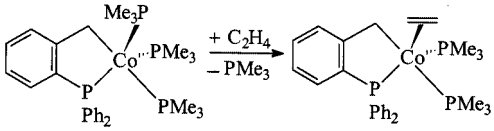
(4)

4 **8**

On dissolution of **4** in diethyl ether under 1 bar of ethene, complex **8** is obtained as orange crystals. In the ^{31}P NMR spectrum of **8**, three doublets of doublets are seen at δ = −12, 9, and 17 ppm. These signals are in the same region as those of a four-membered cobaltacycle, as expected from the data of compounds **1**−**5**.

When heated under argon, decomposition of **8** occurs with the release of ethene, and no alteration of the four-membered metallacycle is indicated (IR) prior to the deposition of cobalt.

Without thermal pretreatment of complex **6**, which contains a five-membered cobaltacycle, substitution of trimethylphosphane by ethene occurs [Equation (5)].

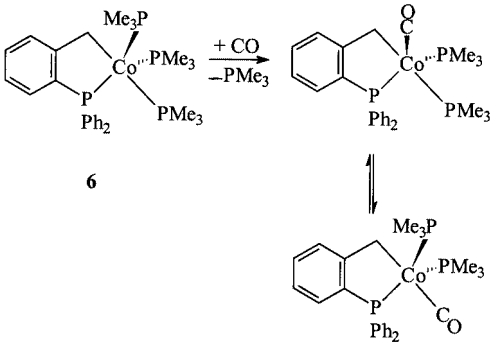


6 **9** (5)

The orange-yellow needles of **9** (from pentane, decomp. > 87 °C) exhibit a better thermal stability than π-ethene complexes containing five-membered cobaltacycles with (P,N) and (P,O) ligands,[4,10] which are isoelectronic. From the ^{31}P NMR spectrum, the doublet of doublets pattern, with characteristic shifts at δ = 66, 18, and 11 ppm, indicates that the π-ethene ligand occupies an equatorial position.

e) Reactions with Carbon Monoxide

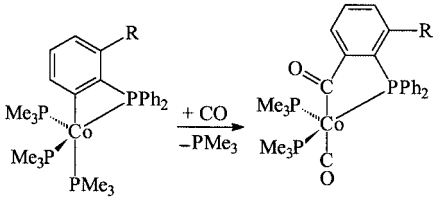
Carbonylated methylcobalt(I) compounds, $[CoCH_3(CO)(PMe_3)_3]$ or $[Co(CH_3CO)(CO)_2(PMe_3)_2]$,[11] are unreactive towards diphenyl(2-substituted phenyl)phosphanes and do not undergo a cyclometalation reaction of the proscribed type. However, CO ligands are smoothly introduced into metallacyclic product complexes. In solution under 1 bar of CO at 20 °C, **6** forms the monocarbonyl complex **10** [Equation (6)].



6 **10** (6)

The dark-red crystals of **10** are thermally more stable (by 30 K) and less air-sensitive than those of complexes containing five-membered cobaltacycles with (P,N) and (P,O) ligands.[4,10] The ^{31}P NMR spectra in THF solutions show mixtures of isomers, with couplings consistent with a tbp configuration where a terminal carbonyl ligand resides either in an axial or in an equatorial position. In toluene solutions, only the isomer with the CO ligand in the axial position is observed.

When carbonylation reactions of complexes **3** and **4**, which contain four-membered cobaltacycles, take place under the same conditions, monosubstitution is accompanied by insertion of CO into the Co–C bond under ring expansion [Equation (7)], thus affording the aroylcobalt complexes **11** and **12**, respectively.



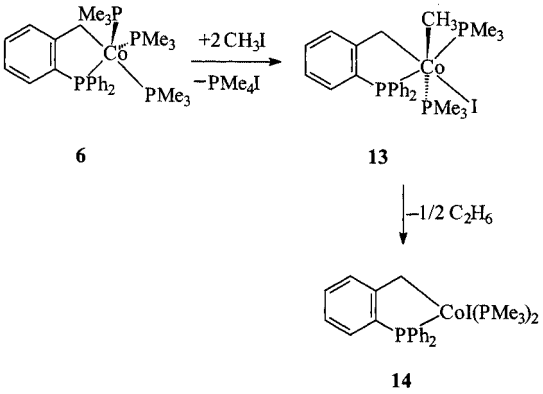
3, 4 **11**: R = C_2H_5 **12**: R = $CH(CH_3)_2$ (7)

The lustrous red crystals of **11** and **12** have narrow melting ranges (**11**: 152–153 °C; **12**: 161–162 °C) and melt without decomposing. The IR spectra contain two conspicuous new bands which are assigned to the terminal carbonyl ligand and to the benzoylcobalt group [**11**: $\tilde{\nu}$ = 1913 (C≡O), 1542 cm^{-1} (C=O); **12**: $\tilde{\nu}$ = 1906 (C≡O), 1513 cm^{-1} (C=O)].

In the ^{31}P NMR spectra, the ring expansion causes a low-field shift of the chelating phosphorus resonance by 85 ppm, which appears as a triplet by coupling to two equatorial trimethylphosphane groups. The observed doublet and triplet pattern is only compatible with the acyl and carbonyl ligands arranged in the axial positions.

f) Reactions with Iodomethane

Complex **6** reacts with excess iodomethane in diethyl ether by dissociation and quaternization of a trimethylphosphane [Equation (8)], thus undergoing an oxidative substitution reaction.



6 **13** **14** (8)

All volatile materials were removed in vacuo as soon as the precipitation of white tetramethylphosphonium iodide began. Extraction of the remaining solid with diethyl ether at 20 °C and cooling of the red-brown solution gave a moderate yield of short orange rods. Complex **13** is air-stable, but decomposes above 82 °C. In tetrahydrofuran at 20 °C,

spontaneous evolution of ethane transforms hexacoordinate **13** into the pentacoordinate cobalt(II) complex **14** [Equation (8)]. More conveniently, **14** is obtained by performing the synthesis in THF.

A $^{31}P\{^{1}H\}$ NMR spectrum of **13** in [D_8]THF at 213 K shows three multiplet signals, suggesting three P-donor functions in an octahedral coordination geometry, but allows no clear distinction between the *mer* and *fac* configurations. The molecular structure of *mer*-**13** was revealed by a single-crystal X-ray diffraction analysis (Figure 4).

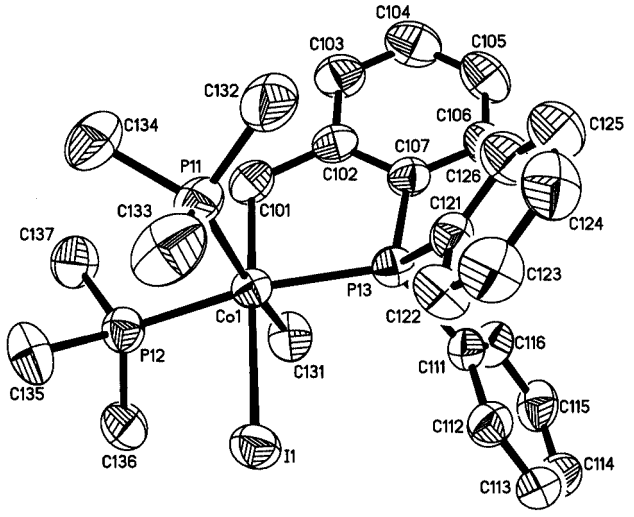


Figure 4. Molecular structure of *mer*-**13** (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C101 2.016(5), Co−C131 2.053(5), Co−I 2.7250(9), Co−P11 2.2749(17), Co−P12 2.2581(19), Co−P13 2.2301(18), C101−C102 1.515(8), C102−C107 1.386(8), P13−C107 1.818(5); C101−Co−P13 86.89(18), C101−Co−I 178.47(17), C101−Co−P12 94.70(18), P11−Co−P12 95.82(7), P11−Co−P13 98.31(6), P12−Co−P13 165.85(6), C107−P13−Co 102.8(2), P13−C107−C102 112.4(4), C101−C102−C107 122.3(5), Co−C101−C102 114.9(4)

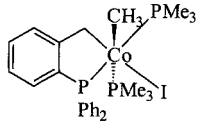
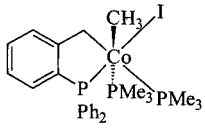
The iodide ion and one of the trimethylphosphane ligands are coplanar with the cobaltacycle, while the other trimethylphosphane ligand and the $CoCH_3$ group are below and above the plane. While the Co−P and Co−C bond lengths are as expected, the Co−I bond is slightly elongated by the benzylic CH_2−Co interaction in *trans* position.



mer-**13**

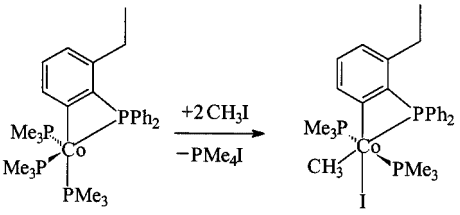


fac-**13**

As the *trans* influences along Me_3P−Co−CH_3 would be very similar to that of Me_3P−Co−CH_3 in the *fac* configuration, *mer*-**13** would appear to be the product of a *cis* addition under kinetic control. However, when compared with **6**, the chelate bite angle [C101−Co−P13 = 86.89(13)°] is augmented by 10°, while the Co−C bond is shortened by 6.5 pm. The sum of the internal angles is 539.3°, indicating considerable relaxation of the metallacycle towards planarity. These differences could make *mer*-**13** the thermodynamically most stable isomer. Eventually, *mer*-**13** is metastable with respect to a C−C-coupling reaction forming **14**.

Although the molecular geometry of **14** has not been clarified due to poor crystal quality and broad and overlapping NMR signals, the magnetic moment (μ_{eff}/μ_B = 1.93) is as expected for a tbp configuration of cobalt (d^7).[13−15]

Under the same conditions, **3** oxidatively adds iodomethane after substitution and quaternization of a trimethylphosphane group [Equation (9)].



3 **15** (9)

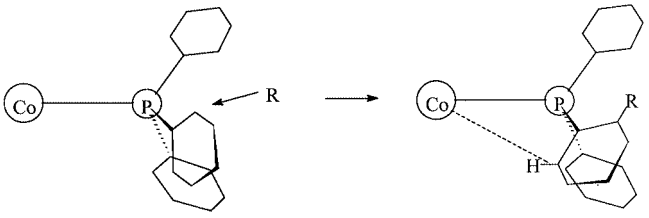
The dark-red crystals of **15** melt at 115−116 °C under argon, and are stable for more than 1 d in air at 20 °C. The IR spectrum resembles that of **3**, except for an additional band [$\tilde{\nu}$ = 1165 cm^{-1} ($CoCH_3$)]. The ^{31}P NMR spectrum at 213 K shows a triplet resonance at δ = −32 ppm, characteristic of a PPh_2 group in a four-membered cobaltacycle, and a doublet at δ = 10 ppm containing a typical *cis* coupling (^2J = 23 Hz). The observed pattern is consistent with two isochronic trimethylphosphane ^{31}P nuclei in *trans* positions, and a meridional arrangement of the three P-donor atoms which appears to result from a regioselective *cis* addition of iodomethane.[3] At variance with the spontaneous transformation of *mer*-**13** [Equation (8)], solutions of **15** in THF at 20 °C remain stable for at least 1 d.

While cobalt(I) compounds containing five-membered metallacycles in a reaction with iodomethane undergo oxidative substitution, followed by reductive elimination of ethane, those containing four-membered cobaltacycles attain the cobalt(III) state without a subsequent C−C-coupling reaction. In both transformations the endocyclic Co−C bonds remain unaffected.

Conclusion

The reactivity in irreversible cyclometalation processes with [$CoMe(PMe_3)_4$] appears to be controlled by a high electron density on the metal atom, and is lost in the presence of a single strongly π-accepting ligand, e.g. in $CoMe(CO)(PMe_3)_3$. The observed selectivity, which is based on the orientation of the C−H bonds that are in the proximity of the metal atom, is sterically controlled by the preferred substrate conformation. The usual fan-type conformation of a triphenylphosphane ligand is most effectively distorted by a 2-substituent, whereby the substituted phenyl group is rotated in such a way that only this particular *ortho*-CH group closes in on the metal atom (Scheme 2) and the four-

membered cobaltacycle is formed. Thus, a sterically hindered rotation of an aryl group renders the cyclometalation reaction regiospecific.



Scheme 2. Sterically controlled proximity conformation

A five-membered cobaltacycle is formed as the preferred ring size, by activation of a benzylic C−H bond only in the absence of steric strain. In a monosubstituted triphenylphosphane steric crowding is significant as the substituents are changed from 2-methyl to the 2-ethyl substituents. Once formed, the five-membered cobaltacycle does not insert a CO ligand in a process that accompanies carbonylation of complexes with four-membered cobaltacycles. Neither metallacycle shows insertion of a π-ethene ligand.

While cobalt(I) compounds containing five-membered metallacycles in a reaction with iodomethane undergo oxidative substitution, followed by reductive elimination of ethane, those containing four-membered cobaltacycles attain the cobalt(III) state without a subsequent C−C-coupling reaction. In both transformations the endocyclic Co−C bonds remain unaffected.

Experimental Section

General Procedures and Materials: All air-sensitive and volatile materials were handled using standard vacuum techniques and were kept under argon. Microanalyses: Kolbe Microanalytical Laboratory, Mülheim/Ruhr, FRG. Melting points/decomposition temperatures: Sealed capillaries, uncorrected values. Chemicals (Merck/Schuchardt) were used as purchased. Literature methods were applied for the preparation of 2-(diphenylphosphanyl)-*N*,*N*-dimethylaniline,[16] [2-(diphenylphosphanyl)benzyl]dimethylamine,[17] 1-(diphenylphosphanyl)-2-ethylbenzene, 1-(diphenylphosphanyl)-2-isopropylbenzene,[18] 2-(diphenylphosphanyl)benzonitrile,[19] 2-(diphenylphosphanyl)toluene,[20] benzyldiphenylphosphane,[21] and [CoMe(PMe$_3$)$_4$].[11] IR: Nujol mulls between KBr discs, Bruker spectrophotometer type FRA 106. ^{1}H and ^{13}C NMR spectra (300 MHz and 75 MHz, respectively) were recorded with a Bruker ARX-300 spectrometer, ^{31}P NMR spectra (81 MHz) with a Bruker AM-200 instrument. ^{13}C and ^{31}P resonances were obtained with proton decoupling. Magnetic susceptibility data were obtained by the Faraday method using a Cahn D 200 torsion balance (Bruker) at 1.5 Tesla.

[3-(Dimethylamino)-2-(diphenylphosphanyl)phenyl-*C^I*,*P*]tris(trimethylphosphane)cobalt (1): 2-(Diphenylphosphanyl)-*N*,*N*-dimethylaniline (549 mg, 1.79 mmol) in 50 mL of diethyl ether was combined at −70 °C with [CoMe(PMe$_3$)$_4$] (680 mg, 1.79 mmol) in 30 mL of diethyl ether. The reaction was accompanied by the evolution of a gas. After the solution had warmed up, the red-brown mixture was kept at 20 °C for 16 h. The volatiles were removed in vacuo, the solid residue was extracted with 80 mL of pentane, and the solution cooled to 4 °C, affording dark-red rectangular crystals of **1**. Yield 270 mg (85%); m.p. 112−114 °C (dec.). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 1.02 [d, ^2J(PH) = 5.6 Hz, 9 H, PCH$_3$], 1.23 [s (br), 18 H, PCH$_3$], 2.13 (s, 6 H, NCH$_3$), 5.90−6.23 (m, 3 H, CH), 7.22−7.24 (m, 6 H, CH), 7.75−7.79 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 22.2−22.7 (m, PCH$_3$), 23.3 (m, PCH$_3$), 43.3 (s, NCH$_3$), 109.3 (s, CH), 125.9 [d, ^3J(PC) = 3.1 Hz, CH], 126.0 (s, CH), 126.3 [d, ^3J(PC) = 5.6 Hz, CH], 126.9 (s, CH), 133.2 [d, ^2J(PC) = 7.6 Hz, CH], 133.3 [d, ^2J(PC) = 7.6 Hz, CH], 139.1 [d, ^2J(PC) = 9.2 Hz, CH], 171.3 (m, CoC) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = −24 [dt, ^2J(PP) = 89 and 68 Hz, 1 P, PPh$_2$], −4 [dd, ^2J(PP) = 89 and 68 Hz, 2 P, PCH$_3$], 22 [dt, ^2J(PP) = 68 and 47 Hz, 1 P, PCH$_3$] ppm. $C_{29}H_{46}CoNP_4$ (591.5): calcd. C 58.89, H 7.84, N 2.37, P 20.95; found C 58.92, H 7.82, N 2.27, P 20.83.

{3-[(Dimethylamino)methyl]-2-(diphenylphosphanyl)phenyl-*C^I*,*P*}tris(trimethylphosphane)cobalt (2): [2-(Diphenylphosphanyl)benzyl-]dimethylamine (608 mg, 1.90 mmol) in 50 mL of diethyl ether was combined at −70 °C with [CoMe(PMe$_3$)$_4$] (720 mg, 1.90 mmol) in 30 mL of diethyl ether. The reaction was accompanied by the evolution of a gas. After keeping the red-brown mixture at 20 °C for 16 h, the volatiles were removed in vacuo and the solid residue was extracted with two 70-mL portions of pentane. When the solution was kept at −27 °C, dark-red crystals of **2** were obtained. Yield 967 mg (84%); m.p. 107−109 °C (dec.). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.90 [d, ^2J(PH) = 6.2 Hz, 9 H, PCH$_3$], 1.28 [s (br), 18 H, PCH$_3$], 1.73 (s, 6 H, NCH$_3$), 2.78 (s, 2 H, NCH$_2$), 6.68−6.77 (m, 3 H, CH), 7.24−7.26 (m, 6 H, CH), 7.72−7.78 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 22.1−22.5 (m, PCH$_3$), 23.3 [d, ^1J(PC) = 20.1 Hz, PCH$_3$], 27.3 (s, NCH$_3$), 58.1 (s, NCH$_2$), 118.5 [d, ^3J(PC) = 3.1 Hz, CH], 126.4 (s, CH), 126.5 [d, ^3J(PC) = 5.6 Hz, CH], 126.9 (s, CH), 134.8 (s, CH), 135.6 [d, ^2J(PC) = 7.6 Hz, CH], 135.7 [d, ^2J(PC) = 7.6 Hz, CH], 138.1 [d, ^2J(PC) = 9.2 Hz, C], 151.1 [d, ^2J(PC) = 10.7 Hz, C], 1511.5 [d, ^2J(PC) = 10.7 Hz, C], 169.9 (m, CoC) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = −26 [dt, ^2J(PP) = 89 and 70 Hz, 1 P, PPh$_2$], −4 [dd, ^2J(PP) = 89 and 48 Hz, 2 P, PCH$_3$], 21 [dt, ^2J(PP) = 70 and 48 Hz, 1 P, PCH$_3$] ppm. $C_{30}H_{48}CoNP_4$ (605.5): calcd. C 59.50, H 7.99, N 2.31, P 20.46; found C 59.36, H 8.10, N 2.18, P 20.38.

[2-(Diphenylphosphanyl)-3-ethylphenyl-*C^I*,*P*]tris(trimethylphosphane)cobalt (3): 1-(Diphenylphosphanyl)-2-ethylbenzene (590 mg, 2.03 mmol) in 50 mL of THF was combined at −70 °C with [CoMe(PMe$_3$)$_4$] (770 mg, 2.03 mmol) in 30 mL of THF. As the solution warmed up, the slow evolution of a gas was observed. After keeping the dark-red mixture at 20 °C for 16 h, the volatiles were removed in vacuo and the solid residue was extracted with two 50-mL portions of pentane. Reduction of the volume to 60 mL and keeping of the red solution at 4 °C afforded dark-red rectangular crystals of **3**, which were suitable for X-ray diffraction. Yield 809 mg (69%); m.p. 120−121 °C. ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.53 (t, ^3J = 7.5 Hz, 3 H, CCH$_3$), 1.09 [d, ^2J(PH) = 6.3 Hz, 9 H, PCH$_3$], 1.25 [t′, |^2J(PH) + ^4J(PH)| = 4.5 Hz, 18 H, PCH$_3$], 2.43 (q, ^3J = 7.5 Hz, 2 H, CH$_2$), 6.29 (d, ^3J = 6.4 Hz, 1 H, CH), 6.67 (t, ^3J = 7.1 Hz, 1 H, CH), 6.73 (m, 1 H, CH), 7.21−7.27 (m, 6 H, CH), 7.72−7.80 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 22.1 (s, CH$_3$), 22.1−22.9 (m, PCH$_3$), 23.7 (s, CH$_2$), 117.9 [d, ^2J(PC) = 11.5 Hz, CH], 126.9 (s, CH), 128.6 [d, ^3J(PC) = 9.0 Hz, CH], 129.3 [d, ^4J(PC) = 3.1 Hz, CH], 130.1 [d, ^1J(PC) = 15.1 Hz, CH], 131.5 [d, ^2J(PC) = 12.3 Hz, CH], 137.9 [d, ^2J(PC) = 10.5 Hz, CH], 138.2 (s, C), 145.5 (m, C), 171.5 (m, CoC) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = −26 [dt, ^2J(PP) =

87 and 69 Hz, 1 P, PPh_2], −4 [dd, ^2J(PP) = 87 and 47 Hz, 2 P, PCH_3], 21 [dt, ^2J(PP) = 69 and 47 Hz, 1 P, PCH_3] ppm. $C_{29}H_{45}CoP_4$ (576.5): calcd. C 60.42, H 7.87, P 21.49; found C 60.51, H 8.13, P 21.19.

[2-(Diphenylphosphanyl)-3-isopropylphenyl-*C*^{1},*P*]tris(trimethylphosphane)cobalt (4): 1-(Diphenylphosphanyl)-2-isopropylbenzene (732 mg, 2.40 mmol) in 50 mL of THF was combined at −70 °C with [$CoMe(PMe_3)_4$] (910 mg, 2.40 mmol) in 50 mL of THF. After the solution had warmed up, the dark-red mixture was kept at 20 °C for 16 h. The volatiles were removed in vacuo and the solid residue was extracted with two 80-mL portions of pentane. When the solution was kept at 4 °C, dark-red rectangular crystals of **4** were obtained. Yield 1040 mg (73%); m.p. 95−98 °C. ^{1}H NMR (300 MHz, [D_8]THF, 296 K): δ = 0.61 [d, ^3J = 6.8 Hz, 6 H, $C(CH_3)_2$], 1.08 [d, ^2J(PH) = 6.3 Hz, 9 H, PCH_3], 1.25 [t′, $|^2J(PH) + {}^4J(PH)|$ = 4.4 Hz, 18 H, PCH_3], 2.52 (sept, ^3J = 6.8 Hz, 1 H, CH), 6.34 (d, ^3J = 7.2 Hz, 1 H, CH), 6.66 (t, ^3J = 7.2 Hz, 1 H, CH), 6.72 (m, 1 H, CH), 7.24−7.26 (m, 6 H, CH), 7.75−7.82 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D_8]THF, 296 K): δ = 21.2 (s, CH_3), 22.5−22.6 (m, PCH_3), 27.9 (s, CH), 114.8 (s, CH), 126.5 [d, ^2J(PC) = 8.5 Hz, CH], 126.9 (s, CH), 131.7 [d, ^3J(PC) = 13.2 Hz, CH], 135.2 (s, CH), 135.4 [d, ^1J(PC) = 16.6 Hz, CH], 138.2 (m, C), 138.4 (s, CH), 140.4 (s, C), 171.2 (m, CoC) ppm. ^{31}P NMR (81 MHz, [D_8]THF, 233 K): δ = −26 [dt, ^2J(PP) = 87 and 71 Hz, 1 P, PPh_2], −4 [dd, ^2J(PP) = 87 and 47 Hz, 2 P, PCH_3], 21 [dt, ^2J(PP) = 71 and 47 Hz, 1 P, PCH_3] ppm. $C_{30}H_{47}CoP_4$ (590.5): calcd. C 61.02, H 8.02, P 20.98; found C 61.35, H 8.37, P 20.54.

[3-Cyano-2-(diphenylphosphanyl)phenyl-*C*^{1},*P*]tris(trimethylphosphane)cobalt (5): 2-(Diphenylphosphanyl)benzonitrile (486 mg, 1.69 mmol) in 50 mL of THF was combined with [$CoMe(PMe_3)_4$] (640 mg, 1.69 mmol) in 50 mL of THF, at −70 °C. After the solution had warmed up, the dark-brown mixture was stirred at 20 °C for 16 h. The volatiles were then removed in vacuo. The solid residue was extracted with two 80-mL portions of pentane. At 4 °C, black needles of **5** were obtained. Yield 408 mg (42%); m.p. 114−116 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 2209 cm^{-1} (C≡N). ^{1}H NMR (300 MHz, [D_8]THF, 296 K): δ = 1.11 [d, ^2J(PH) = 6.6 Hz, 9 H, PCH_3], 1.30 [t′, $|^2J(PH) + {}^4J(PH)|$ = 4.5 Hz, 18 H, PCH_3], 6.66 (d, ^3J = 4.7 Hz, 1 H, CH), 6.68 (d, ^3J = 8.2 Hz, 1 H, CH), 7.01 (m, 1 H, CH), 7.24−7.30 (m, 6 H, CH), 7.80−7.86 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D_8]THF, 296 K): δ = 21.8 (m, PCH_3), 22.3 (m, PCH_3), 119.3 [m, *C*(CN)], 121.7, 125.5 (s, CH), 126.4 [d, ^2J(PC) = 7.7 Hz, CH], 127.4 (s, CH), 132.4 [d, ^2J(PC) = 13.5 Hz, CH], 134.2, 136.5 (s, CH), 138.8 (s, C), 139.6 (m, C), 169.9 (m, CoC) ppm. ^{31}P NMR (81 MHz, [D_8]THF, 233 K): δ = −26 [dt, ^2J(PP) = 89 and 73 Hz, 1 P, PPh_2], −4 [dd, ^2J(PP) = 89 and 50 Hz, 2 P, PCH_3], 21 [dt, ^2J(PP) = 73 and 50 Hz, 1 P, PCH_3] ppm. $C_{28}H_{41}CoNP_4$ (574.5): calcd. C 58.54, H 7.19, N 2.44, P 21.57; found C 58.41, H 7.48, N 2.41, P 21.51.

[2-(Diphenylphosphanyl)tolyl-*C*,*P*]tris(trimethylphosphane)cobalt (6). Method a): 2-(Diphenylphosphanyl)toluene (616 mg, 2.23 mmol) and $CoCl(PMe_3)_3$ (720 mg, 2.23 mmol) in 40 mL of THF were combined at −70 °C with 1.6 M MeLi in diethyl ether (1.4 mL, 2.23 mmol), whilst stirring. The dark-green mixture turned red-brown. After the solution had warmed up, and after stirring at 20 °C for 30 min, the volatiles were removed in vacuo and the solid residue was extracted with two 80-mL portions of diethyl ether. Removal of the solvent afforded a dark-brown solid of **6**. Raw yield 928 mg (74%). **Method b):** 2-(Diphenylphosphanyl)-toluene (489 mg, 1.77 mmol) in 50 mL of THF was combined with [$CoMe(PMe_3)_4$] (670 mg, 1.77 mmol) in 50 mL of THF, at −70 °C. As the solution warmed up, the mixture turned red-brown and was stirred at 20 °C for 16 h. The volatiles were removed in vacuo, and the solid residue was extracted with three 80-mL portions of pentane. At 4 °C, black crystals of **6**, which were suitable for X-ray diffraction, were obtained. Yield 806 mg (81%); m.p. 124−126 °C (dec.). ^{1}H NMR (300 MHz, [D_8]THF, 296 K): δ = 0.93 [d, ^2J(PH) = 6.5 Hz, 9 H, PCH_3], 1.19 [t′, $|^2J(PH) + {}^4J(PH)|$ = 4.3 Hz, 18 H, PCH_3], 1.80 [m (br), 2 H, $CoCH_2$], 6.71 (t, ^3J = 7.2 Hz, 1 H, CH), 6.80 (tt, ^3J = 7.2, ^4J = 1.4 Hz, 1 H, CH), 6.92 (d, ^3J = 7.2 Hz, 1 H, CH), 7.08 (t, ^3J = 6.3 Hz, 1 H, CH), 7.22−7.24 (m, 6 H, CH), 7.56−7.65 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D_8]THF, 296 K): δ = 21.1−22.9 (m, PCH_3), 24.8 (m, $CoCH_2$), 108.2 (m, C), 117.3 (m, CH), 120.4 (s, CH), 122.9 [d, ^2J(PC) = 13.0 Hz, CH], 125.1 (s, CH), 125.9 [d, ^4J(PC) = 3.1 Hz, CH], 130.1 [d, ^1J(PC) = 15.1 Hz, CH], 131.5 [d, ^2J(PC) = 12.3 Hz, CH], 137.9 [d, ^2J(PC) = 13.1 Hz, CH], 126.4 [d, ^1J(PC) = 22.4 Hz, C], 130.2 (s, CH), 132.6[d, ^2J(PC) = 12.3 Hz, C], 141.2 (m, C) ppm. ^{31}P NMR (81 MHz, [D_8]THF, 233 K): δ = −4 [dd, ^2J(PP) = 94 and 44 Hz, 2 P, PCH_3], 22 [dd, ^2J(PP) = 50 and 44 Hz, 1 P, PCH_3], 58 [dt, ^2J(PP) = 94 and 50 Hz, 1 P, P Ph_2] ppm. $C_{28}H_{43}CoP_4$ (562.5): calcd. C 59.79, H 7.71, P 22.03; found C 59.97, H 7.30, P 22.08.

[2-(Diphenylphosphanyl)benzyl-*C*^{2},*P*]tris(trimethylphosphane)cobalt (7): Benzyldiphenylphosphane (679 mg, 2.45 mmol) in 50 mL of THF was combined with [$CoMe(PMe_3)_4$] (930 mg, 2.45 mmol) in 50 mL of THF, at −70 °C. The color of the solution changed from brown to deep-red. After the solution had warmed up, the mixture was stirred at 20 °C for 4 h. The volatiles were then removed in vacuo to give a light-red solid. This was dissolved in 50 mL of diethyl ether and crystallized at 4 °C to give red cubes of **7**, which were suitable for X-ray diffraction. Yield 856 mg (62%); m.p. 75−77 °C (dec.). ^{1}H NMR (300 MHz, [D_8]THF, 296 K): δ = 0.97 [d, ^2J(PH) = 6.3 Hz, 9 H, PCH_3], 1.16 [t′, $|^2J(PH) + {}^4J(PH)|$ = 4.6 Hz, 18 H, PCH_3], 1.80 [d, ^2J(PH) = 8.2 Hz, 2 H, PCH_2], 6.49 (m, 2 H, CH), 6.70 (m, 1 H, CH), 7.19−7.25 (m, 6 H, CH), 7.42 (m, 1 H, CH), 7.56−7.62 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D_8]THF, 296 K): δ = 23.4 [d, ^1J(PC) = 20.8 Hz, PCH_3], 23.9 [dd, ^1J(PC) = 12.6, ^3J(PC) = 6.4 Hz, PCH_3], 50.4 [d, ^1J(PC) = 27.1, ^3J(PC) = 8.7 Hz, PCH_2], 119.9 (s, CH), 121.6 (s, CH), 121.9 (s, CH), 127.5 [d, ^3J(PC) = 8.0 Hz, CH], 127.6 (s, CH), 132.8 [d, ^2J(PC) = 11.6 Hz, CH], 141.6 (m, C), 143.6 (m, C), 144.6 (s, CH), 171.6 (m, CoC) ppm. ^{31}P NMR (81 MHz, [D_8]THF, 233 K): δ = −4 [dd, ^2J(PP) = 104 and 54 Hz, 2 P, PCH_3], 22 [dd, ^2J(PP) = 54 and 51 Hz, 1 P, PCH_3], 63 [dt, ^2J(PP) = 104 and 51 Hz, 1 P, PPh_2] ppm. $C_{28}H_{43}CoP_4$ (562.5): calcd. C 59.79, H 7.71, P 22.03; found C 59.63, H 7.79, P 22.12.

[2-(Diphenylphosphanyl)-3-isopropylphenyl-*C*^{1},*P*](ethene)bis(trimethylphosphane)cobalt (8): A sample of **4** (610 mg, 1.03 mmol) was heated in vacuo at 100 °C for 3 h. It was then dissolved in 70 mL of diethyl ether at 20 °C, and was stirred under 1 bar of ethene for 3 h. The volatiles were removed in vacuo and the solid residue was extracted with two 50-mL portions of pentane. Crystallization at 4 °C afforded orange crystals of **8**, together with the dark crystals of **4**. After mechanical separation the yield was 185 mg (33%); m.p. 105−107 °C (dec.). ^{1}H NMR (300 MHz, [D_8]THF, 296 K): δ = 0.85 [d, ^2J(PH) = 5.8 Hz, 9 H, PCH_3], 0.97 (d, ^3J = 6.9 Hz, 6 H, CCH_3), 1.01 [d, ^2J(PH) = 5.9 Hz, 9 H, PCH_3], 1.51 (m, 1 H, =CH_2), 1.88 (m, 2 H, =CH_2), 2.35 (m, 1 H, =CH_2), 2.46 (sept, ^3J = 6.9 Hz, 1 H, C*H*CH_3), 6.42 (t, ^4J = 2.4 Hz, CH), 6.45 (t, ^4J = 2.2 Hz, CH), 6.72 (dt, ^3J = 7.5, ^4J = 1.8 Hz, 1 H, CH), 7.26−7.28 (m, 3 H, CH), 7.38 −7.41 (m, 3 H, CH), 7.64−7.70 (m, 2 H, CH), 7.94−8.00 (m, 2 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D_8]THF, 296 K): δ = 16.4 [d, ^1J(PC) = 22.7 Hz, PCH_3], 18.9 [d, ^1J(PC) = 18.4 Hz, PCH_3], 20.9 (s, CH*C*H_3), 28.5 [d, ^3J(PC) =

4.5 Hz, *C*HCH$_3$], 31.4 [d, ^2J(PC) = 16.1 Hz, =CH$_2$], 37.1 [d, ^2J(PC) = 15.5 Hz, =CH$_2$], 116.2 [d, ^3J(PC) = 6.1 Hz, CH], 126.6 [d, ^3J(PC) = 8.2 Hz, CH], 127.4 [d, ^2J(PC) = 12.6 Hz, C], 128.9 (s, CH), 131.4 [d, ^2J(PC) = 11.1 Hz, CH], 132. 1 [d, ^2J(PC) = 112.3 Hz, CH], 136.1 [d, ^1J(PC) = 15.9 Hz, C], 138.2 (s, C), 141.7 (s, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 193 K): δ = −21 [dd, ^2J(PP) = 49 and 56 Hz, 1 P, PPh$_2$], 9 [dd, ^2J(PP) = 49 and 33 Hz, 1 P, PCH$_3$], 17 [dd, ^2J(PP) = 33 and 56 Hz, 1 P, PCH$_3$] ppm. $C_{29}H_{42}CoP_3$ (542.5): calcd. C 64.21, H 7.80, P 17.13; found C 63.85, H 7.90, P 17.15.

[2-(Diphenylphosphanyl)tolyl-*C*,*P*](ethene)bis(trimethylphosphane)cobalt (9): A sample of **6** (820 mg, 1.45 mmol) in 50 mL of diethyl ether was stirred under 1 bar of ethene for 1 h. A light-red solution formed. The volatiles were removed in vacuo and the solid residue was extracted with three 50-mL portions of pentane. Crystallization at 4 °C afforded orange needles of **9**. Yield 584 mg (78%); m.p. 87−89 °C (dec.). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.71 [d, ^2J(PH) = 6.1 Hz, 9 H, PCH$_3$], 1.21 [d, ^2J(PH) = 5.4 Hz, 9 H, PCH$_3$], 1.65 (m, 2 H, =CH$_2$), 1.97 (m, 2 H, =CH$_2$), 6.82 (m, 1 H, CH), 6.90 (m, 2 H, CH), 7.14 (t, ^3J = 6.5 Hz, 1 H, CH), 7.32−7.36 (m, 6 H, CH), 7.45 (m, 2 H, CH), 8.02−8.04 (m, 2 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 16.9 [d, ^1J(PC) = 18.4 Hz, PCH$_3$], 19.7[d, ^1J(PC) = 16.6 Hz, PCH$_3$], 31.7 (m, CoCH$_2$), 38.7 [d, ^2J(PC) = 16.5 Hz, = CH$_2$], 39.8 [d, ^2J(PC) = 20.5 Hz, =CH$_2$], 121.9 [d, ^4J(PC) = 4.9 Hz, CH], 124.9 [d, ^2J(PC) = 11.0 Hz, CH], 127.3 [d, ^3J(PC) = 8.4 Hz, CH], 127.5 [d, ^3J(PC) = 8.3 Hz, CH], 127.6 [d, ^3J(PC) = 7.2 Hz, CH], 128.2 [d, ^1J(PC) = 22.0 Hz, CH], 133.2 [d, ^2J(PC) = 10.5 Hz, CH], 134. 1 [d, ^2J(PC) = 11.6 Hz, CH], 141.1 [d, ^1J(PC) = 20.9 Hz, C], 162.1 (s, C).) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = 11 [dd, ^2J(PP) = 40 and 25 Hz, 1 P, PCH$_3$], 18 [dd, ^2J(PP) = 25 and 38 Hz, 1 P, PCH$_3$], 66 [dd, ^2J(PP) = 40 and 38 Hz, 1 P, PPh$_2$] ppm. $C_{27}H_{38}CoP_3$ (514.5): calcd. C 63.04, H 7.45, P 18.06; found C 63.12, H 7.07, P 18.72.

(Carbonyl)[2-(diphenylphosphanyl)tolyl-*C*,*P*]bis(trimethylphosphane)cobalt (10): A sample of **6** (590 mg, 1.05 mmol) in 30 mL of THF was stirred under 1 bar of CO for 30 min. A light-red solution formed. The volatiles were removed in vacuo and the solid residue was extracted with 50 mL of pentane. Crystallization at 4 °C afforded red crystals of **10**, which were suitable for X-ray diffraction. Yield 410 mg (76%); m.p. 132−135 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1894 cm^{-1} (C≡O$_{ax}$), 1850 cm^{-1} (C≡O$_{eq}$). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): C≡O$_{ax}$ isomer (88%): δ = 1.00 [t′, $|^2J$(PH) + ^4J(PH)| = 6.2 Hz, 18 H, PCH$_3$], 2.09 (m, 2 H, CoCH$_2$), 6.84 (t, ^3J = 7.3 Hz, 1 H, CH), 7.02 (m, 2 H, CH), 7.18 (d, ^3J = 6.9 Hz, 1 H, CH), 7.26−7.31 (m, 6 H, CH), 7.43−7.47 (m, 4 H, CH); C≡O$_{eq}$ isomer (12%): δ = 0.86 [d, ^2J(PH) = 7.3 Hz, 18 H, PCH$_3$], 1.29 [d, ^2J(PH) = 7.5 Hz, 18 H, PCH$_3$], 2.35 (m, 2 H, CoCH$_2$), 6.95−7.62 (m, 14 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): C≡O$_{ax}$ isomer (88%): δ = 20.1 (s, PCH$_3$), 24.0 (m, CoCH$_2$), 124.1 [d, ^3J(PC) = 4.6 Hz, CH], 127.4 (s, CH), 127.4 [d, ^1J(PC) = 16.4 Hz, CH], 128.5 [d, ^2J(PC) = 8.3 Hz, CH], 128.8 (s, CH), 129.9 (s, CH), 133.1 [d, ^2J(PC) = 12.3 Hz, CH], 140.1 (s, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): CO$_{ax}$ isomer (88%): δ = 6 [d, ^2J(PP) = 98 Hz, 2 P, PCH$_3$], 73 [t, ^2J(PP) = 98 Hz, 1 P, PPh$_2$]; CO$_{eq}$ isomer (12%): δ = −1 [dd, ^2J(PP) = 82 and 38 Hz, 1 P, PCH$_3$], 25 [dd, ^2J(PP) = 38 and 51 Hz, 1 P, PCH$_3$], 67 [dd, ^2J(PP) = 82 and 51 Hz, PPh$_2$] ppm. $C_{26}H_{34}CoOP_3$ (514.4): calcd. C 60.71, H 6.66, P 18.06; found C 60.94, H 7.45, P 17.62.

(Carbonyl)[2-(diphenylphosphanyl)-3-ethylbenzoyl-*C*,*P*]bis(trimethylphosphane)cobalt (11): A sample of **3** (580 mg, 1.01 mmol) in 50 mL of THF was stirred under 1 bar of CO for 30 min. A light-red solution formed. The volatiles were removed in vacuo and the solid residue was extracted with two 50-mL portions of pentane. Crystallization at 4 °C afforded dark red plates of **11**. Yield 475 mg (85%); m.p. 152−153 °C. IR (Nujol): $\tilde{\nu}$ = 1913 cm^{-1} (C≡O). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.52 (t, ^3J = 7.5 Hz, 3 H, CH$_3$), 1.09 [t′, $|^2J$(PH) + ^4J(PH)| = 7.2 Hz, 18 H, PCH$_3$], 2.43 (q, ^3J = 7.5 Hz, 2 H, CH$_2$), 7.26−7.40 (m, 9 H, CH), 7.54−7.61 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 17.2 (s, PCH$_3$), 18.2 (m, PCH$_3$), 19.9 (s, CH$_3$), 26.7 (s, CH$_2$), 47.5 (s, CH), 55.9 (s, CH$_2$), 117.6 [d, ^1J(PC) = 21.2 Hz, CH], 126.9 (s, CH), 128.6 [d, ^2J(PC) = 9.0 Hz, CH], 129.3 [d, ^3J(PC) = 3.1 Hz, CH], 128.8 (s, CH), 130.1 [d, ^1J(PC) = 15.1 Hz, CH], 130.4 (s, CH), 137.8 (s, C), 138.2 (s, C), 145.5 (s, C), 157.7 (s, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 193 K): δ = 9 [d, ^2J(PP) = 81 Hz, 2 P, PCH$_3$], 84 [t, ^2J(PP) = 81 Hz, 1 P, PPh$_2$] ppm. $C_{28}H_{36}CoO_2P_3$ (556.4): calcd. C 60.44, H 6.52, P 16.70; found C 60.40, H 6.72, P 16.53.

(Carbonyl)[2-(diphenylphosphanyl)-3-isopropylbenzoyl-*C*,*P*]bis(trimethylphosphane)cobalt (12): A sample of **4** (750 mg, 1.27 mmol) in 50 mL of THF was stirred under 1 bar of CO for 3 h. A light-red solution formed. The volatiles were removed in vacuo and the solid residue was extracted with two 50-mL portions of pentane. Crystallization at 4 °C afforded dark-red crystals of **12**. Yield 572 mg (79%); m.p. 161−162 °C. IR (Nujol): $\tilde{\nu}$ = 1906 cm^{-1} (C≡O). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.65 [d, ^3J = 6.7 Hz, 6 H, C(CH$_3$)$_2$], 1.05 [t′, $|^2J$(PH) + ^4J(PH)| = 7.3 Hz, 18 H, PCH$_3$], 3.04 (sept, ^3J = 6.7 Hz, 1 H, CH), 7.30−7.39 (m, 9 H, CH), 7.58−7.65 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 21.7 (s, CH$_3$), 18.2 [dt, ^1J(PC) = 12.6, ^3J(PC) = 4.2 Hz, PCH$_3$], 30.9 (s, CH), 117.6 (s, CH), 117.9 (s, CH), 126.9 [d, ^2J(PC) = 8.9 Hz, CH], 127.2 (s, CH), 130.2 (s, CH), 130.5 [d, ^3J(PC) = 12.2 Hz, CH], 137.6 (s, C), 137.9 (s, C), 138.3 (m, C), 150.3 (s, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = 8 [d, ^2J(PP) = 79 Hz, 2 P, PCH$_3$], 85 [t, ^2J(PP) = 79 Hz, 1 P, PPh$_2$] ppm. $C_{29}H_{38}CoO_2P_3$ (570.5): calcd. C 61.06, H 6.71, P 16.29; found C 61.05, H 6.86, P 16.21.

***mer-cis*-[2-(Diphenylphosphanyl)tolyl-*C*,*P*](iodo)(methyl)bis(trimethylphosphane)cobalt (13):** A sample of **6** (810 mg, 1.44 mmol) in 50 mL of diethyl ether at −70 °C was combined with a slight excess of iodomethane (552 mg, 3.89 mmol). The mixture was allowed to warm to 20 °C, after which it turned brown and deposited an off-white solid of tetramethylphosphonium iodide (IR). After 4 h, the solid was removed by filtering. Crystallization at 4 °C afforded orange crystals of **13**·0.5OEt$_2$, which were suitable for X-ray diffraction. Yield 440 mg (46%); m.p. 82−84 °C (dec.). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.53 (m, 3 H, CoCH$_3$), 0.95 [s (br), 18 H, PCH$_3$], 1.12 (m, 2 H, CoCH$_2$), 6.56 (m, 1 H, CH), 7.05 (m, 2 H, CH), 7.31−7.74 (m, 11 H, CH) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 213 K): δ = −11 (m, 1 P, PCH$_3$), −1 (m, 1 P, PCH$_3$), 10 (m, 1 P, PPh$_2$) ppm. $C_{28}H_{42}CoIO_{0.5}P_3$ (665.4): calcd. Single-Atom *O*-Bridged Urea in a Dinickel(II) Complex together with Ni_4^{II}, Cu_2^{II} and Cu_4^{II} Complexes of a Pentadentate Phenol-Containing Schiff Base with (O,N,O,N,O)-Donor Atoms

Soumen Mukherjee,[a] Thomas Weyhermüller,[a] Eberhard Bothe,[a] Karl Wieghardt,[a] and Phalguni Chaudhuri*[a]

Keywords: N,O ligands / Nickel / Copper / Magnetic properties / Radicals / Electrochemistry

A pentadentate phenol-containing ligand (H_3L) with N_2O_3 donor atoms yields Ni_2^{II} (**1**), Ni_4^{II} (**2**), Cu_2^{II} (**3**) and Cu_4^{II} (**4**) complexes, which have been structurally characterized by X-ray diffraction. Complex **1** contains a single-atom *O*-bridged urea. The compounds were characterized by IR, UV/Vis, mass spectrometry, electrochemistry and variable-temperature (2–295 K) magnetic susceptibility measurements. Analysis of the susceptibility data shows antiferromagnetic interactions between the metal centers indicating a diamagnetic ground state for complexes **1**, **3** and **4**, whereas complex **2**, a tetranuclear Ni^{II} cubane, has a complicated low-lying magnetic structure with a non-diamagnetic ground state. A plot of *J* vs. Ni–O–Ni angles for all structurally characterized Ni_4O_4 cubane cores, including **2**, irrespective of their symmetry exhibits a large variation of *J* values within a small range of Ni–O–Ni angles. The electrochemistry of all complexes was investigated in detail and the ligand-centered oxidation to a radical-ligand is inferred from the occurrence of oxidation processes at potentials which are similar.

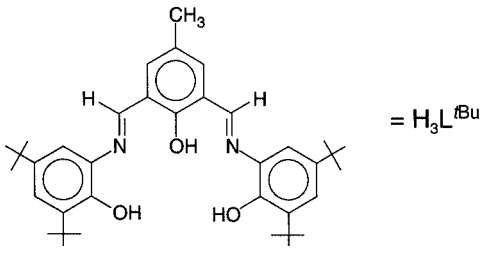
Introduction

Polynuclear metal complexes are of current interest to chemists owing to their relevance to metallobiochemistry,[1] materials science[2] and theoretical chemistry.[3] Particular interest has been directed towards the exchange phenomena in di- and polynuclear complexes of nickel(II) and copper(II), in which studies, particularly of the latter, have led to essential insights into magnetostructural correlations.

Since the first report by Robson[4] in 1970 of a dinucleating Schiff-base ligand obtained by condensation of 2,6-diformyl-4-methylphenol with 2-aminophenol, many examples of similar compartmental ligands have been reported.[5] The dinucleating ability of these ligands stems from the readiness of the phenol to deprotonate and bridge two metal ions. Recently, we have reported trinuclear and tetranuclear complexes with the ligands derived from the condensation of 2,6-diformyl-4-methylphenol and selected diamines or hydroxylamines, which yield heteronuclear complexes of the type $M_AM_BM_C$ [6] and $M_AM_BM_BM_A$.[7]

In another field of coordination chemistry, interest in phenol-containing ligands was sparked and fueled by the discovery that tyrosyl radicals, derived from oxidation of the amino acid tyrosine, play an important role in a rapidly growing number of oxygen-dependent enzymatic radical catalysis reactions.[8] Since then chemists have attempted to model tyrosine by phenolate ligands.[9,10]

It has already been reported[10] that *tert*-butyl substituents at the *ortho* and *para* positions of the phenolates facilitate one-electron oxidation to the corresponding phenoxyl radicals, because these substituents decrease the oxidation potential of the phenolates and provide enough steric bulk to suppress bimolecular decay reactions of the generated phenoxyl radicals. Accordingly, we report here the synthesis and characterization of dinuclear and tetranuclear complexes of Ni^{II} and Cu^{II} ions with the Schiff-base ligand H_3LtBu derived from the (1+2) condensation of 2,6-diformyl-4-methylphenol and 6-amino-2,4-di-*tert*-butylphenol. A few square-planar dinickel(II) and dicopper(II) complexes have already been described by Robson,[4] but no structural data are available for these complexes, except one with the composition $[LCo^{II}Co^{III}(OH)(CH_3COO)]_2$.[11]



Scheme 1 shows the complexes of the ligand H_3LtBu prepared, along with their labels. Compounds **5**–**8** will not be described in this paper but in a subsequent one, and are

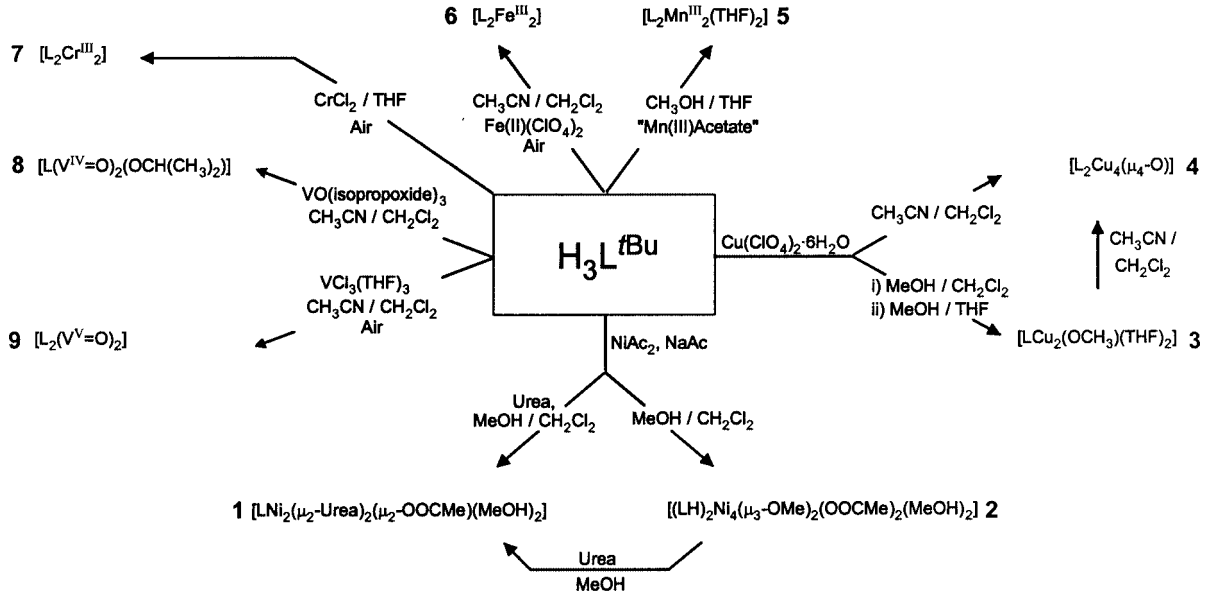

Scheme 1

mentioned here only to exemplify the diversified ligating properties of H_3LtBu. For the sake of simplicity the ligand will be denoted as H_3L without the suffix *t*Bu. We report here a dinuclear nickel(II) complex **1** with a bridging urea through a single-atom *O*-bridging of the carbonyl oxygen, as a model for a binding mode of the substrate urea in the nickel-dependent hydrolase enzyme urease (E.C. 3.5.1.5),[12−13] which is present in bacteria, fungi and higher plants, and catalyzes the hydrolysis of urea to ammonia and carbon dioxide.

$$H_2N\text{-}\underset{\underset{O}{\|}}{C}\text{-}NH_2 \xrightarrow[H_2O]{\text{urease}} 2\,NH_3 + CO_2$$

Several dinuclear nickel(II) complexes with urea[14] have been reported as models for possible binding modes of urea in urease. But none of the complexes reported so far, except one,[15] contain a carbonyl single-atom bridging urea.

Results and Discussion

When nickel acetate and H_3L are allowed to react in the presence of sodium acetate with a slight excess of urea in methanol, complex **1** is obtained. In the absence of urea, the tetranuclear complex **2** is obtained. Complex **2** can also be transformed into **1** by adding urea to the red solution of **2** in methanol (Scheme 1). Formation of **1** from **2** implies that the driving force for formation of **1** lies in the strong tendency of urea to bind to the dinickel center embedded in the dinucleating ligand L^{3-}. The solid-state FTIR spectrum of complex **1** exhibits a shift in the carbonyl stretching frequency of urea from 1690 to 1670 cm^{-1} upon coordination to the dinickel center. Mass spectrometry in the EI mode indicates unambiguously the presence of urea and an acetate ion in **1**. In the ESI positive mass spectrum of **1** a peak with an abundance of 100% is observed centered around m/z = 743, corresponding to $[LNi_2(OOCCH_3)]^+$, with the expected isotope pattern. The EI mass spectrum does not provide much useful information regarding the tetranuclear nature of **2**. It exhibits signals around m/z = 714−720 (100%) with the expected isotope pattern for a dinickel compound, clearly indicating the presence of $[LNi_2(OCH_3)]^+$ in the gas phase.

The electronic spectra of **1** and **2** show intense π-π* transitions below 480 nm, attributable to the ligand, as judged by their high absorption coefficients and comparison with the spectrum of the ligand Additionally, there are three broad, weak transitions in the visible-near IR region at 779, 858 and 1284 nm for **1**, indicating that the nickel ions are in an octahedral environment in solution as well as in the solid state (X-ray structure). Interestingly only one broad absorption is observed in the range 800−1300 nm for **2**.

The reaction of copper perchlorate and the Schiff-base ligand afforded either **3** or **4**, depending on the solvent system, in relatively high yield. In the absence of protic solvents, complex **3**, a methoxy-bridged dicopper(II) species, is transformed easily into **4** — a μ_4-oxo-tetracopper(II) complex — in the presence of the solvent mixture CH_3CN/CH_2Cl_2 (Scheme 1) indicating the stability of **4**. Adventitious water in the solvent serves as a source of the μ_4-oxo ligand. Selected IR data for complexes **3** and **4** are given in the Exp. Sect. The sharp peaks in the solid state FTIR spectrum due to ν(OH) of the ligand LH_3 occur at $\tilde{\nu}$ = 3523, 3492 and 3348 cm^{-1}. These bands are missing in **3** and **4**, indicating that the phenol character of the ligand has been lost upon complexation. For **4** a sharp band of medium intensity at 510 cm^{-1} is associated with the $\nu_{Cu\text{-}O}$ vibration in the Cu_4O core. Support for this assignment is obtained by comparison with the vibrational spectrum of **3**, which exhibits, similar to that for **4**, two sharp bands of medium intensity at 564 and 539 cm^{-1} attributable to ν(Cu−O) vibrations for bonds to the phenolate groups. These three bands are missing in the spectrum of the free ligand. In the

EI mass spectrum of **3** a molecular peak at $m/z = 724$, with an abundance of 100%, corresponding to the $LCu_2(OCH_3)$ species is observed. Additionally, a clear indication of the presence of THF in **3** is found at $m/z = 72$. Mass spectrometry in the EI mode has been proved to be very useful for **4**, for which the molecular peak at $m/z = 1404$, with the expected isotope pattern, confirms the presence of $[L_2Cu_4(O)]$. The electronic spectra of **3** and **4** in CH_2Cl_2 display four intense bands in the 600−200 nm region attributed to the Schiff-base ligand.

Single Crystal X-ray Diffraction Studies

Molecular Structure of 1

The structure of **1** (Figure 1, Table 1) shows the formation of a dinickel(II) complex with a bridging urea through

the carbonyl oxygen. Ni(1) and Ni(2) are additionally bridged by a phenolate oxygen [O(10)] and an acetate ion. Each nickel is in a distorted octahedral NO_5 environment, and is equatorially bound to the NO_3 donor set [Ni−N: av. 1.975 Å; Ni−O: av. 2.01 Å], with axial interactions to a carboxylic *O*-donor of a bridging $MeCO_2^-$ group [Ni−O: av. 2.09 Å] and a methanol *O*-donor [Ni−O: 2.165, 2.159 Å] trans to the $MeCO_2^-$ group. The hydrogen atoms of the hydroxy group in MeOH and the urea molecules were located from a difference map and are shown as circles of arbitrary radii in Figure 1. The hydrogen atoms on the NH_2 groups of urea enter into hydrogen bonding with the phenolate oxygens O(1) and O(17), with O(1)···N(71) and O(17)···N(70) distances of 2.784 and 2.813 Å, respectively, thus making urea presumably not susceptible to alcoholysis (see later). The intramolecular hydrogen bonds between the methanol molecules *cis*-ligated to two different nickel(II) ions [O(40)···O(50) 2.928 Å] are shown as dotted lines. The Ni(1)···Ni(2) distance of 2.966(1) Å in **2** is significantly shorter than those observed in comparable complexes.[14−15] The bridging Ni−O(urea) distances [2.080(3) and 2.065(3) Å] are significantly shorter than those in the only other single-atom *O*-bridged urea compound [Ni−O(urea): 2.158(3) Å].[15] The Ni−O(urea) bond lengths for compounds containing non-bridging urea lie within the range 2.05−2.13 Å.[14] The Ni(1)−O(70)−Ni(2) angle at the bridging urea is 91.4(1)°, whereas the phenoxide bridging angle Ni(1)−O(10)−Ni(2) is significantly greater [97.1(2)°].

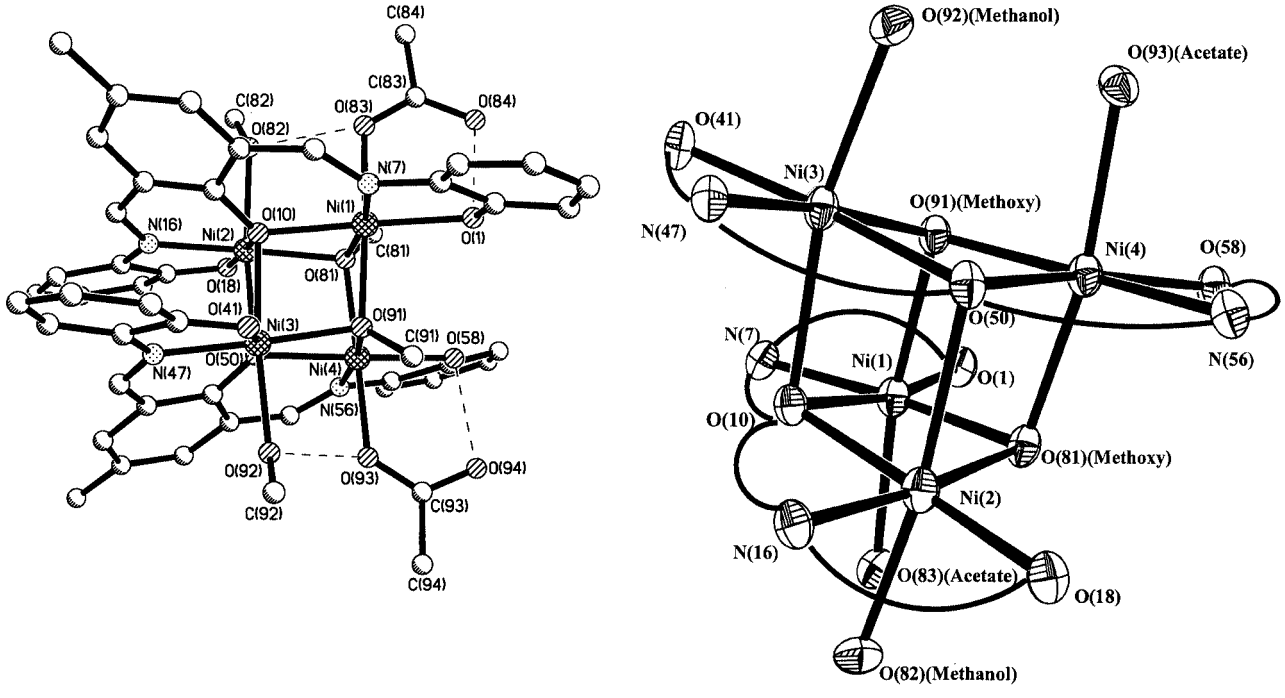

Figure 2. (a) Molecular structure of **2**, $[(LH)_2Ni^{II}_4(OCH_3)_2(OOCCH_3)_2(CH_3OH)_2]\cdot 3CH_2Cl_2$; (b) a view of **2** highlighting the Ni_4O_4 cubane core; the pentadentate ligand L is denoted only by the donor atoms joined by the curved lines

Relevant bond lengths and angles are summarized in Table 2.

Molecular Structure of 2

The crystal structure of **2** is shown in Figure 2, with selected bond lengths and angles provided in Table 3. The molecule is based on a roughly cubic Ni_4O_4 [16] unit, consisting of two interpenetrating tetrahedra, one of four nickel atoms and one of four μ_3-oxygen atoms originating from the cresol phenolate [O(10), O(50)] part of the ancillary ligand L and methoxide groups [O(81), O(91)]. Each Ni^{II} is in a distorted octahedral environment with an NO_5 donor set. For Ni(1) and Ni(4) a peripheral ligation is provided by a monodentate acetate ion, whereas for Ni(2) and Ni(3) a methanol molecule [O(82) and O(92), respectively] completes the sixth coordination position. The ancillary Schiff-base ligands are present in their monoprotonated form HL and are protonated at O(1) and O(58), forming hydrogen bonds with O(84) and O(94) of the acetate ions, respectively [O(1)···O(84): 2.426 Å; O(58)···O(94): 2.449 Å]. Although it was not possible to locate all the hydrogen atoms in the structure, the intramolecular contacts between the oxygen atoms of the methanol molecules [O(82) and O(92)] and the oxygen atoms of the acetate groups [O(83) and O(93), respectively] of 2.657 Å and 2.684 Å, can be interpreted as hydrogen bonds. The Ni−O−Ni angles vary between 94.4(2) and 102.2(3)°. The Ni···Ni distances on different cubic faces are also different, the shortest being Ni(1)···Ni(2) (3.047 Å) and the longest Ni(2)···Ni(3) (3.227 Å). Average Ni−N and Ni−O bond lengths of 1.99 and 2.10 Å, respectively, lie well within the range of reported values for the corresponding bond lengths of the tetranuclear cubane-like Ni^{II}.[16] No substantial differences in bond lengths and angles are found between the two crystallographically independent molecules.

Table 3. Selected bond lengths (Å) and angles (deg) for $[(LH)_2Ni^{II}_4(OCH_3)_2(OOC{\cdot}CH_3)_2(CH_3OH)_2]{\cdot}3CH_2Cl_2$ (**2**)

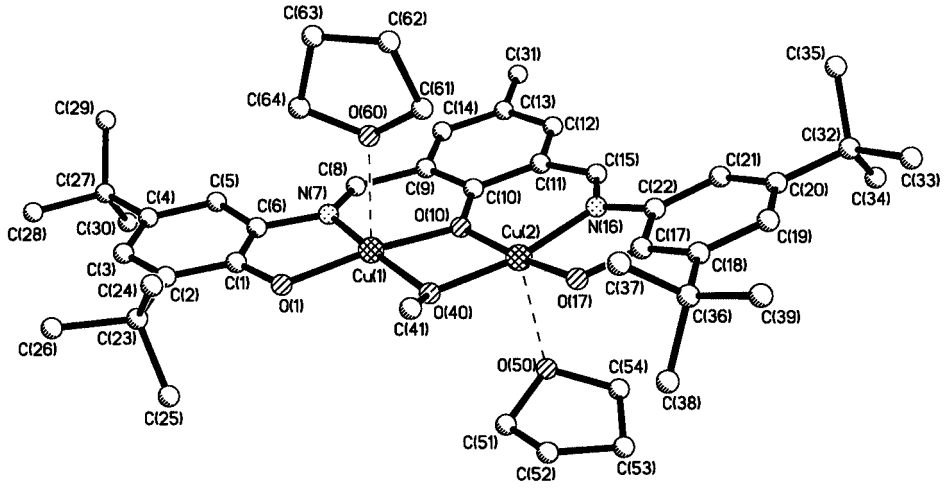

Figure 3. A perspective view of the neutral complex $[LCu_2(OCH_3)(THF)_2]$ **3**

$[C_{46}H_{66}N_2O_6Cu_2 \cdot 2THF$, monoclinic, space group $P2_1/n$, $a = 11.7459(12)$, $b = 30.236(3)$, $c = 15.640(2)$ Å, $\beta = 110.19(3)°$, $V = 5213.2$ Å^3, $T = 100(2)$ K, final $R = 0.092$ for 5150 independent reflections] diffract X-rays very weakly. In spite of the high R factor and large standard deviations, the crystal structure analysis of **3** confirmed its dinuclear structure. Because of its unacceptable quality, we are refraining from publishing the crystal data in detail. Selected bond lengths and angles are given in Table 4. The crystal structure reveals that the copper atoms are doubly bridged by the phenoxo and by a methoxide group (Figure 3). The pentacoordination of copper atoms is achieved by a tetrahydrofuran oxygen with Cu(1)−O(60) and Cu(2)−O(50) distances of 2.444 Å and 2.566 Å, respectively, which are oriented *trans* to each other in the dicopper complex. The coordination polyhedron for the copper centers is a distorted square pyramid with O(1)N(7)O(10)O(40) for Cu(1) and O(10)N(16)O(17)O(40) for Cu(2) forming the equatorial planes, where Cu(1) and Cu(2) are located 0.102 Å and 0.134 Å, respectively, out of the equatorial planes. The ring Cu(1)O(10)Cu(2)O(40) is not planar, the dihedral angle being 12.7°. The distances Cu−N and Cu−O are in the ranges reported for comparable complexes.[17]

Molecular Structure of 4

The molecular structure of **4** is shown in Figure 4. Selected interatomic distances and bond angles are listed in Table 5. Compound **4** consists of four copper(II) ions

bridged by a central μ_4-oxygen atom in an approximately tetrahedral environment. The phenolate oxygen atoms O(10) and O(50) of the cresol part of the ligand bridge two copper centers, resulting in very similar Cu(1)−O(10)−Cu(2) and Cu(3)−O(50)−Cu(4) angles of 99.49(9)° and 99.12(9)°, respectively. Each copper center is coordinated by three oxygen atoms and one nitrogen atom, with the bond lengths ranging from 1.891(2) to 1.953(2) Å. There are considerable deviations of the geometry of the copper center from the ideal square plane, as indicated by the basal plane angles (Table 5), although each CuO_3N portion is essentially planar. The dihedral angles between the Cu(1)/Cu(2) planes, and between the Cu(3)/Cu(4) planes are 8.5° and 3.2°, respectively. The two $Cu_2O_4N_2$ dinuclear units are nearly perpendicular, as evidenced by the dihedral angle of 75.2° between the Cu(1)O(10)Cu(2)O(99) and Cu(3)O(50)-Cu(4)O(99) planes.

The copper tetrahedron around the μ_4-oxygen O(99) is distorted, as the bond angles Cu−O(99)−Cu range from 122.37(1)° for Cu(2)−O(99)−Cu(3) to 90.23(8) for Cu(4)−O(99)−Cu(1), the smallest among the six angles at O(99). Perhaps as a consequence, the Cu(2)···Cu(3) distance of 3.356 Å is substantially longer than that of Cu(4)···Cu(1) (2.759 Å). The remaining Cu···Cu distances are Cu(1)···Cu(2) (2.963 Å), Cu(1)···Cu(3) (3.368 Å), Cu(2)···Cu(4) (3.345 Å) and Cu(3)···Cu(4) (2.945 Å). These differences can be explained by the steric forces of the chelating ligand L^{3-}, which contracts the Cu(1)−O(99)−Cu(4) angle with a concomitant expansion of the opposite angle Cu(2)−O(99)−Cu(3). Examples of tetranuclear copper(II) complexes with a μ_4-O kernel are abundant,[18−20] but all of them involve bridging ligands like halides or carboxylates between the edges of the tetrahedron. Compound **4** without any such bridging ligand is an exception. Figure 5 highlights the core structure for greater clarity and to emphasize the unique structure of the $Cu_4(\mu_4\text{-}O)$ unit present in **4**.

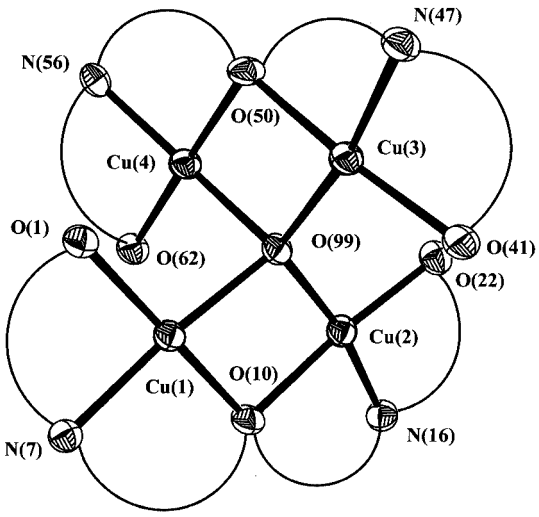

Figure 5. The atom connectivity in the core of complex **4**

Magnetic Susceptibility Studies

Magnetic susceptibility data for polycrystalline samples of complexes **1**−**4** were collected in the temperature range 2−290 K in an applied magnetic field of 1 T to characterize the nature and magnitude of the exchange interaction propagated by the bridging ligands. We use the Heisenberg spin-Hamiltonian in the form $H = -2JS_AS_B$ for an isotropic exchange coupling, with $S_{Ni} = 1$ for **1** and **2** and $S_{Cu} = 1/2$ for **3** and **4**. The experimental magnetic data were simulated using a least-squares fitting computer program[21] with a full-matrix diagonalization of exchange coupling, Zeeman splitting, and axial single-ion zero-field interactions [DS_z^2], if necessary. The susceptibility data were cor-

rected for diamagnetism (Pascal corrections), temperature-independent paramagnetism (TIP) and the presence of paramagnetic monomer impurities (P) in the following way: $\chi_{calc} = (1 - P)\chi + \chi_{TIP} + P\chi_{mono}$. The experimental data are displayed in Figure 6 as the effective magnetic moment (μ_{eff}) versus temperature (T). The solid lines in the figure represent the simulations.

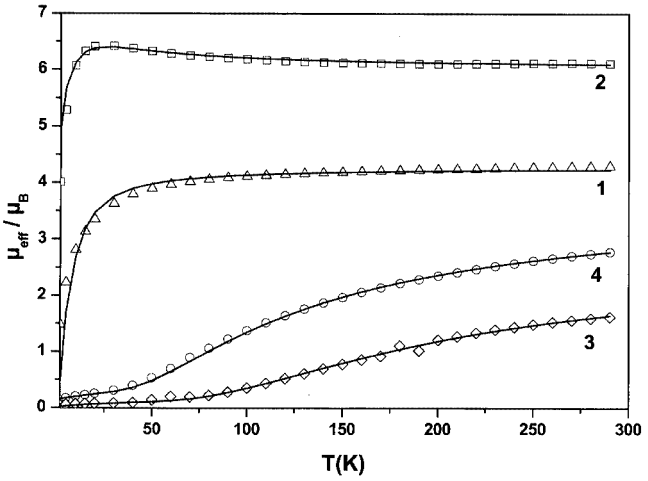

Figure 6. Plots of μ_{eff} vs. T for solid **1**, **2**, **3** and **4**; the solid lines represent the best fit of the data to the exchange coupling models

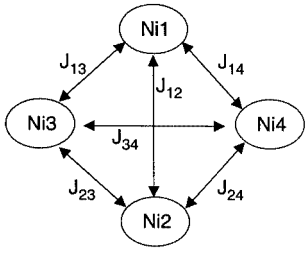
The magnetic moment μ_{eff}/molecule for **1** of 4.280 μ_B ($\chi_M \cdot T$ = 2.291 cm^3·K·mol^{-1}) at 290 K decreases monotonically with decreasing temperature until it reaches a value of 1.474 μ_B ($\chi_M \cdot T$ = 0.2717 cm^3·K·mol^{-1}) at 2 K; this temperature dependence of μ_{eff} is a clear indication of an antiferromagnetic exchange coupling between two paramagnetic centers Ni^{II} (S_{Ni} = 1) with a resulting diamagnetic ground state. Using only D (i.e. J = 0), a fit of poor quality with unusually large D was obtained and hence discarded. Attempts to fit the data using both D and J yield physically meaningless D values. For example, a good fit (not shown) was obtained with the following parameters: J = −2.6 cm^{-1}, D = +27.1 cm^{-1}, g = 2.13, P = 0.005. As the zero-field splitting D is unusually large for a six-coordinate Ni^{II} ion, this solution was also discarded. Finally, the solid line in Figure 6 represents the best fit with the following parameters: J = −3.5 cm^{-1}, $g_1 = g_2$ = 2.137, P = 0.005. The quality of the fit (Figure 6) is insensitive to D varying between 0 and 5 cm^{-1}.

For **2**, the effective magnetic moment of 6.08 μ_B ($\chi_M \cdot T$ = 4.629 cm^3·K·mol^{-1}) at 290 K increases monotonically with decreasing temperature reaching a broad maximum at 20−30 K with μ_{eff} = 6.39 μ_B ($\chi_M \cdot T$ = 5.1073 cm^3·K·mol^{-1}). Below 20 K, μ_{eff} starts to decrease reaching a value of 3.99 μ_B ($\chi_M \cdot T$ = 1.992 cm^3·K·mol^{-1}) at 2 K (Figure 6); it is clear that the magnetic properties of **2** are dominated by a ferromagnetic exchange interaction between four $^3A_2$ nickel(II) ions as propagated by bridging phenoxides and methoxides. The structural parameters of **2** strongly suggest a lower symmetry than T_d (idealized D_{2d}) for the molecule. The magnetic analyses were carried out using either a two-J or three-J model based on the diagram shown in Scheme 2.



Scheme 2

The data were fit initially by using a higher symmetry model, i.e. $J_{12} = J_{34}$ and $J_{13} = J_{14} = J_{24} = J_{23}$, which yielded a good fit (not shown) with $J_{12} = J_{34}$ = +1.5 cm^{-1}, $J_{13} = J_{14} = J_{24} = J_{23}$ = +0.25 cm^{-1}, g = 2.133, D = 14.8 cm^{-1}. We discarded this solution as the zero-field splitting D is unusually large for a six-coordinate $^3A_2$ Ni^{II} ion.[22] We therefore fitted the data with three different exchange parameters, which also corroborate with three different types of faces present in the Ni_4O_4 cubane core of **2**. The best fit parameters are: $J_{12} = J_{34}$ = +0.47 cm^{-1}, $J_{13} = J_{24}$ = +4.25 cm^{-1}, $J_{14} = J_{23}$ = −1.45 cm^{-1}, g = 2.122 and D = 0 (fixed). The most important parameter in the magnetostructural correlation of the Ni_4O_4 cubane cores has been described in the literature[16] to be the averaged Ni−O−Ni angle of a cubane face. A ferromagnetic exchange interaction is observed when this angle is close to orthogonality. On the other hand, Ni−O−Ni angles in the vicinity of, and larger than, 99° lead to an antiferromagnetic interaction. Thus, the strongest ferromagnetic coupling, $J_{13} = J_{24}$ = +4.25 cm^{-1}, should be associated with the average Ni(1)−O−Ni(3) angle of 99.0°, which is not in agreement with the magnetostructural correlation reported in the literature.[16] This suggested that a better fitting model should be used. We therefore fitted the data by again using three different exchange parameters, but with the following constraints: J_{12}, J_{13} and $J_{14} = J_{24} = J_{23} = J_{34}$, as three different ranges of average Ni−O−Ni angles of 96°, 97−98° and 99° are present in **2**. The best fit obtained with the parameter set J_{12} = +8.0 cm^{-1}, $J_{14} = J_{24} = J_{23} = J_{34}$ = +0.9 cm^{-1}, J_{13} = −3.95 cm^{-1}, g = 2.120, D = 0 (fixed) is shown as a solid line in Figure 6. The differences and nature of the signs of the exchange parameters are in full agreement with the Ni−O−Ni angle correlation and support the three-J model used, which takes into account the reduced symmetry of the cubane core observed in the X-ray structure of **2**. Thus, these results for **2** predict a switch from ferromagnetic to antiferromagnetic coupling only for Ni−O−Ni angles above 98°.

Recently it has been demonstrated[16i] that the major contributor to the superexchange constants observed in $[Ni_4(OR)_4]^{4+}$ cubanes is the Ni−O−Ni angle. Accordingly, a linear correlation between J and the Ni−O−Ni angle has

been reported.[16i,16m] We have also plotted the observed J values for **2** and other structurally characterized $[Ni_4(OR)_4]^{4+}$ cubanes against average Ni−O−Ni angles (Figure 7). The solid line drawn as a guide for the eyes shows a fairly good correlation between J and these angles. This guide allows us to notice that the antiferromagnetic interactions ($-J$) fall fairly well on the correlated line with respect to Ni−O−Ni angles. In contrast, the positive J values scatter appreciably. This is not surprising considering the high tolerance attached in general to the positive J values (ferromagnetic interactions) evaluated through simulation of the susceptibility data.

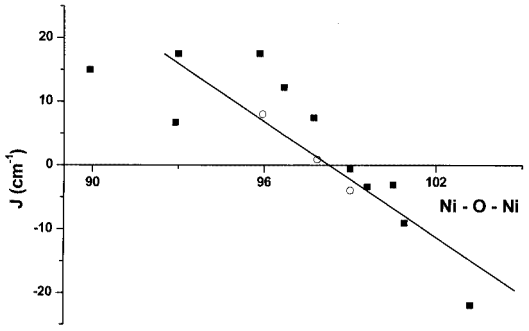


Figure 7. A plot of average Ni−O−Ni angles vs. the exchange interactions (J); closed circles are literature data and open circles are from this work; the solid line is drawn only as a guide

The non-zero magnetic moment of 3.99 μ_B at 2 K and the broad maximum with μ_{eff} = 6.39 μ_B at 20−30 K indicate that **2** has a complicated low-lying magnetic structure with a non-diamagnetic ground state smaller than the spin state of S_t = 4 expected for a ferromagnetically coupled tetranuclear nickel(II) moiety (S_{Ni} = 1). The ground state can be determined by examining the magnetization of the compound at low temperatures as a function of the applied magnetic fields. We have performed magnetization measurements at applied magnetic fields of 1, 4 and 7 T. The field-dependent magnetizations as a function of temperature, and their simulations, are depicted in Figure 8. It is clear from Figure 8 that the saturated magnetization value reaches a value of approximately 3.035 in the temperature range 2.0−2.8 K at the highest field of 7 T. The simulated parameters are: J_{12} = +8.0 cm^{-1}, J_{13} = −3.95 cm^{-1}, J_{14} = J_{24} = J_{23} = J_{34} = +0.60 cm^{-1}, g = 2.12, $|D|$ = 3.0 cm^{-1}. These values agree well with those from the susceptibility measurements. As J_{12}, J_{13} and D are of similar magnitude, it is not possible to calculate the ground state in the form of an S_t value; S is not a good quantum number to describe the ground state, but rather M_S.

Variable-temperature magnetic data for **3** exhibit a steady decrease of μ_{eff} from 1.634 μ_B (χ_M·T = 0.3338 cm^3·K·mol^{-1}) at 290 K to 0.049 μ_B (χ_M·T = 0.03 × 10^{-3} cm^3·K·mol^{-1}) at 2 K, which is indicative of very strong intramolecular antiferromagnetic coupling. The experimental data were simulated with the parameter set J = −192.1 cm^{-1}, g = 2.055, TIP = 30 × 10^{-6}, P = 0 and is shown in Figure 6. The major factor controlling the exchange interactions in hydroxy-, alkoxy- and phenoxy-bridged copper(II) is the Cu−O−Cu bridge angle.[20,23] The average Cu−O−Cu bridge angle of 100.9° for **3** would result in an approximate J value of −250 cm^{-1} according to the empirical equation reported in the literature and it deviates appreciably from the experimentally determined value of −192 cm^{-1} for **3**. A possible reason for the weak exchange coupling in **3** may be the deviation from co-planarity within the central Cu_2O_2 ring. It seems plausible that the methoxide ion, with shorter Cu(1)−O(40) (1.911 Å) and Cu(2)−O(40) (1.905 Å) distances and a larger Cu(1)−O(40)−Cu(2) angle (102.43°) than those with the phenoxide ion, provides a better pathway for antiferromagnetic exchange coupling.[17]

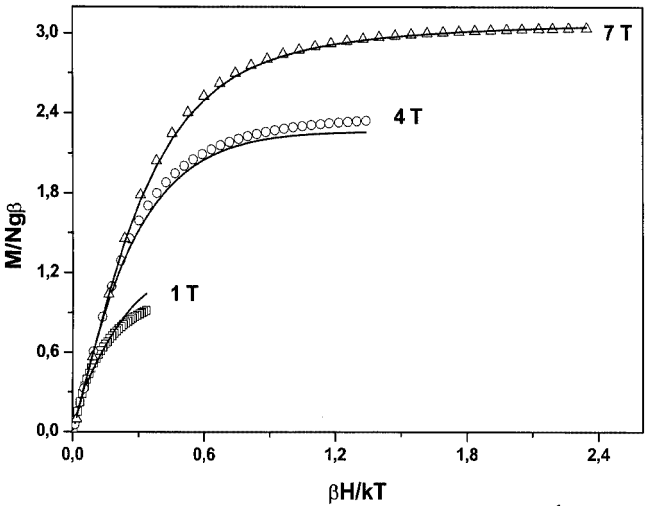

Figure 8. The field-dependent magnetizations of **2** as a function of temperature and their simulations; see text for the parameters

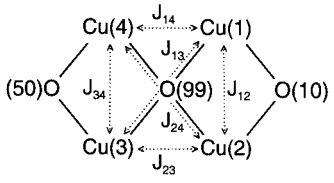
The effective magnetic moment μ_{eff}/molecule for **4** of 2.768 μ_B (χ_M·T = 0.9582 cm^3·K·mol^{-1}) at 290 K decreases monotonically with decreasing temperature until it reaches a value of 0.133 μ_B (χ_M·T = 0.0022 cm^3·K·mol^{-1}) at 2 K, indicating dominant antiferromagnetic interactions between four $^2B_2$ copper(II) ions; the data clearly show an S_t = 0 ground state for **4**.

Two different exchange pathways are possible for **4**: Cu-phenoxo-Cu and Cu-μ_4-oxo-Cu. Scheme 3 shows the connection of the copper centers through the phenoxo and the oxo groups.



Scheme 3

As the Cu(3)/Cu(4) and Cu(2)/Cu(1) pairs are bridged by both phenoxo and oxo groups and the Cu(4)/Cu(1), Cu(2)/Cu(3), Cu(2)/Cu(4) and Cu(1)/Cu(3) pairs only through the oxo group, O(99), the experimental magnetic data were analyzed as a first approximation with a three-J model: J_{12} = J_{34}, J_{14} = J_{23} and J_{24} = J_{13}. In this model we have neglected the differences in the Cu−O−Cu angles. A very good fit

(not shown) was obtained with the following parameters: $J_{12} = J_{34} = -86.3$ cm^{-1}, $J_{14} = J_{23} = +40.8$ cm^{-1} and $J_{24} = J_{13} = -86.1$ cm^{-1}, $g = 1.976$, $D = 0$ (fixed), $P = 0.007$ and TIP $= 240 \times 10^{-6}$ which imply that the spin exchange is dominated by antiparallel coupling in **4**. The low g value and the positive coupling constants for both J_{14} and J_{23}, which represent the couplings between the copper centers with the angles Cu(4)−O(99)−Cu(1) (90.23°) and Cu(2)−O(99)−Cu(3) (122.37°), however, suggest that a better fitting model should be used. The data were consequently fitted to a more accurate model, again using a three-J model but with a different constraint based on the three ranges of Cu−O−Cu angles, 90.2, 99.12−99.98° and 120.30−122.37°. Thus, the following correlations between the six coupling constants depicted in Scheme 3 were used to fit the experimental data: $J_{12} = J_{34}$, $J_{23} = J_{24} = J_{13}$ and J_{14}. The fit shown in Figure 6 was obtained with $J_{12} = J_{34} = -122.3$ cm^{-1}, $J_{23} = J_{24} = J_{13} = -90.0$ cm^{-1} and $J_{14} = 0$, $g = 2.088$, $P = 0.003$, TIP $= 240 \times 10^{-6}$ and $D = 0$ (fixed). The susceptibility data consistent with this data set were found to be relatively insensitive to J_{14}, but very sensitive to J_{12} and J_{23}; J_{14} values lying in the range −20 to +20 cm^{-1} have no influence on the quality of simulation.

For copper(II) centers bridged by a ligand oxygen atom (oxo, hydroxo, alkoxo, phenoxo, etc.), a linear relationship of exchange coupling J with the average Cu−O−Cu angles in the Cu_2O_2 ring has been reported.[17,20,23] We note that although a J_{12} value of −122 cm^{-1} assigned to an angle of 99.5° does not deviate significantly from the reported linear relationship, the J_{23} value of −90.0 cm^{-1} deviates remarkably. This is not very surprising as the electronic structures of the μ-OR and μ_4-O groups are clearly different. J_{14} is nondeterminant for **4** within the measured temperature range 2−290 K.

Electrochemistry

Electrochemical voltammetric measurements (cyclic voltammetry, CV, and square-wave voltammetry, SQW) were performed with the complexes in CH_2Cl_2 solutions containing 0.1 M $TBAPF_6$. The copper(II) complexes **3** and **4** show very similar behavior. They exhibit an oxidation wave at +0.490 and +0.530 V, vs. Fc^+/Fc for **3** and **4**, respectively. The waves have a reversible appearance, although the peaks in CV and SQW are broad; the peak separation of the oxidative and reductive peaks in the CVs is relatively high (0.110 V even at low scan rates) and in SQW shoulders on the forward and reverse peaks are discernible. This leads us to assume that each of the complexes is oxidized at two different sites with redox potentials that differ somewhat in less than 0.1 V. Since a copper(II) oxidation is not feasible at such low potentials, we assign these redox processes to ligand-centered oxidation yielding two phenoxyl radicals in each complex.

The nickel(II) complexes **1** and **2** are oxidized in a similar potential range. There are waves at +0.470 (**1**) and +0.440 V (**2**), which are preceded by broad peaks (with shoulders in the SQW) at +0.270 V for **1** and +0.153 V for **2**. Additionally, with increasing scan rate the oxidation and re-reduction peaks in the CV were found to split into two components. We assign this more complex behavior to an involvement of the nickel(II) ion in the redox processes leading to radical through oxidation. Ligand-centered oxidation to a radical is inferred from the occurrence of oxidation processes at potentials that are similar, irrespective of the nature of the central metal ion. Involvement of central nickel ions in oxidation processes of radical complexes was documented earlier in detail,[24] including digital simulations of complex cyclic voltammograms.

Concluding Remarks

That single-atom *O*-bridging of urea in a dinuclear nickel(II) complex can be achieved with suitably designed ligands has been demonstrated by isolation of **1**. Unfortunately, **1** is not able to catalyze the ethanolysis of urea [conditions: 1 mmol of **1** and 50 mmol of urea in ethanol (10 mL) was refluxed at 80 °C for 14 hours, which was then worked up for the GC analysis] to form ethyl carbamate presumably because of the hydrogen bonding network involving urea in **1**, which is also maintained in solution. Due to the presence of a stable hydrogen-bonded structure in solution, there is no possibility of intramolecular OH^- delivery to the π*-orbital of urea, as has been proposed for the mechanism of action of urease.[13e,15] It is noteworthy that the bond lengths within the coordinated urea,[14] bridging or nonbridging, are very similar, in contrast to the compound which exhibits catalytic activity.[14g] In the latter compound two different C−N bond lengths — 1.348(4) and 1.303(4) Å — are observed within the coordinated urea.

Complex **2** contains the low-symmetry cubane core $[Ni_4(\mu_3\text{-phenoxide})_2(\mu_3\text{-methoxide})_2]^{4+}$ with differing Ni···Ni distances and Ni−O−Ni angles, resulting in three types of Ni_2O_2 faces. The observation of three discrete exchange parameters for **2** is consistent with the lower symmetry of the cubane than that of all others but one[16m] reported in the literature.[16] Figure 7, a plot of J vs. Ni−O−Ni angles for all structurally characterized Ni_4O_4 cubane cores, irrespective of their symmetry, exhibits a large variation of J values within a small span of Ni−O−Ni angles (90−103°). This figure also indicates that the symmetry of the cubane core has a profound effect on the magnetostructural correlation. It is likely that other structural parameters like Ni···Ni and Ni−O distances take the upper hand in the magnetostructural correlation for the low-symmetry cubane core. Thus, more such distorted cubane-type Ni^{II} complexes are needed to resolve this open question.

Complex **3** containing a (μ-methoxo)(μ-phenoxo)dicopper(II) unit belongs to a ubiquitous class of coordination complexes of copper(II). It is pertinent at this point to compare the magnetic properties of **3** with these related dicopper(II) complexes. Regardless of the coordination geometry of the copper centers — square planar, square pyramidal or trigonal bipyramidal — all complexes with a $Cu^{II}_2(\mu\text{-OPh})(\mu\text{-OCH}_3)$ core as in **3** are antiferromagnetic and show relatively moderate to strong spin coupling with values ran-

ging from −47 to −315 cm^{-1}. These observations extend over eight compounds,[17] in which it has been demonstrated that the $Cu(d_z^2)-O-Cu(d_z^2)$ pathway would yield weaker antiferromagnetic coupling than in related $Cu(d_{x^2-y^2})-O-Cu(d_{x^2-y^2})$ systems. The $-J$ values for six of these compounds lie in the range 150−224 cm^{-1}. The evaluated J value of −192 cm^{-1} for **1** falls at the upper end of the observed range and is in agreement with the paramagnetic copper(II) centers with $(d_{x^2-y^2})^1$ magnetic orbitals. The sum of the angles around the phenoxo-oxygen, O(10), is 357.7°, a planar phenoxo group capable of transmitting spin exchange effectively.

Complex **4**, $[L_2Cu_4(\mu_4\text{-}O)]$, is the first example of a (μ_4-oxo)tetranuclear copper(II) complex without any bridging ligand between the tetrahedral edges. In accordance with the three averaged Cu−O−Cu angles of 90°, 99.5° and 121.3°, a three-J model was used to analyze the magnetic data. It is interesting to note that an exchange coupling constant J_{14} corresponding to the Cu−O−Cu angle of 90° could not be evaluated.

Experimental Section

Materials and Physical Measurements: Reagent or analytical grade materials were obtained from commercial suppliers and used without further purification, except those for electrochemical measurements. Elemental analyses (C, H N) were performed by the Microanalytical Laboratory Dornis & Kolbe, Mülheim, Germany. Fourier transform infrared spectroscopy on KBr pellets was performed on a Perkin−Elmer 2000 FT-IR instrument. Electronic absorption spectra in solution were measured on a Perkin−Elmer Lambda 19 spectrophotometer. Magnetic susceptibilities of *powdered samples* were recorded on a SQUID magnetometer in the temperature range 2−295 K with an applied field of 1 T. Experimental susceptibility data were corrected for the underlying diamagnetism using Pascal's constants and for the TIP contributions. Cyclic voltammetric and coulometric measurements were performed on EG&G equipment (potentiostat/galvanostat model 273A). Mass spectra were obtained with either a Finnigan MAT 8200 (electron ionization, EIMS) or a MAT 95 (electrospray ESI-MS) instrument. A Bruker DRX 400 instrument was used for NMR spectra. Instrumental conditions for liquid chromatography are as follows: Shimadzu SPD-10 AV, Nucleodur-5-C_{18} Sel 220 column, UV-280 nm, eluent = CH_3CN (0.8 mL/min), room temperature, sample size 5 μL, recorder 0.5 cm/min.

H_3LtBu: 6-Amino-2,4-di-*tert*-butylphenol (4.4 g; 20 mmol) was added to a solution of 2,6-diformyl-4-methylphenol (1.6 g, 10 mmol) in methanol (70 mL), and the resulting solution was refluxed for 1 h, during which the color changed to deep red, and a yellow microcrystalline solid precipitated out. The solution was cooled, filtered and the solid was washed with cold methanol, and air-dried. Yield: 5.1 g (ca. 90%). The purity of the ligand was checked by liquid chromatography: Retention time of 13.2 min for the eluent CH_3CN with a rate of 0.8 mL/min. EI-MS: m/z = 570. ^1H NMR ($CDCl_3$): δ = 8.94, 7.26 (6 H, aromatic), 7.12 (2 H, −CH=N-), 2.38 (3 H, CH_3), 1.43 (18 H, tBu), 1.32 (18 H, tBu) ppm. IR (KBr disk): $\tilde{\nu}$ = 3523 cm^{-1}, 3492, 3348w, 2954, 2868s, 1625m, 1580m, 1482s, 1456s, 1361s, 1250s, 987s, 960s, 867m. *For the sake of simplicity the ligand is denoted by H_3L without the suffix tBu.* UV/Vis (CH_2Cl_2): λ_{max} (ε) = 270 nm (18600 $M^{-1}\cdot cm^{-1}$), 306 (17700), 401 (21800). UV/Vis [CH_2Cl_2 in the presence of eight equivalents of $(Bu_4N)OCH_3$]: λ_{max} (ε) = 300 nm (sh), 350 (sh), 496 (13900 $M^{-1}\cdot cm^{-1}$).

$[LNi^{II}_2(NH_2CONH_2)(OAc)(MeOH)_2]\cdot 4.5CH_3OH$ (1): $Ni(CH_3COO)_2\cdot 4H_2O$ (0.24 g; 1 mmol), CH_3COONa (0.16 g, 2 mmol) and urea (0.18 g, 3 mmol) were dissolved in methanol, and a solution of the ligand H_3L (0.28 g, 0.5 mmol) in dichloromethane (30 mL) was added. The resulting solution was refluxed for 15 min and filtered to remove any solid particles. The solution was allowed to evaporate slowly at ambient temperature to yield orange-red crystals. Yield: 0.24 g (60%). $C_{46.5}H_{80}N_4Ni_2O_{12.5}$ (1012.54): calcd. C 55.16, H 7.91, N 5.53, Ni 11.59; found C 55.8, H 7.4, N 6.0, Ni 11.7. MS-ESI pos. (in CH_2Cl_2): m/z = 743.5 $[M - (NH_2CONH_2)(CH_3OH)_2]^+$ (100%). EI-MS indicates the presence of both acetate and urea. IR (KBr disk): $\tilde{\nu}$ = 3586w cm^{-1}, 3382m, 3139m, 2950s, 2965m, 1670m, 1654m, 1568s, 1469s, 1444s, 1410s, 1250s, 1159m, 831m. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 329 nm (14770 $M^{-1}\cdot cm^{-1}$), 464 (16900), 779 (19), 858 (27), 1284 (ca. 12).
Compound **1** can also be obtained from **2** by addition of urea and refluxing the resulting solution.

$[(LH)_2Ni^{II}_4(OMe)_2(OAc)_2(MeOH)_2]\cdot 3CH_2Cl_2$ (2): A solution of methanol (15 mL) containing $Ni(CH_3COO)_2\cdot 4H_2O$ (0.24 g, 1 mmol) and CH_3COONa (0.24 g, 3 mmol) was added to a solution of the ligand H_3L (0.28 g, 0.5 mmol) in dichloromethane (30 mL). The resulting solution was refluxed for 15 min, then cooled and filtered. On reduction of the volume of the filtrate orange-red microcrystals separated out. X-ray quality crystals were obtained by recrystallization from a dichloromethane/methanol mixture. Yield: 0.19 g (47%). $C_{82}H_{116}N_4Ni_4O_{14}$ (1616.60): calcd. C 60.92, H 7.23, N 3.47, Ni 14.52; found C 58.9, H 7.0, N 3.2, Ni 13.1. EI-MS: m/z = 714−720 (100) $[LNi_2(OCH_3)^+]$. IR (KBr disk): $\tilde{\nu}$ = 3440br cm^{-1}, 2955s, 1624s, 1552m, 1477s, 1446s, 1410s, 1259s, 1039s, 805m. UV/Vis (CH_2Cl_2): λ_{max} (ε): 331 nm (40300 $M^{-1}\cdot cm^{-1}$), 405 (32300), 474 (40600), 917 (26).

$[LCu^{II}_2(OCH_3)(THF)_2]\cdot 2THF$ (3): H_3L (0.29 g, 0.5 mmol), $Cu(ClO_4)_2\cdot 6H_2O$ (0.37 g, 1 mmol) and NEt_3 (0.3 mL) were added to a methanol/dichloromethane (1:3) solvent mixture, and the resultant solution refluxed for 0.5 h. The deep-red solution yielded an orange-red microcrystalline solid on slow evaporation of the solvent at ambient temperature. Yield: 0.13 g (70%). $C_{38}H_{50}Cu_2N_2O_4$ (725.92): calcd. C 62.87, H 6.94, N 3.86, Cu 17.51; found C 63.1, H 6.9, N 3.8, Cu 17.4. X-ray quality crystals were obtained by recrystallization with a THF/CH_3OH solvent mixture. EI-MS: m/z = 726 (100) $[LCu_2(OCH_3)]$; a clear indication of the presence of THF. IR (KBr disk): $\tilde{\nu}$ = 2954s cm^{-1}, 2867m, 2816w, 1597m, 1557m, 1474s, 1445s, 1256s, 1159s, 1077m, 830m. UV/Vis (CH_2Cl_2): λ_{max} (ε): 486 nm (17100 $M^{-1}\cdot cm^{-1}$).

$[L_2Cu^{II}_4(\mu_4\text{-}O)]\cdot 3.3CH_2Cl_2\cdot 0.7CH_3CN$ (4): A solution of the ligand H_3L (0.29 g; 0.5 mmol) $Cu(ClO_4)_2\cdot 6H_2O$ (0.37 g; 1 mmol) and NEt_3 (0.3 mL) in acetonitrile/dichloromethane (1:3) was refluxed for 0.5 h and then kept at room temperature to allow the separation of an orange-red microcrystalline substance, which was recrystallized from a CH_3CN/CH_2Cl_2 mixture to yield X-ray quality crystals. Yield: 0.21 g (60%). $C_{74}H_{94}Cu_4N_4O_7$ (1405.76): calcd. C 63.23, H 6.74, N 3.99, Cu 18.08; found C 62.4, H 6.9, N 4.0, Cu 17.8. EI-MS: m/z = 1402 $[M^+]$. IR (KBr disk): $\tilde{\nu}$ = 2952s cm^{-1}, 2904s, 2867m, 1593m, 1557m, 1467s, 1445s, 1409m, 1360m, 1317m, 1254s, 1200m, 1159s, 1077m, 829m, 564m, 539m, 510m. UV/Vis (CH_2Cl_2): λ_{max} (ε): 484 nm (35700 $M^{-1}\cdot cm^{-1}$), ca. 680sh (ca. 430).

Compound **4** can also be obtained by refluxing **3** in CH_3CN/CH_2Cl_2 for 0.5 h.

X-ray Crystallographic Data Collection and Refinement of the Structures: A single crystal of **1** (orange-red), **2** (red), **3** (orange-red) or **4** (orange-red) was coated with perfluoropolyether, mounted on a glass fiber and placed in a Kappa-CCD diffractometer equipped with a cold nitrogen stream at 100 K. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used. Crystallographic data of the compounds **1**, **2** and **4** are listed in Table 1. Cell constants were obtained from a least-squares fit of the diffraction angles of several thousand strong reflections. Intensity data were corrected for Lorentz and polarization effects. The data sets of **1** and **2** were corrected for absorption, whereas the intensities of **4** were left uncorrected. The Siemens ShelXTL software package (G. M. Sheldrick, Universität Göttingen) was used for solution, refinement and artwork of the structures; the neutral atom scattering factors of the program were used. All structures were solved and refined by direct methods and difference-Fourier techniques. Non-hydrogen atoms were refined anisotropically, and hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters.

CCDC-191305 (**1**), -191306 (**2**), and -191307 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Financial support from the DFG (Grant: Priority program Ch111/2−1), the Max-Planck Society and Fonds der Chemischen Industrie is gratefully acknowledged. Thanks are due to Mrs. H. Schucht, Mrs. P. Höfer and Mr. A. Göbels for skilful technical assistance.

(Allenylidene)ruthenium Complexes with Redox-Active Substituents and Ligands

Stephan Hartmann,[a] Rainer F. Winter,*[a] Birgit M. Brunner,[a] Biprajit Sarkar,[a] Axel Knödler,[a][‡] and Ingo Hartenbach[a][‡]

Keywords: Electrochemistry / Sandwich complexes / Ruthenium / Spectroelectrochemistry

We describe the allenylidene complexes $[TpL_2Ru{=}C{=}C{=}CPhR]^+ SbF_6^-$ [Tp = $HB(pz)_3^-$, L_2 = 2 PPh_3 or 1,1′-bis(diphenylphosphanyl)ferrocene (dppf), R = Ph or ferrocenyl] and their spectroscopic and electrochemical characteristics. Three of these compounds possess redox-active, ferrocene-based substituents or ligands – that are oxidized at lower potentials than the ruthenium center itself – attached either to the terminal carbon atom of the allenylidene ligand or to the ruthenium atom. The Fc/Ph-substituted complexes **3a** and **3b** provide unique examples of hindered rotation of the allenylidene substituent around the M=C bond. For **3a** (L_2 = 2 PPh_3), two isomers differing in the orientation of the vertically aligned, unsymmetrically substituted allenylidene ligand are discernible even at 388 K. The dppf-substituted congener **3b** has the allenylidene ligand in a horizontal orientation and exhibits a rotational barrier, as determined by dynamic ^{31}P NMR spectroscopy, of $\Delta G^{\neq}$ = 47 kJ/mol at T_C = 238 K. The changes in the spectroscopic and electrochemical properties upon replacement of the PPh_3 by a dppf ligand and the Ph by an Fc moiety can be explained in terms of the bonding within these systems. These effects are attenuated when the ferrocene-based redox tags are oxidized, as shown by IR and UV/Vis spectroelectrochemistry. Thus, infrared spectroelectrochemistry reveals a blue shift of the allenylidene stretch upon oxidation of the dppf ligand, while oxidation of the ferrocene covalently linked to the unsaturated C_3 ligand has the opposite effect. Oxidation of the ruthenium atom influences the bonding within the unsaturated ligand more profoundly. Results from IR spectroelectrochemistry point to a vinylidene structure in the Ru^{III} state. Reduction enhances the contribution of alkynyl-type resonance forms to the overall bonding description, as also shown by IR spectroelectrochemistry. For the ferrocenyl-substituted allenylidene complexes, oxidation and reduction result in bleaching of the intense optical low-energy absorption band attributed to a ferrocenyl-to-allenylidene charge-transfer process. The EPR spectra of the paramagnetic reduced forms of these complexes also indicate spin delocalization into the aryl substituents attached to the allenylidene ligand. The complexes Tp(dppf)RuCl and $[Tp(dppf)Ru{=}C{=}C{=}CPh_2]^+ SbF_6^-$ were also characterized by X-ray crystallography.

Introduction

In connection with our interest in the reactivity of primary butatrienylidene intermediates *trans*-$[Cl(L_2)_2Ru{=}C{=}C{=}C{=}CH_2]^+$ (L_2 = chelating diphosphane ligand) we have established new routes to heteroatom-substituted allenylidene complexes *trans*-$[Cl(L_2)_2Ru{=}C{=}C{=}C(ER_n)(R')]^+$, in part with unprecedented (ER_n = SR, SeR) substitution patterns.[1,2] These rely either on the regioselective addition of protic nucleophiles to the terminal C=C double bond of the unsaturated ligand or on the regioselective addition of aprotic, allyl-substituted nucleophiles to carbon atom C-γ. In this latter case, the initial addition is followed by a Cope-type rearrangement of the resulting 3-heterohexa-1,5-diene moiety.[1−4] The former approach had also been employed by Bruce and others in the synthesis of amino-substituted allenylidene complexes $[Cp(PPh_3)_2Ru{=}C{=}C{=}C(NR_2)(CH_3)]^+$ [5,6] and the related alkoxy-substituted iron derivative $[Cp^*(dppe)Fe{=}C{=}C{=}C(OCH_3)(CH_3)]^+$.[7] Characteristic attributes of allenylidene complexes include: (i) the asymmetric valence band known as the "allenylidene stretch", giving rise to highly intense absorption bands in their infrared spectra, (ii) low-field signals for the carbon atoms of the unsaturated ligands in their ^{13}C NMR spectra,[4,8] and (iii) their optical spectra, which feature two bands in the visible region. The band at lower energy is due to the forbidden HOMO → LUMO transition and so is only weak, while that at higher energy is much more intense and represents the allowed transition from the lower lying second-highest occupied molecular orbital HOMO-1. Systematic studies on the complexes *trans*-$[Cl(L_2)_2Ru{=}C{=}C{=}C(ER_n)(R')]^+$ revealed that their spectroscopic and electrochemical properties critically depend on the substituent ER_n (ER_n = NR_2, SR, SeR, aryl) and the diphosphane ligands L_2. Replacement of amino substituents NR_2 by the less potent π-donors SR, SeR, or aryl groups induces a systematic red shift of the electronic and infrared absorption bands and a low-field shift of the resonance signals of the

[‡] X-ray structure determination

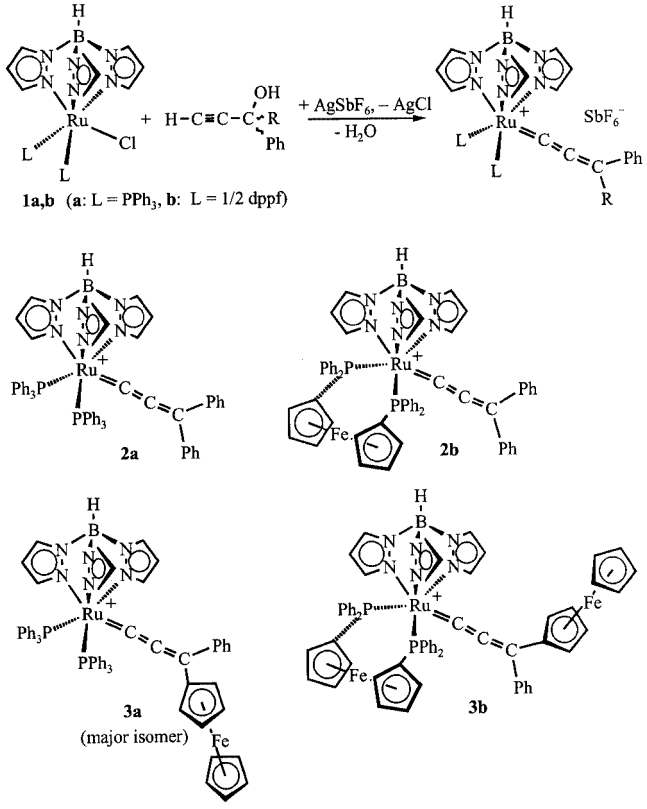
metal-bound carbon atom C-α and the carbon atom C-β adjacent to it.[1,2] Electrochemical investigations by cyclic voltammetry revealed a cathodic displacement of the half-wave potentials of the reduction and, albeit only to a minor degree, of the oxidation potentials upon substitution of NR_2 by SR, SeR, or aryl moieties. Broadly similar effects are observed when the π-acidity of the diphosphane chelate ligands is decreased. This mirrors the push-pull characteristics of these complexes, with the $ClRu(L_2)_2^+$ moiety acting as the donor and the allenylidene unit as the acceptor. One remarkable difference between the effects concomitant with ligand and substituent replacement is their effect on the redox potentials: replacement of the π-acidic ligands dppe and dppm by the more basic depe facilitates oxidation by more than 300 mV but leaves the reduction potential essentially unchanged. This has been taken as an indication of a ruthenium-based oxidation but a largely allenylidene-based reduction. Spectroelectrochemical experiments, monitoring the spectroscopic changes associated with bulk electrolysis by IR, UV/Vis, and EPR techniques, and results from quantum mechanical calculations strongly support this view.[1,4,9−11]

We have now turned our attention to allenylidene complexes with either an additional redox-active moiety attached to the C_3 ligand or a redox-active diphosphane ligand. These were chosen such that they would undergo reversible electron transfer at lower potentials than the parent allenylidene complex itself. This was to allow examination of the effect of variation of the electron density at each of these sites *within the same basic system*, without the need for additional ligand or substituent replacement. Since structural perturbations of the metallabutatriene chromophore associated with electron transfer at a peripheral site would be expected to be reasonably limited, the results from such studies should reflect the effects of changes in the electron density at these sites more truly than any substitution. In this respect, ferrocenyl-based systems are ideal candidates, as they are known to undergo facile and reversible oxidation at substantially lower potentials than the $Ru^{II/III}$ couple. We have already reported on the ferrocenyl-substituted allenylidene complexes *trans*-$[Cl(dppm)_2Ru{=}C{=}C{=}C(NMe_2)(C_2H_4Fc)]^+$ [Fc = $(\eta^5\text{-}C_5H_4)Fe(\eta^5\text{-}C_5H_5)$][12] and *trans*-$[Cl(dppm)_2Ru{=}C{=}C{=}C(SeFc)(C_2H_4CH{=}CH_2)]^+$.[2] In the amino-substituted complex the insulating ethylene spacer separating the allenylidene chromophore from the redox-active ferrocenyl unit prevents effective conjugation between these entities. The spectroscopic changes associated with ferrocene oxidation are therefore small. In the seleno-substituted allenylidene complex, the redox-active group is directly attached to the heteroatom. Electron transfer from this site induces more substantial spectroscopic changes, with a red shift of the IR frequency by 10 cm^{-1}. Here we present our results on a different class of allenylidene complexes based on $TpRuL_2$ units, as pioneered by Puerta and Hill [Tp = $HB(pz)_3^-$, tris(pyrazolyl)borate].[13−15] These complexes offer the opportunity to introduce ferrocene-based redox tags either into the allenylidene ligand or into the diphosphane chelate ligand − or into both − while maintaining the same overall structure. We compare our results for these systems with those for the corresponding "parent" diphenylallenylidene complex $[Tp(PPh_3)_2Ru{=}C{=}C{=}CPh_2]^+$, which lacks any additional redox-active moiety, as a reference system.[13]

Results and Discussion

Synthesis, Molecular Structures, and Spectroscopic Properties

The synthesis of allenylidene complexes containing the $[TpRuL_2]$ moiety is straightforward and follows the method elaborated by Hill and co-workers.[13] Treatment of a CH_2Cl_2 solution of $[TpRuL_2Cl]$ (L_2 = 2 PPh_3: **1a**; L_2 = dppf: **1b**) with the appropriate propargylic alcohol PhR(OH)CC≡CH [R = Ph, Fc; Fc = $(\eta^5\text{-}C_5H_4)Fe(\eta^5\text{-}C_5H_5)$] in the presence of $AgSbF_6$ gave the corresponding cationic allenylidene complexes $[TpL_2Ru{=}C{=}C{=}CRPh]^+$ (**2a**−**3b**) in good to reasonable yields and as intensely purple-colored, microcrystalline solids (Scheme 1). In the course of these syntheses we obtained single crystals of [Tp(dppf)RuCl] and the corresponding diphenyl-substituted allenylidene complex $[Tp(dppf)Ru{=}C{=}C{=}CPh_2]^+$ (**2b**). Their molecular structures in the solid state were established by X-ray crystallography and are presented in Figures 1−3, while selected bond parameters are provided in Tables 1 and 2.



Scheme 1

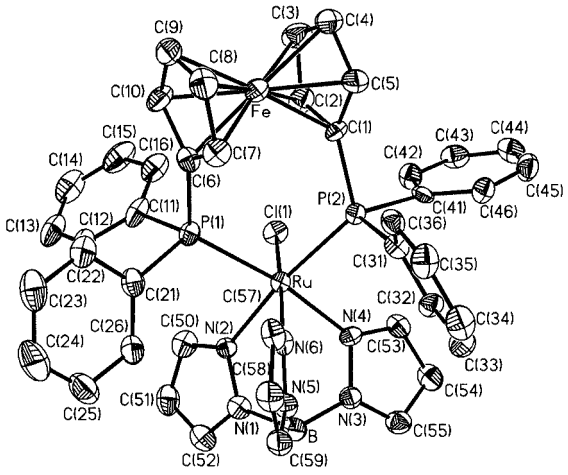


Figure 1. Structure of [Tp(dppf)RuCl] in the solid state

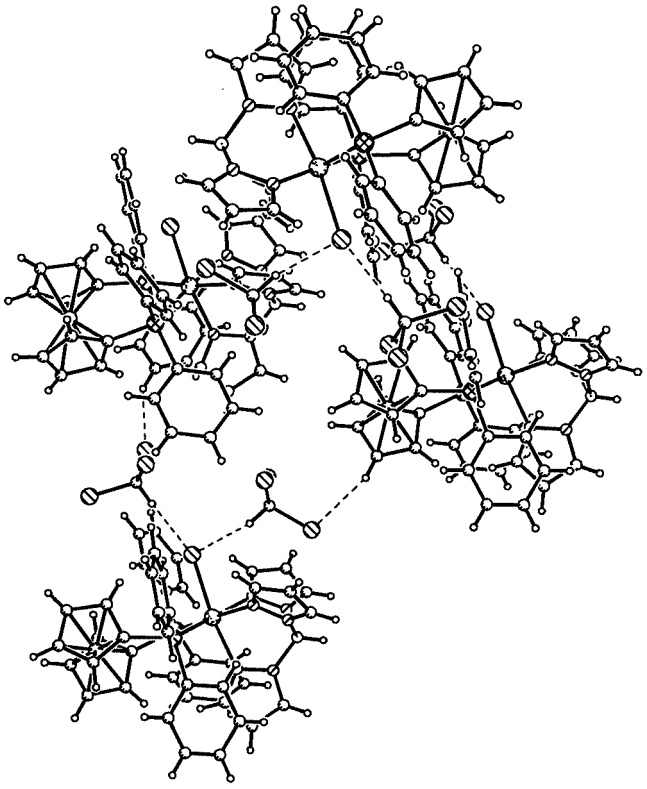

Figure 2. Intermolecular contacts between the chloride ligand and the solvate molecules of [Tp(dppf)RuCl]

[Tp(dppf)RuCl] (**1b**) crystallizes as a bis(solvate) from chloroform, and a plot of its structure is presented as Figure 1. Complex **1b** displays bond parameters (Table 1) very similar to those of the PPh_3-substituted congener.[17] The P(1)−Ru−P(2) bite angle of the chelating dppf ligand is only slightly smaller than the P−Ru−P angle in the other complex [99.23(6) against 101.9(1)°] and induces a compression of the opposite angle N(2)−Ru−N(4) to 81.9(2)°. All other angles between *cis*-disposed ligands are in the 85.0−93.8° range, while mutually *trans*-disposed ligands make angles of approximately 171° at the metal atom.

The close similarity between [Tp(dppf)RuCl] and [Tp(PPh_3)$_2$RuCl] is also evident from the essentially identical Ru−P and Ru−Cl bond lengths in these two complexes [2.336(2), 2.350(2) and 2.420(2) against 2.332(3), 2.349(3) and 2.409(3) Å]. As is often observed for complexes of the Tp ligand,[13,18,19] the nitrogen atom *trans* to the chloride ligand is closer to the metal center than those opposite to the π-accepting phosphane ligands. Both the cyclopentadienyl (Cp) rings of the dppf ligand are essentially planar, and the phosphorus atoms are situated in the plane of the ring to which they are attached. The ring centroids and the Fe atom make an angle of 178.2°, while the two rings adopt a staggered conformation and are rotated by 38° with respect to one another. The packing in the crystal lattice is stabilized by several inter- and intramolecular hydrogen bonds involving the solvate molecules, the chloride ligand, some nitrogen atoms of the pyrazolyl rings, and one hydrogen atom of each phenyl ring, as well as one of the Cp-hydrogen atoms of the dppf ligand. Intramolecular hydrogen bonds of 2.528 and 2.663 Å are observed between the *ortho*-hydrogen atom attached to C(26) and the nitrogen atoms N(1) and N(2). A similar contact is found for H(32a) − the hydrogen atom at C(32) − and N(4) (2.677 Å). The chloride ligand forms a pair of contacts to one of the *ortho*-hydrogen atoms of each of the adjacent phenyl rings, with a fairly short bond of 2.590 Å to H(42) and a weaker contact of 2.871 Å to H(16) on the other phenyl ring. The chloride ligand also forms strong intermolecular contacts to the protons of the two cocrystallized $CHCl_3$ solvate molecules, as evidenced by H···Cl distances of 2.393 and 2.423 Å. The solute molecules are additionally fixed through weaker interactions to hydrogen atoms on the aromatic substituents. Thus, one chloroform molecule makes a contact of 2.834 Å to one of the phenyl protons, while the other is 2.792 Å away from H(8a) at the 3-position of one of the Cp rings of the dppf ligand. Additional weaker interactions are observed between the other chlorine atoms of the cocrystallized solvent molecules and hydrogen atoms H(13) [3.292 Å to Cl(5), 3.249 Å to Cl(7)], H(14) [3.247 Å to Cl(2), 3.289 Å to Cl(4)], and H(43) [3.274 Å to Cl(3)] on the phenyl rings as well as to H(9) [3.175 Å to Cl(6)] on the Cp ring. The H-bridges resulting from the stronger intermolecular H···Cl contacts are shown in Figure 2.

The diphenylallenylidene complexes **2a** and **2b**, including the solid-state structure of compound **2a**, have already been reported by Hill.[13] We were able to obtain single crystals of the dppf-substituted congener **2b**, but these gave a data set of only poor quality, preventing meaningful discussion of bond lengths and angles within the allenylidene chain. We only note that, as in the chloro precursors **1a** and **1b**, the Ru−P bond lengths and the P−Ru−P angles are nearly identical for both allenylidene complexes [2.376(11) and 2.416(9) against 2.3779(7) and 2.4327(11) Å as well as 99.1(3) against 101.11 (3)°]. We also note that the terminal CPh_2 group of the allenylidene ligand lies approximately in the mirror plane of the molecule [the torsional angle N(2)−Ru−C(62)−C(81) is 18.5°] and roughly bisects the P−Ru−P angle. This orientation has been termed vertical. A plot of the structure is provided as Figure 3, while the most pertinent bond parameters are collected in Table 2.

Complexes **2a** and **2b** and their Fc-substituted congeners **3a** and **3b** have very similar spectroscopic characteristics in their IR and NMR spectra. These are compared in Table 3. Samples (as KBr pellets) display the C=C=C stretch of the unsaturated ligand as a very intense band at 1946 cm^{-1} for **3a** and at 1941 cm^{-1} for **3b**, which are some 5 cm^{-1} higher in energy than in the diphenyl-substituted complexes **2a** and **2b** (see also Table 3). Replacement of the dppf by the less basic PPh_3 ligands induces a blue shift of similar size. The observed effects, albeit small, match previous observations that the presence of a weaker π-donor at the terminal carbon atom C-γ (phenyl versus ferrocenyl) or of a more basic metal center at the opposite end of the metallabutatriene chain (the dppf versus two PPh_3 ligands) shifts the IR absorption of the allenylidene ligand to lower energies. This has been explained in terms of a larger contribution from the alkynyl-type resonance form **II** as opposed to the genuine cumulenylidene-type resonance form **I** (Scheme 2) when the metal center is more electron-rich and the substituents at C-γ are less able to support a positive charge adjacent to them.[1,2,4,20,21] In the light of the stability of the ferrocenylmethylene carbenium ion[22] the ferrocenyl substituent may be expected to stabilize the alternative alkynyl resonance form **III**, as indicated in Scheme 2, in line with the results from IR spectroscopy. We note here that Le Bozec et al. arrived at a similar conclusion in their study of [(C_6Me_6)-Cl(PMe_3)Ru=C=C=C(Ph)(Fc)]$^+$ PF_6^-, closely related to **3a** and **3b**.[23] The ^{13}C NMR spectra also bear witness to this notion. Comparison of the relevant data for the pairs of complexes **2a/3a** and **2b/3b** reveals that replacement of a phenyl by the more strongly electron-donating ferrocenyl substituent shifts the resonance signals of the carbon atoms of the allenylidene ligand to higher field by ca. 30, 25, and 8 ppm. The largest shift is observed for the metal-coordinated carbon atom C-α, while the terminal carbon atom C-γ − where the actual substitution occurs − is influenced least. The sign and relative magnitude of the observed effects agree well with results from previous studies on the allenylidene complexes *trans*-[Cl(L_2)$_2$Ru=C=C=C(ER_n)(R′)]$^+$ (ER_n = NR_2, SR, SeR, aryl, R′ = alkyl).[1,4,24]

The triphenylphosphane-substituted complex **3a** was found to exist as two isomers, as shown by the two sets of resonance signals for the carbon atoms of the cumulenylidene ligand. These are observed at δ = 287.0, 184.3, and 168.2 ppm for the major isomer and δ = 282.8, 180.5 and 169.1 ppm for the minor counterpart, and point to hindered rotation of the allenylidene ligand around the Ru=C bond. Each isomer exhibits a singlet resonance signal in the ^{31}P NMR spectrum. We therefore conclude that the plane of the terminal CR_2 unit of the allenylidene ligand runs parallel to the molecular symmetry plane and bisects the P−Ru−P angle, an orientation that has been termed vertical.[25] Scheme 3 offers a Newman-type projection along the Ru=C=C=C axis. The isomers differ in which of the Ph or the Fc substituents points toward the Tp and the

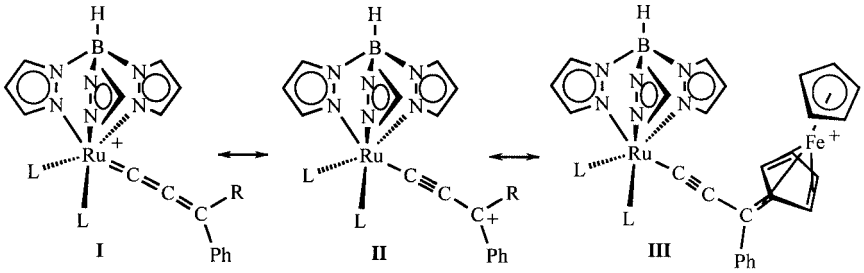
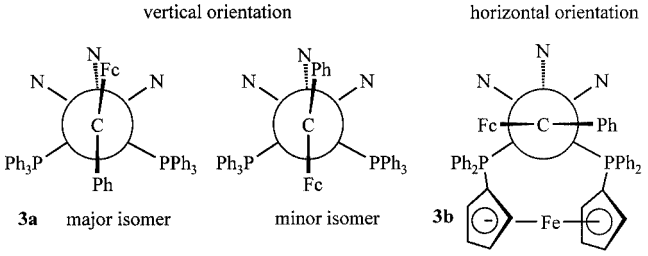


Scheme 2

phosphane ligands. We propose that the major isomer has the less bulky phenyl substituent oriented toward the PPh_3 ligands. By integration of the ^{31}P NMR resonance signals the isomeric distribution was established as 4:1. Unfortunately, we have not yet succeeded in growing X-ray quality crystals of this complex to support this view. We note, however, that both $[Tp(PPh_3)_2Ru{=}C{=}C{=}CPh_2]^+$ PF_6^- (**2a**) and its dppf analogue **2b** (vide supra) crystallize with the allenylidene ligand in just this orientation.[13]



Scheme 3

To the best of our knowledge, complex **3a** represents the first instance of an allenylidene complex in which the energy barrier to rotation of the allenylidene moiety is so high as to allow observation of two different rotamers at ambient temperature. Hindered rotations around M=C double bonds have, however, been noted in the related vinylidene complexes $\{M\}{=}C{=}CR_2$.[26−28] Experimentally measured energy barriers are usually of the order of 30−57 kJ/mol and depend on the substituents on the vinylidene ligand and the coordination environment at the metal center. More recent examples include ruthenium complexes of the tripodal $CH_3C(\eta^5\text{-}C_5H_4)(CH_2PPh_2)_2$ ligand, which coordinates the metal ion through its Cp ring and the two pendant phosphane side-arms ($\Delta G^{\neq} \approx 33$ kJ/mol for secondary vinylidene ligands and 44 kJ/mol for tertiary ones),[29] the dinuclear bis(vinylidene) manganese complex $[(\eta^5\text{-}C_5H_4Me)(dmpe)Mn{=}C{=}C(Ph)C(Ph){=}C{=}Mn(dmpe)(\eta^5\text{-}C_5H_4Me)]^{2+}$ ($\Delta G^{\neq} = 56.7$ kJ/mol),[30] and the cycloheptatrienylmolybdenum complex $[(\eta^7\text{-}C_7H_7)(dppe)Mo{=}C{=}CH_2]^+$ (dppe = $Ph_2PC_2H_4PPh_2$; $\Delta G^{\neq} = 51.9$ kJ/mol).[31] The highest activation energy for vinylidene rotation of which we are aware has been observed for the rhenium complexes $[(\eta^5\text{-}C_5H_5)(NO)(PPh_3)Re{=}C{=}CPhMe]^+$ and $[(\eta^5\text{-}C_5H_5)(NO)(PPh_3)Re{=}C{=}CH_2]^+$ ($\Delta G^{\neq} = 77.9$ kJ/mol).[32] The butyl/methyl-substituted vinylidene complex $[(\eta^7\text{-}C_7H_7)(dppe)Mo{=}C{=}C(C_4H_9)(CH_3)]^+$ displays separate resonance signals for the two different rotamers at 348 K.[31] The rotational barriers are usually thought of as being more steric than electronic in origin. Calculations on (vinylidene)-metal complexes indicate that the intrinsic (electronic) energy difference between the vertical and horizontal rotamers amounts to no more than 10−20 kJ/mol.[25,33] The energy barrier interconnecting them is thus expected to be fairly low. In view of the further remoteness of the terminal methylene group from the metal−ligand array it is therefore not surprising that allenylidene complexes present even lower rotational barriers than their vinylidene counterparts, and so the observation of a truly significant rotational barrier in an allenylidene ligand is quite unusual. This prompted us to study the dynamic behavior of **3a** in 1,2-$D_2C_2Cl_4$ solution by ^{31}P NMR spectroscopy. Upon warming there was a very slight shift of the two singlet resonance signals, but no broadening was observed up to 388 K, at which point **3a** decomposed.

The sterically less hindered complex **3b** exhibits one sharp singlet in its room-temperature ^{31}P NMR spectrum.

When a solution in CD_2Cl_2 is cooled, this signal starts to broaden at 258 K. At 233 K, splitting into two equally intense, broad signals is observed, and at even lower temperatures the four resonance lines of a well-resolved AB spectrum are seen. The coupling constant − 30.65 Hz at 213 K − is typical of *cis*-disposed phosphane ligands (Figure 4). These findings would place the free energy of activation for rotation of the allenylidene ligand at 47 kJ/mol at the coalescence temperature of 238 K. They also indicate a horizontal orientation of the allenylidene ligand with the substituents on the terminal carbon atom orthogonal to the symmetry plane of the [TpRuL$_2$] moiety. This is in sharp contrast to the vertical arrangement proposed for the bis(triphenylphosphane)-substituted counterpart **3a**. In the absence of X-ray data we can only speculate that in the vertical orientation the substituents on the terminal carbon atom would each approach the ferrocenyl backbone of the dppf ligand such that the horizontal orientation would be preferred on steric grounds (see Scheme 3).

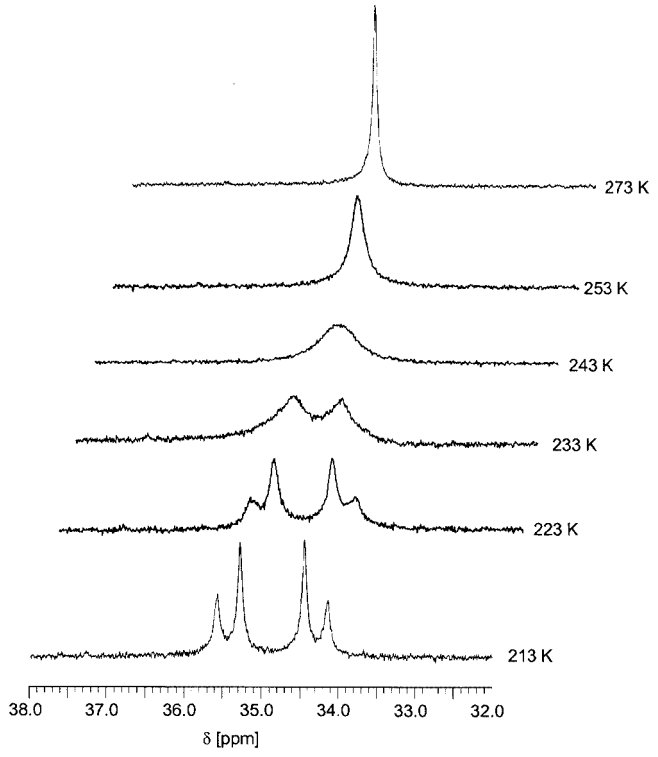


Figure 4. Dynamic ^{31}P NMR spectroscopy of compound **3b** in CD_2Cl_2 solution

In the visible range the electronic spectra of the intensely colored complexes **2a** and **3a** are each dominated by a strong absorption band, at 527 (**2a**) or 522 nm (**2b**) in CH_2Cl_2 solution. This band is only very slightly solvatochromic, shifting to somewhat higher energies in the more polar solvent CH_3CN. For related allenylidene complexes of the *trans*-[Cl(L$_2$)$_2$Ru] moiety, this absorption band has been assigned to an allowed transition from the metal-based second highest molecular orbital HOMO-1 to the LUMO, which is delocalized over the allenylidene ligand. This accounts for the strong Metal-to-Ligand Charge-Transfer (MLCT) character of this band.[4] This assignment also seems to be valid here, since a much weaker absorption at considerably lower energies (907 nm in **2a** and at 902 nm in **2b**) was observed for the forbidden HOMO → LUMO transition. With reference to the *trans*-[Cl(dppm)$_2$Ru]-derived complexes, the HOMO should also be dominated by the metal unit and have appreciable MLCT character as well. As found for the HOMO-1 → LUMO transition, it exhibits negative solvatochromism of a magnitude comparable to that of the main absorption band. We note that replacement of the *trans*-[Cl(L$_2$)$_2$Ru] moiety by [TpRuL$_2$] apparently results in a somewhat smaller energy gap between the two highest occupied levels and the LUMO. This is inferred by comparison of the data for **2a** and **2b** with those for the related complex *trans*-[Cl(dppm)$_2$Ru=C=C=CPh$_2$]$^+$, which has its absorption maxima at 506 and 817 nm. The data also point to a slightly larger energy gap between the two highest occupied levels for the [TpRuL$_2$]-derived complexes. The energy difference between the HOMO-1 → LUMO and the HOMO → LUMO transitions thus amounts to 1.01 eV for **2a** and 0.98 eV for **2b**, as compared to 0.93 eV for *trans*-[Cl(dppm)$_2$Ru=C=C=CPh$_2$]$^+$.

In the ferrocenyl-substituted complexes **3a** and **3b** the intense HOMO-1 → LUMO transition band is shifted to somewhat lower energies, as in the diphenyl-substituted analogues (λ_{max} = 538 nm for **3a**, 540 nm for **3b**, see Table 3). At even lower energies another very intense, broad band is found at 723 (**3a**) and 713 (**3b**) nm, tailing far into the near IR region and burying the HOMO → LUMO band. Again, a slight negative solvatochromism is noted when spectra in CH_2Cl_2 and CH_3CN are compared. This band has no counterpart in **2a** and **2b** and is consequently attributed to a ferrocenyl-to-ligand MLCT charge transfer absorption. If the ferrocenyl substituent and the cumulenic carbon atoms are regarded as belonging to the same chromophore, this band may also be termed an Intraligand Charge Tranfer (ILCT) band, the charge density being shifted between two different sites within the same basic ligand. Irrespective of the exact interpretation, the presence of this additional band points to effective conjugation between the ferrocenyl substituent and the allenylidene chromophore. As discussed later, the above assignment is strongly supported by our results from UV/Vis spectroelectrochemical investigations on the ferrocenyl-based one-electron oxidation.

Spectra of the dppf-substituted complexes **2b** and **3b** are compared in Figure 5. The ferrocene-based absorption of the dppf ligand could not be located, since it is obscured by the much more intense, broad HOMO-1 → LUMO transition. All complexes presented here display another intense band at 350−356 nm (log ε ≈ 4). This feature seems to be characteristic of aryl-substituted allenylidene complexes and so is tentatively assigned to ILCT excitation from the arene substituent(s) to the metallacumulene chromophore. Absorptions at even higher energies in the UV region arise from the n → π* and π → π* transitions of the aryl-substituted phosphane ligands.[34]

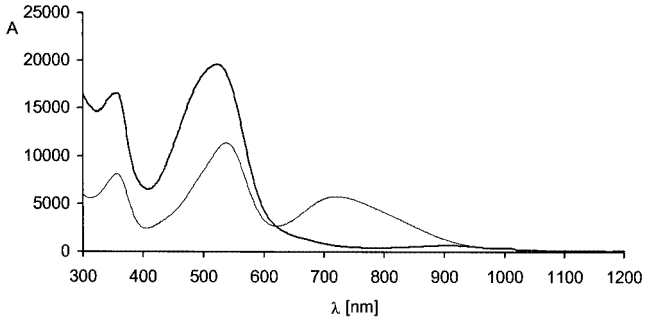

Figure 5. Optical spectra of complexes **2b** and **3b** in CH_2Cl_2

Electrochemistry

Electrochemical studies on the allenylidene complexes *trans*-$[Cl(L)_2Ru{=}C{=}C{=}C(ER_n)(R')]^+$ have shown that each of these complexes undergoes a one-electron oxidation and a one-electron reduction.[1,4] By combining electrochemical and spectroscopic methods we have been able to characterize the oxidation as a primarily metal-based process (i.e., the $Ru^{II/III}$ couple) and the reduction as ligand-based, the latter assignment being confirmed by EPR and IR spectroscopy on their reduced forms. The reduction of the diphenyl-substituted complex *trans*-$[Cl(dppe)_2Ru{=}C{=}C{=}CPh_2]^+$ (**4**), related to **2a**, has meanwhile been investigated by Touchard and co-workers. These authors arrived at essentially the same conclusions and also corroborated the reduction site by exploring the chemical reactivity of the corresponding neutral radical.[35] In that particular compound, a second, irreversible one-electron reduction was observed at a potential −1.10 V lower than the first reversible reduction process. The PPh_3-substituted diphenylallenylidene complex **2a** exhibits essentially identical electrochemical behavior (Figure 6, bottom trace). The one-electron oxidation appears to be only partially reversible under ambient conditions but a meaningful analysis of the degree of chemical reversibility is precluded by its proximity to the anodic discharge limit of the electrolyte solution. Cooling to −78 °C renders the voltammetric wave chemically reversible even at low sweep rates and allowed us to determine its half-wave potential as +1.05 V against the internal ferrocene/ferrocenium standard (Table 4). As with the dppm-substituted complex **4**, two consecutive one-electron reductions are observed. While the first reduction at $E_{1/2}$ = −1.00 V is chemically reversible under ambient conditions, the second reduction is not, and requires cooling to allow detection of the associated anodic return peak. Even so, only partial chemical reversibility could be achieved. It was, however, still possible to determine the half-wave potential of this redox couple as −2.05 V. We note that these potentials are very similar to those of *trans*-$[Cl(dppe)_2Ru{=}C{=}C{=}CPh_2]^+$.[35] This further corroborates our previous finding that − given the same allenylidene ligand − the reduction potentials are virtually independent of the electron density on the metal, a further indication of the ligand-centered nature of this process.[4]

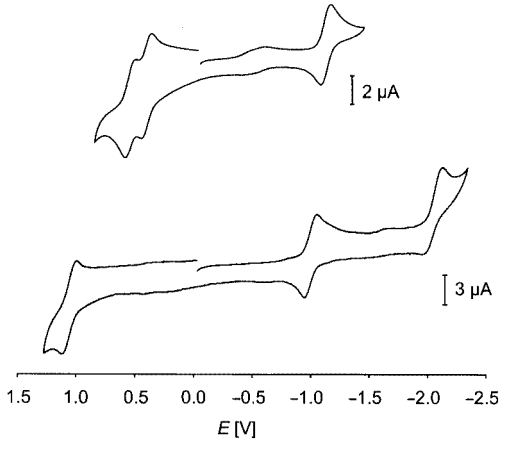

Figure 6. Cyclic voltammograms of complexes **2a** (CH_2Cl_2, 215 K, v = 0.1 V/s, bottom trace) and **3b** (CH_2Cl_2, 298 K, v = 0.1 V/s, top trace)

The analogous compound **2b** contains an electroactive dppf ligand, which would be expected to oxidize at considerably lower potential than the L_nRu^{II} entity. Thus, **2b** displays a reversible one-electron wave at +0.485 V, more than 550 mV more negative than the $Ru^{II/III}$ couple of the PPh_3-substituted congener **2a**. No further anodic processes could be observed within the accessible potential window. During our studies on the ferrocenylethyl-substituted aminoallenylidene complex *trans*-$[Cl(dppm)_2Ru{=}C{=}C{=}C(NMe_2)(C_2H_4Fc)]^+$ we noticed that the $Ru^{II/III}$ couple is shifted anodically by ca. 60 mV relative to closely related complexes upon oxidation of the electroactive ferrocenyl moiety.[12] In that particular example, the observed shift largely reflects the increased electrostatic repulsion between the positively charged centers. A much larger effect is to be expected in **2b**, in which the electroactive ferrocenyl moiety is directly linked to the metal ion. Given the proximity of the $Ru^{II/III}$ process to the anodic discharge limit of the solvent in complex **2a**, it is thus not surprising that it lies outside the accessible potential range in the case of **2b**. The first reduction of this complex is again a fully reversible one-electron process, occurring at almost the same potential as in **2a** (−1.01 V), but no further reduction was observed in this solvent. Complex **3a** has the electroactive ferrocenyl substituent attached to the terminal carbon atom of the allenylidene ligand and gives rise to a reversible one-electron wave at $E_{1/2}$ = +0.36 V. As was the case for **2a**, the ruthenium-based oxidation is again shifted outside the potential window of the electrolyte solution. While this precludes us from quantifying the potential shift of the $Ru^{II/III}$ couple induced by ferrocene oxidation, it nevertheless provides further evidence for effective conjugation between the ferrocene substituent and the cumulenic system, as already inferred from the optical data. Complexes **2a** and **3a** also offer the opportunity to assess the effect on the reduction potentials of replacement of a phenyl by a more strongly donating ferrocene substituent on the terminal carbon atom of the allenylidene ligand. Given the allenylidene-centered nature of the reduction processes, one would expect a cathodic shift of the (+/0) and the (0/−) couples. This is indeed the case. The two reductions for **3a** are observed at potentials 160

Table 4. Electrochemical data for complexes **2a**−**3b**

	DMF	n. d.	n. d.	n. d.	−1.00 (78)	−2.13[b]

[a] $E_{1/2}$ values (in V) are calibrated against the internal Fc/Fc^+ standard, ΔE_p values (in mV) are given in brackets. [b] Peak potential of an irreversible process. n. d. = not detected; n. a. = not applicable.

and ca. 320 mV more negative than in its congener **2a**. Despite all efforts, no return peak for the second reduction of **3a** was observed. The reported shift of the (0/−) potential is therefore based on the respective positions of the forward peaks and provides only a qualitative measure.[36]

Lastly, complex **3b** contains both secondary redox sites employed in this study, the dppf ligand on the metal and the ferrocenyl substituent on the terminal carbon atom C-γ. Consequently, two reversible one-electron waves at potentials considerably more negative than those of the $Ru^{II/III}$ couple of **2a** are observed in the cyclic voltammogram of this complex (Figure 6, top trace). The half-wave potentials were determined as +0.37 and +0.51 V relative to the ferrocene/ferrocenium standard. Comparisons with those of **2b** and **3a** argue for an assignment of the less anodic wave to the oxidation of the allenylidene-bound ferrocene moiety and the other one to that of the dppf ligand on the metal ion. Further evidence for this comes from spectroelectrochemical experiments, as detailed below. Paralleling the situation in compounds **2a** and **3a**, the reversible reduction of **3b** is shifted cathodically by 155 mV relative to the diphenyl-substituted **2b**, which again reflects the higher electron density on the allenylidene ligand. No second reduction was observed for **3b** in CH_2Cl_2/Bu_4NPF_6 solution. In order to assess the potential shifts induced on the second reduction by the presence of the ferrocenyl substituent, we also recorded voltammograms in DMF/Bu_4NPF_6 solution. Thanks to its superior cathodic window we were now able to observe this process for all compounds, albeit as an irreversible event. The data in Table 5 show that in this solvent the effect of substitution of one phenyl by a ferrocenyl substituent is probably very similar for both reductions, although the irreversible nature of the second process only allows for a qualitative statement.[36] No useful data, however, could be obtained for any of the oxidations in the DMF solvent.

The voltammetric data for all compounds under study are listed in Table 4. The peak potential splittings significantly exceed the predicted theoretical values of 59 mV at 298 K and 39 mV at 195 K.[36] This effect is largely due to uncompensated resistance of the electrolyte solution, as shown by the nearly identical peak-to-peak separations of the internal ferrocene standard, which is thought to represent an ideal Nernstian redox system, and the much less distorted responses in the more conducting DMF/NBu_4PF_6 electrolyte.

Spectroelectrochemistry

a) Oxidation

We now address the question of how electron transfer from the secondary electroactive moieties attached either to the ruthenium or to the terminal carbon atom of the allenylidene ligand affects the spectroscopic properties of these complexes. As may be inferred from the above discussion, a combination of bulk electrolysis with infrared spectroscopy in an optically transparent thin-layer electrolysis (OTTLE) cell provides the most sensitive tool with which to examine bonding changes accompanying oxidation within the metallacumulene chromophore. The PPh_3-ligated diphenylallenylidene complex **2a** does not contain any additional redox-active moiety and thus serves as a benchmark system for elucidating the spectral changes concomitant with oxidation of the $[\{Ru\}=C=C=C(R)(Ph)]^+$ system itself. It is thus discussed first.

Upon oxidation with IR monitoring, the strong C=C=C stretch of the allenylidene ligand vanishes and is replaced by a weaker absorption at 1587 cm^{-1}. This new band is best accommodated by the vinylidene resonance forms **IV** and **V** (Scheme 4). Both place the unpaired spin on the internal carbon atom C-β of the allenylidene ligand. At a first approximation, one may expect that the electron lost upon oxidation should originate from the HOMO orbital. According to recent DFT calculations on the parent cumulenylidene complexes of the $Cr(CO)_5$ entity,[4,37] and also our own work on the amino-substituted model complex *trans*-$[Cl(PH_3)_4Ru=C=C=C\{N(CH_3)_2\}(CH_3)]^+$,[4] this orbital is mainly composed of the ligand *trans* to the allenylidene ligand, the metal atom, and carbon atom C-β. Spin density calculations performed on *trans*-$[Cl(PH_3)_4Ru=C=C=C(ER_n)(CH_3)]^{2+}$ [ER_n = $O(CH_3)$, $S(CH_3)$, $Se(CH_3)$, CH_3] show that the orbital composition of the HOMO orbital faithfully translates into spin densities in the oxidized form. The mesomeric structures **IV** and **V** agree with these considerations.

Vinylidene complexes of ruthenium are characterized by a fairly intense IR band at around 1690−1580 cm^{-1}.[38] The literature shows a clear trend toward lower energy absorp-

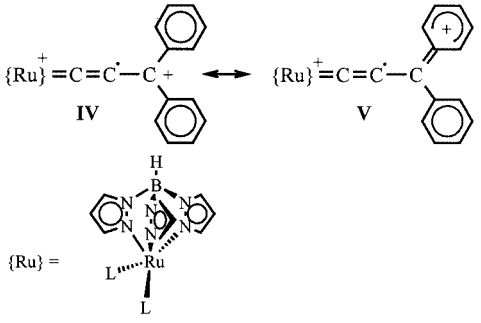

Scheme 4

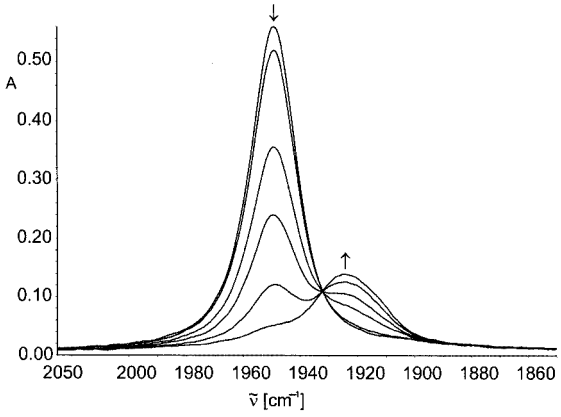

Figure 7. IR spectroelectrochemistry of complex **3a** (1,2-$Cl_2C_2H_4$, 298 K); oxidation of the ferrocenyl substituent attached to the allenylidene ligand

tions for acceptor-substituted vinylidene ligands. This is demonstrated by the complexes $[Cp(PPh_3)_2Ru{=}C{=}C(Ph)(R)]^+$ [$\tilde{\nu}$(C=C) = 1675 cm^{-1} for R = C_7H_7, 1655 cm^{-1} for R = CH_2Ph, 1638 cm^{-1} for R = I or Br, and 1585 cm^{-1} for R = NNPh).[39−42] The IR band observed for the oxidized form of complex **2a** is at the low-energy border of this regime. In contrast to all other (vinylidene)ruthenium complexes so far reported it has the metal atom in a formal +III oxidation state, which may account for its fairly low energy. In any case, it is clear that ruthenium oxidation induces major bonding changes within the metallacumulene chromophore.

In complex **3a**, oxidation involves the ferrocenyl moiety at the terminal carbon atom of the allenylidene ligand. This allows us to examine the effect of decreased electron density at this site on the position of the IR band directly. As shown in Figure 7, electrolysis at a potential positive to the anodic wave of the ferrocenyl substituent induces a red shift of the allenylidene band by ca. 20 cm^{-1} to a value of 1924 cm^{-1}, together with an appreciable decrease in absorptivity. Subsequent reduction restores the original spectrum in nearly quantitative optical yield, showing that the smaller absorptivity is not an artifact of partial decomposition. In the dipositive, monooxidized form, the unsaturated C_3 ligand bridges two positively charged entities. This should reduce the change in dipole moment during this vibration and decrease the absorptivity of this band. The same reasoning has been employed in explaining the considerably lower intensity of the allenylidene stretch in neutral allenylidene complexes as opposed to cationic ones, a situation qualitatively equivalent to the case here.[43]

The dppf-substituted complex **2b** has its additional electroactive moiety at exactly the opposite end of the metallacumulene chromophore. It provides a study case for the effect on the position of the IR band of diminished electron density on the metal. Here, oxidation results in the disappearance of the original IR band and the simultaneous growth of a pair of closely spaced, equally intense bands at 1957 and 1948 cm^{-1}, a blue shift relative to the Ru^{II}/Fe^{II} precursor of an average of 15 cm^{-1} (Figure 8). The observation of a pair of bands instead of just one is most probably the result of Fermi coupling of the asymmetric C=C=C valence stretch with an overtone or a combination mode of other vibrational mode(s) of closely related energies. Although too weak to be detected by themselves, they gain intensity through coupling to the intense C=C=C stretch of the unsaturated ligand, which then causes the additional band. Similar observations have been made for the reduced forms of complexes **2a** and **2b** (vide infra). Notably, such apparent splitting of the valence stretch is observed only in certain oxidation states. Generally speaking, Fermi coupling is only encountered when there is a good energy match between the two underlying fundamentals. It is reasonable to assume that electron transfer alters the energy of at least one of the vibrational modes involved in this coupling, which would explain why such an effect may be observable in one oxidation state but not in another. Paul, Lapinte, and co-workers have very recently reported on such oxidation-state-dependent Fermi coupling between C≡C and, presumably, C−C≡ modes[44] for alkynyl complexes $[Cp^*(dppe)Fe-C\equiv C-C_6H_4R\text{-}4]^{n+}$ (n = 0, 1, $Fe^{II,III}$).[45,46] Similar coupling between the C≡N stretch and the C≡N−C bending modes of the isocyanide ligands in the triruthenium clusters $[Ru_3(NCR)_3(\mu^3\text{-}O)(\mu\text{-}CH_3COO)_6]^{n-}$ (n = 0, 1) has recently been described by Kubiak et al.[47] Since the band energy of the fundamental coupling with the C=C=C valence stretch is unknown, we adopt the center of the Fermi doublet as the energy of the unperturbed C=C=C stretch (and also of the other mode), but this is only an approximation. The alternative explanation of there being two distinct conformers with appreciably different $\tilde{\nu}$(C=C=C) values cannot be discounted, but seems much less likely. No splitting of this band is observed for complexes **3a** or **3b**, in which such rotamers are known to exist and, from NMR spectroscopy (vide supra), not to interconvert on the IR timescale. We also note that oxidation at the [Tp(dppf)Ru] site results in a net increase of absorptivity. This can be explained well by the above reasoning, since the charge difference between the two sites bridged by the cumulenic chain, and hence the change in dipole moment associated with the asymmetric C=C=C stretch, is now enhanced.

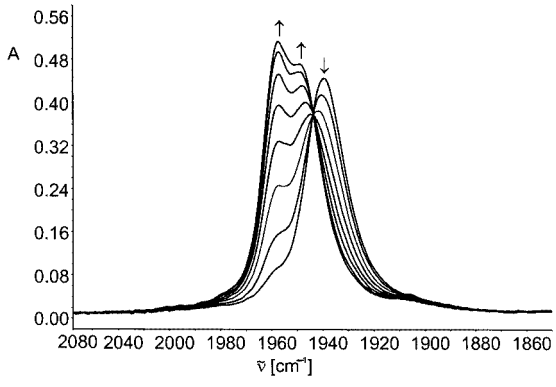

Figure 8. IR spectroelectrochemistry of complex **2b** (1,2-$Cl_2C_2H_4$, 298 K); effect of oxidation of the ferrocene moiety of the dppf ligand

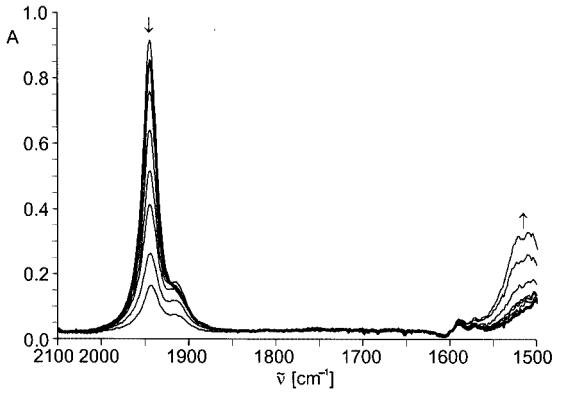

Figure 9. IR spectroelectrochemistry of complex **3b** (1,2-$Cl_2C_2H_4$, 298 K); spectral changes concomitant with ruthenium oxidation

Complex **3b**, which features both types of secondary redox centers, constitutes the most demanding case under study, since it poses the question of which ferrocenyl entity is oxidized first. We have already pointed out that the measured redox potentials favor the first oxidation as involving the ferrocenyl substituent attached to the allenylidene ligand. IR spectroelectrochemistry provides compelling evidence for this assignment. During the first oxidation the C=C=C valence stretch at 1945 cm^{-1} is replaced by a significantly less intense absorption band at 1916 cm^{-1}. The second oxidation occurs at the dppf ligand and shifts the IR band back to exactly its original position. This shows that − at least in terms of IR spectroscopy − the effects of one-electron oxidation of the electroactive moieties positioned at opposite ends of the allenylidene ligand exactly cancel each other. Both oxidized species display a high degree of chemical stability even on the longer timescales of spectroelectrochemical investigations. After bulk electrolysis following the first and second oxidation the starting material was recovered in ca. 95 and 92% optical yields, respectively.

Despite being obscured by the rising background current of the supporting electrolyte in cyclic voltammetry experiments, it still proved possible to examine the ruthenium-centered oxidation of complexes **3a** and **3b** under thin layer spectroelectrochemistry conditions. The results are very similar to those obtained for complex **2a**: the IR bands in the region typical of the C=C=C stretch of the cumulenic ligand vanish and are replaced by new absorptions at 1507 ($\mathbf{3a}^{2+}$) or 1524 cm^{-1} ($\mathbf{3b}^{3+}$), again pointing to a vinylidene structure (see Figure 9). We also note a significant red shift of the vinylidene band relative to the oxidized Ru^{III} form

of **2a** as the electron density of these complexes decreases further.

Electrolysis under UV/Vis monitoring conditions revealed the effects on the optical spectra of complexes **2b**, **3a**, and **3b** of electron transfer from the secondary redox sites. Spectral changes induced by oxidation of the dppf ligand in **2b** are rather small, the most prominent effects being a blue shift of the HOMO → LUMO band by 775 cm^{-1} and the development of a former shoulder at 361 nm into a distinct band located at 369 nm, while the main absorption band at 526 nm remains virtually unchanged. The most likely explanation is provided by reference to our earlier work on amino-substituted allenylidene complexes of the *trans*-[Cl(dppm)$_2$Ru] fragment.[48] Here we found that the electron density on the phosphane ligands was quite small for both occupied frontier levels, and this may also hold for the mixed Tp/diphosphane complexes described here. Our experimental observations can then be accommodated by the assumption that the HOMO level has some contribution from the phosphane ligands while there is only a negligible one to the lower-lying HOMO-1 orbital. For complexes **3a** and **3b**, oxidation of the ferrocene moiety would be expected to have a much more profound effect on the UV/Vis spectra, since the ferrocene moiety now constitutes an integral part of the chromophore. Bulk electrolysis of **3a** at a potential more positive than the first anodic wave indeed causes a bleaching of the intense low-energy absorption band at 723 nm (Figure 10), this finding lending further support to our assignment of this band as resulting from charge transfer from the ferrocene donor to the allenylidene acceptor moieties within this chromophore. As the ferrocene moiety is oxidized, no such transition is possible any longer. Further changes are a slight red shift of the prominent absorption band by some 200 cm^{-1} and an absorptivity decrease of the third prominent feature near 355 nm, accompanied by a slight shift to higher energies. The direction of the shift of the former band is as would be anticipated on the basis of our results on heteroatom-substituted allenylidene complexes *trans*-[Cl(dppm)$_2$Ru=C=C=C(ER$_n$)(R′)]$^+$, but its magnitude is again fairly small. Nearly identical observations were made during the first anodic step of compound **3b**, featuring both kinds of secondary redox centers (Table 5). This reconfirms our previous assignment that it is the ferrocene moiety at the allenylidene ligand that is oxidized first. The second oxidation of this compound causes only a slight blue shift of the lower energy band, along with a further decrease in absorptivity.

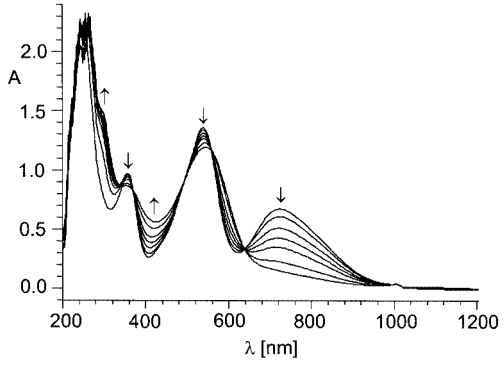

Figure 10. UV/Vis spectroelectrochemistry of complex **3a** (1,2-$Cl_2C_2H_4$, 298 K); oxidation of the ferrocenyl substituent attached to the allenylidene ligand

For complexes **2a**, **2b**, and **3b** we were even able to monitor the spectral changes accompanying oxidation at the ruthenium center. For **2a** and **2b** the effects are very similar. As an example, Figure 11 displays the spectroscopic traces during the second oxidation of **2b**. The HOMO → LUMO and HOMO-1 → LUMO bands experience shifts to higher energies, by 1050 and 1300 cm^{-1} (**2a**) or 625 cm^{-1} for the HOMO-1 → LUMO transition in **2b**. In this latter compound there is no distinct band for the excitation from the HOMO level but only a broad absorption at ca. 700 nm. As the oxidation proceeds, an intense band develops at 411 nm (**2a**) or 351 nm (**2b**). Since only one band in the 350−600-nm region is observed for the Ru^{III} forms of allenylidene complexes of the ClRu(dppm)$_2$ entity, we assume that the additional band (probably the one at higher energy) arises from ligand-to-metal charge transfer from the Tp ligand to Ru^{III}. The fully oxidized form of complex **3b** differs from the other two in that its spectrum, in terms of band positions, is surprisingly similar to that of the Ru^{II}/Fe^{II}(Fc)/Fe^{II}(dppf) starting material. The intensities of the band near 700 and the one near 550 nm, however, are just the opposite of what they were in the beginning, the band at lower energy now being very strong and the one at higher energy being rather weak. At present we have no plausible explanation for this pattern, but note that it seems to be associated with the ferrocenium moiety at the allenylidene ligand. This follows from comparison of the spectra of **2b**$^{2+}$ and **3b**$^{3+}$. Another intense band at 468 nm may again arise from a LMCT transition from the Tp ligand to Ru^{III}.

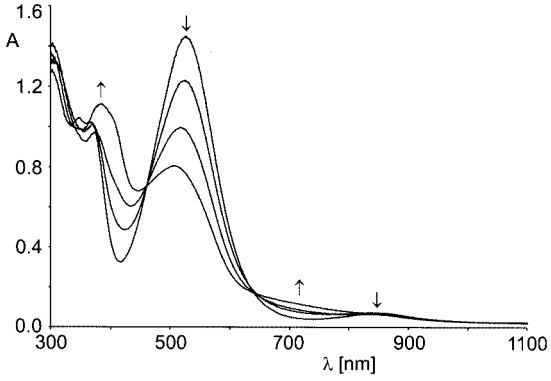

Figure 11. UV/Vis spectroelectrochemistry of complex **2b** (1,2-$Cl_2C_2H_4$, 298 K); effect of oxidation of the ferrocene moiety of the dppf ligand

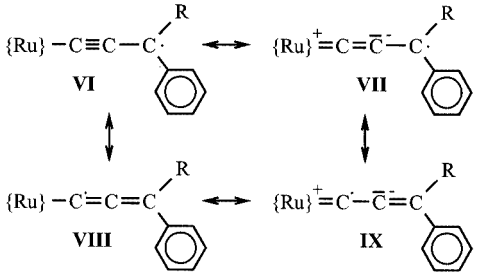
b) Reduction

It has already been mentioned that the reduction of allenylidene complexes mainly involves the allenylidene ligand. From the shift of the IR band upon reduction of the SR and SeR substituted complexes *trans*-[Cl(dppm)$_2$Ru=C=C=C(ER)(R′)]$^+$ and the coupling pattern of the unpaired

electron in their reduced forms, we have concluded that the unpaired spin mainly resides on the terminal carbon atom.[1,2] Touchard and co-workers have recently presented convincing evidence that this is also true for the reduced form of the diphenyl-substituted *trans*-$[Cl(dppe)_2Ru{=}C{=}C{=}CPh_2]^+$, closely related to the complexes discussed here.[35] DFT calculations on variously substituted model complexes *trans*-$[Cl(PH_3)_4Ru{=}C{=}C{=}C(ER_n)(CH_3)]^+$ [ER_n = $N(CH_3)_2$, $O(CH_3)$, $S(CH_3)$, $Se(CH_3)$, CH_3], which we will detail elsewhere, have broadly confirmed these conclusions but also indicate considerable spin density on the metal-bound carbon atom C-α. This in turn fully agrees with the orbital composition of the LUMO as established by quantum mechanical calculations[4,9−11,37] and the well established regiochemistry of nucleophilic addition to the allenylidene ligand.[8,49] The reversible nature of the first reduction for each of the complexes presented here provided us with the opportunity also to examine the spectral changes accompanying this process. Again, we expected the most revealing results to come from IR spectroelectrochemistry. Since none of the appended secondary redox sites can be reduced, the results are very similar for all complexes. Figure 12 displays the spectral traces recorded during the reduction of complex **2b** as a representative example. In each case we observe a blue shift of the C=C=C band by some 20 wavenumbers, along with an appreciable decrease in intensity. We again confirmed that this was not caused by decomposition of the reduced species, back-electrolysis in each case restoring the original spectrum in optical yields of more than 95%. We note that two IR bands spaced by ca. 10 cm^{-1} were observed for the reduced forms of complexes **2a** and **2b**, while there was only one for complexes **3a** and **3b**. The average shift, however, is almost constant within the entire series and amounts to ca. 20 cm^{-1}. While all the mesomeric structures depicted in Scheme 5 place the unpaired spin either on the carbon atom C-α or on C-γ, we note that **VI** accounts for the high-energy shift of the IR band. Relevant data are listed in Table 5.

In UV/Vis spectroelectrochemical experiments, reduction was observed to change the intensities of the original absorption bands rather than their positions. Representative examples are provided in Figures 13 and 14, while the corresponding data are listed in Table 5. This somewhat unexpected result points to a nearly parallel energy shift of all frontier orbitals involved in the electronic transitions upon reduction. The lower absorptivities may originate from partial loss of the charge-transfer character of these bands as the electron-accepting propensity of the allenylidene ligand is diminished. We note that the main absorption band originating from the HOMO-1 → LUMO transition seemingly splits into two individual bands, which remain unresolved for complex **2b** but are clearly resolved for all other complexes, the energy difference increasing in the order **2b** < **2a** < **3a** ≈ **3b**. Another striking observation is the complete loss of the ferrocenyl-to-ligand (or intraligand) charge-transfer absorption for the ferrocenyl-substituted complexes **3a** and **3b**, while a weak band identical to that seen for the HOMO → LUMO transition in the reduced forms of complexes **2a** and **2b** is now observed for **3b** (Table 5). Des-



Scheme 5

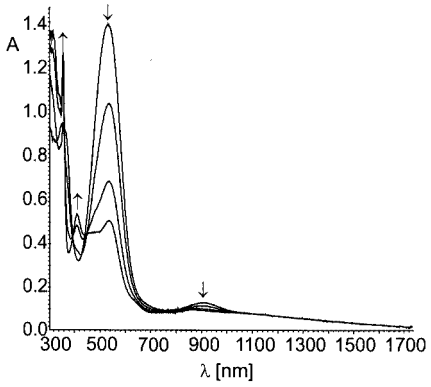


Figure 13. UV/Vis spectroelectrochemistry of complex **2b** (1,2-$Cl_2C_2H_4$, 298 K); spectral changes accompanying reduction

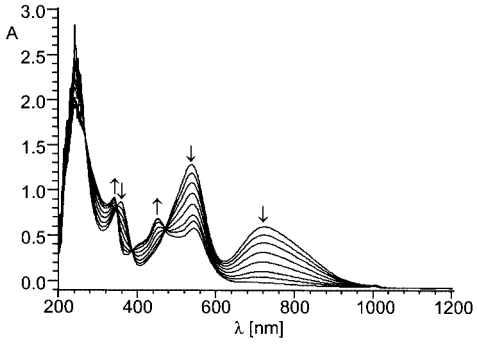

Figure 14. UV/Vis spectroelectrochemistry of complex **3a** (1,2-$Cl_2C_2H_4$, 298 K); spectral changes accompanying reduction

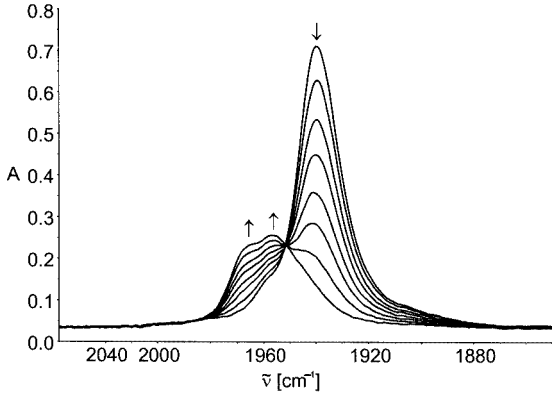

Figure 12. IR spectroelectrochemistry of complex **2b** (1,2-$Cl_2C_2H_4$, 298 K); spectral changes accompanying reduction

pite their loss of intensity, the transition bands in the visible region are still quite strong and obscure the expected ferrocenyl-based absorptions. A new band at 400−410 nm was observed for all complexes and cannot conclusively be assigned at present. Another feature common to all reduced forms is an intense absorption at ca. 350 nm. Bands of this type are familiar for aryl-substituted methyl radicals of the type $Ar_nCR_{3-n}^{\cdot}$, which are characterized by sharp, intense absorptions at 325−360 nm.[50−53] This argues for efficient incorporation of the aryl substituents into the Ru=C=C=C(R)(R′) chromophore and the relevance of resonance forms **VI** and **VII**, which both place the unpaired spin on the carbon atom adjacent to the aromatic rings.

More evidence for spin delocalization into the aromatic substituents was provided by EPR spectroscopy. The reduced forms of complexes **2a** and **2b**, frozen in a 1,2-$Cl_2C_2H_4$ glass at 4 K, display slightly broadened isotropic signals at *g*-values typical of organic paramagnetic species (i.e., close to the free electron value of 2.0023; Table 6). For **3a** and **3b**, however, the spectra were of the rhombic type, with small but clearly detectable *g*-value anisotropies indicating some transition metal contribution, most probably from the ^{57}Fe nucleus of the Fc substituent. Such coupling also prevails in liquid solution, as is evident from a satellite doublet with a signal splitting of 22.3 G (Figure 15; ^{57}Fe has a nuclear spin of 1/2 and a natural abundance of 2.15%). No further resolution of the EPR signal was obtained, however. This is in sharp contrast to observations made by Rigaut, Dixneuf, and co-workers and in our own laboratory on the reduced forms of allenylidene complexes bearing the *trans*-[Cl(L$_2$)$_2$Ru] fragment (L$_2$ = dppm, dppe). These display resolved couplings to the hydrogen atoms on the substituents bonded to the allenylidene ligand and the phosphane P atoms coordinated to the metal ion.[1−3,5] In the mixed Tp/phosphane complexes described here, coupling to the arene protons, the two magnetically different sets of nitrogen atoms of the Tp ligand, and the phosphane P atoms would therefore be expected. It is possible that the larger number of magnetically independent nuclei together with some participation by a metal atom give rise to strongly overlapping resonance lines that cannot be resolved. It is quite revealing to note that the resonance signals are significantly broadened relative to the analogous complexes of the *trans*-[Cl(dppm)$_2$Ru] entity.

Table 6. EPR data for the reduced forms of complexes **2a**−**3b**

	4 K g_{iso} or g_{xx}, g_{yy}, g_{zz} (g_{av})[a]	298 K g_{iso} (A{^{57}Fe})
2a	2.0027	2.0018 (−)
2b	2.0027	2.0030 (−)
3a	2.0228, 2.0094, 2.0011 (2.0111)	2.0108 (22.3 G)
3b	2.0215, 2.0111, 2.0016 (2.0114)	2.0110 (22.3 G)

[a] $g_{av} = \{1/3\ (g_{xx}^2 + g_{yy}^2 + g_{zz}^2)\}^{1/2}$.

c) The IR Frequency of the B−H Stretch

The position of the B−H stretch in infrared spectra has been recognized as an indicator for the coordination mode of the Tp ligand (i.e., κ^3 versus κ^2 coordination).[54,55] It has, however, only very recently been realized that the frequency of this band also corresponds to the electron density on the metal ion to which it is coordinated and, more specifically, to its oxidation state. Thus, O'Hare and co-workers have just published a series of mixed-sandwich complexes containing both the Cp and the Tp ligand or the 3,5-dimethyl derivative thereof, several of them in the adjacent M^{II} and M^{III} oxidation states (M = V, Cr, Co, Ni).[55] In all these cases oxidation of the metal atom was found to induce a shift of the B−H band to higher energies, though of a strongly varying magnitude (7−72 cm^{-1}). We have made the same observations with the complexes reported here. As the data for complexes **2a** and **3b** show (see Table 5), oxidation at the ruthenium atom increases the energy of the B−H stretch by about 30 cm^{-1} while the decreasing electron density on the ruthenium atom by oxidation at the dppf ligand has a somewhat smaller effect of some 25 cm^{-1} (**2b**). Ferrocene oxidation at the allenylidene ligand also shifts the B−H band to higher energy (**3a**). Likewise, the reduced forms of these allenylidene complexes display their B−H band at some 15−25 cm^{-1} lower energy, although this process mainly involves the organic ligand. Thus, variation of the B−H stretch with the oxidation state

of the metal atom or that of any redox-active ancillary ligand bonded to it seems to be a quite general result and we expect additional examples of such behavior as more redox pairs of this type are characterized.

Conclusions

We have investigated allenylidene complexes $[TpL_2Ru{=}C{=}C{=}C(Ph)(R)]^+$. Substitution of dppf by less strongly donating PPh_3 ligands or of the phenyl by a ferrocenyl substituent shifts the IR and electronic absorption bands to lower energies, in line with previous results on complexes based on the *trans*-$[Cl(dppm)_2Ru]$ moiety. Oxidation of ferrocene-based redox sites attached either to the metal atom (L_2 = dppf: **2b**, **3b**) or to the allenylidene ligand (R = Fc: **3a** and **3b**) strongly attenuates these effects. The same holds for reduction, which mainly involves a ligand-centered, delocalized orbital. These studies also show that aromatic substituents at the allenylidene ligand are efficiently incorporated into the chromophoric system. Thus, the Fc-substituted complexes **3a** and **3b** display an intense, low-energy absorption band attributable to charge transfer from the ferrocenyl substituent to the allenylidene ligand. Oxidation of the Fc moiety and reduction both cause bleaching of this feature. EPR studies on the reduced forms of **3a** and **3b** reveal coupling of the unpaired spin with the ^{57}Fe nucleus of the ferrocenyl substituent. In their IR spectra some of the oxidized or reduced forms display an apparent splitting of the allenylidene band. This is interpreted in terms of Fermi coupling between the C=C=C fundamental and an overtone or combination of (an)other vibration(s).

Cyclic voltammetry studies reveal that both types of ferrocene-based redox systems are oxidized at much lower potential than the ruthenium center. Although the $Ru^{II/III}$ process lies outside the anodic window of the supporting electrolyte solution in voltammetric studies, it was still possible to perform this oxidation under thin layer conditions in an OTTLE cell. This latter oxidation induces more substantial bonding changes within the cumulenylidene system. Results from IR spectroelectrochemistry point to a vinylidene resonance structure for the Ru^{III} forms of these complexes. The frequency of the B−H stretch of the Tp ligand is also sensitive to the overall oxidation state of the molecule. Oxidation of any of the ferrocene entities or the ruthenium shifts this band to higher energies, while a red shift is observed upon reduction.

The unsymmetrically substituted allenylidene complexes $[TpL_2Ru{=}C{=}C{=}C(Ph)(Fc)]^+$ (**3a** and **3b**) are dynamic in solution, due to an energy barrier to rotation around the Ru=C bond. Two isomeric forms differing in the relative positions of the Fc and the Ph substituents are discernible for the PPh_3-substituted congener **3a** up to 388 K in 1,2-$D_2C_2Cl_4$, at which point this compound decomposes. The observation of just one singlet resonance for each isomer by ^{31}P NMR spectroscopy argues for a vertical orientation of the allenylidene ligand. This is in agreement with the crystallographically determined structures for **2a** and **2b**, the latter presented here.[13] For the dppf-substituted **3b**, however, splitting of the singlet ^{31}P NMR resonance into a well-resolved AB quadruplet is observed upon cooling in CD_2Cl_2, pointing to a horizontal alignment of the allenylidene ligand. The energy barrier for allenylidene rotation is determined as 47 kJ/mol at the coalescence temperature of 238 K.

Experimental Section

General: All manipulations were performed by standard Schlenk techniques under argon. CH_2Cl_2 and 1,2-$Cl_2C_2H_4$ were distilled from CaH_2 and stored over molecular sieves (4 Å). All solvents were deoxygenated by at least three freeze-pump-thaw cycles and saturation with argon prior to use. Benzoylferrocene, [Tp(dppf)RuCl], $[TpRu(PPh_3)_2Cl]$, and $[TpL_2Ru{=}C{=}C{=}CPh_2]^+$ (L_2 = 2 PPh_3, dppf) were obtained by literature methods.[13,18,56,57] Electrochemistry and spectroelectrochemistry were performed as described in an earlier publication.[4] All experiments were performed in the presence of 0.2 M Bu_4NPF_6 as the supporting electrolyte and the given potentials are referenced to the ferrocene/ferrocenium couple, set as 0.00 V. This scale can be related to saturated calomel electrode (SCE) conditions by adding +0.46 V for CH_2Cl_2 and +0.45 V for DMF solutions.[58] NMR: Bruker AC 250. IR: Elmer Paragon 1000 PC. UV/Vis: Omega 10 from Bruins Instruments or J&M TIDAS diode array UV/Vis/NIR spectrometer equipped with a fiber-optic cable and operated with the SCAN 2017 and SPECTRALYS software packages. Electrochemistry: EG&G potentiostat 273 A, BAS glassy carbon working electrode (Ø, 3 mm), Pt wire as counter-electrode and Ag wire as pseudo-reference electrode, potential calibration by addition of ferrocene or decamethylferrocene as internal standard. EPR: Bruker ESP 300, HP frequency counter 5350 B, Bruker NMR gaussmeter ER 035 M, continuous flow cryostat ESR 900 from Oxford Instruments for low-temperature work.

1-Ferrocenyl-1-phenylprop-2-yn-1-ol Trimethylsilyl Ether: *n*BuLi (4.6 mL of a 2.5 M solution in *n*-hexane) was added to trimethylsilylacetylene (1.6 mL, 1.11 g, 11.2 mmol) in degassed THF (250 mL). The clear, colorless solution was allowed to warm to room temperature, and benzoylferrocene (2.32 g, 8 mmol) was added. The resulting solution was stirred for 20 h, whereupon the color visibly brightened to orange. It was hydrolyzed with 5 mL of distilled water and the organic phase was taken to dryness. The brownish residue was taken up in dichloromethane, washed with several portions of a 5% solution of Na_2CO_3, and dried with $MgSO_4$, and the solvent was removed in vacuo. The product was purified by column chromatography on neutral alumina with *n*-hexane/Et_2O (3:1, v/v) as the eluent. Slow evaporation of the solvents deposited orange crystals (1.67 g, 4.3 mmol, 54%).

1-Ferrocenyl-1-phenylprop-2-yn-1-ol: Finely ground KOH (1.68 g, 30 mmol) was dissolved in MeOH, and the silyl ether (1.165 g, 3 mmol) was added. The orange solution was kept under a gentle reflux for 18 h and the solvent was then distilled off. The residue was hydrolyzed in water and carefully acidified with dilute HCl, and the product was extracted with Et_2O. The organic phase was washed with water and dried with $MgSO_4$, and the solvent was removed in vacuo, which deposited the pure product as orange crystals (0.81 g, 2.6 mmol, 85%).

$[Tp(PPh_3)_2Ru{=}C{=}C{=}CPh_2]^+$ SbF_6^- (2a): UV/Vis (CH_3CN): λ_{max} (ε) = 359 (10500), 527 (16500), 901 nm (710 M^{-1} cm^{-1}); (CH_2Cl_2): λ_{max} (ε) = 356 (13000), 527 (16000), 907 nm (660 M^{-1} cm^{-1}).

[Tp(dppf)Ru=C=C=CPh$_2$]$^+$ SbF$_6^-$ (2b): UV/Vis (CH_3CN): λ_{max} (ε) = 346 (11000), 520 (13000), 901 nm (350 M^{-1} cm^{-1}); (CH_2Cl_2): λ_{max} (ε) = 356 (16500), 522 (19600), 902 nm (580 M^{-1} cm^{-1}).

[Tp(PPh$_3$)$_2$Ru=C=C=CFcPh]$^+$ SbF$_6^-$ (3a): Compound **1a** (250 mg, 0.286 mmol), 1-ferrocenyl-1-phenylprop-2-yn-1-ol (260 mg, 0.82 mmol), and $AgSbF_6$ (190 mg, 0.55 mmol) were mixed in THF (10 mL) in a Schlenk flask and stirred in the dark at ambient temperature for 40 min, whereupon an intense purple color developed. THF was removed in vacuo and the solid residue was extracted with CH_2Cl_2 (15 mL). Filtration through a fine frit covered with Celite (10 cm) and silica (5 cm), with use of small portions of CH_2Cl_2, removed the AgCl. The solid residue obtained after the solvent had been pumped off, was subjected to column chromatography on silica (Merck 60) with CH_2Cl_2/CH_3CN (10:1,v/v) as the eluent. The first, orange band contained the excess propargylic alcohol, while the second, purple-black zone was slightly impure product. Further purification was performed by three successive reprecipitations from CH_2Cl_2/hexanes. After drying in vacuo, spectroscopically pure product (251 mg, 0.183 mmol, 64%) was obtained. Data for the major isomer: ^{1}H NMR (CD_2Cl_2): δ = 4.28 (s, 5 H, C_5H_5), 4.81, 5.05 (each t, $^3J_{H,H}$ = 2.0 Hz, 2 H, Cp_{subst}), 5.58 [t, $^3J_{H,H}$ = 2.3 Hz, 1 H, 4-H(pz)], 5.69 [d, $^3J_{H,H}$ = 2.3 Hz, 1 H, 3-H(pz)], 5.72 [t, $^3J_{H,H}$ = 2.3 Hz, 2 H, 4-H(pz)], 6.31 [d, $^3J_{H,H}$ = 2.3 Hz, 2 H, 3-H(pz)], 6.85−8.03 (several m, 36 H, 2 PPh_3, Ph, HB), 7.66 [d, $^3J_{H,H}$ = 2.3 Hz, 2 H, 5-H(pz)], 7.85 [d, $^3J_{H,H}$ = 2.3 Hz, 1 H, 5-H(pz)] ppm. ^{13}C{^{1}H} NMR (62.9 MHz, CD_2Cl_2): δ = 71.6 (C_{ipso}, Fc), 73.2 (C_5H_5), 74.5, 78.3 (C-2−5, Cp_{sub}), 105.7, 106.5 [br., C-4(pz)], 125.5−134.5 (several m, 2 PPh_3, Ph), 136.5, 137.0 (br., C-5(pz)], 144.9 (C_{ipso}, Ph), 145.3, 147.0 (C-3(pz)], 168.2 (t, $^4J_{P,C}$ = 1.6 Hz, C-γ), 184.3 (t, $^3J_{P,C}$ = 1.5 Hz, C-β), 287.0 [t, J_{PC} = 18.2 Hz, C-α] ppm. ^{31}P{^{1}H} NMR (101.3 MHz, CD_2Cl_2): δ = 40.8 (s) ppm. IR (KBr): $\tilde{\nu}$ = 1946 (vs, C=C=C), 1458 (s, Fc), 1436 (s, Ph), 1382 (m, Ph), 1309 (m, Ph), 1049 (m, Ph), 749 (m, Ph), 699 (s, Ph), 658 cm^{-1} (SbF_6). UV/Vis (CH_3CN): λ_{max} (ε) = 355 (3600), 534 (5200), 719 (2650 M^{-1} cm^{-1}); 825 nm (sh); (CH_2Cl_2): λ_{max} (ε) = 356 (8000), 538 (11500), 724 nm (5700 M^{-1} cm^{-1}). $C_{64}H_{54}BF_6FeN_6P_2RuSb$ (1372.59): calcd. C 56.00, H 3.97, N 6.12; found C 55.78, H 4.20, N 5.61.

[Tp(dppf)Ru=C=C=CFcPh]$^+$ SbF$_6^-$ (3b): This compound was prepared analogously to the method described for the synthesis and purification of compound **3a**. The product (289 mg, 74.7%) was obtained from **1b** (250 mg, 0.276 mmol), 1-ferrocenyl-1-phenylprop-2-yn-1-ol (0.26 g, 0.82 mmol), and $AgSbF_6$ (190 mg, 0.55 mmol). ^{1}H NMR (CD_2Cl_2): δ = 4.22 (s, 5 H, C_5H_5), 4.67, 4.76 [each br., 4 H, 2,3-H(dppf)], 5.05, 5.12 (each t, $^3J_{H,H}$ = 2.1 Hz, 2 H, Cp_{subst}), 5.39 [t, $^3J_{H,H}$ = 1.9 Hz, 2 H, 4-H(pz)], 5.93 [t, $^3J_{H,H}$ = 2.2 Hz, 1 H, 4-H(pz)], 6.33 [d, $^3J_{H,H}$ = 2.2 Hz, 1 H, 3-H(pz)], 6.39 [d, $^3J_{H,H}$ = 1.9 Hz, 2 H, 3-H(pz)], 6.42−8.20 (several m, 26 H, 2 PPh_2, Ph, HB), 7.64 [d, $^3J_{H,H}$ = 2.2 Hz, 1 H, 5-H(pz)], 7.81 [d, $^3J_{H,H}$ = 1.9 Hz, 2 H, 5-H(pz)] ppm. ^{13}C{^{1}H} NMR (62.9 MHz, CD_2Cl_2): δ = 70.6 (C_{ipso}, Fc), 73.3 [t, $^2J_{P,C}$ = 3.6 Hz, C-2/5(dppf)], 73.59 [C_{ipso}(dppf)], 73.63 (C_5H_5), 73.9 (Cp_{sub}), 74.6 [t, $^3J_{P,C}$ = 2.9 Hz, C-3/4(dppf), 79.0 (Cp_{sub}), 106.0, 106.5 [C-4(pz)], 128.0−133.5 (several m, 2 PPh_2, Ph), 135.4, 137.3 [br., C-5(pz)], 144.0 (t, $^5J_{P,C}$ = 0.7 Hz, C_{ipso}, Ph), 144.8 [t, $^3J_{P,C}$ = 1.1 Hz, C-3(pz)], 147.3 (t, $^3J_{P,C}$ = 1.5 Hz), 167.9 (t, $^4J_{P,C}$ = 1.5 Hz, C-γ), 180.6 (br., C-β), 283.7 [t, J_{PC} = 18.2 Hz, C-α] ppm. ^{31}P{^{1}H} NMR (101.3 MHz, CD_2Cl_2): δ = 29.9 (s) ppm. IR (KBr): $\tilde{\nu}$ = 1941 (vs, C=C=C), 1457 (s, Fc), 1435 (s, Ph), 1395 (m, Ph), 1382 (m, Ph), 1309 (m, Ph), 1049 (m, Ph), 749 (m, Ph), 697 (s, Ph), 658 (SbF_6) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 348 (14000), 534 (15500), 709 (10000), 1030 nm (800 M^{-1} cm^{-1}); (CH_2Cl_2): λ_{max} (ε) = 350 (16500), 540 (19500), 712 (13000), 1030 nm (2000 M^{-1} cm^{-1}). $C_{62}H_{52}BF_6Fe_2N_6P_2RuSb$ (1402.40): calcd. C 53.10, H 3.73, N 5.99; found C 52.32, H 3.85, N 5.54.

Table 7. Crystallographic data for [TpRu(dppf)Cl]·2$CHCl_3$ and [Tp(dppf)RuC_3Ph_2]$^+$ SbF_6^-

	[TpRu(dppf)Cl]·2$CHCl_3$	[Tp(dppf)RuC_3Ph_2]$^+$ SbF_6^-
Empirical formula	$C_{45}H_{40}BCl_7FeN_6P_2Ru$	$C_{58}H_{48}BF_6FeN_6P_2RuSb$
Formula mass	1142.65	1294.44
Temperature [K]	173(2)	293(2)
Wavelength [Å]	0.71073	0.71073
Crystal system	monoclinic	orthorhombic
Space group	$P2_1/n$	Pbca
a [Å]	13.977(3)	21.9546(14)
b [Å]	17.287(4)	27.959(3)
c [Å]	19.645(4)	22.152(2)
β [°]	91.85(3)	90
V [Å^3]	4744.1(16)	13597(2)
Z	4	8
Density (calculated) [Mg/m^3]	1.600	1.265
Absorption coefficient [mm^{-1}]	1.127	0.924
F(000)	2304	5184
Crystal size [mm]	0.3 × 0.25 × 0.15	0.25 × 0.07 × 0.07
θ range for data collection [°]	1.57 to 29.03.	1.96 to 19.04
Index ranges for data collection	$0 \le h \le 19$, $-14 \le k \le 23$, $-22 \le l \le 26$	$-18 \le h \le 20$, $-25 \le k \le 25$, $-18 \le l \le 19$
No. of reflections measured	12760	15729
No. of independent reflections	8069 [R(int) = 0.0526]	4616
Refinement method	full-matrix least-squares on F^2	full-matrix least-squares on F^2
Data/restraints/parameters	12373/0/573	4616/0/360
Goodness-of-fit on F^2	1.288	1.522
Final R indices [$I > 4\sigma(I)$]	$R1$ = 0.0757, $wR2$ = 0.1829	$R1$ = 0.156, $wR2$ = 0.4112
R indices (all data)	$R1$ = 0.1269, $wR2$ = 0.2218	$R1$ = 0.2473, $wR2$ = 0.4528
Largest diff. peak/hole [e·Å^{-3}]	2.10/−2.34	1.648/−1.863

X-ray Crystallography: Crystals of complex **1b** were grown by slow concentration of a saturated solution in $CHCl_3$ while those of **2b** were obtained by cooling a solution in a THF/Et_2O mixture to −15 °C. Experimental details regarding the X-ray structure solutions are provided in Table 7. The structures were solved by direct methods, least-squares refinement, and Fourier techniques. Structure solution and refinement were performed with SHELXTL.[59] CCDC-192092 (**2b**) and -192093 (**1b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to the Volkswagenstiftung for financial support within their program on intra- and intermolecular electron transfer. We also wish to acknowledge Johnson & Matthey Company for a generous loan of $RuCl_3$ hydrate.
