first and second oxidation peaks (around 1 V) (Figure 7, a) Reduction of **1** is believed to be difficult, as no cathodic wave is located within the solvent limit. The electrochemical behavior of **1** and $[PPN][Os_4(\mu\text{-}H)_3(CO)_{12}]$ is similar. The incorporation of the $\{AuPPh_3\}$ ligand seems to have no significant effect on the energy level of the HOMO of $[PPN][Os_4(\mu\text{-}H)_3(CO)_{12}]$.

The isolobal parent cluster $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ unexpectedly has a different redox behavior to **1**. The cyclic voltammogram of $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ contains an irreversible cathodic wave and an irreversible anodic wave. Accurate data of the controlled potential coulometry cannot be obtained because of the limited solubility of $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ in organic solvents. Compared to **1** and $[PPN][Os_4(\mu\text{-}H)_3(CO)_{12}]$, the reduction of $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ is believed to be more feasible but the oxidation is more difficult. The large positive shift (600 mV) in the oxidation potential implies that the substitution of the isolobal $\{AuPPh_3\}$ for hydrogen in $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ seems to be able to activate the tetraosmium cluster towards the oxidation reaction by raising the HOMO.

Although the metal frameworks of **1** and **2** are exactly the same, the substitution of the carbonyl ligand by a trimethylamine ligand leads to different electrochemical behavior. The cyclic voltammogram of **1** exhibits both irreversible cathodic and anodic peaks (Figure 7, b). There is a positive shift in both the cathodic and anodic peaks with reference to those with equivalent values of **1**. This suggests that the coordination of the trimethylamine ligand lowers both the HOMO and the LUMO, which makes the oxidation more difficult while the reduction becomes easier.

The redox properties of the known compound **3** were also studied as a reference. The electrochemical behavior of **3** is similar to that of **1**. There are two irreversible anodic peaks, but no cathodic peak was located within the solvent limit. Controlled potential coulometry revealed that each oxidation peak involves 1 F/mol of **3**, which is different from the double-electron oxidation process observed in **1**. The first oxidation potential of **3** is similar to the value of **1**; however, it displays a 520 mV positive shift in the second oxidation potential. This shows that the monoanion of **3** undergoes a second oxidation, which is much easier since the oxidation process involves only one electron. The difference in the redox properties of **3** from **1** might be attributed to the presence of the Au−Au bond, which might alter the relative positions of the HOMO and LUMO.

As expected, the redox behavior of **4** is significantly different from that of **3**. This is probably due to the different arrangement in the metal core and the ligand effect of an extra osmium−triphenylphosphane ligand, which is similar to the case of the trimethylamine ligand observed in **2**. In fact, the cyclic voltammogram of **4** closely resembles that of **2**. The less negative reduction potential of **4** suggests that the osmium−triphenylphosphane ligand significantly lowers the LUMO of the cluster and makes the reduction easier. However, the oxidation potential of **4** is similar to the value obtained in **3** and **1**. The HOMO and LUMO of these kinds of mixed-metal clusters are believed to be metal- and ligand-based, respectively.

The cyclic voltammograms of **5** and **6** are similar, and also similar to that of **3**. Both exhibit two irreversible anodic waves. Comparing the oxidation potentials of $[Os_4(\mu\text{-}H)_4(CO)_{12}]$, **1**, **3**, **5**, and **6** (Os/Au range from 0 to 4), they display a slightly negative shift in the first oxidation potential as the number of gold atoms increase. This is probably because the delocalization of electrons in the high-nuclearity cluster is more significant, and the effect of losing an electron can be shared by more metal centers, making the oxidation easier. The energy level of the metal-based HOMO is believed to be raised, corresponding to the decrease in the oxidation potential. The second oxidation potential of **6** is similar to the equivalent value of **3**. However, **5** exhibits a significantly lowered second oxidation potential, with a negative shift of ca. 300 mV as compared with **6**. This suggests that the novel metal core arrangement of **5** might interrupt the arrangement of the HOMO and LUMO, making the cluster more reactive towards oxidation. It is difficult to correlate the reduction potential with the change in gold atom numbers, since the cathodic

wave of **1**, **3**, and **5** are not observed within the solvent limit.

Electronic Absorption Properties

Clusters **1**−**6** displayed a trend of color changes from yellow to red in the solid state, prompting us to examine them by optical spectroscopy. Table 2 presents the electronic absorption spectroscopic data for **1**−**6** together with the cluster $[PPN][Os_4(\mu\text{-}H)_3(CO)_{12}]$ in dichloromethane at ambient temperature.

The energy absorption bands of these osmium−gold mixed-metal clusters are within the range of 320 to 401 nm. Cluster **2** exhibits the highest energy absorption band at 320 nm. This implies that the energy gap between the HOMO and LUMO is the largest and is consistent with the large peak-to-peak separation (ca. 2.5 V) of the redox potentials observed in its cyclic voltammogram. On the other hand, both of the clusters **4** and **6** have the lowest energy absorption band at 401 nm, which corresponds to the small HOMO−LUMO energy gap. Consequently, the peak-to-peak separation of the redox waves (ca. 1.9 V) observed in their cyclic voltammograms is significantly small in comparison to the value of **2**. The similar separations in **4** (1.91 V) and **6** (1.96 V) suggest that the energy gap between HOMO and LUMO might be directly proportional to the separation of redox potentials in the cyclic voltammogram, in cases where the HOMO−LUMO involved in the electronic transition is assumed to have the same orbitals where the redox reaction occurs. According to this assumption, it might be possible to estimate the redox potential out of the solvent limit by using the electronic absorption spectroscopic data as a reference. As the electronic energy absorption bands of **1**, **3**, and **5** are observed in the range of 320 to 401 nm, the separation of their first anodic peak and first cathodic peak is believed to be within the range of 1.9 to 2.5 V. The transition energy gap between the HOMO−LUMO seems to decrease slightly as the HOMO is raised due to the increasing number of gold atoms in the cluster (Figure 8). This is fully consistent with their electrochemical behavior. Cluster **5** is an exceptional case, having a high-energy electronic absorption band that is attributable to the large separation of HOMO and LUMO. The reason might be related to the novel coordination mode of the gold atoms.

Catalytic Properties of 1 and 6 towards the Oxidative Carbonylation of Aniline

The catalytic performance of **1** and **6** towards the oxidative carbonylation of aniline in methanol was investigated

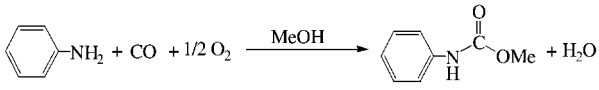
[a] About 10^{-3} M cluster in 0.1 M TBAHFP in acetonitrile at 298 K, the working electrode was a glassy carbon electrode, the auxiliary electrode and the reference electrode were a platinum wire and $Ag/AgNO_3$ (0 V) under the same conditions, calibrated with ferrocene. Scan rate was 100 $mV \cdot s^{-1}$. [b] E_{pa} and E_{pc} are the anodic and cathodic potentials, respectively, Values in parentheses are Faraday per mol of cluster. [c] Limited solubility in acetonitrile.

[Equation (1)]. The effect of reaction time, temperature, concentration of methanol, pressure (P_{CO} and P_{O_2}) and promoters (sulfuric acid and triphenylphosphane) were studied and optimized. Some selected catalytic results are presented in Table 3. The catalytic properties of the polynuclear and mononuclear homometallic starting materials, including $[Au(PPh_3)Cl]$, $[Os(CO)_3(DEAAB)Cl]$, $[Os(CO)_2(PAN)Cl]$, and $[N(PPh_3)_2][Os_4(\mu\text{-}H)_3(CO)_{12}]$ were also studied under the same conditions as a reference.



(1)

The catalysts **1** and **6** are active towards the oxidative carbonylation of aniline even without the promoters (Entries 2 and 3). However, the selectivity to carbamate is relatively low. The presence of promoters (triphenylphosphane and sulfuric acid) seems extremely important in achieving a reasonable selectivity in carbamate (Entries 5 and 6). Although catalysts **1** and **6** display slightly different interactions with the promoters, the overall catalytic performance towards the oxidative carbonylation of aniline in yielding carbamate is similar. This suggests that the effect of the osmium/gold ratio on this catalytic reaction is not significant. Consequently, a similar catalytic performance is believed to be found in the catalytic systems involving **2**−**5.**

The catalytic properties of catalysts $[Au(PPh_3)Cl]$ and $[PPN][Os_4(\mu\text{-}H)_3(CO)_{12}]$ are similar (Entries 4 and 7), but much less selective than the dimetallic systems. The synergism of dimetallic catalyst systems is believed to be significant in enhancing the selectivity towards carbamate. Two mononuclear osmium systems $[Os(CO)_2Cl(PAN)]$ and $[Os(CO)_3Cl(DEAAB)]$ were also studied, and exhibited a much lower TOF as compared with the cluster systems. In ad-

dition, it is interesting to note that the distribution of by-products observed in polynuclear and mononuclear systems is different. Formaniline is the major by-product of mononuclear osmium systems, while the cluster systems favor the formation of azobenzene. This implies that the two systems might follow different catalytic pathways, which supports the proposition that the cluster is the active catalytic species in solution.

Conclusion

A series of novel osmium−gold mixed-metal clusters, exhibiting an osmium/gold ratio range from 1 to 4, were prepared in a systematic manner. The electrochemical studies show that the incorporation of an $\{AuPPh_3\}$ unit may activate the tetraosmium−carbonyl cluster toward oxidation by lowering the oxidation potential. A slightly negative shift of oxidation potential was observed as the number of gold atoms increased. This was further confirmed by the electronic absorption studies. The correlation between the redox behavior and the electronic absorption properties was established. Clusters **1** and **6** catalyze oxidative carbonylation of aniline yielding carbamate with a good activity and selectivity in the presence of promoters. The dimetallic synergism is proved, and the effect of the Os/Au ratio on catalytic performance does not seem to be significant. The dimetallic cluster is believed to be the active catalyst in the solution.

Experimental Section

General Remarks: All reactions and manipulations were carried out under argon using standard Schlenk techniques, except for the chromatographic separations. Solvents were purified by standard procedures and distilled prior to use.[35] Reactions were monitored by analytical thin-layer chromatography (Merck Kieselgel 60 F_{254}), and the products were separated by thin-layer chromatography on plates coated with silica (Merck Kieselgel 60 F_{254}). All chemicals, unless otherwise stated, were purchased commercially and used as

received. [$Os_4(\mu\text{-}H)_4(CO)_{12}$] and [$N(PPh_3)_2$][$Os_4(\mu\text{-}H)_3(CO)_{12}$] were prepared by the literature methods.[36−38] Infrared spectra were recorded with a Bio-Rad FTS-135 IR spectrometer, using 0.5 mm calcium fluoride solution cells, ^1H and ^{31}P NMR spectra with a Bruker DPX400 spectrometer using CD_2Cl_2, and referenced to $SiMe_4$ and 85% H_3PO_4, respectively. Variable-temperature ^1H and ^{31}P NMR spectra were obtained with a Bruker DPX500 spectrometer. Positive ionization fast atom bombardment (FAB) mass spectra were recorded with a Finnigan MAT 95 mass spectrometer, using *m*-nitrobenzyl alcohol as the matrix solvent. Electronic absorption spectra were obtained with a Hewlett−Packard 8453 diode array UV/Vis spectrophotometer using quartz cells, with a 1-cm path length at room temperature. Butterworth Laboratories, UK performed the microanalyses. The Energy Dispersive X-ray Analysis measurements were performed with a Scanning Electron Microscope (Leica Cambridge Stereo 360, 20KV).

Synthesis of [$Os_4Au(\mu\text{-}H)_3(CO)_{11}(NMe_3)(PPh_3)$] (2): Solid samples of [$Os_4(\mu\text{-}H)_4(CO)_{12}$] (110 mg, 0.1 mmol) and 1 equiv. of [$AuPPh_3Cl$] (49 mg, 0.1 mmol) were dissolved in 30 mL of dichloromethane; 1 equiv. of Me_3NO was then added dropwise to the solution mixture, followed by several drops of Et_3N at ambient temperature. The solution became yellow after stirring for 15 min, and the solvent was removed under reduced pressure. The residue was chromatographed by TLC using a mixture of *n*-hexane/dichloromethane (1:1, v/v) as eluent. The yellow band of [$Os_4Au(\mu\text{-}H)_3(CO)_{11}(NMe_3)(PPh_3)$] (**2**) was isolated. Yield: ca. 24 mg (15%). ^1H NMR (400 MHz, CD_2Cl_2, 298 K): δ = −25.32 (s, 2 H, hydride), −18.98 (s, 1 H, hydride), 2.95 (s, 9 H, methyl), 7.42 (m, 15 H, phenyl) ppm. ^{31}P NMR (400 MHz, CD_2Cl_2, 298 K): δ = 85.09 (s, PPh_3) ppm. IR [ν(CO)/cm^{-1}; CH_2Cl_2]: $\tilde{\nu}$ = 1933 m, 1975 w, 1983 w, 1989 w, 2024 s, 2028 s, 2039 s, 2074 m. FAB-MS [M^+]: *m*/*z* = 1590. $C_{32}H_{27}AuNO_{11}Os_4P$ (1590.31): calcd. Reaction of [$Os_4(\mu\text{-}H)_4(CO)_{12}$] with [$AuPPh_3Cl$] in Excess Et_3N: A solid sample of [$Os_4(\mu\text{-}H)_4(CO)_{12}$] (110 mg, 0.1 mmol) and excess [$AuPPh_3Cl$] (196 mg, 0.4 mmol) were dissolved in 30 mL of dichloromethane under argon. Excess Et_3N was added dropwise to this pale yellow solution, giving a dark brownish red clear solution after stirring for an additional 3 h. The decomposition of products was observed and then the solvent was reduced in vacuo. The residue was filtered, some unchanged [$Os_4(\mu\text{-}H)_4(CO)_{12}$] (32 mg, 0.029 mmol) was recovered. The filtrate was then subjected to preparative TLC using a solution mixture of *n*-hexane/dichloromethane (2:3, v/v) as eluent. The four consecutive orange bands were characterized as [$Os_4Au_2(\mu\text{-}H)_2(CO)_{12}(PPh_3)_2$] (**3**) (10 mg, 5%), [$Os_4Au_2(\mu\text{-}H)_2(CO)_{11}(PPh_3)_3$] (**4**) (9 mg, 4%), [$Os_4Au_3(\mu\text{-}H)_3(CO)_{11}(PPh_3)_3$] (**5**) (7 mg, 3%), and [$Os_4Au_4(\mu\text{-}H)_2(CO)_{11}(PPh_3)_4$] (**6**) (20 mg, 7%). **4**: ^1H NMR (400 MHz, CD_2Cl_2, 298 K): δ = −19.69 (s, 1 H, hydride), −19.66 (s, 1 H, hydride), 7.21 (m, 15 H, $OsPPh_3$), 7.38 (m, 30 H, $AuPPh_3$) ppm. ^{31}P NMR (400 MHz, CD_2Cl_2) 298 K: δ = 76.09 (s, PPh_3); 223 K: 76.10 (s, PPh_3), 75.17 (s, PPh_3) ppm. Reaction of 1 with [$AuPPh_3Cl$] in Excess Et_3N: A solution of **1** (96 mg, 0.06 mmol) and excess [$AuPPh_3Cl$] in dichloromethane was stirred at room temperature. To this yellow solution, excess Et_3N was added dropwise to give a dark orange red solution. After stirring for 3 h, decomposition of products was observed. The solvent was then removed in vacuo. The residue was then subjected to TLC separation using *n*-hexane/dichloromethane (1:1, v/v) as the eluent. Three bands were obtained in the order of elution as **3** (17 mg, 14%), **4** (33 mg, 24%), and **6** (24 mg, 14%).

Reaction of 2 with [$AuPPh_3Cl$] in Excess Et_3N: To a yellow solution of **2** (32 mg, 0.02 mmol) and excess [$AuPPh_3Cl$] in dichloromethane, excess Et_3N was added. The yellow solution changed to orange after stirring for 3 h, accompanied by some decomposition prod-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ucts. The solvent was reduced under reduced pressure and the residue was chromatographed on silica with *n*-hexane/dichloromethane (1:1, v/v) as the eluent. Cluster **6** (7 mg, 12%) was isolated in moderate yield together with some unchanged **2** (12 mg, 0.008 mmol).

Reaction of 3 with [AuPPh$_3$Cl] in Excess Et$_3$N: An orange sample of **3** (40 mg, 0.02 mmol) and excess [AuPPh$_3$Cl] were mixed in dichloromethane. Excess Et$_3$N was added and the resultant orange solution was stirred at ambient temperature for 4 h. The solvent was reduced under reduced pressure and the residue was subjected to preparative TLC with *n*-hexane/dichloromethane (1:1, v/v) as the eluent. Two consecutive orange bands were identified as **4** (14 mg, 31%) and **6** (10 mg, 17%).

Reaction of 4 with [AuPPh$_3$Cl] in Excess Et$_3$N: An orange solution of **4** (47 mg, 0.02 mmol) and excess [AuPPh$_3$Cl] in dichloromethane were stirred with excess Et$_3$N for 6 h. No observable change could be detected, but a slight decomposition of starting material occurred.

Reaction of 5 with [AuPPh$_3$Cl] in Excess Et$_3$N: The reactivity of **5** cannot be thoroughly studied due to the limited availability of sample.

Reaction of 6 with [AuPPh$_3$Cl] in Excess Et$_3$N: A red solution of **6** (32 mg, 0.01 mmol) and excess [AuPPh$_3$Cl] were mixed in dichloromethane. Excess Et$_3$N was added and the resulting solution was stirred for an additional 6 h; purple insoluble microcrystalline precipitates appeared. These solids were confirmed as mixed-metal clusters with an Os/Au ratio of 3:2 by Energy Dispersive X-ray Analysis with SEM. IR [ν(CO)/cm^{-1}; KBr]: $\tilde{\nu}$ = 1952 m, 1979 s.

Catalytic Reactions: The catalytic reactions were performed inside a Parr high-pressure stainless steel reactor (100 mL) with internal magnetic stirring. The methanol, aniline, catalysts and promoters were charged into the reaction vessel. The reactor was sealed with six cap screws in a split-ring cover clamp. The air in the vessel was replaced with dinitrogen by 3 freeze-pump-thaw cycles. It was ensured that there was no leakage of gas. The reaction gas (CO and O_2) was then introduced into the reactor inside the fumehood. The reactor was heated to the preset temperature with a thermoregulated heater for a preset time period. At the end of the reaction, the reactor was cooled with an ice bath in order to quench the reaction immediately and the reaction gas was evacuated in the fumehood. The resulting liquid mixture was analyzed by GC and GC-MS with an HP 5890A and G1800C GCD Series II, respectively.

Electrochemical Studies: Electrochemical measurements were performed with an EG&G Princeton Applied Research (PAR) Model 273A potentiostat, connected to an interfaced computer employing PAR 270 electrochemical software. Cyclic volatmmograms and bulk electrolyses were carried out in a gas-tight cell consisting of three chambers that were separated at the bottom by fine frits equipped with a glassy carbon (Bioanalytical) or a carbon cloth (80 mm^2) working electrode, a platinum gauze auxiliary electrode (Aldrich), and an Ag/AgNO$_3$ reference electrode (Bioanalytical) at room temperature; 0.1 M *n*-tetrabutylammonium hexafluorophosphate (TBAHFP) in anhydrous deoxygenated acetonitrile was used as a supporting electrolyte. Ferrocene was added at the end of each experiment as an internal standard. The working potential (E_w) for redox processes was ca. 0.15 V more positive/negative than the corresponding electrode potential (E_p); the coulometric experiment was performed in duplicate.

X-ray Crystallographic Study: Single crystals were grown from their appropriate solvent systems under favorable conditions. Intensity data were collected at ambient temperature using a Bruker SMART 1K CCD diffractometer with graphite-monochromated Mo-K_α radiation using ω scans. Details of the intensity data collection and crystal data are given in Table 4, and selected bond lengths and angles are listed in Table 5. The data were corrected for Lorentz and polarization effects. The structures were solved by direct methods (SIR92[39] or SHELXS-86[40]), and expanded using Fourier techniques (DIRDIF94).[41] Some non-hydrogen atoms were refined anisotropically, while the rest were refined isotropically. Hydrogen atoms were included but not refined. All calculations were

Coordination of Actinide Ions in Wells−Dawson Heteropolyoxoanion Complexes

Ming-Hsi Chiang,[a] Clayton W. Williams,[a] L. Soderholm,*[a] and Mark R. Antonio*[a]

Keywords: Actinides / Electrostatic interactions / Lanthanides / Polyoxometalates / X-ray absorption spectroscopy

Although many low-valent (III, IV) actinide (An) ions are known to form coordination complexes with the α-2 isomer of the lacunary Wells–Dawson polyoxoanion, $[P_2W_{17}O_{61}]^{10-}$, there is little structural information about the An–O interactions, particularly in solution. We have probed the An–O coordination environment for the series of clusters $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ with An^{4+} (Th^{4+}, U^{4+}, Np^{4+}, Pu^{4+}) and An^{3+} (Np^{3+}, Pu^{3+}, Am^{3+}) in both solution and solid phases using X-ray absorption fine structure (XAFS). Comparisons are made with the lanthanide (Ln) coordination environments in the series of 4*f*-ion clusters, $[Ln^{n+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-20}$, and with the related monovacant Lindqvist anions, $[Ln^{n+}(W_5O_{18})_2]^{n-12}$, for $n = 3, 4$. The average An–O_8 and Ln–O_8 distances correlate with their cationic VIII-coordinate ionic radii, indicating that the An and Ln ions have indistinguishable coordination behavior. Metrical details are consistent with simple charge and size considerations for both trivalent and tetravalent An ions as well as Ln ions coordinated with α-2-$[P_2W_{17}O_{61}]^{10-}$ and $[W_5O_{18}]^{6-}$. This result is contrasted to trends established for these *f*-ions coordinated to the Preyssler anion $[Ln^{n+}P_5W_{30}O_{110}]^{n-15}$.

Introduction

A significant body of international work demonstrates that polyoxometalates like the lacunary monovacant Wells−Dawson anion $[P_2W_{17}O_{61}]^{10-}$ act as stabilizing chelators of tetravalent actinide (An) ions.[1] The stabilization of these otherwise-reactive cations of uranium and the *trans*-U elements provides the basis for the application of polyoxoanions to selected aspects of An separations science in nuclear waste processing.[2] One recent practical application conceived at the CEA (Commissariat à l'Energie Atomique − France) concerns the use of α-2-$[P_2W_{17}O_{61}]^{10-}$ as a reagent for the confinement and off-line analysis of U^{4+} as part of the plutonium recovery process known as PUREX.[3,4] Another application advanced by the CEA to separate Am^{3+} from Cm^{3+} and trivalent lanthanide (Ln) elements involves its selective oxidation to Am^{4+} in the presence of α-2-$[P_2W_{17}O_{61}]^{10-}$ followed by solvent extraction. In this process, known as SESAME,[5,6] neither Cm^{3+} nor Ln^{3+} (except Ce) are oxidized thereby facilitating their separation from Am^{4+} as a valence-stabilized complex of α-2-$[P_2W_{17}O_{61}]^{10-}$. In research at JAERI (Japan Atomic Energy Research Institute), the process known as PARC is similarly planned to exploit the chemistry of α-2-$[P_2W_{17}O_{61}]^{10-}$ for separation of Am.[7] These applications are driven by the oxidizing power of α-2-$[P_2W_{17}O_{61}]^{10-}$ and its coordination chemistry, specifically its service as a valence-controlling complexant.

Despite current practice and future promise, there are few metrical details about the coordination of An^{4+} ions in complexes with α-2-$[P_2W_{17}O_{61}]^{10-}$. Such information would provide insights about the strength and nature of the An-ligand interactions. A large collection of previous work has shown that An^{4+} ions are strongly chelated by the α-2-$[P_2W_{17}O_{61}]^{10-}$ anion in butterfly-like complexes with 1:2 stoichiometry wherein one An cation is coordinated between two α-2-$[P_2W_{17}O_{61}]^{10-}$ anions. Although there is considerable physical and spectroscopic evidence for clusters of the general form $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ ($n = 16$ for An^{4+}, and $n = 17$ for An^{3+}),[1,4,8] no complete crystal structures are available.[9] The combination of results from exhaustive studies of the coordination chemistry of U^{4+} in $[U(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ both in the solid state and in aqueous solution indicates a square antiprismatic environment of 8 O about U.[4] The oxophilic *trans*-uranium elements are assumed to maintain this same coordination environment throughout the 5*f* series of $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ complexes. Similar, albeit weaker, complexation with the trivalent actinides is also known.[10] The crystal structures of the lanthanide clusters $[Lu(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{17-}$ and $[Ce(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ reveal eight-coordinate square antiprism geometries for both Lu^{3+} and Ce^{4+}.[11,12] The common structure is illustrated in Figure 1(a). It shows that the central 4*f*-ion is coordinated to 2 α-2-$[P_2W_{17}O_{61}]^{10-}$ anions in a *syn* conformation through 4 O atoms on each.

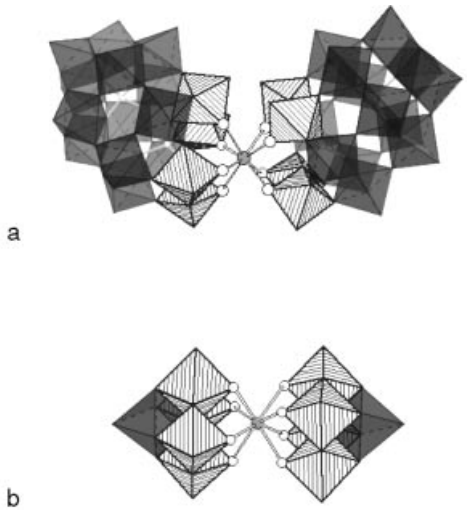

Figure 1. Molecular structures of (a) $[Lu(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{17-}$ [11] and (b) $[Np(W_5O_{18})_2]^{8-}$ [13] that emphasize the square antiprism oxygen coordination environments of the Lu^{3+} (IR = 0.977 Å) and Np^{4+} (IR = 0.98 Å) ions, depicted as the central solid circles. The striped WO_6 octahedra contain the O atoms, depicted as open circles, that bind the Ln and An ions. The shaded WO_6 polygons complete the ligand structures

Insights about the structural aspects of An−O coordination and its influence on the stability of the An^{4+} complexes are what interest us for both fundamental and practical reasons. In order to probe An^{4+}−O bonding and stabilization throughout the 5*f*-series of complexes $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ for An ≡ Th, U, Np, Pu we report the An L_3-edge XANES (X-ray absorption near edge structure) and EXAFS (extended X-ray absorption fine structure). These techniques provide access to a quantitative understanding of the An−O coordination for the solution specimens generated under electrochemical control and for the poorly-crystalline solids examined herein, for which conventional molecular level measurements like X-ray diffraction can be problematic. The results are compared with those for the An^{3+} complexes of $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{17-}$ for An ≡ Np, Pu, Am, and discussed in light of available metrical information for Ln^{3+} polyoxoanion complexes of $\alpha\text{-}2\text{-}[P_2W_{17}O_{61}]^{10-}$ and $[W_5O_{18}]^{6-}$. This latter tungsten oxide is known as the monovacant Lindqvist isopolyoxoanion. It binds tetravalent An as well as trivalent and tetravalent Ln ions to form complexes of 1:2 stoichiometry, $[An(W_5O_{18})_2]^{8-}$ and $[Ln^{n+}(W_5O_{18})_2]^{n-12}$. Many crystal structures have been determined of the actinide[13−15] and lanthanide[16−24] decatungstate clusters, as typified by the illustration in Figure 1(b). The direct comparisons of the An^{4+}−O and An^{3+}−O bonding in terms of interatomic distances provides an atomic-level perspective of the An coordination environments in polyoxometalates.

Results and Discussion

The An L_3 XANES data for the solid salts and aqueous solutions of the $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ anions are shown in Figure 2. All spectra reveal a steeply rising edge peak whose position is diagnostic of the An oxidation state. The U, Np, and Pu solution XANES collected at rest potential all have edge energies consistent with An^{4+}. After obtaining these spectra, the Np and Pu samples were electrochemically reduced in situ, and the XANES spectra were recorded of the blue solutions held at reducing potentials. These data, shown as the dashed lines in Figure 2, have edge energies shifted with respect to the data obtained at rest potential. Analyses of the edge positions indicate that both Np^{4+} and Pu^{4+} have been reduced to An^{3+}. The 4.6 and 4.3 eV differences between the $Np^{4+} - Np^{3+}$ and $Pu^{4+} - Pu^{3+}$ edge peak positions of Table 1 attest to the An^{4+}/An^{3+} redox activity in the clusters, which is an independent subject of interest.[1] The edge resonances and their shifts with oxidation state are consistent with previous work on the trivalent and tetravalent An ions.[25,26] The results from the fits to the XANES spectra, including peak positions, line widths, and intensities, are detailed in Table 1.

The L_3-edge $k^3\chi(k)$ EXAFS for the heteropolyoxoanion complexes with An^{3+} and An^{4+} is shown in the left panels of Figure 3 as solid lines. These data were Fourier trans-

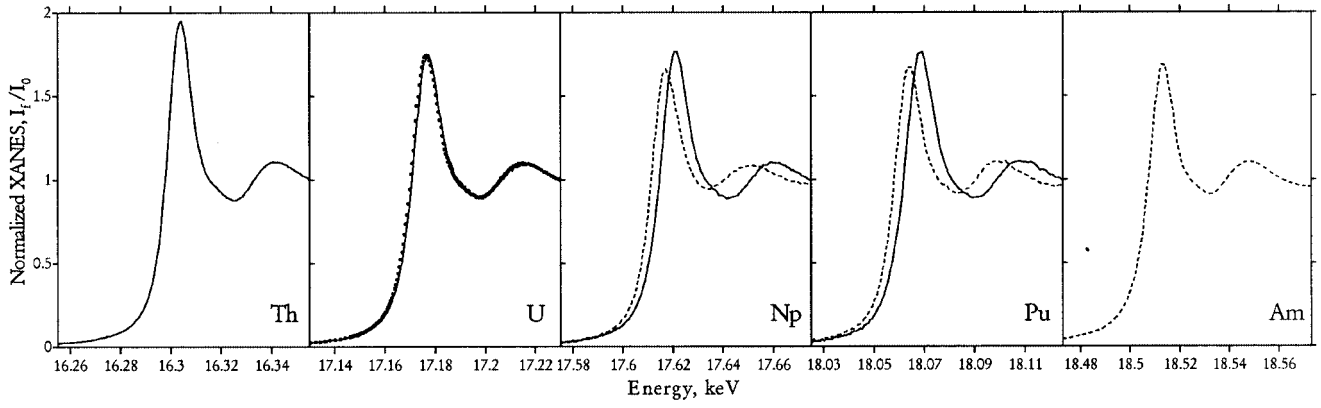

Figure 2. Normalized fluorescence L_3-edge XANES for the series of clusters $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ with An of, in left to right panel order, Th; U; Np; Pu; Am. The An^{4+} and An^{3+} spectra are shown as solid and dashed lines, respectively. All Np and Pu XANES spectra were obtained as solution samples. Th and Am XANES were obtained as solid samples, and the U spectra were obtained as both solution and solid samples, shown here with open circles and a solid line, respectively

formed without phase-shift corrections to reveal a single strong peak, due to An−O coordination, as shown in the right panels of Figure 3 (solid lines). There are no other features of physical significance, despite the presence of the distant P and W atoms in the framework structure. The An−O interatomic distances obtained from the curve fitting of the $k^3\chi(k)$ EXAFS are presented in Table 2. The fits to the experimental $k^3\chi(k)$ EXAFS are shown as dashed lines in the left panels of Figure 3. The FTs representing the best fits (dashed lines) exhibit good correspondence with the primary data (solid lines), thereby confirming that the one-shell fits of 8 oxygen atoms adequately describe the An−O coordination in $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ for both An^{3+} and An^{4+} in solution as well as in the solid phase. These results are consistent with the previous EXAFS model for Ln bonding with the monovacant Wells−Dawson anion $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$,[11] and with the independent work of Bion et al.[4] who have shown that the 8 O environment of U^{4+} is the same for the solid and the solution. The average An−O_8 and Ln−O_8 bond lengths for the $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ and $[Ln(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ series of clusters are presented in Figure 4 as a function of 5*f*- and 4*f*-ionic radii (IR) of Shannon[27] for coordination number (CN) VIII.

The 8 data points for the An-coordinated complexes [Pu^{4+}, Np^{4+}, U^{4+} (solid and solution), Th^{4+}, Am^{3+}, Pu^{3+}, and Np^{3+}] are shown as solid squares in Figure 4(a). There is a linear dependence of the bond lengths from the smallest (Pu^{4+}, IR = 0.960 Å) and highest charge cations to the largest (Np^{3+}, IR = 1.12 Å) and lowest charge ones. The overall increase of the An−O distances with increasing ionic radii is evident from the linear least-squares fit (R^2 = 0.929), which is shown as the solid line in the figure. The slope and intercept are 0.77(9) and 1.58(9) Å, respectively.

The Ln−O distances in the isostructural $[Ln^{3+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{17-}$ and $[Ce^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ complexes are plotted against their published eight-coordinate ionic radii[27] in Figure 4(b). The 11 open squares illustrate the systematic increase of the Ln−O distances with the increasing ionic radii of Ce^{4+}, Lu^{3+}, Er^{3+}, Y^{3+}, Dy^{3+}, Tb^{3+}, Gd^{3+}, Eu^{3+}, Nd^{3+}, Pr^{3+}, and Ce^{3+}. The linear least-squares fit (R^2 = 0.949) is shown as the solid line in the figure. The slope, 0.78(6), and intercept, 1.56(6), of this fit are statistically equivalent to those obtained from the fit to the An−O distances of Figure 4(a), suggesting that the An and Ln ions have similar coordination behavior as a function of ionic size.

As with the An and Ln Wells−Dawson butterfly complexes of Figure 1(a), the Lindqvist decatungstate complexes provide an 8 O square antiprism coordination environment, illustrated in Figure 1(b), for both An and Ln cations. In view of the resemblance of the innermost O coordination environments provided by these two polyoxoanions, evaluation of the Lindqvist Ln−O bond length dependence on IR as shown in Figure 4(c) is informative. For the six $[Ln^{3+}(W_5O_{18})_2]^{9-}$ (Ln^{3+} ≡ Dy, Tb, Gd, Sm, Nd, Pr) previously published[18] crystal structures with the same countercations−$K_3Na_4H_2$−there is a linear dependence of bond length with IR. The least-squares fit (R^2 = 0.846) to the 6 distances − open squares in Fig-

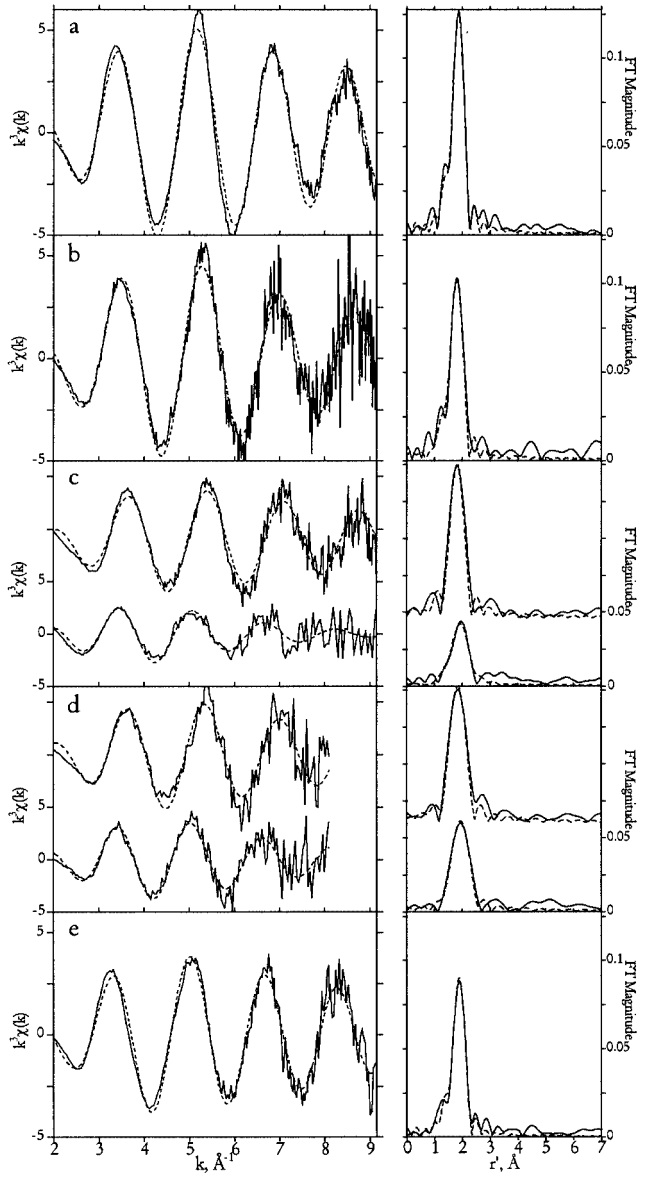

Figure 3. (Left panel) The experimental $k^3\chi(k)$ EXAFS data (solid lines) for $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ with An of (a) Th^{4+}, (b) U^{4+}; (c) Np^{4+} (top) and Np^{3+} (bottom); (d) Pu^{4+} (top) and Pu^{3+} (bottom); (e) Am^{3+}. (Right panel) Fourier transform data (solid lines) of the $k^3\chi(k)$ EXAFS to the immediate left. The best fits are shown as dashed lines in both the Left and Right panels

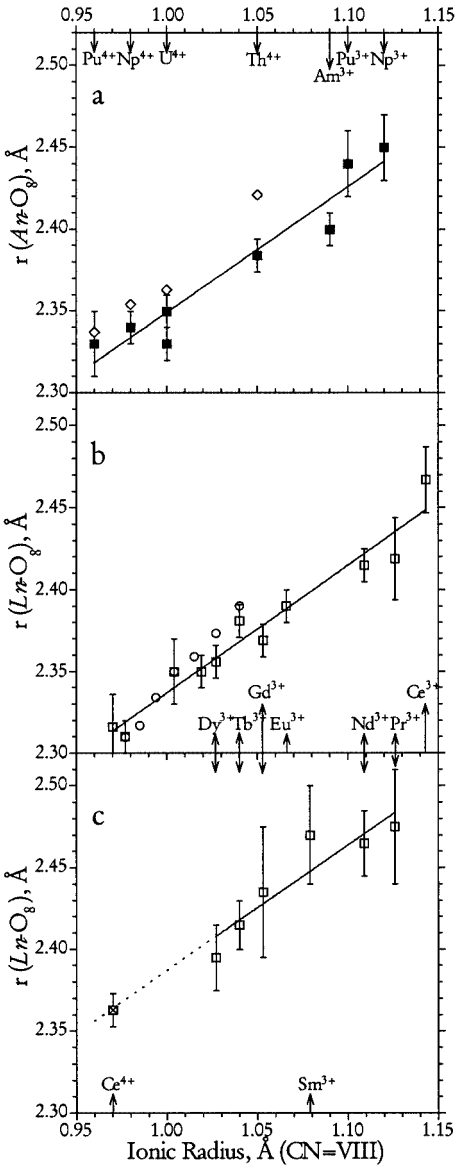

Figure 4. Variation of the $An-O_8$ and $Ln-O_8$ interatomic distances with the appropriate ionic radii of Shannon[27] for CN= VIII. (a) The EXAFS results for the solid K^+ salts and solutions of $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ with An^{3+} and An^{4+} ions (solid squares) and the least-squares fit (solid line). Open diamonds are the $An-O_8$ distances for the AnO_2 solids of Th^{4+}, 2.421(1) Å;[43] U^{4+}, 2.363(1) Å;[44] Np^{4+}, 2.354(1) Å;[45] Pu^{4+}, 2.337(1)[45] Å. (b) The EXAFS-determined $Ln^{n+}-O_8$ distances (open squares) for the solid K^+ salts of $[Ln^{n+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-20}$ and the least-squares fit (solid line) with 11 ions (Ce^{4+}, Lu^{3+}, Er^{3+}, Y^{3+}, Dy^{3+}, Tb^{3+}, Gd^{3+}, Eu^{3+}, Nd^{3+}, Pr^{3+}, and Ce^{3+}, in order of increasing IR). The EXAFS-determined distances of Ishiguro et al.[32] for the trivalent aquo ions of Lu−Tb are shown as open circles. (c) The crystallographically-determined average distances of Ozeki et al.[18] for 6 $Na_4K_3H_2[Ln^{3+}(W_5O_{18})_2]$ salts (open squares) and the least-squares fit (solid line), which is extrapolated to the IR for Ce^{4+} (0.97 Å) for comparison with the average crystallographic $Ce^{4+}-O_8$ distance determined for $Na_8[Ce^{4+}(W_5O_{18})_2]$[24]

ure 4(c) − is shown as the solid line, which was extrapolated (dashed line) to the IR minimum (0.96 Å) of Figure 4(a). The soundness of the extrapolation is evident from the coincidence of the crystallographically determined $Ce^{4+}-O$ interatomic distance (square at 0.97 Å) for $[Ce^{4+}(W_5O_{18})_2]^{8-}$.[24] The slope, 0.77(16), and intercept, 1.62(18), of the Ln−O distance vs. IR correlation for the Lindqvist complexes are statistically equivalent with those for the Ln and An Wells−Dawson complexes, thus providing quantitative evidence for the similarity of coordination environments in these two tetradentate polyoxometalate ligands.

Having viewed the Ln- and An−O distances in the context of polyoxometalate structural chemistry, it is informative to gauge the distances of Figure 4(a) and (b) (solid and open squares, respectively) with those for other systems in which Ln and An ions are known to be 8 coordinate with

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

O atoms. For example, the solid dioxides, AnO_2, are prototypical materials in which all An^{4+} are 8 coordinate. The An−O bond lengths for Pu^{4+}, Np^{4+}, U^{4+}, and Th^{4+} in the AnO_2 fluorite structures are presented in Figure 4(a) as open diamonds. Although these are generally longer than the An−O distances [Figure 4(a), solid squares] for the Wells−Dawson complexes of An^{4+}, they are within agreement in view of the experimental uncertainties, including the 0.04 Å difference between the $[Th(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ and ThO_2 distances.

Comprehensive studies of the $Ln^{3+}\cdot nH_2O$ aquo species indicate that the hydration number (n) is 8 for the small, heavy ions at the end of the 4*f* series, $Tb^{3+}-Lu^{3+}$.[28−31] The Ln−O bond lengths, from the work of Ishiguro et al.,[32] for these 8 coordinate Ln aquo ions is shown in Figure 4(b) (open circles). The bond lengths for the $[Ln(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{17-}$ complexes [Figure 4(b), open squares] with Tb−Lu ($0.977 \leq IR \leq 1.04$ Å) generally agree with those for the corresponding aquo ion species. In view of the differences in nuclearity and charge between the tetradentate anionic (10−) heteropolyoxometalate and the monodentate neutral water molecule, it is surprising that the bond lengths are so much alike.

Because the large, light Ln^{3+} and An^{3+} ions can assume hydration numbers of 9 or more, there is a dearth of metrical detail for additional systematic comparisons. In fact, the fixed eightfold O coordination for all An/Ln ions in the Wells−Dawson butterfly series of Figure 1(a) may not result in the formation of especially robust complexes with the large Ln^{3+} and An^{3+} compared with the smaller ones, including the tetravalent ions. This view is borne out in the data of Figure 5, which is a plot of the formation constants, $\log\beta_2$, available from the work of Bion et al.[10] versus 1/IR for CN = VIII of Ce^{3+}, Am^{3+}, Eu^{3+}, U^{4+}, Ce^{4+}, and Pu^{4+}. Based upon interpretations of similar plots for other Ln^{3+} complexes,[29,31] the overall direct dependence of $\log\beta_2$ with 1/IR is evidence that the coordination does not change.

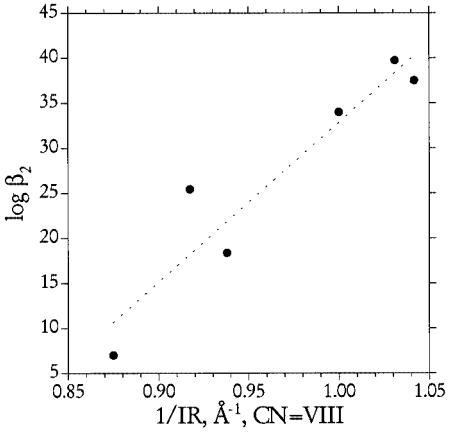

Figure 5. The absolute formation constants, log β_2, of Bion et al.[10] versus 1/IR of Shannon[27] for CN = VIII of the Ce^{3+}, Am^{3+}, Eu^{3+}, U^{4+}, Ce^{4+}, and Pu^{4+} ions (in order of increasing 1/IR) for the Wells−Dawson butterfly complexes of Figure 1(a). The least-squares fit (dashed line, $R^2 = 0.889$) with slope = 177±31 and intercept = −145±30.

Moreover, the regular variation of $\log\beta_2$ with 1/IR indicates similar cation-anion interactions throughout the 4*f*- and 5*f*-series of Wells−Dawson complexes. Although detailed insights are not available with the limited data (six points) of Figure 5, the approximately linear correlation ($R^2 = 0.889$) is consistent with our EXAFS data. The fairly large formation constants of Figure 5 for U^{4+}, Ce^{4+}, and Pu^{4+} are consistent with their short bond lengths and, hence, strong complexation. As expected, the largest ion, Ce^{3+}, of the series in Figure 5, has the smallest formation constant and the longest distance.

The variation of interatomic distances and formation constants with IR, depicted in Figures 4 and 5, show no indication of precipitous changes in An−anion interactions that would account for the stability of the An^{4+} complexes. Instead, a simple electrostatic explanation, arising from ionic charge and size changes, is consistent with all the data in hand. Although the Wells−Dawson and Lindqvist anions stabilize the small An^{4+} ions, this is not general behavior in An and Ln polyoxometalate chemistry. For example, we have found that the Preyssler anion, $[P_5W_{30}O_{110}]^{15-}$, stabilizes Ce^{3+} over Ce^{4+},[33,34] despite the large negative charge on the anion. Tetravalent Ce forms one of the strongest complexes of the Wells−Dawson series, $[Ce(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$, but has yet to form a complex with the Preyssler anion.[33,34] Similarly, although Pu^{4+} is stabilized in $[Pu(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$, it is Pu^{3+} that is stabilized in $[PuP_5W_{30}O_{110}]^{12-}$.[35] Whereas the present results support the use of the monovacant α-2-$[P_2W_{17}O_{61}]^{10-}$ isomer in the PUREX and SESAME processes for U^{4+} analyses and Am^{4+} valence control, respectively, a predictive understanding of the effects of different polyoxometalates on An redox speciation is not yet available.

Conclusion

The technological prospects of polyoxometalates, in general, and of α-2-$[P_2W_{17}O_{61}]^{10-}$, in particular, for use in radioactive waste processing operations are due to, in part, the strength of their chemical interactions with *f*-elements, particularly the tetravalent 5*f* (actinide) ions. By comparisons with published structures of An dioxides with 8 O coordination environments, we have shown that the $An^{4+}-O$ interactions in complexes of $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ are of the expected magnitude. The variations of An−O interatomic distances and formation constants with An ionic radii are consistent with behavior expected from simple electrostatic considerations of charge and size. Identical behavior was found for $Ln^{3+}-O$ and $Ce^{4+}-O$ coordination in $[Ln(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{17-}$ and $[Ce(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ as well as for the Lindqvist complex anions, $[Ln^{3+}(W_5O_{18})_2]^{9-}$ and $[Ce(W_5O_{18})_2]^{8-}$. The stability of U^{4+}, Np^{4+}, and Pu^{4+} in complexes $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ and $[An(W_5O_{18})_2]^{8-}$ is understood in terms of strong electrostatic interactions between the spherical An^{4+} cations and the anionic polyoxometalate ligands.

Experimental Section

CAUTION. Th, U, Np, Pu, and Am are radioactive elements. All experiments with these isotopes were performed in specialized laboratories using procedures designed and approved to minimize radiological and chemical hazards. For the transuranic elements, i.e., Np, Pu, and Am, their limited availability, together with radiation exposure concerns, require the use of only mg quantities and thereby limit studies to small sample sizes.

Syntheses: The lacunary, monovacant isomer, $K_{10}[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]\cdot 20H_2O$, was isolated as described elsewhere.[36] The 1:2 $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ complexes with natural Th and U, ^{237}Np, ^{242}Pu, and ^{243}Am were prepared in milligram-scale quantities, by methods adapted from larger-scale syntheses of the lanthanide complexes,[37] through the dropwise addition of one equivalent of Th^{4+}, U^{4+}, Np^{4+}, Pu^{4+}, and Am^{3+} in 1 M $HClO_4$ to warm (60 °C) stirred solutions containing two equivalents of $K_{10}[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]\cdot 20H_2O$ in 0.5 M CH_3CO_2Li buffers of pH = 4.7. The resulting white, violet, yellow, pink, and orange colored solid potassium salts, respectively, were obtained by cooling and slow evaporation of the mother liquor. The An sources were $Th(NO_3)_4\cdot nH_2O$ (Alfa−Aesar); UCl_4 (Strem); purified ^{237}Np stock solution of $[Np(V)O_2]ClO_4$ that was electrochemically reduced to Np^{4+} according to previous procedures;[26,38] purified ^{242}Pu stock solution of $[Pu^{4+}(ClO_4)_4]$ in which the tetravalent oxidation state of Pu was maintained by vigorous sparging with NO; column-purified $^{243}AmCl_3$. The series of 1:2 $[Ln^{3+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{17-}$ complexes for Ce, Pr, Nd, Eu, Gd, Tb, Dy, Y, Er, and Lu as well as $[Ce^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ were synthesized and isolated as solid potassium salts in the same manner from $K_{10}[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]\cdot 20H_2O$ and commercial Ln nitrates and Ln chlorides.

Measurements: Aqueous electrolytes consisting of 2:1 v/v mixtures of 0.5 M CH_3CO_2Li buffer at pH = 4.7 and 1 M $HClO_4$ were used for the solution XAFS experiments and in situ bulk electrolyses, which were performed with a BAS 100B/W electrochemical workstation and a purpose-built cell of previous design.[26,39] Carbon rod (Alfa) working and auxiliary electrodes and a Ag/AgCl reference electrode (BAS) were used as described elsewhere.[34] We first collected data for dilute (ca. 1 mM) solutions of $[An^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ for An ≡ U, Np, and Pu in the spectroelectrochemical cell with the electrodes at rest potential. This was followed by exhaustive (99−99.9%) electrolysis at −1.00 V and −0.30 V to produce the reduced heteropoly blue species with Np^{3+} and Pu^{3+}, $[An^{3+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$, that were maintained throughout the data acquisition with the electrode polarized at these potentials. Subsequent oxidation of the heteropoly blues provided X-ray and electrochemical signals that were the same as those for the starting materials, indicating reversibility of the redox chemistry. All XAFS data were obtained at the 7 GeV APS BESSRC CAT station 12 BM-B with a Si<111> monochromator and focusing optics.[40] The An L_3-edge X-ray data were acquired with a multi-element fluorescence detector (Canberra) and the Ln L_3-edge data were acquired with a Lytle-type ion chamber (The EXAFS Co.) in the conventional 45/45° configuration without slits and filters. Energy calibration was maintained with respect to Y metal powder (Th and U L_3-XAFS), Zr foil (Np and Pu L_3-XAFS), and Nb foil (Am L_3-edge XAFS) by setting the inflection points in the first differential transmission XANES data to 17.038, 17.998, and 18.986 eV, respectively. Between four and twelve scans were summed for the solution species and solid samples. XANES and EXAFS data analyses were performed with WinXAS.[41] All EXAFS data were truncated at $k_{max} \approx 9$ Å^{-1} to reduce noise in the FT data and to keep the inner-sphere An−O structural information clear. In view of the range of data available here ($\Delta k \approx 7$ Å^{-1}, $\Delta r \approx 2$ Å^{-1}) and the maximum number of independent parameters ($N_{idp} \approx 8$), we were careful to use conservative models in the curve fitting with single-scattering phase and backscattering amplitude calculations from FEFF8.01.[42] Three or, at most, 4 parameters (O coordination number, N_O; An−O interatomic distance, r; Debye−Waller factor, σ^2; energy shift, ΔE_0) were refined in the single-shell curve fitting with $S_0^2 = 1$.[38]

Three Novel Polymeric Frameworks Assembled from Cd^{II}, Co^{II}, and Mn^{II} with the Mixed Organic Ligands 3,4-Pyridinedicarboxylate, 1,3-Bis(4-pyridyl)propane, or 1,2-Bis(4-pyridyl)ethane

Keywords: Coordination polymer / Crystal engineering / Mixed ligands / Structural topology

Hydrothermal reactions of Cd^{II}, Co^{II}, and Mn^{II} with the mixed ligands 3,4-pyridinedicarboxylate (pydc), 1,3-bis(4-pyridyl)-propane (bpp), or 1,2-bis(4-pyridyl)ethane (bpe) gave crystals of $\{[Cd(pydc)(bpp)]\cdot 0.5H_2O\}_n$ (**1**), $\{[Co(pydc)(H_2O)(bpe)_{0.5}]\cdot 0.5H_2O\}_n$ (**2**), and $\{[Mn(pydc)(H_2O)(bpe)_{0.5}]\cdot 0.5H_2O\}_n$ (**3**), respectively. Single-crystal X-ray analyses reveal that these are all three-dimensional non-interpenetrating coordination polymers. Their structures alter markedly with the conformation and the function of the ligands. In **1**, the 3,4-pyridinedicarboxylate acted as a three-connector, a coordination topology of the type (3,5) [containing 3 and 5 connected centers] being generated through self-assembly, while in **2** and **3**, with the help of the four-connector 3,4-pyridinedicarboxylate and the terminal ligand water molecule, another three-dimensional framework with a coordination topology of the type (**4**, **5**) was obtained.

Introduction

The design and construction of coordination polymers are of great interest due to their intriguing new structural topologies and potential applications as functional materials.[1−6] Many attractive networks with various structural motifs, including honeycomb,[7−8] brick wall,[9] rectangular grid,[10−11] bilayer,[12−15] ladder,[16−17] herringbone,[18] diamondoid,[19−21] and octahedral[22−23] geometries, have been constructed in the past decade by use of single bridging organic ligands such as 4,4′-bipyridine, pyrazine, and related species. Recently, in order to fabricate more novel complicated supramolecular networks, the employment of metal ions with different kinds of organic ligands has gradually become established as a useful strategy.[24−25] This method may provide new structural motifs not accessible by the application of metal ions with a single ligand. The structural and functional features of the whole self-assembled entities contain the information of their components.[26] To date, however, there has been only one reported polymer with pydc as ligand,[27] and no frameworks constructed by it together with other organic ligands have been observed. This paper reports the synthesis and characterization of three new coordination polymers assembled from metal ions and the mixed ligands 3,4-pyridinedicarboxylate, 1,3-bis(4-pyridyl)propane, or 1,2-bis(4-pyridyl)ethane: namely $\{[Cd(pydc)(bpp)]\cdot 0.5H_2O\}_n$ (**1**), $\{[Co(pydc)(H_2O)(bpe)_{0.5}]\cdot 0.5H_2O\}_n$ (**2**), and $\{[Mn(pydc)(H_2O)(bpe)_{0.5}]\cdot 0.5H_2O\}_n$ (**3**) [pydc = 3,4-pyridinedicarboxylate, bpp = 1,3-bis(4-pyridyl)propane, bpe = 1,2-bis(4-pyridyl)ethane]. Single-crystal X-ray analyses show that the conformations and the functions of the ligands play an important role in affecting the final structural motifs of the polymers. In **1,** with 3,4-pyridinedicarboxylic acid acting as a tritopic subunit and 1,3-bis(4-pyridyl)propane acting as a ditopic subunit, the self-assembly results in an interesting three-dimensional framework with a coordination topology of the (3,5) type, while in **2** and **3**, with 3,4-pyridinedicarboxylic acid acting as a tetratopic subunit, 1,2-bis(4-pyridyl)ethane acting as a ditopic subunit, and a water molecule acting as terminal ligand, another appealing three-dimensional framework with a coordination topology of the (4,5) type is obtained. To the best of our knowledge, these are two new, previously unreported types of structural motifs.

Results and Discussion

Syntheses

In the synthesis of **1**, a molar ratio of 2:2:1 (Cd/pydc/bpp) was used in the preparation, but a framework with a stoichiometric ratio of 1:1:1 was obtained. In order to investigate what would happen if the latter ratio was applied, more experiments were done, but unfortunately no single crystal was obtained. When Co^{II} and Mn^{II} were used to repeat the above experimental procedure, complexes **2**

and **3**, with 2:2:1 stoichiometric ratios exactly the same as those of the original reactants, were generated.

Crystal Structures

Single-crystal X-ray analysis reveals that **1** has a three-dimensional, non-interpenetrating coordination network. Each Cd^{II} center has a slightly distorted $\{CdN_3O_4\}$ pentagonal bipyramid coordination sphere, with one 1,3-bis(4-pyridyl)propane nitrogen donor and four oxygen donors of two chelating bidentate carboxylate groups of the 3,4-pyridinedicarboxylate in the equatorial plane. The coordination sphere is completed by one nitrogen donor of 1,3-bis(4-pyridyl)propane and one nitrogen donor of 3,4-pyridinedicarboxylate in the axial direction (Figure 1). The metal centers provide the penta-connecting trigonal bipyramid nodes, while the ligands act as di-connectors and tri-connectors, respectively. The spontaneous association of these subunits results in a new kind of 3D framework (Figure 2, a). In a side view of the network (Figure 2, b), it is interesting to observe that two kinds of rings exist. One is a cyclohexane-like ring, made up of three Cd^{II} ions and three centers of 3,4-pyridinedicarboxylate, displaying a chair conformation, while the other is also a six-membered ring, formed by four Cd^{II} ions and two centers of the 3,4-pyridinedicarboxylate, exhibiting a boat conformation. Viewed onto the *ac* plane, the whole feature of the framework looks like the bellows of an accordion, showing folds. The metal centers, which are distributed in the sheets, are not all coplanar. Rather, half fall in one plane, and half in an adjacent plane, displaying a helical conformation. Two rods of the 1,3-bis(4-pyridyl)propane two-connectors form two edges of the sheet and two rods of the 3,4-pyridinedicarboxylate tri-connectors make up the other edges (connections between nodes within the structure are referred to in general as rods). The third rod of 3,4-pyridinedicarboxylate links to the adjacent layer, producing a remarkable three-dimensional framework. Infinite narrow channels exist in the framework and their arrangement fits the symmetry of the space group *C*2/*c*. The height of one channel is exactly the width of another and each pair of diagonal channels displays a centrosymmetric configuration. Close examination of the channels revealed that water molecules acting as guests were embedded in the cavities and formed hydrogen bonds with the framework (O2···O5 2.776 Å).

Compounds **2** and **3** have the same structural motif, except for the difference in the metal center (Co for **2**, Mn for **3**). The local coordination geometry around the centrosymmetric metal center can be described as a slightly distorted octahedron configuration (Figure 3). One nitrogen atom of the 3,4-pyridinedicarboxylate and one nitrogen atom of 1,2-bis(4-pyridyl)ethane occupy the axial positions of the coordination sphere. Three oxygen atoms of 3,4-pyridinedicarboxylate and one oxygen atom of a water molecule coordinate the metal center in the equatorial plane. What is different from **1** is that two kinds of coordination modes exist in the carboxylate groups of the 3,4-pyridinedicarboxylate in **2** and **3** (Scheme 1). One is bidentate and the other is monodentate, which makes the 3,4-pyridinedicarboxylate ligands act as tetra-connectors. While the water molecule acting as a terminal ligand occupies one reaction site of the octahedral coordination sphere, this makes the six-coordinate metal center also provide a penta-connecting node. Nevertheless, it has a tetragonal pyramid configuration, different from the penta-connecting trigonal bipyramid conformation existing in **1**. The self-assembly of the tetra-connectors and the penta-connecting nodes creates a two-dimensional layer (Figure 4, a). Viewed down the *b* axis, the metal centers of the dinuclear units, located in the layer, are distributed in two different planes (Figure 4, b). The di-connector 1,2-bis(4-pyridyl)ethane occupies the other two reaction sites of the penta-connecting nodes and links the adjacent metal double layers from top and bottom, extending the structural motif into three dimensions (Figure 5). Just as in **1**, the water molecule is also enclathrated in the small cavity of the framework and it also forms a hydrogen bond with its host (O4···O6 2.743Å for **2** and O4···O6 2.819Å for **3**).

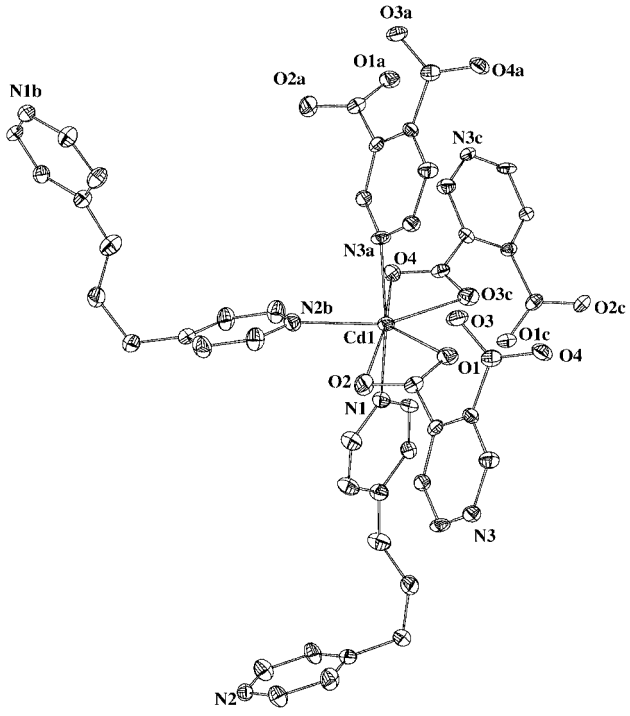

Figure 1. ORTEP drawing (at 30% probability) of **1** around the Cd center; the hydrogen atoms are omitted for clarity; symmetry code: a = x, $-1 + y$, z; b = $3/2 - x$, $-1 + y$, $1/2 + z$; c = $1 - x$, $2 - y$, $-1/2 + z$

Carboxylate ligands (such as trimesate, terephthalate, pydc etc.) have a great ability to construct coordination architectures with metal ions, adopting several different coordination fashions, ranging from unidentate to bidentate, sometimes in more than one way in the coordination architecture[28] Their bridging modes are highly dependent on the coordination modes of the carboxy groups, which can affect the final structural motifs of the polymers.[29] In compound **1**, in which the carboxy groups have a chelating bidentate coordination mode, the pydc ligands act as tri-connectors and connect the Cd centers, forming parts of the

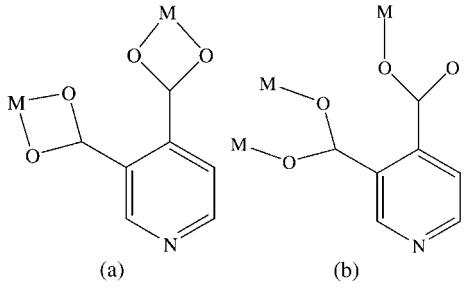

Scheme 1. The coordination fashions of the carboxylate group: (a) compound **1**: chelating bidentate; (b) compounds **2** and **3**: bi- and monodentate

rings, while in compounds **2** and **3** the bi- and monodentate coordination modes make the pydc act as tetra-connectors, which interlock the M (Co, Mn) centers, resulting in M(pydc) layers. The water molecule in **2** and **3** acting as an end-capping unit, also plays an important role affecting the structural feature of the polymers, which making the hexa-coordinate metal center provide a penta-connecting node. The whole structural feature of a coordination architecture results from the conformation of ligand and the coordination mode of metal center.[30−31] Different metal coordination geometries and different orientations of the interaction sites in a given ligand cause the framework to display various structural motifs.

Thermal Stability

To study the stability of these materials, thermogravimetric analyses (TGA) were performed on polycrystalline samples of these three compounds. The data for **1** showed

the two following, strikingly clean and well-separated, weight loss steps. In the first region (100−130 °C), it lost all guest water molecules (2% observed, 1.86% calculated). On further heating, the material lost weight continuously, corresponding to the preliminary decomposition of the whole framework, and an obvious decomposition was observed at 300 °C, corresponding to the final decomposition of the whole framework (Figure 6, a). The thermal decomposition behavior of compounds **2** and **3** was similar. The first weight loss in **2** started at ca. 105 °C up to 150 °C to give a weight loss of ca. 3%, corresponding to the loss of the solvated water molecule (2.62% calculated). On further heating, it lost one coordinated water molecule per formula unit between 150 °C and 250 °C (5.4% observed, 5.25% calculated). Immediately above 250 °C, an obvious weight loss continuing to 290 °C was observed, corresponding to the loss of half a bpe molecule per formula unit (27.4% observed, 26.84% calculated). The decomposition of **2** was complete at ca. 500 °C (Figure 6, b). In compound **3**, an initial weight loss of 2.7% at 150 °C, corresponding to the removal of the solvated water molecule (2.65% calculated), was followed by further weight loss of 5.92% (5.31% calculated) at 305 °C for evacuation of the coordinated water molecule. From 305 to 350 °C, the TGA trace of **3** showed a sharp decline to give a total weight loss of ca. 28.3% (27.16% calculated), corresponding to the loss of half a bpe molecule per formula unit. Finally, compound **3** decomposed completely at about 510 °C (Figure 6, c). All TGA data indicate that the guest water molecules play an important role in stabilizing these coordination networks. When these are liberated from the cavities, the frameworks im-

mediately begin to collapse. The corresponding X-ray powder diffraction (XRPD) data also confirm these changes (Figure 7).

Fluorescent Properties

The emission spectra of complexes **1**−**3** in the solid state at room temperature are shown in Figure 8. It can be observed that the intense emissions occurring in the same range for the three different metals can be assigned to ligand-metal charge-transfer (LMCT) bands, similar to those observed for dipyridinocrown ether ligands[32] (Figure 8, a: λ_{ex} = 210 nm, λ_{em} = 326 nm for **1**; Figure 8, b: λ_{ex} = 300 nm, λ_{em} = 398 nm for **2**; Figure 8, c: λ_{ex} = 220 nm, λ_{em} = 350 nm for **3**). Interestingly, a weak emission occurring at 486 nm for **2** (Figure 8, b: λ_{ex} = 300 nm), assigned as metal-ligand charge-transfer (MLCT) band, can be also observed. The reason for the MLCT phenomenon only occurring in compound **2** and not in compounds **1** and **3** may be that compound **2** contains the d^7 Co^{2+} metal center, in which d-electronic transition is easier than in the d^{10} Cd^{2+} metal center and in the d^5 Mn^{2+} metal center in the other two compounds.

Conclusion

Three new coordination polymers have been obtained by self-assembly of Cd^{II}, Co^{II}, and Mn^{II} with the mixed ligands 3,4-pyridinedicarboxylate (pydc), 1,3-bis(4-pyridyl)-propane (bpp), or 1,2-bis(4-pyridyl)ethane (bpe). The stabilities of these compounds are dependent on the existence of their guest molecules; when these guest molecules are liberated, the frameworks collapse. The structural figures of these whole frameworks contain the information of their components. In **1**, the penta-connecting trigonal bipyramid nodes combining with the di- and tri-connectors result in a (3,5) connected framework, while in **2** and **3**, with the penta-connecting tetragonal pyramid nodes cooperating with the di- and tetra-connectors, another interesting (4,5) connected framework was obtained.

This work shows that the conformations and the functions of the ligands play an important role in affecting the final structural motifs of the polymers. Investigation of the different coordination modes of the ligands may also help in the design of novel structural frameworks and fabrication of new functional materials.

Experimental Section

Materials and Methods: All chemicals were purchased and used without further purification. The C, H and N microanalyses were carried out with a Vario EL III elemental analyzer. Infrared spectra

(KBr pellets) were recorded in the 4000−400 cm^{-1} range with a Nicolet Magna 750 FT-IR spectrometer. Thermogravimetric analysis (TGA) was performed under nitrogen with a heating rate of 10 °C·min^{-1} using a TA5200/MDSC2910 system (TA Instruments, Inc.). Fluorescent spectra were measured with an Edinburgh FL-FS90 TCSPC system. X-ray powder diffraction were recorded with a Bruker AXS D8 advanced automated diffractometer with Cu-K_α radiation; the sample was heated in air and the measurement was performed after the sample had cooled down to room temperature.

Synthesis of $C_{20}H_{19}CdN_3O_{4.5}$ (1): An aqueous mixture (10 mL) containing 3,4-pyridinedicarboxylic acid (1 mmol), $Cd(NO_3)_2{\cdot}4H_2O$ (1 mmol), 1,3-bis(4-pyridyl)propane (0.5 mmol), and NaOMe (2 mmol) was placed in a Parr Teflon-lined stainless steel vessel (25 mL), and the vessel was sealed and heated to 150 °C for 168 h, then cooled at 2.5 °C h^{-1} to room temperature. Colorless needle-like crystals (0.14 g) were obtained in 56% yield. $C_{20}H_{19}CdN_3O_{4.5}$ (484.77): calcd. C 49.28, H 3.93, N 8.63; found C 48.29, H 3.67, N 8.62. X-ray Crystallographic Study: Crystallographic data for compounds **1**, **2**, and **3** are listed in Table 1. Data for **1**, **2**, and **3** were collected at room temperature with a Siemens SMART-CCD area-detector diffractometer with Mo-K_α radiation (λ = 0.71073 Å) and graphite monochromator using the ω-scan mode. Data reductions and absorption corrections were performed with SMART and SADABS software, respectively. The structures were solved by direct methods by use of SHELXS-97[33] and refined on F^2 by full-matrix, least squares.[34] All non-hydrogen atoms were treated anisotropically. The positions of hydrogen atoms were generated geometrically. The selected bond lengths and bond angles for the cluster cores of **1**, **2**, and **3** are listed in Table 2. CCDC-196855 to -196857 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work is supported by grants from the State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, the Chinese Academy of Sciences (CAS), and also the Ministry of Science and Technology of China (001CB1089), the National Science Foundation of China (20273073, 90206040), and the Science Foundation of CAS and Fujian Province, for research funding support (2002F014). Z.-Y. F. and J.-C. D. wish to thank Dr. J.-M. Lin for the PRXD determination and Prof. W.-D. Cheng for useful discussions on fluorescent properties.

Syntheses and Crystal Structures of Two Novel Zinc(II) Coordination Polymers

Jun Tao,*[a] Xin Yin,[a] Yun-Bao Jiang,[a] Le-Fu Yang,[a] Rong-Bin Huang,[a] and Lan-Sun Zheng*[a]

Keywords: Coordination polymers / Zinc / N ligands / Hydrogen bonds / Photoluminescence

Two novel zinc(II) coordination polymers, $[Zn_3(\mu_3\text{-}OH)_2(nip)_2]$ (**1**) and $[Zn_2(nip)_2(4,4'\text{-bpy})_3\cdot(OH_2)]$ (**2**) (H_2nip = 5-nitroisophthalic acid, 4,4′-bpy = 4,4′-bipyridyl), were obtained by the hydrothermal reactions of zinc nitrate, 5-nitroisophthalate (nip) (for **1**) and zinc nitrate, 5-nitroisophthalate and 4,4′-bipyridyl (for **2**). Complex **1** displays a two-dimensional structure that is built from $[Zn_3(\mu_3\text{-}OH)_2]_n$ chains, while complex **2** is a three-dimensional structure formed by the interpenetration of two-dimensional hydrogen-bonded bilayers. The photoluminescent properties of complex **1** have also been investigated.

Introduction

Recently, coordination polymer frameworks have attracted great attention not only owing to their fascinating applications in the areas of magnetism, optics, electronics, catalysis and sorption,[1−5] but also to their interesting topologies.[6] Among the frameworks reported so far, two types of interactions — coordinate covalent bonds and non-covalent intermolecular forces such as hydrogen bonding and π-π stacking — play major roles in constructing and stabilizing these polymers. Currently, the direct mixing of metal ions and a single organic ligand by means of coordinative covalent and/or hydrogen-bonding interactions has produced a great variety of such frameworks. One of our research interests has focused on a systematic study of the construction of coordination polymers by using mixed organic ligands under hydrothermal conditions,[7] and recently we have been investigating the influences of substituted isophthalate derivatives, such as 5-nitroisophthalate (nip), in which the two carboxylate groups can form covalent bonds with metal centers while the nitro group acts as a hydrogen-bond acceptor and can form strong hydrogen bonds, on the assembly process of coordination polymers.[8] Here we report the syntheses and crystal structures of two novel zinc(II) coordination polymers with the 5-nitroisophthalate ligand (nip), namely $[Zn_3(\mu_3\text{-}OH)_2(nip)_2]$ (**1**) and $[Zn_2(nip)_2(4,4'\text{-bpy})_3\cdot(OH_2)]$ (**2**). Interestingly, the nitro groups in complex **1** play important roles in the formation of the hydrogen bonds, while in complex **2** the 4,4′-bpy ligands act as hydrogen-bond acceptors.

Results and Discussion

The structures of $[Zn_3(\mu_3\text{-}OH)_2(nip)_2]$ (**1**) and $[Zn_2(nip)_2(4,4'\text{-bpy})_3\cdot H_2O]$ (**2**) were determined by single-crystal X-ray crystallography. Selected bond lengths and angles for **1** and **2** are listed in Table 1 and 2, respectively,

with crystallographic and refinement data in Table 3. As shown in Figure 1, compound **1** contains two-dimensional sheets constructed from $[Zn_3(\mu_3\text{-}OH)_2]_n$ chains and nip ligands, in which the crystallographically equivalent unit is one half of a nip ligand, one half of a Zn1 center, one quarter of a Zn2 center and one half of a μ_3-hydroxy group. The Zn1 center has pseudo-tetrahedral coordination symmetry, and is ligated by two oxygen atoms from two crystallographically equivalent μ_3-hydroxy groups [Zn1−O1 = 1.997(1) Å] and two oxygen atoms from two carboxylate groups [Zn1−O2 = 1.902(1) Å] of two symmetry-related nip ligands. The Zn2 atom is bound to four oxygen atoms from four different nip ligands in the equatorial plane and two oxygen atoms from two μ_3-hydroxy groups to give a pseudo-octahedral center [Zn2−O1 = 2.086(1) Å and Zn2−O3 = 2.135(1) Å]. The average Zn−O(H)−Zn angle (108.26°) in **1** is close to those found in typical tetrahedral Zn complexes containing μ_3-hydroxy groups, rather than the trigonal-planar one generally observed for μ_3-hydroxy groups.[9] The infinite $[Zn_3(\mu_3\text{-}OH)_2]_n$ chain-like structural motif shown in Figure 2 is also observed in the structures of three-dimensional basic zinc 4,4′-biphenyldicarboxylate and discrete basic zinc crotonate.[9a,10]

The infinite $[Zn_3(\mu_3\text{-}OH)_2]_n$ chains are stacked in parallel and connected by the nip ligands to give a two-dimensional undulating sheet. Viewed along the crystallographic *a* axis (Figure 3), the resulting two-dimensional framework is reminiscent of the shape of a compressed square, and obviously contains the C_{2h} point group. The nitro groups are found on the wave crest of both sides of the sheet, and the μ_3-hydroxy groups point away from the $[Zn_3(\mu_3\text{-}OH)_2]_n$ chains and into the trough. These undulating two-dimensional sheets are stacked in a parallel fashion with the wave crests coinciding with the troughs of adjacent sheets, and vice versa. The whole three-dimensional structure is then stabilized by inter-layer moderate hydrogen bonds (O1···O4 = 3.109 Å) between the μ_3-hydroxy groups in one

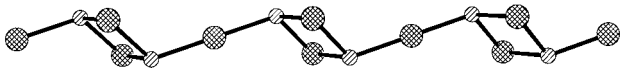

Figure 2. Perspective view of the one-dimensional $[Zn_3(\mu_3\text{-}OH)_2]_n$ structural motif

sheet and the nitro oxygen atoms in the adjacent sheet (Figure 4); they are bifurcated hydrogen bonds with $d_1 = d_2$.[11]

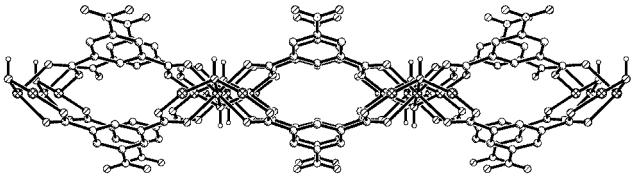

Figure 3. The two-dimensional structure of **1** viewed along the *a* axis

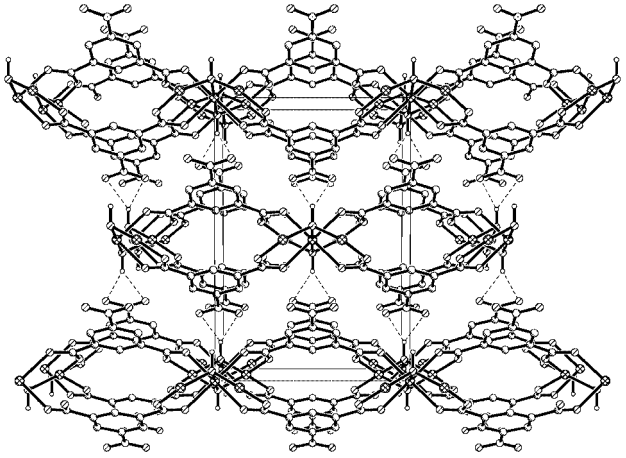

Figure 4. The hydrogen-bonded three-dimensional structure of **1** packed along the *a* axis

The crystal structure of **2** consists of hydrogen-bonded two-dimensional bilayered cuboids as the fundamental building unit. In the asymmetric unit there are two crystallographically unique Zn atoms, three 4,4′-bpy ligands, two nip ligands and one water molecule. The immediate coordination arrangement around the zinc centers in **2** is shown in Figure 5. The Zn1 atom lies in a slightly distorted octahedral environment, consisting of three nitrogen atoms from three different 4,4′-bpy ligands and three oxygen atoms from two symmetry-related nip carboxylate groups. The Zn2 atom, slightly different from Zn1 in its coordination environment, is ligated by two nitrogen atoms from two different 4,4′-bpy ligands, three oxygen atoms from two symmetry-related nip carboxylate groups and one water molecule, completing an octahedral coordination at Zn2. It is interesting to note that the 4,4′-bpy ligand containing the N5 and N6 atoms is linked to the Zn1 atom through only one of the nitrogen ends (N5), while the other end (N6) is hydrogen bonded to the coordinated water molecule in the adjacent layer [O1W···N6D = 2.758(7) Å], the water molecule is also hydrogen-bonded to the oxygen atom [O1W···O9B 2.653(7) Å] of a nip carboxylate group. Even more interesting is the fact that the three crystallographically unique 4,4′-bpy ligands are all non-coplanar, as can be seen from their different dihedral angles (N1−N2 = 36.4°, N3−N4 = 20.6° and N5−N6 = 29.6°).

The distinctive feature of **2** is that the alternating $[Zn(nip)(4,4'\text{-bpy})]_n$ and $[Zn(nip)(H_2O)]_n$ chains are covalently linked by μ_2-4,4′-bpy bridges, resulting in an interesting two-dimensional (4,4) coordination sheet with 4,4′-bpy ligands (N5−N6) suspended on one side (Figure 6). Two such sheets, located at an inversion center, are linked into a

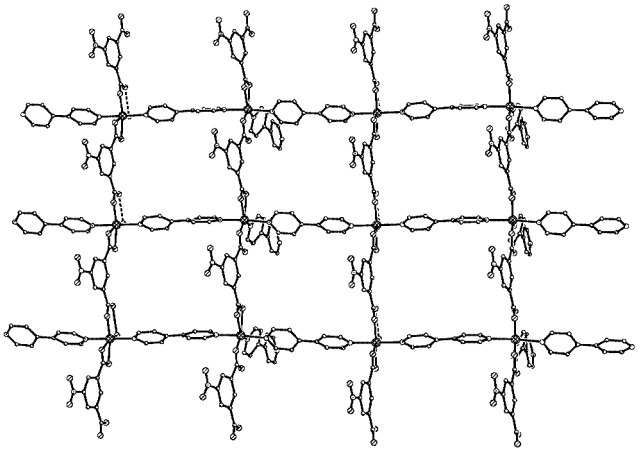

Figure 6. Perspective view of the two-dimensional (4,4) sheet of **2**

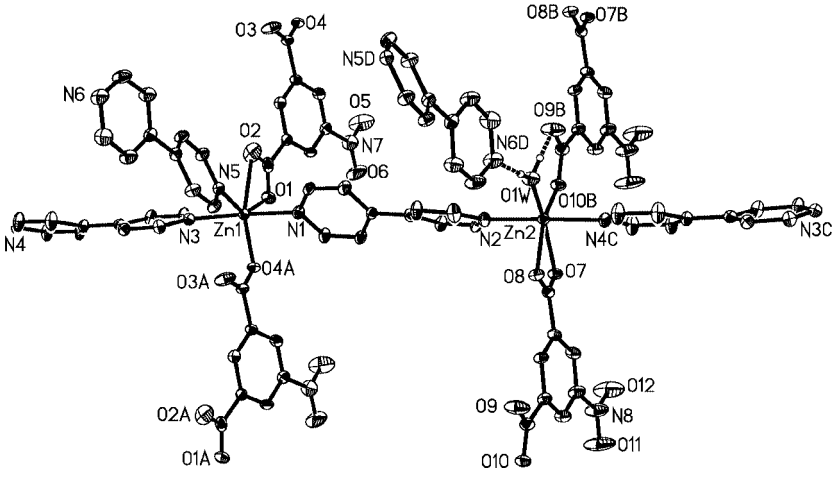

Figure 5. The coordination environments of zinc atoms in **2** with the atomic labeling scheme (30% probability)

two-dimensional bilayer by inter-layer hydrogen bonds [O1W···N6 = 2.758(7) Å] in a face-to-face fashion, whereas the nitro groups adopt an orientation that can be regarded as being *trans* to one another on either side of the bilayer, as shown in Figure 7. To the best of our knowledge, although several coordination bilayers having been reported,[7c,12] this is the first example of a bilayer connected through hydrogen bonds in coordination polymers. The cuboidal $[Zn_8(nip)_8(4,4'\text{-bpy})_8]$ building block with dimensions of ca. $10.100 \times 11.456 \times 13.971$ Å^3 in the bilayer is significantly different from those in other bilayer structures or three-dimensional structures.[7b,7c,12]

Although large void spaces exist within a single bilayer, there are no encapsulated guest molecules because of interpenetration. As shown in Figure 8, each bilayer is interpenetrated by two adjacent identical ones in a parallel fashion, the resulting extended array is therefore an infinite catenane of 2D architecture, as reported previously.[7c,12a] This is consistent with the fact that crystal structures with large cavities are inclined to self-interpenetrate.

As we previously reported, zinc oxide or hydroxide coordination polymers exhibit photoluminescent properties,[7a,7d] and we have also investigated the photoluminescent properties of **1** (Figure 9). In the solid state, **1** exhibits intense photoluminescence upon photoexcitation at 308 nm, the emission of **1** (λ_{max} = 354 nm) might be attributable to the formation of $[Zn_3(\mu_3\text{-}OH)_2]_n$ chains and/or ligand-to-metal charge transfer (LMCT).[7a,7d,13]

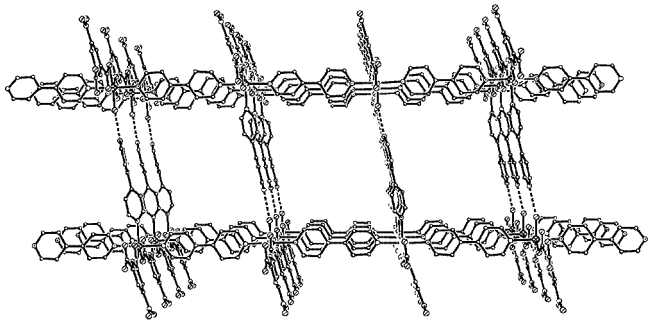

Figure 7. Perspective view of the two-dimensional bilayer of **2**

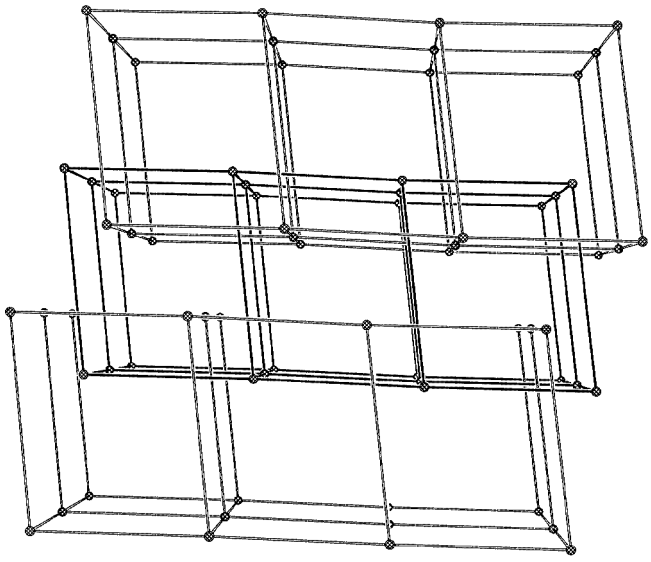

Figure 8. Perspective view of the twofold interpenetrated framework of **2**

Thermogravimetric analyses (TGA) of complexes **1** and **2** performed on polycrystalline samples reveal that **1** and **2** are thermally stable up to ca. 295 and 300 °C, respectively, indicating that even hydrogen-bonded frameworks can also be thermally stable at high temperatures.

In summary, two novel zinc(II) coordination polymers $[Zn_3(\mu_3\text{-}OH)_2(nip)_2]$ (**1**) and $[Zn_2(nip)_2(4,4'\text{-bpy})_3\cdot(OH_2)]$ (**2**) have been hydrothermally synthesized. Their structures are both two-dimensional with inter-layer hydrogen bonds, and **2** is the first hydrogen-bonded bilayer in coordination polymers.

Experimental Section

General Remarks: All starting materials were reagent grade and used as purchased. The elemental analyses were performed on a

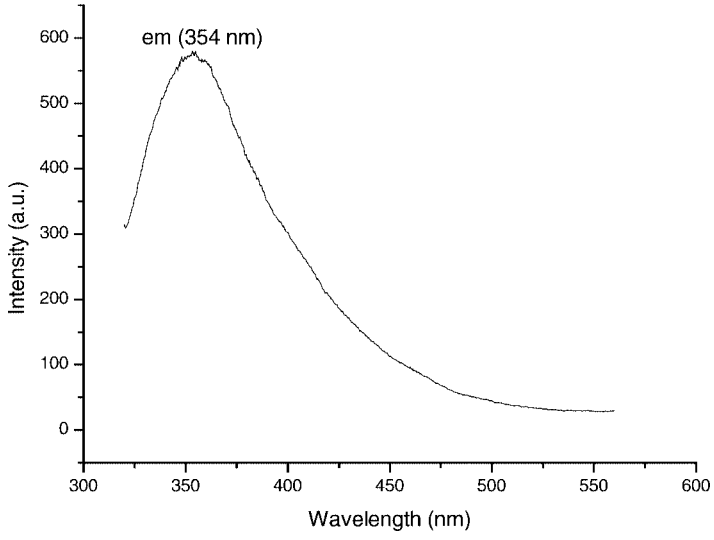

Figure 9. The solid-state photoluminescent spectrum of **1** at room temperature

Perkin−Elmer 240 elemental analyzer. The infrared spectra were recorded on a Nicolet 5DX spectrometer with KBr pellets. Thermal gravimetric analyses were performed in dinitrogen on a Perkin−Elmer 7 thermogravimetric analyzer with a heating rate of 10 °C/min.

Synthesis of 1: An aqueous mixture of $Zn(NO_3)_2{\cdot}6H_2O$ (0.158 g, 0.5 mmol), H_2nip (0.106 g, 0.5 mmol) and NaOH (0.04 g, 1 mmol) in a molar ratio of 1:1:2 was placed in a Teflon-lined stainless vessel, then the mixture was heated at 180 °C for 80 h. Colorless plate-like crystals were obtained in 50% yield based on zinc after the mixture was cooled to room temperature. $C_{16}H_8N_2O_{14}Zn_3$ (648.35): calcd. C 29.64, H 1.24, N 4.32; found C 30.01, H 1.40, N 4.22. IR (KBr): $\tilde{\nu}$ = 3538(m), 3084(w), 2925(w), 1636(s), 1614(vs), 1571(s), 1522(m), 1425(m), 1385(s), 1352(vs), 1206(w), 1127(s), 1065(w), 1027(w), 835(w), 785(m), 556(w) cm^{-1}.

Synthesis of 2: This compound was prepared as colorless plate-like crystals by the procedure described above for **1** except for the addition of 4,4′-bpy (H_2nip:4,4′-bpy = 1:2). Yield: 65% based on zinc. $C_{46}H_{32}N_8O_{13}Zn_2$ (1035.54): calcd. C 53.35, H 3.11, N 10.82; found C 53.10, H 2.83, N 11.01. IR (KBr): $\tilde{\nu}$ = 3427(s), 3090(w), 2924(w), 1610(vs), 1566(m), 1531(s), 1414(s), 1368(vs), 1345(s), 1219(m), 1073(m), 1064(w), 821(m), 789(w), 542(w) cm^{-1}.

Crystallographic Analysis: Data collection (single crystal with dimensions of 0.37 × 0.12 × 0.05 mm^3 for **1** and 0.40 × 0.20 × 0.05 mm^3 for **2**) was performed at 296(2) K on a Bruker APEX CCD-based diffractometer equipped with Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods using SHELXS-97[14] and refined with full-matrix least-squares technique using SHELXL-97.[15] All non-hydrogen atoms were refined anisotropically and the hydrogen atoms of the organic ligands were placed geometrically. The H atom of the hydroxyl group in **1** was located in the calculated position, and the H atoms of the coordinated water in **2** were found by Fourier syntheses. Selected crystallographic data and structure determination parameters for complexes **1** and **2** are presented in Table 3.

CCDC-201058 (**1**) and -201059 (**2**) contain the supplementary crystallographic data for this paper. The structure of **2** was re-refined after the data were deposited to CCDC. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Molecular Structures of Nickel(II) and Cobalt(III) Complexes with 2-(Arylimino)-3-(hydroxyimino)butane

Ennio Zangrando,*[a] Manuela Trani,[b] Elisa Stabon,[a] Carla Carfagna,[c] Barbara Milani,[a] and Giovanni Mestroni[a]

Keywords: Cobalt / Crystal structures / N-donor ligands / Nickel / Stacking interactions

We report new series of Ni^{II} and Co^{III} complexes with nitrogen-donor chelating ligands of the (*E*,*E*)-2-(arylimino)-3-(hydroxyimino)butane type (Ar–N⌒N–OH). These ligands are characterized by a hydrophilic (OH group) and a hydrophobic region (aryl group). Ni^{II} derivatives were obtained either as trimers of formula $[Ni_3(Ar–N⌒N–OH)_3Br_4(OH)][Br]$, with the hydrophobic groups oriented on the same side, or as bis(chelated) derivatives with *cis* geometry, depending on the steric hindrance of the aryl groups. Co^{III} complexes were obtained only as bis(chelated) derivatives, with the two ligands coplanar. The "*iso*-oriented" arrangement of ligands in bis(chelated) Co^{III} complexes is favored by weak interactions between the two ligands, namely O–H···O hydrogen bond and stacking interactions between the aryl groups. Co^{III} complexes might find application as catalysts for *living* or *controlled* radical polymerization of polar olefins, and preliminary results are reported.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Recent studies report that the molecular weights of polymers synthesized from olefin monomers with the aid of transition-metal catalysts or promoters can be tuned by the steric hindrance of the ancillary ligands.[1–6] In particular, the steric properties can be modulated by the introduction of 2- or 2,6-substituted aryl groups in planar bi-, tri- and tetradentate nitrogen-donor chelates. Some notable examples are reported in Figure 1.

When the substituted aryl groups are arranged perpendicular to the plane of the chelate, they create a particular steric hindrance above and below the plane of the chelate itself (Figure 1). Bi- and tridentate ligands of variable steric hindrance are easily accessible thanks to the synthetic procedure based on the condensation reaction between biacetyl (or 2,6-diacetylpyridine) and an appropriate aromatic amine.[1,2] On the other hand, convenient modulation of the steric hindrance is more difficult to achieve for tetradentate N-donor chelating ligands such as porphyrins or bis(dimethylglyoximate) derivatives.

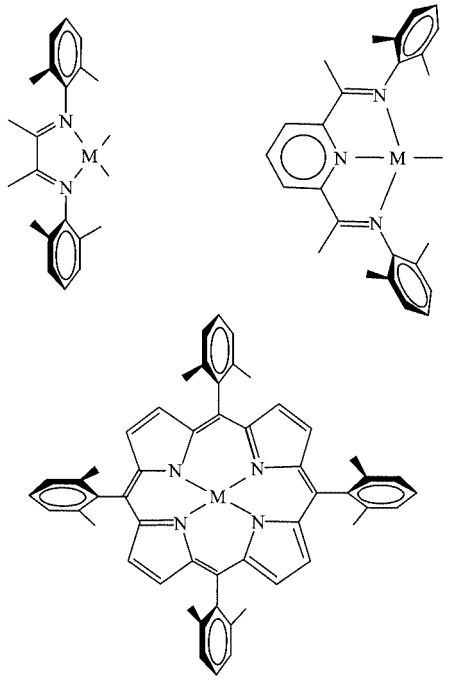

Figure 1. Examples of bi-, tri-, and tetradentate nitrogen-donor ligands and of the corresponding complexes

Such nitrogen-donor chelating ligands are of particular interest in the field of homogeneous catalysis. Depending on the nature of the metal, the olefin, and the experimental conditions, different reactions can be performed: nickel

complexes with bidentate chelating ligands or cobalt and iron complexes with tridentate chelating ligands, in the presence of MAO, promote the oligomerization or polymerization of ethylene or propylene by a coordinative mechanism.[1−5] Moreover, cobalt complexes with planar tetradentate chelating ligands have successfully been used in oligomerization and polymerization of polar olefins by a radical mechanism in the presence of AIBN [2,2′-azobis(isobutyronitrile)].[6−10] In particular, organometallic Co^{III} complexes with planar sterically hindered N-donor tetradentate chelating ligands polymerize polar olefins by a *living* radical mechanism.[6] In the absence of steric bulk, these complexes promote the oligomerization of the same substrates, yielding oligomers characterized by terminal C=C double bonds.[7] Cobalt derivatives with dimethylglyoxime (cobaloximes)[9] and analogous complexes, in which the bridging H atom is replaced by a BF_2 group,[10] turned out to be very efficient and cheap oligomerization catalysts. The presence of two OH···O bridging moieties in cobaloxime derivatives ensures coplanarity of the two molecules of ligand, which is necessary for these complexes to show catalytic activity.[7]

Interestingly, the effect of steric hindrance induced by chelating ligands is the same regardless of the type of polymerization mechanism. In both cases the chain termination step, a β-H elimination process, proceeding either through a coordinative[1] or a radical mechanism,[9,11,12] is slowed down with increasing bulkiness of the aryl moiety.

Very recently we reported that complexes of type *cis*-$[Co(CH_2Ph)_2(N-N)_2][PF_6]$ (N−N = bipy, phen) promote acrylonitrile polymerization by a *controlled* radical mechanism,[13] with behavior intermediate between that exhibited by cobalt complexes with sterically hindered and nonhindered planar tetradentate N-donor chelating ligands.

In this study we report the synthesis and characterization of nickel and cobalt complexes with a series of bidentate N-donor chelating ligands: namely, (*E*,*E*)-2-(arylimino)-3-(hydroxyimino)butanes (Ar−N∩N−OH) (Figure 2, a). The ligands in which the aryl group is phenyl or *o*-tolyl, are known[14,15] and the series has now been extended to other substituted amines.

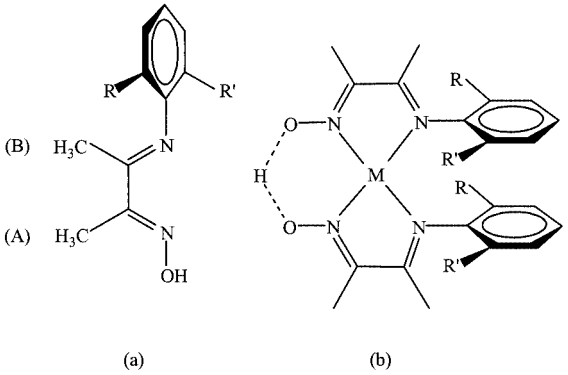

Figure 2. (a) Generic 2-(arylimino)-3-(hydroxyimino)butane ligand (Ar−N∩N−OH);(b) corresponding bis(chelated) planar complex

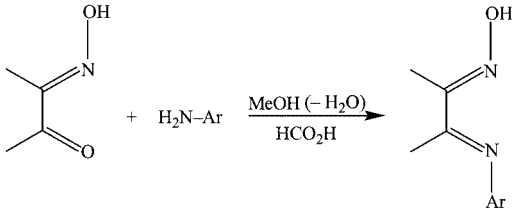
These ligands are characterized by a hydrophilic (OH) and a hydrophobic region (Ar). Therefore, with a ligand/metal ratio of 2:1, the formation of planar bis(chelated) species can be predicted, thanks to the possibility of establishing weak interactions between the two molecules of Ar-N∩N−OH, such as the hydrogen bond between the oxygen atoms and/or the stacking interaction between the aromatic rings (Figure 2, b). Unlike that in the planar bis(dimethylglyoxime) derivatives, the steric bulk in these complexes is directed normally to the equatorial plane and can be modulated by varying the nature of substituents in the 2- and the 6-positions of the aromatic ring.

Some results on the catalytic activity of the cobalt derivatives in the polymerization of methyl methacrylate (MMA) are also presented.

Results and Discussion

Synthesis and Characterization of 2-(Arylimino)-3-(hydroxyimino)butane Ligands 1a−1i

The chelating ligands (*E*,*E*)-2-(arylimino)-3-(hydroxyimino)butane are obtained by condensation of biacetyl monoxime with a series of different substituted aromatic amines (Scheme 1).



Ar = Ph **1a** 2-MeC_6H_4 **1b** 4-MeC_6H_4 **1c**
2-*i*PrC_6H_4 **1d** 2-*t*BuC_6H_4 **1e** 2,6-$Me_2C_6H_3$ **1f**
3,5-$Me_2C_6H_3$ **1g** 2,4,6-$Me_3C_6H_2$ **1h** 2,6-*i*PrC_6H_3 **1i**

Scheme 1. Synthesis of Ar−N∩N−OH ligands **1a−1i**

Syntheses were conducted in methanol at reflux for 5 h, starting from stoichiometric amounts of reagents, and in the presence of formic acid in catalytic amount. All ligands were obtained in high yields as white, crystalline solids. Crystals of **1h** suitable for X-ray diffraction analysis were obtained upon slow cooling of the reaction mixture.

Its structural characterization, with regard to the two N=C double bonds, shows a *syn*-methyl,*syn*-methyl conformation (Figure 3) that would require a rotation about the C(2)−C(3) bond in order to behave as a chelating ligand. The planarity of the O−N=C−C=N fragment, with a torsion angle of 162.7(5)°, is indicative of π-electron delocalization in the heterodiene fragment, as confirmed by the C(2)−C(3) bond length of 1.462(6) Å. This in fact appears to be slightly shorter than the accepted value of 1.48 Å for a $C(sp^2)-C(sp^2)$ single bond.[16] It may be of interest to point out the difference between the C=N−C angles at the N(2) imino and the N(1) oxime nitrogen atoms [120.1(5) and 111.8(4)°, respectively]. The mesitylene ring is roughly

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

perpendicular to the planar residue of the molecule, making a dihedral angle of 73°, an arrangement induced by steric hindrance between the groups. The crystal packing consists of chains with a zigzag motif, running along the crystallographic *c* axis, where O(1)−H ··N(2) hydrogen bonds [O···N = 2.749(5) Å] connect adjacent molecules. The molecular geometry and the packing resemble those found in the *p*-tolyl analogue.[15]

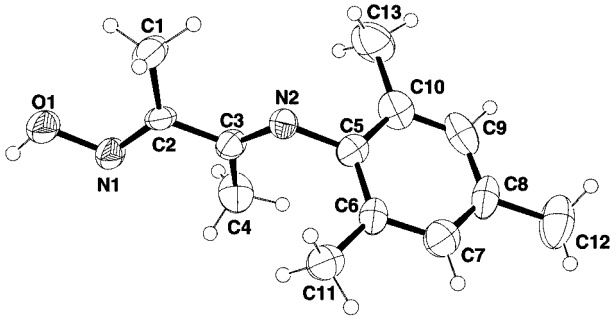


Figure 3. Molecular structure of ligand **1h** (ORTEP drawing, thermal ellipsoids 40% probability); selected bond lengths [A] and angles [°]: O(1)−N(1) 1.395(4), N(1)−C(2) 1.283(5), N(2)−C(3) 1.269(5), N(2)−C(5) 1.434(6), C(1)−C(2) 1.487(5), C(2)−C(3) 1.462(6), C(3)−C(4) 1.493(5); C(2)−N(1)−O(1) 111.8(4), C(3)−N(2)−C(5) 120.1(5)

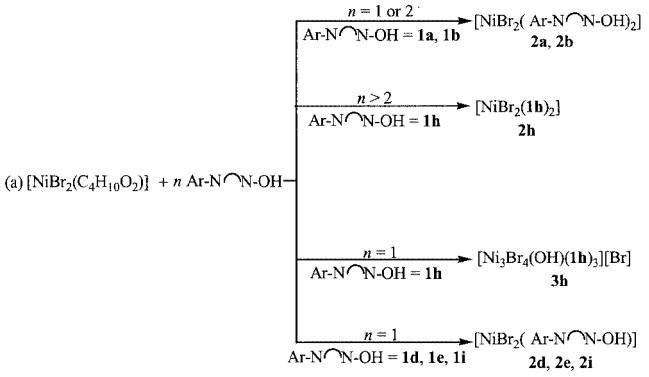
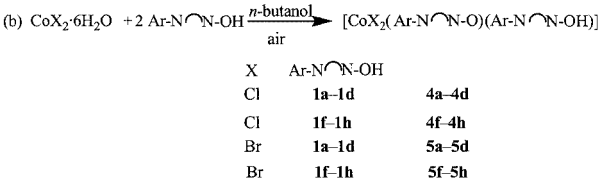
The ligands have been characterized by ^{1}H NMR spectroscopy in $CDCl_3$ (Table 1). ^{1}H NMR spectra exhibit two characteristic regions: aromatic (protons of the aryl groups at δ ≈ 6−7.5 ppm) and aliphatic (methyl groups of the biacetyl monoxime backbone and aromatic ring substituents at δ ≈ 2−3 ppm). A broad peak belonging to the OH group is also visible between δ ≈ 7.80 and 8.40 ppm. The assignment of signals to protons was based on NOE and COSY experiments. The signal of methyl group (A) in all the ligands was further downfield than that of the methyl group (B) (Figure 2, a); for the aryl protons, a downfield shift is observed on going from the β to the γ and to the α protons. The latter trend was also observed for alkyl substituents on the aromatic ring. These chelating ligands were used for the synthesis of both Ni^{II} and Co^{III} complexes.

Synthesis and Characterization of the Ni^{II} Complexes 2a, 2b, 2d, 2e, 2h, 2i; 3h

Synthesis of complexes was carried out in CH_2Cl_2, at room temperature, for 3 h, starting from $[NiBr_2(C_4H_{10}O_2)]$ ($C_4H_{10}O_2$ = ethylene glycol dimethyl ether) and using a ligand/nickel ratio of 1:1 or 2:1 (Scheme 2, a). The products were isolated as brown solids upon addition of diethyl ether or *n*-pentane to the reaction mixture.





Scheme 2. Synthesis of (a) nickel and (b) cobalt complexes

The products of the reaction were characterized by elemental analyses (Table 2) and, depending on the nature of the ligand, complexes of different stoichiometry were obtained. In particular, when ligands of low steric hindrance, such as **1a** and **1b**, were used, the products were bis(chelated) complexes of formula $[NiBr_2(Ar-N^{\cap}N-OH)_2]$ (**2a**, **2b**), regardless of the ligand/nickel ratio used in the synthesis. With the more hindered ligands **1d**, **1e**, and **1i**, a monochelated species was obtained when the synthesis was carried out with a ligand/nickel ratio of 1:1 (**2d**, **2e**, **2i**). No

[a] Calculated values in parentheses. [b] The yield was calculated by formulating the complex as [$NiBr_2$(Ar−N∩N−OH)].

bis(chelated) species was isolated when a ligand/nickel ratio > 1:1 was used. For the ligand with the mesityl group, **1h**, the bis(chelated) derivative [$NiBr_2$(**1h**)$_2$] (**2h**) was the product when the synthesis was performed with an excess of ligand. On the other hand, a monochelated species was obtained when a ligand/nickel ratio of 1:1 was used.

Single crystals suitable for X-ray analysis were obtained for the complexes with ligands **1a** (Figure 4) and **1h** (Figure 5), by slow precipitation from a dichloromethane solution with diethyl ether.

The structural determination of complex **2a** confirms its formulation as a bis(chelated) species with the nickel atom in a distorted octahedral coordination geometry. The two bromide ions are in a *cis* arrangement and the two *cis* chelating ligands **1a** are bound to the metal atom in a *head-to-tail* configuration with a dihedral angle of 85.8(4)° (Figure 4). The Ni−N coordination bond lengths involving oxime nitrogen donors *trans* to bromide are longer than the Ni−N(1) and Ni−N(3) bonds *trans* to each other by about 0.08 Å. The Ni−Br bond lengths of 2.561(2) Å are between the values found for the bridging Br^- in **3h** (see below). The N(2)−Ni−Br(1) and N(4)−Ni−Br(2) bond angles of about 165.5° deviate significantly from those expected for a regular octahedron. Nevertheless, each oxime hydrogen atom is pointing, at about 2.5 Å, toward the halide ion and the values for the bond angles could give support to an OH···Br interaction.

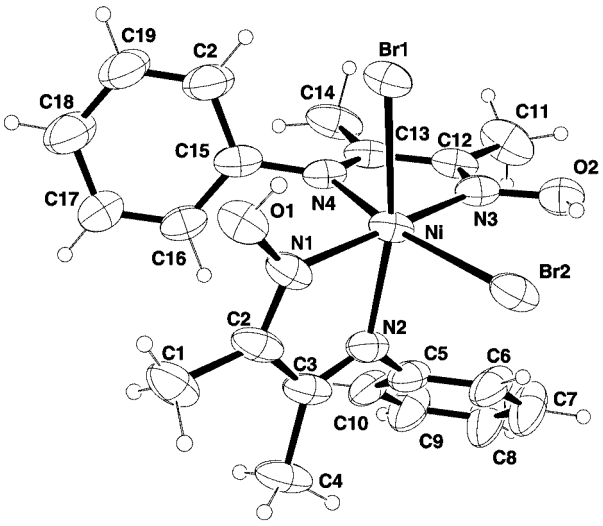

Figure 4. Molecular structure of compound **2a** (ORTEP drawing, thermal ellipsoids 40% probability); selected bond lengths [Å] and angles [°]: Ni−N(1) 2.026(8), Ni−N(2) 2.109(7), Ni−N(3) 2.018(8), Ni−N(4) 2.094(8), Ni−Br(1) 2.561(1), Ni−Br(2) 2.561(2); N(1)−Ni−N(2) 76.4(3), N(3)−Ni−N(4) 75.8(3), N(1)−Ni−N(3) 172.5(3), N(2)−Ni−Br(1) 166.1(3), N(4)−Ni−Br(2) 165.0(2), Br(1)−Ni−Br(2) 93.38(5)

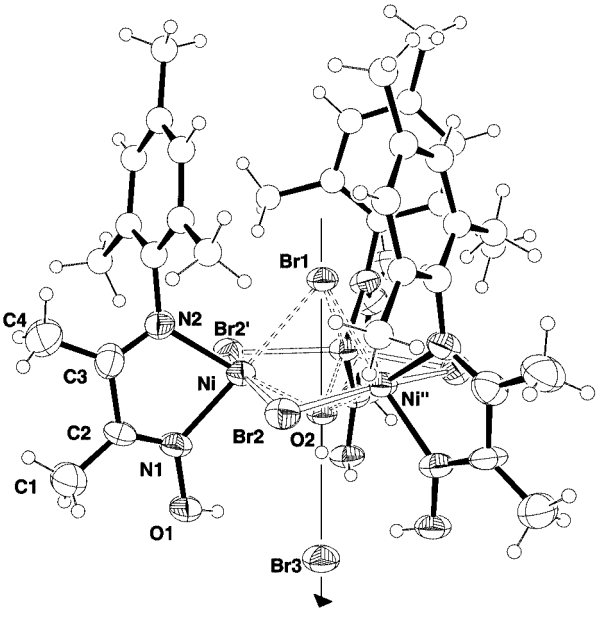

Figure 5. Molecular structure of compound **3h**; for sake of clarity aryl C atoms are indicated as spheres of fixed radius; selected bond lengths [Å] and angles [°]: Ni−Ni′′ 3.026(2), Ni−Br(1) 2.598(2), Ni−Br(2′) 2.551(2), Ni−Br(2) 2.578(2), Ni−O(2) 1.999(5), Ni−N(1) 2.024(8), Ni−N(2) 2.051(8); N(1)−Ni−N(2) 78.6(4), O(2)−Ni−N(1) 105.9(4), O(2)−Ni−N(2) 175.5(4), O(2)−Ni−Br(1) 76.8(3), O(2)−Ni−Br(2) 82.02(5), O(2)−Ni−Br(2′) 82.73(5), N(1)−Ni−Br(1) 175.4(3), N(2)−Ni−Br(1) 98.8(2), Br(2)−Ni−Br(2′) 164.67(7), Ni−Br(1)−Ni′′ 71.24(6), Ni−Br(2)−Ni′′ 72.32(6), Ni−O(2)−Ni′′ 98.4(3); symmetry codes: (′) $-x + y + 1, -x + 1, z$; (′′) $-y + 1, x - y, z$

The X-ray analysis of the complex with ligand **1h** reveals that it is a trinuclear species, corresponding to the formulation [Ni_3Br_4(OH)(**1h**)$_3$][Br] (**3h**).

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The unique and unexpected structure of complex **3h** is shown in Figure 5, together with selected bond lengths and angles. Its C_3 symmetry is illustrated by the view along the symmetry axis (Figure 6). The metal ions of three monochelated Ni(**1h**) fragments form an equilateral triangle. On each edge, the pair of nickel atoms, separated by 3.026(2) Å, is μ_2-bridged by a bromide ligand, slightly displaced by 0.2 Å from the Ni_3 plane, with Ni−Br(2) bond lengths of 2.551(2) and 2.578(2) Å. Another bromide ion and a hydroxy oxygen atom μ_3-bridge all the nickel ions with coordination distances of 2.578(2) and 1.999(5) Å, respectively. These capping species lie on the threefold axis, above [Br(1) +1.923(2) Å] and below [O(2) −0.97(1) Å] the metal plane. The coordination geometry around each nickel atom thus involves the nitrogen-donor atoms of a chelating ligand **1h**, three bromide ions, and a hydroxy group with bond angles that considerably deviate from the ideal octahedral values.

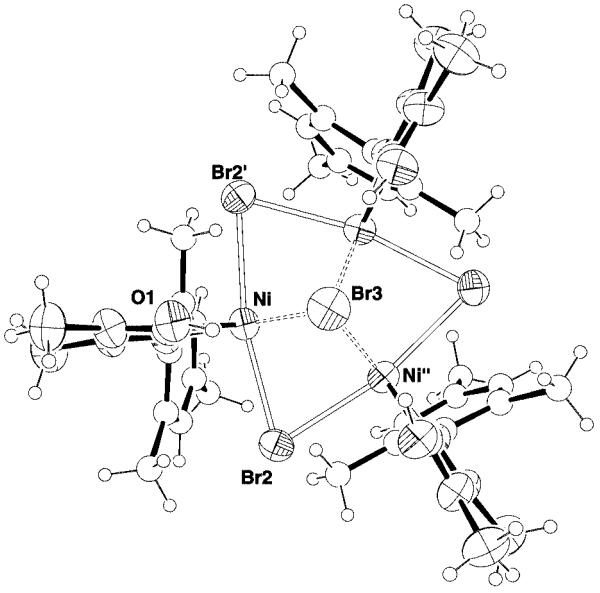

Figure 6. Projection down the threefold axis of the molecular structure of **3h**

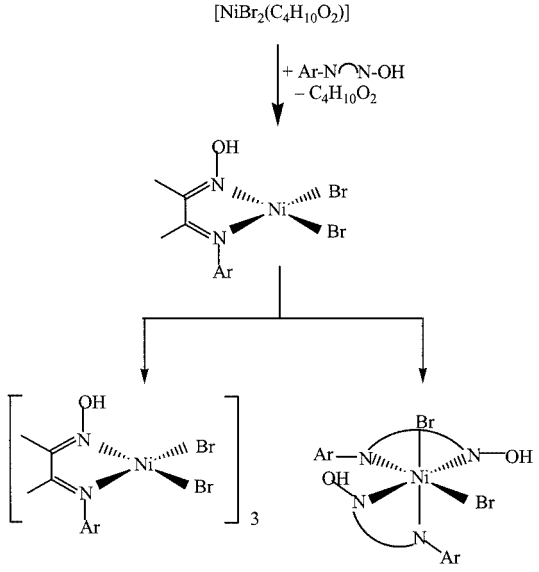
In the ligand, the C(2)−C(3) bond length of 1.522(14) Å, although of low accuracy, agrees with a single bond character indicating that, upon coordination, the delocalization inside the O−N=C−C=N moiety of the ligand seems to be removed.

To the best of our knowledge, two structures containing a strictly analogous Ni_3X_3 core (X = halide)[17,18] and with metal atoms capped by an oxygen atom and another halide ion have been reported; their Ni−Ni distances, averaged to 3.05 Å, are closely similar to those here. One of these, with tetramethylethylenediamine as chelating ligand (L) and with chloride replacing the bromide anions, has the same stoichiometry $[Ni_3X_4(OH)L_3][X]$.[17a] A trimeric copper species $[Cu_3(ClO_4)(OH)L'_3]^+$ containing the deprotonated ligand **1a** (L′) has also been reported.[17b] However, the crystal structure shows that L′ behaves as a tridentate species: it chelates a metal ion with the N atoms and simultaneously binds a close copper unit through the O donor, becoming almost coplanar with the metal triangle.

It is worth noting that in the current compound the electronic structural features of ligand **1h** give rise to an assembly possessing well-defined hydrophobic and hydrophilic domains. The former is delimited by the mesitylene groups. The aromatic rings, inclined to form an angle of 80.7(3)° with the Ni_3 plane, enclose the μ_3-bridging Br(1). The hydrophilic area is confined at the oxime groups side, where a bromide ion is displaced by an hydroxy oxygen μ_3-bridge. The bromide ion, Br(3), is settled on the threefold axis and accounts for the neutral charge of the whole compound. The latter anion is located at 3.236(10) Å from the oxime oxygen atoms O(1) and at 3.322(7) Å from O(2), probably interacting with the hydrogen atoms of the hydroxy groups (Figure 5).

On the basis of these results, a reaction mechanism is proposed for the formation of the different synthetic products (Scheme 3).



Scheme 3. Proposed mechanism for the synthesis of nickel complexes

The reaction proceeds by initial formation of the monochelated monomeric species, which, depending on the steric hindrance of the ligand, can then evolve along different pathways. For ligands of low steric hindrance (**1a**, **1b**), the reaction moves rapidly towards the formation of bis(chelated) complexes, even at low ligand/Ni ratios. For the mesityl derivative, with ligand/Ni = 1:1, the monochelated derivative is isolated as the trimer **3h**, while with an excess of ligand the bis(chelated) species **2h** is the product. With the sterically more hindered ligands **1d**, **1e** and **1i**, only the formation of monochelated species of unknown nuclearity is observed.

Synthesis and Characterization of Co^{III} Complexes 4a−4d, 4f−4h, 5a−5d, 5f−5h

Synthesis was carried out in the presence of air, in *n*-butanol, at room temperature, for 3 h, starting from

$CoX_2 \cdot nH_2O$ salts (X = Cl, Br) and using a ligand/cobalt ratio of 1:1 or 2:1 (Scheme 2, b). In all cases, the formation of a red solid is observed immediately after addition of the ligands, followed by its transformation in the final product into a green microcrystalline solid. A total of 14 complexes (chloro and bromo derivatives) have been synthesized. However, the synthesis of **4a** and **5a** derivatives was reported several years ago.[14]

On the basis of elemental analyses (Table 2), all the complexes were formulated as $[CoX_2(Ar-N^{\cap}N-O)(Ar-N^{\cap}N-OH)]$ [X = Cl (**4**), Br (**5**)]. Therefore, in contrast to the nickel derivatives, only octahedral bis(chelated) species are obtained with all the ligands tested, regardless of the ligand/cobalt ratio used.

Single crystals suitable for X-ray analysis were obtained for **5b** and **5h** by crystallization from CH_2Cl_2/*n*-pentane. Figures 7 and 8 (ORTEP drawings, thermal ellipsoids at 50% probability) give perspective views of the molecular structures of compounds **5b** and **5h**, the latter being located on a crystallographic twofold axis passing through the metal atom and in the middle between the oxime oxygen atoms. Unlike in the nickel derivatives, the two bromide ions are in a *trans* arrangement, so the chelating ligands define the equatorial plane of the molecule. Moreover, they are bound to the cobalt atom in a *head-to-head* configuration, in contrast to the *head-to-tail* arrangement proposed for **4a** and **5a** on the basis of steric considerations.[14] The Co−Br and Co−N coordination bond lengths have comparable values in the two complexes. In contrast, the values of the Br−Co−Br bond angles, probably affected by steric hindrance between the bromide ions and the proximal

Figure 7. methyl groups on the phenyl rings, are 174.1(1) and 165.64(7)° in the *o*-tolyl and in the mesityl derivative, respectively. The atoms of the five-membered rings are close to coplanar and the calculated angles of 1.6 (**5b**) and 5.4° (**5h**) represent a slight tilting between the chelating ligand moieties.

The *head-to-head* arrangement of the mixed Schiff-base/oxime ligands favors the formation of an OH···O bridge. The mean O···O distance for the two structures of 2.42(1) Å is shorter than those found in the widely studied $[Co(DH)_2]$ and [Co(DO)(DOH)(pn)] complexes[19] [mean values of 2.487(2) and 2.45(1) Å,[20] respectively]. It was suggested that the O···O distance should parallel the ease of deprotonation, as indicated by the slower exchange of the proton in (DO)(DOH)pn than in $(DH)_2$ complexes of similar axial ligands.[21,22] The formation of the H-bridge in **5h** causes a remarkable shortening of the N−O [1.288(7) Å] and of the N(oxime)=C [1.292(9) Å] bonds with respect to those detected in the free ligand, and the same trend is also observed for **5b**, although the values found here are less accurate.

Moreover, the aromatic rings, with an orientation similar to that found in the uncoordinated ligand, ensure intramolecular π-stacking. In fact, the interplanar angle formed by the facing *o*-tolyl rings in **5b** is 15.0(3)° and the C···C distances between the *ipso*-carbon atoms and the carbon atoms in *para* positions are 3.35 and 3.84 Å, respectively. It is worth noting that the dihedral angle between the aryl

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

groups in **5h** is reduced to 5.5(3)°, and that the C···C separations are correspondingly somewhat shorter (3.18 and 3.76 Å, respectively), indicating a closer approach and hence a more efficient π-interaction between the bulky mesitylene groups.

Therefore, the *head-to-head* arrangement of the chelating ligands gives rise to an H-bridge and to an aryl π-stacking that act as a double clamp providing additional stability to the complexes. The geometrical data for the cobalt compounds reported here are quite comparable, but a detailed analysis shows that the steric effects around the metal center can be modulated by changing the nature of the aryl substituents.

These complexes were characterized in solution by recording NMR spectra in $CDCl_3$ at room temperature (Table 3). The signal of the methyl group (A) bound to the carbon atom closest to the oxime nitrogen atom is the most shifted (almost 0.40 ppm downfield shift) with respect to the signals of the free ligand. No signal due to the hydroxy group is visible in the spectra of the complexes. It can be seen that the spectrum of complexes with the *o*-tolyl-substituted ligand presents two sets of signals of different intensity both for the alkyl and aryl protons, thus indicating the presence of two species in solution. At room temperature the signals are quite broad. An NOE was observed between the methyl group of *o*-tolyl and $H^{\alpha'}$ and H^{β}. On the other hand, when the signals of the methyl groups (A and B) of the skeleton were irradiated in different NOE experiments, no NOE was seen, other than that expected between the two signals themselves. These results suggest that the two species in solution correspond to two rotamers, differing in the relative orientations of the methyl group of the *o*-tolyl substituents: namely *syn* and *anti* isomers. The broadness of the signals suggests that the two rotamers are in equilibrium and the rate of this equilibrium is slow on the NMR timescale.

The Co^{III} complex with ligand **1g**, [Co(Cl)$_2${**1g**-(H)}(**1g**)], was treated with $NaBH_4$ in methanol in the presence of CH_3I, to yield a red, microcrystalline solid. The elemental analysis confirms the ratio Co/**1g** = 1:2 and is in agreement with the formation of the organometallic derivative [Co(CH_3)(I){**1g**-(H)}(**1g**)] (**6g**). The ^{1}H NMR spectrum, recorded in $CDCl_3$ at room temperature, shows three singlets of the same intensity in the region of the aromatic protons, and five singlets for the methyl groups, one of which is of half intensity with respect to the other four peaks. This last is therefore attributed to the methyl group bound to the cobalt atom. The other assignments of signals to protons were based on comparison with the spectrum of the starting complex **4g**. In particular, the groups in the α- and β-positions of the aromatic rings generate two different signals, thus indicating the lack of the equatorial plane of the complex as a plane of symmetry. The Co−CH_3 and Co−I bonds are therefore in a *trans* configuration. Finally, it is reasonable to assume that the two N$^\frown$N ligands are bound to the cobalt atom in the *head-to-head* arrangement, as in the starting complex. This behavior is analogous to that typical of the dimethylglyoxime and (DO)(DOH)pn derivatives.[23]

Polymerization of Methyl Methacrylate

Some preliminary test polymerizations of methyl methacrylate were performed with complex **5b** by carrying out the reaction in the presence of AIBN as initiator, in THF as solvent. The result is compared with the activity of the system based on AIBN itself (Table 4).

Table 4. Polymerization of methyl methacrylate

Promoter[a]	Yield [g]	Mw	*Mw*/*Mn*
AIBN	2.34	420 000	1.7
AIBN + **5b**[b]	5.59	83 300	1.4

[a] Reaction conditions: $n_{AIBN} = 2.9 \cdot 10^{-2}$ mmol; solvent THF V = 11 mL; MMA V = 12 mL; T = 60 °C; t = 5 h. [b] [AIBN]/[Co] = 15.

The addition of the complex, even if in low amount with respect to AIBN, resulted in a doubling of the yield of polymerization and, at the same time, in a fivefold decrease in the molecular weight together with a decrease in polydispersity. These complexes therefore show a behavior typical of chain-transfer catalysts (CCTCs).[7]

Conclusion

The coordination chemistry of the new N-ligands towards Ni^{II} and Co^{III} has been studied, different behavior being observed depending both on the ligand and on the metal. In the case of Ni^{II}, when unhindered ligands were used, octahedral bis(chelated) species were obtained, while the product with more hindered ligands was a monochelated trimer. In this last compound the three molecules of chelating ligands are "*iso*-oriented", producing one hydrophilic and one hydrophobic hole. In the case of Co^{III}, octahedral bis(chelated) species are obtained with all the ligands used. Their main structural feature is the presence of weak interactions between the two coplanar N-ligands, namely O−H···O hydrogen bond and stacking interactions between the aryl groups.

These bis(chelated) Co^{III} complexes have several similarities to the well-known cobaloximes[7] and to (DO)-(DOH)pn derivatives,[24] previously studied by us and further investigated by Finke.[25,26] As reported in the introduction, these complexes are efficient chain transfer catalysts, and give oligomers in high yield for methyl methacrylate and styrene. The new complexes reported here could behave very similarly but, thanks to the variable steric hindrance, could give polymers instead of oligomers. The molecular mass of the polymers should increase on increasing the steric bulk of the N-ligands. The study of their catalytic behavior and the characterization of polymers is currently under investigation.

Experimental Section

Materials and Instrumentation: Chemicals and solvents were obtained from commercial sources (Aldrich, Carlo−Erba) and were used as received. NMR spectra were recorded with a Jeol EX 400 spectrometer operating at 400.0 MHz for ^1H. ^1H chemical shifts were measured relative to the residual solvent peak versus TMS ($CDCl_3$ at $\delta = 7.26$ ppm and CD_2Cl_2 at $\delta = 5.33$ ppm for ^1H). Two-dimensional correlation spectra (COSY) were obtained with the automatic program of the instrument. NOE experiments were run with a ^1H pulse of 90° and 12.5 μs. THF was dried with metallic sodium. MMA used in the polymerization reactions was purified by extraction with a water solution of NaOH and distilled.

Synthesis of Ligands: (*E*,*E*)-2-(Hydroxyimino)-3-(phenylimino)butane (**1a**), (*E*,*E*)-2-(hydroxyimino)-3-(*o*-tolylimino)butane (**1b**), (*E*,*E*)-2-(hydroxyimino)-3-(*p*-tolylimino)butane (**1c**), (*E*,*E*)-2-(hydroxyimino)-3-[(2-isopropylphenyl)imino]butane (**1d**), (*E*,*E*)-2-[(2-*tert*-butylphenyl)imino]-3-(hydroxyimino)butane (**1e**), (*E*,*E*)-2-[(2,6-dimethylphenyl)imino]-3-(hydroxyimino)butane (**1f**), (*E*,*E*)-2-[(3,5-dimethylphenyl)imino]-3-(hydroxyimino)butane (**1g**), (*E*,*E*)-2-(hydroxyimino)-3-[(2,4,6-trimethylphenyl)imino]butane (**1h**), (*E*,*E*)-2-[(2,6-diisopropylphenyl)imino]-3-(hydroxyimino)butane (**1i**)]. These ligands were synthesized by heating a solution of biacetyl monoxime (0.02 mol) and the stoichiometric amount of amine at reflux in methanol (5 mL) in the presence of formic acid (3 drops) as catalyst for 4−5 h. Ligands **1a**, **1b**, **1c**, and **1d** were obtained by cooling the solutions at 4 °C for 2−3 h after reflux. White crystals were filtered off, washed with ether, and dried in vacuo. Ligand **1d** was recrystallized from *n*-pentane. Ligands **1e**, **1f**, **1g**, **1h**, and **1i** were obtained by cooling the solutions at room temp after reflux. Ligand **1i** precipitated from the heated solution after 1.5 h reaction time. Crystalline precipitates were filtered, washed with ether, and dried in vacuo. All ligands are colorless, with the exception of **1e**, which precipitated as a yellow solid. The values of elemental analyses are reported in Table 5.

1h	71.50 (71.52)	8.28 (8.31)	12.83 (12.83)
1i	74.60 (74.38)	9.45 (8.58)	10.90 (10.84)

Synthesis of Bis(chelated) Ni^{II} Complexes 2a, 2b, and 2h: Bis(chelated) Ni^{II} complexes were synthesized by addition of [$NiBr_2$-($C_4H_{10}O_2$)] ($9.7\cdot10^{-4}$ mol) to a stirred solution of ligand ($1.94\cdot10^{-3}$ mol) in CH_2Cl_2 (7 mL). Solutions were stirred for 3 h. Complexes **2a**, **2b**, and **2h** were isolated upon concentration of the solution and addition of diethyl ether or *n*-pentane. The products precipitated as brown solids, which were filtered and dried under vacuum.

Synthesis of Monochelated Ni^{II} Complexes 2d, 2e, 2i, and 3h: Monochelated Ni^{II} complexes were prepared by addition of [$NiBr_2$-($C_4H_{10}O_2$)] ($C_4H_{10}O_2$ = ethylene glycol dimethyl ether) ($9.7\cdot10^{-4}$ mol) to a stirred solution of ligand ($1.56\cdot10^{-3}$ mol) in CH_2Cl_2 (7 mL). Solutions were stirred for 3 h. For **3h**, **2d**, and **2e**, insoluble impurities were filtered off. Solutions were concentrated under vacuum to 1−2 mL, and then treated with ether. Light brown powders were filtered, washed with ether or *n*-pentane, and dried in vacuo. Insoluble **2i** precipitated as a light brown powder, which was filtered, washed with ether, and dried in vacuo.

Synthesis of Bis(chelated) Co^{III} Complexes 4a−4d, 4f−4h, 5a−5d, and 5f−5h: Syntheses of bis(chelated) Co^{III} complexes were performed by addition of the ligand ($2.9\cdot10^{-3}$ mol) to a stirred solution of the Co^{II} salt hexahydrate ($CoCl_2\cdot6H_2O$, $CoBr_2\cdot6H_2O$) ($1.4\cdot10^{-3}$ mol) in *n*-butanol (10 mL). Solutions were stirred for 3 h. Solids were filtered off, washed with *n*-butanol, and dried in vacuo. Crystalline precipitates were obtained by recrystallization from CH_2Cl_2/pentane or CH_2Cl_2/ether (**4a** and **5a** only). Complexes **5f**, **5h**, and **5d** are brown, while all other complexes are green.

Synthesis of Bis(chelated) Organometallic Co^{III} Complex 6g: Complex **6g** was prepared by addition of CH_3I (0.5 mL) and an excess of $NaBH_4$, in that order, to a stirred solution of the chloride derivative **4g** (0.16 g) in methanol (10 mL) under an inert gas. The solution was stirred at room temperature for 1 h, and the red crystalline

solid was then filtered off and dried in vacuo. $C_{25}H_{34}CoIN_4O_2$ (608.40): calcd. C 49.35, H 5.63, N 9.21; found C, 50.00, H 5.73, N 9.26. ^{1}H NMR ($CDCl_3$) δ = 1.68 (s, 3 H), 1.73 (s, 6 H), 2.12 (s, 6 H), 2.15 (s, 6 H), 2.30 (s, 6 H), 5.96 (s, 2 H), 6.60 (s, 2 H), 6.89 (s, 2 H) ppm.

X-ray Crystallographic Study: Crystal data, data collections, and refinement parameters for the structures reported are summarized in Table 6. Data sets of **1h**, **2a**, **3h**, **5b**, and **5h** were collected at room temperature by the ω/2θ scan technique with a CAD4 Enraf−Nonius diffractometer, equipped with graphite monochromator using Mo-K_α radiation (λ = 0.71073 Å). Intensities of three standard reflections, monitored during data collections, showed no noticeable variation in intensity for any of the crystals. Intensities were corrected for Lorentz polarization effects and data sets of **3h**, **5b**, and **5h** also for absorption, based on an empirical ψ-scan method. Diffraction data of **2a** were obtained with a Nonius DIP-1030H system with Mo-K_α radiation (graphite-monochromated). A total of 30 frames were collected, each with an exposure time of 20 min, over a half of reciprocal space with a rotation of 6° about the detector being located at 100 mm from the crystal. Cell refinement and data reduction were carried out with the aid of the programs Mosflm[27] and Scala.[27] The structures were solved by Patterson or direct methods and successive Fourier analyses (SHELXS-97)[28] and refined by the full-matrix least-squares method based on F^2, with the aid of SHELXL-97.[28] A difference Fourier map allowed a disordered molecule of CH_2Cl_2 to be detected (half occupancy) in **2a**, while a residual in **3h** was assigned to a water oxygen atom. All the calculations were performed with the aid of the WinGX System, version 1.64.03.[29] CCDC-199885, -199886, -199887, -199888, and -199889 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Polymerization Reactions: The polymerization reactions were carried out by use of Schlenk techniques, under an inert gas. The AIBN and the cobalt complex were added to the dry THF solution containing MMA at 60 °C for 5 h. The amounts are reported in Table 4. The polymer was obtained as a white powder after the addition of ethanol. The powder was filtered and vacuum-dried.

Molecular Mass Measurements: The analyses were recorded with a Knauer HPLC (pump K-501, UV detector K-2501) with a PLgel 5 μm 10^4 Å column and THF as solvent (flow rate 0.6 mL/min). Polystyrene standards were used. The polyMMA samples were dissolved as follows: 3 mg of each sample in 120 μL of 1,1,1,3,3,3-hexafluoro-2-propanol, and THF was then added up to 10 mL. The statistical calculations were performed by use of the Bruker Chromstar software program.

New Tris(pyrazolyl)triazine and Pyrazolylpyridine Gold(I) and Palladium(II) Derivatives Based on the 3,5-Bis(4-butoxyphenyl)pyrazole Group – Architectures with Different Types of Bonding Interactions

Rosa M. Claramunt,[a] Pilar Cornago,[a] Mercedes Cano,*[b] José V. Heras,[b] M. Luz Gallego,[b] Elena Pinilla,[b,c] and M. Rosario Torres[c]

Keywords: Gold / Hydrogen bonds / Palladium / Supramolecular Chemistry / Triazine

The 3,5-bis(4-butoxyphenyl)pyrazolyl group (Pz^{bp2}) has been used as a building block for mono- and polymetallic derivatives of 2,4,6-tris[3,5-bis(4-butoxyphenyl)pyrazol-1-yl]-1,3,5-triazine ($TPz^{bp2}Tz$, **1**), 2-[3,5-bis(4-butoxyphenyl)pyrazol-1-yl]pyridine ($Pz^{bp2}Py$, **2**), and 3,5-bis(4-butoxyphenyl)pyrazole (HPz^{bp2}, **3**) ligands. The synthesis and characterisation of the new hexadentate ligand **1** are described, together with the chemistry of its metal complexes containing $[Pd(\eta^3\text{-}C_3H_5)]^+$ and $[Au(PPh_3)]^+$ fragments. The related complexes containing $Pz^{bp2}Py$ (**2**) were also studied and their structural characteristics were compared to those of the $TPz^{bp2}Tz$ species. The role of the counter-ion on the supramolecular assembly of complexes containing the HPz^{bp2} ligand **3** was made clear by the X-ray structures of $[Pd(\eta^3\text{-}C_3H_5)(HPz^{bp2})_2](BF_4)$ and $[Au(HPz^{bp2})(PPh_3)](NO_3)$. Hydrogen bonds and/or bonding interactions are responsible for pseudohelical one-dimensional polymers or supramolecular columnar arrays, respectively.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Research into the self-assembly of transition metal complexes is of increasing interest for the design of supramolecular structures.[1–7] Of the strategies currently in use to control molecular aggregates, non-covalent interactions such as metal coordination and hydrogen bonding have been of much use in recent years.[8,9]

Our group has acquired some expertise in studying metal complexes containing long chain-substituted pyrazole groups. The coordinative ability of 3,5-bis(4-butoxyphenyl)-pyrazolate towards gold(I) derivatives, for example, yielded complexes such as $[Au(Pz^{bp2})(PPh_3)]$, with supramolecular aurophilic Au···Au interactions,[10a,11,12] and $[(PPh_3)Au(\mu\text{-}Pz^{bp2})Au(PPh_3)]^+$, presenting intramolecular Au···Au contacts and molecular entities controlled by interactions through the corresponding counter-ions.[10b] Similar effects have also been described for related silver(I) derivatives.[5] On the other hand, π-allyl palladium(II) fragments are useful to provide stable complexes containing *N*,*N*′-bidentate ligands,[13] making these metal groups suitable for our coordinative purposes.

In addition, 1,3,5-triazine ligands have also been shown to be versatile for the preparation of metal complexes with a large variety of structural architectures.[14]

To extend these results, we decided to study new metal derivatives of a polydentate ligand, 2,4,6-tris[3,5-bis(4-butoxyphenyl)pyrazol-1-yl]-1,3,5-triazine ($TPz^{bp2}Tz$, **1**), containing three pyrazole groups in addition to the three nitrogen atoms of the triazine core (Scheme 1). Their coordination capability towards $[Pd(\eta^3\text{-}C_3H_5)]^+$ and $[Au(PPh_3)]^+$ fragments is analysed in a search for polymetallic complexes. The nature of the counter-ion and the effect of the

OR substituents on the pyrazole groups are also considered as elements for potential supramolecular architectures.

The chemistry of the new complexes is described and compared to that observed on treatment of the same metal fragments with bidentate 2-[3,5-bis(4-butoxyphenyl)pyrazol-1-yl]pyridine (**2**) and monodentate 3,5-bis(4-butoxyphenyl)pyrazole (**3**) ligands, regarded as building blocks presenting coordinative positions related to those of the new ligand $TPz^{bp2}Tz$ (**1**) (Scheme 1).

Results and Discussion

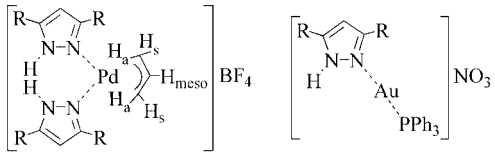
Synthesis and Structural Characterisation of the 2,4,6-Tris[3,5-bis(4-butoxyphenyl)pyrazol-1-yl]-1,3,5-triazine Ligand ($TPz^{bp2}Tz$, 1)

We treated 3,5-bis(4-butoxyphenyl)pyrazole (**3**) with 2,4,6-trichlorotriazine (stoichiometry 3:1) in dry THF under argon atmosphere, by the procedure that we have already described for several 2,4,6-tris(pyrazol-1-yl)-2,4,6-triazines,[15] to obtain the 2,4,6-tris[3,5-bis(4-butoxyphenyl)-pyrazol-1-yl]-1,3,5-triazine ligand (**1**, $TPz^{bp2}Tz$) in a 30% yield.

This ligand was fully characterized by spectroscopic techniques and its main properties in relation to the gold(I) and palladium(II) complexes are commented on in the following sections.

Treatment of $[Pd(\eta^3\text{-}C_3H_5)]^+$ and $[Au(PPh_3)]^+$ with 3,5-Bis(4-butoxyphenyl)pyrazole. Formation of $[Pd(\eta^3\text{-}C_3H_5)(HPz^{bp2})_2](BF_4)$ (4) and $[Au(HPz^{bp2})(PPh_3)](NO_3)$ (5)

Both pyrazole derivatives **4** and **5** (Scheme 2) were isolated as stable, white solids, soluble in dichloromethane and acetone. Elemental analysis, IR and ^1H NMR spectroscopy data agree with the proposed formulations.



4 **5**

R = $C_6H_4OC_4H_9$

Scheme 2

Compound **4** was synthesised by treatment of the cationic complex $[Pd(\eta^3\text{-}C_3H_5)(S)_2]^+$ (S = solvent), prepared in situ, with **3** in the same solvent in a 1:2 molar ratio. The IR spectrum of **4** displays characteristic bands of the pyrazole ligand. Between them, a ν(NH) absorption band at 3307 cm^{-1} was observed. This band was slightly shifted to higher frequencies in relation to that of the free ligand (3229 cm^{-1}), which has been shown to have a strong hydrogen bond.[16] Related, but weaker, hydrogen bond interactions are therefore suggested for **4** (it has been reported that HPz-type ligands with free NH bonds present a ν(NH) absorption band at 3400 cm^{-1}).[17] Two ν(BF) absorption bands at 1067 and 1039 cm^{-1}, from the BF_4^- group, were also observed and support the presence of interactions towards that counter-ion (two bands agree with a distorted tetrahedral geometry in contrast to the broad single band at 1070 cm^{-1} for the tetrahedral free anion).[18]

On the other hand, the ^1H NMR results indicate the presence of an η^3-allyl group, together with two equivalent coordinated pyrazole ligands, each of these showing non-equivalence in the two butoxyphenyl substituents. The allylic part of the spectrum can be interpreted in terms of a symmetrical η^3-allyl group, so there are three different proton environments: H_{meso} in the central carbon, H_s (*syn*) and H_a (*anti*). The signal at highest field (δ = 3.18 ppm), and with the largest coupling constant (J = 12.7), is assigned to the H_a protons nearest to the metal, with the other doublet signal at δ = 3.92 ppm (J = 6.8) being assigned to the H_s protons. The H_{meso} signal appears a as multiplet at lower field (δ = 5.70 ppm).

Compound **5** was prepared by addition of one equivalent of **3** to a dichloromethane solution of $[Au(NO_3)(PPh_3)]$, previously obtained by treatment of $[AuCl(PPh_3)]$ with $AgNO_3$.[19] A ν(NH) absorption band at 3250 cm^{-1} in the IR spectrum of **5** suggests the presence of hydrogen bond interactions, analogously to what was observed in **4**. A band for the ionic NO_3^- group at 1384 cm^{-1} [18,19] agrees with the formation of a cationic complex $[Au(HPz^{bp2})(PPh_3)]^+$.

On the other hand, a 1:1 PPh_3/HPz ratio is established from the ^1H NMR spectrum (clearly observed from the 15:1

ratio between the integrated signals of aromatic PPh_3 and H4 pyrazole protons). In contrast to the behaviour observed for palladium derivative **4**, complex **5** features two equivalent butoxyphenyl substituents, suggesting the presence of a metallotropic equilibrium as previously found for related complexes.[20]

Crystal and Molecular Structures of 4 and 5

Single crystals of **4** and **5** suitable for single-crystal X-ray analysis were obtained after recrystallisation from dichloromethane/diethyl ether and dichloromethane/hexane, respectively. Selected bond lengths and angles with their estimated standard deviations are listed in Tables 1 and 2.

[a] $R_1 = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$.

The palladium derivative **4** crystallises in the monoclinic system, space group $P2_1/n$, as three $[Pd(\eta^3\text{-}C_3H_5)(HPz^{bp2})_2]^+$ species (A, B, and C, showing different dihedral angles between phenyl and pyrazole groups) associated through BF_4^- groups in the asymmetric unit (Figure 1, top). Each BF_4^- group was bonded through strong N−H···F hydrogen bonds (Table 1) with two N−H pyrazole groups bridging two neighbouring complexes. The geometry of each palladium(II) atom in A, B, and C can be described as approximately square-planar. Two pyrazole ligands coordinate to each palladium(II) centre through the corresponding unsubstituted pyrazole atoms N1 and N3, with bond lengths in the 2.10−2.12 Å range. The maximum deviation of the allylic terminal atoms in these units A, B, and C, if we define the coordination plane as that containing the palladium and the two nitrogen atoms mentioned, is 0.17(1) Å for C9 in molecule A. The central allyl carbon C10 also deviates, by 0.51(9), 0.53(1), and 0.59(1) Å in A, B, and C, respectively. The dihedral angles between the allyl planes C11C10C9 and C11PdC9 in each of the A, B, and C molecules are 63.8(9), 67.4(8), and 66.6(8)°. The Pd−allyl distances are in the range expected for complexes containing *N*,*N*′-ligands coordinated *trans* to palladium-allyl fragment.[13c,21]

The crystal structure of **4** could be defined as a pseudohelical polymer, consisting of $[Pd(\eta^3\text{-}C_3H_5)(HPz^{bp2})_2]^+$ units bonding through BF_4^- anions as shown in Figure 1 (bottom). The F12 moiety of the third unit (C) is hydrogen-bonded to the N−H pyrazole group of the neighbouring A′ molecule from the new asymmetric unit (symmetry operation *x*, *y*, *z* + 1). The $[Pd(\eta^3\text{-}C_3H_5)(HPz^{bp2})_2]^+$ moiety is thus arranged pseudohelically along the *c* axis, with the pitch of the pseudohelix (i.e., the

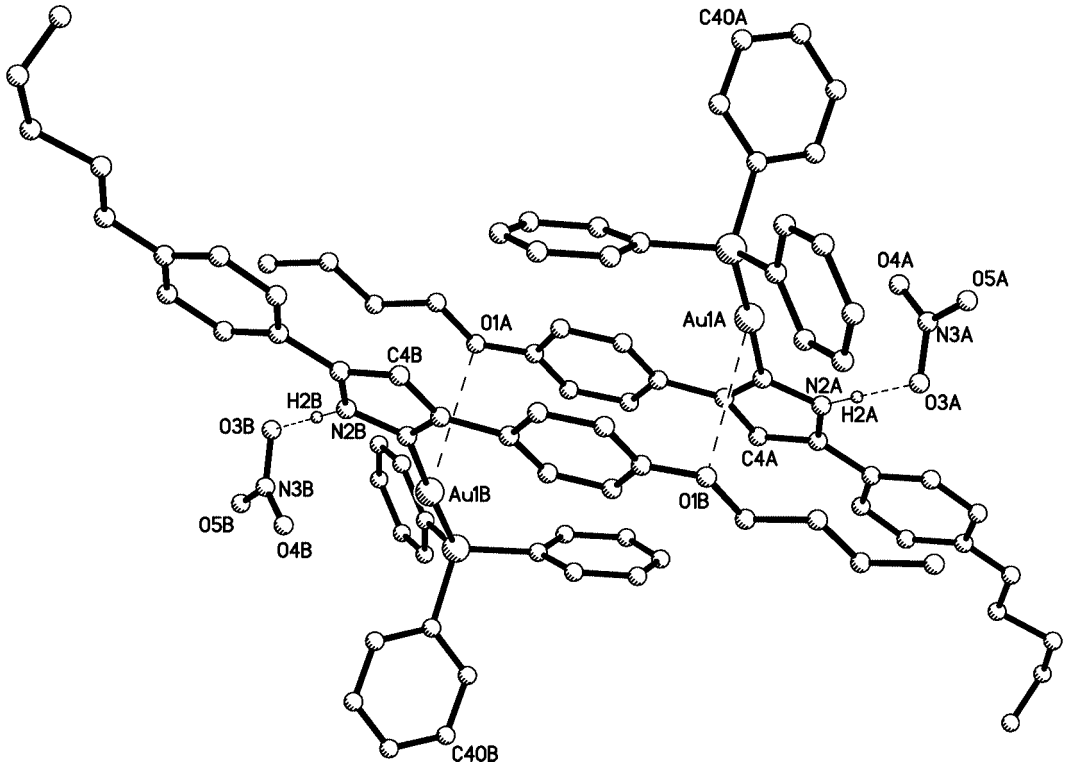

Figure 2. Molecular structure of **5** showing the dimeric unit through Au···O intermolecular bonds

distance between palladium(II) atoms of each four units) corresponding to the *c* axis. The molecular packing could be described as a columnar distribution of pseudohelical chains lying along the *c* axis. The formation of this polymer in the solid state demonstrates the important role played by intermolecular interactions through counter-ions in the supramolecular arrangements.

The crystal structure of **5** (Figure 2) consists of a mononuclear gold(I) cationic complex and a nitrate counter-ion. Both were bonded by a strong hydrogen bond (N2−H2···O3, with a N2···O3 distance of 2.764(9) Å; Table 2). The geometry around the gold(I) can be described as almost linear, the P1−Au1−N1 angle being 178.1(2)°. The Au1−N1 and Au1−P1 bond lengths are similar to

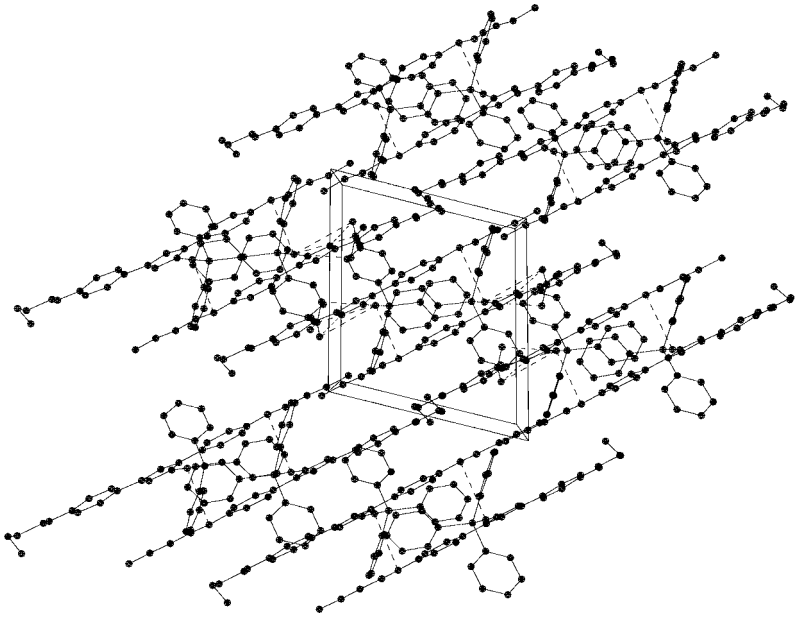

Figure 3. Molecular packing of **5** through *c* axis

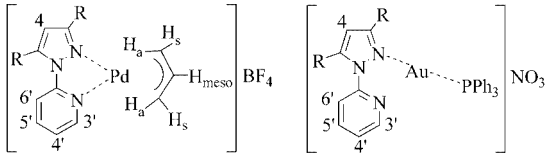
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

those reported for some neutral complexes of the [Au(L)(PPh_3)] type (HL = 1-methylthymine, 6-methylpyridone, 7-azaindole).[22] The most interesting feature in **5** was the presence of a very weak intermolecular coordinative interaction [Au···O, at 3.540(6) Å, ca. 0.30 Å longer than the sum of Van der Waals radii] between two neighbouring molecules. This interaction occurs through the oxygen atom of the $C_6H_4OC_4H_9$ substituent at the 5-position of the pyrazole ligand and the metal centre of the adjacent molecule and appears to be responsible for the formation of "dimers" in an antiparallel head-to-tail disposition (Figure 2). The adjacent aromatic rings of opposite substituents of each molecule of "dimers" are parallel, but are separated face-to-face by a distance of 4.4 Å. This distance suggests that π-π stacking interactions need not be considered, although they might be of help in adopting the observed dimeric arrangement.

The molecular packing could be described as a columnar distribution of these dimeric units along the *b* axis. Layers almost orthogonal to the columnar axis defined by the substituents on the pyrazole are also observed (Figure 3). New weak interactions through the O4 and O5 atoms of the NO_3^- group (not implicated in the hydrogen bond described above) between dimeric units from neighbouring columns are also present (Table 2). As a consequence, the effect of the counter-ion on the supramolecular assembly again seems to be determinant for the crystalline structure here.

Treatment of $[Pd(\eta^3\text{-}C_3H_5)]^+$ and $[Au(PPh_3)]^+$ with 2-[3,5-Bis(4-butoxyphenyl)pyrazol-1-yl]pyridine. Formation of $[Pd(\eta^3\text{-}C_3H_5)(Pz^{bp2}Py)](BF_4)$ (6) and $[Au(Pz^{bp2}Py)(PPh_3)](NO_3)$ (7)

Compounds **6** and **7** (Scheme 3) were both isolated as stable yellow solids, soluble in dichloromethane and acetone, as described in the Exp. Sect. Elemental analysis and IR and ^1H and ^{13}C NMR spectroscopy data agree with the proposed formulations. Conductivity measurements in acetone solution are consistent with 1:1 electrolytic behaviour in both cases.



6 **7**

$R = C_6H_4OC_4H_9$

Scheme 3

On addition of an equivalent of **2** to $[Pd(\eta^3\text{-}C_3H_5)(S)_2](BF_4)$, the ionic complex **6** is formed. The gold(I) complex **7** was prepared by starting from cleavage of the chloride in [AuCl(PPh_3)] by addition of $AgNO_3$, giving rise to [Au(NO_3)(PPh_3)], and the subsequent replacement of the NO_3^- group by the *N*,*N*′-bidentate ligand **2**. The ν(C=N) absorption bands in the IR spectra of both compounds were not significantly modified in relation to that of the free ligand, indicating that the metal coordination had almost no effect on this bond, behaviour also observed for related gold(I) derivatives containing *N*-heterocyclic ligands.[23] Characteristic bands of BF_4^- and NO_3^- anions were observed for **6** and **7**, respectively.

The ^1H NMR spectrum of **6** in $CDCl_3$ at room temperature, in the allylic region, consisted of three broad signals: a multiplet at δ = 5.68 ppm, a doublet at δ = 3.87 ppm (J = 6.5) − partially overlapping with that of the OCH_2 signal at δ = 4.06 ppm − and a doublet at δ = 3.21 ppm (J = 12.8) corresponding to the H_{meso}, H_s, and H_a protons (the last of these clearly assigned from the observed coupling constant). The broadness of the allyl signals suggests a fluxional behaviour based on the asymmetry of the *N*,*N*′-coordinated ligand and attributable to a rapid *syn-syn* and *anti-anti* interchange. The remaining signals in the ^1H NMR spectrum are assigned to the pyrazolylpyridine ligand.

The ^1H NMR spectra of **7** was measured at room temperature in CD_2Cl_2. All the ligand proton signals were slightly modified by coordination. The general behaviour involves small shifts downfield for these signals, the largest shifts being observed for the 3′-H and 5′-H pyridine protons (Scheme 3). However, the position of 6′-H pyridine proton was almost unchanged (δ = 8.41 ppm for the free ligand and δ = 8.38 ppm for the complex), suggesting a very weak metal interaction towards the *N*-pyridine atom. On the other hand, the 4-H pyrazole proton shows a downfield coordination shift of δ = 0.12 ppm, and both downfield and upfield effects were observed for the phenyl substituents in positions 3 and 5. Related behaviour has also been observed for copper and ruthenium derivatives containing pyrazolylpyridine-type ligands.[24,25] The downfield shifts occurring for pyrazole protons and substituents on the 4- and 5-positions were attributed to ligand-metal coordination, whereas upfield shifts for substituents on the 3-position were attributed to ring current anisotropy effects. The above ^1H NMR results agree with a monodentate coordination of the ligand towards the pyrazole N atom, allowing the characteristic twofold coordination of gold metal centres. In this context it should be pointed out that tri- and tetracoordinate gold(I) derivatives with PPh_3 and *N*-donor ligands have also been described, although less frequently,[26] and so an interaction with the pyridine N atom should not be excluded for complex **7**. However, the well defined signals observed for all the protons suggest that exchange of gold(I) between the two nitrogen coordination sites does not occur at room temperature. This fact, probably due to steric effects of substituents on the pyrazole group, favours the linear complex.

On close examination of the ^{13}C NMR spectroscopic data and after complete assignment of all signals by means of NMR experiments with pulse field gradients — (^1H-^1H) COSY, (^1H-^{13}C) HMQC, and (^1H-^{13}C) HMBC — it can be concluded that the complexation chemical shift effects (CCSEs) in the palladium(II) and gold(I) complexes **6** and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

7 are positive, save for the carbon adjacent to the pyridine nitrogen, which bonds the pyrazole group. Such increments are larger in the palladium complex **6** (around 4 ppm) than in the gold complex **7** (around 2 ppm).

In order to establish more conclusive results regarding the metal ligand coordination, ^{15}N NMR studies were carried out by means of (^{1}H-^{15}N) HMBC experiments on the ligand and the palladium(II) and gold(I) derivatives

Table 3. ^{15}N NMR spectroscopic data (in $CDCl_3$ at 298 K) for the free ligand **2**and its Pd(η^3-C_3H_5) (**6**) and Au(PPh_3) (**7**) derivatives

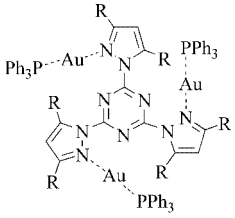
7[a]	−168.0	−104.1	−88.0

[a] ^{15}N NMR data in CD_2Cl_2.

(Table 3). For the palladium complex **6** it was clearly observed that coordinative nitrogen atoms, N2 from pyrazole and N3 from pyridine, were significantly shifted upon coordination relative to the free ligand. For gold derivative **7**, in contrast, such an effect was only produced on the pyrazole nitrogen atom N2. Consequently, an *N*,*N*′-bidentate pyrazolylpyridine coordinative mode was proposed for the palladium derivative but only a monodentate coordination involving the pyrazole group for the gold complex **7**. Both results also agree with the expected tetracoordinate square-planar and two-coordinate linear environments around the palladium(II) and gold(I) metal centres, respectively.

Treatment of [Pd(η^3-C_3H_5)]$^+$ and [Au(PPh_3)]$^+$ with 2,4,6-Tris[3,5-bis(4-butoxyphenyl)pyrazol-1-yl]-1,3,5-triazine. Formation of [Pd_2(η^3-C_3H_5)$_2$($BPz^{bp2}TzO$)](BF_4) (8) and [Au_3($TPz^{bp2}Tz$)(PPh_3)$_3$](NO_3)$_3$ (9)

Treatment of **1** with [Pd(η^3-C_3H_5)]$^+$ or [Au(PPh_3)]$^+$ fragments resulted in bimetallic and trimetallic complexes,



9

$R = C_6H_4OC_4H_9$

Scheme 4

respectively. The gold(I) derivative was isolated from treatment of three equivalents of [Au(NO_3)(PPh_3)] with one of **1** in dichloromethane solution as a yellow solid product, stable enough in solution for NMR purposes. It was characterized as the complex [Au_3($TPz^{bp2}Tz$)(PPh_3)$_3$](NO_3)$_3$ (**9**, Scheme 4) on the basis of its ^{1}H NMR spectroscopic and mass spectrometric data.

On the other hand, it was interesting to note that a side product, in the form of a microcrystalline white solid accompanying the main compound **9**, was also isolated from the reaction. Treatment of this mixture in dichloromethane/diethyl ether allowed crystals of this by-product to be separated, and these were identified as the pyrazolate complex [Au_2(μ-Pz^{bp2})(PPh_3)$_2$](NO_3).[10b]

The IR spectrum of **9** shows the main absorption bands of the $TPz^{bp2}Tz$ ligand. A very weak unexpected band was also observed at 1682 cm^{-1}, and was attributed to a ν(C=O) absorption arising from partial hydrolysis of the $TPz^{bp2}Tz$ ligand in the complex. This band increases after repeated attempts to purify the product confirming that the hydrolysis process is enhanced.

The structural ^{1}H NMR spectroscopic data, in relation to those obtained for [Au($Pz^{bp2}Py$)(PPh_3)](NO_3) (**7**), suggest monodentate *N*-pyrazole coordination towards the Au(PPh_3) fragment. The tris(pyrazoly)ltriazine ligand bridges three metal centres coordinated with three *N*-pyrazole atoms from the three asymmetric *N*,*N*′-chelating sites. The 15:1 relationship between the aromatic PPh_3 and the 4-H pyrazole protons agrees with the proposed formulation.

A relevant aspect of the molecular behaviour observed at room temperature is the effect that the metals induce on the pyrazole substituents, those in the proximity of Au(PPh_3) fragment (3-position) being different to those at the 5-position. The former thus show defined signals for all protons of the chains but the related signals for the latter are broad. This behaviour is consistent with the proposed monodentate coordination of gold(I) centres only towards the pyrazole groups. Rotation of the pyrazole group bonded to the Au(PPh_3) fragment around the pyrazole-triazine bonding axis is possible, and the environment of the substituents on the 3-position close to the Au(PPh_3) fragment is not modified, unlike that of 5-position substituents, which change in their spatial proximity to gold metal centres.

To confirm the proposed trimetallic formulation of **9**, a study by mass spectrometry (FAB and ESI) was carried out. Figure 4 displays a fragmentation scheme for this complex. The parent ion was not observed either by FAB or by ESI (dry acetonitrile and chloroform) mass spectra. In contrast, in all the cases mentioned above, two ion peaks at m/z = 2444.7 and 1277.2 were detected. The former (m/z = 2444.7) corresponds to the [$TPz^{bp2}Tz$ + B]$^+$ fragment (a_1) arising from the association of the $TPz^{bp2}Tz$ ligand with a metallic cluster B {B = [Au_2(PPh_3)NO_3($OH)_2$]}. From this fragment, the second ion peak (m/z = 1277.2) is formed by the loss of $TPz^{bp2}Tz$. On the other hand, the ESI spectrum (in dry acetonitrile) shows a new peak at m/z = 867.7 (0.3 mass units separated from their counterparts) for the tric-ation [{Au_3($TPz^{bp2}Tz$)(PPh_3)$_3$(NO_3)} − 2 H]$^{3+}$ (a_3) (calcd.

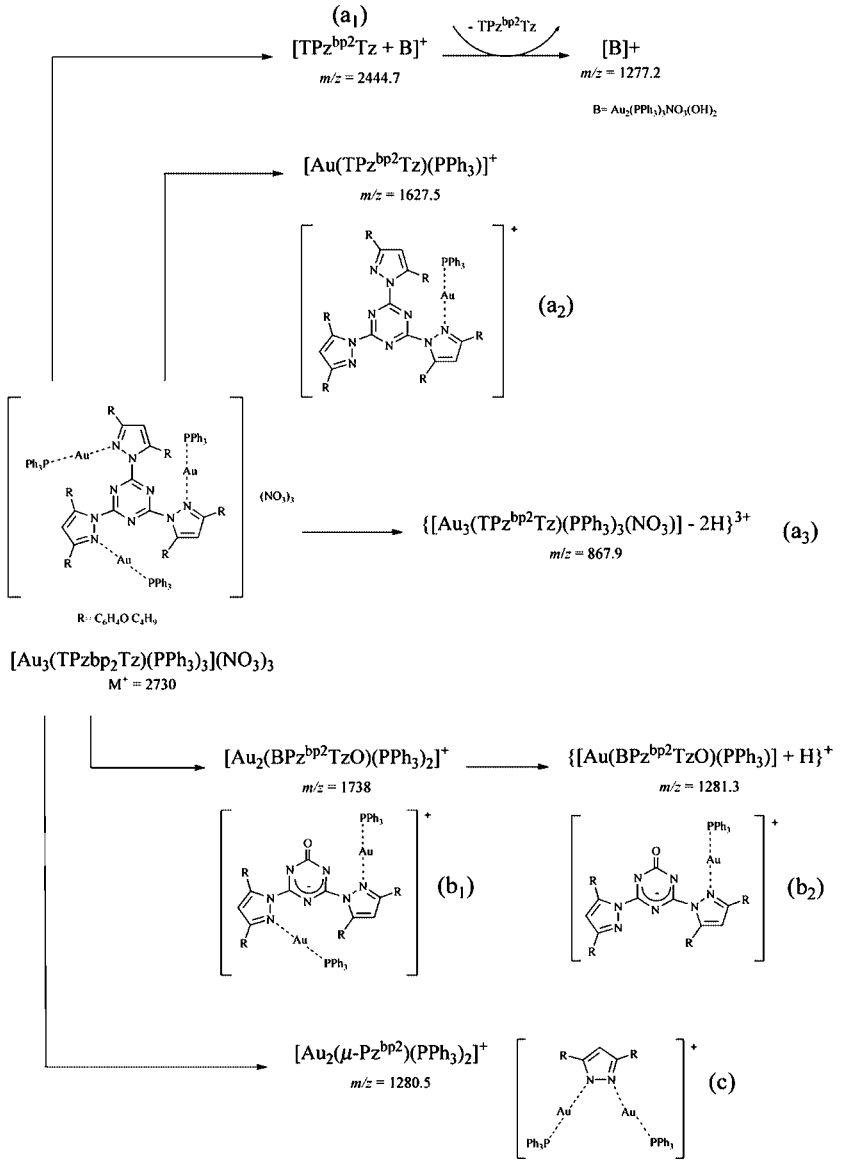

Figure 4. Fragmentation scheme for the complex $[Au_3(TPz^{bp2}Tz)(PPh_3)_3](NO_3)_3$ **9**; symbols (a), (b), and (c) indicate: (a) fragments containing the $TPz^{bp2}Tz$ ligand, (b) fragments containing the hydrolysed $TPz^{bp2}Tz$ ligand ($BPz^{bp2}TzO$), and (c) side product

2605). Another fragment, observed in all spectra, at m/z = 1627.5 was related to the mononuclear species $[Au(TPz^{bp2}Tz)(PPh_3)]^+$ (a_2). The above results agree with the presence of a $TPz^{bp2}Tz$ ligand in a trimetallic species.

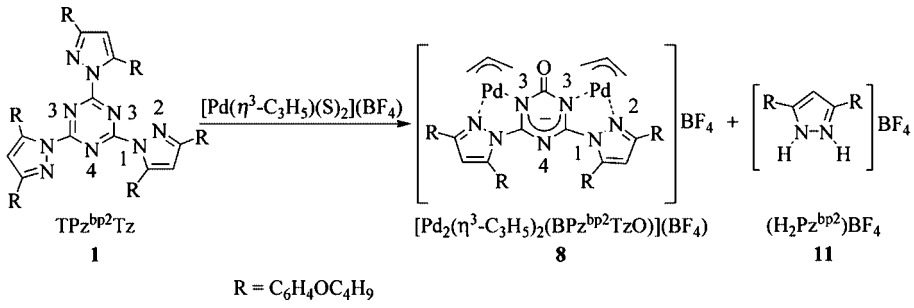
On the other hand, additional ion peaks at m/z = 1738.6 and 1281.3 were also observed and related to a hydrolysis process of the $TPz^{bp2}Tz$ ligand, producing binuclear $[Au_2(BPz^{bp2}TzO)(PPh_3)_2]^+$ (b_1) and mononuclear $[\{Au(BPz^{bp2}TzO)(PPh_3)\} + H]^+$ (b_2) species, respectively. These were the sole peaks observed when the ESI spectrum was recorded in solvents favouring hydrolysis, such as methanol. Finally, the presence of the side product formulated as $[(PPh_3)Au(\mu\text{-}Pz^{bp2})Au(PPh_3)]^+$ (c) at m/z = 1280.5 was also evidenced, in agreement with the isolation of that compound from the reaction.

Several attempts to crystallise **9** from different solvents were carried out, but hydrolysis products prevent the obtention of crystals suitable for X-ray purposes.

Similar results were also obtained for the related complex $[Au_3(TPz^{bp2}Tz)(PPh_3)_3](CF_3SO_3)_3$ (**10**), containing $CF_3SO_3^-$ as counter-ion.

The binuclear complex $[Pd_2(\eta^3\text{-}C_3H_5)_2(BPz^{bp2}TzO)](BF_4)$ (**8**) was obtained by treatment of **1** with $[Pd(\eta^3\text{-}C_3H_5)(S)_2]^+$ in a 1:3 molar ratio. The suggested molecular structure (Scheme 5) was defined by bonding two $[Pd(\eta^3\text{-}C_3H_5)]^+$ fragments bound in two bidentate positions of the hydrolysed tris(pyrazolyl)triazine ligand $BPz^{bp2}TzO$, which has lost a pyrazolyl group. A related hydrolysis product has precedent in the described cationic complex $[\{(\eta^3\text{-}2\text{-}Me{-}C_3H_4)Pd\}_2(Me{-}BPzTO)]^+$,[21] and also in the estab-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 5

lished nucleophilic displacement reactions of some 1,3,5-triazines.[27] This was the sole metal derivative isolated from the above reaction. It was interesting to note, though, that the first solid to separate from the reaction mixture was a white crystalline product, identified as the pyrazolium salt $[H_2Pz^{bp2}](BF_4)$ **11** (see Exp. Sect.).

The IR spectrum of **8** shows the characteristic bands due to the ν(C=O) absorption at 1696 cm^{-1} and the ^1H NMR spectrum present all the expected pyrazolyl signals as well as the 1:1 ratio of H4 pyrazole and H_{meso} allyl protons.

From the analysis of the ^{13}C NMR spectroscopic data and having assigned all signals by means of NMR experiments with pulse field gradients — (^1H-^1H) COSY, (^1H-^{13}C) HMQC and (^1H-^{13}C) HMBC — we observed that the CCSE signs for complexes **8** and **9** are similar, but that the absolute values of **9** are approximately half those of **8**. The appearance of the additional carbonyl signal in the spectrum of the palladium(II) complex **8** confirms the hydrolysis process.

The ^{15}N NMR spectroscopic data obtained from (^1H-^{15}N) HMBC correlation experiments for the free $TPz^{bp2}Tz$ ligand **1** and the palladium complex **8** are presented in Table 4. As in the previous $[Pd(\eta^3\text{-}C_3H_5)(Pz^{bp2}Py)](BF_4)$ complex **6**, the observed chemical shift effects on the palladium derivative in relation to the free ligand agree with a bidentate coordination by *N*-pyrazole and *N*-triazine coordinating nitrogen atoms and confirm the proposed formulation.

Table 4. ^{15}N NMR spectroscopic data in $CDCl_3$ at 298 K of the free ligand **1** and its $Pd(\eta^3\text{-}C_3H_5)$ derivative **8**

	Pyrazole[a]		Triazine[a]	
	N1	N2	N3	N4

8	−170.2	−138.8	−123.8	−197.4

[a] The atomic numbering as in Scheme 5.

Finally, the ESI mass spectrum (in chloroform) of **8** shows the molecular ion peak *m*/*z* = 1116.3 confirming the formation of the hydrolysis derivative $[Pd_2(\eta^3\text{-}C_3H_5)_2(BPz^{bp2}TzO)](BF_4)$.

Conclusion

The designed complexes $[Pd(\eta^3\text{-}C_3H_5)(HPz^{bp2})_2](BF_4)$ (**4**) and $[Au(HPz^{bp2})(PPh_3)](NO_3)$ (**5**) each show strong hydrogen bonding between each NH-pyrazole of one cationic unit and their corresponding counter-ions. In view of the molecular geometries around the metal centres − square-planar for the palladium derivative and linear for gold − as well as those of their counter-ions, tetrahedral BF_4^- and planar NO_3^-, these hydrogen bonds − N−H···F for **4** and N2−H2···O3, C4−H4A···O4′′ and C40−H40A···O5′′′ for **5** — are responsible for the observed supramolecular structures, of the pseudohelical type for **4** and with columnar features for **5**. In addition, **5** forms "dimers" produced by coordinative Au···O interactions between the pyrazole OR groups and the metal centres of two neighbouring molecules. We can therefore conclude that factors such as hydrogen bonding, the counter-ion effect, the presence of coordinating substituents on the ligand and a suitable molecular geometry are crucial for specific supramolecular assemblies.

Moreover, the following structural features should be pointed out:

i) The palladium complex of $TPz^{bp2}Tz$ is hydrolysed, giving rise to a bimetallic species $[Pd_2(\eta^3\text{-}C_3H_5)_2(BPz^{bp2}TzO)](BF_4)$ (**8**), containing two allyl-palladium moieties, which occupy two symmetrical *N*,*N*′-bidentate chelating positions of the ligand. The central carbon atom of the triazine core is now bonded to an oxygen, thus producing a C=O group instead of the initial C-Pz^{bp2} one, due to the nucleophilic displacement of the pyrazole group in the hydrolysis process.

ii) The formation of a trimetallic derivative $[Au_3(TPz^{bp2}Tz)(PPh_3)_3](NO_3)_3$ (**9**), containing three $Au(PPh_3)$ fragments coordinated in a monodentate fashion towards the *N*-pyrazole atoms of the $TPz^{bp2}Tz$ ligand, has been established.

The natures of the metal fragments determine the mono- or bidentate coordination of each *N*,*N*′-chelating position in the $TPz^{bp2}Tz$, analogously to what occurs in similar complexes of the related bidentate $Pz^{bp2}Py$ ligand. The presence of a square-planar or more flexible linear metal environments for **8** and **9**, respectively, appears to be correlated with the isolation of a binuclear palladium complex or a

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trinuclear gold derivative. These results offer new insights into the attainment of polymetallic complexes with supramolecular organisations.

Experimental Section

Materials and Instrumentation: The commercial starting materials $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2$ and $[AuCl(PPh_3)]$ were used as supplied. Ligands 2-[3,5-bis(4-butoxyphenyl)pyrazol-1-yl]pyridine (**2**, $Pz^{bp2}Py$)[24] and 3,5-bis(4-butoxyphenyl)pyrazole (**3**, HPz^{bp2})[16] were prepared as described in the literature. Commercial solvents were dried prior to use.

Melting points were determined on a microscope hot stage apparatus and are uncorrected.

Elemental analyses for carbon, hydrogen, and nitrogen were carried out by the Microanalytical Service of the Complutense University. IR spectra were performed on a FTIR Nicolet Magna-550 spectrophotometer in the 4000−400 cm^{-1} region with samples as KBr pellets.

^1H, ^{13}C, and ^{15}N NMR spectra were recorded on a Bruker DRX-400 at 27 °C. Chemical shifts (δ) are given in ppm from TMS for ^1H and ^{13}C NMR spectroscopy. ^{15}N NMR chemical shifts were obtained by the Inverse Gated ^1H-Decoupling Technique and are referenced to external nitromethane. *J* coupling constants are in Hz. The assignments are based on NMR experiments with pulse field gradients: (^1H-^1H) COSY, (^1H-^{13}C) HMQC, (^1H-^{13}C) HMBC, and (^1H-^{15}N) HMBC.[28]

FAB-MS positive spectra were performed on a VG AutoSpec spectrometer. ESI-MS positive spectra were carried out by the Mass Spectrometry Service of the Complutense University with a LC-SQUIRE spectrometer, in dry acetonitrile, chloroform, or methanol as solvents. The ion peaks are given in *m*/*z*.

Synthesis of 2,4,6-Tris[3,5-bis(4-butoxyphenyl)pyrazol-1-yl]-1,3,5-triazine ($TPz^{bp2}Tz$, 1): NaH (95%, 44 mg, 1.74 mmol) was added to a solution of 3,5-bis(4-butoxyphenyl)pyrazole (**3**, 600 mg, 1.65 mmol) in freshly distilled dry THF (30 mL). After 1.5 h at 90 °C, the solution was allowed to cool down, and 2,4,6-trichlorotriazine (cyanuric chloride, 90%, 102 mg, 0.55 mmol) was added. The solution, which had turned from a yellow to a white colour, was heated for 11 h at 90 °C and for 15 h at 60 °C. The solvent was evaporated and the residue was chromatographed on 60 F_{254} silica gel with chloroform/acetonitrile (95:5) as eluent. R_f = 0.55, m.p. 158−160 °C. Yield: 193 mg, 30%. Exact mass: calcd. for $C_{72}H_{81}N_9O_6$: 1168.49; found 1168.63. IR (KBr): $\tilde{\nu}$ = 1613 cm^{-1} ν(C=N). ^1H NMR (400 MHz, $CDCl_3$, 298 K): δ = 7.76 ppm (d, ^3J = 6.9 Hz, 6 H, H_o), 7.24 (d, ^3J = 6.8 Hz, 6 H, H_o), 6.98 (d, ^3J = 6.9 Hz, 6 H, H_m), 6.85 (d, ^3J = 6.8 Hz, 6 H, H_m), 6.63 (s, 3 H, H4), 4.04 (t, ^3J = 6.5 Hz, 6 H, OCH_2), 3.87 (t, ^3J = 6.6 Hz, 6 H, OCH_2), 1.82 (m, ^3J = 6.7 Hz, 6 H, CH_2), 1.72 (m, ^3J = 6.8 Hz, 6 H, CH_2), 1.51 (m, ^3J = 7.4 Hz, 6 H, CH_2), 1.43 (m, ^3J = 7.5 Hz, 6 H, CH_2), 1.01 and 0.94 (t, ^3J = 7.4 Hz, 18 H, CH_3). ^{13}C NMR (400 MHz, $CDCl_3$, 298 K): δ = 164.5 ppm (Tz), 159.9 (^3J = ^3J = 7.6 Hz, C_p), 159.2 (^3J = ^3J = 9.2 Hz, C_p), 154.3 (^2J = ^3J = ^3J = 3.7 Hz, C3), 147.8 (^2J = 8.1, ^3J = ^3J = 4.0 Hz, C5), 130.2 (^1J = 160.3, ^3J = 7.1 Hz, C_o), 127.7 (^1J = 159.5, ^3J = 7.0 Hz, C_o), 124.1 (^3J = ^3J = 7.6 Hz, C_{ipso}), 123.1 (^3J = ^3J = 8.0 Hz, C_{ipso}), 114.5 (^1J = 160.2, ^3J = 4.6 Hz, C_m), 113.9 (^1J = 160.5, ^3J = 4.2 Hz, C_m), 109.4 (^1J = 175.5 Hz, C4), 67.6 (^1J = 142.1, ^2J = 3.5 Hz, OCH_2), 31.3 and 31.2 (^1J = 126.3 Hz, CH_2), 19.2 and 19.1 (^1J = 127.2 Hz, CH_2), 13.79 and 13.77 (^1J = 125.3 Hz, CH_3).

Synthesis of $[Pd(\eta^3\text{-}C_3H_5)(HPz^{bp2})_2](BF_4)$ (4): $AgBF_4$ (35 mg, 0.18 mmol) was added under nitrogen to a solution of $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2$ (33 mg, 0.09 mmol) in freshly distilled acetone (15 mL). After stirring for 6 h in the darkness, the solution was filtered through a plug of Celite and cooled with an ice bath. Compound **3** (HPz^{bp2}, 131 mg, 0.36 mmol) was then added and the mixture was stirred for 5 h. The solvent was removed under vacuum and the white product was crystallised from dichloromethane/diethyl ether. Yield: 73 mg, 42%. $C_{49}H_{61}BF_4N_4O_4Pd$ (962.21): calcd. C 61.11, H 6.34, N 5.82; found C 60.96, H 6.11, N 5.66. IR (KBr): $\tilde{\nu}$ = 3307 cm^{-1} ν(N−H), 1613 ν(C=N), 1067 and 1039 ν(BF). ^1H NMR (400 MHz, $CDCl_3$, 298 K): δ = 11.87 ppm (s, 2 H, NH), 7.61 and 7.41 (d, ^3J = 8.5 Hz, 8 H, H_o), 6.96 and 6.78 (d, ^3J = 8.5 Hz, 8 H, H_m), 6.54 (s, 2 H, H4), 5.70 (m, ^3J_s = 6.8, ^3J_a = 12.7 Hz, 1 H, H_{meso}), 3.99 and 3.94 (t, ^3J = 6.6 Hz, 8 H, OCH_2), 3.92 (d, ^3J_s = 6.8 Hz, 2 H, H_s), 3.18 (d, ^3J_a = 12.7 Hz, 2 H, H_a), 1.87−1.70 (m, 8 H, CH_2), 1.64−1.40 (m, 8 H, CH_2), 1.00 and 0.98 (t, ^3J = 7.3 Hz, 12 H, CH_3).

Synthesis of $[Au(HPz^{bp2})(PPh_3)](NO_3)$ (5): $AgNO_3$ (34 mg, 0.20 mmol) was added under nitrogen to a solution of $[AuCl(PPh_3)]$ (100 mg, 0.20 mmol) in acetone (25 mL). After stirring for 2 h in darkness, the solution was filtered through a plug of Celite and the solvent was evaporated. Compound **3** (HPz^{bp2}, 73 mg, 0.20 mmol) was added to a solution of the obtained product in dry dichloromethane and the mixture was stirred for 5 h at room temperature. The solvent was removed under vacuum to provide a oil, from which a white solid was isolated by addition of dichloromethane and hexane. This solid was crystallised from dichloromethane/hexane. Yield: 90 mg, 51%. $C_{41}H_{43}N_3O_5AuP$ (884.94): calcd. C 55.60, H 4.86, N 4.75; found C 55.82, H 4.73, N 4.88. IR (KBr): $\tilde{\nu}$ = 3250 cm^{-1} ν(N−H), 1613 ν(C=N), 1384 $\nu_{as}(NO_3)$. ^1H NMR (400 MHz, $CDCl_3$, 298 K): δ = 7.78 ppm (d, ^3J = 8.8 Hz, 4 H, H_o), 7.57−7.40 (m, 15 H, PPh_3), 6.92 (d, ^3J = 8.8 Hz, 4 H, H_m), 6.71 (s, 1 H, H4), 3.97 (t, ^3J = 6.6 Hz, 4 H, OCH_2), 1.78 (m, 4 H, CH_2), 1.49 (m, 4 H, CH_2), 0.99 (t, ^3J = 7.3 Hz, 6 H, CH_3).

Synthesis of $[Pd(\eta^3\text{-}C_3H_5)(Pz^{bp2}Py)](BF_4)$ (6): This compound was prepared in a similar way to **4**, from $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2$ (110 mg, 0.30 mmol), $AgBF_4$ (117 mg, 0.60 mmol), and **2** ($Pz^{bp2}Py$) (265 mg, 0.60 mmol). White crystals were obtained by crystallisation from dichloromethane/hexane. Yield: 215 mg, 53%. $C_{31}H_{36}BF_4N_3O_2Pd$ (675.21): calcd. C 55.09, H 5.33, N 6.22; found C 54.75, H 5.30, N 6.21. IR (KBr): $\tilde{\nu}$ = 1609 and 1571 cm^{-1} ν(C=N), 1069 and 1027 ν(BF). ^1H NMR (400 MHz, $CDCl_3$, 298 K): δ = 8.85 ppm (m, 1 H, H6′), 7.81 (ddd, ^3J = 8.6, ^3J = 7.3, ^4J = 1.6 Hz, 1 H, H4′), 7.58 (d, ^3J = 8.6 Hz, 2 H, H_o), 7.53 (m, 1 H, H5′), 7.39 (d, ^3J = 8.5 Hz, 2 H, H_o), 7.06 (d, ^3J = 8.5 Hz, 2 H, H_m), 7.04 (d, ^3J = 8.6 Hz, 2 H, H_m), 6.99 (d, ^3J = 8.6 Hz, 1 H, H3′), 6.70 (s, 1 H, H4), 5.68 (m, ^3J_s = 6.5, ^3J_a = 12.8 Hz, 1 H, H_{meso}), 4.06 (t, ^3J = 6.5 Hz, 4 H, OCH_2), 3.87 (d, ^3J_s = 6.5 Hz, 2 H, H_s), 3.21 (d, ^3J_a = 12.8 Hz, 2 H, H_a), 1.82 (m, 4 H, CH_2), 1.54 (m, 4 H, CH_2), 1.01 (t, ^3J = 7.4 Hz, 6 H, CH_3). ^{13}C NMR (400 MHz, $CDCl_3$, 298 K): δ = 161.3 and 161.2 ppm (C_p), 157.4 (^3J = ^3J = 4.6 Hz, C3), 153.8 (^1J = 187.7 Hz, C6′), 149.7 (C2′), 147.1 (^2J = 8.8, ^3J = ^3J = 5.0 Hz, C5), 141.2 (^1J = 167.6 Hz, C4′), 130.4 (^1J = 160.5, ^3J = 7.5 Hz, C_o), 130.1 (^1J = 160.2, ^3J = 7.3 Hz, C_o), 124.5 (^1J = 170.3 Hz, C5′), 122.9 (^3J = ^3J = 7.8 Hz, C_{ipso}), 119.7 (^3J = ^3J = 7.7 Hz, C_{ipso}), 117.4 (^1J = 164.6 Hz, CH allyl), 115.7 (^1J = 161.8, ^3J = 4.7 Hz, C_m), 114.7 (^1J = 161.2, ^3J = 4.5 Hz, C_m), 114.6 (C3′), 111.3 (^1J = 181.7 Hz, C4), 68.1 (^1J = 142.7 Hz, OCH_2), 63.6 (CH_2

allyl), 31.2 (^1J = 126.5 Hz, CH_2), 19.2 (^1J = 127.5 Hz, CH_2), 13.8 (^1J = 125.0 Hz, CH_3).

Synthesis of [Au(Pz^{bp2}Py)(PPh$_3$)](NO$_3$) (7): Compound **7** was prepared similarly to **5**, from [AuCl(PPh$_3$)] (80 mg, 0.16 mmol), $AgNO_3$ (27 mg, 0.16 mmol), and **2** (Pz^{bp2}Py) (71 mg, 0.16 mmol). The obtained yellow solid was purified by treatment with dichloromethane. Yield: 74 mg, 48%. $C_{46}H_{46}AuN_4O_5P$ (961.94): calcd. C 57.38, H 4.78, N 5.82; found C 57.48, H 4.90, N 5.62. IR (KBr): $\tilde{\nu}$ = 1611 and 1576 cm^{-1} ν(C=N), 1357 $\nu_{as}(NO_3)$. ^{1}H NMR (400 MHz, CD_2Cl_2, 298 K): δ = 8.38 ppm (m, 1 H, H6′), 7.87 (d, ^3J = 8.8 Hz, 2 H, H_o), 7.82 (ddd, ^3J = 8.1, ^3J = 7.5, ^4J = 1.6 Hz, 1 H, H4′), 7.54−7.41 (m, 15 H, PPh_3), 7.40 (m, 1 H, H5′), 7.35 (d, ^3J = 8.1 Hz, 1 H, H3′), 7.25 (d, ^3J = 8.8 Hz, 2 H, H_o), 6.91 (d, ^3J = 8.8 Hz, 4 H, H_m), 6.83 (s, 1 H, H4), 4.00 (t, ^3J = 6.5 Hz, 4 H, OCH_2), 1.78 (m, 4 H, CH_2), 1.51 (m, 4 H, CH_2), 1.00 (t, ^3J = 7.4 Hz, 6 H, CH_3). ^{13}C NMR (400 MHz, CD_2Cl_2, 298 K): δ = 161.1 and 161.0 ppm (C_p), 154.9 (^3J = ^3J = 4.1 Hz, C3), 151.7 (C2′), 149.8 (^1J = 182.9, ^3J = 7.2 Hz, C6′), 147.4 (^2J = 7.3, ^3J = ^3J = 3.7 Hz, C5), 140.1 (^1J = 166.1 Hz, C4′), 135−130 (PPh_3), 130.9 (^1J = 159.9, ^3J = 7.3 Hz, C_o), 129.1 (^1J = 159.4, ^3J = 7.4 Hz, C_o), 124.7 (^1J = 167.0 Hz, C5′), 124.4 (^3J = ^3J = 8.0 Hz or ^3J = ^3J = 7.7 Hz, C_{ipso}), 121.9 (^3J = ^3J = 8.0 Hz or ^3J = ^3J = 7.7 Hz, C_{ipso}), 120.9 (^1J = 175.2 Hz, C3′), 115.6 (^1J = 160.8 Hz or ^1J = 159.7, ^3J = 4.3 Hz, C_m), 115.5 (^1J = 160.8 Hz or ^1J = 159.7, ^3J = 4.3 Hz, C_m), 107.7 (^1J = 178.5 Hz, C4), 68.7 (^1J = 143.6 Hz, OCH_2), 32.0 (^1J = 125.3 Hz, CH_2), 20.0 (^1J = 126.2 Hz, CH_2), 14.4 (^1J = 124.7 Hz, CH_3).

Synthesis of [Pd$_2$(η^3-C$_3$H$_5$)$_2$(BPz^{bp2}TzO)](BF$_4$) (8): The synthetic procedure used for **8** was similar to that described for **4**, from [Pd(η^3-C_3H_5)(μ-Cl)]$_2$ (21 mg, 0.06 mmol), $AgBF_4$ (23 mg, 0.12 mmol), and **1** (TPz^{bp2}Tz) (46 mg, 0.04 mmol). The resulting yellow solid was purified by crystallisation in dichloromethane/hexane. Yield: 36 mg, 75%. $C_{55}H_{64}BF_4N_7O_5Pd_2$ (1201.61): calcd. C 54.93, H 5.33, N 8.15; found C 55.00, H 5.66, N 8.00. IR (KBr): $\tilde{\nu}$ = 1696 cm^{-1} ν(C=O), 1611 ν(C=N), 1066 ν(BF). ^{1}H NMR (400 MHz, $CDCl_3$, 298 K): δ = 7.59 and 6.99 ppm (d, ^3J = 6.8 Hz, 8 H, H_o), 7.03 and 6.62 (d, ^3J = 6.8 Hz, 8 H, H_m), 6.52 (s, 2 H, H4), 5.44 (m, ^3J_s = 6.5, ^3J_a = 13.0 Hz, 2 H, H_{meso}), 4.05 (t, ^3J = 6.5 Hz, 4 H, OCH_2), 3.99 (t, ^3J = 6.4 Hz, 4 H, OCH_2), 3.79 (br., ^3J_s = 6.5 Hz, 4 H, H_s), 3.21 (br., ^3J_a = 13.0 Hz, 4 H, H_a), 1.80 (m, 8 H, CH_2), 1.53 (m, 8 H, CH_2), 1.00 and 0.99 (t, ^3J = 7.5 Hz, 12 H, CH_3). ^{13}C NMR (400 MHz, $CDCl_3$, 298 K): δ = 163.1 ppm (Tz), 161.2 (^3J = ^3J = 8.9 Hz, C_p), 160.0 (^3J = ^3J = 8.8 Hz, C_p), 158.2 (^2J = ^3J = ^3J = 4.1 Hz, C3), 158.0 (CO), 149.2 (^2J = 6.5, ^3J = ^3J = 3.3 Hz, C5), 130.1 (^1J = 160.5, ^3J = 7.1 Hz, C_o), 129.9 (^1J = 160.3, ^3J = 7.0 Hz, C_o), 122.3 (^3J = ^3J = 7.8 Hz, C_{ipso}), 119.7 (^3J = ^3J = 8.0 Hz, C_{ipso}), 114.7 (^1J = 161.3, ^3J = 4.2 Hz, C_m), 114.2 (^1J = 160.8, ^3J = 4.6 Hz, C_m), 114.1 (^1J = 156.2 Hz, CH allyl), 111.9 (^1J = 181.7 Hz, C4), 68.18 (^1J = 142.2, ^2J = 4.0 Hz, OCH_2), 67.74 (^1J = 142.9, ^2J = 3.7 Hz, OCH_2), 63.8 (^1J = 162.8 Hz, CH_2 allyl), 31.26 and 31.17 (^1J = 124.7 Hz, CH_2), 19.17 and 19.15 (^1J = 125.4 Hz, CH_2), 13.8 (^1J = 124.9 Hz, CH_3).

Treatment of TPz^{bp2}Tz with [Au(NO$_3$)(PPh$_3$)]. Formation of [Au$_3$(TPz^{bp2}Tz)(PPh$_3$)$_3$](NO$_3$)$_3$ (9): This compound was prepared by a procedure analogous to that described for **5**, from [AuCl(PPh_3)] (74 mg, 0.15 mmol), $AgNO_3$ (26 mg, 0.15 mmol), and **1** (TPz^{bp2}Tz) (58 mg, 0.05 mmol). The obtained yellow solid was purified by treatment with dichloromethane/hexane. Yield: 82 mg, 60%. $C_{126}H_{126}Au_3N_{12}O_{15}P_3$ (2729.82): calcd. C 55.39, H 4.61, N 6.15; found C 55.00, H 4.39, N 6.01. IR (KBr): $\tilde{\nu}$ = 1611 cm^{-1} ν(C=N), 1384 $\nu_{as}(NO_3)$. ^{1}H NMR (400 MHz, CD_2Cl_2, 298 K): δ = 7.83 ppm (d, ^3J = 6.8 Hz, 6 H, H_o), 7.60−7.40 (m, 45 H, PPh_3), 7.3−7.5 (br., 6 H, H_o), 7.02 (br., 6 H, H_m), 6.92 (d, ^3J = 6.8 Hz, 6 H, H_m), 6.83 (s, 3 H, H4), 4.00 (t, ^3J = 6.5 Hz, 6 H, OCH_2), 3.94 (br., 6 H, OCH_2), 1.80 (m, ^3J = 7.0 Hz, 6 H, CH_2), 1.75 (br., 6 H, CH_2), 1.54 (m, ^3J = 7.5 Hz, 6 H, CH_2), 1.49 (br., 6 H, CH_2), 1.01 (t, ^3J = 7.4 Hz, 9 H, CH_3), 0.98 (br., 9 H, CH_3). ^{13}C NMR (400 MHz, CD_2Cl_2, 298 K): δ = 162.1 ppm (br., Tz), 160.9 (C_p), 156.5 (br., C_p), 154.8 (C3), 149.1 (br., C5), 135−130 (PPh_3), 129.7 (C_o), 128.9 (br., C_o), 124.9 (C_{ipso}), 122.1 (br., C_{ipso}), 115.7 (C_m), 115.1 (br., C_m), 112.1 (br., C4), 68.7 (OCH_2), 32.00 and 31.98 (CH_2), 20.04 and 19.97 (CH_2), 14.4 (CH_3).

Treatment of TPz^{bp2}Tz with [Au(CF$_3$SO$_3$)(PPh$_3$)]. Formation of [Au$_3$(TPz^{bp2}Pz)(PPh$_3$)$_3$](CF$_3$SO$_3$)$_3$ (10): $AgCF_3SO_3$ (54 mg, 0.21 mmol) was added under nitrogen to a solution of [AuCl(PPh_3)] (102 mg, 0.21 mmol) in dry THF (25 mL). After stirring for 2 h in the darkness, the solution was filtered through a plug of Celite. Compound **1** (TPz^{bp2}Tz, 80 mg, 0.07 mmol) was then added and the mixture was stirred for 4 h at room temperature. The solvent was removed under vacuum to afford an oil, from which a yellow solid was isolated by addition of diethyl ether and hexane. This solid was purified by treatment with dichloromethane. Yield: 119 mg, 57%. $C_{129}H_{126}Au_3F_9N_9O_{15}P_3S_3$ (2990.82): calcd. C 51.76, H 4.21, N 4.21; found C 52.03, H 4.28, N 4.25.

Synthesis of [H$_2$Pz^{bp2}](BF$_4$) (11): HBF_4−diethyl ether complex (85%, 37 mg, 0.36 mmol) was added to a solution of **3** (HPz^{bp2}, 131 mg, 0.36 mmol) in diethyl ether (5 mL) and the mixture was stirred for 1 h at room temperature. A white crystalline precipitate was filtered off and washed with diethyl ether. Yield: 73 mg, 45%. IR (KBr): $\tilde{\nu}$ = 3238 and 3178 cm^{-1} ν(N−H), 1619 ν(C=N), 1067 ν(BF). ^{1}H NMR (400 MHz, $CDCl_3$, 298 K): δ = 13.2 ppm (br., 2 H, NH), 7.67 (d, ^3J = 8.5 Hz, 4 H, H_o), 7.03 (d, ^3J = 8.5 Hz, 4 H, H_m), 6.86 (s, 1 H, H4), 4.02 (t, ^3J = 6.6 Hz, 4 H, OCH_2), 1.80 (m, 4 H, CH_2), 1.51 (m, 4 H, CH_2), 0.99 (t, ^3J = 7.3 Hz, 6 H, CH_3).

X-ray Structure Determination

Prismatic single crystals of [Pd(η^3-C_3H_5)(HPz^{bp2})$_2$](BF$_4$) (**4**) were obtained by crystallisation from dichloromethane/diethyl ether. Single needle crystals of [Au(HPz^{bp2})(PPh$_3$)](NO$_3$) (**5**) were obtained by crystallisation from dichloromethane/hexane.

The data for both compounds were collected on a Smart Bruker CCD detector diffractometer. A summary of the fundamental crystal data and refinement parameters for the two crystals is given in Table 5.

The structure of **4** was solved by direct methods and conventional Fourier techniques. The refinement was carried out by blocked full-matrix, least-squares on F^2.[29] The F atoms of the BF_4^- groups and some carbon atoms (including the allyl group) were refined for only two cycles anisotropically and in the last cycles the thermal factors were fixed. These carbon atoms were refined with geometrical restraints and a variable common carbon-carbon distance. The rest of the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were calculated and refined as riding on the carbon bonded atom with common isotropic displacement parameters.

The molecular structure of **5** was solved by direct methods and conventional Fourier techniques and refined by full-matrix, least-squares on F^2.[29] All non-hydrogen atoms were refined anisotropically except for the oxygen atoms in the nitrate group and the last carbon atoms of the butoxy group, which were refined isotropically. The hydrogen atoms were calculated and refined as riding on the carbon-bonded atom with a common isotropic displacement parameter, except for the H2 bonded to N2, which was lo-

Synthesis, Crystal Structure and Fluorescence of Two Novel Mixed-Ligand Cadmium Coordination Polymers with Different Structural Motifs

Junhua Luo,[a] Maochun Hong,*[a] Ruihu Wang,[a] Rong Cao,[a] Lei Han,[a] and Zhenzhong Lin[a]

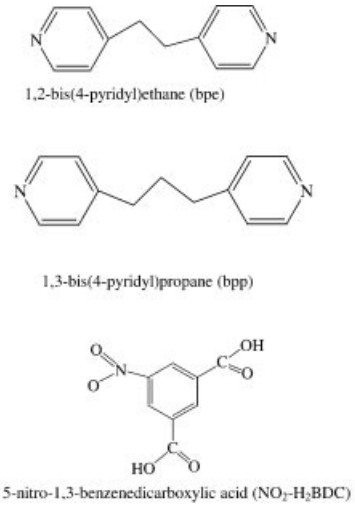
Keywords: Cadmium / Coordination polymers / Fluorescence / N ligands

Two novel cadmium(II) coordination compounds, $[Cd(bpe)_{1.5}(NO_2\text{-}BDC)]\cdot 0.25H_2O$ (**1**) and $[Cd(bpp)(NO_2\text{-}BDC)(H_2O)]\cdot 0.25H_2O$ (**2**) [NO_2-$BDCH_2$ = 5-nitro-1,3-benzenedicarboxylic acid, bpe = 1,2-bis(4-pyridyl)ethane, bpp = 1,3-bis(4-pyridyl)propane] have been hydrothermally synthesized by reaction of cadmium chloride and NO_2-BDC with the homologous ligands bpe and bpp, respectively. The former compound displays a remarkable three-dimensional architecture sustained by the catenation of 2D bilayers, while the latter exhibits a unique twofold interpenetrating three-dimensional architecture. The thermal and fluorescence properties associated with their crystal structures have been measured.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Polymeric coordination compounds have recently received much attention due to their interesting potential applications and various coordination architectures,[1,2] in which supramolecular polymeric architectures containing topological bonds, such as polycatenanes and polyrotaxanes, are of special interest for chemists.[3,4] The structural topology of coordination polymers can be specially designed by the careful selection of the coordination geometry of the metals, the structure of the spacer ligands, the counteranions, and the reaction conditions.[5−7] To date, of diverse elegant efforts to find key factors in the development of the polymers, the main rational synthetic strategy has been the use of unique spacer ligands where the network topology can be controlled and modified by changing the chemical structure of the organic ligand.[8,9] *N*,*N*′-bipyridine-type ligands are convenient linkers for constructing metal-organic frameworks, and a wide range of one-, two-, and three-dimensional coordination polymers has been generated with them.[10−12] At the same time, phenyldicarboxylates, which can serve as bifunctional ligands, have been effectively utilized to build coordination networks.[13,14] We anticipated using the mixed phenyldicarboxylate/*N*,*N*′-bipyridine-type ligand system [(NO_2-BDC)/(bpe or bpp); Scheme 1] to generate some coordination polymers with interesting topologies. Here, we report the crystal structure and fluorescence properties of two novel mixed organic ligand coordination polymers $[Cd(bpe)_{1.5}(NO_2\text{-}BDC)]\cdot 0.25H_2O$ (**1**) and $[Cd(bpp)(NO_2\text{-}BDC)(H_2O)]\cdot 0.25H_2O$ (**2**).



Scheme 1.

Results and Discussion

1,2-Bis(4-pyridyl)ethane (bpe) and 1,3-bis(4-pyridyl)propane (bpp) were selected as starting materials as they have different linkers between the two pyridine rings and show different structures. The two *N*,*N*′-bipyridine-type ligands react with NO_2-BDC (NO_2-$BDCH_2$ = 5-nitro-1,3-benzene-

[a] State Key Laboratory of Structural Chemistry, Fujian Institute of the Research on the Structure of Matter, Chinese Academy of Sciences,

E-mail: hmc@ms.fjirsm.ac.cn

dicarboxylic acid) and a cadmium salt under the same reaction conditions. The two *N*,*N*′-bipyridine-type ligands have different structures, which finally results in different coordination frameworks as in **1** and **2**.

Crystal Structures

Single-crystal X-ray diffraction revealed a unique 2D bilayer structure of **1** with molecular formula $[Cd(bpe)_{1.5}(NO_2\text{-}BDC)_2]\cdot 0.25H_2O$. Each Cd^{II} center is heptacoordinated with a distorted $\{CdN_3O_4\}$ pentagonal bipyramidal coordination sphere, as shown in Figure 1. Four oxygen atoms belonging to two chelating didentate carboxylate groups from two NO_2-BDC moieties and one nitrogen atom from a bpe molecule coordinate to the cadmium center in the equatorial plane, with two nitrogen atoms from another two bpe ligands located at the axial positions of the coordination sphere. The Cd−O distances range from 2.322(10) to 2.599(9) Å, and the Cd−N distances are 2.328(13) and 2.345(12) Å. All the bpe ligands adopt an *anti* conformation and link the cadmium(II) ions into a $[Cd(bpe)_{1.5}]_n$ ladder as shown in Figure 2. The bpe ligands adopt two ligand conformations (A and B) in the ladder: the sides of the ladder adopt conformation A (bpe^A), with a dihedral angle of the two pyridyl rings of 44.1°; the rungs of the ladder adopt conformation B (bpe^B), where the two pyridyl rings are coplanar. The NO_2-BDC ligand acts as a μ_2-bridge through two chelating didentate carboxylate groups to link the ladders into a 2D bilayer (Figure 3). As seen in Figure 3b, the bpe^A and NO_2-BDC moieties in the also the link the cadmium ions into a (4,4) net sheet where the bpe^B ligands act as pillars forming bilayer galleries in which the planar sheets separated by them define 1D channels with dimensions of 13.848 × 14.054 $Å^2$. In the 2D bilayer structure of **1**, a cuboidal box containing eight cadmium(II) ions at the corners, connected by four short NO_2-BDC and eight long bpe linkers, making up the 12 edges, forms the fundamental building unit of **1** (Figure 4). This cuboidal structural motif is clearly different from the tetrahedral building blocks used to form other bilayer structures.[15,16] Interpenetration occurs in **1**, and each bilayer is interlocked by two adjacent identical frameworks (the upper and the lower identical motifs) as seen in Figure 5. This threefold interpenetration means that the void volume in **1** is very small; it is filled by the free water molecules. The resulting 3D array is, therefore, an infinite catenane of decked layers of an unprecedented interwoven type.

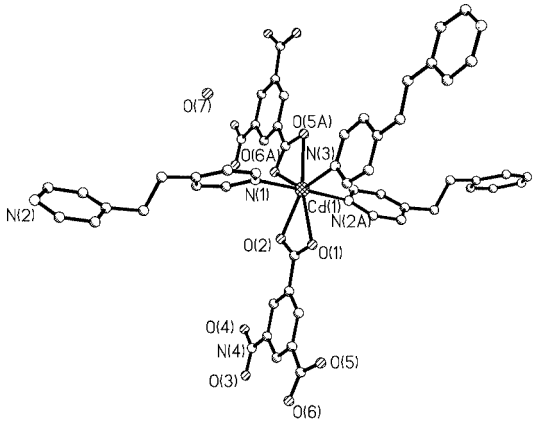

Figure 1. Perspective view of the coordination environment of the cadmium atom in **1**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

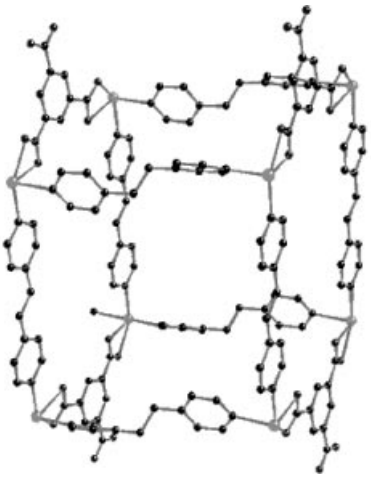

Figure 4. View of the cuboidal structural motif in **1**

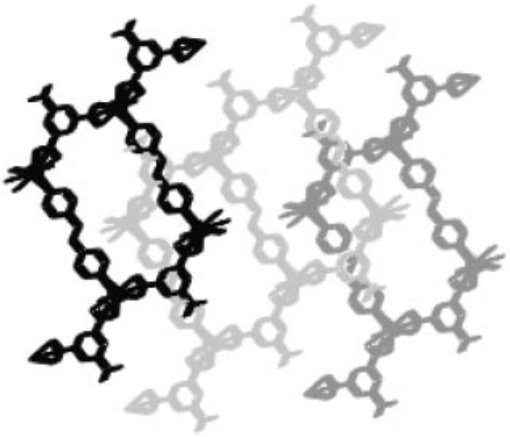

Figure 5. View of the interpenetration in **1**

The structure of **2** is a remarkable extended three-dimensional framework with molecular formula $[Cd(bpp)(NO_2\text{-}BDC)(H_2O)]\cdot 0.25H_2O$, in which the cadmium(II) atoms are bridged by mixed NO_2-BDC and bpe ligands. The asymmetric unit contains one cadmium(II) atom, one coordinated NO_2-BDC molecule, one coordinated bpp molecule, one coordinated water molecule and 0.25 free water molecules. All the Cd atoms are equivalent and each cadmium center is six-coordinate in a distorted octahedral geometry. Three carboxylate oxygens (O1, O2 and O3a) belonging to one chelating didentate carboxylate group, a monodentate carboxylate group from two NO_2-BDC molecules and one pyridyl N atom from a bpe ligand coordinate to the Cd center in the equatorial plane with *cis*-bond angles around the Cd center ranging from 54.2(2) to 128.9(2)°; the water molecule (O7) and another pyridyl N atom (N2b) from one bpe ligand are located at the axial positions of the distorted octahedral coordination sphere of Cd, with an O7−Cd−N2b bond angle of 167.7(2)° as shown in Figure 6. The $Cd-O_{carboxylate}$ distances range from 2.204(5) to 2.450(6) Å, and the Cd−N distances are 2.284(6) and 2.330(7) Å. Two NO_2-BDC and four bpp ligands link six Cd atoms to form a Cd_6 ring, which may be taken as the basic building block for the whole 3D framework of **2** (Figure 7). In the Cd_6 ring, the bpp ligands separate the Cd atoms at a distance of 11.598 Å; the two pyridine rings in dpp are almost perpendicular (dihedral angle of 97.2°), which is very different from the values found in **1** (44.1° or 0°). At the same time, the two pyridine rings coordinated to the same Cd atom are also almost perpendicular (dihedral angle of 79.4°). The Cd_6 rings are fused to form the ultimate unique 3D framework of **2**, which contains large channels with dimensions of 17.814×6.596 Å^2 (Figure 8). The 3D networks interlock with each other displaying a twofold-interpenetrating mode, which means that the void volume in **2** is very small; it is filled by the free water molecules (Figure 9).

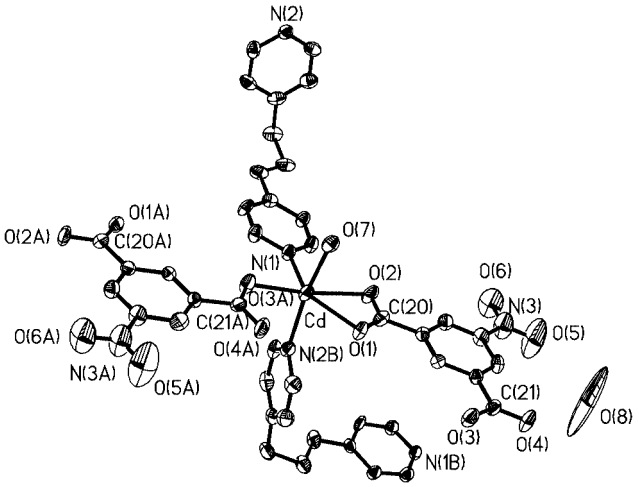

Figure 6. Perspective view of the coordination environment of the cadmium atom in **2**

IR Spectroscopy

The IR spectra of the two compounds show the characteristic bands of the dicarboxylate groups of NO_2-BDC at 1150−1620 cm^{-1} for the asymmetric vibration and at 1390−1420 cm^{-1} for the symmetric vibration. The absence of the expected absorption at 1690−1730 cm^{-1} for the protonated carboxylate groups illustrates the complete deprotonation of NO_2-BDC in the reaction with cadmium.[17]

Thermal and Fluorescent Properties

To study the thermal stability of the two compounds, thermogravimetric analysis (TGA) was performed on them. The TGA results of the two compounds are similar and show a very slow and gradual release of 0.25 water molecules in the 40−135 °C temperature range for **1** and 0.25 water molecules over the temperature range 35−120 °C for **2**. No obvious decomposition was observed until about 410 °C. Compounds **1** and **2** begin to decompose at 418 °C and 426 °C, respectively.

Metal-organic polymer compounds with a d^{10} configuration (such as Zn^{2+} and Cd^{2+}) have been found to exhibit photoluminescent properties,[18,19] and Zaworotko and co-

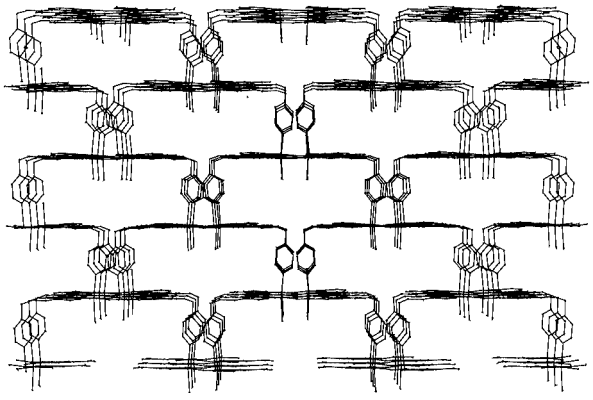

Figure 8. View of the 3D framework in **2** with large channels

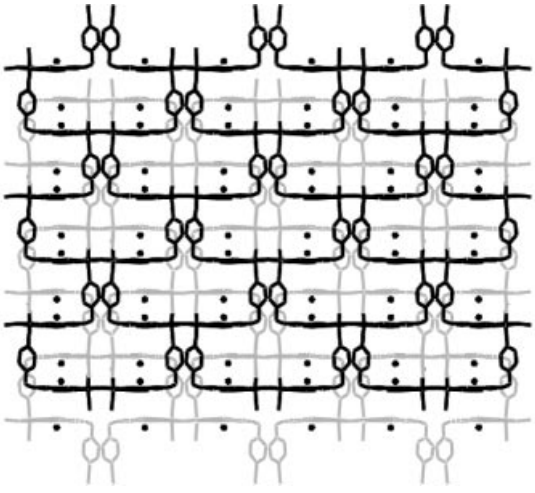

Figure 9. View of the interpenetration in **2** and the free water molecules in the void volumes

workers recently reported the first coordination polymer that traps a fluorescent guest.[20] Here, we want examine the photoluminescence of **1** and **2**. The solid-state emission spectra of complexes **1** and **2** at room temperature are shown in Figure 10. It can be seen that the maximum of the emission bands of **1** is located at 435 nm (λ_{ex} = 280 nm), while **2** also exhibits an intense photoluminescence emission at 439 nm (λ_{ex} = 310 nm). These emissions bands may be due to σ-donation from the cooperation of NO_2-BDC and bpp or bpe to the Cd center,[18a] and may be assigned to the ligand-to-metal charge-transfer (LMCT) band.[18,19] It is noticeable that **1** and **2** exhibit quenching of the fluorescence, with τ = 3.45 ns for **1** and τ = 3.64 ns for **2**.

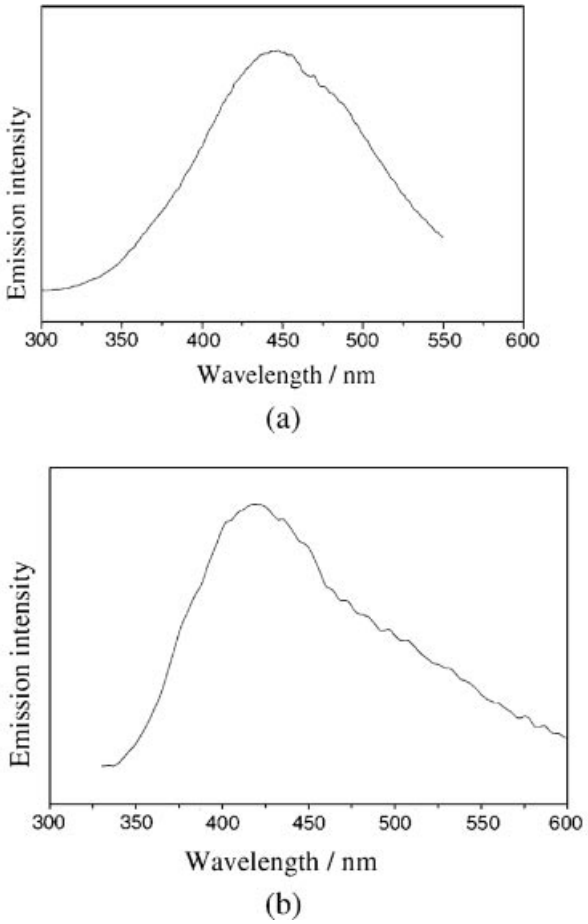

Figure 10. Solid-state emission spectra of the two compounds at room temperature: a) compound **1**; b) compound **2**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Although **1** and **2** have different structural motifs, it is interesting to note that they exhibit similar thermal behaviors and emission bands. As the thermal behaviors and photoluminescence behaviors are closely associated with the metal ions and ligands coordinated around them, we need to compare the coordination environments of the Cd ions in **1** and **2**. The Cd atom in **1** has two chelating bis-didentate carboxylate groups and three bpp ligands, and in **2** there is one chelating bis-didentate carboylate group, one monodentate carboxylate group, and two bpp ligands. These similar environments may be the reason for the similar thermal and fluorescence behaviors of **1** and **2**.

Conclusion

Two coordination polymers formed by a cadmium salt and NO_2-BDC with the homologous ligands bpe and bpp have been prepared and characterized. Because of the different structures of the selected organic ligands (bpe for **1** and bpp for **2**), complex **1** exhibits a remarkable three-dimensional architecture sustained by the catenation of 2D bilayers, while complex **2** displays a unique twofold interpenetrating three-dimensional structural motif. Because of interpenetration, the two compounds all have small void volumes filled by free water molecules. They have similar thermal behaviors and fluorescence spectra.

Experimental Section

General: $CdCl_2 \cdot 2.5H_2O$ and NO_2-BDC were purchased commercially and used without further purification. The bpe and bpp were purchased from Fluka. C, H and N analyses were determined on a Perkin−Elmer 240C analyzer. IR spectra were measured as KBr pellets on a Nicolet Magna 750 FT-IR spectrometer in the range 200−4000 cm^{-1}. Thermogravimetric analyses were performed on a NETSCHZ STA-449C thermoanalyser under N_2 (26−750 °C range) at a heating rate of 10 °C/min. Fluorescent characterization was performed on an Edinburgh F900 analytical instrument at Fuzhou University**.** Fluorescence spectra of the solid samples were obtained by direct front-face emission from the solid powder bonded to a quartz support oriented at 40° to both the excitation and emission light paths, with excitation at 280 nm for **1** and 310 nm for **2**.

$[Cd(bpe)_{1.5}(NO_2\text{-BDC})]\cdot 0.25H_2O$ (1): The pH value of an aqueous mixture (10 mL) containing NO_2-BDC (0.5 mmol), $CdCl_2 \cdot 2.5H_2O$ (0.5 mmol) and bpe (0.5 mmol) was pre-adjusted to about 6 with a 0.1 M aqueous NaOH solution. The mixture was then transferred into an Teflon-lined, stainless-steel autoclave (18 mL), and the vessel was sealed and heated to 180 °C for 72 h, then cooled to room temperature at a rate of 10 °C/h. Colorless crystals of **1** were obtained (0.165 g, 82%). $C_{26}H_{21.5}CdN_4O_{6.25}$ (602.4): calcd. C 51.80, H 3.57, N 9.30; found C 51.41, H 3.62, N 9.24.

$[Cd(bpp)(NO_2\text{-BDC})(H_2O)]\cdot 0.25H_2O$ (2): The pH value of an aqueous mixture (10 mL) containing NO_2-BDC (0.5 mmol), $CdCl_2 \cdot 2.5H_2O$ (0.5 mmol) and bpp (0.5 mmol) was pre-adjusted to about 6 with a 0.1 M aqueous NaOH solution. The mixture was then transferred into an Teflon-lined, stainless-steel autoclave (18 mL), and the vessel was sealed and heated to 180 °C for 72 h, then cooled to room temperature at a rate of 10 °C/h. Colorless crystals of **2** were obtained (0.213 g, 78%). $C_{21}H_{19.55}CdN_3O_{7.25}$ (542.3): calcd. C 46.47, H 3.60, N 7.74; found C 45.02, H 3.67, N 7.65.

X-ray Crystallography: Single crystals of **1** and **2** were selected for an X-ray diffraction study. The unit-cell parameters and intensities were collected at 299 K on a Siemens SMART CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073Å) and a graphite monochromator using the ω-scan mode. The structures were solved by direct methods and refined on F^2 by full-matrix least-squares procedures using the SHELXTL software suite.[21] All non-hydrogen atoms were refined anisotropically. All H-atoms were located theoretically and not refined. A summary of the crystallographic data of **1** and **2** is presented in Table 1, with selected bond lengths and angles in Table 2.

CCDC-203638 (**1**) and -203639 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Diorganotin(IV) Complexes of a Cyclic Thiosemicarbazone Ligand: Crystal Structures of $[SnPh_2(C_{15}H_{10}N_3S)Cl]$ and $[SnMe_2(C_{15}H_{10}N_3S)_2]$

Elena López-Torres,[a] M. Antonia Mendiola,*[a] César J. Pastor,[b] and Jesús R. Procopio[c]

Keywords: Nitrogen heterocycles / S ligands / Tin

Treatment of 5-methoxy-5,6-diphenyl-4,5-dihydro-2*H*-[1,2,4]triazine-3-thione (LH_2OCH_3) with compounds SnR_2X_2 (R = Me and Ph; X = Cl and NO_3) afforded, for the first time, metal derivatives of a cyclic thiosemicarbazone. Treatment of LH_2OCH_3 with the appropriate diorganotin(IV) chloride in dichloromethane provided 1:1 complexes, but 1:2 derivatives were isolated when the nitrate salts in distilled water were used. The complexes were studied by mass spectrometry, IR and multinuclear (^1H, ^{13}C and ^{119}Sn) NMR in solution, and also by ^{119}Sn CP/MAS NMR spectroscopy and by X-ray diffraction in the solid state. In all the complexes, the thiosemicarbazone had been modified by formation of a new C=N bond. In addition, the ligand LH had lost a hydrogen atom, acting as an anion. The crystal structures of $[SnPh_2(C_{15}H_{10}N_3S)Cl]$ (**1**) and $[SnMe_2(C_{15}H_{10}N_3S)_2]$ (**4**) each consist of discrete molecules with the tin atom bonded to the sulfur and amine nitrogen atoms to give a four-membered chelate ring with the [1,2,4]triazine modified. For phenyl derivative **1**, the tin atom is in a trigonal-bipyramidal environment with the phenyl rings in equatorial positions, and for complex **4** it is in an octahedral arrangement, with the methyl groups in axial positions. The ^{119}Sn CP/MAS NMR spectra of the complexes are in accordance with these structures. The values obtained indicate a five-coordinate geometry for $[SnMe_2(C_{15}H_{10}N_3S)Cl]$ (**2**) and suggest a coordination number of six for complex **3**. The ^{119}Sn spectra of complexes in solution depend on the coordinating capacity of the solvents.

Introduction

The increasing interest in thiosemicarbazones (TSCs) that has arisen in the last decades is related to their wide range of biological properties as, for example, antiviral, antibacterial and anticancer agents.[1−8] In particular, the National Cancer Institute (USA) has requested from us a sample of the molecule studied in this work in order to test it against a full panel of 60 human tumours (NSC no. 711635-Y). From the data obtained, this molecule seems to be active against breast cancer. Moreover, octahedral Sn^{IV} complexes are potential anti-tumour and anti-viral agents, a number of them having been shown to be active. Diorganotin(IV) derivatives appear to be the most active.[9,10]

A combination of the ligand and the metal chemistry is therefore an interesting topic to pursue, since it involves organotin and C=S moieties, both of which should have good biological activity. The mechanism of the activity of these complexes requires understanding of their structures and isomerism. In attempts to correlate anti-tumour activity with structure, it has generally been assumed that the organic ligand should facilitate the transport of the complex across cell membranes, while the actual anti-tumour activity would be exerted by the dissociated diorganotin(IV) moieties.[11−13] Moreover, TSC ligands are very versatile as the π delocalisation (enhanced upon deprotonation) and the presence of different types of donor atoms, such as sulfur, imine and amine nitrogen atoms, makes several coordination modes possible.[14,15]

In previous work, we have studied the synthesis and characterisation of macroligands with common functional groups, but containing different numbers of donor atoms and variable structures. In particular, we have prepared open-chain [1+2] and cyclic [1+1] molecules derived from the reaction between benzil and thiosemicarbazide.[19,20] A macrocyclic [2+2] condensation product was obtained in methanol from the cyclic [1+1] species in the presence of copper(II) chloride, through a metal template macrocyclization.[21] We have also studied their complexation reactions with metal ions, in order to ascertain the structural features of the complexes relating to biological systems and to evaluate their potential use in determination of toxic metals.[22−26] Previously, the cyclic [1+1] compound 5-methoxy-5,6-diphenyl-4,5-dihydro-2*H*-[1,2,4]triazine-3-thi-

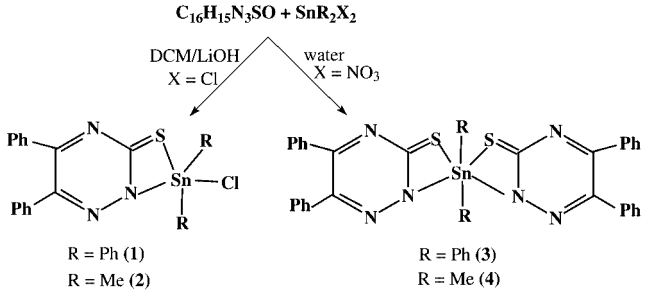
one (LH_2OCH_3) had been observed to undergo a macrocyclization process in the presence of copper(II) nitrate and mercury salts, yielding macrocyclic complexes.[21,27] In this paper we report the synthesis and characterisation of the first complexes from a cyclic thiosemicarbazone obtained by treatment of LH_2OCH_3 with diorganotin(IV) compounds (SnR_2X_2: R = Me, Ph; X = Cl, NO_3). We have observed that the nature of the anionic ligand (Cl and NO_3), results in complexes of different stoichiometry and geometry for the tin atom: 1:1 with a coordination number of five for chloride and 1:2 with a coordination number of six for nitrate derivatives.

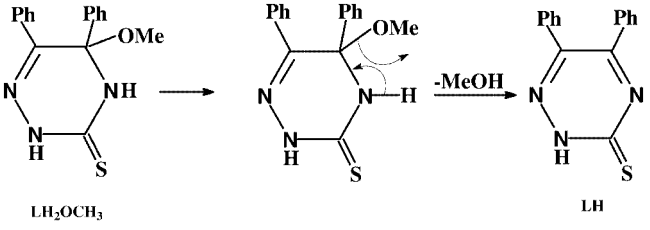
Solid-state ^{119}Sn NMR is known to provide insight into the local symmetry properties of the central tin(IV) atom and, in combination with solution ^{119}Sn NMR spectroscopic data, to provide information about the structural changes occurring upon dissolution of the organotin compounds.[12,16–18] The availability of X-ray data for two structurally related complexes prompted us to complement this work with the solid-state and solution NMR spectroscopic data.

Results and Discussion

Tin complexes were prepared by the general procedure outlined in Scheme 1. The reactions with chlorides were carried out in dichloromethane in the presence of a basic medium and those from nitrates in distilled water. The presence of basic medium or of water induces the loss of methanol, probably due to acid-base reaction with the relatively highly acidic N–H bond, yielding LH (Scheme 2), which has an additional C=N bond.[20]



Scheme 1



Scheme 2

Analytical data for the complexes show metal/ligand 1:1 stoichiometries for the chloride derivatives **1** and **2**, and 1:2 stoichiometries, with the absence of nitrate groups, for complexes **3** and **4**. Conductivity measurements for complex **2** in dimethylformamide and dichloromethane indicate the presence of non-ionic species in these solvents. Mass spectra confirm the molecular mass and also show fragments corresponding to the loss of R (Me or Ph), chlorine ligand or $C_{15}H_{10}N_3S$ (L^-). Experimentally measured isotopic distributions showed the same patterns as the theoretical ones in all compounds.

Crystallography

The crystal structure of **1** consists of discrete molecules of $[SnPh_2(C_{15}H_{10}N_3S)Cl]$. A perspective view of the complex, together with the atom-labelling scheme, is given in Figure 1 (hydrogen atoms are omitted for better clarity, and the thermal ellipsoids are shown at 40% probability) and selected bond angles and distances are given in Table 1. The coordination sphere of the tin atom is made up of the sulfur, amine nitrogen, chloro atoms and two phenyl rings, giving a pentacoordinate geometry. The Sn–L distances are in the range expected for this kind of complexes.[14,33] The three heteroatoms are in the same plane, with a maximum deviation of 0.1611 Å for Cl(1). The coordination mode of the ligand produces a four-membered chelate ring with the phenyl rings in the equatorial positions and the third position occupied by the sulfur atom. As is to be expected, the axial positions are occupied by nitrogen and chlorine atoms, in agreement with the polarity rule. The distortion from the ideal trigonal-bipyramidal configuration is manifested by the Cl(1)–Sn(1)–N(1) angle of 154.4°, which deviates from the ideal value of 180°, probably due to the ligand constraint. An alternative estimate of the geometry is given by the structural parameter τ introduced by Addison et al.[34] to analyse degrees of distortion from tetragonal-pyramidal (τ = 0.00) to trigonal-bipyramidal geometries (τ = 1.00). In this complex τ is 0.61. The phenyl rings form dihedral angles of 69.12, 74.14, 40.38 and 49.53° with respect to the equatorial plane for C(1)–C(6), C(7)–C(12), C(16)–C(21) and C(22)–C(27), respectively. An important change is observed with respect to LH_2OCH_3, where the dihedral angles are 36.94 [C(16)–C(21)] and 95.07° [C(22)–C(27)].[20] This change in one of the phenyl rings can be explained by the loss of the OMe group.

The crystal structure of **4** consists of discrete molecules of $[SnMe_2(C_{15}H_{10}N_3S)_2]$. A perspective view of the complex, together with the atom-labelling scheme, is given in Figure 2 (hydrogen atoms are omitted for better clarity, and thermal ellipsoids shown at 30% probability) and selected bond angles and distances are given in Table 2. Within the complex the tin(IV) ion is hexacoordinate in a distorted octahedral arrangement, four of the coordination positions belonging to the deprotonated ligands, which occupy the equatorial positions through the amine nitrogen atoms N(1) and N(4) and the sulfur atoms S(1) and S(2). The Sn–N distances are longer than in complex **1** and in other related

compounds.[14,33] The two remaining positions in the octahedral geometry are occupied by two methyl groups, with a deviation from the expected angle of 24.4°.

The coordination mode of the ligand gives rise to two four-membered chelate rings. The core formed by the two thiosemicarbazone backbones and the tin atom can be considered planar, with a maximum deviation from the mean plane of 0.1104 Å for N(1), while the phenyl rings form dihedral angles of 41.46, 39.64, 48.2 and 42.53° with respect to this plane for C(6)−C(11), C(12)−C17), C(21)−C(26) and C(27)−C(32), respectively. These values are modified with respect to LH_2OCH_3 in the same way as in complex **1**.

Bond lengths in both complexes agree well with an iminethione form of the ligand, as does the NMR spectroscopy (see below), but with considerable electronic delocalisation through the thiosemicarbazone backbone, owing to the deprotonation of the ligands. As a consequence of this delocalisation, all the C−N bonds have almost the same length (Tables 1 and 2), which does not occur in LH_2OCH_3 (1.284−1.459 Å).[20] The thione bonds in both complexes (Tables 1 and 2) are longer than in the precursor molecule (1.628 Å in LH_2OCH_3) and are intermediate between the theoretical C−S single and double bonds,[35] as is also the case with the N−N bonds. Both S−C−N angles are also modified, especially that in which the nitrogen atom is involved in the bond to the tin atom. In addition, the N(2)−C(15)−C(14) angle in LH_2OCH_3 is 108.5°, corresponding to sp^3 hybridisation, while those in the complexes are close to 120°, as would be expected for sp^2 hybridisation. The remaining bond lengths and angles are similar to those found in similar organotin(IV) complexes and do not merit further comment.[14,33]

IR Spectroscopy

The IR assignment of LH_2OCH_3 is reported in the Exp. Sect. The absence of any band in the 2600 cm^{-1} region in all complexes suggests the absence of any thiol tautomer.[36] There are no bands in the 3000−3300 cm^{-1} region, indicating the absence of N−H bonds. In complexes **3** and **4** the absence of any band attributable to the nitrate group confirms that the organic fragment acts as an anion. The coordination through the sulfur atom can be observed in a decrease of the ν(C=S) frequency in the spectra of all the

complexes. The presence of two bands attributable to C=N bonds indicates the formation of a new imine group, due to the loss of the methoxy group of the ligand. These moieties are non-coordinate to the tin atom. In complexes **1** and **3**, a new band at 729 cm^{-1} corresponding to phenyl rings appears. In all complexes the ν(Sn−C) bands are in the same region found in other diorganotin(IV) complexes.[37]

NMR Spectroscopy

The NMR assignments for LH_2OCH_3 are listed in the Exp. Sect. The ^1H NMR spectra of complexes **1** and **3** each show only a multiplet in the aromatic carbon atom region, corresponding to phenyl rings bonded to the tin atom and to the ligand. In each of the complexes **2** and **4** a singlet corresponding to the methyl group bonded to the metal atom can be observed, together with the multiplet for the phenyl rings of the ligand. In all complexes the absence of any signal corresponding to amine protons supports the presence of L. The loss of the methoxy group is confirmed by the absence of the singlet corresponding to the OCH_3 moiety (δ = 3.3 ppm).

In the ^{13}C NMR spectra the signals corresponding to the methoxy group carbon atoms and to the tetrasubstituted carbon atoms have disappeared and two signals attributable to imine carbon atoms have appeared. These groups are not bonded to the metal ion, as established by the X-ray diffraction. In addition, the thione group carbon atoms are deshielded in all complexes, due to the presence of metal−sulfur bonds, suggesting that the ligand retains the thione form. The numbers of signals corresponding to the phenyl carbon atoms are as expected for the proposed structures.

For methyl derivatives **2** and **4**, substitution of $^2J(^{119}Sn-^1H)$ values (72.20 and 75.02 Hz, respectively) and $^1J(^{119}Sn-^{13}C)$ values (518.69 and 557.00 Hz, respectively) into the corresponding Lockhart-Manders equations[38] (empirical relationship between the coupling constants and the C−Sn−C angle) gives C−Sn−C angle values of 122.0 and 124.4° for complex **2** and 125.0 and 125.5° for complex **4**. These similarities indicate that the data are reliable.

The ^{119}Sn chemical shifts of tin complexes appear to depend not only on coordination number, but also on the type of donor atoms bonded to the metal ion.[16,39,40] To bridge the information gap between X-ray diffraction and solution NMR spectroscopic data, solid-state NMR is an important

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

routine technique.[17b] ^{119}Sn chemical shifts are summarised in Table 3. The values for the ^{119}Sn chemical shift in the solid state for complexes **1** and **4** are those expected for penta- and hexacoordinate environments for the tin atom. That obtained for complex **2** agrees with a five-coordinate structure as suggested by other measurements. The ^{119}Sn CP/MAS NMR spectrum of complex **3** is of lower resolution than the other complexes, but seems to show a δ(^{119}Sn) from −280 to δ = −335 ppm. This value corresponds to hexacoordination for the tin atom and, in comparison with the methyl derivative with the same stoichiometry, it is in the range expected.

Table 3. ^{119} Sn NMR spectroscopic data for the complexes (δ in ppm)

Compound	Solid	$CDCl_3$	[D_6]DMSO
1	−199	−181.5	−224.8
2[a]	−170	−24.5	−213.5
3	−280 to −335[b]	−206.8	−220.9
4	−251	− 84.3	−108.7

[a] −160.7 in dimethylformamide. [b] Low-resolution spectrum.

Holecek[16] established for *n*-butyl derivatives that four-coordinate compounds have δ(^{119}Sn) values in solution ranging from δ = +200 to −60 ppm, five-coordinate compounds δ = −90 to −190 ppm, and six-coordinate compounds δ = −210 to −400 ppm. The value of δ = −181.5 ppm for complex **1** is within the range expected for five-coordinate complexes, which agrees with the environment of the tin atom persisting in solution (Table 3). The value of δ = −24 ppm for complex **2** in $CDCl_3$ correlates well with a four-coordinate complex, which indicates a strong change in the coordination sphere of the metal atom, probably due to the rupture of one (Sn−L) bond (the complex is a non-electrolyte in CH_2Cl_2). The spectrum in DMF, however, shows a signal at δ = −160.7 ppm, as would be expected for pentacoordination (slightly shifted from the value in the solid state), so the five-coordination for the tin atom remains in DMF. The ^{119}Sn values observed for complex **3** are smaller than those seen in the solid state (Table 3), and could reflect a coordination number of either five or six, depending on the atoms bonded to the tin atom. For a particular geometry, relatively lower δ(Sn) values are observed with higher electronegativity of the atom directly bonded to the metal atom.[41] In comparison with complex **1** (five-coordinate by Ph_2SNCl) the elimination of the chlorine ligand and the addition of a new Sn−L bond will give a slightly more negative δ value. On the other hand, replacement of methyl by phenyl, with the same geometry, should shift the signal to a more negative value. If these factors are taken into account, the δ value in complex **3** suggests five-coordination for the tin atom in chloroform.

The chemical shift for complex **4** in $CDCl_3$ indicates a change to a lower coordination than in the solid state (Table 3). Since a value of δ = −181 ppm in solution for complex **1** corresponds to five-coordination, a value of δ = −84.3 ppm seems to indicate tetracoordination (Me_2S_2)[42] instead of hexacoordination. This change could be explained by the rupture of the weak Sn−N bonds in solution, these bonds being longer than those in other previously published complexes with related ligands[14,33] and in those presented in this work.

The ^{119}Sn chemical shift values in [D_6]DMSO are more negative than in $CDCl_3$ and − for complexes **1** and **2** − than in the solid state, as would be expected for this coordinating solvent. [D_6]DMSO can increase the coordination sphere of the tin atom and/or substitute Sn−L bonds, increasing the coordination number to six for complexes **1**−**3** and to five for complex **4**.

Conclusions

The cyclic thiosemicarbazone LH_2OCH_3 reacts with diorganotin species to give non-electrolyte complexes (**1**−**4**). The stoichiometry of the complexes depends on the organotin compound used (chloride or nitrate). X-ray diffraction studies of complexes **1** and **4** revealed that the tin atoms in both are bonded to the sulfur and to the deprotonated amine nitrogen atoms, giving a four-membered chelate ring, with the organic molecule modified. In complex **1** the tin atom is in a trigonal-bipyramid environment with the phenyl rings in equatorial positions, and in complex **4** it is in an octahedral arrangement, with the methyl groups in axial positions. We have also studied the structural changes accompanying the dissolution of the complexes by ^{119}Sn CP/MAS and multinuclear solution NMR spectroscopy. These complexes are promising from the biological point of view, because they contain organotin, the precursor molecule appearing to be active against human tumours, and also contain the C=S moiety, which displays good antimicrobial activity.

Experimental Section

Physical Measurements: Microanalyses were carried out with a Perkin−Elmer 2400 II CHNS/O Elemental Analyser. IR spectra in the 4000−400 cm^{-1} range were recorded on KBr pellets with a Jasco FT/IR-410 spectrophotometer. ^{1}H, ^{13}C and ^{119}Sn NMR spectra were recorded with a Bruker AMX 300 spectrophotometer in $CDCl_3$, [D_6]DMSO and DMF as solvents and with TMS (^{1}H, ^{13}C) and $SnMe_4$ (^{119}Sn) as internal references. Fast atom bombardment mass spectra were recorded with a VG Auto Spec instrument with Cs as the fast atom and *m*-nitrobenzyl alcohol (*m*NBA) as the matrix. ^{119}Sn MAS and CP/MAS NMR spectra were obtained at room temperature with a Bruker MSL 400 spectrometer. The external magnetic field was 9.4 T and samples were spun at 10 kHz around an axis inclined at 54°44′ with respect to this field. The spectrometer frequency was set to 149.11 MHz. For spectra recorded with use of a standard single-pulse sequence, a π/2 pulse of 6 μs and a period between successive accumulations of 10 s were used. In CP-MAS conditions, a contact time of 1 ms was used. The number of scans was 800. Chemical shift values were referenced to $Sn(CH_3)_4$. The analysis of ^{119}Sn NMR spectra was done with the WINFIT Program.

Crystallography: Single crystals, prismatic in shape, of complexes **1** and **4** were obtained by recrystallisation from ethanol. Measurements were carried out with a Bruker SMART 6 K CCD area detector three-circle diffractometer with a Rigaku Rotating Anode (Cu-K_α radiation). For complexes **1** and **4**, the substantial redundancy in the data allows empirical absorption corrections (SADABS)[28] to be applied by use of multiple measurements of symmetry-equivalent reflections. The unit cell parameters were obtained by full-matrix, least-squares refinements of 8312 and 5730 reflections for complexes **1** and **4**, respectively. Crystallographic details are reported in Table 4. The crude intensity data frames were integrated by use of the SAINT[29] program, which also applied corrections for Lorentz and polarisation effects. The SHELXTL[30] software package, version 6.10, was used for space group determination, structure solution and refinement. The space group determination was based on a check of the Laue symmetry and systematic absences and was confirmed by the structure solution. The structure was solved by direct methods (SHELXS-97),[31] completed with difference Fourier syntheses, and refined by full-matrix, least squares by use of SHELXL-97,[32] with minimisation of $\omega(F_o^2 - F_c^2)^2$. Weighted R factors (R_w) and all goodnesses of fit S are based on F^2; conventional R factors (R) are based on F. All non-hydrogen atoms were refined with anisotropic displacement parameters. All scattering factors and anomalous dispersions factors are contained in the SHELXTL 6.10 program library. The high quality of the data set allowed all hydrogen atoms to be located by difference maps and refined isotropically in both complexes. CCDC-188698 (**4**) and -188699 (**1**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Syntheses: $SnMe_2Cl_2$ and $SnPh_2Cl_2$ were used as provided by Aldrich. Dichloromethane was dried by standard procedures.

5-Methoxy-5,6-diphenyl-4,5-dihydro-2*H*-[1,2,4]triazine-3-thione (LH_2OCH_3):[20] A solution of thiosemicarbazide (1.14 g, 12.50 mmol) in methanol (150 mL), hydrochloric acid (25 mL, 2 M), concd. HCl (1 mL) and a solution of benzil (2.63 g, 12.50 mmol) in methanol (100 mL) were alternatively added dropwise and slowly, with strong stirring, to methanol (75 mL). After completion of the addition of all reactants, the mixture was stirred for 8 h. Overnight a crystalline solid formed, which was filtered off, washed and dried in vacuo (yield 95%), m.p. 222 °C. $C_{16}H_{15}N_3OS$ (297.4): calcd. C 64.64, H 5.05, N 14.14; found C 64.45, H 5.09, N 14.05. MS (FAB+): m/z (%) = 298 (35) [$C_{16}H_{15}N_3SO + 1$]$^+$. Selected spectroscopic data: IR: $\tilde{\nu}$ = 3184 s, 3131 s (NH); 1608 w (C=N); 1550 s (thioamide I); 846 w (thioamide IV) cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.1 (s, 3 H, OCH_3), 7.2−7.4 (m, 8 H, Ph), 7.5 (m, 2 H, Ph), 10.0 (d, 1 H, NH), 12.1 (d, 1 H, NH) ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 25 °C): δ = 169.7 (C=S); 142.4 (C=N); 126.5, 129.3, 133.7, 141.7 (Ph); 83.2 (CH_3O); 50.7 (CR_3) ppm.

[$SnPh_2(C_{15}H_{10}N_3S)Cl$] (1): LH_2OCH_3 (0.50 g, 1.68 mmol) and $LiOH{\cdot}H_2O$ (0.071 g, 1.68 mmol) were stirred in dried dichloromethane (50 mL) at room temperature for 15 min. $SnPh_2Cl_2$ (0.58 g, 1.68 mmol), dissolved in the same solvent (10 mL), was then added. After the mixture had been heated at reflux for 7 d, it was filtered, and the clear yellow solution was concentrated until a yellow solid was formed (yield 95%), m.p. 170 °C. $C_{27}H_{20}ClN_3SSn$ (572.66): calcd. C 56.63, H 3.49, N 7.34, S 5.59; found C 56.44, H 3.76, N 7.14, S 5.52. MS (FAB+): m/z (%) = 537.9 (35) [$SnPh_2(C_{15}H_{10}N_3S)$]$^+$, 574.3 (5) [$SnPh_2(C_{15}H_{10}N_3S)Cl + 1$]$^+$. Selected spectroscopic data: IR (KBr): $\tilde{\nu}$ = 1598 w, 1578 w (C=N); 1489 s (thioamide I); 819 w (thioamide IV); 729 m (Ph) cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.31−8.07 (m, Ph). ^{13}C NMR (300 MHz, $CDCl_3$, 25 °C): δ = 128.5, 128.7, 129.3, 129.7, 129.9, 130.0, 130.6, 131.7, 134.3, 134.4, 135.8, 139.8 (Ph); 153.8, 159.8 (C=N); 175.0 (C=S) ppm; $^2J(^{119}Sn-^{13}C)$ = 60.0 Hz; $^3J(^{119}Sn-^{13}C)$ = 17.4 Hz. ^{119}Sn NMR (300 MHz, $CDCl_3$, 25 °C): δ = −181.5 ppm. ^{119}Sn NMR (300 MHz, [D_6]DMSO, 25 °C): δ = −224.8 ppm. ^{119}Sn CP/MAS NMR: δ = −199 ppm.

[$SnMe_2(C_{15}H_{10}N_3S)Cl$] (2): A solution of $SnMe_2Cl_2$ (0.37 g, 1.68 mmol) in dried dichloromethane (10 mL) was added to a boiling mixture of LH_2OCH_3 (0.80 g, 2.69 mmol) and $LiOH.H_2O$ (0.071 g, 1.68 mmol) in the same solvent (80 mL). The mixture was stirred at reflux for 10 days. The white solid was filtered off and discarded. The yellow solution was concentrated until a yellow solid was produced. Yield 90%. m.p. 186 °C. $C_{17}H_{16}ClN_3SSu$ (448.15): calcd. C 45.52, H 3.57, N 9.37, S 7.14; found C 45.29, H 3.71, N 9.12, S 6.95. MS (FAB+): m/z (%) = 414.1 (100) [$SnMe_2(C_{15}H_{10}N_3S)$]$^+$, 450.1 (9) [$SnMe_2(C_{15}H_{10}N_3S)Cl + 1$]$^+$. Selected spectroscopic data: IR (KBr): $\tilde{\nu}$ = 1597 w, 1578 w (C=N); 1489 s (thioamide I); 790 w (thioamide IV); 562 w (ν_{asy} Sn−C); 520 w (ν_{sym} Sn−C) cm^{-1}. Λ_M (DMF) = 4.5 Ω^{-1}cm^{2}mol^{-1}; Λ_M (CH_2Cl_2) = 0.7 Ω^{-1}cm^{2}mol^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.23 [s, 6 H, CH_3, $^2J(^{119}Sn-^1H)$ = 72.2 Hz]; 7.30−7.53 (m, 10 H, Ph) ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 25 °C): δ = 5.8 [CH_3, $^1J(^{119}Sn-^{13}C)$ = 518.6 Hz]; 128.6, 128.8, 129.1, 129.8, 130.0, 131.6, 134.4, 134.5 (Ph); 153.7, 159.1 (C=N); 174.7 (C=S) ppm. ^{119}Sn NMR (300 MHz, $CDCl_3$, 25 °C): δ = −24.5 ppm. ^{119}Sn NMR (300 MHz, DMF, 25 °C): δ = −160.7 ppm. ^{119}Sn NMR (300 MHz, [D_6]DMSO, 25 °C): δ = −213.5 ppm. ^{119}Sn CP/MAS NMR: δ = −170 ppm.

[$SnPh_2(C_{15}H_{10}N_3S)_2$] (3) and [$SnMe_2(C_{15}H_{10}N_3S)_2$] (4): A solution of $AgNO_3$ (3.37 mmol) in distilled water (10 mL) was added to a suspension of SnR_2Cl_2 (1.68 mmol) in the same solvent (10 mL). The mixture was stirred for 30 min and filtered. The filtrate was added slowly, with stirring, to a suspension of LH_2OCH_3 (3.36 mmol) in distilled water (50 mL). After the mixture had been heated at reflux for 3 d, the solid was filtered off, washed with methanol and vacuum dried.

Complex 3: Yield 98%, m.p. 180 °C. $C_{42}H_{30}N_6S_2Sn$ (801): calcd. C 62.90, H 3.75, N 10.49, S 7.99; found C 62.58, H 3.88, N 10.81, S 8.14. MS (FAB+): m/z (%) = 538.1 (100) [$SnPh_2(C_{15}H_{10}N_3S)$]$^+$,

COVER PICTURE

The cover picture shows a hexamolybdate anion bearing a diazenido ligand. This is a member of a promising family of functionalized polyoxomolybdates $[Mo_6O_{18}(N_2Ar)]^{3-}$ with a variety of substituents on the aryl ring. The influence of these substituents on the properties of the molybdate framework is exemplified by their different ^{95}Mo NMR spectra, where a special attention should be drawn to the signal of the Mo^{II} center at very high frequencies. Details on the preparation and characterization of these and related compounds can be found in the article by P. Gouzerh et al. on p. 2757 ff.

P-Modular Homochiral Bis(phosphanes) with 1,2-Disubstituted Cyclopentane Backbones in Asymmetric Hydrogenation[‡]

Lutz Dahlenburg[a]

Keywords: Chirality / Asymmetric synthesis / Hydrogenation / Chelate phosphanes / Rhodium

The review surveys synthetic aspects of a class of bidentate phosphanes based on the *trans*-1,2-disubstituted cyclopentane framework and the application of such ligands in transition-metal-catalyzed enantioselective hydrogenation. In particular, we address the preparative potential of the isomerically pure multi-purpose P–H and P–Cl reagents (*R*,*R*)- and (*S*,*S*)-$C_5H_8(PX_2)_2$ (X = H, Cl), which can serve to construct a family of optically active bis(phosphanes) with structural components ("modules") that are easily and systematically interchanged. The so-designed chelate ligands allow access to rhodium catalysts with stereodiscriminating properties, depending on parameters such as (i) presence of P-substituents that are equal or pairwise different in steric demand, (ii) spatial orientation of such substituents as defined by the *endo*- and *exo*-chelate P–C–C–P and P–Rh–P–C torsion angles, and (iii) existence of *C*- and *P*-chirogenic stereoelements in matched (or mismatched) combination.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The discovery of soluble transition metal complexes which catalyze enantioselective hydrogenation and oxidation reactions is amongst the most outstanding developments of organometallic chemistry.[2] The first homogeneously catalyzed hydrogenations of olefins were reported independently by Knowles[3] and Horner,[4] who demonstrated that the use of Wilkinson-type complexes, bearing resolved chiral monodentate phosphane ligands in place of PPh_3, resulted in the formation of enantiomerically enriched products, albeit in low optical yields. Shortly after, Kagan introduced the easily prepared (4*R*,5*R*) and (4*S*,5*S*) enantiomers of 4,5-bis[(diphenylphosphanyl)methyl]-2,2-dimethyl-1,3-dioxolane (diop) as the first C_2-symmetric chelating bis(phosphanes), which were found to control the chiral induction in rhodium-catalyzed hydrogenation reactions much more precisely than monophosphane ligands, particularly in the reduction of *N*-acylated dehydroamino acids and their esters.[5] As an equally important contribution, Knowles and co-workers subsequently established the commercial L-DOPA process using *P*-chirogenic (R_P,$R_{P'}$)-bis[(2-methoxyphenyl)phenylphosphanyl]ethane, (*R*,*R*)-DIPAMP, as a steering ligand.[2a,6] These developments gave rise to the immediate supposition that homochiral bis(phosphanes) as such are endowed with superior properties, allowing the bidentate species to control the stereochemical outcome of the rate-determining step in catalysis more precisely than a monodentate phosphane. As a result, research aimed at the improvement of chiral catalysts of low performance has predominantly been concentrated on the design of new and possibly optimized chelate phosphanes, of

Lutz Dahlenburg was born in 1944 in Dresden. He received his Dr. rer. nat. in 1975 from the University of Hamburg with Prof. Reinhard Nast (topic: transition metal alkynyl complexes). In 1982 he finished his habilitation at the Institute of Inorganic and Applied Chemistry at the University of Hamburg (Prof. Heindirk tom Dieck), working in the field of metal-complex-mediated C−H activation. Since 1991, he holds a professorship in Inorganic Chemistry at the Friedrich-Alexander University of Erlangen-Nürnberg. He has authored more than 110 publications in reviewed journals. His main research interests are focused on the design of novel optically active chelate ligands, asymmetric catalysis (>C=C< hydrogenation, >C=O reduction), and heterolytic H_2 activation.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

which the DuPHOS-type *o*-phenylenebis(2,5-dialkylphospholanes)[7] and 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl (BINAP)[2b] represent impressive examples. Note, however, that the generally accepted superiority of homochiral bidentate phosphanes in asymmetric hydrogenation has recently been challenged by the discovery that enantiopure monodentate P-ligands containing biaryl[8−13], spirobiindane,[14] oxaphosphinane[15] or carbohydrate[16] building blocks may likewise provide optical yields similar to those obtained with chelating phosphanes.[17]

Our approach to properly designed chiral hydrogenation catalysts has primarily been focussed on the construction of a class of optically active bidentate phosphanes with structural components (“modules” in Burk’s notation[7]) that can be systematically and easily interchanged in order to adapt the catalyst to a given purpose in the best possible fashion. Due to their “modular nature”[7] the so-defined ligands should be particularly suitable for adjusting the reactivity and catalytic behavior of metal complexes by judiciously selecting and changing parameters such as: (i) sets of donor groups, i.e., electronically different P−C-, P−N- or P−O-bonded substituents on the phosphorus atom; (ii) structural motifs, e.g., *P*- and/or *C*-chirality in, and steric demand of, substituent groups of that kind; (iii) torsion angles within the chelate framework, which in turn will influence the spatial orientation of selected parts of the ligand; and (iv) chelate bite angles, if variations of the backbone structure are also considered. Use of such ligands in transition-metal-mediated asymmetric catalysis can give insight into the relations and regularities existing between the performance of the catalytic system and the stereoelectronic characteristics of the metal−ligand template, provided viable synthetic schemes are available.

The traditional route to most of the widely used optically active bis(phosphanes), viz. those in which the phosphorus atoms bear two electron-withdrawing aryl groups, involves the alkylation of alkali metal diarylphosphides with disulfonates containing homochiral carbon backbones. The disadvantage of this protocol is that it cannot automatically be applied to the preparation of the more electron-rich *P*-alkylated analogues. Because of their high basicity, alkylated phosphide nucleophiles tend to engage in a number of troublesome side reactions to the effect that attempted displacement reactions using alkyl-substituted phosphide reagents will frequently result in products originating from metal−halogen exchange, P−P coupling and elimination[18] rather than substitution, especially when sterically hindered dialkylphosphides are used as nucleophiles.[18b] Previous work carried out in other laboratories has shown that these difficulties can be mastered either by the use of cyclic sulfates as substrates (particularly in displacement reactions employing relatively unhindered phosphide nucleophiles derived from primary phosphanes)[19] or, as an even more versatile method, by making use of less basic and, hence, less reactive phosphide−borane adducts.[20]

The key compounds of our synthetic strategy are the resolved enantiomers of bis(primary phosphanes), $H_2P^*\cap^*PH_2$, and bis(phosphonous dichlorides), $Cl_2P^*\cap^*PCl_2$, having their reactive $-PCl_2$ and $-PH_2$ functions supported on a rigid 1,2-*trans*-disubstituted cycloalkane backbone as represented, e.g., by the cyclopentane-based ligands $\mathbf{L^H}$ and $\mathbf{L^{Cl}}$ shown in the top row of Scheme 1. Their usefulness in the synthesis of optically active chelate phosphanes, to be discussed hereafter, is a result of the following features: First, the addition of P−H bonds across the >C=C< double bonds of different alkenes and cycloalkenes is likely to open a feasible route to various alkylated bis(secondary) and bis(tertiary) P_2 ligands with or without additional stereogenic centers at the phosphorus atom. Second, substitution reactions undergone by P−Cl functional phosphorus(III) compounds upon treatment with carbon, nitrogen or oxygen nucleophiles are among the most general and most easily accomplished coupling methods in organic chemistry. Finally, the possibility of incorporating virtually any other P−O-, P−N- or P−C-bonded residue into a homochiral bis(phosphane) framework should allow the preparation of a wide range of optically active chelate ligands having fine-tunable and, perhaps, rationally designable steric and electronic attributes.

The Ligands

Resolution of the Enantiomers

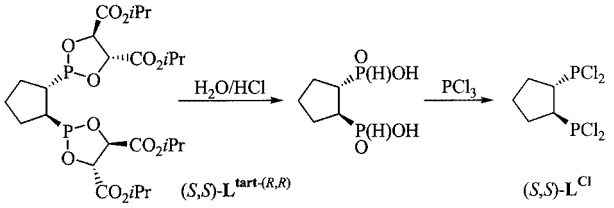
Analogous to the preparation of $Cl_2PC_2H_4PCl_2$ from ethylene, white phosphorus, and phosphorus trichloride,[21] racemic $C_5H_8(PCl_2)_2$, *rac*-**L**^{Cl}, can be obtained easily by heating cyclopentene with P_4 and PCl_3 at 220 °C in an autoclave, as reported by Green et al. as early as 1983.[22a]

Treatment of the racemate with Grignard reagents RMgBr (R = Me, Ph) afforded (±)-$C_5H_8(PR_2)_2$, **L**^{Me} and **L**^{Ph}, as the first P−C-substituted derivatives.[22] Resolution of the isomeric mixture was originally achieved by reaction with $NiBr_2$ in dichloromethane giving [$NiBr_2$(**L**^{Ph})]·CH_2Cl_2. Upon separation from solution, the complex underwent spontaneous resolution to deposit a conglomerate of crystals which were separated by hand and treated with sodium cyanide to yield **L**^{Ph} as its (*R*,*R*) and (*S*,*S*) stereoisomers.[22a]

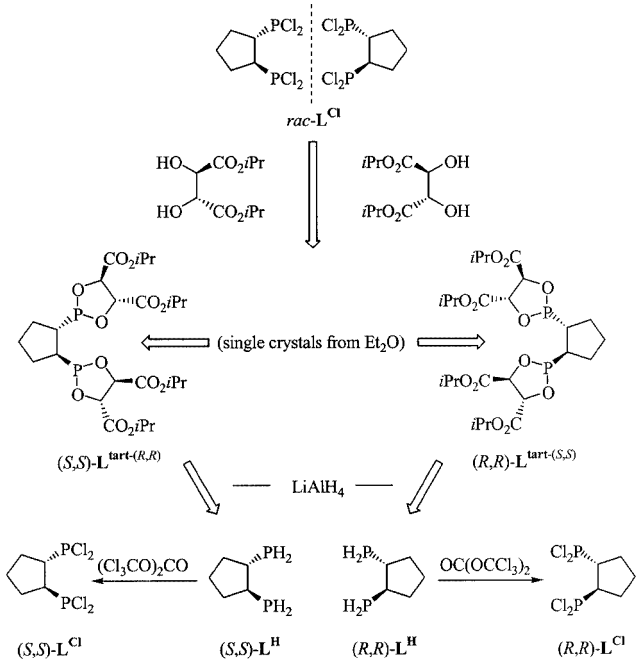
We entered the field in 1995 in an early attempt to accomplish stereodiscriminative C−H activation by treating 2,2′-disubstituted biphenyls and binaphthyls as racemates with the (+)- and (−)-enantiomers of the (hydrido)neopentylplatinum complex [{$C_5H_8(PCy_2)_2$}Pt(H)CH_2CMe_3] bearing the bis(dicyclohexylphosphane) ligand $C_5H_8(PCy_2)_2$ (**L**^{Cy}) in the optically active form.[23] For this particular bis(phosphane), effective resolution was brought about according to the strategy previously developed by Brunner and Pieronczyk for the separation of the stereoisomers of 2,3-bis(diphenylphosphanyl)norbornene (NORPHOS),[24] i.e., reduction with Ph_2SiH_2 of the *P*,*P*′-dioxides (+)- and (−)-C_5H_8{P(O)Cy_2}$_2$, which themselves were isolated by resolving their racemic mixture with (+)-di-*O*-benzoyltartaric acid.[23]

As an important breakthrough in the resolution of the enantiomers of the bis(phosphonous dichloride) **L**^{Cl}, we found that the cyclopentane-1,2-diyl[bis(1′,3′,2′-dioxaphospholane] **L**^{tart} resulting from the reaction of *rac*-**L**^{Cl} with (2*R*,3*R*)-(+)-diisopropyl tartrate (Scheme 2) could be crystallized from the isomeric mixture as a single (1*S*,2*S*,4′*R*,5′*R*) diastereomer, (*S*,*S*)-**L**$^{tart\text{-}(R,R)}$.[25] As expected, the (1*R*,2*R*,4′*S*,5′*S*) enantiomer, (*R*,*R*)-**L**$^{tart\text{-}(S,S)}$, was isolated, isomerically pure, from a similar reaction employing (2*S*,3*S*)-(−)-diisopropyl tartrate as the diol component.[26a] Reduction, with $LiAlH_4$, of these two phosphonites gave the bis(primary phosphane) **L**^{H} as resolved (*S*,*S*) and (*R*,*R*) enantiomers, and subsequent oxidation of the P−H bonds with bis(trichloromethyl)carbonate ("triphosgene") allowed for the routine preparation of either antipode of the multi-purpose P−Cl reagent **L**^{Cl}.[25,26b,27,28a]

In an alternative approach to the optically pure isomers of **L**^{Cl}, Brunner and co-workers preferred to hydrolyze the phosphonite enantiomers (*S*,*S*)-**L**$^{tart\text{-}(R,R)}$ and (*R*,*R*)-**L**$^{tart\text{-}(S,S)}$ to the free phosphinic acids, from which the resolved bis(phosphonous dichloride) enantiomers were recovered by chlorination with PCl_3 (Scheme 3).[29]



Scheme 3. Preparation of the optically pure $C_5H_8(PCl_2)_2$ enantiomers according to Brunner[29]



Scheme 2. Resolution of *rac*-$C_5H_8(PCl_2)_2$ into (*R*,*R*)- and (*S*,*S*)-$C_5H_8(PCl_2)_2$ via (*R*,*R*)- and (*S*,*S*)-$C_5H_8(PH_2)_2$[25,26b,27,28a]

Representative Examples

From the abundance of optically pure diphosphorus ligands containing various P−C-, P−N- and P−O-bonded donor groups that have been prepared by treating **L**^{Cl}, as either mirror image isomer, with alcohols, phenols, diols, secondary amines, Grignard reagents, or organolithium compounds,[26b,27−32] we will outline only selected cases that serve to illuminate the synthetic potential of the isomerically pure PCl_2-functional starting materials.

By combining the two enantiomers with both (*R*)-(+)- and (*S*)-(−)-1,1′-bi(2-naphthol) we were able to isolate the four diastereomeric forms of the cyclic bis(phosphonous acid diester) **L**^{binol} depicted in Scheme 1, which offered the opportunity to study matching and mismatching effects on the outcome of asymmetric hydrogenation reactions (vide infra), as caused by the mutual interaction of the different stereogenic elements in such steering ligands.[32]

The Brunner group described both divergent and convergent reaction sequences leading from enantiomers (*S*,*S*)-**L**^{Cl} and (*R*,*R*)-**L**^{Cl} to a second generation of optically active dendritically expanded bis(phosphanes).[29] These contained their stereochemically uniform dendritic extensions

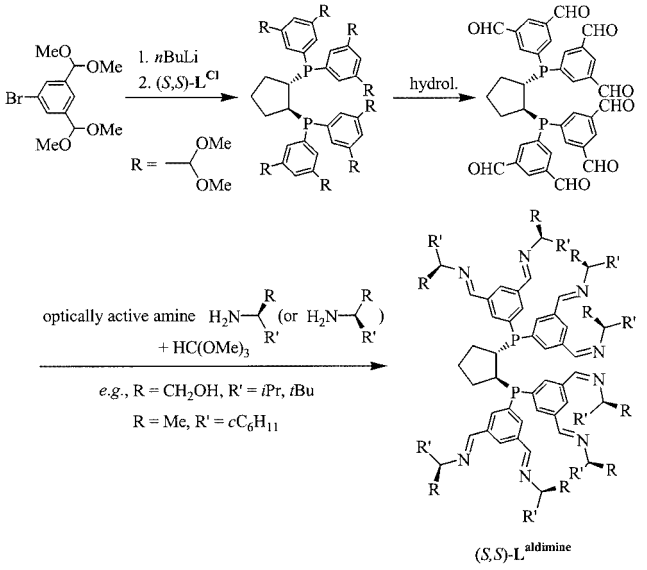
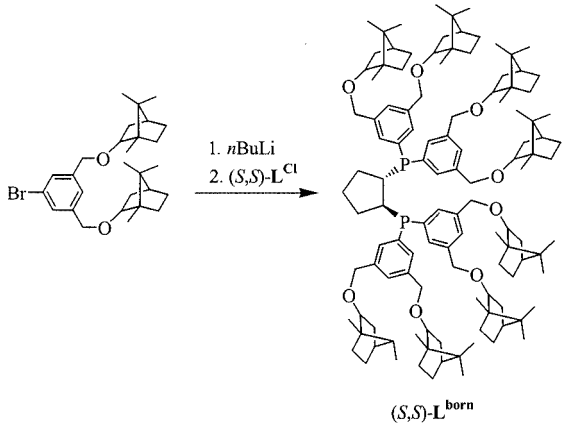
supported on a homochiral 1,2-disubstituted cycloalkane framework as defined by the phosphanes under discussion rather than on achiral 1,2-ethylene- or *ortho*-phenylene linkages as were originally used for optically active expanded P_2 ligands.[33] In the divergent synthetic approach, the enantiomerically pure $\mathbf{L^{Cl}}$ starting material was first coupled to branched aryllithium building blocks bearing acetal-protected formyl functions. Following deprotection of the acetals, multiple homochiral units were then introduced into the periphery of the expanded molecules by condensation of the aldehyde groups with different optically active amines and amino alcohols to afford branched ligands of the "$\mathbf{L^{aldimine}}$" type, as shown in Scheme 4. The alternative convergent strategy made use of pre-built branched aromatic bromides bearing (−)-borneol groups attached as benzylic ethers. Metallation followed by reaction with (*S*,*S*)-$\mathbf{L^{Cl}}$ and (*R*,*R*)-$\mathbf{L^{Cl}}$, respectively, produced the corresponding expanded "octaborneol-bis(phosphane)" ligand $\mathbf{L^{born}}$ depicted in Scheme 5 as either of the two possible diastereomers.



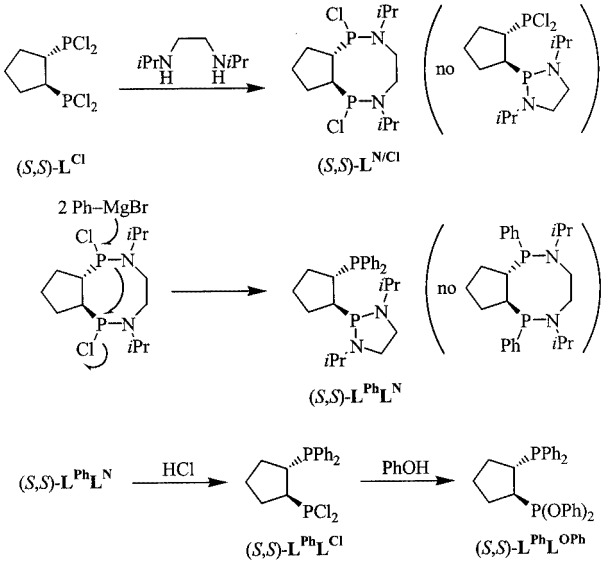
Scheme 4. Divergent approach to dendritically expanded bis(phosphanes)[29]

Dissymmetric P_2 ligands such as phosphane-phosphites[34] or bis(phosphanes) bearing different donor groups[35,36] have attracted considerable attention in homogeneous catalysis, in particular because of the impressive performance of their rhodium complexes as carbonylation and hydrogenation catalysts. Bis(phosphanes) with C_1 symmetry of the type $Ar_2PC_2H_4PAr'_2$ have previously been prepared either by base-catalyzed addition of a diarylphosphane to a suitable diarylvinylphosphane[35a] or by combining the phosphane-phosphonous dichloride $Ph_2PC_2H_4PCl_2$ with an appropriate Grignard or organolithium reagent.[35b] Analogous key intermediates having a rigid 1,2-disubstituted cyclopentane backbone rather than a flexible ethylene linkage, $C_5H_8(PPh_2)(PCl_2)$, were obtained as pure (*S*,*S*) and (*R*,*R*) enantiomers by the reaction sequence outlined in



Scheme 5. Convergent approach to a dendritically expanded "octaborneol-bis(phosphane)"[29]

Scheme 6. The exclusive formation of the still C_2-symmetric initial product containing an eight-membered perhydro-1,6,2,5-diazadiphosphocine ring, $\mathbf{L^{N/Cl}}$ [$\delta(^{31}P)$ = 161.4 (s) ppm], was unexpected as was its subsequent reaction with phenylmagnesium bromide yielding the now C_1-symmetric $C_5H_8(PPh_2)\{P[N(iPr)CH_2]_2\text{-}c\}$ ($\mathbf{L^{Ph}L^{N}}$) {$\delta(^{31}P)$ = 5.7, 115.6 [both d, J(PP) = 9.3 Hz] ppm} − probably as a result of nucleophilically induced ring contraction. Cleavage of the P−N bonds with HCl proceeded smoothly to afford the desired dissymmetric phosphane-phosphonous dichloride 1,2-$C_5H_8(PPh_2)(PCl_2)$ ($\mathbf{L^{Ph}L^{Cl}}$) {$\delta(^{31}P)$ = 9.5, 211.8 [both d, J(PP) = 13.0 Hz] ppm}, which similar to 1,2-$C_5H_8(PCl_2)_2$ proved to be a convenient starting material for further derivatization, e.g., to $C_5H_8(PPh_2)_2\{P(OPh)_2\}$ ($\mathbf{L^{Ph}L^{OPh}}$).[31]

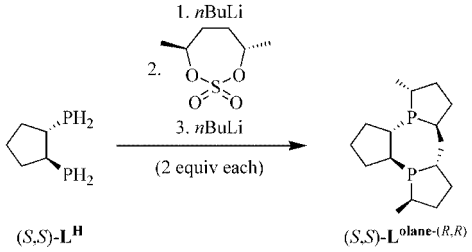


Scheme 6. Dissymmetric cyclopentane-based *P*,*P*′ ligands from C_2-symmetric $C_5H_8(PCl_2)_2$[31]

The more important diphosphorus ligands derived from the resolved bis(primary phosphane) $\mathbf{L^{H}}$ include the diastereomeric 1,2-bis(phospholano)cyclopentanes (*S*,*S*)- and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(*R*,*R*)-$C_5H_8\{P[(R)\text{-}CH(Me)CH_2]_2\text{-}c\}_2$ [$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$], described by Pringle et al.,[37] and the stereoisomers of the *C*- and *P*-chirogenic bis(phosphanes) $C_5H_8\{P(Me)R\}_2$ ($\mathbf{L}^{\mathbf{Me/R}}$), prepared in our laboratory.[32,38] The former were constructed in order to demonstrate how the enantioselectivity in asymmetric hydrogenation reactions of a rhodium catalyst which bears the flexible ethylene-bridged (*R*,*R*)-bis(phospholano)ethane ligand $1,2\text{-}C_2H_4\{P[(R)\text{-}CH(Me)CH_2]_2\text{-}c\}_2$ and, hence, exists in solution as an equilibrium mixture of interconverting λ and δ chelate conformers, can be rationally improved by placing an inflexible carbon skeleton between the two phosphorus atoms (vide infra). Similar to other bis(phosphanes) containing 2,5-dialkylphospholane building blocks, the two diastereomeric [$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$] ligands resulted from consecutive treatment of the pertinent $\mathbf{L}^{\mathbf{H}}$ enantiomer with *n*BuLi (2 equiv.), followed by the required 1,4-diol cyclic sulfate and another 2 equiv. of butyllithium as summarized by Scheme 7.[37]



Scheme 7. Synthesis of bis(phospholane) ligands with cyclopentane skeletons[37]

In the first step of the synthesis leading to the *C*,*P*-chirogenic bis(phosphanes) $\mathbf{L}^{\mathbf{Me/R}}$, which are to be regarded as conformationally rigid counterparts of Imamoto's "(S_P,$S_{P'}$)-bisP*" ligands $1,2\text{-}C_2H_4\{(S)\text{-}P(Me)R\}_2$ (R = *i*Pr, *t*Bu, Et_3C, cC_5H_9, cC_6H_{11}, $cC_6H_{10}Me$, 1-adamantyl),[39] a radical-initiated addition of the $-PH_2$ functions of optically pure $\mathbf{L}^{\mathbf{H}}$, across the carbon−carbon double bonds of cycloalkenes C_nH_{2n-2} (n = 5−8), was employed as a method of preparation for the bis(secondary phosphanes) $C_5H_8\{P(H)R\}_2$, where R = cC_5H_9, cC_6H_{11}, cC_7H_{13}, or cC_8H_{15}.[38a]

As exemplified in Scheme 8 for the product obtained with cyclooctene ($\mathbf{L}^{\mathbf{H/cOc}}$), formation of higher alkylated byproducts originating from consecutive P−H/>C=C< addition steps did not occur. Although the dialkylated bis(phosphanes) were formed without any notable diastereoselectivity and, hence, were isolated as more or less statistical mixtures of their (R_P,$R_{P'}$), (R_P,$S_{P'}$) [= (S_P,$R_{P'}$)], and (S_P,$S_{P'}$) diastereomers, separation of these stereoisomers was feasible by further derivatization and subsequent metal complex formation.[32,38] Thus, treatment of the isomeric mixtures with alkyllithium compounds, followed by alkylation with methyl iodide, caused the diastereomeric distributions to change in favor of the (*S*,*S*)-$C_5H_8\{(S)\text{-}P(Me)C_8H_{15}c\}_2$ and (*R*,*R*)-$C_5H_8\{(R)\text{-}P(Me)C_8H_{15}c\}_2$ stereoisomers,[38a] the rhodium(I) complexes of which − $[Rh\{(S,S)\text{-}C_5H_8[(R)\text{-}P(Me)C_8H_{15}c]_2\}(COD)]O_3SCF_3$ and $[Rh\{(R,R)\text{-}C_5H_8[(S)\text{-}P(Me)C_8H_{15}c]_2\}(COD)]O_3SCF_3$, respectively − were isolated as diastereomerically pure crystals by precipitation from a THF/diethyl ether solvent mixture.[32,38b] Conversely, successive combination of the bis(secondary phosphane) isomers $\mathbf{L}^{\mathbf{H/cOc}}$ first with "triphosgene" (vide supra) and then with methylmagnesium bromide led to an enrichment of the (*S*,*S*)-$C_5H_8\{(R)\text{-}P(Me)C_8H_{15}c\}_2$ and (*R*,*R*)-$C_5H_8\{(S)\text{-}P(Me)C_8H_{15}c\}_2$ stereoisomers, which in turn were treated with $[Rh(COD)_2]O_3SCF_3$ to furnish diastereomerically pure $[Rh\{(S,S)\text{-}C_5H_8[(S)\text{-}P(Me)C_8H_{15}c]_2\}(COD)]O_3SCF_3$ and $[Rh\{(R,R)\text{-}C_5H_8[(R)\text{-}P(Me)C_8H_{15}c]_2\}(COD)]O_3SCF_3$, following chromatographic workup (Scheme 8).[32]

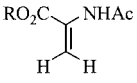
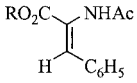
Catalytic Hydrogenation: Results of Comparative Studies



R = H: **acrH**; R = Me: **acrMe**



R = H: **cinH**; R = Me: **cinMe**

One of the most useful features of the ligands derived from the $\mathbf{L^H}$ and $\mathbf{L^{Cl}}$ precursors is their adjustability which enables the possibility of influencing the enantioselectivity by varying the substituents on the phosphorus atoms. Many of these optically active ligands have therefore been examined by us and others for their utility in Rh-catalyzed asymmetric hydrogenations of standard enamide substrates such as (acetylamino)acrylic (**acrH**) and -cinnamic (**cinH**) acid and their corresponding methyl esters **acrMe** and **cinMe**, respectively. The main purpose of these investigations was to reveal potential correlations between the outcome of the hydrogenation reactions and structural properties of the metal complexes in order to elucidate the factors governing the stereoselectivity of the catalysts. The results of these studies are collected in Table 1. For the sake of comparison, the catalytic results obtained with Rh catalysts derived from structurally related P_2 ligands[29,37,39a,39d,40] are also included in Table 1.

A first conclusion that can be drawn from Table 1 is that the catalytic activity of the different $[Rh(\mathbf{L})(COD)]^+$ complexes, as judged from the reaction times needed for full substrate conversion, increases with increasing electron-richness of the phosphorus atoms: $\mathbf{L^{binol}} << \mathbf{L^{Ph}} < \mathbf{L^{Me/cOc}}$. One further conclusion to be drawn for hydrogenations using either unsubstituted $\mathbf{L^{Ph}}$ steering ligands or dendritically expanded homologues with different multiple homochiral units in the periphery is that the generally high enantioselectivity for the (*S*)- or (*R*)-products displayed by the rhodium catalysts summarized under Entries **2** and **3** in Table 1 is governed by the (*R*,*R*) or (*S*,*S*) configuration and, respectively, λ or δ conformation of the chiral cyclopentane backbone rather than being controlled by the chiral dendritic expansions.[29] The rhodium chelate complexes of these ligands thus follow the empirical λ/δ rule predicting that a λ chelate will give the (*S*) enantiomer, while a δ chelate will produce the (*R*) enantiomer.[41] While this holds true for all ligands bearing two aryl substituents, the 1,1′-bi(2-naphthol)-derived bis(phosphonous acid diesters) $\mathbf{L^{binol}}$ reveal such a strong influence of the axially chiral binaphthoxy groups on the orientation of induction that their sense of chirality can override the contribution of the chiral ligand core. Thus, the catalyst complexes bearing (*R*,*R*)-

[a] Diolefin = 1,5-cyclooctadiene (Entries **1**,[32] **2**,[32] **3**,[29] **4**,[37] **5**,[19a,19c] **6**,[32,38b] and **8**[40]) or norbornadiene (Entry **7**[39a,39d]); $X^- = Cl^-$ {Entry **3**: in situ catalysts generated from $[Rh(\mu\text{-}Cl)(COD)]_2$ and bis(phosphane) ligands}, BF_4^- (Entries **4**, **7**, and **8**) or $F_3CSO_3^-$ (Entries **1**, **2**, **5**, and **6**). Experimental conditions: methanol or ethanol solvents (the latter only for Entry **7c** with **acrH** or **acrMe** as substrates); ambient temperature; initial H_2 pressure either ambient (Entries **1**−**3**, **6**, and **8**) or ca. 2 bar (Entries **4**, **5**, and **7**); typical Rh/substrate ratios of about $1-2 \times 10^{-3}$ (Entries **4**, **5**, and **7**), $3-5 \times 10^{-3}$ (Entries **1** and **2**), and 10^{-2} (Entries **3**, **6**, and **8**), respectively. Reaction times given for 100% conversion; *ee* values of Entries **3**, **4**, and **8** (no reaction times detailed in the original literature) likewise determined after complete hydrogenation. [b] For the hydrogenation of (benzoylamino)acrylic and -cinnamic acid using an in situ catalyst composed of $[Rh(\mu\text{-}Cl)(COD)]_2$ and (*S*,*S*)-$\mathbf{L^{Ph}}$ in methanol, Green et al. reported *ee* values of 100 ± 2%.[22a] [c] See Schemes 4 and 5.[29] [d] 1,2-C_2H_4{P-[(*R*)-CH(Me)CH_2]$_2$-*c*}$_2$. [e] ($R_{P(P')}$) and ($S_{P(P')}$) denote the configuration at the phosphorus atom for the *free* ligands, which is inverted upon coordination to the rhodium atom as a consequence of the CIP sequence rules; see also Table 2 and Scheme 8.

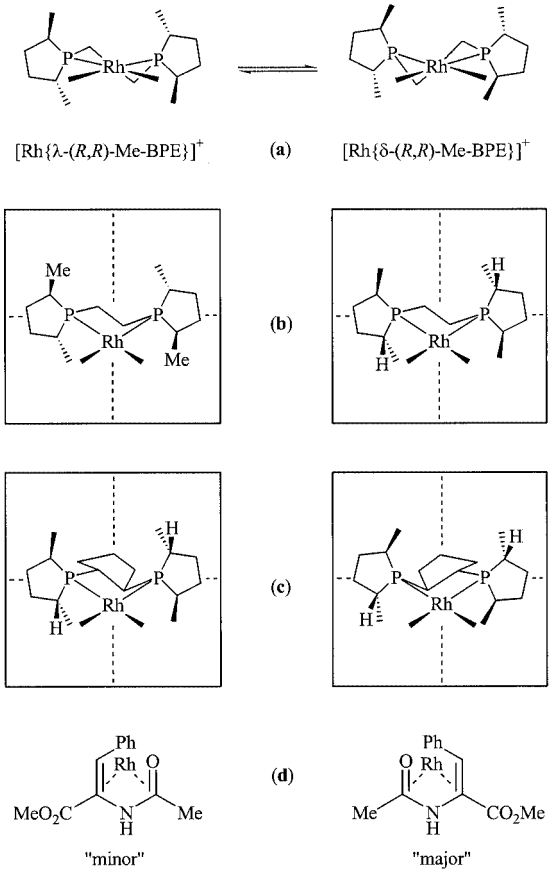
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

or (*S*,*S*)-$\mathbf{L}^{\mathbf{binol}\text{-}(R)}$ ligands invariably afforded hydrogenation products with (*S*) configuration (Entries **1b** and **1c**) whereas the (*R*) enantiomers predominated in the isomeric mixtures formed with the two diastereomeric Rh−$\mathbf{L}^{\mathbf{binol}\text{-}(S)}$ catalysts (**1a** and **1d**). From the results collected in Table 1 it is also clear that the optical yields achieved with (*S*,*S*)-$\mathbf{L}^{\mathbf{binol}\text{-}(S)}$ are by far superior to those obtained with (*S*,*S*)-$\mathbf{L}^{\mathbf{binol}\text{-}(R)}$ and that the (*R*,*R*)-$\mathbf{L}^{\mathbf{binol}\text{-}(R)}$ ligand is much more selective than its (*R*,*R*)-$\mathbf{L}^{\mathbf{binol}\text{-}(S)}$ diastereomer. Obviously, the (*R*,*R*)-$\mathbf{L}^{\mathbf{binol}\text{-}(R)}$ and (*S*,*S*)-$\mathbf{L}^{\mathbf{binol}\text{-}(S)}$ enantiomers represent the beneficial matched combination of stereochemical elements while the (*R*,*R*)-$\mathbf{L}^{\mathbf{binol}\text{-}(S)}$ and (*S*,*S*)-$\mathbf{L}^{\mathbf{binol}\text{-}(R)}$ forms must be looked at as the disadvantageous mismatched counterparts.[32]

Distinct matched−mismatched effects in enantioselective hydrogenation also occur for the >C=C< reductions catalyzed by the more electron-rich rhodium complexes possessing either the diastereomeric $\mathbf{L}^{\mathbf{olanc}}$ or the *C*,*P*-chirogenic $\mathbf{L}^{\mathbf{Me}/c\mathbf{Oc}}$ ligands of Entries **4**[37] and **6**.[32,38b]

The bis(phospholane) (*S*,*S*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$ clearly exhibits a stronger ability for chiral discrimination than its (*R*,*R*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$ stereoisomer. Interestingly, the enantiodiscriminating properties of the derived rhodium complex [Rh{(*S*,*S*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$}(COD)]$BF_4$ ("**Rh-4a**" hereafter) are also superior to those of the more flexible ethylene-bridged Rh−(*R*,*R*)-Me-BPE catalyst (Entry **5**[19a,19c]), which in turn is seen to be superior to [Rh{(*R*,*R*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$}(COD)]$BF_4$ (**Rh-4b**), in spite of existing, in solution, as a labile mixture of readily interconverting λ and δ conformers; Scheme 9 (a).

On the one hand, these observations further corroborate the previously drawn conclusion that greater conformational rigidity of the backbones of bis(phospholane) chelate ligands will result in a more efficient transfer of chirality during Rh^I-catalyzed asymmetric hydrogenation.[19c] On the other hand, the finding that the Rh−(*S*,*S*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$ complex with δ backbone stereochemistry proved to be much more selective for the (*R*) products than the λ-Rh−(*R*,*R*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$ catalyst was unexpected:[37] So far, the heuristic stereochemical model used for the understanding of the origin of enantioselection by Rh−(*R*,*R*)-Me-DuPHOS and Rh−(*R*,*R*)-Me-BPE catalysts was based on the premise that two of the four equatorially aligned phospholane substituents adjacent to the phosphorus atoms effectively block the top left and bottom right "coordination quadrants"[6c] indicated on the left of Scheme 9 (b).[7,19c] In the more stable (less reactive) enamide adduct, the substrate should therefore be coordinated through its *si* face, the less favored (more reactive) adduct diastereomer being that in which the enamide is *re*-face-bound. Since Rh−DuPHOS catalysts have been confirmed both experimentally[19d] and theoretically[42b,42c,42d] to nicely reproduce the Halpern-Brown-type "anti-lock-and-key"[42] mechanistic behavior in which the major product enantiomer is formed by hydrogenation of the less favorably bonded enantioface,[43,44] both the excellent (*R*)-selectivity of the Rh−(*S*,*S*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$ complex and the somewhat lower (*R*)-discriminating ability of the Rh−(*R*,*R*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$ diastereomer are indicative of *si*-face binding of the substrate in the less stable adducts and, respectively, of *re*-face binding in the sterically favored



Scheme 9. (**a**): λ/δ equilibrium of Rh−(*R*,*R*)-Me-BPE catalysts; (**b**): quadrant-blocking in Rh−(*R*,*R*)-Me-BPE chelate complexes by equatorial methyl groups (left) or, alternatively, by axial hydrogen atoms (right); (**c**) and (**d**): quadrant-blocking in λ- and δ-shaped Rh−$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$ complexes together with "minor" *si*- and "major" *re*-face binding of substrate enamides as proposed by Pringle[37]

intermediates. In sharp contrast to the original stereochemical model proposed for chelate complexes of bis(phospholane) ligands, Pringle et al. therefore concluded that it is the bottom left and top right quadrants which are more effectively blocked in the ground-state geometries of the two diastereomers than the quadrants left side up and right side down − actually, to a higher degree in matched δ-[Rh{(*S*,*S*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$}(COD)]$^+$ but to a lesser extent in mismatched λ-[Rh{(*R*,*R*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$}(COD)]$^+$. Indeed, crystal structures of two model complexes, δ-[PtI_2{(*S*,*S*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$}] (**Pt-4a**) and λ-[$PtI_2${(*R*,*R*)-$\mathbf{L}^{\mathbf{olane}\text{-}(R,R)}$}] (**Pt-4b**) confirmed that the equatorial methyl substituents of the phospholane rings shielding the top left and bottom right quadrants are ca. 0.5 Å closer to the iodo binding sites in the λ than in the δ conformer, whereas the axial α-hydrogen atoms occupying the quadrants left side down and right side up are ca. 0.3 Å closer to the other ligands in the δ than in the λ diastereomer. It was therefore proposed that it is the steric interaction of the enamide substrate with these hydrogen atoms which crucially contributes to the facially discriminating abilities of the catalyst complexes; Scheme 8 (c).[37] For a different interpretation, however, see below.

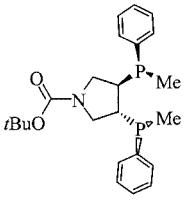
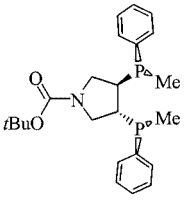
$R,R,R_P,R_{P'}$-pyrL$^{Me/Ph}$



$R,R,S_P,S_{P'}$-pyrL$^{Me/Ph}$



$R,R,R_P,S_{P'}$-pyrL$^{Me/Ph}$

With regard to the diastereomeric complexes bearing the four stereochemically different **L$^{Me/cOc}$** ligands, Entries **6a**−**d** of Table 1 make it clear that it is the bis(phosphanes) with opposite configuration at the carbon and phosphorus atoms (Note footnote[e] of Table 1!) that lead to the superior hydrogenation catalysts. Although less stereodiscriminating than Imamoto's catalysts with alkylated (S_P,$S_{P'}$)-bisP* ligands $C_2H_4\{(S)\text{-P(Me)R}\}_2$ having voluminous *P*-bound *tert*-butyl or 1-adamantyl groups in addition to the methyl residue (Entries **7a** and **7b**, Table 1),[39a,39d] the rhodium complexes of the two ($S,S,R_P,R_{P'}$)-**L$^{Me/cOc}$** and ($R,R,S_P,S_{P'}$)-**L$^{Me/cOc}$** enantiomers appear to perform better than those derived from (S_P,$S_{P'}$)-cC$_5$H$_9$-bisP* (Entry **7c**, Table 1), which has a cyclopentyl substituent roughly comparable in steric demand near the metal center to cyclooctyl. Also of interest is a comparison with Nagel's diastereomeric *N*-(*tert*-butoxycarbonyl)-3,4-bis[methyl(phenyl)phosphanyl]pyrrolidines ($R,R,R_P,R_{P'}$)-, ($R,R,S_P,S_{P'}$)-, and ($R,R,R_P,S_{P'}$)-pyrL$^{Me/Ph}$. Rhodium(I) chelate complexes of these ligands are λ-shaped as are Imamoto's Rh−bisP* catalysts; but unlike the latter, which yield (*R*) hydrogenation products[39a,39d] unless the enamide contains a very bulky α-substituent,[39c,39f] Nagel's catalysts induce the preferential formation of amino acids and esters as (*S*) enantiomers irrespective of the stereochemistry at the two phosphorus atoms; the different −P(Me)Ph configurations are only seen to modulate the extent of the enantiomeric excess (Entries **8a**−**c**, Table 1).[40] Thus, it is the configuration of the backbone carbon atoms that controls the sign of chiral induction imposed by the Rh−pyrL$^{Me/Ph}$ catalysts and, vice versa, it is the configuration at the phosphorus atom that outplays the influence of the carbon skeleton in hydrogenations catalyzed by Rh−bisP* complexes. In other words, while the Rh−pyrL$^{Me/Ph}$ catalysts obey the λ/δ rule (vide supra), this empirical rule is not valid for catalysts possessing the very successful electron-rich bisP* steering ligands![39b] Rhodium complexes derived from the four diastereomeric electron-rich **L$^{Me/cOc}$** bis(phosphanes) (Entries **6a**−**6d**, Table 1) and also from the more electron-poor Rh−**L^{binol}** complexes (Entries **1a**−**d**, Table 1), are intermediate in that the ligands showing the matched combination of stereoelements (Entries **1a**, **1b**, **6c**, **6d**, Table 1) follow the rule, whereas the mismatched catalysts (Entries **1c**, **1d**, **6a**, **6b**, Table 1) do not. It should be noted that the catalytic results obtained with Pringle's diastereomeric Rh−**L^{olane}** complexes **Rh-4a** and **Rh-4b** are akin: the matched δ-conformer **Rh-4a** provokes (*R*) stereoselection and thus conforms to the rule; mismatched λ-shaped **Rh-4b** similarly yields amino acids with (*R*) configuration and, hence, breaks the rule.

Although no structural data are currently at hand for metal complexes containing bis(phosphonites) of the **L^{binol}** type, substantial structural information exists on complexes possessing **L$^{Me/cOc}$** ligands and other bis(phosphanes) with P−C-bonded substituents, which strongly suggests that the very different enantioselectivities displayed by the Rh−**L$^{Me/cOc}$** systems with *like* or *unlike* stereochemistry at the donor and backbone atoms is causally related to slight differences in the spatial orientation of the bulky cycloalkyl rings in the diastereomeric complex cations.[32,38]

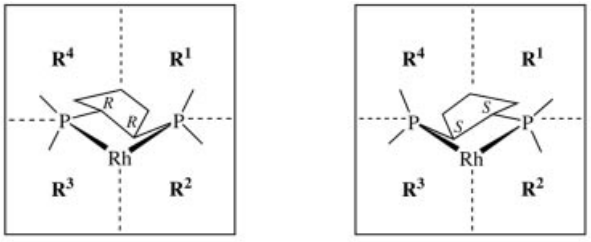
λ,δ conformer precatalysts $[Rh(\mathbf{L})(COD)]^+$ and the sign and the extent of the stereoinduction that can be achieved with the actual catalysts, X-ray data have been collected for several of the cationic Rh^I precursors. The most important stereochemical features of these complexes comprise (i) the chelate torsion angle P−C−C−P analytically describing the folding of the chelate ring, (ii) the exocyclic torsion angles P−Rh−P−R defining the orientation (axial or equatorial) of the four *P*-bonded substituents R with respect to the coordination plane, and (iii) the twist angle between the P−Rh−P plane and the plane spanned by the central metal and the midpoints of the two coordinated olefinic bonds. A tabulation of these values is presented in Table 2 (see also Scheme 10 and Figures 1−5) So far we have been unable to isolate the diastereomerically pure complex $[Rh\{(R,R,R_P,R_{P'})\text{-}\mathbf{L^{Me/cOc}}\}(COD)]O_3SCF_3$ (**Rh-6d**) or its enantiomer $[Rh\{(S,S,S_P,S_{P'})\text{-}\mathbf{L^{Me/cOc}}\}(COD)]O_3SCF_3$ (**Rh-6c**) as crystals suitable for X-ray crystallography. By way of alternative, we therefore derived the stereochemical features discussed below for **Rh-6d** from the structure of $[Rh\{(RS,RS,R_PS_P,R_{P'}S_{P'}\text{-}\mathbf{L^{Me/cOc}}\}(COD)]O_3SCF_3$ (**Rh-6c/6d**), made up of equal proportions of either mirror image isomer. For the sake of brevity, the salient stereochemical features of only one of the two enantiomeric forms present in the racemic crystal are considered; see also footnote [e] of Table 2.



Rh-2b:	R^1–$R^4 = C_6H_5$	**Rh-2a:**	R^1–$R^4 = C_6H_5$

Scheme 10. Definition of P-substituents R^1−R^4 for structurally characterized metal complexes

For the purpose of comparison, data for the two platinum compounds $[PtI_2\{(S,S)\text{-}\mathbf{L^{olane\text{-}(R,R)}}\}]$ (**Pt-4a**) and $[PtI_2\{(R,R)\text{-}\mathbf{L^{olane\text{-}(R,R)}}\}]$ (**Pt-4b**) modelling the related rhodium catalysts **Rh-4a** and **Rh-4b**[37] are also included, as are the pertinent parameters of ethylene-bridged $[Rh\{C_2H_4[(R)\text{-}P(Me)But]_2\}(C_7H_8)]BF_4$ (**Rh-7a**) (Note footnote [d] of Table 2!).[39a,39d]

As expected, all rhodium complexes containing $C_5H_8(PR_2)_2$ chelate phosphanes show torsion angles spanned by the two endocyclic P−CH bonds and the connecting ethylene chain of similar magnitude but opposite sign for the λ and δ conformations imposed by the (*R*,*R*) and (*S*,*S*) forms of the individual ligands. For λ-shaped $[Rh\{(R,R,R_P,R_{P'})\text{-}\mathbf{L^{Me/cOc}}\}(COD)]O_3SCF_3$ (**Rh-6d**), the value of the P−C−C−P torsion angle almost coincides with that of the *t*Bu-bisP* compound **Rh-7a**, in which the λ conformation is stabilized by the bulky CMe_3 substituents. A major structural difference between **Rh-7a** and **Rh-6d** arises from the contrasting orientations of the sterically demanding *tert*-butyl and cyclooctyl groups with respect to the P−Rh−P coordination plane; these are equatorial in the former (R^2 and R^4 in Scheme 10 and Table 2; torsion angles P−Rh−P−CMe_3, −127.1 and −139.5°) but tend to be axial in the latter (R^1 and R^3 in Scheme 10 and Table 2; torsion angles P−Rh−P−$C_8H_{15}c$, +114.3 and +113.8°; cf. Figure 2.)

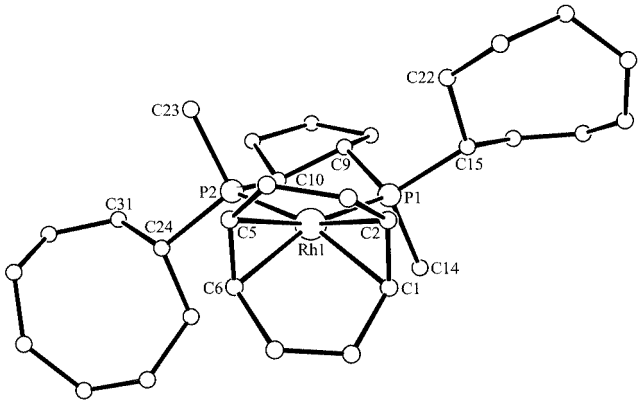

Figure 1. Perspective view of the cation $[Rh\{(S,S,R_P,R_{P'})\text{-}\mathbf{L^{Me/c\text{-}Oc}}\}(COD)]^+$ (**Rh-6a$^+$**); selected bond lengths [A] and angles [°]: Rh1−P1, 2.305(1); Rh1−P2, 2.316(1); Rh1−C1, 2.216(5); Rh1−C2, 2.226(5); Rh1−C5, 2.238(5); Rh1−C6, 2.227(6). P1−Rh−P2, 84.33(3)[38b]

$[Rh\{(S,S,R_P,R_{P'})\text{-}\mathbf{L^{Me/cOc}}\}(COD)]O_3SCF_3$ (**Rh-6a**), on the other hand, resembles **Rh-7a** in the equatorial arrangement of the large substituents (R^1 and R^3 in Scheme 10 and Table 2; torsion angles P−Rh−P−$C_8H_{15}c$, +137.2 and +131.5°; see Figure 1), with the methyl groups pointing to an axial direction in both cases. From the optical inductions achieved in the asymmetric hydrogenation of, e.g., methyl acetamidocinnamate it is clear, however, that the bisP* complex **Rh-7a** is much more enantioselective than **Rh-6a** containing the mismatched combination of *C*- and *P*-chirogenic stereoelements and is also superior in its stereodiscriminating power to that of the matched catalyst **Rh-6d**. This raises the question as to how the spatial orientation of the sterically demanding substituents in **Rh-6a**, **Rh-6d**, and **Rh-7a** contribute to the varying degrees of enantioselectivity

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

observed in >C=C< hydrogenations catalyzed by these complexes.

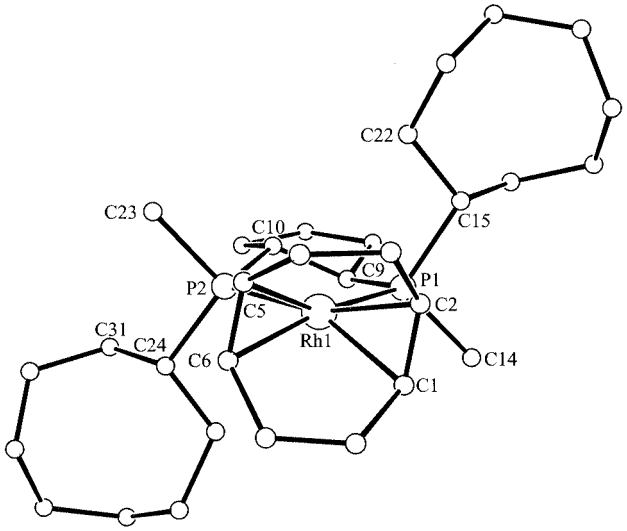

Figure 2. Perspective view of the cation [Rh{(*R*,*R*,R_P,$R_{P'}$)-$L^{Me/c\text{-}Oc}$}(COD)]$^+$ (**Rh-6d$^+$**), as present in the structure of [Rh{(*RS*,*RS*,$R_P$$S_P$,$R_{P'}$$S_{P'}$-$L^{Me/c\text{-}Oc}$}(COD)]$O_3SCF_3$ (**Rh-6c/6d**); selected bond lengths [Å] and angles [°]: Rh1−P1, 2.312(2); Rh1−P2, 2.323(2); Rh1−C1, 2.230(7); Rh1−C2, 2.237(7); Rh1−C5, 2.249(7); Rh1−C6, 2.249(7). P1−Rh−P2, 85.20(6)[32,47]

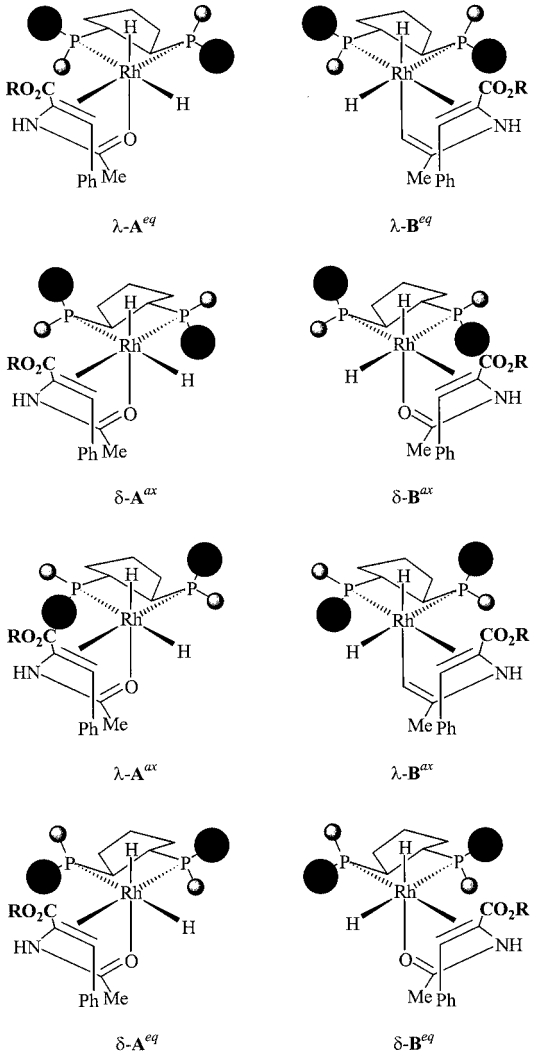
According to the "quadrant classification" established by Knowles in 1983,[6c] Gridnev and Imamoto[39b] as well as Ohashi[36d] have recently presented convincing evidence that any rhodium catalyst with C_2- or C_1-symmetric *P*-chirogenic bis(phosphanes), in which the difference in size between the terminal substituents is as apparent as in **Rh-6a**, **Rh-6d**, and **Rh-7a**, will furnish (*R*) hydrogenation products irrespective of a λ or δ conformation of the backbone, if the more voluminous groups are arranged in the upper left and lower right quadrants (cf. **Rh-7a**), while opposite orientation (as in **Rh-6a** and **Rh-6d**) will provoke (*S*) stereoselection.[39b] This is because the migratory insertion of the enamide to form an alkyl hydride, which has been identified as the enantiodetermining irreversible step of asymmetric hydrogenation both experimentally[39b−39g] and computationally,[42a] is controlled in an enantiofacially discriminating fashion by repulsive interaction between the chelate ring made up by the substrate and the bulky P-substituents in short-lived diastereomeric dihydrido enamide intermediates as depicted in Scheme 11. For **Rh-7a**, e.g., the (ethylene-connected) diastereomer λ-**A**^{eq}, containing the substrate bonded through its *si* face to give (*R*)-amino acids as observed, is definitely lower in energy than λ-**B**^{eq} because it is the smaller *P*-bound residue that undergoes direct steric repulsion with the carboxyl group attached to the chelate cycle.

For the three structurally characterized compounds under discussion, steric blocking of two diagonally arranged quadrants is most complete in the most stereoselective catalyst **Rh-7a**, where the bulky but nevertheless compact *tert*-butyl groups *exclusively* shield the quadrants left side up and right side down. Thus, the two $(H_3C)_3C$ hydrogen



Scheme 11. Possible diastereomers of cationic dihydrido enamide intermediates with chiral bis(phosphane) ligands having P-substituents pairwise differing in size (after Gridnev and Imamoto)[39b]

atoms that are closest to the >C=C< binding sites (H-11 and H-21 in the original publication[39a]) are located *within* the area spanned by the two quadrants and − equally important − are directed towards the diolefin in such a fashion that they are almost in a straight line with the central metal atom, the distances of the three atoms from the least-squares plane defined by the four olefinic carbon atoms being 1.53 and 1.51 Å for the two hydrogen atoms and 1.73 Å for the rhodium atom (angle H···Rh··H, 169.4°). As a result of their distinct equatorial alignment, the spatially expanded cyclooctyl rings of mismatched complex **Rh-6a** (Figure 1), on the other hand, not only fill out the two top right and bottom left quadrants but slightly penetrate into the adjacent parts of the coordination sphere as well, thereby contributing to some *unwanted shielding* of the upper left and lower right quadrants.[38b] Moreover, owing to the "face-on" orientation of the equatorial pairs of cyclooctyl groups the degree of *favorable quadrant-blocking*, thought to make δ-**B**^{eq} more readily accessible than δ-**A**^{eq},

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is much less effective in **Rh-6a** than in **Rh-7a** (in this context, note also the decreased *ee* values achieved on substituting cC_5H_9 for *t*Bu or 1-Ad in Rh−bisP* catalysts!), as is evident from the deviations of the central metal atom and the *ipso*-C-bonded hydrogen atoms from the calculated least-square plane through the four coordinated >C=C< carbon atoms, which are 2.26 and 2.44 Å for the two hydrogen atoms but only 1.58 Å for rhodium (angle H···Rh··H, 155.5°). Matched catalyst **Rh-6d** which (as outlined above) is superior in stereodiscriminating power to **Rh-6a** but inferior to **Rh-7a**, differs in structure from mismatched **Rh-6a** by a more axial arrangement of the cyclooctyl rings, the methyl substituents being more equatorially aligned (Figure 2). This results in steric blocking of *only* the top right and bottom left quadrants, making λ-$\mathbf{B}^{ax}$ lower in energy than λ-$\mathbf{A}^{ax}$. Exclusive shielding of these two quadrants seems to be the main factor contributing to the stereoselective abilities of **Rh-6d**, since the "face-on" orientation of the cyclooctyl substituents is similar to **Rh-6a** and results in even slightly longer distances (2.36 and 2.70 Å) of the two *ipso*-C-bonded hydrogen atoms from the $(>C=C<)_2$ least-squares plane.

Interestingly, the Pt−$\mathbf{L}^{olane}$ complex **Pt-4a**, which served as an analogue of the matched catalyst [Rh{(*S*,*S*)-$\mathbf{L}^{olane\text{-}(R,R)}$}(COD)]$BF_4$ (**Rh-4a**),[37] similarly features quadrant-blocking methyl groups at the 2,5 positions of the phospholane ring showing a decidedly *axial* alignment in the upper left and lower right coordination quadrants (torsion angles P−Rh−P−$C^{2,5}$, −99.6/−110.7°). This arrangement should favor dihydride intermediate δ-$\mathbf{A}^{ax}$ over δ-$\mathbf{B}^{ax}$ to give high optical yields of the (*R*) hydrogenation products as observed. In marked contrast, the **Pt-4b** diastereomer, which was used to model the structure of mismatched [Rh{(*R*,*R*)-$\mathbf{L}^{olane\text{-}(R,R)}$}(COD)]$BF_4$ (**Rh-4b**), presents the same two methyl groups in the same quadrants in *equatorial* orientation (torsion angles P−Rh−P−$C^{2,5}$, −131.1° each), which can safely be predicted to lower the energy of λ-$\mathbf{A}^{eq}$ as compared to λ-$\mathbf{B}^{eq}$, but because of the equatorial alignment of the quadrant-shielding residues to a lesser degree than anticipated for δ-$\mathbf{A}^{ax}$ vs. δ-$\mathbf{B}^{ax}$. As the location of the phospholane substituents in the quadrants is independent of the λ or δ conformation of the five-membered chelate ring in the case of the two platinum complexes (large CH_3 groups top left and bottom right; small H atoms bottom left and top right) and as both rhodium analogues **Rh-4a** and **Rh-4b** induce (*R*) stereoselection, it becomes clear that Pringle's Rh−(*S*,*S*)-$\mathbf{L}^{olane\text{-}(R,R)}$ and Rh−(*R*,*R*)-$\mathbf{L}^{olane\text{-}(R,R)}$ catalysts also fit the aforementioned Gridnev/Imamoto rule for catalysts bearing *P*-chirogenic bis(phosphanes) with substituents pairwise differing in size.

We furthermore emphasize that the enhancement of enantioselectivity achieved by changing the alignment of a large substituent from a more equatorial to a more axial orientation as observed on going from **Rh-6a** to **Rh-6d** and, respectively, from **Rh-4b** to **Rh-4a** satisfies a prediction formulated by Nagel years ago: "We feel that to build a good catalyst for the hydrogenation of *N*-acylacrylic acid derivatives, it is necessary to have two large groups in the chelating diphosphane as axial as possible".[40] In view of the excellent enantioselectivities obtained with Imamoto's Rh−bisP* catalysts bearing compact bulky substituents in an equatorial arrangement, "axial" should, however, be qualified by "axial or focused to a single quadrant" rather than be understood as a sine qua non.

The results of the X-ray structure analyses carried out on the enantiomers [Rh{(*S*,*S*)-$\mathbf{L}^{Ph}$}(COD)]O_3SCF_3 (**Rh-2a**) and [Rh{(*R*,*R*)-$\mathbf{L}^{Ph}$}(COD)]O_3SCF_3 (**Rh-2b**) are worth mentioning regarding several aspects. As anticipated, single-crystals of the two complexes belonged to the same space group, $P2_1$, but because of different conditions of crystal growth, the unit-cell volumes of two of the three specimens investigated differed significantly: V = 1789.8(7) $Å^3$ and, comparably, V = 1791.1(5) $Å^3$ for the mirror image isomers taken from recrystallized samples of the enantiomerically pure complexes,[32] but V = 1772.3(5) $Å^3$ for a crystal of **Rh-2b** (**Rh-2b*** hereafter) picked from a conglomerate of [Rh(*rac*-$\mathbf{L}^{Ph}$)(COD)]O_3SCF_3, which − similar to the nickel complex [$NiBr_2$($\mathbf{L}^{Ph}$)]·CH_2Cl_2 [22a] − underwent spontaneous resolution upon crystallization from THF/*n*-pentane.[31] As a result of the different crystal packing in **Rh-2b** and **Rh-2b***, the endo- and exocyclic torsion angles measured for these two chelate systems were found to diverge considerably (Table 2) as did some of the bond lengths and angles (see captions of Figures 3−5). This demonstrates unequivocally that the two enantiomeric P_2 ligands do not build up absolutely inflexible coordination spheres but that some conformational freedom is associated with the ligand backbones. Previously, Oliver and Riley have pointed out that such adaptability of putatively stiff chiral phosphanes may be essential for high hydrogenation rates.[45] As a further and rather unexpected consequence, the diene ligand of the *same* enantiomers **Rh-2b** and **Rh-2b*** is seen to be skewed with respect to the P−Rh−P coordination plane *in opposite senses* (clockwise by +3.4° and anticlockwise by −4.1°). This clearly disproves the view that the sense of diene rotation is intimately correlated with the handedness of the catalyst pocket made up by the chiral steering ligand.[46] As complexes **Rh-2a** and **Rh-2b** catalyze the hydrogenation of standard enamide substrates giving high optical yields with opposite sign, it is furthermore concluded that no correlation whatsoever can be made between the sense of the diene twist and the enantioselectivity displayed by the catalysts. This goes against an early hypothesis of Kyba et al. that the forces causing the diolefin rotation would be the same that would induce the stereodiscrimination,[46] but corresponds to conclusions of Imamoto et al. that no interdependencies whatsoever exist between enantioselectivity and the sign of the diene skewness in the case of the bisP*−Rh catalysts, since these are highly stereoselective irrespective of an essentially ideal diene coordination with the double bonds perpendicular to the P−Rh−P plane.[39a,39b,39d]

Similar to several structures discussed in detail by Oliver and Riley already in 1983,[45] the arrangement of the phenyl rings in molecules **Rh-2a**, **Rh-2b**, and **Rh-2b*** does not obey the *ax*.−*eq*.−*ax*.−*eq*.-"edge−face−edge−face" relation[6c]

generally assumed for square-planar rhodium complexes with chiral bis(phosphane) ligands having terminal $-PPh_2$ donor groups: On moving from the upper right quadrant in a clockwise sense, one best describes the alignment of the phenyl substituents with respect to the five-membered chelate structures of the three molecules as *ax.*−*eq.*−*eq.*−*ax.*, as is readily evidenced from the magnitudes of the P−Rh−P−C_{ipso} torsion angles collected in Table 2. In the same sense, the Rh−P−C_{ipso}−C_{ortho} torsion angles given in the captions to Figures 3−5 define the

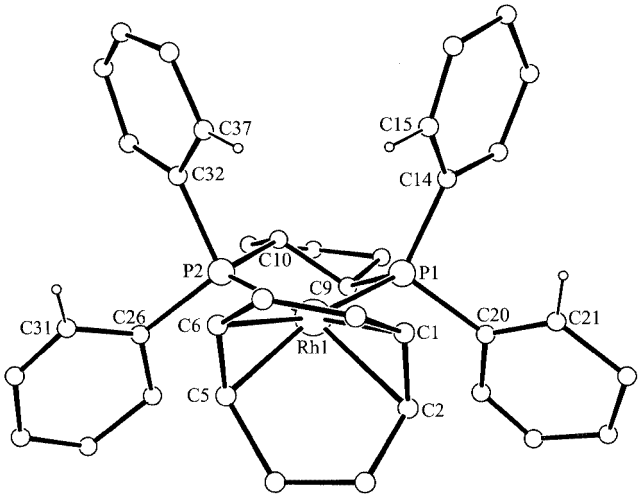

Figure 5. Perspective view of the cation [Rh{(*R*,*R*)-$\mathbf{L^{Ph}}$}(COD)]$^+$ of specimen **Rh-2b***; selected bond lengths [Å] and angles [°]: Rh1−P1, 2.309(2); Rh1−P2, 2.293(2); Rh1−C1, 2 .188(9); Rh1−C2, 2.312(7); Rh1−C5, 2.158(9); Rh1−C6, 2.264(7). P1−Rh−P2, 84.08(5); torsion angles Rh−P−C_{ipso}−C_{ortho} [°]: Rh1−P1−C14−C15, −6.2; Rh1−P1−C20−C21, −94.4; Rh1−P2−C26−C31, 91.1; Rh1−P2−C32−C37, 1.5[31,47]

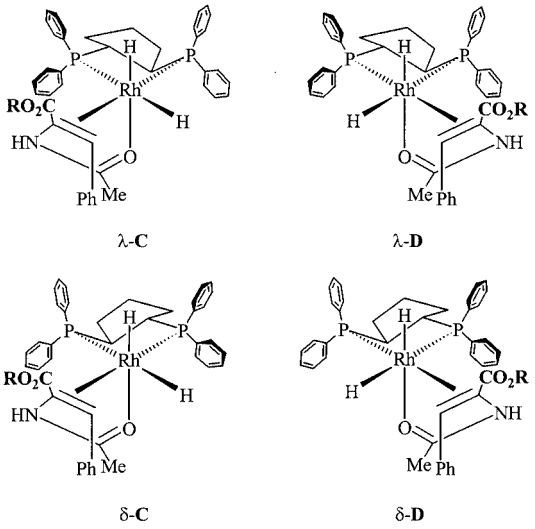
orientations of the aromatic rings with respect to the binding sites of the diene as close to "edge−face−face−edge". Thus, while the backbone symmetry of the P_2 ligands in the stable conformation of the three complexes is C_2, the local symmetry at the metal atom as determined by the spatial orientation of the phenyl rings in the donor groups at first glance seems to approach C_s − were there not some subtleties that make the difference!

In **Rh-2a** we see the *ortho*-hydrogen atoms in the top right and bottom right quadrants at distances of 2.27 and 2.13 Å from the least-squares plane through the coordinated olefinic carbon atoms, the separations between that plane and the *ortho*-H atoms in the quadrants left side up and left side down amounting to 2.73 and 2.53 Å. For enantiomer **Rh-2b** (recrystallized sample), we face the opposite arrangement of the four *ortho*-hydrogen atoms with respect to the $(>C=C<)_2$ least-squares plane: 2.39 (2.28) Å and 1.96 (2.15) Å for the separations in the upper left and lower left quadrants vs. twice 2.76 (2.63, 2.48) Å for the corresponding distances in the quadrants right side up and right side down (values for specimen **Rh-2b*** picked from the conglomerate given parenthetically).

In view of the enhanced axial interactions in octahedral dihydro complexes directly preceding the enantiodetermining migratory insertion step (vide supra) it has been suggested that in RhP_2 complexes with backbone chirality and four equivalent phenyl substituents on the phosphorus atom, i.e., in catalysts *conforming* to the λ/δ rule, it is the axial phenyl rings which lend the decisive steric hindrance to the stereodiscriminating step.[39b,40] We conclude that the two phenyl groups in the top right and top left quadrants of **Rh-2a** and **Rh-2b** or **Rh-2b*** are identified by the substrate as being larger than the aryl residues in the quadrants that are bottom right and bottom left. In the critical dihydro enamide intermediates with *trans*-positioned hydride

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and acetyl ligands, steric crowding would therefore be minimized if the axial phenyl substituents point away from the equatorial plane containing the enamide chelate in addition to the five-membered metal−bis(phosphane) ring. As a consequence, the equatorially aligned aryl groups would be forced into the plane spanned by the metal atom and the >C=C< double bond of the substrate; see structures **C** and **D** in Scheme 12. Comparing the relative bulkiness of the phenyl substituents as estimated from the distances between the *ortho*-H atoms and the least-squares plane made up by the olefinic carbon atoms in the enantiomeric diene precursors, we would anticipate more steric repulsion between the enamide chelate and the phenyl groups in the top and bottom right quadrants of **Rh-2a** and, vice versa, in the upper and lower left quadrants of **Rh-2b** and **Rh-2b***, respectively. The corollary of this conclusion is that in a dihydro enamide complex resulting from **Rh-2a**, the chelated substrate should experience the least steric strain if bonded through its *si* face as in δ-**C** to give, by migratory insertion, the experimentally observed (*R*) hydrogenation products; *re*-face-bonding with formation of the (*S*) enantiomers would only be expected if the least repulsive interactions occur in the quadrants right side up and right side down, i.e., in dihydride intermediates of type λ-**D** for which **Rh-2b** and **Rh-2b*** are suitable precursors. The preferred coordination of the enamide substrate as described by structures λ-**D** and δ-**C** not only minimizes the axial repulsions but also reduces steric crowding between the enamide chelate cycle and those equatorially aligned substituents that are nearest to the olefinic binding sites in the ground state structures of the diene precursors **Rh-2a** (bottom right) and **Rh-2b** or **Rh-2b*** (bottom left). Even if the equatorial interactions have been considered as less important for stereoselection than the axial repulsions,[39b,40] they can help to make isomers λ-**D** and δ-**C** more readily accessible than their diastereomers λ-**C** and δ-**D** featuring an unfavorable close contact between the chelate cycle and the phenyl substituents. Interpreted like this, the quadrant rule changes into a "left−right" criterion, valid for RhP_2 (pre)catalysts which, from a structural point of view, do not adhere to the *ax.*−*eq.*−*ax.*−*eq.*-"edge−face−edge−face" relation.



Scheme 12. Possible diastereomers of cationic dihydrido enamide intermediates with chiral bis(phosphane) ligands that have phenyl substituents of equal size but do not conform to the *ax.*−*eq.*−*ax.*−*eq.*-"edge−face−edge−face" relation

Acknowledgments

Financial support from the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged. The author is also indebted to Degussa AG for many generous gifts of platinum salts. Furthermore, it is a pleasure to thank all coworkers who contributed to the success of this project over the past years, in particular Dr. Andrea Saare, Dr. Corinna Becker, Dr. Christine Eckert, Dr. Volker Kurth, Dr. Stefan Mertel, Dr. Nils Osthoff, Dr. Andreas Wühr, and Dipl.-Chem. Anja Kaunert. Finally, I wish to thank Mrs. Susanne Kammerer for skilful technical assistance.

A Diiminoplatinum(II) Complex of 4-Ethynylbenzo-15-crown-5 as a Luminescent Sensor for Divalent Metal Ions

Phyllis K. M. Siu,[a] Siu-Wai Lai,[a] Wei Lu,[a] Nianyong Zhu,[a] and Chi-Ming Che*[a]

Keywords: Crown compounds / Platinum / Luminescence / Magnesium / Sensors

The binding of a diiminoplatinum(II) complex of 4-ethynylbenzo-15-crown-5 to divalent metal ions such as Mg^{2+} or Zn^{2+} is accompanied by substantial enhancement of emission intensity (1035- and 870-fold increase, respectively, with 40 equivalents of metal salt) at $\lambda_{max} \approx 555$ nm; H^+, Cd^{2+} and alkali-metal ions cause minor enhancement of the photoluminescence (≤ 10-fold) under similar conditions.

Introduction

The design of new luminescent sensors for metal ions has continued to attract considerable interest.[1,2] An efficient luminescent probe should exhibit a substantial "switch-on" effect upon binding to metal ions. Using emission as a signalling reporter, luminescent metal complexes are of interest due to their long emission lifetimes, tunable emission energies in the visible region and large Stokes shifts between absorption and emission spectra.[3] In our design of luminescent sensors for metal ions, we were attracted to the following: (1) encapsulation of divalent metal ions such as Zn^{2+} by $[(\eta^5\text{-}C_5H_4SiMe_3)_2Ti(C{\equiv}CR)_2]$ [R = $SiMe_3$ or $(\eta^5\text{-}C_5H_4)FeCp$] via side-on coordination of alkynyl ligands has been reported;[4] (2) crown ethers are known to complex metal ions;[5] (3) neutral organoplatinum(II) complexes are known to form dative bonds with divalent metal ions;[6] and (4) square-planar cyclometalated[7] and aromatic[8,9] diiminoplatinum(II) complexes possess rich photoluminescent properties that are sensitive to the microenvironment. Herein we describe the synthesis of [Pt(4-ethynylbenzo-15-crown-5)$_2$(tBu$_2$bpy)] (**1**) (tBu$_2$bpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine) and [Pt(4-ethynylbenzo-15-crown-5)(C^N^N)] (**2**) (HC^N^N = 6-phenyl-2,2′-bipyridine), and their luminescence responses towards metal ions. A dramatic photoluminescence switch-on effect has been observed for **1** in the presence of $Zn(ClO_4)_2$ and $Mg(ClO_4)_2$ and the binding of Mg^{2+} to **1** found to be selective in the presence of alkali or alkaline earth metal ions.

Results and Discussion

Treatment of [PtCl$_2$(tBu$_2$bpy)][10] with two molar equivalents of 4-ethynylbenzo-15-crown-5 (**L**)[11] in the presence of copper(I) iodide and diisopropylamine afforded **1**. The molecular structure of **1** (Figure 1) shows that the Pt^{II} core is *cis*-coordinated by two 4-ethynylbenzo-15-crown-5 moieties and the tBu$_2$bpy ligand. The cyclometalated counterpart **2** was similarly synthesised by reacting equimolar amounts of [PtCl(C^N^N)][12] and **L** (Figure 2).

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

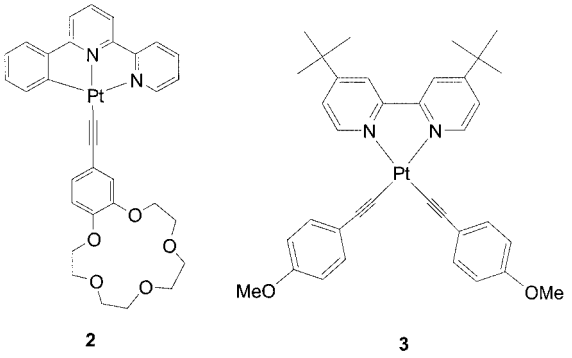

Figure 2. Structures of **2** and **3**

The absorption spectrum of **1** in acetonitrile features a moderately intense band at λ_{max} = 393 nm ($\varepsilon \approx 7900$ dm^3 mol^{-1} cm^{-1}) which is attributed to the [5d(Pt) → π* (*t*Bu$_2$bpy)] metal-to-ligand charge transfer (MLCT) transition. This absorption occurs at the same energy as that reported for [Pt(C≡CC$_6$H$_4$OMe-4)$_2$(*t*Bu$_2$bpy)] (**3**; Figure 2) in acetonitrile.[13] Complex **2** shows an intense ^{1}MLCT [5d(Pt) → π*(C^N^N)] absorption in the 400−450 nm range similar to that typically observed for cyclometalated Pt^{II} derivatives.[7] Addition of 20 equivalents of M(ClO$_4$)$_2$ (M^{2+} = Zn^{2+}, Mg^{2+}) to a 0.1 M *n*Bu$_4$NPF$_6$ acetonitrile solution of **1** (3.2×10^{-5} mol dm^{-3}) blue-shifts the MLCT absorption band from λ_{max} = 393 to 383 nm ($\varepsilon \approx 9600$ dm^3 mol^{-1} cm^{-1}); no significant change in the absorption at λ_{max} = 284 nm is observed. In contrast, addition of up to 100 equivalents of M(ClO$_4$)$_2$ to a 0.1 M *n*Bu$_4$NPF$_6$ acetonitrile solution of **2** or **3** results in no significant shift of the MLCT absorption. Thus, the presence of the *cis* crown ether moieties in **1** appears to be critical to affect the shifting of the MLCT absorption upon interaction with Mg^{2+}/Zn^{2+}.

The weak emission of **1** ($\varphi_o = 1.1 \times 10^{-4}$) in acetonitrile at λ_{max} = 635 nm is assigned as being ^{3}MLCT [5d(Pt) → π*(*t*Bu$_2$bpy)] in nature.[13] Addition of M^{2+} (as a perchlorate salt) to a 0.1 M *n*Bu$_4$NPF$_6$ acetonitrile solution of **1** induces a substantial enhancement of the emission intensity at 553 and 560 nm for Mg^{2+} and Zn^{2+}, respectively, and reaches a maximum of 1035-fold (Figure 3) and 870-fold, respectively, at 40 equivalents of M^{2+}. With reference to previous work,[14] the emission at $\lambda_{max} \approx$ 555 nm may be an admixture with both ^{3}MLCT and $^3\pi\pi^*$ character.

The effect of different Zn^{2+} salts upon binding properties was also examined. Addition of 100 equivalents of ZnCl$_2$ or Zn(NO$_3$)$_2$ to an acetonitrile solution of **1** (3.2×10^{-5} mol dm^{-3}) shows a similar blue shift in the emission maximum from 635 to approx. 560 nm, but the emission intensity was enhanced by only 105- and 250-fold, respectively. This indicates that the binding of **1** to Zn^{2+} ions weakens as the anion nucleophilicity increases in the order: ClO$_4^-$ < NO$_3^-$ < Cl$^-$ in acetonitrile. The effect of protons was investigated by addition of 200 equivalents of HBF$_4$ to a 0.1 M *n*Bu$_4$NPF$_6$ acetonitrile solution of **1**; no emission enhancement was detected. The binding properties of **1** with

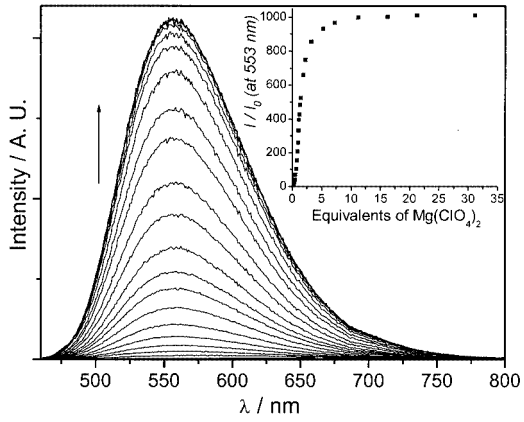

Figure 3. Emission spectral traces and (inset) luminescence enhancement factor (≡ I/I_o; monitored at 553 nm) of **1** at increasing equivalents of Mg^{2+} in 0.1 M *n*Bu$_4$NPF$_6$ acetonitrile solution at 298 K (λ_{ex} = 405 nm, [**1**] = 1.0×10^{-5} mol dm^{-3})

other metal ions have also been studied. Addition of 100 equivalents of KClO$_4$, NaClO$_4$, or Cd(ClO$_4$)$_2$ induces a relatively insignificant increase (≤ 10-fold) in the emission intensity of **1**. However, a 300-fold luminescence enhancement at λ_{max} = 563 nm was observed for **1** in the presence of 100 equivalents of Ca(ClO$_4$)$_2$. As depicted in Figure 4, the luminescence enhancement factor (LE ≡ I/I_o) induced by 40 equivalents of Mg^{2+} decreases by less than 20% in the presence of 40 equivalents of other cations, such as Na$^+$, K$^+$, Cd^{2+} and H$^+$, indicating that the binding of Mg^{2+} to **1** remains selective in their presence. For the binding of Zn^{2+} to **1**, the LE is reduced from 870 to 736 and 160 in the presence of K$^+$ and Na$^+$ respectively. This indicates that Na$^+$ is able to bind to **1** even in the presence of Zn^{2+}.

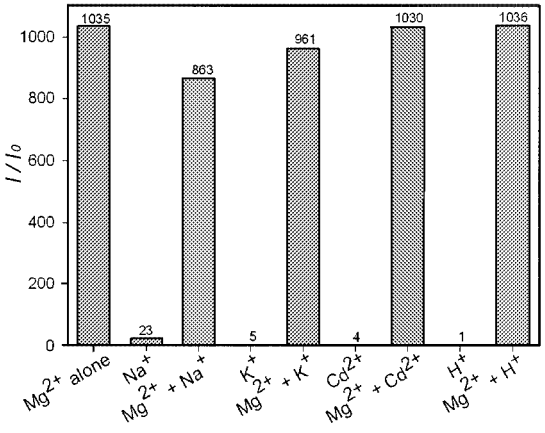

Figure 4. Luminescence enhancement factor induced by 40 equivalents of Mg^{2+} with or without the presence of M^{x+} ions in a 0.1 M *n*Bu$_4$NPF$_6$ acetonitrile solution of **1** (3.2×10^{-5} mol dm^{-3}) at 298 K

Complex **3** displays a weak ^{3}MLCT [5d(Pt) → π* (*t*Bu$_2$bpy)] emission at λ_{max} = 610 nm in acetonitrile.[13] Addition of Zn(ClO$_4$)$_2$ to **3** yields virtually no change in emission intensity with or without the presence of the free

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

crown-ether ligand **L**. The ^{3}MLCT emission of the mono-crown derivative **2**, which appears at λ_{max} = 560 nm, undergoes around a 10-fold increase in intensity, together with a slight red-shift to λ_{max} = 581 nm upon addition of 100 equivalents of $Zn(ClO_4)_2$. This signifies that, as observed in the absorption studies, the two crown ether moieties in **1** are essential for the dramatic ion-induced luminescence enhancement.

In order to elucidate the ion-binding nature of **1**, we have attempted to fit the emission data to stepwise equilibrium equations, where M^{x+} ions are consecutively bound by the platinum complex.

$$\begin{aligned} Pt + M^{x+} &\rightleftharpoons PtM^{x+} & K_{11}\\ PtM^{x+} + M^{x+} &\rightleftharpoons Pt(M^{x+})_2 & K_{12}\\ \vdots \quad + M^{x+} &\rightleftharpoons \vdots & \vdots\\ Pt(M^{x+})_{n-1} + M^{x+} &\rightleftharpoons Pt(M^{x+})_n & K_{1n} \end{aligned}$$

The stepwise (K_{11}, K_{12}, K_{13}) and overall (β) binding constants for the complexation of Na^+, Mg^{2+} and Zn^{2+} ions to **1** were determined under the assumptions stated in the supporting information and compared to the total number of M^{x+} ions bound by **1** (*n*) and the β value obtained from the Hill equation (Table 1).[15] In the case of *n* = 3, the discrepancy of β values between the nonlinear least-squares fits and Hill plots for these ions suggests unreasonable data fitting, and that this can be disregarded in the analysis. The similarity in β values determined by stepwise equilibrium binding reactions and Hill plots for the case of *n* = 2 imply that two M^{x+} ions are bound per molecule of **1**. For Na^+, the values of K_{11} and K_{12} are similar, whereas for Zn^{2+} and Mg^{2+}, the K_{12} values are around 20 and 54 times larger, respectively, than the corresponding K_{11} values. The electrospray mass spectra of **1** in the presence of 20 equivalents of $M(ClO_4)_x$ (M^{x+} = Mg^{2+}, Na^+) in acetonitrile reveal peaks attributable to [**1** + nM^{x+}] species (*n* = 1 and 2). For Mg^{2+}, the intensity ratio of peaks for [**1** + M^{x+}]:[**1** +2M^{x+}] is about 2:1, whereas that for Na^+ is about 1:3.

Table 1. Stepwise and overall equilibrium constants of **1** with Na^+, Mg^{2+}, Zn^{2+}

Ions	Nonlinear least-squares fits (*n* = 2)			Hill equation	
	K_{11}	K_{12}	β[a]	n	β
Na^+	7.27×10^3	1.08×10^4	7.9×10^7	1.7	6.5×10^6
Mg^{2+}	3.11×10^3	1.69×10^5	5.3×10^8	2.2	3.7×10^9
Zn^{2+}	2.11×10^3	4.41×10^4	9.3×10^7	2.0	5.5×10^7

[a] β is the overall equilibrium constant = $\Pi^n K_{1n}$

We suggest that the electrophilic M^{2+} ion functions as a Lewis acid that can be bound by the crown ether moieties. This type of interaction induces substantial perturbation upon the luminescence but is prone to competitive interaction of M^{2+} with counteranions. The switching on of substantial emission intensity in **1** with added M^{2+} may be rationalised by the destabilisation of the ^{3}MLCT excited state, leading to an increase in ^{3}IL character for the excited state. Binding of the first M^{2+} ion by **1** may widen the *cis*-[Pt(C≡CR)$_2$] angle, which could facilitate subsequent chelation of the second M^{2+} ion by the crown ether and/or bis-alkynyl moieties. This is consistent with the increase of the K_{12} binding constant relative to K_{11}.

Experimental Section

General Remarks: Acetonitrile for photophysical measurements was distilled over potassium permanganate and calcium hydride. All other solvents were of analytical grade and purified according to conventional methods.[16] 4,4′-Di-*tert*-butyl-2,2′-bipyridine,[17] [PtCl$_2$(*t*Bu$_2$bpy)],[10] 4-ethynylbenzo-15-crown-5,[11] 6-phenyl-2,2′-bipyridine,[18] and [PtCl(C^N^N)][12] were prepared by published methods. Fast atom bombardment (FAB) and electrospray mass spectra were obtained on a Finnigan MAT 95 (3-nitrobenzyl alcohol matrix) and LCQ quadrupole ion trap mass spectrometers, respectively. ^{1}H (500 MHz) NMR spectra were recorded on DPX 500 Bruker FT NMR spectrometers; chemical shift (in ppm) are quoted relative to tetramethylsilane. Elemental analysis was performed by the Institute of Chemistry at the Chinese Academy of Sciences, Beijing. IR spectra were recorded on a BIO RAD FT-IR spectrophotometer. UV/Vis spectra were recorded on a Perkin−Elmer Lambda 19 UV/Vis spectrophotometer.

Steady-state emission spectra were recorded on a SPEX 1681 Fluorolog-2 series F111AI spectrophotometer. The emission spectra were corrected for monochromator and photomultiplier efficiency and for xenon lamp stability.

Solutions for titration experiments were prepared by mixing 5 mL of **1** (6.4×10^{-5} mol dm^{-3}) in a 0.1 M *n*Bu$_4$NPF$_6$ acetonitrile solution with the required molar equivalents of M^{x+} in the same supporting electrolyte and made up to a total of 10 mL with a 0.1 M *n*Bu$_4$NPF$_6$ acetonitrile solution. All the sample solutions were degassed with at least four freeze-pump-thaw cycles. The emission quantum yield was measured by the method of Demas and Crosby.[19] Errors for λ values (± 1 nm) and φ (± 10%) are estimated.

[Pt(4-ethynylbenzo-15-crown-5)$_2$(*t*Bu$_2$bpy)] (1): Reaction of [PtCl$_2$(*t*Bu$_2$bpy)] and two equivalents of 4-ethynylbenzo-15-crown-5 (**L**) in the presence of copper(I) iodide and diisopropylamine afforded **1** (85%). ^{1}H NMR (CD$_3$CN): δ = 1.45 (s, 18 H, *t*Bu), 3.61−3.67 (m, 16 H, CH$_2$), 3.78−3.81 (m, 8 H, CH$_2$), 4.05−4.12 (m, 8 H, CH$_2$), 6.82−6.98 (m, 6 H, C$_6$H$_3$), 7.75 (dd, *J* = 6.0, *J* = 2.0 Hz, 2 H), 8.30 (d, *J* = 1.7 Hz, 2 H), 9.54 (d, *J* = 6.0 Hz, 2 H) ppm. $C_{32}H_{30}N_2O_5Pt$ (717.69): calcd. C 53.55, H 4.21, N 3.90; found C 53.29, H 3.96, N 4.06.

X-ray Crystallographic Study of 1: $C_{50}H_{62}N_2O_{10}Pt$, M = 1046.11, orthorhombic, space group *Pccn*, a = 23.888(5), b = 10.653(2), c = 18.467(4) Å, V = 4699.5(16) Å^3, Z = 4, D_c = 1.479 g cm^{-3}, μ(Mo-K_α) = 3.045 mm^{-1}, F(000) = 2136. A crystal of dimensions 0.4 × 0.2 × 0.1 mm^3 mounted in a glass capillary with mother liquor was used for data collection at 20 °C on a MAR diffractometer with a 300 mm image plate detector using graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å). Data collection was made with 3° oscillation step of φ, 600 seconds exposure time and a scanner distance of 120 mm; 60 images were collected. The images were interpreted and intensities integrated using the program DENZO.[20] The structure was solved by direct methods employing the SHELXS-97 program suite[21] on a PC. Pt and many non-H atoms were located by direct methods. The positions of other non-hydrogen atoms were found after successful refinement by full-matrix least-squares using SHELXL-97[21] on a PC. The *tert*-butyl group is disordered over two kinds of positions. 2849 independent reflections from a total of 11694 reflections were used in the full-matrix least-squares refinement against F^2. R_1 = 0.044 and wR_2 = 0.103 with a goodness-of-fit of 0.853 for 1291 observed reflections with $I \geq 2\sigma(I)$. The final difference Fourier map shows maximum residual peaks and holes of 0.457 and −0.642 e·Å^{-3} respectively. CCDC-177975 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information for this article (scheme for synthesis of **1**; emission spectral traces of **1** at increasing equivalents of Zn^{2+}, Ca^{2+}, Na^+ and K^+ ions; table for fluid-state emissions of **1**−**3** in acetonitrile with 100 equivalents of $M(ClO_4)_x$; analysis of the complexation of ions using nonlinear least-squares fits and Hill plots) is available (see footnote on the first page of this article).

A Novel Tetranuclear $[MeZn(\mu_3\text{-}OCH_2CH_2SMe)Zn(\mu\text{-}Cl)Me]_2$ Adduct Derived from the Interaction of CH_2Cl_2 with an Alkylzinc Complex

Janusz Lewiński,*[a] Wojciech Marciniak,[a] Zbigniew Ochal,[a] Janusz Lipkowski,[b] and Iwona Justyniak[b]

Keywords: Zinc / Alkoxides / Chelates / O,S ligand / Solvent effects

The treatment of 2-(methylthio)ethanol (methioH) with two equivalents of Me_2Zn in CH_2Cl_2 affords a tetranuclear aggregate with two monomeric MeZn(methio) units joined by two MeZnCl moieties. This result demonstrates that transfer of a chloride ion to Zn takes place on the addition of a donor-functionalized alcohol to Me_2Zn in CH_2Cl_2 solution.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Dichloromethane is one of the most commonly used solvents for organic and organometallic reactions involving alkylzinc reagents, especially the Simmons−Smith cyclopropanation of olefins[1] or the enantioselective addition of organozinc reagents to prochiral carbonyl compounds in the presence of catalytic amounts of a chiral ligand,[2] arguably the most important application of organozinc reagents in organic synthesis, as well as other types of reactions involving alkylzinc reagents.[3] The great interest and simple procedure of both reactions have motivated extensive work to better understand the reaction, including detailed mechanistic studies. For instance, very recent theoretical studies on the reaction pathways of the Simmons−Smith reaction have demonstrated that "the Lewis acid coordination to the halogen atom on the halomethyl ligand is likely to be a key event in the cyclopropanation reaction".[4] However, as far as we are aware, an influence of CH_2Cl_2 on the course or outcome of these various reactions has not been considered. Herein we report the isolation and structural characterization of the novel tetranuclear zinc adduct $[MeZn(\mu_3\text{-}OCH_2CH_2SMe)Zn(\mu\text{-}Cl)Me]_2$ (**1**), derived from the reaction of Me_2Zn with a bifunctional alcohol in the presence of CH_2Cl_2.

Results and Discussion

The treatment of 2-(methylthio)ethanol (methioH) with two equivalents of Me_2Zn in toluene/CH_2Cl_2 affords a yellow solution from which a white precipitate deposits after cooling at −15 °C for several hours. The complex could be isolated in moderate yield from the reaction, and it was studied by ^1H NMR spectroscopy and elemental analysis. ^1H NMR spectroscopy revealed two Zn-bonded methyl groups with a 1:1 Me-Zn/ligand ratio.[5] The occurrence of several sets of broad signals due to the O,S-bifunctional ligand indicated the operation of a dynamic process, likely to be the reversible dissociation of the tetranuclear complex, and the inversion of configuration at the sulfur atoms. The obtained ambiguous data of the precipitate led us to carry out a single-crystal X-ray diffraction study to elucidate the product structure. To our surprise, this study revealed **1** to be a tetranuclear aggregate with two monomeric MeZn(methio) units joined by two MeZnCl moieties (Figure 1). Interestingly, in contrast to the commonly observed μ_2-O bonding mode of the alkoxide oxygen atoms in dimeric $[RZn(\mu\text{-}O,N)]_2$ complexes,[6] the analogous oxygen atoms of **1** function as μ_3-O donors; this bonding mode is typical for the cubane-type structure of alkylzinc alkoxides $[RZn(\mu_3\text{-}OR)]_4$.[7] The aggregate **1** has C_1 symmetry with a central $Zn_2(\mu_3\text{-}O)_2$ ring. The chloride acts as a bridge between the two Zn atoms with the formation of Zn_2ClO rings which take up a trans conformation with an angle of 74.92(5)° to the Zn_2O_2 plane [the Zn_2ClO ring is slightly folded about the Zn−Zn vector with a dihedral angle of 168.72(6)°]. The geometry of the *O*,*S*-chelate may be described as an open envelope with the S−Me methyl groups trans to each other. The ligand used becomes chiral upon complexation of the SMe group to the zinc atom; the two sulfides have an opposite chirality and the resulting achiral complex possesses C_i symmetry. The geometry about the zinc centers is distorted tetrahedral. Selected bond lengths and bond angles of **1** are given in the legend of Figure 1. The Zn−O bond lengths lie in the range 2.043(2)−2.101(2) Å and are slightly longer than those in dimeric $[RZn(\mu\text{-}O,N)]_2$ complexes.[8]

The chloride bridges are essentially symmetrical with Zn−Cl distances of 2.365(1) Å and 2.370(1) Å and this fact indicates that the formation of these bridges is geometrically favorable. The Zn−C bond length of the bridging MeZnCl moiety does not differ from the value for the terminal Zn−Me group.

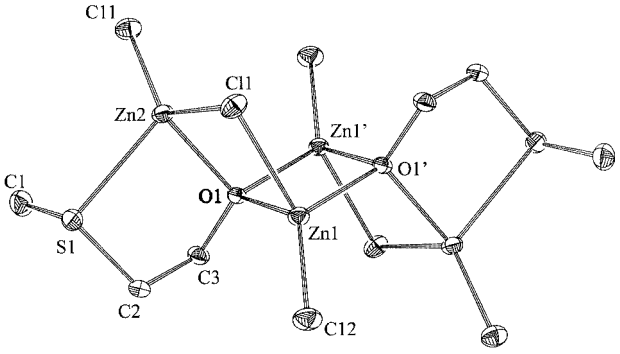

Figure 1. Molecular structure of **1** with thermal ellipsoids drawn at the 30% probability level; selected bond lengths [Å] and angles [°]: C12−Zn1 1.956(3), Zn1−O1 2.101(2), Zn1′−O1 2.043(2), Zn1−Cl1 2.370(1), Zn2−Cl1 2.365(1), Zn2−O1 2.072(2), Zn2−S1 2.475(2), Zn2−C11 1.960(3); C12−Zn1−Cl1 123.97(8), Zn1′−O1−Zn1 96.38(6), O1−Zn2−Cl1 87.59(4), Zn2−Cl1−Zn1 84.70(2)

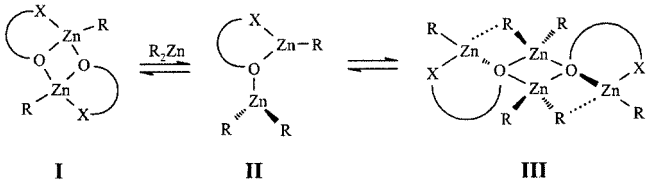
Compound **1**, apart from being a novel organozinc aggregate, may also serve as a useful model compound for the donor-functionalized-alcohol promoted addition of dialkylzinc reagents to carbonyl compounds (vide infra). So, can related tetranuclear aggregates be formed and observed in the reaction without additional stabilization provided by the chloride bridges? In order to answer this question we conducted an analogous reaction of methioH with two equivalents of Et_2Zn in benzene as a solvent. Cryoscopic weight measurements on the post reaction mixture indicated the presence of some higher aggregated species in solution [MW found 270; for example, calcd. 309 for $EtZn(methio)ZnEt_2$]. The ^1H NMR spectrum of the same solution showed several multiple resonances, presumably due to dynamic processes and skeletal rearrangement of the resulting products in solution. Unfortunately, the above studies only confirm that zinc alkoxides have a tendency to form higher aggregates.

The reported studies revealed several important aspects of various transformations involving alkylzinc reagents. Of particular importance is the fact that on the addition of a bifunctional alcohol to R_2Zn in CH_2Cl_2 solution, the transfer of a chloride ion to Zn takes place. In this regard, our studies demonstrate that CH_2Cl_2 seems to be the least desirable solvent for reactions involving alkylzinc reagents supported by donor-functionalized alcohols and a large number of investigations reported in the literature may be invalid.[9] Furthermore, in our opinion adduct **1** mimics a potential intermediate in the donor-functionalized-alcohol promoted addition of dialkylzinc to aldehydes (especially in the case of the *O*,*X*-bifunctional auxiliary ligand with sterically non-encumbered alkyl substituents at the α-carbon atom). The commonly accepted mechanism for the latter reaction assumes the participation of the monomeric three-coordinate zinc species **II** as the sole reactive species, which exists in equilibrium with the inactive dimer **I** (Scheme 1).[2] Some uncertainties, however, in the mechanistic analysis of this reaction have been observed,[10] which are probably introduced by the presence of multiple equilibria of different Zn aggregates, and in this regard the question as to whether the reaction can proceed through different pathways arises. All the above facts indicate that a more in-depth understanding of this reaction is necessary to better interpret the results from the experiments and raises the question as to whether the reaction can proceed through different pathways. However, alternative structural models for the dormant and active species present within the donor-functionalized-alcohol promoted addition of dialkylzinc to aldehydes are lacking.



Scheme 1

Based on the isolation of **1**, we suggest that higher aggregate species, such as the tetrametallic dimer of type **III**, are possible primary reactants in the reaction. The speculated structures of the dimer **III** are presented in Scheme 1. As far as we are aware, in all the recent mechanistic discussions, as well as in the field of zinc alkoxide chemistry, such a possibility has never been taken into consideration. The considered tetrametallic species can be easily stabilized by weak intramolecular interactions resulting from metal-alkyl agostic interactions or the formation of a relatively stable carbon-bridge between zinc atoms. There is no relevant experimental evidence for this hypothesis, however, we can anticipate that both the increased nucleophilicity of the alkyl group of the R_2Zn fragment (due to the Zn coordination to two alkoxide centers) and the presence of the unsaturated three-coordinate Zn atom of the monometallic $RZn(O,X)$ subunit will favour these types of interactions.[11] The symmetrical strong chloride bridges observed for **1** also indicate that such interactions are geometrically favorable. In our opinion further studies should require serious consideration of the contribution of the associative mechanism in the case of less sterically encumbered reaction systems than the "DAIB system".[12] It seems likely that the monomeric dimetallic adduct or dimeric tetrametallic aggregate may be the active catalyst in the latter reaction depending on the nature of the auxiliary ligand and reaction conditions.[13] We fully intend to investigate this problem further based on these preliminary studies.

The reported results should be helpful for a rational catalyst design and stimulate further experimental and theoretical investigations to clarify the correlation between the structure and activity of organozinc species. Further studies on the factors controlling the degree of aggregation of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

alkylzinc chelate complexes and the extent to which CH_2Cl_2 reacts with various organozinc reagents are in progress.

Conclusion

The reported studies revealed that the transfer of a chloride ion to the zinc atom takes place upon the addition of a bifunctional alcohol to R_2Zn in CH_2Cl_2 solution. In this regard, CH_2Cl_2 seems to be the least-desirable solvent for reactions involving alkylzinc reagents supported by donor-functionalized alcohols. The reaction results in the formation of the novel tetrametallic adduct [MeZn(μ$_3$-OCH$_2$CH$_2$SMe)Zn(μ-Cl)Me]$_2$ (**1**). In our opinion, the latter compound mimics a new potential intermediate in the donor-functionalized-alcohol promoted addition of dialkylzinc to aldehydes.

Experimental Section

General Remarks: All reactions were carried out under dry nitrogen using standard Schlenk techniques. Solvents were dried and distilled prior to use. NMR spectra were recorded on a Varian Mercury 400 spectrometer.

[MeZn(μ$_3$-OCH$_2$CH$_2$SMe)Zn(μ-Cl)Me]$_2$ (1): 2-(Methylthio)-ethanol (2 mmol, 0.17 mL, 0.18 g) was added at −78 °C to a stirred toluene/CH_2Cl_2solution of Me_2Zn (2 M, 2 mL, 4 mmol). The reaction mixture was then allowed to warm to room temperature and stirred for 4 h. The solvents were then removed under vacuum, leaving a white solid that was crystallized from toluene at −15 °C. Yield 42% (0.24 g). $C_{10}H_{26}Cl_2O_2S_2Zn_4$ (574.9): calcd. C 20.89, H 4.56, Cl 12.33; found C 20.75, H 4.62, Cl 12.43. ^{1}H NMR: δ = −0.30 (s, 6 H, Zn-C*H*$_3$), 2.10 (s, 3 H, S-C*H*$_3$), 2.58 (t, 2 H, C*H*$_2$-O), 3.83 (t, 3 H, S-C*H*$_2$) ppm.

X-ray Crystallographic Study: A single crystal of **1** suitable for X-ray diffraction studies was placed in a thin-walled capillary tube (Lindemann glass 0.5 mm) under an inert atmosphere. The tube was plugged with grease, then flame-sealed and mounted on a goniometer head.

Crystal Data for 1: M = 574.86, crystal dimensions 0.40 × 0.36 × 0.16 mm^3, monoclinic, space group $P2_1/c$ (no. 14), a = 7.0040(3), b = 13.0070(6), c = 11.7400(6) Å, β = 104.5840(18)°, U = 1035.07(8) Å^3, Z = 4, F(000) = 576, D_c = 1.844 g m^3, T = 293(2) K, Mo-K_α radiation (λ = 0.71073 Å), Nonius Kappa-CCD diffractometer, θ_{max} = 27.48°, 2357 unique reflections which were used in all calculations. The structure was solved by direct methods[14] and refined by full-matrix least-squares on F^2.[15] H atoms were included in idealized positions and refined isotropically. Refinement converged at $R1$ = 0.0340, $wR2$ = 0.0624 for all data and 91 parameters [$R1$ = 0.0274, $wR2$ = 0.0606 for 2083 reflections with $I_o > 2\sigma(I_o)$]. The goodness-of-fit on F^2 was equal to 1.083. A weighting scheme $w = [\sigma^2(F_o^2 + (0.0418P)^2 + 3.1964P]^{-1}$ where $P = (F_o^2 + 2F_c^2)/3$ was used in the final stage of refinement; residual electron density = 0.42/−0.48 e·Å^{-3}. CCDC-197262 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Lindqvist-Type (Aryldiazenido)polyoxomolybdates − Synthesis, and Structural and Spectroscopic Characterization of Compounds of the Type $(n\mathrm{Bu_4N})_3[\mathrm{Mo_6O_{18}(N_2Ar)}]$

Carlos Bustos,[a] Bernold Hasenknopf,[b] René Thouvenot,[b] Jacqueline Vaissermann,[b] Anna Proust,[b] and Pierre Gouzerh*[b]

Keywords: Molybdenum / NMR spectroscopy / Polyoxometalates / N ligands

A series of aryldiazenido compounds of the type $(n\mathrm{Bu_4N})_3[\mathrm{Mo_6O_{18}(N_2Ar)}]$ have been prepared by treatment of $(n\mathrm{Bu_4N})_4[\mathrm{Mo_8O_{26}}]$ with the appropriate arylhydrazines in acetonitrile or in methanol. All these compounds are isostructural. Two members of the series, the *o*-nitro and the *p*-carboxy derivatives, have been characterized by single-crystal X-ray diffraction. The aryl ring in the first anion lies in a mirror plane of the polyoxometalate, while in the second one it is tilted, allowing hydrogen bonding between the carboxylic acid function and a neighbouring anion. The aryldiazenido ligands exhibit the characteristic features of the singly bent coordination mode with short Mo–N and N–N bond lengths indicative of multiple bond character. The compounds have been characterized by ^{95}Mo and ^{17}O NMR spectroscopy in acetonitrile. Their spectra indicate C_{4v} symmetry, and hence stereochemical nonrigidity in solution. The ^{95}Mo chemical shifts are mainly determined by variation in the paramagnetic shielding term, σ_{para}. The strongly deshielded resonance of the Mo^{II} centre spans a large range (600–1100 ppm).

Introduction

The functionalization of polyoxometalates (i.e., the replacement of one or several oxo ligands by other ligands) allows their properties to be tuned and provides a route to their application in supramolecular chemistry through the introduction of suitable pendent functions.[1,2] As part of a broad program centred on the functionalization of polyoxometalates, we have for some time been interested in the replacement of terminal oxo ligands by other multiply bonded ligands such as nitrosyl,[3−7] imido[8,9] and nitrido[10] ligands. From electronic considerations, these ligands fall into two categories, the first being the π-donor imido and nitrido ligands, RN^{2-} and N^{3-}, respectively, which can substitute for oxo ligands without a change in the oxidation state of the metal atom − although reduction of Mo^{VI} to Mo^{V} is sometimes observed in the course of the reactions of polyoxomolybdates with precursors of imido and nitrido ligands − and the second being the π-acceptor nitrosyl ligand, which cannot bind to a d^0 metal centre. Consequently, (nitrosyl)polyoxometalates always contain reduced centres, for example, d^4 (M^{II}) and d^6 (M^0) in $\{M(NO)\}^{3+}$ [3−7] and $\{M(NO)_2\}^{2+}$ [11] units (M = Mo, W), respectively. Because of the analogy between nitrosyl and diazenido ligands,[12] there should be structurally related pairs of nitrosyl and diazenido derivatives of polyoxometalates, which might be obtained − at least in principle − through analogous reactions between hydroxylamine or monosubstituted hydrazines and polyoxomolybdates. However, the reactivity of hydrazines towards polyoxomolybdates contrasts with that of hydroxylamine. Nitrosyl derivatives containing $\{M(NO)\}^{3+}$ units are quite easily obtained by treatment of polyoxomolybdates with hydroxylamine in nonaqueous solvents,[3,4,6] while the incorporation of $\{Mo(NO)_2\}^{2+}$ units in polyoxomolybdates requires the use of additional ligands, such as amidoximes.[11] In contrast, the products of the reactions between hydrazines and polyoxomolybdates most often contain $\{Mo(N_2Ar)_2\}^{2+}$ units,[13] while derivatives containing $\{Mo(N_2Ar)\}^{3+}$ units are not easily obtained. The phenyldiazenido Lindqvist-type molybdate $(n\mathrm{Bu_4N})_3[\mathrm{Mo_6O_{18}(N_2Ph)}]$ was described as early as 1986,[14] but in our hands the reported procedure failed to give the expected compound. The perfluoro derivative, $(n\mathrm{Bu_4N})_3[\mathrm{Mo_6O_{18}(N_2C_6F_5)}]$, was reported soon after, but without full details about its preparation.[15] This latter paper also included a preliminary study of these compounds by ^{95}Mo NMR spectroscopy. In our experience, the synthesis of $(n\mathrm{Bu_4N})_3[\mathrm{Mo_6O_{18}(N_2Ar)}]$ is quite sensitive to the boundary conditions. We report here the synthesis and characterization of an extended series of these compounds (Scheme 1).

Results and Discussion

Synthesis

Arylhydrazines, $ArNHNH_2$, react with dioxomolybdenum(VI) complexes, $[MoO_2L_x]$, to give bis(aryldiazenido)molybdenum complexes of the type $[Mo(N_2Ar)_2L_x]$. While sulfur- and/or nitrogen-ligated ancillary ligands[16,17] are usually not displaced in the course of the reaction, oxygen-ligated ligands such as acetylacetone[18] and 2,3-butanediol[19] may be displaced. When the reaction is carried out in methanol this eventually produces tetranuclear complexes of the type $[Mo_4O_8(OMe)_2(N_2Ar)_4]^{2-}$.[19,20] These complexes are also easily obtained by treatment of $(nBu_4N)_4[Mo_8O_{26}]$ with arylhydrazines in refluxing MeOH,[13] and this approach can be generalized, compounds of the type $(nBu_4N)_2[Mo_4O_8(OR)_2(N_2Ar)_4]$ being obtainable from the reaction between an arylhydrazine and an isopolyoxomolybdate such as $(nBu_4N)_2[Mo_6O_{19}]$ or $(nBu_4N)_4[Mo_8O_{26}]$ in an alcohol (ROH). It was originally thought that the formation of Lindqvist-type derivatives, $(nBu_4N)_3[Mo_6O_{18}(N_2Ar)]$, would be favoured in acetonitrile, but complexes containing $\{Mo(N_2Ar)_2\}^{2+}$ moieties, such as $[Mo_8O_{20}(N_2Ar)_6]^{4-}$,[21] are again the major compounds formed. We have now found that the solvent is not critical. Indeed, $[Mo_6O_{18}(N_2C_6H_4$-*p*-$NO_2)]^{3-}$ can be obtained in acetonitrile as well as in MeOH or EtOH. In fact, the formation of the $\{Mo(N_2Ar)\}^{3+}$ unit, and hence the $[Mo_6O_{18}(N_2Ar)]^{3-}$ complexes **1**−**13**, depends critically upon the temperature and the composition of the reactant mixture. In a typical preparation, the arylhydrazine was added to a solution of $(nBu_4N)_4[Mo_8O_{26}]$ in degassed acetonitrile and the mixture was stirred at ca. 50 °C for a short period of time. Heating must not be prolonged after the colour of the mixture has changed to red-brown. Addition of triethylamine, even if the arylhydrazine was not introduced in the form of its hydrochloride, is beneficial to the reaction. It has also been found that the yield of $(nBu_4N)_3[Mo_6O_{18}(N_2Ar)]$ can be significantly increased by addition of $(nBu_4N)Br$, which is likely to help precipitation of the target compounds.

The $[Mo_6O_{18}(N_2Ar)]^{3-}$ derivatives **1**−**13** are only moderately stable in solution. In most cases, the progressive increase of the ^{95}Mo NMR signals of $[Mo_6O_{19}]^{2-}$ and α-$[Mo_8O_{26}]^{4-}$ indicates decomposition. For example, at 50 °C the parent complex $[Mo_6O_{18}(N_2Ph)]^{3-}$ was found to transform mainly into $[Mo_6O_{19}]^{2-}$ in DMF while α-$[Mo_8O_{26}]^{4-}$ was the major decomposition product in acetonitrile.

X-ray Diffraction Analysis

The *o*-nitro (**10**), *p*-nitro (**11**) and *p*-carboxy (**13**) derivatives have been characterized by single-crystal X-ray diffraction. Soon after the study of **11** had been completed, we became aware of the report by Li et al.[22] on the same compound. As there are no significant differences between the two sets of data, we will not enlarge on the crystal structure of **11**. Three other compounds of the type $(nBu_4N)_3[Mo_6O_{18}(N_2Ar)]$, namely **1**,[14] **9**[15] and **12**,[23] had been characterized previously. With the exception of **13**, all the compounds of the type $(nBu_4N)_3[Mo_6O_{18}(N_2Ar)]$ characterized to date are isomorphous (space group *Pmcn*) and the anion displays C_s symmetry with the aryl group lying in the plane of symmetry passing through the two apical Mo centres and two bridging oxygen atoms of the equatorial belt (Mo1, O33, Mo6 and O44 in Figure 1). Compound **13** crystallizes in the $P2_1cn$ space group, the noncentrosymmetric counterpart of the *Pmcn* space group. In this structure, the aromatic ring does not lie in the plane defined above. Instead, it lies almost in the plane of an $\{Mo_4O_4\}$ ring comprising Mo1, Mo2, Mo4 and Mo6 (Figure 2), the deviation being fairly small (13.5°) and the arrangement perhaps being the result of intermolecular interactions in the solid. The anions are linked into chains through O−H···O bonds involving the carboxylic acid function of one anion and a terminal oxygen atom of another anion [O···O 2.796(16) and 2.788(16) Å]. The aryldiazenido ligands in $[Mo_6O_{18}(N_2Ar)]^{3-}$ exhibit the characteristic features of the singly bent coordination mode with a linear Mo−N−N arrangement and short Mo−N and N−N bond lengths indicative of multiple-bond character (Table 1).[13−17] The bond angle at the β-nitrogen atom is around 120° as expected for an sp^2-hybridized atom. The Mo−O distance between the functionalized Mo centre and the central oxygen atom (O_c, see Scheme 1) is significantly shorter than other Mo−O_c distances. Analogous contractions have been observed in other monofunctionalized Lindqvist-type hexamolybdates such as $[Mo_6O_{18}(NNMePh)]^{2-}$,[24] $[Mo_6O_{18}(NC_6H_4$-*p*-$CH_3)]^{2-}$ [25] and $[Mo_6O_{18}(\eta^5$-$C_5Me_5)]^-$,[26] reflecting the weaker *trans* influence of diazenido, hydrazido, imido and cyclopentadienyl ligands relative to the oxo ligand. Inspection of bond lengths in the Mo_4O_4 rings going through Mo(1) (Figures 1 and 2) reveals the same pattern of bond length alternation as observed in other monosubstituted

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hexamolybdates.[24−27] Because of the disorder in the solid-state structure of $(n\mathrm{Bu_4N})_3[Mo_6O_{18}(NO)]$,[5] no accurate comparison can be made between the structural parameters of $[Mo_6O_{18}(N_2Ar)]^{3-}$ and those of $[Mo_6O_{18}(NO)]^{3-}$. However, there is no doubt that the bonding features within the $\{Mo(N_2Ar)\}^{3+}$ unit are quite similar to those of the $\{Mo(NO)\}^{3+}$ unit. In such coordination modes, diazenido and nitrosyl ligands are commonly regarded as RN_2^+ and NO^+ species, respectively. According to this formalism, $\{Mo(N_2Ar)\}^{3+}$ and $\{Mo(NO)\}^{3+}$ units contain Mo^{II} centres.

IR Spectroscopy

In the low-wavenumber region of the IR spectra ($\tilde{\nu} < 1000\ cm^{-1}$), all the $(n\mathrm{Bu_4N})_3[Mo_6O_{18}(N_2Ar)]$ compounds **1**−**13** display similar patterns characteristic of the Lindqvist structure. Actually, the IR bands of the aryldiazenido ligand in this region (mostly C−C and C−H deformations) are of low intensity with respect to those of the polyoxometalate framework. $(n\mathrm{Bu_4N})_3[Mo_6O_{18}(N_2Ar)]$ presents more complex features than $(n\mathrm{Bu_4N})_2[Mo_6O_{19}]$, especially in the 1000−700 cm^{-1} range characteristic of Mo−O stretchings. In particular, the strong $\nu_{as}(Mo-O_t)$ band observed at 958 cm^{-1} in $(n\mathrm{Bu_4N})_2[Mo_6O_{19}]$[28] splits into two more or less resolved bands ($\Delta\tilde{\nu} \approx 20\ cm^{-1}$) in the aryldiazenido derivatives. Similarly, the broad band observed at 796 cm^{-1} in the parent hexamolybdate and assigned to a $Mo-O_b$ stretching mode, also splits into two components ($\Delta\tilde{\nu} \approx 25\ cm^{-1}$) in $(n\mathrm{Bu_4N})_3[Mo_6O_{18}(N_2Ar)]$ (Figure 3). Such splittings are commonly observed in monofunctionalized hexamolybdates, such as imido,[8,9] nitrosyl,[4,5] and cyclopentadienyl[26] derivatives, and they have been ascribed to the reduction in symmetry of the oxometalate framework from O_h to C_{4v} upon the substitution of MoX for MoO. According to group theory, this should result in the splitting of all IR-active triply degenerated F_2 modes into A_1 and E modes. A detailed analysis, using Mo−N and $Mo-O_t$ internal coordinates, allows four IR-active modes to be predicted: one Mo−N and three $Mo-O_t$, according to the following representation:[8]

$$\Gamma(Mo-O_t) = 2A_1(IR, R) + B_1(R) + E(IR, R)$$

$$\Gamma(Mo-N) = A_1(IR, R)$$

In the approximation of separate $Mo-O_t$ and Mo−N vibrators, the stronger band, at low energy ($\tilde{\nu} \approx 940\ cm^{-1}$), should be assigned to the E-type $\nu_{as}(Mo-O_t)$ mode, whereas the less intense band ($\tilde{\nu} \approx 965\ cm^{-1}$) might correspond to an A_1-type mode, associated principally with the Mo−N vibrator. Mechanical coupling between the $Mo-O_t$ and Mo−N vibrators are not excluded, however. Isotopic

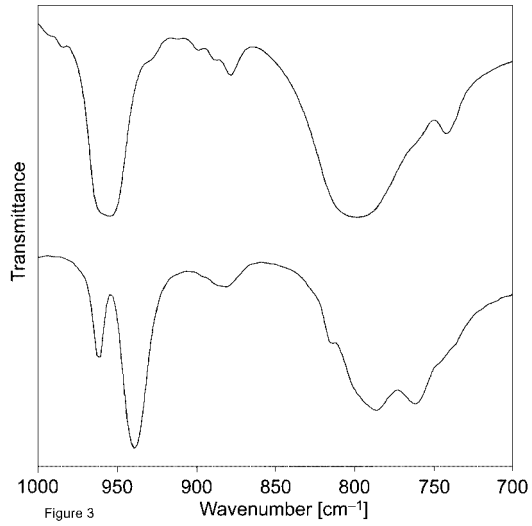

Figure 3. Part of the IR spectra of $[Mo_6O_{19}]^{2-}$ (top) and $[Mo_6O_{18}(N_2C_6H\text{-}p\text{-}CH_3)]^{3-}$ (bottom); note the splitting of the Mo=O (left) and Mo−O−Mo (right) bands in the diazenido complex

^{15}N and/or ^{18}O labelling is needed to reach a definite conclusion.

In all compounds **1**−**13**, the aromatic ν(C−H) bands ($\tilde{\nu} > 3000$ cm^{-1}) are hardly visible, due to their low intensity, and the complex pattern around 2900 cm^{-1} contains aliphatic ν(C−H) bands both of the tetrabutylammonium cation and of the substituent on the aromatic ring. The IR spectra of compounds **1**−**13** differ markedly in their band positions but also in their intensities in the medium-frequency region (1650−1300 cm^{-1}) where ν(N=N) and various bands from the arene occur.[29] It should be noted that this part of the IR absorption spectrum is more complex and more intense for a given (aryldiazenido)hexamolybdate than for the (arylimido)hexamolybdate $[Mo_6O_{18}(NAr)]^{2-}$ with the same Ar group.[8,30] By use of extensive isotopic labelling on mononuclear (aryldiazenido)metal complexes, Ibers and co-workers have shown that the intensity of the intrinsically weak ν(N=N) band may be considerably enhanced by resonance interaction with phenyl modes. This also results in differences between the experimentally observed band position and the real ν(N=N) frequency.[29] Apparently, resonance interactions also occur in the aryldiazenido hexamolybdates, because of the intense features observed between 1650 and 1300 cm^{-1}. Without isotopic labelling it is then impossible to determine the exact frequency of the N=N stretching mode, and thus the strength of the N=N bond.

UV/Vis Spectroscopy

The UV/Vis electronic spectra were recorded in acetonitrile solutions at room temperature. Slow changes were observed on standing, in line with the ^{95}Mo NMR study, indicating progressive transformation mainly into α-$[Mo_8O_{26}]^{4-}$. The electronic spectrum of the phenyldiazenido derivative **1** was recorded in different solvents, and almost identical spectra were obtained except in methanol, in which a fast transformation occurs. The electronic spectra of compounds **1**−**13** split into two groups. Those of compounds **1**−**3** and **5**−**9** exhibit two bands at ca. 390 and 290 nm, the second being more intense than the first. In addition, there are two shoulders on the lower energy side of each main band. The second group of compounds comprises the nitro derivatives **10**−**12**, for which the more intense band lies in the visible region. Compounds **4** and **13** are somewhat intermediate. The lower energy absorptions are clearly associated with the $\{Mo(N_2Ar)\}$ chromophore and their high molar absorptivity is indicative of charge-transfer character. This contrasts with $[Mo_6O_{18}(NO)]^{3-}$ and other polyoxomolybdates containing $\{Mo(NO)\}^{3+}$ units, which display a band most probably associated with a $d_{xz},d_{yz} \rightarrow d_{xy}$ transition.[3−6] Although we prefer not to speculate extensively on the origin of the absorption bands until a theoretical study has been performed, the difference between nitrosyl and diazenido derivatives might be related to the change from C_{4v} to C_s symmetry on going from $[Mo_6O_{18}(NO)]^{3-}$ to $[Mo_6O_{18}(N_2Ar)]^{3-}$. Indeed in six-coordinate complexes, bending of the diazenido ligand has a stabilizing effect on the π* N_2Ar orbital in the plane of bending.[31,32]

NMR Spectroscopy

The characterization of compounds **1**−**13**, $(n\text{Bu}_4\text{N})_3[Mo_6O_{18}(N_2Ar)]$, by multinuclear NMR ($^{17}O$ and ^{95}Mo) spectroscopy was carried out in the same way as used for the nitrosyl derivatives $(n\text{Bu}_4\text{N})_3[M_5O_{18}\{M'(NO)\}]$ (M, M′ = Mo, W)[6] and the imido derivatives $(n\text{Bu}_4\text{N})_2[Mo_6O_{19-x}(NR)_x]$ ($x = 1-6$):[8,9] in acetonitrile and at elevated temperatures (usually 50 °C). This allows the relaxation rate of the quadrupolar nuclei (^{17}O and ^{95}Mo) to be decreased and the linewidths of the resonance signals to be reduced. Even under these conditions, some of the expected ^{95}Mo resonances were not observed, probably because of extreme broadening. In some cases, such as **8**, **9** and **11**, however, full ^{95}Mo spectra could be obtained at room temperature, although the signals were significantly broadened with respect to the high-temperature spectra. Unlike the nitrosyl and imido derivatives, the diazenido compounds proved to be only fairly stable at 50 °C, even in dried acetonitrile. Decomposition was evident from the progressive growth of the ^{95}Mo NMR signals characteristic of $[Mo_6O_{19}]^{2-}$ (δ = 125 ppm) and of α-$[Mo_8O_{26}]^{4-}$ (δ = 21 and −11 ppm). In particular, decomposition could not be avoided for compounds with a donor substituent on the aryl group, and in some cases it was nearly complete during the time required for the acquisition of the ^{95}Mo spectrum, so measurement of a full set of NMR spectroscopic data was not possible for each member of the series $(n\text{Bu}_4\text{N})_3[Mo_6O_{18}(N_2Ar)]$. Results are listed in Tables 2 and 3. No significant data could be collected for **3** and **6**, and nearly complete sets of ^{17}O and ^{95}Mo data were obtained only for

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

7, **8**, **9** and **12**. Nevertheless, this allows a comparison with $(n\mathrm{Bu_4N})_3[\mathrm{Mo_6O_{18}(NO)}]$ and reveals some trends within the series of diazenido compounds.

[a] Spectra recorded in acetonitrile solutions. [b] Chemical shifts in ppm with respect to neat H_2O. [c] Not observed.

Before discussing the NMR spectroscopic data in detail, let us remember briefly the two terms determining the shielding (σ) and the chemical shift (δ = −σ) of a given nucleus.[33] Shielding is usually expressed as the sum of two opposite terms: the diamagnetic term σ_{dia} (positive) and the paramagnetic term σ_{para} (negative).

$$-\delta = \sigma = \sigma_{dia} + \sigma_{para}$$

An increase in the electron density at the nucleus results in an increase in the diamagnetic contribution and hence shifts the resonance to lower chemical shifts. In contrast, an enhanced paramagnetic contribution results in reduced shielding and shifts the NMR line to higher δ values. Furthermore, σ_{para} depends on all electronic excitation energies; in favourable cases it is inversely proportional to the HOMO−LUMO gap. Then, within a congruent set of complexes, the net deshielding of the NMR signal may reflect the decrease in the HOMO−LUMO gap through the increase of the paramagnetic contribution.

^{95}Mo NMR Spectroscopy

The ^{95}Mo NMR spectrum of $(n\mathrm{Bu_4N})_3[\mathrm{Mo_6O_{18}}(\mathrm{N_2C_6H_4}$-*p*-$\mathrm{NO_2})]$ (**11**) in acetonitrile displays three signals in an approximate ratio of 1:4:1 in order of increasing shielding (Figure 4). This spectrum is quite similar to that of $(n\mathrm{Bu_4N})_3[\mathrm{Mo_6O_{18}(NO)}]$, so the two more-shielded signals at δ = 197 ppm (4 Mo, $\Delta\nu_{1/2} \approx 200$ Hz) and at δ = 150 ppm (1 Mo, $\Delta\nu_{1/2} \approx 350$ Hz) may be assigned to the equatorial and axial Mo^{VI} centres, respectively, while the strongly deshielded and broad signal ($\Delta\nu_{1/2} \approx 600$ Hz) at δ = 845 ppm may be assigned to the Mo^{II} centre. According to these data, the apparent symmetry of $[\mathrm{Mo_6O_{18}(N_2C_6H_4}$-*p*-$\mathrm{NO_2})]^{3-}$ in solution is C_{4v}, while its actual symmetry is at most C_s, as observed in the solid state.[22] Because other members of the series behave similarly, and because analysis of the ^{17}O NMR spectra suggests the same conclusion (see below), accidental degeneracy of signals can be ruled out. The NMR spectroscopic data in solution thus indicate fast rotation of the aryldiazenido ligand on NMR timescales. There is precedent for such a rotation.[34]

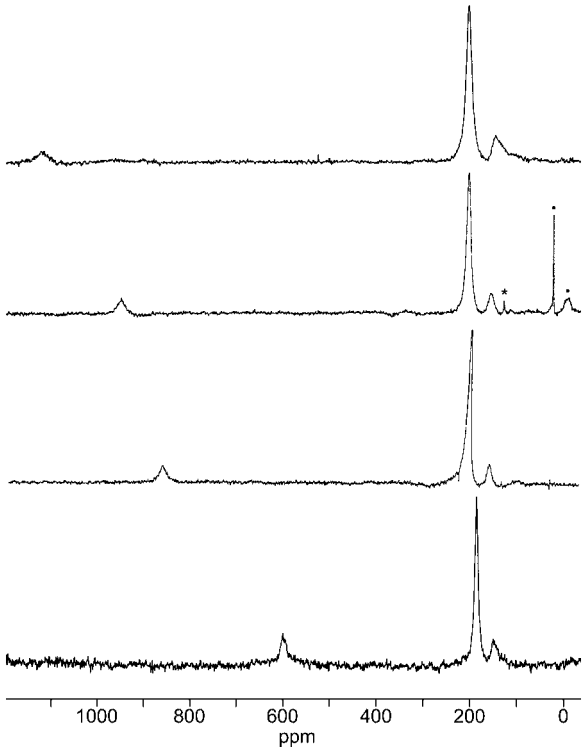

Figure 4. 32.6 MHz ^{95}Mo NMR spectra of all NO_2-substituted diazenido hexamolybdates; from top to bottom: $[\mathrm{Mo_6O_{18}(N_2C_6H_4}$-*m*-$\mathrm{NO_2})]^{3-}$ (**8**), 25 °C, 20 mM, 288·10^3 transients; $[\mathrm{Mo_6O_{18}(N_2C_6H_4}$-*o*-$\mathrm{NO_2})]^{3-}$ (**10**), 50 °C, 50 mM, 77·10^3 transients; $[\mathrm{Mo_6O_{18}(N_2C_6H_4}$-*p*-$\mathrm{NO_2})]^{3-}$ (**11**), 50 °C, 28 mM, 120·10^3 transients; $[\mathrm{Mo_6O_{18}\{N_2C_6H_3}$-*o*,*p*-$\mathrm{(NO_2)_2\}}]^{3-}$ (**12**), 50 °C, 20 mM, 54·10^3 transients; note the relative broadness of the room-temperature spectrum of **8** and the spurious signals from $[\mathrm{Mo_6O_{19}}]^{2-}$ (*) and of α-$[\mathrm{Mo_8O_{26}}]^{4-}$(·) in the spectrum of **10**; general conditions for all spectra: spectral width 45 kHz (ca. 1400 ppm); pulse width 10 μs (ca. 30° flip angle); acquisition time 45 ms; no relaxation delay; the time domain data (4 K points) were multiplied by an exponential window (LB, 20 Hz) prior to Fourier transformation without zero-filling; baseline distortions were corrected by use of the Bruker software

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The deshielding of the functionalized Mo can be attributed to the dominant role of the paramagnetic contribution. In addition, the similarity between the chemical shifts supports similar electronic structures (i.e., d^4 Mo^{II} centres) both in $[Mo_6O_{18}(N_2C_6H_4\text{-}p\text{-}NO_2)]^{3-}$ and in $[Mo_6O_{18}(NO)]^{3-}$ compounds. Any compound of the type $(n\text{Bu}_4\text{N})_3[Mo_6O_{18}(N_2Ar)]$ should display the same type of ^{95}Mo spectrum, with a strongly deshielded signal and two resonances at $\delta \approx 200$ and 150 ppm. The deshielded resonance is always quite broad and could not be observed for compounds **1**, **2** and **7**. Otherwise, all data agree with the typical spectra of Figure 4. Let us note that Zubieta and Ellis have already reported ^{95}Mo NMR spectroscopic data on compound **1**.[15] Like us, they only observed two signals, lying in a range typical of Mo^{VI} centres, though their reported chemical shifts are not in agreement with our observations. In our hands, $[Mo_6O_{18}(N_2Ph)]^{3-}$ proved to be amongst the less stable diazenido complexes, and the data reported by Zubieta and Ellis might correspond to decomposition products.

The chemical shifts for both equatorial and axial $\{^{95}MoO\}$ sites in the diazenido derivatives are uniformly deshielded with respect to those of $[Mo_6O_{19}]^{2-}$. In contrast to the wide variance of the $\{^{95}MoN_2Ar\}$ resonances, the $\{^{95}MoO\}$ resonances fall within a narrow range: δ = 185−214 ppm for the equatorial sites, and δ = 149−156 ppm for the axial site. A trend can be established for those compounds in which the three signals are observed: deshielding of the $\{^{95}MoN_2Ar\}$ resonance is accompanied by definite, albeit smaller, deshielding of the $\{^{95}MoO\}$ resonances (Figure 5). By extrapolation of this trend to all the members of the series, the $\{^{95}MoN_2Ph\}$ resonance for **1** would be expected at $\delta \approx 1300$ ppm.

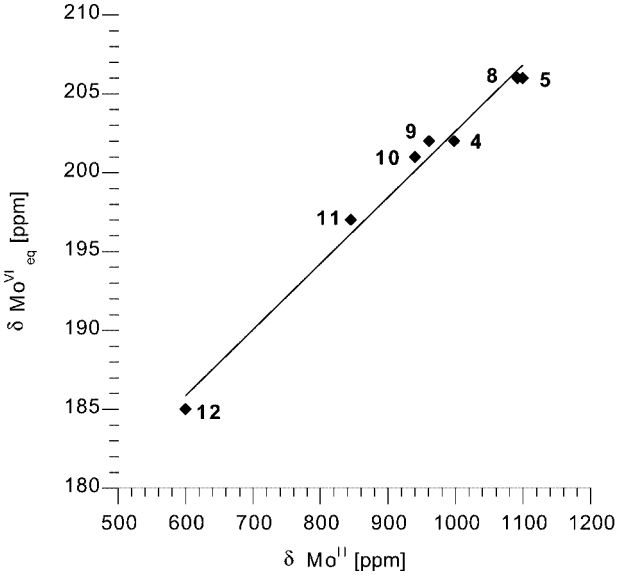

Figure 5. Plotting of the ^{95}Mo chemical shifts of the equatorial Mo^{VI} centres as a function of those of the Mo^{II} centre in the (diazenido)hexamolybdates; the heavy line represents the best fit from a linear regression $\delta(Mo^{VI}) = 4.19\cdot10^{-2}\ \delta(Mo^{II}) + 160.7$ ppm ($R = 0.993$)

It may be inferred from these observations, and from comparison with the nitrosyl complexes $[M_5O_{18}\{M'(NO)\}]^{3-}$ (M, M′ = Mo, W)[6] and the imido complexes $[Mo_6O_{18}(NR)]^{2-}$,[8,9] that all the ^{95}Mo chemical shifts for $[Mo_6O_{18}(N_2Ar)]^{3-}$ are mainly determined by variation in the paramagnetic shielding term, σ_{para}. While imido ligands are superior to oxo ligands as electron donors, nitrosyl and diazenido ligands − to be regarded as NO^+ and RN^{2+}, respectively − are strong Lewis acids and their complexes have low-lying excited states. Accordingly, there is a bathochromic shift of the lower energy absorptions of $[M_5O_{18}\{M'(NO)\}]^{3-}$ and $[Mo_6O_{18}(N_2Ar)]^{3-}$ in relation to $[Mo_6O_{18}(NR)]^{2-}$. While the $\{^{95}MoN\}$ chemical shifts correlate with λ_{max} for the arylimido complexes $[Mo_6O_{18}(NAr)]^{2-}$,[9,30] no such correlation could be found for the aryldiazenido complexes $[Mo_6O_{18}(N_2Ar)]^{3-}$, whether the lowest energy transition (which most often appears as a shoulder) or the next one is considered. Attempts were also made to correlate the ^{95}Mo chemical shifts of the *p*-substituted compounds with either Hammett function σ_p or σ_p^+: although there is no evident correlation, it is clear that both $\{^{95}MoN\}$ and $\{^{95}Mo_{eq}O\}$ resonances move to lower frequency on going from electron-donating (Me) to electron-withdrawing substituents (CN, CF_3, NO_2). For the (dinitrophenyl)diazenido species **12**, the cumulative effect of the two strongly electron-withdrawing substituents produces the most shielded spectrum of the series. A similar trend has been observed for $\delta\{^{95}MoN\}$ in the (arylimido)hexamolybdates $(n\text{Bu}_4\text{N})_2[Mo_6O_{18}(NC_6H_4\text{-}p\text{-}X)]$,[8,9,30] as well as for $\delta(^{51}V)$ in the (arylimido)vanadium(v) complexes $[VCl_3(NC_6H_4N\text{-}p\text{-}X]$,[35] and was explained by variations in the paramagnetic shielding term. We therefore suggest that the same effect is likely to apply to the aryldiazenido series. Nevertheless, further studies, in particular theoretical calculations, are needed to provide a full account of the variation of the ^{95}Mo chemical shifts in this series.

^{17}O NMR Spectroscopy

As noted above, the low solubilities and the long-term instabilities of the diazenido complexes hampered the acquisition of natural-abundance ^{17}O spectra. Moreover the sensitivity of most of these compounds to hydrolysis did not allow ^{17}O-enriched samples to be obtained. ^{17}O NMR spectra were therefore obtained only for **7**, **8**, **9** and **12** (Table 3). As a typical example, the room-temperature spectrum of $[Mo_6O_{18}(N_2C_6H_4\text{-}m\text{-}NO_2)]^{3-}$ (**8**) is displayed in Figure 6. This spectrum is very similar to that of $[Mo_6O_{18}(NO)]^{3-}$ [5] and is consistent with the C_{4v} symmetry of the species. The ^{17}O spectra of **8**, **9** and **12** all display six signals in an approximate intensity ratio of 4:1:4:4:4:1, which may be assigned to the terminal (O_t) resonances at $\delta \approx 880-900$ ppm, to the bridging (O_b) resonances between δ = 530 and 600 ppm and to the central (O_c) resonance at $\delta \approx -30$ ppm (Table 3). The signal of O_c in **7**, and also those of the nitro groups in **7** and **12**, were not detected. The four diazenido compounds measured here and the

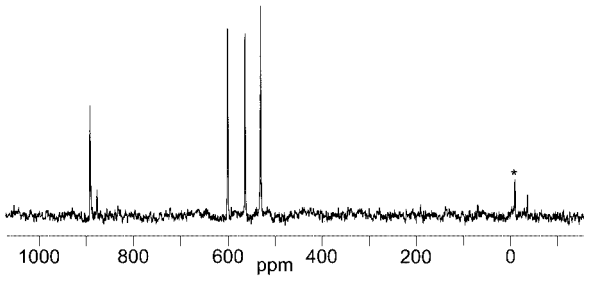

Figure 6. 67.8 MHz natural-abundance ^{17}O NMR spectrum of a 20 mM solution of $[Mo_6O_{18}(N_2C_6H_4\text{-}m\text{-}NO_2)]^{3-}$ (**8**) in CH_3CN; experimental conditions: spectral width 83 kHz (> 1200 ppm); pulse width 20 μs (ca. 45° flip angle); acquisition time 25 ms; no relaxation delay; $1.8\cdot10^6$ transients were acquired for a total spectrometer time of 12.5 h; the time domain data (4 K points) were multiplied by an exponential window (LB, 40 Hz) prior to Fourier transformation without zero-filling; baseline distortions were corrected by use of the Bruker software; the signal marked with an asterisk corresponds to H_2O

nitrosyl derivative provide a homogeneous set of ^{17}O data, again not in agreement with those reported by Zubieta and Ellis for $[Mo_6O_{18}(N_2C_6F_5)]^{3-}$.[15]

According to Klemperer,[36,37] the general pattern of the ^{17}O NMR spectra of polyoxometalates is determined by the paramagnetic shielding term, which accounts for the sequence $\delta(O_t) > \delta(O_b) > \delta(O_c)$, following decreasing π-bond order. However, variations in the diamagnetic term must be considered in order to explain the relatively subtle chemical shift modulations within each group. As with the nitrosyl derivatives, the signals of the terminal oxygen atoms in the diazenido derivatives are shielded with respect to that of $[Mo_6O_{19}]^{2-}$, in keeping with the net increase in negative charge over the polyoxometalate framework when $[Mo^{II}NO]^{3+}$ or $[Mo^{II}NNAr]^{3+}$ is substituted for $[Mo^{VI}O]^{4+}$. In contrast to the ^{95}Mo chemical shifts, the most deshielded O_t resonances in the series are shown by the dinitro derivative (**12**). This is in accordance with IR data, which indicate the highest $Mo-O_t$ stretching energy, and thus the strongest $Mo-O_t$ bond, for this compound.

With regard to the O_b signals, one appears at higher frequency than the unique O_b resonance of $[Mo_6O_{19}]^{2-}$; it had already been assigned to the oxygen atoms (O_{b1}) bridging Mo^{II} and the four equatorial Mo^{VI}.[5] The central O_b resonance does not move significantly throughout the series: it lies approximately at the same position, within ± 3 ppm, as the hexamolybate signal, a situation already encountered in the monoimido series.[8,9] Finally, the most shielded O_b signal, at −25 to −30 ppm from the previous one, seems to be the only one reflecting the overall negative charge increase.

Conclusion

A series of aryldiazenido compounds of the type $(n\text{Bu}_4\text{N})_3[Mo_6O_{18}(N_2\text{Ar})]$ has been prepared by treatment of $(n\text{Bu}_4\text{N})_4[Mo_8O_{26}]$ with the appropriate arylhydrazines in acetonitrile or in methanol. All these compounds are isostructural and belong to the family of Lindqvist-type polyoxometalates. Two members of the series, the *o*-nitro and *p*-carboxy derivatives, have been characterized by single-crystal X-ray diffraction. The first anion displays C_s symmetry, in the second one the aromatic ring is tilted and thus allows hydrogen bonding of the carboxylic acid to a neighbouring anion. The aryldiazenido ligands exhibit features characteristic of the singly bent coordination mode with short Mo−N and N−N bonds indicative of multiple-bond character. The compounds have been characterized by ^{95}Mo NMR spectroscopy in acetonitrile. Their spectra are normally composed of three signals in an intensity ratio of 1:4:1, although the strongly deshielded resonance ($\delta \approx 1100-600$ ppm) is quite broad and was not always observed. The large deshielding of the Mo^{II} centre arises from paramagnetic contributions.

We have shown here the possibility of obtaining a family of functionalized polyoxometalates differing in the substituents on the aromatic rings. These substituents influence the physical and chemical properties of the hexamolybdate, as can be seen by the spectroscopic characterization of the compounds and their different stabilities in solution. The presence of reactive groups on the aromatic ring allows further derivatization, and we are now investigating the possibilities of carbon−carbon coupling and elaboration on the carboxylic acid.

Experimental Section

General Procedures and Materials: All reactions were performed under dry nitrogen. Reagents and chemicals were purchased from commercial sources and were used as received. Solvents were purified and dried by standard procedures. $(n\text{Bu}_4\text{N})_4[Mo_8O_{26}]$ was prepared as reported in the literature.[38] IR spectra were recorded in KBr pellets with a BioRad FTS 165 FT-IR spectrophotometer. UV/Vis spectra were recorded in acetonitrile solutions (concentration ca. $2.5\cdot10^{-4}$ M) with a Shimadzu UV-2101 spectrophotometer. Natural-abundance ^{17}O and ^{95}Mo NMR spectra were recorded at 67.8 and 32.6 MHz, respectively, by use either of a Bruker AM 500 or of a Bruker DRX 500 spectrometer. All spectra were obtained without lock from nearly saturated acetonitrile solutions in 10-mm o.d. tubes. Sample concentrations ranged from 40 to 200 mg in 2.5 mL of CH_3CN (from 0.01 to 0.05 M). Chemical shifts δ are reported in ppm with respect to external H_2O (^{17}O) and external aqueous alkaline solution of 2 M Na_2MoO_4 (^{95}Mo) according to the IUPAC recommendation. Positive δ corresponds to high frequency shift (deshielding) with respect to the reference. Elemental analyses were performed by the "Service de microanalyse", Université Pierre et Marie Curie, Paris, France and by the "Service central d'analyse", CNRS, Vernaison, France.

Syntheses: The preparations of the compounds $(n\text{Bu}_4\text{N})_3[Mo_6O_{18}(N_2\text{Ar})]$ divide into two groups, differing mainly in the solvent used, and in the presence of base.

Compounds 1−8: $(n\text{Bu}_4\text{N})_4[Mo_8O_{26}]$ (2.15 g, 1.00 mmol), twice the molar amount of the appropriate arylhydrazine ($C_6H_5NHNH_3Cl$, 0.289 g; *p*-Me-$C_6H_4NHNH_3Cl$, 0.317 g; *p*-F-$C_6H_4NHNH_3Cl$, 0.325 g; *p*-NC-$C_6H_4NHNH_3Cl$, 0.339 g; *p*-F_3C-$C_6H_4NHNH_2$, 0.352 g; *p*-MeO-$C_6H_4NHNH_3Cl$, 0.349 g; *o*-Cl-$C_6H_4NHNH_3Cl$, 0.358 g; *m*-O_2N-$C_6H_4NHNH_3Cl$, 0.379 g), $(n\text{Bu}_4\text{N})Br$ (0.50 g, 1.55 mmol) and NEt_3 (2.8 mL, 20 mmol) were added to MeCN

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(15 mL). The mixture was vigorously stirred and heated at ca. 50 °C until its colour had turned dark brown (20 min at most). The product sometimes started to precipitate at this stage. Filtration was carried out after the solution had been concentrated to ca. 10 mL and cooled to room temperature. The collected solid was washed with a 1:1 mixture of MeCN and Et_2O, then with pure Et_2O, and dried under vacuo. In some cases (**1**, **3**, **5**, **6**), the solid had to be washed with cold MeCN to remove traces of $(nBu_4N)_4[Mo_8O_{26}]$. Each compound was recrystallized from MeCN by slow diffusion of Et_2O.

Compounds 9−13: $(nBu_4N)_4[Mo_8O_{26}]$ (2.15 g, 1.00 mmol) and twice the molar amount of the appropriate arylhydrazine [$C_6F_5NHNH_3Cl$, 0.408 g; *o*-O_2N-$C_6H_4NHNH_2$, 0.306 g; *p*-O_2N-$C_6H_4NHNH_2$, 0.306 g; *o*,*p*-$(O_2N)_2$-$C_6H_3NHNH_2$, 0.396 g] were added to MeOH (30 mL). The mixture was vigorously stirred and heated at reflux for 30 min at the most. The solution was concentrated to about 15 mL, and the precipitate was then collected by filtration, washed with MeOH and Et_2O, and dried in vacuo. The products were recrystallized by diffusion of Et_2O into MeCN solutions. The preparation of **13** required some modifications in the above procedure. A mixture of $(nBu_4N)_4[Mo_8O_{26}]$ (2.15 g, 1.00 mmol) and *p*-HO_2C-$C_6H_4NHNH_2$ (0.152 g, 1.00 mmol) was heated at ca. 50 °C for ca. 20 min, during which time its colour had changed to dark brown. The methanol was removed in vacuo and the residue was extracted with several portions (20 mL) of acetone. The extracts were combined and concentrated to ca. 10 mL. The insoluble material was removed by filtration and the filtrate was exposed to vapours of Et_2O. The complex may be recrystallized by diffusion of Et_2O in MeCN or Me_2CO solutions.

Only IR bands that could be unambiguously assigned are listed below. All spectra display the bands characteristic of the tetrabutylammonium cations.

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H_5)]$ (1): Yield: 1.49 g (66% based on Mo). $C_{54}H_{113}Mo_6N_5O_{18}$ (1696.17): calcd. C 38.24, H 6.72, Mo 33.94, N 4.13; found C 37.99, H 6.68, Mo 33.78, N 4.14. UV/Vis (MeCN): λ_{max} (log ε) = 486 (sh, 3.49), 383 (4.26), 331 (sh, 4.32), 286 nm (4.62). IR (KBr): $\tilde{\nu}_{max}$ = 962 (m), 939 (s) [ν(Mo=O,Mo=N)], 786 (s), 762 (s) cm^{-1} [ν(MoOMo)]. ^{95}Mo NMR: see Table 2.

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H$-*p*-Me)] (2): Yield: 1.28 g (56% based on Mo). $C_{55}H_{115}Mo_6N_5O_{18}$ (1710.19): calcd. C 38.63, H 6.78, Mo 33.66; N 4.10; found C 38.70, H 6.79, Mo 33.30, N 4.04. UV/Vis (MeCN): λ_{max} (log ε) = 498 (sh, 3.41), 385 (4.19), 331(4.26), 284 nm (4.55). IR (KBr): $\tilde{\nu}_{max}$ = 962 (m), 939 (s) [ν(Mo=O,Mo=N)], 786 (s), 762 (s) cm^{-1} [ν(MoOMo)]. ^{95}Mo NMR: see Table 2.

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H$-*p*-F)] (3): Yield: 1.33 g (58% based on Mo). $C_{54}H_{112}FMo_6N_5O_{18}$ (1714.15): calcd. C 37.84, H 6.59, F 1.17, Mo 33.58, N 4.08; found C 37.97, H 6.60, F 1.21, Mo 33.49, N 4.03. UV/Vis (MeCN): λ_{max} (log ε) = 483 (sh, 3.42), 378 (sh, 4.15), 325 (sh, 4.25), 283 nm (4.55). IR (KBr): $\tilde{\nu}_{max}$ = 963 (m), 940 (s) [ν(Mo=O,Mo=N)], 788 (s), 763 (s) cm^{-1} [ν(MoOMo)].

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H_4$-*p*-CN)] (4): Yield: 1.35 g (59% based on Mo). $C_{55}H_{112}Mo_6N_6O_{18}$ (1721.18): calcd. C 38.38, H 6.56, Mo 33.44, N 4.88; found C 38.31, H 6.49, Mo 33.52, N 4.93. UV/Vis (MeCN): λ_{max} (log ε) = 421 (4.48), 308 nm (4.30). IR (KBr): $\tilde{\nu}_{max}$ = 2207 (m) [ν(C≡N)], 965 (m), 941 (s) [ν(Mo=O,Mo=N)], 788 (s), 762 (s) cm^{-1} [ν(MoOMo)]. ^{95}Mo NMR: see Table 2.

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H_4$-*p*-$CF_3)]$ (5): Yield: 1.22 g (52% based on Mo). $C_{55}H_{112}F_3Mo_6N_5O_{18}$ (1764.16): calcd. C 37.45, H 6.40, F 3.23, Mo 32.63, N 3.97; found C 37.27, H 6.62, F 3.34, Mo 32.44, N 3.92. UV/Vis (MeCN): λ_{max} (log ε) = 481 (sh, 3.69), 400 (4.37), 330 (sh, 4.27), 296 nm (4.46). IR (KBr): $\tilde{\nu}_{max}$ = 965 (s), 942 (s) [ν(Mo=O,Mo=N)], 788 (s), 764 (s) cm^{-1} [ν(MoOMo)]. ^{95}Mo NMR: see Table 2.

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H_4$-*p*-OMe) (6): Yield: 0.86 g (38% based on Mo). $C_{55}H_{115}Mo_6N_5O_{19}$ (1726.19): calcd. C 38.27, H 6.72, Mo 33.35, N 4.05; found C 38.22, H 6.71, Mo 33.27, N 4.09. UV/Vis (MeCN): λ_{max} (log ε) = 509 (sh, 3.37), 388 (sh, 4.30), 327 (sh, 4.26), 284 nm (4.58). IR (KBr): $\tilde{\nu}_{max}$ = 961 (m), 939 (s) [ν(Mo=O,Mo=N)], 787 (s), 762 (s) cm^{-1} [ν(MoOMo)].

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H_4$-*o*-Cl) (7): Yield: 1.22 g (53% based on Mo). $C_{54}H_{112}ClMo_6N_5O_{18}$ (1730.61): calcd. C 37.48, H 6.52, Cl 2.28, Mo 33.26, N 4.05; found C 37.40, H 6.50, Cl 2.07, Mo 33.16, N 4.07. UV/Vis (MeCN): λ_{max} (log ε) = 491 (sh, 3.61); 390 (4.36), 334 (sh, 4.36), 288 nm (4.68). IR (KBr): $\tilde{\nu}_{max}$ = 963 (m), 941 (s) [ν(Mo=O,Mo=N)], 788 (s), 761 (s) cm^{-1} [ν(MoOMo)]. ^{95}Mo NMR: see Table 2. ^{17}O NMR: see Table 3.

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H_4$-*m*-$NO_2)]$ (8): Yield: 1.74 g (75% based on Mo). $C_{54}H_{112}Mo_6N_6O_{20}$ (1741.16): calcd. C 37.25, H 6.48, Mo 33.06, N 4.83; found C 37.31, H 6.52, Mo 33.12, N 4.52. UV/Vis (MeCN): λ_{max} (log ε) = 487 (sh, 3.67), 383 (4.38), 281 nm (4.71). IR (KBr): $\tilde{\nu}_{max}$ = 965 (s), 940 (s) [ν(Mo=O,Mo=N)], 788 (s), 763 (s) cm^{-1} [ν(MoOMo)]. ^{95}Mo NMR: see Table 2. ^{17}O NMR: see Table 3.

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6F_5]$ (9): Yield 1.60 g (67% based on Mo). $C_{54}H_{108}F_5Mo_6N_5O_{18}$ (1786.12): calcd. C 36.31, H 6.09, F 5.32, Mo 32.23, N 3.92; found, C 36.21, H 5.95, F, 5.12, Mo 31.90, N 3.94. UV/Vis (MeCN): λ_{max} (log ε) = 467 (sh, 3.48), 379 (4.19), 279 nm (4.50). IR (KBr): $\tilde{\nu}_{max}$ = 964 (m), 942 (s) [ν(Mo=O,Mo=N)], 792 (s), 768 (s) cm^{-1} [ν(MoOMo)]. ^{95}Mo NMR: see Table 2. ^{17}O MNR: see Table 3.

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H_4$-*o*-$NO_2)]$ (10): Yield: 1.39 g (60% based on Mo). $C_{54}H_{112}Mo_6N_6O_{20}$ (1741.16): calcd. C 37.25, H 6.48, Mo 33.06, N 4.83; found C 37.14, H 6.34, N 4.79. UV/Vis (MeCN): λ_{max} (log ε) = 548 (3.76), 373 (3.88), 274 nm (4.4). IR (KBr): $\tilde{\nu}_{max}$ = 965 (s) 943 (s) [ν(Mo=O,Mo=N)], 790 (s), 762 (s) cm^{-1} [ν(MoOMo)]. ^{95}Mo NMR: see Table 2.

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H_4$-*p*-$NO_2)]$ (11): Yield: 1.74 g (75% based on Mo). $C_{54}H_{112}Mo_6N_6O_{20}$ (1741.16): calcd. C 37.25, H 6.48, Mo 33.06, N 4.83; found; C 37.62, H 6.81, Mo 32.80, N 5.04. UV/Vis (MeCN): λ_{max} (log ε) = 548 (4.59), 305 (sh, 4.25), 267 nm (4.50). IR (KBr): $\tilde{\nu}_{max}$ = 967 (m), 943 (s) [ν(Mo=O,Mo=N)], 791 (s), 762 (s) cm^{-1} [ν(MoOMo)]. ^{95}Mo NMR: see Table 2.

$(nBu_4N)_3[Mo_6O_{18}\{N_2C_6H_3$-*o*,*p*-$(NO_2)_2\}]$ (12): Yield: 1.88 g (79% based on Mo). $C_{54}H_{111}Mo_6N_7O_{22}$ (1786.16): calcd. C 36.31, H 6.26, Mo 32.22, N 5.48; found C 37.08, H 6.29, Mo 32.26, N 5.52. UV/Vis (MeCN): λ_{max} (log ε) = 525 (4.60) 300 (sh, 4.29), 258 nm (4.53). IR (KBr): $\tilde{\nu}_{max}$ = 969 (m), 946 (s) [ν(Mo=O,Mo=N)], 791 (s), 765 (s) cm^{-1} [ν(MoOMo)]. ^{95}Mo NMR: see Table 2. ^{17}O NMR: see Table 3.

$(nBu_4N)_3[Mo_6O_{18}(N_2C_6H_4$-*p*-$CO_2H)]$ (13): Yield 0.74 g (32% based on Mo). $C_{55}H_{113}Mo_6N_5O_{20}$ (1740.18): calcd. C 37.96, H 6.48, Mo 33.08, N 4.03; found C 37.67, H 6.68, Mo 32.92, N 3.89. UV/Vis (MeCN): λ_{max} (log ε) = 428 (4.16), 338 (sh, 3.86), 312 nm (3.94). IR (KBr): $\tilde{\nu}_{max}$ = 1701 (m), 1592 (s) [ν(C=O)], 966 (m), 943 (s) [ν(Mo=O,Mo=N)], 789 (s), 767 (s) cm^{-1} [ν(MoOMo)].

CAD4 Enraf−Nonius or a Kappa-CCD Bruker-AXS diffractometer with use of graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Crystals were mounted on glass fibres and sealed with an epoxy cement. Lattice parameters and the orientation matrix were obtained from a least-squares fit of 25 automatically centred reflections in the range 15−15.2° for **10** (230 reflections between 4 and 21° for **13**). Intensities were corrected for Lorentz and polarization effects. An empirical absorption correction was applied.[39] Only the reflections with $I > 3\sigma(I)$ were retained for calculations. Data processing was performed with the aid of the CRYSTALS program.[40] The structures were solved by direct methods[41] and subsequent Fourier synthesis. All atoms were refined anisotropically, except for one of the three tetrabutylammonium cations which was poorly defined in both structures. Hydrogen atoms were not included in the refinements. Neutral-atom scattering factors were used with anomalous dispersion corrections applied.[42] Molecular structures were drawn with the program CAMERON.[43] CCDC-204770 (**10**) and -204771 (**13**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

Remote Rotamer Control: The Effect of a 4-*tert*-Butyl Group on the Coordination Chemistry of Tp^R Ligands

Arnold L. Rheingold,[a] Louise M. Liable-Sands,[a] James A. Golan,[a] and Swiatoslaw Trofimenko*[a]

Keywords: Scorpionates / Cobalt / Rotamer control / Borates / N ligands

Three novel homoscorpionate ligands containing a *tert*-butyl group in the 4-position have been synthesized: hydrotris(4-*tert*-butylpyrazol-1-yl)borate (Tp^{4tBu}), hydrotris(4-*tert*-butyl-3-*p*-tolylpyrazol-1-yl)borate ($Tp^{Tol,4tBu}$), and hydrotris(4-*tert*-butyl-3-isopropylpyrazol-1-yl)borate ($Tp^{iPr,4tBu}$). The 4-*tert*-butyl group does not alter the coordination chemistry of the first two ligands, relative to their 4-H analogues, however, the coordination chemistry of the third ligand is dramatically changed, making it a "tetrahedral enforcer". The complexes $Co[Tp^{4tBu}][Tp^{Np}]$ (**1**), $Tl[Tp^{Tol,4tBu}]$ (**2**), $Rh[Tp^{Tol,4tBu}](CO)_2$ (**3**), $Co[Tp^{iPr,4tBu}]Cl$ (**4**), $Co[Tp^{iPr,4tBu}]N_3$ (**5**) and $Co[Tp^{iPr,4tBu}]NCS$ (**6**) have been structurally characterized.

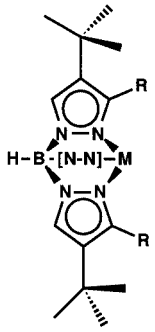
Introduction

Many of the reported highlights of homoscorpionate [hydrotris(pyrazol-1-yl)borate] coordination chemistry were associated with the use of Tp^R ligands containing a specific R substituent in the 3-position.[1] This defined and restricted the size and geometry of the hydrophobic pocket surrounding the coordinated metal atom. In addition to the size of the 3-substituent, it was also important to exert some control over the orientation of asymmetric substituents with regard to the pyrazolyl plane. These substituents included planar rings, such as a phenyl or substituted phenyl, or asymmetric aliphatic groups, such as isopropyl or cycloalkyl (cyclopropyl,[2] cyclobutyl,[3] cyclopentyl,[2] and cyclohexyl[4]), which could exist as different rotamers. In the case of phenyl, its coplanarity with the pyrazolyl ring was approached by means of an ethylene tether,[5] and achieved by means of an ethyne,[6] or methylene tether.[5] Conversely, approximate orthogonality of the phenyl ring to the pyrazolyl plane resulted from placing 2,6-dimethyl substituents on the phenyl group, as in Tp^{Ms},[7] or fusing two benzo rings in the 2,3- and 5,6-positions, as in Tp^{Ant}.[8] Since the last two methods of restricting the rotational freedom of the phenyl ring also altered its nature, by converting a phenyl into a mesityl or a 9-anthryl substituent, we sought to investigate the restriction of rotation of the 3-R group through "remote control", by placing a *tert*-butyl group in the 4-position of the Tp^R ligand.

To this end we have synthesized ligands of the general type $Tp^{R,4tBu}$ with R = isopropyl or *p*-tolyl, and also the ligand Tp^{4tBu}, where R = H. Some aspects of their coordination chemistry were studied, and compared with the behavior of Tp^x analogues containing either H or Br in the 4-position. Although a number of homoscorpionate ligands have been described containing 4-substituents (halide, linear alkyl groups, phenyl), none possess the steric bulk of a *tert*-butyl group.[1]



-[N-N]- is the third, hidden, 3-R-4-(*tert*-butyl)pyrazolyl ring

R = H, isopropyl, *p*-tolyl

Results and Discussion

The new ligands Tp^{4tBu}, $Tp^{Tol,4tBu}$, and $Tp^{iPr,4tBu}$ were synthesized by reaction of KBH_4 with an excess of the appropriate molten pyrazole. They were isolated, purified, and characterized as their respective Tl salts.[9]

The ligand with R = H (Tp^{4tBu}) was sterically unhindered around the 3-position, as in the parent ligand Tp. It was structurally characterized as part of the heteroleptic complex $Co[Tp^{4tBu}][Tp^{Np}]$ (**1**) by NMR spectroscopy and by X-ray crystallography (Figure 1). The Co−N bonds of the Tp^{4tBu} ligand are shorter than those of Tp^{Np} (average

[a] Department of Chemistry and Biochemistry, University of Delaware,
Newark, DE 19716, USA

bond lengths 2.13 and 2.17 Å, respectively), consistent with the unsubstituted 3-position. In the structure of Co[Tp^{4tBu}][Tp^{Np}], unidirectional sideways twisting of the neopentyl groups around the B−Co axis can be seen. This was also observed in other structurally characterized Tp^{Np} derivatives.[10] Furthermore, the paramagnetic NMR spectrum of **1** closely resembles that of the known analogue Co[Tp][Tp^{Np}][11] with each proton type uniquely defined. However, the signal in the 40−50 ppm range assigned to the 4-H proton is absent, and a new signal for the *tert*-butyl group is prominent at $\delta = -6.1$ ppm. As expected, Tp^{4tBu} forms stable octahedral M[Tp^{4tBu}]$_2$ complexes and labile tetrahedral M[Tp^{4tBu}]X complexes, which are unstable with respect to the octahedral species.

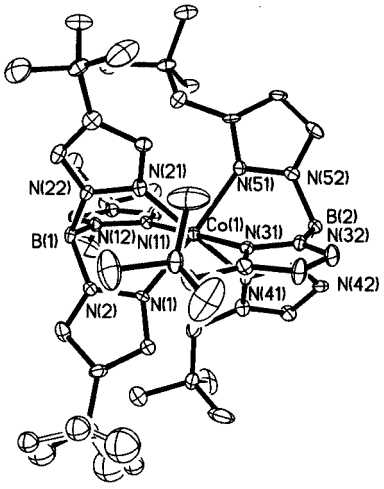


Figure 1. ORTEP plot of the structure of Co[Tp^{4tBu}][Tp^{Np}] (**1**); selected bond lengths [Å] and angles [°]: Co−N(1) 2.128(6), Co−N(11) 2.129(7), Co−N(21) 2.131(7), Co−N(31) 2.163(7), Co−N(41) 2.164(7), Co−N(1) 2.175(7); N(1)−Co−N(11) 84.8(3), N(1)−Co−N(21) 84.6(3), N(21)−Co−N(11) 87.1(3), N(31)−Co−N(41) 86.9(3), N(31)−Co−N(51) 87.4(3), N(41)−Co−N(51) 87.7(3)

Reaction of Tl[Tp^{4tBu}] with [Pd(η^3-methallyl)Cl]$_2$ yielded the stable complex Pd[Tp^{4tBu}][η^3-methallyl]. The NMR spectrum of this compound shows only one type of 3-(*tert*-butyl)pyrazolyl group, which is consistent with the rapid exchange of the coordinated and uncoordinated pyrazolyl groups, as was observed earlier in similar Pd[Tp^x][η^3-methallyl] complexes. In short, [Tp^{4tBu}] behaves similarly to the parent ligand Tp.

The ligand [Tp^{Tol,4tBu}]$^-$ was synthesized by reaction of KBH_4 with molten 4-(*tert*-butyl)-3-(*p*-tolyl)pyrazole, and it was characterized as Tl[Tp^{Tol,4tBu}] (**2**) by NMR spectroscopy and X-ray crystallography (Figure 2). The twist angles of the tolyl group with respect to the pyrazolyl plane are 101, 102, and 121°, respectively. The deviation from orthogonality of the pyrazolyl and tolyl molecular planes is, on average, 18°. Unlike the closely related Tl[Tp^{Tol}],[12] which forms a head-to-head dimer in the crystal, Tl[Tp^{Tol,4tBu}] is monomeric. The Tl−N distances are the same for both compounds (2.58 Å), and fall within the range for Tl[Tp^x] compounds (2.50−2.73 Å).[13] However, in Tl[Tp^{Tol,4tBu}], the N−Tl−N angles are smaller than those in Tl[Tp^{Tol}] (average angles 74° and approximately 77°, respectively). In other Tl[Tp^x] compounds, such angles range from 65.3 to 79.4°.[13]

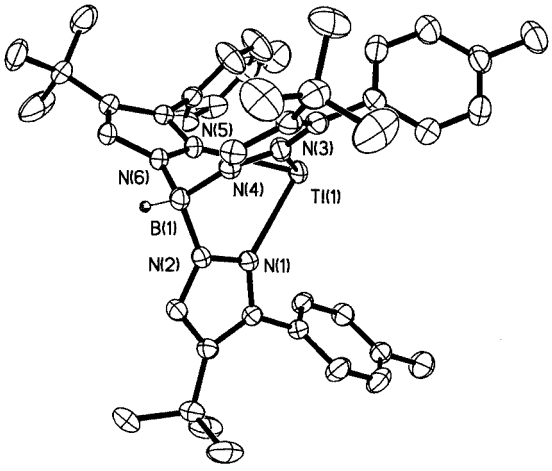

Figure 2. ORTEP plot of the structure of Tl[Tp^{Tol,4tBu}] (**2**); selected bond lengths [Å] and angles [°]: Tl−N(1) 2.580(2), Tl−N(3) 2.550(3), Tl−N(5) 2.560(2); N(1)−Tl−N(3) 73.55(8), N(5)−Tl−N(3) 74.15(8), N(1)−Tl−N(5) 73.58(8)

The reaction of Tl[Tp^{Tol,4tBu}] with anhydrous $CoCl_2$ in chloroform yielded the tetrahedral complex Co[Tp^{Tol,4tBu}]Cl, which could be used to synthesize mixed complexes. For instance, its reaction with Tl[Tp] proceeded easily, producing the heteroleptic species Co[Tp^{Tol,4tBu}][Tp]. The proton NMR spectrum of Co[Tp^{Tol,4tBu}][Tp] is in agreement with a structure that has not undergone any rearrangement. Assignment of the NMR resonances was aided by comparison with the related complex Co[Tp^{Tol}][Tp], which was synthesized from Co[Tp^{Tol}]Cl and Tl[Tp]. The *ortho*- and *meta*-protons of the tolyl substituent in both complexes appear as sharp resonances, rather than as two separate peaks or as broad resonances. This indicates a sufficient degree of oscillation of the tolyl group around the C-3 bond (despite the presence of the 4-*tert*-butyl substituent) to render them spectroscopically equivalent on the NMR timescale.

The complex Rh[Tp^{Tol,4tBu}](CO)$_2$ (**3**) was prepared by bubbling CO into a solution of the Rh[Tp^{Tol,4tBu}](COD) intermediate prepared in situ from **2** and the Rh(COD)Cl dimer. The IR spectrum of this compound contains two sets of carbonyl peaks: 2080, 2059, 2015, and 1980 cm^{-1}, with the BH stretching frequency at 2443 cm^{-1}. The presence of four CO peaks suggests that the compound contains both κ^3 and κ^2 species, which is not unusual for complexes of this general type.[14] The structure of **3** was determined by X-ray crystallography (Figure 3). The Rh center is five-coordinate, with one long (2.43 Å) and two short (2.12 and 2.13 Å) Rh−N bonds. This type of five-coordination leads to the lowest energy structure for Rh[Tp^x](CO)$_2$ complexes, as has been predicted by Webster and Hall on the basis of density functional calculations for the various structures that a Rh[Tp^x](CO)$_2$ species can adopt.[14] The deviation from orthogonality of the tolyl and pyrazolyl planes varied: 26 and 25° for the pyrazolyl arms containing the two short

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Rh−N bonds, and 10° for the arm with the long axial Rh−N bond. The N−Rh−N angles average 83.4°.

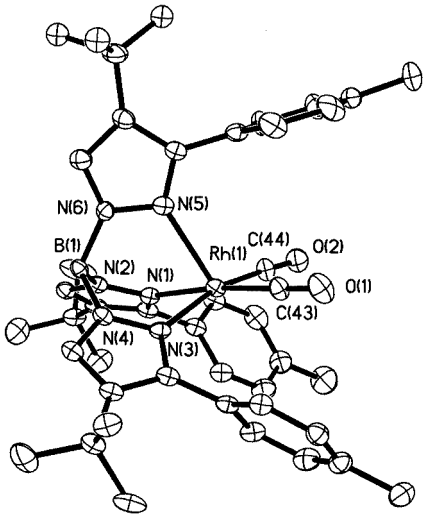

Figure 3. ORTEP plot of the structure of $Rh[Tp^{Tol,4tBu}](CO)_2$ (**3**); selected bond lengths [Å] and angles [°]: Rh−N(1) 2.116.4(4), Rh−N(3) 2.132.4(4), Rh−N(5) 2.426.4(4), Rh−C(44) 1.851(5), Rh−C(43) 1.856(5); N(1)−Rh−N(3) 85.05(13), N(1)−Rh−N(5) 84.02(13), N(5)−Rh−N(3) 81.34(13), C(43)−Rh−C(44) 85.4(2)

By comparison, the related complex $Rh[Tp^{Br3}](CO)_2$ shows only two CO bands in its IR spectrum: $\tilde{\nu}$ = 2080 and 2012 cm^{-1}, each with a hint of a shoulder at higher frequency. This compound also has one long (2.53 Å) and two short (2.12 and 2.12 Å) Rh−N bonds.[15] The somewhat longer Rh−N bond might reflect the lower nucleophilicity of the tribromopyrazolyl arm, and would be consonant with the rather high frequency of the B−H stretch, which is at 2585 cm^{-1}. In other structurally characterized $Rh[Tp^x](CO)_2$ complexes, the axial Rh−N bonds are longer, ranging from 2.55 to 2.64 Å.[14] From all the above data we can conclude that while the *tert*-butyl group in the 4-position does not permit free rotation of the 3-aryl substituent, neither does it enforce orthogonality between the pyrazolyl and tolyl planes. The 4-*tert*-butyl group allows for sufficient oscillation of the tolyl group around the C-3 bond, so that the tolyl substituent can deviate considerably from orthogonality relative to the pyrazolyl plane (we have examples which deviate by up to 31°) in order to accommodate other ligands attached to the metal atom. Thus, the difference in steric hindrance between Tp^{Tol} and $Tp^{Tol,4tBu}$ becomes rather insignificant.

While the coordination behavior of $[Tp^{Tol,4tBu}]^-$ is still fairly similar to that of $[Tp^{Tol}]^-$, major spectroscopic differences and differences in chemical reactivity can be observed between $[Tp^{iPr,4tBu}]^-$ and its closest steric analogue, $[Tp^{iPr,4Br}]^-$. The ^1H NMR spectrum of $Tl[Tp^{iPr,4Br}]$ exhibits a sharp doublet and septuplet,[11] assigned to the isopropyl groups. However, in the ^1H NMR spectrum of $Tl[Tp^{iPr,4tBu}]$, the resonances assigned to the methyl groups appear as a small broad hump at δ = 1.4 ppm. The signal for the tertiary hydrogen atom is not visible, and can only be discerned through integration in the δ = 3.1−3.5 ppm range. The difference was even more dramatic in the ^{13}C NMR spectrum. In the spectrum of $Tl[Tp^{iPr,4Br}]$, the resonance assigned to the isopropyl methyl group is only slightly broadened. However, it is split into a doublet in the spectrum of $Tl[Tp^{iPr,4tBu}]$. The value of J = 218 Hz, is the largest known ^{13}C-^{205}Tl coupling observed in $Tl[Tp^x]$ complexes. It significantly exceeds those found in $Tl[Tp^{tBu,iPr}]$ (J = 167 Hz),[16] $Tl[Tp^{tBu}]$ (J = 171 Hz),[17] $Tl[Tp^{tBu,Tn}]$ (J = 183 Hz),[11] and $Tl[Tp^{tBu,Me}]$ (J = 197 Hz).[18]

In terms of their coordination chemistry, $[Tp^{iPr,4tBu}]$ forms different complexes from those of $[Tp^{iPr,4Br}]$,[19] and resembles those of $[Tp^{tBu}]$.[20] Thus, stable compounds of the type $M[Tp^{iPr,4tBu}]X$, where X = halide or pseudohalide, are readily prepared. They do not add solvent molecules, as was observed in the case of the $M[Tp^{iPr,4Br}]X$ analogues, which readily form five-coordinate complexes with small donor molecules, such as methanol or THF (although on air-drying, the solvent is gradually lost). Thus, one could regard $[Tp^{iPr,4tBu}]$ as a bona fide "tetrahedral enforcer", no less so than $[Tp^{tBu}]$. The complex $Co[Tp^{iPr,4tBu}]Cl$ (**4**) was structurally characterized (Figure 4).

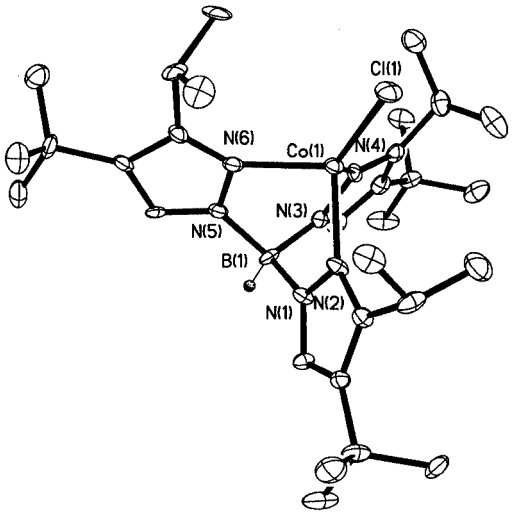

Figure 4. ORTEP plot of the structure of $Co[Tp^{iPr,4tBu}]Cl$ (**4**); selected bond lengths [Å] and angles [°]: Co−N(2) 2.040(3), Co−N(4) 2.024(6), Co−N(6) 2.058(7); N(2)−Co−N(4) 95.4(3), N(2)−Co−N(6) 94.2(3), N(4)−Co−N(6) 95.74(11)

Another distinguishing feature of $[Tp^{iPr,4tBu}]^-$, as compared with $[Tp^{iPr,4Br}]$, is the fact that while reaction of $Co[Tp^{iPr,4Br}]X$ with Tl[Tp] or Tl[Tp*] readily yields the heteroleptic complexes $Co[Tp^{iPr,4Br}][Tp]$ and $Co[Tp^{iPr,4Br}][Tp^*]$, respectively,[21] **4** does not undergo such reactions. For instance, stirring a solution of **4** with the least-hindered homoscorpionate ligand, Tl[Tp], for 26 h, did not produce the heteroleptic complex, but only a very small amount of $Co[Tp]_2$. This type of behavior was also observed for $Co[Tp^{tBu}]Cl$. Obviously, the 4-*tert*-butyl group does not permit rotation of the isopropyl substituent so as to direct the two methyl groups away from the coordinated metal atom and toward the 4-position of the pyrazolyl ring, which is a precondition for the formation of heteroleptic species

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

M[Tp$^{i\mathrm{Pr,4Br}}$][Tp^{x}]. On the contrary, it locks the isopropyl substituent, so that it straddles the pyrazolyl plane with both methyl groups forking towards the coordinated metal atom. Such rotameric disposition of the isopropyl methyl groups has been established only for a few structurally characterized tetrahedral compounds of the type M[Tp$^{i\mathrm{Pr,4Br}}$]X.[19,22] However, the rotameric disposition of a 3-isopropyl group with the two methyl groups directed away from the coordinated metal atom is ubiquitous in all heteroleptic complexes M[Tp$^{i\mathrm{Pr,4Br}}$][L],[21,23] as well as in other homoscorpionate complexes containing a 3-*i*Pr substituent, such as those of Tp$^{i\mathrm{Pr,Me}}$,[24] and of Tp$^{i\mathrm{Pr2}}$.[25]

Despite the failure to form the heteroleptic complex Co[Tp$^{i\mathrm{Pr,4}t\mathrm{Bu}}$][Tp] by reaction of Co[Tp$^{i\mathrm{Pr,4}t\mathrm{Bu}}$]Cl with [Tp]$^-$, displacement of the chloride ion by other simple monodentate ions is feasible, as was demonstrated by the heterogeneous reaction of **4** with solid NaN_3 in ethyl acetate, which resulted in the formation of Co[Tp$^{i\mathrm{Pr,4}t\mathrm{Bu}}$]$N_3$ (**5**) as the only product, in good yield. Its structure, as well as that of the related complex Co[Tp$^{i\mathrm{Pr,4}t\mathrm{Bu}}$]NCS (**6**), which was prepared by the heterogeneous reaction of Tl[Tp$^{i\mathrm{Pr,4}t\mathrm{Bu}}$] and $Co(NCS)_2$, was determined by X-ray crystallography (Figures 5 and 6, respectively).

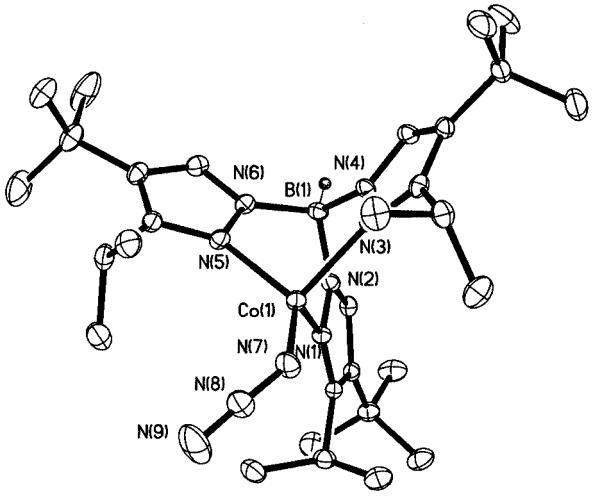

Figure 5. ORTEP plot of the structure of Co[Tp$^{i\mathrm{Pr,4}t\mathrm{Bu}}$]$N_3$ (**5**); selected bond lengths [Å] and angles [°]: Co−N(1) 2.011(2), Co−N(3) 2.044(2), Co−N(5) 2.032(2), Co−N(7) 1.911(2); N(1)−Co−N(3) 96.38(9), N(1)−Co−N(5) 93.82(9), N(5)−Co−N(3) 94.84(9), N(1)−Co−N(7) 121.61(10), N(3)−Co−N(7) 117.81(10), N(5)−Co−N(7) 125.47(10)

If one compares the Co−N bond lengths and N−Co−N angles in three related and structurally characterized complexes, Co[Tp$^{i\mathrm{Pr,4Br}}$]NCS, Co[Tp*t*Bu]NCS, and **6**, we see that **6** has the longest Co−N bond (average bond length 2.029 Å), Co[Tp$^{t\mathrm{Bu}}$]NCS has the shortest (2.019 Å), and Co[Tp$^{i\mathrm{Pr,4Br}}$]NCS has a bond length of intermediate value (2.024 Å). Compound **6** also has the widest average N−Co−N angle (95.7°), followed by Co[Tp$^{t\mathrm{Bu}}$]NCS (95.4°) and Co[Tp$^{i\mathrm{Pr,4Br}}$]NCS (95.2°).

Comparing the average Co−N bond lengths and N−Co−N angles of complex **4** with those of Co[Tp$^{i\mathrm{Pr,4Br}}$]Cl and Co[Tp$^{t\mathrm{Bu}}$]Cl, we find that the above-

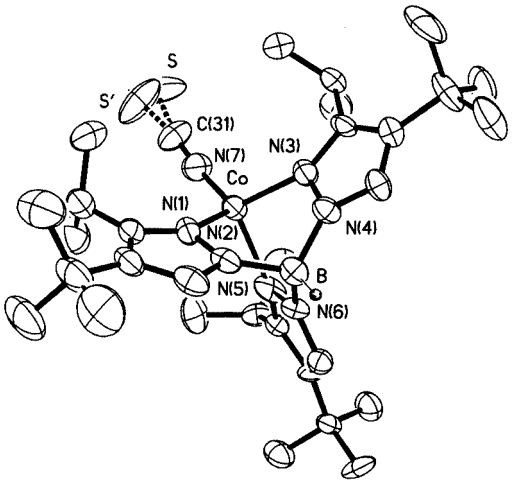

Figure 6. ORTEP plot of the structure of Co[Tp$^{i\mathrm{Pr,4}t\mathrm{Bu}}$]NCS (**6**); selected bond lengths [Å] and angles [°]: Co−N(1) 1.984(8), Co−N(3) 2.021(7), Co−N(5) 2.081(9), Co−N(7) 1.898(10); N(1)−Co−N(3) 97.0(3), N(1)−Co−N(5) 94.4(3), N(5)−Co−N(3) 95.6(3)

mentioned bond lengths and angles in **4** are closer to those of Co[Tp$^{t\mathrm{Bu}}$]C, than to those of Co[Tp$^{i\mathrm{Pr,4Br}}$]Cl. In **4**, the two values are 2.033(5) Å and 95.1°, in Co[Tp$^{t\mathrm{Bu}}$]Cl they are 2.038 Å and 95.1°,[26] while in Co[Tp$^{i\mathrm{Pr,4Br}}$]Cl they are 2.039(6) Å and 94.4°, respectively.[22] In the related complex **5**, these values are 2.029 Å and 95.0°, respectively.

Conclusion

We have prepared several Tp^{x} ligands of the general type [Tp$^{\mathrm{R,4}t\mathrm{Bu}}$]$^-$ where R = H, isopropyl, or *p*-tolyl, and found that the presence of the 4-*tert*-butyl group strongly blocks the rotational freedom of a 3-isopropyl group. Therefore, the 3-isopropyl group behaves like a 3-*tert*-butyl group (a "tetrahedral enforcer") with a fixed rotameric conformation in which the two methyl groups are forked towards the coordinated metal atom. This significantly changes the coordination chemistry of [Tp$^{i\mathrm{Pr,4}t\mathrm{Bu}}$]$^-$, relative to all other Tp^{x} ligands containing 3-isopropyl substituents. On the other hand, the effect of a 4-*tert*-butyl group on the 3-*p*-tolyl substituent in [Tp$^{\mathrm{Tol,4}t\mathrm{Bu}}$] is less pronounced, since the 4-*tert*-butyl substituent still permits substantial latitude for oscillation, if not free rotation, of the 3-tolyl group. Thus, the formation of the heteroleptic complex Co[Tp$^{\mathrm{Tol,4}t\mathrm{Bu}}$][Tp] was as easy as that of Co[Tp$^{\mathrm{Tol}}$][Tp]. When 3-R = H, [Tp$^{4t\mathrm{Bu}}$]$^-$ behaves like the parent ligand [Tp]$^-$, except that the melting points of its derivatives are higher, and its NMR spectrum is simpler.

Experimental Section

General: All chemicals were commercial reagent grade and were used as received. 4-(*tert*-Butyl)-3-isopropylpyrazole and 4-*tert*-butyl-3-(*p*-tolyl)pyrazole were prepared according to a literature procedure,[27] as was Co[Tp$^{\mathrm{Np}}$]Cl.[10] [Pd(η^3-methallyl)Cl]$_2$ was pur-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

chased from Strem. Elemental analyses were done by Microanalysis, Inc., Wilmington, DE. Infrared spectra were obtained as Nujol mulls or as KBr pellets with a Perkin−Elmer 1625 FTIR infrared spectrophotometer, using 16 scans. ^{1}H NMR spectra were obtained with a Nicolet NT360WB spectrometer. The compounds were studied under typical conditions, with 16 K data points, a sweep width of 3000−4000 Hz, 90° pulse angles, and a recycle time of 4−5 s. ^{13}C NMR: pulse width, 9.00 μs; acq. time 819.20 ns; recycle time 1.0 s; number of acq. 8192; frequency 75.43 MHz; spec. width 20000 H_3.

4-*tert*-Butylpyrazole: A mixture of pyrazole (136 g, 2 mol) and *tert*-butyl chloride (279 g, 3 mol) was heated for 6 h at 220 °C in an autoclave. After cooling, the autoclave contents were stirred in a mixture of alkaline ice water, and the products were extracted with chloroform. The extracts were filtered through alumina, stripped, and distilled under atmospheric pressure. The fraction boiling in the 176−196 °C range was obtained in 28 g yield. It was (by NMR) 40% pyrazole and 60% 1,4-di(*tert*-butyl)pyrazole. The residue obtained was almost pure 4-*tert*-butylpyrazole (90 g, 36%, by NMR spectroscopy), contaminated only by a small amount of 1,4-bis(*tert*-butyl)pyrazole. The product was purified by recrystallization the 176−196 °C range was obtained in 28 g yield. It was (by NMR) δ = 11.2 (s, broad, 1 H, NH), 7.44 (s, 2 H, H-3,5), 1.27 (s, 9 H, *t*Bu) ppm. The literature reports 4-*tert*-butylpyrazole to be a yellowish oil.[28]

K[Tp^{4tBu}]: A mixture of 4-*tert*-butylpyrazole [50 g, 0.40 mol, contaminated with traces of the innocuous 1,4-bis(*tert*-butyl)pyrazole] and KBH_4 (5.4 g, 0.10 mol) was stirred and heated gradually without any solvent. Hydrogen began to evolve at 140 °C, and evolution of the theoretical 7.5 L was completed at 220 °C. Excess 4-*tert*-butylpyrazole, and traces of 1,4-bis(*tert*-butyl)pyrazole, were removed by distillation under vacuum. The molten product was cooled, transferred to a 500-mL Erlenmeyer flask, and boiled with 300 mL of octane. The slurry was cooled, the solid was filtered off, and washed with hexane, producing the crude potassium salt in a 90% (38 g) yield. IR: $\tilde{\nu}$ = 2390 (BH, broad) cm^{-1}.

Tl[Tp^{4tBu}]: All of the above crude K[Tp^{4tBu}] was converted into Tl[Tp^{4tBu}] by dissolving it in a minimum amount of THF, and stirring the resulting solution with an excess of aqueous $TlNO_3$ solution for 1 h. Thereafter, 1 L of water was added, along with 500 mL of chloroform. The organic layer was separated, and passed through a layer of alumina. Evaporation of the solvent gave the crude product in an 86% (45 g) yield. The product was purified by recrystallization from undecane. The fine needles sintered from 280 °C, and melted and decomposed at 282−283 °C. IR: $\tilde{\nu}$ = 2450 (BH, broad) cm^{-1}. NMR: δ = 7.54 (s, 3 H, 5-H), 7.42 (s, 3 H, 3-H), 1.24 (s, 27 H, *t*Bu) ppm; BH (1 H) was detected by integration in the δ = 3.4−5.4 ppm range. ^{13}C NMR: δ = 29.6 (*C*Me_3), 32.3 (C*Me_3*), 131.4 (C-4), 132.3 (C-5), 136.4 (C-3) ppm. $C_{21}H_{37}BN_6Tl$ (588.76): calcd. C 43.1, H 5.81, N 14.4; found C 43.0, H 6.10, N 14.2.

Pd[Tp^{4tBu}][η^3-methallyl]: A mixture of Tl[Tp^{4tBu}] (1.2 g, 2 mmol) and the Pd(η^3-methallyl)Cl dimer (0.76 g, 2 mmol) was stirred in 30 mL of chloroform for 1 h. The slurry was filtered, and the filtrate concentrated to give a white solid, which was recrystallized from toluene/heptane. M.p. 154−156 °C (dec.). IR: $\tilde{\nu}$ = 2462 (BH) cm^{-1}. ^{1}H NMR: δ = 7.39 (s, 3 H, 3-H), 7.35 (s, 3 H, 5-H), 3.66 (s, 2 H, *syn*), 2 87 (2 H, *anti*), 2.09 (s, 3 H, Me), 1.21 (s, 27 H, *t*Bu) ppm. $C_{25}H_{41}BN_6Pd$ (542.88): calcd. C 55.4, H 7.56, N 15.5; found 55.6, H 7.72, N 15.3.

Co[Tp^{4tBu}][Tp^{Np}] (1): A mixture of Tl[Tp^{4tBu}] (1.2 g, 2 mmol) and Co[Tp^{Np}]Cl (1.1 g, 2 mmol) was stirred in 150 mL of dichloromethane. Within 10 min, the blue color changed to a pale yellow. The slurry was filtered through Celite, yielding a bright yellow solution, which on evaporation yielded **1** (1.3 g, 74%) as a pale yellow solid. It was recrystallized from undecane. M.p. 295−296 °C (with darkening and dec.). IR: $\tilde{\nu}$ = 2442 (BH, Tp^{Np}) and 2449 (BH, Tp^{4tBu}) cm^{-1}. ^{1}H NMR: δ = 115.6 and 113 (1 H each, BH, BH′) 93.2 and 82.2 (3 H each, 5-H and 5′-H), 44.7 (3 H, 4-H), −6.26 (27 H, 4-*t*Bu), −21.3 (27 H, neopentyl *t*Bu), −100.7 (3 H, 3-H), −103.7 (6 H, CH_2) ppm. $C_{45}H_{74}B_2CoN_{12}$ (863.72): calcd. C 62.6, H 8.57, N 19.5; found C 62.7, H 8.69, N 19.2.

Tl[$Tp^{Tol,4tBu}$] (2): A mixture of 4-(*tert*-butyl)-3-tolylpyrazole (8.9 g, 42 mmol) and KBH_4 (0.56 g, 10 mmol) was heated in a test tube until the borohydride could not be seen anymore, and the initially vigorous evolution of hydrogen ceased. The product was cooled, dissolved in DMF, and stirred with excess aqueous $TlNO_3$. The product was extracted with dichloromethane, the extracts were washed three times with water, and were passed through a bed of alumina. Concentration of the filtrate gave **2** as a fibrous white solid, which was washed with methanol to remove unchanged 4-(*tert*-butyl)-3-tolylpyrazole. **2** was obtained in a 70% (6.5 g) yield. It was recrystallized from octane. M.p. 222−224 °C. IR: $\tilde{\nu}$ = 2435, 2472 sh (BH) cm^{-1}. ^{1}H NMR: δ = 7.53 (s, 1 H, 5-H), 7.23 (d, 2 H, tolyl A_2B_2), 7.11 (d, 2 H, tolyl A_2B_2), 2.34 (s, 3 H, Me) 1.63 (s, 9 H, *t*Bu) ppm. $C_{42}H_{52}BN_6Tl$ (856.11): calcd. C 59.0, H 6.08, N 9.82; found C 59.2, H 6.17, N 9.67.

Co[$Tp^{Tol,4tBu}$]Cl: A sample of **2** (1.7 g, 2.0 mmol) was stirred in 50 mL of chloroform with excess anhydrous $CoCl_2$. After 6 h, the slurry was filtered, and the filtrate was concentrated, yielding Co[$Tp^{Tol,4tBu}$]Cl (1.2 g, 82%), which was purified by recrystallization from a toluene/octane mixture; m.p. dec. > 280 °C. IR: $\tilde{\nu}$ = 2466 (BH) cm^{-1}. $C_{42}H_{52}BClCoN_6$ (746.11): calcd. C 67.6, H 6.97, N 11.3; found C 67.9, H 7.18, N 11.1.

Co[$Tp^{Tol,4tBu}$]NCS: This complex was prepared as above; however, $Co(NCS)_2$ was used instead of $CoCl_2$. It was obtained in a 78% yield. M.p. gradual dec. > 240 °C. IR: $\tilde{\nu}$ = 2476 (BH), 2068 (NCS) cm^{-1}. $C_{43}H_{52}BCoN_7S$ (768.75): calcd. C 67.2, H 6.77, N 12.8; found C 67.6, H 6.89, N 12.6.

Co[$Tp^{Tol,4tBu}$][Tp]: A mixture of Co[$Tp^{Tol,4tBu}$]Cl (0.75 g, 1.0 mmol) and Tl[Tp] (0.42 g, 1.0 mmol) was stirred in 50 mL of chloroform for 6 h. The slurry was filtered, and the filtrate was chromatographed on alumina. On concentration of the yellow-orange eluent, yellowish-orange crystals (0.51 g, 68%) were obtained. M.p. gradual dec. > 270 °C. IR: $\tilde{\nu}$ = 2452 (BH) cm^{-1}. NMR: δ = 114 (1 H, BH), 112 (1 H, BH′), 90.1 (3 H, 5-H), 80.9 (3 H, 5′-H), −3.15 (27 H, *t*Bu), −5.9 (9 H, Me), −9.2 (6 H, *m*-H), −49.1 (6 H, *o*-H), −103.4 (3 H, 3-H H) ppm. $C_{51}H_{62}B_2CoN_{12}$ (923.63): calcd. C 66.3, H 6.72, N 18.2; found C66.5, H 6.79, N 17.9.

Co[Tp^{Tol}][Tp]: This complex was prepared as above from Co[Tp^{Tol}]Cl (0.58 g, 1 mmol) and Tl[Tp] (0.42 g, 1 mmol), in an 82% (0.62 g) yield. M.p. sintered from 265 °C, gradual dec. > 275 °C. IR: $\tilde{\nu}$ = 2470 (BH) cm^{-1}. NMR: δ = 113 (1 H, BH), 112 (1 H, BH′), 89.4 (3 H, 5-H), 77.3 (3 H, 5′-H), 44.2 (3 H, 4-H), 41.8 (3 H, 4′-H), −1.88 (9 H, Me), −2.18 (6 H, *m*-H), −55.4 (6 H, *o*-H), −99.1 (3 H, 3-H) ppm. $C_{39}H_{38}B_2CoN_{12}$ (755.36): calcd. C 62.0, H 5.03, N 22.3; found C 62.1, H 5.15, N 22.1.

Rh[$Tp^{Tol,4tBu}$]$(CO)_2$ (3): A mixture of **2** (0.86 g, 1 mmol) and the RhCl(COD) dimer (0.30 g, 1 mmol) was stirred in chloroform at room temperature for 2 h. The slurry, containing precipitated TlCl was stirred further with a stream of CO bubbling in for 1 h, and was then filtered through a pad of Celite. The filtrate was concen-

trated and the product, obtained in a 68% (0.55 g) yield, was recrystallized from toluene/heptane. M.p. 233−235 °C (dec.). IR: $\tilde{\nu}$ = 2443 (BH); 2028, 2059, 2015, 1980 (CO) cm^{-1}. ^1H NMR: slightly broadened resonances at δ = 7.6 (1 H, 5-H), 7.3 and 7.2 (2 H each, tolyl A_2B_2 pattern), 2.4 (3 H, Me), 1.2 (9 H, *t*Bu) ppm. $C_{44}H_{52}BN_6O_2Rh$ (810.66): calcd. C 65.2, H 6.42, N 10.4; found C 65.5, H 6.57, N 10.2.

Tl[Tp^{iPr,4tBu}]: A mixture of 4-(*tert*-butyl)-3-isopropylpyrazole (24 g, 130 mmol) and KBH_4 (2.0 g, 36 mmol) was heated to 220 °C, until the theoretical amount of hydrogen evolved. Excess 4-(*tert*-butyl)-3-isopropylpyrazole was sublimed out at 220 °C/1.5 Torr. The unsublimed crude K[Tp^{iPr,4tBu}] had $\tilde{\nu}$ = 2460 (BH) cm^{-1}, and it was converted into Tl[Tp^{iPr,4tBu}] as described for **2**. M.p. 222−224 °C. IR: $\tilde{\nu}$ = 2432 (BH) cm^{-1}. ^1H NMR: δ = 7.29 (s, 3 H, 5-H), 3.1−3.5 (very broad, 1 H, tertiary CH), 1.37 (broad hump, 18 H, isopropyl Me) and 1.26 (sharp s, 27 H, *t*Bu) ppm. ^{13}C NMR: δ = 26.1 (somewhat broad d, J = 218 Hz, CH*Me*$_2$), 27.5 (s, *C*HMe$_2$), 30.1 (sharp s, *C*Me$_3$), 31.7 (sharp s, C*Me*$_3$) 125.8 (broad s, C-5), 133.3 (very sharp s, C-4), 156.9 (broad s, C-3) ppm. $C_{30}H_{52}BN_6Tl$ (711.98): calcd. C 50.6, H 7.31, N 11.8; found 50.9, H 7.46, N 11.6%.

Co[Tp^{iPr,4tBu}]Cl (4): This complex was prepared by stirring Tl[Tp^{iPr,4tBu}] (2.8 g, 4 mmol) in dichloromethane with a large excess of anhydrous $CoCl_2$. After 3 h, the blue slurry was filtered, the filtrate was chromatographed on alumina, and the deep blue eluent was concentrated. The crude product, obtained in a 73% (1.8 g) yield, was recrystallized from octane, producing deep blue needles, which did not melt up to 304 °C. IR: $\tilde{\nu}$ = 2502 (BH) cm^{-1}. NMR: δ = 34.6 (3 H, 5-H), 23.9 (3 H, C*H*Me$_2$), 10.7 (18 H, CH*Me*$_2$), 4.3 (27 H, *t*Bu) and −21.4 (1 H, BH) ppm. $C_{30}H_{52}BClCoN_6$ (601.98): calcd. C 59.8, H 8.63, N 14.0; found C 60.0, H 8.78, N 13.7.

Co[Tp^{iPr,4tBu}]N$_3$(5): This compound was obtained when **4** (0.6 g, 1 mmol) was stirred overnight in ethyl acetate with a large excess of solid NaN_3. The slurry was filtered through Celite, and the solution was concentrated, producing dark blue **5** in an 83% (0.50 g) yield. It melted at 272−274 °C, and on further heating fumes could be seen and the blue product turned purple. IR: $\tilde{\nu}$ = 2493 (BH), 2081 (N_3) cm^{-1}. NMR: δ = 42.2 (3 H, 5-H), 22.4 (3 H, C*H*Me$_2$), 9.03 (18 H, CH*Me*$_2$), 3.60 (27 H, *t*Bu), −9.2 (1 H, BH) ppm. $C_{30}H_{52}BCoN_9$ (609.12): calcd. C 59.2, H 8.55, N 20.7; found C 59.5, H 8.67, N 20.4.

Co[Tp$^{iPr,4-tBu}$]NCS (6): This compound was prepared as in the case of **4**, instead, Tl[Tp^{iPr,4tBu}] (1.4 g, 2 mmol) and a large excess of $Co(NCS)_2$ was used. It was obtained in a 65% (0.81 g) yield, as a deep blue solid. M.p. 269−271 °C. IR: $\tilde{\nu}$ = 2490 (BH), 2054 (NCS) cm^{-1}. NMR: δ = 41.3 (3 H, 5-H), 26.2 (3 H, C*H*Me$_2$), 9.18 (18 H, CH*Me*$_2$), 3.53 (27 H, *t*Bu), −6.15 (1 H, BH) ppm. $C_{31}H_{52}BCoN_7S$ (625.06): calcd. C 59.6, H 8.33, N 15.7; found C 59.7, H 8.41, N 15.5.

Attempts to Prepare the Heteroleptic Complex Co[Tp^{iPr,4tBu}][Tp]: Stirring equimolar amounts of Co[Tp^{iPr,4tBu}]Cl and TpTl in dichloromethane for 26 h showed no signs of a reaction. The greenish-blue solution was chromatographed, yielding two fractions: a minor yellow, and a dominant blue one. The material from the yellow fraction was identified as Co[Tp]$_2$ by its characteristic IR spectrum, while the blue fraction was unchanged Co[Tp^{iPr,4tBu}]Cl. A similar result was obtained when Co[Tp^{tBu}]Cl was stirred with Tl[Tp].

X-ray Crystal Structure Determinations: Diffraction intensity data were collected with Siemens P4 (**6**), Siemens P4/CCD (**1**), and

Bruker Smart Apex CCD (**2**−**5**) diffractometers. Crystal data collections and refinement parameters are given in Table 1. The space groups for structures **1**−**5** were chosen based on systematic absences in the diffraction, and for **6**, based on intensity statistics. Structure **3** was solved using a Patterson function and the other structures were solved by direct methods, completed by subsequent Fourier syntheses and refined by full-matrix least-squares procedures on reflection intensities (F^2). SADABS absorption corrections were applied to all data [G. M. Sheldrick, *SADABS* (2.01), Bruker/Siemens Area Detector Adsorption Correction Program, Bruker AXS, Madison Wisconsin, USA, **1998**]. In all the structures, non-hydrogen atoms were refined with anisotropic displacement coefficients and the hydrogen atoms were treated as idealized contributions. In structure **1**, carbon atoms C5−C7 of the *tert*-butyl group were disordered over two positions with 50:50 occupation. Similar disorder was found for one of the *tert*-butyl groups in structure **3**, where the disorder atoms had occupation of 47:53. In structures **2** and **4**, the solvent molecules were quite disordered and were left as isotropic in the refinement. The solvent molecules (dichloromethane and acetonitrile) in structure **5** were quite disordered and were treated using the program SQUEEZE.[29] Correction of the X-ray data for **5** by SQUEEZE (249 electrons/cell) was close to the required value of (256 electrons/cell) for the mixed solvent. Structure **6** diffracted rather poorly, and the S atom was found to be disordered over two positions with 50:50 occupation. All other software and sources, scattering factors are contained in the SHELXTL (5.10) program package (G. M. Sheldrick, Bruker AXS, Madison, WI). CCDC-198497 (**1**), -198498 (**2**), -198499 (**3**), -198500 (**4**), -198501 (**5**), and -198502 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Pyrene-Bridged Bis(phenanthroline) Ligands and Their Dinuclear Ruthenium(II) Complexes

Latif Chouai,[a] Feiyue Wu,[a] Youngchan Jang,[a] and Randolph P. Thummel*[a]

Keywords: Ruthenium / Bridging ligands / Pyrene / Phenanthroline

The Friedländer condensation of 8-amino-7-quinolinecarbaldehyde with a series of four isomeric diacetylpyrenes provides the corresponding 1,3-, 1,6-, 1,8-, and 2,7-bis(2′-[1′,10′]phenanthrolinyl)pyrenes. These ligands, along with the tetrahydro analogue to the 2,7-pyrene-bridged isomer, have been treated with $[Ru([D_8]bpy)_2Cl_2]$, where $[D_8]$bpy = $[D_8]$2,2′-bipyridine, to afford the dinuclear Ru^{II} complexes, ^{1}H NMR and X-ray crystallographic analysis of which indicate that the bridging pyrene is layered between a $[D_8]$bpy auxiliary ligand coordinated to each metal atom. Although well situated for π–π interactions, little such effect is seen on the photophysical and electrochemical properties of these complexes.

Introduction

Polynuclear transition metal complexes are of considerable current interest due to their potential for metal−metal cooperativity, an important design aspect in constructing molecular devices.[1] A critical component in such polynuclear complexes is the bridging ligand, which typically consists of two or more metal chelation sites connected by an appropriate linker. The most common chelators are 2,2′-bipyridine (bpy), 1,10-phenanthroline (phen), 2,2′;6′,2"-terpyridine (tpy), or closely related derivatives. These binding sites have been connected by linkers designed to control both the distance between the metal centers and the electronic communication between the sites. Distance control can be effected by using rigid linkers of known dimensions.[2] Spatial control will also depend on the point of attachment of the linker to the bpy, phen, or tpy end groups.

To attain better electronic communication between linked metal centers, substantial attention has been paid to the conjugating ability of the linker. Linkers with one or more π-bonds are common, while the inclusion of a tetrahedral center such as an sp^3-carbon atom can serve as an insulating junction.[3] Conjugated π-systems as linkers pose further problems, the most important of which is the potential for orthogonality between any two adjacent π-links. Such an orthogonal junction can also behave as an insulator, as has been noted with polyene and polyphenylene linkers.[4] Polyalkynyl linkers seem to avoid the problem and have come into use.[5]

Our interest in pyrene as part of a ligand system is due to the promising symmetry and electronic structure of this polynuclear aromatic compound. Firstly, the pyrene nucleus has three twofold axes which allow some symmetry to be retained in various mono- and disubstituted derivatives. Secondly, the pyrene nucleus is electroactive, having an oxidation potential of +1.28 V and a reduction potential of −2.09 V.[6] Thirdly, pyrene has a strong chromophore that extends over the entire molecule. It also has a reasonable excited-state lifetime (650 ns) and shows a strong emission at 372 nm.[7] Pyrene fluorescence has led to its being utilized in various sensor applications where fluorescence quenching is a useful reporter characteristic.[8] Finally the large π-surface of pyrene gives it some organizational qualities. The π-stacking of two pyrene molecules is concentration dependent, leading to the formation of an excimer which emits at lower intensity and longer wavelength than the monomer.[9]

Consequently, we sought to use pyrene as a linker in bridging ligand design. The availability of several isomers of diacetylpyrene[10] and our ability to elaborate an acetyl into a 2-phen group[11] led us to prepare and study the family of bridging ligands **1**−**5** reported here. Previously we have prepared 1,4-bis(2′-phen)benzene (**6**) and its dinuclear Ru^{II} complex,[12] and have studied the 4,4′-disubstituted biphenyl analogue **7**. Although the ligands experience free rotation about the bond connecting phen to the linker, the incorporation of an $[Ru(bpy)_2]^{2+}$ unit rigidifies the system by inhibiting this rotation. Nevertheless, the dinuclear complex of **7** can still rotate freely about the central biphenyl linkage. In addition to complexes of **6** and **7**, we have also studied the Ru^{II} complex of 1-(2′-phen)pyrene (**8**), the mononuclear analogue of the complexes derived from **3**−**5**.[13]

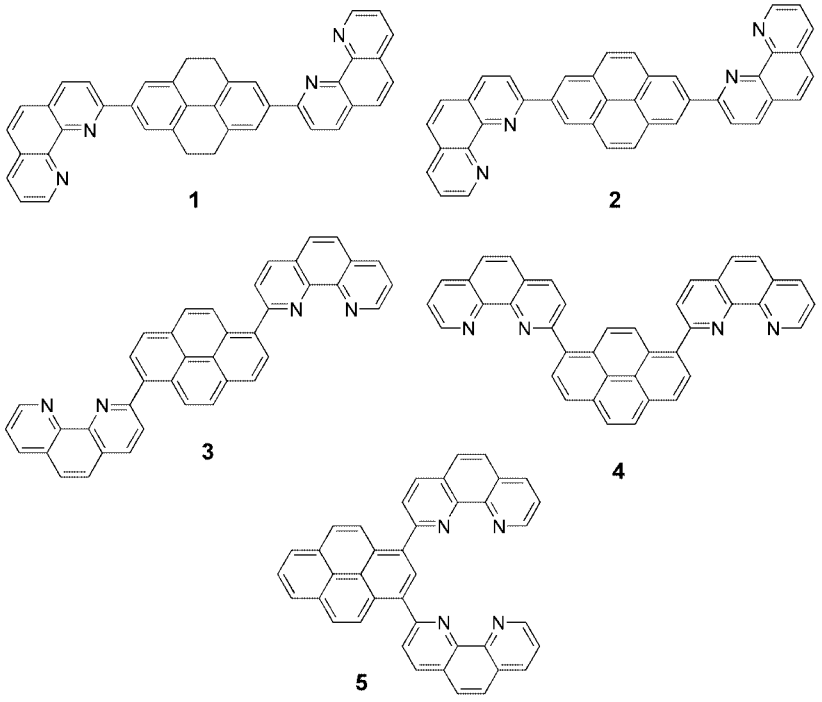
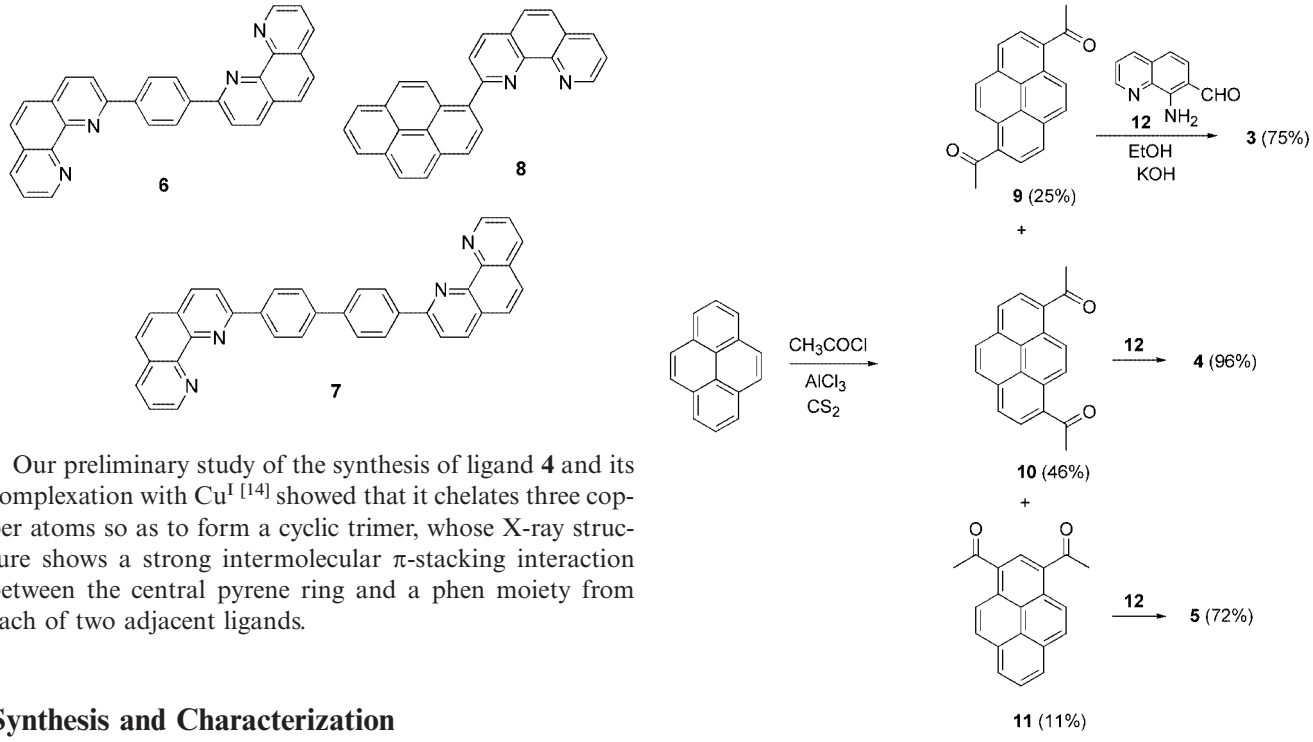


Scheme 1. Bridging pyrene-based ligands



Our preliminary study of the synthesis of ligand **4** and its complexation with Cu^{I} [14] showed that it chelates three copper atoms so as to form a cyclic trimer, whose X-ray structure shows a strong intermolecular π-stacking interaction between the central pyrene ring and a phen moiety from each of two adjacent ligands.

Synthesis and Characterization

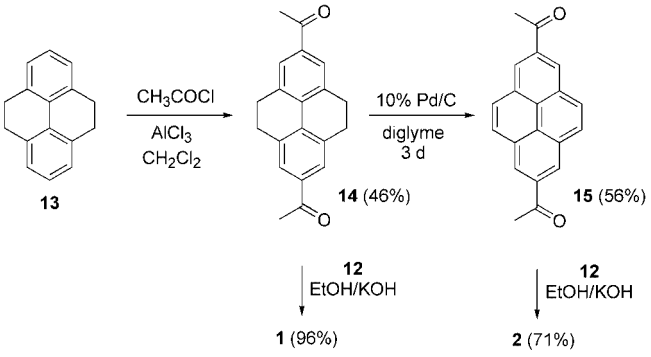
The strategic and selective introduction of acetyl groups onto the pyrene nucleus is key to the synthesis of **1**−**5**. Friedel−Crafts monoacetylation of pyrene is specific to the 1-position. Under normal conditions the 2-isomer cannot be isolated. If excess acetyl chloride is employed, a second acetyl group may be introduced at the 3-, 6-, or 8-position. Further acetylation is not readily accomplished. According to a published procedure, we produced a mixture of the three diacetyl isomers **9**−**11**, which may be separated by a combination of chromatography and crystallization.[10]

We have demonstrated that the Friedländer condensation of 8-amino-7-quinolinecarbaldehyde (**12**) with acetyl-substituted aromatic compounds is a convenient way to prepare 2-arylphen derivatives.[11] In this manner 2 equiv. of **12** were condensed with each of the diacetylpyrenes to provide the corresponding bis(phen)pyrenes **3**−**5** in yields of 72−96%.

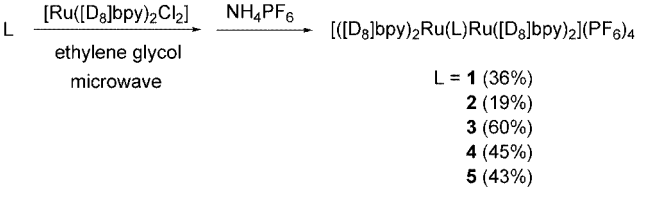
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Each of these ligands possesses a C_2 symmetry axis so that in the ^{1}H NMR spectrum only four (**3** and **4**) or five (**5**) pyrene signals appeared along with the characteristic seven signals for the phen ring.

The more problematic substitution at the 2-position of pyrene was achieved by Harvey and co-workers by carefully controlled hydrogenation of purified pyrene to afford the 4,5,9,10-tetrahydro derivative **13**.[15] This material is actually a bis(dimethylene)-bridged derivative of biphenyl which can be specifically monoacetylated at the 2-position or diacetylated at the 2,7-positions. The reaction of 2 equiv. of **12** with the diacetyl derivative **14** provides the bis(phen)-tetrahydropyrene **1**. Alternatively, **14** may be dehydrogenated to provide the diacetylpyrene **15** which can then be converted into the bis(phen) species **2**.



These five bis(phen)pyrenes were then treated with 2 equiv. of $[Ru([D_8]bpy)_2Cl_2]$ to incorporate two Ru^{II} centers at the vacant phen binding sites. This reaction was sluggish under the normal conditions of reflux in aqueous ethanol, due partially to poor solubility of the ligands, but when carried out in ethylene glycol under microwave irradiation[16] (30−40 min) yields of 19−60% of the purified complexes as their hexafluorophosphate salts were obtained.



The use of $[D_8]$bpy greatly facilitates NMR characterization of the complexes by eliminating all signals from the bpy auxiliary ligands (Figure 1).[17] The phen protons could be readily identified by their characteristic coupling patterns and chemical shifts. The H-4′ to H-9′ protons were narrowly grouped in ranges spanning about 0.1 ppm. The H-3′ resonance was most affected by the adjacent linker. For the complexes of **2**−**4** the signal of this proton appeared in the range δ = 8.02−8.11 ppm. For the complex of the tetrahydropyrene ligand **1**, the H-3′ signal appeared at δ = 7.70 ppm, very similar to the δ = 7.72 ppm recorded for the analogous complex of **7**.[12]

It should be noted that each Ru^{II} center is chiral and thus may exist in either the Δ or Λ configuration. For dinuclear complexes such as those under study, this would lead to two sets of diastereomers, a *d*,*l* form (ΔΔ and ΛΛ) and a *meso* form (ΔΛ). For the dinuclear Ru^{II} complex of **6** the metal centers were sufficiently interacting that two clear sets of NMR signals were visible and could, in fact, be assigned to specific stereoisomers which were present in an approximate 1:1 ratio.[12] For the dinuclear complexes of **2**−**4**, a mixture of diastereomers was similarly evidenced by the NMR spectra. Although some enrichment may have occurred during chromatographic purification, no attempt was made to separate these diastereomers and so they were further evaluated as a mixture.

Figure 1 shows the 600 MHz ^{1}H NMR spectrum of the dinuclear complex of ligand **2**. All the peaks are clearly resolved and 2D analysis allowed their complete assignment. The phen subunits are sufficiently non-interacting that they only show one set of signals for both diastereomers. The H4′ to H7′ protons are remote from the complexation site and their signals appear in the downfield region. The H3′, H8′, and H9′ proton signals are shifted upfield due to shielding by the auxiliary $[D_8]$bpy ligands or the central pyrene ring. The multiplicities and chemical shifts of the pyrene proton signals may be explained by symmetry effects associated with the *d*,*l* or *meso* diastereoisomer. For the *meso* isomer H3 = H8 and the signal of this proton appears as a singlet at δ = 6.81 ppm, strongly shielded by an auxiliary $[D_8]$bpy ligand. For this isomer H1 = H6 and this atom is deshielded, its signal appearing at δ = 8.18 ppm. For the *meso* isomer H4 = H9 ≠ H5 and thus H4 and H9 (as well as H5 and H10) appear as doublets at δ = 7.97 and 7.56, respectively. For the *d*,*l* isomer the symmetry plane lies along the short axis of the pyrene bridge so that H3 = H6 (singlet at δ = 6.89 ppm). Likewise H4 and H5 as well as H9 and H10 are equivalent, giving the singlets at δ = 7.63 and 7.89 ppm.

Structure and Properties

We have previously described the dinuclear Ru^{II} complexes of **6** and **7**.[12] With $[(bpy)_2Ru(\mathbf{6})Ru(bpy)_2](PF_6)_4$ we had expected that π-stacking between the central benzene ring and a pyridine ring of an auxiliary bpy associated with each metal center would provide some communication between the metal atoms. Both photophysical and electrochemical data suggested that no such communication existed and the two metal centers behaved quite independently. A crystal structure analysis of this system indicated that the two π-stacked pyridine rings were bent out of a parallel arrangement and thus π−π interaction might well be diminished.

The pyrene-bridged systems might be less congested, resulting in better π-overlap. Furthermore, the 16π-electron central pyrene ring would provide better delocalization of

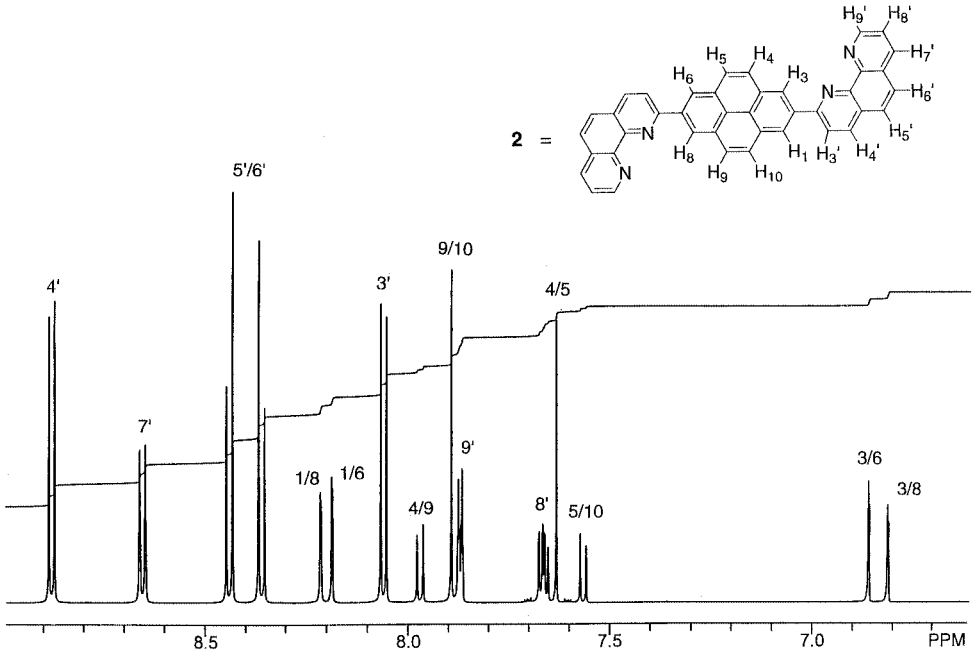

Figure 1. Downfield region of the 600 MHz ^{1}H NMR spectrum of [([D_8]bpy)$_2$Ru(**2**)Ru([D_8]bpy)$_2$](PF_6)$_4$ in CD_3CN at 25 °C

the excited state. A structural comparison between the two dinuclear complexes was made by determining the crystal structure of [([D_8]bpy)$_2$Ru(**3**)Ru([D_8]bpy)$_2$](PF_6)$_4$ (Figure 2 illustrates an ORTEP drawing of the cation). Figure 3 shows a side view of the same cation as well as the analogous dinuclear [Ru(bpy)$_2$] complex of ligand **6**.

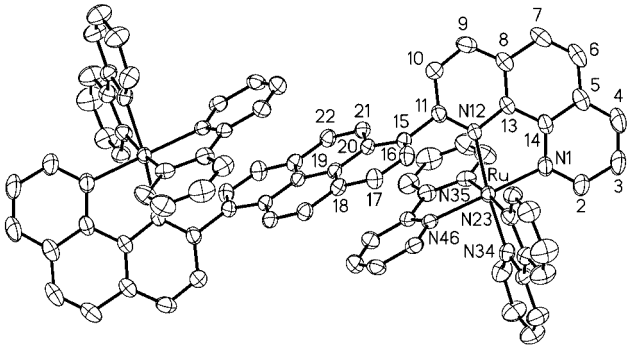

Figure 2. ORTEP drawing of the cation of [([D_8]bpy)$_2$Ru(**3**)-Ru([D_8]bpy)$_2$](PF_6)$_4$ showing the atom-numbering scheme

The larger pyrene, as compared with benzene, leads to a greater separation of the two [(phen)Ru(bpy)$_2$] halves of the molecule. All the Ru−N bond lengths fall in the range 2.05−2.07 Å, except for Ru−N12 which is 2.13 Å. This elongation is caused by interaction of pyrene with one of the auxiliary bpy groups, The bpy groups are less distorted than in the complex of **6**, and two bpy groups that form the outer layers of the central π-sandwich are more planar, with a dihedral angle between the two bpy pyridine rings of 6.6° as compared with 21.6° in the benzene-bridged complex. The other bpy is even more planar with a dihedral angle of only 1.8°, which compares to 7.5° in the benzene-bridged complex. The phen and pyrene are also more orthogonal with a dihedral angle of 76.4°, some 16° greater than for the benzene-bridged system.

The decreased congestion is due mainly to the increased distance between the inner bpy on one Ru and the phen complexed to the other Ru. In the complex of **6**, this C26′−C10 distance is 3.73 Å, pushing the pyridine out of a plane that would be parallel with the central benzene. This distortion is illustrated in Figure 2 where the C26−C26′ distance is 8.76 Å. For the pyrene complex, the bpy−phen interaction is relieved and the C43′−C10 distance lengthens to 5.19 Å while C43−C43′, at 6.73 Å, is over 2 Å less than the corresponding distance for the benzene-bridged complex. The atoms in the pyridines that form the π-sandwich and the central benzene of **6** are between 2.91 and 4.21 Å apart, while for the pyrene-bridged complex these distances are 3.09−3.39 Å. The average distance between these planes is 3.24 Å, indicating possible strong π−π interaction.

Surprisingly, the photophysical properties of the pyrene-bridged complexes do not evidence any strong coupling between the metal centers. Table 1 lists the absorption and emission data for the ligands and complexes as well as for **8** and the mononuclear model compounds [Ru(**8**)(bpy)$_2$]$^{2+}$ and [Ru(phen)([D_8]bpy)$_2$]$^{2+}$. The 1,3-, 1,6-, and 1,8-diphenpyrenes **3**−**5** all show quite similar absorption and emission spectra. The 2,7-diphen isomer absorbs at slightly higher energy, very similar to the 2-phenpyrene **8**. This is consistent with electronic decoupling of the 2,7-positions as reported by Müllen and co-workers.[18] The emission maxima for the pyrene systems appear in the range 432−488 nm and are all lower in energy than the corresponding bridged biphenyl system **1**.

Fages and co-workers have carried out a detailed photophysical study on two systems related to **3** and **8** in which a 4-(2,2′-bpy) group is attached to pyrene in place of phen.[20]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

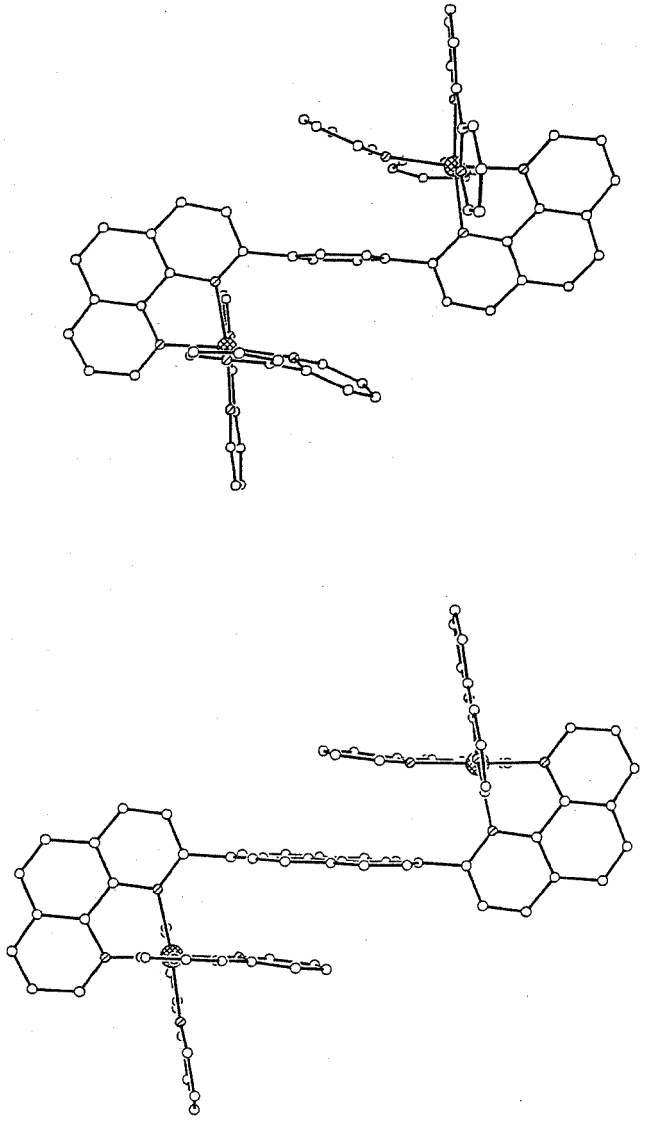

Figure 3. Analogous side views of the cation of $[(bpy)_2Ru(\mathbf{6})Ru(bpy)_2](PF_6)_4$ (top) and $[([D_8]bpy)_2Ru(\mathbf{3})Ru([D_8]bpy)_2](PF_6)_4$ (bottom)

These molecules show absorption and emission characteristics consistent with what we observe, but at higher energy, apparently due, in part, to conformational mobility about the 2,2′ bond of bpy, which thus provides less delocalization than phen. The fact that the electronegative nitrogen atom in the 4-bpy-substituted systems is two bonds further remote from pyrene than for the 2-phen of **3** and **8** may also have some influence.

The Stokes shift is the difference between the absorption and emission maxima and, to some extent, provides a measure of geometric changes that occur upon electronic excitation. For **3**−**5** we observe values of 65−71 nm which are consistent with the model compound **8** (73 nm) and slightly larger than the 58 and 67 nm Fages observed for his two bpy-based systems in acetonitrile at room temperature. A similar 5-bpy-substituted pyrene reported by Rettig and coworkers shows a Stokes shift of 92 nm.[21] The 2,7-disubstituted pyrene **2** shows a large Stokes shift of 101 nm, consistent with the more longitudinal organization of this molecule.

The longest wavelength absorption for Ru^{II} complexes of this type typically involves a metal-to-ligand charge transfer (MLCT) in which the photoexcited electron is promoted from a metal d-orbital to a low-lying ligand π*-orbital. One expectation for the pyrene-bridged complexes was that π−π interaction through the central bpy-pyrene-bpy stack would affect an MLCT state associated with the bpy ligand. Increased delocalization should produce a bathochromic shift in the MLCT absorption. For the four dinuclear pyrene complexes involving **2**−**5** as well as the mononuclear model **8** and the tetrahydropyrene **1**, the lowest energy absorption band appears at 447−450 nm. The dinuclear pyrene-containing systems also show a pyrene π−π* absorption at 367−382 nm, which is lower in energy than the mononuclear analogue **8** (357 nm). Interestingly, the complex $[Ru(phen)([D_8]bpy)_2]^{2+}$ absorbs at 448 nm, within 1−2 nm of all four pyrene-bridged complexes.

At room temperature the dinuclear complexes of **2**−**5** show weak emissions at 612−615 nm that are similar to the

model compounds. At 77 K, the emission properties do not change appreciably for the complexes of **3**−**5** while those of the complex of **2** is shifted to 605 nm. By comparison, the dinuclear complex of the bridged biphenyl system **1**, which does not possess the pyrene chromophore, shows a stronger 77 K emission shifted to 584 nm. This 29-nm thermally induced Stokes shift compares well with that of 35 nm observed for $[Ru(phen)(bpy)_2]^{2+}$ and is characteristic for emission of a triplet MLCT state. The implication is that, due to the lack of a thermally induced Stokes shift, the emissions from the complexes involving the pyrenyl ligands **2**−**5** may not be MLCT-based but rather associated with an intraligand (IL) state, possibly a triplet IL state involving pyrene.

Schmehl and co-workers[22] have recently examined a similar dinuclear Ru^{II} complex involving the 1,6-bis(2,2′-bipyrid-4-yl)pyrene bridging ligand reported earlier by Fages.[20] A detailed photophysical study indicated that emission was not consistent with a ^{3}MLCT state, rather a triplet IL state was suggested instead. An easy test for this possibility is to measure the 77 K luminescence of the ligands **2**−**5** in the presence of an external heavy atom donor, which should promote intersystem crossing and emission of the triplet state (phosphorescence). Low-temperature spectra of the ligands were, therefore, recorded in the presence of ethyl iodide. For ligand **3** we observe a band at 615 nm, which is virtually identical to the spectrum of $[([D_8]bpy)_2Ru(\mathbf{3})Ru([D_8]bpy)_2](PF_6)_4$. The data for the other systems was less clear. Future time-resolved measurements and transient spectroscopy should help in elucidating the origin of the emissive state. It is noteworthy that other Ru^{II} complexes of bpy and phen have been reported in which each ligand contains one or two pyrene appendages attached at the 5-position.[23−24] These systems emit rather strongly and the excited state lifetime can be related to the number of pyrene appendages.

The electrochemical data summarized in Table 2 further verify the lack of metal−metal interaction. The oxidations are all in the range +1.29 to +1.32 V, as expected for the metal-based Ru^{II}-to-Ru^{III} conversion. The reductions are typically ligand-based and fall in the expected range of −1.27 to −1.31 V. It is difficult to assign this reduction to a phen or a bpy ligand in the complex. If the reduction involved a phen-type ligand, then the second reduction would involve a bpy and variation in the second reduction potential might be expected. These second reductions, however, fall in the narrow range of −1.41 to −1.44 V, excluding this possibility.

Conclusions

We have described the preparation of four new pyrene-bridged bis(phen) ligands **2**−**5** and the tetrahydro precursor **1**. Dinuclear Ru^{II} complexes prepared from all five systems, with $[D_8]$bpy as the auxiliary ligand, have been characterized by ^{1}H NMR and electronic spectroscopy and by electrochemical analysis. A crystal structure of the dinuclear complex of **3** evidences a much less congested environment than its benzene-bridged analogue. Nevertheless, the expected electronic effects of π−π interactions through the central bpy-pyrene-bpy sandwich appear to be lacking. Future studies will involve systems with pyrene more intimately involved in the 1,4-diimine chelating unit.

Experimental Section

General: Nuclear magnetic resonance spectra were recorded at 300 or 600 MHz for ^{1}H and at 75 MHz for $^{13}C\{^1H\}$ referenced to TMS in $CDCl_3$ and to the solvent peak in all other solvents (CD_3CN). Electronic spectra were obtained with a Perkin-Elmer Lambda 3B spectrophotometer. Fluorescence spectra were obtained with a Perkin-Elmer LS-50 luminescence spectrometer. Cyclic voltammetry (CV) was carried out in a conventional three-electrode cell with a BAS-27 voltammeter and a Houston Instruments model 100 X-Y recorder according to a previously described procedure.[25] Mass spectra were obtained with a Hewlett−Packard 5989B mass spectrometer (59987A electrospray) using atmospheric pressure ionization at 160 °C. Elemental analyses were performed by National Chemical Consulting, P. O. Box 99, Tenafly, NJ 07670, U.S.A. Melting points were measured with a Hoover capillary melting point apparatus and are not corrected. The microwave reactions were carried out in a household microwave oven modified according to a previously published description.[16] The 2,7-diacetyl-4,5,9,10-tetrahydropyrene,[15] 2,7-diacetylpyrene,[15] 1,6-, 1,8-, and 1,3-diacetylpyrene,[10] $[Ru([D_8]bpy)_2Cl_2]\cdot 2H_2O$,[17] and 8-amino-7-quinolinecarbaldehyde (**8**)[11] were prepared according to known procedures. CH_3CN used for cyclic voltammetry was dried by reflux with calcium hydride followed by distillation. All other solvents were used without further purification.

2,7-Bis(2′-[1′,10′]phenanthrolinyl)-4,5,9,10-tetrahydropyrene (1): A mixture of 2,7-diacetyl-4,5,9,10-tetrahydropyrene (**14**, 300 mg, 0.69 mmol), 8-amino-7-quinolinecarbaldehyde (**12**, 240 mg, 138 mmol) and KOH (120 mg) in absolute EtOH (25 mL) was refluxed for 8 h. The solid which formed was collected, washed with H_2O (2 × 20 mL), EtOH (3 × 10 mL), and dried to provide **1** as an orange solid (370 mg, 96% yield), m.p. > 270 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 9.27 (d′, *J* = 4.7, 2.5 Hz, 2 H, H-9), 8.31 (m, 4 H), 8.18 (d, 2 H), 8.14 (s, 4 H, H-1, H-3, H-6, H-8), 7.80 (AB q, 4 H, H-5′, H-6′), 7.66 (dd, *J* = 7.9, 3.4 Hz, 2 H, H-8′), 3.13 (s, 8 H, CH_2) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = 157.8, 149.9, 138.0, 136.5, 136.2, 136.0, 131.5, 128.9, 127.3, 126.3, 125.7, 125.4, 122.6, 120.5, 28.3 ppm. MS: *m*/*z* (%) = 562 (100) [M]. $C_{40}H_{26}N_4 \cdot 3H_2O$ (647): calcd. C 77.92, H 5.19, N 9.09; found C 77.08, H 4.53, N 8.74.

2,7-Bis(2′-[1′,10′]phenanthrolinyl)pyrene (2): According to the procedure described for **1**, 2,7-diacetylpyrene (**15**, 80 mg, 0.28 mmol) was condensed with **12** (100 mg, 0.58 mmol) in absolute EtOH (15 mL) for 8 h. The resultant yellow-orange residue was crystallized from chloroform to give **2** as a pale yellow solid (110 mg, 71% yield), m.p. > 270 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 9.33 (d, *J* = 4.3 Hz, 2 H, H-9′), 9.21 (s, 4 H, H-4, H-5, H-9, H-10), 8.47 (AB q, 4 H, H-3′,4′), 8.35 (d, 2 H, H-7′), 8.32 (s, 2 H, H-1, H-3, H-6, H-8), 7.86 (AB q, 4 H, H-5′, H-6′), 7.69 (dd, *J* = 7.6, 3.1 Hz, 2 H, H-8′) ppm. A ^{13}C{^{1}H} NMR spectrum could not be obtained due to poor solubility. MS: *m*/*z* (%) = 558 (100) [M]. $C_{40}H_{22}N_4 \cdot H_2O$ (576): calcd. C 83.33, H 4.16, N 9.72; found C 83.36, H 4.08, N 9.07.

1,6-Bis(2′-[1′,10′]phenanthrolinyl)pyrene (3): A mixture of 1,6-diacetylpyrene (**9**, 200 mg, 0.69 mmol), **12** (265 mg, 1.53 mmol), and KOH (120 mg) in absolute EtOH (30 mL) was refluxed overnight. After cooling to 25 °C, the residue was filtered off, washed with H_2O (2 × 20 mL) then $CHCl_3$ (2 × 20 mL). The resulting solid was then recrystallized from $CHCl_3$ to provide **3** as a pale yellow solid (290 mg, 75% yield), m.p. > 280 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 9.24 (dd, *J* = 4.4, 1.4 Hz, 2 H, H-9′), 8.53 (d, *J* = 9.5 Hz, 2 H), 8.47 (dd, *J* = 8.3, 2.9 Hz, 4 H), 8.31 (d, *J* = 8.9 Hz, 4 H), 8.12 (dd, *J* = 8.9, 4.5 Hz, 4 H), 7.95 (AB q, 4 H, H-5′, H-6′), 7.65 (dd, *J* = 8.6, 4.4 Hz, 2 H, H-8′) ppm. A ^{13}C{^{1}H} NMR spectrum could not be obtained due to poor solubility. MS: *m*/*z* (%) = 559 (100) [M + 1]. $C_{40}H_{22}N_4 \cdot H_2O$ (558): calcd. C 83.33, H 4.16, N 9.72; found C 83.83, H 3.83, N 9.85.

1,8-Bis(2′-[1′,10′]phenanthrolinyl)pyrene (4):[14] A mixture of 1,8-diacetylpyrene (**10**, 146 mg, 0.51 mmol), **12** (183 mg, 1.06 mmol), and KOH (100 mg) in absolute EtOH (20 mL) was refluxed for 12 h. After cooling to 25 °C, H_2O (20 mL) was added and the aqueous layer extracted with CH_2Cl_2 (3 × 30 mL). The organic layer was then dried ($MgSO_4$) and the solvent evaporated to dryness. The resultant residue was washed with Et_2O (2 × 25 mL) to provide **4** as a yellow solid (265 mg, 93% yield), m.p. > 270 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 9.14 (d, *J* = 3.3 Hz, 2 H, H-9′), 8.32−8.23 (m, 8 H), 8.16−8.13 (m, 4 H), 7.96 (d, *J* = 8.1 Hz, 2 H), 7.74 (d, *J* = 8.7 Hz, 2 H), 7.65−7.57 (m, 4 H) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = 159, 149, 145.8, 145.7, 136.3, 136.1, 136, 131, 128.8, 128.5, 128.4, 127.9, 127.1, 126.4, 126.3, 125.7, 125.5, 125.2, 124, 123 ppm. MS: *m*/*z* (%) = 559 (100) [M + 1]. $C_{40}H_{22}N_4 \cdot 0.5H_2O$ (567): calcd. C 84.66, H 4.05, N 9.88; found C 84.73, H 3.67, N 9.50.

1,3-Bis(2′-[1′,10′]phenanthrolinyl)pyrene (5): A mixture of 1,3-diacetylpyrene (**11**, 109 mg, 0.38 mmol), **12** (131 mg, 0.76 mmol), and KOH (120 mg) in absolute EtOH (35 mL) was refluxed for 24 h. After cooling to 25 °C, H_2O (60 mL) was added and a yellow solid precipitated. The solid was purified on Al_2O_3, eluting with CH_2Cl_2, to provide **5** (152 mg, 72% yield), m.p. > 270 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 9.14 (d, *J* = 4.1 Hz, 2 H, H-9′), 8.80 (s, 1 H), 8.41 (dd, *J* = 8.0, 2.6 Hz, 4 H), 8.22 (dd, *J* = 10.3, 7.7 Hz, 4 H), 8.0−8.15 (m, 5 H), 7.84 (AB q, 4 H, H-5′, H-6′), 7.60 (dd, *J* = 8.1, 4.8 Hz, 2 H, H-8′) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = 150.6, 136.6, 136.1, 136 (2 C), 131.6, 130.9, 129.7, 129.3, 129, 128.6, 127.7, 126.8 (2 C), 126.7 (2 C), 126.3, 126.2, 125.6, 125.4, 123, 120.2 ppm. MS: *m*/*z* (%) = 560 (100) [M + 2]. $C_{40}H_{22}N_4 \cdot 1.45CH_2Cl_2$ (698): calcd. C 73.30, H 3.65, N 8.22; found C 73.30, H 3.60, N 7.86.

[([D$_8$]bpy)$_2$Ru(1)Ru([D$_8$]bpy)$_2$](PF$_6$)$_4$: A mixture of **1** (60 mg, 0.10 mmol) and $[Ru([D_8]bpy)_2Cl_2] \cdot 2H_2O$ (111 mg, 0.21 mmol) in ethylene glycol (6 mL) was heated in a microwave oven under Ar for 30 min. After cooling, the mixture was poured into H_2O (20 mL). A solution of NH_4PF_6 (49 mg, 0.3 mmol) in H_2O (2 mL) was then added, and the mixture stirred for 15 min. The resultant precipitate was filtered off, dried, and purified by chromatography on alumina, eluting with toluene/CH_3CN (1:1), to provide an orange solid (75 mg, 36% yield), m.p. > 280 °C. ^{1}H NMR (600 MHz, CD_3CN, 25 °C): δ = 8.73 (d, *J* = 9.3 Hz, H-4′), 8.62 (d, *J* = 8.8 Hz, H-7′), 8.33 (AB q, H-5′, H-6′), 7.90 (d, *J* = 4.9 Hz, H-9′), 7.69 (d, *J* = 7.3 Hz, H-3′), 7.65 (dd, *J* = 6.8, 4.9 Hz, H-8′), 7.0 (s, H-2/H-5), 5.7 (s, H-4/H-9), 2.15−2.30 (CH_2 under solvent peak). MS: *m*/*z* (%) = 1857 (100) [M + 1 − PF_6].

[([D$_8$]bpy)$_2$Ru(2)Ru([D$_8$]bpy)$_2$](PF$_6$)$_4$: According to the procedure described for [([D$_8$]bpy)$_2$Ru(**1**)Ru([D$_8$]bpy)$_2$](PF$_6$)$_4$, a mixture of **2** (40 mg, 0.07 mmol) and $[Ru([D_8]bpy)_2Cl_2] \cdot 2H_2O$ (77 mg, 0.14 mmol) in ethylene glycol (6 mL) was heated in a microwave oven to provide a red solid (26.5 mg, 19% yield), m.p. > 280 °C. ^{1}H NMR (600 MHz, CD_3CN, 25 °C, two sets of peak in a 1:1 ratio for the two diastereomers): δ = 8.88 (d, *J* = 7.3 Hz, H-4′), 8.65 (d, *J* = 8.4 Hz, H-7′), 8.4 (AB q, H-5′, H-6′), 8.21 (s, H-1/H-8), 8.18 (s, H-1/H-6), 8.06 (d, *J* = 7.0 Hz, H-3′), 7.97 (d, *J* = 5.1 Hz, H-4/H-9), 7.89 (s, H-9/H-10), 7.87 (d, *J* = 5.6 Hz, H-9′), 7.66 (dd, *J* = 7.0, 5.3 Hz, H-8′), 7.63 (s, H-4/H-5), 7.56 (d, *J* = 9.0 Hz, H-5/H-10), 6.85 (s, H-3/H-6), 6.81 (s, H-3/H-8) ppm. MS: *m*/*z* (%) = 1851 (100) [M − PF_6].

[([D$_8$]bpy)$_2$Ru(3)Ru([D$_8$]bpy)$_2$](PF$_6$)$_4$: According to the procedure described for [([D$_8$]bpy)$_2$Ru(**1**)Ru([D$_8$]bpy)$_2$](PF$_6$)$_4$, a mixture of **3** (60 mg, 0.10 mmol) and $[Ru([D_8]bpy)_2Cl_2] \cdot 2H_2O$ (115 mg, 0.21 mmol) in ethylene glycol (6 mL) was heated in a microwave oven to provide a red solid (120 mg, 60% yield), m.p. > 280 °C. ^{1}H NMR (600 MHz, CD_3CN, 25 °C, two sets of peaks in a 5:1 ratio for the two diastereomers), major isomer: δ = 8.97 (d, *J* = 7.3 Hz, H-4′), 8.71 (d, *J* = 8.4 Hz, H-7′), 8.48 (AB q, H-5′, H-6′), 8.13 (d, *J* = 7.0 Hz), 8.10 (d, *J* = 7.0 Hz, H-3′), 7.97 (d, *J* = 7.0 Hz), 7.88 (d, *J* = 5.7 Hz, H-9′), 7.69 (dd, *J* = 7.0, 5.3 Hz, H-8′), 7.21 (d, *J* = 7.8 Hz, 1 H), 6.42 (d, 2 H) ppm. MS: *m*/*z* (%) = 1853 (100) [M + 2 − PF_6].

[([D$_8$]bpy)$_2$Ru(4)Ru([D$_8$]bpy)$_2$](PF$_6$)$_4$: The same procedure described for [([D$_8$]bpy)$_2$Ru(**1**)Ru([D$_8$]bpy)$_2$](PF$_6$)$_4$ was used. A mixture of **4** (60 mg, 0.10 mmol) and $[Ru([D_8]bpy)_2Cl_2] \cdot 2H_2O$ (115 mg, 0.21 mmol) in ethylene glycol (6 mL) was heated in a microwave oven to provide a red solid (89 mg, 45% yield), m.p. > 280 °C: ^{1}H NMR (600 MHz, CD_3CN, 25 °C, two sets of peaks in a 9:1 ratio for the two diastereomers), major isomer: δ = 8.94 (d, *J* = 7.3 Hz, H-4′), 8.67 (d, *J* = 8.4 Hz, H-7′), 8.45 (AB q, H-5′, H-6′), 8.10 (d, *J* = 7.0 Hz), 8.08 (d, *J* = 7.0 Hz, H-3′), 7.95 (d, *J* = 7.0 Hz), 7.87 (d, H-9′), 7.68 (dd, *J* = 7.0, 5.3 Hz, H-8′), 7.57 (d, *J* = 7.0 Hz, 1

H), 7.18 (d, 1 H, J = 7.8 Hz), 7.40 (d, 2 H) ppm. MS: m/z (%) = 1853 (100) [M + 2 − PF_6].

[([D$_8$]bpy)$_2$Ru(5)Ru([D$_8$]bpy)$_2$](PF$_6$)$_4$: According to the procedure described for [([D$_8$]bpy)$_2$Ru(**1**)Ru([D$_8$]bpy)$_2$](PF$_6$)$_4$, a mixture of **5** (60 mg, 0.10 mmol) and [Ru([D$_8$]bpy)$_2$Cl$_2$]·2H$_2$O (115 mg, 0.21 mmol) in ethylene glycol (6 mL) was heated in a microwave oven under Ar for 30 min to provide a red solid (60 mg, 43% yield), m.p. > 280 °C. ^{1}H NMR (600 MHz, CD_3CN, 25 °C): δ = 8.81 (d, J = 7.3 Hz, H-4′), 8.69 (d, J = 8.4 Hz, H-7′), 8.45 (AB q, H-5′, H-6′), 8.38−8.31 (m, H-6, H-7), 7.85 (s, H-2), 7.82 (d, J = 7.0 Hz, H-9′), 7.67 (dd, J = 7.0, 5.3 Hz, H-8′), 7.62 (d, J = 7.0 Hz, H-3′), 7.43 (d, J = 7.8 Hz, H-3), 6.26 (d, J = 7.8 Hz, H-4) ppm. MS: m/z (%) = 1853 (100) [M + 2 − PF_6].

X-ray Determination of [([D$_8$]bpy)$_2$Ru(3)Ru([D$_8$]bpy)$_2$](PF$_6$)$_4$: All measurements were made with a Siemens SMART platform diffractometer equipped with a 1 K CCD area detector. A hemisphere of data (1271 frames at 5 cm detector distance) was collected using a narrow-frame method with scan widths of 0.30° in ω and an exposure time of 30 s per frame. The first 50 frames were re-measured at the end of data collection to monitor instrument and crystal stability, and the maximum correction on I was < 1%. The data were integrated using the Siemens SAINT program, with the intensities corrected for Lorentz factor, polarization, air absorption, and absorption due to variation in the path length through the detector faceplate. A ψ scan absorption correction was applied based on the entire data set. Redundant reflections were averaged. Final cell constants were refined using 7934 reflections having $I > 10\sigma(I)$, and these, along with other information pertinent to data collection and refinement, are listed in Table 3. The Laue symmetry was determined to be −1, and the space group was shown to be either $P1$ or $P\bar{1}$; the letter was chosen based on successful refinement. The asymmetric unit consists of one-half cation situated about an inversion center, two PF_6 anions, two acetonitrile molecules, one toluene and one dichloromethane molecule. One of the anions, and all of the various solvent molecules, are disordered and were modeled as ideal rigid bodies or by using distance constraints. Three separate orientations were found for the dichloromethane, with a total population of about 75%. It is presumed that some solvent was lost during sample handling, and all calculations are based on 100% occupancy of the solvent.CCDC-199738 contains the supplementary crystallographic data which can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retreiving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Monomeric 1-Borylimidazoles: Syntheses, Structure and Reactivity of 1-[Bis(diisopropylamino)boryl]imidazoles

Daniela Görz,[a] Hans Pritzkow,[a] and Walter Siebert*[a]

Dedicated to Prof. Heinrich Nöth on the occasion of his 75th birthday

Keywords: Boranes / Imidazoles / Donor-acceptor interaction / Metal complexes

Reactions of chlorobis(diisopropylamino)borane with 1-(trimethylsilyl)imidazole and 4,5-dimethyl-1-(trimethylsilyl)imidazole lead to the monomeric 1-borylimidazoles **3a** and **3b**. Treatment of **3a** with the Lewis acid BF_3 results in the quantitative formation of the corresponding trifluoroborane adduct **4a**. In contrast, **3a** reacts with the stronger Lewis acids BCl_3, BBr_3, and BI_3 to partially substitute the diisopropylamino groups and form the corresponding adducts, depending on the Lewis acidity of the reagent; **3a** forms, with $Mo(CO)_5$thf and Cp′$Mn(CO)_2$thf, the complexes 3-[$(OC)_5$Mo]**3a** (**8**) and 3-[$(OC)_2$Cp′Mn]**3a** (**6**). The product compositions agree with spectroscopic and analytical data and with X-ray structure analyses of **3a**, **3b**, **4a**, **8**, and **9**.

Introduction

1-(Diorganoboryl)imidazoles have been prepared either by cleavage of the silicon−nitrogen bond in silylimidazoles with haloboranes or by reaction of (dimethylamino)diethylborane with imidazole. The resulting colorless, glassy materials readily dissolve in organic solvents to form solutions of high viscosity due to intermolecular association by Lewis acid−base interactions.[1] Inherent viscosity and cryoscopical measurements, as well as mass spectrometric data, confirm the presence of polymeric structures.

Analogously, some discrete cyclic tetra-[1a,2] and -pentameric[2c] 1-(diorganoboryl)imidazoles, as well as a boryl-substituted bis(imidazole),[2d] have been obtained. Few monomeric 1-borylimidazoles are known[3] and the reactivity of their unsubstituted nitrogen atom has not been investigated.

This report describes the preparation and characterization of 1-[bis(diorganoamino)boryl]imidazoles. In contrast to former assumptions,[3] bulky substituents are necessary as the electron-donating effects of two small amino groups do not stabilize sufficiently the three-coordinate boron atom to inhibit intermolecular association. Monomeric 1-[bis(diisopropylamino)boryl]imidazoles may be obtained due to the sterically demanding boryl groups. In addition, we examined the reactivity of these compounds toward boron halides of different Lewis acidity, toward BH_3, BEt_3 and photochemically activated carbonylmetal compounds. We previously showed that *N*-borane-substituted imidazoles can be deprotonated to form anionic imidazol-2-ylidenes, which are even more nucleophilic than the classic imidazol-2-ylidenes.[2d,4] Deprotonation of 1-[bis(diisopropylamino)boryl]-3-(trifluoroborio)imidazole is, likewise, possible − despite the electrophilic three-coordinate boron atom − if bulky deprotonation reagents are used.[4d] The anionic carbene reacts with transition metal−halogen compounds to yield (diborylimidazole-2-ylidene)metal complexes containing a reactive boryl group.

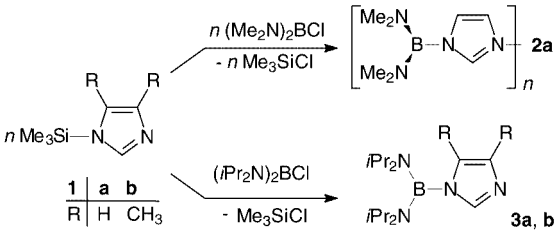
Results and Discussion

Monomeric 1-Borylimidazoles 3a,b

Chlorobis(dimethylamino)borane reacts with 1-(trimethylsilyl)imidazole (**1a**) in THF to yield colorless **2**, which is soluble in $CDCl_3$ (Scheme 1). Its ^{11}B NMR shift is in the region expected for compounds with four-coordinate boron atoms,[5] indicating that **2** undergoes intermolecular association by Lewis acid−base interactions. In contrast, the bulkier reagent chlorobis(diisopropylamino)borane affords the crystalline 1-[bis(diisopropylamino)boryl]imidazoles **3a** and **3b**, which exhibit broad ^{11}B NMR signals in the range typical for three-coordinate boron atoms.[5] The ^1H NMR spectra of **3a** and **3b** show signals for the aromatic hydrogen atoms of both molecules as singlets, the methyl substituents of the imidazole ring in **3b** exhibit only one resonance, whereas two signals appear in the ^{13}C NMR spectrum. The aliphatic resonances of **3a** coincide as a single doublet for the methyl and a septuplet for the methine protons, indicat-

ing that free rotation about the boron−imidazole as well as about the boron−diisopropylamino bonds occurs at room temperature on the NMR time scale. For the same reason the ^{13}C NMR spectrum shows only two resonances for the diisopropylamino substituents as well as three signals for the imidazole ring.



Scheme 1

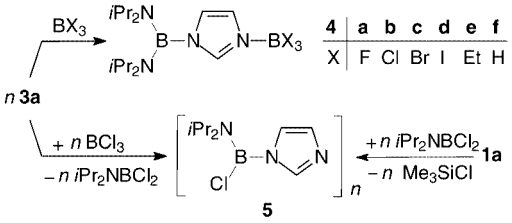
By contrast, in the ^1H NMR spectrum of **3b** the methyl groups of the diisopropylamino substituents appear as two groups of diastereomeric protons, each signal split to a doublet, at slightly different fields. Likewise, two ^{13}C NMR absorptions are assigned to these chemically inequivalent methyl carbon atoms. Thus, in **3b**, due to the methyl substituent at the 5-position of the imidazole ring, free rotation of the diisopropylamino groups about the boron−imidazole bond at room temperature is assumed to be inhibited. Nevertheless, the corresponding methine carbon atoms show only one septuplet as well as one signal in the ^{13}C NMR spectrum on account of the unhindered rotation of all four isopropyl groups about the diisopropylamino−boron axis.

To determine the height of the rotation barrier for the bis(diisopropylamino)boryl group, temperature-dependent NMR experiments have been performed. From the Eyring equation,[6] using the method of the peak separation, a free energy of activation of $\Delta G^{\neq} = 84.6$ kJ/mol of the rotation barrier has been calculated. (The coalescence temperature of the corresponding peaks has been determined by temperature-dependent spectra in [D$_8$]toluene to $T_c = 318$ K; for these signals a frequency difference of up to $|\nu_A - \nu_B| = 7.1$ Hz has been ascertained.) This $\Delta G^{\neq}$ is about 20 kJ/mol higher than that obtained for (2,2′,6,6′-tetramethylpiperidino)boryl-substituted bis(imidazole).[2d]

The EI mass spectrometric data on **3a** and **3b** agree with monomeric structures for both molecules. The highest boron-containing sets of peaks in each case correspond to the respective monomeric molecules, and high-resolution spectra confirm their compositions.

Donor−Acceptor Compounds 4, 5 and 7

Imidazole−trifluoroborane adduct formation has been studied extensively,[7] whereas only one report on imidazole−trichloroborane adducts is available.[7a] We examined the reactivity of **3a** toward the haloboranes BF_3, BCl_3, BBr_3, and BI_3 as well as toward BEt_3 and BH_3 (Scheme 2).



Scheme 2

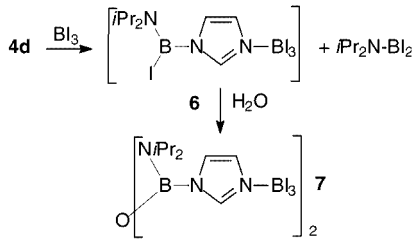
Treatment of **3a** with the weak Lewis acid BF_3 in THF yields the donor−acceptor compound **4a** quantitatively. The ^{11}B NMR spectrum of **4a** has a broad signal for the three-coordinate boron atom and a sharp 1:3:3:1 quadruplet at high field. Its ^1H NMR spectrum exhibits signals for the ring protons that are slightly shifted down-field compared with the corresponding resonances of **3a**. Only a small influence on the shift of the signals of the diisopropylamino groups is observed. In the ^{13}C NMR spectrum, the imidazole carbon atoms and the diisopropylamino substituents appear nearly unchanged compared with the starting material. Mass spectrometric studies (EI, CI) on **4a** reveal that the Lewis acid−base interaction between the nitrogen and boron atoms is too weak to permit ionization without dissociation.

Treatment of **3a** with the stronger Lewis acid BCl_3 in toluene leads to a small amount of a white precipitate (**5**); NMR spectra of the crude product, obtained by evaporation of the solvent, indicate a product mixture. Recrystallization gave **4b** (68%), which shows a broad signal at low field and a sharp absorption at high field in its ^{11}B NMR spectrum. Accordingly, the ^1H NMR spectrum exhibits a doublet and a septuplet as well as three absorptions in the aromatic region. Additional signals for **3a** and for dichloro(diisopropylamino)borane are found. These observations show that, as well as the expected adduct **4b**, BCl_3 cleaves the diisopropylamino−boron bond of **3a** to give 1-[chloro(diisopropylamino)boryl]imidazole (**5**) as a white precipitate; **5** was obtained separately from **1a** and dichloro(diisopropylamino)borane (Scheme 2).[4d]

Under the same conditions, with the stronger Lewis acids BBr_3 and BI_3, the amount of side products increases, as indicated by the smaller yields of **4c** (55%) and of **4d** (< 30%). However, in contrast to **4c**, purification of **4d** by recrystallization was unsuccessful, due to the formation of [iPr$_2$NH$_2$]I. The ^1H NMR spectra showed increased low-field shifts of the aromatic protons. Additionally, the corresponding signals for the four-coordinate boron atoms are shifted to high field. Apart from the two resonances of the boron atoms of **4c** and **4d**, each ^{11}B NMR spectrum of the crude products shows an additional signal assigned to the (diisopropylamino)haloborane by-products. As (diisopropylamino)diiodoborane, not yet described, was prepared separately by treating diisopropylamine with BI_3. During crystallization of **4d**, extremely air-sensitive yellow crystals of **7** were obtained, confirming that compound **6** is formed

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

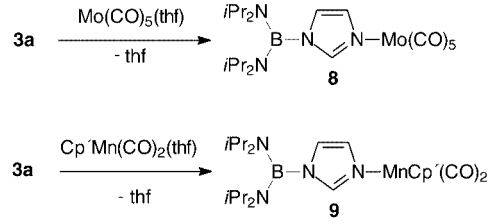
by the reaction of BI_3 and **4d** (Scheme 3). Treatment of **3a** with BEt_3 and BH_3 gave the adducts **4e** and **4f** in excellent yields. Unlike the observed down-field shift of the imidazole proton signals in the ^1H NMR spectrum of the haloborane adducts **4**, the corresponding proton signals of **4e** and **4f** remain nearly unchanged compared to those of **3a**. The ^{11}B NMR resonances for the tetracoordinate boron atoms are at $\delta = -3$ (**4e**) and -20 (**4f**) ppm.



Scheme 3

Formation of Metal Complexes

Examination of the reactivity of **3a** towards photochemically generated $[Mo(CO)_5thf]$ and $Cp'Mn(CO)_2thf$ complexes ($Cp' = C_5H_4Me$)[8] revealed that THF is readily displaced by the two-electron donor ligand **3a** at low temperature to give good yields of **8** and **9**, respectively (Scheme 4).



Scheme 4

In the ^1H NMR spectrum of **8** all resonances remain unchanged compared with those of the starting material, but the corresponding signals in the ^{13}C NMR spectrum appear at slightly different fields. The IR spectrum of **8** exhibits three absorptions, at $\tilde{\nu} = 1979$, 1933 and 1891 cm^{-1}.

Unlike that of **8**, the ^1H NMR spectrum of **9** exhibits clearly broadened lines that are significantly shifted in comparison with the starting material, hinting at the formation of a paramagnetic compound. The reasons for this unexpected paramagnetism at room temperature for the 18VE carbonylmetal complex of manganese(I) lie, as described by Kaim et al.,[9] in the generally small ligand-field splitting of low-valent manganese, which favors spin crossover. Other factors are the ligand strength and coordination geometry. Reduction of the symmetry of the $Cp'Mn(CO)_3$ parent to C_s in **9** and weakening of the bond to the imidazole substituent lead to an arrangement of d orbitals that favors the occupation of magnetically excited states. Conversely, the correlated ^{13}C NMR spectra exhibit all expected resonances as sharp lines at slightly different fields compared with **3a**. Infrared spectroscopy shows two CO bands at $\tilde{\nu} = 2017$ and 1928 cm^{-1}. As with the haloborane adducts **4**, no mass spectrometric data for **8** and **9** could be obtained.

Crystal Structures

To confirm their monomeric structures, we performed X-ray single-crystal analyses of the colorless and orange crystals obtained by cooling hexane solutions of **3a** and **3b**, respectively, to -80 °C. Their molecular structures are shown in Figures 1 and 2.

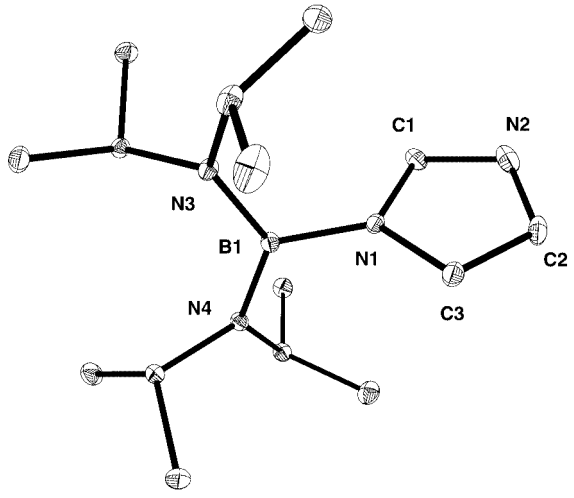


Figure 1. Molecular structure of **3a** in the crystal; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: B1–N1 1.514(2), B1–N3 1.420(1), B1–N4 1.425(1), N1–C1 1.361(2), N1–C3 1.387(2), N2–C1 1.316(2), N2–C2 1.389(3); C1–N1–C3 104.6(1), N2–C1–N1 114.1(2), C1–N2–C2 104.4(1); angle between planes N1/B1/N3/N4 and ring 68.5

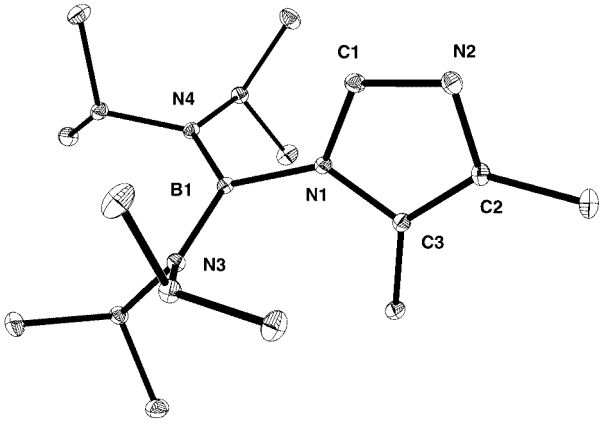

Figure 2. Molecular structure of **3b** in the crystal; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: B1–N1 1.507(1), B1–N3 1.429(1), B1–N4 1.426(1), N1–C1 1.368(1), N1–C3 1.397(1), N2–C1 1.318(1), N2–C2 1.390(1); C1–N1–C3 105.3(1), N2–C1–N1 113.7(1), C1–N2–C2 104.5(1); angle between planes N1/B1/N3/N4 and ring 63.7

In **3a** the imidazole ring is disordered over two positions (3:1); the distances and angles of the higher occupied part are given. The imidazole rings are planar with short internal

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ring bond lengths, which are very similar to those in imidazole.[10] More significant differences are found in the ring angles, especially at N1 (decreasing) and C1 (increasing) compared with imidazole.

As expected for a substituted imidazole, the N1/2−C1 bond lengths of **3a** and **3b** show single- and double-bond character.[11] Because the B1−N1 distance is about 0.10 Å longer than that from B1 to the diisopropylamino nitrogen atoms, π-interactions of the vacant p-orbital of B1 with the free electron pair of N1 can be excluded, while the short B1−N2/N3 distances indicate strong interactions with these nitrogen atoms. This is in agreement with the angles between the planes through the imidazole ring and B1 and the adjacent nitrogen atom (**3a**: 68.5°; **3b**: 63.7°).

Single crystals of **4a** have been obtained from a toluene solution. The crystal cell contains two crystallographically independent molecules in the asymmetric unit with very similar distances and angles; only one structure is shown in Figure 3 and the average values are listed.

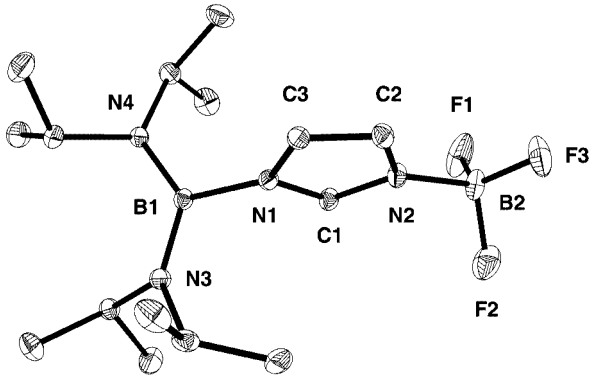

Figure 3. Molecular structure of **4a** in the crystal; hydrogen atoms are omitted for clarity; average values of selected bond lengths [Å] and angles [°]: B1−N1 1.527(2), B1−N3 1.412(2), B1−N4 1.414(2), B2−N2 1.579(2), N1−C1 1.336(2), N1−C3 1.388(2), N2−C1 1.327(2), N2−C2 1.379(2); C1−N1−C3 106.8(1), N2−C1−N1 110.7(1), C1−N2−C2 107.0(1); angle between planes N1/B1/N3/N4 and ring 73.4

Comparing the structural data of **4a** with that of **3a** enables the following observations: First, the N1/N2−C1 distances [N1−C1 1.336(2) Å and N2−C2 1.327(2) Å] exhibit significantly smaller bond-length alternations as at **3a**, indicating uninterrupted aromaticity. Second, the angles at N1 and C1 in **4a** resemble those in imidazole[10] more than in **3a** and **3b**. Third, as expected, the distance [1.577(2) Å] between N2 and the four-coordinate boron atom is longer than between N1 and B1 [1.527(2) Å].

The X-ray diffraction study of yellow **7** confirms the structure; as the quality of the data is poor, however, it will not be further discussed here. Crystals of **8** and **9** suitable for X-ray analysis were grown from a toluene solution. **8** contains four independent molecules in the asymmetric unit. As the obtained distances and angles of these molecules are similar, only one structure is shown in Figure 4, and the range of selected bond lengths and angles is listed. The values for **9** are given in the caption of Figure 5.

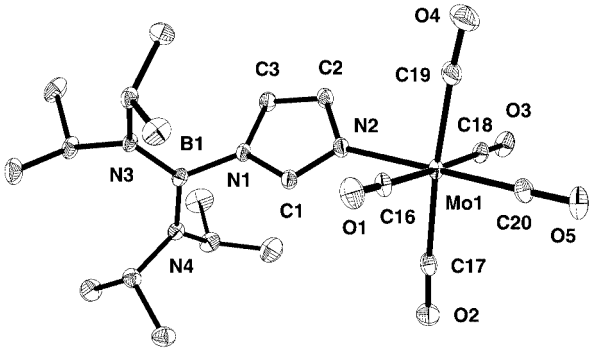

Figure 4. Molecular structure of **8** in the crystal; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: B1−N1 1.517(5)−1.527(5), B1−N3 1.406(5)−1.412(5), B1−N4 1.404(5)−1.422(5), N1−C1 1.344(4)−1.350(5), N2−C1 1.317(5)−1.326(4); C1−N1−C3 105.0(3)−105.4(3), N2−C1−N1 112.9(3)−113.5(3), C1−N2−C2 104.2(3)−105.0(3); angle between planes N1/B1/N3/N4 and ring 108.7−117.9

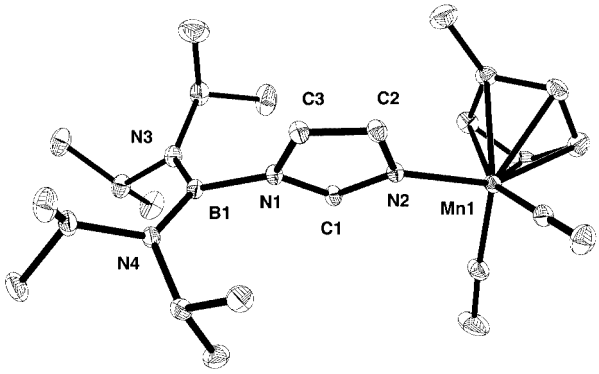

Figure 5. Molecular structure of **9** in the crystal; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: B1−N1 1.527(2), B1−N3 1.416(2), B1−N4 1.423(2), N1−C1 1.353(2), N2−C1 1.327(2); C1−N1−C3 105.7(1), N2−C1−N1 112.5(1), C1−N2−C2 105.0(1); angle between planes N1/B1/N3/N4 and ring 118.8

Both molecules exhibit less bond-length alternations than **3a** but more than **4a** and, following this structural pattern, the angles at N1 and C1 resemble those in imidazole more than those of **3a** and **3b**. Further, the Mo−CO bonds of **8** *trans* to the nitrogen atoms (1.97 Å) are shorter than the average length of the *cis* Mo−C bonds (2.04 Å). This is due to the stronger π-bonding from Mo to CO, indicating good σ-donor and poor π-acceptor capacity of the imidazole ligand.

Conclusion

The monomeric imidazoles **3a** and **4a** are obtained by using electron-donating *and* sterically demanding boryl substituents. Contrary to **3a**, restricted rotation about the B−N(imid.) bond is observed for **4a**. X-ray structure analyses of **3a** and **4a** reveal that π-interaction of the vacant p-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

orbital of the boron atoms exists only with the diisopropylamino groups and not with the imidazole nitrogen atoms. Treatment of **3a** with the weak Lewis acids BF_3, BEt_3 and BH_3 leads to the corresponding zwitterionic adducts in excellent yields. In contrast, the stronger Lewis acids BCl_3, BBr_3, and BI_3 give decreasing yields with increasing Lewis acidity. The observed side reactions involve splitting off of the diisopropylamino groups of **3a** and the corresponding adducts. With $Mo(CO)_5$thf and $Cp'Mn(CO)_2$thf the complexes 3-[$(OC)_5$Mo]**3a** (**8**) and 3-[$(OC)_2Cp'Mn$]**3a** (**9**) are formed readily, and X-ray diffraction measurement of **8** reveals the good σ-donor and poor π-acceptor capacity of the borylimidazole ligand.

Experimental Section

General: Reactions were carried out under dry argon, using standard Schlenk techniques. Solvents were dried, distilled and saturated with nitrogen. Glassware was dried with a heat-gun under high vacuum. ^1H, ^{13}C, ^{11}B NMR: Bruker AC 200 spectrometer, with $(CH_3)_4Si$ and $BF_3{\cdot}Et_2O$ as references. IR spectra were recorded with a Bruker IFS 28 Fourier-transformation spectrometer with CaF_2 cells. Mass spectra were obtained with a Finnigan MAT 8200 plus spectrometer using the EI technique. Melting points (uncorrected) were obtained with a Büchi apparatus, using a capillary filled under argon and sealed. Chlorobis(dimethylamino)borane,[12] chlorobis(diisopropylamino)borane[13] and 4.5-dimethyl-1-(trimethylsilyl)imidazol[14] were prepared according to literature procedures. (Trimethylsilyl)imidazole, $BF_3{\cdot}Et_2O$, BBr_3, $BH_3{\cdot}THF$, $BEt_3{\cdot}THF$ and $Cp'Mn(CO)_3$ were purchased from Sigma Aldrich and $Mo(CO)_6$ from Fluka.

1-[Bis(dimethylamino)boryl]imidazole (2): Chlorobis(dimethylamino)borane (190 mg, 1.4 mmol) in THF (10 mL) was added dropwise at −30 °C to a solution of **1a** (200 mg, 1.4 mmol) in THF (40 mL). After slowly warming to room temperature and stirring for 10 h, the solvent was removed in vacuo, leaving the white crude product, m.p. (dec.) > 240 °C. ^1H NMR (200.1 MHz, $CDCl_3$): δ = 0.7−1.2 (m, CH_3), 6.8−7.5 (m, im.) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 1.3 ($\Delta\nu_{1/2}$ = 145 Hz) ppm.

1-[Bis(diisopropylamino)boryl]imidazole (3a): Chlorobis(diisopropylamino)borane (713 mg, 2.9 mmol) in THF (10 mL) was added dropwise at −30 °C to a solution of **1a** (410 mg, 2.9 mmol) in THF (40 mL). The resultant mixture was allowed to warm to room temperature and stirred for 24 h. The solvent was then removed in vacuo, and the remaining solid extracted with hexane and filtered. The product was recrystallized from hexane solution at −80 °C. Yield: 685 mg (85%) of colorless crystals, sensitive to air and moisture, m.p. 67−68 °C. ^1H NMR (200.1 MHz, $CDCl_3$): δ = 0.98 [d, $^3J_{H,H}$ = 6.8 Hz, 24 H, $CH(CH_3)_2$], 3.41 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, $CH(CH_3)_2$], 6.85 (s, 1 H, C*H*−CH=N), 7.01, (s, 1 H, CH−C*H*=N), 7.47 (s, 1 H, N=CH−N) ppm. ^1H NMR (200.1 MHz, [D_8]THF): δ = 1.04 [d, $^3J_{H,H}$ = 6.8 Hz, 24 H, $CH(CH_3)_2$], 3.47 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, $CH(CH_3)_2$], 6.90 (s, 2 H, C*H*−C*H*=N), 7.44 (s, 1 H, N−CH=N) ppm. ^1H NMR (200.1 MHz, [D_8]toluene): δ = 1.08 [d, $^3J_{H,H}$ = 6.8 Hz, 24 H, $CH(CH_3)_2$,], 3.45 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, $CH(CH_3)_2$], 6.92 (s, 1 H, C*H*−CH=N), 7.46 (s, 1 H, CH−C*H*=N), 7.72 (s, 1 H, N−CH=N) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 28 ($\Delta\nu_{1/2}$ = 145 Hz) ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 24.4 [$CH(CH_3)_2$], 47.0 [$CH(CH_3)_2$], 122.2 (*C*H−CH=N), 128.1 (CH−*C*H=N), 141.4 (N−CH=N) ppm. ^{13}C NMR (50.3 MHz, [D_8]THF): δ = 25.5 [$CH(CH_3)_2$], 48.5 [$CH(CH_3)_2$], 123.1 (*C*H−CH=N), 129.7 (CH−*C*H=N), 142.8 (N−CH=N) ppm. ^{13}C NMR (50.3 MHz, [D_8]toluene): δ = 24.4 [$CH(CH_3)_2$], 47.0 [$CH(CH_3)_2$], 122.2 (*C*H−CH=N), 128.1 (CH−*C*H=N), 141.4 (N−CH=N) ppm. HR-EI: *m*/*z* = 278.2670, calcd. for $C_{15}H_{31}N_4B$ 278.2698 (Δμ = 2.8).

1-[Bis(diisopropylamino)boryl]-4,5-dimethylimidazole (3b): The same procedure as for **3a** was used in treating **1b** (300 mg, 1.8 mmol) with chlorobis(diisopropylamino)borane (443 mg). After workup an air- and moisture-sensitive orange solid was obtained (484 mg; 88%), m.p. 94−95 °C. ^1H NMR (200.1 MHz, $CDCl_3$): δ = 0.96 [d, $^3J_{H,H}$ = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.01 [d, $^3J_{H,H}$ = 6.8 Hz, 12 H, $CH(CH_3)_2$]], 2.12 [2 s, 6 H, CH_3(im.)], 3.39 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, $CH(CH_3)_2$], 7.24 (s, 1 H, N=CH−N) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 28 ($\Delta\nu_{1/2}$ = 145 Hz) ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 11.2 [CH_3 (im.)], 12.4 [CH_3 (im.)], 23.8 [$CH(CH_3)_2$], 24.6 [$CH(CH_3)_2$], 47.1 [$CH(CH_3)_2$], 124.3 (*C*Me−CMe=N), 133.9 (CMe−*C*Me=N), 138.7 (N−CH=N) ppm. EI-MS: *m*/*z* (%) = 306 (10) $[M]^+$, 211 (100) $[C_{12}H_{28}N_2B]^+$. HR-EI: *m*/*z* = 306.2953, calcd. for $C_{17}H_{35}N_4B$ 306.2947 (Δμ = 0.6).

General Procedure for the Preparation of the 1-[Bis(diisopropylamino)boryl]imidazole Adducts 4: To a solution of **1a** (200 mg, 0.7 mmol) in the corresponding solvent (40 mL), $BF_3{\cdot}OEt_2$ (120 mg, 0.84 mmol) was added at −78 °C to give **4a**; BCl_3 (81 mg, 0.7 mmol) to give **4b**; BBr_3 (174 mg, 0.7 mmol) to give **4c**; BI_3 (274 mg, 0.7 mmol) to give **4d**; $BH_3{\cdot}$thf (0.7 mL, 0.7 mmol; 1 M solution in THF) to give **4e** and $BEt_3{\cdot}$thf (0.7 mL, 1 M solution in THF) to give **4f**. The reaction mixtures were allowed to warm to room temperature and stirred for 7 h.

1-[Bis(diisopropylamino)boryl]imidazole(N^3-B)Trifluoroborane (4a): Yield after evaporation of THF: 242 mg (100%) of a white powder, sensitive to air and moisture, m.p. 112−114 °C. ^1H NMR (200.1 MHz, $CDCl_3$): δ = 1.01 [d, $^3J_{H,H}$ = 6.8 Hz, 24 H, $CH(CH_3)_2$], 3.45 [m, $^3J_{H,H}$ = 7 Hz, 4 H, $CH(CH_3)_2$], 6.98 (s, 1 H, C*H*−CH=N), 7.30 (s, 1 H, CH−C*H*=N), 7.98 (s, 1 H, N=CH−N) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = −0.3 (q, $^2J_{B,F}$ = 14 Hz, $\Delta\nu_{1/2}$ 36 Hz, BF_3), 28 [$\Delta\nu_{1/2}$ = 145 Hz, N−B(N*i*Pr$_2$)$_2$] ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 24.4 [$CH(CH_3)_2$], 47.4 [$CH(CH_3)_2$], 122.0 (*C*H−CH=N), 123.7 (CH−*C*H=N), 138.6 (N−CH=N) ppm.

1-[Bis(diisopropylamino)boryl]imidazole(N^3-B)Trichloroborane (4b): A colorless precipitate (20 mg) was filtered off and the volatile compounds of the toluene solution removed under vacuum. The NMR spectra of the crude product show signals of **4b**, **3a** and dichloro(diisopropylamino)borane. The residue was recrystallized from toluene at −18 °C. Yield: 187 mg (68%) of colorless **4b**, which is sensitive to air and moisture, m.p. 145−148 °C. ^1H NMR (200.1 MHz, [D_8]toluene): δ = 0.87 [d, $^3J_{H,H}$ = 6.8 Hz, 24 H, $CH(CH_3)_2$], 3.21 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, $CH(CH_3)_2$], 6.35 (s, 1 H, C*H*−CH=N), 7.67 (s, 1 H, CH−C*H*=N), 8.60 (s, 1 H, N−CH=N) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 5.3 ($\Delta\nu_{1/2}$ = 30 Hz, BCl_3), 28 [$\Delta\nu_{1/2}$ = 360 Hz, N−B(N*i*Pr$_2$)$_2$] ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 23.7 [$CH(CH_3)_2$], 47.0 [$CH(CH_3)_2$], 124.7 (CH−CH=N), 128.9 (CH−CH=N), 137.4 (N−CH=N) ppm.

1-[Bis(diisopropylamino)boryl]imidazole(N^3-B)Tribromoborane (4c): A yellowish precipitate was filtered off and the volatile compounds of the toluene solution removed under vacuum. The NMR spectra of the crude product show signals of **4c**, **3a** and dibromo(di-

isopropylamino)borane. The residue was then recrystallized from toluene at −18 °C. Yield: 202 mg (55%) of colorless **4c**, which is sensitive to air and moisture, m.p. decomp. > 150 °C. ^{1}H NMR (200.1 MHz, [D$_8$]toluene): δ = 0.90 [d, $^3J_{H,H}$ = 6.8 Hz, 24 H, CH(CH_3)$_2$], 3.23 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, CH(CH$_3$)$_2$], 6.42 (s, 1 H, CH−CH=N), 7.84 (s, 1 H, CH−CH=N), 8.81 (s, 1 H, N−CH=N) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = −11.8 (Δν$_{1/2}$ = 30 Hz, BBr_3), 28 [Δν$_{1/2}$ = 360 Hz, N−B(NiPr$_2$)$_2$] ppm. ^{13}C NMR (50.3 MHz, [D$_8$]toluene): δ = 24.1 [CH(CH_3)$_2$], 47.4 [CH(CH$_3$)$_2$], 124.0 (CH−CH=N), 129.3 (CH−CH=N), 141.1 (N−CH=N) ppm.

1-[Bis(diisopropylamino)boryl]imidazole(N^3−B)Triiodoborane (4d): A yellow precipitate was filtered off and the volatile compounds of the toluene solution were removed under vacuum. The NMR spectra of the crude product show signals of **4d**, **3a** and (diisopropylamino)diiodoborane. The residue was recrystallized from toluene at −18 °C, but was still contaminated with diisopropylammonium iodide. ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 1.06 [d, $^3J_{H,H}$ = 6.8 Hz, 12 H, CH(CH_3)$_2$], 1.58 [d, $^3J_{H,H}$ = 6.8 Hz, 24 H, CH(CH_3)$_2$], 3.48 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, CH(CH$_3$)$_2$], 3.65 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, CH(CH$_3$)$_2$], 7.11 (s, 1 H, CH−CH=N), 7.91 (s, 1 H, CH−CH=N), 8.68 (s, 1 H, N−CH=N) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = −68.5 (Δν$_{1/2}$ = 50 Hz, BI_3), 28 [Δν$_{1/2}$ = 360 Hz, N−B(NiPr$_2$)$_2$] ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 19.1 [CH(CH_3)$_2$], 24.5 [CH(CH_3)$_2$], 47.4 [CH(CH$_3$)$_2$], 48.6 [CH(CH$_3$)$_2$], 128.2 (CH−CH=N), 129.0 (CH−CH=N), 137.6 (N−CH=N) ppm.

1-[Bis(diisopropylamino)boryl]imidazole(N^3−B)Triethylborane (4e): The volatile compounds of the THF solution were removed under vacuum, leaving **4e** quantitatively as a white powder that is sensitive to air and moisture, m.p. 97−98 °C. ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 0.24 (q, 6 H, CH_2CH$_3$), 0.60 (t, 6 H, CH$_2$CH_3), 1.00 [d, $^3J_{H,H}$ = 6.8 Hz, 24 H, CH(CH_3)$_2$], 3.43 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, CH(CH$_3$)$_2$], 6.83 (s, 1 H, CH−CH=N), 7.07 (s, 1 H, CH−CH=N), 7.56 (s, 1 H, N−CH=N) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = −3 (Δν$_{1/2}$ = 380 Hz, BEt_3), 28 [Δν$_{1/2}$ = 360 Hz, N−B(NiPr$_2$)$_2$] ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 9.7 (CH$_2$$CH_3$), 15.0 ($CH_2CH_3$) 24.4 [CH($CH_3$)$_2$], 47.2 [$C$H(CH$_3$)$_2$], 122.6 ($C$H−CH=N), 123.5 (CH−$C$H=N), 138.3 (N−CH=N).

1-[Bis(diisopropylamino)boryl]imidazole(N^3−B)Trihydroborane (4f): The volatile compounds of the THF solution were removed under vacuum. The residue was then recrystallized from toluene at −18 °C. Yield: 190 mg (93%) of a white powder that is sensitive to air and moisture, m.p. 93−95 °C. ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 1.00 [d, $^3J_{H,H}$ = 6.8 Hz, 24 H, CH(CH_3)$_2$], 3.42 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, CH(CH$_3$)$_2$], 6.83 (s, 1 H, CH−CH=N), 7.05 (s, 1 H, CH−CH=N), 7.68 (s, 1 H, N−CH=N) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = −20 (Δν$_{1/2}$ = 400, $^2J_{B,H}$ = 90 Hz, BH_3), 28 [Δν$_{1/2}$ = 360 Hz, N−B(NiPr$_2$)$_2$] ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 24.4 [CH(CH$_3$)$_2$], 47.3 [CH(CH$_3$)$_2$], 123.1 (CH−CH=N), 126.7 (CH−CH=N), 140.3 (N−CH=N) ppm.

(Diisopropylamino)diiodoborane: Diisopropylamine (160 mg, 1.6 mmol) in toluene (30 mL) was added dropwise at −50 °C to a solution of BI_3 (310 mg, 0.8 mmol) in toluene (100 mL), after which the mixture was refluxed for 5 h. After removal of the diisopropylammonium iodide by filtration, the solvent of the resultant yellow solution was removed in vacuo. The product was recrystallized from hexane/toluene at −15 °C. Yield 170 mg (60%) of a yellow powder that is sensitive to air and moisture, m.p. (decomp.) > 100 °C. ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 1.4 [br., 24 H, CH(CH_3)$_2$], 4.3 [br., 4 H, CH(CH$_3$)$_2$] ppm. ^{11}B NMR (64.2 MHz,

$CDCl_3$): δ = −1 ($\Delta\nu_{1/2}$ = 30 Hz) ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 21.9 [$CH(CH_3)_2$], 58.6 [$CH(CH_3)_2$] ppm. CI-MS: *m*/*z* (%) = 238 (100) $[M - I + H]^+$.

1-Bis[diisopropylamino)boryl]imidazole(N^3−*Mo*)(Pentacarbonyl)-molybdenum (8): A solution of freshly prepared $Mo(CO)_5$thf (150 mg, 0.5 mmol) in THF (30 mL) was slowly added to **1a** (140 mg, 0.5 mmol), dissolved in THF (50 mL) at −78 °C. After warming to room temperature and stirring, a brown solution formed. The solvent was then removed in vacuo and the remaining brown oil extracted with toluene. After filtration, the product was crystallized at −30 °C. Yield 170 mg (56%) of a yellow powder that is sensitive to air and moisture (containing traces of **3a**), m.p. (decomp.) > 100 °C. ^1H NMR (200.1 MHz, $[D_8]$THF): δ = 1.04 [d, $^3J_{H,H}$ = 6.8 Hz, 24 H, $CH(CH_3)_2$], 3.47 [m, $^3J_{H,H}$ = 6.8 Hz, 4 H, $CH(CH_3)_2$], 6.90 (s, 2 H, CH−CH=N), 7.43 (s, 1 H, N−CH=N) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 27 ($\Delta\nu_{1/2}$ = 145 Hz) ppm. ^{13}C NMR (50.3 MHz, $[D_8]$THF): δ = 24.0 [$CH(CH_3)_2$], 25.5 [$CH(CH_3)_2$], 48.2 [$CH(CH_3)_2$], 48.5 [$CH(CH_3)_2$], 123.1 (CH−CH=N), 129.1 (CH−CH=N), 129.3 (CH−CH=N), 129.7 (CH−CH=N), 132.6 (N−CH=N), 142.8 (N−CH=N) ppm. IR (THF): $\tilde{\nu}$ = 1979 (s), 1933 (vs), 1891 (w) cm^{-1}.

1-[Bis(diisopropylamino)boryl]imidazole(N^3−*Mn*)Dicarbonyl[η^5-(methylcyclopentadienyl)]manganese (9): The same procedure as for the preparation of **8** was used by treating freshly prepared Cp′$Mn(CO)_2$thf (130 mg, 0.5 mmol) with **1**(139 mg, 0.5 mmol). Crystallization from toluene yielded orange crystals (112 mg, 48%), which are sensitive to air and moisture, m.p. (decomp.) > 110 °C. ^{11}B NMR (64.2 MHz, $[D_8]$THF): δ = 32 ($\Delta\nu_{1/2}$ = 145 Hz) ppm. ^{13}C NMR (50.3 MHz, $[D_8]$THF): δ = 13.5 [$CH(CH_3)_2$], 47.8 [$CH(CH_3)_2$], 83.0 [CH_3(Cp)], 83.4 [CH_3(Cp)], 122.4 (CH−CH=N), 129.4 (CH−CH=N), 142.3 (N−CH=N), 226.7 (C=O) ppm. IR (THF): $\tilde{\nu}$ = 2017 (s), 1928 (vs) cm^{-1}.

Crystal Structure Determinations of 3a, 3b, 4a, 4f, 8, and 9: Crystal data and details of the structure determinations are listed in Table 1. Unique sets of intensity data were collected at low temperature with a Bruker−AXS SMART 1000 diffractometer (Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator, ω-scan). Empirical absorption corrections were applied. The structures were solved by direct methods (SHELXS-86)[15] and refined by least-squares methods based on F^2 with all measured reflections (SHELXS-97).[16] All non-hydrogen atoms were refined anisotropically. The imidazole ring in **3a** is disordered. CCDC-193535 (**3a**), -193536 (**3b**), -193537 (**4a**), -193538 (**8**), -193539 (**9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

Keywords: Vitamins / Tin / IR spectroscopy / Mössbauer spectroscopy / NMR spectroscopy

For comparison with the corresponding pyridoxine complexes we have prepared dimethyl-, diethyl-, dibutyl- and diphenyltin(IV) complexes of *N*-methylpyridoxine (MePN). The compounds [$SnMe_2$(MePN–H)]I (**1**), [$SnEt_2$(MePN–H)]I (**2**), [$SnBu_2$(MePN–H)]I (**3**) and [$SnPh_2$(MePN–H)]I·H_2O (**4**) were isolated and characterized by IR, Raman, Mössbauer, ^1H, ^{13}C and ^{119}Sn NMR spectroscopy, and by EI and FAB mass spectrometry. The crystal structures of [HMePN]I and of compounds **1**, **2**·2H_2O and **3** were determined by X-ray diffractometry. Their lattices contain dimeric [SnR_2-(MePN–H)]$_2^{2+}$ units (R = Me, Et, Bu) in which two bridging-chelating methylpyridoxinato anions link pentacoordinate Sn atoms with coordination polyhedra closer to square pyramids than to trigonal bipyramids. NMR results show that the dimeric cations persist in $(CD_3)_2SO$.

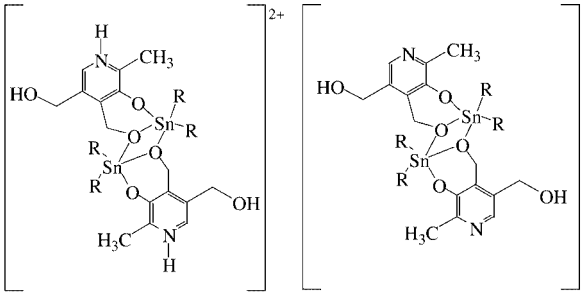
Introduction

As part of our research on the interaction of diorganotin compounds with vitamins and derivatives,[1,2] we have described the interaction of pyridoxine (PN, vitamin B_6) with dimethyltin(IV) and diethyltin(IV) cations in water/ethanol mixtures in the presence of biologically relevant anions such as Cl^- and NO_3^- in various molar ratios.[3,4] These reactions led to complexes containing mono- or di-deprotonated pyridoxine ligands ([PN−H] and [PN−2H], respectively) in dimeric [SnR_2(PN−H)]$_2^{2+}$ or [SnR_2(PN−2H)]$_2$ units. In these species (**I**, **II**) the tin centre was usually pentacoordinated to the two R groups, the deprotonated phenolic oxygen atom of one PN molecule and the deprotonated 4-(hydroxymethyl) oxygen atoms of this and another PN molecule, the latter oxygen atoms bridging the tin atoms of each dimer. In some dimethyltin derivatives the tin atom was hexacoordinate owing to an additional bond with the 5-(hydroxymethyl) group of a neighbouring dimer or with a water molecule.



I **II**

N-Methylation suppresses the normal biological activity of PN[5] and methylation of its 4-(hydroxymethyl) group makes it toxic.[6] To find out whether *N*-methylation also significantly affects its coordination to diorganotin cations, in this work we have determined the structures of [HMePN]I and of the complexes resulting from its reaction with SnR_2O (R = Me, Et, Bu), and compared them with those of PN and its diorganotin complexes.

We first attempted to use [HMePN]I to prepare *N*-methylpyridoxine [MePN (**III**)] with a view to treating the latter with the diorganotin oxides in reactions that parallel those previously[7] carried out with PN. However, since the resistance of MePN to deprotonation caused its reaction with SnR_2O to afford mainly impure MePN, we eventually treated the oxides (R = Me, Et, Bu and Ph) with PN and methyl iodide in a one-pot synthesis. This afforded the complexes $[SnMe_2(MePN-H)]I$, $[SnEt_2(MePN-H)]I$, $[SnBu_2(MePN-H)]I$ and $[SnPh_2(MePN-H)]I\cdot H_2O$, the first three of which were characterized, as with [HMePN]I, by single-crystal X-ray diffractometry. This appears to be the first study of MePN complexes and the first structural study of MePN.

Results and Discussion

Synthesis

The four complexes $[SnR_2(MePN-H)]I$ were prepared by adding solid SnR_2O and methyl iodide to a solution of pyridoxine in toluene/ethanol (Scheme 1). Compounds **1** and **3** crystallized as such from methanol, but compound **2** acquired two H_2O molecules during crystallization.

$$SnR_2O + PN + MeI \xrightarrow[-H_2O]{\text{toluene/ethanol}} [SnR_2(MePN\text{–}H)]I$$

R = Me (**1**)
Et (**2**)
Bu (**3**)
Ph (**4**)

Scheme 1

Description of the Structures

[HMePN]I

Figure 1 shows the structure of [HMePN]I together with the numbering scheme used. Selected distances and angles are listed in Table 1. The crystal is composed of $[HMePN]^+$ cations and iodide anions. In the cation the pyridine ring is planar and C(7), C(8), C(9), O(2) and O(3) are close to this plane, while C(10) and O(1) lie farther away.

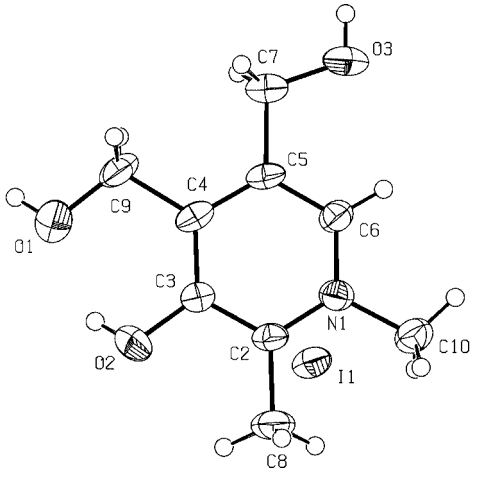

Figure 1. Crystal structure of [HMePN]I, showing the numbering scheme

Although limited by the high e.s.d.s, a comparison of bond lengths with those found for PN[8] shows that *N*-methylation and protonation do not change the ring parameters very much, even for bonds involving or close to the N atom; the most affected bond, C(3)−O(2), is shortened from 1.374(4) to 1.348(10) Å. Such changes are similar, bearing in mind the high e.s.d.s, to those caused by *N*-protonation, as observed in HPNCl[9] [except, of course, for N(1)−C(10)]. The bond angle most affected by *N*-methylation or protonation is C(2)−N(1)−C(6) [119.3(3), 123.8(5) and 122.4(7)° in PN, HPNCl and [HMePN]I, respectively].

As in HPNCl,[9] the O(2) atom of the phenolic hydroxy group and the O(1) atom of the C(4)−CH_2OH group are linked by an intramolecular hydrogen bond [0.82, 1.84 and 2.512(5) Å; 138.1°], which, by pulling O(1) out of the ring plane, is responsible for the different arrangements of the C(4)−CH_2OH and C(5)−CH_2OH groups. Each CH_2OH group is also involved in a structure-stabilizing intramolecular hydrogen bond with a neighbouring iodide ion [O(1)−H(1)···I(1)$^{\#1}$: 0.82, 2.71 and 3.423(6) Å, 146.3°; O(3)−H(3)···I(1)$^{\#2}$: 0.82, 2.86 and 3.593(8) Å, 150.0°; #1: $x + 1/2, -y + 3/2, z + 1/2$; #2: $-x, -y + 1, -z + 2$].

[SnMe$_2$(MePN−H)]I (1)

The dimethyltin derivative consists of dimeric $[SnMe_2(MePN-H)]_2^{2+}$ units and iodide ions. Figure 2 shows the structure of the dimeric unit and the numbering scheme used. Selected distances and angles are listed in Table 1.

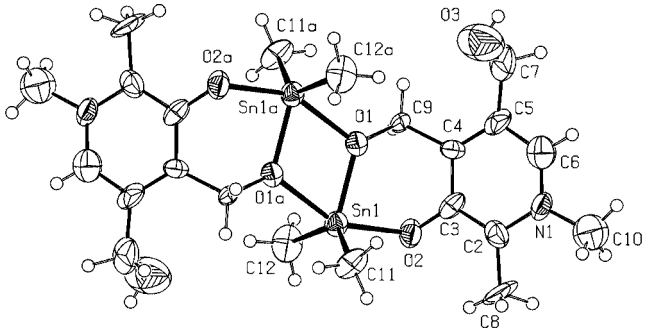

Figure 2. Crystal structure of the cation in the complex $[SnMe_2(MePN-H)]I$ (**1**), showing the numbering scheme (a: $-x, -y + 1, -z$)

In the dimeric unit the two methylpyridoxinato ligands bridge the tin atoms with their deprotonated C(4) substituents. Each tin atom coordinates to two methyl C atoms, to the deprotonated O(2) and O(1) atoms of one methylpyridoxinato ligand and to the similarly deprotonated O(1) atom of the other. As τ[10] = 0.35 for the coordination polyhedron, it is closer to a square pyramid, with the "foreign" O(1) apical, than to a trigonal bipyramid.

In the central Sn_2O_2 ring the length of one Sn−O bond, Sn−O(1), like that of Sn−O(2), is slightly less than the sum

of the covalent radii of Sn and O (2.13 Å),[11] whereas that of the other, Sn−O(1)^a, is slightly larger [2.231(9) Å]. The parameters of this ring are similar to those in other dimeric compounds with rings based on O-bridges.[12] The ring is planar, and makes an angle of 46.26° with the pyridine rings of the [MePN−H] ligands, which are, likewise, practically planar (r.m.s. deviation = 0.0160 Å).

Although the structural parameters of $[HMePN]^+$ change upon double deprotonation and coordination, the high e.s.d.s hinder rigorous analysis of the smaller changes, such as those undergone by the C(9)−O(1) and C(3)−O(2) bonds involving the coordinating oxygen atoms. However, the C(3)−C(4)−C(9) angle narrows significantly from 123.6(9)° in [HMePN]I to 114.6(14)° in **1** due to formation of the SnO(2)C(3)C(4)C(9)O(1) chelate ring.

The iodide ion is hydrogen-bonded to the noncoordinating hydroxymethyl group, C(5)−CH_2OH [O(3)−H(3)···I(1)$^{\#2}$: 0.82, 2.75 and 3.517(15) Å, 157.0°; #2: $x, -y + 1/2, z - 1/2$].

Comparison of this structure with those[3] of [$SnMe_2$(PN−H)]NO_3·2H_2O and [$SnMe_2$(H_2O)(PN−H)]Cl·H_2O, which like **1** are composed of dimeric units, reveals similar central Sn_2O_2 rings [although Sn−O(2) is shorter in **1**] but their tin environments are different, the PN−H derivatives being hexacoordinate. They also have different hydrogen-bond networks.

[$SnEt_2$(MePN−H)]I·2H_2O (2·2H_2O)

The diethyltin derivative consists of [$SnEt_2$(MePN−H)]$_2^{2+}$ units, iodide ions and water molecules. Figure 3 shows the structure of the dimeric unit and the numbering scheme used. Selected distances and angles are listed in Table 1.

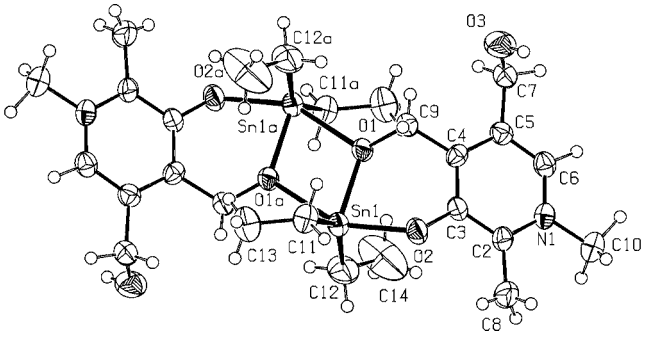

Figure 3. Crystal structure of the cation in the complex [$SnEt_2$(MePN−H)]I·2H_2O (**2**·2H_2O), showing the numbering scheme (a: $-x + 1, -y, -z + 1$)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The essential structural features of the dimeric unit are, as in **1**, a central Sn_2O_2 ring and the two methylpyridoxinato ligands linked to this ring. However, the following differences deserve comment.

In the Sn_2O_2 ring, the Sn−O bonds are longer in **2**·$2H_2O$ than in **1**, so that even though the Sn−O(1)−Sn^i angle is narrower in **2**·$2H_2O$ than in **1** [109.80(16)° as against 111.6(4)°] the two tin atoms are separated by a greater distance in **2**·$2H_2O$ [3.5815(9) Å] than in **1**. The coordination polyhedron is closer to a square pyramid in **2**·$2H_2O$ than in **1** (τ = 0.12 versus 0.35), mainly because the C−Sn−C angle is wider in **2**·$2H_2O$ than in **1** [145.9(3)° versus 131.8(7)°]. The dihedral angles between the planar Sn_2O_2 ring and the practically planar pyridine rings (r.m.s. deviation = 0.0073 Å) are narrower in **2**·$2H_2O$ than in **1** (33.86° as against 46.26°).

The main difference in crystal packing between **1** and **2**·$2H_2O$ is the presence in **2** of a denser network of hydrogen bonds involving the iodide ion, the water molecules, and the C(5)−CH_2OH group [O(4)−H(4B)···I(1): 1.00(8), 2.52(8) and 3.501(7) Å, 168(6)°; O(4)−H(4A)···O(3)$^{\#2}$: 0.98(8), 2.33(9) and 2.839(9) Å, 112(7)°; O(3)−H(3)···O(4)$^{\#3}$: 0.82, 2.27 and 2.839(9) Å, 126.4°; #2: x, $-y$ + 1/2, z + 1/2; #3: x, $-y$ + 1/2, z − 1/2].

The structure of **2**·$2H_2O$ is very similar to that of $[SnEt_2(PN-H)]NO_3 \cdot 2H_2O$.[3] In particular, the Sn_2O_2 rings are practically identical. The most noteworthy differences are the shorter Sn−C bonds of **2**·$2H_2O$ and its narrower C−Sn−C angles [145.9(3)° versus 152.77(13)°].

[SnBu$_2$(MePN−H)]I (3)

The dibutyltin derivative consists of dimeric $[SnBu_2(MePN-H)]_2^{2+}$ units and iodide ions. Figure 4 shows the structure of the dimeric unit (for clarity the butyl carbon atoms are reduced in size) and the numbering scheme used. Selected distances and angles are listed in Table 1.

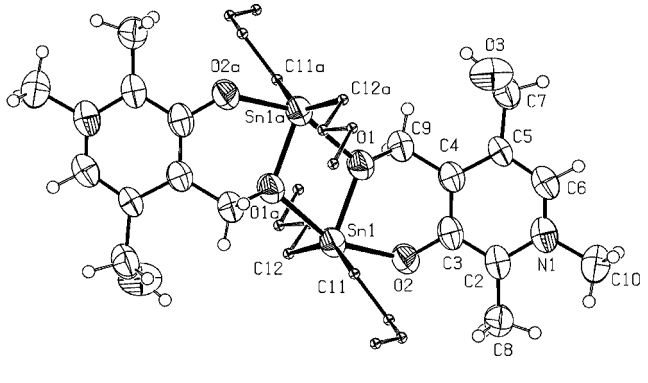

Figure 4. Crystal structure of the cation in the complex $[SnBu_2(MePN-H)]I$ (**3**), showing the numbering scheme; for clarity the butyl carbon atoms are reduced in size (a: $-x$, $-y$, $-z$)

The dimeric unit has a similar structure to **1** and **2**·$2H_2O$, its bond lengths and angles differing only very slightly from those of **2**·$2H_2O$. The Sn−O(1)^a distance is slightly shorter in **3**, but the tin environment has a similar degree of distortion. The hydrogen-bond network in **3** is practically identical to that of **1** [O(3)−H(3)···I(1)$^{\#2}$: 0.82, 2.56 and 3.372(6) Å, 172.4°; #2: x − 1/2, $-y$ + 1/2, $-z$ + 1/2].

Conversely, the angle between the planar Sn_2O_2 ring and each of the practically planar py rings (r.m.s. deviation = 0.0082 Å) is only 29.26° in **3**, falling from 46.26° for R = Me and 33.86° for R = Et, possibly due to the increasing bulk of R.

Vibrational Spectra

In addition to those given in the Exp. Sect., the IR spectrum of [HMePN]I exhibits bands at 3429, 3344, 3249 and 3150 cm^{-1}, attributed to stretching vibrations of the three OH groups. Deprotonation to [MePN] clears the IR spectrum in this region, leaving one broad band at 3160 cm^{-1} and another band at 3101 cm^{-1}, owing to the absence of phenolic ν(OH) and to alteration of the hydrogen-bonding network, which must likewise be responsible for the appearance of a broad medium-strong band at 2850 cm^{-1}.

The ν(C−O) bands for the C(4)- and C(5)−CH_2OH groups[13] of the complexes (see Exp. Sect.) are, like the vibrations of the pyridine ring, close to those of MePN. Near 1300 cm^{-1} the complexes show a strong IR band (medium in the Raman spectra) that is attributed[14] to ν(C−O) of the coordinated phenolic group.

For the methyl and ethyl derivatives the ν_{asym}(Sn−C) and ν_{sym}(Sn−C) vibrations are present in both the IR and Raman spectra, as expected for a nonlinear C−Sn−C fragment. Their positions are close to those[3,4] of unmethylated pyridoxine complexes.

Mössbauer Spectra

The Mössbauer spectra, recorded at 80 K, consist of well-resolved, slightly asymmetric doublets with isomer-shift and quadrupole-splitting values that are consistent with penta coordination around the tin(IV) centre. As usual, the isomer shifts increase on going from the methyl to the butyl derivative, while the diphenyl compound has a lower value due to its different electronegativity. Because of the marked distortion of the complexes from ideal trigonal-bipyramidal geometry, only the contributions of the covalently bonded organic groups were used in calculating Q.S. by means of the point charge model and the simplified formula[15] Q.S. = $-4[R](1-3/4\ \sin^2\ \theta)^{1/2}$. Using the experimental C−Sn−C bond angles, the Q.S. values are quite close to the experimental ones whether the p.q.s. is taken as −0.94 mm/s (valid for organic moieties in tba positions) or −1.13 mm/s (typical of tbe positions). The fact that the experimental Q.S. value of the diphenyl derivative is much lower than those calculated for the dialkyl derivatives suggests that it is even more strongly distorted.

Only the data for the diethyltin derivative can be compared with those of the corresponding PN complex,[3] the dimethyltin derivative of PN being hexacoordinate. The isomer shifts of $[SnEt_2(PN-H)]NO_3 \cdot 2H_2O$ and $[SnEt_2(PN-H)]Cl$, 1.63 and 1.61, respectively, are larger than the 1.49 found for $[SnEt_2(MePN-H)]I$, and as the iso-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mer shift reflects the s-electron density at the tin nucleus, this suggests that MePN−H has less donor ability than PN−H (vide infra).

NMR Spectroscopy

^{1}H, ^{13}C and ^{119}Sn NMR spectroscopic data recorded in [D_6]DMSO solution, and solid-state ^{13}C CP MAS NMR spectroscopic data, are given in the Exp. Sect.

a) Solid State

Satisfactory ^{13}C CP MAS spectra were obtained for all compounds except the diphenyltin complex. Most carbon atoms afforded separate signals, which were assigned on the basis of previously reported data for similar compounds[3,7c] and on the results of solution studies (see below). *N*-Methylation of PN shifted the C(3) signal ca. 10 ppm downfield. The C(6) and C(4) signals were also deshielded (but to a lesser extent), and the other carbon atoms were shielded, especially C(5) and C(8). This re-distribution of charge in the ring must have a substantial effect on the C(3)−O(2) bond and the charge on the potential donor atom O(2). Protonation of O(2) upon formation of [HMePN]I shielded C(3) by ca. 10 ppm, and C(2), C(6) and C(4) less markedly, while the other carbon atoms were deshielded [C(5) by ca. 9 ppm and the others by ca. 3 ppm]. These results, the X-ray data and the fact that protonation of O(2) in PN to give PN·H$^+$ shifts the C(3) signal slightly downfield (from δ = 151.4 to 153.4 ppm[3]) suggest that *N*-methylation of PN increases the order of the C(3)−O(2) bond, which should affect the donor ability of O(2).

The ^{13}C NMR spectra of the ligand after deprotonation and coordination to the organometallic moieties are very similar, indicating that, as found in the X-ray study of **1**−**3**, they all have the same coordination mode. As in the PN analogues,[3] C(3) and C(4) are deshielded and all other carbon atoms are shielded.

At high field, the spectra show signals corresponding to the organometallic moieties. Compound **1** gives two peaks for the dimethyltin carbon atoms, one at a position similar to that observed in solution (vide infra), δ = 5.6 ppm, and the other slightly upfield at δ = 1.8 ppm, showing the methyl groups to be magnetically different. Similarly, the spectrum of compound **3** shows seven peaks instead of the four found in solution, in keeping with the high anisotropy exhibited by this compound in the X-ray study.

b) Solution

The published ^{1}H NMR data for the PN analogues[3,4] contain an error: the position of the H(6) signal being reported as δ = 8.17 ppm instead of δ = 7.88 ppm. In the present study, methylation of PN markedly shielded H(6), and to a lesser extent the C(9)H_2 and C(7)H_2 protons, and deshielded the C(8)H_3 protons and H(O3). ^3J for the coupling of H(O3) with C(7)H_2 is now 5.2 Hz as against 5.8 Hz in PN. The H(O2) signal was not located, the high acidity of this OH group probably resulting in fast exchange with the deuterium atoms of the solvent. In [HMePN]I, in which MePN is protonated, all the protons are deshielded with respect to MePN, especially H(6) (by 1.07 ppm).

Coordination to SnR_2^{2+} shielded all the protons of [HMePN]I except C(9)H_2, which were slightly deshielded. Flanking the C(9)H_2 singlet in the spectra of **1**, **2** and **3** were satellites corresponding to coupling between these protons and ^{119}Sn, showing that the interaction between O(1) and the tin atoms observed in the solid state persists in solution. The absence of satellites around the signal at δ ≈ 4.5 ppm, assigned to C(7)H_2, rules out interaction between O(3) and the metal atom.

The chemical shifts of the organometallic fragments are similar to those found[3,4,7c] for tin complexes in [D_6]DMSO. Substitution of the ^2J(^{1}H-^{119}Sn) value of **1** (87.0 Hz) in Equation (2) of Lockhart and Manders'[16] study of dimethyltin compounds predicts a C−Sn−C angle of 140°; this is wider than that observed in the X-ray study (131.8°) which may be due to interaction with the solvent.

The chemical shifts of the ligand carbon atoms agree well with the ^{13}C CP-MAS data (taking into account the breadth of the CP-MAS signals). This suggests that the MePN ligand has the same stereochemistry in both states.

^1J(^{13}C-^{119}Sn) constants were only measurable for **1** and **3**. The value for **3** is in the range 500−700 Hz, found[17] for other five-coordinate diorganotin complexes. That of the methyl derivative is outside this range, but also outside the 800−1000 Hz range found[17] for hexacoordinate compounds. When the value for **1** is substituted into Lockhart and Manders' equation,[18] a C−Sn−C angle of 145° is obtained, which is 5° wider than that obtained using the ^2J value but, likewise, suggests that the angle is widened due to the effect of the solvent. By contrast, substitution of ^1J(^{13}C-^{119}Sn) of **3** in the relationship obtained by Holecek et al.[19] for dibutyltin compounds predicts a C−Sn−C angle of 141°, close to the 146.7° observed in the solid state and indicative of the persistence of pentacoordination in solution. The bulky butyl groups may prevent incorporation of the solvent in **3**.

The single ^{119}Sn resonance of the complexes shows that they each have only one type of organotin moiety. Although ^{119}Sn chemical shifts are influenced by several factors,[20] the coordination number of the tin atom is one of the most important:[21] our compounds show a very narrow range, δ = −170.2 to −233.5 ppm, which is within that reported for pentacoordinate organotin compounds.[17,21,22]

Experimental Section

Material and Methods: Pyridoxine (Aldrich), methyl iodide (Aldrich), silver carbonate (Aldrich), dimethyltin oxide (Alfa) and dibutyltin oxide (Aldrich) were used as received. Diethyl- and diphenyltin oxides were obtained by treating the corresponding chlorides with sodium hydroxide. Elemental analyses were performed with a Fisons 1108 microanalyser. Melting points were determined with a Büchi Dr. Tottoli apparatus and are uncorrected. The conductivities of 10^{-3} M solutions in DMF were measured with a Crison MicroCM2202 conductivity meter. Mass spectra were recorded with a Kratos MS50TC spectrometer connected to a DS90 system,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

operating under either EI conditions (direct insertion probe, 70 eV, 250 °C) or in FAB mode (*m*-nitrobenzyl alcohol, Xe, 8 eV; ca. 1.28 × 10^{-15} J); ions were identified by DS90 software and the data characterizing the metallated peaks were calculated using the isotope ^{120}Sn. IR spectra (KBr pellets or Nujol mulls) and Raman spectra (polycrystalline samples) were recorded with a Bruker IFS66V FT-IR spectrometer equipped with an FRA-106 Raman accessory and are reported below using the following abbreviations: vs = very strong, s = strong, m = medium, w = weak, sh = shoulder, br = broad. Mössbauer spectra were recorded at 80.0 K in a Harwell cryostat; the $Ca^{119m}SnO_3$ source (15 mCi, NEN) was kept at room temperature and moved with a triangular velocity wave form; suitable computer programs were employed to fit Lorentzian lineshapes to the experimental data. Solid-state NMR spectra were recorded with a Bruker AMX 300 spectrometer at 75.40 MHz using 7-mm o.d. zirconia rotors and the standard Bruker CPTOSS or CP_2LEV pulse programs at 3 and 4 kHz spinning speeds, a contact time of 1 ms and a recycle delay of 5 s; linewidths varied between 100 and 200 Hz, and chemical shifts are referred to glycine (δ = 176.3 ppm). ^{1}H and ^{13}C NMR spectra in solution were recorded at room temperature with a Bruker AMX 300 operating at 300.14 and 75.40 MHz, respectively, by using 5-mm o.d. tubes; chemical shifts are reported relative to TMS using the solvent signal [δ(^{1}H) = 2.50 ppm; δ(^{13}C) = 39.5 ppm] as reference. ^{119}Sn NMR spectra were recorded at 186.50 MHz with a Bruker AMX 500 spectrometer by using 5-mm o.d. tubes and are reported relative to external neat $Sn(CH_3)_4$. Elemental analyses, mass, IR, Raman and NMR spectra and X-ray data were obtained at CACTUS, University of Santiago de Compostela.

Synthesis of [HMePN]I and MePN

[HMePN]I: This compound was prepared by a published procedure[23] as follows. Methyl iodide (8 mL) was added to a solution of pyridoxine (0.52 g, 3.1 mmol) in benzene/ethanol (12:1, v/v, 260 mL). The resultant solution was refluxed overnight, affording small crystals, and then concentrated to one-third of its volume; the crystals formed were filtered off, washed with diethyl ether to remove traces of hydriodic acid, and recrystallized from absolute ethanol as well-shaped single crystals. IR (Raman) : ν̃ [cm^{-1}] = 1644 w (1643 m), δ(OH); 1579 m (1583s), 1530 m (1525 w), 1460 vs (1461sh), ν(ring); 1064 s (1061 m), 1015 s (1015 w), ν(CO). ^{13}C CP MAS NMR (see **III** for numbering): δ = 152.5 [C(3)], 143.4 [C(2)], 134.5 [C(6)], 133.2 [C(4)], 131.9 [C(5)], 62.2 [C(7)], 58.4 [C(9)], 47.7 [C(10)], 15.8 [C(8)] ppm. ^{1}H NMR ([D$_6$]DMSO, TMS): δ = 8.43 [s, 1 H, C(6)−H], 5.65 [s, br, 1 H, O(3)−H], 4.80 [s, 2 H, C(9)−H], 4.68 [s, 2 H, C(7)−H], 4.23 [s, 3 H, C(10)−H], 2.59 [s, 3 H, C(8)−H] ppm. ^{13}C{^{1}H} NMR ([D$_6$]DMSO, TMS): δ = 152.6 [C(3)], 144.4 [C(2)], 139.7 [C(6)], 138.2 [C(4)], 134.9 [C(5)], 58.0 [C(7)], 56.5 [C(9)], 46.6 [C(10)], 13.8 [C(8)] ppm.

[MePN]: This compound was prepared from [HMePN]I by reaction with silver carbonate.[23] IR (Raman): ν̃ [cm^{-1}] = 1653 w, δ(OH); 1558 vs (1556 s), 1498 vs (1480 w), 1467 s (1453 m), ν(ring); 1066 m (1066 w), 1020 vs, ν(CO). ^{13}C CP MAS NMR: δ = 161.9 [C(3)], 146.9 [C(2)], 139.2 [C(6)], 134.3 [C(4)], 123.0 [C(5)], 58.4 [C(7)], 53.8 [C(9)], 44.7 [C(10)], 12.1 [C(8)] ppm. ^{1}H NMR ([D$_6$]DMSO, TMS): δ = 7.36 [s, 1 H, C(6)−H], 5.27 [t, ^3J = 5.2 Hz, 1 H, O(3)−H], 4.58 [s, 2 H, C(9)−H], 4.38 [d, 2 H, C(7)−H], 3.95 [s, 3 H, C(10)−H], 2.36 [s, 3 H, C(8)−H] ppm. ^{13}C{^{1}H} NMR ([D$_6$]DMSO, TMS): δ = 165.9 [C(3)], 142.0 [C(2)], 136.8 [C(6)], 134.6 [C(4)], 121.6 [C(5)], 58.8 [C(7)], 58.0 [C(9)], 45.0 [C(10)], 11.9 [C(8)] ppm.

Synthesis of the Complexes

[SnMe$_2$(MePN−H)]I (1): Methyl iodide (8 mL) and solid dimethyltin(IV) oxide (0.51 g, 3.1 mmol) were added to a solution of pyridoxine (0.52 g, 3.1 mmol) in toluene/ethanol (3:1, v/v, 200 mL) and the mixture was refluxed for 24 h. Water was then removed by azeotropic distillation in a Dean−Stark funnel, and the resultant yellow solid was filtered off, washed with diethyl ether and vacuum-dried. Yield 96% (1.36 g). $C_{11}H_{18}INO_3Sn$ (457.9): calcd. C 28.8, H 4.0, N 3.1; found C 28.9, H 4.2, N 3.0. M.p. 205 °C. Λ_M = 57.2 S cm^2 mol^{-1}. The main signals of metallated species in the EI spectrum are at *m*/*z* (%) = 302 (4.1) [Sn(MePN−H)], 150 (30.8) [SnMe$_2$], 135 (28.8) [SnMe] and 120 (46.9) [Sn]. In addition, the EI spectrum shows signals for pyridoxine and its fragments, and the FAB spectrum exhibits signals at *m*/*z* (%) = 664 (43.1) [SnMe$_2$(MePN−H)]$_2$, 332 (100) [SnMe$_2$(MePN−H)] and 302 (10.0) [Sn(MePN−H)]. IR (Raman): ν̃ [cm^{-1}] = 1619 w (1618 w), δ(OH); 1568 m (1568s), 1498 m (1483 w), 1451 s (1450 m), ν(ring); 1067s, 1017 m (1017 w), ν(CO); 587 sh (587 w), ν_{asym}(Sn−C); 518 w (528vs), ν_{sym}(Sn−C); 467 m (461 w), 427 m (425 w), ν(Sn−O). Mössbauer: I.S. = 1.37, Q.S. = 3.20, Γ = 0.92 mm·s^{-1}, $A_{2/1}$ = 1.00. ^{13}C CP MAS NMR: δ = 159.0 [C(3)], 149.0 [C(2)], 143.6 [C(4)], 132.8 [C(6)], 132.8 [C(5)], 60.7 [C(7)], 57.4 [C(9)], 48.4 [C(10)], 16.5 [C(8)], 5.6, 1.8 [C−Sn] ppm. ^{1}H NMR ([D$_6$]DMSO, TMS): δ = 8.05 [s, 1 H, C(6)−H], 5.53 [t, ^3J = 5.2 Hz, 1 H, O(3)−H], 4.89 [s, ^3J(^{1}H-^{119}Sn) = 60.6 Hz, 2 H, C(9)−H], 4.55 [d, ^3J = 5.2 Hz, 2 H, C(7)−H], 4.11 [s, 3 H, C(10)−H], 2.49 [s, 3 H, C(8)−H], 0.58 [s, ^2J(^{1}H-$^{119/117}$Sn) = 87.0/84.4 Hz, 6 H, CH_3−Sn] ppm. ^{13}C{^{1}H} NMR ([D$_6$]DMSO, TMS): δ = 158.9 [C(3)], 145.1 [C(2)], 142.4 [C(4)], 134.9 [C(6)], 130.8 [C(5)], 58.6 [C(7)], 57.9 [C(9)], 45.7 [C(10)], 12.6 [C(8)], 6.1 [^1J(^{13}C-^{119}Sn) = 780.5 Hz, (C−Sn)] ppm. ^{119}Sn NMR {[D$_6$]DMSO, $Sn(CH_3)_4$}: δ = −170.2 ppm. Crystals suitable for X-ray study were obtained by crystallization from methanol.

[SnEt$_2$(MePN−H)]I (2): Methyl iodide (8 mL) and solid diethyltin(IV) oxide (0.59 g, 3.1 mmol) were added to a solution of pyridoxine (0.52 g, 3.1 mmol) in toluene/ethanol (3:1, v/v, 200 mL). After refluxing for 24 h, water was removed by azeotropic distillation in a Dean−Stark funnel and the resultant yellow solid was filtered off and vacuum-dried. Yield 97% (1.46 g). $C_{13}H_{22}INO_3Sn$ (485.9): calcd. C 32.1, H 2.9, N 4.5; found C 32.4, H 2.8, N 4.5. M.p. 239 °C. Λ_M = 73.8 S cm^2 mol^{-1}. The main signals of metallated species in the EI spectrum are at *m*/*z* (%) = 302 (71.5) [Sn(MePN−H)], 178 (10.0) [SnEt$_2$], 149 (36.6) [SnEt] and 120 (30.1) [Sn]. Also, the EI spectrum shows signals for pyridoxine and its fragments, and the FAB spectrum has signals at *m*/*z* (%) = 720 (26.6) [SnEt$_2$(MePN−H)]$_2$, 360 (100) [SnEt$_2$(MePN−H)] and 302 (18.3) [Sn(MePN−H)]. IR (Raman): ν̃ [cm^{-1}] = 1619 w (1618 w), δ(OH); 1564 m (1568s), 1501 w (1500 w), 1455 s (1456 m), ν(ring); 1068 s (1064 w), 1029 m (1033 w), ν(CO); 541 m (545 w), ν_{asym}(Sn−C); 500 w (502 vs), ν_{sym}(Sn−C); 462 m (456 w), 435 m (428 w), ν(Sn−O). Mössbauer: I.S. = 1.49, Q.S. = 3.21, Γ = 0.85 mm·s^{-1}, $A_{2/1}$ = 1.08. ^{13}C CP MAS NMR: δ = 158.9 [C(3)], 147.1 [C(2)], 141.8 [C(4)], 133.9 [C(6)], 133.9 [C(5)], 54.1 [C(7)], 54.1 [C(9)], 46.5 [C(10)], 14.0 [C(8)], 9.7 [C(α)−Sn] ppm. ^{1}H NMR ([D$_6$]DMSO, TMS): δ = 8.07 [s, 1 H, C(6)−H], 5.53 [t, ^3J = 5.2 Hz, 1 H, O(3)−H], 4.91 [s, ^3J(^{1}H-^{119}Sn) = 47.7 Hz, 2 H, C(9)−H], 4.55 [d, ^3J = 5.1 Hz, 2 H, C(7)−H], 4.13 [s, 3 H, C(10)−H], 2.53 [s, 3 H, C(8)−H], 1.29 [m, 4 H, CH(α)−Sn], 1.16 [t, ^3J(^{1}H-$^{119/117}$Sn) = 135.0/128.5 Hz, 6 H, CH(β)−Sn] ppm. ^{13}C{^{1}H} NMR ([D$_6$]DMSO, TMS): δ = 159.3 [C(3)], 144.5 [C(2)], 142.0 [C(4)], 134.7 [C(6)], 130.2 [C(5)], 59.5 [C(7)], 57.7 [C(9)], 45.4 [C(10)], 17.7 [C(β)−Sn], 12.2 [C(8)], 9.6 [C(α)−Sn] ppm. ^{119}Sn NMR {[D$_6$]DMSO, $Sn(CH_3)_4$}: δ = −209.5

Crystal Structure Determination

X-ray Data Collection and Reduction: Crystals were mounted on glass fibres for data collection with Enraf−Nonius automatic diffractometers (a CAD4 for [HMePN]I and a MACH3 for **1**, **2**·2H_2O and **3**).[24] Cell constants and an orientation matrix for data collection were calculated by least-squares refinement of the diffraction data for 25 reflections. Data were collected at 293 K by the ω-scan technique using Cu-K_α radiation (λ= 1.54184 Å) for [HMePN]I and Mo-K_α radiation (λ= 0.71073 Å) for **1**, **2**·2H_2O and **3**, and were corrected for Lorentz and polarization effects.[25] Semiempirical absorption corrections (ψ-scan) were also made.[26]

Structure Solution and Refinement: The structure was solved by direct methods[27] and subsequent Fourier maps, and was refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters.[28] Hydrogen atoms were placed at calculated positions (C−H 0.93−0.97 Å) and refined using a riding model. Atomic scattering factors were taken from ref.[29] Molecular graphics were generated with PLATON.[30] The crystal data, experimental details and refinement results are summarized in Table 2.

CCDC-187692 for [HMePN]I, -187693 for [$SnMe_2$(MePN−H)]I, -187694 for [$SnEt_2$(MePN−H)]I·2H_2O and -187695 for [$SnBu_2$(MePN−H)]I contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Designing Ionic Liquids: 1-Butyl-3-Methylimidazolium Cations with Substituted Tetraphenylborate Counterions

Joep van den Broeke,[a] Marjolijn Stam,[a] Martin Lutz,[b] Huub Kooijman,[b] Anthony L. Spek,[b] Berth-Jan Deelman,*[c] and Gerard van Koten[a]

Keywords: Ionic liquids / Cations / Anions / X-ray diffraction / Hydrogen bonds

The hydrophobic, low melting, 1-butyl-3-methylimidazolium (BMIm) salts [BMIm][BPh_4] (**1**), [BMIm][$B(C_6H_4Me\text{-}4)_4$] (**2**), [BMIm][$B\{C_6H_4(CF_3)\text{-}4\}_4$] (**3**), [BMIm][$B\{C_6H_3(CF_3)_2\text{-}3,5\}_4$] (**4**), [BMIm][$B\{C_6H_4(C_6F_{13})\text{-}4\}_4$] (**5**), [BMIm][$B\{C_6H_4(SiMe_3)\text{-}4\}_4$] (**6**), [BMIm][$B(C_6H_4\{SiMe_2(CH_2CH_2CF_3)\}\text{-}4)_4$] (**7**), [BMIm][$B\{C_6H_4(SiMe_2C_8H_{17}\text{-}4\}_4$] (**8**) and [BMIm]-[$B(C_6H_4\{SiMe_2(CH_2CH_2C_6F_{13})\}\text{-}4)_4$] (**9**) have been prepared. Systematic variation of the substituents on the tetraphenylborate anion allowed an assessment of their influence on the physical properties of the imidazolium salts. Structural investigations using NMR and IR spectroscopy, combined with single crystal X-ray structure determinations for **2**, **3**, **5** and **6**, revealed hydrogen-bonding interactions between the imidazolium ring protons and the borate anion, both in the solid state and in solution. These interactions are weakened upon the introduction of electron-withdrawing substituents in the anion and follow the order 3,5-$(CF_3)_2$ < $-C_6F_{13}$ < $-CF_3$ < $-SiMe_2CH_2CH_2C_6F_{13}$ < $-SiMe_2CH_2CH_2CF_3$ < $-H$ < $-Me$ < $-SiMe_3$. The melting points of the salts depend primarily on the bulk of the lipophilic substituents, and decrease with increasing size. Bulky lipophilic substituents dramatically enhance the solubility of the imidazolium borates **8** and **9** in hexane and reduce their relative polarity. These unique properties make imidazolium borates **8** and **9** interesting as amphiphilic ionic liquids with low polarity. Attempts to crystallise **7** resulted in decomposition. A single-crystal X-ray structure determination of the product, isolated in 6% yield, showed that a carbene–tris[4-{dimethyl(3,3,3-trifluoropropyl)silyl}phenyl]borane adduct was formed.

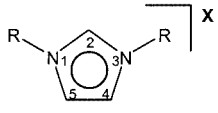
Introduction

The extremely low vapour pressure[1] of room-temperature ionic liquids (ILs) based on *N*,*N*-dialkylimidazolium cations and weakly coordinating anions (Scheme 1) makes them an interesting alternative to highly volatile organic solvents, such as CH_2Cl_2, that cause environmental concern and are subject to ever more stringent regulations.[2] The



X^- = *e.g.* $AlCl_4^-$, BF_4^-, PF_6^-, $CF_3SO_3^-$

Scheme 1

miscibility of ILs with other solvents can also be controlled, through a careful choice of the ions,[3] making them attractive as easily containable solvents. Especially noteworthy is their use as a polar phase in biphasic solvent systems, which is of interest for catalyst recycling. In such a system, the advantages of both homogeneous and heterogeneous catalysis, good catalyst efficiency under mild reaction conditions and facile catalyst recovery, respectively, can be combined.[1]

The physical properties, and chemical and physical stability of an IL govern its suitability as a reaction medium. The potential of ILs as solvents for catalysis was first demonstrated with the discovery of 1-ethyl-3-methylimidazolium tetrafluoroborate,[4] which combines the favourable properties of a liquid salt with high air and water stability. Subsequently, a broad range of cation-anion combinations has been developed,[5] and their chemical and physical properties,[5,6] as well as their application as solvents in catalysis, examined[1,7] These studies focussed on varying the alkyl substitution pattern on the imidazolium ring, while the anions employed have predominantly remained limited to inorganic or small organic anions such as BF_4^-, PF_6^-, SbF_6^-, NO_2^-, $CF_3SO_3^-$, $[N(CN)_2]^-$ and $[N(SO_2CF_3)_2]^-$.[1,5a,6a] The incorporation of large and lipo-

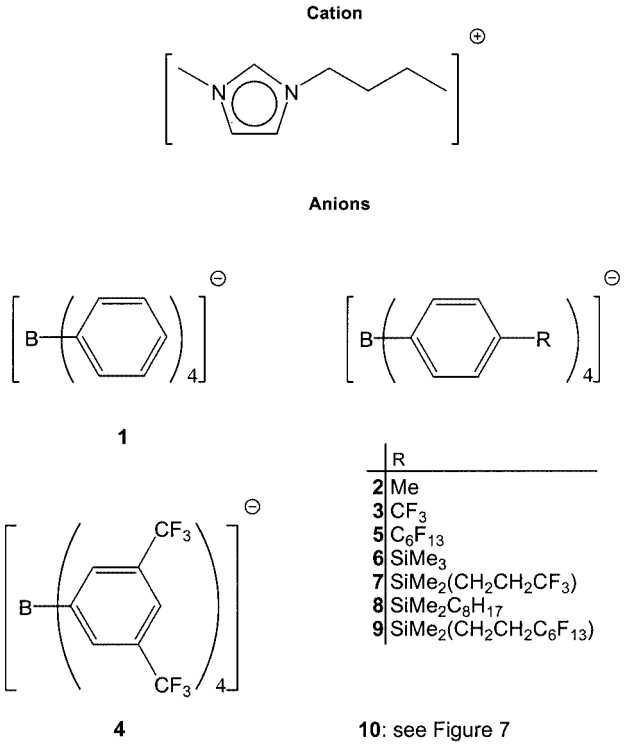
philic organic anions is virtually unexplored,[5a,7e,8] even though anions such as tetraphenylborates[9] and carboranes[10] efficiently delocalise their negative charge, resulting in a very low coordinating strength. The interaction of the anions, and to a lesser extent the cation, with solvent or substrate molecules plays a major role in determining the (im)miscibility of an IL with other liquids.[11] Large organic anions permit a broad range of substituents, which could allow the facile tailoring of an ionic liquid. In a first example of this approach[12] we showed that $-SiMe_2(CH_2CH_2C_6F_{13})$ substituents produced an imidazolium salt, [BMIm][$B(C_6H_4\{SiMe_2(CH_2CH_2C_6F_{13})\}\text{-}4)_4$] (**9**), that is highly miscible with apolar solvents. Furthermore, **9** displayed phase behaviour similar to perfluorinated solvents when combined with apolar organic solvents. This facilitated efficient catalyst recycling by biphasic separation following a reaction under homogeneous conditions[12] – a unique feature for ionic liquids.

After this initial demonstration a more systematic study of the effects of a range of alkyl-, perfluoroalkyl- and silyl-substituted tetraarylborates on the physical properties of the corresponding $[BMIm]^+$-salts was performed.

Results and Discussion

Synthesis: A series of 1-butyl-3-methylimidazolium salts of tetraphenylborate and alkyl-, perfluoroalkyl- and silyl-substituted derivatives thereof was prepared by metathesis of the sodium borates with dialkylimidazolium halides (Scheme 2). All imidazolium salts were purified by washing a solution in CH_2Cl_2 or toluene with demineralised water, followed by removal of residual water with $MgSO_4$ and subsequent drying of the IL in vacuo.



Scheme 2

The resulting compounds were characterised by ^1H, $^{13}C\{^1H\}$ and $^{11}B\{^1H\}$ NMR spectroscopy, IR spectroscopy and elemental analysis, and found to be pure. Furthermore, for **4**, **5**, **7** and the previously communicated **9**,[12] elemental analyses found no evidence of contamination by trace amounts of chloride or iodide. The remaining compounds were not analysed for halide ions. As the synthetic and workup procedures were identical, they were presumed to be halogen free at the level detectable by elemental analysis. The salts **2**–**9** are not hygroscopic, are stable in air, and are insoluble in water. Crystals suitable for single-crystal X-ray structure determination were obtained for **2**, **3**, **5** and **6**. Single crystals of **2**, **3** and **5** were grown by slow diffusion of hexane into CH_2Cl_2 solutions of these imidazolium salts. Crystals of **6** were obtained by slow evaporation of acetone from a concentrated solution. The molecular structures of **2** (Figure 1), **3** (Figure 2), **5** (Figure 3) and **6** (Figure 4) are

represented; relevant bond angles and distances are collected in Table 1.

The 1-butyl-3-methylimidazolium cation, common to all four structures, shows little variation in bond lengths and angles for each compound, having a planar pentagonal imidazolium ring that contains two pairs of C−N bonds, with C(2)−N bonds (1.32−1.33 Å) that are shorter than the C(4)−N and C(5)−N bonds (1.37−1.40 Å). Although the precision of the bond lengths in **6** and especially in **5** is poor due to the considerable structural disorder, they are similar to those of **2** and **3**. The configuration of the imidazolium ring is identical to those observed in related structures, such as [BMIm][BPh_4],[8] [EMIm][$CB_{11}H_{(12-n)}X_n$] (X = Cl, Br, I, n = 0, 1),[13] [OMIm][$CB_{11}H_6Cl_6$],[13] and [EMIm]X (X = Br, I, $AlBr_4$)[14] [N−C(2) 1.29−1.33 Å, N−C(4) and N−C(5) 1.35−1.38 Å, N−C(2)−N 108−109°], showing that the ring's internal dimensions are largely insensitive to its environment. The orientation of the butyl substituent relative to the imidazolium ring differs with each anion due to packing effects in the respective crystal lattices.

The anions all consist of a tetraphenylborate core, with different *para* substituents. The bond lengths and angles show that substitution does not significantly affect the geometry around the boron atom, with all anions having a slightly distorted tetrahedral configuration with practically identical B−C distances (1.64−1.65 Å) and C−B−C angles (103−113°). These data correspond with that previously reported for the borate anions in [BMIm][BPh_4],[8] and [$(THF)_2$Na(18-crown-6)][B{$C_6H_4(SiMe_3)$-4}$_4$] and [Rh(dppe)$_2$][B{$C_6H_4(SiMe_3)$-4}$_4$][15] (B−C 1.64−1.72 Å, C−B−C 106−112°). Unfortunately, no molecular structures of complexes containing [$B(C_6H_4Me$-4)$_4$]$^-$, [B{$C_6H_4(CF_3)$-4}$_4$]$^-$ and [B{$C_6H_4(C_6F_{13})$-4}$_4$]$^-$ are available for comparison.

In the crystal lattice the ions in **2** and **3** form well-defined layers of cations and anions. In **2** the interlayer distances between hydrogen atoms on the imidazolium ring and the π-electron system of the phenyl groups of the anions are around 2.8 Å (Table 2), suggesting that the layers of cations

and anions are inter-connected by weak hydrogen-bonding interactions (for a representative picture of this hydrogen-bonding pattern between layers, see Figure 5).[16,17] Similar behaviour has been reported for [BMIm][BPh_4].[8] In **3**, such layering of cations and anion was not observed. However, weak hydrogen bonding is present: The C(2)−*H* and C(4−*H* imidazolium protons are in close contact with the CF_3 groups of neighbouring anions (see Figure 2 and Table 2). Some of the inter-ionic H···F interactions may be unavoidable, due to steric congestion, but the H···F of F to C(4)−*H* (2.44 Å) clearly indicates weak hydrogen-bonding interactions.[18] The packing diagram of **6** did not reveal the separation of cations and anions into distinct layers. Nevertheless, the cations' orientation allows attractive interactions between C(2)−*H* and the π-systems of neighbouring phenyl rings (Figure 4). Their distance (2.65 Å) is similar to that for the C−H···π interactions in **2**, suggesting weak hydrogen bonding.

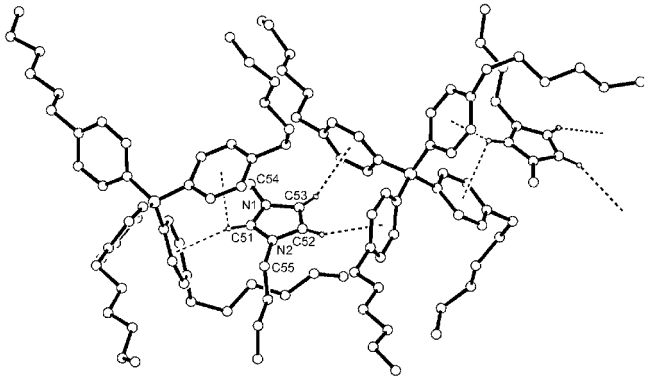

Figure 5. Representation of hydrogen bridging interactions in the crystal lattice of **5**. Hydrogen and fluorine atoms have been omitted for clarity

In the crystal lattice of fluorous borate salt **5**, an alternative ion ordering could be discerned. Instead of layers of cations and anions, a division into fluorous and non-fluorous regions is present (Figure 6). The perfluoroalkyl parts of the ions are assembled in fluorous regions, which alternate with non-fluorous layers that contain the organic and charged parts of the salts. In other words, the structure organises the imidazolium cations and the tetraarylborate cores of the anions into layers with the perfluoroalkyl groups pointing outwards (Figure 5). In these organic domains, the cations and anions form chains with each cation being connected to two anions through hydrogen···π interactions (Figure 5) and vice versa. Furthermore, the butyl substituents of the cation are also oriented towards the fluorous domains. Such layered structures are well known for perfluoroalkyl-substituted compounds,[19] and are related to the inability of the perfluoroalkyl groups to participate in stabilising interactions with other molecules. This lack of interaction excludes these substituents from the ionic organic layers, allowing optimum inter-ion interactions not involving the fluorous tails. The absence of interactions with neighbouring molecules is also reflected in the high disorder in the fluorous tails.

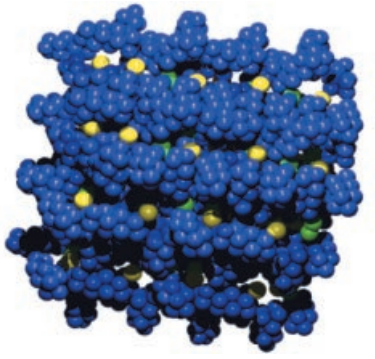

Figure 6. Packing diagram of **5** (F = blue, B = yellow, N = green, all other atoms are omitted for clarity)

During attempts to crystallise **7** from a saturated solution in warm MeOH/H_2O (v:v, 95:5), a crystalline material was isolated in low yield (6%). A single-crystal X-ray diffraction study of this material showed, unexpectedly, it to be a carbene−tris[4-{dimethyl(3,3,3-trifluoropropyl)-silyl}phenyl]borane adduct. The molecular structure **10** (formula see Figure 7) shows a carbene connected to the boron atom of a BAr_3 moiety through the C(2) carbon of the imidazolium ring, which has replaced the fourth phenyl group present in the original tetraarylborate anion. The geometry around the boron centre is a slightly distorted tetrahedral one with C−B−C angles between 105.53(11)° and 113.26(11)°, and B−C bond lengths of 1.642(2)−1.657(2) Å for the phenyl substituents and 1.659(2) Å for the carbene moiety (Table 3). These values are similar to those for the tetraarylborate anions in **2**, **3**, **5** and **6**, suggesting that the nature of the boron atom in **10** is identical and that it formally bears a single negative charge. The chemical shift in the $^{11}B\{^1H\}$ NMR supports

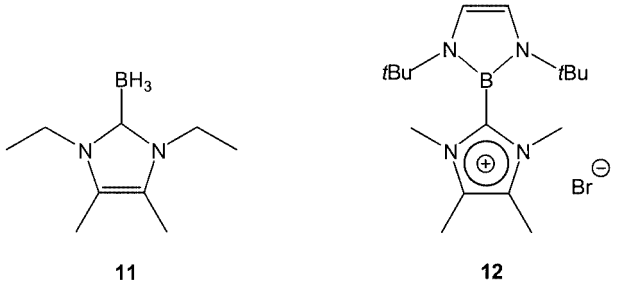
Table 3. Selected bond angles [°] and distances [Å] for **10**

Bond lengths		Bond angles	
B−C(1)	1.642(2)	C(1)−B−C(12)	113.26(11)
B−C(12)	1.645(2)	C(1)−B−C(23)	110.78(12)
B−C(23)	1.657(2)	C(1)−B−C(34)	105.53(11)
B−C(34)	1.659(2)	C(12)−B−C(34)	108.01(11)
		C(23)−B−C(34)	112.28(11)
N(1)−C(34)	1.3611(19)		
N(1)−C(35)	1.3784(19)	N(1)−C(34)−N(2)	104.20(12)
N(2)−C(34)	1.3583(18)		
N(2)−C(36)	1.3845(19)	C(34)−N(1)−C(37)	126.93(12)
C(35)−C(36)	1.337(2)	C(34)−N(2)−C(38)	128.29(12)

this suggestion, as the observed resonance corresponds with that of other $[BAr_4]^-$ (Ar = aryl) ions.[20]

However comparing the five-membered carbene ring with the imidazolium rings in the molecular structures for **2**, **3**, **5** and **6** reveals a consistent deviation in the bond lengths. The lengthening of the N−C(2) bonds in **10** compared to those in the imidazolium borate salts, N−C(34) 1.3612(19) Å (**10**) vs. N−C(2) 1.312(4)−1.3325(19) Å, combined with the shortening of the C−C bond, C(35)−C(36) 1.337(2) Å (**10**) vs. C−C 1.333(5)−1.350(2) Å, and a reduced N−C−N angle, 104.20(12)° in **10**, indicate a reduced aromatic character in the pentacycle. The bond lengths in **10** correspond with those observed for carbene adducts of transition-metals, in which the N−C bonds have single bond character and the C−C bond has a double bond character.[21] Bond lengths in such carbene moieties are around 1.36−1.40 Å for N−C(2), 1.31−1.34 Å for C(4)−C(5), with an angle of 101−104° for N(1)−C(2)−N(3). The similar angles and distances observed in **10** show it to be a carbene−borane adduct. A similar geometry has been reported for 2-borane-1,3-diethyl-4,5-dimethylimidazolin (**11**), for which N(1)−C(2) and N(3)−C(2) of 1.352(2) Å, N(1)−C(5) and N(2)−C(4) of 1.393(2) Å, C(4)−C(5) of 1.350(2) Å and N−C−N of 104.7(1)° were observed (Scheme 3).[22] However, the B−C(2) of 1.659(2) Å in **10** deviates significantly from that in **11** [1.603(3) Å] as well as that in the only related compound 2-(1,3,2-diazaborolyl)-1,3,4,5-tetramethylimidazolium bromide (**12**) that has been studied using single-crystal X-ray crystallography [1.580(11) Å].[23]



11 **12**

Scheme 3

The B−C(2) bond length is highly dependent on its σ-character.[22] Delocalisation of the electron density on the boron through the phenyl substituents in **10** results in a partial positive charge on the boron.[24] This lowers its ability to participate in the σ-bond with C(34) in comparison to the boron atom in **11** and **12**, where such a delocalisation is not possible. Hence, B−C(34) in **10** is somewhat longer than this bond in **11** and **12**.

The slightly acidic proton at C(2) of the imidazolium ring (pK_a = 7.5),[25] supplemented by the increased basicity of the borate's aryl groups due to the silyl substitution, may well be responsible for the conversion of **7** into **10**. Proton abstraction from the imidazolium moiety by one of the aryl groups will afford **10** as well as dimethyl(3,3,3-trifluoropropyl)silylbenzene. A related decomposition mode of the tetraphenylborate anion is found in the reaction of [Ru(η^3-1,2,3-η^2-5,6-(1,5-cyclooctadienyl)][BPh_4] with HF, HBF_4 and HPF_6, to form [Ru{η^3-1,2,3-η^2-5,6-(1,5-cycloocta-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dienyl)}(η^6-$PhBF_3$)].[26] Given the weak acidity of the C(2)H proton compared to the strong acids HF, HBF_4 and HPF_6, and the absence of any transition metals that may lead to hydrides, the formation of **10** is still remarkable. Another explanation that cannot be completely ruled out is the involvement of traces of low-valent late transition metals that can oxidatively add imidazolium cations to give *N*-heterocyclic carbene hydride complexes.[27]

Infrared Spectroscopy: The aromatic C−H stretching vibrations in the imidazolium ring result in three highly characteristic infrared bands, between 3200 and 3050 cm^{-1}, that depend on the presence and strength of hydrogen-bonding interactions between these protons and the anions of the ionic liquid.[5a,28] For **1**, **2** and **6**−**9** the bands for ν[C(5)−*H*] and ν[C(4)−*H*] are observed at approximately 3140 and 3105 cm^{-1}. Furthermore, a separate stretching frequency at 3080 cm^{-1} was observed, which corresponds with ν[C(2)−*H*]. For compounds **3** and **5** these vibrations are shifted to higher frequencies, with bands at 3150, 3110 and 3091 cm^{-1}, respectively (Table 4). Furthermore, for **4**, a further shift for ν[C(5)−*H*] and ν[C(4)−*H*] to 3179 and 3130 cm^{-1} was seen, while the absorption corresponding with ν[C(2)−*H*] was not detectable. This shift is caused by a reduction in the strength of the C−H bonds in the imidazolium ring as their participation in hydrogen-bonding interactions increases.[29] Therefore, the shift of the stretching vibrations to higher frequencies in the imidazolium salts containing borate anions with electron-withdrawing substituents indicates that the hydrogen-bridging interactions are weakened by these substituents. For related imidazolium salts similar observations have been reported; [EMIm]X (X = Cl^-, Br^-, I^- and $AlBr_4^-$) shows IR bands at 3150, 3135 and 3080 cm^{-1};[14] [BMIm]X (X = BF_4^-, PF_6^-) at 3166 and 3123 cm^{-1},[28b] and [EMIm]X (X = various carboranes) at 3165, 3150 and 3110 cm^{-1}.[5a] In these salts an increase in the strength of the hydrogen bonds between the cation and the anion also resulted in lower ν(CH) stretching frequencies.

The sensitivity of the C−H stretching frequencies to the strength of the hydrogen-bonding interactions varies with the position on the imidazolium ring. Whereas ν[C(4)−*H*] and ν[C(5)−*H*] change by more than 30 cm^{-1}, a maximum shift of 20 cm^{-1} in ν[C(2)−*H*] was observed. The H(2) proton bears the largest positive charge (δ^+) of the aromatic imidazolium protons[6f,30] and is, therefore, the strongest hydrogen-bond donor. Upon reduction of the hydrogen-bonding capabilities of the anion the relatively strong C(2)H···π interactions remain intact, but the weaker bonds C(4)−*H* and C(5)−*H* are more likely to be significantly affected. This results in the relatively low sensitivity of ν[C(2)−*H*] to a reduced participation of the imidazolium cation in hydrogen bonding.

^{1}H NMR Spectroscopy: The dependence of the ^{1}H NMR chemical shifts of the imidazolium ring protons on various borate anions and different concentrations was investigated. The chemical shifts C(2)−*H*, C(4)−*H*, C(5)−*H*, NCH_2 and NCH_3 for 0.08 M solutions of **1**−**9** in dry [D_6]acetone (Table 5) proved to be highly sensitive to the substituent on the borate anion. The largest variations were observed for the C(2)−*H* resonances, which shifted by as much as 1.7 ppm, depending on the anion. With [BMIm][BPh_4] (**1**) as a reference compound, the imidazolium salts containing an anion with CF_3 or C_6F_{13} substituents exhibit a positive Δδ, i.e., the imidazolium proton resonances shift to lower field relative to **1** (Figure 8). Conversely, alkyl- or nonfluorous silyl substituents induce a negative Δδ, except for [BMIm][B{C_6H_4($SiMe_2C_8H_{17}$)-4}$_4$] (**8**) which shows no significant shifts relative to **1**. Furthermore, the largest downfield shifts were observed for the compounds with perfluoroalkyl groups connected directly to the phenyl rings of the anion.

For imidazolium compounds the chemical shifts of the protons on the ring are determined by both hydrogen-bonding interactions and shielding due to ring current effects of the tetraarylborate anions and of neighbouring imidazolium cations.[3a] Hydrogen bonding causes the protons to shift to lower field, and shielding of the protons from the magnetic field by the aromatic system of the borate and imidazolium aromatic systems results in an upfield shift.[31]

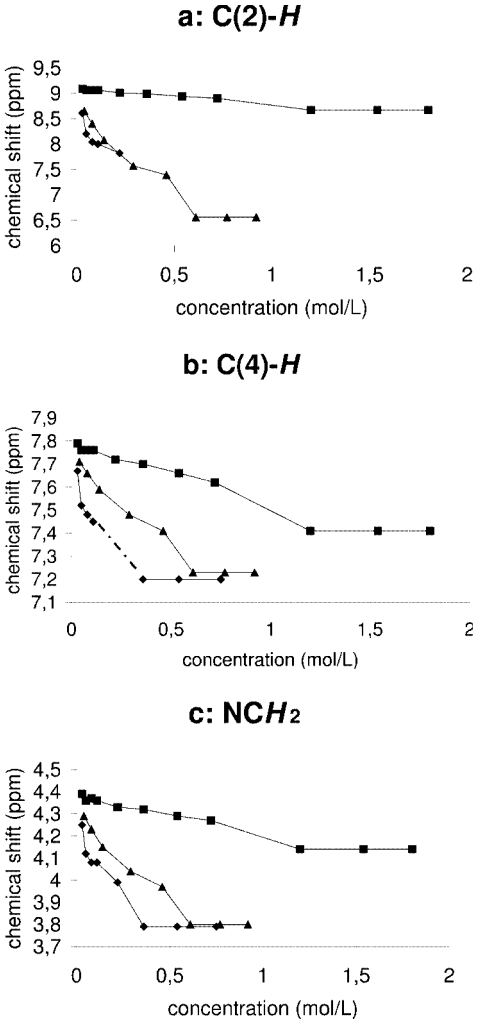

Figure 9. Concentration dependence of the ^{1}H NMR chemical shifts (δ in ppm) in [D_6]acetone for **1**, **3** and **9**. ◆ = $[BPh_4]^-$. ■ = $[B\{C_6H_4(CF_3)\text{-}4\}_4]^-$. ▲ = $[B(C_6H_4\{SiMe_2(CH_2CH_2C_6F_{13})\}\text{-}4)_4]^-$. ·-·-·-: peaks in this concentration range were obscured by resonances of the tetraarylborate anion

The IR data established that the hydrogen-bonding strength is reduced when electron-withdrawing groups are present on the borate anion. This would correspond with an upfield shift in the ^{1}H NMR spectrum;[31] however, the opposite effect is observed because the weakened cation−anion interactions reduce the proximity of the imidazolium protons to the π-orbitals of the anion. This reduces the magnetic shielding experienced by these protons. As a negative Δδ is observed with increasing hydrogen-bond strength, the effect of the shielding apparently outweighs the influence of the hydrogen-bonding interactions on the chemical shift.

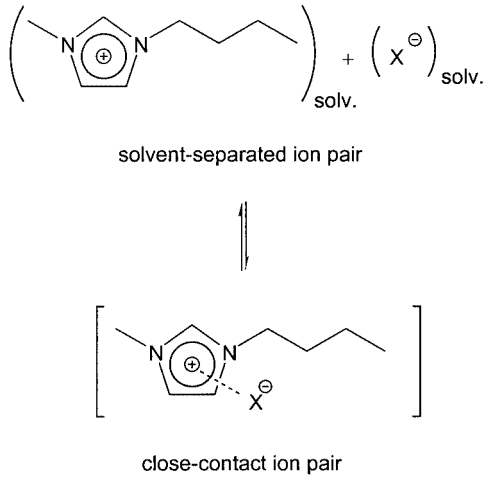
Although magnetic shielding proved to be the most important factor in determining the chemical shift of C(2)−*H*, C(4)−*H* and C(5)−*H*, the C−H···π interactions affect the sensitivity of the chemical shift of the imidazolium protons to the nature of the anion. As C(2)−*H* is the strongest hydrogen-bond donor of the imidazolium ring protons it will be closer to the phenyl rings of the borate anion than C(4)−*H* and C(5)−*H*, and therefore the shielding C(2)−*H* experiences will be increased. This is reflected in the enhanced sensitivity of its chemical shift towards changes in the anion.

The concentration dependence of the chemical shifts of the imidazolium ring protons of **1**, **3** and **9** in acetone was investigated in the range 0.03−1.80 M. As reported previously,[3a] the ^{1}H NMR signals of these protons were anion- and concentration-dependent (Figure 9). The order of magnitude of these effects varied with each proton, with C(2)−*H* being the most sensitive. Smaller displacements were observed for the pairs of signals corresponding with C(4)−*H* and C(5)−*H* and with NCH_3 and NCH_2. The protons within these pairs displayed comparable concentration-related shifts.

Compounds **1** and **9** show similar behaviour − the resonances shifting to higher field at higher molarities. The C(2)−*H* signal displayed the largest Δδ (Δδ = −2.09 ppm) when increasing the concentration of **9** from 0.04 to 0.92 M (Figure 9). For **1** a similar trend could be discerned; however, broadening of the C(2)−*H* resonance at concentrations above 0.22 M prevented accurate observation. No change in the chemical shifts was observed above 0.36 M and 0.61 M for **1** and **9**, respectively. The imidazolium ring protons of **3** showed a more modest concentration-related displacement, the C(2)−*H* signal shifting by a mere −0.4 ppm over the concentration range 0.11 to 1.20 M. Below 0.11 M and above 1.20 M, all of the chemical shifts of **3** were constant.

The changes in the chemical shifts upon increasing concentration of the imidazolium salts in acetone can be explained by an equilibrium between a solvent-separated ion pair and a close-contact ion pair (Scheme 4).[3a]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 4

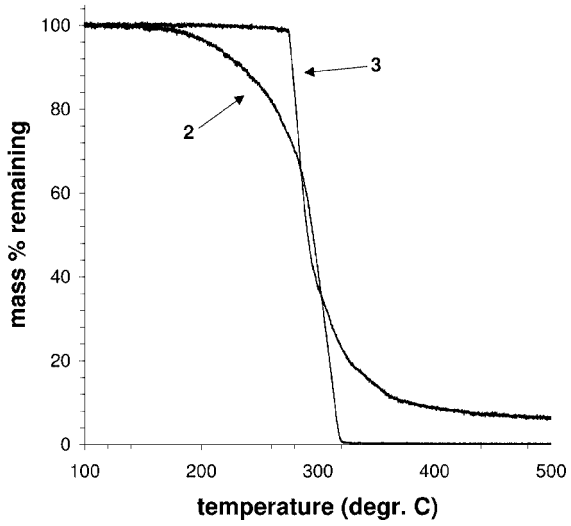


Figure 10. Thermogravimetric analysis for [BMIm][B{C_6H_4Me-4}$_4$] (**2**) and [BMIm][B{$C_6H_4(CF_3)$-4}$_4$] (**3**)

With increasing concentration, this equilibrium shifts to the right, resulting in an increase in close-contact ion pairing. In such ion-pairs the magnetic shielding of the imidazolium ring protons by the phenyl groups of the anion will be stronger than in the solvent-separated ion pairs, which explains the observed shift of the proton resonances to higher field with increasing concentrations Further increases in proton shielding in concentrated solutions are caused by ring stacking of the cations.[3a,32] This predominantly affects the C(2)−*H* proton,[3a] which could explain the high concentration sensitivity of the corresponding signal in comparison with the other imidazolium proton resonances.

The reduced cation−anion interactions in **3**, which contains the more weakly coordinating [B{$C_6H_3(CF_3)$-4}$_4$]$^-$ anion, reduces the amount of close-contact ion pairing at a given concentration. This results in weaker magnetic shielding on the imidazolium ring protons and, thus, in a smaller Δδ than observed for **1** and **9**. Furthermore, as hydrogen bonding interactions in **3** are weaker, cation−cation aggregation at higher concentration will be weaker, further reducing shielding of the imidazolium protons with respect **1** and **9**. This weakening of the inter-ionic interactions in **3** is supported by the IR data.

Melting Points and Thermal Stability: For the imidazolium salts **1**−**9** the melting points and thermal stability were determined (Table 6). All compounds are white solids that melt well above room temperature, except for **8** and **9** for which DSC measurements indicated possible glass transition temperatures in the range −20 °C to −10 °C.[33] Whereas the NMR and IR data showed an obvious influence of the electron-withdrawing CF_3 and C_6F_{13} substituents on cation−anion interactions, such a correlation with the observed melting points is difficult. However, the increasing bulk and orientational flexibility of the substituents[34] clearly depress the melting points of the imidazolium borates, as observed for **8** and **9** and to a lesser extent in **5** and **7**, since the bulky substituents disturb the most efficient packing of ions in the crystal lattice.[35]

The thermal stability of the compounds was assessed by thermogravimetric analysis under nitrogen, heating **1**−**9** from 100 to 500 °C at 5 °C/min. All compounds were stable up to 170 °C, after which the alkyl- and silyl-substituted salts **1**, **2**, **7**, **8** and **9** started to decompose. For all ionic liquids the decomposition process was complete above 450 °C (Figure 10). The only exception is $SiMe_3$-substituted **6**, which decomposes at 250 °C.

The borate anions with CF_3 or C_6F_{13} substituents directly connected to the aryl rings yielded more stable salts, with decomposition starting, on average, 70 °C higher than

Table 6. Melting points and liquid range of imidazolium salts **1**−**9**

	Anion	Melting point [°C]	Decomposition temperature [°C]	Liquid range [°C]
8	[B{$C_6H_4(SiMe_2C_8H_{17})$-4}$_4$]$^-$	−20[a]	170	190

for the alkyl- or silyl-substituted compounds. As the only variable in these studies is the anion, the changes in the decomposition temperature are connected with the stability of the tetraarylborate anions. The increased thermal stability for **3**−**5** is a direct result of the increased delocalisation of the negative charge due to the electron-withdrawing substituents on the phenyl groups of the anion.[9] The high stability of **6** is remarkable and remains unexplained as this anion does not contain stabilising functionalities, and because the other silyl-substituted anions do not show increased stability over $[BPh_4]^-$.

Polarity: For **8** and **9**, which are liquids at room temperature, the relative polarity was estimated by measuring λ_{max}^{abs} of the solvatochromatic dye Nile Red dissolved in these ILs. The observed solvatochromatic shifts, and the molar transition energy (E_{NR}) calculated using λ_{max}^{abs}, indicate that **8** is less polar than **9**, and that both are considerably less polar than the common ILs $[BMIm]BF_4$ and $[BMIm]PF_6$ (Table 7).[36] Nevertheless, the polarity of **8** and **9** is of the same order of magnitude as that of a polar solvent such as acetone.

Earlier work using Nile Red to assess the polarity of *N*,*N*-dialkylimidazolium ILs showed that, in general, the polarity decreased with increasing anion size. This was correlated with a reduction in electron density and, correspondingly, a reduction in the ability of the anion to interact with the dye. However, only BF_4^-, PF_6^-, NO_2^-, NO_3^- and $[N(SO_2CF_3)_2]^-$ were assessed. When comparing **8** and **9** with these anions, the increased size and efficient charge delocalisation further reduce the relative polarity of the BMIm salts. The relatively high polarity of **9** could be the result of local dipoles, caused by the electron-withdrawing C_6F_{13} substituents. Such dipole moments could lead to stronger interactions with the dye molecules and thus increase the relative polarity observed.[36]

Table 7. Polarity of **8** and **9** determined using the solvatochromatic dye Nile Red (values other than for **8** and **9** were taken from ref.[36a] and ref.[37])

[a] Calculated from $E_{NR} = (hcN_A/\lambda_{max}^{abs}) \times 10^6$, where h is Planck's constant, c is the speed of light, N_A is Avogadro's number and λ_{max}^{abs} is the wavelength of maximum absorption for Nile Red. [b] $C_{10}MIm$ = 1-decyl-3-methylimidazolium.

Solubility and Miscibility with Other Liquids: The solubility of the imidazolium salts in a range of organic solvents was examined (Table 8). All ILs were immiscible with water and showed good solubility in acetone. Furthermore, the solubility in the solvents investigated proved to be highly dependent on the substituents present in the tetraarylborate anions. In methanol the solubility of **1**−**9** was moderate; however, the imidazolium salts with CF_3- and C_6F_{13}-substituted anions displayed significantly better solubility than those without perfluoroalkyl groups. This was especially evident in **3** and **4**, which exhibit the best solubility in methanol. In acetone, the substituent effect is less evident, with all compounds showing high solubilities. Upon going from acetone to Et_2O and hexane, the solubility of the imidazolium borates, except for **8**, decreases rapidly with decreasing solvent polarity. In Et_2O the compounds with CF_3 or large silyl substituents are still highly soluble, but only **8**, and to some extent **9**, retain significant miscibility with hexane. This is a consequence of the large, lipophilic substituents in the borate anion, which reduce the ILs to relatively apolar compounds and partially compensate the ionic character with a large lipophilic domain. The lipophilic character of **9** has been demonstrated previously,[12] where a phase behaviour resembling that of perfluorinated solvents was observed in combinations of **9** with toluene, hex-1-ene and oct-1-ene. Similar characteristics are expected for highly lipophilic **8**, but were not investigated.

The relatively low solubility in methanol and the immiscibility with water are no doubt the result of the poor hydrogen bonding character of the borate anions in **1**−**9**.[11] The

Table 8. Solubility of **1**−**9** in various organic solvents

comparatively high solubility of the CF_3-substituted ionic liquids could be due to the additional O−H···F hydrogen bonding possibilities such substituents introduce,[16] which would enhance solvent−solute interactions and thus enhance solubility.

Application as Solvents: Based on the melting points of the imidazolium tetraarylborate salts described here, only **8** and **9** qualify as true room-temperature ionic liquids. Although their melting point is significantly higher than that of the widely used [BMIm]BF_4 and [BMIm]PF_6 salts, which melt at −81 °C and −62 °C, [1a][7a][28b] it allows their application as solvents for reactions at room temperature. The thermal stability of **8** and **9**, up to 170 °C, is sufficient for general application in homogeneous catalysis, even though the borate anion reduces their stability relative to ionic liquids with inorganic anions such as BF_4^-.[38] Conversely, the use of the borate anions eliminates the main source of decomposition in [BMIm]BF_4 and [BMIm]PF_6. Halogen-containing inorganic anions, and especially PF_6^-, might form acids in the presence of water.[1a,39] As the conventional ionic liquids often contain trace amounts of water, HF formation is a serious concern, in particular for [BMIm]PF_6. In **8** and **9** this is prevented by the elimination of fluorine atoms that are sensitive to hydrolysis and by the possibility of removing even trace amounts of water.[40] However, isolation of **10** when attempting to crystallise **7** shows that chemical stability could be an issue. This indicates that the borate could be prone to decomposition under the influence of the acidic C(2)−*H* proton of the imidazolium cation.

The high miscibility of **8** and **9** with apolar solvents is unique amongst ionic liquids. [BMIm]PF_6 shows limited miscibility with apolar organic liquids such as oct-1-ene (65 g/L);[41] however, the high solubility of **8** and **9**, and the phase behaviour displayed by the latter, is unprecedented. In catalysis this would offer increased solubility of apolar substrates, which could be beneficial in catalytic processes that suffer from phase transfer limitations due to the high polarity of the common ILs. The lipophilic character of **8** and **9** would enable their use as a polar phase that can dissolve and immobilise ionic catalysts, with affinity for apolar substrates.

Conclusions

An interesting feature of ionic liquids that favours their use as solvents is the possibility of adapting their properties by choosing different cation−anion combinations. This concept has been applied successfully, but a thorough understanding of the effects that govern the physical properties of ionic liquids is lacking. Here the effects of systematically varying the anion on the physical properties of BMIm tetraarylborate salts are reported. The hydrogen-bonding interactions, between the imidazolium ring protons and the borate anion, that are present both in the solid state and in solution are reduced upon introducing electron-withdrawing perfluoroalkyl substituents in the anion. In addition, bulky silyl substituents depress the melting point of these salts. [BMIm][B{$C_6H_4(SiMe_2C_8H_{17}$}-4}$_4$] and [BMIm][B(C_6H_4{$SiMe_2(CH_2CH_2C_6F_{13}$)}-4)$_4$] even proved to be liquid down to −10 °C, making them true room-temperature ILs. These two imidazolium borates displayed significant solubility in hexane, due to their large lipophilic anions. As conventional ionic liquids display poor miscibility with apolar compounds, this lipophilic character makes them a unique reaction media. However, before their application as solvents, their stability under reaction conditions should be assessed carefully as they are not chemically inert.

Experimental Section

General Procedures: All reactions were performed under dry N_2 using standard Schlenk techniques. Tetrahydrofuran (THF) and diethyl ether (Et_2O) were distilled from sodium benzophenone ketyl, CH_2Cl_2 from CaH_2 and benzene from sodium. Dimethyloctylsilyl chloride,[42] 1-butyl-3-methylimidazolium chloride,[43] 1-butyl-3-methylimidazolium bromide,[44] 1-butyl-3-methylimidazolium iodide,[44] Na[B(C_6H_4Me-4)$_4$],[45] Na[B{$C_6H_4(CF_3)$-4}$_4$],[46] Na[B{$C_6H_3(CF_3)_2$-3,5}$_4$],[47] Na[B{$C_6H_4(SiMe_3)$-4}$_4$],[15] Na[B{$C_6H_4(C_6F_{13})$-4}$_4$],[48] and [BMIm][B(C_6H_4{$SiMe_2$-$(CH_2CH_2C_6F_{13})$}-4)$_4$] (**9**)[12] were prepared according to literature procedures. All other chemicals were used as received. NMR spectra were recorded with a Varian Inova 300 spectrometer at 25 °C (δ in ppm and *J* in Hz) with TMS (^{1}H, ^{13}C) and BF_3·Et_2O (^{11}B) as external references. Infrared spectra were recorded with a Mattson Galaxy FT-IR 5000 spectrometer at 25 °C under N_2 (as KBr pellets). DSC traces were recorded with a Mettler-Toledo DSC-821, and melting points were determined with a Büchi melting point apparatus. UV/Vis absorption spectra were recorded with a Perkin−Elmer Lambda 16 spectrophotometer. TGA measurements were performed with a Perkin−Elmer thermal analysis system 4 coupled to a Perkin−Elmer TGS2 thermogravimmetric system. Elemental analyses were carried out by H. Kolbe, Mikroanalytisches Laboratorium, Mülheim an der Ruhr.

4-Bromo{dimethyl(3,3,3-trifluoropropyl)silyl}benzene: *n*BuLi (17.2 mL, 1.54 M in hexanes, 26.5 mmol) was added to a solution of 1,4-dibromobenzene (6.25 g, 26.5 mmol) in Et_2O (100 mL). The resultant mixture was stirred at room-temperature for 5 min and then cooled to −78 °C. Chlorodimethyl(3,3,3-trifluoropropyl)silane (4.55 mL, 26.5 mmol) was added and the mixture warmed to room temperature over 2 h. This mixture was then poured into H_2O (100 mL), extracted with Et_2O (3 × 100 mL) and the combined organic layers dried with $MgSO_4$. Removal of the solvents in vacuo yielded 7.07 (86%) of a colourless oil. ^{1}H NMR ($CDCl_3$, 300.1 MHz): δ = 0.39 (s, SiCH_3), 1.01 (m, SiCH_2), 2.01 (m, CH_2CF_3), 7.43 (d, $^3J_{H,H}$ = 7.8 Hz, 2 Ar-H_m), 7.58 (d, $^3J_{H,H}$ = 7.8 Hz, 2 Ar-H_o) ppm. ^{13}C{^{1}H} ($CDCl_3$, 75.5 MHz): δ = −3.4 (s), 7.7 (s), 29.0 (q), 124.5 (s), 131.5 (s), 135.4 (s), 136.5 (s) ppm. $C_9H_{14}BrF_3$ (310.00): calcd. C 42.45, H 5.43, F 18.31; found C 42.22, H 4.65, F 18.18.

4-Bromo{dimethyl(octyl)silyl}benzene: Using a procedure similar to that for 4-bromo[dimethyl(3,3,3-trifluoropropyl)silyl]benzene, 1,4-dibromobenzene (14.28 g, 60.5 mmol), *n*BuLi (38 mL, 1.6 M in hexanes, 61.0 mmol) and chlorodimethyloctylsilane (12.62 g, 61.0 mmol) yielded 15.51 g (78%) of a light yellow oil. ^{1}H NMR ($CDCl_3$, 300.1 MHz): δ = 0.25 (s, SiCH_3), 0.77 (s, SiCH_2), 0.91 (m,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$SiC_7H_{14}CH_3$), 1.31 (m, $SiCH_2C_6H_{12}CH_3$), 7.38 (d, $^3J_{H,H}$ = 7.8 Hz, 2 Ar-H_m), 7.53 (d, $^3J_{H,H}$ = 7.8 Hz, 2 Ar-H_o) ppm. $^{13}C\{^1H\}$ ($CDCl_3$, 75.5 MHz): δ = −2.8 (s), 0.7 (s), 14.4 (s), 15.9 (s), 22.9 (s), 241. (s), 29.6 (s), 32.2 (s), 33.8 (s), 123.8 (s), 131.1 (s), 135.4 (s), 138.7 (s) ppm. $C_{16}H_{27}Br$ (326.11): calcd. C 78.70, H 8.41; found C 78.56, H 8.35.

Sodium Tetrakis{4-[dimethyl(3,3,3-trifluoropropyl)silyl]phenyl}-borate: *t*BuLi (12.6 mL, 1.5 M in pentane, 20.2 mmol) was added to 4-bromo{dimethyl(3,3,3-trifluoropropyl)silyl}benzene (3.14 g, 10.1 mmol) in Et_2O (50 mL) at −78 °C. The mixture was allowed to warm to room temperature over 16 h and then cooled to −78 °C with subsequent addition of $BF_3{\cdot}Et_2O$ (0.21 mL, 1.67 mmol). This solution was then warmed to room temperature over 16 h, poured into H_2O and saturated with NaCl. After extraction with Et_2O (3 × 50 mL) the combined organic layers were dried with $MgSO_4$ and the solvents removed in vacuo. The residue was taken up in THF (25 mL), filtered through Celite and dried in vacuo, yielding 1.33 g (83%) of a white solid. ^1H NMR ([D$_4$]MeOH, 300.1 MHz): δ = 0.25 (s, 24 H, $SiCH_3$), 0.89 (m, 8 H, $SiCH_2$), 2.01 (m, 8 H, CH_2CF_3), 7.17 (d, $^3J_{H,H}$ = 7.9 Hz, 8 Ar-H_m), 7.37 (m, 8 Ar-H_o) ppm. $^{13}C\{^1H\}$ ([D$_4$]MeOH, 75.5 MHz): δ = −4.2 (s), 7.7 (s), 28.5 (s), 128.3 (s), 128.3 (s), 130.2 (s), 130.7 (s), 135.9 (s), 166.5 (q, $^1J_{BC}$ = 49.5 Hz, B−*C*) ppm. $C_{44}H_{56}BF_{12}NaSi_4$ (958.33): calcd. C 55.10, H 5.89, Na 2.40; found C 54.84, H 5.85, Na 2.48.

Sodium Tetrakis{4-[dimethyl(octyl)silyl]phenyl}borate: A procedure similar to that for sodium tetrakis{4-[dimethyl(3,3,3-trifluoropropyl)silyl]phenyl}borate and 4-bromo{dimethyl(octyl)-silyl}benzene (5.77 g, 21.5 mmol), *t*BuLi (23.5 mL, 1.5 M in pentane, 35.2 mmol) and $BF_3{\cdot}Et_2O$ (0.44 mL, 3.50 mmol) yielded a brown oil. After washing with α,α,α-trifluorotoluene (3 × 5 mL) a white solid (2.42 g; 71%) was collected. ^1H NMR ([D$_4$]MeOH, 300.1 MHz): δ = 0.21 (s, 24 H, $SiCH_3$), 0.75 (s, 8 H, $SiCH_2$), 0.92 (m, 12 H, $C_7H_{14}CH_3$), 1.32 (m, 48 H, $CH_2C_6H_{12}CH_3$), 7.19 (d, $^3J_{H,H}$ = 7.8 Hz, 8 Ar-H_m), 7.48 (m, 8 Ar-H_o) ppm. $^{13}C\{^1H\}$ ([D$_6$]-acetone, 75.5 MHz): δ = −2.9 (s), 13.9 (s), 16.2 (s), 22.8 (s), 24.2 (s), 33.9 (s), 130.4 (s), 131.3 (s), 135.9 (s), 165.8 (q, $^1J_{BC}$ = 49.5 Hz, B−*C*) ppm. $C_{64}H_{108}BNaSi_4$ (1022.75): calcd. C 75.09, H 10.63; found C 74.88, H 10.75.

1-Butyl-3-methylimidazolium Tetraphenylborate (1):[8] In a procedure adapted from the literature (2.18 g, 6.37 mmol) $Na[BPh_4]$ and (1.26 g, 5.79 mmol) [BMIm]Br were dissolved in H_2O (30 mL) and CH_2Cl_2 (30 mL). After stirring for 24 h, the layers were separated and the CH_2Cl_2 layer was washed with water (2 × 50 mL). Drying in vacuo yielded a white solid (2.12 g; 80%). ^1H NMR ([D$_6$]acetone, 300.1 MHz): δ = 0.92 (t, $^3J_{H,H}$ = 7.4 Hz, CH_2CH_3), 1.31 (m, CH_2CH_3), 1.79 (m, NCH_2CH_2), 3.75 (s, NCH_3), 4.09 (t, $^3J_{H,H}$ = 7.4 Hz, NCH_2), 6.78 (t, $^3J_{H,H}$ = 7.8 Hz, 4 Ar-H_p), 6.94 (t, $^3J_{H,H}$ = 7.5 Hz, 8 Ar-H_m), 7.36 (m, 8 Ar-H_o), 7.42 [s, C(5)*H*], 7.49 [s, C(4)*H*], 8.19 [s, C(2)*H*] ppm. $^{13}C\{^1H\}$ ([D$_6$]acetone, 75.5 MHz): δ = 13.0 (s), 19.5 (s), 32.0 (s), 35.9 (s), 49.5 (s), 122.5 (s), 124.0 (s), 131.0 (s), 135.7 (s), 136.3 (s), 165.0 (q, $^1J_{BC}$ = 49.5 Hz, B−*C*) ppm. $^{11}B\{^1H\}$ ([D$_6$]acetone, 96.3 MHz): δ = −12.21 (s) ppm. $C_{32}H_{35}BN_2$ (458.29): calcd. C 83.84, H 7.70; found C 83.17, H 7.59.

1-Butyl-3-methylimidazolium Tetrakis{4-(methyl)phenyl}borate (2): A mixture of (0.79 g, 1.98 mmol) $Na[B(C_6H_4Me\text{-}4)_4]$ and (0.58 g, 2.18 mmol) [BMIm]I was dissolved in H_2O (20 mL). After stirring for 2 d the mixture was extracted with CH_2Cl_2 (2 × 20 mL), dried with $MgSO_4$, filtered and all volatiles removed in vacuo. The resulting solid was washed with hexane (2 × 20 mL) and dried in vacuo, yielding a white solid (0.64 g; 63%). ^1H NMR ([D$_6$]acetone, 300.1 MHz): δ = 0.93 (t, $^3J_{H,H}$ = 7.4 Hz, CH_2CH_3), 1.38 (m, CH_2CH_3), 1.96 (m, NCH_2CH_2), 2.15 (s, 12 H, $ArCH_3$), 3.79 (s, NCH_3), 4.16 (t, $^3J_{H,H}$ = 7.5 Hz, NCH_2), 6.75 (d, $^3J_{H,H}$ = 7.5 Hz, 8 Ar-H_m), 7.25 (m, 8 Ar-H_o), 7.51 [s, C(5)*H*], 7.59 [s, C(4)*H*], 8.12 [s, C(2)*H*] ppm. $^{13}C\{^1H\}$ ([D$_6$]acetone, 75.5 MHz): δ = 13.0 (s), 19.3 (s), 20.6 (s), 32.1 (s), 35.9 (s), 49.5 (s), 122.5 (s), 123.9 (s), 126.2 (s), 129.5 (s), 136.3 (s), 161.2 (q, $^1J_{BC}$ = 49.4 Hz, B−*C*) ppm. $^{11}B\{^1H\}$ ([D$_6$]acetone, 96.3 MHz): δ = −12.79 (s) ppm. $C_{36}H_{43}BN_2$ (514.35): calcd. C 84.03, H 8.42; found C 83.78, H 8.54.

1-Butyl-3-methylimidazolium Tetrakis{4-(trifluoromethyl)phenyl}-borate (3): A mixture of $Na[B\{C_6H_4(CF_3)\text{-}4\}_4]$ (3.87 g, 6.30 mmol) and [BMIm]I (1.85 g, 6.93 mmol) was dissolved in CH_2Cl_2 (100 mL). After stirring for 2 d the mixture was poured into demineralised water (40 mL) and the resulting mixture was washed with demineralised water (5 × 40 mL). The organic layer was then dried with $MgSO_4$, filtered and the solvent was removed in vacuo. The resulting solid was washed with hexane (5 × 100 mL) and dried in vacuo, yielding a white solid (2.88 g; 63%). ^1H NMR ([D$_6$]acetone, 300.1 MHz): δ = 0.95 (t, $^3J_{H,H}$ = 7.4 Hz, CH_2CH_3), 1.38 (m, CH_2CH_3), 1.96 (m, NCH_2CH_2), 4.08 (s, NCH_3), 4.39 (t, $^3J_{H,H}$ = 7.2 Hz, NCH_2), 7.34 (d, $^3J_{H,H}$ = 8.4 Hz, 8 Ar-H_m), 7.42 (m, 8 Ar-H_o), 7.74 [s, C(5)*H*], 7.80 [s, C(4)*H*], 9.09 [s, C(2)*H*] ppm. $^{13}C\{^1H\}$ ([D$_6$]acetone, 75.5 MHz): δ = 13.0 (s), 19.3 (s), 32.1 (s), 36.1 (s), 49.6 (s), 120.5 (s), 122.5 (s), 124.1 (q, $^1J_{C,F}$ = 30.9 Hz, CF_3), 125.0 (s), 131.3 (s), 135.9 (s), 136.7 (s), 167.4 (q, $^1J_{BC}$ = 48.3 Hz, B−*C*) ppm. $^{11}B\{^1H\}$ ([D$_6$]acetone, 96.3 MHz): δ = −12.34 (s) ppm. $C_{36}H_{31}BF_{12}N_2$ (730.24): calcd. C 59.20, H 4.28; found C 59.00, H 4.04.

1-Butyl-3-methylimidazolium Tetrakis{3,5-(trifluoromethyl)phenyl}-borate (4): In a procedure similar to **3**, $Na[B\{C_6H_3(CF_3)_2\text{-}3,5\}_4]$ (1.40 g, 1.58 mmol) and [BMIm]I (0.39 g, 1.42 mmol) yielded a white solid (1.31 g; 82%). ^1H NMR ([D$_6$]acetone, 300.1 MHz): δ = 0.95 (t, $^3J_{H,H}$ = 6.6 Hz, CH_2CH_3), 1.38 (m, CH_2CH_3), 1.97 (m, NCH_2CH_2), 4.09 (s, NCH_3), 4.40 (t, $^3J_{H,H}$ = 7.4 Hz, NCH_2), 7.33 (d, 8 Ar-H_m), 7.47 (m, 8 Ar-H_o), 7.76 [s, C(5)*H*], 7.81 [s, C(4)*H*], 9.18 [s, C(2)*H*] ppm. ^{13}C ([D$_6$]acetone, 75.5 MHz): δ = 12.9 (s), 19.5 (s), 32.2 (s), 36.0 (s), 49.6 (s), 117.8 (s), 122.0 (s), 122.8 (s), 127.4 (s), 129.3 (q, $^1J_{C,F}$ = 31.8 Hz, CF_3), 134.8 (s), 136.8 (s), 162.5 (q, $^1J_{BC}$ = 49.9 Hz, B−*C*) ppm. $^{11}B\{^1H\}$ ([D$_6$]acetone, 96.3 MHz): δ = −12.27 (s) ppm. $C_{40}H_{27}BF_{24}N_2$ (1002.19): calcd. C 47.93, H 2.71, I 0.00; found C, 47.93, H 2.79, I 0.00.

1-Butyl-3-methylimidazolium Tetrakis{4-(perfluorohexyl)phenyl}-borate (5): In an analogous procedure to the synthesis of **3**, $Na[B\{C_6H_4(C_6F_{13})\text{-}4\}_4]$ (2.39 g, 1.44 mmol) and [BMIm]I (0.42 g, 1.59 mmol) yielded a white solid (0.48 g; 20%). ^1H NMR ([D$_6$]acetone, 300.1 MHz): δ = 0.95 (t, $^3J_{H,H}$ = 7.4 Hz, CH_2CH_3), 1.38 (m, CH_2CH_3), 1.97 (m, NCH_2CH_2), 4.09 (s, NCH_3), 4.40 (t, $^3J_{H,H}$ = 7.2 Hz, NCH_2), 7.33 (d, $^3J_{H,H}$ = 8.4 Hz, 8 Ar-H_m), 7.47 (m, 8 Ar-H_o), 7.76 [s, C(5)*H*], 7.81 [s, C(4)*H*], 9.18 [s, C(2)*H*] ppm. $^{13}C\{^1H\}$ ([D$_6$]acetone, 75.5 MHz): δ = 12.8 (s), 19.3 (s), 32.1 (s), 36.0 (s), 49.6 (s), 108.1 (m), 111.3 (m), 115.1 (m), 118.4 (m), 121.4 (m), 122.9 (m), 124.1 (s), 125.7 (s), 135.9 (s), 136.8 (s), 167.7 (q, $^1J_{BC}$ = 49.0 Hz, B−*C*) ppm. $^{11}B\{^1H\}$ ([D$_6$]acetone, 96.3 MHz): δ = −12.31 (s) ppm. $C_{56}H_{31}BF_{52}N_2$ (1730.17): calcd. C 41.67, H 3.45, Cl 0.00; found C 41.88, H 3.61, Cl 0.00.

1-Butyl-3-methylimidazolium Tetrakis{4-(trimethylsilyl)phenyl}-borate (6): A mixture of $Na[B\{C_6H_4(SiMe_3)\text{-}4\}_4]$ (1.48 g, 2.35 mmol) and [BMIm]Br (0.47 g, 2.14 mmol) was dissolved in acetone (30 mL) and H_2O (5 mL). After stirring for 24 h a white solid was collected, taken up in acetone and filtered through Celite. Slow evaporation of solvents yielded 0.61 g (38%) of a white crys-

talline solid. ^{1}H NMR ([D$_6$]acetone, 300.1 MHz): δ = 0.16 (s, 36 H, SiC*H*$_3$), 0.95 (t, $^3J_{H,H}$ = 7.4 Hz, CH$_2$C*H*$_3$), 1.37 (m, C*H*$_2$CH$_3$), 1.90 (m, NCH$_2$C*H*$_2$), 4.00 (s, NC*H*$_3$), 4.31 (t, $^3J_{H,H}$ = 7.5 Hz, NC*H*$_2$), 7.15 (d, $^3J_{H,H}$ = 7.5 Hz, 8 Ar-*H*$_m$), 7.46 (m, 8 Ar-*H*$_o$), 7.68 [s, C(5)*H*], 7.74 [s, C(4)*H*], 8.92 [s, C(2)*H*] ppm. ^{13}C{^{1}H} ([D$_6$]acetone, 75.5 MHz): δ = −1.2 (s), 13.0 (s), 19.4 (s), 32.1 (s), 36.0 (s), 49.5 (s), 122.4 (s), 130.8 (s), 135.8 (s), 136.4 (s), 165.6 (q, $^1J_{BC}$ = 49.3 Hz, B−*C*) ppm. ^{11}B{^{1}H} ([D$_6$]acetone, 96.3 MHz): δ = −12.04 (s) ppm. $C_{44}H_{67}BN_2Si_4$ (746.45): calcd. C 70.73, H 9.04; found C, 70.86, H 8.94. Single crystals were obtained from acetone.

1-Butyl-3-methylimidazolium Tetrakis{4-[dimethyl(3,3,3-trifluoropropyl)silyl]phenyl}borate (7): A mixture of Na[B(C$_6$H$_4$-{SiMe$_2$(CH$_2$CH$_2$CF$_3$)}-4)$_4$] (0.50 g, 0.52 mmol) and [BMIm]I (0.13 g, 0.47 mmol) was dissolved in acetone (20 mL) and stirred for 4 h. A white precipitate that formed upon the addition of H$_2$O (10 mL) was then collected, washed with H$_2$O (3 × 20 mL) and dried in vacuo. The solid was taken up in toluene (50 mL), washed with demineralised water (2 × 30 mL) and dried in vacuo to yield a white solid (0.45 g; 75%). ^{1}H NMR ([D$_6$]acetone, 300.1 MHz): δ = 0.29 (s, 24 H, SiC*H*$_3$), 0.96 (m, 8 H, SiC*H*$_2$), 0.98 (t, $^3J_{H,H}$ = 7.4 Hz, CH$_2$C*H*$_3$), 1.33 (m, C*H*$_2$CH$_3$), 1.78 (m, NCH$_2$C*H*$_2$), 2.17 (m, 8 H, C*H*$_2$CF$_3$), 3.67 (s, NC*H*$_3$), 4.02 (t, $^3J_{H,H}$ = 7.5 Hz, NC*H*$_2$), 7.25 (d, $^3J_{H,H}$ = 7.9 Hz, 8 Ar-*H*$_m$), 7.36 [s, C(5)*H*], 7.45 [s, C(4)*H*], 7.49 [s, C(2)*H*], 7.56 (m, 8 Ar-*H*$_o$) ppm. ^{13}C{^{1}H} ([D$_6$]acetone, 75.5 MHz): δ = −2.7 (s), 8.7 (s), 13.9 (s), 20.2 (s), 33.0 (s), 36.8 (s), 50.4 (s), 123.5 (s), 125.0 (s), 127.7 (s), 129.3 (s), 132.0 (s), 134.6 (s), 135.9 (s), 137.0 (s), 167.0 (q, $^1J_{BC}$ = 49.2 Hz, B−*C*) ppm. ^{11}B{^{1}H} ([D$_6$]acetone, 96.3 MHz): δ = −12.15 (s) ppm. $C_{52}H_{71}BF_{12}N_2Si_4$ (1074.46): calcd. C 58.08, H 6.06, I 0.00; found C 57.86, H 6.10, I 0.00.

1-Butyl-3-methylimidazolium Tetrakis{4-[dimethyl(octyl)silyl]-phenyl}borate (8): In a procedure similar to that for **3**, Na[B{C$_6$H$_4$(SiMe$_2$C$_8$H$_{17}$)-4}$_4$] (3.78 g, 3.69 mmol) and [BMIm]I (1.47 g, 5.40 mmol) yielded a brown oil. This was washed with a hexane/methanol mixture (1:1) (3 × 60 mL), yielding a yellow oil (0.73 g; 17%). ^{1}H NMR ([D$_6$]acetone, 300.1 MHz): δ = 0.17 (s, 24 H, SiC*H*$_3$), 0.71 (s, 8 H, SiC*H*$_2$), 0.89 (t, $^3J_{H,H}$ = 7.4 Hz, NC$_3$H$_6$C*H*$_3$), 0.92 (m, 12 H, SiC$_7$H$_{14}$C*H*$_3$), 1.27 (m, NC$_2$H$_4$C*H*$_2$CH$_3$), 1.34 (m, 48 H, SiCH$_2$C$_6$*H*$_{12}$CH$_3$), 1.72 (m, NCH$_2$C*H*$_2$), 3.52 (s, NC*H*$_3$), 3.86 (t, $^3J_{H,H}$ = 7.5 Hz, NC*H*$_2$), 6.67 [s, C(2)*H*], 7.20 (d, $^3J_{H,H}$ = 7.8 Hz, 8 Ar-*H*$_m$), 7.27 [s, C(5)*H*], 7.37 [s, C(4)*H*], 7.53 (m, 8 Ar-*H*$_o$) ppm. ^{13}C{^{1}H} ([D$_6$]acetone, 75.5 MHz): δ = −2.9 (s), 13.2 (s), 13.9 (s), 16.2 (s), 19.5 (s), 22.8 (s), 24.2 (s), 32.1 (s), 33.9 (s), 35.8 (s), 49.5 (s), 122.2 (s), 123.8 (s), 130.4 (s), 131.3 (s), 134.2 (s), 135.9 (s), 165.8 (q, $^1J_{BC}$ = 49.5 Hz, B−*C*) ppm. ^{11}B{^{1}H} ([D$_6$]acetone, 96.3 MHz): δ = −12.10 (s) ppm. $C_{72}H_{123}BN_2Si_4$ (1138.89): calcd. C 75.86, H 10.88; found C 75.65, H 11.06.

Carbene−2-Tris[4-{dimethyl(3,3,3-trifluoropropyl)silyl}phenyl]-borane Adduct 10: Crystallisation of **7** (0.20 g, 0.19 mmol) from a mixture of warm MeOH/H$_2$O (95:5) yielded white crystals (0.01 g; 6%) and a yellow oil that solidified upon standing. The ^{1}H NMR spectrum of the oil was identical to that for **7**. The white crystals were suitable for X-ray single crystal analysis. ^{1}H NMR ([D$_6$]acetone, 300.1 MHz): δ = 0.34 (m, 18 H, SiC*H*$_3$), 0.67 (m, 3 H, CH$_2$C*H*$_3$), 0.76 (m, 2 H, CH$_2$C*H*$_2$CH$_3$), 0.94 (m, 6 H, SiC*H*$_2$), 1.29 (m, 2 H, NCH$_2$C*H*$_2$), 2.12 (m, 6 H, C*H*$_2$CF$_3$), 3.09 (s, 3 H, NC*H*$_3$), 3.51 (m, 2 H, NC*H*$_2$), 7.33 (m, 12 H), 7.40 (s, 1 H) ppm. ^{13}C{^{1}H} ([D$_6$]acetone, 75.5 MHz): δ = −3.9 (s), 7.7 (s), 13.1 (s), 19.6 (s), 33.1 (s), 37.8 (s), 49.3 (s), 121.1 (s), 123.3 (s), 126.6 (s), 131.7 (s), 132.2 (s), 135.0 (s) ppm. ^{11}B{^{1}H} ([D$_6$]acetone, 96.3 MHz): δ = −14.90 (s) ppm.

Solubility Studies: Saturated solutions of **1**−**9** in a solvent were prepared and allowed to settle at 25 °C for 1 h, until the solution was completely clear upon visible inspection. A sample [2.0(1) mL] was taken while ensuring that no undissolved material was

sampled. The solvent was removed in vacuo and the residue kept under vacuum (0.1 mbar) for 1 h, after which the weight was constant to within ± 1 mg. The weight of the residue was then determined and the solubility calculated.

Polarity Measurements: A Nile Red solution in methanol (1 mL, 1.89 10^{-3} M) was added to 0.5 g of **8** or **9**. After the mixture had become homogeneous, the methanol was evaporated off in vacuo and the maximum absorbance of Nile Red determined by transmission UV/Vis spectroscopy of a thin film of the ionic liquid. An absorption maximum of 534 (**8**) or 542 nm (**9**) was observed, which corresponds to E_{NR}s of 224.0 kJ/mol (**8**) and 220.7 kJ/mol (**9**).

Structure Determination and Refinement of 2, 3, 5, 6 and 10: X-ray intensities were measured on a Nonius KappaCCD diffractometer with a rotating anode and Mo-K_α radiation (graphite monochromator). The structures were solved by direct methods with the programs SHELXS-97[49] (compounds **2** and **6**) and SIR97[50] (compounds **3**, **5** and **10**). The structures were refined with the program SHELXL-97[51] against F^2 of all reflections. Non-hydrogen atoms were refined freely with anisotropic displacement parameters, hydrogen atoms were refined as rigid groups. The drawings, structure calculations, and checking for higher symmetry were performed with the program PLATON.[52] In the crystal structure of compound **2**, the *n*-butyl group was refined with a disorder model. For compound **3**, one of the trifluoromethyl groups was rotationally disordered. The absolute structure of compound **5** could not be determined reliably. Friedel pairs were therefore merged in the refinement. In the crystal structure of compound **6**, one of the 1-butyl-3-methylimidazolium ions is located on an inversion centre and is, therefore, disordered. Further details of the crystal structure determinations are given in Table 9. CCDC-207227 (**2**), -207228 (**3**), -207229 (**5**), -207230 (**6**), and -207231 (**10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44 1223 336033; E-mail: deposit@ccdc.cam.ac.uk)

Allosteric Manipulation of Photoexcited State Relaxation in a Series of $Ru^{II}(bpy)_2$(bipyridine−crown ethers)

Subodh K. Dutta,[a] Daqing Gan,[a] and Marc W. Perkovic*[a]

Keywords: Luminescence / Sensors / Photophysics / Lead

A series of ruthenium(II) crown ether complexes containing 4-, 5-, or 6-oxygen crowns tethered to a bipyridine at the 3,3′ position were prepared and examined for their ability to act as luminescent sensors. The complexes $[(bpy)_2Ru(2,2'\text{-bipyridine-}3,3'\text{-16-crown-4})](PF_6)_2$ and $[(bpy)_2Ru(2,2'\text{-bipyridine-}3,3'\text{-19-crown-5})](PF_6)_2$ were characterized by X-ray crystallography. The 4-oxygen crown crystallizes in the $P\bar{1}$ space group. The 5-oxygen crown crystallizes in the $P\bar{1}$ space group. In both complexes, the inter-pyridine ring angle in the tethered bipyridine is twisted substantially away from 0°. Coordination of a heavy metal ion such as Pb^{2+} by the crown ether, and the geometric changes that result, were examined by UV/Vis, luminescence and NMR spectroscopy. The results show that there is a weak allosteric interaction between the Pb^{2+} ion and the Ru complexes, and that this interaction alters the luminescent behavior of the Ru complexes.

Introduction

The ability to manipulate the physical and chemical properties of an electronically excited molecule is widely accepted as a necessary component of developing molecular devices. The development of luminescent sensors for a host of analytes has been an active area of research.[2−5] Sensors that are based on coordination complexes of transition metals have been of particular interest.[6] Regardless of the nature of the luminophore, the mechanism by which the act of sensing results in a change in the photophysical behavior of the electronically excited molecule is of particular importance.[7] We have been investigating such mechanisms by examining molecules in which the change in photophysical behavior is the result of geometric perturbations of the transition metal center of the luminophore complex.[8]

When considering the photophysical behavior of transition metal excited state complexes, it is often difficult to distinguish between geometric and electronic effects since the two effects are rarely isolable. For example, to what extent do alterations of the substituents on a ligand effect the electron density on the metal, the electron distribution of the M−L bond, and subsequently the energy and lifetime of the photoexcited state? We have attempted to address this ambiguity by examining a series of complexes based on the well-understood $Ru(bpy)_3^{2+}$ molecule, where one of the bipyridine rings has been functionalized at the 3,3′ positions with a crown ether tethered to the bpy pyridine ring.

The oxygen atoms on the crown ethers are not part of the π-system of the bipyridine ligands to any appreciable extent, yet their motion may be telegraphed to the metal center by altering the inter-pyridine ring angle, as has been observed in the complex containing 3,3′-binicotinic acid.[9] Using this approach, we can change the geometry around the metal through an allosteric interaction between the crown ether and the free cations in solution, without changing the ligands.

Results and Discussion

Synthesis and Characterization of the Complexes

The preparation of the Ru(crown-ether) complexes proceeds via facile ligand exchange between the free crown ligands and the chloride ligands of $[cis\text{-}Ru(bpy)_2Cl_2]$. It has previously been reported that the crown ligands adopt a geometry that is unfavorable for coordination to the ru-

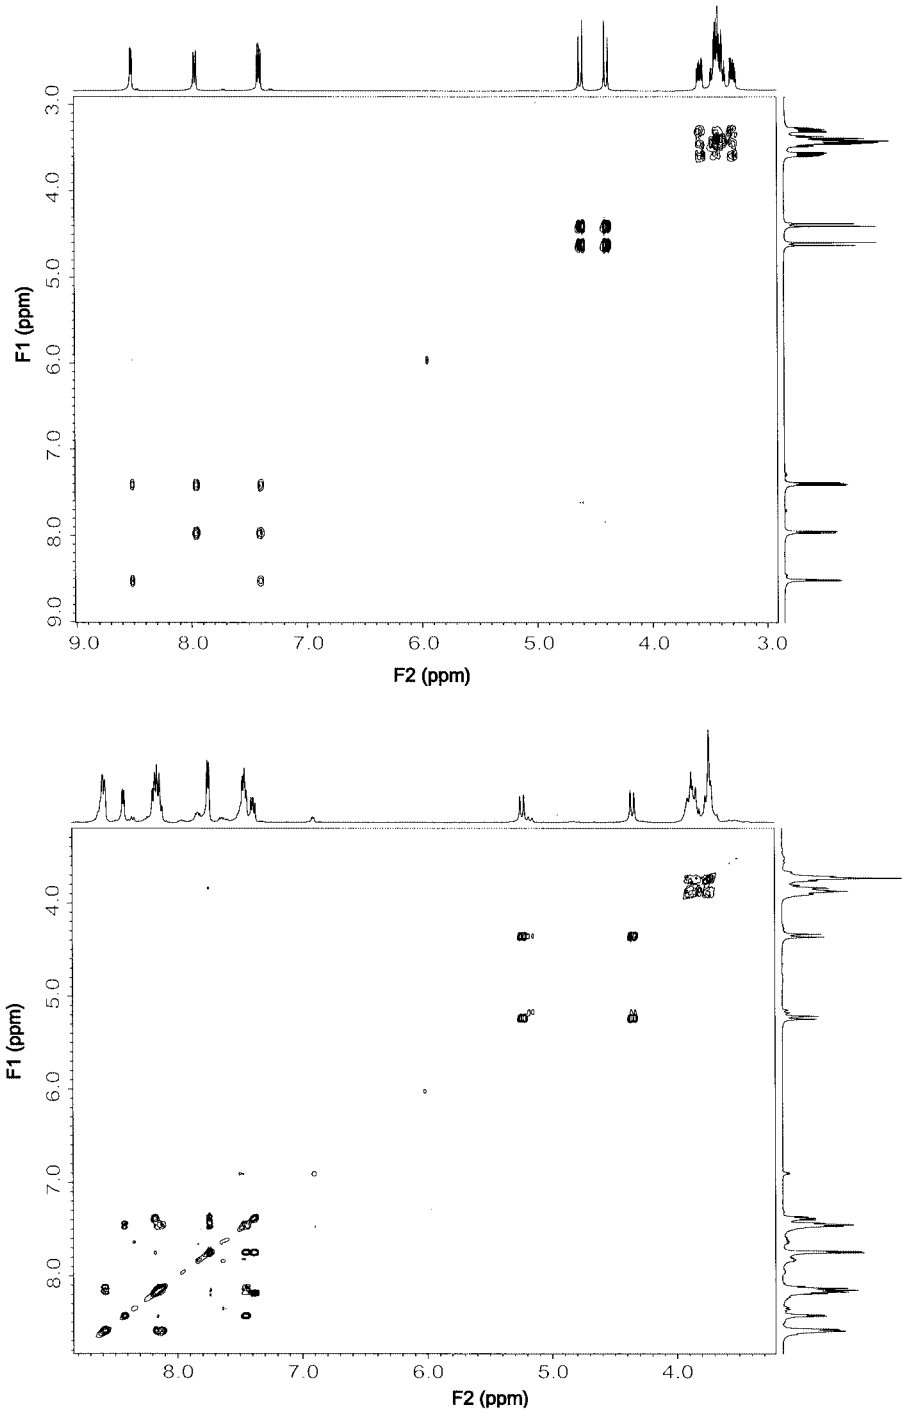

Figure 1. Proton-proton 2D COSY spectrum in CH_3CN of bipyridine-3,3′-16-crown-4 at room temperature (**A**) and $[(bpy)_2Ru(2,2'$-bipyridine-3,3′-16-crown-4)$](PF_6)_2$ at −20 °C (**B**). Changing the temperature does not alter the chemical shifts, but clarifies the coupling constants for the ruthenium complex

thenium(II) atom, with the coordinating nitrogen atoms on opposite sides of the bipyridine bridge.[15] Complex formation nevertheless readily occurs, resulting in a $[(bpy)_2Ru(crown)]^{2+}$ complex where the inter-pyridine ring angle in the crown tethered bipyridine is substantially twisted away from 0°.[9] The geometric change is reflected

in the NMR spectrum, particularly in the resonances of the correlated benzylic protons at ≈ 5 ppm, as shown in Figure 1. Peak assignments are presented Table 5.

X-ray Structure Determination

X-ray Determination of [(bpy)$_2$Ru(2,2′-bipyridine-3,3′-16-crown-4)](PF$_6$)$_2$

X-ray quality crystals were grown by slow diffusion of diethyl ether into a solution of the crown complex in pyridine. A deep red, rectangular plate, approximately 0.25 × 0.12 × 0.1 mm, was chosen by size, habit, and polarized light microscopy. The complex crystallized in the triclinic system in the space group $P\bar{1}$(#2),[10] as determined from 25 high angle reflections. The data collection and refinement parameters are presented in Table 6. The structure was solved by direct methods using SIR,[11] and refined by full-matrix least-squares methods using SHELXL.[12] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions. The largest unassigned peak in the final difference map was 0.51e/Å^3, located near the Ru ion. No absorption correction was applied. The structure was refined to a final *R* value of 7.52%. The refined cation is shown in Figure 2, and structural details are presented in Table 1.

X-ray Determination of [(bpy)$_2$Ru(2,2′-bipyridine-3,3′-19-crown-5)](PF$_6$)$_2$

A deep red, rectangular plate, approximately 0.25 × 0.25 × 0.12 mm, crystallized from an aqueous solution of the crown complex on standing. The crystal was chosen by size, habit, and polarized light microscopy. The complex also crystallized in the triclinic system in the space group $P\bar{1}$. The structure was solved by direct methods using SIR, and refined by full-matrix least-squares methods using SHELXL. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions. The largest unassigned peak in the final difference map was 0.8 e/Å^3, located near a PF_6 anion. No absorption correction was applied. Two waters of crystallization were observed. The structure was refined to a final *R* value of 7.41%. The refined cation is shown in Figure 2, and structural details are presented in Table 2.

In both complexes, the Ru−N bond lengths and angles are typical of a ruthenium diimine, spanning a range from 2.04 to 2.08Å. The two non-crown containing bipyridine rings in both complexes are flat to within 5°. However, the bipyridine containing the tethered crown ether was distorted by about 35° for the 4-oxygen crown, and by 24° for the 5-oxygen crown. As we expected, the presence of the crown ethers caused a geometric distortion at the ruthenium center. The magnitude of the distortion reflects the flexibility in the tethered crown ether. We were unable to obtain satisfactory crystals for the 6-oxygen crown complex.

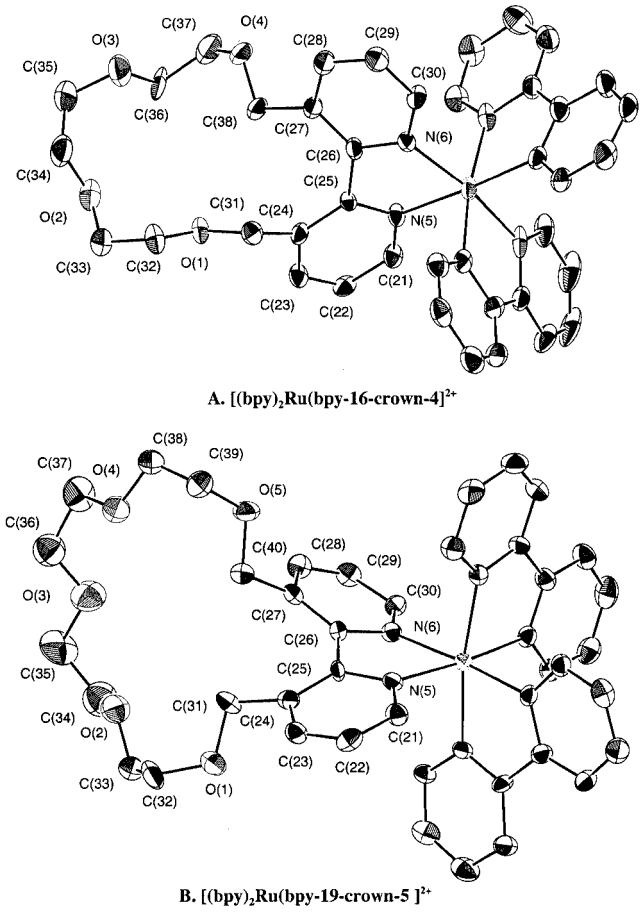

Figure 2. ORTEP diagram of [(bpy)$_2$Ru(bpy-16-crown-4)]$^{2+}$ (**A**) and [(bpy)$_2$Ru(bpy-19-crown-5]$^{2+}$ (**B**)

Electrochemistry

Half-wave potentials were determined by cyclic voltammetry (Figure 3) and are listed in Table 3. The cyclic voltammograms of each of the three [Ru(bpy)$_2$(crowns)]$^{2+}$ complex cations in CH_3CN exhibit one reversible Ru^{II}/Ru^{III} wave at a slightly lower potential than that observed for [Ru(bpy)$_3$]$^{2+}$. Three reversible reduction waves are also observed, with no significant shift in their positions relative to [Ru(bpy)$_3$]$^{3+}$. These data suggest that the slight twist of the inter-pyridine rings on the crown ligands does not alter the ground state electronics of the aromatic ring system, although the loss in angular overlap between the ligand and the ruthenium atom may slightly raise the energy of the ruthenium d-orbitals.

Emission Spectroscopy

The luminescence spectra for the three ruthenium crown complexes are also typical for ruthenium(II) *tris*-bipyridine analogs. At room temperature, the broad charge transfer spectra for the three complexes show little dependence on

the size of the tethered crown ether. At 77 K, only the 6-oxygen crown shows a small red shift in emission. The activation energies for the three complexes are within experimental error of each other (Table 4). The addition of Pb^{2+} ions to the complexes results in a small, but significant, increase in the emission intensity, but no significant change in the emission energy. The change in emission intensity for the three ligand complexes are similar and a typical response is shown in Figure 4. This result differs from that observed for $[(bpy)_2Ru(2,2'\text{-bipyridine-}3,3'\text{-}16\text{-crown-}4)]^{2+}$ in the presence of Group I metal ions.[13] However, it is not clear to what extent ion pairing impacts the observed emission behavior. We have observed that varying the concentration of the perchlorate ion causes shifts in the emission spectrum, similar to those previously reported.[14] For the results discussed here, the measurements were performed in DMSO/water solutions at constant ionic strength. Plotting the magnitude of the emission change over an extended range of Pb^{2+} concentrations yields a Ru−Pb complex stoichiometry of 1:1, with an equilibrium constant of $K \approx 0.4\ M^{-1}$.

[a] Quantum yields were determined by comparing the integrated intensity of the samples to that of an absorbance-matched standard, $[Ru(bpy)_3]^{2+}$ $\Phi = 0.062$. I. Dupry, T. J. Meyer, *Inorg. Chem.* **1996**, *35*, 6299. [b] DMSO/water used because of its low temperature glass properties. Results in CH_3CN are the same to within experimental error.

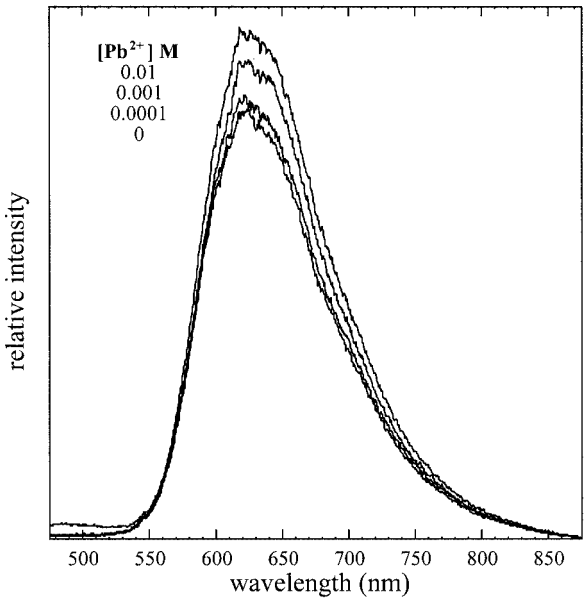

Figure 4. Emission spectrum of $(bpy)_2Ru(2,2'\text{-bipyridine-}3,3'\text{-16-crown-}4)^{2+}$ at room temperature with variable $[Pb^{2+}]$

teric ions, as their metal triflates, were added to the solution of $[Ru(bpy\text{-crown})]^{2+}$ in $CDCl_3$ and/or $[D_6]$acetone so that any equilibria present would be shifted towards the products.

The NMR spectra of the crown ethers and their ruthenium complexes have two distinct spectral features that are well-separated: the aromatic region corresponding to the bipyridine moiety of the molecule (7−9 ppm), and the aliphatic (methylene) portion of the cyclic ethers (≈ 3−5.5 ppm). As an uncoordinated molecule, the bipyridine rings are twisted such that they are *anti* to each other with respect to the pyridine−pyridine bond. On coordination to the ruthenium atom via the pyridine nitrogen atoms, the benzylic protons are forced into close proximity. The resulting anisotropic field causes an AB splitting pattern in the benzylic resonances. As has been previously reported for the free ligands,[18] we observed that all regions of the ^1H spectrum undergo considerable changes on addition of Li^+, Na^+, K^+, Pb^{2+}, and Cs^+ ions. The most dramatic changes occur in the aromatic region, followed by a smaller change in the benzylic region, and finally a relatively small change in the region of the methylene groups. However, in the case of the ruthenium complexes, a different behavior is observed. For these complexes, essentially no change is seen in the aromatic region and very small changes in the methylene resonances. The largest change is observed for the resonances of the benzylic protons. For example, $[(bpy)_2Ru(2,2'\text{-bipyridine-}3,3'\text{-19-crown-}5)]^{2+}$ shows two doublets assigned to the benzylic protons 8a-H and 8b-H, at $\delta = 4.47$ and 4.73 ppm, respectively (Figure 5 and Table 5). In the presence of Pb^{2+} ions, these two resonances shift to $\delta = 4.63$ and 4.72 ppm, respectively. The coupling constant ($J_{8a\text{-}H-8b\text{-}H}$) decreases from 12.4 to 12.1 Hz. This indicates that the Pb^{2+} ion is interacting with the crown ether oxygen atoms, but that the interaction is not telegraphed to the bipyridine ring system. Similar results were observed for the 5-crown and 6-crown complexes in the

presence of Pb^{2+} ions. The NMR shifts are substantially smaller for the other cations examined.

Conclusions

The smaller than expected, and previously observed,[9] photophysical response of the ruthenium crown complexes when exposed to Pb^{2+} ions is the result of stereochemical constraints exerted by the tethered crown ethers on their host bipyridine. Molecular modeling shows that in the ruthenium crown complexes, the protons on the benzylic carbon atoms (8a-,8b-H in Figure 5) are the major source of steric repulsion. These protons restrict the ability of the two pyridine rings from approaching co-planarity to less than about 15°. Regardless of the number of oxygen atoms in the ring, the oxygen atoms attached to the benzylic carbons are always positioned such that their lone pairs are no longer pointing inward towards the crown cavity.[14,15] In this way it is impossible for these two oxygen atoms to coordinate a guest ion. As the crown ring size increases, additional oxygen atoms are available to coordinate guest ions. However, these oxygen atoms are sufficiently removed from the bipyridine so as to offer little or no leverage for an allosteric perturbation of the ruthenium coordination sphere, since the flexibility of the crown framework is substantial. This, coupled with the proximity of the benzylic protons, prohibits any substantial change in the bipyridine ring geometry or motion. Without a substantial impact on the coordinated bipyridine, either in terms of geometry or electronics, no photophysical change is possible. We have prepared analogous crown complexes where the crowns are tethered directly to aromatic rings at the 3,3′ positions without a benzylic carbon and the problematic protons. The results of those studies will be reported elsewhere.

Experimental Section

Syntheses: All chemicals used were of reagent grade, or better, and used without further purification. The bipyridine crown-ether ligands 2,2′-bipyridine-3,3′-16-crown-4, 2,2′-bipyridine-3,3′-19-crown-5, 2,2′-bipyridine-3,3′-21-crown-6, and [*cis*-$(bpy)_2RuCl_2$]·$2H_2O$[16] were prepared by literature methods.[17] Metal triflates were prepared by treating the metal carbonates with neat CF_3SO_3H, (3M FC-43, technical grade), followed by recrystallization from dichloromethane.

Preparation of [$(bpy)_2$Ru(2,2′-bipyridine-3,3′-16-crown-4)]$(PF_6)_2$: [$Ru(bpy)_2Cl_2$]·$2H_2O$ (0.43 g) was added to an ethanolic solution of 2,2′-bipyridine-3,3′-16-crown-4 (0.27 g in 20 mL) in a 50-mL flask. The mixture was refluxed for 24 h, and was filtered when it was still hot. Ammonium hexafluorophosphate was added to the cooled filtrate, and the mixture was stored in a refrigerator overnight. The resulting orange−yellow precipitate was collected by filtration, washed with ether (30 mL), then dried under vacuum. The compound was purified by column chromatography (2 × 25 cm) on neutral alumina using an acetone/CH_2Cl_2 (4:7) mixture as the eluent. The first fraction was evaporated to near dryness and dissolved in a minimum volume of water. Addition of solid NH_4PF_6, followed by overnight refrigeration resulted in 500 mg of a crystalline product (86%yield). UV/Vis in (1:1) DMSO/0.1 M $NaCF_3SO_3$ [λ nm, ε ($mol^{-1}cm^{-1}$)]: 227 (61620), 290 (69714), 450 (13950). ^{1}H NMR ([D_6]acetone): δ = 8.78 (d), 8.20 (m), 7.97 (m), 7.54 (m), 5.20, 4.50, 3.80, 3.70 ppm. ^{13}C NMR ([D_6]acetone): δ = 152.2 ppm, 138.0, 127.8, 72.0, 70.4, 70.1, 69.5. MS: *m*/*z* = 889, 372, corresponding to a monocation PF_6 salt and the parent dication, respectively.

Preparation of [$(bpy)_2$Ru(2,2′-bipyridine-3,3′-19-crown-5)]$(PF_6)_2$: This compound was synthesized and purified following the same procedure as that described for the 2,2′-bipyridine-3,3′-16-crown-4 complex. Reacting 0.25 g of the crown ligand resulted in 512 mg of the ruthenium complex. (91.9% yield). UV/Vis in (1:1) DMSO/0.1 M $NaCF_3SO_3$ [λ nm, ε ($mol^{-1}cm^{-1}$)]: 236 (78126), 290 (40660), 450 (6460). ^{1}H NMR ([D_6]acetone): δ = 8.8 (d), 8.2 (m), 8.00 (m), 7.55 (m), 4.92, 4.70, 3.65, 3.00 ppm. ^{13}C NMR ([D_6]acetone): δ = 157.5 ppm, 152.2, 137.8, 127.6, 126.8, 71.0−69.0(5 peaks). MS: *m*/*z* = 395.

Preparation of [$(bpy)_2$Ru(2,2′-bipyridine-3,3′-21-crown-6)]$(PF_6)_2$: This compound was synthesized and purified following the same procedure as that described for the 2,2′-bipyridine-3,3′-16-crown-4 complex, without significant modification, except that acetone was used as the eluent. Reacting 0.31 g of the crown ligand resulted in 496 mg of the ruthenium complex. (76.2% yield). UV/Vis in (1:1) DMSO/0.1 M $NaCF_3SO_3$ [λ nm, ε ($mol^{-1}cm^{-1}$)]: 236 (30878), 290 (69714), 450 (13950). ^{1}H NMR ([D_6]acetone): δ = 8.8 (d), 8.20 (m), 8.00 (m), 7.50 (m), 5.00, 3.65, 3.55 ppm. ^{13}C NMR ([D_6]acetone): δ = 152.3 ppm, 138.5, 127.8, 124.8, 68.1−70.0. MS: *m*/*z* = 416.

Physical Measurements

Spectroscopic Measurements: IR spectra were recorded using KBr pellets on a Perkin−Elmer 1710 FTIR or a Bruker Equinox 55 FTIR. UV/Vis spectra were recorded on a Beckman 7400 diode array spectrometer. NMR spectra were recorded on a JEOL Eclipse+ 400 multinuclear NMR (400 MHz ^{1}H) equipped with a *z*-axis gradient probe. Luminescence spectra were recorded on a

PTI Quanta Master spectrometer. Spectra were corrected for wavelength response and lamp intensity fluctuations. Mass spectra were obtained from a Micromass QUATTRO II mass spectrometer by direct insertion.

Photophysical Measurements: Quantum yield determinations were performed using nitrogen purged, absorbance matched (0.1 A @450 nm) samples in DMSO/water (1:1 v/v) solutions. $[Ru(bpy)_3]^{2+}$ was used as the standard. Luminescent lifetimes were determined by exciting the samples with the third harmonic from a Continuum Surelite-I Nd:YAG laser. The laser was run at minimum flash lamp power and the beam was attenuated so that sample irradiation occurred with a less than 100 μJ/10 ns pulse @355 nm. The emitted light was filtered with a 450 nm cut-off filter to eliminate laser scatter, and collected by a fiber optic interfaced to an Acton SP300i monochromator/Hamamatsu R928 PMT. The photomultiplier was run at a constant −1000 V, and the light level was adjusted using the monochromator slits in order to provide a signal no larger than 100 mV across 50 W. Typically 16 transients were recorded on a LeCroy LT342 DSO, and the data fit by non-linear least-squares methods. Sample temperatures were maintained to ±0.5 K with an Oxford Optistat liquid-nitrogen cryostat. All device control and data manipulations were performed with a computer program developed in-house. Variable temperature lifetime data were fit to an Arrhenius function for the determination of activation energies.

Electrochemical Data: Cyclic voltammograms were recorded in nitrogen purged CH_3CN at room temperature, using a BAS 50 W potentiostat equipped with a Pt working and auxiliary electrodes and an $Ag/AgNO_3$ reference electrode. Tetrabutylammonium perchlorate was used as the supporting electrolyte.

X-ray Structure Data: Single crystal data (Table 6) were recorded on a Nonius CAD4 diffractometer at −100 °C by using graphite-monochromated Mo-$K\alpha$ radiation. The crystal was mounted on a glass fiber with epoxy and placed with a random orientation on the diffractometer. The unit cell and data collection parameters were determined from 25 high angle reflections. The space group and structural parameters were determined using the maXus suite of programs. Intensity standards were recorded after each 100 minutes of exposure.

Chiral [(Dialkylamino)methyl](phospholyl)ferrocene Ligands as a New Class of 1,2-Disubstituted Ferrocene Ligands

Sophie Mourgues,[a] Daniel Serra,[a] Franck Lamy,[a] Sandrine Vincendeau,[a] Jean-Claude Daran,[a] Eric Manoury,*[a] and Maryse Gouygou*[a]

Keywords: Ferrocenes / Phospholes / N,P ligands / Asymmetric catalysis

An efficient synthesis of new chiral [(dialkylamino)methyl](phospholyl)ferrocenes in an enantiomerically pure form has been developed. These new chiral N,P ligands have been tested in the palladium-catalyzed allylic substitution reaction. High activities and moderate enantioselectivities (up to 67% *ee*) were observed.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Enantiopure 1,2-disubstituted ferrocene derivatives, especially ferrocenylphosphane ligands, are widely used as ligands in homogeneous transition metal catalysis.[1] Some of these ligands have proved to be especially efficient, in particular the aminophosphanes PPFA and BPPFA,[2] TRAP ligands,[3] Josiphos ligands,[4] in particular the industrially important Xyliphos,[5] pyrazolylphosphane ligands[6] or, more recently, ferrocenyloxazolines.[7] However, most of these chiral ferrocene-based ligands possess classical tertiary phosphane groups and no attention has been paid to ferrocenyl ligands with nonclassical phosphanes such as phosphole. Although phospholes are efficient ligands in homogeneous transition metal catalysis,[8] only a few enantiomerically pure chiral phospholes[9] have been used as chiral ligands for asymmetric catalysis.[10] In addition, a new approach has recently emerged where conformationally flexible ligands are intentionally used to magnify the effect of the chiral part of the catalytic system.[11] Unsymmetrically substituted phospholes can be useful in this context, because, owing to the low inversion barrier of the phosphorus in phospholes, a ligand bearing an unsymmetrically substituted phosphole could adjust the configuration of the asymmetric phosphorus atom to accommodate the metallic center through the catalytic cycle.

So, as part of our continuing interest in ferrocene chemistry[12] and in the design and synthesis of new chiral phosphole-based ligands,[13] we decided to investigate the efficiency of mixed phospholylferrocene ligands in asymmetric catalysis. Herein, we report the synthesis and characterization of the [(dialkylamino)methyl](phospholyl)-ferrocene ligands **8a,b** as a new class of 1,2-disubstituted ferrocene ligands and their use in palladium-catalyzed asymmetric allylic substitution.

Results and Discussion

Synthesis of [(Dialkylamino)methyl](phospholyl)ferrocene Ligands 8a,b

The synthetic pathway used to produce enantiopure 1,2-disubstituted ferrocene derivatives **8a,b** is based on six stereochemically controlled reactions, as shown in Scheme 1. In the first step, the required planar chirality was introduced by diastereoselective ortho-lithiation of acetal **1** according to Kagan's procedure,[14] followed by treatment with 1-cyanophosphole (**2**)[15] as the electrophile, giving the expected phospholylferrocene product, which was directly converted by sulfurization to the air-stable compound **3**. This compound, isolated in 89% yield after purification by column chromatography, was obtained as an enantiomerically pure diastereoisomer. The new planar chirality in **3** was predicted to have an (*S*) configuration as the planar chirality is defined in the first step of the reaction, namely the lithiation of **1**, and is then independent of the electrophile used to quench the lithiated intermediate, as shown by Kagan et al.[14]

In the next step, the acid hydrolysis of the acetal (*S*)-**3** led quantitatively to the corresponding aldehyde (*S*)-**4**. This compound, which is slightly unstable, was only characterised by ^{1}H and ^{31}P NMR spectroscopy and then reduced with sodium tetrahydroborate to the stable alcohol (*S*)-**5**. This compound, obtained in 90% yield by column chromatography, was fully characterized by ^{1}H, ^{13}C and ^{31}P NMR spectroscopy and the (*S*)-configuration was confirmed by an X-ray diffraction analysis. A molecular view of the alcohol (*S*)-**5** is shown in Figure 1, with the atom-labelling

scheme. The X-ray crystal structure analysis clearly shows the nearly eclipsed conformation of the two Cp rings, with a twist angle of 4.75°. The phosphole ring is planar, with the largest deviation being 0.016 Å at C(2), and it makes a dihedral angle of 61.6° with the Cp to which it is attached. This phosphole ring is *endo* with respect to the Cp ring, whereas the S atom is *exo*. Such an arrangement is probably due to the hydrogen bond occurring between the OH of the hydroxyl group and the sulfur atom [O(1)−H(1)···S(1): O(1)−H(1) = 0.818(5) Å, O(1)···S(1) = 3.288(2) Å, H(1)···S(1) = 2.55(2) Å, O(1)−H(1)···S(1) = 150.5(8)°]. This hydrogen bond is responsible for the slight tilt angle of 4.2° observed between the Cp rings.

In the next step, the alcohol (*S*)-**5** was transformed quantitatively into the acetate (*S*)-**6** by treatment with acetyl chloride. This crude acetate was used directly for a nucleophilic substitution reaction with secondary amines, following the procedure described by Kumada et al.[16] Compounds (*S*)-**7a** and (*S*)-**7b** were obtained in 25% and 42% yield respectively. Compounds **7a,b** were fully characterized and the structure of **7a** was confirmed by X-ray analysis. A molecular view of **7a** is shown in Figure 2, with the atom-

Figure 1. labelling scheme. As in (*S*)-**5**, the phosphole ring is planar with the largest deviation being 0.044 Å at C(3). However, there is no hydrogen bond and the phosphole is *exo* with respect to the ferrocene moiety, whereas the sulfur is *endo*. The dihedral angle between this phosphole and the Cp ring to which it is attached is 72.3°. The amine group is *exo* with respect to the ferrocene moiety and the nitrogen lone pair is oriented towards the phosphole ring. The two Cp rings are nearly eclipsed, with a twist angle of 4.71°; the tilt angle between the Cp rings is 1.7°.

In the last step, desulfuration of (*S*)-**7a,b**, performed in refluxing toluene with tris(2-cyanoethyl)phosphane as reducing agent, led to the corresponding ligands (*S*)-**8a,b** in 92% and 82% yield respectively.

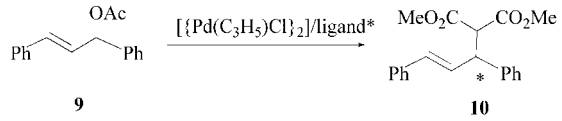
Application of the [(Dialkylamino)methyl](phospholyl)-ferrocenes 8a,b in Palladium-Catalyzed Asymmetric Allylic Substitution

As a preliminary evaluation of the catalytic properties of the chiral ligands **8a** and **8b**, we explored the palladium-catalyzed asymmetric allylic substitution reaction.[17] Thus, the reaction of 1,3-diphenylprop-2-enyl acetate (**9**) with the anion of dimethyl malonate in the presence of $[Pd(C_3H_5)Cl]_2$ (1mol %) and the chiral ligand **8a**,**b** (1mol %) provided the expected allylic substitution product **10** in high yields and moderate enantioselectivities (up to 67% *ee*) depending on the conditions (see Scheme 2). The results are summarised in Table 1.



Scheme 2

This reaction occurred with 62% and 65% *ee* for **8a** and **8b**, respectively (entries 1,3), with high activities in both cases and complete conversion after 45−90 min at room temperature using CH_2Cl_2 as solvent and *N*,*O*-bis(trimethylsilyl)acetamide (BSA)/AcOK as base. The use of THF as solvent decreased the rate of the reaction (entry 2), and complete conversion was not observed even after 24 h, although the enantioselectivity was not affected.

Similar activities and enantioselectivities were observed when using NaH as base instead of the BSA/AcOK system (entries 4−5).

Conclusion

We have described a new and efficient method for the preparation of [(dialkylamino)methyl](phospholyl)ferrocenes in an enantiomerically pure form. Palladium-catalysed allylic substitution of 1,3-diphenylprop-2-enyl acetate with the anion of dimethyl malonate can be achieved with these new N,P ligands with high activities but still moderate enantioselectivities (up to 67% *ee*) compared to analogous ligands.[17,18] These new [(dialkylamino)methyl](phos-

pholyl)ferrocenes are very modular: for example, the substituents on the phosphole ring or in the amino part can be easily changed in order to improve significantly the performances of the catalytic system. Further studies in this direction are currently in progress in our laboratory.

Experimental Section

General: All reactions were carried out under dry argon using Schlenk glassware and vacuum-line techniques. Solvents were freshly distilled from standard drying agents. ^{1}H, $^{13}C\{^{1}H, ^{31}P\}$ and $^{31}P\{^{1}H\}$ NMR spectra were recorded on a Bruker WMX 400 instrument operating at 400, 162, and 100 MHz, respectively. Chemical shifts are reported in parts per million (ppm) relative to Me_4Si (^{1}H and ^{13}C) or 85% H_3PO_4 (^{31}P). Mass spectra were obtained on a Nermag R10-10 instrument. Elemental analyses were performed by the "Service d'Analyse du Laboratoire de Chimie de Coordination" at Toulouse. Optical rotations were measured with a Perkin−Elmer 241 polarimeter.

Acetal **1**[14] and 1-cyano-3,4-dimethylphosphole (**2**)[15] were prepared as described in the literature.

(2*S*,4*S*,S_{Fc})-4-(Methoxymethyl)-2-[(3,4-dimethyl-1-thio-1*H*-1λ^5-phosphol-1-yl)ferrocenyl]-1,3-dioxane (3): In a Schlenk tube, a 1.5 M solution of *tert*-butyllithium in pentane (8.1 mL, 12.1 mmol, 1.1 equiv.) was added dropwise, at −78 °C under argon, to a solution of acetal **1** (3.47 g, 11 mmol) in 40 mL of dry diethyl ether. The solution was stirred at −78 °C during 15 minutes, then for 2 h at room temp. The solution was cooled to −30 °C and a solution of 1-cyano-3,4-dimethylphosphole (**2**; 1.81 g, 13.2 mmol, 1.2 equiv.) in 20 mL of dry diethyl ether was introduced with a cannula. The reaction mixture was stirred overnight at room temp. Dry triethylamine (0.5 mL) was then added by syringe, followed by water (2 mL). Under argon, the reaction mixture was extracted with diethyl ether and washed with brine. The organic fraction was dried over sodium sulfate and the solvents evaporated in vacuo to yield an orange oil. This oil was dissolved in 30 mL of dichloromethane. Sulfur (2 g, 62.mmol, 5.7 equiv.) was added and the mixture was stirred overnight. After evaporation, the mixture was chromatographed on silica gel using a pentane/dichloromethane mixture (7:3, v/v) to yield 4.47 g of a brown orange oil (Yield: 89%). ^{1}H NMR ([D$_6$]acetone): δ = 1.50 (d of m, J = 12.5 Hz, 1 H, CH_2-CH_2-CH), 1.66 (br. q of d, J = 12.5 Hz and 5 Hz, 1 H, CH_2-CH_2-CH), 2.03 (br. s, 3 H, CH_3), 2.12 (br. s, 3 H, CH_3), 3.33 (dd, J = 10.4 Hz and 4.2 Hz, 1 H, CH_2-OCH_3), 3.34 (s, 3 H, OCH_3), 3.43 (dd, J = 10.4 Hz and 6.5 Hz, 1 H, CH_2-OCH_3), 4.00 (br. t of d, J = 12 Hz and 2.7 Hz, 1 H, $O-CH_2CH_2$), 4.07 (m, 1 H, O−CH), 4.24 (br. dd, J = 11.2 Hz and 4.3 Hz, 1 H, $O-CH_2CH_2$), 4.33 (m, 1 H, subst Cp), 4.36 (m, 1 H, subst Cp), 4.42 (s, 5 H, Cp), 4.69 (m, 1 H, subst Cp), 6.14 (s, 1 H, O−CH−O), 6.20 (br. d, $J_{H,P}$ = 29.7 Hz, 1 H, CHP), 6.39 (br. d, $J_{H,P}$ = 29.5 Hz, 1 H, CHP) ppm. ^{13}C NMR ([D$_6$]acetone): δ = 17.0 (d, $J_{C,P}$ = 14.4 Hz, CH_3), 17.1 (d, $J_{C,P}$ = 14.1 Hz, CH_3), 28.2 (CH_2-CH_2-CH), 58.6 (OCH_3), 67.0 ($O-CH_2CH_2$), 69.0 (d $J_{C,P}$ = 10.5 Hz, subst Cp), 70.5(d, $J_{C,P}$ = 12.6 Hz, subst Cp), 71.1 (Cp), 72.2 (d, $J_{C,P}$ = 86.5 Hz, quat Cp), 75.3 (*C*H); 72.4 (d, $J_{C,P}$ = 13.5 Hz, subst Cp), 75.8 (CH_2-OCH_3), 90.1 (d, $J_{C,P}$ = 0.9 Hz, quat Cp), 99.6 (O−CH−O), 125.2 (d, $J_{C,P}$ = 85.4 Hz, CHP), 128.1 (d, $J_{C,P}$ = 84.1 Hz, CHP), 149.8 (d, $J_{C,P}$ = 18.9 Hz, $C-CH_3$), 152.6 (d, $J_{C,P}$ = 19.1 Hz, $C-CH_3$) ppm. ^{31}P NMR ([D$_6$]acetone): δ = 48.3. $[\alpha]_D$ = −2.47 (c = 0.5, $CHCl_3$). MS (DCI, NH_3): m/z (%) = 459 (100%) $[M + H]^+$. $C_{22}H_{27}FeO_3PS$ (458.34): calcd. C 57.65, H 5.94; found C 57.85, H 5.85.

(S_{Fc})-2-(3,4-Dimethyl-1-thio-1*H*-1λ^5-phosphol-1-yl)ferrocenecarbaldehyde (4): Acetal **3** (3.35 g, 7.3 mmol), dichloromethane (120 mL) and an aqueous solution (50 mL) of *p*-toluenesulfonic acid monohydrate (2 g, 10.5 mmol, 1.4 equiv.) were introduced into a round-bottomed flask equipped with a condenser and placed under argon. The reaction mixture was stirred at reflux for 20 h. After cooling back to room temp. the dark red solution was extracted with dichloromethane, washed with distilled water, dried over sodium sulfate and the solvents evaporated. Compound **4**, obtained quantitatively as a red oil, was only characterised by ^{1}H and ^{31}P NMR spectroscopy and used without purification. ^{1}H NMR ($CDCl_3$): δ = 2.10 (m, 6 H, CH_3), 4.40 (s, 5 H, Cp), 4.75 (m, 1 H, subst Cp), 4.95 (m, 1 H, subst Cp), 5.10 (m, 1 H, subst Cp), 6.20 (d, $J_{H,P}$ = 28.5 Hz, 2 H, CHP), 10.30 (s, 1 H, CHO), ppm. ^{31}P NMR ($CDCl_3$): δ = 44.9 ppm.

(S_{Fc})-[2-(3,4-Dimethyl-1-thio-1*H*-1λ^5-phosphol-1-yl)ferrocenyl]-methanol (5): The crude compound **4** was dissolved in methanol (200 mL) and an aqueous solution (140 mL) of sodium borohydride (2.78 g, 18.3 mmol) and sodium hydroxide (11.2 g, 280 mmol) was added. The solution turned rapidly from red to orange. After 15 minutes stirring at room temp. the reaction mixture was extracted with dichloromethane. The organic phase was washed with dilute hydrochloric acid then water, and finally dried over sodium sulfate. After evaporation of the solvents, the crude materials was purified by flash chromatography on silica gel using a pentane/diethyl ether mixture (2:8, v/v) to yield 2.36 g of **5** (90% from **3**) as an orange solid. Crystals suitable for X-ray analysis were obtained by diffusion of pentane into a dichloromethane solution. ^{1}H NMR ($CDCl_3$): δ = 2.08 (d, J = 1.6 Hz, 3 H, CH_3), 2.14 (d, J = 1.6 Hz, 3 H, CH_3), 3.26 (dd, J = 7.4 Hz and 6.3 Hz, 1 H, OH), 4.29−4.35 (m, 2 H, subst Cp), 4.31 (s, 5 H, Cp), 4.38 (dd, J = 12.7 Hz and 7.4 Hz, 1 H, CH_2), 4.48 (m, 1 H, subst Cp), 4.81 (dd, J = 12.7 Hz and 6.3 Hz, 1 H, CH_2), 6.16 (br. d, $J_{H,P}$ = 30.8 Hz, 1 H, CHP), 6.22 (br. d, $J_{H,P}$ = 30.4 Hz, 1 H, CHP) ppm. ^{13}C NMR ($CDCl_3$): δ = 17.80 (d, $J_{C,P}$ = 17.8 Hz, CH_3), 17.84 (d, $J_{C,P}$ = 18.0 Hz, CH_3), 59.6 (d, $J_{C,P}$ = 7.8 Hz, CH_2), 69.8 (d, $J_{C,P}$ = 10.8 Hz, subst Cp), 70.5 (d, $J_{C,P}$ = 71.5 Hz, quat Cp), 70.7 (Cp), 72.5(d, $J_{C,P}$ = 14.2 Hz, subst Cp), 74.2 (d, $J_{C,P}$ = 9.6 Hz, subst Cp), 92.1 (d, $J_{C,P}$ = 12.3 Hz, quat Cp), 125.6 (d, $J_{C,P}$ = 86.1 Hz, CHP), 126.5 (d, $J_{C,P}$ = 84.0 Hz, CHP), 151.9 (d, $J_{C,P}$ = 18.6 Hz, $C-CH_3$), 152.2 (d, $J_{C,P}$ = 18.7 Hz, $C-CH_3$) ppm. ^{31}P NMR ($CDCl_3$): δ = 49.3 ppm. $[\alpha]_D$ = −104.6 (c = 0.5, $CHCl_3$). MS (DCI, NH_3): m/z (%) = 359 (100) $[M + H]^+$. $C_{17}H_{19}FeOPS$ (358.22): calcd. C 57.00, H 5.35; found C 57.11, H 5.00.

(S_{Fc})-Acetoxy-[2-(3,4-dimethyl-1-thio-1*H*-1λ^5-phosphol-1-yl)ferrocenyl]methane (6): (*S*)-[2-(thio-3,4-dimethylphospholyl)ferrocenyl]-methanol (240 mg, 0.7 mmol) was dissolved in dry dichloromethane (7 mL) and anhydrous triethylamine (0.25 mL) in a Schlenk tube under argon. The solution was then cooled to 0 °C and acetyl chloride (70 μL, 1 mmol, 1.5 equiv.) was added with a syringe. The solution was stirred at 0 °C for 30 minutes then for 1 h at room temp. The solution was washed with dilute hydrochloric acid then water, and dried over sodium sulfate. After evaporation of the solvents, the crude compound **6** was quantitatively obtained as a yellow oil that was used without further purification in the next step. ^{1}H NMR ($CDCl_3$): δ = 1.98 [s, 3 H, $C(O)CH_3$], 2.04 (m, 6 H, CH_3), 4.34 (s, 5 H, Cp), 4.45 (m, 1 H, subst Cp), 4.50 (m, 1 H, subst Cp), 4.60 (m, 1 H, subst Cp), 4.90 (d, J = 11.8 Hz, 1 H, CH_2), 5.20 (d, J = 11.8 Hz, 1 H, CH_2), 6.05 (br. d, $J_{H,P}$ = 29.6 Hz,

(S_{Fc})-{2-[(3,4-Dimethyl-1-thio-1*H*-1λ^5-phosphol-1-yl)ferrocenyl]-methyl}dimethylamine (7a): The crude acetate, methanol (40 mL) and dimethylammonium chloride (3.58 g, 44 mmol, 40 equiv.) were introduced into a three-necked, round-bottomed flask equipped with a condenser and purged with argon. The reaction mixture was stirred at reflux for 40 h. After cooling back to room temp. the solvents were evaporated and the residue was dissolved in diethyl ether and washed with a dilute hydrochloric acid solution. Unreacted starting materials could be obtained from the organic phase after evaporation of the solvents and flash chromatography. An aqueous sodium hydroxide solution (ca. 2 M) was added to the aqueous phase in order to adjust the pH close to 13. A precipitate formed, which was dissolved by adding diethyl ether to the suspension. This second organic phase was dried over sodium sulfate and the solvents evaporated to give 105 mg of amine **7a** (yield 25%) as a yellow oil. This compound was purified by column chromatography on alumina using a pentane/diethyl ether mixture (4:6, v/v). Crystals suitable for X-ray analysis were obtained by diffusion of pentane into a dichloromethane solution. ^{1}H NMR ($CDCl_3$): δ = 2.05 (m, 3 H, CH_3), 2.10 (m, 3 H, CH_3), 2.18 (s, 6 H, N CH_3), 3.05 (d, J = 12.7 Hz, 1 H, CH_2−Cp), 4.08 (d, J = 12.7 Hz, 1 H, CH_2−Cp), 4.30 (m, 1 H, subst Cp), 4.34 (s, 5 H, Cp), 4.41 (m, 1 H, subst Cp), 4.47 (m, 1 H, subst Cp), 6.15 (br. d, $J_{H,P}$ = 29.7 Hz, 1 H, CHP), 6.21 (br. d, $J_{H,P}$ = 29.9 Hz, 1 H, CHP) ppm. ^{13}C NMR ($CDCl_3$): δ = 17.75 (d, $J_{C,P}$ = 17.9 Hz, CH_3), 17.83 (d, $J_{C,P}$ = 17.8 Hz, CH_3), 45.3 (s, N CH_3), 57.4 (s, CH_2), 69.6 (d, $J_{C,P}$ = 11.0 Hz, subst Cp), 70.8 (d, J $J_{C,P}$ = 88.4 Hz, quat Cp), 71.0 (s, Cp), 72.6 (d, $J_{C,P}$ = 14.9 Hz, subst Cp), 75.0 (d, $J_{C,P}$ = 9.4 Hz, subst Cp), 89.0 (d, $J_{C,P}$ = 12.5 Hz, quat Cp), 125.6 (d, $J_{C,P}$ = 85.5 Hz, CHP), 127.5 (d $J_{C,P}$ = 84.6 Hz, CHP), 150.8 (d, $J_{C,P}$ = 19.0 Hz, C−CH_3), 152.6 (d, $J_{C,P}$ = 18.1 Hz, C−CH_3) ppm. ^{31}P NMR ($CDCl_3$): δ = 49.1 ppm. $[\alpha]_D$ = −1.2 (c = 0.4, $CHCl_3$). $[\alpha]_{546}$ = −20.2 (c = 0.4, $CHCl_3$). MS (DCI, NH_3): m/z (%) = 386 (100) $[M + H]^+$.

(S_{Fc})-{2-[(3,4-Dimethyl-1-thio-1*H*-1λ^5-phosphol-1-yl)ferrocenyl]-methyl}diethylamine (7b): A similar procedure with 40 equiv. of pure diethylamine instead of the mixture dimethylammonium chloride/triethylamine gave compound **7b** as an orange oil (yield: 42%). ^{1}H NMR ($CDCl_3$): δ = 0.96 (t, J = 7.1 Hz, 6 H, CH_3CH$_2$), 2.01 (d, J = 1.4 Hz, 3 H, CH_3), 2.06 (d, J = 1.4 Hz, 3 H, CH_3), 2.4−2.6 (m, 4 H, CH_2CH$_3$), 3.30 (d, J = 13.2 Hz, 1 H, CH_2−Cp), 4.03 (d, J = 13.2 Hz, 1 H, CH_2−Cp), 4.24 (m, 1 H, subst Cp), 4.32 (s, 5 H, Cp), 4.36 (m, 1 H, subst Cp), 4.44 (m, 1 H, subst Cp), 6.09 (br. d, J_{H-P} = 29.7 Hz, 1 H, CHP), 6.23 (br. d, J_{H-P} = 29.7 Hz, 1 H, CHP) ppm. ^{13}C NMR ($CDCl_3$): δ = 11.6 (NCH$_2$$CH_3$), 17.77 (d, $J_{C,P}$ = 16.0 Hz, CH_3), 17.85 (d, $J_{C,P}$ = 17.7 Hz, CH_3), 45.9 (NCH$_2$CH$_3$), 52.0 (CH_2), 69.1(d, $J_{C,P}$ = 11.0 Hz, subst Cp), 70.8 (d, $J_{C,P}$ = 88.7 Hz, quat Cp), 71.0 (Cp), 72.4 (d, $J_{C,P}$ = 14.9 Hz, subst Cp), 74.9 (d, $J_{C,P}$ = 9.7 Hz, subst Cp), 90.5 (d, $J_{C,P}$ = 11.9 Hz, quat Cp), 125.5 (d, $J_{C,P}$ = 85.2 Hz, CHP), 127.7 (d, $J_{C,P}$ = 84.7 Hz, CHP), 150.5 (d, $J_{C,P}$ = 18.7 Hz, C−CH_3), 152.5 (d, $J_{C,P}$ = 18.7 Hz, C-CH_3) ppm. ^{31}P NMR ($CDCl_3$): δ = 49.3 ppm. $[\alpha]_D$ = −1.8 (c = 0.5, $CHCl_3$). $[\alpha]_{546}$ = −23.4 (c = 0.5, $CHCl_3$). MS (DCI, NH_3): m/z (%) = 414 (100) $[M + H]^+$.

(S_{Fc})-{2-[(3,4-Dimethyl-1*H*-1λ^3-phosphol-1-yl)ferrocenyl]methyl}-dimethylamine (8a): Tris(2-cyanoethyl)phosphane (0.130 mg, 0.673 mmol) was added to a solution of **7a** (0.130 mg, 0.338 mmol) in toluene (10 mL) and the resulting mixture was refluxed for 6 hours. After cooling to room temp. the mixture was filtered through celite, the solvents evaporated in vacuo and the residue extracted four times with pentane. After evaporation of the solvents, the crude compound **7a** was purified by column chromatography on alumina using a pentane/diethyl ether mixture (1:1, v/v) to yield 105 mg of amine (yield: 92%) as an orange-red oil. ^{1}H NMR ($CDCl_3$): δ = 2.08 (br. s, 3 H, CH_3), 2.16 (br. s, 3 H, CH_3), 2.22 (s, 6 H, NCH_3), 3.41 (d, J = 12.8 Hz, 1 H, CH_2−Cp), 3.63 (dd, $J_{H,P}$ = 2.6, J = 12.8 Hz, 1 H, CH_2−Cp), 3.85 (m, 1 H, subst Cp), 4.20 (m, 1 H, subst Cp), 4.21 (s, 5 H, Cp), 4.39 (m, 1 H, subst Cp), 6.40 (br. d, $J_{H,P}$ = 37.3 Hz, 1 H, CHP), 6.54 (br. d, $J_{H,P}$ = 36.5 Hz, 1 H, CHP) ppm. ^{13}C NMR ($CDCl_3$): δ = 8.2 (CH_3), 18.3 (s, CH_3), 45.3 (s, NCH_3), 58.1 (d, J_{C-P} = 6.1 Hz, CH_2), 69.9 (s, Cp), 70.0 (d, J_{C-P} = 2.4 Hz, subst. Cp), 71.7 (s, subst. Cp), 71.9 (d, $J_{C,P}$ = 7.7 Hz, quat Cp), 72.7 (d, $J_{C,P}$ = 4.1 Hz, subst Cp), 89.7 (d, $J_{C,P}$ = 22.9 Hz, quat Cp), 129.7 (CHP), 132.1 (s, CHP), 147.8 (d, $J_{C,P}$ = 7.5 Hz, C-CH_3), 148.9 (d, $J_{C,P}$ = 9.7 Hz, C-CH_3) ppm. ^{31}P NMR ($CDCl_3$): δ = −16.4 ppm. MS (DCI, NH_3): m/z (%) = 353 (100) [M + H].

(S_{Fc})-{2-[(3,4-Dimethyl-1*H*-1λ^3-phosphol-1-yl)ferrocenyl]methyl}-diethylamine (8b): The synthesis of **8b** was accomplished by the same procedure as described above for **8a.** Compound **8b** was obtained as orange-red oil (82%). ^{1}H NMR ($CDCl_3$): δ = 1.06 (t, J = 7.1 Hz, 6 H, CH_3CH$_2$), 2.08 (br. s, 3 H, CH_3), 2.20 (br. s, 3 H, CH_3), 2.4−2.6 (m, 4 H, CH_2CH$_3$), 3.50 (d, J = 13.1 Hz, 1 H, CH_2−Cp), 3.82 (m, 1 H, subst Cp), 3.84 (dd, J = 13.1, J = 2.3 Hz, 1 H, CH_2−Cp), 4.17 (t, J = 2.4 Hz, 1 H, subst Cp), 4.21 (s, 5 H, Cp), 4.37 (m, 1 H, subst Cp), 6.40 (d, $J_{H,P}$ = 36.4 Hz, 1 H, CHP), 6.54 (d, $J_{H,P}$ = 36.4 Hz, 1 H, CHP) ppm. ^{13}C NMR ($CDCl_3$): δ = 12.5 (s, NCH$_2$$CH_3$), 18.2 (s, CH_3), 18.3 (s, CH_3), 46.4 (s, NCH$_2$CH$_3$), 52.1 (d $J_{C,P}$ = 5.9 Hz, CH_2), 69.6 (s, subst Cp), 69.9 (Cp), 71.5 (s, subst Cp), 71.9 (d, $J_{C,P}$ = 26.4 Hz, quat Cp), 72.9 (d, $J_{C,P\ P}$ = 4.4 Hz, subst Cp), 90.6 (d, $J_{C,P}$ = 26.4 Hz, quat Cp), 129.6 (s, CHP), 132.4 (s, CHP), 147.7 (d, $J_{C,P}$ = 9.0 Hz, C−CH_3), 148.8 (d, $J_{C,P}$ = 10.0 Hz, C−CH_3) ppm. ^{31}P NMR ($CDCl_3$): δ = −15.9 ppm. MS (DCI, NH_3): m/z (%) = 381 (100) [M + H].

General Procedure for Palladium-Catalyzed Allylic Substitution Dimethyl Malonate/BSA/KOAc System: A mixture of ligand **8**, 1,3-diphenylprop-2-enyl acetate (0.454 g, 1.8 mmol) and $[Pd(C_3H_5)Cl]_2$ (3.3 mg, 0.009 mmol) in dry solvent (20 mL) was stirred at room temperature for 2 h. Dimethyl malonate (0.411 mL, 3.6 mmol), potassium acetate and BSA (0.880 mL, 3.6 mmol) were added to the resulting solution. The reaction was carried out at room temperature and monitored by TLC for disappearance of acetate. After complete reaction, the mixture was diluted with diethyl ether (5 mL) and quenched with a saturated aqueous solution of ammonium chloride (5 mL). The aqueous phase was extracted with Et_2O, the combined organics were dried over magnesium sulfate, filtered and the solvents evaporated. The conversion was calculated from the crude reaction mixture by ^{1}H NMR spectroscopy. Subsequent purification by chromatography on silica eluting with ethyl acetate/pentane (15:85) afforded the product as a white solid. The enantiomeric excess was determined by ^{1}H NMR spectroscopy using the chiral shift reagent Eu(hfc)$_3$.

Dimethyl Malonate/NaH System: A mineral oil dispersion of NaH (87 mg, 60% NaH, 2.17 mmol) was washed with dry pentane (3 × 5 mL). The oil-free NaH was suspended in dry dichloromethane (10 mL), cooled to 0 °C and treated dropwise with dimethyl malonate (0.297 mL, 2.6 mmol). After the reaction was complete, the resulting sodium dimethyl malonate was transferred by cannula under argon into a Schlenk tube containing a mixture of ligand **8**, 1,3-diphenylprop-2-enyl acetate (0.328 g, 1.3 mmol) and $[Pd(C_3H_5)Cl]_2$ (2.4 mg, 0.0065 mmol) in dry dichloromethane (10 mL) previously stirred at room temperature for 2 h. The reac-

Largest diff. peak and hole	0.47 and −0.33 e·Å^{-3}	0.51 and −0.3 e·Å^{-3}

tion was carried out at room temperature and monitored by TLC for disappearance of acetate. Treatment, extraction and purification were accomplished by the same procedure as described above.

X-ray Structure Determination: Data for **(*S*)-5** and **7a** were collected on a Stoe IPDS diffractometer. The final unit cell parameters were obtained by the least-squares refinement of 8000 reflections. Only statistical fluctuations were observed in the intensity monitors over the course of the data collections.

Both the structures were solved by direct methods (SIR97[18]) and refined by least-squares procedures on F_{obs}. All H atoms attached to carbon or oxygen were introduced at their idealised positions [d(CH) = 0.96 Å] and were refined using a riding model. They were given isotropic thermal parameters 20% higher than those of the atom to which they are attached. The absolute configuration was confirmed by the refinement of the Flack parameter[19] and careful examination of the sensitive reflections. Least-squares refinements were carried out by minimising the function $\Sigma w(F_o - F_c)^2$, where F_o and F_c are the observed and calculated structure factors. The weighting scheme used in the last refinement cycles was $w = w'[1-\{\Delta F/6\sigma(F_o)\}^2]^2$ where $w' = 1/\Sigma_i^n A_r T_r(x)$ with three coefficients A_r for the Chebyshev polynomial $A_r T_r(x)$ where x was F_c/F_c(max).[20] Models reached convergence with $R = \Sigma(F_o - F_c)/\Sigma(F_o)$ and $Rw = [\Sigma w(F_o - F_c)^2/\Sigma w(F_o)^2]^{1/2}$, with the values listed in Table 2. The calculations were carried out with the CRYSTALS programs package.[21] The views of the molecules were produced with the ORTEP-III for Windows program.[22]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-198748 (**5**) and CCDC-198749 (**7a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Degradation of the Second-Generation Grubbs Metathesis Catalyst with Primary Alcohols and Oxygen − Isomerization and Hydrogenation Activities of Monocarbonyl Complexes

Maarten B. Dinger[a] and Johannes C. Mol*[a]

Keywords: Ruthenium / Metathesis / Carbene ligands / Alcohols / Isomerization / Hydrogenation

Reaction of the second-generation Grubbs metathesis catalyst [$RuCl_2$(=CHPh)(H_2IMes)(PCy_3)] (**2**) (H_2IMes = 1,3-dimethyl-4,5-dihydroimidazol-2-ylidene) with primary alcohols in the presence of a base produced the complexes [RuClH(CO)(PCy_3)$_2$] (**3**) and [RuClH(CO)(H_2IMes)(PCy_3)] (**5**). When benzyl alcohol was used, the ruthenium phenyl complexes [RuClPh(CO)(PCy_3)$_2$] (**4**) and [RuClPh(CO)(H_2IMes)(PCy_3)] (**7**) were formed in addition to **3** and **5**. Complex **7**, characterised by an X-ray structure analysis, was also formed on exposure of **2** to oxygen. The isomerization and hydrogenation activity of **7** was determined and compared with that of **3** and **4**.

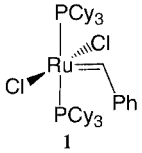
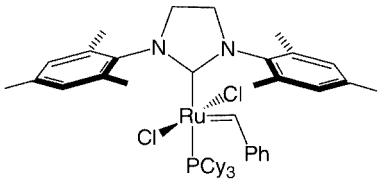
Introduction

With the advent of the Grubbs metathesis catalysts [$RuCl_2$(=CHPh)(PCy_3)$_2$] (**1**) and [$RuCl_2$(=CHPh)(H_2IMes)(PCy_3)] (**2**) olefin metathesis has become an increasingly useful tool for organic transformations.[1] Moreover, these metathesis catalysts can catalyse a number of other reactions,[2] and can also be transformed in situ into various catalytically active species. Single-component tandem catalysis in the presence of **1** and **2** has, so far, included metathesis followed by hydrogenation,[3] dehydrogenation,[3c] and, most recently, isomerization.[4] Relatively little effort, however, has been made to identify the active species responsible for the secondary reaction(s), although various hydride species are thought to be involved.



1



2

Recently, we[5] and others,[3a−3c,6,7] described how the transformation of the first-generation Grubbs catalyst [$RuCl_2$(=CHPh)(PCy_3)$_2$] (**1**) to the hydride species [RuClH(CO)(PCy_3)$_2$] (**3**) could be affected by aliphatic primary alcohols, and we established that the addition of a suitable base greatly facilitates this reaction. Additionally, if benzyl alcohol is used in place of the aliphatic alcohol, the phenyl complex [RuClPh(CO)(PCy_3)$_2$] (**4**) is produced in good yields. The reactions occur via an alcohol dehydrogenation pathway, with toluene and an alkane being the major organic products. Complex **4** was of particular interest because it was also formed when **1** was treated with oxygen, this reaction being especially effective in the solid state, where the undesirable oxidation of the phosphane ligands is suppressed.

Complexes **3** and **4** proved to be excellent α-olefin isomerization catalysts, producing the β-olefin with high (95%) selectivity. Extending the first-generation research to the important second-generation metathesis catalyst **2** was a natural step. The results of these studies are described here.

Results and Discussion

Reaction of 2 with Primary Aliphatic Alcohols

When the second-generation catalyst **2** was treated with methanol in the presence of triethylamine, the initially dark brown solution slowly became dark orange. Catalyst **2** was more active than the first-generation system **1**, and the reactions proceeded readily at lower temperatures than used previously for **1** (60 vs. 80 °C).[5] However, ^{1}H and ^{31}P NMR spectroscopy revealed an unexpectedly complex reaction in which three different hydrides were produced, in marked contrast to **1** where only one hydride species was formed.[5] Two of these hydride complexes were identified spectroscopically.

The major reaction product (≈30−40% yield by NMR spectroscopy), showing a doublet at δ = −27.8 ppm in the ^{1}H NMR spectrum, was assigned as the expected mixed-ligand hydride species [RuClH(CO)(H_2IMes)(PCy_3)] (**5**). The formation of **5** was verified by comparison of ^{1}H and ^{31}P NMR spectra with those obtained from the model reaction of **3** with H_2IMes. Unfortunately, repeated attempts to isolate complex **5** from either synthetic route were unsuccessful due to the product's extremely high solubility in all common organic solvents, ranging from pentane to methanol. The surprisingly high solubility of **5** — the very closely related complex [RuClH(CO)(IMes)(PCy_3)] (**6**) was reported to be insoluble in methanol[8] — may be because it is not a solid at room temperature. Complex **5** could be precipitated from pentane solutions at −78 °C, but subsequent removal of the supernatant by syringe, followed by warming of the solid to room temperature, gave only a highly air-sensitive, oily residue.

A second hydride (about 25−30% yield by NMR spectroscopy) shows δ = −24.2 ppm as a triplet, and was determined to be complex **3** by comparison with the spectrum of an authentic sample.[5] The formation of complex **3** from **2** is especially noteworthy since it could only have originated from an unexpected H_2IMes ligand exchange with PCy_3. *N*-Heterocyclic carbene (NHC) ligands in ruthenium systems generally show stronger covalent bonds (more exothermic reaction enthalpies) than phosphanes, and so tend not to readily dissociate.[9] We were unable to unambiguously identify the reaction by-products, but the observed ligand exchange must consume the starting material (or products), and should lead to RuCl(H_2IMes) and free H_2IMes fragments which could subsequently combine to produce bis-H_2IMes complex(es). While free H_2IMes displaced PCy_3 in separate reactions (vide infra), in this case any released H_2IMes might also react with the excess alcohol, thereby limiting its immediate availability for further reaction. Reaction of the ligand with alcohol is not available for PCy_3, and so the degradation becomes considerably more complicated than that observed for **1**.

Surprisingly, the addition of an NHC ligand has virtually no effect on the ^{31}P NMR spectrum of the complexes, rendering ^{31}P NMR of less use than usual in monitoring the reaction outcomes; **3**, **5** and **6** show chemical shifts of 47.6,[5] 46.9, and 47.5[8] ppm, respectively.

The third detected hydride species shows a doublet at δ = −7.43 ppm in the ^{1}H NMR spectrum, and was only a minor product (about 10%). While the large downfield shift relative to **3** and **5** suggested a ligand *trans* to the hydride group, the $^2J_{P,H}$ coupling constant of 50.4 Hz is both too high for a phosphorus *cis* and too low for a phosphorus *trans* to the hydride moiety, indicating a distorted coordination environment. The associated phosphorus resonance appears at δ = 47.5 ppm in the ^{31}P NMR spectrum, and so was not separated from those of **3** and **5**.

A fourth, unidentified complex that was definitely not a hydride species shows a phosphorus resonance at δ = 51.2 ppm in the ^{31}P NMR spectrum, and represented about 20−25% of the total phosphorus content of the crude reaction mixture. This peak appeared in a similar location as that found for the reaction of **1** with water,[5] and might arise from the reaction of **2** with adventitious water in the reagents/solvents used.

Ethanol, 1-propanol and 1-nonanol also gave the hydrides **3** and **5** as the dominant products, but with much smaller amounts (<5%) of the unknown hydride. Interestingly, 1-propanol and 1-nonanol gave significantly higher relative yields of **5**; **3**:**5** was 15:85 for these two alcohols, compared with 40:60 and 35:65 for methanol and ethanol, respectively. Ethanol, 1-propanol and 1-nonanol also produced the unknown complex with a ^{31}P NMR peak at δ = 51 ppm, and in approximately the same quantities. Such a significant side-product was never observed in otherwise identical reactions of **1**, further highlighting the quite different behaviour of **1** and **2** in the alcoholic degradation experiments.

The volatile components of the 1-nonanol reaction were analysed by GCMS and showed that, as with **1**, toluene and octane were the major constituents, indicative of an alcohol dehydrogenation/decarboxylation mechanism.[5] Reaction with 1-^{13}C enriched ethanol ($CH_3{}^{13}CH_2OH$) confirmed that the hydride complexes were formed by this pathway. Most of the ^{13}C label was incorporated as the carbonyl groups in **3** and **5**, and the associated hydride signals clearly showed additional coupling due to an adjacent spin-active carbon isotope. A third ^{13}C-labeled carbonyl group, which showed no splitting from phosphorus (singlet), appeared at δ = 204.7 ppm; this complex may possibly be a bis-NHC complex. Interestingly, the third, unidentified, hydride species (δ = −7.43 ppm) showed no additional splitting (remaining a simple doublet), indicating that it does not contain a carbonyl group and, therefore, probably does not form from an alcohol dehydrogenation pathway.

Reaction of 2 with Benzyl Alcohol

As with aliphatic alcohols, when complex **2** was reacted with an excess of benzyl alcohol, in the presence of triethylamine, several products were observed by ^{31}P NMR spectroscopy. This was in sharp contrast to the reaction of **1** with benzyl alcohol under the same conditions, which cleanly generated the phenylruthenium complex **4** in good yield.[5] Again, the main reason for the relatively unsatisfactory reaction is the apparently significant lability of the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

H_2IMes ligand under the conditions used, which readily scrambled with the phosphane. Additionally, whereas no hydride complexes formed with **1**, catalyst **2** also produced hydride complexes. Complexes **3** and **5** represented about 25% and 10% of the total phosphorus-containing complexes, respectively, while **4** and the desired product, [RuClPh(CO)(H_2IMes)(PCy_3)] (**7**), were formed in 5% and 30% yield, respectively. The remaining about 30% was due to an unknown species that shows a ^{31}P NMR signal at δ = 51.9 ppm. This chemical shift is very similar to that of the complex(es) formed with aliphatic alcohols, although the about 0.7 ppm difference implies that it may possibly be a slightly different species.

The ^{1}H NMR spectrum revealed that a third hydride species had again formed, in addition to **3** and **5**, but this species was distinct from that present in the aliphatic alcohol reactions, showing a sharp singlet at $\delta = -6.59$ ppm that indicates the complete absence of phosphorus ligands and a substituent *trans* to the hydride atom. This complex might be the bis-carbene [RuClH(CO)(H_2IMes)$_2$], although this could not be confirmed synthetically; complex **3**, with excess H_2IMes, even at 100 °C, gave only the mono-substituted complex **5**. However, this does not rule out a bis-NHC complex; the failure of bis-phosphanes to fully substitute with NHCs can be attributed to the lowered lability of the remaining phosphane after mono-substitution.[6] To gain further insight we analysed the crude reaction mixture by FAB/MS. Unfortunately, this yielded little new information since only **4** and **7** (and their fragmentation products) were detected.

Reaction of 2 with Oxygen

Like complex **1**,[5] complex **2** also reacted with oxygen. However, the reactions were much lower yielding. Thus, **2** reacted with dry air at room temperature in toluene to give, mainly, tricyclohexylphosphane oxide, and only very low amounts of **7**. Furthermore, the diphosphane product **5** was also produced. Higher temperatures gave O=PCy_3 as the only phosphorus-containing species according to ^{31}P NMR spectroscopy.

In the solid state, the reaction of **2** with oxygen (5 bar) was cleaner. Nonetheless, only about 30% of **2** had reacted after 48 h, and, of that, only about 30% was complex **7**. The major product peak in the ^{31}P NMR spectrum appears at δ = 48 ppm, possibly due to O=PCy_3, although the lability of phosphane in the solid state should be relatively low, disfavouring the formation of this product. At higher pressures (50 bar) and 60 °C the complete reaction of **2** was achieved over three days to give, after workup, a 29% yield of the air-stable, bright pink **7**. The fate of the remaining **2** could not be determined; a phosphorus-containing material gave a ^{31}P NMR peak at δ = 54.4 ppm, but could not be isolated. The lower reactivity of **2** compared with **1** towards oxygen is foretold by its superior air tolerance; it can even be purified by chromatography using non-degassed solvents.[10] Nonetheless, the NHC ligand, being a better σ-donor than phosphanes, should render the ruthenium more electron-rich, thereby increasing the nucleophilicity of the benzylidene group toward an electrophile.[11]

Unsurprisingly, complex **7** was more easily prepared, and in better yield, by reaction of **4** with H_2IMes in toluene at 100 °C.

Crystal Structure of 7

Red blocks of **7** suitable for X-ray diffraction were grown by the slow evaporation of a CH_2Cl_2/MeOH solution in air. Figure 1 shows the structure of **7**, with selected bond lengths and angles in the caption.

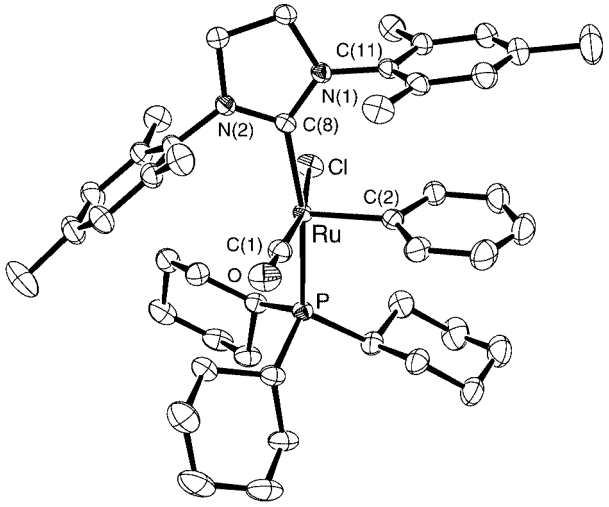

Figure 1. ORTEP representation of complex **7** with thermal ellipsoids drawn at the 30% probability level; hydrogen atoms have been omitted for clarity; selected bond lengths (Å) and angles (°): Ru−Cl 2.4542(8), Ru−P 2.4499(7), Ru−C(1) 1.805(3), Ru−C(2) 2.039(3), Ru−C(8) 2.118(3), O−C(1) 1.142(4), N(1)−C(8) 1.335(3), N(2)−C(8) 1.345(4); P−Ru−Cl 89.76(3), Cl−Ru−C(1) 168.6(1), Cl−Ru−C(2) 102.7(1), Cl−Ru−C(8) 86.05(7), P−Ru−C(1) 89.6(1), P−Ru−C(2) 94.25(8), P−Ru−C(8) 168.81(7), C(1)−Ru−C(2) 88.7(1), C(1)−Ru−C(8) 92.5(1), C(2)−Ru−C(8) 96.8(1), Ru−O−C(1) 179.2(3)

The ruthenium occupies a typical distorted square-pyramidal coordination geometry. As in related structures, the halogen is *trans* to the carbonyl moiety, so that the phosphorus is *trans* to the other neutral ligand (in this case H_2IMes). Somewhat surprisingly, few structures of complexes of the type [RuArCl(L)$_2$(CO)] (Ar = aromatic, L = phosphane) have been described,[12] and **7** is the first example containing an NHC ligand.

Overall, the structure most closely resembles that of the hydride complex **6** determined by Nolan,[8] with the phenyl group in **7** residing at the position of the hydride at the apex of the pyramid. The main distortions from an ideal square-pyramidal geometry are the P−Ru−C(8) and Cl−Ru−C(1) angles (both about 169°), which compare with analogous angles of 173.4 and 175.9°, respectively, in **6**. The increased distortion is most likely due to the higher steric influence of the phenyl group in **7** relative to the hydrogen in **6**. Surprisingly, the Ru−C(8) and Ru−P distances in **7** are significantly longer (0.035 and 0.083 Å, respectively) than in **6**; typically, these bond lengths are not greatly affected when

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

saturated (H_2IMes) or unsaturated (IMes) NHC ligands are present. Conversely, the Ru−CO bond length in **7** is longer (0.021 Å) than in **6**, concomitant with a shortening (0.038 Å) of the C≡O distance. The different electronic influences of the unsaturated (in **6**) and saturated (in **7**) NHC ligands are probably not responsible for these discrepancies. The increased steric demands of the phenyl group are probably the dominant influence, since the pushing back of the neutral ligands may result in less-ideal orbital overlaps with the metal center. The phenyl ring and one of the mesityl groups are in close contact, and almost perfectly eclipse one another. Because the two rings are not quite co-planar, forming a butterfly angle of 10.0(2)°, C(2)···C(11) represents the minimum distance between the rings at 3.259 Å.

Isomerization Activity of Complexes 3, 4 and 7

Previously we reported that complexes **3** and **4**, while totally metathesis inactive, were potent C=C bond isomerization catalysts for α-olefins.[5] Wagener et al. have recently made a detailed study of the double-bond isomerization activity of the first- and second-generation Grubbs catalysts **1** and **2**, and compared that with the Mo-based Schrock metathesis catalyst.[13] Double-bond isomerization is highly relevant in metathesis chemistry because it is the primary cause of secondary metathesis products; this is generally considered to be a major limitation of olefin metathesis. Nonetheless, double-bond isomerization has also recently been deliberately exploited in a tandem metathesis-isomerization reaction for the synthesis of cyclic enol ethers[4] in which the metathesis catalysts **1** or **2** were converted by hydrogen, after metathesis had ceased, into uncharacterised isomerization catalysts. We decided to determine the isomerization activity of complex **7** towards 1-octene, and compare this with the first-generation systems **3** and **4**.

As we recently reported for metathesis catalysed by **1** and **2**,[14] additional solvents were unnecessary in the isomerization reactions. Because solvents are a major hurdle in the development of "green" chemistry, any reactions where they are not required are particularly relevant to this increasingly timely area.[15] Figure 2 summarises the 1-octene isomerization activity of **7** over a range of temperatures. In each case, the reactions were allowed to proceed to maximal conversion, and, for comparison, the results for **3** and **4** under the same conditions are included.

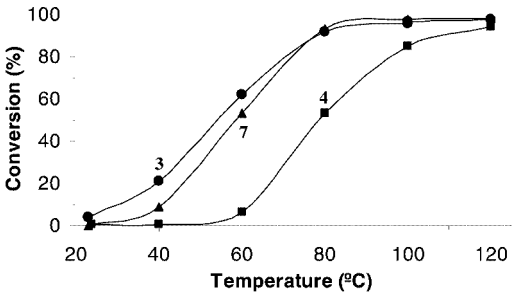

Figure 2. Double-bond isomerization of neat 1-octene (100,000 equivalents) in the presence of catalysts **3**, **4** and **7** as a function of reaction temperature; all reactions were allowed to proceed until 1-octene was no longer consumed

From Figure 2, the hydride complex **3** remains the most active catalyst with respect to turnover number. At lower temperatures, the phenyl-substituted analogue of **3**, complex **4**, displayed considerably lower activity, and was essentially inactive below 50 °C, possibly because the active species has to be generated in situ − for both **3** and **4** this active species is likely to be [RuClH(CO)(PCy_3)].[16] The NHC-substituted analogue **7** was almost as active as the hydride **3**. The loss in activity associated with substituting the hydride moiety (in **3**) for a phenyl group (in **4**) is at least partially offset by the increase in activity associated with replacing one of the tricyclohexylphosphane ligands with H_2IMes (in **7**). Unfortunately, as mentioned above, the H_2IMes-substituted hydride **5** could not be obtained in a sufficiently pure form for comparison.

Interestingly, at higher temperatures, and especially after prolonged reaction times, metathesis products (predominantly tridecene and dodecene, from the cross-metathesis of 1-octene with 2-octene and the self-metathesis of 2-octene, respectively) were detected in the reactions involving catalyst **7**. While these longer chain olefins represented only about 3−5% of the reaction products, it is noteworthy that only the NHC-containing compound initiated only metathesis, i.e. metathesis products have never been observed in reactions involving **3** and **4**.

Figure 3 depicts the relative reaction rates and selectivity over time for the isomerization of 1-octene into 2-octene at 100 °C. Catalyst **7** is clearly much more active than either **3** or **4**. Again, the presumed loss of activity due to the exchange of a hydride for a phenyl group is more than compensated for by the addition of the NHC ligand. Indeed, 97% conversion of 100,000 equivalents of 1-octene in the presence of **7** was achieved in less than 5 minutes, with 95% selectivity for 2-octene. For each catalyst, the selectivity for 2-octene formation rapidly decreased once all of the 1-octene had been consumed. Thus, the selectivity after 8 h was highest for catalyst **4**, followed by **3** and finally **7**, coinciding with their relative activities. We had previously determined that catalyst **4** could not isomerise 2-octene, and so the decrease in selectivity is primarily due to decomposition of the active catalyst into unknown ruthenium complexes that

are also catalytically active toward olefin isomerization but lack the selectivity (and activity) of the parent catalyst.[5] The *cis* to *trans* ratio of the 2-octene produced for each catalyst was approximately 30:70.

Hydrogenation Activity of 3, 4 and 7

Hydrogenation of alkenes is an important organic transformation, and can be facilitated by traditional homogeneous catalysts such as $[RhCl(PPh_3)_3]$ (Wilkinson catalyst), $[RuClH(PPh_3)_3]$ and $[RuH(CO)(PPh_3)_3]$.[17] More recently, catalyst **3** has been found to be an excellent olefin hydrogenation catalyst,[8,16,18] and has also been exploited for the hydrogenation of polybutadiene rubber.[19] Furthermore, the second-generation analogue **6** has recently been tested for hydrogenation activity, and displayed activity similar to **3** at higher temperatures.[8] Due to the current interest in single-component tandem metathesis-hydrogenation reactions,[3] we tested the efficacy of catalysts **4** and **7** for the hydrogenation of 1-octene, and compared the results with those of **3** (Table 1). Various reaction conditions were tested, and, again, the reaction proceeds very well in neat substrate, i.e. no additional solvents were required for good conversions and reaction rates.

From the data in Table 1 catalyst **3** is clearly the most active catalyst for the hydrogenation of 1-octene. Indeed, only **3** shows appreciable hydrogenation activity at room temperature. At 100 °C, **4** and **7** were "activated", and also became good hydrogenation catalysts, comparable in activity to **3**, and gave complete conversion into octane when 100,000 equivalents (mol) of 1-octene were reacted.

To better test the limits of the catalysts, reactions with lower catalyst loadings were examined. Thus, 350,000 equivalents (mol) of 1-octene were hydrogenated in the presence of **3**, **4** or **7** at 100 °C. All the catalysts consumed the 1-octene completely, but none gave selective conversion into octane. Catalysts **3** and **4** showed comparable activity and selectivity, whereas **7** produced lower amounts of octane, with isomerization clearly competing with the hydrogenation. This result is perhaps not surprising given the very high activity of **7** with regard to isomerization (vide supra), while the hydrogenation activity of **7** towards 2-octene is clearly lower.

Remarkably, the absence of solvent may benefit these reactions. Whereas Nolan reported turnover rates for the hydrogenation [$P(H_2)$ = 4 bar) of 1-hexene in benzene at 100 °C of 21,500 and 24,000 (mol product)(mol catalyst)$^{-1}h^{-1}$ for **3** and **6**, respectively,[8] we attained turnover frequencies of well over 100,000 h^{-1} for all the systems tested at 100 °C, even at only $P(H_2)$ = 1 bar.

Conclusions

The chemistry previously developed for the first-generation ruthenium metathesis catalyst **1**,[5] could be extended to include the second-generation catalyst **2**. However, the reactions were complicated by an unanticipated exchange involving the NHC ligand, even at relatively low temperatures (60 °C). The lability of the NHC ligand allowed not only the formation of the desired mixed-ligand systems, but also the corresponding diphosphane complexes. In theory these complexes could hinder olefin metathesis reactions that employ **2** in alcoholic solvents, but the higher temperatures and relatively long time needed for their formation limits their role in potential side-reactions.

Complex **7**, a fully air-stable solid, is a highly active isomerization catalyst − considerably more active than either of the first-generation systems **3** and **4**. We tentatively suggest that the higher σ-donation of the NHC ligand (relative to phosphanes), which ultimately renders the second-generation metathesis catalysts more active than their first-generation congeners, may also explain their (or their decomposition products') efficacy as isomerization catalysts. We also found that complexes **4** and **7** are efficient hydrogenation catalysts at higher temperatures, which may aid in the development of single-component tandem metathesis-hydrogenation of olefins[3a,3b] when employing the second-generation metathesis catalysts.

Experimental Section

Unless otherwise stated, all manipulations were performed under a nitrogen atmosphere on a vacuum line using standard Schlenk techniques. Complex **1** (Fluka), potassium *tert*-pentoxide solution (1.7 M in toluene, Fluka), and 1-octene (98%, Aldrich) were obtained from commercial sources. 1,3-Dimesityl-4,5-dihydroimidazolinium chloride[20] and the complexes **2**,[21] **3**,[22] and **4**[5] were prepared by the literature procedures. NMR spectra were recorded on a Varian Mercury 300 spectrometer, at 300.14, 75.48 and 121.50 MHz for the proton, carbon and phosphorus channels, respectively. Elemental analyses were performed by H. Kolbe Mikroanalytisches Laboratorium, Germany.

[RuClH(CO)(H_2IMes)(PCy_3)] (5): Potassium *tert*-pentoxide solution (1.7 M in toluene, 260 μL, 0.442 mmol) was added to a suspension of 1,3-dimesityl-4,5-dihydroimidazolinium chloride (0.150 g, 0.437) in toluene (5 mL) and stirred for 10 min. The resulting solution was transferred, via a steel cannula fitted with a filter, to a second flask containing a toluene (2 mL) solution of **3** (0.100 g, 0.138 mmol). The mixture was then heated to 100 °C for 3 h. No colour change was observed. The solvent was removed under reduced pressure, leaving an oily residue that was miscible with all common organic solvents at room temperature. Cooling a concentrated pentane solution to −78 °C produced a yellow solid. The mother liquor was then carefully removed by syringe and the solid allowed to warm to room temperature, during which time it slowly melted. The resultant highly air-sensitive oil was spectroscopically characterised as complex **5** (≈75% purity). IR (toluene): $\tilde{\nu}$ = 1896 cm^{-1} (vs, C≡O). ^1H NMR (CD_2Cl_2): δ = 25.37 (d, J_{HP} = 21.3 Hz, 1 H, Ru-*H*), 2.5−1.1 (multiple peaks, 51 H, H-aliphatic), 3.17 (br. s, 2 H, CH_2CH_2), 3.78 (br. s, 2 H, CH_2CH_2), 6.80 (br. s, 2 H, $C_6Me_3H_2$), 6.99 (br. s, 2 H, $C_6Me_3H_2$) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 46.7 ppm.

[RuClPh(CO)(H_2IMes)(PCy_3)] (7), Method A: Potassium *tert*-pentoxide solution (1.7 M in toluene, 220 μL, 0.374 mmol) was added to a suspension of 1,3-dimesityl-4,5-dihydroimidazolinium chloride (0.130 g, 0.379) in toluene (4 mL) and stirred for 10 min. The resulting solution was then transferred, via a steel cannula fitted with a filter, to a second flask containing a toluene (2 mL) solution of **4** (0.100 g, 0.125 mmol). The mixture was heated to 100 °C for 3 h, during which time the solution became a brighter orange/red. The solvent was then removed under reduced pressure, and methanol subsequently added to the residue. Rapid stirring (1 h) produced a bright pink precipitate, which was collected by filtration and then washed with methanol (4 × 10 mL) and pentane (2 × 5 mL) to give complex **7** as a crimson powder (0.072 g, 70%).

Method B: Finely powdered **2** (0.050 g, 0.059 mmol) was deposited as a solid in an autoclave that was subsequently pressurised with oxygen (50 bar) and then heated in an oil bath to 60 °C for 3 days. After releasing the pressure, workup in the same manner as Method A gave complex **7** (0.014 g, 29%). IR (KBr): $\tilde{\nu}$ = 1901 cm^{-1} (vs, C≡O). ^1H NMR (CD_2Cl_2): δ = 1.07 [m, 11 H, $P(C_6H_{11})_3$], 1.24 [m, 4 H, $P(C_6H_{11})_3$], 1.54 (s, 3 H, *p*-Me $C_6Me_3H_2$), 1.62 [br. s, 14 H, $P(C_6H_{11})_3$], 1.88 [m, 4 H, $P(C_6H_{11})_3$], 2.20 (s, 9 H, *o*-Me/*p*-Me $C_6Me_3H_2$), 2.63 (s, 6 H, *o*-Me $C_6Me_3H_2$), 3.85 (br. s, 4 H, CH_2CH_2), 5.89 (d, $^3J_{H,H}$ = 7.50 Hz, 1 H, *m*-H C_6H_5), 6.24 (d, $^3J_{H,H}$ = 7.20 Hz, 1 H, *p*-H C_6H_5), 6.30 (d, $^3J_{H,H}$ = 7.50 Hz, 1 H, *m*-H C_6H_5), 6.46 (br. s, 2 H, $C_6Me_3H_2$), 6.83 (d, $^3J_{H,H}$ = 7.80 Hz, 1 H, *o*-H C_6H_5), 6.88 (s, 2 H, $C_6Me_3H_2$), 7.14 (d, $^3J_{H,H}$ = 7.20 Hz, 1 H, *o*-H C_6H_5) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 19.3, 19.4 (*o*-Me/*p*-Me $C_6Me_3H_2$), 21.2 (*o*-Me $C_6Me_3H_2$), 26.9 [s, $P(C_6H_{11})_3$], 28.4 [d, $J_{C,P}$ = 8.5 Hz, $P(C_6H_{11})_3$], 29.6 [d, $J_{C,P}$ = 16.6 Hz, $P(C_6H_{11})_3$], 34.5 [d, $J_{C,P}$ = 16.2 Hz, $P(C_6H_{11})_3$], 118.5, 124.3, 125.6, 129.6, 130.0, 136.2, 136.8, 137.1, 138.2, 139.1, 140.5 (C-Ar), 155.9 (d, $^2J_{C,P}$ = 12.0 Hz, *i*-C C_6H_5), 205.6 (d, $^2J_{C,P}$ = 13.7 Hz, Ru-*C*O), 210.8 [d, $^2J_{C,P}$ = 94.9 Hz, Ru-*C*$(N)_2$] ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 22.2 ppm. $C_{46}H_{64}ClN_2OPRu$: calcd. C 66.69, H 7.79, N 3.38; found C 66.78, H 7.72, N 3.31.

Isomerization Reactions: Immediately before use, the 1-octene was passed through a column (20 cm × 1.5 cm) of neutral alumina (Acros, 50-200 μm), containing 15 g of alumina per 100 mL of octene, into a Schlenk flask. The 1-octene was then deoxygenated by a series of degassings (by evacuation of the flask), followed by refilling with nitrogen. For each reaction, 20 mL (127 mmol) of 1-octene was used. The reaction vessel was immersed in an oil bath and allowed to equilibrate to the desired temperature. An appropriate quantity (six-figure analytical balance) of the catalyst under investigation was then added to the 1-octene. No additional solvents were used. All reactions were thoroughly stirred, by way of a magnetic stirrer bar, and were allowed to proceed to completion, i.e. the reported results are those obtained when 1-octene consumption had ceased. The product distribution of the isomerization reactions was measured by GC/FID (Carlo Erba 8000 Top) using a ZB-5 (5% phenyl polysiloxane) column (Zebron).

Hydrogenation Reactions: 1-Octene was prepared in the manner described above for the isomerization reactions. A small quantity of the catalyst under investigation was introduced into an autoclave fitted with a glass liner, and the autoclave was subsequently evacuated and flushed with hydrogen. 1-Octene (10 mL) was introduced by syringe, and the autoclave pressurised with the desired level of hydrogen; this pressure was maintained throughout the experiment. The autoclave was heated, where appropriate, by way of an oil bath. After completion of the reaction, the hydrogen was vented off, and the solution analysed as for the isomerization reactions.

Crystal Structure Determination of 7: Red blocks of **7** suitable for X-ray diffraction were grown by the slow evaporation of a CH_2Cl_2/MeOH solution. Intensity data were collected on an Enraf−Nonius CAD-4 diffractometer, using a crystal of dimensions 0.50 × 0.45 × 0.125 mm, with graphite-monochromated Mo-K_α X-rays (λ = 0.71069) and ω-2θ scan. A total of 7461 unique reflections in the range 1.6° < 2θ < 25° were collected at room temperature, and these were subsequently corrected for Lorentz effects, polarization effects, and for linear absorption by a Ψ-scan method. Crystal data: $C_{46}H_{64}ClN_2OPRu$, FW = 828.48, crystal class monoclinic, space group $P2_1/c$, a = 12.2573(8), b = 15.6707(12), c = 22.358(4) Å, β = 94.686(10)°, V_c = 4280.2(9) $Å^3$, D_c = 1.286 g cm^{-3}, Z = 4, $F(000)$ = 1752, μ(Mo-K_α) = 0.502 mm^{-1}.

The structure of **7** was solved using the direct methods option of SHELXS-97[23] and subsequently refined using SHELXL-97.[24] All non-hydrogen atoms were assigned anisotropic temperature factors and all hydrogen atom positions were determined by calculation. For the methyl groups of the mesityl substituents, where the location of the hydrogen atoms was uncertain, the AFIX 137 card was used to allow the hydrogen atoms to rotate to the maximum area of residual density, while fixing their geometry. The refinement converged with R_1 = 0.0422 for 6751 data with $I \geq 2\sigma(I)$, 0.0466 for all data; wR_2 = 0.1146 $\{w = 1/[\sigma^2(F_o^2) + (0.0752P)^2 + 2.3804P]$ where $P = (F_o^2 + 2F_c^2)/3\}$, and GoF = 1.046. No parameter shifted in the final cycle. The final difference map showed no peaks or troughs of electron density greater than +1.29 and −1.02 e·$Å^{-3}$ respectively, both near Ru.

CCDC-199892 contains the supplementary crystallographic data for complex **7**. These data can be obtained free of charge at

Effect of Mixed Pendant Groups on the Solution Properties of 12-Membered Azapyridinomacrocycles: Evaluation of the Protonation Constants and the Stability Constants of the Europium(III) Complexes

Jean-Michel Siaugue,[a] Alain Favre-Réguillon,[b] Fabienne Dioury,[a] Gabriel Plancque,[c] Jacques Foos,[a] Charles Madic,[d] Christophe Moulin,[c] and Alain Guy*[b]

Keywords: Macrocyclic ligands / Protonations / Stability constants / Europium / Luminescence

The protonation constants ($\log K_i^H$) of new *N*-acetate or *N*-propionate substituted azamacrocycles derived from 12-membered pyridinoazamacrocycles were determined by potentiometric methods. The number of coordinated water molecules, determined from the luminescence lifetime of the Eu^{III} complexes, indicates a decreasing degree of hydration upon increasing the ring size of the pendant arms. Each ligand forms a 1:1 complex with Eu^{III}, for which the stability constants ($\log K_{therm}$) have been measured by time-resolved laser-induced europium luminescence. The replacement of acetate pendant groups by propionate increases the overall basicity of 12-membered pyridinoazamacrocycles but decreases the stability constant of the Eu^{III} complexes from $\log K = 21.1$ with three *N*-acetate pendant arms to $\log K = 13.7$ with two *N*-propionate and one *N*-acetate pendant arms and to $\log K = 10.7$ with three *N*-propionate pendant arms.

Introduction

Polyazamacrocyclic paramagnetic and radioactive metal ion chelates are of interest in biomedical applications such as Magnetic Resonance Imaging (MRI),[1,2] diagnostic[3] and therapeutic radiopharmaceuticals,[4] and as luminescent probes to investigate biochemical systems.[5]

Numerous 12-membered tetraazamacrocycles derived from "cyclen" with acetate, substituted acetate or propionate side chains have been studied.[2,6] The selectivity of complexation of such ligands towards various metal ions (i.e. the relative stability of the resulting complexes) can be tuned by adjusting the ring size, the number and the nature of coordinating atoms in the ring, and the type of side chains. Introduction of a pyridine in the 12-membered tetraazamacrocycles "cyclen" is expected to increase the conformational rigidity of the resulting macrocycle, and changing chelate ring size from five- to six-membered may influence the ion selectivity and properties of the macrocyclic compounds. Therefore, we studied the effect of the pendant arms (acetate versus propionate side chains) on protonation constants and Eu^{III} stability constants in a series of 12-membered pyridinoazamacrocycles L^1, L^2, and L^3 (Figure 1).

Potentiometric titrations have been used to determine the stability constants of L^1 ligands with alkaline-earth metal and first-row transition-metal ions[7] but this could not be applied to lanthanide ions due to both their extremely high constants ($\log K_{ML} > 20$) and their slow kinetics of formation. The "out-of-cell" potentiometric and competition titrations performed on cyclen derivatives are, necessarily, indirect, and the results depend on the validity of the assumptions made concerning the species present in the solution and the attainment of equilibrium at the time of the measurement. Gd^{III} complexes formed with L^1 ligand have been characterized by relaxometric experiments.[8,9]

The low extinction coefficients of Laporte-forbidden lanthanide f−f transitions mean that lanthanide ions have very small absorption coefficients, resulting in inefficient direct excitation.[10] This problem can be solved by using heterocycles as sensitizers or laser beams.[11] Tunable dye lasers excite the $^7F_0 \rightarrow {}^5D_0$ transition of the Eu^{III} ion in the range 577−581 nm, while the $^5D_0 \rightarrow {}^7F_2$ emission is monitored at 614 nm.[11] This provides an original method to directly monitor the binding of Eu^{III} to ligands in solution and has been used to determine the stability constants of lanthanides with polyaminocarboxylates.[12] However, complex and expensive tunable dye laser apparatus are required.

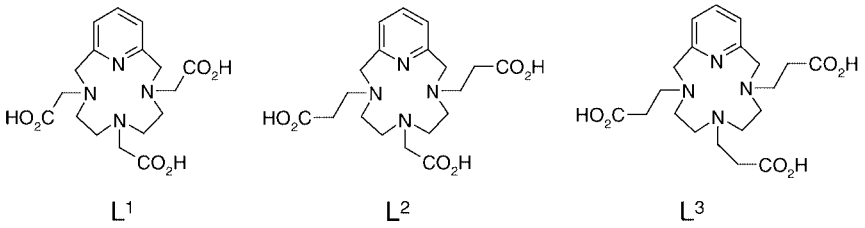

Figure 1. Structure of the ligands

Time-Resolved Laser-Induced Fluorescence (TRLIF) is widely used as a very sensitive and selective method for several luminescent actinides (U, Cm, Am) and lanthanides (Eu, Tb, Dy, Sm) in nuclear, environment, and medicinal chemistry, and is of growing interest in inorganic and organic speciation.[13,14] It is, therefore, an attractive analytical technique to apply to stability constant measurements.

Here we report, the protonation constants, the stoichiometries and the stability constants of the Eu^{III} complexes of ligands L^1, L^2, and L^3 bearing three carboxylic acid functions as well as seven potential donor atoms of various hardness.

Results and Discussion

Acidity Constants of L^1, L^2, and L^3

The ligands L^1, L^2, and L^3 each have seven basic centers, but only four constants could be determined by the potentiometric technique used. The protonation constants were found by potentiometric titrations of the fully protonated ligands. Figure 2 shows the potentiometric titration curve of macrocyclic ligands L^1, L^2, and L^3 with KOH. Analysis of the potentiometric titration curves with the Hyperquad program[15] yielded the protonation constants (Table 1).

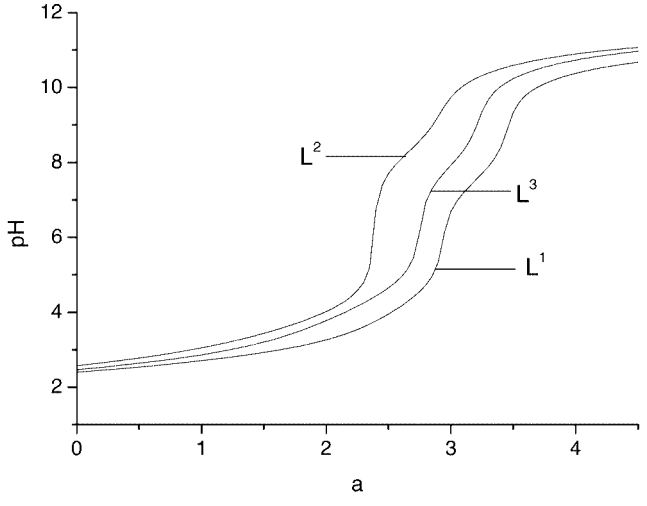

Figure 2. Potentiometric titration curve for 0.005 mM ligand: a = mol of base added per mol of ligand; solution temperature T = 25 °C, ionic strength I = 0.1 M (KCl)

Table 1. Comparison of the protonation constants of L^1, L^2, and $L^3$with the constants of an analogue (DOTA); the values in parentheses are standard deviations for the last figure given by the program[15]

Equilibrium quotient	L^1 [a]	L^2 [a]	L^3 [a]	L^1 [b]	L^1 [c]	DOTA[d]
[HL]/[H] [L]	10.73(5)	10.74(2)	10.72(3)	10.90	10.6	12.09
$[H_2L]/[HL]$ [H]	7.52(9)	8.27(6)	7.89(9)	7.11	7.6	9.76
$[H_3L]/[H_2L]$ [H]	4.2(1)	3.97(7)	4.5(1)	3.88	4.4	4.56
$[H_4L]/[H_3L]$ [H]	2.4(1)	3.26(7)	3.7(1)	2.27	–	4.09
$[H_4L]/[L]$ $[H]^4$	24.86	26.24	26.85	24.16	–	30.50

[a] 0.1 M KCl. [b] Ref.[7] 0.1 M NMe_4NO_3. [c] Ref.[16] 0.1 M KCl. [d] Ref.[17] 0.1 M NMe_4NO_3.

Ligands L^2 and L^3 differ from L^1 in their carboxylic acid side chains and, consequently, have significantly different protonation constants. All ligands have two high (or fairly high) and two low protonation constants. The first two are due to the protonation of two nitrogen atoms of the ring and the last two correspond to the protonation of carboxylate groups.[7,8] The separation of the pK_a values for a given ligand is greater than 0.7, which is consistent with non-interacting pendant arms.[18] For ligand L^3, the pK_a values are higher than those for L^1 owing to the presence of a second methylene group, which acts as an electron donor.[19]

Stoichiometry of the Complexes

The stoichiometry of the Eu^{III} complexes formed with L^1, L^2, or L^3 were determined by a mol ratio method. By monitoring the Eu^{III} luminescence at the wavelength of the $^5D_0 \rightarrow {}^7F_2$ transition peak as the function of Eu^{III} added to an aqueous solution of ligand (50 μM), at a pH such that the competition of protons is negligible (pH = 7.0), a binding curve is obtained (Figure 3). Since the ligand concentration is well above the dissociation constant for lanthanide complexes, the titration curve is expected to break sharply when the stoichiometric quantity of Eu^{III} has been added. Figure 3 shows a typical plot of the relative Eu^{III} luminescence intensity versus equivalents of added Eu^{III} with L^2 as ligand.

The macrocyclic ligands L^1, L^2, and L^3 have a 1:1 stoichiometry that is consistent with the size of the cavity as well as the number of donor atoms.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

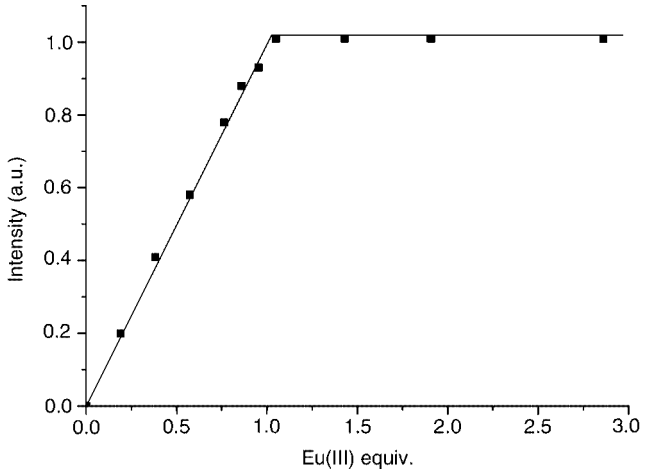

Figure 3. Intensities of the $^5D_0 \rightarrow {}^7F_2$ transition peak as the function of Eu^{III} added to an aqueous solution of ligand L^2 (50 μM), 0.085 M KCl and 0.015 M HEPES-buffered medium (pH = 7.0)

Luminescence Lifetimes, Quantum Yields

For each solution, the emission spectra are homothetical with I_{592}/I_{614} constant. Furthermore, a pulsed laser excitation source allows the measurement of characteristic Eu^{III} excited state lifetimes for each solution. The luminescence intensity of each europium complex decreases according to mono-exponential kinetics (Figure 4). Thus, under the conditions of our experiments, only 1:1 complexes for ligands L^1, L^2, and L^3 were present.

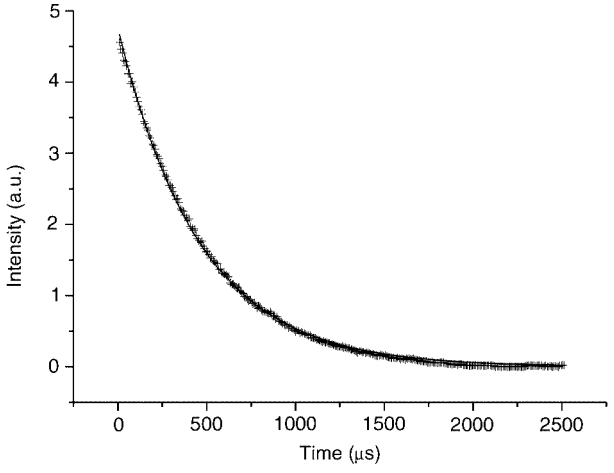

Figure 4. Excited-state luminescence decay for the system containing the macrocyclic ligand L^2 (50 μM) in the presence of $EuCl_3$ (60 μM) at pH = 5.28, [MES] = 0.015 M, [KCl] = 0.085 M

The luminescence lifetimes of Eu^{III} complexes with L^1, L^2, and L^3, and the overall quantum yields measured in H_2O and D_2O, are given in Table 2. From such measurements the estimated number of water molecules coordinated to the Eu^{III} complexes (Table 2), using the empirical relation proposed by Horrocks and co-workers,[20,21] Parker and co-workers,[22] or Kimura and co-workers,[23] show a decreasing degree of hydration with increasing ring size. The presence of 2.3, 1.6, and 1.4 coordinated water molecules for $[L^1 \subset Eu^{3+}]$, $[L^2 \subset Eu^{3+}]$, and $[L^3 \subset Eu^{3+}]$, respectively, agrees with the expected seven-coordinating nature of ligands since Eu^{III} prefers a coordination number of 8−9.

Table 2. Lifetimes of Eu^{III} complexes formed with L^1, L^2, and L^3, average number of water molecules coordinated to the complexes, and luminescence quantum yields

	Lifetimes τ [ms][a]		n H_2O[b]	n H_2O[c]	n H_2O[d]	Luminescence quantum yield[e]	
	H_2O	D_2O				H_2O	D_2O
$[L^1 \subset Eu^{3+}]$	0.37	2.12	2.3	2.3		2.32.9%	19.1%
$[L^2 \subset Eu^{3+}]$	0.43	1.35	1.7	1.7		1.94.6%	–
$[L^3 \subset Eu^{3+}]$	0.48	1.39	1.4	1.3		1.62.4%	8.1%

[a] Measured at room temperature; excitation into the lowest-energy ligand-centered absorption band in correspondence with the hypersensitive $5D_0 \rightarrow 7F_2$ transition; experimental error 5%. [b] Number of coordinated H_2O molecules estimated using Horrock's equation:[20,21] $n = 1.05 \cdot (\tau^{-1}_{H2O} - \tau^{-1}_{D2O})$. [c] Number of coordinated H_2O molecules estimated using Parker's equation:[24] $n = 1.2 \cdot [(\tau^{-1}_{H2O} - \tau^{-1}_{D2O}) - 0.25]$. [d] Number of coordinated H_2O molecules estimated using Kimura's equation:[23] $n = 1.07 \cdot (\tau^{-1}_{H2O}) - 0.62)$. [e] Measured at room temperature with reference to quinine sulfate;[25] excitation in the lowest energy ligand-centered absorption band (269 nm); experimental error 10%.

Determination of the Stability Constants of L^1, L^2, and L^3 with Eu^{III}

Since the multidentate ligands L^1 to L^3 form 1:1 complexes with Eu^{III} the general complexation equilibria apply [Equation (1)].

$$[Eu^{3+}] + [L^{3-}] \rightleftarrows [EuL] \quad (1)$$

The equilibrium constant for Equation (1) can be expressed as in Equation (2).

$$K(Eu^{3+}) = \frac{[EuL]}{[Eu^{3+}][L^{3-}]} \quad (2)$$

Depending on its intrinsic basicity, each ligand has a different response to the proton competition that limits the metal-ion binding, leading to the conditional stability constants [Equation (3)].

$$K_{cond.}(Eu^{3+}) = \frac{[EuL]}{[Eu^{3+}]\{[L^{3-}] + [HL^{2-}] + [H_2L^{-}] + [H_3L] + [H_4L^{+}]\}} \quad (3)$$

The thermodynamics and conditional stability constants are related by Equation (4)

$$K_{cond.}(Eu^{3+}) = K(Eu^{3+})\alpha_H \quad (4)$$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with α_H defined by Equation (5)

$$\alpha_H{}^{-1} = 1 + K_{a1}\cdot[H^+] + K_{a1}\cdot K_{a2}\cdot[H^+]^2 + K_{a1}\cdot K_{a2}\cdot K_{a3}\cdot[H^+]^3 + K_{a1}\cdot K_{a2}\cdot K_{a3}\cdot K_{a4}\cdot[H^+]^4 \quad (5)$$

and K_{a1}, K_{a2}, K_{a3}, and K_{a4} being the protonation constants of the studied ligand.

Provided a constant amount of energy is furnished to the studied system, the luminescence intensity is proportional to [EuL]. Consequently, the luminescence intensity may be expressed as a function of the pH and of the stability constant of the complex (K) by Equation (6)[11]

$$I = \frac{k'}{2}\left\{[Eu]_0 + [L]_0 + \frac{\alpha_H^{-1}}{K} - \left[\left([Eu]_0 + [L]_0 + \frac{\alpha_H^{-1}}{K}\right)^2 - 4[Eu]_0[L]_0\right]^{1/2}\right\} \quad (6)$$

where $[Eu]^0$ and $[L]_0$ stand for the initial total concentrations of Eu^{III} and ligand respectively, k' is the proportionality constant between maximal intensity and $[Eu]_0$.

Plotting the luminescence intensity at the wavelength of the $^5D_0 \rightarrow {}^7F_2$ transition peak as a function of the pH after a suitable equilibration time, give a binding curve (Figure 5). The fitting (least-squares method) of the theoretical curve obtained from Equation (6) (Figure 5, solid curve) to the experimental data (Figure 5, squares) leads to a log$K$ value of 21.1, 13.7, and 10.7 for complexes with L^1, L^2, and L^3, respectively.

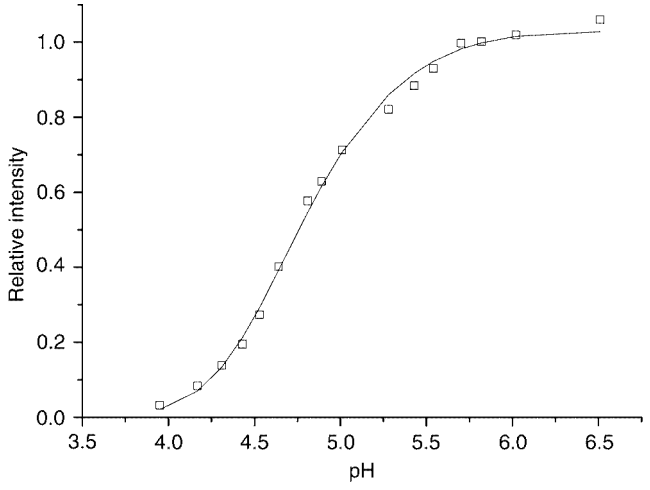

Figure 5. Binding curve obtained by monitoring the luminescence intensity (614 nm) of samples containing the macrocyclic ligand L^2 (50 μM) in the presence of $EuCl_3$ (50−60 μM) as a function of pH, [KCl] = 0.085 M, 4 < pH < 5 [HOMOPIPES] = 0.015 M, 5 < pH < 6.5 [MES] = 0.015 M; the luminescence resulted from Nd-YAG laser excitation at 266 nm; the squares represent actual data points and the solid line the theoretical fit of data with log$K$ = 13.7

Compared with L^1, an important diminution of the complexation constant is observed for L^2 and L^3 (Table 3). Thus, increasing the length of the acid group has a negative influence on the complexation of Eu^{III}.

Table 3. Stability constants (log K_{EuL}) of the complexes formed with the ligands L^1, L^2, L^3, and DOTA

Ln	L^1 [a]	L^2 [a]	L^3 [a]	DOTA

Gd^{III}	20.8 [c]			24.6 [d]

[a] 0.1 M KCl, 25 °C. [b] Ref.[12] 0.1 M KCl. [c] Ref.[8] [d] 0.1 M NaCl, ref.[26]

Conclusion

In conclusion, we report here the protonation constants of new *N*-acetate or *N*-propionate substituted azamacrocycles and an extended characterization of Eu^{III} complexes formed with these ligands based on time-resolved laser-induced Eu^{III} luminescence. This enabled us to determine the stoichiometry of the complexes, the luminescence quantum yield and the stability constant, which revealed the influence of the chelate ring size of the pendant arms on the stability constant of the Eu^{III} complex. This successful outcome has encouraged us to embark on a program to characterize various similar ligands with different macrocyclic and chelate ring sizes.

Experimental Section

Materials and Chemicals: All measurements were performed at 293 K and the solutions were prepared with deionized water (Millipore system). All glassware was thoroughly rinsed with water. The ionic strength of the solutions was adjusted to 0.1 M with KCl. Europium(III) chloride hexahydrate (Aldrich), sodium formate, 2-[*N*-(2-hydroxyethyl)piperazin-*N*′-yl]ethanesulfonic acid sodium salt (HEPES-Na), hexahydro-1*H*-1,4-diazepine-1,4-diylbis(2-ethanesulfonic acid) (Homo-PIPES) and 2-(*N*-morpholinyl)ethanesulfonic acid monohydrate (MES) were purchased as their purest form from Fluka. The potentiometric titrations were performed using an automatic titrator system DMS 716 Titrino (Metrohm) with a combined glass electrode (Metrohm, filled with saturated KCl solution) and connected to a microcomputer. $EuCl_3$ stock solutions (ca. 10 mM) were titrated by ICP-AES. The concentrations of the ligand stock solutions (ca. 0.1 M) were determined by titration with a standardized Eu^{III} solution at pH = 7 for L^1 and L^2 and at pH = 8 for L^3, on equilibrated samples using time-resolved laser-induced Eu^{III} luminescence.

Time-Resolved Laser-Induced Fluorescence: An Nd-YAG laser (Model Minilite, Continuum, Santa Clara, USA), operating at 266 nm (quadrupled) and delivering ca. 0.2 mJ of energy in a 4 ns pulse with a repetition rate of 15 Hz, was used as the excitation source. The laser output energy was monitored by a laser power meter (Scientech, Boulder, USA). The laser beam was directed into the 4-mL quartz cell of a "FLUO 2001" spectrofluorometer (Dilor, Lille, France). The radiation coming from the cell was focused on the polychromator's entrance slit. Taking into account the dispersion of the holographic grating used in the polychromator, the measurement range extended to approximately 200 nm into the visible spectrum with a resolution of 1 nm. An intensified photodiodes (1024) array, cooled by the Peltier effect (−30 °C) and posi-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tioned at the polychromator exit, was used as detector. Spectra were recorded by integration of the pulsed light signal from the intensifier. The integration time, adjustable from 1 to 99 s, allows for variation in detection sensitivity. Logic circuits, synchronized with the laser shot, allow the intensifier to be active with a determined time delay (from 0.1 to 999 μs) and during a determined aperture time (from 0.5 to 999 μs). The whole system was controlled by a microcomputer. Data analysis was performed using the iterative least-squares fitting procedure in Microsoft Excel program. Fluorescence quantum yields were determined at 293 K by comparison with that of quinine sulfate in aqueous sulfuric acid solution (1 N), for which a reference yield of 0.55 was taken.[25] Luminescence lifetimes (at 293 K) were determined at 600 nm by excitation with a B.M. Industries frequency-quadrupled Nd-YAG laser (266 nm, pulse duration 8 ns FWHM) using an oscilloscope Tektronix 9310 to monitor the output signal of the photomultiplier.

Synthesis of Ligands: The ligands L^1, L^2, and L^3 were synthesized as reported.[8,27,28]

Potentiometric Titrations: The electrodes were calibrated to read the pH by a classical method.[29] .The ligand (5 mL, 0.001 M) was titrated with standardized 0.01 M sodium hydroxide. Argon was bubbled through the solution to exclude CO_2 and O_2. Sodium hydroxide was prepared from 0.1 M NaOH (Prolabo) and standardized against potassium hydrogen phthalate. The carbonate content was checked by Gran's method. The titration for each ligand was carried out at least three times. Each titration consisted of about 70 points collected over the pH range of 2.5−10.9. The titration data were refined by the non-linear least-squares refinement program Hyperquad[15] to determine the protonation constants. The pK_a values were calculated from the cumulative constants determined with the program. The uncertainties in the pK_a values correspond to the added standard deviations in the cumulative constants.

Spectrophotometric Experiments

Preparation of Samples for the Stoichiometry Determination: The pH of an aqueous stock solution containing HEPES (sodium salt, 0.015 M), KCl (0.085 M), and ligand (50 μM) was adjusted to pH = 7 for L^1 and L^2 and to pH = 8 for L^3 with an aqueous solution of HCl. A series of 11 samples was prepared in separate sealed containers with concentrations of $EuCl_3$ ranging from 0 to 200 μM. After overnight incubation at 60 °C, the samples were allowed to cool to room temperature and then monitored by absorption spectroscopy until no further spectral change was detected (typically 24 h). The Eu^{III} excited state lifetime was monitored and the luminescence intensity of each sample was measured at the wavelength of the $5D_0 \rightarrow 7F_2$ transition peak.

Preparation of Samples for Lifetime and Quantum Yield Measurements: Samples containing HEPES (sodium salt, 0.015 M), KCl (0.085 M), ligand (50 μM), and $EuCl_3$ (75 μM) were prepared in H_2O (D_2O). The pH (pD) was adjusted with an aqueous solution of HCl (DCl) to pH = 7.0 (7.4) (pD = pH + 0.41).

Preparation of Samples Used To Determine the Stability Constant of the Eu^{III} Complex: An aqueous stock solution containing buffer (0.015 M), KCl (0.085 M), ligand (50 μM), and a slight excess of $EuCl_3$ (55 to 60 μM) was prepared. A series of 15 samples was produced in separate sealed containers at various pH by addition of an aqueous solution of HCl (KCl/HCl buffer for pH = 1−2, HCO_2Na/HCO_2H buffer for pH =2−4, HOMOPIPES buffer for pH = 4−5, MES buffer for pH = 5−6.5, and HEPES buffer for pH = 6.5−8). After overnight incubation at 60 °C, the samples were allowed to cool to room temperature, and then monitored by absorption spectroscopy until no further change was detected. At equilibrium the samples were irradiated, and the Eu^{III} excited state lifetime monitored and the luminescence intensity of each sample measured at the wavelength of the $5D_0 \rightarrow 7F_2$ transition peak.

Synthesis, Crystal and Magnetic Structure of the Double Perovskites A_2NiMoO_6 (A = Sr, Ba): A Neutron Diffraction Study

María J. Martínez-Lope,[a] José A. Alonso,*[a] and María T. Casais[a]

Keywords: Perovskites / Neutron diffraction / Magnetic properties / Nickel

A_2NiMoO_6 (A = Sr, Ba) perovskites have been prepared in polycrystalline form by thermal treatment, in air, of previously decomposed citrate precursors. These materials have been studied by X-ray (XRD) and neutron powder diffraction (NPD) data. At room temperature, the crystal structure is tetragonal, space group $I4/m$, for Sr_2NiMoO_6 and for Ba_2NiMoO_6 the crystal structure is cubic, space group $Fm\bar{3}m$. Both perovskites contain divalent Ni cations. The low temperature antiferromagnetic ordering has been followed from sequential neutron diffraction data. Peaks of magnetic origin appear in the NPD patterns below temperatures of T_N = 81.2 K and T_N = 64.3 K for the Sr and Ba compounds, respectively. The magnetic structures are defined by a propagation vector **k** = (1/2,0,1/2) for Sr_2NiMoO_6 and **k** = (1/2,1/2,1/2) for Ba_2NiMoO_6. The refined magnitude of the Ni magnetic moments also suggests a divalent oxidation state with $S = 1$.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The double-perovskite oxides of general formula $A_2B'B''O_6$, in which A is a rare-earth metal and B′ and B″ are transition metal cations, constitute a wide family of materials displaying varied and appealing electronic and magnetic properties. More than 300 compounds with the double-perovskite structure have been synthesized so far,[1] in which the perovskite B sites are occupied alternately by different cations B′ and B″. These materials have recently attracted the interest of materials scientists for possible applications in magnetoresistive devices, since the report of room temperature colossal magnetoresistance (CMR) in the double perovskite Sr_2FeMoO_6.[2] Similar CMR properties have also been described in other complex perovskites, such as Sr_2ReMoO_6 and Ba_2FeMoO_6,[3−8] for which the CMR effect seems to be due to intergrain tunneling.[8,9]

The ideal structure of these compounds can be viewed as a regular arrangement of corner-sharing $B'O_6$ and $B''O_6$ octahedra, alternating along the three directions of the crystal, with the voluminous A cations occupying the voids between the octahedra. When the size of the A cations decreases with respect to that of B′ and B″ cations, there is a reduction in symmetry from cubic to tetragonal or even monoclinic due to the tilting of the $B'O_6$ and $B''O_6$ octahedra. For instance, Ba_2FeMoO_6 is cubic over the temperature range 2−300 K, whereas Sr_2FeMoO_6 is cubic above the ferromagnetic Curie temperature, and undergoes a structural phase-transition and becomes tetragonal ($I4/m$) below this temperature.[10−12] Sr_2CoMoO_6 is tetragonal[13] and the crystal contains alternating CoO_6 and MoO_6 octahedra, moderately tilted by 6.7° in the basal *ab* plane. Ca_2FeMoO_6 is monoclinic,[14] with a significant tilt of the FeO_6 and MoO_6 octahedra, due to the small size of the Ca cations found at the A positions.

The Ni analogues of A_2FeMoO_6 (A = Sr, Ba) have attracted our attention. The double perovskites Sr_2NiMoO_6 and Ba_2NiMoO_6 were studied in the sixties and then forgotten for more than 30 years. Sr_2NiMoO_6 was described as tetragonal,[15−17] and an antiferromagnetic behaviour has been observed below T_N = 80 K (17). Ba_2NiMoO_6 was described as cubic with a = 4.02 Å.[15−16]

In the present work we describe the synthesis of A_2NiMoO_6 (A = Sr, Ba), prepared by soft chemistry procedures, and the results of a neutron powder diffraction (NPD) study on well-crystallized samples. The crystal structures have been revised and we report complete structural data for these perovskites. Low-temperature NPD data allowed us to probe the microscopic origin of the antiferromagnetic ordering, and the evolution of the ordered Ni^{2+} magnetic moment.

Results

The double perovskites A_2NiMoO_6 (A = Sr, Ba) were obtained as nicely crystalline powders, the XRD diagrams for which are shown in Figure 1. The diffraction pattern for the Ba compound is characteristic of a cubic perovskite structure, showing superstructure peaks corresponding to the Ni/Mo ordering. The Sr_2NiMoO_6 XRD diagram shows the splitting of certain reflections, characteristic of a tetragonal distortion [for instance the (004) and (220) reflections].

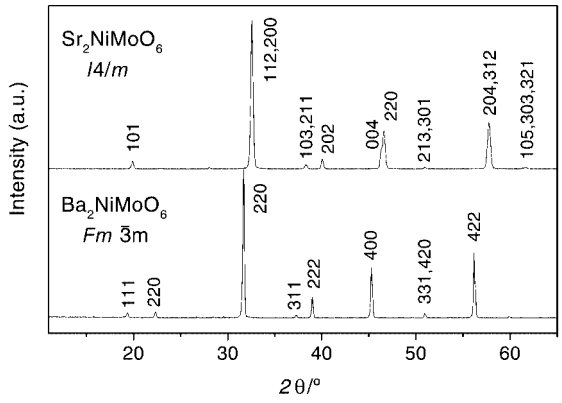

Figure 1. XRD patterns for A_2NiMoO_6 (A = Sr, Ba), indexed in a tetragonal unit cell with $a = b = \sqrt{2}a_0$, $c = 2a_0$ (A = Sr) and $a = 2a_0$, (A = Ba), $a_0 \approx 4$ Å

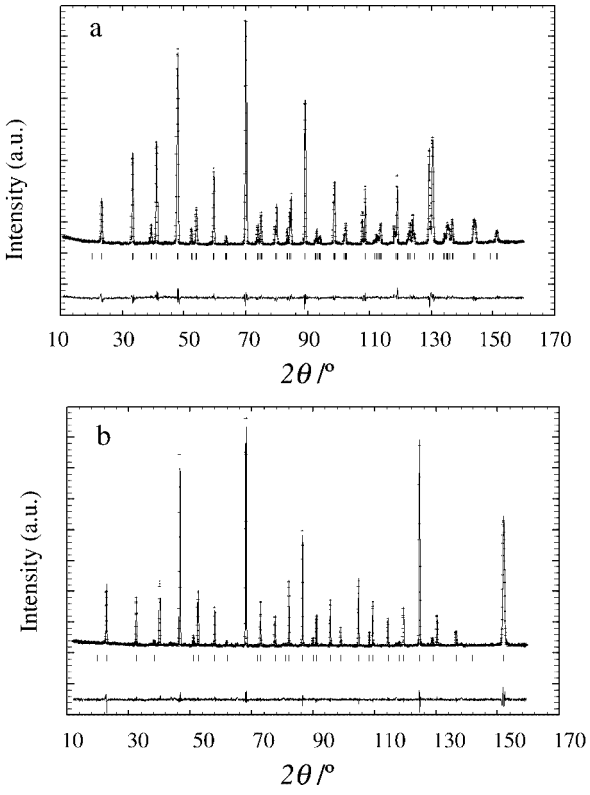

Figure 2. Observed (crosses), calculated (full line) and difference (bottom) high resolution NPD Rietveld profiles for A_2NiMoO_6 collected at 295 K with λ = 1.594 Å for (a) A = Sr, (b) A = Ba

Structural Refinement

For Sr_2NiMoO_6, the structural refinement from room temperature high resolution NPD data was performed in the *I*4/*m* space group (no. 87), $Z = 2$, with unit-cell parameters related to $\mathbf{a_o}$ (ideal cubic perovskite: $\mathbf{a_o}$ = 3.9 Å) as $\mathbf{a} = \mathbf{b} = \sqrt{2}\mathbf{a_o}$, $\mathbf{c} = 2\mathbf{a_o}$. The Sr atoms were located at 4d positions, Ni at 2a, Mo at 2b sites, and oxygen atoms at 4e and 8 h positions. For Ba_2NiMoO_6, the structural refinement from room temperature high-resolution NPD data was performed in the *Fm*$\bar{3}$*m* space group (no. 225), $Z = 4$, with unit-cell parameters related to $\mathbf{a_o}$ (ideal cubic perovskite, $\mathbf{a_o}$= 3.9 Å) as $\mathbf{a} = \mathbf{b} = \mathbf{c} = 2\mathbf{a_o}$. The Ba atoms are located at the 8c positions, Ni at 4a, Mo at 4b sites, and oxygen atoms at the 24e positions. An excellent fit was obtained for these models, as shown in Figure 2. In the final refinement, the possibility of anti-site disordering was checked by assuming that some Ni atoms could occupy Mo sites, and vice-versa: the refinement of the inversion degree led to less than 1% of anti-site disordering. The oxygen stoichiometry was also checked by refining the occupancy factors of the oxygen atoms; no deficiency was detected within the standard deviations. The most important structural parameters of the crystallographic structure at room temp. and the discrepancy factors after the refinements are listed in Table 1. The main interatomic distances and angles are included in Table 2. A view of the crystal structures is shown in Figure 3.

The tetragonal unit-cell of Sr_2NiMoO_6 is smaller than the cubic one of Ba_2NiMoO_6, normalizing per formula unit, as expected for the smaller ionic radius of Sr^{2+} (1.26 Å) versus Ba^{2+} (1.42 Å) in 12-fold coordination.[19] It is interesting to note the significant expansion of the Ni−O interatomic distances (Table 2) from the Sr compound [Ni−O: 2.024(4) Å] to the Ba perovskite [Ni−O: 2.097(2)] upon scaling the larger size of the unit cell for the Ba compound.

Magnetic Structure

The magnetic structure for A_2NiMoO_6 (A = Sr, Ba) and its thermal evolution was analyzed from a set of NPD patterns collected in the temperature range 2< T <87 K, with λ = 2.42 Å. In Sr_2NiMoO_6, on cooling to below 81.2 K, new reflections appear at positions forbidden for the Bragg reflections in the space group *I*4/*m*. These new peaks arise from the establishment of a long-range magnetic ordering defined by a propagation vector $\mathbf{k}$ = (1/2, 0, 1/2). An antiferromagnetic structure was modeled with magnetic moments at the Ni positions; after the full refinement of the profile, including the magnetic moment magnitude, a best discrepancy factor of R_{mag} = 12.6% was reached for the 2 K diagram considering the Ni moment to be approximately aligned along the [101] direction. In Ba_2NiMoO_6 the new peaks appear below T_N = 64.3 K and are indexed in the cubic cell with the propagation vector $\mathbf{k}$ = (1/2, 1/2, 1/2). The determination of the orientation of the moments is not possible in a cubic structure from powder data, therefore in the refinement we supposed that the moments lie along the [0 0 1] direction. After the refinement of the antiferromagnetic structure, a discrepancy factor of R_{mag} = 14.0% was obtained for the 2 K diagram. The goodness of both fits at 2 K is illustrated in Figures 4a and 4b.

The magnetic structure of the two compounds is stable from 2 K to T_N, as demonstrated in a sequential refinement of all the available temperature range. The thermal evolution of the Ni magnetic moments is illustrated in Fig-

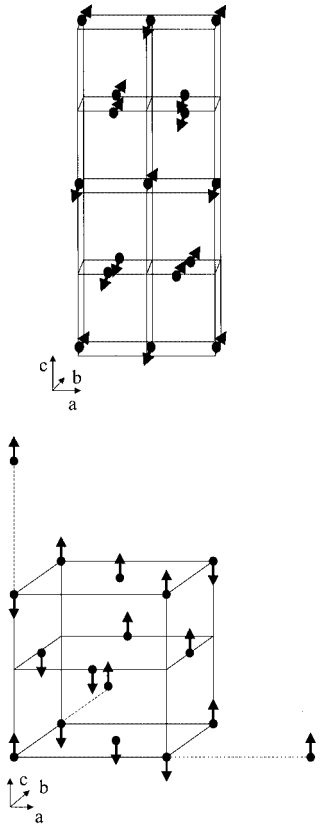

Figure 6. A sketch of the magnetic structures for: (a) Sr_2NiMoO_6, with k = (1/2 0 1/2); the magnetic unit cell consists of four crystallographic cells, and (b) Ba_2NiMoO_6, with k = (1/2 1/2 1/2); for the sake of clarity, the figure shows the chemical cell ($a \approx 8$ Å) and part of three adjacent cells

Discussion

The Ba compound adopts the well-known $(NH_4)_3FeF_6$ structure, which has been described for a large number of complex perovskites showing 1:1 long range order at the B sublattice. In this cubic structure, the BO_6 octahedra are not tilted, with B−O−B angles of 180°. The reduction of ionic size from Ba to Sr implies a reduction in symmetry from cubic to tetragonal, due to the tilting of the NiO_6 and MoO_6 octahedra along the c axis. According to Glazer's nomenclature,[20] the observed tilting is described as $a^0a^0c^-$, implying an antiphase tilting (from layer to layer) along c. The space group $I4/m$ is the one deduced by Woodward[21] for 1:1 double perovskites for the $a^0a^0c^-$ system. The magnitude of the tilting can simply be derived from the Ni−O−Mo angle (φ), as (180 − φ)/2 = 5.75°.

In both perovskites, NiO_6 and MoO_6 octahedra are almost fully ordered and alternate along the three directions of the crystal in such a way that each NiO_6 octahedron is linked to six MoO_6 octahedra, and vice versa. Figure 3 illustrates this particular feature nicely. The driving force for the Ni/Mo ordering is the charge difference between both kinds of cations, since the size difference is not too large. As shown in Table 2, the NiO_6 octahedra are only slightly larger (expanded) than the MoO_6 octahedra in both perovskites. This observation is consistent with the larger ionic size of Ni^{2+} vs. Mo^{6+}. The average Ni−O bond lengths at room temperature compare well with the expected values calculated as the sum of the ionic radii:[19] for A = Sr, <Ni−O> = 2.024(4) Å (calcd. 2.090 Å); <Mo−O> = 1.921 (4) Å (calcd. 1.99 Å); for A = Ba, <Ni−O> = 2.097(2) Å (calcd. 2.090 Å); <Mo−O> = 1.927 (2) Å (calcd. 1.99 Å).

A bond-valence calculation[22,23] from the observed bond lengths can give some insight into the actual oxidation states of the different cations present in the crystal structure. In Sr_2NiMoO_6, the calculated valences for Sr, Ni and Mo are 2.08, 2.21 and 5.78, respectively; in Ba_2NiMoO_6, the calculated valences for Ba, Ni and Mo are 2.66, 1.81 and 5.70, respectively. These values suggest an electronic configuration for these compounds at 298 K given by $Ni^{2+}(3d^8) - Mo^{6+}(4d^0)$. The electronic configuration for Ni^{2+} is in good agreement with the results of the magnetic-structure determination at 2 K. These configurations seem to exclude the presence of a mixed valence at the Ni atoms and imply a hexavalent oxidation state for the Mo cations, accounting for the electrical insulating behavior and colored aspect of these samples. The Ba cation seems to be significantly overbonded, exhibiting a valence much higher than the expected 2+ value. In fact, the observed Ba−O distances are much shorter (2.85 Å, see Table 2) than expected from the sum of the ionic radii (3.01 Å). It seems

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that the much more covalent network determined by NiO_6 and MoO_6 octahedra mainly determines the size of the unit cell; the low degree of freedom of this cubic structure constrains the Ba−O bond lengths outside of the optimal values. However, in the tetragonal structure of Sr_2NiMoO_6, the observed valence for Sr, very close to 2+, suggests that the tilt of the octahedra effectively relieves the stress at the A positions, thus optimizing the Sr−O distances.

In relation to the ordered magnetic moment obtained for Ni cations from the refinement of the magnetic structure at 2 K, it saturates to values close to 2 μ_B for both the Sr and Ba compounds. Again, this fact suggests a divalent oxidation state for the Ni cations ($t_{2g}^6e_g^2$, $S = 1$). The slightly higher Néel temperature observed for the Sr compound ($T_N = 81.2$ K) with respect to the Ba perovskite ($T_N = 64.3$ K) implies the presence of stronger magnetic interactions for the former oxide. These interactions are related to the significantly shorter Ni−O distances observed in Sr_2NiMoO_6, which account for a stronger overlap between the Ni 3d and O 2p orbitals, thus enhancing the superexchange process giving rise to the establishment of the antiferromagnetic ordering. In agreement with this observation, the saturation moment of the Ni^{2+} cations is slightly lower for the Sr compound (see Figure 5), again indicating a stronger covalent contribution to the Ni−O bonding in the Sr material, and a more ionic, weaker Ni−O bond with a larger localized magnetic moment for Ni in Ba_2NiMoO_6.

Conclusions

We have presented a detailed crystallographic study of the double perovskites A_2NiMoO_6 (A = Sr, Ba) from NPD data, allowing us to characterize subtle structural features relating the nature and strength of the Ni−O chemical bonds to the ordered magnetic moments determined by neutron diffraction. These compounds experience a low-temperature, long-range antiferromagnetic ordering, concerning the Ni^{2+} magnetic moments. For Sr_2NiMoO_6 the magnetic structure is defined by $\mathbf{k} = (1/2, 0, 1/2)$, and for Ba_2NiMoO_6 the magnetic structure is defined by $\mathbf{k} = (1/2, 1/2, 1/2)$. The slightly lower ordered magnetic moment and the greater Néel temperature observed for the Sr perovskite is related to the shorter, more covalent Ni−O bonds determined for this compound. It seems clear that Ni adopts a divalent oxidation state, and Mo is in an hexavalent $4d^0$ configuration, thus explaining the insulating behavior and the colored nature of these complex oxides.

Experimental Section

A_2NiMoO_6 (A = Sr, Ba) perovskites were prepared as ochre (A = Sr) or yellowish green (A = Ba) polycrystalline powders from citrate precursors obtained by soft chemistry procedures. Stoichiometric amounts of analytical grade $Sr(NO_3)_2$, $Ba(NO_3)_2$, $Ni(NO_3)_2{\cdot}6H_2O$ and $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ were dissolved in citric acid. The citrate + nitrate solutions were slowly evaporated, leading to organic resins containing a random distribution of the involved cations at an atomic level. These resins were first dried at 120 °C and then slowly decomposed at temperatures up to 600 °C. All the organic materials and nitrates were eliminated in a subsequent treatment at 800 °C in air, for 2 h. This treatment gave rise to highly reactive precursor materials, which were then treated in air for 12 h at 1000 °C (Sr perovskite) or at 1100 °C (Ba perovskite).

The initial characterization of the products was carried out by laboratory X-ray diffraction (XRD) (Cu-K_α, $\lambda = 1.5406$ Å). Neutron powder diffraction (NPD) diagrams were collected at the Institut Laue-Langevin (ILL) in Grenoble (France). The crystallographic structures were refined from the high resolution NPD patterns, acquired at room temperature at the D2B diffractometer with $\lambda = 1.594$Å. For the determination of the magnetic structures and the study of their thermal variation, a series of NPD patterns were obtained at the D20 high-flux diffractometer (ILL-Grenoble) with a wavelength of 2.42 Å, in the temperature range from 2 to 87 K for (A = Sr, Ba). The refinements of both crystal and magnetic structures were performed by the Rietveld method, using the FULLPROF refinement program.[24] A pseudo-Voigt function was chosen to generate the line shape of the diffraction peaks. The coherent scattering lengths for Sr, Ba, Ni, Mo and O were 7.02, 5.70, 10.300, 4.86 and 5.803 fm, respectively.

Preparation of Hydroxylamine Complexes of Ruthenium(II), Osmium(II) and Iridium(III)

Gabriele Albertin,*[a] Stefano Antoniutti,[a] Samuele Beraldo,[a] and Fabio Chimisso[a]

Keywords: Hydroxylamines / N ligands / P ligands / Ruthenium / Osmium / Iridium

The hydroxylamine complexes $[MH(NH_2OH)P_4]BPh_4$ (M = Ru, Os) and $[Ru(NH_2OH)_2P_4](BPh_4)_2$ [P = $P(OEt)_3$, $PPh(OEt)_2$] were prepared by allowing the triflate species $MH(\kappa^1\text{-}OSO_2CF_3)P_4$ and $[Ru(\kappa^2\text{-}O_2SOCF_3)P_4]^+$ to react with an excess of hydroxylamine. The iridium complexes $[IrCl_2(NH_2OH)PL_2]BPh_4$ [P = $P(OEt)_3$, $PPh(OEt)_2$; L = PPh_3, $AsPh_3$] and $[IrH_2(NH_2OH)(PPh_3)_3]BPh_4$ were also prepared by reacting the hydride species $[IrHCl_2PL_3]$ and $[IrH_3(PPh_3)_3]$ first with triflic acid and then with an excess of NH_2OH. The *O*-iminoacylated hydroxylamine complexes $[M\{\eta^2\text{-}NH{=}C(R)ONH_2\}P_4](BPh_4)_2$ and $[M\{\eta^2\text{-}NH{=}C(R)ONH(CH_3)\}P_4](BPh_4)_2$ (M = Ru, Os; R = CH_3, 4-$CH_3C_6H_4$) were prepared by allowing the nitrile complexes $[M(RCN)_2P_4](BPh_4)_2$ to react with hydroxylamine (NH_2OH) or *N*-methylhydroxylamine [$NH(CH_3)OH$]. The compounds were characterised spectroscopically (IR, ^1H, ^{13}C and ^{31}P NMR) and a geometry in solution was also established.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Hydroxylamine is a bifunctional molecule of simple constitution and structure, which has a somewhat unexplored coordination chemistry. Apart from the proposed $[IrCl_3(NH_2OH)(PPh_3)_2]$ compound,[1] obtained by protonation of $[Ir(NO)(PPh_3)_3]$ with HCl, and the $[Fe(TPP)(NH_2OH)_2]$ derivative (TPP = tetraphenylporphyrinate),[2] prepared by reacting Fe(TPP) with NH_2OH at low temperature, only recently[3] have some examples of hydroxylamine complexes of the type $[MX(NH_2OH)(CO)_2(PPh_3)_2]CF_3SO_3$ (M = Ru, Os; X = Cl, Br) and $[Re(NH_2OH)(CO)_3(PPh_3)_2]CF_3SO_3$ been reported. In contrast with numerous studies on hydrazine derivatives,[4,5] no further studies have been reported on the chemistry of hydroxylamine complexes, although NH_2OH is isoelectronic and somewhat similar to NH_2NH_2.

We have previously reported[6] the synthesis and the reactivity of mono- and bis(hydrazine) complexes of transition metals such as Mn, Fe, Ru, Os and Ir and have now extended these studies to hydroxylamine and methylhydroxylamine with the aim of testing the behaviour of these molecules as a ligand on appropriate metal fragments and, if possible, of carrying out a comparison with related hydrazine complexes. The results of these studies, which also include hydroxylamine reactions with coordinated nitriles,[7] are reported here.

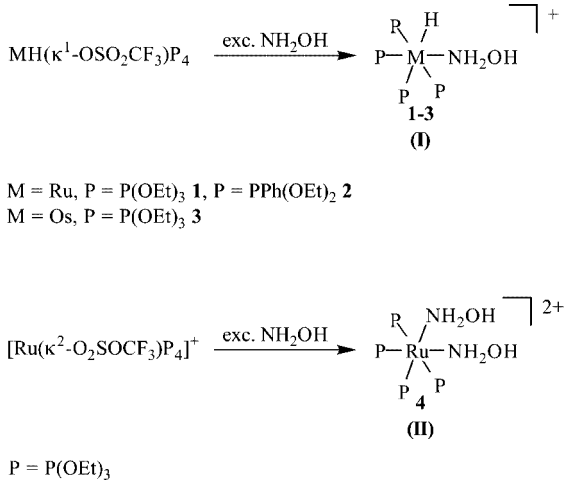
Results and Discussion

Preparation of Hydroxylamine Complexes

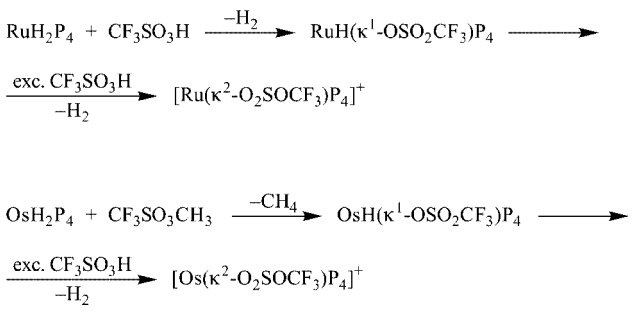
Mono- and bis(hydroxylamine) complexes of ruthenium and osmium $[MH(NH_2OH)P_4]BPh_4$ (**1**−**3**) and $[M(NH_2OH)_2P_4](BPh_4)_2$ (**4**) [P = $P(OEt)_3$, $PPh(OEt)_2$], were prepared by substituting the triflato ligand in the corresponding precursors, as shown in Scheme 1.



Scheme 1

The triflate precursors $[MH(\kappa^1\text{-}OSO_2CF_3)P_4]$ and $[M(\kappa^2\text{-}O_2SOCF_3)P_4]^+$ were generated in situ, in the case of ruthenium,[6a] by reacting the hydride complexes $[MH_2P_4]$ with an equimolar or an excess amount of triflic acid, while

with osmium[6c] the reaction first with methyl triflate and then with CF_3SO_3H was used (Scheme 2).



Scheme 2. P = $P(OEt)_3$, $PPh(OEt)_2$

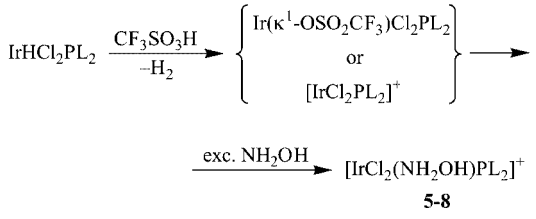
Substitution of the triflato ligand was easy for ruthenium, allowing the preparation of both mono- (**1, 2**) and bis(hydroxylamine) (**4**) complexes. In the case of osmium, however, only the mono-substituted derivative **3** was obtained in pure form. Attempts to prepare the bis-species, in fact, gave white solids, which probably contain (by NMR) a mixture of $[Os(NH_2OH)_2P_4]^{2+}$, $[Os(\kappa^1\text{-}OSO_2CF_3)(NH_2OH)P_4]^+$ and decomposition products whose separation was unsuccessful.

The hydroxylamine complexes **1**−**4** are white or pale-yellow solids that are stable in air and in solution in polar organic solvents, where they behave as 1:1 (**1**−**3**) or as 1:2 (**4**) electrolytes.[8] Analytical and spectroscopic data (Table 1) support the proposed formulations. Both the IR and ^1H NMR spectroscopic data are diagnostic for the presence of the NH_2OH ligand. The IR spectra, in fact, show a slightly broad medium-intensity band at 3487−3318 cm^{-1}, attributed to ν(OH), and two ν(NH) absorptions at 3326−3223 cm^{-1} of the hydroxylamine ligand. In the spectra of the mono-substituted derivatives **1**−**3** one weak band is also present at 1955−1820 cm^{-1}, due to the ν(MH) absorption of the hydride ligand. Its presence is confirmed by the ^1H NMR spectra, which show the characteristic high-field multiplet due to the coupling with the phosphorus nuclei, simulated using an AB_2CX model (X = H) with the parameters reported in Table 1.

Further support for the presence of the NH_2OH ligand comes from the ^1H NMR spectra, which show, for compounds **1** and **2**, a slightly broad multiplet at δ = 6.13−6.02 ppm, attributed to the NH_2 protons, and a broad signal at δ = 4.98−4.44 ppm, attributed to the OH hydrogen atom of the hydroxylamine ligand. These assignments are confirmed by integration and ^1H COSY experiments. In the spectra of compounds **3** and **4**, on the other hand, only the NH_2 proton signal at δ = 6.61−5.80 ppm is unambiguously attributable, while the OH signal is masked by the signals of the CH_2 protons. The low-frequency values observed for our proton OH signals as compared with those (δ = 8−9 ppm) of known hydroxylamine derivatives[1,3] may suggest an O-coordination of the NH_2OH ligand. However, the ^1H NMR spectra show a small coupling ($^3J_{P,H} \approx 1$ Hz) of the NH_2 protons with the phosphorus nuclei which seems to support, like the known hydroxylamine complexes,[3] an N-bonded NH_2OH ligand. Therefore, in the absence of an X-ray structure determination, the N-coordination (Scheme 1) should be considered more likely in this case.

In the temperature range between +30 and −80 °C the $^{31}P\{^1H\}$ NMR spectra of mono-hydroxylamine complexes **1**−**3** appear as AB_2C multiplets, which can be simulated using the parameters reported in Table 1, suggesting a mutual *cis* arrangement (**I**) of the hydride and NH_2OH ligands (Scheme 1). An A_2B_2 multiplet, instead, is present in the spectra of the bis(hydroxylamine) complex **4**, in agreement with a mutually *cis* position (**II**) of the two NH_2OH ligands.

These studies on the synthesis of NH_2OH complexes have been extended to other metals with a d^6 configuration. We found that, in the case of iridium, the use of appropriate precursors containing mixed phosphite-phosphane (or arsane) ligands allows the synthesis of stable hydroxylamine derivatives. Treatment of $[IrHCl_2PL_2]$, first with triflic acid and then with an excess of NH_2OH, gives the hydroxylamine complexes $[IrCl_2(NH_2OH)PL_2]^+$ (**5**−**8**) [P = $P(OEt)_3$, $PPh(PEt)_2$; L = PPh_3, A_5Ph_3], which were isolated as their BPh_4 salts and characterised (Scheme 3).



Scheme 3. L = PPh_3, P = $P(OEt)_3$ **5**, P = $PPh(OEt)_2$ **6**; L = $AsPh_3$, P = $P(OEt)_3$ **7**, P = $PPh(OEt)_2$ **8**

Protonation of $[IrHCl_2PL_2]$ with CF_3SO_3H leads[6d] to the evolution of H_2 and probable formation of either the triflate $[Ir(\kappa^1\text{-}OSO_2CF_3)Cl_2PL_2]$ or the pentacoordinate cations $[IrCl_2PL_2]^+$, which, when treated with an excess of hydroxylamine, give the final complexes **5**−**8**.

The $IrCl_2PL_2$ fragment seems to be peculiar to the formation of stable hydroxylamine complexes, since the use of other precursors such as $[IrHCl_2(PPh_3)_3]$, $[IrHCl_2(AsPh_3)_3]$ or $[IrH_2Cl(PPh_3)_3]$ does not allow the preparation of NH_2OH derivatives. The only other fragment we found to be able to bind NH_2OH is $[IrH_2(PPh_3)_3]$, which gives the stable and isolable complex $[IrH_2(NH_2OH)(PPh_3)_2]BPh_4$ (**9**). In fact, treatment of the trihydride $[IrH_3(PPh_3)_3]$, first with an equimolar amount of triflic acid and then with an excess of NH_2OH, produces the hydroxylamine complex **9**, which was isolated and characterised (Scheme 4).

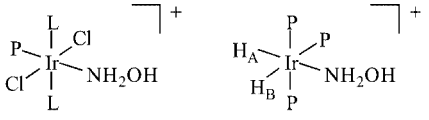
The reaction of $[IrH_3(PPh_3)_3]$ with CF_3SO_3H proceeds also in this case with the evolution of H_2 and probable formation of either κ^1-OSO_2CF_3 or pentacoordinate intermediates which, on treatment with NH_2OH, afford the final hydroxylamine derivative **9**. We also attempted to prepare bis(hydroxylamine) derivatives by reacting $[IrH_3(PPh_3)_3]$ sequentially, first with two equivalents of CF_3SO_3H and then with NH_2OH, but only a mixture of products not containing the NH_2OH ligand was isolated.

The hydroxylamine complexes of iridium (**5**−**8**) are yellow solids, while **9** is white, and all are stable in air and in solution in polar organic solvents, where they behave as 1:1 electrolytes.[8] Good analytical data were obtained for all compounds, and their IR and NMR spectroscopic data (Table 1) confirm the proposed formulations.

The IR spectra show the characteristic ν(NH) bands at 3275−3213 cm^{-1} and one of medium intensity at 1624−1607 cm^{-1}, attributed to δ(NH_2) of the NH_2OH ligands. The ν(OH) absorption in these complexes is weak and rather broad, and was unambiguously assigned only for **6** at 3490 cm^{-1}. In the spectrum of hydride complex **9** two weak bands at 2179 and 2130 cm^{-1} are also present. These were assigned to the ν(IrH) absorption of the two H^- ligands in a mutually *cis* position.

The presence of the hydroxylamine ligand in complexes **5**−**9** was further confirmed by the ^1H NMR spectra, which show the characteristic signal at δ = 5.83−5.25 ppm of the NH_2 protons of the hydroxylamine ligand. The OH proton is clearly observed at δ = 3.39 ppm only in the case of **9**; in the other complexes it is probably masked by the methylene protons of the phosphite ligands.

In the temperature range between +30 and −80 °C the $^{31}P\{^1H\}$ NMR spectra of the phosphane-phosphite complexes $[IrCl_2(NH_2OH)PL_2]BPh_4$ (**5** and **6**) [P = $P(OEt_3$, $PPh(OEt)_2$; L = PPh_3] appear as AB_2 multiplets in agreement with the magnetic equivalence of the two PPh_3 ligands. Taking into account that the far-IR spectrum of **5** shows only one ν(IrCl) band at 393 cm^{-1}, indicating that the two Cl^- ligands are in a mutually *trans* position, we may propose a *mer-trans* geometry (**III**) for our hydroxylamine derivatives **5** and **6** (Chart 1).



III **IV**

The $^{31}P\{^1H\}$ NMR spectra of the related arsane complexes $[IrCl_2(NH_2OH)PL_2]BPh_4$ (**7** and **8**) [P = $P(OEt)_3$, $PPh(OEt)_2$; L = $AsPh_3$] show only one singlet at δ = 32.8 and 64.3 ppm, respectively, for the phosphite ligand, and therefore no plausible hypothesis for the geometry of complexes can be made. However, taking into account that the far-IR spectra show only one ν(IrCl) band, we propose, by analogy with the related complexes **5** and **6**, a *mer-trans* geometry (**III**) for compounds **7** and **8** as well.

In the temperature range between +30 and −80 °C the $^{31}P\{^1H\}$ NMR spectra of $[IrH_2(NH_2OH)(PPh_3)_3]BPh_4$ (**9**) show an A_2B multiplet indicating the presence of two magnetically equivalent phosphanes, different from the third. In the hydride region, the ^1H NMR spectra also appear as a complicated multiplet, which can be simulated as the XY part (X, Y = H) of an A_2BXY spin system, with the parameters reported in Table 1. On this basis, we can reasonably propose a *mer-cis* geometry of type **IV** for our hydride-hydroxylamine complex **9**.

A comparison between the results for the NH_2OH complexes and those for related hydrazine NH_2NH_2 complexes shows that these two ligands are very similar in their behaviour toward metal fragments containing phosphite as supporting ligand. Similar complexes of Ru[6a] and Ir,[6d] containing either NH_2NH_2 or NH_2OH as monodentate ligand, can be isolated in the solid state. Furthermore, in the case of iridium only the mixed phosphane-phosphite fragment $IrCl_2PL_2$ can give stable hydrazine complexes, so the hydroxylamine derivative can be prepared exclusively with the same mixed-ligand fragment. Some differences, however, can be observed with osmium, which allows the synthesis of only mono-hydroxylamine complexes (**3**) with $P(OEt)_3$ phosphite ligand, whereas both mono- and bis(hydrazine) derivatives[6c] $[OsH(NH_2NH_2)P_4]^+$ and $[Os(NH_2NH_2)_2P_4]^{2+}$ can easily be prepared. In every case, although the comparison is still restricted to a few complexes, it seems that when a metal fragment is able to bind hydrazine, it can also coordinate hydroxylamine, affording the corresponding stable derivatives. Support for this hypothesis comes from the results on other complexes[3] suggesting a synthetic pathway for NH_2OH derivatives.

O-Iminoacylated Hydroxylamine Complexes

The synthesis of hydroxylamine complexes by substituting a labile ligand has prompted us to extend these studies to other precursors, such as the nitrile complexes $[M(RCN)_2P_4]^{2+}$ with the aim of testing whether new hydroxylamine derivatives may be prepared. Surprisingly, the reaction of bis(nitrile) complexes of ruthenium and osmium with hydroxylamine does not produce NH_2OH complexes, but affords a yellow solid which was characterised as containing an *O*-iminoacylated ligand of the type shown in Scheme 5.

[a] In $(CD_3)_2CO$ at 203 K.

pared in pure form, while with the related $PPh(OEt)_2$ compounds only intractable mixtures of product were obtained. Compounds **10** and **12** are pale-yellow solids stable in air and in solution in polar organic solvents, diamagnetic and 1:1 electrolytes.[8] The analytical and spectroscopic data (IR and NMR, Table 1 and 2) support the proposed formulation. The infrared spectra show, in the 3481−3217 cm^{-1} region, two or three medium-intensity bands, attributed to ν(NH) of the η^2-HN=C(R)ONH_2 ligand. The $\delta(NH_2)$ absorptions at 1668−1636 cm^{-1} also appear in the spectra. At room temperature, in CD_2Cl_2 as solvent, the ^1H NMR spectra of complexes **10** and **12** show, in the high-frequency region, a broad resonance at δ = 8.32−7.84 ppm. In $(CD_3)_2CO$, however, this resonance splits into two slightly broadened signals at δ = 12.36−9.06 and at 8.97−8.28 ppm, respectively, of intensity ratio 1:2. This split is observed at room temperature, except for compound **12a**, for which a lowering of the temperature to −20 °C is required. The highest frequency signal is assigned to the iminic =NH proton (H1), while the lowest is assigned to the ONH_2 (H2) group of the *O*-iminoacylated ligand. In the ^1H NMR spectra one sharp singlet between δ = 1 and 3 ppm due to the methyl group of the substituent R (CH_3 or 4-$CH_3C_6H_4$) of the η^2-ligand is also present.

Support for these assignments comes from a ^1H COSY spectrum of compound **10a**, which shows that the iminic HN= proton (H1) correlates with the methyl substituent of the iminic carbon atom HN=$C(CH_3)$ of the ligand. No correlation was observed between the iminic H1 and the aminic H2 proton resonances, in agreement with an *O*-iminoacylated molecule.

The ^{13}C NMR spectra confirm the formulation of the complexes showing, apart from the signals of the $P(OEt)_3$ and the BPh_4 anion, the imine carbon (C1) resonance of the η^2-ligand as a singlet at δ = 172.8 ppm for **10a** and at δ = 156.3 ppm for **12b**. An HMBC experiment for compound **10a** correlates the imine carbon signal at δ = 172.8 ppm with the methyl proton resonances at δ = 2.91 ppm of the methyl group bonded to the iminic C1 carbon atom, in agreement with the proposed assignment.

In the osmium complex **12b** the HMBC experiment shows a correlation between the iminic C1 carbon resonance and the signals of the phenyl protons of the *p*-tolyl substituent. On the basis of these data, and taking into account that in any solvent and in the temperature range between +20 and −80 °C the $^{31}P\{^1H\}$ NMR spectra of the *O*-iminoacylated derivatives **10**, **12** appear as an ABC_2 or A_2BC multiplet, a type-**V** geometry can reasonably be proposed.

We then thought to extend the studies to other hydroxylamines and treated the bis(nitrile) complexes $[M(CH_3CN)_2P_4]^{2+}$ with *N*-methylhydroxylamine $NH(CH_3)OH$. We observed that the reaction proceeds as with NH_2OH to give the chelated $[M(\eta^2\text{-}HN{=}C(CH_3)ONH(CH_3)\}P_4]^{2+}$ cations **11** and **13**, which were isolated as their BPh_4^- salts and characterised (Scheme 6).

$\delta[NH(CH_3)]$ at 1610−1608 cm^{-1} for the HN=$C(CH_3)ONH(CH_3)$ ligand.

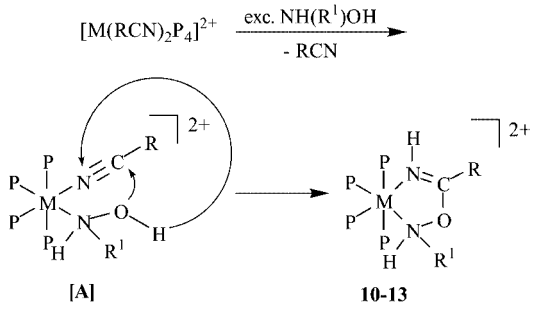
In the ^1H NMR spectra (Table 1) of both compounds **11** and **13** two singlets between δ = 3.29 and 2.08 ppm appear, due to the two methyl groups of the η^2-ligand. One broad signal at δ = 4.75 ppm (**11**) and at δ = 5.24 ppm (**13**) is also present in the spectra, which was attributed to the aminic $ONHCH_3$ (H2) proton. A ^1H COSY spectrum of **11** confirms this assignment, showing a strong correlation between the signal at δ = 4.75 ppm and the methyl singlet at δ = 2.08 ppm of CH_3N2. A weak correlation was also observed between the other methyl singlet at δ = 3.27 ppm (CH_3C1) and a signal near δ = 7.0 ppm, which appears to be masked by the phenyl protons of the BPh_4 anion and can be attributed to the iminic proton (H1) of the ligand.

The $^{13}C\{^1H\}$ NMR spectrum of **11** (Table 2) shows, besides the signals of the phosphites and the BPh_4 anion, two singlets at δ = 39.2 and 19.3 ppm attributed to the two methyl carbons of the $N2CH_3$ and $C1CH_3$ groups, respectively, and one singlet at δ = 154.7 ppm due to the iminic C=N carbon atom (C1). An HMBC experiment confirms this attribution showing a strong correlation between the imino carbon signal at δ = 154.7 ppm and the proton signal at δ = 2.08 ppm of the methyl $N2CH_3$ substituent and also a weak correlation with the ^1H signal at δ = 3.27 ppm of the $C1CH_3$ methyl group. Furthermore, the methyl carbon resonance of the HN=CCH_3 group at δ = 19.3 ppm correlates with the aminic H2 proton signal at δ = 4.75 ppm, in agreement with the presence of the *O*-iminoacylated ligand.

In the temperature range between +30 and −80 °C, the $^{31}P\{^1H\}$ NMR spectra of both the ruthenium and osmium complexes **11** and **13** appear as ABC_2 multiplets; these spectra can be simulated with the parameters reported in Table 1. On the basis of these data, we can reasonably propose a geometry of type **VI** for our *O*-iminoacylated methylhydroxylamine derivatives.

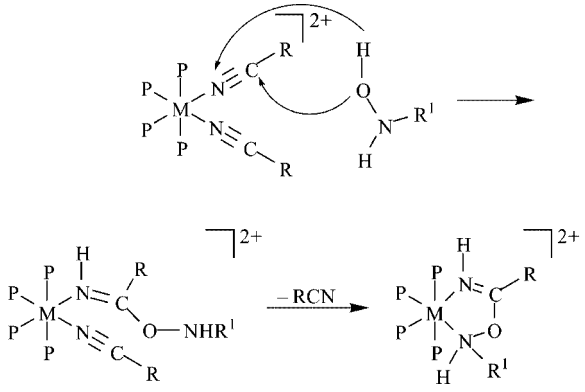
Formation of *O*-iminoacylated hydroxylamine complexes from the reaction of a coordinated nitrile with NH_2OH or $NH(CH_3)OH$ is not surprising, taking into account that a metal-bonded RCN molecule can undergo nucleophilic attack by alcohols, amines and carbanions to give iminoether-, amidine- and imine derivatives.[7,9−12] Furthermore, nitrile precursors $[Ru(RCN)_2P_4]^{2+}$ are reported[6a−6c] to react with hydrazine or methylhydrazine to give amidrazone complexes $[M\{\eta^2\text{-}NH{=}C(R)N(R^1)NH_2\}P_4]^{2+}$ (R^1 = H, CH_3), probably through the nucleophilic attack of the hydrazine on the cyanide carbon atom of the coordinated nitriles, followed by an H-shift, giving a five-membered metallacycle. Finally, it is well documented[13−15] that NH_2OH can react with free nitriles through the more usual N-addition, giving amide oximes $RC(NH_2)$=NOH, or through O-addition, affording carboxamides $RC(=O)NH_2$ as the final products.

A nucleophilic attack of the hydroxylamine by the oxygen atom on the coordinated nitrile can therefore also be proposed in our case for the formation of *O*-iminoacylated hydroxylamine complexes **10**−**13**, which represents the first example[7] of the addition of hydroxylamine NH_2OH to a coordinated nitrile. Doubts remain, however, regarding the reaction path. Treatment of bis(nitrile) complexes $[M(RCN)_2P_4]^{2+}$ with $NH(R^1)OH$ (R^1 = H, CH_3) could result in the substitution of only one nitrile ligand to afford the $[M(RCN)(NH_2OH)P_4]^{2+}$ intermediate **A**. The *O*-iminoacylated hydroxylamine complex can be obtained (Scheme 7) by a nucleophilic attack of the coordinated hydroxylamine's oxygen atom on the coordinated RCN's nitrile carbon atom, followed by an H-shift.



Scheme 7. P = $P(OEt)_3$, R = CH_3, 4-$CH_3C_6H_4$, R^1 = H, CH_3

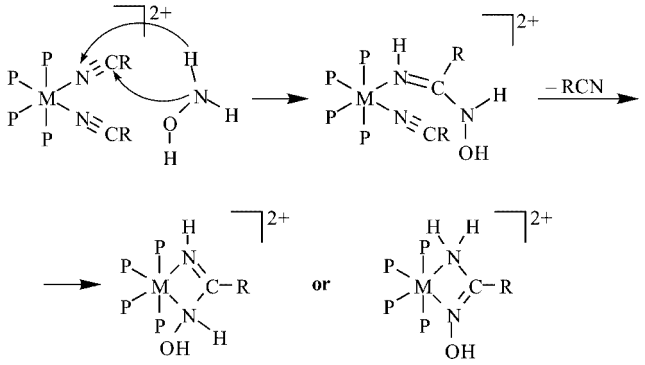
The hydroxylamine, however, could react with one of the coordinated nitriles through the oxygen atom without being bonded to the central metal, resulting in the *O*-iminoacylated ligand, which, by substitution of the second RCN ligand, yields the final chelate complexes (Scheme 8).



Scheme 8

The formation of complexes **10**−**13**, in fact, means that hydroxylamine, which possesses two sites of attack, reacts with the coordinated nitrile through the oxygen atom. The N-addition of hydroxylamine should give different products, such as complexes containing either the imine NH=C(R)NHOH or the tautomer amide oxime $RC(NH_2)$=NOH as a ligand (Scheme 9).

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 9

We have studied the reactions between $[M(RCN)_2P_4]^{2+}$ cations and hydroxylamine by NMR spectroscopy and observed that no signals attributable to a nitrile-hydroxylamine intermediate of the type $[M(RCN)(NH_2OH)P_4]^{2+}$ were detected, with the resonances of the initial and the final products and of free nitrile being the only signals observed in the spectra. However, since the reaction of this intermediate would be intramolecular, one could expect it to be much faster than substitution of one RCN to give $[M(RCN)(NH_2OH)P_4]^{2+}$, making this intermediate undetectable. On this basis, although our data do not give conclusive information, a mechanism involving the initial substitution of one RCN with NH_2OH (Scheme 7) may be reasonably proposed.

Apart from the mechanism, the behaviour of both the hydroxylamine and the hydrazine toward a coordinated nitrile of the $[M(RCN)_2P_4]^{2+}$ cations containing $P(OEt)_3$ as ancillary ligand is very similar. In both cases they result in a nucleophilic attack on the nitrile carbon atom followed by an H-shift, yielding a new chelate ligand. A different atom, however, is used by the two nucleophiles, i.e. N-addition with hydrazine and O-addition with hydroxylamine, affording different molecules which behave, in every case, as bidentate ligands. The attack of the oxygen atom of the hydroxylamine in these reactions is rather surprising, since the reaction with free nitriles involves, in the majority of cases, N-addition.[13–15] An O-addition has been reported[16] in the reaction of the platinum complex $[PtCl_4(CH_3CN)_2]$ with *N*-substituted hydroxylamine R_2NOH, but the steric hindrance at the N-atom makes the O-attack plausible in this case. This is the only known example[16] of the reaction of a substituted hydroxylamine with coordinated RCN. In our $[M(RCN)_2P_4]^{2+}$ complexes the coordination of the nitrile to the MP_4 fragment probably makes the nitrile carbon increasingly susceptible to nucleophilic attack by the more electronegative oxygen, yielding the *O*-iminoacylated derivatives.

Conclusions

In this contribution we have reported the synthesis of several new hydroxylamine complexes of Ru, Os and Ir, including the first bis(hydroxylamine) $[Ru(NH_2OH)_2P_4](BPh_4)_2$ derivatives. The preparation of *O*-iminoacylated complexes $[M\{\eta^1\text{-}HN{=}C(R)ONHR^1\}P_4](BPh_4)_2$ (M = Ru, Os) was also achieved by O-addition of hydroxylamine to an organonitrile in a metal-assisted reaction.

Experimental Section

General: All synthetic work was carried out under an inert atmosphere using standard Schlenk techniques or a Vacuum Atmosphere dry-box. Once isolated, the complexes were found to be relatively stable in air, but were stored under an inert atmosphere at −25 °C. All solvents were dried over appropriate drying agents, degassed on a vacuum line and distilled into vacuum-tight storage flasks. The phosphite $P(OEt)_3$ (Aldrich) was purified by distillation under nitrogen, while $PPh(OEt)_2$ was prepared by the method of Rabinowitz and Pellon.[17] $RuCl_3{\cdot}3H_2O$ was obtained from Chempur, while $[(NH_4)_2(OsCl_6)]$ was purchased from Johnson Matthey and $IrCl_3{\cdot}3H_2O$ from Pressure Chemical Co.; all salts were used as received. Hydroxylamine (NH_2OH) and *N*-methylhydroxylamine [$NH(CH_3)OH$] were prepared by slight modification of a reported method,[18] involving treatment of hydroxylamine hydrochloride with sodium ethoxide in ethanol. The free NH_2OH was isolated as a white solid, while $NH(CH_3)OH$ was prepared in solution just prior to use. Other reagents were purchased from commercial sources in the highest available purity and used as received. Infrared spectra were recorded on a Nicolet Magna 750 FT-IR spectrophotometer. NMR spectra (^1H, ^{13}C, ^{31}P) were obtained on Bruker AC200 and AVANCE 300 spectrometers at temperatures varying between −90 °C and +30 °C, unless otherwise noted. ^1H and ^{13}C spectra are referred to internal tetramethylsilane, while $^{31}P\{^1H\}$ chemical shifts are reported with respect to 85% H_3PO_4, with downfield shifts considered positive. The SWAN-MR software package[19] was used to treat NMR spectroscopic data and for the simulation. The conductivity of 10^{-3} M solutions of the complexes in CH_3NO_2 at 25 °C was measured with a Radiometer CDM 83 instrument.

Preparation of the Complexes: The hydride complexes RuH_2P_4 and OsH_2P_4 and the nitrile complexes $[Ru(RCN)_2P_4](BPh_4)_2$ and $[Os(RCN)_2P_4](BPh_4)_2$ [R = CH_3, 4-$CH_3C_6H_4$; P = $P(OEt)_3$, $PPh(OEt)_2$] were prepared following the reported methods.[6,20] The iridium complexes $[IrHCl_2P(PPh_3)_2]$, $[IrHCl_2P(AsPh_3)_2]$ [P = $P(OEt)_3$, $PPh(OEt)_2$] and $[IrH_3(PPh_3)_3]$ were synthesised by published methods.[6d,21]

$[RuH(NH_2OH)P_4]BPh_4$ [P = $P(OEt)_3$ 1, $PPh(OEt)_2$ 2]: An equimolar amount of CF_3SO_3H (0.40 mmol, 35 μL) was added to a solution of the appropriate hydride RuH_2P_4 (0.40 mmol) in 10 mL of ethanol cooled to −196 °C and the reaction mixture, after warming to 0 °C, was stirred for 1 h. An excess of hydroxylamine (0.60 mmol, 0.43 mL of a 1.4 M solution in ethanol) was then added and the resulting solution stirred for about 2 h. The solvent was removed under reduced pressure to give an oil, which was treated with ethanol (2 mL) containing an excess of $NaBPh_4$ (0.8 mmol, 0.27 g). A white solid slowly separated out upon stirring the resulting solution. This solid was filtered off and recrystallised from CH_2Cl_2 and ethanol; yield 336 mg for **1** (75%); 384 mg for **2** (77%).
1: $C_{48}H_{84}BNO_{13}P_4Ru$ (1118.97): calcd. C 51.52, H 7.57, N 1.25; found C 51.41, H 7.60, N 1.18. Λ_M = 57.4 S cm^2 mol^{-1}.
2: $C_{64}H_{84}BNO_9P_4Ru$ (1247.14): calcd. C 61.64, H 6.79, N 1.12; found C 61.48, H 6.82, N 1.17. Λ_M = 58.6 S cm^2 mol^{-1}.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[OsH(NH_2OH)\{P(OEt)_3\}_4]BPh_4$ (3): An equimolar amount of $CF_3SO_3CH_3$ (0.12 mmol, 11 μL) was added to a solution of $[OsH_2\{P(OEt)_3\}_4]$ (0.12 mmol, 0.100 g) in 5 mL of toluene cooled to −196 °C and the reaction mixture, after warming to room temperature, was stirred for 1 h. An excess of NH_2OH (0.3 mmol, 0.48 mL of a 0.63 M solution in ethanol) was added and the solution stirred for about 4 h. The solvent was then removed under reduced pressure to give an oil which was treated with ethanol (2 mL) containing an excess of $NaBPh_4$ (0.24 mmol, 0.082 g). Upon stirring the resulting solution, a white solid separated out which was filtered off and recrystallised from CH_2Cl_2 and ethanol; yield 104 mg (72%). $C_{48}H_{84}BNO_{13}OsP_4$ (1208.10): calcd. C 47.72, H 7.01, N 1.16; found C 47.89, H 7.08, N 1.09. Λ_M = 55.0 S cm^2 mol^{-1}.

$[Ru(NH_2OH)_2\{P(OEt)_3\}_4](BPh_4)_2$ (4): An equimolar amount of CF_3SO_3H (0.40 mmol, 35 μL) was added to a solution of $[RuH_2\{P(OEt)_3\}_4]$ (0.40 mmol, 0.307 g) in 10 mL of toluene cooled to −196 °C. The reaction mixture was warmed to 0 °C, stirred for 1 h, and then cooled to −196 °C again. Triflic acid (0.40 mmol, 35 μL) was added and the solution, after warming to 0 °C, was stirred for 90 min. An excess of hydroxylamine (1.60 mmol, 1.14 mL of a 1.4 M solution in ethanol) was then added and the solution stirred for about 20 min. The solvent was removed under reduced pressure to give an oil which was treated with ethanol (2 mL). Addition of an excess of $NaBPh_4$ (1.60 mmol, 0.55 g) in ethanol (2 mL) to the resulting solution caused the separation of a white solid, which was filtered off and recrystallised from CH_2Cl_2 and ethanol; yield 476 mg (81%). $C_{72}H_{106}B_2N_2O_{14}P_4Ru$ (1470.22): calcd. C 58.82, H 7.27, N 1.47; found C 58.65, H 7.38, N 1.58. Λ_M = 119.6 S cm^2 mol^{-1}).

$[IrCl_2(NH_2OH)P(PPh_3)_2]BPh_4$ [P = $P(OEt)_3$ 5, $PPh(OEt)_2$ 6]: An equimolar amount of CF_3SO_3H (0.12 mmol, 11 μL) was added to a solution of the appropriate hydride $[IrHCl_2P(PPh_3)_2]$ (0.12 mmol) in 8 mL of CH_2Cl_2 cooled to −196 °C, and the reaction mixture was warmed to room temperature and stirred for 90 min. An excess of hydroxylamine (1.20 mmol, 1.46 mL of 0.82 M solution in ethanol) was added and the resulting mixture stirred for about 4 h. The solvent was removed under reduced pressure giving an oil, which was triturated with ethanol (2 mL) containing an excess of $NaBPh_4$ (0.24 mmol, 0.082 g). A yellow solid slowly separated out from the resulting solution, which was filtered off and recrystallised from CH_2Cl_2 in ethanol; yield 98 mg (63%) for **5**; 109 mg (68%) for **6**.
5: $C_{66}H_{68}BCl_2IrNO_4P_3$ (1306.12): calcd. C 60.69, H 5.25, N 1.07, Cl 5.43; found C 60.55, H 5.32, N 1.06, Cl 5.37. Λ_M = 58.2 S cm^2 mol^{-1}.
6: $C_{70}H_{68}BCl_2IrNO_3P_3$ (1338.17): calcd. C 62.83, H 5.12, N 1.05, Cl 5.30; found C 63.01, H 5.24, N 1.10, Cl 5.08. Λ_M = 61.6 S cm^2 mol^{-1}.

$[IrCl_2(NH_2OH)P(AsPh_3)_2]BPh_4$ [P = $P(OEt)_3$ 7, $PPh(OEt)_2$ 8]: These complexes were prepared exactly as for compounds **5** and **6**; yield 113 mg (68%) for **7**; 125 mg (73%) for **8**.
7: $C_{66}H_{68}As_2BCl_2IrNO_4P$ (1394.02): calcd. C 56.87, H 4.92, N 1.00, Cl 5.09; found C 56.64, H 5.01, N 0.92, Cl 5.27. Λ_M = 55.7 S cm^2 mol^{-1}.
8: $C_{70}H_{68}As_2BCl_2IrNO_3P$ (1426.07): calcd. C 58.96, H 4.81, N 0.98, Cl 4.97; found C 59.13, H 4.70, N 1.06, Cl 4.79. Λ_M = 59.0 S cm^2 mol^{-1}.

$[IrH_2(NH_2OH)(PPh_3)_3]BPh_4$ (9): An equimolar amount of CF_3SO_3H (0.12 mmol, 11 μL) was added to a solution of $[IrH_3(PPh_3)_3]$ (0.12 mmol, 0.118 g) in 5 mL of toluene cooled to −196 °C, and the reaction mixture warmed to room temperature and stirred for 10 min. An excess of hydroxylamine (1.20 mmol, 1.46 mL of 0.82 M solution in ethanol) was added and the solution stirred for 4 h. The solvent was removed under reduced pressure to give an oil, which was triturated with ethanol (3 mL) containing an excess of $NaBPh_4$ (0.24 mmol, 0.082 g). A white solid separated out from the resulting solution, which was filtered off and recrystallised from CH_2Cl_2 and ethanol; yield 128 mg (80%). $C_{78}H_{70}BIrNOP_3$ (1333.37): calcd. C 70.26, H 5.29, N 1.05; found C 70.35, H 5.37, N 1.11. Λ_M = 54.8 S cm^2 mol^{-1}.

$[Ru\{\eta^2\text{-}NH{=}C(R)ONH_2\}\{P(OEt)_3\}_4](BPh_4)_2$ (R = CH_3 10a, 4-$CH_3C_6H_4$ 10b): An excess of NH_2OH (0.52 mmol, 0.62 mL of a 0.84 M solution in ethanol) was added to a solution of the appropriate nitrile complex $[Ru(RCN)_2\{P(OEt)_3\}_4](BPh_4)_2$ (0.13 mmol) in 10 mL of CH_2Cl_2 and the reaction mixture was stirred for 24 h. The solvent was removed under reduced pressure to give an oil which was treated with ethanol (2 mL). The addition of an excess of $NaBPh_4$ (0.26 mmol, 0.089 g) in 2 mL of ethanol to the resulting solution caused the separation of a white solid, which was filtered off and recrystallised from CH_2Cl_2 and ethanol; yield 123 mg (64%) for **10a**; 135 mg (67%) for **10b**.
10a: $C_{74}H_{106}B_2N_2O_{13}P_4Ru$ (1478.24): calcd. C 60.13, H 7.23, N 1.90; found C 59.97, H 7.17, N 1.86. Λ_M = 117.4 S cm^2 mol^{-1}.
10b: $C_{80}H_{110}B_2N_2O_{13}P_4Ru$ (1554.34): calcd. C 61.82, H 7.13, N 1.80; found C 61.98, H 7.20, N 1.75. Λ_M = 120.7 S cm^2 mol^{-1}.

$[Ru\{\eta^2\text{-}NH{=}C(CH_3)ONH(CH_3)\}\{P(OEt)_3\}_4](BPh_4)_2$ (11): This complex was prepared similarly to **10** by reacting $[Ru(CH_3CN)_2\{P(OEt)_3\}_4](BPh_4)_2$ (0.17 mmol, 0.250 g in 10 mL of CH_2Cl_2) with an excess of $NH(CH_3)OH$ (1.7 mmol, 2.9 mL of 0.58 M solution in ethanol) for 24 h; yield 140 mg (55%). $C_{75}H_{108}B_2N_2O_{13}P_4Ru$ (1492.27): calcd. C 60.37, H 7.29, N 1.88; found C 60.49, H 7.35, N 1.80. Λ_M = 119.1 S cm^2 mol^{-1}.

$[Os\{\eta^2\text{-}NH{=}C(R)ONH_2\}\{P(OEt)_3\}_4](BPh_4)_2$ (R = CH_3 12a, 4-$CH_3C_6H_4$ 12b): An excess of hydroxylamine (1.3 mmol, 1.8 mL of a 0.72 M solution in ethanol) was added to a solution of the appropriate nitrile complex $[Os(RCN)_2\{P(OEt)_3\}_4](BPh_4)_2$ (0.13 mmol) in 8 mL of CH_2Cl_2 and the reaction mixture stirred for 20 h. The solvent was removed under reduced pressure to give an oil, which was treated with ethanol (2 mL) containing an excess of $NaBPh_4$ (0.26 mmol, 0.089 g). Upon stirring the resulting solution a white solid slowly separated out, which was filtered off and recrystallised from CH_2Cl_2 and ethanol; yield 124 mg (62%) for **12a**; 126 mg (59%) for **12b**.
12a: $C_{74}H_{106}B_2N_2O_{13}OsP_4$ (1567.37): calcd. C 56.71, H 6.82, N 1.79; found C 56.59, H 6.98, N 1.68. Λ_M = 123.4 S cm^2 mol^{-1}.
12b: $C_{80}H_{110}B_2N_2O_{13}OsP_4$ (1643.47): calcd. C 58.47, H 6.75, N 1.70; found C 58.30, H 6.81, N 1.62. Λ_M = 121.6 S cm^2 mol^{-1}.

$[Os\{\eta^2\text{-}NH{=}C(CH_3)ONH(CH_3)\}\{P(OEt)_3\}_4](BPh_4)_2$ (13): This complex was prepared similarly to **12** by reacting $[Os(CH_3CN)_2\{P(OEt)_3\}_4](BPh_4)_2$ with a 10-fold excess of *N*-methylhydroxylamine; yield 93 mg (45%). $C_{75}H_{108}B_2N_2O_{13}OsP_4$ (1581.40): calcd. C 56.96, H 6.88, N 1.77; found C 57.13, H 6.96, N 1.69. Λ_M = 115.9 S cm^2 mol^{-1}.

Preparation and Reactivity of Hydrazine Complexes of Rhenium: Synthesis of 1,2-Diazene (NH=NH) and Methyleneimine (CH_2=NH) Derivatives

Gabriele Albertin,*[a] Stefano Antoniutti,[a] and Maria Teresa Giorgi[a]

Keywords: Hydrazine / N ligands / Oxidation / Rhenium

The hydrazine complexes $[Re(RNHNH_2)(CO)_nP_{5-n}]BPh_4$ [R = H, CH_3, Ar; n = 1–4; P = $P(OEt)_3$, $PPh(OEt)_2$, PPh_2OEt] were prepared by allowing the hydride species $[ReH(CO)_nP_{5-n}]$ to react first with a Brønsted acid and then with hydrazine. The reaction of either $[Re(NH_2NH_2)(CO)_nP_{5-n}]BPh_4$ or $[Re(ArNHNH_2)(CO)_nP_{5-n}]BPh_4$ with $Pb(OAc)_4$ at –40 °C proceeds with the selective oxidation of the hydrazine ligand to yield either $[Re(NH=NH)(CO)_nP_{5-n}]BPh_4$ or $[Re(ArN=NH)(CO)_nP_{5-n}]BPh_4$. The oxidation of $[Re(CH_3NHNH_2)(CO)_nP_{5-n}]BPh_4$ (n = 1, 2) with $Pb(OAc)_4$ at –40 °C gives both $[Re(CH_3N=NH)(CO)_nP_{5-n}]BPh_4$ and $[Re(\eta^1\text{-}NH=CH_2)(CO)_nP_{5-n}]BPh_4$. Reduction reactions of both hydrazine and diazene complexes with Zn amalgam were also studied and yielded ammonia in moderate yield (20–25%).

Introduction

Complexes containing partially reduced dinitrogen molecules such as hydrazine ($RNHNH_2$), hydrazido (RNHNH), diazene (RN=NH), and diazenido (RN_2) as ligands continue to be studied not only for their relationship with the nitrogen-fixation process intermediates, but also because their properties lead us to consider this class of compounds as having an identity and chemistry of their own,[1–3] with potentially interesting developments.

The hydrazine complexes are the least studied[1,2] among these diazo species even though NH_2NH_2 has been shown to be a substrate[4] as well as a product of functioning nitrogenase and has been isolated by quenching the enzyme.[5] Furthermore, rhenium complexes containing NH_2NH_2 or substituted hydrazine $RNHNH_2$ are very rare and include, apart from the pioneering work on $[Re(NCO)(CO)_2(NH_2NH_2)P_2]$ (P = tertiary phosphane),[6] only two papers,[7,8] one on $[ReCp^*Me_3(NH_2NH_2)]CF_3SO_3$ (Cp^* = pentamethylcyclopentadienyl) and $[Re(NH_2NH_2)(CO)_3(PPh_3)_2]CF_3SO_3$, and another on the substituted-hydrazine complex $[ReCl_2(PPh_3)_2\{NNC(O)Ph\}\{H_2NNHC(S)Ph\}]$.[9]

We have previously reported the synthesis and reactivity of mono- and bis(hydrazine) complexes of the iron triad[10] and manganese[11] of the type $[MH(RNHNH_2)P_4]BPh_4$, $[M(RNHNH_2)_2P_4](BPh_4)_2$ (M = Fe, Ru, Os) and $[Mn(RNHNH_2)(CO)_nP_{5-n}]BPh_4$ (P = phosphites). We have now extended these studies to rhenium with the aim of preparing hydrazine complexes and studying their reactivity toward oxidizing and reducing reagents in an attempt to test whether the rhenium fragments are able to stabilize diazene species. The results of these studies, which include the synthesis of stable 1,2-diazene complexes and the unprecedented methyleneimine (CH_2=NH) derivatives, are reported here. A preliminary paper on part of this work has previously been published.[12]

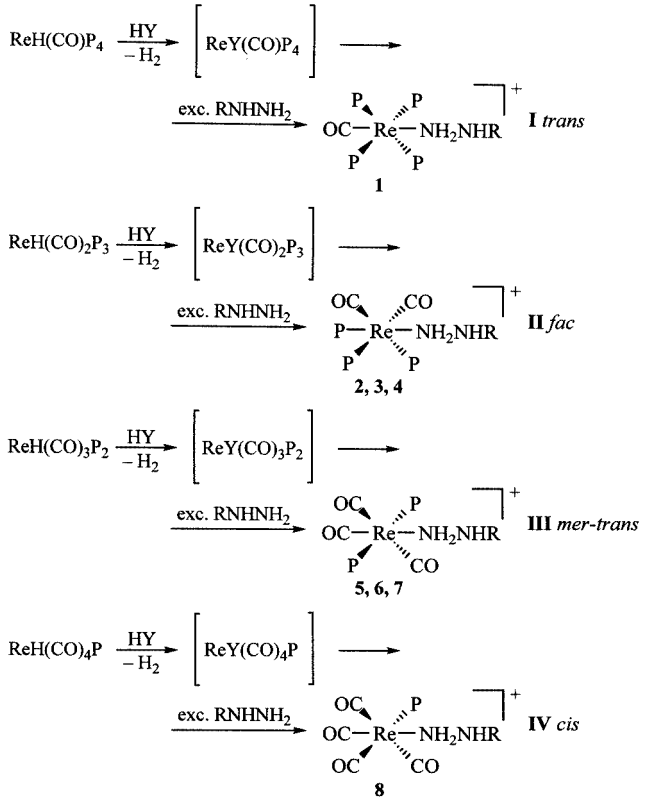
Results and Discussion

Preparation of Hydrazine Complexes

The hydrazine complexes $[Re(RNHNH_2)(CO)_nP_{5-n}]BPh_4$ (**1**–**8**) were prepared by reacting the hydride species $[ReH(CO)_nP_{5-n}]$ first with an equimolar amount of a Brønsted acid (CF_3SO_3H or HBF_4) and then with an excess of hydrazine, as shown in Scheme 1.

Treatment of the hydrides $[ReH(CO)_nP_{5-n}]$ with the Brønsted acid CF_3SO_3H or HBF_4 (HY) gives the dihydrogen-containing cationic complexes $[Re(\eta^2\text{-}H_2)(CO)_nP_{5-n}]^+$,[13] which are thermally unstable and easily lose H_2 yielding either the neutral $ReY(CO)_nP_{5-n}$ species, containing the labile Y^- ligand, or the coordinatively unsaturated $[Re(CO)_nP_{5-n}]^+$ cations. Reaction of these intermediates with an excess of hydrazine gives the final derivatives $[Re(RNHNH_2)(CO)_nP_{5-n}]^+$ (**1**–**8**), which were isolated as their BPh_4^- salts and characterised. 1,1-Dimethylhydrazine reacts with these rhenium intermediates giving the final derivatives $[Re\{(CH_3)_2NNH_2\}(CO)_nP_{5-n}]BPh_4$ (**1e** and **3e**).

Good analytical data were obtained for all the hydrazine complexes **1**–**8**, which are white or pale-yellow solids,



Scheme 1. P = $P(OEt)_3$ (**1**, **2**, **5**), $PPh(OEt)_2$ (**3**, **6**), PPh_2OEt (**4**, **7**, **8**); Y = $CF_3SO_3^-$, BF_4^-; R = H (**a**), CH_3 (**b**), C_6H_5 (**c**), 4-$NO_2C_6H_4$ (**d**); $(CH_3)_2NNH_2$ (**e**)

stable in air and in solution in polar organic solvents, where they behave as 1:1 electrolytes.[14] The IR and NMR spectroscopic data (Table 1) support the proposed formulation and allow a geometry in solution to be established.

The presence of a hydrazine ligand in the complexes is confirmed by the IR spectra, which show the characteristic ν(NH) bands between 3366 and 3202 cm^{-1}. In some complexes the δ(NH_2) absorption at 1624−1611 cm^{-1} is also observed. Furthermore, the ^1H NMR spectra confirm the presence of the hydrazine ligand, showing the characteristic NH and NH_2 signals, which were clearly assigned by accurate integration and homodecoupling experiments, and are reported in Table 1. The spectra also show that, in the case of the NH_2NH_2 complexes, two NH_2 proton signals are present, thus excluding the formation of a dimeric complex with an NH_2NH_2 bridging ligand.

In the temperature range between +30 and −80 °C the ^{31}P NMR spectra of the monocarbonyl complexes **1** show a sharp singlet suggesting a mutual *trans* position (geometry **I**) of the carbonyl and hydrazine ligands. This is confirmed by the IR spectra, which show the ν(CO) band at 1887−1888 cm^{-1}.

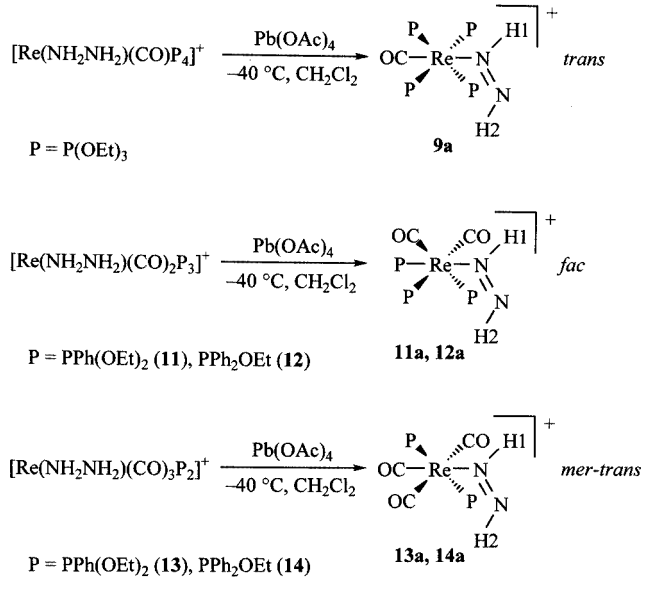
The IR spectra of the dicarbonyl complexes **2**−**4** show two strong bands in the ν(CO) region indicating the mutual *cis* position of the two carbonyl ligands. The ^{13}C NMR spectra also indicate that the two CO groups are magnetically equivalent, showing only one multiplet for **2b** in the carbonyl carbon region at δ = 194.2 ppm. Furthermore, the $^{31}P\{^1H\}$ NMR spectra display either an A_2B- or an AB_2-type coupling pattern, suggesting the magnetic equivalence of two P atoms, different from the third. On this basis a *fac* geometry (**II**) may be proposed for the dicarbonyl derivatives.

In the temperature range between +30 and −80 °C, the ^{31}P NMR spectra of the tricarbonyl compounds **5**−**7** show a sharp singlet, in agreement with two magnetically equivalent phosphane ligands. The IR spectra show three ν(CO) bands, two strong and one of medium intensity, suggesting a *mer* arrangement of the carbonyl ligands. On this basis, a *mer-trans* geometry (**III**) in solution may be reasonably proposed for the tricarbonyl derivatives.

Finally, the presence of four ν(CO) bands in the carbonyl region of its IR spectrum strongly suggests a *cis* geometry (**IV**) for the tetracarbonyl derivative $[Re(NH_2NH_2)(CO)_4(PPh_2OEt)]^+$ (**8**).

Oxidation Reactions

The hydrazine complexes $[Re(NH_2NH_2)(CO)_nP_{5-n}]BPh_4$ react with $Pb(OAc)_4$ at −40 °C to give the 1,2-diazene derivatives $[Re(NH{=}NH)(CO)_nP_{5-n}]BPh_4$, which were isolated in the solid state and characterised (Scheme 2).



Scheme 2

The reaction proceeds with the selective oxidation of the hydrazine ligand to 1,2-diazene, which is stabilized by coordination to all the $[Re(CO)_nP_{5-n}]$ (n = 1, 2, 3) fragments, thus allowing the complexes to be isolated. The use of a temperature below −30 °C during the reaction course is crucial for a successful synthesis, as is crystallisation of the products at 0 °C. If these temperatures are not maintained, large amounts of decomposition products are obtained that contain only traces of the diazene complexes. In pure form, however, the NH=NH compounds **9**−**14** are stable at room temperature both as a solid and in solution in polar organic solvents, where they behave as 1:1 electrolytes.[14] Analytical and spectroscopic data (Table 1) support the proposed for-

mulation and a geometry in solution can also be established from the IR and NMR spectroscopic data.

Diagnostic evidence for the presence of the NH=NH ligand are the ^{1}H NMR spectra, which show a multiplet of the type shown in Figure 1 in the high-frequency region, which can reasonably be attributed to the H1 and H2 protons of the diazene ligand coupled to the phosphorus nucleus of the phosphane. This multiplet, in fact, can easily be simulated by using A_2XY, AB_2XY or A_4XY models (X, Y = H), with the parameters reported in Table 1. The value of $^3J_{H,H}$ was found to fall in the range 35−27 Hz, suggesting a probable *trans*-NH=NH geometry of the ligand.[16a]

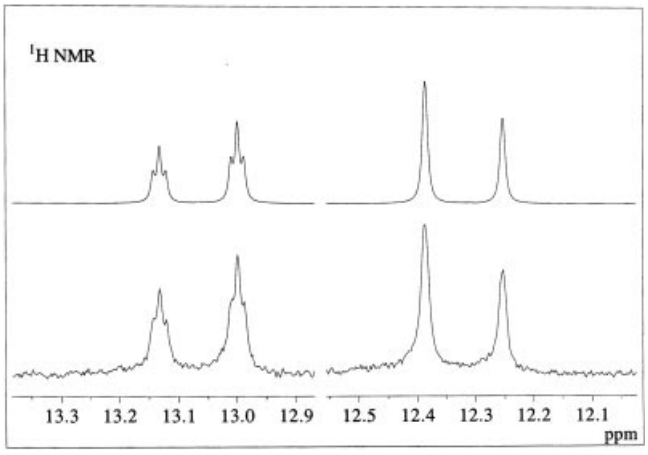

Figure 1. Observed (bottom) and calculated (top) ^{1}H NMR spectrum in the diazene region of $[Re(NH=NH)(CO)_3(PPh_2OEt)_2]BPh_4$ (**14a**), in CD_2Cl_2 at 25 °C; the simulated spectrum was obtained using the parameters reported in Table 1

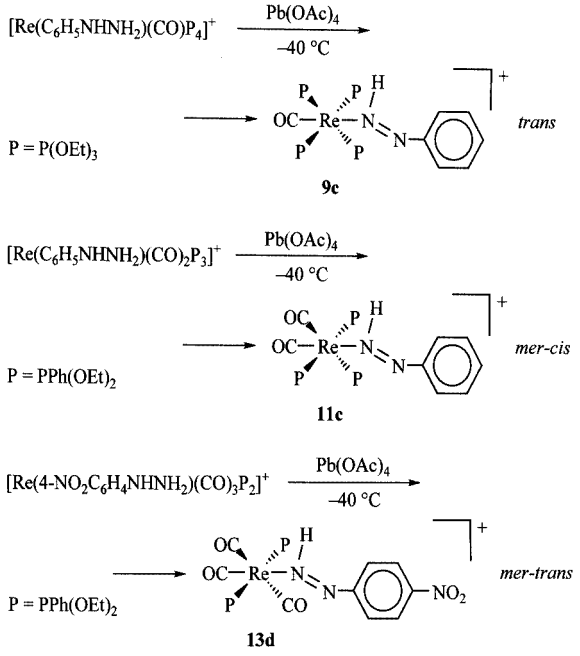
IR and NMR spectroscopic data support the geometry shown in Scheme 2 for the diazene complexes **9**−**14**, which proves to be the same as that of the related hydrazine precursors. The oxidation of the NH_2NH_2 ligand does not change the geometry of the complexes, and a *trans* geometry is proposed for the monocarbonyl complex **9a** on the basis of the sharp singlet present in the ^{31}P NMR spectrum. A *fac* structure is proposed for the dicarbonyl complexes **11a** and **12a**, as their IR spectra show two ν(CO) bands, while an AB_2 multiplet appears in the ^{31}P NMR spectra. Finally, the presence of three ν(CO) bands, one medium and two strong, in the IR spectra of the tricarbonyl complexes **13a** and **14a**, and only one sharp singlet in the ^{31}P NMR spectra, suggest a *mer-trans* geometry for the complexes.

The stabilization of the very reactive molecule NH=NH by coordination to a transition metal has been achieved in a few cases, mainly in bimetallic complexes containing a μ-NH=NH ligand.[15] Stable derivatives containing a monodentate diazene have been reported,[16] but they are rather rare and include only one example for rhenium.[17] The use of a mixed-ligand phosphite-carbonyl $Re(CO)_nP_{5-n}$ fragment allows new examples of the stabilization of monodentate diazene to be achieved. It should be noted that the related manganese complexes $[Mn(NH_2NH_2)(CO)_nP_{5-n}]BPh_4$ also react with $Pb(OAc)_4$,[11] but give only thermally unstable diazene complexes, which cannot be isolated.

The arylhydrazine complexes $[Re(ArNHNH_2)(CO)_nP_{5-n}]BPh_4$ also react with $Pb(OAc)_4$ to give the corresponding aryldiazene complexes $[Re(ArN=NH)(CO)_nP_{5-n}]BPh_4$, which were isolated and characterised (Scheme 3).



Scheme 3

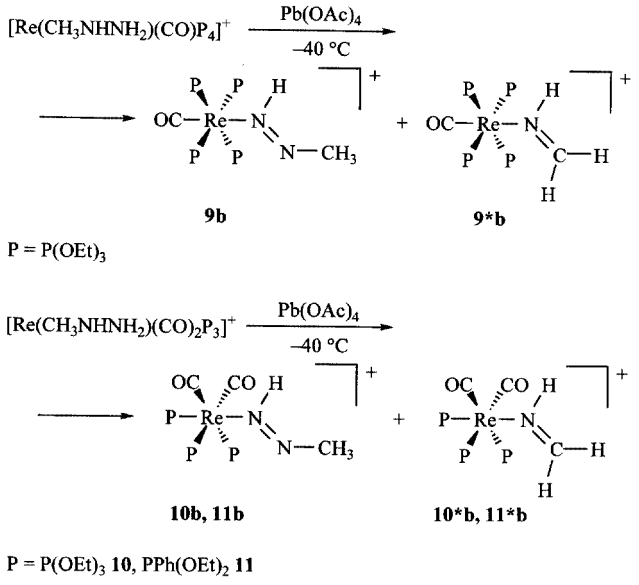
These complexes are yellow or orange solids that are stable in air and in solution in polar organic solvents, where they behave as 1:1 electrolytes.[14] Analytical and spectroscopic data (Table 1) confirm the proposed formulation. Furthermore, the spectroscopic data of complex **9c** are identical to those of samples we have previously prepared by reacting the $ReH(CO)P_4$ hydride with a phenyldiazonium cation;[18] this feature strongly supports the proposed formulation. Moreover, this result highlights that stable aryldiazene complexes of rhenium can be prepared following two different methods, which involve the oxidation of a coordinated arylhydrazine, in one case, and the insertion of an aryldiazonium cation into the Re−H bond of the appropriate hydride complex, in the other.

The presence of the aryldiazene ligand in complexes **9c**, **11c** and **13d** is confirmed by the ^{1}H NMR spectra, which show the characteristic high-frequency signal of the ArN=NH ligand. The IR and NMR spectra also allow a geometry in solution to be established (Scheme 3). Apart from the *trans* geometry of the monocarbonyl complex **9c**,[18] a *mer-cis* arrangement of the ligands, like that of the related compound $[Re(C_6H_5N=NH)(CO)_2(PPh_2OEt)_3]BPh_4$,[18] can be proposed for the carbonyl complex **11c**. The IR spectra, in fact, show two ν(CO) bands, while an AB_2 multiplet is observed in the ^{31}P NMR spectrum.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In the temperature range between +20 and −80 °C the ^{31}P NMR spectrum of the tricarbonyl compound **13d** appears as a sharp singlet, while the IR spectrum shows one medium-intensity and two strong bands in the ν(CO) region. On this basis, a *mer-trans* geometry for the complex can be proposed.

Surprisingly, the reaction of methylhydrazine complexes with an equimolar amount of $Pb(OAc)_4$ gives a mixture of methyldiazene $[Re(CH_3N{=}NH)(CO)_nP_{5-n}]^+$ and methyleneimine $[Re(\eta^1\text{-}NH{=}CH_2)(CO)_nP_{5-n}]^+$ derivatives, which were separated and characterised (Scheme 4).



Scheme 4

The two monocarbonyl complexes **9b** and **9*b** were characterised not only spectroscopically (IR and NMR spectroscopic data) but also by two X-ray crystal structure determinations. These structures were reported in a preliminary communication[12] and will not be discussed further.

The dicarbonyl complexes **10b** and **10*b**, containing the $P(OEt)_3$ ligand, can be separated by fractional crystallisation or by the Pasteur method, obtaining the methyldiazene (**10b**) and the methyleneimine (**10*b**) species as white microcrystalline solids, while the related $PPh(OEt)_2$ derivatives **11b** and **11*b** were characterised spectroscopically as a mixture of the two species. The presence of the $CH_2{=}NH$ ligand in **10*b** is confirmed by the ^1H NMR spectrum, which shows the NH signal at δ = 13.82 ppm and the two inequivalent CH_2 protons as an AB quadruplet at δ = 3.75 ppm. The IR spectra show two strong bands at 2002 and 1915 cm^{-1} attributed to two CO ligands in a mutually *cis* position. These two carbonyls are also magnetically equivalent, since the ^{13}C NMR spectrum shows only one multiplet at δ = 194.7 ppm for the carbonyl carbon atoms. A singlet at δ = 67.8 ppm is also present in the ^{13}C NMR spectrum and is attributed to the methylene carbon atom of the $CH_2{=}NH$ ligand. A ^1H, ^{13}C HMQC experiment correlates this signal with that at δ = 3.75 ppm for the $=CH_2$ protons, in agreement with the proposed assignment. In the temperature range between +20 and −80 °C the ^{31}P NMR spectrum appears as an A_2B multiplet indicating that two of the phosphites are magnetically equivalent and different from the third. On the basis of these data a *fac* geometry (Scheme 4) can reasonably be proposed.

A similar *fac* geometry can also be proposed for the methyldiazene derivative **10b** on the basis of the presence of two ν(CO) bands in the IR spectrum and only one multiplet for the carbonyl carbon atoms at δ = 196.2 ppm in the ^{13}C NMR spectrum, indicating the magnetic equivalence of the two *cis* carbonyl ligands. A singlet at δ = 71.7 ppm is also present in the ^{13}C NMR spectrum; it was attributed, with the help of an HMQC experiment, to the methyl carbon atom of the $CH_3N{=}NH$ ligand. The presence of this ligand is confirmed by the ^1H NMR spectrum, which shows the characteristic diazene signal at δ = 15.86 ppm and the methyl protons as a doublet at δ = 4.44 ppm. The ^{31}P NMR spectrum appears as an A_2B multiplet, in agreement with the proposed geometry.

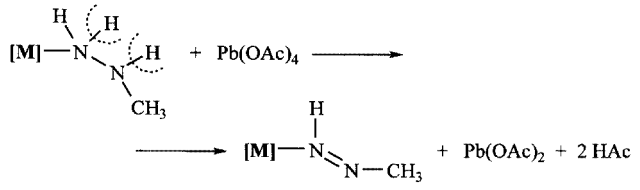
The results on the oxidation of methylhydrazine complexes seem to indicate that the formation of an η^1-NH=CH_2 ligand is general for the $[Re(CO)_nP_{5-n}]$ [n = 1, 2; P = $P(OEt)_3$, $PPh(OEt)_2$] fragments containing the CH_3NHNH_2 ligand, but appears to be specific for $Pb(OAc)_4$, as attempts to carry out the reaction with other oxidants like MnO_2 or H_2O_2 were unsuccessful. Furthermore, while oxidation of a coordinated hydrazine to the related diazene is a known reaction, the formation of the methyleneimine molecule in the reaction of methylhydrazine with $Pb(OAc)_4$ is completely new and involves the cleavage of the N−N bond.[19] Finally, it is worth noting that methyleneimine is a very reactive molecule which has never been isolated since it is unstable above −80 °C in the free state.[20] It has been detected in outer space,[21] and has been proposed as a possible precursor[22] of the simplest α-amino acid glycine. As a ligand, it has been found in only one case, through π-coordination to an osmium centre,[23] and no other report has been found on this molecule, which displays a simple constitution and structure and whose chemical properties are still unknown.

We have also investigated the products of the oxidation of methylhydrazine complexes in order to establish a stoichiometry and/or a possible reaction path. In the reaction mixture we have unambiguously identified, beside the methyldiazene complexes **9b** and **10b** and the methyleneimine complexes **9*b** and **10b***, only acetic acid, dinitrogen and traces of NH_3. Both the NMR spectra and GC analysis of the reaction mixture also revealed the presence of other species, but all were present in very small amounts and were not identified.

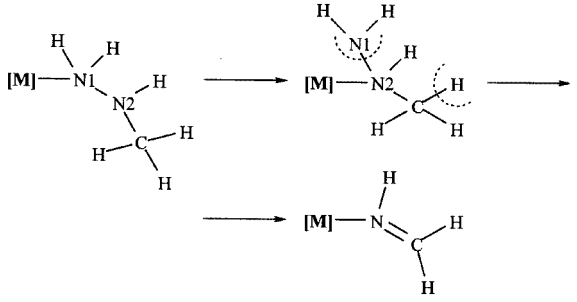
The oxidation of methylhydrazine to methyldiazene by $Pb(OAc)_4$ probably proceeds to give acetic acid and lead(II) acetate (Scheme 5) and should involve the loss of two hydrogen atoms and two electrons with cleavage of two N−H bonds to give the final methyldiazene species. The formation of the coordinated methyleneimine, however, seems to be much more complicated and should involve the cleavage

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of one N−N and one C−H bond (Scheme 6), with the loss of fragments such as H or NH_2 to give the final species. However, the lack of identified reaction products, as well as of any intermediates, does not allow us to determinate either the stoichiometry or to propose a path for the reaction.



Scheme 5

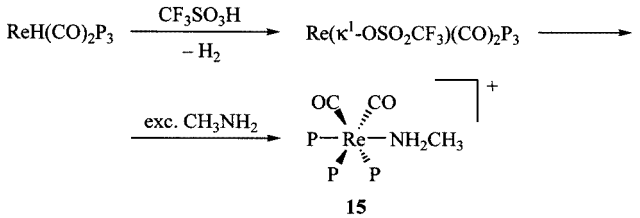


Scheme 6

In light of the reagent and the η^1-NH=CH_2 species formed, an N1 to N2 shift in the coordination of the methylhydrazine followed by N−N and C−H bond cleavage with loss of NH_3 and formation of the methyleneimine ligand may be hypothesized. The presence of only traces of NH_3 in the reaction mixture, however, seems to exclude such a mechanism in which the $Pb(OAc)_4$ does not behave as an oxidant, but only as a catalyst.

Further studies on other metal complexes will, therefore, be required to shed light on the mechanism of this new reaction.

The stabilization of the methyleneimine molecule by coordination to appropriate metal fragments prompted us to attempt to prepare similar η^1-NH=CH_2 complexes following a different method involving, for example, the reaction of a methylamine (CH_3NH_2) derivative with $Pb(OAc)_4$. The synthesis of the precursor complex $[Re(CH_3NH_2)(CO)_2\{P(OEt)_3\}_3]BPh_4$ (**15**) was achieved by reacting the hydride complex $[ReH(CO)_2\{P(OEt)_3\}_3]$ first with triflic acid and then with an excess of CH_3NH_2, as shown in Scheme 7.



Scheme 7. P = $P(OEt)_3$

The complex was isolated as its BPh_4 salt and characterised in the usual way (Table 1). The IR spectrum shows two strong ν(CO) bands at 2005 and 1894 cm^{-1} due to two carbonyls in a mutually *cis* position. Two absorptions of medium intensity are also present at 3329 and 3283 cm^{-1}, attributed to ν(NH) of the methylamine ligand. The presence of this ligand is confirmed by the ^1H NMR spectrum, which shows a triplet at δ = 2.73 ppm for the CH_3 group and a broad signal at δ = 2.65 ppm for the NH_2 group of the CH_3NH_2 ligand. The ^{13}C NMR spectrum further supports the proposed formulation for the complex and indicates that the two CO ligands are magnetically equivalent, showing only one multiplet at δ = 194.2 ppm for the carbonyl carbon atom. In the temperature range between +20 and −80 °C, the ^{31}P NMR spectrum appears as an A_2B multiplet indicating that two of the phosphanes are magnetically equivalent and different from the third. On the basis of these data, a *fac* geometry can be proposed for our methylamine complex **15**.

The reaction of this complex with $Pb(OAc)_4$ was studied extensively in an attempt to prepare a methyleneimine complex by selective oxidation of the CH_3NH_2 ligand. Unfortunately, the reaction does not proceed under any conditions [at −40 or at +20 °C, with an equimolar or an excess amount of $Pb(OAc)_4$; Scheme 8], and the starting amine complex was recovered almost quantitatively. The coordinated methylamine does not react with $Pb(OAc)_4$ and this reaction, therefore, cannot be used to prepare methyleneimine complexes. Until a new method can be found, only the reaction of coordinated methylhydrazine can give a stable complex containing methyleneimine as a unidentate ligand, even though it is formed as a mixture.

Scheme 8

Reduction Reactions

The hydrazine complexes $[Re(NH_2NH_2)(CO)_2P_3]BPh_4$ [P = $PPh(OEt)_2$ and PPh_2OEt] are reduced by zinc amalgam in tetrahydrofuran (THF) in the presence of 2,6-lutidine hydrochloride (Lu·HCl) to give NH_3 in about a 20−25% yield (Table 2). The reaction was carried out at room temperature under argon and found to be relatively slow, with the formation of NH_3 in appreciable amounts after 24 h. The conversion is, however, rather low and the addition of free NH_2NH_2 does not increase the conversion into NH_3, thus excluding any catalytic involvement of the rhenium complexes. Also, the related 1,2-diazene complex $[Re(NH{=}NH)(CO)_2\{PPh(OEt)_2\}_3]BPh_4$ is reduced by zinc amalgam to give NH_3 but, as expected, with a lower yield (about 7%) than the hydrazine precursors. Instead, a relatively high conversion (about 27%) was observed with the methylhydrazine complex $[Re(CH_3NHNH_2)(CO)_2\{PPh(OEt)_2\}_3]BPh_4$ and this result may be connected with the

[a] At 25 °C. [b] Mean value from two or three experiments. [c] Containing added NH_2NH_2 ($9.4\cdot10^{-4}$ mol, ratio 10:1). [d] Mol of NH_2NH_2.

observed easy cleavage of the N−N bond of methylhydrazine bonded to $[Re(CO)_2P_3]$ or $[Re(CO)P_4]$ fragments. In the presence of $Pb(OAc)_4$, in fact, the methyleneimine species $[Re]\eta^1$-NH=CH_2 is formed, whereas ammonia is obtained with Zn amalgam and Lut·HCl; in both cases cleavage of the N−N bond of the coordinated methylhydrazine takes place.

Although these data must be considered as preliminary results, they indicate that both hydrazine and diazene molecules bonded to the $[Re(CO)_2P_3]$ fragment can be reduced to ammonia by zinc amalgam, and this seems to be an interesting observation in organometallic diazo chemistry.

Conclusions

In this contribution we have shown that a series of hydrazine complexes of rhenium of the type $[Re(RNHNH_2)(CO)_nP_{5-n}]BPh_4$ can easily be prepared from precursor $ReH(CO)_nP_{5-n}$ hydrides. Among the properties shown by these complexes we can highlight the reaction of the methylhydrazine species with $Pb(OAc)_4$, which gives the unprecedented methyleneimine derivative $[Re(\eta^1\text{-}NH{=}CH_2)(CO)_nP_{5-n}]BPh_4$ as well as the methyldiazene derivative $[Re(CH_3N{=}NH)(CO)_nP_{5-n}]BPh_4$. Also, 1,2-diazene can be stabilized by the $Re(CO)_nP_{5-n}$ fragment, allowing stable $[Re(NH{=}NH)(CO)_nP_{5-n}]BPh_4$ complexes to be obtained through the selective oxidation of the hydrazine precursors with $Pb(OAc)_4$. Finally, reduction of hydrazine and diazene complexes with zinc amalgam in the presence of Lu·HCl was also tested and found to give NH_3 in low yield.

Experimental Section

General: All synthetic work was carried out under an inert atmosphere (Ar, N_2) using standard Schlenk techniques or a Vacuum Atmosphere dry-box. Once isolated, the complexes were found to be relatively stable in air, but were stored under an inert atmosphere at −25 °C. All solvents were dried over appropriate drying agents, degassed on a vacuum line and distilled into vacuum-tight storage flasks. $Re_2(CO)_8$ was a Pressure Chem. (USA) product, and used as received. Triethylphosphite $P(OEt)_3$ (Aldrich) was purified by distillation under nitrogen, while $PPh(OEt)_2$ and PPh_2OEt were prepared by the method of Rabinowitz and Pellon.[24] The hydrazines CH_3NHNH_2, $C_6H_5NHNH_2$, 4-$NO_2C_6H_4NHNH_2$, and $(CH_3)_2NNH_2$ are Aldrich products and were used as received. High purity (99.99%) $Pb(OAc)_4$ is an Aldrich product was used as received. Hydrazine (NH_2NH_2) was prepared by decomposition of hydrazine cyanurate (Fluka) following the reported method.[25] Other reagents were purchased from commercial sources in the highest available purity and used as received. Infrared spectra were recorded on a Nicolet Magna 750 FT-IR spectrophotometer. NMR spectra (^1H, ^{31}P, ^{13}C) were obtained on Bruker AC200 or Bruker AVANCE 300 spectrometers at temperatures varying between −90 and +30 °C, unless otherwise noted. ^1H spectra are referenced to internal tetramethylsilane, while $^{31}P\{^1H\}$ chemical shifts are reported with respect to 85% H_3PO_4, with downfield shifts considered positive. The SwaN-MR software package[26] was used in treating the NMR spectroscopic data. The conductivities of 10^{-3} M solutions of the complexes in CH_3NO_2 at 25 °C were measured with a Radiometer CDM 83 instrument.

Synthesis of Complexes: The hydrides $[ReH(CO)_nP_{5-n}]$ [n = 1−4; P = $P(OEt)_3$, $PPh(OEt)_2$, PPh_2OEt] were prepared following the method reported previously.[13]

$[Re(NH_2NH_2)(CO)\{P(OEt)_3\}_4]BPh_4$ (1a) and $[Re\{(CH_3)_2NNH_2\}(CO)\{P(OEt)_3\}_4]BPh_4$ (1e): An equimolar amount of CF_3SO_3H (0.2 mmol, 18 μL) was added to a solution of the hydride $[ReH(CO)\{P(OEt)_3\}_4]$ (0.2 mmol, 196 mg) in 8 mL of CH_2Cl_2 cooled to −196 °C, and the reaction mixture warmed to room temperature and stirred for about 1 h. An excess of the appropriate hydrazine (0.6 mmol) was added to the resulting solution which was stirred for a time varying between 3 (**1a**) and 24 (**1e**) h and then the solvent was removed under reduced pressure. The oil obtained was triturated with 3 mL of ethanol containing an excess of $NaBPh_4$ (0.4 mmol, 137 mg). Upon cooling of the resulting solution to −25 °C, a white solid separated out which was filtered off and recrystallised from CH_2Cl_2 (3 mL) and ethanol (3 mL); yield between 80% (**1a**) and 15% (**1e**).

1a: $C_{49}H_{84}BN_2O_{13}P_4Re$ (1230.11): calcd. C 47.84, H 6.88, N 2.28; found C 47.58, H 6.94, N 2.20. Λ_M = 55.4 Ω^{-1} mol^{-1} cm^2

1e: $C_{51}H_{88}BN_2O_{13}P_4Re$ (1258.17): calcd. C 48.69, H 7.05, N 2.23; found C 48.92, H 7.24, N 2.08. Λ_M = 58.6 Ω^{-1} mol^{-1} cm^2.

$[Re(C_6H_5NHNH_2)(CO)\{P(OEt)_3\}_4]BPh_4$ (1c): An equimolar amount of $HBF_4\cdot Et_2O$ (0.2 mmol, 28 μL) was added to a solution of the hydride $[ReH(CO)\{P(OEt)_3\}_4]$ (0.2 mmol, 176 mg) in 5 mL of CH_2Cl_2 cooled to −196 °C, and the reaction mixture warmed to room temperature and stirred for 1 h. An excess of $C_6H_5NHNH_2$ (0.6 mmol, 60 μL) was added to the resulting solution, which was stirred for about 150 min, and then the solvent was removed under reduced pressure. The oil obtained was treated with ethanol (3 mL), and then an excess of $NaBPh_4$ (0.4 mmol, 137 mg) in 3 mL of etha-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nol was added. A white solid slowly separated out which was filtered off and recrystallised from CH_2Cl_2 (2 mL) and ethanol (2 mL); yield ≥40%. $C_{55}H_{88}BN_2O_{13}P_4Re$ (1306.21): calcd. C 50.57, H 6.79, N 2.14; found C 50.49, H 6.87, N 2.10. Λ_M = 55.8 Ω^{-1} mol^{-1} cm^2.

[Re(CH$_3$NHNH$_2$)(CO)$_2${P(OEt)$_3$}$_3$]BPh$_4$ (2b): An equimolar amount of $HBF_4{\cdot}Et_2O$ (0.2 mmol, 28 μL) was added to a solution of [ReH(CO)$_2${P(OEt)$_3$}$_3$] (0.2 mmol, 143 mg) in 5 mL of CH_2Cl_2 cooled to −196 °C, and the reaction mixture warmed to room temperature and stirred for 1 h. An excess of methylhydrazine (0.3 mmol, 16 μL) was added to the resulting solution which was stirred for 3 h and then the solvents evaporated to dryness. The oil obtained was treated with ethanol (2 mL) containing an excess of $NaBPh_4$ (0.4 mmol, 137 mg). Upon cooling the resulting solution to −25 °C a white solid slowly separated out which was filtered off and recrystallised from CH_2Cl_2 (2 mL) and ethanol (2 mL); yield ≥65%. $C_{45}H_{71}BN_2O_{11}P_3Re$ (1105.99): calcd. C 48.87, H 6.47, N 2.53; found C 48.80, H 6.55, N 2.48. Λ_M = 50.8 Ω^{-1} mol^{-1} cm^2.

[Re(RNHNH$_2$)(CO)$_2$P$_3$]BPh$_4$ 3, 4 [R = H a, CH$_3$ b, 4-NO$_2$C$_6$H$_4$ d; P = PPh(OEt)$_2$ 3, PPh$_2$OEt 4]: These complexes were prepared similarly to **1** by reacting the appropriate hydride $ReH(CO)_2P_3$ (0.2 mmol) first with an equimolar amount of CF_3SO_3H and then with an excess (0.6 mmol) of the appropriate hydrazine. The reaction time was 20 h for **3a**, **3b**, **4a** and 24 h for **3d** and **4b**; yields between 60 and 80%.

3a: Yield ≥ 60% $C_{56}H_{69}BN_2O_8P_3Re$ (1188.10): calcd. C 56.61, H 5.85, N 2.36; found C 56.43, H 5.89, N 2.28. Λ_M = 58.9 Ω^{-1} mol^{-1} cm^2.

3b: Yield ≥ 70% $C_{57}H_{71}BN_2O_8P_3Re$ (1202.13): calcd. C 56.95, H 5.95, N 2.33; found C 57.11, H 6.03, N 2.20. Λ_M = 58.1 Ω^{-1} mol^{-1} cm^2.

3d: Yield ≥ 80% $C_{62}H_{72}BN_3O_{10}P_3Re$ (1309.20): calcd. C 56.88, H 5.54, N 3.21; found C 56.95, H 5.62, N 3.17.. Λ_M = 49.3 Ω^{-1} mol^{-1} cm^2.

4a: Yield ≥ 75% $C_{68}H_{69}BN_2O_5P_3Re$ (1284.23): calcd. C 63.60, H 5.42, N 2.18; found C 63.46, H 5.51, N 2.15. Λ_M = 49.4 Ω^{-1} mol^{-1} cm^2.

4b: Yield ≥ 65% $C_{69}H_{71}BN_2O_5P_3Re$ (1298.26): calcd. C 63.84, H 5.51, N 2.16; found C 63.66, H 5.59, N 2.20. Λ_M = 60.0 Ω^{-1} mol^{-1} cm^2.

[Re(C$_6$H$_5$NHNH$_2$)(CO)$_2${PPh(OEt)$_2$}$_3$]BPh$_4$ (3c): This complex was prepared similarly to **2b** by treating [ReH(CO)$_2${PPh(OEt)$_2$}$_3$] (0.2 mmol) first with an equimolar mount of $HBF_4{\cdot}Et_2O$ and then with an excess of $C_6H_5NHNH_2$. The reaction time was 150 min; yield approx. 40%. $C_{62}H_{73}BN_2O_8P_3Re$ (1264.20): calcd. C 58.91, H 5.82, N 2.22; found C 59.05, H 5.90, N 2.27. Λ_M = 51.3 Ω^{-1} mol^{-1} cm^2.

[Re{(CH$_3$)$_2$NNH$_2$)(CO)$_2${PPh(OEt)$_2$}$_3$]BPh$_4$ (3e): This compound was also prepared similarly to complexes **3** and **4** using CF_3SO_3H as the protonating agent, but in this case a large excess of $(CH_3)_2NNH_2$ was used; yield approx. 75%. $C_{58}H_{73}BN_2O_8P_3Re$ (1216.15): calcd. C 57.28, H 6.05, N 2.30; found C 57.37, H 6.12, N 2.28. Λ_M = 49.5 Ω^{-1} mol^{-1} cm^2.

[Re(RNHNH$_2$)(CO)$_3$P$_2$]BPh$_4$ 5−7 [R = H a, CH$_3$ b, 4-NO$_2$C$_6$H$_4$ d; P = P(OEt)$_3$ 5, PPh(OEt)$_2$ 6, PPh$_2$OEt 7]: An equimolar mount of CF_3SO_3H (0.2 mmol, 18 μL) was added to a solution of the appropriate hydride $ReH(CO)_3P_2$ (0.2 mmol) in 7 mL of CH_2Cl_2 cooled to −196 °C, and the reaction mixture warmed to room temperature and stirred for 1 h. An excess of the appropriate hydrazine (0.6 mmol) was added and the resulting solution was stirred for 3 h for **5a**, **6a**, **7a**; 8 h for **6d** and 15 h for **7b**. The solvent was removed under reduced pressure to give a yellow oil, which was triturated with ethanol containing an excess of $NaBPh_4$ (0.4 mmol, 137 mg). Upon cooling of the resulting solution to −25 °C a white solid separated out, which was filtered off and recrystallised from CH_2Cl_2 and ethanol; yield between 55 and 80%.

5a: Yield ≥ 55% $C_{39}H_{54}BN_2O_9P_2Re$ (953.82): calcd. C 49.11, H 5.71, N 2.94; found C 48.94, H 5.80, N 3.02. Λ_M = 56.6 Ω^{-1} mol^{-1} cm^2.

7a: Yield ≥ 60% $C_{55}H_{54}BN_2O_5P_2Re$ (1082.00): calcd. C 61.05, H 5.03, N 2.59; found C 61.23, H 5.15, N 2.68. Λ_M = 60.2 Ω^{-1} mol^{-1} cm^2.

7b: Yield ≥ 70% $C_{56}H_{56}BN_2O_5P_2Re$ (1096.03): calcd. C 61.37, H 5.15, N 2.56; found C 61.19, H 5.25, N 2.62. Λ_M = 57.4 Ω^{-1} mol^{-1} cm^2.

[Re(NH$_2$NH$_2$)(CO)$_4$(PPh$_2$OEt)]BPh$_4$ (8a): This complex was prepared similarly to complexes **5a**, **6a** and **7a**; yield approx. 65%. $C_{42}H_{39}BN_2O_5PRe$ (879.76): calcd. C 57.34, H 4.47, N 3.18; found C 57.13, H 4.50, N 3.10. Λ_M = 57.0 Ω^{-1} mol^{-1} cm^2.

[Re(NH=NH)(CO){P(OEt)$_3$}$_4$]BPh$_4$ (9a): A solid sample of the hydrazine complex [Re(NH$_2$NH$_2$)(CO){P(OEt)$_3$}$_4$]BPh$_4$ (**1a**; 0.1 mmol, 123 mg) was placed in a three-necked 25-mL round-bottomed flask fitted with a solid-addition sidearm containing a slight excess of $Pb(OAc)_4$ (0.12 mmol, 53 mg). Dichloromethane (10 mL) was added, the solution cooled to −40 °C and the $Pb(OAc)_4$ added portionwise over 20−30 min to the cold stirring solution. The solution was then warmed to 0 °C, stirred for 15 min and the solvent removed under reduced pressure. The oil obtained was treated at 0 °C with ethanol (2 mL) containing an excess of $NaBPh_4$ (0.2 mmol, 68 mg) and the white solid separated was filtered off and recrystallised at 0 °C from CH_2Cl_2 (2 mL) and ethanol (2 mL); yield approx. 45%. $C_{49}H_{82}BN_2O_{13}P_4Re$ (1228.10): calcd. C 47.92, H 6.73, N 2.28; found C 48.01, H 6.77, N 2.19. Λ_M = 54.8 Ω^{-1} mol^{-1} cm^2.

[Re(C$_6$H$_5$N=NH)(CO){P(OEt)$_3$}$_4$]BPh$_4$ (9c): This complex was prepared by oxidation of the corresponding hydrazine derivatives with $Pb(OAc)_4$ at low temperature (−40 °C) following the method used for the related 1,2-diazene derivative **9a**; yield approx. 55%. $C_{55}H_{86}BN_2O_{13}P_4Re$ (1304.20): calcd. C 50.65, H 6.65, N 2.15; found C 50.43, H 6.70, N 2.09. Λ_M = 52.8 Ω^{-1} mol^{-1} cm^2.

[Re(CH$_3$N=NH)(CO)$_2${P(OEt)$_3$}$_3$]BPh$_4$ (10b) and [Re(η^1-NH=CH$_2$)(CO)$_2${P(OEt)$_3$}$_3$]BPh$_4$ (10*b): A sample of [Re(CH$_3$NHNH$_2$)(CO)$_2${P(OEt)$_3$}$_3$]BPh$_4$ (**2b**; 200 mg, 0.18 mmol) was placed in a three-necked 25-mL round-bottomed flask fitted with a solid-addition sidearm containing $Pb(OAc)_4$ (0.18 mmol, 80 mg). Dichloromethane (8 mL) was added, the solution cooled to −40 °C and the $Pb(OAc)_4$ added portionwise over 10−20 min to the cold stirring solution. The solution was then warmed to 0 °C, stirred for 10 min, and the solvent removed under reduced pressure. The oil obtained was treated at 0 °C with ethanol (2 mL) containing an excess of $NaBPh_4$ (0.2 mmol, 68 mg). A white solid slowly separated out, which was filtered and crystallised fractionally to separate the two complexes. A typical separation involved the slow cooling from +25 to −25 °C of a saturated solution of the complexes prepared by adding 10 mL of ethanol to the white solid and enough CH_2Cl_2 to obtain a saturated solution at room temperature. The first crystals obtained were **10b**, and the second

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a mixture, which was further recrystallised. Upon further cooling, white microcrystals of **10*b** were obtained. Pure samples of **10b** and **10*b** were also obtained by Pasteur separation of the crystals obtained by cooling a saturated solution of the reaction product in ethanol/CH_2Cl_2; yield: 38% for **10b** and 25% for **10*b**
10b: $C_{45}H_{69}BN_2O_{11}P_3Re$ (1103.98): calcd. C 48.96, H 6.30, N 2.54; found C 49.11, H 6.23, N 2.43. Λ_M = 51.1 Ω^{-1} mol^{-1} cm^2.
10*b: $C_{45}H_{68}BNO_{11}P_3Re$ (1088.96): calcd. C 49.63, H 6.29, N 1.29; found C 49.45, H 6.37, N 1.35. Λ_M = 58.9 Ω^{-1} mol^{-1} cm^2.

[Re(CH$_3$N=NH)(CO)$_2${PPh(OEt)$_2$}$_3$]BPh$_4$ (11b) and [Re(η^1-NH=CH$_2$)(CO)$_2${PPh(OEt)$_2$}$_3$]BPh$_4$ (11*b): These complexes were also prepared by oxidation of the methylhydrazine complex [Re(CH$_3$NHNH$_2$)(CO)$_2${PPh(OEt)$_2$}$_3$]BPh$_4$ (**3b**) with Pb(OAc)$_4$ at −40 °C following exactly the same method as used for the synthesis of **10b** and **10*b**. The reaction afforded a mixture of the two species which, in this case, could not be separated. The IR and NMR spectroscopic data, however, confirm the formation of both the methyldiazene (**11b**) and methyleneimine (**11*b**) derivatives.

[Re(NH=NH)(CO)$_2$P$_3$]BPh$_4$ [P = PPh(OEt)$_2$ 11a, PPh$_2$OEt 12a]: These complexes were prepared by oxidation of the hydrazine precursors [Re(NH$_2$NH$_2$)(CO)$_2$P$_3$]BPh$_4$ (**3a**, **4a**) with Pb(OAc)$_4$ at −40 °C following the method used for the related compound **9a**; yield between 40 and 55%.
11a: $C_{56}H_{67}BN_2O_8P_3Re$ (1186.09): calcd. C 56.71, H 5.69, N 2.36; found C 56.58, H 5.73, N 2.29. Λ_M = 59.2 Ω^{-1} mol^{-1} cm^2.
12a: $C_{68}H_{67}BN_2O_5P_3Re$ (1282.22): calcd. C 63.70, H 5.27, N 2.18; found C 63.56, H 5.33, N 2.08. Λ_M = 57.7 Ω^{-1} mol^{-1} cm^2.

[Re(NH=NH)(CO)$_3$P$_2$]BPh$_4$ [P = PPh(OEt)$_2$ 13a, PPh$_2$OEt 14a]: These complexes were obtained similarly to the related complexes **9a**, **11a** and **12a** by oxidation of the related hydrazine derivatives [Re(NH$_2$NH$_2$)(CO)$_3$P$_2$]BPh$_4$ (**6a**, **7a**) with Pb(OAc)$_4$ at −40 °C; yield approx. 65%.
13a: $C_{47}H_{52}BN_2O_7P_2Re$ (1015.89): calcd. C 55.57, H 5.16, N 2.76; found C 55.38, H 5.05, N 2.64. Λ_M = 58.1 Ω^{-1} mol^{-1} cm^2
14a: $C_{55}H_{52}BN_2O_5P_2Re$ (1079.98): calcd. C 61.17, H 4.85, N 2.59; found C 61.06, H 4.97, N 2.50. Λ_M = 56.5 Ω^{-1} mol^{-1} cm^2.

[Re(4-NO$_2$C$_6$H$_4$N=NH)(CO)$_3${PPh(OEt)$_2$}$_2$]BPh$_4$ (13d): This compound was prepared exactly like the related phenyldiazene compound **9c** by oxidation of the related *p*-nitrophenylhydrazine derivative; yield approx. 55%. $C_{53}H_{55}BN_3O_9P_2Re$ (1136.99): calcd. C 55.99, H 4.88, N 3.70; found C 56.17, H 5.00, N 3.79. Λ_M = 56.0 Ω^{-1} mol^{-1} cm^2.

[Re(CH$_3$NH$_2$)(CO)$_2${P(OEt)$_3$}$_3$]BPh$_4$ (15): An equimolar amount of HBF$_4$·Et$_2$O (0.27 mmol, 39 μL of a 54% solution in Et$_2$O) was added to a solution of [ReH(CO)$_2${P(OEt)$_3$}$_3$] (200 mg, 0.27 mmol) in 10 mL of CH_2Cl_2 cooled to −196 °C, and the reaction mixture warmed to room temperature and stirred for 1 h. An excess of CH_3NH_2 (0.88 mmol, 0.44 mL of a 2 M solution in THF) was added and, after 3 h of stirring, the solvent was removed under reduced pressure to give an oil which was treated with ethanol (1 mL). The addition of an excess of NaBPh$_4$ (0.54 mmol, 0.185 g) in 2 mL of ethanol to the resulting solution caused the separation of a white solid, which was filtered off and recrystallised from CH_2Cl_2 and ethanol; yield approx. 70%. $C_{45}H_{70}BNO_{11}P_3Re$ (1090.98): calcd. C 49.54, H 6.47, N 1.28; found C 49.35, H 6.55, N 1.29. Λ_M = 58.5 Ω^{-1} mol^{-1} cm^2.

Reduction Reactions: The reduction of hydrazine and diazene complexes was carried out in THF at room temperature under argon using an excess of Zn/Hg as reducing agent in the presence of lutidine hydrochloride. A typical experiment involved the addition of a 10-fold excess of Zn (20 mmol), as 2% zinc amalgam, to a solution of the appropriate diazo complex (about 0.1 mmol) in 10 mL of THF. A 16-fold excess of lutidine hydrochloride in 10 mL of THF was then added to the reaction mixture, which was stirred at room temperature under an argon atmosphere for a reaction time varying from 23 to 96 h. An excess of hydrochloric acid (1 mL of 1 M solution in Et$_2$O) was added to the reaction mixture, which was stirred for 1 h. The solvent was then removed under reduced pressure. The solid obtained was treated with five 5-mL portions of H_2O and, after filtration, ammonia from the solution was quantified by the indophenol method.[27]

Synthesis, Crystal Structure and Characterization of a Novel Three-Dimensional Polymer: $[Cu_4V_2(OH)_2O_8]$

Chuan-De Wu,[a] Can-Zhong Lu,*[a] Hong-Hui Zhuang,[a] and Jin-Shun Huang[a]

Keywords: Hydrothermal synthesis / Oxo ligands / Vanadium / Copper / TGA

The three-dimensional polymeric compound $[Cu_4V_2(OH)_2O_8]$ (**1**) has been synthesized by the hydrothermal reaction of sodium vanadate and copper acetate in an aqueous solution basified with a 35% aqueous ammonia solution. Detailed experiments suggest that pH values within the range 8.5–11.3 are best for the formation of crystals of compound **1**. X-ray diffraction analysis reveals that the structure of **1** is a three-dimensional polymer constructed from wave-like polymeric oxocuprate layers linked by vanadate tetrahedra, of which the sub-layer is formed by joining the zigzag ribbons together in *cis* zigzag way. Thermogravimetric analysis (TGA) suggests that the structure of compound **1** is quite stable in the temperature range 40–440 °C.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

As oxygen is the most abundant and highly reactive terrestrial element, the transition metal oxides represent an expanding class of materials, which are ubiquitous as both naturally existing and synthetic materials.[1−3] Because of their stability, diversity of chemical composition and variety of topological architectures, they exhibit a vast range of solid-state properties giving rise to wide applications in areas as diverse as catalysis, sorption, ion-exchange, molecular electronics, energy storage, optical materials and ceramics, heavy construction and biomineralization. The synthesis and characterization of metal oxide-based solids has provoked significant contemporary interest.[4−11]

Since the discovery of the high-temperature oxide superconductors, oxocuprates have been a focus of interest,[12] particularly the study of the relationship between crystal structures and physical properties. It has been found that the coordination environments of copper atoms and the linkages of these coordination polyhedra seem to be crucial. Inorganic chemists have devised many approaches to synthesize such kinds of materials. One very important way is the hydrothermal synthesis method, which operates at a relatively low temperature (110−220 °C) under autogenous pressure and provides a suitable technique to bring suitable metal-oxide building units together to generate polymeric oxometallic materials.[13−16]

The ability of vanadium in its higher oxidation states to form various polynuclear anionic metal-oxygen clusters is well known, and many polyvanadates with an extraordinary variety of relevant topological and electronic structures have been reported.[17−21] On the other hand, copper(II) cations tend to form various oxygen- and/or hydroxyl-bridged polymers under different reaction conditions.[12] There have been a large number of copper vanadates and related compounds reported in the past decades.[22−48] Neutral copper vanadates were first described by solid-state chemists (and later found to occur naturally; for example Blossite,[22,23] Stoiberite,[24] Ziesite,[25] McBimeyite,[26] Volborthite,[27,28] Vesignieite,[29] Calciovolborthite,[30] Mottramite,[31] Averievite,[32] Sengierite,[33] Fingerite,[34] Lyonsite,[35] Howardevansite,[36] etc.), and $Cu_3(VO_4)_2$, for instance, exists in two allotropic forms, one with the spinel structure[41] and the other[26] being isotypic with $Cu_3(PO_4)_2$.[49] Based upon the inherent properties of vanadium and copper atoms, we report here the hydrothermal synthesis, X-ray crystal structure and characterization of a three-dimensional polymeric compound $[Cu_4V_2(OH)_2O_8]$ (**1**).

Results and Discussion

Dark-blue crystals of compound **1** were synthesized by the hydrothermal reaction of sodium vanadate and copper acetate in an aqueous solution basified with 35% aqueous ammonia solution. Detailed experiments suggest that pH values within the range 8.5−11.3 are best for the formation of crystals of compound **1**. When the pH value is below 8.5, only green sediments are obtained instead of crystals. It is very interesting that the crystal size increases with the pH value of the reaction solutions. However, no product was obtained at pH values above 11.3. The aqueous ammonia solution plays a significant role in the formation of

[a] The State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, the Chinese Academy of Sciences,

E-mail: czlu@ms.fjirsm.ac.cn

compound **1**, which might help the formation of polyoxocuprate fragments and monomeric vanadate. However, if the concentration of NH_3 is above the value where the $[Cu(NH_3)_4]^{2+}$ cation is stabilzed, the formation of polyoxocuprate is prevented. A bond-valence sum calculation[50] reveals that two oxygen atoms are protonated, of which each hydroxyl group bridges three copper centers. Multiple bands from $\tilde{\nu}$ = 947 to 559 cm^{-1} in the IR spectrum of **1** are attributed to the V−O stretching or the bridging [Cu−O−V(Cu)] group absorptions, while the band at 1620 cm^{-1} is attributed to the O−H bending.[51]

The X-ray diffraction analysis reveals that the structure of **1** is a neutral three-dimensional polymeric compound constructed from wave-like polymeric oxocuprate layers linked by vanadate tetrahedra. The asymmetric unit in **1** consists of two $\{VO_4\}$ tetrahedra, two $\{CuO_5\}$ square pyramids and one $\{CuO_6\}$ octahedron (Figure 1). The oxocuprate layer is built up from three crystallographically independent copper(II) atoms, of which two copper centers exhibit a square-pyramidal geometry with Cu−O distances in the 1.881(10)−2.213(9) Å range; the other copper center has an octahedral geometry with Cu−O distances in the 1.914(7)−2.318(8) Å range. These copper atoms form a ribbon through edge sharing in a zigzag arrangement with all copper atoms coplanar (Figure 2). Adjacent ribbons are further joined together by bridging oxygen atoms also through edge sharing. Interestingly, as shown in Figure 3, these ribbons turn by an angle of 47.3(1)° and shift one polyhedral length at the "step" junction. Consequently, the adjacent ribbons are joined together in a *cis* zigzag manner to form a wave-like layered sub-framework. The wave-like oxocuprate sub-layer can also be seen as being constructed from twelve-membered copper rings, which are formed by edge sharing copper square-pyramids or octahedra. These chair-shaped rings are further attached into wave-like layers through edge-sharing copper square-pyramids or octahedra (Figure 4).

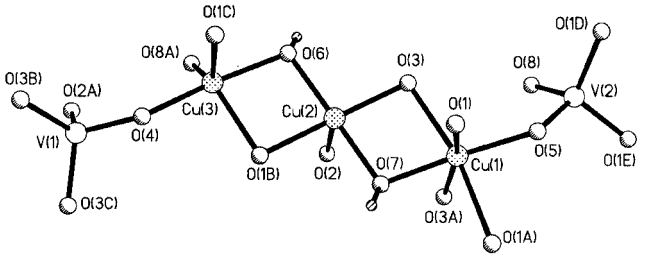

Figure 1. The symmetry-expanded unit in **1**, showing the atom connectivities and the coordination environments (the small right-hatched rings represent hydrogen atoms)

Two crystallographically independent vanadium atoms are both coordinated by four oxygen atoms in tetrahedral geometries. The V−O distances range from 1.638(8) to 1.775(9) Å, with O−V−O angles in the range 107.9(4)−111.4(5)°. The tetrahedrally coordinated vanadium(V) centers link the wave-like sub-layers together to form a three-dimensional polymeric framework (Figure 5) where each vanadate is coordinated to seven or eight $\{CuO_6\}$ octahedra and $\{CuO_5\}$square pyramids by corner sharing.

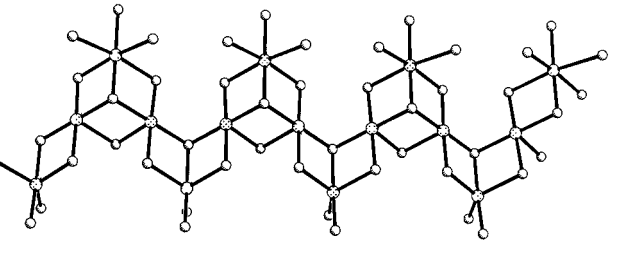

Figure 2. The one-dimensional zigzag ribbon in **1** constructed by linking $\{CuO_6\}$ octahedra and $\{CuO_5\}$ square pyramids

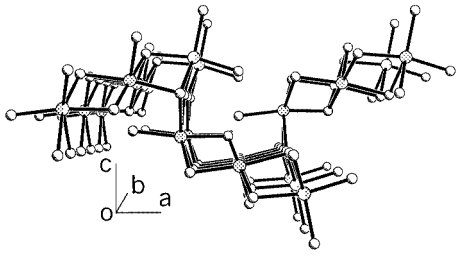

Figure 3. Side view of the linkages between the coplanar chains achieved through bridging oxygen atoms along the *b* axis (the adjacent angle between two planes is 47.3°)

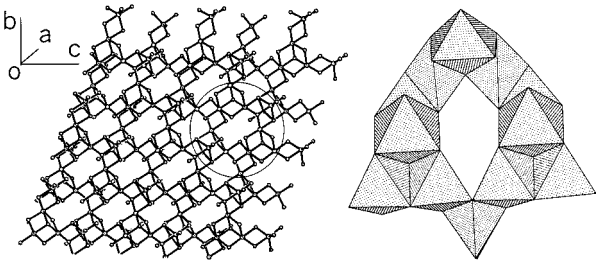

Figure 4. The layered sub-framework of **1** viewed down the *a* axis (right: polyhedral representation of a twelve-membered copper ring in **1**, which is outlined on the left-hand side)

The overall structure of **1** suggests that it should be very stable, and this was confirmed by the thermogravimetric analysis (TGA). The TGA data, recorded from 40 to 1000 °C under inflowing N_2, show that the weight of **1** is almost unchanged from 40 to 440 °C (Figure 6). Above 440 °C, compound **1** began to decompose gradually. The observed weight loss (3.32%) is slightly lower than that of losing one water molecule per empirical formula unit (3.47%). This fact suggests that the hydroxyl groups are changed into H_2O after a complicated reaction process and released from

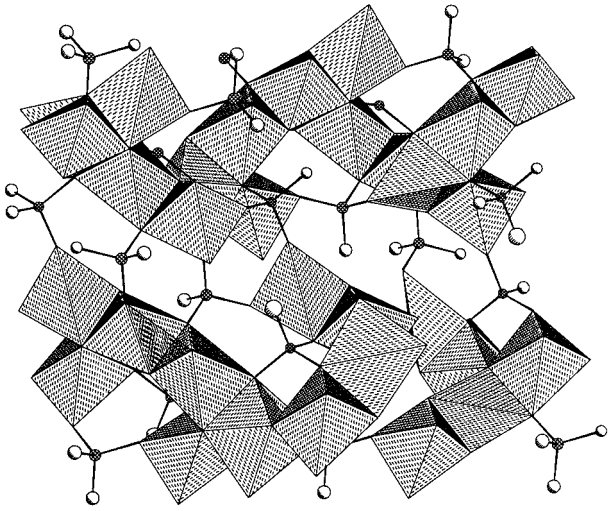

Figure 5. Polyhedral representation of the $\{CuO_6\}$ octahedra and $\{CuO_5\}$ square pyramids as well as a ball-and-stick representation of the $\{VO_4\}$ tetrahedra, showing the three-dimensional polymeric framework of **1**

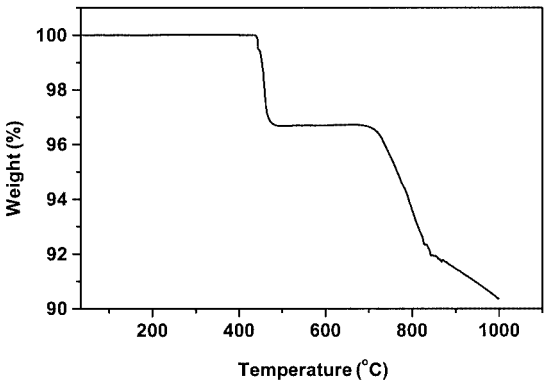

Figure 6. Thermogravimetric (TGA) analysis of **1** between 40 and 1000 °C

the sample above 440 °C. The TGA chart shows that the weight is almost unchanged in the next stage (490−700 °C). Above 700 °C, the product begins to decompose completely.

Conclusion

In conclusion, we have synthesized a three-dimensional polymeric compound under hydrothermal reaction conditions. This result shows that basic reaction conditions can help the formation of polymeric oxocuprate building blocks and monomeric vanadate, and that the pH value of the reaction conditions is a very important impact factor for the formation of novel target materials. The thermogravimetric

analysis suggests that the framework of compound **1** is stable up to 440 °C.

Experimental Section

General Remarks: All chemicals were of reagent grade and were used as received. Infrared spectra were recorded on a FTS-40 spectrophotometer using pressed KBr pellets. Thermogravimetric analysis (TGA), using a universal V2.4F TA Instrument, was performed on a powdered sample of **1** under inflowing N_2 with heating rate of 10 °C·min^{-1} in the temperature range 40−1000 °C.

$[Cu_4V_2(OH)_2O_8]$ (1): $NaVO_4 2H_2O$ (0.079 g, 0.5 mmol) and $Cu(CH_3COO)_2{\cdot}H_2O$ (0.10 g, 0.5 mmol) were dissolved in H_2O (16 mL) at room temperature. The pH value of the solution was adjusted to 8.67 by adding 35% aqueous ammonia solution dropwise, resulting in a deep-blue solution. The solution was transferred into a 30 mL polytetrafluoroethylene-lined Parr acid digestion vessel. The vessel was then sealed and heated at 195 °C for five days under autogenous pressure. After cooling, dark blue crystals were filtered off and washed with water and ethanol. Yield: about 76% (based on Cu). IR (KBr pellet): $\tilde{\nu}$ = 1620 m cm^{-1}, 947 m, 877 s, 822 m, 769 s, 559 m.

X-ray Crystallographic Study: $Cu_4H_2O_{10}V_2$, M = 518.06, orthogonal, space group *Pnma*, a = 14.9251(1), b = 6.0607(1), c = 8.5460(1) Å, V = 773.04(2) Å^3, Z = 4, D_c = 4.451 g·cm^{-3}, μ = 13.167 mm^{-1}, $F(000)$ = 976, crystal size = 0.32 × 0.26 × 0.12 mm^3. The determination of the unit cell and the data collection for a dark-blue crystal of compound **1** were performed on an Enraf−Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) in the ω-2θ range 2.73 < θ < 30.03°. Lorentz-polarization corrections and an empirical absorption were applied to the data. The structure was solved by direct methods and refined by full-matrix least-squares, leading to a convergence with final $R1$ = 0.0734, $wR2$ = 0.1279 and S = 1.089 for 705 reflections with $F_o > 4\sigma(F_o)$ and 87 parameters. The structure analysis and refinement were carried out using the SHELXL-97 software package.[52] Selected bond lengths and angles are listed in Table 1.

Further details of the crystal-structure investigation may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-412990.

Great Framework Variation of Polymers in the Manganese(II) Maleate/α,α′-Diimine System: Syntheses, Structures, and Magneto-Structural Correlation

Chengbing Ma,[a,d] Changneng Chen,[a] Qiutian Liu,*[a] Feng Chen,[a] Daizheng Liao,[b] Licun Li,[b] and Licheng Sun[c]

Keywords: Crystal structure / Maleic acid / Magnetic properties / Manganese / Structural topology

Three novel manganese(II) coordination polymers, $[Mn(maleate)(phen)]_n$ (**1**; phen = 1,10-phenanthroline), $[Mn(maleate)(phen)]_n \cdot nH_2O$ (**2**), and $[Mn(maleate)(bpy)]_n$ (**3**; bpy = 2,2′-bipyridine), have been synthesized by treatment of Mn^{2+} with maleic acid with participation of chelate diimine ligands, and have been identified by single-crystal X-ray diffraction to have either one-dimensional (1D) zigzag chain structures (**1** and **2**) or a two-dimensional (2D) sinuous layer structure (**3**). Each maleate dianion coordinates to three Mn centers, in different bridging modes (*syn-anti* in **1** and **2**, *syn-syn* and *anti-anti* in **3**). These compounds represent an interesting example of structural topology variation from 1D to 2D mediated by chemically similar auxiliary chelate ligands. Variable-temperature magnetic susceptibility measurements show weak anti-ferromagnetic exchange interactions between the adjacent Mn^{II} ions, with $J = -0.06$ cm^{-1} (**2**) and $J = -1.3$ cm^{-1}, $zJ' = -0.27$ cm^{-1} (**3**). The differences in the magnitudes of these coupling interactions agree well with the nature of the carboxylate-bridging coordination of maleate.

Introduction

There is currently great interest in the construction of metal-organic hybrid extended solids containing paramagnetic metal ions, driven to a large extent by their fascinating network topologies and their wide applications, such as in the field of molecular magnetism.[1] The key to the fabrication of such networks is the selection of appropriate bridging ligands capable of mediating magnetic interaction and coordination geometries of metal ions.[2] The recent exponential growth in the synthesis and study of such coordination polymers has provided elegant examples of how the metal ion geometry and the appropriate bridging ligand symmetry can be exploited for the design of materials with unusual structures and properties. In this respect, polycarboxylate ligands are frequently used as magnetic superexchange pathways between the metal ions, due to their versatile carboxylate-bridging coordination modes (*syn-syn*, *anti-anti*, and *syn-anti*) capable of transmitting magnetic coupling interactions to different degrees.[3]

The product architecture that will spontaneously self-assemble from a metal node and a single organic spacer can to some extent be predicted in the light of the known metal coordination preference and the ligand configuration.[4] The introduction of another ligand, however, will greatly reduce the reliability of the prediction. In this situation, the auxiliary ligand may affect the combination mode of the metal ion with a primary ligand, finally resulting in topologically different complexes.

In the course of our study on manganese complexation by polyacids, we pay special attention to the influence of auxiliary ligands on the structural topology,[5] since at present it is not possible to know for certain the differences between the compounds.[6] In this work, we selected maleate as a primary ligand, in view both of its versatile bonding modes, capable of linking more than one metal ion, and also of its specific conformation, which was predicted to yield extended structures. We obtained two types of manganese(II) polymers with 1D and 2D frameworks in the presence of phen and bpy, respectively, as the secondary ligands. The result shows profound influences of the auxiliary chelate ligand both on the structural topology and on the simultaneous adoption of maleate coordination modes (Scheme 1), followed accordingly by the alteration of the magnetic properties of the product.

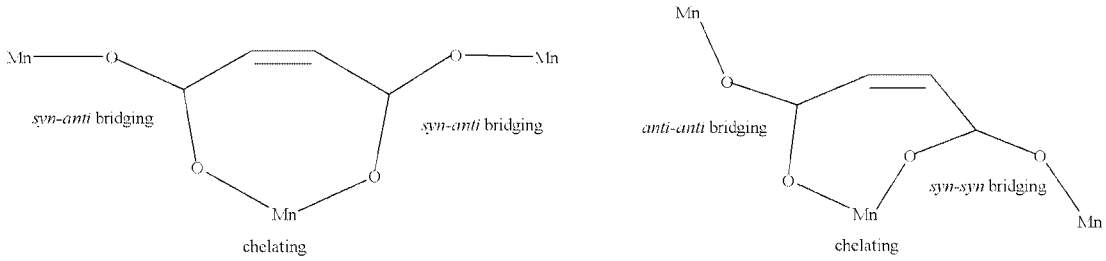

Scheme 1. A schematic illustration showing the coordination modes of maleate dianion observed in complexes **1**−**3** (left for **1** and **2**, right for **3**)

Results and Discussion

Synthesis

Three polymers were produced from the Mn^{2+}/maleate/diimine self-assembly system. Although structurally unexpected complexes are frequently encountered, as the metal−ligand self-assembly is strongly influenced by factors such as the solvent system, template, and counter-ion, as well as the preferences of metal center and organic spacer conformation, the dramatic difference derived from chemically very similar ancillary ligands, such as observed in the present work, is rather surprising. Attempts to obtain a complex topologically similar to **3** with bpy instead of phen under various reaction conditions did not succeed, and vice versa. The production of great structural variation, from 1D to 2D, for the two types of polymers (vide supra) may be due to the difference in conjugate ring area in the auxiliary ligands bpy and phen.

Structure Descriptions of Complexes 1−3

Single-crystal X-ray diffraction analysis reveals that the complex **1** is a 1D, neutral, chain-like polymer consisting of [Mn(maleate)(phen)] units. The Mn^{II} center has a distorted octahedral geometry with four O atoms of three maleate ligands [Mn−O 2.117(2)−2.208(2) Å] and two N atoms of one phen ligand [Mn−N 2.334(2) and 2.308(2) Å] at the six corners. Selected bond lengths and angles are listed in Table 1. Each Mn ion is coordinated by three maleate ions, while each maleate coordinates to three Mn ions through its two carboxylate groups in chelating and bridging modes. Two oxygen atoms of the two ends of the maleate ion chelate one Mn atom to form a seven-membered ring (**A**); meanwhile, each of the carboxylate groups bridges two Mn atoms in a *syn-anti* fashion, resulting in double μ-OCO bridges and a bridging eight-membered ring (**B**), as shown in Figure 1. Consequently, these different non-planar **A** and **B** rings alternately interlock by sharing the C−O−Mn edges to produce a one-dimensional zigzag chain (Figure 2), in which every two neighboring symmetry-related Mn atoms are separated by 4.976 Å. In addition, there is a significant π−π-stacking interaction between the phen ligands belonging to the inversion-related chains ($-x$, $1 - y$, $1 - z$) with a perpendicular ring separation of 3.363 Å, which further promotes the stabilization of the zigzag chain.

Complex **2** is made up of a one-dimensional chain and solvate water molecules. The chain is constructed from basic [Mn(maleate)(phen)] units, the structures of which are almost identical to those in **1**, and all the structural parameters are also very close to those of **1**, as can be seen from Table 1. Two hydrogen bonds link the lattice water molecule

O5 and two carboxylate oxygen atoms of symmetry-related polymer chains to generate a two-dimensional network sheet (Figure 3).

Interestingly, the replacement of phen by bpy resulted in the crystallization of the architecturally significantly different complex **3**, the structure of which involves a two-dimensional layer framework composed of neutral [Mn(maleate)(bpy)] units. Selected bond lengths and angles are listed in Table 2. Each Mn^{II} ion completes its pseudoctahedral geometry with four oxygen atoms of three maleate ions and two nitrogen atoms of a chelating bpy ligand (Figure 4). Each maleate ligand is also bonded to three different Mn atoms in chelating and bridging modes, and the chelating mode results in a seven-membered ring **A**, like those in **1**. Two carboxylate groups act as triatomic bridges in two distinct bridging modes (*syn-syn* and *anti-anti*), which are greatly different from that found in **1** (*syn-anti*). The *syn-syn* bridge forms an eight-membered ring $Mn_2(\mu\text{-}OCO)_2$ unit (**B**), which is fused together with two **A** rings by shar-

ing Mn−O−C edges to form **ABA** fused rings. The *anti-anti* bridge bridges between the two **ABA** moieties, resulting in a 22-membered macrocycle **C**, containing four Mn atoms alternately linked by four maleate ligands. The *syn-syn* and *anti-anti* bridges give rise to two spans with Mn−MnA distances of 4.666 Å and Mn−MnB distances of 6.390 Å, respectively. These rings extend sequentially to build up a two-dimensional sinuous layer-type architecture (Figures 5 and 6) with bpy ligands protruding towards the interlayer region, as shown in Figure 6. It is indicated that the **ABA-BAB**... zigzag chain of **1** arises from the mutual interlock of the **A** and **B** rings, while the linkage of the **ABA** moieties through the carboxylate group bridge gives rise to the clearly different framework topology of **3**. Surprisingly, this dramatic difference between the two complexes actually derives from chemically very similar ancillary ligands, phen and bpy. It is believed that the larger ring area of the phen ligand may be preferable for production of π−π interactions (vide supra) between the aromatic rings, albeit weak. This would favor the formation of a zigzag chain. However the larger ring area may also produce a spatial hindrance

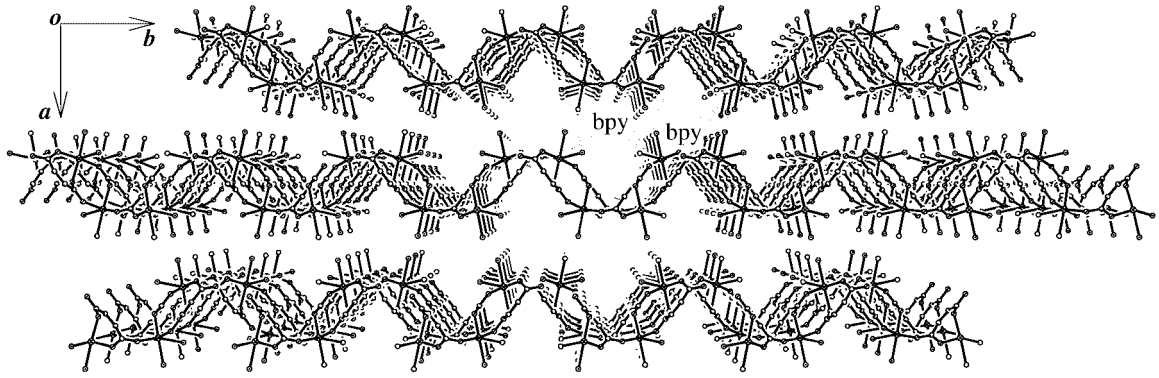

Figure 6. The packing diagram of **3** focused on the sinusoid-like layer framework; carbon atoms of bpy ligands are excluded for clarity

between the two sinuous layers (Figure 6). Consequently, the participation of the two ancillary ligands results in different framework topologies.

To the best of our knowledge, the coordination mode of maleate in **1**−**3** is unique in metal maleate/diimine systems, and different from that found in a tetramanganese cluster $[Mn_4(maleate)_2(bpy)_8](ClO_4)_4$,[7] in which each maleate ligand carboxylate group bridges two manganese ions in an *anti-anti* fashion, and also from that found in a manganese polymer $[Mn(maleate)(L)]_n$ (L = 4,4′-bipyridine),[8] in which two carboxylate groups of the maleate ligand act as a triatomic bridge in a *syn-anti* fashion and a monoatomic bridge to link two manganese ions, respectively, with the fourth carboxylate oxygen atom free. In addition, there were three previously reported dinuclear Cu/Zn maleate/bpy (or phen) complexes[9] in which the metal ions are five-coordinate and the maleate ion serves as a bidentate ligand linking two metal ions through two oxygen atoms of its two ends, and one mononuclear complex $[Co(maleate)(bpy)(H_2O)_3]\cdot H_2O$,[10] in which the maleate ion binds to the six-coordinate Co center through only one carboxylate oxygen atom. No other metal maleate/α-α′-diimine polymeric complexes have been reported so far.

IR Spectroscopy

The IR spectra of the three complexes clearly show both the presence of the maleate ion and its coordination mode. The strong absorptions at 1560 and 1425 cm^{-1} for **1**, 1558 and 1427 cm^{-1} for **2**, and 1551 and 1429 cm^{-1} for **3** correspond to asymmetric and symmetrical stretching vibrations − $\nu_{as}(COO)$ and $\nu_s(COO)$, respectively − of the coordinated carboxylate groups. The differences ($\Delta = \nu_{as} - \nu_s$) between $\nu_{as}(COO)$ and $\nu_s(COO)$ (135 cm^{-1} for **1**, 131 cm^{-1} for **2**, and 122 cm^{-1} for **3**) are significantly smaller than the corresponding value of 200 cm^{-1} for the free maleate dianions,[11] indicating a bidentate bridging coordination mode of the carboxylate groups.[12] This is in accordance with the result of X-ray diffraction analysis. In addition, the strong and broad band centered at 3450 cm^{-1} for **2** is attributable to the H−O−H stretching vibration of the lattice water molecule on the basis of the known structure. The medium absorptions at 3051 cm^{-1} for **1**, 3053 cm^{-1} for **2**, and 3046 cm^{-1} for **3** can be attributed to δ(=C−H) of maleate.

Magnetic Properties

Variable-temperature magnetic susceptibility measurements in the 5−300 K range were carried out for complexes **2** and **3**, and are shown in Figure 7. For **2**, the effective experimental magnetic moment (μ_{eff}) per Mn^{II} ion at room temperature is 5.70 μ_B, slightly lower than that of the uncoupled Mn^{2+} ion ($S = 5/2$; 5.91μ_B), remaining practically constant down to 30 K, and then gradually decreasing with decreasing temperature, reaching a value of 5.20 μ_B at 5 K. The $1/\chi_M$ vs. T plot is essentially linear (see inset in Figure 7), and obeys the Curie−Weiss law [$\chi_M = C/(T - \theta)$] with $C = 4.0\ cm^3\cdot K^{-1}\cdot mol$ and $\theta = -0.85$ K. In view of the known structure of the complex, the experimentally determined magnetic behavior was fitted by use of Equation (1) according to an isotropic Heisenberg model for a linear chain of metal ions with coefficients generated by Hiller et al.[13] for $S = 5/2$, where $A = 2.9167$, $B = 208.04$, $C = 15.543$, $D = 2707.2$, and $X = J/kT$. The best fitting parameters obtained are $J = -0.06\ cm^{-1}$, $g = 1.96$, with an agreement factor $R = 4.00\cdot10^{-4}$. This very small J value indicates very weak coupling interactions between the metal ions mediated by a triatomic *syn-anti* carboxylate group bridge, or practically a non-coupled system.

$$\chi_M = \left(Ng^2\beta^2/kT\right)(A + BX^2)(1 + CX + DX^3)^{-1} \quad (1)$$

For **3**, the experimentally determined effective magnetic moment at room temperature is 5.89 μ_B per Mn^{II} ion, very close to that of a magnetically isolated Mn^{2+} ion ($S = 5/2$; 5.91 μ_B). Upon cooling, the value decreases continuously down to 2.95 μ_B at 5 K, indicating an overall antiferromagnetic coupling interaction between the metal ions. From the known structural data, there are two types of magnetic exchange pathways between adjacent Mn^{2+} centers: one occurs between two doubly carboxylate-bridged (*syn-syn*

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

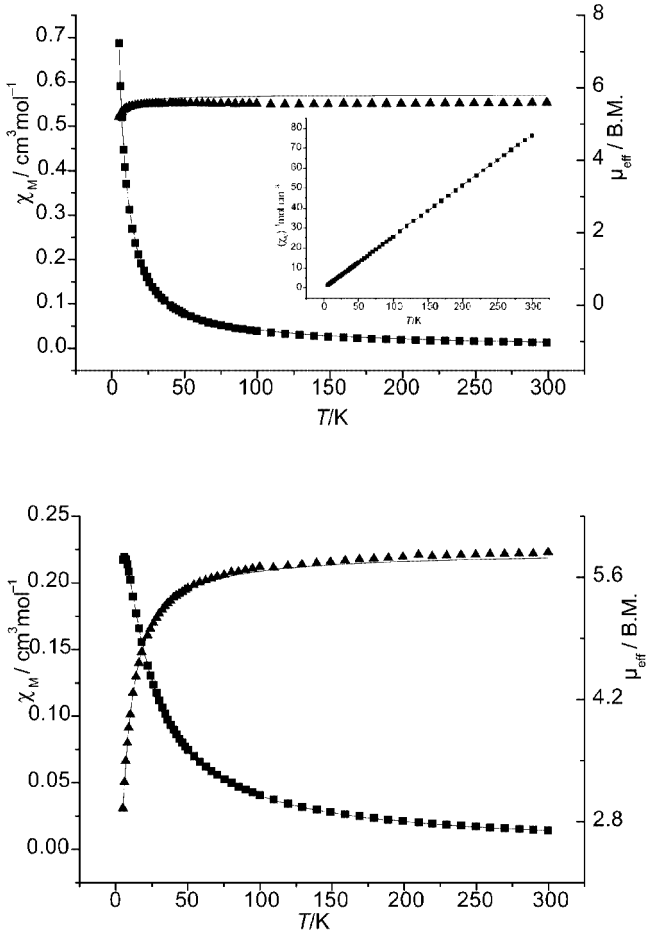

Figure 7. Experimental susceptibilities (χ_M, marked as square) and effective magnetic moment (μ_{eff}, marked as triangle) as functions of the temperature for complex **2** (top) and **3** (bottom); the solid lines represent the calculated values

mode) Mn^{2+} ions, and the other between singly carboxylate-bridged (*anti-anti* mode) Mn^{2+} ions. In view of the long separation (6.390 Å) of the *anti-anti*-bridged Mn^{2+} ions, we can simplify the coupling interaction system as a dimanganese(II) moiety, and simulate the magnetic behavior by use of Equation (2)[14] deduced from the Hamiltonian $\hat{H} = -J\hat{S}_1 \cdot \hat{S}_2$.

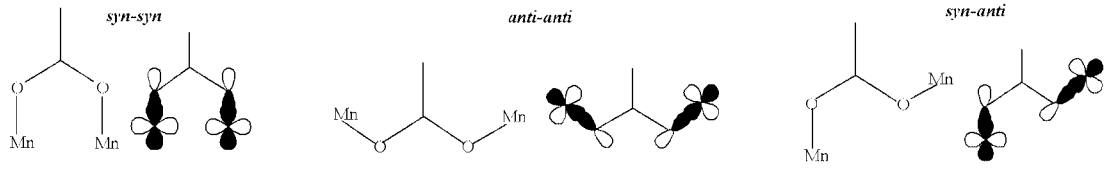
$$\chi_{bi} = \frac{2Ng^2\beta^2}{kT}\left[\frac{55+30\exp\left(-\frac{5J}{kT}\right)+14\exp\left(-\frac{9J}{kT}\right)+5\exp\left(-\frac{12J}{kT}\right)+\exp\left(-\frac{14J}{kT}\right)}{11+9\exp\left(-\frac{5J}{kT}\right)+7\exp\left(-\frac{9J}{kT}\right)+5\exp\left(-\frac{12J}{kT}\right)+\exp\left(-\frac{14J}{kT}\right)}\right] \quad (2)$$

To improve on the calculated expression, a mean molecular field approximation term[15] zJ' was added to describe the inter-dimer Mn^{2+} unit exchange interactions. The expression for the magnetic susceptibility becomes $\chi_M = \chi_{bi}/(1 - zJ' \cdot \chi_{bi}/Ng^2\beta^2)$. A satisfactory fitting result with parameters $J = -1.3$ cm^{-1}, $zJ' = -0.27$ cm^{-1}, $g = 1.99$, and the agreement factor $R = 3.25 \cdot 10^{-5}$ was obtained over the full temperature range.

All magnetic coupling interaction parameter values (J and zJ') fall in the normal range for two adjacent Mn^{2+} ions through the carboxylate group pathway, and the difference in the magnitude of the magnetic coupling interactions found for **2** and **3** can be explained in terms of the bridging modes of the carboxylate group and the overlap of d-p magnetic orbitals. As would be expected on the basis of the respective geometries, there is an efficient overlap between the 3d magnetic orbital of the Mn^{2+} center and the 2p magnetic orbital of the carboxylate group O in the order *syn-syn* > *anti-anti* > *syn-anti* (Scheme 2).[16] In good agreement with this, despite the larger separation of Mn···Mn (6.390 Å) in **3** than in **2** (4.976 Å), the corresponding exchange interaction value $zJ' = -0.27$ cm^{-1} in the *anti-anti* mode is larger than that of the *syn-anti* mode ($J = -0.06$ cm^{-1}, so small that the interaction is actually negligible) for **2**. Also, the *syn-syn* mode in complex **3** results in the largest J value, showing that the *syn-syn* carboxylate group bridge is more favorable than the others for transmission of the magnetic coupling interaction.[17]

Conclusion

We have obtained three novel manganese(II) polymeric complexes **1**, **2**, and **3**, variously possessing 1D zigzag chain and 2D sinuous layer structures, based on maleic acid in the presence of ancillary α,α′-diimine ligands (1,10-phenanroline and 2,2′-bipyridine). Very similar ancillary chelate ligands result in different structural topologies, which may be attributable to the different ring areas of the two delocalized aromatic diimine ligands, suggesting that the polymeric coordination framework may be designed and synthesized according to the inherent steric constraint and interactive information stored in organic ligands and metal ions,[4a,18] or modified through appropriate ancillary ligands. Studies on the magnetic properties of the complexes revealed weak antiferromagnetic coupling interactions between the paramagnetic Mn^{II} sites mediated to different degrees by the carboxylate group bridges in *syn-syn*, *anti-anti*,



Scheme 2. Schematic representations of the coordination modes for the triatomic carboxylate bridge and the overlap of d-p magnetic orbitals

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and *syn-anti* modes. The magnitudes of the *J* values for the interactions can be explained in terms of the efficient overlap between the magnetic orbitals. Various bridging modes of the carboxylate groups give the order *J* (*syn-syn*) > *J* (*anti-anti*) > *J* (*syn-anti*) for the interactions.

Experimental Section

General: All chemicals were of reagent grade and were used as received. Elemental analyses were performed with a Vario EL III CHNOS element analyzer, and the metal analysis was carried out by standard EDTA titration methods. IR spectra of KBr pellets (4000−400 cm^{-1}) were recorded with a Magna-75-FT-IR spectrophotometer.Variable-temperature susceptibility was measured with a model CF-1 superconducting magnetometer with a crystalline sample kept in a capsule at 4.5−300 K. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms of the determined complexes.

Synthesis of [[Mn($C_4H_2O_4$)($C_{12}H_8N_2$)]$_n$ (1): A solution of 1,10-phenanthroline (0.20 g, 1 mmol) in ethanol (10 mL) was added to a suspension of $MnCO_3$ (0.12 g, 1 mmol) and maleic acid (0.17 g, 1 mmol) in water (20 mL). The mixture was heated at reflux for 8 d, during which yellow crystals were produced. These were collected to afford **1** (0.08 g, yield 22.6% based on Mn). $C_{16}H_{10}MnN_2O_4$ (349.20): calcd. C 55.03, H 2.89, Mn 15.73, N 8.02; found C 54.76, H 3.07, Mn 15.98, N 8.11. IR: $\tilde{\nu}$ = 3051 (m), 1633 (m), 1620 (s), 1560 (vs), 1514 (m), 1425 (s), 1402 (w), 1346 (w), 1309 (vs), 1200 (w), 1144 (w), 1101 (w), 1088 (w), 889 (m), 850 (s), 783 (m), 731 (s), 661 (w), 634 (w), 619 (m), 550 (m), 418 (m) cm^{-1}.

Synthesis of [Mn($C_4H_2O_4$)($C_{12}H_8N_2$)]$_n$·$n$$H_2O$ (2): 1,10-Phenanthroline (0.40 g, 2 mmol) in ethanol (5 mL) was added dropwise with continuous stirring to an EtOH/H_2O (ca. 1:2, v/v, 20 mL) solution of maleic acid (0.34 g, 2 mmol), NaOH (0.16 g, 4 mmol), and $MnSO_4$·H_2O (0.34 g, 2 mmol). The resulting yellow solution was stirred for 10 min at room temperature, then filtered. The filtrate was left undisturbed for about one week to produce yellow crystals, which were collected and air-dried to afford **2** (0.48 g, yield 65.5% based on Mn). $C_{16}H_{12}MnN_2O_5$ (367.22): calcd. C 52.33, H 3.29, Mn 14.96, N 7.63; found C 52.56, H 3.13, Mn 15.21, N 7.41. IR: $\tilde{\nu}$ = 3450 (br), 3053 (m), 1635 (m), 1616 (s), 1558 (vs), 1516 (m), 1427 (s), 1394 (m), 1346 (m), 1306 (vs), 1200 (m), 1144 (m), 1101 (m), 991 (w), 891 (m), 866 (m), 850 (vs), 779 (m), 729 (s), 667 (w), 638 (w), 621 (m), 550 (m), 418 (m) cm^{-1}.

Synthesis of [Mn($C_4H_2O_4$)($C_{10}H_8N_2$)]$_n$ (3): The procedure used was similar to that for the preparation of **2**, except that 2,2′-bipyridine (0.31 g, 2 mmol) was used instead of 1,10-phenanthroline. Yellow crystals of **3** (0.26 g) were obtained in 40% yield. $C_{14}H_{10}MnN_2O_4$ (325.18): calcd. C 51.71, H 3.10, Mn 16.89, N 8.61; found C 51.64, H 2.98, Mn 16.97, N 8.54. IR: $\tilde{\nu}$ = 3046 (m), 1647 (w), 1595 (w), 1585 (w), 1551 (vs), 1491 (w), 1475 (m), 1429 (s), 1396 (s), 1317 (vs), 1284 (w), 1248 (w), 1217 (m), 1173 (w), 1157 (m), 1101 (w), 1059 (m), 1014 (s), 974 (m), 895 (m), 862 (m), 835 (w), 816 (w), 773 (s), 737 (m), 650 (m), 631 (m), 559 (m), 417 (m) cm^{-1}.

X-ray Crystallography: Intensity data were collected at 293 K with a Siemens SMART CCD diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Data were corrected for LP factors and empirical absorption correction was applied. The structures were solved by direct methods and refined on F^2 by the full-matrix, least-squares technique through use of the SHELXTL-97 program package.[19] All non-hydrogen atoms were refined anisotropically, and hydrogen atoms were introduced geometrically, with the exception of the lattice water hydrogen atoms, which were located from the difference Fourier syntheses. Crystallographic data of **1**−**3** are outlined in Table 3. CCDC- 201331 to -201333 contain the supplementary crystallographic data for complexes **1**−**3**. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat. + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Ferromagnetism in $[Mn(Cp^*)_2]^+$-Derived Complexes: the "Miraculous" Stacking in $[Mn(Cp^*)_2][Ni(dmit)_2]$

Christophe Faulmann,*[a] Eric Rivière,[b] Stéphane Dorbes,[a] François Senocq,[c] Eugenio Coronado,[d] and Patrick Cassoux[a]

Dedicated to Patrick Cassoux on the occasion of his recent retirement[‡]

Keywords: Metallocenes / Magnetic properties / Manganese / S ligands

The synthesis and characterisation (X-ray structure and magnetism) of metal complexes (Ni, Au) with the $[Mn(Cp^*)_2]^+$ cation and the $dmit^{2-}$ and $dmid^{2-}$ ligands are reported. $[Mn(Cp^*)_2][Ni(dmit)_2]$ (**1**) and $[Mn(Cp^*)_2][Au(dmit)_2]$ (**2**) exhibit the same structural arrangement, built on stacks of $[Ni(dmit)_2]^-$ pairs separated by two $[Mn(Cp^*)_2]^+$ cations, showing a $\cdots D^+D^+A^-A^-D^+D^+A^-A^-\cdots$ motif. On the contrary, the $dmid^{2-}$ derivative $[Mn(Cp^*)_2][Ni(dmid)_2]\cdot CH_3CN$ (**3**) exhibits a totally different structure, built on mixed layers composed of one $[Ni(dmid)_2]^-$ unit separated by two $[Mn(Cp^*)_2]^+$ cations, showing a $\cdots D^+D^+A^-D^+D^+A^-\cdots$motif. The layers are separated from each other by perpendicular $[Ni(dmid)_2]^-$ units and solvent molecules. Compound **2** exhibits antiferromagnetic interactions, whereas **1** and **3** exhibit ferromagnetic interactions at low temperature. Moreover, as confirmed by AC and DC magnetic susceptibility measurements, **1** is a ferrimagnet, the first ever derived from a 1,2-bis-dithiolene ligand. The ferromagnetic interactions in **1** and **3** are explained using the McConnell I mechanism.

Introduction

Since the discovery of metamagnetism in the molecule-based solid, $[Fe(Cp^*)_2](TCNQ)$,[1] (Cp^* = pentamethylcyclopentadienyl; TCNQ = tetracyanoquinodimethane), several studies have been carried out with the aim of substituting planar metal-organic complexes with the organic TCNQ acceptor and varying the nature of the metallocene; the complexes $[Fe(Cp^*)_2](TCNE)$[2] (TCNE = tetracyanoethylene), $[Mn(Cp^*)_2](TCNQ)$[3] and $[Mn(Cp^*)_2](TCNE)$[4] have been proven to be bulk ferromagnets. These compounds are structurally analogous, and their structures consist of parallel chains of alternating donor cations (D^+) and acceptor anions (A^-), thus showing a $D^+A^-D^+A^-$ motif.

There are two possible models that may explain the ferromagnetic coupling between the metallocenium $[M(Cp^*)_2]^+$ cation and the acceptor ($TCNE^-$ or $TCNQ^-$) (see ref.[5] and papers cited therein). The first explanation was proposed by Miller et al.[2] and is based on the McConnell II mechanism[6] which involves charge transfer, whereas the second one (based on the McConnell I mechanism[7]) was proposed later by Kahn and co-workers[8] and involves spin polarisation effects. Schweizer and co-workers recently[5] showed that the McConnell I mechanism can partly explain the ferromagnetic interactions within $[Fe(Cp^*)_2](TCNE)$, however no clear-cut evidence for the first or the second mechanism has really emerged. Even more recently, the results of a solid-state NMR study on various paramagnetic metallocenium ions[9] were in agreement with all the requirements for the McConnell I mechanism. Whatever the mechanism, a 1-D structure with a $D^+A^-D^+A^-$ motif was believed to be a prerequisite for the synthesis of molecular ferromagnets.[10] The metal bis-dithiolene complexes $[M(S_2C_2R_2)_2]^-$ have been used as acceptors in order to achieve such 1D-chains, since they are able to form either alternating or segregated stacks, depending on the associated cations. These metal complexes are excellent candidates for achieving the requirements for cooperative magnetic phenomena, due to the presence of peripheral het-

[‡] For his enormous contribution in the field of the $M(dmit)_2$ systems.

eroatoms which might favour extended magnetic interactions. Most of the molecular charge-transfer salts previously synthesised and studied are based on the decamethylferrocenium cation, $[Fe(Cp^*)_2]^+$, in combination with metal bis-dithiolene complexes including those involving the $dmit^{2-}$ ligand[11–14] ($dmit^{2-}$ = $C_3S_5^{2-}$= 2-thioxo-1,3-dithiole-4,5-dithiolato), the mnt^{2-} ligand[15,16] [mnt^{2-} = $(NC)_2C_2S_2^{2-}$ = maleonitriledithiolato] and the tfd^{2-} ligand[15,17] [tfd^{2-} = $(F_3C)_2C_2S_2^{2-}$ = bis(trifluoromethyl)-ethylenedithiolato]. Recent studies have also focused on complexes of edt^{2-} and $dmid^{2-}$ (also called $dmio^{2-}$)[14,18–20] (edt^{2-} = $C_2H_2S_2^{2-}$ = ethylenedithiolato; $dmid^{2-}$ = $C_3OS_4^{2-}$= 2-oxo-1,3-dithiole-4,5-dithiolato).

From the studies on all these complexes, two conclusions can be drawn: their structures do not always exhibit a $D^+A^-D^+A^-$ motif (which is, a priori**,** considered as a disadvantage for producing ferromagnetic molecular compounds), and very few of them exhibit ferromagnetic interactions. Nevertheless, substituting Mn for Fe in the metallocenium part has led to complexes with interesting magnetic properties: $[Mn(Cp^*)_2][Ni(tfd)_2]$,[21] $[Mn(Cp^*)_2][Ni(bdt)_2]$[18] (bdt^{2-} = $C_6H_4S_2^{2-}$ = 1,2-benzenedithiolato) and $[Mn(Cp^*)_2][Ni(dmit)_2]$[22] (**1**) exhibit long range magnetic ordering at low temperature, whereas the $[Fe(Cp^*)_2]$-based analogues only exhibit ferromagnetic interactions. Therefore, with the intention of understanding the differences in the magnetic behaviour, and after the promising results obtained for $[Mn(Cp^*)_2][Ni(dmit)_2]$,[22] we here present a more detailed characterisation of the latter compound and the synthesis and characterisation of two new compounds based on the manganocenium cation, namely $[Mn(Cp^*)_2][Au(dmit)_2]$ (**2**) and $[Mn(Cp^*)_2][Ni(dmid)_2]\cdot CH_3CN$ (**3**).

Results and Discussion

Synthesis

Complexes **1**, **2** and **3** were obtained by slow addition of an acetonitrile solution of $[Mn(Cp^*)_2]PF_6$ [23] in slight excess to an acetonitrile or acetone solution of the appropriate $(nBu_4N)[M(ligand)_2]$ (ligand = $dmit^{2-}$, $dmid^{2-}$) complex. After concentration, a brown microcrystalline powder was collected by filtration, washed several times with acetonitrile and dried in vacuo. Recrystallisation of this powder from various solvents failed and resulted in the same brown powder. In the case of **1**, small single crystals suitable for an X-ray analysis were sometimes isolated from the microcrystalline powder. On the contrary, a large number of single crystals of **2** and **3** suitable for X-ray analyses could be easily isolated from the corresponding microcrystalline powders.

X-ray Structure of 1, 2 and 3

Although the size of the crystals of **1** was very small (0.1 × 0.1 × 0.03 mm^3), an X-ray study was undertaken and resulted in the collection of 15817 reflections, for which only 596 were observed above $2\sigma(I)$. Nevertheless, in spite of this low quality data set, we have been able to solve the structure of **1** without great difficulty. The crystal and experimental data for **1**, **2**, and **3** are summarised in Table 1.

Complexes **1** and **2** are isostructural with $[Fe(Cp^*)_2]$-$[Ni(dmit)_2]$.[11] The asymmetric unit of **1** and **2** contains one $[Mn(Cp^*)_2]^+$ cation and one $[M(dmit)_2]^-$ anion (M = Ni, Au; Figure 1).

The overall structural arrangement consists of $\cdots D^+D^+A^-A^-D^+D^+A^-A^-\cdots$ stacks comprising side-by-

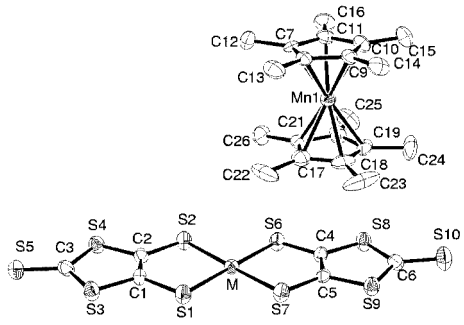

Figure 1. Atomic numbering scheme for complexes **1** and **2** (M = Ni, Au)

side $[Mn(Cp^*)_2]^+$ cations alternating with face-to-face $[M(dmit)_2]^-$ anions, the latter forming slipped dyads (Figure 2)

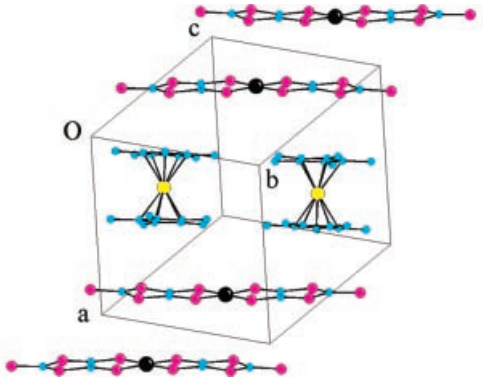

Figure 2. Structure of complexes **1** and **2** showing the ···$D^+D^+A^-A^-D^+D^+A^-A^-$··· motif

The intramolecular distances do not show any significant deviation from those observed for manganocenium-cation-based compounds[3,21] and $M(dmit)_2$-based compounds (M = Ni, Au).[11,12] The pentamethylcyclopentadienyl rings adopt approximately an eclipsed conformation, which is the opposite of the staggered conformation observed in neutral $[Mn(Cp^*)_2]$,[24] but similar to that observed in other decamethylmanganocenium-cation-containing compounds.[3,21] The planes of the Cp* rings are almost parallel to the planes of the $M(dmit)_2$ units (averaged angles of 7.84° and 5.59° for **1**; 6.27° and 4.83° for **2**) and are at averaged distances of 3.52 and 3.63 Å (for **1**) and 3.60 and 3.72 Å (for **2**).

Selected intramolecular distances and angles for **1**, **2**, $[Fe(Cp^*)_2][Ni(dmit)_2]$ and $[Fe(Cp^*)_2][Au(dmit)_2]$ are listed in Table 2. The intermolecular distances between the metal centres are very close to those found for $[Fe(Cp^*)_2]$-$[M(dmit)_2]$ (M = Ni, Au).[11,12] For an identical $M(dmit)_2$ complex, no drastic differences can be seen either between the metallic centres of a D^+D^+ pair (distance M−M in Table 2) or between the metallic centres of an A^-A^- pair (distance M′−M′ in Table 2), The largest difference (0.034 Å) occurs for the M−M′ distances, involving the metal of the cation and the metal of the anion.

Complex **3** is isostructural to $[Fe(Cp^*)_2]$-$[Ni(dmid)_2]\cdot CH_3CN$, reported in 1995 by Fettouhi and co-workers.[20] The asymmetric unit of **3** contains one molecule of acetonitrile, one $[Mn(Cp^*)_2]^+$ cation, and two halves of an $[Ni(dmit)_2]^-$ anion, each Ni atom lying on a centre of inversion (Figure 3).

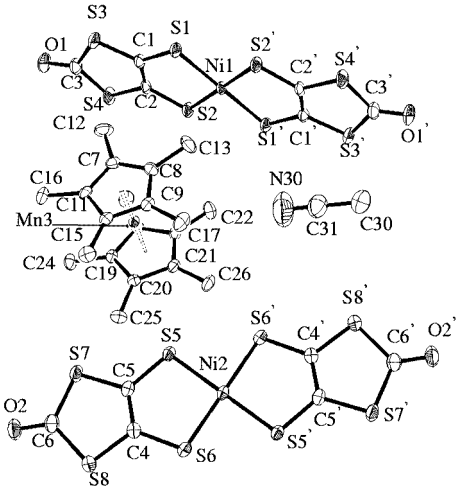

Figure 3. Atomic numbering scheme for the complex **3**

Contrary to what is observed in **1** and **2**, the overall structural arrangement of **3** consists of ···$D^+D^+A^-D^+D^+A^-$··· mixed layers parallel to the *ab* plane and separated in the *c* direction by anionic sheets of $[Ni(dmid)_2]^-$ units, which ensure neutralisation and are almost perpendicular to the mixed layers [angle of 74.35(2)° between the $Ni(dmid)_2$ units; Figure 4].

As for **1** and **2**, the planes of the Cp* rings in **3** are almost parallel to the planes of the $Ni(dmid)_2$ units in the mixed layers: they form angles of 3.38° and 3.96° and are at distances of 3.97 and 4.26 Å. Averaged and selected bond lengths and angles for **3** and $[Fe(Cp^*)_2][Ni(dmid)_2]\cdot CH_3CN$ are shown in Table 3. The Mn−Mn distance within the mixed layers is 8.250(1) Å, the shortest Mn−Ni distances are 5.911(1), 6.778(1), 6.805(1) and 7.218(1) Å and the

shortest Ni−Ni distance is 9.770(1) Å. Selected intermolecular distances in **3** and in $[Fe(Cp^*)_2][Ni(dmid)_2]\cdot CH_3CN$ are also reported in Table 3. All intermolecular distances observed between metallic centres are smaller in **3** than in $[Fe(Cp^*)_2][Ni(dmid)_2]\cdot CH_3CN$, but the differences seem rather small, the largest one (0.17 Å) occurring for a large distance of ca. 11.7 Å. The Mn−S or Fe−S intermolecular distances are also similar.

Powder Diffraction

Powder diffraction was performed on sample **1** only. Analysis of the results at room temperature showed that the space group remains triclinic with the following calculated cell parameters: a = 11.5252(4) Å, b = 15.1281(5) Å, c = 10.1050(4) Å, α = 97.446(3)°, β = 94.662(3)°, γ = 109.683(3)°, to be compared with the values of 11.415(3), 14.940(3), 10.020(2) Å and 97.40(3) °, 94.58(3) °, 109.63(3)° from the single-crystal analysis at 160 K. The observed slight expansion of the lattice can be attributed to the fact that powder data were collected at room temperature, whereas the ones for single-crystal measurement were obtained at 160 K. However, the good agreement between experimental and calculated data (see Table S1 and Figure S1 in the Supporting Information) shows that the analysed powder sample retains the structure obtained from the single crystal.

Magnetic Properties of 1, 2 and 3

Magnetic studies were performed on polycrystalline powders, between 2 and 300 K.

[Mn(Cp)₂][Ni(dmit)₂] (1)*

The magnetic behaviour of **1** (in the form $\chi_M T$ versus T) is shown in Figure 5. $\chi_M T$ is equal to 1.71 emu·mol^{-1}·K at room temperature which is slightly higher than the value expected for two magnetically isolated Mn^{III} and Ni^{III} ions {1.61 emu·mol^{-1}·K, taking g values equal to 2.20 and 2.06 for $[Mn(Cp^*)_2]^+$ and $[Ni(dmit)_2]^-$, respectively}.[25,26] Such an experimental value is not surprising, since it has also been observed for several dithiolene complexes,[15,17,21,27] and is generally attributed to the anisotropic nature of the g factors of the decamethylmanganocenium[23] ion and to a partial orientation of the polycrystalline powder.

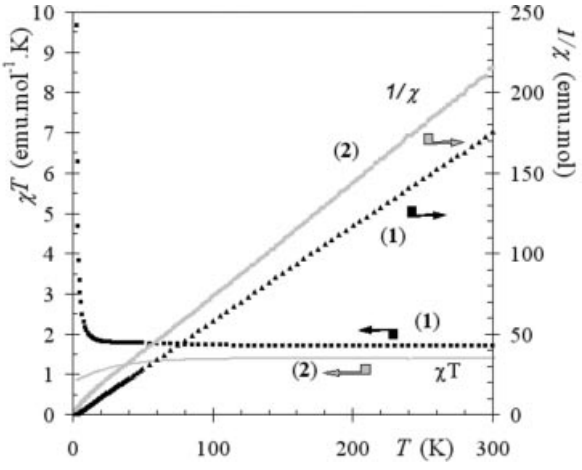

Figure 5. Temperature dependence of the magnetic susceptibility for **1** and **2**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The $\chi_M T$ value is constant down to ca. 30 K, and the plot of χ_{M-1} versus T is linear, indicating that the susceptibility of **1** follows the Curie−Weiss law, with a Weiss parameter, θ, of 2.5 K. This positive value indicates that ferromagnetic interactions dominate. As the temperature is lowered, $\chi_M T$ increases rapidly and reaches a value of 9.65 emu K mol^{-1} at 3 K. This behaviour is typical of ferromagnetic interactions. Below this temperature, the magnetic susceptibility becomes field dependent indicating that the compound exhibits a long-range magnetic ordering. This is confirmed by the field cooled (FCM), zero field cooled (ZFC) and remnant (REM) magnetisation curves shown in Figure 6a. The FCM curve presents a break around 2.5 K and the REM vanishes at the same temperature suggesting an ordering temperature, T_c, of about 2.5 K. Magnetisation versus field behaviour at 2 K is given in Figure 6b and bears out the ferromagnetic coupling between the Mn^{III} and Ni^{III} ions. At first sight, the magnetisation increases very rapidly at low field, as expected for a magnet, and then increases smoothly above 1000 G. At 50000 G, the magnetisation is equal to 2.31 μ_B, which is below the expected saturation value (3.23 μ_B), but well above the expected value for a ferrimagnetic compound (about 1.17 μ_B). Nevertheless, by carefully checking the magnetic-field dependence of **1** (see inset in Figure 6b), one can observe that the magnetisation increases sharply only up to about 1.3 μ_B. This value is already reached around 200 G, and then increases smoothly up to 2.31 μ_B at 50000 G. Such a behaviour is not consistent with the properties of a ferromagnet. Therefore **1** must be regarded as a ferrimagnet instead of a ferromagnet. Indeed, antiferromagnetic interactions between the $[Ni(dmit)_2]^-$ units ($S = 1/2$) and the $[Mn(Cp^*)_2]^+$ cations ($S = 1$) result in an $S = 1/2$ system. This is in accordance with the observed value of about 1.3 μ_B, slightly larger than 1.17 μ_B, probably due to the large anisotropy of the g factor for the $[Mn(Cp^*)_2]^+$ unit. At higher field, the antiferromagnetic interactions between the $[Ni(dmit)_2]^-$ units and the $[Mn(Cp^*)_2]^+$ cations tend to decrease, resulting in an increase of the magnetisation. Even at high field (55000 G), a slight antiferromagnetic coupling still exists between the $[Ni(dmit)_2]^-$ units and the $[Mn(Cp^*)_2]^+$ cations, which explains why saturation is not reached.

A hysteresis curve was determined at 2 K and is shown in Figure 7. The coercive field H_c is about 3.5 G and confirms that **1** is a magnet. Since these measurements were made just below T_c, this might explain the low value of H_c. Complex **1** is indeed a ferrimagnet and not a metamagnet, as confirmed by the plot of M as a function of H that does not present any curvature at low field, as was observed for $[Fe(Cp^*)_2][Ni(edt)_2]$,[19] $[Mn(Cp^*)_2][Ni(bdt)_2]$[18] and $[Mn(Cp^*)_2][M(tfd)_2]$ (M = Ni, Pd, Pt).[21]

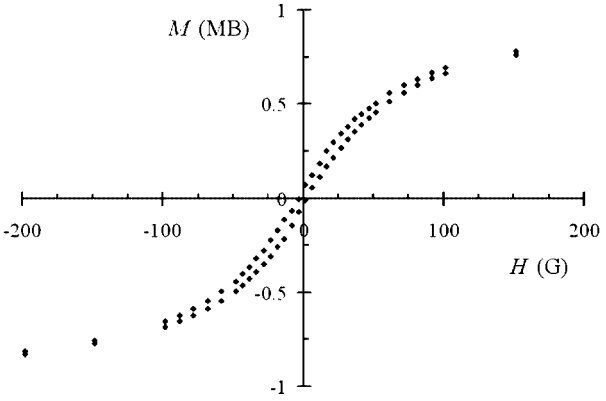

Figure 7. Hysteresis curve at 2 K for **1**

Finally, AC susceptibility measurements (Figure 8) confirm this interpretation: an out-of-phase signal is observed at 2.5 K, indicating a ferromagnetic ordering below this temperature

Such a behaviour has never been observed for any other bis-dithiolene complex. Previously studied metallocenium/metal bis-dithiolene compounds either behave as metamagnets,[18,19,21] or exhibit ferromagnetic interactions[11,15,20] but no ferromagnetic ordering has been reported. Depending on the authors, the ferromagnetic interactions in

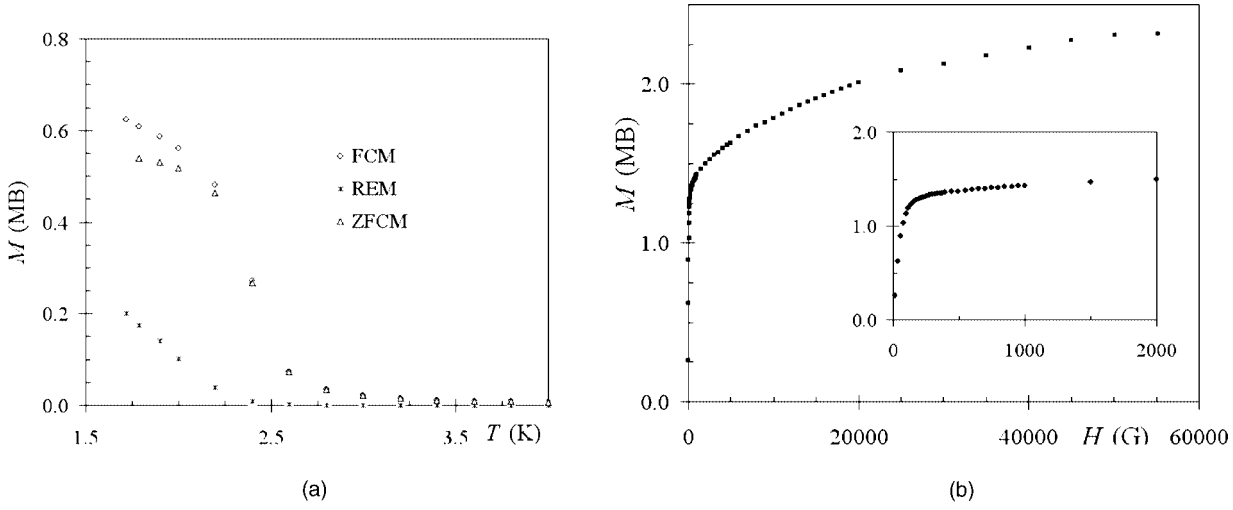

Figure 6. Temperature (a) and field dependence (b) of the magnetisation for **1**

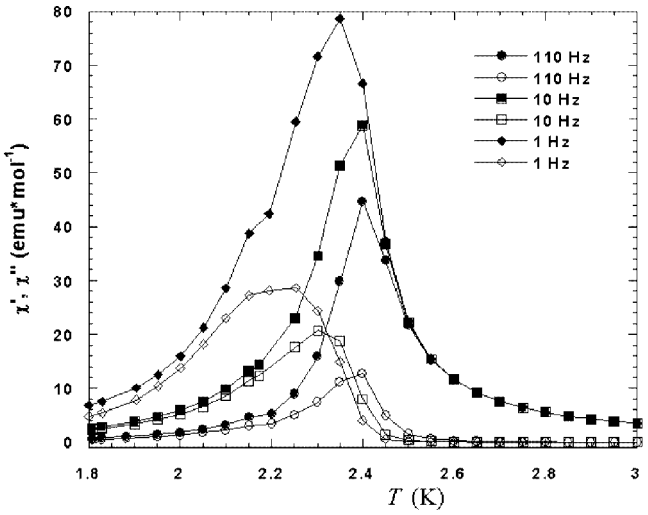

Figure 8. AC susceptibility for compound **1**

these metallocenium/metal bis-dithiolene compounds are explained by using either the McConnell mechanism II[6,11,15] (which involves charge transfer and requires the formation of $[D^{2+}]$ and $[A^{2-}]$ species) or the McConnell mechanism I[7,20] (which involves coupling between spin densities). In the latter, a global ferromagnetism arises when the interaction between spin densities of opposite sign are predominant, whereas a net antiferromagnetism results from dominant interactions between spin densities of the same sign.[28] Such a mechanism, which implies a negative spin-density located on the carbon atoms of the Cp* ring, was proposed by Kahn and co-workers[8] to explain the ferromagnetic properties in $[Fe(Cp^*)_2](TCNE)$, whereas Miller and co-workers preferred the McConnell II mechanism.[2,6] A doubt still existed as to the sign of the spin density on the carbon atoms of the Cp* ring in $[Fe(Cp^*)_2]^+$. A recent reassessment[5] of the magnetic interactions within $[Fe(Cp^*)_2](TCNE)$ has shown that a negative spin density is located on the carbon atoms of the Cp* ring, with a positive density on the carbon atoms of the methyl groups. These conclusions have been confirmed by the work of Heise and co-workers[9] on various paramagnetic metallocenium ions. Using solid-state NMR spectroscopy, these authors have shown unambiguously that a negative spin-density is located over the Cp* ring of $[Mn(Cp^*)_2]^+$ in $[Mn(Cp^*)_2](TCNE)$ and in $[Mn(Cp^*)_2](PF_6)$, and to a certain extent on the H atoms of the methyl groups, whereas a positive density on the C atoms of the methyl groups has been found, confirming previous results.[5,29] Although the stacking in **1** ($\cdots D^+D^+A^-A^-\cdots$) is different from that of $[Mn(Cp^*)_2](TCNE)$ ($\cdots D^+A^-D^+A^-\cdots$), the nature of the molecules constituting these complexes is identical: both are built from one acceptor part [TCNE or $Ni(dmit)_2$] and the same metallocenium ion. Taking these similarities and the various results into account,[5,9,29] the ferromagnetic behaviour of **1** could result from spin-polarisation effects within the McConnell I mechanism.[7] Such a mechanism is based on the interaction between the spin densities of the Cp* rings and the spin densities of the $[Ni(dmid)_2]^-$ anions.[8,30] In the $[Ni(dmit)_2]^-$ anions, positive spin-densities are observed on almost all atoms, except for the S atoms of the outer rings.[31] Three types of interaction may be considered between the spin densities of $[Mn(Cp^*)_2]^+$ and $[Ni(dmit)_2]^-$: the first interaction, between the $[Mn(Cp^*)_2]^+$ cations, should be negligible because of the large inter-cation distances ($d_{Mn-Mn} > 8.4$ Å), with the second one being between the $[Mn(Cp^*)_2]^+$ cations and the $[Ni(dmit)_2]^-$ anions and the third one between $[Ni(dmit)_2]^-$ anions within the slipped $\{[Ni(dmit)_2]_2\}^{2-}$ dyads (see Figure 2). Figure 9a clearly shows that negative-positive spin-density interactions are predominant when considering the overlap between the $[Mn(Cp^*)_2]^+$ cation and the $[Ni(dmit)_2]^-$ anion, which may result in a global ferromagnetic interaction. Within a dyad (Figure 9b), there are only two areas in which negative-positive density interactions can occur, compared to three positive-positive interactions. However, the former two zones imply the NiS_4 core, for which the spin density is larger than on the rest of the molecule, which leads to the conclusion that ferromagnetic interactions dominate also in the dyads.

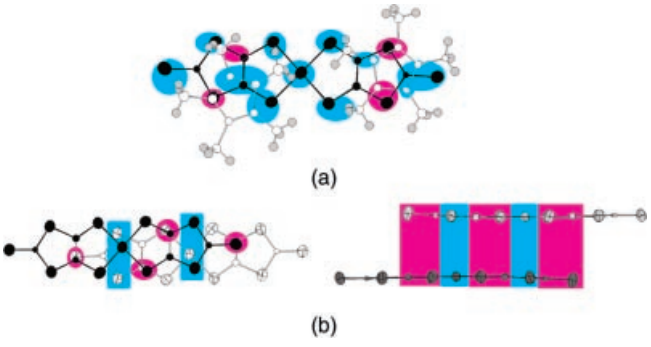

Figure 9. Modes of overlap in **1**: (a) between $[Mn(Cp^*)_2]^+$ and $[Ni(dmit)_2]^-$; (b) within a $\{[Ni(dmit)_2]_2\}^{2-}$ diad; the cyan zones represent the interactions between spin densities of opposite sign and the magenta ones represent the interactions between spin densities with the same sign

This rather qualitative approach seems to be confirmed by the preliminary results of the DFT calculations of the energy of the antiferromagnetic singlet and of the ferromagnetic triplet states as a function of the slipping within a $\{[Ni(dmit)_2]_2\}^{2-}$ dyad.[31] These calculations indicate that the minimum of energy and a ferromagnetic coupling (positive singlet-triplet gap) are observed only for slipping values close to the experimental one (3.55 Å). Consequently, the molecular arrangement in **1** could be described as favourable for ferromagnetic interactions.

$[Mn(Cp^*)_2][Au(dmit)_2]$ (2)

Magnetic measurements on **2** between 300 and 2 K lead to $\chi_M T$ values of around 1.75 emu·K·mol^{-1} at 300 K (much larger than the expected value of 1.21 emu·K·mol^{-1} calculated for an $S = 1$ isolated system, with $<g> = 2.20$). Such

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a large value has already been observed in β-$[Fe(Cp^*)_2]_2$-$[Co(mnt)_2]_2$,[16] but was attributed to contamination by a small amount of ferromagnetic impurities or to traces of other metals in the starting gold complex $HAuCl_4$. If this explanation holds true in the case of **2** (in this case, the impurity might be Fe), a more reasonable value of 1.39 emu·K·mol^{-1} for the $\chi_M T$ product is reached when subtracting this ferromagnetic contribution (see Figure 5). A perfect Curie−Weiss law is then obtained, with a Weiss temperature of −4.2 K and a Curie constant of 1.42.

When lowering the temperature, the product $\chi_M T$ decreases slightly down to ca. 70 K, below which it decreases abruptly. Such a behaviour is typical of dominant antiferromagnetic interactions and is easily explained by the absence of spin carriers (Au^{III} in the $[Au(dmit)_2]^-$ units) between the pairs of manganocenium cations, which are totally isolated from each other. Therefore, no cooperative ferromagnetic interactions can occur in this complex.

[Mn(Cp)$_2$][Ni(dmid)$_2$].CH$_3$CN (3)*

The temperature dependence of $\chi_M T$ and $1/\chi_M$ for **3** is shown in Figure 10. At room temperature, the $\chi_M T$ product is 1.87 emu·K·mol^{-1}, and it increases slightly as the temperature is lowered to about 30 K. Below this temperature $\chi_M T$ increases rapidly and reaches a value of 3.66 cm^3·K·mol^{-1} at 3 K. Below 3 K, $\chi_M T$ decreases but χ_M still continues to increase. This behaviour is similar to that reported by Fettouhi and co-workers for $[Fe(Cp^*)_2]$-$[Ni(dmid)_2]$·CH_3CN.[20] and is typical of dominant ferromagnetic interactions to which weak antiferromagnetic interactions are superimposed. The plot of χ_{M-1} versus T is linear, indicating that the susceptibility of **3** follows the Curie−Weiss law, with a Weiss temperature, θ, of 2.80 K, larger than the one obtained for $[Fe(Cp^*)_2]$-$[Ni(dmid)_2]$·CH_3CN.

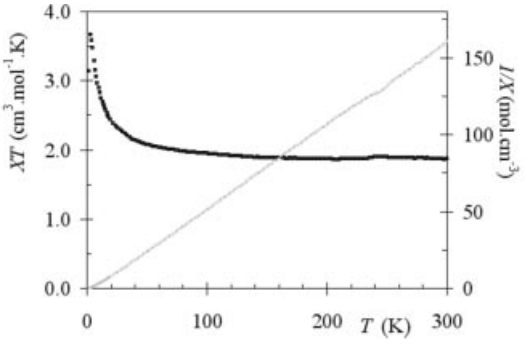

Figure 10. Temperature dependence of the magnetic susceptibility for **3**

The similarity in the behaviours of **3** and $[Fe(Cp^*)_2]$-$[Ni(dmid)_2]$·CH_3CN is not totally surprising as it is only the nature of the metal that changes in the decamethylmetallocenium ion. In contrast, we did not expect that substituting an oxygen atom for a sulfur atom when going from the $Ni(dmit)_2$ complex (**1**) to the $Ni(dmid)_2$ complex (**3**) could lead to such different structural arrangements, and consequently to very different magnetic properties. A possible explanation for the magnetic properties of **3** could be similar to that proposed by Fettouhi and co-workers in the case of $[Fe(Cp^*)_2][Ni(dmid)_2]$·CH_3CN,[20] which is based on the interaction between the negative spin-density of the Cp* rings and the positive spin-density of the sulfur atoms of the $[Ni(dmid)_2]^-$ anions.[30] Indeed, as shown in Figure 11, the overlap between $[Mn(Cp^*)_2]^+$ and $[Ni(dmid)_2]^-$ is such that interactions between spin densities of opposite sign are largely predominant. Unfortunately, however, in the case of **3** there is no clear-cut experimental evidence supporting this interpretation, as was the case for **1**.

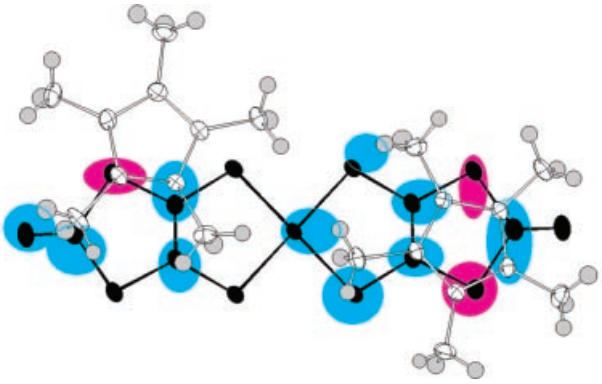

Figure 11. Modes of overlap in **3** between $[Mn(Cp^*)_2]^+$ and $[Ni(dmid)_2]^-$ in the mixed layer; the cyan zones represent the interactions between spin densities of opposite sign and the magenta ones the interactions between spin densities with the same sign

Conclusion

We have shown that by using the same cation $[Mn(Cp^*)_2]^+$ with two different 1,2-bisdithiolene metal complexes $[Ni(dmit)_2$ and $Ni(dmid)_2]$, drastic changes in the structural arrangements occur. This leads to various magnetic properties, with different behaviour. The present study has allowed us to reiterate that in compounds based on metal bis-dithiolene complexes $[M(S_2C_2R_2)_2]^-$ a $D^+A^-D^+A^-$ motif in the structural arrangement is not a prerequisite for promoting ferromagnetic interactions, let alone ferromagnetism. The selection of the $[Mn(Cp^*)_2]^+$ cation, as already recommended by Broderick et al.,[21] has led to compounds which exhibit even more interesting properties than the $[Fe(Cp^*)_2]^+$-based compounds. For example, **1** is the first ferrimagnet to be derived from a metal bis-dithiolene complex whereas $[Fe(Cp^*)_2][Ni(dmit)_2]$ exhibits only ferromagnetic interactions, and **3** presents stronger ferromagnetic interactions than its iron analogue, $[Fe(Cp^*)_2][Ni(dmid)_2]$·CH_3CN. Nevertheless, due to the complexity and diversity of the structures, and in spite of possible comparison with various compounds, the understanding of their magnetic behaviour remains at the qualitative level. Theoretical DFT calculations are currently in progress to give a better insight into

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the origin of the ferromagnetism in **1**.[31] Solid-state NMR spectroscopy, as shown by Heise and co-workers,[9] should provide qualitative as well as quantitative information on the interactions within these materials. Such a study seems to be a very promising tool, since it will take both the intra- and intermolecular effects into account. Indeed, the determination of structure-magnetism relationships in molecular magnetic materials requires not only the study of the direct overlap between neighbouring molecules, but also the consideration of the global packing of the structure, as shown by Veciana and co-workers for α-nitronyl nitroxide radicals.[32] It is important to note that only short intermolecular effects have been considered for the qualitative interpretation of the results reported here. Several complexes based on the $[Mn(Cp^*)_2]^+$ cation and metal complexes of the $dmid^{2-}$ ligand are being studied at present, in order to expand the range of compounds exhibiting such ferromagnetic interactions without the $D^+A^-D^+A^-$ motif.[33]

Experimental Section

General Remarks: Bis(pentamethylcyclopentadienyl)manganese(III) hexafluorophosphate $[Mn(Cp^*)_2]PF_6$ was synthesised from pentamethylferrocenium hexafluorophosphate $[FeCp_2]PF_6$ following the procedure reported by Robbins and co-workers.[23] Tetrabutylammonium bis(1,3-dithiol-2-thione-4,5-dithiolato)nickelate(III), $(nBu_4N)[Ni(dmit)_2]$, tetrabutylammonium bis(1,3-dithiol-2-thione-4,5-dithiolato)aurate(III), $(nBu_4N)[Au(dmit)_2]$, and tetraphenylarsonium bis(1,3-dithiol-2-one-4,5-dithiolato)nickelate(III), $(AsPh_4)[Ni(dmid)_2]$, were synthesised following the literature procedures.[26,34,35] All solvents were dried and distilled prior to use. All syntheses were carried out in an inert atmosphere box or using Schlenk techniques.

$[Mn(Cp^*)_2][Ni(dmit)_2]$ (1): This compound was obtained after slow addition of an acetonitrile solution of $[Mn(Cp^*)_2]PF_6$ (194 mg, 0.413 mmol) to an acetonitrile solution of $(nBu_4N)[Ni(dmit)_2]$ (265 mg, 0.382 mmol). Partial removal of the solvent under reduced pressure, followed by filtration, afforded a brown microcrystalline powder, which was washed several times with acetonitrile and dried in vacuo. $C_{26}H_{30}MnNiS_{10}$ (776.75): calcd. C 40.20, H 3.89, S 41.27; found C 39.62, H 3.26, S 41.15.

$[Mn(Cp^*)_2][Au(dmit)_2]$ (2): Compound **2** was synthesised following the same procedure as for **1**, using 26 mg (0.031 mmol) of $(nBu_4N)[Au(dmit)_2]$, dissolved in 15 mL of acetone and 18 mg (0.038 mmol) of $[Mn(Cp^*)_2]PF_6$ dissolved in 10 mL of acetonitrile. $C_{26}H_{30}AuMnS_{10}$ (915.01) (**2**): calcd. C 34.12, H 3.31, S 35.04; found C, 34.02, H 3.30, S 34.97.

$[Mn(Cp^*)_2][Ni(dmid)_2]\cdot CH_3CN$ (3): Compound **3** was synthesised following the same procedure as for **1**, using 196 mg (0.244 mmol) of $(AsPh_4)[Ni(dmid)_2]$ dissolved in 30 mL of acetonitrile and 122 mg (0.259 mmol) of $[Mn(Cp^*)_2]PF_6$ dissolved in 25 mL of acetonitrile. $C_{28}H_{33}MnNNiO_2S_8$ (785.68): calcd. C 42.80, H 4.24, S 32.64; found C, 42.52, H 4.16, S 31.85.

Magnetic Measurements: DC magnetic data were recorded on a MPMS5 magnetometer (Quantum Design Inc.). The calibration was made at 298 K using a palladium reference sample furnished by Quantum design Inc. AC susceptibility was measured on a SQUID magnetometer Quantum Design MPMS-XL-5.

X-ray Crystallographic Study: The experimental details and crystal data are listed in Table 1. Data collection and cell refinement were performed with a sealed Mo-K_α (λ = 0.71073 Å) X-ray source on a Stoe Imaging Plate Diffraction System (IPDS) diffractometer, using the IPDS software.[36] Crystal decay was monitored by measuring a maximum of 200 reflections per image. The structures were solved using Sir97[37] or Shelxs97[38] and refined with Shelxl97.[39] The calculations were carried out with the WinGX package program[40] running on a PC. The drawings of the molecular structures were performed with CAMERON,[41] ORTEP.[42] The atomic scattering factors are taken from the International Tables for X-ray Crystallography.[43]

$[Mn(Cp^*)_2][Ni(dmit)_2]$ (1): A brown rhombic plate (0.1 mm side and 0.02 mm thick) was selected for the X-ray study. The crystal-to-detector distance was 70 mm. 133 exposures (6 min per exposure) were obtained with $0 < \Phi < 250°$ and with the crystals rotated through 1.5° in Φ in the oscillation mode.

$[Mn(Cp^*)_2][Au(dmit)_2]$ (2): A brown elongated bar ($0.37 \times 0.05 \times 0.05$ mm^3) was selected for the X-ray study. The crystal-to-detector distance was 70 mm. 167 exposures (5 min per exposure) were obtained with $0 < \Phi < 250°$ and with the crystals rotated through 1.5° in Φ in the oscillation mode.

$[Mn(Cp^*)_2][Ni(dmid)_2]\cdot CH_3CN$ (3): A black squared-shaped thick plate (0.23 mm side and 0.1 mm thick) was selected for the X-ray study. The crystal-to-detector distance was 70 mm. 209 exposures (3 min per exposure) were obtained with $0 < \Phi < 250°$ and with the crystals rotated through 1.2° in Φ in the oscillation mode.

Full details related to every compound are given in the Supporting Information.

CCDC-203647 (**1**), -203646 (**2**) and -203645 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

X-ray Powder Diffraction Studies

The sample was prepared in a side-filling cell, in order to minimise preferred orientations. The data were collected with a Seifert XRD 3000 TT diffractometer in Bragg−Brentano (Θ − Θ) configuration, using Cu-K_α radiation, fitted with a graphite diffracted-beam monochromator, in the interval $2° < \Theta < 30°$. The raw data were treated with the PowderX program,[44] in order to recalculate the cell parameters, and compared to the simulated diagram obtained with CaRine.[45]

Supporting Information [Table S1 (Miller indices and experimental and calculated $1/d^2hkl$ with the relative intensity of the experimental value], Figure S1 [experimental and calculated X-ray powder diagram for compound **1**, and the cif files for **1**, **2** and **3**] is available. See footnote on the first page of this article.

COVER PICTURE

The cover picture shows the multi-faceted approach required to unravel the complicated electrochemistry presented by Wells–Dawson coordinated actinide (*An*) ions, $[An(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ (*An* = Th, U, Np, Pu, Am). These *An*-polyoxometalate (POM) clusters contain two redox centers: the central *An* ion (magenta), except Th^{4+}, and the ligands, $(\alpha\text{-}2\text{-}P_2W_{17}O_{61})^{10-}$, for which P is orange, W is black, and O is teal blue. The formal potentials of the *An* ions are extracted by in situ XANES (X-ray absorption near edge structure) spectroelectrochemistry, using the Nernst formalism. This approach provides a unique avenue to quantifying the *An* redox response, because the multi-redox active centers, together with the deep blue color of the ligands upon reduction, exclude more standard experiments. The Nernst approach to XANES data provides information about the electronic influence of POM complexation, which is of fundamental interest as related to correlated electron behavior and of practical significance to separations science in nuclear waste processing. Details are presented in the article by M.-H. Chiang, L. Soderholm and M. R. Antonio on p. 2929 ff.

The Study of Inorganic Systems by NMR Spectroscopy in Conjunction with Parahydrogen-Induced Polarisation

Simon B. Duckett*[a] and Damir Blazina[a]

Keywords: NMR spectroscopy / Parahydrogen / Iridium / Rhodium / Ruthenium

The study of reaction mechanisms by NMR spectroscopy normally suffers from limitations in sensitivity that result in substantial difficulties in the detection and characterisation of reaction intermediates. One technique that can circumvent this problem is the use of *para*-enriched hydrogen. Here, an overview of the developments in the study of chemical reactions using parahydrogen-assisted NMR spectroscopy is presented, with the characterisation of a number of new hydride complexes of iridium, rhodium, ruthenium and tantalum being described. A number of studies involving transition metal clusters and catalytic applications are also considered.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

1. Introduction

An obvious aim in understanding the detailed mechanism of a chemical reaction is the unambiguous detection and characterisation of any associated reaction intermediates. Unfortunately, such species are often both transient in nature and present in low concentrations. Since this makes their direct detection difficult, indirect techniques, such as reaction kinetics or isotopic labelling, are often used to impart mechanistic information. However, there will always be a degree of ambiguity associated with a mechanism that is determined in this fashion.

One technique that has found widespread use in the characterisation of compounds in all branches of chemistry is NMR spectroscopy. In many ways, NMR is an ideal technique for such studies since most important elements exhibit at least one NMR-active isotope, and isotopic labelling can be undertaken if greater sensitivity is required. The benefits of this approach when coupled with the wealth of available pulse sequences mean that it is often possible to determine molecular structures using NMR alone. Other factors, such as the ability to choose between solution and solid-state NMR and the possibility of monitoring slower dynamic processes, make this technique even more attractive for studying reactions. However, since NMR is inherently insensitive, its application in mechanistic studies has been somewhat limited.

In 1986 Bowers and Weitekamp proposed,[1] and later proved,[2] that greatly enhanced ^{1}H NMR signals could be obtained from molecules that were formed by the addition of hydrogen in the *para* spin-state. Since this report, the use of parahydrogen-enhanced NMR spectroscopy has revolutionised the study of reactions involving H_2 as a substrate by providing opportunities to study reaction intermediates directly by NMR for essentially the first time.

Simon Duckett (left) was born in Preston in England in 1965. He graduated with a B.Sc. degree in Chemistry from the University of York in 1986 and was awarded a D.Phil. from the same institution in 1990 (with Prof. R. N. Perutz). During 1990 he was a postdoctoral fellow with Prof. W. D. Jones at the University of Rochester and returned there in late 1991 to work as a postdoctoral fellow with Prof. R. Eisenberg on projects relating to parahydrogen. In 1993 he returned to the University of York to take up an appointment as Lecturer in Inorganic Chemistry and in 2001 he was promoted to Reader. He has authored 30 publications in the parahydrogen field and has research interests in using NMR to probe reaction mechanisms and help develop new catalysts.

Damir Blazina (right) was born in Zagreb, Croatia in 1977. He graduated with an MChem. degree in Chemistry from the University of York in 1999 and was awarded a Ph.D. from the same institution in 2003 (with Dr. S. Duckett and Prof. P. J. Dyson). He is currently a postdoctoral fellow in the same Department. He started working in the parahydrogen area on a project sponsored by Bruker UK in 1999 and has research interests in cluster-based catalysis and NMR spectroscopy.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

2. Principles Behind the Parahydrogen Effect

The existence of two isomers of molecular hydrogen derives from the symmetrisation principle of quantum mechanics, which states that the overall wave function of fermions (such as protons) must be antisymmetric with respect to exchange of nuclei. Furthermore, since the product of rotational and nuclear wave functions has to be antisymmetric, it follows that antisymmetric rotational states (odd values of J) are associated with symmetric, or *ortho*, nuclear spin-states. Likewise, antisymmetric nuclear spin-states (called *para*) are reserved for symmetric rotational states (even values of J). Hydrogen therefore might be thought to consist of a 3:1 mixture of *ortho* and *para* isomers in accordance with the threefold degeneracy of the former state (spin configurations $\alpha\alpha$, $\alpha\beta+\beta\alpha$, $\beta\beta$) over the latter (spin configuration $\alpha\beta-\beta\alpha$). However, since these two forms have different rotational (internal) energies, their populations are temperature dependent, and since interconversion between the two isomers is forbidden, the isolation of pure parahydrogen is possible. This is readily achieved by cooling H_2 in the presence of a paramagnetic species. The degree of enrichment simply depends on the temperature of the catalyst; 50% enrichment is possible at 77 K.[3,4]

An important feature of parahydrogen (p-H_2) is that it is NMR silent. However, if it adds to a metal centre in such a way that two chemically distinct hydrides are formed, the energy level diagram shown in Figure 1 is obtained. Since parahydrogen selectively populates the $\alpha\beta$ and $\beta\alpha$ spin states of the product, the population difference between the states will approach unity. This reflects a substantial increase over the normal situation where populations are controlled by the corresponding energy level separations. Because the intensity of an NMR signal depends on this population difference, enhanced signals are observed in the spectra of parahydrogen-derived molecules. Furthermore, this novel population distribution results in two of the transitions occurring in the opposite sense to that which is normally seen and the associated resonances therefore have antiphase character. This process has been termed PASADENA (Parahydrogen And Synthesis Allow Dramatically Enhanced Nuclear Alignment)[2a] and PHIP (ParaHydrogen Induced Polarisation).[2b]

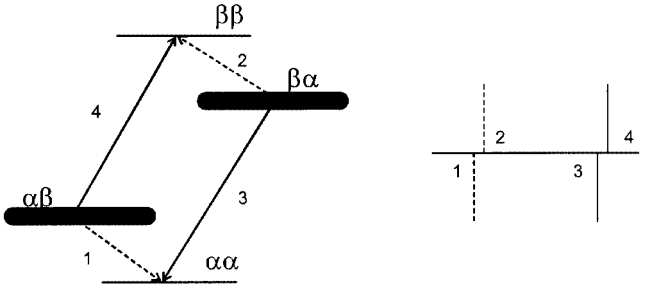

Figure 1. Idealised spin-state populations (represented by line thickness) and corresponding NMR signal patterns for an AX spin system, such as those found in $[(Me_2AsCH_2CH_2AsPh_2)Pt(H)_2]$, formed under parahydrogen-derived PASADENA conditions; the situation where $^2J_{H,H}$ is negative is illustrated

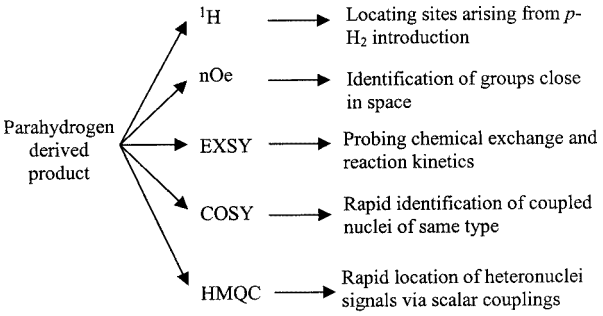
It is important to note that this situation corresponds to the chemical synthesis of an extreme spin-state, and that the system will subsequently re-establish the Boltzmann population distribution via relaxation. However, if a radio frequency pulse is applied prior to this point, the newly formed spin state can be interrogated and larger than normal coherences can be generated for detection. Scheme 1 summarises some of the ways that this approach has been harnessed in the literature.



Scheme 1. NMR approaches facilitated by parahydrogen

A different effect is observed if the reaction involving parahydrogen takes place in a weak magnetic field, such as outside the NMR spectrometer. This effect, called ALTADENA (Adiabatic Longitudinal Transport After Dissociation Engenders Net Alignment)[5] occurs because under such conditions, the coupling between the nuclei is large relative to the frequency difference between them. Consequently, the added parahydrogen nuclei selectively move from their initial spin state into either the $\alpha\beta$ or $\beta\alpha$ states of the AX system, depending on which is lower in energy. Only two enhanced transitions are therefore observed in the resulting NMR spectrum. The ALTADENA effect is transitory in nature; if the reaction is not complete outside the strong magnetic field of an NMR spectrometer, PASADENA and ALTADENA effects will compete in the early stages of the reaction. Any subsequent reaction in the strong magnetic field will result in the PASADENA effect being observed.

A number of articles have appeared that have reviewed the parahydrogen effect and its chemical applications (see Scheme 2).[6] This article focuses on inorganic reports since 1999.

3. Applications of Parahydrogen to Mononuclear Transition Metal Complexes

If the parahydrogen effect is to be useful, it must make possible the detection of new species. For example, oxidative addition of H_2 to Vaska's Complex, *trans*-[IrCl(CO)(PPh_3)$_2$],[7] and its many analogues has been the subject of much synthetic investigation and was accepted to proceed exclusively over the OC−Ir−Cl axis. Calculations by Sargent and Hall,[8] however, revealed that H_2 addition over the OC−Ir−Cl axis rather than the P−Ir−P axis is favoured by only 9.5 kJ·mol^{-1} in the case of [IrCl(CO)(PMe_3)$_2$], and that increasing the π-accepting nature of the phosphane further favours H_2 addition across the P−Ir−P axis. Studying the oxidative addition of H_2 to Vaska's complex is therefore an ideal test of the *p*-H_2 approach, viz., is another isomer detectable? Figure 2a shows the resultant ^{1}H NMR spectrum, focusing on the hydride region, when *p*-H_2 adds to *trans*-[IrCl(CO)(PPh_3)$_2$] at 295 K. The expected resonances for *cis*-*trans*-[IrCl(H)$_2$(CO)(PPh_3)$_2$] are clearly visible, while those for a minor species are indeed detected.[9] In this case, the extra signals arise from a product with two chemically equivalent hydride protons that are magnetically distinct, i.e. *cis*-*cis*-[IrCl(H)$_2$(CO)(PPh_3)$_2$]. Further studies demonstrated that when PMe_3 was employed, a similar species could be observed, and when $AsPh_3$ was utilised, H_2 addition over the As−Ir−As axis was shown to be kinetically preferred, with slow isomerisation over the course of several days leading to the thermodynamic product *cis*-*trans*-[IrCl(H)$_2$(CO)($AsPh_3$)$_2$].

Evidence was also presented in this paper that the formation of trihydride complexes of the type [Ir(H)$_3$(CO)$_2$(L)] was possible when CO and *p*-H_2 are warmed together in the presence of [IrCl(CO)(L)$_2$] (L = PPh_3 and PMe_3). The trihydride product was shown to be formed via [IrCl(H)$_2$(CO)$_2$(L)], which undergoes competitive HCl and H_2 elimination thereby accounting for the observation of [IrH(Cl)$_2$CO(PPh_3)$_2$]. The spectral features of the associated hydride resonances of [Ir(H)$_3$(CO)$_2$(L)] are worthy of special comment (see Figure 2b) since they yield anti-phase components that have different frequency separations. This situation arises due to the internal cancellation of the central triplet feature in the unique IrH resonance.[10] Interestingly, a very different result was obtained when *trans*-[IrCl(CO)(PPh_3)$_2$] was subjected to UV radiation while un-

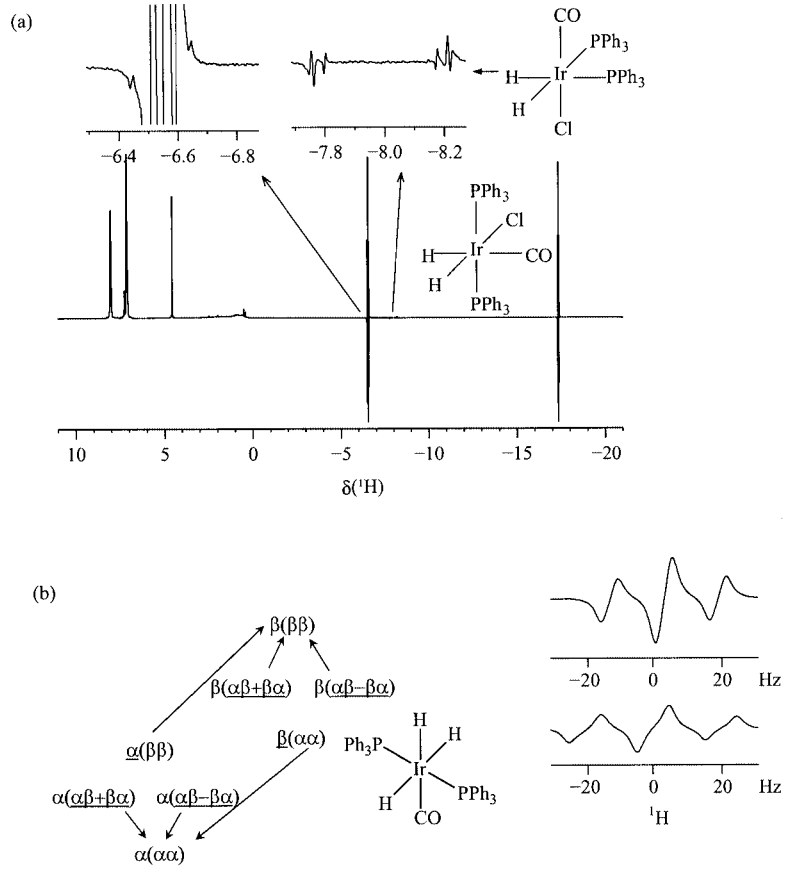

Figure 2. (a) 128 scan ^{1}H NMR spectrum obtained when a sample of [IrCl(CO)(PPh_3)$_2$] reacts with *p*-H_2 in C_6D_6 at 295 K; enhanced hydride resonances for the major isomer (corresponding to addition over the Cl−Ir−CO axis) dominate the spectrum; insets illustrate how ^{13}C satellites and signals due to the minor product, corresponding to H_2 addition over the P−Ir−P axis, are visible; (b) energy level diagram for a *p*-H_2 derived metal trihydride complex containing two magnetically equivalent hydride ligands; the *p*-H_2 enhanced hydride resonances of the inset trihydride complex are illustrated (same scale) with the lower trace containing the resonance for the hydride that is *trans* to CO, for which the central feature is missing

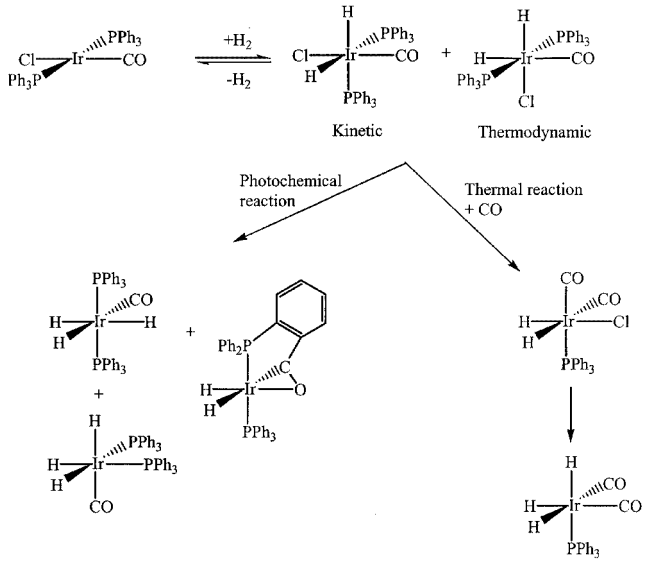
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

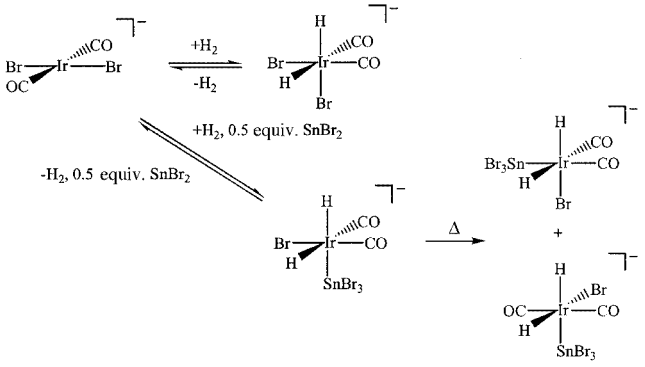
der an atmosphere of *p*-H_2. Now, a dihydride product corresponding to a species containing a five-membered Ir(CO-C_6H_4-P) ring was detected. This product was suggested to form by CO insertion into an unseen *ortho*-metallation product. The above reactions are summarised in Scheme 3.



Scheme 3. Reaction pathways for [IrCl(CO)(PPh_3)$_2$] after H_2 addition as detected by *p*-H_2 NMR spectroscopy

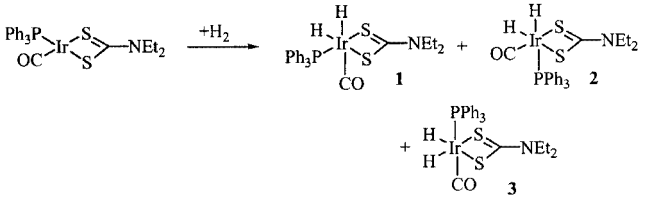
Another example of a complex that was purported not to react with H_2 directly is the 16-electron anion $[IrI_2(CO)_2]^-$ which features in the industrially significant CATIVA process. Oxidative addition of *p*-H_2 to the tetrabutylammonium salt of $[IrI_2(CO)_2]^-$ resulted in the detection of the all-*cis* $[Ir(H)_2I_2(CO)_2]^-$.[11] Kinetic studies employing EXSY methods resulted in the demonstration that this complex eliminates H_2 on the NMR timescale with the associated activation parameters being indicative of reductive elimination from the 18-electron $[Ir(H)_2I_2(CO)_2]^-$ rather than the 16-electron $[Ir(H)_2I(CO)_2]$. Isomerisation into a second product where the two hydride ligands are *trans* to iodide was found to proceed on a slower time scale via $[I]^-$ loss. Subsequently, these species were detected using normal NMR methods, albeit in a high pressure NMR cell.[12]

More recently, Permin et al. have employed *p*-H_2 to study the related complex $(Bu_4N)[IrBr_2(CO)_2]$ and its reactions with $SnBr_2$.[13] In the absence of $SnBr_2$, oxidative addition of *p*-H_2 yields the *all-cis* product $[Ir(H)_2Br_2(CO)_2]^-$, in an analogous manner to that for the iodide complex. However, the addition of 0.5 molar equivalents of $SnBr_2$ to this system results in the formation of the dibromostannyl complex $[Ir(H)_2Br(SnBr_3)(CO)_2]^-$ which isomerises at high temperatures into two other structural forms, as identified in Scheme 4. When a large excess of $SnBr_2$ is employed initially, insertion leads instead to *cis*, *trans*, *cis*-$[Ir(H)_2(SnBr_3)_2(CO)_2]^-$. By studying the relative intensities of the associated PHIP enhanced hydride signals, the authors determined that the presence of one $SnBr_3$ ligand facilitates H_2 addition due to the enhanced σ-donating effect of the new ligand, but that the presence of two such ligands deactivates the system.



Scheme 4. Formation of iridium tribromostannyl anions as detected by PHIP[13]

The utilisation of parahydrogen-induced polarisation to detect minor isomers of metal dihydrides thus clearly marks one of the most widespread successes of the parahydrogen approach. Indeed, when the related d^8 complex [Ir(CO)-(PPh_3)(Et_2dtc)] was examined with normal H_2, three dihydride complexes were rapidly formed and their concentrations were shown to rapidly equilibrate (Scheme 5). As expected, it proved a simple matter to assign product structures based on the coupling patterns of the hydride resonances.[14] When parahydrogen was utilised, the hydride resonances of **1** were estimated to be 40-fold enhanced at 298 K and the ratio of signals for **1**:**2** was about 170:1. This implied a kinetic selectivity of ca. 170:1 for the generation of isomer **1** compared with **2**. At 358 K, exchange peaks between the inequivalent hydrides resonances of **1** and **2** were observed with the exchange pathway shown to involve phosphane dissociation. Interestingly, the dominant reaction pathway corresponds to oxidative addition of H_2 over the axis of the starting square-planar complex that contains the CO ligand.



Scheme 5. Species formed by hydrogen addition to [Ir(S_2CNEt_2)-(CO)(PPh_3)]

Since the parahydrogen approach relies on NMR characterisation, complexes of ^{103}Rh, where $I = 1/2$, have proven to be extremely valuable in establishing this technique. An early example is presented by the oxidative addition of *p*-H_2 to [RhCl(PMe_3)$_4$] and [RhCl(PMe_3)$_3$],[15] where the dihydride products were used to demonstrate that two-dimensional NMR techniques such as COSY, HSQC, HMQC and NOESY could be used with *p*-H_2. In addition, this study

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

laid the groundwork for many subsequent investigations by showing that rapid chemical-shift detection of ^{31}P and ^{103}Rh nuclei was possible despite the inherent insensitivity of the latter (see Figure 3), that the magnitudes and relative sizes of heteronuclear coupling constants could be determined, and that NOESY methods could be used to probe ligand arrangements and monitor hydride ligand exchange.

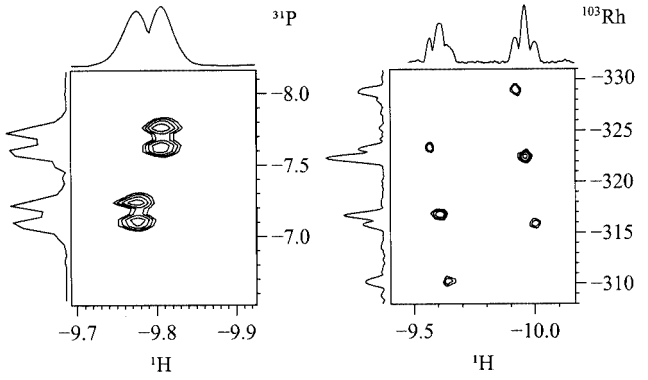


Figure 3. Selected cross-peaks (positive contours) and projections from ^{1}H-^{31}P (left) and ^{1}H-^{103}Rh (right) correlation spectra of $[Rh(H)_2Cl(PMe_3)_3]$ obtained with *p*-H_2 in CD_2Cl_2 at 313 K

As PHIP is still a relatively new NMR technique, an important part of work in this area consists of case studies that contribute to the understanding of the effect or extend its applications. One such discovery was the observation by Aime et al. that the oxidative addition of parahydrogen to a Rh^{I} centre containing a bound alkene resulted in the polarisation of the alkene protons.[16] Previously, such effects had been ascribed to exchange between the hydrides and the alkene protons.[17] However, isotopic labelling indicated that this was not the case here, and that the transfer of polarisation must occur via cross relaxation (NOE) between the hydrides and the alkene protons. This result has implications in catalytic studies since it means that it may be possible to detect unsaturated molecules bound to metal centres even in absence of hydrogenation or hydride exchange.

Recent work at York has involved extending the parahydrogen technique further via low temperature in-situ UV photolysis.[18] In this study, a 325 nm He-Cd continuous-wave laser was employed to irradiate $[Rh(\eta^5\text{-}C_5H_5)(C_2H_3SiMe_3)_2]$ at 203 K in the presence of *p*-H_2. Enhanced hydride resonances assigned to $[Rh(\eta^5\text{-}C_5H_5)(H)_2(C_2H_3SiMe_3)]$ were detected in the associated spectra (see Figure 4). This observation reflects an important result in this field since it overcomes the need for rapid thermally initiated H_2 cycling. In addition, it was concluded, on the basis of the photon flux and an estimate of the quantum yield, that the spectra illustrated the detection of 1 nmol of material.

The reactions of stable 18-electron complexes of ruthenium have also been monitored using the PHIP methodology. Indeed, the value of *p*-H_2 as a mechanistic probe is well illustrated by the highly fluxional system

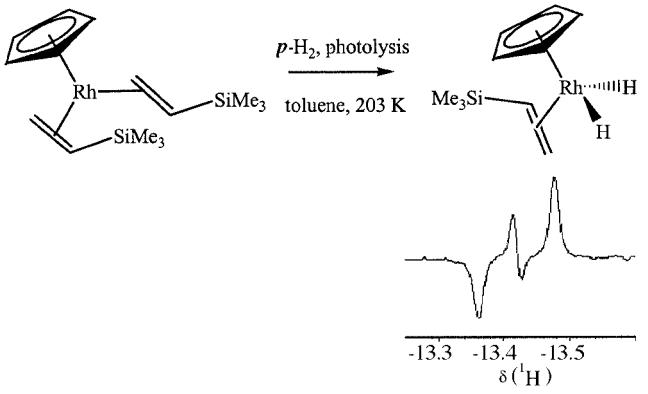

Figure 4. PHIP enhanced ^{1}H spectrum (bottom) showing hydride resonances of the inset dihydride complex obtained during concurrent UV irradiation according to the reaction illustrated

$[Ru(H)_2(CO)_2(Ph_2PCH_2CH_2PPh_2)]$.[19] In this complex, exchange between the hydride ligands and exchange of the phenyl rings was monitored quantitatively by the EXSY approach. In addition, the complex was observed to readily undergo H_2 elimination. The utilisation of *p*-H_2 indicated that H_2 loss proceeds via a diamagnetic intermediate, since a paramagnetic one would quench any enhancement, and facilitated the elucidation of the mechanism for the exchange process, which was proposed to occur via a trigonal bipyramidal transition state containing an η^2-H_2 ligand (see Scheme 6). Since H-H and P-P interchange occurred at the same rate, a concerted rotation was indicated. When $[Ru(H)_2(CO)_2(dppe)]$ was generated by the in situ photolysis of $[Ru(CO)_3dppe]$, the observation of enhanced hydride resonances was taken to indicate that the intermediate $[Ru(CO)_2dppe]$ exists in a singlet electronic state.

The application of *p*-H_2 methods to the study of early transition metal complexes is currently much less common, with one recent study involving the preparation of the dimeric tantalum dinitrogen complex $[(Cp^*_2TaCl)_2(\mu\text{-}N_2)]$.[20] Upon H_2 addition, two isomers of the dihydride complex $[Cp^*_2Ta(H)_2Cl]$ are formed, which are shown in Scheme 7. Since only the asymmetric isomer was expected to show *p*-H_2 enhancement, PHIP provided a ready means of distinguishing between the two isomers.

The oxidative addition of H_2 to the related complex $[Cp^*_2Ta(CH_2)(H)]$ has also been studied with parahydrogen.[21] This reaction leads to the formation of two enhanced products, $[Cp^*_2Ta(CH_3)(H)_2]$ and $[Cp^*_2Ta(H)_3]$. Isotopic labelling was used to show that, in both cases, the enhancement is due to two hydride ligands, and a mechanistic pathway involving the unsaturated methylene complex $[Cp^*_2Ta(CH_3)]$ was proposed.

4. Parahydrogen in the Study of Binuclear Complexes

Work at York has focused on extending the applications of PHIP methods by studying the reactions of the d^8-rho-

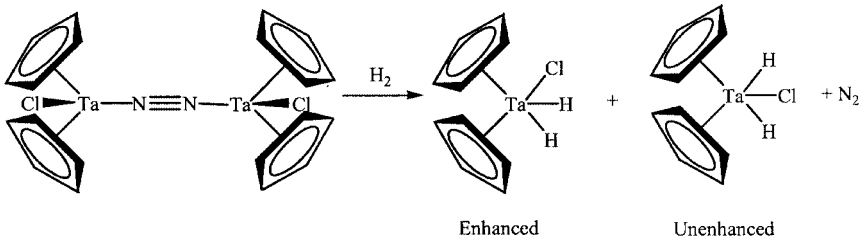
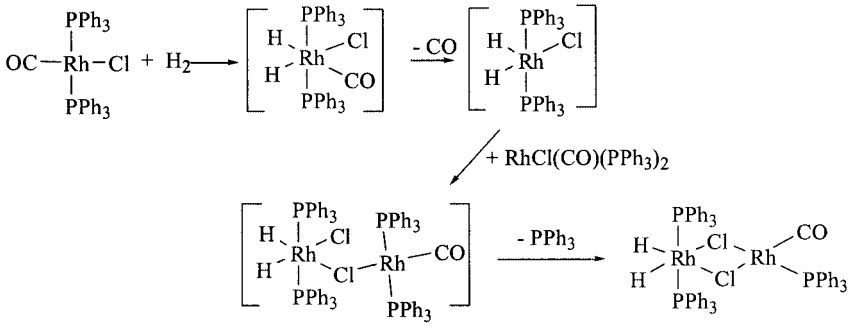


Scheme 7. Reaction of a dimeric tantalum dinitrogen complex with parahydrogen

dium complexes $[RhX(CO)(PR_3)_2]$ where X = Cl, Br, I and R = Ph, Me with *p*-H_2.[22] These complexes were previously not thought to react with hydrogen. In the case of $[RhX(CO)(PPh_3)_2]$, unexpected binuclear products of the general formula $[(H)_2Rh(PPh_3)_2(\mu\text{-}X)_2Rh(PPh_3)(CO)]$ were detected. Since the initial dihydrogen activation product $Rh(H)_2X(CO)(PPh_3)_2$ was not detected in these reactions, it was suggested that facile CO loss led to the generation of the unsaturated species $[Rh(H)_2X(PPh_3)_2]$. The proposed reaction mechanism is shown in Scheme 8.

Surprisingly, when the reaction of $[RhCl(CO)(PMe_3)_2]$ was monitored at 348 K under 3 atm of *p*-H_2, the major product corresponded to $[H(Cl)Rh(PMe_3)_2(\mu\text{-}H)(\mu\text{-}Cl)Rh(PMe_3)(CO)]$ with bridging and terminal hydride li-



Scheme 8. Suggested route to $[(H)_2Rh(PPh_3)_2(\mu\text{-}Cl)_2Rh(PPh_3)(CO)]$, formed in the reaction of $[RhCl(CO)(PPh_3)_2]$ with *p*-H_2

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gands. However, when $RhI(CO)(PMe_3)_2$ was monitored, the reaction complexity increased still further and several new species were detected. A typical ^1H NMR spectrum from such a reaction is shown in Figure 5. Density functional theory indicated that all structural types correspond to reaction intermediates rather than transition states and Scheme 9 shows how they are formed.

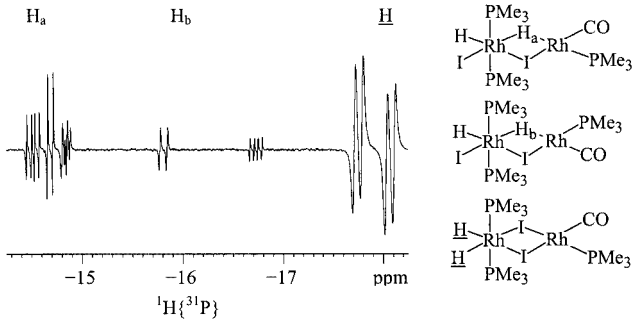


Figure 5. $^1H\{^{31}P\}$ NMR spectrum showing the hydride region after warming a sample of $[RhI(CO)(PMe_3)_2]$ with p-H_2 in C_6D_6 to 348 K; selected product resonances indicated by H_a, H_b and H are assigned according to the inset structures

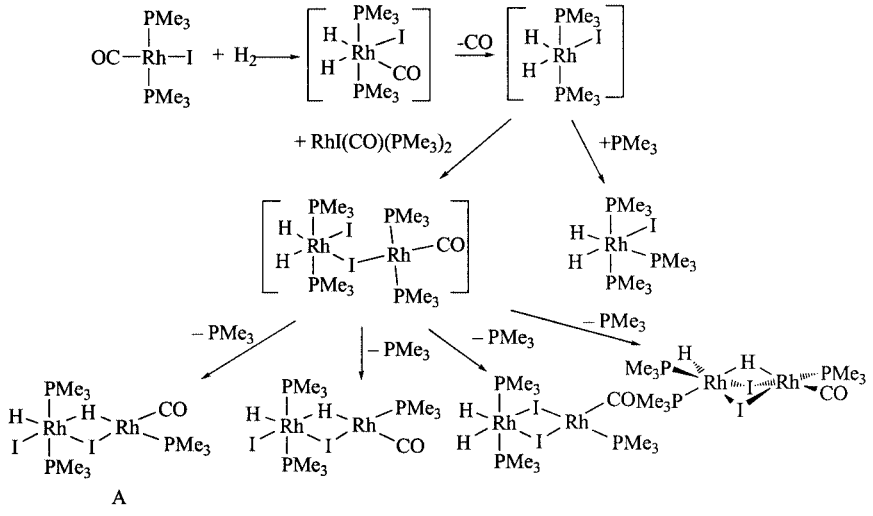
Significantly, when the reaction involving $[RhCl(CO)(PMe_3)_2]$ with p-H_2 was monitored in the presence of styrene, a dramatic increase in the hydride ligand's signal enhancement was observed. This facilitated the detection of $[(H)_2Rh(PMe_3)_2(\mu\text{-}Cl)_2Rh(CO)(PMe_3)]$ and $[HRh(PMe_3)_2(\mu\text{-}H)(\mu\text{-}Cl)_2Rh(CO)(PMe_3)]$ and demonstrated that a sacrificial alkene can dramatically extend the sensitivity of the parahydrogen method by promoting H_2 cycling through the system.[22]

Koch et al. have reported a number of similar complexes that were produced by studying the reactions of the binuclear complex $[RhCl(NBD)_2]_2$ with a range of phosphanes in-situ.[23] The authors noted that if the chloride ligand was replaced by TFA, only mononuclear complexes were observed. More importantly, this paper also described the construction of an apparatus designed to monitor reactions with p-H_2 in situ, by bubbling the gas through the NMR sample via a capillary prior to data acquisition. An NMR method was also reported that eliminated the interference of resonances from unpolarised spin systems. Furthermore, when $[RhCl(NBD)_2]_2$ was examined in methanol at low temperature and in the absence of substrate, an enhanced solvent complex was detected.[24] These techniques have also been used to investigate $SnCl_3$-activated rhodium dihydride complexes.[25] For example, oxidative addition of p-H_2 to the $[RhH(SnCl_3)_5]^{3-}/PR_3$ system (where PR_3 = PPh_3, $PEtPh_2$, PEt_3) in CD_3CN and to $[RhCl(CO)_2]_2/SnCl_2$ yielded enhanced hydride resonances in neutral complexes of the type $Rh(H)_2(PR_3)_3(SnCl_3)$, anions of the form $[Rh(H)_2(PR_3)_2(SnCl_3)_2]^-$, and cations of the form $[Rh(H)_2(PR_3)_3(CD_3CN)]^+$. The relative abundance of these products was found to depend crucially on the type of phosphane. These systems were shown to be active catalysts for the hydrogenation of phenylacetylene.

Another example of the use of parahydrogen in the study of binuclear complexes involved iridium, rhodium and mixed-metal A-frame complexes.[26] For $[Ir_2(\mu\text{-}S)(CO)_2(dppm)_2]$, where dppm = bis(diphenylphosphanyl)methane, reaction with hydrogen was found to proceed by two addition pathways corresponding to oxidative addition inside (*endo*) and outside (*exo*) the pocket of the A-frame complex. The previously unseen *exo* addition pathway yields a kinetically significant dihydride that is a key intermediate in the formation of the thermodynamic product of this reaction (Scheme 10).

5. Applications to Transition-Metal Clusters

Due to the presence of multiple metal atoms in transition-metal clusters, the potential reaction pathways of these species are much more complicated than those available to mononuclear complexes. The study of such species



Scheme 9. Reaction pathways available to $[RhCl(CO)(PMe_3)_2]$ that are detected due to the use of p-H_2; when I is replaced by Cl, only A is detected normally, but in the presence of an alkene the four other structural types are also visible in solution

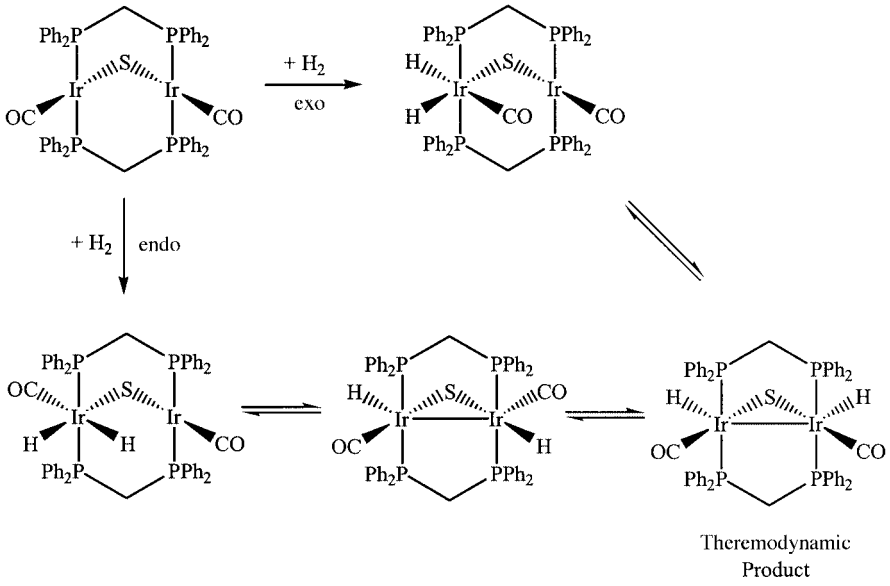

Scheme 10. Hydrogen addition reactions involving an iridium A-frame complex detected by *p*-H_2

might therefore be expected to benefit greatly from the enhanced sensitivity afforded by *p*-H_2.

Aime et al. have utilised a triruthenium system to demonstrate that the transfer of polarisation from NMR-silent *para*-hydrogen to NMR-active *ortho*-hydrogen could be achieved via an intermediate with inequivalent hydrides, as shown in Scheme 11.[27] This phenomenon occurs because the symmetry of parahydrogen is broken in the intermediate, with subsequent H_2 elimination occurring rapidly relative to proton relaxation. Under such conditions, the eliminated H_2 molecule retains a "memory" of the intermediate and is consequently polarised. In practice, under these conditions, a strong emission signal is observed for the free hydrogen resonance.

In York, our work in the area of cluster chemistry developed from the study of the reactions of $[Ru(H)_2(CO)_3(PPh_3)]$ and $[Ru(H)_2(CO)_2(PPh_3)_2]$ with *p*-H_2.[28] These complexes were prepared from $[Ru(CO)_3(PPh_3)_2]$, and two dihydride isomers were detected in both cases, as shown in Scheme 12. The former species was also generated by fragmentation of the trinuclear cluster $[Ru_3(H)(\mu\text{-}H)(CO)_9(PPh_3)_3]$.

Using the full repertoire of NMR approaches illustrated in this review, we have gained insights into the dynamic behaviour and catalytic activity of the triruthenium clusters $[Ru_3(CO)_{12-x}(PR_3)_x]$ (where PR_3 = PPh_3, PMe_2Ph, PMe_3, PCy_3; x = 1−3). Thus, when x = 2, oxidative addition of *p*-H_2 results in the formation of three isomers of $[Ru_3(H)(\mu\text{-}H)(CO)_9(PR_3)_2]$, which differ in the arrangement of their equatorial phosphanes: while one isomer contains both phosphanes on the same ruthenium centre, in the other two the phosphanes are located in different orientations on separate metal centres (see Figure 6).[29] These dihydride products were fully characterised in situ by ^1H, ^{13}C and ^{31}P NMR spectroscopy. Kinetic studies revealed the presence of intra- and inter-isomer hydride exchange processes, with activation parameters and solvent effects indicating the involvement of ruthenium−ruthenium bond heterolysis and CO loss in the respective rate-determining steps. When x = 3, reaction with H_2 proceeds to form identical products to those found with x = 2, although at a slower rate, while when x = 1 a single isomer of $[Ru_3(H)(\mu\text{-}H)(CO)_{10}(PR_3)]$ is formed.

The three isomers of $[Ru_3(H)(\mu\text{-}H)(CO)_9(PPh_3)_2]$ were shown to play a kinetically significant role in the hydrogenation of an alkyne substrate via initial CO loss (see Figure 7), with rates of H_2 transfer being explicitly determined for each isomer.[30] This was achieved by using EXSY to monitor the movement of parahydrogen-enhanced nuclei in complexes that are normally invisible. A less-significant

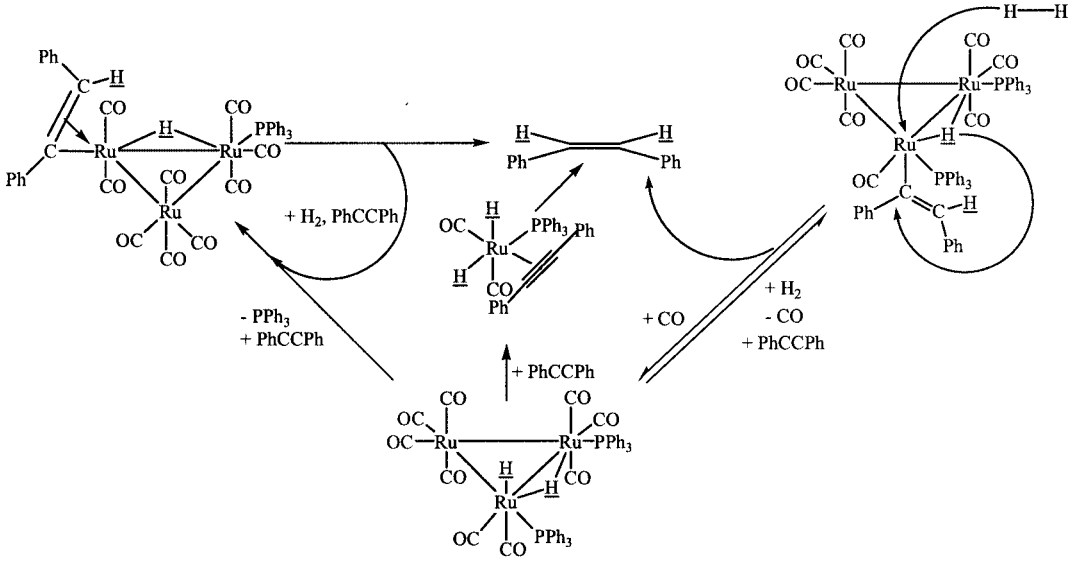
secondary reaction involving loss of L to yield a product containing both a pendant vinyl unit and a bridging hydride ligand was also observed, as were competing pathways involving fragmentation to form the less-active species $[Ru(H)_2(CO)_2(L)(alkyne)]$. The mechanism of catalytic hydrogenation is shown in Scheme 13. The abundance of the dihydride intermediates formed was shown to increase with the steric bulk of the phosphane, while their catalytic activity increased with the basicity of the phosphane, such that PPh_3 was the optimum phosphane for catalysis.[31] Significantly, polar solvents were found to facilitate catalysis by intact clusters while non-polar solvents led to increased cluster fragmentation. Furthermore, the activity of cluster-based intermediates was shown to be much greater than that of mononuclear fragments, a discovery with important implications for the study of catalysis by transition metal clusters.

A study of the hydrogenation of alkynes by the triosmium cluster $[Os_3(\mu\text{-}H)_2(CO)_{10}]$ led to the detection and characterisation of a range of vinyl hydride clusters.[32] Here, transfer of *p*-H_2 nuclei into the bound organic substrates was detected without alkene elimination. Parahydrogen has also been employed to support classical methods in the study of transition metal clusters during the investi-



Scheme 13. Proposed catalytic cycle for the hydrogenation of diphenylacetylene by $[Ru_3(H)(\mu\text{-}H)(CO)_9(PPh_3)_2]$

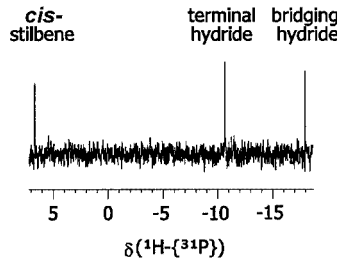

Figure 7. $^1H\{^{31}P\}$ EXSY spectrum obtained during the reaction of $[Ru_3(CO)_{10}(PPh_3)_2]$ with parahydrogen and diphenylacetylene in CD_3NO_2; the resonance corresponding to the terminal hydride of $[Ru_3(H)(\mu\text{-}H)(CO)_9(PPh_3)_2]$ was selectively excited; direct transfer of magnetisation into the bridging site on the cluster and into the hydrogenation product *cis*-stilbene are clearly evident after 700 ms

gations of hydride exchange in $[Os_3(\mu\text{-}H)_2(CO)_{10}]$.[33] Initially, studies using a mixture of H_2 and D_2 led to the proposal that the exchange proceeds via the formation of an $[Os_3(H)_2(D)_2(CO)_{10}]$ species, which is then able to undergo an H-D exchange prior to eliminating a hydrogen molecule as either H_2, HD or D_2. With the signal gain afforded by *p*-H_2, the existence of this process was confirmed and the tetrahydride intermediate was detected. In addition, a second pathway where H_2 dissociates from the cluster to yield a highly unsaturated $[Os_3(CO)_{10}]$ moiety was observed. This latter process results in no isotopic mixing. The rates for the two processes were determined via EXSY methods and subsequent kinetic simulations. It was found that the pathway involving initial hydrogen dissociation was much slower, but its efficiency and importance increased with temperature. More recently, a *p*-H_2 study involving triosmium μ_3-quinolyl trihydride clusters demonstrated that trihydride-containing clusters can be studied using this approach with all three hydride resonances showing polarisation due to fluxionality and cross polarisation effects.[34]

6. Catalytic Studies

Additional catalytic studies have been completed by Bargon et al., who have developed the DYPAS (DYnamic PASadena) method to measure reaction rates.[35] This method, based on the earlier ROCHESTER approach,[36] can be used to determine the rate of any process that involves the formation and decay of a parahydrogen signal. DYPAS involves the introduction of a variable delay between the addition of *p*-H_2 to the system and the 45° excitation pulse, yielding a plot of intensity versus time (see Figure 8). If the mechanistic scheme for the process is known, then the signal decay can be described by a series of differential equations, which can be solved to yield specific rate constants.

Hydrogenation reactions have also been studied using one-dimensional sequences involving the NOESY and ROESY effects. For example, in a study of styrene hydrogenation by $[Rh(dppb)]^+$, two sets of enhanced resonances were observed for the ethylbenzene hydrogenation product.[37] Using NOESY, it proved possible to determine that one of these signals corresponded to free ethylbenzene, while the other was due to ethylbenzene still bound to the Rh catalyst.

PHIP methodology has also been used to study stereoselective hydrogenation reactions. This approach relies on the difference between $^2J_{H,H}$ values for *E* and *Z* alkenes. For instance, Bargon et al. have shown that when [Cp* Ru(alkene)]$^+$ was the catalyst, non-phenyl-substituted alkynes selectively formed the (*E*)-alkene while phenyl-substituted alkynes did likewise at low temperature, but increasingly favoured the (*Z*) isomer as the temperature was raised.[38] The same group has also reported several investigations into the homogeneous hydrogenation of dehydroamino acids using parahydrogen.[39] This work included the determination of the reaction mechanism and the quantification of the reaction rate. Interestingly, the intermediates detected in this reaction (see Figure 9) suggested that an initial agostic hydride species was formed (as evidenced by the ^1H resonance at the unusual δ value of −1.9 ppm, which exhibited a strong $^1J_{H,C}$ coupling of 86 Hz) that subsequently yielded an alkylhydride, which is the active species in hydrogenation.

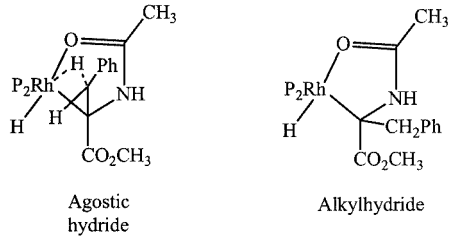

Figure 9. Intermediates detected during homogeneous hydrogenation of dehydroamino acids, where P_2 = PHANEPHOS

If a hydrogenation reaction is rapid, polarisation-transfer effects can be utilised to study secondary reactions and hence more complex catalytic transformations can be inves-

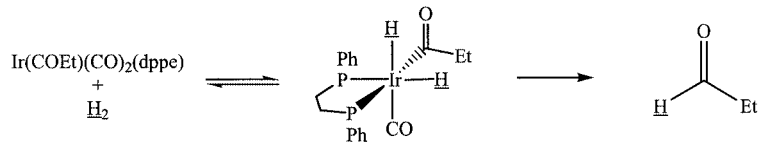

Scheme 14. System used by Eisenberg to detect one-hydrogen PHIP; the marked protons give rise to enhanced resonances

tigated. For instance, Koch et al. monitored the hydrogenation of 1-phenylpropyne by a Rh^I catalyst.[40] In the presence of parahydrogen, enhanced resonances for the product *cis*-1-phenylpropene are observed. If a dilute solution of bromine was added in situ, the subsequent alkane, 1,2-dibromo-1-phenypropane, proved also to be enhanced. This species has two chiral centres, and both diastereoisomers were detected.

This review has already illustrated how PHIP can be used to observe heteronuclei via radio frequency mediated polarisation transfer. However, if hydrogenation occurs in a weak magnetic field (i.e. outside the spectrometer), the resulting spin systems are strongly coupled and efficient polarisation transfer from ^1H to heteronuclei becomes possible via cross-relaxation and can be detected as the ALTADENA effect. A nice example of this result is provided by the hydrogenation of long-chain alkynes (4−8 carbon atoms), where polarisation of all the ^{13}C nuclei in the carbon chain of the alkene is observed.[41]

Very recently, a hydroformylation product containing a single parahydrogen atom has been successfully sensitised. This result was observed during the addition of *p*-H_2 to an acetone solution of *trans*-[PtCl(COEt)(PPh_3)$_2$] and $SnCl_2$ (see Scheme 14), as well as to [Ir(COEt)(CO)$_2$(dppe)]. These systems initially form dihydride products that subsequently eliminate propanal; this product appears with an enhanced aldehydic proton resonance.[42] This effect, termed OH-PHIP (one-hydrogen PHIP) was considerably weaker than regular PHIP and was attributed to the strong coupling that exists between the protons in the initial dihydride product.

7. Other Developments

In addition to the above examples, there have been a number of novel applications of the PHIP phenomenon that stand on their own. For example, Ulrich et al. have reported PHIP hydrogenation experiments in the presence of NMR shift-reagents.[43] The lanthanide shift-reagents cause resonance shifts due to their paramagnetic character, which unfortunately also quenches the parahydrogen enhancement. While small amounts of a racemic shift-reagent were sufficient to cause a substantial resonance shift without fully quenching the parahydrogen, the use of chiral shift-reagents yielded only a small perturbation. The authors concluded that the amount of shift-reagent required was too large to be tolerated by the parahydrogen and that optically active solvents would provide a better method to differentiate enantiomers using PHIP.

Parahydrogen has also been utilised to investigate colloidal catalysis.[44] The reaction of phenylacetylene with hydrogen using the colloidal palladium catalyst Pd_x[N(octyl)$_4$Cl]$_y$ was observed to yield enhanced signals in the product species. In another study, PHIP was used to study reversible H_2 adsorption on ZnO.[45] A prominent enhancement pattern was observed, which was attributed to *p*-H_2 chemisorbed on ZnO. Furthermore, parahydrogen has recently been employed in magnetic resonance imaging (MRI), where it was used to obtain enhanced ^{13}C resonances in vivo via initial polarisation transfer outside the strong field of the spectrometer, corresponding to the utilisation of ALTADENA.[46] Although only preliminary, these studies represent new opportunities for the PHIP effect.

Pendent Arm Formation and Extension accompanying Macrocycle Synthesis – A New Class of Ryongamines?

Jack Harrowfield,*[a] Yang Kim,*[b] Young Hoon Lee,[b] and Pierre Thuéry[c]

Keywords: Macrocycles / Pendent arm / X-ray diffraction

Reaction of the Cu^{II} complex of the podand hexamine "sen", $CH_3C(CH_2NHCH_2CH_2NH_2)_3$, with formaldehyde and nitroethane under basic conditions provides, as one of the principal products, a complex containing a new ligand which is not only macrocyclic but which has resulted also from reactions to extend one podand arm, to introduce an aminal bridge and to oxidise one of the donor-*N* atom units to an imine.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Formaldehyde has been used in a remarkable variety of reactions with polyamines to give macrocyclic and macropolycylic ligands.[1–3] Aminal formation — in general a useful pathway in macrocycle synthesis[4] — is commonly involved in these reactions, as is carbon-carbon bond formation through carbanion addition to intermediate imines, although for a particular product it is usually either one or the other that is involved. Macrocycle formation from the sexidentate amine ligand $CH_3C(CH_2NHCH_2CH_2NH_2)_3$, "sen",[5] when reacted as its Cu^{II} complex with formaldehyde and nitroethane, appears, however, as we show presently, to involve a competition between these two pathways, leading to a product macrocycle with a pendent arm which is both tied back to the macrocycle by an aminal bridge and elongated as a result of carbanion addition to a presumed imine formed at the terminal amino group. Further, the ligand then appears to have undergone alkylation by formaldehyde at the carbon atom derived from nitroethane in the extended arm, as well as partial oxidation within the macrocyclic ring to convert one N-donor unit to an imine!

For metal ions favouring octahedral coordination, the coordination chemistry of sen has been fairly well characterised[6] but surprisingly little is known of the behaviour of this ligand towards Cu^{II}. Evidence is available,[7] however, that a homologue of sen will bind to Cu^{II} through only four of its six *N*-donor atoms and, given the propensity of Cu^{II} to adopt four coordination even in systems such as those involving potentially sexidentate cage amines,[8] it was anticipated that the widely applied reaction of Cu^{II} tetraamine complexes with formaldehyde and nitroethane to give macrocycles[1–3] might, in this case, lead to a macrocycle with a pendent diamine arm. Such a macrocycle could then be used in the formation of multimetallic complexes through, for example, the formation (and capping) of a tris(bidentate) metal complex from the donor atoms in the pendent arm. There are many possible complications in this system arising from isomerism of the complex ions and thus we have attempted, as a preliminary step, to define precisely the chemistry involved in the reaction of the Cu^{II} complex of sen with nitroethane and formaldehyde. This will be described in detail elsewhere, the present report being of the remarkable structure found (Figure 1) for the leading component found during chromatographic treatment (SP Sephadex cation exchange with 0.3 M sodium citrate as eluent) of the reaction mixture inadvertently prepared with the use of a very large excess of formaldehyde.

Results and Discussion

The ligand structure (inset, Figure 1) shows that two arms of the original sen ligand have indeed become involved in the anticipated cyclisation reaction to give a cyclam-like[9] macrocycle but also that the third arm, singly protonated in the isolated complex, has become involved in elaborate related reactions leading to a partially rigidified pendent arm in which two new functional groups — hydroxyl and nitro — have been added to the diamine entity. Further, a reaction well-known with other metal ion complexes of amines but rarely observed with Cu^{II} [10] has led

to the partial oxidation of the macrocyclic ring, converting one amine donor to an imine. As seen in many related instances,[11] the crystal structure of the complex shows the nitro and methyl substituents on the macrocyclic ring to adopt axial and equatorial orientations, respectively, on the chair six-membered ring formed by the macrocyclisation process. Despite this aspect of stereospecificity, there is disorder associated with the chiral centre generated on the

pendent arm, indicating a complete lack of diastereoselectivity in the crystallisation process. This is perhaps in part a consequence of the rigidification of the pendent arm by aminal formation, giving a six-membered heterocyclic ring, between donor atoms N3 and N6, and which may inhibit any significant interaction between the chiral donor centres on the metal and the chiral centre near the arm terminus. A simplified representation of a possible sequence of events leading to the complex is given in Figure 2. Clearly, reduction of the product complex under acidic conditions can be expected to generate a saturated, chiral octaamine-mono-ol ligand in which a macrocyclic unit has two, very different amino-pendent arms in an *anti* (*trans*) arrangement relative to the macrocycle mean plane. The chemistry involved is a remarkably simple pathway to a ligand of such a sophisticated structure, though the detection of the product was a completely fortuitous consequence of an error made in the quantity of formaldehyde used and a systematic evaluation of procedures to optimise the yield of the complex is now in progress. The prospects are that a wide range of podand ligands might be used in similar reactions and our perception of a resemblance between the structure of the molecule presently described and classical oriental representations of a dragon (see graphical abstract), prompts us to suggest the trivial name "ryongamines" for this class of macrocycle, "ryong" being the romanised form of the Korean word for dragon.

Experimental Section

Synthesis: A methanolic solution of sen was prepared by slurrying sen·6HCl[6b] (1.20 g) with NaOH (0.62 g) in methanol (100 mL) and mixed with $CuCl_2 \cdot 2H_2O$ (0. 70 g) in 1:1 water/methanol (100 mL). The resulting blue-violet solution was filtered to remove some $Cu(OH)_2$ before HCHO (36% aqueous solution, 10 g), nitroethane (0.40 g) and triethylamine (4 g) were added and the mixture then heated at reflux for 12 h. On cooling to room temperature, the reaction mixture was acidifed to pH 6 with acetic acid and taken to dryness under vacuum. The residue was dissolved in water and chromatographed on Na^+-form SP Sephadex C25 with 0.13 M sodium citrate. Separate eluate fractions were absorbed on H^+-form Dowex 50Wx2 and elution with HCl used to recover the complexes as their chlorides after evaporation of the solvents to dryness. The first component thus obtained is the subject of the present communication and was precipitated from water as its perchlorate (50 mg) for the structure determination. $C_{20}H_{44}Cl_3CuN_8O_{18.5}$ (862.5): calcd. C 27.59, H 5.09, N 12.87; found C 27.6, H 6.7, N 12.3.

X-ray Crystallography: Data were collected on a Nonius-Kappa-CCD area detector diffractometer[12] using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The crystal was introduced in a glass capillary with a protecting "Paratone-N" oil (Hampton Research) coating. The unit cell parameters were determined from ten frames, then refined on all data. A 180° -range was scanned with 2° steps during data collection, with a crystal-to-detector distance fixed at 28 mm. The data were processed with DENZO-SMN.[13] The structure was solved by Patterson-map interpretation with SHELXS-97[14] and refined by full-matrix least-squares on F^2 with SHELXL-97.[14] Absorption effects were corrected empirically with the program DELABS from PLATON.[15] The terminal CH_2OH and CH_3 groups of the pendent arm are disordered so that each fragment bears a partially occupied oxygen atom site (occupancies constrained to sum to unity). One perchlorate ion is disordered over two sites sharing three oxygen atoms, the disordered chlorine and oxygen atoms having been refined with occupancy parameters constrained to sum to unity. All non-hydrogen atoms were refined with anisotropic displacement parameters, with some restraints for some oxygen atoms of the pendent arm, perchlorate ions and water molecules. Hydrogen atoms bound to nitrogen atoms were found on a Fourier-difference map and all others were introduced at calculated positions, except those bound to oxygen atoms. All protons were treated as riding atoms with a displacement parameter equal to 1.2 (NH, NH_2, CH, CH_2) or 1.5 (CH_3) times that of the parent atom. The molecular plot was drawn with SHELXTL.[16]

Crystal Data and Refinement Details: $C_{20}H_{44}Cl_3CuN_8O_{18.5}$, M = 862.52, triclinic, space group $P\bar{1}$, a = 11.8592(6), b = 12.3654(11), c = 13.3374(13) Å, α = 78.768(4)°, β = 81.703(6)°, γ = 61.386(5)°, V = 1681.1(2) Å^3, Z = 2, D_c = 1.704 g cm^{-3}, $F(000)$ = 896, μM_o = 0.979 mm^{-1}, T = 100(2) K. Refinement of 484 parameters on 5790 independent reflections out of 11446 measured reflections (R_{int} = 0.066) led to R_1 = 0.073, wR_2 = 0.183, S = 1.013, $\Delta\rho_{max}$ = 1.14 e·Å^{-3}.

Silver(I) Complex Crystals Switched by a Water Molecule

Hidekazu Arii,[a] Yamato Saito,[a] Yasuhiro Funahashi,[a] Tomohiro Ozawa,[a] Koichiro Jitsukawa,[a] and Hideki Masuda*[a]

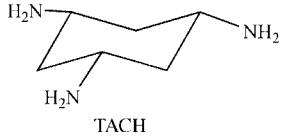
Keywords: Coordination polymers / Hydrogen bonds / Silver

The reaction of $AgPF_6$ and *cis*,*cis*-1,3,5-triaminocyclohexane (TACH) in a 1:1 ratio in methanol solution gave two different coordination polymer crystals depending on the presence/absence of water. The crystal structure in the absence of water is a one-dimensional, tube-like polymer with formula $\{[Ag^{I}(TACH)]PF_6\}_n$, while in the presence of water the structure is a three-dimensionally expanded complex network built up from cage units containing a water molecule, $\{[Ag^{I}_3(TACH)_4](PF_6)_3{\cdot}H_2O\}_{ni}$ this structure is induced even by a trace amount of water.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Molecular regulation at the nanometer-scale level is very important and interesting from the viewpoint of the design and synthesis of nanoporous materials. The investigation of nanoporous compounds prepared by the self-assembly of metal ions and organic compounds has been investigated extensively.[1] Metal ions are often used as a junction between organic molecules as their characteristic geometries — such as trigonal planar, tetragonal planar, tetrahedral, and octahedral — allow the construction of higher-dimensional structures. Recently, some interesting compounds based on non-covalent interactions have been reported. Catenanes are formed by only a π-π interaction between aromatic rings,[2,3] and Aoyama et al. have succeeded in preparing organic zeolites linked by a hydrogen bond.[4]

The hydrogen bond is one of the most important non-covalent interactions in biological systems, and it plays an important role in the stabilization of DNA-protein structures and in mutual recognition between proteins.[5] Such non-covalent interactions contribute significantly to the formation of high-dimensional structures in DNA and/or proteins, even in water. The hydrogen bond participates clearly in such structure maintenance and recognition.[6] However, it is difficult for small molecules to interact intermolecularly in water through hydrogen bonding as the water behaves as an inhibitor. These facts imply that the water molecule is one of the essential factors in the steric interaction of DNA-proteins, although it functions as an inhibitor, too. Recently we prepared a new nanoporous material from the reaction of Cu^{I} ion and *cis*,*cis*-1,3,5-triaminocyclohexane (TACH),[7] in which we used the characteristics of the Cu^{I} ion and TACH ligand: the former prefers two-coordinate linear, three-coordinate trigonal-planar, or four-coordinate tetrahedral structures and the latter has C_{3v} symmetry. In this study, using the Ag^{I} ion instead of Cu^{I}, the reaction of $AgPF_6$ with TACH at 1:1 was carried out. Interestingly, two different complex crystals were prepared in absolute methanol and in methanol/water solutions, indicating that the formation of these silver complex crystals was discriminatively switched by the presence of a water molecule. This water-induced transformation of supramolecular structures in the crystalline state is quite novel, although it has been reported that the supramolecular structures of silver(I)-polynitrile complexes are transformed into each other by a similar anion exchange in the crystalline state.[8] Here we describe the preparation and structural characterization of their complexes in detail.



TACH

Results and Discussion

A methanol solution of TACH was added to an absolute methanol solution of $AgPF_6$ in a 1:1 ratio. Allowing the reaction solution to stand for a few hours afforded a colorless crystal suitable for an X-ray diffraction measurement, which was identified as $\{[Ag^{I}(TACH)]PF_6\}_n$ (**1**) from the elemental analysis. Complex **1** crystallizes in the monoclinic system with space group $P2_1/n$. It contains one Ag^{I} ion, one

TACH molecule, and one PF_6^- ion as crystallographically independent components of the unit cell. The Ag^I ion has a trigonal planar geometry, with coordination of three primary amine nitrogens from three TACH molecules, and the TACH molecule has a chair-form with the three amino groups oriented in the equatorial direction as expected from its *cis*,*cis*-conformation. The Ag^I and TACH units are linearly linked to each other to form a tube-like structure with a small pore of ca. 4×4 Å^2, as shown in Figure 1B, which is a one-dimensional infinite coordination polymer related by a crystallographic screw axis. The tube-like coordination polymers are weakly linked to each other by PF_6^- anions, as shown in Figure 1A. The tube-like coordination polymer may best be described by the formula $\{[Ag^I(TACH)]PF_6\}_n$. The Ag−N bond lengths agree well with those found in analogous Ag^I complexes reported hitherto (2.2−2.4 Å).[9] The nearest Ag−Ag distance is 5.689(3) Å.

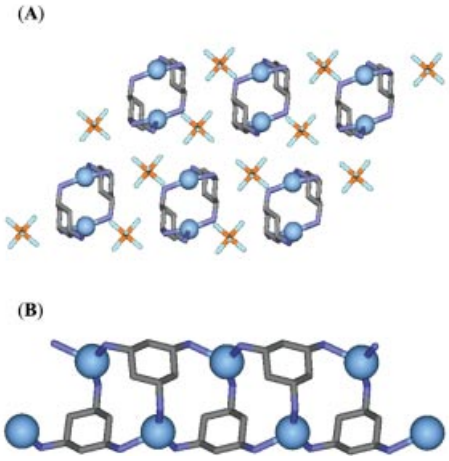

Figure 1. Wire models of the one-dimensional infinite structures of **1** viewed along the crystallographic *ac* (**A**) and *ab* planes (**B**); the blue and gray colored atoms denote nitrogen and carbon atoms, respectively; the large blue-colored atom is a silver(I) ion; hydrogen atoms have been omitted for clarity; selected bond lengths (Å) and angles (°): Ag(1)−N(1) 2.228(9), Ag(1)−N(2) 2.251(8), Ag(1)−N(3) 2.398(8); N(1)−Ag(1)−N(2) 148.4(3), N(1)−Ag(1)−N(3) 111.5(3), N(2)−Ag(1)−N(3) 100.1(3)

The addition of a methanol/water (20:1 v/v%) solution of TACH to a methanol solution of $AgPF_6$ in a 1:1 ratio and allowing the reaction solution to stand for a few hours afforded a colorless crystal suitable for an X-ray diffraction measurement. The complex was identified as $\{[Ag^I_3(TACH)_4](PF_6)_3 \cdot H_2O\}_n$ (**2**) from the elemental analysis. Complex **2** crystallizes in the cubic system with space group $I2_13$, and contains half an Ag^I ion, two units of one-third parts of TACH molecule, half a PF_6^- ion, and six units of one-sixth parts of disordered water molecules as the independent atoms in the unit cell. In spite of the same reaction conditions as for the synthesis of **1**, except for the presence of water, the crystal structure of **2** is quite different from that of **1**. The geometry around the Ag^I ion is tetrahedral, with four primary amine nitrogens from four TACH molecules, although the conformation of the cyclohexane ring and the orientation of three amino groups are the same

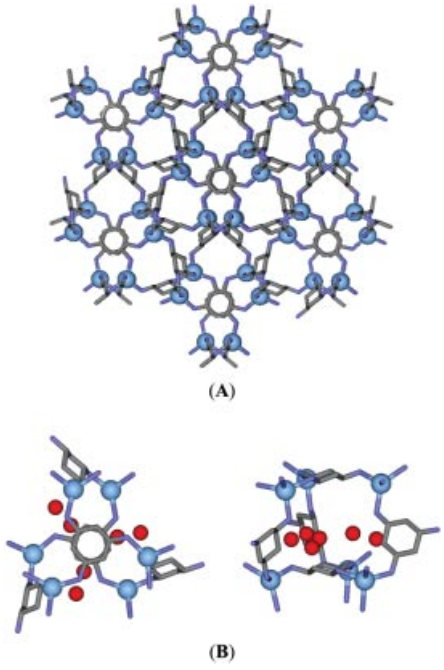

Figure 2. Wire models of the three-dimensionally expanded structure of **2** viewed along the apex of the unit cell (**A**), and top (left) and side (right) views of the cage structure (**B**) of **2** consisting of six Ag^I ions and five TACH molecules; the large blue- and red-colored atoms denote a silver ion and a disordered water molecule, respectively; the counteranions and hydrogen atoms have been omitted for clarity; selected bond lengths (Å) and angles (°): Ag(1)−N(1) 2.383(7), Ag(1)−N(2) 2.356(7); N(1)−Ag(1)−N(2) 100.9(2), N(1)−Ag(1)−N(1*) 128.8(4), N(1)−Ag(1)−N(2*) 101.0(2) (atoms with and without an asterisk are related by a crystallographic threefold axis)

as those of **1**. The dihedral angle of the two planes defined by three atoms, N(1)−Ag(1)−N(2) and N(1*)−Ag(1)−N(2*), is 69°. Judging from the bond angles (denoted in the caption of Figure 2) and the dihedral angle, the Ag^I ion is distorted from a regular tetrahedron.

As is clear from the crystal structure of **2** viewed through the apex of the unit cell (the crystallographic threefold axis), the Ag^+ ions and TACH ligands form three-dimensionally expanded networks (Figure 2). The network is made up of cage units consisting of six silver(I) ions and five TACH molecules (Figure 2B). As shown in the left and right figures of Figure 2B, exhibiting the top and side views of the cage structure, respectively, the center of the TACH molecule lies on the threefold axis and the two cyclohexane rings of the top and bottom TACHs of the cage are twisted with a rotation angle of about 30°. The cage unit is surrounded by six PF_6^- counteranions that are related by threefold axis symmetry; the inner space of the cage is occupied by disordered water molecules, which are incorporated by a hydrophilicity inside the cage. The cage contains pores with a height of about 6 Å and an inner diameter of about 4 Å based on the van der Waals radius of the atoms.[10] The existence of this porosity is also obvious from the lower density of **2** ($\rho = 1.810$ g·cm^{-3}) compared with that of **1** ($\rho = 2.054$ g·cm^{-3}).

Although **1** and **2** were prepared under the same conditions except for the absence/presence of water, respec-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tively, **1** has a one-dimensional infinite tube-like structure, while **2** exhibits a three-dimensionally expanded network structure constructed from cage units. Both **1** and **2** were obtained from the same starting materials in the same ratio ($AgPF_6$:TACH = 1:1), and **2** was isolated even in the presence of a trace amount of water. Interestingly, a crystal obtained from a suspended solution of **1** in water showed the same X-ray diffraction pattern as the simulation pattern estimated from the single crystal X-ray diffraction measurements of **2** (Figure S1; Supporting Information, see footnote on the first page of this article). A single crystal obtained from the suspended solution also exhibited the same lattice parameters as those of **2**. It is therefore clear that water promotes such a large difference in the coordination structure and the dimensionality.[11] This may be induced by the strong hydrogen bonding ability of water and the difference in the polarity or permittivity of the solvents [H_2O (ε_r = 78.3) and CH_3OH (ε_r = 32.6) at 25 °C].[12] The difference in their formula may be due to the different coordination of TACH molecules to the Ag^I ion: **1** is three-coordinate trigonal-planar and **2** is four-coordinate tetrahedral. The above facts suggest that the water raises the Lewis acidity of the Ag^I ion and assists the linkage of the TACH ligand to the Ag^+ ion. Also, based on the O···(H)N distance of about 2.9 Å, the cage structure could be derived from the hydrogen bonding interaction between the water molecule and the hydrophilic primary amine of the TACH ligands.

In conclusion, we succeeded in the discriminative preparation and structural characterization of two kinds of Ag^I coordination polymers, which gave one- and three-dimensional infinite structures from absolute methanol and from methanol/water, respectively. These structures are switched by the presence of a water molecule.

Experimental Section

$\{[Ag^I(TACH)]PF_6\}_n$ (1): A mixture of TACH (12.9 mg, 0.100 mmol) in methanol (4 mL) was added to an absolute methanol solution (4 mL) of $AgPF_6$ (25.3 mg, 0.100 mmol). After removal of an insoluble material by filtration, allowing the reaction solution to stand for a few hours gave colorless crystals of the title compound (38 mg, 25%). $C_6H_{15}AgF_6N_3P$ (382.04): calcd. C 18.86, H 3.96, N 11.00; found C 19.05, H 3.89, N 11.08.

Crystal Data: $C_6H_{15}AgF_6N_3P$, M = 382.04, monoclinic, space group $P2_1/n$ (no. 14), a = 9.608(8), b = 7.725(6), c = 17.18(1) Å, β = 104.44(1)°, V = 1235(1) Å^3, Z = 4, $\rho_{calcd.}$ = 2.054 g cm^{-3}, μ = 18.14 cm^{-1}, $2\theta_{max}$ = 55.0 °, Mo-K_α radiation (λ = 0.71070 Å), T = 173 K, R = 0.090, Rw = 0.215 (for all reflection data), and GOF = 1.30 for 2814 independent reflections with $I > 2\sigma(I)$ and 154 variables.

$\{[Ag^I_3(TACH)_4](PF_6)_3\cdot H_2O\}_n$ (2): A mixture of TACH (12.9 mg, 0.100 mmol) in methanol (4 mL) and water (0.2 mL) was added to a methanol solution (4 mL) of $AgPF_6$ (25.3 mg, 0.100 mmol). After removal of an insoluble material by filtration, allowing the reaction solution to stand for a few hours gave colorless crystals of the title compound. $C_{24}H_{62}Ag_3F_{18}N_{12}OP_3$ (1293.33): calcd. C 22.29, H 4.83, N 13.00; found C 22.68, H 4.69, N 12.86.

Crystal Data: $C_{24}H_{62}Ag_3F_{18}N_{12}OP_3$, M = 1293.33, cubic, space group $I2_13$ (no. 199), a = 16.8048(7) Å, V = 4745.7(3) Å^3, Z = 4, $\rho_{calcd.}$ = 1.810 g cm^{-3}, μ = 14.31 cm^{-1}, $2\theta_{max}$ = 54.8°, Mo-K_α radiation (λ = 0.71070 Å), T = 173 K, R = 0.066, Rw = 0.176 (for all reflection data), and GOF = 1.36 for 911 independent reflections with $I > 2\sigma(I)$ and 102 variables.

Conversion of 1 to 2: Suspension of a crystal of **1** (10 mg) in water for four days gave colorless crystals that exhibit almost the same X-ray powder diffraction pattern as that of **2** estimated from the single-crystal X-ray diffraction measurements. The single crystal obtained has the same lattice parameters as the crystal of **2**.

CCDC-212323 (**1**) and -212322 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Two Polymeric Complexes of Norfloxacin with Iron(II) and Their Magnetic Properties

Zhi-Rong Qu,[a] Hong Zhao,[a] Li-Xin Xing,[a] Xi-Sen Wang,[a] Zhen-Feng Chen,*[a] Zhi Yu,*[a] Ren-Gen Xiong,*[a] and Xiao-Zeng You[a]

Keywords: Nofloxacin / Iron / Coordination polymers / Magnetic properties / Hydrothermal synthesis

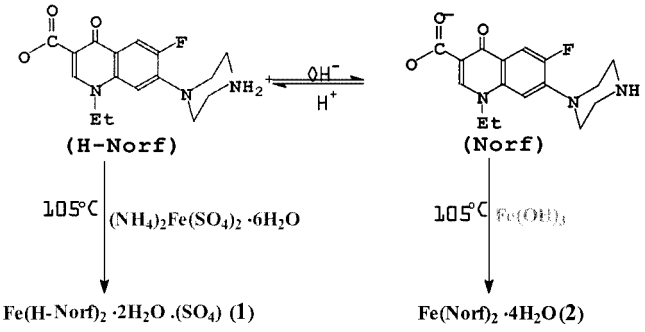
The reaction of H-Norf with $(NH_4)_2Fe(SO_4)_2{\cdot}6H_2O$ and $Fe(OH)_3$ (or Fe_2O_3) affords $Fe(H\text{-}Norf)_2(SO_4){\cdot}2H_2O$ (**1**) and $Fe(Norf)_2{\cdot}4H_2O$ (**2**), respectively, both of which have 2D polymeric structures. Their interesting magnetic properties are also reported. Crystal data for **1**: monoclinic, $P2_1/c$, a = 23.166(1), b = 10.0492(4), c = 7.7264(3) Å, β = 98.379(1)°, V = 1779.50(13) Å^3, Z = 2; for **2**: monoclinic, $P2_1/c$, a = 5.8411(12), b = 21.685(4), c = 13.265(3) Å, β = 99.20(3)°, V = 1658.6(6) Å^3, Z = 2.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Norfloxacin (H-Norf, 1-ethyl-6-fluoro-1,4-dihydro-4-oxo-7-(1-piperazinyl)-3-quinoline carboxylic acid), an extremely potent antibacterial agent with a wide spectrum of activity, is increasingly used for the treatment of many infections.[1] The suggested modes of action of H-Norf are either an inhibition of metalloenzyme DNA-gyrase or an interaction with the DNA molecule via a metal complex intermediate, and it has been proposed that a copper or iron complex could be involved in these interactions with DNA.[2] Some quinolones inhibit the cytochrome P450 system, which also involves an iron(II) ion, and it has been reported that iron(II) sulfate impairs the absorption of quinolones due to the formation of chelates.[3] To date, no solid-state structure of an Fe-quinolone complex has been available to support this theory.

Iron deficiency anaemia is rather common but can be treated easily. By comparison, iron overload disease (IOLD) is relatively rare but can result in serious medical complications, including cirrhosis, primary liver cancer, diabetes, cardiomyopathy and arthritis. Since humans are unable to actively excrete iron, excess iron, once taken up, deposits in tissue in the form of solid FeOOH which then can lead to organ damage and ultimately death. More than 500000 patients world-wide who suffer IOLD (haematological defects such as β-thalassaemia major) can be treated by an iron chelator such as Desferal (siderophore desferrioxamine-B).[4] To date, no reaction product of a metal ion with quinolone derivatives is known to be a polymeric structure both in weakly acidic and basic solutions, although a number of metal ion complexes have been reported.[5] To our surprise, the reaction of H-Norf with $(NH_4)_2Fe(SO_4)_2{\cdot}6H_2O$ and $Fe(OH)_3$ (or Fe_2O_3) affords $Fe(H\text{-}Norf)(SO_4){\cdot}2H_2O$ (**1**) and $Fe(Norf)_2{\cdot}4H_2O$ (**2**) (Scheme 1), respectively, both of which have a 2D polymeric structure. Herein we report the synthesis of **1** and **2**, their solid-state structures, and magnetic properties.



Scheme 1

Results and Discussion

Crystals of dark brown **1** and brown-red **2** were harvested from the reaction of H-Norf with $(NH_4)_2Fe(SO_4)_2{\cdot}6H_2O$ and $Fe(OH)_3$, respectively (Scheme 1). The IR spectra of both **1** and **2** show two very strong peaks at 1621 and 1571cm^{-1} for **1**, and 1621 and 1462 cm^{-1} for **2**, indicating that the carboxylic acid groups of H-Norf are deprotonated (in comparison, those of free H-Norf are at 1710 and 1621 cm^{-1}). A strong peak at 1023 cm^{-1} in the IR spectrum of **1** indicates that there is an uncoordinated SO_4^{2-}. It is

interesting to note that in weakly basic solution the N atom of the piperidyl ring can take part in the coordination to the metal ion, while in weakly acidic solution, this N atom is protonated and does not bind to the metal ion, as evidenced by the crystal-structure determinations below. Both **1** and **2** are insoluble in common solvents. The solubilities of **1** and **2** in water were estimated by ICP-AE (Inductively Coupled Plasma-Atomic Emission) to be 0.2 and 0.03 μg/mL, respectively.

The X-ray crystal analysis of **1** revealed that the Fe^{II} ion is coordinated in a distorted octahedral geometry defined by six oxygen atoms from four different H-Norf ligands (Figure 1). Two H-Norfs afford one 4-oxo and one carboxyl oxygen to bind Fe^{II} to form two six-membered rings and one equatorial plane defined by O(1), O(2), O(1A) and O(2A), while the apical positions are occupied by two oxygen atoms [(O3B) and O(3C)] from two different carboxylates of H-Norf. Thus, the carboxylate group of H-Norf in **1** clearly binds in a bidentate manner and links the $Fe(H\text{-}Norf)_2$ unit to form a 2D framework, as shown in Figure 1 (bottom). The framework core, composed of the 4-oxo and the 3-carboxyl oxygen atoms, is like a small 2D square grid. The N atom of the piperidyl ring in **1** loses its coordination capacity as a result of protonation. The crystal packing view also indicates that the anions (sulfate) and water are intercalated between two adjacent layers (see Supporting Information). There are also many hydrogen bonds, such as those between water and sulfate (2.547 Å), and water and the protonated N atom (2.711 Å), that hold two adjacent layers together.

The apical positions in **2** (Figure 2), unlike those in **1**, are occupied by two N atoms [N(1) and N(2)] of piperidyl rings,

resulting in the formation of a 2D square grid with a cavity dimension of 13.538 × 13.538 Å.[6] The coordination environment around Fe^{II} in **2** is also slightly distorted octahedral with an equatorial plane defined by O(2), O(3), O(2A) and O(3A) from two different Norfs. Unlike in **1**, the carboxylate group of Norf in **2** acts as monodentate ligand, and one of the O atoms of the carboxylate group is uncoordinated. This mode of bonding is similar to that of $Zn(Norf)_2{\cdot}4H_2O$.[5h]

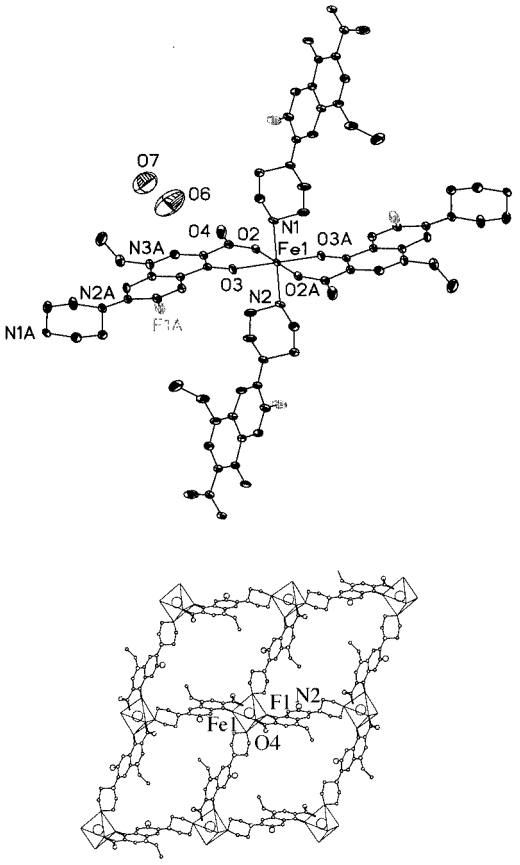

Figure 2. (top) An ORTEP symmetric unit diagram of $[Fe(Nor)_2]{\cdot}4H_2O$ (**2**); H atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Fe(1)−O(2) 2.067(2), Fe(1)−O(3) 2.105(2), Fe(1)−N(1) 2.303(3); O(2)−Fe(1)−O(3) 84.99(9), O(2)−Fe(1)−O(3A) 95.01(9), O(2)−Fe(1)−N(1B) 89.73(9), O(2A)−Fe(1)−N(1B) 90.27(9), O(3)−Fe(1)−N(1B) 92.90(10), O(3A)−Fe(1)−N(1B) 87.10(10); (bottom) an extended 2D molecular square presentation of $[Fe(Nor)_2]{\cdot}4H_2O$ (**2**) highlighting the Fe octahedron

Studies of the magnetic susceptibility of **1** versus temperature (Figure 3) show strong antiferromagnetic coupling between 20 K and 300 K and a weak ferromagnetic phenomenon at lower temperatures (5−20 K). In contrast, **2** shows a weak ferromagnetic interaction throughout this whole temperature range. This is in good agreement with the shorter distance between the Fe ions in **1** than in **2**. At room temperature the value of $\chi_{mol}T$ (≈3.5 cm^3/mol K) for both compounds is rather close to the expected value for ferrous ion ($S = 2$) in a high-spin state; this was confirmed by Mössbauer spectra at room temperature. However, $\chi_{mol}T$ for **1** is discontinuous around 15 K, which is indicative of a magnetic phase-transition originating from a spin-canting phenomenon as a consequence of neighboring spin units of iron being aligned in a canted antiparallel manner.[7] The magnetization of **1** at 5 K performed up to 50 kOe (Figure 4) shows that the field dependence of the magnetization departs from linearity. A hysteresis loop at very low magnetic field range (< 2000 Oe) was obtained. When the magnetic field was cycled, a remnant magnetization of about 0.3 μ_B and a coercive field of about 130 Oe were observed as a result of magnetic ordering at this temperature. This observation shows that **1** is a hard magnet material.

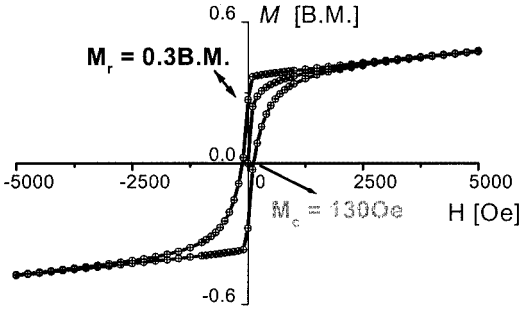

Figure 4. The magnetization of **1** in an applied field of −5 kOe to 5 kOe

In conclusion, the reaction products of H-Norf with iron(II) were found to be mainly dependent upon the pH of the solutions. In basic solution, the product is a 2D square network involving the coordination of the N atom of the piperidyl ring to iron(II), while in weakly acidic solution the product is also a 2D framework with a μ_3-carboxylate coordination mode.

Experimental Section

Compound 1: Samples of 1 mmol of $(NH_4)_2Fe(SO_4)_2{\cdot}6H_2O$ and 2 mmol of H-Norf were thoroughly mixed in a mortar with a pestle, and placed in thick-walled Pyrex tubes (ca. 20 cm long; pH ≈ 5.8 in the solution). After addition of 0.5 mL of EtOH and 1.5 mL of H_2O, the tube was frozen with liquid N_2, evacuated under vacuum and sealed with a torch. The tube was heated at 105 °C for one day to give pale-yellow block crystals (0.454 g) in 55% yield based on H-Norf. $C_{32}H_{40}F_2FeN_6O_{12}S$ (826.61): calcd. C 46.45, H 4.84,

N 10.16; found C 46.58, H 4.90, N 10.28. The crystals showed only one phase. Solid reflectance UV/Vis (nm): 328.6, 271.7. IR (KBr): $\tilde{\nu}$ = 3402(m), 1621(s), 1462(vs), 1371(w), 1262(m), 1108(s), 1021(w), 925(w), 804(w), 791(w), 745(w) and 620(w) cm^{-1}.

Compound 2: The procedures are similar to those of **1** and $Fe(OH)_3$ was used as starting material (pH ≈ 8.2). The brown-red rod crystals (0.497 g; one phase) were harvested in 65% yield based on H-Norf. $C_{32}H_{42}F_2FeN_6O_{10}$ (764.57): calcd. C 50.22, H 5.49, N 10.99; found C 50.30, H 5.55, N 11.12. IR (KBr): $\tilde{\nu}$ = 3400(m), 1620(vs), 1578(m), 1482(s), 1380(m), 1340(m), 1261(s), 182(w),1118 (w), 1000(w), 928(m), 884(w),811(w), 790(w), 740(w) and 628(w) cm^{-1}.

Crystal Data for 1: $C_{32}H_{40}F_2FeN_6O_{12}S$, M_r = 826.61, monoclinic, $P2_1/c$, a = 23.166(1), b = 10.0492(4), c = 7.7264(3) Å, β = 98.379(1)°, V = 1779.50(13) $Å^3$, Z = 2, $\rho_{calcd.}$ = 1.543 g·cm^{-3}, T = 293(2) K, μ = 0.565 mm^{-1}, R_1 = 0.0633, $wR2$ = 0.1589 for 1975 observed reflections from 3121 independent reflections, GOF = 1.032.

Crystal Data for 2: $C_{32}H_{42}F_2FeN_6O_{10}$, M_r = 764.57, monoclinic, $P2_1/c$, a = 5.8411(12), b = 21.685(4), c = 13.265(3) Å, β = 99.20(3)°, V = 1658.6(6) $Å^3$, Z = 2, $\rho_{calcd.}$ = 1.531 g cm^{-3}, T = 293(2) K, μ = 0.534 mm^{-1}, R_1 = 0.0496, wR_2 = 0.1456 for 2033 observed reflections from 2869 independent reflections, GOF = 1.189.

The structures were solved by direct methods using the program SHELXTL. All the non-hydrogen atoms were located from the trial structure and then refined anisotropically with SHELXTL using a full-matrix least-squares procedure. The hydrogen atom positions were fixed geometrically at calculated distances and allowed to ride on the parent carbon atoms. The final difference Fourier map was found to be featureless.

Structural and Magnetic Characterization of a Linear Trinuclear Copper Complex Formed through Ligand Sharing

Yufei Song,[a] Patrick Gamez,[a] Olivier Roubeau,[b] Martin Lutz,[c] Anthony L. Spek,[c] and Jan Reedijk*[a]

Keywords: Copper / Magnetochemistry / Bioinorganic chemistry / N,O ligands

Reaction of bis(2-hydroxybenzyl)-1,3-diamino-2-propanol (H_2bhbdp) with copper perchlorate in methanol leads to the assembly of a trinuclear complex with the general formula $[Cu_3(bhbdp)_2(CH_3OH)_2(ClO_4)_2]$ (**1**). The complex was characterized by X-ray crystallography, Ligand Field, IR and ESR spectroscopy, and magnetic susceptibility. The structure of the complex contains a linear trinuclear array of copper ions [the Cu(1)–Cu(2)–Cu(1a) angle is 180° by symmetry], in octahedral, square planar and octahedral environments, respectively. The external Cu1 and Cu1a centers are coordinated by two amine nitrogens, two phenolate oxygen donors, one methoxide oxygen and one oxygen from a perchlorate, while the central Cu2 is coordinated by four phenolate oxygens through ligand sharing. A strong antiferromagnetic interaction between the adjacent Cu^{II} ions dominates the magnetic properties of **1** leading to an $S = 1/2$ ground state which is fully populated below 150 K.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Many multinuclear copper(II) complexes have been reported during the past decades with a great number of simple and intricate bridging ligands.[1−3] This interest arises from the search for models of the active sites of multicopper proteins, like ascorbate oxidase,[4] ceruplasmin[5] or laccase,[6] and from their potential use in catalysis.[7] The trinuclear active site in laccase,[8] the ferromagnetically coupled Cu^{II} triad in the subunit of methane mono-oxygenase[9] and the angled trinuclear Cu^{II} unit as well as the mononuclear type-1 copper(II) centre of ascorbate oxidase from zucchini,[10] have drawn much attention in the study of trinuclear copper systems.[11] In addition, the study of such compounds has allowed a better understanding of the magnetic properties of molecular compounds, because copper(II) ions have the simplest magnetic spin possible i.e. 1/2. Only a limited number of linear trinuclear compounds have been structurally and magnetically characterized until now.[12−14] In particular, there is still no example of Cu−Cu bonding interactions in such closely packed multimetal systems, while many other metal ions do form M−M bonds under the same conditions.[15]

In the present study, a homometallic, linear, trinuclear complex, $[Cu_3(bhbdp)_2(CH_3OH)_2(ClO_4)_2]$ (**1**), was synthesized and characterized, in which, due to the basicity of the coordinated phenols, two octahedral Cu^{II} complexes function as didentate ligands for the square-planar central Cu^{II} ion. Strong anti-ferromagnetic exchange interactions between neighboring Cu^{II} ions are inferred from the temperature dependence of the magnetic susceptibilities of **1**.

Results and Discussion

The trinuclear copper compound of formula $[Cu_3(bhbdp)_2(CH_3OH)_2(ClO_4)_2]$ (**1**) was obtained by reaction of one equivalent of H_2bhbdp with two equivalents of copper(II) perchlorate in methanol. Diethyl ether diffusion into the methanolic solution led to the formation of deep-blue square crystals suitable for X-ray crystallography. A molecular plot representing the complex together with the atom-labeling scheme is shown in Figure 1. The hydrogen-bonding network linking the trinuclear units is presented and depicted in Figure 2.

The asymmetric unit of the coordination compound contains one $[Cu_3(bhbdp)]^{2+}$ cation, one ClO_4^- anion and one coordinated methanol molecule. The $[Cu_3(bhbdp)_2]^{2+}$ cation contains three Cu^{2+} atoms in a linear array. The two terminal Cu^{2+} atoms, Cu(1) and Cu(1a), are coordinated by two amine nitrogens and four oxygen atoms (two phenolate

Displacement ellipsoid plot (50% probability level) of the trinuclear copper complex $[Cu_3(bhbdp)_2(CH_3OH)_2(ClO_4)_2]$ showing the crystallographic numbering scheme; hdrogen atoms have been omitted for clarity; symmetry operation a: $1 - x$, $1 - y$, $1 - z$; selected bond lengths and angles: Cu1−O30 1.956(3), Cu1−N18 1.996(3), Cu1−N22 2.014(3), Cu1−O10 1.958(3), Cu1−Cu2 2.9869(4), Cu1−O1 2.387(3), Cu1−O2 2.813, Cu2−O10 1.910(2), Cu2 −O30 1.911(3) Å; O10−Cu1−O30 76.59(11), O10−Cu1−N18 91.90(12), O10−Cu1−N22 169.14(11), O30−Cu1−N18 166.22(12), O30−Cu1−N22 92.58(12), N18−Cu1−N22 98.71(13), Cu2−Cu1−O1 100.27(8), Cu2−Cu1−O30 38.87(8), Cu2−Cu1−N22 130.34(9), O1−Cu1−O10 91.92(11), O1−Cu1−O30 92.81(12), O1−Cu1−N18 95.16(13), O1−Cu1−N22 89.40(12)°

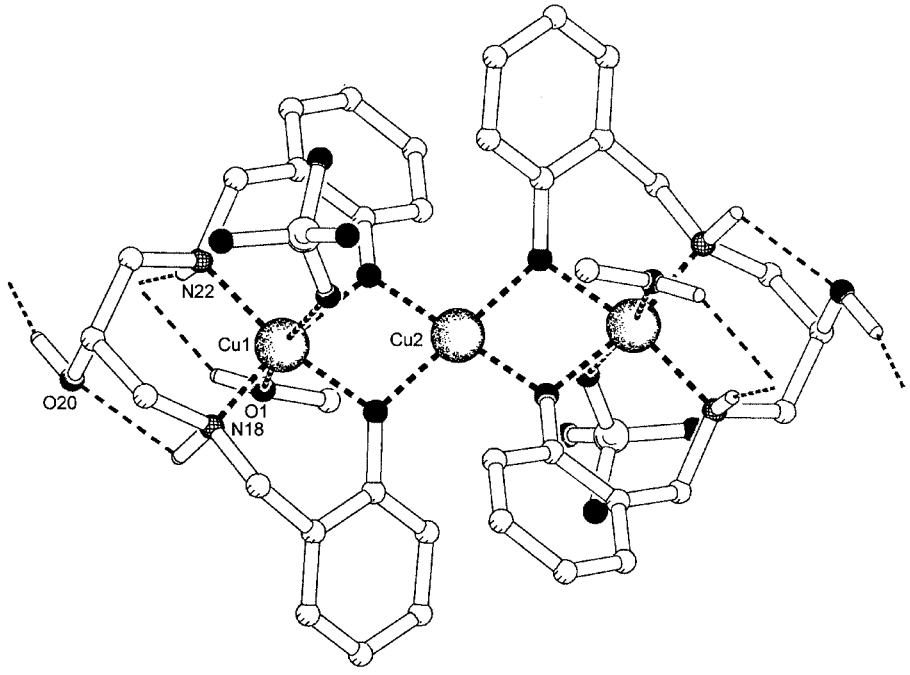

Figure 2. Perspective view exhibiting the hydrogen bonds; intramolecular D−H···A hydrogen bond (D···A, Å): N18−H18N···O20 2.735(5); intermolecular hydrogen bonds (D···A, Å): O1−H1O···O3 2.946(6); O20−H20O···O5 2.869(5); N22−H22N···O3 3.086(5)

oxygens, one methanol oxygen and one oxygen from a ClO_4^-). The central copper(II) atom, Cu(2), is coordinated by four oxygen atoms (from four phenolate oxygens). As Cu(2) occupies an inversion center, the resulting Cu(1)−Cu(2)−Cu(1a) array is linear by symmetry. The two terminal Cu(1) and Cu(1a) atoms are both coordinated by

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bhbdp^{2-} in a *cis* fashion with respect to the phenolate moieties. Thus, their coordination environment is described as an N_2O_4 donor set. Each phenolate unit further bridges to the central Cu(2) atom of the trinuclear moiety, resulting in a four-coordinate CuO4 chromophore. The central Cu^{2+} ion has a square-planar geometry due to the site symmetry, and the dihedral angle between the two Cu(1)−O(10)−Cu(2) and Cu(1)−O(30)−Cu(2) planes is 18.19(19)°. The terminal Cu(1) ions present a Jahn−Teller-distorted octahedral environment, resulting from the very long axial Cu(1)−O bonds from the semi-coordinated perchlorate O(2) and the methanol O(1). Therefore, the equatorial coordination plane is an N_2O_2 donor set [for Cu(1); N18, N22, O10, O30]. The Cu−O bond lengths of the central Cu(2) atom [1.910(2)−1.911(3) Å] are shorter than those of the equatorial Cu−O bonds of the terminal Cu(1) atoms [1.956(3)−1.958(3) Å], which is attributed to the two different coordination geometries (octahedral and square-planar, respectively). The Cu(2)−Cu(1) distance is 2.9869(4) Å, while the Cu(1)−O−Cu(2) angles of each pair of neighbors are 101.15(12)° and 101.08(12)° respectively for O(30) and O(10). Each Cu_2O_2 pair is almost planar as shown by the Cu(2)−O(30)−O(10)−Cu(1) torsion angle of 165.18(15)°.

Electronic Properties

The ligand-field spectrum of **1** shows three absorption bands centered at approximately 262 nm (38.2×10^3 cm^{-1}), 402 nm (24.8×10^3 cm^{-1}) and 567 nm (17.6×10^3 cm^{-1}). The intensity of the absorption at 402 nm clearly precludes it being a d-d transition, hence this feature is assigned as being due to a phenolate oxygen to Cu^{II} charge-transfer (CT) transition.[14] The absorption at 262 nm is another CT from phenolate oxygen to Cu^{II}. One of these phenolate oxygen to Cu^{II} CT bands is due to the terminal Cu^{II} CT and the other to the central Cu^{II} CT.[14] The transition in the visible region of the electronic spectrum of this complex is a much-less-intense absorption at 567 nm, which is assigned to d-d transitions of both square-planar and octahedral species.[16,17]

Magnetic Susceptibility and ESR

The ESR spectrum of a powered polycrystalline sample of **1** at room temperature shows a broad isotropic copper(II) signal centered around a g value of 2.0976. The main EPR signal $g_\perp = 2.0646$ sharpens upon cooling to 77 K and a very weak $g_{//}$ at ca. $g = 2.1945$ becomes visible (no $A_{//}$ resolved). The frozen solution spectrum in a CH_3CN/CH_3OH (1:1) solution shows only a broad signal at $g = 2.0794$. No structural conclusions can be drawn from these spectra.

The temperature dependence of the product $\chi_m T$ of **1** is shown in Figure 3, together with magnetization vs. field measurements at 1.8 K. Even at 390 K, $\chi_m T$ is much lower than that of three uncoupled Cu^{II} ions (0.593 cm^3·K/mol instead of 1.125 cm^3·K/mol for $g = 2$), thus indicating the presence of strong antiferromagnetic interactions. It decreases upon lowering the temperature to reach a plateau

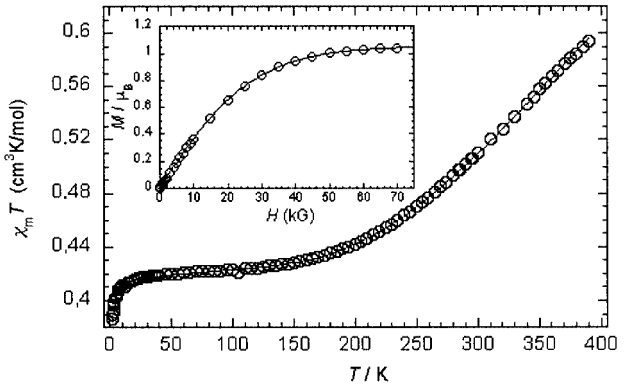

Figure 3. $\chi_m T$ vs. T plot for complex **1**; the solid line is the best fit obtained with a nearest neighbor interaction of −511(2) cm^{-1} (see text); insert: field dependence of magnetization measured at 1.83 K

below 150 K at about 0.42 cm^3·K/mol, corresponding to an $S = 1/2$ ground state (0.375 cm^3·K/mol for $g = 2$). Indeed, the magnetization vs. field data at 1.83 K (inset in Figure 3) tend to saturate at a value of 1.06. Below 10 K, a further decrease of $\chi_m T$ sets in, which can only be attributed to intermolecular interactions between $S = 1/2$ trimeric units. Therefore this behavior was modelled using the spin Hamiltonian given in Equation (1).

$$H = g\beta S_z H - J_1(S_1 \cdot S_2 + S_{1a} \cdot S_3) - J_2(S_1 \cdot S_{1a}) - zJ' \langle S_z \rangle S_z \quad (1)$$

The first term of this hamiltonian corresponds to the Zeeman term, for which a single isotropic g tensor has been considered for the two different Cu^{II} ions in **1**. The second and third terms include isotropic nearest neighbor and next-nearest neighbor interactions, respectively, with J_1 representing the exchange parameter between neighboring Cu^{II} ions and J_2 the exchange parameter between terminal Cu^{II} ions. The fourth term takes into account intermolecular interactions in the mean-field approximation,[18] with J' being the intermolecular exchange interaction and z the number of trimeric neighbors, in this case four. In cases like **1**, where the trinuclear array is perfectly linear and the dominant nearest neighbor interaction is antiferromagnetic, J_2 can be neglected, and was thus set to zero. The resulting expression of the molar magnetic susceptibility in the $\beta H/k_B T << 1$ approximation, with an additional term to take into account a Temperature-Independent Paramagnetism (TIP), is given in Equation (2).

$$\chi_M(T) = \frac{N_A g^2 \beta^2 F(T)}{4k_B(T - zJ'F(T))} + TIP$$
$$F(T) = \frac{1 + \exp(J_1/k_B T) + 10\exp(3J_1/2k_B T)}{1 + \exp(J_1/k_B T) + 2\exp(3J_1/2k_B T)} \quad (2)$$

The best set of parameters obtained (full line in Figure 3) was $J_1 = -511(2)$ cm^{-1}, $g = 2.15(1)$ and $zJ' = -1.9(1)$ cm^{-1} with a TIP value of $61(3) \times 10^{-6}$ cm^3/mol. Thus, the ground state of the trinuclear unit is, in the (S_{total}, $S_1 + S_{1a}$)

format, the doublet (1/2,0), with the excited doublet (1/2,1) and quadruplet (3/2,1) lying 511 and 766 cm^{-1} above it, respectively. It is well-known that in planar dinuclear copper(II) complexes with di-μ-alkoxo bridges, the exchange parameter varies linearly with the Cu−O−Cu angle.[19] Indeed, the value expected for the average Cu−O−Cu angle in **1** — 101.1° — is −495 cm^{-1} and almost perfectly matches the value obtained for J_1 in the present work. In addition, the Cu−Cu separation is large (2.987 Å), indicating that no direct exchange mechanism is likely to contribute to the magnetic coupling. Therefore, the strong antiferromagnetic coupling in **1** is ascribed solely to superexchange mechanisms within the central-terminal copper(II) pairs. The moderately weak intermolecular interactions observed in **1** can be explained by the hydrogen bonding network (see Figure 2) in which the coordinated perchlorate is involved.

In summary, the ligand bis(2-hydroxybenzyl)-1,3-diamino-2-propanol allows the formation of a stable, linear, homometallic, trinuclear complex $[Cu_3(bdbhp)_2(CH_3OH)_2(ClO_4)_2]$. A strong antiferromagnetic coupling between adjacent copper(II) ions in the triad dominates the magnetic properties of this complex. Further studies of its catalytic activity for the polymerization of 2,6-dimethylphenol (DMP) and oxygen binding chemistry at room temp. and low temperature are under investigation. By developing additional model systems of copper proteins, a better insight may be obtained into the magnetic properties of multicopper proteins and the relationship between structure and activity.

Experimental Section

General Remarks: All reagents and solvents were purchased from commercial sources and used as received. The ligand bis(2-hydroxlybenzyl)-1,3-diamino-2-propanol was prepared from salicylaldehyde and 1,3-diamino-2-propanol by reductive amination in methanol with $NaBH_4$. C,H,N analyses were carried out by the Microanalysis Department of Leiden University. Infrared spectra were recorded on a Perkin−Elmer Paragon 1000 spectrophotometer equipped with a Golden Gate Diamond ATR as a sample support. X-Band EPR spectra were recorded on a JEOL ESR spectrometer equipped with an Esprit 330 data system, at room temperature and at 77 K, with dpph as an internal reference (g = 2.0036). The ligand-field spectra of the solid compounds were recorded in the 300−2000 nm range on a Perkin−Elmer Lambda 900 UV/Vis/NIR spectrometer in the diffuse reflectance mode with MgO as reference. Field cooled measurements (300 to 1.8 to 390 K) of the magnetization of smoothly powdered microcrystalline **1** (m = 23.71 mg) were performed with a Quantum Design MPMS-7XL squid magnetometer in a 1kG applied field. Corrections for diamagnetic contributions of the sample (5.26×10^{-4} cm^3/mol) to the magnetic susceptibility were calculated using Pascal's constants.

Preparation of the Compound: A solution of the ligand (12.1 mg, 0.01 mmol) in methanol (2 mL) was added to copper(II) perchlorate (29.8 mg, 0.02 mmol) in methanol (2 mL). Diffusion of diethyl ether into the solution led to the formation of brown crystals after one day. Yield 36% (1.9 mg). $C_{36}H_{48}Cl_2Cu_3N_4O_{16}$ (1054.3): calcd. C 40.97, H 4.55, H 5.31; found C 40.58, H 4.32, N 5.55. IR (solid): $\tilde{\nu}$ = 3536, 3268, 3232, 1600, 1486, 1456, 1247, 1041, 759, 625 cm^{-1}. UV/Vis/NIR (solid): λ_{max} = 24875 cm^{-1}. EPR (solid, room temp.): g = 2.0976.

Crystal structure determination: $C_{36}H_{48}Cl_2Cu_3N_4O_{16}$, mol. wt. = 1054.30, brown needle, 0.24 × 0.06 × 0.06 mm^3, monoclinic, $P2_1/c$ (no. 14), a = 11.4981(2), b = 13.7442(2), c = 16.0767(3) Å, β = 123.5141(8)°, V = 2118.26(7) $Å^3$, Z = 2, D_x = 1.653 g/cm^3, μ = 1.694 mm^{-1}. 21805 Reflections were measured on a Nonius KappaCCD diffractometer with rotating anode (λ = 0.71073 Å) at a temperature of 150(2) K up to a resolution of $(\sin\theta/\lambda)_{max}$ = 0.59 $Å^{-1}$; 3641 reflections were unique (R_{int} = 0.086). An absorption correction based on multiple measured reflections was applied (0.68−0.91 transmission). The structure was solved by direct methods (SHELXS-97[20]) and refined with SHELXL-97[21] against F^2 of all reflections. Non-hydrogen atoms were refined freely with anisotropic displacement parameters. C−H hydrogen atoms were refined as rigid groups; O−H and N−H hydrogen atoms were located in the difference Fourier map and kept fixed in that position. 278 refined parameters, no restraints. R values [$I > 2\sigma(I)$]: $R1$ = 0.0398, $wR2$ = 0.0998. R values [all refl.]: $R1$ = 0.0696, $wR2$ = 0.1142. GoF = 1.091. Residual electron density between −0.76 and 1.13 e/$Å^3$. Molecular illustration, structure checking and calculations were performed with the PLATON package.[22]

Redox Chemistry of Actinide Ions in Wells−Dawson Heteropolyoxoanion Complexes

Ming-Hsi Chiang,[a] L. Soderholm,*[a] and Mark R. Antonio*[a]

Keywords: Actinides / Cyclic voltammetry / Polyoxometalates / Redox chemistry / Nernst analysis / Intermediate valence / Spectroelectrochemistry / XANES

The redox behavior has been characterized for several actinide (*An*) complexes with the monovacant Wells–Dawson anion, of the form $[An^{n+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-20}$ (*An* = Th^{4+}, U^{4+}, Np^{4+}, Pu^{4+}, and Am^{3+}). Two complexes, with *An* = U^{4+} and Am^{3+}, show redox activity under oxidizing conditions, which is attributed to the actinide oxidation. Am^{3+} is oxidized to Am^{4+} with an $E_{1/2}$ = +1.21±0.01 V, and U^{4+} oxidizes to U^{5+} with a measured $E_{1/2}$ = +0.55±0.01 V vs. Ag/AgCl. Although the cyclic voltammetry (CV) data are consistent with a reversible redox couple, bulk oxidative electrolysis of $[U^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ results in the decomposition of this complex to produce uranyl acetate and the free monovacant Wells–Dawson anion. In contrast, all of the CV data from the actinide coordination complexes differ from equivalent data obtained from the $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$ ligand itself. There are two complexed An^{4+} ions, Np and Pu, that undergo reduction over the same potential range as the ligands themselves. In situ X-ray spectroelectrochemistry is used to quantify the actinide response. The Np^{4+}/Np^{3+} redox behavior is a classically single ion process, with a formal potential of –0.84±0.01 V that was determined from a Nernst plot of X-ray absorption near-edge structure (XANES) data. The Pu^{4+}/Pu^{3+} formal reduction potential in the complex $[Pu(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ was determined to be –0.17±0.01 V using the same methodology. However, in this latter case, the slope of the Nernst plot indicates that 0.72±0.03 electrons are involved in the reduction. This is a significant deviation from the 1 electron expected for the Pu couple, and is discussed in terms of the concomitant reduction of the P–W–O framework of the Wells–Dawson anion.

Introduction

Polyoxometalates (POMs) are inorganic, anionic ligands with properties that have found application in such diverse areas as catalysis,[1,2] energy storage[3] and nuclear waste processing.[4−6] Unlike more familiar ligands (e.g., H_2O, NH_3, halides, carbonates, etc.), many POMs are electroactive,[7] particularly the heteropolyoxoanions of general composition $[X_aM_bO_c]^{d-}$ (X = Si, P, S; M = Mo, W). It is this intrinsic electrochemical functionality of POMs that accounts for their renowned behavior as reversible multielectron oxidants. They can accommodate substantial variation in their overall net charge without significant structural change or decomposition. The reduced species are known as heteropoly blues[7] because of their intense coloration, which arises from the delocalization of the added electrons in bands attributable to the metal oxide framework atoms (M = Mo^{6+}, W^{6+}).

The Wells−Dawson heteropolyanion $\alpha\text{-}[P_2W_{18}O_{62}]^{6-}$, shown in Figure 1, is an electroactive POM that accepts 1−6 electrons into its P−W−O framework upon reduction in aqueous media, while retaining its framework structure.[8−10] Selected $-WO^{4+}-$ units can be removed, from either the belt (α-1) or the cap (α-2) positions, to form an anion that acts as a ligand, which forms complexes with a variety of cations. Specific to our interests are complexes with 5f actinide ions, of the form $[An^{n+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-20}$ (n = 3 and 4), which have been reported for Pu,[11] Am,[11−17] and Bk.[14] These actinide ions, together with U^{4+} and Np^{4+}, are known to be electroactive themselves.[18] The one-electron redox chemistry for the An^{4+}/An^{3+} aquo ions of U, Np, Pu, and Bk is generally

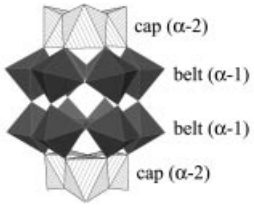

Figure 1. Polyhedral representation of the $\{W_{18}O_{62}\}$ framework of the plenary Wells−Dawson anion, $\alpha\text{-}[P_2W_{18}O_{62}]^{6-}$ showing the 6 capping W atoms (α-2 positions) as striped octahedra and the 12 belt W atoms (α-1 positions) as shaded octahedra; the two central $[PO_4]^{3-}$ tetrahedra are not shown

facile and reversible, with tabulated standard electrode potentials in the range of $-0.773 \leq E^{\circ} \leq +1.47$ V vs. Ag/AgCl.[19]

In 1976, Saprykin et al.[11,20] reported that electroactive POMs, including the monovacant Wells–Dawson, exert a significant influence on the standard electrode potentials of the An^{4+}/An^{3+} redox couples. For example, in complexes of $[An^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ (An^{4+} = Am, Cm, and Cf) the metal ions are stabilized toward reduction,[21] which would otherwise occur irreversibly on contact with water. From experimental measurements of the Wells–Dawson complexes of Pu^{4+},[11] Am^{3+},[11–17] and Bk^{3+},[14] the potentials for the An^{4+}/An^{3+} redox couple are approximately 1 V less than those tabulated for the standard reduction potentials, which correspond to the aquo ions in noncomplexing electrolytes.

Whereas it has been demonstrated that the substituted Wells–Dawson ligand can systematically shift the redox potential of bound 5f metal ions,[11–15,21] little work has been done to look for changes in the reduction response of the complexed anion. Of specific interest is the case, expected for the Np^{4+}/Np^{3+} and Pu^{4+}/Pu^{3+}couples, in which the reduction of the complexed *An* ion occurs over the same potential range as the reduction waves of the Wells–Dawson ligand itself. Under such conditions the localized f states are at the Fermi level of the P–W–O ligand states. Similar situations have been studied for f ions in transition-metal alloys, where correlated-electron and intermediate-valent phenomena have been observed.[22,23] Indeed, strong evidence of intermediate valence has been observed for Eu encrypted in the Preyssler anion, $[EuP_5W_{30}O_{110}]^{n-}$,[24] when the Eu f valence states are isoenergetic with the framework Fermi level. The systems under study herein provide a uniquely tunable and structurally simple model for extending studies of correlated electron behavior.

The objective of this study is to probe the electronic response of *An* Wells–Dawson complexes, in which both the f ion and the POM ligand are electroactive, to look for interactions that indicate f-state bonding or other unusual electronic responses. We report cyclic voltammetry and in situ XANES spectroelectrochemistry data on Th^{4+}, U^{4+}, Np^{4+}, and Pu^{4+} as well as Am^{3+}, some of which may give evidence of electronic interactions, but no strong evidence of intermediate valence is observed, even in cases where the P–W–O and f states are reduced concomitantly.

Results and Discussion

The CV data are shown in Figure 2 for the free ligand, $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$ (a, a′), and the cluster complexes, $[An^{n+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-20}$ with Th^{4+} (b, b′), U^{4+} (c, c′), Np^{4+} (d, d′), Pu^{4+} (e, e′), and Am^{3+} (f, f′). These data were obtained under identical conditions, with the potential window limited by H_2 evolution at ≤ -1 V vs. Ag/AgCl and O_2 evolution at $\geq +1.4$ V vs. Ag/AgCl. The fundamental electrochemical parameters obtained from the data in Figure 2 are provided in Table 1 and compared in Table 2

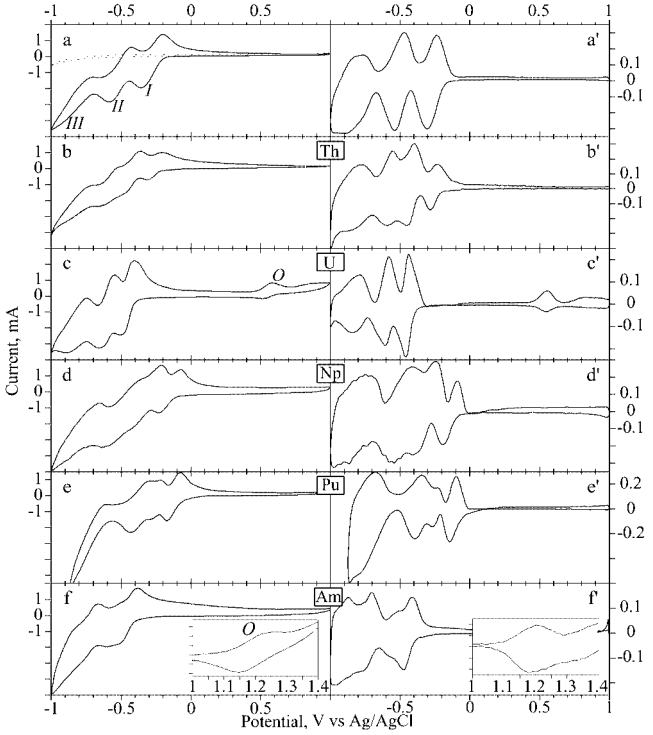

Figure 2. Left panels: cyclic voltammograms obtained at room temp. at 5 mV s^{-1} in supporting aqueous electrolytes (pH = 3.5) of 2:1 (v/v) mixtures of 0.5 M CH_3CO_2Li buffer at pH = 4.7 and 1 M $HClO_4$; right panels: the corresponding semi-differential data of the primary voltammograms; (a, a′) the uncomplexed ligand, $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$, including background scan (dashed line), revealing two well-resolved (*I*, *II*) redox waves and a third (*III*) less-resolved one; each arises from two-electron reduction processes of W^{6+} in the P–W–O band; by comparison, the complexes of Th^{4+} (b, b′), U^{4+} (c, c′), Np^{4+} (d, d′), Pu^{4+} (e, e′), and Am^{3+} (f, f′) with $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$ as $[An^{n+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-20}$ cluster anions affect the reduction behavior of the ligand in significant fashion; all the solution species form heteropoly blues due to reduction of the P–W–O framework at potentials between 0 and −1 V; although the U^{4+} and Am^{3+} oxidation waves (labeled *O*) are visible in the CV data of (c, c′) and (f, f′), respectively, any evidence for the reduction of An^{4+} in $[An^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ is not obvious because of the interfering response from the reduction of the ligand

with results from previous electrochemical investigations of $[An^{n+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-20}$, as well as with the corresponding An^{n+} aquo ions.

The data in Figure 2 (a, a′) indicate that the free ligand has no electrochemical response under an oxidizing, positive, applied potential, consistent with the expectation that the W^{6+}–O valence band is empty. In contrast, the CV data for $[Am^{3+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{17-}$, shown in Figure 2 (f, f′), exhibit an isolated redox wave under an oxidizing potential, at $E_{1/2} = +1.21 \pm 0.01$ V, that is attributed to the Am^{3+}/Am^{4+} couple. As evident from Table 2, our $E_{1/2}$ value is in agreement with previous polarographic and potentiometric measurements of the Am^{3+} oxidation potential in the $[Am^{3+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{17-}$ complex measured in solutions with pH ranges of 2–5.[11,13–15] The measured reduction potential of +1.21 V is about 1.2 V less than the estimated standard electrode potential of +2.4 V for the Am^{4+} reduction in aqueous solution. This shift for the Am reduction potential upon complexation with the Wells–Dawson

anion is somewhat larger than the −0.9 V that is typically seen for similarly complexed *An* ions.[11,15,21] Were it not for complexation with $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$, Am^{4+} would not be stable in aqueous solution. This stabilization of Am^{4+} by complexation with $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$ is the scientific basis for the separation process known as SESAME[5] and for aspects of the PARC process[6] in nuclear waste treatment operations.

$[U(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ also shows an electrochemical response under an oxidizing applied potential, with a redox wave [labeled *O* in Figure 2 (c, c′)] centered at $E_{1/2}$ = +0.55±0.01 V. Previous work has shown that, under the synthetic conditions employed in this study, U is tetravalent in $[U(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$.[25] We argue that the redox wave observed here is due to the one-electron U^{4+}/U^{5+} couple. The one-electron oxidation of U^{4+} has been previously reported in both Keggin and Wells−Dawson heteropolyoxoanion complexes, $[U^{4+}(X^nW_{11}O_{39})_2]^{2n-20}$ ($X = Si^{4+}$; P^{5+}) and $[U^{4+}(P_2W_{17}O_{61})_2]^{16-}$.[26] The oxidation was achieved through electrolytic means, with electrode potentials of $+0.23 \le E^{\circ\prime} \le +0.64$ V, and through potentiometric titrations with dichromate and permanganate.[27] Our $E_{1/2}$ value agrees with the formal potential of +0.56±0.01 V obtained through a Nernst analysis of potentiometric data for $[U^{4+}(P_2W_{17}O_{61})_2]^{16-}$ by Maslov et al.[27]

A reliable standard potential for the one-electron oxidation of U^{4+}, unaccompanied by the formation of the linear dioxo moiety $[O{=}U^{5+}{=}O]^+$ is not available for comparison with our results. U^{5+} is unstable, so that, on contact with water, it invariably takes the form of the *trans*-dioxo cation $[UO_2]^+$, which itself is unstable with respect to disproportionation.[28] The observation of an apparently reversible voltammogram indicates that the coordination provided by the two Wells−Dawson ligands[25,29] provides a stabilizing environment for the dioxo-free (i.e., the so-called nude) U^{5+} cation.

In attempts to further characterize the U^{5+} complex of $[U(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{15-}$, bulk electrolysis experiments were performed with the electrode polarized at +0.80 V. The solution color, which was initially violet, changed to red and then gradually faded to light pink as a white precipitate developed over the course of 1−18 h. Powder X-ray diffraction and EXAFS (extended X-ray absorption fine structure) data of the precipitate are consistent with a uranyl(VI) acetate phase.[30] On the longer time scale needed for bulk electrolysis, the U^{4+} oxidation is seen to be irreversible. On the significantly shorter time scale of cyclic voltammetry measurements, the U^{4+}/U^{5+} redox couple [*O* in Figure 2 (c, c′)] appears reversible, with a 0.070 V peak separation. This is likely to be a kinetic effect, in that the nude U^{5+} is sterically hindered, by the bulky Wells−Dawson ligands, from access

to the oxygen ligands necessary to form the dioxo moiety,

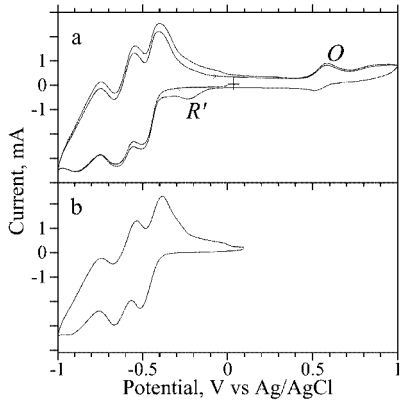

Figure 3. Cyclic voltammograms of $[U^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$; (a) starting from the initial potential of +0.1 V in a negative sweep to −1 V then to +1 V and back, showing the reversible U^{4+}/U^{5+} couple labeled *O* and the cathodic peak response labeled *R′* at −0.23 V attributed to reduction of $[UO_2]^{2+}$; (b) recorded 60 min after (a) starting from the initial potential of +0.1 V in a negative sweep to −1 V and back

$O{=}U^{5+}{=}O$. Yet, as shown in the CV data of Figure 3 (a), U demetalation is evident in successive sweeps with scan rates of 10 mV s^{-1} and slower between −1 and ≥ +0.6 V as the cathodic peak at −0.23 V labeled *R′*. This peak, which is otherwise not observed in shorter scans to ≤ +0.4 V as shown in Figure 3 (b), is the direct result of the redox couple *O* in Figure 3 (a). We suggest that peak *R′* is due to the reduction of $[UO_2]^{2+}$ (from cluster demetalation)[30] to U^{4+}, which subsequently combines with free ligand to reform the $[U^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ complex. This would account for the absence of an anodic counterpart of *R′*, as would the irreversibility of the coupled electron transfer/chemical conversion between U^{4+} and $[UO_2]^{2+}$. No evidence is found for the reorganization of $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$, which can be readily reconstituted as $\alpha\text{-}[P_2W_{18}O_{62}]^{6-}$ and easily detected by CV.

In contrast to the sparse electrochemical responses of the actinide-coordinated, monovacant Wells−Dawson anions under oxidizing conditions, complicated redox responses are observed for all complexes under reducing conditions. The free ligand itself exhibits two well-resolved redox waves followed by one less-resolved wave, as indicated by *I*, *II*, and *III* in the voltammogram of Figure 2 (a). Previous work has attributed the waves to three 2-electron processes,[8,10,31−33] involving W^{6+} reduction. Extended Hückel calculations on the uncomplexed, plenary Wells−Dawson anion, $\alpha\text{-}[P_2W_{18}O_{62}]^{6-}$, indicate that the lowest unoccupied molecular orbital (LUMO) has a_1'' symmetry and is composed almost exclusively (96%) of metal orbitals derived from the 5d t_{2g} orbitals centered on the belt (α-1) tungsten atoms.[34] Symmetry requires that all 12 belt W atoms contribute with equal weight. The next higher energy state has e'' symmetry and is composed of both belt (61%) and cap (33%) positions.[34] Above these states in energy is another doubly degenerate set of orbitals that are located primarily (81%) on the cap positions, with only 12% on the belt positions.[34] The removal of a $W{=}O^{4+}$ moiety from the cap position, to form the α-2 derivative, lifts the threefold rotational symmetry of the parent ligand, and will lift the e states degeneracies. The first redox wave seen for $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$ in Figure 2 (a, a′) can thus be understood as arising from electron occupation in the LUMO that resides primarily on the belt (α-1) positions of Figure 1, and has a'' symmetry.[34−36]

Of the five *An* ions considered here, only Th^{4+} has no electroactivity of its own in the electrochemical region of interest. Yet, the complexation of electrochemically silent Th^{4+} modifies the voltammetric response of the P−W−O framework so that the $[Th(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ cluster has four redox waves. The first three are visible in the primary CV data of Figure 2 (b). The fourth one is less resolved but is seen clearly in the corresponding semiderivative data of Figure 2 (b′).

The reduction potentials of the An^{4+} ions coordinated by the monovacant Wells−Dawson anion are estimated by assuming a −0.9 to −1.0 V shift to the standard electrode potentials upon complexation.[15] Using this assumption, Np^{4+} and Pu^{4+} complexed with $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$ have reduction potentials that are expected to be accessible under our experimental conditions, whereas the estimated U^{4+}/U^{3+} potential of −1.73 V[37] is expected to be too low to be measurable. However, except for minor shifts in peak positions, the CV data for $[Np(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$, shown in Figure 2 (d, d′), are essentially the same as those for $[Th(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ [Figure 2 (b, b′)], in which Th^{4+} has no redox activity. So, from the CV data alone, it is not possible to assign Np electrochemical activity to any specific feature that may otherwise arise from the redox activity of the P−W−O framework. Therefore, in order to evaluate the electrochemical response of these 5f ions under reducing conditions, optical spectroscopy and X-ray absorption experiments were undertaken.

Optical spectra were obtained for the yellow Np^{4+} solution complex and for the blue solution resulting from bulk electrolysis at −0.3 V vs. Ag/AgCl in order to assess the Np^{4+}/Np^{3+} redox activity in $[Np(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$. These spectra are shown in Figure 4. The blue solution is optically dense and the electronic spectrum consists of weak bands attributable to the Np^{4+} complex superimposed on a strong and essentially featureless broad-band (460−1250 nm) ab-

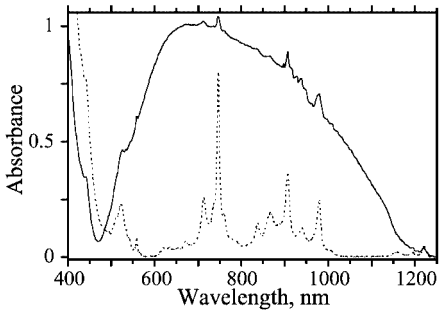

Figure 4. Optical spectrum of the transparent yellow solution of $[Np^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ consistent with previous spectra[48−50] (dashed line) and the opaque heteropoly blue solution (solid line), following exhaustive electrolysis at −0.3 V

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sorption associated with the reduction of the ligands. Absorption bands of similar breadth are found in the spectra for the heteropoly blues of $[\alpha\text{-}1\text{-}P_2W_{17}O_{61}]^{n-}$ [38] as well as $[PMo_{12}O_{40}]^{n-}$ in protic[39] and aprotic media.[40] In the heteropoly blues of $[Np(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ produced by bulk electrolysis at potentials more negative than −0.3 V, any evidence for absorption bands due to Np was obscured by the broad, intense absorption by the P−W−O anions. Because of this, we exploited element-specific in situ XANES spectroelectrochemistry[41] to quantify the Np^{4+}/Np^{3+} redox couple.

The Np L_3-edge XANES spectra for the valence-pure α_2 Wells−Dawson complexes of Np^{3+} and Np^{4+} are shown in Figure 5 as solid lines. These spectra are discussed in detail elsewhere.[25] The data collected at intermediate potentials, after exhaustive bulk electrolysis, are shown as dashed lines. The XANES spectra can be treated as linear combinations of the two end-member, valence-pure spectra,[41,42] thereby extracting the relative ratio of the oxidized to the reduced species for each potential. These data serve as input into the Nernst equation, $E = E^{\circ\prime} + RT\{\log([ox]/[red])\}/nF$, for which [ox] and [red] are the concentrations of the oxidized and reduced species, respectively; E is the applied potential, R is the gas constant, and F is Faraday's constant.

The number of electrons (n) involved in the Np redox reaction, as well as the formal electrode potential ($E^{\circ\prime}$) for the Np^{4+}/Np^{3+} couple are determined from the Nernst plot shown in Figure 6. The variation of applied potential with $\log([Np^{4+}]/[Np^{3+}])$ shown by the solid circles has a linear dependence. The best fit, with $R^2 = 0.988$, is shown as the solid line. The slope (RT/nF) of the fitted line is 0.061±0.003 V, corresponding to $n = 0.97\pm0.05$ electrons transferred at 25 °C, and the intercept is equal to $E^{\circ\prime} = -0.84\pm0.01$ V. The observation of a slope consistent with that expected for a 1-electron transfer indicates that the Np ion in the Wells−Dawson complex is acting as a well-behaved, single-ion redox couple. The measured Np^{4+} reduction potential of −0.84 V is similar to the value of −0.95 V estimated from published trends.[37]

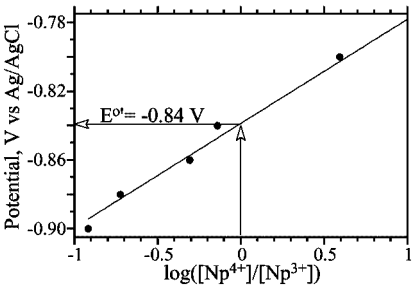

Figure 6. Nernst plot (circles) and best fit (line) with $R^2 = 0.988$ for $[Np(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$; the slope, $RT/nF = 0.061\pm0.003$ V, provides the number of electrons (n) transferred in the Np^{4+}/Np^{3+} redox couple; at 25 °C, a slope of 0.05916 V corresponds to $n = 1$; we obtain $n = 0.97\pm0.05$; the X-axis intercept as indicated by the arrows provides the formal potential, $E^{\circ\prime} = -0.84\pm0.01$ V

The Pu^{4+} Wells−Dawson ion presents a situation similar to that of complexed Np^{4+} in that, under reducing conditions the CV data for $[Pu(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$, shown in Figure 2 (e, e′), provide no obvious evidence for a Pu^{4+}/Pu^{3+} couple. This couple has been reported to have a formal potential of −0.12 V,[11] which is in the potential range for the observed P−W−O redox activity. Pu L_3-edge XANES experiments are used to quantify the Pu response, as a function of applied potential, from $[Pu(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$. These data are shown in Figure 7. The concentrations, following bulk electrolysis, of Pu^{4+} and Pu^{3+} at each applied potential were used to construct the Nernst plot shown in Figure 8. The direct, linear dependence of potential vs. $\log([Pu^{4+}]/[Pu^{3+}]$ is evident in the primary data (solid circles) and by the best fit (solid line) with $R^2 = 0.998$. The formal potential, $E^{\circ\prime} = -0.17\pm0.01$ V, is determined from the intercept of this plot, and can be compared with that of -0.12 ± 0.01 V obtained by Saprykin et al.[11] This latter value was obtained by measurements of Eh in

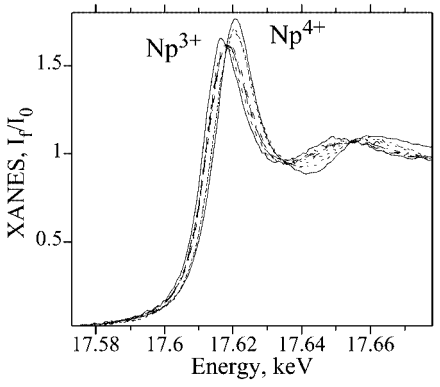

Figure 5. Normalized fluorescence XANES of the cluster anions containing valence-pure Np^{3+} and Np^{4+} (solid lines) obtained with the electrode polarized at −1.00 and +0.20 V, respectively, and with admixtures of both Np^{3+}- and Np^{4+}-containing anions (dashed lines) obtained with the electrode polarized at −0.900, −0.880, −0.860, −0.840, −0.800, and −0.780 V; as discussed elsewhere,[25] the L_3 XANES peaks for Np^{3+} and Np^{4+} are well resolved with a separation of 4.6 eV; this makes possible the quantitative analyses of the relative equilibrium concentrations of Np^{4+} and Np^{3+} in the admixtures[41]

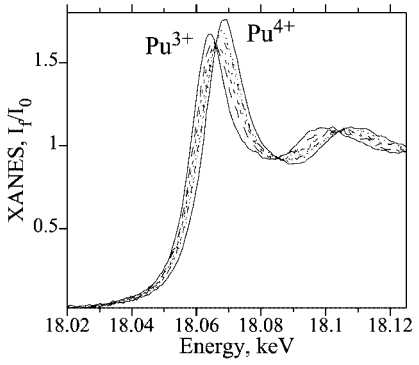

Figure 7. Normalized fluorescence XANES of the cluster anions containing valence-pure Pu^{3+} and Pu^{4+} (solid lines) obtained with the electrode polarized at −0.30 and +0.20 V, respectively, and with admixtures of both Pu^{3+}- and Pu^{4+}-containing species (dashed lines) obtained with the electrode polarized at −0.200, −0.180, −0.160, −0.140, and −0.120 V; as discussed elsewhere,[25] the L_3 XANES peaks for Pu^{3+} and Pu^{4+} are well resolved with a separation of 4.3 eV; this makes possible the quantitative analyses of the relative equilibrium concentrations of Pu^{4+} and Pu^{3+} in the admixtures[41]

non-blue solutions containing known mixtures of $[Pu^{4+/3+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-/17-}$, prepared with preformed Pu^{4+} and Pu^{3+}. The slope (0.082 ± 0.003) of the Nernst plot of Figure 8 is 38% larger than expected for a one-electron Pu^{4+}/Pu^{3+} redox couple, and provides a smaller than expected value of $n = 0.72\pm0.03$ electrons transferred in the redox reaction. This value is significantly different from that expected for a well-behaved Nernstian system.[43]

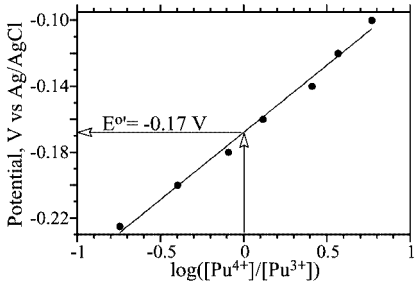

Figure 8. Nernst plot (circles) and best fit (line) with $R^2 = 0.998$ for $[Pu(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$; the slope, $RT/nF = 0.082\pm0.003$ V, provides the number of electrons ($n = 0.72\pm0.03$) transferred in the Pu^{4+}/Pu^{3+} redox couple; the X-axis intercept as indicated by the arrows provides the formal potential, $E^{\circ\prime} = -0.17\pm0.01$ V

The high slope measured for the Pu^{4+} reduction may indicate weak interactions between the localized Pu f states and the P−W−O d-band states arising from correlated electron behavior. The redox couple, which has a formal potential of −0.17 V, is almost coincident with the first W-redox wave of the $[Pu(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ complex itself, which occurs at −0.12 V. This energy coincidence of localized f states with the W−O band states raises the possibility for correlated-electron behavior.[22,23] We have seen evidence for such f-P−W−O hybridization during the reduction of Eu^{3+} in the Preyssler POM, $[EuP_5W_{30}O_{110}]^{n-}$.[24] A Nernst plot, obtained from XANES data following a similar procedure to that used herein, is non-linear, with an applied potential range of 60 mV over which no change is observed in the $[Eu^{3+}]/[Eu^{2+}]$ ratio. Such behavior is consistent with that expected for a hybridization of the localized f_{Eu} states with the d_{W-O} band states because the added electrons are going into states comprised of both Eu and a large number of W. If the Pu f states and the d states on the 2 cap tungsten atoms had fully hybridized states, the electron would be shared between three centers, and the slope measured for the Pu reduction alone would be expected to be about 1/3. Therefore, an increased slope can be argued to be consistent with some degree of electron sharing among the cap-position ions. The linearity of the Pu Nernst response, as a function of applied potential, is consistent with the understanding that the W−O states that are reduced in the −0.12 V wave are those in the anion belt positions.[34−36] These states are expected to be electronically isolated from the cap-position states and therefore, although the criterion for intermediate-valent behavior is satisfied in terms of energetically isolated states in this experiment, the system symmetry prohibits the necessary spatial overlap of the appropriate wave functions.

The isolation of the first reduction wave, arising from the W atom in the belt positions, from the electronic states on the cap positions is further exemplified by the plot shown in Figure 9. The measured potentials of the W_{belt} redox waves are plotted as a function of An^{4+}−O bond length.[25] U^{4+} is not included in this plot because of the effects of the U^{5+}/U^{4+} couple (Figure 3) on cluster demetalation leading to the presence of free $[\alpha\text{-}2\text{-}P_2W_{17}O_{61}]^{10-}$ and $[UO_2]^{2+}$. The linear behavior ($R^2 = 0.999$) of this plot suggests dipolar interactions alone are primarily responsible for the slightly increased stability, of the W−O a′′ belt states, to reduction with increasing An−O bond length.

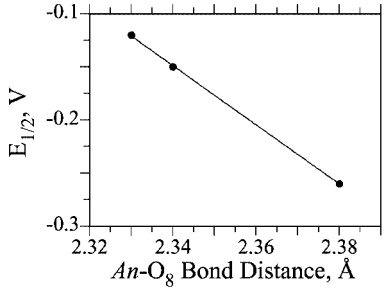

Figure 9. The decreasing half-wave, $E_{1/2}$, potentials of Table 1 for redox couple I (belt W reduction) of the Pu^{4+}, Np^{4+}, and Th^{4+} complex anions are plotted (circles) as a function of their increasing $An^{4+}-O_8$ bond lengths;[25] the best fit ($R^2 = 0.999$) is shown as a line with a slope of -2.79 ± 0.04 V/Å and an intercept of 6.37 ± 0.10 V

Conclusion

Although the reduction behaviors of both the actinide ion and the monovacant Wells−Dawson anion are altered upon their complexation, there is no evidence of significant hybridization between the An localized f states and the W−O band states. Specifically, the Pu^{4+}/Pu^{3+} redox couple is centered amongst the reduction waves of the anion itself. This situation may lead to intermediate valence[23] as has been demonstrated for $[EuP_5W_{30}O_{110}]^{n-}$ under similar conditions.[24] However, the Nernst plot obtained for Pu in $[Pu(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-}$ is linear, although there appears to be an anomalously low number of electrons involved in the reduction. This result is interpreted in terms of electron delocalization into $Pu-W_{cap}$ states.

Experimental Section

CAUTION: Th, U, Np, Pu, and Am are radioactive elements. All experiments with these isotopes were performed in specialized laboratories using procedures designed and approved to minimize radiological and chemical hazards. For the transuranic elements, i.e., Np, Pu, and Am, their limited availability, together with radiation exposure concerns, require the use of only milligram quantities and thereby limit studies to small sample sizes. The $[An^{n+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-20}$ complexes with natural Th^{4+} and U^{4+}, $^{237}Np^{4+}$, $^{242}Pu^{4+}$, and $^{243}Am^{3+}$ were prepared as described elsewhere.[25] Aqueous electrolytes of pH = 3.5, prepared from 2:1 (v/v) mixtures of 0.5 M CH_3CO_2Li buffer (pH = 4.7) and 1 M $HClO_4$, were used

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for all measurements, which included optical, in situ Np and Pu XANES spectroelectrochemistry, and cyclic voltammetry (CV). Vis/NIR data were obtained with a Cary-14 Olis-conversion spectrometer. The in situ XANES was obtained with a purpose-built cell for spectroelectrochemistry.[41,44] CV data for the dilute (ca. 1 mM) solutions of $[An^{n+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{n-20}$ were obtained under static conditions with scan rates of 5 mV s^{-1} in a single-compartment cell. The primary voltammograms were convolved by a semi-derivative method to provide clear visual resolution of the redox waves. All electrochemical operations (bulk electrolyses and CV) were performed with a BAS 100B/W electrochemical workstation and 6.15 mm diameter graphite rod (Alfa 14739) working and auxiliary electrodes, and a BAS (RE-5B) Ag/AgCl reference electrode (3 M NaCl). Unless specified otherwise, all measured and reported potentials are with reference to this electrode, with a redox potential of +0.196 V vs. SHE at 25 °C.[45] The background voltammogram of the neat electrolyte and clean electrodes was smooth and featureless over the range of potentials from −1 to +1.4 V. Np and Pu XANES spectra were recorded at the 7 GeV APS BESSRC CAT station 12-BM-B[46] as described previously.[25] With the dilute solutions of $[Np^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ and $[Pu^{4+}(\alpha\text{-}2\text{-}P_2W_{17}O_{61})_2]^{16-}$ in the X-ray beam under vigorous sparging with N_2, we first collected data for the fully oxidized clusters at rest potential. This was followed by exhaustive (≥ 98%) electrolysis at −1.00 V and −0.30 V to produce the reduced heteropoly blue species with valence-pure Np^{3+} and Pu^{3+}, respectively, and XANES data acquisition. Thereafter, we recorded XANES data throughout the course of the stepwise oxidation by bulk electrolyses as a function of controlled potentials with the electrode polarized at −0.900, −0.880, −0.860, −0.840, −0.800, and −0.780 V for the Np complex, and at −0.225, −0.200, −0.180, −0.160, −0.140, −0.120, and −0.100 V for the Pu complex. X-ray and electrochemical spectra, obtained from the full re-oxidation of the reduced, Wells−Dawson complex, were indistinguishable from those obtained from the starting materials. This result confirms the reversibility of the redox chemistry. The Np and Pu XANES spectra obtained at the intermediate potentials were fit in a linear combination regression analysis with the pure An^{3+} and An^{4+} spectra using procedures in WinXAS[47] that have been described in detail elsewhere.[41,42] The relative partial concentrations for An^{4+} and An^{3+} obtained therewith were used for the Nernst plots of potential vs. $\log[Np^{4+}]/[Np^{3+}]$ and $\log[Pu^{4+}]/[Pu^{3+}]$.

Solution Structures of Binary and Ternary Metal Ion Complexes of 9-(5-Phosphonopentyl)adenine (3′-deoxa-PEEA). A Nucleotide Analogue Related to the Antivirally Active 9-[2-(Phosphonomethoxy)ethyl]adenine (PMEA)

Raquel B. Gómez-Coca,[a] Antonín Holý,[c] Rosario A. Vilaplana,[b] Francisco González-Vílchez,[b] and Helmut Sigel*[a]

Keywords: Antiviral agents / Chelates / Equilibrium constants / Nucleotides / Stacking interactions

The acidity constants of the twofold protonated acyclic 9-(5-phosphonopentyl)adenine, H_2(dPEEA)$^{\pm}$, as well as the stability constants of the M(H;dPEEA)$^+$ and M(dPEEA) complexes with the metal ions M^{2+} = Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} or Cd^{2+}, have been determined by potentiometric pH titrations in aqueous solution at I = 0.1 M ($NaNO_3$) and 25 °C. Application of previously determined straight-line plots of log $K^{M}_{M(R\text{-}PO_3)}$ versus p$K^{H}_{H(R\text{-}PO_3)}$ for simple phosph(on)ate ligands, R-PO_3^{2-}, where R represents a residue which cannot participate in the coordination process, proves that the primary binding site of dPEEA^{2-} is the phosphonate group with all the metal ions studied. However, for the M(dPEEA) systems with Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} and Cd^{2+} a (in part rather small) stability increase is observed which is due to macrochelate formation with the adenine residue, i.e. most likely with N7. The formation degrees of the macrochelates are 17 ± 15%, 28 ± 10%, 46 ± 12%, 42 ± 28%, and 42 ± 9% (3σ), respectively. This means that in this respect dPEEA^{2-} resembles the parent nucleotide adenosine 5′-monophosphate (AMP^{2-}) more than its chain-shortened analogue 9-(4-phosphonobutyl)adenine (dPMEA^{2-}); indeed, in a first approximation macrochelate formation increases for a given metal ion within the series M(dPMEA) < M(dPEEA) < M(AMP). However, the coordinating properties of all three mentioned ligands differ significantly from those of the antivirally active 9-[2-(phosphonomethoxy)ethyl]adenine (PMEA^{2-}) which, due to the presence of an ether oxygen in the aliphatic side chain, has a different coordination chemistry which involves five-membered chelates with the ether oxygen atom. In addition, the stability constants of the mixed ligand complexes formed between Cu(Arm)$^{2+}$, where Arm = 2,2′-bipyridine (Bpy) or 1,10-phenanthroline (Phen), and the H(dPEEA)$^-$ or dPEEA^{2-} species were also measured. Detailed stability constant comparisons reveal that in the monoprotonated ternary Cu(Arm)(H;dPEEA)$^+$ complexes the proton is at the phosphonate group and that stacking between Cu(Arm)$^{2+}$ and H(dPEEA)$^-$ plays a significant role. For the Cu(Arm)(dPEEA) complexes a large increase in complex stability (compared to the stability expected on the basis of the basicity of the phosphonate group) is observed, which is due to intramolecular stack formation between the aromatic ring systems of Phen or Bpy and the purine moiety of dPEEA^{2-}. The formation degree of the stacked isomers is in the order of 65 to 80%. Comparisons of the Cu(Arm)(PA) systems, where PA^{2-} = dPEEA^{2-}, dPMEA^{2-} or AMP^{2-}, reveal that here dPEEA^{2-} resembles its parent AMP^{2-} less closely than dPMEA^{2-} does. The biological implications of these results, including antiviral activities, are shortly discussed.

1. Introduction

Viruses and the diseases they may cause have been studied for more than 100 years. Viruses are classified according to their genetic material into two major groups: RNA and DNA viruses. The human hepatitis A virus (HAV) and polioviruses belong to the first group, whereas the hepatitis B virus (HBV) is classified as a DNA-containing organism.[1]

Within the RNA-virus group special attention has been paid to the *Retroviridae* family to which the human immunodeficiency viruses (HIV-1 and HIV-2) belong.[2] It is well-known today[3] that, at least in theory, the viral replication cycle may be interrupted in many ways. One of the possibilities is to employ acyclic nucleotide analogues[4] and in this category 9-[2-(phosphonomethoxy)ethyl]adenine (PMEA; Figure 1),[5−7] also known as Adefovir,[8] appears to be especially promising. This compound may be con-

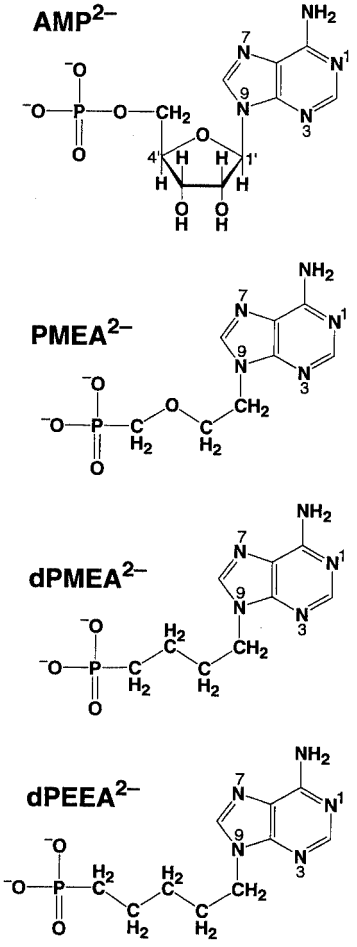

Figure 1. Chemical structures of the dianions of 9-[2-(phosphonomethoxy)ethyl]adenine (= $PMEA^{2-}$ = *Adefovir*), 9-(4-phosphonobutyl)adenine (= $dPMEA^{2-}$ = 3′-deoxa-$PMEA^{2-}$), 9-(5-phosphonopentyl)adenine (= $dPEEA^{2-}$ = 3′-deoxa-$PEEA^{2-}$) and of their parent nucleotide adenosine 5′-monophosphate (AMP^{2-}). The latter is shown in its *anti* conformation.

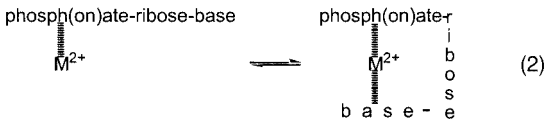
sidered as an analogue of (2′-deoxy)adenosine 5′-monophosphate [(d)AMP^{2-}; Figure 1]; it is active against HBV and HIV.[8,9] Indeed, its bis(pivaloyloxymethyl)ester (Adefovir dipivoxil) was very recently approved by the US Food and Drug Administration (FDA) for use in hepatitis B therapy.[10]

Since PMEA has a phosphonate group instead of a phosphate unit, it circumvents in blood plasma or in its passage through the cellular membrane the enzyme-catalyzed dephosphorylation that is suffered by nucleotide analogues which contain a monophosphate ester residue.[8,11] Instead, PMEA is diphosphorylated to give the triphosphate-like form PMEApp which is responsible for the therapeutic effect.[8,12] PMEApp is accepted as a substrate by DNA polymerases[13] and after incorporation of the nucleotidyl-like unit into the growing nucleic acid chain leads to its termination due to the lack of a 3′-hydroxyl group. It has been suggested[14,15] that the higher basicity of the phosphonyl group compared to that of a phosphoryl one, together with the presence of the ether-oxygen atom in the aliphatic side chain of $PMEApp^{4-}$, facilitate the correct positioning of the two metal ions needed in the reaction and thus make it initially an even better substrate[16,17] for DNA polymerases than $dATP^{4-}$.[14,15]

Indeed, PMEA forms with divalent metal ions (M^{2+}), like Mg^{2+}, Mn^{2+} or Zn^{2+}, five-membered chelates involving the ether oxygen as expressed in the intramolecular Equilibrium (1):

Replacement of the ether oxygen by a CH_2 unit gives 9-(4-phosphonobutyl)adenine, also termed 3′-deoxa-PMEA (dPMEA; Figure 1).[18] This compound shows no biological activity,[16] in agreement with the suggestions summarized above, and it also has a coordination pattern[18] different from that of $PMEA^{2-}$,[18–21] yet one which in fact is similar to that of AMP^{2-}.[20,22,23] This means, phosph(on)ate-coordinated metal ions may form macrochelates by interacting with N7 of the adenine residue; this is expressed in the intramolecular Equilibrium (2):[24–26]



Having a broad interest in the metal ion-binding properties of nucleotide analogues,[27–30] we decided to study 9-(5-phosphonopentyl)adenine, which is also known as 3′-deoxa-PEEA (dPEEA; Figure 1), since it is the deoxa analogue of 9-[2-(2-phosphonoethoxy)ethyl]adenine.[31] As expected, dPEEA does not show a useful biological activity but its additional CH_2 group enabled the investigation of the effect that the lengthening of the side chain of dPMEA has on the metal ion-binding properties. Thus, we measured the stability constants of the binary complexes formed between dPEEA and the alkaline earth ions, the divalent ions of the second half of the 3d series as well as Zn^{2+} and Cd^{2+}. We compared the results regarding the position of Equilibrium (2) with those obtained previously for the M(dPMEA) and the M(AMP) complexes.[18,23]

Since weak interactions[32–34] like the aromatic-ring stacking are important for the anchoring process of a substrate in the active site cavity of an enzyme,[35,36] we had previously quantified the extent of intramolecular stacking according to Equilibrium (3)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for the ternary complexes Cu(Arm)(AMP/dPMEA),[37,38] where Arm = 2,2′-bipyridine (Bpy) or 1,10- phenanthroline (Phen). Now the corresponding Cu(Arm)(dPEEA) complexes were studied leading to the interesting result that lengthening of the aliphatic chain by a CH_2 unit diminishes intramolecular stacking [Equilibrium (3)], whereas in the binary M(dPEEA) species macrochelate formation [Equilibrium (2)] is favored.

2. Results and Discussion

2.1 Acidity Constants of $H_2(dPEEA)^{\pm}$

From the structure of $dPEEA^{2-}$ (see Figure 1) it is evident that this species can accept three protons, two at the phosphonate group and one at the N1 site of the adenine residue.[39] Further protonations at an adenine residue are possible at N7 and N3, but these protons are released with $pK_a < 0$;[39−42] similarly, release of the first proton from a twofold protonated phosphonate residue occurs with a pK_a of about 2.[18,43] Hence, in the present study, for which all potentiometric pH titrations were carried out at pH > 4.0, only the following two deprotonation reactions, in which $dPEEA^{2-}$ is abbreviated as PA^{2-}, need to be considered:

$$H_2(PA)^{\pm} \rightleftharpoons H(PA)^{-} + H^{+} \quad (4a)$$

$$K^{H}_{H_2(PA)} = [H(PA)^{-}][H^{+}]/[H_2(PA)^{\pm}] \quad (4b)$$

$$H(PA)^{-} \rightleftharpoons PA^{2-} + H^{+} \quad (5a)$$

$$K^{H}_{H(PA)} = [PA^{2-}][H^{+}]/[H(PA)^{-}] \quad (5b)$$

Indeed, all the experimental data from the pH titrations in aqueous solution (25 °C; I = 0.1 M, $NaNO_3$) could be excellently fitted by taking into account Equilibria (4) and (5). The acidity constants obtained in the present study for $H_2(dPEEA)^{\pm}$ are given in Table 1 together with some related data.[44−46]

Table 1. Negative logarithms of the acidity constants of $H_2(dPEEA)^{\pm}$ [Equations (4) and (5)] together with the corresponding values of some related systems in aqueous solution at 25 °C and I = 0.1 M ($NaNO_3$)[a][b]

No.	Protonated species	$pK^{H}_{H_2(PA)}$ $(N1)H^{+}$	$pK^{H}_{H(PA)}$ $P(O)_2(OH)^{-}$	Ref.
1	$H(9MeAde)^{+}$	4.10 ± 0.01	−	[41]
2	$CH_3P(O)(OH)_2$	−	7.51 ± 0.01	[43]
3	$CH_3OP(O)(OH)_2$	−	6.36 ± 0.01	[44]
4	$H_2(AMP)^{\pm}$	3.84 ± 0.02	6.21 ± 0.01	[22]
5	$H_2(PMEA)^{\pm}$	4.16 ± 0.02	6.90 ± 0.01	[45]
6	$H_2(dPMEA)^{\pm}$	4.17 ± 0.02	7.69 ± 0.01	[18]
7	$H_2(dPEEA)^{\pm}$	4.17 ± 0.01	7.75 ± 0.01	[c]

[a] The error limits given are three times the standard error of the mean value or the sum of the probable systematic errors, whichever is larger. [b] So-called practical, mixed or Brønsted constants are listed (see [46] for details). [c] This work.

Comparison of the values listed in Table 1 (entries 1 and 4−7) reveal that the first proton of $H_2(dPEEA)^{\pm}$ is from the $(N1)H^{+}$ site of the adenine residue and the second one from the monoprotonated phosphonate group (see entries 2−7). However, more comparisons are possible; a few are given:

(i) From the comparison of entries 3 and 4 with those of 2 and 5−7 it follows that protonated phosphonate groups are less acidic than the corresponding phosphate groups; this agrees with the lower electronegativity of a C atom compared to an O atom.

(ii) The ether oxygen, due to its electron-withdrawing effect, makes the monoprotonated phosphonate species of $PMEA^{2-}$ more acidic than those of $dPMEA^{2-}$ or $dPEEA^{2-}$ (entries 5−7).

(iii) In fact, the acid-base properties of $H_2(dPMEA)^{\pm}$ and of $H_2(dPEEA)^{\pm}$ are very similar, indicating that the additional CH_2 unit in PEEA has little effect (entries 6, 7).

Finally, it needs to be pointed out that due to the different affinities of the phosph(on)ate groups for protons, the formation degree of the free ligands, PA^{2-}, differs considerably in the physiological pH range around 7.5: Under these conditions, for example, AMP^{2-} is formed to about 95% whereas $dPEEA^{2-}$ occurs only to about 36%.

2.2 Stability Constants of the $M(H;dPEEA)^{+}$ and M(dPEEA) Complexes

The experimental data of the potentiometric pH titrations (see Section 4.3) allow the determination of the stability constants defined by Equilibria (6a) and (7a):

$$M^{2+} + H(PA)^{-} \rightleftharpoons M(H;PA)^{+} \quad (6a)$$

$$K^{M}_{M(H;PA)} = [M(H;PA)^{+}]/([M^{2+}][H(PA)^{-}]) \quad (6b)$$

$$M^{2+} + PA^{2-} \rightleftharpoons M(PA) \quad (7a)$$

$$K^{M}_{M(PA)} = [M(PA)]/([M^{2+}][PA^{2-}]) \quad (7b)$$

Together with Equilibria (4a) and (5a) they are sufficient to obtain excellent fitting of the titration data provided the evaluation is not carried into the pH range where formation of hydroxo species occurs, which was evident from titrations without ligand. Of course, Equilibria (6a) and (7a) are also connected via Equilibrium (8a)

$$M(H;PA)^{+} \rightleftharpoons M(PA) + H^{+} \quad (8a)$$

$$K^{H}_{M(H;PA)} = [M(PA)][H^{+}]/[M(H;PA)^{+}] \quad (8b)$$

and the corresponding acidity constant [Equation (8b)] may be calculated with Equation (9):[47]

$$pK^{H}_{M(H;PA)} = pK^{H}_{H(PA)} + \log K^{M}_{M(H;PA)} - \log K^{M}_{M(PA)} \quad (9)$$

The results are listed in Table 2; the stability constants given for the $M(H;dPEEA)^{+}$ complexes are in part estimates since the formation degree of these species was low (see Section 4.3). The stability constants of the M(dPEEA)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complexes show the usual trends. For the alkaline earth ions the stability of the complexes decreases with increasing ionic radii indicating that metal ion binding at the phosphonate group is (at least) in part inner-sphere. For the divalent 3d metal ions the long-standing experience[48] is confirmed that the stabilities of phosph(on)ate-metal ion complexes often do not strictly follow[18,20,27,28,44,45,49] the Irving−Williams sequence,[50] an observation in agreement with the fact that in ligands of this kind the phosph(on)ate group is always the main stability-determining binding site.[19,22,24,25,51]

Table 2. Logarithms of the stability constants of the $M(H;dPEEA)^+$ [Equation (6b)] and M(dPEEA) complexes [Equation (7b)], together with the negative logarithms of the acidity constants of the protonated complexes [Equations (8b) and (9)] in aqueous solution at 25 °C and $I = 0.1$ M ($NaNO_3$)[a]

M^{2+}	$\log K^{M}_{M(H;dPEEA)}$	$\log K^{M}_{M(dPEEA)}$	$pK^{H}_{M(H;dPEEA)}$

Zn^{2+}	1.47 ± 0.22	2.9 ± 0.2[c]	6.32 ± 0.30
Cd^{2+}	1.38 ± 0.15	3.19 ± 0.05	5.94 ± 0.16

[a] For the error limits see footnote [a] of Table 1. The error limits (3σ) of the derived data, in the present case for column 4, were calculated according to the error propagation after Gauss. [b] The constants listed for these $M(H;dPEEA)^+$ complexes are estimates (see Section 4.3). [c] The experiments with Zn^{2+} were significantly hampered by precipitation; i.e., the pH range accessible for the evaluation of the constants was severely restricted (see Section 4.3).

As far as the $M(H;dPEEA)^+$ complexes are concerned, it is evident that the evaluation of potentiometric pH titration data only allows the determination of their stability constants. Further information is required to detect the binding sites of the proton and the metal ion. At first one may ask where the proton is located because binding of a metal ion to a protonated ligand commonly leads to an acidification of the ligand-bound proton.[52,53] Indeed, the acidity constants of the $M(H;dPEEA)^+$ complexes given in column 4 of Table 2 are by about 1.2 to 1.9 log units smaller than $pK^{H}_{H(dPEEA)}$. This shows that the proton in $M(H;dPEEA)^+$ is bound to the phosphonate group, hence, one may tentatively assume that the metal ion is bound preferentially to the nucleobase, since a monoprotonated phosphonate group is only a weak binding site. Indeed, this suggestion agrees with evidence obtained previously for other related $M(H;PA)^+$ species.[20,21,45,54]

Furthermore, the stability constants of the $M(H;dPEEA)^+$ complexes are, within the error limits, identical to the values determined[45] for the corresponding $M(H;PMEA)^+$ and $M(H;dPMEA)^+$ species.[18] Considering that the basicity of the N1 sites in $H(dPEEA)^-$ and $H(dPMEA)^-$ or $H(PMEA)^-$ are also identical (see Table 1; column 3, entries 5−7) and that evidence has been provided for the $M(H;PMEA)^+$ complexes[20,21,45] that the metal ion is mainly located at the nucleobase residue, one may not only conclude that in the $M(H;dPEEA)^+$ complexes the proton is at the phosphonate group, but also that the metal ion is mainly at the adenine residue. The N1 versus N7 dichotomy for metal ion binding to the adenine residue is well-known[55] though there are indications that binding to N7 dominates.[55,56] In any case, the fact that the stabilities of the $M(H;dPEEA)^+$ complexes *follow* the Irving−Williams sequence[50] [in contrast to phosph(on)ate coordinations] also supports[48a] the above conclusion that metal ion binding in the monoprotonated species occurs preferably to a nitrogen atom.

2.3 Evaluation of the Stabilities of the M(dPEEA) Complexes

For the M(dPEEA) complexes the question arises: Does the adenine residue also participate in metal ion binding next to the phosphonate group? Should such an additional interaction with the adenine residue occur, then it has to be reflected in an increased complex stability.[57] Hence, it is necessary to define the stability of a pure $-PO_3^{2-}/M^{2+}$ interaction. This can be done by applying the previously defined[45] straight-line correlations which are based on $\log K^{M}_{M(R\text{-}PO_3)}$ versus $pK^{H}_{H(R\text{-}PO_3)}$ plots for simple phosphate monoesters[58] and phosphonates;[45] these ligands are abbreviated as $R\text{-}PO_3^{2-}$, where R represents a non-coordinating residue. The parameters for the corresponding straight-line equations, which are defined by Equation (10),

$$\log K^{M}_{M(R\text{-}PO_3)} = m \cdot pK^{H}_{H(R\text{-}PO_3)} + b \qquad (10)$$

have been tabulated,[19a,25,45,51] i.e., the slopes m and the intercepts b with the y-axis. Hence, with a known pK_a value for the deprotonation of a $-P(O)_2(OH)^-$ group an expected stability constant can be calculated for any phosph(on)ate-metal ion complex.

The plots of $\log K^{M}_{M(R\text{-}PO_3)}$ versus $pK^{H}_{H(R\text{-}PO_3)}$ according to Equation (10) are shown in Figure 2 for the 1:1 complexes of Ca^{2+}, Co^{2+}, Cd^{2+} and Cu^{2+} as examples, with the data points (empty circles) of the eight simple ligand systems used[45] for the determination of the straight base lines. The four solid circles refer to the corresponding M(dPEEA) complexes; those for the Cd^{2+} and Cu^{2+} species, and possibly also for the Co^{2+} ones, are somewhat above their reference lines, thus proving an increased stability for these complexes, whereas the data point for the Ca^{2+} complex fits within the error limits on the line. Similar properties are observed for the corresponding M(dPMEA) and M(AMP) complexes (crossed circles). In contrast, *all* of the data points[45] of the M(PMEA) complexes (solid squares) are clearly above their reference lines indicating that all these

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

species are more stable than is expected on the basis of the basicity of the phosphonate group of $PMEA^{2-}$.

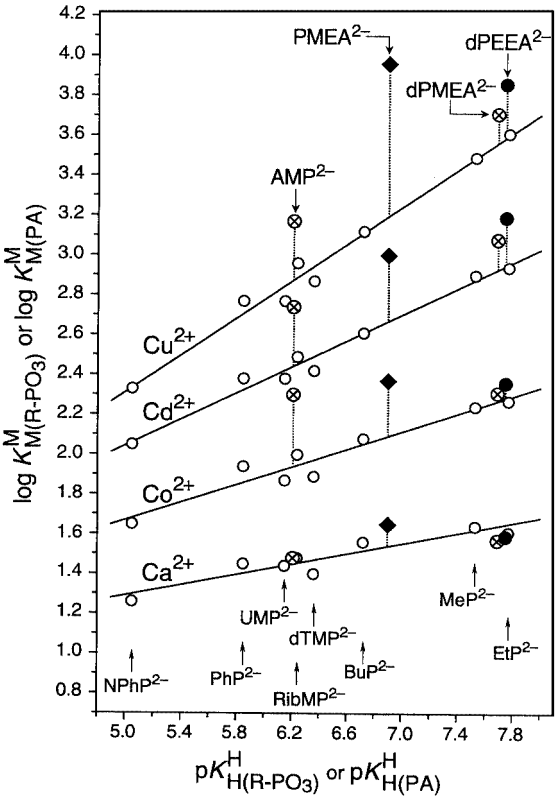

Figure 2. Evidence for an enhanced stability of the Cd(dPEEA) and Cu(dPEEA) and possibly also the Co(dPEEA) complexes, and for the lack of such an enhanced stability of the Ca(dPEEA) species (●), together with the data points for the corresponding metal ion complexes of $dPMEA^{2-}$, AMP^{2-} (⊗) and $PMEA^{2-}$ (◆) based on the relationship between log $K^{M}_{M(R\text{-}PO_3)}$ and $pK^{H}_{H(R\text{-}PO_3)}$ for M(R-PO_3) complexes of some simple phosphate monoester and phosphonate ligands (R-PO_3^{2-}) (○): 4-nitrophenyl phosphate ($NPhP^{2-}$), phenyl phosphate (PhP^{2-}), uridine 5′-monophosphate (UMP^{2-}), D-ribose 5-monophosphate ($RibMP^{2-}$), thymidine [= 1-(2-deoxy-β-D-ribofuranosyl)thymine] 5′-monophosphate ($dTMP^{2-}$), *n*-butyl phosphate (BuP^{2-}), methanephosphonate (MeP^{2-}), and ethanephosphonate (EtP^{2-}) (from left to right). The least-squares lines [Equation (10)] are drawn through the corresponding 8 data sets (○) taken from [58] for the phosphate monoesters and from [45] for the phosphonates. The points due to the equilibrium constants for the M^{2+}/dPEEA systems (●) are based on the values listed in Tables 1 and 2; those for the M^{2+}/dPMEA (⊗), M^{2+}/AMP (⊗), and M^{2+}/PMEA systems (◆) are from [18,23] and [45], respectively. The vertical broken lines emphasize the stability differences from the reference lines; they equal log $\Delta_{M/PA}$ as defined in Equation (11). All the plotted equilibrium constants refer to aqueous solutions at 25 °C and I = 0.1 M ($NaNO_3$).

The increased stability of the M(PMEA) complexes has been proven[45] to be largely due to the involvement of the ether oxygen atom in metal ion binding (see Figure 1) which gives rise to the formation of five-membered chelates and thus to the intramolecular Equilibrium (1).[15,19,45] In certain systems, like Ni(PMEA) and Cu(PMEA), a third isomer exists which involves, in addition, N3 of the adenine residue[15,19–21,45] as well as a fourth one involving N7 which, however, occurs only to a minor extent.[18]

Naturally, in the complexes of $dPEEA^{2-}$, $dPMEA^{2-}$ and AMP^{2-}, whose side chains or sugar residue is devoid of an ether oxygen atom (Figure 1), Equilibrium (1) cannot exist and therefore, any possibly observed stability increase has to be attributed to an interaction with the adenine residue. Stability enhancements, like those seen in Figure 2, can be quantified by the differences between the experimentally (exptl) measured stability constants and those calculated (calcd) according to Equation (10); this difference is defined in Equation (11),

$$\log \Delta_{M/PA} = \log K^{M}_{M(PA)_{exptl}} - \log K^{M}_{M(PA)_{calcd}} \quad (11a)$$

$$= \log K^{M}_{M(PA)} - \log K^{M}_{M(PA)_{op}} \quad (11b)$$

where the expressions log $K^{M}_{M(PA)calcd}$ and log $K^{M}_{M(PA)op}$ are synonymous because the calculated value equals the stability constant of the "open" isomer, $M(PA)_{op}$ [see, for example, Equilibria (1) and (2)], in which only a -PO_3^{2-}/M^{2+} interaction occurs. In columns 2–4 of Table 3 the values for the three terms of Equation (11) are listed. The log $\Delta_{M/dPEEA}$ values for Ni(dPEEA), Cu(dPEEA) and Cd(dPEEA) are clearly positive; the same is most likely true for those due to Co(dPEEA) and Zn(dPEEA), especially if one takes into account that the error limits refer to *three times* the standard error. Hence, in all these instances Equilibrium (2) needs to be considered.

Table 3. Stability constant comparisons for the M(dPEEA) complexes between the measured stability constants (exptl; Table 2, column 3) and the calculated stability constants (calcd) based on the basicity of the phosphonate group in $dPEEA^{2-}$ ($pK^{H}_{H(dPEEA)}$ = 7.75; Table 1) and the baseline equations established previously[25,45,51] (see Equation (10) and Figure 2), together with the stability differences log $\Delta_{M/dPEEA}$, as defined by Equation (11). The previously determined stability differences, log $\Delta_{M/dPMEA}$, for M(dPMEA) complexes[18] are given for comparison (aqueous solution; 25 °C; I = 0.1 M, $NaNO_3$)[a]

M^{2+}	log $K^{M}_{M(dPEEA)}$ exptl[b]	log $K^{M}_{M(dPEEA)}$ calcd	log $\Delta_{M/dPEEA}$	log $\Delta_{M/dPMEA}$
Mg^{2+}	1.87 ± 0.05	1.88 ± 0.03	−0.01 ± 0.06	−0.03 ± 0.05
Ca^{2+}	1.59 ± 0.06	1.65 ± 0.05	−0.06 ± 0.08	−0.07 ± 0.07
Sr^{2+}	1.31 ± 0.07	1.37 ± 0.04	−0.06 ± 0.08	−0.06 ± 0.06
Ba^{2+}	1.25 ± 0.06	1.30 ± 0.04	−0.05 ± 0.07	−0.07 ± 0.07
Mn^{2+}	2.55 ± 0.03	2.53 ± 0.05	0.02 ± 0.06	−0.04 ± 0.06
Co^{2+}	2.36 ± 0.05	2.28 ± 0.06	0.08 ± 0.08	0.04 ± 0.08
Ni^{2+}	2.46 ± 0.03	2.32 ± 0.05	0.14 ± 0.06	0.10 ± 0.08
Cu^{2+}	3.86 ± 0.08	3.59 ± 0.06	0.27 ± 0.10	0.16 ± 0.09
Zn^{2+}	2.9 ± 0.2	2.66 ± 0.06	0.24 ± 0.21	0.1 ± 0.2
Cd^{2+}	3.19 ± 0.05	2.95 ± 0.05	0.24 ± 0.07	0.15 ± 0.11

[a] Regarding the error limits (3σ) see footnote [a] of Table 2. [b] These values are from column 3 of Table 2.

A comparison of the log $\Delta_{M/PA}$ values given in columns 4 and 5 of Table 3 for the M(dPEEA) and M(dPMEA) complexes, respectively, reveals that their properties are quite alike with a slightly more enhanced stability of some of the M(dPEEA) species.

2.4 Extent of Macrochelate Formation in M(dPEEA) Systems and Comparison with That Occurring in M(dPMEA) and M(AMP) Species

The position of the concentration-independent Equilibrium (2) between the simple phosphonate-bound species, which we designate as the "open" isomer, $M(dPEEA)_{op}$, and the macrochelated isomer involving the adenine residue, designated as the "closed" species, $M(dPEEA)_{cl}$, is defined by the intramolecular, and hence dimensionless, equilibrium constant K_I given in Equation (12):

$$K_I = [M(dPEEA)_{cl}]/[M(dPEEA)_{op}] \quad (12)$$

Values for K_I can be calculated by known procedures,[22,45,57] i.e., via Equation (13):

$$K_I = 10^{\log \Delta_{M/dPEEA}} - 1 \quad (13)$$

Knowledge of K_I allows then to obtain the percentage of the closed isomer, $M(dPEEA)_{cl}$, according to Equation (14):

$$\% M(dPEEA)_{cl} = 100 \cdot K_I/(1 + K_I) \quad (14)$$

The results are summarized in Table 4 for the M(dPEEA) complexes of the 3d ions including Zn^{2+} and Cd^{2+}. For the complexes of the alkaline earth ions the formation degree of the closed species in Equilibrium (2) is zero within the error limits as follows from the log $\Delta_{M/dPEEA}$ values listed in column 4 of Table 3.

From the results listed in columns 2−4 of Table 4 it follows that at least for Ni^{2+}, Cu^{2+}, Zn^{2+} and Cd^{2+}, which have the most pronounced affinity for N sites among the ten metal ions studied,[48a] Equilibrium (2) operates and that the adenine residue is involved in metal ion binding. From the three nitrogen atoms available in the purine ring, i.e., N1, N3 and N7 (see Figure 1), N1 cannot be reached by a metal ion already coordinated to the phosphonate group;[19] hence, N3 and N7 remain for macrochelate formation. At this stage one cannot distinguish with absolute certainty between these two possibilities, but we strongly favor an interaction of the phosphonate-coordinated metal ion with N7 because N7 is known to be considerably more basic than N3.[39−42] Furthermore, macrochelate formation in the M(AMP) complexes occurs with certainty via N7;[22,59] hence, it appears that M(dPEEA) and M(dPMEA) resemble in this respect their parent complexes, i.e., M(AMP), more than the M(PMEA) species which contain the antivirally active ligand $PMEA^{2-}$ and involve the ether oxygen atom in metal ion binding (see Section 1).

With the above evidence for macrochelate formation involving N7 in mind, it is interesting to compare the properties of the $dPEEA^{2-}$, $dPMEA^{2-}$ and AMP^{2-} ligands (Figure 1). From the results given in columns 4−6 of Table 4 it follows that the extent of macrochelate formation increases within the series M(dPMEA) < M(dPEEA) < M(AMP). The changes are not dramatic, but the trend within the series seems to be clear for each metal ion. A further interesting observation is that for Cu^{2+}, Zn^{2+} and Cd^{2+} the formation degrees of the $M(dPEEA)_{cl}$ and $M(AMP)_{cl}$ species are quite alike. Hence, it seems that $dPEEA^{2-}$ mimics AMP^{2-} even better than $dPMEA^{2-}$; most likely this is due to the by one CH_2 unit longer side chain of $dPEEA^{2-}$, compared to the one of $dPMEA^{2-}$, and that this allows the phosphonate-bound M^{2+} to reach N7 with less strain.

2.5 Stability of the Mixed Ligand Cu(Arm)(H;dPEEA)$^+$ and Cu(Arm)(dPEEA) Complexes

For the ternary complexes composed of $H(dPEEA)^-$ or $dPEEA^{2-}$, Cu^{2+} and a heteroaromatic amine (Arm), i.e., 2,2′-bipyridine (Bpy) or 1,10-phenanthroline (Phen), the same evaluation procedure holds as described in the first paragraph of Section 2.2 for the binary complexes because complex formation of $Cu(Bpy)^{2+}$ and $Cu(Phen)^{2+}$, due to their high stability,[60] is complete (see also Section 4.3) before the onset of the formation of the mixed ligand complexes occurs. This means that in the case of the ternary systems the experimental data of the potentiometric pH titrations can also be fully described by taking Equilibria (4a)−(7a) into account, but now $M^{2+} = Cu(Arm)^{2+}$. The corresponding stability constants are given in Table 5.

A comparison of the acidity constants of $H_2(dPEEA)^{\pm}$, $pK^H_{H_2(dPEEA)} = 4.17$ and $pK^H_{H(dPEEA)} = 7.75$ (Table 1), with those of the $Cu(Arm)(H;dPEEA)^+$ complexes, i.e.,

Table 4. Increased complex stability, log $\Delta_{M/dPEEA}$ [Equation (11)], and extent of chelate formation according to Equilibrium (2) for some M(dPEEA) complexes, as quantified by the dimensionless equilibrium constant K_I [Equations (12), (13)] and the percentage of $M(dPEEA)_{cl}$ [Equation (14)]. The corresponding percentages for $M(dPMEA)_{cl}$ [18] and $M(AMP)_{cl}$ [23] are given for comparison (aqueous solution; 25 °C; I = 0.1 M, $NaNO_3$)[a]

M^{2+}	log $\Delta_{M/dPEEA}$ [b]	K_I	% $M(dPEEA)_{cl}$	% $M(dPMEA)_{cl}$	% $M(AMP)_{cl}$
Mn^{2+}	0.02 ± 0.06	0.05 ± 0.14	5 ± 13	≤ 5	15 ± 11
Co^{2+}	0.08 ± 0.08	0.20 ± 0.22	17 ± 15	9 ± 17	56 ± 7
Ni^{2+}	0.14 ± 0.06	0.38 ± 0.19	28 ± 10	21 ± 15	75 ± 4
Cu^{2+}	0.27 ± 0.10	0.86 ± 0.43	46 ± 12	31 ± 14	50 ± 7
Zn^{2+}	0.24 ± 0.21[c]	0.74 ± 0.84[c]	42 ± 28	21 ± 37[d]	44 ± 12
Cd^{2+}	0.24 ± 0.07	0.74 ± 0.28	42 ± 9	29 ± 18	50 ± 8

[a] Regarding the error limits (3σ) see footnote [a] of Table 2. [b] From column 4 of Table 3. [c] See footnote [c] in Table 2. [d] The measurements for the Zn(dPMEA) systems were also affected by precipitation.[18]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 5. Logarithms of the stability constants of the $M(H;dPEEA)^+$ [Equation (6b)] and M(dPEEA) complexes [Equation (7b)], where $M^{2+} = Cu^{2+}$, $Cu(Bpy)^{2+}$ or $Cu(Phen)^{2+}$, as determined by potentiometric pH titrations in aqueous solution, together with the negative logarithms for the acidity constants of $M(H;dPEEA)^+$ [Equations (8b), (9)] at 25 °C and $I = 0.1$ M ($NaNO_3$)[a]

M^{2+}	log $K^{M}_{M(H;dPEEA)}$	log $K^{M}_{M(dPEEA)}$	$pK^{H}_{M(H;dPEEA)}$
Cu^{2+}	1.92 ± 0.12	3.86 ± 0.08	5.81 ± 0.15
$Cu(Bpy)^{2+}$	1.87 ± 0.11	4.07 ± 0.07	5.55 ± 0.13
$Cu(Phen)^{2+}$	2.14 ± 0.12	4.36 ± 0.14	5.53 ± 0.18

See footnote [a] of Table 2.

$pK^{H}_{Cu(Arm)(H;dPEEA)} \approx 5.5$ (Table 5, column 4), reveals that in these complexes, just as in the binary ones, the proton must be located at the phosphonate group, since metal ion coordination must give rise to an acidification.[52,53] In fact, the acidity constants of the $Cu(Arm)(H;dPEEA)^+$ complexes are about 2.2 log units smaller than $pK^{H}_{H(dPEEA)}$, but approximately 1.4 log units larger than $pK^{H}_{H_2(dPEEA)}$.

However, where is the $Cu(Arm)^{2+}$ unit located? Indeed, the $Cu(Arm)(H{\cdot}dPEEA)^+$ species, where the notation $(H{\cdot}dPEEA)^-$ indicates that the proton is at the phosphonate group, may exist in two principally different forms: One, where $Cu(Arm)^{2+}$ is stacked with the purine system of $(H{\cdot}dPEEA)^-$, designated as $[Cu(Arm)/(H{\cdot}dPEEA)]^+_{st}$, and another one, where $Cu(Arm)^{2+}$ is simply coordinated either to the N1/N7 sites of the adenine residue (see Section 2.2), $[(H{\cdot}dPEEA){\cdot}Cu(Arm)]^+_{ade}$, or to the phosphonate group which already carries the proton. However, the formation of the latter species with both the proton and $Cu(Arm)^{2+}$ at the phosphonate group is unlikely, in agreement with the conclusions given in Section 2.2 for the binary $Cu(H;dPEEA)^+$ species, where Cu^{2+} is mainly located at the adenine residue and H^+ at the phosphonate group. Hence, we have to consider the $[(H{\cdot}dPEEA){\cdot}Cu(Arm)]^+_{ade}$ and the $[Cu(Arm)/(H{\cdot}dPEEA)]^+_{st}$ species and take into account the following intramolecular Equilibrium (15):

$$[(H{\cdot}dPEEA){\cdot}Cu(Arm)]^+_{ade} \rightleftharpoons [Cu(Arm)/(H{\cdot}dPEEA)]^+_{st} \qquad (15)$$

An evaluation of the various equilibrium constants, identical to the procedure described recently,[38,61] leads to the conclusion that the stacked species in Equilibrium (15) dominate in the $Cu(Phen)^{2+}$ system with a formation degree of about 70% for the $[Cu(Phen)/(H{\cdot}dPEEA)]^+_{st}$ species. In the case of the $Cu(Bpy)^{2+}$ system the two isomeric species of Equilibrium (15) occur in about *equal* amounts. These results are very similar to those obtained previously[38] for the $Cu(Arm)^{2+}/(H{\cdot}dPMEA)^-$ systems. Furthermore, that stacking is somewhat more pronounced in the system containing Phen is in agreement with the expectation (see also Section 2.7).

2.6 Proof of an Increased Stability of the Mixed Ligand Cu(Arm)(dPEEA) Complexes

One way to quantify the stability of mixed ligand complexes[62,63] is to consider Equilibrium (16a) with its corresponding equilibrium constant [Equation (16b)], which is calculated from Equation (17):

$$Cu(Arm)^{2+} + Cu(dPEEA) \rightleftharpoons Cu(Arm)(dPEEA) + Cu^{2+} \qquad (16a)$$

$$10^{\Delta \log K} = \frac{[Cu(Arm)(dPEEA)][Cu^{2+}]}{[Cu(Arm)^{2+}][Cu(dPEEA)]} \qquad (16b)$$

$$\Delta \log K = \log K^{Cu(Arm)}_{Cu(Arm)(dPEEA)} - \log K^{Cu}_{Cu(dPEEA)} \qquad (17)$$

According to the general rule for complex stabilities, $K_1 > K_2$, Equilibrium (16a) is expected to lie on the left with negative values for $\Delta \log K$ in agreement with statistical considerations, i.e. $\Delta \log K_{Cu/statist} \approx -0.5$.[63] The results for $\Delta \log K_{Cu/Bpy/dPEEA}$ and $\Delta \log K_{Cu/Phen/dPEEA}$ according to Equation (17) are 0.21 ± 0.11 and 0.50 ± 0.16, respectively (see Table 5). These values are clearly larger than the statistically expected value. Hence, it is clear that Equilibrium (16a) is significantly displaced to the right hand side and that these ternary complexes show an increased stability. However, it is difficult to draw quantitative conclusions from these results because the binary Cu(dPEEA) complex itself also shows an increased stability due to macrochelate formation [see Section 2.4 and Equilibrium (2)]. Yet, despite this shortcoming the given results for Equation (17) still prove definitely an increased stability for the Cu(Arm)(dPEEA) complexes.

Another way to evaluate the stability of the ternary Cu^{2+} complexes, independently of that of the corresponding binary complexes, is analogous to the procedure used in Section 2.4 for the binary systems. This means, straight-line correlations for log $K^{Cu(Arm)}_{Cu(Arm)(R\text{-}PO_3)}$ versus $pK^{H}_{H(R\text{-}PO_3)}$ plots, where $R\text{-}PO_3^{2-}$ represents phosphate monoester or phosphonate ligands in which the residue R is unable to interact with $Cu(Arm)^{2+}$, have been defined and they are valid in the pK_a range between 5 and 8.[51][61] These reference lines are seen in Figure 3 where the stability constants log $K^{Cu(Arm)}_{Cu(Arm)(dPEEA)}$ versus the acidity constant $pK^{H}_{H(dPEEA)}$ are also plotted (square symbols) together with the corresponding data[38] of the $Cu(Arm)^{2+}/dPMEA^{2-}$ systems (circles).

The data points in Figure 3 for the two ternary Cu(Arm)(dPEEA) complexes are far above their reference lines proving again the increased complex stability and this must now mean[57] that, aside from the phosphonate-$Cu(Arm)^{2+}$ coordination, further interactions occur. Such an increased stability, which in fact is even more pronounced, is also observed for the ternary Cu(Arm)(dPMEA) systems[38] as one can see in Figure 3. The vertical differences between the mentioned data points and their reference lines can be defined according to Equation (11) (Section 2.3) by keeping in mind that now $M^{2+} = Cu(Arm)^{2+}$. The needed stability of the "open" isomers, $Cu(Arm)(dPEEA)_{op}$, is calculated with $pK^{H}_{H(dPEEA)} = 7.75$ (Table 1, entry 7) and the straight-line parameters given

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

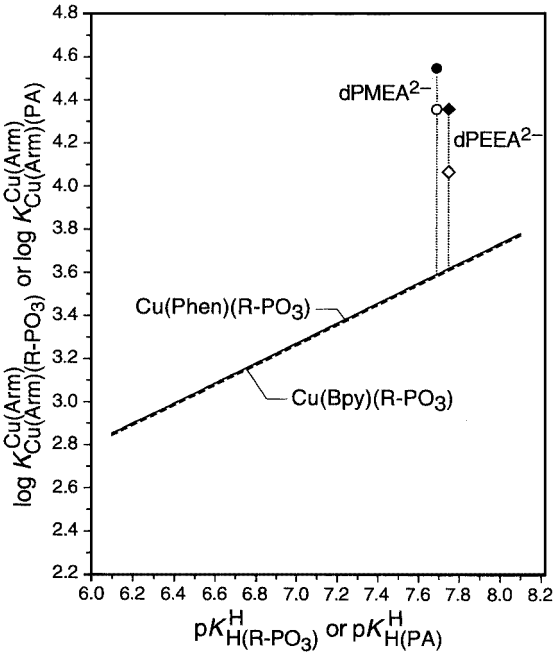

Figure 3. Evidence for an enhanced stability of the ternary Cu(Bpy)(dPEEA) (◇) and Cu(Phen)(dPEEA) (◆) as well as the Cu(Bpy)(dPMEA) (○) and Cu(Phen)(dPMEA) (●) complexes, based on the relationship between log $K^{Cu(Arm)}_{Cu(Arm)(R\text{-}PO_3)}$ or log $K^{Cu(Arm)}_{Cu(Arm)}$ and $pK^{H}_{H(R\text{-}PO_3)}$ or $pK^{H}_{H(PA)}$ in aqueous solution at $I = 0.1$ M ($NaNO_3$) and 25 °C. The plotted data corresponding to the $dPEEA^{2-}$ systems are from Tables 1 and 5 and those corresponding to $dPMEA^{2-}$ are from ref.[38] The two reference lines represent the log K versus pK_a relationship for the ternary Cu(Arm)($R\text{-}PO_3$) complexes [Equation (10)]; it should be emphasized that $R\text{-}PO_3^{2-}$ symbolizes here phosph(on)ate ligands with a group R unable to undergo any kind of hydrophobic, stacking or other type of interaction. The parameters for the straight-line equations are listed in ref.[61]

in refs.[51,61]: log $K^{Cu(Bpy)}_{Cu(Bpy)(dPEEA)op}$ = 3.61 ± 0.07 and log $K^{Cu(Phen)}_{Cu(Phen)(dPEEA)op.}$ = 3.62 ± 0.06. Application of these values together with the corresponding experimental results given in Table 5 (column 3) to Equation (11) leads to the log $\Delta_{Cu/Arm/dPEEA}$ values which quantify in an exact way the enhanced stability of the ternary Cu(Arm)(dPEEA) complexes. These values are listed in the third column of Table 6 (see below).

2.7 Evaluation of the Increased Stability of the Cu(Arm)(dPEEA) Complexes

It is clear[57] that the described enhanced complex stabilities (Table 6, column 3) must originate in additional interactions, i.e., beyond the coordination of $Cu(Arm)^{2+}$ to the phosphonate group. The ligand $dPEEA^{2-}$ offers only two such possibilities: The phosphonate-coordinated $Cu(Arm)^{2+}$ forms (i) a macrochelate with N7 of the adenine residue, as is the case with the binary Cu(dPEEA) complex (Section 2.4), or (ii) an intramolecular stack between the aromatic ring systems of Bpy or Phen and the adenine moiety. This latter type of interaction is known for many examples and can be very significant;[32,35−38,54,63] it is also evident from the results indicated in Section 2.5 for the monoprotonated $Cu(Arm)(H;dPEEA)^{+}$ species.

That the first of these two possible interactions is of no importance was demonstrated in detail recently for the $Cu(Arm)^{2+}$ systems with $dPMEA^{2-}$ [38] as well as for related analogues[36,54,61] and also for AMP^{2-} itself.[37] Hence, the enhanced complex stabilities may only be attributed to intramolecular stack formation; in fact, for Cu(Arm)(AMP) this was also proven to occur in the solid state by crystal structure analyses.[6b,64] Consequently, the Cu(Arm)(dPEEA) complexes occur in the two isomeric forms indicated in Equilibrium (3): In one, $Cu(Arm)^{2+}$ is only coordinated to the phosphonate group and this isomer is designated as $Cu(Arm)(dPEEA)_{op}$ as already indicated in Section 2.6; in the other form, designated as $Cu(Arm)(dPEEA)_{st}$, intramolecular stack formation occurs. A tentative structure of this latter isomer is shown in Figure 4. Consequently, the dimensionless equilibrium constant $K_{I/st}$ due to the intramolecular Equilibrium (3) is defined by Equation (18):

$$K_{I/st} = [Cu(Arm)(dPEEA)_{st}]/[Cu(Arm)(dPEEA)_{op}] \quad (18)$$

Values for $K_{I/st}$ as well as for the percentage of the stacked isomer, $Cu(Arm)(dPEEA)_{st}$, are calculated in analogy to Equations (13) and (14), respectively, and summarized in columns 4 and 5 of Table 6.

The results of Table 6 lead to the following conclusions: (i) Stack formation is always more pronounced in the Cu(Phen)(PA) systems, where PA^{2-} = $dPEEA^{2-}$,

Table 6. Extent of intramolecular stack formation in ternary Cu(Arm)(PA) complexes, where PA^{2-} = $dPEEA^{2-}$, $dPMEA^{2-}$ or AMP^{2-}, as calculated from stability constants determined via potentiometric pH titrations: Given are the stability enhancement log $\Delta_{Cu/Arm/PA}$ [Equation (11)], the intramolecular and dimensionless equilibrium constant $K_{I/st}$ [Equations (13), (18)], and the percentage [Equation (14)] of the stacked $Cu(Arm)(PA)_{st}$ species in aqueous solution at 25 °C and $I = 0.1$ M ($NaNO_3$)[a]

No.	Cu(Arm)(PA)	log $\Delta_{Cu/Arm/PA}$	$K_{I/st}$	%$Cu(Arm)(PA)_{st}$	Ref.
1a	Cu(Bpy)(dPEEA)	0.46 ± 0.10	1.88 ± 0.66	65 ± 8	[b]
1b	Cu(Phen)(dPEEA)	0.74 ± 0.15	4.50 ± 1.90	82 ± 6	[b]

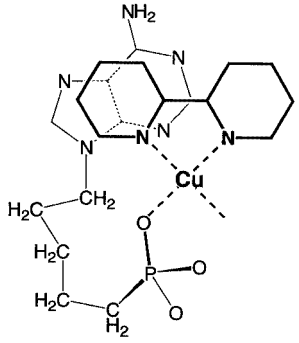

Figure 4. Tentative and simplified structure of a species with an intramolecular stack for Cu(Bpy)(dPEEA) in solution. The orientation of the aromatic rings may vary somewhat from one stacked species to the next; such a stacked complex in solution should not be considered as being rigid.

dPMEA^{2-} or AMP^{2-} (compare entries a with b). This result is understandable, since the overlap of the aromatic ring systems is expected to be more pronounced with the 3-ring system of Phen than with the 2-ring system of Bpy. (ii) The extent of stack formation for a given Arm is within the error limits clearly identical for dPMEA^{2-} and AMP^{2-} (entries 2, 3) and still similar if the Phen/dPEEA^{2-} system (entry 1b) is included in the comparisons (entries 2b, 3b). However, (iii) this is different if the Bpy systems (entries 1a, 2a, 3a) are compared; here the formation degree of Cu(Bpy)(dPEEA)$_{st}$ is clearly lower than the one for Cu(Bpy)(dPMEA) and Cu(Bpy)(AMP). Most likely the pentyl chain is too long to allow an optimal fit with one of the Bpy rings. Indeed, for C_6H_5-$(CH_2)_n$-COO^-/M^{2+}/Phen[63,65] and related systems[66] it has previously been shown that the $(CH_2)_n$ chain may become too long and reach then beyond the rings needed for the intramolecular interaction. In accord with this interpretation are the results for the Cu(Phen)(dPEEA) and Cu(Phen)(dPMEA) systems (entries 1b, 2b); Phen with its 3-ring system is less sensitive than the 2-ring Bpy with regard to the chain length, i.e., to an exchange of the butyl by a pentyl chain. Hence, as far as the stacking interaction in Cu(Arm)(PA) systems is concerned, dPMEA^{2-} mimics AMP^{2-} somewhat better than dPEEA^{2-}.

3. Conclusions

The coordinating properties of dPEEA^{2-} and dPMEA^{2-} do not differ dramatically. However, it is still interesting to note that in binary complexes of divalent 3d metal ions including Zn^{2+} and Cd^{2+}, dPEEA^{2-} resembles the parent nucleotide AMP^{2-} somewhat better than its chain-shortened analogue dPMEA^{2-} (Figure 1): In other words, macrochelate formation between the phosphonate-coordinated metal ion and N7 of the adenine moiety seems to be somewhat more favored in M(dPEEA) than in M(dPMEA) species. In fact, in a first approximation, the extent of macrochelate formation increases for a given M^{2+} within the series M(dPMEA) < M(dPEEA) < M(AMP), though, e.g., for Cu^{2+} and Cd^{2+} the extent is within the error limits identical for the dPEEA^{2-} and AMP^{2-} systems. However, the metal ion-binding properties of all three mentioned ligands differ significantly from those of the antivirally active PMEA^{2-} (see Figure 1); for all its M(PMEA) complexes an ether oxygen-M^{2+} interaction is of relevance which does not occur, of course, with its deoxa analogues or with AMP^{2-}.

In the mixed ligand Cu(Arm)(PA) complexes dPMEA^{2-} resembles its parent AMP^{2-} more closely than dPEEA^{2-}. This means, the extent of intramolecular stack formation is similar in the Cu(Arm)(dPMEA) and Cu(Arm)(AMP) systems and also more pronounced than in Cu(Arm)(dPEEA); this is especially true for Arm = Bpy. It seems that the pentyl chain is somewhat too long and does therefore not favor an ideal fit for the aromatic ring stacks as it appears to be the case with the butyl chain.

It has been suggested[14,15] that diphosphorylated PMEA^{2-}, i.e., PMEApp^{4-}, is initially an excellent substrate for DNA polymerases because of the facilitated formation of the M(P_α)-binding mode which leads then to the also facilitated formation of the reactive M(P_α)-M(P_β,P_γ) mode which is crucial for the transfer of a nucleotidyl unit in the polymerase reaction.[15] This M(P_α) binding is facilitated due to the M^{2+} interaction with the ether oxygen. At present no data are available on the metabolism of dPMEA or dPEEA but if it is assumed that dPMEA and dPEEA are transported to the cell and also diphosphorylated, like PMEA,[12,13] then it would become understandable why these two analogues lack antiviral activity. A facilitated M(P_α) binding (via the ether oxygen) is not possible[14] with dPMEApp^{4-} or dPEEApp^{4-} and thus the transfer of a nucleotidyl unit in the polymerase reaction[15] would also not be facilitated.

4. Experimental Section

4.1 Materials

Twofold protonated 9-(5-phosphonopentyl)adenine, i.e., H_2(dPEEA)$^{\pm}$, was synthesized as described below in Section 4.2 with 1,5-dibromopentane, triethyl phosphite, 1,8-diazabicyclo[1.3.0]undec-1-ene, bromotrimethylsilane and dimethylformamide, which were purchased from Sigma−Aldrich, Prague, Czech Republic.

All aqueous stock solutions for the potentiometric pH titrations were prepared by dissolving the various compounds in deionized, ultrapure (MILLI-Q185 PLUS; from Millipore S.A., 67120 Molsheim, France) CO_2-free water.

2,2′-Bipyridine and 1,10-phenanthroline monohydrate were from Merck AG, Darmstadt, FRG. All the other reagents were the same as used recently.[18]

4.2 Synthesis of 9-(5-Phosphonopentyl)adenine

This compound has been mentioned in the literature[67] in the context of enzyme-catalyzed deamination reactions but its synthesis has not been described and therefore it is given here.

The first step in the synthesis of 9-(5-phosphonopentyl)adenine [= 5-(adenin-9-yl)pentylphosphonic acid] was heating of a mixture of 1,5-dibromopentane (100 g, 0.43 mol) and triethyl phosphite (90 mL, 1.125 equiv.) for 2 days at 110 °C; the resulting ethyl bro-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mide was distilled off. The portion volatile up to a maximum of 100 °C/2 kPa was removed. The residue, i.e. diethyl 5-bromopentylphosphonate, was utilized in the next step without further purification.

The mixture of adenine (20.0 g, 0.148 mol), 1,8-diazabicyclo[1.3.0]undec-1-ene (30 mL) and crude diethyl 5-bromopentylphosphonate (60 mL) in dimethylformamide (200 mL) was heated at 100 °C for 5 h and the solvent evaporated. The residue was extracted with hot chloroform (in total 500 mL) and the solvent evaporated to give by chromatography on a silica gel column (300 mL) in chloroform by extraction with chloroform-methanol mixtures oily diethyl 5-(adenin-9-yl)pentylphosphonate (yield: 11.6 g; 23%). This compound (34 mmol) in acetonitrile (100 mL) was stirred with bromotrimethylsilane (20 mL) till dissolution and left to stand overnight at ambient temperature. The mixture was evaporated in vacuo and the residue codistilled with toluene (2 × 25 mL). Water (150 mL) was added and, after 20 min, the mixture was basified with conc. aqueous ammonia and the solvents evaporated. The residue in minimum water was applied to a column of Dowex 50 × 8 (H^+-form) (250 mL), the column was washed with water to the loss of acidity and UV-absorption of the eluate (monitored at 254 nm). Subsequent elution of the column with diluted (1:10) aqueous ammonia gave a UV-absorbing eluate which was evaporated to dryness in vacuo. This residue in minimum water was basified with ammonia to pH 10 and applied onto a column of Dowex 1 × 2 (acetate form) prewashed with water (200 mL); the column was eluted with water (1 L) and the resin was then stirred batchwise with 1 M formic acid (500 mL), filtered off and washed with boiling water (four 500 mL portions). The combined eluates were evaporated in vacuo, the residue codistilled with water (five 50 mL portions) and crystallized from water. Yield, 5.1 g (52.5%), m.p. 330 °C. $C_{10}H_{16}N_5O_3P$ (285.2): calcd. C 42.11, H 5.65, N 25.55, P 10.86; found C 42.25, H 5.41, N 25.28, P 11.03. ^{1}H NMR (in D_2O, 500 MHz): δ = 8.28 and 8.21 (2 s, 1 H each, H2 and H8 of Ade), 4.27 (t, J = 6.9 Hz, 2 H, H1′), 1.90 (m, 2 H), 1.53 (m, 4 H), 1.36 (m, 2 H, H2′, -3′, -4′, -5′) ppm. ^{13}C NMR (in D_2O, 125.7 MHz): saturated solution − low concentration allowed the detection of proton-bearing carbons only: δ = 154.09 (s, C2), 145.90 (s, C8), 46.92 (s, C1′), 31.63 (s, C2′), 29.98 (d, $J_{C,P}$ = 5.4 Hz, C3′), 35.54 (d, $J_{C,P}$ = 4.4 Hz, C4′), 30.58 (d, $J_{C,P}$ = 121.1 Hz, C5′) ppm.

4.3 Potentiometric pH Titrations. Determination of Equilibrium Constants

The equipment for the titrations,[18] the buffers used for calibration[18] and the evaluation procedures including the computers were the same as before.[43]

The acidity constants $K^H_{H_2(dPEEA)}$ and $K^H_{H(dPEEA)}$ of $H_2(dPEEA)^{\pm}$, where one proton is at the base moiety and the other at the phosphonate group, were determined by titrating 50 mL of aqueous 0.9 m M HNO_3 (25 °C; I = 0.1 M, $NaNO_3$) in the presence and absence of 0.3 mM $dPEEA^{2-}$ under N_2 with 1.6 mL of 0.03 M NaOH. The differences in NaOH consumption between such a pair of titrations were used for the calculations. These conditions correspond to those used recently for the dPMEA system;[18] it needs to be emphasized that at a ligand concentration[22] of 3×10^{-4} M the well-known[32] self-association (via π-stacking) of purines is of no significance. The results for the acidity constants of $H_2(dPEEA)^{\pm}$ are the averages of 19 pairs of independent titrations.

The stability constants $K^M_{M(H;dPEEA)}$ and $K^M_{M(dPEEA)}$ of $M(H;dPEEA)^+$ and M(dPEEA) were determined under the same conditions as the acidity constants, but $NaNO_3$ was partly or fully replaced by $M(NO_3)_2$ (25 °C; I = 0.1 M). The conditions correspond to those given recently for the M^{2+}/dPMEA systems,[18] but the M^{2+}/dPEEA ratios were 111:1 (Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Mn^{2+}), 55.6:1 (Co^{2+}, Ni^{2+}), 53.3:1 (Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}), 50:1 (Mn^{2+}), 26.9:1 (Cd^{2+}), 25:1 (Co^{2+}, Ni^{2+}), 13.4:1 (Cd^{2+}), 12.3:1 (Zn^{2+}), 10.6:1 (Cu^{2+}, $Cu(Bpy)^{2+}$, $Cu(Phen)^{2+}$), 5.3:1 (Cu^{2+}, $Cu(Bpy)^{2+}$, $Cu(Phen)^{2+}$) and 5:1 (Zn^{2+}). Since the stability of the $Cu(Arm)^{2+}$ complexes is high,[60] the formation of these species is practically complete under the experimental conditions (titrations of solutions with HNO_3 and HNO_3 + Cu^{2+}/Arm were identical in the lower pH range) and therefore, the evaluation of the titration data of the ternary systems could be done in the way described for the binary ones.[28]

The evaluation of the Zn^{2+}/dPEEA systems was significantly hampered by precipitation, and therefore the pH range accessible for the calculations of the stability constants was severely restricted. In fact, for Zn(dPEEA) only a formation degree of about 2% was reached; hence, the value for Zn(dPEEA) must be considered as an estimate.

However, several of the constants given for the $M(H;dPEEA)^+$ complexes must also be considered as estimates (see Table in Section 2.2), since the formation degree of these species reached only about 3%, in the maximum 18% was reached; for the ternary $Cu(Arm)(H;dPEEA)^+$ complexes a formation degree of nearly 25% was achieved.

The individual results for the stability constants showed no dependence on pH or on the excess of metal ion concentration used. The results are in each case the average of at least five independent pairs of titration curves.

Acknowledgments

The competent technical assistance of Mrs. Rita Baumbusch and Mrs. Astrid Sigel in the preparation of this manuscript is gratefully acknowledged. Thanks are also due to Dr. M. Buděšinský (IOCB) for measurement and interpretation of NMR spectra. This study was supported by the Swiss National Science Foundation (H.S.) and the Programme of Targeted Projects (S4055109) of the Academy of Sciences of the Czech Republic (A.H.) as well as within the COST D20 programme by the Swiss Federal Office for Education and Science (H.S.) and the Ministry of Education of the Czech Republic (D.20.002; A.H.). This study is also part of a research project (No. 4055905) of the Institute of Organic Chemistry and Biochemistry (IOCB) in Prague.

Keywords: Magnetic properties / Barium / Iron / Cobalt / Thermochemistry

Complexes with formula $[BaM(C_3H_2O_4)_2(H_2O)_4]$, where M = Fe or Co, were synthesised and characterised. These two types of complexes are isostructural and crystallise in the *Pccn* space group. Their structure consists of two-dimensional networks of octahedral MO_6 polyhedra in which the transition metal ions are coordinated by bridging malonate ligands, through the O-C-O atoms. These M-malonate units are extended along the crystallographic [101] plane. Spectroscopic data are consistent with the cations being in a high-spin octahedral symmetry. The two types of compounds exhibit 2D antiferromagnetic interactions as well as weak ferromagnetism below the Néel temperature, as a result of an intralayer misalignment of the spins. Thermal treatment of the metallo-organic precursors gave rise to $BaMO_{3-y}$ oxides at lower temperatures and reaction times than those found in the literature using the ceramic method.

Introduction

The chemistry of heteronuclear complexes involving bridging carboxylate ligands has been exhaustively investigated using a wide variety of physical techniques such as electronic spectroscopy, susceptibility measurements, EPR spectroscopy,... with the aim of understanding the structural and chemical factors that govern the exchange coupling between paramagnetic centres.

The malonate ligand, with two neighbouring carboxylate groups, is a very flexible ligand which can adopt a monodentate mode, various bischelating coordination modes and different carboxylate bridging modes (*syn-syn, syn-anti,* and *anti-anti*).[1] It is a useful tool for connecting different metal ions and transmitting different magnetic interactions. In this way, ferromagnetically[2] or antiferromagnetically[3] coupled dimers, alternating chains,[4,5] polymeric trinuclear antiferromagnetic complexes[6,7] and two-dimensional ferromagnetic and antiferromagnetic compounds[8,9] have been obtained and studied.

On the other hand, these complexes can be used as an alternative to the ceramic method in the synthesis of mixed oxides.[10,11] In this sense, several studies with different metallo-organic precursors, employing carboxylate ligands such as edta,[12] oxalate[13] and tartrate,[14] or nitrite[15] have been carried out, and more recently using the malonate ligand.[8,16−18]

Malonate complexes such as $[AM(C_3H_2O_4)_2(H_2O)_4]$, where A is Sr or Ba and M is Mn or Cu, showed interesting spectroscopic and magnetic properties. Furthermore, their usefulness as precursors of mixed oxides was proved, and homogeneous oxides with small particles were obtained by thermal treatment of $[AM(C_3H_2O_4)_2(H_2O)_4]$.[8] In this paper we describe the synthesis and the spectroscopic and magnetic properties of the $[BaM(C_3H_2O_4)_2(H_2O)_4]$ (M = Fe or Co) compounds, together with their thermal study. These complexes will be abbreviated as BaFe and BaCo.

Results and Discussion

Crystallographic Study

Powder X-ray diffraction patterns of the microcrystalline products were recorded. Indexation of the diffraction profile and refinement of the cell parameters were made by FULLPROF (pattern-matching analysis)[19] on the basis of the space group *Pccn* and the cell parameters found for a single crystal of $[SrCu(C_3H_2O_4)_2(H_2O)_4]$, as published previously[8] (see Figure 1). The obtained crystallographic data for the $[BaM(C_3H_2O_4)_2(H_2O)_4]$ (M = Fe or Co) complexes are given in Table 1. The variation of the cell volume is in good agreement with the corresponding cation size. Taking these results into account, we have considered the two phases to be isostructural to the already characterised phase SrCu.[8] The structure consists of two-dimensional networks of transition metal ions coordinated by bridging malonate ligands. These M-malonate units are infinitely extended along the crystallographic [101] plane (see Figure 2). The metallic centres are octahedrally coordinated, with two oxygen atoms from two bidentate malonate anions at basal sites and two oxygen atoms from two malonate anions at apical sites. These bridging arrangements by carboxylate

groups form infinite sheets where the shortest M···M distances occur through the O-C-O atoms. The alkaline earth cations are located between the M-malonate layers and are coordinated to four oxygens of different malonates and to two lattice water molecules, forming a distorted antiprism.

Thermal Study

The thermal decomposition steps of the compounds were obtained from the TG curves shown in Figure 3. The thermogravimetric data are summarised in Table 2. Decomposition arises from three consecutive processes: dehydration, ligand pyrolysis and inorganic residue formation.

The first process takes places in the 75−100 °C temperature range and corresponds to the loss of four water molecules. This process occurs in only one step, suggesting that all the water molecules are similar. This was also deduced from the crystallographic data of the SrCu compound. No significant differences between the treatments in air and nitrogen atmospheres were observed, except for slight displacements in the decomposition-temperature ranges.

The second stage involves the decarboxylation of the ligand, and takes place in the 250−450 °C temperature range. The following reaction schemes are the most plausible way of describing the decomposition process:$MM'L_2$ (s) → MCO_3 (s) + $M'CO_3$ (s) + R (g) (a)$MM'L_2$ (s) → MO (s) + $M'CO_3$ (s) + R (g) (b)$MM'L_2$ (s) → MO (s) + $M'O$ (s) + R (g) (c)

The main factor controlling the pyrolysis process is the nature of the cation coordinated to the ligand[20] and, depending on the stability of the metal carbonates, reactions *(a)*, *(b)* or *(c)* can occur. In our case, as alkaline-earth metal carbonates are stable, the ligand pyrolysis can be described by the second reaction. The weight loss is in good accordance with the decarboxylation of the malonate ligand to yield $BaCO_3$ and the corresponding transition metal oxide. The oxide obtained can vary depending on the applied atmosphere. Therefore, we propose that the Fe_2O_3 and Co_3O_4 oxides are formed in air while the Fe_2O_3 and CoO oxides are obtained under a nitrogen atmosphere.

Finally, a gradual mass loss is observed at temperatures above 600 °C, when carbonate decomposes and mixed oxides are formed. At this stage, the applied atmosphere plays an important role; either complete decomposition under nitrogen is not reached or more reduced mixed oxides are obtained. In fact the inorganic residues analysed by X-ray diffraction indicated the presence of different $BaFeO_{3-y}$ and $BaCoO_{3-y}$ mixed oxides.

Following this study, and in order to obtain pure phases of mixed oxides, several thermal treatments in tubular furnaces were carried out. After firing the BaFe and BaCo malonate precursors at 400 °C, investigations at higher temperatures and different atmospheres were performed for each case. The resulting products were characterised at each stage by X-ray powder diffraction (see Figure 4). The thermal decomposition of the $[BaFe(C_3H_2O_4)_2(H_2O)_4]$ precursor was carried out under an oxygen atmosphere at 800 °C to yield the non-stoichiometric oxide $BaFeO_{3-y}$.[21] In the case of the barium cobalt metallo-organic precursor, a treatment at 700 °C in air was needed in order to obtain the non-stoichiometric $BaCoO_{3-y}$ as a pure phase.[22]

Spectroscopic Properties

Infrared Spectroscopy

The IR spectra of the $[BaM(C_3H_2O_4)_2(H_2O)_4]$ (M = Fe or Co) compounds are very similar. Broad bands observed

[a] Theoretical values in brackets.

in the 3300–3500 cm^{-1} region, can be assigned to the stretching vibration, ν(O-H), of the hydroxyl groups in the water molecules. The next group of bands appearing at around 2900 cm^{-1} corresponds to the stretching vibration, ν(C-H), of the malonate ligands. The band observed at 1730 cm^{-1} for the malonic acid is shifted in the titled compounds to 1600 cm^{-1}. This fact is indicative of the coordination of the carboxylate groups to the metal ions. This band appears together with the antisymmetric $\nu_a(OCO^-)$ vibration, whereas the band corresponding to the symmetric $\nu_s(OCO^-)$ vibration is localised at 1370 cm^{-1}. Taking the relative position of the antisymmetric $\nu_a(OCO^-)$ and symmetric $\nu_s(OCO^-)$ vibration bands into account, we can conclude that the bonding between the metal and the ligand gives rise to a chelate.[23] This observation is supported by the crystal data obtained from the SrCu compound. Finally, the bending vibration corresponding to the δ(C=O) group is observed at around 1300 cm^{-1}.

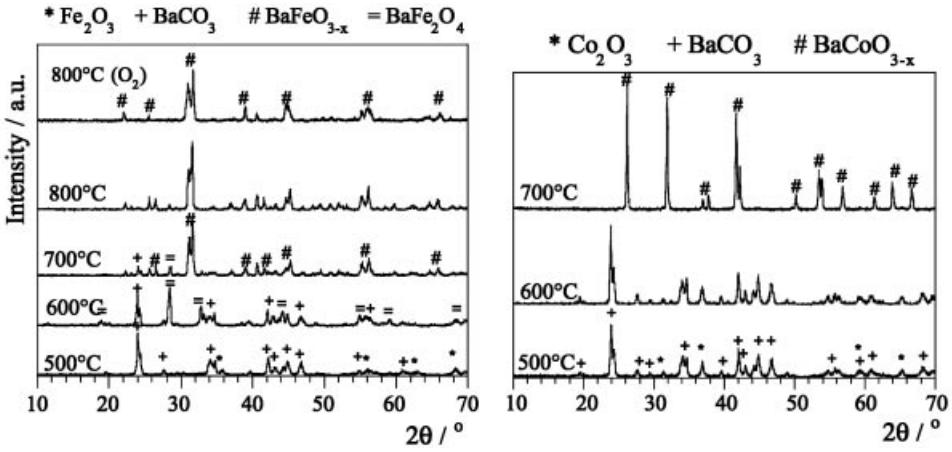

Figure 4. XRD patterns of the phases obtained from the thermal treatment of the BaFe and BaCo precursors

Diffuse Reflectance Spectroscopy

The reflectance spectra of the BaFe and BaCo complexes were recorded at room temperature in the 5000−45000 cm^{-1} range. For the iron phase, a single band appears which corresponds to the ${}^5E_g \leftarrow {}^5T_{2g}$ transition and is characteristic of a high-spin d^6 configuration in octahedral coordination. From the position of this band, the Dq parameter was calculated to be 1150 cm^{-1}, in good agreement with the usual values found for octahedrally coordinated iron(II). The spectrum of the BaCo compound shows three bands: at (ν_1) 8300, (ν_2) 15500 and (ν_3) 20600 cm^{-1}, which were assigned to the following three allowed transitions: ${}^4T_{2g} \leftarrow {}^4T_{1g}\ (F)$, ${}^4A_{2g} \leftarrow {}^4T_{1g}\ (F)$ and ${}^4T_{1g}\ (P) \leftarrow {}^4T_{1g}\ (F)$, respectively. By considering an octahedral model, the values of Dq (940) and B (753 cm^{-1}) were calculated from the ν_1 and ν_3 transitions. These values agree with those obtained for cobalt(II) compounds in an octahedral geometry.[24]

Magnetic Properties

Magnetic susceptibility measurements of powdered samples of $[BaM(C_3H_2O_4)_2(H_2O)_4]$ (where M = Fe or Co) were carried out in the 1.8−300 K temperature range, with applied magnetic fields of 1 and 0.1 kG. The χ_m and $\chi_m T$ vs. T curves of both compounds are shown in Figure 5, together with those of BaMn, given for comparison. All the calculated magnetic data are summarised in Table 3.

The μ_{eff} values measured at room temperature are 5.23 and 4.96 μ_B, for the BaFe and BaCo complexes respectively, and correspond to high-spin states for both metallic cations. In both cases, the $\chi_m T$ data decrease with decreasing temperature, reaching a minimum value at about 15 K. Then, the curves suddenly increase and at lower temperatures decrease again, reaching a maximum in $\chi_m T$ at around 12 K.

The χ_m^{-1} vs. T curves follow Curie−Weiss behaviour above 20 K, the Weiss constant, θ, being negative (−19.33 and −48.94 K), and the Curie constant, C_m, being 3.636 and 3.59 $cm^3 \cdot K \cdot mol^{-1}$ for the iron and cobalt compounds, respectively. The high value of θ found for the cobalt complex can be attributed to the spin-orbit coupling effect.

The initial progressive decrease of the $\chi_m T$ data until 15 K, together with the negative values of θ, are indicative of the presence of antiferromagnetic interactions. Considering the structural features of these compounds, the high-temperature susceptibility data were fitted to a two-dimensional Heisenberg antiferromagnetic model, employing the expansion series given by Rushbrooke and Wood.[25] Equation (1), (2) and (3) were deduced by taking into account the S = 5/2, 2 and 3/2 values for the Mn^{II}, Fe^{II} and Co^{II}, respectively, and are based on the spin Hamiltonian $H = -2J \Sigma_{<i,\ j>} S_i S_j$:

$$\chi_m = 2.91\ (Ng^2\beta^2)/(kT)\ [1 + 23.33x + 147.78x^2 + 405.48x^3 + 8171.3x^4 + 64968x^5 + 15811x^6]^{-1} \quad (1)$$

$$\chi_m = 2.00\ (Ng^2\beta^2)/(kT)\ [1 + 16x + 72x^2 + 195.067x^3 + 1781.87x^4 + 10301.4x^5 + 14736.4x^6]^{-1} \quad (2)$$

$$\chi_m = 1.25\ (Ng^2\beta^2)/(kT)\ [1 + 10x + 30x^2 + 42.6667x^3 + 262.917x^4 + 1043.85x^5 + 790.112x^6]^{-1} \quad (3)$$

where $x = J/kT$.

The BaMn susceptibility data gave the following values: g = 1.99 and J/k = −0.59 K,[8] indicating the presence of weak antiferromagnetic interactions. The best fit found for the iron and cobalt complexes is represented by the corresponding continuous lines in Figure 5. In the case of BaFe, the experimental data agree with values of g = 2.187 and J/k = −0.95 K only up to 30 K. At lower temperatures the curve clearly deviates from the theoretical model. As the maximum in χ_m is out of the fitting range, the calculated J value should be considered as a simple approximation. In this case, the zero-field splitting effect should be taken into account, especially at low temperatures. For the cobalt compound, the calculated J/k and g values are −3.24 K and 2.679, respectively, even though the inaccuracy of the model is obvious. The spin-orbit coupling effect progressively changes from a spin state S = 3/2 in the octahedral cobalt(II) ion to an effective spin state S' = 1/2 at low temperatures. Nevertheless, we can assume that until 15 K the

Table 3. Magnetic parameters of the BaFe, BaCo and BaMn compounds

		T_N/K	C_m/cm^3·K·mol^{-1}	θ /K	μ $_{eff}$/μ_B
BaFe	AF + weak FM	13.2	3.64	−19.3	5.23
BaCo	AF + weak FM	13	3.59	−48.9	4.96
BaMn[8]	AF + weak FM	7	4.34	−13.8	5.76

three compounds show two-dimensional Heisenberg antiferromagnetic behaviour with a weak intralayer antiferromagnetic interactions between the $M^{II}\cdots M^{II}$ atoms through the O-C-O bridges. Below 15 K, the presence of the minimum in the $\chi_m T$ curve together with a sudden increase indicates that total antiparallel alignment of the spins is not reached, suggesting the presence of long-range magnetic ordering due to the existence of interlayer ferromagnetic coupling. Moreover, this is a field-dependent effect: the less intense is the applied field (0.1 kG), the sharper is the maximum observed (see insets in Figure 5). In both cases, the field dependency is more intense than that observed for the BaMn compound.

In order to study this effect, magnetization measurements were performed. The results are shown in Figure 6. The magnetization shows a linear dependence on the magnetic field at 20 K. However, at 5 K both curves became nonlinear, indicating the presence of a ferromagnetic component at this temperature. For the BaFe compound, an anomalous dependence is also observed, probably due to the zero-field splitting effect (see Figure 6a).

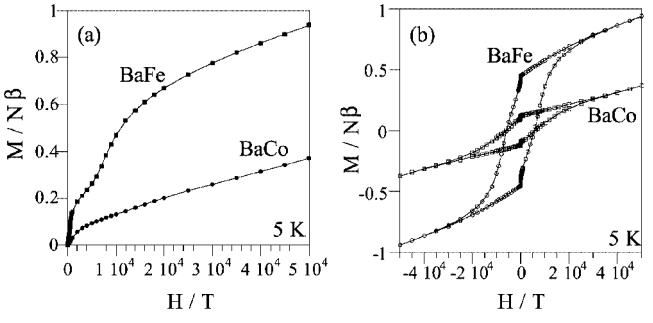

Figure 6. (a) M vs. H and (b) hysteresis curves at 5 K for the BaFe and BaCo compounds

The hysteresis curves M vs. H measured at 5 K are also indicative of the presence of ferromagnetic interactions. Both compounds show small hysteresis loops, with coercive fields of 6000 G, and remnant magnetization values of 0.44 and 0.12 in $N\beta$ units for the iron and cobalt complexes, respectively (see Figure 6b).

Finally, the thermoremnant magnetization was measured at a magnetic field of 100 G. The M_r vs. T curves are shown in Figure 7. The Néel temperatures are 13.2 K and 13 K for BaFe and BaCo, respectively. Both curves show a rapid increase reaching saturation with thermoremnant magnetization values of 0.44 and 0.12 in $N\beta$ units for the BaFe and BaCo compounds, respectively. These values agree with the M_r ones found in the hysteresis loops, and corroborate the existence of weak ferromagnetism in both samples. For BaMn, complete ordering was not reached even at 4 K (see inset in Figure 7), the ferromagnetic component in this compound being weaker than in BaFe and BaCo. Following these results, we must assume that the magnitude of the

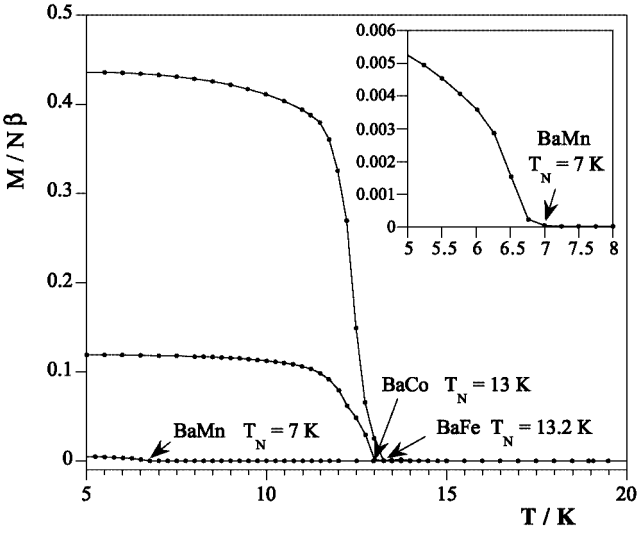

Figure 7. Zero-field magnetization vs. T curves for the BaFe, BaCo and BaMn compounds, after cooling, under a magnetic field of 100 G

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ferromagnetic component cannot depend only on the spin value of the metallic cation. Other parameters such as magnetic anisotropy of the cations, exchange angles and bond lengths should be considered in order to explain the magnetic behaviour observed in these compounds. Notwithstanding, and taking all the results into account, we can conclude that the BaMn, BaFe and BaCo compounds show 2D Heisenberg antiferromagnetic behaviour above 15 K, as a result of an intralayer antiferromagnetic interaction between M···M atoms, through the O-C-O bridges. Below this temperature, the total coupling of the antiparallel spins is not reached, probably due to the existence of an intralayer misalignment of the spins (or canting)[8] and a long-range ferromagnetic ordering between layers, with a weak ferromagnetism being observed.

Conclusions

Two new two-dimensional compounds, $[BaFe(C_3H_2O_4)_2(H_2O)_4]$ and $[BaCo(C_3H_2O_4)_2(H_2O)_4]$, have been synthesised. They are isostructural with the $[SrCu(C_3H_2O_4)_2(H_2O)_4]$ phase. These complexes exhibit two-dimensional antiferromagnetic interactions and below 12 K the presence of weak ferromagnetism has also been detected. This observation was attributed to the presence of long-range magnetic ordering of the canted spins between layers.

The thermal decomposition of the compounds occurs in three steps: dehydration, pyrolysis of the ligand and evolution of the inorganic residue to yield mixed oxides. Different thermal treatments in tubular furnaces at temperatures between 700−850 °C and under different atmospheres gave rise to non-stoichiometric $BaFeO_{3-y}$ and $BaCoO_{3-y}$ phases at temperatures and reaction times much lower than those of the ceramic method.

Experimental Section

Materials: Cobalt(II) chloride and malonic acid were purchased from Fluka, iron(II) chloride was purchased from Aldrich and sodium carbonate from Merck. They were all used without further purification.

Physical Measurements: Microanalyses were performed with a LECO CHNS-932 elemental analyser. Analytical measurements were carried out on an ARL 3410+ICP with Minitorch equipment. The powder X-ray diffraction (XRD) pattern was taken using a Philips X′pert diffractometer equipped with graphite-monochromated Cu-$K\alpha_1$ radiation. Data were collected by scanning in the range $5 < 2\theta < 70°$ with increments of 0.02° (2θ). Thermogravimetric measurements were performed on a Perkin−Elmer System-7 DSC-TGA instrument. Crucibles containing 20 mg of sample were heated at 5 °C·min^{-1} under dry nitrogen and air atmospheres. IR spectra (400−4000 cm^{-1}) were recorded on a MATTSON FTIR 1000 spectrophotometer with samples prepared as KBr pellets. Diffuse reflectance spectra were carried out on a CARY 2415 spectrometer in the range 5000−45000 cm^{-1}. Magnetic susceptibility measurements of powdered samples were carried out in the 1.8−300 K temperature range using a Quantum Design MPMS-7 Squid magnetometer. The magnetic measurements were performed at magnetic fields between 0 and 7 T.

Preparation of the Metallo-organic Precursors: To a solution of 2.5 mmol of disodium malonate, previously formed from 2.5 mmol (0.2601 g) of malonic acid neutralised with 2.5 mmol (0.7419 g) of sodium carbonate, 1 mmol of the corresponding transition metal salt was added. The mixture was stirred for 30 minutes and 1 mmol of barium chloride was added. Polycrystalline powders of the two phases were obtained in a few seconds. They were then stirred for 1−2 hours until complete precipitation was attained. For the iron compound, a closed system with a nitrogen atmosphere was needed to prevent oxidation. The powders obtained, white and light pink for the BaFe and the BaCo complexes respectively, were filtered and washed with ethanol/water followed by diethyl ether. Elemental analysis together with Inductively Coupled Plasma measurements were consistent with the following stoichiometries: $BaFeC_6H_{12}O_{12}$ and $BaCoC_6H_{12}O_{12}$. $BaFeC_6H_{12}O_{12}$: calcd. C 15.35, H 2.58, Fe 11.90, Ba 29.26; found. C 15.56, H 2.91, Fe 12.06, Ba 29.83; $BaCoC_6H_{12}O_{12}$: calcd. C 15.25, H 2.56, Co 12.48, Ba 29.07; found. C 15.10, H 2.11, Co 11.90, Ba 28.90.

Synthesis and Characterisation of Ternary Cage Compounds with Adamantane-Like $M_4P_4Si_2$ (M = Al, Ga, In) Core Structures

Carsten von Hänisch[a]

Keywords: Aluminium / Gallium / Silicon / Indium / Phosphorus

The reactions of $[LiAl(PH_2)_4]$ or $[NaAl(PH_2)_4]$ with Et_2SiCl_2 or iPr$_2$SiCl$_2$ yield the dialkyldiphosphanylsilanes $Et_2Si(PH_2)_2$ (**1**) and iPr$_2$Si(PH$_2$)$_2$ (**2**), respectively. Both compounds were identified by NMR spectroscopy as well as mass spectrometry. Compound **2** reacts with MEt_3 (M = Al, Ga, In) to form the cage compounds $[i\text{Pr}_2\text{Si}\{\text{P(H)ME}t_2\}_2]_2$ (**3**: M = Al, **4**: M = Ga, **5**: M = In). These three clusters were fully characterised by NMR and IR spectroscopy as well as by single-crystal X-ray diffraction. The central structural motif of **3**–**5** is an adamantane-like cage composed of four metal, four phosphorus and two silicon atoms. They are the first ternary clusters with these combinations of elements and crystallise isotypical in the triclinic space group $P\bar{1}$; the lattice constants are: **3**: a = 1129.0(6), b = 1164.8(8), c = 1750.6(8) pm; α = 83.63(5), β = 81.53(4), γ = 73.39(5)°; **4**: a = 1125.9(7), b = 1159.0(7), c = 1744.7(7) pm; α = 83.71(4), β = 81.89(4), γ = 73.05(5)°; **5**: a = 1147.4(2), b = 1174.7(2), c = 1753.3(4) pm; α = 85.32(3), β = 82.03(3), γ = 73.40(3)°.

Introduction

In the last few years reactions of primary silylphosphanes or -arsanes (R_3SiEH_2, E = P, As) with hydrido- or alkylaluminium, -gallium or -indium compounds have been applied several times to synthesise molecular compounds of these element combinations.[1−3] Cyclic and also cage-like 13/15 compounds were obtained from these reactions. The molecular structures of the reaction products can be influenced by the silyl group attached to the P or As atom. The reactions of $InEt_3$ with R_3SiPH_2 may serve as an example. Starting from iPr$_3$SiPH$_2$, the heterocubane-like compound $[EtInPSi\textit{i}Pr_3]_4$ is formed whereas the reaction of ThexMe$_2$SiPH$_2$ (Thex = CMe$_2$$i$Pr) with $InEt_3$ yields the hexagonal prismatic molecule $[EtInPSiThexMe_2]_6$.[2] By using the sterically less demanding $SiMe_3$ group a $SiMe_3$/H substituent exchange occurs and results in the formation of the cyclic compound $[Et_2InP(SiMe_3)_2]_2$.[3]

Whereas the dimethyldiphosphanylsilane $Me_2Si(PH_2)_2$ has been known in the literature for several years, dialkyldiphosphanylsilanes with sterically demanding alkyl groups such as ethyl or isopropyl are as yet unknown.[4] Reaction of these compounds with alkylaluminium, -gallium or -indium species will result in the formation of novel ternary group13/Si/P compounds. The first species of this class of compounds $[i\text{Pr}_2\text{Si}\{\text{P(H)ME}t_2\}_2]_2$ (**3**: M = Al, **4**: M = Ga, **5**: M = In), which could be obtained by the reactions of iPr$_2$Si(PH$_2$)$_2$ (**2**) with MEt_3, are described herein.

Results and Discussion

A solution of $[LiAl(PH_2)_4]$ in tetraglyme reacts with Et_2SiCl_2 to form the dialkyldiphosphanylsilane $Et_2Si(PH_2)_2$ (**1**). This compound can be isolated from the reaction mixture by vacuum condensation in about 50% yield. The less volatile compound iPr$_2$Si(PH$_2$)$_2$ (**2**) can be obtained in about 70% yield from the reaction of $[NaAl(PH_2)_4]$ with iPr$_2$SiCl$_2$ in DME. The ^{31}P NMR spectra of both molecules show a triplet of higher order at δ = −242.7 (**1**) and −254.2 ppm (**2**). The high resolution spectrum of **1** (see Figure 1) allows the complete analysis of all coupling constants by an iterative process;[5] the fine structure of the

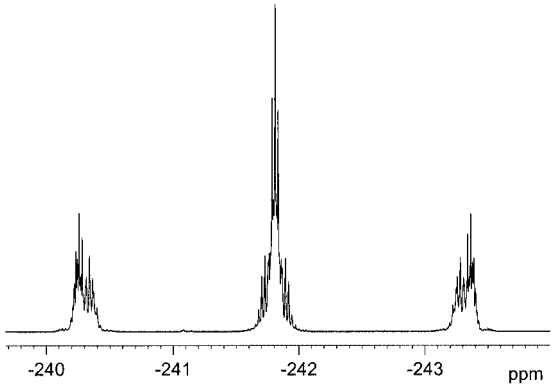

Figure 1. ^{31}P NMR Spectrum of **1** in C_6D_6

triplet of **2** cannot be fully resolved. Therefore only the $^1J_{P,H}$ coupling constants were determined. The mass spectra of both compounds show the molecule peaks at m/z = 152 (**1**) and 180 (**2**) as well as peaks for the fragments $R_2SiPH_2^+$, $RSi(H)PH_2^+$ and $H_2SiPH_2^+$.

Reaction of **1** with triethylgallium or triethylindium results in the formation of oily precipitates, which have not been characterised so far. $^{31}P\{^1H\}$ NMR investigations of the reaction mixtures showed several broad signals, which indicate that polymeric compounds have been formed. In contrast to the latter, the sterically more demanding compound **2** reacts with MEt_3 (M = Al, Ga, In) in heptane at ambient temperature with elimination of ethane and the formation of a white, crystalline precipitate. These products can be dissolved by warming the reaction mixtures slightly. Subsequent cooling of the solutions to 6 °C yields colourless crystals.[6] X-ray analysis (Table 1) confirmed that the compounds $[i\mathrm{Pr}_2\mathrm{Si}\{\mathrm{P(H)MEt}_2\}_2]_2$ (**3**: M = Al, **4**: M = Ga, **5**: M = In) had formed as described in Equation (1). Recently, Kaskel and co-workers reported reactions of $Si(NHEt)_4$ with AlR_3, which result in the formation of the ternary Al/Si/N compounds $[RAl(\mu\text{-}NHEt)(\mu\text{-}NEt)_2Si(NHEt)_2]_2$ (R = Me, Et).[7] Whereas compounds **3** and **4** are stable in solution, too, a benzene solution of the indium compound **5** decomposes after several days with further elimination of ethane. At the same time a yellow, oily, precipitate appears.

$$2\ i\mathrm{Pr}_2\mathrm{Si(PH_2)_2} + 4\ \mathrm{MEt_3} \rightarrow [i\mathrm{Pr}_2\mathrm{Si}\{\mathrm{P(H)MEt}_2\}_2]_2\ (\mathrm{M = Al, Ga, In}) + 4\ \mathrm{C_2H_6} \quad (1)$$

Compounds **3**, **4** and **5** crystallise isotypical in the triclinic space group $P\bar{1}$ (the structure of **3** is shown in Figure 2 as an example). The central structural motif is an adamantane-like cage composed of four aluminium, gallium or indium atoms, four phosphorus and two silicon atoms. Cage compounds of these element combinations have not been reported so far. In these moieties, the phosphorus atoms are in the bridgehead positions and the metal and silicon atoms are in the secondary positions. This results in an eight-membered M_4P_4 (M = Al, Ga, In) ring, where the opposite phosphorus atoms [P(1), P(3) and P(2), P(4)] are bridged by $i\mathrm{Pr}_2\mathrm{Si}$ groups on different sides of the ring. The M_4P_4 ring is therefore strongly distorted and shows a boat-like conformation.

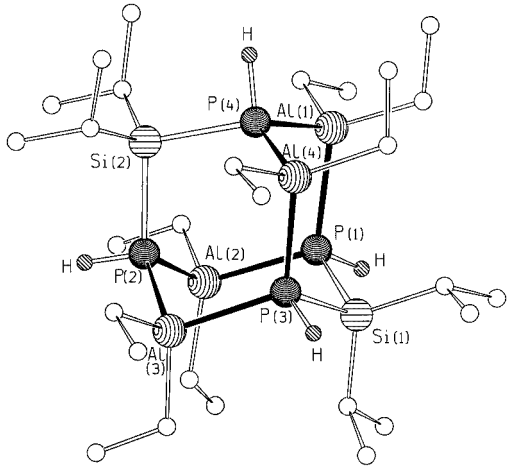

Figure 2. Molecular structure of **3**

The observed P−M and P−Si bond lengths are in the typical range for single bonds between these elements (seen Table 2).[1−3,8] The very similar Al−P and Ga−P bond

lengths reflect the fact that the covalent radii of Al and Ga are almost identical due to d-block contraction. Each of the metal atoms is bound to two exocyclic ethyl groups and the silicon atoms possess two isopropyl groups each. The phosphorus atoms bind to one hydrogen atom, which was localised during the refinement of the crystal structures. Moreover, the IR spectra of **3**, **4** and **5** show strong peaks at 2306 cm^{-1} (**3**), 2305 cm^{-1} (**4**), 2303 cm^{-1} (**5**) which can be assigned to the P−H stretching vibrations. The ^{31}P NMR spectra reveal multiplets of higher order for all three compounds ([AX]$_4$ spin system). Figure 3 displays the ^{31}P NMR spectrum of **5**. Unfortunately, the comparatively broad signals in the ^{31}P NMR spectra of **3**−**5** (see Figure 3 inset) do not allow an iterative determination of the coupling constants with satisfactory accuracy. As expected, the $^{31}P\{^1H\}$ NMR spectra only show singlets at δ = −250.0 (**3**), 244.2 (**4**) and −273.5 ppm (**5**).

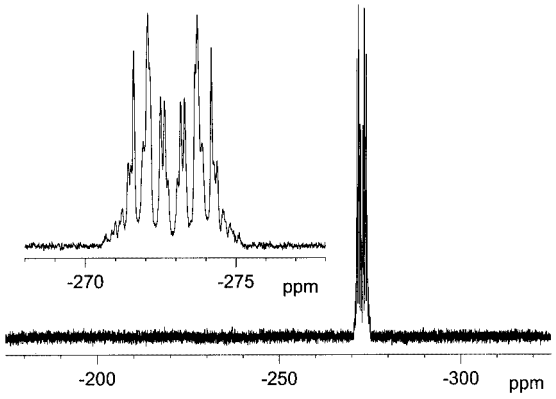

Figure 3. ^{31}P NMR Spectrum of **5** in C_6D_6

Experimental Section

All manipulations were performed with rigorous exclusion of oxygen and moisture using a Schlenk line and nitrogen atmosphere. Solvents were dried and freshly distilled before use. NMR spectra were recorded on a Bruker DPX Avance 300 or on a Bruker AC 250 instrument. $[NaAl(PH_2)_4]$, $[LiAl(PH_2)_4]$, $GaEt_3$ and $InEt_3$ were prepared according to the literature.[9−11] $AlEt_3$ was purchased from Aldrich and used as received.

1: Et_2SiCl_2 (4.0 g, 0.025 mol) was added to 100 mL of a 0.13 M solution of $[LiAl(PH_2)_4]$ in tetraglyme at −40 °C. The colour of the solution changed from slightly yellow to colourless. During this time a white precipitate also formed. After agitation for ten minutes the product was condensed into a cold trap at −196 °C under oil pump vacuum. During the condensation the reaction mixture was warmed up to room temperature. After five hours the condensation was complete. Trace amounts of solvent were removed from the product by a second condensation under a stationary vacuum of $5{\cdot}10^{-3}$ mbar. Compound **1** was obtained as a colourless, pyrophoric liquid. Yield: 2.0 g (52%). $^1H\{^{31}P\}$ NMR (C_6D_6): δ = 0.670 (q, $^3J_{H,H}$ = 7.9 Hz, 4 H, CH_2), 0.909 (t, $^3J_{H,H}$ = 7.9 Hz, 6 H, CH_3), 1.350 (m, 4 H, PH_2) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 8.4 (t $^2J_{C,P}$ = 2.6 Hz, CH_3), 10.3 (t $^3J_{C,P}$ = 7.3 Hz, CH_2) ppm. $^{29}Si\{^1H\}$ NMR (C_6D_6): δ = 12.8 (t $^1J_{Si,P}$ = 33 Hz) ppm. ^{31}P NMR (C_6D_6): δ = −242.7 [m/t, coupling constants from iterative optimisation: $^1J_{PH}$ = −184.1, $^2J_{P,P}$ = 11.9, $^3J_{PH(PH2)}$ = −4.4, $^4J_{H,H(PH2/PH2)}$ = 0.4, $^3J_{PH(CH2)}$ = 3.0 Hz (corresponds with $AA'X_2X'_2Y_2Y'_2$ spin system)].[5] MS (EI, 70 eV): *m*/*z* (%) = 152 (8.6) [M^+], 119 (56) [$M^+ - PH_2$], 95 (10) [$HSi(PH_2)_2^+$] 91 (100) [$EtSi(H)PH_2^+$], 63 (42) [$H_2Si(PH_2)_2^+$].

2: iPr_2SiCl_2 (7.4 g, 0.04 mol) was added to 100 mL of a 0.25 M solution of $[NaAl(PH_2)_4]$ in DME at −50 °C. The reaction mixture was then warmed up to room temperature over a period of 16 hours. Subsequently 100 mL pentane was added and the yellow precipitate removed by filtration. Finally, the solvent was distilled off under reduced pressure at room temperature and the residue was distilled under vacuum to give **2** as a colourless, pyrophoric liquid at 90−100 °C (25 Torr). Yield: 5.0 g (70%). ^1H NMR (C_6D_6): δ = 1.050 (s, 14 H, *i*Pr), 1.367 (m/d, $^1J_{P,H} \approx$ 190 Hz, 4 H, PH_2) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 15.2 [t $^2J_{C,P}$ = 6.3 Hz, $CH(CH_3)_2$], 18.6 (t $^3J_{C,P}$ = 2.2 Hz, CH_3) ppm. ^{31}P NMR (C_6D_6): δ = −254.2 (t, $^1J_{PH} \approx$ −190 Hz) ppm. MS (EI, 70 eV): *m*/*z* (%) = 180 (24) [M^+], 147 (100) [$M^+ - PH_2$], 105 (65 [$iPrSi(H)PH_2^+$], 43 (12.5) [iPr^+].

3: $AlEt_3$ (0.62 g, 5.4 mmol) was added to a stirred solution of $iPr_2Si(PH_2)_2$ (0.5 g, 2.78 mmol) in 20 mL of heptane. After 20 minutes a white precipitate formed. The latter was dissolved by warming the reaction mixture slightly. Compound **3** formed as large colourless crystals within three days at 6 °C. Yield: 0.9 g (96%); $C_{28}H_{72}Al_4P_4Si_2$ (696.9): calcd. C 48.26, H 10.41; found C 48.13, H 10.20. ^1H NMR (C_6D_6): δ = 0.58 (q, $^3J_{H,H}$ = 8.0 Hz, 16 H, CH_2CH_3), 1.14 [d, $^3J_{H,H}$ = 7.5 Hz, 24 H, $CH(CH_3)_2$], 1.46 (t, $^3J_{H,H}$ = 8.0 Hz, 24 H, CH_2CH_3), 1.70 [hep, $^3J_{H,H}$ = 7.5 Hz, 4 H, $CH(CH_3)_2$] ppm; P*H* not observed. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 4.1 (br. s, CH_2), 10.0 (s, CH_2CH_3), 19.4 [s, $CH(CH_3)_2$], 21.7 [s, $CH(CH_3)_2$] ppm. ^{31}P NMR (C_6D_6): δ = −250.0 (m) ppm. Linear and Helical Chains in Hydrothermally Synthesized Coordination Polymers $[Co(bpdc)(H_2O)_2]$ and $[Ni(bpdc)(H_2O)_3]\cdot H_2O$ Involving in situ Ligand Synthesis

Xian-Ming Zhang,[a] Hai-Shun Wu,[a] and Xiao-Ming Chen*[b]

Keywords: Coordination polymers / N ligands / Helical structures / Hydrothermal synthesis / Cobalt / Nickel

Hydrothermal treatment of $M(MeCO_2)_2$ (M = Co or Ni) and 1,10-phenanthroline-5,6-dione (pdon) resulted in two chain-like coordination polymers $[Co(bpdc)(H_2O)_2]$ and $[Ni(bpdc)(H_2O)_3]\cdot H_2O$. X-ray single-crystal structural analysis revealed that the organic reagent pdon was transformed in situ into 2,2′-bipyridine-3,3′-dicarboxylate (bpdc). The different coordination modes concomitant with the difference of the dihedral angles between two bpdc pyridine rings results in simple linear chains and helical chains in **1** and **2**, respectively. The one-dimensional coordination chains of **1** and **2** are further extended into two-dimensional supramolecular arrays by hydrogen-bond interactions. A possible mechanism for the new hydrolysis reaction with the formation of bpdc under hydrothermal conditions was also discussed.

Introduction

The self-assembled construction of coordination polymers has become the subject of many current studies,[1−15] due to their potential optoelectronic,[16−19] magnetic,[20,21] microporous,[22−25] and catalytic applications.[26] The design of coordination polymers takes certain factors into account such as the coordination nature of the metal ion, structural features of the polydentate organic ligand, metal/ligand ratio, and possible counterion influence. A subtle alteration to any of these factors may lead to new extended network structures. Although most of these insoluble solids have been synthesized by controlled mixing of suitable soluble molecular components, hydro(solvo)thermal conditions have demonstrated increasing success in providing alternative pathways to the preparation of crystalline supramolecular solids, including metal-organic coordination networks and hydrogen-bonded systems. Hydro(solvo)thermal syntheses carried out in superheated solvent systems provide ideal conditions for the crystal growth owing to the enhanced transport ability of the solvents.[4] Besides, recent studies revealed that crystal growth under hydrothermal conditions occasionally involves in situ ligand synthesis which not only provides a powerful synthesis method for organic ligands that are difficult to synthesise but also represents a potential new direction for novel inorganic−organic hybrid network construction through crystal engineering.[16−19,27−32] Examples of in situ ligand syntheses under hydrothermal conditions include hydrolysis of −CN and −COOR groups,[16−19] hydroxylation,[27−29] carbon−carbon bond formation by reductive coupling or oxidative coupling,[30,31] and replacement of $-CO_2^-$ with $-SO_3^-$.[32]

We have paid considerable interest to the reactivity of chelate ligands such as 2,2′-bipyridine and 1,10-phenanthroline under hydrothermal conditions and found that their hydroxylation reactivity was promoted by copper(II) ions.[27,28] As an extension of our previous work, we are paying attention to 1,10-phenanthroline-5,6-dione (pdon) because of its peculiar reactivity (Scheme 1) in organic chemistry.[33,34] Two nucleophilic centers (nitrogen and oxygen lone pairs) are contained in the quinone-like pdon molecule with all the non-hydrogen atoms being sp^2-hybridized. The presence of two electronegative heteroatoms not only creates the basic properties in the Lewis sense but also, because of conjugation, makes it possible to alter the electron density in different parts of the molecule. As a result, a dramatic change in reactivity can occur, which is not observed in the case of the corresponding aromatic homocyclic analogue, phenanthrenequinone. We report herein on the in situ hydrothermal synthesis of 2,2′-bipyridine-3,3′-dicarboxylate (bpdc) from pdon and its two coordination polymers $[Co(bpdc)(H_2O)_2]$ and $[Ni(bpdc)(H_2O)_3]\cdot H_2O$.

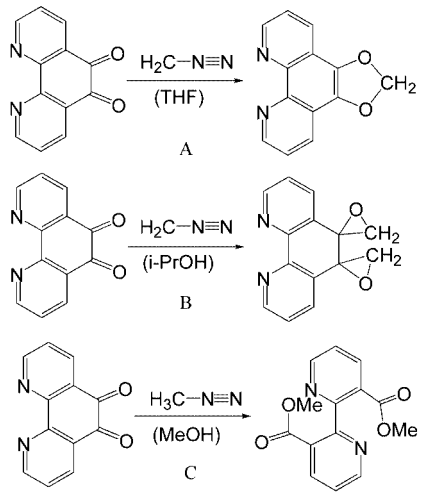

Scheme 1. Schematic representation of some known organic reactions of pdon

Results and Discussion

IR Spectra

The infrared spectra of the two compounds show strong broad bands at 3344 (**1**) or 3390 (**2**) cm^{-1} that are attributable to the stretching modes of hydrogen-bonded H_2O groups. The ν_{as}(COO) vibration is identified by the strong bands at 1566 (**1**) or 1568 (**2**), and the ν_s(COO) bands at 1394 (**1**) and 1392 (**2**) cm^{-1}. The separations Δ(COO) between the ν_{as}(COO) and ν_s(COO) bands, in both compounds, imply that the carboxylate groups act in a monodentate coordination mode.[35]

Structural Description

X-ray single-crystal structural analysis revealed that compound **1** crystallizes in the monoclinic space group *C*2/*c* and that the pdon ligand was transformed in situ into bpdc during the hydrothermal process. The asymmetric unit in **1** consists of 0.5 Co^{II}, 0.5 bpdc and 1 H_2O. The Co^{II} atom lies on a crystallographic twofold axis, which bisects one bpdc. The Co^{II} site shows a distorted octahedral geometry, being coordinated by two nitrogen atoms of one bpdc in a chelate mode and two oxygen atoms of two carboxylate groups in the equatorial plane, as well as two aqua ligands in the axial positions, as shown in Figure 1. The Co−N(1), Co−O(2) and Co−O(1w) distances are 2.123(2), 2.133(2) and 2.151(3) Å, respectively. The *cis*-L−Co−L angles are in the range of 76.70(11)−99.37(9)° and the *trans*-L−Co−L angles are 168.02(7) and 174.85(9)°. The dihedral angle between two bydc pyridine rings is 20.5°, indicating a slight non-coplanarity, which may reduce mutual repulsion between the two carboxy groups in each bpdc. Metal complexes synthesized directly from the bpdc ligand,[36,37] show the tridentate bridging and bis(monodentate) bridging coordination modes in $[Cu(bpdc)(H_2O)_2]$ and $[Mn(bpdc)(H_2O)_4]$, respectively. In contrast, each bpdc ligand utilizing the pair of nitrogen atoms and two oxygen

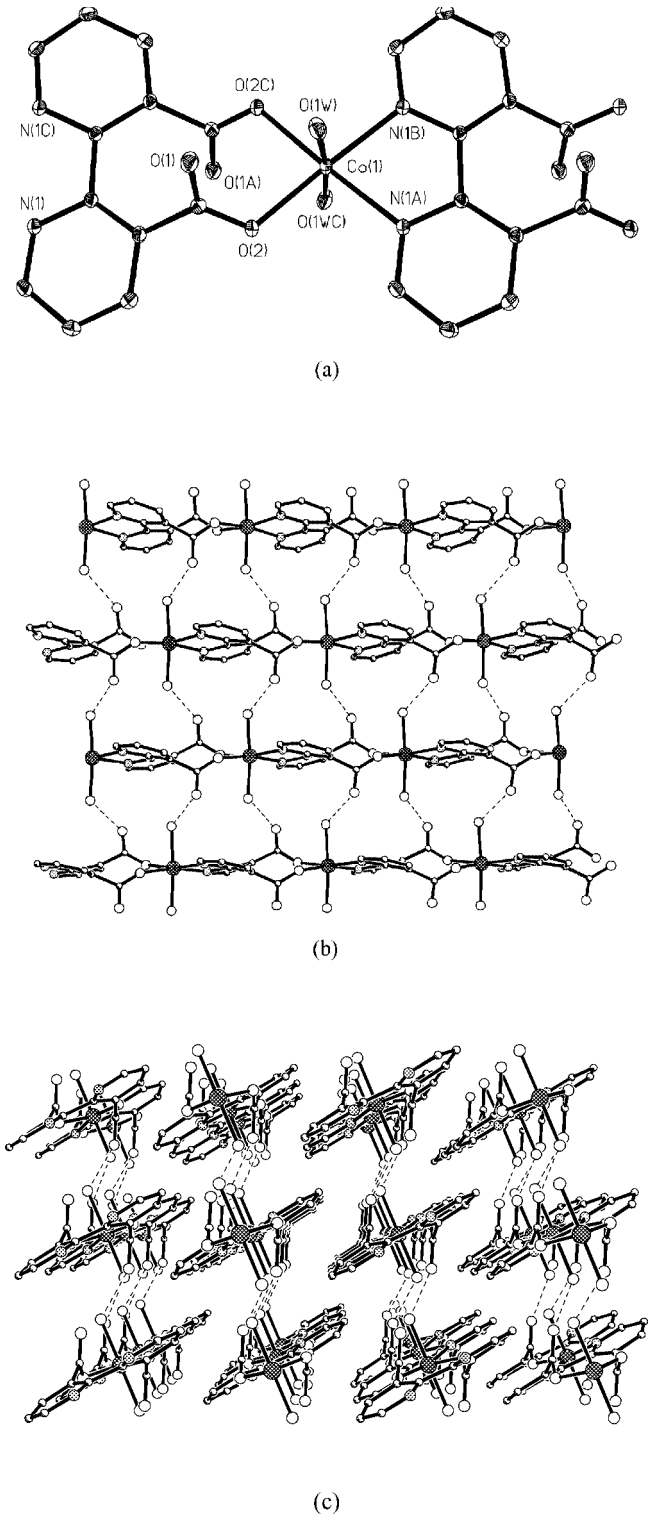

Figure 1. Perspective views of the coordination environment of the cobalt(II) atom (a), two-dimensional supramolecular network (b) and stacking array (c) in **1**

atoms of two carboxylate groups bridge two Co^{II} atoms in **1** to generate one-dimensional chains (Figure 1, b) in which all cobalt atoms are located linearly at a twofold axis. It should be noted that the aqua O(1W) atom forms a donor hydrogen bond with the uncoordinated carboxy oxygen

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

atom O(1) [O(1W)···O(1) 2.786 Å], which extend the one-dimensional chains into two-dimensional supramolecular networks. Such two-dimensional networks are arranged in a repeated ···AAA··· fashion in the lattice, as shown in Figure 1, c.

In contrast to **1**, compound **2** crystallizes in the monoclinic space group $P2_1/n$ and each asymmetric unit consists of 1 Ni^{II}, 1 bpdc, 3 H_2O and one lattice H_2O. All atoms are located at general positions. The Ni^{II} site shows a distorted octahedral geometry, being ligated by two nitrogen atoms of one bpdc in a chelate mode, one carboxylate oxygen atom and three *cis*-related aqua ligands (Figure 2, a). The Ni−N and Ni−O distances are in the range of 2.080(3)−2.118(3) and 2.071(3)−2.110(3) Å, respectively, which are slightly shorter than the Co−N and Co−O distances observed in **1**. The *cis*-L−Co−L angles are in the range of 78.53(11)−96.26(12) and *trans*-L−Co−L angles are 169.35(11)−178.94(10)°, indicating that the Ni^{II} site has a more regular octahedron than the Co^{II} center in **1**. The two pyridine rings of bpdc in **2** are more twisted with a larger dihedral angle of 31.6° than that in **1**. Besides, with only one carboxylate group utilizing one oxygen atom to ligate a nickel(II) atom, the coordination mode of the bpdc molecule in **2** is different from that in **1**, in which each bpdc has two carboxylate groups coordinated, but similar to that found in $[Cu(bpdc)(H_2O)_2]$.[36] Different from the linear chain-like structure in **1**, the coordination modes of the bpdc ligand and the configuration of the Ni^{II} atom with three *cis*-related aqua ligands in **2** result in helical chains in which equivalent atoms are related by a 2_1-screw axis (Figure 2, b). This fact implies that the tridentate coordination mode of bpdc may play an important role in the

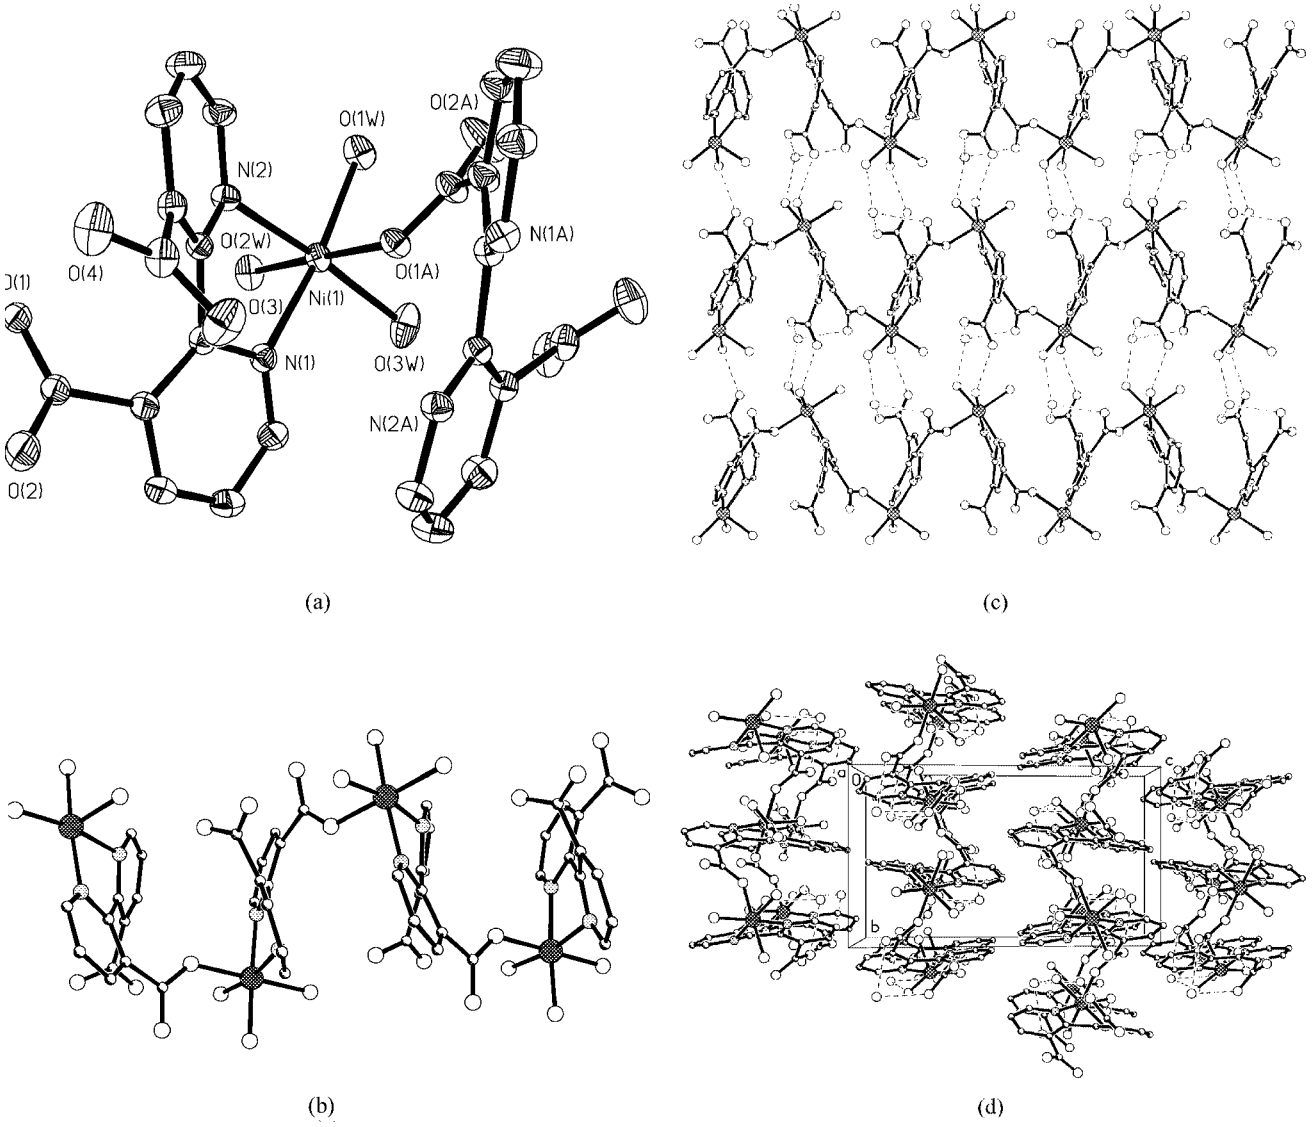

Figure 2. Perspective views of the coordination environments of the nickel atom (a), helical chain (b), and two-dimensional supramolecular network (c) and stacking array (d) in **2**

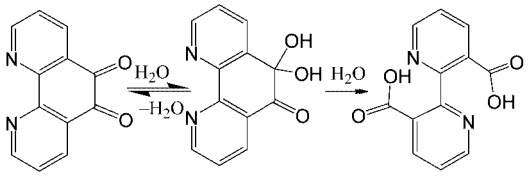
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

formation of the chiral helical chains in **2**. On the other hand, there are a number of hydrogen bonds [O(1W)···O(4), 2.674; O(2W)···O(3), 2.744; O(3W)···O(4W), 2.716; O(4W)···O(3), 2.891; O(4W)···O(3W), 2.71 Å] which extend the helical chains into two-dimensional supramolecular networks (Figure 2, c). Such networks are arranged in an ···ABAB··· fashion as shown in Figure 2, d. Within each layer, all helical chains have the same chirality. However, helical chains of opposite chiralities construct adjacent layers and thus **2** crystallizes in the centrosymmetric space group.

Synthesis Chemistry

Although pdon was used as the original organic reagent in the preparation of **1** and **2** the bipyridine-3,3′-dicarboxylate ligand was unexpectedly found in the final products, which indicates an in situ transformation of pdon into bpdc during the course of hydrothermal treatment. As shown in our previous investigation[27−29] on ligand reactions under hydrothermal conditions in the presence of metal ions, the ligation of the metal ion will cause some decrease of electron density on the aromatic ring of the organic ligand, hence promote nucleophilic attack by water molecules or hydroxy groups. In this case, it seems most probable that the solvent aqua molecules act effectively as nucleophiles, attacking the carbonyl carbon atoms of pdon. As a result, the hydration of carbonyl groups of pdon furnishes an intermediate diol or even a double diol. When the sp^2 carbonyl carbon atoms become sp^3-hybridized, the carbon−carbon bond is then cleaved probably because of the crowdedness, resulting in the formation of bpdc. A recent study, indeed revealed that there is a tautomerism between a pdon complex of Co^{II} and its corresponding diol complex in aqueous solution.[38] The formation mechanism of bpdc in **1** and **2** shows some similarity to that of dimethyl 2,2′-bipyridine-3,3′-dicarboxylate in a previously reported pure organic reaction (Scheme 1, C).[34] Although the exact mechanism of ligand transformation is not yet proved, slow hydrolysis of the carbonyl groups ensures that an excess of metal ions remains in solution, thereby promoting the formation of less soluble polymeric networks. Equally important, the in situ slow bpdc formation also ensures the growth of large single crystals that are suitable for X-ray structure determination.



Scheme 2. Schematic representation of the possible transformation mechanism of pdon to bpdc

Conclusion

A new hydrolysis reaction of 1,10-phenanthroline-5,6-dione to 2,2′-bipyridine-3,3′-dicarboxylate has been achieved under hydrothermal conditions in the presence of metal acetates, resulting in the formation of two chain-like coordination polymers $[Co(bpdc)(H_2O)_2]$ and $[Ni(bpdc)(H_2O)_3]\cdot H_2O$. The different coordination modes concomitant with the difference of the dihedral angles between two pyridine rings of bpdc results in simple linear and helical chains, respectively.

Experimental Section

General Remarks: Elemental analyses were performed with a Perkin−Elmer 240 elemental analyzer. The FT-IR spectra were recorded from KBr pellets in the range of 400−4000 cm^{-1} with a Nicolet 5DX spectrometer.

Synthesis

$[Co(bpdc)(H_2O)_2]$ (1): A mixture of $Co(MeCO_2)_2\cdot 4H_2O$ (0.25 g, 1.0 mmol), 1,10-phenanthroline-5,6-dione (pdon) (0.208 g, 1.0 mmol), methanol (3 mL) and water (5 mL) in a molar ratio of 1:1:74:278 was stirred for 10 min in air, then transferred and sealed in a 23-ml Teflon-lined stainless steel container, which was heated to 140 °C for 72 h. After cooling to room temperature at the rate of 5 °C per hour, 0.34 g (ca. 50% yield) of brown block crystals of **1** was recovered. $C_{24}H_{20}Co_2N_4O_{12}$ (674.3): calcd. C 42.75, H 2.99, N 8.31; found C 42.67, H 3.08, N 8.23. IR (KBr): $\tilde{\nu}$ = 3751 w cm^{-1}, 3344 bs, 3102 m, 1796 w, 1566 s, 1438 m, 1394 s, 1227 w, 1152 w, 1096 wm, 826 w, 783 m, 750 m, 662 m, 518 w, 447 m.

$[Ni(bpdc)(H_2O)_3]\cdot H_2O$ (2): A mixture of $Ni(MeCO_2)_2\cdot 4H_2O$ (0.25 g, 1 mmol), pdon (0.208 g, 1 mmol), methanol (3 mL) and water (5 mL) in a molar ratio of 1:1:74:278 was stirred for 10 min in air, then transferred and sealed in a 23-ml Teflon-lined stainless steel container, which was heated to 140 °C for 72 h. After cooling to room temperature at a rate of 5 °C per hour, 0.373 g (35% yield) of blue block crystals of **1** were recovered. $C_{24}H_{28}N_4Ni_2O_{16}$ (745.9): calcd. C 38.65, H 3.78, N 7.51; found C 38.60, H 3.82, N 7.44. IR (KBr): $\tilde{\nu}$ = 3673 w cm^{-1}, 3390 bs, 1603 w, 1568 s, 1392 s, 1158 w, 1122 w, 1097 m, 772 m, 699 w, 442 w.

X-ray Crystallography: Diffraction intensities were collected at 293 K with a Siemens R3 diffractometer (Mo-K_α, λ = 0.71073 Å). Lorentz-polarization and absorption corrections were applied. The structure was solved with direct methods (SHELXS-97) and refined with a full-matrix least-squares technique (SHELXL-97).[39] Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated. In all cases, all non-hydrogen atoms were refined anisotropically and hydrogen atoms of organic ligands were geometrically placed. CCDC-200013 and -200014 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Helical Ribbons of Cadmium(II) and Zinc(II) Dicarboxylates with Bipyridyl-Like Chelates − Syntheses, Crystal Structures and Photoluminescence

Ling-Yun Zhang,[a] Gao-Feng Liu,[a] Shao-Liang Zheng,[a] Bao-Hui Ye,[a] Xian-Ming Zhang,[a] and Xiao-Ming Chen*[a]

Keywords: Coordination polymers / Cadmium / Zinc / N ligands / Pi interactions

Four mixed-ligand complexes of $[M(mpa)(phen)]_n$ [M = Cd (**1**) or Zn (**2**) and mpa = *m*-phthalate and phen = 1,10-phenanthroline) and $[M_2(mpa)_2(2,2'\text{-bpy})_2]_n$ [M = Zn (**3**) or Cd (**4**) and 2,2′-bpy = 2,2′-bipyridine] have been synthesized and their crystal structures have been established by single-crystal X-ray diffraction. They all consist of one-dimensional ribbons featuring dinuclear units. Both **1** and **2** crystallize isomorphously in the monoclinic space group $P2/c$ and feature helical chains. While **3** and **4** crystallize in the triclinic space group $P\bar{1}$. The one-dimensional ribbons are assembled into three-dimensional networks by π–π stacking interactions. They all show strong blue photoluminescence and are stable in air up to ca. 402, 371, 365 and 370 °C, respectively.

Introduction

The construction of supramolecular architectures is currently of great interest owing to their intriguing network topologies and potential functions such as adsorption, ion exchange, shape-selective catalysis, non-linear and magnetic materials.[1−3] The strategies for design and tailor-making of such supramolecular architectures with dicarboxylate spacers such as terephathlate, malate, oxalate, 4,4′-oxybis-(benzoic acid) are currently interesting. Recently, we and others have reported some interesting polymeric architectures containing linear, nonlinear flexible and V-shaped dicarboxylates together with bipyridyl-like ligands.[4−11] Chelating bipyridyl-like ligands such as 1,10-phenanthroline and 2,2′-bipyridine are important in maintaining the one dimensionality of the coordination polymers and may provide potential supramolecular recognition sites for π−π aromatic stacking interactions to form interesting supramolecular structures such as double-stranded helices and molecular zippers.[7,8]

On the other hand, polynuclear d^{10} metal complexes are very attractive in that they not only exhibit intriguing structures but also photoluminescent properties.[12−17] As a sequel to our previous reports on a series of d^{10} complexes, which show strong luminescent properties,[4,5,14−16] we now describe four one-dimensional coordination polymers $[M(mpa)(phen)]_n$ [M = Cd (**1**) or Zn (**2**); mpa = *m*-phthalate and phen = 1,10-phenanthroline] and $[M_2(mpa)_2(2,2'\text{-bpy})_2]_n$ [M = Zn (**3**) or Cd (**4**) and 2,2′-bpy = 2,2′-bipyridine], which exhibit different structures compared to the related Cu^{II} complexes,[7,8] all of which show blue luminescence.

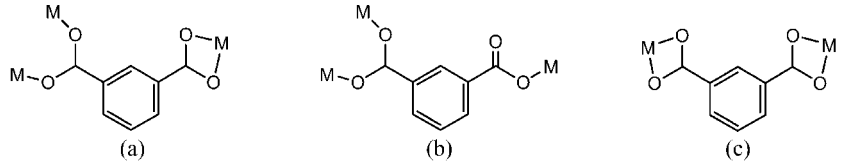
Results and Discussion

Characterization

The IR spectrum of **1** shows characteristic bands of the dicarboxylate groups in the usual region at 1564 and 1515 cm^{-1} for the asymmetric stretching and at 1400 cm^{-1} for the symmetric stretching. The separations (Δ) between $\nu_{asym}(CO_2)$ and $\nu_{sym}(CO_2)$ are at 164 and 115 cm^{-1}, which are attributed to the existence of both bridging and chelate modes of the carboxylate groups, respectively (Scheme 1, a).[18] For **2**, the bands are at 1614 and 1558 cm^{-1} for the asymmetric stretching and at 1397 cm^{-1} for the symmetric stretching; the Δ values are at 217 and 161 cm^{-1}, and are attributable to the co-existence of the monodentate and bridging modes (Scheme 1, b). For **3**, the bands of the dicarboxylate units are shown at 1562 and 1532 cm^{-1} for the asymmetric stretching and at 1431 cm^{-1} for the symmetric stretching; the Δ values are at 131 and 101 cm^{-1}, which are attributed to co-existence of the bridging and chelate modes (Scheme 1a, c). Whereas for **4**, the characteristic bands and Δ values are very similar to those found for **1**, indicating that the carboxylate groups exhibit both a bridging and chelate mode. The IR spectra indicate that the mpa carboxylate groups function in different coordination modes, consistent with the crystal structures of **1**, **2**, **3** and **4**.

Thermogravimetric analysis (TGA) was performed on polycrystalline samples in air. There was no decomposition



Scheme 1. Coordination modes of mpa: (a) chelate-bidentate, (b) monodentate-bidentate and (c) chelating bis(bidentate)

up to ca. 402, 371, 365 and 370 °C for **1**, **2**, **3** and **4**, respectively, suggesting that the products are more stable than the related ones synthesized by the conventional solution method, at room temperature.[17]

Crystal Structures

Complexes **1**, **2**, **3** and **4** all consist of one-dimensional ribbons. Both **1** and **2** crystallize isomorphously in the monoclinic space group $P2/c$, while **3** and **4** crystallize in the triclinic space group $P\bar{1}$ (see Tables 1 and 2).

In the crystal structure of **1**, there is one Cd^{II} atom, one mpa ligand and one phen ligand in each independent crystallographic unit. As shown in Figure 1, each Cd^{II} atom in **1** is primarily coordinated by two nitrogen atoms [Cd1−N1 = 2.395(4), Cd1−N2 = 2.377(5) Å, N2−Cd1−N1 = 70.5(2)°] of a chelating phen ligand, two oxygen atoms of two μ-carboxylate ends of two mpa ligands [Cd1−O2A = 2.255(4), Cd1−O1B = 2.301(4) Å, O2A−Cd1−O1B = 99.7(2)°] and two oxygen atoms of one chelating carboxylate end of one mpa ligand [Cd1−O4 = 2.453(4), Cd1−O3 = 2.331(4) Å, O3−Cd1−O4 = 55.2(1)°] to furnish a highly distorted octahedral geometry. Two Cd^{II} atoms related by a twofold axis are bridged by a pair of the mpa μ-carboxylate ends into a dinuclear unit [Cd1···Cd1A = 3.99 Å]. A face-to-face distance of 3.51 Å between a pair of phen ligands coordinated to the two Cd^{II} atoms is observed, showing significant intramolecular π−π interactions.

In fact, the V-shaped mpa ligand acts in the chelate-bidentate coordination mode (see Scheme 1, a) to link the adjacent Cd^{II} atoms into one-dimensional helical ribbons with a pitch of 9.55 Å running along the c axis (Figure 2, a). Pairs of phen ligands are alternately attached to both sides of the ribbon; the adjacent zigzag ribbons are packed through intercalation of the lateral phen ligands (face-to-face distance 3.32 Å), in the zipper-like fashion, into two-dimensional networks parallel to the bc plane. Adjacent ribbons also have strong intermolecular π−π interactions[19−23] between the mpa phenyl rings in an offset fashion with a face-to-face distance of ca. 3.38 Å, which

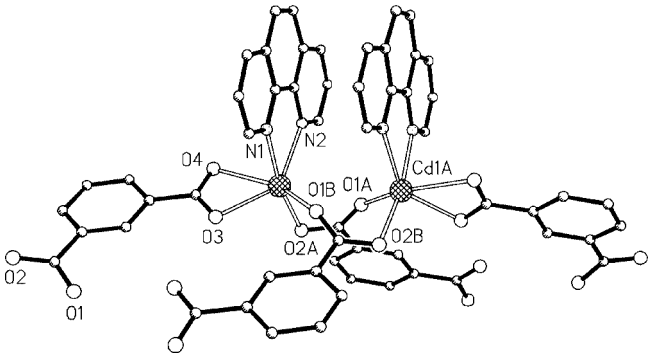

Figure 1. Perspective view of the coordination environments of the metal atoms with atomic labels in **1**

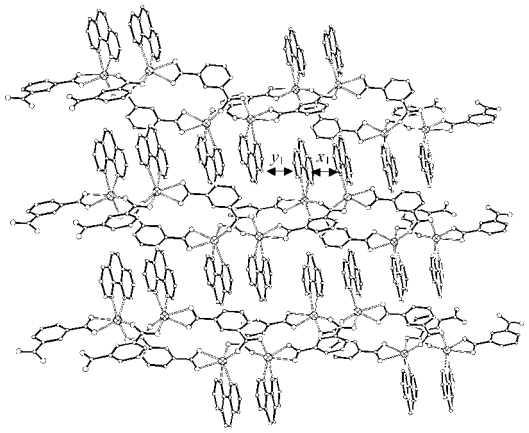
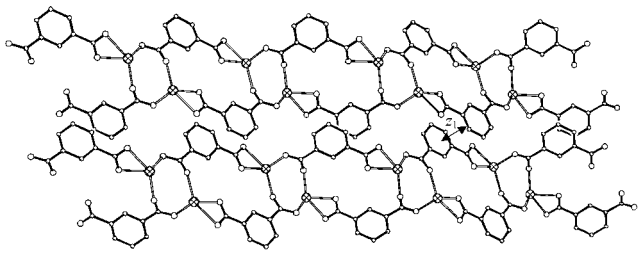


(a)



(b)

Figure 2. Perspective views of the two-dimensional networks parallel to the *bc* plane (a) and the *ac* plane (b) in **1**; the arrow in (b) highlights the intermolecular π−π interaction between the mpa phenyl rings; the face-to-face distances for the π−π interactions are x_1 = 3.51 Å, y_1 = 3.32 Å and z_1 = 3.38 Å

also extend the ribbons into two-dimensional networks (Figure 2, b) in another direction parallel to the *ab* plane. Therefore, these ribbons are in fact stacked through two different kinds of aromatic π−π stacking interactions, between phen ligands and mpa ligands, into a three-dimensional architecture in the lattice.

In the crystal structure of **2**, each Zn^{II} atom is primarily coordinated by two nitrogen atoms [Zn−N = 2.175(4) or

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

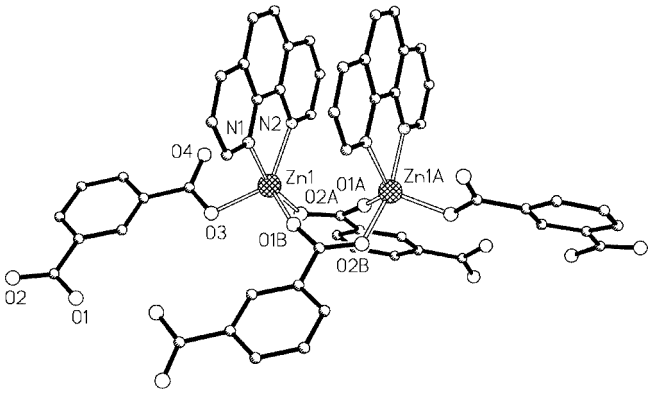


Figure 3. Perspective view of the coordination environments of the metal atoms with atomic labels in **2**

2.218(4) Å] from a chelating phen ligand and three oxygen atoms [Zn−O = 2.026(3)−2.045(3) Å] from two μ-carboxylate ends and one monodentate carboxylate end of three mpa ligands in a distorted trigonal arrangement, in which the N1 and O2A atoms occupy the axial positions and the pendant carboxy O4 atom has no significant interaction with Zn1 [Zn1···O4 = 2.675(4) Å] (Figure 3). The intradinuclear Zn···Zn distance (3.933 Å) and the face-to-face distance (3.52 Å) between the two phen ligands are similar to those found in **1**.

All the mpa ligands in **2** exhibit the monodentate-bidentate coordination mode (Scheme 1, b), and the pitch of the helical ribbon is 9.29 Å, being shorter than that in **1**. These differences may be attributed to the radius of the Cd^{II} atom being larger than that of the Zn^{II} atom, resulting in different coordination environments. On the other hand, adjacent ribbons in **2** are packed in a highly similar fashion to **1** through the π−π stacking interactions between the lateral phen ligands with face-to-face distances of ca. 3.29 Å and between the mpa phenyl rings with face-to-face distances of ca. 3.35 Å, into a three-dimensional network in the solid.

When 2,2′-bpy, an aromatic chelate ligand of smaller size, was used instead of phen, different ribbons were formed in **3** and **4** under similar reaction conditions. As illustrated in Figure 4 (a), there are two different metal coordination environments in **3**. Zn1 is coordinated by two oxygen atoms of one chelating carboxylate end of one mpa ligand [Zn1−O1 = 2.454(5), Zn1−O2 = 2.085(4) Å, O1−Zn1−O2 = 58.2(2)°], two oxygen atoms of two μ-carboxylate ends of two mpa ligands [Zn1−O5A = 2.039(4), Zn1−O6 = 2.095(5) Å, O5A−Zn1−O6 = 105.5(2)°] and two nitrogen atoms of a chelate 2,2′-bpy ligand [Zn1−N1 = 2.165(5), Zn1−N2 = 2.198(6) Å, N1 −Zn1−N2 = 75.5(2)°] to furnish a highly distorted octahedral environment, whereas Zn2 is ligated by four oxygen atoms of two chelating carboxylate ends of two mpa ligands [Zn2−O = 2.012(5)−2.469(5) Å, O3B−Zn2−O4B = 57.9(2), O7−Zn2−O8 = 59.7(2)°] and two nitrogen atoms of a chelate 2,2′-bpy ligand [Zn2−N4 = 2.086(5), Zn2−N3 = 2.165(6) Å, N3 −Zn2−N4 = 77.7(2)°] to complete a highly distorted octahedral geometry.

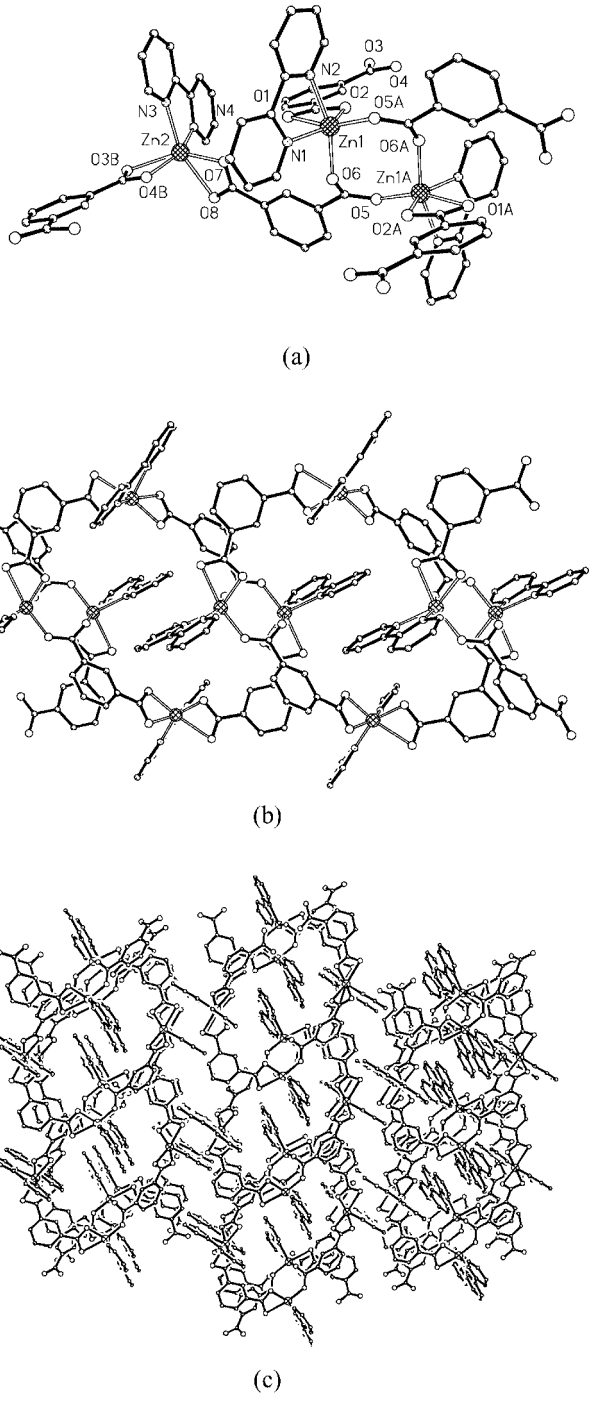

Figure 4. Perspective views of the coordination environments of the metal atoms with atomic labels (a), the one-dimensional ribbon running along the *b* axis (b) and the three-dimensional network (c) in **3**

The Zn1 atom in **3** is bridged by two μ-carboxylate ends to a crystallographically equivalent Zn^{II} atom to generate a dinuclear unit [Zn1···Zn1A = 4.324 Å] (Figure 4, a). The distance of Zn1···Zn1A is longer than in **2**, which may be attributed to the different coordination geometry and the orientation of the two 2,2′-bpy ligands around the two Zn^{II} atoms. The dinuclear units are interconnected to the mononuclear Zn2 sites, furnishing one-dimensional ribbons

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

along the *b* axis, which exhibit large rings each comprising four bridging V-shaped mpa ligands, two dinuclear units and two mononuclear units. The ribbon is decorated by 2,2′-bpy ligands in four different orientations (Figure 4, b). In fact, the V-shaped mpa ligands in **3** exhibit two different modes, chelate-bidentate (Scheme 1, a) and chelating bis(bidentate) (Scheme 1, c). The bridging bidentate ends of the chelate-bidentate mpa ligands contribute to the formation of the dinuclear units, whereas the chelate ends are connected to both the mono- and dinuclear Zn^{II} sites. The 2,2′-bpy ligands are orientated outwards of the ribbon and thus play an important role in packing adjacent ribbon chains into three-dimensional networks (Figure 4, c) through π−π stacking interactions (face-to-face distance ca. 3.56 or 3.62 Å). It should be pointed out that the π−π stacking interactions for mpa ligands in **3** are insignificant compared to those of **1** and **2**.

In the crystal structure of **4**, there are two Cd^{II} atoms, two mpa ligands and two phen ligands in each independent crystallographic unit. Cd1 is coordinated by two oxygen atoms from one chelating carboxylate end of one mpa ligand [Cd1−O1 = 2.281(3), Cd1−O2 = 2.524(3) Å, O1−Cd1−O2 = 54.08(8)°], two oxygen atoms of two μ-carboxylate ends of two mpa ligands [Cd1−O5A = 2.252(3), Cd1−O6 = 2.246(2) Å, O5A−Cd1−O6 = 117.1(1)°] and two nitrogen atoms of a chelate 2,2′-bpy ligand [Cd1−N1 = 2.379(3), Cd1−N2 = 2.333(3) Å, N1−Cd1−N2 = 69.27(9)°] to furnish a highly distorted octahedral coordination. Similarly to Cd1, Cd2 is also coordinated in a highly distorted octahedral geometry (see Table 2). The two crystallographically independent Cd^{II} atoms are each bridged by two μ-carboxylate ends to its crystallographically equivalent Cd^{II} atom to generate a dinuclear unit (Figure 5, a). Such dinuclear units are further extended by the bridging mpa ligands into one-dimensional helical ribbons with a pitch of 9.71 Å running along the $(1\bar{1}1)$ direction, which are decorated by 2,2′-bpy ligands at both sides. Since the pair of 2,2′-bpy ligands are orientated in opposite directions of the dinuclear unit, the geometry of the unit is hence different, concomitant with larger intradinuclear metal−metal distances (Cd1···Cd1A = 4.364 Å, Cd2···Cd2A = 4.181 Å) compared to that in **1**. These geometric differences may be attributed to the significant intramolecular π−π stacking interactions in **1**. The V-shaped mpa ligands in **4** exhibit uniquely the chelate-bidentate coordination mode (Scheme 1, a). Adjacent ribbons are intercalated in a zipper fashion into two-dimensional layers through the π−π stacking interactions between the 2,2′-bpy ligands with face-to-face distances of ca. 3.47−3.64 Å (Figure 5, b), and the layers are further packed into a three-dimensional network by van der Waals interactions. Similar to **3**, there are no significant π−π stacking interactions from the mpa ligands.

In our previous reports, we have shown that appropriate combinations of nonlinear flexible/V-shaped dicarboxylates with chelating phen can furnish interesting one-dimensional supramolecular structures such as molecular zippers as well as single- and double-stranded helices.[7,8] In particular, a

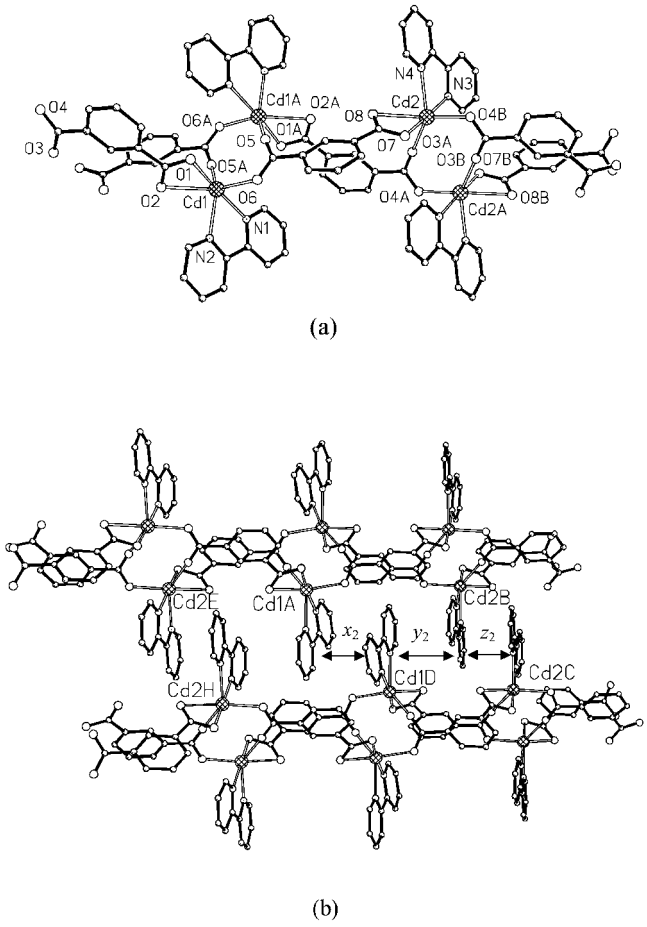

Figure 5. Perspective views of the coordination environments of the metal atoms (a) and the two-dimensional ribbons (b) in **4**; the face-to-face distances for the π−π interactions are x_2 = 3.48 Å, y_2 = 3.64 Å and z_2 = 3.47 Å

combination of V-shaped mpa ligands with chelating phen and 2,2′-bpy ligands along with the Cu^{II} ions generated single-stranded helical chains, namely $[Cu_2(mpa)_2(phen)_2(H_2O)]_n$ and $[Cu(mpa)(2,2'\text{-bpy})]_n{\cdot}2nH_2O$.[7] In contrast, using Cd^{II} or Zn^{II} atoms in place of Cu^{II} atoms under similar reaction conditions, the one-dimensional ribbons of **1**−**4** comprising dinuclear units were isolated. These observations may be attributed to the fact that the Cu^{II} has a greater tendency towards square-planar coordination tendency than the Cd^{II} and Zn^{II} atoms and the fact that Cd^{II} and Zn^{II} atoms have a tendency to form dinuclear structural units in the presence of the aromatic chelates. Actually, in $[Cu_2(mpa)_2(phen)(H_2O)]_n$ and $[Cu(mpa)(2,2'\text{-bpy})]_n{\cdot}2nH_2O$ as well as other related coordination polymers,[7] the one-dimensional chains are based on mononuclear structural units featuring primarily a square-planar geometry, compared to those in **1**, **2**, **3** and **4**. Therefore the dinuclear structural units in **1**, **2**, **3** and **4** represent new examples of building blocks among the dicarboxylate-bridged one-dimensional coordination polymers. On the other hand, different aromatic chelates also have a significant effect on the structures, as evidenced by the fact that the structure of **3** is significantly different from that of **1** and **2**.

Photoluminescence

The solid-state photoluminescent spectra of **1**, **2**, **3** and **4** at room temperature are depicted in Figure 6. Complexes **1** and **2** both exhibit intense blue photoluminescence with an emission maximum at ca. 423 and 420 nm upon excitation at 317 and 334 nm, respectively. According to the previous observations,[4,16,24−29] these emission bands would be assigned to the emission of ligand-to-metal charge transfer (LMCT). Whereas there are two intense emission maxima at ca. 397 and 413 nm for **3**, and ca. 405 and 422 nm for **4** upon excitation at ca. 347 and 355 nm, respectively. The peaks at 413 and 422 nm would be assigned to the emission of LMCT,[4,5,26,28,29] while the peaks at 397 and 405 nm would be distributed to the intraligand emission from the 2,2′-bpy ligand.[5,30] It is known that the free 2,2′-bpy molecule displays a weak luminescence at ca. 530 nm in the solid state at room temperature. The enhancement and significant blue-shift (up to 400 nm)[30] of the luminescence of the 2,2′-bpy ligand compared to that of the free 2,2′-bpy molecule may therefore be attributed to the chelating of the 2,2′-bpy ligand to the metal ion, which effectively increases the rigidity of the ligand and reduces the loss of energy by radiationless decay of the intraligand emission excited state.[24]

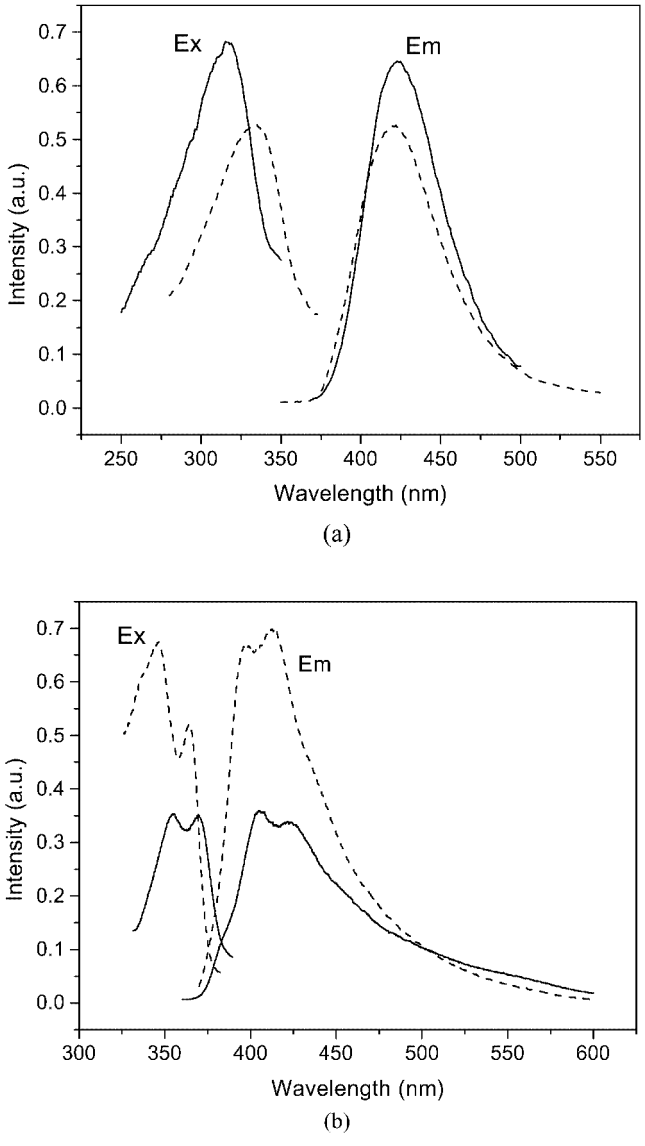

Figure 6. The excitation and emission spectra of **1**−**4** in the solid state at room temperature; the solid lines represent **1** and the dash-dot ones represent **2** in (a); the solid lines represent **4** and the dash-dot ones represent **3** in (b)

Conclusion

We have synthesized four stable one-dimensional ribbon-like coordination polymers under hydrothermal conditions, which show new dinuclear structural units as building blocks among the dicarboxylate-bridged one-dimensional coordination polymers as well as interesting photoluminescent properties. Compared to our previous one-dimensional copper(II) analogues, it has been found that different coordinations may have a very significant effect on the structures of the one-dimensional chains. Different combinations of nonlinear flexible/V-shaped dicarboxylates with chelating phen and 2,2′-bpy ligands in the presence of different metal ions, such as Cu, Cd and Zn, can furnish different one-dimensional supramolecular structures, such as molecular zippers, single- and double-stranded helices,[7,8] as well as helical ribbons.

Experimental Section

General Remarks: All chemicals were commercially available and used as received without further purification. The C, H and N microanalyses were carried out with a Perkin−Elmer 240 elemental analyzer. The FT-IR spectra were recorded from KBr pellets in the range 4000−400 cm^{-1} with a Nicolet 5DX spectrometer. All the excitation and emission spectra were measured with an Aminco Bowman Series 2 with a xenon arc lamp as the excitation light source for the solid-state samples. Thermogravimetric analysis (TGA) data were collected with a Perkin−Elmer TGS-2 analyzer in air at a heating rate of 10 °C min^{-1}.

Preparation of [Cd(mpa)(phen)]$_n$ (1): A mixture of $Cd(NO_3)_2{\cdot}9H_2O$ (1.0 mmol), H_2mpa (0.5 mmol), phen (1.0 mmol), NaOH (1.0 mmol) and water (10 mL) was stirred in air for 15 min, then transferred and sealed in a 23-mL Teflon-lined reactor, which was heated at 160 °C for 5 d and then cooled to room temperature at a rate of 5 °C h^{-1}. Colorless prisms were obtained, washed with deionized water and absolute ethanol (yield > 40% based on Cd). $C_{20}H_{12}CdN_2O_4$ (456.72): calcd. C 52.59, H 2.65, N 6.13; found C 52.70, H 2.59, N 6.20. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3417 s, 3169 s, 1979 w, 1615 s, 1564 s, 1515 m, 1481 w, 1400 s, 1145 m, 1102 m, 1049 w, 909 w, 859 s, 825 w, 783 m, 729 s and 635 m. TGA analysis of **1** shows a weight loss starting at ca. 402 °C.

Preparation of [Zn(mpa)(phen)]$_n$ (2): Complex **2** was prepared as for **1**. Pale yellow blocks of **2** were obtained, washed with deionized water and absolute ethanol (yield > 60% based on Zn). $C_{20}H_{12}N_2O_4Zn$ (409.69): calcd. C 58.63, H 2.95, N 6.84; found C 58.58, H 2.88, N 6.90. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3433 s, 3334 m, 3193 m, 3000 w, 1614 s, 1558 m, 1515 m, 1453 m, 1397 s, 1271 w, 1168 m, 1098 w, 850 s, 782 m, 744 w, 723 s, 592 m and 528 w. Decomposition of the polymeric framework of **2** began at ca. 371 °C.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Preparation of $[Zn_2(mpa)_2(2,2'\text{-bpy})_2]_n$ (3): A mixture of $Zn(NO_3)_2{\cdot}9H_2O$ (1.0 mmol), H_2mpa (0.5 mmol), 2,2′-bpy (1.0 mmol), NaOH (1.0 mmol) and water (10 mL) was stirred in air for 15 min, then transferred and sealed in a 23-mL Teflon-lined reactor, which was heated at 160 °C for 5 d and then cooled to room temperature at a rate of 5 °C h^{-1}. Colorless prisms were obtained, washed with deionized water and absolute ethanol (yield > 35% based on Zn). $C_{36}H_{24}N_4O_8Zn_2$ (771.33): calcd. C 56.05, H 3.14, N 7.26; found C 56.11, H 3.01, N 7.33. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3424 s, 3108 s, 3069 s, 1902 w, 1943 w, 1612 s, 1562 s, 1532 s, 1431 s, 1383 s, 1159 m, 1074 m, 1020 m, 934 w, 849 m, 827 m, 750 m, 658 s, and 583 m. TGA analysis of **3** shows a weight loss starting at ca. 365 °C.

Preparation of $[Cd_2(mpa)_2(2,2'\text{-bpy})_2]_n$ (4): Complex **4** was prepared as for **3**. Colorless blocks of **4** were obtained, washed with deionized water and absolute ethanol (yield > 50% based on Zn). $C_{36}H_{24}Cd_2N_4O_8$ (856.39): calcd. C 49.96, H 2.80, N 6.47; found C 49.88, H 2.85, N 6.54. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3414 s, 3109 m, 3050 m, 1602 s, 1552 s, 1474 m, 1436 s, 1381 s, 1314 m, 1247 w, 1154 m, 1078 m, 1016 s, 908 w, 827 m, 727 m, 717 s, and 652 w. Decomposition of the polymeric framework of **4** began at ca. 370 °C.

X-ray Crystallographic Study: A summary of the crystal data for **1**, **2**, **3** and **4** is given in Table 1. Selected bond lengths and angles are listed in Table 2. Drawings were produced with SHELXTL. The intensity data of **1**, **2** and **3** were collected with a Siemens R3m diffractometer using the ω-scan technique with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation at room temperature and the intensity data of **4** were collected with a Bruker Apex CCD diffractometer with the graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation at 228 K in the ω-2θ scan mode. Lorentz-polarization and absorption corrections were applied.[31] The structures were solved with direct methods and refined with a full-matrix least-squares technique using the SHELXS-97 and SHELXL-97 programs,[32,33] respectively. Anisotropic thermal parameters were assigned to all non-hydrogen atoms. The organic hydrogen atoms were generated geometrically (C−H 0.96 Å); the aqua hydrogen atoms were located from difference maps and refined with isotropic temperature factors. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated.[34] CCDC-212917 (**1**), -212918 (**2**), -212919 (**3**), -212920 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Mechanistic Insight Gained into the Ligand Substitution Reactions of Bis(*o*-benzosemiquinonediiminato)(triphenylphosphane)cobalt(III) – Kinetic, Solvent, and Volume Profile Studies

Basam M. Alzoubi,[a] Mohamed S. A. Hamza,[a][‡] Carlos Dücker-Benfer,[a] and Rudi van Eldik*[a]

Keywords: Cobalt / Kinetics / Ligand substitution / Mechanism / Pressure dependence / Solvent effects

The ligand substitution reactions of bis(*o*-benzosemiquinonediiminato)(triphenylphosphane)cobalt(III), $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$, were studied with imidazole (Imid) and 4-dimethylaminopyridine (4-Me_2Npy) as entering nucleophiles in MeOH and CH_3CN as solvents (S). The complex $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)S]^+$ undergoes dissociation of the solvent to form a five-coordinate intermediate, $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$, which binds the entering nucleophile in a rate-determining step through a six-coordinate transition state, $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)L]^+$, followed by the release of triphenylphosphane to form $[Co^{III}(s\text{-}BQDI)_2L]^+$. From the temperature and pressure dependence of the substitution of triphenylphosphane by imidazole, the activation parameters for the forward and reverse reactions of $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ with imidazole in MeOH were found to be $\Delta H^{\ddagger}$ = 58±2 and 43.4±0.5 kJ·mol^{-1}, $\Delta S^{\ddagger}$ = −116±6 and −73±2 J·K^{-1}·mol^{-1}, and $\Delta V^{\ddagger}$ = −10.6±0.1 and −8.7±0.3 cm^3·mol^{-1}, respectively. In CH_3CN, however, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta V^{\ddagger}$ for the forward reaction were found to be 50±3 kJ·mol^{-1}, −111±9 J·mol^{-1}·K^{-1}, and −12.9±0.3 cm^3·mol^{-1}, respectively. The activation parameters for the reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and 4-dimethylaminopyridine in MeOH for the forward and reverse reactions were found to be $\Delta H^{\ddagger}$ = 76±2 and 47.9±0.4 kJ·mol^{-1}, $\Delta S^{\ddagger}$ = −51±7 and −64±2 J·K^{-1}·mol^{-1}, and $\Delta V^{\ddagger}$ = −10.5±0.3 and −11.1±0.2 cm^3·mol^{-1}, respectively. From these reported rate and activation parameters, the substitution of triphenylphosphane by imidazole and 4-dimethylaminopyridine follows an associative mechanism. The ligand substitution reactions of $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ in CH_3CN were found to be faster than those in MeOH, which is attributed to the potential for hydrogen bond formation with the entering nucleophile in the case of MeOH as solvent.

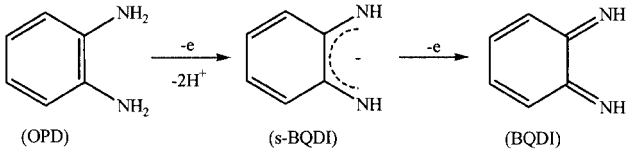
Introduction

The chemistry of transition metal complexes of benzosemiquinonediimine (s-BQDI), derived from *o*-phenylenediamine (OPD), are rather important because of their interesting redox properties[1,2] and their relation to biologically relevant catechol and benzoquinone derivatives.[3]

The bidentate ligand *o*-benzosemiquinonediiminato(−1), derived from the one-electron oxidation of *o*-phenylenediamine, can be stabilised by complex formation.[4] By removal of a second electron it is converted into the unstable *o*-benzoquinonediimine (BQDI) [Equation (1)], which can also be stabilised through complexation.[2]



(1)

X-ray diffraction shows that the structure of $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]ClO_4$ is square-pyramidal in the solid state, with PPh_3 occupying one of the axial positions.[5] Upon dissolution in a coordinating solvent such as MeOH, the sixth position becomes occupied by a weakly bound solvent molecule, which cannot be observed in the solid-state structure.[3,6] Complexes such as $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]PF_6$, $[Co^{III}(s\text{-}BQDI)_2I]$, $[Co^{III}(s\text{-}BQDI)_2SCN]$, or $[Fe(s\text{-}BQDI)_2(Ph_3P)]$ are potentially five-coordinate in CH_3CN as solvent.[2]

We are interested generally in equilibria between five- and six-coordinate species in such complexes, since this should provide a better understanding of their mechanistic behaviour in ligand displacement processes. Alkyl cobalamines and cobinamides (vitamin B_{12} derivatives) with stronger donor ligands (e.g., vinyl, methyl, sulfite, dialkyl phosphite) exist as temperature-dependent mixtures of yellow five-coordinate and red six-coordinate aqua (solvent) complexes. Increasing the temperature favours the five-coordinate form with diethyl phosphite as ligand, whereas increasing the

pressure favours the six-coordinate form.[7] The reaction volume for the formation of the six-coordinate species in water as solvent was found to be $-12.5\ cm^3\ mol^{-1}$, suggesting that the entering water molecule is fully bound in the six-coordinate complex.[7]

The ligand substitution reactions of $[Co^{III}(s\text{-}BQDI)_2L]^+$, where L = Ph_3Sb and Ph_3As, and of $[Co^{III}(s\text{-}CBQDI)_2(Ph_3As)]^+$, where s-CBQDI = 4,5-dichloro-1,2-benzosemiquinonediiminato, were studied in methanol with different nucleophiles such as pyridine, pyrrolidine, and imidazole as entering ligands.[3,6] It was found that these nucleophiles easily displace the coordinated solvent molecule to form the six-coordinate $[Co^{III}(s\text{-}BQDI)_2LL']^+$ complexes, where L′ represents the entering nucleophile.[3] In a subsequent step, substitution of L by the entering nucleophile takes place, and an associative interchange mechanism was suggested.

In this investigation we performed a detailed analysis of the axial ligand substitution reactions of $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)S]^+$ by imidazole and 4-$(Me)_2$Npy, where S is MeOH or CH_3CN, in order to study the intimate nature of the ligand displacement mechanism and the effect of the selected solvent on these reactions.

Results and Discussion

We started our studies by investigating the effect of temperature and pressure on the UV/Vis spectra of $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ in methanol as solvent. The UV/Vis spectrum of $5\cdot10^{-5}$ M $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ was recorded as a function of temperature, as shown in Figure S-1 (Supporting Information). With decreasing temperature, from 60 to 5 °C, it exhibits isosbestic points at 508, 600, and 760 nm, a significant absorbance decrease at 712 and 450 nm, and an increase in absorbance at 550 nm. Similar spectra were obtained either on decreasing the temperature or on increasing the pressure.

The effect of temperature and pressure on the UV/Vis spectra suggests an equilibrium between five- and six-coordinate forms of the complex $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)S]^+$, where the sixth coordination site is occupied by a solvent molecule. The six-coordinate form is favoured by increasing pressure or decreasing temperature, and vice versa for the five-coordinate complex. Similar trends could be observed in both solvents (MeOH and CH_3CN). In the case of CH_3CN as solvent, however, the change in the UV/Vis spectrum was not as significant as in that of MeOH as solvent, which is attributed to the fact that CH_3CN is a much stronger nucleophile than MeOH and will form a less labile six-coordinate species. For this reason a smaller fraction of the five-coordinate species will exist in equilibrium with the six-coordinate species in the case of CH_3CN as solvent. In the solid state the complex is square-pyramidal with a Ph_3P ligand occupying the axial position.[5]

Reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and Imidazole in Methanol

The UV/Vis spectrum of $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ exhibits two bands at 710 and 478 nm, with a shoulder at 423 nm ($\varepsilon = 2.2\cdot10^4$, $1.1\cdot10^4$, and $7.9\cdot10^3\ M^{-1}\cdot cm^{-1}$, respectively). Upon mixing of the complex with imidazole or 4-$(Me)_2$Npy in the stopped-flow instrument, there is a small and very rapid initial increase in absorbance prior to the reaction with the entering nucleophile. This rapid increase can be ascribed to a fast equilibration between the complex and the solvent (methanol) as a result of the equilibrium between the five- and six-coordinate complexes in solution as discussed above. This rapid absorbance change is also observed in the absence of imidazole or 4-$(Me)_2$Npy, just by dilution of a solution of the complex with solvent in a stopped-flow instrument, and occurs within the mixing time of the instrument (2 ms) at room temperature. With the use of a Biologic low temperature stopped-flow unit, however, the spectral changes associated with this reaction could be recorded at −40 °C, and a typical kinetic trace (see Figure S-2, Supporting Information) indicates that this reaction is over within 2 s at −40 °C. Subsequently, there is a much larger absorbance decrease at 710 and 450 nm, and an increase at 540 nm, associated with the coordination of imidazole. The $[Co^{III}(s\text{-}BQDI)_2(Imid)]^+$ complex shows two bands at 716 and 496 nm, with a shoulder at 420 nm ($\varepsilon = 1.1\cdot10^5$, $5.7\cdot10^4$, and $3.9\cdot10^4\ M^{-1}\cdot cm^{-1}$, respectively), whereas $[Co^{III}(s\text{-}BQDI)_2(4\text{-}Me_2Npy)]^+$ has characteristic UV/Vis bands at 714 and 520 nm, with a shoulder at 422 nm ($\varepsilon = 6.7\cdot10^4$, $5.2\cdot10^4$, and $3.1\cdot10^4\ M^{-1}\cdot cm^{-1}$, respectively).

The reaction between $2.5\cdot10^{-5}$ M $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and an excess of imidazole (0.05 to 1.0 M) was studied in methanol as a function of temperature (15−45 °C). Kinetic traces for this reaction revealed perfect pseudo-first order behaviour, and the kinetic results as a function of the imidazole concentration are shown in Figure 1. It follows that good linear plots with significant intercepts are obtained within the experimental error limits. Furthermore, the plots do not indicate any saturation at high [Imid]. This kinetic behaviour can be expressed by the rate law given in Equation (2), where k_a and k_b represent the rate constants for the forward (slope) and reverse (intercept) reactions, respectively. Values of k_a and k_b as a function of temperature, along with the corresponding activation parameters, are summarised in Table 1. Values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for the forward reaction (k_a) were found to be $58\pm2\ kJ\cdot mol^{-1}$ and $-116\pm6\ J\cdot K^{-1}\cdot mol^{-1}$, whereas those for the reverse reaction (k_b) were found to be $68\pm1\ kJ\cdot mol^{-1}$ and $-82\pm3\ J\cdot K^{-1}\cdot mol^{-1}$, respectively.

$$k_{obsd.} = k_a[L] + k_b \quad (2)$$

The results in Figure 1 clearly indicate that we are dealing with an unfavourable displacement of triphenylphosphane by imidazole, as can be seen from the magnitude of the intercepts of the plots that represent the contribution of the reverse reaction. Under the selected experimental conditions (no free phosphane added), the reverse displacement of imidazole by phosphane will follow second-order kinetics, with the result that the kinetic data measured under

[a] First-order rate constant obtained from the intercept of plots of $k_{obsd.}$ versus [Imid].

pseudo-first order conditions at low imidazole concentrations could become unreliable due to a contribution of the second-order reverse process. We therefore studied the rate and activation parameters for the reverse substitution of imidazole by Ph_3P separately, by first treating $2.5\cdot10^{-4}$ M of $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ with 1 M imidazole to form the imidazole complex, followed by the addition of an excess of Ph_3P to form the $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ complex again. Figure 2 shows a linear plot of $k_{obsd.}$ versus $[Ph_3P]$ for the reaction between $[Co^{III}(s\text{-}BQDI)_2(Imid)]^+$ and an excess of Ph_3P (0.005−0.025 M). The linear plot exhibits a negligible intercept, indicating that the displacement of imidazole by phosphane goes to completion under the selected conditions. The slope of the line in Figure 2 represents k_b, for which the results are reported as a function of temperature

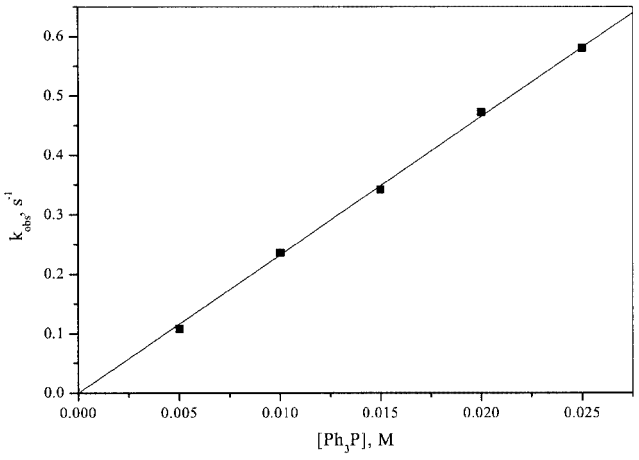

Figure 2. Plot of $k_{obsd.}$ versus $[Ph_3P]$ for the reaction between $1.25\cdot10^{-4}$ M $[Co^{III}(s\text{-}BQDI)_2(Imid)]^+$ and Ph_3P in methanol at 25 °C; the best fit (solid line) gives $k_b = 23.3\ M^{-1}\cdot s^{-1}$

Table 2. Kinetic data for the reaction between $[Co^{III}(s\text{-}BQDI)_2(Imid)]^+$ and Ph_3P in methanol as a function of temperature and pressure

[a] Second-order rate constant calculated from the slope of plots of k_b versus $[Ph_3P]$. [b] $[Co^{III}(s\text{-}BQDI)_2(Imid)]^+ = 1.25\cdot10^{-4}$ M, $[Ph_3P] = 2.5\cdot10^{-2}$ M. [c] $[Co^{III}(s\text{-}BQDI)_2(Imid)]^+ = 1.25\cdot10^{-4}$ M, $[Ph_3P] = 1.25\cdot10^{-2}$ M.

in Table 2. The $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values for k_b were found to be 43.4±0.5 $kJ\cdot mol^{-1}$ and −73±2 $J\cdot K^{-1}\cdot mol^{-1}$, respectively.

The reaction between $2.5\cdot10^{-5}$ M $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and imidazole ([Imid] = 0.05−1 M) was studied at different pressures (10−130 MPa). The results are shown in Figure 3, from which it follows that good linear plots with significant intercepts are obtained within the experimental error limits. The values of k_a and k_b as a function of pressure, along with the corresponding activation volumes, are summarised in Table 1. Plots of ln k_a and ln k_b versus pressure were linear within the error limits (Figures S-3 and S-4, Supporting Information), and values of $\Delta V^{\ddagger}$ for the forward and the reverse reactions were found to be −10.6±0.1 and −7.2±0.3 $cm^3\cdot mol^{-1}$, respectively.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Because of the possible unreliability of k_b under these conditions, as indicated above, its pressure dependence was also measured directly by treatment of the imidazole complex with an excess of phosphane, the results of which are included in Table 2. A plot of ln k_b versus pressure gave a good linear relationship, from which $\Delta V^{\ddagger}$ was calculated to be -8.7 ± 0.3 cm^3·mol^{-1}.

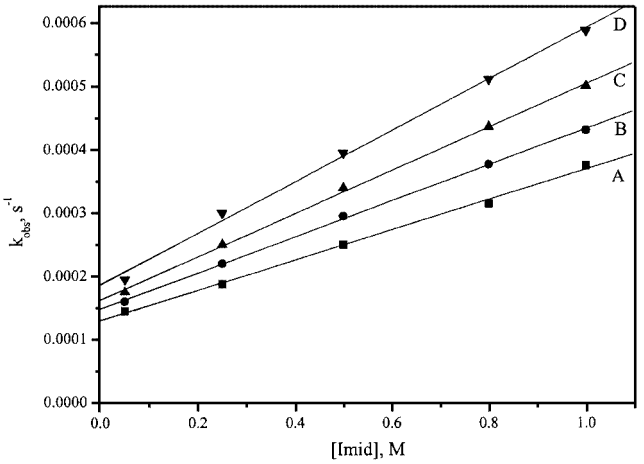

Figure 3. Plots of $k_{obsd.}$ versus [Imid] for the reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and phosphane in methanol as a function of pressure; experimental conditions: $[Co^{III}] = 2.5\cdot10^{-5}$ M, pressure: 10 (A), 50 (B), 90 (C), 130 MPa (D)

From the available kinetic and spectroscopic data, we suggest that the reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)S]^+$ and imidazole (or 4-Me_2Npy, see later) takes place in two consecutive steps. There is rapid dissociation of coordinated solvent in Equation (3) to form a five-coordinate intermediate, followed by the rate-determining associative ligand exchange process Equation (4) to form the product complex.

$$[Co^{III}(s\text{-}BQDI)_2(Ph_3P)S]^+ \rightleftarrows [Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+ + S \quad (3)$$

$$[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+ + L \underset{k_b}{\overset{k_a}{\rightleftharpoons}} [Co^{III}(s\text{-}BQDI)_2(L)]^+ + PPh_3 \quad (4)$$

From the activation parameters and the constructed volume profile shown in Figure 4, it is reasonable to conclude that the reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and imidazole in methanol follows an associative mechanism through the formation of a six-coordinate intermediate/transition state.

Reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and 4-$(Me)_2$Npy in Methanol

The reaction between $2.5\cdot10^{-5}$ M $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and an excess of 4-Me_2Npy (0.05 to 1 M) in methanol as a function of temperature (15−45 °C) was studied in a similar way. The results are presented in Figure S-5 (Supporting Information), from which it follows that good linear plots with significant intercepts are obtained

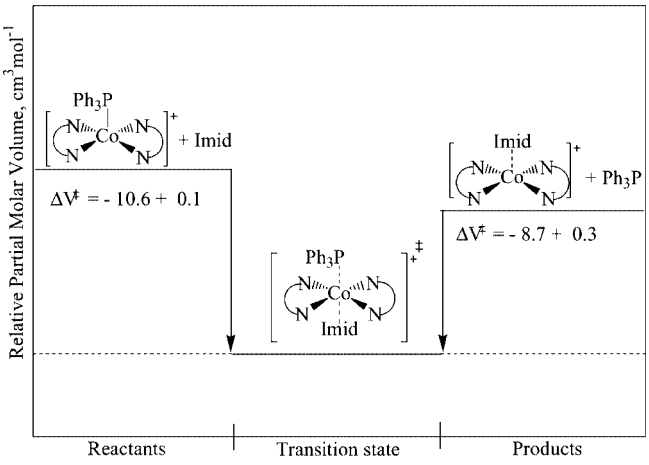

Figure 4. Volume profile for the reaction (the given structures are schematic presentations)

within the experimental error limits. Furthermore, the plots do not indicate any saturation at high 4-Me_2Npy concentrations. In this case the intercepts are smaller and the slopes of the plots larger than in the case of the reaction with imidazole, indicating that a more favourable equilibrium situation is reached in the reaction with 4-Me_2Npy. The same rate law and data treatment as used for the reaction with imidazole can be adopted, and the results are summarized as a function of temperature and pressure in Table 3. The values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for the forward reaction (k_a) were found to be 76 ± 2 kJ·mol^{-1} and -51 ± 7 J·K^{-1}·mol^{-1}, respectively, and those for the reverse reaction to be 61 ± 4 kJ·mol^{-1} and -115 ± 12 J·K^{-1}·mol^{-1}, respectively. Because of the possible contribution of a second-order reverse reaction at low 4-Me_2Npy concentration, we also determined the rate and activation parameters for the substitution of 4-Me_2Npy by Ph_3P to form $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ directly, by treatment of $2.5\cdot10^{-4}$ M $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ with 1 M 4-Me_2Npy, followed by the reaction with phosphane. A plot of $k_{obsd.}$ versus $[Ph_3P]$ for the reaction between $[Co^{III}(s\text{-}BQDI)_2(4\text{-}Me_2Npy)]^+$ and excess Ph_3P (0.005−0.025 M) is shown in Figure S-6 (Supporting Information), from which it follows that the back reaction does not contribute significantly under these conditions. The data for k_b are summarised in Table 4. The values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were found to be 47.9 ± 0.4 kJ·mol^{-1} and -64 ± 2 J·K^{-1}·mol^{-1}, respectively.

The reaction between $2.5\cdot10^{-5}$ M $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and 4-Me_2Npy (0.05 to 1 M) as a function of pressure (10−130 MPa) was also studied, and the results are reported in Figure S-7 (Supporting Information). The data show good linear plots with significant intercepts within the experimental error limits. The values of k_a and k_b as a function of pressure, along with the corresponding activation parameters, are summarised in Table 3. Plots of lnk_a and lnk_b versus pressure gave good linear fits, from which the values of $\Delta V^{\ddagger}$ for the forward and reverse reactions were calculated to be -10.5 ± 0.3 and -8.7 ± 0.6

$\Delta S^{\ddagger}$, J·K^{-1}·mol^{-1}		−64±2
$\Delta V^{\ddagger}$, cm^3·mol^{-1}		−11.1±0.2

[a] Second-order rate constant calculated from the slope of plots of k_b versus $[Ph_3P]$. [b] $[Co^{III}(s\text{-}BQDI)_2(4\text{-}Me_2Npy)]^+ = 1.25\cdot10^{-4}$ M, $[Ph_3P] = 2.5\cdot10^{-2}$ M. [c] $[Co^{III}(s\text{-}BQDI)_2(4\text{-}Me_2Npy)]^+ = 1.25\cdot10^{-4}$ M, $[Ph_3P] = 1.25\cdot10^{-2}$ M.

cm^3·mol^{-1}, respectively. The values of k_b were also measured directly as a function of pressure, with use of the displacement of 4-Me_2Npy by phosphane, and a plot of $\ln k_b$ versus pressure resulting in a $\Delta V^{\ddagger}$ value of −11.1±0.2 cm^3·mol^{-1} (see Table 4). From the reported activation parameters, we can conclude that the reverse reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and 4-$(Me)_2$Npy follows the same associative reaction mechanism, in which the entering nucleophile is coordinated to the Co^{III} centre in the six-coordinate intermediate/transition state.

The forward rate constants for the reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]$ and 4-$(Me)_2$Npy or imidazole are $6.7\cdot10^{-4}$ and $4.5\cdot10^{-4}$ $M^{-1}\cdot s^{-1}$ at 25 °C, respectively, whereas the rate constants for the reverse reactions are 12.1 and 23.2 $M^{-1}\cdot s^{-1}$ at 25 °C, respectively. This indicates that the forward rate constant (k_a) increases with increasing basicity of the entering ligand, whereas the reversible reaction rate constant (k_b) decreases with increasing basicity due to the stronger cobalt−ligand bond.

Reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and Imidazole in Acetonitrile

The reaction between $2.5\cdot10^{-5}$ M $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and excess imidazole ([Imid] = 0.025−1 M) in acetonitrile was studied at different temperatures (11−32 °C). The results are presented in Figure 5 and show a significant deviation from linearity at high imidazole concentrations, as well as negligible intercepts. This behaviour can be accounted for in terms of the interchange mechanism presented in reactions according to Equations (5) and (6), for which the rate law is given in Equation (7), where K represents the equilibrium constant for precursor formation, and k the interchange rate constant. Since acetonitrile is a much more strongly coordinating solvent than methanol, this presumably prevents formation of a five-coordinate intermediate and forces the reaction to proceed through an interchange instead of an associative mechanism involving a five-coordinate intermediate.

$$[Co^{III}(s\text{-}BQDI)_2(Ph_3P)S]^+ + Imid \rightleftarrows \{[Co^{III}(s\text{-}BQDI)_2(Ph_3P)S]^+\cdot Imid\};\ K \quad (5)$$

$$\{[Co^{III}(s\text{-}BQDI)_2(Ph_3P)S]^+\cdot Imid\} \rightarrow [Co^{III}(s\text{-}BQDI)_2(Imid)S]^+ + Ph_3P;\ k \quad (6)$$

$$k_{obs} = \frac{k\cdot K[Imid]}{\{1 + K[Imid]\}} \quad (7)$$

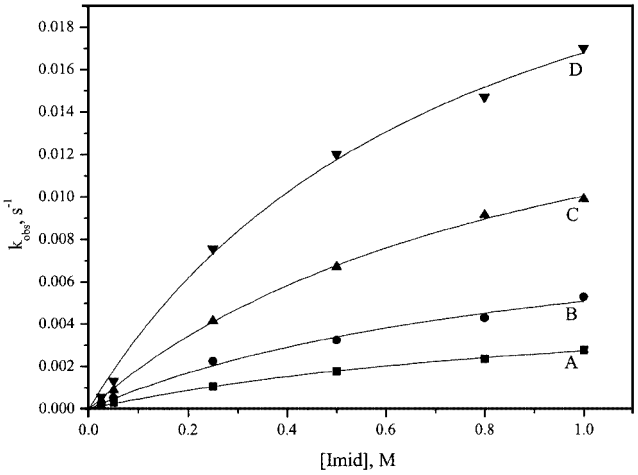

Figure 5. Plots of $k_{obsd.}$ versus [Imid] for the reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and imidazole in acetonitrile as a function of temperature; experimental conditions: $[Co^{III}] = 2.5\cdot10^{-5}$ M, temperature: 11.0 (A), 18.0 (B), 25.0 (C), 32.0 °C (D)

Table 5. Kinetic data for the reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and imidazole in acetonitrile as a function of temperature and pressure

Pressure, MPa	Temp., °C	$k{\cdot}K \times 10^3$, $M^{-1}\,s^{-1}$ [a]	K, M^{-1} [b]	$k \times 10^3$, s^{-1} [b]
0.1	11.0	5.8±0.1[c]	0.9±0.1	5.8±0.5
	18.0	10.4±0.5[c]	1.0±0.2	10±2
	25.0	18±4[c]	1.1±0.1	19±1
	32.0	26±2[c]	1.3±0.1	29±3
10	5.0	4.9±0.2[d]		
50		6.1±0.3[d]		
90		7.5±0.1[d]		
130		9.6±0.1[d]		
$\Delta H^{\ddagger}$, $kJ{\cdot}mol^{-1}$		50±3[c]		
$\Delta S^{\ddagger}$, $J{\cdot}mol^{-1}{\cdot}K^{-1}$		−111±9[c]		
$\Delta V^{\ddagger}$, $cm^3{\cdot}mol^{-1}$		−12.9±0.3[d]		

[a] $k{\cdot}K$ was calculated from $k_{obsd.}$/[Imid] at [Imid] = 0.05 M. [b] K and k were calculated from the nonlinear least-squaresfit by use of Equation (7). [c] $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+ = 2.5{\cdot}10^{-5}$ M. [d] $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+ = 2.5{\cdot}10^{-5}$ M, [Imid] = 0.025 M.

The values of k and K as a function of temperature were calculated from a nonlinear fit of the measured rate constants and are summarised, along with the corresponding activation parameters, in Table 5. The values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for the overall reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and imidazole in CH_3CN were calculated for $k{\cdot}K = k_{obsd.}$/[Imid] at [Imid] = 0.05 M (i.e., where the imidazole concentration dependence is still linear), and were found to be 50±3 $kJ{\cdot}mol^{-1}$ and −111±9 $J{\cdot}K^{-1}{\cdot}mol^{-1}$, respectively. The pressure dependence of the reaction was studied at 0.025 M imidazole and 5 °C, and the plot of $\ln k_{obsd.}$ vs. pressure gave a good linear fit from which the value of $\Delta V^{\ddagger}$ was calculated to be −12.9±0.3 $cm^3{\cdot}mol^{-1}$. The results are summarized in Table 5. The reported activation parameters favour an associative interchange (I_a) mechanism.

Mechanistic Interpretation

Most ligand substitution reactions of Co^{III} complexes, such as those in vitamin B_{12}, its derivatives and model complexes, follow a D or I_d mechanism.[9−17] Surprisingly, the substitution reactions investigated in the current study between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and imidazole or 4-Me_2Npy clearly follow an associative mechanism. Simandi et al. studied the ligand substitution reactions of $[Co^{III}(s\text{-}CBQDI)_2(Ph_3As)]^+$ with pyridine, pyrrolidine, and imidazole in methanol and suggested an I_a mechanism, but no activation parameters were reported.[3]

The second-order rate constant for the reaction between $[Co^{III}(s\text{-}BQDI)_2(Ph_3P)]^+$ and imidazole in methanol at 25 °C ($4.5{\cdot}10^{-4}$ $M^{-1}{\cdot}s^{-1}$) is significantly smaller than that obtained in the case of CH_3CN as solvent ($1.78{\cdot}10^{-2}$ $M^{-1}{\cdot}s^{-1}$). This suggests either that hydrogen bonding plays an important role in methanol as solvent by deactivating the attacking nucleophile, or that the stronger donor properties of acetonitrile labilizes the *trans* position and induces a rapid displacement of phosphane.

The rates of associative substitution reactions can in principle be affected by the nature of the solvent. Especially in the case of protic solvents, partial protonation of the nucleophile, directly or through hydrogen bonding, can cause a significant decrease in the nucleophilicity of the entering nucleophile. Specific solvation of the nucleophile by a protic solvent strongly stabilizes the nucleophile and lowers its reactivity toward an electrophilic metal centre in an associative reaction mode. In contrast, polar non-protic solvents such as acetonitrile favour associative reaction modes.[8]

In the case of the benzosemiquinonediimine chelate, delocalization of electron density from the unsaturated equatorial ligand (s-BQDI) onto the Co^{III} centre could partially induce Co^{II} character, which could in turn account for the higher liability and the observed associative mechanism. The strongly negative activation entropies and volumes support the associative nature of the substitution mechanism for these complexes. By way of comparison, in complexes of ethylenediamine, the chelate is fully saturated and an I_d mechanism is more likely to account for the observed kinetic behaviour. It seems clear that the phenylenediamine ligand in the equatorial plane controls the ligand displacement mechanism. The induced electron density at the metal centre favours the unsaturated five-coordinate state and lowers the energy barrier to bind the entering nucleophile in the absence of a strongly coordinating solvent to favour the associative reaction pathway. In the presence of a more strongly coordinating solvent such as acetonitrile, the absence of a vacant coordination site will force the system to follow an interchange substitution mechanism.

Experimental Section

Materials: All chemicals were of p.a. grade and were used as received. Imidazole was purchased from Aldrich and 4-dimethylaminopyridine was purchased from Across. $[Co(s\text{-}BQDI)_2(Ph_3P)]ClO_4{\cdot}0.5C_6H_6$ was prepared as described previously[5] by treatment of $Co(ClO_4)_2{\cdot}6H_2O$ with *o*-phenylenediamine and triphenylphosphane in the presence of oxygen. The complex was characterised by elemental analysis and by IR and NMR spectroscopy, and the results were in agreement with those reported in the literature.[5]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Instrumentation: UV/Vis spectra and kinetic measurements were recorded in thermostatted cell compartments of Shimadzu UV-2101 and Cary 5 spectrophotometers. Measurements at high pressures were carried out by use of the Shimadzu spectrophotometer equipped with a home-made high-pressure unit.[18] For faster reactions a high pressure, stopped-flow instrumentation was used.[19] Kinetic data were analysed with the OLIS KINFIT programme. All instruments used were thermostatted to the desired temperature (±0.1 °C). Kinetic measurements were carried out under pseudo-first order conditions (i.e., the ligand concentration was in at least a tenfold excess).

Rational Design, Synthesis and Crystal Structure Investigation of Hydrogen-Bonded Coordination Polymers of Bicyclic Bis-Lactam Dicarboxylates[‡]

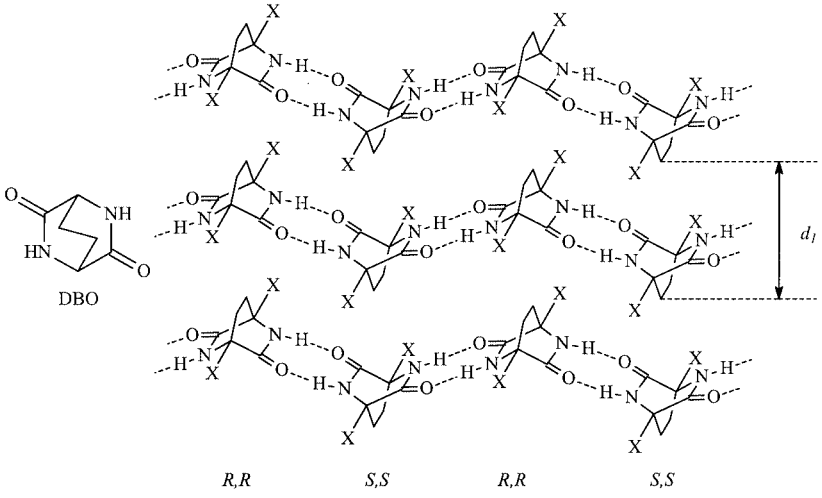
Denis A. Lenev,[a] Konstantin A. Lyssenko,[b] and Remir G. Kostyanovsky*[a]

Keywords: Carboxylate ligands / Chirality / Crystal engineering / Hydrogen bonding / Lactams

The crystal structures of the racemic coordination polymers (±)-**1** to (±)-**4** and the coordination dimers (±)-**6** and (±)-**7**, containing molecular "brick walls" with inorganic coatings and molecular "brick walls" with mixed organic-inorganic coatings, respectively, were predicted and verified on the basis of the zigzag $R_2^2(8)$ H-bonded tape columnar packing motif of the purely organic racemic dialkyl 3,6-dioxo-2,5-diazabicyclo[2.2.2]octane-1,4-dicarboxylates.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

H-bonded supramolecular aggregation of metal ion-coordinated assemblies is a promising approach in crystal engineering, combining a variety of coordination types and well established organic motifs of H-bonding.[1−8] In a preceding paper[9] we have shown that functionalized derivatives of chiral C_2-symmetric bicyclic dipeptide, 2,5-diazabicyclo[2.2.2]octane-3,6-dione (DBO), viz. corresponding dialkyl 1,4-dicarboxylates, form predictable heterochiral zigzag tapes with lactamic $R_2^2(8)$ H-bonding, in which molecules of different chirality alternate strictly (Scheme 1), as in the crystal structures of (±)-DBO and other bis-lactams[10−14] (for other important works on lactamic H-bonded tapes, see refs.[15−17]). A new two-dimensional motif appears in all investigated crystals of the racemic and chiral quasi-racemic esters, with homochiral columns being formed by stacking of the heterochiral tapes orthogonally to their propagation axes. We refer to this two-dimensional motif as molecular "brick walls" with non-polar coating (Scheme 1) (compare ref.[18]). An attempt to extend the "brick walls" into the third dimension (and thus explain the design of the whole crystal structure) through H-bonding, involving carboxylic acid moieties (Scheme 1, X = CO_2H)



Scheme 1. Molecular "brick wall" with nonpolar coating (X = CO_2alkyl) observed in crystal structures of dialkyl DBO-1,4-dicarboxylates, where d_1 is the distance between adjacent molecules in the column and is equal to the corresponding translation (crystal lattice parameter)

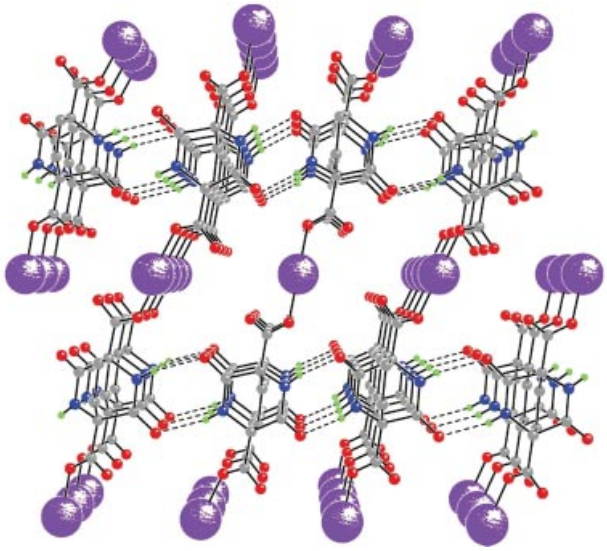
failed because of hydrate formation.[9] In the case of competitive H-bonding carbamoyl substituents (X = $CONH_2$), either nanochannels or unbalanced chiral, triply interpenetrated, diamondoid networks form.[19] We therefore tried to use supramolecular forces from another field, metal−carboxylate ligand interactions, which it was hoped might direct self-assembly of the desired three-dimensional crystal structure (Scheme 2). In addition, we were also very interested in the senses of chirality of the assemblies formed. In this study we report the results of the initiated research. In fact, examples of coordination structures of cyclic dipeptides have already been published for Na and Tl^I salts of *cyclo*-(L-α-aspartyl-L-phenylalanine)[20,21] and in particular for a coordination polymer of Ag^I with *cyclo*-(L-methionyl-L-methionyl).[22] However, little attention is given in those papers to the supramolecular aspects of the structures.

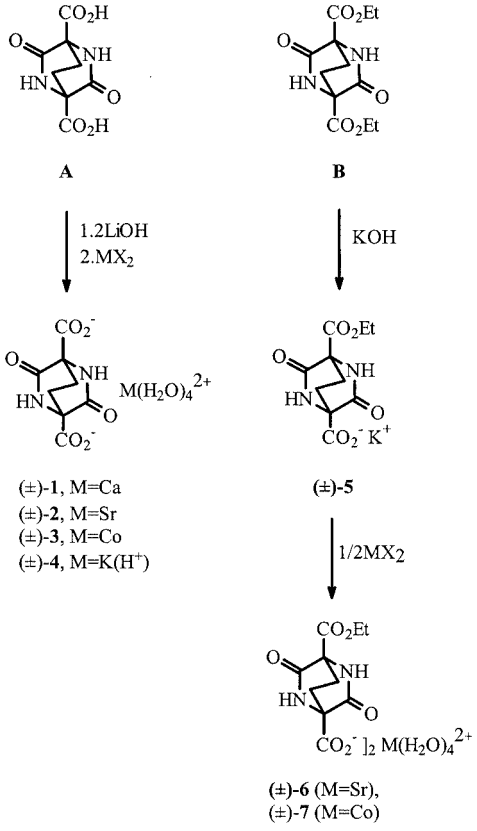


Scheme 2. Hypothetical three-dimensional self-assembly of H-bonded tapes of DBO-1,4-dicarboxylate dianions by coordination with metal cations (M lilac, C grey, N blue, O red, H green)

Results and Discussion

The synthesis of the metal DBO-1,4-dicarboxylates is depicted in Scheme 3. Metal salts of the diacid (±)-**A**[9] (±)-**1** to (±)-**3** were prepared in aqueous solution through exchange reactions. The potassium acid salt (±)-**4** was prepared by treatment of **A** with one equivalent of KOH. Monosaponification of diester (±)-**B**[9] gave compound (±)-**5**, which was converted into salts (±)-**6** and (±)-**7** through exchange reactions. All the salts were racemic. For the compounds (±)-**1** to (±)-**4**, (±)-**6** and (±)-**7**, single crystals were grown and X-ray diffraction investigation was undertaken (Table 1).

The molecular structures of the bis-lactam dicarboxylate anions in all structures studied remain practically unchanged, with variation of the bicyclic conformation from synchro- to asynchro-twist, as previously observed for the diester derivatives.[9] The dianion symmetry in **1** to **3** is close



Scheme 3. Synthesis of metal DBO-1,4-dicarboxylates

to C_2 (in **1**, the dianion occupies the special position on the twofold axis) with some deviation due to variations of the disposition of the CO_2^- groups and the bicyclic skeleton. In contrast, the symmetry of the monoanionic species in the compounds **4**, **6** and **7** cannot exceed C_1.

It is remarkable that all the studied compounds **1** to **4**, **6** and **7** are tetrahydrates. X-ray diffraction investigation has shown that in **1** to **4** the bicyclic anions assemble in heterochiral zigzag tapes and form the expected "brick walls" (Scheme 1) with carboxylic groups on the outer surfaces. The carboxylic oxygen atoms of neighbouring "brick walls', together with four water molecules, form the coordination sphere of each metal ion. Metal ion coordination crosslinks the "brick walls', so the observed structures consist of alternating organic and inorganic layers (Figure 1). Consequently we may regard compounds **1** to **4** as coordination polymers. Their crystal structures differ in the building of the inorganic layers, but **1** and **2** are practically isostructural (if we do not take into account the crystallographic axis 2, which is present in **1** but missing in **2**). A change in the metal ion results only in slight deviations in lactam H-bond strength (N···O distance) and d_1 separation (Scheme 1). The N···O distance increases systematically from 2.854(4) Å in **4** to 3.042(5) Å in **2**. The same trend is observed for the d_1 separation, being 5.49 Å in **4** (even shorter than in the corresponding esters; see below) and going up to 6.12 Å in **2**. Thus, even bigger cations, such as Sr, although making lactam H-bonding weaker, do not change the observed molecular "brick wall" motif. The construction of the inor-

M−O_{carb}	2.371(1)−2.480(1)	2.498(6)−2.615(5)	2.056(2)−2.084(2)	2.357(2)−2.437(2)	2.491(3)−2.582(3)	2.057(3)−2.092(3)
M−O_w	2.466(1)−2.497(1)	2.584(6)−2.645(6)	2.041(2)−2.125(2)	2.426(3)−2.571(3)	2.601(3)−2.604(3)	2.083(3)−2.096(3)

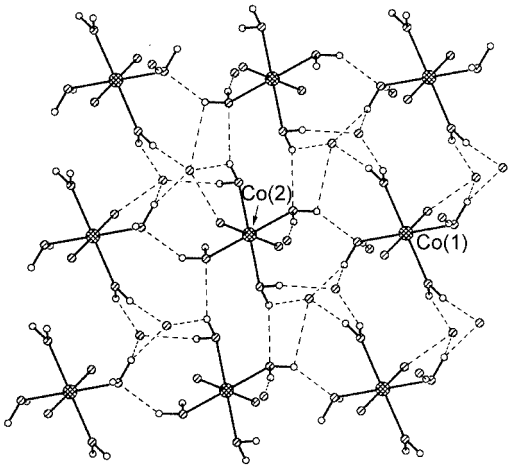

Figure 2. Projection of the H-bonded inorganic layer in **3** on the *ac* crystallographic plane

oxygens (Figure 2 shows an example of H-bonded inorganic layer in **3**). The O···O distance, which characterizes the strength of the O−H···O bonds in the inorganic layer, varies between 2.732 and 3.034 Å and is practically unaffected by the nature of the cation. If one takes only the H-bonded network into consideration, the water molecules interconnect the H-bonded tapes in **1** to **4** in a three-dimensional framework.

The number and the chirality of bicyclic bis-lactam anions coordinated by metal ions vary, thus giving rise to differences in the structures of the inorganic layers and the positioning of the "brick walls'. In the cases of **1** and **2**, the alkaline earth metal ion is surrounded by four aqua ligands and four carboxylate oxygens. Each carboxylate group of the bis-lactams in these compounds is bound to two cations and thus serves as a bridging ligand. It is noteworthy that the coordination spheres of Ca and Sr in **1** and **2** both contain two (*R*,*R*) and two (*S*,*S*) enantiomers (Figure 3, a). In contrast, in the potassium complex **4** the bicyclic monoanions have two different kinds of carboxylate groups. In the first, only one of the carboxylate oxygen atoms is coordinated by metal ion, in the second both oxygen atoms are coordinated. This molecular asymmetry is not cancelled and propagates along the screw axis 2_1, so the acentric crystal structure (space group $Pca2_1$) has a polar axis in the *c* direction (Figure 1, c). In addition, the coordination polyhedron of K is homochiral (three bicyclic ligands are characterized by the same chirality; Figure 3, b). The observed difference in the chirality of the ligands is due to the fact that potassium forms bonds with anions from three separate H-bonded tapes: one from one "brick wall' and the two others from another. The latter two anions lie in

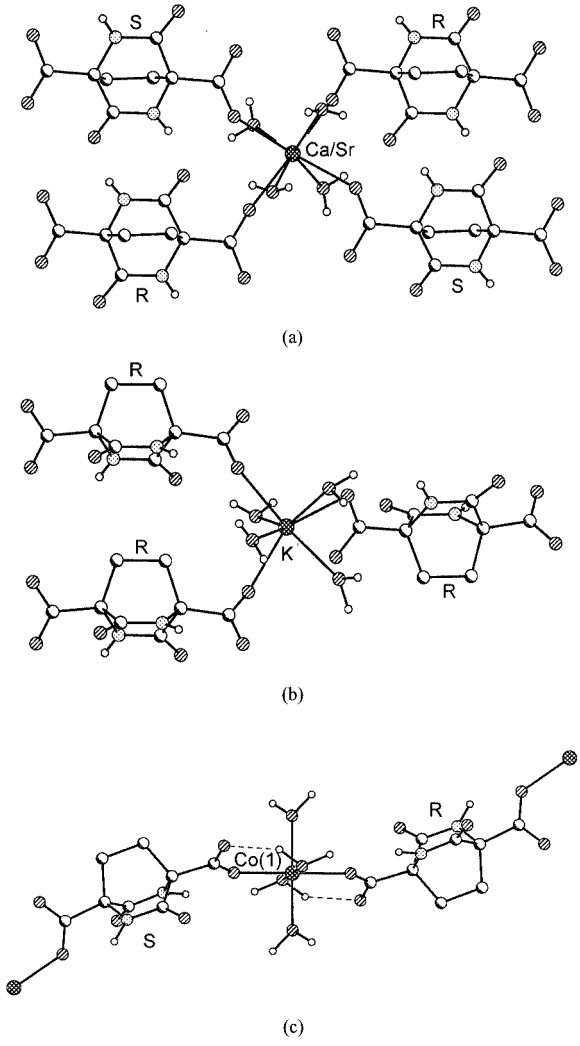

Figure 3. Coordination polyhedra and ligand chirality in **1** and **2** (a), **4** (b) and **3** (c)

the same column, one under the other, so that coordination causes a pronounced contraction of the d_1 distance (5.49 Å) in relation to the 5.57 Å in the crystal structure of the ester (±)-**B**.[9] Finally, in the crystal structure of the cobalt(II) salt **3** the metal ion (two independent cations each in the centre of symmetry) is characterized by the usual octahedral coordination with a *trans* arrangement of the monodentate ligands of opposite chirality (Figure 3, c).

If we take only the coordination connectivity into account, cations interconnect the anions, depending on the nature of the metal, in corrugated heterochiral layers (**1** and **2**) in the plane orthogonal to the axes of homochiral columns, or in the homochiral layers orthogonal to the axes

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the heterochiral tapes (**4**), or in heterochiral chains (**3**) orthogonal to the "brick walls'.

All the coordination polymers obtained thus possessed the same general structure regardless of the type of metal (alkali, alkaline earth or transition), so that any desired property (e.g., magnetic) of the resulting material should be fine-tuneable simply by a change in the cation (compare ref.[2]).

Using the distinct and stable supramolecular organization of the "brick walls' in the crystal structures of covalent[9] (for example, (±)-**B**) and ionic DBO-1,4-dicarboxylates **1** to **4**, and also the well known analogy of the structure of biological membranes, we also tried to obtain coordination dimers **6** and **7**. In these structures, polar ionic and nonpolar alkyl residue regions should alternate, similarly to what has been observed in, for example, the structure of the monohydrate of the diketopiperazine *cyclo*-(L-leucyl-L-hystidyl).[24] Indeed, X-ray analysis has shown that the main features of packing remain unchanged, and we observe coordination dimerization of carboxylic ions. Strongly polar inorganic water-containing layers and nonpolar alkyl regions alternate as anticipated (Figure 4 shows the crystal structure of **7**). Comparison of the structures of organic and inorganic layers with those of the corresponding coordination polymers **2** and **3** has shown that the structure remains practically unchanged in the case of Sr, except for insignificant variations in the H-bonding in the inorganic layer. In **7** these changes are much more pronounced, and this is reflected in the homochirality of the coordination octahedron (Figure 5). The example of the Co complexes **3** and **7** thus implies that the chiralities of the ligands are practically independent of each other ((*RR*,*SS*) in one case and (*RR*,*RR*) in the other) and, unfortunately, are defined by peculiarities of crystal symmetry (centrosymmetric arrangement in **3** and acentric structure of **7**) and packing. It is noteworthy that the d_1 distances in **6** and **7** are approximately the average of those in the structures of (±)-**B** and **2** and **3**, respectively: in **6** d_1 equals 5.96 Å, in **7** 5.59 Å, whereas in **2** it is 6.12 Å, in **3** 5.80 Å, and in **B** 5.57 Å.

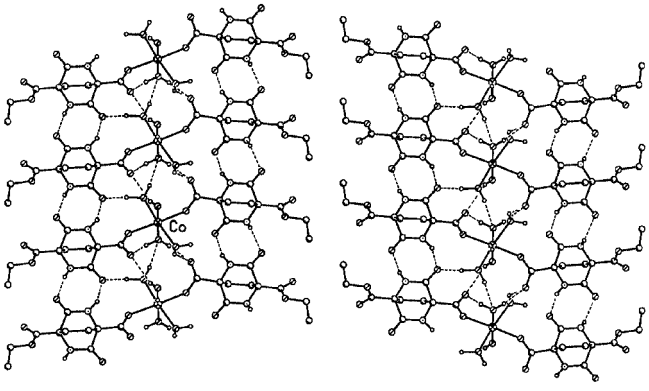

Figure 4. The projection of the crystal structure of coordination dimer **7** on the *ac* crystallographic plane

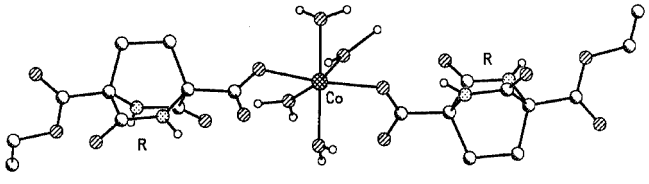

Figure 5. The coordination polyhedron and homochirality of the ligands in **7**

Compounds **6** and **7** thus represent hybrid-type materials. Firstly, the organic part makes the introduction of substituents with various functionalities possible; secondly, the nature of the cation itself may be varied. Moreover, the structures of these complexes are similar to those of biological membranes and offer perspectives for construction of ionoactive monolayers on that basis.

Conclusion

In this paper we have used a productive approach to crystal engineering − rational design of metal-organic H-bonded solids by combining a well defined H-bonded motif derived from pure organic crystal structures with the well known geometries of carboxylate metal complexes. Metal ion-assisted assembly of the bicyclic bis-lactam-dicarboxylate ions results in the predicted coordination polymers **1** to **4**, in which the molecular "brick wall" motif, found previously in dialkyl dicarboxylates (now with an inorganic ionic coating), is preserved. Formation of layers, stabilized by H-bonding of aqua ligands, is also observed. The salts' structures differ insignificantly as the coordinating centre changes. Monocarboxylate ion coordination results in other types of predicted structures, represented in the paper by coordination dimers **6** and **7**. In these compounds, "brick wall" formation is "coordinationally doubled", resulting in alternation of polar and non-polar layers (wall coatings) in the crystal.

We should also underline the limitations of our approach. Although we control the chirality of bis-lactam anions in the "brick walls", the examples of Co coordination polymer **3** and coordination dimer **7** imply that the chiralities of two anions coordinated by metal in a spatially distinct *trans* arrangement are independent of each other and depend only on the crystal symmetry and packing. Moreover, taking the strength of ionic interactions in comparison to hydrogen bonds into account, we believe that *both* organic dipole−dipole and van der Waals interaction-stabilized "brick walls" *and* inorganic H-bonded layers are responsible for the three-dimensional structure as a whole, their dimensionalities fortunately being complementary.

Finally, it should be mentioned that in the overall series of **1** to **4**, **6** and **7**, three crystal structures (**2**, **4**, **7**) are noncentrosymmetric (though achiral) and therefore offer perspectives for pyroelectric, piezoelectric and NLO applications.

Experimental Section

General Method for Preparation of Salts of (±)-A: A solution of LiOH in H_2O (2 mL, 0.2 M) was added to diacid (±)-**A** (25 mg,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

0.1 mmol), and the mixture was heated until it became clear, was filtered through cotton wool, and 1 mol equiv. of solution of metal salt [$CaCl_2$, $Sr(NO_3)_2$ or $CoCl_2$] in H_2O (1 mL) was added. On standing at ambient temperature a fine powder usually crystallized. This was filtered off, dried in air, weighed and then suspended in H_2O (2 mL). The suspension was heated at reflux with slow addition of water until complete dissolution of the precipitate (5−15 min). The clear solutions were left to cool down and were kept at ambient temperature under the conditions suitable for slow evaporation of the solvent. Separate crystals formed over several days. Besides the complexes **1** to **4**, well defined crystals also formed in the cases of Zn, Mn^{II}, Ni^{II} and Cu^{II}. The Ba and Ag^{I} salts were insoluble in hot H_2O.

Calcium 3,6-Dioxo-2,5-diazabicyclo[2.2.2]octane-1,4-dicarboxylate Tetrahydrate (±)-(1): Yield 30 mg (88%). Colourless needles, becoming turbid in air. $C_8H_{14}CaN_2O_{10}$ (338.3): calcd. C 28.4, H 4.2, N 8.3, Ca 11.6; found C 28.7, H 3.9, N 8.1, Ca 12.0.

Strontium 3,6-Dioxo-2,5-diazabicyclo[2.2.2]octane-1,4-dicarboxylate Tetrahydrate [(±)-2]: Yield 15 mg (40%). Colourless prisms. $C_8H_{14}N_2O_{10}Sr$ (385.8): calcd. C 24.9, H 3.7, N 7.3; found C 25.0, H 3.8, N 7.3.

Cobalt(II) 3,6-Dioxo-2,5-diazabicyclo[2.2.2]octane-1,4-dicarboxylate Tetrahydrate [(±)-3]: Yield 21 mg (58%). Transparent pink prisms, becoming blue and turbid in air. $C_8H_{14}CoN_2O_{10}$ (357.1): calcd. C 26.9, H 4.0, N 7.8; found C 28.0, H 4.0, N 8.1 (the significant deviation of the amount of C found from the calculated value may be attributed to water loss).

Potassium 3,6-Dioxo-2,5-diazabicyclo[2.2.2]octane-1,4-dicarboxylate Tetrahydrate [(±)-4]: For preparation of this acid salt, 1 mol equiv. of KOH was taken per mol of (±)-**A**. Yield 18 mg (52%). Colourless blocks. $C_8H_{15}KN_2O_{10}$ (338.3): calcd. C 28.4, H 4.5, N 8.3; found C 28.0, H 4.3, N 8.3.

Potassium 3,6-Dioxo-4-(ethoxycarbonyl)-3,6-dioxo-2,5-diazabicyclo[2.2.2]octane-1-carboxylate [(±)-5]: A solution of KOH in EtOH (0.0546 M, 20 mL) was slowly (10 min) added, with heating and vigorous stirring, to a boiling solution of (±)-**B** (1.551 g, 5.456 mmol) in 96% EtOH (130 mL). As soon as the mixture started to become turbid (≈ 15−20 min after the start of addition), heating was stopped, the mixture was cooled to 40 °C, and, with this temperature being maintained, KOH (0.0546 M, 80 mL) was added (slowly, 2 h). The mixture was cooled to 0°C and left for 24 h. The white precipitate of a mixture of mono- and disalts was filtered off, washed with EtOH and dried in vacuo. It was then recrystallized from the minimum possible amount of boiling water. The product crystallized as thin plates, which were filtered off, washed with cold H_2O and dried in air. Yield is 977 mg (61%), m.p. 380−390° C(dec.). ^1H NMR (400 MHz, D_2O, 60° C): δ = 1.32 (t, ^3J = 7 Hz, 3 H, CH_3,), 2.2−2.35 (m, 4 H, CH_2CH_2,), 4.38 (m, 2 H, CH_2Me) ppm. $C_{10}H_{11}KN_2O_6$ (294.3): calcd. K 13.3, C 40.8, H 3.7, N 9.5; found K 13.7, C 39.7, H 4.0, N 9.5.

Preparation of Salts (±)-6 and (±)-7: A solution of $CoCl_2$ (6.5 mg, 0.05 mmol) or $Sr(NO_3)_2$ (10.6 mg, 0.05 mmol) in H_2O (0.5 mL) was added to a hot solution of (±)-**5** (30 mg, 0.10 mmol) in H_2O (1 mL). After 1 h the precipitate was filtered off, dried in air and recrystallized from water in the same manner as for the coordination polymers.

Strontium Bis{4-(Ethoxycarbonyl)-3,6-dioxo-2,5-diazabicyclo[2.2.2]-octane-1-carboxylate} tetrahydrate [(±)-6]: Yield 8 mg (25%). Very thin colourless plates. $C_{20}H_{30}N_4O_{16}Sr$ (670.1): calcd. C 35.9, H 4.5, N 8.4; found C 36.0, H 4.3, N 8.2.

Cobalt(II) Bis{4-(Ethoxycarbonyl)-3,6-dioxo-2,5-diazabicyclo[2.2.2]-octane-1-carboxylate} Tetrahydrate (±)-7: Yield 8 mg (27%). Transparent pink prisms. $C_{20}H_{30}CoN_4O_{16}$ (641.4): calcd. C 37.5, H 4.7, N 8.7; found C 37.5, H 4.5, N 8.9.

Crystallographic data and parameters of the refinement for complexes **1** to **4**, **6** and **7** are presented in Table 1. The data collection was carried out by use of the θ/2θ scan mode for the 4-circle diffractometer (Siemens P3) and the ω-scan mode with 0.3° step in ω and 10 s (for **1** and **3**) or 20 s (**6** and **7**) exposure for SMART CCD diffractometer. The X-ray diffraction data for SMART CCD were processed by use of the SAINT PLUS program package. All structures were solved by direct methods and refined by full-matrix, least-squares against F^2 in the anisotropic (H atoms isotropic) approximation, by use of the SHELXTL-97 package. The positions of hydrogen atoms were located from the Fourier electron density synthesis and included in refinement in isotropic or riding model approximation. The hydrogen atom of the CO_2H groups in the monohydropotassium salt **4** was not located, probably due to the superposition of the CO_2^- and CO_2H groups, reflected in the equalization of the corresponding C−O bond lengths. The absolute structures in the cases of **2**, **4** and **7** were determined on the basis of the Flack parameter.

CCDC entries 204270−204275 (**1** to **4**, **6** and **7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

HREM and CIP Characterization of Complex Superstructures in Cu-Co Related Perovskites

Luisa Ruiz-González,[a] Khalid Boulahya,[a] Marina Parras,[a] José Alonso,[b] and José M. González-Calbet*[a]

Keywords: Perovskite phases / Superstructures / Electron diffraction / Electron microscopy

Two compositions in the La-Ba-Cu-Co-O system – $La_2Ba_3Cu_2Co_3O_{13}$ and $La_2Ba_3Cu_3Co_2O_{13}$ – have been synthesized and characterized by means of SAED (Selected Area Electron Diffraction) and HREM (High Resolution Electron Microscopy). The $La_2Ba_3Cu_2Co_3O_{13}$ phase leads to a fivefold perovskite superstructure along the *c* axis, which can be described as formed by the recurrent intergrowth of the two alternating blocks ···*PP*··· and ···PO_hP··· (*P* = pyramid and O_h = octahedron). Pyramidal and octahedral sites are randomly occupied by Cu/Co cations, while La/Ba cations exhibit an ordered distribution. The $La_2Ba_3Cu_3Co_2O_{13}$ composition gives rise to a mixture of phases in which a new phase showing a threefold superstructure due to the sequence ···PO_hP··· coexists with a fivefold superstructure with the same polyhedra sequence (···*PPPO*$_h$*P*···) as the previous one, but a disordered arrangement of lanthanum-barium cations.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Extensive research on compositional variations in perovskite ABO_3 related compounds has led to the stabilization of new oxygen-deficient phases $AA'BB'O_{6-x}$ as a consequence of ordered arrangement at the cation and/or oxygen sublattices. Cationic order can be found in both A and B sublattices, and is related to the size and charge differences of each set of cations. Moreover, the coordination tendencies of B cations in the host lattice of oxygen-deficient perovskites can lead to new mixed frameworks with ordered anionic vacancies in which polyhedra-sharing corners can involve octahedral (O_h), square-pyramidal (*P*), tetrahedral (T_h) or square-planar (S_p) units.

For instance, $YBaCuFeO_5$[1] can be described as being built up from the ordered stacking sequence ···*PP*···, whereas octahedra and tetrahedra alternate in an ordered way in $Ca_2(Fe,Al)_2O_5$[2] according to ···$O_hT_hO_hT_h'$··· (T_h' stands for a change of the T_h orientation), and $La_2Ni_2O_5$[3] accommodates square-planar coordination according to the stacking sequence ···O_hS_p···. Other perovskite-related types can be formed when combining the above structural units in a more complex way. For instance, $YBa_2Fe_3O_8$[4] is a threefold perovskite superstructure with iron in octahedral and square-pyramidal coordination according to the sequence ···PO_hP···. Related phases of higher periodicity are obtained if more octahedral layers are added. This is the case for $Ln_2Ba_2Cu_2M_2O_{11}$ (M = Ti, Sn)[5] and $Ln_2Ba_2Ca_2Cu_2Ti_4O_{11}$,[6] which have four- (···$PO_hO_hO_hO_h$···) and sixfold (···$PO_hO_hO_hO_hO_hO_h$···) perovskite superstructures, respectively. On the other hand, ordered intergrowths between perovskite (O_h) and brownmillerite (O_hT_h) units lead to intermediate phases, such as $Ca_2LaFe_3O_8$,[7] $Ca_4Fe_2Ti_2O_{11}$,[8] and $Ca_4YFe_5O_{13}$[9] which stabilize three-, eight-, and tenfold superstructures, exhibiting the ···$O_hO_hT_h$···, ···$O_hO_hO_hT_hO_hO_hO_hT_h'$··· and ···$O_hO_hT_hO_hT_h'O_hO_hT_h'O_hT_h$··· sequences, respectively. In a similar way, $La_4Ni_4O_{11}$[10] stabilizes the ···$O_hO_hO_hS_p$··· sequence, in the La-Ni-O system.

The above compounds are examples of perovskite-related superlattices formed by recurrent intergrowth of two different, but related, structural types. Cases in which intergrowths are non-recurrent, i.e., they do not show long-range ordering along the crystal, have also been described.[11,12] This order-disorder situation can be understood on the basis of the rather complex compositions embracing two or more types of cations for each A and B site of the perovskite sublattice $AA'BB'O_{6-x}$ and the subsequent different oxygen polyhedra. As a consequence of the local nature of such a phenomenon, some of these structures cannot be detected by X-ray powder diffraction (XRD) techniques. This makes the microstructural characterization by means of SAED and HREM essential. Furthermore, the Crystallographic Image Processing (CIP) technique, which is based on the combination of SAED and HREM, has been shown to be useful to gather more reliable structural information, after compensation of the transfer-contrast function (CTF), amplitude and phase correction and symmetry averaging.

Among the oxygen-deficient perovskite-related phases, cobaltites and cuprates have been widely studied due to their intriguing electronic and magnetic properties. Since different coordination environments are available for both Cu and Co cations, they are suitable for rather complex pathways of vacancy ordering in non-stoichiometric phases $AA'BB'O_{6-x}$, as recently reported for $LaBaCuCoO_{5.2}$.[13] Its structure (Figure 1) can be described as formed by the recurrent intergrowth of two alternating blocks of $2a_c$, $\cdots PP\cdots$, and $3a_c$, $\cdots PO_hP\cdots$, periodicities (a_c means the basic perovskite unit cell parameter) characteristic of the $YBaCuFeO_5$[1] and $YBa_2Fe_3O_8$[4] structural types, respectively. However, evidence of a cation-ordered arrangement was not found and therefore a random distribution was assumed. In this work, we have tried to induce cation ordering by changing the cationic ratio in both A-A′ and B-B′ perovskite sublattices. In this sense, according to the polyhedra model depicted in Figure 1, corresponding to $LaBaCuCoO_{5.2}$,[13] the La/Ba ratio was kept as 2:3 taking into account the preferred twelve coordination of Ba cations,[14] while different Cu/Co ratios were considered.

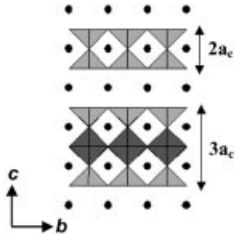

Figure 1. $LaBaCuCoO_{5.2}$ polyhedra model

Results and Discussion

$La_2Ba_3Cu_3Co_2O_y$

The XRD pattern can be indexed on the basis of an orthorhombic unit cell, $a = 0.3948$, $b = 0.3958$, and $c = 1.1683$ nm (Figure 2), characteristic of a threefold perovskite superstructure.[15] However, EDS, SAED, and HREM studies indicate that, besides the threefold superlattice, another phase is apparent. Actually, two kinds of crystals exhibiting a different Cu/Co ratio − $Cu_{0.6}Co_{0.4}$ and $Cu_{0.55}Co_{0.45}$ − have been detected. The corresponding SAED patterns along the $[100]_c$ zone axis are shown in Figure 3 a and b, respectively (subindex c refers to the cubic cell sublattice). In both cases, strong reflections appear, in agreement with the basic perovskite cell. In spite of this, weaker reflections are also present indicating different structural arrangements. In the case of the $Cu_{0.6}Co_{0.4}$ sample, spots at 1/3 and 2/3 appear along c^*, suggesting a threefold perovskite superlattice. Moreover, b^* and $c^*/3$ reciprocal parameters are clearly different, confirming the structural distortion shown in the X-ray diffraction pattern. This is in agreement with the XRD information. When the

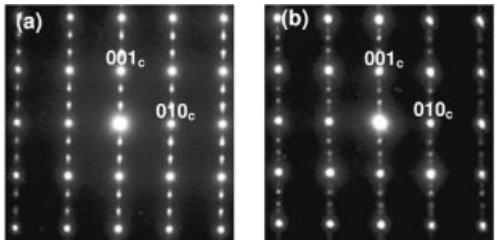

Figure 3. SAED patterns along $[100]_c$ zone axis corresponding to $La_2Ba_3Cu_3Co_2O_y$ sample (a) $Cu_{0.6}Co_{0.4}$ and (b) $Cu_{0.55}Co_{0.45}$ ratio, respectively

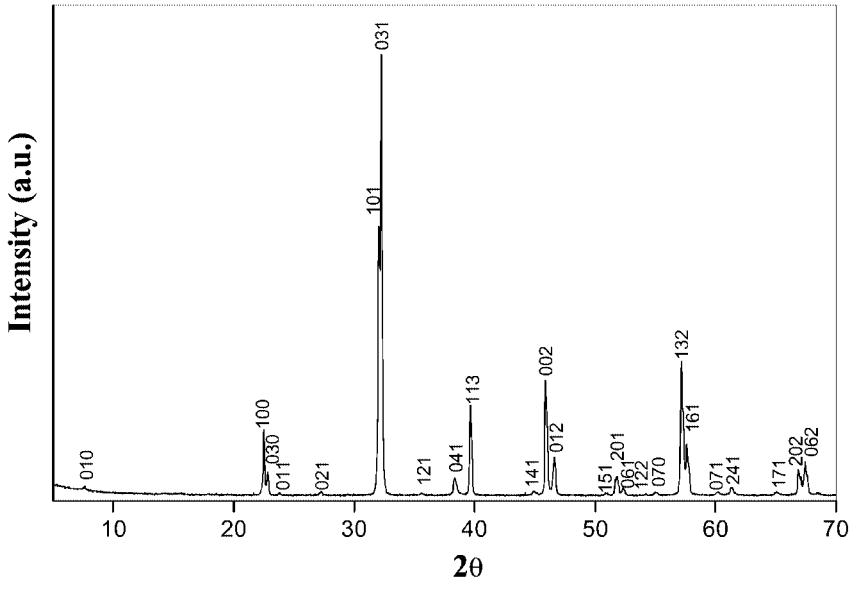

Figure 2. XRD diffraction pattern corresponding to $La_2Ba_3Cu_3Co_2O_y$

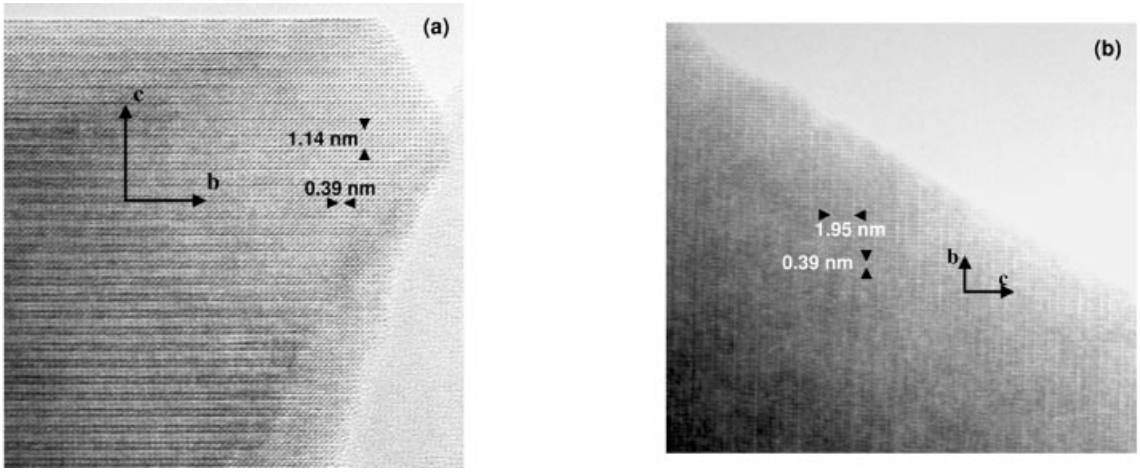

Figure 4. HREM images along $[100]_c$ zone axis corresponding to $La_2Ba_3Cu_3Co_2O_y$ sample (a) $Cu_{0.6}Co_{0.4}$ and (b) $Cu_{0.55}Co_{0.45}$ ratios, respectively

Cu/Co ratio is $Cu_{0.55}Co_{0.45}$, superlattice reflections are placed at 2/5 and 3/5 along c^*, indicating a fivefold perovskite superstructure. The corresponding HREM images (Figure 4, a and b) confirm the above periodicities, i.e, 1.14 and 1.95 nm, along c, for crystals $Cu_{0.6}Co_{0.4}$ and $Cu_{0.55}Co_{0.45}$, respectively.

The threefold order assigned to the $Cu_{0.6}Co_{0.4}$ orthorhombic phase is detected in the XRD pattern. However, the fivefold order previously reported for $LaBaCuCoO_{5.2}$,[13] is not observed. This could be related to the small X-ray powder scattering factor of the oxygen atoms together with the fact that no significant distortions from the basic perovskite sublattice are observed.[13] In this sense, the cubic pattern corresponding to the $Cu_{0.55}Co_{0.45}$ phase (related to $LaBaCuCoO_{5.2}$) must overlap with the one corresponding to $Cu_{0.6}Co_{0.4}$, thus precluding the identification of the former phase by means of XRD.

It is therefore clear that the nominal composition $La_2Ba_3Cu_3Co_2O_y$ leads to a phase mixture, in contrast to $LaBaCuCoO_{5.2}$, which stabilizes a fivefold superlattice built up from the polyhedra sequence $\cdots PO_hPPP\cdots$. The crystal showing Cu/Co = 0.6/0.4 = 1.5 is related to a threefold perovskite superstructure along c. This framework could be obtained by modifying the $2a_c$ periodicity blocks ($\cdots PP\cdots$) in the $LaBaCuCoO_{5.2}$ phase either by suppressing such a block or keeping it while adding one octahedral layer between the two square pyramids. Both pathways would give rise to the stacking sequence $\cdots PO_hP\cdots$, i.e., the basic unit of the $YBa_2Fe_3O_8$ structural type. Threefold periodicity is also found in the well-known lower-oxygen-content $YBa_2Cu_3O_7$[15] superconducting material, in which S_p instead of O_h gives rise to the polyhedra sequence $\cdots PS_pP\cdots$. Furthermore, the oxygen content can be enhanced by Co substitution, i.e., $LnBa_2Cu_{3-x}Co_xO_y$[16] leading, again, to the $\cdots PO_hP\cdots$ unit. Therefore, a similar phase, with Cu/Co = 1.5, seems to be present in this sample. However, since the Cu content in the phase Cu/Co = 0.6/0.4 (1.5) is higher than that corresponding to the fivefold ordered phase (Cu/Co = 0.5/0.5 = 1), we tentatively propose the second mechanism considering that the Cu excess is placed between the two pyramids of the $2a_c$ blocks, leading to the observed $3a_c$ periodicity. On the other hand, crystals exhibiting a higher Co content, i.e., a Cu/Co ratio close to one, Cu/Co = 0.55:0.45 (1.22), show the fivefold superlattice characteristic of $LaBaCuCoO_{5.2}$.[13] This situation could, again, be understood by adding $2a_c$ periodicity blocks, $\cdots PP\cdots$. Accordingly, since the $\cdots PP\cdots$ stacking sequence constitutes the structural unit of $LnBaCo_2O_5$ phases,[17,18] it is feasible to assume that $2a_c$ periodicity blocks are also present in the Cu/Co = 1.2 crystals as they are Co-rich.

Further annealing of this sample does not lead to a single phase. A threefold ordered superlattice is always present and attempts to avoid it were performed by changing the Cu/Co ratio. Since the excess of Cu over Co seems to stabilize a related $YBa_2Cu_3O_7$ phase, the Cu_3Co_2 ratio was reversed, i.e, the nominal $La_2Ba_3Cu_2Co_3O_y$ composition was prepared and characterized.

$La_2Ba_3Cu_2Co_3O_y$

In contrast to $La_2Ba_3Cu_3Co_2O_y$, the X ray diffraction pattern of the title material can be indexed on the basis of a cubic perovskite unit cell (Figure 5), as also reported for $LaBaCuCoO_{5.2}$.[13] EDS analysis, performed on twenty crystals, indicates an average Cu/Co ratio of 0.4:0.6 (0.66), in agreement with the nominal value. However, it is worth pointing out that small areas of some crystals showed a different ratio (Cu/Co = 0.31:0.69 = 0.45), and are therefore Cu-deficient. The oxygen content was estimated to be 13 atoms per unit formula. The compositional data fit with an average composition $La_2Ba_3Cu_2Co_3O_{13}$.

The SAED pattern along $[001]_c$ (Figure 6) is in agreement with the basic cubic perovskite cell, according to the XRD information. Further study of the reciprocal lattice indicates a more complex situation due to the presence of weaker additional reflections (Figure 7). The SAED pattern along $[100]_c$ (Figure 7, a) shows superlattice reflections at 1/5, 2/5, 3/5, and 4/5 of the c^* axis, suggesting a fivefold superstructure. It is worth recalling that this situation is similar

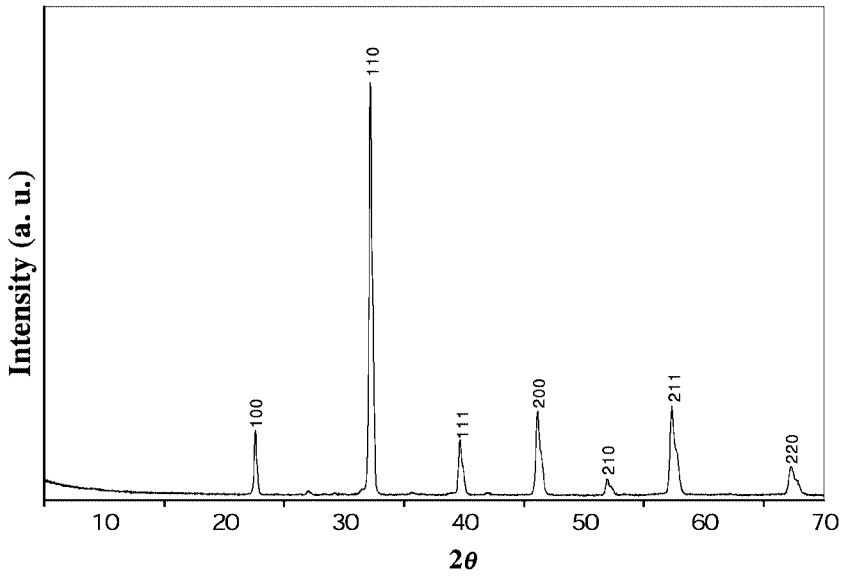

Figure 5. XRD diffraction pattern corresponding to $La_2Ba_3Cu_2Co_3O_y$

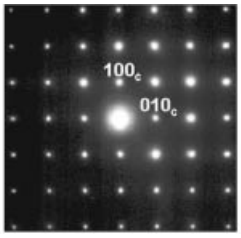

Figure 6. SAED pattern along $[001]_c$ zone axis corresponding to $La_2Ba_3Cu_2Co_3O_y$

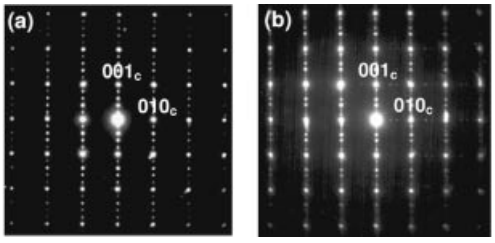

Figure 7. SAED pattern along $[100]_c$ for (a) Cu/Co = 0.4:0.6 and (b) Cu/Co= 0.31:0.69

to that reported for $LaBaCuCoO_{5.2}$,[13] although in this material superstructure streaked spots only appear at 2/5 and 3/5.[13] This difference will be discussed later. Occasionally, another kind of pattern (Figure 7, b), suggesting a sevenfold superlattice, is observed in small areas of the same crystal.

Figure 8 shows an HREM image along the $[100]_c$ zone axis. Two areas, labelled in the image as **1** and **2**, can be observed. Regarding zone **1**, the periodicity along c is 1.95 nm, i.e., related to $5a_c$, in agreement with a fivefold superlattice. FFT (Fourier Transform) performed over this area shows the presence of the corresponding superlattice spots, reinforcing the above suggestion. EDS analysis performed on this area indicates a Cu/Co ratio of 0.4:0.6. A different periodicity is observed at zone **2**, 2.73 nm, i.e., related to $7a_c$, according to the previously suggested sevenfold superstructure. Once again, FFT performed over this area confirms the indicated order. EDS analysis showed a lower Cu/Co ratio (0.31:0.69) in this area.

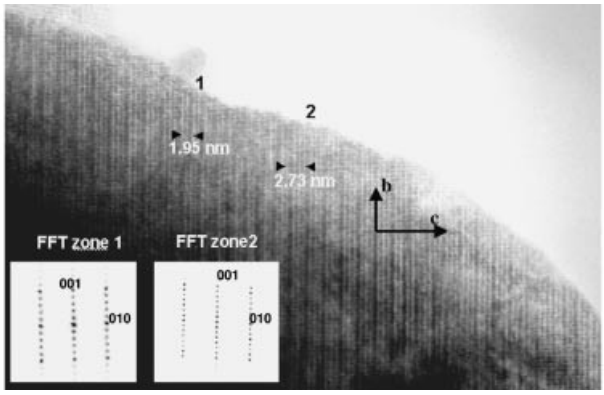

Figure 8. HREM image along $[100]_c$ zone axis corresponding $La_2Ba_3Cu_3Co_2O_y$ sample; two areas, **1** and **2**, exhibiting $5a_c$ and $7a_c$ periodicities, respectively, are labelled

According to these results, it can be concluded that $La_2Ba_3Cu_2Co_3O_{13}$ stabilizes a majority phase, showing a fivefold superlattice, as $LaBaCuCoO_{5.2}$ does. Based on this previous information and also on the structural facts described above, crystallographic image processing (CIP) was performed in order to obtain more reliable structural information. The CIP technique, which combines both SAED and HREM information, allows the gathering of potential maps after performing several corrections and symmetry averaging. In this work, the CRISP program[19] was used for image processing.

Figure 9 (a) corresponds to a thin area of the experimental image along $[100]_c$. Figure 9 (b) is a potential map obtained after the correction of tilt, CTF and the phases and amplitudes of the diffracted beams. After imposing *P2mm*

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

symmetry, according to the space group *P*4/*mmm* determined by SAED and CBED (Convergent Beam Electron Diffraction), the final potential map depicted in Figure 9 (c) is obtained, in agreement with the fivefold superstructure. Moreover, differences in the black contrast (related to the cation positions) are observed in sites corresponding to La and Ba positions (pointed in Figure 9, c). Such differences are not appreciated at the corresponding B-type positions; in fact, hypothetical order of Cu and Co in these sites could not be detected by this technique, since both cations have close atomic scattering amplitudes for electrons.[20] Although it is not possible to determine the exact oxygen position by CIP, differences in white contrast are observed. It is, in fact, well known that under the optimum defocus conditions the brightest contrast corresponds to the lower potential areas, i.e., oxygen and unoccupied oxygen positions. In this sense, the superstructure must be induced, as also happens with $LaBaCuCoO_{5.2}$, by an ordered arrangement of oxygen vacancies in agreement with the polyhedral model previously mentioned $\cdots PO_hPPP\cdots$, superposed on the potential map. Cobalt and copper must be randomly arranged at the B positions of the basic $AA'BB'O_{6-x}$ perovskite structure, i.e., at the octahedral and pyramidal environments, while La and Ba seem to be ordered along the eight and twelve oxygen coordination sites. According to this, the situation in $La_2Ba_3Cu_2Co_3O_y$ is different to that observed from CIP for $LaBaCuCoO_{5.2}$,[13] whose final potential map does not reveal any cation order arrangement.

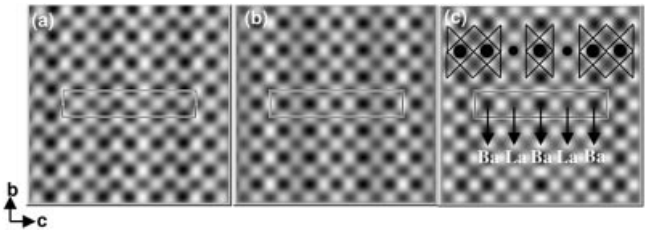

Figure 9. (a) Experimental HREM image corresponding to $La_2Ba_3Cu_3Co_2O_y$; (b) processed image; (c) potential map obtained after applying *pmm* symmetry; the unit cell and structural model are outlined

At this point, it is worth recalling the differences observed between the SAED patterns along $[100]_c$ of the $La_2Ba_3Cu_2Co_3O_{13}$ (Figure 7, a) and $LaBaCuCoO_{5.2}$ (see Figure 2c of ref.[13]) samples, respectively. The first one shows superlattice spots at 1/5, 2/5, 3/5, and 4/5 while the second one only at 2/5 and 3/5, with additional diffuse streaking. On the other hand, since atomic scattering amplitudes for electrons corresponding to La and Ba are different,[20] an ordered distribution of these cations must be detected in the SAED patterns. Accordingly, it seems clear that the observed differences in the above patterns are related to the La/Ba distribution. In order to confirm this assumption, SAED patterns corresponding to the proposed $\cdots PPPO_hP\cdots$ polyhedra sequence with La/Ba ordered and randomly arranged were calculated using the Mac Tempas software package.[21] Table 1 displays the structural parameters used in this calculation for an ordered distribution of La and Ba cations. The corresponding disordered situation has been calculated considering La and Ba distributed at 50% over the three different crystallographic positions.

Table 1. Structural parameters corresponding to $La_2Ba_3Cu_2Co_3O_{13}$ sample; an ordered La/Ba arrangement is considered [space group P4/*mmm* (123), a = 3.9352(3) Å, c = 19.538(2) Å]

Ba	0.5	0.5	0.5	1

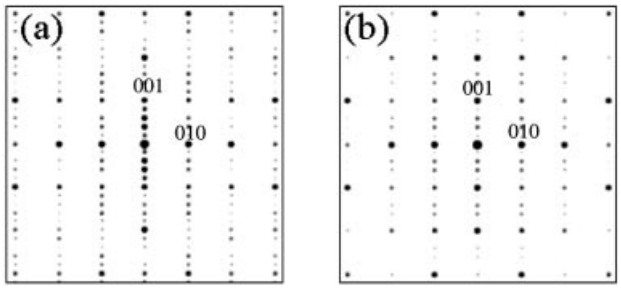

Figure 10. Calculated SAED patterns along $[100]_c$ for $La_2Ba_3Cu_3Co_2O_y$ taking into account the polyhedra sequence $\cdots PO_hPPP\cdots$ and both ordered (a) and random(b) La/Ba distributions

The calculated patterns are shown in Figure 10. When an ordered La/Ba distribution is considered all superlattice reflections are evident (Figure 10, a), while only two extra spots clearly appear when a random distribution is assumed (Figure 10, b). Finally, if La and Ba are ordered in $La_2Ba_3Cu_2Co_3O_{13}$ it could be expected that this fact should also be reflected in the XRD pattern. However, characteristic reflections of the fivefold superstructure do not appear in the experimental pattern (Figure 5). This fact can be explained by taking into account that the atomic scattering factors for X-rays corresponding to La and Ba are equal.[20] In fact, an ordered La/Ba distribution leads to the same X-ray diffraction pattern as for the disordered one.

On the other hand, areas showing sevenfold periodicity can be understood if a $2a_c$ periodicity block ($\cdots PP\cdots$) is added to the $\cdots PO_hPPP\cdots$ sequence, leading to $\cdots PO_hPPPPP\cdots$. At this point, it is worth emphasizing that these areas are Co-rich, so it is plausible to assume that additional $2a_c$ blocks are constituted by pyramidal layers, since this sequence is the basic structural unit of LnBa-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Co_2O_5 compounds.[17,18] Attempts to isolate this sevenfold superstructure are in progress.

This set of results shows that the increase of Co content is accompanied by an increase of the square-pyramidal units in the stacking sequence. In fact, $LnBaCo_2O_{5+\delta}$ [17,18] oxides crystallize in the $\cdots PP\cdots$ stacking sequence whereas $LnBa_2Cu_{3-x}Co_xO_{7\pm\delta}$ [16] shows threefold ordering due to the sequence $\cdots PO_hP\cdots$. When Cu/Co attains a ratio around 1, the $\cdots PPPO_hP\cdots$ polyhedral sequence is stabilized and a fivefold superstructure of the cubic basic cell is observed. This is the case for both $LaBaCuCoO_{13}$[13] and $La_2Ba_3Co_3Cu_2O_{13}$. The difference between both oxides resides in the type of ordering along the A sublattice. While a random situation is obvious in the former, cationic ordering is detected in the latter. The presence of order/disorder in the A sublattice is related to the different oxygen environments involving the A cations in this fivefold superstructure: three sites of twelve coordination and two eight-coordinate sites. This is why only a La/Ba ratio of 2/3 is adequate to obtain an ordered situation.

Experimental Section

Samples of nominal compositions $La_2Ba_3Cu_3Co_2O_y$ and $La_2Ba_3Cu_2Co_3O_y$ were prepared from the apropriate amounts of $BaCO_3$, La_2O_3, Co_3O_4, and CuO. These mixtures were ground in an agate mortar and heated, after carbonate decomposition, at 960 °C for one week with intermediate milling. Cationic compositions were estimated by energy-dispersive X-ray spectroscopy (EDS) using a field-emission electron microscope (FEG) Philips CM200 equipped with an EDAX microanalytical system. Powder X-ray diffraction (XRD) was performed using a Philips X'Pert diffractometer with Cu-K_α radiation. Selected-area electron diffraction (SAED) and high-resolution electron microscopy (HREM) studies were carried out with both JEOL 2000-FX and JEOL 4000-EX electron microscopes. Oxygen content was determined by thermogravimetric analysis using a Cahn D-200 electrobalance equipped with a furnace and a two-channel recorder, allowing simultaneous recording of the weight loss and the reaction temperature. The oxygen content can be determined within $\pm 5\cdot 10^{-3}$ mg for a sample of total mass of about 50 mg.

Synthesis, Characterisation, and X-ray Crystal Structure of New Ni^{II}, Pd^{II}, and Pt^{II} Complexes of Tridentate Pyrazole-Based Ligands with an NOS-Donor Set

Jordi García-Antón,[a] Josefina Pons,*[a] Xavier Solans,[b] Mercè Font-Bardia,[b] and Josep Ros*[a]

Keywords: Nickel / N ligands / O ligands / Palladium / Platinum / S ligands

Treatment of the ligands 1-(3-thia-5-hydroxypentyl)-3,5-dimethylpyrazole (thpd) and 1-(3-thia-6-hydroxyhexyl)-3,5-dimethylpyrazole (thhd) with $[PdCl_2(CH_3CN)_2]$, $[PtCl_2(CH_3CN)_2]$, and $NiCl_2{\cdot}6H_2O$ produces the complexes $[MCl_2(L)]$ [M= Pd, L = thpd (**1**), thhd (**2**); M = Pt, L = thpd (**3**), thhd (**4**); M = Ni, L = thpd (**5**), thhd (**6**)], which have been characterised by elemental analyses, conductivity, IR, electronic spectra, and NMR spectroscopy (when possible). The crystal structures of **2**, **3**, and **4**, determined by single-crystal X-ray diffraction, each consist of discrete $[MCl_2(L)]$ units. Each M^{II} atom is coordinated by the pyrazolyl nitrogen and the thioether sulfur from the ligand and two *cis* chloride ions in a square-planar geometry. Crystallisation of $[NiCl_2(thpd)]$ in non-anhydrous alcohols yields $[NiCl(H_2O)_2(thpd)]Cl$ ([**7**]Cl), the crystal structure of which was determined by single-crystal X-ray diffraction to reveal nickel atoms coordinated by two water molecules, one chloride ion and one thpd ligand (coordinating via all three donor atoms, N, S, and O) in a skew-trapezoidal bypyramid (distorted octahedral) geometry.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The coordination chemistry of chelating ligands containing mixed functionalities is of continued importance.[1] In particular, the chemistry of ligands that contain both inert and labile groups has received considerable attention.[2] Jeffrey and Rauchfuss first introduced the term ''hemilabile ligand'' in 1979[3] to describe polydentate chelates that contain at least two different types of bonding groups — a hard and a soft donor group[4] — making them attractive for catalytic purposes.

Our group has previously synthesised and characterised pyrazolic ligands with two donor groups, in particular N−N(amine),[5] N−P,[6] N−O,[7] and N−S.[8] Our next goal is to study the coordinative properties of ligands with three donor groups.

Here, we report the synthesis and full characterisation of two new ligands, 1-(3-thia-5-hydroxypentyl)-3,5-dimethylpyrazole (thpd), and 1-(3-thia-6-hydroxyhexyl)-3,5-dimethylpyrazole (thhd), the three different donor atoms in this case being nitrogen, sulfur, and oxygen. The complexation of these ligands with $[MCl_2(CH_3CN)_2]$ (M = Pd^{II}, Pt^{II}) and $NiCl_2{\cdot}6H_2O$ is also reported, to give the complexes: $[MCl_2(L)]$ [M= Pd, L = thpd (**1**), thhd (**2**); M = Pt, L = thpd (**3**), thhd (**4**); M = Ni, L = thpd (**5**), thhd (**6**)]. Treatment of **5** with non-anhydrous alcohols produces $[NiCl(H_2O)_2(thpd)]Cl$ ([**7**]Cl). These complexes have been characterised by elemental analyses, conductivity, IR spectroscopy and, when possible, ^1H NMR, $^{13}C\{^1H\}$ NMR, and $^{195}Pt\{^1H\}$ NMR spectroscopy. The X-ray crystal structures of complexes **2**, **3**, **4**, and [**7**]Cl are also presented.

Results and Discussion

The ligands 1-(3-thia-5-hydroxypentyl)-3,5-dimethylpyrazole (thpd) and 1-(3-thia-6-hydroxyhexyl)-3,5-dimethylpyrazole (thhd), not previously reported, were synthesised to initiate a new study of pyrazole-based ligands with N1 alkyl substituents containing two different donor atoms (in this case O and S). In this respect, 2-(3,5-dimethyl-1*H*-pyrazol-1-yl)ethyl 4-methylbenzenesulfonate[9] on treatment with 2-mercaptoethanol gave thpd and 1-(2-mercaptoethyl)-3,5-dimethylpyrazole[10] on treatment with 3-chloro-1-propanol gave thhd (Scheme 1). These ligands were characterised by elemental analysis, MS spectrometry, and infrared, ^1H NMR and $^{13}C\{^1H\}$ NMR spectroscopy.

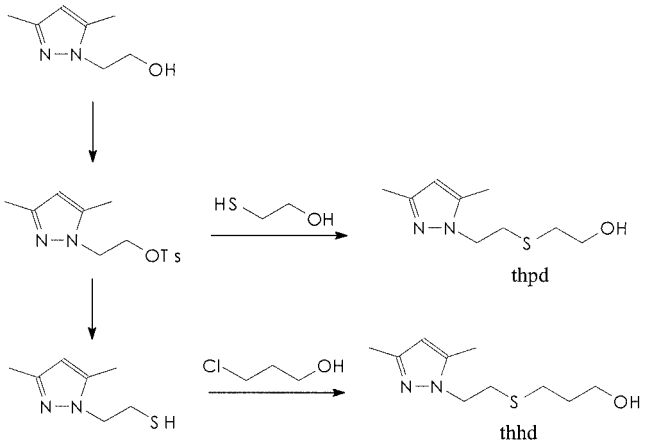

Scheme 1

Treatment of thpd and thhd with $[MCl_2(CH_3CN)_2]$ (M = Pd^{II} [11] and Pt^{II} [12]) produced four chloro complexes whose elemental analyses agree with the formula $[MCl_2(L)]$ [M = Pd, L = thpd (**1**), L = thhd (**2**); M = Pt, L = thpd (**3**), L = thhd (**4**)]. Conductivity values in acetonitrile for complexes **1**−**4** reveal a non-electrolyte nature [1.8−6.4 $\Omega^{-1}cm^2mol^{-1}$]. The reported values for 10^{-3} M solutions of non-electrolyte complexes are lower than 120 $\Omega^{-1}cm^2mol^{-1}$ in acetonitrile.[13]

The IR spectra of the complexes **1**−**4** are similar to those of the ligands, the most characteristic bands being those attributable to the pyrazolyl group, ν(C = C) and ν(C = N) between 1553 and 1548 cm^{-1} and $\delta(C-H)_{oop}$ between 828 and 785 cm^{-1}.[14]

Suitable single crystals for X-ray structure determination were obtained by recrystallisation from methanol for **2**−**4**.

^1H and ^{13}C NMR spectra of **1**−**4**, recorded in $[D_3]$acetonitrile, show the signals of the coordinated ligands (data are reported in the Exp. Sect.). HMQC spectra at 253 K were used to assign the proton signals (e.g. for **3** in Figure 1).

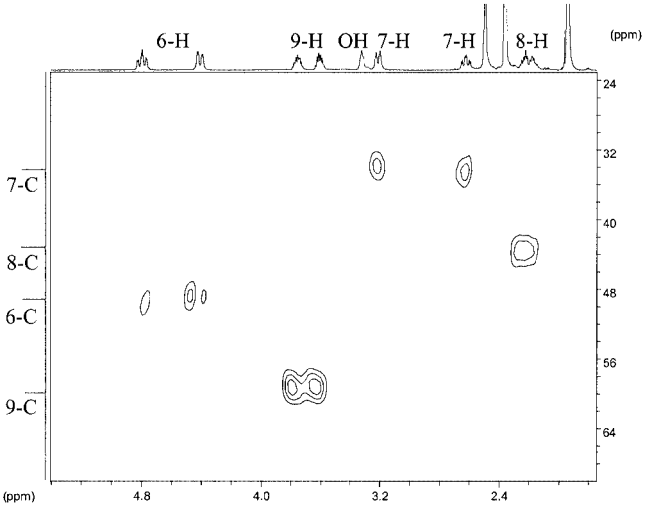

Figure 1. 250 MHz 2D HMQC spectrum of **3** at 253 K

The ^1H NMR spectra of complexes **1**−**4** at 298 K show sharp resonances for the CH and CH_3 groups of the pyrazolyl cycles. For **1** and **2**, only one broad band can be attributed to each CH_2 in the $S-(CH_2)_2-N$ and $S-(CH_2)_x-OH$ (x = 2 for **1** and x = 3 for **2**) chains, whereas at 253 K, the two protons of each CH_2 (in both chains) can be assigned to two different signals (although some of the signals are partially superposed and are given as a single multiplet in the Exp. Sect.). These two signals for each CH_2 are due to the rigidity of these chains, at 253 K, giving rise to two diastereotopic hydrogens for each CH_2.

At 298 K, for complexes **3** and **4**, two broad bands can be assigned to each CH_2 in the $S-(CH_2)_2-N$ chain but only one signal for each CH_2 in the $S-(CH_2)_x-OH$ (x = 2 for **3** and x = 3 for **4**) chain. At 253 K, signals attributable to the CH_2 in the $S-(CH_2)_2-N$ chain become well-defined multiplets and the CH_2 corresponding to the $S-(CH_2)_x-OH$ chain show two well-defined signals for each of them (but, as for the Pd^{II} complexes, some of these signals are superposed and are given as a single multiplet in the Exp. Sect.).

The broad bands for **1**−**4** at 298 K arise from fluxional processes that involve the $S-(CH_2)_2-N$ and $S-(CH_2)_x-OH$ (x = 2 for **1**, **3** and x = 3 for **2**, **4**) chains. This led us to record variable-temperature spectra for **1**−**4** (spectra for 6-H, 9-H and the alcohol group for **3** are shown in Figure 2). The two different chains [$S-(CH_2)_2-N$ and $S-(CH_2)_x-OH$] were studied separately.

For the $S-(CH_2)_2-N$ chain, the two CH_2 signals coalescence to one at 273 and 293 K for complexes **1** and **2**, respectively, whereas **3** and **4** required heating to 338 and 345 K, respectively, to bring about coalescence. These temperature coalescences and the separation of the two signals attributed to each CH_2 correspond to $\Delta G^{\ddagger}$ values of ca. 55, 59, 66, and 68 $kJ \cdot mol^{-1}$ for **1**−**4**, respectively.[15]

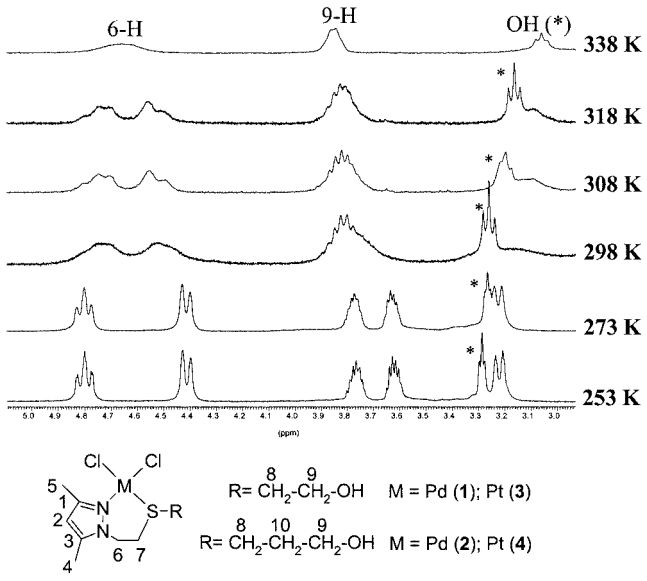

Figure 2. Numbering scheme for the complexes **1**−**4** and ^1H NMR variable-temperature experiments for 6-H and 9-H in **3**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The $\Delta G^{\ddagger}$s are consistent with a chelate ring-flipping process due to the rocking of the pyrazolyl cycle around the M−N bond without any metal−ligand bond breaking.[5e,7c] At higher temperatures, with ring-flipping, the two hydrogens of each CH_2 are interconverted and only one signal can be observed. These energy values could also be consistent with a mechanism that implies an inversion of the sulfur atom configuration.[16,17]

For the S−$(CH_2)_x$−OH chains (x = 2 for **1** and **3** and x = 3 for **2** and **4**) the rigidity could be attributed to hydrogen bonds that occur only at low temperatures. This would explain why the hydrogens of these chains appear as diastereotopic at 253 K. Definitive evidence for O−H···Cl interactions in the solid state is given by the X-ray analyses of **2**−**4**. The existence of these interactions in solution was proved by the variable-temperature spectra of the alcohol group (example for **3** in Figure 2) in which the chemical shift of the alcohol group varied with temperature (from δ = 3.23 and 2.78 ppm at 298 K to δ = 3.36 and 3.03 ppm for **1** and **2**, respectively and from δ = 3.06 and 2.83 ppm at 338 K to δ = 3.29 and 3.09 at 253 K for **3** and **4**, respectively). The R−OH resonances shift to lower fields with decreasing temperature, as expected for this kind of process.[18]

For the S−$(CH_2)_x$−OH chains the two CH_2 signals coalescence at 298 K for complexes **1**−**4**, which, together with the separations of the two signals, corresponds to $\Delta G^{\ddagger}$s of ca. 61 kJ·mol^{-1} for **1** and **3** and ca. 63 and 66 kJ·mol^{-1} for **2** and **4**, respectively.[15]

Additional ^{195}Pt{^{1}H} NMR experiments for complexes **3** and **4** at 298 K revealed only one band for each complex (δ = −2868 ppm for **3** and −2879 ppm for **4**). This suggests that all of the bands in the ^{1}H NMR spectra belong to only one complex, as expected from the data obtained with the variable-temperature experiments.

Treatment with $NiCl_2{\cdot}6H_2O$ led to the isolation of one complex for each ligand. Their elemental analyses agree with the formula [$NiCl_2$(L)] [L = thpd (**5**) and thhd (**6**)]. The molar conductivities in absolute ethanol are consistent with non-electrolyte complexes [14.3−18.7 Ω^{-1}cm^{2}mol^{-1}]. Reported values for 10^{-3} M solutions of non-electrolyte complexes in absolute ethanol are lower than 35 Ω^{-1} cm^2 mol^{-1}.[13] The IR spectra (4000−400 cm^{-1}) of complexes **5** and **6** are similar to those of the ligands.[14] Additional spectra in the region 500−100 cm^{-1} present well-defined bands corresponding to ν(Ni−N) (450, 461 cm^{-1}), ν(Ni−Cl) (368, 387 cm^{-1}), and ν(Ni−S) (328, 344 cm^{-1}) bands for **5** and **6**, respectively, and a band attributable to ν(Ni−O) at 498 cm^{-1} for **5** and 520 cm^{-1} for **6**.[19]

Electronic spectra of the complexes **5** and **6** measured in absolute ethanol show a single d-d band at 422 nm (ε = 55 mol^{-1}cm^{-1}L) for **5** and 414 nm (ε = 75 mol^{-1}cm^{-1}L) for **6** that can be attributed to the ^{3}E′(F)→^{3}E′′(P) transition, which is characteristic for pentacoordinate Ni^{II} complexes.[20] It was not possible to obtain single crystals of these complexes.

When **5** was dissolved in methanol or ethanol it reacted with the water in the solvent to give a complex that was obtained as suitable single crystals for X-ray structure determination. This complex {[$NiCl(H_2O)_2$(thpd)]Cl ([**7**]Cl)} has an IR spectrum with bands that can be attributed to water molecules not observed for complex **5**. The electronic spectrum of complex [**7**]Cl was measured in ethanol and shows two bands in the visible region at 731 (ε = 4 mol^{-1}cm^{-1}L) and 403 nm (ε = 10 mol^{-1}cm^{-1}L), which can be attributed to $^3A_{2g}$→$^3T_{1g}$(F) and $^3A_{2g}$→$^3T_{1g}$(P) transitions, respectively, these being characteristic for octahedral Ni^{II} complexes.[20] An equivalent complex with thhd could not be isolated.

Crystal Structure of [MCl_2(L)] [M= Pd, L = thhd (2); M = Pt, L = thpd (3), thhd (4)]

The structure of **2** consists of discrete [$PdCl_2$(thhd)] units (Figure 3), while **3** and **4** consist of discrete [$PtCl_2$(L)] (L = thpd and thhd, respectively) units (Figures 4 and 5, respectively). Crystallographic data for complexes **2** and **4** indicate that they are isostructural.

The metal atom of each structure is surrounded by an identical *core* composed of the nitrogen and thioether sulfur from the pyrazole ligand and two chlorine atoms. The metal atoms have a slightly distorted square-planar geometry, with the chloride ions in a *cis* arrangement. A small tetrahedral distortion can be observed in the mean separation of the atoms linked to the metal cation in relation to the mean plane [±0.065(4) Å for **2**, ±0.001(3) Å for **3**, and ±0.050(3) Å for **4**].

Some selected bond lengths and bond angles are listed in Table 1. There are two complexes in the literature with a $PdCl_2NS$ *core* (terminal chloride ion, pyrazolic nitrogen, and tioether sulfur). For complex **2**, Pd−Cl, Pd−N, and

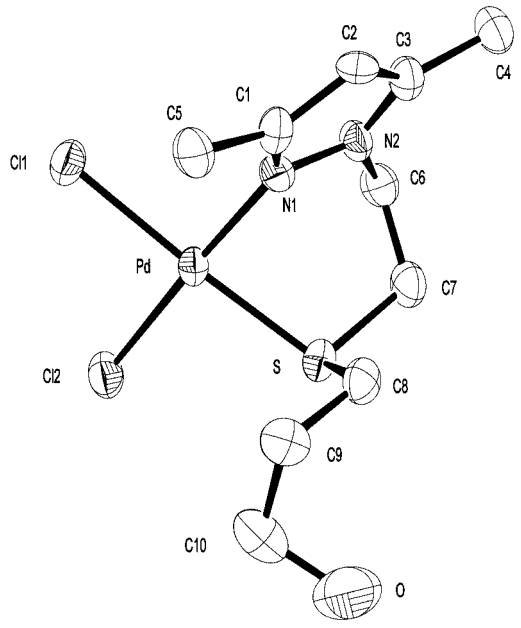

Figure 3. ORTEP drawing of [$PdCl_2$(thhd)] (**2**, 293 K determination) showing all non-hydrogen atoms and the atom-numbering scheme; 50% probability amplitude displacement ellipsoids are shown

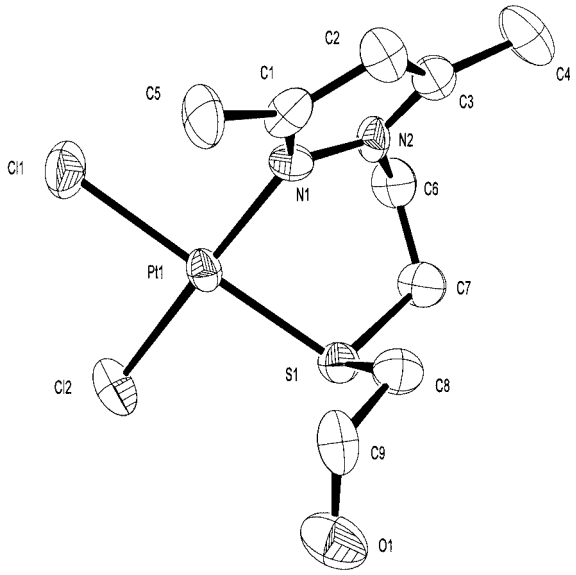

Figure 4. ORTEP drawing of $[PtCl_2(thpd)]$ (**3**, 293 K determination) showing all non-hydrogen atoms and the atom-numbering scheme; 50% probability amplitude displacement ellipsoids are shown

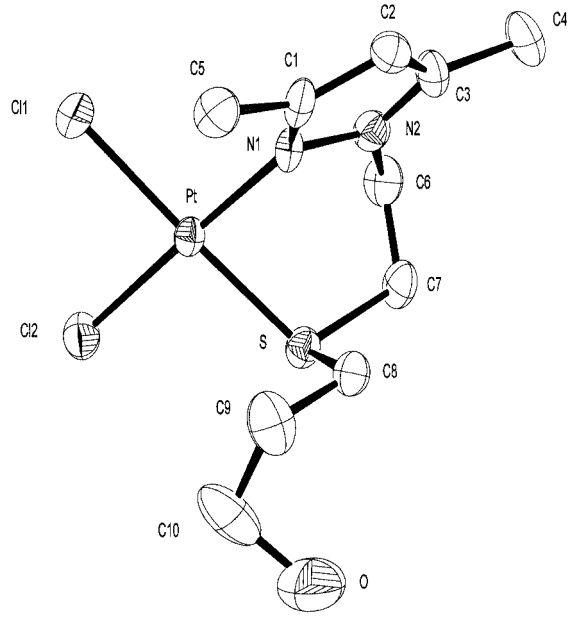

Figure 5. ORTEP drawing of $[PtCl_2(thhd)]$ (**4**, 293 K determination) showing all non-hydrogen atoms and the atom-numbering scheme; 50% probability amplitude displacement ellipsoids are shown

Pd−S bond lengths are similar to those found for the two reported complexes.[21]

No structural data for complexes with a $PtCl_2NS$ *core* (terminal chloride ion, pyrazolic nitrogen, and thioether sulfur) have been reported, although two structures with a $PtCl_2NS$ *core* (aromatic amine) have been described[22] in addition to five complexes with a PtN_2Cl_2 *core* (terminal chloride and pyrazolic nitrogen) have been described.[23] For complexes **3** and **4**, the Pt−S,[22] Pt−N,[23] and Pt−Cl[24] bond lengths are of the same order as those found in the literature.

The thpd and thhd ligands act as bidentate chelates, and form one M−S−C−C−N−N six-membered ring in each complex, all of which have a boat conformation. Bite angles are 86.9(1)° for N(1)−Pd−S in **2** and 87.7(1)° and 87.5(3)° for N(1)−Pt−S in **3** and **4**, respectively. For complex **2** this bite angle is similar to those reported for $[Pd(bddo)](BF_4)_2 \cdot H_2O$ [bddo = 1,8-bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane], 88.8(2) and 86.2(1)°,[8a] and $[Pd(pdto)](ClO_4)_2$ [pdto = 1,8-bis(2-pyridyl)-3,6-dithiaoctane], 86.9° and 87.2°.[25]

Distortion of the boat conformation in six-membered rings is observed in ΔC_s [for, **2** ΔC_s(Pd) = 6.8(4)° and ΔC_s(S−C7) = 11.0(5)°; for **3** ΔC_s(Pt) = 16.0(9)° and ΔC_s(S−C7) = 16.3(10)°; and for **4** ΔC_s(Pt) = 6.1(3)° and ΔC_s(S−C7) = 13.7(4)°; $\Phi_i + \Phi_i' =$ torsion angles related to the considered plane;[26] m = equivalent torsion angles].

$$\Delta C_s = \sqrt{\frac{\sum_{i=1}^{m} (\phi_i + \phi_i')^2}{m}}$$

Complexes **2**−**4** contain intermolecular hydrogen bonds between Cl and OH (Table 2). Complexes **2** and **4** yield infinite chains parallel to the crystallographic vector *b*, whereas the chains for complex **3** are parallel to the crystallographic vector *c* (an example for **4** is given in Figure 6).

Crystal Structure of $[NiCl(H_2O)_2(thpd)]Cl$ ([7]Cl)

The structure of [**7**]Cl consists of cationic units of $[NiCl(H_2O)_2(thpd)]^+$ and chloride anions (Figure 7). The ligand is coordinated to the metallic centre by the nitrogen, sulfur, and oxygen atoms. Nickel(II) completes its coordination with one chloride ion and two water molecules in a skew-trapezoidal bipyramid (distorted octahedral) geometry (Cl1, N1, O2, O3, and Ni atoms being in a plane) with angles at Ni^{II} in the range 83.68(8)−96.90(9)° and 168.32(6)−176.16(7)°. Water molecules are arranged *trans* to the sulfur and the nitrogen atoms, and the chloride ion is *trans* to the alcohol group.

Some selected bond lengths and bond angles are listed on Table 3. No other complex with a $NiClNO_3S$ *core* appears in the literature. The Ni−O, Ni−OH_2, Ni−S, Ni−Cl, and Ni−N bond lengths are of the same order as those found for Ni−O(alcohol),[27] Ni−OH_2 (complexes containing two water molecules),[28] Ni−S(thioether),[9,27a,29] Ni−Cl(terminal),[27b,28d,29b,29d,30] and Ni−N(pyrazole)[9,27−30] bond lengths, respectively.

The thpd ligand acts as a tridentate chelate and forms one Ni−S−C−C−O five-membered ring with an envelope conformation [C9 being ±0.457(4) Å out of the plane formed by the other four atoms] and one Ni−N−N−C−C−S six-membered ring with a boat conformation. Distortion of the boat in the six-membered ring is observed in ΔC_s(Ni) = 13.2(2)° and ΔC_s(S−C7) = 55.9(2)°.

For the six-membered ring, the N(1)−Ni−S bite angle is 93.12(8), while for the five-membered ring the S−Ni−O(3) bite angle is 83.68(8)°. The N−Ni−S bite angle is greater and the S−Ni−O is similar to those reported in the literature for $[Ni_3(bdnol)Cl_5(EtOH)]\cdot 3EtOH$ (N−Ni−S bite angles are 89.991° and 91.634° and S−Ni−O bite angles are 82.177° and 84.090°) and $[Ni_2(bdnol)Cl_3]\cdot MeCN$ [bdnol = 1,9-bis(3,5-dimethyl-1-pyrazolyl)-3,7-dithia-5-nonanol] (N−Ni−S bite angles are 91.514°and 91.755° and S−Ni−O bite angles are 83.952° and 84.016°).[29b]

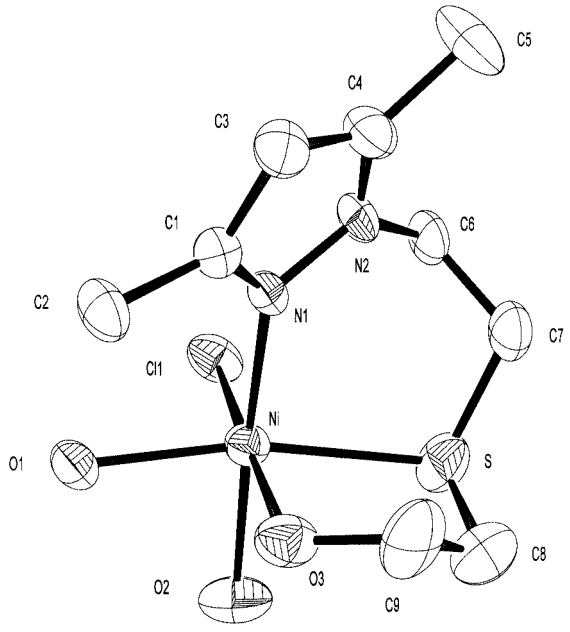

Figure 7. ORTEP drawing of $[NiCl(H_2O)_2(thpd)]^+$ ([**7**]$^+$, 293 K determination) showing all non-hydrogen atoms and the atom-numbering scheme; 50% probability amplitude displacement ellipsoids are shown

This complex contains three types of hydrogen bonds, intramolecular O(1)−H(10)···Cl(2) and intermolecular O(2)−H(20)···Cl(2) and O(3)−H(30)···Cl(2). The O(2)−H(20)···Cl(2) bonding yields a four-membered circuit and O(3)−H(30)···Cl(2) furnishes infinite chains parallel to the crystallographic vector *a* (Table 2, Figure 8).

Conclusion

The structures of the chlorocomplexes presented here were originally investigated to discover the configuration of the new potentially tridentate N, O, S ligands 1-(3-thia-5-hydroxypentyl)-3,5-dimethylpyrazole (thpd) and 1-(3-thia-6-hydroxyhexyl)-3,5-dimethylpyrazole (thhd) when com-

plexed to group 10 metals. These ligands present different coordination environments, depending on the metal ion, as observed in the X-ray structures. Hence, coordination is N, S for Pd^{II} and Pt^{II}, but N, S, O for Ni^{II}. NMR studies proved very useful in determining the configuration of ligands in the complexes. These results will enable the study of the hemilabile behaviour of these novel N, O, S ligands when coordinated to transition metals.

Experimental Section

Generals Remarks: Preparations were performed using the usual vacuum line and Schlenk techniques. All reagents were commercial grade and were used without further purification. Acetonitrile was dried and distilled by standard methods and deoxygenated in the vacuum line.

2-(3,5-Dimethyl-1*H*-pyrazol-1-yl)ethyl 4-methylbenzenesulfonate[9] and 1-(2-mercaptoethyl)-3,5-dimethylpyrazole[10] were prepared according to published methods, as were samples of $[PdCl_2(CH_3CN)_2]$[11] and $[PtCl_2(CH_3CN)_2]$.[12]

Analyses (C, N, H, S) were performed in our analytical laboratory on a Carlo Erba CHNS EA-1108 instrument. Conductivity measurements were performed at room temperature in 10^{-3} M absolute ethanol or acetonitrile solutions employing a Crison, micro CM 2200 conductimeter. Infrared spectra were recorded as KBr pellets or polyethylene mulls in the range 4000−100 cm^{-1} under a nitrogen atmosphere. Electronic spectra in solution were run on a Kontron-Uvikon 860 in acetonitrile between 750 and 350 nm. The ^1H and $^{13}C\{^1H\}$ NMR and HMQC spectra were obtained either on a Bruker AC-250 MHz or a Bruker 500 MHz instrument. $^{195}Pt\{^1H\}$ NMR spectra were obtained on a Bruker Advance DRX 250 MHz instrument. ^1H and ^{13}C chemical shifts (δ) were determined relative to internal TMS and are given in ppm. ^{195}Pt chemical shifts (δ) are relative to external 0.1 mol·dm^{-3} Na_2PtCl_6 and are given in ppm. Mass spectra were obtained on a HP 5989A apparatus.

Synthesis of 1-(3-Thia-5-hydroxypentyl)-3,5-dimethylpyrazole (thpd): A solution of 2-(3,5-dimethyl-1*H*-pyrazol-1-yl)ethyl 4-methylbenzenesulfonate (6.26 g, 21.3 mmol), mercaptoethanol (1.50 mL, 21.2 mmol) and sodium hydroxide (0.94 g, 22.8 mmol) in distilled water (30 mL) was refluxed for 5 h. After cooling to room temperature, the reaction mixture was extracted with CH_2Cl_2 (3 × 25 mL). The collected organic layers were dried with anhydrous sodium sulfate and removed in vacuo to give a brown oil that was then washed with diethyl ether to afford the desired product as a white solid. Yield: 2.70 g (61%). M.p.: 46.6−47.5 °C. $C_9H_{16}N_2OS$ (200.1) C 53.97, H 8.00, N 13.99, S 16.04; found C 54.17, H 7.93, N 14.10, S 15.91. X-ray Crystallographic Study: Suitable crystals for X-ray diffraction experiments of compounds 2−4 and [7]Cl were obtained by crystallisation from methanol. Data for 2 and 4 were collected on a MAR345 diffractometer with an Image Plate detector, using the - scan technique. Data for 3 and [7]Cl were collected on an Enraf−Nonius CAD4 four-circle diffractometer, using the omega/2θ scan technique. All crystal data were collected using graphite-monochromated Mo-K_α radiation. The structures were solved by direct methods using the SHELXS-97 computer program[31] and refined by full-matrix least-squares method with a SHELXL-97.[32]

Fivc H atoms in structure [**7**]Cl were located from a difference synthesis and refined with an overall isotropic temperature factor. Thirteen Hs for [**7**]Cl and all hydrogen atoms for structures **2**−**4** were computed and refined using a riding model. The final *R* (on *F*) factor and ωR (on F^2) values, as well as the numbers of parameters refined and other details concerning the refinement of the crystal structure, are presented in Tables 4 and 5.

CCDC-199097 (**2**), -199096 (**3**), -199095 (**4**), and -199098 ([**7**]Cl) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

NMR and Molecular Modelling Studies on the Solution Structure of the In^{III}–Bleomycin A2 Complex

Athanasios Papakyriakou[a] and Nikos Katsaros*[a]

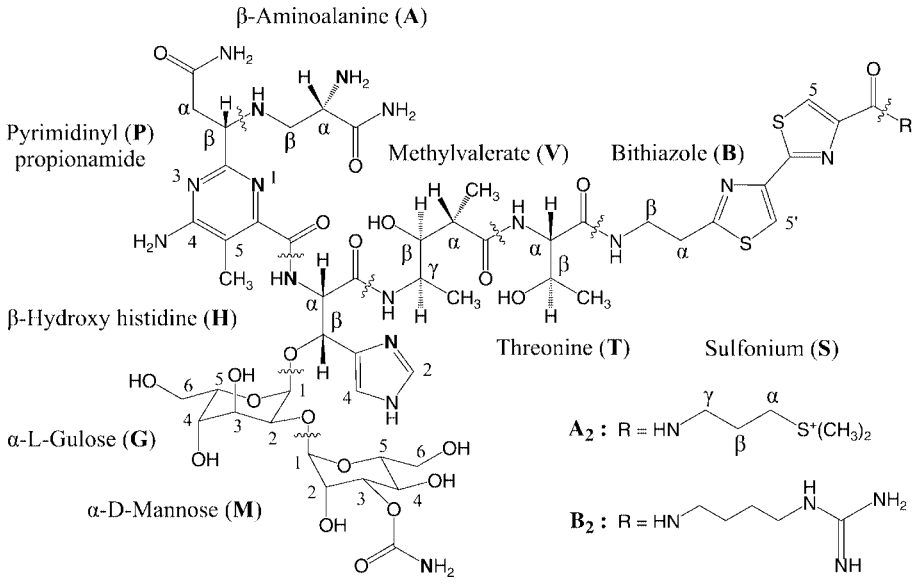
Keywords: Antitumor agents / Indium / Molecular dynamics / N ligands / NMR spectroscopy

The solution structure of the In^{III}–bleomycin A2 complex (InBLM) has been determined by NMR studies in combination with molecular modelling. Our data indicate that BLM is coordinated to In^{III} through five nitrogen ligands in a distorted tetragonal pyramid configuration. The stability and homogeneity of InBLM has allowed us to obtain a well-defined model of the complex formed at low pH, which is a very potent tumour-imaging agent.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The bleomycins (BLMs) are a family of natural antibiotics, exhibiting activity against a broad spectrum of neoplasias.[1,2] Umezawa and co-workers were the first to isolate and characterize BLMs, as their copper chelates, from the culture medium of Streptomyces verticillus.[3,4] The clinically administered drug (Blenoxane or Bleocin) consists predominantly of BLM A2 (55−70%) and BLM B2 in their apo forms (Scheme 1). Their cytotoxicities were recognized to be dependent on the reaction between the ferrous BLM complex and O_2 to produce [HOO−Fe^{III}−BLM], which mediates DNA single- and double-strand scissions.[5−7] Because the biologically active species, designated as "activated bleomycin", is short-lived and unsuitable for direct structural studies, several other metallo-BLMs have been employed as models.[8,9]

The glycopeptide-derived BLM molecule can be divided into four functional domains:



Scheme 1. Structure of bleomycin (BLM) A2 and B2; wavy lines separate their functional domains, and atoms in bold are the proposed N ligands

i. the metal-binding domain, made up of β-aminoalanine (**A**), pyrimidinyl propionamide (**P**) and β-hydroxy histidine (**H**)

ii. the linker domain: methyl valerate (**V**) and threonine (**T**)

iii. the DNA-binding domain, with the bithiazole moiety (**B**) intercalating mainly between G-Py base pairs and the sulfonium tail (**S**), different in each BLM

iv. the disaccharide moiety, made up of α-L-gulose (**G**) and 3-*O*-carbamoyl-α-D-mannose (**M**) and considered to be responsible for the sequence specificity of DNA recognition exhibited by the metallo-BLMs.

The equatorial planes of all the metallo-BLMs and analogues studied so far are defined by the secondary amine of **A**, the N1 of pyrimidine, the deprotonated amide of **H** and the N1 of imidazole (Scheme 1).[10−33] In most of these cases, the primary amine of **A** is an axial ligand, as is also the case in the X-ray crystal structure of Cu^{II}−BLM bound to a BLM-binding protein.[18] On the other hand, some NMR studies have introduced a controversy regarding the coordination of the **M** carbamoyl group.[19,26,31,32] Recent conformational analysis of all the binding geometries of Co^{III}−BLMs has been used to explore the configurations available in the proposed binding geometries.[34,35]

A large number of radioactive metal ion complexes of BLM have been prepared and tested as tumour imaging agents.[36−38] Most of them have failed because of a lack either of in vivo stability or of tumour affinity. Among the divalent metal cations of copper, nickel, zinc and cobalt to have demonstrated high affinity for BLM, ^{57}Co−BLM has been clinically used in lung cancer patients and exhibited high specificity. Because of the high toxicity and the inconveniently long half-life of ^{57}Co, other metals such as ^{67}Ga, ^{99m}Tc and ^{111}In have also been introduced as radiolabels. The complex formed at low pH values between ^{111}In and BLM has exhibited a remarkable stability in vivo, since it has no affinity for transferrin.[39−41] In clinical trials, ^{111}InBLM has demonstrated excellent specificity and sensitivity in head and neck cancer.[42−45]

With the aim of obtaining additional structural information for metallo-BLMs, we have undertaken the characterization of the In^{III}−BLM complex in aqueous solutions. Its high stability at low pH values has allowed us to obtain a wealth of information from 2D NMR experiments. The detection of all exchangeable amine and amide protons, especially those of the **A** primary amine, has played the key role in its structure determination. A molecular mechanics force field, specially parameterised for InBLM, was employed in combination with the experimentally obtained results in order to define the chirality of the complex formed. Structural implications and comparison with other metallo-BLMs are discussed.

Results and Discussion

The interaction between In^{III} and BLMs was monitored by ^{1}H NMR spectroscopy, with use being made both of the clinically administered form and of the pure BLM A2. Immediately after the addition of $In(NO_3)_3$ to solutions of the BLMs at room temperature, pH decreases from 4.5 to less than 2.5 were observed, a fact indicating release of protons. The reaction rate is quite high, so formation of InBLM had been completed by the time that the spectra were acquired (ca. 10 min). 1D NMR spectra of InBLM were acquired at a broad range of temperatures from 278 to 333 K, and at pH values ranging from 2.5 to 7.8. The complex demonstrated high stability even after several months at 298 K, equally well in acidic and in neutral solutions. Although 2D NMR experiments were performed at pH = 6.8 and 3.3, only the latter are presented here. Apart from the successful use of the complex formed at the lower pH as a tumour imaging agent, NMR experiments were also better resolved. In particular, the NOESY spectra acquired in H_2O at 278 K exhibited more intense signals, as the exchange and molecular tumbling rates were lower.

Assignment of the NMR Spectra

The ^{1}H and ^{13}C chemical shifts of InBLM are presented in the Supporting Information (Tables S1 and S2), in comparison with those obtained for the metal-free BLM.[19] The ^{1}H chemical shifts of the sugar moieties were assigned by complementary use of ^{1}H−^{13}C heteronuclear and homonuclear experiments. The HMQC experiment (Supporting Information; Figure S1) provides a dispersion in the carbon dimension, sufficient to spread out all the disaccharide H−C cross-peaks. In combination with the long-range couplings observed in the HMBC and TOCSY spectra, complete assignment can be carried out. The strategy for the assignment of the non-exchangeable protons has already been described in detail,[19,25−27] so we present only the assignment procedure for the exchangeable amine and amide protons, which in some cases have proved to be ambiguous.

The amide protons **V**−NH, **T**−NH, **B**−NH and **S**−NH, as well as the secondary amine proton **A**−NH, were readily assigned by observation of their vicinal scalar couplings. No resonance for the amide proton of histidine was detected, as in cases of previously studied metallo-BLMs.[19,20,25−27] This strongly suggests that this amide is deprotonated and coordinated to In^{III}. Four additional pairs of exchangeable protons, strongly coupled to each other, were detected, along with a broad singlet. The first pair of exchangeable protons with signals at δ = 3.57/5.42 ppm was assigned to the primary amine of **A**, due to the detected scalar couplings with **A**−CαH. Moreover, the δ = 5.42 ppm signal exhibits a weak cross-peak to **A**−CβH in the DQF-COSY spectrum, with a ^4J coupling implying that the bonds linking the coupled nuclei are in a sterically fixed "W" configuration (Supporting Information: Figure S2). The next pair of protons, with chemical shifts at δ = 7.13/7.90 ppm, was assigned to **P**−$CONH_2$, due to the weak couplings observed between the δ = 7.90 ppm signal and the two **P**−Cα protons, also supported by the observed NOEs (Supporting Information: Figure S3). The set of coupled protons at δ = 7.68/8.40 ppm was assigned to **A**−$CONH_2$, by virtue of the scalar coupling between the δ = 8.40 ppm signal and **A**−CαH. This ^4J coupling is also quite weak and its detection indicates a fixed conformation between the coupled nuclei. The broad signal at δ = 7.31 ppm was assigned to 4-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

NH_2 of the pyrimidine ring, in view of the medium-sized NOE exhibited with the neighbouring **P**−5-CH_3. The last pair of protons at δ = 5.96/6.63 ppm exhibits only quite weak NOEs with **P**−5-CH_3 and was assigned to the remaining **M**−$CONH_2$ group. This was also the case for Ga^{III}−BLM, while their chemical shift values are also comparable.

Analysis of the NMR Data

Detection and assignment of the exchangeable protons has revealed very important information regarding the structure of InBLM. The degeneration of the **A**−αNH_2 resonance at δ = 3.57 and 5.42 ppm is a strong indication of its coordination to the metal ion. In the opposite case, only one signal would be detected for the equivalent amine protons, due to fast rotation around the Cα−N bond. In contrast, the potential carbamoyl N ligand of **M** is disfavoured by the fact that it should be deprotonated, the histidine amide likewise. Owing to the high pK_a of **M**−NH_2 (ca. 13) and the detection of two proton resonances, **M**−CO is thus more likely to be a ligand.[46]

A wealth of structural data and distance constraints has been obtained from NOESY spectra acquired at low temperature (278 K; Supporting Information: Table S3). The observed NOEs between the protons of **H**, **V** and **T** suggest that the linker domain is folded underneath the equatorial plane from the side of the imidazole, in the same way as for the Cu^{II}, Co^{III} and Ga^{III}−BLMs.[18,25,27,33] The thiazolium rings are probably in a *trans* conformation, since through-space coupling between their aromatic protons is absent. On the other hand, **B**−5′H exhibits NOEs with the methyl groups of **V**, indicating that the bithiazole tail is close to the linker domain.

Probably the most interesting piece of information is the observation of NOEs between **A**−αNH_2 and the disaccharide protons. Medium-sized signals with **M**−C3H and **M**−C2 H, as well as weak ones with **M**−C1H and **G**−C5 H, restrain the aminoalanine moiety near the sugars. Consequently, it would be expected that both **A** and **M** moieties should share the same side of the equatorial plane. The existence only of one weak NOE between **M**−NH_2 and **P**−CH_3 points to the stacking of the carbamoyl group over the **P** ring, just as in Cu^{II}, Co^{III} and Ga^{III}−BLMs.[18,25,27,33]

Molecular Dynamics Calculations

Three different models of InBLM were used as starting structures for restrained simulated annealing calculations (Figure 1). These models were constructed with In^{III} bound to the four common N ligands of most metallo-BLMs studied so far. Only four-coordinate species were used, so as to make a direct comparison between their potential energies. Model **I** was constructed with both **A**−αNH_2 and **M**−$CONH_2$ at the same side of the equatorial plane, while in models **II** and **III** they occupy apical positions across the equatorial plane. In this way, we were able to examine whether **A**−αNH_2 and **M**−$CONH_2$ are potential axial ligands for InBLM. The coordinates of model **I** were based on the crystal structure of Cu^{II}−BLM (PDB accession no. 1JIF)[18] and models **II** and **III** were constructed on the basis of the NMR structure of Co^{II}−BLM (PDB accession no. 1DEY).[31]

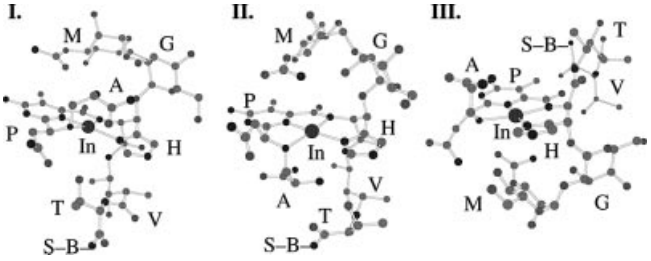

Figure 1. Starting four-coordinate models of InBLM employed in the molecular dynamics calculations; the equatorial ligands are similar in all structures, while the **A** primary amine and the **M** carbamoyl group are located at different sites: both at the same side of the equatorial plane (**I**) and each one occupying an axial position (**II** and **III**); hydrogen atoms, bithiazole and sulfonium moieties have been excluded for clarity

The results obtained by the 10 best structures, by virtue of the lowest potential energies and deviations from the NMR constraints, are summarized in Table 1. All the starting models resulted in structures with the aminoalanine and the disaccharide moieties on the same side of the equatorial plane (Supporting Information: Figure S3). In addition to

Table 1. Structural and energy statistics of the InBLM best models obtained from the simulated annealing calculations

this, structures resulting from model **I** exhibit lower energies and deviations from the distance constraints. Model **I** with **A**−αNH$_2$ and **M**−CONH$_2$ on the same side of the equatorial plane is therefore strongly favoured.

Coordination of **A**−αNH$_2$ is supported not only by the NMR spectroscopic data, but also by the molecular dynamics results. In most of the final structures, especially those resulting from models **I** and **II**, the primary amine is to be found at the axial site, while the carbamoyl group is stacked over the pyrimidine ring. Even though the calculated distance between In^{III} and the **A** amine nitrogen (ca. 2.9 Å) cannot be regarded as a metal−ligand bond length, it is evident that **A**−αNH$_2$ is a favoured axial ligand. The distance between the **M** carbamoyl oxygen atom and In^{III} is > 4.5 Å in all the final structures and can thus be discounted as ligand.

The average structure of the 10 best models **I** was subjected to energy minimization, but with **A**−αNH$_2$ bonded to In^{III}. All the experimental constraints were applied with no violation > 0.1 Å and the total energy was calculated to be even lower than those of the four-coordinate models. The resulting structure, as illustrated in Figure 2, represents the favourable solution structure of InBLM. On the basis of the higher thermodynamic and in vivo stabilities of the six-coordinate In^{III} complexes,[47] we can hypothesize that an H_2O molecule or a Cl^- ion might occupy an axial site *trans* to the primary amine ligand.

Structural Implications and Comparisons with Other Metallo-BLMs

An examination of InBLM structure (Figure 2) has revealed potential H bonds between different domains of BLM. A very strong one is exhibited by (**T**)O−H···O=C(**P**) (distance 1.7 Å, angle 166°). Moreover, the hydroxy oxygen atom of **T** can act as an acceptor to **A**−NH (distance 1.9 Å, angle 170°). These two H bonds, along with those between **T**−NH, **V**−NH and the potential sixth exogenous ligand (H_2O or Cl^-), might be responsible for the folded conformation of the linker domain. The result of electron shielding by the imidazole ring current is exhibited by the upfield-shifted resonances of valerate.

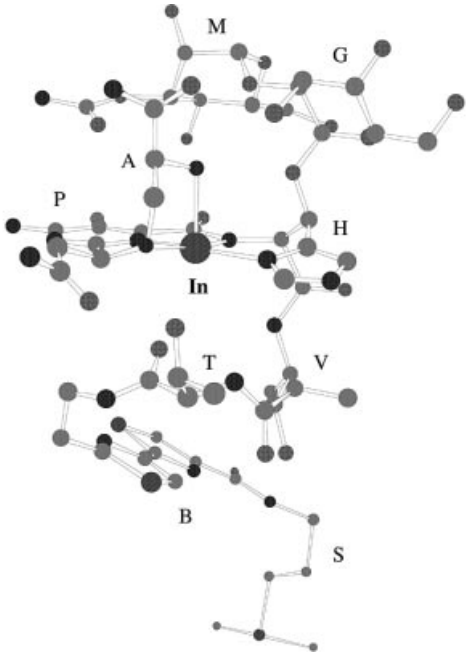

Figure 2. Favoured model for the solution structure of InBLM with the primary amine of aminoalanine occupying the axial site; this model was calculated by averaging of the coordinates of the 10 best models **I** and energy minimization with all the distance restraints

Some potential H bonds were also observed at the other side of the InBLM equatorial plane: (**M**)O4−H···O=C(**H**) (distance 1.7 Å, angle 175°), (**G**)O3−H···O=C(**A**) (distance 1.8 Å, angle 161°), (**A**)αN−H···O−C3(**G**) (distance 2.1 Å, angle 154°) and the weak (**A**)αN−H′···O=C3(**M**) (distance 2.7 Å, angle 116°). These interactions may account for an approach of the disaccharide moiety towards the axial amine ligand, which was also observed in the crystal structure of Cu^{II}−BLM,[18] as well as in the solution structures of Co^{III} and Ga^{III}−BLMs.[25,27,33] A noticeable difference between the structures of these metallo-BLMs is the location of the DNA-binding domain. While for CoBLM ("brown form") and GaBLM no NOEs were detected between **B** or **S** and any other moieties, the NMR structures of CoBLM ("green form") and InBLM have revealed some sort of folding for the BLM's tail. Since no interactions such as the H bonds mentioned above were found, we cannot provide an explanation for this variation.

Conclusion

The anticancer drug BLM forms a very stable complex with In^{III} at low pH values. Our NMR spectroscopic data indicate that InBLM is also stable at neutral pH for several months. The five N ligands of BLM form a distorted tetragonal pyramid around the metal cation, as in the case of Cu^{II}−BLM crystal structure. The carbamoyl group of mannose is not a ligand, but is constrained to the second coordination sphere of InBLM through H-bonding interactions with the axial amine ligand.

Experimental Section

Sample Preparation: Bleocin and BLM A2 were a kind gift from Nippon Kayaku Co. and were used without further purification. The complex was prepared at room temperature by addition of In(NO$_3$)$_3$·3H$_2$O (0.1 M) to aqueous solutions of BLM (10 mM) and the pH was adjusted with aliquots of dilute NaOD or DCl. For the NMR experiments, lyophilised samples were dissolved either in 90% H_2O/10% D_2O or in D_2O (99.99%) (final concentrations were 3−5 mM). The purity of InBLM was judged to be $> 95\%$ from the ^{1}H NMR spectra. All the samples were stable over a period of several months at room temperature, since no changes were detected in their periodically recorded ^{1}H NMR spectra .

NMR Experiments: NMR spectra were recorded with a Bruker Avance 500 MHz instrument and were processed by X-WIN NMR 2.6 (Bruker Analytik GmbH). The program SPARKY 3.100,[48] running on a Linux PC, was used for assignment and analysis of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the 2D spectra. ^1H and ^{13}C chemical shifts were referenced to sulfonium tail methyl groups of BLM at $\delta = 2.93$ and 25.0 ppm, respectively. 2D NOESY (100, 200 and 400 ms mixing times), DQF COSY[49] and TOCSY experiments (MLEV-17 sequence with 35 and 70 ms mixing times)[50] were recorded at 278 and 298 K in H_2O and D_2O. Data sets with 4096 × 512 complex points were acquired with 7 kHz sweep widths in both dimensions and 32 scans per t_1 increment. $^1H-^{13}C$ HMQC[51] and HMBC[52] experiments were also recorded at 278 and 298 K in H_2O and D_2O. Data sets with 2048 × 256 points were collected with 32 or 64 scans per t_1 increment and spectral widths of 6 kHz in the proton and 25 kHz in the carbon dimension. Solvent suppression for the H_2O samples was performed by use of excitation sculpting with gradients,[53] while for the D_2O samples a presaturation pulse was used during the relaxation delay of 2.0 s. The indirect dimension was zero-filled to 2048 data points and the FIDs were processed either with a combination of exponential and Gaussian weighting functions or with a 90°-shifted sine bell function.

Distance Constraints: The NOE signals from the 200-ms NOESY spectrum of InBLM at pH = 3.3 and 278 K were classified as strong, medium and weak, by visual inspection of the cross-peak intensities. Integration of the cross-peaks was performed by the sum-over-ellipse method. The constraints were set to upper distance limits of 3.0, 4.0 and 5.0 Å, respectively, while an additional 1.0 Å was allowed for NOEs involving methyl groups and ambiguous methylene protons. A total of 88 distance constraints were applied with a 50 kcal mol^{-1} $Å^{-2}$ force constant, by use of a square bottom well function with parabolic sides out to 0.5 Å and then linear sides beyond that.

Force Field Parameters: All the molecular modelling calculations were performed with Amber 6,[54] running on a Linux PC. In order to model InBLM accurately, the Amber-1994 force field was modified according to the guidelines of its authors.[55] Standard atom types were assigned to the atoms of BLM by analogy to their chemical environment, except for the disaccharide moiety, for which we used parameters from a force field for modelling glycoproteins (GLYCAM).[56] A new atom type was created for In^{III}, with van der Waals parameters estimated as $R^* = 1.9$ Å (from Bondi crystallographic data)[57] and $\varepsilon = 0.2$ kcal mol^{-1}. The bond, angle and dihedral angle parameters of BLM were also chosen among the existing Amber force field parameter, on the basis of atom type analogy. The metal−ligand parameters were adapted from those calculated by Welch et al.[58] Bond lengths of In−N were applied with $R_o = 2.38$ Å and a 50 kcal mol^{-1} $Å^{-2}$ force constant. For the N−In−N angles we applied θ_o of 90 or 180° with 50 kcal mol^{-1} rad^{-2} force constant, while dihedral angles involving In^{III} were set with zero force constants. The atom-centred point charges of the complex were generated from the electrostatic potential of its molecular fragments. For this purpose, we used the ab initio program package GAMESS,[59] at the Hartree-Fock level of theory. The Stevens/Basch/Krauss/Jasien/Cundari-21G relativistic effective core potentials (SBKJC VDZ ECPs)[60] were used for indium, the 6-31G* basis set for all other atoms.[61] The point charges were fitted to reproduce the electrostatic potential by use of the RESP method,[62] a two-stage approach in which the equivalent methyl and methylene hydrogen atoms are restrained to have the same charge. The equatorial plane of InBLM comprising the β-aminoalanine, pyrimidinylpropionamide and histidine moieties was fitted as a whole. For the remaining domains of BLM we used the atom charges, previously calculated for GaBLM.[33]

Restrained Molecular Dynamics: Molecular dynamics calculations in vacuo were carried out at a time step of 1 fs with the Amber distance-dependent dielectric constant algorithm. The cut-off distance was set to 16.0 Å and the nonbonded pair list was updated every 10 steps. Temperature regulation was performed by use of the Berendsen algorithm. For the heating and cooling stages a bath coupling constant of 0.1−0.5 ps was applied, so as to assure a tighter coupling to the heat bath, while for the equilibration stages it was increased to 2.0 ps to allow sampling of more natural trajectories. The simulated annealing procedure used is the same as that described in the structural characterization of GaBLM.[33] Starting models were initially energy-minimized with no restraints by 500 steps of the steepest descent method and followed by the conjugate gradient method to an rms gradient < 0.1. Every model was then subjected to 20 individual runs starting with a different seed for the initial velocities assigned. A final structure from each iteration was generated by mass-weighted rms fitting and averaging of the coordinates from the last 20 ps of the trajectory (100 structures), followed by energy minimization as above but with all the restraints applied. The results presented in Table 1 are derived from the final 10 best models, by virtue of the lowest energy and deviations from the NMR constraints.

Supporting Information (see footnote on the first page of this article): Two tables with the ^1H and ^{13}C chemical shifts of InBLM in comparison with those reported for apo-BLM and a table with the categorized NOE intensities of InBLM in comparison with those obtained for GaBLM. Three figures with expanded regions from the HMQC, DQF-COSY and NOESY spectra of InBLM and a figure with ensembles of the superimposed structures calculated for each starting model.

Thermodynamic and Structural Properties of Eu^{3+}, Gd^{3+} and Tb^{3+} Complexes with 1,4,7,10-Tetra(2-glutaryl)-1,4,7,10-tetraazacyclododecane in Solution: EXAFS, Luminescence, Potentiometric Studies, and Quantum Calculations

Keywords: Lanthanides / Imaging agents / EXAFS spectroscopy / Luminescence / Ab initio calculations

The stability of the various complexes formed by racemic solutions of the title ligand (L) with Gd^{3+}, Eu^{3+} and Tb^{3+} was investigated by potentiometry. The reaction of complexation proceeds through the quick formation of metastable species leading, after a slow reorganisation of the macrocycle, to thermodynamically stable complexes. The mean numbers of water molecules coordinated to the lanthanides were determined by luminescence and EXAFS spectroscopy. This last method, applied to solutions of complexes, allowed us to precisely determine the nature of the atoms that surround the metal atom and the distance between the lanthanide ion and the various ligands. These structural data that are in good agreement with the results found using quantum mechanics allow us to propose a reaction mechanism, from the hydrated lanthanide ion to the final stable complexes through intermediate species. The specific stability of these final complexes arises from the formation of transitory bonds between the metal ion and two pendant arms, which bear carboxylate groups. The stability constants of the final complexes have high values, close to those obtained with DOTA [log $\beta_{110}(EuL^{5-}) = 24.01$; log $\beta_{110}(GdL^{5-}) = 24.03$; log $\beta_{110}(TbL^{5-}) = 23.97$]. This induces a notable in vivo dissociation inertness, which is essential for a potential contrast agent in magnetic resonance imaging.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

For over two decades, there has been a continuous interest in the study of lanthanide complexes, particularly those of gadolinium(III) with tetraazamacrocyclic ligands, due to their use as paramagnetic contrast agents in diagnostic magnetic resonance imaging (MRI).[1] The main clinically approved gadolinium contrast agents have low molecular weights, and are non-specific agents, which diffuse rapidly in the vascular endothelium.[2] This property limits their use in magnetic resonance coronary angiography and functional imaging.[3] This disadvantage is overcome by the development of Blood Pool Agents, characterised by a high molecular weight, and, consequently, a limited diffusion rate through the endothelium.[4]

The potential contrast agent studied, 1,4,7,10-tetra(2-glutaryl)-1,4,7,10-tetraazacyclododecane, called P730, is a tetracarboxylated derivative of DOTA and a precursor in the synthesis of new MRI macromolecular contrast agents.[3−5] Recent publications, which involved NMR spectroscopy, relaxometry, and luminescence spectrophotometry,[6,7] and which dealt with the structure and dynamics of the numerous stereoisomers formed by this ligand with europium, gadolinium, and terbium, have highlighted the important role of the rate of water exchange.

The ligand P730 may exist as six different stereoisomers, determined by the configuration at each of the stereogenic centres of the carbon atom, (*RRRR*) [(*SSSS*)] and (*RSSS*) [(*SRRR*)] and the achiral diastereoisomers, (*RSRS*) and (*RRSS*) (Scheme 1).

For a given isomer in solution, each chelate formed with the lanthanide usually adopts the same configuration so that four stereoisomers occur, which may interconvert by concerted ring inversions ($\delta\delta\delta\delta \rightarrow \lambda\lambda\lambda\lambda$) or co-operative arm rotation ($\Delta \rightarrow \Lambda$) (Scheme 2).[6,7]

The ratio of diastereoisomers in solution also varies as a function of the lanthanide ion. For the (*RRRR*) isomer, the ratio of the twisted (m) to the regular (M) square-antiprismatic complex was measured by ^{1}H NMR spectroscopy[7] to be4:1 for Eu and 1.5:1 for Tb.

The aqua ions and simple lanthanide salts are toxic for human use. Consequently, lanthanide ions are complexed

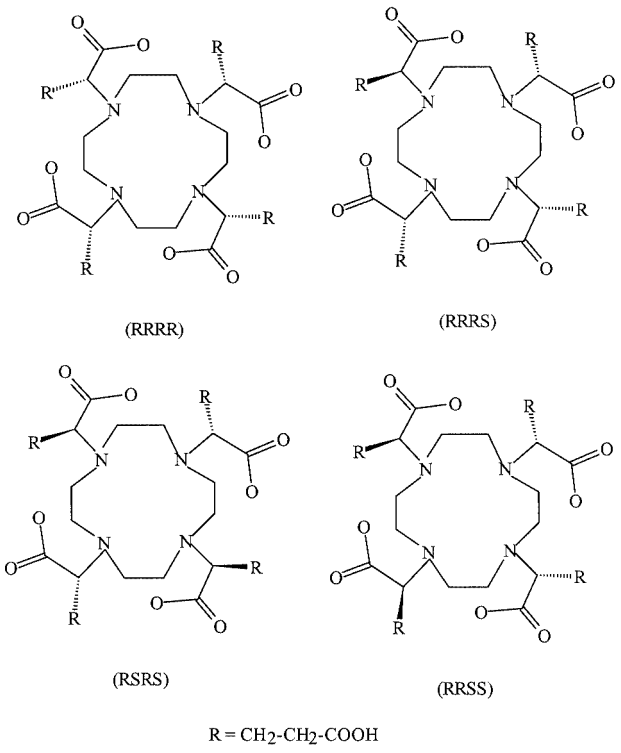

Scheme 1

in order to improve their safety and the toxicity of the lanthanide complexes is related to their stability in vivo. A high thermodynamic stability, slow kinetics, and an inertness to transmetallation, limit the dissociation of these complexes.[8,9]

Some preliminary results on transmetallation and on the stability of Gd-P730 have recently been published.[10] In this paper, we report on the thermodynamic parameters that result from potentiometric measurements performed on the complexes formed after slow complexation reactions (2−3 weeks at 40 °C) between racemic solutions of P730 and the three ions Eu^{3+}, Gd^{3+} and Tb^{3+}. The determination of the logarithms of the protonation constants, a preliminary and indispensable step, leads to the assignment of the log K_h values to the different acidic groups borne by the ligand. The mechanism of complexation of the lanthanide ions proceeds through different stages, leading to the rapid formation of metastable intermediate species, whose formation constants were also calculated.

Results and Discussion

Ligand Protonation Studies in Solution

P730 (LH_8) has 12 potential sites of protonation and, consequently, of complexation: 8 carboxylic groups and 4 tertiary ammonium groups of the macrocycle. The solubility of the neutral ligand is low, close to 10^{-3} mol·L^{-1}. The saturated racemic solution contains 70% of the neutral species LH_8 and also the minor anions LH_7^- (20%) and LH_6^{2-} (10%).

The logarithmic values of the overall protonation constants and of the corresponding successive protonation constants for DOTA and ligand P730, determined in 0.1 mol·L^{-1} Me_4NCl at 25 ± 0.1 °C from the data of 10 titrations, are listed in Table 1. An example of a titration curve is shown in Figure 1.

The protonation sequence of L^{8-} is similar that for the DOTA ligand, which was clearly evidenced by means of NMR spectroscopic studies in solution[11](Table 1). The first two protons are probably bound to two nitrogen atoms of the macrocycle (β_{011}, β_{012}) (see Scheme 1); the next four may correspond to the protonation of the external carboxylate groups [COOH(3): β_{013}, β_{014}, β_{015}, β_{016}]; at pH values < 4, the two central carboxylate groups bound to the tertiary amines are protonated [COOH(2): β_{017}, β_{018}] before the carboxylate group bound to a quaternary ammonium ion in a more acidic medium [COOH(1): β_{019}] (Scheme 3).

In the pH range 3.2−6.5, the titration curve shows a progressive increase similar to that observed with the polycarboxylic acids, which corresponds to the successive and simultaneous neutralisations of the seven carboxylic groups (see Figure 1).

Lanthanide Complexation in Solution

Preliminary tests showed that complexation of the three lanthanides with the ligand proceeds through at least two steps with very different reaction rates.

Formation of Intermediate Species

Figure 1 shows the titration curves obtained 1 h after the mixing of equal volumes of solutions of ligand and metal ion at the same concentrations of approximately 5×10^{-4} mol·L^{-1}. The waiting time between each addition of Me_4NOH is the only variable parameter. The time period is between 0.1 and 30 min. A decrease in pH, accompanying complexation, is observed between the titration curve of the ligand alone and the curves of the solutions that also contain Gd^{3+} at the same concentration.

This set of curves is composed of three parts:

pH range from 3.2 to 5.5, equiv. of OH^- from 0 to 5: The titration curves are well superimposed; the pH values are independent of the waiting time between the additions of base. Protonated metastable complexes are formed during the first and fast kinetic step (less than 30 min). Their notable stability allows the determination of their formation constants.

pH range from 5.5 to 11, equiv. OH^- from 5 to 10: The number and the position of the equivalence points are functions of the waiting time between the additions of base. For short waiting times (0.1−2 min), two equivalence points corresponding to 6 and 8 OH^- equiv. are observed. For longer times, such as 30 min, a single equivalence point remains for 7 OH^- equiv.. This pH range corresponds to the

Table 1. Logarithmic values of the overall protonation constants and of the corresponding successive protonation constants for P730 and DOTA (0.1 mol·L^{-1} Me_4NCl; 25 ± 0.1 °C); values in parentheses represent 1 σ standard deviation; $\beta_{01h} = \prod_{1}^{h} K_i$ and log K_h refer to the equilibrium $LH_{h-1} + H^+ \rightleftarrows LH_h$

Logarithms of the overall protonation constants P730	Logarithms of the successive protonation constants P730	Logarithms of the successive protonation constants DOTA[12]	Function
log β_{011} = 12.22(11)	log K_1 = 12.22(11)	log K_1 = 11.45(2)	NH^+
log β_{012} = 21.40(14)	log K_2 = 9.18(4)	log K_2 = 9.64(1)	NH^+
log β_{013} = 27.69(15)	log K_3 = 6.29(3)	−	COOH(3)
log β_{014} = 33.38(15)	log K_4 = 5.69(3)	−	COOH(3)
log β_{015} = 38.42(16)	log K_5 = 5.04(5)	−	COOH(3)
log β_{016} = 43.22(16)	log K_6 = 4.80(5)	−	COOH(3)
log β_{017} = 47.39(16)	log K_7 = 4.17(5)	log K_3 = 4.60(1)	COOH(2)
log β_{018} = 51.32(16)	log K_8 = 3.93(3)	log K_4 = 4.11(1)	COOH(2)
log β_{019} = 54.20(16)	log K_9 = 2.88(2)	log K_5 = 2.29(2)	COOH(1)
−	log K_{10} < 2	log K_6 < 2	COOH(1)

neutralisation of one or two protons bound to nitrogen atoms (the complexation increases the acidity of these protons). These observations indicate the existence of several reaction mechanisms that lead to the formation of unstable species and to significant rearrangements of the macrocyclic ring.

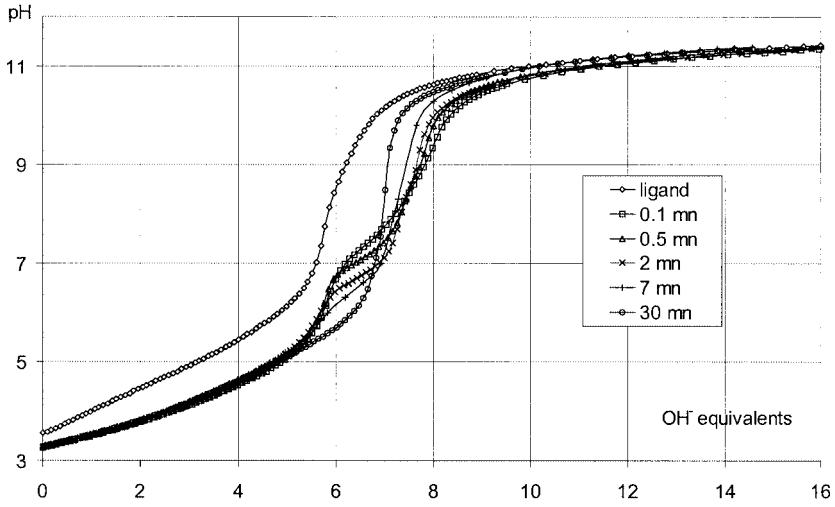

Figure 1. Titration curves of equimolar solutions of P730 and Gd^{3+} (5×10^{-4} mol·L^{-1}) (25 °C, 0.1 mol·L^{-1} Me_4NCl); the upper curve corresponds to the titration of P730 alone; the waiting times values between two successive additions of base vary from 0.1 to 30 min

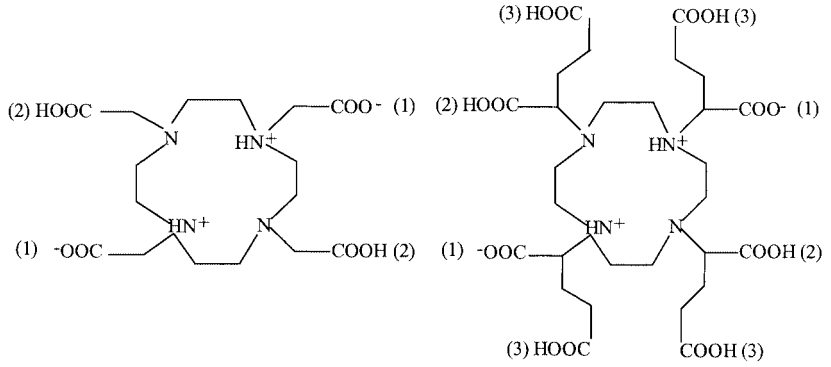

Scheme 3

pH > 11: All the curves are similar to those of the ligand.

A quantitative study is realised from the data of the first part of the titration curves, which corresponds to the formation of metastable complex species (also called intermediate complexes) with a life-time greater than 30 min. The results obtained for the three lanthanides are listed in Table 2.

The logarithms of the overall constants that correspond to the three intermediate Ln^{3+}/P730 systems are very close and follow the general trend Eu > Gd > Tb. The log K_{mh}* values correspond to the protonation of the central ($[MLH_7]^{2+}$*) or external (from $[MLH_6]^{+}$* to $[MLH_3]^{2-}$*) carboxylate groups. These values are indeed lower than those of the ligand. Figure 2 shows the variations of log K

Table 2. versus the number of protonated carboxylates *h* in the case of the ligand P730 alone and of the intermediate gadolinium complexes. The maximum difference is observed at $h = 2$ and 4 ($\Delta\log K = 1.1$ and 1.2, respectively). This indicates notable interactions, maybe the formation of bonds or a network of hydrogen bonds, between two external carboxylate groups and the lanthanide ions.

Formation of Thermodynamically Stable Species

The determination of the stability of the final, stable complexes was done using batch solutions of variable pH.[8,9] Table 3 shows the logarithms of the overall formation constants and of the successive protonation constants.

The values of log β_{mlh} show little variation when the nature of the metal ion changes: the differences observed are of the same order as the calculated standard deviations. The values of log K_{mh} of the external carboxylate groups, from $[MLH]^{4-}$ to $[MLH_4]^{-}$, are only 0.2−0.5 pH units lower than the corresponding ligand log K_h values (see Figure 2). Obviously, these groups are not directly involved in the formation of bonds with the lanthanide ion. The complex $[Gd(P730)]^{5-}$ has a high thermodynamic stability (log $\beta_{110} = 24.03$) as the complex $[Gd(DOTA)]^{-}$ (in Me_4NCl 0.1 mol·L^{-1}, at 25 °C: log $\beta_{110} = 25.58$,[12] 25.30,[13] 24.70,[14] 24.0,[15] 24.67,[9] 25.4,[16] 27.0[17]).

Variation of the logarithms of the successive protonation constants of the carboxylates versus the number of protons *h* in the case of the gadolinium (external carboxylates $h = 1-4$, central carboxylate $h = 5$); squares: ligand P730 (log K_h); circles: intermediate species (log K_{mh}*); triangles: thermodynamically stable species (log K_{mh})

Luminescence Measurements

Horrocks et al.[18,19] have established from experimental results obtained from solid lanthanide complexes that the rate of de-excitation is, to a good approximation, directly proportional to the number of OH oscillators in the first coordination sphere. More recently, an improved approach[20] including other oscillators has shown that, in solution, the intramolecular transfer of energy to the unbound water molecules constitute a significant term in the overall quenching effect. However, this improved approach has also proposed the use of empirical corrections subject to an error of around 25%. A more pragmatic process is to consider that the decay constants determined for Eu^{3+} or Tb^{3+} in D_2O/H_2O mixtures integrate the quenching of water molecules in the first and outer spheres.

The following equation describes the best least-squares lines through the experimental data Δk versus the molar fraction of H_2O in D_2O/H_2O mixtures containing low concentrations of europium or terbium chloride or P730 complexes: $Q = A^*_{Ln}\cdot(k_{H2O} - k_{D2O}) = A^*_{Ln}\cdot\Delta k$. A^*_{Ln} integrates the overall contribution of the vibronic quenching of the OH oscillators, Δk is the slope of the mean straight line, and *q* the hydration number. The values of A^*_{Ln} are calculated by using the hydration numbers determined from EXAFS data[21,22] [8 and 9 for (aquo)terbium and -europium complexes, respectively]. For europium, $A^*_{Eu} = 1.05 \pm 0.02$ ms ($k_{H2O} = 8.77$ ms^{-1}; $k_{D2O} = 0.17$ ms^{-1}) and for terbium, $A^*_{Tb} = 4.86 \pm 0.12$ ms ($k_{H2O} = 2.52$ ms^{-1}; $k_{D2O} = 0.88$ ms^{-1}).

To determine the mean hydration number of the final stable species, racemic solutions of ratio Ln/P730 = 1 were prepared one month before the measurements. The values obtained under these conditions represent a concentration-weighted average of the *q* values of each isomeric species. The results obtained by Woods et al.[7] from solutions of 4 of the 6 pure Eu-P730 stereoisomers correspond to *q* values near to unity in agreement with our average value of *q*(Eu-P730) = 1.04 ± 0.12 ($k_{H2O} = 1.66$ ms^{-1}; $k_{D2O} = 0.67$ ms^{-1}) [Eu-P730 stereoisomers: *q*(*RRRR*) = 1.06; *q*(*RRRS*) = 1.01; *q*(*RRSS*) = 0.92; *q*(*RSRS*) = 1.02]. A notable discrepancy is observed between the corresponding results ob-

tained with the isomers of Tb-P730[7] [Tb-P730 stereoisomers: $q(RRRR) = 0.60$; $q(RRRS) = 0.75$; $q(RRSS) = 1.00$; $q(RSRS) = 0.95$]. Our result obtained from the mixture of the conformers, q(Tb-P730) = 0.96 ± 0.06 (k_{H2O} = 0.46 ms^{-1}; k_{D2O} = 0.27 ms^{-1}), seems to point out that the isomers (*RRRR*) and (*RRRS*) are minor species.

In order to understand the mechanism of formation of the intermediate species formed between europium and the ligand, the mean number of water molecules coordinated to the metal atom was determined under various experimental conditions. The measurements of luminescence were carried out with three series of solutions of ratio P730/Eu^{3+} equal to 10 ([P730] = 10^{-3} mol·L^{-1}), to minimise the concentration of free metal ions at low pH values (Table 4).

Table 4. Experimental and calculated values of q; $q_{calcd.}$ (1): values of q calculated from the first hypothesis; $q_{calcd.}$ (2): values of q calculated from the second hypothesis; percentages of Eu^{3+} for each species (P730/Eu^{3+} = 10; [P730] = 10^{-3} mol·L^{-1}), pH = 3.46: Eu^{3+} 8.1; $[EuLH_7(OH_2)_5]^{2+}$* 0.7; $[EuLH_6(OH_2)_5]^{+}$* 43.1; $[EuLH_5(OH_2)_4]$* 43.9; $[EuLH_4(OH_2)_3]^{-}$* 3.9; $[EuLH_3(OH_2)_3]^{2-}$* 0.4; $[EuLH_2(OH_2)_3]^{3-}$* 0.0. pH = 4.87: Eu^{3+} 0.0; $[EuLH_7(OH_2)_5]^{2+}$* 0.0; $[EuLH_6(OH_2)_5]^{+}$* 0.4; $[EuLH_5(OH_2)_4]$* 10.1; $[EuLH_4(OH_2)_3]^{-}$* 22.8; $[EuLH_3(OH_2)_3]^{2-}$* 56.9; $[EuLH_2(OH_2)_3]^{3-}$* 9.8 (the numbers of molecules of water in the formula correspond to the second hypothesis)

pH	Waiting time	q_{exp}	$q_{calcd.}$ (1)	$q_{calcd.}$ (2)
3.46	none	4.6 ± 0.4	5.32	4.80
3.46	1 h	4.5 ± 0.3	5.32	4.80
4.87	1 h	2.8 ± 0.5	5.00	3.11

The q_{exp} value is a concentration-weighted average of the q values of all the intermediate species and of the (aquo)europium ion bound to 9 molecules of water. Two hypotheses for the intermediate complexes were used to simulate these experimental results. In the first hypothesis, the europium ion is bound only by the 4 central carboxylate groups and 5 water molecules, whatever the pH value and the corresponding deprotonated external carboxylate groups. Second hypothesis: the metal ion is bound by the 4 central carboxylate groups, 1 then 2 external carboxylate groups and 4 then 3 molecules of water according to the pH value. This hypothesis is relevant to the results of the potentiometric study, which points out notable interactions between the external carboxylate group and the lanthanide ion. In this case, the number of water molecules coordinated varied for each one of the protonated species: $[EuLH_7(OH_2)_5]^{2+}$*; $[EuLH_6(OH_2)_5]^{+}$*; $[EuLH_5(OH_2)_4]$*; $[EuLH_4(OH_2)_3]^{-}$*; $[EuLH_3(OH_2)_3]^{2-}$*; $[EuLH_2(OH_2)_3]^{3-}$*. The percentages of Eu^{3+} corresponding to each intermediate complex and to the free ion were calculated, from the concentrations of the reactant using the protonation constants and the stability constants, for each solution that was studied (Table 4).

The calculated values of q corresponding to the possible formation of a bond between the external carboxylate group and the metal ion are in good agreement with the experimental mean results. The similarity of the values of q obtained at pH = 3.46 immediately after preparation of the solutions and after waiting 1 h allows the exclusion of the formation of Eu−N bonds, which correspond to a slow kinetic step.

These results are consistent with the fast formation at a pH near 3.5 of an intermediate complex where the metal atom is bound to the 4 central carboxylate groups of the ligand and to 5 molecules of water. At a pH of around 5, the external carboxylic functions are neutralised which allows the formation of 2 transitory carboxylate bonds and reduces the number of coordinated molecules of water to 3.

EXAFS Measurements

EXAFS experiments were carried out on solutions of the final, stable complex formed with each lanthanide. The environment of the nine-coordinate metal ion was specified and the mean distances corresponding to each type of bond metal atom−coordinated atom determined. An additional experiment enabled the environment of the Gd^{3+} ion in a metastable intermediate complex to be specified.

The number and postulated nature of neighbours, the absorber−neighbour distances, and the Debye−Waller factors resulting from the EXAFS fitting procedure are summarised in Table 5. All four complexes have been fitted considering only single scattering paths.

The k^3-weighted EXAFS spectra and the Fourier transforms of solutions of Ln-P730 final complexes are displayed in Figure 3. Absorptions were collected at k = 12.5 $Å^{-1}$, resulting in a good resolution of peaks in the Fourier transforms. The similarity of the experimental $k\chi(k)$ values and their corresponding Fourier transforms allows us to assume that the local structure of the Ln^{3+} ions is almost the same for the three compounds, the slight differences being attributed to the Ln-P730 distance, which reflects the small ionic radius change from the Eu to the Tb ion. In particular, the amplitudes of the EXAFS oscillations appear almost unchanged. Then, there is the same number of nearest neighbours in the three compounds. In fact, Fourier transforms comprise three main peaks: the first one located at 1.2−2.1 Å (peak 1, Figure 3) corresponds to five oxygen atoms, four from the carboxylic moieties and one from a water molecule, the second one located at 2.1−2.6 Å (peak 2) corresponds to the four nitrogen atoms from the macrocyclic cavity, and the third one located at 2.6−3.4 Å is divided into two components, which correspond to the carbon atoms that belong to the macrocyclic cavity (peak 3′) and to the chains that contain the carboxylic groups (peak 3). Within the frame of the single-scattering approach, we analysed the first three coordination spheres. An additional signal is present at a distance between 3.8 and 5.0 Å for the three complexes. This signal is assigned to the multiple scattering signals on the basis of a previous investigation concerning the compound $[Gd(DOTA)]^{-}$,[22] which is confirmed by the multiple scattering paths obtained by FEFF calculations.[46]

The data available in Table 5 confirms the above qualitative discussion. Within the single-scattering approach, the lanthanide ions are surrounded by the four neighbouring nitrogen atoms of the macrocyclic cavity with an average

Ln−N bond length of 2.68 Å. The decrease of the absorber−coordinated atom distances Ln−N (Eu^{3+} > Gd^{3+} > Tb^{3+}) is in accordance with the slight decrease in ionic radius from the Eu^{3+} to the Tb^{3+} ion.

The absorber ions are also surrounded by four oxygen atoms (carboxylate) with an average Ln−O distance of 2.37 Å. A molecule of water completes the coordination sphere of the three lanthanides. The data are coherent with an EXAFS study of Gd(DOTA) which confirmed that the local environments of the Gd^{3+} centre are similar in solution and in crystals.[7] The Gd−OH_2 distance is in good agreement with the preceding result (2.44 Å), but the bond lengths corresponding to the Eu and Tb complexes are distinctly higher (Eu: 2.51 Å; Tb: 2.50 Å). This could be explained by the fact that water molecules form relatively weak and labile bonds with the lanthanide ions, which gives rise to a

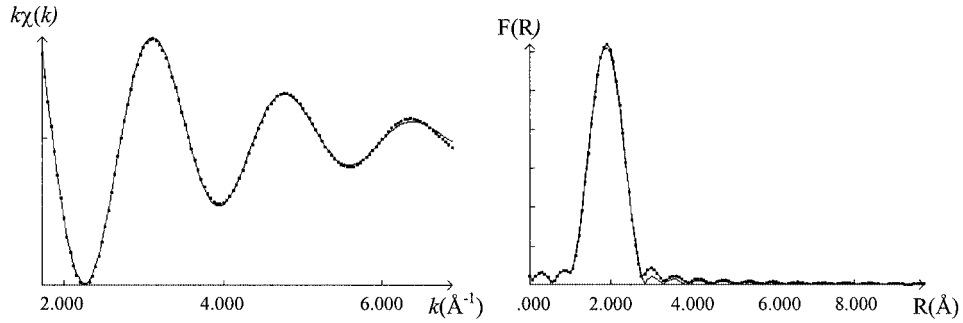

Figure 4. k^3-weighted EXAFS and the corresponding Fourier transform of the first coordination shell of a solution of the intermediate $[Gd(P730)H_n]^{(5-n)-}$* complexes; $[Gd^{3+}] = 9\times10^{-4}$ mol·L^{-1}, [P730] = 9.9×10^{-4} mol·L^{-1}

higher thermal disorder, compared to those of Ln−N or Ln−O (carboxylic), which is in accordance with a fast exchange. Moreover, the two oxygen contributions (carboxylic moieties and water molecules) are difficult to isolate due to their same scattering behaviour. These two phenomena (thermal disorder and scattering behaviour) lead to these relatively unexpected Ln−OH_2 distances.

In accordance with potentiometric studies, an intermediate gadolinium complex has been underlined. Indeed, the radial distribution function of Gd-P730 at 10 °C presents only one main peak located at 1.2−2.6 Å, which corresponds to oxygen atoms from carboxylic groups and water molecules. The k^3-weighted EXAFS, the corresponding Fourier transform, and the fitted curves of the filtered first shell of a solution of the intermediate Gd-P730 species are shown in Figure 4.

The numerical values obtained (Table 5) are in agreement with the main species of a monocapped square-antiprism geometry around the gadolinium centre with four oxygen atoms of carboxylic moieties at 2.40 Å, and five water molecules at 2.42 Å. These results are confirmed by ab initio calculations, which show a relatively stable $[GdLH_6(OH_2)_5]^+$* species with a mean Gd−O(COOH) distance equal to 2.40 Å (see Table 6).

Quantum Chemical Investigation

Quantum calculations were carried out in order to propose a mechanism for the insertion of the lanthanide ion into the ligand. All the complexes optimised by means of ab initio calculations are pictured on Figure 5 (monocapped square-antiprism geometry).The main geometrical parameters computed for these complexes are gathered in Table 6. Ab initio energies computed at the RHF level are reported in Table 7.

In this study, three different complexes {$[GdLH_6(OH_2)_5]^+$*, $[GdLH_4(OH_2)_3]^-$* and $[GdLH_4(OH_2)]^-$} have been found on the potential energy surface (see Figure 5).

The localisation of these complexes allows us to propose a mechanism for the insertion of the gadolinium atom into the ligand. At first, an initial $[GdLH_6(OH_2)_5]^+$* compound is formed in acidic solution. It is a nine-coordinate compound with five water molecules and four central carboxylate oxygen atoms linked to the gadolinium ion. When the pH increases, this complex evolves into the intermediate $[GdLH_4(OH_2)_3]^-$* complex by deprotonation of two external carboxylate groups. These two new carboxylate extremities replace two water molecules for the complexation

of Gd^{3+}. We also tried to optimise another intermediate complex $[GdLH_2(OH_2)]^{-}$* in which the four external carboxylates of the initial complex were deprotonated. However, the existence of such a compound cannot be put forward since we did not succeed in optimising it. Finally, we suggest that the $[GdLH_4(OH_2)_3]^{-}$* complex evolves to a final $[GdLH_4(OH_2)]^{-}$ one by deprotonation of the two nitrogen atoms and reprotonation of the two external carboxylate moieties. The calculation of the distances between the Gd atom and the plane defined by the four nitrogen atoms in these three successive complexes indicates that the gadolinium ion moves more and more into the plane of the ligand as the reaction path proceeds (see Table 6). However, the difference is much less marked from the initial to the intermediate complex (4.274 vs. 3.776 Å) than from the intermediate complex to the final complex (3.776 vs. 1.7−1.8 Å).

For the final $[GdLH_4(OH_2)]^{-}$ complex, two conformers (*RRRR*) and (*SSSS*) in a diastereoisomeric relationship have been optimised in monocapped square-antiprism geometry. Relative energies computed at the RHF/3-21G level show that the (*SSSS*) conformer is more stable than the (*RRRR*) one by 52.3 kcal/mol (see Table 7). It must be pointed out that the energy difference between the two conformers greatly decreases at the RHF/6-31G(d) level (20.2 kcal/mol). This underlines that it is necessary to employ an extended basis set to obtain reliable energies. The main geometrical parameters of the (*SSSS*) species have been reported in Table 6 and compared with an available crystallographic structure recently obtained by Woods et al.[7] Our calculations give Gd−O bonds that are too short and Gd−N bonds that are too long. These results are in line with those found in the case of other gadolinium complexes with similar ligands (DOTA or DOTMA).[23] These two parameters could be corrected by the use of a more extended basis set and the inclusion of the solvent by means of a continuous model[24] but such a calculation would be too time-consuming. Nevertheless, the overall agreement between experimental and theoretical data is good since the average deviation is only 0.05 Å for the distances and 2.2° for the angles. This confirms that the RHF/3-21G method was a good choice to investigate such a compound and allowed us to use this method confidently in order to optimise other complexes. The geometry of the (*RRRR*) has also been reported. The comparison with (*SSSS*) results reveals that the main structural parameters are quite similar in the two conformers. The principal difference comes from the lengthening of the Gd−N bonds in the (*RRRR*) conformer (2.806 vs. 2.742 Å). In the latter, the gadolinium atom is therefore slightly further from the ligand. This is confirmed by the calculation of the distance between this atom and the plane formed by the four nitrogen atoms.

Conclusion

The aim of the magnetic resonance imaging contrast agents is to affect the nuclear magnetic relaxation times of the water protons, increasing the contrast between normal and diseased tissues. Interpreting relaxivity data requires a detailed knowledge of the structures of the complexes in solution. This data does not necessarily correspond to the crystal data because of the lability of these species. The determination of the luminescence decay constants of the lanthanide complexes seems to provide a direct measure of the number of water molecules bound to the metal atom. However, some non-integral values have been interpreted as the result of either a mixture of eight and nine coordinated species, or of a significant contribution of the second-sphere of hydration, or the occurrence of a elongated $Ln-OH_2$ bond. In the present work, the EXAFS data agrees well with the results obtained from the luminescence study ($q \approx 1$); moreover, these results do not show the interaction of the second sphere of hydration and gives reasonable $Ln-OH_2$ bond-length values. An additional EXAFS recording at 10 °C immediately after the preparation of the solution has shown the formation of an intermediate pentahydrate species coordinated to the four central carboxylate groups. The thermodynamic data determined from the potentiometric titrations corresponding to the formation of metastable intermediate complexes indicates strong interactions between two central carboxylate groups and the metal ion. The luminescence measurements confirm the evolution of the number of water molecules coordinated to the lanthanide ion versus time; moreover, they show unambiguously the formation of transitory bonds between the metal ion and one or two external carboxylate groups, which explains the unusual stability of the intermediate complexes. These experimental results as a whole are fully compatible with the complexation mechanism suggested by the quantum chemical investigation.

This whole study allows us to determine the complexation mechanism, in solution, of the lanthanides Gd^{3+}, Eu^{3+}, and Tb^{3+} by the ligand P730. This mechanism is the same for the three lanthanides. Whereas fluorescence experiments were carried out on the europium and terbium complexes, EXAFS was performed on the complexes of the three lanthanides, and the modelling on the gadolinium complexes.

The first step consists of the formation of the species $[LnLH_6(OH_2)_5]^{+}$*, which is presented in Scheme 4.

This complex forms very rapidly, starting at pH = 3.2, in equimolar solutions of Ln^{3+} and P730. In this complex, the four central carboxylic oxygen atoms are bound to the lanthanide atom; the coordination of 9 is ensured by 5 molecules of water. Therefore, the nitrogen atoms, two of which are protonated, do not take part in the complexation. The number of water molecules is characterised by fluorescence and EXAFS experiments, and theoretical calculations predict a stable structure. This complex can be found in solution under the form $[LnLH_6(OH_2)_5]^{+}$* presented above, as well as under the form $[LnLH_7(OH_2)_5]^{2+}$*. The latter species has an additional proton, whose log K_{mh}* is close to 3−3.5. This proton is fixed on an oxygen atom that is not bound to the lanthanide atom, and which belongs to a central carboxylic group. This assumption was put forward by

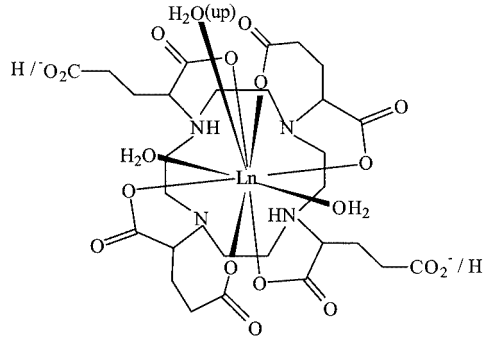
$[GdH_6L(OH_2)_5]^{+}$*

Scheme 4

Szilagyi et al.[27] in the compound Gd(HDOTA). These authors have demonstrated the position of the proton, by fluorescence, UV/Vis spectrophotometry, and NMR spectroscopy. Such a proton can also be found in the structure of the complexes Eu(HP730) in the solid state by Howard et al.[6] and Woods et al.[7]

While the pH increases from 3.2 to 5, the external carboxylic groups are gradually deprotonated. The number of water molecules bound to the lanthanide atom, calculated via fluorescence measurements, goes progressively from 5 to 3. As a result, one, then two additional oxygen atoms of the external carboxylic groups bind to form $[LnLH_5(OH_2)_3]^{2-}$* and then $[LnLH_4(OH_2)_3]^{-}$*, presented in Scheme 5.



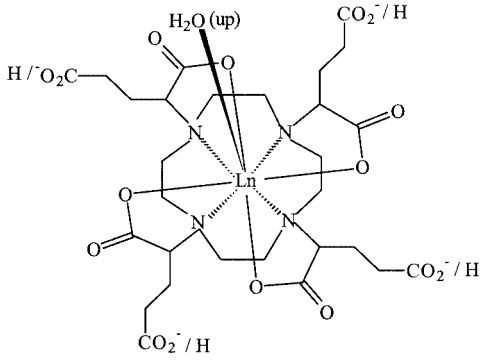
$[GdH_4L(OH_2)_3]^{-}$*

Scheme 5

These species, as well as the ones issued from the deprotonation of the external carboxylic groups $[LnLH_3(OH_2)_3]^{2-}$* and $[LnLH_2(OH_2)_3]^{3-}$*, are put in evidence by potentiometric experiments. The increase of the acidity of two carboxylic groups, shown in Figure 2 (h = 2 and 4), is in accordance with their complexation to the lanthanide. The absence of kinetics noted during these steps shows that there is no modification of the mode of complexation. The nitrogen atoms, two of which are still protonated, are not bound to the lanthanide atom. Our theoretical RHF results confirm the stability of $[GdLH_4(OH_2)_3]^{-}$*.

The coordination of the external carboxylic oxygen atoms was contemplated by Lowe et al.[28,29] in lanthanide complexes with ligands derived from P730, in which a chain $-CH(COO)-CH_2-CH_2-COOH$ linked to the nitrogen atom is replaced with a dansyl substituent.

After several weeks at ambient temperature, or 2 or 3 weeks at 40 °C, all of these compounds evolve towards a series of thermodynamically stable compounds of the formula $[LnLH_n(OH_2)]^{(5-n)-}$ with $0 \leq n \leq 5$. The kinetics corresponds to a significant modification in the nature of the coordinating atoms. The lanthanide atom, which always used to be located above the plane formed by the oxygen atoms of the central carboxylic groups, is now inserted between this plane and the one formed by the nitrogen atoms (Scheme 6).



$[GdH_4L(OH_2)]^{-}$

Scheme 6

All these species are identified using potentiometric experiments. In the complex $[LnLH_4(OH_2)]^{-}$ pictured above, the four central carboxylic oxygen atoms and the four deprotonated nitrogen atoms are bound to the lanthanide atom, whereas the coordination number 9 is ensured by one water molecule. The coordinated water molecule is characterised by fluorescence and EXAFS. The latter technique also confirms the nature of the set of atoms linked to the lanthanide atom. Quantum mechanics calculations show the stability of this complex. In the complex $[LnLH_5(OH_2)]$, an additional proton (log K_{mh} close to 3.5) is fixed on the oxygen atom that is not linked to the lanthanide atom, and which belongs to a central carboxylate group.

The variations of the logarithm of the free metal ratio versus pH for the systems Gd/DOTA and Gd/P730 are drawn in Figure 6. Such a plot clearly shows the similarity in the behaviour of the two systems. At physiological pH (7.4), for the same analytical concentrations of metal ion and ligand (5×10^{-4} mol·L^{-1}), the free concentrations of gadolinium(III), in the presence of DOTA and P730, are 3.8×10^{-12} mol·L^{-1} and 3.3×10^{-11} mol·L^{-1}, respectively. These values confirm the high thermodynamic stability of

the ligand studied, providing a potential in vivo dissociation inertness essential for medical applications.

Experimental Section

Reagents: All chemicals used were of a pure analytical grade. Distilled and argon-bubbled water was used for the preparation of all solutions. Tetramethylammonium chloride (Fluka Biochemika) was used for ionic strength control in all studies. The standard solutions of the lanthanides (Eu, Gd, Tb) were prepared from trichloride hexahydrate salts (Aldrich). Their concentrations were determined by EDTA titrations using xylenol-orange indicator. Carbonate-free solutions of tetramethylammonium hydroxide (Riedel-de Haën) were used for potentiometric titrations. The ligands DOTA and P730 were a gift of Guerbet SA.

Protometric Measurements: All pH-metric measurements used in the determination of protonation and complexation constants were carried out in a thermo-regulated cell (25 ± 0.1 °C) with an argon stream over the solution to avoid the dissolution of carbon dioxide. The glass microelectrode Metrohm type T has a low alkaline error. The procedures and apparatus used for protometric measurements have been described previously.[30] Titrations of acetic acid with CO_2-free Me_4NOH allowed us to determine the ionic product of water pK_w = 13.78 (1), at 25 ± 0.1 °C in 0.1 mol·L^{-1} Me_4NCl. For each ligand, the protonation constants were determined from several experiments; DOTA: 9 titrations corresponding to 1079 pairs of data, concentration range of the ligand 10^{-3} to 3×10^{-3} mol·L^{-1} in the presence of HCl ($0 <$ [HCl]/[DOTA] < 8). P730:10 titrations corresponding to 1261 pairs of data, concentration range of the ligand 2.2×10^{-4} to 9.7×10^{-4} mol·L^{-1} in the presence of HCl ($0 <$ [HCl]/[P730] < 10.2). The complexation reactions of lanthanides with DOTA and P730 are slow at room temperature. Intermediate species formed in the first hour, after the mixing of the ligand and metal ion, transform into final and stable complexes in some weeks. Titrations performed 1 h after mixing allowed for the determination of the formation constants of the intermediate complexes. At least seven measurements (about 60 points each one) were performed for each system Ln/P730 in the pH range 3.8−6 for complexation experiments. The ligand and metal concentration were about 5×10^{-4} mol·L^{-1}, the ratio ligand/metal being slightly above 1. For each metal, in order to study the final equilibria, three or four batch experiments were performed in which 40 individual solutions, in the approximate pH range 2.8−9, corresponding to single points of conventional titrations, were stored in a thermostat at 40 ± 0.1 °C for 25 d. This time was determined from the pH of reference solutions periodically controlled to ensure the achievement of the conditions of equilibrium.

Protometric Computations: The protometric data were processed by the code Protaf[31] in order to obtain the best-fit chemical model and refined overall stability constants β_{mlh} (β_{mlh} refers to the species $M_mL_lH_h$). The program Protaf,[31] which is based on the weighted least-squares of the residues of the experimental variables (volume of titrant, pH), allows a simultaneous processing of ten titrations, each including 150 pairs of data (volume, pH).

Luminescence Measurements: The measurements were determined in D_2O/H_2O mixtures, the molar fraction of H_2O varying from a value nearing 0 to the value 1, the concentration of the lanthanide chlorides, used as references, or of the corresponding P730 complexes varying from 2×10^{-3} to 2.5×10^{-2} mol·L^{-1} in neutral or basic media. Luminescence spectra for europium and terbium complexes were recorded with a Perkin−Elmer LS50B equipped with a Hamamatsu R928 photo-multiplier and operating in time-resolved mode. Lifetimes were measured at 25 °C by excitation of the sample solution by a short pulse of light (europium species: 394 nm; terbium species: Tb^{3+} 221 nm, Tb-P730 229 nm). The emission was monitored at 616 nm for Eu^{3+} and 544 nm for Tb^{3+} using the program Lemming Ver 1.01. The gate time was 0.1 ms and the slit widths were 15 and 5 nm for Eu^{3+} and less for Tb^{3+}. The rate constants k, inverse of the lifetimes τ, are the average values from 10 series of 20−40 measurements realised for each D_2O/H_2O mixture. The luminescence decay curves were fitted by the following equation using the general curve fitting program Origin: $F = F_o\cdot\exp^{(-kt)}$. High correlation coefficients were determined. The quoted k_{D2O} values were estimated and the k_{H2O} values verified from linear extrapolation of k versus the molar fraction of H_2O.

EXAFS Study: Ln^{3+} L_3-edge spectra were recorded with the XAS4 beamline at the Laboratoire d'Utilisation du Rayonnement Electromagnétique (LURE) of the University of Paris-Sud. Standard operating conditions were a beam energy of 1.85 GeV and a mean intensity of 200−300 mA. The measurements were carried out in the transmission mode with an Si (111) channel-cut monochromator, which was de-tuned to 30% of the maximum intensity for Eu, Gd and 15% for Tb, to remove the higher-order harmonics. The detectors were low-pressure (ca. 0.2 atm) air-filled ionisation chambers. Each spectrum is the sum of three to four recordings in the range from 150 eV below to 600−700 eV above the absorption edge. Spectra were recorded using sampling steps of 2 eV with an integration time of 2.0 s per point. The EXAFS spectra at the Ln^{3+} L_3-edge were measured for the aqueous solution at room temperature at a pH around 9.0. Moreover, the intermediate Gd^{3+} complex spectra was registered at 10 °C and at a pH around 3.2 in order to slow down the kinetic formation of the final complex. The EXAFS data analysis was performed with the "EXAFS pour le Mac" and EXAFS98 programs.[32,33] The $\chi(k)$ functions were extracted from the data[34−36] with a linear pre-edge background, a combination of polynomials (of order 5) and spline atomic-absorption background, and normalised by using the Lengeler−Eisenberger method.[37] The energy threshold, E_0, was taken at the half maximum of the absorption edge. Radial distribution functions $F(R)$ were calculated by Fourier transforms of $k^3w(k)\mu(k)$ in the range 2.0−12.5 Å^{-1}; $w(k)$ is a Kaiser−Bessel apodisation window with a smoothness coefficient $\tau = 2.5$ (k is the photoelectron wave-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

number). The peaks corresponding to the successive atomic shells were then isolated and Fourier back-transformed into k space to determine the mean coordination number, N, the bond length, R, and the Debye-Waller factor, σ, by a least-squares fitting procedure using the standard EXAFS formula, without multiple scattering:

$$\chi(k) = S_0^2 \sum_i \left[\frac{N_i}{R_i^2} A_i(k) e^{-2\sigma_i^2 k^2} e^{-2R_i/\lambda(k)} \sin(2kR_i + \Phi_i(k)) \right] \quad (1)$$

The backscattering phase, $\Phi_i(k,R_i)$, and amplitude, $A_i(k,R_i)$, functions have been obtained using two approaches: the experimental and the theoretical one. The experimental back-scattering phase, $\Phi_i(k,R_i)$, and amplitude, $A_i(k,R_i)$, functions have been extracted from the EXAFS data of the model compounds of known crystallographic structure: aqueous rare earth solution,[21] $[Gd(DOTA)]^-$,[22] $[Eu(DOTA)]^-$,[38] and $[Tb(TETA)]^-$.[39] The theoretical back-scattering functions have been calculated using the ab initio code FEFF7,[46] with input data based on the X-ray crystal structure of $[Gd(DOTA)]^-$,[41,42] $[Eu(DOTA)]^-$,[38] and $[Tb(TETA)]^-$.[39]

Computational Methods: Traditional quantum mechanical methods are in general applied with great success for systems containing first-row atoms. However, they cannot be applied for systems with atoms further down the periodic table, e.g. lanthanide atoms, because of the sharp increase in computation time required to treat atoms of large atomic numbers. The effective core potential (ECP) method avoids this problem by replacing the core electrons with an approximate pseudo-potential which is only dependent upon the coordinates of the valence electrons, but takes into account the influence of the core electrons. In this study, geometries of the gadolinium complexes have been optimised in vacuo at the Restricted Hartree−Fock (RHF) level of theory using the (1s−4d, $4f^7$) ECP developed by Dolg et al.[40] with the [5s4p3d]-GTO valence basis set for the metal and the 3-21G basis set for the ligands. Previous studies have shown that inclusion of 4f electrons into the core yields a better description of large molecular systems.[23,44] For energy calculations, the 6-31G(d) basis set has also been used for the ligands. The Restricted Hartree−Fock theory is based on the resolution of the Schrödinger equation. As an exact solution of this equation is not possible, some assumptions are made within this theory. Comparison with experiments indicates that the RHF theory gives reasonably good computed structures and can be confidently used to determine the geometry of large systems. A basis set is the mathematical description of the orbitals within a system used to perform the theoretical calculation. Larger basis sets approximate the orbitals more accurately by imposing fewer restrictions on the location of the electrons in space. The 3-21G and 6-31G(d) are two standard basis sets; the 6-31G(d) one being the most extended one. The methodology described above has previously been used by Cosentino et al.[23−26] in their investigation of 5 complexes of gadolinium with macrocyclic and linear polyamino carboxylate ligands. By comparisons with experimental data, the authors concluded that geometry optimisations can be confidently performed at the RHF/3-21G level because it is a good compromise between accuracy and computational effort. In addition, they showed that RHF/6-31G(d) energy calculations on RHF/3-21G optimised geometries provide a satisfactory representation of the potential energy surface. In addition, other RHF calculations using ECP have been performed on multiply bonded transition metal complexes.[45] Computed structures are in good agreement with corresponding X-ray crystallographic data. All the calculations in this study have been carried out using the Gaussian 98 program.[47]

Acknowledgments

We would like to thank the Groupe Guerbet (Aulnay-sous-Bois, France) for their financial support and the supply of the ligands P730 and DOTA, Dr. Andrew Beeby (University of Durham, Great Britain) for the supply of the Lemming program Ver 1.01. The authors also wish to acknowledge S. Belin (Université Paris Sud, LURE, France) for her help in EXAFS data recording and for helpful discussions.

Potential MRI Contrast Agents Based on Micellar Incorporation of Amphiphilic Bis(alkylamide) Derivatives of $[(Gd-DTPA)(H_2O)]^{2-}$

Kristof Kimpe,[a] Tatjana N. Parac-Vogt,[a] Sophie Laurent,[b] Corinne Piérart,[b] Luce Vander Elst,[b] Robert N. Muller,[b] and Koen Binnemans*[a]

Keywords: Imaging agents / Contrast agents / Lanthanides / Micelles / N,O ligands / NMR spectroscopy

DTPA-bisamide derivatives with alkyl chains containing 14, 16 and 18 carbon atoms were synthesized and complexes of various trivalent lanthanide ions (Ln = Gd, La, Pr, Eu) were formed. Variable temperature proton NMR spectroscopy of paramagnetic praseodymium(III) and europium(III) complexes revealed that long aliphatic substituents considerably increase the energy barrier for the intramolecular rearrangement around the lanthanide ion. The gadolinium(III) complexes were incorporated into mixed micelles, and photon correlation spectroscopy showed that the mean sizes of all the micelles were within the same range. The NMRD curves of all three DTPA-bisamide-gadolinium complexes incorporated in mixed micelles display higher relaxivity values than the commercially available Gd–DTPA contrast agent. The higher relaxivity obtained for the micellar DTPA-bisamide-gadolinium complexes with C_{14} and C_{16} chains relative to the micellar DTPA-bisamide-Gd^{III} C_{18} chain complex could be attributable to the fact that the alkyl chain containing 18 carbon atoms is longer than the alkyl chain of the major component of the micelles, DPPC, in which it is inserted. This would allow increased mobility of the polar head and hence a lower relaxivity.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Complexes of lanthanides with diethylenetriamine-*N*,*N*,*N*′,*N*′′,*N*′′-pentaacetate ($DTPA^{5-}$) and with its amide derivatives have attracted considerable attention in recent years. The anionic $[Gd(DTPA)(H_2O)]^{2-}$, the first contrast agent approved for use in humans, is nowadays routinely used in clinical magnetic resonance imaging for contrast enhancement under the name Magnevist® (Schering, Berlin, Germany). This paramagnetic complex contains one inner-sphere water molecule[1−4] that exchanges rapidly[5] with the bulk water in the human body, therefore providing an efficient mechanism for the enhancement of the relaxation rates of the water protons. The negative charge of the complex, however, results in a relatively high osmolality of the clinical formulation. In order to neutralize two negative charges of $[Gd(DTPA)(H_2O)]^{2-}$, numerous bis-amide derivatives of DTPA have been developed. The bis-methylamide derivative of Gd−DTPA, Gd−DTPA-BMA, [H_3DTPA-BMA = *N*, *N*′′-bis(methylcarbamoylmethyl)−carboxymethyliminobis(ethylenediamino) diacetic acid] has been in clinical use nearly as long as its parent complex.[6] The practical application of Gd−DTPA-BMA has stimulated extensive research on the synthesis and study of new DTPA amide derivative ligands. In general, the methyl groups of DTPA-BMA have been replaced by various alkyl or aryl groups,[7−16] and in addition, macrocyclic bis(amide) derivatives of DTPA have also been successfully synthesized.[17−19] X-ray crystal structures of the lanthanide(III) complexes of some DTPA bis(amide) derivatives have revealed that the ligands coordinate to the lanthanide ion in an octadentate mode, while the ninth coordination site is occupied by a water molecule.[9,10,14,16] In solution, the presence of H_2O molecule in the inner sphere was detected in the europium(III) complex by luminescence lifetime measurements[3,20] and for some dysprosium(III) complexes by ^{17}O NMR studies.[11]

In attempt to achieve higher proton relaxivity, the Gd^{III} complexes of (DTPA-bisamide) alkyl copolymers with alkyl chains containing six, ten, or twelve $-CH_2$ groups have been synthesized.[21] The unexpectedly high proton relaxivities of these polymers were attributed to the formation of rigid, micelle-like structures in solution, these structures forming as a consequence of hydrophobic interactions between long alkyl chains. Detailed ^{17}O NMR and EPR spectroscopic studies showed that the rates and mechanisms of water exchange of all Gd (DTPA-bisamide) alkyl copolymers are the same as in the monomer chelate unit, and the proton relaxivity difference was explained in terms of differences in global motion.

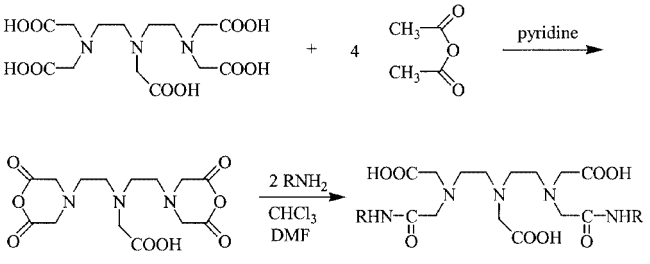
Bis(amide) derivatives of Gd−DTPA containing long alkyl chains were also incorporated into the membranes of liposomal vesicles, yielding gadolinium-labelled liposomes. These liposomes, containing paramagnetic amphiphilic agents, significantly enhanced the proton relaxivity and were shown to be especially suitable for contrast enhancement in the liver, where the highly soluble parent Gd−DTPA complex does not accumulate efficiently.[22] Other attempts to slow down the rotational motion of gadolinium-based contrast agents, and thus to improve their relaxation efficiency, have included the synthesis of macromolecular gadolinium(III) chelates such as dendrimers,[23] linear polymers[24−26] or proteins.[27−29] The strategy proved rather disappointing, since the relaxivity gain obtained by increasing the molecular size is often far less than expected, as a result of internal flexibility or non-rigid attachment of the chelate to the macromolecule.[23−30] An interesting approach to high-relaxivity contrast agents is to synthesize amphiphilic gadolinium(III) complexes which can self-assemble into micelles.[30] An example is the Gd−DOTA derivative (DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) with a long alkyl chain, reported by André et al.[31]

In this study we describe the synthesis of neutral, amphiphilic bisamide derivatives of DTPA with alkyl chains containing 14, 16 and 18 carbon atoms. The gadolinium complexes of these ligands were incorporated into mixed micelles to produce supramolecular structures with decreased rotational motion, and the NMRD profiles of the paramagnetic micelles are reported. The solution dynamics of europium and praseodymium complexes were investigated by NMR, and comparison was made with the related Ln-DTPA complexes.

Results and Discussion

The Ligands and Complexes

The ligands DTPA-bis-tetradecylamide (DTPA-BC14), DTPA-bis-hexadecylamide (DTPA-BC16) and DTPA-bis-octadecylamide (DTPA-BC18) were synthesized in high yields according to Scheme 1.



DTPA-BC14, R = $C_{14}H_{29}$
DTPA-BC16, R = $C_{16}H_{33}$
DTPA-BC18, R = $C_{18}H_{37}$

Scheme 1. Synthesis of DTPA bis(amide) derivatives

Under slightly alkaline solutions, these all readily formed complexes with lanthanide(III) ions (Ln = Gd, La, Eu, Pr), as shown in Figure 1. IR spectroscopic data of all ligands showed strong absorptions in the 3350−3360 and 1625−1670 cm^{-1} regions, corresponding to NH and CO stretching modes, respectively.[32] Shifts of around 20 cm^{-1} to lower energy were observed for the carbonyl stretching frequencies upon complexation, indicating amide oxygen coordination to the lanthanide ion. These findings are consistent with previous studies, which have shown that DTPA bis(amide) derivatives coordinate to Ln^{III} through three acetate oxygens, three nitrogen atoms and two carbonyl oxygens of the amide group, while the ninth coordination site is occupied by a water molecule.[9,10,14,16]

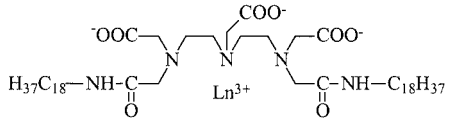


Figure 1. Schematic representation of the Ln−DTPA-BC18 complex; the ligand coordinates to lanthanide ion through three carboxylate oxygens, three nitrogen atoms and two carbonyl oxygens of the amide group, while a water molecule occupies the ninth coordination site

Solution Structures and Dynamics of Ln−DTPA-BC14, DTPA-BC16 and DTPA-BC18 Complexes

The coordination polyhedron of the nine-coordinate lanthanide complexes can best be described as a tricapped trigonal prism,[33] with the bis-amide-DTPA ligand arranged around lanthanide ion in such a way that eight different enantiomers are possible. The eight possible enantiomers of the bound ligand give rise to the complex geometries, in which four are the mirror images of the other four. Thus, in theory, four NMR signals could be detectable for each nucleus in the bis-amide-DTPA ligand. However, rapid interconversion of the bis-amide-DTPA complexes on the NMR timescale very often results in a reduction of the number of NMR signals.[11] In order to examine the solution dynamics of the lanthanide complexes with DTPA-BC14, DTPA-BC16 and DTPA-BC18, the ^1H NMR spectra were recorded at various temperatures. Unfortunately, due to the low solubility of all the complexes in the common NMR solvents we were unable to collect ^{13}C NMR spectra of good quality.

The ^1H NMR spectra of lanthanum(III) complexes with DTPA-BC14, DTPA-BC16 and DTPA-BC18 ligands at room temperature were quite complex, due to the broadening and overlapping of proton resonances originating from various isomers. This made the interpretation of the spectra quite difficult. The proton NMR spectra of the praseodymium(III) complexes were much more informative, however, since the presence of the paramagnetic ion increased the chemical shift range and resulted in separate signals for CH_2 protons. At room temperature (298 K), the praseodymium(III) complexes with DTPA-BC14, DTPA-BC16 and DTPA-BC18 show eighteen resonances for ten acetate and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

eight ethylenic protons in the range from −35 to +35 ppm. Exact distinction between ethylenic and acetate resonances was not possible, since this would require use of partially deuterated ligand. It is reasonable to assume that, analogously to the previously assigned proton NMR spectra of the parent Pr−DTPA and Eu−DTPA complexes, the acetate resonances should in general experience significant downfield shifts, while the ethylenic protons should be shifted upfield.[34]

We also extended our observation to the DTPA-BC14, DTPA-BC16 and DTPA-BC18 complexes of europium(III), because we expected that increased charge/size ratio should

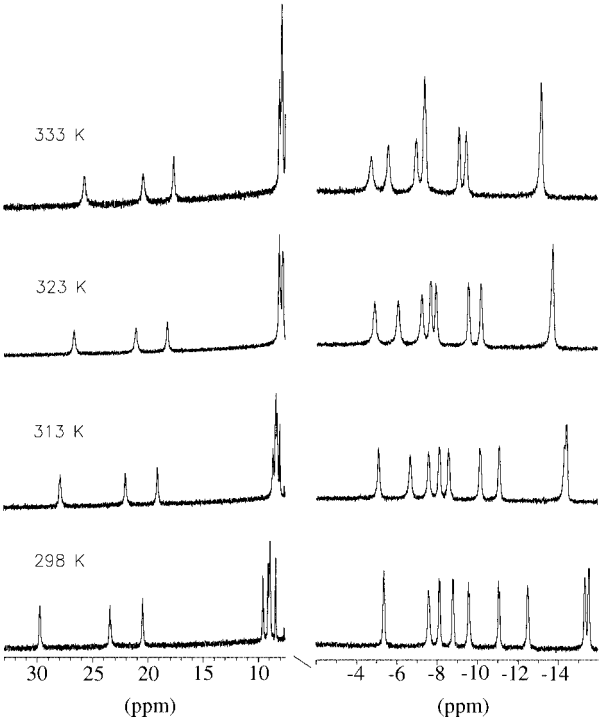

Figure 2. Variable temperature NMR spectra of Eu−DTPA-BC16 in $CDCl_3/CD_3OH$ solution; only the regions containing resonances of acetate protons (at low field) and ethylenic protons (at high field) are shown; the relative assignment was based on the assignment of the parent Eu−DTPA complex reported in ref.[34] the region containing solvent peaks as well as aliphatic proton resonances was omitted for clarity

favour even higher rigidity of the system. As Figure 2 shows, in the proton NMR spectrum of Eu-DTPA-BC16 the "frozen" structures could already be detected at 298 K. In theory, eight possible enantiomers of the bound ligand are possible, and since four of those geometries are mirror images of the other four, four signals can be expected for each group of magnetically equivalent protons in the Eu−DTPA-BC16 ligand. Examination of the NMR spectra shown in Figure 2 suggests that the spectra are consistent with the occurrence either of two static structures or of two pairs of interconverting isomers. To test this, the temperature of the solution was increased to 333 K, but only the coalescence of two pair of peaks was detected. Unfortunately, the chloroform/methanol solution in which the complexes were dissolved did not allow us to record high temperature spectra in order to observe the coalescence process. However, the broadening of the resonances supports the view that the observed spectral pattern is due to the existence of interconverting isomers.

This dynamic behaviour of the praseodymium and europium complexes with DTPA-BC14, DTPA-BC16 and DTPA-BC18 is rather surprising, since the parent Pr−DTPA and Eu−DTPA complexes are known to undergo fast intramolecular rearrangement at room temperature, so that "frozen" structures could be detected only at temperatures below 268 K, while the exchange process leading to coalescence was already observed at 338 K.[34]

Detailed kinetic study on bispropylamide-DTPA complex of neodymium(III) showed that the activation barrier for the conformational interconversion at the middle nitrogen atom in the diethylenetriamine backbone (so called "wagging" process) was virtually the same as the activation barrier of the parent DTPA complex, indicating that the replacement of two carboxylate groups by the relatively weak coordinating amide groups has no influence on this process.[11] However, the inversion of the terminal diethylenetriamine nitrogen atoms, which is characterized by a higher activation barrier, requires partial decomplexation of the ligand. It is likely that, for steric reasons, the long aliphatic substituents on DTPA-BC14, DTPA-BC16 and DTPA-BC18 ligands considerably alter the rate of this inversion, thus increasing the energy barrier for the intramolecular rearrangement around the lanthanide ion.

Mixed Micelle Formation and Size Distribution

The gadolinium(III) complexes of DTPA-BC14, DTPA-BC16 and DTPA-BC18 ligands were incorporated into mixed micelles made of phospholipid (DPPC), a surfactant (Tween 80) and the gadolinium complex. The micelle size was determined at room temperature by photon correlation spectroscopy. All micelles were monodisperse (i.e., there was only one main kind of particles in the size distribution histogram). As can be seen from Figure 3, the mean diameters of the micelles are all within the same range (15−20 nm) and can be regarded as similar. This indicates that the size of the micelles is virtually independent of the length of the bisamide chain, and that the factor that determines the size is the phospholipid DPPC.

Nuclear Magnetic Relaxation Dispersion (NMRD) Measurements

Figure 4 shows the proton NMRD profiles of the relaxivity (defined as the longitudinal relaxation rate enhancement produced by one millimole per litre of Gd complex) of Gd−DTPA-BC14, Gd−DTPA-BC16 and Gd−DTPA-BC18, incorporated in micelles, at 37 °C. As would be expected, the inclusion of the gadolinium complexes into micelles results in an increased relaxivity relative to the parent complex Gd−DTPA and in a maximum at high magnetic fields, induced on the one hand by the decreased rotational mobility of the paramagnetic complex and on the other hand by the increase in the electronic longitudinal relax-

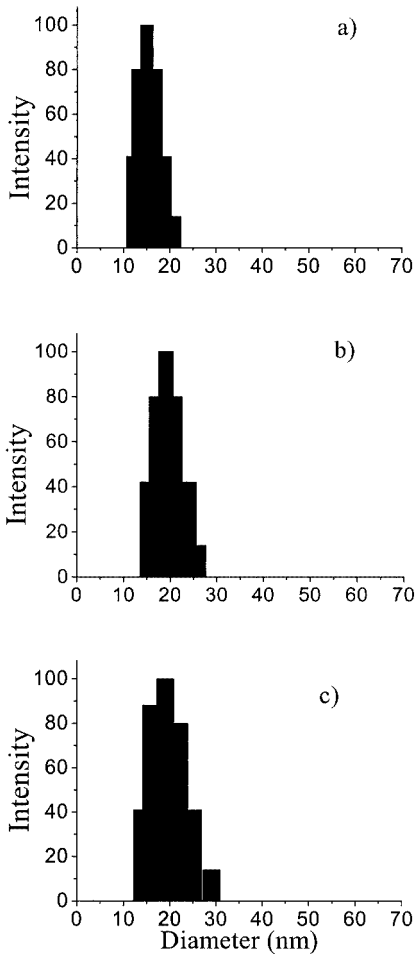

Figure 3. Histogram representing micelle size distribution, as measured by photon correlation spectroscopy: a) Gd−DTPA-BC14; b) Gd−DTPA-BC16; c) Gd−DTPA-BC18

ation time at high fields. The relaxivities of micellar Gd−DTPA-BC14 and Gd−DTPA-BC16 are quite similar, and are larger than for micellar Gd−DTPA-BC18.

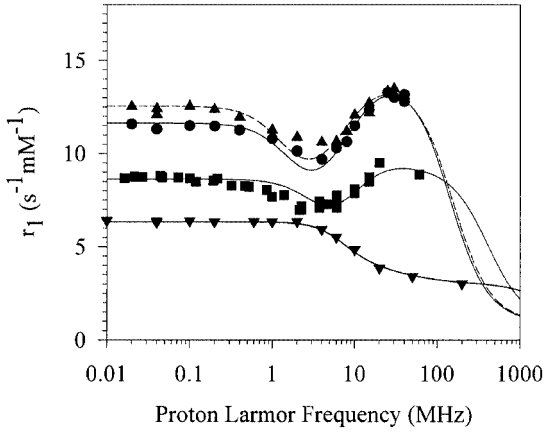

Figure 4. NMRD profile of micellar Gd−DTPA-BC14 (circles), Gd−DTPA-BC16 (triangles up) and Gd−DTPA-BC18 (squares) at 37 °C; the NMRD profile of Gd−DTPA (triangles down) has been added for comparison[47]

The data were analysed by use of the classical inner sphere[35,36] and outer sphere[37] theories. The distance of closest approach was set to 0.36 nm, the relative diffusion constant was fixed to 2.93 10^{-9} m^2s^{-1}, the distance for the inner sphere interaction was set to 0.31 nm, and the number of coordinated water molecule was assumed to be equal to 1 by analogy with other bisamide derivatives of Gd−DTPA.[35,38] The parameters describing the electronic relaxation of Gd (τ_{SO} is the electronic relaxation rate at very low magnetic field and τ_V the correlation time modulating the electronic relaxation) as well as the "global" rotational correlation time (τ_R) and the residence time of the coordinated water molecule (τ_M) were simultaneously fitted. The results are shown in Table 1.

Table 1. Parameters obtained from the theoretical fitting of the proton NMRD data (T = 37 °C)

	τ_R (ns)	τ_M (ns)	τ_{SO} (ps)	τ_V (ps)
Gd−DTPA-BC14	3.05	1300	175	30
Gd−DTPA-BC16	2.97	1280	209	30
Gd−DTPA-BC18	0.62	1470	101	27
Gd−DTPA[a]	0.059	143	82	23
Gd−DTPABMA[b]	0.047	1050	85	24

[a] From ref.[47] τ_R, τ_{SO} and τ_V obtained from the fitting of the proton NMRD data, τ_M obtained from the fitting of the ^{17}O transverse relaxation rates. [b] Calculated at 37 °C with the parameters obtained from the simultaneous fitting of EPR, ^{17}O NMR and NMRD data by Powell et al.[39]

The parameters obtained for Gd−DTPA-BC14 and Gd−DTPA-BC16 are quite similar, with a rotational correlation time of about 3 ns, a value two order of magnitude lower than the rotational correlation time calculated by the Stokes-Einstein theory for a rigid sphere (τ_R ranging between 285 and 675 ns depending on the micelle size). The observed difference can be related to the local motion of the Gd complex within the micellar structure. For micelles made of compound Gd−DTPA-BC18, which contains hydrophobic chains longer than that of DPPC, the fitted τ_R is smaller, indicating an increased local mobility in relation to the other complexes. The τ_M values are similar for the three complexes and larger than for the parent compound Gd−DTPA. Such increases in the residence time of the coordinated water molecule have already been reported for numerous Gd−DTPA bisamide derivatives.[39,40] Moreover, the insertion of both hydrophobic chains of the Gd complex in the micellar structure could also prevent the exchange of the water molecule.

Conclusions

Amphiphilic Gd−DTPA bis(amide) complexes were incorporated into mixed micelles in order to obtain supramolecular structures with decreased mobility. As already reported for other gadolinium complexes incorporated into mixed micelles,[41,42] the relaxivities of the micellar solutions

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the three complexes Gd−DTPA-BC14, Gd−DTPA-BC16 and Gd−DTPA-BC18 are higher than that seen for the hydrophilic Gd−DPTA, as a result of the reduced mobility of the gadolinium complexes. In the case of Gd−DTPA-BC18, the immobilization inside the micellar structure is less effective, probably because the aliphatic chains of the complex are longer than the alkyl chain of DPPC, in which it is inserted. The increase in relaxivity can be related to the lower mobility of the paramagnetic complex inside the micelle. We are currently developing other amphiphilic complexes of gadolinium, which will be incorporated into micelles with the goal of achieving higher increases in relaxivity.

Experimental Section

Chemicals: Reagents were obtained from Aldrich Chemical Co. Inc., Acros Organics and Fluka, and were used without further purification. DTPA was obtained from Koch Light Laboratories. 1,2-Dipalmitoyl-sn-glycero-3-phosphocholine (DPPC) was obtained from Genzyme Pharmaceuticals (Switzerland). Gadolinium chloride hexahydrate was obtained from GFS chemicals (USA).

Instruments: Elemental analysis was performed on a CE Instruments EA-1110 elemental analyser. ^{1}H NMR spectra were run on a Bruker Avance 300, operating at 300 MHz. IR spectra were measured on a Bruker IFS66 FT IR spectrometer, in KBr discs. Mass spectra were run on a Q-tof 2 (Micromass, Manchester UK). Samples for the mass spectra were prepared as follows: the complex (2 mg) was dissolved in methanol (1 mL), and 200 μL of this solution was added to 800 μL of a mixture of a 50:50 water methanol solution. The resulting solution was injected, with a flow rate of 5 μL/min.

Synthesis of the Ligands: DTPA bisanhydride was prepared by the published procedure.[43] DTPA-BC14, DTPA-BC16 and DTPA-BC18 were prepared by the method of Jasanda and Nepveu.[44]

Analytical Data for the Ligands

DTPA-BC14: ^{1}H NMR (CF_3COOD, 298 K, ref. CF_3COOD at δ = 11.62 ppm): δ = 0.88 (t, 6 H, 2 × CH_3), 1.31 (m, 44 H, 22 × CH_2), 1.61 (m, 4 H, 2 × CH_2), 3.39 (t, 4 H, 2 × CH_2), 3.80 (m, 4 H, 2 × CH_2), 4.08 (m, 4 H, 2 × CH_2), 4.14 (s, 2 H, CH_2), 4.52 (s, 4 H, 2 × CH_2), 4.54 (s, 4 H, 2 × CH_2) ppm. IR: $\tilde{\nu}$ = 3350 cm^{-1} (N−H amide), 2960, 2920, 2850 (C−H alkyl), 1655 (CO, amide I), 1625 (COOH), 1550 (amide II). $C_{42}H_{81}N_5O_8$ (784.1): calcd. C 64.33, H 10.41, N 8.93; found C 64.42, H 10.39, N 8.99.

DTPA-BC16: ^{1}H NMR (CF_3COOD, 298 K, ref. CF_3COOD at δ = 11.62 ppm): δ = 0.91 (t, 6 H, 2 × CH_3), 1.34 (m, 52 H, 26 × CH_2), 1.64 (m, 4 H, 2 × CH_2), 3.42 (t, 4 H, 2 × CH_2), 3.88 (m, 4 H, 2 × CH_2), 4.12 (m, 4 H, 2 × CH_2), 4.18 (s, 2 H, CH_2), 4.56 (s, 4 H, 2 × CH_2), 4.58 (s, 4 H, 2 × CH_2) ppm. IR: $\tilde{\nu}$ = 3356 cm^{-1} (N−H amide), 2960, 2918, 2849 (C−H alkyl), 1666 (CO, amide I), 1624 (COOH), 1541 (amide II). $C_{46}H_{89}N_5O_8$ (840.2): calcd. C 65.76, H 10.68, N 8.34; found C 65.80, H 10.64, N 8.35.

DTPA-BC18: ^{1}H NMR (CF_3COOD, 298 K, ref. CF_3COOD at δ = 11.62 ppm): δ = 0.90 (t, 6 H, 2 × CH_3), 1.34 (m, 60 H, 30 × CH_2), 1.63 (m, 4 H, 2 × CH_2), 3.41 (t, 4 H, 2 × CH_2), 3.82 (m, 4 H, 2 × CH_2), 4.11 (m, 4 H, 2 × CH_2), 4.18 (s, 2 H, CH_2), 4.56 (s, 4 H, 2 × CH_2), 4.58 (s, 4 H, 2 × CH_2) ppm. IR: $\tilde{\nu}$ = 3350 cm^{-1} (N−H amide), 2960, 2920, 2850 (C−H alkyl), 1655 (CO, amide I), 1625 (COOH), 1550 (amide II). $C_{50}H_{97}N_5O_8$ (896.3): calcd. C 66.99, H 10.90, N 7.81; found C 66.82, H 10.85, N 7.77.

Synthesis of the Ln^{III} Complexes: All complexes were synthesized by the General Procedure as follows: a solution of hydrated $LnCl_3$ salt (1.1 mmol) in H_2O (1 mL) was added to the ligand (1 mmol) dissolved in pyridine (30 mL), and the mixture was heated at 70 °C for 3 hours. The solvents were evaporated under reduced pressure and the crude product was then heated at reflux in ethanol for 1 hour. After the mixture had cooled to room temperature, the complex was filtered off and dried in vacuo. The absence of free gadolinium was checked with xylenol orange indicator.[45]

Analytical Data for the Ln^{III} Complexes

Gd−DTPA-BC14: $C_{42}H_{78}N_5GdO_8$ (938.4): calcd. C 53.76, H 8.37, N 7.32; found C 53.49, H 8.64, N 7.28. IR: $\tilde{\nu}$ = 3093 cm^{-1} (N−H amide), 2919, 2850 (C−H alkyl), 1667 (CO, amide I), 1617 (COO^- assym. stretch), 1394 (COO^- sym. stretch). ES-MS+: *m/z* = 939 ($[M + H]^+$), 961 ($[M + Na]^+$), 1430 ($[3M + 2Na]^{2+}$).

Eu-DTPA-BC14: $C_{42}H_{80}N_5EuO_9$ (951.1): calcd. C 52.89, H 8.48, N 7.36; found C 53.04, H 8.38, N 7.25. IR: $\tilde{\nu}$ = 3093 cm^{-1} (N−H amide), 2923, 2854 (C−H alkyl), 1631 (CO, amide I), 1600 (COO^- assym. stretch), 1394 (COO^- sym. stretch). ES-MS+: *m/z* = 956.5 ($[M + Na]^+$), 1422 ($[3M + 2Na]^{2+}$), 1890 ($[2M + Na]^+$).

Pr-DTPA-BC14: $C_{42}H_{78}N_5O_8Pr$ (922.0): calcd. C 54.71, H 8.53, N 7.60; found C 55.00, H 8.63, N 7.56. IR: $\tilde{\nu}$ = 3088 cm^{-1} (N−H amide), 2920, 2850 (C−H alkyl), 1640 (CO, amide I), 1600 (COO^- assym. stretch), 1386 (COO^- sym. stretch). ES-MS+: *m/z* = 945 ($[M + Na]^+$), 1405 ($[3M + 2Na]^{2+}$), 1867 ($[2M + Na]^+$).

La-DTPA-BC14: $C_{42}H_{78}LaN_5O_8$ (920.0): calcd. C 54.83, H 8.54 , N 7.61; found C 54.37, H 8.39, N 7.44. IR: $\tilde{\nu}$ = 3089 cm^{-1} (N−H amide), 2926, 2850 (C−H alkyl), 1641 (CO, amide I), 1600 (COO^- assym. stretch), 1386 (COO^- sym. stretch). ES-MS+: *m/z* = 943 ($[M + Na]^+$), 1403 ($[3M + 2Na]^{2+}$), 1862 ($[2M + Na]^+$).

Gd−DTPA-BC16: $C_{46}H_{86}GdN_5O_8$ (994.5): calcd. C 55.56, H 8.72, N 7.04; found C 56.39, H 8.74, N 7.02. IR: $\tilde{\nu}$ = 3093 cm^{-1} (N−H amide), 2960, 2918, 2849 (C−H alkyl), 1666 (CO, amide I), 1624 (COO^- assym. stretch), 1395 (COO^- sym. stretch). ES-MS+: *m/z* = 1017 ($[M + Na]^+$), 1514 ($[3M + 2Na]^{2+}$).

Eu-DTPA-BC16: $C_{46}H_{88}EuN_5O_9$ (1007.2): calcd. C 54.86, H 8.81, N 6.95; found C 54.53, H 8.73, N 6.80. IR: $\tilde{\nu}$ = 3090 cm^{-1} (N−H amide), 2919, 2850 (C−H alkyl), 1635 (CO, amide I), 1601 (COO^- assym. stretch), 1391 (COO^- sym. stretch). ES-MS+: *m/z* = 1035 ($[M + Na]^+$), 1540 ($[3M + 2Na]^{2+}$), 2047 ($[2M + Na]^+$).

Pr-DTPA-BC16: $C_{46}H_{86}N_5O_8Pr$ (978.1): calcd. C 56.49, H 8.86, N 7.16, found C 56.61, H 8.74, N 7.09. IR: $\tilde{\nu}$ = 3094 cm^{-1} (N−H amide), 2921, 2844 (C−H alkyl), 1635 (CO, amide I), 1596 (COO^- assym. stretch), 1395 (COO^- sym. stretch). ES-MS+: *m/z* = 1001 ($[M + Na]^+$), 1490 ($[3M + 2Na]^{2+}$), 1977 ($[2M + Na]^+$).

La-DTPA-BC16: $C_{46}H_{88}LaN_5O_9$ (994.1): calcd. C 55.58, H 8.92, N 7.04; found C 55.50, H 8.73, N 6.90. IR: $\tilde{\nu}$ = 3085 cm^{-1} (N−H amide), 2920, 2850 (C−H alkyl), 1667 (CO, amide I), 1624 (COO^- assym. stretch), 1385 (COO^- sym. stretch). ES-MS+: *m/z* = 999 ($[M + Na]^+$), 1486 ($[3M + 2Na]^{2+}$), 1975 ($[2M + Na]^+$).

Gd−DTPA-BC18: $C_{50}H_{96}GdN_5O_9$ (1068.6): calcd. C 56.14, H 9.05, N 6.55; found C 56.09, H 9.55, N 6.38. IR: $\tilde{\nu}$ = 3094 cm^{-1} (N−H amide), 2960, 2920, 2850 (C−H alkyl), 1633 (CO, amide I), 1596 (COO^- assym. stretch), 1390 (COO^- sym. stretch). ES-MS+: *m/z* = 1073 ($[M + Na]^+$), 1599 ($[3M + 2Na]^{2+}$).

Eu-DTPA-BC18: $C_{50}H_{100}EuN_5O_{11}$ (1099.3): calcd. C 54.62, H 9.16, N 6.37; found C 54.58, H 9.87, N 6.23. IR: $\tilde{\nu}$ = 3105 cm^{-1} (N−H amide), 2916, 2851 (C−H alkyl), 1634 (CO, amide I), 1595 (COO^- assym. stretch), 1386 (COO^- sym. stretch). ES-MS+: *m*/*z* = 1068 ($[M + Na]^+$)

Pr-DTPA-BC18: $C_{50}H_{96}N_5O_9Pr$ (1052.2): calcd. C 57.07, H 9.20, N 6.66; found C 57.46, H 9.19, N 6.57. IR: $\tilde{\nu}$ = 3089 cm^{-1} (N−H amide), 2915, 2844 (C−H alkyl), 1635 (CO, amide I), 1597 (COO^- assym. stretch), 1386 (COO^- sym. stretch). ES-MS+: *m*/*z* = 1057 ($[M + Na]^+$)

La-DTPA-BC18: $C_{50}H_{98}LaN_5O_{10}$ (1068.3): calcd. C 56.22, H 9.24, N 6.56; found C 56.19, H 8.82, N 6.39. IR: $\tilde{\nu}$ = 3083 cm^{-1} (N−H amide), 2925, 2850 (C−H alkyl), 1640 (CO, amide I), 1596 (COO^- assym. stretch), 1385 (COO^- sym. stretch). ES-MS+: *m*/*z* = 1055 ($[M + Na]^+$)

Sodium and Potassium Ion Content Measurements: Before the compounds were used for incorporation into micelles, the potassium and sodium ion contents were checked by flame photometry (IL, 943, Instrumentation Laboratories, Massachusetts, USA). The Na^+ and K^+ ion contents were measured on samples obtained by extraction of the solutions of complex (1.7 mg) dissolved in a 1:1 chloroform/methanol mixture with 500 μL of water. Na^+ contents (mmol:mol of the complex): (Gd−DTPA-BC14) 0.10, (Gd−DTPA-BC16) 0.15, (Gd−DTPA-BC18) 0.15. K^+ contents: no K^+ was found in any of the complexes.

Preparation of Micelles: 1,2-Dipalmitoyl *sn-glycero*-3 phosphatidyl choline (DPPC, 225 mg) and the complex (25 mg) were dissolved in a 1:1 solution of chloroform/methanol (50 mL). Evaporation under reduced pressure yielded a thin film, which was then rehydrated with hot water (5 mL, 70 °C). This solution was sonicated for 15 min with a 70-W sonicator while the temperature was maintained at 65 °C with a thermostatic bath. After the sonication, 75 mg of a surfactant was added (Tween 80® − polyoxyethylene sorbitan monooleate), followed by another 15 minutes of sonication.

Determination of Micelle Size: The mean micelle sizes were determined by photon correlation spectroscopy performed with a BIC multiangle laser light scattering system at room temperature and with a 90° scattering angle (Brookhaven Instruments Corporation, Holtsville, USA). The intensity weighted micellar diameter was measured on diluted suspensions and calculated by a non-negatively constrained least-squares (multiple pass) routine. The diameters obtained are as follows: micelles with (Gd−DTPA-BC14): 15 nm, with (Gd−DTPA-BC16): 20 nm, with (Gd−DTPA-BC18): 19 nm.

T_1 Measurements: Proton Nuclear Magnetic Relaxation Dispersion (NMRD) profiles were recorded between 0.24 mT and 1.2 T with Field Cycling Relaxometers (Field Cycling Systems, Oradell, New Jersey, USA or Stelar Spinmaster FFC-2000, Stelar S.R.L., Mede, Italy) on 0.6 mL solutions contained in 10 mm o.d. tubes. Proton relaxation rates were also measured at 0.47 T and 1.5 T on Minispec PC-120 and mq-60 instruments (Bruker, Karlsruhe, Germany). All samples were diluted 10 times and the temperature was maintained at 37 °C. ^1H NMRD data were fitted according to the theoretical inner-sphere model described by Solomon[35] and Bloembergen[36] and to the outer-sphere contribution described by Freed.[37] Calculations were performed with the aid of previously described software.[46−48]

Adducts of Schiff Bases with Tris(β-diketonato)lanthanide(III) Complexes: Structure and Liquid-Crystalline Behaviour

Koen Binnemans,*[a] Katleen Lodewyckx,[a] Tatjana N. Parac-Vogt,[a] Rik Van Deun,[a] Bart Goderis,[a] Bernard Tinant,[b] Kristof Van Hecke,[a] and Luc Van Meervelt[a]

Keywords: Lanthanides / Liquid crystals / Metallomesogens / Supramolecular chemistry

Adducts of the Schiff base 2-hydroxy-*N*-octadecyloxy-4-tetradecyloxybenzaldimine with tris(β-dibenzoylmethanato)-lanthanide(III) complexes are described. The stoichiometry of the complexes is $[Ln(dbm)_3L_x]$, where Ln is a trivalent lanthanide ion (all lanthanides except Ce and Pm), Hdbm is dibenzoylmethane and L is the Schiff base; x = 2 for Ln = La–Er and x = 1 for Ln = Tm–Lu. The Schiff-base ligands are in a zwitterionic form and coordinate through the phenolic oxygen only. The X-ray single-crystal structure of $[La(dbm)_3L'_2]$ with *L'* = *N*-butyl-2-hydroxy-4-methoxybenzaldimine is described. The solution structure of lanthanum(iii) complexes has been investigated by 1D and 2D ^{1}H NMR techniques. Although the long-chain Schiff-base ligand and the tris(β-dibenzoylmethanato)lanthanide(III) complexes are non-mesomorphic, some of the adducts exhibit a monotropic smectic A phase. The mesomorphic behaviour depends on the lanthanide ion, in the sense that only a mesophase is observed for the series Ln = La–Eu, not for the heavier lanthanides.

Introduction

Tris(β-diketonato)lanthanide(III) complexes are well-known as NMR shift reagents.[1−3] Examples are $[Pr(fod)_3]$ and $[Eu(fod)_3]$ (fod = anion of 6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedione). The shift of the proton resonances is related to the fact that organic molecules with free electron pairs (i.e. Lewis bases) can form adducts with the tris-β-diketonate complexes of paramagnetic and magnetically anisotropic lanthanide(III) ions. The coordination sphere of the lanthanide ion in a tris(β-diketonato)lanthanide(III) complex is unsaturated, since the coordination number of the metal ion in these complexes is only six, whereas lanthanide ions prefer to be coordinated to eight or nine donor atoms.[4] The lanthanide ion in the tris-β-diketonate complexes can expand its coordination sphere by forming adducts with neutral molecules containing oxygen- or nitrogen-donor atoms. Such a molecule can be water, and therefore the tris(β-diketonato)lanthanide(III) complexes can easily be transformed into bis(hydrates). However, polydentate ligands (e.g. 1,10-phenanthroline) can replace water in the first coordination sphere, and the resulting lanthanide complexes often show a strong photoluminescence. A typical example of a luminescent lanthanide complex is $[Eu(tfa)_3(phen)]$, (tta = anion of thenoyltrifluoroacetone, phen = 1,10-phenanthroline).[5−7] These luminescent complexes can find application in organic light-emitting diodes (OLEDs).[8] Binnemans and Moors have shown that Lewis-base adducts of tris(β-diketonato)lanthanide(III) complexes can be doped into a nematic liquid-crystal mixture to obtain luminescent liquid crystals.[9] Hapiot and co-workers obtained similar results by doping cholesteryl alkanoate adducts of $[Eu(tta)_3]$ into a cholesteric liquid crystal.[10,11] Of course, it would be interesting to design lanthanide β-diketonate complexes that exhibit a liquid-crystalline phase themselves, rather than relying on host-guest systems. Earlier trials to prepare liquid-crystalline lanthanide complexes with β-diketonate ligands were unsuccessful,[12] but recently two new independent approaches gave encouraging results. Galyametdinov and co-workers made monotropic liquid-crystalline lanthanide complexes starting from mesomorphic β-diketone ligands.[13] Binnemans and Lodewyckx reported in a communication on a monotropic smectic A mesophase in adducts of salicylaldimine Schiff bases to $[Ln(dbm)_3]$ complexes (dbm = anion of dibenzoylmethane).[14] In these compounds, neither the Schiff base nor the tris(β-diketonato)lanthanide(III) complex exhibit a mesophase, but the resulting bisadducts are liquid crystalline. It should be noted that the Schiff bases are the same as the ones which have been used in the past to synthesise liquid-crystalline lanthanide complexes with Schiff-base ligands.[15−18]

In the work of Binnemans and Lodewyckx,[14] the compounds were not structurally characterised, and the mesophase was investigated by polarising optical microscopy

only. In this paper, we give a detailed description of the structural and thermal properties of Schiff-base adducts of tris(dibenzoylmethanato)lanthanide(III) complexes. The crystal structure of an adduct of a Schiff base with short alkyl chains to $[La(dbm)_3]$ is described. The solution structure of diamagnetic complexes was investigated by 1D and 2D ^1H NMR methods. A series of compounds was prepared in order to investigate the influence of the lanthanide ion on the thermal properties (Figure 1). The thermal behaviour of the lanthanide complexes was investigated by polarising optical microscopy (POM), differential scanning calorimetry (DSC) and by time-resolved temperature-dependent synchrotron X-ray diffraction measurements at the DUBBLE-beamline of the ESRF (Grenoble, F).

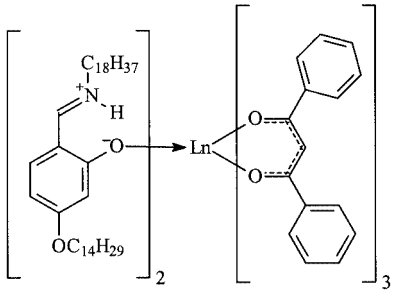

Figure 1. Schematic structure of the $[Ln(dbm)_3L_2]$ complexes

Results and Discussion

Synthesis

The Schiff-base ligands were prepared according to a literature method.[15] The tris(dibenzoylmethanato)lanthanide(III) complexes were synthesised in an ethanolic solution by first transforming dibenzoylmethane Hdbm (1,3-diphenyl-1,3-propanedione) into its sodium salt by reaction with sodium hydroxide. Secondly, the tris complexes were precipitated out of solution by addition of an aqueous solution of the corresponding lanthanide nitrate to the solution of the sodium salt of dibenzoylmethane. After drying the tris(dibenzoylmethanato)lanthanide(III) complex in a vacuum oven, the anhydrous compound was redissolved in absolute ethanol and added to two equivalents of the Schiff base dissolved in absolute ethanol. The adducts precipitated immediately. All the adducts were bisadducts (two Schiff bases bound to one lanthanide ion) whereas monoadducts were obtained for the lanthanide ions at the end of the series: thulium, ytterbium and lutetium. These ions have the smallest ionic radii among the trivalent lanthanide ions and therefore show less tendency to expand their coordination sphere. The complexes were characterised by CHN analysis and by infrared spectroscopy. The main difference between the mono- and the bis adducts is the position of the C=N stretching vibration: 1604−1606 cm^{-1} for the monoadducts and 1647−1653 cm^{-1} for the bis adducts. The stoichiometry of the complexes was not influenced by the ratio $[Ln(dbm)_3]/L$. We worked with a 1:1 ratio, so that $[Ln(dbm)_3]$ was present in excess. Complexes of all the lanthanide ions except cerium and promethium were prepared. Additionally, the lanthanum complex of the small Schiff-base ligand with methoxy and butyl chain (*N*-butyl-2-hydroxy-4-methoxybenzaldimine) was prepared for the growth of single crystals.

Crystal Structure

The X-ray single-crystal structure of $[La(dbm)_3L'_2]$ with L′ = *N*-butyl-2-hydroxy-4-methoxybenzaldimine was determined (Figure 2). According to the crystal structure, the Schiff bases coordinate as neutral ligands to the La^{III} ion i.e. the oxygen atoms of the OH group are deprotonated and the hydrogen atoms have been transferred to the nitrogen atoms. As a consequence, a zwitterionic structure (negative charge on the oxygen atom, positive charge on the imine nitrogen atom) is generated. The coordination polyhedron of the La^{III} ion, which can be described as a distorted bicapped trigonal prism, is built up of eight oxygen atoms (six oxygen atoms of the three dibenzoylmethanato ligands and two oxygen atoms of the two Schiff bases). Intramolecular N−H···O hydrogen bonds appear between the protonated nitrogen and the deprotonated oxygen atoms [average H···O distance: 1.989(8) Å]. One hydrogen (on N63) forms a second, but longer, H bond with an oxygen atom (O23) of a dibenzoylmethanato ligand [H···O distance: 2.429(5) Å]. The dihedral angle between the phenyl rings of the two Schiff-base ligands is 87.2(2)°, so the phenyl rings are positioned nearly perpendicular to each other. Both butyl chains of the Schiff bases are in the all-*trans* conformation. The dibenzoylmethanato ligands are considerably distorted: the maximum dihedral angle observed between two phenyl planes of this ligand is 24.0(2)°. A

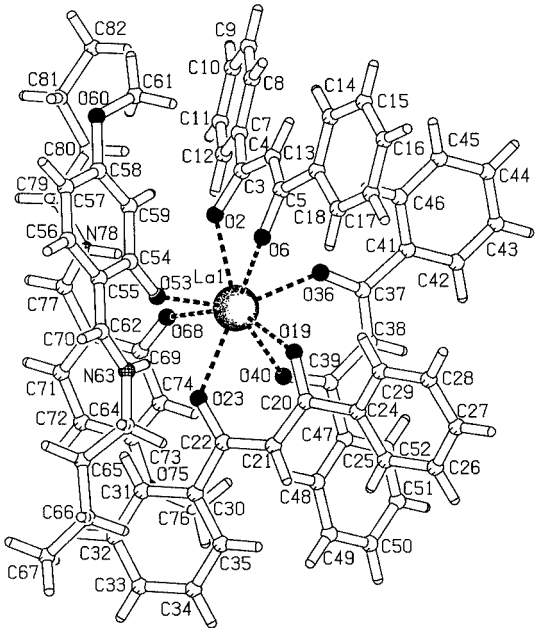

Figure 2. Molecular structure of $[La(dbm)_3L'_2]$, where L′ = *N*-butyl-2-hydroxy-4-methoxybenzaldimine

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

slight stacking of phenyl rings is noticed in the packing: the shortest ring···ring distance [3.948(3) Å] is found between ring C41−C46 and ring C47−C52 of a symmetry-related complex generated by [1 − *x*, 1 − *y*, 1 − *z*]. A void of 100 Å^3 at position (0, 1/2, 1/2) contains diffuse solvent.

Structure in Solution

The coordination mode of the lanthanide ion in solution was examined by measuring one- and two-dimensional proton NMR spectra of the [La(dbm)$_3$] and [La(dbm)$_3$L$_2$] complexes (L = 2-hydroxy-*N*-octadecyloxy-4-tetradecyloxybenzaldimine) and comparing them with the ^{1}H NMR spectra of the Schiff-base ligand L and the β-diketone Hdbm. A list of all NMR resonances is given in the Exp. Sect. The proton resonances of the free ligands are sharp and show the expected splitting pattern, with the exception of the phenolic proton resonance of L, which is extremely weak and broad, due to its fast exchange with the solvent. Surprisingly, the ^{1}H NMR spectrum of the [La(dbm)$_3$L$_2$] complex at room temperature shows that the proton resonances of the dbm ligand appear as broad humps, while the proton resonances of the Schiff base L in [La(dbm)$_3$L$_2$] appear as well-resolved peaks (Figure 3). The dbm proton resonances are also very broad in the parent [La(dbm)$_3$] complex, implying either the presence of different conformers in the solution which undergo dynamic exchange, or the presence of two different modes of dbm binding to the La^{III} ion. Variable temperature ^{1}H NMR spectra of both [La(dbm)$_3$] and [La(dbm)$_3$L$_2$] complexes were measured in order to investigate the dynamic process which leads to the broadening of the dbm resonances. When the temperature of the [La(dbm)$_3$] solution was lowered to 258 K, two resolved sets of dbm peaks could be detected. The larger set of peaks, at δ = 6.85, 7.42, 7.92 and 15.52 ppm, was assigned to the free Hdbm ligand, which was confirmed by independently recording the ^{1}H NMR spectrum of the free Hdbm ligand at the same temperature. Clearly, at low temperatures the dissociation of the [La(dbm)$_3$] takes place, and at 258 K almost 95% of the complex is dissociated. However, in the [La(dbm)$_3$L$_2$] complex, dissociation at low temperatures occurs to a much smaller extent, and at 258 K only about 10% of the Hdbm ligand is dissociated from the La^{III} ion. It is likely that the adduct formation with the L ligand stabilises the binding of dbm to the central lanthanide ion.

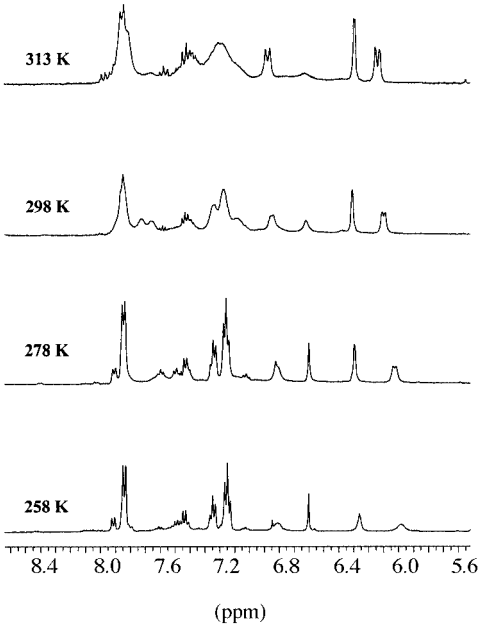

Figure 3. ^{1}H NMR spectra (400 MHz) of [La(dbm)$_3$L$_2$] in CD_2Cl_2 at different temperatures; at 313 K, the aromatic resonances of Schiff-base ligand L appear at δ = 6.16, 6.29 and 6.87 ppm; the broad humps at ca. δ = 6.65, 7.20 and 7.85 ppm belong to the diketonate ligand

The solid-state structure of the [La(dbm)$_3$L′$_2$] complex reveals the presence of intramolecular hydrogen bonding in the Schiff-base ligand. This hydrogen bonding, which occurs between the phenolic oxygen and the protonated imino nitrogen, is also found in solution. A strong, broad peak at δ = 13.3 ppm, which occurs upon complexation of the Schiff base to La^{III}, is a clear indication of the hydrogen bonding. Although the solid state structure of [La(dbm)$_3$L$_2$] suggests that the ligand L binds in a zwitterionic form, the two-dimensional ^{1}H NMR correlation spectroscopy (COSY), which was successfully used to confirm the presence of zwitterionic form of the Schiff ligand in related [LnL$_3$Cl$_3$] complexes,[19] gave no evidence that in the solution the phenolic proton has been completely transferred to the imino nitrogen. The absence of coupling between the proton at δ = 13.3 ppm and either the CH=N or N−CH$_2$ protons suggests that two extreme forms are in fast exchange: one in which the proton is bound to the phenolic oxygen, and the other in which this proton has been completely transferred to the imino nitrogen. Due to this exchange process, which takes place in the complex in solution, the N−**CH$_2$** protons appear as a broad peak (*FWHM* = 31 Hz). Even at 258 K this exchange is too fast on the NMR time scale for the two extreme forms to be distinguished by 2D COSY NMR spectroscopy.

Thermal Properties

The thermal behaviour of the complexes [Ln(dbm)$_3$L$_x$] was investigated by differential scanning calorimetry (DSC), polarising optical microscopy (POM) and high-temperature X-ray diffraction in a time-resolved mode. It should be noticed that neither L or [La(dbm)$_3$] are mesomorphic: the melting point of L is 73 °C and [La(dbm)$_3$] decomposes when heated in air.

Upon heating, [La(dbm)$_3$L$_2$] melts at 95 °C to an isotropic liquid. Upon cooling, a monotropic mesophase is formed at 81 °C. This mesophase was identified as a smectic A phase (SmA) by the typical defect texture (Figure 4): when cooling the isotropic liquid, bâtonnets formed at the clearing point and they coalesced to the focal-conic texture (fan texture). The rather low viscosity of the mesophase gives an indication that a real mesophase is present and not a plastic crystal phase. The mesophase ordering could be frozen into a glassy state. In the mesophase, the X-ray diffractograms show sharp Bragg reflections in the small angle region. The *d*-spacing values are in the ratio 1:1/2:1/3...1/*n*,

pointing to the presence of a lamellar structure. In most of the measurements only the first-order peak and a very weak second-order peak are observable. Higher orders can be detected after longer measuring times. The *d*-spacing does not show a pronounced temperature dependence. The broad halo in the wide angle region (at $d = 4.6$ Å) shows that the alkyl chains are in a molten state. These results support identification of the phase as a smectic A phase. The *d*-spacing (ca. 27.0 Å) is much smaller than the calculated length (45.5 Å) of the Schiff-base ligand in the fully extended (all-*trans*) conformation. The most probable explanation is an interdigitation of the alkyl chains of molecules situated in adjacent smectic layers, as this is an efficient way of space filling. No major changes are seen in the X-ray diffractograms when the sample is cooled to room temperature. This is an indication that the mesophase order is frozen into a glassy state and is in agreement with the observations made on the polarising optical microscope. X-ray diffractograms of $[La(dbm)_3L_2]$ at different temperatures are shown in Figure 5.

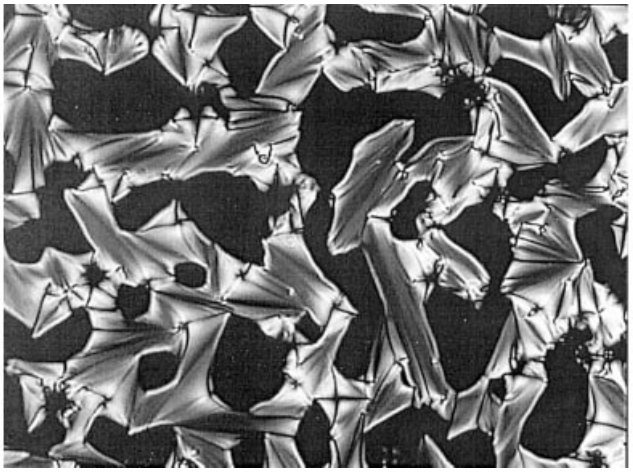

Figure 4. Texture observed for the smectic A mesophase of $[La(dbm)_3L_2]$ at 81 °C (clearing point)

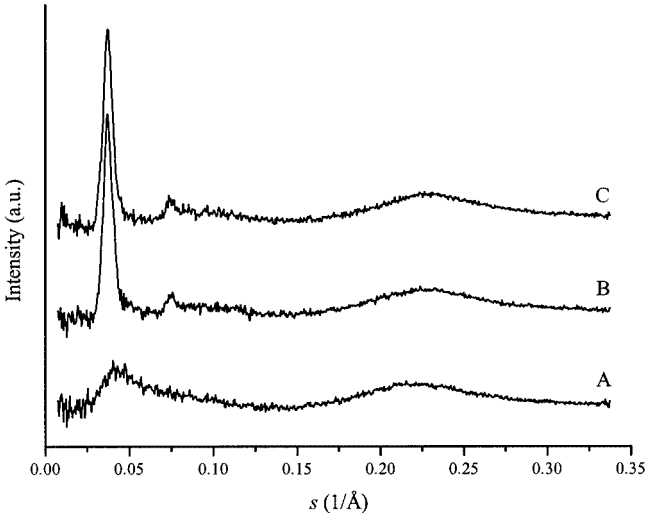

Figure 5. X-ray diffractograms for $[La(dbm)_3L_2]$. A: in isotropic liquid, B: in mesophase, C: at room temperature

The thermal behaviour of the complexes $[Ln(dbm)_3L_2]$ (Ln = Pr, Nd, Sm, Eu) resembles that of $[La(dbm)_3L_2]$ (Table 1). Hardly any variation is observed for the melting point and all these complexes form a monotropic smectic A phase. However, the temperature interval between the melting point and the clearing point becomes larger and larger when the size of the lanthanide ion decreases: $\Delta T =$ 12 °C for $[La(dbm)_3L_2]$, but $\Delta T = 30$ °C for $[Eu(dbm)_3L_2]$. The compounds of the heavier lanthanides do not form a mesophase; crystallisation occurs before a mesophase can be formed. It was difficult to decide whether or not $[Gd(dbm)_3L_2]$ and $[Tb(dbm)_3L_2]$ exhibit a mesophase, because bâtonnet-like features were observed during cooling of the melt. However, these features turned out to be very fine crystals floating in the melt. In contrast, $[Dy(dbm)_3L_2]$ and the other compounds in the lanthanide series did exhibit fast crystallisation without first forming tiny crystals. The melting point gradually decreases over the lanthanide series, with a discontinuity between Er^{III} and Tm^{III}. This can be attributed to the fact that a change in stoichiometry occurs between Er^{III} and Tm^{III} in the sense that the compounds at the end of the series contain only one Schiff-base ligand, not two.

Table 1. Transition temperatures of the $[Ln(dbm)_3L_x]$ complexes ($x = 2$ for La−Er, $x = 1$ for Tm-Lu)

Ln	Transition[a]	Temperatures (°C)
La	Cr → I	95
	I → SmA	81
Pr	Cr → I	94
	I → SmA	75
Nd	Cr → I	93
	I → SmA	71
Sm	Cr → I	93
	I → SmA	64
Eu	Cr → I	90
	I → SmA	60
Gd	Cr → I	86
Tb	Cr → I	80
Dy	Cr → I	74
Ho	Cr → I	72
Er	Cr → I	67
Tm	Cr → I	73
Yb	Cr → I	72
Lu	Cr → I	69

[a] Cr = crystalline solid; I = isotropic liquid; SmA = smectic A mesophase

These compounds are of special importance, because they form a quite unusual class of metal-containing liquid crystals (metallomesogens). It is a paradigm in metallomesogen research that in order to obtain high coordination number calamitic metallomesogens, one needs to make ligands with a very extended rigid rod-like core, or to incorporate a large number of long terminal alkyl chains.[20] None of the conditions is fulfilled in the case of the metal complexes described in this study, but nevertheless we observed a well-characterised low viscous mesophase for several of our compounds. Even more remarkable is the fact that although the size of the $[Ln(dbm)_3]$ complexes are not

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

much less than that of fullerene C_{60}, it is much easier to induce a mesophase in the lanthanide complexes.[21,22] Of course, however, the [Ln(dbm)$_3$] complexes are not as space-filling as C_{60}, in the sense that free space is present between the dibenzoylmethane rings.

Conclusions

The tris(dibenzoylmethanato)lanthanide(III) complexes can form Lewis-base adducts with long-chain salicylaldimines. The number of Schiff bases bound to a metal complex depends on the size of the lanthanide ion: two for most of the lanthanides and one for the ions at the end of the lanthanide series (Tm, Yb, Lu). The molecular structure and crystal structure of an adduct of [La(dbm)$_3$] with a short-chain Schiff base were determined, and this shows that the Schiff bases line up parallel to one another. Both the X-ray crystal structure and NMR spectroscopic data show that the Schiff base in the adducts is present in a zwitterionic form. Both the stoichiometry and the thermal behaviour of the complexes depend on the size of the lanthanide ion. The complexes [Ln(dbm)$_2$L$_2$] of the series Ln = La−Eu exhibit a monotropic smectic A phase. The temperature difference between the melting point and the clearing point of the monotropic mesophase increases over the lanthanide series. The complexes of the heavier lanthanides are not liquid-crystalline. Having determined the influence of the lanthanide ion on the thermal behaviour, further studies will focus on the influence of length of the alkyl and alkoxy chain of the Schiff base and on the influence of the type of 1,3-diketone.

Experimental Section

General: ^{1}H NMR spectra were recorded with a Bruker Avance 300 and a Bruker AMX-400 spectrometer. In variable-temperature experiments the temperature error was within 0.1 K. Two-dimensional correlation spectroscopy (COSY) was used as a tool to confirm the assignment of the proton resonances. CHN elemental analyses were performed on a CE Instruments EA-1110 elemental analyser. FTIR spectra were recorded with a Bruker IFS-66 spectrometer, using the KBr pellet method. The optical textures of the mesophase were observed with an Olympus BX60 polarised optical microscope equipped with a Linkam THMS-600 hot stage and a Linkam TMS-93 programmable temperature-controller. Synchrotron X-ray measurements were made on the DUBBLE-beam line (BM26) at the European Synchrotron Radiation Facility (ESRF) in Grenoble (France).[23,24] Intensities at scattering angles between 0.134° and 6.00° were collected with a quadrant-type detector at 0.70 m from the sample.[25] Distances in real space between 133 and 2.97 Å could be covered by using an X-ray wavelength of 0.62 Å (E = 20 keV). Flat samples of 1 mm thick, placed in a brass mould and covered by aluminium foil, were mounted in a Linkam THMS600 hot stage for temperature control. The heating rate used was 10 °C min^{-1} throughout. Scattering patterns were collected sequentially for six seconds, corresponding to one pattern for each degree centigrade in the temperature ramp. The scattering angles were calibrated using the reflections of silver behenate at room temperature. No corrections were performed to account for the use of a flat detector. Data were corrected for the detector response and normalised to the intensity of the primary beam, measured at the detector position. For data reduction the XOTOKO program was used.[26]

Crystallography: Yellow crystals of [La(dbm)$_3$L′$_2$] were obtained by slow evaporation of a solution of the complex in a CH_2Cl_2/EtOH mixture. A crystal of dimensions 0.25 × 0.15 × 0.10 mm^3 was mounted in a nylon loop for data collection at 110 K on a MAR diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) and which was equipped with a 300 mm imaging plate detector. The images were interpreted and intensities integrated with the program DENZO.[27] The structure was solved by direct methods and refined by full-matrix least-squares on F^2 using the SHELXTL program package.[28] Non-hydrogen atoms were refined anisotropically and the hydrogen atoms in the riding mode with isotropic temperature factors fixed at 1.2-times U(eq) of the parent atoms (1.3-times for methyl groups). The disordered solvent in the void of 100 Å^3 at position 0, 1/2, 1/2 was modelled with SQUEEZE[29] (contribution of 13 electrons). Data: formula: $C_{69}H_{67}LaN_2O_{10}$; M_r = 1223.16; crystal system: triclinic, space group $P\bar{1}$, a = 10.9860(5), b = 15.4480(8), c = 19.1880(9) Å, α = 108.840(3), β = 94.240(3), γ = 103.960(4)°, V = 2949.8(2) Å^3, Z = 2; F(000) = 1264, $\rho_{calcd.}$ = 1.377 g cm^{-3}, μ = 0.786 mm^{-1}, $2\theta_{max}$ = 52.9°. No. of data collected = 34983, no. of unique data = 11756 (R_{int} = 0.075), no. of parameters refined = 744; R_1 = 0.0515 for 10049 observed reflections [$F_o > 4\sigma(F_o)$], ωR_2 = 0.1360 for all data {weighting scheme $w^{-1} = \sigma^2(F_o^2) + (0.0632P)^2 + 4.2517P$, where $P = [\max(F_o^2,0) + 2F_c^2]/3$}, S = 1.085, maximum positive and negative peaks in final difference Fourier map: 1.06 and −1.59 e·Å^{-3}. CCDC-194640 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.uk).

Synthesis of Schiff-Base Ligand L (R = C$_{14}$, R′ = C$_{18}$): 2-Hydroxy-4-tetradecyloxybenzaldehyde was prepared by refluxing 2,4-dihydroxybenzaldehyde (0.1 mol, 13.82 g) with 1-bromotetradecane (0.1 mol, 27.73 g) in DMF for 4 hours, with $KHCO_3$ (0.1 mol, 10.01 g) as the base. After leaving to cool to room temperature, the reaction mixture was poured into an aqueous HCl solution (6 N). The organic layer was separated and the aqueous layer was extracted with diethyl ether. The combined organic layers were dried over anhydrous $MgSO_4$ and the solvent was removed under reduced pressure. The crude aldehyde was purified by crystallisation from hot acetonitrile. Yield: 73% (24.33 g). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.90 (t, 3 H, CH_3), 1.02−1.60 (m, 22 H, CH_2), 1.80 (m, 2 H, CH_2−CH_2−O), 4.00 (t, 2 H, CH_2-O), 6.40 (d, 1 H, H-aryl), 9.70 (s, 1 H, CH=O) ppm. J_o = 8.5, J_m = 2.5 Hz.

The Schiff-base ligand was prepared by refluxing 2-hydroxy-4-tetradecyloxybenzaldehyde (0.05 mol, 16.72 g) with *n*-octadecylamine (0.05 mol, 13.45 g) in toluene for 3 hours. A Dean−Stark trap was used to extract the released water and a few drops of glacial acetic acid (catalyst) were added. The solvent was evaporated and the crude product was crystallised from absolute ethanol. Yield: 93% (27.20 g). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.88 (t, 6 H, CH_3), 1.10−1.50 (m, 52 H, CH_2), 1.67 (m, 2 H, N−CH_2−CH_2), 1.77 (m, 2 H, CH_2−CH_2−O), 3.50 (t, 2 H, N−CH_2), 3.96 (t, 2 H, CH_2−O), 6.32 (dd, 1 H, H-aryl), 6.36 (d, 1 H, H-aryl), 7.06 (d, 1 H, H-aryl), 8.08 (s, 1 H, CH=N), 14.1 (s, 1 H, OH) ppm. J_o = 8.5,

J_m = 2.5 Hz. $C_{39}H_{71}NO_2$ (585.99): calcd. C 79.94, H 12.21, N 2.39; found C 80.05, H 12.12, N 2.17.

Synthesis of [La(dbm)$_3$]: An aqueous solution of $La(NO_3)_3{\cdot}6H_2O$ (0.01 mol, 4.33 g) was added to a solution of dibenzoylmethane (0.01 mol, 2.24 g) in ethanol and 10 mL of $NaOH_{aq}$ (1 M). The mixture was stirred overnight, and then filtered and dried in vacuo. Yield: 85% (6.84 g). $C_{45}H_{33}LaO_6$ (808.7): calcd. C 66.84, H 4.11; found C 67.02, H 4.27.

Synthesis of [La(dbm)$_3$(L)$_2$]: A solution of [La(dbm)$_3$] (3 mmol; 2.42 g) in absolute ethanol was added dropwise to a solution of 2-hydroxy-*N*-octadecyloxy-4-tetradecyloxybenzaldimine (L) (3 mmol; 1.76 g) in absolute ethanol at 50 °C. The adduct precipitated immediately. After the mixture had been stirred overnight at room temperature, the precipitate was filtered off, washed with ethanol and dried in vacuo. The compound was obtained as a pale-yellow powder. Yield: 91% (2.72 g). IR (KBr): $\tilde{\nu}$ = 1654 (C=N, str.), 1552 (C=O, str.) cm^{-1}. $C_{123}H_{175}LaN_2O_{10}$ (1980.6): calcd. C 74.57, H 8.91, N 1.42; found C 74.74, H 8.97, N 1.30.

For further details of yields, elemental analysis and spectral data of the complexes, see Supporting Information (see also the footnote on the first page of this article).

Acknowledgments

KB, RVD and BG are Postdoctoral Fellows of the Fund for Scientific Research-Flanders (Belgium). Funding by the K.U.Leuven (GOA, 03/03 and a PhD grant to KL) and by the F.W.O.-Vlaanderen (G.0117.03) is gratefully acknowledged. CHN microanalyses were performed by Ms. P. Bloemen. KB, KL and BG thank FWO-Flanders and prof. H. Reynaers for their continuous support of the DUBBLE project. I.P. Dolbnya (DUBBLE, ESRF, Grenoble) assisted at the synchrotron X-ray measurements.

Radical Ion Salts Obtained from Substituted Ferrocene Cations and the Organic Acceptor TCNQ − Synthesis, Structure and Physical Properties

Loreto Ballester,[a] Ana M. Gil,[a] Angel Gutiérrez,*[a] M. Felisa Perpiñán,[a] Ana E. Sánchez,[b] Marina Fonari,[c] Kinga Suwinska,[d] and Vitalii Belsky[e]

Keywords: Metallocenes / Radical ions / Stacking interactions / Supramolecular chemistry

The compounds $[Fe(C_5H_5)(C_5H_4CH_2NMe_3)][TCNQ]$ (**1**), $[Fe(C_5H_5)(C_5H_4CH_2NMe_3)][TCNQ]_2{\cdot}MeCN$ (**2**) and $[Fe(C_5H_5)(C_5H_4CH{=}CH\text{-}p\text{-}C_5H_4NMe)][TCNQ]$ (**3**) have been obtained from reaction of the corresponding ferrocene iodide and TCNQ or LiTCNQ. Their crystal structures have been determined, showing that **1** and **3** have only mononegative TCNQ radicals forming one-dimensional stacks. In compound **3** the pyridine substituent also overlaps with the stacked TCNQ. The formation reaction of **2** implies the reduction of neutral TCNQ by the iodide anion; in this reaction the reduction is partial and the formal charge of every TCNQ is approximately 0.5 e^- with some degree of electron delocalization. The TCNQs also overlap to form a one-dimensional stack in the solid. The three compounds are diamagnetic, indicating a strong antiferromagnetic coupling between the TCNQ spins.

Introduction

Charge-transfer salts of substituted ferrocenes with organic polynitriles have been extensively studied following the report of the bulk ferromagnetic behavior of $[Fe(C_5Me_5)_2][TCNE]$ (TCNE= tetracyanoethylene).[1] Although this is the best known derivative several other examples show a wide range of properties and stoichiometries. For example, the previously synthesized analogue $[Fe(C_5H_5)_2][TCNE]$[2−5] has a similar crystal structure, showing 1D stacks of alternating ferrocene and TCNE units, but it is, however, diamagnetic due to the higher oxidation potential of the unsubstituted ferrocene, which can not reduce the tetracyanoethylene. Consequently, the stack should be viewed as a charge-transfer complex for $[Fe(C_5H_5)_2][TCNE]$, with essentially neutral ferrocene and TCNE molecules but as an ionic salt for $[Fe(C_5Me_5)_2][TCNE]$, with alternating ferrocenium cations and $TCNE^-$ anions.[6]

The derivative with TCNQ (7,7,8,8-tetracyanoquinodimethane), $[Fe(C_5Me_5)_2][TCNQ]$, exhibits an equivalent structure, with alternating ions along the stack, and shows metamagnetic behavior.[7−8] Another phase with the same composition shows isolated dimeric $[TCNQ]_2^{2-}$ anions, with paramagnetic behaviour,[9] and a third phase with ferromagnetic behavior has a packing similar to that of the metamagnetic phase.[10] Another derivative, of formula $[Fe(C_5Me_5)_2][TCNQ]_2$, is conducting and shows a one-dimensional stack of acceptors.[11]

This variety of structural motifs and properties shows how subtle changes in electronic density or in the interionic interactions can influence the bulk properties of the material. A degenerate ground state is a necessary but not sufficient condition to obtain cooperative magnetic properties, implying the use of symmetrical ferrocenes.[12] In this way examples of ferromagnetic coupling in the stacks but without three-dimensional ferromagnetic ordering have been found in $[Fe(C_5Me_4H)_2][TCNE]$,[13] $[Fe(C_5Me_4H)_2][TCNQ]$,[13] $[Fe(C_5Me_5)_2][TCNQI_2]$,[14] or $[Fe(C_5Et_5)_2][TCNQ]$.[15] By using the stronger acceptor perfluorotetracyanoquinodimethane ($TCNQF_4$), dimerization of the anion radical similar to that in the paramagnetic phase of $[Fe(C_5Me_5)_2][TCNQ]$[9] has been observed for $[Fe(C_5Me_5)_2][TCNQF_4]$[16] and $[Fe(C_5Et_5)_2][TCNQF_4]$.[17]

Contrarily, with less symmetrically substituted ferrocenes the steric effects and intermolecular interactions determine

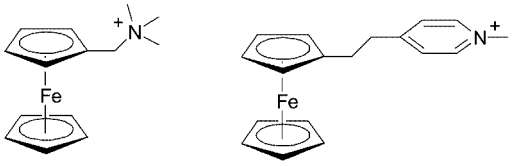
the structural motif and the crystal packing. In this way several examples of TCNQ derivatives have been obtained. The bridged ferrocenyl $[Fe(C_5H_4)_2(CH_2)_3][TCNQ]_2$ shows dimeric anions $[TCNQ]_2^-$ stacked in non-uniform columns.[18] Substituted ferrocenes having π delocalization can overlap the π system of the TCNQ, orientating the acceptor molecules in the stack. Thus, for $[Fe(C_5H_4R)_2][TCNQ]_2$, R = CH=CHC$_6$H$_4$-*p*-SMe, the crystal structure is described as an alternating stack of TCNQ and the phenyl rings of the ferrocene substituents, giving rise to an insulating, diamagnetic derivative.[19] Similar structural features are found in $[Fe(C_5H_5)(C_5H_4CH{=}CH\text{-}9\text{-}C_{16}H_9)][TCNQ]$ with pyrene acting as both a substituent on the cyclopentadienyl ring and overlapping with the TCNQ, which remains essentially neutral.[20]

Of more interest, structurally, are compounds obtained with octamethylferrocenyl thioethers, $[Fe(C_5Me_4SR)_2]$, R = Me, *t*Bu, and TCNQ or $TCNQF_4$,[21] of which $[Fe(C_5Me_4SMe)_2]_3[TCNQ]_7$ and $[Fe(C_5Me_4S\textit{t}Bu)_2][TCNQ]_3$ show a TCNQ stack with electronic delocalization and semiconducting behaviour, while $[Fe(C_5Me_4SR)_2][TCNQF_4]$ derivatives consist of anionic dimers $[TCNQF_4]_2^{2-}$.

In designing molecular solids by controlling the crystal packing the distribution of electrostatic interactions is important. In this way we have studied the reactions of positively charged substituted ferrocenes with either neutral or anionic TCNQ. The cationic ferrocenes used are $[Fe(C_5H_5)(C_5H_4CH_2NMe_3)]^+$ and $[Fe(C_5H_5)(C_5H_4CH{=}CH\text{-}p\text{-}C_5H_4NMe)]^+$, both as iodide salts.



Our objective is to use these ferrocenes to build up a net of positive charges that will control the TCNQ stacking through electrostatic interactions. The size and orientation of the ferrocene cations can control the number of TCNQ units that will stack, thus inducing either the localization or the partial delocalization of electronic charges on the TCNQs. We have previously observed several examples of this modulation of charges, which gives rise to different degrees of electronic delocalization that depend on the size and packing of the counterion.[22–23]

We chose ferrocene cations as iodide salts so as to use the counterion to change the oxidation state of the TCNQ molecules involved; the half-reaction potential I_2/I^- is similar to that of TCNQ and the equilibrium $TCNQ^0 + I^- \rightleftarrows TCNQ^- + 1/2I_2$ can easily be displaced in either direction, depending on factors such as differences in solubilities of the products formed or addition of any reagents to the reaction mixture. Thus, the reaction on the right-hand side of the equilibrium is the usual method of preparing the anion radical as its lithium salt.[24] We have used the reverse reaction in forming [Cu(cyclam)(TCNQ)$_2$][TCNQ] (cyclam: 1,4,8,11-tetraazacyclotetradecane), which has one neutral and two anionic TCNQ units, from [Cu(cyclam)(TCNQ)$_2$] and I_2.[25]

The cationic charge in the ferrocene allows us to obtain derivatives of anionic TCNQ, either by iodide metathesis or by reduction from the neutral acceptor, but without any charge transfer that implies the iron atom.

Results and Discussion

The metathesis reaction of $[Fe(C_5H_5)(C_5H_4CH_2NMe_3)]^+I^-$ and LiTCNQ involves displacement of the iodide anion and crystallization of $[Fe(C_5H_5)(C_5H_4CH_2NMe_3)][TCNQ]$ (**1**). However, in the reaction of the same ferrocene salt with neutral TCNQ partial reduction of the organic molecule occurs and the derivative $[Fe(C_5H_5)(C_5H_4CH_2NMe_3)][TCNQ]_2{\cdot}MeCN$ (**2**) is formed. Since the reaction takes place in a 1:1 ratio only half of the TCNQ molecules are reduced by the iodide.

When the ferrocene salt $[Fe(C_5H_5)(C_5H_4CH{=}CH\text{-}p\text{-}C_5H_4NMe)]^+I^-$ is used $[Fe(C_5H_5)(C_5H_4CH{=}CH\text{-}p\text{-}C_5H_4NMe)][TCNQ]$ (**3**) is always obtained, either by reaction with LiTCNQ or with neutral TCNQ. In contrast to the formation of **2**, the reaction between this ferrocene salt and neutral TCNQ implies the complete reduction of the organic acceptor.

Crystal Structure Determinations

Crystal structure studies of solid compounds **1**–**3** show that they are built up of cationic ferrocene and anionic TCNQ units. Table 1 contains the more relevant bond lengths and angles.

Compound **1** crystallizes in the orthorhombic system, space group $Pna2_1$. An ORTEP view showing the labeling scheme is given in Figure 1. The structure consists of rows of TCNQ anions separated by the ferrocene cations. No close contacts between anions and cations were observed. Fe–C bond lengths are in the range 1.95(3)–2.06(2) Å and the Fe···Cp plane distances are 1.611(3) and 1.628(4) Å, the shorter distance corresponding to the substituted cyclopentadienyl ring. The Cp rings form an angle of 4.0(6)° and are within 6.7(6)° of the eclipsed conformation. All these features are similar to those previously reported for the $[Fe(C_5H_5)(C_5H_4CH_2NMe_3)]^+$ cation.[26–29]

All the TCNQ groups in the unit cell are crystallographically equivalent. Since they must neutralize the positive charges on the ferrocenes, all the TCNQ should be radical anions, bearing one negative charge per molecule. The charge located on every TCNQ can be related with the observed variation in the C–C bond lengths on reduction. The extra electron occupies an antibonding orbital and this is mainly reflected in a lengthening of the quinoid bond. A linear relation between the C–C bond lengths and the electronic charge held on the TCNQ has been established.[30–31] The values observed for compound **1** agree with the mononegative state expected for the TCNQ units. These radical-anions form a regular one-dimensional stack along the *c* axis (Figure 2) by overlap of the π clouds

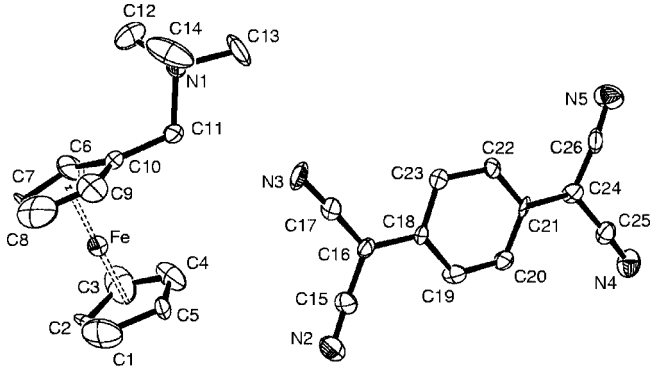

Figure 1. ORTEP view (20% probability ellipsoids) and atom labeling of compound **1**

of adjacent groups, in the ring over external bonds mode, with an intrastack separation of 3.27(1) Å. Such overlap in a regular stack of anion radicals has previously been observed;[32−33] however, dimerization is much more common, to form the dianion $[TCNQ]_2^{2-}$ which can either be isolated or form part of a non-uniform stack with alternating short and long intermolecular distances.[34−51]

Compound **2** crystallizes in the triclinic system, space group $P\bar{1}$. The asymmetric unit consists of one ferrocene cation, two TCNQ groups and one crystallization acetonitrile molecule. Figure 3 shows the numbering scheme.

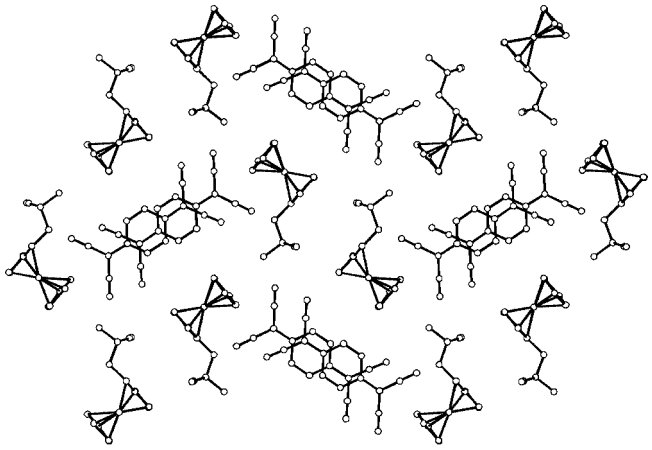

Figure 2. View of the crystal packing of compound **1** in a direction perpendicular to the *c* axis

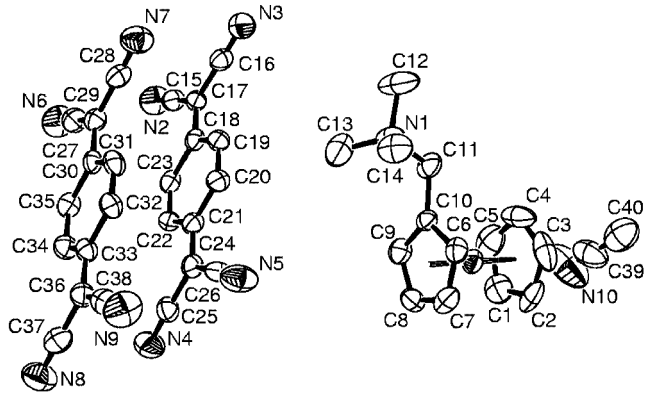

Figure 3. ORTEP view (30% probability ellipsoids) and atom labeling of compound **2**

The ferrocene cation shows similar features to those of compound **1**, with Fe−C bond lengths in the range 2.014(6)−2.048(4) Å and Fe···Cp plane distances of 1.634(6) and 1.658(5) Å − again the shortest distance corresponds to the substituted ring. The Cp rings are almost parallel, with 1.7(1)° of deviation, and are within 7.8(1)° of the eclipsed conformation.

There are two crystallographically different TCNQ molecules, types A and B. According to the Kistenmacher relation between C−C bond lengths and the negative charge located on every TCNQ,[31] we have found that TCNQ A has an approximate charge of 0.4 e^- while TCNQ B bears, approximately 0.6 e^-, i.e. two TCNQ neutralize the positive charge on the substituted ferrocene. The TCNQs are stacked in the ring over external bond mode (Figure 4) to form a one-dimensional row with the pattern ···TCNQ A···TCNQ B···TCNQ B···TCNQ A···TCNQ A···. The TCNQ As are related by inversion centers located between adjacent units. The same applies for TCNQ Bs. The angle between least-squares ring planes of TCNQ A and TCNQ B is 1.8(1)°. Thus, all the TCNQs in the stack are practically parallel since all TCNQ As are parallel, due to symmetry, as occurs with TCNQ Bs.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

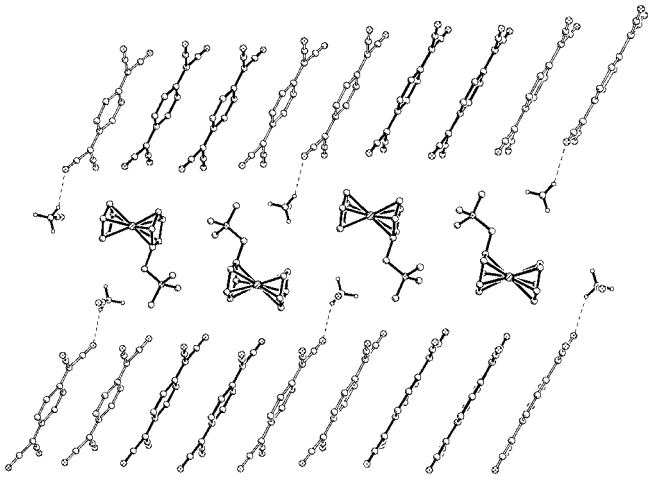

Figure 4. TCNQ stack in compound **2**; TCNQ A is depicted in black and TCNQ B in white, showing close contacts with the acetonitrile solvent molecules

The very similar intermolecular distances give rise to a quasi-uniform stack; with the shortest distance being between least-squares ring planes of TCNQ A and TCNQ B, 3.27(1) Å, followed by the separation between adjacent TCNQ As, 3.32(1) Å, and that between two TCNQ Bs, 3.34(1) Å. We can reconcile this stack with several reported examples of regularly spaced $TCNQ^{0.5-}$.[52−56]

The ferrocene cations and the acetonitrile molecules are located between the parallel rows of TCNQ. The acetonitrile molecule binds TCNQ A and B that belong to neighboring rows at the distances 3.268(9) and 3.445(8) Å

The (ethylenepyridinium)ferrocene **3** crystallizes in the triclinic system, space group $P\bar{1}$. The asymmetric unit is composed by two crystallographically independent ferrocene cations and two independent TCNQ anions. The numbering scheme is shown in Figure 5.

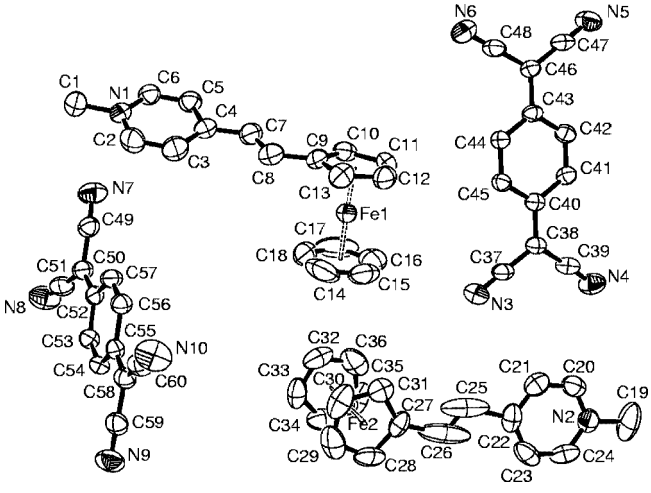

Figure 5. ORTEP view (30% probability ellipsoids) and atom labeling of compound **3**

Both ferrocene units show equivalent features and, in general terms, are similar to the trimethylammoniummethyl derivatives in **1** and **2**. For the two ferrocene units the Fe−C bond lengths are in the range 1.997(6)−2.039(4) and 2.016(5)−2.028(5) Å, respectively, with Fe···Cp plane distances of 1.630(6) and 1.647(5) Å for the first ferrocene (labeled A) and 1.642(5) and 1.649(5) Å for the second (labeled B); in both cases the shortest distance corresponds to the substituted ring. The Cp rings are almost parallel, deviating by 1.1(1)° in ferrocene A and 2.9(1)° in ferrocene B, and are, respectively, within 9.2(1)° and 22.3(1)° of the eclipsed conformation. Both ferrocene cations are almost perpendicular, forming an angle of 84(1)° between them.

There are also two crystallographically different TCNQ molecules (A and B) in the crystal; both are negatively charged to neutralize the ferrocene cations and thus bear one electron per molecule, as the C−C distances confirm.

The TCNQ As are dimerized by a ring over external bond overlap, with a distance between mean planes of 3.12(1) Å. These dimers are stacked to form a non-uniform

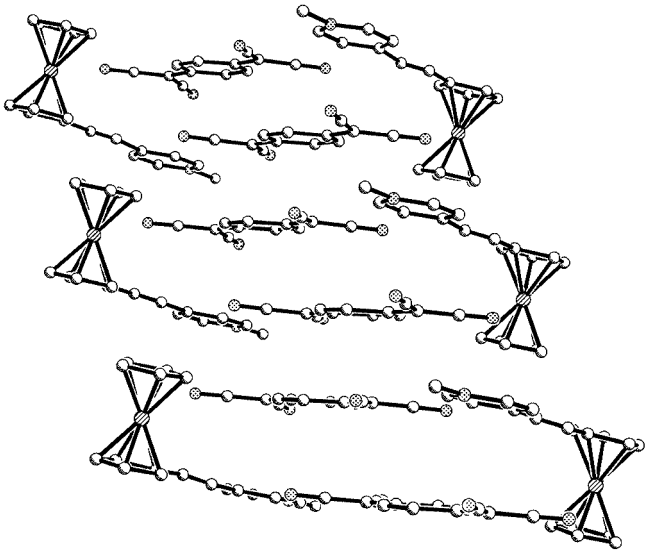

Figure 6. View of the stack of TCNQ A in compound **3** showing the overlap with the pyridine rings (see text)

one-dimensional chain (Figure 6) by overlap of the exocyclic dicyanomethyl groups of one end of the molecule, with a shortest distance of 3.35(1) Å. The other extreme of each TCNQ overlaps with the pyridine ring of the ferrocene B cations, showing a shortest contact of 3.33(2) Å. Overlap with the substituent π systems has been observed in other ferrocene derivatives, but only for neutral TCNQ[19,20] or isolated radical anions,[57] leading in all cases to alternated stacks of donors and acceptors. In our case, such overlap occurs at one end only of each TCNQ, thus allowing the formation of the TCNQ stack.

In the crystal packing, zig-zagged TCNQ chains are stacked parallel to each other, leaving holes that are occupied by the ferrocene cations. The other TCNQs, type B, form isolated dimers $[TCNQ]_2^{2-}$, with an interplanar spacing of 3.05(1) Å, and ring over external bond overlap. These dimers are oriented almost perpendicularly to the TCNQ A

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

chains, forming an angle of 88.4° between the respective molecular planes (Figure 7).

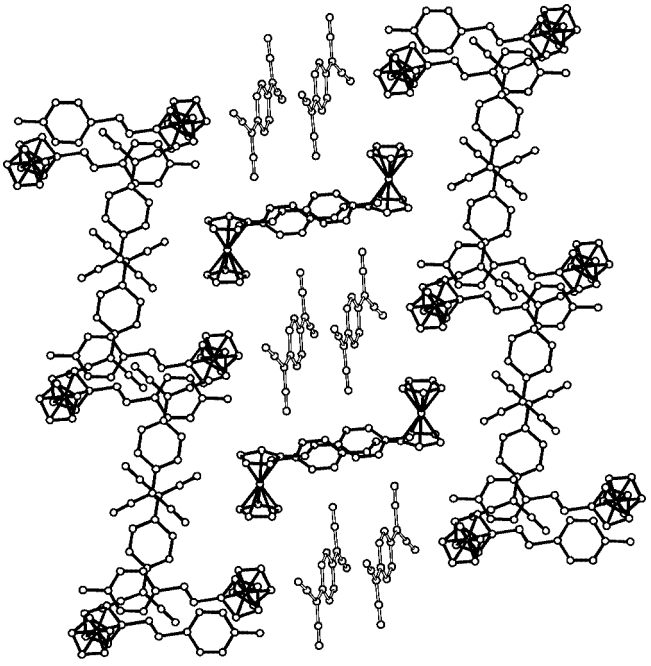

Figure 7. Crystal packing in compound **3**; TCNQ A is in black and TCNQ B in white

Finally the ferrocene A cations are located in the channels left by the stacks of TCNQ A and the dimers of TCNQ B (Figure 7). This ferrocene is perpendicular to all of the TCNQs and no π interactions are found.

Spectroscopic Studies

IR spectra are a very useful source of information about the formal oxidation state of the TCNQ molecules. The most characteristic bands[58−60] are ν(CN), which appears at 2228 cm^{-1} in neutral TCNQ and is shifted to lower frequencies and split (2194/2177 cm^{-1}) in the radical anion, the $\nu_{20}(b_{1u})$ and the $\nu_4(a_g)$ bands assignable to C−C stretching modes and which appear at 1530 and 1424 cm^{-1} in the neutral TCNQ and are shifted to 1507 and 1386 cm^{-1} in the anionic TCNQ. The last significant band is $\nu_{50}(b_{3u})$, an out-of-plane bending mode appearing at 860 cm^{-1} in neutral and 824 cm^{-1} in anionic TCNQ. The last three vibration modes are shifted almost linearly to lower frequencies with increasing negative charge on the TCNQ and are, thus, a good indication of its oxidation state.[60]

In compound **1** these bands appear at 2188, 2173, 2161, 2149, 1508, 1356 and 821 cm^{-1} respectively, clearly indicating the mononegative nature of TCNQ suggested by the crystal structure. The large split of the ν(CN) bands can be attributed to the non-equivalence of the TCNQ nitrile groups that are crystallographically different. Similar features are observed in the IR spectrum of compound **3**, with bands at 2184, 2168, 2146, 1506, 1350 and 823 cm^{-1}.

In contrast, the IR spectrum of compound **2** is dominated by the tail of an electronic absorption with broad vibrational bands superimposed on it − a typical feature of derivatives with a degree of electronic delocalization along the TCNQ stacks.[61−62] This electronic absorption is observed in the Vis/NIR spectrum centered at 4500 cm^{-1} and can be assigned to the low energy charge-transfer transition, CT_2, between radical-anion and neutral TCNQ.[63] The most significant TCNQ IR bands appear at 2197, 2156, 1519, 1410 and 833 cm^{-1}. Assuming a linear relation between the electronic charge in the TCNQ and the frequency shift of ν_{20} we can attribute a formal charge of 0.5 e^- per TCNQ, in agreement with the assignation made by crystallographic means. The other bands, ν_4 and ν_{50}, do not show this linear shift although their intermediate values clearly indicate that the TCNQ are in an intermediate oxidation state.[22−23]

Due to the partial electronic delocalization compound **2** is weakly semiconducting, with a room temperature conductivity of 10^{-4} S cm^{-1} (measured in a powder pressed sample). Conversely, compounds **1** and **3**, with only the mononegative radical anion present, have conductivities below 10^{-6} S cm^{-1} at room temperature.

The three compounds are diamagnetic, implying that the radical anions formed must interact antiferromagnetically with adjacent molecules in order to pair their spins. This is common for TCNQ derivatives that form the dimeric dianion $[TCNQ]_2^{2-}$.[25,48] The diamagnetism of compound **2** is surprising since the electronic delocalization is usually reflected in the magnetic susceptibility, either as a weak Pauli paramagnetism[64] or as the contribution of an $S = 1/2$ spin 1D system with antiferromagnetic coupling.[23,65] The unexpected diamagnetism of **2** could suggest a higher localization of the TCNQ unpaired electrons, giving rise to a stronger antiferromagnetic coupling in the bulk.

Conclusion

Cationic ferrocenium salts react with LiTCNQ by a metathesis process to form the corresponding [Ferrocene][TCNQ] derivatives **1** and **3**, which behave as typical salts of the anion radical $TCNQ^-$, forming dimeric anions, $[TCNQ]_2^{2-}$, that overlap with neighbouring dimers to give a non-uniform one-dimensional stack. A typical stack is found in **1**, but that of **3** is highly unusual as the TCNQ radical anions also overlap with the π-delocalized system of the pyridinium substituent. Such overlap is common in integrated systems of neutral TCNQ but extremely rare with anionic TCNQ, and in the reported cases the integrated stack is formed by dimeric $[TCNQ]_2^{2-}$ [66] or trimeric $[TCNQ]_3^{2-}$ [67] overlapping with the cationic donor. To the best of our knowledge there are no previous reports of overlap between 1D-stacked TCNQ and the counterion.

Compound **2** is also formed by rows of stacked TCNQ separated by the cationic ferrocenes, with only electrostatic interactions between them. The TCNQ are, however, partially reduced as a consequence of the crystal packing conditions, which will probably determine the equilibrium between the TCNQ and the iodide anion. Figure 4 shows that the TCNQ stack leaves space for two ferrocene cations and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

two acetonitrile molecules. If these solvent molecules were removed the ferrocene could be closely packed, occupying the space equivalent to three TCNQ. The resulting stoichiometry [ferrocene]$_2$[TCNQ]$_3$ is also well known,[22,51] with structures described as trimeric dianions [TCNQ]$_3^{2-}$ stacked in infinite rows. Inside the trimer every TCNQ bears approximately $^2/_3$ of an electron and the difference between this oxidation state and that found on our compound (0.5 of an electron) is small and would not determine the extent of TCNQ reduction. Therefore, we attribute the partial reduction to the need to accommodate two TCNQ groups in the stack per ferrocene and acetonitrile molecules.

The complete displacement of the reaction with iodide in the formation of **3** by either metathesis with LiTCNQ or by reduction of neutral TCNQ supports the influence of the crystal structure on the TCNQ reduction. The driving force here is the overlap between the TCNQ anions and the pyridinium substituent in the ferrocenes. Figure 6 shows that TCNQ and pyridinium alternate along the stack and that consecutive TCNQ anions overlap with ferrocenes of different rows. This packing does not allow room for extra TCNQ molecules and thus the reduction with iodide must be complete since there is only now one TCNQ per ferrocenium cation. The remaining cations and TCNQ anions in this structure are oriented perpendicularly relative to the stacks, forcing the isolation of both the anions as dimeric [TCNQ]$_2^{2-}$ and the cations, and leaving electrostatic interactions as the only force that holds them together.

Experimental Section

General Remarks: All reactions were carried out under an inert gas. LiTCNQ was obtained according to a published method[24] and its purity checked by elemental analysis. Elemental analyses were carried out by the Servicio de Microanálisis of the Universidad Complutense de Madrid. Infrared spectra were recorded as KBr pellets with a Nicolet Magna-550 FT-IR spectrophotometer. Magnetic susceptibility experiments were made on polycrystalline samples using a Quantum Design SQUID magnetometer, Model MPMS-5S in the temperature range 2−250 K and at constant field of 0.5 T. Electrical conductivity measurements at room temperature were performed by the two points method in pressed powdered samples.[68]

[Fe(C$_5$H$_5$)(C$_5$H$_4$CH$_2$NMe$_3$)][TCNQ] (1): [Fe(C$_5$H$_5$)(C$_5$H$_4$CH$_2$NMe$_3$)](I) (135 mg; 0.35 mmol) was dissolved in methanol/water (20 mL of 3:1 mixture) and then LiTCNQ (148 mg; 0.70 mmol), dissolved in methanol (35 mL), was slowly added to the double layer. After 3 d, dark blue crystals of the title compound appeared, which were filtered off and washed with methanol. The crystals were suitable for X-ray analysis. Yield: 104 mg, 64%. IR (KBr): $\tilde{\nu}$ = 2188, 2173, 2161, 2149, 1582, 1508, 1485, 1369, 1356, 1324, 1179, 881, 843, 821, 480 cm^{-1}. C$_{26}$H$_{24}$FeN$_5$ (462.3): calcd. C 67.6, H 5.2, N 15.1; found C 67.4, H 5.1, N 14.9.

[Fe(C$_5$H$_5$)(C$_5$H$_4$CH$_2$NMe$_3$)][TCNQ]$_2$·MeCN (2): A solution of TCNQ (79 mg; 0.39 mmol) in acetonitrile (40 mL) was mixed with a solution of [Fe(C$_5$H$_5$)(C$_5$H$_4$CH$_2$NMe$_3$)](I) (150 mg; 0.39 mmol) in acetonitrile/water (15 mL of a 2:1 mixture). The resulting green solution was concentrated to half of its original volume and cooled to −20 °C. Dark-violet platelets then appeared after 2 d. Yield: 48 mg, 35%. IR (KBr): $\tilde{\nu}$ = 2197, 2156, 1558, 1519, 1469, 1410, 1298, 1104, 1045, 870, 833, 683, 593, 480 cm^{-1}. C$_{40}$H$_{31}$FeN$_{10}$ (707.6): calcd. C 67.9, H 4.4, N 19.8; found C 67.8, H 4.4, N 19.6.

[Fe(C$_5$H$_5$)(C$_5$H$_4$CH=CH-*p*-C$_5$H$_4$NMe)][TCNQ] (3): This was obtained by reaction in a double layer of [Fe(C$_5$H$_5$)(C$_5$H$_4$CH=CH-*p*-C$_5$H$_4$NMe)](I) (150 mg; 0.35 mmol) in methanol (15 mL) with either an acetonitrile (20 mL) solution of TCNQ (71 mg; 0.35 mmol) or a methanolic (30 mL) solution of LiTCNQ (147 mg; 0.70 mmol). In both cases dark red prismatic crystals suitable for X-ray were obtained after 1 week. Yield: 55 mg, 31%. IR (KBr): $\tilde{\nu}$ = 2184, 2168, 2146, 1646, 1607, 1577, 1506, 1475, 1458, 1370, 1350, 1195, 1180, 950, 879, 823, 716, 475 cm^{-1}. C$_{30}$H$_{22}$FeN$_5$ (508.4): calcd. C 70.9, H 4.4, N 13.8; found C 70.6, H 4.4, N 13.4.

X-ray Crystallographic Studies: A summary of the relevant data collection parameters is given in Table 2. Data were collected with a Bruker AXS-CCD, Enraf−Nonius CAD-4, and Nonius CCD[69] for **1**, **2** and **3**, respectively, by using graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å) at room temperature. The structures were solved by Patterson or direct methods and refined by full-matrix least squares on F^2 with anisotropic thermal parameters for the non-hydrogen atoms. The hydrogen atoms were included with fixed isotropic contributions at their calculated positions determined by molecular geometry. The calculations were carried out with SHELX-97 software package.[70] CCDC-201484 (**1**), -201485 (**2**), -201486 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 2. Crystal and refinement data for compounds **1**−**3**

Homogeneous Hydrogenation Catalyzed by Trinuclear Rh^{I}-Os^{III}-Rh^{I} Complexes

Peter Comba,*[a] Andrey Mayboroda,[a] and Hans Pritzkow[a]

Keywords: Osmium / Rhodium / Heterometallic complexes / Hydrogenation

Reaction of $[Os(Hbiim)_2(O{=}PPh_3)_2](NO_3)$ (H_2biim = 2,2′-biimidazole) with $[RhCl(cod)]_2$ (cod = 1,5-cyclooctadiene) or $[Rh(OH)(cod)]_2$ yields biimidazolato-bridged trinuclear Rh^{I}-Os^{III}-Rh^{I} complexes, which are highly efficient catalysts for the homogeneous hydrogenation of 1-hexene and cyclohexene. The reactivity of the trinuclear compounds compared with the mononuclear subunits indicates that this is due to cooperative effects. This is confirmed by spectroscopic and electrochemical data. The solid-state structure of $[\{RhCl(cod)\}_2(\mu\text{-}Hbiim)_2\{Os(O{=}PPh_3)_2\}](NO_3)$ was determined by single-crystal X-ray diffraction.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Heterobimetallic complexes are receiving considerable attention in the area of homogeneous catalysis in particular;[1] the enhanced reactivity of oligonuclear complexes is thought to be due to synergistic effects.[2−5] For homogeneously catalysed hydrogenation cooperative effects have been reported for some binuclear complexes of platinum-group metals with nitrogen-containing bridging ligands, for example $[\{H(CO)(PPh_3)Ru\}(\mu\text{-}pz)_2\{Ir(TFB)\}]$ (pz = pyrazole; TFB = tetrafluorobenzobicyclo[2.2.2]octadiene)[4] and $[\{H(CO)(PPh_3)Ru\}(\mu\text{-}biim)\{M(cod)\}]$ (M = Rh, Ir).[5] Generally, the proposed mechanism involves one catalytically active site; the other metal ion provides this active site with the appropriate environment and has the role of a donor or acceptor of electron density.[6] The enhanced reactivity is believed to be due to a variation of the ligand field of the active site by the "spectator" chromophore.

2,2′-Biimidazole has been extensively studied as a bridging ligand.[5,7] The recently reported complex $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**1**)[8] has two 2,2′-biimidazole ligands in the equatorial plane of the octahedral complex and, after deprotonation of the NH sites of 2,2′-biimidazole, transition metal complex fragments can be added. It is therefore a versatile building block for trinuclear complexes.[8] The use of $[Rh(cod)]^+$ as such a fragment allowed us to obtain trinuclear Rh^{I}-Os^{III}-Rh^{I} compounds. Here, we report the synthesis, characterization and catalytic properties of $[\{RhCl(cod)\}_2(\mu\text{-}Hbiim)_2\{Os(O{=}PPh_3)_2\}](NO_3)$ (**5**) and $[\{Rh(cod)\}_2(\mu\text{-}biim)_2\{Os(O{=}PPh_3)_2\}](NO_3)$ (**6**).

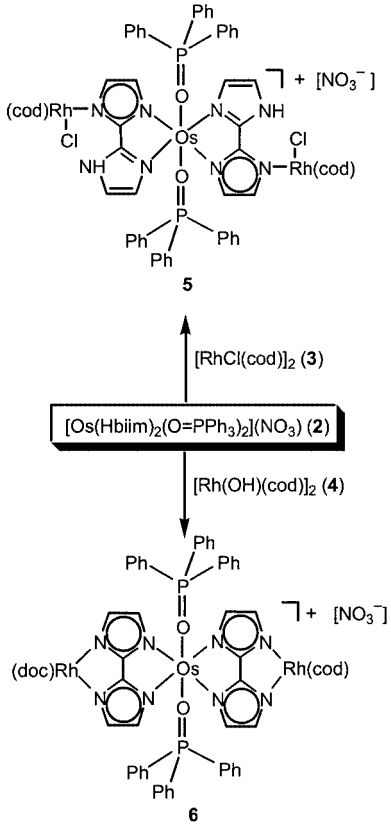
Result and Discussion

Synthesis and Characterization

The two trinuclear complexes **5** and **6** were obtained from reactions of $[Os(Hbiim)_2(O{=}PPh_3)_2](NO_3)$ (**2**)[8] with $[RhCl(cod)]_2$ (**3**) and $[Rh(OH)(cod)]_2$ (**4**), respectively (Scheme 1). The desired products were isolated as red (**5**)



Scheme 1

or brown (**6**) air-stable solids that are insoluble in aromatic and aliphatic hydrocarbons but moderately soluble in dichloromethane and methanol.

Slow evaporation of a solution (dichloromethane/methanol, 4:1, 20 °C) of **5** resulted in single crystals suitable for structural analysis. The geometry of **5**, determined by the analysis of single-crystal X-ray diffraction data, is shown in Figure 1, structural parameters are given in Table 1.

Table 1. Selected geometric parameters of $[\{RhCl(cod)\}_2(\mu\text{-}Hbiim)_2\{Os(O{=}PPh_3)_2\}](NO_3)\cdot CH_2Cl_2$ (**5**)

Bond lengths [Å]	
Os1−O1	2.027(3)
Os1−N1	2.065(4)
Os1−N3	2.080(4)
P1−O1	1.504(3)
C2−C3	1.376(7)
Rh1−N2	2.082(4)
Rh1−C7	2.119(6)
Rh1−C8	2.107(5)
Rh1−C11	2.137(5)
Rh1−C12	2.155(5)
Rh1−Cl1	2.396(2)
Valence angles [°]	
O1−Os1−N1	85.66(14)
O1−Os1−N3	91.93(14)
N1−Os1−N3	77.85(15)
P1−O1−Os1	151.5(2)
N2−Rh1−Cl1	89.92(12)

The coordination sphere of the osmium center is approximately octahedral; the rhodium centers have a square-planar geometry. The Os(1)−N(1) and Os(1)−N(3) distances [2.065(4) and 2.080(4) Å, respectively], are in the range found in related Os^{III} biimidazole[8] and biimidazolate[9] complexes. Comparison with the molecular structure of **1**[8] reveals a distinct difference in the binding of the triphenylphosphane oxide ligand. The Os(1)−O(1) distance in **5** [2.027(3) Å] is somewhat longer than that in **1** [2.012(2) Å], and the P(1)−O(1)−Os(1) angle in **5** [151.5(2)°] is significantly larger than that in **1** [146.53(11)°]. This, together with the EPR spectra (see below), is evidence for significant differences in the electronic structure of the osmium centers between the mononuclear compound **1** and the trinuclear compounds **5** and **6**, and it is an indication of a modification of the electronic properties of the catalytically active rhodium sites.

The EPR spectra (X-band) of **1**, **5** and **6**, recorded in frozen solution [dichloromethane/methanol/tetrahydrofuran (7:1:2), 77 K], are axial, with a large anisotropy;[10] this is a common observation in EPR spectroscopy of osmium(III) complexes.[11] The large difference in $\Delta g_{1,2}$ between **1** ($\Delta g_{1,2} = 0.695$) and **5**, **6** ($\Delta g_{1,2} = 1.450, 1.372$) is attributed to the increasing axial distortion (see discussion of the X-ray structural data above) and concomitant changes in the electronic structure.

Electrochemical studies of **2**, **5** and **6** were carried out in methanol at 25 °C; cyclic voltammograms of **2** and **5** are shown in Figure 2. A comparison of the electrochemical behavior of the mononuclear complex **2** with that of the trinuclear compounds **5** and **6** indicates that the deprotonation of 2,2′-biimidazole and formation of the heterotrimetallic complexes results in a significant cathodic shift of the redox potentials of osmium. The Os^{III}/Os^{II} reduction wave, which

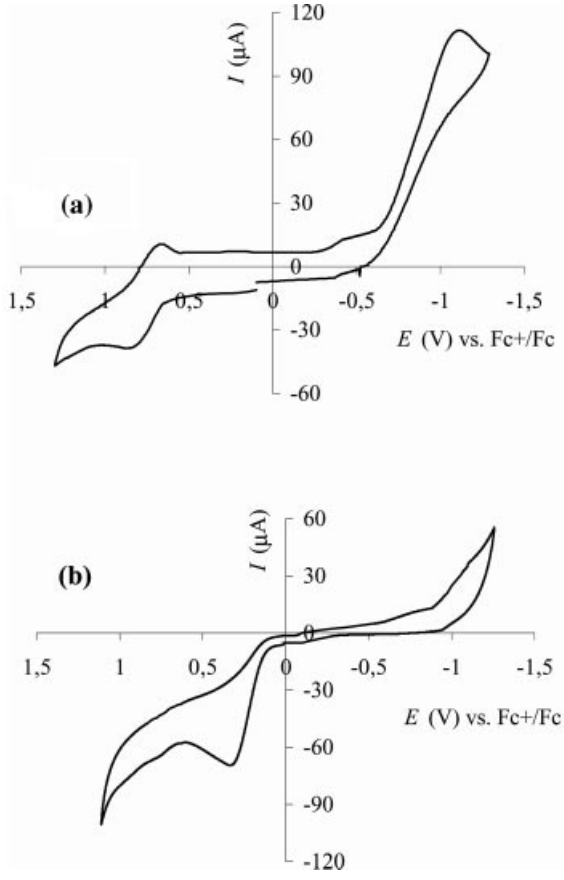

Figure 2. Cyclic voltammograms of: (a) $[Os(Hbiim)_2(O{=}PPh_3)_2](NO_3)$ (**2**) and (b) $[\{RhCl(cod)\}_2Os(\mu\text{-}Hbiim)_2(O{=}PPh_3)_2](NO_3)$ (**5**)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is observed at −1.14 V for **2**, is beyond the accessible potential range for **5** and **6**. The Os^{III}/Os^{IV} redox couple was found at +0.77 V for **2** and seems to be shifted cathodically for **5** and **6**. These signals are broad and irreversible. The fact that they are not well resolved might be due to overlap of the cyclovoltammetric responses for Os^{III} and Rh^{I}. The oxidation wave of **5** is at +0.37 V and that of **6** is at +0.38 V. Well-resolved cyclic voltammograms have been reported for biimidazolate-bridged Pt^{II}-Os^{III}-Pt^{II} and Pd^{II}-Os^{III}-Pd^{II} complexes.[9] Under the same conditions as those reported here the Os^{III}/Os^{IV} couple was observed at +0.53 V for $[\{Pt(C_5H_3(CH_2NMe_2\text{-}2,6)\}_2Os(\mu\text{-}Hbiim)_2(O{=}PPh_3)_2](NO_3)(SO_3SF_3)_2$ [$C_5H_3(CH_2NMe_2$-2,6) = pincer ligand] and at +0.23 V for $[\{Pd(en)\}_2Os(\mu\text{-}biim)_2(O{=}PPh_3)_2](NO_3)_3$ (en = ethylene-1,2-diamine).[9] These observations and interpretations are consistent with a modification of the donor properties of 2,2′-biimidazole due to the deprotonation and coordination to a second metal ion. In agreement with the structural comparison and the EPR spectra, the electrochemical data indicate that the osmium centers in **5** and **6** act as Lewis acids and therefore modify the electronic properties of the catalytically active rhodium sites.

Catalytic Activity

Compounds **5** and **6** catalyze the hydrogenation of 1-hexene and cyclohexene under homogeneous conditions. The results are summarized in Table 2. The reactivities of the mononuclear complexes **1**, **3** and **7** (fragments of **5** and **6**) are included for comparison. The trinuclear complexes **5** and **6** are significantly more active and selective catalysts than the corresponding building blocks **1**, **3** and **7**. The mononuclear osmium complex **1** is almost inactive. This implies that the transformation of the substrate takes place at the rhodium centers of the trinuclear catalysts **5** and **6**. The observation that the mononuclear rhodium complex **7** catalyzes the migration of a double bond in the linear alkene rather than its hydrogenation is interesting. The reduction of 1-hexene in the presence of the trinuclear catalysts **5** and **6** occurs very selectively. The hydrogenation of cyclohexene is much slower than the reduction of 1-hexene. However, for cyclohexene, the enhancement of the catalytic activity by the trinuclear compounds **5** and **6** is more pronounced. A plausible catalytic pathway includes the hydrogenation of the cyclooctadiene ligand in **5** and **6**, and the formation of a coordinatively unsaturated intermediate by removal of cyclooctane.[6] The enhancement of the catalytic activity with the trinuclear complexes is due to a modification of the electronic properties of the rhodium centers, and this might occur by electrostatic effects or by electronic communication between the osmium and rhodium centers through the π-conjugated bridging ligand. Catalytic hydrogenation by rhodium complexes usually involves oxidative addition of hydrogen and formation of a π-complex with the alkene, followed by an intramolecular alkene insertion reaction, leading to a Rh-alkyl complex.[6] The last step is usually rate-determining. A decrease of the electron density on Rh^{I}, due to the Os^{III} center, must lead to a reduction of the energy barrier, and promote the nucleophilic attack of the alkene and formation of Rh-alkyl species. Here, the additional metal center is used as a weak electron acceptor and, therefore, improves the properties of the catalytically active metal ion. The osmium center provides a subtle modification of the electronic structure of rhodium, which promotes the Rh-alkyl complex formation and does not inhibit the oxidative addition of hydrogen.

In summary, we have prepared and characterized trinuclear Rh^{I}-Os^{III}-Rh^{I} complexes with 2,2′-biimidazole as a bridging ligand and shown their utility as catalysts for the homogeneous hydrogenation of 1-hexene and cyclohexene. The significant enhancement of the catalytic activity, relative to the mononuclear building blocks, is believed to be due to a variation of the ligand field induced by the "spectator" metal ion.

Experimental Section

General: $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**1**) was prepared by a published procedure.[8] Its conjugate base $[Os(Hbiim)_2(O{=}PPh_3)_2](NO_3)\cdot 2H_2O$ (**2**) was obtained by reaction of **1** with KOH

Table 2. Homogeneous hydrogenation[a] of 1-hexene and cyclohexene in the presence of $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**1**), $[RhCl(cod)]_2$ (**3**), $[Rh(H_2biim)(cod)](SO_3CF_3)$ (**7**), $[\{RhCl(cod)\}_2(\mu\text{-}Hbiim)_2\{Os(O{=}PPh_3)_2\}](NO_3)$ (**5**) and $[\{Rh(cod)\}_2(\mu\text{-}biim)_2\{Os(O{=}PPh_3)_2\}](NO_3)$ (**6**)

Catalyst	Cat. [mol %]	Time [h]	Hydrogenation of 1-hexene			Hydrogenation of cyclohexene
			Conversion [%]	Yield of by-products [%]		Conversion [%]

in methanol/dichloromethane.[8] IR spectra (KBr pellets) were recorded on a Perkin−Elmer 16PC RT-IR instrument. UV/Vis spectra were obtained with a Cary 1E spectrophotometer. EPR spectra were recorded with a Bruker ESP300E spectrometer (9.4635 GHz) as approx. 1 10^{-3} mol·dm^{-3} frozen (liquid nitrogen temperature) solutions in dichloromethane/methanol/tetrahydrofuran (7:2:1). Electrochemical measurements (CV) were performed in solutions of [N*n*Bu$_4$]PF$_6$ (0.1 mol·dm^{-3}) in methanol at 293 K, using a BAS 100B system with a glassy-carbon working electrode, a platinum auxiliary electrode and an Ag/AgCl reference electrode. All potentials are quoted versus the ferrocene/ferrocenium couple (E = 0.0 V). Mass spectra were recorded on a Finnigan MAT 8230 instrument. GC-MS analyses were performed on a Fison GC 8000/MD 800 series instrument, equipped with a ZB-1 (Zebron) column. Melting (decomposition) points were determined with a Gallenkamp MFB 595 010 M melting point apparatus. Organic solvents (methanol, dichloromethane) were freshly distilled before use. Microanalyses were obtained from the microanalytical laboratory of the chemical institute of the University of Heidelberg.

Catalytic Hydrogenation of 1-Hexene and Cyclohexene: All experiments were performed in a 100 mL stainless steel autoclave with an inner polytetrafluorethylene vessel. In a typical experiment, 0.016 mmol of the catalyst was placed as a solid in the autoclave, supplied with a magnetic stirrer. Whilst stirring, the catalyst was dissolved in dichloromethane (6 mL) or a mixture of dichloromethane and methanol (90:10). The alkene (0.16 mmol) was then added to the solution of the catalyst. The autoclave was evacuated three times and filled with hydrogen. The pressure of hydrogen was then increased to 5 bar. The reaction mixture was stirred for 5 h. The autoclave was then degassed and all volatile materials were evaporated from the reaction mixture under oil-pump vacuum, and condensed (liquid nitrogen). The resulting solution was analysed by GC-MS.

Synthesis of [{RhCl(cod)}$_2$(μ-Hbiim)$_2${Os(O=PPh$_3$)$_2$}](NO$_3$)·CH$_2$Cl$_2$ (5): [Os(Hbiim)$_2$(O=Ph$_3$)$_2$](NO$_3$)·2H$_2$O (**2**; 300 mg, 0.27 mmol) was dissolved in a dichloromethane/methanol mixture (4:1, 15 mL) at 25 °C. [RhCl(cod)]$_2$ (**3**; 0.27 mmol), in methanol (5 mL) was added to the solution. The reaction mixture immediately turned from violet to red. The solution was stirred for 2 h, and the volume of the solution was then reduced to 4 mL. After 10 h red crystals of **5** precipitated. The slurry was decanted and the crystalline precipitate was washed twice with acetone (5 mL) and dried under an oil-pump vacuum to afford **5**. Yield: 290 mg (73% based on **2**). Mp: gradual decomposition above 150 °C. IR (KBr): ν(P=O) 1120 cm^{-1}, ν$_a$(NO$_3^-$) 1332, ν(Ar, C=C) 1438, ν(NH) 3050. UV/Vis (CH$_2$Cl$_2$): λ$_{max}$ = 360 nm (ε = 7.5 × 10^3 mol^{-1}·dm^3·cm^{-1}), 541 nm (ε = 4.7 × 10^2 mol^{-1}·dm^3·cm^{-1}). CV (CH$_3$OH, 25 °C): E_{ox} = +0.37 V (irr.). MS (FAB): *m*/*z* (%) = 1507 (21) [C$_{64}$H$_{64}$N$_8$Cl$_2$O$_2$P$_2$OsRh$_2$]$^+$, 1260 (32) [C$_{56}$H$_{52}$N$_8$ClO$_2$P$_2$OsRh]$^+$, 1014 (66) [C$_{48}$H$_{40}$N$_8$O$_2$P$_2$Os]$^+$, 736 (100) [C$_{30}$H$_{25}$N$_8$OPOs]$^+$. C$_{64}$H$_{64}$Cl$_2$N$_9$O$_5$P$_2$OsRh$_2$·CH$_2$Cl$_2$ (1653.03): calcd. C 47.23, H 4.02, N 7.64; found C 46.80, H 4.41, N 7.72.

Synthesis of [{Rh(cod)}$_2$(μ-biim)$_2${Os(O=PPh$_3$)$_2$}](NO$_3$) (6): [Os(Hbiim)$_2$(O=Ph$_3$)$_2$](NO$_3$)·2H$_2$O (**2**; 300 mg, 0.27 mmol) was treated with [Rh(OH)(cod)]$_2$ (125 mg, 0.27 mmol) in dichloromethane/methanol (4:1, 20 mL) solution at 25 °C. The reaction mixture was stirred for 2 h and the solvent was then removed under an oil-pump vacuum to afford **6** as a brown solid in quantitative yield. Mp: gradual decomposition above 150 °C. IR (KBr): ν(P=O) 1118 cm^{-1}, ν$_a$(NO$_3^-$) 1332, ν(Ar, C=C) 1436. UV/Vis (CH$_2$Cl$_2$): λ$_{max}$ = 349 nm (ε = 6.3 × 10^3 mol^{-1}·dm^3·cm^{-1}), 556 nm (ε = 4.7 × 10^2 mol^{-1}·dm^3·cm^{-1}). CV (CH$_3$OH, 25 °C): E_{ox} = +0.38 V (irr.). MS (FAB): *m*/*z* (%) = 1434 (100) [C$_{64}$H$_{62}$N$_8$O$_2$P$_2$OsRh$_2$]$^+$, 1224 (28) [C$_{56}$H$_{52}$N$_8$lO$_2$P$_2$OsRh]$^+$, 1156 (31) [C$_{46}$H$_{47}$N$_8$OPOsRh$_2$]$^+$, 946 (42) [C$_{38}$H$_{35}$N$_8$OPOsRh]$^+$. C$_{64}$H$_{62}$N$_9$O$_5$OsP$_2$Rh$_2$ (1513.3): calcd. C 51.41, H 4.18, N 8.43; found C 51.01, H 4.79, N 8.76.

X-ray Crystallographic Analysis of 5: Crystallized from CH$_2$Cl$_2$/MeOH, formula C$_{64}$H$_{64}$Cl$_2$N$_9$O$_5$OsP$_2$Rh$_2$, M = 1568.13 ([C$_{64}$H$_{64}$Cl$_2$N$_8$O$_2$OsP$_2$Rh$_2$]·NO$_3$), red crystal 0.28 × 0.25 × 0.14 mm^3, triclinic, space group $P\bar{1}$, a = 10.7225(9), b = 13.3347(11), c = 13.3707(11) Å, α = 110.312(2)°, β = 100.589(2)°, γ = 107.462(2)°, Z = 1, V = 1619.3(2) Å^3, ρ$_{calcd.}$ = 1.682 g·cm^{-3}, θ scan range 1.77 < θ < 32.05, Mo-K$_α$ radiation (λ = 0.71073 Å), T = 103(2) K. 28335 reflections collected, 10965 independent reflections, 8432 observed reflections [I ≥ 2σ(I)], 551 refined parameters, R = 0.0435, wR^2 = 0.1214, semi-empirical absorption correction from equivalents. Structure was solved by direct methods. Refinement was carried out by full-matrix least-squares techniques on F^2. Program used: structure solution and refinement: SHELXTL NT5.1 (G. M. Sheldrick, Bruker-AXS, Madison, Wisconsin, USA, 1998) Hydrogen atoms were located from the difference-Fourier map. All hydrogen atoms were fully refined. All non-hydrogen atoms were refined anisotropically.

New Rhodium(I) Complexes with Hemilabile Amphiphilic Phosphanes

Esteve Valls,[a] Joan Suades,*[a] René Mathieu,[b] and Noel Lugan[b]

Keywords: Phosphanes / Rhodium / Hemilabile ligands / Amphiphiles

A series of Rh^I complexes was prepared and characterised with the following hemilabile amphiphilic phosphanes: R–(C_6H_4)–(OCH_2CH_2)$_n$–PPh_2 [**1** (R = *tert*-octyl, *n* = 1), **2** (R = *tert*-octyl, $\bar{n}$ = 5), **3** (R = *tert*-octyl, $\bar{n}$ = 13), **4** (R = *n*-nonyl, $\bar{n}$ = 1.4), **5** (R = *n*-nonyl, $\bar{n}$ = 5), **6** (R = *n*-nonyl, $\bar{n}$ = 11)]. The reactions between **1**–**6** and $[Rh(COD)(THF)_2]^+$, and the subsequent reaction with CO were studied by ^{31}P NMR and IR spectroscopy. The data are consistent with the formation of P-coordinated and chelated (P,O) species for ligands **2**–**6**, in agreement with the hemilabile character of these ligands. In the case of ligand **1**, the complex *trans*-$[Rh(\mathbf{1})_2(CO)_2]^+$ has been isolated and the *cis*-$[Rh(\mathbf{1})_2(CO)_2]^+$ compound has been detected. $[Rh(\mathbf{1})_2(CO)]^+$ was prepared by decarbonylation of *trans*-$[Rh(\mathbf{1})_2(CO)_2]^+$, and low-temperature NMR spectroscopic studies have shown the hemilabile character of **1** with a very weak P–O interaction. The molecular structure of *trans*-$Rh(CO)(\mathbf{1})_2Cl$ was determined by X-ray crystallography and shows that the conformation of the *tert*-octylphenoxyethyl chains is nearly identical to that previously reported in the complex *trans*-$PdCl_2(\mathbf{1})_2$.

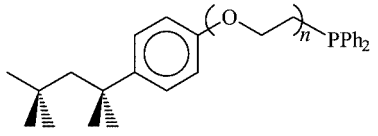
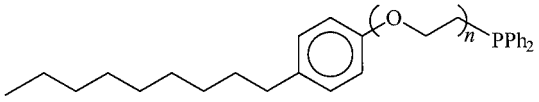
Introduction

The preparation of new functionalised ligands is a central strategy for improving certain properties in transition metal complexes. Phosphanes are among the most versatile ligands, since they allow the introduction of very different functionalities by means of the different groups bound to the phosphorus atom. In this way, phosphane ligands have become water-soluble,[1] asymmetric,[2] hemilabile[3] and, more recently, amphiphilic.[4] The amphiphilic ligands contain hydrophilic and hydrophobic groups in the same molecule, and their metal complexes may aggregate forming supramolecular arrangements, such as micelles and vesicles.[5] Such micro-heterogeneous systems are attractive for improving catalytic processes, especially those that present phase-transfer limitations, such as those occurring under biphasic conditions.[6] This approach has been utilised in the study of a catalytic reaction accelerated by vesicle formation.[7]

In previous papers, we described the synthesis of neutral amphiphilic phosphanes with hemilabile properties,[8] and anionic water-soluble amphiphilic phosphanes.[9] Ligands were prepared in a straightforward manner from polyethylene glycol monoalkyl ethers, which are common starting compounds as they are used extensively as non-ionic surfactants. In subsequent papers, we have reported on the complexing properties of the neutral ligands **1**−**6** (Scheme 1) towards Ru^{II},[8] Pd^{II},[10] and hydridorhodium(I) complexes.[11] Hemilabile properties were clearly observed with the Ru^{II} complexes.[8] Here, we present a study of the reactivity of the neutral ligands **1**−**6** (Scheme 1) towards Rh^I.



1 (n =1), **2** ($\bar{n}$ = 5), **3** ($\bar{n}$ = 13)



4 ($\bar{n}$ = 1.4), **5** ($\bar{n}$ = 5), **6** ($\bar{n}$ = 11)

Scheme 1

Results and Discussion

1. Ligands

Ligands **1**−**6** were synthesised from commercial non-ionic Igepal® surfactants.[12] In agreement with the nature of these starting non-ionic surfactants, the ligands were obtained as mixtures of compounds with the same structure but with different ethoxylation grades (Scheme 1). The only exception is **1**, which was obtained as a single compound

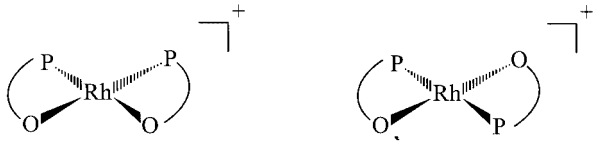
because it crystallised from the reaction mixture as a white solid.

2. Reactivity of Ligands 1−6 towards [Rh(COD)(THF)$_2$][ClO$_4$]

Two equivalents of the ligand (**1**−**6**) in THF were added to a solution of [Rh(COD)(THF)$_2$][ClO$_4$] prepared by the usual reaction between Rh(COD)(acac) and HClO$_4$ in THF. Complexation was evidenced by the change in the colour of the solution, which became darker, and by the $^{31}P\{^1H\}$ NMR spectroscopic data. Although several attempts were made, no solid compounds could be obtained. Difficulties in the isolation of solid compounds were also observed in previous complexation studies of ligands **1**−**6** with Ru^{II} [8] and Pd^{II}.[10]

The $^{31}P\{^1H\}$ NMR spectra of solutions obtained after the reactions of **1**−**6** with [Rh(COD)(THF)$_2$][ClO$_4$] show the complete absence of the corresponding free ligand, and display several doublets with coupling constants in the range 121 to 153 Hz. This result agrees with the formation of Rh−P bonds for all the ligands studied. Significant differences are also observed between the spectra for the different ligands. A comparison of the ^{31}P NMR spectroscopic data obtained from the resulting reaction mixtures with published data reporting the reactivity of related hemilabile phosphanes $Ph_2PCH_2CH_2OCH_3$[13] and $Ph_2P(CH_2CH_2O)_2CH_3$[14] is very helpful in the interpretation of our results. The spectrum of the complex obtained with ligand **1** only displays a doublet at δ = 17.6 ppm ($^1J_{PRh}$ = 144 Hz). This is in good agreement with the presence of a sole [Rh(COD)(PO)$_2$]$^+$ species (PO = P-coordinated ether−phosphane ligand). The spectra of the complexes obtained with ligands **2**−**6** also show a doublet with similar characteristics at 17−18 ppm, however, other doublets are also observed in the δ = 28 ppm region. In these spectra, as the polyether chain length increases (i.e. more oxygen atoms are added), the signal that appears at 17−18 ppm is smaller. At the same time, the signals at around δ = 28 ppm become more significant. These results agree with the simultaneous formation of the above-mentioned P-coordinated species [Rh(COD)(PO)$_2$]$^+$ (δ = 17−18 ppm region), and the chelated (P,O) complexes [Rh(COD)(P∩O)]$^+$ (δ = 28 ppm region)[14] (P∩O = chelated ligand). The absence of the signal in the δ = 28 ppm region in the spectrum with ligand **1** is consistent with the unfavourable bidentate coordination of this ligand, since it is hindered by electronic and steric effects of the aryl group bonded to the oxygen atom.[10] Finally, some observations can be made from the spectra of the complexes with ligands **4** and **6**. The spectrum of the complex with ligand **4** shows two doublets at δ = 17.5 and 17.8 ppm that can be assigned to a mixture of [Rh(COD)(PO)$_2$]$^+$ complexes, since this ligand is a mixture that contains a molecule similar to **1** and another species with a longer polyether chain. In the spectrum of the complex with ligand **6**, other signals are also observed at δ = 32.4 and 39.5 ppm. These signals could be justified by the presence of species in which the labile COD ligand could have been replaced by oxygen atoms of the polyether chain,[15] as represented in Scheme 2.

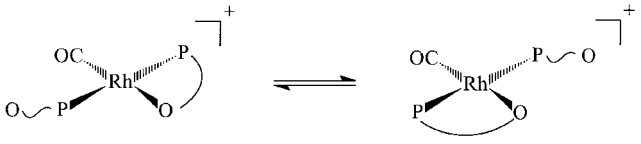


Scheme 2

3. Reaction of [Rh(COD)(L)$_2$]$^+$ Complexes with CO

a) Case where L = Ligands 2−6

After CO was bubbled into THF solutions of the Rh^I complexes described above, the colour turned from orange to yellow. After solvent evaporation, the reaction products were studied by IR and ^{31}P NMR spectroscopy, since, as in the previous section, no solids could be obtained. The $^{31}P\{^1H\}$ NMR spectra show that the previously observed signals are now absent and a new main signal at δ = 22−25 ppm, with the characteristic shape of a doublet ($J_{Rh\text{-}P}$ = 110−130 Hz) is observed for all the complexes studied. The IR spectra in the ν_{CO} region display a strong ν_{CO} band at around 1980 cm^{-1}. The position of this band is very similar to that reported for related complexes with the [Rh(CO)(P∩O)(PO)]$^+$ structure as *trans*-[Rh(CO)(Ph$_2$PCH$_2$CH$_2$OMe)$_2$]$^+$ (ν_{CO} = 1982 cm^{-1}).[13] For these last complexes, equilibrium between the κ^1 and κ^2 modes of bonding for the two ligands has been suggested (Scheme 3).[13] The $J_{Rh\text{-}P}$ coupling constant observed at room temperature in the $^{31}P\{^1H\}$ NMR spectra for our complexes is also consistent with this formulation.



Scheme 3

b) Case where L = Ligand 1

As in previously reported studies,[8,10] more detailed work was performed with ligand **1** since it is the only compound that it is not a mixture of polyether ligands,[12] and therefore, the solid compounds can be expected to be isolated. With this aim, the COD complex with the tetrafluoroborate anion was synthesised by reaction of the [Rh(COD)Cl]$_2$ complex with two equivalents of AgBF$_4$ and four equivalents of ligand **1** in THF. A solid complex was isolated by subsequent reaction with CO, followed by crystallisation in diethyl ether. This complex displays an IR ν_{CO} band at 2040 cm^{-1}, and a broad doublet in the $^{31}P\{^1H\}$ NMR spectrum at δ = 21.0 ppm (J = 104.8 Hz). These spectroscopic parameters are in accordance with published data for *trans*-[Rh(CO)$_2$L$_2$]$^+$ complexes with related hemilabile ether ligands $Cy_2PCH_2CH_2OCH_3$[16] and $Ph_2PCH_2CH_2OPh$.[17] Although other published data indicate that formation of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the *trans*-$[Rh(PPh_3)_2(CO)_2]^+$ is uncertain,[18] its existence has been unequivocally demonstrated with the ether ligand $Ph_2PCH_2CH_2OPh$, using ^{31}P NMR spectroscopy of ^{13}CO labelled complexes.[17] The low-temperature $^{31}P\{^1H\}$ NMR spectrum of the dichloromethane solution of the *trans*-$[Rh(\mathbf{1})_2(CO)_2]^+$ complex shows that the broad doublet becomes sharp at a temperature lower than 233 K. A plausible explanation of this could be the restricted rotation around the phosphorus−metal bond at lower temperatures as a result of hydrophobic interactions between the two *tert*-octyl chains. The two reported crystal structures of metallic complexes with this ligand (see reference[10] and section 4 of Results and Discussion) have shown that these hydrophobic interactions could be related to the configuration of the molecules in solid state. The IR spectrum of the mother solution after crystallisation of the *trans*-$[Rh(\mathbf{1})_2(CO)_2]^+$ complex shows two signals at 2040 and 1990 cm^{-1}, and suggests the existence of the kinetically favoured *cis*-$[Rh(\mathbf{1})_2(CO)_2]^+$ complex in solution.[16]

The formation of the monocarbonyl complex *trans*-$[Rh(CO)(P\cap O)(PO)]^+$ with ligands **2**−**6** and the dicarbonyl complex *trans*-$[Rh(\mathbf{1})_2(CO)_2]^+$ can be justified by the propensity of ligand **1** to avoid the P,O chelation because of electronic and steric effects.[10] To force the coordination of the oxygen atom in ligand **1**, the synthesis of the monocarbonyl complex was undertaken by refluxing a dichloromethane solution of the *trans*-$[Rh(\mathbf{1})_2(CO)_2]^+$ complex. This reaction was monitored by IR spectroscopy, which showed the quick formation of a new complex with a ν_{CO} band at 1990 cm^{-1}. The $^{31}P\{^1H\}$ NMR spectrum at room temperature shows a broad doublet at δ = 29.5 ppm (J = 120.1 Hz). The low-temperature $^{31}P\{^1H\}$ NMR spectroscopic measurements (Figure 1) show the evolution of the broad doublet to a broad band at 253 K and a very broad band (22−37 ppm) at 233 K. At lower temperatures, a sharp doublet is formed at δ = 23.8 ppm (J = 134.3 Hz) and a broad doublet at δ = 34.8 ppm (J = 110 Hz) in a 1:1 ratio. These data are consistent with the existence of a κ^1(P)-coordinated ligand (doublet at δ = 23.8 ppm) and a κ^2 (P,O)-coordinated ligand (doublet at δ = 34.8 ppm). The fact that the κ^2 (P,O) resonance remains broad at this temperature illustrates the previously mentioned unfavourable κ^2 (P,O) coordination mode for **1**. Reported studies with the $Ph_2PCH_2CH_2OPh$ ligand have shown the existence of coordinated arene complexes, and the κ^2 (P,O) coordination of this ligand has been postulated in reaction intermediates.[17] The low-temperature ^1H NMR spectra show the splitting of the signal for the two methylene groups of **1** at 193 K. Furthermore, the arene protons of the phenoxy groups show two sharp doublets at room temperature at δ = 6.63 and 7.16 ppm, which are assigned to the *ortho*- and *meta* arene hydrogen atoms of the phenoxy group, respectively. At low temperatures, the signal for the *meta* hydrogen atom shows insignificant changes. In contrast, the signal for the *ortho*-hydrogen atom shows a broad band at 213 K, which splits into two signals: a sharp band at δ = 6.38 ppm and a broad signal at δ = 6.65 ppm. All these observations − the splitting of the signal for the methylene groups that shows the existence of two different $CH_2CH_2O(C_6H_4)C_8H_{17}$ fragments and the splitting of the signal for the *ortho* hydrogen atoms of the phenoxy groups − are consistent with the co-existence of a κ^1 (P) and a κ^2 (P,O)-coordinated ligand and corroborate the $^{31}P\{^1H\}$ NMR spectroscopic data. It should be emphasised that a η^6-coordination of the arene group is not favourable for electronic reasons and a η^2-coordination of the arene is not supported by the ^1H NMR spectroscopic data.

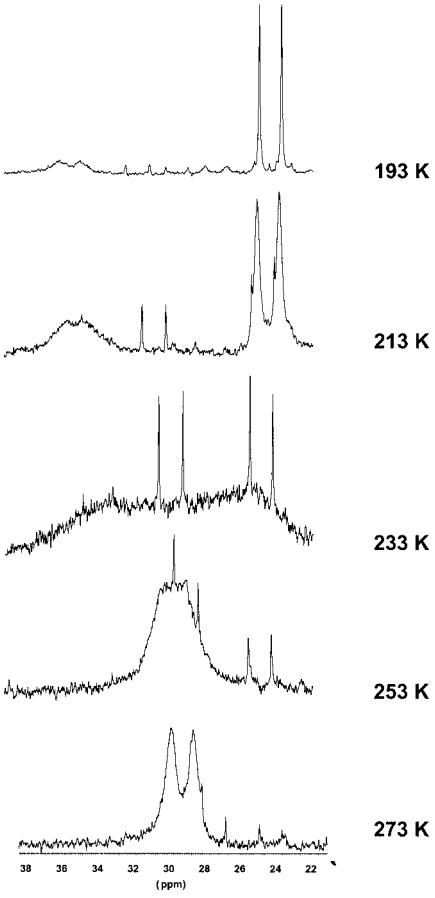


Figure 1. Low-temperature $^{31}P\{^1H\}$ NMR spectra of $[Rh(CO)(\mathbf{1})_2][BF_4]$

Finally, the attracting properties of this ligand should be noted because it can be considered as an hemilabile (P,O) ligand with a very weak, but possible, interaction between the oxygen atom and the metal atom. This observation is supported by our previous studies with Ru^{II} and Pd^{II} complexes. Those studies show the prevailing trend of this ligand to coordinate only by means of the phosphorus atom.[8,10] Finally, further support is available from the published reports on the ligand $Ph_2PCH_2CH_2OPh$, where the P,O coordination was only postulated in the reaction intermediates.[17]

4. Synthesis and X-ray Structure of *trans*-[Rh(CO)(1)$_2$Cl]

As it was not possible to get single crystals of the cationic complexes of ligand **1**, another attempt was made with neutral chloro rhodium complexes. The reaction of

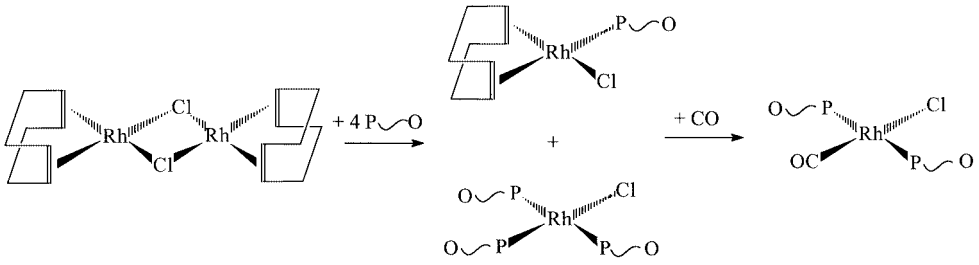

Scheme 4

$[Rh(COD)(\mu\text{-}Cl)]_2$ with four equivalents of ligand **1** leads to a mixture of two species, according to the $^{31}P\{^1H\}$ NMR spectrum of the reaction medium (Scheme 4). The first is observed as a doublet at $\delta = 28.2$ ppm ($^1J_{PRh} = 150$ Hz) and is assigned to the species [Rh(COD)(**1**)Cl]. The second complex displays a set of signals consisting of a doublet of doublets at $\delta = 22.3$ ppm ($^1J_{PRh} = 137$ Hz; $^2J_{P,P} = 39$ Hz) and a doublet of triplets centred at $\delta = 37.3$ ppm ($^1J_{PRh} = 187$ Hz; $^2J_{P,P} = 39$ Hz), and is assigned to the $[Rh(\mathbf{1})_3Cl]$ species. After bubbling CO into the previous reaction mixture, only one doublet at $\delta = 21.3$ ppm ($^1J_{PRh} = 124$ Hz) is observed. This signal and the presence of an IR band at 1975 cm^{-1} are in good agreement with the formation of a *trans*-$[Rh(CO)(\mathbf{1})_2Cl]$ species. Single crystals of this complex were obtained by crystallisation from an acetone/methanol solution, and the structure of complex was determined by X-ray methods. A perspective view of the molecule with the labelling scheme is shown in Figure 2. The rhodium atom displays a square-planar geometry with phosphane ligands in the *trans* positions, confirming previous assignment from NMR spectroscopic data. Bond lengths and angles around the metal centre are similar to other *trans*-$[Rh(CO)L_2Cl]$ complexes with monodentate phosphane ligands.[19] Note, however, that the most interesting information is attained on comparing the structure of *trans*-$[Rh(CO)(\mathbf{1})_2Cl]$ (Figure 2) with that of the previously reported *trans*-$[PdCl_2(\mathbf{1})_2]$ (Figure 3).[10] Indeed, on comparing both figures, the great similarity between the conformations of the two *tert*-octylphenoxyethyl chains in both complexes can be seen. In both complexes, the phenyl groups bonded to the phosphorus atoms are nearly eclipsed, and the values of the C2−P1−P2−C4 torsion angle in both complexes are very similar {*trans*-$[Rh(CO)(\mathbf{1})_2Cl] = 22(1)°$; *trans*-$[PdCl_2(\mathbf{1})_2] = 24.0(2)°$}. This implies that the two *tert*-octylphenoxyethyl chains are close to each other, an arrangement that could be explained by the tendency of the more hydrophobic parts of the molecule to be close together. The analysis of the structure of the $[PdCl_2(\mathbf{1})_2]$ complex led us to consider, jointly with the proposed hydrophobic interactions, that other factors should also be taken into account. Thus, hydrogen bonds between the Cl atom and the hydrogen atoms of the methylene groups bonded to the oxygen atom, or between one oxygen atom and one phenyl group were considered.[10] The noteworthy similarity between the conformation of the hydrophobic groups in the structures of these metal complexes with the two different metal fragments, $PdCl_2$ and Rh(CO)Cl, suggests that the interaction between the *tert*-octylphenoxyethyl chains can play a central role in the conformation of these complexes. It should be emphasised that in the homologous *trans*-$[PdCl_2L_2]$[20] and *trans*-$[Rh(CO)ClL_2]$[19b] complexes with the ligand PPh_2Me, which cannot lead to significant hydrophobic interactions between the methyl groups, the conformation of the two complexes is different (Figure 4). Thus, the phenyl groups

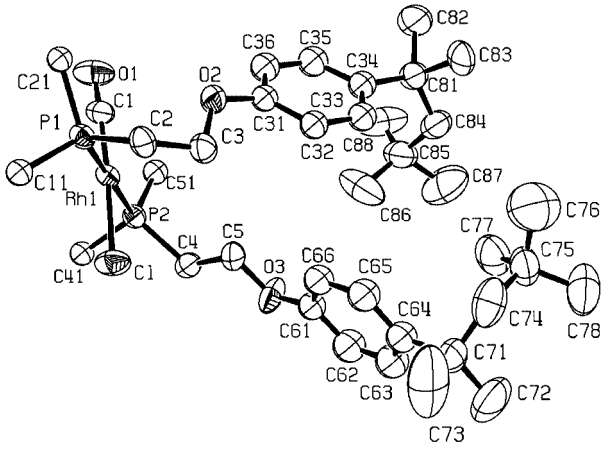

Figure 2. ORTEP diagram of *trans*-$[Rh(CO)(\mathbf{1})_2Cl]$ showing the atom numbering scheme. The phenyl rings bonded to phosphorus have been omitted

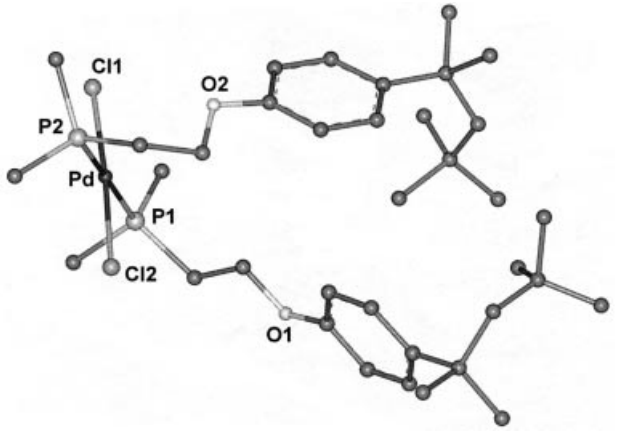

Figure 3. View of the molecular structure of *trans*-$[PdCl_2(\mathbf{1})_2]$. The phenyl rings bonded to phosphorus have been omitted

Figure 4. Molecular structures of *trans*-[Rh(CO)(PPh_2Me)$_2$Cl][19b] (left) and *trans*-[$PdCl_2$(PPh_2Me)$_2$][10] (right) showing the different conformations of the coordinated phosphane ligands

are nearly eclipsed in the rhodium complex and the methyl groups are closer, whereas in the palladium complex the two methyl groups are located as far apart as possible.

Experimental Section

General Remarks: All reactions were performed under nitrogen by standard Schlenk tube techniques. The NMR spectra were recorded by the *Servei de Ressonància Magnètica Nuclear de la Universitat Autònoma de Barcelona* on a Bruker AC250 instrument. All chemical shift values are given in ppm and are referenced with respect to residual protons in the deuterated solvents for ^{1}H spectra, to solvent signals for ^{13}C spectra and to external phosphoric acid for ^{31}P{^{1}H} spectra. Coupling constants, in parentheses, are expressed in Hz. Infrared spectra were recorded on a Perkin−Elmer FT-2000.

Compounds **1**−**6** were prepared by published procedures.[8b] Microanalyses were performed in the Servei d'Anàlisi Química de la Universitat Autònoma de Barcelona.

Reactivity of 1−6 toward [Rh(COD)(THF)$_2$]$^+$: In a representative procedure 70% $HClO_4$ (0.16 mmol) was added to a yellow solution of [Rh(COD)(acac)] (0.16 mmol) in 10 mL of THF. The solution turned slightly orange. After stirring for several minutes, the corresponding phosphane ligand (0.32 mmol) in 5 mL of THF was added. The orange colour became more intense. The reaction mixture was stirred for over one hour at room temperature. The ^{31}P{^{1}H} NMR spectrum of the reaction mixture was recorded by adding [D$_6$]acetone to the THF solutions. **1**: 17.6 d (J = 144 Hz). **2**: 17.6 (d, J = 142 Hz), 23.8 (d, J = 122 Hz), 28.7 (d, J = 139 Hz). **3**: 17.0 (b), 28.8 (d, J = 139 Hz). **4**: 17.5 (d, J = 150 Hz), 17.8 (d, J = 142 Hz). **5**: 17.7 (d, J = 142 Hz), 26.8 (b). **6**: 17.6 (d, J = 144 Hz), 28.5 (d, J = 153 Hz), 32.4 (d, J = 121 Hz), 39.5 ppm (d, J = 130 Hz).

Reactivity of 2−6 toward [Rh(COD)(THF)$_2$]$^+$ and CO: When CO was bubbled into the previous reaction mixture its colour rapidly turned pale yellow. Bubbling was maintained for one hour after which the reaction solvents were evaporated to dryness. The ^{31}P{^{1}H} NMR and IR spectra of the resulting oily products were recorded by adding [D$_6$]acetone to the dichloromethane solutions. ^{31}P{^{1}H} NMR spectroscopic data: **2**: 22.0 (d, J = 130 Hz), 23.6 (d, J = 127 Hz). **3**: 21.8 (d, J = 124 Hz). **4**: 25.4 (broad d, $J \approx$ 110 Hz). **5**: 23.8 (d, J = 110 Hz), 30.7 (d, J = 113 Hz). **6**: 23.2 (d, J = 113 Hz), 32.5 ppm (d, J = 118 Hz). IR data (νCO, CH_2Cl_2 solution): **2**, 1980; **3**, 1972; **4**, 1980; **5**, 1979; **6**, 1983 cm^{-1}.

Reactivity of 1 toward [Rh(COD)(THF)$_2$][BF$_4$] and CO: Synthesis of *trans*-[Rh(CO)$_2$(1)$_2$][BF$_4$]: [Rh(COD)(μ-Cl)]$_2$ (100 mg, 0.2 mmol) was dissolved in 10 mL of THF and $AgBF_4$ (80 mg, 0.41 mmol) was added to the solution. The solution was stirred for 1 h. Precipitated AgCl was eliminated by filtration through a small pad of Celite. **1** (340 mg, 0.81 mmol) was added to the resulting yellow solution and the solution was stirred for 1 h. CO was bubbled into the solution for 1 h and during this time the solution lightened. THF was then evaporated under vacuum and the residue was dissolved in 5 mL of CH_2Cl_2. 15 mL of diethyl ether was added to this solution and the resulting mixture was cooled to −20 °C. 250 mg of *trans*-[Rh(CO)$_2$(**1**)$_2$][BF$_4$] was isolated as a white powder (57% yield). IR (νCO): 2041 cm^{-1} (CH_2Cl_2 solution); ^{31}P{^{1}H} NMR ($CDCl_3$): (293 K) 20.9 (bd, J = 104.8 Hz); (233 K) 20.1 ppm, (d, J = 107.1 Hz). (^{1}H) NMR (CD_2Cl_2): (293 K) 0.66 (s, 9 H), 1.31 (s, 6 H), 1.69 (s, 2 H), 3.16 (m, 2 H), 4.27 (m, 2 H), 6.57 (d, J = 8.7 Hz, 2 H), 7.21 (d, J = 8.7 Hz, 2 H), 7.44−7.65 ppm (m, 10 H). $C_{58}H_{70}BF_4O_4P_2Rh$ (1082.8): calcd. C 64.3, H 6.5; found C 63.9, H 7.0.

Synthesis of [Rh(CO)(1)$_2$][BF$_4$]: *trans*-[Rh(CO)$_2$(**1**)$_2$][BF$_4$] (250 mg) was dissolved in 15 mL of CH_2Cl_2 and the solution was refluxed for 5 h. The solution was evaporated to dryness and the residue was crystallised in a CH_2Cl_2/hexane mixture at −20 °C. 200 mg of [Rh(CO)(**1**)$_2$][BF$_4$] was isolated (82%). IR (νCO): 1990 cm^{-1} (CH_2Cl_2 solution); ^{31}P{^{1}H} NMR (CD_2Cl_2): (293 K) 29.5 (bd, J = 120.1 Hz); (193 K) 23.8, (d, J = 134.3 Hz), 34.8 ppm, (bd, J = 110 Hz). (^{1}H) NMR (CD_2Cl_2): (293 K) 0.69 (s, 9 H), 1.31 (s, 6 H), 1.69 (s, 2 H), 2.83 (m, 2 H), 4.21 (m, 2 H), 6.63 (d, J = 8.7 Hz, 2 H), 7.16 (d, J = 8.7 Hz, 2 H), 7.47−7.70 ppm (m, 10 H). (193 K) 0.56 (bs, 18 H), 1.23 (bs, 12 H), 1.62 (s, 4 H), 2.57 (b, 2 H), 3.01 (b, 2 H), 3.92 (b, 2 H), 4.22 (m, 2 H), 6.38 (2 H), 6.66 (2 H), 7.05 (b, 4 H), 7.41−7.63 ppm (m, 20 H). $C_{57}H_{70}BF_4O_3P_2Rh$ (1054.8): calcd. C 64.9, H 6.7; found C, 65.0, H 6.5.

Synthesis of *trans*-Rh(CO)(1)$_2$Cl: Ligand **1** (0.27 mmol) and [Rh(COD)(μ-Cl)]$_2$ (0.06 mmol) were dissolved in 25 mL of CH_2Cl_2. The yellow reaction mixture was stirred for one hour. The ^{31}P{^{1}H} NMR spectrum of this reaction mixture was recorded by adding [D$_6$]acetone: 22.3 (dd, $^1J_{RhP}$ = 137, $^2J_{P,P}$ = 39 Hz); 28.2 (d, $^1J_{RhP}$ = 150 Hz); 37.3 ppm (dt, $^1J_{RhP}$ = 187, $^2J_{P,P}$ = 39 Hz).

CO was bubbled into the reaction mixture for one hour and during this time the colour changed to pale yellow. The solution was evaporated to dryness and the residue was crystallised in a acetone/methanol mixture at −20 °C. 75 mg of *trans*-[Rh(CO)(**1**)$_2$Cl] was isolated (62%). IR (νCO): 1975 cm^{-1} (CH_2Cl_2 solution). ^{31}P{^{1}H} NMR (CD_2Cl_2): 21.3 ppm d ($^1J_{RhP}$ = 124 Hz). $C_{57}H_{70}O_3ClP_2Rh$: calcd. C 68.2, H 7.0; found C, 67.5, H 7.4.

X-ray Crystallographic Study: Data were collected on an Enraf−Nonius CAD4 diffractometer at room temperature. Full crystallographic data for *trans*-[Rh(CO)(**1**)$_2$Cl] are gathered in Table 1. All calculations were performed on a PC-compatible computer using the WinGX system.[21] The structures were solved by direct methods, using the SIR92 program,[22] which revealed in each instance the position of most of the non-hydrogen atoms. All remaining non-hydrogen atoms were located by the usual combination of full-matrix least-squares refinement and difference electron density syntheses using the SHELXS-97 program.[23] One *tert*-octyl group showed structural disorder and it was split; final s.o.f. was 0.5/0.5. The phenyl rings have been refined as rigid groups (D_{6h} symmetry; C−C = 1.39 Å; C−H = 0.93 Å). Atomic scattering factors were taken from the usual tabulations.[24] Anomalous dispersion terms for Rh, P, and Cl were included in F_c.[25] All non-hydrogen atoms were allowed to vibrate anisotropically. All the hydrogen atoms were set in idealised positions (R_3CH, C−H = 0.96 Å; R_2CH_2 = 0.97 Å; C(sp^2)−H = 0.93 Å; U_{iso} 1.2 times greater than the U_{eq} of the carbon atom to which the hydrogen atom is attached) and held fixed during refinements. Final atomic coordinates for all atoms, anisotropic thermal parameters, lists of structure factor amplitude for compounds for the X-ray study are available from the authors upon request.

Table 1. Crystal data and structure refinement for *trans*-[Rh(CO)(**1**)$_2$Cl]

Empirical formula	$C_{57}H_{70}ClO_3P_2Rh$
Molecular mass	1003.43
Temperature	293(2) K
Wavelength	0.71073 Å
Crystal system	triclinic
Space group	$P\bar{1}$ (#2)
Unit cell dimensions	a = 16.2300(10) Å, α = 101.98(2)°
	b = 17.057(2) Å, β = 96.83(2)°
	c = 10.0310(10) Å, γ = 77.830(10)°
Volume	2647.2(4) Å^3
Z	1.259 Mg/m^3
Absorption coefficient	0.475 mm^{-1}
F(000)	1056
Theta range for data collection	1.24 to 21.98°
Index ranges	$0 \le h \le 17$, $-17 \le k \le 17$, $-10 \le l \le 10$
Independent reflections	6462
Completeness to theta = 21.98°	99.8%
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	6462/11/544
Goodness-of-fit on F^2	1.054
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0420, $wR2$ = 0.1064

CCDC-203524 contains the supplementary crystallographic data for this paper. COVER PICTURE

The cover picture shows a disc that contains a suspension of the complex $[(C_6F_5)_2Au\{\mu\text{-}Ag(OClO_3)\}Au(C_6F_5)_2]$ (solid) (Figure 1 in the Microreview) under ultraviolet light. The border of the disc is cooled with liquid nitrogen to a temperature close to 77 K and the centre of the disc is at room temperature. The luminescence and the colour of the complex changes from red (near 77 K), through orange and yellow, to green (room temperature). Details are discussed in the Microreview by M. Bardajía and A. Laguna on p. 3069 ff.

Heteronuclear Metal−Metal Contacts between Gold(I) and Group-11, -12, and -13 Centers

Manuel Bardají[a][‡] and Antonio Laguna*[a]

Keywords: Gold / Heterometallic complexes / Metal-metal interactions / Silver

Closed-shell interactions occur mainly for some heavy late transition metals and main-group elements. In fact, these are dispersion forces reinforced by relativistic effects and by ionic components, of which the former are maximized in heteronuclear interactions. Heteronuclear compounds containing gold(I) and group-11, -12, and -13 metals display d^{10}–d^{10} or d^{10}–s^2 closed-shell interactions of intermediate strength relative to the homonuclear metal–metal interactions. The number of examples of gold(I)–gold(I) contacts is large, but representatives of heteronuclear gold(I)–metal contacts are still scarce. There are two general types of derivatives displaying short gold–metal distances: those with bridging ligands and those with unbridged ones, of which the latter are always the more indicative of the presence of a real bond. Derivatives featuring unsupported gold–metal bonds have been obtained mainly through reactions between basic gold(I) complexes and acid complexes, and also by encapsulation of metal centers in metallocryptands. Most derivatives with supported gold–metal bonds have been synthesized by use of C-donor ligands or ambidentate ligands. The gold–metal contacts dramatically affect the conformations and the aggregation of the molecules, and also their optical properties. Some of these derivatives are, in fact, intensely luminescent.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

1. Introduction

Closed-shell species with opposite electric charges form strong ionic bonds, but such bonds should not be expected if their charges are similar. However, it has been shown experimentally that such closed-shell interactions do occur, mainly for some heavy late transition metals and main-group elements; these interactions are weaker than ionic bonds but stronger than other van der Waals bonds.[1]

The most typical case is found in gold(I) chemistry, and the term aurophilicity was coined by Schmidbaur to refer to this phenomenon. Linear two-coordinate gold(I) compounds with d^{10} configurations tend to associate into dimers, oligomers, or polymers through gold−gold contacts, showing gold−gold distances in the 2.69−3.35 Å range. The energies associated with these aurophilic interactions go from 20 to 50 kJ/mol, close to those found in hydrogen bonds.[2−4] Aurophilicity has been used in crystal engineering of homo- and heterometallic systems to design supra-

Doctor Manuel Bardají completed his Ph.D. degree with Professors Antonio and Mariano Laguna in 1994 (Universidad de Zaragoza), and undertook a two-year postdoctoral stay at the Laboratoire de Chimie de Coordination (Toulouse, France) under the supervision of Bruno Chaudret. He returned to the Universidad de Zaragoza, where he has been working in the field of gold chemistry. He has been a "Profesor Titular" of Inorganic Chemistry (Profesor Titular de Química Inorgánica) at the Universidad de Valladolid since December 2002.

Professor Antonio Laguna completed his Ph.D. degree with Professor R. Usón in 1973. He also completed a postdoctoral period at the University of Bristol in 1975, under the supervision of Professor F. G. A. Stone. Since 1976 he has worked at the University of Zaragoza as Profesor Titular or Professor of Inorganic Chemistry. He is the author of more than 270 scientific papers on the organometallic and coordination chemistry of silver and gold.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

molecular structures, because it affects molecular conformations and intermolecular aggregation.[5−7]

Similarly, the terms cuprophilicity (Cu−Cu < 2.8 Å) and argentophilicity (Ag−Ag < 3.4 Å) have been used to describe this phenomenon in the cases of copper and silver, respectively, the energies involved being lower than in the case of gold but close to those of standard van der Waals interactions. The same phenomenon was also found for the close heavy metals mercury, thallium, and platinum; it was again less energetic, although some small contributions from metal−metal bonding could not be ignored.[1,8,9] Curiously, the first direct observation of a d orbital was achieved in charge-density maps of cuprite (Cu_2O), thanks to the hole in the d^{10} configuration due to Cu^I−Cu^I interactions.[10,11]

Great efforts have been devoted to theoretical studies trying to explain this phenomenon by different approaches. Pyykkö and co-workers have concluded that the aurophilic attraction is an electronic correlation effect strengthened by the relativistic effect, which has a maximum for gold. They extended their studies to other closed-shell metallic interactions in d^{10}, d^8, or s^2 systems and also to mixed systems; the term metallophilic attraction was coined to describe this phenomenon. From these, it is a dispersion force reinforced by relativistic effects (for heavy atoms) and by ionic components, the former already being important for gold−gold interactions but being more clearly seen for heteronuclear interactions.[1,12−15]

Heteronuclear compounds containing gold(I) and group-11, -12, and -13 metals display d^{10}−d^{10} or d^{10}−s^2 closed-shell interactions of intermediate strength relative to the homonuclear metal−metal interactions. The natures of the ligands and competition with other weak forces, such as hydrogen bonds or π−π interactions between aromatic rings, play an important role. It is important to note that these interactions are invoked for copper−, silver−, mercury−, indium−, and thallium−gold distances shorter than the sums of the corresponding van der Waals radii (3.06, 3.38, 3.21, 3.59 and 3.62 Å, respectively; values taken from Table 3 in ref.[1]) and are regarded as strong if they are less than or close to the sums of the metallic radii (2.72, 2.89, 3.04, 3.07 and 3.14 Å, respectively).[16]

Three general strategies are used to build these heteronuclear compounds: a) supported gold−metal bonds in which bridging ligands are present, b) unsupported gold−metal bonds through reactions between basic/donor gold(I) complexes and acid/acceptor complexes to give acid−base/acceptor−donor stacking, and c) unsupported gold−metal bonds by encapsulation of a metal center of a dinuclear gold(I) cryptand.

Moreover, there are gold−metal clusters in which the metallic centers can be formally considered to be in an oxidation state between 0 and 1, and display similar or shorter gold−metal distances. In the same kind of clusters, $Au(PR_3)^+$ fragments can be added or scrambled to give a mixture of $Au(PR_3)^+$ and $M(PR_3)^+$ (M = Cu, Ag) units. These have been reviewed elsewhere and are not considered here, at least for clusters bigger than heptanuclear.[17−19]

The metal−metal contacts dramatically affect the conformations and the aggregation of the molecules, as happens in the most typical case of aurophilicity, and this in turn affects some properties, such as the optical properties.[20] The optical properties of these derivatives (generally gold or platinum compounds) have applications in sensor technology,[21,22] and they have been used to detect oxygen,[23] volatile organic compounds,[24,25] potassium,[26] or phosphane[27] in solution, whilst other display solvoluminescence.[28] Similarly, some results for gold−silver derivatives have recently been obtained.[29]

The number of examples of gold(I)−gold(I) contacts is large, but examples of the heteronuclear gold(I)−metal contacts are still scarce. In this microreview we summarize the state of the art in heteronuclear metal−metal contacts of gold(I) with group-11, -12, and -13 centers − mainly with silver(I) and thallium(I) − for which the gold−metal distances have been determined and show the presence of d^{10}−d^{10} or d^{10}−s^2 closed-shell interactions.

The microreview is organized as follows:

2. Derivatives with Unsupported Gold−Metal Bonds
2.1. With Bis(halophenyl)aurate(I) Salts as Bases
2.1.1. Unsupported Gold−Silver Contacts
2.1.2. Unsupported Gold−Thallium Contacts
2.2. By Use of Trinuclear Cyclic Gold(I) Complexes as Bases
2.3. By Encapsulation of a Metal Center by a Dinuclear Gold(I) Cryptand
2.4. Other Cases
3. Derivatives with Supported Gold−Metal Bonds
3.1. Dinuclear Derivatives
3.2. Trinuclear Derivatives
3.3. Higher Nuclearities

2. Derivatives with Unsupported Gold−Metal Bonds

The clearest cases of metal−metal bonding are produced by the presence of short metal−metal distances in the absence of bridging ligands. In such cases, the gold−metal contacts produce aggregation, which usually dramatically affects the optical properties. Some heteronuclear derivatives, for instance, become luminescent after formation of the gold−metal bond. These derivatives can be obtained mainly by two approaches: 1) by use of bis(halophenyl)aurate(I) or trinuclear cyclic gold(I) complexes as a base, therefore maximizing the electrostatic component of these closed-shell interactions, and 2) by encapsulation of a metal center by a dinuclear gold(I) cryptand.

2.1. With Bis(halophenyl)aurate(I) Salts as Bases

Because of the number of examples, we divide this section into two parts: one for silver derivatives, and the other for

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thallium derivatives, the latter being prepared by the same type of reaction.

2.1.1. Unsupported Gold−Silver Contacts

In 1981 we characterized the first example of such a gold(I)−silver(I) interaction in a chain polymer containing the moiety $[(C_6F_5)_2Au(\mu\text{-}AgSC_4H_8)_2Au(C_6F_5)_2]_\infty$, with Ag−Au acceptor−donor (or acid−base) bonds based on dispersive and electrostatic attraction between their metal centers.[30] There is a rhomboidal arrangement of the four metallic centers, in which the gold−silver distances are as short as 2.718(2) and 2.726(2) Å, whilst the inter-unit gold−gold distance is 2.889(2) Å; for the analogue with benzene (η^2-bonded symmetrically to the silver center) in place of tetrahydrothiophene (SC_4H_8) the gold−silver distances are 2.702(2) and 2.792(2) Å, and the gold−gold distance is 3.013(2) Å (see Figure 1).[31] Therefore, the gold−silver contacts are shorter than the gold−gold contacts in these compounds.

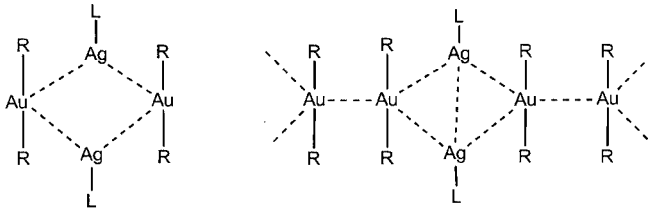

Figure 1. Complexes $[R_2Au(\mu\text{-}AgL)_2AuR_2]$ with rhomboidal geometry and unsupported gold−silver bonds; additional inter-unit gold−gold and intramolecular silver−silver contacts are possible

The basic aurate anion reacts with silver(I) to give a yellow solution. From this, through addition of ligand, yellow or orange polymers ($[R_2Au(\mu\text{-}AgL)_2AuR_2]_\infty$) are available with a variety of O-, N-, S-, or P-donors as auxiliary ligands, and R being a halophenyl ligand (R = C_6F_5, $C_6F_3H_2$ or C_6Cl_5). By this method, 35 different complexes have been prepared. These complexes are only soluble in coordinating solvents, but color loss is related to the cleavage of the gold−gold bonds.

Chain formation can be avoided by the use of bulky ligands at the gold centers, preventing aggregation through gold−gold interaction. We have thus synthesized the neutral or cationic tetrametallic phosphorus ylide gold−silver complexes $[(R_3PCH_2)_2Au(\mu\text{-}AgL)_2Au(CH_2PR_3)_2]$ (PR_3= PPh_3, PPh_2Me, $PPhMe_2$; L = $OClO_3$, PPh_3). X-ray diffraction studies carried out for L = PR_3 = PPh_3 show short gold−silver distances of 2.760(2) and 2.783(2) Å, within the previously observed range for these unsupported contacts, but there are no gold−gold interactions.[32]

We have recently revisited these polymeric derivatives in order to study their optical properties, because aggregation through gold(I)−gold(I) interactions has a dramatic effect on these properties in solution and in the solid state.[33] The absorption and emission spectra of $[(C_6F_5)_2Au(\mu\text{-}AgOCMe_2)_2Au(C_6F_5)_2]_\infty$ in acetone are consistent with molecular aggregation through gold−gold interactions when this compound goes from dilute solution conditions to concentrated ones. This derivative is also strongly luminescent in the solid state (546 nm at room temperature and 554 at 77 K). DFT calculations agree with the experimentally observed behavior and show the natures of the orbitals involved in each transition. In fact, the emission is attributable to pentafluorophenyl ππ* excited states or π-MMCT transitions in dilute solutions and to metal-centered excited states in concentrated solutions or in the solid state. Moreover, the gold−silver distances in this derivative are 2.7829(9) and 2.7903(9) Å; the gold−gold distance is 3.1674(11) Å, which is different from the previous structures. There is also a short silver−silver distance of 3.1810(13) Å.

By the same strategy, we have prepared a polymeric chain containing the dinuclear moiety $[Ag(py)_3][Au(C_6F_5)_2]$py rather than a tetranuclear one. An X-ray study showed disorder in the silver atom position, but the geometry was confirmed. Theoretical calculations reveal the presence both of metallophilic gold−silver (with ionic and dispersion contributions) and of aromatic pentafluorophenyl−pyridine interactions (dispersion effect).[34]

2.1.2. Unsupported Gold− Thallium Contacts

In 1998 we characterized the first extended unsupported gold−thallium linear chain containing the $[Tl(OPPh_3)_2][Au(C_6F_5)_2]$ moiety, with gold−thallium distances of 3.0358(8) and 3.0862(8) Å (Figure 2).[35] It was synthesized in the same way as the gold−silver polymers, through the reaction between the electron-rich $[Au(C_6F_5)_2]^-$ anion and a thallium salt in the presence of ligand.

In the same manner, we also prepared $[Tl(OPPh_3)][Tl(OPPh_3)L][Au(C_6Cl_5)_2]_2$ (L = THF, acetone), which also displayed extended unsupported chains with short gold−thallium distances, in the 3.0529(3)−3.3205(3) or 3.0937(3)−3.2705(4) Å ranges for tetrahydrothiophene or acetone, respectively (Figure 2).[36] Moreover, the thallium centers show two different types of geometrical environments, such as pseudotetrahedral and distorted trigonal-bi-

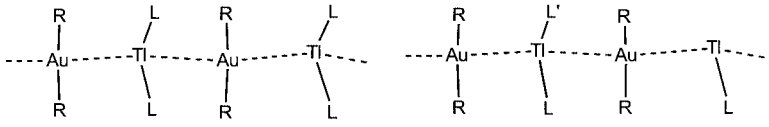

Figure 2. Asymmetric unit of linear chains with unsupported gold−thallium bonds; left: L = $OPPh_3$, R = C_6F_5; right: L = $OPPh_3$, L′ = THF, acetone; R = C_6Cl_5

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

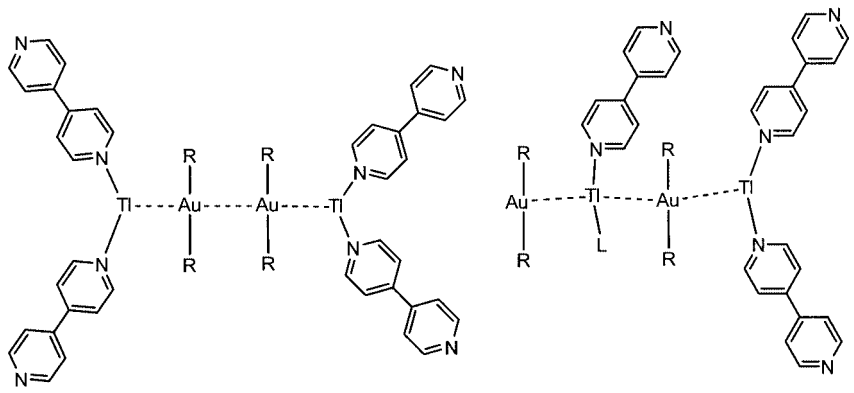

Figure 3. Tetranuclear moieties, further linked to others through bipy bridging ligands to give two-dimensional polymers; left: R = C_6F_5; right: L = THF, R = C_6Cl_5

pyramidal, due to the presence of solvent molecules that act as ligands in the solid state. Ab initio calculations, performed for the model $[Tl(OPH_3)_2][Au(C_6H_5)_2]$, are consistent with the presence of a high ionic contribution (80%) and a dispersion type with a charge-transfer contribution (20%). These three derivatives emit at 494, 497, and 501 nm, respectively, in the solid state at room temperature. Moreover, the last two derivatives show site-selective excitation at 77 K, which could be related to the different environments around the thallium centers. In fact, TD-DFT (density functional level by the time-dependent perturbation theory approach) calculations were in agreement with the experimental excitation spectra for all complexes and confirm the qualitative explanation that the excitation has $AuR_2 \rightarrow Tl$ charge-transfer character, whereby the thallium centers act as fluorophores. Again, the polymer structure is lost in donor solvents, so the colored crystals became uncolored in solution and do not luminesce.

Similar reactions resulted in the synthesis of the tetranuclear derivatives $[Tl(bipy)]_2[Au(C_6F_5)_2]_2$ (bipy = 4,4′-bipyridine) and $[Tl(bipy)][Tl(bipy)_{0.5}(THF)][Au(C_6Cl_5)_2]_2$.[37] In the first compound, a strong unsupported gold−thallium interaction of 3.0161(2) Å is found, together with gold−gold contacts of 3.409(3) Å, to give an unusual linear Tl−Au−Au−Tl arrangement in which repulsive instead of attractive forces might be expected {this non-fulfillment of the Coulomb rule was also observed[38] in $[Au(PPhMe_2)_2][Au(GeCl_3)_2]$, with the same unusual + − − + sequence}. The tetranuclear moiety is further linked through bidentate bridging bipy ligands (one bipy ligand bridging two thallium centers in two different moieties) to give a two-dimensional array. Finally, adjacent planes are connected through two additional Tl−F contacts to form an infinite three-dimensional polymer. The second compound displays a Tl−Au−Tl′−Au arrangement with two short gold−thallium distances of 3.0323(4) and 3.0540(4) Å and, again, bidentate bridging bipy ligands to form a two-dimensional polymer (Figure 3). Both complexes are strongly luminescent at room temperature, losing this property in solution (even in concentrated solutions), and so the luminescence is attributed to interactions between metal atoms. TD-DFT calculations agree with this proposal, and the obtained theoretical excitation spectra match the experimental results.

A similar reaction, however, carried out without addition of any ligand other than the solvent, produced the derivative $[Au_2Tl_2(C_6Cl_5)_4](OCMe_2)$, the crystal structure of which consists of a tetranuclear unit with four short unsupported gold−thallium contacts within the 3.0331(6)−3.1887(6) Å range and a longer thallium−thallium interaction of 3.6027(6) Å (Figure 4).[39] Two $[Au(C_6Cl_5)_2]^-$ units are held together by two thallium centers in a butterfly geometry, reminiscent of the silver−gold tetranuclear structures with unsupported gold−silver bonds, but now without additional gold−gold bonds; in addition to this, the thallium atoms show weak interaction with the oxygen atom of an acetone molecule. This complex luminesces at 556 nm at room temperature in the solid state, with lifetimes in the order of microseconds. Moreover, the starting materials do not luminesce, so this phenomenon could be assigned to the metal−metal bonds. Unlike in the case of other unsupported gold−thallium bonds, the structure of this complex is maintained in solution, in which it luminesces and shows solvent dependence. TD-DFT calculations carried out for $[Au_2Tl_2(C_6H_5)_4]$ show that the orbital from which the emission is produced is almost completely based on the two thallium(I) atoms, so these are therefore perturbed in solution by the presence of solvent molecules with donor capabilities.

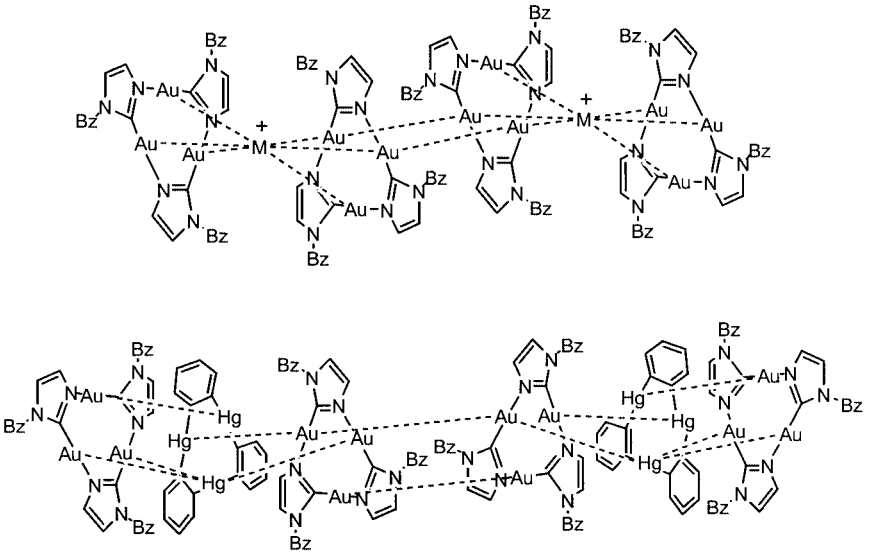

Figure 5. Sandwich heterometalllic clusters; top: silver(I)− or thallium(I)−gold(I) (M = Ag, Tl); bottom: mercury(II)−gold(I)

2.2. By Use of Trinuclear Cyclic Gold(I) Derivatives as Bases

Burini et al. have recently described[40−42] a series of sandwich derivatives obtained through the interaction between π-base trinuclear gold(I) complexes, such as $[Au(\mu\text{-}N^3,C^2\text{-bzim})]_3$ (N^3,C^2-bzim = 1-benzylimidazolate) and $[Au(\mu\text{-}C(OMe)=NCH_3)]_3$, and either acid cations such as Ag^+ or Tl^+, or the π molecular acid trinuclear complex of mercury(II) $[Hg(\mu\text{-}C,C\text{-}C_6F_4)]_3$, giving $[M\{[Au(\mu\text{-}N^3,C^2\text{-bzim})]_3\}_2]^+$ (M= Ag, Tl), $[Tl\{[Au(\mu\text{-}C(OMe)=NCH_3)]_3\}_2]PF_6$, $\{[Au(\mu\text{-}N^3,C^2\text{-bzim})]_3\}_2[Hg(C_6F_4)]_3$ or $\{[Au(\mu\text{-}C(OMe)=NCH_3)]_3\}_2[Hg(C_6F_4)]_3$, containing $[Au_3MAu_3]$ (M = Ag^I, Tl^I) or $[Au_3Hg_3Au_3]$ units (Figure 5). Additional gold−gold contacts therefore produce a supramolecular chain.

The naked silver or thallium ion center is bonded to six gold atoms to form a distorted trigonal prism, with gold−silver distances from 2.731(2) to 2.922(2) Å and gold−thallium distances from 2.9711(7) to 3.1075(4) Å. In addition to this, there are also gold−gold interactions in the cyclic trimer moiety (an average of 3.19 Å in the mixed gold−silver cluster, for instance) and between two close sandwich units [3.116 and 3.268 Å for the gold−silver cluster, or from 3.0588(4) to 3.1089(7) Å in the gold−thallium clusters].

The mercury centers interact with the gold centers in adjacent rings, with gold−mercury distances as short as 3.27 and 3.24 Å, for bzim and $C(OMe)=NCH_3$ ligands, respectively. DFT calculations showed positive electrostatic potential values above and below the plane of the mercury ring, while similar regions for the gold ring had negative values, thus clearly demonstrating the electrostatic nature of the interaction between the electron-poor mercury and the electron-rich gold rings.

The emission spectra of these compounds (silver and thallium) display low-energy phosphorescence, consistent with the extended chain structure. Furthermore, they exhibit luminescence thermochromism with red shifts in their emission maxima when they are cooled from room temperature to 77 K. The gold−mercury derivatives luminesce both at ambient and at low temperatures, the intensity of the emission increasing upon gold−mercury interaction.

2.3. By Encapsulation of a Metal Center by a Dinuclear Gold(I) Cryptand

Catalano and co-workers have recently developed an interesting approach to this subject. They have prepared metallocryptands with a cavity in which metallic centers can be encapsulated by use of metal−metal closed-shell interactions. Firstly, they synthesized a dinuclear gold(I) cryptand, employing the ligand 2,9-bis(diphenylphosphanyl)-1,10-phenantroline (P_2phen), which is able to selectively host Tl^I, Na^I (weakly; dissociates readily as there are no important closed-shell interactions), or Hg^0 (Figure 6).[43,44] Complexes $[Au_2M(P_2phen)_3](PF_6)_3$ (M = Tl, Hg) each display an almost linear arrangement with very short gold−thallium distances [2.9109(5) and 2.9171(5) Å] or gold−mercury distances [2.7807(4) and 2.7847(4) Å]. The structures contain two trigonal Au^I centers capping a D_3 symmetric cage. The gold−thallium derivative is strongly luminescent at 600 nm, both in solution and in the solid state; the emission can be attributed to metal-centered phosphorescence based on its large Stoke's shift, long lifetime, and solvent independence. The gold−mercury derivative is weakly emissive at 580 nm.

These workers have also extended the system to d^{10} Pd^0- and Pt^0-based metallocryptates [rather than gold(I)] capable of hosting a Tl^I or a Pb^{II} center through $d^{10}-s^2$ closed-shell interactions.[45−47] They have also changed the P_2phen ligand for other ligands such as 2,9-bis(diphenylphosphanyl)-1,8-naphthyridine (dppn) or PPh_2py; gold(I) centers have also been exchanged for silver(I). X-ray studies of $[Au_2$-

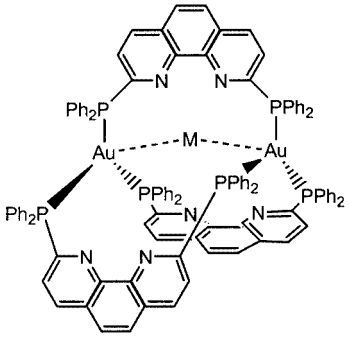

Figure 6. Metallocryptates $[Au_2M(P_2phen)_3](PF_6)_3$

$Na(dppn)_3](PF_6)_3$ display long gold−sodium interactions around 3.5 Å.[48] Moreover, these workers have also prepared a series of alkaline encapsulated derivatives $[Au_2M(dppn)_3](PF_6)_3$ (M = Li, Na, K, Cs), which also display luminescence around 580 nm in the solid state; the emission has been assigned to a gold-centered phosphorescence due to the tricoordinate gold centers.

2.4. Other Cases

Haupt and co-workers have prepared the trimetallic tetrahedron complexes $[Re_2(AuPPh_3)(MPPh_3)(\mu\text{-}PCy_2)(CO)_7(-)\text{-thiocamphanate}]$ (M = Cu, Ag), which show the short metal−metal distances of 2.584(2) Å (copper−gold) and 2.7026(18) Å (gold−silver).[49] The rhenium core is supported by phosphido ligands, but the gold−silver or gold−copper bond is unsupported. Moreover, the copper or silver center is coordinated to the sulfur atoms of the thiocamphanate ligand.

M. Laguna and co-workers have crystallographically characterized the pentanuclear derivative $[Au_4Ag(CH_2SiMe_3)_4(\mu\text{-dppm})_2]CF_3SO_3$ (dppm = $PPh_2CH_2PPh_2$) (Figure 7)[50] with an Au_4Ag core, which displays a silver atom bonded solely to four gold atoms in a distorted tetrahedral environment. The four silver−gold distances lie between the values of 2.7179(13) and 2.7822(13) Å and are almost identical to those found for our unsupported silver(I)−gold(I) bonds. Similarly, the gold−gold distances are 3.2170(9) and 3.2773(12) Å.

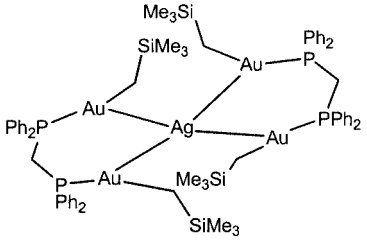

Figure 7. Pentanuclear Au_4Ag derivative with a tetrahedral geometry

The same workers have also synthesized the heptanuclear cluster $[Au_6Ag\{\mu\text{-}C_6H_2(CHMe_2)_3\}_6]CF_3SO_3$ with an almost planar Au_6Ag core, resembling a "cartwheel", in which the silver(I) atom is at the center of a regular hexagon of gold atoms (Figure 8).[51] The gold−silver distances are quite short − 2.797(1), 2.802(1), and 2.809(1) Å − whilst the gold−gold distances range from 2.795(1) to 2.817(1) Å, slightly longer than in the homoleptic pentamer $[\{Au(mes)\}_5]$ [2.692(1), 2.697(1) and 2.708(2) Å; mes = 2,4,6-$Me_3C_6H_2$].[52] The tris(isopropylphenyl) groups serve as bridges between two consecutive gold atoms within the hexagon. The derivative shows a deep green color, but it is not luminescent.

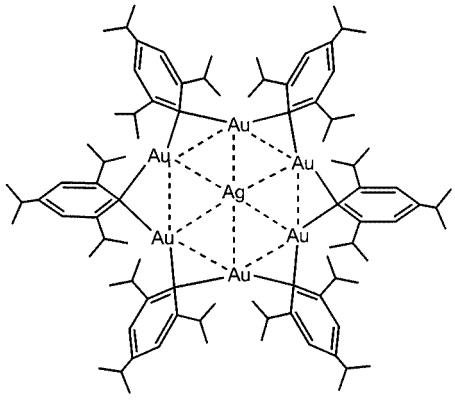

Figure 8. Heptanuclear Au_6Ag derivative with hexagonal geometry

Table 1 summarizes the gold−silver distances for this type of derivatives, their main characteristic being that all of them are quite short, often with additional gold−gold interactions. Table 2 summarizes the gold−thallium distances for unsupported bonds, which are also very short, although the presence of gold−gold interactions is less common.

3. Derivatives with Supported Gold-Metal Bonds

The use of bridging ligands favors the proximity of metal centers and therefore the presence of short distances. Moreover, these short distances are easily preserved in solution, thanks to the bridge. As is the case of unsupported gold(I)−metal bonds, the conformations of the ligands, the aggregation of the molecules, and the optical properties can be dramatically changed by the presence of these gold−metal closed-shell interactions. Very common is the use of C-donor bridging ligands that are good σ-donor ligands. These form deficient bonds and induce very short metal−metal distances. Nevertheless, ambidentate bridging ligands favor heteronuclear complexes.

3.1. Dinuclear Derivatives

For dinuclear derivatives, the simplest case, no example of copper−gold is yet known, but four gold−silver compounds have recently been crystallographically characterized. The first, reported by Schmidbaur and co-workers,[53] is $[AuAg(PPh_2py)_2](ClO_4)_2$, with a gold−silver distance of 2.820(1) Å. Two more examples − [Au-

$[Au_2Tl(P_2phen)_3](PF_6)_3$	2.9109(5), 2.9171(5)	no	no	[43]

$Ag(PPh_2CH_2SPh)_2](CF_3SO_3)_2$ and $[AuAg(PNH_2)_2]$-$(CF_3SO_3)_2$ [PNH_2 = 2-(diphenylphosphanyl)aniline] − with longer gold−silver distances [2.9314(5) and 2.9931(12) Å, respectively] have been prepared by us.[54,55] Finally, Fackler and co-workers have prepared $[AgAu(\mu\text{-}CH_2P(S)Ph_2]_2$, with a gold−silver distance of 2.9124(13) Å and an intermolecular gold−silver distance of 3.635 Å, forming a chain structure (Figure 9, b).[56] The same strategy − use of a bridging ambidentate ligand capable of selectively coordinating to the gold(I) center through a P- or C-donor atom, whilst the silver(I) center is coordinated to the second donor atom (N or S) − was used in all four cases. According to ab initio calculations carried out on a model based in the derivative $\{[AuM(PH_2CH_2SH)_2]^{2+}$; M= Cu, Ag, Au}, the presence of only one gold atom is sufficient to induce metallophilic attractions in copper and silver, and this effect can be modulated depending on the gold ligand. It has also been shown theoretically that the isomer found (phosphorus−gold-bonded system) is not only the most stable, but it also produces the shortest gold−silver distance (3.060 Å).

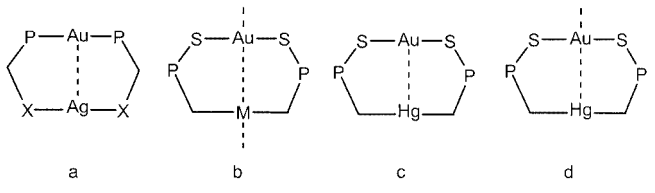

Figure 9. Doubly bridged dinuclear gold−silver(I), −mercury(II), or −thallium(I) derivatives: a) P−C−X = PPh_2py, PPh_2CH_2SPh, 2-(diphenylphosphanyl)aniline; b), c), d) M = Ag, Tl; C−P−S = $CH_2P(S)Ph_2$

Fackler and co-workers have prepared a dinuclear derivative, $[AuHg\{\mu\text{-}CH_2P(S)Ph_2\}_2]PF_6$, which displays a short gold(I)−mercury(II) distance of 3.088(1) Å (Figure 9, c).[57] It is a doubly bridged complex with the mercury centers coordinated to the ylide carbon atom and the gold centers coordinated to the sulfur atom (mercury and gold are not easy distinguished by X-ray diffraction studies, but NMR could determine the isomer: one kind of methylene signals with mercury satellites). A second X-ray structure was found for this derivative: it has a dimeric structure with gold−mercury distances of 2.9891(9) Å and a gold−gold intermolecular distance of 3.150(2) Å. These workers have also prepared the same derivative but with $[AuCl_4]$ as anion; in this case the gold(I)−mercury distance is 3.079 (2) Å and there is a gold(I)−gold(III) distance of 3.402(2) Å.[58]

Similarly, they have also prepared the dinuclear derivative $[AuTl\{\mu\text{-}CH_2P(S)Ph_2\}_2]_\infty$, a doubly bridged complex with the thallium centers coordinated to the ylide carbon atom and the gold centers coordinated to the sulfur atom. This also displays a short gold(I)−thallium(I) distance of 2.959(2) Å (Figure 9, d), but it forms an extended one-dimensional linear-chain polymer with an additional gold−thallium distance of 3.003(2) Å. This derivative is strongly photoluminescent, emitting at 575 nm (solid state 298 K) with a lifetime of 0.98 μs; the long lifetime and large separation between excitation and emission peaks indicate that the emission process is phosphorescence. This optical

property has been related to the gold−thallium bonds by calculation by the Fenske−Hall method.[59,60]

3.2. Trinuclear Derivatives

There are no trinuclear copper−gold clusters in which the presence of short metal−metal distances has been reported. For gold−silver derivatives there are three examples, two of them using a C-donor bridging ligand and one with a diphosphane ligand.

Vicente and co-workers have structurally characterized the trinuclear derivative $[(AuPPh_3)_2\{\mu\text{-}[C(PPh_3)(C_5H_4N\text{-}2)]\}\{\mu\text{-}Ag(O_2NO)(OClO_3)\}]$, with a triangular geometry for the metallic centers (Figure 10) and the presence of supported gold−gold [3.078(1) Å] and gold−silver interactions [2.926(1) and 3.006(1) Å].[61,62] In that work, in order to distinguish clusters with weak interactions from conventional clusters in which some or all metal atoms are tightly bonded, the former were denoted as "loose" clusters. This nomenclature has been adopted by other authors.

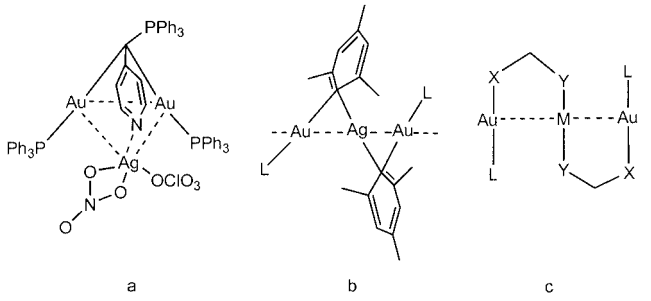

Figure 10. Molecular structures found for trinuclear Au_2Ag compounds: a) $[(AuPPh_3)_2\{\mu\text{-}[C(PPh_3)(C_5H_4N\text{-}2)]\}\{\mu\text{-}Ag(O_2NO)(OClO_3)\}]$, b) $[\{LAu(\mu\text{-mes})\}_2Ag](ClO_4)$, L = $AsPh_3$, c) M = Ag, L = mes, X−C−Y = dppm; M = Hg, L = Cl, X−C−Y = $CH_2P(S)Ph_2$

The mesityl group (2,4,6-$Me_3C_6H_2$) acts as a bridge, through three-center, two-electron bonds, and it is able to induce very short metal−metal distances, as, for instance, in the homoleptic derivatives $[\{Au(mes)\}_5]$ [2.692(1), 2.697(1) and 2.708(2) Å] and $[\{Ag(mes)\}_4]$ [2.733(3) and 2.7553(3) Å].[52] We have used this ligand to prepare heteronuclear gold−silver compounds containing trinuclear moieties $[\{(AsPh_3)Au(\mu\text{-mes})\}_2Ag](ClO_4)$ with a linear arrangement of the metallic core and a short gold−silver distance of 2.7758(8) Å; these trinuclear units are connected by gold−gold contacts of 3.132(2) Å to form a chain polymer.[63] By a similar approach, we have also prepared a diphosphane-bridged trinuclear derivative $[\{(mes)Au(\mu\text{-dppm})\}_2Ag](ClO_4)$ with longer gold−silver distances [2.944(2) and 2.946(2) Å] due to the bridging ligand (Figure 10).[64]

Fackler and co-workers have prepared the trinuclear derivative $[Au_2Hg\{\mu\text{-}CH_2P(S)Ph_2\}_2Cl_2]$, which displays a linear arrangement with a central mercury atom and gold−mercury distances of 3.310(1) and 3.361(1) Å (Figure 10). As found in the dinuclear gold−mercury derivative, the mercury center is coordinated to the ylide carbon atom and the gold centers coordinated to the sulfur atom.[58]

3.3. Higher Nuclearities

Abu-Salah et al. reported the tetranuclear cluster $[(PPh_3)Ag\{\mu\text{-}Au(CCPh)_2\}_2Ag(PPh_3)]$, with the same metallic core as in the derivatives described above (Ag_2Au_2 in section 2.1.1., Figure 1), except for a change in the positions of gold and silver (Figure 11).[65] Moreover, the main structural differences are as follows: silver centers do not aggregate (or show a lesser tendency than gold in the presence of a bulky phosphane) and so no polymer is formed; the alkyne fragments are coordinated to the silver centers, thus acting as bridging ligands. The gold−silver distances range from 2.894(1) to 3.028(1) Å, indicating appreciable metal−metal bonding; there are no gold−gold contacts (4.013 Å).

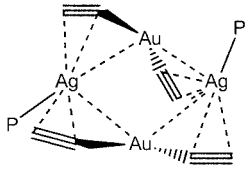

Figure 11. Rhomboidal, nearly square-planar geometry with supported gold−silver bonds; P = PPh_3

Pentanuclear clusters $[Au_3M_2(\mu\text{-}CCPh)_6]^-$ (M = Cu, Ag) displaying a trigonal-bipyramidal arrangement for the metallic core with the copper or silver centers in the apical positions have also been reported.[66−68] The gold−copper distances range from 2.783(3) to 3.016(3) Å [from 2.800 to 3.115(3) Å in a second X-ray diffraction study] whilst the gold−silver distances range from 2.911(1) to 3.096(1) Å [from 2.877(1) to 2.998(1) Å in a second X-ray determination]; there are no gold−gold contacts. Each gold center is coordinated to two alkynyl ligands, whilst the copper or silver centers are coordinated to the alkyne groups and to the gold atoms.

Eisenberg and co-workers have reported the tetranuclear heterodimetallic derivative $[\{AuCu(\mu\text{-}SPy)(\mu\text{-}PPh_2py)\}_2](PF_6)_2$, which is composed of two $AuCu(\mu\text{-}SPy)(\mu\text{-}PPh_2py)$ units (Cu bonded through N- and Au through P- and S-donor atoms) held together by bridging thiolate ligands (Figure 12).[69] There are strong gold−copper interactions of 2.6339(7) and 2.6455(7) Å in each dinuclear unit. This derivative is strongly emissive in the solid state at 77 K and in solution, whilst the mononuclear starting derivative $[Au(SPy)(PPh_2py)]$ shows weaker photoluminescence. The emitting state has been tentatively assigned to LMCT transition (from S to Au), but it has been strongly modified by the coordination of Cu to S and the formation of gold−copper bonds.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

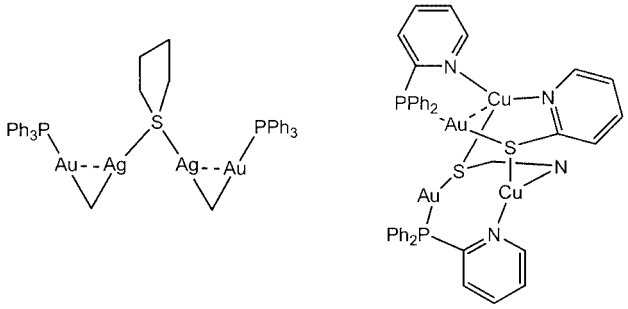

Figure 12. Two dimers bridged by ligands

We have also used the mesityl ligand to prepare heteronuclear gold−silver derivatives, such as $[(PPh_3)Au(\mu\text{-mes})\{Ag(\mu\text{-}SC_4H_8)\}_2(\mu\text{-mes})Au(PPh_3)]$, which has a gold−silver distance of 2.8245(6) Å, quite short but longer than the first unsupported bonds.[70] The structure possesses a dinuclear gold−silver core, which is bonded to an equal second unit through two tetrahydrothiophene bridges (Figure 12).

We have prepared the tetranuclear mixed derivative $[Au_2Ag_2(C_6F_5)_2(PPh_2CH_2SPh)_2(CF_3CO_2)_2]$ by treating the mononuclear *P*-bonded derivative $[Au(C_6F_5)(PPh_2CH_2SPh)]$ with $AgCF_3CO_2$.[54] The silver(I) centers are coordinated to the sulfur atom and bridged to each other by the trifluoroacetate ligands. There are two short gold−silver distances of 3.0335(8) Å and one short silver−silver distance of 2.8155(9) Å, so its geometry is a zigzag chain (Figure 13).

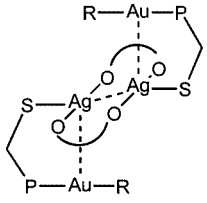

Figure 13. Tetranuclear derivative with a zigzag chain; O−O = CF_3CO_2, R = C_6F_5, P−C−S = PPh_2CH_2SPh

Henkel and co-workers have characterized the heterodimetallic clusters $[Au_3Cu_3L_4]^{2-}$ and $[Au_2Ag_4L_4]^{2-}$ (L = ethane-1,2-dithiolate), each of which displays a typical M_6S_8 cage skeleton with two gold atoms in the apical position, as shown in Figure 14.[71] The copper derivative shows short

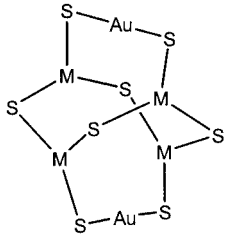

Figure 14. M_6S_8 cage skeleton

copper−gold distances of 2.862 Å on average, whilst the silver derivative displays gold−silver distances of 2.996 Å on average and silver−silver distances of 3.170 Å on average.

Salter et al. have reported the X-ray structures of heterotrimetallic hexanuclear clusters $[AuCuRu_4(\mu_3\text{-}H)_2(\mu\text{-dppf})(CO)_{12}]$ [dppf = 1,1′-bis(diphenylphosphanyl)ferrocene] and $[AuCuRu_4(\mu_3\text{-}H)_2(\mu\text{-dppe})(CO)_{12}]$ (dppe = $PPh_2CH_2CH_2PPh_2$), obtained through metal exchange reactions.[72,73] The metal-framework structures of both can be described as intermediate between a capped trigonal bipyramid and a capped square pyramid (Figure 15). There are short copper− and gold−ruthenium distances and also short copper−gold distances of 2.641(1) and 2.614(2) Å, respectively, for dppf and dppe. Moreover, the diphosphane ligand is bridging the copper and gold centers.

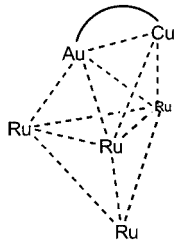

Figure 15. $AuCuRu_4$ cluster core in which a diphosphane ligand is bridging the copper and gold centers

We summarize silver(I)− and copper(I)−gold(I) distances found in mixed derivatives with supported bonds in Tables 3 and 4, respectively. Table 5 summarizes thallium−(supported bonds) and mercury−gold distances.

Finally, we describe two cases not exactly within the scope of this microreview, the first for copper(I)−gold(III) bonds, the second for gold−indium bonds. In the first case, Coucouvanis and co-workers have reported that the X-ray structure of $[AuCu_4L_4]^-$ [L = 2,2-bis(*tert*-butoxycarbonyl)-1-thiolatoethene-1-perthiolate consists of a rectangular pyramidal $AuCu_4$ core with mean $Au^{III}-Cu^{I}$ bonds of 3.029(7) Å.[74]

Now, to date there are only two clusters showing short gold−indium distances, and although the oxidation state of the starting materials is +1 for both metals, their final oxidation states are unclear. Schmidbaur and co-workers have reported the hexanuclear clusters $[Au_3In_3Cl_6(THF)_6(dppe)_2]$ and $[Au_3In_3Br_7(THF)_6(dppe)_2]^-$, obtained by the insertion of InX into the Au−X bond of $[AuXPPh_3]$.[75,76] The metallic core is formed by an isosceles triangle of three gold atoms, two indium atoms capping the gold triangle on both faces, while the third indium atom bridges the shortest edge of the gold triangle. Thus, there are two short gold−gold distances of 2.931(1) and 2.939(1) Å (for Cl), 2.860(1) and 2.858(1) Å (for Br), and one very short gold−gold distance of 2.562(1) Å and 2.571(1) Å, respectively, for Cl and Br. The gold−indium distances range from 2.761(1) to 2.973(1) Å (for Br). Theoretical investigations proposed two gold(0) and one gold(I)

Nanoparticulated Gold: Syntheses, Structures, Electronics, and Reactivities

Günter Schmid*[a] and Benedetto Corain[b]

Keywords: Gold / Nanoparticles / Synthetic methods / Quantum dots / Self-assembly / Heterogeneous catalysis

This microreview deals mainly with the synthesis and the electronic and chemical properties of gold nanoparticles. Modern synthetic routes, based on physical and on chemical procedures, as well as structural and optical features, are described. The bulk-to-molecule transition is discussed by studying size-controlled quantum-size effects, resulting in the determination of discrete electronic energy levels in Au_{55} clusters. Conductivity measurements of three- and two-dimensionally organized ligand-protected Au_{55} clusters are described, as well as the current techniques for the generation of ordered monolayers and artificial patterns of quantum dots. Finally, some aspects of the chemical activity of gold nanoparticles are discussed by considering ligand-exchange processes and, last but not least, the expanding role of gold nanoparticles in catalysis is considered.

1. Introduction

Gold: quintessence of beauty and nobility among the metals. Some time during the Stone Age man discovered and learned to appreciate gold not only for its beauty but also for its resistivity against corrosion. Moreover, because of its relative scarcity, gold has been considered a substance of great value over millennia and today it still serves as monetary parity in many countries. The Old Testament is full of stories dealing with gold and numerous wars have been started because of gold. The early historical use of gold has also to do with its natural deposits as nuggets, which meant that no chemical processes were needed to be able to use it. Due to its softness it could be hammered into articles of jewellery even in ancient times. Numerous civilizations therefore had already started gold mining by at least the 4th millennium BC. However, the mines operated by the Egyptians in Nubia surpassed all of them by far. Gold became a decisive reason for the power of the Egyptian rulers. It was, and still is, synonymous of wealth.

In contrast to the long history of gold, the development of its chemistry was retarded because of its noble character. It can only be dissolved in oxidising media like aqua regia or by complexing species such as cyanides under air. Nowadays, the chemistry of gold is rather broad, beginning with classical complex chemistry via novel organometallic chemistry up to solid-state chemistry where so-called aurides give evidence of the high electronegativity of this unique metal.

Long before the development of modern gold chemistry the special appearance of gold was appreciated by mankind: its ruby red colloids were used to color glasses and cer-

Günter Schmid studied chemistry at the University of Munich. He received his Diploma in 1962 and his Doctor's Degree in Inorganic Chemistry in 1965, both at the University of Munich. In 1966 he moved to the University of Marburg, Germany, and finished his Habilitation in 1969. In 1971 he got a professorship at the University of Marburg and he then moved to the University of Essen, Germany, where he became the director of the Institute for Inorganic Chemistry (1977). His main research interests include the synthesis and investigation of large transition metal clusters and colloids, the generation of three-, two- and one-dimensional arrangements of quantum dots, and heterogeneous catalysis.

Benedetto Corain graduated in Chemistry at the University of Padova in 1965. After serving as Assistant Professor and Associate Professor in Padova, he moved to the University of L'Aquila in 1993 as full Professor of Chemistry and he was called back with the same status from his previous University in 1999 (Faculty of Sciences). He spent one year as a Research Assistant at the Department of Chemistry, Imperial College, London in 1966 and as a Visiting Professor (Humboldt fellow) at TU Munich in 1981 and 1998 and at the University of Essen in 2002. His present research interests include basic and applied metal coordination chemistry and macromolecular chemistry, with particular emphasis on reactive and functional cross-linked polymers as supports for metal nanoclusters.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

amics. Solutions of colloidal gold were also used as tonics and elixirs, especially in combination with alcohol. Colloidal gold is still applied to treat arthritis.[1]

Scientifically, the beginning of the chemistry of gold colloids dates from the middle of the nineteenth century, when Michael Faraday performed his famous experiments to generate gold colloids.[2] He reduced tetrachloroaurate using white phosphorus to yield deep-red gold sols. At the beginning of the 20th century it was Wilhelm Ostwald who contributed decisively to the further development of colloid science.[3] He was the first to point out that the properties of metal particles in the nanometer range are predominantly determined by surface atoms and he concluded that those nanoparticles, called colloids, should exhibit novel properties with respect to bulk particles. The term "colloid" has meanwhile been mostly substituted by "nanoparticle" or "cluster". Both expressions are not very precise. They simply tell us that a particle consists of an assembly of atoms, from a few up to several hundred thousands or millions, in the size range between 1 and usually not more than 50 nm.

The miniaturization of gold to the nanometer range has dramatic consequences for its physical and chemical properties. (In principle these consequences are also valid for other metals. Gold, however, is an outstanding example.) Two examples shall elucidate the change of bulk properties when the nanosize regime is reached: the melting point and the color. Figure 1 shows the melting points of gold nanoparticles from ca. 20 to 2 nm in diameter.[4]

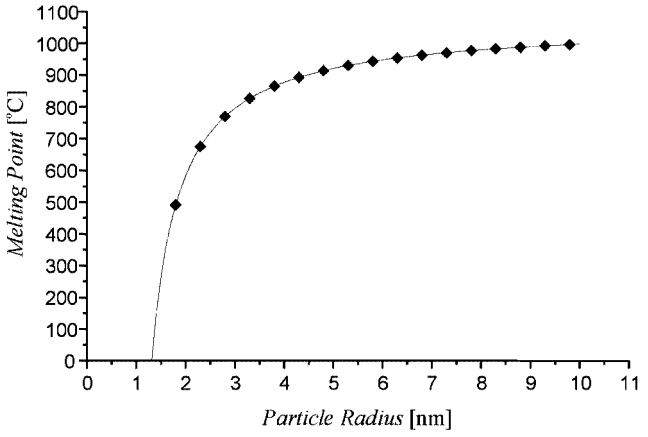

Figure 1. Relationship between particle size and melting point of gold nanoparticles

As we can see, the melting point drops below that of bulk gold (1064 °C) if the particle radius is less than 10 nm. This has to do with the increasing number of surface atoms with decreasing particle size. Surface atoms have lower coordination numbers than inner atoms and therefore become mobile more easily.

Figure 2 shows the typical color of 10 ± 5 nm gold particles.[5] In this particular case the particles are embedded in the pores of a transparent alumina membrane. The reason for the special color of metal nanoparticles is the so-called plasmon resonance, a well understood phenomenon, which is quantitatively described by the Mie theory.[6,7]

Figure 2. Photograph of a nanoporous alumina membrane, filled with 10 ± 5 nm gold nanoparticles

2. Syntheses

The number of procedures for generating gold nanoparticles is almost indeterminable. Most of them have been known for decades. For this reason only some relevant and general synthetic techniques shall be discussed here briefly. Two main routes to gold nanoparticles are available: a physical and a chemical one. Physical methods are defined as those by which gold nanoparticles are directly generated from bulk gold via atoms by various distribution techniques, whereas chemical routes use gold compounds as a starting material, linked with reduction steps.

An important aspect is the stabilization of the particles to avoid coalescence between them. This stabilization can occur in many different ways, for instance by electrostatic repulsion, steric hindrance, ligand molecules or embedding in nanocapsules such as micelles. Some of these opportunities will be discussed as part of the synthetic routes.

2.1 Physical Methods

Metal vapours usually consist of atoms. The simplest way of obtaining nanoparticles is therefore the generation of metal atoms in the gas phase followed by their controlled condensation to nanoparticles. This is the well-known metal-vapour synthesis.[8] In special cases the colloidal metals can be studied in the gas phase; however, in order to obtain them as matter, the vapours have to be condensed into a dispersing medium. Numerous modifications of this established technique have been successfully applied in the past[9] and will not be repeated in this article. Only some more recent and promising results shall be discussed.

Laser ablation methods have become commonly used techniques.[10–14] However, the size distribution of the resulting particles is usually rather broad. Improvements were obtained by the so-called "laser-induced size reduction". This is based on the well expressed plasmon resonance of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gold nanoparticles around 520 nm and was used to change the size and geometry of the particles.[15−20] Very narrowly distributed gold nanoparticles with a diameter of 1.7 and 3.4 nm were obtained with a 532 nm pulsed laser irradiation of gold metal plates in diluted sodium dodecylsulfate solutions.[21]

A gram-scale synthesis of thiol-stabilized gold nanoparticles by solvated metal atom dispersion and digestive ripening was recently reported.[22] The method is based on the so-called solvated metal atom dispersion technique (SMAD). A well-known reactor was used to generate atoms from a piece of bulk gold.[23] The Au atoms were frozen at 77 K in acetone vapour and were then warmed up to give gold colloids, stabilized by acetone molecules. In order to attain further stabilization, they were then reacted with dodecanethiol and this enabled good dispersion in toluene. A dramatic effect on the narrowing of the gold particles was obtained by digestive ripening of the gold-toluene dispersion at 120 °C. Particles of 1−40 nm in size were narrowed down to 4−4.5 nm.

As we shall see from the following examples, wet-chemical routes to generate gold nanoparticles are much more versatile.

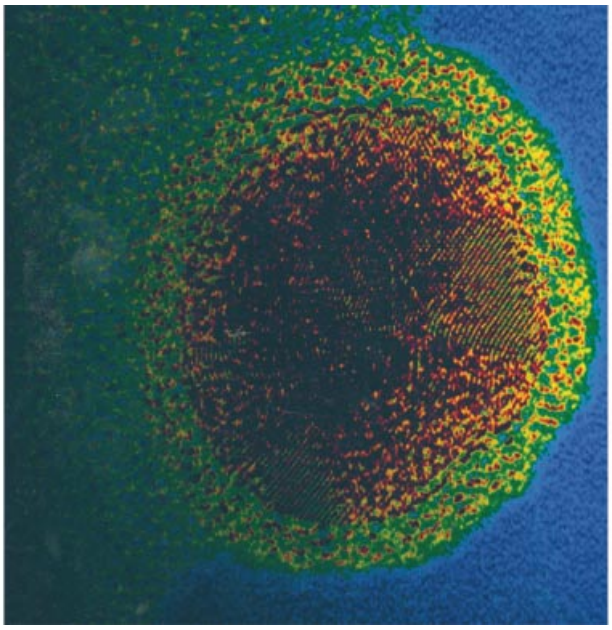

Figure 3. High-resolution transmission electron microscopic (TEM) image of a ligand-protected 11 × 13 nm gold nanoparticle; the polycrystalline gold core and the protecting shell of $P(C_6H_4SO_3Na)_3$ molecules can clearly be distinguished

2.2 Chemical Routes

As already mentioned, Michael Faraday was the first to study the formation of gold sols from a scientific point of view.[2] Phosphorus was the agent he used for the reduction of $[AuCl_4]^-$ ions. In the course of the last century numerous easier to handle reducers were found. A few of the more relevant procedures, especially the newer ones, are mentioned below.

Among the so-called salt reduction methods, the Turkevitch route still is one of the most applied procedures.[24] Sodium citrate reduces $[AuCl_4]^-$ in hot aqueous solution to give colloids of 15−20 nm. Citrate itself and its oxidation products (e.g. acetone dicarboxylate) can act as protecting agents, if no other stabiliser is used.[25,26] Dozens of variations have meanwhile been found. The use of stronger ligands than citrate was a major improvement for the synthesis and handling of gold sols. Phosphanes and thiols turned out to be excellent stabilisers due to rather strong Au−P bonds and even better Au−S bonds. These molecules allow the isolation of gold nanoparticles as solid materials that can be redispersed in appropriate solvents. This is not possible with weakly binding stabilisers such as citrate. Water-soluble phosphanes have been successfully used to shield gold colloids.[27] For instance, $P(C_6H_4SO_3Na)_3$ stabilises gold particles of 15−20 nm to such an extent that they become isolable as golden leaves that can be redispersed in deionized water with the typical purple-red color. Figure 3 shows a TEM image of an individual gold nanoparticle where the envelope of stabilizing phosphanes can be observed.[28]

PPh_3 acts as a rather good ligand for 1.4 nm Au_{55} clusters in $Au_{55}(PPh_3)_{12}Cl_6$. The latter is easily obtained by reduction of Ph_3PAuCl by gaseous B_2H_6 in benzene or toluene at elevated temperatures.[29,30] This compound will be the focus of attention of the following chapters because of its particular electronic properties. It is readily soluble in CH_2Cl_2 however, it can also be transformed into a water-soluble species by exchanging PPh_3 with $Ph_2PC_6H_4SO_3Na$ or $Ph_2PC_6H_4SO_3H$.[31]

Besides phosphanes, thiols are the most important type of stabilizing molecule for gold nanoparticles of any size. It is an accepted assumption that the use of thiols leads to the formation of RS^- thiolates that form strong covalent Au−S bonds. Since they bind more strongly to gold than phosphanes do, phosphanes can usually be substituted by thiols. However, it is also observed that the size of the original gold particles may change during the exchange process.[32,33] $[B_{12}H_{11}SH]^-Na^+$ [34] and SH-functionalized silsesquioxanes such as $(cyclopentyl)_7Si_8O_{12}(CH_2)_3SH$[35] have been successfully applied to remove phosphanes quantitatively from the surface of Au_{55} clusters. The ionic $[B_{12}H_{11}SH]^-Na^+$ transforms the CH_2Cl_2-soluble phosphane-stabilized clusters into water-soluble ones, whereas the alkyl terminated silsesquioxane makes the same particle soluble in apolar solvents such as hexane or pentane.

One of the most popular modern methods for preparing gold nanoparticles of various sizes comes from Brust et al.[36] It uses $NaBH_4$ to reduce gold salts in the presence of alkanethiols to yield gold particles of 1−3 nm. By varying the thiol concentration, the particles sizes can be controlled between 2 and 5 nm.[37] Recently, thiol-stabilized gold nanoparticles have become available following a seeding growth approach starting with 3.5 nm particles. The particle size can be varied by changing the seed-particle-to-metal-salt ratio.[38] Gold nanoparticles in the size range of about 10 to 30 nm or more have been synthesized by the $NaBH_4$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

method using mercaptosuccinic acid for stabilization.[39] By varying the succinic-acid-to-$HAuCl_4$ ratio from 2.5 to 0.5, particles of 10.2, 10.8, 12.8, 19.4, and 33.6 nm were isolated as water-redispersable powders.

11-Mercaptoundecanoic acid was also used to cover gold nanoparticles generated by the Brust method.[40] The carboxylic functions were then treated with trifluoroacetic anhydride to give the corresponding carboxylic anhydrides which are highly reactive and can, for instance, be used to anchor the nanoparticles on silica supports.

An elegant and valuable route is the generation of gold nanoparticles inside "nano-reaction vessels". Micelles can be considered appropriate chemical reactors. Due to their limited size, the control of growth by ligand concentration or other experimental conditions is not required. Möller et al. contributed decisively to this modern field of nanoscience. They used diblock co-polymers exhibiting regularly organized micelles into which tetrachloroaurates were transported, followed by a reductive step with hydrazine or $NaBH_4$ and formation of the nanoparticles.[41−45] Figure 4 shows one of those nanoparticle arrangements in a diblock co-polymer.

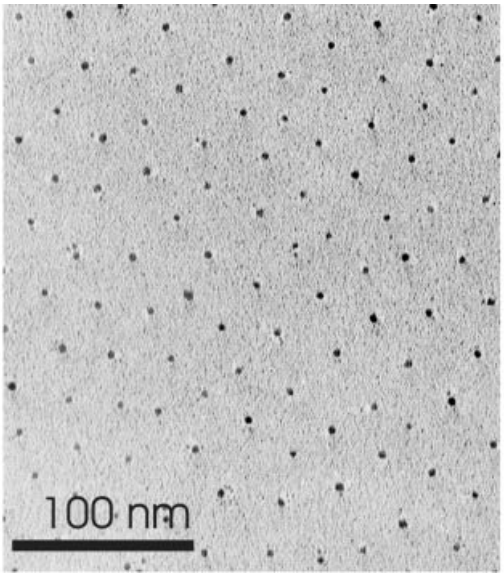

Figure 4. TEM image of 4 nm gold particles in micelles of diblock co-polymers

It must be stated that the above-mentioned examples of synthetic strategies for generating gold nanoparticles are very incomplete. A full overview of all known synthesis techniques would exceed this microreview by far. The purpose of this article is simply to report some novel improvements of well-known methods. We can conclude that since Faraday's time the syntheses have been improved, especially with respect to a better control of the particles size, however, the chemical principles are still just the same: it is the facile reduction of Au^{III} or Au^{I}. Amongst all transition metals, gold is the most electronegative one and consequently it can be generated from its salts by a huge number of reducing species. Not only classical reducers such as hydrides, hydrogen, hydrazine, hydroxylamine, alcohols etc. can be used, but any kind of organic species with some reducing character is suited to produce gold nanoparticles from salts. A so-called "green chemistry" has evolved in recent years, meaning that gold nanoparticles can be generated by natural organic materials via reduction.[46,47] Even different types of fungi have been found to work up gold salts into elemental gold.[48]

3. Structures and Optics

Transmission electron microscopy (TEM) is by far the most valuable tool for studying particle size, distribution, and structure. From thousands of TEM investigations we know that gold nanoparticles exhibit either a mono- or a polycrystalline structure of hexagonal close-packed (hcp) atoms, just like in the bulk state. Even bimetallic core-shell-structured nanoparticles can be identified by various imaging contrasts and by Energy Dispersive X-ray Analysis (EDX) of individual particles.[49,50] An example with a ca. 20 nm gold core and a palladium shell is shown in Figure 5.

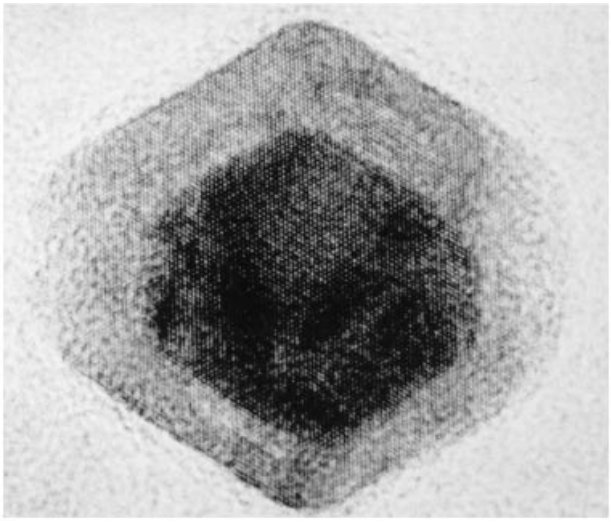

Figure 5. TEM image of a monocrystalline core-shell-structured gold-palladium particle

The smallest particle in this sense is ligand-stabilized Au_{55} which has been investigated not only by TEM, but, for instance, also by X-ray diffraction, EXAFS and Mössbauer spectroscopy. All results indicate an hcp structure.[29,51−55] However, there is an interesting transition with respect to the development of bulk structures. The smallest ligand-stabilized, so-called full-shell cluster, consists of only one central and 12 gold atoms in a first shell (Au_{13}). These have been shown to build up icosahedra.[56,57] An Au_{39} cluster has also been characterized by X-ray diffraction. It consists of a distorted hexagonal close-packed core, protected by 14 PPh_3 and 6 Cl ligands, indicating the transition to bulk structure.[58] Finally $Au_{55}(PPh_3)_{12}Cl_6$ fully reached the bulk structure. These three examples illustrate the development of the bulk state from a molecular level. However, it should

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

be emphasized that these findings are only valid for ligand-stabilized particles. Conclusions on the situation in bare clusters are not possible.

A characteristic of all gold colloids is the color which can vary between light red via purple-red to bluish-red. This effect is caused by a plasmon resonance, quantitatively described by the Mie theory, as already mentioned. The plasmon resonance is initiated by the interaction of the electric field of visible light with the confined electron-gas of the particle. The wavelength, in the case of gold usually in the region of 500−600 nm, depends on the size of the particle and on the shape and the dielectric properties of the surrounding medium. These facts are quite well understood and will not be discussed here. However, a recent result shall briefly be mentioned, since it shows not only the influence of the particle size on the plasmon resonance, but also on the particles' arrangement and the nature of the surrounding medium.[59] For that purpose nanoporous alumina was filled with various gold nanoparticles. Owing to its transparency, alumina is ideally suited to study the optical properties of nanosized particles inside its pores.[60] Two approaches for placing gold nanoparticles in nanopores are available: the thermal decomposition of $Au_{55}(PPh_3)_{12}Cl_6$ clusters inside the pores to generate larger particles and the use of preformed particles to be filled into the pores by vacuum induction of solutions. An example of a membrane prepared in this manner has already been shown in Figure 2.

As expected, the size of the gold nanoparticles increases with increasing decomposition-temperature, due to the increasing melting point of larger particles (see Figure 1). In the temperature range of 100−800 °C particles with diameters of 4.5 up to 11 nm were observed in sectioned membranes by means of TEM. For example, Figure 6 shows the extinction spectra of a composite consisting of 4.5 ± 1.4 nm particles in 50 nm pores in two different media, namely in air and in toluene.

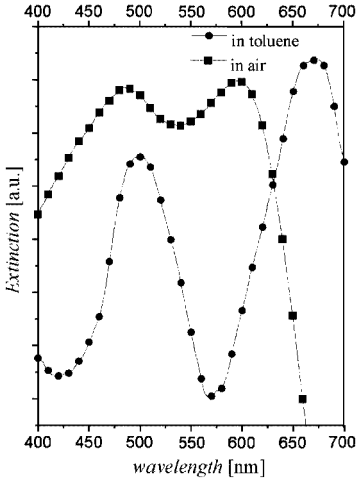

Figure 6. UV/Vis extinction spectra of 4.5 ± 1.4 nm gold nanoparticles in 50 nm alumina pores in air and in toluene, respectively

In air, two absorption peaks are observed at 480 and 600 nm. The low-energy absorbance is probably caused by the excitation of the plasmon resonance along the axis of the wire-like arranged particles. This effect can be seen even by the naked eye: when viewed perpendicularly to the membrane's surface the color is deep red (Figure 2), whereas the edge of the membrane looks blue. On immersing the sample in toluene, not only does the intensity of the peaks increase, but both peaks are red-shifted to 500 and 675 nm, respectively. This red-shift is caused by the change in the refractive index from air to toluene, whereas the increase in intensity comes from the reduction of scattering effects, since toluene has almost the same refractive index as alumina.

The use of preformed nanoparticles has the advantage of narrower size distribution and allows one to observe changes by repeated filling. If 50 nm pores are filled once with 15 nm gold colloids, only one plasmon resonance peak at 525 nm is observed because of the lack of wire-like arrangements. Repeated filling broadens out and shifts the signal to 580 and 590 nm, indicating initial formation of wire-like arrangements. Additional effects have been observed using unpolarised and polarised light with different polarization angles. Theoretical calculations, using the generalized Mie theory,[7,61−63] support the interpretation of the experimental observations.

Plasmon resonance is a size-dependent phenomenon of several metals. Bulk metals reflect light, whereas small molecular clusters do not show any kind of plasmon resonance. This is due to the lack of *quasi* delocalized electrons that are necessary for the interaction with light. On the contrary, the electrons between metal atoms in small clusters are localised. This is known for thousands of oligonuclear organometallic cluster compounds.

A decisive question, which will also be the focus of attention of the following chapters, is: how large or how small should a metal particle be in order for us to observe molecular or metallic properties? In relation to optical properties this question has to be formulated as: when does the plasmon resonance disappear if miniaturization proceeds? In this context, ligand-stabilized Au_{55} clusters play an important role. Ligand-stabilized Au_{13} and Au_{55} clusters were investigated and in both cases the vanishing of the Mie resonance was observed.[64] Again we should remember that the observed effects always include the existence of ligand shells on the particles. In spite of this restriction it can be stated that the 1.4 nm Au_{55} clusters, from an optical point of view, belong rather to the molecular world than to the metallic one. However, we will learn that such statements cannot be generalised, since the method of investigation, temperature and other experimental parameters play a decisive role with respect to what we "see". To conclude these considerations we have to accept that $Au_{55}(PPh_3)_{12}Cl_6$ and its variations do not possess enough mobile electrons to exhibit plasmon resonance. Of course, these findings are related to the special electronic situation in the Au_{55} cluster core. Therefore, the following section will deal exclusively with the electronic properties of this compound.

4. Electronics

4.1 The Quantum Size Effect

In a bulk piece of metal the valence electrons of the participating atoms occupy energy bands instead of discrete levels, as we know from atoms and molecules. In a thought experiment we can proceed with a continuous reduction of dimensions. From a 3D situation with its typical bulk behavior we turn to a film of only a few atoms' thickness (2D). Here, the electrons can only move in two dimensions, whereas in a wire of only a few atoms in diameter, one-dimensionality (1D) of the electronic degree of freedom is enforced. If we cut off a small piece of that wire we reach the zero-dimensional (0D) situation where the remaining electrons are constrained in such a way that they begin to occupy discrete energy levels. A particle of such size no longer follows classical physical laws and has to be described by the quantum mechanical rules used to describe atoms. That is why such pieces of matter are also called "quantum dots" or, with a somewhat more popular expression, "artificial atoms". Pieces of metals following these conditions must exhibit very different physical and chemical properties compared to bulk ones and to typical molecular ones. It was the enormous interest in these novel properties that brought nanoscience to such a level that a wide public, economic and political interest arose. It is the general opinion of experts that nanotechnology will decisively influence man's life in the following century.

Back to the facts, we have to repeat the question we asked in the previous section in a more general way: how many atoms do we need, to cause metallic behavior or how small should a piece of metal be in order to see metallic properties disappearing?

4.2 Physical Tools

There are many physical methods to investigate quantum-size effects. It would exceed this article by far to mention and to discuss all of them, therefore only a few shall be selected to explain what happens when particles size is continuously reduced. It should be mentioned that many of the investigations during the last two decades involved other metals as well as gold, since quantum-size effects can be studied with any kind of metal, and, of course, also with semiconductors. However, gold played once again an important role in the process of our understanding. Some hints have already been given by the optical phenomena discussed in section 3.

One important contribution to this major problem was made by the observation of electron-phonon coupling in gold particles of different size.[65] This relation informs us on the interplay between the rate of energy transfer from electrons to lattice and the number of atoms in the particle. It was found that the electronic relaxation-speed, induced by laser pulses of 200 fs of an energy of 250 μJ/pulse at 780 nm, varies characteristically with the particle size. $Au_{13}(dppm)_6(NO_3)_4$ (dppm = $Ph_2P\text{-}CH_2\text{-}PPh_2$)[56] (core diameter 0.7 nm), $Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6$ [31] (core diameter 1.4 nm) and 15 nm colloids were tested. Figure 7 shows the results.

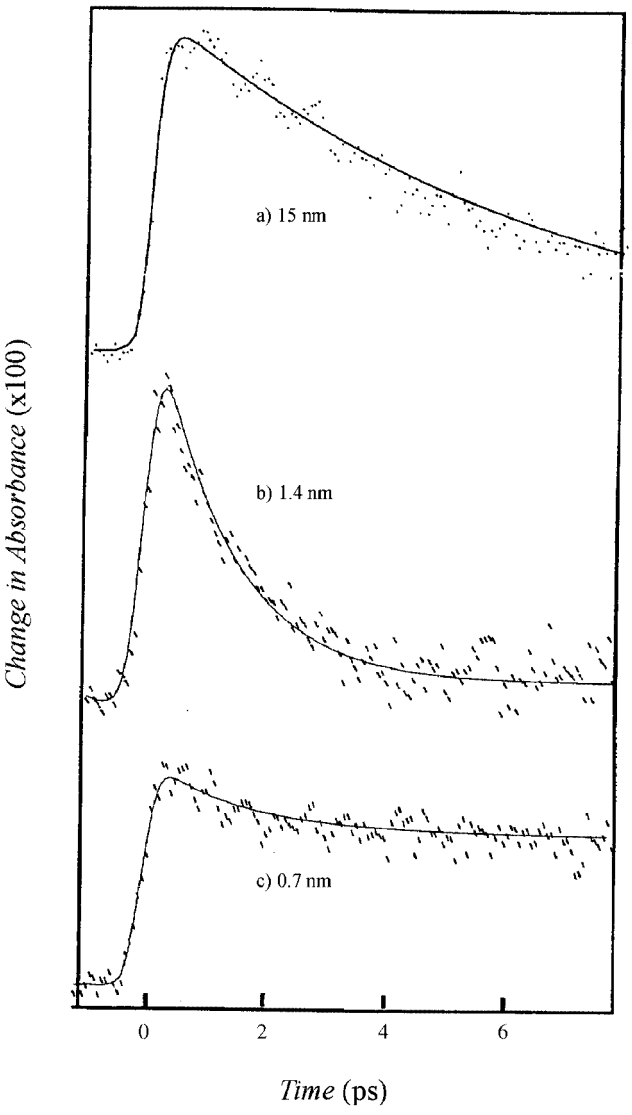

Figure 7. Relaxation behavior of gold nanoparticles of different sizes after excitation by femtosecond laser pulses

As we can see, the relaxation speed increases from the 15 nm particles to Au_{55}, also compared to the bulk. This effect is explained by the weakening of the electron-plasmon interaction, and the increase of the electronic collision-rate on the surface. For Au_{13} it decreases due to the existence of localized electrons. This cluster behaves like a molecule, whereas Au_{55} represents the very last "metal" before the typical molecular region begins. This example demonstrates that the decision "metal or not", cannot be precisely answered. As shown, optically Au_{55} is definitely no longer a colloid, and we have just learnt that it is not yet a molecule!

Probably the most informative method for studying the electronic situation inside a nanoparticle is to measure its current-voltage characteristics under different conditions. This can be performed by bringing an individual particle, bearing a non-conducting protecting shell (usually the li-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gands), into contact with two electrodes to which a variable voltage is applied. The insulating barrier is necessary to make tunnelling of individual electrons observable, as is indicated in Figure 8.

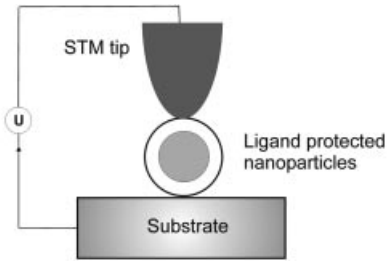

Figure 8. Sketch of a tunnelling contact consisting of an STM tip, a ligand-protected metal nanoparticle and a conducting substrate

The barrier conditions are responsible for the electron transport. Among others, they depend on the temperature. Owing to the relationship $E_C = e^2/2C >> k_BT$ (E_C = electrostatic energy, C = capacity of the island between the electrodes, k_BT = thermal energy), the thermal energy should be small in order to observe Single Electron Tunnelling (SET). If not, uncontrolled electron transitions occur. This fact was demonstrated by placing a ligand-protected 17 nm Pd particle next to two platinum tips.[66] At 295 K the particle exhibits a linear current-voltage ($I-V$) relationship and therefore indicates metallic behavior (Ohm Law). However, when measured at 4.2 K, a so-called Coulomb gap is observed: if k_BT is small enough, tunnelling of a single electron onto the particle blocks the transfer of a second one, due to Coulomb repulsion, until an appropriate voltage is reached.

$Au_{55}(PPh_3)_{12}Cl_6$ clusters on gold substrates have been investigated by bringing individual particles into contact with an STM tip so that information on $I-V$ characteristics can be gained. The result is very exciting: these particles indeed show well-expressed Coulomb blockades already at room temperature, as we can see in Figure 9.[67]

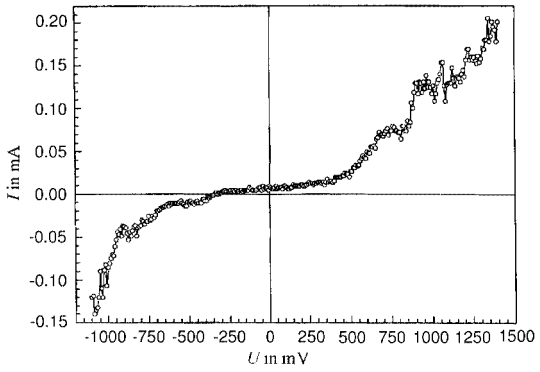

Figure 9. Room temperature $I-V$ characteristics of an individual $Au_{55}(PPh_3)_{12}Cl_6$ cluster indicating a well-expressed Coulomb blockade

This means that these 1.4 nm, ligand-protected particles behave as single electron-switches at room temperature! This opens up unexpected future applications in nanoelectronics.

The same Au_{55} species have very recently been studied by the same technique, however at 7 K under ultra high vacuum (UHV) conditions.[68] This method allows one to acquire not only tunnelling spectra, but also detailed images of individual particles. Figure 10 shows one of them together with a space-filling model in the corresponding orientation.

The light dots in Figure 11 indicate the positions of the phenyl rings of the PPh_3 ligands and **a** and **b** show two different sites where the STM tip was positioned for recording the tunnelling spectra: **a** above a C_6H_5 ring, **b** on the side of the ring, but with the same distance from the gold surface. Figure 11**A** shows the Coulomb blockade, which is the same size for both positions, indicating that the ligands do not visibly contribute to the tunnelling process;

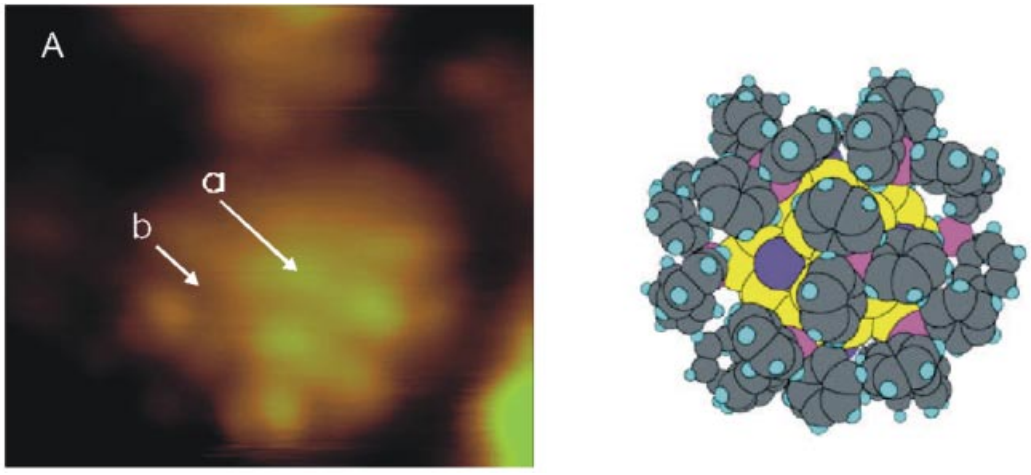

Figure 10. STM image of an individual $Au_{55}(PPh_3)_{12}Cl_6$ cluster at 7 K under UHV conditions together with a full-space model; the light dots indicate phenyl rings; the positions **a** and **b** indicate where the measurements have been performed to yield the $I-V$ characteristics in Figure 11

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

they simply act as distance holders. Still more interesting is the high resolution of the blockade region by using d*I*/d*V* instead of *I* (**B**). The arrows indicate conductivity signals which coincide precisely for both positions. For the very first time the existence of discrete energy levels inside the Au_{55} core could be proven. The occupied as well as the unoccupied levels are visible, due to conductivity oscillations. The average level spacing in vicinity to the Fermi level is about 170 meV.

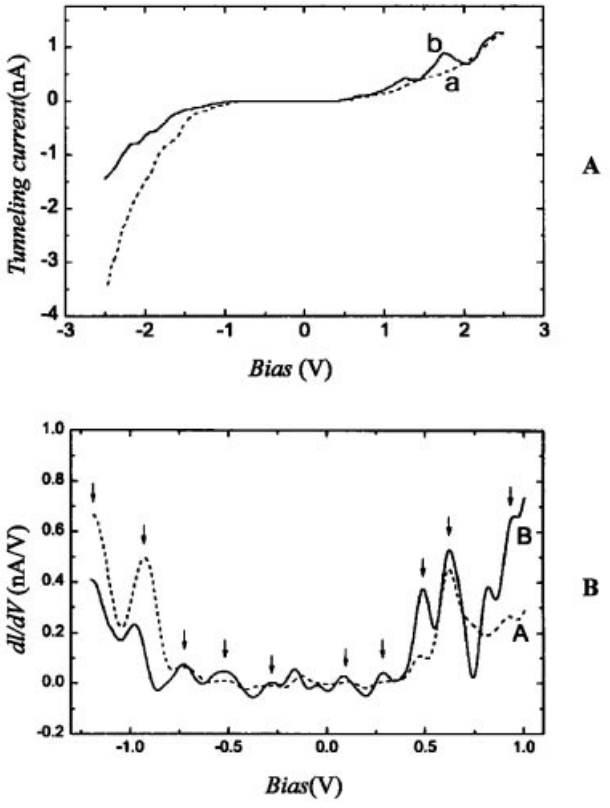

Figure 11. A) $I-V$ characteristic of an individual $Au_{55}(PPh_3)_{12}Cl_6$ cluster at 7 K under UHV conditions; **a** and **b** indicate equivalent Coulomb blockades although measured at different positions on the cluster's surface; B) d*I*/d*V* characteristic of the same particle indicating discrete electronic energy levels (arrows) in the Au_{55} cluster core

This experiment now justifies the expression "artificial atom" for those quantum dots and proves the assumptions of paragraph 4.1 that on the way from bulk to molecule at some point a situation arises where the electronic band structure begins to form discrete energy levels.

As a consequence of these unique properties it seems interesting to study the electron-transfer processes between the quantum dots. This was done for three-dimensionally organized Au_{55} clusters with variable distances.[69] However, as it turned out, it is not only the distance between the nanoclusters which determines the activation energy for the charge transfer, but also the nature of the interlinking species and the kind of linkage. If the clusters are simply separated from each other by ligand shells of different thickness or by non-covalently binding spacer molecules (ionic interactions), there is indeed only a simple linear relation between cluster-cluster distance and activation energy to be observed. On the contrary, if spacer molecules linking the particles via covalent S−Au bonds are used, it is not the distance that contributes decisively to the activation energy, but the chemical nature of the spacers. Figure 12 illustrates these results.

5. Approaches to Two-Dimensional Organizations

The two- and in some respect also the one-dimensional organization of metal nanoparticles is very relevant since one can think about the use of these particles in nanoelectronics only in an organized form. This is why numerous groups worldwide are dealing with this problem. It is again gold that plays an important role because of the easy availability of gold nanoparticles and their resistivity to air. So, there is a vast amount of reports, mainly on regular 2D arrangements of gold nanoparticles, most of them in the size regime of a few, up to 15 and 20 nm. Here we will only focus on recent results of organized Au_{55} clusters, since they are of promising electronic nature, as has been discussed in section 4.

After numerous attempts, rather extended self-assembled monolayers of $Au_{55}(Ph_2PC_6H_4SO_3H)_{12}Cl_6$ and of $Au_{55}(PPh_3)_{12}Cl_6$ became available.[70−72] The acidified cluster gives hexagonal and square structured 2D arrangements on poly(ethyleneimine) (PEI) films, whereas the neutral species is best organized at the phase transition between water and dichloromethane, supported by a layer of poly(vinylpyrrolidone) (PVP) or, still better, of poly(*p*-phenylene ethynylenes) (PPE). Although there is no doubt that PEI acts as a basic surface towards the SO_3H-modified Au_{55} cluster, the role of PVP and PPE in connection with $Au_{55}(PPh_3)_{12}Cl_6$ is somewhat more delicate. Relatively strong interactions, like those between the acidified cluster and PEI, prevent formation of extended ordered layers due to the lack of flexibility of the particles. On the contrary, PVP and PPE interact only weakly with the PPh_3-covered cluster, probably via hydrophobic-hydrophobic and π-π interactions, respectively. These weak forces between the clusters and the supports enable the formation of perfect arrangements since the particles are only weakly attracted and are allowed to find the best order. Figure 13 shows TEM images of cut-outs of square planar (**a**) and hexagonal (**b**) arrangements of Au_{55} clusters, generated on PEI and PPE, respectively.

An interesting electrical behavior of these ordered monolayers was observed when conductivity measurements were carried out.[73] Monolayers deposited between two tungsten electrodes on silica surfaces, 50−150 nm apart and 25 nm in height, and prepared on PVP films, as described above, were checked by scanning electron microscopy (SEM). Due to charging effects of the electron beam (10 keV, 10 s) the layers become conductive in the pA region in contrast to a not measurable conductivity without irradiation. However, if irradiation occurs on only one of the electrodes and part

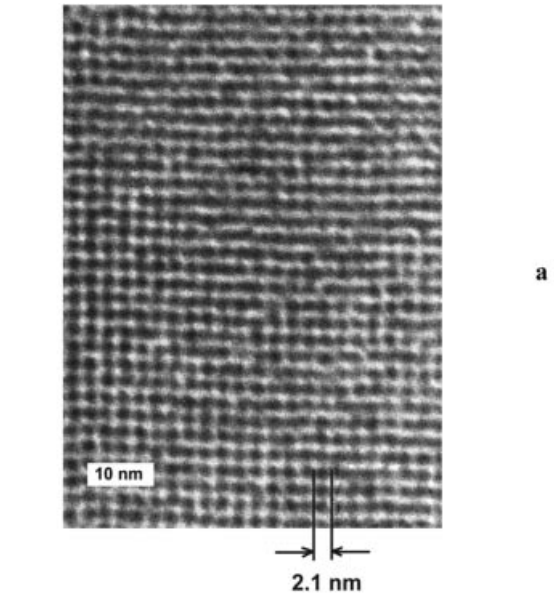

Figure 13. TEM images of square planar (**a**) and hexagonal (**b**) monolayers of ligand-stabilized Au_{55} clusters

of the monolayer, diode-like behavior is observed. The $I-V$ characteristics depend on the contact distances, the irradiation time, the energy of the electron beam, the exposure time and finally on the irradiated area. Figure 14 shows a typical diode curve (**a**) gained with a set-up of electrodes of 122 nm distance (**b**) and an exposure time of 5 s at 16 keV.

In all cases the systems relax in the course of 24−36 h after switching off the voltage. However, reactivation is possible, indicating that there is no chemical change with respect to the starting situation. In order to explain this unusual behavior we assume that electrons from irradiation, trapped in the silica layer, create so-called image charges in the cluster layer. This activation makes the particles order themselves so as to reach a minimum energy arrangement with a maximum delocalization of the additional electrons. The rearrangement of the clusters may happen very quickly due to the electron irradiation, whereas the deactivation takes much more time.

Self-organization of quantum dots must be considered only as a first step for collecting information on their electronic interchange. However, for practical use with respect to future data storage or related applications, it is necessary to create artificial architectures. A first approach as to how this high goal might be reached will be described below. It is based on the generation of appropriately modified surfaces.[74] A metallized AFM tip was used as a tool for transforming methyl groups of a self-assembled monolayer into carboxylic functions by electrical pulses under air. The total process is sketched in Figure 15.

The COOH groups are used to add silane molecules to C=C double bonds which can then be transformed to thiol-functionalized derivatives. Finally, water-soluble $Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6$ clusters are chemisorbed from solution by the thiol functions. The width of the traces simply depends on the quality of the tip. As we can see from Figure 16, arranged dots of clusters (a), as well as single gold clusters between wires made of single rows of particles (b), have been created, and of course any other structure could be created.

There is no doubt that these structures offer great advantages compared with self-assembled arrangements. How-

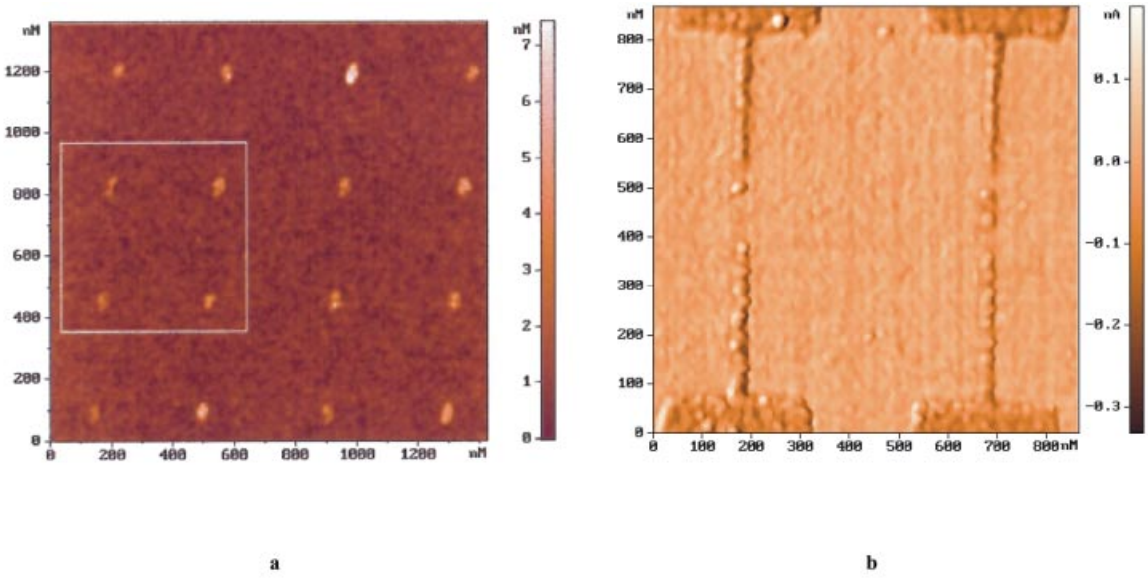

Figure 16. a, b Patterns of Au_{55} clusters deposited on chemically modified surfaces as shown in Figure 15

ever, it is also clear that there is still a lot of work to be done to develop a working system. One major problem will be to study individual quantum dots and to connect them with the outer world. There are ideas on how to do this, but many efforts will be necessary to reach this goal.

6. Chemical Activity

Two main aspects concerning chemical activity of gold nanoparticles will be treated in this chapter: ligand-exchange reactions and catalytic activity. Ligand-exchange reactions are quite common and are used to change solubility or to introduce special functions. Catalytic properties of gold nanoparticles are currently developing into an attractive and important field in gold chemistry. Therefore, a rather detailed discussion of catalytic properties will be found in this section.

6.1 Ligand-Exchange Reactions

As discussed in chapter 2.2, wet chemical syntheses of gold nanoparticles are always linked to the presence of protecting ions or molecules since without them, coalescence would quickly occur. As an example we should remember the famous citrate route for the generation of 15−20 nm gold colloids. Without any other stabilizing species the gold particles are covered by excessive citrate, but also by Cl^- ions and acetone dicarboxylate, an oxidation product of citrate. These species bind strongly enough to keep the colloids in solution for a long time. However, they can easily be substituted by stronger binding molecules. For instance, the water-soluble phosphane $P(C_6H_4SO_3Na)_3$ can easily re-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

move the original ions and molecules to form such a strong ligand-shell that these gold nanoparticles can even be isolated as solid products.[27] We must assume that phosphane molecules on the surfaces of gold nanoparticles are rather mobile in solution. This was shown long ago by ^{31}P NMR investigations of $Au_{55}(PPh_3)_{12}Cl_6$ with excess PPh_3.[75] Gradual addition of free PPh_3 to cluster solutions causes a shift of the ^{31}P signal from $\delta = 34$ ppm towards that of free phosphane ($\delta = -5.5$ ppm). This is due to the fast exchange processes between free and coordinated PPh_3 molecules. The mobility of ligand molecules is also the reason why $Au_{55}(PPh_3)_{12}Cl_6$ is rather labile in solution (due to the loss of PPh_3), and as a consequence, coalescence processes are inhibited. The formation of the water-soluble compound $Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6$, from $Au_{55}(PPh_3)_{12}Cl_6$, dissolved in dichloromethane, is also based on that ligand mobility. The fact that the water-soluble derivative is formed in quantitative amounts is due to the phase transfer from CH_2Cl_2 to H_2O and to the somewhat better coordination of $Ph_2PC_6H_4SO_3Na$ compared to PPh_3.

The high mobility of phosphanes on gold-particle surfaces can be used to substitute them with stronger ligands, above all by thiols. As already mentioned in section 2.2, the thiol-functionalized silsesquioxane $(cyclopentyl)_7Si_8O_{12}(CH_2)_3SH$, as well as the anionic thiol $[B_{12}H_{11}SH]^{2-}$, quantitatively substitute phosphanes in Au_{55} clusters with the help of phase transitions.[35,34] The alkyl-terminating silsesquioxane, readily soluble in apolar solvents such as pentane or hexane, transfers the water-soluble cluster $Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6$ into the pentane-soluble derivative with silsesquioxane ligands, whereas the dichloromethane-soluble $Au_{55}(PPh_3)_{12}Cl_6$ becomes water-soluble if reacted with $Na_2[B_{12}H_{11}SH]$. Figure 17 illustrates these transfer reactions that indicate that the same cluster particle can change its solubility from dichloromethane to pentane or even to water.

A very special kind of "phosphane substitution" in $Au_{55}(PPh_3)_{12}Cl_6$ is observed when the latter is reacted with an excess of a fourth-generation dendrimer bearing 96 terminal SH functions.[76] The excess dendrimer obviously re-

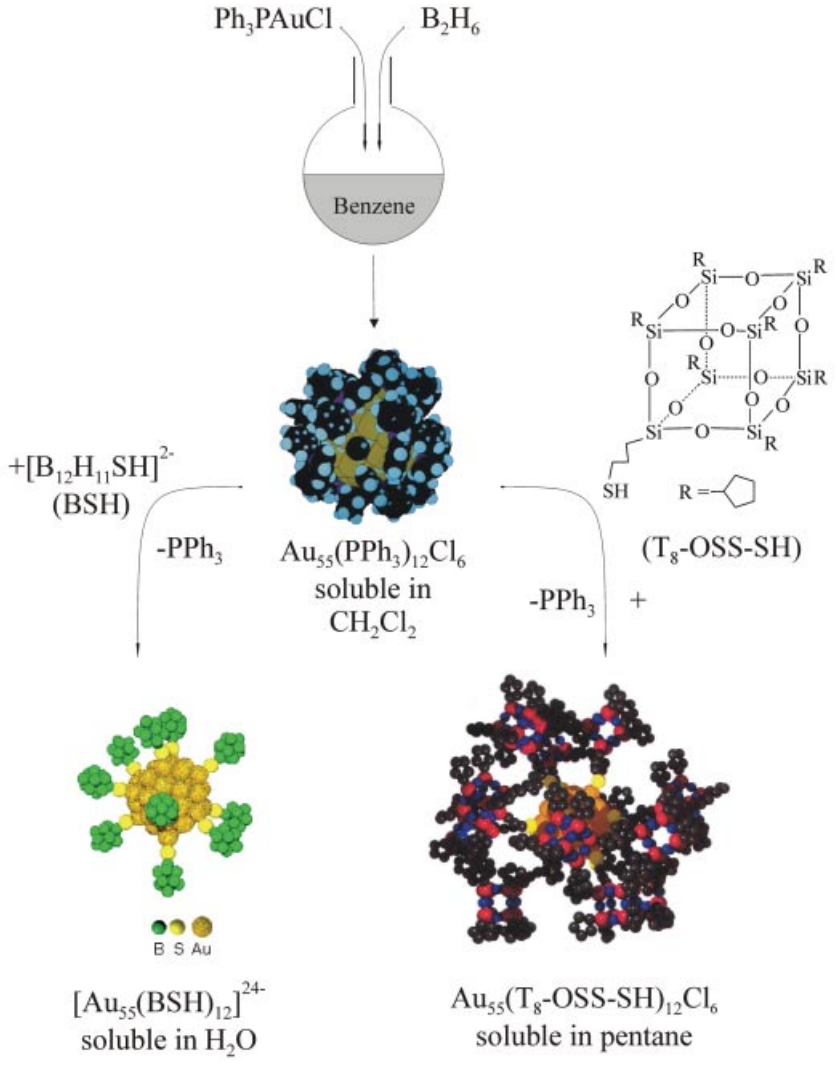

Figure 17. Sketch of synthetic routes to $Au_{55}(PPh_3)_{12}Cl_6$ and some of its derivatives

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

moves all the phosphanes from the clusters' surface. However, Au−Au interactions between the bare clusters occur and the coordination of dendrimers is not observed . Consequently, naked Au_{55} particles grow to regular microcrystals inside a matrix of dendrimers.

Finally, a very unexpected behavior of naked Au_{55} clusters will be mentioned. While surfaces of bulk gold and particles of 7.9, 2.9, 1.6, 1.3, and <1 nm are all oxidized when deposited on top of a silicon wafer and exposed to atomic oxygen, bare Au_{55} resists these extreme oxidative conditions.[77] Moreover naked Au_{55} clusters are formed in oxygen plasma by burning off the ligand shell, as can clearly be followed from the X-ray photoelectron spectra. Only traces of oxides appear, as indicated by the presence of a weak shoulder, the main part of the particles remaining unchanged. Figure 18 shows the Au-4f photoelectron spectra of the oxidized particles including Au_{55} clusters.

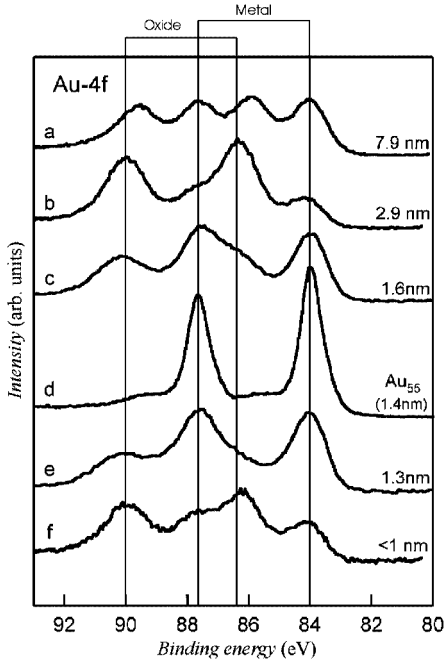

Figure 18. X-ray photoelectron spectra of various gold particles after exposure to an oxygen plasma; all particles except for Au_{55} show well expressed gold oxide signals

In all cases except for Au_{55} there are well-developed signals for gold oxides. This phenomenon has led to the formulation that Au_{55} is "nobler than bulk gold".[78] As an explanation of this unique behavior it is assumed that it is the special stability of Au_{55} as a closed-double-shell structure. It is excluded that a special electronic situation might cause this inertness. As a consequence it can be predicted that other full-shell clusters such as Au_{147} or Au_{309} etc. should also resist oxidation. Owing to the non-availability of these particles, this prediction cannot yet be proven . However, it can be suggested that these gold full-shell clusters might act as special oxidation catalysts.

6.2 Nanoparticulated Gold in Modern Catalysis

6.2.1 Historical Survey

In contrast to the catalytic potential of its neighbors silver and platinum,[79] bulk gold metal appeared for long time an essentially useless material for catalysis.[80,81]

The first documented exhibition of catalytic activity of bulk gold occurred at the beginning of the past century when Bone and Wheeler showed in 1906 that gold foils catalyse the combustion of dihydrogen and dioxygen to give water.[82] The relevant paper is remarkable in that the authors also collected good quantitative kinetic data on the same reaction. It was believed for a long time that the inability of Au^0 to activate (chemisorb) O_2 in any catalytic oxidation reaction was a straight manifestation of its thermodynamic reluctance to form metal oxides (ΔH_f^0 of Au_2O_3 = +19.3 kcal·mol^{-1} [81]). Ironically, the extremely facile Au^0-catalyzed oxidation of CO to CO_2 by O_2 is the most striking result in Au^0-catalytic chemistry, but only when Au^0 occurs as metal nanoparticles supported on suitable metal oxides.

Information on the catalytic chemistry of Au^0, obtained in the decades following Bone and Wheeler's observation, was not considered very exciting.[83] However, in the course of the seventies, three major observations were made: a) Au^0 supported on silica (0.01−0.05%) was found by Bond and Sermon to catalyse the hydrogenation of alkenes at 373 K, with no effect on the potentially concomitant double bond migration reaction,[84] b) Au^0 supported on MgO or Al_2O_3 was found by Galvagno and Parravano to catalyse oxygen- and hydrogen-transfer reactions [85] and c) a green $Au(O_2)$ molecular species with side-on bonded dioxygen could be obtained at extremely low temperatures in a solid matrix.[86,87] Most interestingly, this very remarkable molecule was found to react with CO at a suitable temperature to give eventually free Au^0 and CO_2. Indeed this was a prophetic observation!

Among the many good review papers quoted in this report, the 2002 review by Choudhary and Goodman as a general and critical reading on Au^0 catalytic chemistry is particularly recommended.[88]

6.2.2 Synthesis of Supported Gold(0) Catalysts

The overall grey scenario of Au^0 catalytic chemistry became suddenly lightened in 1989 when Haruta et al. reported on a real breakthrough in this field of research.[89] They observed, in fact, that the oxidation of CO to CO_2, a technologically relevant reaction under various circumstances, could be effectively catalyzed by supported-Au^0. Moreover, it was later observed that the reaction occurs even at 200 K.[90] It soon became apparent that the key to this success was twofold: a) the presence of gold nanoparticles in the gold catalysts and b) a strong co-catalytic role played by the support that had to be an inorganic oxide such as Fe_2O_3, TiO_2, or Co_3O_4. It also became apparent that the optimal nanocluster diameter was ca. 3 nm, the size at which metal nanoclusters start to exhibit quantum-size behavior.[91,92]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

This discovery promoted an incredible amount of research and an avalanche of papers and patents in a manifestation of a modern-day "gold rush".

We believe that the catalysis community was particularly stricken by Haruta's discovery in that it represented an unprecedented example of both extreme catalyst structure-sensitivity and of an impressive co-catalytic role played by the metal-supporting microphase (vide infra). In fact, the issue of catalyst preparation and the full understanding of the role of the support appeared immediately very complex, still to be fully evaluated nowadays and, in this connection, the reader is referred to an authoritative review paper by Bond and Thomson who critically examined the matter in the year 2000, in terms of both consensual and disputed literature observations and to other general as well as specific readings.[93−99]

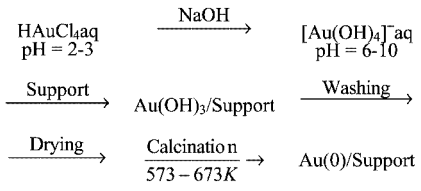
Supported gold nanoparticles (1−5 nm) are currently prepared according to a dozen or so rather different methods, which can be reduced in essence to three major procedures.

The precursor of Au^0 is mixed with the precursor(s) of the supports (or with the support itself) to give a system that, after controlled calcination, produces Au^0/S catalysts. The metal nanoparticle's size is controlled by the calcination temperature, and lower temperatures seem to favor the formation of smaller particles.[100,101]

The precursor of Au^0 is deposited or grafted onto the surface of the support, which has been pre-formed from the gas or from the liquid phase,[99] and subsequently thermally decomposed to give the Au^0/S catalysts. We would like to mention, in this respect a recent outcome from these laboratories, i.e. the preparation of an Au^0/resin catalyst obtained from the chemical reduction of an $Au^{I,III}$/resin-macromolecular complex prepared simply by complexation of aqueous $AuCl_3$ with a thioethereal gel-type resin.[102]

The Au^0 nanoparticles are pre-produced in a given solution where they are stabilized by soluble polymers[103] or by kinetic conditions, and subsequently left to be adsorbed by the surface of the desired support particles.[104]

As anticipated above, it is now widely accepted that at least for CO oxidation and for the water gas shift reaction, catalytic activity depends critically on the metal nanoparticles' size, on the nature of the support and on the detailed synthetic procedure. In this context, the deposition precipitation (DP) procedure is generally widely considered the most suitable one (Scheme 1).



Scheme 1. Deposition precipitation procedure to give Au/S catalysts[99]

In fact, DP turns out to be particularly suitable for producing hemispherical (ca. 3 nm) nanoparticles (Figure 19) that are believed to cause a particularly strong attractive force between a given nanoparticle and the crystal lattice of the support located just underneath it.

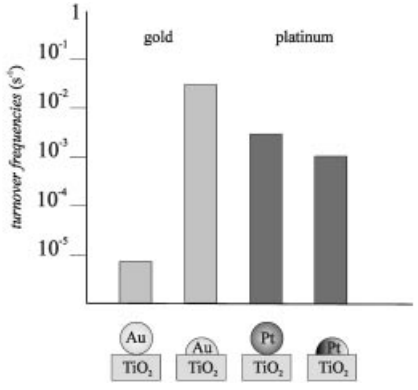


Figure 19. Dramatic effect of the Au^0-support interaction on the CO oxidation reaction rate over spherical vs. hemispherical nanoclusters; it is important to note the quite different effect of the nanoclusters's shape on the action of Pt^0

This phenomenon has two major consequences: i) a marked thermal stability of the Au^0 nanoparticles (thus contrasting the particles' coalescence) and ii) a peculiar local electronic situation at the lattice interface of the metal nanoparticles and the support, that is likely to be responsible for the particular mechanism of oxygen transfer to chemisorbed carbon monoxide to give carbon dioxide (see below).

6.2.3 Nanoparticulated-Gold(0) on Metal Oxides: Facile Oxidation of Carbon Monoxide to Carbon Dioxide

No measurable oxidation of CO by O_2 on micro-sized (in fact "bulk") supported-Au^0 is observed at ambient conditions. On the contrary, if a mixture of CO and O_2 is allowed to interact with 2−5 nm gold particles dispersed on the same support, under identical Au^0 molar fraction, a rapid and quantitative oxidation to CO_2 is observed even at 200 K.[90]

Wallace and Whetten observed an effective formation of CO_2 when CO and O_2 were reacted with Au_6^- in the gas phase (Figure 20).[105] Moreover, theoretical calculations carried out by Lopez and Norskov[106] revealed that isolated Au_{10} clusters are expected to catalyse CO oxidation even below room temperature. All these observations seem to provide an explanation of the established activity of the nanoparticles' surface gold atoms in the CO oxidation. However, reality is more complex than that!

An Au^0 nanoparticle of 2−3 nm in size, exposes ca. 50% of its atom constituents to the action of gaseous species that find possible reaction sites at the edge-, corner- or step-sites of the nanoparticle surface. Consequently, we might consider that the electronic and geometrical features of these potential activation sites are related to Au_6^- and to

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

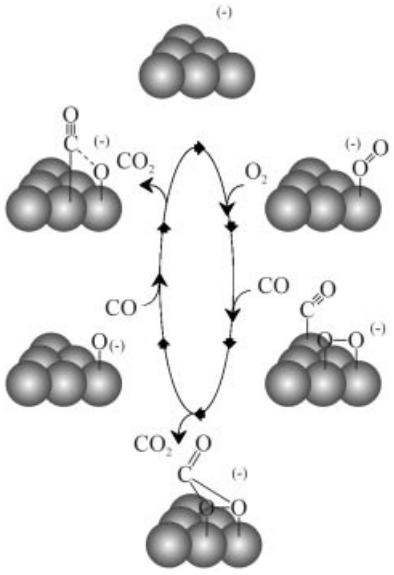

Figure 20. Schematic illustration of the formation of CO_2, catalyzed by Au_6^- in the gas phase

Au_{10} molecular clusters. However, this is probably not the case and several authors[93,88,99] provide evidence that, while CO is activated by its end-on coordination to the nanocluster surface, O_2 is activated by a combined action of the Au^0 nanoparticle surface and of the nanoparticle-support interface surface (Scheme 2).

$$CO + Au(0)/TiO_2 \text{ ---> } Au(0)(CO)/TiO_2$$

$$O_2 + Au(0)/TiO_2 \text{ ---> } Au(0)/TiO_2 \cdots O_2$$

$$CO + Au(0)/TiO_2 \cdots O_2 + Au(0)(CO)/TiO_2 \text{ ---> } CO_2 + Au(II)(CO)(O)/TiO_2 \cdots Au(0)/TiO_2$$

$$Au(II)(CO)(O)/TiO_2 \text{ ---> } CO_2 + Au(0)/TiO_2$$

Scheme 2. Reaction steps proposed for CO oxidation to CO_2 by Au^0/TiO_2

Apparently, this synergic mechanism makes Au^0/S catalysts uniquely active in CO oxidation to such an extent that Au^0/S is able to catalyse CO oxidation even more rapidly than H_2 oxidation.[107] This observation is a fundamental

Table 1. A selection of reactions relevant to chemical processing, catalyzed by supported gold(0)

Entry	Reaction	Catalyst	Remarks	Ref.
1	CH_2=CH-CH=CH_2 + H_2 → butenes	Au/S	gas phase, structure and support insensitive	[109]
2	CH_2=CH-C(O)H + H_2 → allyl alcohol	Au/ZrO_2	gas phase, structure sensitive	[110]
3	R-OH $\xrightarrow{air}$ R-C(O)H	Au/SiO_2	gas phase	[111]
4	R-OH, MeCO, Ph-CH_3 $\xrightarrow{air}$ catalytic combustion	Au/Fe_2O_3	gas phase	[112]
5	*o*-hydroxybenzyl alcohol $\xrightarrow{O_2}$ salicylic aldehyde	Au/Fe_2O_3	liquid phase, 50 °C, 1 atm, chemoselective	[113]
6	ethane-1,2-diol $\xrightarrow{O_2}$ glycolate	Au/C	liquid phase (H_2O), 70 °C, 2 atm	[114]
7	diols $\xrightarrow{O_2}$ hydroxymonocarboxylates β-amino alcohols $\xrightarrow{O_2}$ β-amino acids aliphatic aldehydes $\xrightarrow{O_2}$ carboxylic acids D-glucose $\xrightarrow{O_2}$ gluconic acid	Au/C or Au/TiO_2	liquid phase (H_2O), 70–85 °C, 1–3 atm	[103]
8	citral $\xrightarrow{H_2}$ geraniol + nerol	Au/Fe_2O_3	liquid phase, ethanol, 1 atm, 60 °C, chemoselective (95%) hydrogenation of C=O, 100% conversion	[115]
9	benzalacetone $\xrightarrow{H_2}$ phenyl-3-buten-2-ol	Au/Fe_2O_3	liquid phase, ethanol, 1 atm, 60 °C, chemoselective (60%) hydrogenation of C=O, 100% conversion	[116]
10	$H_2 + O_2 \rightarrow H_2O_2$	Au·Pd/Al_2O_3	liquid phase, methanol, 2 °C, 97 atm, chemoselective (50%)	[117]
11	aromatic amines $\xrightarrow[MeOH]{CO,\ O_2}$ carbamates	Au/resin	solvent-free, P_{CO} = 40 atm, P_{O2} = 40 atm, 175 °C. Good conversion and selectivity	[118]
12	propylene + O_2 → propylene oxide	Au/Ti-MCM48	gas phase, presently limited yields	[114]

premise to the commercial development of fairly innovative dihydrogen-air PEM (Polymer Electrolyte Membrane) fuel cells for vehicle propulsion and auxiliary power units. In this context, CO-free dihydrogen has to be employed and various Au^0/S catalysts, in particular $Au^0/Al_2O_3/MgO/MnO$, are known to allow the removal of CO (ppm levels) from the dihydrogen stream that feeds the fuel cells at 60−100 °C (PROX reactor),[108] without a significant consumption of dihydrogen. The technical problem to be solved for a straight commercialization of PROX technology is the achievement of a suitable stability of the catalyst itself.

6.2.4 Gold(0)-Based Catalysis for Chemical Processing

Haruta's discovery, which was published in 1989, not only produced an explosion of interest for the catalytic chemistry of gold nanoparticles, mainly around the problem of CO and O_2 activation, but it also promoted a huge amount of research on a variety of possible applications of gold nanoparticles in pollution-control technologies and in chemical processing, i.e. in the potential industrial synthesis of commodities, semi-commodities, and fine and specialty chemicals.

A few recent examples of these valuable prospects are presented in Table 1.

It is apparent from Table 1 that the prospects for employing supported nano-sized-Au^0 in industrial catalysis are excellent, both in the gas and the liquid phase, with good prospects for using water as the solvent[103][114] in oxidation processes. The facile synthesis of H_2O_2 from O_2 and H_2 seems to be one of the major listed results that allow us to imagine the achievement of small-scale industrial facilities for the production of hydrogen peroxide.

6.2.5 Ongoing and Future Applications of Gold(0)-Based Catalysis

This topic is presented and discussed in references 93, 96, 99 and 119.

A peculiar current application is provided by Au^0 deposited on Fe_2O_3, supported on a zeolite wash-coated honeycomb. This sophisticated setup catalyses effectively the oxidative decomposition of bad smelling alkylamines (with a minimal production of N_2O) that are responsible for the unpleasant atmosphere in toilets ("odour eaters").[99]

Au^0/La_2O_3, integrated with Pd/SnO_2 and Ir/La_2O_3 is likely to become employed as a catalyst for the oxidative decomposition of dioxins coming from incinerator outlet gases at temperatures below 473 K.[99]

The long-awaited direct epoxidation of propylene is expected to become an Au^0-catalyzed synthetic technology once the yield in propylene oxide has been improved to ca. 10% and this goal seems to be feasible on Au^0/Ti-MCM48.[99]

Composite films of Co_2O_3 nanocrystals (5−10 nm) are expected to form the basis for optical sensors able to simultaneously detect H_2 and CO at 1% levels.[93]

Au^0/S catalysts are likely to become key components of CO safety masks and of devices for the efficient removal of CO from contaminated atmospheres.[96,119]

Finally, a little-explored and quite promising sector of gold catalytic chemistry is the employment of Au^0/S catalysts in liquid-phase synthetic processes. The brilliant results obtained by a few research groups, even in water, (Table 1) are indeed promising, quite in line with the emerging view of "Green Chemistry".

"Although we are well past the beginning of the discovery of gold's catalytic potential, the best may be yet to come, and a golden future lies ahead" (G. C. Bond, 2002).[81]

Conclusions

Nanoparticulated gold has turned out to play an important role in various fields of nanoscience. Besides their unique color, gold nanoparticles became of scientific and technological interest because of their stability to air which means that they can be used even in nanosized form for many applications. Well-expressed quantum-size effects have been observed for particles smaller than 2 nm even at room temperature, making these artificial atoms valuable candidates for future nanoelectronics once appropriate techniques allow the generation of artificial structures on surfaces. The first steps in this direction look very promising. The moderate chemical reactivity of gold atoms on particle surfaces allows them to act as catalysts for distinct reactions, for example oxidation reactions. Indeed, there are several catalytic reactions where gold nanoparticles act as highly efficient catalysts.

It can be assumed that the use of particulated gold will dramatically increase in the near future in very different fields. Gold quantum dots may act as single-electron switches and transistors, at the latest when silicon technology has reached its physical limits. Gold nanowires as conducting contacts in nanoelectronics will also contribute to the progress of nanotechnology. A renaissance in gold catalysis seems to have started. Gold nanoparticles in combination with biomolecules are already at a point where even commercial applications in medical diagnostics have become known.

Another developing field is sensorics where gold nanoparticles might play the most important role. Other applications, not yet to be foreseen, may come up and make the next decades a "golden age".

1,2-Bis-*N*-[2′-(diphenylphosphanyl)benzoyl]diaminobenzene, a New Chelating Ligand with Versatile Coordination Properties

Sylvain Burger,[a] Bruno Therrien,[a] and Georg Süss-Fink*[a]

Keywords: Palladium / Platinum / N,P ligands / Ligand design

1,2-Bis-*N*-[2′-(diphenylphosphanyl)benzoyl]diaminobenzene (dppbH; **1**) was prepared by peptidic coupling and shown to exist, in the solid state, in the form of hydrogen-bonded dimers by single-crystal X-ray structure analysis. As expected, **1** reacts with [MCl_2(cod)] (M = Pd, Pt; cod = cyclooctadiene) to form square-planar complexes. However, in the case of palladium [$PdCl_2$(dppbH)] (**2**) is obtained, while in the case of platinum [Pt(dppb)] (**3**) is formed. Thus, the nature of the metal induces a completely different coordination mode: In **2**, the dppbH ligand only coordinates through the two phosphorus atoms, while in **3** a dppb ligand, formed by deprotonation of the two amino functions in dppbH, coordinates through the two phosphorus atoms and through the two nitrogen atoms. The single-crystal X-ray analyses of the two square-planar complexes reveal **2** to contain the two phosphorus atoms in a *trans* coordination mode and **3** to contain the two phosphorus atoms in a *cis* coordination mode.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The synthesis of new, highly active complexes for homogeneously catalyzed processes is a challenge in coordination chemistry. Square-planar complexes of Pd^{II} and, to a minor extent, Pt^{II} have long been recognized to play a central role in catalytic reactions such as the classical Wacker process[1] and, more recently, in the co-polymerization of carbon monoxide and olefins.[2] Pd^{II} and Pt^{II} complexes are used in organic synthesis reactions such as Diels−Alder cycloadditions,[3] Baeyer−Villiger oxidation of ketones,[4] hydrogenolysis[5] or Sonogashira cross-coupling.[6]

Electron-rich ligands have been used to increase the electron density at the metal center in order to facilitate the oxidative addition step in a catalytic cycle.[7] Phosphane ligands have been extensively studied because of their electron-donating power. Diphosphane ligands have received special attention because they form, in general, more-stable (chelate) complexes than monophosphane ligands under catalytic conditions.[8] In the co-polymerization of olefins with carbon monoxide, Dosset et al.[7] showed that the catalytic activity of diphosphanylpalladium(II) complexes of the type [$PdCl_2\{Ar_2P(CH_2)_nPAr_2\}$] ($n$ = 1−3) depends upon the length of the carbon chain and upon the nature of the aryl groups. The six-membered chelate (n = 3) is an order of magnitude more active than the five-membered analogue (n = 2), while the four-membered chelate (n = 1) is essentially inactive. Complexes containing an *ortho* substituent at the aryl groups have a higher catalytic potential than those with *para* and *meta* substituents. It has been suggested that mononuclear *trans* bidentate complexes are more stable with large metallacycles than with medium-size metallacycles due to the increased flexibility of the larger ring size.[9] In general, the stability of the *trans* monomer increases with increasing chain length and reaches a maximum for a metallacycle containing 15 ring members.[10]

Herein, we report the synthesis of a new diphosphane ligand containing an *ortho*-phenylene spacer group for the synthesis of *trans*-dicoordinate as well as *cis*-tetracoordinate square-planar palladium(II) and platinum(II) complexes.

Results and Discussion

2-(Diphenylphosphanyl)benzoic acid, easily available from Wurtz coupling of sodium 2-chlorobenzoate and sodium diphenylphosphide,[11] is an attractive building block for the synthesis of diphosphane ligands by condensation of the acid function with diols, diamines or amino alcohols.[12] Peptidic coupling between *ortho*-diaminobenzene and two equivalents of 2-(diphenylphosphanyl)benzoic acid affords

1,2-bis-*N*-[2′-(diphenylphosphanyl)benzoyl]diaminobenzene (dppbH; **1**) as a microcrystalline powder in good yield (Scheme 1).

The diphosphane ligand **1** is symmetrical and shows only one resonance in the $^{31}P\{^1H\}$ NMR spectrum at $\delta = -8.83$ ppm. In the ^1H NMR spectrum, **1** gives rise to a singlet at $\delta = 8.63$ ppm (in $CDCl_3$) corresponding to the amido protons. The amido function is also easily identified in the IR spectrum by two absorptions at 3324 cm^{-1} (ν_{NH}) and 1640 cm^{-1} (ν_{CO}). The molecular structure of **1**, established by single-crystal X-ray structure analysis, is shown in Figure 1.

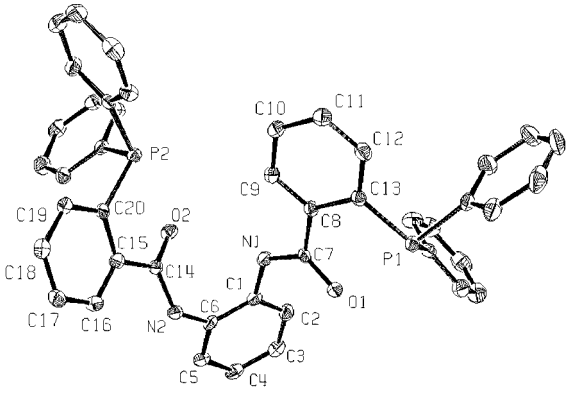

Figure 1. ORTEP view of **1**, displacement ellipsoids are drawn at the 50% probability level, hydrogen atoms are omitted for clarity; selected bond lengths (Å) and angles (°): C(7)−O(1) 1.237(3), C(14)−O(2) 1.235(3), C(7)−N(1) 1.348(4), C(14)−N(2) 1.355(4), C(13)−P(1) 1.847(3), C(20)−P(2) 1.853(3); O(1)−C(7)−N(1) 121.6(3), O(2)−C(14)−N(2) 121.8(3)

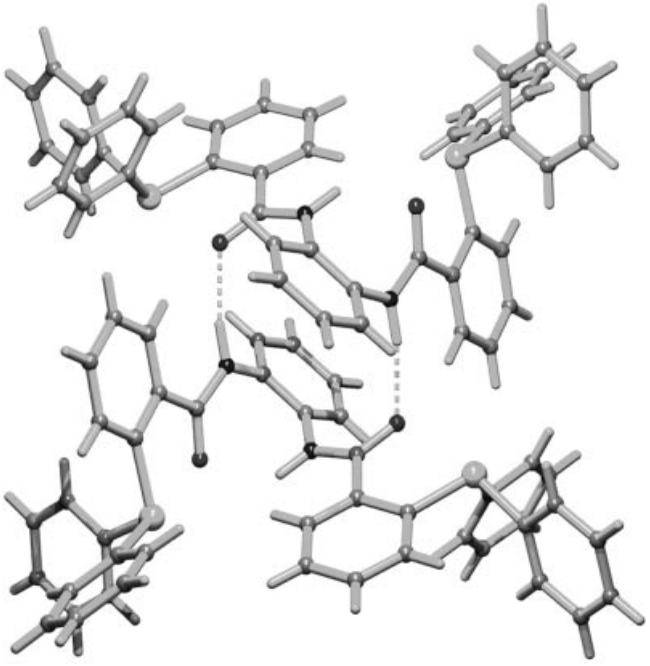

Figure 2. Dimeric structure of compound **1**

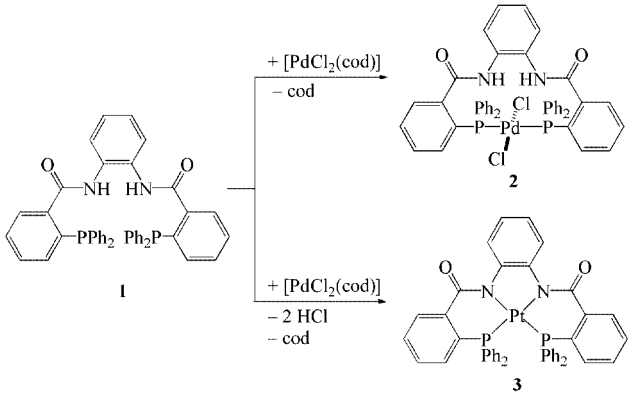
The crystal structure analysis reveals **1** to exist as a dimer in the solid state, thanks to hydrogen bonding between an NH and a CO function (see Figure 2). The N−O distance of the hydrogen bond [N(2)−H···O(1)] is 2.867(3) Å, with an N−H···O angle of 164.6°. The intramolecular distance between the two phosphorus atoms is 7.794(1) Å. In the crystal structure, there is no significant interaction between compound **1** and the dichloromethane molecule.

One equivalent of dppbH (**1**) reacts with $[MCl_2(cod)]$ (M = Pd, Pt; cod = cyclooctadiene) to afford the corresponding complexes $[PdCl_2(dppbH)]$ (**2**) and [Pt(dppb)] (**3**) in good yield (Scheme 2). The reaction was carried out in dilute solution to avoid the formation of di- or polynuclear species as observed for other diphosphane ligands.[13]



Scheme 2

$[PdCl_2(dppbH)]$ (**2**) gives only one singlet at $\delta = 24.03$ ppm in the $^{31}P\{^1H\}$ spectrum, which is indicative of the coordination of both phosphorus atoms to the metal. The mass spectrum is in accordance with the presence of a mononuclear species containing two chloride ligands. The IR spectrum shows two bands at 3324 (ν_{NH}) and 1640 cm^{-1} (ν_{CO}) assigned to the amido functions.

The molecular structure of **2** shows the palladium atom to be in a square-planar geometry, surrounded by two chlorines and two phosphorus atoms (Figure 3). The chelating diphosphane ligand adopts a *trans* coordination geometry. The Cl−Pd−Cl as well as the P−Pd−P axes are almost linear, the corresponding angles being 177.03(10)° and 178.40(9)°, respectively. The two Pd−Cl distances are equivalent [2.310(2) and 2.311(2) Å], but interestingly one Pd−P distance is slightly longer (by 0.042 Å) than the other one. There is no meaningful interaction in the apical position of the palladium atom, the shortest distance to another atom being 2.96 Å [Pd(1)−O(2)]. In the crystal structure, only one chloroform molecule interacts with complex **2**, forming a weak hydrogen bond with one of the chlorine atoms, the Cl(2)−C(1S) distance being 3.49(1) Å and the C(1S)−H···Cl(2) angle being 150.3(1)°.

The formation of **3** is best monitored by $^{31}P\{^1H\}$ spectroscopy, the complex showing a triplet centered at $\delta = 6.20$ ppm due to the coupling between the two equivalent phosphorus atoms and the platinum atom (coupling con-

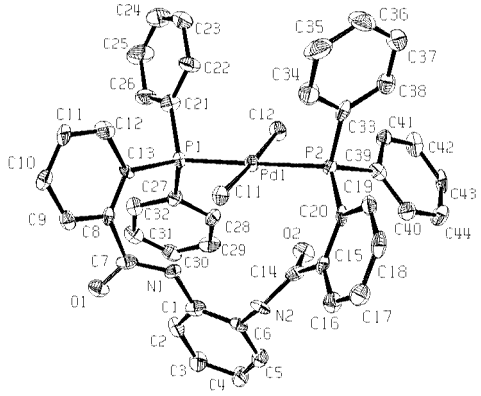

Figure 3. ORTEP view of complex **2**, displacement ellipsoids are drawn at the 50% probability level, hydrogen atoms and solvent molecules are omitted for clarity; selected bond lengths (Å) and angles (°): P(1)−Pd(1) 2.318(2), P(2)−Pd(1) 2.360(2), Cl(1)−Pd(1) 2.310(2), Cl(2)−Pd(1) 2.311(2), C(7)−O(1) 1.232(9), C(14)−O(2) 1.222(8), C(7)−N(1) 1.336(9), C(14)−N(2) 1.362(9), C(13)−P(1) 1.859(7), C(20)−P(2) 1.832(7); Cl(1)−Pd(1)−Cl(2) 177.03(10), Cl(1)−Pd(1)−P(1) 91.91(7), Cl(2)−Pd(1)−P(1) 86.27(8), Cl(1)−Pd(1)−P(2) 89.67(8), Cl(2)−Pd(1)−P(2) 92.17(8), P(1)−Pd(1)−P(2) 178.40(9), O(1)−C(7)−N(1) 123.2(7), O(2)−C(14)−N(2) 121.6(7)

stant 3120 Hz). IR spectroscopy shows that there is no ν_{NH} absorption (around 3300 cm^{-1}) any more, but a strong ν_{CO} band at 1602 cm^{-1} showing a strong bathochromic effect. It appears that the formation of **3** is accompanied by the loss of two equivalents of HCl. Unlike $[Pt\{Ph_2PC_6H_4NC(O)C_6H_4\}_2]$,[14] complex **3** does not give the dichloroplatinum complex $[PtCl_2(dppbH)]$ in the presence of HCl.

The molecular structure of **3** shows the platinum atom in a distorted square-planar geometry (Figure 4). Unlike in **2**, the chelating diphosphane ligand adopts a *cis* coordination geometry, with the two nitrogen atoms also coordinating to the metal. The formation of five- and six-membered chelate rings imposes a considerable distortion around the platinum atom. The N−Pt−P angles [83.47(16) and 89.71(16)°] are slightly acute due to the bidentate $PC_6H_4C(O)N$ units. The atoms Pt(1), P(1), P(2), N(1) and N(2) are almost coplanar, with an average deviation of 0.0674 Å; the metal lies out of the plane by 0.078(2) Å. In the crystal structure, there is no meaningful interaction between complex **3** and the chloroform molecule.

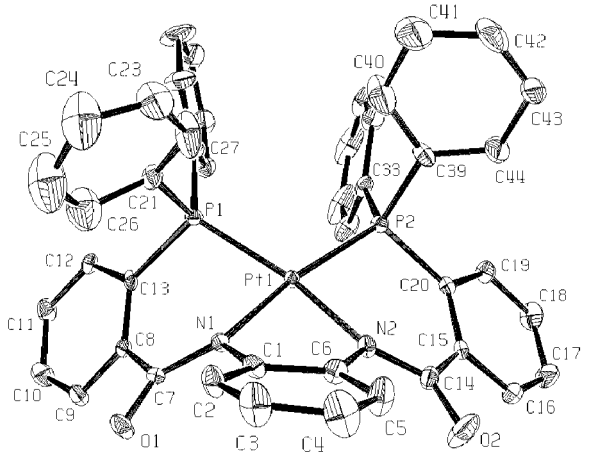

Figure 4. ORTEP view of complex **3**, displacement ellipsoids are drawn at the 35% probability level, hydrogen atoms and solvent molecules are omitted for clarity; selected bond lengths (Å) and angles (°): P(1)−Pt(1) 2.243(2), P(2)−Pt(1) 2.234(2), N(1)−Pt(1) 2.035(6), N(2)−Pt(1) 2.067(5), C(7)−O(1) 1.215(8), C(14)−O(2) 1.240(9), C(7)−N(1) 1.367(8), C(14)−N(2) 1.356(10), C(13)−P(1) 1.830(6), C(20)−P(2) 1.820(7); N(1)−Pt(1)−N(2) 80.3(2), N(1)−Pt(1)−P(1) 83.47(16), N(2)−Pt(1)−P(1) 161.74(18), N(1)−Pt(1)−P(2) 169.92(15), N(2)−Pt(1)−P(2) 89.71(16), P(1)−Pt(1)−P(2) 106.26(6), O(1)−C(7)−N(1) 125.2(6), O(2)−C(14)−N(2) 122.8(7)

The stability of complex **2** towards base attack and that of complex **3** towards acid attack has been studied in order to check the possibility of converting these *cis* or *trans* complexes into their corresponding deprotonated or protonated species. However, complex **2** is not deprotonated by an excess of triethylamine to give [Pd(dppb)], the $^{31}P\{^1H\}$ NMR signal of **2** being unchanged in $CDCl_3$ even after 24 hours in the presence of NEt_3 (100 equiv.). Likewise, complex **3** is not protonated by concentrated hydrochloric acid to give $[PtCl_2(dppbH)]$, the $^{31}P\{^1H\}$ NMR signal of **3** being unchanged in $CDCl_3$ even after 24 hours in the presence of HCl (100 equiv.).

Conclusion

We have synthesized a new diphosphane ligand, 1,2-bis-*N*-[2′-(diphenylphosphanyl)benzoyl]diaminobenzene (dppbH; **1**), which shows a different coordination pattern towards palladium(II) and platinum(II): it reacts with $[MCl_2(cod)]$ (M = Pd, Pt; cod = cyclooctadiene) to form the square-planar complexes $[PdCl_2(dppbH)]$ (**2**) and [Pt(dppb)] (**3**), respectively. In **2**, the dppbH ligand is coordinated by the two phosphorus atoms in a *trans* configuration, while in **3** the two phosphorus atoms are coordinated in a *cis* configuration, the two nitrogen atoms of the dppb ligand being coordinated as well.

Experimental Section

General Remarks: Dichloromethane was dried and distilled under nitrogen prior to use. All reactions were carried out under nitrogen, using standard Schlenk techniques. All other reagents were purchased (Aldrich, Fluka) and used as received. NMR spectra were recorded using a Varian Gemini 200BB instrument and referenced to the signals of the residual protons in the deuterated solvents. Electrospray mass spectra were obtained in positive-ion mode with an LCQ Finnigan mass spectrometer. IR spectra were recorded with a Perkin−Elmer Spectrum One FTIR spectrometer. Microanalyses were carried out by the Laboratory of Pharmaceutical Chemistry, University of Geneva, Switzerland.

Preparation of 1,2-Bis-*N*-[2′-(diphenylphosphanyl)benzoyl]diaminobenzene (dppbH; 1): A solution of 2-diphenylphosphanylbenzoic acid (1.0 g, 3.26 mmol), *N*,*N*-dicyclohexylcarbodiimide (2.7 g, 13.05 mmol), 4-(dimethylamino)pyridine (100 mg, 0.82 mmol), 4-pyrrolidinopyridine (100 mg, 0.68 mmol), and 1,2-diaminobenzene (175 mg, 1.62 mmol) in CH_2Cl_2 (40 mL) was allowed to stand at

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

room temperature under nitrogen, until the esterification was complete. The resulting solution was concentrated and filtered three times to remove *N*,*N*-dicyclohexyl urea. The filtrate was then concentrated under reduced pressure. The residue was submitted to column chromatography on silica, eluting with hexane/acetone (3:1). The product was isolated from the third fraction by the evaporation of the solvent, giving **1** (550 mg, 0.81 mmol; 50%) as a white solid. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 8.63 (s, 2 H, NH), 7.5−6.9 (m, 32 H, ArH) ppm. ^{13}C{^{1}H} NMR (50 MHz, $CDCl_3$): δ = 168.12, 143.45, 141.20, 141.00, 140.50, 137.62, 137.39, 134.62, 133.90, 130.84, 129.68, 128.94, 128.80, 128.65 ppm. ^{31}P{^{1}H} NMR (81 MHz, $CDCl_3$): δ = −8.83 ppm. IR (KBr): $\tilde{\nu}$ = 3324 m (N−H amide), 1640 s (C=O amide) cm^{-1}. ESI-MS: *m*/*z* = 685 [M + H$^+$]. $C_{44}H_{34}N_2O_2P_2$ (684.21): calcd. C 77.2, H 5.0, N 4.1; found C 76.8, H 4.8, N 4.3.

Preparation of [PdCl$_2$(dppbH)] (2): A solution of [$PdCl_2$(cod)] (42 mg, 0.15 mmol) and **1** (100 mg, 0.15 mmol) in CH_2Cl_2 (20 mL) was allowed to stand for 3 hours at room temperature and then filtered. The filtrate was concentrated under reduced pressure. The residue was submitted to column chromatography on silica, eluting with dichloromethane/ethanol (4:1). The product was isolated from the first fraction by the evaporation of the solvent, giving **2** (95 mg, 0.11 mmol; 79%) as a yellow-orange solid. 1H NMR (200 MHz, $CDCl_3$): δ = 8.66 (s, 2 H, NH), 8.1−6.9 (m, 32 H, ArH) ppm. ^{31}P{^{1}H} NMR (81 MHz, $CDCl_3$); δ = 24.03 ppm. IR (KBr): $\tilde{\nu}$ = 3302 m (N−H amide), 1662 s (C=O amide) cm^{-1}. ESI-MS: *m*/*z* = 885 [M + Na$^+$]. $C_{44}H_{34}Cl_2N_2O_2P_2Pd$ (861.51): calcd. C 61.3, H 4.0, N 3.3; found C 61.1, H 4.1, N 3.2.

Preparation of [Pt(dppb)] (3): A solution of [$PtCl_2$(cod)] (55 mg, 0.15 mmol) and **1** (100 mg, 0.15 mmol) in CH_2Cl_2 (20 mL) was allowed to stand for two hours at room temperature and then filtered. The filtrate was concentrated under reduced pressure. The residue was submitted to column chromatography on silica, eluting with dichloromethane/ethanol (3:1). The product was isolated from the first fraction by the evaporation of the solvent, giving **3** (80 mg, 0.09 mmol; 61%) as a yellow-green solid. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.9−6.7 (m, 32 H, ArH) ppm. ^{31}P{^{1}H} NMR (81 MHz, $CDCl_3$); δ = 6.20 (t, $^1J_{Pt,P}$ = 3120 Hz) ppm. IR (KBr): $\tilde{\nu}$ = 1602 s (C=O amide) cm^{-1}. ESI-MS: *m*/*z* = 878 [M + H$^+$], 900 [M + Na$^+$]. $C_{44}H_{32}N_2O_2P_2Pt$ (877.28): calcd. C 60.2, H 3.7, N 3.2; found C 60.0, H 3.6, N 3.4.

X-ray Crystallographic Study

1·CH$_2$Cl$_2$: $C_{45}H_{36}Cl_2N_2O_2P_2$, *M* = 769.60 g·mol^{-1}, triclinic, *P*$\bar{1}$ (no. 2), *a* = 9.2473(8), *b* = 14.0068(14), *c* = 14.5320(16) Å, α = 89.904(12), β = 89.630(12), γ = 89.693(11)°, *U* = 1882.2(3) Å^3, *T* = 153 K, *Z* = 2, μ(Mo-K_α) = 0.300 mm^{-1}, 12481 reflections measured, 6853 unique (R_{int} = 0.0607) which were used in all calculations. The final *wR* (F^2) was 0.1126 (all data).

2·2CHCl$_3$: $C_{46}H_{36}Cl_8N_2O_2P_2Pd$, *M* = 1100.71 g·mol^{-1}, triclinic, *P*$\bar{1}$ (no. 2), *a* = 9.9013(11), *b* = 15.1734(18), *c* = 16.7870(18) Å, α = 78.059(14), β = 76.629(13), γ = 78.630(14)°, *U* = 2370.8(5) Å^3, *T* = 153 K, *Z* = 2, μ(Mo-K_α) = 0.950 mm^{-1}, 17568 reflections measured, 8657 unique (R_{int} = 0.1286) which were used in all calculations. The final *wR*(F^2) was 0.1015 (all data).

3·CHCl$_3$: $C_{45}H_{33}Cl_3N_2O_2P_2Pt$, *M* = 997.11 g·mol^{-1}, monoclinic, $P2_1/n$ (no. 14), *a* = 12.0140(17), *b* = 11.259(3), *c* = 28.720(4) Å, β = 95.026(16)°, *U* = 3870.0(13) Å^3, *T* = 153 K, *Z* = 4, μ(Mo-K_α) = 3.958 mm^{-1}, 20851 reflections measured, 7307 unique (R_{int} = 0.0544) which were used in all calculations. The final *wR*(F^2) was 0.0984 (all data).

The data were measured using a Stoe Image Plate Diffraction system equipped with a φ circle, using Mo-K_α graphite-monochromated radiation (λ = 0.71073 Å) with φ range 0−200°, increment of 1.5, 1.4 and 0.8° respectively, 2θ range from 2.0−26°, $D_{max}-D_{min}$ = 12.45−0.81 Å. The structures were solved by direct methods using the program SHELXS-97.[15] The refinement and all further calculations were carried out using SHELXL-97.[16] The H-atoms were included in calculated positions and treated as riding atoms using the SHELXL default parameters. The non-H atoms were refined anisotropically, using weighted full-matrix least-square on F^2. Figures were drawn with ORTEP.[17]

CCDC-212037 (**1**), -212039 (**2**), and -212038 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work is supported by the Swiss National Science Foundation (grant no. 20−61227−00). We thank Professor H. Stoeckli-Evans for free access to X-ray facilities.
