A Novel Water-Soluble Tripodal Imidazolyl Ligand as a Model for the Tris(histidine) Motif of Zinc Enzymes: Nickel, Cobalt and Zinc Complexes and a Comparison with Metal Binding in Carbonic Anhydrase

Peter C. Kunz,[a] Guido J. Reiß,[a] Walter Frank,[a] and Wolfgang Kläui*[a]

Dedicated to Professor Bernt Krebs on the occasion of his 65th birthday

Keywords: Bioinorganic chemistry / Cobalt / Enzyme models / N ligands / Nickel / Tripodal ligands / Zinc

Tris[2-isopropylimidazol-4(5)-yl]phosphane (4-TIP^{iPr}), a novel model ligand for the tris(histidine) motif of many zinc enzymes, has been prepared. 4-TIP^{iPr} is hydrolytically stable and soluble in protic solvents. It readily forms chloro- and nitratocobalt, -nickel and -zinc complexes in aqueous methanol. The crystal structures of the solvates [(4-TIP^{iPr})Co(MeOH)(NO$_3$)]NO$_3$·2Et$_2$O (**3**·2Et$_2$O), [(4-TIP^{iPr})Ni(MeOH)(NO$_3$)]NO$_3$·Et$_2$O·MeOH (**4**·Et$_2$O·MeOH), [(4-TIP^{iPr})CoCl]Cl·MeOH·2.5H$_2$O (**5**·MeOH·2.5H$_2$O), and [(4-TIP^{iPr})ZnCl]Cl·MeOH·2.5H$_2$O (**6**·MeOH·2.5H$_2$O) have been determined. The complex **3** shows striking structural similarities to the hydrogencarbonate complex of cobalt-substituted human carbonic anhydrase II (HCA II).

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

In mammalian carbonic anhydrases (CAs) and many other metalloenzymes, the metal-binding site is formed by histidine imidazole rings.[1] In HCA II the three histidine residues His-94, His-96, and His-119 complete a tetrahedral coordination geometry around a Zn−X moiety.

The hydrotris(pyrazolyl)borates (Tp$^{R,R'}$) are the best known of the structural model ligands (Figure 1).[2−4] Their complexes have many of the structural and spectroscopic properties of the active sites of metalloenzymes, though these compounds have been studied mainly in nonprotic solvents, due to the vulnerability of the Tp ligands towards hydrolysis. Attempts to substitute the B−N bonds, to yield more stable ligands, have been made. We have recently re-

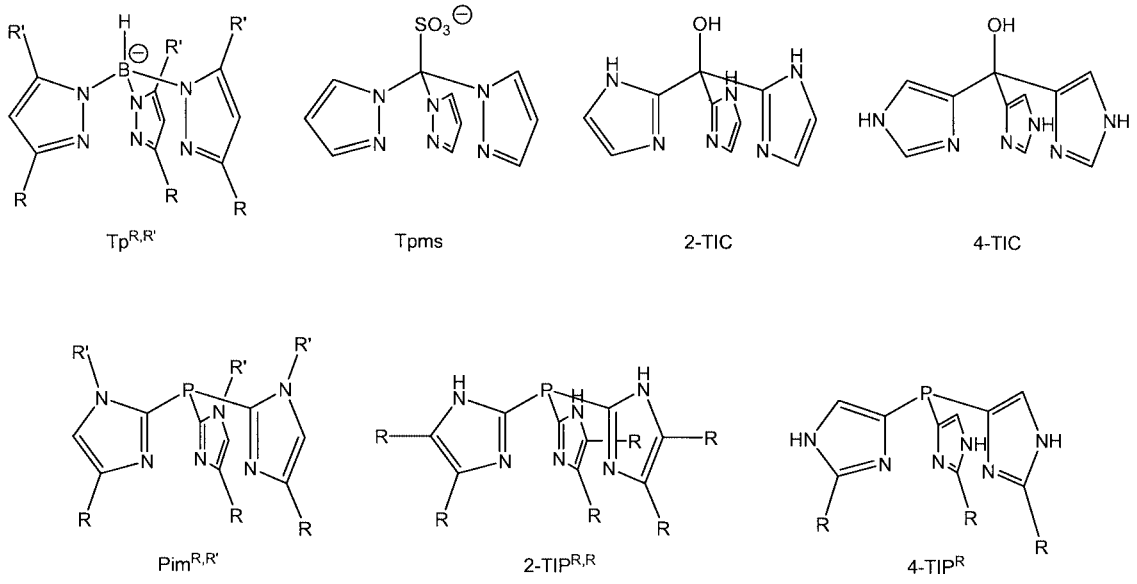

Figure 1. Schematic structures of the novel model ligand 4-TIP^{R} and of related tripodal nitrogen ligands based on pyrazoles and imidazoles

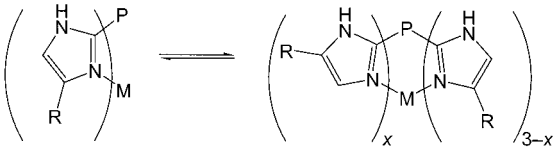
ported on tris(pyrazolyl)methanesulfonate (Tpms) as a water-soluble Tp-like ligand.[5]

Imidazole ligands should model the actual binding site even better than pyrazole ligands. Attachment of imidazole rings at the 2-position to a molecular framework by the use of 2-lithioimidazoles is relatively simple. In nature, though, the imidazole ring is attached to the histidine side chain through the 4(5)-position. In the early 1980s, Breslow and co-workers synthesized a number of tripodal ligands bearing imidazolyl groups. Tris(imidazol-2-yl)carbinol (2-TIC) and tris(imidazol-4-yl)carbinol (4-TIC), together with M^{2+} complexes (M = Zn, Co) of these ligands, were synthesized as models for the zinc binding site of carbonic anhydrase and alkaline phosphatase.[6,7] Because of the small steric demand of these ligands, however, bis(ligand) formation could not be prevented. Attempts to introduce bulky substituents in the 2-position of 4-TIC resulted in the formation of fulvene-like dehydration products.[7,8]

From Carbinol to Phosphane

Tris(imidazolyl)phosphanes seem to be suitable *N*,*N*,*N*-ligands as models for the active site of the facial His triad in zinc-containing enzymes.[9] Substitution of the central carbinol unit by a phosphorus atom circumvents the dehydration reaction. We have recently reported on tris([2-(1-methyl-4-tolylimidazolyl)]phosphane ($Pim^{Me,pTol}$) and its zinc complexes as structural models of the active site of carbonic anhydrase.[10] The aromatic substituents of this ligand form a hydrophobic cavity around the metal centre and, unlike in the larger substituents, such as the tris(4-*tert*-butyl-1-isopropylimidazol-2-yl)phosphane ($Pim^{iPr,tBu}$),[9] the smaller methyl group in the 1-position provides better solubility in polar solvents.

By this concept, the next step would be not to have any substituent in the 1-position. However, the resulting tris[4(5)-organylimidazol-2-yl]phosphane would undergo prototropic shift reactions. All of the resulting tautomeric forms, after rotation around the phosphorus−carbon bonds, could act as tripodal nitrogen ligands, but with different orientations of the substituents R (Scheme 1).



Scheme 1. The different tautomeric forms of tris[4(5)-organylimidazol-2-yl]phosphane; x = 0, 1, 2

This problem can be circumvented by symmetric disubstitution in the 4- and 5-positions of the imidazolyl rings (2-$TIP^{R,R}$),[11] but the introduction of three additional bulky substituents makes these ligands insoluble in protic solvents. To solve this problem we designed an isomeric ligand type, the tris[2-organylimidazol-4(5)yl]phosphanes (4-TIP^{R}s).[12] Here, the prototropic equilibrium and the rotation around the phosphorus−carbon bonds also creates a series of ligands with different binding modes, but only one can now act as a tripodal ligand and here all three substituents R form the desired hydrophobic cavity around the metal ion (Scheme 2).

Below we report on the synthesis of the first member of this class of ligands and of its coordination chemistry toward cobalt, nickel and zinc ions.

Results and Discussion

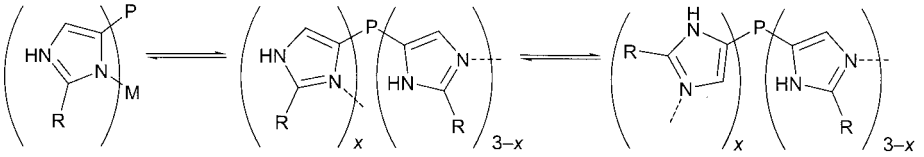
Synthesis and Spectroscopic Characterisation

2-Isopropylimidazole was protected with an easily removable diethoxymethyl group. In the following step the protected imidazole **1** was lithiated in the 5-position and was then treated with PCl_3 in diethyl ether at −78 °C. Tris[2-isopropylimidazol-4(5)-yl]phosphane (4-TIP^{iPr}, **2**) was isolated as a colourless solid after removal of the protective group (Scheme 3).

The ^{1}H NMR spectrum of **2** in [D_4]methanol shows the expected C_{3v} symmetry of the ligand. The isopropyl groups show a doublet at δ = 1.32 ppm and a septuplet at δ = 3.09 ppm, the signal at δ = 7.00 ppm being assigned to the protons of the imidazolyl rings. In the ^{31}P{^{1}H} NMR spectrum the ^{31}P signal appears as a singlet at δ = −80 ppm. The EI mass spectrum of **2** shows the peak for the molecular ion at the expected *m*/*z* value, together with a characteristic fragmentation pattern.

Cobalt, nickel, and zinc complexes were prepared in high yield by stirring the ligand **2** with the corresponding metal salts in wet methanol at ambient temperature (Scheme 4). The nitrato complexes [(4-TIP^{iPr})M(MeOH)(NO_3)]NO_3 form as violet (**3**) (M = Co) and as grass-green (**4**) (M = Ni) needles, while the chloro complexes [(4-TIP^{iPr})MCl]Cl form as deep blue rhombic (**5**) (M = Co) and colourless crystals (**6**) (M = Zn) by diffusion-controlled crystallisation from diethyl ether in methanolic solutions of the complexes.

The ^{1}H NMR spectrum of **6** has a doublet at δ = 1.39 ppm and a septuplet at δ = 3.62 ppm for the isopropyl groups and a doublet at δ = 7.55 with a $^1J_{PH}$ coupling constant of 2 Hz for the imidazolyl ring protons. The signals of the methyl protons of the isopropyl group show no



Scheme 2. Of all tris(2-organylimidazol-4(5)yl)phosphanes (4-TIP^{R}s), only one form can act as a tripodal ligand

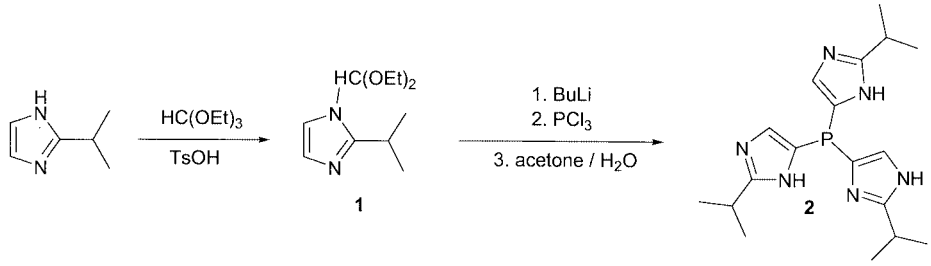

Scheme 3. Synthesis of tris[2-isopropylimidazol-4(5)-yl]phosphane (4-TIP^{iPr}, **2**) from 2-isopropylimidazole

Scheme 4. Synthesis of the nitrato (**3**, **4**) and chloro complexes (**5**, **6**)

significant shift upon coordination, whereas the methine proton of the isopropyl groups and the imidazolyl protons are shifted by about 0.5 ppm to lower field. Upon coordination the ^{31}P NMR signal of the Zn complex **6** is shifted to higher field ($\delta = -106$ ppm), whereas the ^{31}P NMR signals of the cobalt and nickel complexes are shifted to lower field (**3**: $\delta = +27$ ppm; **4**: $\delta = -40$ ppm; **5**: $\delta = -54$ ppm). The NMR spectra of the Co^{II} and Ni complexes show paramagnetic broadening. The FAB mass spectra of all complexes exhibit the peaks for the molecular ions at the expected *m*/*z* values, together with characteristic fragmentation patterns.

The IR spectra of the complexes in nujol and in fluorolube show the characteristic bands of the ligand. Upon preparation of the KBr pellet, the colour of the pellet of the Co^{II} complex turned from violet to deep blue and that of the Ni^{II} complex from green to red. This phenomenon is interpreted in terms of ligand exchange of NO_3^- with Br^- and a simultaneous change in coordination number from 6 to 4 [Equation (1)].

$$[(4\text{-TIP}^{iPr})M(MeOH)(NO_3)]^+ + KBr \rightarrow [(4\text{-TIP}^{iPr})MBr]^+ \quad (1)$$

This interpretation was confirmed by UV/Vis spectra of 1 mM methanolic solutions of **3** saturated with NaX (X = F^-, Cl^-, Br^-, I^-, N_3^-, OAc^-) (Figure 2). The spectrum of $[(4\text{-TIP}^{iPr})Co]^{2+}$ is markedly dependent upon the presence of added anions, indicating association of monovalent anions with the metal ion.

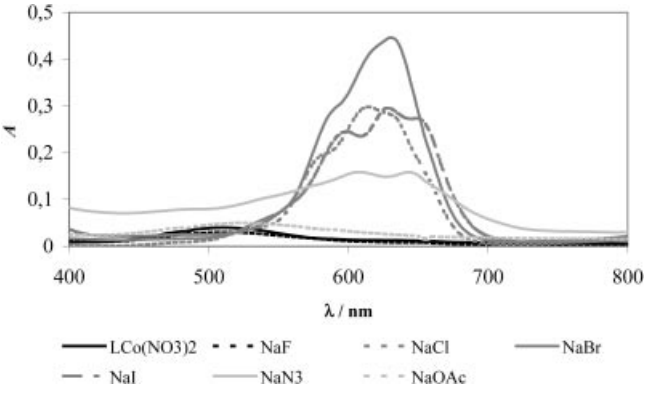

Figure 2. UV/Vis spectra of 1 mM methanolic solutions of **3** saturated with NaX (X = F^-, Cl^-, Br^-, I^-, N_3^-, OAc^-)

Solid-State Structures

The solid state structures of **3**, **4**, **5**, and **6** were determined by crystal structure analysis. The complexes crystallise from wet methanol/diethyl ether. The nitrato complex **3**·2Et_2O crystallises in the triclinic space group $P\bar{1}$, **4**·Et_2O·MeOH in the monoclinic space group $P2_1/c$. The central metal ions in the nitrato complexes are each coordinated facially by three N donor atoms of the 4-TIP^{iPr} li-

gand, in bidentate fashion by the nitrato ligand, and by a methanol molecule to complete the distorted octahedral coordination geometry. Interestingly, the crystal structures each show the expected hydrogen bonds of the imidazolyl N−H protons to solvent molecules. Figure 3 shows an ORTEP plot of **3**·2Et_2O. Selected bond lengths and angles are summarised in Tables 1 and 2.

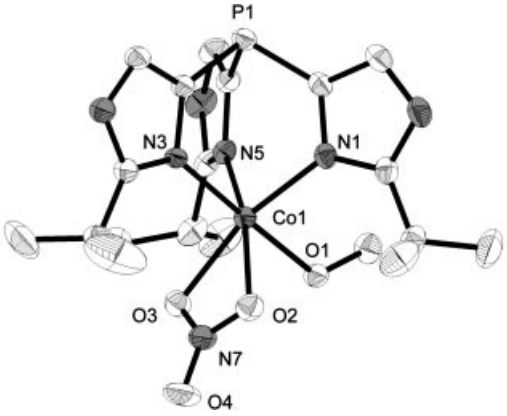

Figure 3. Structure of the cation [(4-TIP^{iPr})Co(HOMe)(NO_3)]$^+$ in **3**·2Et_2O; displacement ellipsoids are shown at the 20% probability level and H atoms are omitted for clarity

N1−Co1−N3	88.69(10)	N1−Co1−N5	92.47(12)
N3−Co1−N5	88.50(10)	N1−Co1−O1	90.29(10)
N1−Co1−O2	103.57(12)	N1−Co1−O3	162.76(12)
N3−Co1−O1	178.22(10)	N3−Co1−O2	97.56(10)
N3−Co1−O3	97.29(10)	N5−Co1−O1	90.09(10)
N5−Co1−O2	162.92(12)	N5−Co1−O3	103.79(11)
O1−Co1−O2	84.09(10)	O1−Co1−O3	84.10(10)
O2−Co1−O3	59.70(11)	O2−N7−O3	115.3(3)
O2−N7−O4	122.0(4)	O3−N7−O4	122.8(4)
N7−O2−Co1	92.1(2)	N7−O3−Co1	92.9(2)

The tripodal ligand is bound facially with non-equivalent M−N bond lengths. The M−N bond *trans* to methanol is slightly longer than the M−N bond *trans* to the nitrato ligand [**3**: *d*(Co−N) *trans* to NO_3 ≈ 2.10 Å, *d*(Co−N) *trans* to MeOH = 2.140(3) Å; **4**: *d*(Ni−N) *trans* to NO_3 ≈ 2.04 Å, *d*(Ni−N) *trans* to MeOH ≈ 2.101(3) Å]. Similar behaviour is observed for the M−O bond lengths. The differences in M−O bond lengths and dihedral angles of the NO_3 ligand indicate a bidentate coordination mode ($\Delta d \approx 0.02$ Å; $\Delta\theta$(N−O−M) ≈ 1°).[13]

The chloro complexes **5**·MeOH·2.5H_2O and **6**·MeOH·2.5H_2O crystallise in the monoclinic space group *C2/m*. Figure 4 shows an ORTEP plot of **5**·MeOH·2.5H_2O. Selected bond lengths and angles are summarised in Tables 3 and 4.

In the chloro complexes **5**·MeOH·2.5H_2O and **6**·MeOH·2.5H_2O the central metal ion is coordinated tetrahedrally by the 4-TIP^{iPr} ligand and by one of the chloride ions. The angles around the central metal ion deviate significantly from tetrahedral angles; the N−M−Cl angles are larger (119−123°) and the N−M−N angles are smaller (93−96°). In the crystal of **5**·MeOH·2.5H_2O and **6**·MeOH·2.5H_2O, the imidazolyl N−H atoms of the cations

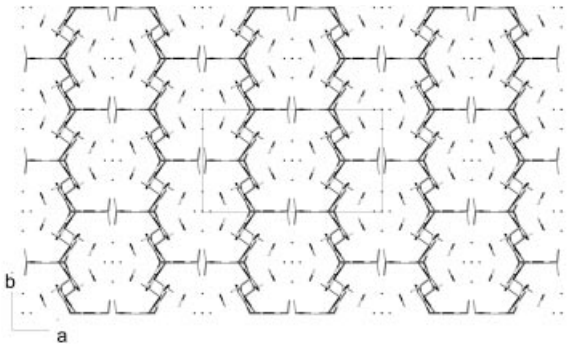

Figure 5. Molecular packing diagram of **5**·MeOH·2.5H_2O; view along the *c* axis; positions of the methanol and water molecules are represented by sticks and single balls; some are partially occupied

form hydrogen bonds to the chloride counter-ion. This results in the formation of hexagonal tubular structures (see Figure 5), filled with solvent molecules showing substantial disorder.

The bond lengths and angles of **6** do not differ significantly from those observed in the X-ray structure of dichloro[tris(4,5-diisopropylimidazol-2-yl)phosphane]zinc(II) bis(*N*,*N*-dimethylformamide).[11b]

The isopropyl groups in all complexes take up a conformation in which the methyl groups point away form the metal centre and the methine protons are oriented towards the metal centre. If this is also the favoured conformation in solution, this would explain the shift of the methine protons in the ^{1}H NMR spectrum of the zinc complex **6**.

Conclusion

We have synthesized the new tris(imidazolyl)phosphane ligand 4-TIP$^{i\mathrm{Pr}}$, which to the best of our knowledge is the first representative of tris[imidazol-4(5)-yl]phosphane ligands. These ligands possess all the minimum features a CA model compound should have: (i) large substituents around the metal centre to suppress bis(ligand) formation and model a hydrophobic cavity, (ii) sufficient solubility in aqueous solvents, and (iii) stability towards hydrolysis.

In 1992, Håkansson and Wehnert reported on the structure of cobalt carbonic anhydrase bearing a hydrogencarbonate ligand.[14] They found that the Co^{II} ion is coordinated by three histidyl ligands of the enzyme, one water molecule and two oxygen atoms of hydrogencarbonate. The structure of **3** shows exactly this motif: Co^{II} is coordinated in a distorted octahedral fashion by the three imidazolyl groups, methanol and two oxygen atoms of nitrate. In **3** we therefore observe a structure in which the coordinated water ligand of the active site of Co^{II}-CA is substituted by methanol and hydrogencarbonate is replaced by the isoelectronic nitrate.

Experimental Section

General: The preparation of the ligand **2** was carried out in Schlenk tubes under dry nitrogen with use of anhydrous solvents purified by standard procedures. The metal complexes were prepared with use of wet solvents. Crystals suitable for X-ray structure analysis were prepared by slow diffusion of diethyl ether into solutions of the complexes in wet methanol. All chemicals were used as purchased. ^{1}H and ^{31}P NMR spectra were recorded with a Bruker DRX 200 spectrometer. The ^{1}H and ^{13}C{^{1}H} NMR spectra were calibrated against the residual proton signals and the carbon signals of the solvents as internal references ([D_1]chloroform: δ_H = 7.30 ppm and δ_C = 77.0 ppm; [D_4]methanol: δ_H = 5.84 ppm and δ_C = 49.1 ppm), while the ^{31}P{^{1}H} NMR spectra were referenced to external 85% H_3PO_4. The EI mass spectra were recorded with a double focussing mass spectrometer, model 311 A Varian MAT, ionisation energy 70 eV. The FAB mass spectra were recorded with a Finnigan mass spectrometer, model MAT 8200, in an NBA matrix. Infrared spectra were recorded with a Bruker IFS 66 FT-IR spectrometer.

Synthesis of *N*-(Diethoxymethyl)-2-isopropylimidazole (1): 2-Isopropylimidazole (22 g, 0.2 mol), triethyl orthoformate (120 g, 0.8 mol), and *p*-toluenesulfonic acid (1 g) were heated at 130 °C for 24 h. Ethanol and excess orthoformate were removed in vacuo, solid Na_2CO_3 (1 g) was added, and the residue was fractionally distilled to yield a colourless oil (26 g, 62%). b.p. 65 °C ($2\cdot10^{-2}$ mbar). ^{1}H NMR ($CDCl_3$, 200 MHz, ppm): δ = 1.13 (t, *J* = 6.8 Hz, 6 H, CH_2CH_3), 1.24 [d, *J* = 6.8 Hz, 6 H, $CH(CH_3)_2$], 3.03 [sept, *J* = 6.8 Hz, 1 H, $CH(CH_3)_2$], 3.3−3.6 (m, 4 H, CH_2CH_3), 5.94 [s, 1 H, $CH(OEt)_2$], 6.83 (d, *J* = 1.3 Hz, 1 H, 4-*H* im), 6.98 (d, *J* = 1.3 Hz, 1 H, 5-*H* im). ^{13}C NMR ($CDCl_3$, 500 MHz, ppm): δ = 15.2 (CH_3CH_2), 22.4 [$(CH_3)_2CH$], 27.0 [$(CH_3)_2CH$], 62.0 (CH_3CH_2), 101.2 [$CH(OEt)_2$], 116.3 (C5 im), 127.2 (C4 im), 153.1 (C2 im). EI MS (70 eV, 30 °C): *m*/*z* (%) = 212 (3) $[M]^+$, 167 (11) $[M - OEt]^+$, 103 (99) $[HC(OEt)_2]^+$.

Synthesis of Tris[2-isopropylimidazol-4(5)-yl]phosphane (4-TIP$^{i\mathrm{Pr}}$) (2): *n*-Butyllithium in hexane (1.6 M, 33 mL, 53 mmol) was added at −78 °C to a solution of **1** (10.6 g, 50.0 mmol) in diethyl ether (300 mL). The solution was stirred at −78 °C for 30 min and additionally at room temperature for 30 min. After the mixture had been cooled to −78 °C, PCl_3 (1.49 mL, 16.7 mmol) in diethyl ether (10 mL) was added. The white suspension was stirred at room temperature overnight, concd. aqueous ammonia (75 mL) was added, and the organic layer was separated, washed with water, and dried with $MgSO_4$. After removal of the solvent, the oily residue was redissolved in acetone/water (10:1, 100 mL) and heated to reflux for 12 h. The resulting white precipitate was collected and recrystallized from methanol/acetone. Yield: 2.1 g (35%). ^{1}H NMR (200 MHz, [D_4]methanol, ppm): δ = 1.32 [d, *J* = 7 Hz, 6 H, $CH(CH_3)_2$], 3.09 [sept, 1 H, *J* = 7 Hz, $CH(CH_3)_2$], 7.00 (s, 1 H, H_{im}). ^{31}P{^{1}H} NMR (200 MHz, [D_4]methanol, ppm): δ = −80. EI MS (70 eV, 250 °C): *m*/*z* (%) = 358 (30) $[M]^+$, 249 (38) $[M - im^iPr]^+$. $C_{18}H_{27}N_6P_3\cdot H_2O$ (374.42): calcd. C 57.4, H 7.7, N 22.3; found C 58.5, H 7.4, N 22.4.

Synthesis of [(4-TIP$^{i\mathrm{Pr}}$)Co(NO_3)(MeOH)](NO_3) (3): A methanolic solution of **2** (180 mg, 50.0 μmol) and $Co(NO_3)_2\cdot6H_2O$ (145 mg, 50.0 μmol) was stirred for 2 h, diethyl ether was added, and the violet precipitate was washed with additional diethyl ether and dried in vacuo. Yield: 0.23 g (85%). ^{31}P{^{1}H} NMR (200 MHz, [D_4]methanol, ppm): δ = 27 ($h_{1/2}$ = 49 Hz). FAB^+ MS (NBA matrix): *m*/*z* (%) = 479 (100) $[(4\text{-}TIP^{i\mathrm{Pr}})Co(NO_3)]^+$, 416 (46) $[(4\text{-}TIP^{i\mathrm{Pr}})Co - H]^+$. $C_{19}H_{30}CoN_8O_7P_3\cdot H_2O$ (591.43): calcd. C 38.6, H 5.6, N 18.9; found C 38.3, H 5.5, N 18.3.

Synthesis of [(4-TIP$^{i\mathrm{Pr}}$)Ni(NO_3)](NO_3) (4): A methanolic solution of **2** (180 mg, 50.0 μmol) and $Ni(NO_3)_2\cdot6H_2O$ (145 mg, 50.0 μmol)

was stirred for 2 h, diethyl ether was added, and the green precipitate was washed with additional diethyl ether and dried in vacuo. Yield: 0.22 g (65%). $^{31}P\{^1H\}$ NMR (200 MHz, [D$_4$]methanol, ppm): δ = −40 (HWB = 138 Hz). FAB$^+$ MS (NBA-matrix): *m*/*z* (%) = 478 (100) [(4-TIP^{iPr})Ni(NO$_3$)]$^+$. $C_{19}H_{30}N_8NiO_7P_3$·3MeOH (669.30): calcd. C 39.5, H 6.5, N 16.7; found C 41.2, H 6.1, N 16.5.

[(4-TIP^{iPr})CoCl]Cl (5): A methanolic solution of **2** (180 mg, 50.0 μmol) and $CoCl_2$ (65 mg, 50.0 μmol) was stirred for 2 h, diethyl ether was added, and the violet precipitate was washed with additional diethyl ether and dried in vacuo. Yield: 0.18 g (65%). $^{31}P\{^1H\}$ NMR (200 MHz, [D$_4$]methanol, ppm): δ = −54 ($h_{1/2}$ = 91 Hz). FAB$^+$ MS (NBA matrix): *m*/*z* (%) = 479 (100) [(4-TIP^{iPr})CoCl]$^+$, 416 (8) [(4-TIP^{iPr})Co − H]$^+$. $C_{18}H_{27}Cl_2CoN_6P_3$·MeOH·H$_2$O (538.32): calcd. C 45.3, H 6.5, N 15.1; found C 45.4, H 6.2, N 14.6.

[(4-TIP^{iPr})ZnCl]Cl (6): A methanolic solution of **2** (180 mg, 50.0 μmol) and $ZnCl_2$ (68 mg, 50.0 μmol) was stirred for 2 h, diethyl ether was added, and the colourless precipitate was washed with additional diethyl ether and dried in vacuo. Yield: 0.10 g (40%). ^1H NMR (200 MHz, [D$_4$]methanol, ppm): δ = 1.39 [d, *J* = 7 Hz, 6 H, CH(C*H*$_3$)$_2$], 3.62 [sept, *J* = 7 Hz, 1 H, C*H*(CH$_3$)$_2$], 7.55 (d, J_{PH} = 2 Hz, 1 H, H$_{im}$). $^{13}C\{^1H\}$ NMR (500 MHz, [D$_4$]methanol, ppm): δ = 21.7 [CH(*C*H$_3$)$_2$], 29.3 [*C*H(CH$_3$)$_2$], 104.3, 125.6 (d, *J* = 56 Hz), 133.3, 159.9 (*C*2$_{im}$). $^{31}P\{^1H\}$ NMR (200 MHz, [D$_4$]methanol, ppm): δ = −106 ($h_{1/2}$ = 3 Hz). FAB$^+$ MS (NBA matrix): *m*/*z* (%) = 457 (100) [(4-TIP^{iPr})ZnCl]$^+$. $C_{18}H_{27}Cl_2ZnN_6P$·MeOH (526.76): calcd. C 43.5, H 5.9, N 16.0; found C 43.1, H 5.7, N 16.4.

X-ray Crystallographic Study: Crystal structure determinations of compounds **3**·2Et$_2$O, **4**·Et$_2$O·MeOH, **5**·MeOH·2.5H$_2$O, and **6**·MeOH·2.5H$_2$O: Crystals suitable for X-ray study were selected by use of a polarisation microscope and investigated with area detector diffractometers by use of graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å). Unit cell parameters were determined by least-squares refinements on the positions of 6449, 3557, 8000, and 8000 reflections in the range 4° < θ < 25.1°, 4° < θ < 25.5°, 2° < θ < 22.9°, and 2° < θ < 25.8°, respectively. For **3**·2Et$_2$O, $P\bar{1}$ was confirmed to be the correct one of the two triclinic space groups in the course of refinement. Space group type no. 14 was uniquely determined in the case of **4**·Et$_2$O·MeOH. For the isotypical compounds **5**·MeOH·2.5H$_2$O and **6**·MeOH·2.5H$_2$O, systematic extinctions were consistent with space group types *I*2, *Im*, and *I*2/*m*. In accordance with E-statistics, significantly better results were

observed for disordered models in the centrosymmetric type *I*2/*m*. All data sets were corrected for Lorentz and polarization effects. The structures were solved by direct methods[15] and subsequent ΔF-syntheses. Approximate positions of the hydrogen atoms of all the complex cations were found in different stages of the refinements by full-matrix, least-squares calculations on F^2.[16] The hydrogen atom positions of the uncoordinated solvent molecules needed to be calculated with account being taken of plausible hydrogen bonding. In all cases refinements suffered from the high mobility of the incorporated solvent molecules, and appropriate distance and displacement parameter restraints and constraints had to be applied in order to achieve convergence. Anisotropic displacement parameters were refined for all atoms heavier than hydrogen, with the exception of the carbon and oxygen atoms of the highly mobile solvent molecules of **5**·MeOH·2.5H_2O and **6**·MeOH·2.5H_2O. For the OH group of the methanol molecule of **3**·2Et_2O a weak O−H bond length restraint was applied and the isotropic displacement parameter of the H atom were refined. With idealised bond lengths and angles assumed for the CH_3, CH_2, CH, NH groups of all the compounds, as well as for the methanol and water molecules of **4**·Et_2O·MeOH, **5**·MeOH·2.5H_2O, and **6**·MeOH·2.5H_2O, the riding model was applied for the H atoms. In addition, the H atoms of the CH_3 groups of **3**·2Et_2O and **4**·Et_2O·MeOH were allowed to move collectively around the neighbouring C−C axis. In the case of **4**·Et_2O·MeOH the H atoms of the OH groups of the methanol molecules were also given allowance for rotation around the neighbouring O−C axis. Isotropic displacement parameters of H atoms were kept equal to 120% of the equivalent isotropic displacement parameters of the parent O, N, and C atoms for the NH, CH, and CH_2 groups and equal to 150% for the CH_3 groups, the water molecules and the OH group of the methanol molecule in **4**·Et_2O·2MeOH. Scattering factors, dispersion corrections and absorption coefficients were taken from International Tables for Crystallography (1992, vol. C, Tables 6.114, 4.268, and 4.2.4.2). Details are listed in Table 5. CCDC-208099 to -208102 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of New Pd^{II} Complexes Containing a Thioether-Pyrazole Hemilabile Ligand − Structural Analysis by ^1H, ^{13}C NMR Spectroscopy and Crystal Structure of $[PdCl(bdtp)]BF_4$ [bdtp = 1,5-Bis(3,5-dimethyl-1-pyrazolyl)-3-thiapentane]

Jordi García-Antón,[a] Josefina Pons,*[a] Xavier Solans,[b] Mercè Font-Bardia,[b] and Josep Ros*[a]

Keywords: Palladium / N,S ligands / Hemilabile ligands

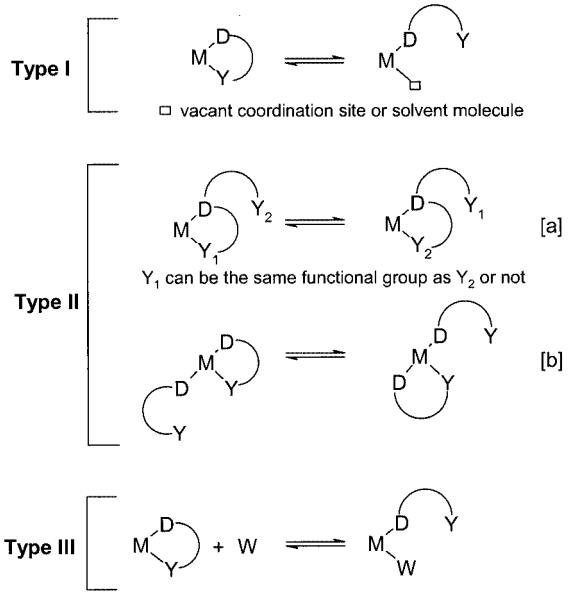
Treatment of the ligand 1,5-bis(3,5-dimethyl-1-pyrazolyl)-3-thiapentane (bdtp) with $[PdCl_2(CH_3CN)_2]$ led to a $[PdCl_2(bdtp)]$ complex. Subsequent treatment of this complex with $AgBF_4$ gave $[PdCl(bdtp)](BF_4)$. These Pd^{II} complexes were characterised by elemental analysis, conductivity measurements, IR spectroscopy, and ^1H and ^{13}C NMR spectroscopy. Complex $[PdCl_2(bdtp)]$ was again obtained when the complex $[PdCl(bdtp)](BF_4)$ was heated under reflux in a solution of NEt_4Cl in CH_2Cl_2/MeOH (1:1). Ligand bdtp in complexes **1** and **2** exhibited a hemilabile character. The X-ray structure of the complex $[PdCl(bdtp)](BF_4)$ was determined. The metal atom is tricoordinated by the two azine nitrogen atoms and one thioether sulfur atom of the thioether-pyrazole ligand, its coordination (distorted square planar) being completed with one chloride ion.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The chemistry of hemilabile ligands in coordination and organometallic chemistry has been widely studied in recent years due to their potential application in catalysis. In particular, bidentate ligands containing two donor centres of different strengths with respect to substitution (labile Y and inert D) have been reviewed in recent reports and articles.[1] According to the review by P. Braunstein and F. Naud[1a] there are three types of hemilability. In type I hemilability, the labile donor group coordinates and decoordinates from the metal centre spontaneously. In type II, there is intramolecular competition between donor groups of the same ligand (a) or between donor groups of two identical ligands (b). Finally, in type III, the hemilabile character is due to the presence of an external reagent (Scheme 1 shows these types of hemilability for mononuclear complexes).

In recent years, we have studied and reported on the properties of hemilabile ligands based on the pyrazolyl group and on some other groups containing N,[2] P[3] or O[4] atoms. This paper continues the study of the potential hemilability of ligands containing pyrazolyl and thioether groups.[5]



Scheme 1

The bonding properties of this family of ligands are also well documented,[6] especially the synthesis and structural characterisation of complexes of Co^{II},[7] Zn^{II},[8] Cd^{II},[8] Cu^{I} [7,9] and Ag^{I} [7] with 1,5-bis(3,5-dimethylpyrazol-1-yl)-3-

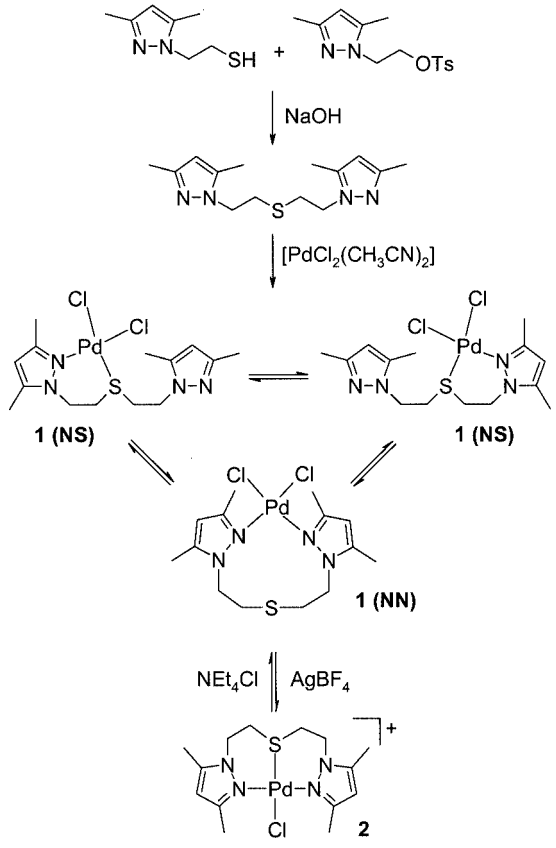
thiapentane (bdtp). The ligand acts in a tridentate manner (NSN) in all these complexes except [$ZnCl_2$(bdtp)], in which it behaves in a bidentate fashion (NN).

In this paper, we report on the study of the coordination of the ligand bdtp[10] with Pd^{II}, and the isolation of the complex [$PdCl_2$(bdtp)] (**1**). Treatment of this complex with $AgBF_4$ gives [PdCl(bdtp)](BF_4) (**2**; Scheme 2). NMR spectroscopic studies and the X-ray crystal structure of **2** are also presented.



Scheme 2

Results and Discussion

Although 1,5-bis(3,5-dimethylpyrazol-1-yl)-3-thiapentane (bdtp) has previously been reported in the literature,[10] in this paper we describe an alternative synthetic route. Treatment of 1-(2-mercaptoethyl)-3,5-dimethylpyrazole and 1-[2-(*p*-tolylsulfonyloxy)ethyl]-3,5-dimethylpyrazole in the presence of sodium hydroxide in water gave the desired product (Scheme 2). The ligand bdtp was characterised by elemental analysis, mass spectrometry, IR spectroscopy, and ^1H and ^{13}C NMR spectroscopy.

[$PdCl_2$(bdtp)] (**1**) was obtained by treatment of the ligand with [$PdCl_2(CH_3CN)_2$] in a 1:1 M/L ratio. Treatment of **1** with one equivalent of $AgBF_4$ gave a compound of formula [PdCl(bdtp)](BF_4) (**2**). Both products are yellow and gave satisfactory C, H, N and S elemental analyses. When complex **2** was heated under reflux in a solution of Et_4NCl in CH_2Cl_2/MeOH (1:1) for 24 hours, complex **1** was again obtained.

Conductivity data in acetonitrile are in agreement with a non-electrolyte nature for compound **1** (37 Ω^{-1} cm^2mol^{-1}) and 1:1 electrolyte for compound **2** (123 Ω^{-1} cm^2mol^{-1}). The reported values for 10^{-3} M solutions of non-electrolyte compounds are lower than 120 $\Omega^{-1}cm^2mol^{-1}$ and between 120−160 Ω^{-1} cm^2mol^{-1} for 1:1 electrolyte compounds in acetonitrile.[11]

According to IR data for compound **1**, the Pd atom is coordinated to nitrogen atoms [ν(Pd−N) 456 cm^{-1}], two chlorine atoms in a *cis* arrangement [two bands are observed, ν(Pd−Cl) 367 and 336 cm^{-1}] and to sulfur atoms [ν(Pd−S) 280 cm^{-1}]. In compound **2** only one band for ν(Pd−Cl) (334 cm^{-1}) was observed as well as ν(Pd−N) (450 cm^{-1}) and ν(Pd−S) (256 cm^{-1}) bands.[12]

NMR Experiments

^1H and ^{13}C NMR spectra of compounds **1** and **2** were recorded in $CDCl_3$ and CD_2Cl_2, respectively, and show the signals of the coordinated ligands. NMR spectroscopic data are reported in the Exp. Sect.

The ^1H NMR spectrum of **1** in solution at 298 K shows sharp resonances for the CH and CH_3 groups of the pyrazolyl cycles, but poorly defined broad bands for the N−CH_2−CH_2−S chain. This suggests a fluxional process occurring in solution, which was studied carrying out a variable temperature ^1H NMR study in $CDCl_3$ (Figure 1). Lowering of the temperature induces a progressive broadening and splitting of the signal corresponding to the CH group of the pyrazolyl rings until 233 K, where three well-defined signals are observed at δ = 5.90, 5.82 and 5.77 ppm. The two signals at lower δ integrate for one H atom each, while the signal at δ = 5.90 ppm integrates for two H atoms. This suggests that at 298 K there is a fluxional process in which the thioether-pyrazole ligand alternates between the *N*,*N* and *N*,*S* bidentate coordinations (in the ratio of approximately 1:1). At 233 K, where both species can be observed, the *N*,*N* coordination shows only one signal for the CH group of the pyrazolyl rings,[5a] whereas in the *N*,*S* coordination mode the pyrazolyl groups are not equivalent

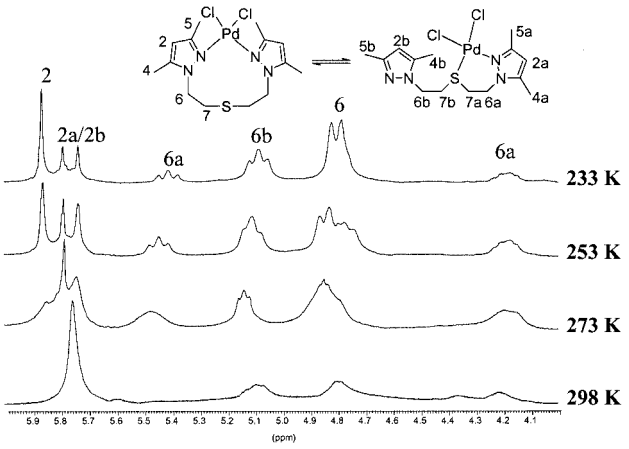


Figure 1. Numbering of complex [$PdCl_2$(bdtp)] and 400 MHz ^1H NMR variable temperature experiments for 2-H and 6-H

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(coordinated and free pyrazolyl groups) and there is one signal for each.

Ill defined broad bands corresponding to the methylenic groups of the $N-CH_2-CH_2-S$ chain at 298 K become assignable signals at 233 K. Thus, if we focus on 6-H (7-H is superimposed with other signals) at 233 K, four groups of signals can be attributed to the methylene functionalities directly linked to the pyrazolyl group in the NN and NS isomers. One of them (at $\delta = 4.84$ ppm) can be attributed to the CH_2 of the NN isomer (6-H, Figure 1), as it integrates for four H atoms. The signal at $\delta = 5.12$ ppm can be assigned to the CH_2 of the open arm of the NS isomer (6b-H). It integrates for two H atoms and resembles a triplet. Finally, signals at $\delta = 4.21$ and 5.45 ppm can be assigned to the CH_2 group in the chelating arm of the NS isomer (6a-H), as they integrate for one H atom each. The rigid conformation of this arm in this isomer leads to the two hydrogens of this CH_2 group becoming diastereotopic, and therefore they have different chemical displacements. Although they are not completely defined, these signals resemble those observed for complexes found in the literature with similar $Pd-N-N-C-C-S$ rings.[5]

The ^{13}C NMR spectrum, at room temperature, of complex **1** also shows broad bands. This is consistent with the fluxional process explained for the ^1H NMR spectra.

From the structure of complex **2** it can be seen that the two protons of each CH_2 moiety in the $S-CH_2-CH_2-N$ chains are diastereotopic, thus leading to four groups of signals which can be associated to a single hydrogen atom in each chain. This happens because of the rigid conformation of the ligand when complexed. Thus, each group of signals can be assigned as doublets of doublets of doublets (Figure 2). The HMQC spectrum allowed us to assign the two doublets of doublets of doublets of lower δ to 7-H and the ones at higher δ to 6-H.

Study of the $S-CH_2-CH_2-N$ fragment (in **2**) as an AA′XX′ system gave a set of coupling constants (Table 1). These constants were consistent with the simulated spectra obtained with the aid of the gNMR program.[13]

Table 1. ^1H NMR results: chemical shifts (ppm, CD_2Cl_2) and $^1H,^1H$ coupling constants (Hz) for **2**

δ H (6*S*)	4.92	^2J(6*R*,6*S*)	−15.9
δ H (6*R*)	5.20	^2J(7*R*,7*S*)	−14.8
δ H (7*R*)	2.97	^3J(7*R*,6*S*)	2.5
δ H (7*S*)	3.78	^3J(7*S*,6*S*)	3.2
		^3J(7*R*,6*R*)	12.1
		^3J(7*S*,6*R*)	1.6

In the NOESY spectrum it can be seen that the methyl group at $\delta = 2.40$ ppm shows an NOE interaction with the doublet of doublets of doublets at $\delta = 4.92$ ppm, but not with the one at $\delta = 5.20$ ppm. From the X-ray structure of **2** (Figure 3), it can be observed that the nearest proton to the $CH_3(5)$ moiety is 6S-H and therefore it should be the one with the NOE interaction. This information leads us to assign 6*S*-H to the doublet of doublets of doublets at $\delta = 4.92$ ppm and 6R-H to the signal at $\delta = 5.20$ ppm.

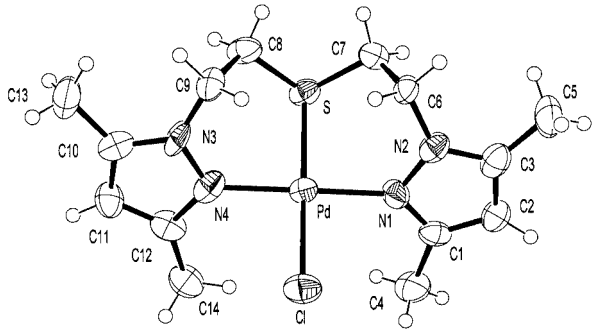

Figure 3. ORTEP drawing of $[PdCl(bdtp)]^+$ cation (293 K determination); 50% probability amplitude displacement ellipsoids are shown

The coupling constants enabled us to differentiate 7*R*-H and 7*S*-H. These coupling constants agree with the conformation of the $S-CH_2-CH_2-N$ chain as seen in Figure 2, which has been corroborated by an X-ray crystal study. Ge-

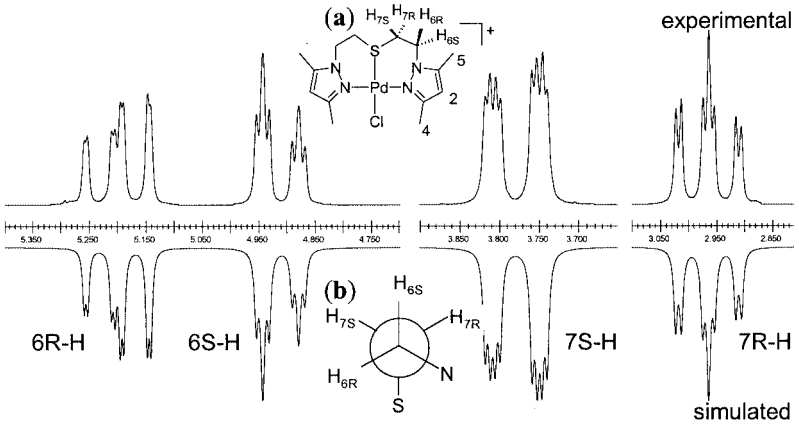

Figure 2. The 250 MHz ^1H NMR and the simulated gNMR spectrum for the NCH_2CH_2S fragment of $[PdCl(bdtp)](BF_4)$ including (a) the numbering and (b) the dihedral angles for the NCH_2CH_2S fragment

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

minal ^2J and ca. 180° ^3J coupling constants have significantly higher values than ca. 30° and ca. 60° ^3J coupling constants .[14] Thus, 7*R*-H should correspond to the doublet of doublets of doublets at δ = 2.97 ppm and 7*S*-H to the one at δ = 3.78 ppm.

Crystal Structure of [PdCl(bdtp)](BF$_4$) (2)

The molecular structure of compound **2** consists of discrete $[PdCl(bdtp)]^+$ cations and BF_4^- anions (Figure 3), packed according to normal van der Waals forces.

The cation complex is mononuclear. The Pd^{II} ion is coordinated to the bdtp ligand by its three donors atoms via two pyrazole nitrogens and one thioether sulfur, along with one chlorine atom. The PdN_2SCl *core* (S thioether) is found in three complexes in the literature.[15] Some selected bond lengths and bond angles for this complex are listed in Table 2.

Table 2. Selected bond lengths (Å) and bond angles (°) for **2** with estimated standard deviations (e.s.d.s.) in parentheses

Pd−N1	2.004(7)
Pd−N4	2.040(7)
Pd−S	2.308(2)
Pd−Cl	2.291(2)
N1−Pd−S	90.5(2)
N4−Pd−S	88.5(2)
N1−Pd−N4	176.6(3)
N1−Pd−Cl	89.8(2)
N4−Pd−Cl	91.5(2)
S−Pd−Cl	175.18(8)

The Pd−N bond lengths [2.004(7) Å and 2.040(7) Å], the Pd−S bond length [2.308(2) Å] and the Pd−Cl bond length [2.291(2) Å] can be regarded as normal compared with the distances found in the literature.[16] The coordination geometry is square planar with a tetrahedral distortion, as can be deduced from the bond angles and the mean separation [0.0765 Å] of the atoms coordinated to the Pd atom in relation to the mean plane that contains these four atoms and the Pd atom. The dihedral angle between the planes N1−Pd−Cl and N4−Pd−S is 5.85°. Ligand bdtp acts as a tridentate chelate and forms two Pd−*N*−N−C−C−S six-membered rings with a boat conformation, sharing an edge (Pd−S). The boat distortions in the six-membered rings are $\Delta C_S[(S-C7)] = 12.4(6)°$ and $\Delta C_S[(N1-N2)] = 14.8(10)°$ for Pd−N1−N2−C6−C7−S and $\Delta C_S[(S-C8)] = 4.0(6)°$ and $\Delta C_S[(N3-N4)] = 5.2(9)°$ for Pd−N4−N3−C9−C8−S, respectively [see Equation (1)].

$$\Delta C_S = \sqrt{\frac{\sum_{i=1}^{m}(\phi_i + \phi_i')^2}{m}} \quad (1)$$

m = equivalent torsion angles

$\Phi_i+\Phi_i'$ = torsion angles related to the considered plane [17]

The nitrogen-thioether bite angles of the ligand are 90.5(2)° and 91.5(2)°, respectively, which are similar to the corresponding bite in the $[Co(NO_3)_2(bdtp)]$ and [CuBr(bdtp)] complexes.[7]

Conclusions

The thioether-pyrazole ligand bdtp can coordinate Pd^{II} centres in different ways. In this paper we describe all the possible polydentate coordinations in mononuclear complexes: two bidentate coordinations (NN and NS) and a tridentate coordination (NSN). Furthermore, we have demonstrated the hemilabile properties of this ligand when coordinated to Pd^{II}. In complex **1** the ligand alternates the NN and NS coordination types at room temperature, which would be type II hemilability.[1a]

Complex **2** (where ligand bdtp uses NSN coordination) is obtained from **1** by treatment with $AgBF_4$. When **2** is heated under reflux in a solution of Et_4NCl in CH_2Cl_2/MeOH (1:1), **1** is obtained once again. This could be considered as type III hemilability.

Experimental Section

Generals Remarks: Preparations were performed using usual vacuum line and Schlenk techniques. All reagents were commercial grade materials and were used without further purification. Acetonitrile and dichloromethane were dried and distilled by standard methods and previously deoxygenated in the vacuum line.

Samples of $[PdCl_2(CH_3CN)_2]$ were prepared as described in the literature.[18]

Analyses (C,N,H,S) were performed in our analytical laboratory on a Carlo Erba CHNS EA-1108 instrument. Conductivity measurements were performed at room temperature in ca. 10^{-3} M acetonitrile solutions employing a Crison, micro CM 2200 conductometer. Infrared spectra were recorded from KBr pellets or polyethylene mulls in the range 4000−100 cm^{-1} under a nitrogen atmosphere. The ^1H NMR, $^{13}C\{^1H\}$ NMR and HMQC spectra were obtained either on a Bruker 250 MHz or Bruker 400 MHz instrument. Chemical shifts (δ) were determined relative to internal TMS and are given in ppm. A mass spectrum was obtained with an Esquire 3000 ion trap mass spectrometer from Bruker Daltonics.

Synthesis of the Ligand 1,5-bis(3,5-dimethyl-1-pyrazolyl)-3-thiapentane (bdtp): Although the synthesis of the ligand bdtp has been previously reported in the literature,[10] here, we describe an alternative synthetic route. A solution of 1-(2-mercaptoethyl)-3,5-dimethylpyrazole (2.00 g, 12.8 mmol), 1-[2-(*p*-tolylsulfonyloxy)ethyl]-3,5-dimethylpyrazole (3.77 g, 12.8 mmol) and of sodium hydroxide (0.53 g, 12.9 mmol; 97%) of water (25 mL) was refluxed for five hours. After cooling to room temperature, the reaction mixture was extracted three times with $CHCl_3$ (15 mL). The collected organic layers were dried with anhydrous sodium sulfate and removed under vacuum to give a white solid. Yield: 2.17 g (61%). M.p. 80.3−80.9 °C. $C_{14}H_{22}N_4S$ (278.42): calcd. C 60.39, H 7.96, N 20.12, S 11.52; found C 60.20, H 7.73, N 20.41, S 11.23. IR (KBr, cm^{-1}): $\nu(C\text{-}H)_{al}$ = 2924, ν(C=C), ν(C=N) 1550, $\delta(CH_3)_{as}$ = 1481−1436, $\delta(CH_3)_s$ 1302, $\delta(C-H)_{oop}$ = 800−775. ^1H NMR (250 MHz, $CDCl_3$): δ = 2.22 (s, 6 H, Me), 2.27 (s, 6 H, Me), 2.84

(t, ^3J = 6.9 Hz, 4 H, pz-CH_2−CH_2−S), 4.10 (t, ^3J = 6.9 Hz, 4 H, pz-CH_2−CH_2−S), 5.79 (s, 2 H, pz-CH). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 63 MHz): δ = 11.4 (Me), 13.7 (Me), 32.5 (pz-CH_2−CH_2−S), 48.7 (pz-CH_2−CH_2−S), 105.3 (pz-CH), 139.5 (pz-C), 148.1 (pz-C) ppm. MS (ESI): *m*/*z* (%) = 279 (72) [M + H^+], 301 (100) [M + Na^+].

Synthesis of [$PdCl_2$(bdtp)] (1): A solution of [$PdCl_2(CH_3CN)_2$] (0.097 g, 0.374 mmol) in dichloromethane (15 mL) was added to a solution of bdtp (0.105 g, 0.378 mmol) in dichloromethane (10 mL). After the mixture had been stirred for 12 h, most of the solvent was removed under vacuum. Diethyl ether was then added to induce precipitation. The resulting precipitate was then filtered and washed with diethyl ether, yielding the desired compound. Yield: 0.157 g (92%). Conductivity ($\Omega^{-1}cm^2mol^{-1}$, $9.98\cdot10^{-4}$ M in acetonitrile): 37. $C_{14}H_{22}Cl_2N_4PdS$ (455.74): calcd. C 36.90, H 4.87, N 12.29, S 7.04; found C 36.58, H 4.92, N 12.11, S 6.93. IR (KBr, cm^{-1}): ν(C−H)$_{al}$ = 2920, ν(C=C), ν(C=N) 1557, δ$(CH_3)_{as}$ = 1467−1420, δ$(CH_3)_s$ = 1313, δ(C−H)$_{oop}$ = 788. IR (polyethylene, cm^{-1}): ν(Pd−N)$_{as}$ = 456, ν(Pd−Cl) = 336, 367, ν(Pd−S) = 280 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$, 233 K): (For simplicity we have used the numeration as in Figure 1; peaks from 2.20 ppm to 2.69 ppm are not integrated because they are superimposed with other signals, although these peaks all together integrate the expected 31 H atoms.) δ (isomer **N,N**) = 2.24, 2.55 [s, Me (4/5)], 2.69 [br., pz-CH_2−CH_2−S (7)], 4.84 [br., 4 H, pz-CH_2−CH_2−S (6)], 5.91 [s, pz-CH (2)]. δ (isomer **N,S**) = 2.25, 2.56 [s, Me (4a/b, 5a/b)], 2.20 [br., pz-CH_2−CH_2−S (7b)], 2.85 [br., 1 H, pz-CH_2−CHH−S (7a)], 3.37 [br., 1 H, pz-CH_2−CHH−S (7a)], 4.21 [br., 1 H, pz-CHH−CH_2−S (6a)], 5.12 [br., 2 H, pz-CH_2−CH_2−S (6b)], 5.45 [br., 1 H, pz-CHH−CH_2−S (6a)], 5.77, 5.83 [s, 1H each, pz-CH (2a/2b)]. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 63 MHz, 298 K): δ = 12.3 (br., Me), 15.3 (br., Me), 29.9 (br., pz-CH_2−CH_2−S), 49.8 (br., pz-CH_2−CH_2−S), 108.2 (br., pz-CH), 143.6 (br., pz-C), 150.7 (br., pz-C).

Synthesis of [PdCl(bdtp)]BF_4 (2): A solution of $AgBF_4$ (0.063 g, 0.324 mmol) in methanol (2 mL) was added dropwise with vigorous stirring to a solution of **1** (0.149 g, 0.327 mmol) in dichloromethane (5 mL) and methanol (5 mL). The reaction was carried out in the dark to prevent reduction of Ag^I to Ag^0. After five minutes, stirring was stopped, and AgCl was filtered off through a pad of Celite. When the volume of the resultant solution had been reduced to roughly 5 mL, the product precipitated as a yellow solid. This solid was filtered and dried under vacuum. Yield: 0.146 g (89%). Conductivity ($\Omega^{-1}cm^2mol^{-1}$, $9.87\cdot10^{-4}$ M in acetonitrile): 123. $C_{14}H_{22}BClF_4N_4PdS$ (507.09): calcd. C 33.16, H 4.37, N 11.05, S 6.32; found C 33.45, H 4.40, N 10.93, S 6.12. IR (KBr, cm^{-1}): ν(C−H)$_{ar}$ = 3014, ν(C−H)$_{al}$ = 2967−2923, ν(C=C), ν(C=N) 1554, δ$(CH_3)_{as}$ = 1468−1423, δ$(CH_3)_s$ = 1319, ν(B−F) = 1049, δ(C−H)$_{oop}$ = 817. IR (polyethylene, cm^{-1}): ν(Pd−N)$_{as}$ = 450, ν(Pd−Cl) = 334, ν(Pd−S) = 256. ^1H NMR (250 MHz, CD_2Cl_2): δ = 2.40 (s, 6 H, Me), 2.70 (s, 6 H, Me), 2.97 (ddd, 2 H, pz-CH_2−CHH), 3.78 (ddd, 1 H, pz-CH_2−CHH), 4.92 (ddd, 1 H, pz-CHH−CH_2), 5.20 (ddd, 1 H, pz-CHH−CH_2), 6.08 (s, 2 H, pz-CH) ppm. $^{13}C\{^1H\}$ NMR (63 MHz, CD_2Cl_2): δ = 12.2 (Me), 15.7 (Me), 39.8 (S−CH_2−CH_2), 51.2 (pz-CH_2−CH_2), 109.3 (pz-CH), 145.1, 154.1 (pz-C).

Synthesis of [$PdCl_2$(bdtp)] (1) from [PdCl(bdtp)](BF_4): A solution of **2** (0.053 g, 0.104 mmol) and NEt_4Cl (0.033 g, 0.199 mmol) in a mixture (1:1) of dichloromethane and methanol (20 mL) was refluxed for 24 hours. After cooling to room temperature, the reaction mixture was extracted three times with 15 mL of $CHCl_3$. The collected organic layers were dried with anhydrous sodium sulfate and removed in vacuo to yield the desired product. Yield: 0.038 g (80%).

X-ray Crystallographic Study: Suitable crystals of compound **2** were obtained by crystallisation from CH_2Cl_2. Data were collected on an Enraf−Nonius CAD4 four-circle diffractometer, using the ω/2θ scan technique. The crystals were collected with graphite-monochromated Mo-K_α radiation. 2977 reflections were measured in the range $2.11° < \theta < 29.98$. 1529 reflections were assumed as observed applying the condition $I > 2\sigma(I)$. Three reflections were measured every two hours as orientation and intensity control and significant intensity decay was not observed. Lorentz-polarisation but no absorption corrections were performed. The structure was solved by direct methods using the SHELXS 97 computer program and refined by the full-matrix least-squares method with a SHELXL 97 computer program.[19] All hydrogen atoms were computed and refined with an overall isotropic temperature factor using a riding model. The final *R* (on *F*) factor and *wR* (on F^2) values, as well as the numbers of parameters refined and other details concerning the refinement of the crystal structure are presented in Table 3.

Binuclear Hydridoplatinum(II): One-Pot Synthesis, INS Spectra and X-ray Crystal Structure of $[Pt_2(dcype)_2(H)_3][BPh_4]$ {dcype = 1,2-Bis(dicyclohexylphosphanyl)ethane}

Anna Laura Bandini,*[a] Guido Banditelli,[a] Mario Manassero,*[b] Alberto Albinati,*[b] Daniele Colognesi,[c] and Juergen Eckert[d,e]

Keywords: Hydride ligands / INS spectroscopy / Phosphane ligands / Platinum / X-ray diffraction

The binuclear platinum(II) hydride $[Pt_2(dcype)_2(H)_3][Cl]$ (**1b**) has been isolated in high yields by treatment of $Pt(dcype)Cl_2$ with $NaBH_4$ (molar ratio 1:2) in ethanol solution at room temperature. This one-pot synthesis is not straightforward when starting from diphenylphosphanylalkane complexes. The compounds $[Pt_2(dppp)_2(H)_3][OH]$ (**3b**) and $[Pt_2(dppb)_2(H)_3][OH]$ (**4**) were isolated by starting from the mononuclear hydrides {*cis*-$[Pt(P\text{-}P)(H)_2]$} while mixtures of both binuclear {$[Pt_2(dppe)_2(H)_3]^+$, **5**} and trinuclear {$[Pt_3(dppe)_3(H)_3]^+$, **6**} trihydrides were obtained with the dppe ligand. Various salts of the cation **1**, $[Pt_2(dcype)_2(H)_3][X]$ (X = BF_4, **1a**; OH, **1c**; BPh_4, **1d**), were isolated either from $[Pt(dcype)(\mu\text{-}OH)]_2[BF_4]_2$ (**2**) by a general procedure (**1a**), or by decomposition of the complex *cis*-$[Pt(dcype)(H)_2]$ in solution (**1c**), as well as by metathesis reactions (**1a**, **1c**, and **1d**). Compounds **1a**, **1b**, and **1d** react with CO under mild conditions to afford the corresponding Pt^I binuclear hydrides $[Pt_2(dcype)_2(\mu\text{-}CO)(\mu\text{-}H)][X]$ (X = Cl, **7a**; BF_4, **7b**; BPh_4, **7c**). The binuclear core of cation **1** is broken by KCN in methanol solution, yielding the mononuclear complex *cis*-$[Pt(dcype)(CN)(H)]$ (**8**). The complexes **1a–d**, **2**, **7a–c**, and **8** have been characterised by FAB MS, IR, and NMR (^1H, ^{31}P, and ^{195}Pt) spectroscopic techniques; the **1** and **7** cations show fluxional behaviour on the NMR timescale. The structure of compound **1d** was determined, at 200 K, by single-crystal X-ray diffraction. All the hydrido ligands were located. The Pt–Pt separation is 2.696(1) Å and the coordination geometry around each platinum centre can be regarded as distorted square planar. Incoherent Inelastic Neutron Scattering (INS) spectra were obtained for **1a** and $[Pt_2(dppe)_2(H)_3][BF_4]$ (**5a**); the spectra reflect the different geometries of the two "$P_4Pt_2(H)_3$" cores as found by single-crystal structure determinations.

Introduction

Since the first examples – $[Pt_2(PR_3)_2(H)_2(SiR_3)_2]$, reported by M. Green and co-workers[1] – binuclear platinum hydrides have been a topic of continuous interest. Besides complexes with monodentate tertiary phosphanes[2] or exobidentate (bridging) diphosphane,[3] a number of species with chelating diphosphanes (P-P) have also been described.[4–6] These complexes include 30-electron species, both neutral $[Pt(P\text{-}P)(H)]_2$[5] and cationic $[Pt_2(P\text{-}P)_2(H)_3]^+$,[4] as well as 28-electron $[Pt(P\text{-}P)(H)]_2^{2+}$ species.[6] The observed differences in their formation, spectroscopic properties and molecular structures seem to be largely dependent on the ancillary diphosphanyl ligand. Moreover, when chelating diphosphanes have been used, only a few examples of mononuclear *cis*-dihydrides {*cis*-$[Pt(P\text{-}P)(H)_2]$} have been described.[4d,5a,5c,7]

The trihydrido cations $\{[Pt_2(P\text{-}P)_2(H)_3]^+\}$ have been widely investigated. In solution they show fluxional behaviour on the NMR timescale over a wide temperature range, at least down to 183 K. Typically, only one resonance for the hydrides is observed in the ^1H NMR spectrum, coupled to four ^{31}P and two ^{195}Pt magnetically equivalent nuclei. In the solid state, however, two distinct types of structure have been observed, with either a $(H)Pt(\mu\text{-}H)_2Pt$ or a $(H)Pt(\mu\text{-}H)Pt(H)$ core. The former arrangement, with two bridging

and one terminal hydride, implies different environments for the two platinum atoms, as found in the structures of $[Pt_2\{Ph_2P(CH_2)_2PPh_2\}_2(H)_3]^+$ [4c,8] and $[Pt_2\{(Ph_2PC_5H_4)_2Fe\}_2(H)_3]^+$.[4f] On the other hand, the coordination geometries of the two platinum atoms in the structures of $[Pt_2(dtbpp)_2(H)_3]^+$ [4b] and $[Pt_2(butaphos)_2(H)_3]^+$ [4g] are approximately the same, and are consistent with the presence of two terminal and one bridging hydrides.

Different factors could be considered in order to explain the observed differences in the solid state, in particular: (i) the influence of the bite angle of the chelating ligands, and (ii) the steric demand of the substituents on the phosphorus atoms. Moreover, more subtle factors, such as crystal-packing forces, could also be responsible for the existence of different structures involving small energy differences.

In pursuit of our interest in platinum polynuclear hydrides, we report here the synthesis of the complexes $[Pt_2(dcype)_2(H)_3][X]$ (X= BF_4, **1a**; Cl **1b**; OH, **1c**; BPh_4, **1d**) and the X-ray crystal structure of the BPh_4 salt. In addition, the Incoherent Inelastic Neutron Spectra of complexes **1a** and $[Pt_2(dppe)_2(H)_3][BF_4]$ (**5a**) are also reported.

Complex **1b** can be obtained in good yields directly from $[Pt(dcype)Cl_2]$ by a one-pot reaction. This synthetic approach has also been used with less sterically demanding bis-diphenylphosphanylalkanes: satisfactory yields have been obtained in the case of dppp {$[Pt_2(dppp)_2(H)_3]^+$, **3**} and dppb {$[Pt_2(dppb)_2(H)_3]^+$, **4**} ligands, but the quantitative conversion of $Pt(P\text{-}P)Cl_2$ was only obtained when the corresponding mononuclear hydrides {*cis*-$[Pt(P\text{-}P)(H)_2]$} were isolated and then converted into the corresponding binuclear cations. With dppe mixtures, both binuclear {$[Pt_2(dppe)_2(H)_3]^+$, **5**} and trinuclear {$[Pt_3(dppe)_3(H)_3]^+$, **6**} trihydrides were obtained.

The $[Pt_2(dcype)_2(H)_3][X]$ species react with CO under mild conditions to give the binuclear p1atinum(I) hydrides $[Pt(dcype)_2(\mu\text{-}CO)(\mu\text{-}H)]^+$ (X = Cl, **7a**; BF_4, **7b**; BPh_4, **7c**).

The monuclear hydrido complex *cis*-[Pt(dcype)(CN)(H)] (**8**) has been obtained from the reaction between **1b** and KCN in methanol solution.

A preliminary report of this work has already appeared.[9]

Throughout this paper the chelating diphosphanyl ligands (P-P) are indicated as follows: dcype, 1,2-bis(dicyclohexylphosphanyl)ethane; dtbpe, 1,2-bis(di-*tert*-buthylphosphanyl)ethane; dppe, 1,2-bis(diphenylphosphanyl)ethane; dfepe, 1,2-bis[bis(perfluoroethyl)phosphanyl]ethane $(C_2F_5)_2PCH_2CH_2P(C_2F_5)$; dtbpp, 1,3-bis(di-*tert*-butylphosphanyl)propane; dippp, 1,3-bis(diisopropylphosphanyl)propane; dppp, 1,3-bis(diphenylphosphanyl)propane; butaphos, 1-(diphenylphosphinoxy)-2-[*N*-ethyl-*N*-(diphenylphosphanyl)amino]butane; dppb, 1,4-bis(diphenylphosphanyl)butane.

Results and Discussion

Our previously reported platinum binuclear trihydrides $[Pt_2(P\text{-}P)_2(H)_3]^+$ were synthesised from two different intermediates: cationic bis-pyrazole adducts (i) or μ-hydroxo binuclear cations (ii), as summarised in Scheme 1.

In the current case (P-P = dcype), attempts to operate according to path (i) were unsuccessful, owing to difficulties in isolating the pyrazolato precursor. Similarly, pathway (ii) was also unsatisfactory; compound $[Pt_2(dcype)_2(H)_3][BF_4]$ (**1a**) was isolated, but yields were erratic and often modest.[10] Analytical and NMR spectroscopic data suggested the formation of complex reaction mixtures in the first step: the synthesis of the binuclear μ-hydroxo complex $[Pt(dcype)(\mu\text{-}OH)]_2[BF_4]_2$ (**2**). The $^{31}P\{^1H\}$ NMR spectra of the crude products showed, besides the signals of compound **2**, a number of resonances in the 55−75 ppm range, probably due to other platinum species with oxygen donors. The values of the $^1J_{P,Pt}$ coupling constants, 3900−3400 Hz, suggest species with a *trans* P−Pt−O arrangement with anionic (OH or OR) rather than neutral (H_2O or CH_3OH) ligands (e.g. ref.[11b]). The chelating behaviour of dcype is confirmed by the large ^{31}P downfield shift with respect to the free ligand ($\Delta\delta$ = 50−70 ppm).

An analytical sample of the intermediate **2** was isolated from the crude product as a less soluble species in acetone. Its spectroscopic (IR, $^{3l}P\{^1H\}$ NMR, and FAB MS) properties (see Exp. Sect.) are highly reminiscent of those of homologous cations with various bis(diphenylphosphanyl)alkanes.[11]

The cation $[Pt_2(dcype)_2(H)_3]^+$ (**1**) had previously been detected in solution by multinuclear NMR spectra either as the final product of the decomposition of *cis*-$[Pt(dcype)(H)_2]$[7b] or as that of the protonation of the platinum(I) dihydride $[Pt(dcype)(H)]_2$,[5a] this compound also being reversibly obtained from *cis*-$[Pt(dcype)(H)_2]$[5a] (see Scheme 2).

It therefore seemed that cation **1** might be directly obtainable in a one-pot reaction, through the controlled decomposition of *cis*-$[Pt(dcype)(H)_2]$. Indeed, we were able to obtain the complex $[Pt_2(dcype)_2(H)_3][Cl]$ (**1b**) in high yields by treatment of a dichloromethane solution of $[Pt(dcype)Cl_2]$ with an ethanol solution of $NaBH_4$ (Pt/BH_4^- mo1ar ratio 1:2) at room temperature (under dinitrogen atmosphere). At lower reaction temperatures the yield was decreased and unchanged $[Pt(dcype)Cl_2]$ was recovered. Significant amounts of the mononuclear dihydride *cis*-$[Pt(dcype)(H)_2]$ have occasionally been detected in the crude products of synthesis reactions of compound **1b**; these could be converted into the compound $[Pt_2(dcype)_2(H)_3][OH]$ (**1c**) by treatment with wet methanol.

The corresponding tetrafluoroborate **1a** and the tetraphenylborate $[Pt_2(dcype)_2(H)_3][BPh_4]$ (**1d**) were easily obtained from **1b** through a metathesis reaction with a large excess of the sodium salt of the appropriate anion in methanol solution. Moreover, the more nucleophilic CN^- anion disrupts the binuclear core. Under analogous experimental conditions, complex **1b** and KCN react to give, in high yields, the mononuclear hydride *cis*-[Pt(dcype)(CN)(H)] (**8**), which in turn, in $CDCl_3$ solution, slowly decomposes to afford mixtures of *cis*-$[Pt(dcype)Cl_2]$ and *cis*-[Pt(dcype)(CN)(Cl)] (**9**). This decomposition path gave a clue for

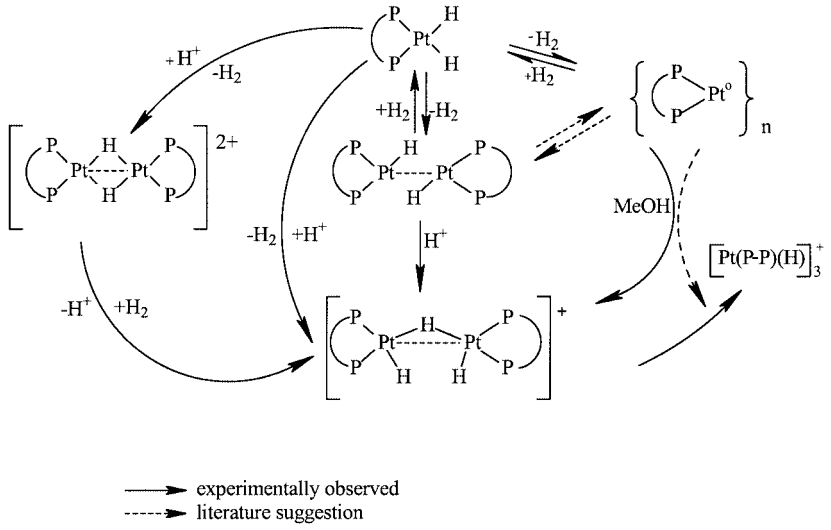
Scheme 1



Scheme 2. For a detailed discussion of the steps summarised in this scheme see references [4−8]

reliable assignment of the NMR parameters of complex **8** (see Exp. Sect.), which indicate a larger *trans* influence from the terminal hydride [$^1J_{P(trans\text{-}H)\text{-}Pt}$ = 1714 Hz] than from the cyanide ligand [$^1J_{P(trans\text{-}CN)-Pt}$ = 2706 Hz].

A significant improvement was obtained on carrying out the synthesis of compound **1b** starting from [Pt(COD)Cl_2], the commonest precursor of Pt(P-P)Cl_2 species. Yields of **1b** close to 65% were obtained under the same experimental conditions by sequential addition of dcype ligand and $NaBH_4$ to a dichloromethane solution of [Pt(COD)Cl_2].

The role of the mononuclear *cis*-[Pt(P-P)$(H)_2$] complexes to give platinum polyhydrides is summarised in Scheme 2.

It is also worth notice that the neutral Pt^I and 28 e^- dihydrido species have been isolated only with aliphatic diphosphanes and that the complex *cis*-[Pt(dcype)$(H)_2$] seems to be the unique complex that acts as an effective precursor of all the known types of binuclear polyhydrides.

Thus, if the *cis*-[Pt(P-P)$(H)_2$] complexes are assumed to function as effective precursors in the formation of the binuclear trihydrides directly from [Pt(P-P)Cl_2], a dimerisation (see Scheme 2) aimed at a one-step synthesis could be envisaged under experimental conditions designed to enhance the lifetime of the mononuclear *cis*-dihydrides and avoid total dihydrogen loss (the most favoured reaction). We tested this approach to obtain complexes bearing bis(diphenylphosphanyl)alkane derivatives (dppe, dppp, and dppb) as ligands.

As far as we know, only two examples of *cis*-[Pt(P-P)$(H)_2$] compounds with (diphenylphosphanyl)alkane ligands (P-P = dppp, dppb) have been isolated and characterised; both are unstable in the absence of a dihydrogen atmosphere.[7c] In the dppe case, the mononuclear hydride was reported to be a source either of Pt^0 species[7a] or of various hydrides.[4d] Carmichael and co-workers inferred from a VT. NMR study (from 233 K to room temperature) that the hydride formation follows the sequence:[4d] *cis*-[Pt(dppe)$(H)_2$], [Pt(dppe)$(H)]_2$, [Pt_2(dppe)$_2(H)_3]^+$, and then [Pt_3-(dppe)$_3(H)_3]^+$.

We carried out a few attempts under different conditions (see Exp. Sect.) starting from the appropriate [Pt(P-P)Cl_2] precursor and obtained the binuclear hydrides [Pt_2(P-P)$_2(H)_3$][Cl] (P-P = dppp, **3a**; P-P = dppe, **5b**). However the one-pot reaction was unattractive, due to the unsatisfactory yields. With the dppe ligand, the major product was always the trinuclear cation [Pt_3(dppe)$_3(H)_3]^+$ (**6**),[4d,12] the product of a formal addition of a (P-P)Pt^0 fragment to the binuclear cation **5**.

However, compounds [Pt_2(P-P)$_2(H)_3$][OH] (P-P = dppp, **3b**; P-P = dppb, **4**) were obtained in nearly quantitative yields, provided that the corresponding mononuclear hy-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

drides were isolated. These were quickly converted into **3b** and **4**, respectively, after dissolution, under dinitrogen, in common organic solvents (e.g. chloroform).

The same conversion also occurs in the solid state: after two months, a not carefully stored sample of *cis*-[Pt(dppp)$(H)_2$] was found to have been fully converted into compound **3b**. Dimerisation reactions in the solid state are not unprecedented, but in the present case, in addition to a facile H_2 loss, the process requires a proton source, reasonably atmospheric moisture. In solution we cannot exclude different processes, as previously suggested for, for example, the formation of the cations $[Pt_2\{R_2P(CH_2)_nPR_2\}_2(H)_3]^+$ [R = *t*Bu, *n* = 2 (dtbpe), 3 (dtbpp)].[4b]

In the case of the dppe ligand, the one-pot reaction seems to be more profitable for synthesis of the trinuclear **6** species than of the binuclear **5**. The yield of compound **6**, calculated from the amounts of [Pt(dppe)Cl_2] consumed, reached 65%, a significant improvement with respect to the values obtained with other precursors {26% from the hydride **5** and from [Pt(dppe)(μ-OH)]$_2^{2+}$, and 30% from [Pt(dppe)$(Hdmpz)_2]^{2+}$},[12b] which in turn require at least two other synthetic steps from [Pt(dppe)Cl_2]. On the other hand, the isolation of the *cis*-[Pt(dppe)$(H)_2$] is ruled out by its well established instability, even though its formation during the one-pot reaction is suggested by the occasional presence in the ^{1}H NMR spectra of a complex multiplet [hydrido region in $(CD_3)_2CO$: δ ≈ −3.6, $^2J_{P-H}$ ≈ 168 and 10 Hz] with satellites (1:4:1; $^1J_{Pt-H}$ ≈ 880 Hz).

All the compounds **1**−**8** reported here have been identified by analytical and spectroscopic data, while the solid-state structure of complex **1d** has been established by single-crystal X-ray diffraction at 200 K.

The spectroscopic data for cation **1** are consistent with those reported for the analogous hydrides and are not significantly affected by the nature of the counter-ions.

The IR spectra show a strong and broad ν_{Pt-H} vibration at 1980 cm^{-1} (in CH_2Cl_2), not observed in the corresponding deuterides and thus attributable to terminal Pt−H bonds.

The ^{1}H, ^{31}P{^{1}H}, and ^{195}Pt NMR spectra confirm fluxional behaviour, not frozen at least down to 183 K. The hydrido resonance appears as a typical quintet with four satellites (intensity ratios: 1:8:18:8:1) indicating the magnetic equivalence of the four phosphorus and two platinum atoms.

Consistently, the ^{195}Pt{^{1}H} NMR spectra show the resonance of the most abundant isotopomer (^{195}Pt-Pt: 44.8%) as a triplet of triplets. In the ^{195}Pt{^{31}P} spectrum the central resonance is split into a quadruplet, giving unequivocal evidence for the number of hydrido ligands.

This determination is obviously a crucial point for the correct assignment of a new compound to the appropriate family of the different binuclear hydrides, namely the 30 e$^-$ species {[Pt(P-P)$(H)]_2$ or [Pt$_2$(P-P)$_2(H)_3]^+$} or the 28 e$^-$ derivatives {[Pt(P-P)$(H)]_2^{2+}$}. As these compounds are often formulated on the basis of spectroscopic data in solution, it is worth comparing their relevant IR and NMR spectroscopic properties (see Table 1).

In the IR spectra, the region of the terminal Pt−H stretching seems to be a diagnostic feature: the 28 e$^-$ species do not in fact show any vibration in this region, while one or two bands are observed in the case of 30 e$^-$ complexes (the Pt^{II} cations and the neutral Pt^I species, respectively).

In the NMR spectra the multiplicities of the main resonances, as well as the satellites' intensities, have no diagnostic value, owing to the fluxionality and identical nuclearity mentioned above. Significant differences between various NMR parameters are observed, however. Provided that the same diphosphanyl ligand is present, the following points can be used in order to distinguish the different binuclear hydrides: (i) greater $^1J_{H-Pt}$ values are associated with 28 e$^-$ species, (ii) shifts towards higher field of the hydrido resonances and smaller $^2J_{P,P}$ values are observed in the case of the 30 e$^-$ cations, and (iii) the neutral Pt^I complexes show the greatest $^2J_{P,Pt}$ values.

These observations allowed, inter alia, the proposal of a binuclear platinum(I) dihydride [Pt(dppp)$(H)]_2$ [^{1}H NMR in CD_2Cl_2 (hydrido region): δ = −1.5 (quintet with 1:8:18:8:1 satellites, $^1J_{Pt-H}$ = 529, $^2J_{P-H}$ = 39 Hz) ppm; ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 19.2, $^1J_{P,Pt}$ = 2420, $^2J_{P,Pt}$ = 318, J_{P-P} = 37 Hz] as a by-product in the crude mixtures isolated in the attempts to synthesise cation **3** directly from Pt(dppp)Cl_2.

Compounds **1a**, **1b**, or **1c** do not react with excess $NaBH_4$, unlike **5**, which gave rise to the trinuclear cation **6** $[Pt_3(dppe)_3(H)_3]^+$. We observe that these trinuclear hydrides are not known with diphosphanyl ligands that stabilise mononuclear *cis*-dihydrides in respect to Pt^0 species (i.e., with dppp, dppb, dtbpe, dtbpp, dippp, and dcype ligands).

Compounds **1a**, **1b**, and **1d** react with CO to give the corresponding μ-hydrido μ-carbonyl platinum(I) derivatives [Pt$_2$(dcype)$_2$(μ-H)(μ-CO)][X] (X = Cl, **7a**; BF_4, **7b**; BPh_4, **7c**), isolated as blue-green powders. The reactions, carried out as reported previously for the analogous species with various diphosphanyl ligands,[4e,13] seem to be dependent on the counter-ions: species **7b** and **7c** are in fact obtained nearly quantitatively, while the yields of **7a** are lower, due to the formation of minor by-products often including [Pt(dcype)Cl_2].

Their spectroscopic features (IR and NMR spectra) are reminiscent of those observed for the homologous complexes with different diphosphanes either of platinum[4e,13] or of palladium.[14] The IR spectra show the strong absorption due to the bridging carbonyl group at about 1710 cm^{-1}. Slight differences are observed with the different anions.

In the ^{1}H NMR spectra (300 MHz), the main resonance of the hydride (δ ≈ +0.7) and of the diphosphanyl ligand resonances overlap, so that only the two external satellites of the hydrido ligand ($^1J_{H-Pt}$ = 984 Hz) are observed. Their multiplicity (up to 323 K) is intermediate between the previously reported limiting spectra,[13] a quintet (fast exchange region) and a triplet of triplets (frozen), suggesting that the exchange process is slower in this case. Variable

temperature $^{31}P\{^1H\}$ NMR spectra (121.5 MHz) show a broad singlet with satellites at 323 K, which is split at room temperature. The dynamic behaviour of compounds **7a−c** seems to be frozen at ca. 223 K, allowing the full set of coupling constants for the hydrido resonance and for the two couples of equivalent P nuclei to be evaluated.

X-ray Crystal Structure of Compound 1d

The structure of compound **1d** consists of packing of $[Pt_2(dcype)_2(H)_3]^+$ cations and BPh_4^- anions in the molar ratio of 1:1 with normal van der Waals contacts. An ORTEP view of the cation is shown in Figure 1, while selected interatomic distances and angles are listed in Table 2. The cation consists of two five-membered rings, each made up of a Pt atom and a chelating dcype ligand, separated by a

P(3)−Pt(2)−Hb	89.7(8)	P(4)−Pt(2)−Ht(2)	90.2(8)
P(4)−Pt(2)−Hb	171(1)	Ht(2) −Pt(2)−Hb	92(1)

Pt-Pt distance of 2.696(1) Å, which is the shortest value observed in these trihydrido cations but similar to that reported in the case of the doubly hydrido bridged 28e$^-$ species $[Pt(dcypp)(H)]_2^{2+}$ [Pt−Pt = 2.698(1) Å].[6] The two Pt atoms are also bonded to three hydride ligands, one bridging the Pt−Pt vector, and two terminally bonded, one for each metal atom.

The dihedral angle between the Pt1−P1−P2 and Pt2−P3−P4 planes is 82.74(1)°, in agreement with the "overall conformation" detected in homologous cations. At variance with this, the same dihedral angle ranges from "90° to 180° conformations" in the reported structures of the dihydrido platinum species,[5,6] either neutral Pt^I complexes $[Pt(P\text{-}P)(H)]_2$ or 28 e$^-$ platinum(II) cations $[Pt(P\text{-}P)(H)]_2^{2+}$, in which the geometry around each platinum centre was assumed to be square-planar as in cation **1**. The

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

accommodation of the third hydride in the $Pt_2(P\text{-}P)_2(H)_2$ core may be responsible for the "90° conformation" which appears as a typical feature of these platinum(II) 30 e^- cations.

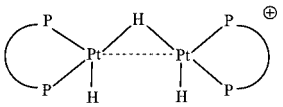
Bond lengths and angles involving the Pt atoms in the current cation can be compared with those found in cation $[Pt_2(butaphos)_2(H)_3]^+$ (**10**).[4g] Cation **10** differs from the present one only in the substitution of the two dcype ligands with two butaphos ones. In both cations the overall coordination around the Pt atom, if the Pt−Pt bond is neglected, can be described as distorted square planar, and the idealised symmetry of the two cations is C_2, with the two-fold axis passing through the bridging hydride ligand and the midpoint of the Pt−Pt vector. The Pt−P distances are of two kinds: two shorter [Pt1−P2 2.223(1) vs. 2.222(3) Å in **10**, and Pt2−P4 2.227(1) vs. 2.217(3) in **10**], and two longer [Pt1−P1 2.281(1) vs. 2.324(3) Å in **10**, and Pt2−P3 2.277(1) vs. 2.309(3) Å in **10**]. The longer bonds are approximately *trans* to the terminal hydrides, displaying the expected *trans* influence. We also note that the Pt1−P1 and Pt2−P3 bonds are significantly longer in **10**, possibly due to the different steric requirements of the butaphos and dcype ligands and the formation of seven vs. five-membered metallacycles, respectively.

Whereas in **10** only two hydride atoms had been detected in the final Fourier maps, and the third was placed in its position on the basis of symmetry considerations, in the current cation the three hydrides have been found in the final Fourier maps and included in the refinement with isotropic thermal parameters, thus confirming the stereochemistry suggested for **10**.[4g] The current structure is the first X-ray determination of a complex of the type $[Pt_2(P\text{-}P)_2(H)_x]^{n+}$ ($x = 2$, $n = 0, 2$; $x = 3$, $n = 1$) in which all the hydride ligands have been experimentally located, and the resulting bond parameters are consistent with those reported in the more precise neutron diffraction structure of the cation $[Pt_2(dppe)_2(H)_3]^+$.[8,15]

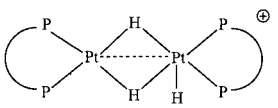
It was previously suggested that the geometry of the $Pt_2(P\text{-}P)_2(H)_3$ cores is controlled by the steric bulk of the phosphorus substituents,[4f] rather than by the bite angle of the chelating diphosphane. This view is supported by the current structure if comparison is made with the analogous cation with dppe: different structures are indeed observed with two diphosphanes with different steric bulk but similar bite angles. On the other hand, the same structure was reported for cations with diphosphanes displaying the same bite angle but different substituents (as in **10** or with dtbpp).[4b,4g] The available X-ray structure determinations therefore suggest that no conclusive statement can be made on this point, and that misleading conclusions may be drawn by use of comparison criteria focused only on these ligand features. As previously emphasised,[4c] the fluxional behaviour in solution suggests a very soft energy surface producing different core conformations, so that even apparently weak forces, such as crystal packing forces, could well be responsible for structural differences involving small energy changes. In this connection, it is worth noting the significant change, from a 90° to a 180° conformation, in the polymorphic platinum(I) hydride $[Pt(dfepe)H]_2$[5b] observed to occur at very low energy, also in the solid state.

Incoherent Inelastic Neutron Spectroscopy (INS) of 1a and 5a

As the structures of $[Pt_2(dcype)_2(H)_3][BF_4]$ (**1a**) and $[Pt_2(dppe)_2(H)_3][BF_4]$ (**5a**) have been shown by diffraction methods (X-ray and neutron for **1a** and **5a**,[4c,8] respectively) to be different, we have carried out an INS spectroscopic study of these complexes to obtain additional information on the nature of the Pt−H interactions.



1a



5a

While the vibrational modes of bridging hydrides can be investigated by optical spectroscopy,[16] this is in general rather difficult because of severe line broadening and interference from other modes. Instead, INS has the major advantage that the incoherent neutron scattering cross section for hydrogen is much larger than that for all other atomic species and that modes involving H atoms therefore dominate the INS spectra. To distinguish the vibrational modes of the hydrides from those of the hydrogens in the ligands unambiguously, however, a "sample difference"[17] technique has been used (see Exp. Sect.).

The INS difference spectra of **5a** and of **1a** are shown in Figures 2 and 3, respectively. As can be seen, the two spectra are quite different, reflecting the different coordination of the two "Pt_2H_3" moieties.

Although a complete assignment of the vibrational modes would require a normal coordinates analysis, a qualitative assignment of the main spectral features may still be carried out on the basis of published data for similar binuclear complexes[18] and other metal hydrides.[16,19] We note that the stretching frequency for a terminal "Pt−H" group is to be expected in the 1900−2100 cm^{-1} region,

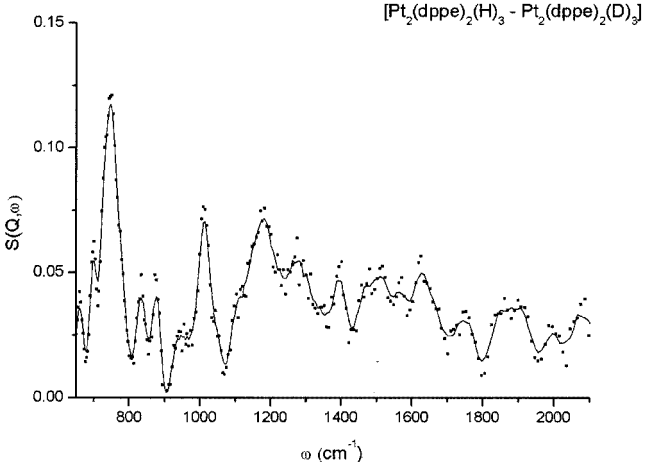


Figure 2. INS difference spectrum for compound **5a**; the line is drawn only as a guide for the eye

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

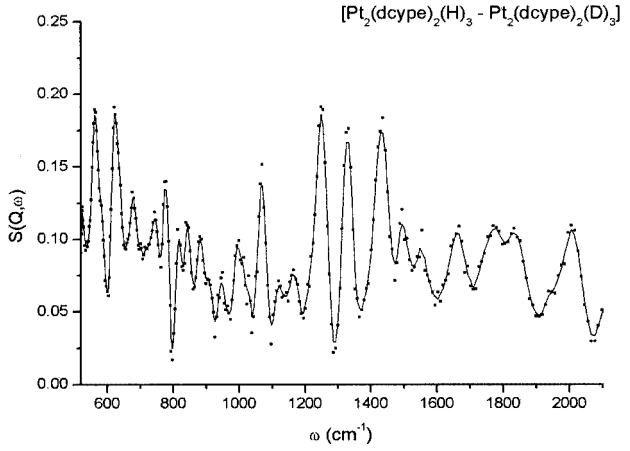

Figure 3. INS difference spectrum for compound **1a**; the line is drawn only as a guide for the eye

while the modes involving the μ-bridging H may be described in terms of a symmetric (ν_s) and anti-symmetric (ν_{as}) M−H−M stretching modes (1000−1400 cm^{-1}) as well as skeletal deformations and torsions (i.e., δ_{PMH} and δ_{MHM}) at lower frequencies.[18−20] As the intensities of the INS bands depend on the displacements of the H ligands, one would expect that the intensities of the deformation and torsional modes should be greater than those of the stretching modes, if coupling between the modes is small. These qualitative criteria allow for a relative straightforward assignment of the principal bands.

Thus, in the difference spectrum of **5a**, we assign the band at 2080 cm^{-1} to the Pt−H stretch (based on the correspondence with the IR broad band at ca. 2000 cm^{-1}), the 1170 cm^{-1} band to the ν_{as} and that at 1010 cm^{-1} to the ν_s mode of the "Pt(μ-H)Pt" moiety. The very intense bands at 750 cm^{-1} correspond to the δ_{MHM} mode of the same moiety.

It is worth noting that it is possible to obtain structural information on the M−H−M bridge from the ν_s/ν_{as} ratio. Howard and co-workers[21] have in fact shown that, if the metal framework may be regarded as rigid and the angle-bending force constant is small, then the following relation holds: $\nu_{as}/\nu_s = \tan(\theta/2)$, where θ is the M−H−M angle. We have also shown[18] that the above equation also holds accurately for compounds of the type [$PR_3LPt(\mu$-H)$PtLPR_3$] (L = Ph, H; PR_3 = PMe_3, PEt_3).

From the above assignment for **5a**, a value of θ = 98° is obtained from this relationship, in very good agreement with the average value of 97° for the Pt−H−Pt angle obtained from single-crystal neutron diffraction.[8]

The difference spectrum of **1a** clearly reflects a different disposition of the H ligands around the Pt centres, as found by X-ray diffraction. The Pt−H stretch is now at 2000 cm^{-1} [1970−1950 cm^{-1} in the IR (Nujol)], while the deformation modes are at lower frequencies (560−620 cm^{-1}), possibly reflecting the different electron densities at the metal centres due to the different basicity of the phosphanes.

A more complex pattern than in **5a** is found in the 1200−1600 cm^{-1} region. The ν_s mode is at 1080 cm^{-1}, while the ν_{as} bands are at 1240 cm^{-1} and 1340 cm^{-1}. These two bands are consistent with two slightly different environments around the two Pt atoms. Moreover, the new band at 1420 cm^{-1} may be connected with the presence of a single bridging hydride and thus a less rigid metal framework. To help with this assignment we have carried out a DFT calculation[22] on the model compound [$(PMe_3)_2HPt(\mu$-H)-$PtH(PMe_3)_2]^+$ and have found a mode at 1490 cm^{-1} corresponding to a combination of the $\nu_s(\mu$-H) and the out of plane bending of both terminal hydrides, a vibrational mode not possible when the platinum atoms are bridged by two hydrides.

These results, as also observed previously,[18] show that coupling between stretching and bending modes may be important in these bridging hydrides.

Experimental Section

Evaporation was always carried out under reduced pressure. The analytical samples were pumped to constant weight (room temperature, ca 0.1 Torr). Elemental analyses were performed by the Analytical Laboratory of the University of Milan and the Mikroanalytisches Labor Pascher (Remagen-Bandorf).

The infrared spectra were recorded on a Jasco FT/IR 420 spectrometer. NMR spectra were recorded at ambient temperature in $CDCl_3$ solutions unless otherwise stated, on a Bruker DRX 300 Avance spectrometer operating at 300 (^{1}H), 121.5 (^{31}P), and 64.5 MHz (^{195}Pt), respectively. The shift values are given in ppm from the usual standards; δ = ^{195}Pt is referred to $Na_2[PtCl_6]$ aqueous solution. Abbreviations used in the description of NMR spectroscopic data are as follows: br., broad; s., singlet; d., doublet; t., triplet; q., quintet; m., multiplet.

Solvents (RPE grade; Carlo Erba) were distilled prior to use. $NaBH_4$, $NaBD_4$ and KBH_4 were purchased from Merck, Aldrich and Fluka, respectively. The diphosphanyl ligands were obtained from Strem Chemicals and employed as received.

The [Pt(P-P)Cl_2][4d,23] from [Pt(COD)Cl_2] and the *cis*-[Pt(P-P)-$(H)_2$][7] complexes were synthesised by literature methods.

Synthesis and Characterisation. [Pt(dcype)(μ-OH)]$_2$[BF_4]$_2$ (2): The products isolated by previously reported procedures[11] were mixtures of different p1atinum species with O-donors; compound **2** was always the most abundant product (NMR). Starting from [Pt(dcype)Cl_2] (636 mg, 0.92 mmol) and $AgBF_4$ (360 mg, 1.9 mmol), the analytical sample was isolated as follows. After accurate elimination of the insoluble AgCl, the crude reaction product was crystallised from CH_2Cl_2/Et_2O. A first crop was precipitated by slow addition of diethyl ether to the dichloromethane solution; it was filtered off and then washed with acetone. Compound **2** was obtained as a residue (150 mg) slightly soluble in acetone. A second fraction (40 mg) of the same compound was obtained from the mother liquor by concentration in the presence of diethyl ether and of a few drops of MeOH. Yield 30%. IR (nujol, cm^{-1}): 3550 vbr. ν_{OH}, 1065 br. ν_{BF4}. $^{31}P\{^1H\}$ NMR: δ = 59.9 (s., $^1J_{P,Pt}$ = 3513 Hz) ppm. FAB MS (NBA): 1266 *m/z* $[M - 2H]^{+\cdot}$. M.p. 235 °C (dec). $C_{52}H_{98}B_2F_8O_2P_4Pt_2$ (1443.01): calcd. C 43.28, H 6.86, B 1.50, F 10.53, O 2.22, P 8.58, Pt 27.04; found C 43.32, H 7.10, F 9.93, P 8.4, Pt 26.7.

$[Pt_2(dcype)_2(H)_3][X]$ (X: BF_4, 1a, Cl 1b; OH, 1c; BPh_4, 1d): The salts **1a**, **1b**, and **1c** were obtained from compound **2** (i), from $[Pt(dcype)Cl_2]$ (ii), or from *cis*-$[Pt(dcype)(H)_2]$[5a] (iii), respectively.

(i) $[Pt_2(dcype)_2(H)_3][BF_4]$ (1a): From $[Pt(dcype)(\mu\text{-}OH)]_2[BF_4]_2$ (**2**). A suspension of KBH_4 (7.5 mg. 0.14 mmol) in methanol (20 mL) was added under dinitrogen atmosphere to a stirred solution of compound **2** (172 mg, 0.12 mmol) in the same solvent (10 mL). After ten minutes the colourless solution was evaporated to dryness and the residue was extracted with CH_2Cl_2 (ca. 7 mL). The insoluble material was filtered off, and the white product (99 mg, yield 62%) was precipitated by addition of diethyl ether (ca. 20 mL) to the clear solution. IR (nujol, cm^{-1}): $\tilde{\nu}$ = 1970 s,br ν_{PtH}, 1050 s,br ν_{BF4}. FAB MS: 1237 *m/z* $[M]^+$. M.p. 218 °C (dec.). $C_{52}H_{99}BF_4P_4Pt_2$ (1325.22): calcd. C 47.14, H 7.54; found C 47.18, H 7.44.

(ii) $[Pt_2(dcype)_2(H)_3][Cl]$ (1b): From *cis*-$[Pt(dcype)Cl_2]$. A solution of $NaBH_4$ (120.0 mg, 3.17 mmol) in ethanol (50 mL) was added dropwise under dinitrogen atmosphere to a stirred solution of $[Pt(dcype)Cl_2]$ (1.00 g, 1.45 mmol) in dichloromethane (70 mL). After ten minutes, the turbid solution was evaporated to dryness and the white solid residue was extracted with few millilitres (ca. 5) of CH_2Cl_2. The crude product (830 mg) was precipitated by addition of diethyl ether to the clear, filtered solution. The analytical sample was obtained by crystallisation from CH_2Cl_2/Et_2O (790 mg; yield 85.6%). IR (nujol, cm^{-1}): 1970−1950 s,br (1980 s,br in CH_2Cl_2) ν_{PtH}. ^1H NMR (ppm): δ = 1.6−1.9 and 1.3−1.1 (m. unresolved, CH_2), δ = −2.77 (q. with satellites, H, $^1J_{H-Pt}$ = 480, $^2J_{H-P}$ = 38 Hz). $^{31}P\{^1H\}$ (ppm): δ = 84.0 (s., $^1J_{P,Pt}$ = 2803, $^2J_{P,Pt}$ = 150, $^3J_{P,P}$ = 8.1, $^1J_{Pt-Pt}$ = 801 Hz); $^{195}Pt\{^1H\}$ and $^{195}Pt\{^{31}P\}$ [$(CD_3)_2CO$, ppm]: δ = −5141 tt. ($^1J_{Pt-P}$ = 2795; $^2J_{Pt-P}$ = 148 Hz) or quadruplet ($^1J_{Pt-H} \approx$ 480 Hz), respectively. M.p. 185 °C (dec.). $C_{52}H_{99}ClP_4Pt_2$ (1273.87): calcd. C 49.04, H 7.85, Cl 2.79, P 9.74, Pt 30.65; found C 48.82, H 7.87, Cl 2.90, P 9.52, Pt 31.0.

[Depending on the $NaBH_4$ stock, indefinable salts of the binuclear cation (NMR data), possibly with B_xH_y type anions (IR suggestion), were isolated as white powders. By addition of a large excess (400%) of a methanolic solution of NH_4Cl to the reaction crude, it is converted to **1b** in few minutes (15′). This procedure is near quantitative (yield 80% after crystallisation). Take care that working with NaCl in acetone solution the major product was a yellow oily, in which 4-hydroxy-4-methyl-2-pentanone was identified by GC.MS and ^1H NMR data as the most abundant product.]

(iii) $[Pt_2(dcype)_2(H)_3][OH]$ (1c): From *cis*-$[Pt(dcype)(H)_2]$. A solution of *cis*-$[Pt(dcype)(H)_2]$ in methanol was stirred overnight under dinitrogen atmosphere, and was then evaporated to dryness. The white solid residue was dissolved in the minimum amount of CH_2Cl_2, and compound **1c** was precipitated by slow addition of diethyl ether (yield 95%). IR (nujol, cm^{-1}): 3400−3200 vs,br ν_{OH}, 1968 s,br ν_{PtH}. $C_{52}H_{100}OP_4Pt_2$ (1255.42): calcd. C 49.75, H 8.04; found C 49.31, H 7.90.

The tetraphenylborate salt **1d** was obtained variously from **1a**, **1b**, or **1c** by exchange reactions carried out in methanol solution with a large excess of $NaBPh_4$. The yields referred to analytical1y pure samples were: 80% from **1a**, 90% from **1b**, and 84% from **1c**. IR (nujol, cm^{-1}): $\tilde{\nu}$ = 1966br. s ν_{PtH}, 1580 m (BPh_4^-). M.p. 240 °C (dec). $C_{76}H_{119}BP_4Pt_2$ (1557.68): ca1cd. C 58.62, H 7.72; found C 58.71, H 7.68.

$[Pt_2(dcype)_2(D)_3][Cl]$ (1b-d_3): The deuteride was obtained by procedure (ii), but with use of $NaBD_4$ and deuterated solvents. The crude material was crystallised twice (yield 36%). $^{31}P\{^1H\}$ NMR (ppm): δ = 83.9 (br. s, $^1J_{P,Pt}$ = 2788, $^2J_{P,Pt}$ = 149, $^3J_{P,P}$ = not detectable, J_{Pt-Pt} = 802 Hz).

Reactions of $Pt(P\text{-}P)Cl_2$ (P-P = dppe, dppp, dppb) with BH_4^-: These reactions were attempted by procedure (ii) as reported above for **1b**, but under various experimental conditions [i.e., with or without H_2 atmosphere, with $NaBH_4$ or KBH_4, with use of different BH_4/Pt ratios (from 1:1 to 4:1), and at different temperatures (from −15 °C to room temperature]. Even though the formation of the $[Pt_2(P\text{-}P)_2(H)_3]^+$ cations was always observed, only the compounds $[Pt_2(dppp)_2(H)_3][Cl]$ (**3a**) and $[Pt_3(dppe)_3(H)_3][Cl]$ (**6**) were isolated as analytical samples.

The former product (**3a**) was isolated (yield 40%) by crystallisation from acetone/diethyl ether of reaction products obtained by procedure (ii), but with use of a BH_4/Pt ratio of 1:1.

With dppe ligand, under dihydrogen atmosphere but independently of temperature and BH_4/Pt ratio, the isolated powders were found to be mixtures of unchanged $Pt(dppe)Cl_2$ and variable amounts of the binuclear (**5**) and trinuclear (**6**) hydrides. Compound **6** was isolated as a pale yellow powder by slow addition of diethyl ether to clear solutions of these mixtures in a few millilitres (4−5) of dichloromethane. The best results (yield 63%) were obtained by carrying out the reactions in ethanol/dichloromethane mixtures (1:1), with use of a BH_4/Pt ratio of 4:1, either at −15 °C or at room temperature. The reaction times were 2 hours and 30 minutes, respectively.

Reaction of 1 with CO and KCN. $[Pt_2(dcype)_2(\mu\text{-}CO)(\mu\text{-}H)][X]$ (X: Cl, 7a; BF_4, 7b; BPh_4, 7c): The compounds were synthesised by bubbling CO through acetone solutions of the appropriate hydrido salt at room temperature. The colourless solutions quickly turned blue. The compounds were isolated by addition of diethyl ether to the concentrated solutions at different reaction times: 30 minutes (**7a**) or 4 hours (**7b** and **7c**). Compounds **7b** and **7c** were isolated as analytical samples (yields: 83% and 95%, respectively), while **7a** was crystallised from acetone/diethyl ether (yield 68%). IR (nujol, cm^{-1}): $\tilde{\nu}$ = 1710s ν_{CO} (1053 s,br, ν_{BF4}, **7b**; 1579 m, BPh_4, **7c**). $^{31}P\{^1H\}$ NMR [$(CD_3)_2CO$, under CO atmosphere, ppm]: δ = 64.3 (br, $^1J_{P,Pt}$ = 2260 Hz, $P_{trans\text{-}C}$), δ = 64.1 (br, $^1J_{P,Pt}$ = 4390, $^2J_{P,Pt}$ = 460 Hz, $P_{trans\text{-}H}$). ^1H NMR [$(CD_3)_2CO$, under CO atmosphere, at 243 K, ppm]: δ = +0.72 (hydrido resonance; external satellites observed as triplets of triplets: $^1J_{H-Pt}$ = 454, $J_{H-Ptrans}$ = 76, J_{H-Pcis} = 10 Hz). $^{31}P\{^1H\}$ NMR [$(CD_3)_2CO$, under CO atmosphere, at 223 K, ppm]: δ = 65.8 (d, $^1J_{P,Pt}$ = 2240, $^2J_{P,P}$ = 26 Hz, $P_{trans-C}$), δ = 65.0 (d, $^1J_{P,Pt}$ = 4370, $^2J_{P,Pt}$ = 470, $^2J_{P,P}$ = 26 Hz, $P_{trans-H}$). M.p. (dec) 200 °C, **7a**; 215 °C, **7b**; 190 °C, **7c**. $C_{53}H_{97}BF_4OP_4Pt_2$ (1351.21), **7b**: ca1cd. C 47.14, H 7.25, found C 47.42, H 7.22.

***cis*-Pt(dcype)(H)(CN) (8):** A suspension of KCN (100 mg; 1.54 mmol) in methanol (20 mL) was added to a vigorously stirred solution of **1b** (400 mg, 0.314 mmol) in the same solvent (25 mL). The solution immediately fizzed and a white precipitate was formed. After ten minutes the suspension was evaporated to dryness, the white residue was dissolved in CH_2Cl_2, and the insoluble material was filtered off; this was repeated twice. The analytical sample (300 mg; yield 75.3%) was obtained by addition of a large excess of diethyl ether to few millilitres of a dichloromethane solution of the crude product. IR (nujol, cm^{-1}) 2118 vs ν_{CN}, 1992 vs ν_{PtH}. ^1H NMR (hydrido region, ppm): δ = −2.01 (dd, $^2J_{H-Ptrans}$ = 178.4, $^2J_{H-Pcis}$ = 15; $^1J_{H-Pt}$ = 986 Hz). $^{31}P\{^1H\}$ NMR (ppm): δ = 71.8 (s, $^1J_{P(transCN)-Pt}$ = 2706 Hz), δ = 69.0 (s, $^1J_{P(transH)-Pt}$ = 1714 Hz). $^{195}Pt\{^1H\}$ NMR [$(CD_3)_2CO$, ppm]: δ = −5244 (dd). FAB MS (NBA): 644 *m/z* $[M]^{+\cdot}$. M.p.: 180 °C (dec). $C_{27}H_{49}NP_2Pt$ (644.72): calcd. C 50.30, H 7.68, N 2.17; found C 49.93, H 7.70,

[a] $R_2 = [\Sigma(F_o^2 - kF_c^2)/\Sigma F_o^2]$, $R_{2w} = [\Sigma w(F_o^2 - kF_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$. [b] $[\Sigma w(F_o^2 - kF_c^2)^2/(N_o - N_v)]^{1/2}$, where $w = 4F_o^2/\sigma\ (F_o^2)^2$, $\sigma(F_o^2) = [\sigma^2(F_o^2) + (0.02F_o^2)^2]^{1/2}$, N_o is the number of observations and N_v the number of variables.

N 2.16. During the $^{195}Pt\{^1H\}$ NMR spectrum ($CDCl_3$ solution) acquisition, compound **8** was converted into [Pt(dcype)Cl$_2$] and *cis*-[Pt(dcype)(Cl)(CN)] (**9**): $^{31}P\{^1H\}$ NMR (ppm): δ = 65.4 (s, $^1J_{P(trans\,Cl)-Pt}$ = 3337 Hz), δ = 63.0 (s, $^1J_{P(trans\,CN)-Pt}$ = 2568 Hz). $^{195}Pt\{^1H\}$ NMR (ppm): δ = −4839 (dd).

X-ray Data Collection and Structure Determination: Crystal data and other experimental details are summarised in Table 3. The diffraction experiment was carried out on a Bruker SMART CCD area-detector diffractometer at 200 K by use of Mo-$K\alpha$ radiation (λ = 0.71073 Å) with a graphite crystal monochromator in the incident beam. Cell parameters and orientation matrix were obtained from least-squares refinement of 123 reflections each measured in three different sets of 15 frames, in the range $3 < \theta < 23°$. At the end of data collection the first 50 frames, containing 235 reflections, were recollected to monitor crystal decay. No correction was necessary. The collected frames were processed with the SAINT software package,[24] and an absorption correction was applied (SADABS)[25] to the 63529 collected reflections, 12751 of which are unique with R_{int} = 0.0378 ($R_{int} = \Sigma|F_o^2 - F_{mean}^2|/\Sigma F_o^2$).

The calculations were performed on a Pentium III Pc by use of the Personal Structure Determination Package[26] and the physical constants tabulated therein. Scattering factors and anomalous dispersion corrections were taken from ref. 27. The structure was solved by direct methods (SHELXS 86)[28] and refined by full-matrix, least-squares, by using all reflections and minimising the function $\Sigma w(F_o^2 - kF_c^2)^2$. Anisotropic displacement factors were refined for all the non-hydrogen atoms. The three hydrides were found in the final Fourier maps and refined isotropically. The other hydrogen atoms were placed in their ideal positions (C−H = 0.97 Å, B 1.10 times that of the carbon atom to which they are attached) and not refined. In the final difference Fourier map the maximum residual was 1.06(14) Å^{-3} at 0.78 Å from Pt(2). CCDC-208551 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

Inelastic Incoherent Neutron Scattering (INS) Measurements: The INS experiments were carried out on TOSCA-I, a crystal-analyser inverse-geometry spectrometer[29] operating at the ISIS pulsed-neutron source. The incident neutron beam spans a broad energy (E_0) range and energy selection is carried out on the secondary neutron flight-path by use of the (002) Bragg reflection of a graphite analyser placed in back-scattering position (≈ 136°). The resolving power of TOSCA-I is fairly good ($2\% < \Delta\hbar\omega/E_0 < 3.5\%$) in the accessible energy transfer range (24 cm^{-1} < ħω < 8065 cm^{-1}) making this instrument a neutron equivalent of a Raman optical spectrometer. All the intramolecular vibrations can in principle be easily observed by INS spectroscopy, but it should be also pointed out that, due to molecular recoil, the neutron-measured frequencies might be slightly different from those observed on a conventional Raman spectrometer.

The measurements were carried out on samples of [Pt$_2$(dppe)$_2$(H)$_3$][BF$_4$] (**5a**) and [Pt$_2$(dcype)$_2$(H)$_3$][BF$_4$] (**1b**) and their deuterium analogues (approximately 1 g each), all contained in individual thin Al-film bags. During the data collection, the samples were maintained at ca. 12 K and the spectra were recorded up to an integrated proton current of 1967 μA/h (roughly 10 hours of beam time).

In order to distinguish the M−H vibrational modes from all other vibrations involving hydrogen atoms of the ligands, a "sample difference" technique[17] was used. The method is based on the fact that the incoherent neutron scattering cross sections of hydrogen and deuterium are very different [79.91(4) and 2.94(3) barn, respectively),[30] making vibrational modes involving D atoms difficult to detect by INS in the presence of many hydrogen atoms. The difference between two experimental INS spectra (i.e., those containing the "Pt−D" and "Pt−H" moieties) should thus only leave the peaks involving the motion of the hydrides (bridging or terminal), provided that any possible coupling of the hydride modes to other molecular modes is negligible (on the scale of the resolution of the INS experiment). Therefore, as the contribution from the ligand modes is subtracted out, it is unnecessary to prepare samples with fully deuterated ligands.

Synthesis and Characterisation of New Nickel-Iron Complexes with an S_4 Coordination Environment around the Nickel Centre

Johanna A. W. Verhagen,[a] Martin Lutz,[b] Anthony L. Spek,[b] and Elisabeth Bouwman*[a]

Keywords: Nickel / Iron / S ligands / Electronic structure / Electrochemistry

The nickel complex [Ni(xbsms)] [H_2xbsms is α,α′-bis(4-mercapto-3,3-dimethyl-2-thiabutyl)-*o*-xylene] was reacted with $FeCl_2$, $[Fe_2(CO)_9]$, $[Fe(CO)_2(NO)_2]$ and $[Fe(CO)_4I_2]$. The reaction with $FeCl_2$ gives the heterotetranuclear nickel–iron complex $[Ni(xbsms)FeCl_2]_2$. The complex was characterised by analytical, spectroscopic and electrochemical methods and by X-ray diffraction. $[Ni(xbsms)FeCl_2]_2$ crystallises in the monoclinic space group $P2_1/c$, with the dimer located on the inversion centre. The nickel ions are in a square-planar $S_2S'_2$ environment, comprised of two thioether and two thiolate sulfur atoms. The thiolate sulfur atoms form a bridge between the nickel ion and the iron centre. The iron ions are in a pseudo square-pyramidal S_2Cl_3 environment, with two chloride ions forming a bridge between the two iron centres. The Ni–Fe distance is 3.0403(3) Å. The reaction with $[Fe_2(CO)_9]$, $[Fe(CO)_2(NO)_2]$ or $[Fe(CO)_4I_2]$ gives the heterodinuclear complexes $[Ni(xbsms)Fe(CO)_4]$, $[Ni(xbsms)Fe(NO)_2]$ and $[Ni(xbsms)Fe(CO)_2I_2]$, respectively. These complexes were characterised by analytical, spectroscopic and electrochemical methods. In $[Ni(xbsms)Fe(CO)_4]$, one thiolate group bridges the Ni and Fe centres, whereas in $[Ni(xbsms)Fe(NO)_2]$ and $[Ni(xbsms)Fe(CO)_2I_2]$, two thiolate groups form a bridge between the centres. These newly synthesised nickel–iron complexes appear to be suitable complexes for new structural models for [NiFe]-hydrogenases.

Introduction

Hydrogenases are widespread among several classes of anaerobic and occasionally aerobic bacteria, and were first discovered in the 1930s.[1] These enzymes catalyse the reversible oxidation of dihydrogen, which allows the cell to generate or dispose of reducing equivalents during respiration. In vitro hydrogenases also catalyse H^+/D_2 exchange.[2] The reactivity of nickel enzymes in the generation or consumption of dihydrogen is interesting because of the fact that possible future energy problems may be solved using an hydrogen economy.[3] By studying the synthesis and characterisation of structural and functional models for the hydrogenases, we hope to contribute to the development of catalysts for, for example, fuel cells.

The hydrogenases have been divided into two main classes, based on their metal content, namely [NiFe]-hydrogenases and [Fe]-hydrogenases.[2] A subset of the first class has been shown to contain selenium, the [NiFeSe]-hydrogenases. Furthermore, a hydrogenase that does not contain any transition metal has been discovered.[4] Extensive studies and characterisations, including single-crystal X-ray diffraction, have revealed the structure of several [NiFe]-hydrogenases.[5,6] The X-ray studies have shown that the active sites of the [NiFe] enzymes isolated from *Desulfovibrio gigas*[5] and *Desulfovibrio vulgaris*[6] contain the heterodinuclear site $[(Cys\text{-}S)_2Ni^{II}(\mu\text{-}S\text{-}Cys)_2Fe^{II}(CN)_2(CO)]$, in which the nickel centre has an S_4 coordination environment. Two thiolate sulfur atoms form a bridge between the nickel and the iron centres. Furthermore, three diatomic molecules are coordinated to the iron centre, two CN molecules and one CO molecule. In the last few years, considerable interest has been shown in the structural modelling of the [NiFe]-hydrogenases.[7−12] However, most of the structural models have a mixed-donor environment around the nickel centres. A variety of square-planar nickel complexes have been synthesised with only sulfur donor atoms in the coordination environment,[13] and several nickel−iron complexes relevant for hydrogenase modelling have been synthesised.[2,14−18] However, so far only one heterodimetallic nickel−iron complex that has an S_4 coordination environment around the nickel centre has been reported.[19] In this paper, we describe the synthesis of new heterometallic nickel−iron complexes, starting from a nickel complex with an S_4 coordination environment.[20]

Results and Discussion

Syntheses: Four new nickel−iron complexes were synthesised by the reactions of [Ni(xbsms)] with the iron com-

plexes $FeCl_2$, $[Fe_2(CO)_9]$, $[Fe(CO)_2(NO)_2]$ and $[Fe(CO)_4I_2]$. The ligand H_2xbsms, α,α′-bis(4-mercapto-3,3-dimethyl-2-thiabutyl)-*o*-xylene, is a tetradentate ligand, which coordinates to the nickel centre through two thiolate groups that are forced in the *cis* positions. These thiolate groups provide a potential binding site for an iron centre.

The reaction of [Ni(xbsms)] with $FeCl_2$ produces the complex $[Ni(xbsms)FeCl_2]_2$ (**1**). In this synthesis either anhydrous $FeCl_2$ or $FeCl_2{\cdot}4H_2O$ can be used. Single crystals suitable for X-ray diffraction were obtained from the filtrate on standing at room temperature, after the removal of the initially formed precipitate.

The reaction of [Ni(xbsms)] with half an equivalent of $[Fe_2(CO)_9]$ gives the complex $[Ni(xbsms)Fe(CO)_4]$ (**2**), and that with $[Fe(CO)_2(NO)_2]$ the complex $[Ni(xbsms)Fe(NO)_2]$ (**3**).

The synthesis of $[Ni(xbsms)Fe(CO)_2I_2]$ (**4**) was performed in chloroform and the reaction mixture was cooled to 273 K in the absence of light. These conditions are necessary for the two CO molecules to remain coordinated to the iron centre. If the synthesis of **4** is carried out in acetonitrile, a compound is formed that lacks CO signals in its IR spectrum. This compound might have a structure that is similar to that of **1**; however, the exact nature of this product is still unknown.

All the complexes are moderately soluble in polar solvents. Furthermore, all the complexes decompose very rapidly in air and in solution. Complex **1** is the most stable, followed by complex **4**, and thereafter complexes **2** and **3**. Decomposition of complexes **2** and **3** leads to the regeneration of the parent nickel complex. Decomposition of **4** begins with the loss of the CO groups. The instability of complexes **2**, **3** and **4** is reflected in their NMR spectroscopic and magnetic susceptibility data. These complexes are diamagnetic as is confirmed by ^1H NMR spectroscopy; however, the μ_{eff} values are higher than expected as a result of decomposition to the paramagnetic species. The regenerated parent nickel complex can also be seen in the NMR spectra.

Structure of $[Ni(xbsms)FeCl_2]_2$ (1): A projection of the structure of the complex $[Ni(xbsms)FeCl_2]_2$ is shown in Figure 1. Crystal data are given in Table 1 and selected bond lengths and angles are given in Table 2.

$[Ni(xbsms)FeCl_2]_2$ crystallises in the space group $P2_1/c$ with two molecules in the unit cell. The complex is hetero-tetranuclear with two Ni^{II} centres in a square-planar $S_2S'_2$ environment and two Fe^{II} centres in a pseudo square-pyramidal S_2Cl_3 environment. The molecule is located around an inversion centre. The two thiolate groups of the ligand xbsms are forced in the *cis* positions, and form a bridge between one nickel and one iron centre. Furthermore, two thioether sulfur atoms are coordinated to the nickel centre. Two chloride ions form a bridge between the iron centres. The complex $[(BME\text{-}DACO)NiFeCl_2]_2$, reported by Darensbourg et al., has a similar hetero-tetranuclear structure, although, the nickel centre has an S_2N_2 coordination environment.[11]

[a] $R1 = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$. [b] $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. $S = \{\Sigma[w(F_o^2 - F_c^2)^2]/(n - p)\}^{1/2}$.

The coordination environment around the nickel ion has a small tetrahedral distortion, with an interplanar angle of 5.75(2)° between the planes S(6)−Ni(1)−S(9) and S(16)−Ni(1)−S(19).

The pseudo square-pyramidal environment of the iron centre is defined by the two thiolate sulfur atoms and two bridging chloride ions in the basal plane, and the terminal chloride ion Cl(2) in the apical position. The distortion towards a trigonal bipyramidal geometry is shown by S(6) and Cl(1a) in the apical positions and S(16), Cl(1) and Cl(2) in the trigonal plane. The two largest angles around the iron centre give a τ value of 0.45 (with τ = 0 for square-pyramidal and τ = 1 for trigonal bipyramidal geometries).[21] The distance between the two symmetry-related iron centres is 3.6947(5) Å, indicating that no metal-metal interaction is present. From the geometry around the iron centre, it can be concluded that the iron centre is in a high spin state. This

		Fe(1)−Cl(1)−Fe(1a)	97.273(15)	S(16)−Fe(1)−Cl(1a)	92.062(15)

observation has been confirmed by the room temperature magnetic susceptibility measurements, which give a μ_{eff} value of 5.35 μ_B per iron centre. This is consistent with a high spin Fe^{II} centre without any interaction between the two iron centres in the molecule.[22]

The Fe−S−Ni angles of 80.301(14) and 82.005(15)° lead to a Ni−Fe distance of 3.0403(3) Å. All distances and angles around the nickel centre are consistent with data of similar complexes in the literature.[2,13]

Proposed Structure of [Ni(xbsms)Fe(CO)$_4$] (2): A proposed structure based on elemental analysis and NMR spectroscopic studies is shown in Figure 2. This structure, containing a square-planar low spin Ni^{II} ion and a low spin Fe(0) moiety, is similar to that of [(BME-DACO)Ni-Fe(CO)$_4$].[16] In the IR spectrum of complex (2), three signals assigned to the CO groups are observed at 2009, 1945 and 1860 cm^{-1}. These are slightly different from those reported for a THF solution of [(BME-DACO)Ni-Fe(CO)$_4$];[16] however, they are in the same region as the CO absorption observed at 1943 cm^{-1} for [NiFe]-hydrogenase.[23] The ^{1}H NMR spectrum shows resonance signals for every proton and every methyl group, which is in agreement with the proposed asymmetric structure. Using NOESY and COSY NMR spectra, full assignments of all resonance signals could be made. The ^{1}H NMR spectrum, recorded at 253 K, is shown in Figure 3. The parent nickel complex can also be seen in the NMR spectrum, as a result of the decomposition of the [NiFe] complex. The ^{13}C NMR spectrum also reflects the asymmetry of the complex, all carbon atoms appear to be inequivalent. However, the CO resonance signals are not observed. This may be attributed to the low concentration and the instability of the complex, or to poor relaxation properties of the complex. The instability of the complex is confirmed by mass spectroscopy: $\{[Ni(xbsms)Fe(CO)_3]+H\}^+$ is observed as the main peak, indicating that one CO molecule is only loosely bound.

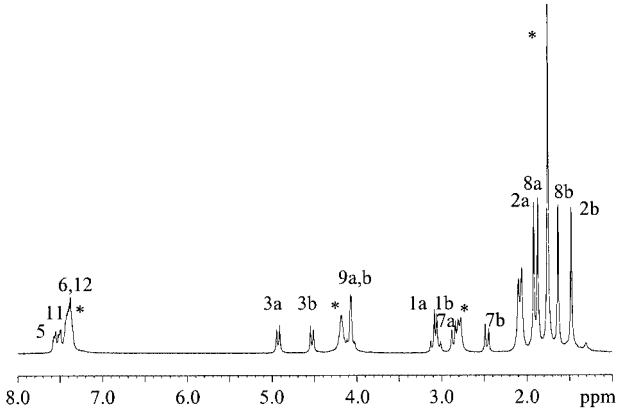

Figure 3. ^{1}H NMR spectrum of [Ni(xbsms)Fe(CO)$_4$] in [D$_6$]acetone at 253 K. Assignments in the figure correspond to numbers in Figure 2. The asterisks indicate signals from the decomposition product [Ni(xbsms)]

Proposed Structure of [Ni(xbsms)Fe(NO)$_2$] (3): A proposed structure based on elemental analysis and ^{1}H NMR spectroscopy is also shown in Figure 2. This structure, containing a square-planar low spin Ni^{II} ion and a low spin $[Fe(NO)_2]$ moiety, is similar to that of the Ni-Fe-nitrosyl complex reported by Osterloh et al.[15] In the IR spectrum, strong signals assigned to the NO groups are clearly observed at 1771 and 1733 cm^{-1}. These absorptions are at significantly higher energies compared with those in the reported complex (1663 and 1624 cm^{-1}),[15] and are also shifted relative to the starting Fe complex $[Fe(CO)_2(NO)_2]$ (1810 and 1766 cm^{-1}); however, they compare with those reported by Liaw et al. (1767 and 1725 cm^{-1}).[17] The NO stretches in the IR spectrum are in the range reported for linearly coordinated NO^+ molecules.[24] This indicates only a small increase in transfer of electron-density from Fe into

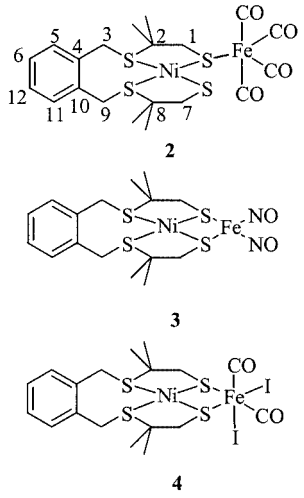

Figure 2. Schematic drawings of the postulated structure of [Ni(xbsms)Fe(CO)$_4$] (**2**), [Ni(xbsms)Fe(NO)$_2$] (**3**) and [Ni(xbsms)-Fe(CO)$_2$I$_2$] (**4**)

the π* orbitals of the NO ligands, which is accompanied by the weakening of the NO triple bonds.

Proposed Structure of [Ni(xbsms)Fe(CO)$_2$I$_2$] (4): A proposed structure based on elemental analysis and mass spectrometry is also shown in Figure 2. The proposed structure is dinuclear with a square-planar low spin Ni^{II} ion, bridged via both thiolate sulfur atoms to the octahedral Fe^{II} ion. The IR spectrum of 4 is clearly different from that of 1, excluding a tetranuclear structure. Two signals which are assigned to CO vibrations are observed at 2048 and 2096 cm^{-1}. The mass spectra indicate that the iodide ions are coordinated to the iron centre.

UV/Visible-NIR Spectroscopy of the Complexes: The square-planar coordination environment of the nickel centres in all of the complexes is reflected in their ligand field spectra. The data are presented in Table 3. All complexes are brown solids and yield pale brown solutions in both chloroform and acetonitrile. Only small differences are observed between the UV/Visible-NIR spectra of the complexes in chloroform and in acetonitrile, indicating that in all cases solvent coordination does not take place and decomposition in solution is not within the timescale of the experiment.

The d−d transitions involving the nickel centre in the complex [Ni(xbsms)$FeCl_2$]$_2$ are at a higher energy than those in the complex [Ni(xbsms)], and the LMCT transitions are at a lower energy.[20] This can be explained by the fact that the iron centre in complex **1** has electron-donating chloride ions, and this results in a higher electron-density on the thiolate sulfur atoms. These thiolate sulfur atoms then donate more electron-density to the nickel centre, and as a result the nickel-thiolate distance is shorter. This observation is in agreement with the crystal structure. The shortening of this nickel−thiolate bond leads to longer thioether sulfur−nickel distances.

For **2** and **3**, the shift in energy is the opposite. As a result of the π back-donation from the iron centre to the CO ligands in **2** and NO ligands in **3**, the iron centre can accept electron-density from the thiolate sulfur atoms. Hence a lower ligand field splitting occurs, and the d-d absorption maxima are observed at lower energies relative to the parent nickel complex. The absorptions around 35 000 cm^{-1} in **2** can be explained by a d-d transition involving the iron centre.[25]

For **4**, which has electron-donating iodide ions and electron-withdrawing carbonyl molecules coordinated to the iron centre, both effects are observed. The d-d transitions are at a lower energy relative to [Ni(xbsms)], as is the case for **2**; however, the LMCT absorption maxima are also at a lower energy, as is the case for **1**. The latter observation also confirms the proposed structure with coordinated iodide ions.

Electrochemical Results: The electrochemical behaviour of the synthesised nickel−iron complexes was investigated using cyclic voltammetry. For complexes 1, 2 and 3 only quasi-reversible and irreversible redox couples were found, which cannot be interpreted unequivocally.

For complex **4**, the relevant data are presented in Table 4 and the cyclic voltammogram is shown in Figure 4. For comparison, the cyclic voltammograms of FeI_2 and NEt_4I have been recorded. In MeCN, with NBu_4PF_6 as the supporting electrolyte, FeI_2 shows two reversible waves at 232 mV (ΔE = 220 mV) and 654 mV (ΔE = 78 mV), and NEt_4I shows two reversible waves at 238 mV (ΔE = 191 mV) and 646 mV (ΔE = 92 mV). This indicates that the redox couples at around 250 and 640 mV most likely result from the iodide ions. The couple at around 250 mV appears to arise from a two-electron process, which might result from the oxidation of the iodide ions to I_2. The redox couple at 1246 mV could result from oxidation of the iron centre. Furthermore, **4** shows an irreversible reduction wave at around −500 mV.

The redox behaviour of **4** was also tested in dichloromethane. These data are included in Table 4. In CH_2Cl_2, the oxidation wave at 1206 mV is irreversible. The difference in the redox behaviour in both solvents is significant and probably due to the difference in solubility and ionisation of the complex, and of I^- and I_3^-.

Conclusions and Outlook

Four new nickel−iron complexes have been synthesised from the reactions of the nickel complex [Ni(xbsms)] with $FeCl_2$, [$Fe_2(CO)_9$], [$Fe(CO)_2(NO)_2$] and [$Fe(CO)_4I_2$].

The [NiFe] complexes with the ligand xbsms are generally less stable than other complexes with the ligands xbsms and bme-daco.[11,26] This might be as a result of the S_4 coordination environment around the nickel centre, instead of an S_2N_2 coordination environment. Furthermore, most of the [NiFe] complexes show quasi-reversible or irreversible oxidation waves when studied by cyclic voltammetry.

The synthesised compounds appear to be promising complexes for new structural models for the [NiFe]-hydro-

genases. An improved model for the hydrogenase active site may be achieved by exchanging the iodide ions in complex **4** for cyanide molecules, and this work is in progress.

In the near future, the complexes will be screened for hydrogenase activity by means of reaction with dihydrogen or protons.

Experimental Section

Chemicals: All preparations were carried out with reagent grade solvents. All chemicals used in the syntheses were obtained from Acros or Aldrich and were used without further purification, unless otherwise mentioned. The complexes were synthesised under argon using standard Schlenk techniques. Solvents were deoxygenated by bubbling a stream of argon through the solution, or by the freeze-pump-thaw method, and were dried with molecular sieves. The complexes [Ni(xbsms)],[20] [Fe(CO)$_2$(NO)$_2$][27] and [Fe(CO)$_4$I$_2$][28] were synthesised according to published methods.

Physical Measurements: The IR spectra were recorded with a Perkin−Elmer FT-IR Paragon 1000 spectrophotometer equipped with a golden gate ATR device, using the reflectance technique (4000−300 cm^{-1}, resolution 4 cm^{-1}). Elemental analyses were carried out with a Perkin−Elmer series II CHNS/O analyzer 2400. Metal analyses were performed with a Perkin−Elmer 3100 atomic absorption (AAS) and flame emission spectrometer using a linear calibration method. Ligand field spectra were recorded with a Perkin−Elmer Lambda 900 spectrophotometer. The diffuse reflectance technique, with MgO as a reference, was used for the solid compounds. Ligand field spectra of the solutions were obtained with the used solvent in the reference beam. NMR spectra were recorded with a Bruker WM 300 MHz spectrometer or on a Bruker AV 400 MHz spectrometer. Proton and carbon chemical shifts are indicated in ppm relative to tetramethylsilane (TMS). The electrochemical measurements were performed with an Autolab PGstat10 potentiostat controlled by GPES4 software. A three-electrode system was used, consisting of a platinum working electrode, a platinum auxiliary electrode and an Ag/AgCl reference electrode. The experiments were carried at room temperature under argon with tetrabutylammonium hexafluorophosphate (0.10 M) as the electrolyte. Under these conditions the ferrocenium-ferrocene couple is at +430 mV, with a peak separation of 59 mV. All potentials are reported relative to Ag/AgCl. Mass analyses were performed with a Finnigan MAT 900 equipped with an Electrospray interface (ESI). Spectra were collected by constant infusion of the sample dissolved in methanol/water containing 1% HOAc. Room temperature magnetic susceptibility measurements were performed using a magnetic susceptibility balance type MK1 or using the NMR method.[29]

[Ni(xbsms)FeCl$_2$]$_2$ (1): $FeCl_2 \cdot 4H_2O$ (0.049 g, 0.25 mmol) was added to a solution of [Ni(xbsms)] (0.100 g, 0.25 mmol) in acetonitrile (20 mL). After stirring for 2 h, the precipitate formed was collected by filtration. A brown product was obtained, with a yield of 0.082 g (62%). Single crystals suitable for X-ray diffraction were obtained from the filtrate on standing. IR: $\tilde{\nu}_{max}$ = 2975 w, 2947 w, 1486 w, 1440 m, 1380 m, 1362 m, 1300 w, 1256 m, 1223 m, 1192 m, 1135 s, 1075 s, 1007 w, 952 m, 890 m, 865 w, 772 s, 756 w, 730 m, 684 s, 608 s, 580 m, 544 m, 469 m, 418 w, 373 w, 310 s cm^{-1}. $C_{32}H_{48}Cl_4Fe_2Ni_2S_8$ (1060.1): calcd. C 36.25, H 4.56, S 24.19, Ni 11.08, Fe 10.54; found C 36.47, H 4.61, S 22.87, Ni 11.17, Fe 10.21.

[Ni(xbsms)Fe(CO)$_4$] (2): [$Fe_2(CO)_9$], (0.090 g, 0.25 mmol) was added to a solution of [Ni(xbsms)] (0.20 g, 0.50 mmol) in acetonitrile

(30 mL). After stirring for 3 h, $[Fe_2(CO)_9]$ had completely dissolved. The acetonitrile was partly evaporated in vacuo until a precipitate was formed. The precipitate was collected by filtration, giving a brown product with a yield of 0.11 g (41%). ^{1}H NMR [300.13 MHz, CD_3CN, 298 K, see Figure 2 for numbering scheme): δ = 7.52 (m, 1 H, C^5-H), 7.46 (m, 1 H, C^{11}-H), 7.38 (m, 2 H, C^6-H, C^{12}-H), 4.76 (d, $^2J_{H,H}$ = 10.9 Hz, 1 H, C^3H*H*), 4.38 (d, $^2J_{H,H}$ = 10.9 Hz, 1 H, C^3*H*H), 4.01 (d, $^2J_{H,H}$ = 11.6 Hz, 1 H, C^9H*H*), 3.91 (d, $^2J_{H,H}$ = 11.6 Hz, 1 H, C^9*H*H), 3.05 (d, $^2J_{H,H}$ = 13.0 Hz, 1 H, C^1H*H*), 2.97 (d, $^2J_{H,H}$ = 13.0 Hz, 1 H, C^1*H*H), 2.81 (d, $^2J_{H,H}$ = 12.3 Hz, 1 H, C^7H*H*), 2.46 (d, $^2J_{H,H}$ = 12.3 Hz, 1 H, C^7*H*H), 1.82 (s, 3 H, C^2-Me), 1.71 (s, 3 H, C^8-Me), 1.60 (s, 3 H, C^8-Me), 1.43 (s, 3 H, C^2-Me) ppm. ^{13}C APT NMR [100.62 MHz, [D$_6$]acetone, 253 K]: δ = 135.37 (C^{10}), 134.20 (C^4), 133.41 (C^5), 131.63 (C^{11}), 129.38 (C^6), 129.11 (C^{12}), 67.19 (C^2), 62.41 (C^8), 48.01 (C^3), 40.63 (C^9), 35.29 (C^1), 34.92 (C^7), 27.04 (C^2-*C*H$_3$), 26.43 (C^2-*C*H$_3$), 25.20 (C^8-*C*H$_3$), 25.13 (C^8-*C*H$_3$) ppm. IR: $\tilde{\nu}_{max}$ = 2930 w, 2922 w, 2830 w, 2009 vs, 1944 vs, 1861 vs, 1456 m, 1435 m, 1380 m, 1260 m, 1234 w, 1212 w, 1188 w, 1165 w, 1133 m, 1070 m, 1002 w, 948 w, 892 m, 871 w, 781 s, 759 m, 706 m, 684 w, 616 s, 595 s, 571 s, 559 s, 490 m, 468 m, 436 m, 398 m, 368 s, 340 m cm^{-1}. $C_{20}H_{24}FeNiO_4S_4$ (571.2): calcd. C 42.06, H 4.23, S 22.45, Ni 10.28, Fe 9.78; found C 41.67, H 4.78, S 22.07, Ni 10.59, Fe 9.29. ESI-MS: *m*/*z* = 543 [M − "CO" + H]$^+$.

[Ni(xbsms)Fe(NO)$_2$] (3): A solution of $[Fe(CO)_2(NO)_2]$ (0.058 g, 0.34 mmol) in acetonitrile (3 mL) was added to a solution of [Ni(xbsms)] (0.137 g, 0.34 mmol) in acetonitrile (40 mL) at 273 K. Whilst stirring for 2 h, the evolution of a gas was observed, indicating the loss of CO. After the reaction was completed, the acetonitrile was partly evaporated until a precipitate was formed. This precipitate was collected by filtration to give a brown solid with a yield of 0.71 g (55%). ^{1}H NMR [300.13 MHz, $CDCl_3$, 300 K]: δ = 7.25 (m, 4 H, Ph-H), 3.98 (s, 4 H, Ph-C*H*$_2$−S−), 3.20 (s, 4 H, −C(CH$_3$)−C*H*−S−), 1.61 (s, 12 H, C*H*$_3$) ppm. IR: $\tilde{\nu}_{max}$ = 2934 w, 2928 w, 1809 w, 1771 s, 1733 vs, 1700 m, 1456 m, 1381 m, 1360 m, 1228 w, 1136 m, 1118 m, 1085 m, 957 m, 886 w, 786 m, 702 m, 554 w, 492 w, 469 m, 350 w, 302 m cm^{-1}. $C_{16}H_{24}FeN_2NiO_2S_4$·0.5 CH_3CN (539.8): calcd. C 37.83, H 4.76, N 6.49, S 23.76, Ni 10.81, Fe 10.35; found C 38.22, H 5.48, N 6.06, S 21.43, Ni 10.96, Fe 10.21.

[Ni(xbsms)Fe(CO)$_2$I$_2$] (4): $[Fe(CO)_4I_2]$ (0.105 g, 0.25 mmol) was added to a solution of [Ni(xbsms)] (0.101 g, 0.25 mmol) in chloroform (12 mL) at 273 K. After stirring for 1.5 h in the absence of light, the precipitate was collected by filtration. A brown product was obtained, with a yield of 0.050 g (24%). IR: $\tilde{\nu}_{max}$ = 2959 m, 2948 m, 2096s, 2048s, 1456s, 1417 m, 1389 m, 1372s, 1225 m, 1136s, 1081s, 955 m, 882 m, 772 vs, 694s, 606s, 570 m, 492s, 468s, 350s, 310m cm^{-1}. $C_{18}H_{24}FeI_2NiO_2S_4$ (769.0): calcd. C 28.11, H 3.15, S 16.68, Ni 7.64, Fe 7.26; found C 27.63, H 3.38, S 16.18, Ni 7.85, Fe 6.86. ESI-MS: *m*/*z* = 644 $[Ni(xbsms)Fe(CO)_2I]^+$, 616 $[Ni(xbsms)Fe(CO)I]^+$, 257 $[Ni(xbsms)Fe(CO)_2]^{2+}$, 243 $[Ni(xbsms)Fe(CO)]^{2+}$, 229 $[Ni(xbsms)Fe]^{2+}$.

Crystal Structure Determination of [Ni(xbsms)FeCl$_2$]$_2$: X-ray intensities were measured with a Nonius KappaCCD diffractometer with rotating anode (λ = 0.71073 Å) at a temperature of 150 K. The structure was solved with automated Patterson methods (DIRDIF97[30]) and refined with SHELXL-97[31] against F^2 for all reflections. Molecular illustration, structure checking and calculations were performed with the PLATON package.[32] The crystals were obtained as dark purple plates. The absorption correction was based on multiple measured reflections (program PLATON[32] routine MULABS, 0.79−0.89 transmission). Non-hydrogen atoms were refined freely with anisotropic displacement parameters. Hydrogen atoms were located in the difference Fourier map and refined freely with isotropic displacement parameters (methyl groups) or as rigid groups (all other H atoms). Further crystallographic details are given in Table 1.

CCDC-212533 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows a typical bent-sandwich *commo*-metallacorborane product as well as its starting *nido*-carborane precursor of the smaller carborane cage system, together in a novel cluster. Details are discussed in the Microreview by N. S. Hosmane and J. A. Maguire on p. 3989 ff. The authors are indebted to their many students and coworkers who have borne the brunt of doing, and to the National Science Foundation, Alexander von Humboldt-Stiftung (to N. S. H.) and the R. A. Welch Foundation (to J. A. M.) for their generous support.

Recent Advances in the Chemistry of Metallacarboranes

Narayan S. Hosmane*[a] and John A. Maguire[b]

Keywords: Carboranes / Boranes / Lanthanides / *ansa* ligands / Sandwich complexes / Main group elements

Most carborane derivatives of the icosahedral (C_2B_{10}) or small cage (C_2B_4) systems are formed by varying the groups on the cage carbon atoms. This is usually accomplished in the original carborane synthesis by treating substituted acetylenes with either the decaborane(14) or pentaborane(9) precursors to give directly carboranes that have adjacent carbon atoms in the cage ("carbon atoms adjacent"). The larger cages are obtained as *closo*-icosahedra, while the small-cage C_2B_4 carboranes have *nido* structures as well as a cage geometry in which the carbon atoms are separated by a boron atom. Although these "carbon atoms apart" or *nido*-2,4-$(CR)_2B_4H_6$ carboranes are thermodynamically more stable and are more symmetric than the "carbon atoms adjacent" isomers, they have not been as well studied, mainly because they must be synthesized from their "carbon atoms adjacent" analogues through a sequential series of oxidative cage-closure/reductive cage-opening reactions. We have concentrated much of our recent research on the reactivity patterns of $C_{(cage)}$-appended alkyl- and silylamido, alkyloxo, alkylphosphido, and alkylthio derivatives of the "carbon atoms apart" carboranes. We have also sought to develop a safe, bench-scale preparation of small-cage carboranes that does not require isolating and handling dangerous and toxic carborane precursors such as pentaborane(9). This microreview discusses the latest developments towards such a process and the subsequent reaction chemistry of the "carbon atoms apart" carboranes.

Introduction

Extensive research has been reported on the chemical and structural properties of metallacarboranes in pentagonal-bipyramidal (MC_2B_4) and icosahedral (MC_2B_9) cage systems.[1] They are generally synthesized by the reaction of the mono- or dianions of their respective *nido*-C_2B_4 or C_2B_9

Narayan S. Hosmane was born in Gokarn, Southern India in 1948. He is a B.S. and MS graduate of Karnatak University, Karnataka State, India. He obtained a Ph.D. degree in Inorganic Chemistry in 1974 from the University of Edinburgh, Scotland, under the supervision of Professor Evelyn Ebsworth. After brief postdoctoral research training in Professor Frank Glockling's laboratory at the Queen's University of Belfast, he joined the Lambeg Research Institute in Northern Ireland, and then moved to the USA to study carboranes and metallacarboranes. After postdoctoral work with Professors W. E. Hill and F. A. Johnson at Auburn University and Russell Grimes at the University of Virginia, in 1979 he joined the faculty at the Virginia Polytechnic Institute and State University. In 1982 he joined the faculty at the Southern Methodist University, where he became Professor of Chemistry in 1989. In 1998, he moved to Northern Illinois University and is currently a Presidential Research Professor of Chemistry and Biochemistry. He was the founder of Boron in the Americas (formerly known as BUSA) and hosted the organization's first meeting in Dallas in April 1988. He has published over 200 papers in leading scientific journals. Later this year he will serve as the Jawaharlal Nehru Distinguished Chair of Chemistry for five weeks, at the University of Hyderabad, India, and in 2001 he received the Humboldt Research Prize for Senior US Scientists from the Alexander von Humboldt-Stiftung, and also received the University's Presidential Research Professorship. He has previously received a Camille and Henry Dreyfus Scholar Award, and has been honored with the Mother India International Award and the Boron in the USA Award for his distinguished achievements in boron science. In 1987 he was given the Sigma Xi Outstanding Research Award. A fellow of the Royal Society of Chemistry and the American Institute of Chemists, he has been listed in Who's Who in the World. His research interests are in main-group organometallic chemistry including the synthesis and structure of carboranes, metallacarboranes and organosilicon compounds, with particular emphasis on the Ziegler−Natta catalysis, and also bioboron chemistry and its applications in cancer treatment.

John Maguire is Professor of Chemistry at Southern Methodist University. He was born in Alabama in 1936, received his B.S. Degree in Chemistry from Birmingham Southern College in 1958 and his PhD Degree in Physical Chemistry in 1963 from Northwestern University under the direction of Ralph G. Pearson. He joined the faculty of Southern Methodist University as an Assistant Professor of Chemistry and is now Professor of Chemistry. From 1976 to 1979 he was Associate Dean of University College at SMU and from 1979 to 1981 he was Dean of University College and General Education at SMU. His research interests are in the structure and properties of intercalation compounds and in the bonding, structure and reactivity in carborane cage compounds. He has received several awards including the "M" Award for service to the University in 1979, the outstanding professor award for teaching in both 1975 and 1995, and the Perrine Prize for research. He has published over 120 scientific peer-reviewed papers and reviews and has been listed in the ISI's 10858 most cited chemists (1981−1997) in the world. In 2002 he was appointed University Distinguished Teaching Professor.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

carboranes with suitable metal reagents. Much of the interest in them stems from the fact that three primary metal-binding carborane π-type molecular orbitals that are localized on the C_2B_3 open pentagonal faces, which are quite similar to those in cyclopentadienide $[C_5R_5]^-$ ligands. Our research has involved synthetic, structural, reactivity and theoretical studies on the full- and half-sandwich metallacarboranes derived from the interactions of [*nido*-2-($SiMe_3$)-*n*-(*R*)-2,*n*-$C_2B_4H_4]^{2-}$ (n = 3, 4; R = $SiMe_3$, *n*Bu, *t*Bu, Me, H) with main-group,[2] d-group,[3] and f-group metals.[4] Originally, pentaborane(9) (B_5H_9), which reacts with various alkynes to furnish small-cage C_2B_4 carboranes, could be obtained from an extensive US-government surplus. However, at present, that source is no longer available, and no commercial source has taken its place.[5] Thus, a new, convenient and safe method of producing pentaborane(9) is needed − ideally a one-pot method from a readily available starting material so that the pentaborane(9) can then further react with the appropriate alkyne to generate, in situ, the corresponding small-cage carborane; such a method is described herein. With a steady source of starting materials available, we have extended our studies of the "carbon atoms apart" metallacarboranes. We have also embarked on the construction of $C_{(cage)}$-appended alkyl- and silylamido and alkyloxo derivatives of the larger C_2B_9 cage systems and have investigated their reactivity toward group-4 and -14 metals so as to prepare metallacarboranes with new geometries that could function as precursors to catalysts or possibly exhibit intrinsic catalytic activity. We hope that the reader will realize that there is still a wealth of fascinating research to be explored in this area.

1. Synthesis of Boron-10 Enriched Pentaborane(9) from Boric Acid and Its Conversion into *nido*-$^{10}B_{10}H_{14}$ and *anti*-$^{10}B_{18}H_{22}$

Pentaborane(9) is an important synthon for several higher polyhedral borane cages, including $[B_9H_{14}]^-$,[6] $[B_{11}H_{14}]^-$,[7] $[B_{12}H_{12}]^{2-}$ as well as other cage-expanded borane anions,[8] and the neutral decaborane, $B_{10}H_{14}$.[9] The corresponding ^{10}B-enriched species could function as precursors for several boron-based drugs for use in boron neutron capture therapy (BNCT). With the exception of the expensive $^{10}B_{10}H_{14}$,[10] there is no commercial supplier for any of these boranes. Therefore, a convenient synthesis for ^{10}B-enriched pentaborane(9) has an obvious appeal. It was this incentive that led us to explore alternative routes to ^{10}B-enriched polyhedral boranes, starting from the readily available ^{10}B-enriched boric acid, $H_3{}^{10}BO_3$. Specifically, $H_3{}^{10}BO_3$, was converted into the corresponding sodium borohydride, $Na^{10}BH_4$, in essentially quantitative yields, by using a slightly modified literature method, involving the formation of butyl borate, $(n\text{BuO})_3{}^{10}B$, and then treating it with NaH in mineral oil at 250 °C.[11,12] Subsequent oxidation of $Na^{10}BH_4$ with I_2 in diglyme, followed by the addition of dioxane during the purification step, gave the dioxane-complexed sodium salt of octahydrotriborate(−1), $Na[^{10}B_3H_8]{\cdot}3C_4H_8O_2$, in almost quantitative yields [Equation (1)].[13]

$$3\ Na^{10}BH_4 + I_2\ (\text{in diglyme/dioxane}) \rightarrow 2\ H_2 + 2\ NaI + Na[^{10}B_3H_8]{\cdot}3C_4H_8O_2 \quad (1)$$

Treatment of $Na[^{10}B_3H_8]{\cdot}3C_4H_8O_2$ with $NiCl_2$ in anhydrous benzene or heavy mineral oil at 110 °C [Equation (2)] gave the corresponding $^{10}B_5H_9$ as the first isolated ^{10}B-enriched pentaborane(9) in a laboratory environment.[14]

$$2\ Na[^{10}B_3H_8]{\cdot}3C_4H_8O_2 + NiCl_2 \xrightarrow[\text{heavy mineral oil}\ 110^{\circ}C/12\ h]{\text{Benzene or}} {}^{10}B_5H_9 + 2\ H_2 + C_4H_8O_2{\cdot}{}^{10}BH_3 \quad (2)$$
$$\text{– } 2\ NaCl/\text{– } Ni^0 \text{ – } 2\ C_4H_8O_2$$

Of the various reported methods of preparing natural B_5H_9,[15,16] that in Equation (2) is by far the most convenient and straightforward. Since the ^{10}B-enriched pentaborane is the only borane product of high volatility, its safe production, easy isolation and storage in heavy mineral oil make this method most attractive, to both those who work with small-cage (C_2B_4) carboranes and to researchers who did not have previous access to these materials. Boron-10 enriched decaborane, $^{10}B_{10}H_{14}$, is the key chemical in preparing almost all of the $C_{(cage)}$-substituted bio-boron molecules that are currently undergoing clinical trials as boron drugs for BNCT.[17] We therefore devised an alternative synthesis that started with the $^{10}B_5H_9$ prepared as described previously to afford, with slight modifications, using different oxidizing agents and reaction temperatures, either $^{10}B_{10}H_{14}$ or *anti*-$^{10}B_{18}H_{22}$ (Scheme 1).[18a] The conversion of natural pentaborane(9) to decaborane(14) has been previously demonstrated by Brewer and Grimes using the iron(II) and iron(III) chloride mediated cage fusion reactions.[18b]

This procedure constitutes the first systematic synthetic approach to pentaborane(9) and decaborane(14) of both natural and ^{10}B-enriched analogues and to their cage-expanded neutral and anionic borane species.[14,18]

2. Reductive Cage-Opening Process with Concomitant Metalation of the Resulting Carborane Ligand: A Novel Route to Metallacarborane Synthesis

The two-electron reductive cage-opening of the *closo*-carboranes has been well-documented.[19−21] In a series of papers Stone and co-workers reported the simultaneous cage reduction and metalation of *closo*-carboranes in the C_2B_n (n = 6, 8, 9) cage systems, using a number of zero-valent nickel, platinum, and palladium complexes.[22] The monocarbon carbaborane [*closo*-$CB_{10}H_{11}]^-$ reacts in a similar manner,[23] and the icosahedral *closo*-$(RC)_2B_{10}H_{10}$ cage has been opened by reaction with a group-1 metal, in both the

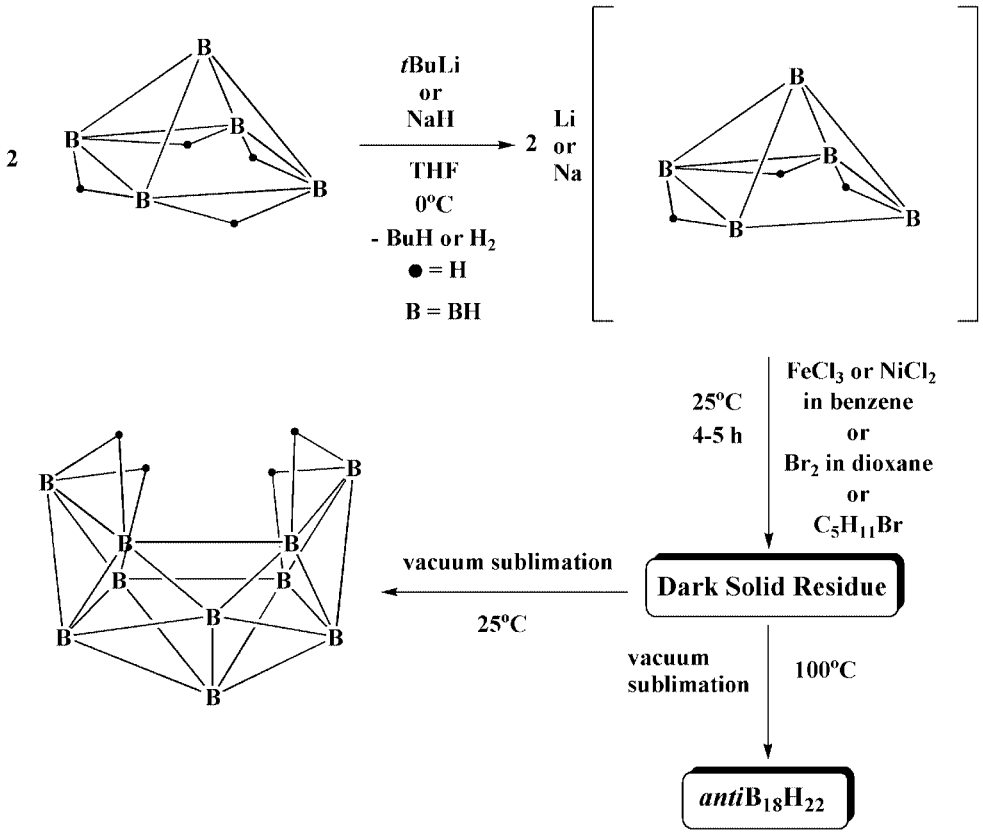

Scheme 1. Synthesis of *nido*-$^{10}B_{10}H_{14}$ and *anti*-$^{10}B_{18}H_{22}$ from $^{10}B_5H_9$

presence and absence of catalysts, to give the corresponding *nido*-carboranes.[24,25] In addition, Mg (group 2) reacts with *closo*-1,2-$C_2B_{10}H_{12}$ in the presence of catalytic amounts of 1,2-dibromomethane.[26] Conversely, Xie and co-workers have reported a noncatalyzed reduction of Na[1-$Me_2C(C_5H_5)$-*closo*-1,2-$C_2B_{10}H_{11}$] by Na metal to give the *ansa*-ligand Na_3[1-$Me_2C(C_5H_5)$-*nido*-1,2-$C_2B_{10}H_{11}$], in which a Cp^- group is tethered to a dianionic *nido*-$C_2B_{10}H_{11}$ moiety via an Me_2C bridge; metal complexes of this ligand were also described.[27] All such reductive cage opening processes yield *nido*-carborane products with a "carbon atoms apart" geometry in which the two cage carbon atoms are separated by at least one boron atom on the open faces of the carboranes. When the two-cage carbon atoms are bridged, by either an organic group or a metal complex, cage reduction produced the "carbon atoms adjacent" *nido*-C_2B_{10} cage, which seems to be susceptible to further reduction to give the respective *arachno*-carboranes.[28] There are a number of catalyzed and noncatalyzed approaches to cage reduction/opening processes for large-cage *closo*-carboranes, but only a few for small C_2B_4 cage systems. Despite some very interesting, but isolated, reports of reductive cage openings of *closo*-$C_2B_4H_6$ by Lewis bases, such as $(CH_3)_3N$,[29] and low-valent metal compounds,[30] the only general, high-yield method of transforming either *closo*-1,6-$(CR)_2B_4H_4$ (R = H or a cage carbon substituent) or its 1,2-isomer to the corresponding [*nido*-2,4-$(CR)_2B_4H_4]^{2-}$ species is by naphthalene-catalyzed group-1 metal reduction.[20]

The use of naphthalene in these traditional two-electron reductive cage-opening reactions has several disadvantages. It introduces an additional reagent that must be removed from the reaction mixture before the *nido*-carborane products can be treated further. In addition, naphthalene also has a tendency to co-crystallize with any product or to substitute for a terminal B−H hydrogen atom, which often interferes with the reactivity of these dianionic ligands. The subsequent metalations of these ligands, in the conventional synthetic procedure (Scheme 2) produce metallacarboranes of different geometries depending on the ratios of reactants involved.[31−40] The structures of some recently reported representative compounds are depicted in Figures 1 and 2.[39,40]

The seeming inability of the *closo*-carboranes to undergo reduction in the absence of naphthalene led us to question whether such carboranes could be reductively opened by the in situ generation of reactive metal atoms whose cations are good coordinators of the carborane. To explore this possibility, anhydrous $ErCl_3$ was treated with 4 equiv. of freshly cut potassium metal, under refluxing conditions in THF, to produce what we believe to be an active erbium metal alloy of the form of Er/K* (Scheme 3).

The alloy was immediately treated with the *closo*-carborane 1,2-$(SiMe_3)_2$-1,2-$C_2B_4H_4$ which, after refluxing overnight with constant stirring, produced a light-orange crystalline solid, identified as the "carbon atoms apart" erbacarborane sandwich, 2,2′,4,4′-$(SiMe_3)_4$-3,6′-[$(\mu$-$H)_2K(THF)_2$]-1,1′-*commo*-Er(η^5-2,4-$C_2B_4H_4)_2$, in 82%

yield (Scheme 3 and Figure 3).[41] It is noteworthy that, under the same reaction conditions, neither the Er or K metals alone, nor the one generated in situ by treating K with $ErCl_3$ in a 3:1 ratio, underwent reductive cage opening; in both cases the *closo*-carborane precursor was recovered. Although the Na/Hg alloy has been widely used in coupling reactions of many organometallic species,[42] there have been no reports of its use either in the reductive cage opening of the carboranes or in the synthesis of mercuracarborane complexes. Therefore, the reaction shown in Scheme 3 is an unprecedented example of a new reductive cage-opening process that could prove applicable to the *closo*-carboranes in both the icosahedral and sub-icosahedral cage systems, thus affording hitherto unknown metallacarborane species.

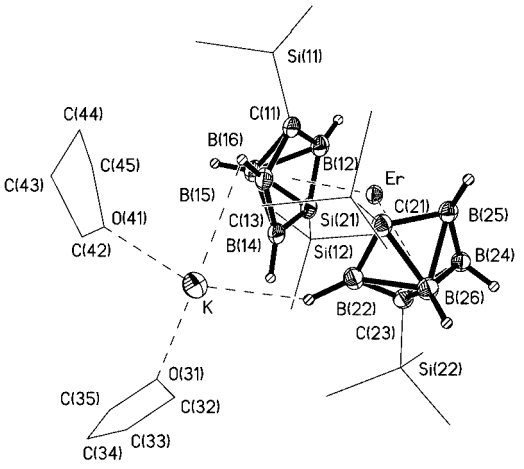

Figure 3. Crystal structure of a full-sandwiched erbacarborane complex

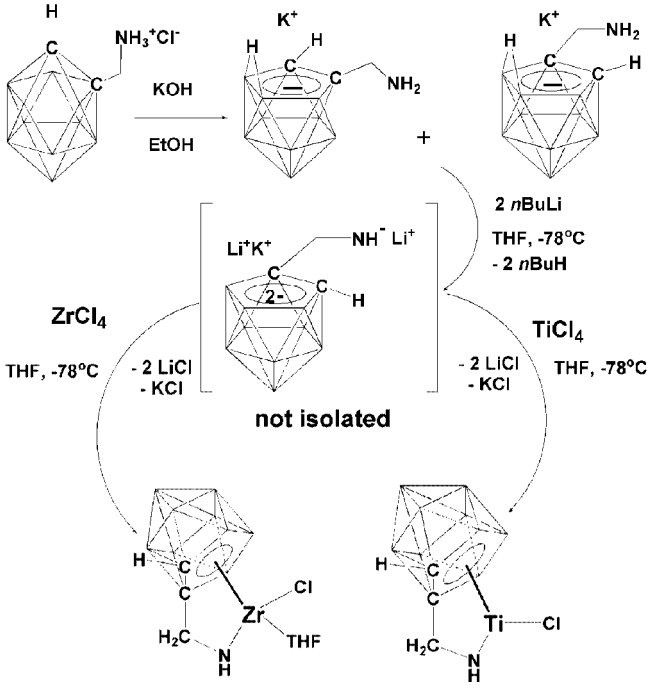
3. Chemistry of Half-Sandwich, Constrained-Geometry C_2B_9 Metallacarboranes

The potential applications of functionalized carborane clusters in catalytic organic reactions have resulted in reports of the syntheses and reactivities of several new metallacarboranes.[43] Our preliminary research has shown that the trianionic ligand [*nido*-7-(CH_2NH)-7,8-$C_2B_9H_{10}$]$^{3-}$, prepared from the reaction of [*nido*-7-(CH_2NH_2)-7,8-$C_2B_9H_{11}$]$^-$ with 2 equiv. of *n*BuLi, reacts with MCl_4 (M = Ti, Zr) to give the corresponding half-sandwich metallacarboranes (Scheme 4).[44]



Scheme 4. Synthesis of *ansa*-alkylamidometallacarboranes; unlabelled vertices are BH groups

Of the handful of reports in which the appended moiety forms either a coordinate covalent bond or another delocalized π-bond with the metal atom *exo*-polyhedrally, none have demonstrated the additional stabilization of the metal atom by σ-bonding to the $C_{(cage)}$-appended moiety.[43] Therefore, our results are the first examples of half-sandwiched group-4 metallacarboranes in which the nitrogen atom of the *exo*-polyhedral $C_{(cage)}$-alkylamido unit is $\eta^1(\sigma)$-bonded to the metal atom that is complexed with the open C_2B_3-bonding face of the carborane ligand (Scheme 4). Other constrained-geometry ligands, such as the *ansa*-alkyloxocarborane, can thus be used to prepare a series of $C_{(cage)}$-appended half-sandwich alkyloxometallacarboranes (Scheme 5)[45] In these syntheses, the in situ generated trianionic ligand is treated with anhydrous $MeMCl_3$ (M = Si, Ge), followed by re-crystallization from a toluene/heptane solution to form the corresponding half-sandwich group-14 metallacarboranes, *closo*-1-M(Me)-2-[1-$\eta^1(\sigma)$-OCH_2]-3-Me-η^5-2,3-$C_2B_9H_9$ (M = Si, Ge), in 48 and 56% yields, respectively. The NMR spectra, IR spectra and the microanalytical data for these species confirmed the formulations shown in Scheme 5.[45]

4. Syntheses and Reactivities of $B_{(cage)}$-Alkyl- and -Silylamido C_2B_4 Carborane Ligands

The usefulness of the carborane ligands would be extended if substituents could be systematically introduced on the boron atoms of both 2,3- and 2,4-C_2B_4 carboranes. While there have been several isolated reports of the syntheses of such derivatives,[46–48] only Davis and Grimes have reported a systematic study of the *B*-alkylation of the *nido*-C_2B_4 cage.[49] They found that the reactions of the [*nido*-2,3-$R_2C_2B_4H_5$]$^-$ (R = Et, CH_2Ph) anion with the organic halides R′X [R′ = Me, Et, CH_2Ph, $(CH_2)_3Ph$ and $CH_2C_6H_4Me$; X = Cl or Br] gave exclusively *nido*-4-(R′)-2,3-$(R)_2$-2,3-$C_2B_4H_5$ products. The triethyl- and tribenzyl-alkylated carboranes undergo both metalation and cage-fusion reactions. However, this study was not systematically extended to further alkylation reactions. To investigate the reactivities of alkylated and polyalkylated carboranes, we examined the regiospecific alkylation of the *nido*-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_6$ carborane and investigated the chemical behavior of any *B*-alkylated products. The following questions were addressed: (1) Is it possible to systematically alkylate and/or polyalkylate carboranes having such bulky substituents as the $SiMe_3$ groups? (2) If so, what is the effect of the $SiMe_3$ groups in determining the distribution of products? (3) Could any alkylated product undergo standard deprotonation and oxidation reactions preparatory to the formation of metallacarboranes and the "carbon atoms apart" analogues, respectively? (4) How effective are the standard techniques of ^1H, ^{11}B, and ^{13}C NMR spectroscopy in identifying the structures of any alkylated products? To address these concerns, the sodium compound of *nido*-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_6$ was treated with standard alkylating agents, MeI and *i*BuBr, to produce the corresponding neutral monoalkylated carboranes, *nido*-5-(*R*)-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_5$ (R = Me and *i*Bu) in 75% yields (see Scheme 6).[50]

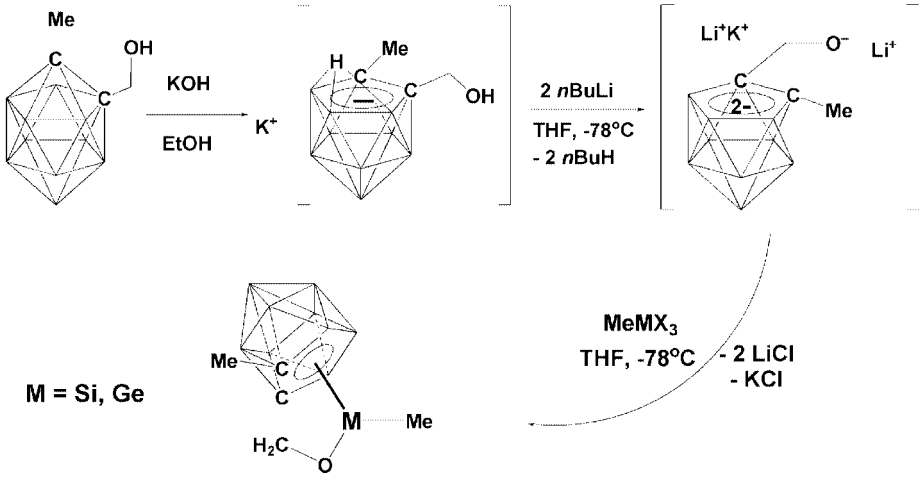
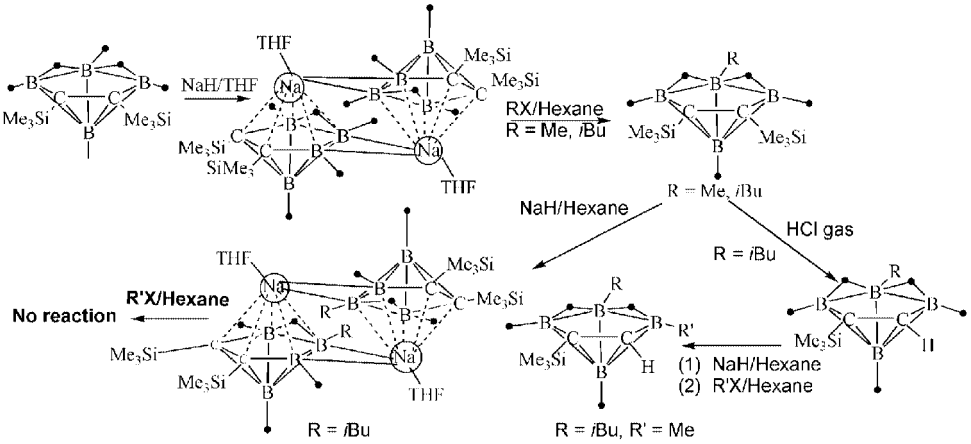


Scheme 5. Synthesis of *ansa*-alkyloxometallacarboranes; unlabelled vertices are BH groups



Scheme 6. Systematic $B_{(cage)}$-alkylation of *nido*-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_6$

The alkylation reaction seems to be a general one that leads exclusively to $B_{(unique)}$-alkylated products. These reactions presumably proceed through an intermediate in which the incoming alkyl unit is bridged between the unique boron atom and one of its neighboring basal boron atoms. The intermediate then collapses with the alkyl group migrating to the terminal position of one of the two boron atoms, changing places with its terminal hydrogen atom. The difference in the directing ability of $SiMe_3$ compared with *C*-alkyl groups is probably due to the steric bulk of the former. This unique directive property of the $SiMe_3$ group was profitably exploited in the synthesis of the corresponding $B_{(cage)}$-silylamido-substituted carborane derivatives. The reactions of $RNHSi(Me)_2Cl$ [R = *t*Bu, 2,6-$(Me_2CH)_2C_6H_3$] with the carborane ligands *nido*-1-Na-(C_4H_8O)-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_5$ and Li[*closo*-1-R′-1,2-$C_2B_{10}H_{10}$] produced two kinds of neutral ligand precursors, *nido*-5-[$Si(Me)_2N(H)R$]-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_5$ (R = *t*Bu) and *closo*-1-R′-2-[$Si(Me)_2N(H)R$]-1,2-$C_2B_{10}H_{10}$ [R = *t*Bu, R′ = Ph; R = 2,6-$(Me_2CH)_2C_6H_3$, R′ = H], in 85, 92, and 95% yields, respectively (Scheme 7).[51] Treatment of *closo*-2-[$Si(Me)_2NH$(2,6-$(Me_2CH)_2C_6H_3$)]-1,2-$C_2B_{10}H_{11}$ with 3 equiv. of freshly cut sodium metal in the presence of naphthalene produced, in almost quantitative yield, the corresponding cage-opened sodium salt of the "carbon atoms apart" carborane trianion, [*nido*-3-{$Si(Me)_2N$(2,6-$(Me_2CH)_2C_6H_3$)}-1,3-$C_2B_{10}H_{11}$]$^{3-}$, whose reaction with anhydrous MCl_4 (M = Ti and Zr) in 1:1 molar ratios gave the corresponding half-sandwich neutral d^0-metallacarboranes, *closo*-1-M[$(Cl)(THF)_n$]-2-{1′-η^1,σ-N[2,6-$(Me_2CH)_2C_6H_3$]$(Me)_2Si$}-2,4-η^6-$C_2B_{10}H_{11}$ (M = Ti, *n* = 0; M = Zr, *n* = 1) in 47 and 36% yields, respectively (Scheme 7).[51] Conversely, the small-cage species 5-*t*BuNHSi$(Me)_2$-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_5$ had limited use as a ligand since it could not withstand deprotonation with a strong base. Therefore, the reactivity of the neutral carborane with $M(NMe_2)_4$ (M = Zr and Ti) was studied. However, while possible metalation occurred, no characterizable products could be isolated.[51] All compounds were characterized by elemental analysis, ^1H, ^{11}B, and ^{13}C NMR spectra and IR spectra, and the ligand processor, *closo*-2-[$Si(Me)_2NH${2,6-$(Me_2CH)_2C_6H_3$}]-1,2-$C_2B_{10}H_{11}$, was also characterized by single-crystal X-ray diffraction.

The crystal structure (Figure 4) of this *ansa* ligand shows that it consists of a closed C_2B_{10} polyhedron with a distorted icosahedral cage geometry. The intracage bond

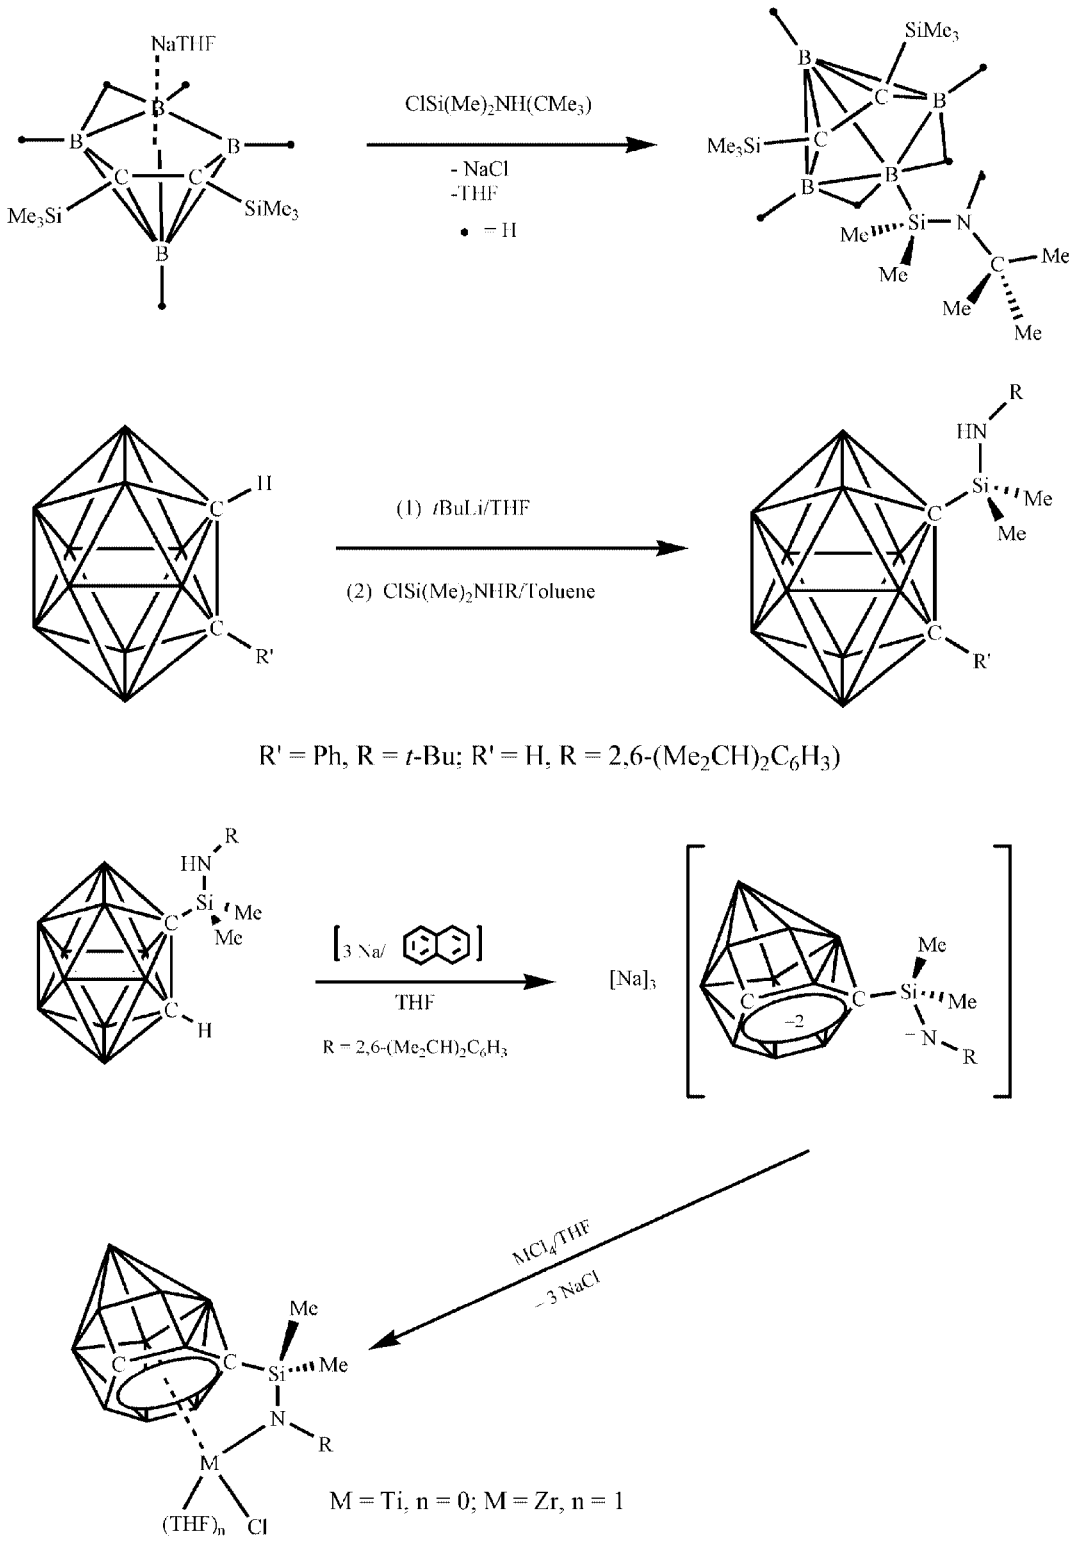

Scheme 7. Syntheses, cage-opening and concomitant metalation of the $B_{(cage)}$- and $C_{(cage)}$-substituted silylamidocarborane ligands; unlabelled vertices are BH groups

lengths are quite similar to those reported for *closo*-1-(methyl)-2-(phthalimidomethyl)-1,2-$C_2B_{10}H_{10}$.[52] The *exo*-polyhedral $Si(Me)_2NH[2,6\text{-}(Me_2CH)_2C_6H_3]$ group is attached to a cage carbon atom by a standard 2*c*2*e* bond, and the Si−C(02) bond of 1.911(3) Å is longer than the Si−C bonds in $(C_5Me_4SiMe_2NtBu)$Ti(prone-2,4-hexadiene) [1.869(6) Å],[53] and $\eta^5{:}\sigma\text{-}Me_2Si(C_9H_6)\text{-}\eta^6\text{-}(C_2B_{10}H_{10}\text{-}CH_2NMe)Zr(NC_5H_5)]$ [1.861(6) Å].[54] The four groups on

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the silicon atom are in a distorted tetrahedral arrangement, with X−Si−Y angles ranging from 103.53° for N−Si−C(02) to 114° for N−Si−C(03/04). The most interesting aspect of this structure is the large C(1)−N−Si angle of 125.5(2)°.[51] This is probably due to repulsion between the Si−Me groups and the large diisopropylphenyl moiety. Such an angle indicates that the lone pair on the nitrogen atom would not be particularly available for bonding. However, from its conversion to the corresponding half-sandwich neutral d^0-metallacarborane, *closo*-1-M[(Cl)(THF)$_n$]-2-{1′-η^1,σ-N[2,6-$(Me_2CH)_2C_6H_3$](Me)$_2$Si}-2,4-η^6-$C_2B_{10}H_{11}$ (M = Ti, n = 0; M = Zr, n = 1), it seems that η^1-coordination of the N atom is possible after removal of its H atom to form the amido group.

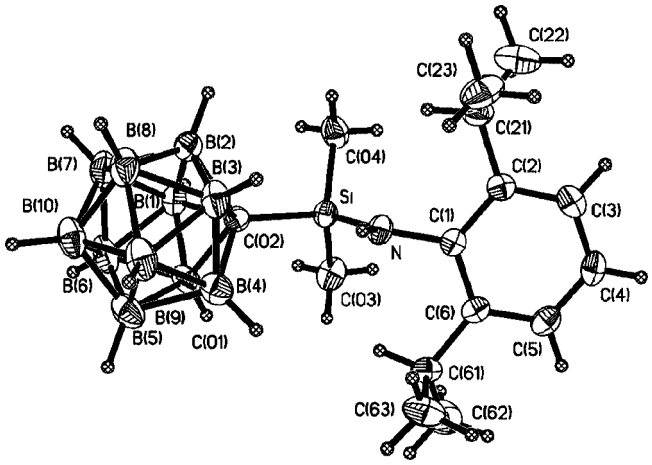

Figure 4. Crystal structure of the *ansa*-carborane ligand, *closo*-2-[Si(Me)$_2$NH{2,6-$(Me_2CH)_2C_6H_3$}]-1,2-$C_2B_{10}H_{11}$

5. Novel Synthetic Approach to Heavier Group-2 Metallacarboranes

The reaction of tetrakis(tetrahydrofuran)barium bis[tris(trimethylsilylmethyl)zincate] with 2,3-bis(trimethylsilyl)-2,3-dicarba-*nido*-hexaborane in THF yielded nearly quantitatively the bis(carborane)barium complex (Scheme 8).[55]

Only one of the trimethylsilylmethyl groups of the zincate is active in this metalation. The formed bis(trimethylsilylmethyl)zinc neither reacts with the carborane nor with the bis(carborane)barium complex. Each barium atom in the dimeric complex shows a coordination number of nine (Figure 5).[55]

The Ba−O bond lengths (ca. 2.74 Å) lie in the expected range. Furthermore, two carborane ligands are bonded via hydride bridges with Ba−H distances of approximately 2.90 Å, which were refined isotropically and can be interpreted as Ba−H−B three-center bonds. A third carborane ligand is coordinated with Ba−C distances of 3.16 Å and a bridging hydrogen atom [Ba1−H356 = 2.93(4) Å]. This corre-

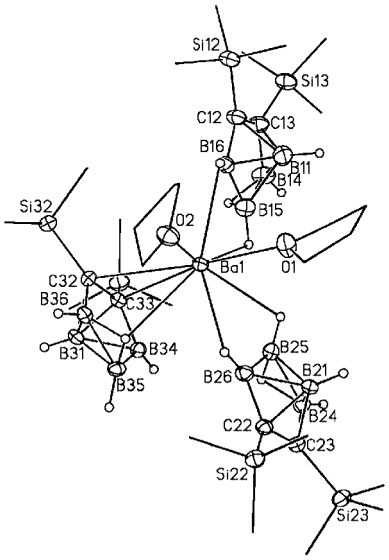

Figure 5. Crystal structure of a baracarborane complex

sponds to a four-center $BaHB_2$ bond. In the highly ionic solvated $Ba(BH_4)_2$ the boranate anions coordinate via three H atoms to the alkaline earth metal atom, thus forming three-center Ba−H−B bonds.[56] The Ba−C distances are similar to those of barium bis[tris(trimethylsilylmethyl)zincates][57] where bridging trimethylsilylmethyl moieties between barium and zinc atoms were found. The Ba−C distances of substituted barocenes vary between 2.90 and 3.00 Å.[58] This coordination of the carborane to the barium center is quite different from that of (carborane)magnesium and -calcium complexes.[31,59−61] In the magnesacarborane complex the metal center bonds to the hydride substituents but not to the carbon atoms. With the doubly deprotonated carborane ligands the metal centers show shorter contacts to the boron atoms than to the carbon atoms. The barium complex has very long Ba−B bonds due to the coordination geometry about the metal center. Nevertheless, this baracarborane was the first example of the heaviest group-2 metallacarborane. Similarly, the corresponding calca- and strontacarboranes have been synthesized and structurally characterized.[62]

Conclusions

Our recent work on carborane chemistry has concentrated on developing synthetic routes to new carborane ligands in both large and small cage systems. The aim is to establish general procedures for the systematic production of specific metallacarboranes that have potentially useful and interesting properties. We have also developed synthetic routes to precursor boranes that might otherwise be unavailable. Such routes invite chemists to explore the properties of these fascinating molecules.

Self-Assembly and Characterisation of Grid-Type Iron(II), Cobalt(II) and Zinc(II) Complexes

Violetta Patroniak,[a,b] Paul N. W. Baxter,[a,d] Jean-Marie Lehn,*[a] Maciej Kubicki,[b] Maija Nissinen,[c] and Kari Rissanen[c]

Keywords: Grid-type complexes / Iron / Cobalt / Zinc / Supramolecular chemistry / Self-assembly

The reaction of the ligands **5** and **6**, containing two tridentate binding units, with iron(II), cobalt(II) and zinc(II) leads to the self-assembly of supramolecular architectures of [2 × 2] grid type containing four ions in octahedral coordination sites. The grid-type structures have been assigned on the basis of the spectroscopic data in solution, and confirmed in the solid state in the case of complexes **6b** and **6c** by X-ray crystallography. The latter study revealed that each metal ion is situated in a distorted octahedral coordination environment comprising two N,N,O ligand donor sets.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Self-assembly has been defined as the spontaneous but directed formation of a closed superstructure or polymer from a mixture of components (organic ligands, salt crystals, and sometimes molecules of solvents).[1] The product exhibits a notable thermodynamic and kinetic stability and its components should contain all the information necessary for a correct assembly to occur. Self-assembly has recently been achieved in many types of organic and inorganic systems.[2] Inorganic self-assembly involves the spontaneous generation of well-defined metallo-supramolecular architectures from mixtures of organic ligands and metal ions. This latter approach has proven particularly successful for the generation of a wide spectrum of architectural types such as, for example, inorganic double and triple helicates,[1,3] rotaxanes,[4] clusters,[5] racks,[6] cages,[7] grids[8] etc., based on ligand design and on the application of suitable coordination geometries for the assembly process. Among them, there is an increasing interest in grid-shaped complexes, based on ligands containing oligopyridine-type groups and various transition metal ions. The grids are the thermodynamically most stable motif when metal ions of octahedral coordination geometry are combined with a linear ligand containing two tridentate binding subunits. Such compounds may exhibit novel physical (electronic,[8a] magnetic[8g−8i]) and chemical properties with potential applications in supramolecular engineering, nanotechnology, biomedical inorganic chemistry or biological catalysis. Transistors incorporating complexes containing a cobalt ion bonded to polypyridyl ligands have been reported recently, and this development is expected to be important in molecular electronics and in the study of the physics of nanoscale systems.[9]

In this paper we describe the syntheses, structural characterisation and luminescence properties of some polynuclear metal complexes prepared from hexadentate ligands **5** and **6** containing pyridine, pyrimidine, and carbonyl donor groups. The syntheses of the new ligands and their precursors have been achieved in good overall yield. The coordination chemical investigations of **5** and **6** with metal ions of preferred octahedral coordination geometry, such as Fe^{II}, Co^{II} and Zn^{II} revealed that the ligands are correctly preorganised for the assembly of tetranuclear grid-type complexes.

Results and Discussion

Synthesis of Ligands 5 and 6

We have designed heterotopic ligands **5** and **6**, which each possess two unusual N,N,O tridentate binding subunits for the complexation of ions of octahedral coordination geometry. Ligands **5** and **6** comprise heterocyclic pyrimidine and pyridine units synthesised as outlined in Scheme 1.

2-Methyl-6-(trimethylstannyl)pyridine **(1)** was obtained from 2-bromo-6-methylpyridine by a halogen/lithium ex-

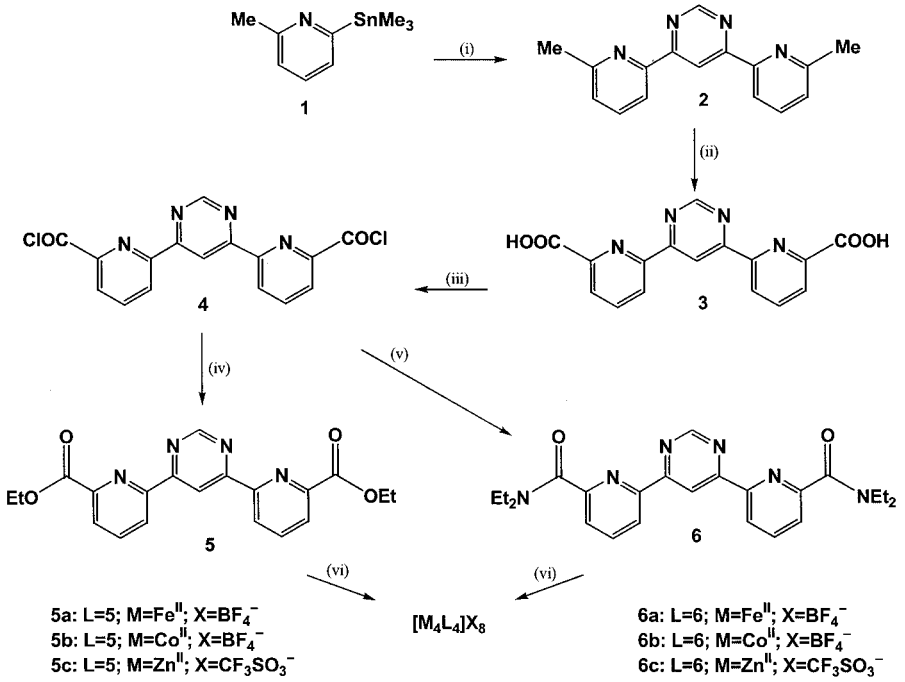

Scheme 1. Reaction scheme for the synthesis of the [2 × 2] grid complexes **5a**−**c** and **6a**−**c**. i) 4,6-dichloropyrimidine, LiCl, $Pd(PPh_3)_4$, toluene (90%), ii) H_2SO_4, CrO_3 (81%), iii) $SOCl_2$, iv) EtOH, (88%), v) Et_2NH, THF (38%), vi) $Fe(BF_4)_2$, $Co(BF_4)_2$ or $Zn(CF_3SO_3)_2$, CH_3CN

change protocol at low temperature in THF with *n*-butyllithium, followed by quenching the pyridyllithium intermediate with $ClSnMe_3$.[10] The twofold Stille-type[11] coupling reaction of **1** with 4,6-dichloropyrimidine in toluene using $[Pd(PPh_3)_4]$ as a catalyst furnished **2** in 90% yield after workup. The methyl groups of **2** were further oxidized with CrO_3 in concentrated H_2SO_4 to afford diacid **3** in 81% yield. The acid is insoluble in most organic solvents and only slightly soluble in DMSO. Precursor **3** was converted into the diacid dichloride **4** upon refluxing in $SOCl_2$. The diacid dichloride **4** was used subsequently in further transformations without purification. Thus, when **4** was refluxed with EtOH or stirred with Et_2NH in THF ligands **5** and **6** were obtained in 88% and 38% yields, respectively, after purification. The structures of **5**, **6** and precursors were confirmed by NMR spectroscopy, FAB-MS and elemental analysis. Ligands **5** and **6** were also structurally characterised by X-ray crystallography (Figure 1 and 2).

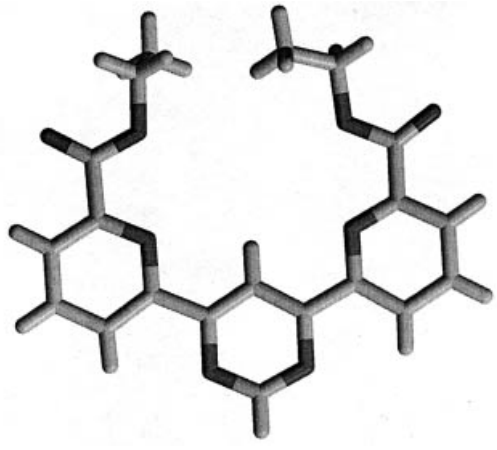

Figure 1. Single-crystal X-ray structure of ligand **5**

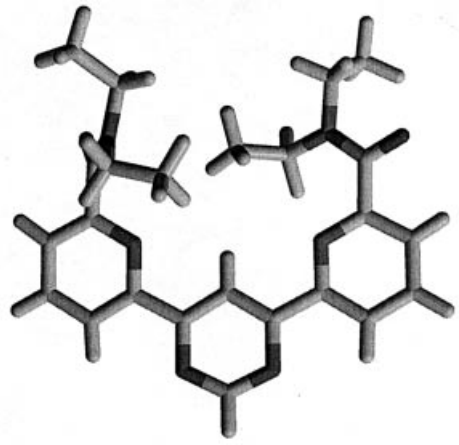

Figure 2. Single-crystal X-ray structure of ligand **6**

Both **5** and **6** exist in the solid state as *transoid* conformers (Figure 1 and 2) for N−C−C−N torsion angles (Table 1). This conformation is energetically favoured, as shown in earlier work.[12] It presents C−H···N intramolecular hydrogen bond interactions for further stabilisation (Table 2). However, in the metal complexes presented below the ligands exist in a *cisoid* conformation in which the terminal carbonyl oxygens form chelating coordination bonds with metal ions.

	5A	5B	6
N1−C6−C7−N8	−178.9(5)	177.8(5)	−178.4(2)
N3−C4−C13−N14	177.6(5)	−179.9(5)	−169.7(2)
N14−C15−C19−O20	175.3(7)	178.0(6)	−119.5(2)
N8−C9−C24−O25	−172.8(6)	−172.6(7)	
N8−C9−C26−O27			−151.3(2)
C19−O21−C22−C23	159.9(7)	−98.0(7)	
C24−O26−C27−C28	97.6(7)	−162.3(6)	

The aromatic rings of **5** and **6** are essentially planar, with a maximal deviation from the least-squares plane of 0.022(3) Å. In **5** the dihedral angles between the aromatic ring planes are small [up to 5(1)°], and the ester COO fragments are almost coplanar with the ring plane. The carbonyl oxygen atoms are *trans* with respect to the nitrogen atoms of the neighbouring pyridine rings, suggesting that weak intramolecular C−H···O=C interactions stabilise this conformation (in a carboxylate group the carbonyl oxygen atom is a better hydrogen bond acceptor than the ester one). In both symmetry-independent molecules the ethoxy fragments on either side of the molecule are differently oriented. This is probably a result of steric interactions between the ethyl groups within the bay region of the molecule. In one of the ethyl groups, the terminal C−C bond is almost coplanar with the main plane of the molecule, while in the other it is almost perpendicular (Figure 1, Table 1).

In **6** the amide groups are essentially planar, but they are more twisted with respect to the respective pyridine ring planes. The twist angles are as large as 58.2(5)° — this may be caused by the steric requirements of four relatively bulky CH_2CH_3 groups. Interestingly, even in this case the carbonyl oxygen atoms are in a *pseudo-trans* orientation with respect to the pyridine nitrogen atom (Table 1). The steric stress is transferred to some extent to the central part of the molecule, and therefore the dihedral angles between the aromatic ring planes are in this case much larger than in **5**, up to 12.02(14)°. The space between the oxygen atoms in the *transoid* conformation of ligand **6** is 8.58 Å.

The bond lengths and angles are unexceptional, and similar in both compounds. The differences between the intraannular bond angles in the terminal pyridine rings can be attributed to the presence of the different substituents.[13] The intraannular angles show a difference between C−C−C and N−C−C angles, the former being about 5°

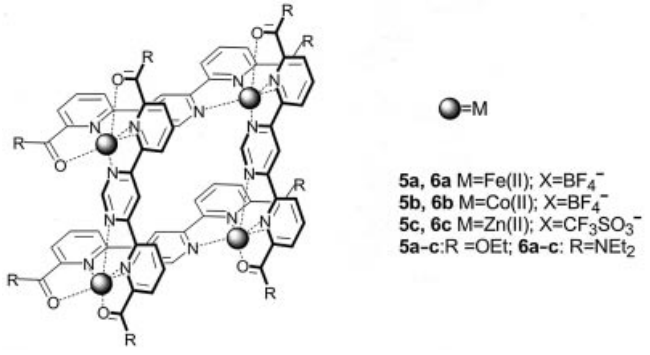
greater than the latter; similar differences have been observed in related compounds.[14]

The crystal packing is governed by van der Waals interactions, weak intermolecular C−H···O(N) interactions (Table 2) and, to some extent, by the π-stacking between the heterocyclic rings.

Synthesis and Characterisation of the Complexes

Multitopic ligands with N,N,O(carbonyl) type donor sets have only infrequently been employed in the metal ion directed assembly of coordination architectures. However, such ligands have been successfully demonstrated to form helicate complexes, in particular with lanthanide metal ions.[3a] The reason for the propensity of the N,N,O (carbonyl) donor set to bind to lanthanides presumably originates from the strong hard-hard, oxygen-lanthanide(III) interaction. The following account describes the successful utilisation of ligands of this type (**5** and **6**) for the generation of [2 × 2] grid architectures with certain first row transition metal ions. Specifically, the syntheses of the new [2 × 2] grid-type complexes **5a**−**c** and **6a**−**c** were performed by reaction of **5** and **6** with iron(II), cobalt(II) and zinc(II) salts (Scheme 2).



Scheme 2. Schematic representation of the self-assembly of the [2 × 2] grids

The self-assembly of [2 × 2] grid-type compounds was achieved by reaction at room temperature or under reflux in acetonitrile, using the triflate or tetrafluoroborate salt of the corresponding metal ion. The complexation reactions were followed by ESI-MS and NMR spectroscopy. The ^{1}H NMR spectra of the paramagnetic complexes (**5a**, **5b**, **6a**, and **6b**) show strongly shifted signals, as expected, and are strongly supportive of the grid-type structures. In the case of the iron complexes **5a** and **6a**, signals are observed between δ = 88.25 and 1.42 ppm, and δ = 90.96 and −7.79 ppm, respectively, indicating the presence of high-spin iron centres, similar to related grid structures with N,N,N donor sets reported earlier.[15] For the cobalt complexes **5b** and **6b** the signals were found to be shifted to an even greater extent, lying between δ = 130.27 and 1.40 ppm and between δ = 114.33 and −15.23 ppm, respectively. The ^{1}H NMR spectra of the diamagnetic zinc complexes **5c** and **6c** show the signals of a symmetrically coordinated ligand in a single chemical and magnetic environment, in agreement with the grid structure. Interestingly, significant coordination-induced shifts of the signals are observed when the spectra of **5c** and **6c** are compared to those of uncomplexed ligands **5** and **6**.

ESI-MS is a highly sensitive and accurate analytical tool widely used for the characterisation of large, charged biomolecules such as proteins and DNA. The technique has also been found to be particularly successful for the identification of large metallosupramolecular architectures in solution, in which multiply charged ions are generated by sequential loss of counterions, resulting in characteristic isotopic patterns in the spectrum. The ESI-MS investigations of all complexes were performed on acetonitrile solutions at approximately 10^{-4} M. For example, the ESI mass spectrum of **5c** shows peaks corresponding to the multiply charged species: *m/z* = 839.2 (5%, $\{[Zn_4(\mathbf{5})_4](CF_3SO_3)_5\}^{3+}$), 591.0 (100%, $\{[Zn_4(\mathbf{5})_4](CF_3SO_3)_4\}^{4+}$) and 345.2 (5%, $\{[Zn_4(\mathbf{5})_4](CF_3SO_3)_2\}^{6+}$. These data confirm the presence of the grid **5c** in solution. At higher dilutions, significant dissociation of the grid complexes to mononuclear species was found to occur.

The UV/Visible spectrum of complex **6c** in acetonitrile shows an absorption band at around 300 nm. Complex **6c** also affords an intense emission at 372 nm upon excitation at 270 nm at room temperature (Figure 3). The luminescence of this complex may be attributed to emission from the lowest ligand-centred excited singlet level. The absence of emission for the cobalt complex **6b** is due to the presence of the low-lying nonemissive Co^{II}-centred MLCT excited state which inhibits luminescence.[16]

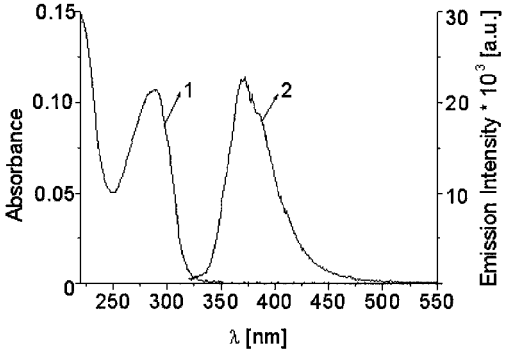


Figure 3. Absorption (1) and emission (2) spectra of $Zn_4L_4(OTf)_8$ complex **6c** at 1×10^{-5} mol/dm^{-3} in CH_3CN solution (λ_{exc} = 270 nm, λ_{em} = 372 nm)

Crystallographic Characterisation of Grid Complexes 6b and 6c

Complexes **6b** and **6c** were crystallographically characterised by X-ray diffraction. The results unambiguously demonstrated the [2 × 2] tetranuclear grid-type structure of the complexes in which the metal ions are hexacoordinated by four nitrogen atoms and the remaining outer positions by oxygen atoms of the carbonyl groups.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Crystal Data for Complex 6b

Crystals of complex **6b** were obtained by diffusion of benzene into a solution of the complex in acetonitrile and its structure was determined by X-ray crystallography (Figure 4 and Table 3). The architecture of this grid is similar to that of the structures of similar compounds.[15,16] The complex **6b** crystallises with two cations per unit cell. The size of this grid is within nanoscopic dimensions, as the intraligand methyl-methyl and pyridine H4-pyridine H4 distances are respectively 15.9−17.9 Å (width) and 9.2−9.4 Å (height). The ligands in the grid are not totally planar but somewhat distorted. The distortion angle varies from 4.4° to 14.5°. There are two anions partially encapsulated inside the cavity of the grid. The size of the cavity is between 6.39 and 6.75 Å. In addition, each anion inside the cavity is surrounded by two molecules of acetonitrile. These molecules of solvent are sandwiched between opposite pyridine moieties. The rest of the anions are positioned between adjacent grids in a layer-like fashion. A limited degree of van der Waals contact between aromatic groups and ethyl chains of adjacent grids is also observed. The Co^{II} ions are situated in a distorted octahedral coordination polyhedron and the Co−Co distances are in the range 6.328−6.395 Å. The Co−N and Co−O bond lengths lie between 2.033 and 2.200 Å and 2.068 and 2.135 Å, respectively.

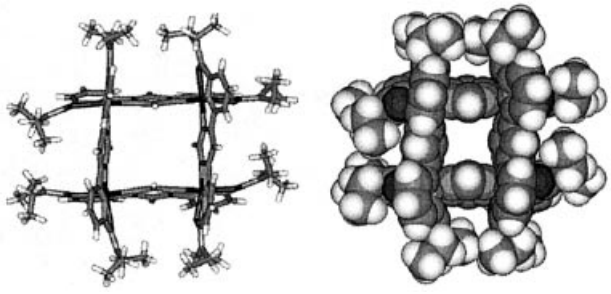

Figure 4. Crystal structure of [2 × 2] grid-type complex **6b**; counterions and solvent molecules are omitted for clarity

Table 3. Selected averaged bond lengths [Å] and angles [°] for complex **6b** (each of the two molecules in the asymmetric unit are presented) and for complex **6c**

Bond/angle[a]	6b	6c

$N_{eq}-M-N_{eq}$	95.5 95.9	101.3
O−M−O	100.6 102.2	97.2

[a] M = Co^{II} in **6b** and Zn^{II} in **6c**. ax = M−N bonds to the pyridine moiety, eq = M−N bonds to the pyrimidine moiety.

Crystal Data for Complex 6c

Crystals of complex **6c** were obtained by diffusion of *tert*-butyl methyl ether into a solution of the complex in acetonitrile and its structure was determined by X-ray crystallography (Figure 5 and Table 3). The Zn^{II} ions in complex **6c** also display a distorted octahedral coordination. The Zn−Zn distances are in the range 6.255−6.390 Å. The lengths of the coordinative Zn−N bonds vary from 2.052 to 2.199 Å and the Zn−O bond lengths lie between 2.134 and 2.188 Å. Two CF_3SO_3 ions are partially encapsulated in the cavity of this grid.

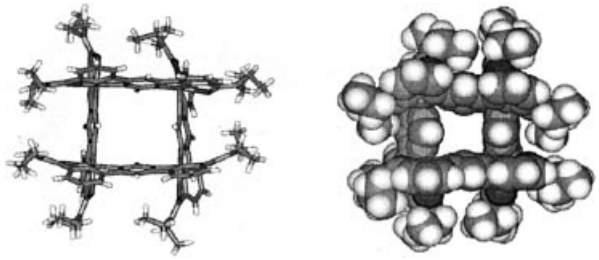

Figure 5. Crystal structure of [2 × 2] grid-type complex **6c**; counterions and solvent molecules are omitted for clarity

Conclusion

The two novel ligands **5** and **6** containing two tridentate N,N,O(carbonyl) binding subunits, have been prepared and their solid-state conformational properties characterised by X-ray crystallography. Reaction of **5** and **6** with Fe^{II}, Co^{II} and Zn^{II} resulted in the clean and quantitative formation of [2 × 2] grid-type complexes, which were characterised in solution on the basis of ESI-MS and ^1H NMR spectroscopy. The structures of the Zn^{II} and Co^{II} complexes **6b** and **6c** were also investigated by X-ray crystallography which confirmed that they were indeed [2 × 2] grid-type architectures with each metal ion octahedrally coordinated by two N,N,O donors. The above work therefore details a particularly facile and rapid synthetic protocol for the preparation of [2 × 2] grid-type coordination scaffolds with first row transition metal ions. Of particular significance is the fact that the N,N,O(carbonyl) donor set approach should enable a wide range of substituents to be externally connected onto the outer surface of the grid. Such substituents may for example be electroactive or mesogenic, or may enable attachment of the complex to gold or graphite surfaces. Many potential future applications may be envisioned for materials of this type, for example, as functional components of molecular electronic devices. These and related avenues of exploration will be reported in due course.

Experimental Section

General: CH_3CN was freshly distilled under argon from CaH_2. 2-Methyl-6-(trimethylstannyl)pyridine (**1**) was prepared according to a literature procedure.[10] The reagents were used as received from Aldrich or Acros without further purification. The NMR spectra were run on a Bruker AC 200 at 200.1 MHz, a Varian Gemini 300, and 500 MHz spectrometer, and were calibrated against residual protonated solvent signal ($CDCl_3$: δ = 7.24 ppm; $[D_6]$DMSO: δ = 2.50 ppm; CD_3CN: δ = 1.94 ppm). Mass spectra were determined by FAB^+ using a ZAB-HF VG apparatus in a *m*-nitrobenzyl alcohol matrix and by ESI-MS using a Waters Micromass ZQ spec-

trometer in acetonitrile. IR spectra were obtained with a Perkin−Elmer 580 spectrophotometer and are reported in cm^{-1}. The electronic absorption spectrum of **6c** was measured on a Shimadzu UV 2401 PC spectrometer in acetonitrile, with λ_{max} in nm and ε ($\times 10^4$) in $M^{-1}cm^{-1}$. The luminescence spectrum for complex **6c** was recorded in CH_3CN using a Perkin−Elmer MPF-3 spectrofluorimeter. Microanalyses were obtained using a Perkin−Elmer 2400 CHN microanalyzer. Melting points were recorded on an Electrothermal Digital melting point apparatus.

4,6-Bis[6-(2-methylpyridyl)]pyrimidine (2): 2-Methyl-6-(trimethylstannyl)pyridine (**1**; 5 g, 20 mmol) and degassed toluene (45 mL) were added consecutively by syringe to a mixture of 4,6-dichloropyrimidine (0.9818 g, 6 mmol), $Pd(PPh_3)_4$ (0.27 g, 0.9 mmol) and LiCl (1.7 g, 29 mmol) under an argon atmosphere. The reaction was refluxed and stirred at 120 °C for 24 h, and the toluene was then evaporated on a water bath under reduced pressure. The residue was purified by column chromatography on alumina, eluting with dichloromethane, to afford 1.547 g (90%) **2**. ^1H NMR (400 MHz, $CDCl_3$): δ = 9.32 (s, 1 H, H2), 9.30 (s, 1 H, H5), 8.26 (d′, *J* = 5.49 Hz, 2 H, H5′, -5′), 7.75 (t, *J* = 5.95 Hz, 2 H, H4′, -4′′), 7.28 (d, *J* = 5.19 Hz, 2 H, H3′, -3′′), 2.75 (s, CH_3) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 164.07, 158.46, 158.34, 153.49, 136.98, 124.78, 118.77, 113.85, 24.70 ppm. FAB-MS: *m*/*z* (%) = 263.0 (100) [**2** + H]. IR (KBr): ṽ = 3408, 2917, 1597, 1571, 1530, 1448, 1379, 1228, 1158, 1090, 989, 904, 808, 771, 640, 438 cm^{-1}. $C_{16}H_{14}N_4$ (262.31): calcd. C 73.26, H 5.38, N 21.36; found C 73.04, H 5.46, N 21.24. M.p. 126−128 °C.

2,2′-Bis(4,6-pyrimidinediyl)pyridine-6,6′-dicarboxylic Acid (3): Product **2** (0.35 g, 1.3 mmol) was added to concentrated H_2SO_4 (10 mL) and cooled to 0 °C with stirring in an ice-bath. Chromium(VI) oxide (0.80 g, 8 mmol) was then added in 0.1 g portions to the stirred solution of **2** at a rate that maintained the reaction temperature below 3 °C. When the addition of CrO_3 was completed (about 5 h) the mixture was stirred for 9 hours at 0−5 °C, and 42 hours at room temperature. The viscous reaction solution was then poured onto excess crushed ice with stirring. The precipitated product was finally isolated by filtration under reduced pressure, washed with distilled water and air dried to yield 0.348 g (81%) of **3**. ^1H NMR (200 MHz, DMSO): δ = 9.50 (s, 1 H, H2), 9.35 (s, 1 H, H5), 8.72 (t′, *J* = 4.75 Hz, 2 H, H4′, -4′), 8.27 (d, *J* = 4.57 Hz, 4 H, H3′, -3′′, -5′, -5′′) ppm. IR (KBr): ṽ = 3411, 2926, 1746, 1646, 1581, 1533, 1452, 1367, 1252, 1168, 1086, 995, 905, 838, 752, 636, 607, 471, 427 cm^{-1}. $C_{16}H_{10}N_4O_4{\cdot}2H_2O$ (358.31): calcd. C 53.63, H 3.91, N 15.64; found C 53.25, H 3.70, N 15.03. M.p. 253 °C

2,2′-Bis(4,6-pyrimidinediyl)pyridine-6,6′-dicarboxylic Acid Chloride (4): Compound **3** (0.133 g, 0.4 mmol) was refluxed for 5 h in thionyl chloride (20 mL) and then the $SOCl_2$ evaporated under reduced pressure on a water bath. The crude **4** was then used immediately for the subsequent synthesis of diester **5** and diamide **6** without further purification.

Diethyl 2,2′-Bis(4,6-pyrimidinediyl)pyridine-6,6′-dicarboxylate (5): EtOH (20 mL) was added to **4** (0.148 g, 0.41 mmol) and the resulting mixture refluxed for 15 h and subsequently cooled to room temperature. The reaction was then reduced in volume to 8 mL under pressure on a water bath, and the mixture cooled in an ice-bath. The crystalline solid was isolated by filtration under vacuum, washed with a small quantity of ice-cold EtOH and air dried to yield 0.138 g (88%) **5** as white needles. ^1H NMR (300 MHz, $CDCl_3$): δ = 9.51 (s, 1 H, H2), 9.38 (s, 1 H, H5), 8.70 (d, *J* = 8.1 Hz, 2 H, H5′, -5′′), 8.24 (d, *J* = 7.8 Hz, 2 H, H3′, -3′′), 8.05 (t, *J* = 7.8 Hz, 2 H, H4, -4′), 4.52 (q, *J* = 6.9 Hz, 4 H, CH_2), 1.51 (t, *J* = 7.2 Hz, 6 H, CH_3) ppm. ^{13}C NMR (DEPT, 75 MHz, $CDCl_3$): δ = 165.16, 163.57, 158.55 (CH), 154.51, 148.70, 138.09 (CH), 126.40 (CH), 124.84 (CH), 115.05 (CH), 61.95 (CH_2), 14.29 (CH_3) ppm. FAB-MS: *m*/*z* (%) = 379.4 (100) [**5** + H]. IR (KBr): ṽ = 3410, 2982, 1715, 1646, 1575, 1529, 1447, 1318, 1259, 1150, 1083, 992, 919, 838, 756, 701, 636, 471, 433 cm^{-1}. $C_{20}H_{18}N_4O_4$ (378.39): calcd. C 63.49, H 4.79, N 14.81; found C 63.17, H 4.82, N 14.44. M.p. 162 °C.

2,2′-Bis(4,6-pyrimidinediyl)pyridine-6,6′-diethyl Diamide (6): Anhydrous THF (5 mL), and a solution of Et_2NH (10 mL) in anhydrous THF (50 mL) were added consecutively by syringe to **4** (0.2592 g, 0.72 mmol) under an atmosphere of argon. The resulting mixture (pale brown suspended solid) was then stirred for 20 h at ambient temperature, and filtered under gravity. The filtrate was evaporated to dryness and the remaining solid dissolved in boiling *n*-hexane (100 mL), filtered under gravity, and left to stand overnight. The crystalline solid which formed was isolated by filtration under vacuum, washed with ice-cold hexane and air dried to yield 0.118 g (38%) **6** as white needles. ^1H NMR (300 MHz, $CDCl_3$): δ = 9.37 (s, 2 H, H2, H5), 8.58 (d, *J* = 7.8 Hz, 2 H, H5′, -5′′), 8.00 (t′, *J* = 7.8 Hz, 2 H, H4′, -4′), 7.79 (d′, *J* = 7.8 Hz, 2 H, H3′, -3′), 3.62 (q, *J* = 7.2 Hz, 4 H, CH_2), 3.47 (q, *J* = 7.2 Hz, 4 H, CH_2), 1.33 (t, *J* = 6.9 Hz, 6 H, CH_3), 1.29 (t, *J* = 7.2 Hz, 6 H, CH_3) ppm. ^{13}C NMR (DEPT, 75 MHz, $CDCl_3$): δ = 167.70, 163.42, 158.36 (CH), 154.83, 152.42, 137.60 (CH), 125.05 (CH), 122.04 (CH), 113.93 (CH), 43.48 (CH_2), 40.52 (CH_2), 14.69 (CH_3), 13.01 (CH_3) ppm. FAB-MS: *m*/*z* (%) = 433.2 (100) [**6** + H]. IR (KBr): ṽ = 3412, 2975, 1636, 1569, 1477, 1443, 1377, 1316, 1117, 1080, 993, 827, 756, 636, 608, 472, 409 cm^{-1}. $C_{24}H_{28}N_6O_2$ (432.53): calcd. C 66.58, H 6.52, N 19.43; found C 66.39, H 6.42, N 18.50. M.p. 123 °C.

Fe Complex (5a): An equimolar mixture of $Fe(BF_4)_2{\cdot}6H_2O$ (9.8 mg, 29 μmol) and ligand **5** (11.0 mg, 29 μmol) in MeCN (5 mL) was stirred at room temperature for 10 h. The solvent was evaporated under reduced pressure to give a quantitative yield of **5a** as a blue powder. ^1H NMR (300 MHz, CD_3CN): δ = 88.25, 64.59, 34.53, 31.15, 9.36 (d), 8.75, 8.75, 8.27, 4.47, 3.75, 2.57, 1.42 ppm. IR (KBr): ṽ = 3349, 2991, 1635, 1577, 1533, 1444, 1381, 1247, 1219, 1033, 929, 875, 795, 755, 703, 657, 581, 417 cm^{-1}. $Fe_4(\mathbf{5})_4(BF_4)_8$ (2469.34): calcd. C 38.91, H 2.44, N 9.08; found C 39.21, H 2.53, N 9.78.

Co Complex (5b): A solution of ligand **5** (10.0 mg, 26 μmol) and $Co(BF_4)_2{\cdot}6H_2O$ (9.0 mg, 26 μmol) in MeCN (5 mL) was heated under reflux for 10 h. The red complex **5b** was isolated in quantitative yield by evaporation of the solvent. ESI-MS: *m*/*z* = 1135 $\{[Co_4(\mathbf{5})_4](BF_4)_6\}^{2+}$, 218 $\{[Co_4(\mathbf{5})_4]\}^{8+}$. ^1H NMR (300 MHz, CD_3CN): δ = 130.27, 100.79, 97.26, 87.88, 72.57, 68.41, 62.20, 34.07, 14.48, 11.42, 9.49 (d), 8.75, 8.27, 8.04, 6.56, 5.98, 4.45, 3.56, 2.95, 1.76, 1.42, 1.40 ppm. IR (KBr): ṽ = 3371, 3084, 1613, 1573, 1531, 1442, 1385, 1265, 1212, 1158, 1034, 928, 878, 794, 759, 701, 672, 657, 587, 444 cm^{-1}. $Co_4(\mathbf{5})_4(BF_4)_8$ (2481.69): calcd. C 38.72, H 2.92, N 9.03; found C 39.07, H 2.98, N 9.65.

Zn Complex (5c): An equimolar mixture of $Zn(CF_3SO_3)_2$ (9.6 mg, 26 μmol) and ligand **5** (10.0 mg, 26 μmol) in MeCN (5 mL) was stirred at room temperature for 22 h. The solvent was evaporated under reduced pressure to yield the dark yellow complex **5c** in quantitative yield. ESI-MS: *m*/*z* = 839.2 $\{[Zn_4(\mathbf{5})_4](CF_3SO_3)_5\}^{3+}$, 591.0 $\{[Zn_4(\mathbf{5})_4](CF_3SO_3)_4\}^{4+}$, 345.2 $\{[Zn_4(\mathbf{5})_4](CF_3SO_3)_2\}^{6+}$. ^1H NMR (300 MHz, CD_3CN): δ = 9.71 (s), 9.57 (d), 9.36 (s), 8.70 (d), 8.33 (t), 4.50 (m), 1.71 (t, *J* = 5.1 Hz) ppm. IR (KBr): ṽ = 3452, 3095, 1724, 1693, 1620, 1582, 1538, 1475, 1452, 1404, 1381, 1342, 1263, 1163, 1100, 1031, 857, 840, 758, 723, 704, 638, 574, 518, 446,

405 cm^{-1}. $Zn_4(\mathbf{5})_4(CF_3SO_3)_8$ (2967.65): calcd. C 35.62, H 2.45, N 7.55; found C 36.12, H 2.44, N 7.07.

Fe Complex (6a): An equimolar mixture of $Fe(BF_4)_2{\cdot}6H_2O$ (5.5 mg, 16 μmol) and ligand **6** (7.1 mg, 16 μmol) in MeCN (4 mL) was stirred at room temperature for 16 h. The solvent was evaporated under reduced pressure to give a quantitative yield of **6a** as a blue powder. ESI-MS: *m*/*z* = 1236.9 $\{[Fe_4(\mathbf{6})_4](BF_4)_6\}^{2+}$, 291.1 $\{[Fe_4(\mathbf{6})_4](BF_4)\}^{7+}$. ^{1}H NMR (200 MHz, CD_3CN): δ = 90.96, 87.54, 74.31, 63.69, 48.69, 32.52, 29.96, 27.64, 18.19, 16.91, 14.04, 12.03, 9.89, 7.64, 5.32, 3.98, 0.07, −4.80, −5.54, −7.79 ppm. IR (KBr): $\tilde{\nu}$ = 3403, 2926, 2854, 1632, 1570, 1530, 1485, 1447, 1379, 1363, 1299, 1259, 1221, 1182, 1120, 1084, 1071, 1042, 993, 827, 810, 756, 640, 574, 533, 522 cm^{-1}. $Fe_4(\mathbf{6})_4(BF_4)_8$ (2647.89): calcd. C 43.55, H 4.26, N 12.70; found C 40.36, H 4.03, N 12.53.

Co Complex (6b): A solution of ligand **6** (14.8 mg, 34 μmol) and $Co(BF_4)_2{\cdot}6H_2O$ (11.7 mg, 34μmol) in MeCN (7 mL) was heated under reflux for 19 h. The red complex **6b** was isolated in quantitative yield upon evaporation of the solvent. ESI-MS: *m*/*z* = 799.9 $\{[Co_4(\mathbf{6})_4](BF_4)_5\}^{3+}$, 578.1 $\{[Co_4(\mathbf{6})_4](BF_4)_4\}^{4+}$, 356 $\{[Co_4(\mathbf{6})_4](BF_4)_2\}^{6+}$. ^{1}H NMR (200 MHz, CD_3CN): δ = 114.33, 71.57, 21.68, 14.66, 10.51, 6.30, 5.45, 4.72, −2.11, −4.31, −10.13, −13.40, −15.23 ppm. IR (KBr): $\tilde{\nu}$ = 3439, 2978, 2931, 1719, 1636, 1609, 1572, 1534, 1485, 1442, 1386, 1363, 1266, 1208, 1083, 1033, 827, 756, 657, 522 cm^{-1}. $Co_4(\mathbf{6})_4(BF_4)_8$ (2660.24): calcd. C 43.34, H 4.24, N 12.64; found C 46.95, H 4.31, N 11.84.

Zn Complex (6c): A solution of ligand **6** (6.2 mg, 14 μmol) and $Zn(CF_3SO_3)_2$ (5.2 mg, 14μmol) in MeCN (3 mL) was stirred at room temperature for 19 h. The pale yellow complex **6c** was isolated in quantitative yield upon evaporation of the solvent. ^{1}H NMR (300 MHz, CD_3CN): δ = 9.70 (s), 9.42(s), 9.23 (d, *J* = 7.8 Hz), 8.68 (t, *J* = 7.8 Hz), 8.29 (d, *J* = 7.8 Hz), 3.48 (q), 3.12 (q, *J* = 6.3 Hz), 1.32 (t, *J* = 6.9 Hz) ppm. IR (KBr): $\tilde{\nu}$ = 3441, 2981, 1613, 1533, 1487, 1461, 1377, 1364, 1279, 1259, 1224, 1159, 1031, 993, 829, 757, 638, 574, 517 cm^{-1}. $Zn_4(\mathbf{6})_4(CF_3SO_3)_8{\cdot}10CH_3CN{\cdot}H_2O$ (3612.72): calcd. C 41.22, H 4.02, N 13.18; found C 44.01, H 4.30, N 12.21. UV/Vis: 298.0 (1.1).

Crystal Structure Determination of Ligands 5 and 6: Colourless crystals of dimensions 0.05 × 0.1 × 0.5 mm (compound **5**) and 0.2 × 0.25 × 0.25 mm (compound **6**) were chosen for X-ray data collection (see also Table 4). For ligand **5**, diffraction data were collected at room temperature by the ω-scan technique up to 2Θ = 40°, on a KUMA KM4CCD four-circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073Å). For ligand **6**, the data collection was performed with KUMA KM4 κ-geometry diffractometer equipped with point detector, using graphite-monochromated Cu-K_α radiation (λ = 1.54178Å) and ω-2θ scan method. All data were corrected for Lorentz-polarisation effects. The structures were solved with direct methods with SHELXS-97[17] and refined by full-matrix least-squares procedures on F^2 with SHELXL-97.[17] All non-hydrogen atoms were refined anisotropically, for **5** hydrogen atoms were located at calculated positions and refined as a ''riding model' with isotropic thermal parameters fixed at 1.2-times the U_{eq}'s of appropriate carrier atom, while for **6** both positional and thermal parameters of hydrogen atoms were refined.

Compound **5** crystallises with two molecules in the asymmetric part of the unit cell. A normal probability plot shows that the differences in geometrical parameters between these two symmetry-independent molecules are of a statistical nature.

Crystal Structure Determination of Complexes 6b and 6c: A summary of crystal data and refinement parameters is given in Table 5. Data were collected on a Nonius Kappa CCD diffractometer at 173.0 ± 0.1 K using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The CCD data were processed with Denzo-SMN v0.95.373.[18] Corrections for Lorentz and polarisation effects were applied. The structures were solved by Patterson method (SHELXS-97)[17] and refined on F^2 by full-matrix least-squares techniques (SHELXL-97).[17] Empirical absorption correction from multiple reflections was performed for both data (Platon for Windows).[19] Scattering factors, corrected for anomalous dispersion, were used as implemented in the refinement program.

The asymmetric unit of complex **6b** contains two of each species. Of 150268 measured reflections in the range 2.10−50.04° in 2θ (and ω scans), 54918 were unique (R_{int} = 0.1215). A red 0.20 × 0.20 × 0.40 mm block-shaped crystal of $2[C_{96}H_{112}Co_4N_{24}O_8]^{8+}\cdot 16BF_4^-\cdot 14.5CH_3CN\cdot 8C_6H_6\cdot H_2O$ was used for data collection. Minimum and maximum transmission factors of 0.758/0.824. All non-hydrogen atoms were refined with anisotropic displacement parameters, except for seven anions, five acetonitriles, a benzene molecule and a water molecule, which were refined isotropically owing to large thermal movement and disorder. Thirteen anions, two acetonitriles, the water molecule and carbon C23H of one of the grids are disordered over two positions. One acetonitrile molecule was refined with population parameter 0.5. A bond restraint in the C−N bond of the disordered part of the grid had to be used to keep the disorder model chemically reasonable. Hydrogen atoms were calculated to their idealised positions with isotropic temperature factors (1.2- or 1.5-times C temperature factor) and refined as riding atoms. No hydrogen atoms were determined for water and one of the disordered acetonitriles. Final agreement factors were obtained for 3865 parameters and one restraint; GOF 1.023. The largest peak and hole in the final difference map were 1.257 and −0.945 e·Å^{-3} and are located near disordered benzene and disordered anion.

A pale yellow 0.20 × 0.30 × 0.30 mm block-shaped crystal of $[C_{96}H_{112}O_8N_{24}Zn_4]^{8+}\cdot 8CF_3SO_3^-\cdot 5CH_3CN\cdot 4C_6H_6\cdot H_2O$ was used for data collection. Of 67176 measured reflections in the range 2.34−50.02° in 2θ (and ω scans), 25963 were unique (R_{int} = 0.0713). Minimum and maximum transmission factors of 0.646/0.710. All non-hydrogen atoms were refined with anisotropic displacement parameters, except for five anions, which were refined partly isotropically owing to large thermal movement and disorder. Two acetonitrile molecules were refined with population parameter 0.5. Five anions and two methyl carbons (C22B and C24) of the grid are disordered over two positions. Temperature factor of disordered methyl C22F was equalised with C22B. Hydrogen atoms were calculated to their idealised positions with isotropic temperature factors (1.2- or 1.5-times C temperature factor) and refined as riding atoms. No hydrogen atoms were determined for water. Final agreement factors were obtained for 1898 parameters; GOF 1.027. The largest peak and hole in the final difference map were 1.330 and −1.100 e·Å^{-3} and are located near one of the disordered anions.

CCDC-205374 (**5**), -205375 (**6**), -205462 (**6b**) and -205463 (**6c**). contain the supplementary crystallographic data for this paper. Novel Complexes of Ligands Containing Phenol and Alcohol Groups: From Polynuclear Cluster, 1D Coordination Polymer to 2D Supramolecular Assemblies

Yongshu Xie,[a] Qingliang Liu,*[a] Hui Jiang,[a] and Jia Ni[a]

Keywords: Copper / Cobalt / Silver / Coordination polymers / N,O ligands

A series of Co^{II}, Cu^{II}, Zn^{II}, Ag^{I} and mixed-valence cobalt complexes **1**–**9** with tridentate and tetradentate chelating ligands containing oxygen-bridging and hydrogen-bonding groups have been synthesized, four of which have been structurally characterized: $[Co_6L^1_6(OH)(H_2O)_3]Cl_2{\cdot}10H_2O$ (**1**) [H_2L^1 = *N*-(2-hydroxybenzyl)ethanolamine] is a hexanuclear $Co^{III}_3Co^{II}_3$ complex, with a core of quadruple face-sharing defective cubane-like units; $[CuNaL^2(ClO_4)]_\infty$ (**3**) [H_2L^2 = *N*,*N*′-bis(2-hyroxybenzyl)ethylenediamine] is a μ_3-phenoxo- and μ_4-perchlorato-bridged 1D heterometallic $Cu^{II}Na^{I}$ coordination polymer; the coordination moieties of $[CuL^3]_4{\cdot}4H_2O$ (**6**) [H_2L^3 = *N*,*N*′-bis(2-hyroxy-5-methylbenzyl)ethylenediamine] form a 2D hydrogen-bonded network structure of monophenoxo-bridged dimeric moieties; and the molecules of $[Ag(H_2L^2)(HL^2)]$ (**9**) are connected to give an undulated 2D structure, consisting of hydrogen-bonded hexagonal units. The variety of these structures is discussed on the basis of the stereoelectronic preferences of the metal atoms, hydrogen bonds, disposition of the bridging groups, steric effect, and conformational flexibility of the ligands. Variable-temperature magnetic properties of **1** and **6** are also reported.

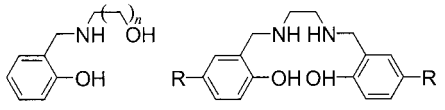
Introduction

Assemblies of polynuclear complexes, coordination polymers and hydrogen-bonded supramolecular coordination networks have potential applications and are aesthetically appealing.[1−3] The assemblies of these frameworks are influenced by factors such as the structures of the ligands and the stereoelectronic preferences of the metal ions.[4] The assembly of metal atoms with chelating ligands containing endogenous bridging atoms is one promising route to unexpected, interesting coordination structures, wherein the most commonly utilized bridging atoms are from carboxylate functionalities.[5] In contrast, chelating ligands containing phenol groups have been much less explored.[6] We demonstrate here the successful construction of various novel coordination architectures, utilizing chelating ligands containing phenol and/or alkoxy groups (H_2L^1 − H_2L^3) (Scheme 1), which have been synthesized by the reduction of the corresponding Schiff bases. The phenol and the alkoxy groups can act as bridging and hydrogen-bonding functionalities. Compared with the corresponding Schiff bases, $H_2L^1-H_2L^3$ have greater flexibility and conformational freedom. In addition, the amino groups, which are absent in the Schiff bases, may also affect the structures of the products via intermolecular hydrogen bonds. Consequently, these ligands may be promising for the construction of novel coordination assemblies, and so we have investigated several of their metal complexes. Our interest in ligands containing phenoxy and alkoxy groups also lie in their relevance to the coordination environments of active sites of metalloenzymes.[7]



Scheme 1. Molecular structures of the ligands (H_2L^1: n = 1, H_2L': n = 2, H_2L^2: R = H, H_2L^3: R = CH_3)

Divalent metals with pseudooctahedral coordination preferences, namely, Co^{II}, Cu^{II} and Zn^{II}, have been used for the synthesis of the complexes. For comparison, the soft metal Ag^{I}, which has a tetrahedral preference, has also been used. Thus, a series of Co^{II}, Cu^{II}, Zn^{II}, Ag^{I} and mixed-valence cobalt complexes have been synthesized, four of which have been characterized by X-ray crystal analyses to reveal structures varying from hexanuclear cluster, 1D bimetallic coordination polymers to 2D supramolecular assemblies. The structures of the complexes are discussed on the basis of various structure-directing factors, including the metal coordination preferences, hydrogen bonds, bridging groups, steric effect, and conformational flexibility of the ligands. Variable-temperature magnetic properties of two of the complexes are also reported. The results ob-

tained are valuable for the design and synthesis of further such novel complexes.

Results

Synthesis and Spectroscopic Results: To promote the deprotonation and subsequent coordination of the phenol and the alkoxy groups, complexes **1**−**8** were synthesized at alkaline pH by the addition of stoichiometric aqueous NaOH solution. For the Ag^I complex (**9**), Ag_2O precipitates upon the addition of NaOH, and the direct reaction of H_2L^2 with $AgNO_3$ in methanol resulted in a white precipitate of **9**, which was gradually dissolved by the addition of an excess of concentrated ammoniacal solution. Probably, the coordinated H_2L^2 is initially displaced by NH_3, which then evaporates to allow H_2L^2 to reform complex **9**, which gradually crystallized. Attempts to synthesize Ag^I complexes of H_2L^1 and H_2L^3 gave only the free ligands, possibly due to the weak coordinating abilities of the ligands and the instability of the resulting complexes.

In the IR spectra of complexes **1**−**8**, the coordination of the phenol groups is exhibited by the shifting of ν(C−O) to higher wavenumbers. For complexes **3**−**5**, and **7**, the intense bands near 1100 cm^{-1} show distinct splittings, indicative of coordinated ClO_4^-.

Isotropic EPR spectra of complex **3** and **6** in DMF containing four copper hyperfine lines are observed at 300 K (Figure 1), while the spectra at 100 K have axial symmetries, with four hyperfine peaks in the parallel region derived from the coupling of the copper nucleus and the unpaired electron. The EPR parameters (**3**: $g_{//} = 2.229$, $g_{\perp} = 2.004$, $A_{//} = 186.4$ G, $A_{iso} = 85.7$ G; **6**: $g_{//} = 2.231$, $g_{\perp} = 2.006$, $A_{//} = 188.7$ G) are indicative of tetragonal coordination environments with $(d_{x^2-y^2})^1$ ground states for complexes **3** and **6**.[8]

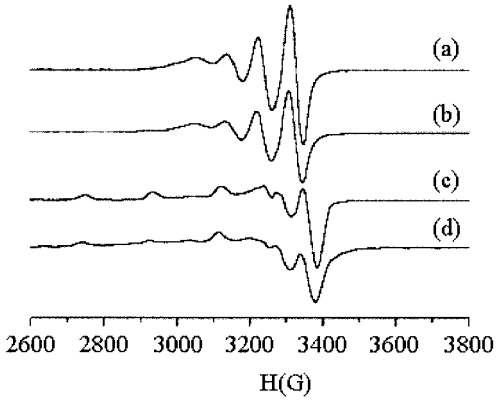

Figure 1. EPR spectra of the complexes in DMF: (a) **3**, 300 K; (b) **6**, 300 K; (c) **3**, 100 K; (d) **6**, 100 K

The electronic spectra of the copper and cobalt complexes in DMF (Table 1) exhibit intraligand transitions, and d−d transitions in addition to strong LMCT bands, confirming the coordination of the deprotonated phenoxy groups.

Structural Results: The crystal structure of **1** consists of a discrete $[Co_6L^1_6(OH)(H_2O)_3]^{2+}$ hexameric entity (Figure 2, a, Table S1 of the Supporting Information; see also the footnote on the first page of this article), two noncoordinated chloride counter anions, and ten water molecules of crystallization. Bond lengths, charge balance considerations

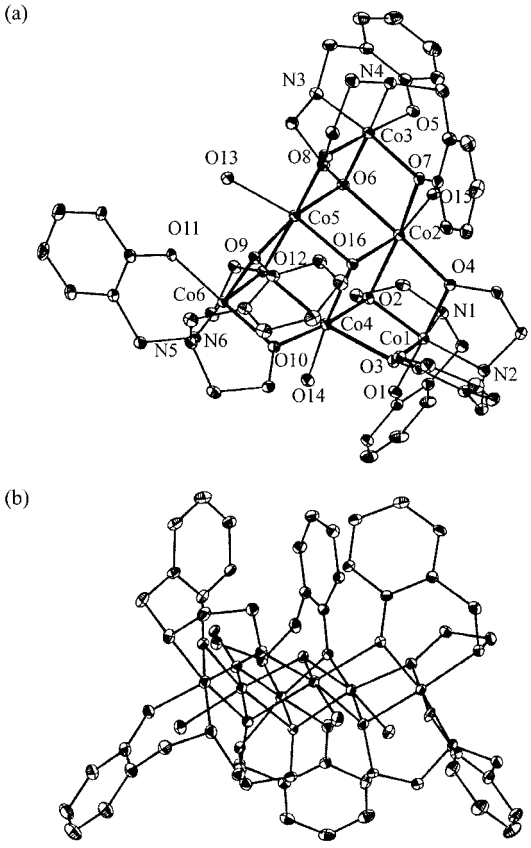

Figure 2. Complementary views of the structure of **1** showing 20% probability displacement ellipsoids. H atoms have been omitted for clarity

Table 1. Electronic spectra of the complexes in DMF

Complexes	λ_{max}/nm (ε/$dm^3 \cdot mol^{-1} \cdot cm^{-1}$)			
$\pi \rightarrow \pi^*$	$n \rightarrow \pi^*$	$L \rightarrow M$	$d \rightarrow d$	
1	264 (9.63×10^3)	290 (5.30×10^3)	358 (1.35×10^3)	598 (100)

and magnetic measurements (vide infra) reveal that the three inner cobalt atoms are Co^{II}, and the outer ones are Co^{III}. Each Co^{III} has an N_2O_4 ligation, namely the two phenoxo, two alkoxo and two amino groups of two *fac*-$(L^1)^{2-}$ ligands. The phenoxo and alkoxo groups of the $(L^1)^{2-}$ ligands, together with a μ_3-hydroxo ligand, bridge the six cobalt atoms, resulting in, apparently, the first Co_6O_{10} face-sharing quadruple defective cubane-like complex. The whole hexameric entity adopts a crown shape (Figure 2, b), with the three phenyl rings at the upper rim tilted inward, and the phenyl rings at the lower rim tilted outward. According to the "Harris" notation,[9] the upper $(L^1)^{2-}$ and lower $(L^1)^{2-}$ ligands are involved in $32_{12}2_{13}1_1$ and $31_13_{123}1_1$ bridging modes, respectively (Figure 3). The $Co^{III}-N$ and $Co^{III}-O$ distances are in the ranges 1.944(7)−1.980(7) and 1.862(5)−1.956(5) Å, respectively. The $Co^{II}-O$ distances are in the range 1.991(5)−2.286(5) Å, and the $Co^{II}-O-Co^{II}$ angles are 94.44(19)−107.8(3)°, with $Co^{II}\cdots Co^{II}$ separations of 3.240, 3.253 and 3.270 Å, respectively.

[a] Symmetry transformations used to generate equivalent atoms: $-1+x, y, z$. [b] $2-x, 2-y, 2-z$. [c] $1-x, 2-y, 2-z$.

The asymmetric unit of **3** (Table 2) consists of one Cu^{II}, one $(L^2)^{2-}$, one ClO_4^- anion and two partially occupied Na^I atoms lying on the special positions of the inversion centers with occupation factors of 50%. Thus, **3** can be understood as a 1:1 adduct of CuL^2 with $NaClO_4$, wherein $(L^2)^{2-}$ coordinates with Cu^{II} as a tetradentate ligand in the equatorial plane. The neighboring CuL^2 units are arranged in an alternating up/down-up/down mode, and act as neutral ligands to coordinate Na^I atoms via the phenoxo O atoms, affording an infinite zigzag arrangement of alternating Cu^{II} and Na^I centers along the *a* axis (Figure 4). The final coordination polymer involves phenoxo and perchlorato groups in the unusual μ_3- and μ_4-bridging modes, respectively, and the final coordination geometries around Cu^{II} and Na^I are elongated octahedral and irregular octahedral, respectively. This appears to be the first coordination polymer of H_2L^2.[10]

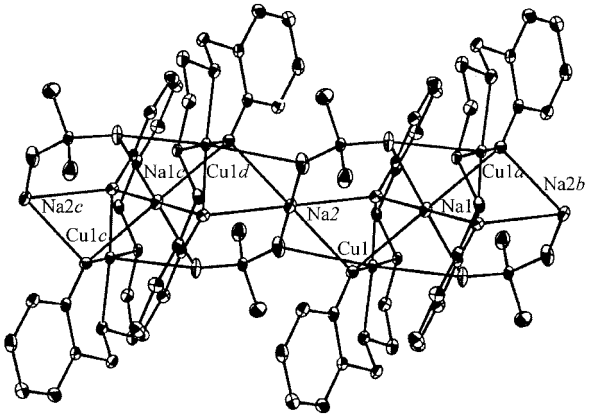

Figure 4. One-dimensional linear structure of **3**, showing the atom labeling scheme at the 20% probability level with H atoms omitted for clarity

The asymmetric unit of crystal **6** (Table 3) consists of four crystallographically independent, and chemically similar, CuL^3 moieties and four water molecules of crystallization. In each CuL^3 moiety, the tetradentate $(L^3)^{2-}$ ligand is coordinated in the basal plane of Cu^{II}. The four CuL^3 units are connected into two dimers via axial monophenoxo bridging, with Cu−O bridging distances of 2.562(2) and 2.490(3) Å, and Cu−O−Cu angles of 98.49(10) and 103.56(10)°, respectively. The dimers are further connected by multiple hydrogen bonds, i.e., every two water molecules are connected via hydrogen bonds to form a structural unit, which in turn connects the amino and the phenoxo functionalities to form a 2D sheet approximately along the *ab* plane (Figure 5). In the final structure, half of the water molecules are quadruple-connecting, and the other half are triple-connecting. Interestingly, a nearly planar six-membered ring is formed by Cu(4), O(7), O(8), and the water molecule via hydrogen bonds.

In the crystal structure of the Ag^I complex **9** (Figure 6, and Table 4), Ag^I is coordinated with four N atoms from two L^2 ligands, with one ligand in the protonated H_2L^2 form, and the other in mono-deprotonated $(HL^2)^-$. The noncoordinated phenol and phenolate groups are involved

in intermolecular hydrogen bonds, resulting in an undulated 2D network of hexagonal units; each corner of the hexagons is occupied by an Ag^{I} atom. Interestingly, the hydrogen bond O3···H···O4A [O3···O4A 2.444(3) Å, bond angle of 173.56°] can be regarded as a (−)CAHB type; such strong bonds have been observed mostly in systems containing carboxylate and carboxylic acid molecules.[11] Their occurrence between the phenolate and the phenol groups is rather unusual.

Magnetic Studies: The magnetic behavior of **1** and **6** was studied. With the decreasing of temperature, the observed $\chi_M T$ for **1** (Figure S1, see Supporting Information) gradually decreases from 8.47 (300 K) to 3.02 $cm^3 \cdot mol^{-1} \cdot K$ at 5 K, which is characteristic of an antiferromagnetically cou-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pled Co^{II}_3 moiety, and is consistent with the crystal structure (vide supra). For **6**, however, $\chi_M T$ (Figure S2, Supporting Information) increases slowly from 0.633 (300 K) to a maximum of 0.737 $cm^3 \cdot mol^{-1} \cdot K$ at 9 K, and then decreased to 0.730 $cm^3 \cdot mol^{-1} \cdot K$ at 5 K, indicating a net weak ferromagnetic interaction between the Cu^{II} centers due to the coexistence of ferro- and antiferromagnetic interactions, which can be assigned to interactions within the dimers with the bridging angles of 98.49° and 103.56° (vide supra), respectively.

Discussion

The unsymmetrical tridentate ligand H_2L^1 contains both phenol and alkoxy groups. It forms the hexanuclear cluster **1**, with both the phenoxy and alkoxy groups involved in bridging. A few polynuclear clusters have also been reported for similar tridentate unsymmetrical ligands.[12,13] While the number of polynuclear transition metal complexes reported continues to grow rapidly, some nuclearities remain rare. Only a few hexanuclear cobalt complexes containing N or O donors have been reported,[14] along with some larger cobalt cages[15] and a number of hexanuclear cobalt-chalcogen clusters.[16] The occurrence of complex **1** may be related to the properly disposed bridging functionalities from the $(L^1)^{2-}$ ligand and the suitable chelate ring size. In contrast to the *fac*-coordination mode of $(L^1)^{2-}$ in **1**, in the related tetranuclear cubane Cu^{II} complex $[Cu_4L'_4]$ [L′ = *N*-(2-hydroxybenzyl)propanolamine, Scheme 1],[12] the two O atoms from $(L')^{2-}$ occupy the *trans* positions in the basal plane of the square pyramidal coordination polyhedron of Cu^{II}, which can be ascribed to the tendency for the six-membered chelate ring in $[Cu_4L'_4]$ to span a larger distance, as compared to the corresponding five-membered ring in complex **1**. In $[Cu_4L'_4]$, all the alkoxo groups act as μ_3-bridges, with the phenoxo groups at the *trans* positions not involved in bridging. In contrast, the neighboring alkoxo and phenoxo groups in complex **1** are involved in more complicated bridging modes (vide supra), resulting in the larger nuclearity.

Considering the distances between the O, N, and Cl^- atoms, the water molecules, and the chlorides, form complicated hydrogen-bond networks with the amino, phenoxo, and alkoxo groups of the $(L^1)^{2-}$ ligands. These multiple hydrogen bonds may contribute to the stability of the complex, and thus the crystal structure can readily be determined at room temperature. For the polynuclear Cu^{II} complex of $(L^1)^{2-}$, the crystal structure cannot be obtained due to its efflorescence during measurement.[8] In the Zn^{II} complex $[ZnHL^1Cl]$ (**2**), the alkoxy group is not deprotonated, even if an excess of NaOH is added, which can be ascribed to the weaker coordination of Zn^{II}, as compared to Co^{II} and Cu^{II}. The positive charge of Zn^{II} is balanced by a chloride, in addition to the deprotonated phenoxo group.

In contrast to H_2L^1, the tetradentate ligand H_2L^2 has an additional phenyl ring, and H_2L^3 has a further two methyl groups on the two phenyl rings − severe steric hindrance can be anticipated if similar polynuclear clusters of these two ligands are formed. Thus, the 1D heterometallic coordination polymer and the weak axial monophenoxo-bridged binuclear moieties are seen for **3** and **6**, respectively. For $[CoL^2NaClO_4] \cdot CH_3OH$ (**4**), $[ZnL^2 \cdot NaClO_4] \cdot H_2O$ (**5**), and $[CoL^3NaClO_4] \cdot 1.5H_2O$ (**7**), structures similar to that of **3** may also be assigned.

For the complex of H_2L^2 with the soft Ag^I atom, which prefers a tetrahedral coordination, the ligand acts in bidentate mode in complex **9** via coordination of the N atoms. H_2L^2 is usually a tetradentate ligand,[10] but the unusual bidentate coordination mode can be rationalized by the tendency of Ag^I to coordinate with N rather than O atoms, and by the tetrahedral preference of four-coordinate Ag^I, which cannot be satisfied without great strain if the ligand coordinates in a tetradentate mode. Thus, the 1:2 complex $[Ag(H_2L^2)(HL^2)]$ is formed, irrespective of the molar ratio of the reagents, and the noncoordinated phenol groups are involved in intermolecular hydrogen bonds, resulting in an undulated 2D network.

The rich coordination modes of the ligands can also be related to their conformational flexibility, as evidenced by the large values of 36.9°, 52.0° and 84.9° for the dihedral angles between the two mean planes through the aromatic rings of the same ligands in complexes **3**, **6**, and **9**, respectively. In contrast to the approximately planar trinuclear salen adduct $[Cu(salen)]_2NaClO_4$,[17] the totally different arrangement in complex **3** provides a perfect match between the coordination environment provided by the donor atoms of $(L^2)^{2-}$ and the pseudooctahedral coordination preferences of the Cu^{II} and Na^I centers, and, also, the positive and the negative charges are exactly balanced. This perfect match gives extreme thermal stability to the novel coordination polymer: no weight loss was observed for **3** until about 328 °C. These subtle matching factors are delicate, and extremely sensitive to the structures of the ligands. As for H_2L^2, similar complexes with other divalent metals, namely, the Co^{II} complex $[CoL^2] \cdot NaClO_4 \cdot CH_3OH$ (**4**) and the Zn^{II} complex $[ZnL^2 \cdot NaClO_4] \cdot H_2O$ (**5**) were also obtained; however, for H_2L^3, only the corresponding Co^{II} complex $[CoL^3NaClO_4] \cdot 1.5H_2O$ (**7**) was obtained. No $NaClO_4$ is included in the Cu^{II} and Zn^{II} complexes of H_2L^3.

Conclusions

Various novel coordination assemblies can be successfully obtained by altering the ligands and metal atoms. For metal atoms with octahedral coordination preferences, with increasing steric hindrance and the decreasing bridging ability of the ligands, the structures of the products vary from polynuclear cluster and 1D heterometallic coordination polymer to weak axial monophenoxo-bridged binuclear moieties. For the soft Ag^I atom, which prefers tetrahedral coordination, H_2L^2 coordinates bidentately via the N atoms to give a 1:2 complex. These results provide further insight into the subtle structure-directing factors of metal complexes, including the metal coordination preferences, the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

disposition of the bridging groups, the conformational flexibility, the hydrogen bonds, and the steric effect of the ligands. This work may be valuable in our aim to design and synthesize novel complexes; for example, coordination assemblies could arise by modifying the aliphatic chains or the phenyl rings of the ligands or by adding further donor groups into the phenyl rings.

Experimental Section

Physical Measurements: IR spectra were recorded with a Bruker Vector-22 spectrometer (KBr Disc.). UV-Vis spectra were obtained with a Shimadzu UV-Vis 2401 PC spectrophotometer. EPR measurements were performed with a Bruker ER200D-SRC spectrometer at X-band (9.46 GHz). Microanalyses of C, H and N were carried out with a GmbH VarioEL elemental analyzer. Magnetic susceptibility data were collected with a Quantum Design Squid magnetometer in the temperature range 5−300 K. The data were corrected for the diamagnetism of the sample holder and for diamagnetic contributions with Pascal's constants.

Caution! *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only a small amount of the material should be used and it should be handled with extreme care.*

5-Methylsalicylaldehyde was prepared by the reaction of *p*-cresol and $CHCl_3$ in aqueous ethanol according to the Reimer−Tiemann procedure. $H_2L^1{\cdot}HCl{\cdot}1.5H_2O$ was synthesized by the method reported earlier;[8] H_2L^2 was prepared by a similar method., and H_2L^3 was prepared in analogues fashion starting from 5-methylsalicylaldehyde and ethylenediamine.

$[Co_6L^1_6(OH)(H_2O)_3]Cl_2{\cdot}10H_2O$ (1): $Co(OAc)_2{\cdot}4H_2O$ (100 mg, 0.40 mmol), $H_2L^1{\cdot}HCl{\cdot}1.5H_2O$ (89 mg, 0.40 mmol), aqueous NaOH (0.3 mL, 4 M, 1.2 mmol), and a few drops of H_2O_2 were added successively to methanol (100 mL). The resulting solution was then boiled under reflux for 3 h, and concentrated in vacuo. The so-obtained microcrystalline brown solid was collected and washed with diethyl ether and dried (yield 97 mg, 87%). $C_{54}H_{93}Cl_2Co_6N_6O_{26}$: calcd. C 38.91, H 5.62, N 5.04; found C 38.69, H 5.63, N 4.89. IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ 3386 br. (H_2O), 3190 s (N−H), 1596 s, 1567 m, 1483 s, 1448 s, 1304 m, 1284 s (C−O), 1270 vs (C−O), 882 m, 759 s, 685 s, 630 m, 602 w, 535 w.

$[ZnHL^1Cl]$ (2): A solution of $Zn(ClO_4)_2{\cdot}6H_2O$ (149 mg, 0.40 mmol), $H_2L^1{\cdot}HCl{\cdot}1.5H_2O$ (89 mg, 0.40 mmol), and aqueous NaOH (0.2 mL, 4 M, 0.8 mmol) was boiled under reflux for 4 h, and then concentrated in vacuo. The resulting colorless solid was collected and washed with diethyl ether and dried (yield 91 mg, 85%). $C_9H_{12}ClNO_2Zn$: calcd. C 40.48, H 4.53, N 5.25; found C 40.59, H, 4.75, N 5.06. IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3260 m (N−H), 2922 w, 2859 w, 1597 s, 1569 m, 1483 s, 1453 s, 1277 s (C−O), 1086 s, 1021 s, 874 m, 760 s, 623 m, 592 w, 528 w.

$[CuNaL^2(ClO_4)]_\infty$ (3): The microcrystalline brown solid complex **3** was prepared by a procedure similar to that of **2**, starting from $Cu(ClO_4)_2{\cdot}6H_2O$ (0.142 g, 0.40 mmol), H_2L^2 (117 mg, 0.40 mmol), and NaOH (0.2 mL, 4 M, 0.8 mmol) (yield 170 mg, 93%). $C_{16}H_{18}ClCuN_2NaO_6$: calcd. C 42.12, H 3.98, N 6.14; found C 42.04, H 4.01, N 5.88. IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3263 s (N−H), 3059 w, 2884 w, 1597 w, 1566 w, 1483 s, 1451 s, 1290 s, 1270 s (C−O), 1116 s, 1108 s, 1088 s, 1055 m, 1038 m, 992 m, 958 w, 926 w, 883 m, 858 w, 755 s, 729 m, 626 s, 596 w, 570 m, 530 w, 408 w.

$[CoL^2NaClO_4]{\cdot}CH_3OH$ (4): $Co(OAc)_2{\cdot}4H_2O$ (100 mg, 0.40 mmol), H_2L^2 (117 mg, 0.40 mmol), aqueous NaOH (0.2 mL, 4 M, 0.8 mmol) and $NaClO_4$ (49 mg, 0.40 mmol) were added successively to methanol (50 mL). The resulting solution was boiled under reflux for 4 h, and then concentrated in vacuo to give a yellowish green powder that was collected and washed with diethyl ether and dried (yield 153 mg, 79%). $C_{17}H_{22}ClCoN_2NaO_7$: calcd. C 42.21, H 4.58, N 5.79; found C 42.63, H 4.67, N 5.77. IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3424 br., 3226 m (N−H), 2927 m, 1598 s, 1481 s, 1451 s, 1399 m, 1272 s (C−O), 1116 s, 1106 s, 1085 s, 881 m, 759 s, 625 m, 594 w, 508 w.

$[ZnL^2{\cdot}NaClO_4]{\cdot}H_2O$ (5): Complex **5** was prepared by a procedure similar to that of **3**, using $Zn(ClO_4)_2{\cdot}6H_2O$ instead of $Cu(ClO_4)_2{\cdot}6H_2O$ (yield 173 mg, 91%). $C_{16}H_{20}ClN_2NaO_7Zn$: calcd. C 40.36, H 4.23, N 5.88; found C 40.23, H 4.34, N 6.05. IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3440 br., 3254 m (N−H), 2922 m, 1597 s, 1481 s, 1452 s, 1366 m, 1272 s (C−O), 1110 s, 1039 s, 928 m, 877 m, 760 s, 733 m, 623 m, 591 m.

$[CuL^3]_4{\cdot}4H_2O$ (6): The microcrystalline green solid complex **6** was prepared by a procedure similar to that of **3**, using H_2L^3 instead of H_2L^2 (yield 128 mg, 84%). $C_{72}H_{96}Cu_4N_8O_{12}$: calcd. C 56.90, H 6.37, N 7.37; found C 56.69, H 6.07, N 7.01. IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3443 br. (H_2O), 3256 s (N−H), 2919 m, 1642 w, 1488 vs, 1290 s, 1272 s (C−O), 1254 s (C−O), 1122 s, 1093 s, 1055 s, 998 w, 957 w, 863 m, 818 s, 796 s, 635 m, 500 m.

Single crystals of **1**, **3**, and **6** were grown by slow evaporation of their methanol solutions.

$CoL^3NaClO_4{\cdot}1.5H_2O$ (7): Complex **7** is a yellowish green powder that was prepared by a procedure similar to that of **4**, using H_2L^3 instead of H_2L^2 (yield 158 mg, 78%). $C_{36}H_{50}Cl_2Co_2N_4Na_2O_{15}$: calcd. C 42.66, H 5.53, N 4.97; found C 42.69, H 5.21, N 5.36. IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3442 br., 3226 m (N−H), 2919 m, 1612 s, 1487 s, 1272 s (C−O), 1118 s, 1108 s, 1082 s, 1046 s, 969 w, 927 w, 798 m, 625 m, 517 m.

$[ZnL^3]{\cdot}2H_2O$ (8): Complex **8** was prepared by a procedure similar to that of **7**, using H_2L^3 instead of H_2L^2 (yield 128 mg, 80%). $C_{18}H_{26}N_2O_4Zn$: calcd. C 54.08, H 6.55, N 7.01; found C 54.24, H 6.24, N 7.05. IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3408 br., 3253 m (N−H), 2916 m, 2859 m, 1611 s, 1488 s, 1269 s (C−O), 1127 m, 1047 m, 825 s, 790 s, 756 m, 726 w, 531 w, 492 m.

$[Ag(H_2L^2)(HL^2)]$ (9): A solution of $AgNO_3$ (68 mg, 0.40 mmol) in H_2O (5 mL) was added to a solution of H_2L^2 (117 mg, 0.40 mmol) in methanol (5 mL). The resultant precipitate was redissolved by the addition of concentrated ammoniacal solution (5 mL). The resulting solution was then filtered and left in a P_2O_5 desiccator in a dark place to slowly evaporate. Single crystals were obtained after several days in 35% yield (91 mg). $C_{32}H_{39}AgN_4O_4$: calcd. C 58.99, H 6.03, N 8.60; found C 58.80, H 5.78, N 8.31. IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3300 m (N−H), 2922 m, 2857 m, 1595 s, 1454 s, 1385 m, 1329 w, 1251 s (C−O), 1186 m, 876 m, 829 m, 752 s, 504 m.

X-ray Crystallography: All measurements were made with a Rigaku RAXIS-IV image plate area detector with Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. The final cycle of full-matrix least-squares refinement was based on observed reflections [$I > 2.00\sigma(I)$] and variable parameters. All calculations were performed by using the SHELX-97 software package.[18] A summary of the crystal data is presented in Table 5.

New Ag^{I} Organometallic Coordination Polymers and M^{II} ($M = Cu^{II}$ and Co^{II}) Inorganic Supramolecular Complexes Generated from New Fulvene-Type Ligands

Yu-Bin Dong,*[a,b] Xia Zhao,[a] Guo-Xia Jin,[a] Ru-Qi Huang,[a] and Mark D. Smith[c]

Keywords: Coordination polymers / Supramolecular chemistry / Silver / Cobalt / Copper

Two novel fulvene-type organic ligands **L1** and **L2** have been synthesized by aroylation reaction of substituted cyclopentadienyl anions. **L1** crystallized in the monoclinic space group $P2_1$, a = 6.7498(4), b = 20.5769(11), c = 8.9532(5) Å, β = 109.5060(10)°, and Z = 2. **L2** crystallized in the triclinic space group $P\bar{1}$, a = 11.4126(10), b = 11.4763(10), c = 11.7719(10) Å, α = 67.050(2), β = 74.509(2), γ = 61.148(2)°, and Z = 2. The coordination chemistry of **L1** and **L2** has been investigated. One novel Ag^{I}-containing organometallic coordination polymer **3**, based on both Ag^{I}–C and Ag^{I}–N interactions, has been synthesized by combination of **L1** and $AgClO_4$ in a benzene/dichloromethane mixed-solvent system. Two new M^{II}-containing [M = Cu^{II} (**4**) and Co^{II} (**5**)] supramolecular complexes with seven-membered metalla-ring unit have been prepared by combination of **L2** and the corresponding $M(OAc)_2{\cdot}2H_2O$ (M = Cu^{II} and Co^{II}) salts in ethanol. The isostructural compounds **4** and **5** crystallized in the triclinic space group $P\bar{1}$ [**4**: a = 8.8808(5), b = 10.9928(7), c = 14.2196(9) Å, α = 99.9750(10), β = 95.8190(10), γ = 93.5610(10)°, and Z = 1; **5**: a = 8.7964(10), b = 10.8103(12), c = 14.3765(15) Å, α = 99.681(2), β = 95.930(2), γ = 93.429(2)°, and Z = 1]. In the solid state, molecular complexes **4** and **5** are bound by strong intermolecular N···O–H hydrogen bonds in a hand-in-hand fashion to give a novel one-dimensional chain motif.

Introduction

The construction of new inorganic−organic coordination polymers and supramolecular complexes through the rational combination of organic ligands and metal ions is of intense current interest.[1−3] Two types of organic ligands have proven popular in construction of coordination polymers or supramolecular complexes. The first type contains heteroatom donors separated by various spacers such as bipyridine-type or biphenyl-cyanide-type ligands,[4] and the second type contains sp^2 electron-rich carbon atoms, such as small aromatic molecules and polycyclic aromatic hydrocarbons.[5] During the past decade, a number of inorganic coordination polymers based on metal−heteroatom bonding interactions and organometallic coordination polymers based on metal−carbon bonding interactions have been generated successfully with various structural motifs. In contrast, coordination polymers or supramolecular complexes based on both metal−heteroatom and metal−carbon bonding interactions have received considerably less attention. In principle, such materials might exhibit enhanced physical properties, such as electrical conductivity or fluorescence resulting from the synergy between the two distinctly different types of interactions. We are investigating the coordination chemistry of fulvene-type ligands that could provide both heteroatom and carbon atoms as coordination sites (Scheme 1). Recently, a series of novel organometallic coordination polymers based on both metal−carbon and metal−heteroatom interactions were obtained in our laboratory.[6] Conversely, fulvene-type organic spacers act not only as multidentate ligands but also as chelating ligands. Their specific geometry affords a good opportunity to synthesize seven-membered metalla-ring complexes that are not achievable easily with other 1,4-diketone organic ligands.

We report here the synthesis and characterization of two new fulvene-type ligands (**L1** and **L2**), one new organometallic coordination polymer $[Ag(\mathbf{L1})(ClO_4)]{\cdot}CH_2Cl_2$ (**3**), based on both metal−heteroatom and metal−carbon interactions, and two new M^{II} ($M = Co^{II}$, Cu^{II}) seven-membered metalla-ring supramolecular complexes, $[Co(\mathbf{L2})_2(C_2H_5OH)_2]$ (**4**) and $[Cu(\mathbf{L2})_2(C_2H_5OH)_2]$ (**5**), based on them.

Results and Discussion

Synthesis and Structural Analysis of L1 and L2

Ligands **L1** and **L2** were prepared in moderate yields as deep-yellow crystalline solids by the respective reactions of 4- and 3-cyanobenzoyl chloride with substituted cyclopentadienyl anions, derived from 6,6′-dimethylfulvene and *p*-methylphenyllithium and phenyllithium in diethyl ether at 0 °C (Scheme 1). **L1** and **L2** are very soluble in common organic solvents, such as CH_2Cl_2, $CHCl_3$, THF, and C_6H_6. Their structures were determined by ^1H NMR and IR spectroscopy, elemental analyses, and standard single-crystal X-ray diffraction techniques. Their IR spectra show −CN absorption bands at $\tilde{\nu}$ = 2250 cm^{-1}. In the ^1H NMR spectrum of **L1** and **L2** the proton resonances at δ = 18.20 and 17.79 ppm as singlets, respectively, are due to the chelated proton, which is hydrogen-bonded to the neighboring carbonyl group on the 1-benzoyl group.[6,9] Their IR spectra do not show absorptions above 1630 cm^{-1} in the region normally assigned to organic carbonyl groups. However, the strong band at 1615 cm^{-1} is consistent with the hydrogen-bonded enol structure since conjugation and chelation lead to a large shift of the carbonyl infrared band. The structures of **L1** and **L2** were further confirmed by X-ray diffraction techniques. The corresponding molecular structures of **L1** and **L2** are shown in Figures 1 and 2, respectively; that of **L2** reveals that the two aroyl groups on the substituted cyclopentadienylenyl ring are adjacent. The C−C bonds on

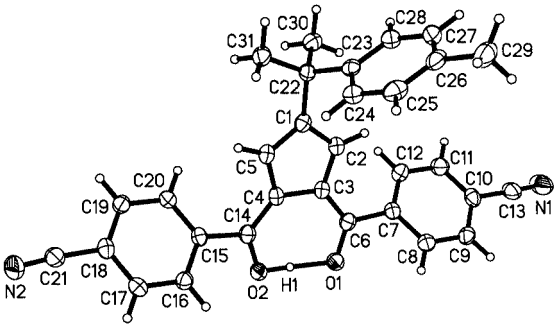

Figure 1. ORTEP plot of compound **L1** with 30% probability ellipsoids

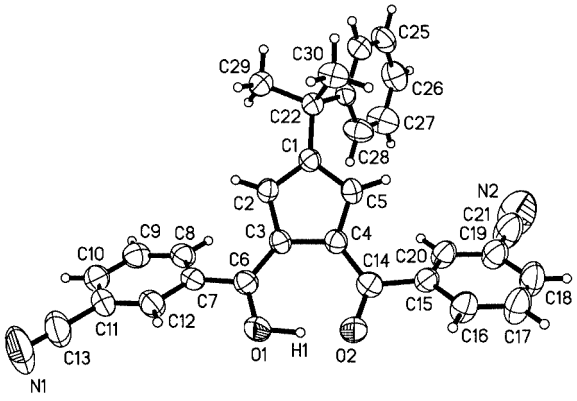

Figure 2. ORTEP plot of compound **L2** with 30% probability ellipsoids

the substituted Cp ring and also C(3)−C(6) and C(4)−C(14) range from 1.377(2) to 1.468(2) Å, which are significantly shorter than a normal C−C single bond. Thus, **L2** is a fulvene[6,8] – an important organometallic moiety.[10] The enol hydrogen atom [H(1)] is hydrogen-bonded to the carbonyl oxygen atom [O(2), $d_{O(2)\cdots H(1)}$ = 1.35(3) Å, ∠O(1)−H(1)···O(2) = 171(2)° and $d_{O(1)\cdots O(2)}$ = 2.464(18) Å] to provide a hydrogen-bonded seven-membered ring. Interestingly, two $-C_6H_4-$CN-*m* rings and the hydrogen-bonded seven-membered ring are not in the same plane. The dihedral angles between the $-C_6H_4-$CN-*m* ring and the seven-membered ring are 10.4(3) and 13.4(3)°, respectively. In the solid state, two −*m*-CN functional groups on **L2** are oriented in opposite directions and the terminal (−CN) N···N separation is 17.32(5) Å. A similar molecular structure was found for **L1**, with a slightly shorter terminal (−CN) N···N separation [16.88(5) Å]. In addition to the two −CN groups, the carbonyl and enol groups in **L1** and **L2** could act as potential chelating coordinating sites to bind transition metal ions into seven-membered metalla-ring-containing complexes; they could also potentially be transferred to other types of organic functional groups, such as heterocycles, by reaction with hydroxylamine, hydrazine or the like.[6b] Compounds **L1** and **L2** are a new type of ligands that can be used to construct polymeric compounds containing both inorganic and organometallic moieties.

Synthesis and Structural Analysis of 3

Silver-containing polymeric compound **3**, $[Ag(\mathbf{L1})(ClO_4)]\cdot CH_2Cl_2$, was synthesized in 85% yield by the combination of **L1** and $Ag(ClO_4)\cdot H_2O$ in a benzene/dichloromethane mixed-solvent system at ambient temperature. Crystals of **3** lose solvent molecules and turn opaque within several minutes under ambient atmosphere, preventing investigation of the host-guest chemistry of **3**. Single-crystal analysis revealed (Figure 3) a distorted tetrahedral coordination sphere around the silver atom, consisting of two N-donors [N(1) and N(2)] from two ligands **L1** [Ag−N(1) = 2.242(2) and Ag−N(1) = 2.242(2) 2.190(2) Å], one O-donor [O(11)] from the ClO_4^- counterion [Ag−O(11) = 2.416(2) Å], and one carbon atom [C(27)] from the *p*-methylphenyl group on the third ligand **L1**. The Ag−C distance is 2.763(3) Å while the remaining Ag−C contacts (> 2.958 Å) are beyond the limits (2.47−2.80 Å) commonly observed in Ag^I−aromatic complexes. Thus, the benzene ring in **L1** coordinates to the Ag^I ion with an η^1-bonding mode, which is normally observed in arene−metal complexes.[11]

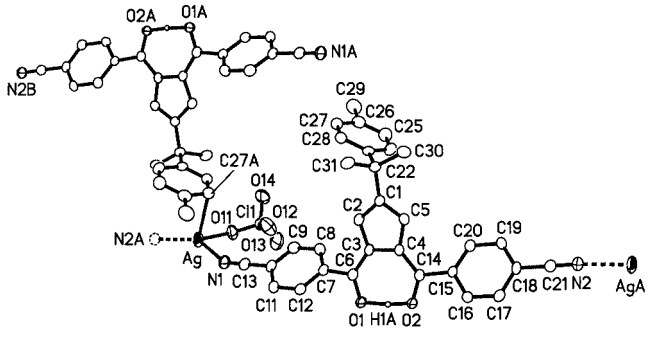

Figure 3. ORTEP plot of compound **3** with 30% probability ellipsoids

In the solid state, the silver centers are connected by **L1** through the two terminal −CN groups into mild zigzag one-dimensional chains which further associate into inversion-related pairs by Ag−C organometallic interactions along the crystallographic [211] direction (Figure 4). In addition, the ladder-like chains stack together to create two kinds of rectangular channels: large ones along the crystallographic [100] direction (crystallographic dimensions of the rings ca. 14 × 12 Å), which are filled by CH_2Cl_2 guest

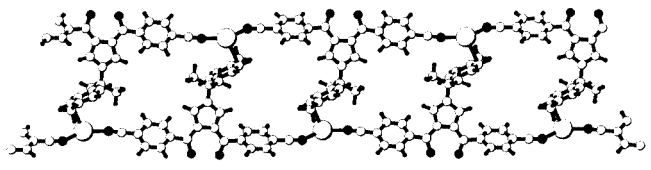

Figure 4. One-dimensional organometallic chain found in **3** (along crystallographic [211] direction), H atoms, ClO_4^- counterions and CH_2Cl_2 guest molecules are omitted for clarity

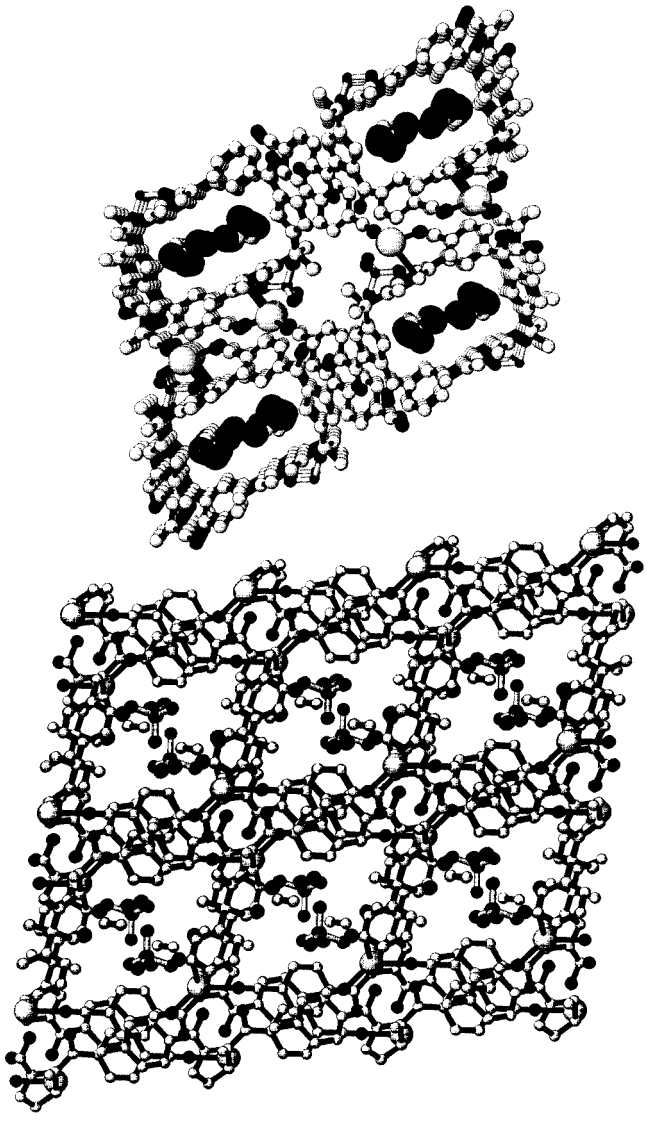

Figure 5. Top: channels in **3** (down the *a* axis), H atoms are omitted for clarity; bottom: channels in **3** (down the [011] direction), H atoms are omitted for clarity

molecules (Figure 5, a), and small ones (around 10 × 10 Å) that extend along the crystallographic [011] direction, in which both ClO_4^- counterions and CH_2Cl_2 guest molecules are located (Figure 5, b). Extended frameworks composed of organic spacers containing heteroatom donors via metal−heteroatom coordination bonds[4] and organometallic coordination polymers generated from smaller aromatics and also polycyclic aromatic hydrocarbons based on cation−π interactions[5] are well established; however, supramolecular complexes based on both metal−aromatic carbon and metal−heteroatom interactions appear to be quite unusual. A related example is the coordination of the rigid tridentate ligand 1-(4-cyanobenzoyl)-6-(4-cyanophenyl)-6-hydroxy-3-(4-phenylcyclohexyl)fulvene with Ag-OTf in benzene that led to the open-framework material $[Ag_2(C_{33}H_{26}N_2O_2)(H_2O)_2(SO_3CF_3)_2]\cdot 0.5C_6H_6$,[6a] which contains 21 × 15 Å parallelogram-like channels in which benzene guest molecules are located.[6a] The smaller chan-

nels found in **3**, however, differ in shape (rectangle-like in **3**, Figure 5) due to the different coordination mode of the silver(I) ion and the different templating effect of counterions.

To confirm **L1** as a chelating ligand to bind metal ions by two carbonyl oxygen atoms, $M(OAc)_2{\cdot}2H_2O$ ($M = Cu^{II}$, Co^{II}) were used instead of inorganic Ag^I salts in the reactions in ethanol. Elemental analyses and IR spectra showed that the resultant compounds have the chemical formula $[M(\mathbf{L1})_2(C_2H_5OH)_2]$. Unfortunately, no single-crystal structures were obtained. To confirm the structures by single-crystal X-ray diffraction, ligand **L2** was treated instead of **L1** under the same conditions.

Synthesis and Structural Analysis of 4 and 5

Synthesis

Complexes **4** and **5** were synthesized by solution reactions between the new **L2** and $Cu(OAc)_2{\cdot}2H_2O$ and $Co(OAc)_2{\cdot}2H_2O$ in ethanol, respectively. When a solution of **L2** in ethanol was treated with $Cu(OAc)_2{\cdot}2H_2O$ and $Co(OAc)_2{\cdot}2H_2O$, respectively, in a metal/ligand molar ratio of 1:2, compounds **4** and **5** were obtained as neutral molecular compounds with seven-membered metalla-rings. It is noteworthy that the coordination chemistry of **L2** with transition metal templates Cu^{II} and Co^{II} is independent of the metal/ligand molar ratio. For example, ratios of 2:1 and even 3:1 yielded **4** and **5** as the only products.

Structural Analysis of Compounds 4 and 5

Compounds **4** and **5** are isostructural and crystallize in the triclinic system. For example, the Cu^{II} center lies in an octahedral coordination environment defined by four O-donors from two bidentate ligands **L1** and two O-donors from two coordinated ethanol solvent molecules (Figure 6). The octahedral coordination polyhedron is slightly distorted — all angles around the copper center deviate significantly from 90° [O(1)−Cu−O(2) = 93.85(7)°, O(1)−Cu−O(3) = 87.77(8)°, O(2)−Cu−O(3) = 96.99(8)°]. The Cu−O bond lengths on the basal plane are 1.9318(15) and 1.9451(16) Å, respectively, which compare well with the Cu−O distance found in copper−oxygen complexes (e.g., $[Cu(C_6O_4Cl_2)(C_4H_4N_2)]$,[12] $[Cu(HLOX)Ni(N_3)]_2{\cdot}2CH_3OH$[13]). The distances between the copper center and the two axial O-donor atoms are the same [d_{Cu-O} = 2.390(2) Å], again consistent with the corresponding bond lengths in, for example, $Ag[Cu(2\text{-pyrazinecarboxylate})_2](H_2O)(NO_3)$[14] and $[Cu(HBIP)(C_2O_4)(H_2O)]{\cdot}2H_2O$.[15] 1,2-Diketone or 1,3-diketone compounds are known to chelate transition metal ions into five- or six-membered metalla-ring systems which engender less strain (Scheme 2),[16] because the atoms on the rings are allowed to adopt more closely their natural bond angles. However, seven-membered metalla-ring complexes generated from 1,4-diketone-containing ligands and transition metal ions are much less known, probably due to conformational strain.[16] **L2** reported herein, however, is perfect for the synthesis of such complexes because of its specific molecular geometry. In **4**, the carbon−carbon bond lengths on the substituted Cp ring and also the exocyclic carbon−carbon double bonds are almost the same as their corresponding bond lengths in the free ligand **L2** [ranging from 1.393(2) to 1.457(2) Å]. The four −CN groups in **4** are uncoordinated as two pairs oriented in opposite directions. The IR spectrum of **4** shows that the −C≡N stretch (2260 cm^{-1}) in **4** is essentially unchanged from that of the free ligand **L2**, indicating that the nitrile nitrogen atom does not enter the coordination sphere of the Cu^{II} center. A similar phenomenon occurs in the reaction of $[Ru_2\{O_2C(CH_2)_6CH_3\}_4]$ in toluene and $[Cu(hfacac)_2]{\cdot}H_2O$ (hfacac = hexafluoroacetylacetonate) in dichloromethane with 4-cyanopyridine and 3-cyanopyridine, respectively.[17] The discrete molecular 1:2 adducts $[Ru_2\{O_2C(CH_2)_6CH_3\}_4(4\text{-cyanopyridine})_2]$ and $[Cu(hfacac)_2(3\text{-cyanopyridine})_2]$ were obtained instead of the expected 4-cyanopyridine- and 3-cyanopyridine-bridged transition metal complexes. 4-Cyanopyridine and 3-cyanopyridine spacers have been used as bridging ligands to link transition metal species into dimers and polymers.[18,19] It appears that the nitrile N-donor atom has a poor coordinating ability to effectively link 3d metal ions. For example, in $[Cu(4\text{-cyanopyridine})_4(H_2O)(ClO_4)_2]_n$ the nitrile nitrogen atom only weakly coordinates with copper centers through a "semi-coordinated" bond [Cu−N≡C 2.649(4) Å], which is much longer than a normal Cu−N coordinative bond.[20] It is noteworthy that **4** contains uncoordinated N-donors, which have recently been suggested as potential new metal-containing building blocks,[21] that could be connected by other suitable metal ions (Ag^+ or Cd^{2+}, for example) or unsaturated metal complexes via bonding interactions with the free nitrile nitrogen atoms in **L2** (a possibility that we are pursuing).

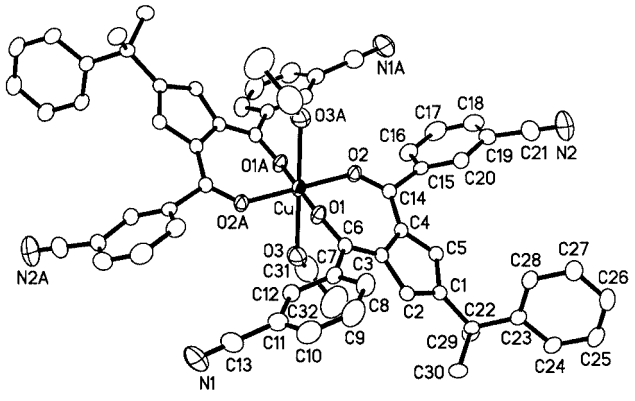

Figure 6. ORTEP plot of compound **4** with 30% probability ellipsoids

In the solid state (Figure 7) the neutral building blocks **4** arrange parallel to the crystallographic *c* axis, and moreover are bound by strong intermolecular N···O−H hydrogen bonds in a hand-in-hand fashion to create a one-dimensional chain motif along the crystallographic *b* axis. The hydrogen-bonding system in **4** consists of the one uncoordi-

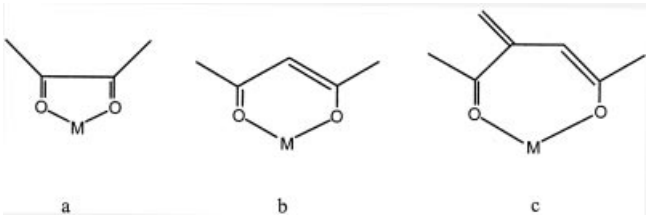

Scheme 2. Five-membered metalla-ring (a); six-membered metalla-ring (b); seven-membered-ring (c)

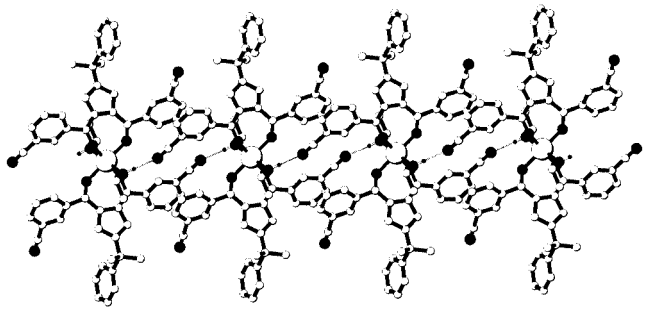

Figure 7. Hydrogen-bonded one-dimensional chain motif found in compounds **4** and **5**; hydrogen bonds are shown as dotted lines; this view is down the *a* axis

nated nitrogen atom N(1) on a −CN group with the hydrogen atom H(3) on the coordinated ethanol molecule O(3) of a neighboring Cu^{II} complex. The N(1)···H(3) distance is 1.94(2) Å. The corresponding O(3)···N(1) distance is 2.906(4) Å, and the corresponding O(3)−H(3)···N(1) angle is 170(4)°. The existence and structural importance of strong hydrogen-bonding interactions generated from −CN (as the hydrogen-bond acceptor) are now well established and have been observed in many compounds.[22] These strong hydrogen-bonding interactions contribute significantly to the alignment of the molecules of **4** in the crystalline state. The intrachain Cu···Cu distance is 10.99(3) Å.

In compound **5**, the Co^{II} center adopts a distorted octahedral $\{CoO_6\}$ coordination sphere, which is identical with the $\{CuO_6\}$ coordination environment found in **4**. In the corresponding single-crystal structure of **5** (Figure 8) the Co−O bond lengths on the basal plane lie in the range of 2.0059(19)−2.0226(16) Å. The distance between the Co^{II} center atom and the axial O-donor atom is 2.1385(19) Å, which is significantly longer than the equatorial Co−O distance. However, it is similar to the bond lengths in other Co^{II} compounds.[23]

In the solid state, compound **5** presents the same hydrogen-bonded one-dimensional chain as in **4** (Figure 7). The N···H distance is 1.94(2) Å and the corresponding O···N distance is 2.906(4) Å, with a corresponding O−H···N angle of 170(4)°.

Luminescent Properties

The fluorescence properties and potential applications as light-emitting diodes (LEDs) of aromatic organic molecules, all-organic polymers and mixed inorganic−organic hybrid coordination polymers have been investigated.[24] Owing to the higher thermal stability of inorganic−organic coordination polymers and the ability to alter the emission wavelength of organic materials, syntheses of inorganic−organic coordination polymers by the judicious choice of organic spacers and transition metal centers can be an efficient method for obtaining new electroluminescent materials.[25] The luminescent properties of the free ligand **L2**, and its metal complexes **4** and **5** have been investigated in the solid state and CH_2Cl_2 solution. In the solid-state spectra of **L2**, **4**, and **5** (Figure 9) **L2** exhibits one emission maximum at 523 nm and complexes **4** and **5** exhibit emission bands that are blue-shifted to 346 nm and 347 nm, respectively; however, the fluorescence intensity was not enhanced. The emission maximum of **L2** in CH_2Cl_2 is at 542 nm, and those of complexes **4** and **5** in CH_2Cl_2 are blue-shift to 518 nm and 521 nm, respectively (Figure 10). Due to its instability, the luminescent properties of **3** could not be investigated. In summary, the emission color of free **L2** is significantly affected by its incorporation into the M-containing (M = Co^{II} and Cu^{II}) complexes.

Conclusions

The two new fulvene-type ligands **L1** and **L2**, synthesized by the aroylation of substituted cyclopentadienyl anions, have been shown to be tridentate or bidentate chelating ligands to coordinate transition metal ions into coordination polymers or supramolecular complexes. The specific coordination behavior of ligand **1** resulted in a novel a Ag^{I}-containing organometallic coordination polymer (**3**) based on both metal−carbon and metal−heteroatom interactions. The special geometry of **2** resulted in complexes **4** and **5** with unusual seven-membered metalla-ring structures. In the solid state, **4** and **5** adopt a novel hydrogen-bonded one-dimensional chain motif. We are currently preparing new such fulvene ligands, with different substituted organic functional groups, so as to construct various new transition metal complexes and coordination polymers (including dimetallic polymeric compounds) with potentially novel structures.

Experimental Section

Materials and Methods: 4-Cyanobenzoyl chloride, 3-cyanobenzoyl chloride, 6,6′-dimethylfulvene, and aryllithium were prepared according to literature methods.[7] Inorganic metal salts were purchased from Acros and used without further purification. Infrared (IR) samples were prepared as KBr pellets, and spectra were obtained in the 400−4000 cm^{-1} range using a Perkin−Elmer 1600 FTIR spectrometer. ^1H NMR spectroscopic data were collected using a JEOL FX 90Q NMR spectrometer. Chemical shifts (δ) are relative to TMS. Element analyses were performed with a Perkin−Elmer Model 240C analyzer.

Preparation of L1: A solution of 4-cyanobenzoyl chloride (1.80 g, 10.8 mmol) in anhydrous diethyl ether (20 mL) was added dropwise to a solution of substituted cyclopentadienyl anions (16.2 mmol) in anhydrous diethyl ether at 0 °C, which in turn was derived from 6,6′-dimethylfulvene (16.2 mmol) and 4-methylphenyllithium (16.2 mmol) in anhydrous diethyl ether. The mixture was then stirred at room temperature overnight. The solvent was then reduced to about 10 mL under vacuum. Hexane was added and an orange solid precipitated that was washed with hexane several times and stirred in HCl (5% in water) overnight. The final product was purified by column chromatography on silica gel (CH_2Cl_2/hexane, 6:5) to afford an orange crystalline solid in 50% yield. IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3110 (w), 2250 (s), 1635 (s), 1600 (s), 1575 (m), 1540 (vs), 1500 (m), 1475 (s), 1413 (vs), 1410 (s), 1365 (s), 845 (m). ^1H NMR (90 MHz, $CDCl_3$, 25 °C, TMS, ppm): δ = 18.20 (s, 1 H, OH), 7.85 (s, 8 H, C_6H_4), 7.25, 7.20 (d, 2 H, C_5H_3), 6.57 (t, 1 H, C_5H_3). $C_{21}H_{13}N_2O_2$ (456.52): calcd. C 77.78, H 4.01, N 8.64; found C 77.80, H 4.00, N 8.66.

Preparation of L2: A solution of 3-cyanobenzoyl chloride (1.47 g, 8.87 mmol) in anhydrous diethyl ether (20 mL) was added dropwise into a solution of substituted cyclopentadienyl anions (13.3 mmol) in anhydrous diethyl ether (20 mL) at 0 °C, which derived from 6,6′-dimethylfulvene (13.3 mmol) and phenyllithium (13.3 mmol) in anhydrous diethyl ether. The mixture was then stirred at room temperature overnight, and the solvent then reduced to about 10 mL under vacuum. Hexane was subsequently added and an orange solid precipitated, which was then washed with hexane several times and stirred in HCl (5% in water) overnight. The final product was purified by column chromatography on silica gel (CH_2Cl_2/hexane, 3:2) to afford an orange crystalline solid (1.0 g, 51%). IR (KBr pellet, cm^{-1}) $\tilde{\nu}$ = 2995 (m), 2885 (w), 2250 (s), 1615 (s), 1590 (s), 1555 (m), 1525 (s), 1490 (m), 1435 (s), 1415 (s), 1347 (s), 760 (s). ^1H NMR (90 MHz, $CDCl_3$, 25 °C, TMS, ppm): δ = 17.74 (s, 1 H, -OH), 7.99−7.51 (m, 8 H, C_6H_4), 7.25 (s, 5 H, C_6H_5), 6.96 (s, 2 H, C_5H_2), 1.61 (s, 6 H, CH_3). $C_{30}H_{22}N_2O_2{\cdot}0.5CH_3OH$ (458.52): calcd. C 79.82, H 5.23, N 6.11; found C 79.80, H 5.22, N 6.10.

Preparation of 3: Compound **3** was synthesized in 85% yield by layering a benzene solution (4 mL) of $Ag(ClO_4){\cdot}H_2O$ (9.5 mg, 0.046 mmol) over a dichloromethane solution (4 mL) of **L1** (13.9 mg, 0.03 mmol). IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 2998 (s), 2920 (w), 2280 (s), 2250 (m), 1615 (w), 1595 (s), 1540 (w), 1510 (s), 1435 (m), 1410 (m), 1350(s), 1255 (vs), 1180 (s), 1100 (vs), 850 (s). $C_{32}H_{26}AgCl_3N_2O_6$ (748.77): calcd. C 51.28, H 3.47, N 3.74; found C 51.49, H 3.54, N 3.75. Crystals of **3** lose solvent molecules and turn opaque within several minutes under ambient atmosphere, and so the host-guest chemistry of **3** could not be investigated.

Preparation of 4: A mixture of **L2** (24 mg, 0.054 mmol) and $Cu(OAc)_2{\cdot}2H_2O$ (5 mg, 0.027 mmol) in anhydrous EtOH (15 mL) was heated under reflux for 5 min and allowed to cool. The resultant clear red-brown solution was allowed to stand for a week at room temperature. Deep brown crystals were then collected, washed with hexane and dried in air (80% yield). IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3510 (br), 2990 (m), 2260 (s), 1600 (m), 1584 (s), 1555 (vs), 1530 (s), 1490 (w), 1450 (w), 1415 (s), 1360 (m), 1335 (s), 1310 (s), 775 (s). $C_{64}H_{54}CuN_4O_6$ (1038.65): calcd. C 73.94, H 5.20, N 5.39; found C 74.01, H 5.30, N 5.36.

Preparation of 5: A mixture of **L2** (24 mg, 0.054 mmol) and $Co(OAc)_2{\cdot}2H_2O$ (7 mg, 0.027 mmol) in anhydrous EtOH (15 mL) was heated under reflux for 5 min and allowed to cool. The clear red solution was allowed to stand at room temperature for 3 d. Deep red crystals were collected, washed with hexane and dried in air (95% yield). IR (KBr pellet, cm^{-1}): $\tilde{\nu}$ = 3475 (br), 2995 (m), 2260 (s), 1600 (m), 1585 (s), 1560 (vs), 1530 (s), 1494 (s), 1440 (w), 1430 (m), 1415 (s), 1360 (m), 1315 (s), 775 (s). $C_{64}H_{54}CoN_4O_6$ (1034.04): calcd. C 74.27, H 5.22, N 5.42; found C 74.27, H 5.23, N 5.38.

Crystal Structure Determination: Suitable single crystals of **L1**, **L2** and **3**−**5** were selected and epoxied in inert oil onto thin glass fibers. X-ray intensity data were measured with a Bruker SMART

APEX CCD-based diffractometer system (Mo-K_α radiation, λ = 0.71073 Å). Recollection of the first 50 frames at the end of the process revealed no significant crystal decay. The raw frame data for all new compounds were integrated into SHELX-format reflection files and corrected for Lorentz and polarization effects using SAINT.[8] Corrections for incident and diffracted beam absorption effects were applied using SADABS.[8] All structures were solved by direct methods and refined against F^2 by the full-matrix least-squares technique. Hydrogen atoms were calculated and refined as riding atoms; all non-hydrogen atoms were refined with anisotropic displacement parameters. For compounds **4** and **5**, one C_6H_4CN group of the $C_{30}H_{21}N_2O_2$ ligand was found to be rotationally disordered over two orientations in ratios of 0.675:0.325 (**4**) and 0.78:0.22 (**5**). Solution and refinement in the space group *P*1 did not remove the disorder; the space group $P\bar{1}$ was therefore retained. Crystal data, data collection parameters, and refinement statistics for **L1** and **L2** and **3**−**5** are listed in Tables 1 and 2. Selected interatomic bond lengths and bond angles for **L1** and **L2** and **3**−**5** are given in Tables 3, 4, 5, 6, and 7. CCDC-175505 (**L1**), -191568 (**L2**), -175506 (**3**), -191569 (**4**), and -191570 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.

A New Diazacyclooctane Dihydroxamate as a Siderophore Analogue − Synthesis and Equilibrium Studies of Iron(III) and Copper(II) Complexes

Margarida Gaspar,[a,b] J. Paulo Telo,[a] and M. Amélia Santos*[a]

Keywords: Copper / Iron / Aminohydroxamates / Hydroxamic acids / Siderophores

A new siderophore analogue based on the mesocyclic diamine 1,5-diazacyclooctane (DACO) functionalized with two additional hydroxamate donor pendant groups, 1,5-diazacyclooctane-1,5-bis(*N*-methylacetohydroxamic acid) (DACODMAHA), has been synthesized from the corresponding diacetate derivative (DACODA). The complexation behaviour of this ligand towards Cu^{II} and Fe^{III} in aqueous solution has been studied by potentiometry, UV/Vis and EPR spectroscopy and magnetic moment measurements. The Cu^{II} complexation involves the formation of a mononuclear species with a tetradentate mixed amine/hydroxamate coordination mode, whereas the Fe^{III} complexation involves a binuclear species with Fe_2L_3 stoichiometry and normal {*O*,*O*}-hydroxamate coordination mode. The redox potential of the iron complexes and the corresponding electron transfer mechanism are also evaluated.

Introduction

Hydroxamic acid derivatives have been objects of interest for many years due to their natural occurrence and role as microbial iron-transporting compounds (siderophores).[1] Hydroxamate biomimetics have been developed with the aim of obtaining potential constituents of therapeutic agents, for use in chelating therapy (due to their ability to complex iron(III) and related metal ions)[2,3] or as metalloenzyme inhibitors (associated with their complexation with M^{II} transition metal ions).[4,5]

We have been involved in the development and study of a series of polyamine-polyhydroxamate acids as potential siderophore analogues. Their design has been based on macrocyclic or mesocyclic polyamine backbones with *N*-methylacetohydroxamic acids as pendant arms.[6−9] Some of those cyclic diamine-hydroxamate biomimetics − PIPDMAHA and DACHDMAHA (see Scheme 1) − proved to possess interesting properties as siderophore analogues of rhodotorulic acid, a naturally occurring dihydroxamate siderophore.[9] We therefore decided to extend this set of cyclic diamine-dihydroxamic acids by including a PIPDMAHA homologue with a larger backbone skeleton: 1,5-diazacyclooctane-1,5-bis(*N*-methylacetohydroxamic acid) (DACODMAHA, see Scheme 1). Its mesocyclic backbone, 1,5-diazacyclooctane (DACO), presents interesting "boat/chair/crown" configurations and some of its derivatives, those bearing donor pendants such as acetate,[10] thiolate[11] and many other groups,[12−14] have attracted special attention in recent years.

Here we report the preparation of this new ligand (DACODMAHA) as well as the study of its acid−base and complexing properties towards iron(III) and copper(II), mostly by potentiometric and spectroscopic methods. In the absence of X-ray data, because of a lack of suitable crystals, molecular modelling calculations were performed to provide information about the probable topology of the binuclear iron(III)-DACODMAHA complex with 2:3 (metal:ligand) stoichiometry, which can be a mono- or a three-bridged dimer. Since the reduction of the Fe^{III} siderophore complexes has been proposed for the mechanism of microbial Fe release, the redox properties of the iron complexes were studied by voltammetric methods. This set of results is discussed and compared with previous reports on some of the corresponding synthetic or naturally occurring dihydroxamate siderophores.

Results and Discussion

Synthesis

1,5-diazacyclooctane-1,5-bis(*N*-methylacetohydroxamic acid) (DACODMAHA) was prepared by a two-step strategy, starting from the corresponding dicarboxylic acid derivative, 1,5-diazacyclooctane-*N*,*N*′-diacetic acid (DACODA), which was synthesized as described previously.[15] The carboxylic acid groups were condensed with *O*-benzyl-*N*-methylhydroxylamine, in the presence of 1-ethyl-3,3-di-

methylaminopropyl-carbodiimide (EDC), at room temperature and pH 4.8. Next, standard catalytic hydrogenolysis (P_{H_2} = 1 atm) of this bis(*O*-benzylhydroxamate) derivative afforded the free dihydroxamate ligand (DACODMAHA). It is noteworthy that the synthetic scheme used for this ligand is quite different from that previously reported for the smaller size analogues (ex. PIPDMAHA),[6] which involved the coupling of the previously synthesized hydroxamate arms to the amine groups of the cyclic backbones. In the case of the current ligand, however, one of the amine groups in DACO is much more basic than the corresponding groups in the backbones of the previously reported ligands (see below), so the use of the same coupling reaction in the synthesis of DACODMAHA would require more drastic basic conditions, which would probably result in the subsequent hydrolytic scission of the hydroxamate peptidic bond.

Protonation Studies

The acid−base behaviour of this *N*,*N*′-bis(hydroxamate)-diazacyclooctane derivative (DACODMAHA) was studied by potentiometry. A representative pH titration curve for the ligand is presented in Figure 1. The fully protonated form of this ligand can release four protons, although only three protonation constants can be calculated from direct potentiometric data, since the first is too high to be accurately determined by this method (under our experimental conditions it is limited to the range 2−12).[16]

Thus, to achieve a full acid−base characterization of the ligand, a ^{1}H NMR titration was carried out (Figure 2). The indicated peak attribution was based on the corresponding integration areas and multiplicity. The ^{1}H NMR titrations curves corresponding to the three sets of methylenic protons show two well defined inflections at pD* ≈ 2 ($\Delta\delta_a$ = 0.47 ppm, $\Delta\delta_c$ = 0.37 ppm, $\Delta\delta_d$ = 0.40 ppm) and pD* ≈ 13 ($\Delta\delta_a$ = 0.21 ppm, $\Delta\delta_c$ = 0.38 ppm, $\Delta\delta_d$ = 0.33 ppm) regions. A small inflection at pD* ≈ 8 ($\Delta\delta_a$ = 0.04 ppm, $\Delta\delta_c$ = 0.05 ppm, $\Delta\delta_d$ = 0.135 ppm) region is due to the hydroxamate methyl protons, as would be expected. As in the cases studied previously,[17] attribution of the protonation processes (and stepwise protonation constants) to individual basic centres in the ligand is straightforward. The first and last constants (K_1 and K_4) are mainly associated with the protonation of the macrocyclic amines, while the remaining two (K_2 and K_3) are attributable to the protonation of the hydroxamate groups. Further analysis of the sequence of protonation of the four basic sites and calculation of the corresponding microconstants is beyond the scope of this work.

As mentioned above, only three protonation macroconstants (K_2, K_3, K_4) could be determined through fitting analysis of the potentiometric titration data (with the aid of the SUPERQUAD program[18]), while the first protonation constant (K_1) was obtained from fitting of the ^{1}H NMR

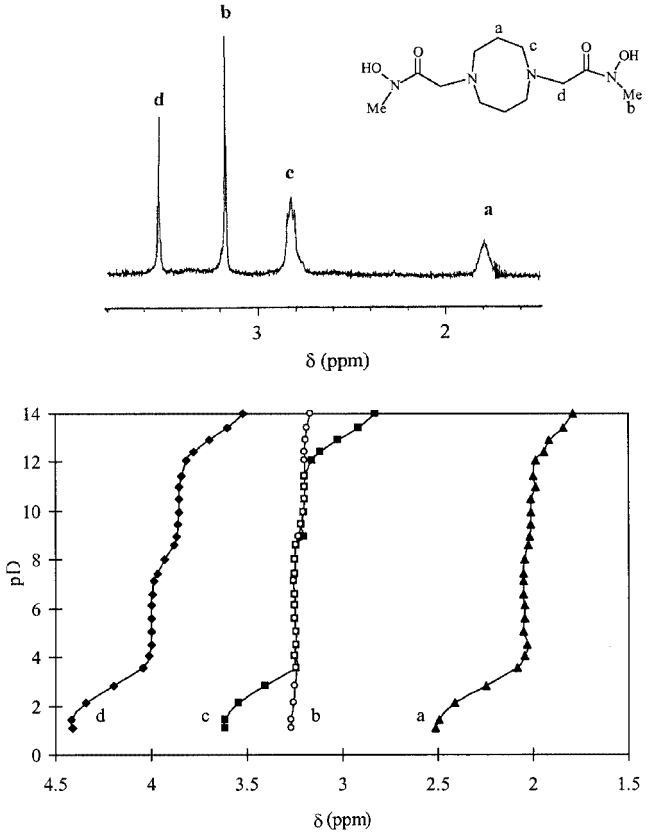

Figure 2. Proton NMR titration curves for DACODMAHA (C_L = 2×10^{-2} M); the pD* of the solution was adjusted with DCl and KOD

titration curves (Figure 2) with the aid of the PSEQUAD program.[16] The refined logarithmic stepwise protonation constants (log K) are listed in Table 1, together with the corresponding values for two structural analogues.

The first protonation constant of DACODMAHA (log K_1 = 13.04), attributable to the protonation of an amine group, is higher than the corresponding value for the cyclic backbone, DACO (log K_1 = 10.74).[19] This feature may be due to the formation of a very stable hydrogen bond between the corresponding ammonium proton and the nearby nitrogen atom of the cyclic backbone, which should be stronger in DACODMAHA than in DACO. The corresponding dicarboxylic derivative, DACODA, showed similar behaviour (log K_1 = 12.27)[15] and it was proposed that the introduction of the acetate groups induces the "boat" as the major macrocyclic conformation, while DACO shows three conformations (boat, chair and crown). Furthermore, of the three conformations of the monoprotonated macrocycle, the "boat" presented the strongest *NH···N* hydrogen bond. Therefore, for similar reasons, the introduction of the hydroxamate arms should favour the "boat" conformation in DACODMAHA. On the other hand, there is an additional stabilization of the DACODMAHA monoprotonated species, due to the hydrogen bond between the ammonium proton and the deprotonated oxygen atom of the adjacent hydroxamate group, through a six-membered ring interaction. The quite low protonation constant of the second nitrogen atom of DACODMAHA (log K_4 = 2.22) supports the existence of such a strong hydrogen bond network, namely between the ammonium proton and the amine *N* atom (>N^+-*H*···*N*<) as well as between the deprotonated amine nitrogen atom and the adjacent hydroxamic proton (>*N*···*HO*−). The remaining protonation constants (log K_2 = 8.91, log K_3 = 7.45) agree with the expected values for hydroxamate groups (log K = 8−10),[20] although their values are slightly lowered by inductive/electrostatic effects of the α-amino/ammonium groups.

Copper(II) Complexation

The complexation behaviour of DACODMAHA toward copper(II) in aqueous solution was studied by potentiometry and UV/Vis spectrophotometry. A representative pH-metric titration curve of this binary system (C_{Cu} = 2.4 × 10^{-3} M, C_L/C_{Cu} = 1:1) is shown in Figure 1. Some precipitation was observed above pH 5. Analysis of the potentiometric titration curves shows that, in the presence of copper(II), the fully protonated form of the ligand is able to dissociate four protons. The global formation constants (Table 1) were calculated from fitting analysis of the titration curve by use of the SUPERQUAD computer program.[18] Below pH ≈ 5, the best model, included only two species, $[CuH_2L]^{2+}$ and $[CuHL]^+$; their overall stability constants (log β) are 29.7 and 24.7, respectively. For higher pH values, neutral species (ex. CuL) or mixed metal-ligand-hydroxo complexes are formed but they are insoluble under our experimental conditions. On the assumption that the last equivalent of base consumption corresponds mainly to the release of the last labile ligand proton, the drastic decrease in the corresponding pH (ca. 5−6) indicates that this proton is being pushed by the metal ion. A rough evaluation of the stability constant of the neutral species (log $\beta_{CuL} \approx 19$) indicates that it would be quite high and closer to the corresponding overall constants of the 1:2 complex (log β_{CuL_2}) for α-aminohydroxamic acids (19.89 for glycinehydroxamic acid)[21] than for simple hydroxamic acids (14.06 for acetohydroxamic acid).[22]

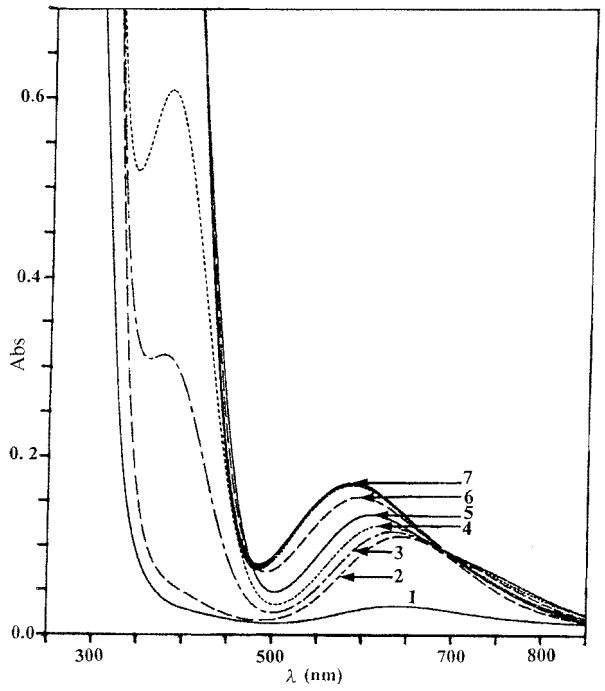

Figure 3. Absorbance spectra of Cu^{II}-DACODMAHA system as function of pH: 1.56 (1), 2.44 (2), 3.73 (3), 4.34 (4), 5.52 (5), 6.36 (6), 7.42−12.03 (7); $C_L = 3 \times 10^{-3}$ M, $C_L/C_M = 3{:}1$, $I = 0.1$ M (KNO_3), $T = 25.0$ °C

In order to obtain further insight into the coordination modes involved in the Cu^{II}-DACODMAHA complexes, UV/Vis spectra were recorded for solutions with $C_L = 3 \times 10^{-3}$ M and 1:3 copper-to-ligand molar ratio at different pH values. We did not observe any precipitate in this study, probably due to the excess of ligand and/or to the higher dilution conditions. The Cu^{II}-DACODMAHA spectra (Figure 3) each exhibit a broad band in the visible region, attributable to the copper d-d transition energy (for pH = 1.6, $\lambda_{max} = 635$ nm, $\varepsilon_{max} = 48$ $dm^3 \cdot mol^{-1} \cdot cm^{-1}$; for pH = 7.4−12.0, $\lambda_{max} = 595$ nm, $\varepsilon_{max} = 170$ $dm^3 \cdot mol^{-1} \cdot cm^{-1}$). At pH = 3.7, a charge transfer (c.t.) band started to appear at $\lambda_{max} = 400$ nm, its intensity increasing with the pH (for pH = 5.52, $\lambda_{max} = 400$ nm, $\varepsilon_{max} = 960$ $dm^3 \cdot mol^{-1} \cdot cm^{-1}$). The isosbestic point at $\lambda = 680$ nm observed for $4 < pH < 7$ suggests the interconversion of two major chromophoric species in that pH range.

Conjugation of spectroscopic and potentiometric data was analysed with care, since different stoichiometries were used. Spectral analysis indicates that, in the highly acidic pH range (pH 1.6−2.4), there is only one major chromophoric species ($\lambda_{max} = 635-640$ nm), which should correspond to the CuH_2L species [or possibly $Cu(H_2L)_2$ for excess of ligand]. Spectra at pH 2.44 ($\lambda_{max} = 640$ nm and the absence of the c.t. band at 400 nm, but around 300 nm) suggest for that complex species a copper coordination sphere involving just one or two amine groups of the macrocycle and water molecules (see Scheme 2). In fact, the DACO-Cu^{II} complex, with Cu^{II} coordinated to the amine groups of the macrocycle, exhibits $\lambda_{max} = 637$ nm,[23] and also some Cu^{II}-α-aminohydroxamic acid complexes with Cu^{II} coordinated to two nitrogen atoms and two water molecules, exhibit $\lambda_{max} = 647-650$ nm.[24] In the pH range around ca. 4−7 there is an interconversion of two species, which is accompanied by a probable change in the coordination mode. In fact the spectral changes that occurred along this pH range − the blue shift and the intensity increase in the d-d transition band, together with the appearance of the band at 400 nm − suggest an increase in the hydroxamate coordination with pH. For some aminohydroxamate ligands, UV bands identical to those seen in the oxygen-hydroxamate to Cu^{II} charge transfer were assigned.[8,25] On the other hand, visible bands with similar λ_{max} values were also found for Cu^{II} complexes with other cyclic polyaminopoly(*N*-methyl-hydroxamate) ligands, for which a mixed coordination of *N*-amine atoms of cyclic backbones and of *O*-hydroxamate atoms of the side arms was considered: $\lambda_{max} = 600$ nm for 1,4-diaazacycloheptane-*N*,*N*′-bis(*N*-methylacetohydroxamic acid);[26] $\lambda_{max} = 590$ nm for 4,8-(12,14-dioxo-1,4,8,11-tetraazacyclotetradecane)bis(*N*-methylacetohydroxamic acid) (DOCYDMAHA).[27] The UV/Vis spectroscopic data of copper(II) complexes with other DACO derivatives bearing different substituents also show absorption maxima around 594−637 nm, attributed to five-coordinate Cu^{II} complex, with distortion from square-pyramidal towards trigonal structures.[12] Furthermore, metal ion coordination through the amine nitrogen atoms and the acetate oxygen atoms has also been proposed for the DACODA-Cu^{II} complexes possessing acetate groups bonded to the macrocycle.[28] Thus, for the CuHL and CuL species, the coordination of Cu^{II} to the ligand should involve not only the mesocyclic amines but also one or two hydroxamate groups, respectively, and one water molecule that occupies the fifth coordination position. The absence of the sixth coordination position, as happens in other similar complexes with DACO derivatives, may also be assumed, consistently with the expected boat-chair conformation of the ligand. The central methylene C−H groups of the boat form in DACO shields the Cu^{II} centre, thus blocking the sixth coordination position.[13]

Electron Paramagnetic Resonance: To advance the study of the type of coordination involved in the DACODMAHA-Cu^{II} complexes further, EPR spectra were obtained over a wide pH range (2−10). No EPR-silent pH region was detected in that pH range, thus suggesting the absence of binuclear species under our experimental conditions. Two EPR spectra were selected (pH 2.99 and 8.40), because the major species under these pH conditions should be CuH_2L and CuL, respectively. All the recorded spectra (Figure 4) present the four lines due to the copper coupling.

The corresponding EPR parameters present $g_{//} > g_{\perp}$ ($g_{//} \cong 2.40$, $g_{\perp} \cong 2.08$, $A_{//} \cong 164 \times 10^{-4}$ cm^{-1}, $A_{\perp} \cong 35 \times 10^{-4}$ cm^{-1}, for pH = 2.99, and $g_{//} \cong 2.26$, $g_{\perp} \cong 2.07$, $A_{//} \cong 167 \times 10^{-4}$ cm^{-1}, $A_{\perp} \cong 30 \times 10^{-4}$ cm^{-1}, for pH = 8.40), indicating an axially elongated-tetragonal copper(II) environment, as is the case with most of the Cu^{II} complexes in solution. For pH = 2.99, the calculated spectral param-

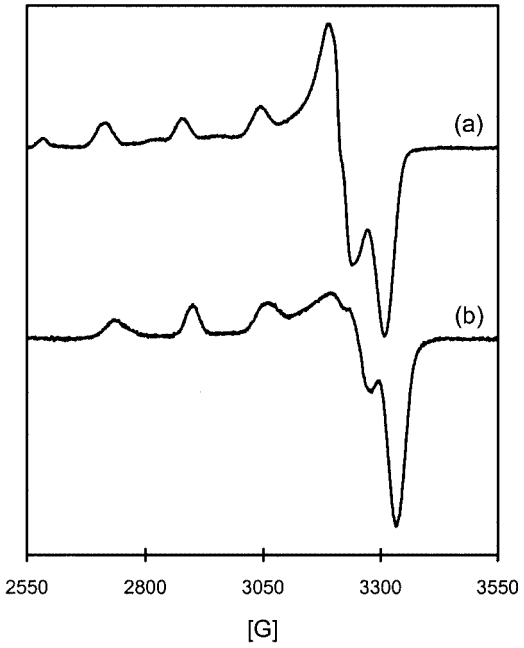

Figure 4. EPR spectra of frozen D_2O solutions with 20% ethylene glycol containing the Cu^{II}-DACODMAHA complexes at: pD* = 2.99 (a), pD* = 8.40 (b) ($C_{Cu} = 6.0 \times 10^{-3}$ M, $C_L/C_{Cu} = 1{:}1$; $T = 100$ K; frequency 9.34 GHz and modulation frequency 100 kHz)

eters indicate complex formation. However, Cu^{II} still seems to be in equilibrium with water molecules ($g_{//} = 2.401$ and $A_{//} = 146 \times 10^{-4}$ cm^{-1} for the Cu^{II} aquo complex)[29] and it is possible that the copper cation is coordinated by two ligand nitrogen atoms. At pD* = 8.40, there is one predominant species, for which the EPR parameters are close to those reported in the literature for some forms of Cu^{II}-α-aminohydroxamic acids complexes ($g_{//} \cong 2.33$; $A_{//} \cong 167 \times 10^{-4}$ cm^{-1}).[29] In this species Cu^{II} is coordinated through mixed (*N*,*N*) and (*O*,*O*) bonding modes. On the other hand, the parameters calculated for this major species, namely $A_{//}$, do not seem to give support to the hypothesis of Cu^{II} being coordinated by two hydroxamate groups ($g_{//} \cong 2.25-2.29$; $A_{//} \cong 189-190 \times 10^{-4}$ cm^{-1}).[30] Furthermore, the difference between $g_{//}$ and $g_{\perp}$ (Δg) is slightly higher at pH 2.99 ($\Delta g = 0.23$) than at pD* 8.40 ($\Delta g = 0.21$), thus suggesting that the presence of the hydroxamate groups in the copper coordination sphere induces less distortion from the square-planar geometry towards the tetragonal than its absence. In conclusion, the EPR spectra support the hypothesis suggested by the UV/Vis spectra, that DACODMAHA-Cu^{II} complexes have a five-coordinate structure with distorted square-pyramidal geometry. In the acid range, CuH_2L should have Cu^{II} coordinated only to the amine groups of the macrocycle and possibly three water molecules; at neutral pH, besides the coordination to the amine groups of the macrocycle, the metal centre should be also coordinated to one and two hydroxamate groups in CuHL and CuL, respectively, with one water molecule in the fifth apical position (see Scheme 2).

Iron Complexion

The interaction of DACODMAHA with iron(III) was studied by UV/Vis spectrophotometric titration ($C_{Fe} = 1.80 \times 10^{-4}$ M with tenfold ligand excess to avoid precipitation of hydroxo complexes). The set of visible spectra registered for the DACODMAHA-Fe^{III} system (Figure 5) shows that complex formation begins at a very low pH (pH < 2). There is a typical ferric-hydroxamate charge-transfer (*c.t.*) band, the intensity enhancement of which and its blue shift with increasing pH indicate greater coordination to the ferric ion (at pH 2.08, $\lambda_{max} = 475$ nm, $\varepsilon = 1660$ M^{-1}·cm^{-1}/Fe; at pH 8.5, $\lambda_{max.} = 420$ nm, $\varepsilon = 2666$ M^{-1}·cm^{-1}/Fe). The isosbestic point at $\lambda = 475$ nm suggests the existence of only two major species in the pH range 3−5. For pH 5−9, $\lambda_{max.}$ and $\varepsilon_{max.}$ are practically pH-independent, indicating the existence of one predominant complex species. Its spectroscopic data is consistent with three hydroxamate moieties coordinated to Fe^{III} [31] (probably as a dimeric structure with Fe_2L_3 stoichiometry). At ca. pH 2.1, according to the spectroscopic data presented above, the major species should already have two hydroxamate moieties coordinated to each ferric centre (probably as a monomeric species). The isosbestic point should therefore be the result of an equilibrium between the monomeric and the dimeric species. Above

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

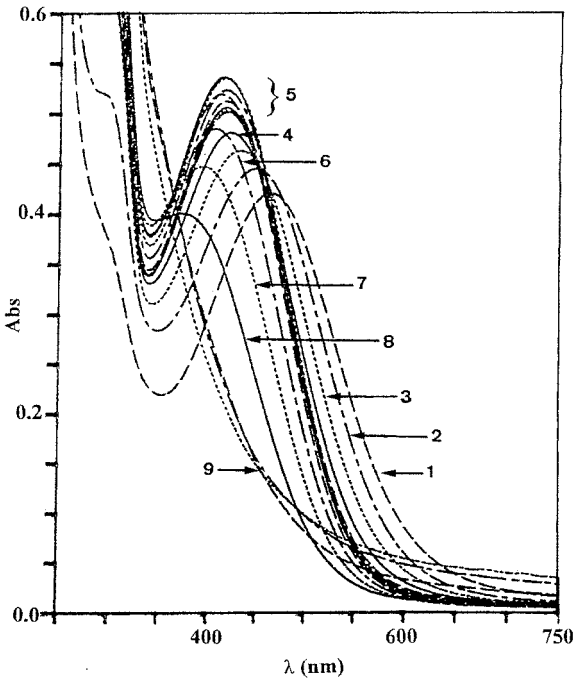

Figure 5. Absorbance spectra of Fe^{III}-DACODMAHA as a function of pH: 2.08 (1), 3.20 (2), 3.77 (3), 4.31(4), 4.91−8.97 (5), 9.38 (6), 9.92 (7), 10.48 (8), 10.92−11.83 (9). $C_{Fe} = 1.8 \times 10^{-4}$ M, $C_L/C_{Fe} = 10:1$; $I = 0.1$ (KNO_3); $T = 25.0$ °C

pH = 9, the corresponding ferric complexes exhibit decreases in their $\varepsilon_{max.}$ and $\lambda_{max.}$ values (orange colour lightens to yellowish) with increasing pH, which is attributable to mixed hydroxo-hydroxamate complexes with only two hydroxamate moieties coordinated to each ferric centre. These results are similar to previously reported for rhodotorulic acid[32] and other synthetic dihydroxamic acids.[6,26,33]

The stability constants of the DACODMAHA-iron(III) complexes were determined by fitting analysis of the spectrophotometric titration data with the aid of the PSEQUAD[16] program. In the pH range from 2−9, the best-fitting model includes one monomeric species $[Fe(HL)]^{2+}$ and two dimeric species ($[Fe_2H_3L_3]^{3+}$ and $[Fe_2H_2L_3]^{2+}$), the global stability constants of which are 28.91, 86.77 and 76.83, respectively. The corresponding species distribution diagram (Figure 6) is consistent with the spectral observations, namely the existence of the monomeric species (FeHL) in the acidic pH range and of the dimeric complex ($Fe_2H_3L_3$) in the neutral zone. The assigned $Fe_2H_2L_3$ species that started to form at ca pH 8 could also be attributable to a mixed $Fe_2H_3L_3(OH)$ complex, or both may possibly occur, but these species are not distinguishable by the PSEQUAD program. Although the first assumption seems consistent with the spectral analysis, above pH = 9, hydrolytic processes compete with the further deprotonation of the complexed ligand.

A brief comparative analysis of the iron affinity of DACODMAHA and other related dihydroxamate ligands can be made from the set of results presented (Table 2), namely from the corresponding pFe values at pH = 7 (pFe = -log [Fe] for $C_L/C_{Fe} = 10$ and $C_L = 10^{-5}$ M), to take account of

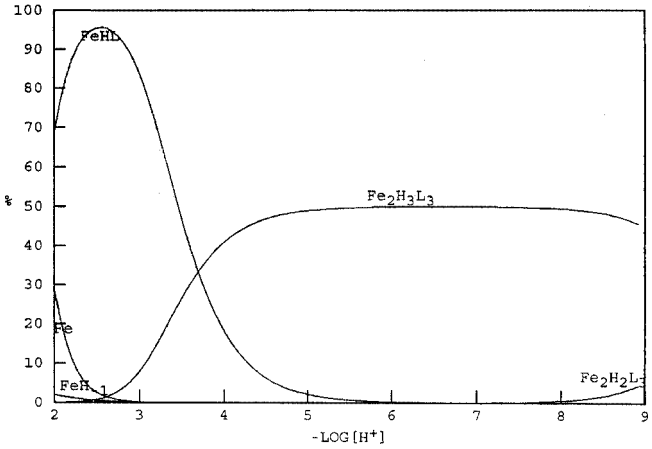

Figure 6. Distribution species diagram for the Fe^{III}-DACODMAHA system as a function of pH ($C_L/C_{Fe} = 10:1$; $C_{Fe} = 1.8 \times 10^{-4}$ M; $I = 0.1$ M (KNO_3); $T = 25$ °C)

the different proton concentration dependency of the different ligands. It is clearly shown that at neutral pH DACODMAHA has less affinity for Fe^{III} (pFe ≈ 17) than the related dihydroxamate derivatives (pFe ≈ 21 for PIPDMAHA and DOCYDMAHA).[9,33]

Since all these ligands form dimeric diiron complexes with the same stoichiometry and probably identical structures under these experimental conditions (the triply ligand-bridged coordination mode, see below), there are no relevant differences in the interaction between the two metal centres. Therefore, the *ca* 4 orders of magnitude difference in the pFe values should be attributable to overall charge differences due to pK_a differences. In fact, protonated DACODMAHA is positively charged as a ligand, whereas the others are neutral Fe^{III} binding ligands. At neutral pH, the current complex ($Fe_2H_3L_3$) therefore has the ligand protonated with the concomitant Fe^{3+}-H^+ electrostatic repulsions and an overall decrease in the stability of the complex, while for the analogous ligands the corresponding complex species are deprotonated. Furthermore, comparison between the calculated pFe values associated with the ferric complexation with the current ligand and *N*-methyl-acetohydroxamic acid (pFe = 16)[34] indicates that the entropic factors associated with the polydenticity of the ligand in this study hardly overcome the destabilizing charge effects on the overall binding interaction. Furthermore, the weaker *O*-donor capacity of the hydroxamate groups is consistent with lower protonation constant found for one of the hydroxamate groups (log $K_3 = 7.45$), due to the electronic effect of the α-ammonium moiety.

Electron Paramagnetic Resonance: To obtain extra information on the dimeric complex of DACODMAHA with iron, the EPR spectrum of DACODMAHA-Fe^{III} system was registered at neutral pH (Figure 7), together with the corresponding spectra for DOCYDMAHA and PIPDMAHA iron complexes, for purposes of comparison.

Each of these spectra shows one single signal at $g = 4.3$, a characteristic value of high-spin octahedral ferric complexes, as previously found for the naturally occurring di-

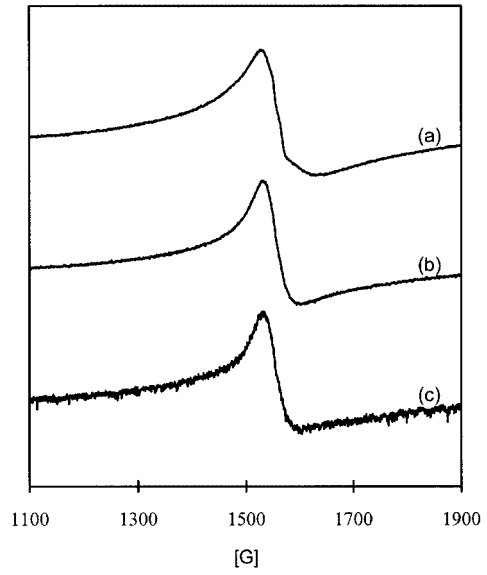

Figure 7. EPR spectra of frozen D_2O solutions containing: (a) ferric-PIPDMAHA, (b) ferric-DOCYDMAHA and (c) ferric-DACODMAHA complexes (C_{Fe}/C_L = 2:3, pD* = 7; C_{Fe} = 1.00 × 10^{-3} M); T = 100 K; frequency 9.34 GHz and modulation frequency 100 kHz)

hydroxamate rhodotorulic acid.[35] The signal linewidth obtained for the dimeric ferric-DACODMAHA complex (72 G) is close to the value found for the DOCYDHAMA-Fe^{III} complex (70 G)[33] and for the ferric rhodotorulate in methanol (51 G), but much lower than the corresponding value for the PIPDMAHA-Fe complex (120 G). The ferric rhodotorulate complex has a distance of ca. 9−10 Å between the two ferric centres, which may be regarded as enough for the existence of significant metal interactions,[35] while the results obtained for the PIPDMAHA dimeric complex indicated dipole-dipole interactions between the metal centres.[6] This type of interaction has also been observed in ferric dimeric complexes of other dihydroxamate ligands, analogues of rhodotorulic acid.[31] These results therefore support the assumption that DACODMAHA forms dimeric species with iron(III), although with weak magnetic interactions between the two metal centres.

Magnetic Properties: The molar magnetic susceptibility (χ_M) and magnetic moment (μ_{Fe}) of the DACODMAHA ferric complexes were measured in D_2O solution as a function of pH (pD*), by Evans' method.[36] In the pH 5−8 range ($Fe_2H_3L_3$ is the major species), the values found for the magnetic moments (μ_{Fe} = 5.83−5.74 BM) are consistent with the existence of a high-spin octahedral complex. They are just between the value for an octahedral unimolecular spin-free iron(III) complex (5.92 BM) and the literature value (5.7 BM) reported for some binuclear iron(III) complexes with very weak interactions between the ferric centres.[31] The ferric rhodotorulate and other dihydroxamate complexes have μ_{Fe} = 5.9 BM, while the ferric PIPDMAHA complex presented μ_{Fe} = 5.5 BM.[6] These results, together with the EPR spectra, suggest that, in the neutral pH range, the DACODMAHA diferric complex has the iron sites enough apart from one another and so only weak or negligible metal−metal interactions.

Molecular Simulation: In order to gain further insight into the $Fe_2H_3L_3$ complex structure, molecular mechanics modelling calculations were performed, through the use of the CERIUS-2 program[37] and also by a previously reported approach.[7] This study was aimed at determining the most probable configuration involved in the DACODMAHA-Fe^{III} dimeric complex, considering two different hypothesis (see Figure 8): (a) three-bridge conformation, similar to that found for the ferric-rhodotorulic acid complex,[38] in which the three ligand molecules each have a hydroxamate moiety coordinated to a different metal centre, and (b) one-bridge conformation, similar to that in the ferric-alcaligin complex,[39] in which only one ligand molecule is coordinated to two metal centres, while the remaining two ligand molecules have both the hydroxamate moieties with intramolecular coordination to the same metal ion.

These theoretical modelling studies showed that, for the dimeric ferric-DACODMAHA complex, conformation (a) is more stable than conformation (b), and that the distance

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

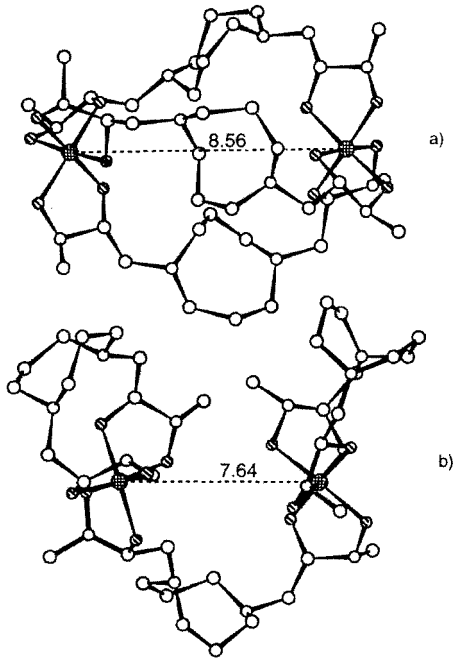

Figure 8. Low-energy conformations simulated for the dimeric complexes of the Fe^{III}/DACODMAHA system

between the ferric centres should be ca. 8.6 Å. This result supports the hypothesis that DACODMAHA forms a binuclear complex with weak interactions between the ferric centres. It is noteworthy that similar theoretical conformational preferences were found for DOCYDHAMA and PIPDHAMA ferric complexes, in which distances between the ferric centres were ca 8.5 Å and 7.7 Å, respectively. The lower stability associated with the structure with the monobridged coordination mode (b) should be mainly due to the existence of some steric strain involved in two ligand molecules, each one tetracoordinate to the same metal centre.

Electrochemistry of the Fe_2L_3 Complex: Cyclic voltammetry studies were carried out for the iron-DACODMAHA system in aqueous solution ($C_{Fe} = 2.5 \times 10^{-4}$ M) containing a 20-fold ligand excess, at pH = 7.0. A cathodic peak and the corresponding anodic counterpart were found. Analysis of the scan-rate effect on the voltammograms suggested a global mechanism involving an electrochemical reversible step (*E*) followed by an irreversible chemical reaction (*C*), perhaps a dissociation. In fact, the diagnostic criteria for (*EC*) global mechanisms are followed because: E_p^c shifts cathodically by around 30/*n* mV (16 mV) for a tenfold increase on *v*, for low scan rates; $i_p/v^{1/2}$ is virtually constant, in the absence of adsorption ($v < 5$ V/s) and the i_p^a/i_p^c ratio approximates to unity with increasing scan rate. The electrochemical reaction should involve a two-electron transfer because for $v = 20$ V/s, where the chemical reaction practically has no time to occur, $\Delta E_p = 30$ mV ($\Delta E_p = 60/n$ for a reversible reaction).[40,41]

This two-electron transfer agrees with $Fe_2H_3L_3$ being the major species at pH = 7 and the expected change of one electron per ferric centre. The fact that E_p^c presented a cathodic shift with increasing pH (pH = 5−8), as a linear variation with a slope of ca 60 mV indicates that the global electrochemistry reaction involves the transfer of two electrons and two protons. On the other hand, the independence of E_p^a and E_p^c of the ligand concentration (C_L/C_{Fe} = 10−30) indicates that both the reduced and oxidized complexes have the same coordination number in relation to the ligand. Thus, the global electrochemical reaction can be represented by the equilibrium Equation (1). The overall stability constant for the reduced species was derived from Equation (2), by the same approach as reported previously.[6,42]

$$[Fe_2^{III}H_3L_3]^{3+} + 2H^+ + 2\bar{e} \rightleftharpoons [Fe_2^{II}H_5L_3]^{3+} \quad (1)$$

$$E_p^c - E_p^s = -\frac{59.15}{2} \times \log\frac{\beta^{III}_{Fe_2H_3L_3}}{\beta^{II}_{Fe_2H_5L_3}} - 59.15 \times pH\ (25\ ^\circ C) \quad (2)$$

The lower stability of the reduced complex ($\log \beta^{II}_{Fe_2H_5L_3} = 67.01$) relative to the oxidized one [$\log \beta^{II}_{Fe_2H_5L_3} = 86.65$) is consistent with the assumed easy dissociation of that species. The reduction potential obtained for the Fe^{III}-DACODMAHA system ($E_{1/2} = -502$ mV) is lower than the corresponding values for other dihydroxamate analogues and rhodotorulic acid[43] (see Table 2). This is not a surprising feature, however, in view of its lower affinity for the iron. Since this potential is closer to the range of physiological reducing agents such as NADH, the complex species is easily reduced and some differences in its possible biological activity are probable. Since many factors influence the biological activity of a siderophore, biological assays need to be done to evaluate the potential of this new siderophore model.

Conclusions

This study reports the preparation of a DACO derivative bearing two hydroxamate arms (DACODMAHA) and its complexation behaviour towards Cu^{II} and Fe^{III} in relation to that of previously reported analogues. With regard to its complexation with copper(II), this ligand can act as a tetradentate ligand, forming stable five-coordinate mononuclear complexes, with the involvement of amine/hydroxamate and H_2O coordination. In the case of iron(III), DACODMAHA-metal binding occurs exclusively through the hydroxamate groups, leaving the amine groups free for potential extra interactions. Although it can act as a tetradentate ligand towards Fe^{III}, forming a mononuclear species under acidic conditions, under conditions of ligand excess and around the physiological pH zone, the Fe^{III} coordination sphere can be completed by formation of a binuclear complex [$Fe_2(HL)_3$] with a triply ligand-bridged structure, in analogy with rhodotorulic acid. At neutral pH, that complex is a three-protonated species, with inherent charge effects, which should account for the lower stability of the DACODMAHA-Fe^{III} complexes, relative to other dihydro-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

xamate siderophore analogues reported previously. This effect is further reflected in the redox potential, which becomes more positive and therefore closer to the range of the physiological reducing agents.

Experimental Section

Chemicals: Analytical grade reagents were used as supplied. The solvents were dried by standard methods.[44] 1,5-Diazacyclooctane-*N*,*N*′-diacetic acid was synthesized as described previously.[15]

Potentiometric Measurements: The pH potentiometric titrations were conducted at 25.0 ± 0.1 °C and at constant ionic strength (0.1 M, KNO_3) by use of a Crison Digital 517 instrument with an Ingold U1330 glass electrode and an Orion 90−00.11 Ag/AgCl reference electrode. The electrode calibration was carried out daily by titration of a strong acid (HNO_3, 0.1 M) with a strong base (KOH, 0.1 M) at the same ionic strength to ensure that we obtained adequate responses in the studied pH range and to control the exact concentration of the ligand (Gran's method).[45] The ligand was weighed directly into the potentiometric cell ($C_L = 2.4 \times 10^{-3}$ M) and the Cu^{II} solution was pipetted from a stock solution of 0.1 M $Cu(NO_3)_2$ in HNO_3 (C_L/C_{Cu} = 1:1). Calculations from potentiometric data were performed with the aid of the superquad[18] program.

Spectrophotometric Measurements: All spectra were measured with a Lambda 9 Perkin−Elmer spectrophotometer at 25 °C and at constant ionic strength (I = 0.1 M, KNO_3). Solutions of the metal complexes were generated in situ by addition, to an excess of the ligand, of a standard metal ion nitrate solution: 5×10^{-2} M $Cu(NO_3)_2$ in HNO_3 (1M) and 1000 ppm $Fe(NO_3)_3$ in HNO_3 (0.5 M). The pH measurements were carried out by use of a 420A Orion pH-meter, equipped with an Orion 91−03 glass calomel combination electrode. The stability constants for the iron(III) complexes were evaluated from the spectrophotometric titration data, by use of the PSEQUAD[16] computer program and speciation curves with the SPEA program.[46]

Electrochemical Measurements: Cyclic voltammograms were recorded with a three-electrode system with a hanging mercury drop working electrode, a platinum auxiliary electrode, and a saturated calomel reference electrode (SCE). All measurements were performed by use of an autolab ecochemie instrument coupled with a computer running the GPES-3 program. The complex in study was generated in situ, in a solution of iron(III) ($C_{Fe} = 2.5 \times 10^{-4}$ M) with a 20-fold excess of ligand, at pH 7.0, with constant ionic strength (I = 1.0 M, KNO_3), thermostatted at 25 °C and degassed with N_2. The pH measurements were performed with a 420A Orion pH meter equipped with an Orion 91−03 combined electrode.

Other Measurements: ^{1}H NMR spectra were recorded with a Varian Unity 300 spectrometer at 25 °C. Chemical shifts are reported in ppm (δ) from internal references {tetramethylsilane (TMS) in $CDCl_3$ solutions and sodium 3-(trimethylsilyl)[2,2,3,3-$^2H_4$]propionate (DSS) in D_2O solutions}. EPR studies were performed with a Bruker ESP ER 200D spectrometer (X-band) in frozen D_2O solutions with 20% ethylene glycol to ensure a good glass (C_L/C_{Cu} = 1:1, $C_{Cu} = 6.0 \times 10^{-3}$ M, T = 100 K, modulation frequency 100 kHz; C_L/C_{Fe} = 3:2, $C_{Fe} = 1.0 \times 10^{-3}$ M, pD* = 7.0, T = 100 K, modulation frequency 100 kHz). The spectra were simulated with the EPR program (version 1.0 by Frank Neese)[47] to calculate the g and A parameters. IR spectra were recorded with a Perkin−Elmer 683 spectrophotometer. Melting temperatures were measured with a Kofler hot-stage apparatus and are uncorrected. Elemental analyses were performed on a Fifons EA1108 CHNF/O instrument. Mass spectra were performed in a VG TRIO-2000 GC/MS instrument.

1,5-Diazacyclooctane-*N*,*N*′-bis(*N*-methyl-*O*-benzyl-acetohydroxamic Acid) (DACODMAHA-Bz): 1-Ethyl-3,3-(dimethylaminopropyl)-carbodiimide (3.60 g, 19 mmol) was added to a solution of 1,5-diazacyclooctane-*N*,*N*′-diacetic acid (1.10 g, 4.7 mmol) and *O*-benzyl-*N*-(methyl)hydroxylamine (2.40 g, 14 mmol) in THF/H_2O (2:1). The pH was adjusted to a constant 4.8 and the mixture was stirred at room temperature for 12 h. The end of the reaction was detected by TLC. The reaction mixture was dissolved in ethyl acetate, washed with saturated NaCl solution and dried with Na_2SO_4. Purification with a silica gel column yielded the pure final product (0.51 g, η = 25%) as a pale oil. IR (film): $\tilde{\nu}$ = 1675 cm^{-1} (C=O). ^{1}H NMR ($CDCl_3$/TMS): δ = 1.96 (t, 4 H, $NCH_2CH_2CH_2N$), 3.01 (br. t, 4 H, $NCH_2CH_2CH_2N$), 3.20 (s, 6 H, CH_3), 3.46 (br. t, 4 H, $NCH'_2CH_2CH'_2N$), 4.01 (s, 4 H, NCH_2CO), 4.95 (s, 4 H, CH_2Ph), 7.39−7.49 (m, 10 H, Ph*H*) ppm. FAB-MS: m/z = 469 [M + 1].

1,5-Diazacyclooctane-*N*,*N*′-bis(*N*-methylacetohydroxamic Acid) (DACODMAHA): Pd/C (10%, 161 mg) was added to a solution of 1,5-diazacyclooctane-*N*,*N*′-bis(*N*-methyl-*O*-benzyl-acetohydroxamic acid) (0.48 g, 1.0 mmol) in dry methanol and the mixture was stirred under H_2 (1 atm) at room temperature for 4 h. After filtration of the solid residue, the solvent was evaporated under reduced pressure and the product was obtained as a white powder, which was then recrystallized from ethanol/acetonitrile (288 mg, η = 98%), m.p. 175 °C (dec.). IR (KBr): $\tilde{\nu}$ = 1640 cm^{-1} (C=O). ^{1}H NMR (D_2O/DSS): δ (ppm) 2.04 (m, 4 H, $NCH_2CH_2CH_2N$), 3.25 (br. s, 14 H, $NCH_2CH_2CH_2N$; CH_3), 4.00 (s, 4 H, NCH_2CO) ppm. (FAB-MS): m/z = 289 [M + 1]. $C_{12}H_{24}N_4O_4 \cdot 2H_2O$: calcd. C 44.43, H 8.70, N 17.27; found C 44.42, H 8.75, N 17.18.

Acknowledgments

The authors are grateful to the Fundação de Ciência e Tecnologia (FCT) and to the COST-D21−001 project program for financial support. One of the authors (M. A. S.) would like also to take the opportunity of Prof. Fraústo da Silva's jubilee to express her acknowledgment for all the encouragement given in introducing her into the bioinorganic chemistry area and for suggestions on biologically relevant ligands.

Preparation, Photo-luminescence and Electro-Luminescence Behavior of Langmuir−Blodgett Films of Bipyridylrhenium(I) Surfactant Complexes

Vivian Wing-Wah Yam,*[a] Bin Li,[a] Yu Yang,[a] Ben Wai-Kin Chu,[a] Keith Man-Chung Wong,[a] and Kung-Kai Cheung[a]

Keywords: Luminescence / Surfactants / Langmuir−Blodgett films / Rhenium

Several bipyridylrhenium(I) surfactant complexes, *fac*-[Re(CO)$_3$(bpy)(L)]PF$_6$ [bpy = 2,2′-bipyridine, L = *trans*-4-dodecyloxy-4′-stilbazole (**L1**), *trans*-4-octadecyloxy-4′-stilbazole (**L2**), 4-(4′-dodecyloxyphenylethynyl)pyridine (**L3**)] were synthesized and characterised. The X-ray crystal structure of *fac*-[Re(CO)$_3$(bpy)(**L1**)]PF$_6$ has been determined. The complexes exhibited intense photo-luminescence which has been ascribed to the dπ(Re) → π*(bpy) metal-to-ligand charge transfer (MLCT) triplet emission. The complexes were found to form stable Langmuir–Blodgett (LB) films with relatively high collapse pressures. The organic light-emitting diodes (OLEDs) fabricated by employing the LB films of various complexes as the emitting layer exhibited electroluminescence (EL) behavior. The luminances of the EL devices were found to vary as a function of the number of LB film layers, hydrocarbon chain length and the deposition types.

Introduction

Efficient electroluminescence (EL) from organic films at low voltages was first reported in 1987.[1] Since then, a variety of EL materials have been synthesised,[1,2] and various techniques for device fabrication have been optimised.[2f,3] Recent works on the fabrication of thin-film devices for organic light-emitting diodes (OLEDs) have mainly concentrated on the use of vacuum deposition,[1,3b,4] spin coating,[5] self-assembly[3g,6,7a] and Langmuir−Blodgett (LB) techniques.[7,8] The LB film technique is interesting in that it is possible to prepare organic functional ultra-thin films with controlled thickness of a molecular size and well-defined molecular orientation.[9] In some circumstances LB films may produce films of higher quality than the general vacuum deposited or spin-coat films and may have potential applications in molecular electronic devices.[9,10]

Employment of transition metal complexes as the emissive layer in OLEDs has become one of the important subjects in recent years,[5,11] since many of them have excellent photoluminescence properties and potential advantages of achieving a maximum internal quantum efficiency of 100%.[2f] The formation efficiency of the triplet state will be triple that of the singlet state in the non-geminate pair electron combination (as in ELs), thus an improvement in the EL yield should be predicted by using triplet state materials as the emitting layer, which makes them promising candidates for OLEDs, and a number of related studies have been reported.[5,11,12] Amongst the transition metal complexes studied, those of the bipyridylruthenium(II) systems, which show ^{3}MLCT emission, have been extensively studied.[5a,5b] Other relatively less studied systems involving ^{3}MLCT emissive states include the well-known tricarbonyl(diimine)rhenium(I) complexes.[13−15]

In order to explore the potential applications of metal-based ultra-thin films in the design and construction of molecular electronic devices and to better understand the mechanism of ELs displayed by transition metal complexes in LB films, it is important to design, fabricate, and study OLEDs using LB films of metal complexes as the emissive layer. However, little attention has been devoted to this area.[8] Herein we report the synthesis of luminescent bipyridylrhenium(I) complexes with long hydrocarbon chain-containing pyridine ligands, *fac*-[Re(CO)$_3$(bpy)(L)]PF$_6$ [bpy = 2,2′-bipyridine, L = *trans*-4-dodecyloxy-4′-stilbazole (**L1**), *trans*-4-octadecyl-4′-stilbazole (**L2**), 4-(4′-dodecyloxyphenylethynyl) pyridine (**L3**); Scheme 1]. The successful preparation of stable LB films of these complexes renders their employment as the emitting layer for OLED fabrication possible and such devices have been found to exhibit electroluminescence, typical of the ^{3}MLCT emission of diiminerhenium(I) complexes. The influence of various factors on the OLEDs performance involving LB films of the complexes has also been described.

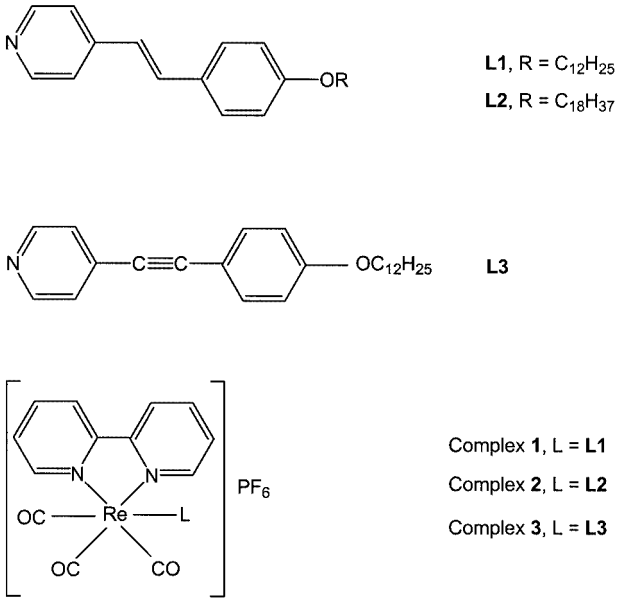

Scheme 1. Structures of ligands and corresponding surfactant Re^{I} diimine complexes

Results and Discussion

Synthesis and Characterization

The ligands **L1**,[16] **L2**,[16] **L3**[17] and the corresponding rhenium(I) complexes **1**, **2**, **3**[14e,18] were prepared according to literature methods, and their structures are shown in Scheme 1. The purity and composition of the rhenium(I) complexes were confirmed by ^{1}H NMR, IR spectroscopy, positive-ion FAB-MS and elemental analyses. The structure of **1** was determined by X-ray crystallography. The observation of three strong bands between 1900 and 2100 cm^{-1} in the infrared spectra for all rhenium(I) complexes confirms that the tricarbonyl Re^{I} moiety is in the facial arrangement.[19]

X-ray Crystal Structure

The perspective drawing of the complex cation of **1** with atomic numbering is shown in Figure 1, and selected bond lengths and angles are given in Table 1. The coordination geometry at the Re atom is distorted octahedral with the three carbonyl ligands arranged in a facial fashion. The N(1)−Re−N(2) angle of 75° is a result of the steric requirement of the bidentate diimine ligand. The C(19)−C(20) bond length of 1.342(8) Å and the bond angles of C(16)−C(19)−C(20) at 121.3(6)° and C(19)−C(20)−C(21) at 126.5(6)° are typical of the sp^2 hybridization of the styryl group. All other bond lengths and bond angles are unremarkable and are similar to those found for other related Re^{I} polypyridyl complexes.[14,19,20] The hydrophobic aliphatic chain is running along an axis that is almost perpendicular to the plane containing the Re atom and the bipyridine unit, which leads to the good LB film forming capability of the complexes.

Surface Pressure−Area (π−A) Isotherms and LB Film Deposition

The π−A isotherms of the Re^{I} complexes which spread from chloroform solutions onto ultrapure water at room temperature were recorded, and are shown in Figure 2. The curves show one well-defined condensed region.

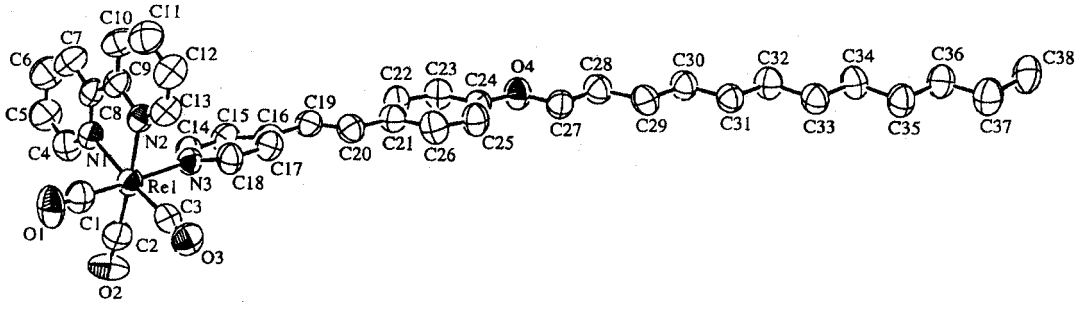

Figure 1. Perspective drawing of the complex cation of **1** with atomic numbering scheme; hydrogen atoms were omitted for clarity; the thermal ellipsoids are shown at the 50% probability level

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

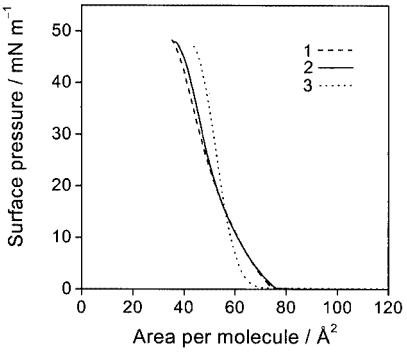

Figure 2. Surface pressure-area (π−A) isotherms of **1** (− − −), **2** (···) and **3** (---)

The molecular areas for these Re^I complexes are obtained by the extrapolation of the condensed region to zero surface pressure. The data are summarized in Table 2. It is worth noting that these complexes have similar π−A isotherms with fairly high collapse pressures as a result of the similarity in their structures.

Table 2. LB film-forming properties for complexes **1**−**3**

Complex	Molecular area (Å)^2	Collapse pressure (mN m^{-1})	Transfer ratio
1	61.5	48	0.65−1
2	60.5	49	0.80−1
3	62	48	0.65−1

The almost identical molecular areas of 61 Å^2 for these Re^I complexes match fairly well with the calculated value of 55 Å^2 based on the crystal structure of **1**. This indicates the formation of a close-packed stable monolayer at the air-water interface, probably with the long alkyl chain vertically oriented with respect to the water surface, resulting in almost no change in the area per molecule upon increasing the chain length of the hydrocarbon. Despite **1** and **3** only containing 12 -CH_2- units, their LB film-forming properties are good and similar to those of **2** which has an alkyl chain

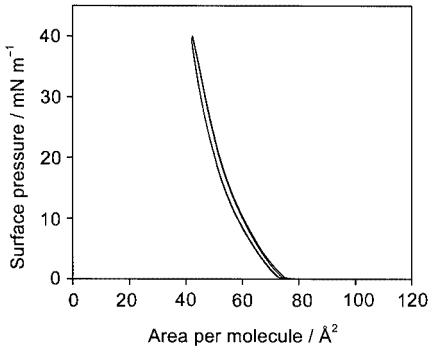

Figure 3. Compression-expanding isotherms for **1**

of 18 -CH_2- units. The formation of stable LB films with relatively short hydrocarbon chains may be advantageous in that it may minimize the resistance of the LB films in the construction of the OLED devices. The compression-expanding cycle isotherms of **1** are shown in Figure 3. No obvious hysteresis was observed, further confirming the good monolayer forming properties of the complexes.

UV/Vis Absorption Spectroscopy

The electronic absorption spectra of **1**−**3** in dichloromethane and in LB films show a high-energy absorption band at ca. 248 nm and a low-energy absorption band at ca. 364−370 nm. The high-energy absorption band is tentatively assigned as a π → π* intra-ligand transition (IL) of bipyridine. With reference to previous spectroscopic studies of the related cationic diiminerhenium(I) complexes, $[Re(CO)_3(diimine)(pyridine)]^+$,[13,14] which also exhibit a low-energy absorption band in a similar region, the low-energy absorption is ascribed to the dπ(Re) → π*(bpy) metal-to-ligand charge transfer (MLCT) transition. However, the extinction coefficients of these low-energy absorption bands in the order of 10^4 dm^3 mol^{-1} cm^{-1} in complexes **1**−**3** are much larger than those for typical MLCT transitions (approx. 10^3 dm^3 mol^{-1} cm^{-1}). In view of the similar absorption energies and extinction coefficients of the free ligands **L1**, **L2** and **L3**, the low-energy absorption band of **1**−**3** is accordingly assigned as an admixture of π → π* IL transitions of **L1**, **L2** and **L3** and dπ(Re) → π*(bpy) MLCT transitions.

Photoluminescence Properties

Complexes **1**−**3** exhibit intense greenish yellow luminescence in solution, solid state and as an LB film. The emission data for the complexes are summarized in Table 3. In general, the emission spectra of the complexes in dichloromethane and in an LB film at room temperature show broad emission bands at ca. 527−548 nm. On the basis of the previous spectroscopic assignments on the related cationic diiminerhenium(I) complexes, $[Re(CO)_3(diimine)(pyridine)]^+$,[13,14] the emission origin is assigned to be derived from the ^{3}MLCT excited state. The emission energies of the complexes in glass at 77 K were found to be blue-shifted with respect to those in solution and in LB films, and are attributed to the phenomenon of luminescence rigidochromism.[21] The emission spectra of **1** in dichloromethane and in LB films at room temperature and in EtOH/MeOH (4:1 v/v) glass at 77 K are shown in Figure 4. It is noteworthy that the luminescence quantum yield (Φ_{lum}) of **3** in fluid solution is larger than those of **1** and **2** by one order of magnitude. The lower luminescence quantum yield observed in **1** and **2** is probably due to the presence of the energy-accepting *trans*-styryl group, which would provide an additional non-radiative decay pathway for the quenching of the ^{3}MLCT excited state via an intramolecular energy transfer process, rendering the lower luminescence quantum yield. Similar observation has also been reported in the related azo- or styryl-containing rhenium(I) complexes.[15g]

Electroluminescence Properties

The rhenium(I) surfactant complexes were deposited as Y-type LB films and were used as the emissive layer in single-layer OLED devices (ITO/LB film/Al; Scheme 2). An LB film thickness of at least 10 monolayers was required to prevent the possibility of a short circuit between the ITO and the aluminium electrode. Upon being forward biased with ITO at positive polarity in a continuous DC mode, the EL devices with a 25-layer LB film of **1**−**3** exhibit yellow electroluminescence (EL) with turn-on voltages of ca. 10 V. The close resemblance of the EL and PL spectra suggests that the EL of these rhenium(I) surfactant complexes involves the same excited state as PL, i.e. the triplet MLCT state or exciton. Upon forward bias, holes injected from ITO and electrons from Al migrate in the LB films and EL is generated upon recombination form excitons. The EL and PL spectra of **1** in a 25-layer LB film are shown in Figure 5.

Scheme 2. Configuration of EL cells

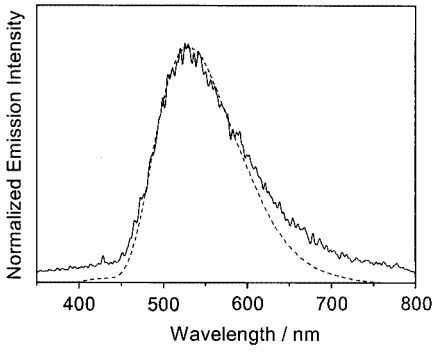

Figure 5. EL (−) and PL (···) spectra of **1** in 25-layer LB films

The EL intensity was found to vary as a function of the number of monolayers in the LB films and the relationship between the LB film layer number and the luminance of the EL devices of **1** is summarized in Table 4. The EL intensity increases with increasing layer numbers in the range of 10−20 layers, reaching a maximum at ca. 20−30 layers and then decrease upon further increase in the layer numbers of 30−40 and beyond. The EL behavior was hardly detectable for the device with an 80-layer LB film. Upon increasing the number of LB film layers, two opposite effects governing EL intensity come into effect. One is an increase in the concentration of charge carriers (both hole and electron) generated by applying DC voltage and hence an increase in the recombination probability, leading to the intensification of EL luminance. The other is an increase in the energy loss for the charge carriers passing through the LB layers, due to the larger resistance across the LB film, resulting in the diminishing of the EL intensity. For devices with 20 layers or less, it is likely that the first effect plays a more important role with such a short distance and the EL intensity is therefore increased. When the number of layers increases further (> 30 layers), the charge carrier concentration reaches a saturation level. On the other hand, fewer charge carriers can pass through the LB layers as a result of the energy loss from the long distance transporting process. Eventually, the

Table 4. Layer number-luminance relations of the EL devices of **1**

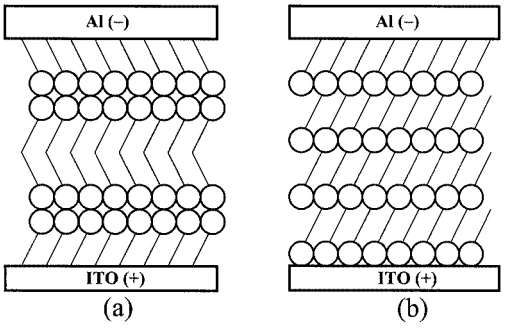
Luminance (cd/cm^2)	<1	5	6	3	<1

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

EL intensity drops for a device with greater than 30 LB film layers. A similar phenomenon has been reported for the EL device using LB films of bis[*N*-hexadecyl-8-hydroxy-2-quinoline carboxamide]cadmium as the emitting layer.[8e,22] Optimum EL efficiency of the present EL device is obtained for the LB film in the range of 20−30 layers. It is interesting to find that complex **1**, with the shorter hydrocarbon chain, shows a higher EL intensity than **2** by a factor greater than four for the same number of LB film layers. This may be attributed to the larger energy loss for the charge carriers transporting the LB film layers with higher resistance in the longer hydrocarbon chain of **2**.

On the other hand, the EL intensity is found to depend on the deposition types of the LB films. For example, an EL device constructed of a 25-layer LB film of complex **1** in the Y-type shows an approximately 180-fold increase in EL intensity relative to that of the same device in the Z-deposition type. It is likely that the head-to-head arrangement in LB films of rhenium(I) complexes may facilitate the charge transport processes, giving rise to better EL performance (Scheme 3).[23]



Scheme 3. Scheme of devices with different deposition types: (a) device in Y-type LB film; (b) device in Z-type LB film

In view of the poor stability of these single-layer devices, a double-layer configuration of ITO/PVK/LB film/Al was employed in order to improve the stability of the EL device. By taking advantage of the LB deposition technique which can control the deposition range, a device using the LB film of **1** was fabricated to cover only half of the area of the ITO glass. One half of the device is the ITO/PVK/Al (single-layer structure) and the other half is the ITO/PVK/**1**(LB film)/Al (double-layer structure). When the device was subjected to a forward bias using a DC power supply, the two halves of the device simultaneously emitted two different colors, a characteristic yellow EL coming from the ITO/PVK/**1**(LB film)/Al and a purple EL from the ITO/PVK/Al, typical of EL arising from PVK. In the double-layer device, PVK itself did not give rise to EL but rather acted as the hole transporting layer. The relatively even distribution of luminance indicates that uniform assemblies are formed by LB deposition on ITO/PVK. An improved performance was observed in the double-layer device. Relatively stable characteristic emission of the Re^{I} complex under the driving voltage of 7 V was observed and a maximum luminance of 9 cd/cm^2 at 18 V was achieved from the ITO/PVK/**1**(LB film)/Al device with a 25-layer LB film of **1**. The forward bias current could be obtained when the ITO electrode was positively biased and aluminium electrode negatively biased. The current increased when the forward bias voltage increased and the reverse current remained small when the ITO electrode was applied, a negative bias voltage and the Al electrode a positive bias. Figure 6 shows the current-voltage characteristics of the double-layer EL device of **1**.

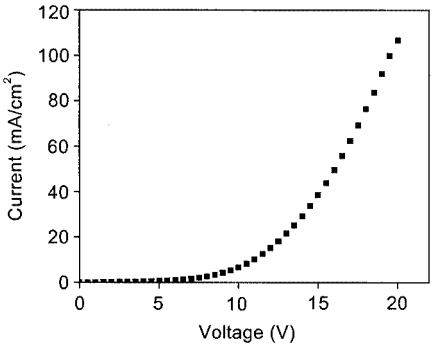


Figure 6. Current-voltage characteristics for the devices of [ITO/PVK/LB film/Al] for **1**

It is interesting to note that the luminance of the single layer device ITO/PVK/Al was 0.8 cd/m^2 when a driving voltage of 18 V was applied. Double-layer devices prepared other than using the LB technique of spin-coating of the rhenium complexes were also fabricated. The luminance of ITO/PVK:**1**/Al, ITO/PVK:**2**/Al and ITO/PVK:**3**/Al are 16, 0.7 and 0.3 cm/m^2, respectively, when the voltage applied is 18 V, similar to that obtained from LB deposition of the complexes.

Conclusions

Three Re^{I} bipyridyl surfactant complexes with hydrocarbon chain lengths of 12 and 18 were synthesised. Yellow luminescence was observed upon visible light excitation and attributed to ^{3}MLCT emission. All of them exhibit stable air-water interface behavior and are capable of forming stable multi-layer LB films on ITO substrates in an electroluminescence (EL) device. The LB films of these complexes were found to show EL behaviors with emission energies similar to those of the photo-luminescence. A decrease in the hydrocarbon chain length of the ligands in the complexes increases the EL intensity. The thickness and the deposition types of the LB films are shown to affect the luminance of the EL devices.

Experimental Section

Materials and Synthesis: 1-Bromododecane (97%, Lancaster), 1-bromooctadecane (98%, Lancaster) and $Re(CO)_5Cl$ (98%, Strem) were used as received. Piperidine (99%, Acros) was distilled over CaH_2. All other solvents for synthesis were of analytical grade and were used without further purification. The ligands **L1**,[16] **L2**,[16]

Yield: 81%. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 9.05 (d, *J* = 4.6 Hz, 2 H, 6,6′-H of bpy), 8.61 (d, *J* = 8.2 Hz, 2 H, 3,3′-H of bpy), 8.32 (m, 2 H, 4,4′-H of bpy), 8.02 (d, *J* = 6.7 Hz, 2 H, pyridyl H *ortho* to N), 7.73 (m, 2 H, 5,5′-H of bpy), 7.42 (d, *J* = 8.8 Hz, 2 H, phenyl H of **L3**), 7.33 (d, *J* = 6.7 Hz, 2 H, pyridyl H *meta* to N), 6.85 (d, *J* = 8.9 Hz, 2 H, phenyl H of **L3**), 3.96 (t, *J* = 6.5 Hz, 2 H, $-OCH_2-$), 1.77 (m, 2 H, $-CH_2-$), 1.44 (m, 2 H, $-CH_2-$), 1.25 [m, 16 H, $-(CH_2)_8-$], 0.87 (t, *J* = 6.6 Hz, 3 H, $-CH_3$) ppm. UV/Vis [CH_2Cl_2, λ/nm (ε × 10^{-4}/dm^{3}mol^{-1}cm^{-1})]: 248 (3.29), 280 (2.12), 311 (1.98), 322 (2.56), 364 (4.44). UV/Vis (LB film, λ/nm): 354. IR (Nujol): 2034 cm^{-1} (s) ν(CO), 1942 (s) ν(CO), 1909 (s) ν(CO), 2185(ν), 2219 (m) ν(C≡C). Positive FAB-MS: *m*/*z* = 790 [M]$^+$, 427 [M − **L3**]$^+$. $C_{38}H_{41}F_6N_3O_4PRe$ (934.9): calcd. C 48.82, H 4.39, N 4.49; found C 48.96, H 4.34, N 4.48.

Instrumentation and Physical Characterization: The UV/Vis spectra were obtained on a Hewlett−Packard 8452A diode array spectrophotometer, IR spectra as Nujol mulls on a Bio-Rad FTS-7 spectrophotometer. ^{1}H NMR spectra were recorded on a Bruker DPX-300 NMR spectrometer with chemical shifts reported relative to tetramethylsilane. Positive-ion fast-atom bombardment (FAB) mass spectra were recorded on a Finnigan MAT95 mass spectrometer. Elemental analyses were performed on a Carlo Erba 1106 elemental analyzer at the Institute of Chemistry, Chinese Academy of Sciences. Steady-state excitation and emission spectra were obtained on a Spex Fluorolog-2 111 spectrofluorometer with or without Corning filters. Low-temperature (77 K) spectra were recorded using an optical Dewar sample holder. The OLED devices were driven at room temperature in air with a DC power supply. The EL spectra were collected on an Oriel Instruments intensified charge-coupled device (ICCD) detector (Model DH520) and were analyzed using the InstaSpec V software. The emission signal was collected by an optical fiber and dispersed onto the CCD detector with an Oriel MultiSpec 115 imaging spectrograph (Model 77480). The system was operated at −15 °C by the single-stage system in order to reduce the dark current signal. The luminance of the OLED devices was measured with a Minolta LS-110 luminance meter. The current-voltage (*I*−*V*) characteristics were studied by a Keithley 2400 autoranging sourcemeter.

X-ray Crystal Structure Determination: Crystals of **1** were obtained by slow diffusion of diethyl ether vapour into a chloroform solution of the complex. A yellow needle-shaped crystal of dimensions of 0.35 × 0.25 × 0.15 mm was used for data collection at 28 °C on a Rigaku AFC7R diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). The space group was uniquely determined based on systematic absences and the structure was solved by direct methods (SIR92)[24a] and expanded by Fourier method and refinement by full-matrix least-squares using the software package TeXsan[24b] on a Silicon Graphics Indy computer. One crystallographic asymmetric unit consists of one formula unit. The F atoms were disordered and were placed at 12 positions with F(1) to F(12) having occupation numbers 0.87, 0.82, 0.52, 0.35, 0.64, 0.43, 0.44, 0.37, 0.49, 0.37, 0.44 and 0.26 respectively. In the least-squares refinement, 47 non-H atoms were refined anisotropically, the 12 disordered F atoms were refined isotropically, and 41 H atoms at calculated positions with thermal parameters equal to 1.3 times that of the attached C atoms were not refined. Crystal and structure determination data of **1** are collected in Table 5. CCDC-

Table 5. Crystal and structure determination data for **1**

Formula	$[C_{38}H_{41}N_3O_4Re]PF_6$
M_r (g·mol^{-1})	934.93
Crystal system	Monoclinic
Space group	$P2_1/a$ (No.14)
T, (K)	301
D_c (g cm^{-3})	1.564
V (Å^3)	3969(1)
Z	4
a (Å)	20.922(3)
b (Å)	9.104(2)
c (Å)	23.302(4)
α (deg)	90
β (deg)	116.573(2)
γ (deg)	90
F(000)	1864
Collection range	$2\theta_{max}$ = 52° (0 > *h* > 25; 0 > *k* > 11; −28 > *l* > 25)
Reflections collected	8553
Independent reflections	8321
Parameters	472
Goodness-of-fit	1.96
Final *R* indices	$R1 = 0.034$, $wR2 = 0.045$[a]
Largest difference peak/hole [e·Å^{-3}]	1.04/−0.66

[a] $w = 4\ F_o^2/\sigma^2(F_o)^2$, where $\sigma^2(F_o)2 = [\sigma^2(I) + (0.024\ F_o^2)^2]$ for 5066 reflections with $I > 3\sigma(I)$.

LB Film Preparation and OLED Device Fabrication: Indium tin oxide (ITO) glass slides with a sheet resistance of about 30 Ω/□ were used as the positive electrode of the OLEDs. The cleaning procedure included sonication in detergent for 30 min and acetone for 30 min, rinsing in de-ionized water and isopropyl alcohol, boiling in $CHCl_3$, treatment by UV-ozone exposure, and repeated rinsing with copious amounts of ultrapure water.[25] The cleaned ITO-coated glass slides present good hydrophilic properties. The quartz substrates were cleaned by well-known standard procedures.[15j] The complexes in chloroform with concentrations of 1.00 mg cm^{-3} were spread onto a pure water sub-phase with a conductivity of 18 MΩ cm (pH, 5.6, 20 °C) using a Nima model-622 computer-controlled trough. After a 15 min. period to allow for the evaporation of chloroform, surface pressure-area (π−A) isotherms were recorded at a barrier compression speed of 150 cm^2 min^{-1}. The monolayers formed under a constant surface pressure of 25 mN m^{-1} were transferred onto hydrophilically treated substrates after maintaining the pressure constant at the transfer pressure for 10 min for stabilization, at a dipping speed of 15 mm min^{-1}. The transfer ratios of these complex films were between 0.6 and 1 (see Table 2). After the LB films were deposited, aluminium was deposited at 10^{-5} Torr to a thickness of 150 nm onto the LB film surface with a deposition rate of 1.0 nm s^{-1}. The devices ITO/[$Re(CO)_3$(bpy)(L)]PF_6/Al were obtained. The emitting area was 20 mm^2. For ITO/PVK/[$Re(CO)_3$(bpy)(L)]PF_6/Al, the [poly(9-vinylcarbazole) (PVK) layer was inserted between the LB films and the ITO electrode by spin casting solutions of PVK in $CHCl_3$ (5 mg/mL) onto the treated ITO-coated glass with a spin speed of 2400 rpm. The PVK surface is regarded as hydrophobic. The first monolayer was transferred onto a hydrophobic PVK surface on the down path. In the fabrication of double-layer devices using the spin-coating technique, the emissive layer was spin-coated onto ITO glass from a 1,1,2,2,-tetrachloroethane solution of the respective complex and PVK (10 mg:5 mg in 1 mL $C_2H_2Cl_4$) followed by deposition of aluminium by vacuum evaporation. The other procedures are the same as described above.

Synthesis, Structure and Characterization of New Olivacine Derivatives and Their Platinum(II) Complexes

Anna Romaniewska,[a] Ryszard Jasztold-Howorko,[b] Andrzej Regiec,[b] Tadeusz Lis,[a] and Janina Kuduk-Jaworska*[a]

Keywords: Antitumor agents / Template synthesis / Platinum / Structure elucidation / Conformational analysis

Three unknown olivacine derivatives (L-OCH_3, L-OH, L-OAc) were synthesized according to a procedure that involves only a few steps, and used as ligands in the synthesis of neutral chelate platinum(II) complexes. The ligands, as well as their platinum complexes were spectroscopically characterized with IR, $^1H/^{13}C$ NMR and UV/Vis spectroscopic techniques. The solid state structures of two ligands (L-OCH_3, L-OAc) and one complex {[(L-OCH_3)$PtCl_2$]} were determined by X-ray diffraction. Molecular structure analysis of the ligands and the complex indicated that complexation resulted in a change in the conformation of the bipyridine fragment of the compounds studied and caused other interesting effects. Two crystallographically independent molecules of the complex were revealed in the measured crystal, with short intramolecular H···H distances. The structural and energetic aspects of the conformational behavior of the ligand L-OCH_3 and the complex [(L-OCH_3)$PtCl_2$] have been analyzed using semiempirical PM3 methods. In vitro antiproliferative activity was preliminarily estimated.

Introduction

The quest for new antitumor agents among the platinum complexes is still active and seems to be deeply grounded because of the fact that two compounds from this group, cisplatin and carboplatin, belong to the most effective and widely used platinum anticancer drugs. However, there are limitations to their applicability because of the high level of resistance observed in various tumors.[1] Moreover, these drugs are cross-resistant to each other which may be as a result of their similarity as they are both compounds of type $[Pt(NH_3)_2X_2]$ and have the same neutral ligands.

The in vivo cisplatin resistance may be caused by three major mechanisms. Firstly, the intracellular concentrations of the drug may be lower as a result of increased efflux or blocked uptake. Secondly, the drug can be inactivated through the quenching of the monofunctional Pt-DNA adducts before the formation of cross-links through reaction with metallothioneins, glutathione or other intracellular ligands. Finally, the removal of the drug-DNA adducts may occur through cell-based repair, which includes nucleotide excision repair.[2] The need to circumvent these processes has led to a search for analogs which avoid the cross-resistance but achieve a similar level of effectiveness. Considering that carboplatin does not fulfil such requirements, probably because of the formation of DNA adducts identical to those formed by cisplatin, one strategy to overcome cisplatin (and carboplatin) resistance would be to employ platinum complexes with bulky neutral ligands that form very different types of DNA lesions and inhibit nucleotide excision repair.[3]

In fact, in vitro studies of complexes that have at least one neutral ligand that is bulkier than NH_3, such as aminocyclohexane or pyridine derivatives, showed diminished cross-resistance to cisplatin.[4,5]

Moreover, it has also been suggested that the bulkier ligand may inhibit the reactivity of the platinum drug with cellular glutathione and other sulfur donors in vivo, and in this way diminish the concentration of GSH-platinum complexes. These complexes are actively transported out of cells and contribute to cisplatin efflux.[6,7]

If the mode of resistance to cisplatin is the efficient repair of specific adducts, then the other effective means of circumventing such resistance might be to prepare platinum complexes with ligands that have intercalative properties.[8,9] This led to the idea of using three new olivacine derivatives (L-OCH_3, L-OH, L-OAc, Figure 1) as ligands in the neutral platinum(II) complexes.

Olivacine is an isomeric form of ellipticine, which is a well-known cytostatic that acts through intercalation. Ellipticine is used as an anticancer drug in the form of elliptinium acetate (Figure 2, **NMHE**).[10,11] Recently, a series of new very promising antitumor olivacine derivatives, such as 9-hydroxy-5,6-dimethyl-6*H*-pyrido[4,3-*b*]carbazole-1-*N*-

(dimethylaminoethyl) carboxamide (Figure 2, **S16020−2**) and 6-(9-hydroxy-5,6-dimethyl)-6*H*-pyrido[4,3-*b*]carbazol-1-yl)picolinic (dimethylamino)ethylamide (Figure 2, **OPA**), has been synthesized and analyzed.[12−14]

The high antitumor activity of the above-mentioned olivacine derivatives encouraged us to search for new analogues which have already been preliminarily tested by us, and which have been shown to have significant cytotoxic activity in vitro.[15] In this paper, we present the synthesis of these analogues.

In Conclusion, we believe that the use of heterocyclic sterically hindered olivacine derivatives as ligands of metal complexes leads to a new group of effective platinum-containing cytostatics that would not be cross-resistant with the platinum-based drugs used so far.

Results and Discussion

Synthesis and Identification

Olivacine derivatives (L-OCH_3, L-OH, L-OAc) were synthesized as shown in Figure 1. The synthesis involved the use of 2-(6-methoxy-1-methylcarbazol-2-yl)ethylamine (**1**) as the starting compound, which was obtained according to an earlier procedure.[12] The reaction of **1** with 5-methyl-2-pyridinecarboxylic acid, and cyclization of the resulting new amide **2** using phosphorous oxychloride in boiling toluene, led to the formation of 9-methoxy-5-methyl-1-(5′-methylpyridin-2-yl)-3,4-dihydro-6*H*-pyrido[4,3-*b*]carbazole (**3**). This was aromatized to **4** by dehydrogenation over 10% palladium on charcoal in boiling diphenyl ether. *N*-6-methylation of **4** to (L-OCH_3) was then performed using an excess of dimethyl carbonate in dimethyl formamide, in the presence of potassium carbonate and 18-crown-6. Compound (L-OCH_3) was 9-*O*-demethylated to give 9-hydroxy-5,6-dimethyl-1-(5′-methylpyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole (L-OH), by heating with a 48% aqueous solution of hydrobromic acid. The 9-hydroxy derivative, (L-OH), was allowed to react with a mixture of acetic anhydride/pyridine (1:1) at room temperature. This led to the formation of 9-acetoxy-5,6-dimethyl-1-(5′-methylpyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole (L-OAc).

The new platinum(II) complexes, [(L-OCH_3)$PtCl_2$], [(L-OH)$PtCl_2$], [(L-OAc)$PtCl_2$], were prepared from K_2PtCl_4

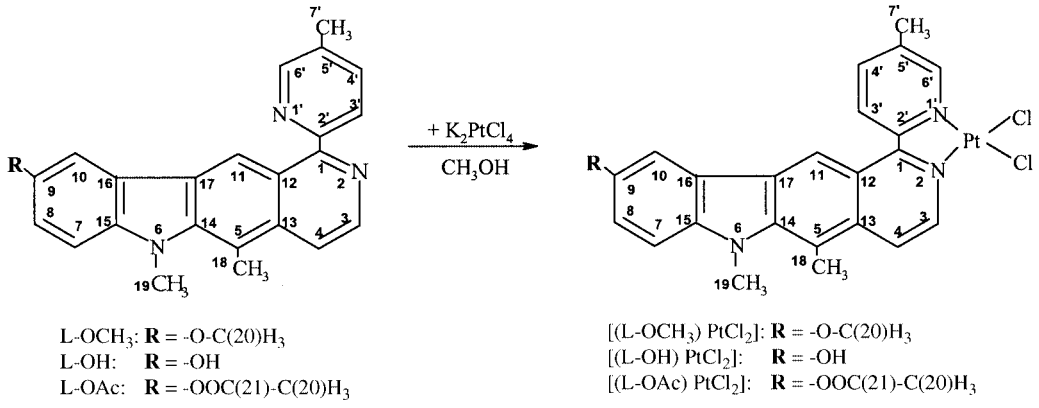

Figure 3. Scheme showing the formation of the complexes and the numbered atoms

and the olivacine derivatives, L-OCH_3, L-OH and L-OAc (Figure 3), respectively, according to a modified version of previously published methods.[16,17]

Chemical analyses, TLC, and spectroscopic techniques [MS (*m*/*z*), ^{13}C and/or ^{1}H NMR, UV/Vis, IR] were used for the characterization of the olivacine derivatives, as well as their platinum complexes. The platinum complexes were characterized additionally using electric conductivity measurements, which showed their neutral character. On the basis of the above physico-chemical studies, the molecular formulae of all the investigated compounds were postulated. The structures of the two ligands (L-OAc, L-OCH_3) and one platinum complex {[(L-OCH_3)$PtCl_2$]} were established by X-ray analysis. The structural and energetic aspects of the conformational behavior of the ligand/complex system have been analyzed.

FT-IR Characterization

The bands were assigned using literature data for the vibrational spectra of pyridine and its derivatives,[18−21] bipyridine,[22] carbazole derivatives [23] and platinum complexes.[24−35] Despite the general similarity of the spectra of the ligands, a few significant differences were noticed. Namely, only the IR spectrum of L-OH contains peaks that are characteristic for ν(C-OH) (at 1235 cm^{-1}) and for δ(O−H) (doublet at 852 and 843 cm^{-1} and band at 665 cm^{-1}). The IR spectrum of L-OAc shows a characteristic strong band at 1753 cm^{-1}, which is assigned to ν(C=O) of the 9-($OOCCH_3$) substituent, whereas the in the IR spectrum of L-OCH_3, a band at 2824 cm^{-1} is assigned to ν_s(C−H) of the OCH_3 group.

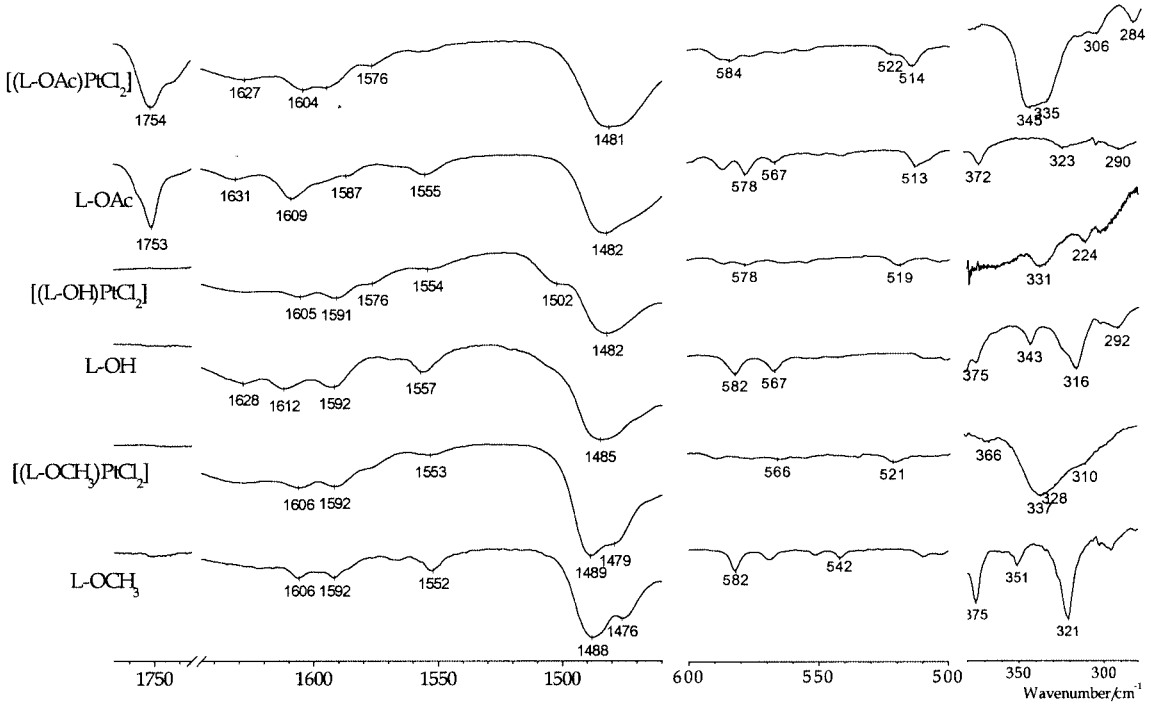

Figure 4. IR spectra of the ligands and Pt complexes

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

After complexation, changes in the position and intensity of some of the above bands and the appearance of new bands are observed (Figure 4). The new bands in the complexes that appear in the range 514−521 cm^{-1} and 330−350 cm^{-1} are assigned to ν(py) + ν(Pt−N) and ν(Pt−Cl), respectively. We can also identify the new bands at around 300 cm^{-1} and below; they seem to occur as a result of the bending vibrations of the N−Pt−N and/or N−Pt−Cl bonds. In general, the IR results show that the N(1′) and N(2) atoms donate electron density to the Pt^{2+} ion that is simultaneously bonded to the Cl anions.

NMR Spectroscopic Characterization

The ^{1}H NMR spectroscopic data for the 9-olivacine derivatives (ligands) and their platinum complexes are listed in Table 1. The ^{13}C NMR spectroscopic data, which were gathered only for the ligands, are presented in Table 2. The atom (H and C) numbering is according to Figure 3. The ^{1}H NMR spectra of the 9-olivacine derivatives were recorded using CD_2Cl_2 and [D_7]DMF as solvents. CD_2Cl_2 was the more convenient solvent since its signals does not overlap those of the olivacine derivatives. However, the Pt

complexes are sparingly soluble in CD_2Cl_2, hence their ^1H NMR spectra were recorded in [D_7]DMF. The use of two solvents was intentional since it allowed us to assign all the proton chemical shift values of the ligands, and in this way help in the analysis of the ^1H NMR spectra of the Pt complexes. The ^{13}C NMR spectra could be recorded only for the ligands since the Pt complexes were relatively insoluble in all the solvents used.

The assignments of the ^1H and ^{13}C NMR chemical shifts for the ligands were completed using two-dimensional HMQC, HMBC and COSY techniques; however, for the Pt complexes, only the ^1H NMR peaks could be assigned by comparing the spectra of the complexes with that of the corresponding ligands, and using data from the literature.[12,14] The proton chemical shift values for compounds **2**, **3** and **4** were measured and the data is presented in the Exp. Sect.

There is an appreciable downfield shift of almost all the signals in the ^1H NMR spectra of the Pt complexes relative to those in the spectra of the free ligands. However, there is a greater downfield shift of the signals for the protons at position 3′, 4′ and 6′. This is in agreement with IR results and leads to the conclusion that ligands exhibit a neutral bidentate function through the N2 and N1′ atoms. The downfield shift of the signals for the protons in neighboring region of the nitrogen atoms that are coordinated to the platinum ion has been reported for other chelate platinum complexes with nitrogen ligands.[36−38]

UV/Vis Characterization

Data obtained from the electronic spectra of the ligands (L-OCH_3, L-OH, L-OAc) and their Pt complexes ([(L-OCH_3)$PtCl_2$], [(L-OH)$PtCl_2$], [(L-OAc)$PtCl_2$]) in methanol and chlorobenzene solutions are presented in Table 3.

The UV/Vis bands of the ligands and Pt complexes were assigned using data from the literature for free bipyridine derivatives and their Pt complexes.[39−47] The authors in the above-mentioned references usually observed two bands, which were assigned as charge transfer transitions from the platinum d-orbital to π-anti-bonding orbitals of the bipyridyl group (MLCT); the energies were strongly dependent on the identity of the other ligands coordinated to the platinum ion and the solvent (e.g. in water, the first MLCT band appeared at 345 nm, whereas in chlorobenzene the band was at 413 nm).[39] In our studies on platinum complexes, in methanol, the band appears between 420−428 nm, and in chlorobenzene, the band appears at 440 nm. These were assigned to the first MLCT. This absorption band, which is correlated to the polarity of solvents, must be due to the platinum d → bipyridyl π* transition.

The second MLCT band in the spectra of our complexes also show a solvent dependency; in methanol, the band appears between 272−278 nm, whereas in chlorobenzene, the band is shifted to 288−292 nm.

According to the data published for other bipyridine platinum complexes, we assigned the intensive band in the

spectra of the ligands at 306 nm to an internal bipyridine ring transition.[38−40] In complexes [(L-OCH_3)$PtCl_2$], [(L-OH)$PtCl_2$] and [(L-OAc)$PtCl_2$], this band is bathochromic shifted by about 40 nm. Such a shift is consistent with reports in the literature on complexation or reduction of bipyridines.[39,46−50]

X-ray Structure

Details of the crystal parameters, data collection and structure refinement for L-OCH_3 (**5**), L-OAc (**7**) and [(L-OCH_3)$PtCl_2$] × DMF × 0.25H_2O (**8**), are given in Table 4. Selected hydrogen interactions are listed in Table 5.

The asymmetric unit of **8** contains two crystallographically independent complex molecules [(L-OCH_3)$PtCl_2$] (hereafter referred to as **a** and **b**), two molecules of DMF (one is disordered) and half a molecule of water.

Both molecular structures of ligands **5** and **7** (presented in Figure 5 and 6) reveal the intramolecular hydrogen bond between C(11)−H(11) and N(18), and a fairly short contact between C(20)−H(20) and N(2). The picoline ring in both ligands is twisted from the core formed by four other rings, with dihedral angles of 38.0(1)° and 36.3(1)° in **5** and **7**, respectively.

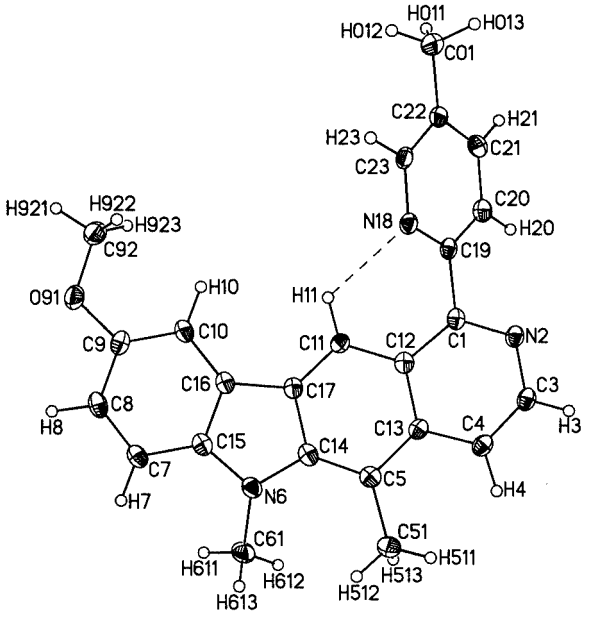

Figure 5. Molecular structure of **5**, showing the atom numbering scheme and displacement ellipsoid plotted at the 50% probability; four fused rings of the molecular core are in the plane of the sheet; the shortest intramolecular C−H···N hydrogen bond is shown as a dashed line

Analysis of the crystal packing reveals stacking interactions between consecutive parallel molecules; these are often observed for compounds with extended π-systems.[51] In the crystal cells of both ligands, columnar structures of the molecules are formed with the nearest neighbors, with a head-to-head orientation, and the distances between them allow for the C···C and C···H and N···H stacking interactions. In both ligands, mutual arene−arene interactions are

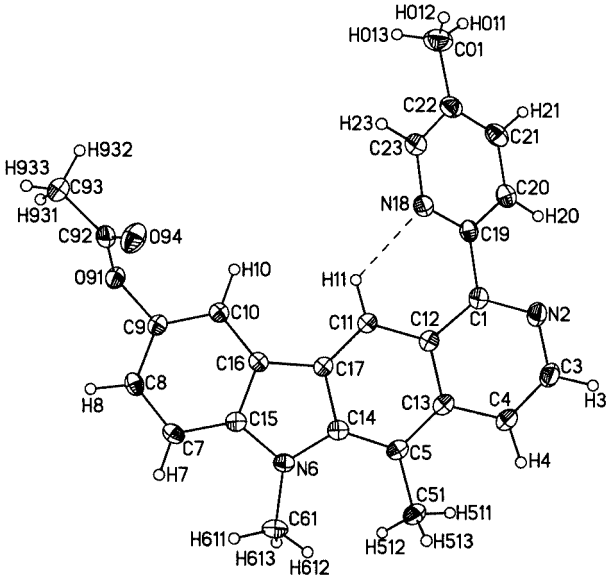

Figure 6. Molecular structure of **7**, showing the atom numbering scheme and displacement ellipsoid plotted at the 50% probability; four fused rings of the molecular core are in the plane of the sheet; the shortest intramolecular C−H···N hydrogen bond is shown as a dashed line

also observed through weak C−H···C and C−H···N intermolecular hydrogen bonds. However, as shown in Figure 7 and 8, some differences are seen in the crystal packing. The adjacent columns of bow-like shaped molecules of **5** are in a head-to-tail nonparallel mutual arrangement, and intermolecular hydrogen bonds are observed between them. In the crystal cell of **7**, the adjacent columns are oriented in an almost perpendicular manner.

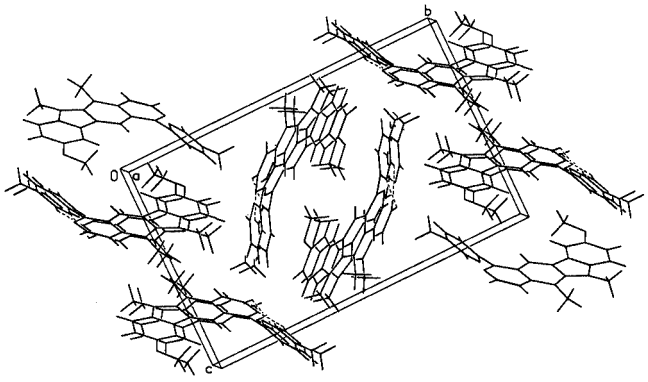

Figure 7. Crystal packing diagram for **5** along axis *a*

The relatively planar molecular structure and stacking interactions seen in **5** and **7** meet the structural requirements for the intercalative type of biological activity mechanism predicted for this type of compounds.[52]

The molecular structure of complex **8** obtained by X-ray diffraction unequivocally confirms that the bipyridine fragment is chelated to the platinum center; the remaining coordination sites are occupied by two *cis* chloride ligands. In molecules **a** and **b**, the coordination geometry around the platinum center is square planar. Although molecules **a** and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

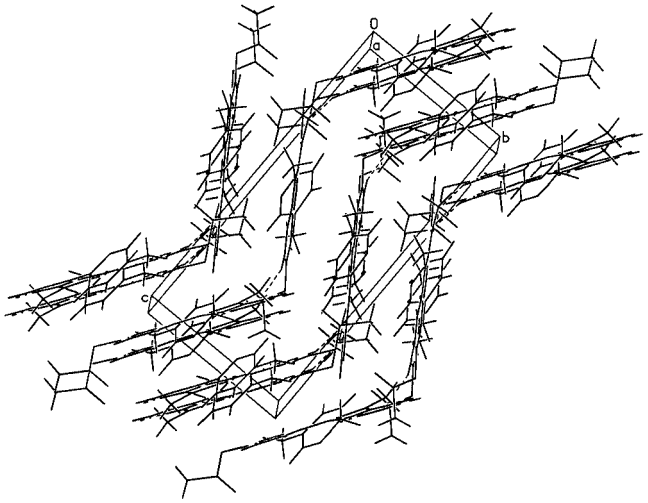

Figure 8. Crystal packing diagram for **7** along axis *a*

b are very similar, as seen in Figure 9, some differences can be observed.

Firstly, the methoxy substituent in molecule **b**, as in **5**, is in a *cis* configuration relative to C(10)−H(10), whereas in **a**, it is in a *trans* configuration.

Another difference is related to the value of dihedral angle between the picoline ring and the skeleton of the molecule (formed by four other rings); 13.9(3)° in **a**, and 16.7(3)° in **b**. This is further related to the proximity of the H(11) and H(20) atoms. Complexation resulted in picoline ring rotation, thus this distance is 1.67 in **a** and 1.88 Å in **b** (with the C−H distance assumed as 1.08 Å). The geometric effect forced by coordination and/or the crystal packing effect cannot be excluded as a reason for achieving such a short contact between H(11) and H(20) and for the appearance of two independent molecules observed in the crystalline state of **8**.

A comparison of the bond lengths reveals the next difference between **a** and **b** (and **5**). The differences in the bond lengths may be due to the change in the conjugation of the π-bonds, and might be related to the above-mentioned H(11)···H(20) interaction.

The Pt−N bond lengths in molecules **a** and **b** are similar to those in other chloro-platinum complexes with bisisoquinoline,[53] as well as with bipyridines.[35,54,55] In molecule **a**, both Pt−Cl bond lengths are within the expected range, whereas in molecule **b**, the Pt−Cl(1) bond is slightly longer [2.315(3) Å]. The chloride ligands are also engaged in weak intramolecular hydrogen bonds with C(23)−H(23) and C(3)−H(3).

The mode of π-π stacking interactions in the unit cell of **8** is more complicated than in **5**. Molecules **a** and **b** show alternative coordination modes of *cis*-[PtN_2Cl_2]. Consecutive molecules of **a** and **b** are not parallel and overlap each other, either with through the bipyridine fragments or through the "tails" of the molecules.

C···C and H···C stacking interactions are observed. Furthermore, N(6)···Pt and Pt···C(14) interactions can also be seen . In contrast to some other Pt complexes with similarly coordinated bipyridine ligands, there is no linear stacking

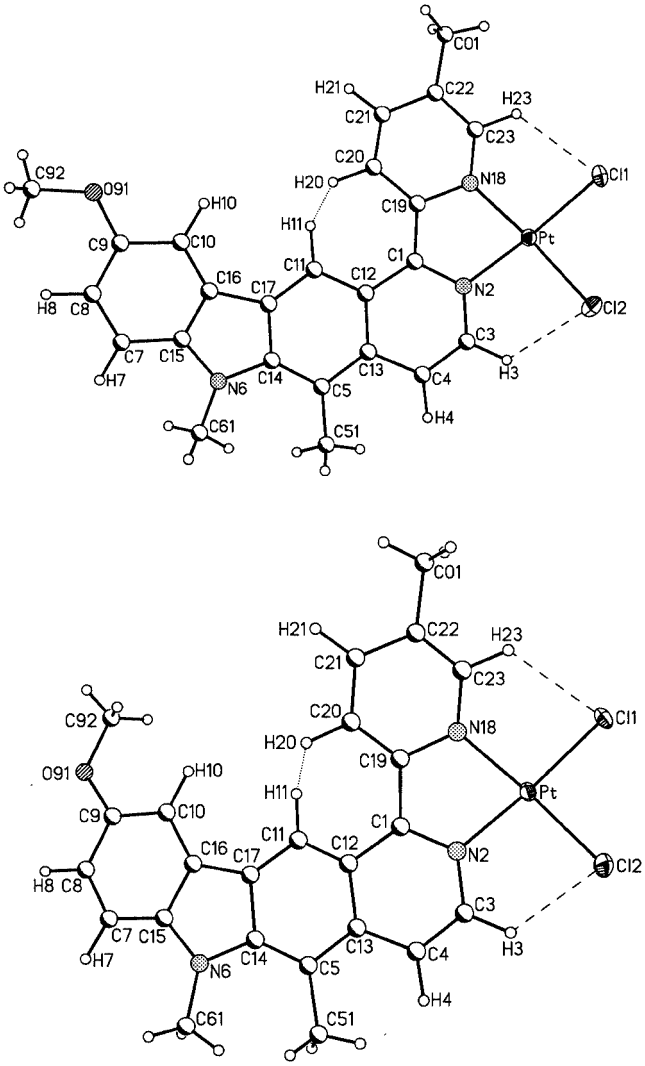

Figure 9. Molecular structure of **8 a** and **8 b**, showing the atom numbering scheme and displacement ellipsoid plotted at the 50% probability for the platinum center and the chloride ligands; the coordination plane defined by [PtN_2Cl_2] is in the plane of the sheet; the intramolecular C−H···Cl hydrogen bonds are shown as dashed lines; the shortest intramolecular distances between the hydrogen atoms are shown as a dotted line

arrangement of the platinum centers.[54] The shortest distance between the platinum centers in **a** and **b** is 6.2 Å, and suggests no significant Pt−Pt interaction (relative to the reported value 3.45 Å in ref.[54]).

Conformational Analysis of L-OCH_3

Due to symmetry, two conformers of the ligand L-OCH_3 can exist in a global energy minimum in the one molecule model gas state, with calculated torsion angles N(2)−C(1)−C(19)−N(18) of approximately −91° or 93,° respectively, for conformers in an energy minimum. The calculated binding energy of these conformers is −5537.71 kcal/mol (Table 6). The calculated standard enthalpy is 56.35 kcal/mol. In the crystalline state, the measured torsion angle N(2)−C(1)−C(19)−N(18) is −141.5(2)°, so the difference between the calculated torsion angle

Table 6. Calculated binding energies, heats of formation and energy barriers for rotation for the conformers of L-OCH_3

Conformers of L-OCH_3	Respected torsion angle N(2)−C(1)−C(19)−N(18)[a] [°]	Binding energy [kcal/mol]	Standard heat (enthalpy) of formation ΔH^{298} [kcal/mol]	Rotational barrier E_{rot} [kcal/mol]
In energy minimum	−91.16 or 92.64[b]	−5537.71	56.35	0.00
Antiplanar	180.0 (−180.0)	−5535.60	58.46	2.11
Synplanar	0.00	−5511.37	82.69	26.34
in [(L-OCH_3)$PtCl_2$] molecule **a**	−11.7(14)[c]	−5531.32	62.74	6.39

[a] Atom numbering according to that used for the X-ray structure. [b] Calculated. [c] From X-ray diffraction measurements.

N(2)−C(1)−C(19)−N(18) in the model gas state and that measured in the crystals is −50.49°. The observed difference might be caused by the fact that intermolecular interactions (e.g. electrostatic, Van der Waals, dispersion, hydrogen bonds) that exist in the real crystalline state, are not taken into consideration in the calculated method. The estimated binding energy for one of the planar conformers, for which N(2)−C(1)−C(19)−N(18) is 180° (or −180°), is −5535.60 kcal/mol, and the standard enthalpy is 58.46 kcal/mol. Moreover, the energy barrier for rotation around the C(1)−C(19) bond (when the torsion angle N(2)−C(1)−C(19)−N(18) changes from −91° to 180°), calculated from the difference in the enthalpies of formation of the proper conformers, is : E_{rot} = 2.11 kcal/mol (E_{rot} = ΔH_{rot} rotational enthalpy). This low energy barrier indicates that the antiplanar conformation of L-OCH_3 is easily achieved, and this may also explain the significant difference between the measured and calculated torsion angles because this fragment of the molecule is flexible enough [in this range for the torsion angle N(2)−C(1)−C(19)−N(18)], although rotation around the C(1)−C(19) bond is not completely free since the energy required is higher than the thermal energy (translation) at 298 K ($E_{rot} > RT$ = 0.592 kcal/mol). The energy barrier for rotation around the C(1)−C(19) bond (torsion angle N(2)−C(1)−C(19)−N(18) changes from −91° or 92° to 0°) in order to adopt a synplanar conformation is very high, E_{rot} = 26.34 kcal/mol (= rotational enthalpy), so this conformation is almost impossible to achieve at standard temperature, hence there is absolutely no rotation around this bond. If the Pt^{2+} ion required a synplanar [torsion angle N(2)−C(1)−C(19)−N(18) = 0°] conformation of the ligand L-OCH_3 for complexation, complex formation would probably not occur. However, according to the literature, the known complexes of Pt^{2+} with 1,1′-biisoquinoline[53] and 2,2′-bipyridines[56] have analogous torsion angles that are not planar. X-ray diffraction measurements show that in the case of [(1,1′-biisoquinoline)$PtCl_2$], these angles are 35.18° and 41.12°, and thus the molecule is very twisted.[53] In the case of unsubstituted [(2,2′-bipyridine)$PtCl_2$], the torsion angle indicated an almost planar molecule and the torsion angle was estimated to be 4.8(6)°, but 3,3′-bisubstituted [(2,2′-bipyridine)$PtCl_2$] is markedly non-planar [25.5(3)°].[56] The measured torsion angle N(2)−C(1)−C(19)−N(18) in the crystal of [(L-OCH_3)$PtCl_2$] for molecule **a** is −11.7(14)°; this shows that the molecule is twisted, however, to a lesser extent than in the complex [(1,1′-biisoquinoline)$PtCl_2$] and the 3,3′-bisubstituted 2,2′-bipyridine complexes. The calculated rotational barrier required to adopt this conformation (torsion angle N(2)−C(1)−C(19)−N(18) equals −11.7(14)°) has been estimated to be E_{rot} = 6.39 kcal/mol. Neglecting the effects of entropy, $E_{rot} \approx \Delta G_{rot} = -RT\ln K$ (ΔG_{rot} is free enthalpy of rotation), hence, the equilibrium constant, K, for rotation between the conformers can be estimated. Therefore, $K_{rot} \approx 2.06 \times 10^{-5}$, which indicates that there is one molecule of the less stable conformer for every 48500 molecules of the more stable conformer. (For comparison, the rotational barrier E_{rot} for 1,1′-biisoquinoline (from 85.06° to 35.18°) is 4.97 kcal/mol; $K_{rot} = 2.28 \times 10^{-4}$; 1 molecule of the less stable conformer for every 4387 molecules of the more stable conformer.)

The results obtained indicate that the concentration of the proper conformer of L-OCH_3 [torsion angle N(2)−C(1)−C(19)−N(18) equals −11.7(14)°] is sufficient for complexation to occur at standard temperatures. Moreover, protogenic polar solvents can stabilize this conformation by the formation of hydrogen bonds, thus the energy barrier for rotation may decrease and complex formation is made easier. This is supported by the experiment in which [(L-OCH_3)$PtCl_2$] is formed.

Antiproliferative Activity

The in vitro growth-inhibitory effect of the ligands L-OH, L-OAc, L-OMe were tested on four human cancer cell lines: A549, SW707, HCV29T, T47D and on mice leukemia L1210. The results, expressed as the IC_{50} values, are presented in Table 7. In general, the ligands are much more

Table 7. The in vitro antiproliferative activity against human cancer cell lines and mice leukemia

Cell line: Compound	A549 IC_{50} [μmol/dm³]	SW707	HCV29T	T47D	L1210
L-OH	9.56	10.19	9.25	9.79	1.7

active against the human lines than the reference carboplatin. The most active was L-OH (ID_{50} against all human cancer cell lines and against L1210). The least active was L-OCH_3 (negative against A549).

The relatively insoluble platinum complexes, [(L-OH)$PtCl_2$] and [(L-OAc)$PtCl_2$], were tested against L1210; they could be measured only as a slurry in DMSO. Although IC_{50} values for the complexes are less than those for the reference compounds, as well as for the ligands, their activity seems to be significant, taking into account that the cytotoxic effect was only caused by a soluble part of sample. More advanced studies will be described elsewhere.[15]

The results obtained indicate that the new olivacine derivatives and their neutral platinum complexes are promising cytotoxic agents of a new class; however, improvement on the solubility of the chloro complexes is necessary. This may be achieved by exchanging the chloride ligands for chosen dicarboxylate ligands, according to our earlier methodology.[57]

Experimental Section

Materials: The starting material for the synthesis of the new 9-olivacine derivatives was 2-(6-methoxy-1-methylcarbazol-2-yl)-ethylamine, which was synthesized from 5-methoxyindol and 4-acetylpyridine, both purchased from Aldrich.

The starting material for the synthesis of the platinum complexes were the new 9-olivacine derivatives, and K_2PtCl_4, which was prepared from metallic Pt by known procedure.[58] Synthetic procedures for the platinum complexes were carried out in the dark. All other chemicals obtained from commercial suppliers were used as received and were of analytical grade.

Physical Measurements: Elemental analyses (C,H,N) were performed on a model Perkin−Elmer Elemental Analyzer 2400 CHN. Pt was analyzed by ICP-AES method on ARL 3410 instrument (with permissible deviation ± 5%), with previous mineralization by microwaves on MDS 200 CEM mineralizator. Thin-layer chromatography was carried out on pre-coated silica gel plates (Poligram) and on plates with the UV marker (Silufol, Cavalier). (A) 1-propanol-1:acetic acid:water (4:16:1) and (B) acetone/chloroform (1:4) were used as developing mixtures. The spots were visualized with rubeanic acid (VEB Laborchemie Apolda) (10% in acetone) and with UV radiation (254 and 366 nm).

Conductivity data (Λ_0 = immediate, Λ_{24} = after twenty four hours [$\Omega^{-1}\cdot mol^{-1}\cdot cm^2$]) were obtained at 298 K in DMF solutions (c = 4.7×10^{-5} M), on a Radelkis OK-104 conductometer.

IR and FIR spectra were run as KBr pellets and nujol mulls, respectively, on a Bruker JFS 113 V FT-IR spectrometer. UV spectra were obtained on Hewlett Packard HP8452A diode array spectrophotometer. ESI-MS measurements were done on a Finnigan MAT TSQ-700 triple-quadrupole mass spectrometer (equipped with a 20 kV conversion dynode for enhanced sensitivity). The ion signals were recorded by a Finnigan ICIS data system operated on a DEC station 3000. The ^1H spectra were recorded at 500.13 MHz and ^{13}C NMR spectra at 125.72 MHz on a Bruker Avance 500 instrument (all at 298 K). Spectra were referenced to the internal solvent peaks.

X-ray Structure Determination: X-ray diffraction data were collected at 100 K on a KUMA KM4CCD diffractometer with graphite−monochromated Mo-K_α radiation (λ = 0.71073 Å) using the ω scan technique. The crystal structures were solved with SHELXS-97 and refined against $|F|^2$ using SHELXL-97.[59]

In the ligands L-OCH_3 (**5**) and L-OAc (**7**), all hydrogen atoms were found from the difference maps and refined isotropically. In the complex [(L-OCH_3)$PtCl_2$] (**8**) all hydrogen atoms were placed in their geometrically calculated positions d(C−H) = 1.08 Å. Platinum atoms and chloride ligands were refined anisotropically. One of the DMF molecules is disordered, with an occupation factor of 0.5. Refinement of the water molecule gave an occupation factor of 0.5.

Single crystals of the ligands were obtained at ambient temperature by slow evaporation of solvents. L-OCH_3 (**5**) was crystallized from dichloromethane and L-OAc (**7**) from methanol. The nucleation process of [(L-OCH_3)$PtCl_2$] (**8**) crystallization was started after dropwise addition of diethyl ether to the DMF solution of **8**. CCDC-203648, -203649, and -203650 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/ retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Methods: Quantum mechanical calculations were performed using semiempirical PM3 methods[60][61] with the computer software − HyperChem. Pro ver. 7.[62] SCF and geometry optimization − Polak−Ribiere (conjugate gradient) minimization algorithm, SCF convergence limit was set to 10^{-6}, energy optimization gradient was set to 0.01 kcal/(mol × Å).

In-Vitro Cytotoxicity Assays: Test on human cancer cell lines (A549, SW707, HCV29T, T47D) were performed at the Institute of Immunology and Experimental Therapy, Polish Academy of Sciences, in Wroclaw, Poland, as described.[15] The test on mice leukemia L1210 was performed at the Curie Institute − Orsay (France), as described.[15]

2-(6-Methoxy-1-methylcarbazol-2-yl)ethylamine (1): Compound **1** was obtained in accordance with ref.[12]

***N*-[2-(6-Methoxy-1-methyl-9*H*-carbazol-2-yl)ethyl]-5-methyl-2-pyridinecarboxamide (2):** Triethylamine (506 mg, 5.0 mmol) was added to the 5-methyl-2-pyridinecarboxylic acid (603 mg, 4.4 mmol) in dry dichloromethane (100 mL). To the resulting mixture, after cooling to 263 K, a solution of ethyl chloroformate (543 mg, 5.0 mmol) in dry dichloromethane (10 mL) was added, whilst stirring. This was stirred for a further 30 min and then 2-(6-methoxy-1-methylcarbazol-2-yl)ethylamine (**1**) (1017 mg, 4.0 mmol) in THF (100 mL) was added dropwise at 263 K, and left to reach room temperature (20 h) whilst stirring. The precipitate was collected and the filtrate was evaporated to dryness. The residue dissolved in water (50 mL), was made basic with concentrated aqueous ammonia and extracted with dichloromethane and dried over magnesium sulfate. Evaporation of the solvent provided a solid residue, which was recrystallized from ethanol to give 900 mg, (60%) of amide **2**. M.p. 458 K. $C_{23}H_{23}N_3O_2$ (373.5): calcd. C 73.97, H 6.21, N 11.25; found C 73.56, H 6.54, N 10.91. ^1H NMR ($CDCl_3$, 298 K): δ = 2.36 (s, 3 H, 5′-CH_3), 2.52 (s, 3 H, 1-CH_3), 3.12 [t, J(α-CH_2−β-CH_2) = 6.2 Hz, 2 H, α-CH_2], 3.70 (t, 2 H, β-CH_2), 3.90 (s, 3 H, 6-OCH_3), 7.05−7.11 (m, 2 H, 3-H +7-H), 7.40 (d, $J_{8,7}$ = 8.7 Hz, 1 H, 8-H), 7.50 (d, $J_{5,7}$ = 2.5 Hz, 1 H, 5-H), 7.74 (dd, $J_{4',3'}$ = 8 Hz, 1 H, 4′-H), 7.84 (d, $J_{4,3}$ = 7.8 Hz, 1 H, 4-H),

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

8.03 (d, $J_{3',4'}$ = 8 Hz, 1 H, 3′-H), 8.31 (s, 1 H, 6′-H), 8.75 (s, 1 H, 9-H).

9-Methoxy-5-methyl-1-(5′-methylpyridin-2-yl)-3,4-dihydro-6*H*-pyrido[4,3-*b*]carbazole (3): The preceding amide (**2**) (1867 mg, 5.0 mmol) was dissolved in boiling toluene (150 mL) and treated dropwise with phosphorous oxychloride (12 mL). Reflux was continued for a 12 h, and evaporation under reduced pressure afforded a residue, which was dissolved in water (100 mL), was made basic to pH 9−10 with concentrated aqueous ammonia, and extracted with dichloromethane. Evaporation of the solvent provided a solid residue, which was recrystallized from ethanol to give yellow crystals (1320 mg, 74%). M.p. 554 K. $C_{23}H_{21}N_3O$ (355.4): calcd. C 77.72, H 5.96, N 11.82; found C 77.52, H 6.03, N 11.91. ^{1}H NMR ($CDCl_3$, 298 K): δ = 2.45 (s, 3 H, 5′-CH_3), 2.68 (s, 3 H, 5-CH_3), 2.83 (t, $J_{4,3}$ = 6.5 Hz, 2 H, 4-H), 3.85 (s, 3 H, 6-OCH_3), 3.90 (t, $J_{3,4}$ = 6.5 Hz, 2 H, 3-H), 7.00 (dd, $J_{8,7}$ = 8.7, $J_{8,10}$ = 2.4 Hz, 1 H, 8-H), 7.34 (d, $J_{7,8}$ = 8.8 Hz, 1 H, 7-H), 7.41 (d, $J_{10,8}$ = 2.3 Hz, 1 H, 10-H), 7.52 (dd, $J_{4',3'}$ = 8.5 Hz, 1 H, 4′-H), 7.88 (d, $J_{3',4'}$ = 8.6 Hz, 1 H, 3′-H), 8.38 (br. s, 1 H, 6-H), 8.70 (s, 1 H, 6′-H), 9.07 (s, 1 H, 11-H).

9-Methoxy-5-methyl-1-(5′-methylpyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole (4): Compound **3** (1422 mg, 4.0 mmol) was refluxed in diphenyl ether (50 mL) in the presence of 10% palladized charcoal (100 mg) for 30 min. After removal of the catalyst, the filtrate was cooled and diluted with hexane. The resulting precipitate was collected and washed with hexane and recrystallized from ethyl acetate to give yellow crystals (1060 mg, 75%). M.p. 544 K. $C_{23}H_{19}N_3O$ (353.4): calcd. C 78.17, H 5.42, N 11.89; found C 77.97, H 5.66, N 11.73. ^{1}H NMR ($CDCl_3$, 298 K): δ = 2.34 (s, 3 H, 5′-CH_3), 2.56 (s, 3 H, 5-CH_3), 3.85 (s, 3 H, 9-OCH_3), 7.12 (dd, $J_{8,7}$ = 8.8, $J_{8,10}$ = 2.4 Hz, 1 H, 8-H), 7.26 (d, $J_{7,8}$ = 8.7 Hz, 1 H, 7-H), 7.65 (d, $J_{10,8}$ = 2.4 Hz, 1 H, 10-H), 7.87 (dd, $J_{4',3'}$ = 8.4 Hz, 1 H, 4′-H), 7.97 (m, 2 H, 4H +3′-H), 8.49 (d, $J_{3,4}$ = 6.5 Hz, 1 H, 3-H), 8.55 (s, 1 H, 6-H), 8.81 (s, 1 H, 6′-H), 9.12 (s, 1 H, 11-H).

9-Methoxy-5,6-dimethyl-1-(5′-methylpyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole (5, L-OCH_3): A mixture of **4** (1060 mg, 3.0 mmol), fine powdered dry potassium carbonate (750 mg), dimethyl carbonate (20 mL), dimethyl formamide (3 mL) and 18-crown-6-ether (3 drops) was heated under reflux, whilst stirring for a 12 h. After evaporation to dryness, the residue was dissolved in water. The solid was collected, air-dried, and recrystallized from isopropyl acetate to give yellow crystals (880 mg, 80%). M.p. 497−498 K. R_f = 0.82 (A), 0.34 (B). $C_{24}H_{21}N_3O$ (367.45): calcd. C 78.45, H 5.76, N 11.44; found C 77.09, H 5.93, N 11.50. MS: *m*/*z* (%) = 368 (100).

9-Hydroxy-5,6-dimethyl-1-(5′-methylpyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole (6, L-OH): A mixture of (**L-OCH_3**) (735 mg, 2 mmol) and hydrobromic acid (48%, 30 mL) was heated under reflux, whilst stirring for 3 h. After evaporation to dryness, the residue was dissolved in water. The resulting mixture was made basic with concentrated ammonia and extracted with dichloromethane. The extract was dried over magnesium sulfate and the solvents evaporated. The solid was recrystallized from dichloromethane to give yellow crystals (676 mg, 96%). M.p. 522−524 K. R_f = 0.82 (A). $C_{23}H_{19}N_3O$ (353.42): calcd. C 78.17, H 5.42, N 11.89; found C 78.01, H 5.61, N 11.72. MS: *m*/*z* (%) = 354 (100).

9-Acetoxy-5,6-dimethyl-1-(5′-methylpyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole (7, L-OAc): A solution of (**L-OH**) (106 mg, 0.3 mmol) in dry pyridine (1 mL) was cooled to 263 K and then treated dropwise with acetic anhydride (1 mL). The mixture was stirred at 263 K for 30 min and allowed to reach room temperature over 3 h. The mixture was then poured into cold water (10 mL) and extracted with dichloromethane. Evaporation of the solvent provided a solid residue, which was recrystallized from isopropyl acetate to give yellow crystals (105 mg, 89%). M.p. 529−530 K. R_f = 0.80 (A); 0.31 (B). $C_{25}H_{21}N_3O_2$ (395.46): calcd. C 75.93, H 5.35, N 10.62; found C 75.18, H 5.41, N 10.43. MS: *m*/*z* (%) = 396 (100).

Dichloro[(9-methoxy-5,6-dimethyl-1-(5′-methyl-pyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole]platinum(II) [8, (L-OCH_3)$PtCl_2$]: 9-Methoxy-5,6-dimethyl-1-(5-methylpyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole (**L-OCH_3**) (150 mg, 0.41 mmol) was dissolved in methanol (250 mL) and an aqueous solution (8 mL) of K_2PtCl_4 (169 mg, 0.41 mmol) was added dropwise. The mixture was stirred at room temperature for several hours and left for 5 weeks. The precipitate obtained was centrifuged, washed with a small amount of water to remove KCl (tested with $AgNO_3$). The platinum complex was dried over P_4O_{10} in vacuo. Yield 239 mg (92%). R_f = 0.88 (A), 0.76 (B). $C_{24}H_{21}Cl_2N_3OPt$ (633.44): calcd. C 45.51, H 3.34, Cl 11.19, N 6.63, Pt 30.68; found C 44.77, H 3.29, N 6.42, Cl 11.08, Pt 30.68. MS: *m*/*z* (%) = 633 (100). $\Lambda_{0\ and\ 24}$ = 4.2 [$\Omega^{-1}\cdot mol^{-1}\cdot cm^2$].

Dichloro[(9-hydroxy-5,6-dimethyl-1-(5′-methylpyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole]platinum(II) [9, (L-OH)$PtCl_2$]: 9-hydroxy-5,6-dimethyl-1-(5′-methylpyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole (**L-OH**) (149 mg, 0.42 mmol) was dissolved in methanol (200 mL), an aqueous solution (8 mL) of K_2PtCl_4 (175 mg, 0.42 mmol) was then added. The mixture was stirred at room temperature for several hours and left for 4 weeks. The precipitate obtained was centrifuged, washed with a small amount of water to remove KCl (tested with $AgNO_3$) and dried over P_4O_{10} in vacuo. Yield 221 mg (85%). R_f = 0.94 (A). $C_{23}H_{19}Cl_2N_3OPt$ (619.41): calcd. C 44.6, H 3.09, Cl 11.45, N 6.78, Pt 31.49; C 44.33, H 3.68, Cl 10.68, N 6.46, Pt 28.44. MS: *m*/*z* (%) = 620 (100). $\Lambda_{0\ and\ 24}$ = 5.0 [$\Omega^{-1}\cdot mol^{-1}\cdot cm^2$].

Dichloro[9-acetoxy-5,6-dimethyl-1-(5′-methyl-pyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazole]platinum(II) [10, (L-OAc)$PtCl_2$]: 9-Acetoxy-5,6-dimethyl-1-(5-methylpyridin-2-yl)-6*H*-pyrido[4,3-*b*]carbazol] (**L-OAc**) (140 mg, 0.35 mmol) was dissolved in methanol (150 mL), an aqueous solution (9 mL) of K_2PtCl_4 (145 mg, 0.35 mmol) was then added. The mixture was stirred at room temperature for several hours and then left for about 4 weeks. The precipitate obtained was centrifuged, washed with a small amount of water to remove KCl (tested with $AgNO_3$). The platinum complex was dried over P_4O_{10} in vacuo. Yield 190 mg (82%). R_f = 0.72 (B). $C_{25}H_{21}Cl_2N_3O_2Pt$ (661.45): calcd. C 45.40, H 3.20, Cl 10.72, N 6.35, Pt 29.49; found C 44.58, H 3.74, Cl 10.05, N 6.00, Pt 25.49. MS: *m*/*z* (%) = 663 (100). $\Lambda_{0\ and\ 24}$ = 3.3 [$\Omega^{-1}\cdot mol^{-1}\cdot cm^2$].

New $[Ru_3(CO)_{12}]$-Based Catalysts with Imidazolinium Salt, Diimine, or Bis(oxazoline) Ligands and Ruthenium Bis(oxazoline) Complex for Tandem Isomerisation/Claisen Rearrangement of Dienyl Ethers − X-ray Structure of [RuCl{(*R*,*R*)-bis(isopropyloxazoline)}(*p*-cymene)]BF_4

Hamed Ben Ammar,[a] Jérôme Le Nôtre,[a] Mansour Salem,[b] Mohamed T. Kaddachi,[b] Loïc Toupet,[c] Jean-Luc Renaud,[a] Christian Bruneau,[a] and Pierre H. Dixneuf*[a]

Keywords: Ruthenium / Isomerisation / Claisen reaction / Aldehydes / N ligands

The reaction of various 1,7-dienes in the presence of the three-component catalyst **A**: $[Ru_3(CO)_{12}]$/imidazolinium salt/Cs_2CO_3 (1:1:2) leads to the tandem alkene isomerisation/Claisen rearrangement affording γ,δ-unsaturated aldehydes. Other three component catalysts: $[Ru_3(CO)_{12}]$/diimine/Cs_2CO_3 and $[Ru_3(CO)_{12}]$/benzoxazoline or chiral bis(oxazoline)/Cs_2CO_3 offer new active catalytic systems for these tandem reactions. Two ruthenium complexes containing optically active bis(oxazoline), [RuCl{(*R*,*R*)-bis(oxazoline)}(*p*-cymene)]BF_4, were prepared and the X-ray structure of one of them (**18**) was established. The combination of chiral **18**/imidazolinium salt/Cs_2CO_3 (1:1:2) catalysed the above reaction of 1,6-dienes and the results suggest initial catalytic isomerisation followed by a thermal Claisen rearrangement.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The [3,3]-sigmatropic rearrangement of allyl vinyl ethers constitutes a powerful method for accessing γ,δ-unsaturated aldehydes[1] since its discovery by Claisen.[2] This reaction is often limited by the difficulty of introducing the vinyl ether group. The most general routes to vinyl ethers involve organometallic intermediates or acid-catalysed reactions.[3] An alternative method is emerging. It is based on selective isomerisation of allyl groups into vinyl heteroatom intermediates. Ruthenium complexes, such as ruthenium hydride[4] or ruthenium carbonyl[5] derivatives have been used for selective alkene isomerisation. This isomerisation process was also applied to enantioselective catalysis.[6] Recently alkene metathesis ruthenium catalysts have shown a propensity to isomerise alkenes, but leading to competition between isomerisation and metathesis.[7,8]

The $[RuCl_2(PPh_3)_3]$-catalysed Claisen rearrangement of diallyl ethers occur at a high temperature (150 °C),[9] whereas selected iridium[10] and rhodium[11] complexes tend to promote this transformation under milder conditions. It is worth noting that an indenylidene ruthenium catalyst has performed ring closing metathesis (RCM), isomerisation and a Claisen rearrangement, successively.[8]

By contrast we found that ruthenium catalysts prepared in situ for the RCM of 1,6-dienes and 1,6-enynes[12−14] did not perform RCM of 1,7-dienyl ethers but selectively led to tandem isomerisation/Claisen rearrangement affording γ,δ-unsaturated aldehydes[15] [Equation (1)]. The in situ generated catalyst, was originally prepared with $[RuCl_2(p\text{-cymene})]_2$ as a ruthenium source,[12] but the combination of $[Ru_3(CO)_{12}]$, with an imidazolinium salt appeared to be more efficient as reported in our preliminary communication.[15]

(1)

We now wish to report (i) the detailed study of in situ prepared catalysts for isomerisation/Claisen rearrangement of 1,7- and 1,6-dienyl ethers into γ,δ-unsaturated aldehydes, (ii) we show that new $[Ru_3(CO)_{12}]$-based catalysts containing sterically hindered diimine or the bis(oxazoline) ligand, and bis(oxazoline)ruthenium complex as the ruthenium source and imidazolinium salt in the presence of Cs_2CO_3, are active catalysts for these tandem catalytic reactions. (iii) The synthesis of new chiral bis(oxazoline)ruthenium arene derivatives, used as catalyst precursors, is described with the X-ray structure of one of them.

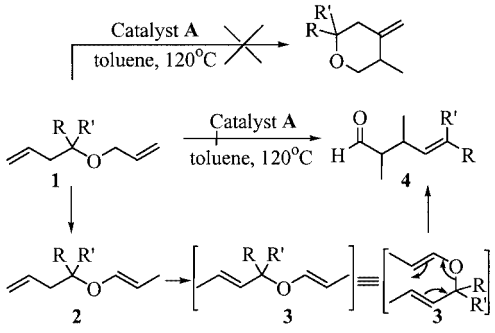
Results and Discussion

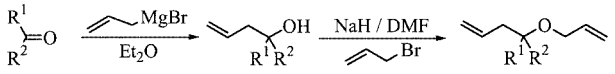
1. Catalytic Reaction Principle and Influence Factors

Recently, in a preliminary study[15] it was revealed that the in situ prepared three-component catalyst for the ring closing metathesis (RCM) reaction of 1,6-dienes and 1,6-enynes: $[RuCl_2(p\text{-cymene})]_2$/a hindered imidazolinium chloride/Cs_2CO_3, when applied to allyl homoallyl ethers with a 1,7-diene structure, the latter were catalytically transformed into γ,δ-unsaturated aldehydes rather than the expected RCM six-membered cyclic compounds. The new three-component system consisting of **A** = $[Ru_3(CO)_{12}]$, 1,3-bis(2,6-diisopropylphenyl)imidazolinium chloride, and cesium carbonate appeared to be the most active catalyst for this transformation of 1,7-dienes **1** into unsaturated aldehydes **4** (Scheme 1). The reaction takes place via a double C=C isomerisation of allyl and homoallyl branches via the intermediates **2** and **3**, followed by a Claisen rearrangement to give **4**.



Scheme 1

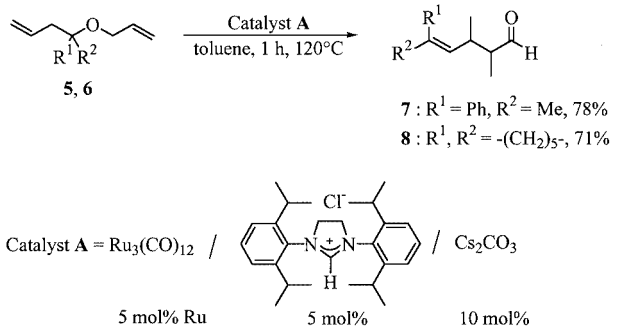
The use of the three-component catalytic system **A** has now been applied to the selective transformation of various 1,7-dienes. The etherated dienes **5** and **6** were easily prepared from the corresponding ketones, in two steps, by addition of allylmagnesium bromide, followed by allylation of the corresponding homoallyl alcohols (Scheme 2).



5 : R^1 = Ph, R^2 = Me, 57%
6 : R^1, R^2 = -$(CH_2)_5$-, 82%

Scheme 2

In the presence of the catalytic system **A** based on $[Ru_3(CO)_{12}]$ (1.67 mol %, that is 5 mol % of ruthenium atoms), 1,3-bis(2,6-diisopropylphenyl)imidazolinium chloride (5 mol %) and cesium carbonate (10 mol %) in toluene, these dienes have been totally converted into their corresponding γ,δ-unsaturated aldehydes after 1 hour at 120 °C (Scheme 3). The aldehydes **7** and **8** were obtained in 78% and 71% yield, respectively, as a mixture of diastereoisomers due to the formation of stereogenic centres, and their



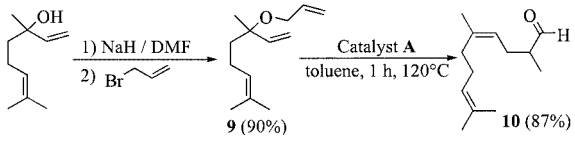
Scheme 3

NMR spectroscopic analyses were in accordance with those in the literature.[10b]

The absence of one of the three components of the catalytic system A gave no conversion, not even isomerisation. This observed reaction indicates that the isomerisation of the terminal alkene branches is faster than the RCM and cycloisomerisation reactions leading to six-membered rings. The RCM involving disubstituted C=C bonds is known to be disfavoured, thus in that case, after isomerisation no competition occurs between isomerisation and metathesis, and hence high selectivity in aldehyde formation is observed.

It is noteworthy that the above in situ generated ruthenium catalyst **A** selectively isomerises terminal alkene branches, by displacing the C=C bond towards the heteroatom, to produce a vinyl ether group.

The influence of the catalyst concentration and temperature has been investigated. This study was performed on the 1,6-diene **9** which is more easily transformed into the corresponding γ,δ-unsaturated aldehyde **10**, than the dienes **5** and **6**. It involves one simple allyl to vinyl isomerisation followed by a Claisen rearrangement (Scheme 4).



Scheme 4

The commercially available linalol was first converted by allylation in 90% yield to the 1,6-diene **9**. In the presence of the catalytic system **A,** using 5 mol % of ruthenium, this diene was transformed into the aldehyde **10**[16] at various temperatures. The transformation of **9** into aldehyde **10** was very slow at 60 °C, it reached completion at 80 °C for 3 h and alternatively within 1 h at 120 °C (see Table l).

A minimum temperature of 80 °C was required to reach completion (Table 1). By performing the transformation at 80 °C, but varying the diene/catalyst ratio, it was observed that decreasing this ratio under 5 mol % (3%, 0.5%) led to longer reaction times (Entries 3,5,6). Thus, for further tandem isomerisation/Claisen reaction of unsaturated ethers, 5 mol % of ruthenium catalyst was used between 80 °C and

Table 1. Influence of temperature, time and ruthenium loading on the transformation **9** → **10**

Entry	Mol-% [Ru]	Temp. (°C)	Reaction time (h)	Conversion (%)
1	5	40	16	0
2	5	60	16	22
3	5	80	3	100
4	5	120	1	100
5	3	80	60	80
6	0.5	80	96	20

120 °C, and a reaction time of 1−3 h was expected according to the nature of the substrate.

2. Use of Dinitrogen Chelating Ligands in Ruthenium Catalyst Precursors

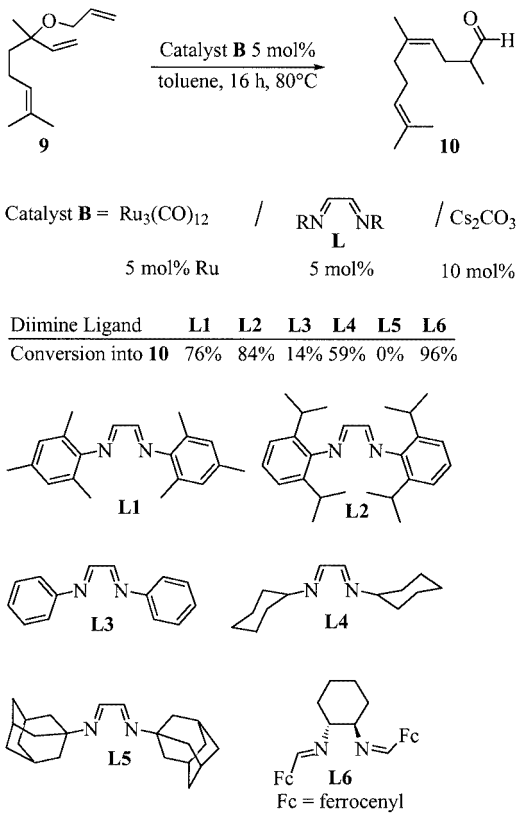
With the objective of finding new efficient catalysts for the above tandem catalytic reactions several catalytic modifications were investigated. Since well-defined chelating dinitrogen containing ruthenium complexes of type [RuCl{bis(oxazoline)}(arene)]$^+$ X^- have already shown some activity for this reaction,[17] we have explored the catalyst modification based on [$Ru_3(CO)_{12}$], as a ruthenium source, by replacing the bulky imidazolinylidene precursor by a sterically hindered diimine or bis(oxazoline)ligand.

2.1 Diimine Ruthenium Precursors

Catalyst **B** was generated in situ by a combination of [$Ru_3(CO)_{12}$] (5 mol % of Ru atoms), diimine **L** (5 mol %) and Cs_2CO_3 (10 mol %) and was evaluated on the transformation of the diene **9** into the aldehyde **10** in toluene at 80 °C and the conversions were monitored using proton NMR spectroscopy by measuring the **10/9** ratio (Scheme 5). Several diimines **L1**−**L6**[18] containing bulky R groups were evaluated.

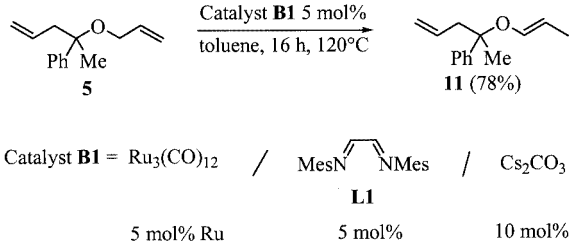
The results show that the diimines lead to an in situ generated catalyst performing the tandem reactions at 80 °C for 16 h. The nature of the diimine drastically influences the catalytic activity. The diimines $\mathbf{L_6}$ (96%) $\mathbf{L_2}$ (84%) and $\mathbf{L_1}$ (76%) offer the best catalyst efficiencies. Especially when the reaction is performed at 120 °C, the ferrocenyl containing diimine $\mathbf{L_6}$ leads to the best activity and the corresponding catalyst **B** completely converts **9** into **10** within 6 hours.

However, the resulting catalyst **B** requires a longer reaction time to reach suitable conversion into aldehyde **10** than catalyst **A**; catalyst **B** requires 16 h at 80 °C with the most activating diimine. These results indicate that the preliminary catalytic alkene isomerisation and the overall tandem reaction are not at all restricted to imidazolinium ruthenium intermediates. Moreover they show that the presence of cesium carbonate does allow the reaction to proceed. Cs_2CO_3 was originally used for the deprotonation of the imidazolinium salt to generate an imidazolinylidene ligand. In the absence of Cs_2CO_3 in catalyst **B** no isomerisation takes place. Although its role is not elucidated, cesium carbonate thus has a crucial influence on the ruthenium-catalysed isomerisation reaction.



Scheme 5

It is noteworthy that profit can be taken from the slightly lower catalytic activity of catalyst **B** to perform the selective isomerisation without Claisen rearrangement. The isomerisation of the diene **5**, containing a phenyl and methyl groups at the homoallylic position, is more difficult to perform than that of **9**. The reaction of **5** with catalyst **B,** containing the $\mathbf{L_1}$ diimine, in toluene, at 120 °C for 16 h does not afford the expected unsaturated aldehyde **7** but is completely transformed into the vinyl homoallyl ether **11** resulting simply from the allyl to vinyl isomerisation (Scheme 6). Thus, the phenyl group inhibits the homoallyl to allyl isomerisation with catalyst **B** that readily takes place with catalyst **A** (Scheme 3). This experiment shows that the *O*-allyl branch of the 1,7-diene **1** is first isomerised to give an intermediate of type **2** and that the ease of the second isomerisation further controls the Claisen rearrangement. It also reveals the interest of less active catalysts to perform only one reaction step.



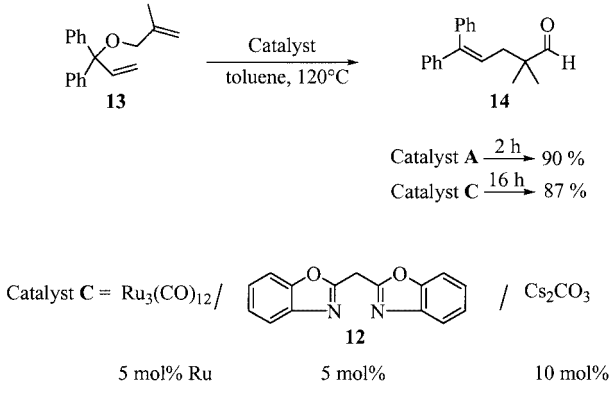
Scheme 6

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The large influence of the nature of the ligand on catalyst activity and the ease of generating these catalysts in situ suggest that the association of various ruthenium sources with various ligands, should be investigated to reveal new active catalysts.

2.2 Bis(oxazoline) Ruthenium Precursors

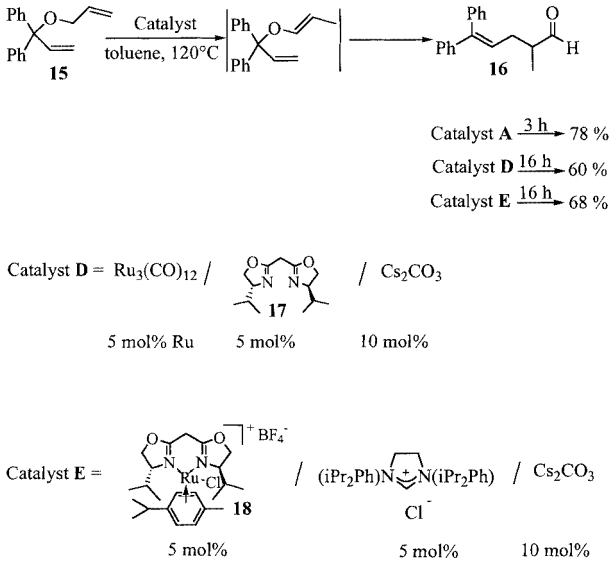
Achiral or chiral bis(oxazolines) are commonly used as chelating nitrogen ligands in catalysis nowadays,[19] because they are easily prepared and have been shown to significantly modify the catalytic metal site with respect to phosphane or carbene ligands.[20] Thus, catalyst **C** analogous to catalyst **B**, by replacing the diimine **L** by the benzoxazoline derivative **12**,[21] has been evaluated for the transformation of 1,6-diene **13** into aldehyde **14** (Scheme 9). The results show that the bis(oxazoline)ligand **12** associated with $[Ru_3(CO)_{12}]$ in the presence of Cs_2CO_3 promotes the tandem reactions with an activity analogous to that of the most active diimine-containing catalysts. The efficiency of catalyst **C** is analogous to that of catalyst **B**, as the transformation was complete after 16 h at 120 °C and led to the isolation of 87% of aldehyde **14**[22] (Scheme 7).



Scheme 7

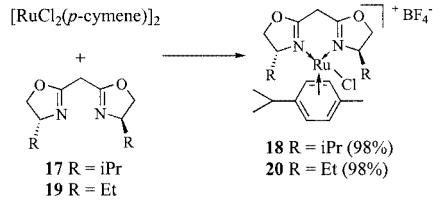
An advantage to generating a catalyst in situ, from a metal source and a ligand, is related to the easy access of the chiral version of the catalyst. Catalysts of type **C** could thus easily be transformed into chiral catalysts using an optically active bis(oxazoline). The transformation of the 1,6-diene **15** into the aldehyde **16**, containing only one chiral centre, was first considered.

The interest in using a chiral catalyst was to investigate whether, after isomerisation, the Claisen step leading to the creation of a chiral centre, was influenced by the catalyst or essentially a thermal process. An enantiomeric excess is expected to be observed in the first process and not in the second. The achiral catalyst **A** performed the tandem reaction at 120 °C, and after 3 h the racemic aldehyde **16** was isolated (78%) (Scheme 8). Then catalyst **C** was modified into catalyst **D** by the introduction of the optically active (*R*,*R*)-bis(oxazoline)**17**,[19] instead of **12**. Catalyst **D** gave an activity similar to that of catalyst **C** and afforded 60% of aldehyde **16**. The isolated aldehyde **16** *showed no enantiomeric excess,* thus indicating that the chiral catalyst **D** gave no stereochemical induction, unless the racemization of the aldehyde takes place (Scheme 8).



Scheme 8

The bis(oxazoline) **17** was then used to prepare a well-defined ruthenium(II) (arene) complex according to the procedure we previously used for *achiral* bis(oxazoline)ruthenium complexes.[17] Two equiv. of the bis(oxazoline) **17** were reacted with the ruthenium complex $[RuCl_2(p\text{-cymene})]_2$ in methanol at room temperature with two equiv. of NH_4BF_4 and the orange complex **18** was isolated in 98% yield (Scheme 9). Analogously, the optically active bis(oxazoline) **19**[19f] led to the ruthenium complex **20.**



Scheme 9

Complex **18** does not catalyse the **15** → **16** transformation, even in the presence of two equiv. of Cs_2CO_3. By contrast complex **18** with one equiv. of imidazolinium salt and two equiv. of Cs_2CO_3 (Catalyst **E**), allowed the transformation of **15** into **16**, isolated in 68% yield after 1 h at 120 °C (Scheme 8). It is worth noting that with the well-defined chiral ruthenium complex **18**, the resulting aldehyde **16,** did not exhibit an enantiomeric excess.

The above results show that a bis(oxazoline) associated with $[Ru_3(CO)_{12}]$ and a bis(oxazoline)ruthenium complex associated with an imidazolinium salt performed the isomerisation of 1,6-dienes, in the presence of Cs_2CO_3. But no enantiomeric excess was observed when a chiral centre was formed in the presence of an optically active catalytic species. This suggests that the ruthenium complex, associated with Cs_2CO_3, plays an isomerisation catalyst role and when the required 1,5-diene is formed in situ, a thermal Claisen

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rearrangement takes place, unless the imidazolylidene ligand displaces the chiral ligand from the ruthenium site.

3. Crystal Structure of Complex 18

The structure of these bis(oxazoline)ruthenium complexes is confirmed by the crystal structure of the complex **18**. The ORTEP is presented in Figure 1 and the principal bond lengths and angles are reported in Table 2. The crystal data and structure refinement are gathered in Table 3.

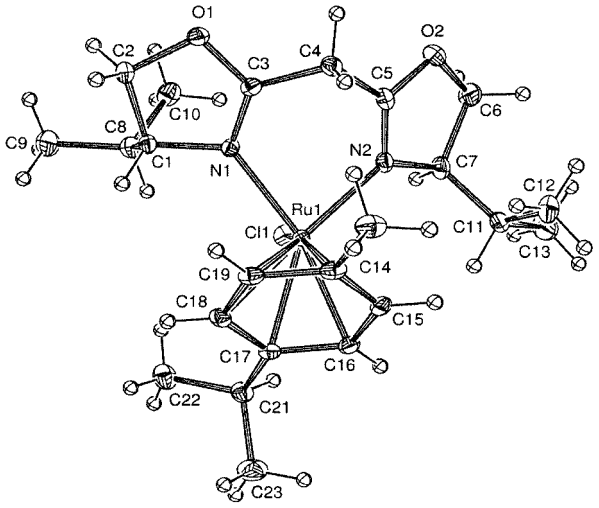


Figure 1. X-ray structure of complex **18**

Table 2. Selected bond lengths and angles

Bond lengths	Å	Angles	°
Ru(1)−N(2)	2.129(2)	C(3)−C(4)−C(5)	110.9(2)
Ru(1)−N(1)	2.130(2)	N(1)−C(3)−C(4)	125.8(2)
N(1)−C(3)	1.285(4)	N(2)−C(5)−C(4)	126.2(2)
N(2)−C(5)	1.279(4)		

The structure shows the chirality of the complex with a classical piano stool geometry. This structure reveals that the bis(oxazoline) ligand presents only slight distortions due to the coordination to the metal centre. Indeed, the C(3)−C(4)−C(5) angle of 110.9° is close to the expected value for an sp^3 carbon atom and the N(1)−C(3)−C(4) and N(2)−C(5)−C(4) angles (125.8(2) and 162.2(2)°) correspond to the value of an sp^2 carbon atom. The two oxazoline rings are nearly in the same plane and the distortion between the two planes is around 10°. The ruthenium-nitrogen bonds have similar distances to those of related complexes.[23]

Conclusion

The above results show that tandem isomerisation/Claisen reactions of etherated 1,7-dienes and 1,6-dienes are catalysed by in situ prepared ruthenium catalysts to selectively produce γ,δ-unsaturated aldehydes. The best catalyst appears to consist of the combination of [$Ru_3(CO)_{12}$], an imidazolinium salt that is a bulky heterocyclic carbene precursor and Cs_2CO_3. However the combination of [$Ru_3(CO)_{12}$], a bulky diimine or bis(benzoxazoline) ligand, in the presence of Cs_2CO_3 results in a slightly less efficient catalyst, which is still able to operate at 80 °C. The use of the optically active bis(oxazoline) ligand or complex in the formation of a chiral centre, in the unsaturated aldehyde product, gave no enantiomeric excess, and thus there is no evidence that the Claisen rearrangement step is also catalysed by the chiral ruthenium catalyst under these conditions. The ease of in situ preparation of such catalysts from a ruthenium source and a variety of ligands open the route to the use of high throughput experiment tools to discover new or more efficient catalysts.

Experimental Section

General Experimental Procedures: All experiments were carried out in Schlenk tubes under nitrogen. Diethyl ether and tetrahydrofuran were dried by refluxing over sodium/benzophenone under argon, while toluene was dried with sodium, and dichloromethane was purified over calcium hydride. Methanol was used without further purification and degassed before use.

^1H and ^{13}C NMR spectra were recorded with a Bruker AC 200 MHz spectrometer. GC-MS were performed with a CE Instrument GC 8000 Top (capillary column OV1, 25 m × 0.35 mm, 0.1−0.15 μm) chromatograph linked to an Automass II Finnigan MAT (70 eV) apparatus. Infra-red spectra were recorded in KBr pellets using a Nicolet 205 FT-IR. UV/Visible spectra were recorded with a KONTRON UVIKON 941 spectrometer in diluted dichloromethane (*ca*, 10^{-4} mol·L^{-1}). Microanalyses were performed by the Service Central d'Analyses du CNRS (Vernaison, France).

General Procedures. Procedure A − Synthesis of the Homoallylic Alcohols via Allylmagnesium Addition to a Ketone: In a two-necked flask under nitrogen, equipped with a reflux condenser, magnesium turnings (2 equiv.) were heated under vacuum for 5 minutes by means of a heat gun. After cooling to room temperature, diethyl ether (1 mL per 2 mmol of magnesium) was added. Allyl bromide (1.2 equiv.) was then slowly added to the vigorously stirred mixture and the flask was introduced into an ice bath as soon as the diethyl ether ebullition started. After the addition was complete the reaction mixture was stirred for 1 h at 0 °C. The ketone (1 equiv.) was then added dropwise in diethyl ether (1 mL per 3 mmol of ketone). The reaction mixture was stirred for 30 minutes at 0 °C, followed by 4 h at room temperature. After addition of a 1 N HCl solution and extraction with diethyl ether, the corresponding homoallylic alcohol was obtained and used without purification.

Procedure B − Alcohol Allylation Reaction: Sodium hydride (1.2 equiv.) and dry dimethylformamide (1.5 mL per mmol of alcohol) were introduced into a Schlenk tube under nitrogen. The alcohol (1 equiv.) in dimethylformamide (1 mL per mmol of alcohol) was slowly added at 0 °C. After 30 minutes, allyl bromide (1.3 equiv.) was added dropwise and the stirring was continued at 0 °C for 30 minutes and at room temperature for 4 h. After hydrolysis extraction with diethyl ether and drying over $MgSO_4$, the crude product was then purified by flash chromatography over silica gel using a low polar mixture of diethyl ether and heptane.

Procedure C − Synthesis of the Allylic Alcohols via Vinylation of Aldehydes and Ketones: A Schlenk tube under nitrogen containing anhydrous $CeCl_3$ (0.1 equiv.) was first heated at 150 °C for 5 minutes and then cooled down to room temperature. Tetrahydrofuran (2 mL per mmol of ketone or aldehyde) was introduced followed by the ketone or the aldehyde (1 equiv.) and the reaction mixture was stirred at room temperature for 30 minutes. After cooling to 0 °C, vinylmagnesium bromide (1.0 M solution in tetrahydrofuran, 1.2 equiv.) was added dropwise. The reaction mixture was stirred at 0 °C for 1 h and then at room temperature 16 h. After quenching by slow addition of a 1 N HCl solution and extraction with diethyl ether, the corresponding allylic alcohol was obtained and used in the following step without purification.

Procedure D − General Procedure using the $[Ru_3(CO)_{12}]$-Based Catalyst for Tandem Isomerisation/Claisen Reaction: $[Ru_3(CO)_{12}]$ (5/3 mol % = 5 mol % of Ru atoms), 1,3-bis(2,6-diisopropylphenyl)imidazolinium chloride (5 mol %), cesium carbonate (10 mol %) and toluene (7.5 mL per mmol of diene) were introduced into a Schlenk tube under nitrogen. The reaction mixture was stirred for 5 minutes at room temperature and the diene was then added. After 1 hour of heating at 120 °C, the solvent was removed under reduced pressure and the crude product was extracted with heptane, filtered and the solvents evaporated to dryness. After chromatography on silica using a mixture of diethyl ether/heptane as eluent and/or bubble-to-bubble distillation the corresponding aldehyde was isolated as a colourless oil as a mixture of diastereoisomers.

Preparation of the 1,7-Dienes

2-Allyloxy-2-phenylpent-4-ene (5):[10b]

Following Procedure A: Allyl bromide (1.92 mL, 20.6 mmol) was added to a solution of magnesium turnings (0.83 g, 34.2 mmol) in diethyl ether (15 mL). Acetophenone (2.0 mL, 17.3 mmol) in diethyl ether (6 mL) was then added. Subsequent treatment gave the corresponding homoallylic alcohol as a yellow oil, which was used without purification for the next step.

Following Procedure B: Homoallylic alcohol (17.3 mmol) in dimethylformamide (17 mL) was added to a solution of sodium hydride (60% in mineral oil, 0.82 g, 20.6 mmol) in of dimethylformamide (30 mL). After addition of allyl bromide (2.0 mL, 22.5 mmol) and subsequent treatment, the crude was purified by flash chromatography over silica gel using diethyl ether/heptane (1:40) as eluent to afford the corresponding 1,7-diene **5** as a colourless oil (2.01 g, 57% yield). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.53 (s, 3 H, CH_3), 2.53−2.64 [m, 2 H, CH_2C(Ph)(Me)OR], 3.61−3.85 (m, 2 H, OCH_2CH=CH$_2$), 4.94−5.45 [m, 4 H, 2 × (CH=CH_2)], 5.58−5.98 [m, 2 H, 2 × (CH=CH$_2$)], 7.20−7.48 (m, 5 H, Ph) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 23.5 (CH_3), 47.9 [CH$_2$C(Ph)(Me)OR], 63.9 (OCH$_2$CH=CH$_2$), 78.9 [C(Ph)(Me)], 115.6 (OCH$_2$CH=CH$_2$), 117.7 [C(Ph)(Me)CH$_2$CH=CH$_2$], 126.3, 127.1, 128.3 (CH arom.), 134.3 (OCH$_2$$C$H=CH$_2$), 135.7 [C(Ph)(Me)CH$_2$$C$H=CH$_2$], 145.1 (C arom.) ppm. MS (EI): *m*/*z* (%) = 202 (<1) $[M]^+$, 161 (35), 143 (11), 129 (52), 115 (25), 105 (15), 103 (18), 91 (19), 77 (48), 65 (15), 63 (15), 57 (15), 51 (35), 43 (100), 41 (56).

1-Allyl-1-allyloxycyclohexane (6):[10b]

Following Procedure A: Allyl bromide (0.96 mL, 10.3 mmol) was added to a solution of magnesium turnings (0.42 g, 17.1 mmol) in diethyl ether (10 mL). Cyclohexanone (0.9 mL, 8.6 mmol) in diethyl ether (3 mL) was then added. Subsequent treatment gave the corresponding homoallylic alcohol as a yellow oil, which was used without purification for the next step.

Following Procedure B: Homoallylic alcohol (8.6 mmol) in dimethylformamide (9 mL) was added to a solution of sodium hydride (60% in mineral oil, 0.41 g, 10.3 mmol) in dimethylformamide (15 mL). After addition of allyl bromide (1.0 mL, 11.3 mmol) and subsequent treatment, the crude was purified by flash chromatography over silica gel using diethyl ether/heptane (1:40) as eluent to afford the corresponding 1,7-diene **6** as a colourless oil (1.32 g, 85% yield). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.61−1.79 (m, 10 H, 5 × CH_2), 2.31−2.43 [m, 2 H, CH_2C(Cy)OR], 3.85−3.91 (m, 2 H, OCH_2CH=CH$_2$), 4.95−5.34[m, 4 H, 2 × (CH=CH_2)], 5.55−6.02 [m, 2 H, 2 × (CH=CH$_2$)] ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 22.0 (2 × *m*-CH_2 of Cy), 26.7 (*p*-CH_2 of Cy), 34.5 (2 × *o*-CH_2 of Cy), 51.2 [CH$_2$C(Cy)OR], 61.3 (OCH$_2$CH=CH$_2$), 74.8 [C(Cy)], 114.6 (OCH$_2$CH=CH$_2$), 116.9 [C(Cy)CH$_2$CH=CH$_2$], 134.3 (OCH$_2$$C$H=CH$_2$), 136.9 [C(Cy)CH$_2$$C$H=CH$_2$] ppm. MS (EI): *m*/*z* (%) = 180 (<1) $[M]^+$, 147 (14), 133 (24), 119 (11), 105 (12), 93 (26), 91 (31), 79 (58), 77 (29), 67 (40), 65 (19), 55 (19), 53 (25), 41 (100), 39 (44).

Tandem Isomerisation/Claisen Rearrangement Reactions

2,3-Dimethyl-5-phenylhex-4-enal (7):[10b]

Following Procedure D: $[Ru_3(CO)_{12}]$ (26.3 mg, 5 mol % of ruthenium), 1,3-bis(2,6-diisopropylphenyl)imidazolinium chloride (52.7 mg, 5 mol %), Cs_2CO_3 (80.5 mg, 10 mol %), toluene (25 mL) and diene **5** (0.5 g, 2.47 mmol) were stirred at 120 °C for 1 h. After treatment and distillation, the aldehyde **7** was obtained as a colourless oil as a mixture of diastereoisomers (0.39 g, 78% yield). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.08−1.19 [m, 6 H, 2 × [CH(CH_3)], 2.07 [s, 3 H, (CH_3)(Ph)C=CH], 2.28−2.43 [m, 1 H, CH(CH$_3$)CH-(CH$_3$)CHO], 2.89−3.05 [m, 1 H, CH(CH$_3$)CH(CH$_3$)CHO], 5.52−5.66 [m, 1 H, (CH$_3$)(Ph)C=CH)], 7.22−7.39 (m, 5 H, Ph), 9.40−9.70 (m, 1 H, CHO) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 11.2 [CH(CH$_3$)CHO], 16.3 [CH(CH$_3$)CH(CH$_3$)CHO], 18.9 [(CH$_3$)-(Ph)C=CH], 34.0 [CH(CH$_3$)CH(CH$_3$)CH], 52.3 [CH(CH$_3$)CH-(CH$_3$)CH], 125.7, 126.9, 128.2 (CH arom.), 130.2 [(CH$_3$)(Ph)C=C], 136.2 [(CH$_3$)(Ph)C=CH], 143.5 (C arom.), 205.2 (CHO) ppm.

Preparation of the 1,6-Dienes

3-Allyloxy-3,7-dimethylocta-1,6-diene (9):

Following Procedure B: Linalol (6.5 mmol) in dimethylformamide (7 mL) was added to a solution of sodium hydride (60% in mineral oil, 0.31 g, 7.8 mmol) in dimethylformamide (15 mL). After addition of allyl bromide (0.73 mL, 8.4 mmol) and subsequent treatment, the crude was purified by flash chromatography over silica gel using diethyl ether/heptane (1:30) as eluent to afford the corresponding 1,6-diene **9** (1.13 g, 90% yield) as a colourless oil. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.22 (s, 3 H, C*H*$_3$), 1.49−1.58 [m, 5 H, CH$_2$C*H*$_2$CH=C(CH$_3$)$_2$, (*E*) CH$_2$CH$_2$CH=C(C*H*$_3$)$_2$], 1.63−1.69 [m, 3 H, (*Z*) CH$_2$CH$_2$CH=C(C*H*$_3$)$_2$], 1.92−2.05 [m, 2 H, C*H*$_2$CH$_2$CH=C(CH$_3$)$_2$], 3.80 (dt, ^3J = 5.2, ^4J = 1.6 Hz, 2 H, OC*H*$_2$CH=CH$_2$), 5.04−5.30 [m, 5 H, C*H*=C(CH$_3$)$_2$, C(CH$_3$)(R)$_2$-CH=C*H*$_2$, OCH$_2$CH=C*H*$_2$], 5.70−5.99 [m, 2 H, C(CH$_3$)(R)$_2$C*H*=CH$_2$, OCH$_2$C*H*=CH$_2$] ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 17.7 (*C*H$_3$), 22.3 [(*E*)-CH$_2$CH$_2$CH=C(*C*H$_3$)$_2$], 22.4 [CH$_2$*C*H$_2$CH=C(CH$_3$)$_2$], 25.7 [(*Z*)-CH$_2$CH$_2$CH=C(*C*H$_3$)$_2$], 39.8 [*C*H$_2$CH$_2$CH=C(CH$_3$)$_2$], 63.5 (O*C*H$_2$CH=CH$_2$), 77.5 [*C*(CH$_3$)(R)$_2$CH=CH$_2$], 114.5 [C(CH$_3$)(R)$_2$CH=*C*H], 115.5 (OCH$_2$CH=*C*H$_2$), 124.5 [*C*H=C(CH$_3$)$_2$], 131.4 [CH=*C*(CH$_3$)$_2$], 136.0 (OCH$_2$*C*H=CH$_2$), 143.0 [C(CH$_3$)(R)$_2$*C*H=CH$_2$] ppm. MS (EI): *m*/*z* (%) = 194 (<1) $[M]^+$, 136 (25), 121 (44), 111 (50), 107 (15), 95 (23), 93 (36), 91 (17), 82 (13), 80 (100), 71 (12), 69 (49), 67 (39), 55 (44), 53 (22), 42 (40), 40 (34).

{1-[Isoprop-2-enyl)oxy]-1-(phenyl)prop-2-enyl}benzene (13):

Following Procedure C: Benzophenone (3.0 g, 16.5 mmol) was added to $CeCl_3$ (0.41 g, 1.65 mmol) in tetrahydrofuran (30 mL) at room temperature. Vinylmagnesium bromide (20.0 mL, 20.0 mmol) was then added at 0 °C. Subsequent treatment afforded the corresponding allylic alcohol as a pale yellow oil used without purification for the next step.

Following Procedure B: Allylic alcohol (16.5 mmol) in dimethylformamide (15 mL) was added to a solution of sodium hydride (60% in mineral oil, 0.86 g, 19.8 mmol) in dimethylformamide (25 mL). After the addition of 2-methylpropenyl chloride (2.2 mL, 19.8 mmol) and subsequent treatment, the crude was purified by flash chromatography over silica gel using diethyl ether/heptane (1:20) as eluent to afford an orange oil which was then bubble-to-bubble distilled to give the corresponding 1,6-diene **13** (3.74 g, 86% yield) as a colourless oil. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.00 (s, 3 H, C*H*$_3$), 3.94−4.00 [m, 2 H, OC*H*$_2$C(CH$_3$)=CH$_2$], 5.15−5.63 [m, 4 H, C(CH$_3$)=C*H*$_2$, C(Ph)$_2$CH=C*H*$_2$], 6.69−6.84 [m, 1 H, C(Ph)$_2$C*H*=CH$_2$], 7.42−7.55 (m, 6 H, H arom.), 7.62−7.72 (m, 4 H, H arom.) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 20.6 (*C*H$_3$), 68.0 [O*C*H$_2$C(CH$_3$)=CH$_2$], 84.8 [*C*(Ph)$_2$(R)$_2$], 111.1 [C(Ph)$_2$CH=*C*H$_2$], 117.0 [OCH$_2$C(CH$_3$)=*C*H$_2$], 127.8, 128.5, 128.7 (*C*H arom.), 141.0 [C(Ph)$_2$*C*H=CH$_2$], 143.4 (*C* quat. arom.), 144.9 [OCH$_2$*C*(CH$_3$)=CH$_2$] ppm. MS (EI): *m*/*z* (%) = 264 (1) $[M]^+$, 193 (32), 191 (15), 178 (18), 165 (14), 144 (12), 116 (19), 115 (100), 106 (43), 103 (19), 91 (40), 77 (45), 55 (69), 41 (13), 39 (25).

(1-Allyloxy-1-phenylprop-1-enyl)benzene (15):

Following Procedure C: Benzophenone (1.67 g, 9.2 mmol) was added to $CeCl_3$ (0.23 g, 0.92 mmol) in tetrahydrofuran (20 mL) at room temperature. Vinylmagnesium bromide (11.1 mL, 11.1 mmol) was then added at 0 °C. Subsequent treatment afforded the corresponding allylic alcohol as a pale yellow oil used without purification for the next step.

Following Procedure B: Allylic alcohol (9.2 mmol) in 10 mL of dimethylformamide was added to a solution of sodium hydride (60% in mineral oil, 0.44 g, 11.1 mmol) in dimethylformamide (15 mL). After addition of allyl bromide (1.1 mL, 12.0 mmol) and subsequent treatment, the crude was purified by flash chromatography over silica gel using diethyl ether/heptane (1:20) as eluent to afford an orange oil which was then bubble-to-bubble distilled to give the corresponding 1,6-diene **15** (1.88 g, 82% yield) as a colourless oil. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.84−3.90 (m, 2 H, OC*H*$_2$CH=CH$_2$), 5.20−5.53 [m, 4 H, CH=C*H*$_2$, C(Ph)$_2$CH=C*H*$_2$], 5.95−6.12 (m, 1 H, OCH$_2$C*H*=CH$_2$), 6.49−6.63 [m, 1 H, C(Ph)$_2$C*H*=CH$_2$], 7.29−7.50 (m, 10 H, H arom.) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 64.8 (O*C*H$_2$CH=CH$_2$), 84.2 [*C*(Ph)$_2$(R)$_2$], 115.3 [C(Ph)$_2$CH=*C*H$_2$], 116.2 (OCH$_2$CH=*C*H$_2$), 127.1, 127.8, 127.9 (*C*H arom.), 135.6 (OCH$_2$*C*H=CH$_2$), 140.2 [C(Ph)$_2$*C*H=CH], 144.0 (*C* quat. arom.) {1-Methyl-1-[prop-1-enyloxy]but-3-enyl}benzene (11) Using Catalyst B1 with the Diimine L1: $[Ru_3(CO)_{12}]$ (13.2 mg, 5mol % per ruthenium atom), bis(imine) **L1** (18.1 mg, 5mol %), cesium carbonate (40.3 mg, 10mol %) and of toluene (10 mL) were introduced into a Schlenk tube under nitrogen. The reaction mixture was stirred at room temperature for 5 minutes and the diene **5** (250 mg, 1.24 mmol) was then added. After heating at 120 °C for 16 hours, the solvent was removed under reduced pressure and NMR spectroscopic analysis of the crude gave a complete conversion into the homoallyl vinyl ether **11**. The crude was dissolved in heptane, filtered and the solvents evaporated to dryness. This material was then purified by a bubble-to-bubble distillation to afford the corresponding compound **11** (195 mg, 78%) as a colourless oil. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.55−1.62 [m, 3 H, C(Ph)(CH_3)], 1.65−1.72 (m, 3 H, OCH=CHCH_3), 2.52−2.65 [m, 2 H, OC(Ph)(Me)CH_2CH=CH_2], 4.33−4.49 (m, 1 H, OCH=C*H*CH_3), 4.96−5.10 (m, 2 H, CH=CH_2), 5.54−5.76 [m, 1 H, OC(Ph)(Me)CH_2C*H*=CH_2], 5.81−5.92 (m, 1 H, OC*H*=$CHCH_3$), 7.20−7.38 (m, 5 H, Ph) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 11.8 (OCH=CH*C*H_3), 25.4 (CH_3), 47.1 [CH_2C(Ph)(Me)OR], 76.2 [*C*(Ph)(Me)], 97.8 (OCH=*C*HCH_3), 117.3 [C(Ph)(Me)CH_2CH=*C*H], 126.1, 126.8, 127.8 (*C*H arom.), 133.9 [C(Ph)(Me)CH_2*C*H=CH], 143.7 (O*C*H=$CHCH_3$), 144.8 (*C* arom.) ppm. MS (EI): *m*/*z* (%) = 202 (7) $[M]^+$, 143 (13), 131 (13), 129 (45), 115 (100), 113 (37), 91 (69), 78 (21), 65 (24), 63 (14), 53 (16), 51 (31), 41 (38), 39 (37).

2,2-Dimethyl-5,5-diphenylpent-4-enal (14) by Using Catalyst D and the 2,2′-Bis(oxazoline) Ligand 17: $[Ru_3(CO)_{12}]$ (10.6 mg, 5mol % ruthenium atom), 2,2′-bis(oxazoline) **17**[19d] (11.9 mg, 5 mol %), cesium carbonate (32.5 mg, 10 mol %) and toluene (10 mL) were introduced into a Schlenk tube under nitrogen. The reaction mixture was stirred at room temperature for 5 minutes and the diene **13** (250 mg, 1.01 mmol) was then added. After heating at 120 °C for 16 hours, the solvent was removed under reduced pressure and NMR spectroscopic analysis of the crude gave 60% of conversion into the aldehyde **14**.

General Procedure for the Preparation of [RuCl{bis(oxazoline)}(*p*-cymene)][BF_4]: A solution of bis(oxazoline) ligand (2 equiv.) in MeOH (10 mL) was added to $[RuCl_2(p\text{-cymene})]_2$ (1 equiv.) and NH_4BF_4 (2 equiv.), and the resulting suspension was stirred at room temperature for 2 h. An orange-brown solution was obtained, which was then evaporated and the crude residue dissolved in CH_2Cl_2. Filtration through celite gave a brown solution, which was evaporated, and the crude complex was washed with diethyl ether (2 × 15 mL) and dried under vacuum. The scale and the yields for individual complexes are shown below.

[RuCl{(*R*,*R*)-4,4′-Diisopropyl-2,2′-methylenebis(1,3-oxazoline)}(*p*-cymene)][BF_4] (18): Complex **18** was prepared in methanol (10 mL) from $[RuCl_2(p\text{-cymene})]_2$ (100 mg, 0.163 mmol), (*R*,*R*)-4,4′-diisopropyl-2,2′-methylenebis(1,3-oxazoline) (**17**) (77 mg, 0.32 mmol) and NH_4BF_4 (34 mg, 0.32 mmol) in a 94 mg yield (98%). Recrystallisation in a mixture of acetone/heptane afforded complex **18** as orange needles. $C_{23}H_{36}BClF_4N_2O_2Ru$: calcd. C 46.36, H 6.09, N 4.70, Cl 5.95; found C 46.45, H 6.33, N 4.51, Cl 5.95. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.52, 0.87, 1.00, 1.07 [4 × d, 12 H, ^3J = 6.6, ^3J = 7.2, ^3J = 7.0, ^3J = 6.8 Hz, 2 $CH(CH_3)_2$], 1.31 [d, ^3J = 7.0 Hz, 6 H, $CH(CH_3)_2$ of *p*-cymene], 2.30 (s, 3 H, $CH_3C_6H_4$), 2.28−2.33 [m, 1 H, C*H*$(CH_3)_2$], 2.60−2.66 [m, 1 H, C*H*$(CH_3)_2$], 3.01−3.09 [m, 1 H, C*H*$(CH_3)_2$ of *p*-cymene], 3.45, 4.00 (AB, 2 H, J_{AB} = 19.7 Hz, CH_2), 4.30−4.92 [m, 6 H, OCH_2C*H*(*i*Pr)N], 5.40−6.05 (m, 4 H, C*H* *p*-cymene) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.4, 14.7 [$CH(CH_3)_2$], 18.4 ($CH_3C_6H_4$), 18.9, 19.5 [$CH(CH_3)_2$], 20.9, 22.9 [$CH(CH_3)_2$ of *p*-cymene], 27.0 (CH_2), 28.1, 28.6, 30.9 [C*H*$(CH_3)_2$], 69.4, 70.3 [2 × *C*H(*i*Pr)], 71.3, 71.7 [OCH_2-CH(*i*Pr)], 79.4, 80.8, 83.8, 85.7 (4 *C*H *p*-cymene), 99.5, 110.0 (2 × *C* *p*-cymene), 165.4, 165.6 (2 × *C*=N) ppm. $L \cdot mol^{-1} \cdot cm^{-1}$) = 421 nm (1012), 322 (1587), 278 (7524), 245 (6780), 230 (7252).

2,2-Dimethyl-5,5-diphenylpent-4-enal (14) by Using Catalyst E with Complex (18) as the Metal Source: Complex **18** (29.7 mg, 5 mol %), 1,3-bis(2,6-diisopropylphenyl)imidazolinium chloride (21.3 mg, 5 mol %), cesium carbonate (32.5 mg, 10 mol %) and toluene (10 mL) were introduced into a Schlenk tube under nitrogen. The reaction mixture was stirred at room temperature for 5 minutes and the diene **13** (250 mg, 1.01 mmol) was then added. After heating at 120 °C for 16 hours, the solvent was removed under reduced pressure and NMR spectroscopic analysis of the crude gave 90% of conversion into the aldehyde **14**. After a column chromatography over silica gel using a mixture diethyl ether/heptane (1/20), the aldehyde **14** (170 mg) was isolated in 68% yield.

X-ray Crystallographic Study of Complex 18: Crystallographic and data collection information as well as a description of the structural analyses and refinements are summarised in Table 3. Single crystals of **18** were obtained by slow diffusion of heptane into an acetone solution of the complex. Data were collected with a Nonius−Kappa CCD diffractometer with graphite-monochromatised Mo-K_α radiation. The cell parameters were obtained with Denzo and Scalepack[24] using 10 frames (psi rotation: 1° per frame). The data collection[25] ($2\Theta_{max}$ = 54°, 128 frames via 21.7° omega rotation and 50 s per frame, *hkl* range: h −14,14; k −17,17; l −25,25) gives 23815 reflections. The data reduction[24] leads to 6792 independent reflections from which 6112 with $I > 2.0\sigma(I)$. The structure was solved with SIR-97,[26] which reveals the non-hydrogen atoms of the structure. After anisotropic refinement, many hydrogen atoms could be found with a Fourier Difference. The whole structure was refined with SHELXL-97[27] by the full-matrix least-squares techniques.

Atomic scattering factors were obtained from International Tables for X-ray Crystallography.[28] ORTEP views were realised with PLATON98.[29]

CCDC-210758 contains the supplementary crystallographic data for this paper. Structural, Photophysical and Chiro-Optical Properties of Lanthanide Complexes with a Bis(benzimidazole)pyridine-Based Chiral Ligand

Gilles Muller,[a,b] Christine L. Maupin,[b] James P. Riehl,[b] Henrik Birkedal,[c,d] Claude Piguet,[e] and Jean-Claude G. Bünzli*[a,b]

Keywords: Lanthanides / Luminescence / Chirality / Complexes / Terdentate ligand

The neutral Ln^{III} 1:1 nitrato complexes with the chiral ligand 2,6-bis(1-*S*-neopentylbenzimidazol-2-yl)pyridine (L^{11}) have been synthesised and their stability constants measured in acetonitrile (log K_1 = 4.0–6.4). The crystal and molecular structure of $[Eu(NO_3)_3(L^{11})(MeCN)]$ shows the typical meridional planar coordination of L^{11} to the metal ion and low symmetry of the coordination polyhedron. The influence of the steric hindrance generated by the substituent at R^2 on the crystal packing and bond lengths is discussed. Photophysical measurements show that ligand L^{11} induces a $^3\pi\pi^*$-to-Ln energy-transfer process in the Eu^{III} complex, while the Tb^{III} compound is ten times less luminescent. Addition of a second molecule of L^{11} to give $[Ln(ClO_4)_2(L^{11})_2]^+$ leads to a large quenching of the Eu^{III} luminescence (140-fold) due to several factors: a less efficient $^1\pi\pi^* \rightarrow {}^3\pi\pi^*$ transfer (ca. fourfold), a smaller intrinsic quantum yield Q^{Eu} (ca. threefold), and a substantially less efficient ligand-to-metal transfer (ca. 12-fold). In the case of the Tb^{III} complex, the decrease in the energy of the triplet state reduces further the Tb^{III} emission through increased back transfer. The specific rotary dispersion of the 1:1 and 1:2 complexes points to the chirality of the complexes arising mainly from the ligand, while the circularly polarized luminescence of these complexes with Eu^{III} and Tb^{III} displays a weak effect, pointing to a small diastereomeric excess in solution. Altogether, this study demonstrates that electronic, thermodynamic and photophysical properties of lanthanide complexes with aromatic terdentate ligands can be tuned by modifying the number and the arrangement of the ligands, as well as their substituents, particularly those in the R^2 and R^3 positions.

Introduction

Present interest in luminescent lanthanide complexes[1] is primarily motivated by applications in life sciences, mainly for developing chemical sensors[2] or tools for medical diagnosis and therapy.[3,4] In this context, the design and use of enantiopure lanthanide compounds present a special advantage with respect to the chiral recognition of biological substrates.[5,6] Lanthanides are subject to fast ligand- and solvent-exchange reactions so that easy interconversion between optical isomers often occurs. Therefore, the use of ligands leading to kinetically inert complexes, such as those derived from the dota (1,4,7,10-tetraazadodecane *N*,*N*′,*N*″,*N*‴,-tetraacetic acid) framework favours the isolation of enantiopure compounds.[7] We have recently reported on the first diastereoselective formation in solution of lanthanide triple helical complexes with a terdentate chiral C_2-symmetric ligand **L(−)** (Scheme 1) derived from terpyridine, as was suggested by their specific rotary dispersion, circularly polarized luminescence (CPL) and NMR spectra.[8] We have also investigated the influence of chiral groups grafted onto aromatic tridentate ligands on the diastereomeric induction in solution. For instance, ligands **L*** and $\mathbf{L^{12}}$, with a chiral group in the pyridine 4-position, form thermodynamically stable 1:3 triple helical complexes with Ln^{III} ions in acetonitrile, and chiro-optical measurements suggest the helical wrapping of the ligand strands around the Ln^{III} ions, while the CPL data are in agreement with a small diastereomeric excess in solution.[9,10]

Working along these lines, we have introduced a chiral substituent onto the benzimidazole sidearms of bis(benzimidazole)pyridine to yield $\mathbf{L^{11}}$. However, the bulky neopentyl group precludes the formation of stable triple helical com-

plexes: in the X-ray structure of $[Eu(\mathbf{L^{11}})_3](ClO_4)_3 \cdot 4.28MeCN$, two of the ligand molecules are wrapped around the Eu^{III} ion in a helical fashion, much as they are in the 1:2 complex with La^{III}, while the third one lies more or less perpendicular to the other two.[11] To further our understanding of the influence of helical wrapping on diastereomeric induction, we investigate here the thermodynamic, structural, luminescent and chiro-optical properties of the neutral nitrato complexes $[Ln(NO_3)_3(\mathbf{L^{11}})]$ (Ln = La, Eu, Tb) and compare them to those of $[Ln(ClO_4)_2(\mathbf{L^{11}})_2]^+$ complexes in solution.

Results and Discussion

Isolation, Structure and Stability of the 1:1 Nitrato Complexes

Neutral 1:1 complexes form easily upon mixing equivalent amounts of hydrated lanthanide nitrate and $\mathbf{L^{11}}$ in dichloromethane/acetonitrile. The general formula of the isolated complexes is $[Ln(NO_3)_3(\mathbf{L^{11}})(MeCN)_x]$ [x = 0, La (**1**), Gd (**3**), Tb (**4**); x = 1, Eu (**2**)] where the acetonitrile molecule sometimes completes the inner-sphere of the Ln^{III} ion to a coordination number of 10 (see below), but can be removed by heating under vacuum. Complexation is evidenced in the IR spectra by the blue shift of the two C=C benzimidazole and pyridine vibrational modes by 2−5 and 11−14 cm^{-1}, respectively (Table S1). Nitrate ions behave as bidentate ligands with local C_{2v} symmetry as exemplified by energy differences $\Delta(\nu_1 - \nu_4)$ larger than 180 cm^{-1}:[12] 221, 228, 229, and 230 cm^{-1} for La, Eu, Gd, and Tb, respectively. Single crystals suitable for X-ray diffraction analysis were obtained for the Eu complex **2**. The atom-numbering scheme is displayed in Figure 1 and selected bond lengths and angles are reported in Table 1, while interplanar angles are listed in Table S2. The structure consists of neutral molecules with 10-coordinate Eu^{III}, the metal ion being bound to six O atoms from the three bidentate nitrate anions, one N atom from the solvating molecule and three N atoms from $\mathbf{L^{11}}$. The ligand is coordinated in the usual meridional planar way, as was observed for $[Eu(NO_3)_3(\mathbf{L^1})(MeOH)]$,[13] with two small and very similar interplanar angles between the pyridine and benzimidazole moieties, α_{pb} = 6.5° and 6.2°, as compared to 3.3° and 5.5° for $\mathbf{L^{11}}$, but in contrast to the situation found in $[Eu(NO_3)_3(\mathbf{L^7})(MeCN)] \cdot 2.5MeCN$[14] and $[Eu(NO_3)_3(\mathbf{L^{10}})]$.[13] Indeed, in the former, $\mathbf{L^7}$ is bent with two different angles

α_{pb} = 4.3° and 13.1°, while in the latter the two benzimidazole arms of $\mathbf{L^{10}}$ are not coplanar with the central pyridine (α_{pb} = 29.7° and 28.3°). The observation of different conformations for these ligands may be explained by the crystal packing and the steric hindrance generated by the R^2 groups. In $[Eu(NO_3)_3(\mathbf{L^{11}})(MeCN)]$, the crystal packing is governed by several weak intermolecular CH···O H-bonds, involving the O-atoms of the nitrate anion N2 (Figure 2 and Table S3). Each coordinated O atom generates one interaction with H atoms located on the neopentyl arms or on the phenyl groups of another complex molecule, while the non-coordinated O-atom is involved in similar interactions with H atoms from acetonitrile or from the neopentyl groups of a different complex molecule. The steric hindrance of the neopentyl groups increases the bend of the ligand slightly, as previously observed for $[Eu(NO_3)_3(\mathbf{L^{10}})]$, so that the interstrand π-stacking interactions evidenced in $[Eu(NO_3)_3(\mathbf{L^1})(MeOH)]$ are lost.[13] Furthermore, the asymmetric conformation of the two benzimidazole units in $[Eu(NO_3)_3(\mathbf{L^7})(MeCN)]\cdot 2.5MeCN$ can be explained by the presence of strong intermolecular interactions, induced by the bulky dimethoxybenzyl substituents, with nitrate anions.[14]

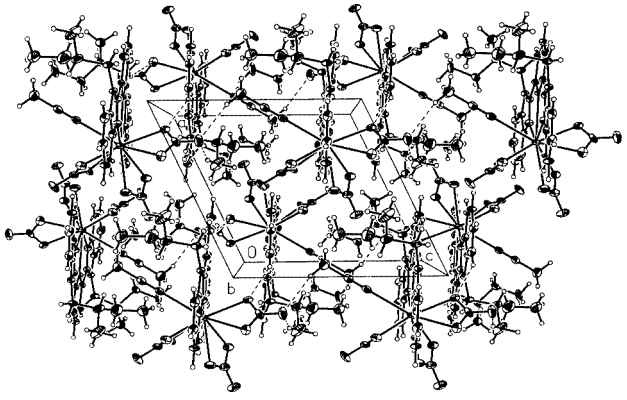

Figure 2. Intermolecular CH···O interactions observed in the crystal structure of $[Eu(NO_3)_3(\mathbf{L^{11}})(MeCN)]$

The coordination environment of the Eu^{III} ion in **2** is best described as a distorted 4:5:1 polyhedron (Figure S1) similar to the arrangement observed in the complexes with $\mathbf{L^1}$ [13] and $\mathbf{L^7}$.[14] In comparison with $[Eu(NO_3)_3(\mathbf{L^1})(MeOH)]$, the complexes with $\mathbf{L^7}$ and $\mathbf{L^{11}}$ feature an acetonitrile molecule coordinated to the Eu^{III} ion instead of a methanol molecule. This difference does not influence the characteristics of the coordination polyhedron. However, the Eu−N(MeCN) distance in **2** (2.735 Å) is substantially longer than those found in the complex with $\mathbf{L^7}$ (2.555 Å)[14] and in the solvate $[Sm(MeCN)_9]^{3+}$ (2.54 Å).[15] This lengthening is a consequence of the acetonitrile molecule in **2** being implied in an intermolecular interaction with a nitrate anion (see above). The capping position of the polyhedron is occupied by N2 from one of the benzimidazole units, while the two planes are defined by O11, O21 and O31 from the three nitrate anions and N5 from the second benzimidazole substituent, and O12, O22 and O32 from the nitrates, N1 from the central pyridine, and N100 from the coordinated acetonitrile molecule. The two Eu−N(benzimidazole) bonds are symmetric (Table 1), in contrast to the situation

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with **L¹**, **L⁷** and **L¹⁰** where the two Eu−N(benzimidazole) distances are different, but in all cases shorter than the Eu−N(pyridine) bond. On the other hand, we note that the mean Eu−N distances in the complexes with **L¹⁰** and **L¹¹** are similar (2.52 Å) and shorter than in the complexes with ligands bearing small R^2 groups such as hydrogen {2.58 Å, $[Eu(NO_3)_2(\mathbf{L^0})_2](NO_3)$[16]} or methyl (2.54 Å, **L¹**).[13] Generally speaking, this mean value decreases with the increase of the steric hindrance generated by the R^2 substituents. However, the mean Eu−N distance of 2.57 Å in the complex with **L⁷**, which contains the bulky dimethoxybenzyl groups, is quite close to the value determined for the complex with **L⁰**, a consequence of the influence of the electron-attracting *p*-nitrophenyl group substituted in the R^3 position of the central pyridine ring.

All three bidentate nitrate anions bound to the metal ion in **2** have an approximate C_{2v} local symmetry and present Eu−O bonds in the range 2.48−2.59 Å, with an average distance of 2.52 Å, similar to the values observed in related nitrato complexes (2.46−2.55 Å).[13,14,16] The ionic radius calculated according to Shannon's definition (1.17 Å) is the same as in the other 10-coordinate complexes (1.16−1.17 Å)[13,14,16] and is close to the expected value of 1.18 Å.[17] Finally, it should be mentioned that the two asymmetric carbon atoms, C21 and C23, retain their absolute configuration *S* in the complex, as was observed in the free ligand.[11]

In order to gain information on the stability of the 1:1 nitrato complexes, we performed spectrophotometric and luminescence titrations of **L¹¹** with $Ln(NO_3)_3$ (Ln = La, Eu, Tb, Lu) at 298 K in MeCN, in the presence of 0.1 M Et_4NClO_4, under N_2 atmosphere. Factor analysis[18] indicates the presence of two absorbing species and the fit converges for $\log K_1 = 4.0 \pm 0.4$, 4.0 ± 0.5, 4.0 ± 0.5, and 6.4 ± 0.2 for La, Eu, Tb, and Lu, respectively. For La, the stability constant is similar to the value determined for **L¹** (4.2 ± 0.3).[19] The $\log K_1$ value of the Eu^{III} complex determined by luminescence titration is in good agreement with that extracted from the spectrophotometric data: 4.1 ± 0.4.

Luminescent Properties of the Nitrato 1:1 and Perchlorato 1:2 Complexes in Solution

The electronic spectrum of **L¹¹** in MeCN displays one intense band centred at 31385 cm^{-1}, which splits into two components upon complexation, reflecting the electronic transformations associated with the *trans-trans* → *cis-cis* conformational change and the complexation of the Ln^{III} metal to the tridentate binding unit (Table 2).[13,20] UV irradiation of **L¹¹** at room temperature yields one broad unresolved fluorescence band, centred around 27100 cm^{-1}, and originating from the $^1\pi\pi^*$ state (Figure 3). Upon complexation to non-luminescent Ln^{III} ions, the energy of the ligand $^1\pi\pi^*$ state decreases by about 2000 and 2770 cm^{-1} in the 1:1 and 1:2 complexes, respectively. At 77 K, the ligand triplet state appears at 21120 cm^{-1} and undergoes a bathochromic shift of 90−185 cm^{-1} in the nitrato complexes and of 755 cm^{-1} in the La^{III} 1:2 perchlorato complex (Table 2); lifetimes decrease from 389 ± 4 ms for the free ligand to 215 ± 1 and 93 ± 5 ms for the La 1:1 and 1:2 complexes, respectively. In addition to the weak metal-centred emission bands, the luminescence spectra of the Eu^{III} and Tb^{III} solutions reveal emission from the ligand $^1\pi\pi^*$ state. The latter is more intense in the case of the 1:2 complexes (see Figure 3), for which the ratio between the integrated ligand-centred singlet state and metal-centred emission bands reaches a factor of 280, compared to about one in the nitrato complexes. The mechanism by which energy is transferred from the ligand to the metal ion involves two essential steps, an intersystem crossing (isc) from the singlet to the triplet state of the ligand and energy transfer to the long-lived excited $^5D_0$(Eu) or $^5D_4$(Tb) states.[1] To get a better insight into the various energy migration processes occurring in the 1:1 and 1:2 complexes, we determined the quantum yield of both the ligand- and metal-centred luminescence of 10^{-4} to 10^{-3} M solutions at 293 K upon ligand excitation, and the ratio between the integrated triplet and singlet state emissions, $R_{TS} = I^T/I^S$, for the free ligand and its La (or Gd) complexes at 77 K.

The fluorescence quantum yield of the free ligand, $Q^F = 78\%$, is smaller than for **L¹**, for which it is close to 100%. It is substantially reduced by factors of 55 (La) and 83 (Gd) in the 1:1 nitrato complexes, but only by a factor of nine in the perchlorato 1:2 complex with La. Simultaneously, the ligand-centred phosphorescence is enhanced upon complexation as shown by R_{TS} which increases from 1.5×10^{-4} for uncomplexed **L¹¹** to 5.5×10^{-3} (La) and 1.5×10^{-2} (Gd) in the nitrato complexes, and to 1.5×10^{-3} in the La 1:2 complex. The better isc efficiency in 1:1 complexes results (i) from a more favourable energy gap between the $^1\pi\pi^*$ and $^3\pi\pi^*$ states: $\Delta E(^3\pi\pi^* - {}^1\pi\pi^*) = 4640$ (La) and 4450 (Gd) cm^{-1}, as compared to 6660 cm^{-1} in the free ligand and to 5690 cm^{-1} in its 1:2 complex with La (ideal value of 5000 cm^{-1}, Figure 4),[21] and (ii) from the mixing of the ligand-centred singlet and triplet wavefunctions promoted by spin-orbit and/or paramagnetic effects.[22]

The overall quantum yield of the europium-centred luminescence obtained upon ligand excitation, Q_L^{Eu}, amounts to 1.4% for the nitrato 1:1 complex, as compared to 2.8% for the corresponding compound with **L¹**.[19] This quantum yield can be broken down according to the following equation:

$$Q_{tot}^{Eu} = \eta_{ISC} \cdot \eta_{ET} \cdot Q^{Eu} = \eta_{sens} \cdot Q^{Eu}$$

where Q^{Eu} is the intrinsic luminescence quantum yield of the Eu^{III} ion, η_{sens} the efficiency of the luminescence sensitisation by the ligand, and η_{ISC} and η_{ET} the yields of the intersystem crossing and of the ligand-to-metal energy transfer, respectively. The intrinsic quantum yield Q^{Eu} is simply the ratio between the observed and radiative lifetimes of the Eu($^5D_0$) level:

$$Q^{Eu} = \tau_{obs}/\tau_R$$

In turn, in the special case of Eu^{III}, for which the intensity of the magnetic dipole $^5D_0 \rightarrow {}^7F_1$ transition is in prin-

[a] sh = shoulder; at the concentration used, about 97, and 72−77% of the metal ion is under the form of the 1:2 and 1:1 complexes and 3, and 23−28% under the form of the 1:1 complex and free ligand in 1:2 and 1:1 solutions, respectively. [b] x = n or π; Logε values are given between parentheses. [c] The 0-phonon transition is given in italics for frozen solutions in MeCN. [d] Not measured. [e] Not observed because of the **L11**-to-Ln energy transfer process.

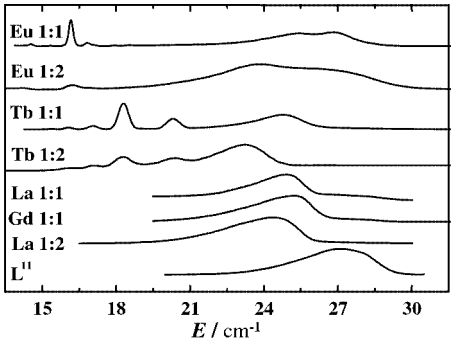

Figure 3. Emission spectra of $[Ln(NO_3)_3(\mathbf{L^{11}})(MeCN)_x]$ (x = 0, 1), $[Ln(ClO_4)_2(\mathbf{L^{11}})_2]^+$, and **L^{11}** 10^{-3} M in MeCN at 293 K

ciple independent of the chemical environment, the radiative lifetime τ_R can be estimated from:[23]

$$\tau_R = [1/(A_{MD,0}\cdot n^3)]\cdot(I_{MD}/I_{tot})$$

in which $A_{MD,0}$ is the spontaneous emission probability of the Eu($^5D_0\rightarrow{}^7F_1$) transition (14.65 s^{-1}), n is the refractive index (1.34 for the acetonitrile solution) and I_{MD}/I_{tot} is the intensity ratio of the Eu($^5D_0\rightarrow{}^7F_1$) transition to the total emission of the $^5D_0$ level. For the 1:1 complex, I_{MD}/I_{tot} = 0.1, leading to τ_R = 2.8 ms, Q^{Eu} = 0.47 (τ_{obs} = 1.32 ± 0.01 ms) and η_{sens} = 0.03. The isc efficiency in $[La(NO_3)_3\mathbf{L^{11}}]$ is about three times larger than in the nitrato La complex with **L^1**. Since the energy gaps $\Delta E(^3\pi\pi^*\text{-}^5D_0)$ are comparable — ca. 3600 cm^{-1} and 3700 cm^{-1} for the complexes with **L^1** and **L^{11}**, respectively, as estimated from $E(^3\pi\pi^*)$ in the La complexes — the smaller overall quantum

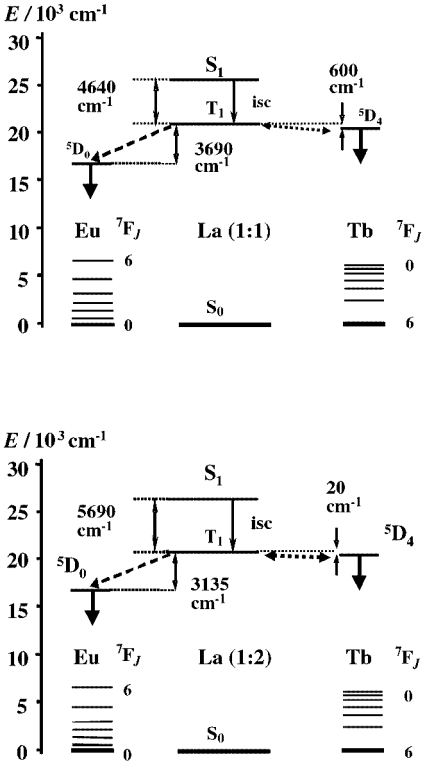

Figure 4. Schematic energy diagram for $[Ln(NO_3)_3(\mathbf{L^{11}})(MeCN)_x]$ (x = 0, 1) and $[Ln(ClO_4)_2(\mathbf{L^{11}})_2]^+$ complexes; data for S_1 and T_1 are those of the La^{III} complexes in frozen solution at 77 K (0-phonon transitions)

yield of $[Eu(NO_3)_3\mathbf{L^{11}}]$ compared with the $\mathbf{L^1}$ complex can be traced back to more efficient non-radiative deactivation processes taking place in the former complex, probably in view of the larger fluxionality induced by the neopentyl substituents.

The situation is different in the Eu 1:2 complexes with $\mathbf{L^{11}}$ for which the quantum yield drops to 1×10^{-2} %. With respect to the nitrato 1:1 complex, the $\Delta(^3\pi\pi^* - {}^5D_0)$ gap decreases from ca. 3700 cm^{-1} to ca. 3100 cm^{-1}, which should be more favourable for the sensitisation of the metal luminescence. On the other hand, the isc process is about four times less efficient (compare the R_{TS} values given above for the La complexes) and the intrinsic quantum yield is smaller: a calculation similar to the one above leads to $I_{MD}/I_{tot} = 0.18$, $\tau_R = 5.1$ ms, $Q^{Eu} = 0.14$ ($\tau_{obs} = 0.73 \pm 0.01$ ms). Consequently, $\eta_{sens} = 7 \times 10^{-4}$, that is 42-fold smaller than in the 1:1 complex. Therefore, the 140-fold drop in the overall quantum yield of the 1:2 complex compared with the 1:1 compound can be roughly broken into three contributions: a less-efficient $^1\pi\pi^* \rightarrow {}^3\pi\pi^*$ transfer (ca. fourfold), a smaller intrinsic quantum yield Q^{Eu} (ca. threefold), and a substantially less efficient ligand-to-metal transfer (ca. 12-fold). A similar, but much more dramatic decrease in the overall quantum yield (3400-fold) has been reported for $[Eu(\mathbf{L^1})_3]^{3+}$ compared with $[Eu(NO_3)_3(\mathbf{L^1})(MeOH)]$. This effect was assigned, both on the basis of experimental data[19] and theoretical modelling,[24] to the presence of a ligand-to-metal charge transfer (LMCT) state with an energy close to that of the ligand singlet state.

The Tb^{III} complexes are about ten times less luminescent than the Eu^{III} analogues, with $Q_L^{Tb} = 1.1 \times 10^{-1}$ and 1.3×10^{-3} % for the 1:1 and 1:2 complexes, respectively. The main reason is a deactivation through energy back-transfer onto the ligand since the energy gap $\Delta(^3\pi\pi^* - {}^5D_4)$ amounts to only 600 and 20 cm^{-1}, respectively. The more efficient back-transfer taking place in the 1:2 complex compared with the nitrato compound is exemplified by the temperature dependence of the $^5D_4$(Tb) lifetimes, which are longer, for solid state samples, than for the nitrato complex.[25]

Chiro-Optical Properties

The specific rotary dispersion of solutions of the $[Ln(NO_3)_3(\mathbf{L^{11}})(MeCN)_x]$ ($x = 0, 1$) complexes (10^{-3} M in anhydrous acetonitrile) amounts to 18.8 ± 0.8 (La), 17.1 ± 0.2 (Eu), 16.8 ± 0.3 (Gd) and 19.1 ± 0.3 (Tb) deg·dm^2·mol^{-1}. These values are close to the one measured for the free ligand (15.1 ± 0.3 deg dm^2 mol^{-1}), pointing essentially to no structural contribution to the chiro-optical effect. For the 1:2 complexes, a similarly small structural contribution (4−5 deg dm^2 mol^{-1}) has been evidenced.[11] As a comparison, 4- to 10-fold larger rotary dispersion values have been observed for 1:3 complexes with ligands $\mathbf{L^{12}}$[10] and $\mathbf{L^*}$[9] compared with the free ligand value, pointing to the importance of the structural contribution in triple-stranded chiral helical complexes.

We have resorted to circularly polarized luminescence (CPL) to determine whether or not the 1:3 complex with $\mathbf{L^{11}}$ presents an enantiomeric excess of one isomer. CPL spectra were measured for solutions of $[Eu(NO_3)_3(\mathbf{L^{11}})(MeCN)]$, $[Ln(ClO_4)_2(\mathbf{L^{11}})_2]^+$ (Ln = Eu, Tb) $1-1.6 \times 10^{-3}$ M and for a perchlorate solution containing an Eu:$\mathbf{L^{11}}$ ratio equal to 1:34. In the latter, high resolution luminescence spectra (in a mixture of anhydrous MeCN:CH_2Cl_2, 97:3) show that the 1:3 species exists in a proportion of about 20% (Figure S2), the remaining Eu-containing species being the 1:2 complex, while only 1% of the Eu^{III} ions are in the 1:3 form in a 10^{-3} M perchlorate solution with a stoichiometric 1:3 ratio. The excitation spectrum of $[Eu(ClO_4)_2(\mathbf{L^{11}})_2]^+$ 10^{-3} M in the range of the $^5D_0 \leftarrow {}^7F_0$ transition reveals the presence of two bands at 17260 and 17244 cm^{-1} originating from the 1:1 and 1:2 complexes, respectively (Figure S3). The presence of the 1:1 species in the 10^{-3} M $[Eu(ClO_4)_2(\mathbf{L^{11}})_2]^+$ solution is confirmed by the speciation that can be calculated from the stability constants:[11] a 10^{-3} M solution contains 97% of the 1:2 species and about 3% of the 1:1 species. However, the quantum yield of the latter is 140 times larger than for the 1:2 compound, which explains the observation of both species in the excitation spectrum with similar intensity.

The emission of the magnetic dipolar $^5D_0 \rightarrow {}^7F_1$ transition is circularly polarized for the three Eu^{III} solutions with very small ΔI values, the smallest effect occurring, as expected, for the 1:1 species (Figure 5). We interpret these data as follows. The CPL properties observed for $[Eu(NO_3)_3(\mathbf{L^{11}})(MeCN)]$ result solely from the effect of the chirality of the ligand, while for the 1:2 and 1:3 compounds, the structural contribution of the helical wrapping of the ligands also contributes to ΔI. It is noteworthy that for the solutions of the perchlorato complexes, ΔI depends on the polarisation of the excitation light, indicating the presence of more than a single species in solution.[26] The CPL spectrum of the corresponding terbium 1:2 perchlorato complex displays a low ΔI value (Figure S4), which also demonstrates that the compound is not a racemic mixture in solution. Therefore, the chiro-optical data presented here are consistent with the presence of small diastereomeric excesses in solutions of the 1:2 and 1:3 complexes, on the short time scale of optical

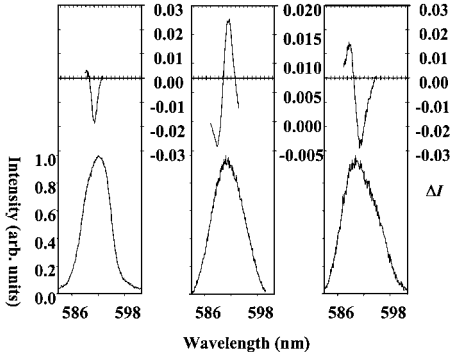

Figure 5. CPL spectrum of the $^5D_0 \rightarrow {}^7F_1$ transition of $1-1.6 \times 10^{-3}$ M solutions of $[Eu(NO_3)_3(\mathbf{L^{11}})(MeCN)]$ (left), $[Eu(ClO_4)_2(\mathbf{L^{11}})_2]^+$ (middle) in anhydrous MeCN and one with an Eu:$\mathbf{L^{11}}$ ratio of 1:34 (right) in a mixture of anhydrous MeCN and CH_2Cl_2 (97:3) at 293 K

measurements, as previously observed for 1:3 complexes with **L12** [10] and **L***.[9]

Conclusion

The structural properties of $[Eu(NO_3)_3(\mathbf{L^{11}})(MeCN)]$ are similar to those of the Eu^{III} complexes with ligands **L1** and **L7**. Upon complexation, the ligand adopts a *cis-cis* configuration which implies a meridional planar coordination of the Eu^{III} metal. The introduction of various substituents in the R^2 position influences both the inner coordination sphere of the metal ion and the crystal packing, which is mainly governed by intermolecular interactions involving hydrogen bonds. The addition of a second ligand in the perchlorato 1:2 complexes significantly modifies the photophysical properties. For Eu^{III}, an efficient quenching of the metal-centred luminescence occurs which is due to several factors, one of which could be lowering of the energy of the LMCT state. Ligand **L11** is not a good sensitizer of the Tb^{III} luminescence in view of its too low-lying triplet state, and the introduction of a second ligand molecule lowers the energy of this state still further, leading to increased energy back-transfer. This study confirms that electronic, thermodynamic and photophysical properties of lanthanide complexes with aromatic terdentate ligands can be tuned by modifying the number, the arrangement and the nature of the ligands. In particular, the nature of electron-attracting or -withdrawing R^2 or R^3 groups influences critically the physicochemical properties of the complexes. Contrary to what was observed for the tris complexes with **L12**,[10] **L*** [9] and **L(−)**,[8] the chiro-optical properties of the 1:2 and 1:3 complexes mainly arise from the chirality of the ligand and not from a structural contribution due to the helical wrapping of the ligand strands around the Ln^{III} ions. On the other hand, small enantiomeric excesses are generated in solutions of 1:2 and 1:3 complexes.

Experimental Section

Solvents and Starting Materials: Acetonitrile and dichloromethane were distilled from CaH_2. Other products were purchased from Fluka AG (Buchs, Switzerland) or Merck and used without further purification. The ligand **L11**, its 1:2 complexes and lanthanide perchlorates and nitrates were synthesised as described previously.[11,27]

Caution: *Dry perchlorates and their complexes with aromatic amines may easily explode and should be handled in small quantities and with extreme precaution.*[28]

Spectroscopic and Analytical Measurements: Electronic spectra in the UV/Vis range were recorded at 293 K with a Perkin−Elmer Lambda 900 spectrometer using 1.0 and 0.1 cm quartz cells. Specific rotary dispersion values were measured from 10^{-3} M solutions in degassed anhydrous acetonitrile at 298 K with the help of a JASCO DIP-370 polarimeter (sodium D line). IR spectra were obtained from KBr pellets with a Mattson α-Centauri FT-IR spectrometer. Ligand excitation and emission spectra were recorded on a Perkin−Elmer LS-50B spectrometer equipped for low temperature (77 K) measurements. The experimental procedures for high resolution, laser excited luminescence studies have been published previously.[29] Emission spectra are corrected for the instrument function. Quantum yields of the ligand-centred emission were measured relative to quinine sulfate in 0.05 M H_2SO_4 ($A_{347} = 0.05$, absolute quantum yield: 0.546).[30] Quantum yields of the metal-centred emission were determined as described previously[19] at excitation wavelengths at which (i) the Lambert−Beer law is obeyed, and (ii) the absorption of the reference $[Ln(terpy)_3]^{3+}$ closely matches that of the sample. CPL measurements were made on an instrument described previously, operating in a differential photon-counting mode.[26] Elemental analyses were performed by Dr H. Eder (Microchemical Laboratory, University of Geneva).

Spectrophotometric Titrations: The electronic spectra in the UV/Visible range were recorded at 298 K from 10^{-4} M solutions in acetonitrile containing Et_4NClO_4 0.1 M as inert electrolyte with a Perkin−Elmer Lambda 7 spectrometer connected to an external personal computer and using quartz cells of 0.100 cm path length. Solutions were prepared in a thermostatted vessel (Metrohm 6.1418.220) and the titrating solution was added with an automated burette from Metrohm (6.1569.150 or -.210) fitted with an anti-diffusion device. In a typical experiment, 5−10 cm^3 of **L11** were titrated with a solution of Ln^{III} nitrate 10^{-4} M in acetonitrile, under N_2 atmosphere. After each addition of 0.10 cm^3 and a delay of 2 min, the spectrum was measured and transferred to the computer. Factor analysis and stability constant determinations were carried out with the program SPECFIT, version 2.10 (± 2σ).[31]

Crystal Structure of $[Eu(NO_3)_3(\mathbf{L^{11}})(MeCN)]$: The block-shaped crystals were directly transferred from the mother liquor into a drop of Hostinert 216 and kept at 210 K. A specimen was selected and placed in a glass capillary. The data collection took place at 150 K on a Stoe IPDS system equipped with Mo-K_α radiation. The detector-crystal distance was set to 80 mm, and a φ interval of 1° was chosen. Two hundred images were collected with an exposure time of 10 min/image. The integration was based on an effective mosaic spread of 0.011 and a profile of between 9 and 21 pixels. The intensities were corrected for Lorentz and polarisation effects. No absorption correction could be applied since the crystal was all but invisible in the frozen oil, but the absorption coefficient appears to be small. The decay during the measurement was negligible. The structure was solved and refined on F^2 with the help of the SHELX system.[32] In the final model, a part of the ligand was described with isotropic atomic displacement parameters and all atoms in **L11** were submitted to rigid link restraints. All hydrogen atoms were clearly visible in the difference electron density maps, and were included in a riding atom model. The last cycles continued to show a non-zero maximal parameter chance over σ. This is due to the fact that the Flack parameter[33] (refined as a component in the least-squares) turns negative at the end of each of the final cycles; it is then reset to zero by the program. The structure was analysed using SHELXTL 5.05[34] and PLATON.[35] The refinement favours the *S* configuration for the chirality centres C21 and C23, as expected from the synthesis.

Crystal Data: $C_{31}H_{36}EuN_9O_9$, $M = 830.65$, monoclinic, space group $P2_1$ (N_0 4), $a = 10.172(2)$, $b = 16.804(3)$, $c = 10.989(2)$ Å, $U = 1697.2(6)$ Å^3, $T = 150(2)$ K, $Z = 2$, $\mu(\text{Mo-}K_\alpha) = 1.915$ mm^{-1}, 10740 reflections measured, 5205 unique ($R_{int} = 0.1013$) which were used in all calculations. The final $wR(F^2)$ was 0.0347 (all data). CCDC-217485 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation of the 1:1 Nitrato Complexes: The 1:1 complexes $[Ln(NO_3)_3(\mathbf{L^{11}})(MeCN)_x]$ [x = 0, La (**1**), Gd (**3**), Tb (**4**); x = 1, Eu (**2**)] were prepared by mixing equivalent amounts of $Ln(NO_3)_3{\cdot}nH_2O$ (Ln = La, Eu, Gd, Tb and n = 5−6) and $\mathbf{L^{11}}$ in dichloromethane/acetonitrile (1:4 v/v) and the residual suspension was refluxed for 30 min. The complexes were crystallised in 70−80% yield by slow evaporation of the solvent and were characterised by their IR spectra (Table S1) and elemental analyses. [$C_{29}H_{33}LaN_8O_9$ (776.53): calcd. C 44.9, H 4.3, N 14.4; found C 44.9, H 4.3, N 14.3. $C_{31}H_{36}EuN_9O_9$ (830.64): calcd. C 44.8, H 4.4, N 15.2; found C 44.6, H 4.3, N 15.0. $C_{29}H_{33}GdN_8O_9$ (794.88): calcd. C 43.8, H 4.2, N 14.1; found C 43.9, H 4.3, N 14.1. $C_{29}H_{33}N_8O_9Tb$ (796.55): calcd. Structure and Magnetism of a New Dodecanuclear Cu^{II} Complex with Acetato and Imidazolato Bridges, Formed by Oxidation of the Chelating Ligand 1,1,7,7-Tetrakis(imidazol-2-yl)-2,6-diazaheptane

Yufei Song,[a] Patrick Gamez,[a] Arno F. Stassen,[a] Martin Lutz,[b] Anthony L. Spek,[b] and Jan Reedijk*[a]

Keywords: Copper / Magnetic properties / N ligands / Chelates

A novel dodecanuclear copper(II) complex $[Cu_{12}(tidhd)_4(MeOH)_8(CH_3COO)_8](MeOH)_{0.8}$ (Htidhd = 1,1,7,7-tetrakis-(imidazol-2-yl)-2,6-diaza-1,6-heptadiene) with imidazolato and acetato bridging ligands was synthesized by reaction of polyimidazole 1,1,7,7-tetrakis(imidazol-2-yl)-2,6-diazaheptane (Htidahp) with copper acetate in a methanol solution. The complex crystallized in the triclinic space group $P\bar{1}$ with a = 9.1204(1), b = 13.5139(2), c = 27.6925(5), α = 76.8006(6)°, β = 82.8066(7)°, γ = 76.4594(9)°, Z = 1. Structure analysis shows that the unit cell of the complex contains twelve copper(II) ions in three different coordination environments. The complex is centrosymmetric and the two hexanuclear units are linked by two μ_3-acetate anions [the Cu1–Cu1a distance is 3.5507(7) Å]. The magnetic superexchange interaction via the bridging imidazolate ligand appears to be the most important magnetic interaction in this complex. Magnetic susceptibility measurement vs. temperature in the range of 6–300 K were fitted to the parameters g = 2.05, J_a = –32.0 cm^{-1} and J_b = –5.45 cm^{-1}.

Introduction

There has been great interest in the magnetostructural studies carried out on polynuclear divalent first-row transition metal complexes in recent years.[1] One of the main interests in this field comes from the need for the design and synthesis of novel functional materials with highly ordered structures in order to provide new molecular-based magnets.[2] Furthermore, many such systems are potential model compounds of multi-metal proteins.[3] This is especially relevant when imidazole is used as a ligand, since it is ubiquitous in proteins.[4]

Over the past decades, much progress has been made in the structural characterisation of copper proteins by different methods,[5] although the specific reaction pathways and mechanisms of action have remained unclear. In order to understand their catalytic mechanisms and their unusual spectroscopic characteristics, the development of relatively simple synthetic models of the active sites of copper proteins is of considerable interest.[6] The ligands most frequently used are based on pyrazole, imidazole and pyridine moieties.[7,8] Since imidazole is present in many natural enzyme and proteins, we have chosen to design and synthesize model compounds of copper proteins with imidazole-containing ligands.[9]

The reaction of 1,1,7,7-tetrakis(imidazol-2-yl)-2,6-diazaheptane (Htidahp) with $Cu(OAc)_2$ leads to an unprecedented imidazolato- and acetato-bridged dodecanuclear complex. In this paper, the synthesis, crystal structure, spectroscopic and magnetic properties of this compound are discussed. Figure 1 shows the schematic structure of the ligand Htidahp.

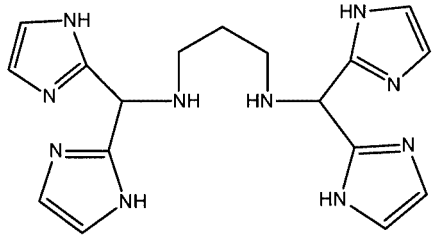

Figure 1. The structure of the ligand1,1,7,7-tetrakis(imidazol-2-yl)-2,6-diazaheptane (Htidahp)

Results and Discussion

The dodecanuclear complex was obtained by reaction of one equivalent of Htidahp with three equivalent of copper(II) acetate in methanol. Diethyl ether diffusion into the methanolic solution led to the formation of deep green,

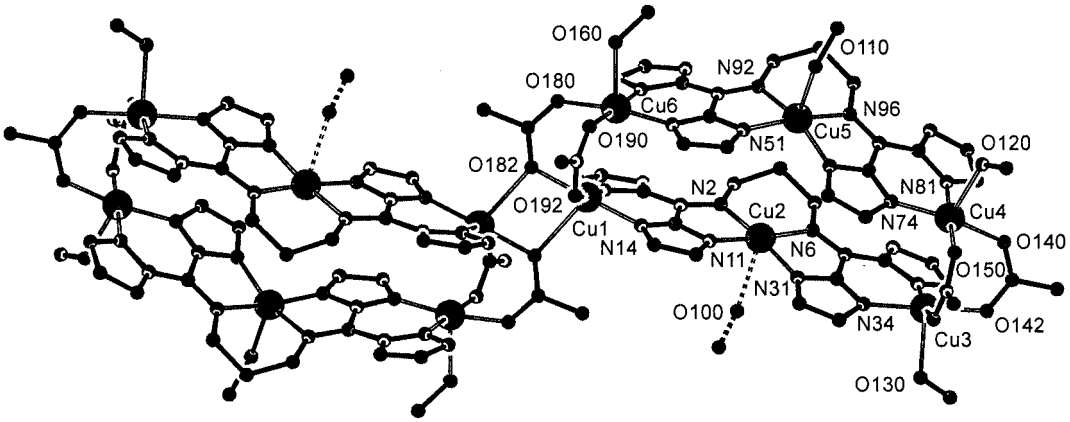

Figure 2. Platon projection[14] of the crystal structure of $[Cu_{12}(tidhd)_4(CH_3OH)_8(CH_3COO)_8](CH_3OH)_{0.8}$; hydrogen atoms are omitted for clarity; only the major component of the disordered methanol molecule at O130 is shown; the methanol molecule at O100 is only partially occupied

square crystals suitable for X-ray crystal structure determination (Figure 2).

The unit cell of the structure encloses one dodecanuclear unit, which is centrosymmetric. The asymmetric unit of the complex contains one $[Cu_6(tidhd)_2]^{4+}$ cation, five methanol molecules, of which one is disordered and one only partially occupied, and four $[CH_3COO]^-$ anions. Disordered solvent molecules occupy 13.5% of the unit cell volume, and they were treated as diffuse electron density (see Exp. Sect.). In the asymmetric unit, the six copper atoms are in different environments. Four dehydronated imidazole groups bridge Cu1 and Cu2 [5.6889(8) Å], Cu2 and Cu3 [5.6731(8) Å], Cu4 and Cu5 [5.7224(8) Å], and Cu5 and Cu6 [5.7148(7) Å], while the acetate anions bridge Cu1 and Cu6 [2.9926(8) Å], and Cu3 and Cu4 [3.0393(8) Å]. Cu1 is coordinated by a bridging imidazolate nitrogen atom, an imidazole nitrogen atom and three bridging acetate oxygen atoms in a distorted square-pyramidal geometry {O192−Cu1−N21 170.23(14)°, O182−Cu1−N14 175.87(14)°; $\tau_1 = 0.094$, where $\tau = 0$ and 1 are for the perfect square pyramidal and trigonal bipyramidal geometries, respectively[10]}, with a N_2O_3 donor set. Cu2 and Cu5 are each coordinated by a bridging imidazolate nitrogen atom, an imidazole nitrogen atom, two nitrogen atoms from the diamine unit, and one oxygen atom from a methanol molecule (N_4O donor set; $\tau_2 = 0.057$, $\tau_5 = 0.194$). The Cu3, Cu4 and Cu6 atoms are coordinated by a bridging imidazolate nitrogen atom, an imidazole nitrogen atom, two oxygen atoms from acetate oxygen atoms and one oxygen from a methanol molecule (N_2O_3 donor set; $\tau_3 = 0.170$, $\tau_4 = 0.123$, $\tau_6 = 0.124$). All the coordination spheres of these six copper atoms are distorted square-pyramidal. The Cu−O distances for the coordinated methanol molecules are in the range of 2.265(3) to 2.294(3) Å. On Cu2 the methanol molecule is only very weakly bound with a Cu−O distance of 2.706(10) Å. It can therefore easily evaporate, which explains the partial occupancy in the crystal. In all cases the methanol ligand is in an axial position. The complex consists of two hexanuclear units bridged by two acetate groups; the distance between Cu1 and Cu1a is 3.5507(7) Å.

It has to be pointed out that the C−N bonds in the original ligand have been oxidized to C=N upon coordination with copper acetate. Such oxidation and dehydrogenation reactions are not uncommon.[9,11] This compound is further stabilized by intramolecular and intermolecular hydrogen bonds. The different molecules are linked by intermolecular stacking between the imidazole rings, and by several hydrogen bonds.

A crystal structure of a related ligand, namely 1,1,6,6-tetrakis(imidazol-2-yl)-2,5-diazahexane (Htidah) was reported by our group with six copper ions in three different coordination environments.[11] The asymmetric unit in that complex consists of three copper ions, a negative tidah ligand, five chloride ions, two coordinated water molecules involved in hydrogen bonding and three lattice water molecules. The imidazole only bridges two copper atoms and the two trinuclear units are linked by two asymmetric chloride bridges (Cl6 and Cl6a) and two further bridges (Cl4 and Cl4a). The present dodecanuclear copper complex has both imidazolato and acetato bridging ligands. Its magnetic and electronic properties are described below.

Electronic Properties

The ligand field diffusion reflectance spectrum of the complex shows three d-d absorption bands centered at approximately $\lambda = 252$ nm (39.6×10^3 cm^{-1}), $\lambda = 368$ nm (27.2×10^3 cm^{-1}) and $\lambda = 603$ nm (16.6×10^3 cm^{-1}) in agreement with such geometries. The intensity of the absorptions at 368 nm and at 252 nm are assigned to the charge-transfer transition from the imidazolate nitrogen atoms to Cu^{II},[12] while the absorption at 603 nm is assigned to d-d transitions.[13]

EPR and Magnetic Susceptibility

The EPR spectrum of a powered polycrystalline sample of the complex at room temperature shows a broad isotropic copper(II) signal centered around a g value of 2.1034. At 77 K, the signals of the powder and a frozen solution of the complex in CH_3CN/MeOH are sharper, but no resolution of $g_{//}$ and $g_{\perp}$ is observed.

Magnetic susceptibility measurements have been performed on crystals of the complex (m = 34.87 mg) at 0.1 Tesla in the temperature range of 6 to 300 K. The plot of χ^{-1} and χT versus the temperature [with χ being the magnetization per copper(II) ion] is shown in Figure 3. At 300 K, $\chi T = 0.35$ cm^3·K·mol^{-1}, which is slightly lower than the expected value for a single, uncoupled copper(II) ion ($\chi T \approx 0.42$ cm^3·K·mol^{-1} for paramagnetic systems). The value of χT decreases upon cooling, with an even sharper decline below 60 K, to a value of $\chi T = 0.06$ cm^3·K·mol^{-1} at 6 K. This decrease indicates the presence of a quite strong antiferromagnetic coupling. The shape of the curve of both χT, and of χ^{-1} vs. the temperature is characteristic for a linear arrangement of three copper(II) ions.[14−16]

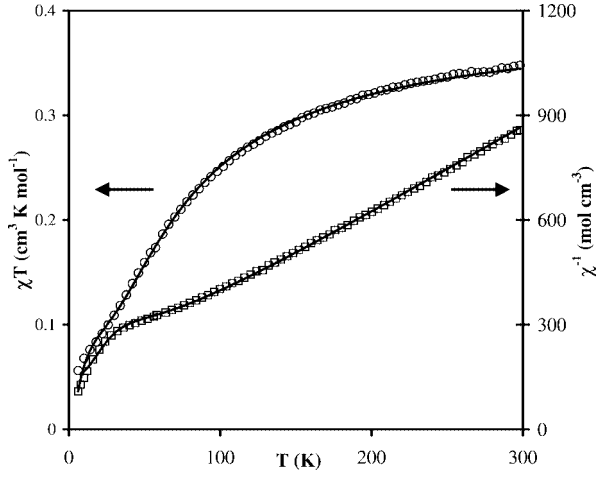

Figure 3. χT vs. T (○) and χ^{-1} vs. T curves (□) of **1**; the solid lines represent the calculated curves with parameters g = 2.05, J_a = −32.0 cm^{-1}, J_b = −5.45 cm^{-2} and $R = 7.6\cdot10^{-5}$ ($J_a = J_1 = J_2 = J_3 = J_4$; $J_b = J_5 = J_6$; $J_7 = 0$)

The fitting of the linear part of the χ^{-1} vs. T curve (between 80 and 300 K) results in a Curie constant, C, of 0.45 cm^3 mol^{-1} and a Curie Weiss temperature, θ, of −80.0 K with $R < 1.6\cdot10^{-4}$. [The fit was accompanied by minimisation of the reliability factor, defined as $R = {}^1/_n\cdot\Sigma(\chi^{-1}_{calc}/\chi^{-1}_{obs})^2/(\chi^{-1}_{obs})^2$, by least-squares procedure.] The Curie constant is in good agreement with the g value measured by EPR spectroscopy.[17] To interpret the magnetic data, the possible magnetic-exchange pathways have to be examined in some detail (Figure 4).

Along with six different magnetic superexchange interactions within the hexanuclear ring, coupling (J_7) between the two hexanuclear units is possible via the acetate anion bridging between Cu1 and Cu6, Cu1 and Cu1a. This interaction is expected to be small, as no equatorial links are involved, and is therefore not taken into account.[18]

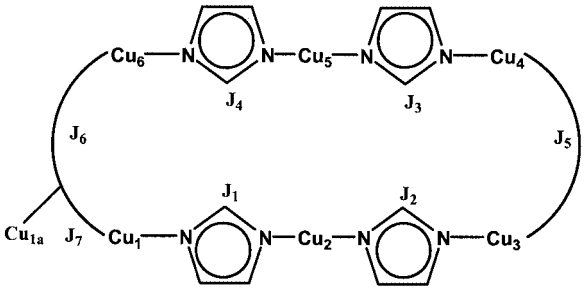

Figure 4. Possible magnetic superexchange pathways of the complex

Magnetic superexchange interaction via a bridging imidazole ligand is known to be relatively strong.[18,19] It is concluded from the short copper-imidazole distances (all between 1.948 Å and 2.022 Å) that the magnetic orbitals of the copper(II) ions are directed in such a way that a considerable electron delocalization occurs over the imidazolate nitrogen atoms. Therefore, an antiferromagnetic interaction is expected between Cu1−Cu2−Cu3 and between Cu4−Cu5−Cu6. Because the difference in Cu−Cu distances and the angles between the copper centers and the C2-atom of the imidazole ring are small (5.698 ± 0.025 Å, 172.12 ± 1.35°), the magnetic-exchange pathways J_{1-4} are considered to be identical (J_a).

These considerations lead to the first part of the expression (1), to describe the magnetic behaviour of this bis-hexanuclear cluster.

$$\chi = \frac{N\beta^2 g^2}{4kT}\,\frac{1+\exp[-2J_a/kT]+10\exp[J_a/kT]}{3+3\exp[-2J_a/kT]+6\exp[J_a/kT]}\times\exp[J_b/kT] \qquad (1)$$

In this formula, N, β and k have their normal value and g is assumed to be equal for all individual metal ions. The first term is an equation for an A-B-A copper(II) trinuclear species.[14,17] A trinuclear copper(II) species will normally lead to spin frustration, resulting in a χT value at low temperature equivalent to that of one uncoupled copper(II) ion.[17] As can be seen in Figure 3, the value of χT at low temperature is even lower than would be expected for such a trinuclear species. The superexchange interactions over the bridging acetate anions (J_5 and J_6) will be virtually identical and are therefore not expected to be equal to zero, and will be called J_b. This interaction forces the two trinuclear units to behave as two antiferromagnetic coupled units. The coupling constant J_b expresses this intertrinuclear superexchange interaction.

A good fit has been obtained for the parameters g = 2.05, J_a = −32.0 cm^{-1}, J_b = −5.45 cm^{-2} and $R = 7.6\times10^{-5}$. [$R = {}^1/_n\cdot\Sigma(\chi^{-1}_{calc}/\chi^{-1}_{obs})^2/(\chi^{-1}_{obs})^2$, where n is the number of points, χ_{calc} is the magnetic susceptibility calculated by formula 1 and χ_{obs} the measured susceptibility]. The magnetic behaviour of the complex can therefore be described as antiferromagnetic dimers of linear antiferromagnetic linear trimers. The value of J_a is in the range commonly observed for imidazolato-bridged Cu^{II} ions.[17−19]

Conclusions

In this paper, the synthesis and the structural and magnetic study of a novel dodecanuclear copper complex $[Cu_{12}(tidhd)_4(MeOH)_8(CH_3COO)_8](MeOH)_{0.8}$ are presented. The imidazole groups of the Htidhd ligand are dehydronated. The C−N bonds from the starting ligands have been oxidatively converted into C=N bonds upon coordination with copper acetate, which results in an unprecedented complex with a unique architecture. The unit cell of the dodecanuclear complex is centrosymmetric. Each asymmetric unit of the complex is composed by one $[Cu_6(tidhd)_2]^{4+}$, four methanol molecules and four acetate anions, and six copper atoms are in different coordination environment. All the coordination spheres of the six copper atoms are of a distorted square-pyramidal geometry. The two hexanuclear units are linked by two μ_3-acetate groups. The magnetic superexchange interaction via the bridging imidazolate ligand plays an important role in the magnetic interaction. The study here provides not only a novel dodecanuclear complex with imidazolato- and acetato- group as bridges, but also more information about the magnetic and structural data for imidazolato-bridged complexes.

Experimental Section

All reagents and solvents were purchased from commercial sources and used as received. C, H and N analyses were carried out in Leiden University. Infrared spectra were recorded on a Perkin−Elmer Paragon 1000 spectrophotometer equipped with a Golden Gate diamond ATR as a sample support. X-band EPR spectra were recorded on a JEOL ESR spectrometer equipped with an Esprit 330 data system, at room temperature and at 77 K, with dpph as internal reference (g = 2.0036). The ligand-field spectra of the solid samples were recorded in the 300−2000 nm range on a Perkin−Elmer Lambda 900 UV/Vis/NIR spectrometer in the diffuse reflectance mode with MgO as reference. Bulk magnetizations of polycrystalline samples were measured in the range 6−300 K with a Quantum Design MPMS-5S SQUID magnetometer, in a 1 kG applied field. The data were corrected for the experimentally determined contribution of the sample holder. Corrections for the diamagnetic responses of the complex, as estimated from Pascal's constants, were applied.[20]

The ligand 1,1,7,7-tetrakis(imidazol-2-yl)-2,6-diazaheptane (Htidahp) was prepared as follows: 1,3-Diaminopropane (0.32 g, 4.34 mmol) was added to a solution of the hydrochloride salt of bis(imidazol-2-yl)nitromethane[21] (2.0 g, 8.69 mmol) in 10 mL of ethanol and 10 mL of sodium hydroxide solution (2.0 M). The solution was stirred for 45 min at 80 °C, during which time the product crystallised from the reaction mixture. After cooling to room temperature, the reaction mixture was filtered. The product was washed with water, ethanol and dried with diethyl ether. Yield 76%. ^{1}H NMR (200 MHz, 1 M DCl, 25 °C): δ = 7.40 (s, 8 H, imidazole), 5.85 (s, 2 H, CH), 2.58 (d, 4 H, CH_2), 1.67 (m, 2 H, CH_2) ppm.

Preparation of the Complex: A solution of the ligand Htidahp (14.64 mg, 0.01 mmol) in 3 mL of methanol was added to a solution of $Cu(CH_3COO)_2$ (24.00 mg, 0.03 mmol) in 5 mL of methanol. The reaction mixture was stirred at room temperature for 10 min and filtered. Diethyl ether diffusion into the filtered solution led to the formation of deep green crystals of sufficient quality for X-ray structure determination. Yield: 11%. $C_{92.8}H_{114.4}Cu_{12}N_{40}O_{24.8}$ (2949.5): calcd. C 37.8, H 3.9, N 19.0; found C 37.5, H 3.7, N 18.4. IR (solid): $\tilde{\nu}$ = 1557.9, 1455.3, 1414.3, 1373.0, 1199.4, 937.9, 764.4, 623.1, 480.4 cm^{-1}. UV/Vis/NIR (solid): λ_{max} = 368 nm (strong); λ = 252 nm and λ = 603 nm (weak). EPR (solid, room temp): g = 2.1034.

X-ray Crystal Structure Determination: $C_{92.8}H_{114.4}Cu_{12}N_{40}O_{24.8}$ + solvent, Fw = 2949.52, green needle, 0.30 × 0.12 × 0.06 mm^3, triclinic, $P\bar{1}$ (no. 2), a = 9.1204(1), b = 13.5139(2), c = 27.6925(5) Å, α = 76.8006(6)°, β = 82.8066(7)°, γ = 76.4594(9)°, V = 3221.33(8) Å^3, Z = 1, ρ_x = 1.520 g cm^{-3}, 36255 measured reflections, 11025 unique reflections (R_{int} = 0.0656), 7472 observed reflections [$I > 2\sigma(I)$]. 785 refined parameters, 16 restraints. R (obs. refl.): $R1$ = 0.0416, $wR2$ = 0.1143. R (all data): $R1$ = 0.0674, $wR2$ = 0.1285. S = 1.038. Intensities were measured on a Nonius KappaCCD diffractometer with rotating anode (Mo-K_α, λ = 0.71073 Å) at a temperature of 150 K. An absorption correction based on multiple measured reflections was applied (μ = 2.014 mm^{-1}, 0.76−0.89 transmission). The structure was solved by direct

methods using the program SHELXS-97,[22] and refined with the program SHELXL-97[23] against F^2 of all reflections up to a resolution of $(\sin\theta/\lambda)_{max} = 0.59$ Å^{-1}. Non-hydrogen atoms were refined freely with anisotropic displacement parameters. O-H hydrogen atoms were fixed in their located positions, all other hydrogen atoms were refined as rigid groups. One weakly coordinated methanol molecule was only partially occupied in the crystal (occupancy 40%); its O-H hydrogen atom could not be located in the difference Fourier map and was therefore not included in the refinement. The crystal structure contains large voids (435.5 Å^3) filled with disordered solvent molecules. Their contribution to the structure factors was secured by back-Fourier transformation (program PLATON,[24] CALC SQUEEZE, 56 e$^-$/unit cell). The drawings, structure calculations, and checking for higher symmetry were performed with the program PLATON.[24]

The Platon projection[24] of the crystal structure of $Cu_{12}(tidhd)_4(CH_3OH)_8(CH_3COO)_8](CH_3OH)_{0.8}$ is shown in Figure 2. Selected bond lengths and angles are given in Table 1.

Dimensionality Variation in Polymeric Metallo-Organic Frameworks

Kalle I. Nättinen,[a] Juha Linnanto,[a] and Kari Rissanen*[a]

Keywords: Crystal engineering / X-ray diffraction / Self-assembly / Coordination polymers

Single crystal X-ray crystallography was used to determine the structures of four metallo-organic complexes derived from pyridyl ligands and the metal ions, Cu^{2+}, Zn^{2+} and Ag^{+}. Two metallo-organic layer framework structures (**1** and **3**), a strand (**2**) and a dimer (**4**) structure were formed when the tetradentate ligands, tetrakis(nicotinoxymethyl)methane (TNM) and tetrakis(isonicotinoxymethyl)methane (TINM), were reacted with the first and second row transition metal cations, copper, silver, and zinc. The choice of anion and ligand was found to affect the outcome of the structure. Contrary to our previous results with the same ligands and similar transition metal cations, no genuine 3D metallo-organic frameworks (MOFs) were obtained. Several factors were found to affect MOF formation: the coordination geometry, the *meta*- or *para*-configuration of the coordinating pyridyl moieties and the size and type of the counter anion. In **1**, the use of TNM (with a shorter "coordination arm" than TINM), in combination with an octahedral coordination geometry (4 Py, SO_4^{2-} and H_2O) and a relatively large sulfate anion, leads to a sandwich-like layer structure with the anions between the MOF layers. The layers have a thickness of 2.1 nm. In complex **3**, similar layer structures are assembled from four- and five-coordinate (2 Py, NO_3^-, H_2O/2 Py, 3 NO_3^-) Ag^+ ions with TINM and nitrate anions. However, in complex **2**, the Zn^{2+} ion is tetrahedrally (2 Py, 2 Cl^-) coordinated, creating an infinite strand structure. Most surprisingly, in complex **4**, two arms of the ligand are uncoordinated and a binuclear square-planar coordination geometry (2 Py, 2 CH_3COO^-) around the Cu^{2+} ions, as well as the acetate anions, create a non-polymeric dimeric structure.

Introduction

The ease with which new polymeric metallo-organic materials can be analyzed and synthesized, as well as their potential capacity for a range of applications, have in the last decade created an interesting field of chemistry dealing with supramolecular, polymeric strands, sheets, and 3D networks. Possible applications include trapping (or chlathrating) of guest molecules,[1] chemical sensing,[2] light element ceramics,[3] electronic switches, and gas-storage.[4,5] Molecular self-assembly enables the synthesis of these complexes by the utilization of molecular tectons[6] and supramolecular synthons[7] to create infinite polymers that form crystals. The tectons are held together by a variety of interactions such as metal−ligand coordination bonds,[8−11] hydrogen-bonds,[12−15] stacking interactions,[16] S− S bonds,[11] metal-metal contacts,[17] weak hydrogen−bonds,[16,18] π··· π interactions or mixtures of these.[9,19] The networks created from the tectons come in many forms such as one-dimensional rods, ladders and tubes,[20] two-dimensional grids, sheets or honeycombs,[9] three-dimensional diamondoid (tetrahedral centers),[12,17,21,22] or simple cubic lattices (octahedral centers).[23−25] The coordination networks offer some attractive properties which include modularity (i.e. the availability of a large number of identical sites), regioselectivity, stereoselectivity, shape selectivity, and exact information on the nature of binding (i.e. position in the crystal lattice), as opposed to absorption or adsorption on the surface.[26] Although crystal engineers try to control the properties of the crystal,[27] the majority of crystallizations lead to unexpected results, such as the formation of two different structures from one crystallization method,[8] or the formation of different MOFs from the *cis*- and *trans*-isomers of a ligand.[28]

We have previously studied the interpenetrating 3D MOFs formed by TINM and the first row transition metal cations, copper, nickel and cobalt.[29] This work deals with metallo-organic complexes that form architectures with fewer dimensions than the MOFs studied in our previous work. Despite some examples of tetradentate ligands used in the synthesis of one- or two-dimensional structures, most of the structures are synthesized from bidentate ligands, such as 4,4′-bipyridine, or tridentate ligands.[17,23,30−32] This is partly due to ease with which the starting materials for the bidentate MOFs are synthesized, and the fact that the tetrahedral conformation typical of tetradentate MOFs tend to lead to 3D networks.[29,33] In this work, we investigate the effect of using the *meta*- (TNM) and *para*-isomers (TINM) of the same ligand with a selection of anions and the first and second row transition metal cations, copper, zinc, and silver. The effects on MOF formation, and on the

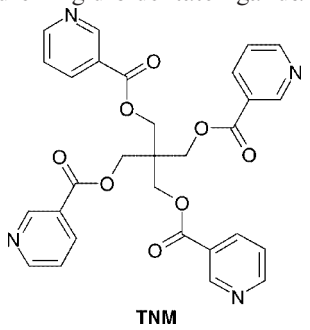
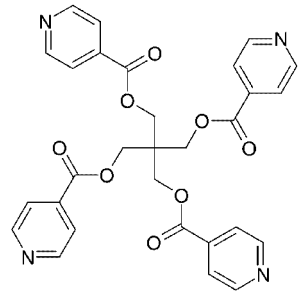
geometry and dimensions of the formed frameworks were investigated. The use of flexible organic ligands adds an element of freedom to the coordination geometry of the metal atoms. Therefore, one would expect a deviation from the structures based on rigid bidentate ligands.



TNM



TINM

Results and Discussion

Synthesis: X-ray quality crystalline solids of complexes **1**−**4** were obtained by evaporation of the solvents. All combinations of the ligands, TNM and TINM, and the metal salts, copper diacetate, copper- and silver nitrate, zinc, cobalt, and nickel chloride, and copper sulfate, and the solvents and solvents mixtures, MeOH, MeCN, CH_2Cl_2, and H_2O, were tried. Almost all the complexation attempts produced fine microcrystalline precipitates. Complexes **1**−**4** were the only single crystalline solids that could be collected. The structures were further confirmed using elemental analysis and TGA. Since complexes **1**−**4** only exist as solid crystalline material, no NMR measurements were performed.

X-ray Single Crystal Structures

The crystal data for complexes **1**−**4** are presented in the Table 1. No unusual metal coordination angles or bond lengths were found in the structures.

Layer Structure 1: The asymmetric unit of **1** consists of half a molecule of TNM, with skewed tetrahedral coordination of the arms, one copper cation, one coordinated disordered sulfate anion, five water molecules, and one methanol molecule. A model to describe the sulfate disorder was built by splitting the sulfate molecule into two positionsr. Two water molecule halves were located in special positions, two were disordered to two and three positions, respectively.

[a] The hydrogens could not be located for all the water and methanol molecules.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Hydrogen atoms could not be located for the disordered water molecules. The TNM ligand is coordinated by the copper cations through the four aromatic nitrogen atoms. The coordination geometry around the copper atom is octahedral.

A schematic presentation of the ligand and its surroundings in complex **1** is displayed in Scheme 1. The 2D MOF of **1** is a grid that is puckered so that the equatorial copper coordination planes are placed both on top and bottom of the layer that is formed. The TNM ligands form the inside of the layer. The equatorial coordination bonds of the copper atoms are coplanar with the layer. Therefore, all the arms of TNM are directed towards center of the layer (Figure 1). The puckering arises as a result of the *meta*-position of the nitrogen atom of TNM and the relatively large size of the sulfate anion. The puckered structure results in the formation of open channels on top and bottom of the layers. The channels are filled by water molecules and occupied by sulfate anions from the neighboring layer (Figure 2).

In our previous work we synthesized two complexes of TINM with copper nitrate.[29] Both of these complexes are two-fold interpenetrating 3D MOF structures with channels formed by cavities that contain nitrate anions and solvent water molecules. The "effective" length (distance between central carbon atom and the coordinating nitrogen atom) of the TINM ligand is longer than that of the TNM ligand. The nitrate anion is also smaller than the sulfate anion. In addition, with the nitrogen atom in the *meta*-position of TNM, the arms of the ligand cannot be straightened so as to satisfy the square-planar coordination geometry around the copper cation. Due to the distorted tetrahedral conformation of the arms, combined with the *meta*-position of the aromatic nitrogen atom, complex **1** forms a pseudo 3D MOF that does not elongate infinitely in all dimensions, but instead creates thick layers perpendicular to the crystallographic *b*-axis. Therefore, it is not a true 3D MOF in this respect. However, its third dimension is in the nanoscale range: the thickness of the layers is 2.1 nm.

In order to provide enough space for the sulfate anion, the structural components of **1** should create a non-interpenetrating MOF rather than the two-fold interpenetrating MOF previously observed with $Cu(NO_3)_2$ and TINM.[29] However, the difference in the size of the anions is probably not enough to allow for the formation of a stable non-interpenetrating MOF: the sulfate anions are not large enough to support the formation of a framework that would not collapse without a second interpenetrating framework. We have performed molecular modeling, the results of which support this hypothesis. The channels contain water molecules with hydrogen atoms pointed towards the highly negative electron potential of the sulfate anions. The negative electron potential of the sulfate anion requires too much space for the 3D network to be formed. All attempts to crystallize a 3D MOF from TNM and a metal cation with octahedral coordination (Cu, Ni, Co) failed, thereby also supporting the spatial and conformational requirements of the TNM ligand.

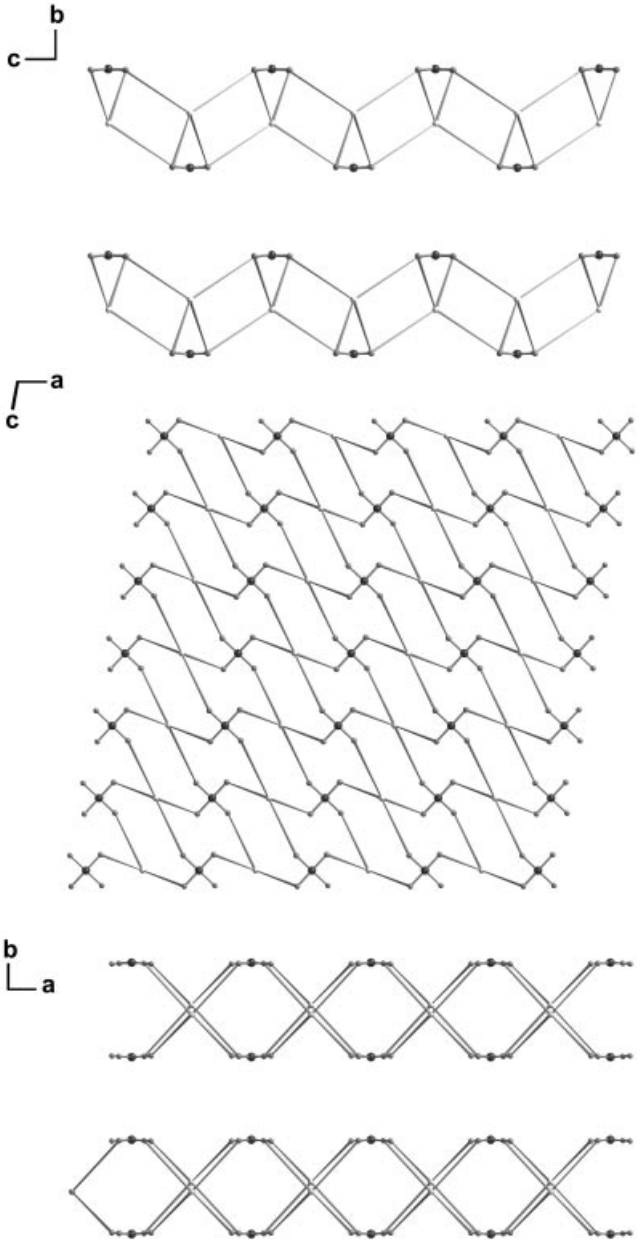

Figure 1. A view of the ball-and-stick model of two layers of **1** along the crystallographic unit cell axes *a, b*, and *c*. Only the central carbon atoms, terminal nitrogen atoms of TNM, the copper atoms, and the bonds between them are shown. The separation between the two layers is 3.5 Å

Strand Structure 2: The asymmetric unit of **2** consists of a Zn atom, half a molecule of TNM coordinated by it, two chloride anions coordinated by the zinc atom, a water molecule, and an acetonitrile molecule. The water molecule is situated in a special position and was located with a population parameter 1/2 and a site occupancy of 1/3. The terminal carbon atom of the acetonitrile molecule is also in a special position. The acetonitrile was located with a population parameter 1/2 (besides the terminal carbon atom for which a population parameter 1/2 and a site occupancy of 1/3 were applied). The solvent molecules are located inside

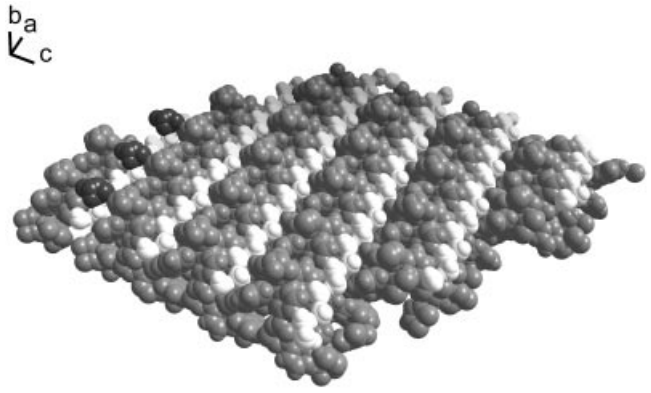

Figure 2. A perspective view of the space-filling model of a square section of the layer in **1**. The oxygen atoms of the water molecules are shown. The sulfate anions of the neighboring layer are displayed on top of the leftmost channel

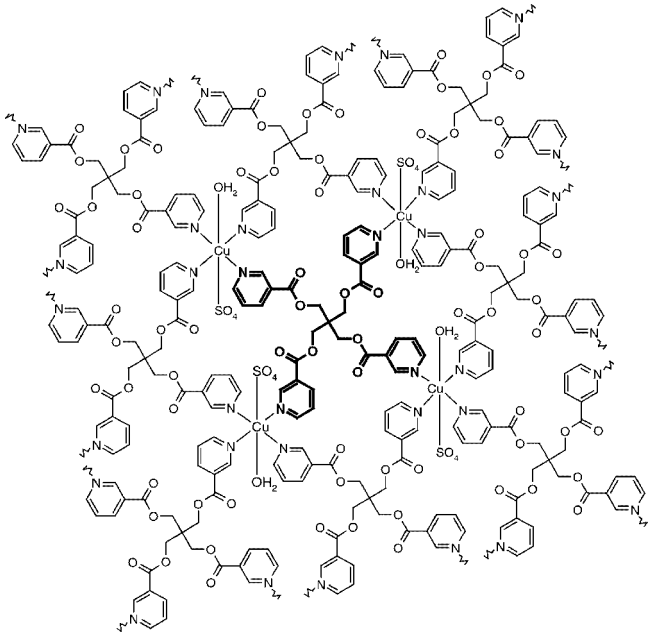
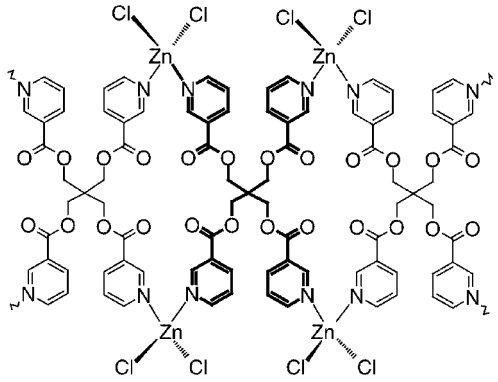


Scheme 1. A schematic representation of the layer network of **1**, with the central ligand shown in bold font

the cavity formed by the links of the chains. The coordination geometry around the zinc atom is tetrahedral.

A schematic representation of a polymeric unit of **2** is presented in Scheme 2. Due to the trigonal symmetry of the structure, each layer of stacked chains forms a 60° angle with those above and below it. The layers are formed perpendicular to the crystallographic *c*-axis (Figure 3).

The formation of a 3D MOF is prevented by two factors: the zinc cation has only two available coordination sites from its tetrahedral coordination sphere for the TNM ligand, and the arms of TNM are paired, i.e. their orientation is not tetrahedral. Therefore, the polymeric structure only grows in one dimension and there are no coordination bonds between individual chains (Scheme 2). Additionally, the chloride anion is not able to act as a bridging anion between two adjacent Cu centers, unlike the acetate or nitrate anions. The planar, cross-like conformation of the ligand arms could create a 2D MOF, with four ligands forming one large square in the grid. This type of structure would probably need to be interpenetrated so as to stabilize the framework. However, only the strand structure **2** could be obtained from the complexation experiments. A probable explanation for not obtaining the 2D layer MOF is the high complementarity requirements of interpenetrating frameworks in the solid state. In our experiments, interpenetration was not observed in the single crystals that were obtained.



Scheme 2. A schematic representation of **2**, with the central ligand shown in bold font

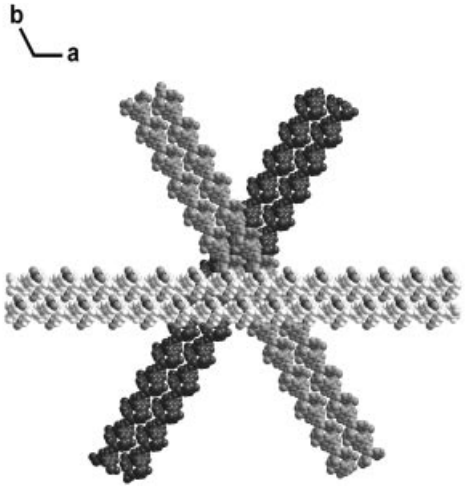


Figure 3. Two chains from each of the three layers with a unique orientation in complex **2** (the planes of the layers are in the plane of the paper). The orientation of the fourth layer is identical to that of the first layer. The chain pairs are displayed with the color intensity increasing along the *c*-axis. The solvent molecules are excluded

Layer Structure 3: The asymmetric unit of **3** consists of a non-tetrahedral TINM ligand that is coordinated to four silver cations, two of which belong to the asymmetric unit. There are also two nitrate anions and one water molecule that are coordinated to the silver cations. A plot with thermal ellipsoids of structure **3** is presented in Figure 4. The linear conformation of TINM is stabilized by π···π interactions between the pyridine rings C36−C41 and C26−C31 (separation between the centroids of the rings is 3.89 Å), as well as CH···π interactions between the remaining two arms [d = 2.72 Å for C17−H17··· centroid (C6−C11)]. The π···π

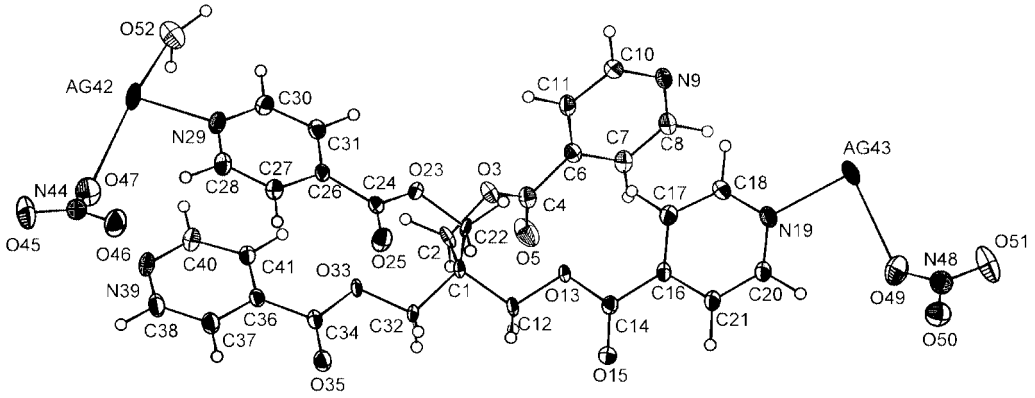

Figure 4. A plot with thermal ellipsoids shown at the 50% probability level for **3**. The non-hydrogen atoms of the asymmetric unit are numbered

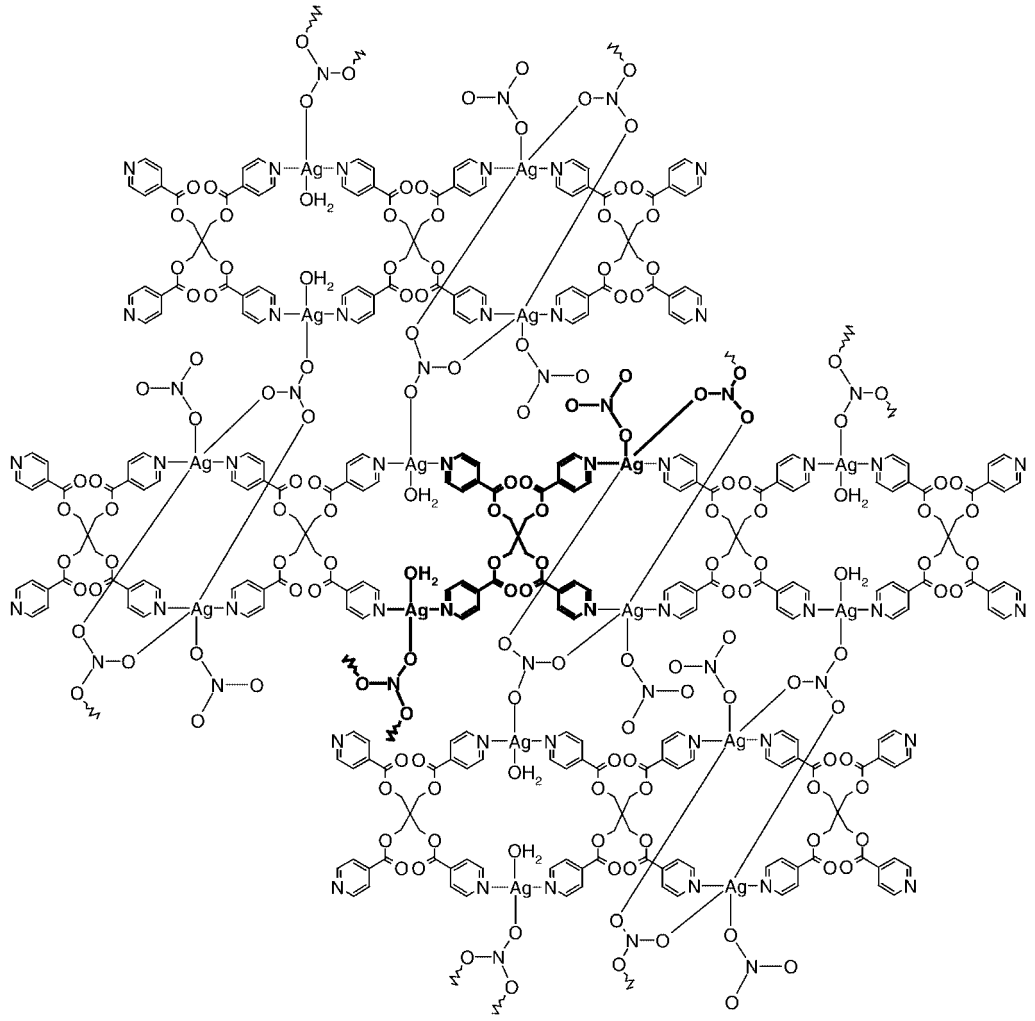
interactions between the aromatic rings are attractive forces that bring the Ag^+ cations closer (within a distance of 4.07 Å from each other).

A schematic representation of the structure of **3** is displayed in Scheme 3. The neighboring chains provide additional nitrate anions for coordination by the Ag^+ cations. This coordination creates additional connections in another direction of the lattice, thus forming a link between the chains of **3**, and leading to the formation of 2D layers (Figure 5) with a thickness of 13.2 Å. One silver cation (Ag42) exhibits a distorted square-planar coordination geometry, while the other (Ag43) exhibits a square-pyramidal ge-



Scheme 3. A schematic representation of the structure of **3**. The central asymmetric unit is shown in bold font. The chains run in a horizontal direction

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

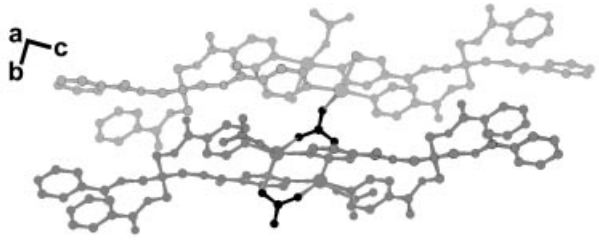


Figure 5. The links between the chains of **3**. Four TINM ligands and silver cations are shown. The different chains are shown in light and medium gray. For clarity, the bridging nitrate anions are shown in black ink and the hydrogen atoms are omitted

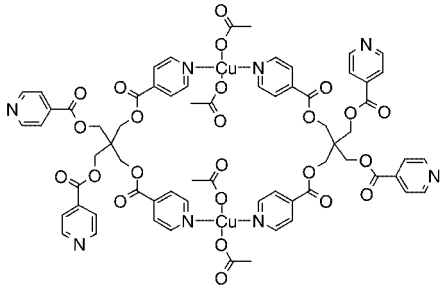
ometry. The two symmetry equivalent Ag43 cations are bridged by two nitrate anions (N44−O47 and its symmetry equivalent). They are also bridged to the neighboring chain Ag42 cations by the same nitrate anions, through the remaining oxygen atom of the nitrate anions. The other nitrate anion coordinated to the Ag43 cation does not form a bridge.

With the planar, cross-like conformation of the ligand arms, a 2D grid-like MOF could hypothetically be created by N−Ag bonds alone (see discussion of complex **2**). Anion coordination between layers could extend this structure into a 3D MOF, assuming that the anions would be suitably positioned. However, neither of these structures are observed. As with complex **2,** the probable explanation for not obtaining the 2D MOF is the high complementarity requirements of the interpenetrating frameworks. These requirements were not met by any quantitative combination of the TINM ligand and silver nitrate, since the layer structure **3** was the only single crystalline material that could be obtained. Since the arms of the TINM are paired, thereby providing an extension of the structure only in one dimension, the structure remains as a stack of anion-bridged 2D layers.

The three bond lengths involving the bridging nitrate anion are both shorter [Ag43−O46: 2.608(1) Å] and longer [Ag42−O47: 2.797(3) Å and Ag43−O45: 3.025(2) Å] than the bond length of the singly coordinated nitrate anion [Ag43−O49 of 2.651(1) Å]. The layers of **3** stack along the crystallographic *a*-axis, forming a dense lattice with no voids.

Dimeric Structure 4: Each asymmetric unit of **4** contains one Cu atom, one TINM ligand coordinated by the copper atom, two coordinated acetate anions and four water molecules. The four water molecules are hydrogen-bonded to the carbonyl oxygen atoms of the acetate anions or to those of the TINM core, except one, which is hydrogen-bonded to one of the water molecules. The coordination geometry around the copper atom is square-planar (Figure 6). The formation of dimers and the π···π interactions between the pyridine rings (3.66 Å between the centroids) of parallel arms (as in **3**) brings the copper cations to within 3.43 Å of each other. A schematic representation of the structure of **4** is displayed in Scheme 4.



Scheme 4. A schematic representation of **4**

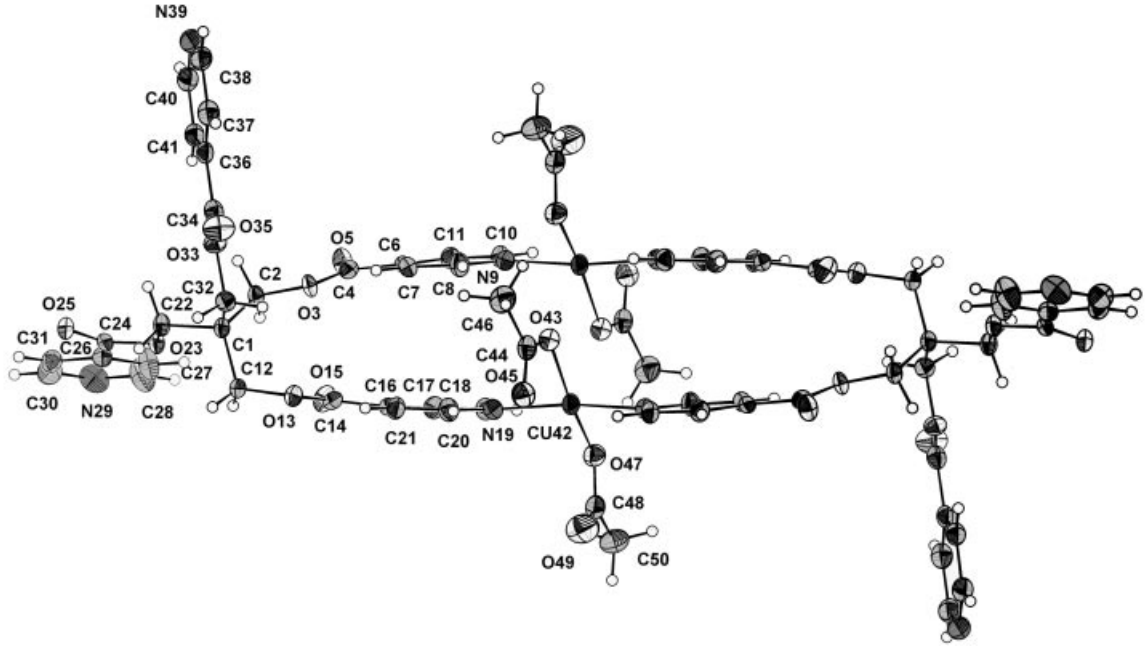


Figure 6. A plot with thermal ellipsoids shown at the 50% probability level for **4**, with the numbering of the non-hydrogen atoms of the asymmetric unit. The solvent water molecules are excluded

Several hydrogen bonds and other weak interactions such as CH···π and π···π interactions are involved in the packing of **4**. Despite the available coordinating sites of the terminal nitrogen atoms, only two arms of each TINM are coordinated. Although the use of copper acetate instead of copper nitrate is the only difference between the synthesis of the 3D MOF in our previous work[29] and the synthesis of **4**, a dimeric rather than a polymeric complex is obtained. A 3D MOF is not formed because the coordination geometry around the copper cation is square-planar. Despite the availability of nitrogen atoms for coordination, the complex remains a dimer, and does not form chains as in structures **2** and **3**. The multiple weak intermolecular interactions between the uncomplexed pyridyl moieties of the dimers could possibly be the reason for the lack of strand or layer formation. A strong hydrogen-bond is formed between the uncoordinated nitrogen atom N29 and a water molecule (DH···A: 2.017Å, D−H−A: 171.3°). The other uncoordinated nitrogen atom N39 is blocked since it intertwines with the ends of neighboring molecules (Figure 7).

The completely different architectures of the layer structure of **3** and the dimeric structure of **4** can be explained by the greater bridging ability of the nitrate anion relative to that of the acetate anion. Since the nitrate anions in the previously reported structures do not participate significantly in the formation of the framework,[29] the difference between these 3D MOF structures and **4** is probably due to polymorphism, rather than differences between the acetate and nitrate anions.

TGA Studies: As expected, the TGA studies do not show the removal of solvents before high temperatures were reached. In complex **1**, a weight loss of 15% is observed before decomposition at 280 °C. This approximately corresponds to the eight uncoordinated water molecules in the lattice (Figure 8). The TGA curve of **2** reveals stepwise decomposition of the structure beginning at 260 °C, and for complex **3**, at 280 °C. In complex **3**, the only solvent molecule is coordinated by the silver cation, thus its removal

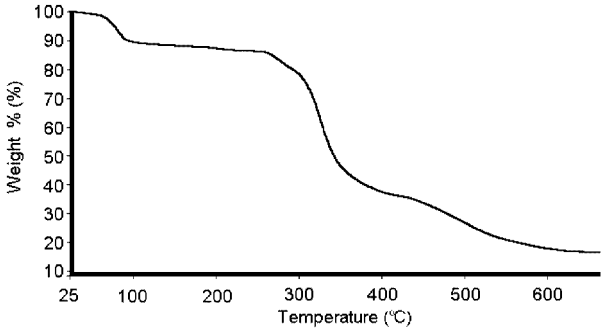

Figure 8. The TGA curve for **1**

results in the rapid collapse of the structure. In the TGA analysis of **4**, no intermediate products are seen. The decomposition occurs in one step, in contrast with the TGA results of the MOFs **1**, **2** and **3**, all of which display stepwise thermal decomposition.

Conclusions

The pseudo 3D MOF structure **1** is in fact a 2D MOF since it does not have an infinite third dimension. The thickness of the layers in **1** is 2.1 nm. In spite of the octahedral coordination geometry around the copper cations and the skewed tetrahedral conformation of the pyridyl moieties of TNM, a 3D MOF is not formed. This is because the branching from the metal center is directed only towards the center of the layer from the metal centers on both the top and bottom of the layer. This is probably due to the lack of space for the sulfate anion. The relatively short arms of TNM, and the large size and long bond length of the sulfate anion relative to the anions used in the synthesis of the 3D MOFs with copper and TNM/TINM ligands in our previous study, prevent the formation of a 3D MOF with suitable cavities for the sulfate anions.[29] Ad-

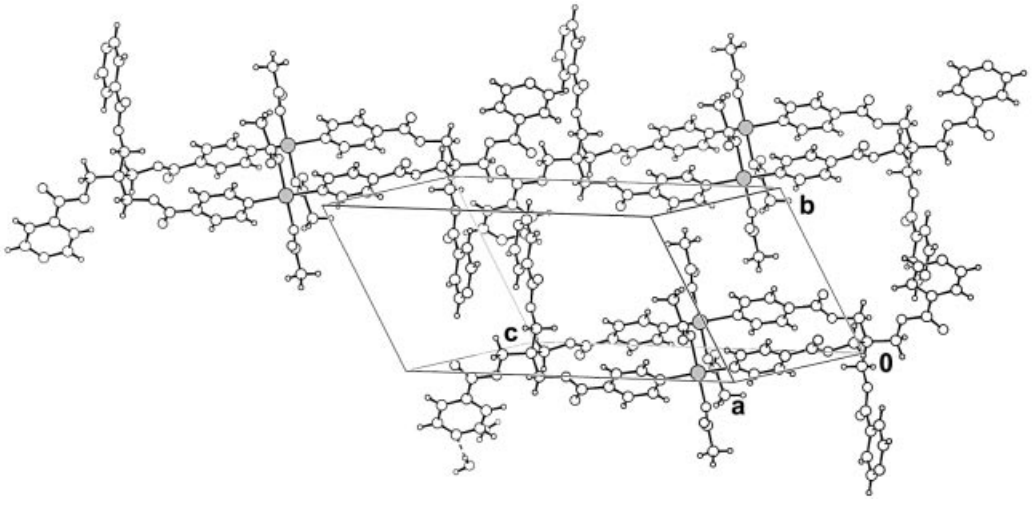

Figure 7. Three dimers of **4** showing the unit cell and the hydrogen-bond between water and N29

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ditionally, due to the *meta*-position of the nitrogen atom, the TNM ligands are incapable of aligning in a co-planar manner to the equatorial metal coordination plane, and therefore are unable to assume a conformation similar to that of the ligands in the 3D MOFs in our previous study.

Structure **2**, a polymeric complex of zinc chloride and TNM, is composed of infinite, flat, linear chains of TINM ligands linked by zinc cations. Despite the potential ability of **2** and **3** to form 2D layers through metal−nitrogen bonds alone, only 1D chain structures are obtained from these interactions. The formation of 3D MOFs is prevented because the zinc cation in **2** has only two coordination sites for the ligand, and the pyridyl moieties of the TNM are paired, i.e. they are not tetrahedrally oriented. In contrast with the nitrate anions in **3**, the chloride anion in **2** is incapable of promoting layer formation by creating links between individual chains. The layers of chains in **2** are tightly packed, and each layer of chains forms a 60° angle with its neighbors. A probable explanation for not obtaining 2D layers (besides those created by the anion bridging in **3**) is the low packing efficiency of these grid structures. The high complementarity requirements for interpenetrating frameworks may not be fulfilled.

The π···π interactions between the pyridyl rings of adjacent arms are probably the driving force for the formation of the structure **3**. A polymeric chain of the TINM ligands, with paired pyridyl moieties coordinated by the silver cations in one dimension is formed. However, by coordinating three silver cations, the nitrate anions create a link between the chains, and thereby form a 2D layer structure with a thickness of 13.2 Å. The cyclic dimeric metal complex formed between TINM and copper acetate, structure **4,** provides interesting possibilities for heterometallic complexation. This is because the remaining, uncomplexed four arms of the dimer are available for further coordination. The completely different architecture of **4** with respect to previous structures[29] with the nitrate anion instead of the acetate anion probably arises as a result of polymorphism.

Experimental Section

Materials and Measurements: All commercially available chemicals were of reagent grade and used as received without further purification. TINM and TNM were synthesized as previously reported.[34] The purity of the complexes was confirmed by elemental analysis. TGA experiments were carried out at a heating rate of 5 °C/min under nitrogen using a Perkin−Elmer TGA 7 instrument. The elemental analyses were performed at the University of Joensuu using CE-Instruments EA1110. The elemental analyses revealed a loss of solvent for structure **1**, and some solvent residuals for **2** and **4**, thus giving inaccurate results for the chemical compositions. Therefore, only the results for the elemental analyses of **1** and **3** are presented. The complexes were not vacuum dried before elemental analysis, so as to avoid decomposition.

Preparation of the Complexes $[Cu(TNM)(SO_4)(H_2O)_2]\cdot(MeOH)_2(H_2O)_8$ (1): $CuSO_4\cdot 5H_2O$ (22.4 mg, 89.8 μmol) in water (10 mL) was added to TINM (50 mg, 89.8 μmol) dissolved in MeOH (30 mL). The solution was evaporated slowly, and the crystalline solid was collected from the solution before complete evaporation of the solvents. The solid was washed with water and dried in air. Yield 54.6% (46.7 mg). $C_{31}H_{44}Cu_1N_4O_{24}S_1$ − ($8H_2O$ + 2MeOH), $[Cu(TNM)(SO_4)(H_2O)_2]$: calcd. C 46.3, H 3.8, N 7.5; found C 46.2, H 3.6, N 7.5.

$[Zn_2(TNM)Cl_4](MeCN)_{2/3}(H_2O)_{1/3}$ (2): $ZnCl_2$ (24.5 mg, 89.8 μmol) in water (10 mL) was added to TNM (50 mg, 89.8 μmol) dissolved in MeCN (35 mL). The solution was evaporated slowly, and the crystalline solid was collected from the solution before complete evaporation of the solvents. The solid was washed with water and dried in air. Yield 100% (76.8 mg).

$[Ag_2(TINM)(NO_3)_2(H_2O)]$ (3): $AgNO_3$ (30.5 mg, 89.8 μmol) in water (10 mL) was added to TINM (50 mg, 89.8 μmol) dissolved in MeCN (30 mL). The solution was evaporated slowly, and the crystalline solid was collected from the solution before complete evaporation of the solvents. The solid was washed with water and dried in air. Yield 100% (82.1 mg). $C_{29}H_{26}Ag_2N_6O_{15}$: calcd. C 38.1, H 2.9, N 9.2; found: C 38.9, H 2.9, N 9.2.

$[Cu(TINM)(O_2CCH_3)_2](H_2O)_4$ (4): $Cu(O_2CCH_3)_2\cdot 3H_2O$ (16.3 mg, 89.8 μmol) in water (5 mL) was added to TINM (50 mg, 89.8 μmol) dissolved in MeOH (30 mL). The solution was evaporated slowly, and the blue crystalline solid was collected from the solution before complete evaporation of the solvents. The solid was dried in air. Yield 20.7% (15.1 mg).

X-ray Diffraction: The single crystal X-ray diffraction was performed using a Nonius−KappaCCD diffractometer with graphite-monochromatized Mo-K_α (λ = 0.71073 Å) radiation. Collect software was used for the measurement and DENZO-SMN[35] for the processing of the data. The structures were solved and refined by full-matrix least-squares on F^2 using the WinGX-software package which utilizes the SHELXS-97 and SHELXL-97 modules.[36−38] Hydrogen atoms were refined using a riding model. Empirical absorption correction was performed for complexes **1**, **2**, and **3**. The graphic presentations of the structures were created with the software package Diamond.[39] CCDC-206599, -206600, -206601 and -206602 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge on applicaton to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223- 336-033; E-mail: deposit@ccdc.cam.ac.uk.

C−H Activation by AlCl Monomers: Characterization of $HAl(Cl)CH_3$ as the Product of the Photoactivated Reaction Between AlCl and CH_4 in a Solid Ar Matrix at 12 K

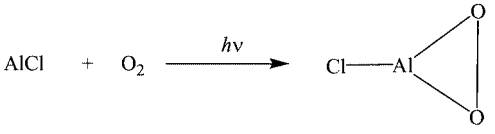
Hans-Jörg Himmel*[a]

Keywords: Aluminum / Hydrides / Matrix isolation / C−H activation / Reaction mechanisms / Photochemistry

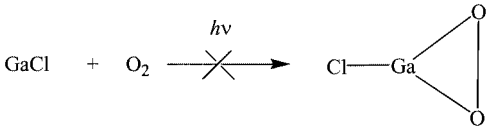
In a solid Ar matrix at 12 K and upon photoactivation AlCl inserts into the C–H bond of CH_4 to give the new monomeric aluminium hydride $HAl(Cl)CH_3$, which was identified and characterized with the aid of the IR spectra recorded for several isotopomers [$Cl(H)Al^{12}CH_3$, $Cl(D)Al^{12}CD_3$, and $Cl(H)Al^{13}CH_3$], comparison with the known IR properties of related molecules and detailed quantum chemical calculations. Calculations yield a C_s symmetric global energy minimum structure for this compound, and that the reaction is slightly exothermic (reaction energy of –43.2 kJ·mol^{-1}). This work demonstrates impressively how reactive photoactivated AlCl molecules are.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Subvalent compounds of the general formula MX [M = Al, Ga or In, and X = F, Cl, I, or a cyclopentadienyl (Cp) derivative] react readily, when photoactivated, with a number of molecules.[1] Examples include the reaction of AlCl with H_2 to give H_2AlCl,[2] with O atoms to give OAlCl,[3] with O_2 to give $ClAlO_2$ [4] or, when the concentration of O_2 is increased, $ClAl(O_2)_2$,[5] and with HX (X = F, Cl or Br) to give HAl(Cl)X.[6,7] With GaCl[8] and InCl,[9] reactions with H_2 and with HCl afford the hydrides H_2MCl and $HMCl_2$ (M = Ga or In), respectively. GaF reacts with O atoms to give OGaF.[10] Finally, matrix-isolated AlCp* reacts with H_2 upon photoactivation to yield H_2AlCp^*.[11] Although these species are generally highly reactive, there are some remarkable differences between AlX, GaX and InX with respect to their reactivities and the structures and composition of the end-products. Whereas AlCl reacts, as already mentioned, upon photoactivation with O_2 [Equation (1)], GaCl or InCl show no matrix reaction, photoactivated or not, with O_2 [Equation (2)].[12]



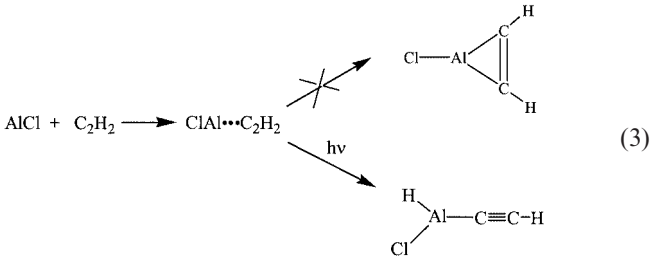
(1)



(2)

Some of the differences can be explained by an "inert-pair" effect. The strength of the bonds in the lighter homologues is usually higher than in their heavier counterparts and can thus more easily compensate the loss of one binding interaction in the reactant. In other cases it might be of some importance that Al prefers a higher coordination number than Ga. For example, a bis(superoxo) complex, $[XM(O_2)_2]$, can be formed for M = Al, but not for M = Ga.

To study in more depth the reactions with small model hydrocarbons we have looked at the reaction with C_2H_2 leading to the acetylide species HAl(Cl)CCH. Interestingly, the cyclic alumina-cyclopropene derivative [see Equation (3)] is not formed.[13] That comparatively small modifications of the reactants can lead to different products is shown by comparing the reaction between AlCl and HCCH with that between AlCl and H_3CCCCH_3. Photoactivated AlCl reacts with 2-butyne to give two products, one of them being the alumina-cyclopropene derivative.[13] Thus, the replacement of the hydrogen atoms in C_2H_2 by methyl groups alters the structures (cyclic vs. acetylide form) of the reaction products.



(3)

We are also currently studying the reaction of AlCl with CpH (C_5H_6).[14] The reaction of AlCp* with H_2 gives H_2AlCp^*, in which the C_5 ring is coordinated in η^5-fashion

[a] Institut für Anorganische Chemie, Universität Karlsruhe
Engesserstr., Geb 30.45, 76128 Karlsruhe
Fax: (internat.) +49-(0)721-608-4854
E-mail: himmel@chemie.uni-karlsruhe.de

to the Al center.[11] Theoretical studies and a series of experimental results obtained with suitable derivatives suggest that the energy differences between η^5-, η^3-, η^2- and η^1-coordination for $CpAlH_2$ are very small ($<$ 13 kJ·mol^{-1}).[15] The coordination mode of the Cp ring in HAl(Cl)Cp, the likely product of the reaction between AlCl and CpH, is therefore difficult to predict. It should, though, be easy to distinguish between these forms on the basis of the matrix IR spectra.

Here it will be shown that matrix-isolated AlCl inserts on photoactivation into the C−H bond of CH_4 to give the new species $Cl(H)AlCH_3$. This reaction shows impressively how reactive photoactivated AlCl molecules are. Such C−H activation mechanisms are important in catalytic processes.

Results

The IR spectrum taken upon deposition of AlCl together with 2% CH_4 in an Ar matrix showed strong absorptions due to CH_4 and AlCl. However, there are no bands due to a reaction product. The matrix was therefore exposed for a period of 10 min to broad-band UV/Visible radiation ($200 < \lambda < 800$ nm). Several new bands in the spectrum recorded after the photolysis period indicate that the photoactivated AlCl molecules readily react with CH_4. The difference between a spectrum taken after and before photolysis is shown in Figure 1, a. A family of bands appears at 3015.2, 2998.1, 2984.4, 1905.2, 1199.7, 743.7, 672.8, 657.7, 604.4, 488.1/482.8, and 421.4 cm^{-1}. With different concentrations of CH_4 and AlCl in the matrix the relative intensities of these bands remain unchanged, indicating that they all belong to the same absorber. The strongest band is at 1905.2 cm^{-1}, a region characteristic of the ν(Al−H) stretching fundamentals of Al^{III} compounds [cf. AlH_3 1882.9,[16] H_2AlNH_2 1899.3,[17,18] H_2AlPH 1874.7/1866.1,[19] $HAlCl_2$ 1967.6,[6] H_2AlCl 1928.1/1915.9,[2] HAl(Cl)CCH 1952.2 cm^{-1} [13]]. Strong, but somewhat broader, features are at 743.7, 672.8 and 657.7 cm^{-1} (the second one being a shoulder of the more intense band at 657.7 cm^{-1}). The band at 743.7 cm^{-1} occurs in the region of the ρ(CH_3) rocking mode of a methyl group (cf. $HGaCH_3$ 752.9,[20] $HBeCH_3$ 704.1 cm^{-1} [21]). The bands at 3015.2, 2998.1 and 2984.4 cm^{-1} qualify for ν(C−H) stretching vibrations.

A weak additional feature at 1965.7 cm^{-1}, which grew in on photolysis, can be assigned to the ν(Al−H) stretching fundamental of HAl(Cl)OH.[13] This species is formed from reaction of AlCl with H_2O that is present as a trace impurity. Additionally, a sharp relatively intense band appeared at 769.9 cm^{-1} and very weak ones at 1928.1, 1915.9, 604.9, 549.9, and 518.6 cm^{-1}. These were previously assigned to H_2AlCl,[2] representing the product of the photoactivated reaction between AlCl and H_2. Traces of H_2 in the matrix are a consequence of the generation of AlCl in the oven, from reaction between liquid Al and HCl at ca. 1000 °C to give AlCl and H_2. Finally, some experiments revealed very small amounts of $HAlCl_2$ in the matrix, arising from traces of HCl in the matrix (HCl that has not reacted with the liquid Al in the oven).[6] These bands were, however, extremely weak.

The experiment was repeated with CD_4 in place of CH_4. Again, no reaction product was evident from the spectrum recorded immediately after deposition. However, photolysis furnished a family of new bands at 2212.0, 1386.1, 947.1, 630.1, 569.0, 518.4, 471.7, 435.4/430.6, and 308.1 cm^{-1} (Figure 2). All the features were red-shifted with respect to their counterparts with CH_4. The strongest band in the spectrum is at 1386.1 cm^{-1}, which can confidently be attributed to a ν(Al−D) stretching fundamental, experienced a marked shift, corresponding to a ν(H):ν(D) ratio of 1.3745:1. The absorptions at 743.7, 672.8 and 657.7 cm^{-1} in the experiments with $^{12}CH_4$ now occurred at 630.1, 518.4 and 569.0 cm^{-1}, respectively. A band at 2212.0 cm^{-1} appeared in a region characteristic of ν(C−D) stretching fundamentals.

Finally, in experiments conducted with $^{13}CH_4$, as with CH_4 and CD_4, no absorption due to any product of a thermal reaction between AlCl and $^{13}CH_4$ appeared in the IR spectrum recorded immediately after deposition. Photolysis

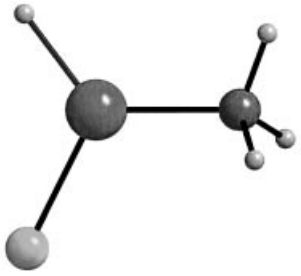
was needed to initiate a reaction. Figure 3 shows the difference between the IR spectrum taken after photolysis and the one taken before photolysis. In its ^{13}C version, the product of the reaction between AlCl and methane is the author of bands at 3003.9, 2972.6, 2951.9, 1905.2, 1375.5, 1191.0, 739.9, 667.2, 652.7, 604.7, 486.5, and 421.1 cm^{-1}.

Discussion

The experimental results clearly show that AlCl reacts with CH_4 upon photoactivation to give a single reaction product.[22] The detection of a ν(Al−H) stretching fundamental and its location indicate that this product contains a terminal Al−H bond; it also shows all the hallmarks of a species featuring a methyl (CH_3) group. Finally, the band at 482.0 cm^{-1} indicates a terminal Al−Cl bond. The obvious inference is that photoactivated AlCl inserts into one of the C−H bonds of CH_4 to give the new monomeric Al hydride species $HAl(Cl)CH_3$.

Quantum chemical calculations on the possible structure of such a product suggest that $HAl(Cl)CH_3$ exhibits a C_s symmetric global energy minimum structure characterized by the bond lengths (in pm) Al−Cl 212.7, Al−H 160.1, C−H 111.2/111.4, Al−C 195.5. The H−Al−Cl, Cl−Al−C and H−Al−C bond angles are 115.8°, 118.5° and 125.7°, respectively. Thus, in agreement with the predictions of VSEPR theory,[23] the smallest angle at the Al center is for H−Al−Cl.



At 195.5 pm, the Al−C bond length is in pleasing agreement with those measured for several compounds containing Al−C bonds. Thus, on the basis of gas-phase electron diffraction studies, the Al−C distance in monomeric $Al(CH_3)_3$ was determined to be 195.7(3) pm.[24] In $(Me_2AlNC_6H_{12})_2$, an example for Al with a coordination number of 4, Al−C bond lengths of 196.3(4) and 198.0(6) pm are adopted according to an X-ray diffraction analysis.[25] One further example is the compound $[(tmpCO_2)_2AlMe]_2$, which features an Al atom with a coordination number of 5 and an Al−C distance of 195.2(4) pm.[26] In general, the Al−C bond lengths cover a large range (189.7 to 236.6 pm) with an average of 198.3 pm according to the Cambridge Structural Database.[27] However, these statistics include compounds with different coordination numbers. Some structurally characterized monomeric alanes containing terminal Al−H bonds are now known. The Al−H bond length (r_0 value) in $(Ar^*)_2AlH$ [Ar* = (*tert*-butyl)$_3C_6H_2$] is 153(4) pm,[28] whereas in $Mes^*Al(H)N(SiMe_3)_2$ an Al−H distance of 151(3) pm was found by X-ray diffraction.[29] However, X-ray measurements give, at best, estimates significantly different from r_e. For AlH_3, an Al−H bond length (r_e value) of 157.1−159.7 was calculated, depending on the applied theoretical method.[16,30] These values compare satisfactorily with the r_e of 160.1 pm calculated for $HAl(Cl)CH_3$. The Al−H bond lengths in general cover a large range, adopting values as low as ca. 125 pm and up to more than 180 pm.[31] Finally, electron diffraction measurements yielded an Al−Cl distance of 206.2(3) pm in monomeric $AlCl_3$ (which is in equilibrium with its dimer in the gas-phase at 400 °C),[32] which is reasonably close to that calculated for $HAl(Cl)CH_3$ (212.7 pm). Thus the dimensions derived for $HAl(Cl)CH_3$ from quantum chemical calculations are wholly reasonable.

Table 1 compares the experimentally observed wavenumbers with those forecast by the DFT calculations, and also includes an attempt to describe the molecular motions of the modes. Obviously any such attempt is limited by the degree of mode coupling in this rather unsymmetrical molecule (C_s symmetry). The ν(C−H) stretching region showed a sharp band at 3015.2 cm^{-1}, red-shifted from the ν(C−H) stretching mode of CH_4, which can be assigned to one of the antisymmetric ν(C−H) stretching modes, namely $\nu_1(a')$. The calculations predict a wavenumber of 3044.4 cm^{-1} for this mode. The calculated shifts upon $^{12}C/^{13}C$ and H/D substitution agree well with the experimental ones (Table 1). Additional weaker bands at 2998.1 and 2984.4 cm^{-1} can be assigned to the second antisymmetric and the symmetric ν(C−H) stretching fundamental, $\nu_{11}(a'')$ and $\nu_2(a')$, respectively. Again, the calculated wavenumbers of 3026.5 and 2944.0 cm^{-1} pleasingly match the experimental ones.

As already mentioned, the wavenumber of the ν(Al−H) stretching mode comes in a region that is characteristic of Al^{III} compounds (ca. 1850−2000 cm^{-1}). The only exception is H_2AlCp^*, for which the antisymmetric and symmetric ν(Al−H) stretching fundamentals were detected at 1801.5 and 1773.7 cm^{-1}, respectively.[11] Such low values can be explained by the back-donation from the Cp* ring

[a] Too weak to be observed. [b] Outside the experimental detection range.

to the Al center which leads to a significant weakening of the Al−H bonds. At 1894.6 cm^{-1}, the calculated wavenumber for the ν(Al−H) mode is in excellent agreement with the experimental one. Calculation and experiment also agree that this mode shows virtually no shift upon $^{12}C/^{13}C$ isotopic substitution. Conversely, H/D substitution strongly affects this mode [calculated and experimental ν(H):ν(D) ratios of 1.3835:1 and 1.3745:1 respectively].

The weak feature at 1199.7 cm^{-1} can be assigned to a mode with a high CH_3 "umbrella" [$\delta_{sym}(CH_3)$] character. Wavenumbers of 1158, 1179, 1147.9 and 1115.3 cm^{-1} have been reported for the $\delta_{sym}(CH_3)$ mode in $LiCH_3$,[33] $BeCH_3$,[21] $GaCH_3$ [20,34] and $InCH_3$,[20,34] respectively. For $Al(CH_3)_3$ and $HGa(CH_3)_2$, isolated in Ar matrices, the "umbrella" mode shows up at 1196[35] and 1202.5 cm^{-1},[36] respectively. The calculations yielded 1196.9 cm^{-1} for this mode in $HAl(Cl)CH_3$. The experimental and calculated ν(H):ν(D) ratios are 1.2667:1 and 1.2707:1, respectively. Unfortunately, with only one exception, the other two $\delta(CH_3)$ deformation fundamentals [$\nu_4(a')$ and $\nu_{12}(a'')$] escaped experimental detection. The only sign of the $\nu_{12}(a'')$ mode was a very weak feature at 1375.5 cm^{-1} in the experiments with $^{13}CH_4$. The calculations predict wavenumbers of 1390.3 and 1386.0 cm^{-1} and very low intensities for these modes.

The 657.7 cm^{-1} band can be assigned to the δ(HAlCl) deformation fundamental. This is close to that measured for the corresponding mode in HAl(Cl)CCH (671.4 cm^{-1}).[13] The calculated value of 651.0 cm^{-1} pleasingly matches the experimental value. As anticipated, the effect of $^{12}C/^{13}C$ substitution is again relatively small. In $Cl(H)Al^{13}CH_3$, the mode appears at 652.7 cm^{-1}, shifted by not more than 5.0 cm^{-1} to lower wavenumbers. Conversely, the large ν(H):ν(D) ratio (observed 1.1559:1 and calculated 1.1580) again indicates substantial H atom motion in this vibration.

The strong band at 672.8 cm^{-1} in the spectra recorded for $^{12}CH_4$ belongs to a mode which can be approximately described as the *out-of-plane* Al−H bending mode, γ. The corresponding mode in H_2AlCl[2] and $HAlCl_2$ [6] occurs at 604.9 and 654 cm^{-1}, respectively. The calculations yielded 675.6 cm^{-1}. This approximate description of this mode is supported by the substantial ν(H):ν(D) ratio (observed 1.2978:1 and calculated 1.2844:1).

The spectra also gave evidence for a band at 604.4 cm^{-1} in the experiments with $^{12}CH_4$ and the corresponding mode should have a high contribution from the ν(Al−C) stretching mode. The value compares with 615.9 cm^{-1} for a mode of HAl(Cl)CCH also with a high contribution from the ν(Al−C) stretching vibration.[13] In the radical $HAlCH_3$, which can be generated by the matrix reaction between Al atoms and CH_4, the ν(Al−C) stretching mode appears at 610 cm^{-1}.[37] In $Al(CH_3)_3$, the ν(Al−C) stretching fundamentals were observed at 691 (e′ mode) and 530 cm^{-1} (a_1' mode) for the molecule in the gas phase.[38] Obviously, this mode couples significantly with other modes of the same symmetry and therefore these wavenumbers cannot be compared directly. The calculations yielded 597.6 cm^{-1}, in close conformity with the experimental value.

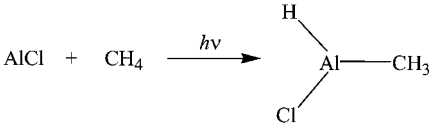
The bands at 488.1/482.8, 486.5 and 435.4/430.6 cm^{-1} in the experiments with $^{12}CH_4$, $^{13}CH_4$ and $^{12}CD_4$ are obvious candidates for modes with a significant degree of ν(Al-Cl) stretching. Modes in related molecules which also exhibit high ν(Al-Cl) stretching mode character have the wavenumbers (in cm^{-1}) H_2AlCl 549.9,[2] $HAlCl_2$ 579,[6] HAl(Cl)CCH 505.8.[13] The small ν(H):ν(D) ratios observed and calculated (1.1210:1 and 1.1010:1, respectively) agree with this assignment. The doublet pattern seen in experiments with $^{12}CH_4$ and $^{12}CD_4$ probably arises from $^{35}Cl/^{37}Cl$ isotopic splitting. The relative intensities of the two components at 488.1 and 482.8 cm^{-1} for $^{12}CH_4$ and at 435.4 and 430.6 cm^{-1} for $^{12}CD_4$ are in good agreement with the relative abundances of ^{35}Cl and ^{37}Cl.

Overall, the comparison of the data measured for the three isotopomers with the properties measured previously for related molecules and the results of quantum chemical

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

calculations affirm that $HAl(Cl)CH_3$ is the product of the photolytically induced matrix reaction between AlCl and CH_4.

AlCl in its ground electronic state is expected to interact only very weakly with CH_4. Quantum chemical calculations suggest, as anticipated, that a complex of the form $ClAl{\cdot}CH_4$ is, if at all, only very weakly bound. The binding energy seems to be even smaller than that calculated for an $Al{\cdot}CH_4$ complex (2.6 kJ·mol^{-1} according to MP2 calculations and a TZVPP basis set, ZPVE corrections included).[39] The effect of photolysis has been discussed previously.[1] The electronic transition in the AlCl molecule is mainly metal atom-centered and leads to the population of a vacant π-orbital that is expected to be ideally suited to interact with a σ* orbital of an E−H bond. As a consequence, the E−H bond is weakened and the Al atom inserts into the bond yielding the $HAl(Cl)CH_3$ end-product.



(4)

The overall reaction [Equation (4)] is slightly exothermic. According to the calculations, the reaction energy amounts to −43.2 kJ·mol^{-1}. The analogous reaction of GaCl with CH_4 to give $HGa(Cl)CH_3$ is, by contrast, *endothermic* and requires, according to DFT calculations, an energy of +32.6 kJ·mol^{-1}. This again shows the differences in reactivity between AlCl and GaCl. The reaction energy calculated for $AlCl/CH_4$ is nevertheless smaller than that calculated for $AlCl/H_2$ (−75.6 kJ·mol^{-1}).[1,2]

Conclusions

Experiments have shown that matrix-isolated and photoactivated AlCl molecules insert readily into a C−H bond of methane to give the new monomeric Al hydride $HAl(Cl)CH_3$. IR spectra of this C_s-symmetric molecule in its $HAl(Cl)^{12}CH_3$, $DAl(Cl)^{12}CD_3$ and $HAl(Cl)^{13}CH_3$ isomeric forms were recorded. The experiments were accompanied by detailed quantum chemical calculations, according to which the reaction of AlCl with CH_4 to give $HAl(Cl)CH_3$ is slightly exothermic (−43.2 kJ·mol^{-1}).

The reaction with CH_4 demonstrates the potential for detailed exploration of the photochemistry of subvalent compounds like AlCl. The experience gained from the matrix-isolated molecules could be vital in developing the photochemistry on a preparative scale.

Experimental Section

Details of the matrix isolation method can be found elsewhere.[40] Very briefly, in a high vacuum apparatus, HCl was passed over liquid Al (at 1000 °C) inside a Knudsen-type graphite container. Hence AlCl was formed and the vapor emitted from the cell. The AlCl vapor was co-deposited with methane in an excess of Ar onto a freshly polished Cu block kept at 12 K (with a Leybold LB510 refrigerator).

IR spectra were recorded with a Bruker 113v spectrometer equipped with a DTGS and a MCT detector, allowing measurements in the region 5000−200 cm^{-1}. The spectra were recorded with a resolution of 0.5 cm^{-1}. A Ge/KBr beam splitter was used for the 5000−400 cm^{-1} range, and a Mylar 3.5 beam splitter for measurements down to 200 cm^{-1}. Photolysis was achieved with the aid of a medium-pressure mercury lamp (Philips LP 125) operating at 100 W.

$^{12}CH_4$ (99.995 Vol-%) was used as purchased from Messer. $^{12}CD_4$ (98 atom% D) and $^{13}CH_4$ (99 atom% ^{13}C) were used as delivered from Aldrich.

Quantum chemical calculations were carried out with the aid of the TURBOMOLE program package.[41] The BP method in combination with a TZVPP basis set for Al (and Ga) and a SV(P) basis set for the other elements was used in all calculations. The reaction energies are given with ZPVE corrections.

X-ray Crystal Structure and Electrical Conductivity of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$ [$ppy^- = C$-deprotonated 2-phenylpyridine(−); $C_8H_4S_8^{2-}$ = 2-{(4,5-ethylenedithio)-1,3-dithiol-2-ylidene}-1,3-dithiole-4,5-dithionate(2−)]

Keywords: Gold / S ligands / Oxidation / Sulfur / Electrochemistry

Crystals of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$ [ppy^- = *C*-deprotonated 2-phenylpyridine(−); $C_8H_4S_8^{2-}$ = 2-{(4,5-ethylenedithio)-1,3-dithiol-2-ylidene}-1,3-dithiole-4,5-dithiolate(2−)] were prepared by current-controlled electrolysis of a benzonitrile solution of $[Au(ppy)(C_8H_4S_8)]$ with $[NEt_4][PF_6]$ as an electrolyte. The X-ray crystal structure analysis revealed the formation of a columnar stacking of two crystallographically independent cations in formally the 0.5-electron-oxidized state. Cation moieties with some S–S non-bonded contacts (< 3.7 Å) along the *a* and *b* axes form a two-dimensional sheet, with the molecular interaction parallel to the *ab* plane. The electrical conductivities measured for a crystal at room temperature were 9.2 and 0.0028 S cm^{-1} along the *a* and *c* axes, respectively. From the activation energy for the electron conduction determined by the conductivities measured for a compacted pellet the complex was estimated to be metallic from room temperature to 110 K. The energy-band calculation for the oxidized species showed two-dimensional electron conduction through the column.

Introduction

Many molecular electron-conducting compounds made from metal complexes containing sulfur-rich dithiolate ligands, such as $C_3S_5^{2-}$ and $C_8H_4S_8^{2-}$, have been extensively studied; their oxidized metal complexes become good electrical conductors and superconductors.[1−6] They construct effective electron-conduction pathways through some sulfur-sulfur non-bonding contacts in the solid state.

Polarized metal complexes containing both a sulfur-rich dithiolate ligand and an N−N or N−C chelating ligand are expected to form unique molecular stackings and/or layered arrangements through electrostatic interaction of the polarized metal-center moieties, metal-metal interactions and some S−S non-bonding contacts in the solid state behaving as an inorganic/organic molecular composite. Recently, we reported the preparation and crystal structures of planar, asymmetric metal complexes of the [M(N−N)(S−S)] type [M = Pd^{II} and Pt^{II}; N−N = diimine ligands and S−S = sulfur-rich dithiolate ligands(2−)][7,8] and of the [Au^{III}(C−N)(S−S)] type [C−N = *C*-deprotonated 2-phenylpyridine(−) (ppy^-); S−S = sulfur-rich dithiolate ligands(2−)];[9] their chemically oxidized species exhibit high electrical conductivities.

This paper reports the crystal structure of the title oxidized species prepared by electrocrystallization of $[Au(ppy)(C_8H_4S_8)]$ in benzonitrile in the presence of $[NEt_4][PF_6]$, together with the electrical conductivities measured for the crystal and energy bands calculated based on the crystal structure.

Results and Discussion

Preparation of the 0.5-Electron-Oxidized Species $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$

The cyclic voltammogram of $[Au(ppy)(C_8H_4S_8)]$ measured in *N*,*N*-dimethylformamide exhibits two oxidation peaks at −60 and +430 mV (versus Ag/Ag^+);[9] the first oxidation occurs on the $C_8H_4S_8$ ligand. The first oxidation potential is slightly higher than that of the diimine/$C_8H_4S_8$-Pt^{II} complex $[Pt(bpy)(C_8H_4S_8)]$ (−180 mV versus Ag/Ag^+).[8] Reactions of $[Au(ppy)(C_8H_4S_8)]$ with iodine and tetracyano-*p*-quinodimethane (TCNQ) also gave the one-electron-oxidized species $[Au(ppy)(C_8H_4S_8)](I_3)$ and the essentially 0.5-electron-oxidized complex $[Au(ppy)(C_8H_4S_8)](TCNQ^{\cdot -})_{0.6}$, respectively.[9] The present 0.5-electron-oxidized species prepared by the electrocrystallization exhibits almost an isotropic ESR signal with g = 2.007 (peak-to-peak linewidth, 5 mT), as observed for other oxidized $C_8H_4S_8$-metal complexes.[7−13] This finding suggests the $C_8H_4S_8$ ligand-centered oxidation, as confirmed from the

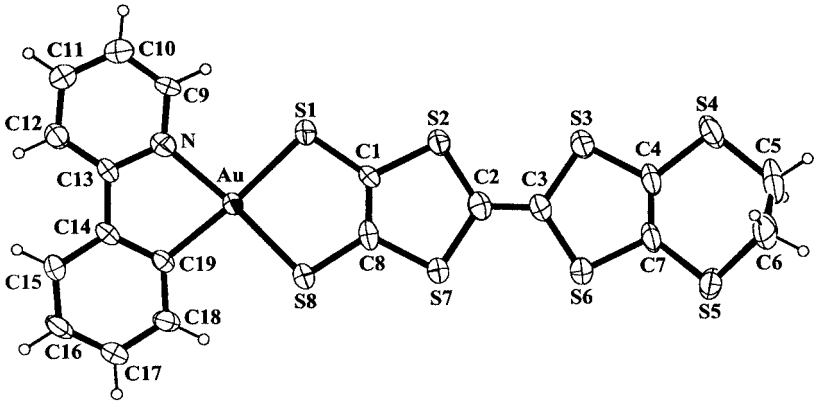

Figure 1. Geometry of one of the cation moieties of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$ together with the atom-labeling scheme

spin densities calculated for the one-electron-oxidized $C_8H_4S_8$-Ti^{IV} complex.[13]

The powder reflectance spectrum of the present oxidized species exhibits a band at 900 nm due to the metal-to-dithiolate ligand charge-transfer transition[7–9] and broad bands at longer wavelengths. They suggest intermolecular interactions through some S−S non-bonding contacts in the solid state.

Molecular and Crystal Structures of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$

The crystal structure of the complex consists of two crystallographically independent cations and octahedral anions. The molecular structure of one of the cation moieties of the complex is shown in Figure 1, together with the atom-labeling scheme. The other cation has also almost the same geometry as this. Selected bond lengths and angles are listed in Table 1.

The Au^{III} ion shows a square-planar coordination, as expected for d^8-metal complexes. The Au(1)−N(1) [2.069(6) Å] and Au(1)−C(19) [2.054(7) Å] distances are close to those of the unoxidized species $[Au(ppy)(C_8H_4S_8)]$ [Au−N = 2.063(3) Å and Au−C = 2.041(5) Å].[9] They are also similar to those of [Au(ppy)(tdt)] [tdt^{2-} = 3,4-toluenedithiolate(2−)] [Au−N = 2.079(5) Å and Au−C = 2.035(7) Å][14] and $[Au(ppy)(S_2CNEt_2)]^+$ [Au−N = 2.058(11) Å and Au−C = 2.036(7) Å].[15] The Au(1)−S(1) bond [2.316(2) Å] trans to the Au(1)−C(19) bond is longer than the Au(1)−S(8) bond [2.298(2) Å] trans to Au(1)−N(1) owing to the structural trans influence. This structural trans influence has also been observed for other $[Au^{III}(C-N)(S-S)]$-type complexes.[9,14–17] The $C_8H_4S_8$

moiety of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$ is almost planar, and is similar to that of the one-electron-oxidized complex $[Pt(bpy)(C_8H_4S_8)][BF_4]$.[8] The planar $C_8H_4S_8$ ligand of the oxidized species is in great contrast to the bent geometries of this ligand observed for unoxidized $C_8H_4S_8$-metal complexes such as $[Au(ppy)(C_8H_4S_8)]$[9] and $[Ti(C_5Me_5)_2(C_8H_4S_8)]$.[12] The C(2)−C(3) bond [1.37(1) Å] of the $C_8H_4S_8$ ligands is somewhat longer than the corresponding bond (1.349 Å) in $[Au(ppy)(C_8H_4S_8)]$.[9] This is consistent with the $C_8H_4S_8$ ligand-centered oxidation in the complex, as described above.

The perspective view of the packing diagram of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$ along the *a* axis is shown in Figure 2. The ppy and $C_8H_4S_8$ ligand moieties of the cations are almost overlapped with themselves in the same molecular orientations along the *a* axis to form a dimer unit with an Au(1)−Au(2) contact of 3.812 Å. This is in a contrast to the unoxidized species $[Au(ppy)(C_8H_4S_8)]$, which has a zigzag arrangement with alternating ppy and $C_8H_4S_8$ ligands because of the polarized orientation around the metal ion.[9] In the present case the cation moieties overlap with one another in the same molecular direction. A similar stacking pattern has also been seen in the cation moieties of $[Pt(bpy)(C_8H_4S_8)][BF_4]$.[8] For these oxidized complexes, some S−S non-bonding contacts (< 3.7 Å) between the oxidized $C_8H_4S_8$ moieties seem to contribute to such molecular arrangements: S(2)−S(14) = 3.682(3); S(6)−S(11) = 3.616(3); S(7)−S(10) = 3.679(2) Å.

As illustrated in Figure 3, the dimer units form a columnar structure along the *a* axis through an S−S non-bonding contact [S(3)−S(15) (1 + *x*, *y*, *z*) = 3.655(3) Å]. Furthermore, there are many S−S non-bonding contacts between the columns (3.339−3.616 Å, in Table 1), resulting in a two-dimensional sheet of molecular interactions parallel to the *ab* plane.

Energy-Band Calculation and Electron Conduction

Figure 4 shows the resultant energy dispersions of several orbitals calculated by the extended Hückel method for the crystal structure of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$ along the symmetry lines *Γ*-*X*, *X*-*V* and *V*-*C*.[18]

Appreciably significant dispersions are found in the *Γ*-*X* zone, which reflects a large orbital overlapping along the column of the cation moieties parallel to the *a* axis. Fur-

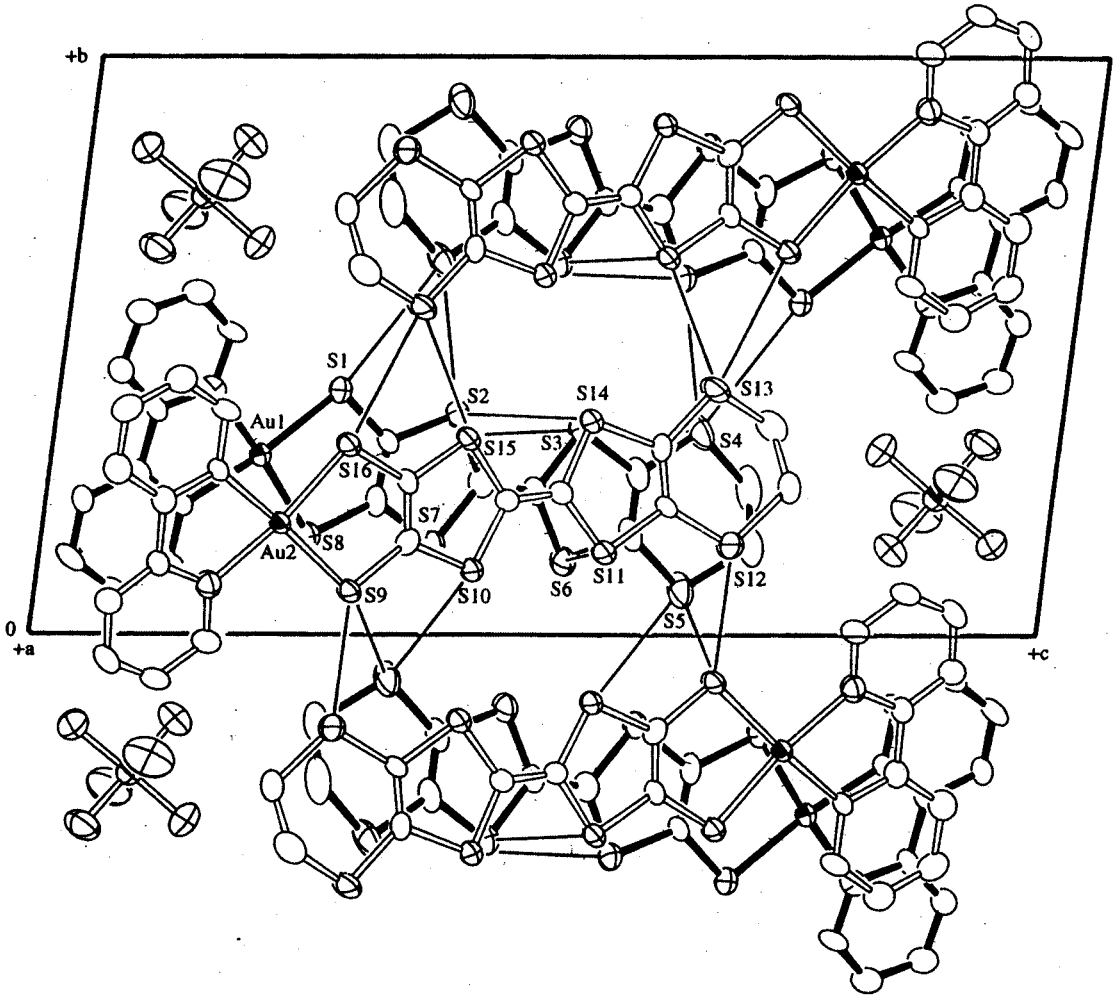

Figure 2. Crystal structure of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$ projected along the *a* axis; fine lines represent S−S non-bonding contacts of less than 3.7 Å

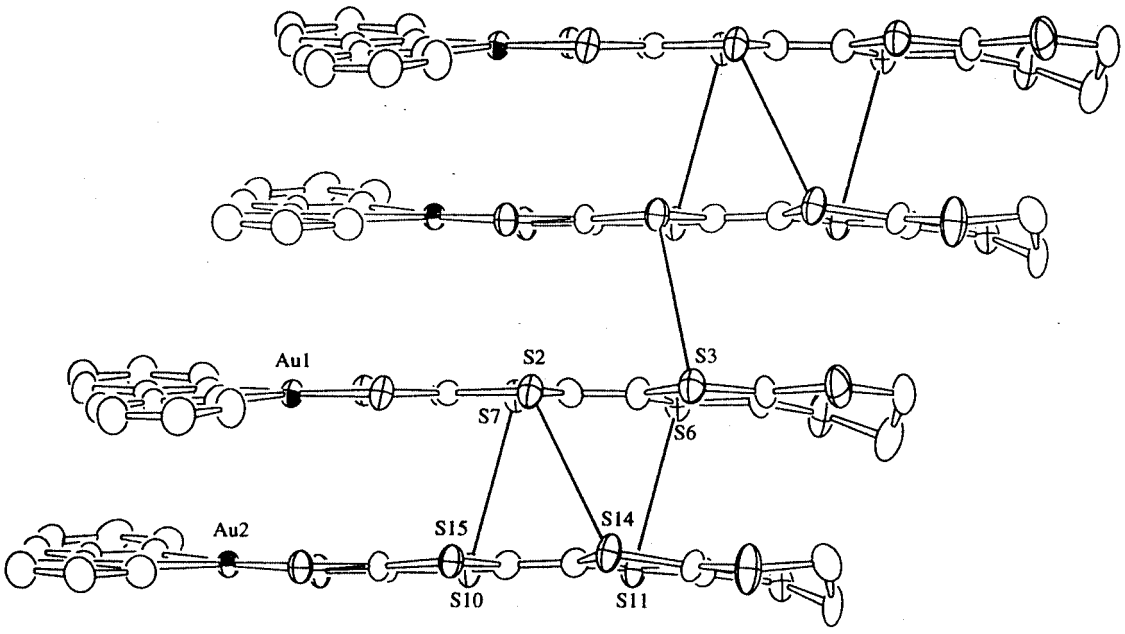

Figure 3. Projection of the overlapping mode of the cation moieties of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$ along the *a* axis; fine lines represent S−S non-bonding contacts of less than 3.7 Å

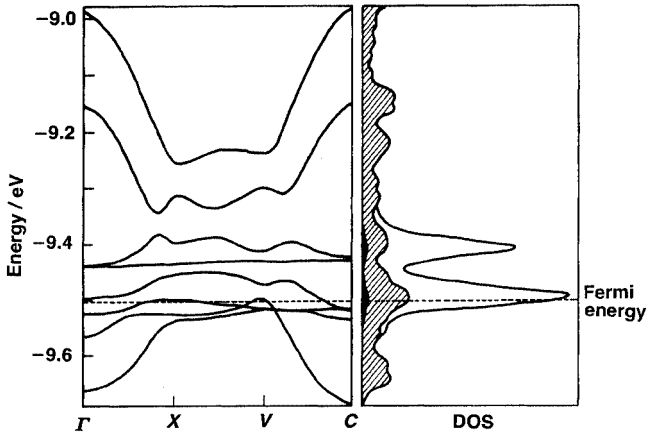

Figure 4. Dispersion of energy bands near the Fermi energy calculated for a crystal of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$, together with total densities of states (DOS) for gold (dark), ppy (open), and $C_8H_4S_8$ moieties (diagonal lines): *Γ, X, V* and *C* refer to the symmetry points with wave vectors 0, $a^*/2$, $(a^* + b^*)/2$ and $(b^* + c^*)/2$, respectively

thermore, large dispersions of some orbitals are observed in the *V*-*C* zone along the *b* axis, which are attributable to a side-by-side overlap of the $C_8H_4S_8$ moieties in neighboring columns. However, no significant dispersions of orbitals are observed in the *X*-*V* zone along the axis including the *c* component. The ppy ligands and PF_6^- anions are located parallel to the *bc* plane. Thus, no significant dispersions are found between the $C_8H_4S_8$ ligand moieties in the neighboring columns along the *c* axis. The Fermi energy level is located in the sharp ppy band, which is overlapped with $C_8H_4S_8$ bands with large dispersions. This band character, as well as the overlapping among the $C_8H_4S_8$ moieties observed in the crystal structure, suggests a metallic character of the complex along the *a* and *b* axes.

The electrical conductivities of the complex measured for a crystal are 9.2 and 0.0028 S cm^{-1} along almost the *a* and *c* axes, respectively, at room temperature. The activation energy for the electron conduction determined by the electrical conductivities measured for a compacted pellet was 0.0 eV from room temperature to 110 K. Thus, the complex is estimated to be metallic along the *a* axis. This finding, together with extremely low conductivity measured along almost the *c* axis, is consistent with the energy-band dispersions calculated based on the crystal structure of the complex, as described above. The present complex exhibits a much higher electrical conductivity than that (2.0×10^{-2} S cm^{-1} for a compacted pellet) of the essentially 0.5-electron-oxidized species $[Au(ppy)(C_8H_4S_8)](TCNQ^{\cdot -})_{0.6}$,[9] which may be due to a variance of molecular packing of these $[Au(ppy)(C_8H_4S_8)]$ moieties in the crystal.

Experimental Section

Preparation of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$: A benzonitrile (15 mL) solution of $[Au(ppy)(C_8H_4S_8)]$[9] (3.0 mg, 4.2 μmol) containing $[NEt_4][PF_6]$ (20 mg, 7.2 mmol) as an electrolyte was electrolyzed under current-controlled conditions (0.1 μA) for 10 days in an H-shaped cell equipped with platinum wire electrodes under an argon atmosphere at 30 C. Black needles of the oxidized species that formed on the surface of the anode were collected and dried in vacuo. The chemical formula of the complex was confirmed by the X-ray crystal structure analysis.

Physical Measurements and Energy-Band Calculations: Electronic absorption, powder reflectance and ESR spectra were recorded as described previously.[19,20] Electrical conductivities were measured

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for a crystal at room temperature. To determine the activation energy for the electron-conduction the conductivities were measured for a compacted pellet from room temperature to 110 K using an apparatus consisting of a Hioki 3552 LCR Hi-tester and a digital temperature controller (Scientific Instrument Model 9650).[21]

Energy-band calculations based on the extended Hückel method[22,23] for the crystal structure of the cation moieties of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$ were carried out using standard extended Hückel parameters[23,24] and the conventional weight of 1.75 for the Wolfsberg−Helmholtz relation.[25−27] In the calculations the PF_6^- parts of the crystal were disregarded since they have negligible contributions to the orbitals near the Fermi energy.

Crystal Structure Determination of $[Au(ppy)(C_8H_4S_8)]_2[PF_6]$: A single crystal of the complex of dimensions 0.10 × 0.06 × 0.025 mm obtained electrolytically was used for the crystal structure determination. Diffraction data were collected on a Rigaku RAXIS-RAPID imaging plate diffractometer equipped with a Rigaku low temperature device (liquid nitrogen as the coolant) and graphite-monochromated Mo-K_α (λ = 0.71069 Å) radiation at the Graduate School of Engineering, Osaka University. Indexing was performed for reflections obtained from three oscillations exposed for 200 s. Final values of the cell parameters were obtained from least-squares refinement of the positions of 23225 observed reflections. Equivalent reflections were merged by use of the PROCESS-AUTO program package. Of 24467 reflections collected, 12826 were unique (R_{int} = 0.060), which were corrected for absorption using the program ABSCOR[28] (transmission factor: 0.449−0.834) and for Lorenz and polarization effects. Crystallographic data are summarized in Table 2.

[a] $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$. [b] $R_w^2 = \Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2$; $w^{-1} = \sigma^2(F_o^2) + (0.0575P)^2 + 1.8569P$, where $P = (F_o^2 + 2F_c^2)/3$.

The structure was solved by the Patterson method (PATTY)[29] and expanded using Fourier techniques (DIRDIF94)[30] and refined on F^2 by the full-matrix least-squares method (SHELXL-97).[31] Non-hydrogen atoms were refined anisotropically with 1.2-times equivalent temperature factors of the parent atoms. Hydrogen atoms were placed on the positions calculated geometrically. Atomic scattering factors were taken from the usual sources.[32] Figures 1 and 2 were drawn with ORTEP II.[33]

General Synthesis and Characterization of Monocrystalline Lanthanide Orthophosphate Nanowires

Ya-Wen Zhang,[a] Zheng-Guang Yan,[a] Li-Ping You,[b] Rui Si,[a] and Chun-Hua Yan*[a]

Keywords: Nanostructures / Lanthanides / Orthophosphates / Solvothermal synthesis

Monocrystalline $LnPO_4$ (Ln = La, Ce, Pr, Nd, Sm, Eu, Gd, Tb) nanowires have been prepared in bulk quantities by a simple, facile, and clean solution-based hydrothermal method at 220–240 °C by finely tuning the acidity of the stock solutions. The length and width of the nanowires were in the range of 1–10 μm and 10–200 nm, respectively.

Introduction

In recent years, one-dimensional (1D) nanomaterials such as nanowires, nanobelts, nanotubes, and nanorods have attracted growing interest not only because of their unique properties with respect to their bulk materials, but also because of their promising applications in mesoscopic physics and fabrication of nanodevices of electronics, optoelectronics, and biochemical sensing.[1−9] Among the 1D nanomaterials, nanowires have played key roles as both interconnectors and active components in fabricating the nanodevices.[1,2,5] Therefore, to synthesize diverse nanowires with well-controlled shape, size, phase purity, crystallinity, and chemical composition on a large scale has become one of the most challenging issues faced by synthetic inorganic chemists.[10] So far, a rich variety of nanowires such as elemental semiconductors, II−VI and III−V semiconductors, metal oxides, and metals have been prepared by methods including templating direction, catalytic growth, electrochemistry, chemical vapor deposition, and solution-based solvothermal or hydrothermal treatment.[1−4]

Based on the electronic, optical, and chemical characteristics originating from their unique 4*f* electron configurations, lanthanides have promised various applications in magnets, phosphors, catalysts, biochemical probes, and medical diagnostics, and thus are of rapidly growing importance. In lanthanide chemistry, much of the recent attention has been focused on the fields of the coordination chemistry of lanthanides, organic transformations mediated or catalyzed by rare-earth compounds, and the preparation and properties of new lanthanide-related materials.[11] More recently, some lanthanide-related materials (oxides, borates, and fluorides) were reported to show exceptional electrical or luminescent behaviors when their grain sizes were reduced to the nanometer regime.[12−14] Nevertheless, the advance in the studies of 1D-nanostructured rare earth related compounds is still very limited, only nanowires/nanotubes of rare earth hydroxides/oxides have been prepared and characterized.[15−18] Amongst the large number of lanthanide inorganic salts, lanthanide phosphates are widely used in the production of luminescent or laser materials, moisture sensors, heat-resistant materials, and hosts for radioactive nuclear waste.[19−23] In this paper, we will report the general synthesis of monocrystalline lanthanide orthophosphate nanowires by a solution-based hydrothermal route by finely tuning the acidity of the stock solutions.

Lanthanide orthophosphates with the chemical formula $LnPO_4{\cdot}nH_2O$ ($n = 0-3$) (Ln^{3+} = lanthanide ion) have five polymorphs: monazite (monoclinic), xenotime (tetragonal), rhabdophane (hexagonal), weinschenkite (monoclinic), and orthorhombic.[23] In this research, $LnPO_4{\cdot}nH_2O$ ($n = 0-0.5$) were hydrothermally prepared at 220−240 °C for 17−24 h, using H_3PO_4, $NH_4H_2PO_4$, $(NH_4)_2HPO_4$, $(NH_4)_3PO_4$, or their mixtures, as both the precipitators and the mediators of acidity. Experimentally, monazite-type $LnPO_4$ (Ln = La, Ce, Pr, Nd, Sm, Eu, Gd) nanowires, rhabdophane-type $TbPO_4{\cdot}0.5H_2O$ nanowires/nanorods, and xenotime-type $LnPO_4$ (Ln = Dy, Ho, Er, Tm, Yb, Lu, Y) nanocrystals were obtained.

Results and Discussion

The crystal structures of the products have been identified by X-ray diffraction analysis (XRD). In Figure 1(a), we show the typical XRD pattern of the $LaPO_4$ nanowires. All the reflections can be distinctly indexed to a pure mono-

clinic phase (space group $P2_1/n$) with lattice constants a = 6.868 Å, b = 7.104 Å, c = 6.521 Å, and β = 103.6° (JC,PDS No. 32-493). Such a monoclinic structure was also identified for the other $LnPO_4$ nanowires. From Figure 1(b), we noted that the $LaPO_4$ colloid precipitate prior to hydrothermal treatment shows a hexagonal structure (JC,PDS No. 46-1439) and consists of nanoparticles as suggested by the line broadening of the diffraction peaks. The XRD pattern shown in Figure 2 informs us that the $TbPO_4{\cdot}0.5H_2O$ product is of hexagonal structure (space group $P3_121$) with lattice constants a = 6.799 Å and c = 6.332 Å (JC,PDS No. 20-1244). XRD analysis also showed that the as-synthesized $LnPO_4$ products of heavy lanthanides exhibit a zircon-type structure with tetragonal symmetry (space group $I4_1/amd$) with grain sizes in the range of 20−150 nm, as estimated by transmission electron microscopy (TEM).

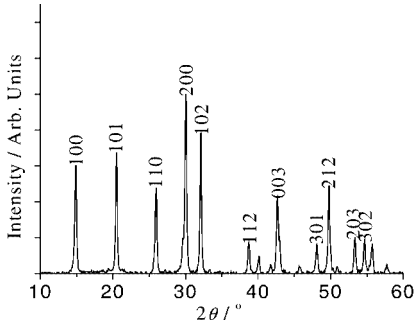

Figure 2. XRD pattern of $TbPO_4{\cdot}0.5H_2O$ nanowires/nanorods

By TEM and high resolution TEM (HRTEM), the morphology, crystallinity, and growth directions of the nanowires were carefully examined. From Figure 3, we can see that the as-prepared monoclinic $LnPO_4$ nanowires have a length of between 1 and 10 μm and a width of between 10 and 200 nm, are pure without any appreciable amount of particulate by-products, and are of a single-crystal nature. The surfaces of the nanowires are perfect without any stacking faults, and clean without any sheathed amorphous phase even at the edges. The preferred growth direction of the monazite-type nanowires was determined along the c axis [001]. Figure 4 shows that the $TbPO_4{\cdot}0.5H_2O$ nanowires/nanorods are perfect single crystals with a length of between 0.5 and 2 μm and a width of between 20 and

150 nm. The HRTEM image and selected area electron diffraction (SAED) pattern shown in Figure 4(b) and (c), respectively, suggest that the $TbPO_4{\cdot}0.5H_2O$ single crystals also grow along the c axis. From Figures 3 and 4, we can see that the nanowires of light lanthanides are more uniform than those of middle lanthanides, possibly resulting from the differences in their intrinsic properties such as solubility, ionic mobility and growth rate in solution associated with the lanthanide contraction.[24] In addition, the smooth morphology and perfect monocrystalline nature of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the as-synthesized nanowires indicate that a reversible pathway between the solution phase and the solid phase, which allows building blocks in $LnPO_4$ crystals to adopt the correct positions, was established during the hydrothermal treatment employed. The optimal preparative conditions, crystal structures, length, and width of the $LnPO_4$ nanowires are summarized in Table 1.

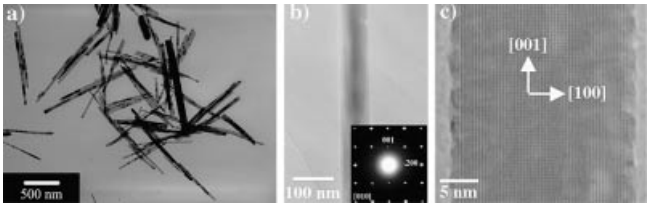

Figure 4. (a) TEM image of $TbPO_4 \cdot 0.5H_2O$ nanowires/nanorods; (b) TEM image of a uniform 70 nm $TbPO_4 \cdot 0.5H_2O$ nanorod with inset showing the electron diffraction pattern; and (c) HRTEM image of a single 25 nm $TbPO_4 \cdot 0.5H_2O$ nanowire

Solution-based hydrothermal/solvothermal methods have already become a commonly used methodology for preparing shaped/sized/oriented nanomaterials, but a quantitative thermodynamic prediction of the crystallization in the nanometer regime for growing 1D nanomaterials by this method is still very difficult and requires extensive research.[2] Herein, the preferred growth direction of the $LnPO_4$ nanowires was understood from the viewpoint of energy by simulating the coordination fashion of the rare earth ions in the monazite structure based on the Kossel model of crystal growth on completely smooth surfaces.[25] As is well-known, the lanthanide atoms in the monazite structure are coordinated to nine oxygen atoms forming a polyhedron of pentagonal interpenetrating tetrahedra, and the nine-coordinate lanthanide atoms are apically combined by the distorted tetrahedral PO_4^{3-} groups forming chains.[26] Figure 5 shows the growth models of $LaPO_4$ nanowires along the [001] (*c* axis) and [100] (*a* axis) directions, which were constructed using the CERIUS2 software package.[27] From Figure 5(a), we can see that two La−O bonds form as a PO_4^{3-} tetrahedron is attached along the [001] direction. However, only one La−O bond forms when

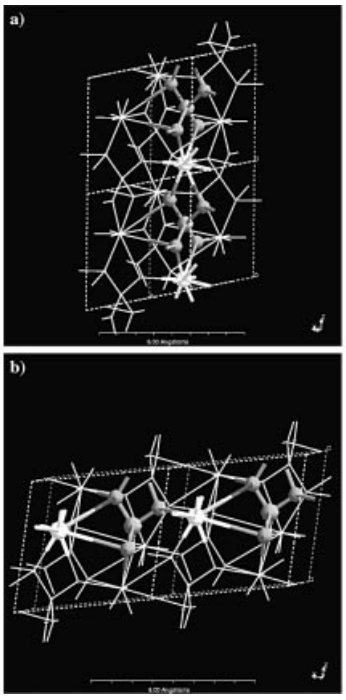

Figure 5. Growth models for $LaPO_4$ along different directions built up by CERIUS2 software: (a) [001] and (b) [100]

the growth is along the [100] direction (Figure 5, b). The growth along the [001] direction can release more energy, and the La−O bond lengths in the two cases show slight differences.[26] Thus, the [001] direction should be preferably taken when $LnPO_4$ nanowires are growing. Moreover, it is inferred that the anisotropic nature of the building blocks in the monazite structure should be one source of the driving forces for the growth of the $LnPO_4$ nanowires.

Control experiments were carried out to screen the optimal conditions for preparing phase-pure monocrystalline $LnPO_4$ nanowires. It was shown that the temperature and the starting acidity in the mother liquors are the major factors governing the crystallinity and the phase purity of the products. Temperature-dependent experiments showed that pure dehydrated monocrystalline nanowires could only be prepared at temperatures above 200 °C, and the dehydration temperature for middle lanthanides is higher than that for light lanthanides. When heat-treated at 220−240

Table 1. Optimal preparative conditions, crystal structures and morphologies of the $LnPO_4$ nanowires

Sample	Preparative conditions		Structure	Morphology	
	pH	Temperature [°C]		Length [μm]	Width [nm]
$LaPO_4$	0.8	220	monoclinic	1−3	20−50
$CePO_4$	0.8	220	monoclinic	2−5	20−100
$PrPO_4$	0.8	220	monoclinic	1−4	10−60
$NdPO_4$	0.8	220	monoclinic	1−3	20−60
$SmPO_4$	0.8	220	monoclinic	2−6	50−150
$EuPO_4$	1	240	monoclinic	3−10	50−200
$GdPO_4$	2	240	monoclinic	1−3	20−200
$TbPO_4 \cdot 0.5H_2O$	1.6	240	hexagonal	0.5−2	20−150

°C, $LnPO_4$ (Ln = La, Pr, Nd, Sm, Eu) products exhibit the monazite structure under the acidities investigated. However, at the same temperatures, pure monazite $CePO_4$ could only be synthesized at pHs less than 1. When the pH is greater than 1, cubic CeO_2 will coexist with monazite-type $CePO_4$ due to the partial oxidization of Ce^{3+} at the reduced acidity in solution. Pure monazite-type $GdPO_4$ instead of mixed phases of rhabdophane and monazite could only be prepared at pHs between 1.5 and 6 at 240 °C. In the case of $TbPO_4$, no monazite phase was obtained under the acidities used at 240 °C; instead, pure rhabdophane and xenotime phase were obtained at pHs greater than 1.5 and lower than 1.5, respectively.

At a given heat-treatment temperature, it was observed that the morphologies of the products depend strongly upon the starting acidity and the formation of colloidal precipitates in the mother liquors. As an example, the effects of the preparative conditions on the morphologies of the $LaPO_4$ products are given in Table 2. It can be seen that $LaPO_4$ nanowires could only be obtained in a fairly narrow pH range (between 0.5 and 1.5) in the presence of the colloidal precipitate. In fact, the acidity of the stock solutions was finely tuned according to the following equation:

$$Ln^{3+} + (NH_4)_mH_{3-m}PO_4 \rightarrow LnPO_4 \downarrow + (3 - m)\cdot H^+ + m\cdot NH_4^+ \quad (m = 0-3)$$

The hexagonal $LaPO_4$ colloidal precipitate was confirmed to be an aggregate of nearly spherical nanoparticles with sizes around 80 nm (Figure 6). Those nanoparticles could serve as anisotropic seeds for the growth of highly anisotropic nanostructures in the solution solid process by a dissolution and crystallization mechanism during the hydrothermal treatment employed.[15,28,29] At pH values between 0.8 and 6, the colloidal precipitate formed instantly in the stock solution. After hydrothermal treatment, the morphologies of the $LaPO_4$ products changed from nanoparticles/nanorods (at pH 6, Figure 7, a) to nanowires/nanorods (at pH 1.6, Figure 7, b), then to nanowires (at pH 0.8−1.3, Figures 3 and 7, a and c, respectively), along with the increasing aspect ratio (also see Table 2). When the starting acidity of the stock solution was further enhanced by the addition of H_3PO_4, the colloidal precipitate formed gradually over a few minutes or even disappeared. After hydrothermal treatment, the morphologies of the $LaPO_4$ products changed from nanowires (at pH 0.8−1.3, Figures 3 and 7, a and c, respectively) to nanowires/nanorods (at 1 mol·L^{-1} H_3PO_4, Figure 7, d), then to nanorods (at 2 mol·L^{-1} H_3PO_4, Figure 7, e), along with the decreasing aspect ratio (see also Table 2).

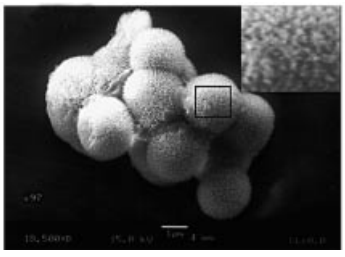

Figure 6. SEM images at different magnifications of the $LaPO_4$ colloidal precipitate prepared at pH 0.8 (inset was taken from the highlighted section)

Previously, Peng et al. have investigated the effects of chemical potential on the shape evolution of CdSe nanocrystals with the wurtzite structure, and observed that the high chemical potential generated by a high monomer concentration in the growth solution favors the growth of elongated nanocrystals.[30] Very recently, Li et al. found that a higher chemical potential was a dominant driving force for the growth of hexagonal lanthanide hydroxide nanowires during hydrothermal treatment.[15] In the present case, the concept of chemical potential was also used to explain the above experimental phenomenon related to the formation of $LnPO_4$ nanowires. We think that the chemical potential of the monoclinic $LnPO_4$ crystals is mainly determined by the apparent concentration of $LnPO_4$ in the solutions, which depends thermodynamically upon the acidity of the reaction system. Previously, the apparent solubility of $LnPO_4$ in aqueous solution was found to decrease upon increasing the precipitation temperature.[31] Under mild to strongly acidic conditions, the apparent concentration of $LnPO_4$ in boiling H_3PO_4 solution decreases gradually upon increasing the concentration of H_3PO_4 from 0.5 to 2 M, and decreases drastically when it is higher than 2 M.[31] Under weakly acidic conditions, Ln^{3+} ions are known to hydrolyze slightly in solution with the formation of both mononuclear and polynuclear species in small amounts before the precipitation of the hydroxide occurs above pH 6.[32] In ad-

Table 2. Effect of the preparative conditions on the morphologies of the $LaPO_4$ products prepared at 220 °C for 17 h

Acidity	Precipitating[a]	Morphology Length [μm]	Width [nm]	
pH = 6	instantly	0.05−0.2	10−20	nanoparticles/nanorods
pH = 1.6	instantly	0.2−0.7	10−60	nanowires/nanorods
pH = 1.3	instantly	0.5−3	30−70	nanowires
pH = 1	instantly	1−3	20−90	nanowires

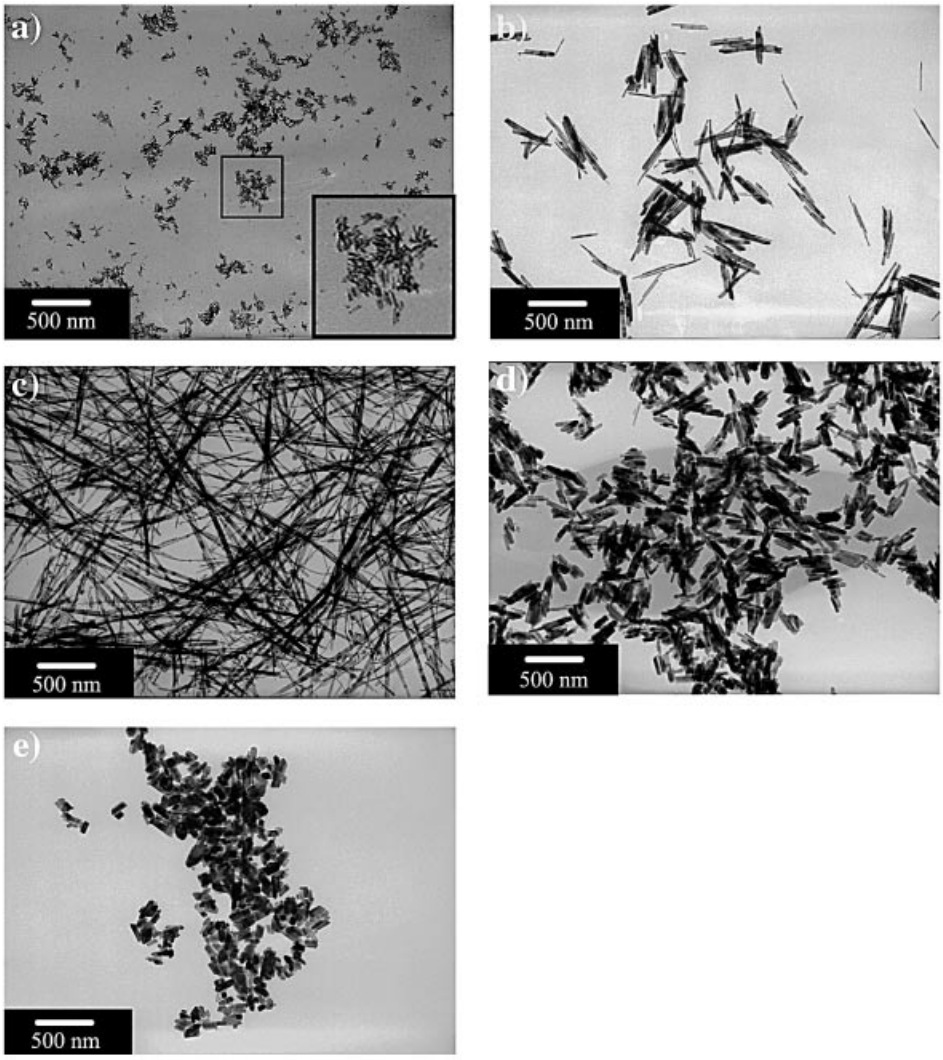

Figure 7. TEM images of the hydrothermal products of $LaPO_4$ prepared at 220 °C for 17 h: (a) pH 6 (inset was taken from the highlighted section); (b) pH 1.6; (c) pH 1.3; (d) 1 mol·L^{-1} H_3PO_4; (e) 2 mol·L^{-1} H_3PO_4

dition, the hydrolysis rate increases with pH value. In the present experiments, both the increasing hydrolysis of La^{3+} ions at pH values greater than 1.5 and the increasing acidity by addition of H_3PO_4 ($\geq$ 0.5 M) are thought to reduce the apparent concentration of $LaPO_4$ and thus its chemical potential in solution. As a result, the $LaPO_4$ nanowires could only be prepared in a fairly narrow pH range (0.5−1.5) where the chemical potential of $LaPO_4$ crystals is higher. Interestingly, the coexistence of the $LaPO_4$ nanorods/nanoparticles (at pH 6, Figure 7, a) or nanowires/nanorods (at pH 1.6 or at 1 M H_3PO_4, Figure 7, b and d) might indicate the mixed-shape evolution of 1D/2D ripening.[30] Conclusively, a high chemical potential of $LnPO_4$ crystals in solution should be another major driving force for the growth of the $LnPO_4$ nanowires.

As demonstrated above by XRD analysis, there is a structural transition from monazite to rhabdophane, then to xenotime with the ionic radius of Ln^{3+} decreasing from La to Lu, and rhabdophane-type $TbPO_4$ sits on the borderline for this transition. Under the synthetic conditions investigated, we found that $LnPO_4$ with larger Ln^{3+} ions could be synthesized in the form of nanowires at suitable pH values, whereas $LnPO_4$ with the heavier and smaller Ln^{3+} ions could only be prepared in the form of nanocrystals. This result might hint that xenotime-type $LnPO_4$ crystals have lower structural anisotropy and lower chemical potential in solution than monazite-type $LnPO_4$ crystals, probably as a result of their lower coordination number and increasing solubility induced by the lanthanide contraction.[31,33] In the xenotime-type structure, Ln ions are eight-coordinate to oxygen atoms from the somewhat-distorted tetrahedral PO_4^{3-} groups to form a polyhedron of bis-bisphenoid.[33]

Conclusion

We have demonstrated the general synthesis of $LnPO_4$ monocrystalline nanowires in bulk quantities and high purity by a simple, facile, and clean solution-based hydrothermal method by finely tuning the acidity of the stock solu-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tions. This successful demonstration can assist us to understand the fundamentals of the reaction and nanowire growth mechanisms under hydrothermal conditions. Our recent experiments also showed that monocrystalline rhabdophane and orthorhombic hydrated $LnPO_4$ 1D nanomaterials and luminescent-active $LaPO_4$:Eu and $LaPO_4$:CeTb nanowires can be also prepared by the same synthetic approach. It is expected that the hydrothermal route employed in this work can be extended to the preparation of other pure and doped 1D nanomaterials with highly anisotropic structures. Moreover, the as-synthesized monocrystalline lanthanide orthophosphate nanowires may promote both academic interest in lanthanide chemistry and novel applications in nanotechnology. Further research on the luminescent behavior of doped $LnPO_4 \cdot nH_2O$ 1D nanomaterials associated with the reduced dimensionality are in progress.

Experimental Section

Synthesis of the $LnPO_4$ Nanowires: Quantitative solutions of $Ln(NO_3)_3$ (AR, > 99.9%) and H_3PO_4 [$NH_4H_2PO_4$/$(NH_4)_2HPO_4$/$(NH_4)_3PO_4$ or their mixtures] of analytical grade in a given molar ratio (usually 1:1.1) were employed to prepare a stock solution (40 mL) with a cation concentration of 0.05 M in a Teflon cup (50 mL). After 15 min of stirring, the cup was transferred into a stainless steel autoclave, and subjected to hydrothermal treatment at 220−240 °C for 17−24 h under autogenous pressure in an electric oven. As the autoclave cooled to room temperature, precipitates with the color of lanthanide ions were formed and collected. The precipitates were washed with deionized water, centrifugally filtered off, and dried at 60 °C for 24 h. The yields of the products were about 80−90%.

The water content in the products was determined with a thermogravimetry and differential thermal analyzer (Du Pont 2100) in air at a heating rate of 10 °C/min, using α-Al_2O_3 as a reference. The crystal structures of the products were obtained on a powder X-ray diffractometer (Rigaku D/max-2000, Japan), employing Cu-K_α radiation (λ = 1.5418 Å). The sizes and morphologies of the products were characterized by scanning electron microscopy (AMARY 1910FE, USA) at 15 kV, transmission electronic spectroscopy (200CX, JEOL, Japan) at 160 kV and high-resolution transmission electronic spectroscopy (H-9000, Hitachi, Japan) at 400 kV.

Mechanism of Reduction of 2,2-Dibromomethyl-1,3-propanediol by Ni^{I}-Tetraazamacrocyclic Complexes in Aqueous Solution − A Pulse Radiolysis and Electrochemical Study

Elisabetha Shandalov,[a] Israel Zilbermann,[a,b] Eric Maimon,[a,b] Yeoshua Nahmani,[a,b] Haim Cohen,[a,b] Eilon Adar,[c] and Dan Meyerstein*[a,d]

Keywords: Halogenated compounds / Pulse radiolysis / Reduction / Electrochemistry / Macrocycles

The reduction, catalytic reduction and the electrocatalytic reduction of halo-organic compounds are of major interest due to their role as pollutants. The mechanism and kinetics of reduction of 2,2-dibromomethyl-1,3-propanediol by several Ni^{I} tetraazamacrocyclic complexes, $(Ni^{I}L^{i})^{+}$ (i = 1–4), in aqueous solutions to yield Br^{-} and the non-halogenated compound was studied using the pulse radiolysis technique. The rate constants $k = 5.3 \times 10^{8}$, 1.6×10^{7}, 6.0×10^{5} and 3.5×10^{4} $M^{-1}s^{-1}$ for L^{1}, L^{2}, L^{3} and L^{4} respectively, of the reactions $(Ni^{I}L^{i})^{+} + RBr \rightarrow (Ni^{II}L^{i})^{2+} + Br^{-} + R^{\cdot}$ increase with the free-energy gain in the reaction. All these complexes are good electrocatalysts for the reduction of this substrate. The mechanisms of the reductions is are discussed.

Introduction

Recently, the underground water of many sites all over the world has become heavily contaminated by halogenated organic compounds.[1,2] Halogenated hydrocarbons such as halogenated methanes and ethanes are mainly used as solvents and are produced on a scale of 10^{6} tons per year.[3] Release of these hazardous compounds into the environment by leakage from industrial effluents causes ecological damage to the subsurface water reservoirs. Thus, the reduction, catalytic reduction and the electrocatalytic reduction of halo-organic compounds is of major interest for the removal of such compounds either from the raw effluents or for remediation of contaminated water. The kinetics and mechanisms of the reactions of nickel(I) macrocyclic complexes with alkyl halides have been investigated.[4,5] Moreover these complexes have attracted considerable attention because they enable the electrocatalytic reduction of alkyl halides.[6,7] $Ni^{II}L^{i}$ complexes, with macrocyclic ligands, are reduced reversibly to relatively stable nickel(I) species in aqueous solution.[8] The redox potentials and lifetimes of the $Ni^{I}L$ complexes are affected mainly by three factors: 1) substitution on the macrocyclic ring (especially on the nitrogens), 2) ring size, and 3) saturation of the macrocyclic ring. Thermodynamic and/or kinetic stabilization of the monovalent nickel complexes is achieved by N-alkylation of the macrocyclic ligands.[8,9]

It seemed of interest to study the effect of the redox potential, and plausibly of steric hindrance, of the nickel complexes on the rate of dehalogenation and on the detailed mechanism of the process. In this framework it was decided to study the reduction of 2,2-dibromomethyl-1,3-propanediol (as a representative contaminant found in the polluted groundwater in the Beer-Sheva region of Israel) by $(Ni^{I}L^{i})^{+}$ in aqueous solution. The tetraazamacrocyclic ligands L^{i} (i = 1−4) were chosen as they affect both the redox potential of the central cation and impose different steric strains on the complex and on the approach of the substrate to the central nickel cation.

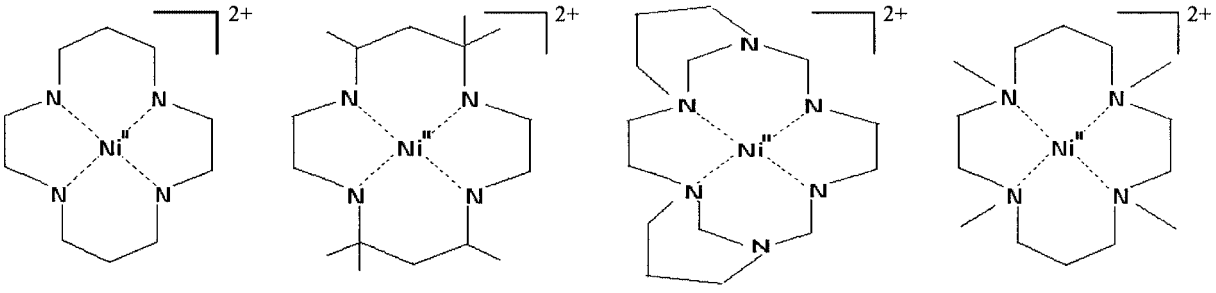
Results and Discussion

Pulse-Radiolysis Studies

He-saturated aqueous solutions containing 0.1 M HCOONa, $2 \times 10^{-4} - 1 \times 10^{-3}$ M $(Ni^{II}L^{i})^{2+}$ and 1×10^{-4} to 2×10^{-3} M $(CH_2Br)_2C(CH_2OH)_2$, at pH 10.0 ± 0.3, were irradiated by a short electron pulse from the linear



accelerator. When ionizing radiation is absorbed by a dilute aqueous solution the following initial products are formed:[10]

$$H_2O \xrightarrow{e^-,\gamma} {}^{\bullet}OH\ (2.65);\ {}^{\bullet}H\ (0.60);\ e^-_{aq}\ (2.65);\ H_2O_2\ (0.75);\ H_2\ (0.45);\ H_3O^+;\ OH^- \quad (1)$$

Where the G values are given in parentheses (G values are defined as the number of molecules of each product per 100 eV of radiation absorbed by the solution).[10]

In the presence of formate ($HCOO^-$), both $H^{\cdot}$ and $^{\cdot}OH$, are scavenged by $HCOO^-$ to generate the $CO_2^{\cdot -}$ radical.

$$^{\cdot}H/^{\cdot}OH + HCOO^- \rightarrow CO_2^{\cdot -} + H_2/H_2O$$
$$(k_{\cdot OH} = 3.2\cdot10^9\ M^{-1}sec^{-1};[11]\ k_{\cdot H} = 2.1\cdot10^8\ M^{-1}sec^{-1}\ [11]) \quad (2)$$

The $CO_2^{\cdot -}$ radical generated and the hydrated electron, e^-_{aq}, are powerful single-electron reducing agents, $E^0 = -1.90$ V[12,13] and $E^0 = -2.87$ V[11] vs. NHE respectively. $CO_2^{\cdot -}$ is an inner-sphere reducing agent[14] due to the fact that it is bent and the product, CO_2, is linear.

The $CO_2^{\cdot -}$ radical and e^-_{aq} react rapidly with $(Ni^{II}L^i)^{2+}$ to produce $(Ni^{I}L^i)^{+}$ [8,15] which, in turn, reacts with the organic substrate in the next step. A typical experimental result is shown in Figure 1.

These results indicate that reactions (3) obey pseudo-first order rate laws. The rates of the dehalogenation reactions depend linearly on the $(CH_2Br)_2C(CH_2OH)_2$ concentration, Figure 2; the rate constants (k) derived from the slopes of the lines are summed up in Table 1.

$$(Ni^{I}L^i)^+ + RBr \xrightarrow{k} (Ni^{II}L^i)^{2+} + R^{\bullet} + Br^- \quad (3)$$

Thus the results are in agreement with the suggestion that the reactions observed are reactions (3).

When the radical yield of reaction (3) is relatively low, i.e. when low pulse intensities are applied, and in the presence of a relatively high concentration of $(Ni^{II}L^1)^{2+}$, the formation of a second intermediate is observed (Figure 3). It is proposed that this intermediate is $L^1Ni^{III}-R$, which is formed by

$$(Ni^{II}L^1)^{2+} + R^{\cdot} \rightarrow (L^1Ni^{III}\text{-}R)^{2+} \quad (4)$$

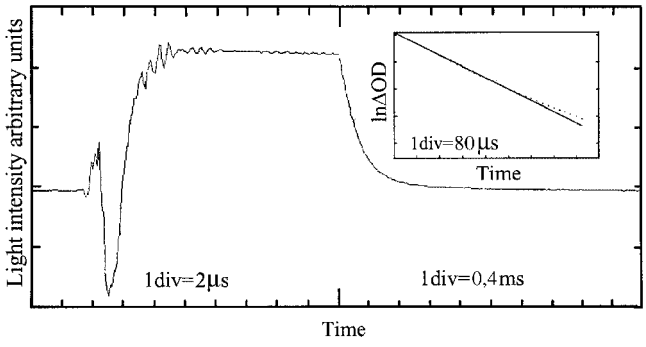


Figure 1. Decrease of the absorbance (at 380 nm) due to the reaction of $(Ni^{I}L^2)^+$ with $(CH_2Br)_2C(CH_2OH)_2$ and first order fit of the data (insert); solution composition: 1×10^{-3} M $(Ni^{II}L^2)^{2+}$, 0.1 M HCOONa and 3×10^{-4} M $(CH_2Br)_2C(CH_2OH)_2$ at pH 10.0 ± 0.3, He sat, pulse intensity (17.2 ± 3.4) Gy/pulse

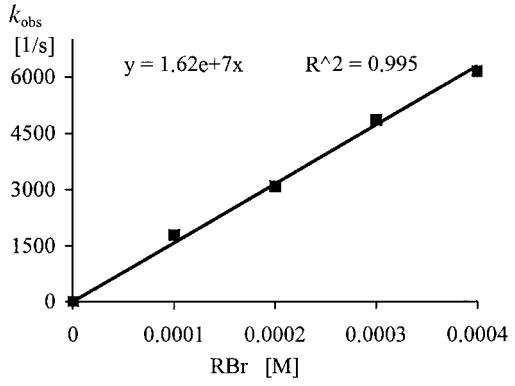

Figure 2. Dependence of k_{obs} on $[(CH_2Br)_2C(CH_2OH)_2]$, for the reaction of $(Ni^{I}L^2)^+$ with $(CH_2Br)_2C(CH_2OH)_2$

Table 1. Rate constants of the debromination reactions by the different nickel complexes

L^i	$E^0_{1/2}$ $Ni^{2+/+}$ [V]	k [$M^{-1}s^{-1}$]
L^1	−1.58	$(5.3 \pm 0.8) \times 10^8$
L^2	−1.42	$(1.6 \pm 0.2) \times 10^7$
L^3	−1.25	$(6.0 \pm 0.9) \times 10^5$
L^4	−1.15	$(3.5 \pm 0.5) \times 10^4$

This suggestion is supported by the observation that the absorbance due to the second intermediate increases with

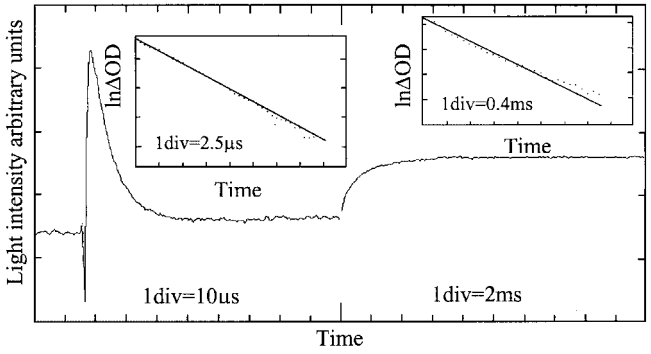

Figure 3. Decay of the absorption (at 370 nm) due to the reaction of $(Ni^{I}L^{1})^{+}$ with $(CH_2Br)_2C(CH_2OH)_2$ followed by increase of the absorption due to the formation of $(L^{1}Ni^{III}\ R)^{2+}$; solution composition: 1×10^{-3} M $(Ni^{II}L^{1})^{2+}$, 0.1 M HCOONa and 4×10^{-4} M $(CH_2Br)_2C(CH_2OH)_2$, pH 10.0 ± 0.3, He sat, pulse intensity (5.9 ± 1.2) Gy/pulse

concentration of $(Ni^{II}L^{1})^{2+}$, as reaction (4) has to compete with reaction (5)

$$2R^{\cdot} \rightarrow R_2 \quad (5)$$

The analogous reaction

$$(Ni^{II}L^{1})^{2+} + {}^{\cdot}CH_3 \rightleftarrows (L^{1}Ni^{III}\text{-}CH_3)^{2+} \quad [k_{4a} = (6.5 \pm 0.7) \times 10^{8}\ M^{-1}s^{-1}]\ k_{-4a} = 57 \pm 6\ s^{-1} \quad (4a)$$

is well documented in the literature.[16,17]

This competition also explains why this intermediate is not observed at high pulse intensities. The lifetime of $(L^{1}Ni^{III}\text{-}R)^{2+}$ is considerably longer than 40 sec, in agreement with the reported lifetime of $(L^{1}Ni^{III}\text{-}CH_3)^{2+}$.[16]

The formation of the second intermediate is not observed for the other complexes studied, probably due to steric hindrance, which slows down reactions analogous to reaction (4), and to the fact that k_3 is slower for these complexes.

It is of interest to note that a plot of log k vs. $E°(Ni^{II/I}L)$ yields a straight line (Figure 4). As the self-exchange rate for the $Ni^{II/I}L^{i}$ couples is relatively slow,[8,15] and as the self exchange for the $RBr/RBr^{\cdot -}$ couple is probably not high and the free energy gain in the outer sphere reduction

$$(Ni^{I}L^{i})^{+} + RBr \rightarrow (Ni^{II}L^{i})^{2+} + RBr^{\cdot -} \quad (3a)$$

is also not high, due to the instability of $RBr^{\cdot -}$, it is proposed that reaction (3) probably proceeds via an inner-sphere mechanism. However, the straight line observed in Figure 4 suggests that steric hindrance does not slow down reaction (3) considerably.

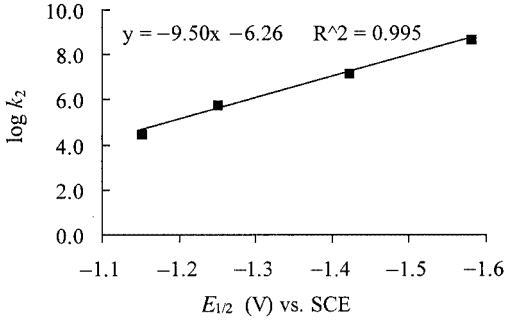

Figure 4. Dependence of log k_2 on $E_{1/2}$ of the complexes

Yield of Bromide

He-saturated aqueous solutions containing 0.1 M HCOONa, 5×10^{-4} M $(Ni^{II}L^{1})^{2+}$ and 2.5×10^{-4} to 7×10^{-3} M $(CH_2Br)_2C(CH_2OH)_2$, at pH 10, were irradiated in the ^{60}Co γ source with a dose rate of 4 Gy/min to an overall dose of 720 Gy. The yields of bromide obtained by the γ irradiation in the ^{60}Co source are summed up in Table 2.

Table 2. Bromide yield as a function of $(CH_2Br)_2C(CH_2OH)_2$ concentration; solution composition: 0.1 M HCOONa, 5×10^{-4} M $(Ni^{II}L^{1})^{2+}$ and 2.5×10^{-4} to 7×10^{-3} M $(CH_2Br)_2C(CH_2OH)_2$, pH 10.0 ± 0.3, He sat., dose 720 Gy at 4 Gy/min; experimental error: ±20%

[RBr] (M)	$[Br^{-}]$ (M)	G (Br^{-})
2.5×10^{-4}	4.9×10^{-4}	> 7.8
5.0×10^{-4}	9.8×10^{-4}	> 15
1.0×10^{-3}	2.0×10^{-3}	> 32
3.0×10^{-3}	2.2×10^{-3}	35
5.0×10^{-3}	2.6×10^{-3}	41
7.0×10^{-3}	2.6×10^{-3}	41

The results clearly indicate that total debromination is obtained at low concentrations of $(CH_2Br)_2C(CH_2OH)_2$ and therefore only lower limits of G(Br^{-}) can be derived. The yield of Br^{-} is considerably larger than the primary yield of radicals, G = 6.0,[10] therefore it has to be concluded that the debromination occurs via a chain reaction.

When blank experiments were performed (in the absence of $(Ni^{II}L^{1})^{2+}$ surprisingly G(Br^{-}) = 112 was obtained.[18]

These results are in agreement with the following mechanism:[18]

$$RBr + CO_2^{\cdot -} \rightarrow R^{\cdot} + CO_2 + Br^{-} \quad (6)$$

$$R^{\cdot} + HCO_2^{-} \rightarrow RH + CO_2^{\cdot -} \quad (7)$$

and the termination reactions:

$$2R^{\cdot} \rightarrow R_2 \text{ or } RH + R_{-H} \quad (8)$$

$$2CO_2^{\cdot -} \rightarrow C_2O_4^{2-} \quad (9)$$

$$CO_2^{\cdot -} + R^{\cdot} \rightarrow RCO_2^{-} \quad (10)$$

In the presence of $(Ni^{II}L^{i})^{2+}$ the following reactions have to be added:

$$(Ni^{II}L^{i})^{2+} + CO_2^{\bullet -} \longrightarrow (Ni^{I}L^{i})^{+} + CO_2 \quad (11)$$

$$(Ni^{I}L^{i})^{+} + RBr \longrightarrow R^{\bullet} + Br^{-} + (Ni^{II}L^{i})^{2+} \quad (3)$$

$$R^{\bullet} + (Ni^{I}L^{i})^{+} \rightleftarrows (L^{i}Ni^{II}\text{–}R)^{+} \quad (12)$$

$$(L^{i}Ni^{II}\text{–}R)^{+} \xrightarrow{H^{+}} RH + (Ni^{II}L^{i})^{2+} \quad (13)$$

$$R^{\bullet} + (Ni^{II}L^{i})^{2+} \rightleftarrows (L^{i}Ni^{III}\text{–}R)^{2+} \quad (14)$$

$$R^{\bullet} + (L^{i}Ni^{III}\text{–}R)^{2+} \longrightarrow (Ni^{II}L^{i})^{2+} + R_2 \text{ or } RH + R_{-H} \quad (15)$$

$$(Ni^{I}L^{i})^{+} + (L^{i}Ni^{III}\text{–}R)^{2+} \longrightarrow (Ni^{II}L^{i})^{2+} + (L^{i}Ni^{II}\text{–}R)^{+} \quad (16)$$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Thus the nickel complex "retards" the radiolytic debromination reactions, as reactions (13) and (15) are also termination steps.

Electrochemical Studies

The complexes $(Ni^{II}L^i)^{2+}$ were electrochemically (CV experiments) reduced on a glassy carbon electrode in He-saturated aqueous solutions, at pH 10, using $NaClO_4$ as the supporting electrolyte. Cyclic voltammograms show pseudo-reversible waves which correspond to the $Ni^{II/I}L^i$ redox couples. Under the same conditions $(CH_2Br)_2C(CH_2OH)_2$ is not reduced in the voltage range required for the reduction of the $(Ni^{II}L^i)^{2+}$ complexes. When $(CH_2Br)_2C(CH_2OH)_2$ is added, at different concentrations — $(2-7) \times 10^{-3}$ M — to a solution containing 5×10^{-4} M $(Ni^{II}L^i)^{2+}$ complex, the voltammetric behavior of $(Ni^{II}L^i)^{2+}$ changes. On addition of low concentrations of $(CH_2Br)_2C(CH_2OH)_2$, the reduction current of the cathodic peak $(Ni^{II/I}L^i)$ is enhanced in comparison with the reference voltammogram of $(Ni^{II}L^i)^{2+}$ alone, whereas that of the anodic peak decreases. On further addition of substrate, the cathodic peak current increases further and no anodic current is observed on the reverse scan, showing that $(CH_2Br)_2C(CH_2OH)_2$ is efficiently reduced electrocatalytically (Figure 5).

The increase in the cathodic peak current is linearly proportional to the concentration of the substrate, suggesting that the electrochemical process is diffusion controlled. This conclusion is in agreement with the rate constants of reaction (3) in Table 1. Thus, the nickel complexes are good electrocatalysts for the reduction of $(CH_2Br)_2C(CH_2OH)_2$.

As the concentration of $(Ni^{II}L^i)^{2+}$ is expected to be low near the electrode, the electrochemical process is probably best described by reaction:

$$(Ni^{II}L^i)^{2+} + e^- \rightarrow (Ni^{I}L^i)^{+} \quad (18)$$

followed by reactions (3), (12) or (14) + (16) and (13).

Preparative electrolysis was carried out at several potentials in the presence of $(Ni^{II}L^3)^{2+}$ as the electrocatalyst. The maximum of the reduction peak for this complex, using a graphite electrode, is observed at −1.15V. The concentration ratio $RBr/(Ni^{II}L^3)^{2+}$ was 10. The results of the yield of Br^- as a function of the applied potentials are summarized in Table 3. As expected, the yield of Br^- increases upon shifting the potential cathodically.

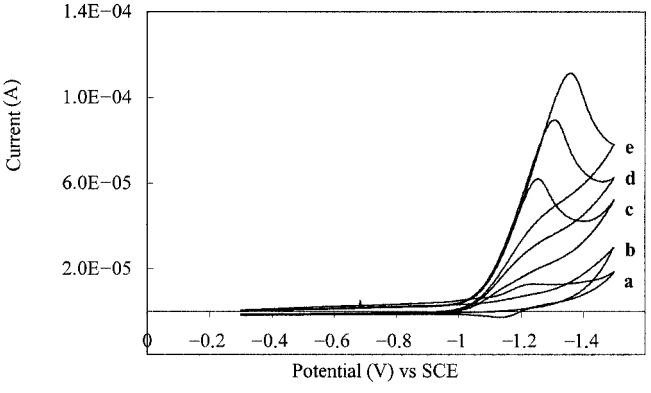

Figure 5. Cyclic voltammograms at pH 10.0 ± 0.3, supporting electrolyte 0.01 M $NaClO_4$, scan rate 50mV/s: (a) 5×10^{-4} M $(Ni^{II}L^3)^{2+}$; (b) 7×10^{-3} M $(CH_2Br)_2C(CH_2OH)_2$; (c) (a) + 3×10^{-3} M $(CH_2Br)_2C(CH_2OH)_2$; (d) (a) + 5×10^{-3} M $(CH_2Br)_2C(CH_2OH)_2$; (e) (a)+ 7×10^{-3} M $(CH_2Br)_2C(CH_2OH)_2$

Table 3. Bromide yield as function of potential; solution composition: 0.1 M $NaClO_4$, 5×10^{-4} M $(Ni^{II}L^3)^{2+}$ and 5×10^{-3} M $(CH_2Br)_2C(CH_2OH)_2$, pH 10.0 ± 0.3, He sat.; experimental error: ±20%

Potential (V)	−1.00	−1.05	−1.10	−1.15	−1.22	−1.30

Concluding Remarks

The results presented here elucidate the mechanism of the electrocatalytic debromination processes. The rate of the debromination step, reaction (3), depends mainly on the redox potential of the $Ni^{II/I}L^i$ couple. It is proposed that these nickel complexes may be bound to modified electrodes, and might be useful as electrocatalysts for the dehalogenation of aliphatic halo-organic compounds.

Surprisingly enough it is shown that formate reduces $(CH_2Br)_2C(CH_2OH)_2$ in a radical-induced catalytic process, i.e. formate acts via a hydrogen-atom-transfer mechanism.

Experimental Section

Materials: All solutions were prepared from analytical-grade chemicals and distilled water that was passed through a Millipore setup, the final resistance being above 10 MΩ.

The complexes $Ni^{II}L^i(ClO_4)_2$ (i = 1−4) were prepared according to literature procedures,[8,19] and were characterized by NMR, UV/Vis and IR spectroscopy.

***Warning*:** Transition metal perchlorates are potentially explosive and have to be handled with care.

Pulse Radiolysis: The solutions were handled by the syringe technique.[20] The experiments were carried out using the Varian 7715 linear accelerator facility of the Hebrew University of Jerusalem. The pulse duration was 0.5−1.5 μs with a 200 mA current of 5 MeV electrons. The dose per pulse was in the range of 10−30 Gy/pulse. The experimental setup and the techniques used for evaluating the results have been described in detail elsewhere.[21,22]

Electrochemical Measurements: The electrochemical experiments were carried out using an EG&G Potentiostat/Galvanostat Model 263. A three-electrode cell was used. The working electrode was a glassy carbon electrode of 3 mm diameter, the auxiliary electrode was a Pt wire and an SCE was used as the reference electrode.
The preparative electrolyses were performed at controlled potential conditions in a three-electrode cell. A graphite electrode was used as the cathode. The counter electrode was a Pt wire and the satu-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rated calomel electrode (SCE) served as a reference electrode. 0.1 M $NaClO_4$ was used as a support electrolyte. The experiments were performed with constant stirring.

Product Analysis: Quantitative analysis of bromide was performed by ion chromatography on a Hamilton-PRP-X100 column (250 × 4.1 mm^2) using a Jasco PU-980 Intelligent HPLC Pump and was optimized utilizing $H_5C_6CO_2Na$ (4 mM) as the eluent. The flow rate was 1.5 mL/min and a suppressed conductivity detector was used.

Irradiation: γ-Irradiations were carried out in a ^{60}Co γ source, Noratom, with a dose rate of about 4.0 Gy/min, which was determined by means of Fricke dosimetry, using a G value of G = 15.6.[23,24]

Acknowledgments

This study was supported in part by a grant from the Budgeting and Planning Committee of The Council of Higher Education and the Israel Atomic Energy Commission. D. M. wishes to express his thanks to Mrs. Irene Evens for her ongoing interest and support.

Design of Calixarene-Type Ligands for Second Sphere Complexation of Noble Metal Ions

Kamel Belhamel,[a] T. K. Dzung Nguyen,[b,c] Mohamed Benamor,[a] and Rainer Ludwig*[c]

Keywords: Macrocyclic ligands / Host-guest systems / Calixarenes / Gold / Solvent extraction

Macrocyclic ligands were designed according to the principle of ion recognition, synthesized and tested in their capability to extract Au^{III}. Different from other complexants which require ligand exchange prior to complexation, the reported ligands bind the complexes $AuCl_3$ and $AuCl_4^-$. With a sufficiently sized macrocyclic cavity, hydrophobic calix[6]arenes derivatized at the "lower rim' were employed for that purpose. Their ligating functionalities contain pyridino, amide or thioamide groups in order to achieve electron donor-acceptor and electrostatic host-guest interactions. We report the synthesis route and results on extraction, selectivity, kinetics and back-extraction and compare with commercial extractants. Quantitative extraction from hydrochloric acid solutions was achieved as well as over 99% recovery in back-extraction in one step each. Data on the selectivity over base metals, which are representative for the matrix in gold ores are provided. The ligands are powerful extractants for Au^{III} and show fast complexation kinetics.

Introduction

The molecular recognition of metal cations,[1] anions[2,3] and of organic molecules[4] can be achieved with macrocyclic ligands having tailor-made structures. Among the design features are complementary interactions, size compatibility, complementary coordination geometry and balanced complex stability which allows decomplexation. Calixarenes are suited to act as a molecular backbone for subsequent derivatizations to achieve these goals as shown by more than 500 papers on complexation of metal ions.[1,5−10] Solvent extraction is useful to test the molecular recognition mechanism and can be applied for chemical separations, as summarized recently.[11−16]

The complexation and extraction of anions such as oxyanions by calixarenes has been investigated to a smaller extent compared with cations. Complexation was for example achieved by incorporating amino-,[17,18] amido-,[19,20] pyridino-[21] or Schiff base groups,[22] or alternatively metal centers.[23,24]

For the complexation of Au^{III}, S-donor[25−27] or P-donor atoms[28−30] were tethered to either the lower or the upper rim of the calixarene backbone. Some of these ligands quantitatively extract Au^{III} from water. If substituted at the upper rim of a calix[4]arene, the cavity is large enough to accommodate the chloro complex. Data for the extraction of Au^{III} by these ligands at different pH values, especially from very acidic solutions, were not reported.

On the other hand, commercial extractants were investigated with respect to Au^{III}. These contain ketones or alcohols,[31] phosphane oxides,[32] amines[33,34] or thiophosphinic acids.[35,36] Some of them have disadvantages, such as low extraction power from strongly acidic solutions, difficult back-extraction and loss of reagent, low selectivity, slight solubility in water, or degradation during use. One aim of this work was to show whether or not calixarenes can compete with those commercial extractants, and which molecular structures may be suitable for that purpose.

In our previous works, we investigated the complexation abilities of various calix[4]arenes towards noble metal ions.[37] We found that calix[4]arenes bearing both acidic and amido groups at the lower rim extract Au^{III}, Pd^{II} and Pt^{IV} ions from acidic solutions, but in case of Au^{III} not quantitatively ($\log D < 2$ at optimum pH 1). Moreover, in the presence of excess sodium ions, Au^{III} is no longer extracted ($\log D < -1$). These results can be interpreted that the ligand cavity size is too small for the Au^{III} complex anion, but matches the size and coordination sphere of the interfering Na^+. In order to improve the selectivity, we changed to calix[6]arenes[38] and would like to report on the ligands, which are able to selectively extract the chloro

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim **DOI: 10.1002/ejic.200300219**

complexes of metal ions and allow the pH control of extraction and back-extraction.

As the new ligands extract Au^{III} selectively from highly acidic media, there is an environmentally friendly application in hydrometallurgy: ores can be leached with acidic thiourea solution and oxidized[39] as an alternative to cyanide leaching.[40] Sulfidic ores are also subjected to acid-leaching. The extractant in this case must both be very selective and chemically stable. Metals present in gold ores such as the one from Algeria are Fe (4.6%), Al (4.5%), Ca (2.5%), Zn (0.02%), Pb(0.02%), alkali etc. and Au (0.001%). Therefore a high selectivity for gold is required for an extractant to be applied.

Results and Discussion

Ligand Structures

Figure 1 shows the structures of the calix[6]arenes used for this study. Their preparation proceeds smoothly in high yields. Ligand **1** was not applied to extraction because of low solubility in organic solvents. This is probably caused by hydrogen bonding and improves significantly upon thionation (ligand **3**). The solubility can also be improved by changing *tert*-butyl to *tert*-octyl groups (ligand **2**), which render the molecule more hydrophobic. The ^1H and ^{13}C NMR spectra of ligands **2** and **3** show sharp signals at room temperature, indicating the predominance of one conformation. From the symmetrical spectral pattern we concluded this to be the cone[41] conformation. It is rare that uncomplexed calix[6]arenes exist in a symmetrical cone shape at room temperature, because of the molecular flexibility. Ligands **4** to **6** and many other calix[6]arenes with smaller functional groups attached to the ethereal oxygens display broadened NMR spectra with temperature-dependent presence of various conformers.

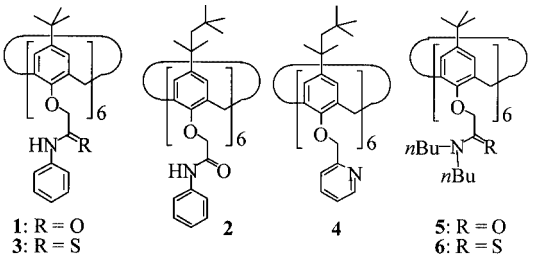

Figure 1. Structures of the investigated calixarenes and numbering

The binding of $AuCl_4^-$ is reflected by changes in the NMR spectra as confirmed for ligand **4**. Compared with the uncomplexed, protonated ligand, the -O-CH_2 and the N-CH_{py} C-signals broaden and shift, the other C_{py} signals shift as well. The C_{Ar} signals of the calixarene backbone shift to a smaller extent. In ^1H NMR spectrum, the δ = 3.3 ppm shift of equatorial Ar-CH_2-Ar protons changes to δ = 3.55 ppm upon complexation, partly off-setting the ring current. The axial and the O-CH_2 protons also shift downfield. The H_{py} signals shift as well and two of them broaden, while H_{Ar} and H_{Oct} of the calixarene backbone scarcely change upon complexation. These results indicate that $AuCl_4^-$ interacts with all the py groups inside the molecular cavity. Probably it coordinates not to all of them at the same time, but exchanges rapidly on the NMR timescale.

In the aqueous phase (>0.1 M Cl^-), the complex ion $AuCl_4^-$ exists exclusively (log β_4 = 25 [42]). The ligand cavity (0.3 × 0.8 nm at the ether oxygens,[6] or 0.5 nm as the inner circle) is large enough and retains conformational freedom to match the size of $AuCl_4^-$ (ca. 0.57 nm diameter). In order to render the complex hydrophobic and to avoid tensidic properties, the upper rim of the calixarene bears branched alkyl groups.

Extraction Properties

Figure 2 shows the distribution ratio D of Au^{III} on a logarithmic scale as a function of the pH in the aqueous phase after extraction for ligands **3**−**6**. D is defined as $c_{Au,org}/c_{Au,aq}$ at equilibrium. In order to characterize and to compare the ligands, their concentration was kept in high excess compared to the concentration of Au^{III}. The pH range was selected to allow protonation of the ligands [approx. pK_a of monomeric functional groups: 5.1 (pyridine), 0.1 (DMF),[43] −0.46 (acetanilide),[44] ≤0 (thioamide)]. pK_a Values of these macrocycles are not known. If more than one N-atom protonates under the experimental conditions (e.g. ligand **4**), this charge is neutralized by Cl^-. The conditional extraction constants take these equilibria into account, because the concentration of Cl^- is nearly constant.

Ligand **3** is characterized by a very high extractability towards Au^{III} (log $D \geq 3$, which was the upper measurement limit), over the investigated pH range. A variation of D could therefore not be observed. Ligands **4**−**6** display a pH dependency in accordance with their ability to pro-

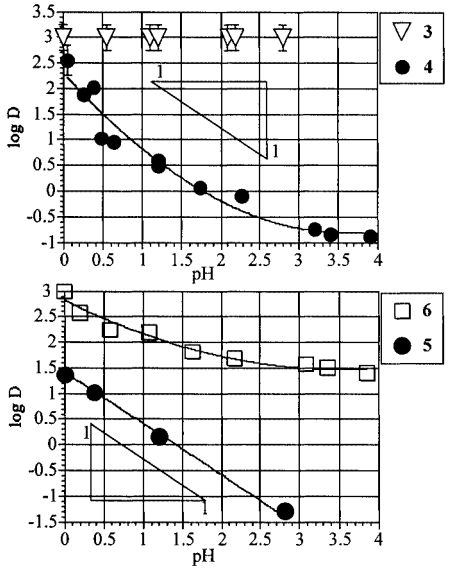

Figure 2. Effect of the pH of the aqueous phase on the extraction of Au^{III} by the ligands **3**−**6**; aq phase: 14 ppm $AuCl_3$ in HCl/NH_4Cl, pH measured at equilibrium; org. phase: 5 mM ligand in $CHCl_3$

tonate. The protonated ligands form ion-pair complexes with $AuCl_4^-$. In cases of **4** (at higher acidity) and **5** the slope of log *D* vs. pH corresponds to (−1) as expected for monoprotonation.

The high extraction power of ligands **3** and **6** is interpreted as the result of the thioamide groups. It resembles synergistic extraction systems, in which an ammonium and a sulfur-donor ligand are mixed in the organic phase and achieve better extraction than the individual ligands.[35] The coordination of the unprotonated ligands **3**, **4**, and **6** to $AuCl_4^-$ via N or S, accompanied by dissociation of one Cl^- from the complex ion (ligand exchange) is concluded from the data, which show remaining extraction power even at pH >2. The neutral ligands probably extract $AuCl_3$, similar to the neutral commercial extractants Cyanex® 301, 302 and 471X.

The capability of the ligands to extract Au^{III} from HCl solutions into the organic phase serves as a measure to estimate their complexation power, although solvent effects during extraction (dehydration, solvation and ion pairing), which were not investigated here, also play a role. Hence, the extraction constant serves as a quantitative measure, assuming comparable solvent effects in the investigated extraction systems.

Complexation Equilibria

By changing the ligand concentration, the extraction mechanism and the stoichiometry can be derived. As concluded from slope 2 in the plot of log *D* vs. log *c* in Figure 3, all investigated extractants form complexes with a stoichiometry of 1:2 (metal/ligand) at low concentrations of Au^{III}. This is interpreted as being due to Au^{III} being sandwiched by two calixarene molecules, although size and charge of one calixarene molecule should be sufficient and the Au^{III}-coordination sphere is saturated with one counterion. However, commercial extractants such as thiophosphinic acid (protonated), phosphane oxide and -sulfide extract Au^{III} also as 1:2 complexes as can be concluded from slope analysis.[35]

Taking into account the ligand protonation, we can derive the following, simplified extraction equilibrium [Equation (1)]:

$$AuCl_4^- + 2L_{(org)} + H^+ \rightleftarrows [AuCl_4^- \cdot L \cdot LH^+]_{(org)} \quad (1)$$

The extraction constants are defined as shown in Equation (2):

$$K_{ex} = \frac{\left[AuCl_4^- \cdot L \cdot LH^+\right]_{(org)}}{\left[AuCl_4^-\right]\left[H^+\right]\left[L_{(org)}\right]^2} \quad (2)$$

In order to compare the four ligands with different pH dependencies, we refer K_{ex} as conditional constants to pH = 0 as well as to the other conditions. Table 1 lists the results, obtained by fitting the experimental data in Figure 3 with Equation (3), which is derived from Equation (2). Among the investigated ligands, the amide **5** is characterized by the lowest extraction. This is, however, not a disadvantage, because 96% extracted Au^{III} at pH 0 can be further increased at higher acidity in the aqueous phase.

$$\log D = \log K_{ex} + 2 \cdot \log[c_L]_{(org)} \quad (3)$$

The stoichiometry at high loading of the organic phase was tested by contacting equal volumes of equimolar (20 mM) Au^{III} with ligand **4** at pH 0. The extraction was near quantitative. The extract was dried and subjected to elemental analysis: found C 69.1, H 7.70, N 3.73%. This corresponds to a stoichiometry of 1:1 ($[AuCl_4]^-$:$[ligandH]^+$): calcd. C 68.9, H 7.48, N 3.83%. We conclude that the stoichiometry changes as a function of metal concentration in the organic phase: From diluted solutions, a second ligand molecule can shield the 'bottom' of the 1:1 complex. At high metal concentration there is no excess of ligand available and the 1:1 complex is extracted. Figure 4 schematically depicts that complex.

Table 1. Calculated extraction constants

Ligand	log K_{ex}
3	7.45
4	8.59
5	6.0
6	8.08

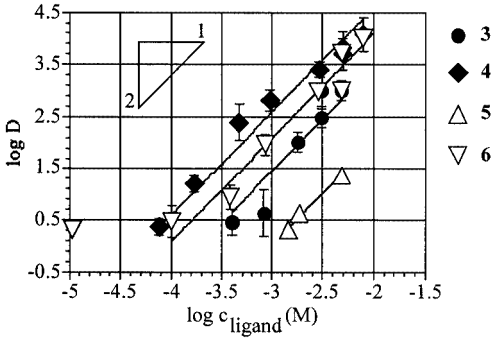

Figure 3. Estimation of the extraction power of the ligands; data are fitted by $\log D = 2 \cdot \log(c) + \log(K_{ex})$ with K_{ex} being the extraction constant at pH = 0; aq. phase: 14 ppm $AuCl_3$ in 1 M HCl; org. phase: $CHCl_3$ containing the corresponding ligand

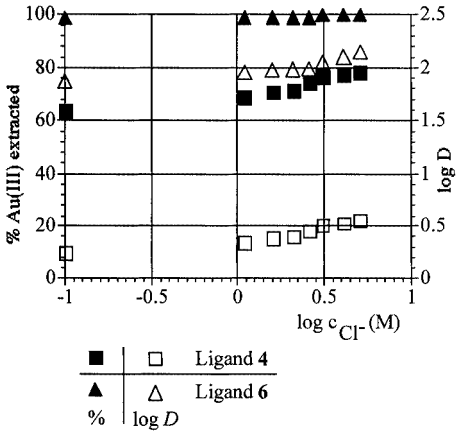

Figure 5. Influence of the chloride concentration on the extraction of Au^{III}; aq. phase: 17 ppm Au^{III} in 0.1 M HCl, up to 5 M NaCl; org. phase: $CHCl_3$ with 5 mM ligand

Variation of the chloride concentration at constant pH of the aqueous phase only causes small changes in the distribution ratio, as tested for ligands **4** and **6** (Figure 5). It is interpreted by the change of activity coefficients (salting-out effect). No change in the extraction mechanism takes place, as concluded from the slope of log D vs. log c_{Cl^-} being $<< +1$.

Back-Extraction

Ligands **4** and **5** have a pronounced pH dependency in their extraction ability (Figure 1). The organic phase, loaded with gold during extraction can therefore be regenerated by contacting with an aqueous phase of higher pH. The metal is back-extracted and, by using a small aqueous volume, enriched for a second time. The sulfur-containing ligands release their complexed metal only partly when the pH is increased. It is possible to completely recover all the metal by repeated mixing with water. More effective for the purpose of back-extraction is a competing, water-soluble ligand (e.g. thiourea, tu). Table 2 lists the results and shows that the ligands may be applicable not only for separation but also for analytical purposes, because both extraction and back-extraction are quantitative. The ligands were stable during four weeks of continuous extraction/back-extraction as concluded from the NMR spectra.

Table 2. Recovery of Au^{III} (in %) from the complexed ligands

Ligand	Buffer (pH, 5.5)	10 mM tu in H_2O	10 mM tu in 1 M HCl
3	5%	64.8%	> 99%
4	86%	89%	> 99%
5	80%	85%	> 99%
6	3.8%	0.1%	> 97%

Selectivity

Taking into account the composition from acidic ore leaching, it is important to achieve a high selectivity for Au over the other metal ions, especially Fe(III). Figure 6 depicts results obtained in competitive extraction tests with ligands **3**, **4** and **6**. Under a 30-fold excess of Fe^{III}, ligand **3** still extracts Au^{III} quantitatively, while Fe^{III} is not extracted over the whole pH range. The separation factor S_f, defined as D_{Au}/D_{Fe} is $> 10^5$. Among the investigated metal ions only Zn^{II}, which has some thiophilic character, is extracted up to 7 and 13% by ligands **4** and **6** respectively. Alkali, alkaline earth and Al^{III} ions were not extracted from 1 M HCl. The overall high selectivity is discussed in terms of the ligand design: (i) the preferred binding of anions over metal cations due to electrostatic interactions, (ii) the suitable cavity, (iii) the preference for class "B" metal ions due to the presence of S and/or aromatic π-systems, and (iv) the macrocyclic effect. On the other hand, various monodentate ligands (except quaternary amines) extract Au^{I} without selectivity over Fe^{III}: a dithiophosphinic acid (91%:99%), a thiophosphinic acid (93%:99%), a phosphinic acid (93%:99%), DEHPA (76%:99%), an 8-hydroxyquinoline (87%:70%), and a bisphosphonic acid (90%:99%) at pH 2.[36]

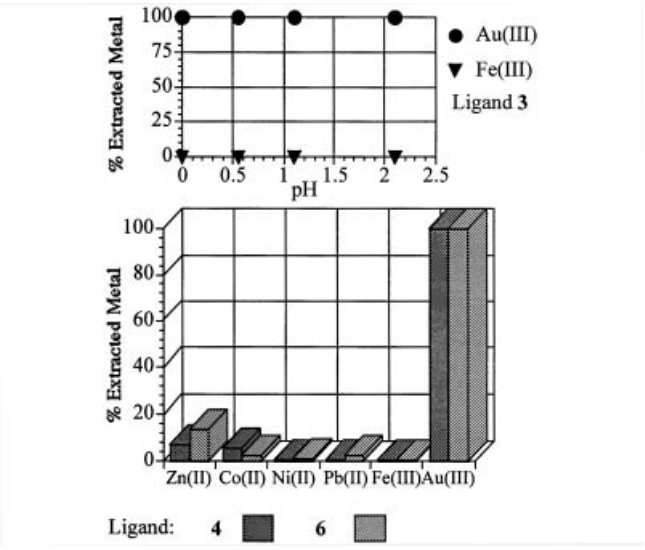

Figure 6 Selectivity of the ligands in competitive extraction; aq. phase:14 ppm Au^{III} and 2 mM Fe^{III} (upper part) or 0.1 mM of each M^{n+} (M = Zn^{2+}, Ni^{2+}, Pb^{2+}, Fe^{3+}, lower part) in 1 M HCl; org. phase: $CHCl_3$ containing 5 mM Ligand

Kinetics

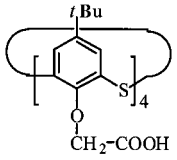
Because the ligands are completely water-insoluble, the extraction consists of complexation at the interface followed by transport into the bulk organic phase. The extraction equilibria are reached very fast as expected for ion pairing in the absence of any interfacial resistance to mass transfer: Ligands **3**−**6** extract > 98% Au within 1 min and > 99% within 5 min. The short contact times required are advantageous for analytical as well as scaled up separation purposes.

Comparison with Cation Exchangers

We tested thiacalix[4]arene **7** [45] and the analogue **8** (CH_2 instead of S)[37], which are known to extract metal ions by

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cation exchange. The distribution ratio D_{Au} changed scarcely from 0.18 to 0.28 (**7**) when the pH was varied from 2 to 0 while that for **8** was even lower. It indicates that these ligands can hardly compete with Cl^- due to the high pK_a of the acid groups and that the S-bridges in **7** are inaccessible to binding due to steric reasons.



Ligand **7**

Figure 7

Conclusion

High distribution ratios of Au^{III} are observed when ligands based on the calix[6]arene contain sulfur and/or nitrogen atoms, resulting in quantitative extraction from strongly acidic solution. Ligands containing only nitrogen as donor atoms extract Au^{III} quantitatively when they are protonated. Thioamide derivatives extract Au^{III} over a wider pH range. The loaded metal is quantitatively back-extracted by pH change or by competing ligands. The ligands have high selectivity which allows potential application in separation chemistry. Further works will be devoted to the extraction of other noble metals by these ligands and to the determination of their protonation constants.

Experimental Section

Complexation Experiments: Metal extraction was carried out batchwise with equal volumes at 298 K. The agitation speed was 54 rpm in an overhead shaker. Metal contents before and after extraction were analyzed by means of AAS (Shimadzu AA 6500) after dilution with 1 M HCl. Solutions were prepared by handling $AuCl_3$ under N_2 in a glove bag and dissolving in HCl. For the pH dependent extraction, the pH was adjusted by adding 1 M NH_3 or 8 M HCl to 0.1 M HCl solutions and mixing them with Au-stock solution. $CHCl_3$ saturated with water served as organic solvent for which reference data are available. The extractants are however, also soluble in less-polar solvents. Equilibrium pH values were measured with a combination glass electrode (Schott N42) after extraction and phase separation. The concentration of uncomplexed ligand ($c_{corrected}$) in Figures showing concentration-dependencies was calculated by taking into account the complexation. Selectivities were determined in competitive extraction. Quantitative stripping was done with 10 mM thiourea solution in 1 M HCl and a 100% mass balance was obtained. Using water or thiourea in water complete stripping was achieved for ligands **4** and **5** after three repetitions. The chemical stability was tested by repeated extraction and stripping cycles, in the course of which no decomposition of the ligands was observed. Metal complex NMR spectra (ligand **4**) were measured after contact with excess amounts of Au^{III} at pH 0 and compared with those of the protonated ligand. These concentrated organic Au^{III} complexes did not decompose. In the case of calix[4]arenes, complexed Au^{III} slowly oxidized thiocarbamoyl groups.[25]

NMR spectra were recorded at room temperature on a Bruker AC-250 instrument at 250 (^1H) or 63 MHz (^{13}C), chemical shifts are referenced to TMS and correspond to the neutral (non-protonated) ligands. H_{Ar}/C_{Ar} indicates the calixarene backbone rather than substituents if not stated otherwise. Mass spectra were measured in the EI mode (200 °C, 80 eV, 8 keV, MAT 711 instrument). Analytical TLC was carried out on dry Merck Silicagel $60F_{254}$, the R_f-values somewhat depend on the concentration. Melting points were determined on a Gallenkamp apparatus under air and are uncorrected. They were reconfirmed by DSC, measured with a Netzsch DSC 200 type calorimeter under N_2 atmosphere at 10 K/min. IR spectra were recorded on a Nicolet 5 SCX instrument with a DTGS detector. All solvents were dried and freshly distilled, chemicals were of synthesis grade. NaH (80% in oil) was washed with hexane prior to use. The air-sensitive reactions were carried out under N_2 atmosphere using transfer techniques. Yields are given for purified products. Parent calix[6]arenes were synthesized according to the literature.[46,47] Their purity was greater than 96%.

Ligand 1: The hexakis(carbomethoxy) derivative[48] of *tert*-butylcalix[6]arene (2.5 g, 1.9 mmol) was dried and treated with $(COCl)_2$ (45 equiv.) in CCl_4 under N_2 for 12 h at 75 °C. Volatiles were completely removed in vacuo, the residue dissolved in dry THF and treated with a mixture of pyridine (28 mmol) and aniline (28 mmol) under cooling with an ice bath. After stirring for 24 h at 35 °C the mixture was filtered. The residue was stirred with CH_2Cl_2/H_2O and filtered to give the pure product as a white residue, which is very insoluble in common organic solvents. Yield 87%.5,11,17,23,29,35-Hexakis(*t*ert-butyl)-37,38,39,40,41,42-hexakis(N-phenylcarbamoylmethoxy)calix[6]arene. $C_{114}H_{126}N_6O_{12}$ (M_r = 1772.21): calcd. C 77.26, H 7.17, N 4.74; found C 76.82, H 7.13, N 4.86; m.p. 277−279 °C. ^1H NMR [$CDCl_3/CD_3C(O)CD_3/CD_3OD$, 3:1:1]: δ = 1.15 (s, *t*Bu, 54 H), 3.56 and 4.76 (2 d, Ar-CH_2, each 6 H, J = 16.5 Hz), 4.33 (s, O-CH_2, 12 H), 6.69 (m, pH_{Ar}, 6 H), 6.83 (m, mH_{Ar}, 12 H), 7.10 (s, H_{Ar} of calix, 12 H), 7.31 (m, oH_{Ar}, 12 H), 8.6 (s, NH) ppm, in [D_8]THF/[D_6]ethanol the spectrum indicates a mixture of conformers frozen on the NMR timescale. IR (KBr): $\tilde{\nu}$ = 1690 cm^{-1} (νCO amide I), 753 and 692 (γCH, 5 neighboring H of aniline), 1531 (Amide II), 3396 (NH); TLC ($CHCl_3$/EtOH, 9:1) R_f = 0.82. Because of the low solubility of 1, we also synthesized the *tert*-octyl analogue and characterized it for reasons of comparison.

Ligand 2: The hexakis(carbomethoxy) derivative of *tert*-octylcalix-[6]arene[47] (3.2 g, 1.9 mmol) was treated with $(COCl)_2$ (45 equiv.) in CCl_4 under N_2 for 8 h at 75 °C. Volatiles were completely removed under reduced N_2 pressure, the residue was dissolved in dry THF and treated with a mixture of triethylamine (23 mmol) and aniline (23 mmol) under cooling with an ice bath. The mixture was filtered after stirring for 24 h at 38 °C. The filtrate was evaporated in vacuo, dissolved in CH_2Cl_2, washed 4 times with 1 M HCl, dried and crystallized by addition of EtOH to a CH_2Cl_2 solution. Yield 83%.5,11,17,23,29,35-Hexakis(*tert*-octyl)-37,38,39,40,41,42-hexakis(*N*-phenylcarbamoylmethoxy)calix[6]arene $C_{138}H_{174}N_6O_{12}$ (M_r = 2108.8): calcd. C 78.59, H 8.32, N 3.99; found C 77.88, H 8.24, N 3.76; m.p. 218−220 °C (dec.); DSC: 25.8 J/g at m.p., endothermic phase transition at 167 °C (−18.2 J/g). This is interpreted as the break-up of hydrogen bonds in the solid state (intramolecular H-bonding was concluded from the NMR spectroscopy), and conformational change from the symmetrical to an unsymmetrical, energetically favoured conformation. The ^1H and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

^{13}C spectra ($CDCl_3$) are characterized by sharp signals, this indicates rigidified and symmetrical conformation (intramolecular H-bonding), while calix[6]arenes with smaller O-substituents usually show broadened peaks in the NMR spectra at room temp. due to conformational flexibility, as do the investigated thioamides. ^1H NMR: δ = 0.72 (s, *t*Oct, 54 H), 1.12 (s, *t*Oct, 36 H), 1.60 (s, *t*Oct, 12 H), 3.57 and 5.03 (2 d, Ar-CH_2, each H, J = 16.5 Hz), 4.31 (s, O-CH_2, 2 H), 6.83 (*m*, *p*$H_{aniline}$, 3 H), 7.08 (s, H_{Ar} of calixarene backbone, 2 H), 7.21 (*o*$H_{aniline}$, 2 H), 8.66 (s, NH, 1 H) ppm, ^{13}C NMR: δ = 29.7 (Ar-CH_2), 31.3 (1,1 dimethyl of *t*Oct), 31.8 (3 × CH_3 of *t*Oct), 32.4 (C_3 of *t*Oct), 38.1 (C_1 of *t*Oct), 57.2 (CH_2 of *t*Oct), 72.0 (O-CH_2), 120.8 (*o*C_{Ar} of aniline), 124.3 (*p*C_{Ar} of aniline), 127.4 (C_{Ar}-H of calix), 128.4 (*m*C_{Ar} of aniline), 131.6 (***C***$_{Ar}$-CH_2), 136.8 (C_{Ar}-NH), 146.0 (C_{Ar}-*t*Oct), 151.1 (C_{Ar}-O), 167.3 (CO) ppm. IR (KBr): $\tilde{\nu}$ = 1691 cm^{-1} (νCO amide I), 752 and 691 (γCH, 5 neighboring H's of aniline), 1533 (Amide II), 3391 (NH); TLC (CH_2Cl_2) R_f = 0.30 (tailing), ($CHCl_3$/EtOH, 9:1) R_f = 0.86.

Ligand 3: The precursor **1** (1 g, 0.56 mmol) was dissolved in dry toluene and treated with 2,4-bis(4-methoxyphenyl)-1,3-dithia-2,4-diphosphetane-2,4-disulfide (4 mmol) at 90 °C for 40 h. After cooling, the mixture was filtered and the solvents evaporated. The product precipitated from the residue upon adding MeOH and was recrystallized twice by addition of MeOH to a CH_2Cl_2 solution. Yield 68%. No interfering side products are formed during thionation reactions even in less polar solvents. 5,11,17,23,29,35-Hexakis(*tert*-butyl)-37,38,39,40,41,42-hexakis(*N*-phenylthiocarbamoylmethoxy)calix[6]arene, $C_{114}H_{126}N_6O_6S_6$ (M_r = 1868.6) calcd. C 73.27, H 6.8, N 4.50, S 10.28; found C 72.02, H 6.86, N 4.35, S 9.8; m.p. 240−242 °C (dec.). In the NMR spectra ($CDCl_3$) chemical shifts in *italics* indicate some of the characteristic changes upon thionation. ^1H NMR: δ = 1.12 (s, 54 H, *t*Bu), 3.62 and 4.41 (2 d, J = 16.25 Hz, 6 H each, CH_2-Ar), 4.5 (s, -O-CH_2, 12 H), 7.0 (s, 12 H, H_{Ar} of calix backbone), 7.13 (m, 18 H, *m* and *p*H_{Ar}), 7.53 (d, 12 H, *o*H_{Ar}), 9.8 (s, 6 H, NH) ppm. ^{13}C NMR: δ = 29.9 (CH_2-Ar), 31.3 (*t*Bu), 34.2 (quart C), *80.0* (-O-CH_2), 123.0 (*o*C_{Ar} of aniline), 126.6 (*p*C_{Ar} of aniline), 126.9 (C_{Ar}−H of calix), 128.6 (*m*C_{Ar} of aniline), 131.3 (*C*$_{Ar}$-CH_2), 137.3 (C_{Ar}-NH), 146.9 (C_{Ar}-*t*Oct), 151.8 (C_{Ar}-O), *194.4* (CS) ppm, no CO. IR (KBr): $\tilde{\nu}$ = 1394 cm^{-1} (thioamide I), 997 (thioamide IV), disappeared 1690; TLC ($CHCl_3$/EtOH, 9:1) R_f = 0.92.

Ligand 4: *tert*-Octylcalix[6]arene (6 g, 4.6 mmol) was deprotonated with NaH (18 equiv.) in dry THF for 12 h at 60 °C under N_2. A filtered mixture of triethylamine (18 equiv., 11.5 mL) and 2-picolyl chloride hydrochloride (9 equiv., 76.8 g), which had been stirred for 3 h, was added dropwise to the grey suspension under N_2 with ice-cooling. The reaction was completed by warming to 50 °C for 48 h, quenched with EtOH after cooling and the solvents evaporated. The residue was dissolved in CH_2Cl_2/EtOH (9:1), washed with brine and 0.1 M HCl, filtered through a Whatman phase separator and crystallized from hexane. Yield 54%. The *tert*-butylcalix[6]-arene analogue was described earlier.[49] 5,11,17,23,29,35-Hexakis-(*tert*-octyl)-37,38,39,40,41,42-hexakis[(2-pyridylmethyl)oxy]-calix[6]arene $C_{126}H_{162}N_6O_6$ (M_r = 1856.62): calcd. C 81.5, H 8.8, N 4.53; found C 81.60, H 8.79, N 3.98; MS (EI), [M^+], 1856 (L); m.p. 243−245 °C. The ^1H NMR spectroscopy ($CDCl_3$): broadened peaks of Ar-CH_2, O-CH_2 and H_{Ar} indicated conformational flexibility, adding CD_3OD (30%) stabilizes a mixture of conformational isomers. ^1H NMR: δ = 0.62 (s, 54H Me of *t*Oct), 1.29 (s, 36 H, dimethyl), 1.77 (s, 12 H, CH_2 of *t*Oct), 3.49 (br., 6 H, Ar-CH_2), 4.0 to 5.0 (br., 18 H, Ar-CH_2 and O-CH_2), 6.79 (s, 6 H, H_{py}), 6.9 to 7.1 (br. s, 24 H, H_{calix} and H_{py}), 8.24 [br. s, 6 H, H_{py}(N-CH)] ppm. ^{13}C NMR: δ = 31.5 (1,1 dimethyl of *t*Oct), 32.1 (3 × CH_3 of *t*Oct), 32.2 (Ar-CH_2), 32.4 (C_3 of *t*Oct), 37.9 (C_1 of *t*Oct), 56.9 (CH_2 of *t*Oct), 75.3 (O-CH_2), 122.0 (*m*C_{py}), 126.5 (C_{Ar}-H of calix), 132.6 (*C*$_{Ar}$-CH_2), 136.6 (*m*C_{py}), 140.2 (*p*C_{py}), 145.3(N-CH_{py}), 147.9 (C_{Ar}-*t*Oct), 151.8 (C_{Ar}-O), 157.9 (CH_2-*C*$_{py}$) ppm. IR (KBr): new (py) 753, 994, 1032, 1147, 1435 cm^{-1}; TLC ($CHCl_3$/EtOH, 9:1) R_f = 0.63 (1 spot); (CH_2Cl_2) R_f = 0 (no starting material).

Ligand 5: The hexakis(carbomethoxy) derivative of *tert*-butylcalix-[6]arene[48] (3 g, 2.27 mmol) was dried and treated with $(COCl)_2$ (60 equiv.) in CCl_4 under N_2 for 12 h at 75 °C. Volatiles were completely removed under reduced N_2 pressure, the residue dissolved in dry THF and treated with a mixture of triethylamine (46 mmol) and di-*n*butylamine (46 mmol) under cooling with an ice bath. After stirring for 12 at 30 °C the mixture was filtered, evaporated to dryness, dissolved in CH_2Cl_2 and washed five times with 1 M HCl. The product crystallized from MeOH and was dried in vacuo at 80 °C. Yield 90%. 5,11,17,23,29,35-Hexaakis(*tert*-butyl)-37,38,39,40,41,42-hexakis[(*N*,*N*-di-*n*butylcarbamoylmethoxy)-calix[6]arene, $C_{126}H_{198}N_6O_{12}$ (M_r = 1988.9): calcd. C 76.08, H 10.03, N 4.23; found C 75.74, H 9.72, N 4.06; m.p. 197−199 °C; DSC: 36 J/g. Within the NMR spectra ($CDCl_3$), the presence of two separate, equal H_{Ar} and two -O-CH_2-signals are interpreted in terms of two conformations present, probably due to H-bonding. The structurally similar *N*,*N*-diethylamide derivative also exists as a mixture of conformers at 298 K in $CDCl_3$.[50] In the case of ligand **5**, the more bulky groups may restrict the number of co-existing conformers to two. ^1H NMR: δ = 0.70 (br. s), 0.95 (q), 1.34 (m), 1.62 (br. s), (Σ23 H); 3.34 and 3.63 (m, 4 H), 3.9−5.1 (br. m, O-CH_2 and CH_2-Ar, 4 H), 7.18 and 7.49 (2 s, H_{Ar}, 1H each) ppm. ^{13}C NMR: δ = 13.8 (CH_3 of *n*Bu), 20.0 and 20.2 (*n*Bu), 29.7 (Ar−CH_2-Ar), 31.1 (*t*Bu), 31.5 (*n*Bu), 34.0 (quart C of *t*Bu), 45.5 (N−CH_2), 71.6 (-O-CH_2), C_{Ar}: 124.7, 127.1, 133.2, 146.4, 151.9; 168.0 (CO) ppm. IR (KBr):1646 cm^{-1} (νCO), no 1755 (COOH); TLC ($CHCl_3$/EtOH 9:1) R_f = 0.28 (characteristic short tailing).

Ligand 6: The ligand **5** (0.5 g, 0.25 mmol) was dissolved in dry toluene and treated with 2,4-bis(4-methoxyphenyl)-1,3-dithia-2,4-diphosphetane-2,4-disulfide (2.5 mmol) at 85 °C for 24 h. After cooling, the mixture was filtered and the solvents evaporated. The product was precipitated from hot acetone by adding 3% water, and was crystallized twice from hexane and washed with hot MeOH/H_2O (1:1). Yield 72%. 5,11,17,23,29,35-Hexakis(*tert*-butyl)-37,38,39,40,41,42-hexakis[(*N*,*N*-di-*n*butylthiocarbamoylmethoxy)-calix[6]arene, $C_{126}H_{198}N_6O_6S_6$ (M_r 2085.3): calcd. C 72.57, H 9.57, N 4.03, S 9.21; found C 71.99, H 9.27, N 3.87, S 8.82; m.p. 171−173 °C. In the NMR spectra ($CDCl_3$) chemical shifts in *italics* indicate some of the characteristic changes upon thionation. Similar to ligand **5**, a conformational mixture exists at 298 K. ^1H NMR: δ = 0.80 (d), 0.96 (s), 1.40 (m), 1.80 (br), (Σ138 H), 2.88 (br. d) and 3.43 (d, Ar-CH_2), 3.9 (br. m, N-CH_2), 4.75−5.05 (br., O-CH_2 and Ar-CH_2) (Σ48 H), H_{Ar}: 6.4, 6.53, 7.28, 7.55 (Σ12 H) ppm. ^{13}C NMR: δ = 13.7 (CH_3 of *n*Bu), 20.2 (*n*Bu), 27.8 (Ar−CH_2-Ar), 31.6 (*t*Bu), 32.0 (*n*Bu), 34.1 (quart C of *t*Bu), *53.5* (N-CH_2), *79.2* (-O-CH_2), 123.1 (C_{Ar}), 128.3 (C_{Ar}), 132.3 (C_{Ar}), 145.4 (C_{Ar}), 153.3 (C_{Ar}), *195.2* (CS), IR (KBr): νCO disappeared, new 1505 cm^{-1} (νCS I), 990 (νCS IV), TLC ($CHCl_3$/EtOH, 9:1) R_f = 0.95 (one spot, no partially substituted material), (CH_2Cl_2) R_f = 0.74 (1 spot, no thionation reagent).

Acknowledgments

A fruitful discussion on pyridine-type calixarenes and their spectral properties with Ass. Prof. K. Ohto (Saga Univ., Japan) is appreciated. We thank Prof. H. Hartl and Ms. Friese (FU Berlin) for the

Synthesis and Structures of Fe^{III} Complexes Bridged by Cyanorhenium Clusters

Seon-Mi Park,[a] Youngmee Kim,[a] and Sung-Jin Kim*[a]

Keywords: Cluster compounds / Nanostructures / Magnetic properties / Rhenium / Iron

The reaction of FeCl(L1) and FeCl(L2) [L1 = bis(3-salicylideneaminopropyl)amine, L2 = bis(3-salicylideneaminopropyl)-methylamine] with the Re_6 clusters $[Re_6Q_8(CN)_6]^{4-}$ (Q = Se, Te) led to the formation of the nanomolecular (≈2.5 nm) compounds $[(CN)_2Re_6Se_8\{(CN)Fe(L1)\}_4]\cdot 7H_2O$ (**1**) and $[(CN)_2Re_6Te_8\{(CN)Fe(L2)\}_4]\cdot 4CH_3CN\cdot 4H_2O$ (**2**). Both compounds were characterized by single-crystal X-ray diffraction analysis. Compound **1** crystallizes in the triclinic space group $P\bar{1}$ with a = 12.2822(10), b = 14.2524(10), c = 15.8474(10) Å, α = 106.093(10)°, β = 101.992(10)°, γ = 92.438(10)°, and Z = 1. Compound **2** crystallizes in the orthorhombic space group *Pbca* with a = 19.3024(2), b = 16.8134(3), c = 35.9842(6) Å, and Z = 4. In these two compounds, only four pentadentate compartments are bonded to the Re_6 cluster for charge balancing. The magnetic-susceptibility data show that there is no evidence for interactions between Fe^{III} ions via the central Re_6 cluster in either compound. The observed effective magnetic moments suggest that there are low-spin Fe^{III} ions and high-spin Fe^{III} ions mixed in each compound.

Introduction

Over the past decade, molecule-based magnetic materials have been investigated extensively in the fields of physics and chemistry. A major target in these fields is to obtain discrete polynuclear compounds with high-spin ground states.[1−5] The well-known high-spin molecules were prepared by connecting a Prussian-blue-like hexacyanometallate and multidentate metal complexes via metal-CN-metal bonding;[6−17] the bridging cyanide ligand plays an important role in the spin interaction between metals.

Recently, water-soluble hexanuclear clusters $[Re_6Q_8(CN)_6]^{4-}$ (Q = S, Se, Te), which are an extended analogue of the Prussian-blue cluster $[Fe(CN)_6]^{4-}$, have been used to synthesize extended solid frameworks.[18−22] In these extended solid frameworks the metal ions are bridged by Re_6 clusters instead of Fe^{II} ions to form bigger cubic cavities which can include plenty of small solvent molecules as well as metal ions.[23−30] In a recent study we synthesized two- and three-dimensional frameworks containing $Mn(salen)^+$ units bridged by Re_6 clusters.[31,32] We found that changing the chalcogen Q in a $[Re_6Q_8(CN)_6]^{4-}$ cluster can control the dimensionality of infinite frameworks. We also synthesized discrete molecules, containing manganese porphyrin complexes instead of extended frameworks, which show a high catalytic activity in the epoxidation reaction of olefins by iodosylbenzene.[33] These results demonstrate that multinuclear metal clusters are good candidates as building blocks in the preparation of new heterogeneous catalysts and high-spin nanomolecules.

We now report new discrete nanomolecules containing high-spin Fe^{III} complexes linked to the Re_6 clusters $[(CN)_2Re_6Se_8\{(CN)Fe^{III}(L1)\}_4]\cdot 7H_2O$ and $[(CN)_2Re_6Te_8\{(CN)Fe^{III}(L2)\}_4]\cdot 4CH_3CN\cdot 4H_2O$ [L1 = bis(3-salicylideneaminopropyl)amine, L2 = bis(3-salicylideneaminopropyl)-methylamine]. These molecules can be described as expanded versions of $[Fe^{II}\{CNFe^{III}(L2)\}_6]Cl_2$.[16,17]

Results and Discussion

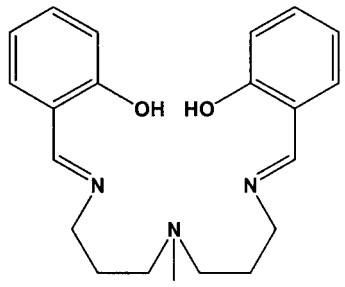
Synthesis and Characterization

Recently, a mixed-valence, mixed-spin, Prussian-blue-like heptanuclear complex was synthesized that contains a central low-spin S = 0 Fe^{II} ion linked to six high-spin S = 5/2 $Fe^{III}(L)$ species through cyanide bridges[16,17] [Equation (1)].

$$K_4[Fe(CN)_6] + Fe(L2)Cl \rightarrow [Fe^{II}\{CNFe^{III}(L2)\}_6]Cl_2 \quad (1)$$

The pentadentate ligand L2 [bis(3-salycylideneaminopropyl)methylamine], shown below, was used in this reaction.

[a] Department of Chemistry, Ewha Women's University, Seoul 120-750, Korea
Fax: (internat.) + 82-2/3277-2384
E-mail: sjkim@ewha.ac.kr



To obtain larger nanomolecules with similar pentadentate ligands, we used a face-capped octahedral Re_6 cluster ion instead of an Fe^{II} central ion. A similar reaction results in enlarged nanomolecules [Equation (2)].

$$Na_4[Re_6Q_8(CN)_6] + Fe(L1 \text{ or } L2)Cl \rightarrow [(CN)_2Re_6Q_8\{(CN)Fe(L1 \text{ or } L2)\}_4] \quad (2)$$

Nanomolecules $[(CN)_2Re_6Se_8\{(CN)Fe(L1)\}_4]\cdot 7H_2O$ (**1**) and $[(CN)_2Re_6Te_8\{(CN)Fe(L2)\}_4]\cdot 4CH_3CN\cdot 4H_2O$ (**2**) were prepared by a direct diffusion technique in which aqueous solutions of $Na_4[Re_6Se_8(CN)_6]$ and $Na_4[Re_6Te_8(CN)_6]$ were carefully layered with ethanol and acetonitrile solutions of FeCl(L1) and FeCl(L2), respectively. Single crystals of **1** and **2** were obtained within three days. We also tried to prepare $[(CN)_2Re_6Se_8\{(CN)Fe(L2)\}_4]$ and $[(CN)_2Re_6Te_8\{(CN)Fe(L1)\}_4]$, but we couldn't obtain suitable single crystals for a single crystal study. The IR spectra of **1** and **2** show all the peaks expected for the L1 and L2 ligand together with two peaks at 2117 and 2130 cm^{-1} originating from the vibrations of bridging and non-bridging cyanides.

Structure Description

$[(CN)_2Re_6Se_8\{(CN)Fe(L1)\}_4]\cdot 7H_2O$ (1, L1 = $C_{20}H_{23}N_3O_2$)

The asymmetric unit contains half an Re_6Se_8 cluster, two Fe(L1) units, and 3.5 water solvent molecules in a triclinic cell with $Z = 1$. A crystallographic center of inversion is located at the center of a Re_6Se_8 cluster. The structure of a complete molecule is shown in Figure 1. Four cyano groups of the Re_6Se_8 cluster are linked to the Fe(L1) unit with Fe−N(cyano) distances of 2.125(9) and 2.146(9) Å. The C(cyano)−N(cyano)−Fe angles are 154.6(9) and 154.1(9)°. The two oxygen atoms of the hydroxyl groups of the pentadentate ligand in $Fe(C_{20}H_{23}N_3O_2)$ unit are coordinated to the Fe^{III} ion, and are trans to the cyano group of the Re_6Se_8 cluster with O(hydroxy)−Fe−N(cyano) angles of 177.9(4)° and 177.6(4)°. Two salicylate groups are perpendicular to each other in linked Fe(L1) units. The distance between two Fe^{III} ions in the trans positions of the Re_6Se_8 cluster is around 14.1 Å. The largest distance between two atoms within compound **1** is over 2.5 nm, making it a nanosized molecule.

$[(CN)_2Re_6Te_8\{(CN)Fe(L2)\}_4]\cdot 4CH_3CN\cdot 4H_2O$ [2; L2 = $C_{20}H_{23}(NCH_3)N_2O_2$]

The asymmetric unit contains half an Re_6Te_8 cluster, two Fe(L2) units, and two acetonitrile and water solvent molecules in the space group *Pbca* with $Z = 4$. The complete

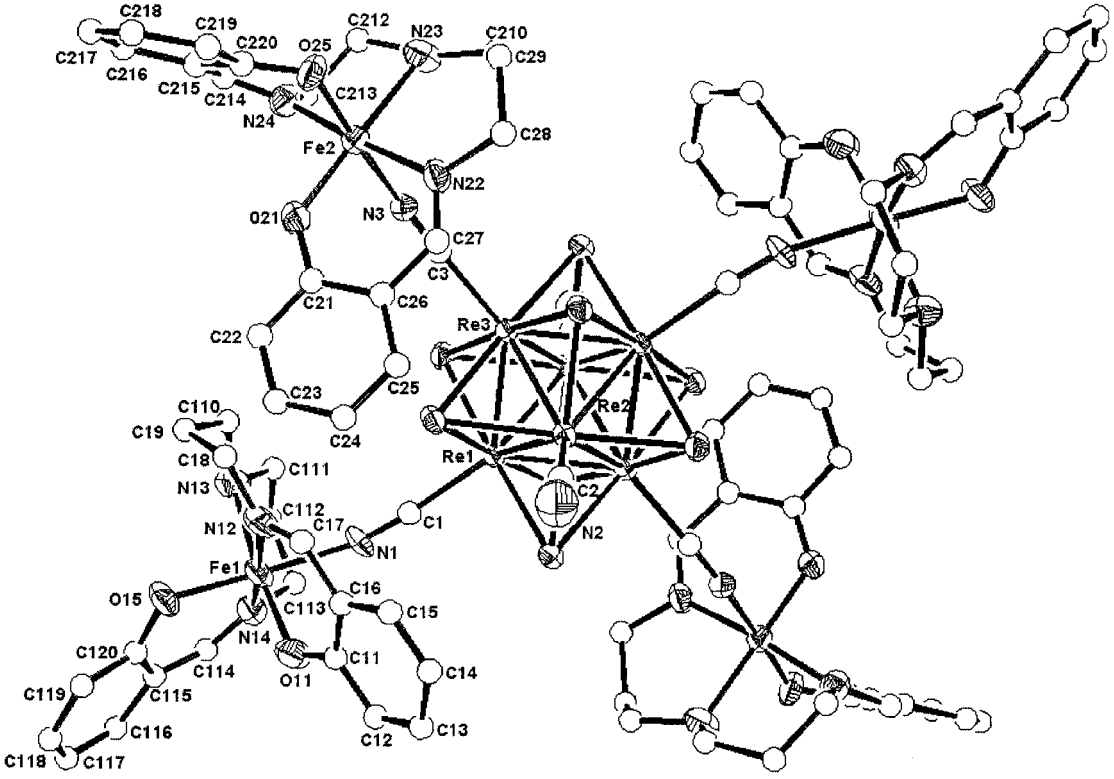


Figure 1. The structure of $[(CN)_2Re_6Se_8\{(CN)Fe(L1)\}_4]$; all hydrogen atoms have been omitted for clarity

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structure is generated by the symmetry operation ($-x$, $-y + 1$, $-z + 1$). Figure 2 shows a whole molecule with Fe−N(cyano) distances of 2.070(10) and 2.070(9) Å. In contrast to compound **1**, The C(cyano)−N(cyano)−Fe angles in compound **2** are almost linear at 175.1(10)° and 177.8(11)°. The O(hydroxy)−Fe−N(cyano) angles are 177.9(4)° and 179.0(4)°. The distance between two Fe^{III} ions in the trans positions of the Re_6Te_8 cluster is around 14.4 Å. The largest distance between two atoms within the compound **2** is over 2.4 nm.

In the Re_6 cluster-centered compounds **1** and **2** the Re_6 clusters are linked to only four Fe^{III} complexes, whereas in the Fe^{II}-centered compound there are six Fe^{III} complexes attached in $[Fe^{II}\{CNFe^{III}(L2)\}_6]Cl_2$. The Re_6 cluster-centered compounds do not need any cations or anions to balance the charge while the Fe^{II}-centered compound contains two chloro anions. It is known that the Fe−N distance of low-spin complexes is shorter(ca. 1.9 Å) than that of high-spin complexes (ca. 2.2 Å). The Fe−N distances observed in the title compounds are between those reported in high-spin Fe^{III} complexes and low-spin Fe^{III} complexes.[40,41] In the Re_6 cluster-centered molecule, the distance between Fe^{III} ions through the central Re_6 cluster is about 14 Å, which is much longer than in the Fe^{II}-containing molecule (ca. 10 Å). The size of the Re_6 cluster-centered molecule is more than 2.5 nm, as compared to that of the Fe^{II}-centered molecule (2 nm).

Magnetic Properties

The temperature-dependent magnetic data of both compounds **1** and **2** are shown in Figure 3. The magnetic susceptibility data of both **1** and **2** can be clearly described using the Curie−Weiss law $\chi = \chi_o + C/(T - \theta)$. At room temperature, the effective magnetic moments of compounds **1** and **2** are 9.97 and 9.91 μ_B, respectively. These values are close to the value for a molecule with two uncoupled high-spin and two uncoupled low-spin Fe^{III} ions. There is no evidence of magnetic exchange coupling between Fe^{III} ions via the central Re_6 cluster in either compound, while the magnetic properties of the Fe^{II} ion-centered compound revealed a ferromagnetic interaction between the high-spin Fe^{III} ions of six ligands around Fe^{II}. The reason for the absence of magnetic coupling between Fe^{III} ligands in the title compounds is because the central diamagnetic Re_6 cluster core is too large to mediate magnetic interactions.

In summary, we have synthesized new Re_6 cluster-centered nanosize molecules with four Fe^{III} complexes connected to $[Re_6Q_8]^{2+}$ (Q = Se, Te) clusters. This demonstrates that an Re_6-type multinuclear metal cluster can be an effective basis to make new molecules by bridging multidentate

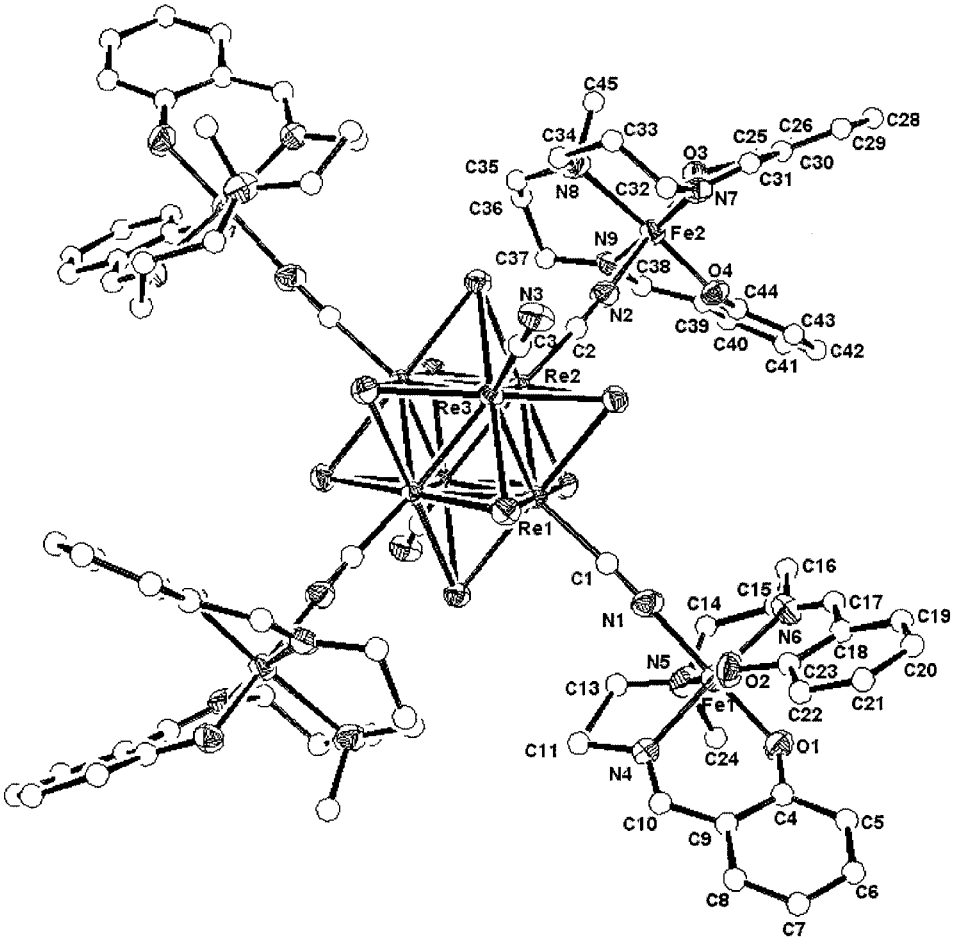

Figure 2. The structure of $[(CN)_2Re_6Te_8\{(CN)Fe(L2)\}_4]$; all hydrogen atoms have been omitted for clarity

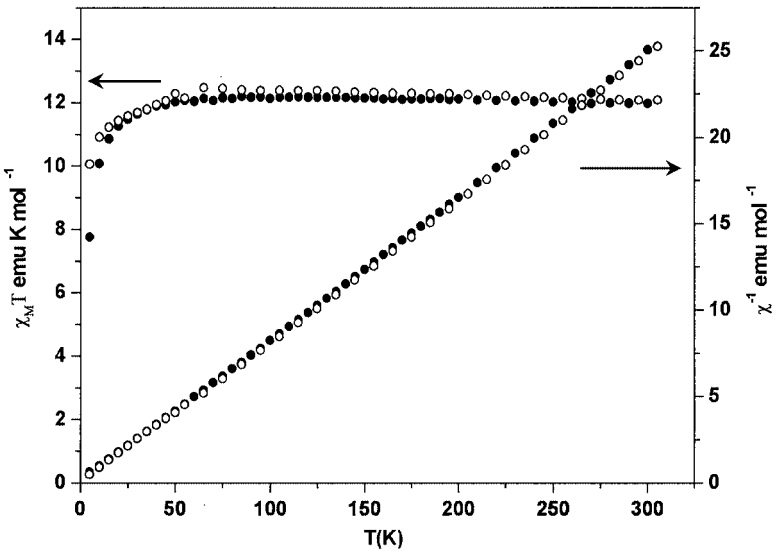

Figure 3. The magnetic susceptibility data and reciprocal susceptibility data of compound **1** (filled circle) and compound **2** (open circle) as a function of temperature

ligands. These results also suggest that if we choose proper magnetic elements for the similar M_6-type (M = transition metals such as Mo, Nb, W) multinuclear metal clusters, magnetic coupling between the M_6-type cluster and the ligand metal complex could be achieved.

Experimental Section

General Remarks: All experimental manipulations were performed in air. The compounds FeCl(L1), FeCl(L2), and $Na_4[Re_6Q_8(CN)_6]$ (Q = Se, Te) were prepared as described previously.[11,18] Other reagents were purchased from Aldrich and used as received. IR spectra were measured on a BIO RAD FTS 135 spectrometer as KBr pellets. Elemental analysis for carbon, nitrogen, and hydrogen was carried by using an EA1108 (Carlo Erba Instrument, Italy). Magnetic susceptibility data were obtained with an MPMS5 Quantum Design SQUID magnetometer. The magnetic measurements on single crystals were carried out under increasing temperatures (5−300 K) with a 5000 G applied field.

FeCl(L1): A typical preparation produced black crystals (yield: 75%). $C_{20}H_{23}ClFeN_3O_2$ (428.7): calcd. C 56.03, H 5.40, N 9.80; found C 55.92, H 5.60, N 9.94.

FeCl(L2): A typical preparation produced black crystals (yield: 78%). $C_{21}H_{25}ClFeN_3O_2$ (442.7): calcd. C 57.99, H 5.82, N 9.56; found C 56.97, H 5.69, N 9.49.

$[(CN)_2Re_6Se_8\{(CN)Fe(L1)\}_4]\cdot 7H_2O$ (1): Dark purple rod-type crystals were obtained by the direct diffusion technique. A water solution of $Na_4[Re_6Se_8(CN)_6]$ was carefully layered with an ethanol solution of FeCl(L1). IR (KBr): ν(CN) 2117 cm^{-1}.

$C_{86}H_{88}Fe_4N_{18}O_{15}Re_6Se_8$ (3586.0): calcd. C 29.34, H 2.65, N 7.11; found C 29.70, H 2.67, N 7.25.

$[(CN)_2Re_6Te_8\{(CN)Fe(L2)\}_4]\cdot 4CH_3CN\cdot 4H_2O$ (2): Dark purple plate crystals were also obtained by the direct diffusion technique. A water solution of $Na_4[Re_6Te_8(CN)_6]$ was carefully layered with an acetonitrile solution of FeCl(L2). IR (KBr): ν(CN) 2117 cm^{-1}. $C_{98}H_{124}Fe_4N_{22}O_{12}Re_6Te_8$ (4163.6): calcd. C 27.44, H 2.51, N 6.36; found C 27.55, H 2.57, N 6.43.

X-ray Crystallographic Study: The X-ray diffraction data for compound **1** were collected on an Enraf−Nonius CAD-4 Mach3 diffractometer equipped with a monochromator in the Mo-K_α (λ = 0.71073 Å) incident beam. The crystal was mounted on a glass fiber. A description of the data collection techniques for this diffractometer has been given before.[34] The final cell parameters for **1** were obtained from least-squares fit to 25 reflections in the range $9.44 \leq \theta \leq 10.62°$. Intensities were corrected for Lorentz and polarization effects but not for absorption. The crystal structure was determined by direct methods and Fourier techniques. All the calculations were performed on an IBM Pentium computer using SHELXS-97 and SHELXL-97, and atomic scattering factors for all non-hydrogen atoms were supplied by SHELXS-97.[35] All hydrogen atoms were located in the calculated positions. The molecular structure was drawn with the Ortep-3 for Windows program.[36] The diffraction data for compound **2** were collected on a Nonius Kappa-CCD diffractometer using Mo-K_α (λ = 0.71073 Å) radiation.[37] The crystals were mounted on glass fibers in epoxy resin. The CCD data were integrated and scaled using the DENZO-SMN software package,[38] and the structures were solved and refined by using SHEXTL V5.0.[39] All non-hydrogen atoms were located in the calculated positions. The crystallographic data for compounds **1** and **2** are listed in Table 1.

CCDC-206671 (**1**) and -206672 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows the structures of two new types of calix[4]arene complexes obtained by deprotonating the calixarene with an alkaline earth metal, or potassium metal, followed by reaction with selected titanium(IV) compounds. The alkaline earth metals form dimeric alkaline earth-titanium(IV) complexes, containing at the core a rhombus of alternating alkaline earth metal and μ_3-oxo centres. Each oxo centre of the rhombic core is the apical ligand of a square-pyramidal titanium(IV) centre, whose basal plane donors are the four phenolate oxygen atoms from a calix[4]arene arrayed in the symmetrical cone conformation. Terminal methanol ligands surround the alkaline earth centres, and simultaneously hydrogen-bond to the adjacent phenolate oxygen atoms. Potassium reacts with calix[4]arene and the titanium(IV) source to give a monomeric mixed potassium-titanium complex. The potassium cation binds within the π-basic calix[4]arene cavity, whilst the titanium centre is octahedrally complexed in the *exo* position by four phenolate and one acetylacetonate ligands. A solution pathway exists for the interconversion between the potassium-titanium calix[4]arene monomer and the alkaline earth-titanium dimers, where the product is dictated by the choice of solvent. Details are discussed in the article by R. N. Lamb et al. on p. 4153 ff.

Keywords: Unsymmetrical binuclear metalloenzymes / Superoxide dismutase / Purple acid phosphatases / Catechol oxidases / Model complexes

This microreview describes the structures, properties and mechanisms of three selected bimetallic enzymes: Cu-Zn superoxide dismutase (SOD), purple acid phosphatases (PAPs) and catechol oxidases (COs). The relevance of the unsymmetrical structures in the binucleating environment to the reaction mechanism and the respective roles of each metal center of these enzymes are discussed. Relevant model compounds are also considered.

Introduction

The active site of numerous homobinuclear and heterobinuclear metalloenzymes contains two metal centers, bridged by oxo, hydroxo, carboxylate or imidazolate groups. Even for homobinuclear sites the two metal centers usually reside in chemically different environments, an asymmetry that may also involve the coordination numbers and the geometry of the metal centers. One, two or three bridging groups may be encountered, for example: one imidazolate bridge in Cu-Zn superoxide dismutase, one oxygen and one carboxylate in the diiron enzyme ribonucleotide reductase B_2, one hydroxy and two carboxylates in the diiron enzyme deoxyhemerythrin.

One challenging problem presented by these binuclear enzymes and their models is to elucidate the overall catalytic mechanism and to identify the roles of the metal ions. These may include:

– activation (fixation) of the substrate,

– stabilization of a transition state by metal ion coordination, hydrogen bonding or proton transfer,

– nucleophile generation via proton abstraction by a basic group,

– nucleophilic attack on the substrate by a functional group or by metal-coordinated hydroxide.

We will focus here on the respective roles of the two metal centers of the selected metalloenzymes (whose essential features are summarized in Table 1). The electronic structures of the metal centers of the enzymes have been described in recent reviews.[1−4] We also indicate selected synthetic models for these enzymes. The identification of small well-defined molecules with unsymmetrical bimetallic centers is

Jean-Louis Pierre was born in France in 1939. He is Professor of Chemistry at the Joseph Fourier University in Grenoble. He worked for several years in the field of stereochemistry before turning to bioinorganic chemistry. His current research interests include iron transport and metabolism in living systems, and biomimetism of redox metalloenzymes. He is the author of several books on Chemistry and Stereochemistry.

Catherine Belle received her Chemical Engineering degree in 1985 in Marseilles. She obtained her PhD in 1988 at the University of Marseilles under the supervision of Pr. R. Gallo. After a two-year postdoctoral stay at the University of Firenze (Italy) with Pr. A. Guarna she joined the research group of Pr. J. L. Pierre in Grenoble in 1991, where she now works as a CNRS researcher (senior researcher). She has launched new research axes in biomimetic chemistry, especially on purple acid phosphatases and catechol oxidases models.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

Table 1. Three selected enzymes with unsymmetrical binuclear sites

Enzyme	Function	Nature of the bridge(s) (Intermetallic distance)	Nature of the asymmetry	Ref.
Cu^{II}-Zn^{II} Superoxide dismutase (SOD)	O_2^- dismutation	Imidazolate (6.3 Å)	Heterobinuclear Cu^{II} ligands: four His and one H_2O removed by substrate Zn^{II} ligands: three His and one carboxylate	[5]
Fe^{II}-Fe^{III} or Zn^{II}-Fe^{III} Purple acid phosphatases (PAP)	Hydrolysis of phosphoric esters	One hydroxo and one monodentate carboxylate (3.31 Å [Fe^{II}-Fe^{III}]) (3.26 Å [Zn^{II}-Fe^{III}])	Mixed valence or heterobinuclear Fe^{III} ligands: one His, one Tyr, one hydroxo and one carboxylate (Asp) Fe^{II} (or Zn^{II}) ligands: two His, one carboxylate (Asp) and one H_2O	[4,6–10]
Cu^{II}-Cu^{II} Catechol oxidase (CO)	Oxidation of *o*-diphenols to quinones	One hydroxo (2.87 Å)	Cu_A ligands: three His, one of them covalently linked by an unusual thioether bond to a cystein Cu_B ligands: three His	[11–13]

relevant in catalysis and in understanding the enzymatic processes, and will increase our understanding of the advantages of asymmetry in binuclear metallocatalysts.

Cu-Zn Superoxide Dismutase: A Redox Heterobinuclear Enzyme with only One Metal Center Involved in the Catalytic Cycle

Structural and Functional Aspects of Cu-Zn SOD

Copper-zinc superoxide dismutase (SOD) is composed of two identical subunits, each containing in its active site an imidazolate-bridged bimetallic center with one copper(II) and one zinc(II) ion.[5] It occurs in the cytosol of eukaryotic cells and protects them from the toxic effects of superoxide ions. It catalyzes the dismutation of superoxide via two diffusion-controlled one-electron redox processes ("ping-pong" mechanism):

$$O_2^- + [Cu^{II}] \rightarrow O_2 + [Cu^{I}]$$

$$O_2^- + [Cu^{I}] + 2\,H^+ \rightarrow H_2O_2 + [Cu^{II}]$$

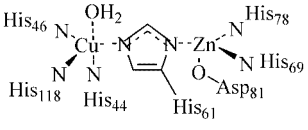

Figure 1. The active site in Cu-Zn SOD

In the metal-binding site (Figure 1) the Cu^{II} ion is coordinated by four histidines in a distorted square-planar coordination sphere and by a fifth axial water ligand, while the tetrahedral zinc ion is coordinated by three histidines, one of them bridging to the copper, and by a carboxylate group. The SOD Cu^{II} center exhibits type-2 copper protein characteristics: a d → d transition in the 500 to 1 μm region and normal EPR signals for tetragonal copper(II) ($g_{//} = 2.229$, $g_{\perp} = 2.041$, $A_{//} = 137 \times 10^{-4}$ cm^{-1}).[3]

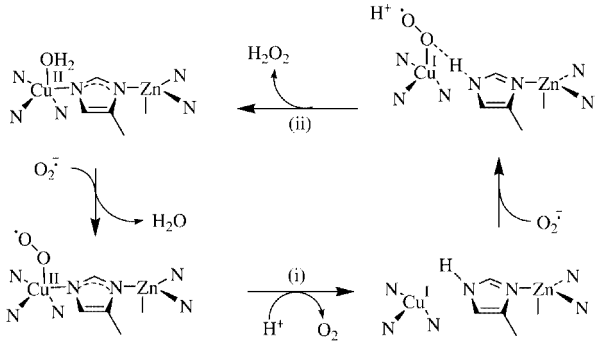

Figure 2. Mechanism for Cu-Zn SOD[5]

The superoxide ion is electrostatically guided by a deep (≈ 13 Å), narrow (≈ 4 Å) channel lined by positively charged amino acid residues. The zinc ion probably assists the protein in adopting the required coordination environment and confers stability to the protein, which is remarkably stable to heat and is active from pH 4.5 to 10. The catalytic mechanism is depicted in Figure 2. The oxidation step (i) is an inner-sphere electron transfer between the coordinated superoxide and the copper(II) center. The concomitant cleavage of the copper-imidazolate bond is assisted by protonation of the imidazolate by the solvent, and oxygen is released. Reoxidation of Cu^{I} to Cu^{II} by the next superoxide reforms the bridge with transfer of a proton to the peroxide ion.

A modified enzyme, having copper in both metal binding sites, Cu-Cu SOD, exhibits the same catalytic activity as native SOD,[14] demonstrating clearly that a copper ion located in the zinc site does not exert catalytic activity.

Cu-Zn SOD Models

Many low-molecular weight copper chelates exhibit, in vitro, superoxide dismutase-like activity. Most lose their activity in the presence of bovine serum albumin (BSA), which can mobilize the complexed copper(II) ions (BSA, a plasmatic protein, is one of the strongest biological chelators of cupric ions; log $K = 16.2$). One of us had described

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

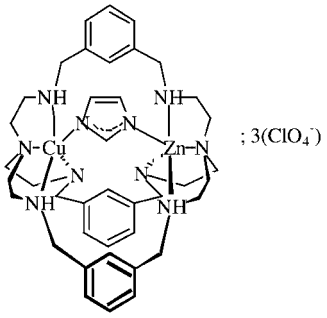

Figure 3. Biomimetic model for the Cu-Zn SOD active site[15]

a biomimetic model[15] that catalyzes the dismutation of superoxide at biological pH and retains its activity in the presence of BSA. Moreover this model shares many of the spectroscopic properties of the enzyme. It is an imidazolate-bridged heterobinuclear copper(II)-zinc(II) complex of a macrobicyclic ligand (Figure 3). The closed bicyclic structure of the ligand is more selective than monocyclic or open-chain ligands: only small ligands (e.g. O_2^-) can access the copper center and the bicyclic structure is expected to mimic the SOD protein channel.

X-ray diffraction studies show a Cu−Zn distance of 5.93 Å (6.3 Å for the enzyme). The EPR and electronic spectral parameters are close to those of the protein. The imidazolate bridge is remarkably stable over a large pH range (6 to 10.5), which is significantly better than other abiotic models that do not involve a protecting bicyclic structure,[16] and is close to that of the enzyme (pH: 4.5 to 10). This is a good structural and functional model, but it does not evidence cooperation between copper and zinc.

An imidazolate-bridged heterobinuclear Cu-Zn complex with a symmetrical ligand, exhibiting SOD activities, has been recently described by Fukuzumi et al.,[17] who tried to clarify the role of the zinc ion (Figure 4). The X-ray structure indicates that the Cu^{II} and Zn^{II} ions have a slightly distorted trigonal-bipyramidal coordination geometry. The cyclic voltammogram in acetonitrile exhibited only one reversible Cu^{I}/Cu^{II} redox couple, at $E_{1/2} = -0.03$ V (vs. Ag/AgCl). This is 0.2 V more positive than for a Cu^{II} mononuclear complex homologue. The authors ascribe this shift to the electronic effect of the imidazolate-bound zinc ion. They conclude that the zinc ion in the heterobinuclear complex may accelerate an outer-sphere electron transfer from superoxide to the Cu^{II}-Zn^{II} complex to produce the Cu^{I}-Zn^{II} complex. The free energy change of electron transfer for the complex is thermodynamically more favorable than that without the Zn^{II} ion. The Zn^{II} ion, which can act as a Lewis acid, may also accelerate electron transfer from the Cu^{I}-Zn^{II} complex to superoxide, since superoxide can form a complex with metal ions acting as a Lewis acid to accelerate the electron transfer reduction of superoxide. Thus, the essential role of Zn^{II} in SOD may be to accelerate both the oxidation and the reduction of superoxide by controlling the redox potential of the Cu^{II} ion and superoxide in the SOD catalytic cycle.

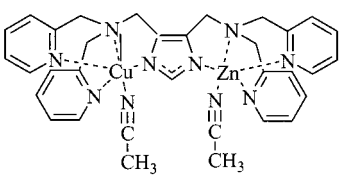

Figure 4. SOD model of Fukuzumi et al.[17]

Purple Acid Phosphatases: An Example of Non-Redox Bimetallic Catalysis

Structural and Functional Aspects of Purple Acid Phosphatases

Purple acid phosphatases (PAPs, Table 1) have been isolated from mammals, plants and fungal sources. They catalyze in vitro the hydrolysis of phosphate esters such as ATP, at a pH range of 4−7.[4,7−9] Their function in vivo is still subject to debate but has been proposed to involve fetal iron transport, control of bone resorption, and phosphate homeostatis in plants.[4] This class of acid phosphatases are purple due to a tyrosinate-to-Fe^{III} charge-transfer at about 560 nm ($\varepsilon \geq 3000$ $M^{-1}\cdot cm^{-1}$ per iron) for their inactive form. The crystal structure of the red kidney bean purple acid phosphatase (kbPAP)[8,10] displays a heterobinuclear $Zn^{II}Fe^{III}$ core, while those of the mammalian PAPs, determined from rat,[18] rat bone[19] and porcine uterus (UfPAP),[20] contain an $Fe^{III}Fe^{III}$ site in the oxidized non-active state.

The crystal structure of kbPAP, first determined at a resolution of 2.9 Å[10] and subsequently at 2.65 Å,[8] reveals a homodimeric 111 kDa enzyme, with two domains in each subunit. In the active site, located in the carboxyl-terminal domain, the two metal ions are 3.26 Å apart, and bridged monodentately by Asp164, each one involving octahedral coordination.

The iron is further coordinated by Tyr167, His325 and Asp135 residues, and the zinc by His286, His323 and Asn201 (Figure 5). Three exogenous ligands are also included in the X-ray model to complete the coordination sphere: one terminal hydroxo ligand to iron, one terminal water ligand to zinc, and one hydroxo bridge (also supported by physical measurements[21]) between the metal ions. In the μ-phosphato derivative structures of mammalian PAPs, the dimetallic ligation appears to be identical and confirms the similarities observed with kbPAP from sequence homologies and spectroscopic studies. The detailed electronic structure of the oxidized and reduced di-iron centers have been characterized by magnetic suscepti-

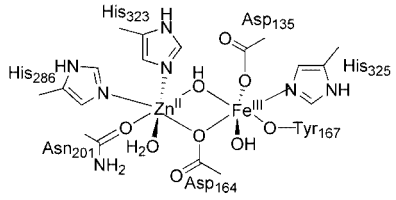

Figure 5. Active site in Zn-Fe kbPAP

bility and EPR measurements, which showed a strong antiferromagnetic interaction ($-2J > 80$ cm^{-1}) in the $Fe^{III}Fe^{III}$ ($S = 0$ ground state) forms and a weaker value in the reduced $Fe^{II}Fe^{III}$ ($S = 1/2$ ground state) forms (typically $-2J = 11$ to 22 cm^{-1}).[2,22] The active forms exhibit a pH-dependent rhombic EPR signal[23] ($g_{av} \approx 1.75$) whereas the inactive forms are EPR silent. Native kbPAP shows a signal at $g = 4.3$, which is characteristic for isolated high-spin Fe^{III} with a $S = 5/2$ ground state, as expected for the $Zn^{II}Fe^{III}$ center.[24]

The crystal structures of kbPAP complexed with μ-phosphate, the product of the reaction, (2.7 Å resolution) and with μ-tungstate inhibitor (3.0 Å) have also been determined, allowing a proposed mechanism for the hydrolysis of phosphomonoesters (Figure 6).[8] In this mechanism, which has not been experimentally demonstrated in such detail, the phosphate group of the substrate binds zinc in monodentate fashion by displacing the presumed water ligand. The terminal Fe^{III}-bound hydroxide ion attacks the phosphorus to form a pentacoordinate intermediate, and the P−O bond opposite the hydroxide ion attack breaks to form the leaving group and phosphate, which is consistent with the inversion at phosphorus. In addition, the three histidines (His202, His295 and His296) located near the bimetallic center can interact with the phosphate. In mammalian PAPs the corresponding residues are two histidines and a glutamate. No similar role is envisaged for the glutamate, which points away from the active site, but the histidines are hydrogen bonded to the bridging phosphate.[18−20]

This proposed mechanism underlines the respective roles of the two metal centers: The substrate first binds the Fe^{II} or Zn^{II} center by removal of the exchangeable water ligand, followed by intramolecular nucleophilic attack of the hydroxide group bound to the Fe^{III} center on the phosphorus P−O bond (activated by its binding to the electrophilic metal center). The well-fitted intermetallic distance allows the overall mechanism. The essential features of the respective roles of the two metal centers are: (*i*) a metal center (bearing an exchangeable ligand) that firstly binds the substrate; (*ii*) a second metal center bearing a reactive OH group that allows the assisted intramolecular reaction; (*iii*) a geometry that allows an intermediate in which the substrate is bound to both metal centers.

Alternative proposed reaction pathways of M^{II}/Fe^{III} purple acid phosphatases have been reviewed recently.[25] Merkx and co-workers propose that the terminal bound hydroxide deprotonates another water molecule from the second coordination sphere of the ferric ion, which then acts as an intramolecular base catalyst (Figure 7, A).[26,27]

As proposed for Fe^{II}/Fe^{III} uteroferrin,[28,29] the two metallic centers are bridged by the phosphate ester. The μ-OH may act as a nucleophile and attack the phosphate (Figure 7, B). When coordinated to one metal ion (Figure 7, A), the hydroxide is expected to be much more nucleophilic

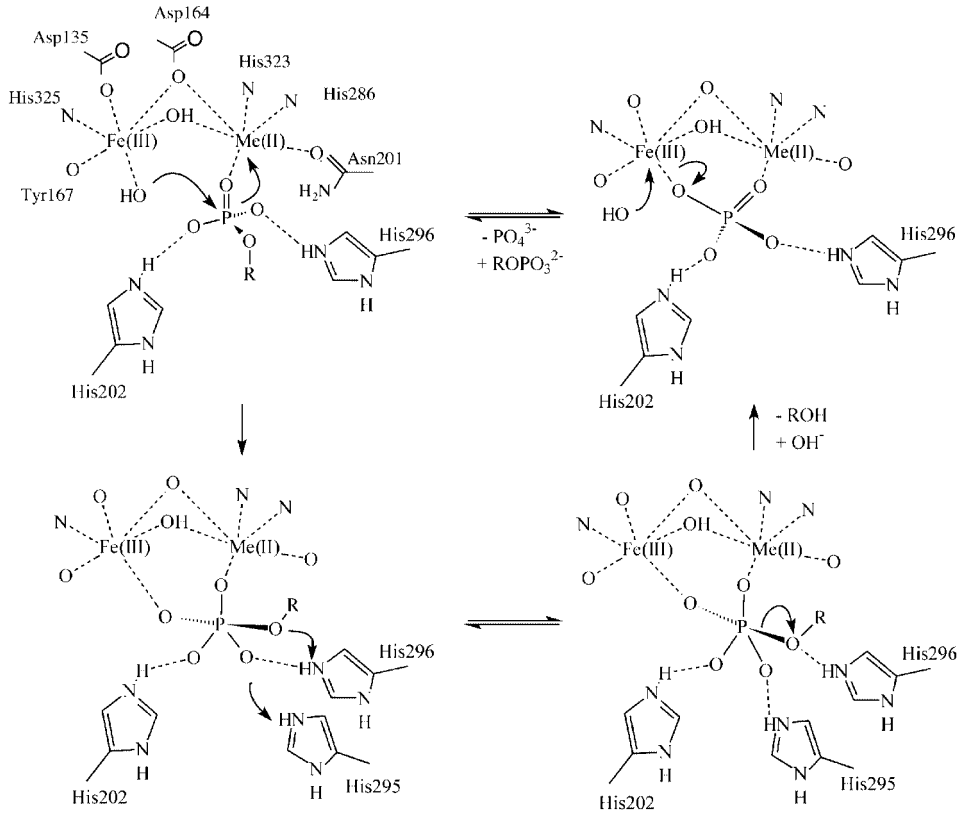

Figure 6. Proposed mechanism of phosphate ester hydrolysis in kbPAP (based on B. Krebs[8])

A B

Figure 7. Proposed reaction intermediates for the hydrolysis of phosphomonoesters by PAPs

than when it bridges two metal ions.[7] The second metal ion may help to generate the nucleophilic hydroxide by lowering the p*K*a of the bridging hydroxo and by converting the hydroxo bridge into a quasi-terminal $M^{II}-OH$ moiety.[29]

However, it is not known whether the phosphate ester binds to both metal ions in a bridging mode (as in the structurally characterized phosphato derivatives of PAPs)[8,18−20] or only to the divalent metal ion. For bovine spleen PAP (bsPAP), the bridging phosphate complex reportedly represents an inactive form of the enzyme−substrate complex.[27] No decisive evidence is available about the fixation mode of the substrate during the enzymatic cycle.

Although the exact mechanism has not been clearly elucidated, in all proposed reaction pathways the two metal centers act cooperatively, with a precise role for each. These proposed mechanisms are fascinating examples of bimetallic catalysis.

To explore the role of each metal center, the Fe^{II} has been selectively substituted with various divalent metal ions, leading to changes in catalytic activity[7] (e.g. the $Zn^{II}Fe^{III}$ Uf reacts with $H_2PO_4^-$ 35 times faster than does the native $Fe^{II}Fe^{III}$ form[30]). Conversely, replacing the Fe^{III} center with Ga^{III} results in small but consistent changes in catalytic activities.[31]

Purple Acid Phosphatase Models

A View on PAPs Models

Most reported model complexes of binuclear metallobiosites imply equivalent environments for the two metal ions, since symmetrical dinucleating ligands greatly simplify the synthetic problem.[32] The structural and functional model compounds of PAPs have been reviewed.[9] To mimic the reactivity of PAPs, two isostructural binuclear complexes, Zn^{II}-Fe^{III} and Fe^{II}-Fe^{III}, of the phenolate-hinged dinucleating ligand H-BPMOP [2,6-bis{[bis(2-pyridylmethyl)-amino]methyl}-4-methoxyphenol] have been prepared and studied to compare their activity towards phosphate ester cleavage, and to allow comparisons between kbPAP and bsPAP.[33] The pH dependence of the acceleration in cleavage of the activated phosphodiester 2-hydroxypropyl-*p*-nitrophenyl phosphate (HPNP) was investigated in acetonitrile/water 1:1 (optimum pH 8.5 ± 0.2). The Zn^{II}-Fe^{III} complex of H-BPMOP shows a twofold higher rate acceleration than the complex with H-BPMP [2,6-bis{[bis(2-pyridylmethyl)amino]methyl}-4-methylphenol], and the di-iron complex from BPMOP is 10-fold more reactive than the homologous complexes from BPMP. As observed with the Zn^{II} substituted $Fe^{II}Fe^{III}$ UfPAP enzyme,[30,31] the heterobinuclear catalyst exhibits a higher reaction rate than the homobinuclear catalyst.

Unsymmetrical Models for PAPs

The rational design of dinucleating ligands that induce a controlled synthesis of the targeted unsymmetrical complexes is a prerequisite for a better understanding of spectroscopic and chemical properties related to metalloenzymes. The search for unsymmetrical dinucleating ligands has been reviewed and discussed by Fenton.[34]

Two essential factors in designing dinucleating ligands are:

– The ligand, which has to accommodate two metals with a well-suited metal−metal separation, allowing bridging by the designed ligand(s).

– The coordination environment, which dictates steric and electronic features, especially the redox properties of each metal center.

Table 2 shows some example ligands and their corresponding unsymmetrical complexes that have been characterized by X-ray structures.

An unsymmetrical binuclear iron complex from a symmetrical ligand, reported by Krebs et al.,[35] involves a monodentate coordinated phosphato ligand. Phosphate (and arsenate) anions have also been found as bidentate bridges between the two metal centers in other model complexes (Table 2). Thus, these biomimetic models do not allow decisive arguments regarding the substrate coordination to the enzyme.

In the complexes described by Latour et al.,[36] the unsymmetrical environment mimics the coordination of the tyrosine residue at the PAP active site. This work shows how the introduction in the iron environment of a single terminal phenolate influences the redox properties (i.e. noticeable destabilization of the diferrous state, less pronounced stabilization of the diferric one, and enhanced stability domain for the mixed valence state). A similar effect has been observed Neves.[42] The stabilizing effect of the mixed valence state compared to the symmetric ligands is attributed to a stereochemical effect of the ligand and to coulombic interactions.

We have described a zinc(II)-iron(III) complex involving two chemically distinct coordination sites, one suited for iron(III) complexation and bearing two phenolate nonbridging ligands, the other bearing pyridine nitrogen donor sites (half part of BPMP); the two sites being connected by the classical bridging phenolate group.[41] We used our previously described unsymmetrical ligand LH_3 (Table 2, last Entry).[43] A heterobinuclear Zn^{II}-Fe^{III} complex has been obtained by the addition (in methanol) of one equivalent of iron(III) perchlorate in the presence of triethylamine to a solution of the zinc complex, followed by the addition of two equivalents of diphenylphosphate. This complex in-

volves two phosphate bridges, as shown in the X-ray structure.[41] The main feature of the electronic absorption in CH_3CN, at 501 nm ($\varepsilon \approx 3077\ cm^{-1}$), is assigned to charge-transfer transitions from the terminal and the bridging phenolates to the iron(III). This complex can act as a structural model of the substrate bound to the active site of kbPAP (a phosphate-bridged species has been tentatively proposed during the catalytic cycle of kbPAP). Moreover, the NO5 coordination sphere around the Fe^{III} reproduces the kbPAP oxygen-rich NO5 coordination sphere of iron.

Functional models have been prepared by a combinational method using a mixture of distinct bidentate ligands, the best activity being obtained with unsymmetrical models.[44]

Catechol Oxidase: Two Copper(II) Ions with Distinct Roles for a Two-Electron Oxidation

Structural and Functional Aspects of Catechol Oxidase

Catechol oxidases (COs) are ubiquitous plant enzymes that catalyze the oxidation of a broad range of *ortho*-diphenols into *ortho*-quinones in the presence of oxygen.[4,11−13,45] They belong to the family of type-3 copper proteins, containing a binuclear copper active site that is EPR silent in the native *met* Cu^{II}-Cu^{II} form, due to a strong antiferromagnetic coupling between the copper(II) atoms. The other prominent type-3 copper proteins are hemocyanins (Hc), the dioxygen carrier for arthropods and mollusks, and tyrosinases (Tyr).[3] The crystal structure of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

CO from sweet potatoes (*Ipomoea batatas*, ibCO) was resolved in 1998.[13] Both metal binding sites in the *met* form involve three histidine ligands. The two cupric ions, probably bridged by a hydroxide ion, are 2.87 Å apart in a trigonal pyramidal coordination sphere. Interestingly, the binuclear metal center has a covalent thioether bond between a carbon atom of His109 (one of the copper ligands) and the sulfur atom of Cys92 (Figure 8).

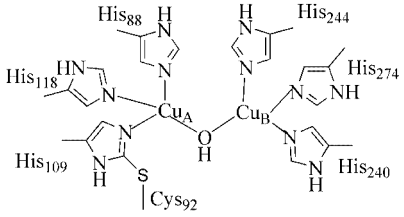

Figure 8. Active site of catechol oxidase from *Ipomoea batatas* (*met* form)[13]

The crystal structure of catechol oxidase reveals that this covalent bond puts additional structural restraints on the ligand sphere of the Cu_A center. Cys-His thioether bridges have been reported for the sequences of ncTyr (*Neurospora crassa* Tyr),[46] odgHc (*Octopus dofleini* Hc),[47] hpHc (*Helix pomatia* Hc)[48] and in all known COs. The absence of the covalent thioether bond in Hcs from arthropods and human Tyr does not support its direct involvement in the catalytic process.[4,11] A thioether bond between cysteine and tyrosine has also been reported for the mononuclear copper enzyme galactose oxidase.[49] In COs, this Cys-His unit may optimize the redox potential of the metal needed for the oxidation of the *ortho*-diphenol substrate and (or) prevents the displacement of His109 and therefore tunes the binding mode of the substrate.

The crystal structure was solved in the *deoxy* Cu^I Cu^I state and with a substrate analogue inhibitor (phenylthiourea, PTU) relevant to the mechanism.[13,45] In the reduced state a water molecule was coordinated to Cu_A. The coordination sphere is a distorted trigonal pyramidal whereas that of Cu_B (three histidine ligands) can be described as square planar with a vacant coordination site. The copper−copper distance is 4.4 Å. In the dimetallic center for the PTU-enzyme complex, the hydroxo bridge is replaced by a sulfur bridge from PTU, increasing the $Cu^{II}-Cu^{II}$ separation to 4.2 Å compared to the *met* form. The amide nitrogen interacts weakly with Cu_B, leading to still more unsymmetrical coordination spheres for the two copper centers.

A catalytic cycle for catechol oxidase activity (Figure 9) has been proposed from a combination of biochemical, spectroscopic, structural data[11] and by comparison with the tyrosinase-related cycle.[3] It begins with the native *met* form. The monodentate binding of the diphenolic substrate to the Cu_B is suggested from the crystal structure of the ibCO-PTU complex.[13] Nevertheless, a bidentate bridging of catechol has also been proposed.[3,45] Stoichiometric amounts of the quinone product are formed immediately after addition of catechol, even in the absence of dioxygen. This excludes the *oxy* form at the start of the catalytic cycle. The *oxy* form may arise from the *deoxy* form in the presence of oxygen. The *oxy* form has been experimentally obtained upon addition of H_2O_2 to the *met* form. In the proposed catalytic cycles, catecholate binds either monodentately or bidentately the *oxy* form, for a two-electron transfer

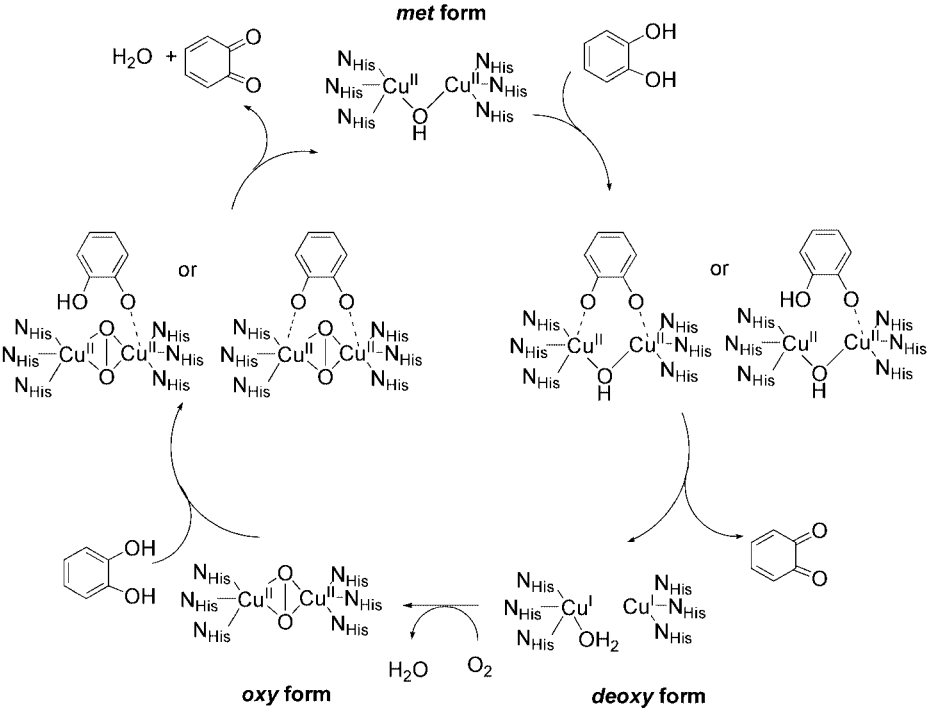

Figure 9. Proposed catalytic cycle for catechol oxidase activity[3,11,45]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

leading to the release of the quinone product and to the *met* form.

Interestingly, Krebs et al.[11] have noted that in copper type-3 proteins the Cu_B site is always strictly conserved, while the varying Cu_A environment seems to tune the proteins to specific activities. Comparison of the metal coordination region from structural data on ibCO and Hcs evidences high similarities. The active site of odgHc has an identical coordination for Cu_A as in ibCO.[45] As no detailed structural information was available for any tyrosinase, it would be of great interest to explain the difference between CO and Tyr, which may be related to the respective roles of each metal center.

Catechol Oxidase Models

Catecholase activity on a model substrate (3,5-di-*tert*-butylcatechol, 3,5-dtbc) has been described, in particular for binuclear compounds.[50,51] A complex with a bridging tetrachlorocatechol between the two Cu^{II} ions has been characterized, by X-ray diffraction studies, and suggested as a model for a substrate-binding intermediate in catechol oxidation.[52] Our group has investigated a series of dicopper(II) complexes as model systems for the catechol oxidase active site. We have described the pH-controlled changes of the metal coordination in one such complex, with a H-BPMP ligand, and shown that its catecholase activity depends on the copper−copper distance, which was modified according to pH changes (Figure 10).[53]

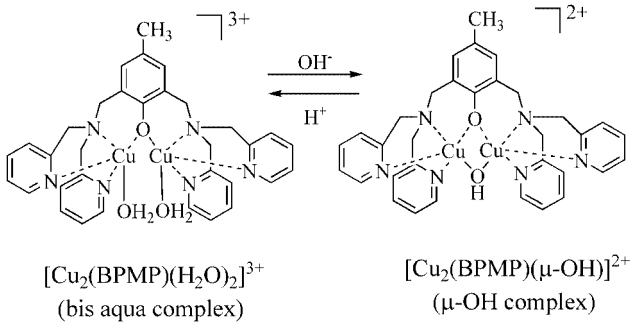

Figure 10. pH-Driven change in dicopper(II) complexes model of catechol oxidase[53]

The complex $[Cu_2(BPMP)(\mu\text{-}OH)](ClO_4)_2$ is EPR silent, in agreement with the antiferromagnetic coupling ($J = -112\ cm^{-1}$) between the two copper(II) atoms, with a very short Cu−Cu distance of 2.87 Å, similar to the enzyme in the *met* form.[12,13,54] Only the μ-OH complex $[Cu_2(BPMP)(\mu\text{-}OH)](ClO_4)_2$ exhibits catecholase activity compared to the bis aqua compound $[Cu_2(BPMP)(H_2O)_2](ClO_4)_3$. Substitution at the 4-position of the bridging phenolate with an electron-donating or an electron-withdrawing group drastically influences the catecholase activity, even though the structural properties are only slightly affected.[55]

These, models, and others in the literature, involve symmetrical ligands leading to the same coordination sphere for each metal center. Nevertheless, mechanistic studies with our model series have shown distinct roles for each metal center. First, a monodentate coordination on one copper center, associated with an interaction between the second phenol group of the catechol substrate and the hydroxy group bound to the second copper center (arising from cleavage of the initial hydroxo bridge). Then the proton transfer occurs followed by displacement of a water molecule and the bridging coordination of the catecholate (Figure 11).[56]

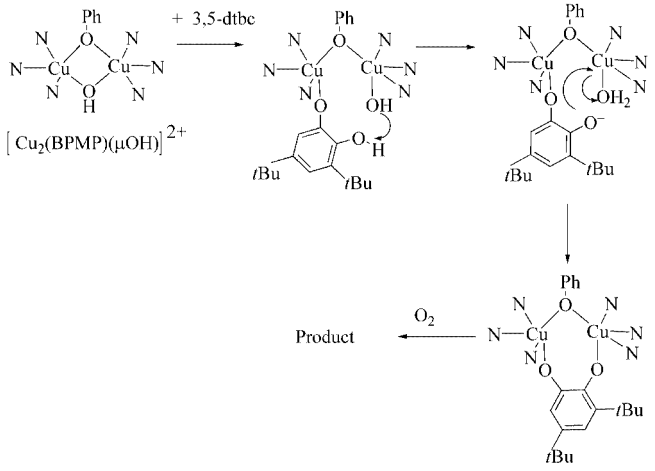

Figure 11. Proposed mechanism for the interaction between dinuclear copper(II) μ-OH complexes and the 3,5-dtbc substrate[56]

It is of interest to prepare CO models from unsymmetrical ligands, differentiating, in a controlled manner, the two metal centers as it is done in the enzyme. Few model complexes for catechol oxidase from unsymmetrical ligands have been reported (Figure 12).[51,57] With such models further studies to identify the roles of each metal ions could shed light on the likely behavior of the two copper atoms in dissimilar environments.

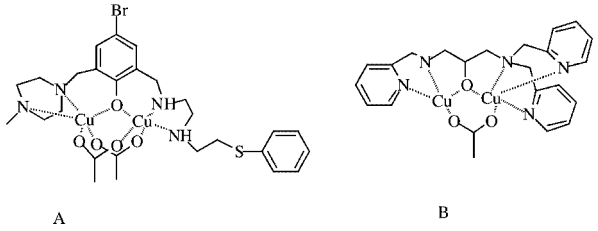

Figure 12. Unsymmetrical dicopper(II) complexes as models of catechol oxidase. (A) from,[57] (B) from[51]

Conclusion

From our briefly developed examples of μ-bridged binuclear metalloenzymes, focusing on the asymmetry of the two metal centers and their respective roles, we can underline the following aspects:

– One redox catalytic metal center; the second metal helps maintain the structural integrity and possibly accelerates the redox processes by controlling the redox potential of the first metal center. This has been observed for Cu-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Zn superoxide dismutase (moreover, the coordination of the bridging histidine nitrogen to the Zn ion lowers the p*K*a of the other nitrogen, which consequently prefers to bind to a proton rather than to Cu^{I} after the first step of the catalytic cycle).

– Coordination number asymmetry that presents the possibility of "open coordination sites" for direct interaction of one metal center with the substrate. The reactant can be bound to the second metal center. Alternatively, the second metal center can "assist" the reaction. This has been encountered with PAPs.

– In another possibility, the substrate is coordinated to both metal centers simultaneously in a bridging manner. The substrate is then activated and reacts with another molecule, either bound or not to one metal center.

– A very tenuous and subtle asymmetry with catechol oxidase (CO): a simple substitution of one ligand of one metal center may confer to CO a distinct reactivity compared with that of the closely related copper type-3 proteins.

Bimetallic catalysis is a fascinating aspect of chemical catalysis.[32] Chemists can even envisage the self-assembly of bimetallic sites during the catalytic event and, in this sense, outdo Nature. Of course, our limiting the discussion to the active site and to the first coordination spheres of the metal centers is an over-simplification. Nevertheless, this approach partly answers the question: Asymmetry in binuclear metalloenzymes: what and why?

Stereodiscrimination in Phosphanylthiolato Nickel(II) Complexes

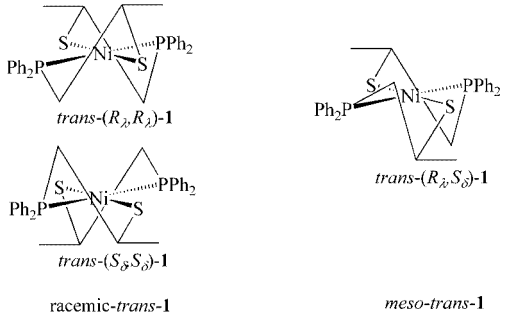
Josep Duran,[a] Alfonso Polo,*[a] Julio Real,*[b] Jordi Benet-Buchholz,[c] Albert Poater,[a,d] and Miquel Solà[a,d]

Keywords: Nickel / P,S ligands / Conformation analysis / Chiral resolution / Density functional calculations

The presence of a stereogenic carbon centre (*R* or *S*) in the racemic ligand 1-(diphenylphosphanyl)propane-2-thiol induces a conformational preference (λ or δ) in the five-membered chelate ring of its 2:1 and 2:2 coordination compounds with Ni^{II}: the mononuclear *trans*-[Ni{SCH(CH_3)CH_2PPh_2-*P*,*S*}$_2$] (**1**) and the binuclear *trans*-[Ni{μ-SCH(CH_3)CH_2PPh_2-*P*,*S*}(Cl)]$_2$ (**2**). Both complexes exist as mixtures of two diastereomers: racemic-*trans* (R_λ, R_λ and S_δ, S_δ) and *meso*-*trans* (R_λ, S_δ), in an equilibrium displaced towards the more stable isomer, the *meso*-*trans* for **1** (calculated $\Delta E = < -0.1$ kcal·mol^{-1}) and the racemic-*trans* for **2** (calculated $\Delta E = -5.1$ kcal·mol^{-1}). This phenomenon is especially evident for complex **2**, in which an efficient chiral recognition between the two enantiomeric forms of the racemic ligand was observed. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The reactivity of 2-phosphanylthiolato nickel(II) complexes has been studied because of their relevance in *S*-alkylation/*S*-dealkylation reactions[1] and their applications in desulfurisation technologies[2] and in understanding the biological pathways of certain sulfur-containing metalloproteins.[3] However, less attention has been given to the importance of the ligand-based stereoelectronic effects in determining the coordination conformations around the metal and the stereochemistries of these compounds.[4] Thus, we decided to focus our attention on these particular aspects. The bis(phosphanylthiolato)nickel(II) complexes *trans*-[Ni($SCH_2CH_2PR_2$-*P*,*S*)$_2$][4,5] exist as mixtures of diastereomers because the five-membered chelate ring can adopt two different conformations (λ and δ) and therefore is able to form three optically isomeric complexes. When both chelate rings are in a λ-conformation, and the two chelate rings of the enantiomer are in a δ-conformation, we have the racemic-*trans* complex and when each chelate ring is in a different conformation, we have the *meso*-*trans* diastereomer (see Scheme 1). These two stereoisomers can be distinguished when a racemic chiral ligand is present, such as in complex [Ni($SCH_2CH_2PMePh)_2$], which has a racemic ligand chiral at the phosphorus centre. This compound exists in solution as a mixture of the racemic-*trans* and the *meso*-*trans* forms that equilibrate slowly ($t_{1/2}$ ca. 12 h) through an intermolecular process to form a 1:1 mixture, since the two diastereomers have very close energies.[4]



Scheme 1. Stereoisomers of mononuclear five-membered ring bis(phosphanylthiolato)nickel(II) complexes exemplified by complex **1**

The same stereochemical analysis can be applied to the 2-phosphanylthiolato-bridged binuclear nickel(II) complexes [Ni(μ-$SCH_2CH_2PR_2$)(X)]$_2$, which form bent *syn*-*endo*-*trans* structures.[6,7] Theoretical studies have shown that for this class of compounds the stabilisation of folded structures with respect to the planar arrangement can be

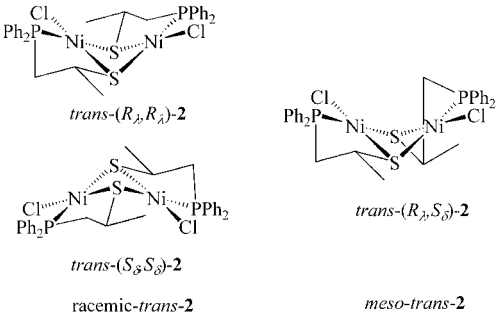
ascribed to the pyramidalisation of the sulfur bridge compounded with a weak Ni−Ni interaction. Furthermore, it has been proposed that in a bent structure the chelate ring involving the bridging sulfur would be highly strained in *syn-exo* or *anti* conformations.[7] As in the case of bis(phosphanylthiolato) complexes, the chelate chain introduces some degree of structural variation, also producing the racemic-*trans* and *meso-trans* diastereomers (see Scheme 2). Nevertheless, it should be noted that the *anti* conformation of the bridging sulfur substituents would be necessary for the *meso-trans* isomer to be formed and that, for this type of complexes, the bent-*anti* structure has been observed neither in the solid state nor in solution.



Scheme 2. Stereoisomers of double 2-phosphanylthiolato-bridged binuclear nickel(II) complexes with bent structures exemplified by complex **2**

For these reasons, we propose that the energy difference between the racemic-*trans* and *meso-trans* diastereomers of bis(phosphanylthiolato) complexes, and the strong tendency of the phosphanylthiolato-bridged binuclear complexes to adopt the folded *syn-endo-trans* conformation, could produce a chiral discrimination between the two enantiomeric conformations of the five-membered chelate ring. In order to demonstrate this hypothesis, we synthesised and characterised the 2:1 and 1:1 coordination compounds of the racemic ligand 1-(diphenylphosphanyl)propane-2-thiol[8] with nickel(II).

Results and Discussion

An alternative method to the literature procedures for the syntheses of $[Ni(SCH_2CH_2PPh_2)_2]$[5,9] and $[Ni(\mu\text{-}SCH_2CH_2PPh_2)(Br)]_2$[9] was applied to prepare the mononuclear bis-chelate *trans*-$[Ni\{SCH(CH_3)CH_2PPh_2\}_2]$ (**1**) and the binuclear *trans*-$[Ni(\mu\text{-}SCH(CH_3)CH_2PPh_2)(Cl)]_2$ (**2**) complexes. Addition of a CH_2Cl_2 solution of two equiv. of racemic 1-(diphenylphosphanyl)propane-2-thiol to a solution of nickel chloride in methanol resulted in the formation of solid **1**, which was isolated in 85 % yield. The same base-free procedure was used for **2**, which was isolated in 80 % yield upon addition of one equiv. of the racemic ligand and precipitation with diethyl ether.[10]

The *trans* geometry of the mononuclear complex **1** was determined by NMR analysis. In the $^{13}C\{^1H\}$ NMR spectra all aliphatic carbon atoms appear as triplets owing to virtual coupling with two equivalent mutually *trans* phosphorus nuclei (see Figure 1). According to the $^{31}P\{^1H\}$ NMR spectrum, bis-chelate **1** exists as a mixture of two diastereomers: freshly prepared $CDCl_3$ solutions of complex **1** show two resonances at δ_P = 52.6 and 54.2 ppm in about an 11:5 intensity ratio. The similar δ_P values point to two diastereomers with the same configuration but different conformations.

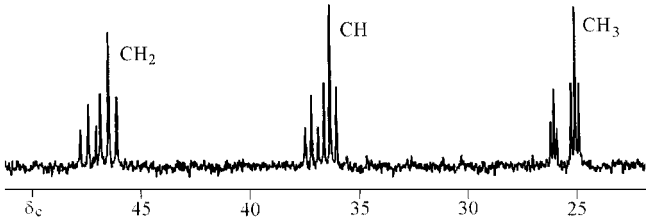


Figure 1. The aliphatic $^{13}C\{^1H\}$ NMR signals of complex **1** appear as triplets owing to virtual coupling with 2 equiv. mutually *trans* phosphorus nuclei

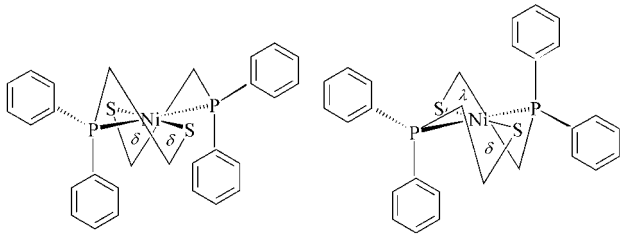
In keeping with the conformational analysis for compound **1** (see Scheme 1), the preferred conformation for the chiral chelate ring depends on the configuration at the stereogenic carbon centre of the ligand.[10a] Thus, the ligand with *R* configuration adopts the λ-conformation, which places the substituent of the chelate ring in the equatorial position. For the same reasons, the ligand with *S* configuration adopts the δ-conformation. As a result of these conformational preferences, complexes carrying two ligands with the same configuration, *trans*-(*R*,*R*)-**1** and *trans*-(*S*,*S*)-**1** are enantiomers (racemic-*trans*-**1**) giving a single $^{31}P\{^1H\}$ NMR signal. The second resonance is then assigned to the diastereomeric complex carrying one ligand in each configuration, *trans*-(*R*,*S*)-**1** (*meso-trans*-**1**). By comparison with the related complex $[Ni(SCH_2CH_2PMePh)_2]$,[4] the major signal could be initially assigned to the racemic-*trans*-**1** stereoisomer, which was claimed to be the kinetic product. However, the intensity ratio of the $^{31}P\{^1H\}$ NMR signals remains constant after 72 h at 50 °C. This behaviour contrasts with that observed for other similar Group VIII metal bis(phosphanylthiolato) complexes, in which the two signals become equal after 24 h at room temperature. In the latter case the two diastereomers have very close energies,[4,10a] suggesting that for complex **1** they have a slight, but significant, difference in energy (experimental $\Delta E \approx 0.41$ kcal·mol^{-1}). The BP86 energy calculations on complex **1** (see below) reveal that this energy difference is really small (less than 0.1 kcal·mol^{-1}) and predict the stabilisation of the *meso-trans*-**1** isomer over the racemic-*trans*-**1**, owing most probably to the steric interactions between the *pseudo*-axial phenyl groups that are mutually *syn* in racemic-*trans*-**1** and *anti* in *meso-trans*-**1** (see Scheme 3).

Binuclear complex **2** adopts a bent *syn-endo-trans* conformation in the solid state (see below) and shows a single, sharp resonance in the $^{31}P\{^1H\}$ NMR spectrum at δ_P = 36.3 ppm, both for freshly prepared and aged solutions,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3. The pseudo-axial phenyl groups of the *trans*-bis(2-diphenylphosphanylthiolato)nickel(II) complexes are mutually *syn* in the stereoisomers carrying both chelate rings in the same conformation (λ, λ or δ, δ) and *anti* in the stereoisomer with one chelate ring in each conformation (λ, δ)

pointing to the presence of only one of the possible diastereomers. It is noteworthy that in the $^{13}C\{^1H\}$ NMR spectrum of binuclear **2**, two of the aromatic carbon atoms (C_o and C_m) show two signals each, and all are pseudo-triplets (see Figure 2). The doubling of these signals is assigned to the different surroundings of each phenyl ring in the same diphenylphosphanyl group, while the fine splitting could be ascribed to a somewhat surprisingly similar coupling to both phosphorus nuclei generated by the P−Ni−Ni−P connection, a special case of the known phenomenon of virtual coupling.[7]

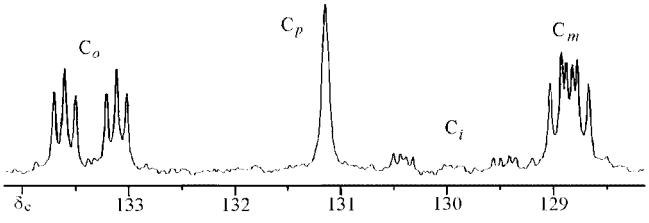


Figure 2. Two of the aromatic $^{13}C\{^1H\}$ NMR signals of complex **2** appear as pseudo-triplets (C_o and C_m), probably owing to a P−Ni−Ni−P coupling; complex **2** is not soluble enough to obtain quality signals for the quaternary carbon atoms, but an unfolded doublet of doublets can be glimpsed in the spectral trace

The conformational analysis of complex **2** shows, as in the case of **1**, that ligands with *R* and *S* configuration adopt λ and δ conformations, respectively, thereby placing the chelate chain substituent in the equatorial position. Thus, two diastereomeric forms of **2** could exist (racemic-*trans*-**2** and *meso*-*trans*-**2**: see Scheme 2), but only one of them was observed in solution. The BP86 energy calculations on complex **2** (see below) gave an energy difference of 5.1 kcal·mol^{-1} between the racemic-*trans*-**2** and the *meso*-*trans*-**2** isomers, in agreement with an equilibrium strongly displaced towards the racemic-*trans*-**2** diastereomer (experimental $\Delta E \geq 2.3$ kcal·mol^{-1}).[11] Furthermore, the minimum in energy for the *meso*-*trans*-**2** isomer represents a folded *syn*-*endo*-*trans* structure with one of the chelate chain substituents in the equatorial position and the other in the axial. This result is in agreement with the instability of the bent *anti* conformations predicted for this type of complex.[7]

An XRD study was carried out on crystals of **2**·$CHCl_3$ (see Figure 3). The crystal structure contains only the racemic-*trans*-**2** diastereomer and reveals an edge-sharing binuclear complex with square-planar coordination geometry around the nickel atoms. The molecule adopts a folded *syn*-*endo*-*trans* conformation (see Figure 3). Although the Ni−S, Ni−P and Ni−Cl distances are in the range observed for the isostructural $[Ni(\mu\text{-}SCH_2CH_2PPh_2)(X)]_2$ complexes (where X = Cl, Br), the fold angle of the central four-membered Ni_2S_2 cycle is appreciably greater (118.1 vs. 100.7−104.1°), increasing the Ni−Ni distance from 2.681−2.695 to 2.906 Å.[6] The reason for this geometrical alteration must be attributed to the presence of the substituent in the chelate chain, because there are no other structural changes. In complex **2**, the requirement to locate the methyl group in the equatorial position increases the bending of the tertiary carbon atom away from the S−S hinge (33.6 vs. 27.1−27.8°) and, since this bending is related to the arching of the Ni_2S_2 group,[7] the central core must unfold.

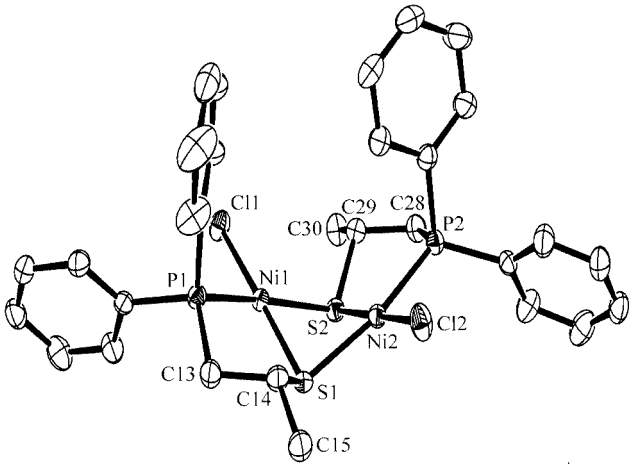

Figure 3. ORTEP plot (50 %) of complex **2**, hydrogen atoms are omitted; selected distances (Å) and angles (°): Ni1−Ni2 2.9065(4), Ni1−S1 2.1556(6), Ni1−S2 2.2244(7), Ni1−P1 2.1705(7), Ni1−Cl1 2.1910(7), Ni2−S1 2.2081(7), Ni2−S2 2.1558(7), Ni2−P2 2.1559(7), Ni2−Cl2 2.1811(7), S1−C14 1.841(3), C13−C14 1.531(4), C14−C15 1.516(4), P1−C13 1.834(3), S2−C29 1.854(3), C28−C29 1.520(4), C29−C30 1.521(4), P2−C28 1.833(3), S1−Ni1−P1 87.99(3), P1−Ni1−Cl1 95.22(3), S1−Ni1−S2 79.51(2), Cl1−Ni−S2 97.74(3), S2−Ni2−P2 88.29(3), P2−Ni2−Cl2 92.58 (3), S2−Ni2−S1 79.81(3), Cl2−Ni2−S1 99.15 (3), Ni1−S1−Ni2 83.52(2), C14−S1−Ni1 105.94(8), C14−S1−Ni2 112.74(9), Ni2−S2−Ni1 83.13(2), C29−S2−Ni2 105.38(8), C29−S2−Ni1 112.77(9).

Computational Results

The reported calculations were carried out by using the Amsterdam density functional (ADF2002.03) program system, developed by Baerends et al.[12−14] The numerical integration scheme employed was that of te Velde and Baerends.[15] An uncontracted triple-ζ basis set[16] was used

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for describing the 3s, 3p, 3d, 4s, and 4p orbitals of nickel. For carbon (2s,2p), phosphorus (3s,3p), sulfur (3s,3p), and hydrogen (1s), double-ζ basis sets[16] were employed and augmented by an extra polarisation function. Electrons in lower shells were treated within the frozen core approximation.[13a] A set of auxiliary s, p, d, f, and g functions,[17] centred in all nuclei, was introduced in order to fit the molecular density and Coulomb potential accurately in each SCF cycle. Both geometry optimisations and energy evaluations have been fully carried out within a generalised gradient approximation (GGA) that includes a GGA exchange and correlation corrections of Becke[18] and Perdew (BP86).[19]

In order to validate the method, the XRD data of complex **2** was geometrically optimised by excluding the solvent molecules. The results show good agreement between the experimental and theoretical data. The experimental and theoretical bond lengths and angles differ by less than 0.08 Å and 3.6°, respectively. The standard deviations for the selected distances and angles listed in Figure 3 were 0.04 Å and 2.1°, respectively, which confirm the validity of the chosen computational method.

All the experimental compounds were analysed computationally. It was found experimentally that both mononuclear and binuclear species are diamagnetic. For this reason, optimisations were carried out for neutral closed-shell singlet ground-state structures. However, since it has been found that the triplet state is close in energy to the singlet state, or it can be even more stable than the singlet state, we checked the relative stability of both states for all compounds by optimising the triplet state. In all cases the triplet state geometry presented a higher energy, indicating that the singlet states are the most favourable. This is in agreement with the sharp peaks in the NMR spectra. The difference between these two states is around 20 kcal·mol^{-1} (*racemic-trans*-**1** 22.2 kcal·mol^{-1}; *meso-trans*-**1** 21.4 kcal·mol^{-1}; *racemic-trans*-**2** 19.4 kcal·mol^{-1}; *meso-trans*-**2** 21.6 kcal·mol^{-1}).

Energy calculations predicted a slight stabilisation, by less than 0.1 kcal·mol^{-1}, of the *meso-trans*-**1** isomer relative to the racemic-*trans*-**1**, showing that the two isomers have similar energies, in line with the fact that experimentally the two isomers are present as final products. On the other hand, the energy calculations on complex **2** gave an energy difference of 5.1 kcal·mol^{-1} between the racemic-*trans*-**2** and the *meso-trans*-**2** isomers, in agreement with an equilibrium strongly displaced towards the racemic-*trans*-**2** diastereomer (experimental $\Delta E \geq 2.3$ kcal·mol^{-1}).[11]

We also attempted to optimise an *anti* conformation for the binuclear complex, but the optimisation process evolved towards the racemic-*trans*-**2** species, as the *anti* conformations are even less stable than the *syn* ones because of the steric requirements of the ligands.

Conclusion

In conclusion, the calculated energy differences between the racemic-*trans* and *meso-trans* diastereomers of these phosphanylthiolato complexes of Ni^{II} are in agreement with the experimentally observed racemic-*trans*/*meso-trans* ratios and are responsible for the chiral recognition between the two enantiomeric forms of the racemic ligand. This phenomenon is especially important in the binuclear complex **2**, in which a destabilised *anti* conformation of the bridging sulfurs would be necessary in order for the *meso-trans* isomer to be stable.

Experimental Section

General Remarks: The complexes were synthesised using standard Schlenk techniques under nitrogen atmosphere. The solvents were dried by standard methods and distilled and deoxygenated before use. The C, H and S analyses were carried out using a Carlo−Erba microanalyser. $CDCl_3$ for NMR measurements was dried over molecular sieves. Proton NMR spectra were recorded at 200 MHz on a Bruker DPX-200 spectrometer. Peak positions are relative to tetramethylsilane as internal reference. $^{31}P\{^1H\}$ NMR spectra were recorded on the same instrument operating at 81.0 MHz. Chemical shifts are relative to external 85 % H_3PO_4 and downfield values are reported as positive. $^{13}C\{^1H\}$ NMR spectra were recorded on the same instrument operating at 50.3 MHz. Chemical shifts are relative to tetramethylsilane as internal reference.

[Ni{SCH(CH$_3$)CH$_2$PPh$_2$-*P*,*S*}$_2$] (1): 1-(diphenylphosphanyl)propane-2-thiol (205.4 mg, 0.79 mmol) in CH_2Cl_2 (1 mL) was added to a solution of $NiCl_2{\cdot}6H_2O$ (75.1 mg, 0.316 mmol) in methanol (2 mL) under a nitrogen atmosphere to produce a green precipitate. The precipitate was washed with hexane yielding complex **1** (155.1 mg, 80 %). ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 1.31 (d, ^3J = 6.4 Hz, 2.72 H, CH_3 racemic-*trans*-**1**); 1.40 (d, ^3J = 6.2 Hz, 6 H, CH_3 *meso-trans*-**1**); 2.33 (tt, ^2J = −13.4, ^3J = 13.4, $^2J_{H,P} \approx$ 2.8 Hz, 2 H, $CH_{2ax.}$ *meso-trans*-**1**); 2.47 (ddt, ^2J = −13.1, ^3J = 10.1, $^2J_{H,P} \approx$ 3.0 Hz, 0.92 H, $CH_{2ax.}$ racemic-*trans*-**1**); 2.6−3.0 (m, 5.8 H, $CH_{2\ equiv.}$, CH, *meso-trans*-**1** and racemic-*trans*-**1**); 7.1−8.3 (m, 29 H, H_{ar}) ppm. $^{13}C\{^1H\}$ NMR (50.3 MHz, $CDCl_3$, TMS): δ = 25.10 (t, $J_{C,P}$ = 9.0 Hz, CH_3 *meso-trans*-**1**); 26.08 (t, $J_{C,P}$ = 7.4 Hz, CH_3 racemic-*trans*-**1**); 36.37 (t, $J_{C,P}$ = 12.3 Hz, CH *meso-trans*-**1**); 37.22 (t, $J_{C,P}$ = 14.4 Hz, CH racemic-*trans*-**1**); 46.51 (t, $J_{C,P}$ = 18.5 Hz, CH_2 *meso-trans*-**1**); 47.44 (t, $J_{C,P}$ = 18.2 Hz, CH_2 racemic-*trans*-**1**); 128.5−129.2 (m, C_m *meso-trans*-**1** and racemic-*trans*-**1**); 129.2−132.3 (m, C_i *meso-trans*-**1** and racemic-*trans*-**1**); 130.66 (s, C_p *meso-trans*-**1**); 130.79 (s, C_p racemic-*trans*-**1**); 131.23 (s, C'_p racemic-*trans*-**1**); 131.41 (s, C'_p *meso-trans*-**1**); 132.85 (t, $J_{C,P}$ = 5.4 Hz, C_o *meso-trans*-**1**); 133.41 (t, $J_{C,P}$ = 5.6 Hz, C_o racemic-*trans*-**1**); 134.58 (t, $J_{C,P}$ = 6.1 Hz, C'_o racemic-*trans*-**1**); 135.10 (t, $J_{C,P}$ = 6.1 Hz, C'_o *meso-trans*-**1**) ppm. $^{31}P\{^1H\}$ NMR (81 MHz, $CDCl_3$, H_3PO_4): δ = 52.56 (s, 1P, *meso-trans*-**1**); 54.23 (s, 0.46P, racemic-*trans*-**1**) ppm. $C_{30}H_{32}NiP_2S_2$ (577.4): calcd. C 62.41, H 5.59, S 11.11; found C 62.22, H 5.70, S 10.99 %.

[Ni{μ-SCH(CH$_3$)CH$_2$PPh$_2$-*P*,*S*}(Cl)]$_2$ (2): 1-(diphenylphosphanyl)-propane-2-thiol (88.1 mg, 0.338 mmol) in CH_2Cl_2 (1 mL) was added to a solution of $NiCl_2{\cdot}6H_2O$ (80.5 mg, 0.338 mmol) in methanol (2 mL) under a nitrogen atmosphere. The green precipitate obtained had redissolved after 3 h stirring, yielding a brown solution. The product was crystallised by addition of diethyl ether to afford complex **2** as brown crystals (91.3 mg, 80 %). ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 1.34 (d, ^3J = 8.0 Hz, 6 H, CH_3); 2.34 (td, ^2J = −13.7, ^3J = 13.7, $^2J_{H,P}$ = 6.4 Hz, 2 H, $CH_{2ax.}$); 2.63

(ddpseudo-t, $^2J = -13.7$, $^3J = 4.5$, $^2J_{H,P} \approx 4.4$ Hz, 2 H, $CH_{2\,equiv.}$); 3.24 (m, 2 H, CH); 7.2−8.4 (m, 20 H, H_{ar}) ppm. $^{13}C\{^1H\}$ NMR (50.3 MHz, $CDCl_3$, TMS): δ = 22.96 (m, CH_3); 39.16 (pseudo-t, $J \approx 3.0$ Hz, CH); 44.97 (d, $^1J_{C,P} = 38.8$ Hz, CH_2); 128.80 (pseudo-t, $^3J_{C,P} = 5.2$ Hz, C_m); 128.95 (pseudot, $^3J_{C,P} = 5.2$ Hz, C'_m); 130.12 (dd, $^1J_{C,P} = 6.7$, $^4J_{C,P} \approx 3.1$ Hz, C_i); 131.09 (dd, $^1J_{C,P} = 5.6$, $^4J_{C,P} \approx 3.0$ Hz, C'_i); 131.84 (s, C_p); 133.14 (pseudo-t, $J_{C,P} \approx 4.9$ Hz, C_o); 133.63 (pseudo-t, $J_{C,P} \approx 5.1$ Hz, C_o) ppm. $^{31}P\{^1H\}$ NMR (81 MHz, $CDCl_3$, H_3PO_4): δ = 36.28 (s) ppm. $C_{30}H_{32}Cl_2Ni_2P_2S_2$ (707.0): calcd. C 50.97, H 4.56, S 9.07; found C 50.66, H 4.69, S 8.93 %.

X-ray Structure Determination of 2: Brown crystals of **2** were obtained by slow evaporation of a chloroform/dichloromethane (1:1) solution at room temperature. Molecular formula: $C_{31}H_{33}Cl_5Ni_2P_2S_2$; $M = 826.30$; monoclinic; $a = 12.8894(4)$, $b = 11.8883(3)$, $c = 22.5265(7)$ Å, β = 96.5500(10)°, $V = 3429.27(17)$ Å^3; space group $P2_1/n$; $Z = 4$, μ = 1.725 mm^{-1}, $D_{calcd.} = 1.600$ g cm^{-3}. The measurements were made on a Siemens P4 diffractometer equipped with a SMART-CCD-1000 area detector, a MAC Science Co. rotating anode with Mo-K_α radiation, a graphite monochromator and a Siemens low temperature device LT2 (T = −120 °C). In the range 1.74 to 31.50°, 49317 reflections were collected, of which 10947 were unique ($R_{int} = 0.0838$). Full-sphere data was collected using ω and scans. Programs used: Data collection Smart V. 5.060 (Bruker AXS, 1999), data reduction Saint + Version 6.02 (Bruker AXS 1999) and absorption correction SADABS (max/min transmission: 1.000000/0.356109, Bruker AXS 1999). Structure solution and refinement was done using SHELXTL Version 5.10 (Sheldrick, Universität Göttingen, Göttingen (Germany), 1998). The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. All hydrogen atoms were refined without constraints. Final $R_1[I > 2\sigma(I)] = 0.0452$ and $wR(F^2)[I > 2\sigma(I)] = 0.1037$. The number of refined parameters was 511. CCDC-216078 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Heterobimetallic Calix[4]arene Complexes: Interconversion of Dimeric (Ca, Sr or Ba)/Ti^{IV} Complexes with a Monomeric K/Ti^{IV} Complex

Antonella J. Petrella,[a] Nicholas K. Roberts,[a] Colin L. Raston,[b] Donald C. Craig,[a] Mark Thornton-Pett,[c] and Robert N. Lamb*[a]

Keywords: Calixarenes / Heterometallic complexes / Alkaline earth metals / Potassium / Titanium

Reaction of calix[4]arene with alkaline earth metals (Ca/Sr/Ba) in methanol followed by the addition of various titanium(IV) sources afforded novel dimeric 1:1 alkaline earth/titanium(IV) calix[4]arene complexes. In each complex the central core of the crystallographically imposed centrosymmetric dimer consists of a rhombus of alternating alkaline earth metals and μ_3-oxo-centres. Five terminal methanol ligands form seven-coordinate calcium and strontium centres, while the barium centres are bridged by two additional methanol ligands, making them nine-coordinate. Each oxo centre is the apical ligand of a square-pyramidal titanium(IV) centre, whose basal plane ligands are the four phenolate oxygens from a calix[4]arene in the symmetrical cone-conformation. Deprotonation of calix[4]arene with potassium metal, followed by the addition of a titanium(IV) source containing at least one acetylacetonate ligand, formed a mixed potassium/titanium complex based on one calix[4]arene. The potassium cation in this complex binds within the π-basic calix[4]arene cavity, whilst titanium is octahedrally complexed in the *exo*-position, by four phenolates and one acetylacetonate. The alkaline earth titanium dimers and potassium/titanium monomers could be interconverted merely by changing the solvent, with the appropriate cations and ligands present in solution.

Introduction

There is currently much interest in the formation and characterisation of heterobimetallic alkoxide species with well-defined stoichiometries.[1] Such complexes have potential as single source precursors to ultra-pure oxide ceramics,[2] or as molecular catalysts.[3] The synthesis and structural characterisation of heterobimetallic alkoxides has typically required the use of inert atmosphere techniques, owing to the inherent instability of such complexes towards hydrolysis and/or facile redistribution reactions.[1] We sought to explore alternative synthetic approaches, using macrocyclic calix[n]arenes as multidentate alkoxy ligands to circumvent the above decomposition reactions, and to impart high thermal stability.

Calix[4]arenes provide a set of four contiguous phenolic oxygen centres poised for metal ion chelation, and their complexes show a wide range of structural types, usually with the macrocycle in the bowl-shaped conformation.[4] While there are many structurally authenticated calix[4]arene transition metal complexes, those for the main group metals are limited. In the case of alkali and alkaline earth metals there are few examples of complexes of calix[*n*]arenes, the main focus of the chemistry concerned with ion extraction processes. In the case of calix[4]arenes there are a few examples of alkali metal[5] and alkaline earth metal[6] complexes, and a few examples of mixed transition-alkali metal complexes,[4,7] yet there are no examples of mixed transition metal alkaline earth complexes.

Herein we report a simple route to the preparation of dimeric alkaline earth/titanium(IV) calix[4]arene complexes, **1**−**3**, and the formation of a monomeric potassium/titanium(IV) calix[4]arene complex, **4** (Scheme 1). The complexes are formed rapidly in good yield, and do not require the use of an inert atmosphere, or dry solvents, although the yield of the dimeric calcium/titanium(IV) complex is higher in dry solvent. We also show that the alkaline earth/titanium(IV) dimers may be inter-converted into the potassium/titanium(IV) monomers by merely changing the solvent, with the appropriate cations and ligands present in solution. Seemingly the relative disposition of the alkoxide groups in the calix[4]arene stabilises these novel structures, with their formation also depending on the nature of the alkali/alkaline earth metal as well as the choice of solvent.

Addition of one equivalent of alkaline earth metal (Ca, Sr or Ba) to a suspension of *p*-*t*Bu-calix[4]arene, *p*-*t*Bu-

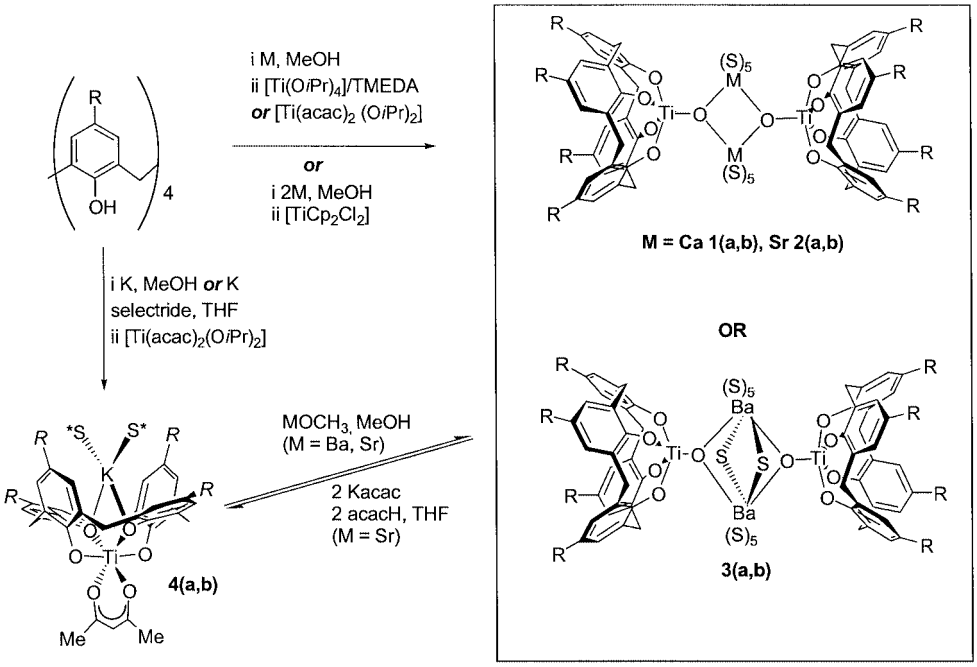

Scheme 1. S = MeOH, S* = MeOH or THF; (a) R = *t*Bu, (b) R = H

$L[OH]_4$, or calix[4]arene, $L[OH]_4$, in methanol, followed by addition of a 1:1 solution of $[Ti(OiPr)_4]$ and TMEDA (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine) in methanol afforded complexes **1**−**3** (Scheme 1). In the case of reactions involving calcium metal, dry methanol was used (see below). Premixing the $[Ti(OiPr)_4]$ and TMEDA before addition of methanol avoids the precipitation of titanium hydroxides/methoxides.

Alternative preparations of **1**−**3** were also established, where $[Ti(acac)_2(OiPr)_2]$ (acac = acetylacetonate) or $[TiCp_2Cl_2]$ (Cp = cyclopentadienyl) and an extra equivalent of alkaline earth metal were used in place of $[Ti(OiPr)_4]$/TMEDA. Base cleavage of both Cp ligands from $[TiCp_2Cl_2]$ is consistent with previous reports that Cp groups are cleaved from titanocene reagents under basic conditions.[8] The success of this synthetic route suggests that the relatively slow reaction of $[TiCp_2Cl_2]$ provides a synthetically engineered pathway for gradually delivering labile titanium(IV) into the reaction mixture, which presumably allows ligation with calix[4]arene to compete successfully against hydrolysis/methanolysis. Similarly, the successful use of $[Ti(OiPr)_4]$/TMEDA or $[Ti(acac)_2(OiPr)_2]$ reagents appears to rely on the chelation of titanium(IV) by TMEDA or acetylacetonate ligand to provide the same slow delivery of titanium(IV).

When TMEDA was omitted from the reaction of $[Ti(OiPr)_4]$ with calix[4]arene deprotonated by strontium or barium, the respective yields of **2(a,b)** and **3(a,b)** were low (< 20%, identified by ^{1}H NMR spectroscopy) and the complexes were contaminated by insoluble titanium hydrolysis/alcoholysis products. For calcium metal, under the same conditions, some dimer products **1(a,b)** precipitated, ca. 50% yield, along with unchanged calix[4]arene. The same modest yield results for calcium, even in the presence of TMEDA, in contrast to the good yields, ca. 80%, for the strontium and barium analogues. However, the yield of the Ca/Ti dimers **1(a,b)** can be improved to ca. 70% by using dry methanol. These findings can be rationalised by the poor solubility of calcium hydroxide in wet methanol, compared to strontium and barium hydroxides. Thus, whereas solutions containing strontium and barium ions and calix[4]arenes in wet methanol remain clear, the corresponding calcium solutions deposit considerable amounts of white material. However, when the latter mixture is formed in dry methanol the solution remains clear. For all three structures oxo-bridges are possibly derived from adventitious water; alternatively they could result from the presence of oxides/hydroxides on the surface of the metal.

The dimeric structures of **1b**, **2b** and **3a** were established using single-crystal X-ray diffraction data. Complexes **1b** and **2b** crystallise in the space group $P2_1/n$ having similar cell dimensions and are strictly isomophous, with the cell volume of the calcium complex slightly smaller than that of the strontium analogue, as expected. Major differences in the molecular structures of **1b** and **2b** (Figure 1, Table 1),[9] relative to that of **3a** (Figure 2, Table 2),[9] other than those associated with the substituents on the calixarene, include two additional methanol ligands which bridge the two barium centres in **3a** and the resulting coordination environment of the alkaline earth metal centres. The ^{1}H NMR spectra of **1b**, **2b** and **3a** are consistent with the persistence of the solid-state structures in solution.

The central cores of the crystallographically imposed centrosymmetric dimers in **1b** and **2b** consist of a rhombus of alternating alkaline earth metals and μ_3 oxo-centres, with each oxygen atom forming the apical ligand to a square-pyramidal titanium(IV) centre. The basal plane ligands are the four phenolate oxygen centres from a calix[4]arene in a

symmetrical cone-conformation, as shown in Figure 1, along with key bond lengths and angles, which are unexceptional. Deviation of the titanium centres from the plane defined by the four phenolate oxygen centres is 0.4016 and 0.4250 Å for **2b** and **1b** respectively. The calcium/strontium centres are seven-coordinate, having a distorted pentagonal bipyramidal geometry with two bridging oxo- and five terminal methanol ligands. An oxo group and one methanol ligand are in apical positions, with the other methanol ligands associated with hydrogen bonding to the oxygen atoms of the calix[4]arene, this presumably contributes to the stability and favourable formation/crystallisation of the complexes from methanol. The calixarene-methanol O···O distances and corresponding O···HO distances (in parentheses) are 2.676, (2.006), 2.645, (1.759), 2.649, (1.881), 2.603, (1.889) for **1b**; and 2.684, (1.920), 2.649, (1.769), 2.648,

(1.910) 2.689, (2.026) for **2b**. There are 15 methanol solvates per dimer, of which 10 are coordinated to the strontium metal centres, two are located within the cavities of the calixarenes, and the remainder are found at interstitial sites in the structure.

Complex **3a** crystallises in the space group *Pbca*. The molecular structure of the complex is essentially the same as in **1b** and **2b**, being also comprised of centrosymmetric dimers. The titanium centres are in a similar environment, the metal centres deviating from the basal plane of four oxygen centres by 0.4021 Å. The expanded coordination sphere of the barium centres, each now with nine ligands, two bridging oxo, two bridging methanol and five terminal methanol solvates, is best described as capped square antiprismatic (Figure 2). The square face opposite the unique capping methanol is comprised of two *trans*-μ_3-oxo groups and two *trans*-μ_2-methanol ligands, which is common to both barium centres, and replaces the rhombus oxo-Ca/Sr core in **1b** and **2b**. Intramolecular hydrogen bonding is also prevalent, with calixarene-methanol O···O distances 2.688, 2.723, 2.631, 2.667Å, and additional interactions between bridging oxo and bridging methanol ligands, O5···O1, O1′ 2.904, 2.974 Å. Overall there are 24 methanol solvent molecules per dimer: 12 are coordinated to barium centres, two are located in the cavities of the calix[4]arenes, and the remaining 10 are located in the interstitial sites in the structure, along with one molecule of water. The titanium(IV) centres have similar geometries to those in **1b** and **2b**.

Previous examples of mixed-metal M/Ti species (M = Ba, Sr, Ca) based on simple alkoxide ligands do not generally have 1:1 stoichiometry,[10] but this is the case for complexes based on β-diketonates (M = Sr, Ba),[11] catecholate (M = Sr, Ba),[12] and aryloxy ligands [M = Ba].[13] The structures of such complexes are similar to the present structures in being dimeric, but are dissimilar in that the titanium centres are octahedrally coordinated. Also, whilst there are several examples of larger M/Ti aggregates displaying oxo-bridging between alkaline earth and titanium(IV) centres,[14] examples of oxo-bridged 2:2 complexes (as in the present structures) have the oxo groups between the titanium centres. Thus our structures are unique in the interplay of the oxo groups with the two different metal centres. This, and the lower coordination number of the titanium centres, possibly relates to the steric constraints imposed by the four phenolato groups of the calixarene, and also the intramolecular hydrogen bonds between the coordinated methanol molecules and the calixarene oxygens.

The monomeric heterobimetallic K/Ti calix[4]arene complexes, **4(a,b)**, were prepared by addition of one equivalent of potassium metal to *p*-*t*Bu-L[OH]$_4$ in either methanol, for **4a**, or THF for **4b**, followed by the addition of one equivalent of [Ti(acac)$_2$(O*i*Pr)$_2$]. The complexes were structurally authenticated using X-ray diffraction data. They crystallise in the space groups *C*2/*c* and *P*2$_1$/*n*, respectively, **4a** having half a molecule in the asymmetric unit, the other half being generated by a twofold rotation operation, whereas **4b** has a full molecule as the asymmetric unit. A molecular projection of **4a** is shown in Figure 3.[9] For both complexes the titanium(IV) centres are octahedral, bound by a bidentate β-diketonate and four phenolato oxygen atoms of a pinched cone conformation calix[4]arene (the pitch of the phenol planes relative to the plane through the oxygens of the calixarene being 18.2° and 70.1° for **4a** and 12.0°, 13.2°, 67.7°, 66.1° for **4b**; see also Table 3). The potassium is accommodated within the cavity of the calix[4]arene, interacting with two of the phenolate oxygen atoms and forming π-interactions to two opposite aromatic rings. Additionally two terminal methanol or THF ligands result in six-coordinate potassium centres. The K^+-η^6-arene(centroid) distances in **4a** and **4b** are 3.142 and 3.180, 3.253 Å, respectively, which are similar to previously reported values for a mixed *endo*-*exo*-potassium *exo* titanium dimeric calix[4]arene complex (3.217 Å).[7b]

The formation of the monomeric species **4(a,b)** is favoured by the incorporation of a chelating β-diketonate ligand, which provides steric protection against the formation of metallo-bridged structures, and predisposes titanium to chelate to only one calix[4]arene. In addition, the potassium ion is bound within the calix[4]arene cavity. Analogous monomeric alkaline earth/titanium calix[4]arene complexes could not be obtained, the dimers **1(a,b)**−**3(a,b)** being formed instead, even in the presence of acetylacetonate. This difference is consistent with the more polarising divalent alkaline earth cations preferring *exo*-cavity coordination, where they can obtain higher coordination numbers relative to the coordination available in the *endo*-cavity.

Dimers **1a**−**3a** possessing the *p*-*t*Bu substituents are sparingly soluble in methanol, and they precipitate from solution in good yield when prepared in this solvent. In contrast, these same dimers are highly soluble in solvents such

as toluene, dichloromethane or THF. We utilised solubility differences to devise methods to interconvert the dimers, in general, with the corresponding K/Ti monomers, **4(a,b)**, the latter being readily recrystallised from a variety of solvents. Thus, the K/Ti monomer **4a** crystallises from THF on addition of two equivalents of K(acetylacetonate) and acetylacetone to the alkaline earth/Ti dimers **2a** or **3a** (Scheme 1). No conversion into monomer could be effected in methanol. In THF, both the K/Ti monomer and Ba/Ti, Sr/Ti dimers are soluble, hence both monomeric and dimeric species can be present in equilibrium in solution. The K/Ti monomer can then be isolated from the mixture by selective crystallisation in the presence of additional ligand, since the Ba/Ti and Sr/Ti dimers cannot be crystallised from THF. Dissolution of the dimers in THF presumably results in ligand solvent displacement with disruption of the tightly coordinated methanol-calix[4]arene hydrogen bonding array (Figure 1).

Conversely the K/Ti monomer **4b** can be converted simply to the dimers by addition of methanolic solutions of Ba/Sr methoxides (>90%). Evidently the insolubility of the Ba/Ti and Sr/Ti dimers in methanol drives their formation. Attempts to interconvert the Ca/Ti dimers with monomers were thwarted by the precipitation of $Ca(OH)_2$.

Dimers **1**−**3** have been tested for application as single source precursors for CVD of perovskite titanate films. Preliminary results indicate that the compounds sublime under high vacuum and that annealing of this sublimate indeed gives a crystalline perovskite phase, and further investigations are underway. This aspect aside, the significance of the above results include (i) the simplicity and versatility of the synthetic approach in gaining access to heterobimetallic complexes, which should have a profound impact on synthetic strategies for gaining access to a wide range of mixed metal complexes, (ii) the novelty of the structures, and (iii) the remarkable control of the interconversion of monomeric and dimeric complexes.

Experimental Section

Synthesis of 1(a,b) 2(a,b) and 3(a,b): Full experimental details are given for **3a**, the synthesis of **1**, **2** and **3b** being very similar. Barium (0.12 g, 0.87 mmol) was added to a suspension of *p*-*t*Bu-calix[4]arene (0.50 g, 0.77 mmol) in methanol (30 mL). The mixture was stirred, affording a clear pale yellow solution on complete reaction of the metal. [Ti(O*i*Pr)$_4$] (0.25 mL, 97%, 0.84 mmol) and TMEDA (0.15 mL, 1 mmol) were mixed together and then diluted in approximately 5 mL methanol and this solution was added to the barium calix[4]arene complex. A fine white solid formed, which was collected after 15 min and recrystallised from 10 mL dichloromethane by the addition of 15 mL of boiling methanol, yielding colorless prisms of **3a** (0.7 g, 80%). The analogous Sr/Ti **2a** (85% yield) and Ca/Ti (**1a**, 51% yield), were prepared as for **3a**. For **1a**, the solution formed by reaction of calcium with *p*-*t*Bu-calix[4]arene required filtering. Also, the solution of crude **1a** in dichloromethane required filtering to remove some precipitated *p*-*t*Bu-calix[4]arene. Crystals of **3a** suitable for X-ray crystallography were grown by layering methanol onto a dichloromethane solution of the complex. Compounds **1b**, **2b**, and **3b** were prepared similarly, calix[4]arene being used in place of *p*-*t*Bu-calix[4]arene, except that recrystallisation was performed directly from hot methanol,[15] yield 71% **1b**,[16] 80% **2b**, 82% **3b**. ^{1}H NMR ($CDCl_3$, 300 MHz, 298 K): δ = **1a**: 6.90 (s, 16 H, aryl), 4.73 (br., 8 H, CH_2), 3.40, (s, 66 H, methanol), 2.88 (br., 8 H, CH_2), 1.15 (s, 72 H, *t*Bu); **2a**: 6.92 (s, 16 H, aryl), 4.64 (d, J = 12 Hz, 8 H, CH_2), 3.33 (s, 66 H, methanol), 2.94 (d, J = 12 Hz, 8 H, CH_2), 1.15 (s, 72 H, *t*Bu); **3a**: 6.94 (s, 16 H, aryl), 4.63 (d, J = 12 Hz, 8 H, CH_2), 3.35 (s, 72 H, methanol), 3.00 (d, J = 12 Hz, 8 H, CH_2), 1.15 (s, 72 H, *t*Bu); **1b**: 6.98 (d, 16 H, J = 6 Hz, aryl), 6.49 (t, J = 6 Hz, 8 H, aryl), 4.79 (d, J = 12 Hz, 8 H, CH_2), 3.40 (s, 45 H, methanol), 3.16 (d, J = 12 Hz, 8 H, CH_2); **2b**: 6.96 (d, 16 H, J = 6 Hz, aryl), 6.51 (t, J = 6 Hz, 8 H, aryl), 4.74 (d, J = 12 Hz, 8 H, CH_2), 3.40 (s, 45 H, methanol), 3.03 (d, J = 12 Hz, 8 H, CH_2); **3b**: 6.96 (d, 16 H, J = 6 Hz, aryl), 6.50 (t, J = 6 Hz, 8 H, aryl), 4.74 (d, J = 12 Hz, 8 H, CH_2), 3.40 (s, 51 H, methanol), 3.06 (d, J = 12 Hz, 8 H, CH_2) ppm.

Synthesis of 4a and 4b: Potassium was added (0.04 g, 1.0 mmol) to a suspension of *p*-*t*Bu-calix[4]arene (0.50 g, 0.77 mmol) in methanol (20 mL). The mixture was stirred, resulting in a clear pale yellow solution on complete reaction of the metal. The addition of [Ti(acac)$_2$(O*i*Pr)$_2$] (0.40 mL, 75%, 0.82 mmol) gave an orange solution, which was concentrated by boiling to incipient crystallisation. On slow cooling to 0 °C orange prisms of **4a** formed[15] (0.6 g, 72%). **4b**: This THF adduct was prepared using dry THF and K-selectride (1 M in THF) in place of methanol and potassium metal, giving **4b** (0.45, 56%). ^{1}H NMR ($CDCl_3$, 300 MHz, 298 K): δ = **4a** 7.13 (s, 4 H, aryl), 6.91 (s, 4 H, aryl), 5.94 (s, 1 H, CH), 4.53 (d, J = 15 Hz, 4 H, CH_2), 3.45 (s, 24 H, methanol), 3.12 (d, J = 15 Hz, 4 H, CH_2), 2.00 (s, 6 H, CH_3), 1.37 (s, 18 H, *t*Bu), 1.10 (s, 18 H, *t*Bu); **4b:** 7.13 (s, 4 H, aryl), 6.93 (s, 4 H, aryl), 5.93 (s, 1 H, CH), 4.52 (d, J = 15 Hz, 4 H, CH_2), 3.69 (m, 12 H, THF), 3.14 (d, J = 15 Hz, 4 H, CH_2), 1.98 (s, 6 H, CH_3), 1.83 (m, 12 H, THF), 1.37 (s, 18 H, *t*Bu), 1.10 (s, 18 H, *t*Bu) ppm.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Conversion of Ba/Ti Dimers to K/Ti Monomers: Acetylacetone (0.12 mL, 1.2 mmol) in methanol (ca. 2 mL) was treated with potassium metal (0.025 g, 0.64 mmol) and the solution was added to a solution of the Ba/Ti dimer **3a** (0.7 g 0.30 mmol) dissolved in THF (20 mL). The orange solution was concentrated by heating until incipient crystallisation. On cooling slowly to room temperature, crystals of **4b** formed (0.22 g, 36%). The Sr/Ti dimer **2a** could be converted into **4b** analogously (38% yield).

Conversion of K/Ti Monomer to Ba/Ti or Sr/Ti Dimer: A solution of **4b** (0.5 g, 0.48 mmol) in methanol (50 mL) was treated with a solution of Ba in methanol (0.07 g, 0.50 mmol) to give a white precipitate of **1a** (0.49 g, 96%); **4b** could be similarly converted into **1b** using Sr in place of Ba (94%).

Crystal Data: The intensity data was collected at 150(1)K on an Enraf−Nonius Kappa CCD diffractometer with Mo-K_α (λ = 0.71073Å) radiation. Structures **1b**, **2b**, **4a** and **4b** were solved by direct methods (SHELXL-97) and refined with a full-matrix least-squares fit refinement on F^2 (SHELXL-97). Structure **3a** was solved by direct methods (SIR92) and refined with a full-matrix least-squares fit on F (RAELS).

Di- and Trinuclear Ruthenium and Osmium Bis(2-pyridyl) Ketone Oximate Derivatives

Javier A. Cabeza,*[a] Ignacio del Río,[a] Víctor Riera,[a] Marta Suárez,[a] Carmen Álvarez-Rúa,[b] Santiago García-Granda,[b] Shih Hsien Chuang,[c] and Jih Ru Hwu*[c]

Keywords: Ruthenium / Osmium / Cluster compounds / Oximes / DNA cleavage

Treatment of $[Ru_3(CO)_{12}]$ with bis(2-pyridyl) ketone oxime (Hdpko) in refluxing THF leads to a separable mixture of $[Ru_3(\mu,\eta^3\text{-dpko-}N,N,O)_2(CO)_8]$ (**1**) and $[Ru_2(\mu,\eta^3\text{-dpko-}N,N,O)_2(CO)_4]$ (**2**). In both complexes, two Ru atoms are doubly bridged by two dpko ligands, which are attached to a Ru atom through the oximate O atom while chelating the other Ru atom through the N atoms of a pyridyl group and the oximate fragment. While the Ru–Ru distance of the bridged edge of complex **1** is very long [3.5388(9) Å], that of complex **2** is very short [2.620(1) Å]. The acetonitrile complexes $[M_3(CO)_{10}(MeCN)_2]$ (M = Ru, Os) react with Hdpko in THF at room temperature to give $[M_3(\mu\text{-H})(\mu,\eta^3\text{-dpko-}N,N,O)(CO)_9]$ [M = Ru (**3**) Os (**4**)], in which the dpko ligand behaves in the same way as in **1** and **2**. The thermal reaction of **3** with Hdpko leads to a mixture of **1** and **2**, while an analogous treatment of complex **4** gives $[Os_3(\mu,\eta^3\text{-dpko-}N,N,O)_2(CO)_8]$ (**5**), which is isostructural with complex **1**. Compounds **1** and **3** are the first examples of ruthenium clusters containing oximate ligands. These oximate complexes display low activity as DNA cleavage agents, requiring high complex concentrations, long incubation times, and the use of UV light as a trigger.

Introduction

Oximes and oximates are attractive ligands because they can interact with metal atoms through either one or both N and O atoms, acting as terminal (monodentate or chelating)[1,2] or, less frequently, as bridging ligands.[3−6] In addition, oximes can remain intact in the coordination sphere of the metals or undergo O−H bond cleavage to afford oximate derivatives.[1−6] In some cases they can also suffer N−OH bond activation to form nitrenium fragments.[2b,2c,3,4] The osmium cluster-promoted O−H vs. N−O bond cleavage of these ligands has been studied.[4] Despite this rich derivative chemistry and the large number of oximate complexes of transition metals known to date,[1−6] it is noteworthy that no ruthenium and only a few osmium[4−6] cluster complexes containing oximate ligands have been reported.

Herein we report the synthesis and structural characterization of triruthenium and triosmium carbonyl clusters derived from bis(2-pyridyl) ketone oxime (Hdpko). We decided to use this oxime because, in addition to its varied coordination possibilities, its chemistry has been little explored.[7]

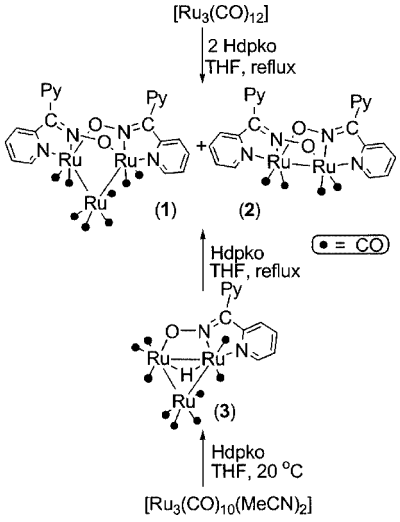
Results and Discussion

Synthesis and Structural Characterization of Oximate Complexes

Treatment of $[Ru_3(CO)_{12}]$ with one equivalent of Hdpko, in THF at reflux temperature, gave a complex mixture of compounds containing some ruthenium carbonyl starting material. When two equivalents of Hdpko were used under the same reaction conditions, the novel trinuclear derivative $[Ru_3(\mu,\eta^3\text{-dpko-}N,N,O)_2(CO)_8]$ (**1**) and the dioximate-bridged binuclear complex $[Ru_2(\mu,\eta^3\text{-dpko-}N,N,O)_2(CO)_4]$ (**2**) were obtained as the major reaction products (Scheme 1).

The ^{1}H NMR spectra of both complexes display no signals attributable to hydride ligands, while the aromatic regions reflect, in both cases, the presence of two inequivalent pyridyl groups. Their IR spectra confirm the absence of bridging carbonyl ligands and display no bands in the O−H stretching region, suggesting O−H bond activation.

The trinuclear nature of **1** was clearly indicated by its microanalysis and FAB MS spectrum, which also show the presence of eight CO ligands and the incorporation of two



Scheme 1. Synthesis of compounds **1**−**3**

oximate ligands to the cluster shell. The structure of **1** was established by X-ray diffraction methods (Figure 1, Table 1). In addition to eight terminal CO ligands, the complex contains two oximate ligands spanning the same edge of the trimetallic core, in a head-to-tail arrangement, through both the N and O atoms. Each dpko ligand is also attached through a pyridine N-atom to one of the metal atoms of the bridged edge, in such a way that the complex

presents a non-crystallographic twofold axis. Such a symmetry was also indicated by its $^{13}C\{^1H\}$ NMR spectrum, which displays only four carbonyl resonances. The length of the bridged edge [Ru(1)−Ru(2) = 3.5388(9) Å] indicates the absence of a metal−metal bond, as expected for a 50-electron trinuclear cluster.[8]

The $^{13}C\{^1H\}$ NMR spectrum of **2** shows only two signals attributable to terminal carbonyl ligands. Its binuclear character and the incorporation of one dpko ligand per Ru atom were pointed out by its microanalysis and FAB MS. Its structure was confirmed by an X-ray diffraction study (Figure 2, Table 2). The ligand arrangement in compound **2** is analogous to that described above for complex **1**, but the $Ru(CO)_4$ fragment present in **1** is now missing. The Ru(1)−Ru(2) distance in **2**, 2.620(1) Å, is in the range expected for a single metal−metal bond, in accordance with the 34-electron count for the complex.[8] It is noteworthy that the oximate NO fragment is able to bridge two metal atoms which are either close to each other (complex **2**) or very far apart (complex **1**).

N(4)−O(2)	1.334(4)		

IR monitoring of the reaction of $[Ru_3(CO)_{12}]$ with Hdpko showed that an intermediate, probably arising from the incorporation of only one equivalent of Hdpko to the cluster, is formed prior to compounds **1** and **2**. Its isolation was not possible under the thermal conditions applied, since it readily reacted with more Hdpko to give **1** and **2** as the two major final products. Fortunately, we managed to isolate this intermediate working at room temperature, using the reactive complex $[Ru_3(CO)_{10}(MeCN)_2]$[9] as starting material. The product was characterized as the novel

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

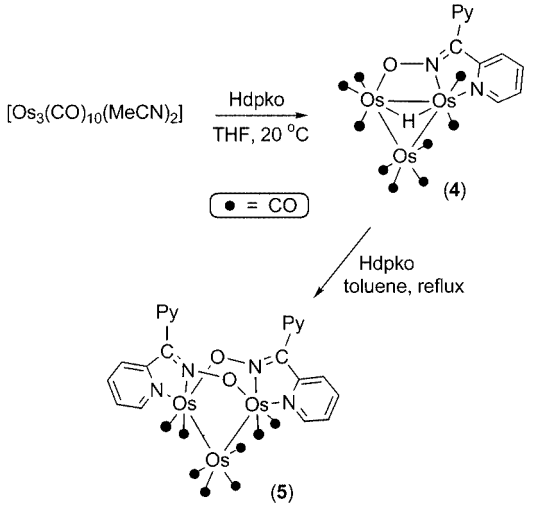
trinuclear derivative $[Ru_3(\mu\text{-H})(\mu,\eta^3\text{-dpko-}N,N,O)(CO)_9]$ (**3**; Scheme 1).

The IR spectrum of **3** strongly suggests O−H bond scission. This was further supported by its ^{1}H NMR spectrum, which shows a singlet resonance at $\delta = -18.85$ ppm attributable to a hydride ligand, while the inequivalence of two pyridine rings is evident in the aromatic region. The incorporation of one equivalent of the oxime to the trinuclear framework and the presence of nine carbonyl ligands were confirmed by its microanalysis and FAB MS.

The structure proposed for **3**, and its role as an intermediate in the formation of **1** and **2** from $[Ru_3(CO)_{12}]$, were further corroborated by treating **3** with one equivalent of the oxime in THF at reflux temperature. This reaction led to complexes **1** and **2**, along with a small amount of $[Ru_3(CO)_{12}]$.

To the best of our knowledge, **1** and **3** are the first ruthenium cluster complexes containing oximate ligands. Some diruthenium(I) complexes structurally related to **2**, namely $[Ru_2(\mu,\eta^2\text{-ONCR}^1\text{R}^2\text{-}O,N)_2(CO)_4L_2]$ (L = intact oxime or other neutral two-electron donor ligands), have been reported.[10] It has also been reported that the reaction of $[Ru_3(CO)_{12}]$ with 1-nitrous-2-naphthol gives a triruthenium cluster structurally related to complex **1**, which also contains two NO bridges.[11]

The triosmium acetonitrile complex $[Os_3(CO)_{10}(MeCN)_2]$[12] reacts with Hdpko in THF at room temperature to give the monohydrido derivative $[Os_3(\mu\text{-H})(\mu,\eta^3\text{-dpko-}N,N,O)(CO)_9]$ (**4**; Scheme 2). The structure of this compound was established by X-ray diffraction methods (Figure 3, Table 3). The cluster consists of a nearly equilateral triangle of Os atoms in which two metal atoms are attached to a dpko ligand in the same way as that found previously for compounds **1** and **2**. A hydride ligand spans the same Os−Os edge as the oximate NO fragment. The cluster shell is completed by nine CO ligands. Therefore, the cluster is a closed-shell, 48-electron trinuclear species.[8] The spectroscopic data of **4** are similar to those of the ruthenium complex **3**, indicating that both compounds are isostructural.



Scheme 2. Synthesis of compounds **4** and **5**

Therefore, the oxime Hdpko reacts with the triruthenium bis(acetonitrile) cluster in the same way as its triosmium analogue, giving isostructural products. However, this is not always the case for other ligands, such as bis(2-pyridyl)-amine,[13] 2-amino-7,8-benzoquinoline,[14] or 2,2′-diamino-1,1′-binaphthalene.[15]

Bearing in mind that the triruthenium complex **3** is an intermediate in the formation of **1**, we reasoned that complex **4** could be a suitable precursor of a triosmium cluster isostructural with complex **1**. Indeed, treatment of complex **4** with Hdpko in toluene at reflux temperature allowed the isolation of $[Os_3(\mu,\eta^3\text{-dpko-}N,N,O)_2(CO)_8]$ (**5**). The structure depicted for this complex in Scheme 2, which is similar to that of the triruthenium complex **1**, was determined by X-ray diffraction methods (Figure 4, Table 4). Accordingly, its IR and NMR spectroscopic data are also similar to those of complex **1**.

Very few triosmium clusters containing oximate ligands have been reported prior to this work. They contain oximate fragments that span two metal atoms through the N and O atoms.[4,5] During the preparation of this manuscript, some triosmium clusters related to compounds **4** and **5**, derived from diphenyl ketone oxime and phenyl (2-pyridyl) ketone oxime, have been reported.[6]

DNA-Cleavage Ability of the Oximate Complexes

Although most metal complex-mediated DNA cleavage reactions use mononuclear complexes as promoters,[16,17] a few interesting results have been reported using bi-[18] and trinuclear[19] complexes. Prompted by the fact that prior to

this work no metal complexes of oximes had been studied as DNA cleaving agents, the ruthenium and osmium oximate complexes **1**−**5** were tested by studying the nicking of supercoiled circular φ*X174* RFI DNA (form I; 50 μM/base pair) into relaxed circular DNA (form II).

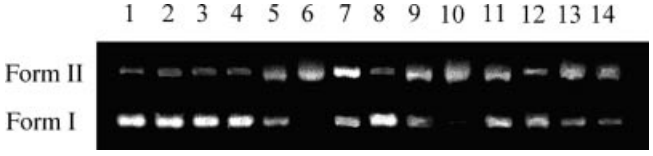

Figure 5. Electrophoresis separation of supercoiled circular φ*X174* RFI DNA (form I) and relaxed circular DNA (form II) after treatment of form I DNA with the ruthenium complexes **1**−**3**; lanes 1, 4, 8, 12 were run in the dark, the remaining ones involved UV light irradiation; lane 1, DNA alone (dark, pH = 7.0); lane 2, DNA alone (pH = 7.0); lane 3, DNA alone (pH = 5.0); lane 4, **1** (1000 μM, pH = 7.0, dark); lane 5, **1** (1000 μM, pH = 7.0); lane 6, **1** (1000 μM, pH = 5.0); lane 7, **1** (500 nM, pH = 5.0); lane 8, **2** (1000 μM, pH = 7.0, dark); lane 9, **2** (1000 μM, pH = 7.0); lane 10, **2** (1000 μM, pH = 5.0); lane 11, **2** (1.0 μM, pH = 5.0); lane 12, **3** (1000 μM, pH = 7.0, dark); lane 13, **3** (1000 μM, pH = 7.0); lane 14, **3** (1000 μM, pH = 5.0)

Figure 5 shows the results obtained with the ruthenium complexes. After UV irradiation of complexes **1**−**3** (1000 μM) and form I DNA, in pH 7.0 buffer for 8.0 h, ratios of (form II)/(form I) of 1.78, 1.63 and 2.57 were found (see lanes 5, 9, and 13). The cleaving ability of **1** and **2** was found to be pH dependent and is greater under slightly acidic conditions, cleaving DNA at pH 5.0 at concentrations of 500 nM (**1**) and 1.0 μM (**2**), with ratios of (form II)/(form I) of 1.27 and 1.08, respectively (lanes 7 and 11).

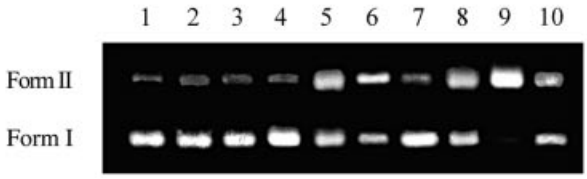

Figure 6. Electrophoresis separation of supercoiled circular φ*X174* RFI DNA (form I) and relaxed circular DNA (form II) after treatment of form I DNA with the osmium complexes **4** and **5**; lanes 1, 4, 7 were run in the dark, the remaining ones involved UV light irradiation; lane 1, DNA alone (dark, pH = 7.0); lane 2, DNA alone (pH = 7.0); lane 3, DNA alone (pH = 5.0); lane 4, **4** (1000 μM, pH = 7.0, dark); lane 5, **4** (1000 μM, pH = 7.0); lane 6, **4** (1000 μM, pH = 5.0); lane 7, **5** (1000 μM, pH = 7.0, dark); lane 8, **5** (1000 μM, pH = 7.0); lane 9, **5** (1000 μM, pH = 5.0); lane 10, **5** (1.0 μM, pH = 5.0)

For the osmium oximate complexes **4** and **5** (Figure 6), it was found that they can also cleave DNA upon UV activation. The ratios of (form II)/(form I) were 1.13 and 1.44 for **4** and **5** (1000 μM), respectively, in pH 7.0 buffer (see lanes 5 and 8). Complex **5** also cleaved DNA at pH 5.0 in concentrations of 1.0 μM to give a (form II)/(form I) ratio of 1.04 (see lane 10).

A comparison of the cleavage activity of the pairs of isostructural clusters **1**, **5** and **3**, **4** indicates that the ruthenium clusters (**1** and **3**) are more active than the osmium ones (**4** and **5**). In addition, the binuclear complex **2** is less active than the trinuclear ones **1** and **3**.

Although the cleaving ability of the Ru cluster complexes **1** and **3** is higher than that reported for other triruthenium carbonyl clusters,[19c] their activity is very low when compared to that of many mono- and binuclear compounds previously studied.[17,18] The high complex concentrations needed (millimolar range), along with long incubation times (8 h) and UV activation, hamper the use of these complexes for experiments in vivo.

Concluding Remarks

By using the oxime Hdpko as a ligand precursor, we have prepared one diruthenium, two triruthenium and two triosmium carbonyl complexes, all containing the oximate ligand dpko η^3-coordinated to two metal atoms through the N and O atoms of the oximate fragment and the N atom of the pyridyl group. Compounds **1** and **3** are the first ruthenium cluster complexes derived from oximes.

The first DNA cleaving studies using oximate metal complexes are described. Unfortunately, the observed activity is very low when compared to those of many mono- and binuclear compounds previously studied.

Experimental Section

General Synthetic and Characterization Data: Solvents were dried over sodium diphenyl ketyl (THF, Et_2O, hydrocarbons) or CaH_2 (dichloromethane) and distilled under nitrogen prior to use. The reactions were carried out under nitrogen, using Schlenk-vacuum line techniques, and were routinely monitored by solution IR spectroscopy (carbonyl stretching region) and spot TLC (silica gel). $[Os_3(CO)_{10}(MeCN)_2]$ was prepared as described previously;[12] the remaining reagents were purchased from commercial suppliers. IR: Perkin−Elmer Paragon 1000 FT. NMR: Bruker AC-200 and DPX-300, room temperature, TMS as internal standard. Microanalyses: Perkin−Elmer 2400. MS: VG Autospec double-focussing mass spectrometer operating in the FAB+ mode; ions were produced with a standard Cs^+ gun at ca. 30 kV; 3-nitrobenzyl alcohol (NBA) was used as matrix; data given refer to the most abundant molecular ion isotopomer.

$[Ru_3(\mu,\eta^3$-dpko-*N,N,O*$)_2(CO)_8]$ (1) and $[Ru_2(\mu,\eta^3$-dpko-*N,N,O*$)_2(CO)_4]$ (2): A solution of $[Ru_3(CO)_{12}]$ (104 mg, 0.163 mmol) and Hdpko (66 mg, 0.331 mmol) in THF (20 mL) was heated under reflux for 20 min. The color changed from orange to black. The solvent was concentrated under reduced pressure to ca. 2 mL and transferred onto TLC silica plates. Dichloromethane/THF (95:5) eluted four bands. The first two were very weak and were discarded. The third (orange) and fourth (pink) bands afforded compounds **1** (21 mg, 14%) and **2** (14 mg, 12%), respectively. A black residue remained uneluted at the base line.

$[Ru_3(\mu$-H$)(\mu,\eta^3$-dpko-*N,N,O*$)(CO)_9]$ (3): A solution of Me_3NO (40 mg, 0.533 mmol) in acetonitrile (10 mL) was slowly added to a solution of $[Ru_3(CO)_{12}]$ (150 mg, 0.235 mmol) in dichloromethane/acetonitrile (10:1, 20 mL) at −78 °C. Once the formation of $[Ru_3(CO)_{10}(MeCN)_2]$ was achieved (IR monitoring), Hdpko (51 mg, 0.256 mmol) was added and the solution was allowed to warm up to room temperature. Solvents were removed under reduced pressure and the residue was redissolved in THF (25 mL), whereupon the color changed from brown to black. The solvent was removed under reduced pressure, the residue was dissolved in ca. 1 mL of toluene and this solution was placed onto a silica gel column (2 × 8 cm) packed in hexanes. Elution with hexanes afforded some unchanged $[Ru_3(CO)_{12}]$. Elution with dichloromethane afforded complex **3** (40 mg, 23%). A black residue remained uneluted at the top of the column. FAB+ MS: *m/z* = 756 [M^+]. $C_{20}H_9N_3O_{10}Ru_3$ (754.55): calcd. C 31.84, H 1.20, N 5.57; found C 31.78, H 1.35, N 5.52. IR (CH_2Cl_2): ν(CO) = 2087 (m), 2047 (s), 2021 (vs), 2000 (s), 1978 (sh), 1959 (sh) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 8.75 (d, *J* = 5.6 Hz, 1 H), 8.72 (dd, *J* = 5.2, 1.2 Hz, 1 H), 8.17 (br. d, *J* = 8.8 Hz, 1 H), 8.11 (d, *J* = 7.8 Hz, 1 H), 7.85 (td, *J* = 7.8, 1.6 Hz, 1 H), 7.71 (td, *J* = 8.8, 1.6 Hz, 1 H), 7.35 (td, *J* = 5.2, 1.2 Hz, 1 H), 7.20 (td, *J* = 5.2, 1.2 Hz, 1 H), −18.88 (s, μ-H) ppm.

$[Os_3(\mu$-H$)(\mu,\eta^3$-dpko-*N,N,O*$)(CO)_9]$ (4): Hdpko (85 mg, 0.427 mmol) was added to a solution of $[Os_3(CO)_{10}(MeCN)_2]$ (270 mg, 0.290 mmol) in THF (25 mL). The solution was stirred at room temperature for 2 h. The color changed from lemon yellow to red. The solvent was removed under reduced pressure, the residue was dissolved in ca. 2 mL of toluene and this solution was placed onto a silica gel column (2 × 10 cm) packed in hexanes. Elution with hexanes afforded some $[Os_3(CO)_{12}]$. Elution with hexanes/dichloromethane (1:1) afforded two bands. The first band (blue) was very weak and was not investigated. The second band (red) afforded complex **4** (125 mg, 42%). FAB+ MS: *m/z* = 1023 [M^+]. $C_{20}H_9N_3O_{10}Os_3$ (1021.90): calcd. C 23.51, H 0.89, N 4.11; found C 23.62, H 0.94, N 4.02. IR (CH_2Cl_2): ν(CO) = 2091 (m), 2051 (m), 2014 (vs), 1994 (m), 1964 (w), 1945 (w) cm^{-1}. ^1H NMR (CD_2Cl_2): δ = 9.04 (br. d, *J* = 5.9 Hz, 1 H), 8.73 (ddd, *J* = 4.7, 1.6, 0.8 Hz, 1 H), 8.40 (br. d, *J* = 8.4 Hz, 1 H), 8.12 (dt, *J* = 7.7, 1.2 Hz, 1 H), 7.87 (td, *J* = 7.7, 1.8 Hz, 1 H), 7.82 (ddd, *J* = 8.4, 7.7, 1.2 Hz, 1 H), 7.40 (ddd, *J* = 7.5, 4.7, 1.2 Hz, 1 H), 7.30 (ddd, *J* = 7.5, 5.9, 1.2 Hz, 1 H), −18.14 (s, μ-H) ppm. $^{13}C\{^1H\}$ NMR (DEPT, CD_2Cl_2): δ = 187.7, 186.7, 184.4, 181.0, 179.9, 177.8, 177.7, 175.0, 168.4 (COs); 154.8 (*C*=N); 154.7 (*C*H), 153.7 (C_{ipso}), 149.3 (*C*H), 148.2 (C_{ipso}), 136.7 (*C*H), 136.5 (*C*H), 127.6 (*C*H), 126.0 (*C*H), 124.6 (*C*H), 124.4 (*C*H) ppm.

$[Os_3(\mu,\eta^3$-dpko-*N,N,O*$)_2(CO)_8]$ (5): A solution of Hdpko (16 mg, 0.080 mmol) and complex **4** (80 mg, 0.078 mmol) in toluene (10 mL) was heated to reflux temperature for 75 min. The color changed from red to black. The solvent was partially removed under reduced pressure (to ca. 2 mL) and this solution was placed onto a silica gel column (2 × 10 cm) packed in hexanes. Elution with hexanes afforded some $[Os_3(CO)_{12}]$. Elution with hexanes/dichloromethane (1:2) afforded two weak bands, which were not investigated. Dichloromethane/THF (20:1) eluted a red band, which afforded complex **5** (18 mg, 19%). A black residue remained uneluted at the top of the column. FAB+ MS: *m/z* = 1192 [M^+]. $C_{30}H_{16}N_6O_{10}Os_3$ (1190.70): calcd. C 30.25, H 1.35, N 7.06; found C 30.42, H 1.42, N 7.06. IR (CH_2Cl_2): ν(CO) = 2071 (m), 1993 (vs), 1921 (m) cm^{-1}. ^1H NMR (CD_2Cl_2): δ = 8.73 (dd, *J* = 4.8, 0.8 Hz, 1 H), 8.33 (dd, *J* = 4.8, 0.8 Hz, 1 H), 7.74 (td, *J* = 8.0, 1.6 Hz, 1 H), 7.45 (td, *J* = 8.0, 2.0 Hz, 1 H), 7.24−7.06 (m, 4 H) ppm.

X-ray Diffraction Studies: Suitable crystals of **1**·C_6H_{14}, **2** and **5**·CH_2Cl_2 were obtained by slow diffusion of hexanes into dichloromethane solutions of the appropriate complexes. Crystals of **4** were obtained by slow diffusion of pentane into a solution of the complex in diethyl ether. Diffraction data for **1**·C_6H_{14} and **5**·CH_2Cl_2 were collected on a Nonius Kappa-CCD diffractometer equipped with a 95-mm CCD camera on a κ-goniostat, using graphite-monochromated Cu-K_α radiation. Diffraction data for **2** and **4** were collected on a Nonius CAD-4 diffractometer, with the ω-2θ scan technique and a variable scan rate, using graphite-monochromated Mo-K_α radiation, applying Lorentz and polarization corrections, and reducing the data to F_o^2 values. All structures were solved by Patterson interpretation using the program DIRDIF-96.[20] Absorption corrections were applied using XABS2[21] (**1**·C_6H_{14}, **2**, and

4) or SORTAV[22] (**5**·CH_2Cl_2). Isotropic and full-matrix anisotropic least-squares refinements were carried out using SHELXL-97.[23] All non H atoms were refined anisotropically. Hydrogen atom positions were geometrically calculated and refined riding on their parent atoms, except the hydride H atom of **4**, which was located by Fourier difference maps. The disordered solvent molecule of **1**·C_6H_{14} was treated with a mixture of constraints and restraints as described elsewhere.[24] The solvent molecule of **5**·CH_2Cl_2 was found disordered over two positions, with partial occupancies of 0.5. The molecular plots were made with the EUCLID program package.[25] The WINGX program system[26] was used thorough the structure determinations. Selected crystal, measurement, and refinement data for the four X-ray structures are given in Table 5. CCDC-182375 (**1**·C_6H_{14}), -182376 (**2**), -203169 (**4**) and -203170 (**5**·CH_2Cl_2) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

DNA-Cleavage Experiments: All reactions were carried out in oven-dried (120 °C) or autoclaved glassware and eppendorf tubes. Supercoiled circular φ*X174* RFI DNA (molecular weight 3.50 × 10^6, 5386 base pairs in length) was purchased from New England Biolabs Co. The remaining reagents were also purchased from commercial suppliers. Photolytic experiments were carried out at 37 °C, using a medium pressure mercury lamp (350 nm, 32-W). The NIH 1.60 image program, provided by Dr. R. Wayne of National Institutes of Health, U. S. A., was used for the quantitative analysis of DNA cleavage.

In a typical experiment, a reaction mixture (10 μL) containing supercoiled circular φ*X174* RFI DNA stock solution (form I, 50 μM/base pair, 1.0 μL), an oximate complex (10 mM, 1.0 μL), and a phosphate buffer (0.10 M, 8.0 μL) was preincubated at 37 °C in a Pyrex vial and irradiated with UV light (350 nm, 32-W) under aerobic conditions for 8.0 h. After addition of the gel-loading buffer (0.25% bromophenol blue, 0.25% xylene cyanol, and 30% glycerol), the reaction mixture was loaded onto a 1% agarose gel with ethidium bromide staining. The electrophoresis tank was attached to a power supply at a constant current of about 100 mA). The gel was visualized by 312-nm UV transilluminator and photographed by an FB-PDC-34 camera. Quantification of DNA cleavage activity was performed by integration of the optical density of the spot as a function of the band area by use of a Microtek scanner and the NIH 1.60 image program.

Ruthenium(II) Complexes with Triphosphane Ligands Combining Planar, Phosphorus, and Carbon Chirality: Application to Asymmetric Reduction of Trifluoroacetophenone

Pierluigi Barbaro,*[a] Claudio Bianchini,[a] Giuliano Giambastiani,*[a] and Antonio Togni[b]

Keywords: Asymmetric catalysis / Tridentate ligands / Ruthenium / Hydrogen transfer / Chiral ferrocenyls

Dichloro-, bis(acetonitrile)chloro-, and tris(acetonitrile)ruthenium(II) complexes with the triphosphane ligands $(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir and $(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir, combining planar, phosphorus, and carbon chirality, were prepared and structurally characterized in solution. The complexes were tested as catalyst precursors for the reduction of trifluoroacetophenone to (*R*)-α-(trifluoromethyl)benzyl alcohol by either hydrogenation or hydrogen transfer from *i*PrOH. The best conversion and enantioselectivity was obtained with the tris(acetonitrile) precursor [{$(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir}Ru-$(CH_3CN)_3$]$(PF_6)_2$ in hydrogen-transfer conditions using a basic co-catalyst.

Introduction

The design of new, enantiomerically pure ligands leading to highly efficient and selective processes is a challenging issue attracting constant attention in the field of asymmetric catalysis. The large majority of stereoselective reactions catalysed by transition metal complexes involve chiral chelating diphosphane ligands, in particular those with C_2 symmetry.[1] Some attempts have been made to use chiral tridentate phosphanes, aimed at exploiting the superior stabilising effect and coordination versatility of tridentate ligands over bidentate ones.[2] However, due to the inherent difficulty of their synthesis, chiral stereohomogeneous triphosphanes have been scarcely investigated so far,[3] which has prevented an in-depth study of their great potential in asymmetric catalysis. In view of the large diversity of coordination modes accessible through tridentate ligands, the characterization and the knowledge of the structure of their metal complexes is of particular importance for the fine tuning of the catalytic activity and for the design of new active species.

The understanding of the chemical and physical factors that control the source of chiral information in metal complexes with tridentate phosphanes is a current research objective in our laboratories. As part of these studies, we have recently reported the synthesis of the *pseudo*-C_2-symmetric bis(ferrocenyl)triphosphanes Pigiphos (Figure 1), together with some applications of their Ru^{II}, Ni^{II} and Rh^{III} complexes in asymmetric catalysis.[4]

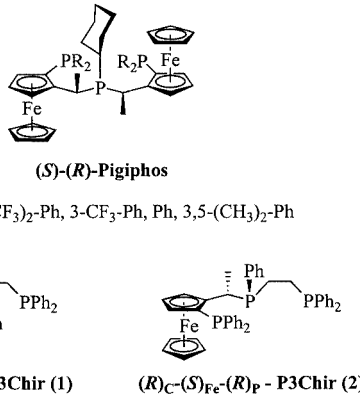

Figure 1. Sketch of the tridentate phosphane ligands (*S*)-(*R*)-Pigiphos = bis{(*S*)-1-[(*R*)-2-(diphenylphosphanyl)ferrocenyl]ethyl}-cyclohexylphosphane, $(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir (**1**) and $(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir (**2**) = (*R*)-1-[(*S*)-2-diphenylphosphanyl)ferrocenyl]-ethyl-(*R*)-[phenylphosphanyl-2-(diphenylphosphanyl)ethane]

The enantiomeric excesses (*ee*) obtained in the hydrogen-transfer reduction of acetophenone by (Pigiphos)Ru^{II} catalysis were relatively good, yet hardly comparable with those reported for the most efficient Ru^{II} systems modified with chiral chelating ligands.[5]

Since the tendency of Pigiphos to adopt a meridional (*mer*) coordination geometry and a *pseudo*-C_2 symmetry have been suggested to be unfavourable features for high asymmetric induction,[4b] we decided to design triphosphane ligands devoid of C_2 symmetry. Two ligands with these characteristics, namely $(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir (**1**) and

$(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir (**2**), have been recently synthesized in diastereomerically pure form through an original procedure developed in our laboratories.[6] The peculiarity of the P3Chir ligands is to combine the planar chirality of the ferrocenyl moiety with phosphorus and carbon stereocenters in an unprecedented molecular assembly.

In this paper, we describe the synthesis and characterisation of the first ruthenium(II) complexes with the P3Chir ligands and also report a preliminary study of their use as catalyst precursors for the asymmetric reduction of trifluoroacetophenone by either hydrogenation or hydrogen transfer from *i*PrOH.

Results and Discussion

Synthesis and Characterization of the Dichlororuthenium Complexes

The diastereomeric, mononuclear Ru^{II} complexes [{$(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir}$RuCl_2$] (**3**) and [{$(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir}$RuCl_2$] (**4**) were straightforwardly synthesized by treating $[RuCl_2(PPh_3)_3]$ in toluene with $(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir and $(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir, respectively (Figure 1). Both compounds were isolated in excellent yields as orange solids that are air-stable and soluble in solutions of non-coordinating, non-chlorinated solvents.

The $^{31}P\{^1H\}$ NMR spectroscopic data in [D_4]methanol for all the complexes described in this paper are listed in Table 1, whereas selected ^1H NMR spectroscopic data are reported in the Exp. Sect.

The $^{31}P\{^1H\}$ NMR spectra of **3** and **4** show the presence of several isomers in methanol solution at room temperature, in particular three isomers A/B/C in about a 5:2:1 molar ratio for **3** and four isomers A/B/C/D in about a 6:2:1.5:1 ratio for **4**. Stereochemical nonrigidity, leading to the formation of isomers in solution, is typical for five-coordinate Ru^{II} complexes with linear tridentate phosphane ligands.[7] Irrespective of the complex, the $^{31}P\{^1H\}$ NMR spectrum of each isomer consists of an AMQ pattern with $^2J_{P,P}$ values ranging from 19.2 to 41 Hz, which anticipates a facial (*fac*) arrangement of the tridentate ligands about the metal center (see Table 1 for the labelling scheme).[8,9]

Based on *trans* influence criteria,[3d,4b,7,10] all isomers have been assigned a square-pyramidal coordination geometry with an apical PhP(2) group (Scheme 1), though considerable distortions from an idealized geometry are possible due to the constraints imposed by the polydentate nature of the ligands. Indeed, from a comparison of the $^{31}P\{^1H\}$ NMR spectra of the Ru^{II} complexes **3** and **4** with those of the free ligands,[6] one may readily distinguish the apical phosphorus atoms (with no *trans* ligand) from the phosphorus atom *trans* to the chloride ion that experience a high-field shift of ca. 30−40 ppm, as previously reported for other dichloro(polyphosphane)ruthenium complexes.[3d,9,11] Once disregarded the formation of trigonal-bipyramidal Ru^{II} species, the isomers observed for **3** and **4** are apparently originated by the two chelate rings that may adopt either a boat or envelope conformation in each complex. A similar behaviour has already been observed in other Ru^{II} and Ir^{I} chiral ferrocenyltriphosphane complexes.[4b,12]

3, 4 **5, 6**

S = CH_3CN

Scheme 1

Conductivity measurements show the complexes to behave as non-electrolytes in methanol solution. In CD_3CN solution, the $^{31}P\{^1H\}$ NMR spectra of **3** and **4** are dramatically different from those recorded in [D_4]methanol due to the formation of acetonitrile adducts (see below).[13]

Synthesis and Characterization of the (Acetonitrile)ruthenium Complexes

Complexes **3** and **4** react at very different rates with acetonitrile to give the six-coordinate bis(acetonitrile)chloro

cationic derivatives [{$(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir}RuCl-$(CH_3CN)_2$]Cl (**5**) and [{$(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir}RuCl-$(CH_3CN)_2$]Cl (**6**), respectively. Monitoring the reactions by $^{31}P\{^1H\}$ NMR spectroscopy in CD_3CN showed the conversion of **3** to occur within seconds at room temperature. In contrast, the quantitative conversion of **4** into **6** was achieved only by heating the solution at 75 °C for 2 h. In CD_3CN solution at room temperature, **5** and **6** exist as single isomers as shown by the $^{31}P\{^1H\}$ NMR spectra in which canonical AMQ spin systems are displayed,[13] with $^2J_{P,P}$ values indicative of a *fac* arrangement of the triphosphane ligands about the metal center.[8,9] The coordination geometry of **5** and **6** in solution can be established on the basis of the *trans* influence of the coligands discussed above, which decreases in the order $CH_3CN > Cl$.[9,11,14,15] In particular, from a comparison of the ^{31}P NMR chemical shifts in each complex with those observed for the corresponding nuclei in the free ligands and in the dichloro complexes **3** and **4**, the PhP(2) group is assigned a *trans* position to the chloride ion in both **5** and **6** (Scheme 1).

Compounds **5** and **6** behave as 1:1 electrolytes in acetonitrile solution, from which they can be isolated in the solid state by addition of diethyl ether (molar conductance in acetonitrile is 61 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ and 68 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ for **5** and **6**, respectively). The IR spectra show weak absorptions in the region 2280−2360 cm^{-1}, where the ν(C≡N) absorption of coordinated CH_3CN is usually observed (see Exp. Sect.).[16] Both **5** and **6** dissolve in methanol generating a dissociation equilibrium concentration with the corresponding dichloro complexes. At room temperature, an approximate 30:70 molar ratio of the bis(acetonitrile) and dichloro complexes was determined on the basis of $^{31}P\{^1H\}$ NMR integration (Scheme 2). $^{31}P\{^1H\}$ NMR spectroscopic data for **5** and **6** in [D_4]methanol are listed in Table 1, whereas selected ^1H NMR spectroscopic data are reported in the Exp. Sect. When CH_3CN is used as solvent the bis(acetonitrile) adducts are stabilized and the equilibrium is completely shifted to the left.

$$\underset{\mathbf{5,\,6}}{[(P3Chir)RuCl(CH_3CN)_2]Cl} \rightleftharpoons \underset{\mathbf{3,\,4}}{(P3Chir)RuCl_2} + 2\,CH_3CN$$

P3Chir = $(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir **3, 5**
P3Chir = $(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir **4, 6**

Scheme 2

The occurrence of the equilibrium shown in Scheme 2 was further substantiated by a ^1H NOESY experiment carried out in [D_4]methanol, where the resonances due to the coordinated acetonitrile molecules can be detected. A section of the ^1H NOESY spectrum of **5** is shown in Figure 2. Strong exchange cross-peaks between coordinated [δ = 1.73 and 1.45 ppm (both s)] and free CH_3CN [δ = 2.06 ppm (s)] molecules are observed together with exchange peaks relating the CHCH_3 signals of **5** [δ = 1.59 ppm (dd)] with those of the A, B and C isomers of **3** [δ = 1.22, 1.16 and 0.94 ppm (all dd), respectively].

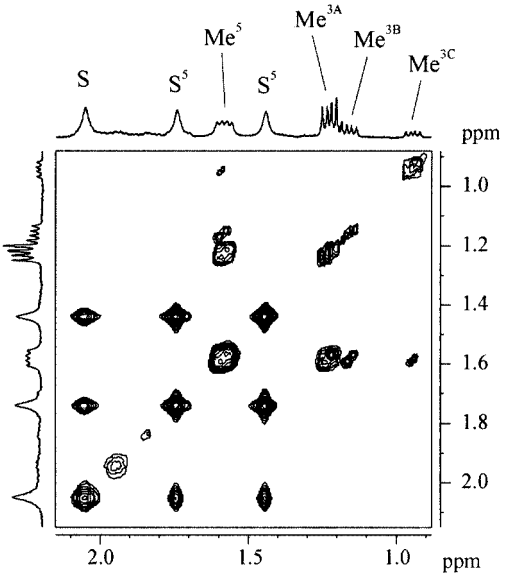

Figure 2. Section of the ^1H NOESY spectrum of **5** ([D_4]methanol, 294 K, 400.13 MHz, τ_m = 0.80 s); signals due to coordinated (S^5) and free (S) CH_3CN molecules and to the CHCH_3 protons of **5** (Me^5) and the A, B and C isomers of **3** (Me^{3A}, Me^{3B}, Me^{3C}) are displayed

The ^1H and ^{13}C NMR resonances of the acetonitrile molecules in each complex could be unambiguously assigned by means of ^1H,^{13}C correlations. $^{13}C\{^1H\}$ NMR spectroscopic data for **5** and **6** in methanol solution are reported in the Exp. Sect.

The dicationic, tris(acetonitrile) adducts [{$(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir}Ru$(CH_3CN)_3$]$(PF_6)_2$ (**7**) and [{$(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir}Ru$(CH_3CN)_3$]$(PF_6)_2$ (**8**) were obtained as orange microcrystals by treatment of the corresponding dichloro complexes **3** and **4** in CH_3CN with $TlPF_6$. The isolated compounds are quite stable in both the solid state and in deaerated methanol solution. The nujol IR spectra show absorptions in the range 2320−2390 cm^{-1}, characteristic of coordinated CH_3CN molecules (see Exp. Sect.).[16] Compounds **7** and **8** are stereochemically rigid on the NMR timescale at room temperature in [D_4]methanol, as shown by the $^{31}P\{^1H\}$ NMR spectra, which consist of canonical AMQ spin systems. A *fac* arrangement of the triphosphane ligands in the octahedral compounds can be assigned on the basis of the $^2J_{P,P}$ values, which range between 18.8 and 38.9 Hz.[8,9] The preservation of a *fac* arrangement of the tridentate ligand on going from chloro to acetonitrile complexes has been previously reported for other (triphosphane)Ru^{II} complexes.[4b,16a] The ^1H and ^{13}C NMR resonances of the acetonitrile molecules in **7** and **8** were readily assigned using ^1H,^{13}C correlations. The $^{13}C\{^1H\}$ NMR spectroscopic data in [D_4]methanol are reported in the Exp. Sect. Due to the small contribution of a neighbouring anisotropy effect,[9,17] ^{13}C chemical shifts generally provide more direct information concerning the electronic environment of a given ligand than proton shifts do. In the case at hand, the observed low-field shift of 0.43−2.01 ppm for the ^{13}C resonances of the CH_3CN carbon atoms, compared to the corresponding signals of free acetonitrile, is unequivo-

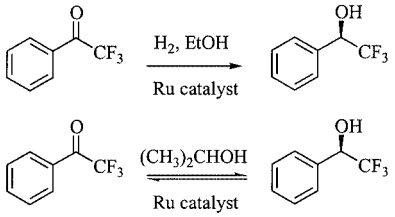
cally indicative of coordinated acetonitrile molecules.[4b,12,18]

Catalytic Reduction of Trifluoroacetophenone

Experiments with 2,2,2-trifluoroacetophenone showed that the Ru^{II} precursors with the P3Chir ligands can form effective asymmetric catalysts for the homogeneous reduction of prochiral ketones to optically pure secondary alcohols by either hydrogenation or hydrogen transfer (Scheme 3 and Table 2).



Scheme 3

The reduction of 2,2,2-trifluoroacetophenone to (*R*)-α-(trifluoromethyl)benzyl alcohol (Scheme 2) is a typical probe reaction to test the efficiency of chiral Ru^{II} catalysts. Indeed, asymmetric reductions of prochiral ketones can be carried out with Ru^{II} compounds through hydrogenation, hydrosilylation or hydrogen transfer. Most examples in the literature involve Ru^{II} complexes stabilised by bidentate ligands with P, N and O donor atoms.[1,19] The reduction of ketones catalyzed by complexes containing tri- and tetradentate ligands has been much less intensely studied.[4b,20]

The hydrogenation reactions were performed in ethanol at 60 °C under a H_2 pressure of 60 atm, while *i*PrOH was the solvent for the hydrogen-transfer reactions which, however, require the addition of *i*PrOK as basic co-catalyst to achieve the reduction of the ketone.[21] Irrespective of the hydrogen source, the yields of (*R*)-α-(trifluoromethyl)benzyl alcohol increased with the number of coordinated acetonitrile molecules in the {$(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir}ruthenium(II) precursors, which reflects the easier displacement of acetonitrile by the ketone as compared to the chloride ion (Table 2). Under the same experimental conditions, 2,2,2-trifluoroacetophenone was quantitatively hydrogenated after 19 h only with the tris(acetonitrile) complex **7** (Table 2, Entry 3), whereas a 78.7% and 23.4% yield was observed using the bis(acetonitrile) complex **5** and the dichloro complex **3**, respectively (Table 2, Entries 2 and 1). Although the hydrogen-transfer reactions occurred even at room temperature, relatively high temperatures (68 °C) were required to obtain appreciable reaction rates. Again, the best results were obtained with the tris(acetonitrile) complex **7**, which gave a nearly complete conversion of the ketone after 2.5 h (Table 2, Entry 6). Under these conditions, the yield of (*R*)-α-(trifluoromethyl)benzyl alcohol using **5** and **3** were 79.2% and 36.2%, respectively (Table 2, Entries 5 and 4). Besides higher activity, the hydrogen-transfer reactions also gave higher enantioselectivities (38−41%) than the hydrogenation reactions (19−23%). This finding prompted us to investigate the behaviour of the $(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir derivative **8** as a hydrogen-transfer catalyst precursor as well. This latter epimer gave a slightly better productivity than **7** in the same experimental conditions, yet the *ee* was almost negligible (Table 2, Entry 7). To summarise, the ruthenium(II) complexes described in this paper are efficient catalyst precursors either for the hydrogenation and the hydrogen-transfer reactions to prochiral ketones under mild conditions. In general, however, the *ee* values are lower than those achieved with other Ru^{II} chiral catalysts.[21a,22] The above results are consistent with those previously obtained in the transfer hydrogenation to acetophenone mediated by the dicationic Ru^{II} complex with the chiral triphosphane Pigiphos.[4b] This latter compound, however, was found to be the best preformed catalyst precursor containing a chiral tridentate ligand reported so far in terms of enantioselectivity for this reaction.[20d]

From a comparison of the results obtained with the P3Chir and Pigiphos ligands, one can see that the design of chiral tridentate ligands for diverse applications in asymmetric catalysis is still a challenging task. Indeed, other factors besides the presence/absence of C_2 symmetry or geometrical (*mer*/*fac*) isomerism of the tridentate ligand, seem to play an important role in controlling the chiral transfer ability.

Conclusion

Five- and six-coordinate Ru^{II} complexes with the first chiral tridentate phosphane ligands combining planar, phosphorus, and carbon chirality have been synthesized

and fully characterized in solution. Irrespective of the co-ligands (chloro or acetonitrile), the absolute configuration of the stereocentres and the temperature, the triphosphane ligands wrap the metal centre in a facial arrangement.

The dichloro, bis(acetonitrile)chloro and tris(acetonitrile) complexes with $(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir and the tris(acetonitrile) complex with $(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir have been tested as catalyst precursors for the reduction of 2,2,2-trifluoroacetophenone to (*R*)-α-(trifluoromethyl)benzyl alcohol by either hydrogenation and hydrogen transfer from *i*PrOH. The catalytic activity was fairly good, particularly using the precursors bearing only acetonitrile co-ligands, yet the asymmetric induction was quite low.

To gain some insight into the chemical and physical factors (ligand conformation, steric and electronic properties of the donor groups) that may control the asymmetric induction by tridentate phosphane complexes, studies are presently ongoing in our laboratories and will be published in due course.

Experimental Section

General Remarks: All manipulations were performed under pure nitrogen unless otherwise stated. Diethyl ether was distilled from Na/benzophenone. Acetonitrile was distilled from CaH_2. Toluene was distilled from sodium. $[RuCl_2(PPh_3)_3]$,[23] $(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir (**1**) and $(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir (**2**)[6] were synthesized as previously reported. Unless otherwise stated, all the other chemicals were obtained from commercial suppliers and were used as received without further purification. The solid compounds were collected on sintered glass frits before being dried in a stream of nitrogen. $^{31}P\{^1H\}$ NMR spectra were recorded with a Bruker Avance DRX-400 spectrometer operating at 161.98 MHz. Chemical shifts are relative to external 85% H_3PO_4 with downfield values reported as positive. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded at 400.13 and 100.61 MHz, respectively, with a Bruker Avance DRX-400 spectrometer. Chemical shifts are calibrated against solvent resonances. The spectrometer was equipped with a variable-temperature control unit accurate to ±0.1 °C. The assignments of the signals were made from 1D spectra, $^1H\{^{31}P\}$ heteronuclear decoupling experiments, ^1H COSY and proton detected ^1H,^{13}C and ^1H,^{31}P correlations using degassed nonspinning samples. 2D NMR spectra were recorded using pulse sequences suitable for phase-sensitive representations using TPPI. The ^1H,^{13}C and ^1H,^{31}P correlations[24] were recorded using an HMQC sequence with decoupling during acquisition. A standard pulse sequence was used for the ^1H-NOESY[25] experiments. Infrared spectra were recorded with a Perkin−Elmer 1600 Series FT-IR spectrometer using samples mulled in Nujol between KBr plates. Reactions under a controlled pressure of hydrogen were performed with a stainless steel autoclave (10 mL internal volume) constructed at ICCOM-CNR (Firenze, Italy) and equipped with a magnetic stirrer, a Teflon inset and a pressure controller. The temperature control was achieved by an oil-bath thermostat accurate to ±0.2 °C. GC analyses were performed with a Shimadzu GC-17A gas chromatograph equipped with a flame-ionization detector and a 30-m (0.25 mm ID, 0.25 μm FT) SPB-1 Supelco fused-silica capillary column. The *ee* values were determined by GC analyses with a Shimadzu GC-17A gas chromatograph equipped with a flame-ionization detector and a 50 m × 0.25 mm ID Chiraldex G-TA capillary column and coupled with a Shimadzu C-R7A Chromatopac. Conductivities were measured with a Model 990101 Orion conductance cell connected to a Model 101 conductivity meter.

$[\{(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir$\}RuCl_2]$ (3): Solid $[RuCl_2(PPh_3)_3]$ (0.08 g, 0.08 mmol) was added to a solution of **1** (0.06 g, 0.08 mmol) in toluene (3 mL) and the suspension was refluxed with stirring for 3 h. During this time, a red solution was obtained from which red microcrystals separated slowly. After cooling to room temperature, the solid obtained was filtered off and washed with diethyl ether (25 mL). Yield: 62 mg (87%). ^1H NMR ([D$_4$]methanol, 400.13 MHz, 294 K): isomer A: δ = 4.51 (m, 1 H, C_5H_3), 4.18 (m, 1 H, C_5H_3), 3.85 (*s*, 5 H, C_5H_5), 3.63 (m, 1 H, C_5H_3), 3.61 (quint, $^3J_{H,H} = {}^2J_{H,P}$ = 7.0 Hz, 1 H, C*H*CH$_3$), 1.22 (dd, $^3J_{H,H}$ = 6.7, $^3J_{H,P}$ = 12.6 Hz, 3 H, CHC*H*$_3$); isomer B: δ = 4.62 (m, 1 H, C_5H_3), 4.46 (m, 1 H, C_5H_3), 4.07 (s, 5 H, C_5H_5), 3.98 (m, 1 H, C_5H_3), 3.75 (quint, $^3J_{H,H} = {}^2J_{H,P}$ = 7.4 Hz, 1 H, C*H*CH$_3$,), 1.16 (dd, $^3J_{H,H}$ = 6.7, $^3J_{H,P}$ = 12.8 Hz, 3 H, CHC*H*$_3$); isomer C: δ = 4.32 (m, 1 H, C_5H_3), 3.96 (s, 5 H, C_5H_5), 3.69 (m, 1 H, C_5H_3), 2.90 (quint, $^3J_{H,H} = {}^2J_{H,P}$ = 7.1 Hz, 1 H, C*H*CH$_3$), 0.94 (dd, $^3J_{H,H}$ = 7.1, $^3J_{H,P}$ = 12.4 Hz, 3 H, CHC*H*$_3$) ppm. $C_{44}H_{41}Cl_2FeP_3Ru$ (890.6): calcd. C 59.34, H 4.64; found C 59.40, H 4.65.

$[\{(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir$\}RuCl_2]$ (4): This compound was prepared as described above for **3** by using $(R)_C$-$(S)_{Fe}$-$(R)_P$-P3Chir (**2**) instead of $(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir (**1**). Yield: 56 mg (78%). ^1H NMR ([D$_4$]methanol, 400.13 MHz, 294 K): isomer A: δ = 4.31 (s, 5 H, C_5H_5), 0.86 (dd, $^3J_{H,H}$ = 6.7, $^3J_{H,P}$ = 12.5 Hz, 3 H, CHC*H*$_3$); isomer B: δ = 4.52 (s, 5 H, C_5H_5), 1.42 (dd, $^3J_{H,H}$ = 6.8, $^3J_{H,P}$ = 13.2 Hz, 3 H, CHC*H*$_3$); isomer C: δ = 4.25 (s, 5 H, C_5H_5), 1.50 (dd, $^3J_{H,H}$ = 7.4, $^3J_{H,P}$ = 13.3 Hz, 3 H, CHC*H*$_3$); isomer D: δ = 4.20 (s, 5 H, C_5H_5), 1.62 (dd, $^3J_{H,H}$ = 7.8, $^3J_{H,P}$ = 13.5 Hz, 3 H, CHC*H*$_3$) ppm. $C_{44}H_{41}Cl_2FeP_3Ru$ (890.6): calcd. C 59.34, H 4.64; found C 59.28, H 4.63.

$[\{(R)_C$-$(S)_{Fe}$-$(S)_P$-P3Chir$\}RuCl(CH_3CN)_2]Cl$ (5): A solution of **3** (0.07 g, 0.08 mmol) in CH_3CN (2 mL) was stirred at room temperature for 1 h. Slow addition of diethyl ether (10 mL) caused the precipitation of an orange solid which was filtered off and washed with diethyl ether (15 mL). Yield: 72 mg (93%). ^1H NMR ([D$_4$]methanol, 400.13 MHz, 294 K): δ = 8.13 (m, 2 H, Ph), 7.91 (m, 2 H, Ph), 7.80 (m, 2 H, Ph), 7.6−7.1 (m, 17 H, Ph), 6.98 (m, 2 H, Ph), 4.86 (m, 1 H, C_5H_3), 4.62 (m, 1 H, C_5H_3), 4.41 (s, 5 H, C_5H_5), 3.80 (quint, $^3J_{H,H} = {}^2J_{H,P}$ = 7.1 Hz, 1 H, C*H*CH$_3$), 3.42 (m, 1 H, C_5H_3), 2.60 (ddddd, $^3J_{H,H}$ = 2.7, $^3J_{H,H}$ = 5.5, $^3J_{H,P}$ = 12.2, $^2J_{H,H}$ = 14.6, $^2J_{H,P}$ = 43.9 Hz, 1 H, PC*H*H), 2.38 (ddddd, $^3J_{H,H}$ = 2.3, $^3J_{H,H}$ = 5.8, $^3J_{H,P}$ = 10.8, $^2J_{H,H}$ = 14.1, $^2J_{H,P}$ = 42.9 Hz, 1 H, PC*H*H), 1.84 (m, 1 H, PCH*H*), 1.73 (s, 3 H, CH_3CN), 1.59 (dd, $^3J_{H,H}$ = 7.1, $^3J_{H,P}$ = 13.2 Hz, 3 H, CHC*H*$_3$), 1.45 (s, 3 H, CH_3CN), 0.74 (tdt, $^3J_{H,H}$ = 5.6, $^2J_{H,H}$ = 14.7, $J_{H,P}$ = 19.2 Hz, 1 H, PCH*H*) ppm. $^{13}C\{^1H\}$ NMR ([D$_4$]methanol, 100.61 MHz, 294 K): δ = 76.79 (d, $J_{C,P}$ = 7.2 Hz, 1 C, C_5H_3), 70.65 (s, 5 C, C_5H_5), 70.15 (d, $J_{C,P}$ = 7.7 Hz, 1 C, C_5H_3), 68.71 (d, C_5H_3, $J_{C,P}$ = 7.5 Hz, 1 C), 32.00 (d, $^1J_{C,P}$ = 19.9 Hz, 1 C, *C*HCH$_3$), 22.80 (dd, $^1J_{C,P}$ = 34.0, $^2J_{C,P}$ = 10.8 Hz, 1 C, PCH$_2$), 15.70 (dd, $^1J_{C,P}$ = 28.8, $^2J_{C,P}$ = 8.6 Hz, 1 C, PCH$_2$), 13.08 (s, 1 C, CH*C*H$_3$), 1.67 (s, 1 C, *C*H$_3$CN), 1.58 (s, 1 C, *C*H$_3$CN) ppm. $C_{48}H_{47}Cl_2FeN_2P_3Ru$ (972.7): calcd. General Procedure for the Reduction of 2,2,2-Trifluoroacetophenone by Hydrogen Transfer: In a typical reaction, a catalyst precursor (0.002 mmol) and freshly distilled 2,2,2-trifluoroacetophenone (28 μL, 0.2 mmol) were introduced under Ar into a flask equipped with a condenser and containing 5 mL of anhydrous *i*PrOH. The mixture was heated at 68 °C with stirring. After 10 min, freshly prepared *i*PrOK (0.1 M in *i*PrOH, 22 μL, 0.002 mmol) was introduced. The addition of *i*PrOK was considered as the starting time of the reaction. The solution was stirred at 68 °C for 3 h. During this time the reaction progress was monitored by GC (SPB-1 capillary column). After cooling the reaction mixture to room temperature, the solvent was removed in vacuo. The residue was dissolved in 1 mL of diethyl ether and chromatographed by short-column chromatography on silica gel using diethyl ether as eluent. The enantiomeric excess was determined on the resulting solution by GC analysis.

General Procedure for the Enantioselective Hydrogenation of 2,2,2-Trifluoroacetophenone: In a typical experiment, a suspension of the catalyst precursor (0.002 mmol) in ethanol (4 mL) was stirred at 60 °C under argon until the complete dissolution of the starting complex occurred (ca. 15 min). 2,2,2-Trifluoroacetophenone (28 μL, 0.2 mmol) was added at room temperature and the resulting solution was transferred via a Teflon capillary into a 10-mL autoclave under argon. Argon was then replaced by hydrogen with three cycles of 5 bar/normal pressure. The autoclave was finally charged with the desired pressure of H_2 and then heated using a thermostatted oil bath with magnetic stirring. After the desired time, the reactor was cooled to room temperature and a sample of the reaction mixture was analyzed by GC.

Synthesis, Structure and Magnetic Properties of the Cobalt(II) 1,1′-Biphenyl-2,2′-dicarboxylate Hydroxide Chain Compound $[Co_3\{O_2CC_{12}H_8CO_2\}_{2.5}(OH)(H_2O)_2]_n$

Jean-Michel Rueff,[a] Sébastien Pillet,[b] Gautier Bonaventure,[a] Mohamed Souhassou,[b] and Pierre Rabu*[a]

Keywords: Carboxylate ligands / Hydrothermal synthesis / Cobalt / Magnetic properties

A new 1D compound $[Co_3(O_2CC_{12}H_8CO_2)_{2.5}(OH)(H_2O)_2]$ (**2**) was synthesised with the hydrothermal method from $Co(NO_3)_2{\cdot}6H_2O$, 1,1′-biphenyl-2,2′-dicarboxylic acid, and KOH under hydrothermal conditions. Its structure was solved by single-crystal X-ray diffraction analysis. Compound **2** crystallises as purple crystals with the monoclinic cell (*C*2/*c*) a = 19.370(1), b = 14.5350(9), c = 22.583(1) Å, β = 89.910(4)°. The structure consists of chains of butterfly motifs of Co^{II} ions in both octahedral and tetrahedral oxygen sites. The structural, IR and UV spectroscopic data and magnetic behaviour are presented and compared to that of the parent pink compound **1**, obtained under slightly different stoichiometric conditions. Ligand-field characteristics, $Dq \approx 1146$ cm^{-1} and $B \approx 811$ cm^{-1} for the octahedral sites, and $Dq \approx 434$ cm^{-1} and $B \approx 782$ cm^{-1} for Co^{II} in the tetrahedral sites, were deduced from the electronic spectra and related to the structural and magnetic findings. From the magnetic point of view, the occurrence of efficient Co–O–Co superexchange pathways contributes to significant antiferromagnetic coupling between the cobalt(II) ions along the chains.

Introduction

The design and construction of new polymeric compounds of tuneable dimensionality, through adapted synthetic routes, is of strong interest in materials chemistry.[1] In particular, the solvothermal or hydrothermal route is currently being developed in solid-state and coordination chemistry,[2,3] for the design of new architectures, such as layered compounds,[4,5] helical chain polymers,[6−9] organic-inorganic compounds,[10−12] or mesoporous materials.[13−15] In this method, the organic ligand acts as a template, the structure of the product being closely related to the geometry and the number of coordination sites provided by the ligand. It has also been shown that solvothermal conditions are quite versatile, slight variations in temperature, reaction time, concentration or molar ratio between reactants may lead to very different products.[13] Nowadays these techniques are applied in the design of new low-dimensional (1D, 2D) magnetic compounds, whose study is particularly useful for a better understanding of the mechanisms responsible for magnetic coupling in solids.[16−19] Indeed, correlations between the magnetic properties of molecule-based solids and their structure, or the nature of the chemical bond between magnetic centres is largely used for the design of new magnetic materials, including high T_C magnets.[20−23] For the synthesis of new coordination compounds with extended structures, the use of dicarboxylate ligands provides many examples where magnetic transition-metal ions are arranged within various kinds of networks. The structural variety of these compounds arises from the carboxylate ligand, which is able to adopt different coordination modes, exhibiting either unidentate or chelating or bridging bidentate modes.

In a previous study[24] we reported on the structural and magnetic properties of two isostructural 1D polymers, obtained from the reaction of 1,1′-biphenyl-2,2′-dicarboxylic acid (diphenic acid) with KOH and $Co(NO_3)_2{\cdot}6H_2O$ and $Ni(NO_3)_2{\cdot}6H_2O$ under hydrothermal conditions. Their structure consists in the stacking of helical chains of M^{II} ions in octahedral coordination. In the case of the Co^{II} analogue, $[Co_2(O_2CC_{12}H_8CO_2)_2(H_2O)_8]$ (**1**), another phase was observed, depending on the synthesis conditions, and appearing as purple needle-shaped crystals. After slightly varying the synthesis conditions, we were able to isolate this purple phase and this paper describes its crystal structure and magnetic properties. A comparison is also made with the previous pink compound **1**.

Results and Discussion

Structural Results

$C_{35}H_{25}Co_3O_{13}$ crystallises in the monoclinic *C*2/*c* space group with $a = 19.370(1)$, $b = 14.5350(9)$, $c = 22.583(1)$ Å, $\beta = 89.910(4)°$. Selected bond lengths and angles are summarised in Table 1. The asymmetric unit (see Figure 1) consists of four non-equivalent cobalt atoms of octahedral and tetrahedral coordination, 2.5 biphenyl dicarboxylate ligands, one hydroxy ion and two water molecules. Moreover, two of the cobalt atoms are located on symmetry elements: Co2 on a centre of symmetry and Co4 on a twofold axis. Three Co atoms (Co1, Co2 and Co3) are located in octahedral environments CoO_6, whereas Co4 lies in a quasi-perfect tetrahedral oxygen surrounding (see Figure 2). The hydroxy ion, the water molecules and the two carboxylate groups of each biphenyl dicarboxylate ligand are involved in the Co coordination.

O8−H17−O12	118(3)	O8−H25−O9	127(4)

The C−O bond lengths in the five carboxylate fragments of the asymmetric unit range from 1.235(6) Å to 1.304(6) Å. This dispersion reflects the weakening of the C−O bonds due to the Co···O interactions. The only oxygen atom, O13, which is not coordinated to a cobalt atom presents the shortest C−O bond [1.235(6) Å], whereas the longest bond lengths, 1.286(6) Å, 1.304(6) Å and 1.296(6) Å, correspond to O1, O5 and O7, respectively, which are all involved in the coordination polyhedron of two Co atoms. The mean C−O bond length for oxygen atoms coordinated to only one cobalt atom is 1.258(10) Å.

Two oxygen octahedra (around Co1 in position *8f* and Co2 in *4a*) and the tetrahedron (around Co4 in *4e*) are connected through chains along the crystallographic *c* axis (see Figure 2) as a repetition of the symmetry block ··Co4···Co1···Co2···Co1···Co4···. The last octahedron around Co3 in the *8f* position is located on the side of the chain. The Co−Co distances range from 3.1416(7) Å to 3.4370(9) Å for Co2−Co3 and Co1−Co3, respectively. Contrary to the tetrahedron, the octahedral sites are far from being regular. As shown by the dispersion in bond lengths given in Table 2, the Co−O bond lengths range

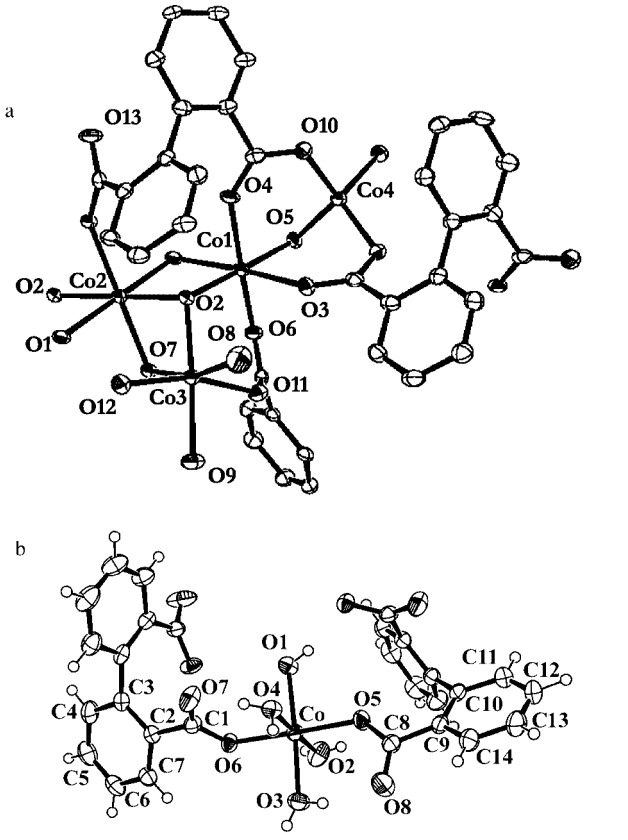

Figure 1. ORTEP drawing of the asymmetric unit of a) compound **2** $Co_3C_{35}O_{13}H_{25}$ and b) for compound **1**, with the atom labelling (some equivalent O atoms have been generated to complete the Co coordination, H atoms omitted; the ellipsoids are plotted at 50% level)

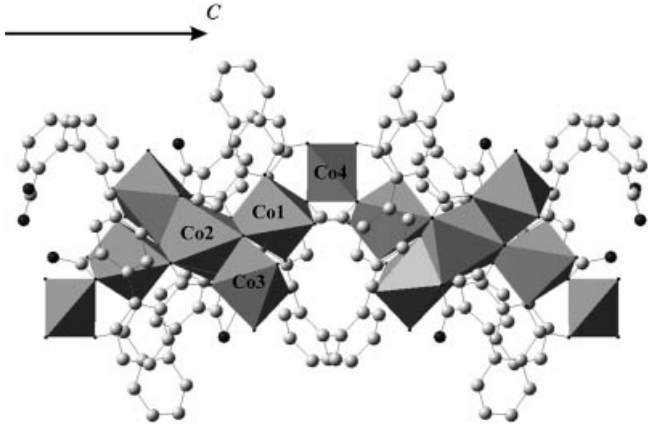

Figure 2. Octahedra and tetrahedron connectivity along one chain in compound **2**

from 2.037(3) Å to 2.329(4) Å for the octahedra, while the metal-oxygen distances for the tetrahedron are 1.922(4) Å and 1.959(3) Å. The particular geometry exhibited by the chain thus implies four specific exchange pathways, with different characteristics (see Table 2). Co1 and Co2 are connected through one oxygen atom from a hydroxy group (O2) and one oxygen from a carboxylate group. The Co2−Co3 pathway involves an identical geometric configuration. The Co1 and Co3 atoms are connected by a hydroxy ion (O2) and through an O−C−O bridge of a carboxylate group. Finally, one oxygen atom from a carboxylate group (O5) and two O−C−O pathways are involved in the Co1−Co4 connection. Based only on these geometric considerations, one can expect a rather complex situation for the Co-Co magnetic interactions along the chain.

As shown in Figure 3, no contact, and especially no hydrogen bonds, are observed between the chains, the phenyl rings of the biphenyl dicarboxylate ligands being located away from the chain axis. The two water molecules are nevertheless involved in four intra-chain hydrogen bonds whose geometrical characteristics are given in Table 1.

Interestingly, the formerly characterised compound **1**, whose structure is shown in Figure 1b, exhibits a helical arrangement of the dicarboxylate ligands. The Co^{II} atoms are interconnected through carboxylate bridges and surrounded by four water molecules. The Co-Co distance along the chains is 4.9981(3) Å.[24] By comparison, the present structure thus corresponds to the condensation of the Co^{II} chains resulting in shorter contacts between magnetic centres and in the occurrence of more efficient metal-oxygen-metal exchange pathways. Another difference is the occurrence of tetrahedral coordination for Co4.

quency difference between the symmetrical and antisymmetrical carboxylate vibrations, $\Delta\nu = 135\ cm^{-1}$, is in agreement with the bridging bidentate coordination mode of the carboxylate groups found in the structure.[25−27] The experimental spectra do not allow to distinguish a doublet corresponding to the minority unidentate mode of one of the carboxylate functions. The presence of broad ν_{O-H} bands at 3429 cm^{-1} is related to the hydrogen-bonded aqua ligands. UV/Vis spectra (reflectance) shown in Figure 4 are consistent with the presence of both octahedral coordination {λ = 1090 nm ($^4T_{1g} \rightarrow {}^4T_{2g}$), 525 nm, [$^4T_{1g} \rightarrow {}^4T_{1g}(P)$]}, and tetrahedral coordination of Co^{II} {λ = 1280 nm [$^4A_2 \rightarrow {}^4T_1(P)$], 590 nm [$^4A_2 \rightarrow {}^4T_1(F)$]}.[28,29] The comparison with the spectrum of compound **1** (see Figure 4) indicates a different octahedral geometry for the Co^{II} ions in compound **2**, where the octahedra are found to be significantly distorted. The corresponding values of Dq (≈ 1146 cm^{-1} for **2**) and Racah's parameter B (≈811 cm^{-1}), deduced from the transitions assigned to the octahedral sites, agree with a low octahedral crystal field ($Dq/B = 1.4$) and high-spin configuration for the metal centres, also inferred from the magnetic findings (see below). The other set of transitions gives $Dq \approx 434\ cm^{-1}$ and $B \approx 782\ cm^{-1}$ in agreement with the presence of Co^{II} in a tetrahedral site.[28,29]

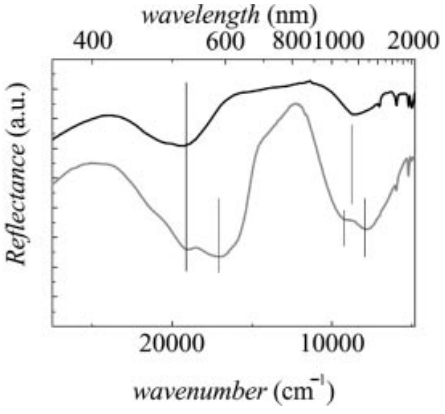

Figure 4. Reflectance UV spectra of compounds **1** (above) and **2** (below); vertical lines are guides for the eyes

Magnetic Properties

The magnetic properties of compound **2** were investigated as described in the Exp. Sect. The temperature variation of the magnetic susceptibilities, χ, is shown in Figure 5. Upon cooling down, $\chi = f(T)$ increases continuously up to a maximum of 1.9 emu·mol^{-1} at 2 K. The χT product exhibits a regular decrease from 8.35 emu·K·mol^{-1} at 300 K without tending to zero but to 2.46 emu·K·mol^{-1} at 2 K. The inverse susceptibility (not shown) varies linearly with the temperature in the high temperature regime ($T >$ 180 K) and is well fitted in this region by using the Curie−Weiss law, giving $C = 8.96$ emu·K·mol^{-1} and θ = −18.6 K. The Curie constant deduced for three metal ions per formula unit agrees with that expected for 5/6 octahedral high spin and 1/6 tetrahedral Co^{II} ions[30,31] with

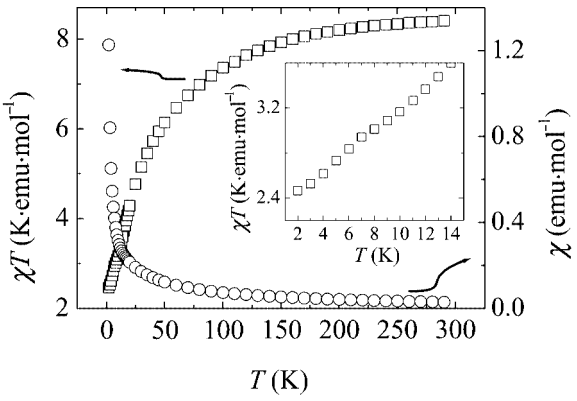

Figure 5. Temperature variation of the magnetic susceptibility (scaled to 1 formula unit) for compound **2**

$C_{octa} = 3.21$ emu·K per Co^{II} mol and $C_{tetra} = 1.875$ emu·K per Co^{II} mol.

The decrease of the χT product together with the negative value of θ might be related to the effect of the spin-orbit coupling for isolated Co^{II} ions in the octahedral crystal field. This results in the splitting of the energy levels arising from the $^4T_{1g}$ ground term, stabilizing the $J = \pm 1/2$ doublet well separated from the excited states.[30] However, the χT value of 2.46 emu·K·mol^{-1} at 2 K is much smaller than the minimum value expected for isolated high-spin octahedral and tetrahedral cobalt(II) centres [ca. 3 × (5/6 × 1.8 + 1/6 × 1.875) = 5.44 K.emu·mol^{-1}],[30] which suggests the occurrence of an antiferromagnetic coupling between the Co^{II} ions. It is also inferred by the magnetisation vs. field curve at 2 K (see Figure 6) that exhibits a very small "saturation" moment, $Ms = 3.3\ \mu_B.mol^{-1}$ for three Co^{II} ions (expected: 2−3 μ_B per cobalt)[30,31] with a slight increase toward the high fields. However, no long-range magnetic order occurs down to 2 K.

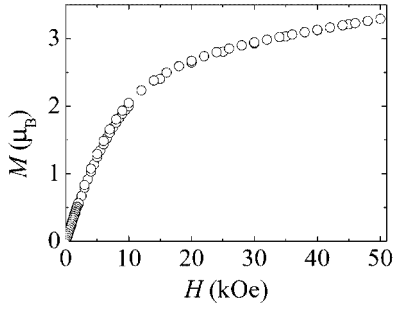

Figure 6. Magnetisation versus field variation at 2 K for compound **2** (scaled to 1 formula unit)

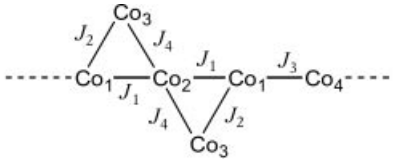
Magnetostructural Relationship

As summarised in Scheme 1, compound **2** can be viewed as chains formed by butterfly motifs of five octahedral Co^{II} centres interconnected through tetrahedral Co4. We identified four different exchange pathways, connecting the cobalt atoms along the chains (see Table 2), corresponding to

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

four magnetic coupling constants: J_1, J_2, J_3 and J_4, each of which corresponds to double or triple bridges between the magnetic centres (see above). Exchange between the Co^{II} ions through the carboxylate bridge is expected to be small and antiferromagnetic.[32,33] All exchange pathways involve at least one Co−O−Co bridge that can lead either to antiferromagnetic or ferromagnetic coupling, as found in hydroxide[14,34−37] or carboxylate[38,39] compounds. The situation is thus rather complex and no analytical expression is available for computing the magnetic behaviour of Co^{II} chains by taking the spin-orbit coupling for the magnetic centres in an octahedral site into account. Also the numerical approach is limited here because of the size of the elemental unit involving six Co^{II} atoms, except for the low temperature region ($T < 30$ K), where the effect of octahedral crystal field and spin-orbit coupling results in a doublet ground-state (effective $S = 1/2$ spin). However, the system appears largely over-parameterized and attempts to fit the susceptibility data in a limited low temperature range, where no anomaly occurs, would be meaningless. What is expected is that J_2 and J_3, which correspond to an exchange through corners of neighbouring coordination polyhedra, are less efficient than J_1 and J_4, which occur through the octahedron's edges. In addition, the Co1−Co2 distance is large (3.437 Å, see Table 2) and J_2 should be negligible compared to J_1 and J_4. In this scheme, and assuming that all the interactions along the chains are antiferromagnetic (the effect of J_2 is neglected), it is worth noticing that an antiferromagnetic arrangement between neighbouring Co^{II} ions would stabilize two resulting moments within the six-centre unit, that is, the moment of one Co^{II} ion per formula unit at low temperature This fits well with the value of ca 3 μ_B observed in the magnetisation versus field curve at 2 K.



Scheme 1

Finally, compared to compound **1**, which was found to be quasi paramagnetic, the present compound, **2**, corresponds to a condensation of the structure along the chains with occurrence of efficient Co−O−Co exchange pathways. This leads to a significant antiferromagnetic interaction between neighbouring Co^{II} ions in the present compound.

Conclusion

A new one-dimensional cobalt(II) 1,1′-biphenyl-2,2′-dicarboxylate was synthesised by the hydrothermal method. The structure was solved on single crystals and consists of decorated chains of Co^{II} ions in octahedral and tetrahedral sites. Compound **2** was obtained by slightly varying the reaction conditions with respect to the previous derivative **1**, thus showing the versatility of the simple 1,1′-biphenyl-2,2′-dicarboxylate bridging ligand towards synthesis conditions. The two compounds can be considered as the result of two competing driving forces, namely templating by the ligand that stabilizes the helical chains in **1**, on the one hand, and templating through the metal coordination that leads to a more compact interconnection of the metal ions in **2**, on the other hand. The IR and UV/Vis data of the two compounds were compared and ligand field characteristics were deduced from the electronic spectra and related to the structural findings. From the magnetic point of view, the diphenic ligand is not good for magnetic exchange-coupling, as shown in compound **1**. However the occurrence of efficient Co−O−Co super-exchange pathways in compound **2** contributes to significant antiferromagnetic coupling between the cobalt(II) ions along the chains.

Experimental Section

General Remarks: The temperature variation of the magnetic moment between 2 K and 300 K was measured by using an MPMS*XL*-Quantum Design SQUID magnetometer at 200 Oe, in the field range corresponding to linear variation of magnetisation versus field. These data were corrected for sample diamagnetism by using Pascal's constants and for diamagnetism of the sample holder consisting of a gel cap. Magnetisation versus field data were recorded in the whole range between −5 and +5 T. UV/Vis-NIR studies were performed with a Perkin−Elmer Lambda 19 instrument (spectra recorded by reflection). FT-IR studies were performed with an ATI Mattson Genesis computer-driven instrument (0.1 mm thick powder samples in KBr). Thermogravimetric (TG) experiments were performed using a Setaram TG92 instrument (heating rate of 3 °C/min, air stream).

$Co_3(O_2CC_{12}H_8CO_2)_{2.5}(OH)(H_2O)_2$ (2): $C_3H_{255}Co_3O_{13}$ was synthesised by the hydrothermal method from $Co(NO_3)_2{\cdot}6H_2O$ (98% Aldrich), diphenic acid (1,1′-biphenyl-2,2′-dicarboxylic acid, 98% Across), and KOH (85%, SDS). The starting mixture corresponding to the molar composition 1:1.5:3.5:195 of $Co(NO_3)_2{\cdot}6H_2O$, $C_{14}H_{10}O_4$, KOH and H_2O was homogenized and transferred into a sealed 23 cm^3 hydrothermal bomb, walled with a Teflon liner, and heated at 170 °C for 74 h under autogenous pressure. The purple needle-shaped crystals obtained were washed with deionized water and rinsed with absolute ethanol [yield > 50% on the basis of $Co(NO_3)_2{\cdot}6H_2O$]. As mentioned above, some platelet-shaped crystals of the pink compound $C_{28}H_{32}Co_2O_{16}$ were also observed and pure compound **2** was isolated by manual separation of the largest crystals. The purity and the chemical formula were confirmed by elemental analysis and are consistent with the structural and magnetic findings: $C_{35}H_{25}Co_3O_{13}$ (830.4): calcd. C 50.63, H 3.03; found C 50.24, H 3.44. Oxidative pyrolysis (TG Analysis, heating in air from 20 to 700 °C at 3 °C/min, maintaining at 700 °C for 30 min to transform cobalt into Co_3O_4, and cooling to 20 °C at 10 °C/min: calcd. Co 21.3; found 21.6). IR (KBr pellet): $\tilde{\nu}$ = 3580 cm^{-1} (ν OH), 3429 (ν OH−O), 3056 (ν C−H), 1612 (δ H_2O), 1579 (ν C−C), 1540 (ν_{as} C=O), 1475 (ν C−C), 1442 (ν C−C), 1405 (ν_s C−O), 1267 (in plane δ_b C−H), 1151 (in plane δ_b C−H), 1108 (in plane δ_b C−H), 1049 (in plane δ_b C−H). UV/Vis (reflectance): see text.

X-ray Crystallographic Study: X-ray data collection was performed on a Nonius Kappa CCD at low temperature (T = 104 K) using a

needle-shaped single crystal. 124314 Reflections were measured up to a resolution of 0.70 $Å^{-1}$ and merged into 9210 unique reflections (R_{int} = 0.097). Crystal faces were indexed and a gaussian integration absorption correction[40] was applied (μ = 1.62mm^{-1}, T_{min} = 0.387, T_{max} = 0.798). The structure was solved by direct methods using SHELX,[41] the H atoms being localised in difference Fourier maps. The structure was refined by full-matrix least-squares on F^2 with anisotropic temperature factors for non H atoms and isotropic ones for H atoms and gave $R[F^2 > 2\sigma(F^2)]$ = 0.062, S = 0.85] final agreement factors. *Crystal data:* $C_{35}H_{25}Co_3O_{13}$, 830.32, monoclinic, *C*2/*c*, a = 19.370(1) Å, b = 14.5350(9) Å, c = 22.583(1) Å, β = 89.910(4)°, V = 6358.1(6) $Å^3$, Z = 8, D_x (g cm^{-3}) 1.727, Mo-K_α, 124314 reflections for cell parameters, μ (mm^{-1}) 1.618, temperature (K) 104(2), crystal form, needle, colour, purple, crystal size (mm) 0.14 × 0.14 × 0.52. *Data collection*: Diffractometer Nonius Kappa CCD; data collection method, ω scans; absorption correction, gaussian integration (DeTitta, 1985), T_{min} = 0.387, T_{max},= 0.798. No. of measured, independent and observed reflections, 124314, 9210, 4544; criterion for observed reflections, $I > 2\sigma(I)$; R_{int} = 0.097; θ_{max} (°) 30.03; range of *h, k, l,* $-27 \geq h \geq 27$, $0 \geq k \geq 20$, $0 \geq l \geq 31$; refinement on F^2, $R[F^2 > 2\sigma(F^2)]$ = 0.0623, $wR(F^2)$ = 0.1332, S = 0.852; no. of reflections and parameters used in refinement, 9210, 552; weighting scheme, $w = 1/[\sigma^2(F_o^2)]$, $(\Delta/\sigma)_{max}$ = 0.004, $\Delta\rho_{max}$ = 1.0984, $\Delta\rho_{min}$ = −1.074. CCDC-209800 contains the supplementary crystallographic data for this paper. X-ray Crystal Structure of a Sodium Salt of $[Gd(DOTP)]^{5-}$: Implications for Its Second-Sphere Relaxivity and the ^{23}Na NMR Hyperfine Shift Effects of $[Tm(DOTP)]^{5-}$

Fernando Avecilla,*[a] Joop A. Peters,[b] and Carlos F. G. C. Geraldes*[c]

Keywords: Gadolinium / Imaging agents / Solid-state structures / Hydration / NMR shift reagents

The X-ray structure of the sodium salt of $[Gd(DOTP)]^{5-}$ shows two different chelates, $[Gd^{(1)}(DOTP)]^{5-}$ and $[Gd^{(2)}(DOTP)]^{5-}$, bound at either surface of a sheet formed by a cluster of hydrated Na^+ ions. Each $[Gd^{(1)}(DOTP)]^{5-}$ anion binds directly to four Na^+ ions of this cluster through the free oxygen atoms of the phosphonate groups of the adjacent ligand, while each $[Gd^{(2)}(DOTP)]^{5-}$ unit is connected to the cluster via hydrogen bonds only. The Gd^{3+} ions in the two moieties do not have any inner-sphere water molecules, and are eight-coordinate. Their coordination polyhedra are twisted square antiprisms, with slightly different twist angles. These **m**′ isomers are found in the crystal structure as racemic mixtures of enantiomers. Only one set of NMR resonances is observed in aqueous solution, corresponding to an averaged **m**′ isomer. In this crystal structure, the Na^+ ions bind the phosphonate oxygen atoms of the $[Gd^{(1)}(DOTP)]^{5-}$ anion at positions far removed from the main symmetry axis. This is significantly different from the binding mode(s) previously proposed to be occurring in solution between Na^+ and $[Tm(DOTP)]^{5-}$, based on the interpretation of solution paramagnetic ^{23}Na NMR shifts. This could arise as a result of the effects of the cluster of hydrated Na^+ ions that are present, which may hinder axial binding modes and distort lateral binding modes. Further, in the crystal structure, both types of Gd^{3+} centers have four second-sphere water molecules that are located at distances (4.2–4.5 Å) significantly longer than those previously proposed from the analysis of the NMRD data of $[Gd^{(1)}(DOTP)]^{5-}$. This is a result of the coordination of Na^+ by these water molecules, thus preventing their direct interaction with the phosphonate oxygen atoms. However, in solution such second-sphere water molecules can interact strongly with the phosphonate ligand oxygen atoms, resulting in efficient relaxation if their binding has relatively long lifetimes (> 50 ps). Rotational immobilization will amplify this contribution, thus making it similar to outer-sphere relaxation.

Introduction

Stable lanthanide chelates of polyazamacrocyclic ligands have been widely used as paramagnetic shift reagents for the in vivo NMR spectroscopy of cations,[1] and as contrast agents for magnetic resonance imaging (MRI).[2–5] The Tm^{3+} complex of 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetrakis(methylenephosphonic acid) (H_8DOTP) has proved to be a particularly favorable NMR shift reagent for the $^{23}Na^+$ NMR spectroscopic study of isolated cells,[6] perfused tissues,[7–11] and intact animals.[12–15] It is also useful as an extracellular in vivo marker of tissues.[16,17] The relaxation properties of the Gd^{3+} complex, $[Gd(DOTP)]^{5-}$, a potential MRI contrast agent, have also been studied.[18–20] Although the solution structures of the Ln^{3+} complexes of this ligand[21–24] have been thoroughly investigated using multinuclear NMR spectroscopic techniques by exploiting the structural information content of the paramagnetic effects of these ions,[25,26] only a preliminary X-ray crystal structure of the $[(NH_4)_5Tm(DOTP)]$ complex has been reported.[27] Here we report on the single-crystal X-ray structural determination of $[Na_5Gd(DOTP)]$. The structural data are used to compare the configuration of the bound ligand with that found in solution.[22] The binding of the Na^+ ions and the positions of the water molecules found in this crystal structure are compared with what has been proposed in solution from ^{23}Na NMR spectroscopic[28,29] and relaxivity studies.[18–20]

Results and Discussion

X-ray Crystal Structure of the Na^+ Salt of $[Gd(DOTP)]^{5-}$

The chemical formula of the compound in the crystal form, as obtained from the X-ray diffraction crystal structural analysis, is $[\{Na_{13}(OH)_3(H_2O)_{29}\}\{Gd^{(1)}(DOTP)\}][Gd^{(2)}(DOTP)]\cdot 7H_2O\cdot 2CH_3CH_2OH$. The overall structure of the crystal is shown in Figure 1, where the asymmetric unit contains two different $[Gd(DOTP)]^{5-}$ moieties, with the $Gd^{(1)}$ and $Gd^{(2)}$ atoms as centers. Within this unit, there are 0.25 $Gd^{(1)}(DOTP)$ moieties, 3.25 Na^+ ions, 0.75 hydroxide groups and 7.25 water molecules that form a hydrated Na^+ cluster. $Gd^{(2)}$ also contributes to the asymmetric unit with an isolated quarter of $Gd^{(2)}(DOTP)$, in which the oxygen atoms of its phosphonate groups are directed to the hydrated Na^+ cluster. 1.75 water and 0.5 ethanol molecules of crystallization complete the structure. This basic unit is repeated according to the crystal symmetry, with the formation of the complete structure.

The $[Gd^{(1)}(DOTP)]^{5-}$ anion, along with the associated Na^+ ions and water molecules is presented in more detail in Figure 2. Four Na^+ ions [Na(4)] are coordinated directly to $[Gd^{(1)}(DOTP)]^{5-}$, each Na^+ ion forms a bridge between the two Gd^{3+}-unbound oxygen atoms of the phosphonate groups of the adjacent ligand. One of these oxygen atoms points towards the azamacrocycle, while the other points towards a cluster of hydrated Na^+ ions that is located next to the methylenephosphonate pendant arms of the macrocycle, connected to the four phosphonate-bound Na^+ ions through four bridging water molecules. The sodium ions are either eight-coordinate [e.g. Na(2)], as in the center of the cluster, six-coordinate at the edges of the cluster [e.g. Na(1)], or four-coordinate when bound to the oxygen atoms of the ligand phosphonate groups [Na(4) in Figure 2]. There are no water molecules directly coordinated to the $[Gd^{(1)}(DOTP)]^{5-}$ moiety. The $[Gd^{(2)}(DOTP)]^{5-}$ anion can also be seen in detail in Figure 2. Although there are many water molecules in the vicinity of the Na^+ ions, no water molecule is directly coordinated by the $[Gd^{(2)}(DOTP)]^{5-}$ chelates. The isolated $[Gd^{(2)}(DOTP)]^{5-}$ unit is connected via hydrogen-bond interactions to the hydrated $[\{Na_{13}(OH)_3(H_2O)_{29}\}\{Gd^{(1)}(DOTP)\}]$ cluster. Table 1 lists some selected interatomic distances. The close proximity of O(1W) to the O(4) and O(5) atoms may indicate a hydrogen-bond between these atoms. The calculated values for the O(1W)···O(4) and O(1W)···O(5) distances, 2.860(13) and 2.966(14), and the angles O(1W)H(1W1)···O(4) and O(1W)H(1W2)···O(5), 169.0 and 149.4°, respectively, fall within the expected ranges.

The molecular geometries of the $[Gd^{(1)}(DOTP)]^{5-}$ and $[Gd^{(2)}(DOTP)]^{5-}$ anions are shown in Figure 3. The Gd^{3+} ion is eight-coordinate, four nitrogen atoms of the macrocycle and four phosphonate oxygen atoms of the pendant arms are bound by it. No inner-sphere water molecule is coordinated by the center. The coordination polyhedra around the Gd^{3+} ions can be described as a twisted intermediate between a prism and a square antiprism. A geometric analysis of the structure was performed in order to

determine the degree of torsion of the prism around the pseudo C_4 axis.[30] The resulting geometry of the coordinated atoms is almost midway between prismatic (twist angle between the planes: 0°) and antiprismatic (twist angle: 45°). Negative twist angles of −27.07 and −23.67° are found in the structures for $[Gd^{(1)}(DOTP)]^{5-}$ and $[Gd^{(2)}(DOTP)]^{5-}$, respectively, which can both be defined as eight-coordinate twisted (or inverted) square-antiprismatic (TSAP) structures, also known as **m′** isomers.[31a] A twisted antiprismatic structure has also been reported for $[La(DOTA)]^-$ crystals: a nine-coordinate twisted capped square-antiprismatic (TCSAP) structure with a twist angle of about −22°, and a water molecule at the capping position.[31b] The two slightly different twist angles observed for the two types of $[Gd(DOTP)]^{5-}$ chelates probably result from their different interactions with the cluster of hydrated Na^+ ions in the crystal structure, and have not been reported in a previous preliminary crystal structural study.[27]

The inherent structural features of the $[Gd(DOTP)]^{5-}$ chelate give rise to two independent sources of chirality, associated with the conformation of each of the four Gd-NCCN chelate moieties in the macrocyclic ring (the helicity of the four C−C bonds relative to the respective Gd^{3+}−N−N planes is defined by two possible forms, δ and λ) and the helicity of the pendant arms (Δ or Λ).[26] The two twisted square-antiprismatic **m′** isomers found in the crystal structure appear both as racemic mixtures of the two Δ(δ,δ,δ,δ) and Λ(λ,λ,λ,λ) enantiomers.

In the coordination polyhedra, the Gd−N bond lengths are 2.660(1) Å (ave.) and the Gd−O bond lengths are 2.314(8) Å (ave.), while in the twisted square-antiprismatic Tm^{3+} coordination polyhedron of $[(NH_4)_5Tm(DOTP)]$, the Tm−N bond lengths were found to be 2.63(1) Å (ave.) and the Gd−O bond lengths 2.26(1) Å (ave.).[27]

These solid-state structural data agree with the results of the solution structural studies on the $[Ln(DOTP)]^{5-}$ complexes carried out using multinuclear and paramagnetic NMR spectroscopy.[21−24] ^{17}O NMR spectroscopic measurements of $[Dy(DOTP)]^{5-}$ in solution have shown that this complex lacks an inner-sphere water molecule.[23] The diamagnetic $[La(DOTP)]^{5-}$ and $[Lu(DOTP)]^{5-}$ complexes have been studied by ^1H and ^{13}C NMR spectroscopy, while the complete paramagnetic series of the $[Ln(DOTP)]^{5-}$ complexes has been studied by ^1H, ^{13}C, ^{31}P, and ^{23}Na NMR spectroscopy, as well as molecular mechanics calculations.[22] Unlike DOTA complexes, which appear in solution as enantiomeric pairs of nine-coordinate capped square-antiprismatic (CSAP, also called **M**) and twisted capped square-antiprismatic (TCSAP, also called **m**) isomers,[25,26,31a] $[Ln(DOTP)]^{5-}$ complexes exist in solution as a single enantiomeric pair. Although the coordination cage appears to be locked into a single conformation, variable-temperature ^1H and ^{13}C NMR spectra suggested dynamic behavior related to the interconversion of the ethylenediamine chelate rings, coupled with the concerted flipping motion of the arms. As a result, $[Ln(DOTP)]^{5-}$ complexes exist as racemic mixtures in solution, and the two enantiomers give indistinguishable NMR signals at room temperature when using conventional NMR spectroscopic techniques.[22,23] Structural analysis of the dipolar contribution to the LIS values and MMX force-field calculations initially suggested a distorted square-antiprismatic (SAP) **M′** arrangement of the ligand, with only minor structural changes throughout the Ln series.[22] However, a recent re-evaluation of the data and of the assignments of the methylenephosphonate protons led to the conclusion that the enantiomeric pair present in solution corresponds to a twisted square-antiprismatic (TSAP) **m′** structure.[32] Thus, the two slightly different **m′**-type enantiomeric pair structures observed in the solid state are replaced by just one pair in solution, as the interaction between the $[Gd(DOTP)]^{5-}$ chelates and the cluster of the hydrated Na^+ ions breaks down

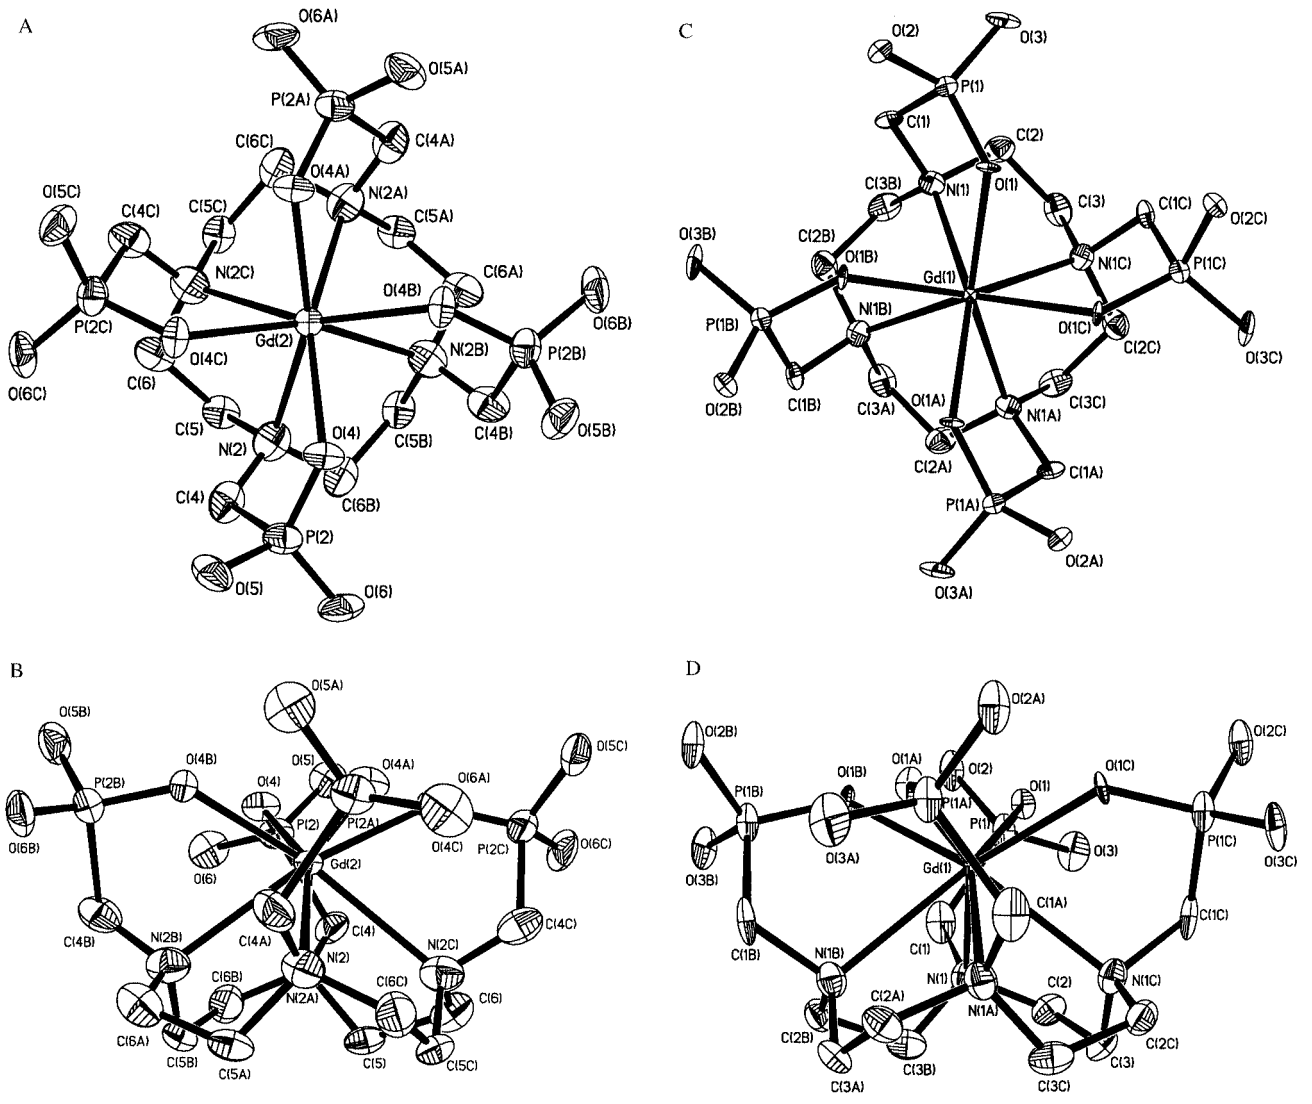

Figure 3. ORTEP diagrams with the top (A, C) and side (B, D) views of the anion complexes $[Gd^{(2)}(DOTP)]^{5-}$ (A, B) and $[Gd^{(1)}(DOTP)]^{5-}$ (C, D), representing the two square-antiprismatic **m**′ isomers; hydrogen atoms have been omitted for simplicity, the ORTEP plots are at the 30% probability level

in solution. Chiral NMR resolution, using the formation of diastereomeric adducts between the two enantiomers of $[Ln(DOTP)]^{5-}$ and a chiral substrate, has provided indirect, but conclusive, evidence for the existence of the two enantiomers of **m**′ in solution.[33−36]

Structural Evaluation of the $[Tm(DOTP)]^{5-}$-Induced ^{23}Na NMR Shifts

The magnitudes of the solution ^{23}Na LIS induced by $[Ln(DOTP)]^{5-}$ complexes, in particular by $[Tm(DOTP)]^{5-}$, are very large and are most likely due to the formation of strong ion-pairs resulting from the high negative charge on the DOTP complexes. Consequently, $[Tm(DOTP)]^{5-}$ is a very efficient shift reagent for in vivo $^{23}Na^+$ NMR spectroscopic studies. The binding sites of the Na^+ ions found in the present crystal structure of the Na^+ salt of $[Gd(DOTP)]^{5-}$ can be used to check the interpretation of the ^{23}Na LIS induced in solution by $[Tm(DOTP)]^{5-}$.[28,29] In this solid-state structure, the $[Gd^{(1)}DOTP)]^{5-}$ center displays four Na^+ ions [Na(4)] that are directly coordinated to the bound ligand and that form bridges between two Gd^{3+}-unbound oxygen atoms of the phosphonate groups of the adjacent ligand (Figure 2). The experimental structural parameters of this binding mode are $\theta = 72.6°$ and $r = 5.29$ Å, where θ is the angle between the four-fold symmetry axis of the $[Gd(DOTP)]^{5-}$ moiety and the $Gd^{3+}-Na^+$ vector, and r is the $Gd^{3+}-Na^+$ distance. The $[Gd^{(2)}(DOTP)]^{5-}$ moiety has no Na^+ ions directly coordinated to the bound ligand (Figure 2), but several of them can be found in its vicinity that belong to the hydrated Na^+ cluster. These ions form two layers in parallel planes perpendicular to the axis

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

connecting $Gd^{(2)}$ and $Gd^{(1)}$, which is the main susceptibility axis of $Gd^{(2)}$. Five Na^+ ions can be found in a layer further away from $Gd^{(2)}$.

Two different types of binding sites for the Na^+ counterions have been proposed in order to interpret the solution ^{23}Na LIS induced by $[Tm(DOTP)]^{5-}$.[28,29] The extremely large ^{23}Na LIS (ca. 420 ppm) observed at low $Na^+/[Tm(DOTP)]^{5-}$ ratios was interpreted as resulting from a type of binding (type A) at a position near the four-fold symmetry axis (low θ). In particular, MMX calculations generated an optimal model where the Na^+ ion interacts with one Tm-bound oxygen atom and another oxygen atom of an adjacent phosphonate group which points away from the tetraazamacrocycle (model A_4, with dipolar angle θ = 26°, $Tm^{3+}-Na^+$ distance r = 3.78 Å).[29] The much smaller shifts (ca. 160 ppm) observed at high $Na^+/[Tm(DOTP)]^{5-}$ ratios were interpreted as resulting from four binding sites of a second type (type B) at higher θ and r values. An MMX-optimized model suggested that the Na^+ ions are associated with two unbound oxygen atoms of adjacent phosphonate groups that point away from the tetraazamacrocycle, with an average θ = 36°, and r = 4.56 Å (model B_2).[29] Both proposed binding sites are located within the positive shift cone of the lanthanide ion.

The structural parameters of the four $Na^+(4)$ ions bound to the $[Gd^{(1)}(DOTP)]^{5-}$ moiety in the crystal show that this binding is similar to the second proposed (type B) binding mode (model B_2), rather than to the first (type A), but with a much larger angle θ (θ > 54.5°) and distance r, thus, the Na^+ ions are located in the negative shift cone of the lanthanide ion. This would lead to a small negative ^{23}Na LIS value for $[Tm(DOTP)]^{5-}$, thereby contradicting the NMR spectroscopic data.[6−15] The $Na^+(4)$ binding mode is very similar to the B_3 model (Na^+ binding to the two oxygen atoms of the same phosphonate group), which has not been considered to contribute to the experimental ^{23}Na LIS.[28,29]

The Na^+ ions in the cluster, near the $[Gd^{(2)}(DOTP)]^{5-}$ moiety but not directly bound to it, occupy three different types of sites. One Na^+ ion [Na(2), θ = 0°, r = 5.17 Å] is located along that susceptibility axis of $Gd^{(2)}$, thus at equal distances from the four phosphonate moieties. It occupies a type-A position, but at a significantly larger distance than the proposed binding model A_1 (θ = 0° and r = 3.22 Å). Four Na^+ ions [Na(1), θ = 36.7°, r = 6.37 Å] occupy a type-B position, but at a larger distance than model B_1, and coordinate one of the metal-unbound oxygen atoms of one bound phosphonate group (θ = 36.7°, r = 5.42 Å). Another four Na^+ ions [Na(3), θ = 56.6°, r = 7.92 Å], which are part of the layer closer to $Gd^{(2)}$, are located at wider angles from the main axis and at larger distances from $Gd^{(2)}$; a position that is similar to the binding model B_3 (θ = 65.5°, r = 6.05 Å), but also at a larger distance.[29]

Therefore, from this analysis we can conclude that the Na^+ binding sites detected in the crystal structure of the Na^+ salt of $[Gd(DOTP)]^{5-}$ at a high $Na^+/[Gd(DOTP)]^{5-}$ ratio of 5 do not represent the binding mode(s) previously proposed to be occurring in solution. This could arise as a result of the effects of the cluster of hydrated Na^+ ions that are present, which may hinder the axial binding mode (type A) and also distort the lateral binding mode (type B).

Simulation of the Parameter Dependence of the Second-Sphere and Outer-Sphere Contributions to the Relaxivity of a Gd^{3+} Complex

The unexpectedly high relaxivities displayed by the NMRD profiles of some small Gd^{3+} chelates such as $[Gd(DOTP)]^{5-}$,[18,19] and also of some small Gd^{3+} chelates bound to macromolecules such as HSA,[37−43] led to the proposal that second-sphere water molecules may, in some cases, significantly contribute to the measured relaxivities.[43−45] Such second-sphere relaxivity contributions could become as important as well-recognized outer-sphere contributions. The Solomon−Bloembergen−Morgan equations, which usually describe the field dependency of the inner-sphere relaxivity, can be adapted to describe second-sphere effects, while Freed's equation is used to describe the outer-sphere contribution of the relaxivity.[46] Both equations depend on a variety of molecular parameters. In order to obtain an insight into the factors that determine the relative importance of both contributions, the values of the second-sphere and outer-sphere relaxivities of the water protons of a Gd^{3+} complex in aqueous solution were simulated at 298 K and at the 0.01 MHz and 40 MHz Larmor frequencies, as a function of various relevant parameters. The set of equations used is given in the Supporting Information.

Second-sphere relaxivity depends on a variety of parameters, some of which were fixed at reasonable values, such as the number of second-sphere water molecules (q' = 1) and the electronic relaxation parameters ($\Delta^2 = 6.94\cdot10^{19}$ s^2, τ_v = 15 ps). The distance (r') from Gd^{3+} to a second-sphere water proton was varied between two reasonable values, 3.5 and 3.9 Å, while its exchange lifetime $\tau_{M'}$ was varied between 10 and 100 ps, assuming fast (τ_R = 50 ps) and slow ($\tau_R = 10^4$ ps) rotational diffusion of the complex. The outer-sphere contribution has been simulated before as a function of the distance of closest approach of a water molecule to Gd^{3+} (a^H), the diffusion constant (D) and the electronic relaxation time at zero field (τ_{S0}), which is a function of the crystal-field parameter Δ^2.[47] Here, the outer-sphere contribution was calculated as a function of the parameter a^H, which took on the values of 3.5, 3.9, and 4.5 Å, with the same electronic relaxation parameters as assumed for second-sphere relaxation and a typical value of the diffusion constant, $D = 2.28\cdot10^{-9}$ $m^2\cdot s^{-1}$. These simulations (Figure 4) show that the second-sphere relaxation is efficient only if the second-sphere water molecules have a reasonably long lifetime $\tau_{M'}$. In such a case, rotational immobilization (long τ_R) may amplify this contribution, so that it becomes similar to outer-sphere relaxation. Thus, the long-lived second-sphere hydration water molecules trapped in the interface of a Gd^{3+} chelate binding at a pocket of a protein such as HSA, together with exchangeable protons from protein residues nearby, have very sizeable contributions to the large relaxivities observed.[5,43]

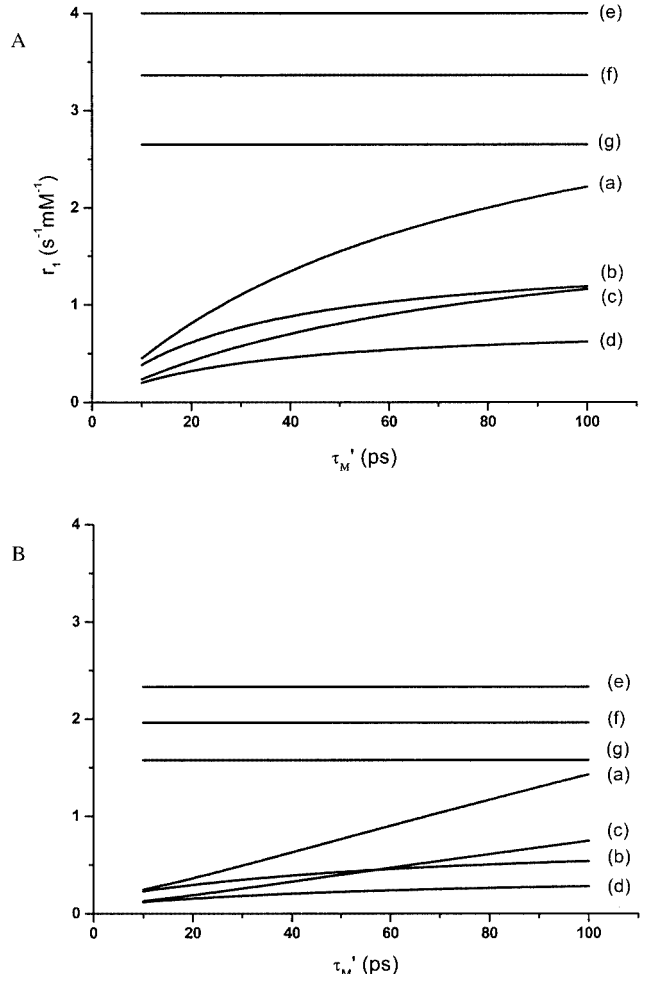

Figure 4. Calculated values at 0.01 MHz (A) and 40 MHz (B) of the parameter dependencies of the contributions to the proton relaxivity r_1 of a Gd^{3+} complex in aqueous solution: (a)−(d) second-sphere relaxivity as a function of $\tau_{M'}$ for $\tau_R = 50$ ps, $r' = 3.5$ Å (b) and $r' = 3.9$ Å (d) and for $\tau_R = 10^4$ ps, $r' = 3.5$ Å (a) and $r' = 3.9$ Å (c) ($q' = 1$, $\Delta^2 = 6.94 \cdot 10^{19}$ s^2, $\tau_v = 15$ ps); (e)−(g) outer-sphere relaxivity for $a^H = 3.5$ Å (e), $a^H = 3.9$ Å (f), and $a^H = 4.5$ Å (g) ($D = 2.28 \cdot 10^{-9}$ $m^2 \cdot s^{-1}$, $\Delta^2 = 6.94 \cdot 10^{19}$ s^2, $\tau_v = 15$ ps)

Structural Evaluation of the Second-Sphere Hydration of Gd^{3+} in $[Gd(DOTP)]^{5-}$ and of Its Contribution to Its Relaxivity

The NMRD profile of $[Gd(DOTP)]^{5-}$ shows a relatively high relaxivity,[18,19] and its unusual features have led to conflicting explanations. Initially, the formation of oligomers containing a mixture of isomers with different q (inner-sphere water molecules) values were considered, leading to fractional q values.[18] Later, the same curve was interpreted on the basis of the collective contributions of one coordinated water molecule ($q = 1$) with an unusually long distance, $r_{GdH} = 3.26$ Å (instead of the standard 2.9 Å value) and a residence time, $\tau_M = 3000$ ps, together with an outer-sphere contribution calculated using a rather short distance of closest approach $a_{GdH} = 3.76$ Å,[19,20] instead of the more commonly used value of $a_{GdH} = 4.5$ Å.[44] As it became evident that this system has $q = 0$,[23] the same data were well-fitted when considering a strong second-sphere contribution, with two water molecules ($q' = 2$) located at a somewhat longer distance ($r'_{GdH} = 3.89$ Å) with short residence times ($\tau'_M \approx 100$ ps), corresponding to water molecules hydrogen-bonded to the phosphonate oxygen atoms of $[Gd(DOTP)]^{5-}$, together with an outer-sphere contribution calculated using standard values of D and $a_{GdH} = 4.5$ Å.[45] The important contribution of second-sphere water molecules to the relaxivity of $[Gd(DOTP)]^{5-}$ was also pinpointed by a reasonable fit of its NMRD curve to a calculated curve based on an outer-sphere hydration model obtained by molecular dynamics simulations. This hydration model was defined by a radial distribution function which contains a second-sphere of four water molecules on the hydrophilic hemisphere encasing the phosphonate groups of the complex, at an average distance $r'_{GdH} = 3.4$ Å, and residence time $\tau'_M = 56$ ps.[48]

We tried to find experimental evidence of the solution hydration model of $[Gd(DOTP)]^{5-}$ from the low-temperature (−100 °C) X-ray structure, in a similar way to what was done previously for $K_2[Yb(DTPA)(H_2O)]$.[44] However, this was not as successful since the presence of the Na^+ counterions in close contact with the complex (Figure 2) significantly affects its hydration. Eight water molecules that are coordinated to the four Na^+ ions, which are bound to the phosphonate groups, are at 7.0−7.3 Å away from $Gd^{(1)}$. Half of these connect the four Na^+ ions to the main hydrated Na^+ cluster. Another four water molecules belonging to the cluster that connect the $Na^+(1)$ and $Na^+(2)$ ions are at 4.5 Å from $Gd^{(1)}$. The $[Gd^{(2)}DOTP]^{5-}$ chelates interact with the hydrated Na^+ cluster through the hydrogen-bonding interaction between one Gd-unbound oxygen atom of each phosphonate group and a water molecule that is coordinated to the $Na^+(3)$ ions of the cluster. These water molecules are located 7.0 Å from $Gd^{(2)}$. However, the layer of eight water molecules within the cluster are closer to $Gd^{(2)}$: four water molecules at 4.2 Å from $Gd^{(2)}$, which connect the $Na^+(1)$ and $Na^+(2)$ ions, and four water molecules at 6.7 Å from $Gd^{(2)}$, which connect the two $Na^+(1)$ and $Na^+(3)$ ions. Thus, in the crystal structure, both the $Gd^{(1)}$ and $Gd^{(2)}$ centers have four second-sphere water molecules located at 4.5 and 4.2 Å, respectively, from them. These distances are significantly longer than those proposed from the analysis of NMRD data.[45,48] The water molecules in the crystal coordinate the Na^+ ions, which prevents their direct interaction with the phosphonate oxygen atoms, significantly increasing their distances from the Gd^{3+} ions.

In summary, the structural information obtained in the solid state for the Na^+ salt of $[Gd(DOTP)]^{5-}$ provides significant clues to the location of Na^+ ions and water molecules around the chelate, which are of value for the rationalization of the solution ^{23}Na paramagnetic NMR shifts induced by $[Tm(DOTP)]^{5-}$, and of the second-sphere water relaxivity of $[Gd(DOTP)]^{5-}$.

Experimental Section

X-ray Crystallographic Study: $Na_5Gd(DOTP) \cdot 2.75\ H_2O$ was provided by Macrocyclics, Richardson, Texas, USA. Single crystals of

$[\{Na_{13}(OH)_3(H_2O)_{29}\}\{Gd^{(1)}(DOTP)\}][Gd^{(2)}(DOTP)]\cdot 7H_2O\cdot 2CH_3CH_2OH$ were recrystallized from a water/ethanol solution of the sodium salt of $[Gd(DOTP)]^{5-}$ and grown by slow diffusion of 2-propanol into this solution, and slow evaporation of the solvent. Colorless crystals of X-ray quality were obtained. A suitable crystal of $[\{Na_{13}(OH)_3(H_2O)_{29}\}\{Gd^{(1)}(DOTP)\}][Gd^{(2)}(DOTP)]\cdot 7H_2O\cdot 2CH_3CH_2OH$ was coated with Fomblin oil, placed on the end of a silica fiber and mounted on a goniometer head of a Bruker SMART CCD diffractometer with a stream of cold nitrogen gas. The crystal was centered optically, and the unit cell parameters and an orientation matrix for data collection were obtained at −100 °C by using the centering program in the SMART system. Details of the crystal data are given in Table 2. The default hemisphere runs required about 3.5 h for full data collection (with 5-s-per-frame scan time) and comprised 3 runs totaling about 1250 frames. They were set up assuming a sample-to-detector distance of about 5 cm, which provided full coverage to better than 0.75 Å (56.6° with Mo radiation). Three-dimensional X-ray data were collected by 3-circle hemisphere runs in the θ-range method. Lorentz, polarization and decay corrections were applied to the data, as well as an absorption correction based on a series of ψ scans. Reflections were measured from a hemisphere of data collected in frames of 0.3°. A total of 35498 reflections was collected, of which 4568 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. Complex scattering factors were taken from the program package SHELXTL/PC V5.1.[49] The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2 using SHELXTL/PC V5.1.[49] Due to the crystal nature and diffraction capabilities, some disagreeable reflections were suppressed. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions and refined with the riding model on their respective heteroatoms, except for the H atoms involved in hydrogen-bonding interactions with the $[Gd^{(2)}(DOTP)]^{5-}$ moieties, which were first located in geometrically calculated positions, left freely and then refined riding on the oxygen atoms of the water molecules. The H atoms of some water molecules and of the ethanol molecule were not included. Minimum and maximum final electron-densities (−1.571 and 3.976 e·Å^{-3}) were 0.84 Å from $Gd^{(1)}$ and 0.76 Å from $Gd^{(2)}$. The weighting scheme used during refinement is given in Table 2. Structure refinement and preparation of figures and tables for publication were carried out on PCs using SHELXTL/PC V5.1.[49] A complete list of atomic coordinates, bond lengths and angles, thermal parameters, and hydrogen atom coordinates are available from the Cambridge Crystallographic Data Centre. CCDC-213923 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Bent and Linear Forms of the (μ-Oxo)bis[trichloroferrate(III)] Dianion: An Intermolecular Effect − Structural, Electronic and Magnetic Properties

Agustí Lledós,*[a] Marcial Moreno-Mañas,*[a] Mariona Sodupe,[a] Adelina Vallribera,[a] Ignasi Mata,[b] Benjamín Martínez,[b] and Elies Molins*[b]

Keywords: Iron / Oxygen / (μ-Oxo)trichloroferrate dianion / Packing effects / Magnetic properties / DFT calculations

We have analyzed the great diversity of Fe–O–Fe angles, 140–180°, found in the X-ray structures of the (μ-oxo)bis-[trichloroferrate(III)] dianion $[Cl_3FeOFeCl_3]^{2-}$ from both experimental and theoretical points of view. Theoretical calculations show that only the linear isomer is found as a minimum on the potential energy surface. Detailed analysis of the crystal packing indicates that the angular form is due to attractive intermolecular interactions. Analysis of a selected reduced set of the 45 crystal structures retrieved from the Cambridge Structural Database allowed us to classify the bending of the $[Cl_3FeOFeCl_3]^{2-}$ dianion in three categories, depending on the balance and strength of the intermolecular O···H–X contacts. A crystal diffraction study on the bis(benzyltrimethylammonium) salt has shown both bent (144.6°) and linear (180°) forms of the (μ-oxo)bis[trichloroferrate(III)] dianion. The magnetic susceptibility of this compound has been fitted by assuming two equally weighted contributions (J_{ang} and J_{lin}) of the two forms, considering $J_{ang} - J_{lin}$ estimated by theoretical calculations. The obtained J_{ang} and J_{lin} of −117 and −133 cm^{-1} respectively, agree well with B3LYP results.

Introduction

Understanding spin coupling in condensed matter is of fundamental interest. Strategies to control this coupling are of paramount importance for several material applications. Colossal magnetoresistive manganites, high T_c superconductors or superparamagnetic clusters like Fe8 and Mn12 are impressive examples of how spin coupling can be fine-tuned to promote outstanding material properties.

Uncoupled transition metal atoms with unpaired electrons behave as paramagnets. When two atoms interact, the most stable ground state usually corresponds to the singlet $S = 0$ state. In metals and alloys, the metal atoms are directly linked, but in ceramic materials they are usually bridged by other atoms. Oxygen is a very suitable bridging atom; it is a two-electron acceptor, and its flexibility allows the transformation of a linear into a square configuration. The very simple M−O−M system is ideal to study the spin coupling between metal atoms through a bridging atom, acting as a model for more complicated systems.

In particular, oxo-bridged iron(III) complexes have received considerable attention as both simple and useful models for non-heme metalloproteins containing dinuclear iron units in their active site,[1,2] and in studies of the intramolecular antiferromagnetic spin exchange coupling between two high-spin ferric ions.[1,3,4] Within this family, the (μ-oxo)bis[trichloroferrate(III)] dianion **1** (Figure 1) is ubiquitous. X-ray diffraction studies on salts of **1** have been described with various different cations.[3,5−7] An interesting feature of the crystal structure determinations is that the Fe−O−Fe angle in the solid state ranges from 180 to ca. 140° depending on the respective countercation (Figure 1). In general, bent structures **1a** have been considered for the anions with Fe−O−Fe angles of 146−171°. The apparently linear conformations **1b** (Fe−O−Fe 180°) found in a few cases have been attributed to orientational disorder.[3] In spite of the different Fe−O−Fe angles found in these structure determinations, only one type of anion (i.e. with a unique angle) was found in each crystal.

Interest in (μ-oxo)bis[trichloroferrate(III)] salts has been renewed by the discovery that the two different forms (bent

and linear) can be simultaneously present in the crystal. A crystal diffraction study on the bis(benzyltrimethylammonium) salt **2** showed that both bent (144.6°) and linear (180°) anions were present in the solid, in a ratio of 1:1.[8] Instead of a linear arrangement, the elongated shape of the ellipsoids at the oxygen atoms is also compatible with the presence of two angular conformers (> 165°). However, the ellipsoids' shape, which could be due to either vibrational behavior or some disorder between two quasi-linear conformers, was not explained. In any case, Mössbauer spectroscopy of **2** showed a doublet exhibiting notorious peak asymmetry. The spectrum was fitted with two symmetric doublets associated with two different environments for the iron atoms in the crystal.[8] Thus, from crystal structure and Mössbauer spectroscopy two different Fe−O−Fe forms were identified. Recently, two different types of crystals were obtained for tetramethylformamidinium disulfide (μ-oxo)bis[trichloroferrate(III)] (Form I: orthorhombic; Form II: monoclinic).[9] Two independent (μ-oxo)bis[trichloroferrate(III)] ions, with Fe−O−Fe angles of 146.4 and 180°, were found in the asymmetric unit of Form I, whereas only one ion (Fe−O−Fe 167.9°) was found in Form II. The Fe−O−Fe antisymmetric vibrations in the IR spectra, at 845 and 890 cm^{-1} for Form I crystals and 875 cm^{-1} for Form II crystals, are consistent with such variations in the Fe−O−Fe bond angles.[9]

The concurrent presence of both bent and linear forms of anion **1** in the same crystal raises the possibility of two minima on the Fe−O−Fe potential energy curve. Moreover, given the small separation between the low-spin ground state ($S = 0$) and the high-spin excited state ($S = 5$), the two minima might be spin isomers, corresponding to antiferromagnetic and ferromagnetic couplings of the $S = 5/2$ Fe^{III} spins, respectively.

The magnetic properties of (μ-oxo)bis[trichloroferrate(III)] salts have been extensively studied,[1,3] but in all cases only one anion was present. Therefore, we decided to study the magnetism of two coexisting $[Cl_3FeOFeCl_3]^{2-}$ anions. In the early 1990s a systematic theoretical study on the geometry dependence of the magnetic exchange constant J of $[Fe_2OCl_6]^{2-}$ was performed by means of UHF calculations.[10] Nowadays, quantitative calculations of the exchange coupling constants in dinuclear transition metal complexes are possible. The application of broken symmetry DFT calculations produces very good estimates of J, as compared to experimental data.[11] However, in most calculations the magnetic coupling constant is related to the singlet/triplet energy difference. In the (μ-oxo)bis[trichloroferrate(III)] anion the low- and high-spin states are singlet and undecaplet, respectively. Therefore, obtaining a good estimate of this energy difference is a challenge for DFT methods. Recent studies[12] on the magnetic exchange interaction in $[Fe_2OCl_6]^{2-}$ using pure density functional methods computed an exchange coupling of -244 cm^{-1} (Hamiltonian $\hat{H} = -2J\ \hat{S}_1\ \hat{S}_2$), which is much larger than the experimental -134 cm^{-1}. It is interesting to analyze how hybrid functionals behave for the present systems because previous theoretical studies[13] for singlet/triplet energy differences have shown that the related magnetic exchange coupling is quite sensitive to the amount of exact exchange included in the functional.

We have two goals here: First to clarify whether two separated minima are present on the potential energy surface of the isolated $[Cl_3FeOFeCl_3]^{2-}$ dianion using theoretical calculations and, if not, to search for possible mechanisms that result in the anion bending. The second goal is to study the dianion's magnetic properties, taking into account the existence of two isomers or forms and combining experimental and theoretical hybrid density functional methods.

Results and Discussion

Structural Aspects

Fe−O−Fe Potential Energy Curve

Regarding the first goal given above, geometry optimizations of $[Cl_3FeOFeCl_3]^{2-}$, both for the high-spin ($S = 5$) and low-spin (broken symmetry) states, led to only one isomer as minimum on the potential energy surface: the linear one with the chlorine atoms in an alternate conformation (dihedral angles between planes Cl−Fe1−O and O−Fe2−Cl are 60°). The optimized geometrical parameters for the high- and low-spin states (Figure 2) show that Fe−O is longer in the former ground state (1.826 vs. 1.788 Å). Even though the optimizations of the low-spin state were performed using a broken symmetry (BS) approach and, e.g., not using a pure singlet wave function, the obtained values are in quite good agreement with those determined experimentally, which range from 1.752 to 1.765 Å.[3,6,7] Moreover, the computed harmonic vibrational frequencies provide an asymmetric Fe−O−Fe stretching frequency of 861 cm^{-1}, which is in very good agreement with

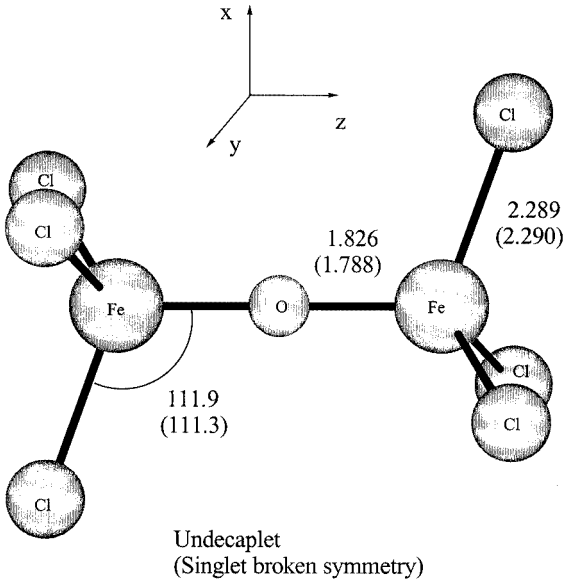

Figure 2. B3LYP-optimized geometries for the undecaplet and singlet (broken symmetry, in parentheses) ground states; distances are in Å and angles in °

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that determined experimentally for several (μ-oxo)diiron complexes (850−880 cm^{-1}). In fact, intense IR absorption in this region is commonly used as a diagnostic criterion to identify monooxo-bridged Fe^{III} complexes.[3,14]

The Fe−O−Fe angular dependence has been analyzed by optimizing the geometry of the anion $[Cl_3FeOFeCl_3]^{2-}$ at different Fe−O−Fe angles (from 180.0 to 130.0°). We have considered both the in-plane (*xz*) and out-of-plane (*yz*) Fe−O−Fe bending. Figure 3 shows that for both the high- and low-spin states the energy slightly increases as the angle is reduced and that no minimum is found at about 140.0°. This behavior is similar to that found in a previous theoretical study.[10] Conversely, the energy cost for the in-plane Fe−O−Fe bending, from 180.0 to 140.0°, is < 3 kcal/mol for the singlet (BS) and < 2 kcal/mol for the undecaplet; indicating a very flat potential energy surface along this direction. The energy cost is even smaller for the out-of-plane bending. Therefore, the presence of two forms, linear and angular, in $([BzlMe_3N]^+)_2$ $[Cl_3FeOFeCl_3]^{2-}$ seems to be due not to electronic effects but probably to packing effects in the crystal.

Crystal Packing Effects

The molecular structure, as well as the Mössbauer and vibrational spectroscopy results, of **2** have been reported previously.[8] However, the crystal packing effects were not analyzed. The crystal packing can be rationalized as a parallel piling of waved sheets along the unique axis *b* (Figure 4). Rows along the *a* axis can be distinguished within each sheet; they are formed of alternating cations and anions. In the five rows depicted in Figure 4 the linear anions lie in the odd ones whereas the angular ones are in the even ones. Although the neighborhood of each anion seems to be very similar, only O4 of the angular anion is involved in hydrogen bonds (numbering of ref.[8]). For symmetry reasons, this oxygen atom is bonded to two HC′3 atoms, which ride on their respective CC′ atoms. Then, while the geometry around O8 is strictly linear, for symmetry reasons, O4 has a tetrahedral bonding scheme

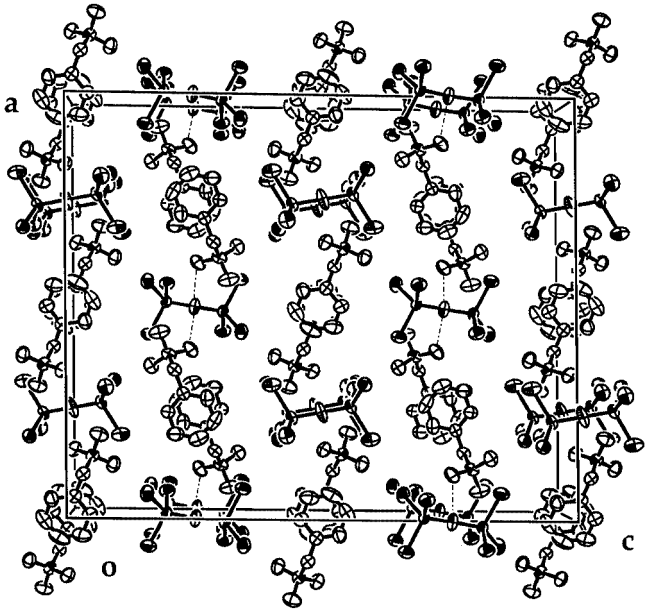

Figure 4. Perspective view of the crystal packing of **2** along the unique axis *b*

(Fe1−O4−Fe1 144.6°, HC′3···O4···HC′3 95°), with their lone pairs roughly pointing to the hydrogen atoms. These two hydrogen bonds, indicated by dashed lines in Figure 4, stabilize the angular conformation of this anion. To estimate the energy involved in this stretching process, the Espinosa model can be used.[15]

As is well known, the position of the hydrogen atoms obtained from conventional X-ray diffraction experiments are biased to their riding atom due to the polarization of the bond and the absence of core electrons in the hydrogen atoms. A correction of this effect[16] available in the PARST program[17] reduces HC′3···O4 from 2.712(6) to 2.603 Å. Introducing this value into the expression of the dissociation energy, D_e, of the Espinosa model gives 0.5 kcal/mol. As O4 is involved in two such hydrogen bonds, the energy afforded by the hydrogen bonds to distort the anion is about 1 kcal/mol, which is in close agreement with the theoretical value obtained from the potential energy curve (Figure 3), and within the range of previous estimations for CH···O hydrogen bonds.[18]

The intermolecular contacts involving the O atom in the $[Cl_3FeOFeCl_3]^{2-}$ anion were then analyzed in a set of structures[3,5−7] taken from the Cambridge Structural Database.[19] The set was formed by 17 structures selected to have no disorder and $R \leq 0.07$. In the 21 $[Fe_2OCl_6]^{2-}$ anions included in the structure set, the environment of the O atom was analyzed. The results allow the structures to be classified as three groups, showing the correlation between Fe−O−Fe angle and the presence of intermolecular interactions involving the O atom (Table 1).

Group I corresponds to anions in the bent configuration that show one or two C−H···O hydrogen bonds. Group III corresponds to linear configurations, and the intermolecular contacts, if they exist, involve pairs of short contacts related by symmetry and situated in opposite directions at

	SUJWEZ	170.23	3.987
	YAFQOL	167.87	3.566, 3.705, 3.771
III	BUTROX	180.00	3.817*
	HEBTEN	180.00	no contact
	HIRTIL	180.00	no contact
	HIRTIL	180.00	no contact
	ICAHUP	180.00	no contact
	KEBYOF	180.00	no contact
	UBENUK	180.00	no contact
	XEDHAP	180.00	3.699*
	YAFQOL01	180.00	3.977*

both sides of the anion. In group II, consisting of anions halfway between those of groups I and III, the Fe−O−Fe angles are in the range 155−170° and the intermolecular contacts are very weak or they pull the oxygen atom from different directions (Figure 5).

Thus, there is a clear dependence between intermolecular interactions and anion configuration. In group I, where the interactions are strong and cooperative, the oxygen atom is displaced from its center position and bending is produced. In group II the interactions are weak or non-cooperative, and the bending is smaller. Finally, in group III there are no interactions or they are opposed and the configuration remains linear at the potential minimum.

Magnetic Behavior

Calculation of the Magnetic Coupling Constants

The magnetic behavior of a complex can be analyzed by using the Heisenberg−Dirac−Van Vleck HDVV spin hamiltonian, where J is the magnetic coupling constant and $\hat{S}_1$ and $\hat{S}_2$ are the spin operators of the magnetically interacting centers 1 and 2 [Equation (1)].

$$\hat{H}_{HDVV} = -2J\hat{S}_1\hat{S}_2 \quad (1)$$

The magnetic coupling constant, which is positive for a ferromagnetic interaction, can be obtained from the energy differences of pure spin sates, by using ab initio configuration interaction procedures [Equation (2)].

$$E(S-1) - E(S) = 2JS \quad (2)$$

Alternatively, one can also efficiently determine magnetic coupling constants by performing unrestricted density functional calculations. However, due to the single determinant nature of the Kohn−Shan procedure, the low-spin state must be treated using the broken symmetry approach, in which the open-shell magnetic orbitals are localized in different centers, with the magnetic electrons having opposite spins. The broken symmetry approach does not lead to a pure spin state and so it is necessary to relate the energy of the broken symmetry solution to that of the pure state.[11a] For a system with two magnetic centers with spins S_1 and S_2, and considering that the overlap between magnetic orbitals is very small (weak bonding regime), J can be obtained by Equation (3).[21]

$$J = \frac{E(Broken-symmetry) - E(high-spin)}{4S_1S_2} \quad (3)$$

For the system considered here, $[Fe_2Cl_6O]^{2-}$, both Fe ions carry a local high spin of $S = 5/2$. The two centers can couple ferromagnetically to give an overall high-spin state with $S = 5$ or antiferromagnetically to provide a low-spin $S = 0$ singlet state. Whereas the high-spin state (undecaplet) can be reasonably described by a single determinant, for the low-spin state (singlet) we have used the broken symmetry approach and the magnetic coupling constant has been obtained according to Equation (4).

$$J = \frac{E(Broken-symmetry) - E(S=5)}{25} \quad (4)$$

In addition to the B3LYP density functional approach, we have also performed calculations using the BHLYP method as previous theoretical studies have shown that the magnetic coupling constant is strongly dependent on the amount of exact exchange introduced in the functional.[13]

The magnetic coupling constants for the linear and angular forms have been computed at the experimentally determined geometry of **2**, using Equation (4). All the performed calculations indicate that antiferromagnetic exchange coupling is the most favorable interaction. Table 2 shows the computed values of J at the B3LYP and BHLYP levels for the two forms. Further enlarging the basis set in the calculation at the B3LYP level had a very small effect on the coupling constant. In contrast, the J value strongly depends on the amount of exact exchange introduced in the used functional. The value determined with the BHLYP functional, for which the amount of exact exchange is 50%, is about half of that obtained using the B3LYP functional with a ca. 20% mixture of exact exchange. Moreover, the B3LYP value is much smaller (in absolute value) than that reported recently[12] using pure density functional methods (-244 cm^{-1}). Similar behavior observed for other complexes has been attributed to the tendency of LDA and even GGA to overstabilize the antiferromagnetic coupling. This trend has been related to an overestimation of the delocalization of the spin density, which is reduced by increasing the percentage of Hartree−Fock mixture in the exchange functional.[13] Spin densities on the metal for the low-spin broken symmetry solution at the B3LYP (3.9) and BHLYP level (4.2) confirm this fact.

Table 2. Magnetic coupling constants [cm^{-1}] for the linear and angular forms at different levels of theory

Method	J_{lin}	J_{ang}
B3LYP/B1	−161	−145
B3LYP/B2	−160	−145
BHLYP/B1	−84	−73
Experimental[a]	−133	−117
	(−130)	(−119)

[a] From the magnetic susceptibility fitting by using the B3LYP/B1 (BHLYP/B1) $J_{ang} - J_{lin}$ difference.

It is also worth noting that the magnetic coupling constant of the linear form is larger than the angular one. This is not due to the different Fe−O−Fe angle, since calculations show a very small dependence of J with the Fe−O−Fe angle,[10] in agreement with experimental observations.[3] The observed difference arises from the different Fe−O distances, which are larger in the angular form due to the larger repulsive interactions between the chlorine atoms. Previous theoretical studies have shown that the absolute value of J decreases sharply as the Fe−O distance increases.[10,12]

Magnetic Measurements

The sample magnetization can be understood as a result of the magnetic coupling among the iron spins. Iron atoms

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in **2** are in the ferric valence state Fe^{3+}, as confirmed by Mössbauer spectroscopy,[8] and are in a distorted tetrahedral environment. The unpaired ferric spins are coupled through the bridging oxygen atom, with the ground state corresponding to an antiferromagnetic spin interaction.

The magnetic susceptibility of powdered samples, $\chi(T)$, has been measured from 5 to 300 K by using a SQUID magnetometer (Figure 6).

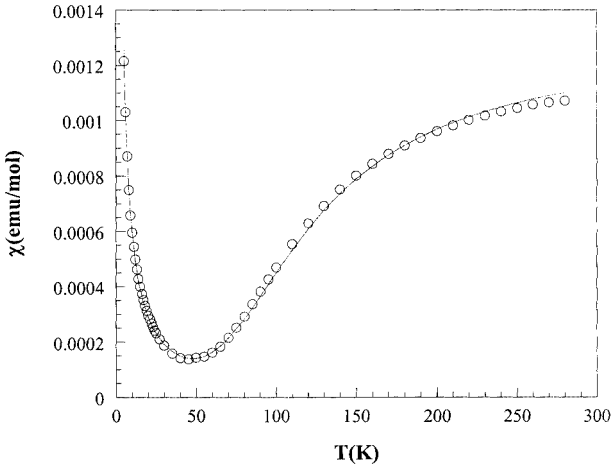

Figure 6. Magnetic susceptibility of compound **2**; the solid line corresponds to the fitting using Equation (5)

The hyperbolic tail in the low-temperature range has been attributed to paramagnetic impurities and treated as a free parameter in fitting the experimental data. After the fitting, the amount of paramagnetic impurities in the sample turns out to be only ca. 0.13 wt%.

The antiferromagnetic nature of the $[Fe_2Cl_6O]^{2-}$ anion is clearly established in the literature and is usually described by Equation (5).[22]

$$\chi_M = \frac{Ng^2\beta^2}{kT}\left[\frac{2e^{2x}+10e^{6x}+28e^{12x}+60e^{20x}+110e^{30x}}{1+3e^{2x}+5e^{6x}+7e^{12x}+9e^{20x}+11e^{30x}}\right](1-p)+p\frac{35N\beta^2}{k(T-\theta)} \quad (5)$$

In Equation (5), p represents the fraction of the paramagnetic impurity,[3] $x = J/k_BT$, J being the intensity of the magnetic coupling. The g value was fixed to 2.00 in all cases and the only fitting parameters were J, P, and θ. Because two different forms with different Fe−O−Fe bonding angles exist, namely 180 and 144.6°, it was not possible to reach an acceptable fitting of the experimental data using a single coupling constant.

The solid line in Figure 6 corresponds to the fitting of the experimental data using Equation (5), but assuming two equally weighted contributions (J_{ang} and J_{lin}) that correspond to the two different forms. As the strong correlation between the coupling constants impedes an independent determination of either of them separately, we used the computed B3LYP/B1 differences between them ($J_{ang} - J_{lin} = 16$ cm^{-1}) to obtain $J_{ang} \approx -117$ cm^{-1} and $J_{lin} \approx -133$ cm^{-1}. Even though the J values significantly depend on the density functional approach used, we expect the difference between coupling constants to be less sensitive and more accurate than the absolute values. The BHLYP values are about half of the B3LYP ones, but the $J_{ang} - J_{lin}$ differences at this level of theory (11 cm^{-1}) is only 5 cm^{-1} smaller.

By using the BHLYP computed difference as the starting point for the magnetic susceptibility fitting, the obtained coupling constants are $J_{ang} \approx -119$ cm^{-1} and $J_{lin} \approx -130$ cm^{-1} and the quality of the fitting is practically the same as that obtained with the B3LYP values. This concordance confirms the validity of the procedure used to determine the magnetic coupling constants from the fitting of the susceptibility. These values lie within the B3LYP and BHLYP values, and even the B3LYP results are in better agreement with that obtained from the fit; the BHLYP values cannot be disregarded.

These results seem to indicate that, at least for this system, a functional with an exact exchange mixing between BHLYP and B3LYP will provide results in close agreement with experiment. Unfortunately, it is not easy to know a priori how much exact exchange needs to be included in the functional to obtain an accurate answer.

Conclusion

Two different forms (bent and linear) of $[Cl_3FeOFeCl_3]^{2-}$ anions coexist in the crystal structure of $(BzlMe_3N)_2^+[Fe_2OCl_6]^{2-}$. Theoretical calculations for the low- and high-spin state of the dianion indicate that only the linear isomer is a minimum on the potential energy surface, although the energy cost for Fe−O−Fe bending is small. A detailed analysis of the crystal packing shows that the oxygen atom of the angular form is involved in two O···HC hydrogen bonds with the $BzlMe_3N$ cation. Therefore, the presence of both linear and angular forms in $([BzlMe_3N]^+)_2$ $[Fe_2OCl_6]^{2-}$ is due to crystal packing rather than electronic effects.

Moreover, analysis of those crystal structures showing bent conformations (Fe−O−Fe angle < 160°) of (μ-oxo)bis-[trichloroferrate(III)] anions shows that the bridging O atom is always involved in at least one intermolecular attractive contact. This contact, although soft, affords enough tension to bend the Fe−O−Fe angle, because the angle potential is flat, while the bulky $FeCl_3$ groups remain anchored in the crystal. The steric contribution to the Fe−O−Fe bending, related to the accommodation of the cation in the anion network holes, which is driven by attractive and repulsive contacts to chlorine atoms, must be included. The very shallow minimum of the Fe−O−Fe angle potential also explains the large vibration of oxygen atoms in the linear conformations.

The magnetic properties of $[Fe_2OCl_6]^{2-}$ have been investigated both experimentally and theoretically. The coexistence of the two forms prevented an acceptable fitting of the magnetic susceptibility when a single coupling constant was used. However, a good fit was possible by assuming two equally weighted contributions (J_{ang} and J_{lin}) that corre-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

spond to the two different forms, and by considering $J_{ang} - J_{lin}$ determined by theoretical calculations. The J_{ang} and J_{lin} values were found to be −117 and −133 cm^{-1}, respectively, and are in reasonably good agreement with those obtained with the B3LYP density functional approach (−145 and −161 cm^{-1}). Considering the low computational cost of density functional methods, compared to conventional post-Hartree−Fock ones, B3LYP appears to be an efficient tool to estimate magnetic coupling constants in such systems.

Experimental Section

General: The magnetic susceptibility of the powder samples, $\chi(T)$, was measured by using a commercial SQUID magnetometer (Quantum Design MPMS-5T), over the temperature range 5−300 K, under an applied field of 5 kOe. Corrections for the diamagnetic response of the sample holder and for the diamagnetic contribution of the samples (Pascal's constants) were carried out.

Computational Details: Calculations were performed using the nonlocal hybrid three-parameter B3LYP density functional method[23] and the following basis sets. For O and Cl we used the Dunning's (9s5p)/[4s2p] and (11s7p)/[6s4p] sets,[24] respectively, supplemented with one d polarization function (ζ = 0.85 for oxygen and ζ = 0.60 for chlorine). The Fe basis set is the [8s4p3d] contraction of the (14s9p5d) primitive set of Wachters[25] supplemented with two diffuse p and one diffuse d functions,[26] the final basis sets were of the form (14s11p6d)/[8s6p4d]. This basis set is referred as Basis1 (B1). To check the effect of further enlarging the basis set, in some calculations the metal basis set was increased by adding one f polarization function,[27] i.e. based on a three-term fit to a Slater orbital of exponent 3.6, and the Cl and O atom basis sets were supplemented with one valence diffuse function. This basis set is referred as Basis2 (B2). The *J* calculations were performed using both the B3LYP and BHLYP[28] density functional methods. All calculations were performed with the Gaussian 98 package.[29]

Acknowledgments

Financial support from MEC and MCyT of Spain (Projects BQU2002-04002, PB98-0916-C02-01, PB98-0912, and MAT2000-2016) and Generalitat de Catalunya (Projects SGR2001-0181 and SGR2001-0335) is gratefully acknowledged. Professor Y. Jean (Orsay) is also acknowledged for helpful discussions.

Platinum−Nitrogen Bond Rearrangements in Isomeric *cis*-$Pt^{II}(NH_3)_2$-bis(9-methyladenine) Complexes under Alkaline Conditions

Jorma Arpalahti*[a] and Karel D. Klika[a]

Keywords: Platinum / Nucleobases / Antitumor agents / N ligands

The migration of coordinated Pt^{II} in the adenine ring was studied in basic aqueous solutions for the isomeric bis(9-methyladenine) complexes: *cis*-$[Pt(NH_3)_2(9\text{-made-N7})_2]^{2+}$ (**1**) and *cis*-$[Pt(NH_3)_2(9\text{-made-N1})(9\text{-made-N7})]^{2+}$ (**2**). In both compounds, coordinated Pt^{II} migrates from the endocyclic nitrogen N(7) or N(1), respectively, to the exocyclic amino group, upon displacement of an NH_2 proton, to give the same first-generation product, viz. *cis*-$[Pt(NH_3)_2(9\text{-made-N6})(9\text{-made-N7})]^{2+}$ (**3**). Although both reactions undergo an intramolecular reaction, the N(1)→N(6) step is faster and far more efficient than the N(7)→N(6) step. This may be attributed to the more favorable electronic effects and to the spatial positioning of the N(1)-bound Pt^{II} in comparison to the platinum coordinated to the N(7) site. However, the contribution of a Dimroth-type rearrangement to the overall N(1)→N(6) conversion cannot be completely ruled out. Attempts to obtain second migration in the N(6),N(7)-bound species to give the N(6),N(6) species were unsuccessful. Rather, prolonged treatment of the N(6),N(7)-bound complex in strongly basic solution resulted in the deamination of the N(7)-bound 9-methyladenine yielding a mixed ligand complex consisting of N(6)-bound 9-methyladenine and N(7)-bound 9-methylhypoxanthine, i.e. *cis*-$[Pt(NH_3)_2(9\text{-made-N6})(9\text{-mhyp-N7})]^{2+}$ (**4**). To the best of our knowledge, this is the first example of such a deamination reaction in Pt^{II} complexes. Both reaction products, **3** and **4**, were characterized by ^1H and ^{195}Pt NMR spectroscopy and by X-ray crystallography of the diperchlorate. In dicationic **3** and **4**, the N(6)-bound 9-made exists in the rare imino tautomer with the N(1) site bearing a proton.

Introduction

The discovery of the anticarcinogenic activity of *cis*-$[PtCl_2(NH_3)_2]$ (cisplatin) by B. Rosenberg in 1969 has led to research interests being focused on the interactions of Pt compounds with nucleic acids and their constituents.[1−3] From a chemical point of view, considerable effort has been paid to the various binding modes[4] of Pt and to the kinetics of complexation.[1,5,6] Due to the general inertness of Pt^{II} and Pt^{IV}, and the high thermodynamic stability of the Pt−N bond, the factors affecting the initial binding step of Pt to DNA are considered crucial for understanding the biological activity of Pt drugs[1,5] and, in this respect, findings on relatively facile Pt−N bond rearrangements at the oligonucleotide level are of prime interest.[7−9] For example, rearrangement of *trans*-$[Pt(NH_3)_2\{d(G^*XG^*)\}]$ intrastrand adducts (where X = A, T, C; * denotes the platination site) into interstrand crosslinks appears as soon as the platinated oligonucleotides are hybridized with their complementary ribonucleotide or deoxyribonucleotide strands.[7] Unfortunately, the exact mechanism for this type of rearrangement is unknown, rendering model studies in this field highly desirable. There have been, however, a few reports on Pt−N bond rearrangements in simple complexes, either within the nucleobase moiety[10,11] or within the auxiliary[12] ligand. Other types of Pt−N bond rearrangements include oxidative Pt migration from the ring nitrogen to the exocyclic amino group in platinated pyrimidine complexes, which involve Pt^{IV} as an intermediate.[13−15] A clear picture, though, is not apparent as regards the factors controlling the migration reactions, and the latter may even require the cooperation of other nucleophiles.[8] In addition, Pt^{II} coordinated to different bioligands has also been found to migrate from the soft S atom to the hard N atom,[16−21] or vice versa.[22]

We have previously examined[23−25] the distribution of Pt^{II} in the adenine ring between the N(7) (kinetically preferred) and N(1) (thermodynamically preferred) binding modes in neutral solutions. Under basic conditions, though, migration of coordinated Pt^{II} to N(6) was observed from both N(1)[10] and N(7)[11] binding sites. In this study we wanted to compare the behavior of *cis*-N(7),N(7) coordinated Pt to the previously examined[11] *trans*-N(7),N(7) system and to contrast directly the N(1) and N(7) binding modes by using a mixed system, namely, *cis*-N(1),N(7) coordinated Pt, by following the reactions of *cis*-$[Pt(NH_3)_2(9\text{-made-N7})_2]^{2+}$ (**1**) and *cis*-$[Pt(NH_3)_2(9\text{-made-N1})(9\text{-made-N7})]^{2+}$ (**2**) under alkaline conditions (9-made = 9-methyl-

adenine). In both complexes **1** and **2**, Pt^{II} migrates from an endocyclic nitrogen atom to the exocyclic amino group upon displacement of an N(6) proton to give a first-generation product, *cis*-$[Pt(NH_3)_2$(9-made-N6)(9-made-N7)$]^{2+}$ (**3**), which is common to the reactions of both **1** and **2**.[26] Further treatment of **3** at high pH results in the deamination of the N(7)-bound 9-made providing the corresponding 9-methylhypoxanthine (9-mhyp) complex, *cis*-$[Pt(NH_3)_2$(9-made-N6)(9-mhyp-N7)$]^{2+}$ (**4**).[26] Both reaction products **3** and **4** were characterized by ^1H and ^{195}Pt NMR spectroscopy and by X-ray crystallography of the diperchlorate.

Results and Discussion

General Considerations

The reactions of the isomeric *cis*-$Pt^{II}(NH_3)_2$-bis(9-methyladenine) complexes **1** and **2** were studied in strongly alkaline aqueous solutions at 65 and 85 °C employing HPLC equipped with an RP-18 column as an analytical tool. Both complexes **1** and **2** were found to undergo two distinct, consecutive reaction steps, the products of which were well resolved from each other, and from the starting material in both cases. Quite interestingly, the major first-generation product, **3**, is the same for the reactions of both **1** and **2** and possesses a much longer retention time than either of the starting compounds. This first-generation product slowly reacts further to yield the major second-generation product, **4**, which elutes earlier than either of the original complexes (see Figure 1). Both reaction steps also produced a small amount of free 9-methyladenine and several unidentified, weakly UV-absorbing (at 260 nm) side products with short retention times. Since the two consecutive reaction steps differ considerably, they are discussed separately.

Intramolecular Migration of Pt^{II}

Although both **1** and **2** give the same major first-generation product **3**, kinetically they behave in a very different manner. While the reaction **2**→**3** is clean and efficient, the reaction **1**→**3** proceeds less efficiently and produces a number of unidentified side products, particularly under more forcing conditions (see Tables S1 and S2). For example, at 338.2 K the overall decomposition of **1** in 1.0 M NaOH solution is rather fast [$k_{obs} = (4.10 \pm 0.04) \times 10^{-3}$ s^{-1}], but only about 6% of the starting material is converted into **3**, with weakly UV-absorbing side products constituting the remainder. At 358.2 K and in 1.0 M NaOH solution, the overall reaction is about five times faster than at 338.2 K, with **3** representing ca. 15% conversion. By contrast, in all cases the efficacy of the reaction **2**→**3** is greater than 95% of the overall decomposition of **2**, with free 9-methyladenine as the principal side product according to HPLC analysis. In 0.03 M NaOH solution, the reaction **2**→**3** is about 30 times faster than the **1**→**3** conversion (at 338.2 K), whereas in 1.0 M NaOH solution this reactivity difference is only a factor of three (see Figure 2). A similar trend is also in place

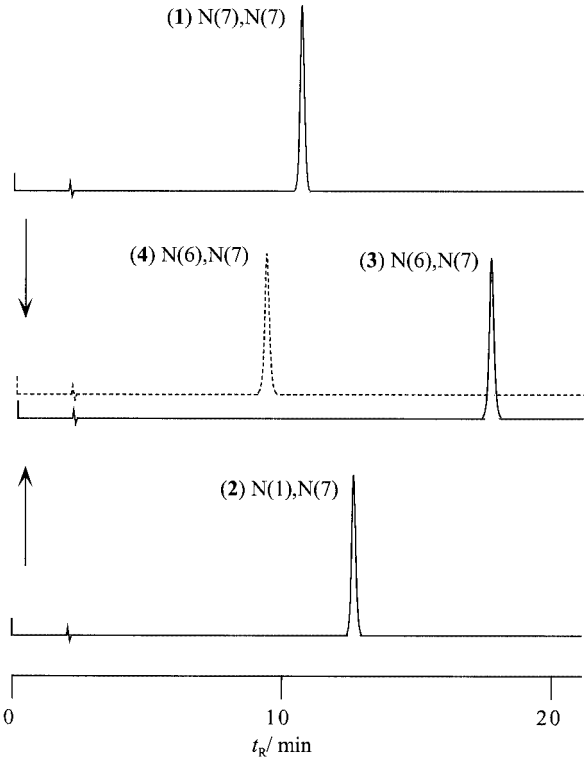

Figure 1. Simplified HPLC traces showing the conversion of **1**→**3** and **2**→**3** under alkaline conditions; the dotted line refers to the second reaction step **3**→**4**; the labeling of the signals refers to the binding sites of Pt^{II}

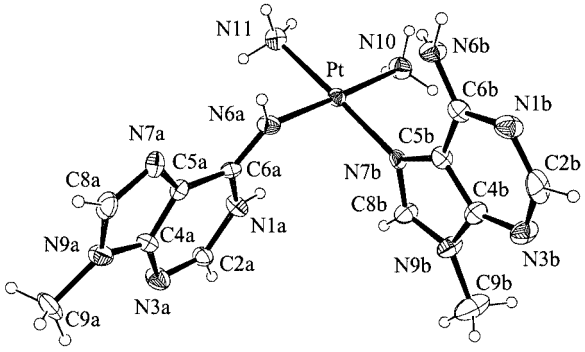

Figure 3. ORTEP plot showing 30% probability ellipsoids of the cation of *cis*-[Pt(NH_3)$_2$(9-made-N6)(9-made-N7)](ClO_4)$_2$·H2O (**3**) with its atom labeling scheme; selected interatomic distances (Å) and angles (°) with estimated deviations in parentheses: Pt−N(6a) 2.016(10), Pt−N(7b) 2.030(9), Pt−N(10) 2.056(9), Pt−N(11) 2.072(10), N(6a)−Pt−N(7b) 93.3(4), N(6a)−Pt−N(10) 177.8(4), N(7b)−Pt−N(10) 88.9(4), N(6a)−Pt−N(11) 86.8(4), N(7b)−Pt−N(11) 177.4(4), N(10)−Pt−N(11) 91.1(4), C(6a)−N(6a)−Pt 129.7(8)

We were able to purify and isolate **3** by fractionating the neutralized reaction solution. It was characterized using ^{1}H and ^{195}Pt NMR spectroscopy (Table 1) and by X-ray crystallography of the diperchlorate (Table 2), thus revealing that the compound is a bis(9-methyladenine) complex of *cis*-$Pt^{II}(NH_3)_2$ where one 9-methyladenine is coordinated to Pt through N(7) and the other through the exocyclic amino group upon displacement of an NH_2 proton which is translocated to N(1) upon acidification. A thermal ellipsoid diagram for the dication of **3** is presented in Figure 3. The platinum atom has nearly square-planar geometry, as is typical for these types of complexes, and lies virtually in the plane defined by the four coordinating nitrogen atoms deviating less than 0.02 Å from this plane. However, the N(6a)−Pt−N(7b) angle is widened [93.3(4)°] at the expense of the N(6a)−Pt−N(11) angle [86.8(4)°]. The Pt−N bond lengths in **3** are comparable to those in **1** and **2** and also to those in the corresponding N(6),N(7)-bound *trans* isomer.[11] It is notable that the Pt−N(6a) bond appears to be significantly shorter by more than three standard deviations[27] than the Pt−NH_3 bonds. Protonation of N(1a) also slightly widens the C(2)−N(1)−C(6) angle [C(2a)−N(1a)−C(6a) 124.5(11)°; C(2b)−N(1b)−C(6b)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

119.8(11)°]; a similar widening was also observed in the corresponding *trans* compound.[11] The packing of **3** is stabilized by hydrogen bonding involving primarily the am(m)ine hydrogens and perchlorate oxygens, e.g. N(11)···O(21) 2.974(16) Å, N(6a)···O(24) 3.223(15) Å, and N(10)···O(22[a]) 3.192(17) Å. Other possible H-bonds include: N(6b)···N(1b[b]) 3.105(14) Å, N(1a)···O(14[c]) 2.849(15) Å, and O(1w)···N(3a[d]) 3.285(29) Å. [Symmetry operations: a) $-x + 1, y - 1/2, -z + 1/2$; b) $-x + 1, -y, -z + 1$; c) $x, -y + 1/2, z + 1/2$; d) $-x, y + 1/2, -z + 1/2$.] However, stacking of the base moieties does not play a significant role in stabilizing the crystal lattice.

In aqueous solution, the dication of **3** shows evidence of dynamic processes as indicated by the splitting of the ^{1}H and ^{195}Pt signals. Most probably, the dynamic process in effect is the restricted rotation of the nucleobase(s) about the Pt−N bond, as has been observed frequently with Pt^{II} complexes of adenine derivatives.[10,11,23] The ^{1}H chemical shifts are in line with the proposed binding modes showing significant downfield shifts for those signals near the proposed Pt^{II} coordination site, whereas the δ_{Pt} values close to −2500 ppm are typical for a PtN_4 coordination sphere[28] and are in agreement with those reported earlier for the corresponding *trans* isomer.[11]

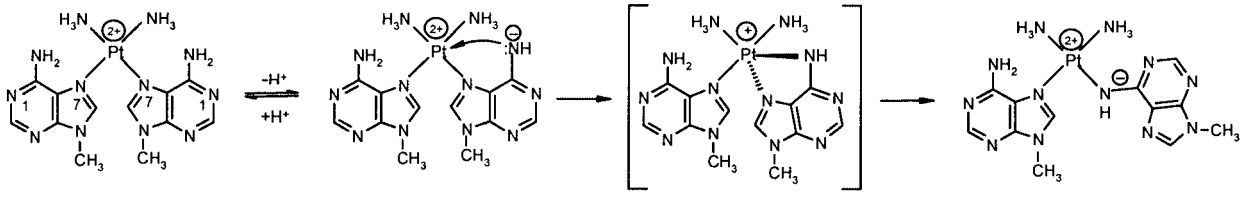
Mechanistically, the formation of **3** is interesting since it forms directly from supposedly inert, isomeric species. The readiness of the reactions **1**→**3** and **2**→**3** rules out the likelihood that the reaction proceeds via hydrolysis of the initial Pt−N bonds and then formation of the Pt−N(6) bond by taking into account the reasoning given earlier for the N(7)→N(6) migration in the N(7)-bound bis(9-methyladenine) complex of *trans*-Pt^{II}(NH$_3$)$_2$.[11] Moreover, the nonlinear dependency of the reactions **1**→**3** and **2**→**3** on [OH$^-$] indicates that the OH$^-$ ion (known as a poor *trans*-labilizing group) does not act as nucleophile on Pt^{II}.[29,30] Rather, the proposed mechanism involves an intramolecular migration of coordinated Pt from endocyclic ring nitrogens, N(7) in **1** or N(1) in **2**, to the exocyclic amino group upon displacement of an NH_2 proton, as depicted in Scheme 1 for the reaction **1**→**3**.

As the first step, deprotonation of the exocyclic amino group provides an imino group close to Pt^{II}, albeit fleetingly transient. Values of 3.430(7) Å and 3.515(7) Å have been reported for the N(6)···Pt distances in the two crystallographically distinct cations of **1**, whilst for **2**, the N(6)···Pt distances are 3.149(8) Å and 3.446(8) Å for the N(1)- and N(7)-bound 9-methyladenines, respectively. For **1**, the attack of the imino group on Pt results in a five-coordinate intermediate, where subsequent cleavage of the presumably weaker Pt−N(7) bond furnishes the N(7)→N(6) migration of Pt in an analogous fashion to the *trans* isomer.[11] Most probably, the same mechanism is also valid for **2** to effect the N(1)→N(6) migration, or at least partly so. Here the efficacy of the migration can be attributed to the shorter N(6)···Pt distance in the N(1)-bound 9-methyladenine and also to the supposedly stronger influence of Pt^{II} on the acidity of the NH_2 protons. However, an alternative mechanistic explanation for the N(1)→N(6) migration of coordinated Pt involves exchanging of the N(1) and N(6) atoms via a Dimroth-type bond rearrangement. It has been proposed that in adenine derivatives, OH$^-$ attacks both protonated (amino form) and deprotonated (imino form) species at C(2), the former being significantly faster than the latter.[31] Although a Dimroth-type bond rearrangement cannot be completely ruled out for **2**, according to our current knowledge, the rate profile nevertheless indicates that the nucleophilic action of the OH$^-$ ion on deprotonated **2** does not play any significant role in the overall migration reaction.

The Second Reaction Step

In **3**, the comparable N(6b)···Pt distance of 3.54(1) Å provided the impetus for attempting a second Pt migration to obtain the N(6),N(6)-bound species. Prolonged treatment of the reaction mixtures of both **1** and **2** ([OH$^-$] > 0.1 M) slowly yielded one major second-generation product, **4**, common to both initial complexes, together with free 9-methyladenine and several unidentified side products. In a 0.1 M NaOH solution (358.2 K), the reaction **3**→**4** is rather inefficient and yields only ca. 15% conversion of **3** to **4**, using **3** as a starting material with the principal side product being 9-methyladenine. However, in 1.0 M NaOH (358.2 K), the yield of **4** rises to ca. 75% and the amount of free 9-methyladenine produced is negligible.

Serendipitously, **4** is virtually insoluble in cold alkali and can thus be easily separated from the reaction mixture. The crude product converts to sparingly soluble in dilute perchloric acid and can be recrystallized as the diperchlorate. The structure provided by X-ray analysis showed Pt^{II} to be bound now to two distinct ligands: 9-made through N(6) and 9-methylhypoxanthine (9-mhyp) through N(7), that is, the N(6),N(7)→N(6),N(6) transformation does not occur and prolonged treatment only results in N(6) deamination of the N(7)-bound ligand. This transformation has not been observed previously for Pt-bound adenines, but substrates have never been subjected to such forcing conditions as they



Scheme 1. Intramolecular N(7)→N(6) migration (**1**→**3**) of coordinated Pt upon displacement of an NH_2 proton

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

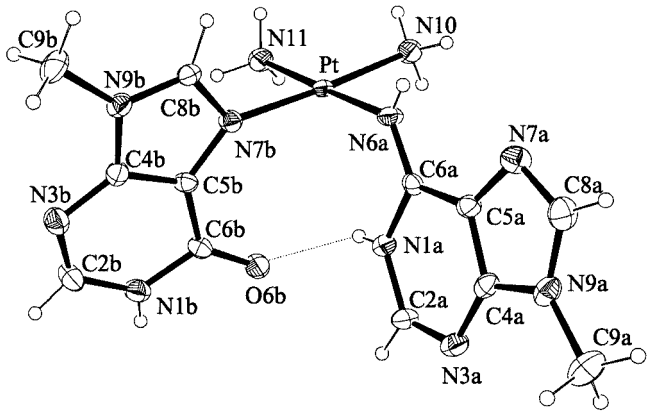


Figure 4. ORTEP plot showing 30% probability ellipsoids of the cation of *cis*-[Pt(NH_3)$_2$(9-made-N6)(9-mhyp-N7)](ClO_4)$_2$·H_2O (**4**) with its atom labeling scheme; selected interatomic distances (Å) and angles (°) with estimated deviations in parentheses: Pt−N(6a) 2.005(6), Pt−N(7b) 2.020(5), Pt−N(10) 2.040(6), Pt−N(11) 2.060(6), N(6a)−Pt−N(7b) 91.6(2), N(6a)−Pt−N(10) 89.3(2), N(7b)−Pt−N(10) 176.9(2), N(6a)−Pt−N(11) 178.6(2), N(7b)−Pt−N(11) 89.6(2), N(10)−Pt−N(11) 89.5(2) C(6a)−N(6a)−Pt 128.4(5)

were here.[11] A thermal ellipsoid diagram for the dication of **4** is shown in Figure 4. The atom bound to C(6b) is best identified as oxygen rather than nitrogen according to the thermal displacement parameters and the *R* values of least-squares refinements. This is supported by the elemental analysis, which provided a composition consistent with this structure.

Only a single platinum signal resonating at δ = −2524 ppm was observed for **4**, which is consistent with a PtN_4 coordination sphere. This species singularity was also evident in the ^{1}H NMR spectrum of **4** where four aromatic protons within the range δ = 7.99−8.57 ppm with nearly equal intensities, together with two methyl groups in a 1:1 ratio further upfield, were observed. These chemical shifts are apt for this structure in comparison to the reference compounds (see Table 2). Finally, treatment of **4** with thiourea (tu), which is known[25] to displace nitrogen-bound ligands from Pt^{II}, provided three HPLC-detectable end products in approximately stoichiometric amounts, namely, $[Pt(tu)_4]^{2+}$-ion, 9-made, and 9-mhyp, identified as such by coelution with authentic samples.

According to the X-ray analysis, the platinum atom in **4** has an almost idealized square-planar geometry with the Pt atom lying in the plane defined by the four coordinating nitrogen atoms, deviating by less than 0.03 Å from this plane. The Pt−N bond lengths in **4** are similar to those in **3**, with the Pt−N(6a) bond being significantly shorter by $> 4.1\sigma$[27] than the Pt−NH_3 distances. The packing of **4** is stabilized by hydrogen bonding involving primarily the am(m)ine hydrogens and the perchlorate oxygens, e.g. N(10)···O(21^a) 3.102(11) Å, N(6a)···O(23^a) 3.092(9) Å, and N(1b)···O(12^b) 2.938(11) Å. Most notable, though, is the intramolecular H-bond N(1a)···O(6b) 2.889(8) Å, where the proton involved was located from the electron density map. Other possible H-bonds include N(10)···O(1w^a) 3.050(9) Å and N(11)···O^a 3.038(12) Å. [Symmetry operations: a) $-x$, $-y+1$, $-z+1$; b) $-x+1$, $-y$, $-z+1$.] The intramolecular H-bond may affect the orientation of the bases in **4**, as seen in the dihedral angle between the base moieties and the Pt coordination sphere, namely 72.5(2)° for the N(6)-bound 9-made and 82.7(2)° for the N(7)-bound 9-mhyp. In **3**, the corresponding angles are 80.5(2) and 86.8(3)°, respectively. Also the dihedral angle between the base moieties is different; 76.5(2)° in **4** and 89.2(2) in **3**. The crystal lattice of **4** is further stabilized by stacking of the six-membered rings of adjacent hypoxanthine bases in a head-to-tail fashion with a distance of 3.44(2) Å between the centers of the rings. Deamination of the N(7)-bound 9-methyladenine and subsequent protonation of N(1b) widens the C(2b)−N(1b)−C(6b) angle from 119.8(11)° to 125.3(7)°, a widening similar to that observed for the N(6)-bound ligand in **3**.

Conclusions

Coordinated Pt^{II} has been found to migrate in the adenine ring from both the N(1) and N(7) sites to the exocyclic amino group, upon displacement of an NH_2 proton in basic aqueous solution. Although both isomeric bis(complexes) of 9-methyladenine with N(7),N(7) and N(1),N(7) binding modes of Pt^{II} undergo an intramolecular reaction and provide the same first-generation product, the N(1)→N(6) migration is faster and far more efficient than the N(7)→N(6) migration. This may be attributed to more favorable electronic effects and to the spatial positioning of the N(1)-bound Pt^{II} in comparison to platinum coordinated to the N(7) site. However, the contribution of a Dimroth-type mechanism to the overall N(1)→N(6) conversion cannot be completely ruled out. Attempts to obtain a second platinum migration from the N(6),N(7)-bound species to produce the N(6),N(6) species were unsuccessful. Rather, the prolonged treatment of the N(6),N(7)-bound complex in strongly basic solution resulted in the deamination of the N(7)-bound 9-methyladenine and yielded the mixed ligand complex consisting of N(6)-bound 9-methyladenine and N(7)-bound 9-methylhypoxanthine. To the best of our knowledge this is the first example of such a deamination reaction in Pt^{II} complexes. By comparison, treatment of free 9-methyladenine in 1.0 M NaOH for 8 h at 85 °C did not provide 9-methylhypoxanthine, though this reaction is known to proceed in the presence of oxidizing agents,[32,33] and thereby it can be concluded that Pt complexation facilitates adenine deamination when migration is not favored. This is quite interesting when considering that for the two major DNA adducts of cisplatin, that is, A-N(7),G-N(7) and G-N(7),G-N(7) (where A = adenine, G = guanine), the former is more mutagenic than the latter, which is cytotoxic.[1,34,35] In addition, in dicationic **3** and **4**, the N(6)-bound 9-made exists in the rare imino tautomer with the N(1) site bearing a proton in an analogous fashion to other N(6)-metalated adenine derivatives.[4,10,11]

Experimental Section

Materials: 9-Methylhypoxanthine (9-mhyp) from Chemogen was used as received. The compounds 9-methyladenine[36] (9-made), $[Pt(tu)_4]Cl_2$[37] (tu = thiourea), *cis*-$[Pt(NH_3)_2(9\text{-made-}N7)_2](ClO_4)_2$ (**1**),[24] and *cis*-$[Pt(NH_3)_2(9\text{-made-}N1)(9\text{-made-}N7)](ClO_4)_2$ (**2**)[24] were obtained as described previously. All other chemicals were of the highest purity available and were used as received. For the preparation of *cis*-$[Pt(NH_3)_2(9\text{-made-}N6)(9\text{-made-}N7)](ClO_4)_2\cdot H_2O$ (**3**), 65 mg of **2** was dissolved in 5 mL of 0.1 M NaOH and the mixture was stirred for 30 min at 85 °C in a stoppered tube. The mixture was neutralized (pH 6) using 1 M $HClO_4$ and the resulting solution concentrated to ca. 1 mL, prior to fractionation using a preparative RP-18 column.[38] After concentration, the combined fractions of **3** afforded 30 mg (50%) of crystalline product upon cooling on ice. $C_{12}H_{22}Cl_2N_{12}O_9Pt$ (744.41): calcd. C 19.36, H 2.98, N 22.58; found C 19.42, H 2.94, N 22.60.

The compound *cis*-$[Pt(NH_3)_2(9\text{-made-}N6)(9\text{-mhyp-}N7)](ClO_4)_2\cdot H_2O$ (**4**) was obtained in a similar manner by dissolving 55 mg of **3** in 5 mL of 1 M NaOH and stirring the mixture for 6 h at 85 °C. Upon cooling to room temperature, crude **4** precipitated from the reaction mixture and was separated by centrifugation. The collected product was first dissolved using a calculated amount of 1 M $HClO_4$ to provide a solution of pH 6 which afforded 28 mg (51%) of **4** as colorless prisms suitable for X-ray analysis upon cooling on ice. $C_{12}H_{21}Cl_2N_{11}O_{10}Pt$ (745.39): calcd. C 19.34, H 2.84, N20.67; found C 19.14, H 2.90, N 20.67.

Methods: NMR measurements were conducted in D_2O (^1H) or in H_2O/D_2O (^{195}Pt) at ambient temperature. Spectra were acquired on a JEOL Alpha 500 spectrometer equipped with a 5 mm tunable probe operating at 500.16 MHz for ^1H, and 107.21 MHz for ^{195}Pt as described earlier.[23,24,38] ^1H spectra were referenced internally to sodium 4,4-dimethyl-4-silapentanesulfonate (δ_H = 0.015 ppm); ^{195}Pt spectra were referenced externally to $[PtCl_4]^{2-}$ (δ_{Pt} = −1625 ppm from $[PtCl_6]^{2-}$). HPLC analyses were conducted on a Merck-Hitachi chromatograph using an end-capped RP-18 column (5 μm, E. Merck AG) and water−methanol mixtures (0.05 M $NaClO_4$, pH 3) as eluents.

Migration Studies: The reactions of the Pt^{II} complexes were followed at 65 and 85 °C at various $[OH^-]$ by HPLC. Samples withdrawn from the aqueous reaction mixtures (I = 1 M, adjusted with $NaClO_4$) were diluted with an appropriate mixture of cold 1 M $HClO_4$ and HOAc/NaOAc buffer (pH 4) prior to chromatographic analysis. First-order rate constants, $k_{1,obs}$, for the disappearance of the starting material were obtained by Equation (1), where $[S]_0$ denotes the initial concentration of the complex and $[S]_t$ the concentration at time t.

$$\ln[S]_t = -k_{1,obs}t + \ln[S]_0 \quad (1)$$

In a few cases the rate constants, $k_{2,obs}$, for the decomposition of **3** were obtained by Equation (2) from the time-dependent concentration of **3**, denoted as $[P]_t$, using $k_{1,obs}$ values obtained from Equation (1) where $[P]_{max}$ is the maximum observed concentration of **3** at moment t_{max}.

$$\frac{[P]_t}{[P]_{max}} = \frac{e^{-k_{1,obs}t} - e^{k_{2,obs}t}}{e^{-k_{1,obs}t_{max}} - e^{k_{2,obs}t_{max}}} \quad (2)$$

When possible, the amount of **3** or **4** formed was approximated by HPLC analysis employing a standard solution of the desired species. In all cases, the signal area was used as the measure of the concentration.

X-ray Diffraction Studies: All X-ray data were collected on a Rigaku AFC5S diffractometer at ambient temperature using Mo−K_α radiation (λ = 0.71069 Å). Unit cell parameters were obtained from a least-squares fit of 20 reflections [11.07 < 2θ < 15.96° (**3**) and 10.70 < 2θ < 16.14° (**4**)]. Intensity data were collected by the ω/2θ scan technique to a maximum 2θ value of 50°. The intensities of three standard reflections were measured every 150 data points in all cases [intensity decays, 3.4% (**3**) and 1.2% (**4**)]. The intensities of the reflections were corrected for Lorenz, polarization, and absorption (empirical) effects.[39] The structures were solved by standard Patterson and difference Fourier methods and refined by full-matrix least-squares calculations employing SHELXL-97.[40] All atoms other than hydrogen were refined with anisotropic temperature factors. The positions of the hydrogen atoms in **3** were calculated except for those located at N(1a), N(6a) and N(6b) which were found from electron density maps. For **4**, the proton at N(6a) and those at the C and N atoms of the aromatic rings were also found from the electron density maps. The water hydrogens could not be located. The final cycle of refinement yielded for the structure of **3**, R_1 = 0.0448 and wR_2 = 0.1052 for the observed data [$I > 2\sigma(I)$] and 342 parameters, and R_1 = 0.1076 and wR_2 = 0.1219 for all data. For **4**, refinement converged at R_1 = 0.0336 and wR_2 = 0.0819 for the observed data and 354 parameters, and R_1 = 0.0407 and wR_2 = 0.0846 for all data. Crystallographic data and experimental details are presented in Table 2. Data reduction and subsequent calculations were performed with *teXsan for Windows*.[41] Figures were drawn with *Ortep-3 for Windows*.[42] CCDC-212435 and CCDC-212436 for **3** and **4**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Ab initio Study on Luminescence and Aurophilicity of a Dinuclear $[(AuPH_3)_2(i\text{-}mnt)]$ Complex (i-mnt = isomer-Malononitriledithiolate)

Qing-Jiang Pan,[a,b] and Hong-Xing Zhang*[a]

Keywords: Ab initio calculations / Luminescence / Aurophilicity / Excited state

The luminescence and Au–Au aurophilicity of the model complex, $[(AuPH_3)_2(i\text{-}mnt)]$ (i-mnt = isomer-malononitriledithiolate in both solid state and solution have been studied by ab initio methods. The structures of the Au^I complex were fully optimized by the MP2 method for the ground state and the CIS method for the excited state. The b^3A' excited-state Au–Au (2.946 Å) and the corresponding Au–Au stretching frequency (83 cm^{-1}) indicate intramolecular Au–Au aurophilicity. Using $[(AuPH_3)_2(i\text{-}mnt)]_2$ to rationalize the solid-state emission to the $[(AuPPh_3)_2(i\text{-}mnt)]$ complex at 20 K we assigned the experimental emission (462 nm) to an Au–Au→i-mnt charge-transfer (^{3}MMLCT) transition from the triplet excited state to the ground state. In the ^{3}MMLCT emissive excited state, the Au–Au aurophilicity, including intra- and intermolecular Au–Au interactions, results in a ca. 120 nm red shift in emission relative to that of mononuclear PH_3AuSH. The calculated absorption and emission in dichloromethane solution agree with the experimental results. These results, combined with our previous studies on both $[Au_2(dpm)_2]^{2+}$ [dpm = bis(diphosphanyl)methane] and $[Au_2(dpm)(i\text{-}mnt)]$, indicate a clear correlation between Au–Au aurophilicity and the excited-state properties of the dinuclear Au^I complexes.

Introduction

The luminescence and aurophilicity of Au^I complexes have been extensively studied over the last two decades.[1−10] Many Au^I complexes luminesce in the solid state and/or in solution, mostly accompanied by intra- and/or intermolecular Au−Au interactions.[11−18] By experiments and accurate theoretical calculations containing electron correlation and relativistic effects, the energy of the Au−Au attraction was estimated to be 5−15 kcal/mol, similar to that of hydrogen bonds.[19−23] The photoluminescence properties of di- and polynuclear Au^I complexes are highly diversified. For various bridging and ancillary ligands, the luminescence properties of such complexes have been suggested to range from MLCT (metal-to-ligand charge transfer), LMCT (ligand-to-metal charge transfer), MCCT (metal-centered charge transfer) and ILCT (intraligand charge transfer).[24−27]

The Au−Au aurophilicity is correlated with the excited-state properties, especially for MCCT in dinuclear Au^I complexes such as those with bridging phosphane ligands, which possess a lower-energy phosphorescence (500−600 nm) in acetonitrile.[26,27] Ab initio calculations indicated that the $^3(d_{\sigma^*}s_\sigma)$ excited state corresponding to the lower-energy emission presents an Au−Au distance of ca. 2.72 Å, which is much shorter than the ca. 3.16 Å in the ground state.[28] The promotion of electron from the d_{σ^*} antibonding orbital to the s_σ bonding orbital affords an Au−Au σ single bond in the MCCT emissive excited state. In addition, for the well-known dinuclear Pt^{II} complex $[Pt_2(pop)_4]^{4-}$ (pop = pyrophosphate), Pt−Pt in the $^3(d_{\sigma^*}p_\sigma)$ excited state shortens by ca. 0.29 Å relative to that in the ground state, which is supported by both the excited-state structure from time-resolved X-ray diffraction and ab initio studies.[29,30]

For Au^I complexes containing both phosphane and thiolate ligands, the lower-energy emissions in the solid state have been experimentally attributed to Au→thiolate charge transfer (MLCT).[11,17,24,31−36] Bruce's studies on a series of dinuclear (phosphane)Au^I thiolates with or without Au−Au interaction showed that the interaction is not a necessary condition for luminescence and that its presence does not significantly perturb the luminescence;[32] however, Fackler and co-workers found that the emission maximum in the luminescence of many mononuclear (phosphane)Au^I thiolate complexes can be affected by an Au−Au interaction.[11] In fact, such studies are not incompatible. The charge transfer from metal to ligand should be divided into metal−metal-to-ligand charge transfer (MMLCT) and metal-to-ligand charge transfer (MLCT).[12,18,37] The former is clearly correlated with the Au−Au interaction but the latter does not.

Unlike those of dinuclear Au^I complexes with bridging phosphane ligands, the excited-state properties of dinuclear (phosphane)Au^I thiolates are clearly related to MMLCT or MLCT, in which the thiolate ligands are greatly involved in the luminescence.[31−36] This is because phosphane ligands always provide lone-pair electrons to form the dative P→Au bond while thiolates, usually as anions, prefer the covalent S−Au bond to coordinating. These different electronic properties may lead to differences in luminescence and aurophilicity when thiolates are introduced into (phosphane)Au^I complexes to form (phosphane)Au^I thiolate complexes.

To study both their luminescent properties and Au−Au aurophilicity, several dinuclear Au^I complexes have been designed, with at least two different structural arrangements: the more common dinuclear Au^I dimers, in which the aurophilicity is sterically imposed,[26,27,38,39] and the open-ring structural disposition, in which the interaction between two Au^I atoms, if it appears, is not sterically imposed.[31−34,40,41] The structurally characterized (phosphane)Au^I thiolate [$(AuPPh_3)_2$(i-mnt)] (i-mnt = isomer-malononitriledithiolate has a nonimposed intramolecular Au−Au interaction.[41] The intense 462 nm phosphorescence of the solid-state complex at 20 K was assigned as an Au→thiolate charge transfer (^{3}MLCT) from the triplet excited state to the ground state.[33,34] Since the π-conjugated i-mnt ligand is greatly involved in the emission and Au−Au aurophilicity is possibly present in the corresponding excited state, the [$(AuPPh_3)_2$(i-mnt)] complex may be an ideal candidate for the ^{3}MMLCT emissive excited state.

Dinuclear Au^I thiolates have also been widely applied in medicine,[42] optical sensors,[12,13,43] and photoredox chemistry.[22,24,27,44] For example, the therapeutic action of gold drugs for rheumatoid arthritis may be related to the ability of the Au^I complexes to quench the singlet oxygen $^1\Delta_g$ state at 7752 cm^{-1}.[42c] Eisenberg and co-workers have reported that [Au{$S_2CN(C_5H_{11})_2$}]$_2$ can be used to monitor efficiently volatile organic compounds (VOCs), by a reversible interaction with VOC vapors that results in both a dramatic color change and a positive "switching on" of luminescence.[13] Such applications make use of excited-state properties. Thus, theoretical investigation of the electronic structures of the ground and excited states for the Au^I complexes is also of practical significance.

Here, ab initio methods have been employed to study the spectroscopic properties and Au−Au aurophilicity of [$(AuPH_3)_2$(i-mnt)] in both solid state and solution. In the solid state, the calculated 450-nm phosphorescence of [$(AuPH_3)_2$(i-mnt)]$_2$ was assigned as an Au−Au→i-mnt charge transfer (^{3}MMLCT) from the triplet excited state to the ground state, similar to the 462-nm solid-state emission of the [$(AuPPh_3)_2$(i-mnt)] complex at 20 K. In the ^{3}MMLCT emissive excited state of polynuclear [$(AuPH_3)_2$(i-mnt)]$_2$, both intra- and intermolecular Au−Au interactions strongly affect the solid-state emission, causing a ca. 120 nm red shift with respect to the 332-nm emission of mononuclear PH_3AuSH. The studies of $[Au_2(dpm)_2]^{2+}$ [dpm = bis(diphosphanyl)methane],[28] [$(AuPH_3)_2$(i-mnt)] and [Au_2(dpm)(i-mnt)] show that the Au−Au aurophilicity is clearly correlated with the excited-state properties of these Au^I complexes.

Computational Details and Theory

In the calculations, [$(AuPH_3)_2$(i-mnt)] was employed to represent the real [$(AuPPh_3)_2$(i-mnt)] complex. A similar model was applied in our previous work[28] by using dpm to stand for dmpm, dppm and dcpm in the $[Au_2(dmpm)_2]^{2+}$, $[Au_2(dppm)_2]^{2+}$ and $[Au_2(dcpm)_2]^{2+}$ complexes respectively [dmpm = bis(dimethylphosphanyl)methane, dppm = bis(diphenylphosphanyl)methane and dcpm = bis(dicyclohexylphosphanyl)methane]. Hydrogen is generally used in place of methyl, phenyl substituents etc. in ab initio studies to save computational resources. Häberlen and Rösch[45] have proved that PH_3 provided a satisfactory model for PMe_3 or PPh_3 for the structural properties of Au^I complexes. Bruce[22] and other researchers[26,46,47] have successfully used such a kind of model in their theoretical studies on the related topics of (phosphane)Au^I complexes.

Here, the C_s symmetry was adopted to settle the conformation of [$(AuPH_3)_2$(i-mnt)] in both the ground and excited states. The structures of the ground and excited states were fully optimized by the second-order Møller−Plesset perturbation (MP2)[48] and the single excitation configuration interaction (CIS)[49] methods, respectively, in which electron correlation effects were considered.[22,23] Based on such calculations, the isodensity-polarized continuum model (IPCM) in the self-consistent reaction field (SCRF) method[50−53] was employed to account for the solvent effect of dichloromethane, by considering the dramatic red shift of emission due to the solvation of acetonitrile on $[Au_2(dpm)_2]^{2+}$ indicated previously.[28] Therefore, the electronic structure of the excited state and the absorption and emission in CH_2Cl_2 solution were obtained.

In the calculations, the quasi-relativistic pseudopotentials of the Au, S and P atoms proposed by Hay and Wadt[54] with 19, 6 and 5 valence electrons, respectively, were employed and the LANL2DZ basis sets associated with the pseudopotential were adopted and implemented by one additional f-type function for Au (α_f = 0.2), and a d-type function for S (α_d = 0.421) and P (α_d = 0.34).[23] The basis sets were taken as Au(8s6p3d1f/3s3p2d1f), S(3s3p1d/2s2p1d), P(3s3p1d/2s2p1d), N(10s5p/3s2p), C(10s5p/3s2p) and H(4s/2s). Thus, 176 basis functions and 104 electrons were included for [$(AuPH_3)_2$(i-mnt)] in the calculations. All the calculations were performed with the Gaussian98 program package[53] using an Origin/3800 server.

Result and Discussion

A. Structures of the Ground and Excited States of [$(AuPH_3)_2$(i-mnt)]

The full MP2 optimizations on [$(AuPH_3)_2$(i-mnt)] indicate that the complex has a $^1A'$ ground state with [(28a′^{2})-

$(24a''^2)$] electronic configuration. The calculated main geometry parameters are listed in Table 1, associated with the data from X-ray crystal diffraction for the $[(AuPPh_3)_2(i\text{-}mnt)]$ complex.[41] The structure of the $^1A'$ ground state (Figure 1, a) consists of two $AuPH_3$ units bridged by an i-mnt ligand. The calculated dihedral angles of 180.0° (P3−Au1−Au2−S6), −179.4° (S5−C7−C8−S6) and −178.1° (Au1−S5−S6−C7) indicate that the molecule is nearly coplanar. The Au^I atom has a linear two-coordinate structure with a P3−Au1−S5 angle of 165.7°, which is similar to the experimental 172.1°. The calculated Au−Au (2.945 Å) bond is shorter than the 3.156 Å determined by experiment for $[(AuPPh_3)_2(i\text{-}mnt)]$ (Table 1) because we used the hydrogen atom in place of the phenyl ligand on the P atoms − the bulky phenyl ligand does not facilitate the approach of two Au^I atoms. Bruce et al.[22] have studied theoretically the luminescent properties and Au−Au aurophilicity of *cis*- and *trans*-$[Au_2X_2CH_2(PH_2)_2]$ (X = Cl, Br and I) complexes, in which the same approximation was employed. Their calculated results agreed well with experimental observations and revealed the nature of the excited states of the real $[Au_2X_2CH_2(PPh_2)_2]$ complex. Thus, our approximation applied here may have little effect on the excited-state properties of the $[(AuPPh_3)_2(i\text{-}mnt)]$ complex. The other distances in the $^1A'$ ground state presented by MP2 calculations accord with those determined experimentally (Table 1).

The frequencies calculated for the ground state of $[(AuPH_3)_2(i\text{-}mnt)]$, performed at the MP2 level, are all low relative to experiment (Table 2), but parallel them because of the ratio of calculation to experiment of 0.80−0.84, excluding the C=C stretching vibration. The 42 cm^{-1} frequency was assigned as the Au−Au stretching vibration and fell

ν(C≡N)	1856	2209	0.8402

[a] Frequencies of ν(Au−Au) from ref.[55]

well within the experimental range reported for such vibrations,[55] suggesting weak aurophilicity between the two Au^I atoms in the $^1A'$ ground state.

The CIS method was used to optimize the structure of the excited state of $[(AuPH_3)_2(i\text{-}mnt)]$. Two triplet excited states were obtained with a^3A' and b^3A' symmetries. The calculated geometry parameters (Table 1) and the corresponding structures (Figure 1, b and c) are given here. Apparently, the geometry of the excited states changes greatly with respect to that of the ground state. In the a^3A' excited state the i-mnt ligand deviates from the $Au_2S_2P_2$ plane due to the dihedral angle of −87.9° for Au1−S5−S6−C7, and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

almost all the ligand bonds are longer than those in the $^1A'$ ground state (Table 1). The two Au atoms are much farther apart (4.753 Å) than in the $^1A'$ ground state (2.945 Å), suggesting no Au−Au aurophilicity as the separation is much more than the van der Waals contact (3.4 Å).[56] Thus, the a^3A' excited state may be related to i-mnt intraligand charge-transfer character.

Unlike the a^3A' excited state, the geometry of the b^3A' excited state is still in a plane, which is intuitively depicted in Figure 1 (c) and quantitatively reflected in Table 1. The Au−Au (2.946 Å) is close to that in the $^1A'$ ground state, but the P···P distance (5.966 Å) in the excited state is far longer than the 3.826 Å in the ground state. This implies a significant Au−Au aurophilicity in the b^3A' excited state as the two P atoms tend to separate in opposite directions. To characterize the Au−Au interaction in the b^3A' excited state of $[(AuPH_3)_2$(i-mnt)], we also carried out frequency calculations. Through vibrational-mode analysis, the calculated frequency of 83 cm^{-1} was attributed to the Au−Au stretching frequency in the excited state, which is much higher than the 42 cm^{-1} frequency in the $^1A'$ ground state. The Au−Au stretching frequency provides evidence of aurophilic attraction between the two gold atoms in both the b^3A' excited state and the $^1A'$ ground state. In addition, the calculated overlap population between the two Au atoms is 0.062 and 0.036 for the b^3A' excited state and $^1A'$ ground state respectively. From such calculated frequencies and overlap populations between the two Au atoms, it is easily seen that although the Au−Au distances are very close in the b^3A' excited state (2.946 Å) and the $^1A'$ ground state (2.945 Å), the Au−Au aurophilicity in the former is stronger. This suggests that there may be some electron transfer to the 6s and/or 6p bonding orbitals of Au atoms in the b^3A' excited state, which then reinforces the Au−Au interaction.

B. Absorption Spectra of $[(AuPH_3)_2$(i-mnt)] in the CH_2Cl_2 Solution

Keeping the optimized structure of the ground state constant, the CIS method was used to calculate the excited state related to absorption. Based on such calculations, the solvent effect of dichloromethane was taken into account by the IPCM in the SCRF method[50−53] and absorption spectra of $[(AuPH_3)_2$(i-mnt)] in solution were obtained. The calculated absorption and the corresponding oscillator strength are given in Table 3, together with the experimental results of $[(AuPPh_3)_2$(i-mnt)] available in the CH_2Cl_2 solution at room temperature.

To assign the absorption in solution, the partial molecular orbital compositions (%) involved in the absorption transition are listed in Table 4, associated with the orbital components. The coordinate orientation of $[(AuPH_3)_2$(i-mnt)] is depicted in Figure 1 (a), in which the z axis parallels the line through the two Au atoms.

The calculated absorption maximum in CH_2Cl_2 solution is at 303 nm with the nature of an $X^1A'\rightarrow A^1A''$ transition. In the excitation, the $24a''\rightarrow 29a'$ configuration has the largest coefficient (ca. 0.6) in the CI wavefunctions, and is responsible for the absorption. The 24a′′ orbital (HOMO-1) has 68% i-mnt ligand composition, mainly contributed by the $S(p_y)$ orbital, while the metal (62%) plays an important role in the 29a′ orbital (LUMO), mainly from the $Au(p_z)$ character (Table 4). Thus, the 303-nm absorption, arising from the $X^1A'\rightarrow A^1A''$ transition, is attributed to $S(p_y)\rightarrow Au(p_z)$ charge transfer (LMCT) mixed with some $Au(d_{z^2})\rightarrow Au(p_z)$ charge transfer (MCCT), which corresponds to the 365-nm absorption observed experimentally for $[(AuPPh_3)_2$(i-mnt)] at room temperature.[33] The large difference between calculated and experimental absorption wavelength is caused mainly by the use of a hydrogen atom to represent the bulky phenyl ligand on P atoms. In a real $[(AuPPh_3)_2$(i-mnt)] system, the relatively longer Au−Au distance may result in less metal participation in the 24a′′ (HOMO-1) orbital. Because the order of the energy level in occupied orbitals is $S(p_\pi) > Au(d_{\sigma^*})$ by analyzing the wavefunctions, the lesser Au contribution to the transition wound reduce the excitation energy. Therefore, if the steric bulk of the phenyl ligands on P atoms was taken into account, the calculated absorption maximum would red-shift relative to the 303 nm of $[(AuPH_3)_2$(i-mnt)] and approach the experimental value of 365 nm.

For the B^1A' excited state, the corresponding absorption was calculated at 295 nm with an oscillator strength of 0.765, which is similar to the 310-nm absorption of the experiment[33] (Table 3). The transition arises mainly from the $28a'\rightarrow 30a'$ configuration with the largest CI coefficient of ca. −0.6. From Table 4, the 295 nm absorption from an $X^1A'\rightarrow B^1A'$ transition was assigned as i-mnt intraligand charge transfer (ILCT) with some LMCT. Because the B^1A' excited state has ILCT character and less metal participation, the approximation overestimating the metal−metal interaction does not significantly perturb the absorption, i.e. the calculated absorption wavelength of 295 nm agrees with the experimental absorption (310 nm).[33] To intuitively understand the absorption process, the density diagrams of the frontier molecular orbitals are depicted in Figure 2. In the 28a′ orbital (HOMO) the electron density mainly focuses around the i-mnt ligand, with the C7−C8 π-bonding orbitals, while in the 30a′ (LUMO+1) and 31a′ (LUMO+3) orbitals the electron density is still distributed on the i-mnt ligand and π* antibonding orbitals form between the two carbon atoms. Thus, we can further assign the 295-nm absorption to a $\pi\rightarrow\pi^*$ transition involving the C=C double bond. Gray et al.[57] have studied the electronic spectra of a series of metal complexes containing the i-mnt ligand in acetonitrile and attributed the absorptions in the range 250−350 nm to $L\rightarrow L^*$ charge transfer.

As a reference, the same methods and basis sets as those of $[(AuPH_3)_2$(i-mnt)] were used to calculate electronic spectra of the organic i-mnt ligand. The ligand also has a C_s symmetry in the calculations of both ground and excited states. The calculated absorption maximum in CH_2Cl_2 solution of 268 nm (Table 3), arising from a $\pi\rightarrow\pi^*$ transition localized on the C=C double bond, supports our assignment for the 295 nm absorption of $[(AuPH_3)_2$(i-mnt)].

The calculated 238-nm absorption from $X^1A' \rightarrow C^1A''$ is related to charge transfer between Au atoms and phosphane ligands. The main configuration 22a′′→29a′, gives rise to the absorption. The 22a′′ orbital has 45% PH_3 and 40% Au orbital character. Therefore, the 238-nm absorption was assigned as $P(p_y) \rightarrow Au(p_z)$ charge transfer (LMCT) mixed with MCCT transitions, which is similar to the observed 225-nm absorption.[33]

C. Emission Spectra of $[(AuPH_3)_2(i\text{-mnt})]$ in the Solid State and CH_2Cl_2 Solution

The excited-state structure was fully optimized by the CIS method to describe the emissive properties of $[(AuPH_3)_2(i\text{-mnt})]$. Two triplet a^3A' and b^3A' excited states were obtained in the CIS calculations and the corresponding emissions were at 593 and 414 nm, respectively, for a single $[(AuPH_3)_2(i\text{-mnt})]$ molecule (Table 3).

By analyzing the wavefunctions of the a^3A' excited state, the calculated 593-nm emission was assigned as a $\pi^* \rightarrow \pi$ charge transfer (i-mnt ^{3}ILCT) involved in the C=C double bond from the triplet excited state to the $^1A'$ ground state, similar to the 595-nm emission of $K_2(i\text{-mnt})$ in the solid state at 20 K.[33] The $\pi^* \rightarrow \pi$ transition is reflected in the structural change of the a^3A' excited state (Table 1). The calculated C7=C8 distance (1.490 Å) in the excited state is longer than that in the $^1A'$ ground state (1.406 Å), suggesting a π^*-orbital character between the two carbon atoms in the excited state. By the combination of the CIS method and the IPCM in the SCRF method, the $[(AuPH_3)_2(i\text{-mnt})]$ complex has a 702-nm emission in the CH_2Cl_2 solution. The solvent effect results in a red shift of ca. 110 nm relative to the emission in the solid state (593 nm). Using the same methods, the lowest-energy emission of the organic i-mnt ligand was calculated at 611 nm, originating from a $^3A' \rightarrow {}^1A'$ transition in the solid state, and at 714 nm in CH_2Cl_2 solution (Table 3), which supports our assignment for such emissions of $[(AuPH_3)_2(i\text{-mnt})]$.

With respect to the $b^3A' \rightarrow {}^1A'$ transition, the corresponding emission is calculated at 414 nm for the single $[(AuPH_3)_2(i\text{-mnt})]$ molecule. To characterize the emission process, we used the difference in the natural atomic orbital populations for the b^3A' excited state and the correspond-

ing $^1A'$ ground state for $[(AuPH_3)_2$(i-mnt)] (Table 5). The electron transition is dominated by the metal centers and the i-mnt ligand (Table 5), while the charge transfer localized on the PH_3 ligand changes little. There are ca. 0.59 electrons to transfer from two Au atoms to the i-mnt ligand in the emissive process, in which 6s and 6p orbitals of Au

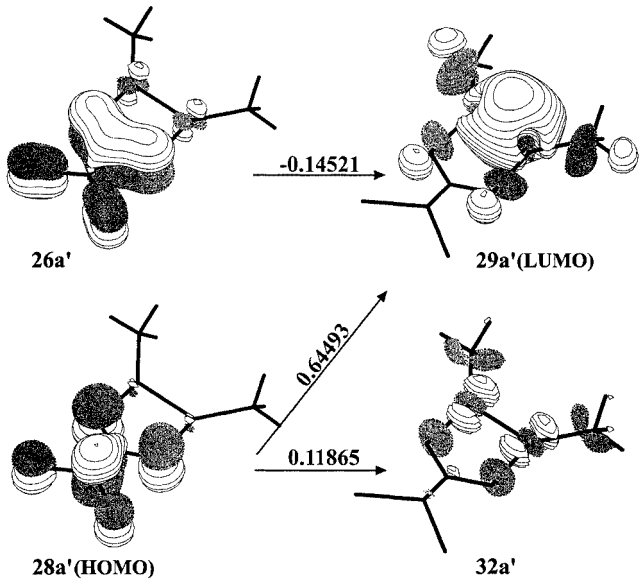

Figure 3. Single-electron transitions with (CI coefficient) > 0.1 in the CIS calculations for the 414-nm phosphorescence of $[(AuPH_3)_2$(i-mnt)]

atom lose ca. 0.24 and 0.06 electrons, respectively, and the $3p_x$ orbital of the S atom and the $2p_x$ orbital of the C8 atom increase by ca. 0.18 and 0.32 electrons, respectively. Therefore, we attributed the 414-nm emission to an Au→i-mnt charge transfer (^{3}MLCT) from the triplet b^3A' excited state to the $^1A'$ ground state. Density diagrams of the frontier molecular orbitals (Figure 3) help us intuitively understand the transition process. In the 26a′ and 28a′ orbitals, the electron density mainly focuses around the i-mnt ligand while the electron density transfers to Au centers to form a σ-bonding orbital in 29a′. Electron promotion from the i-mnt ligand orbitals to s_σ and p_σ orbitals of the Au atoms results in an Au−Au σ bond in the b^3A' excited state. The density diagrams seem to show significant Au−Au aurophilicity in the excited state, and that the Au−Au aurophilicity is relatively stronger in the b^3A' excited state than in the $^1A'$ ground state. Therefore, the 414-nm emission corresponding to the b^3A' excited state should have Au−Au→i-mnt charge transfer (^{3}MMLCT) character.

To reveal the effect of Au−Au aurophilicity on the luminescence in the b^3A' excited state of a $[(AuPH_3)_2$(i-mnt)] molecule, the mononuclear PH_3AuSH molecule was calculated using the same methods and basis sets as those of the dinuclear $[(AuPH_3)_2$(i-mnt)] complex. The 332-nm emission of PH_3AuSH arising from an Au(s,p)→S transition corresponds to the 414-nm phosphorescent emission of $[(AuPH_3)_2$(i-mnt)] from Au−Au[$(sp)_\sigma$]→i-mnt charge transfer. Apparently, there is no Au−Au aurophilicity in the mononuclear PH_3AuSH molecule, but the emissions of 332 nm for PH_3AuSH and 414 nm for $[(AuPH_3)_2$(i-mnt)] are both MLCT in nature. It is the Au−Au aurophilicity in $[(AuPH_3)_2$(i-mnt)] that results in a ca. 80 nm red shift relative to the emission of PH_3AuSH. Bruce and co-workers[22] have studied the relationship between the Au−Au aurophilicity and the spectrum of the excited state for *cis*- and *trans*-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[Au_2X_2C_2H_2(PH_2)_2]$ (X = Cl, Br and I) using ab initio methods. The calculations indicated that the aurophilic interaction stabilizes the first singlet excited state in the *cis* complex and leads to a red shift in the spectrum of the *cis* isomers relative to the *trans* isomers.

The intense 462-nm emission of the $[(AuPPh_3)_2$(i-mnt)] complex observed in the solid state at 20 K, and experimentally attributed to an Au→i-mnt charge transfer (^{3}MLCT),[33] agrees with our assignment for the 414-nm emission of $[(AuPH_3)_2$(i-mnt)]. The 50 nm difference between calculated and experimental emission wavelength may be because the single $[(AuPH_3)_2$(i-mnt)] molecule is not accurate enough to describe the solid-state emission of the $[(AuPPh_3)_2$(i-mnt)] complex at 20 K.

Recent studies on dinuclear $[AuS_2PR(OR)]_2$ (R = alkyl or aryl) complexes with MLCT excited-state properties have shown, by determining emissions of the Au^I complexes at different temperature (298 and 77 K), that the intermolecular Au−Au interaction in the solid state causes a red shift in emissive wavelengths.[14,15] The Au^I complexes were divided into two types: one, containing intermolecular Au−Au interactions in the solid state, has one emission at 298 K and two emissions at 77 K; and the other, without the intermolecular interaction in the solid, has no emissive band at 298 K but one band at 77 K. Apparently, the $[(AuPPh_3)_2$(i-mnt)] complex belongs to the second type because X-ray crystal-diffraction studies showed that it has no intermolecular Au−Au interaction in the solid state (shortest Au−Au of ca. 8.1 Å) and it possesses one emission of 462 nm in the solid state at 20 K.[33,41] Since the Au−Au separation is strongly related to the temperature,[14,15] there may be intermolecular Au−Au interactions between two adjacent $[(AuPPh_3)_2$(i-mnt)] molecules at 20 K. Therefore, the red shift of 50 nm for the solid-state emission at 20 K relative to the calculation can be rationalized by shortening the intermolecular Au−Au separations in the crystal lattice, which results in a lower-energy ^{3}MMLCT emission.

Since an intermolecular Au−Au interaction would affect the solid-state emission, we chose $[(AuPH_3)_2$(i-mnt)$]_2$ to simulate the solid-state luminescent properties of the Au^I complex at 20 K. The intermolecular Au−Au separation changes from 10.0 to 3.5 Å on keeping four Au atoms collinear and considering the least steric hindrance; the calculated emission wavelength varies from 412 to 450 nm. This shows that the intermolecular Au−Au interaction between two adjacent $[(AuPH_3)_2$(i-mnt)] molecules causes a ca. 40-nm red shift in the emission spectrum, which agrees with Fackler's studies mentioned above.[14,15] As the repeating unit of $[(AuPH_3)_2$(i-mnt)] increases it tends to the case of $[(AuPH_3)_2$(i-mnt)] in the solid state. Accordingly, the number of the intermolecular Au−Au interaction in the solid state at 20 K increases and the emission is anticipated to show a larger red shift. In fact, for MMLCT or MLCT transitions the Au−Au interactions have a systematic influence on the energies of the frontier orbitals responsible for the emission. The increasing number of intermolecular interactions in the solid state causes a net decrease of HOMO−LUMO energy gap. Therefore, the calculated 450-nm emission of $[(AuPH_3)_2$(i-mnt)$]_2$ agrees with the experimental 462-nm emission of the $[(AuPPh_3)_2$(i-mnt)] complex in the solid state at 20 K, and both have ^{3}MMLCT character.

The spectroscopic properties of $[(AuPH_3)_2$(i-mnt)] in the CH_2Cl_2 solution corresponding to the b^3A' excited state were also obtained by the CIS/IPCM methods. The calculated 333-nm emission arises from an ^{3}MLCT transition from the triplet excited state to the ground state, which blue-shifts ca. 120 nm relative to the 450-nm emission in the solid state. No emission has been found experimentally in the visible region for the $[(AuPPh_3)_2$(i-mnt)] complex in CH_2Cl_2 solution.[33,34]

Comparison of the calculated solid-state emissions with experiment shows that the single molecule $[(AuPH_3)_2$(i-mnt)] model is satisfactory for the ^{3}ILCT excited state (a^3A'). Because the intermolecular Au−Au interaction between two adjacent $[(AuPH_3)_2$(i-mnt)] molecules has almost no effect on the ^{3}ILCT excited state, the 593-nm phosphorescence corresponding to the excited state (Table 3) agrees well with the 595-nm emission of K_2(i-mnt) in the solid state at 20 K. However, the two-molecule $[(AuPH_3)_2$(i-mnt)$]_2$ model is required to rationalize the ^{3}MMLCT excited state as this excited state is strongly related to intermolecular Au−Au interactions. In the excited state, both intra- and intermolecular Au−Au interactions dramatically affect the solid-state emission, which ranges from 332 nm for mononuclear PH_3AuSH to 414 nm for dinuclear $[(AuPH_3)_2$(i-mnt)] to 450 nm for polynuclear $[(AuPH_3)_2$(i-mnt)$]_2$. Thus, the 450 nm phosphorescence of $[(AuPH_3)_2$(i-mnt)$]_2$ corresponds to the 462-nm emission of the $[(AuPPh_3)_2$(i-mnt)] complex in the solid state at 20 K, and both

are ^{3}MMLCT in nature (triplet excited state to the ground state).

D. Comparison of the Luminescent Properties of $[Au_2(dpm)_2]^{2+}$, $[(AuPH_3)_2(i\text{-}mnt)]$ and $[Au_2(dpm)(i\text{-}mnt)]$

To reveal the luminescence regularity of the dinuclear Au^I complexes with the interchange of phosphane ligand and thiolate ligand, the calculated excited-state properties of $[Au_2(dpm)_2]^{2+}$,[28] $[(AuPH_3)_2(i\text{-}mnt)]$ and $[Au_2(dpm)(i\text{-}mnt)]$[58] are presented in Table 6. The phosphane ligand has little participation in the luminescence while the thiolate ligand is greatly involved in the transition. The excited-state properties of $[Au_2(dpm)_2]^{2+}$, $[(AuPH_3)_2(i\text{-}mnt)]$ and $[Au_2(dpm)(i\text{-}mnt)]$ change from MCCT to MMLCT to ILCT (MLCT), and the corresponding Au−Au distances vary from 2.74 to 2.95 to 3.39 Å. For $[Au_2(dpm)_2]^{2+}$ and $[(AuPH_3)_2(i\text{-}mnt)]$, the promotion of an electron from the antibonding orbitals to the s_σ and/or p_σ bonding orbitals of Au atoms results in an Au−Au σ-bond between the two Au atoms in the excited state; however, the charge transfer only occurs inside the i-mnt ligand and the metal simply modifies the i-mnt ILCT in the emission corresponding to the $^3A''$ excited state of the $[Au_2(dpm)(i\text{-}mnt)]$ complex. The stronger Au−Au aurophilicity causes the greater Au contribution to the transition, favoring an MCCT emissive excited state such as $[Au_2(dpm)_2]^{2+}$. Conversely, the excited state with the weaker Au−Au aurophilicity has less metal contribution and tends to be ILCT in character, such as $[Au_2(dpm)(i\text{-}mnt)]$.

In brief, ab initio investigations on $[Au_2(dpm)_2]^{2+}$, $[(AuPH_3)_2(i\text{-}mnt)]$ and $[Au_2(dpm)(i\text{-}mnt)]$ indicate that the Au−Au aurophilicity has no clear correlation with the emission wavelength but with the excited-state property. With the interchange of phosphane and thiolate ligands, the excited-state properties of such Au^I complexes regularly change from MCCT to MMLCT to ILCT.

Conclusions

The luminescence and Au−Au aurophilicity of $[(AuPH_3)_2(i\text{-}mnt)]$ in both the solid state and CH_2Cl_2 solution have been studied by ab initio methods. For the solid state, $[(AuPH_3)_2(i\text{-}mnt)]$ and $[(AuPH_3)_2(i\text{-}mnt)]_2$ models were employed to describe the spectroscopic properties. The former has been used to accurately calculate the ^{3}ILCT emissive excited state, because the intermolecular Au−Au interaction between the two adjacent $[(AuPH_3)_2(i\text{-}mnt)]$ molecules plays a minor role in the excited state. However, the ^{3}MMLCT emissive excited state is strongly related to the intermolecular Au−Au interaction between the two neighboring $[(AuPH_3)_2(i\text{-}mnt)]$ molecules in the solid state, especially at lower temperatures (20 K). The two-molecular model, $[(AuPH_3)_2(i\text{-}mnt)]_2$, can satisfactorily rationalize the solid-state emission of the $[(AuPPh_3)_2(i\text{-}mnt)]$ complex at 20 K. For dilute CH_2Cl_2 solutions, we used the single $[(AuPH_3)_2(i\text{-}mnt)]$ molecule associated with the IPCM in the SCRF method to calculate the absorption and emission. Most calculated spectra in solution agree with the experimental results.[33]

Studies on $[Au_2(dpm)_2]^{2+}$,[28] $[(AuPH_3)_2(i\text{-}mnt)]$ and $[Au_2(dpm)(i\text{-}mnt)]$ [58] show that the Au−Au aurophilicity is clearly correlated with the excited-state properties. With the interchange of phosphane and thiolate ligands, the excited-state properties of such Au^I complexes regularly change from MCCT to MMLCT to ILCT.

Syntheses, Characterizations, and Crystal Structures of Three New Metal Phosphonocarboxylates with a Layered and a Microporous Structure

Bing-Ping Yang,[a] Jiang-Gao Mao,*[a] Yan-Qiong Sun,[a] Han-Hua Zhao,[b] and Abraham Clearfield[b]

Keywords: Metal phosphonates / Hydrothermal reactions / Lead / Layered compounds / Cluster compounds

Hydrothermal reactions of *N*-(phosphonomethyl)proline (H_3L) with M^{II} (M = Cd, Pb, and Zn) chlorides resulted in three new metal amino-phosphono-carboxylates, namely, $[Cd_2LCl(H_2O)]$ (**1**) and $[Pb_2Cl_2(HL)]$ (**2**) with a layered structure, and $[Zn_7L_6][Zn(H_2O)_6]_2{\cdot}16H_2O$ (**3**) featuring a microporous structure built from centered octahedral $Zn_6(Zn)$ cluster anions. The cadmium(II) ions in complex **1** are octahedrally coordinated [Cd(1)O_5Cl, Cd(2)O_4NCl]. These cadmium octahedra form a 1D zigzag chain along the *b*-axis through edge sharing, and such chains are further interconnected via phosphonate tetrahedra to form a <002> layer. The organic rings of the ligands are orientated to the interlayer space. Complex **2** also has a layered structure, in which Pb(1) is six-coordinated by four phosphonate oxygen atoms and two carboxylate oxygen atoms from four ligands in a distorted octahedral geometry, three Pb–O distances are relatively longer than those of the remaining ones, whereas Pb(2) is six coordinated by three phosphonate oxygen atoms and one carboxylate oxygen from four ligands as well as two chloride anions in a distorted octahedral geometry, one Pb–O bond is much longer than the remaining ones. These two different types of Pb^{II} ions are further interconnected through bridging carboxylate and phosphonate groups to form a <200> layer. Complex **3** contains a novel heptanuclear zinc phosphonate cluster anion $[Zn_7L_6]^{4-}$ and two hexahydrated zinc(II) cations as well as 16 lattice water molecules. The seven Zn^{II} cations in an anion form an unusual centered $Zn_6(Zn)$ octahedron, packing of such cluster anions creates micropores that are occupied by the hexahydrated zinc(II) cations and lattice water molecules.

Introduction

The chemistry of metal phosphonates has been an active research area in recent years due to its potential applications in the areas of catalysis, ion exchange, proton conductivity, intercalation chemistry, photochemistry and materials chemistry.[1] Metal phosphonates also exhibit a variety of open frameworks such as layered and microporous structures.[1] Materials with open-framework and microporous structures are expected to find their use as hybrid composite materials in electro-optical and sensing applications in the future.[2] Attaching additional functional groups such as crown ethers and carboxylate groups to the phosphonic acid has been proved to be very useful methods in building open-framework and microporous structures. A number of porous metal phosphonates with crown ether moieties have been reported recently.[3,4] A series of metal carboxylate-phosphonates with a framework structure, using $H_2O_3PCH_2CO_2H$ and $H_2O_3PCH_2CH_2CO_2H$ as ligands, have also been isolated mainly by the Cheetham, Bujoli, and Sevov groups.[2,5,6] Results of our research and others indicate that amino-carboxylic-phosphonic acids are also capable of forming open frameworks. The structures of amino-carboxylate-phosphonates depend on the extent of deprotonation of the ligands as well as on the nature of the metal ions.[7–10] For example, *N*-(phosphonomethyl)iminodiacetic acid (H_4PMIDA) has been found to be able to adopt various kinds of coordination modes under different reaction conditions.[7–10] A layered zirconium compound of 4-[bis(phosphonomethyl)amino]butanoic acid was reported by the Vivani group,[11a] and two zinc(II) complexes with *N*,*N*-bis(phosphonomethyl)aminoacetic acid and *N*-(phosphonomethyl)-*N*-methylglycine have been also obtained in our laboratory.[11b,11c] The structure of the latter zinc(II) amino-carboxylate-phosphonate features a microporous structure built from heptanuclear $Zn_6(Zn)(ligand)_6$ cluster anions.[11c] A layered Co^{II} compound of *N*-(phosphonomethyl)proline (H_3L) with a 3:2 metal/ligand ratio, $Co_3L_2{\cdot}5H_2O$ and a layered Pb^{II} complex with $H_2O_3PCH_2NHCH_2CO_2H$ have been reported very recently.[11d,11e] Hydrothermal reactions of *N*-(phosphonomethyl)proline with other divalent metal salts resulted in two types of layered materials containing chloride anions, $[Cd_2LCl(H_2O)]$ (**1**) and $[Pb_2Cl_2(HL)]$ (**2**), and a microporous compound, $[Zn_7L_6][Zn(H_2O)_6]_2{\cdot}16H_2O$ (**3**). Herein we

report their syntheses, characterizations and crystal structures.

Results and Discussion

Crystal Structure of $[Cd_2LCl(H_2O)]$ (1)

Complex **1** features a 2D layer built from a zigzag chain of edge-sharing cadmium(II) octahedra. As shown in Figure 1, Cd2 is octahedrally coordinated by a tridentate chelating ligand (O11, N1, O2), one carboxylate (O1b), and one phosphonate oxygen (O12d) atom from two neighboring [Cd(L)] units and a chloride anion (Cl1), whereas Cd1 is octahedrally coordinated by two carboxylate (O1c, O2b) and two phosphonate oxygen (O11, O13a) atoms from four neighboring [Cd(L)] units, an aqua ligand and a chloride anion. These octahedra are severely distorted, probably due to the edge-sharing of the octahedra and the larger size of the chloride anion. The average Cd−N distance is 2.37(1) Å; Cd−O distances range from 2.18(1) to 2.48(1) Å, and the Cd−Cl bonds are in the range from 2.527(3) to 2.665(3) Å. These bond lengths are similar to those reported for other Cd^{II} phosphonates.[3c,12] The phosphonate-carboxylate ligand adopts a coordination mode different from those in the Co^{II} complex.[11d] Both carboxylate oxygen atoms are bidentately bridging, whereas one phosphonate oxygen (O11) is bidentate and the other two are unidentate.

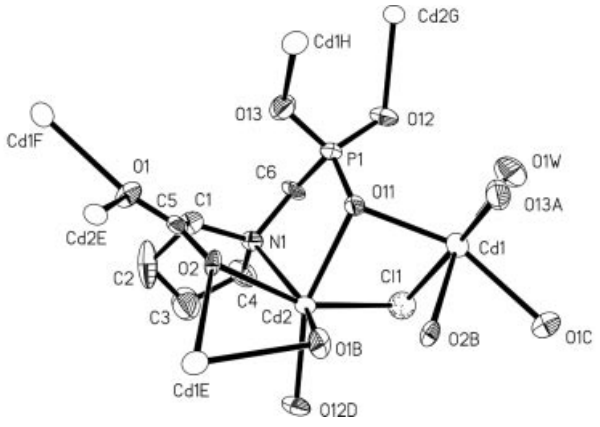

Figure 1. ORTEP representation of the asymmetric unit of complex **1**; thermal ellipsoids are drawn at 50% probability; symmetry codes for generated atoms: a. $x + 1, y + 1/2, -z + 1$; b. $x + 2, y + 1/2, -z + 1$; c. $x, y + 1, z$; d. $x + 1, y, z$; e. $x + 2, -1/2 + y, -z + 1$; f. $x, y - 1, z$; g. $x - 1, y, z$; h. $1 - x, -1/2 + y, 1 - z$

These two types of Cd^{II} octahedra are condensed by edge-sharing (O11−Cl1 and O2−O1b) to form a 1D zigzag chain along the *b* axis. Two types of four-membered rings are found: one is formed by Cd1−O11−Cd2−Cl1 and the other one is composed of Cd2, O2, Cd1e, and O1b atoms. Such 1D chains are further interconnected by bridging phosphonate tetrahedra to form a <002> 2D layer (Figure 2). There are small cavities formed within the 2D layer, each cavity is formed by three edge-sharing Cd^{II} octahedra from one chain and another Cd^{II} octahedron from a neighboring

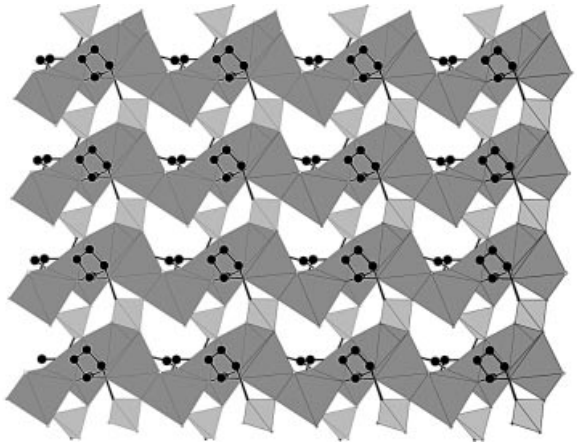

Figure 2. A <002> layer of complex **1**; the Cd^{II} octahedra and $C-PO_3$ tetrahedra are shaded in medium and light gray, respectively, and C atoms are drawn as black circles

chain interconnected by two phosphonate tetrahedra. In the Co^{II} complex, the Co octahedra form a dimer by edge-sharing, and these dimers are interconnected into a 1D chain by corner-sharing. The 1D chains are interconnected through isolated dimers by bridging $C-PO_3$ tetrahedra, hence the cavities of the layered Co^{II} compound are much larger than those in the Cd^{II} complex.[11d] Similar to those in the Co^{II} complex, the double layers of complex **1** are held together by weak Van der Waals forces (Figure 3). The interlayer distance is about 10.3 Å, which is much smaller than that of the Co^{II} compound (11.9 Å) reported previously.[11d]

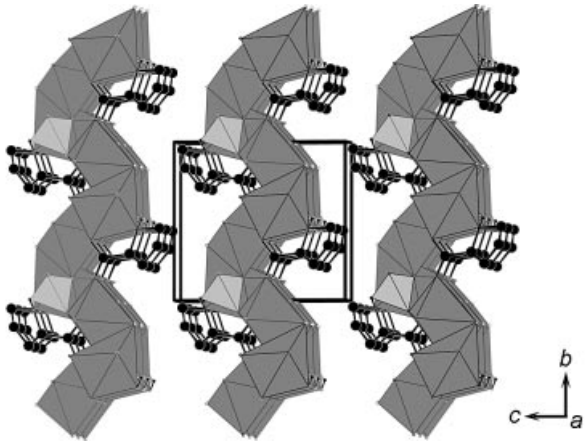

Figure 3. View of structure of complex **1** down the *a* axis; the Cd^{II} octahedra and $C-PO_3$ tetrahedra are shaded in medium and light gray, respectively; the C atoms are drawn as black circles

Crystal Structure of $[Pb_2Cl_2(HL)]$ (2)

Complex **2** has a layered structure quite different from that of complex **1**. The asymmetric unit of complex **2** contains one $[Pb_2Cl_2(HL)]$ unit (Figure 4). In addition to three regular Pb−O bonds (O1b, O11, O12a) with Pb−O distances ranging from 2.400(14) to 2.572(18) Å, the Pb(1) atom also forms three much weaker Pb−O bonds with the O2c, O13a, and O13c atoms. These weak bonds range from

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2.824(14) to 2.851(19) Å (Table 1). Long Pb−O weak bonds have also been reported in other lead(II) phosphonates and lead(II) carboxylates — they are needed to satisfy the bond valences of the Pb^{II} ion.[9b,11e,13] Considering all these bonds, the coordination geometry around Pb(1) can be described as a severely distorted octahedron. Pb(2) is six-coordinated by three phosphonate and one carboxyl oxygen atoms, as well as two chloride anions, and also has a distorted octahedral geometry. The Pb2−O13b distance of 2.811(15) Å is much longer than those of the remaining Pb−O bonds, which range from 2.421(13) to 2.749(14) Å. The Pb−Cl distances are in the range of 2.684(7) to 2.767(5) Å (Table 1). The distortion of the lead polyhedron is due to the presence of the lone pair electrons of the lead(II) ion.

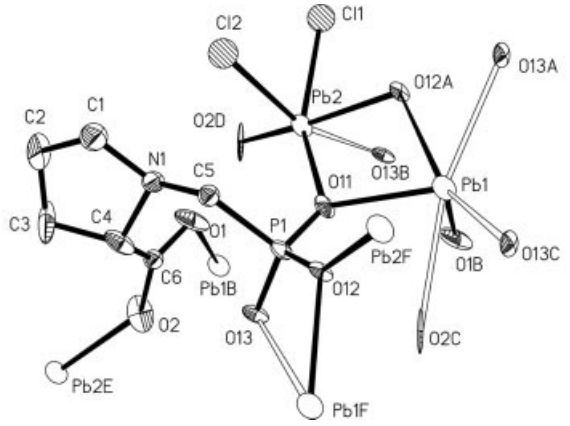

Figure 4. ORTEP representation of the asymmetric unit of complex **2**; thermal ellipsoids are drawn at 50% probability; the longer Pb−O contacts are represented by the open line; symmetry codes for generated atoms: a. $x, -y + 1/2, z - 1/2$; b. $x + 1, -y + 1, -z$; c. $x + 1, y - 1/2, -z + 1/2$; d. $x, -y + 3/2, z - 1/2$; e. $x, 3/2 - y, 1/2 + z$; f. $x, 1/2 - y, 1/2 + z$

The phosphonate-carboxylate ligand adopts a coordination mode that is different from those in its Co^{II} and Cd^{II} complexes. The amine group is protonated, hence it remains non-coordinated. Two phosphonate oxygen atoms (O11 and O12) are bidentate, whereas the third one (O13) forms a weak Pb−O bond. Each carboxylate oxygen atom is bridged to one Pb^{II} ion, however O(2) also forms a weak Pb−O bond with the Pb(1) center.

The interconnection of the above two types of Pb^{II} ions via bridging carboxylate and phosphonate groups results in a <200> layer (Figure 5), and such layers are packed together by weak Van der Waals forces (Figure 6). The d-spacing is about 12.0 Å, very close to that of complex **1**.

Crystal Structure of $[Zn_7L_6][Zn(H_2O)_6]_2 \cdot 16H_2O$ (3)

The structure of complex **3** is similar to that of the Zn^{II} complex with $CH_3N(CH_2CO_2H)CH_2PO_3H_2$ that we reported recently,[11] although the symmetry of the structure is lower due to the presence of the pyrrolidine ring in the ligand. The compound contains a novel heptanuclear zinc(II) phosphonate anion, two hexahydrated zinc(II) cations and 16 lattice water molecules. As shown in Figure 7, Zn1 is five-coordinated by a chelate ligand (N2, O3, O23), and two phosphonate oxygen atoms (O11a and O22a) from neighboring [ZnL] units in a distorted trigonal bipyramidal geometry. The Zn1−N2 and Zn1−O3 distances are 2.138(9) and 2.061(8) Å, respectively. The Zn1−O (phosphonate) distances are in the range of 1.966(8) to 2.125(7) Å. Zn3 is also five-coordinated by a chelate ligand (N1, O2, O13), and two phosphonate oxygen atoms (O21 and O12a) from two neighboring [ZnL] units in a distorted trigonal bipyramidal geometry. The Zn3−N1 and Zn3−O2 bond

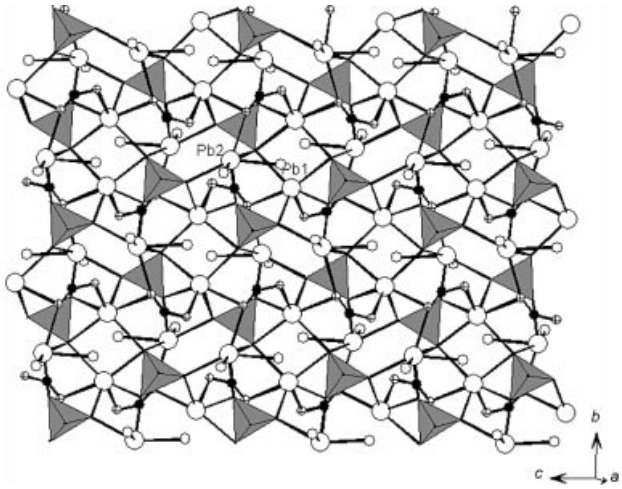

Figure 5. A <200> layer of lead(II) phosphonocarboxylate in complex **2**; the C−PO_3 tetrahedra are shaded in gray, Pb, Cl, C, and O atoms are drawn as open (large), open (small), black, and crossed circles, respectively; the pyrrolidine ring of the ligand has been omitted for clarity

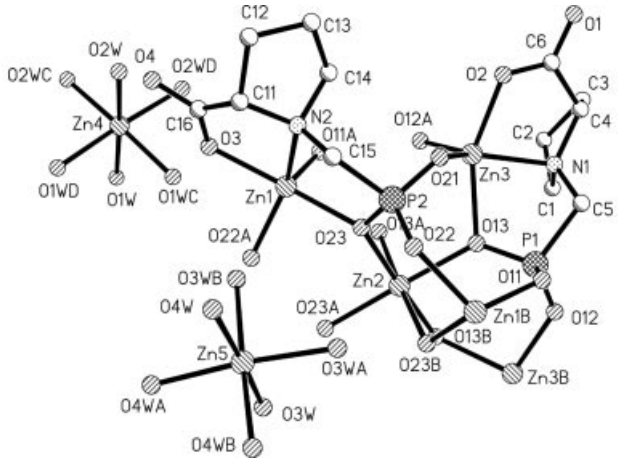

Figure 7. The asymmetric unit of complex **3** with atomic labeling; the lattice water molecules have been omitted for clarity; symmetry codes for generated atoms: a. $y - 1, z, x + 1$; b. $z - 1, x + 1, y$; c. $y - 1/2, -z + 3/2, -x+1$; d. $z + 1, x + 1/2, -y + 3/2$

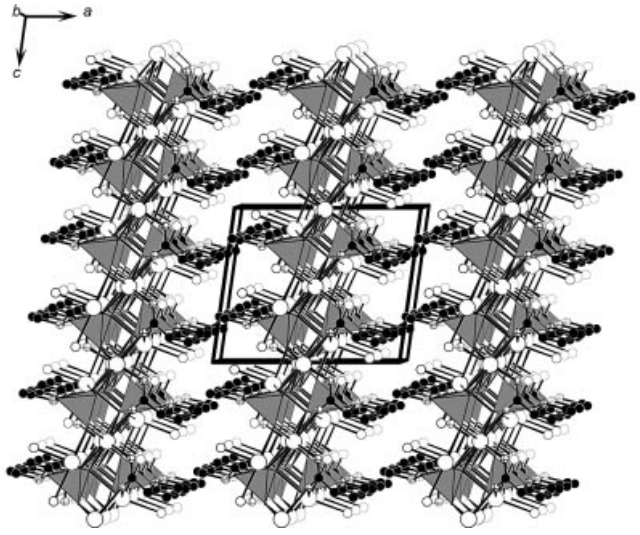

Figure 6. View of the structure of complex **2** down the *b* axis; the C−PO_3 tetrahedra are shaded in gray, Pb, Cl, N, C, and O atoms are drawn as open (large), open (small), octand, black, and crossed circles, respectively

lengths are 2.165(9) and 2.033(8) Å, respectively. The Zn3−O (phosphonate) distances range from 1.955(7) to 2.135(7) Å (Table 1); these distances are similar to those reported for other zinc(II) amino-carboxylate-phosphonates.[9,11]

The Zn2 atom lies on a position with threefold symmetry; it is octahedrally coordinated by six phosphonate oxygen atoms from three [Zn(1)(L)] and three [Zn(3)(L)] units. The Zn−O distances of 2.115(7) Å and 2.122(7) Å are close to those for the Zn1 and Zn3 atoms. The *N*-(phosphonomethyl)proline acts as a hexadentate ligand. It chelates to a Zn1 or a Zn3 atom and bridges three neighboring Zn^{II} ions. The O23 of P(2)O_3C group bridges one Zn1 and one Zn2 atom, and O13 of the P(1)O_3C group connects one Zn3 and one Zn2 atom. Such a coordination mode has been found in Co^{II} and Zn^{II} complexes with *N*-(phosphonomethyl)iminodiacetic acid.[9] Two carboxylate oxygen atoms (O1 and O4) remain non-coordinated. Since all C−O and P−O bonds have very short distances, we would expect both phosphonate and carboxylate groups of the ligand to be completely deprotonated. Each ligand carries three negative charges, thus the heptanuclear anion has a 4− charge.

The seven Zn^{II} cations in the anion form an unusual centered octahedron similar to the Zn^{II} complex with $CH_3N(CH_2CO_2H)CH_2PO_3H_2$. The octahedron is created by six five-coordinate zinc(II) cations (Zn1 and Zn3) with the six-coordinate Zn2 atom as the central atom. The edge Zn···Zn contacts are in the range of 4.515(2) to 5.758(2) Å, and the distances from the central Zn to the octahedral apexes range from 3.610(2) to 3.665(2) Å. It is interesting to compare our heptanuclear zinc(II) phosphonate anions with the hexanuclear zinc(II) cages containing phosphonate and pyrazole reported by the Chandrasekhar group, in which the six zinc atoms are arranged in a chair-like conformation.[14]

The four negative charges of the cluster are balanced by two hexa-hydrated zinc(II) cations. These zinc(II) ions (Zn4 and Zn5) are located at positions with a threefold symmetry. The Zn4−O distances are 2.089(13) and 2.110(12) Å, respectively, and the Zn5−O distances are 2.093(10) and 2.099(11) Å, respectively. Its coordination geometry is a slightly distorted octahedron.

In a similar fashion to the Zn^{II} complex with $CH_3N(CH_2CO_2H)CH_2PO_3H_2$,[11] packing of the cluster anions create large cavities occupied by the hexahydrated zinc(II) cations as well as lattice water molecules (Figure 8). The diameter of the pore is estimated to be around 8.0 Å. The polynuclear cluster anions are located at the centers of the cell edges and the cell body center. A number of hydrogen bonds are formed among the non-coordinated carboxylate oxygen atoms, and coordinated and lattice water molecules (Table 1).

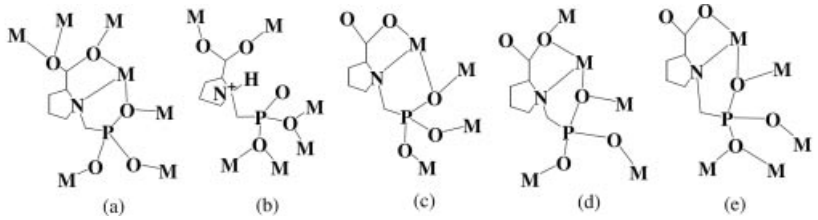
Thermogravimetric Analysis

1The TGA diagram for complex **1** shows two main steps of weight loss. The first step, which corresponds to the loss of one aqua ligand and the chloride anion, starts at about 150 °C and ends at about 350 °C. The weight loss of 9.9% is slightly less than the calculated weight loss of 11.2%. The second step corresponds to the decomposition of the organic groups that starts at about 441 °C and is complete at 926 °C. The final products are $Cd_3(PO_4)_2$ and CdO in a 1:1 molar ratio. The total weight loss of 31.4% is close to the calculated weight loss of 32.3%. The TGA curves of the Pb^{II} complex show only one main weight loss. The compound is stable up to 240 °C. It then starts to decompose from 240 °C and continues up to 800 °C; this process corresponds to the loss of the chloride anions and the burning of the organic groups of the carboxylate-phosphonate ligand. The total weight loss is 32.4%, which is slightly less than the calculated one (35.5%) if the final products are assumed to be PbO. However, the total weight loss is much larger than the calculated value (25.3%) if the final products are $Pb_2P_2O_7$ and PbO in a 1:2 molar ratio. Thus we think our final products are mainly PbO mixed with a small amount of $Pb_2P_2O_7$. The TGA diagram for complex **3** shows two main steps of weight loss. The first step, which corresponds to the loss of 16 lattice water molecules and 12 coordinated water molecules, starts at about 60 °C and is complete at about 250 °C. The weight loss of 28.9% is slightly less than the calculated value (29.6%). The second step corresponds to the decomposition of organic groups starting at about 360 °C and continues up to 800 °C. The total weight loss of 33.7% is less than the calculated weight loss of 50.3% if the final products are assumed to be $Zn_2P_2O_7$ and ZnO; hence, the decomposition process is not complete at 800 °C. The use of N_2 gas to provide an inert atmosphere may be another reason for the incomplete decomposition.

Conclusion

Hydrothermal reactions of *N*-(phosphonomethyl)proline (H_3L) with divalent metal ions afforded four different complexes, $[Cd_2LCl(H_2O)]$ (**1**), $[Pb_2Cl_2(HL)]$ (**2**), a microporous compound, $[Zn_7L_6][Zn(H_2O)_6]_2 \cdot 16H_2O$ (**3**), and the previously reported layered $Co_3L_2 \cdot 5H_2O$.[11d] *N*-(phosphonomethyl)proline (H_3L) exists as a zwitterion where one proton of a phosphonate group has been transferred to the amine group. The molecular units of *N*-(phosphonomethyl)-proline (H_3L) are further interconnected by O−H···O and N−H···O hydrogen bonds into a 2D layer.[15] Upon partial or complete replacement of protons by divalent metal ions, three types of layered structures and a microporous structure are formed. As shown in Scheme 1, the carboxylate-phosphonate ligand adopts five different coordination modes in these four complexes. In the Cd^{II} complex, the phosphonate-carboxylate ligand chelates a Cd^{II} ion and bridges six other metal ions, both carboxylate oxygen atoms are bidentate, and one of the phosphonate oxygen atoms is also bidentate. The other two phosphonate oxygen atoms are unidentate (Scheme 1, a). In the lead(II) complex, the amine group of the ligand is protonated, hence it is not coordinated to the Pb^{II} ion. Without consideration of those weak Pb−O contacts, its coordination mode can be described as a hexadentate bridging mode, where two phosphonate O atoms behave as μ^2 metal linkers and the third phosphonate O remains non-coordinated (Scheme 1, b). In the zinc(II) cluster compound, the ligand chelates in a tridentate manner with a Zn^{II} ion and bridges three other Zn^{II} ions; only one phosphonate O is a μ^2 metal linker (Scheme 1, c). In the layered cobalt(II) complex,



Scheme 1. Coordination modes of amino-carboxylate phosphonate ligand in complexes **1** (a), **2** (b), and **3** (c) as well as in its Co^{II} complex (d and e)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$Co_3L_2{\cdot}5H_2O$, two types of chelating and bridging modes are found, the ligand in one CoL unit chelates with a Co^{II} ion in a tridentate fashion (one N, one carboxyl O and one phosphonate O) and bridges other four metal ions; one carboxyl O and one phosphonate O act as bidentate metal linkers (Scheme 1, d). In another CoL unit, the ligand also chelates a Co^{II} ion and bridges four other metal ions. However, two phosphonate O atoms behave as μ^2 metal linkers (Scheme 1, e).[11d] Transition metal ions such as Co^{II}, Zn^{II}, and Cd^{II} ions have a greater affinity for the nitrogen atom than the Pb^{II} ion, thus the ligand can form a chelate ring with a Co^{II} (or Cd^{II} or Zn^{II}) ion through the amine nitrogen, a phosphonate, and a carboxylate oxygen atom, whereas in the lead(II) complex the amine group remains protonated. The lead(II) complexes also have a coordination geometry different from the transition metal complexes due to the presence of the lone pair of electrons.

We are especially interested in the cluster unit and microporous structure in the zinc(II) complex. This complex has a structure similar to that of zinc(II) complexes with *N*-(phosphonomethyl)-*N*-methylglycine previously reported by us.[11c] Thus, we would expect that each Zn_6(Zn) cluster unit and the microporous structure built from the packing of the cluster units should be relatively stable. Currently, we are investigating the possibility of isolating a similar cluster unit with other magnetic transition metal ions, such as Mn^{II}, Cu^{II}, Ni^{II}, etc.; such materials may be used as single molecular magnets. Due to the number of lattice water molecules and hexahydrated zinc(II) cations located in the micropore of the structure, it would be interesting to replace the hydrated zinc(II) cations with alkaline earth cations or diamines such as ethylenediamine, methylenediamine etc. Such research efforts are in progress and the results will be published later.

Experimental Section

Materials and Methods: All of the starting materials were of reagent grade and were used without further purification. *N*-(Phosphonomethyl)proline (H_3L) was synthesized by a Mannich-type reaction according to the procedures previously described.[11d,15] Elemental analyses were performed on a German Elementary Vario EL III instrument. The FT-IR spectra were recorded on a Nicolet Magna 750 FT-IR spectrometer on KBr pellets in the range of 4000−400 cm^{-1}. Thermogravimetric analyses were carried out with a TGA/SBTA851 unit, at a heating rate of 15 °C/ min under a nitrogen atmosphere.

Synthesis of $[Cd_2LCl(H_2O)]$ (1): $CdCl_2{\cdot}2{\cdot}5H_2O$ (0.4 mmol, 0.091 g), H_3L (0.2 mmol, 0.042 g) and 25% ethanol aqueous solution (13 cm^3) were mixed and the pH was adjusted to between 4 and 5 by addition of Bu_4NOH. The resultant solution was heated at 170 °C in a Teflon-lined stainless steel autoclave for four days. Colorless plate-shaped crystals of **1** were collected in about 86% yield (83 mg). $C_6H_{11}Cd_2ClNO_6P$ (484.38): calcd. C 14.86, H 2.29, N 2.89; found C 15.58, H 1.89, N 2.94%. IR data (KBr, cm^{-1}): 3502−2899 (br), 1535 (s), 1417 (m), 1115 (s), 1051 (s), 964 (s), 559 (s).

Synthesis of $[Pb_2Cl_2(HL)]$ (2): A mixture of $PbCl_2$ (0.4 mmol, 0.111 g), H_3L (0.2 mmol, 0.042 g), and H_2O (10 cm^3) with the pH value adjusted to between 4 and 5 by addition of Bu_4NOH, was heated at 160 °C in a Teflon-lined stainless steel autoclave for two days. Colorless plate crystals were recovered in about 26% yield (36 mg). $C_6H_{10}Cl_2NO_5PPb_2$ (692.40): calcd. C 10.41, H 1.46, N 2.02; found C 10.29, H 1.10, N 1.85%. IR data (KBr, cm^{-1}): 3600−2825 (br), 1566 (s), 1400 (m), 1340 (m), 1292 (w), 1030 (s), 964 (s), 764 (m), 569(m), 478 (m) cm^{-1}.

Synthesis of $[Zn_7L_6][Zn(H_2O)_6]_2{\cdot}16H_2O$ (3): Complex **3** was synthesized by a method similar to that of complex **2**. Yield: 80% (155 mg) based on L. $C_{36}H_{110}N_6O_{58}P_6Zn_9$ (2329.45): calcd. C 18.56, H 4.76, N 3.61; found C 18.65, H 4.64, N 3.57%. IR (KBr, cm^{-1}): 3600−2864 (br), 1605 (s), 1400 (m), 1333 (w), 1234 (w), 1111 (s), 1078 (s), 989 (s), 931 (m), 580 (m).

X-ray Crystallographic Study: Data collections were performed on a Siemens Smart CCD diffractometer, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Intensity data were collected by using narrow frame method with 0.3° per frame in at 293 K. A total of 1389, 2179 and 4713 independent reflections, respectively, for **1**, **2**, and **3**, were collected among which 1361 (for **1**), 1520 (for **2**), and 3341 (for **3**) with $I > 2.0\sigma(I)$ were considered observed. For data of complexes **1** and **3**, absorption corrections

were performed by using the SADABS program.[12] Absorption corrections based on the Ψ scan technique were applied to the data set of complex **2**. From E-value statistics and systematic absence, the space group is either $P2_1$ or $P2_1/m$ for **1**, $P2_1/c$ for **2**, and $P213$ for **3**. When $P2_1/m$ was used for the refinements of complex **1**, the structure was severely distorted, even for the cadmium atom, thus we refined the structure in the non-centrosymmetric $P2_1$ and the results were satisfactory. All three structures were solved by direct methods and refined by full-matrix least-square fitting on F^2 by SHEXLS.[16] All of the non-hydrogen atoms, except C(1), C(5), and C(6) atoms in **2**, were refined anisotropically. All hydrogen atoms were located at geometrically calculated positions and refined with isotropic thermal parameters. The hydrogen atoms for the aqua ligands and lattice water molecules in all three complexes were not refined. A summary of the crystallographic data for these three complexes is listed in Table 2. Selected bond lengths for complexes **1**, **2**, and **3** are given in Table 1.

CCDC-212383 (**1**), -212384 (**2**), and -212385 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Novel Hybrid Porous 3D Networks of Lead(II) Diphosphonate and Triphosphonate Containing 1,3,5-Benzenetricarboxylate

Jun-Ling Song,[a] Jiang-Gao Mao,*[a] Yan-Qiong Sun,[a] and Abraham Clearfield[b]

Keywords: Synthetic methods / Lead / Carboxylate ligands / P ligands

Hydrothermal reactions of lead(II) acetate with 1,3,5-benzenetricarboxylic acid (H_3BTC) and a new aminodiphosphonic acid, [3-pyridyl-$CH_2N(CH_2PO_3H_2)_2$] (H_4L^1), or a new aminotriphosphonic acid, [1-{$(H_2O_3PCH_2)_2NCH_2CH_2$-}-piperazine-4-$CH_2PO_3H_2$] (H_6L^2), afforded two novel porous carboxylate–phosphonate hybrids, $[Pb_4(BTC)(HBTC)(HL^1)]\cdot 3H_2O$ (**1**) and $[Pb_6(BTC)_2(HBTC)(H_2L^2)]\cdot 4.5H_2O$ (**2**). The structure of **1** is built from a 3D porous network of lead(II) tricarboxylate and 1D double chains of lead(II) aminodiphosphonate. The structure of **2** contains <002> lead(II) carboxylate–phosphonate hybrid layers, which are cross-linked by 1D double chains of lead(II) phosphonate through the organic groups of both types of ligands, resulting in the formation of a complex 3D porous network. The lattice water molecules in both compounds are located at the micropores of the structures.

Introduction

Open-framework and microporous materials are very important compounds due to their traditional applications in catalysis, separations, sorbents, and ion exchange, as well as their expected future use as hybrid composite materials in electro-optical and sensing applications.[1,2] Recently a number of metal carboxylates with open-framework network structure have been reported.[3] In the chemistry of metal phosphonates, the use of bifunctional or multifunctional anionic units, such as diphosphonates, aminophosphonates or phosphonocarboxylates has led to a number of new materials with microporous or open-framework structures.[4−7] Recently we have also reported a microporous Cd^{II} complex with *N*,*N*′-bis(phosphonomethyl)-1,10-diaza-18-crown ether.[8] Several porous Zr^{IV} complexes with aza-crown ether functionalised phosphonic acids have been synthesized by using phosphoric acid as the spacer group.[9] Direct use of two types of ligands in the preparation, such as a phosphonic acid and a carboxylic acid, has been found to be a useful method to build hybrid open frameworks, though such reports are still rare.[2,10] A 3D open-framework tin(II) phosphonopropionate oxalate and a layered tin(II) methylphosphonate oxalate have been reported by the Cheetham group,[10] and a microporous zinc(II) complex of phosphonopropionic acid and 1,3,5-benzenetricarboxylic acid (H_3BTC) was isolated; however, the tricarboxylate moiety remains noncoordinated and is also severely disordered.[2] We have synthesized a new amino diphosphonic acid, [3-pyridyl-$CH_2N(CH_2PO_3H_2)_2$] (H_4L^1) and a new amino triphosphonic acid, 1-[{$(H_2O_3PCH2)_2NCH_2CH_2$-}-piperazine-4-$CH_2PO_3H_2$] (H_6L^2) (Scheme 1). These two ligands are different from the aminodiphosphonic and -triphosphonic acids, which we had used previously: H_4L^1 contains an additional nitrogen atom for coordination; H_6L^2 has three methylenephosphonate groups attached to two different amine groups which are far apart, whereas the aminotriphosphonate ligand such as nitrilotris(methylenephosphonic acid) has three phosphonate groups attached to the same amine group.[11,12] Thus these new types of ligands are expected to be more likely to form novel hybrid materials with porous 3D network architectures. Hydrothermal reactions of the above two ligands with lead(II) acetate and 1,3,5-benzenetricarboxylic acid afforded two novel porous

lead(II) carboxylate-phosphonates in which both types of ligands act as multidentate metal linkers, $[Pb_4(BTC)(HBTC)(HL^1)]\cdot 3H_2O$ (**1**) and $[Pb_6(BTC)_2(HBTC)(H_2L^2)]\cdot 4.5H_2O$ (**2**). Herein we report their syntheses, characterizations and crystal structures.

Results and Discussion

The crystal structure of **1** features a 3D porous network of lead(II) tricarboxylate and a 1D double chain of lead diphosphonate, which are interconnected by sharing some Pb^{II} ions. There are four Pb^{II} atoms, one fully deprotonated tricarboxylate anion (BTC, O7 to O12), one 1H-protonated tricarboxylate (HBTC, O1 to O6), one 1H-protonated diphosphonate (HL^1) anion, and three lattice water molecules in an asymmetric unit of **1**. The coordination geometries around the lead(II) ions are shown in Figure 1. Pb1 is four-coordinated by three phosphonate oxygen atoms from three HL^1 ligands and one carboxylate oxygen atom from a BTC anion, whereas Pb3 is four-coordinated by two phosphonate and two carboxylate oxygen atoms from two HL^1 and two HBTC ligands, respectively. Their coordination geometry can be described as a ψ-square pyramidal PbO_4 in which the lone pair occupies the fifth coordination site. Pb2 is solely coordinated by diphosphonate ligands; it is four-coordinated by a tridentate chelating HL^1 ligand (ligating through two O and one N atoms) and a phosphonate oxygen atom from another HL^1 anion with a ψ-square pyramidal PbO_3N, similar to those of Pb1 and Pb3.

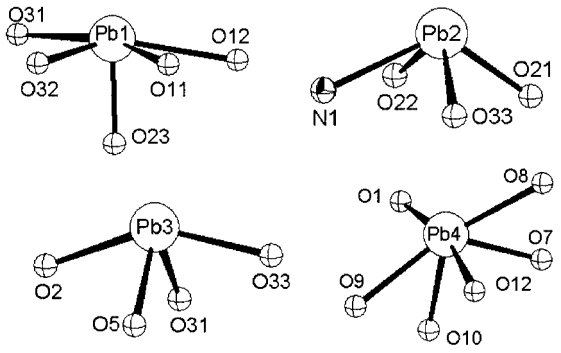

Figure 1. Coordination geometries of the lead(II) ions in **1**

This kind of coordination geometry has been reported in tin(II) phosphonopropionate oxalate and lead phosphonopropionate.[6,10] Pb4 is solely coordinated by tricarboxylate ligands; it is six-coordinated by two bidentate chelating carboxylate groups and two unidentate carboxylate groups from four carboxylate ligands. The coordination geometry around Pb4 can be described as a severely distorted ψ-pentagonal bipyramidal PbO_6 in which the seventh coordination site is occupied by the lone pair of the Pb^{II} ion. The coordination modes of the diphosphonate and BTC ligands are shown in Figure 2.

Each diphosphonate anion chelates with one Pb^{II} ion and bridges six other Pb^{II} ions. Atoms O31 and O33 are bidentate, whereas the remaining phosphonate oxygen atoms are unidentate. The Pb−O distances range from 2.30(2) Å to 2.71(2) Å, similar to those reported for other lead(II) phosphonates and lead(II) carboxylates.[6,7,12,13] The $[BTC]^{3-}$ anion is hexadentate and chelates with two lead(II) ions and also bridges two other lead(II) ions, whereas the $[HBTC]^{2-}$ anion acts as a tridentate ligand and bridges three Pb^{II} ions through two carboxylate groups. The third carboxylate group remains noncoordinated and protonated, as indicated by the longer C18−O4 distance. Based on charge balance, P−O distances, and its coordination mode, the diphosphonate anion should have a charge of −3; hence the pyridyl N atom must be also protonated.

It was noticed that diphosphonate or BTC ligands in $[Pb_4(BTC)(HBTC)(HL^1)]\cdot 3H_2O$ alone can form a coordination polymer with the lead(II) ions. Each pair of $[Pb(HL^1)]$ chelating units is bridged by a pair of phosphonate groups to form a dimer. Such dimers are further interconnected by Pb1 and Pb3 atoms, resulting in the formation of a $[Pb_3(HL^1)]^{3-}$ anionic double chain along the *a*-axis (Figure 3a). The interconnection of lead(II) ions (Pb1, Pb3 and Pb4) by bridging BTC and HBTC ligands results in a $[Pb_3(BTC)(HBTC)]^+$ cation whose structure is also a 3D porous network with two types of tunnels (Figure 3b).

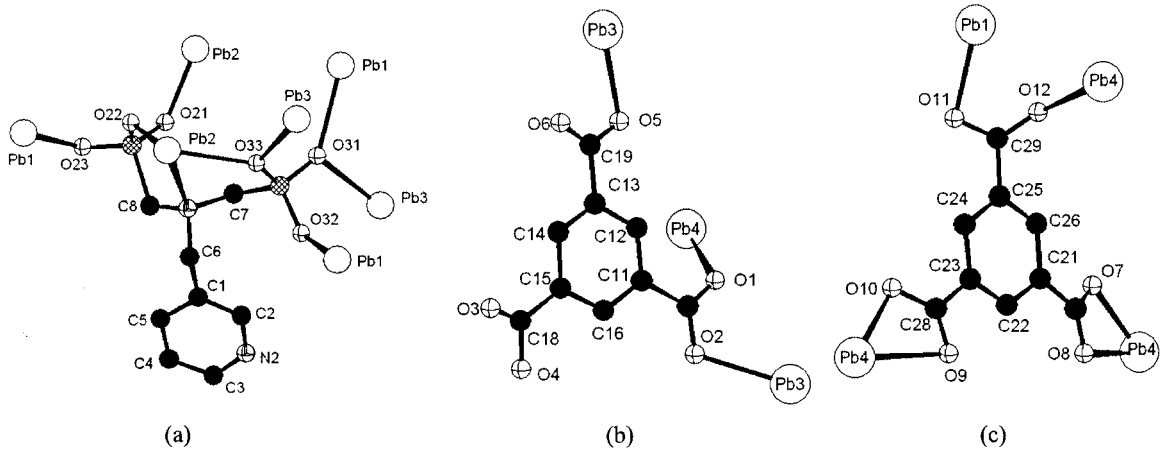

Figure 2. Coordination modes for the diphosphonate and BTC ligands in **1**: (a) HL^1; (b) $[BTC]^{3-}$; (c) $[HBTC]^{2-}$

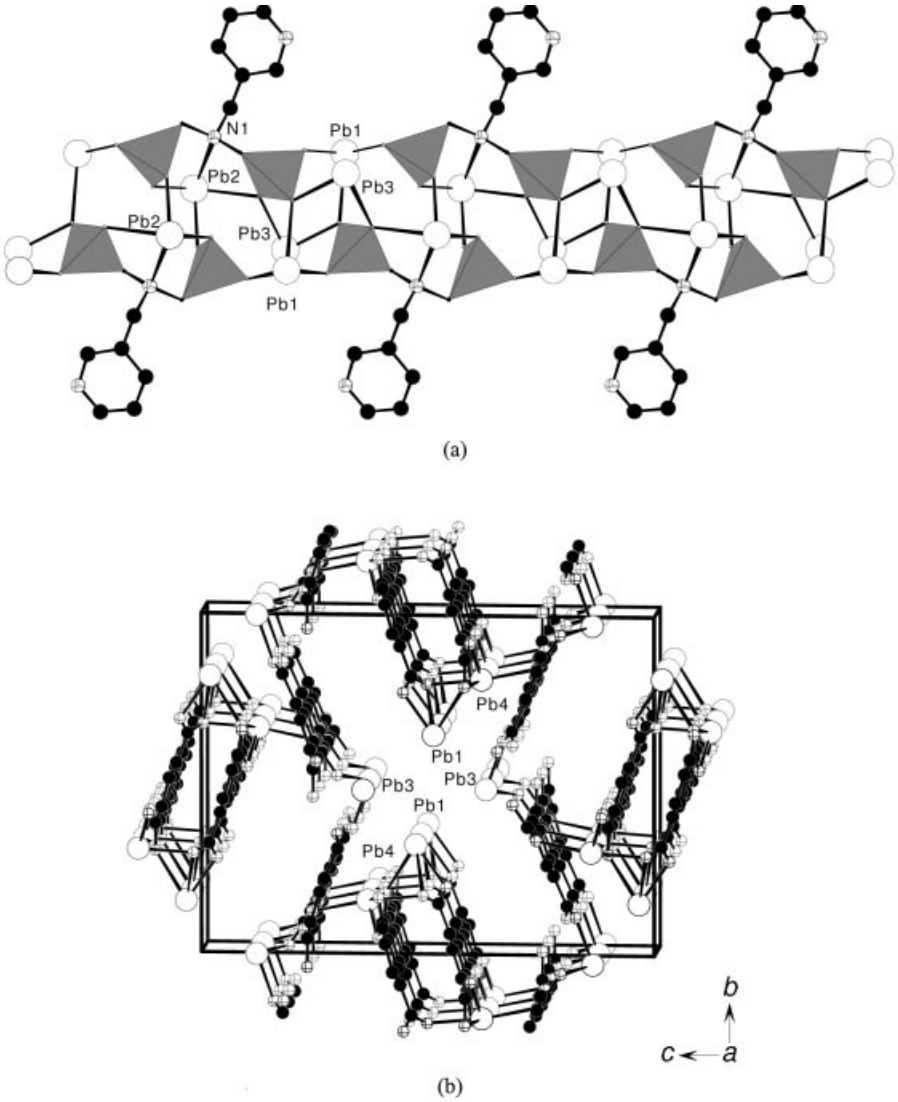

Figure 3. The 1D double chain of lead(II) diphosphonate along the *a*-axis in **1**(a) and the porous 3D network of lead(II) 1,3,5-benzenetricarboxylate in **1** (b); the C-PO_3 tetrahedra are shaded in gray, Pb, N, O and C atoms are represented by open, octanded, crossed and black circles, respectively

The smaller cavity is ca 8.0 $Å^2$ wide and is formed by 16-member rings, each of which is composed of two Pb1 atoms and two BTC ligands. The larger cavity is formed by 54-membered rings, each of which is formed by 8 Pb atoms and 8 BTC ligands. The size of the larger channel is estimated to be about 1/4 of the cell volume. This kind of arrangement is similar to that reported in $Pb_3(BTC)_2{\cdot}H_2O$.[13] These two types of coordination polymeric anions and cations are interconnected through atoms Pb1 and Pb3, resulting in the formation of a new porous network (Figure 4). Such linkage cuts the large cavity of $[Pb_3(BTC)(HBTC)]^+$ in half, thus greatly reducing the cavity size. The pyridine and noncoordinated carboxylate groups are directed towards the micropores. The lattice water molecules also occupy the cavity of the pores, forming hydrogen bonds with noncoordinated carboxylate oxygen atoms, which further increase the stability of the structure (Table 1).

The structure of **2** contains six Pb^{II} ions, two $[BTC]^{3-}$ anions, one $[HBTC]^{2-}$ anion and a 2H-protonated triphosphonate ligand (H_2L^2) in an asymmetric unit. Both Pb1 and Pb3 are five-coordinated by four carboxylate oxygen atoms from two BTC and one HBTC ligands as well as a phosphonate oxygen atom (Figure 5).

Pb2 is six-coordinated by four carboxylate oxygen atoms from one HBTC and two BTC ligands, and two phosphoate oxygen atoms from a bidentate chelating phosphonate group. Pb4 is five-coordinated by three carboxylate oxygen atoms from one BTC and one HBTC anions, and two phosphonate oxygen atoms from two phosphonate groups. Pb5 is four-coordinated by a chelating carboxylate group of a HBTC ligand and two phosphonate oxygen atoms from two L^2 ligands. Pb6 is five-coordinated by a tridentate chelating L^2 ligand (through N2, O41 and O33), a phosphonate oxygen from a neighboring L^2 ligand and a carboxylate oxygen atom of a BTC anion. The four-, five- and six-coordinate

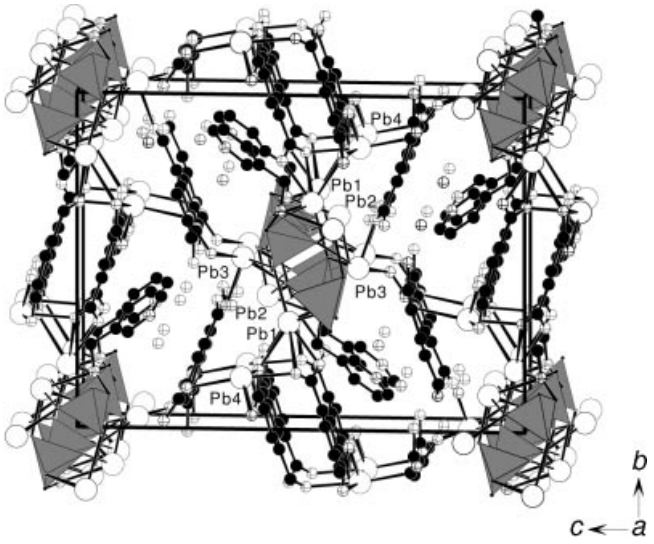

Figure 4. View of the structure of **1** down the *a*-axis; the C-PO_3 tetrahedra are shaded in gray, Pb, N, O and C atoms are represented by open, octanded, crossed and black circles, respectively

lead(II) ions have quite different coordination geometries: ψ-square pyramidal PbO_4, ψ-octahedral PbO_5 (or PbO_4N) and ψ-pentagonal bipyramidal PbO_6 (the lone pairs occupying the fifth, sixth and seventh coordination sites), which are similar to those in compound **1**. The Pb−O distances range from 2.27(1) to 2.75(1) Å and the P−N distance is 2.67(2) Å, which are similar to those in **1** and other lead(II) phosphonates.[6,7,12]

The aminotriphosphonate ligand adopts an interesting coordination mode (Figure 6). The phosphonate group containing P2 forms a chelate with the Pb2 atom (through O21 and O23) and bridges the Pb1 and the Pb3 atom. The O22 atom remains noncoordinated and forms a hydrogen bond with the noncoordinated carboxylate oxygen atom (O10; Table 2). The $N(CH_2PO_3)_2$ moiety of the L^2 ligand is octadentate; it chelates with Pb6 as a tridentate ligand (through N2, O33 and O41) and also bridges five other Pb^{II} ions (two Pb5, two Pb4 and one Pb6 atom). Three phosphonate oxygen atoms (O21, O23 and O41) are bidentate metal linkers. The two nitrogen atoms of the piperazine ring are 1H-

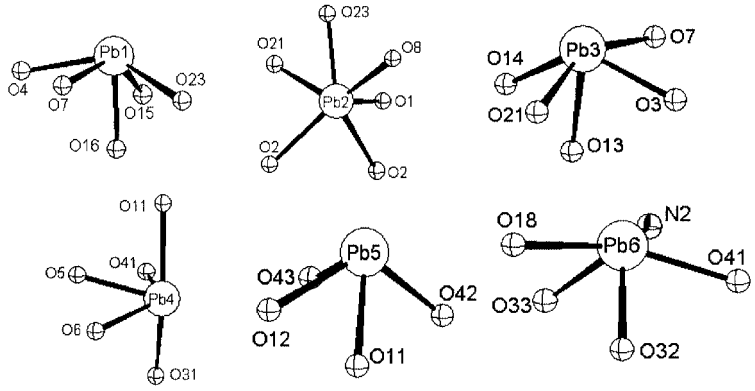

Figure 5. The coordination geometries around the lead(II) ions in **2**

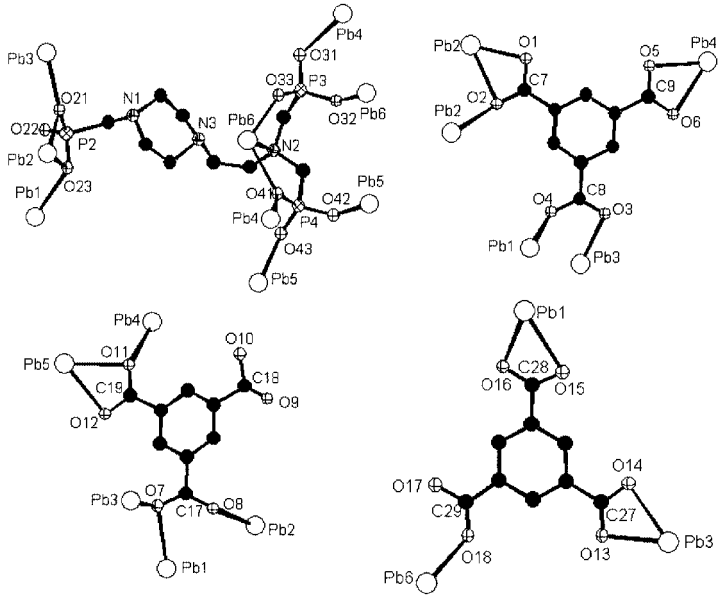

Figure 6. The coordination modes of L^2 and 1,3,5-benzenetricarboxylate ligands in **2**

protonated and remain noncoordinated. The three 1,3,5-benzyltricarboxylate ligands in **2** adopt three different types of coordination modes (Figure 6).

The BTC ligand containing O1 to O6 is heptadentate and bridges five Pb^{II} ions. The carboxylate group CO1O2 forms three bonds, a chelate to one Pb2 atom and a bridge between the two Pb2 atoms, the one containing CO3O4 bridges Pb1 and Pb3 (two-coordinated), whereas the one composed of CO5O6 forms a chelate with Pb4 (two-coordinated). The second tricarboxylate ligand containing O7 to O12 is hexadentate. One carboxylate group CO7O8 bridges three Pb^{II} ions (three bonds to Pb1, Pb2, and Pb3), the second carboxylate group CO11O12 forms three bonds (a chelate with Pb5 and a bridge between Pb4 and Pb5). The third carboxylate group CO9O10 is noncoordinated, and the O10 atom remains protonated as indicated by its longer C−O distance. Thus it is a $[HBTC]^{2-}$ anion. The third BTC ligand (O13 to O18) is pentadentate two carboxylate groups (CO13O14 and CO15O16) are bidentate chelating whereas the third (CO17O18) is unidentate. The atoms O2, O7 and O11 are bidentate metal linkers.

The interconnection of Pb4, Pb5 and Pb6 atoms by the $N(CH_2PO_3)_2$ moieties of L^2 ligands resulted in a 1D double chain along the *a*-axis (Figure 7a). Pb1, Pb2 and Pb3 atoms form a <002> corrugated carboxylate−phosphonate hybrid layer with carboxylate ligands and the phosphonate groups containing P2 atoms (Figure 7b), resulting in the formation of several types of rings. One is the four-membered ring formed by Pb1, O4, Pb3 and O7 atoms. The second type is the six-membered ring formed by Pb1, O23, Pb2, O8, C17 and O7 atoms. The third one is the 12-membered ring composed of four Pb^{II} ions (two Pb2 and two Pb3), two bridging carboxylate groups (two CO7O8) and two bidentate O14 atoms.

The above 1D lead(II) phosphonate double chains and <002> hybrid layers are cross-linked through the organic

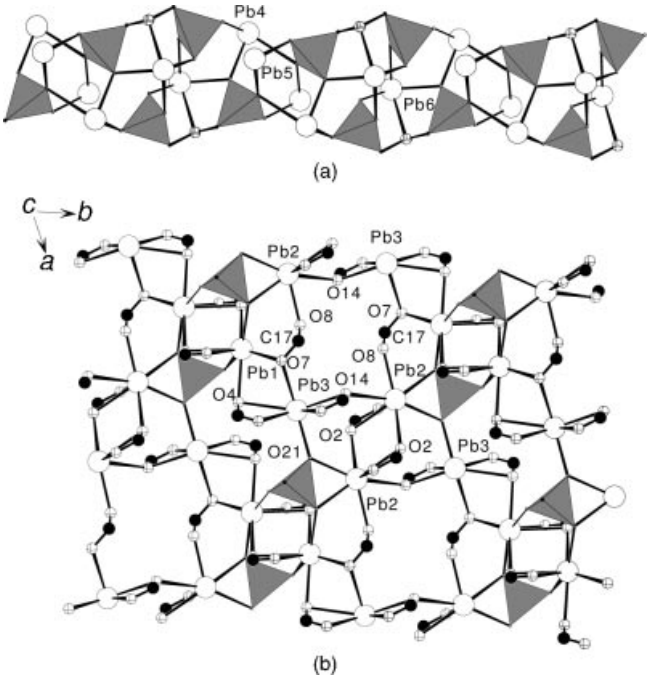

Figure 7. The 1D double chain of lead(II) diphosphonate along the *a*-axis (a) and a <002> lead(II) carboxylate−phosphonate hybrid 2D layer (b) in complex **2**; the C-PO_3 tetrahedra are shaded in gray, Pb, N, O and C atoms are represented by open, octanded, crossed and black circles, respectively.

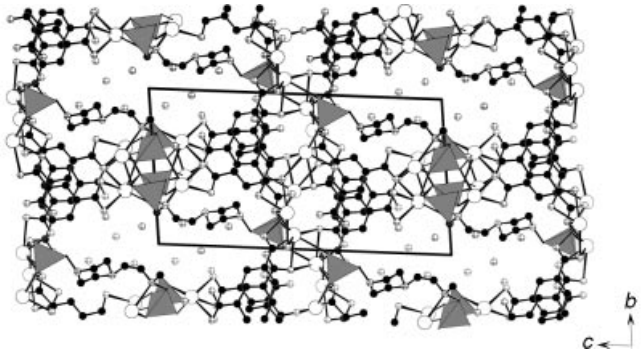

Figure 8. View of the porous 3D network of **2** down the *a*-axis; the C-PO_3 tetrahedra are shaded in gray, Pb, N, O and C atoms are represented by open, octanded, crossed and black circles, respectively

groups of HBTC, BTC and H_2L^2 ligands to form a porous 3D network (Figure 8). The size of the pore is estimated to be 4.0 × 16.0 Å^2. The lattice water molecules are located at these micropores and are involved in hydrogen bonding (Table 2).

The XRD powder patterns for compounds **1** and **2** were collected on a Philips X'Pert-MPD diffractometer using graphite-monochromated Cu-K_α radiation in the angular range $2\theta = 5-70°$. Their powder patterns match with the ones calculated from their single crystal structure data, thus both compounds exist as a single phase.

IR spectra of compounds **1** and **2** show the asymmetric and symmetric vibrations of the carboxyl group at 1543 and 1431 cm^{-1} for **1**, and 1531 and 1433 cm^{-1} for **2**, respectively. The vibrations of the phosphonic groups are in the region 900−1100 cm^{-1}.[7] The broad bands at 3392 cm^{-1} (**1**) and 3396 cm^{-1} (**2**) indicate the presence of the water molecules in both compounds.

The TGA diagram of **1** shows three main steps of the weight losses. The first step is loss of three lattice water molecules, which started at 62 °C and was completed at 165 °C, the observed weight loss of 3.2% is in good agreement with the calculated value (3.4%). The second step covering a temperature range of 320 °C to 633 °C corresponds to the burning of BTC and diphosphonate ligands. The third step overlapped with the second one, corresponding to further decomposition of organic groups. The final products are $Pb_2P_2O_7$ and PbO in a 1:2 molar ratio. The total weight loss of 33.0% is close to the calculated value (35%). The TGA curves of **2** also exhibit three steps of weight loss. The first step is the release of the lattice water molecules, which started at 33°C and was completed at 155°C; the observed weight loss of 3.46% matches with the theoretical one (3.44%). The second and third steps are overlapped, starting at 340 °C and continued up to 1000 °C, during which two processes occurred, firstly, the decomposition of the BTC ligands, and secondly, the burning of the triphosphonate ligand. The final products are assumed to be $Pb_2P_2O_7$ and PbO in a molar ratio of 1:2. The total weight loss of 31.8% is close to the calculated one (34.1%).

Conclusion

In summary, the hydrothermal reactions of lead(II) acetate with an aminodiphosphonic or an aminotriphosphonic acid and 1,3,5-benzenetricarboxylic acid resulted in two novel porous lead(II) carboxylate−phosphonate hybrids in which both ligands act as multidentate metal linkers. The 1,3,5-benzenetricarboxylate ligand may also act as a pillar agent or an intercalated species between two metal phosphonate layers. Thus we believe that a wide range of new open frameworks and microporous materials can be developed by using this technique.

Experimental Section

Materials and Methods: All chemicals were obtained from commercial sources and used without further purification. Elemental analyses were performed on a Vario EL III elemental analyzer. Thermogravimetric analyses were carried out with a TGA/SBTA851 unit at a heating rate of 15 °C/min under an oxygen atmosphere. IR spectra were recorded on a Magna 750 FT-IR spectrometer photometer as KBr pellets in the range 4000−400 cm^{-1}. ^{1}H and ^{31}P NMR spectra were recorded on a Varian Unity 500 NMR in D_2O. H_3PO_4 was used as the ^{31}P standard reference. The XRD powder patterns were collected on a Philips X'Pert-MPD diffractometer using graphite-monochromated Cu-K_α radiation in the angular range $2\theta = 5-70°$ with a step size of 0.02° and a counting time of 3 s per step.

Preparation of H_4L^1 and H_6L^2: H_4L^1 was prepared by a Mannich type reaction according to the procedures previously described.[11] 3-(Aminomethyl)pyridine (100 mmol, 12.6 mL) was mixed with

Synthesis of $[Pb_4(BTC)(HBTC)(HL^1)]\cdot 3H_2O$ (1) and $[Pb_6(BTC)_2(HBTC)(H_2L^2)]\cdot 4.5H_2O$ (2): $[Pb_4(BTC)(HBTC)(HL^1)]\cdot 3H_2O$ (**1**) was prepared by hydrothermal reaction of lead(II) acetate trihydrate (0.75 mmol, 0.29 g), H_4L^1 (0.25 mmol, 0.08 g) and H_3BTC (0.5 mmol, 0.10 g) in a 3:1:2 molar ratio in 10.0 mL of deionized water at 150 °C for 3 days. Colorless crystals of **1** were recovered in 45.8% yield (based on Pb). $C_{26}H_{22}N_2O_{21}P_2Pb_4$ (1591.17): calcd C 19.65, H 1.40, N 1.76; found C 19.53, H 1.27, N 1.72. IR (KBr): $\tilde{\nu}$ = 3392 cm^{-1} m, 1697 m, 1610 s, 1543 s, 1527 s, 1431 s, 1354 vs, 1261 m, 1190 m, 1095 m, 1061 s, 989 w, 939 w, 843 w, 816 w, 760 w, 721 s, 683 w, 586 m, 569 w, 515 m. $[Pb_6(BTC)_2(HBTC)(H_2L^2)]\cdot 4.5H_2O$ (**2**) was prepared by hydrothermal reactions of lead(II) acetate trihydrate (0.75 mmol, 0.29 g) H_6L^2 (0.25 mmol, 0.11 g) and H_3BTC (0.5 mmol, 0.10 g) in a 3:1:2 molar ratio in 10.0 mL of deionized water at 180 °C for 3 days. Colorless crystals of **2** were recovered in 46.4% yield (based on Pb). $C_{36}H_{40}N_3O_{32}P_3Pb_6$ (2353.75): calcd. C 18.30, H 1.71, N 1.78; found C 18.43, H 1.98, N 1.64. IR (KBr): $\tilde{\nu}$ = 3396 cm^{-1} m, 1651 w, 1610 m, 1531 s, 1433 s, 1361 vs, 1311 m, 1219 w, 1095 s, 1039 s, 966 s, 817 w, 802 w, 758 m, 721 s, 694 w, 572 m, 555 w, 509 w, 482 w.

Crystal Structure Determination: Single crystals of **1** and **2** were mounted on a Siemens Smart CCD diffractometer equipped with a graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Intensity data were collected by the narrow frame method at 293 K. The data sets were corrected for Lorentz and polarization as well as for absorption by ψ scan technique. Both structures were solved by direct methods and refined by full-matrix least-squares fitting on F^2 by SHELX-97.[14] All non-hydrogen atoms, except for C7, C11, and O32 in **1**, and C6, C22, C25, C31, C32, C33, C34, C35 and O(7 W) in **2,** were refined with anisotropic thermal parameters. The carbon atoms of the piperazine ring in **2** have large thermal parameters and were refined with a rigid model. Lattice water molecules [O(3 W) to O(7 W)] also have large thermal parameters, and each was assigned with an occupancy factor of 50%. Despite these problems, the refinement of **2** can still be considered satisfactory for such a complicated structure. The final difference Fourier maps showed featureless residual peaks of 2.88 [for, **1**, 1.15 Å from the Pb4 atom] and 1.78 e·Å^{-3} [for **2**, 0.84 from the Pb6 atom], respectively. All hydrogen atoms were located at geometrically calculated positions. The hydrogen atoms for the water molecules were not included in the refinement. Crystallographic data and structural refinement are summarized in Table 3. Important bond lengths and angles are listed in Table 1 for complex **1** and Table 2 for complex **2**. CCDC-209007 and -209008 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Reaction of Methyl Radicals with Metal Powders Immersed in Aqueous Solutions

Irena Rusonik,[a] Hurriyet Polat,[a,b] Haim Cohen,[a,c] and Dan Meyerstein*[a,d]

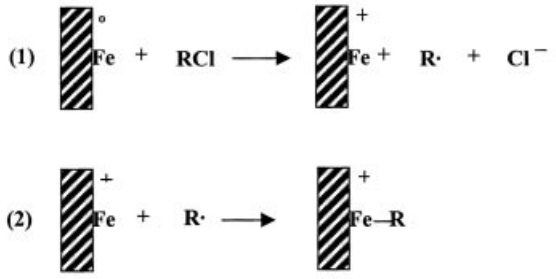
Keywords: Carbon / Energy transfer / Radicals / Oxidation

Methyl radicals radiolytically produced in aqueous solutions react efficiently with Cr^0, Mn^0, Fe^0, Ni^0, Cu^0 and Zn^0 powders immersed in the solution. The Cr^0, Mn^0, Fe^0, Ni^0 and Zn^0 powders reduce the radicals to form methane. On the other hand the Cu^0 powder seems to oxidize the radicals. Surprisingly a part of the energy absorbed by the Cr^0, Fe^0, Ni^0 and Zn^0 powders is transferred to the aqueous solution, thus increasing the radical yield. CH_4, C_2H_4, C_2H_6, C_3H_6 and C_3H_8 are formed when an aqueous deaerated buffer solution, pH 4–5, is added to powders of analytical iron, zinc, manganese and chromium. The source of these gases is carbon traces present, as atoms or atom clusters, in the "analytical" metal powders. These carbon atoms, when present on the surface of the metals, are reduced by the metal particles in aqueous solutions. This mechanism might be the source of light alkanes and alkenes in the prebiotic era.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Extensive use of halogenated aliphatic compounds, as solvents and degreasing agents in industry, and as pesticides in agriculture, has led to environmental problems of contamination of groundwater systems. Therefore, there is considerable interest in developing methods for removing halogenated organic compounds from industrial and agricultural wastes. Zero-valent iron,[1−11] Fe^0, is an effective reagent for the dehalogenation process of contaminated water streams. Despite recent significant progress in the elucidation of this mechanism,[9,12,13] many basic questions remain unanswered. The principle goal of our research program is a detailed investigation of the dehalogenation mechanism. The elucidation of this mechanism is of scientific interest and might enable to improve the process.

The mechanism of the dehalogenation process probably involves in the first stage the reactions:[2,6,14]



Thus, it seemed of interest to study the mechanism of reaction 2 and the mechanism of the decomposition of the transient I formed in it. For this purpose it was decided to form the radicals R˙ in the vicinity of iron powder using radiation chemical techniques. The methyl radical was chosen due to its simplicity and reactivity as a strong oxidizing and reducing agent.[15,16] However blank experiments revealed that light alkanes and alkenes are formed when "analytical" iron is dissolved in slightly acidic aqueous solutions. This observation, which partially corroborates an earlier study,[17] might affect the nature of the final products obtained and was therefore also studied. For comparison purposes the analogous processes in the presence of other metal powders were also studied.

Results and Discussion

Formation of Alkanes during the Dissolution of Analytical Metals in Aqueous Solution

Light alkanes and alkenes are formed when analytical iron is dissolved in He-saturated, CO_2-free, slightly acidic

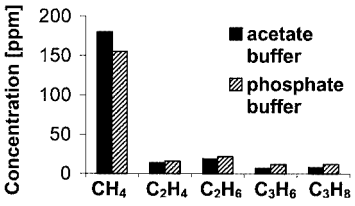

Figure 1. Yield of alkanes and alkenes in the gas phase: 10 g Fe^0, 2.5 mL 0.5 M acetate buffer pH 4.0 or 10 g Fe^0, 2.5 mL 0.1 M phosphate buffer pH 4.0; t = 3 h, T = 25 °C

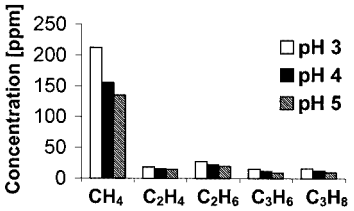

Figure 2. pH dependence of the dissolution of iron in phosphate buffer 0.1 M: 10 g Fe^0, 2.5 mL phosphate buffer 0.1 M; t = 3 h, T = 25 °C; error limit ± 15%

buffers. Typical results are summed up in Figure 1. The major product is always methane. The results suggest that the nature of the buffer slightly affects the relative yields of the different products. The larger methane yield in the acetate buffer is tentatively attributed to the larger buffer capacity of acetate at this pH.

As, at least in the phosphate buffer, the source of the organic gases has to be the iron, an analysis of the carbon content of the iron powder was performed. Indeed the results point out that the carbon/carbide content of the analytical iron is 450 ppm by weight, though this is not mentioned in the analytical data given by Merck. As expected, analysis of the iron ions formed indicates that over 95% of the iron is present as $Fe^{II}_{(aq)}$ and not as $Fe^{III}_{(aq)}$. The yield of $H_{2(g)}$, not shown, is very similar to that of $Fe^{II}_{(aq)}$ and corroborates the previous observation.

Analysis of the time dependence of the process shows that no induction period is observed and the product gases are formed within the first 20 min of the process, during which the pH at the metal surface presumably increases thus stopping, or slowing down, the process. The observation that the process is over within the first 20 min could alternatively suggest that the carbon atoms are present only at the surface of the iron particles. In order to check this possibility, the iron powder was activated in sulfuric acid (0.1 M) for 30 min, it was then washed with excess distilled water, and was bubbled with He for one hour. The water was then removed and the bulb was closed and deaerated with He before adding the phosphate buffer. After a further 20 min the gas phase was analyzed. The gas composition and concentrations were the same as in the previous experiments. This result points out that the carbon atoms are present in the iron bulk.

The emission of organic gases during the dissolution of iron powder in slightly acidic aqueous solutions is surprising. The yield of the organic gases increases with the decrease in pH of the solution (see Figure 2). It seemed of interest to check whether similar results are obtained for other analytical metal powders. The results obtained are summed up in Table 1. The results clearly demonstrate that light alkanes and alkenes are also formed during the dissolution of "analytical" Cr^0, Mn^0 and Zn^0. However, the relative yields of the different gases depend on the nature of the metal.

As the main purpose of our research was to study the mechanism of reaction 2 and the mechanism of decomposition of the transient **I** formed in it, the influence of radiation on the dissolution process of the metal power was studied. When the samples (10 g activated metal powder, 2.5 mL water at pH 4.0) are irradiated in a ^{60}Co γ-source with a dose of 480 Gy, the yield of the alkanes and alkenes increases somewhat. Typical results are shown in Table 1. Clearly the radiation enhances the rate of dissolution of the metals; this might be due to the reactions of the radicals formed by irradiating the aqueous solutions (see below) with the metals.

The mechanism of formation of the alkanes and alkenes probably involves in the first stage one of the following steps:

Table 1. The relative yields of the different gases depend on the nature of the metal and of the radiation[a]

Metal	Radiation	E [V]	Carbon [ppm]	CH_4 [ppm]	C_2H_4 [ppm]	C_2H_6 [ppm]	C_3H_6 [ppm]	C_3H_8 [ppm]
Cr^0	+	−0.41	3000	30.8	16.9	8	9	−
Cr^0	−			28	14	6	8	−
Fe^0	+	−0.44	450	29	17	11	4.9	3.9
Fe^0	−			21	10.1	8	−	3.7
Zn^0	+	−0.76	40	23.6	−	1.8	−	3.2
Zn^0	−			22.2	−	1.8	−	−
Mn^0	+	−1.18	50	87.8	−	5.1	0.4	−
Mn^0	−			72.9	−	3.1	−	−

[a] All samples contained 10 g of activated metal powder and 2.5 mL of water at pH 4.0, t = 3 hours, radiation dose 480 Gy. No buffer was added to these experiments.Error limit ± 15%.

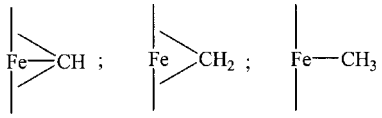
1. Hydrogen atoms adsorbed to the iron particles migrate to exposed carbon atoms forming



groups.

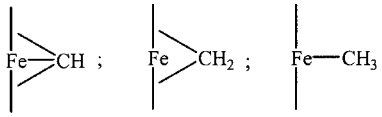
The migration of the hydrogen atoms is equivalent to that involved in the formation of $H_{2(g)}$ via the migration of two hydrogen atoms. The formation of transients containing Fe−alkyl bonds is analogous to the formation of transient complexes in the reaction of alkyl radicals with iron(II) complexes,[18] and other low valent transition metal complexes,[16] in homogeneous solutions.

2. The iron particles act as microelectrodes charging negatively the less electropositive exposed carbon atoms that then reduce the water.

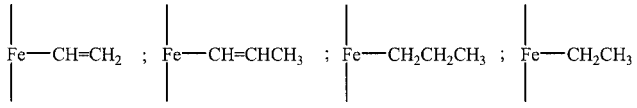
These two mechanisms might contribute in parallel to the process observed.

In addition, the next step might occur via two mechanisms:

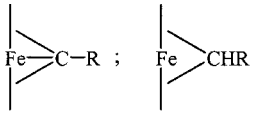
1. Migration of the alkyl groups of



in parallel to hydrogen atom migration, to form



2. The carbon atoms might be dispersed in the metal particles as C_1, C_2 and C_3, which are then reduced. This mechanism does not require migration of alkyl groups which at least for



seems to be difficult.

The results of the study of the mechanism of the reaction of $^{\cdot}CH_3$ radicals with metal powders (see below) seems to suggest that the latter mechanism is more probable. However the considerably smaller ratios of $[CH_4]/[C_2H_4]$ and $[CH_4]/[C_2H_6]$ in non-buffered solutions than in buffered solutions (see Table 2), suggests that the acid-catalyzed heterolysis of the metal−carbon σ-bonds[19,20] in the dissolution process of the metal powder, inhibits alkyl migration, thus increasing these ratios.

Table 2. Ratio comparison of gas concentrations formed in the dissolution process of analytical iron in the presence of a buffer and in its absence[a]

Presence of buffer	$[CH_4]/[C_2H_4]$	$[CH_4]/[C_2H_6]$
+	9.8	7.1
−	2.1	2.6

[a] Every sample contains 10 g of activated iron powder, 2.5 mL H_2O or 0.1 M phosphatebuffer pH 4.0, t = 3 hours, T = 25 °C, No radiation. Error limit ± 15%.

The last step of the mechanism clearly involves the heterolysis of the M−C σ-bonds, in an analogous mechanism to that observed for homogeneously dissolved complexes with metal−carbon σ bonds.[21−23]

The results clearly demonstrate that whenever the reduction of haloalkanes by metals is studied by following the kinetics of formation of the organic products,[24,25] the corresponding blank experiments, in the absence of organic substrates, have to be carried out.

Finally it is tempting to suggest that the production of alkanes and alkenes via this mechanism might have contributed to the formation of light organic compounds[26] including petroleum,[27] in the prebiotic era. Clearly this mechanism does not require the harsh conditions required by many alternative mechanisms.[28]

Reaction of Methyl Radicals

At first the reaction of activated iron powder with methyl radicals was studied. The results (see Table 3) clearly demonstrate that considerably more CH_4 is formed in the irradiated sample containing iron powder than in the sum of the blank experiments (non-irradiated sample and irradiated sample without iron powder). The gases formed in the non-irradiated blank experiment are due to the dissolution process of the iron powder, which contains 450 ppm of carbon by weight. A comparison of the yields of the gases formed in the irradiated sample containing iron powder and the same non-irradiated experiment (see Table 3), demonstrates that the C_2H_4, C_3H_6 and C_3H_8 gases formed in irradiated experiments originate from the dissolution of Fe^0. However the yield of CH_4 and C_2H_6 in this experiment is considerably larger than that in the non-irradiated experiment. It is suggested that the excess CH_4 and C_2H_6 formed in the irradiated samples containing iron powder are

Table 3. Emitted gas composition in reaction with $(CH_3)_2SO$[a]

Presence of Iron	Radiation	CH_4	C_2H_4	C_2H_6	C_3H_6	C_3H_8

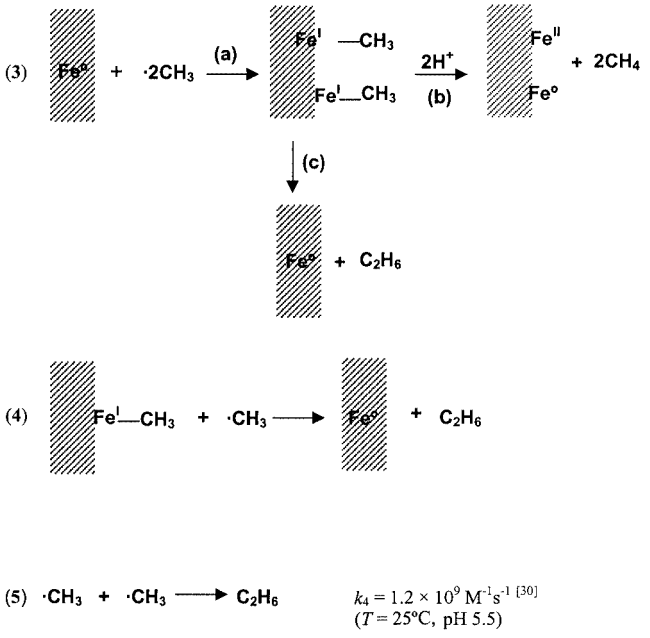
formed via the mechanism outlined in Scheme 1. It is proposed that the reaction proceeds via the inner-sphere mechanism, as the formation of CH_3^- is endothermic in analogy to oxidations by hydrogen atoms.[30,31] The formation of M^I-CH_3 σ-bonds is analogous to the observed mechanism of reaction of $^{\cdot}CH_3$ radicals with a variety of low valent transition metal complexes.[16,21]



Scheme 1. CH_4 and C_2H_6 formation via reaction of methyl radicals with iron powder

It is of interest to note that the yield of $[CH_4] + 2[C_2H_6]$ in irradiated samples containing iron powder is considerably larger than in irradiated samples without iron powder, by at least a factor of two. This result proves that more methyl radicals are formed by radiation in the solution containing the iron powder. This result points out that some of the energy absorbed by the metal powder is transferred to the aqueous solution or to$(CH_3)_2SO$ molecules adsorbed to the powder surface. Energy transfer and charge transfer from irradiated solids to the solvent or to adsorbed molecules is a well-known phenomenon in the literature.[32−37] But the solid systems studied were porous silica, zeolites, porous glass and clay systems i.e. insulators. Nothing is known about energy transfer or charge transfer from irradiated metals to adsorbed molecules or to the solution. Obviously, the present results point out that, surprisingly, this phenomenon occurs also for iron, i.e. for a metal. This means that a band gap between the ground state and the excited state is not required for this process.

The dependence of the yield of CH_4 and C_2H_6 on $(CH_3)_2SO$, in the range 0.02−0.08 M, was studied. The results (not shown) point out that the gas yields are independent of $(CH_3)_2SO$. This suggests that either the energy is transferred from the iron to the solution or that even at the lowest concentration the iron surface is saturated with adsorbed $(CH_3)_2SO$. The latter alternative seems less probable.

The results are pH independent in the range 4−6. Therefore it was decided to omit the acetate buffer from the solutions. This action decreases the $[CH_4]/[C_2H_6]$ ratio in the blank experiments that do not contain iron powder, because reaction 6 contributes to the methane yield.

(6) $^{\cdot}CH_3 + CH_3COO^- \longrightarrow CH_4 + {}^{\cdot}CH_2CO_2^-$ $k_6 = 600\ M^{-1}s^{-1}$ [38] ($T = 25°C$, pH 1.0)

When N_2O-saturated blank solutions containing only 0.05 M $(CH_3)_2SO$ are irradiated, the methane and ethane are formed via reactions 7 and 5. Using the radiation dose 480 Gy and k_5 one can calculate k_7 from the results.

(7) $^{\cdot}CH_3 + (CH_3)_2SO \longrightarrow CH_4 + {}^{\cdot}CH_2S(O)CH_3$ $k_7 = 100 \pm 20\ M^{-1}s^{-1}$ ($T = 25\ °C$, pH 4.0)

The calculated value of k_7 is smaller than the k_6 value, therefore, in the absence of acetate buffer, the contribution of reaction 5 is larger and the yield of ethane is increased in comparison to the methane yield.

At the end of all the reactions the Fe^{II} and Fe^{III} concentrations were measured using a colorimetric method.[39] The measured concentrations of Fe^{III} ions are negligible [$(5 \pm 0.8) \times 10^{-5}$ M] compared to Fe^{II} [$(1.2 \pm 0.2) \times 10^{-3}$ M]. The Fe^{II} and Fe^{III} concentrations were the same at all pHs and for irradiated and non irradiated systems. The calculated concentration of Fe^{II} due to reaction 3, which yields 2100 ppm CH_4 (see Table 4) in the irradiated system is 1.1×10^{-4} M, i.e. within the experimental error of the non-irradiated sample.

Next it was checked whether the methane is formed via the reaction:

(8) $Fe^{2+}_{aq} + {}^{\cdot}CH_3 \xrightarrow{H^+} Fe^{3+}_{aq} + CH_4$

For this purpose N_2O-saturated solutions containing $FeSO_4$ were irradiated. The results (see Table 5) clearly point out that reaction 8 involving the Fe^{2+}_{aq} ions, formed in the corrosion process, is not the source of the methane formed in the presence of the iron powder.

Thus the results illustrate that methyl radicals react with the iron powder to form CH_4 and probably some C_2H_6. Assuming that all the ethane is formed via reaction 5, i.e. that reactions 3c and 4 do not contribute to the ethane yield, one can calculate the apparent rate of reaction 3a from the known dose rate and k_4. Thus $k_{3a} = 20 \pm 10\ s^{-1}$ and is calculated for this powder.

A considerably larger $[CH_4]/[C_2H_6]$ ratio is observed in the irradiated samples containing iron powder than in the blank non-irradiated samples (see Table 4). In the irradiated samples the density of -CH_3 groups bound to the iron particles is clearly considerably higher than in the blank non-irradiated experiments. These observations suggest that the C_2H_6 formed in the blank experiments does not stem from the reaction:

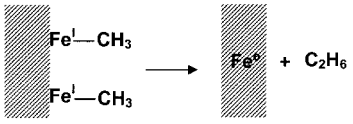
[a] Composition of the gases formed in the reaction of 10 g activated/ non activated metal powders with 2.5 mL $(CH_3)_2SO$ 0.05 M solution, pH 4.0, t = 3 hours (radiation dose 480 Gy), T = 25 °C. All samples N_2O saturated. Error limit ± 15%. Cu^0 powder (Aldrich 99%, <10 μm). [b] Cr^0 powder (Alfa Aesar 99.8%, <10 μm). [c] Fe^0 powder (Merck 99%, ≤10 μm). [d] Zn^0 powder (Aldrich 98%, <10 μm). [e] Mn^0 powder (Aldrich 99%, 325 mesh).

Table 5. Dependence of gas formation in the presence of $Fe^{2+}{}_{aq}$ ions[a]

Sample composition	Irradiated	CH_4 [ppm]	C_2H_6 [ppm]
$FeSO_4$, $(CH_3)_2SO$	+	480	190
$FeSO_4$, $(CH_3)_2SO$	−	−	−
$(CH_3)_2SO$	+	500	370

[a] 2.5 mL of N_2O saturated solutions containing $FeSO_4$ (5×10^{-3} M), $(CH_3)_2SO$ (0.05 M), pH 4.0, t = 3 hours (radiation dose 480 Gy), T = 25 °C. Error limit ± 15%.



i.e. from the migration of -CH_3 groups bound to the iron particle. Thus the results corroborate the suggestion that the C_2H_4, C_2H_6, C_3H_6 and C_3H_8 gases formed in the non-irradiated blank experiments containing iron powder, originate from small carbon clusters present in the iron metal.

It was interesting to check whether analogous reactions of methyl radicals also take place with other metal powders. For this purpose the reactions of Cu, Cr, Zn and Mn powders with methyl radicals were studied. In addition, the role of metal powder activation on the gas yields was investigated; the results are summed up in Table 4. The effect of irradiating metal powders immersed in water at pH 4.0, in the absence of $(CH_3)_2SO$, on the yield of light alkanes is minor (see Table 1).

Conclusions

According to the experimental results the following conclusions can be drawn:

1. For all metals, except for Cu^0 and Mn^0, in the {M^0, $(CH_3)_2SO$, Ra} system the radiolytic yield of methane is considerably larger than that obtained in the absence of the metal powder but the ethane yield decreases, except for the system containing activated Zn. Thus, the results point out that under the experimental condition the rate of reaction 9 is considerably higher than that of reaction 5.

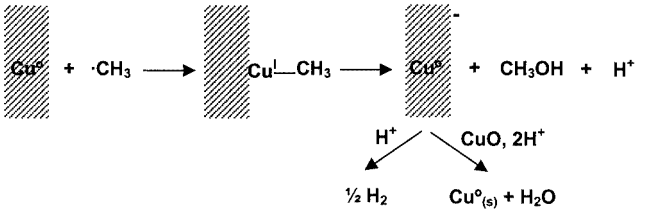
$$(9)\ M^o + \cdot CH_3 \xrightarrow{H^+} CH_4 + M^I$$

2. For all metals except for Cu^0, the total radiolytic alkane yield, $[CH_4] + 2\,[C_2H_6]$, in solutions containing $(CH_3)_2SO$ and metal powder, is considerably larger than the sum of the yields of the two blank experiment, i.e. the non-irradiated solution containing metal powder and the irradiated solution containing only $(CH_3)_2SO$ without the metal. This result points out that some energy transfer from the irradiated metal to the solution or to adsorbed $(CH_3)_2SO$ occurs.

3. The addition of copper powder to $(CH_3)_2SO$ decreases the total radiolytic gas yield considerably (see Table 4). The logic explanation for this observation is that methyl radicals are oxidized by the copper particles. A mechanism for this process is presented in Scheme 2. It should be noted that the oxidation potential of $\cdot CH_3$ radicals is considerably higher than that of $Cu^0{}_{(s)}$. Thus, thermodynamically the methyl radicals can oxidize copper as they oxidize the other

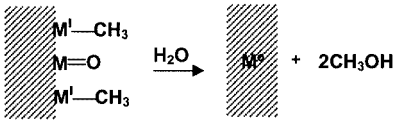
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

metals. The copper system is still under investigation and the yield of the methanol and dihydrogen in the system will be determined.



Scheme 2. Reaction of methyl radicals with copper powder

4. Activation of the metal powders leads to an increase in the radiolytic gas yield. In the activation step oxides are removed from the metal surface, this probably transforms the metal particle into a stronger reducing agent. Oxides present on the surface might react via:



thus decreasing the yields of CH_4 and C_2H_6. Nevertheless, the activation step does not contribute to an increase in the radiolytic gas yield in the case of Cu^0 and Mn^0. The explanation for the Cu^0 system was outlined above. Mn^0 is the strongest reducing metal studied ($E^0 = -1.18$ V) thus, it probably tends to act only as a reductant.

It seemed of interest to check whether the use of metal nano-particles, prepared via reduction of the metal ions with BH_4^-,[40] affects the results. The results of these experiments are summed up in Table 6. A comparison of the results for iron in Tables 4 and 6 reveals that indeed the smaller particles scavenge a larger part of the methyl radicals thus increasing the methane yield and decreasing the ethane yield. Furthermore, the total gas yield, $[CH_4] + 2[C_2H_6]$, is larger for the "nano" particles, that is the smaller particles induce a larger energy transfer from the metal to the solution, as expected.

Table 6. Reaction of methyl radicals with synthesized metal powders[a]

Metal	Irradiated	CH_4 [ppm]	C_2H_6 [ppm]
Fe^0 (synth)	+	2600	152
	−	14	
Ni^0 (synth)	+	25000	606
	−	18	

[a] Gas product composition in reaction of 10 g activated nanoparticle metal powders with 2.5 mL N_2O saturated solution containing 0.05 M $(CH_3)_2SO$ solution, pH 4.0, t = 3 hours (2 h of radiation, 480 Gy), $T = 25$ °C. Error limit ± 15%.

Finally it should be pointed out that:

1. Methyl radicals which are strong reducing and oxidizing agents[15,16] oxidize Cr^0, Mn^0, Fe^0, Ni^0 and Zn^0 powders. The products of these reactions are methane and the corresponding $M^{2+}_{(aq)}$ ions. The analogous reaction with Cu^0 powders probably yields methanol and dihydrogen.

2. As the radicals formed in the dehalogenation reaction 1 are formed in the vicinity of the metal surface, it is clear that, since reaction 9 is fast, reaction 1 is followed by reaction 9.

3. The results suggest that if radioactive wastes are stored as aqueous solutions containing organic materials in metal containers, the formation of alkyl radicals will contribute to the corrosion of the container.

Experimental Section

The sources and properties of the metal powders used in this study are summed up in the footnotes of Table 4. All other chemicals were of AR grade and were used without further purification. The water used was deionized water, which was further purified by a Millipore Milli-Q setup with a final resistivity of > 10 MΩ. The solutions were deaerated by bubbling with N_2O (He was used for studying alkane formation during the dissolution of analytical metals in aqueous solutions) for 15 min using the syringe technique. Then 2.5 mL of the solution were added to a glass bulb (15 mL) sealed with a rubber septum containing 10 g of the metal powder, which was previously activated by H_2SO_4 (0.1 M) for two minutes and then washed 7−8 times by 8 mL portions of water. This bulb was also deaerated by N_2O (or He was used for studying alkane formation during the dissolution of the analytical metals in aqueous solutions) prior to the injection of the solution.

After three hours of reaction the gas phase above the metal was analyzed using an HP 5890 GC fitted with a FID detector (Poropaq QS GC column 10Ft 1/8 in, Supelco). The carrying gas was He (30 mL/min, $T = 70$ °C). Hydrogen was determined using a TCD detector (12 mL/min of N_2, 40 °C). Some of the samples were irradiated for two hours, within the three hour time span, in a ^{60}Co γ source with a dose rate of 4 Gy/min.

The Fe^{II} yield was measured using a colorimetric procedure based on *ortho*-phenanthroline.[39]

The amount of carbon in the metals was determinate using a Carbon-Elementary Analyzer, of LECO.

Metal nanoparticles were synthesized was by reducing $M^{II}/M^{III}_{(aq)}$ ions with $NaBH_4$ in He-saturated aqueous solutions.[40,41]

Formation of Radicals with Ionizing Radiation: When ionizing radiation (γ -radiation) is absorbed by a dilute aqueous solution, the following initial products are formed:[42]

$$\textbf{(10)}\ H_2O \xrightarrow{\gamma,\ e^-} \cdot H\ (0.60), \cdot OH\ (2.65), e^-_{aq}\ (2.65), H_2O_2\ (0.75), H_2\ (0.45)$$

where the G values are given in parentheses (G values are defined as the number of molecules of each product per 100 eV of radiation absorbed by the solution). In concentrated solutions the yields of the radicals are somewhat higher while those of H_2O_2 and H_2 are somewhat lower. In N_2O-saturated solutions the hydrated electron is converted into the hydroxyl radical:[43]

$$\textbf{(11)}\ e^-_{aq} + N_2O \xrightarrow{H^+} N_2 + \cdot OH \qquad k = 8.7 \times 10^9\ M^{-1}\ s^{-1}$$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

At pH > 3 the solvated electrons will all react with N_2O yielding ·OH as the major radical.

Preparation of the $\cdot CH_3$ Radicals: The methyl radicals were formed[44] via the following reactions in N_2O-saturated solutions:

(12) $\cdot OH + (CH_3)_2SO \longrightarrow (CH_3)_2S^{\cdot}(O)OH \qquad k = 7.0 \times 10^9\ M^{-1}\ s^{-1}$

(13) $(CH_3)_2S^{\cdot}(O)OH \longrightarrow (CH_3)_2S(O)OH + \cdot CH_3 \quad k = 1.5 \times 10^7\ M^{-1}\ s^{-1}$

Heterotrimetallic Complexes $[\{Pt(RNH_2)_2(\mu\text{-}NHCOtBu)_2\}_2M](ClO_4)_n$ (M = Mn, Co, Cu, Ni, Cd, and Zn, n = 2; M = In, n = 3), $[\{Pt(NH_3)(\mu\text{-}DACHCOtBu)(\mu\text{-}NHCOtBu)\}_2Ni](ClO_4)_2$, and $[\{Pt(RNH_2)_2(NHCOtBu)_2\}_3Ag_3](ClO_4)_3$ Bridged by Amidate Ligands: A Novel Amidate−Amine Interligand Reaction During the Pt−Ni Bond Formation

Wanzhi Chen,[a] Fenghui Liu,[a] Takuya Nishioka,[a] and Kazulo Matsumoto*[a]

Keywords: Platinum / Amidate ligand / Metal−metal interaction / Heterotrimetallic complexes / Nickel

The neutral square-planar complexes $[Pt(NH_2CH_2CH_2OCH_3)_2(NHCOtBu)_2]$, $[Pt(DACH)(NHCOtBu)_2]$ (DACH = *trans*-1,2-diaminocyclohexane), and $[Pt(NH_2CH_2CH_2NMe_2)(NHCOtBu)_2]$ have been prepared by hydrolysis of the corresponding $[Pt(RNH_2)_2(NCtBu)_2](ClO_4)_2$ with NaOH. Reactions of $[Pt(RNH_2)_2(NHCOtBu)_2]$ with metal ions afforded Pt–M–Pt clusters $[\{Pt(RNH_2)_2(\mu\text{-}NHCOtBu)_2\}_2M](ClO_4)_n$ (M = Mn, Co, Cu, Ni, Cd, Zn, and In; n = 2 or 3) and $[\{Pt(NH_2CH_2CH_2NMe_2)(\mu\text{-}NHCOtBu)_2\}_2M](ClO_4)_2$ (M = Co, Ni). The Pt_2M (M = Mn, Co, Cu, Ni, Zn, and In) complexes consist of a linear Pt–M–Pt core bridged by four pivalamidate ligands. The Pt–M–Pt angles are 180° or nearly so. The central metal ions with an octahedral geometry are coordinated by four equatorial amidate oxygen atoms and two platinum atoms occupy the axial site. One of the two *t*-BuCO group shifts to the neighboring nitrogen atom of DACH (DACH = *trans*-1,2-diaminocyclohexane) in the reaction of $[Pt(DACH)(NHCOtBu)_2]\cdot 4H_2O$ with Ni^{2+} to generate the unexpected $[\{Pt(NH_3)(DACHCOtBu)(\mu\text{-}NHCOtBu)\}_2Ni](ClO_4)_2$. The central Cd ion in $[\{Pt(RNH_2)_2(\mu\text{-}NHCOtBu)_2\}_2Cd](ClO_4)_2$ is trigonal-bipyramidal and the Pt–Cd–Pt is bent. Treatment of $[Pt(NH_2CH_2CH_2OCH_3)_2(NHCOtBu)_2]$ with an equimolar amount of $AgClO_4$ yielded the Pt_4Ag_3 cluster consisting of alternate Pt and Ag atoms either doubly or singly bridged by amidate ligands. The spectroscopic and electrochemical studies show that the metal–metal interactions between platinum and the heterometal ions are very weak.

Introduction

Heteronuclear metal complexes of linearly arranged metal arrays with metal−metal bonds may act as multifunctional catalysts for organic transformation processes and multifunctional materials with versatile physical and chemical properties.[1−6] Heterometallic cluster systems involving platinum(II) and other metal ions of d^{10} and s^2 electronic configuration exhibit unique physicochemical properties such as luminescence based on the d^8 and the closed-shell metal−metal interactions, and have potential applications in chemical devices. The metallophilic interactions are important in determining the solid-state structures and also contribute to the properties of such complexes in solution. Many complexes containing Pt−M bonds, such as $Pt^{II}-Cu^{I}$,[3,4] $Pt^{II}-Cd^{II}$,[7] and $Pt^{II}-Tl^{I}$,[2,7−9] display intense luminescence that is correlated with the metal−metal bonds through metallophilic interactions.[10]

We have found that amidate-bridged dimeric Pt^{III} complexes are efficient catalysts for the epoxidation and dihydroxylation of olefins and can activate the C−H bonds of ketones.[11] The versatile role of transition metal ions of the first row in many organic oxidation reactions suggests it would be of interest to prepare amidate-bridged heterometallic complexes having various Pt−M bonds.

The electron-rich platinum atom in $[Pt(RNH_2)_2(NHCOR')_2]$ can act as a soft base through donating its d_{z^2} electrons to transition metal ions to form Pt−M bonds. Heterometallic Pt−M (M = Mn, Co, Ni, Cu) complexes are potentially useful reagents or catalysts for some organic oxidation processes since the role of these metals in oxidation reactions is well known. Few examples of symmetrical heterotrinuclear Pt−M−Pt complexes have been reported.[2,6] We reported recently that reactions of $[Pt(NH_3)_2(NHCOtBu)_2]$ with M^{2+} (M = Mn, Fe, Co, Ni, and Cu) ions afforded trinuclear complexes $[\{Pt(NH_3)_2(NHCOtBu)_2\}_2M]^{n+}$ exclusively.[6] The present work examines how different substituents on the amine ligands alter the metal−metal interactions and the possibility of obtaining new cluster compounds by introducing additional functional groups such as MeO and Me_2N. The

compound $[Pt(RNH_2)_2(NHCOR')_2]$ is expected to have better donating abilities than $[Pt(NH_3)_2(NHCOR')_2]$. To further investigate such metal−metal bonds, we describe herein the synthesis and structural characterization, including X-ray diffraction analysis, of the trinuclear complexes $[\{Pt(DACH)(\mu\text{-}NHCOtBu)_2\}_2M](ClO_4)_n$ (M = Cu, Co, Mn, and Cd, n = 2; M = In, n = 3), $[\{Pt(\mu\text{-}DACHNHCOtBu)(\mu\text{-}NHCOtBu)\}_2Ni](ClO_4)_2$, $[\{Pt(NH_3)_2(\mu\text{-}NHCOtBu)_2\}_2M](ClO_4)_n$ (M = Cd, n = 2; M = In, n = 3), $[\{Pt(NH_2CH_2CH_2NMe_2)(\mu\text{-}NHCOtBu)_2\}_2M](ClO_4)_2$ (M = Co, Ni), $[\{Pt(NH_2CH_2CH_2OCH_3)_2(\mu\text{-}NHCOtBu)_2\}_2M](ClO_4)_2$ (M = Co, Zn), and heptanuclear $[\{Pt(NH_2CH_2CH_2OCH_3)_2(\mu\text{-}NHCOtBu)_2\}_4Ag_3](ClO_4)_2\cdot 2H_2O$. The electrochemistry of the trinuclear heterometallic complexes as well as their parent platinum complexes has also been studied.

Results and Discussion

Synthesis and Spectroscopic Characterization

The complexes synthesized are depicted in Schemes 1−3. $[Pt(DACH)(NHCOtBu)_2]$ (**2**), $[Pt(NH_2CH_2CH_2OCH_3)_2(NHCOtBu)_2]$ (**3**), and $[Pt(NH_2CH_2CH_2NMe_2)(NHCOtBu)_2]$ (**4**) were easily prepared by basic hydrolysis of the corresponding $[Pt(RNH_2)_2(NCtBu)_2]^{2+}$ in good yields.[12] The heteronuclear complexes **5**−**17** were readily obtained by mixing $[Pt(RNH_2)_2(NHCOtBu)_2]$ and the corresponding metal salts in water or water/acetone. Regardless of the Pt/M ratio used, the trinuclear Pt_2M (M = Mn, Co, Ni, Cu, Zn, Cd, and In) complexes were exclusively obtained in high yields. Attempts to prepare dimeric Pt−M complexes by using a large excess of M ions were unsuccessful. All the compounds were characterized by elemental analyses.

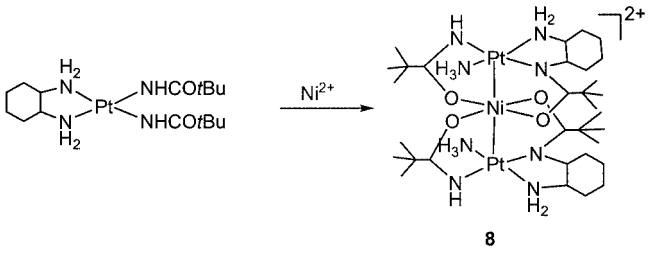
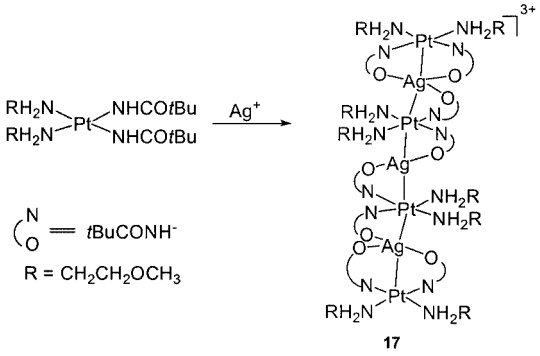
15, RNH_2 = $NH_2CH_2CH_2OCH_3$, M = Zn^{2+}
16, RNH_2 = $NH_2CH_2CH_2OCH_3$, M = Co^{2+}

Scheme 1



Scheme 2



Scheme 3

The reaction of $[Pt(DACH)(NHCOtBu)_2]$ (**2**) and Ni^{2+} under the same conditions did not afford the expected Pt−Ni−Pt complex $[\{Pt(DACH)(\mu\text{-}NHCOtBu)_2\}_2Ni]^{2+}$, but, instead, $[\{Pt(NH_3)(\mu\text{-}DACHCOtBu)(\mu\text{-}NHCOtBu)\}_2Ni]^{2+}$ (**8**) through migration of a BuCO group to the DACH ligand (Scheme 2).

The oligomeric Pt_4Ag_3 complex $[\{Pt(NH_2CH_2CH_2OCH_3)_2(\mu\text{-}NHCOtBu)_2\}_4Ag_3](ClO_4)_2\cdot 2H_2O$ (**17**) was isolated as colorless crystals when $[Pt(NH_2CH_2CH_2OCH_3)_2(NHCOtBu)_2]$ was treated with 1 equiv. of $AgClO_4$ in water (Scheme 3). The compound is moderately soluble in acetone and ethanol and is light-sensitive. Silver(I) tends to form platinum(II)−silver(I) coordination polymers, which have been studied.[13,14]

The ^{195}Pt NMR resonances of $[Pt(DACH)(NCtBu)_2](ClO_4)_2$ (**1**) and $[Pt(DACH)(NHCOtBu)_2]$ (**2**) in [D_6]acetone appear at δ = −2857 and −2625 ppm as singlets, respectively, which are typical for a PtN_4 coordination sphere.[12,15] Both the ^1H NMR spectra of $[\{Pt(DACH)(\mu\text{-}NHCOtBu)_2\}_2In](ClO_4)_3\cdot(CH_3)_2CO$ (**9**) and $[\{Pt(DACH)(\mu\text{-}NHCOtBu)_2\}_2Cd](ClO_4)_2$ (**10**) in [D_6]DMSO show two sets of signals corresponding to the NH protons of amidate ligands, and four sets of signals each corresponding to two NH_2 protons of *trans*-1,2-diaminocyclohexane, respectively, indicating that these protons are magnetically unequal. Simultaneously, the ^1H NMR spectra exhibit two singlets (1:1) assigned to *t*Bu protons for **10**. Singlets at δ = −2429 (**9**) and −2562 ppm (**10**) appear in their ^{195}Pt NMR spectra. The ^1H NMR spectrum of $[\{Pt(NH_3)_2(\mu\text{-}NHCOtBu)_2\}_2In]^{3+}$ (**11**) consists of singlets at δ = 6.46, 4.12, 2.06, and 1.10 ppm assignable to NH, NH_3, $(CH_3)_2CO$, and *t*Bu, respectively. The ^1H NMR spectrum of $[\{Pt(NH_3)_2(\mu\text{-}NHCOtBu)_2\}_2Cd](ClO_4)_2$ (**12**) exhib-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

its signals at δ = 5.42, 4.51, and 1.06 ppm due to NH_3, NH, and *t*Bu groups. The ^{195}Pt NMR spectra of **11** and **12** show singlets at δ = −2474 and −2561 ppm, respectively. No Pt−Cd coupling was observed. For comparison, the ^{195}Pt resonance of the starting compound $[Pt(NH_3)_2(NHCOtBu)_2]\cdot 2H_2O$ appears at δ = −2428 ppm in [D_6]DMSO. The change in chemical shifts of NH and NH_3 between complexes **11**, **12**, and $[Pt(NH_3)_2(NHCOtBu)_2]$ is clearly due to the complexation of Pt. Spin−spin coupling between ^{195}Pt and ^{113}Cd was not observed for the two cadmium complexes, probably because the interaction between the two metals is too weak. The small variation in ^{195}Pt chemical shifts compared to their parent platinum complexes suggests that the metal−metal interactions are weak in **9**−**12**.

The IR spectra of the trinuclear Pt_2M complexes **5**−**16** are very similar to their parent platinum compounds. There are two bands at $\tilde{\nu}$ = 3400 and 3245 cm^{-1} assignable to ν(N−H) of amine and amidate groups, respectively. The amidate bands at $\tilde{\nu}$ = 1556 ($[Pt(NH_3)_2(NHCOtBu)_2]$), 1562 (**2**), 1568 (**3**), and 1560 cm^{-1} (**4**) are assignable to the carbonyl stretching of the amidate ligands and are in the typical range of amidate anions. The δ(N−H) bands appear as shoulder peaks at $\tilde{\nu} \approx 1600$ cm^{-1}. The amide vibrations are only slightly shifted due to the complexation of the transition metal ions, and appear in the narrow range $\tilde{\nu}$ = 1562−1569 cm^{-1}. The carbonyl stretching band of the oligomeric Pt−Ag complex **17** shifts to a lower wavenumber, $\tilde{\nu}$ = 1531 cm^{-1}, showing enhanced electron delocalization within the amidate group. The skeletal vibrations at $\tilde{\nu}$ = 1481−1490 cm^{-1} and δ(NCO) bands at $\tilde{\nu} \approx 600$ cm^{-1} of $[Pt(RNH_2)_2(NHCOtBu)_2]$ complexes are essentially unaffected by heterometal coordination. These observations are consistent with the reported amidate complexes.[14]

Structure of $[\{Pt(RNH_2)(\mu\text{-}NHCOtBu)_2\}_2M](ClO_4)_2$ (M = Mn, Co, and Cu)

A few trimeric Pt_2M complexes derived from $[Pt(NH_3)_2(NHCOtBu)_2]$ have been described.[6] The compounds $[\{Pt(DACH)(\mu\text{-}NHCOtBu)_2\}_2M]^{2+}$ (M = Mn, **5**; Co, **6**, Cu **7**), $[\{Pt(NH_2CH_2CH_2NMe_2)(\mu\text{-}NHCOtBu)_2\}_2Co]^{2+}$ (**13**), and $[\{Pt(NH_2CH_2CH_2OCH_3)_2(\mu\text{-}NHCOtBu)_2\}_2Co]^{2+}$ (**16**) have essentially the same structures (Figures 1−5), and are discussed together below. Selected bond lengths and bond angles are given in Table 1. Overall, despite the different space groups, compounds **5**−**7**, **13**, and **16** have essentially the same structure, which consists of the trimetallic Pt−M−Pt (M = Mn, Co, and Cu) cations. Within the cations the heterometal ions are located at the center, and the three metal atoms are held together through Pt−M interactions and four bridging pivalamidate ligands. The Pt−N distances range from 1.985(8) to 2.052(10) Å, which are normal. The N−Pt−N angles indicate that the geometry about the platinum atom is square-planar. The O−M−O angles suggest that the geometry about the central metal atoms is slightly distorted from an octahedron. The sum of the neighboring O−M−O angles is, or is close to, 360°. The two platinum atoms within a cation sit above and below the coordination planes of MO_4 with Pt−M−Pt angles of 180° or nearly so. The cyclohexyl rings exhibit pseudo-coplanarity due to their disorder.

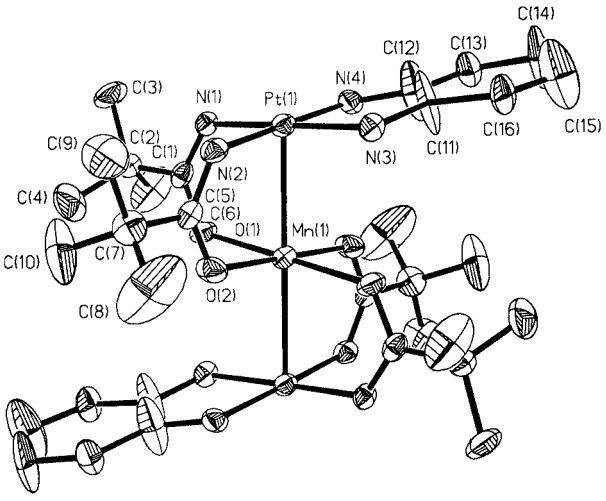


Figure 1. ORTEP plot of $[\{Pt(DACH)(\mu\text{-}NHCOtBu)_2\}_2Mn]^{2+}$ (**5**) with thermal ellipsoids plotted at 30% probability level

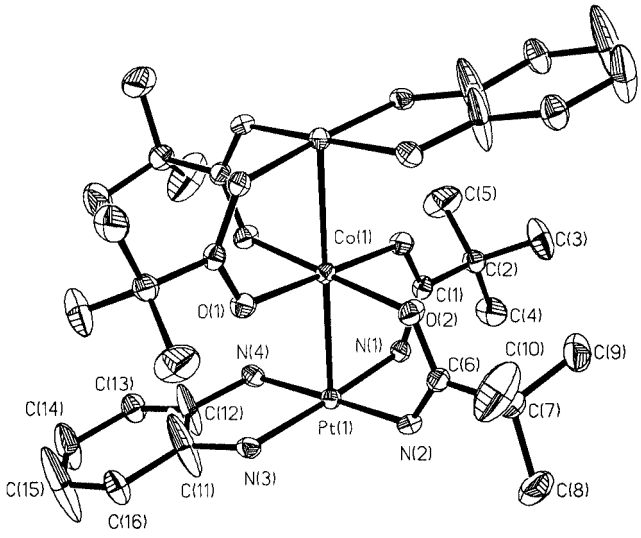

Figure 2. ORTEP plot of $[\{Pt(DACH)(\mu\text{-}NHCOtBu)_2\}_2Co]^{2+}$ (**6**) with thermal ellipsoids plotted at 30% probability level

The Pt−Mn distances [2.643(3) Å] of **5** are shorter than those found in $[\{Pt(NH_3)_2(\mu\text{-}MeT)_2\}_2Mn]^{2+}$ (MeT = 1-methylthymine) [2.704(1) Å], which has a similar Mn^{II} coordination geometry.[16] The Pt−Mn distances of **5** are also shorter than that in $[(dppe)(CH_3)PtMn(CO)_5]$ [2.795 Å] which contains a typical Pt−Mn covalent single bond.[17] The Pt−Cu distances in **7** are 2.6529(8) Å, which are shorter than that in both the PtCu dimer *cis*-$[(NH_3)_2Pt(1\text{-}MeU)_2Cu(H_2O)_2]^{2+}$ [2.756(3) Å] and the Pt_2Cu trimer *cis*-$[(NH_3)_2Pt(1\text{-}MeU)_2Cu(1\text{-}MeU)_2Pt(NH_3)_2]^{2+}$ [2.681(1) Å, 1-MeU = 1-methyluracilato],[18] and much shorter than those in the platinum−copper complexes bridged by alkynyl ligands.[19]

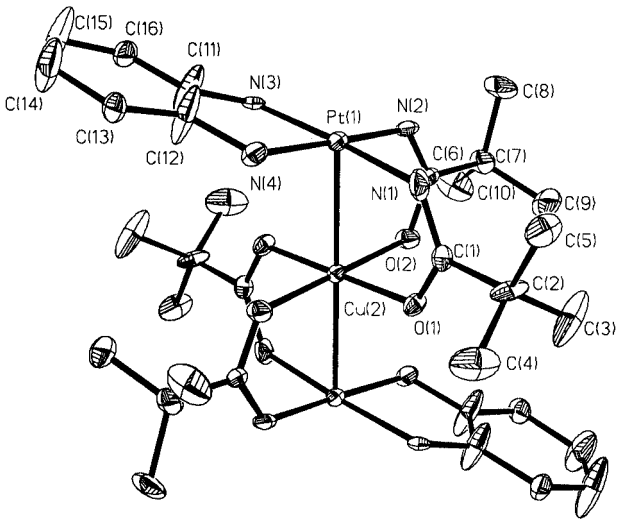

Figure 3. ORTEP plot of $[\{Pt(DACH)(\mu\text{-}NHCO\textit{t}Bu)_2\}_2Cu]^{2+}$ (**7**) with thermal ellipsoids plotted at 30% probability level

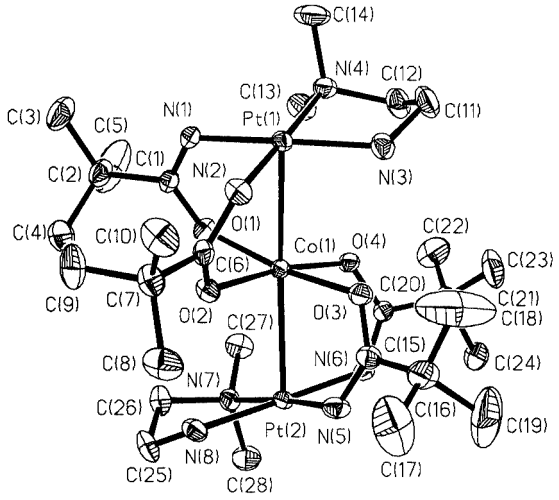

Figure 4. ORTEP plot of $[\{Pt(NH_2CH_2CH_2NMe_2)(\mu\text{-}NHCO\textit{t}Bu)_2\}_2Co]^{2+}$ (**13**) with thermal ellipsoids plotted at 30% probability level

The Pt−Co bonds of **13** [2.6902(10) and 2.6830(9) Å] are slightly longer than those of **6** [2.6087(6) Å] and **16** [2.6031(7) Å] because of the large steric hindrance of the NMe_2 groups. They are also longer than those in the Pt−Co clusters $[PtCo_2(CO)_7(cod)]$ [2.515(1) and 2.514(1) Å] and $[Pt_2Co_2(CO)_8(\mu_3\text{-}EtC_2Et)]$ [2.551(1) and 2.556(1) Å],[20] and in the $(Ph_2P)_2NH$-bridged Pt−Co carbonyl complexes [2.531(2)−2.508(2) Å],[21] indicating weak metal−metal interactions in the amidate-bridged platinum−cobalt complexes **6**, **13**, and **16**.

Structures of 8 and 14

When compound **2** was treated with Ni^{2+} in H_2O/acetone under the same conditions as for **5**−**7**, the expected product $[\{Pt(DACH)(\mu\text{-}NHCO\textit{t}Bu)_2\}_2Ni](ClO_4)_2$ was not obtained, but, instead, $[\{Pt(NH_3)(\mu\text{-}DACHCO\textit{t}Bu)(\mu\text{-}NHCO\textit{t}Bu)\}_2Ni](ClO_4)_2$ (**8**) was isolated in high yield as light green crystals, the structure of which was revealed by X-ray diffraction analysis (Figure 6). One of the two *t*BuCO groups shifts to the adjacent nitrogen atom of 1,2-diaminocyclohexane. This rearrangement is remarkable since the large *t*BuCO group and two hydrogen atoms have to exchange simultaneously. The most striking feature of compound **8** is that, although it has the same linear Pt−M−Pt arrangement, the two amidate bridging ligands are *trans* about the platinum atom. The Pt−Ni distance, 2.5750(14) Å, is slightly shorter than for the closely related trinuclear Pt_2Ni complex $[\{Pt(NH_3)_2(\mu\text{-}NHCO\textit{t}Bu)_2\}_2Ni](ClO_4)_2$.[6]

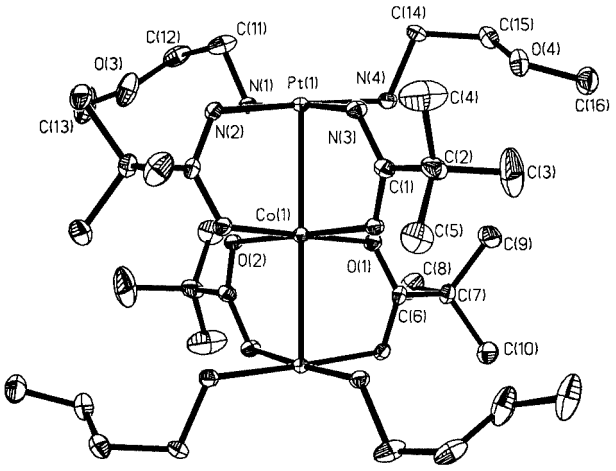

Figure 5. ORTEP plot of $[\{Pt(NH_2CH_2CH_2OCH_3)_2(\mu\text{-}NHCO\textit{t}Bu)_2\}_2Co]^{2+}$ (**16**) with thermal ellipsoids plotted at 30% probability level

Table 1. Important bond lengths [Å] and angles [°] of **5**−**9** and **11**−**17**

	M ion	Pt−M	Pt−M−Pt
5	Mn^{2+}	2.643(3)	180.0
6	Co^{2+}	2.6087(6)	180.0
7	Cu^{2+}	2.6529(8)	180.0
8	Ni^{2+}	2.5750(14)	179.48(17)
9	In^{3+}	2.6358(8)	180.0
11	In^{3+}	2.6422(6), 2.6278(6)	174.78(3)
12	Cd^{2+}	2.8156(9), 2.8196(9)	145.50(3)
13	Co^{2+}	2.6830(9), 2.6902(10)	168.13(2)
14	Ni^{2+}	2.6466(9), 2.6544(10)	169.33(2)
15	Zn^{2+}	2.5932(5)	180.0
16	Co^{2+}	2.6031(7)	180.0
17	Ag^{+}	2.8203(14), 2.8531(14), 2.9161(7)	167.52(6), 180.0

The rearrangement reaction is not generally seen, as illustrated by the isolation and characterization of $[\{Pt(NH_3)_2(\mu\text{-}NHCO\textit{t}Bu)_2\}_2Ni](ClO_4)_2$[6] and $[\{Pt(NH_2CH_2CH_2NMe_2)(\mu\text{-}NHCO\textit{t}Bu)_2\}_2Ni](ClO_4)_2$ (**14**). Both **14** and **15** are the expected Pt_2Ni products. The amine exchange reaction between a free amine and an acetamide is well known, unlike the migration of the BuCO group. It is not clear why such a rearrangement occurs only for complex **8**. The structure of **14** is shown in Figure 7. Because of the steric hindrance of the NMe_2 units, the Pt−Ni distances [2.6466(9), 2.6544(10) Å] of **14** are longer than those of **8**

[2.5750(14) Å], and the Pt−Ni−Pt vector [169.33(2)°] is more bent.

Structure of 15

The trinuclear Pt_2Zn complex $[\{Pt(NH_2CH_2CH_2OMe)_2(\mu\text{-}NHCO\textit{t}Bu)_2\}_2Zn]^{2+}$ (**15**) was isolated as colorless crystals, and its structure is shown in Figure 8. Similar to other heteronuclear Pt_2M (M = Mn, Co, Ni, Cu) complexes, **15** contains a linear trimetallic core, in which Pt and Zn are doubly bridged by the amidate ligands. The methoxy groups remain uncoordinated. The Pt−Zn bond lengths are 2.5932(5) Å — comparable to the sum of covalent radii of the two metals (2.55 Å). Heteronuclear complexes containing direct Pt−Zn interaction have not been reported, but PtZn alloys are known catalysts for the dehydrogenation of alkanes.[22]

Structure of 12

The platinum−cadmium complex $[\{Pt(NH_3)_2(\mu\text{-}NHCO\textit{t}Bu)_2\}_2Cd]^{2+}$ (**12**) crystallizes in the space group $P2_1/n$. Its structure is shown in Figure 9. The platinum and cadmium centers are held together by four amidate ligands, which act as bridging units via their NCO groups. Unlike the analogous Pt_2Zn compound, the central Cd atom adopts tetrahedral geometry, which is completed by the four amidate oxygen atoms, or bicapped tetrahedron when the two rather long Pt−Cd contacts are also considered. The Pt−Cd distances [2.8156(9) and 2.8196(9) Å] are close to the sum of the metallic radii of platinum and cadmium (2.88 Å), indicating some Pt−Cd interaction. However, the Pt−Cd distances in **12** are much longer than the Pt−Cd dative bonds [2.6389(8) and 2.6101(8) Å] found in the complexes $[\{Pt(phpy)_2\}\{Cd(cyclen)\}](ClO_4)_2$ and

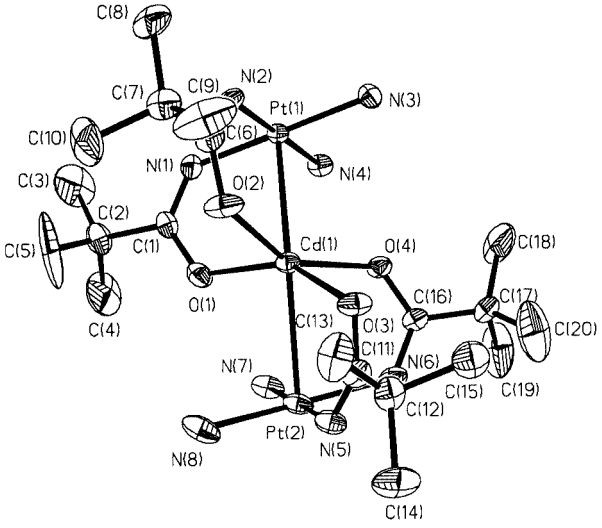

Figure 9. ORTEP plot of $[\{Pt(NH_3)_2(\mu\text{-}NHCO\textit{t}Bu)\}_2Cd]^{2+}$ (**12**) with thermal ellipsoids plotted at 30% probability level

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[{$PtMe_2$(bipy)}{Cd(cyclen)}]$(ClO_4)_2$ (Hphpy = 2-phenylpyridine, bipy = 2,2′-bipyridine; cyclen = 1,4,7,10-tetraazacyclododecane).[23] Pt−Cd distances in **12** are much shorter than those in $(NBu_4)_2$[{Pt(μ-C≡CPh)$_4$}$_2$($CdCl_2$)] [2.960(1) Å][24] and [Pt_4Cd_6(C≡CPh)$_4$(μ-C≡CPh)$_{12}$(μ$_3$-OH)$_4$] [2.8570(14)−3.2234(8) Å].[25] The Pt−Cd−Pt is bent [145.50(3)°]. The Cd−O distances fall in the range 2.214(8)−2.263(9) Å, which are not unusual.[25]

Structures of 9 and 11

[{Pt(DACH)(μ-NHCO*t*Bu)$_2$}$_2$In]$^{3+}$ (**9**) crystallizes in a triclinic space group $P\bar{1}$, whereas [{Pt(NH_3)$_2$(μ-NHCO*t*Bu)$_2$}$_2$In]$^{3+}$ (**11**) crystallizes in a chiral orthorhombic space group $P2_12_12_1$. The indium(III) ions in both **9** and **11** are approximately octahedrally coordinated by four equatorial oxygen atoms of the amidate ligands, and two platinum atoms occupy the axial sites. The structures of **9** and **11** are shown in Figures 10 and 11, respectively. The indium atom and the four oxygen atoms are almost co-planar, with the sum of the neighboring O−In−O angles being 360°. The Pt−In bond lengths are 2.6358(8) Å for **9** and 2.6279(8) and 2.6412(8) Å for **11**. The Pt−In−Pt angle for **9** is 180°, whereas that of **11** (174.81°) deviates slightly from 180°. The two [Pt(RNH_2)$_2$($NHCOtBu$)$_2$] units maintain a square-planar geometry.

The In−O bonds of **9** [2.128(6)−2.167(6) Å] and **11** [2.128(6)−2.16786] Å] are only slightly longer than those in the indium alkoxide complexes [In(μ-OR)(OR)$_2$]$_2$ (R = *t*Bu, CMe_2Et, $CMeEt_2$, and CMe_2iPr) [1.985(4)−2.152(6) Å].[26] Platinum−indium heterometallic complexes containing Pt−In donor−acceptor interactions have been rarely studied. The Pt−In distances of **9** and **11** are similar to those in $LaPtIn_3$ (Pt−In, 2.694 Å),[27] [{$Cy_2P(CH_2CH_2)PCy_2$}Pt(InR_2)(R)] (R = CH_2SiMe_3, Pt−In, 2.601 Å),[28] but longer than those in [Pt{$InC(SiMe_3)_3$}$_4$] (2.441 Å).[29]

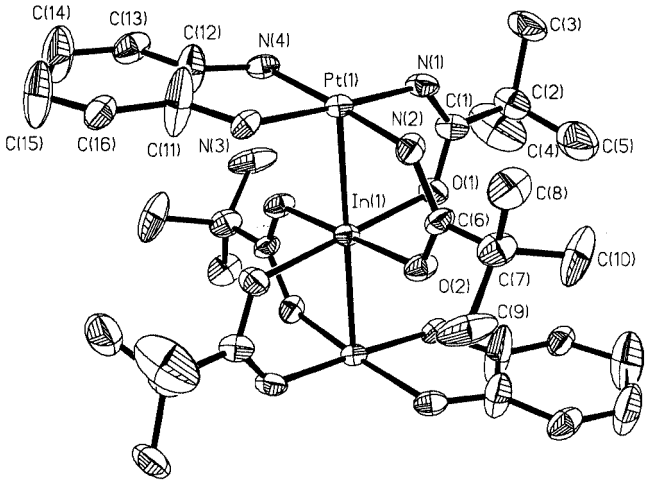

Figure 10. ORTEP plot of [{Pt(DACH)(μ-NHCO*t*Bu)$_2$}$_2$In]$^{3+}$ (**9**) with thermal ellipsoids plotted at 30% probability level

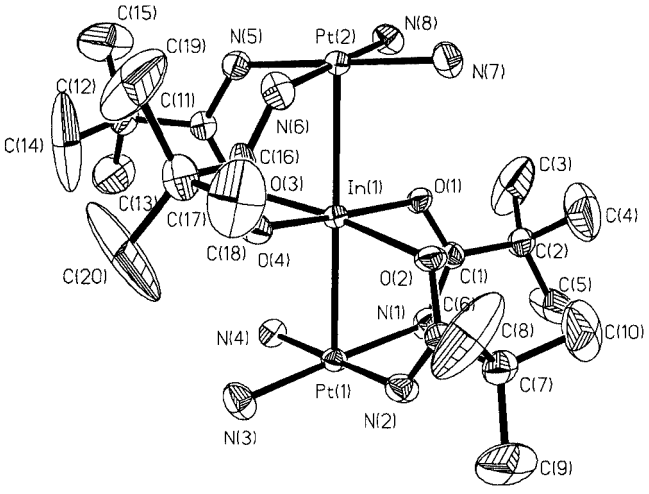

Figure 11. ORTEP plot of [{Pt(NH_3)$_2$(μ-NHCO*t*Bu)$_2$}$_2$In]$^{3+}$ (**11**) with thermal ellipsoids plotted at 30% probability level

Structure of 17

In the structure of the platinum−silver complex [{Pt($NH_2CH_2CH_2OCH_3$)$_2$(μ-NHCO*t*Bu)$_2$}$_4$$Ag_3$]$^{3+}$ (**17**) (Figure 12) the Pt_4Ag_3 cation is a chain of limited length, consisting of alternating Pt and Ag atoms bridged by amidate ligands. The metal−metal distances in the chain are 2.8203(14), 2.8531(14), and 2.9161(7) Å. There are two independent silver atoms, and Ag(2) is at the crystallographic inversion center. Ag(1) adopts a distorted trigonal-bipyramidal geometry with three amidate oxygen atoms at the equatorial positions and two Pt atoms occupying the two axial positions; the Pt(1)−Ag(1)−Pt(2) angle is 167.52(6)°. The coordination geometry around the Ag(2) atom is square-planar, and the Ag atom is linearly coordinated by two amidate oxygen and two Pt atoms, with a Pt(2)−Ag(2)−Pt(2a) angle of 180°. The Pt−Ag [2.8203(17), 2.8531(14), and 2.9161(7) Å] are close to those in other heteronuclear Pt−Ag complexes.[13] In contrast, the reaction

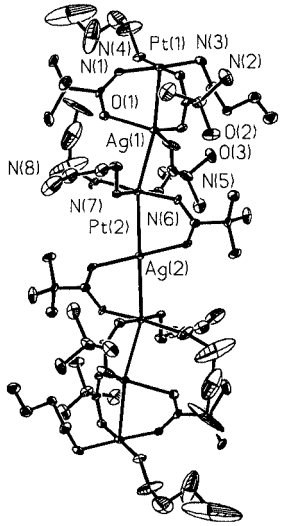

Figure 12. ORTEP plot of [{Pt($NH_2CH_2CH_2OCH_3$)-($NHCOtBu$)$_2$}$_4$$Ag_3$]$^{3+}$ (**17**) with thermal ellipsoids plotted at 30% probability level

of $AgNO_3$ with *trans*- and *cis*-$[Pt(NH_3)_2(NHCOMe)_2]$ yielded the heteronuclear polymeric complexes *cis*- and *trans*-$[(NH_3)_2Pt(NHCOMe)_2Ag]NO_3$, in which Pt and Ag atoms are all singly bridged by acetamidate ligands.[14]

Electrochemistry

Electrochemical data were obtained from freshly prepared nitrogen-purged DMSO, and CH_3CN, solutions of the trinuclear complexes, and for their parent platinum complexes. The cyclic voltammograms of all the compounds exhibit an irreversible oxidation, whose peak potentials in DMSO at 50 $mV \cdot s^{-1}$ are 0.50 ($[Pt(NH_3)_2(NHCOtBu)_2]$), 0.44 (**2**), ca. 0.48 (**3**), and 0.56 V (**4**) versus Fc/Fc^+. The electron-transfer behaviour of the trinuclear complexes **5**−**15** is essentially identical to that of the parent platinum complexes, which involve oxidation potentials in the range 0.41−0.49 V. Thus, the complexation of $[Pt(RNH_2)_2(NHCOtBu)_2]$ to a heterometal ions does not significantly change the platinum-based redox potentials. Obviously, metal−metal charge transfer is not important for these trinuclear complexes and the Pt−M interactions within **5**−**15** are very weak.

Conclusion

A number of amidate-bridged trinuclear complexes containing a trimetallic Pt−M−Pt core, either linear or bent, have been prepared in good yield by reactions between $[Pt(RNH_2)_2(NHCOtBu)_2]$ and the corresponding metal ions. The platinum units can bind heterometal ions through amidate oxygen atoms. The cyclic voltammograms, ^{195}Pt NMR spectra, and solid-state infrared spectra suggest that metal−metal interactions between platinum and the heterometals are limited. The short Pt−M distances of the Pt_2M (M = Mn, Co, Ni, Cu, Cd, Zn, and In) and Pt_4Ag_3 complexes, revealed by X-ray diffraction analyses, may be attributed to geometric requirement of the bridging amidate ligands, although attractions between the platinum and the heterometal ions could not be excluded. The two $[Pt(RNH_2)_2(NHCOtBu)_2]$ units and an M ion are held together mainly by the amidate functionality. The substituents on the amine ligands do not affect significantly the Pt−M interactions.

Experimental Section

General Remarks: $[Pt(NH_3)_2(NHCOtBu)_2]\cdot 2H_2O$[12] and $PtCl_2(DACH)$[30] were prepared according to the published procedure. All other chemicals were of A. R. grade and used as received. Elemental analyses were performed with a Perkin−Elmer PE 2400II analyzer. IR spectra as KBr pellets were recorded with a Perkin−Elmer 2000 spectrophotometer. ^1H and ^{195}Pt NMR spectra were recorded with a Bruker 500 MHz spectrometer. The NMR chemical shifts are given in ppm relative to TMS (^1H) and K_2PtCl_4 (^{195}Pt), and referenced either to residual solvent signals (^1H) or externally (^{195}Pt). UV/Vis spectra were recorded with a JASCO v-570 spectrophotometer. Cyclic voltammograms were obtained by use of a BAS CV-50 W instrument, in 10^{-5} M DMSO solutions containing 0.05 M $(Bu_4N)ClO_4$ as supporting electrolyte at a scan rate of 50 $mV \cdot s^{-1}$, and a three-electrode cell composed of an Ag/$AgNO_3$ reference electrode, a 3.0-mm glassy carbon working electrode, and a platinum counter electrode. The potentials were referenced to the ferrocenium/ferrocene couple.

$[Pt(DACH)(NCtBu)_2](ClO_4)_2\cdot H_2O$ (1): A suspension of $PtCl_2(DACH)$ (1.14 g, 3.0 mmol) in water (15 mL) was treated with $AgClO_4$ (1.24 g, 6.0 mmol), and the resultant mixture was stirred overnight in the dark. After removal of AgCl, *t*BuCN (1.0 g, 12.0 mmol) was added to the filtrate. The so-obtained white precipitate was then separated and washed with H_2O, EtOH, and Et_2O, and dried in air. Yield: 1.95 g (94%). $C_{16}H_{32}Cl_2N_4O_8Pt\cdot H_2O$ (692.45): calcd. C 27.75, H 4.95, N 8.09; found C 27.55, H 4.93, N 7.94. ^1H NMR (500 MHz, [D$_6$]acetone): δ = 1.20−2.75 (m, C_6H_{10}, 10 H), 3.01 (s, H_2O), 1.52 [s, $C(CH_3)_3$, 18 H] ppm. ^{195}Pt NMR (107.00 MHz, [D$_6$]acetone): δ = −2857.2 ppm.

$[Pt(DACH)(NHCOtBu)_2]\cdot 4H_2O$ (2): A suspension of **1** (1.45 g, 2.0 mmol) in water (10 mL) was treated with NaOH (0.20 g, 5.0 mmol). The resultant mixture was then stirred at room temperature overnight to give a white solid that was collected by filtration, washed with cold water, and dried in air. Yield: 1.12 g (96%). $C_{16}H_{34}N_4O_2Pt\cdot 4H_2O$ (581.61): calcd. C 33.04, H 7.28; N 9.63; found C 33.29, H 6.78, N 9.57. ^1H NMR (500 MHz, [D$_6$]DMSO): δ = 6.50, 4.65 (each d, $J_{H,H}$ = 9 Hz, NH_2, each 2 H), 5.59 (s, NH, 2 H), 3.38 (s, H_2O), 1.07 [s, $C(CH_3)_3$, 18 H], 2.21, 1.91, 1.51, 1.29, 1.10 (m, C_6H_{10}, each 2 H) ppm. ^{195}Pt (107.00 MHz, [D$_6$]DMSO): δ = −2625.2 ppm.

$[Pt(NH_2CH_2CH_2OCH_3)_2(NHCOtBu)_2]$ (3): This compound was isolated as a white hygroscopic solid according to the method described for **2**, but starting from $PtCl_2(NH_2CH_2CH_2OCH_3)_2$ (1.20 g, 2.0 mmol). Yield: 0.73 g (67%). $C_{16}H_{38}N_4O_4Pt$ (545.58): calcd. C 35.22, H 7.02, N 10.27; found C 34.89, H 7.46, N 9.72.

$[Pt(NH_2CH_2CH_2NMe_2)(NHCOtBu)_2]$ (4): As described for **3**, but starting from $PtI_2(NH_2CH_2CH_2NMe_2)$ (0.54 g, 1.0 mmol), compound **4** was isolated as a white hygroscopic solid. Yield: 0.20 g (42%). $C_{14}H_{32}N_4O_2Pt$ (483.51): calcd. C 34.78, H 6.67, N 11.59; found C 33.26, H 7.02, N 11.12; the elemental analysis is unsatisfactory due to the compound's hygroscopic properties. ^1H NMR (270.05 MHz, [D$_6$]acetone): δ = 5.21 (s, NH_2, 2 H), 4.89, 4.63 (both s, NH, each 1 H), 2.92, 2.74 (both t, CH_2, $J_{H,H}$ = 6.0 Hz, each 2 H), 2.83 [s, $N(CH_3)_2$, 6 H], 1.15, 1.05 [both s, $C(CH_3)_3$, each 9 H] ppm. ^{195}Pt (57.95 MHz, [D$_6$]DMSO): δ = −2657 ppm.

$[\{Pt(DACH)(\mu\text{-}NHCOtBu)_2\}_2Mn](ClO_4)_2\cdot 2(CH_3)_2CO$ (5): $[Pt(DACH)(NHCOtBu)_2]\cdot 4H_2O$ (58 mg, 0.10 mmol) in acetone (2 mL) was added to a solution of $MnCl_2\cdot 4H_2O$ (20 mg, 0.10 mmol) and $NaClO_4$ (50 mg) in water (2 mL). Pale-yellow crystals were grown by slow concentration of the resultant solution. Yield: 57 mg (81%). $C_{32}H_{68}Cl_2N_8O_{12}Pt_2Mn\cdot 2(CH_3)_2CO$ (1389.09): calcd. C 32.86, H 5.80, N 8.07; found C 32.73; H 5.91, N 7.94.

$[\{Pt(DACH)(\mu\text{-}NHCOtBu)_2\}_2Co](ClO_4)_2\cdot 2(CH_3)_2CO$ (6): This compound was prepared in a similar manner to **5** except that $Co(NO_3)_2\cdot 6H_2O$ (29 mg, 0.10 mmol) was used in place of $MnCl_2\cdot 4H_2O$. Yield: 60 mg (86%). $C_{32}H_{68}Cl_2N_8O_{12}Pt_2Co\cdot 2(CH_3)_2CO$ (1393.08): calcd. C 32.76, H 5.79, N 8.04; found C 32.94; H 6.02; N 7.87.

$[\{Pt(DACH)(\mu\text{-}NHCOtBu)_2\}_2Cu](ClO_4)_2$ (7): The method employed for compound **5** was used to prepare **7**, except that $Cu(ClO_4)_2\cdot 6H_2O$ (37 mg, 0.10 mmol) was used in place of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$MnCl_2·4H_2O$. Yield: 52.5 mg (82%). $C_{32}H_{68}Cl_2N_8O_{12}Pt_2Cu$ (1281.54): calcd. C 29.99, H 5.35, N 8.74; found C 30.03, H 5.15, N 8.67.

[{Pt(NH$_3$)(μ-DACHCO*t*Bu)(μ-NHCO*t*Bu)}$_2$Ni](ClO$_4$)$_2$ (8): Compound **8** was prepared in a similar manner as for **5** except that $Ni(NO_3)_2·6H_2O$ (29 mg, 0.10 mmol) was used instead of $MnCl_2·4H_2O$. Yield: 54 mg (84%). $C_{32}H_{68}Cl_2N_8O_{12}Pt_2Ni$ (1276.68): calcd. C 30.10, H 5.37, N 8.78; found C 30.06; H 5.35; N 8.66.

[{Pt(DACH)(μ-NHCO*t*Bu)$_2$}$_2$In](ClO$_4$)$_3$ (9): Here the method used to synthesize **5** was employed, with $In(NO_3)_3·6H_2O$ (41 mg, 0.10 mmol) in place of $MnCl_2·4H_2O$, to give **9** in 63% yield (45 mg). $C_{32}H_{68}Cl_3N_8O_{16}Pt_2In$ (1432.26): calcd. C 26.83, H 4.79, N 7.82; found C 26.79, H 4.68, N 7.68. ^{1}H NMR (500 MHz, [D$_6$]DMSO): δ = 6.85, 6.01 (both d, $J_{H,H}$ = 9.0 Hz, NH_2, each 2 H), 6.33, 6.30 (both s, NH, each 2 H), 5.70, 4.44 (both t, $J_{H,H}$ = 9.0 Hz, each 2 H), 1.01−2.72 (m, C_6H_{10}, 20 H), 1.12 [s, $C(CH_3)_3$, 36 H] ppm. ^{195}Pt (107.00 MHz, [D$_6$]DMSO): δ = −2439 ppm.

[{Pt(DACH)(μ-NHCO*t*Bu)$_2$}$_2$Cd](ClO$_4$)$_2$ (10): Compound **10** was prepared in a similar manner as for **3**, starting from $CdSO_4·6H_2O$ (32 mg, 0.10 mmol). Yield: 51 mg (76%). $C_{32}H_{68}Cl_2N_8O_{12}Pt_2Cd$ (1330.4): calcd. C 28.89, H 5.15, N 8.42; found C 28.45, H 5.30, N 8.36. ^{1}H NMR (500 MHz, [D$_6$]DMSO): δ = 6.06, 5.55, 5.38, 4.60 (all s, NH_2, each 2 H), 5.57, 5.41 (both s, NH, each 2 H), 1.40−2.73 (m, C_6H_{10}, 20 H), 1.13, 1.04 [both s, $C(CH_3)_3$, each 18 H] ppm. ^{195}Pt (107.00 MHz, [D$_6$]DMSO): δ = −2562 ppm.

[[Pt(NH$_3$)$_2$(NHCO*t*Bu)$_2$]$_2$In](ClO$_4$)$_3$·C$_3$H$_6$O (11): $[Pt(NH_3)_2(NHCOtBu)_2]·2H_2O$ (47 mg, 0.10 mmol) was added to a solution of $In(NO_3)_3·6H_2O$ (41 mg, 0.10 mmol) in H_2O (2 mL). The resultant colorless solution yielded a colorless precipitate immediately after subsequent addition of $NaClO_4$. Cooling at 5 °C overnight gave colorless crystals, which were filtered off and then washed with cold water, EtOH, and Et_2O. Yield: 53 mg (79%). $C_{20}H_{52}Cl_3InN_8O_{16}Pt_2·(CH_3)_2CO$ (1330.08): calcd. C 20.77, H 4.40, N 8.42; found C 20.39, H 4.25, N 8.58. ^{1}H NMR (500.00 MHz, [D$_6$]DMSO): δ = 6.46 (s, NH, 2 H), 4.13 (s, NH_3, 6 H), 2.07 [s, $(CH_3)_2CO$, 6 H), 1.10 [s, $C(CH_3)_3$, 18 H] ppm. ^{195}Pt NMR (107.30 MHz, [D$_6$]DMSO): δ = −2474 ppm.

[{Pt(NH$_3$)$_2$(μ-NHCO*t*Bu)$_2$}$_2$Cd](ClO$_4$)$_2$·2H$_2$O (12): This compound was obtained similarly to **11** by using the corresponding materials $Cd(NO_3)_2·4H_2O$ (24 mg, 0.10 mmol), $NaClO_4$ (50 mg, 0.43 mmol), and $[Pt(NH_3)_2(NHCOtBu)_2]·2H_2O$ (47 mg, 0.10 mmol). Yield: 51 mg (84%). $C_{20}H_{52}CdCl_2N_8O_{12}Pt_2·2H_2O$ (1206.18): calcd. C 19.92, H 4.68, N 9.29; found C 19.79, H 4.83, N 9.20. ^{1}H NMR (500.00 MHz, [D$_6$]DMSO): δ = 5.42 (br. NH_3, 12 H), 4.51 (br. NH, 4 H), 1.06 [s, $C(CH_3)_3$, 36 H] ppm. ^{195}Pt NMR (107.30 MHz, [D$_6$]DMSO): δ = −2561 ppm.

[{Pt(NH$_2$CH$_2$CH$_2$NMe$_2$)(μ-NHCO*t*Bu)$_2$}$_2$Co](ClO$_4$)$_2$·H$_2$O (13): Compound **13** was prepared by an analogous procedure to that of **6** but using **4** (48 mg, 0.10 mmol) and $Co(NO_3)_2·6H_2O$ (29 mg, 0.10 mmol) to isolate **13** as a blue solid. Yield: 50 mg (81%). $C_{28}H_{64}CoCl_2N_8O_{12}Pt_2·H_2O$ (1242.86): calcd. C 27.06, H 5.35, N 9.02; found C 27.30, H 5.30, N 9.20.

[{Pt(NH$_2$CH$_2$CH$_2$NMe$_2$)(μ-NHCO*t*Bu)$_2$}$_2$Ni](ClO$_4$)$_2$·H$_2$O (14): By a similar procedure to that used for **13**, but using $Ni(NO_3)_2·6H_2O$ (29 mg, 0.10 mmol), **14** was isolated as a green solid. Yield: 53 mg (86%). $C_{28}H_{64}Cl_2N_8NiO_{12}Pt_2·H_2O$ (1242.62): calcd. C 27.06, H 5.35, N 9.02; found C 26.93, H 5.47, N 8.96.

[{Pt(NH$_2$CH$_2$CH$_2$OCH$_3$)$_2$(μ-NHCO*t*Bu)$_2$}$_2$Zn](ClO$_4$)$_2$ (15): This compound was prepared as described for **5** but starting from **3** (55 mg, 0.10 mmol) and $Zn(ClO_4)_2·6H_2O$ (37 mg, 0.10 mmol), and was isolated as a white solid. Yield: 52 mg (76%). $C_{32}H_{76}Cl_2N_8O_{16}Pt_2Zn$ (1355.4): calcd. C 28.36, H 5.65, N 8.27; found C 28.34, H 5.42, N 8.05.

[{Pt(NH$_2$CH$_2$CH$_2$OCH$_3$)(μ-NHCO*t*Bu)$_2$}$_2$Co](ClO$_4$)$_2$ (16): Using the method described for **5**, but starting from **3** (55 mg, 0.10 mmol) and $Co(NO_3)_2·6H_2O$ (29 mg, 0.10 mmol), **16** was isolated as a blue solid in 78% yield (53 mg). $C_{32}H_{76}Cl_2CoN_8O_{16}Pt_2$ (1348.98): calcd. C 28.49, H 5.68, N 8.31; found C 28.22, H 5.79, N 8.20.

[{Pt(NH$_2$CH$_2$CH$_2$OCH$_3$)(NHCO*t*Bu)$_2$}$_4$Ag$_3$](ClO$_4$)$_3$·2H$_2$O (17): Compound **17** was prepared from **3** (55 mg, 0.10 mmol) and an equimolar amount of $AgClO_4$ (21 mg, 0.10 mmol) in water. Slow concentration of the resultant colorless solution yielded colorless crystals. Yield: 44 mg (63%). $C_{64}H_{152}Ag_3Cl_3N_{16}O_{28}Pt_4·2H_2O$ (2840.3): calcd. C 27.06, H 5.54, N 7.89; found C 26.82, H 5.63, N 7.45.

X-ray Crystallographic Study: Data collection was performed with a Bruker Smart-CCD diffractometer using monochromatized Mo-K_α radiation, λ = 0.71073 Å, at room temperature. Data reduction was performed using SAINT+ Version 6.02 software.[31] The data were corrected for absorption by using the program SADBAS within the SAINTPLUS package. Structures were solved by the direct method. This solution yielded metal atoms, N, O, and some C atoms. Subsequent Fourier synthesis gave the remaining C-atom positions. The hydrogen atoms were geometrically fixed and allowed to ride on their attached atoms, and refined with the XSHELL software.[32] The final refinement included anisotropic thermal parameters for all of the non-hydrogen atoms and converged to the *R*1 and *wR*2 values listed in Tables 2 and 3. The crystal data collection and refinement parameters are summarized in Tables 2 and 3. CCDC-187851 (**5**), -187852 (**6**), -187853 (**7**), -187854 (**8**), -187855 (**9**), -188637 (**11**), -188638 (**12**), -195593 (**13**), -195594 (**14**), -195595 (**15**), -195596 (**16**), and -195597 (**17**) contain the supplementary crystallographic data for this paper. Ruthenium(III) Complexes with a Phenolate-O, Imine-N, and Amide-O Coordinating Ligand: Syntheses, Structures, Properties, and Protonation Studies of Coordinated Amide

Satyanarayan Pal,[a] and Samudranil Pal*[a]

Keywords: Ruthenium / Acetylhydrazone / Crystal structures / Protonation / Redox chemistry

The reaction of *cis*-[$RuCl_2(dmso)_4$], *N*-(acetyl)-*N′*-(salicylidene)hydrazine (H_2acs), and KOH (1:2:2 molar ratio) in methanol under aerobic conditions produces a ruthenium(III) complex, [Ru(acs)(Hacs)]·H_2O. Addition of one mol equivalent of $HClO_4$ to this complex in methanol affords [$Ru(Hacs)_2$]ClO_4. On the other hand, reaction of one mol equivalent of KOH with [Ru(acs)(Hacs)]·H_2O in methanol produces K[$Ru(acs)_2$]. All three complexes have been characterised by elemental analyses, magnetic, spectroscopic, and electrochemical techniques. In solution, except for [Ru(acs)(Hacs)]·H_2O, the other two complexes are 1:1 electrolytes. Solid state magnetic moments (at 298 K) of the complexes are in the range 1.91–2.15 μ_B. These values reflect a spin state $S = 1/2$ and hence low-spin ruthenium(III) within each complex is observed. X-ray structures of [Ru(acs)(Hacs)]·H_2O and the tetraphenylphosphonium salt of [$Ru(acs)_2$]$^-$ have been determined. In both complexes, the ligands bind to the metal ion meridionally through the phenolate-O, the imine-N and the amide-O atoms. In [Ru(acs)(Hacs)]·H_2O, the amide functionality of one of the ligands is protonated, and in [PPh_4][$Ru(acs)_2$] the amide functionalities of both ligands are deprotonated. Electronic spectra of the complexes display ligand-to-metal charge-transfer bands in the range 626–699 nm. Cyclic voltammetry reveals a $Ru^{III} \rightarrow Ru^{IV}$ oxidation change in the potential range of 0.56–0.84 V (vs. SCE) for these complexes. The charge-transfer band positions and the oxidation potentials are significantly influenced by the protonation state of the O-coordinating amide functionality present in each ligand. The pK_a values of the coordinated amide functionalities have been determined by spectrophotometric titration.

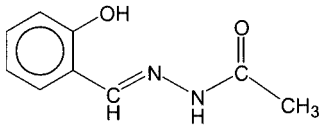
Introduction

The interest in ruthenium chemistry stems from its ability to have a wide range of oxidation states (−2 to +8) and various coordination geometries. Due to these characteristics complexes of ruthenium exhibit versatile electron-transfer properties and hence a wide range of reactivities.[1]



H_2acs

As a result a large variety of ruthenium complexes have been utilized in studies on artificial photosynthesis, photomolecular devices, elucidation of structural and electron-transfer properties of proteins and DNA, catalytic oxidation of water and organic substrates and stoichiometric as well as catalytic reactions for organic synthesis.[1l−1t] Due to such a broad array of applications there is a continuous pursuit for new complexes of ruthenium with diverse types of ligands. The primary objective is to tune the properties of the complex by alteration of the coordination geometry and the nature of the coordinating functionalities. Recently we have reported a series of ruthenium(II) bis complexes with a tridentate pyridine-N, imine-N, and amide-O donor deprotonated Schiff-base system, *N*-(aroyl)-*N′*-(picolinylidene)hydrazines.[2] In these complexes, the energy separation between the metal-dπ and ligand-π* level remains constant regardless of the variation in the polar effect of the substituent on the aroyl fragment of the ligand. In this report, we have explored the coordination chemistry of ruthenium with a similar kind of Schiff base *N*-(acetyl)-*N′*-(salicylidene)hydrazine (H_2acs, the two H′s representing the dissociable phenolic and amide protons). In the deprotonated state the Schiff base acs^{2-} can coordinate to a metal ion via the phenolate-O, the imine-N, and the deprotonated amide-O atoms forming a six- and a five-membered chelate ring. This type of coordination mode by acs^{2-} and similar ligands is known.[3] The reasons for the choice of this Schiff base are as follows: it contains high oxidation state promoting[4] phenolic hydroxy and amide functionalities; the O-coordinating amide functionality provides a rare opportunity to study the influence of the amide protonation state on the coordination geometry and physical properties of the complex, which is not easy for amide-N coordinated species. Herein, we describe three new ruthenium(III) bis-chelates with H_2acs. These complexes differ only in the protonation state

of the coordinated amide functionalities. Solid state molecular structures for two of these three complexes have been determined by X-ray crystallography In solution, dependence of the spectral and the redox features on the amide protonation state has been scrutinized.

Results and Discussion

Syntheses and Characterisation of the Complexes

The neutral complex [Ru(acs)(Hacs)] was isolated from a methanolic medium by reacting *cis*-[$RuCl_2(dmso)_4$], H_2acs and KOH in 1:2:2 molar ratio under aerobic conditions. The monohydrated complex precipitates from the reaction mixture as a green solid in reasonable yield. Atmospheric oxygen is the most likely oxidizing agent in the oxidation of the metal ion during the formation of the complex. If the stoichiometrically required molar ratio (1:2:3) is taken, the amount of the precipitated complex is significantly lower. However, the potassium salt of the anionic complex $[Ru(acs)_2]^-$ can be recovered from the filtrate. The dissociation of the phenolic-OH proton may happen in the absence of a strong base like OH^-. Most likely for this reason the 1:2:2 mol ratio gives a better yield of the neutral complex and for stoichiometric mol ratio (1:2:3) formation of $[Ru(acs)_2]^-$ has been observed. A more convenient and clean method for the synthesis of $K[Ru(acs)_2]$ is the treatment of [Ru(acs)(Hacs)]·H_2O with one molar equivalent of KOH in methanol. By using a similar approach the perchlorate salt of the cationic complex $[Ru(Hacs)_2]^+$ can be prepared by reacting [Ru(acs)(Hacs)]·H_2O and $HClO_4$ in a 1:1 molar ratio in methanol. The elemental analysis data (Table 1) for all three complexes agree with the proposed molecular formulae. Molar conductivity values (Table 1) of the complexes in solutions are consistent with the neutral character of [Ru(acs)(Hacs)]·H_2O and 1:1 electrolyte nature[5] of both $K[Ru(acs)_2]$ and $[Ru(Hacs)_2]ClO_4$. The solid-state magnetic moments (Table 1) of these complexes at 298 K are in the range 1.91−2.15 μ_B. Thus, in each complex, the ruthenium centre is in the +3 oxidation state and is low-spin in character.

Spectral Characteristics

The infrared spectra of [Ru(acs)(Hacs)]·H_2O and $[Ru(Hacs)_2]ClO_4$ display multiple peaks in the range 3206−2710 cm^{-1}. These peaks are most likely associated with the N−H group of the protonated amide functionalities in these complexes.[6a] On the other hand, absence of any such peak in this region of the spectrum of $K[Ru(acs)_2]$ confirms deprotonation of the amide functionalities in both ligands. In addition to the above mentioned peaks, [Ru(acs)(Hacs)]·H_2O displays a broad peak centred at 3427 cm^{-1} ascribable to the lattice water molecules.[6b] All three complexes display three medium to strong peaks at about 1597, 1550 and 1520 cm^{-1}. These peaks are possibly due to the metal-coordinated azomethine and protonated/deprotonated amide functionalities of the ligands.[2,3,6a] The presence of perchlorate ion in $[Ru(Hacs)_2]ClO_4$ is indicated by a broad and strong peak at ca. 1100 cm^{-1} and a sharp peak at ca. 620 cm^{-1}.

The electronic spectroscopic data of the complexes in acetonitrile solutions are listed in Table 1. The spectral profiles are quite similar. In the visible region, the major features displayed by these complexes are a band in the range 626−699 nm and a shoulder within the range 487−504 nm (Table 1). These absorptions are assigned to the phenolate-pπ to the metal-dπ charge-transfer transitions.[7] Interestingly, $[Ru(Hacs)_2]ClO_4$, where both the amide functionalities of the ligands are protonated, displays the first band at lower energy (699 nm) whereas the completely deprotonated species $K[Ru(acs)_2]$ displays the same band at higher energy (626 nm). The band position shift suggests that the energy gap between the phenolate-pπ and the metal-dπ levels is significantly decreased due to the protonation of the O-coordinating amide functionalities of the two ligands. The band position of the neutral complex [Ru(acs)(Hacs)], where only one amide functionality is protonated, shows the same trend but to a much smaller extent. The strong absorptions (Table 1) observed in the ultraviolet region of the spectra are most likely due to transitions involving only ligand orbitals.

The EPR spectra of the complexes in frozen (103 K) methanol/toluene (1:1) solutions are very similar. A representative spectrum is shown in Figure 1. Each of them display three distinct signals (Table 2) indicating the distortion of the N_2O_4 coordination sphere around the metal centre from octahedral symmetry. This distortion can be measured in terms of axial (Δ) and rhombic (V) components. The axial distortion (Δ) splits t_2 into "a" and "e" and the rhombic component again splits "e" into nondegenerate

components (Figure 1). In addition to Δ and V, spin-orbit coupling also influences the extent of the energy gaps between these levels. Thus, two ligand-field transitions of energies ΔE_1 and ΔE_2 ($\Delta E_1 < \Delta E_2$) are possible within these three levels. The distortion parameters and the transition energies have been quantified using the observed *g* values and the *g* tensor theory of low-spin d^5 complexes (Table 2).[8] The distortion parameters suggest that the axial component is significantly larger than the rhombic component in all of the complexes. The ΔE_1 and ΔE_2 transitions are expected to occur in the range 4100−4600 and 5200−6000 cm^{-1} (Table 2), respectively. No absorption was detected in either of the above two regions due to non-transparency of the solvent. Similar EPR spectral profiles and the comparable values of the distortion parameters calculated from the EPR data indicate that the nature and extent of distortions from the octahedral geometry are not very different in these complexes. Thus there is no significant change in the distortion pattern of the N_2O_4 coordination sphere around the low-spin ruthenium(III) centre due to protonation or deprotonation of the amide functionalities of the ligands. Earlier we reported a similar series of three high-spin iron(III) complexes with enolate-O, imine-N, and amide-O donor deprotonated acetylacetone benzoylhydrazone. It may be noted that unlike the present series of complexes, the variation of the protonation state of the amide functionalities changes the distortion pattern from rhombic to near-axial in the iron(III) complexes.[3b]

Description of Structures

The solid-state molecular structure of $[Ru(acs)(Hacs)]\cdot H_2O$ has been determined by X-ray crystallography. The complex crystallises in the *C*2/*c* space group. The structure of the complex molecule is depicted in Figure 2. The bond parameters associated with the metal centre are listed in Table 3. Each ligand binds the metal ion meridionally through the phenolate-O, the imine-N, and the amide-O atoms forming a six- and a five-membered chelate ring. Two ligands are related by a crystallographically imposed twofold axis of symmetry passing through Ru and bisecting the angles O1−Ru−O1′ and O2−Ru−O2′ (Figure 2). The presence of this twofold axis of symmetry indicates that two ligands are crystallographically equivalent. This could also indicate that both ligands are chemically equivalent. Taking into account the neutral character of the complex, this will be possible if the oxidation state of the metal centre is +2 and the ligands are monoanionic ($Hacs^-$). Considering the more acidic character of the phenolic-OH the amide functionality in each ligand has to be protonated. The second possibility is that the oxidation state of the metal centre is +4 and the ligands are dianionic (acs^{2-}). However, the physical properties (vide supra) of the complexes clearly

suggest a +3 oxidation state of the metal ion in all of the complexes. In addition, the observed (Table 3) Ru−O(phenolate) and Ru−N(imine) distances are similar to the distances reported for Ru^{III} complexes with ligands that provide the deprotonated salicylaldimine or similar moiety for metal ion binding.[9] The significantly shorter Ru−O(amide) distance compared to the distances observed in ruthenium(II) complexes[2] containing the same coordinating atom is also consistent with the +3 oxidation state of the metal ion. Thus the two ligands are not chemically equivalent, one of them is dianionic acs^{2-} and the other one is monoanionic $Hacs^{-}$. The origin of the crystallographic equivalence of the two ligands is therefore due to either a static disorder resulting from the crystallographic superposition of an equal number of $Hacs^{-}$ and acs^{2-}, or a dynamic disorder due to rapid (on the crystallographic time scale) H-atom transfer between the two amide-N centres. Rapid H-atom transfer in the solid state is highly unlikely to occur and hence the observed crystallographic equivalence of the two ligands can be attributed solely to a static disorder. The lattice water molecule is also similarly disordered and the O-atom sits at a special position with half occupancy. The distance (2.754 Å) between the amide-N atom (N2) and the water O-atom suggests an N−H···O hydrogen bonding interaction. Due to disorder the amide-N atoms of both ligands show the same interaction. In the crystal lattice, a one-dimensional chain of an alternating complex molecule and a water molecule is formed via this hydrogen bonding. The H_2O hydrogen atoms are also involved in inter-chain weak H-bonding interactions with the amide-O and phenolate-O atoms (O−H···O distances are 3.370 and 3.250 Å, respectively) forming a two-dimensional network of $[Ru(acs)(Hacs)]\cdot H_2O$ in the crystal lattice (Figure 3).

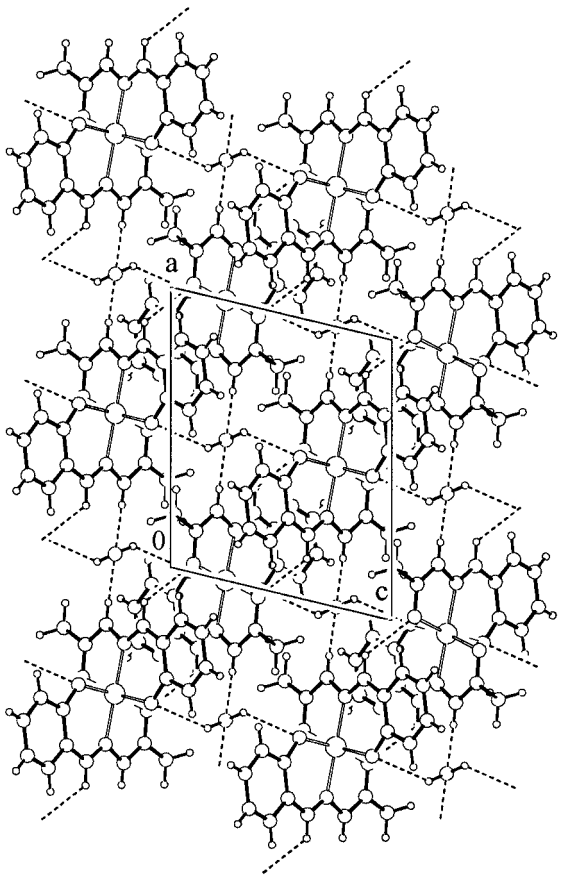

Figure 3. Two dimensional network of $[Ru(acs)(Hacs)]\cdot H_2O$ along *b* axis

We were unable to grow X-ray quality single crystals of $K[Ru(acs)_2]$. However, the tetraphenylphosphonium salt of $[Ru(acs)_2]^{-}$ crystallises in the $P\bar{1}$ space group. Single crystals of $[PPh_4][Ru(acs)_2]$ were obtained by the reaction of $K[Ru(acs)_2]$ and PPh_4Cl in acetonitrile followed by addition of toluene and slow evaporation of the mixture in air. The asymmetric unit contains a PPh_4^{+} cation, a complex anion $[Ru(acs)_2]^{-}$, and a toluene molecule that has been located at two sites. The structure of $[PPh_4][Ru(acs)_2]$ is shown in Figure 4 and selected bond parameters involving the metal centre are collected in Table 4. As in the previous structure the ligands bind the metal ion meridionally. The Ru−O(amide), Ru−O(phenolate) and Ru−N(imine) distances are typical for a ruthenium(III) species.[2,9] These distances clearly indicate that there is essentially no difference with respect to the binding strength of the two ligands. The dianionic nature of both ligands and hence the single negative charge on the complex and the +3 oxidation state of the metal ion are further confirmed by the presence of the PPh_4^{+} ion. The bond parameters of the cation are unexceptional.[10]

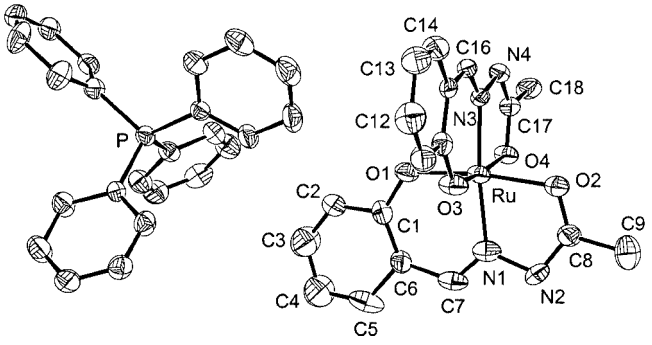

Figure 4. Structure of $[PPh_4][Ru(acs)_2]$ with the atom-labelling scheme; all atoms are represented by their 25% probability thermal ellipsoids; the labelling of the carbon atoms in the cation and hydrogen atoms are not shown for clarity

In contrast to $[Ru(acs)(Hacs)]\cdot H_2O$, there are no good, conventional hydrogen-bond acceptors or donors in $[PPh_4][Ru(acs)_2]\cdot C_6H_5CH_3$. However, this species also forms a two-dimensional network in the crystal lattice via several C−H···π interactions.[11] The H···centroid distances and the C−H···centroid angles are within the ranges 2.742−3.177 Å and 134.98−169.48°, respectively. The methyl group C-H, the aromatic C-H of the ligand and that of the phenyl groups of the cation are involved in these interactions with the π-electrons of the toluene, PPh_4^{+} phenyl groups, ligand phenolate ring and the chelate rings. A few of these interactions are depicted in Figure 5.

Electrochemical Properties

Electron transfer properties of the complexes in acetonitrile/dimethylformamide (9:1) solutions (0.1 M TBAP) have been investigated with the help of cyclic voltammetry. Each of the three complexes displays an oxidation response on the anodic side of SCE (Figure 6). The one-electron stoichiometry for these oxidation processes is ascertained by comparing the current heights with known one-electron redox processes under identical conditions.[2,9a] The anionic complex $[Ru(acs)_2]^-$ has the lowest potential ($E_{1/2}$ = 0.56 V and ΔE_p = 70 mV)[12] and the cationic complex $[Ru(Hacs)_2]^+$ has the highest potential ($E_{1/2}$ = 0.84 V and ΔE_p = 150 mV). The potential ($E_{1/2}$ = 0.76 V and ΔE_p = 240 mV) for the neutral complex [Ru(acs)(Hacs)] is in between the above two values. The free Schiff base H_2acs shows an irreversible oxidation with comparatively much higher current at +1.38 V under identical conditions. Thus the oxidation responses observed for the complexes are assigned to the $Ru^{III} \rightarrow Ru^{IV}$ process. The trend in the $E_{1/2}$ values indicates that the oxidation of the metal centre in the anionic complex where the amide functionality for each of the two ligands is deprotonated, is most favourable, and that in the cationic complex where the amide functionalities are protonated, is most difficult. This behaviour is likely to be primarily due to electrostatic reasons.

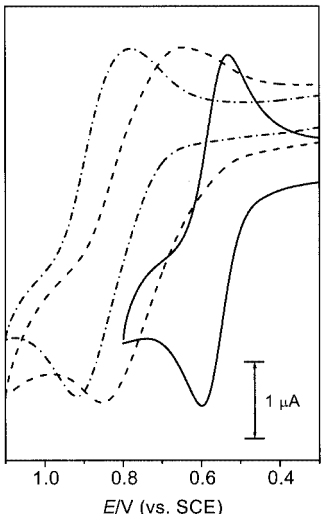

Figure 6. Cyclic voltammograms of $K[Ru(acs)_2]$ (−), $[Ru(acs)(Hacs)]\cdot H_2O$ (-----), and $[Ru(Hacs)_2]ClO_4$ (−·−·−) in acetonitrile/dimethylformamide (9:1) solvent mixture (0.1 M TBAP) at scan rates of 50 mV s^{-1}

On the cathodic side of the SCE, both $K[Ru(acs)_2]$ and [Ru(acs)(Hacs)] display a reduction response. The $E_{1/2}$ values are −1.11 V (ΔE_p = 80 mV) and −1.13 V (ΔE_p = 80 mV), respectively. In both cases, the anodic (i_{pa}) and cathodic (i_{pc}) peak currents are very similar to the current heights observed for the $Ru^{III} \rightarrow Ru^{IV}$ processes. On the other hand, $[Ru(Hacs)_2]ClO_4$ displays three reduction responses at $E_{1/2}$ = −0.20 V (ΔE_p = 100 mV), E_{pc} = −0.90 and −1.63 V. For the highest potential reduction i_{pc} is much larger than the i_{pa}. However, the i_{pc} is similar to that of the $Ru^{III} \rightarrow Ru^{IV}$ process. This first reduction response of $[Ru(Hacs)_2]ClO_4$ and the reduction responses observed for [Ru(acs)(Hacs)] and $K[Ru(acs)_2]$ may be assigned to the $Ru^{III} \rightarrow Ru^{II}$ process and the differences in the potential values can be rationalised considering the electrostatic effect. However, the trend in the reduction potential values is significantly different than that of the oxidation potential values. The reduction potentials observed for $K[Ru(acs)_2]$ (−1.11 V) and [Ru(acs)(Hacs)] (−1.13 V) are very similar and much lower than the first reduction potential (−0.20 V) observed for $[Ru(Hacs)_2]ClO_4$, whereas the $Ru^{III} \rightarrow Ru^{IV}$ potentials are observed in a comparatively smaller range (0.56−0.84 V). Under identical conditions, free perchloric acid also shows a reduction response ($E_{1/2}$ = −0.25 V, ΔE_p = 100 mV). This voltammogram is very similar to that of the first reduction displayed by $[Ru(Hacs)_2]ClO_4$. The free Schiff base (H_2acs) also displays a reduction response under the same conditions. E_{pc} and E_{pa} values for this reduction response are −1.37 and −0.96 V, respectively. Considering all the above, the reductions displayed by the present series of complexes cannot be assigned to the $Ru^{III} \rightarrow Ru^{II}$ process unambiguously.

Protonation and Deprotonation of Coordinated Amide

Spectrophotometric titrations have been performed using acetonitrile solutions of $K[Ru(acs)_2]$ and CF_3SO_3H to study

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the protonation behaviour of the coordinated amide functionalities in the complex. With the progressive addition of the acid the change of spectral profiles is characteristic of successive protonation of the two amide functionalities present in the two acs^{2-} ligands of $K[Ru(acs)_2]$.[2,13] The initial change in the spectral profile gradually decreases and becomes a minimum when the complex/acid mol ratio reaches 1:1.2. At this stage the spectral profile is akin to that of the neutral complex [Ru(acs)(Hacs)] indicating the protonation of the first ligand amide functionality. In this portion of the titration, the shift of band positions occurs through eight isosbestic points (455, 378, 361, 284, 250, 242, 222, and 207 nm) (Figure 7a). Continued addition of the acid causes a further shift of band positions through another set of five isosbestic points (584, 344, 374, 299, and 263 nm) (Figure 7b). The spectral profile becomes constant and similar to that of $[Ru(Hacs)_2]^+$ at a complex/acid molar ratio of about 1:2.6. Quantitative reversibility of this protonation

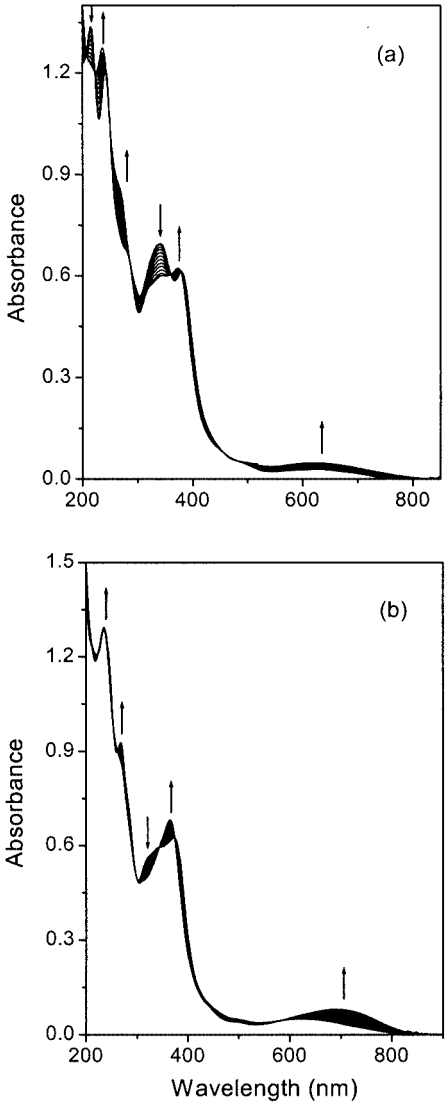

Figure 7. Spectrophotometric titration of $K[Ru(acs)_2]$ in acetonitrile with CF_3SO_3H; (a) first segment and (b) second segment of the titration (see text)

behaviour was confirmed by spectrophotometric back-titration with triethylamine. The values of pK_{a1} and pK_{a2} determined from the two segments of the titration are 6.64(4) and 7.19(1), respectively. These values are much lower than the pK_a ($\approx$15) of the free amide functionality in organic compounds.[14] This difference in the pK_a values is likely to be due to a combination of several factors. Among various explanations one possibility could be the following: the electron deficiency at the imine-N adjacent to the amide-N arising out of coordination of the former to the metal centre is compensated by the amide functionality and thereby contributes to the increase of the amide N−H acidity.[2,15] Interestingly the pK_a values determined in this work are very similar to those [pK_{a1} = 6.85(5) and pK_{a2} = 7.44(9)] determined for the ruthenium(II) complex, $[RuL_2]$, where HL is *N*-(benzoyl)-*N*′-(picolinylidene)hydrazine.[2] It seems there is no effect of the difference in the oxidation states (+3 and +2) on the acidities of the ligand amide functionalities. However, there are two very distinct dissimilarities between the two systems. In the ruthenium(II) complex, after protonation the amide functionalities are no longer bound to the metal centre which is not the case for the present complexes of acs^{2-} and $Hacs^-$ (vide supra). The ligand L^- is a pyridine-N, imine-N, and deprotonated amide-O donor whereas acs^{2-} is a phenolate-O, imine-N, and deprotonated amide-O donor. Perhaps these dissimilarities offset the effect of oxidation state on the acidity of ligand amide functionalities and similar pK_a values are observed for both systems.

Conclusion

In this article, syntheses and physical properties of three new ruthenium(III) complexes with *N*-(acetyl)-*N*′-(salicylidene)hydrazine (H_2acs) have been described. The bis complexes vary in the protonation state of the amide functionality of the ligands. The crystal structures of [Ru(acs)(Hacs)] and $[Ru(acs)_2]^-$ reveal the meridionally spanning phenolate-O, imine-N and amide-O coordinating mode of both $Hacs^-$ and acs^{2-}. In frozen solutions, all the three complexes display the typical rhombic EPR spectra for low-spin ruthenium(III) species, indicating no significant variation in the distortion pattern from octahedral symmetry of the N_2O_4 coordination spheres around the metal centre due to protonation or deprotonation of the amide functionalities. However, the potentials of the $Ru^{III} \rightarrow Ru^{IV}$ oxidation are markedly affected by the protonation state of the amide functionalities. Reversible protonation and deprotonation of the O-coordinating amide functionalities present in the ligands have been demonstrated.

Experimental Section

Materials: The Schiff base H_2acs[3a] and *cis*-$[RuCl_2(dmso)_4]$[16] were prepared by following reported procedures. All other chemicals and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

solvents were of commercially available analytical grade and were used as received.

Physical Measurements: Elemental (C, H, N) analysis data were obtained with a Perkin−Elmer Model 240C elemental analyzer. Infrared spectra were collected by using KBr pellets on a Jasco-5300 FT-IR spectrophotometer. A Shimadzu 3101-PC UV/Vis/NIR spectrophotometer was used to record the electronic spectra. Room temperature solid-state magnetic susceptibilities were measured by using a Sherwood Scientific magnetic susceptibility balance. Diamagnetic corrections calculated from Pascal's constants[17] were used to obtain the molar paramagnetic susceptibilities. EPR spectra were recorded on a Jeol JES-FA200 spectrometer. Solution electrical conductivities were measured with a Digisun DI-909 conductivity meter. A CH-Instruments model 620A electrochemical analyzer was used for cyclic voltammetric experiments with acetonitrile/dimethylformamide (9:1) solutions of the complexes containing $[(n\text{-}C_4H_9)_4N]ClO_4$ (TBAP) as supporting electrolyte. The three-electrode measurements were carried out at 298 K under a dinitrogen atmosphere with a platinum disk working electrode, a platinum wire auxiliary electrode and a saturated calomel reference electrode (SCE). The potentials reported in this work are uncorrected for junction contributions.

Synthesis of the Ruthenium Complexes

[Ru(acs)(Hacs)]·H_2O: Solid *cis*-$[RuCl_2(dmso)_4]$ (242 mg, 0.5 mmol) was added to a methanol solution (40 mL) of H_2acs (178 mg, 1 mmol) and KOH (56 mg, 1 mmol). The mixture was heated under reflux for 8 h. The hot brown solution was cooled to room temperature and left in air for 5 h. The colour of the solution changed to green and the complex was precipitated as a dark green solid. It was collected by filtration, washed with methanol followed by diethyl ether and finally dried in air. The yield was 95 mg (40%). Single crystals suitable for X-ray structure determination were obtained by storing the filtrate at 5 °C for about 3−4 days.

[Ru(Hacs)$_2$]ClO_4: A methanol solution (10 mL) of 70% aqueous $HClO_4$ (0.2 mL) was prepared. To a suspension of [Ru(acs)(Hacs)]·H_2O (118 mg, 0.25 mmol) in 25 mL methanol 1 mL of the above $HClO_4$ solution was added and the mixture was magnetically stirred in air. Initially a clear green solution was obtained and after about 1/2 h a green solid separated. The complex thus obtained was collected by filtration, washed with diethyl ether and dried in air. The isolated yield was 70 mg (49%).

K[Ru(Hacs)$_2$]: [Ru(acs)(Hacs)]·H_2O (150 mg, 0.32 mmol) was dissolved in 50 mL of methanol and KOH (18 mg, 0.32 mmol) was added to the suspension. The mixture was magnetically stirred in air for 6 h. The green solution thus obtained was filtered to remove any unreacted starting complex and the filtrate was evaporated to about ca. 4−5 mL in vacuo. The green solid obtained was collected by filtration, washed with diethyl ether and dried in air. The yield obtained by this procedure was 120 mg (76%).

Spectrophotometric Titration: In a typical titration, a 3 mL aliquot of a stock solution of K[Ru(acs)$_2$] in acetonitrile {3.74×10^{-5} M, prepared by dissolving 1.84 mg (3.74 μmol) of K[Ru(acs)$_2$] in 10 mL of acetonitrile and then diluting 1 mL of this solution to 10 mL by adding the same solvent} was placed in an air-tight cuvette. Protonation of K[Ru(acs)$_2$] was performed by addition of aliquots (1 μL) of an acetonitrile solution of CF_3SO_3H [1.13×10^{-2} M, prepared by dissolving 0.5 mL (5.65 mmol) in 10 mL of acetonitrile and then diluting 0.2 mL of this solution to 10 mL by adding the same solvent] with a gas-tight syringe. Protonation was considered complete when no significant change of the electronic spectrum was observed by further addition of CF_3SO_3H solution. The effective pK_{ai} (i = 1 and 2) values were determined from the two segments (Figure 7a for pK_{a2} and Figure 7b for pK_{a1}) of the spectrophotometric titration curves using Equations (1)−(3).[2,18] The value of $K_a(CF_3SO_3H)$ in acetonitrile used to calculate the pK_{ai} values is 2.512×10^{-3}.[19] The change in absorbance at 364 nm and that at 340 nm were used to calculate K_{c1} and K_{c2}, respectively.

$$K_{ai} = K_a(CF_3SO_3H)/K_{ci} \quad (1)$$

$$K_{c1} = [Ru(Hacs)_2^+][CF_3SO_3^-]/[Ru(acs)(Hacs)][CF_3SO_3H] \quad (2)$$

$$K_{c2} = [Ru(acs)(Hacs)][CF_3SO_3^-]/[Ru(acs)_2^-][CF_3SO_3H] \quad (3)$$

X-ray Crystallography: X-ray data for crystals of both [Ru(acs)(Hacs)]·H_2O and [PPh_4][Ru(acs)$_2$]·$C_6H_5CH_3$ were collected on an Enraf−Nonius Mach-3 single crystal diffractometer using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) by ω-scan method at 298 K. In each case, unit-cell parameters were determined by least-squares fit of 25 reflections having 2θ values in the range 10−22°. Intensities of three check reflections were measured after every 1.5 h during the data collection to monitor the crystal stability. In both cases, there was no significant change in the intensities of the check reflections. Empirical absorption corrections were applied to both datasets based on the ψ-scans.[20] The structures were solved by direct methods and refined on F^2 by full-matrix least-squares procedures. In each case, the asymmetric unit contains one molecule of the complex and one solvent molecule. All non-hydrogen atoms having full occupancy were refined using anisotropic thermal parameters. For both molecules the methyl group H-atoms and the aromatic H-atoms were placed geometrically by using a riding model. In the case of [Ru(acs)(Hacs)]·H_2O, H-atoms attached to the water oxygen atom and the amide nitrogen atom were located in a difference map. For both structures all the H-atoms were included in the structure factor calculation at idealised positions [with U_{iso}(methyl-H) = 1.5U_{eq}(C), U_{iso}(aromatic-H) = 1.2U_{eq}(C), U_{iso}(water-H) = 1.5U_{eq}(O), and U_{iso}(amide-H) = 1.2U_{eq}(N)], but not refined. The programs of WinGX[21] were used for data reduction and absorption correction. Structure solution and refinement were performed with the SHELXL-97 programs.[22] The Ortex6a[23] and Platon98[24] packages were used for molecular graphics. Selected crystal and refinement data are listed in Table 5.

CCDC-208845 for [Ru(acs)(Hacs)]·H_2O and CCDC-208846 for [PPh_4][Ru(acs)$_2$]·$C_6H_5CH_3$ contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Financial assistance for this work was provided by the Department of Science and Technology (DST), New Delhi (Grant No. SP/S1/F23/99). X-ray crystallographic studies were performed at the National Single Crystal Diffractometer Facility, School of Chemistry, University of Hyderabad (funded by the DST). We thank the University Grants Commission, New Delhi for the facilities provided under the Universities with potential for excellence program. Mr. Satyanarayan Pal thanks the Council of Scientific and Industrial Research, New Delhi for a research fellowship.

Keywords: Coordination polymers / Copper / Magnetic properties / N ligands / X-ray crystallography

A one-dimensional polymeric pyridinium chlorocuprate $(HPy)_2[Cu_3Cl_8(H_2O)_2]$, an intermediate between $(HPy)CuCl_3$ and $CuCl_2{\cdot}2H_2O$, has been synthesized and characterized by X-ray analysis [monoclinic, $P2_1/c$, a = 7.8950(10), b = 14.144(2), c = 9.921(10) Å, β = 99.20(2)°]. The structure contains $[Cu_3Cl_8(H_2O)_2]_n^{2n-}$ chains in which both square-pyramidal and octahedral Cu^{II} exist. The chains are composed of linked $[Cu_2Cl_6]^{2-}$ dimers and $CuCl_2(H_2O)_2$ monomeric units. On being heated in the solid state the compound undergoes dehydration followed by dehydrohalogenation to produce a pyridine complex of Cu^{II}: $[Cu_3Py_2Cl_6]$. Other compounds, $(HPy)_2[CuCl_4]$, $CuPyCl_2$ and $CuPy_2Cl_2$, also produce $[Cu_3Py_2Cl_6]$ as an intermediate on thermal analysis. Magnetic studies reveal ferromagnetic coupling within the chains with an intradimer exchange coupling of 12.1 cm^{-1} and a dimer-monomer exchange coupling of 1.34 cm^{-1}.

Introduction

The structural properties of chlorocuprates continue to be of interest, because of a wide variety of stereochemical features as well as unexpected oligomeric species.[1,2] However, most complexes for which structures have so far been reported contain copper atoms with a single coordination geometry, both in polymeric and in monomeric chlorocuprates.[3−7] Distorted octahedral, square-pyramidal, and trigonal-bipyramidal geometries of copper are known in polymeric chlorocuprates, whereas square-planar, square-pyramidal, and distorted tetrahedral anions have been reported with the monomeric $CuCl_{n+2}^{n-}$ complexes.[8−10] Among the hydrated chlorocuprates, the $CuCl_3(H_2O)^-$ species provides a novel intermediate between $CuCl_2(H_2O)_2$ and the $[CuCl_4]^{2-}$ anion.[11] On the other hand, the complexation of $CuCl_2{\cdot}2H_2O$ with pyridine and its derivatives has been studied extensively and the copper atoms in those complexes exhibit interesting structures.[12] With 2-picoline *N*-oxide it is found that $CuCl_2$ (when mixed in exactly 1:1 stoichiometric ratio) does not produce the expected 1:1 complex; instead a complex with empirical formula $Cu_3Cl_6(C_6H_7NO)_2{\cdot}2H_2O$ results, in which two types of copper atoms are present, one in an octahedral environment and the other in a square-pyramidal one. Here we report the synthesis, structure, and magnetic properties of the first example of a one-dimensional polymeric chain of hydrated chlorocuprates containing both hexa- and pentacoordinate copper atoms and possessing the empirical formula $(HPy)_2[Cu_3Cl_8(H_2O)_2]$, which can be regarded as a novel intermediate between $CuCl_2{\cdot}2H_2O$ and $(HPy)CuCl_3$, together with the solid-state synthesis of a new pyridine complex of Cu^{II}, $\{[Cu_3Py_2Cl_6]\}$, by thermal analysis.

Results and Discussion

The general method for the preparation of trichlorocuprates with cations of organic bases is to mix solutions containing the copper compound and a 1:1 molar ratios of the respective base acidified with HCl in aqueous or ethanolic medium. In the current case, however, the expected compound, $(HPy)CuCl_3$, is not produced by this method; instead a complex with empirical formula $(HPy)_2[Cu_3Cl_8(H_2O)_2]$ results. All attempts to prepare $(HPy)CuCl_3$ by changing the acidity of the solution and the ratio of pyridine:$CuCl_2{\cdot}2H_2O$ were unsuccessful.

Description of the Structure of $(Hpy)_2[Cu_3Cl_8(H_2O)_2]$ (1): An ORTEP view of the complex **1** is shown in Figure 1. The complex consists of one-dimensional infinite chains that run parallel to the *c*-axis. These chains contain both six-coordinate (elongated octahedral) and five-coordinate (elongated square-pyramidal) copper ions bridged by the chlorine atoms. The six-coordinate copper ion (Cu1) is located on a center of inversion and bridged to two adjacent copper ions (Cu2) by pairs of chloride ions (Cl1, Cl2) and their inversion-related chloride ions. Two water molecules complete the distorted octahedral coordination around Cu1. Each five-coordinate copper ion (Cu2) is bridged to another five-coordinate copper ion by a pair of chloride ions (Cl4 and its inversion-related counterpart) with a center of symmetry between the pairs of Cu2 ions. Each Cu2 ion is bridged asymmetrically to Cu1 by two chloride ions. A non-bridging chloride ion (Cl3) occupies the fifth coordination site. The symmetry about the pentacoordinate copper ion (Cu2) is that of a square pyramid, with the three bridging chlorine atoms Cl2, Cl4, and Cl4 ($-x + 1$, $-y$, $-z$), and the non-bridging chlorine atom Cl3 forming the base of the pyramid and a bridging chlorine atom (Cl1) at the apex. The basal Cu−Cl distances lie in the 2.2681(8) to 2.3125(7) Å range and the apical Cu−Cl distance is 2.6770(8) Å (Table 1). The least-squares plane through Cl2, Cl3, Cl4, and Cl4($-x + 1$, $-y$, $-z$) is slightly puckered, with a maximum deviation of ±0.1447(8) Å for the two symmetry-related Cl4 atoms. The Cu2 atom is 0.2479(3) Å out of plane in the direction of the apex. The bond from the Cu2 ion to the chlorine atom Cl1 makes an angle of 88.9° with the basal plane. In the case of the hexacoordinate copper atom Cu1, the two chlorine atoms [Cl1 and Cl1($-x + 1$, $-y$, $-z - 1$)] and the two oxygen atoms [O and O($-x + 1$, $-y$, $-z - 1$)] define a perfect plane, since they lie on a center of symmetry. The apical chlorine atoms [Cl2 and Cl2 ($-x + 1$, $-y$, $-z - 1$)] on either side lie at a Cu−Cl distance of 2.8763(8) Å from the base plane. The compound, $(HPy)_2[Cu_3Cl_8(H_2O)_2]$, thus consists of $Cu_2Cl_6^{2-}$ dimers bridged by $CuCl_2{\cdot}2H_2O$ groups through two chlorine atoms, one from each unit, to form infinite chains. In other words, it can be regarded as an intermediate between $CuCl_2{\cdot}2H_2O$ and $CuCl_3^-$, since, of the three molecules of $CuCl_2{\cdot}2H_2O$, two form the dimeric trichlorocuprate anions $Cu_2Cl_6^{2-}$, while the third remains as a monomeric $CuCl_2{\cdot}2H_2O$ species. To the best of our knowledge, no chlorocuprate possessing this composition and structure has been reported to date. On the other hand, the structure of the 2-picoline *N*-oxide complex of Cu^{II}, $[Cu_3Cl_6(C_6H_7NO)_2]{\cdot}2H_2O$, is similar to that of the current complex.[12] It also consists of infinite chains containing both square-pyramidal five-coordinate and distorted octahedral six-coordinate copper ions. The only difference is that the two square-pyramidal copper ions are bridged by the oxygen atoms of two 2-picoline *N*-oxide ligands instead of the chloride ions in the present case.

[a] Symmetry transformation used to generate equivalent atoms: $-x + 1$, $-y$, $-z$.

The crystal structure is stabilized by an extensive network of hydrogen bonds, with the Cl3 atom playing a key role, and also by stacking interactions (Figure 2, and Figure 3, Table 2). The Cl3 atom is the acceptor of two O−H···Cl hydrogen bonds, one from a water molecule of its own chain and the other from a water molecule of an adjacent chain related by a c glide plane. The pyridinium nitrogen atom is involved in a pair of bifurcated N−H···Cl hydrogen bonds with the Cl2 and Cl3 atoms of a polymeric chain acting as acceptors. The Cl3 atom thus accepts three hydrogen bonds: two from water molecules and one from a pyridinium ion. This is a good example of the principle of charge compensation that has been used to interpret the structures of copper(II) halides, in which the negatively charged halide ions compete for electrostatic interactions with the Cu^{II} ions and hydrogen bonding with the organoammonium ions.[13] It can also be observed that the pyridinium rings

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are stacked with the shortest distance between the centroids of two adjacent rings being 4.998(2) Å while the shortest perpendicular distance between the rings is 3.421 Å. This indicates a strong π-π interaction between the aromatic pyridinium moieties.

IR and Electronic Spectroscopy

The electronic spectrum of compound **1** in Nujol mull shows three peaks with λ_{max} values at 24096, 18692, and 12004 cm^{-1}. The spectral pattern and peak positions are quite similar to those of brown dimeric trichlorocuprate ($Cu_2Cl_6^{2-}$), with a square-pyramidal structure and an empirical formula of $(HBz)_2Cu_2Cl_6$ {Bz = benzimidazolium[6]}. The spectrum of **1** is therefore totally dominated by the square-pyramidal copper(II), which obscures the weak Laporte-forbidden transitions originating from the centrosymmetric octahedral copper(II) portion of compound **1**.

The spectrum of $[Cu_3Py_2Cl_6]$ (**1a**) shows two peaks with λ_{max} values at 23981 and 11723 cm^{-1}. Although it is very difficult to infer the exact structure of this type of complex, the presence of flattened tetrahedral (D_{2d}) copper(II) may be predicted from the lower energy of the d−d transition.[1] In addition, the band in the 24000 cm^{-1} region is indicative of the presence of doubly bridged Cu−$(Cl)_2$−Cu or Cu−$(Cl)_3$−Cu linkage.

IR spectra of **1** show a broad band due to the OH stretching modes of water molecules at 3301cm^{-1}. The appearance of the peak at lower wavelength corroborates the presence of extensive hydrogen bonding as found by single-crystal X-ray diffraction.

Thermal Analyses

The TG curves of the compounds $(HPy)_2[Cu_3Cl_8(H_2O)]_2$, $(HPy)_2[CuCl_4]$, $CuPyCl_2$, and $CuPy_2Cl_2$ are given in Figure 4. The thermal behavior of compound **1** shows that the compound loses its water molecules at ca. 105 °C (obsd. loss 5.6%; calcd. 5.4%) to produce the dehydrated compound $(HPy)_2Cu_3Cl_8$ (Table 3), which on being kept in a humid atmosphere (relative humidity > 50%) for several hours at ambient temperature absorbs exactly two molecules of water per three copper atoms to revert to **1**. The process is thus reversible. The X-ray powder diffraction pattern of **1** differs considerably from that of its anhydrous analogue $(HPy)_2Cu_3Cl_8$, but is identical to that of the rehydrated species. As the coordinated water molecules from the hexacoordinate copper (Cu1) are removed on dehydration, there should be a drastic change in the coordination geometry around this copper atom, and it is probably this that is reflected in the difference between the diffraction patterns. However, the structural skeleton of **1** must be retained on dehydration because on being kept in moist atmosphere, compound **1** is obtained again, as is confirmed by the identical diffraction patterns of the re-hydrated species and **1**. It is a reasonable assumption that the structure collapses to one analogous to the $A_nCu_{n+1}Cl_{3n+2}$ structures, in which a repeat sequence of n tribridged units and one bibridged unit occurs in the chain structure.[14] On further heating, $(HPy)_2Cu_3Cl_8$ undergoes dehydrohalogenation (obsd. loss 11.40%; calcd. 10.9%) at ca. 190 °C to produce $[Cu_3Py_2Cl_6]$. It is to be noted here that the pyridine ligand, after losing its proton as HCl, enters into the coordination sphere of the copper(II) in the solid state to yield the pyridine complex **1a**. This compound is thermally stable up to ca. 240 °C, after which it finally decomposes to $CuCl_2$.

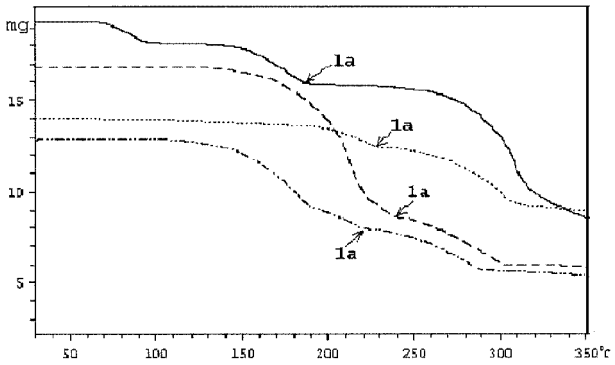

Figure 4. The TG curves: −−, $(HPy)_2[Cu_3Cl_8(H_2O)_2]$; -----, $(HPy)_2[CuCl_4]$; •••••••, $[CuPyCl_2]$ and - •• - •• −, $[CuPy_2Cl_2]$; the labels **1a** denote the temperature at which $[Cu_3Py_2Cl_6]$ is formed

Table 3. Results of thermal analysis of compounds **2, 3** and **4**

Thermal reactions	Temp. range (°C)	Weight loss (%) Obsd.	Calcd.
$(PyH)_2[CuCl_4]$ (2) → $CuPyCl_2$	150−220	42.20	41.59
$3CuPyCl_2 \rightarrow [Cu_3Py_2Cl_6]$	220−250	6.60	7.20
$[Cu_3Py_2Cl_6] \rightarrow 3CuCl_2$	250−305	14.50	14.41
$3CuPyCl_2$ (3) → $[Cu_3Py_2Cl_6]$	190−235	11.40	12.33
$[Cu_3Py_2Cl_6] \rightarrow 3CuCl_2$	245−310	25.50	24.67
$CuPy_2Cl_2$ (4) → $CuPyCl_2$	125−190	26.80	27.00
$3CuPyCl_2 \rightarrow [Cu_3Py_2Cl_6]$	190−220	9.30	9.00
$[Cu_3Py_2Cl_6] \rightarrow 3CuCl_2$	225−293	18.25	18.00

The interesting feature of the thermal analysis is the isolation of $[Cu_3Py_2Cl_6]$ (**1a**), which can be synthesized in the solid state from **1** as discussed in the preceding paragraph. Any attempt to synthesize compound **1a** in solution, either by the addition of pyridine and $CuCl_2 \cdot 2H_2O$ in 2:3 ratio or by crystallization of the title compound from common solvents (methanol, ethanol, water etc.) always results in $CuPyCl_2$ (see Exp. Sect.). Recrystallization of **1a** also results in $CuPyCl_2$. The X-ray powder diffraction results for compounds **1a**, **3**, and anhydrous $CuCl_2$ show that $[Cu_3Py_2Cl_6]$ is not a mixture of $CuPyCl_2$ and $CuCl_2$. It is relevant to mention here that complexes of composition $[M_3Py_2Cl_6]$ have been prepared by pyrolytic techniques with Cr^{II}, Mn^{II}, Co^{II}, Ni^{II}, and Cd^{II}.[15] With copper(II), though, it was thought that the existence of such complexes is not possible, as it does not form regular octahedral complexes because of Jahn−Teller effects.[16] Also, in a recent paper, no isolable intermediate was detected in the thermal analysis of $(Hpy)_2[CuCl_4]$.[17] However, the thermal analysis results for $(HPy)_2[Cu_3Cl_8(H_2O)_2]$, $(HPy)_2[CuCl_4]$, $CuPyCl_2$, and $CuPy_2Cl_2$ presented in this paper show that all of them finally decompose to $CuCl_2$ via the intermediate species $[Cu_3Py_2Cl_6]$. Only compound **1** permits isolation of **1a** in the pure state upon being heated, however, as the TG curve for **1** shows a plateau in the temperature range in which **1a** is stable. Earlier failure in its isolation was therefore a result of the decomposition temperature of copper(II)-pyridine complexes and had nothing to do with the Jahn−Teller effect.

Magnetic Behavior

The plot of $\chi_M T$ vs. T in Figure 5 reveals the presence of ferromagnetic interactions within the system. The value of $\chi_M T$ increases monotonically as T is lowered, with no maximum observed down to 1.9 K. Thus, no significant antiferromagnetic coupling appears to exist in this material. The M vs. H curve at 2.0 K (Figure 6) rises smoothly to a saturation value of $M_{satd.} \approx 3.05\ \mu_\beta$, giving no evidence for significant spin canting nor for a ferrimagnetic ground state of the chain system.

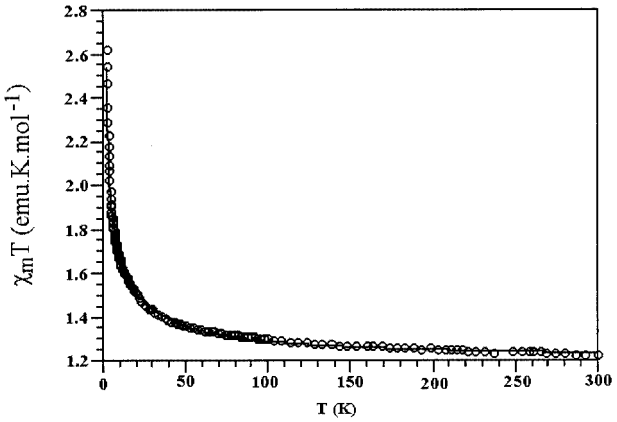

Figure 5. Plot of $\chi_M T$ vs. T for $(HPy)_2[Cu_3Cl_8(H_2O)_2]$; solid line is the calculated curve

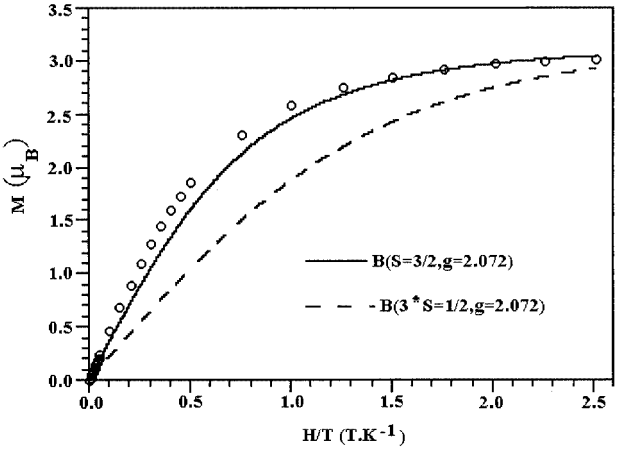

Figure 6. Plot of M vs. H/T at 1.8 K for $(HPy)_2[Cu_3Cl_8(H_2O)_2]$; solid line and dashed line are the calculated Brillouin functions

The data in Figure 5 can be fitted very satisfactorily by use of a model for a chain of alternating dimer and monomer units. The procedure consisted of treatment of the infinite chain as a ring of finite length by use of a closed-chain computational procedure. The infinite chain behavior can be obtained by extrapolation from the exact result for increasing ring length.

$$\hat{H} = -2\sum_{i=0}^{N-1}\left[J_1\hat{S}_{3i}\hat{S}_{3i+1} + J_2\left(\hat{S}_{3i+1}\hat{S}_{3i+2} + \hat{S}_{3i+2}\hat{S}_{3i+3}\right)\right]$$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The exchange Hamiltonian may be written as where 3 N corresponds to the number of interacting spins. J_1 is the intradimer exchange interaction, and J_2 is the interaction between the dimer and the monomer. The calculations are limited up to 18 spins ($N = 6$). Evaluation of the susceptibility curves was performed by use of the MAGPACK programs package.[18] The differences between the curves with $N = 4$ and 6 are less than 0.2% over the full range of temperatures, so the $N = 6$ ring is taken as the exact solution for the infinite change in the experimental temperature range. Under these considerations the best fit obtained by a least-squares analysis of the $\chi_m T$ data is $J_1 = 17.35$ K = 12.1 cm^{-1} (intradimer exchange constant), $J_2 = 1.93$ K = 1.34 cm^{-1} (dimer−monomer exchange constant), $g = 2.072$, and $R = 5.76 \times 10^{-5}$.

The magnetization data (Figure 6) can be compared with the Brillouin function expected for three independent Cu^{II} ions (dashed line) and with a $S = 3/2$ system (solid line). As can be seen, the agreement is much better, as would be expected, for a $S = 3/2$ system, although the experimentally measured values are slightly above the theoretical ones at low fields. This may be due to the presence of the extended interactions within chains that cannot be taken into account with a simple Brillouin function.

Magneto-Structural Correlations

The magnetic studies indicate the presence of ferromagnetic coupling both within the dimeric species and between the dimer and monomer units. Correlation of the exchange coupling with structural parameters in $Cu_2Cl_6^{2-}$ dimers has received considerable attention in the past.[19] The coupling is antiferromagnetic, with $J/k \approx 50$ K for the planar conformation (based on the interaction Hamiltonian $H = -J \mathbf{S}_1 \cdot \mathbf{S}_2$), with the coupling becoming ferromagnetic as distortion from planarity occurs. In particular, for the type of bifold distortion observed in this structure, the crossover is estimated to occur at a bifold angle near 20°. Thus, with a bifold angle of 19.7°, the presence of ferromagnetic coupling within the dimer is consistent with the previous studies. For the dimer/monomer coupling, this pathway is analogous to those found in asymmetric bibridged dimers and chains.[20] This coupling can be either ferro- or antiferromagnetic, depending on details of the pathway (although no simple magneto-structural correlations exist). When the coupling is ferromagnetic, the magnitude of the coupling is invariably small, in agreement with these results.

Finally, it should be noted that hydrogen-bonded Cu−Cl···H_2O−Cu linkages occur between chains (Figure 3). In the absence of any decrease in $\chi_M T$ as $T \rightarrow 0$ K, it is clear that this interaction must also be ferromagnetic. The J' value may thus also include some small contribution from this pathway.

Discussion

The magnetic properties of this system can be compared with those of several other previously examined trimer-type chain systems. The $(Cu_2X_6)Cu(TMSO)_4$ system (TMSO = tetramethylenesulfone) contains chains of $Cu_2X_6^{2-}$ anions bridged by $Cu(TMSO)_4^{2+}$ cations.[21] For these compounds, the Cu^{II} ions in the cations have distorted tetrahedral geometries, which results in quite strong ferromagnetic coupling within the $Cu_2X_6^{2-}$ dimers. The cations and anions are linked by bent Cu−X···Cu interactions, giving ferromagnetic dimer/monomer coupling for the chloride salt, but weak antiferromagnetic coupling is observed at low temperatures in the bromide salt (although this antiferromagnetic coupling may, in reality, be propagated through a short interchain Br···S contact). Thus, the chloride salt behaves as a ferromagnetic chain, while the bromide exhibits ferrimagnetic behavior.

In $[Cu_3Cl_6(dioxane)_2]$, a complex bi-bridged chain with a ferro/ferro/antiferro repeat pattern exists.[22] With J(ferro) >> J(antiferro), the system effectively behaves as an antiferromagnetic $S = 3/2$ chain at low temperature. This can be contrasted with the behavior of the ferrimagnetic trimer chain in (N-methyl-2-picolinium)$_2Cu_3Br_8$.[23] Here, strong antiferromagnetic interactions exist within the planar bibridged $Cu_3Br_8^{2-}$ trimer units, stabilizing a $S = 1/2$ ground state. These are then coupled together in a ferromagnetic fashion, to give a system that behaves as a $S = 1/2$ ferromagnetic chain at low temperature. In addition, there are numerous other known $A_2Cu_3X_8$ salts containing planar bibridged trimers, in which the antiferromagnetically coupled trimers stack in complex fashions, for which the magnetic properties have not been thoroughly analyzed.[24]

Experimental Section

Materials and Measurements: High purity (98%) pyridine and copper(II) chloride dihydrate were purchased from E. Merck, Germany and were used as received. Elemental analyses (carbon, hydrogen, and nitrogen) were performed with a Perkin−Elmer 240C elemental analyzer and the copper contents in all the complexes were estimated spectrophotometrically.[25] IR spectra in KBr (4500−500 cm^{-1}) were recorded with a Perkin−Elmer RXI FT-IR spectrophotometer. Electronic spectra (1200−350 nm) were recorded with a Hitachi U-3501 spectrophotometer in Nujol mull. The thermal analyses (TG-DTA) were carried out with a Mettler Toledo TGA/SDTA 851 thermal analyzer in a dynamic atmosphere of dinitrogen (flow rate: 30 cm^3 min^{-1}). The sample was heated in an alumina crucible at a rate of 5 °C min^{-1}. The X-ray powder diffraction experiments were carried out on a Philips PW 3710 diffractometer equipped with a copper tube anode. Variable-temperature susceptibility measurements were carried out for $(HPy)_2Cu_3Cl_8 \cdot 2H_2O$ in the 2−300 K temperature range at a magnetic field of 0.1 T on ground polycrystalline samples with a SQUID magnetometer (Quantum Design MPMS-XL-5). The susceptibility data were corrected for the diamagnetic contributions deduced by use of Pascal's constant tables. Isothermal magnetization and hysteresis measurements were made for $(HPy)_2Cu_3Cl_8 \cdot 2H_2O$ at different temperatures, after zero field cooling between 0 and 5 T in the SQUID magnetometer.

Preparations

$(HPy)_2[Cu_3Cl_8(H_2O)_2]$ (Brown) (1): $CuCl_2 \cdot 2H_2O$ (5 mmol) was dissolved in a minimum volume of water. Pyridine (5 mmol) was

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mixed into this solution, along with concentrated HCl (4 mL). The resulting solution was concentrated in a water bath to ca. 5 mL and kept in a desiccator. After a few days reddish-brown shiny single crystals suitable for X-ray diffraction were obtained. $C_{10}H_{16}Cl_8Cu_3N_2O_2$ (670.5): calcd. C 17.9, H 2.4, N 4.2, Cu 28.4; found C 18.0, H 2.3, N 4.3, Cu 27.8. λ_{max} = 24096, 18692, 12005 cm^{-1}

[$Cu_3Py_2Cl_6$] (Pale Green) (1a): This compound was prepared by heating of compound **1** for 30 min at ca. 190 °C. $C_{10}H_{10}Cl_6Cu_3N_2$ (561.5) : calcd. C 21.4, H 1.8, N 5.0, Cu 33.9; found C 21.2, H 1.9, N 5.1, Cu 33.6. λ_{max} = 23981 and 11723 cm^{-1}.

$(HPy)_2[CuCl_4]$ (Yellow) (2): This compound was prepared by the same procedure as used in the case of compound **1** except that $CuCl_2{\cdot}2H_2O$ and pyridine were used here in 1:2 molar ratio. $C_{10}H_{12}Cl_4CuN_2$ (365.5): calcd. C 32.8, H 3.3, N 7.7, Cu 17.4; found C 32.5, H 3.2, N 7.4, Cu 17.0. λ_{max} = 24390 and 9200 cm^{-1}.

$CuPyCl_2$ (Pale Yellow) (3) and $CuPy_2Cl_2$ (Blue) (4): The compounds were synthesized by mixing of ethanol solutions of $CuCl_2{\cdot}2H_2O$ and pyridine in the required molar ratios. The compounds can also be synthesized by shaking the compounds **1** and **2** respectively in ethanol. **3:** $C_5H_5Cl_2CuN$ (213.5): calcd. C 28.1, H 2.4, N 6.6, Cu 29.7; found C 28.0, H 2.1, N 6.4, Cu 29.5. UV: λ_{max} = 23585, 20747, 14970, 11723, 10953 cm^{-1}. **4:** $C_{10}H_{10}Cl_2CuN_2$ (292.7): calcd. C 41.0, H 3.4, N 9.6, Cu 21.7; found C 41.0, H 3.6, N 9.4, Cu 21.5. λ_{max} values are as reported in the literature[26] for **4**.

X-ray Crystallography: A suitable single crystal of the complex **1** was mounted on a Bruker AXS CCD area detector system for data collection. The crystal data of the complex were collected at 293(2) K. Intensity data were collected in the ω scan mode by use of graphite-monochromated Mo-K_α radiation (0.71073 Å). The empirical absorption corrections were based on Ψ scans. The structure was solved by SIR-97[27] methods and refinement was made with the SHELXL-97 suite of programs. Anisotropic full-matrix refinements based on F^2 were carried out for all non-hydrogen atoms. The hydrogen atoms were placed geometrically and refined in the "riding" model with isotropic thermal parameters 1.2 times U_{eq} of the atom to which they were attached. Complex neutral atom scattering factors were used throughout the refinement. All calculations were carried out with the aid of the SHELX 97,[28] PLATON 99[29] and ORTEP[30] programs. Selected crystallographic data for complex **1** are displayed in Table 4, while selected bond lengths and bond angles of the complex are presented in Table 1. The H-bonding and non-bonding contacts of **1** are listed in Table 2. CCDC-170243 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Table 4. Crystal data and structure refinement details of $(HPy)_2[Cu_3Cl_8(H_2O)_2]$

Empirical formula	$C_5H_8Cl_4Cu_{1.5}ON$
Molecular mass	335.23
Temperature	293(2) K
Wavelength	0.71069 Å
Crystal system, space group	monoclinic, $P2_1/c$
Unit cell dimensions	a = 7.8950(10) Å
	b = 14.144(2) Å
	c = 9.9210(10) Å
	β = 99.20(2)°
V	1093.6(2) $Å^3$
Z, calculated density	4, 2.036 Mg/m^3
Absorption coefficient	3.876 mm^{-1}
F(000)	658
Crystal size	0.21 × 0.17 × 0.11 mm
Crystal color	brown
θ range for data collection	2.53 to 28.09°
Limiting indices	$-10 \le h \le 10$
	$-18 \le k \le 18$
	$-12 \le l \le 12$
Reflections collected/unique	11396/2460
R(int)	0.0406
Completeness to θ = 28.09°	92.2%
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	2460/2/121
Goodness-of-fit on F^2	1.105
Final R indices [$I > 2\sigma(I)$]	R_1 = 0.0277, wR_2 = 0.0708
R indices (all data)	R_1 = 0.0329, wR_2 = 0.0740
Largest diff. peak and hole	0.467 and −0.610 $eÅ^{-3}$

Preparation of Optically Active α-Amino[3]ferrocenophanes − Building Blocks for Chelate Ligands in Asymmetric Catalysis

Patrick Liptau, Ludger Tebben, Gerald Kehr, Birgit Wibbeling, Roland Fröhlich, and Gerhard Erker*

Keywords: Ferrocenes / Ferrocenophanes / Chelate ligands

We noticed that some mistakes were made in the determination of the Δε and $[\alpha]_D^{20}$ values of compounds ***6*** *and* ***11*** *in our article[1] that need to be corrected. The correct values for* ***6*** *(p. 3597) and* ***11*** *(p. 3598f.) (including the corrected Figure 8, p. 3596) are as follows:*

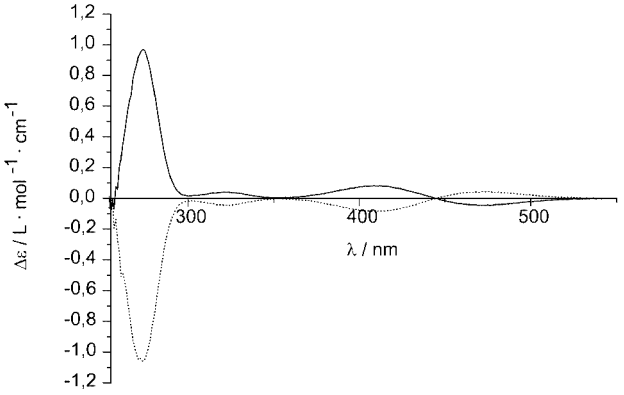

Figure 8. CD spectra of (1*R*,3*R*)-**6** (solid line, 4×10^{-4} g mL^{-1}) and (1*S*,3*S*)-**6** (dotted line, 4×10^{-4} g mL^{-1}) in CH_3CN

(1*S*,3*S*)-**6**: $[\alpha]_D^{20} = -89$ ($c = 2 \times 10^{-3}$ g mL^{-1}, CH_3CN). CD: Δε (λ_{max}) = −1.06 (274), −0.04 (326), −0.08 (412), +0.04 (476) ($c = 4 \times 10^{-4}$ g mL^{-1}, CH_3CN). (1*R*,3*R*)-**6**: $[\alpha]_D^{20} = +91$ ($c = 2 \times 10^{-3}$ g mL^{-1}, CH_3CN). CD: Δε (λ_{max}) = +0.97 (274), +0.04 (326), +0.08 (412), −0.04 (476) ($c = 4 \times 10^{-4}$ g mL^{-1}, CH_3CN).

(1*S*,3*S*)-**11**: $[\alpha]_D^{20} = -109$ ($c = 2 \times 10^{-3}$ g mL^{-1}, CH_3CN). CD: Δε (λ_{max}) = −0.23 (275), +0.02 (334), −0.10 (416), +0.03 (483) ($c = 4 \times 10^{-4}$ g mL^{-1}, CH_3CN). (1*R*,3*R*)-**11**: $[\alpha]_D^{20} = +111$ ($c = 2 \times 10^{-3}$ g mL^{-1}, CH_3CN). CD: Δε (λ_{max}) = +0.23 (275), −0.02 (334), +0.10 (416), −0.02 (483) ($c = 4 \times 10^{-4}$ g mL^{-1}, CH_3CN).

COVER PICTURE

The cover picture shows the multiple characterization methods used to unravel the electronic and geometrical structures of the unit $M_A^{III}M_B^{II}$, in which three oximato groups $(=N-O)^-$ are present as bridging ligands. Variable-temperature magnetic susceptibility and EPR measurements provide a consistent answer to the question of electronic ground states for different heterometallic combinations. Mößbauer spectroscopy helps to differentiate between the species Co^{III}(l.s.)Fe^{II}(l.s.) and Fe^{II}(h.s.)Co^{III}(l.s.). Details on the preparation and characterization of the species $Fe^{III}M^{II}$ and related heterometallic compounds are presented in a forthcoming article by P. Chaudhuri et al.: Asymmetric Heterodinuclear $Fe^{III}M^{II}$ (M = Zn, Cu, Ni, Fe, Mn), $Co^{III}Fe^{II}$ and $Fe^{II}Co^{III}$ Species: Synthesis, Structure, Redox Behaviour and Magnetism.

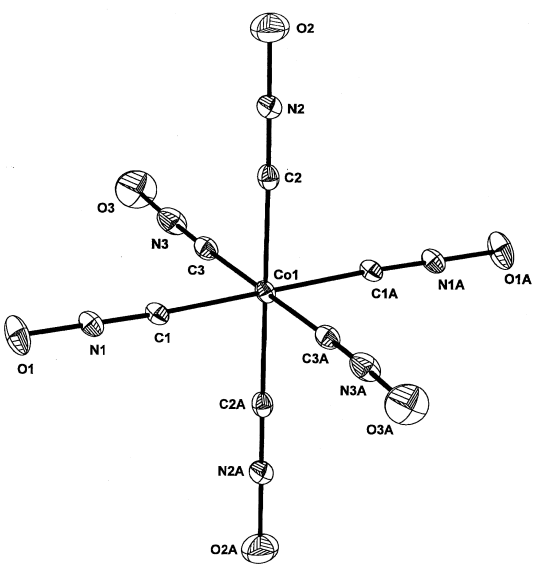
The First Chemical Achievements and Publications by Justus von Liebig (1803–1873) on Metal Fulminates and Some Further Developments in Metal Fulminates and Related Areas of Chemistry



Keywords: Liebig / Fulminates / Silver / Structure elucidation

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The First Chemical Achievements and Publications by Justus von Liebig (1803−1873) on Metal Fulminates and Some Further Developments in Metal Fulminates and Related Areas of Chemistry[‡]

Wolfgang Beck[a]

Dedicated to Professor Wolfgang Steglich on the occasion of his 70th birthday for his great friendship, collaboration and support[‡‡]

Keywords: Liebig / Fulminates / Silver / Structure elucidation

The first chemical investigations and publications by Justus von Liebig dealt with the fulminates of silver and mercury. Even as a boy Liebig had learnt how to prepare silver fulminate, and as student of chemistry in Erlangen (1821) he studied the properties and reactions of silver fulminate. In Paris in 1823 (together with Gay-Lussac) he succeeded in analyzing quantitatively the highly explosive silver compound. This great experimental success with the dangerous silver fulminate was most important in three respects: i. The development of the experimental method later culminated in Liebig's perfected and well-known C,H,N analysis of organic compounds (1830). ii. It led to the concept of isomerism when F. Wöhler found that silver cyanate had the same composition as silver fulminate. iii. It was decisive for furthering the scientific career of Liebig, since Alexander von Humboldt was highly impressed by the great skill and talent of Liebig and — by recommendation of Humboldt — Liebig became Professor in Gießen in 1824 (at the young age of 21). The first (fulminato)metal complex, $K[Ag(CNO)_2]$, was also isolated by Liebig. Later, explosive (fulminato)metal complexes were prepared by Nef, Wieland, and especially by Lothar Wöhler and co-workers. In Munich the HCNO structure of fulminic acid was established by its IR spectrum and the spectroscopic properties of (fulminato)metal complexes were studied. A series of new nonexplosive complexes could be obtained by dilution of the energy-rich species with large cations or ligands. Recent X-ray structure determinations have revealed the almost perfect linear, tetrahedral, square-planar, or octahedral structures of these complexes with linear metal–C≡NO bonds, e.g. $[Au(CNO)_2]^-$, $[Zn(CNO)_4]^{2-}$, $[Ni(CNO)_4]^{2-}$, $[Co(CNO)_6]^{3-}$. DFT calculations have given very good agreement between the calculated and experimental structural parameters and CNO stretching frequencies. The (fulminato)metal complexes closely resemble the analogous cyano compounds.

Liebig's Work on Metal Fulminates

Justus Liebig was born on May 12, 1803 in Darmstadt, Germany. His father owned a pigment and drug shop. Even as a boy he was fascinated by the crackers sold by the pedlars at the market,[1−7] and he watched the preparation of this explosive. Liebig recognised that it was nitric acid

[‡] On the occasion of Liebig's 200th birthday.

[a] Department Chemie der Ludwig-Maximilians-Universität Butenandtstr. 5−13, 81377 München, Germany

[‡‡] Professor Steglich currently holds the chair of Organic Chemistry of the University of Munich, a position previously occupied by J. v. Liebig, A. v. Baeyer, R. Willstätter, H. Wieland, and R. Huisgen.

Wolfgang Beck, born in 1932, received his Ph.D. in 1960 at the Technische Hochschule (TH), München, under the supervision of Prof. W. Hieber. In 1968 he was appointed to the Chair of Inorganic and Analytical Chemistry at the Ludwig-Maximilians-Universität in München (LMU) and is now Emeritus Professor. His research interests are coordination and organometallic chemistry. He started his studies with metal complexes of pseudohalides (fulminato and azido ligands) and later proceeded to (among other topics) complexes of biologically important ligands. He has published over 600 papers and has been awarded the Liebig Medal of the Gesellschaft Deutscher Chemiker.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

which was used for the dissolution of silver or mercury with evolution of brown gases, and that the liquid which was added smelt of brandy and was alcohol. He probably repeated the preparation of silver fulminate in his father's small laboratory, where pigments were usually made and probably the metal fulminates were sold in his father's shop.[5b] The synthesis of mercury and silver fulminate from ethanol, nitric acid, and mercury or silver was reported in 1800 by the English chemist Howard,[8] and 107 years later the complicated process of fulminate formation was interpreted by Wieland in Munich.[9] The young Liebig didn't like to study languages at the gymasium in Darmstadt, so he left in 1817 aged 14 and started an apprenticeship in a pharmacy near Darmstadt where he stayed, although only for a few months. It is only a tale that Liebig caused an explosion (with metal fulminates?) in the school and in the pharmacy and therefore had to leave both.[1,2] (However, the Liebig biography by Brock[3] contains a painting of the explosion).

In these times — during the Napoleonic wars — there was a great demand for mercury fulminate. F. F. Runge has given an amusing report (F. Franz, Grundriß der Chemie, II. Teil, München, **1847**) on his experience and accidents with mercury fulminate when he was a pharmacy apprentice in Lübeck in 1813.

Aged $17^1/_2$, in 1820 Liebig was accepted by Karl Kastner — at that time one of the leading professors of chemistry — to study at the University of Bonn. Liebig (Figure 1) followed Kastner one year later to the University

5.

Einige Bemerkungen über die Bereitung und Zusammensetzung des Brugnatellischen und Howardschen Knallsilbers.

(Vom Herrn Liebig, der Chemie Beflissenen aus Darmstadt *).

Es scheint vielleicht überflüssig, zu den vielen Vorschriften und Bereitungsarten dieses merkwürdigen Salzes noch eine neue hinzuzufügen; allein die älteren Angaben sind mehr oder weniger unbestimmt und unsicher, so, daſs wenn man darnach arbeitet, ohne besondere Uebung das Präparat meistentheils mifslingt. Schon seit 2 Jahren verfertige ich nach der unten gegebenen Vorschrift eine

*) Die Leser mögen diese erste Probe des experimentellen Fleifses eines jungen Chemikers mit Nachsicht aufnehmen. Der Hr. Verf. widmete sich der Chemie bereits in Bonn mit achtungswerthem Eifer und setzte hier seine Studien in gleichem Geiste fort. Kastner.

Figure 2. Liebig's first publication

of Erlangen. In 1822 Liebig published his first paper[10] on the safe preparation and some properties of silver fulminate (Figure 2). This paper contains also some chemical observations on silver fulminate by Kastner, and a kind remark on the skill and dedication of Liebig. In a subsequent, very short paper,[11] Liebig reported that silver fulminate is soluble in aqueous ammonia solution and that NH_3 is formed on reaction with KOH.

In 1822 Liebig got into trouble with the citizens and the police as a member of a student unit, and he left Erlangen. With the aid of Kastner he was awarded a stipend by the Duke of Hessen, Ludwig I, for the study of chemistry at the Sorbonne in Paris, at that time the centre of the scientific study of chemistry, which was founded by Lavoisier. In Paris he could listen to the lectures of famous scientists such as Gay-Lussac, Thenard, Dulong, and Biot.[1−3,5] In the small laboratory of Gaultier de Claubry (who discovered the reaction of iodine with starch) and with the support of Thenard, Liebig could continue his experiments with silver and mercury fulminate. Gay-Lussac presented Liebig's results before the Academy of Science in Paris, which attracted great attention. He himself demonstrated his new compounds at the meeting of the academy. In the publications on these results[12,13] some very interesting remarks on fulminates are to be found: "It is now clear, that the detonating principle is due to a special acid." Liebig recognised the analogy between metal cyanides and metal fulminates, perhaps somewhat instinctively and said: "Although we find in detonating acids (fulminic acid) and det-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

onating salts (metal fulminates) all the elements of cyanic acid they are not cyanides.''

Liebig[13] reported the reactions of silver fulminate and of mercury fulminate with CaO, MgO, KOH, and NaOH. With copper, zinc, and iron he obtained explosive compounds which he called, for example, ''real fulminating copper'' (''wahres Knallkupfer'') and stated that the salts of fulminic acid (metal fulminates) belong to the most beautiful compounds in chemistry. He correctly formulated the products from the reaction of silver fulminate with, for example, CaO or KOH as double salts {in today's terminology (fulminato)metal complexes like $K[Ag(CNO)_2]$} and compared these compounds with (in our words) complexes of cyanide or of tartaric acid. Also the first experiments to analyze silver fulminate were carried out by Liebig,[12,13] for instance, using 100 g (!) of silver fulminate and 400 g of magnesia (MgO) in a retort. Liebig found that the organic parts of silver fulminate and mercury fulminate have the same composition.[12]

With AgCNO and aqueous ammonia Liebig obtained white crystals which proved to be so explosive and dangerous that they could not be handled. He reported several ''terrible'' explosions.[13] Later several binary metal fulminates were obtained from $Hg(CNO)_2$ and amalgams of Na, K, Mn, Cu, Tl, and Cd.[14]

Liebig was very courageous in his studies with the highly explosive and sensitive silver fulminate and used rather large quantities. In later days he admitted that any study with fulminates usually ended with an explosion, and further work was only started when the accident was gradually thrust into the background.[2,15] In November 1830 — after a big explosion with solid silver fulminate and ammonium sulfide solution — Liebig wrote to Wöhler that he didn't want to handle ''fulminic acid'' any more [''Liebig's and Wöhler's Briefwechsel in den Jahren 1829−1873'' (Eds.: A. W. Hoffmann, E. Wöhler), Braunschweig, **1888**; November 18th, 1830]. But Liebig obviously was a most skilful chemist and no serious injury was reported.

Liebig found that Berliner Blau (''Berlin Blue'') is formed from silver fulminate, KOH, and iron sulfate.[13] Later this was confirmed by Schischkoff.[16] Together with F. Lux it was shown[16] that hexa(fulminato)ferrate(II) $[Fe(CNO)_6]^{4-}$ {and also $[Fe(CN)_5CNO]^{4-}$ [16]} is quantitatively reduced (deoxygenated) by $Fe(OH)_2$ to $[Fe(CN)_6]^{4-}$.

At the session of the academy, where Liebig's results were so successfully presented,[13] Alexander von Humboldt was present. Gay-Lussac and von Humboldt were close friends and they worked together on the law of combining gases (Gay-Lussac law).

Humboldt was highly impressed by the talent of Liebig and upon his recommendation Liebig was accepted in the laboratory of Gay-Lussac (Figure 3), where he could profit from Gay-Lussac's and Thenard's vast experience in the elemental analysis of organic compounds (Figure 4). In a short time the collaboration of Liebig and Gay-Lussac led to the perfect analysis of silver fulminate,[17] a masterpiece of exact chemical work. Silver fulminate (200 mg) and copper oxide (8 g) were mixed and heated and gave CO_2 and

Figure 3. Joseph Louis Gay-Lussac (1778−1850)

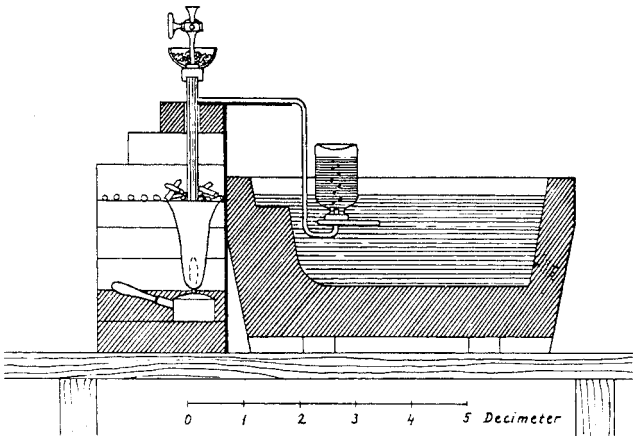

Figure 4. Gay-Lussac and Thenard's apparatus for the combustion and analysis of organic substances (1810)

N_2 in the exact volume ratio 2:1 according to the equation

$$2\ AgCNO + 2\ CuO \rightarrow 2\ Ag + 2\ Cu + 2\ CO_2 + N_2$$

Previously, Gay-Lussac had analyzed hydrocyanic acid (HCN) by combustion with CuO to give CO_2/N_2 in the volume ratio 2:1 (Gay-Lussac, *Ann. Chim.* **1815**, *XCV*, 136−251).

In another quantitative experiment Liebig and Gay-Lussac determined the Ag content of silver fulminate after decomposition with hydrochloric acid, according to the equation

$$AgCNO + 2\ HCl \rightarrow AgCl + Cl(H)C{=}NOH$$

mass of AgCNO used: 2.266 g

mass of AgCl produced: 2.171 g (theoretical value 2.167 g)

They also correctly analyzed the reaction of silver fulminate with KCl according to the equation

$$2\ AgCNO + KCl \rightarrow K[Ag(CNO)_2] + AgCl$$

mass of AgCNO used: 2.552 g

mass of AgCl found: 1.202 g (theoretical value 1.220 g)

In the latter case, the silver complex $[Ag(CNO)_2]^-$ is formed (which was called by Liebig ''knallsaures Kali'').

Only half of the silver present in AgCNO was found in AgCl. The $K[Ag(CNO)_2]$ (''knallsaures Kali'') gave 1.210 g of AgCl after decomposition with HCl (compared with the theoretical value of 1.220 g). Thus, Liebig had discovered the first (fulminato)metal complex. Interestingly, $K[Ag(CNO)_2]$ is also formed by reaction with KBr in the solid state, as monitored by IR spectroscoppy.[18]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Next, Liebig and Gay-Lussac[17] determined the carbon and nitrogen content of silver fulminate. A mixture of silver fulminate and copper oxide was carefully dried with $CaCl_2$ in a tube in vacuo using an air-pump. The measurements were carried out with the apparatus shown in Figure 5. The volumes of CO_2 and N_2 were measured with the apparatus developed by Gay-Lussac and Thenard (Figure 4).

It was found by five analyses (using 30 g of AgCNO for each analysis) from the volumes of CO_2 (which then was absorbed with KOH) and N_2 that 100 mg of AgCNO gave 17.16 mg (theory 17.35 mg) of cyanogen (CN). These analyses of AgCNO were really excellent: Ag: found 72.187, calcd. 71.97, CN: found 17.160, calcd. 17.35, O: found 10.653, calcd. 10.67.

Liebig and Gay-Lussac had carefully eliminated the possibility that silver fulminate contained hydrogen — this was confirmed by decomposition of a mixture of silver fulminate and K_2SO_4.

Twenty years later Berzelius[19] again questioned whether silver fulminate could contain hydrogen; this was immediately rejected by Liebig,[19] as other arguments against his formulation were refuted with irony.[20]

Liebig and Gay-Lussac[17] also measured the gases which are formed from silver fulminate on detonation; they diluted AgCNO with KCl or K_2SO_4 and correctly concluded that the residue must contain a "cyan" compound of silver (AgNCO!).

Finally, Liebig and Gay-Lussac[17] came to the conclusion "that the various salts of fulminic acid contain the same acid which comprises one atom of cyanogen (CN) and one atom of oxygen". In other words they had found the correct formulation (AgCNO). It is quite surprising and somewhat strange that it took about 70−80 years before Nef[24] formulated fulminic acid as the monomeric oxime of carbon monoxide C=N−OH, and Lothar Wöhler proved the monomeric nature of the fulminate ion $C{\equiv}N{-}O^-$.[25]

It was as late as 1965 that, together with K. Feldl,[26] the structure of fulminic acid as formonitrile oxide H−C≡N−O could be proven by its IR spectrum and that Winnewisser et al.[27,32] confirmed this structure by microwave spectroscopy and high resolution IR spectra. The HCNO structure could be deducted from the Huisgen[31] 1,3-dipolar cycloaddition reactions of fulminic acid with unsaturated carbon compounds,[22] which were performed by Quilico,[28] and Huisgen and Christl.[28] More recently, the mechanism of the cycloaddition reactions of HCNO was studied theoretically.[29] L. Pauling[30] calculated in 1926 from the mutual potential energy of the positive cores that fulminic acid has the formula HCNO rather than the tautomer CNOH, which was the possibility accepted at that time.

For excellent reviews of the long and fascinating history of fulminic acid, see refs.[8,21−23] Interestingly in Munich there is a tradition of fulminic acid chemistry: J. v. Liebig, H. Wieland (who first proved the existence of the free fulminic acid[9]) and R. Huisgen (1,3-dipolar cycloaddition reactions of HCNO[28,31]). Fulminic acid and its derivatives have been studied extensively by many chemists. A list of citations on fulminic acid (which was kindly forwarded to the present author by M. Winnewisser) contains 140 titles from 1800 to 1966. After 1966 (ca. 180 papers were published up until 2003), fulminic acid attracted great attention from spectroscopists and theoreticians — mainly through the many important studies by M. and B. Winnewisser[27,32] — because it proved to be a highly interesting unusual quasilinear molecule. The possible CHNO isomers and their stability attracted the interest of theoreticians.[23,33]

HCNO can be prepared by several methods:[22] a) By treatment of aqueous NaCNO solutions with sulfuric acid.[9,26,27] b) From iodoformhydroxime [I(H)C=CNOH] and base (NEt_3);[28] this is obviously a method for preparative work; I(H)C=NOH has been obtained from NaCNO solutions and HI[34] or more conveniently by Huisgen and Christl (avoiding the highly explosive NaCNO), directly from $Hg(CNO)_2$ and HI.[28] c) By gas-phase pyrolysis of 3-phenyl-4-oxoiminoisoxazol-5(4*H*)-one[35] (high yield) for spectroscopic measurements of HCNO.[27] d) In situ preparation of HCNO by hydrolysis of trimethylsilylnitrile oxide Me_3SiCNO,[36] which is accessible from $Hg(CNO)_2$ and Me_3SiBr.[37] A reinvestigation of cycloaddition and polymerisation reactions of HCNO using this method has been reported.[37]

In 1824, Friedrich Wöhler reported the synthesis of silver cyanate,[38] which showed an identical analysis to silver fulminate. This proved to be one of the first examples of isomerism, a term which was coined after some discussion by Berzelius.[39] However, at first Liebig[40] did not believe these results (and at first Berzelius did not believe the silver fulminate analysis).

For a detailed discussion of the history of isomerism see: J. R. Partington, *A History of Chemistry*, Macmillan, London, **1964**, vol. 4, p. 256; C. Graebe, *Geschichte der Organischen Chemie*, Springer, Berlin, **1920**, p. 49.

Liebig[40] repeated Wöhler's work and found a smaller content of oxygen in his silver cyanate sample which he called "cyanichte Säure". But Liebig had probably analyzed an impure sample of silver cyanate (containing AgCN), and later he confirmed Wöhler's findings, together with another analysis of silver fulminate.[41] As it is well known,[1−7] this was the beginning of a close and long-lasting friendship between Liebig and Wöhler. It may be mentioned that the present author has verified the fulminate ($C{\equiv}N{-}O^-$) to cyanate ($N{=}C{=}O^-$) isomerisation,[42] for which a cyclic intermediate seems plausible.[43]

To summarise, these experiments of Liebig were most important, mainly for three reasons:

− Through his studies of silver fulminate, Liebig was introduced to the field of elemental analysis, which, in 1830, he developed into a general method in organic chemistry, by means of his ingenious five-sphere apparatus (Kali-Apparat; Figure 6).

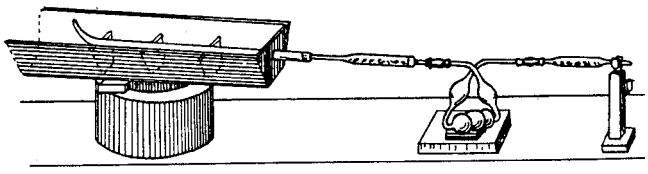

Figure 6. Liebig's method for elemental analysis for the absorption of H_2O ($CaCl_2$) and of CO_2 (KOH) with the five-spheres apparatus

− The identical analyses (but completely different properties) of silver fulminate (Liebig) and silver cyanate (Wöhler) led to the concept of isomerism.

− The work with metal fulminates decided Liebig's future scientific career, and won him − upon recommendation by Humboldt − a professorship at the University of Gießen at a very young age.

In the publication with Gay-Lussac,[17] Liebig also reported reactions of silver fulminate with hydrochloric acid, hydroiodic acid, and hydrogen sulfide. The reaction of AgCNO with H_2S was later separately described by Liebig.[45] This reaction was clarified later.[45]

Liebig had wondered why no gas (HCN) was observed on reaction with hydrochloric acid (Figure 5). It was later found to be due to the formation of Cl(H)C=NOH.[9,21,22,24]

In 1838, Liebig defined acids as compounds in which hydrogen can be replaced by metals (e.g. silver).[46] Following this important definition, fulminic acid was considered by Liebig[47] as a compound in which hydrogen can be substituted by a metal and in which hydrogen is bound to an oxygen-containing "radical".

Liebig published his last paper on metal fulminates in 1855[48] and reported the oligomerisation of fulminic acid (by heating mercury fulminate in a diluted aqueous solution of KCl) to fulminuric acid; this was later studied by Wieland[9,21] and Grundmann.[22,49] Interestingly, Liebig gave, in his first and last publications on metal fulminates, a detailed and safe description for the preparation of silver[10] and mercury[48] fulminate. The preparation of the latter compound was later optimised,[48] and mercury fulminate was also studied by Liebig's student August Kekulé in his habilitation thesis.[50]

Further Developments

Structure of Silver Fulminate and Silver Cyanate

The interesting structure of silver fulminate, Liebig's favourite compound in his young years, was determined by Britton and Dunitz[51] by X-ray crystallography. These X-ray structure determinations were later repeated and confirmed.[51] It was found that AgCNO crystallises in two

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

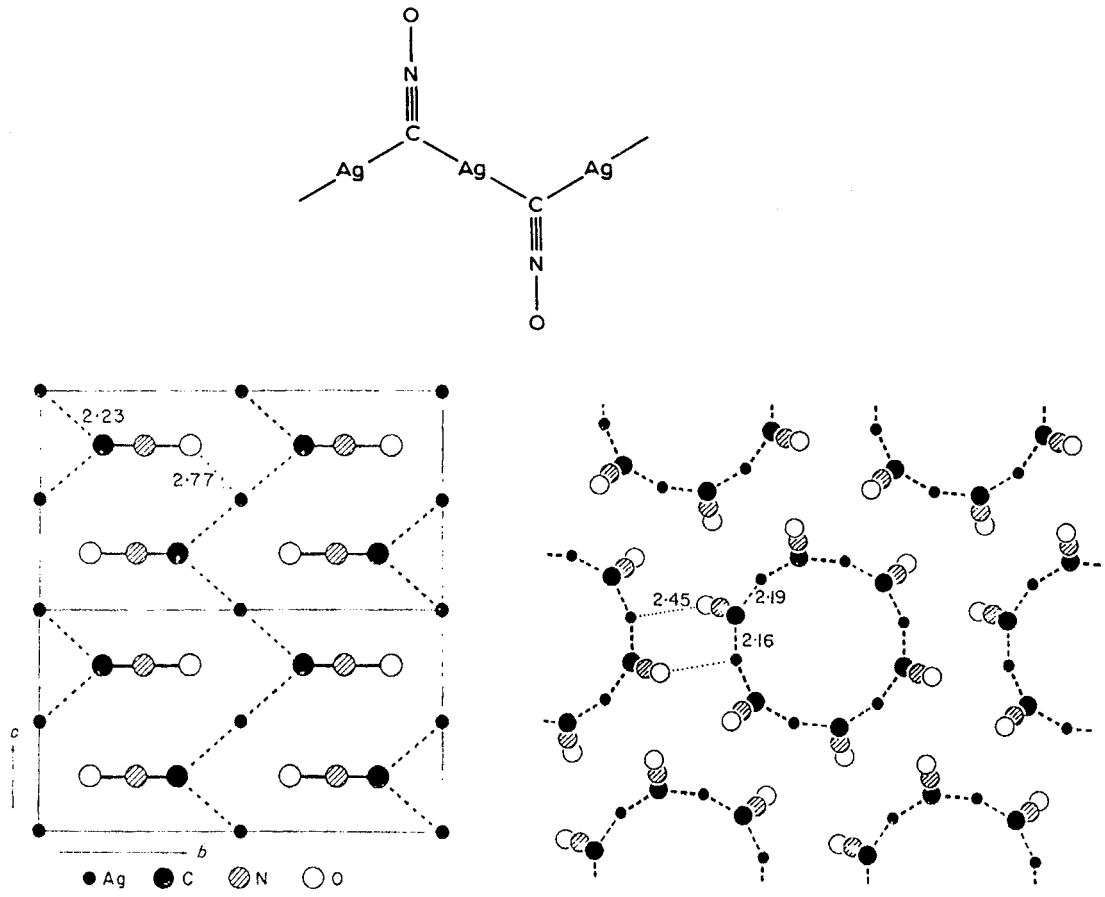

Figure 7. Structural element of orthorhombic (left) and trigonal (right) AgCNO in the crystal

polymorphic forms. In the orthorhombic form, infinite chains with fulminate bridges and three-centred Ag−C−Ag bonds are present (Figure 7), whereas the trigonal silver fulminate structure contains cyclic hexameric units, again with Ag−C−Ag bonds. The crystal structure of the isomeric silver cyanate AgNCO was also determined by Britton and Dunitz[52] and shows Ag−N−Ag−N chains with NCO bridges, where each silver ion has two linearly coordinated N atoms. To the best of our knowledge a full crystal structure determination of mercury fulminate $Hg(CNO)_2$ has not been carried out.[53] Mercury fulminate was widely used as explosive and was introduced by A. Nobel in 1867 as primary explosive to detonate dynamite.[8,54] For this purpose it is now replaced in most industrial countries by lead azide, which is more stable to storage; mercury fulminate can react with metals in moist atmosphere.[55]

Decomposition of Metal Fulminates

Liebig[41] mentioned that oxides of metals (Ag, Hg) which readily loose oxygen form explosive salts of fulminic acid ("Oxide, welche ihren Sauerstoff leicht fahren lassen").

The thermal and photochemical decomposition of $Hg(CNO)_2$, AgCNO, and NaCNO was studied by Boddington and Iqball.[56] Gaseous metal, metal cyanate,[42] CO_2, CO, N_2, and a polymeric material were identified as products by IR and mass spectra.[56] Of interest is the extremely high sensitivity of the ionic fulminates NaCNO or KCNO (in contrast to sodium azide, for example). It was suggested[56] that electron transfer from the fulminate anion to sodium may be involved, to give CNO radicals. Recently, CNO radicals have been generated from anionic precursors in the gas phase.[57] The dimer cyanogen di-*N*-oxide with the linear structure O−N≡C−C≡N−O was also generated in the gas phase.[58] This compound was isolated by Grundmann[22] from dichloroglyoxime and has a rich chemistry.[22,58]

(Fulminato)metal Complexes

Formation of (Fulminato)metal Complexes

As mentioned, the first metal complex with fulminato ligands, $K[Ag(CNO)_2]$, was obtained by Liebig[12,13,17] from the reaction of silver fulminate with potassium chloride. This silver complex was later studied by Wieland.[59] The hexa(fulminato)iron complex $Na_4[Fe(CNO)_6]\cdot 18H_2O$, the analogue of the cyanide $[Fe(CN)_6]^{4-}$, was discovered by Nef.[24] It crystallises with 18 molecules of water, and one can speculate that its structure contains hydrogen bonds between the fulminato ligands and the water molecules (Figure 8).

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

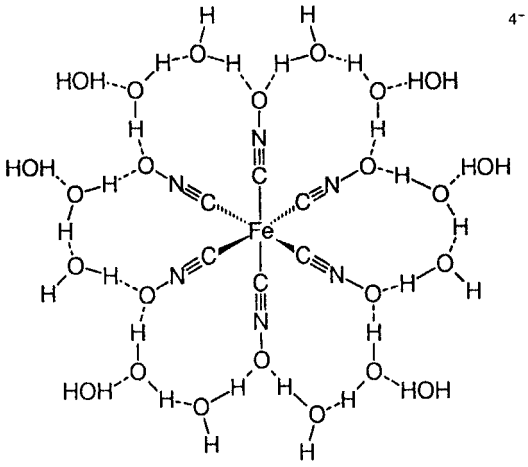

Figure 8. Possible hydrogen bonding in $Na_4[Fe(CNO)_6]\cdot 18\ H_2O$

We found by IR spectroscopy that several (fulminato)-metal complexes like $[Ni(phen)_3][Ru(CNO)_6]\cdot H_2O$, $Na_4[Fe(CNO)_6]\cdot 18H_2O$, and $Na_4[Fe(CN)_5CNO]\cdot H_2O$ are only stable when water of crystallisation is present. On drying, the complexes decompose, with the formation of cyanate.[18,60] Wieland described the explosive mercury complex $Na_2[Hg(CNO)_4]$.[61] The foundations for the coordination chemistry of the fulminate ion were laid by Lothar Wöhler in Darmstadt who, between 1914 and 1929, reported (with his coworkers Martin, Weber, and Berthmann) a series of homoleptic anionic (fulminato)metal complexes, isolated as highly explosive alkali or alkaline earth metal salts.[62] Since that time (about 1930) fulminate complexes did not attract a great deal of attention. The present author studied these complexes in his habilitation work,[18] because a metal−carbon bond had to be assumed, as in transition-metal complexes involving carbon monoxide, isocyanide, cyanide, and acetylide ligands. The coordination chemistry of the metal fulminates up until 1970 has been summarised.[63,64] Therefore, in the following discussion, only the most important features and the newer results will be described. In our group,[60,63] we found that fulminate complexes of transition metals can be stabilised by "diluting" the energy-rich metal−fulminate groups with large cations ($AsPh_4^+$, PPh_4^+, NR_4^+) or with large neutral ligands (e.g. PPh_3). This strategy was also very successfully applied to the isolation and characterisation of (azido)metal complexes, for example $[AsPh_4]_2[Pt(N_3)_6]$.[65]

Usually, these (fulminato)metal complexes were prepared from aqueous sodium fulminate solutions and transition-metal salts, followed by the addition of tetraphenylarsonium chloride.[60,63] The aqueous solution of NaCNO can be prepared from $Hg(CNO)_2$ and sodium amalgam under water.[14,25,62,63] The known homoleptic anionic (fulminato)metal complexes are shown in Table 1; all correspond in their composition to cyano complexes, as it was first pointed out by Liebig[12,13,17] (Table 1). The (fulminato)platinum complex *trans*-$[(Ph_3P)_2Pt(CNO)_2]$ could be obtained by oxidative addition of nitromethane to $[Pt(PPh_3)_4]$ in benzene/ethanol/water.[66] Similarly, Ercolani et al.[67] found that C−C cleavage of α-nitro ketones by platinum(II) and -(0) gives (fulminato)- and (carboxylato)-platinum(II) complexes. Presumably, the formation of fulminate occurs here via a (hydrido)(nitromethyl) complex. The isolation of σ-bonded nitromethyl complexes $[R(R_3P)_2PtCH_2NO_2]$ from zerovalent platinum complexes and nitromethane[68] and the observed conversion of $[R(dppe)PtCH_2NO_2]$ to [R(dppe)PtCNO] by Bennett and co-workers[69] support this assumption. Examples of other nitromethanide compounds are $[R_3SnON(O)CR_2]$[70] and $[(terpy)PtCH_2NO_2]^+$.[71]

Nef[24] and Wöhler[25] showed that mercury fulminate is formed from the sodium salt of nitromethane and $HgCl_2$. In addition, organomercury fulminate compounds RHgCNO can be prepared from RHgOH and CH_3NO_2.[72] Organomercury fulminates RHgCNO are easily formed by synproportionation of diorganylmercury and mercury fulminate[73][74] and can undergo Huisgen[31] [2+3] cycloaddition reactions.[74]

$[(Ph_3P)_2Pt(CNO)_2]$ {which is also accessible from $[Pt(CNO)_4]^{2-}$ and PPh_3 [75]} is best prepared by reaction of $[(Ph_3P)_2Pt(C_2H_4)]$ with nitromethane,[76] since with $[Pt(PPh_3)_4]$ an excess of PPh_3 can lead to reduction of fulminate to give the (cyano)metal complex $[(Ph_3P)_2Pt(CN)_2]$.

A very interesting source of the fulminato ligand is CH_2Cl_2, CO, and nitrate. Bos, Steggerda et al.[77] discovered the formation of the (fulminato)metal complex $[Ph_3PAuCNO]$ and the cluster compound $[Au_{11}(PPh_3)_8(CNO)_2]^+NO_3^-$ by reaction of $[Ph_3PAuNO_3]$ or of $[Au_{9(8)}(PPh_3)_{8(7)}NO_3]$ with carbon monoxide in dichloromethane. It was suggested that the fulminate ligand is formed by reduction of $[Ph_3PAuNO_3]$ with CO to $[Ph_3PAuNO]$, which reacts with CH_2Cl_2 to afford chloroformoxime (Scheme 1). It was demonstrated by ^{13}CO

$$Ph_3PAuNO_3 \xrightarrow[-\ CO_2]{CO} Ph_3PAuNO \xrightarrow{CH_2Cl_2} Ph_3PAuCl + ClHC{=}NOH$$

$$ClHC{=}NOH \xrightarrow{-\ HCl} HCNO \xrightarrow{Ph_3PAuNO_3} Ph_3PAuCNO$$

Scheme 1

Table 1. Homoleptic anionic (fulminato)metal complexes

$[Fe(CNO)_6]^{4-}$	$[Co(CNO)_6]^{3-}$	$[Ni(CNO)_4]^{2-}$	$[Cu(CNO)_2]^-$ $[Cu(CNO)_3]^{2-}$	$[Zn(CNO)_4]^{2-}$
$[Ru(CNO)_6]^{4-}$	$[Rh(CNO)_6]^{3-}$	$[Pd(CNO)_4]^{2-}$	$[Ag(CNO)_2]^-$	$[Cd(CNO)_4]^{2-}$
−	$[Ir(CNO)_6]^{3-}$	$[Pt(CNO)_4]^{2-}$	$[Au(CNO)_2]^-$	$[Hg(CNO)_4]^{2-}$

experiments that the carbon atom of CNO^- originates from CH_2Cl_2.[77] Dehydrochlorination of chloroformoxime with base gives fulminic acid, which can form the (fulminato)-metal complexes. Already Nef[21,22,24] had reported the formation of AgCNO from chloroformoxime and a silver salt.

An unexpected metal cluster with a fulminate bridge $[(C_5Me_5)_3Mo_3(CO)_4(\mu_3\text{-}O)(\mu_2\text{-}CNO)]$ was reported by Dahl et al.[78] from the photochemical reaction of $[(C_5Me_5)_3Mo_3(CO)_4(O)(N)]$ with CO.

Some (fulminato)metal complexes with the metal atom in a low oxidation state could be obtained from the reaction of the hexacarbonyl compounds of Cr, Mo, and W with sodium fulminate[60] as well as from the reaction of $Et_4N[W(CO)_5Br]$ with AgCNO (***Caution!***),[79] for example $[M(CO)_5CNO]^-$ and $[M(CO)_4(CNO)_2]^{2-}$ (as $AsPh_4^+$ or NEt_4^+ salts; M = Cr, Mo, W).

Reactivity of (Fulminato)metal Complexes

Reduction $M-C\equiv N-O \rightarrow M-C\equiv N$

The fulminate ligand can be reduced to the cyano group; for example, $[Fe(CNO)_6]^{4-}$ and $[Fe(CN)_5(CNO)]^{4-}$ can be deoxygenated with $Fe(OH)_2$ to give $[Fe(CN)_6]^{4-}$.[16] Like nitrile oxides,[22] the metal-coordinated fulminate ion can also be deoxygenated with phosphanes; for example, the (cyano)metal complex *trans*-$[(Ph_3P)_2Pt(CN)_2]$ is formed from the reaction of *trans*-$[(Ph_3P)_2Pt(CNO)_2]$ with PR_3 (R = Ph, OEt). The intermediate $[(Ph_3P)_2Pt(CNO)(CN)]$ could be detected by its IR spectrum.[80] The deoxygenation of the fulminato ligand at the metal atom is chemical proof that the fulminate ion is bonded to the metal atom through the carbon atom.[16,18,64a]

Isomerisation $M-C\equiv N-O \rightarrow M-N=C=O$

Thermal isomerisation of fulminate (at temperatures above 200 °C) to the much more stable[81] isocyanate has been observed for several complexes.[60,63,67,79] As for the fulminate anion[42,43] and nitrile oxides,[22,82] the rearrangement may occur via a cyclic intermediate.

The isomerisation of CNO to NCO was also observed during attempts to stabilise the isofulminic acid or fulminic acid ether complexes ($M-C\equiv N-OH$ or $M-C\equiv N-OR$) by reaction of $[(Ph_3P)_2Pt(CNO)_2]$ with acetic acid or Et_3OBF_4,[79][80] in a similar manner to the formation of hydrogen isocyanide by protonation of cyano complexes.[83] Until now isofulminic acid (HONC) could not be detected, even not by the elegant and thorough studies of Maier and co-workers.[84] However, Wentrup and co-workers[85] were able to generate "organic fulminates" $R-O-N\equiv C$ from 4-oximinoisoxazol-5(4*H*)-ones.

The isomerisation of $[(Ph_3P)_2Pt(CNO)_2]$ to $[(Ph_3P)_2Pt(NCO)_2]$ occurs in the presence of organic carbonyl compounds (e.g. acetone, benzaldehyde) at much lower temperatures.[80] This can be explained by a Huisgen [2+3] cycloaddition of the carbonyl group to the fulminato ligand, to give an (unstable) dioxazolone, similar to nitrile oxides.[22,31,86] The formation of $[(Ph_3P)_2Pt(NCS)_2]$[80] from $[(Ph_3P)_2Pt(CNO)_2]$ and CS_2 or thiobenzophenone can be attributed to a [2+3] cycloaddition of the C−S group to the fulminato ligand — as occurs with organic nitrile oxides[22] — and subsequent elimination of COS or benzophenone, respectively.

Substitution of the fulminato ligand in $[(Ph_3P)_2Pt(CNO)_2]$ by Ph_4AsCN led to Ph_4AsCNO, from which several (fulminato)metal complexes could be safely prepared.[80]

Reactions of Nitrile Oxides with Metal Complexes

The reactions of nitrile oxides with $Co_2(CO)_8$ resulted in deoxygenation to the corresponding nitriles.[87] By reaction of stable nitrile oxides with zerovalent platinum complexes $[(Ph_3P)_2Pt(L)]$ (L = 2 × PPh_3, C_2H_4) the nitrile oxide is deoxygenated and one of the phenyl groups on PPh_3 migrates to the platinum atom to give the complexes $[(Ph_3P)(RCN)Pt(OPPh_2)(Ph)]$,[88] in which the $OPPh_2$ group is bonded by the P atom to the metal atom. The only complex in which an intact RCNO group is present appears to be the cluster $[Cp_3Co_3(\mu_3\text{-}CR)(\mu_2\text{-}RCNO)]$ which is formed from $Cp_3Co_3(\mu_3\text{-}CR)_2$ and NO^+.[89]

With electron-rich carbonyliridium complexes, nitrile oxides undergo Huisgen [2+3] cycloadditions (with the metal−carbon bond as the 1,3-dipolarophile) to give metallacycles $[L_nM-C^a(R)=N-O-C^b(O)(M-C^b)]$.[90] Interestingly, decomposition of these metallacycles gives π-bonded nitrile complexes and can lead to activation of C−H bonds.[90]

Spectra

The IR spectra of binary metal fulminates[42,91] and of (fulminato)metal complexes[18,63,64b,92] are particularly characteristic. The overtone of the ν_s(CNO) [ν(NO)] stretching vibration (at ca. 1100 cm^{-1}) absorbs near the ν_{as}(CNO) band. So, Fermi resonance occurs, and two strong bands appear in the region 2000−2200 cm^{-1}. This is typical for metal fulminates, which can thus be easily identified by their IR spectra. It was observed that ν_{as}(CNO) and ν_s(CNO) are coupled, that is, they move in the same direction for various metal fulminates.[63] Also ^{15}N-containing metal fulminates[93a] and (fulminato)metal complexes[92] have been studied and the frequencies of coordinated cyanate and fulminate groups have been theoretically analyzed.[64b,94] The metal isotope technique was employed to assign the iron−CNO stretching vibration at 533 cm^{-1} of Fe(*o*-phenanthroline)$_2$(CNO)$_2$.[93b] DFT calculations of ν_{as}(CNO) and ν_s(CNO) frequencies of (fulminato)metal complexes are in very good agreement with the observed data.[95]

The ^{14}N chemical shifts in the NMR spectra of metal fulminates are similar to those of nitrile oxides and differ considerably from those of isomeric isocyanate complexes.[96]

The electronic spectra of fulminate complexes reveal that the fulminato ligand is near cyanide in the spectrochemical series[97] (just a little lower in ligand field strength) and also has a similarly strong *trans* influence.[98]

Table 2. Bond lengths [pm] and angles [°] in metal fulminates

	Ref.	M−C	C≡N	N−O	M−C≡N	C≡N−O
$(Ph_3P)_2Pt(CNO)_2$	[76]	198	113	127	179	178
$[Au(CNO)_2]^-$	[103]	201	110	125	179	178
$[Ph_3PAuCNO]$	[104]	194	115	127	163	179
AgCNO	[51]	218	116	125		180
$[Hg(CNO)_4]^{2-}$	[100]	219	114	125	173	179
$[Co(CNO)_6]^{3-}$	[101]	191	113	127	178	178
$[Ni(CNO)_4]^{2-}$	[102]	187	114	126	174	179
$[Pt(CNO)_4]^{2-}$	[102]	199	115	126	179	179
$[Zn(CNO)_4]^{2-}$	[102]	200	114	125	178	179

The formation constant of $[Hg(CNO)_4]^{2-}$ has been determined ($K_2 = 10^{36}$). This is smaller than that for $[Hg(CN)_4]^{2-}$ by a factor of 10^5, but it is nevertheless still high.[99]

Crystal and Molecular Structures of (Fulminato)metal Complexes

Recently, a series of (fulminato)metal complexes, which had been prepared about 35 years ago and which "survived", were structurally characterised by X-ray diffraction.[100−102]

Table 2 shows the (fulminato)metal complexes, which have so far been studied by X-ray diffraction. In the crystals of, for example, $[AsPh_4][Au(CNO)_2]$, $[AsPh_4]_2[Hg(CNO)_4]$, $[N(C_3H_7)_4]_2[Ni(CNO)_4]$, and $[N(C_3H_7)_4][Pt(CNO)_4]$, it is clearly evident that in the crystal the energy-rich (fulminato)metallate anions are separated and surrounded by the large cations (Figures 9−12). So the metal fulminate groups are "diluted" and the fulminate compounds are thermally stabilised. Already the IR and Raman spectra had indicated the high symmetry of the homoleptic anionic (fulminato)-metal complexes, since only one ν_{as}(CNO) and ν_s(CNO) absorption was observed in the solutions of these compounds.[18,63,92] The X-ray structure determinations of the $AsPh_4^+$ salts of $[Au(CNO)_2]^-$,[103] $[Hg(CNO)_4]^{2-}$,[100] $[Ni(CNO)_4]^{2-}$,[102] $[Pt(CNO)_4]^{2-}$,[102] $[Zn(CNO)_4]^{2-}$,[102] and $[Co(CNO)_6]^{3-}$ [101] reveal the almost ideal linear, tetrahedral, square-planar or octahedral structure of these anions (Figures 9−14).

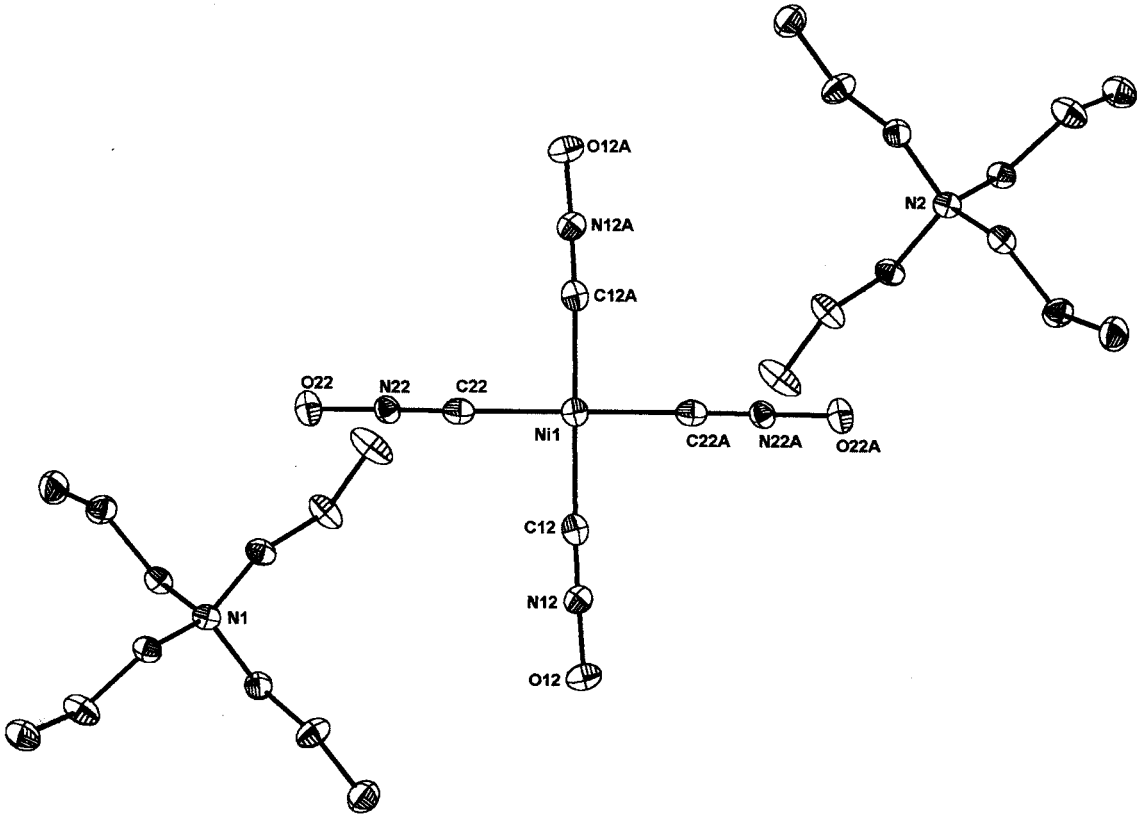

Figure 11. Crystal structure of $[N(C_3H_7)_4]_2[Ni(CNO)_4]$

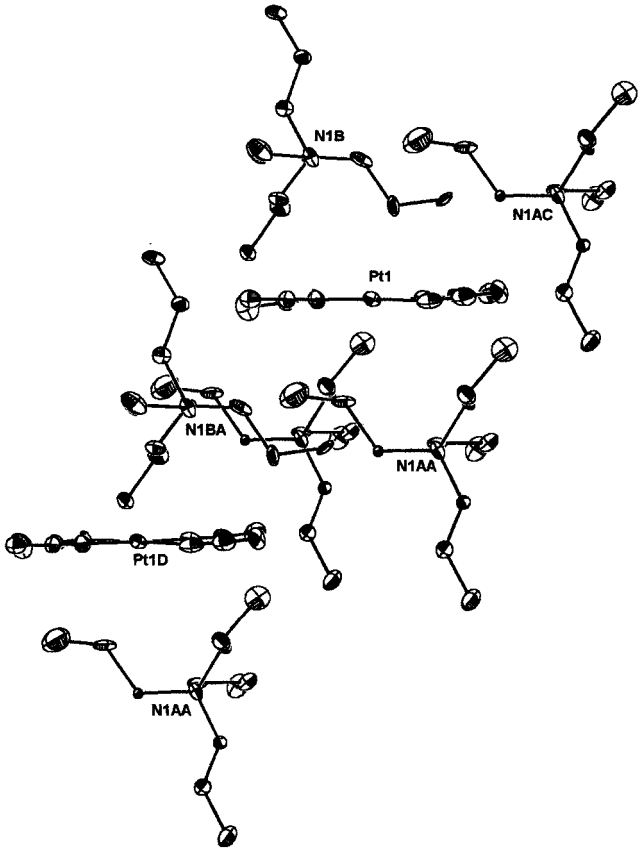

Figure 12. Crystal structure of $[N(C_3H_7)_4]_2[Pt(CNO)_4]$

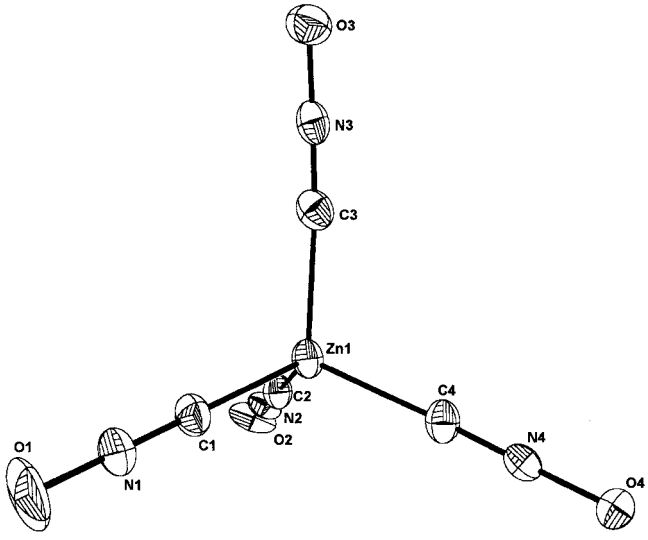

Figure 13. Crystal structure of $[Zn(CNO)_4]^{2-}$

The bonding parameters of the (fulminato)metal complexes are very similar (Table 2) with C≡N and N−O bond lengths of 114−116 pm and 125−126 pm, respectively, and M−C≡N and C≡N−O angles close to 180°. Remarkably, the metal−C and C≡N bond lengths in corresponding (fulminato)- and (cyano)metal complexes are almost identical (Table 3). Therefore, the formula M−C≡N−O| is a good description for the bonding in fulminato complexes. As mentioned earlier, Liebig emphasised the analogy be-

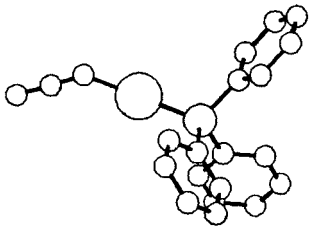

Figure 16. Crystal structure of $[Ph_3PAuNCO]$

tween metal cyanides and fulminates.[12,13,17] The fulminate ion, which is best formulated as C≡N−O$^-$,[42,91,93] behaves predominantly as a σ-donor to the metal ion through an sp-carbon atom in the linear M−C≡N−O group (Figures 9−15), whereas the metal isocyanate group M−N=C=O is bent with an sp^2-nitrogen atom (e.g. in $Ph_3PAu-N=C=O$,[104] Figure 16). DFT (Density Functional Theory) calculations by Klapötke[95] are in good agreement with the observed structural parameters (Table 4).

Table 4. Observed (X-ray) and computed structural parameters

Complex anion	Sym.	*d*(M−C) [Å] calcd./exptl.	*d*(C−N) [Å] calcd./exptl.	*d*(N−O) [Å] calcd./exptl.
$[Co(CNO)_6]^{3-}$	O_h	1.919/1.915(6)	1.181/1.130(6)	1.269/1.269(6)
$[Ni(CNO)_4]^{2-}$	D_{4h}	1.863/1.875(5)	1.184/1.138(5)	1.259/1.261(4)

Acknowledgments

Generous support over many years by the Technische Hochschule München, the Ludwig-Maximilians-Universität München, the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie and Wacker Chemie München GmbH is gratefully acknowledged. I thank Drs. Erich Schuierer, Klaus Feldl, Peter Swoboda, Claus Oetker, Karl Schorpp, Werner Becker, Florian Holsboer, Wolfgang Weigand, Walter Ponikwar, Professor Franz Lux and the X-ray crystallographers Ulrich Nagel, Peter Mayer, and Holger Pietrowski for their great enthusiasm, skill, and dedication while working with me on metal fulminates. I thank Professor Fritz Eiden for literature on Liebig and Professor Karlheinz Sünkel for looking through the manuscript.

Stoichiometric Control of the Magnetic Properties in Copper(II) Cyano-Bridged Bimetallic Complexes

Eugenio Coronado,[a] Carlos Giménez-Saiz,[a] Alicia Nuez,[a] Víctor Sánchez,[a] and Francisco M. Romero*[a]

Keywords: Magnetic properties / Heterometallic complexes / N ligands / Copper / Iron

Control of the Cu^{2+} ion coordination environment affords a 1D, magnetically diluted compound, $[Cu(cis\text{-chxn})_2]_3[Fe(CN)_6]_2\cdot 7H_2O$ (**1**) and the 2D ferromagnetic material $[Cu(cis\text{-chxn})]_3[Fe(CN)_6]_2\cdot 6H_2O$ (**2**) with a critical temperature, T_c, of 3.5 K.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The search for bimetallic cyanide systems based on Prussian blue has given rise to a rich and well-documented family of molecule-based magnets. Most of these systems are obtained from the assembly of unsaturated cations of the $[M^{II}(L)_n]^{2+}$ type (where M = Ni[1−9] or Cu;[1,9−18] L = polydentate ligand) and hexacyanometallate anions: $[M^{II}(CN)_6]^{4-}$ or $[M^{III}(CN)_6]^{3-}$ (where M^{II} = Fe^{II}; M^{III} = Fe^{III}, Mn^{III}, Co^{III}, or Cr^{III}). The choice of the polydentate ligand, the metal ion and its number of free coordination sites in the cationic unit endow us with potential control over the dimensionality and magnetic properties of these systems. Ni^{2+} ions invariably present six-coordination, whereas d^9 Cu^{2+} ions are stereochemically more versatile and can be either tetra-, penta- or hexacoordinate. Therefore, the use of $[Cu(L)_n]^{2+}$ building blocks should enable the preparation of new compounds with novel structures and perhaps improved magnetic properties. However, not very many examples of these have been reported to date. Only two of such copper-containing compounds, $[Cu(EtOH)_2][Cu(en)]_2[Cr(CN)_6]_2$ (en = 1,2-diaminoethane)[15] and $[Cu(tn)]_3[Cr(CN)_6]_2\cdot 3H_2O$ (tn = 1,3-diaminopropane),[18] have been structurally characterised and exhibit spontaneous magnetisation, with critical temperatures, T_c, of 57 K and 9.5 K, respectively. To the best of our knowledge, no $Cu^{II}-Fe^{III}$ cyanide-bridged compounds showing magnetic ordering have been reported so far, as most of the $Cu^{II}-Fe$ bimetallic systems are indeed formed by diamagnetic hexacyanoferrate(II) units. By stoichiometric control of the copper-coordination environment, allowing either axial or equatorial coordination of the hexacyanometallate anions, the compounds $[Cu(cis\text{-chxn})_2]_3[Fe(CN)_6]_2\cdot 7H_2O$ (**1**) and $[Cu(cis\text{-chxn})]_3[Fe(CN)_6]_2\cdot 6H_2O$ (**2**) (where *cis*-chxn = *cis*-cyclohexane-1,2-diamine), respectively, were obtained. Herein we report their syntheses, structural characterizations and magnetic properties.

Results and Discussion

Compound **1** crystallises in the centrosymmetric $P\bar{1}$ space group. A view of the crystal structure along the *a* axis (see Figure 1) shows the existence of Cu(1)−NC−Fe(1)−CN−Cu(2) zigzag chains running along the [011] direction and composed of alternating *trans*-$[Cu(cis\text{-chxn})_2]^{2+}$ cations and $[Fe(CN)_6]^{3-}$ anions. The latter exhibit an octahedral environment and bind axially to the copper ions in a μ^2-mode. The Cu(1) and Cu(2) atoms of the cationic unit show centrosymmetric, elongated, octahedral geometries due to Jahn−Teller effects, with long axial Cu−N distances as compared to those of equatorial ligands [Cu(1)−N(ax): 2.818(3) Å; Cu(1)−N(eq): 1.995(3) Å and 2.027(2) Å; Cu(2)−N(ax): 2.676(3) Å; Cu(2)−N(eq): 1.996(3) Å and 2.017(2) Å]. Cu−N−C angles within the chain deviate greatly form linearity, with values ranging between 120.8° and 109.4°. Similar values have been reported for other copper-containing compounds.[4,12−14,17,18] Isolated from the chain, square planar $[Cu(cis\text{-chxn})_2]^{2+}$ cations compensate the charge of the polymer. The shortest Cu(3)−N[Fe(1)] distances is 3.123(3) Å. Seven water molecules of crystallisation are present in the structure per formula unit. Four of them [O(1) and O(2)] are hydrogen-bonded to each other and to terminal cyanide groups belonging to adjacent chains, leading to a two-dimensional network.

The thermal variation of the $\chi_m T$ product for **1** is shown in Figure 2. At room temperature $\chi_m T$ equals 2.42 emu·K·mol^{-1}. This value differs from the spin-only value

 DOI: 10.1002/ejic.200300641 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

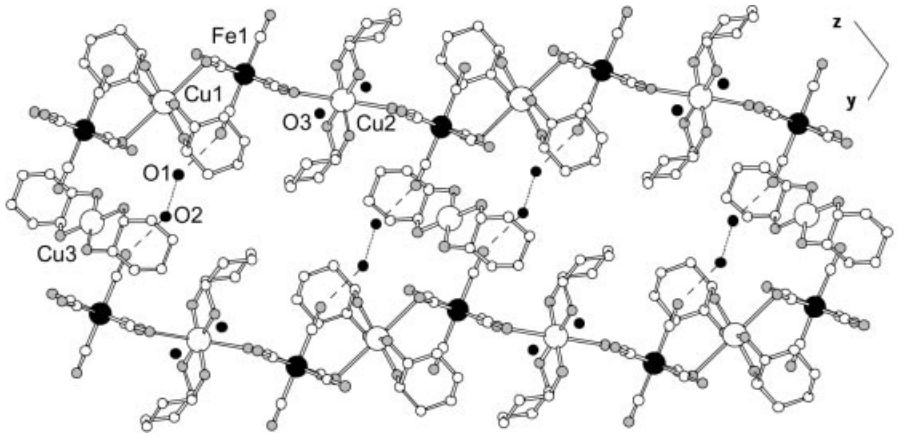

Figure 1. View of the crystal molecular structure of **1** along the *a* axis; dashed and dotted lines refer to hydrogen bonds

of 1.875 emu·K·mol^{-1} calculated for uncorrelated spins, owing to the orbital contribution in low-spin Fe^{III} complexes. Spin-orbit coupling accounts for the smooth decrease in $\chi_m T$ observed on cooling. Below 4 K, $\chi_m T$ decreases on lowering the temperature, indicating the existence of weak intermolecular magnetic interactions.

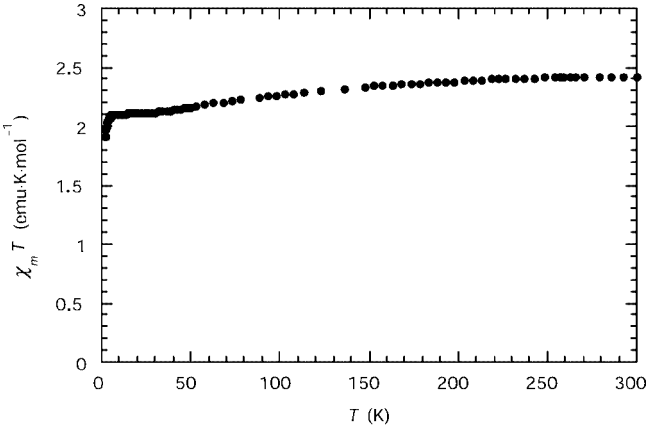

Figure 2. Temperature dependence of the χT product for **1**

Compound **2** also crystallises in the $P\bar{1}$ space group. It presents a structure similar to that reported previously for compound [Cu(tn)]$_2$[Fe(CN)$_6$]·KCl·5H$_2$O[18] (see Figure 3). The binding of [Cu(*cis*-chxn)]$^{2+}$ cations and [Fe(CN)$_6$]$^{3-}$ anions yields a two-dimensional [Cu(*cis*-chxn)]$_2$[Fe(CN)$_6$] monocationic assembly made up of defective cubane units. The structure can also be viewed as a hexagonal close packing of copper ions, in which the iron atoms occupy the octahedral sites ($CdCl_2$-type layered structure). Thus, every [Fe(CN)$_6$]$^{3-}$ moiety links to six copper atoms in a μ^6-mode, whereas each copper ion presents a square-based pyramidal geometry and links to three iron units. Two cyanide ligands and a bidentate *cis*-chxn ligand bind to the equatorial positions of the square-based pyramids and the apical sites are occupied by the third bridging CN$^-$ anion (see Table 1). One *cis*-chxn ligand is disordered over two positions in the coordination sphere of the Cu(3) metal centre. Cu−N−C angles are close to linear; the values range between 163.9° and 177.3°. Fe(2) ions occupy an inversion centre in the structure. A view along the *b* axis (see Figure 3) shows all iron atoms lying in the same *ab* plane and all copper atoms, as well as bulky cyclohexane rings, lying on both sides of this central plane. A very long interlayer Cu···Cu separation of 12.290 Å results. It should be noted that the presence of isolated [Fe(CN)$_6$]$^{3-}$ anions between the layers ensures electroneutrality and yields an overall two-component material.

The value of the $\chi_m T$ product of **2** at room temperature (2.32 emu·K·mol^{-1}) is slightly higher than the spin-only value and accounts for the orbital contribution of the low-spin iron(III) ions. A continuous decrease of $\chi_m T$ is observed on cooling (see Figure 4), as expected from the spin-orbit coupling of the iron sites. Below 15 K, $\chi_m T$ increases sharply, pointing to the onset of long-range ferromagnetic order. The first magnetisation curve performed at 2 K reaches a value of 4.69 μ_B at 5 T, close to the one expected for complete saturation. AC susceptibility measurements performed between 2 and 5 K show the appearance of an out-of-phase signal below the critical temperature, T_c = 3.5 K (Figure 4, inset). The frequency dependence of this signal appears to be a common feature in bimetallic magnets based on chxn ligands.[7,8] Finally, the magnetic order was confirmed by specific-heat measurements. The typical metamagnetic behaviour reported for several bimetallic cyanide systems was not observed in our case, a result that is attributed to the large interplanar distance induced by the presence of the bulky chxn ligands.[1,8]

Conclusion

Simple molecular orbital considerations predict the observation of ferromagnetic interactions between hexacyanoferrate(III) anions (t_{2g}^5 electronic configuration) and copper(II) ions (t_{2g}^6 e_g^3) in octahedral geometry. Surprisingly, this type of interaction has rarely been observed in such bimetallic systems and there is no previously reported example of a Cu^{II}−Fe^{III} cyano-bridged magnet, despite the fact that several two-dimensional structures have been de-

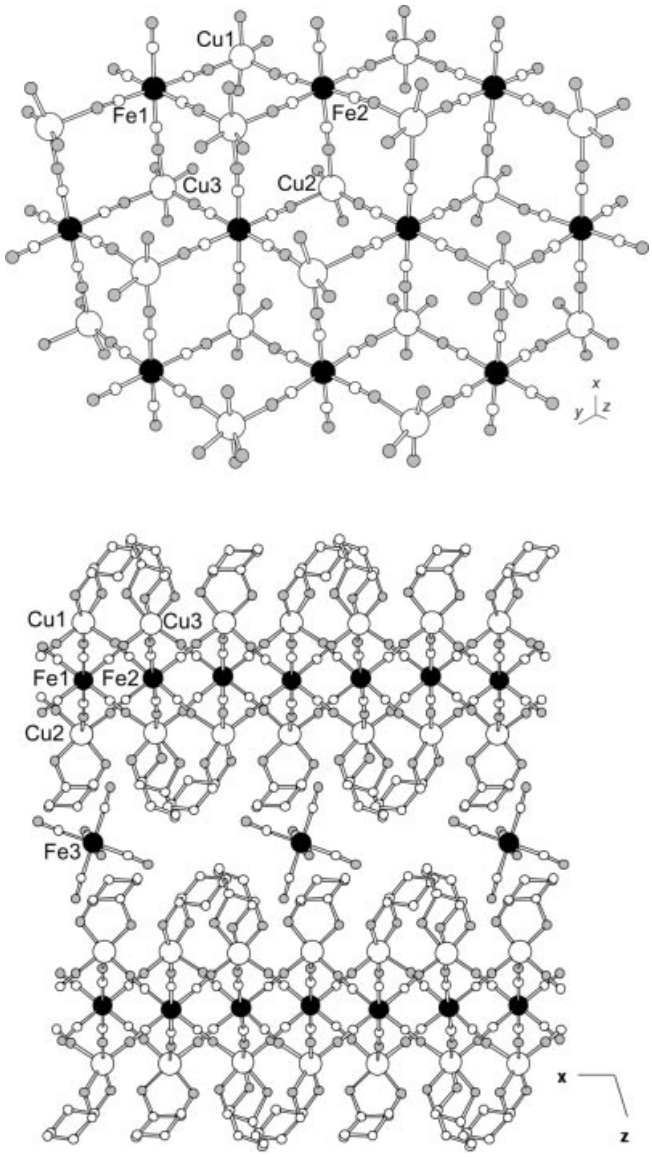

Figure 3. Crystal structure of **2**: (top) projection of the 2D monocationic network showing the defective cubane units (cyclohexane rings have been omitted for clarity); (bottom) view along the *b* axis of the interlayer arrangement and the isolated hexacyanoferrate(III) anions

scribed. It can be anticipated that the use of $[Cu(L)_2]^{2+}$ precursors (where L = diamine) in the synthesis of Cu_3Fe_2 bimetallic complexes compels axial coordination of the cyanide ligands. In fact, the soft, stronger diamine ligands are expected to occupy the equatorial positions of the Cu^{2+} coordination sphere. Due to the Jahn−Teller effect, long intrachain Cu···N(Fe) distances result and a magnetic behaviour of quasi-isolated spins is observed. As shown here, compound **1**, obtained from the $[Cu(cis\text{-chxn})_2]^{2+}$ precursor (either prepared in situ or isolated), follows exactly the same behaviour. These occurrences are overcome by the use of $[Cu(cis\text{-chxn})]^{2+}$ building blocks, enabling cyanide-bridging ligands to bind to the equatorial positions in the Cu^{II} coordination environment. Shorter Cu···N(Fe) distances and higher dimensionality are achieved in this coordination

Table 1. Cu−N distances (Å) for compound **2**

Bond	Distance (Å)
Cu(1)−N(1)	2.012(3)
Cu(1)−N(2)	2.024(2)
Cu(1)−N(3)	1.977(2)
Cu(1)−N(4)	1.987(2)
Cu(1)−N(5)	2.209(3)

Cu(2)−N(7)	2.004(3)
Cu(2)−N(8)	2.235(3)
Cu(2)−N(9)	1.981(2)
Cu(2)−N(10)	1.971(3)
Cu(3)−N(11)	2.021(4)
Cu(3)−N(11′)	2.031(7)
Cu(3)−N(12)	2.007(3)
Cu(3)−N(13)	2.111(3)
Cu(3)−N(14)	1.967(2)
Cu(3)−N(15)	2.024(3)

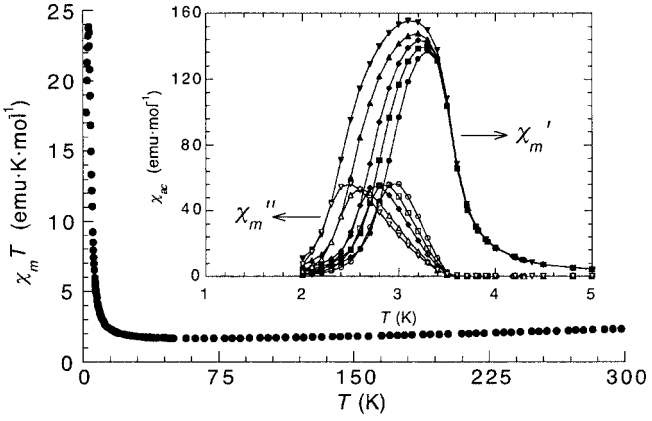

Figure 4. Temperature dependence of the *dc* $\chi_m T$ product for **2**; inset: real (filled symbols) and imaginary (open symbols) components of the *ac* magnetic susceptibility for **2** at frequencies of 997 (circles), 332 (squares), 110 (rhombuses), 10 (up triangles) and 1 Hz (dow

mode. It is also interesting to compare the quasi-linear Cu···Fe bridges of **2** with the extremely bent angles observed in **1**. This is expected to enhance the ferromagnetic components of the magnetic interactions for the former compound. All these features allow the observation of long-range magnetic ordering, despite the poor energy match between the orbitals of the different metal centres. Indeed, compound **2** is the only $Cu^{II}-Fe^{III}$ cyano-bridged ferromagnet reported to date. In addition, it exhibits a two-component structure comprising ferromagnetic layers and paramagnetic ferricyanide anions located in between. Experiments in progress (Mössbauer and single-crystal EPR) may provide information about the magnetic environment of the different sites present in the structure.

Experimental Section

General Remarks: Compounds $Cu(NO_3)_2{\cdot}3H_2O$ (Panreac), $K_3[Fe(CN)_6]$ (Fluka) and *cis*-chxn (Fluka) were of reagent grade and used without further purification.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[Cu(*cis*-chxn)$_2$(NO$_3$)$_2$]: This precursor was prepared by a method similar to that reported previously for the *trans*-chxn analogue.[19] A solution of *cis*-chxn (228 mg, 2 mmol) in methanol (5 mL) was added dropwise to a stirred solution of Cu(NO$_3$)$_2$·3H$_2$O (242 mg, 1 mmol) in the same amount of methanol. The violet precipitate was filtered off, washed with methanol and air-dried. $C_{12}H_{28}CuN_6O_6$ (415.94): calcd. C 34.65, H 6.79, N 20.2; found C 34.60, H 7.08, N 20.91. IR (KBr): $\tilde{\nu}$ = 3288, 3237, 2935, 2858, 1603 cm^{-1}.

[Cu(*cis*-chxn)$_2$]$_3$[Fe(CN)$_6$]$_2$·7H$_2$O (1): Cu(NO$_3$)$_2$·3H$_2$O (72 mg, 0.3 mmol) and *cis*-chxn (68 mg, 0.6 mmol) were dissolved in the minimum amount of water. Slow diffusion of this solution and an aqueous solution of K$_3$[Fe(CN)$_6$] (66 mg, 0.2 mmol) produced brown crystals of the title compound. Complex **1** was also obtained by slow diffusion of [Cu(*cis*-chxn)$_2$(NO$_3$)$_2$] (125 mg, 0.3 mmol) and K$_3$[Fe(CN)$_6$] (66 mg, 0.2 mmol) in water. $C_{48}H_{98}Cu_3Fe_2N_{24}O_7$ (1425.80): calcd. C 40.44, H 6.93, N 23.58; found C 40.27, H 6.78, N 24.13. IR (KBr): $\tilde{\nu}$ = 3309 cm^{-1}, 3242 (N−H), 2930, 2853 (C−H), 2118, 2105 (C≡N).

[Cu(*cis*-chxn)]$_3$[Fe(CN)$_6$]$_2$·6H$_2$O (2): This compound was obtained by slow diffusion of Cu(NO$_3$)$_2$·3H$_2$O (72 mg, 0.3 mmol), *cis*-chxn (34 mg, 0.3 mmol) and K$_3$[Fe(CN)$_6$] (66 mg, 0.2 mmol) in water as described above for **1**. IR (KBr): $\tilde{\nu}$ = 3309 cm^{-1}, 3145 (N−H), 2925, 2853 (C−H), 2172, 2141, 2105, 2100, 2090 (C≡N).

Magnetic Measurements: Variable-temperature susceptibility measurements were carried out on polycrystalline samples in the 2−300 K temperature range at magnetic fields of 1 T (**1**) and 0.1 T (**2**) using a magnetometer (Quantum Design MPMS-XL-5) equipped with a SQUID sensor. Diamagnetic contributions were corrected with Pascal's constants. Isothermal magnetization measurements at 2 K were carried out up to 5 T by using the same equipment.

X-ray Crystallographic Study: X-ray diffraction data of **1** and **2** were collected at room temperature with a Nonius−KappaCCD diffractometer using a graphite monochromated Mo-K_α radiation source (λ = 0.71073 Å). Denzo and Scalepack[20] programs were used for cell refinements and data reduction. The structures were solved by direct methods using the SIR97[21] program with the WinGX[22] graphical user interface. The structure refinements were carried out with SHELX-97.[23] All non-hydrogen atoms were refined anisotropically. Multiscan absorption corrections, based on equivalent reflections, were applied to the data using the program SORTAV.[24] Crystallographic data are summarized in Table 2.

For **1**, three independent H$_2$O solvent molecules were found in the asymmetric unit and were well behaved. The sample, however, showed the presence of further disordered water molecules. Calculations with PLATON[25] indicated a solvent-accessible void centred around the inversion point (*1/2*, *1/2*, *1/2*) with an area of 73 Å^3. There was some indication of electron density at this site. The presumed solvent was heavily disordered and no realistic atomic model could be satisfactorily refined. Therefore, the SQUEEZE procedure of Spek and van der Sluis[26] was used to accommodate this extra density. A total of 20 electrons per unit cell were recovered and they fit quite well with one water molecule. This extra H$_2$O molecule was added to the final formula of **1**. H atoms of water molecules were found in difference maps and refined positionally with geometric restraints (O−H = 0.82 Å, N−H = 0.90 Å and H···H = 1.35 Å) and with U_{iso}(H) = 1.2U_{eq}(O). The remaining H atoms were placed in calculated positions and refined with a riding model, with C−H = 0.97 Å, N−H = 0.90 Å and U_{iso}(H) = 1.2U_{eq}(C, N).

In compound **2**, one of the three independent cyclohexanediamine ligands [coordinating to Cu(3)] shows a positional disorder over two sets of sites having refined occupancies of 0.668 and 0.332. This disorder only affects three atoms of the ligand: N(11), C(28) and C(29). H atoms on O(1 W), O(2 W), O(3 W) and N atoms were found in difference maps and refined positionally with geometric restraints as described previously. The H atoms on atoms O(4 W), O(5 W) and O(6 W) could not be found clearly in difference maps.

For both compounds, six low-angle reflections were omitted from the final cycles of refinement because the observed intensities were much lower than the calculated values, as a result of being partially obscured by the beam stop.

CCDC-213881 and -213882 contain the supplementary crystallographic data for this paper. These data can be obtained free of

Analysis of Coordination and Organometallic Compounds Using Photoionisation Mass Spectrometric Techniques

Antoine Dorcier,[a] Paul J. Dyson,*[a] and J. Scott McIndoe[a,b]

Keywords: Atmospheric chemistry / Electrospray ionisation / Mass spectrometry / Transition metals

A range of coordination and organometallic compounds have been analysed by quadrupole ion-trap mass spectrometry using various photoionisation methods. Atmospheric-pressure photo ionisation (APPI), which combines atmospheric-pressure chemical ionisation (APCI) with a photolysis lamp, was compared with the new technique photo-assisted electrospray ionisation (PAESI). Additionally, the atmospheric-pressure matrix-assisted laser desorption ionisation (AP-MALDI) was also evaluated and compared to MALDI quadrupole ion-trap time-of-flight (MALDI-QIT-TOF) mass spectrometry.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

An armoury of mass spectrometric techniques is already available for determining the molecular weight and obtaining structural data on a plethora of different types of compounds. Coordination and organometallic chemists once relied almost exclusively on electron impact, chemical ionisation and fast-atom bombardment methods, but now they routinely employ electrospray ionisation (ESI) and matrix-assisted laser desorption ionisation (MALDI) techniques.[1] Although these techniques were largely developed with biomolecules and polymers in mind, various strategies have been developed to assist the analysis of coordination and organometallic compounds. For example, MALDI is sometimes most effective in the absence of a matrix; hence, LDI is a better description of the experiment. ESI mass spectrometry seems to be ideally suited to naturally charged coordination and organometallic compounds, although variations including ambient temperature ESI[2] and cold-spray ionisation[3] have been applied to compounds with labile ligands and unstable reaction intermediates, and instrument modifications made for high-throughput catalyst screening.[4] Apart from charged compounds, neutral compounds with ligands that have basic pendant groups are readily protonated and analysed; however, where such ligands are not present, a range of derivatisation reagents have been evaluated, which are now in widespread use.[5] Clearly, chemical derivatisation complicates the experiment and alternative ionisation sources would be advantageous. Since many coordination and organometallic compounds are photoactive, we have evaluated a series of photoionisation methods and indicate where they exhibit greatest utility.

A range of coordination and organometallic compounds, including metallocenes, phosphane compounds, metal-carbonyl complexes and clusters, porphyrin and phthalocyanine complexes, and bi- and tripyridine complexes (see Exp. Sect. for a full list), were investigated using a quadrupole ion-trap mass spectrometer. Initial experiments were carried out using an atmospheric-pressure photoionisation (APPI) source,[6] which comprises a krypton photolysis lamp that emits photons with energies of 10.0 and 10.6 eV combined with an atmospheric-pressure chemical-ionisation (APCI) source. APCI mass spectrometry has been previously applied to the analysis of coordination[7] and organometallic[8] compounds and we find that essentially any compound that is amenable to APCI can be analysed by APPI. The lamp can be switched on or off as the analyte enters the mass spectrometer and in certain cases large increases in the signal intensity can be obtained when the lamp is on. Perhaps the most interesting results were provided by the analysis of ruthenocene in aromatic solvents. Figure 1 shows a series of spectra of ruthenocene in toluene recorded using APCI only, APPI (i.e. APCI with PI) and APPI in which the plasma source of the APCI unit was switched off. In the APCI spectrum the dominant peak at m/z = 232 corresponds to the ruthenocenium cation $[Ru(C_5H_5)_2]^+$, but in addition, a peak of quite high relative intensity is observed at m/z = 259 and corresponds to a complex in which one cyclopentadienyl ligand has been replaced by a toluene molecule, viz. $[Ru(C_5H_5)(C_7H_8)]^+$. This type of arene exchange reaction has been observed previously, but under very different conditions, with $AlCl_3$ as a Lewis acid catalyst.[9]

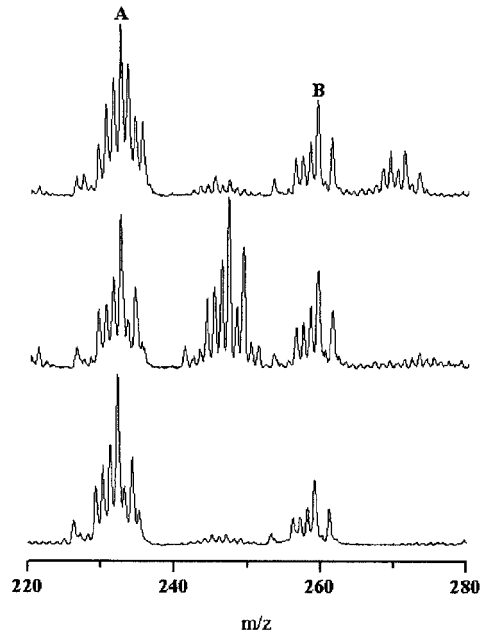

Figure 1. The positive ion mass spectra of ruthenocene in toluene recorded using (top) APCI, (middle) APPI and (bottom) APPI without the plasma: **A** corresponds to $[Ru(C_5H_5)_2]^+$ and **B** to $[Ru(C_5H_5)(C_7H_8)]^+$

Other peaks are also present, but these are less readily assigned. Using APPI the same two peaks are present, but the most intense is observed at $m/z = 247$ which cannot be assigned to any simple species (see below). However, if the APCI plasma is turned off and PI is used alone, the spectrum becomes much cleaner with the dominant peaks corresponding to $[Ru(C_5H_5)_2]^+$ and $[Ru(C_5H_5)(C_7H_8)]^+$. If the PI lamp is switched off, no peaks are observed. Clearly, the PI lamp has a significant effect, but it is very difficult to separate from the thermal effect of the APCI source (even when the plasma is off the source is maintained at a very high temperature) and the ligand exchange reaction is thermally driven. The same arene exchange process occurs with other arenes when these are used as the solvent. Solvent has already been shown to be very important in APPI mass spectrometry,[6] and here it seems probable that the PI source ionises the solvent molecules, and the solvent ions then ionise the ruthenocene. The peak of highest relative intensity obtained under APPI conditions is 15 mass units above the parent ion and might correspond to the parent ion with a methyl group attached, possibly arising from a side reaction related to the primary ionisation mechanism.

In general, most of the compounds analysed by APPI afforded spectra, but the effect of PI was minimal compared to the effect of the APCI source, which is too harsh for most coordination and organometallic compounds, resulting in extensive fragmentation and reactivity. As such, we combined PI with the considerably softer ESI source, which, as far as we are aware, has not been attempted before, and we term the technique photo-assisted ESI (PAESI). In keeping with ESI, no peaks were observed when neutral compounds were studied using PAESI mass spectrometry, but any compound that can be analysed with

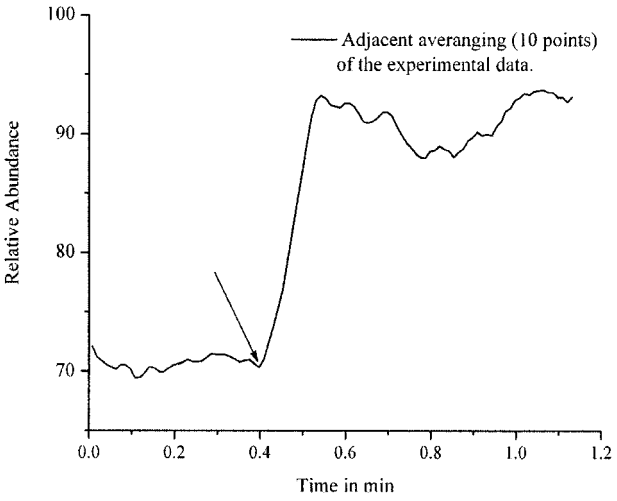

Figure 2. The effect of PI on ESI; the arrow indicates when the PI lamp was switched on, resulting in a higher ion current and hence an improved signal-to-noise ratio

ESI mass spectrometry, can be analysed by PAESI. The main effect was found for some positively and negatively charged coordination and organometallic compounds which tended to give higher ion currents, and hence improved the signal-to-noise ratio (Figure 2). However, characteristic photolysis products, such as carbonyl dissociation products, were not observed. In comparison to APPI, where photoionisation takes place in the gas-phase, in the PAESI experiment the analyte remains in the solvent during photolysis. As such, it is likely that the PI effect will be relatively dilute, since the exposure of the ions in the solvent spray is very short. As in APPI, it is likely that the solvent will play an important role and further experiments are required in this respect.

MALDI mass spectrometry, in which a laser is used to photolyse the analyte, has been used for the analysis of coordination and organometallic compounds. Atmospheric-pressure MALDI has been developed recently,[10] but the types of compounds considered here have not been analysed using this method. Since the AP-MALDI source is compatible with the quadrupole ion-trap instrument, we evaluated the method for coordination and organometallic compounds. The same method was used to great success for coordination and organometallic compounds, (viz. when no matrix[11] was present). In general, the only compounds that could be detected were those with strong chromophores such as porphyrin and phthalocyanine complexes. Metal-carbonyl compounds, for example, gave only very weak signals in AP-LDI in contrast to those in spectra obtained from LDI-TOF experiments, which reveal extensive gas-phase reaction products.[12] In the LDI-TOF experiments, the energetic ions formed by the laser desorption process undergo gas-phase reactions with little interference from other molecules or ions, because the experiment is conducted under a high vacuum. In contrast, the ions formed in the AP-LDI experiment may undergo collisional deactivation by reaction with the gas molecules present in the source. Porphyrin and phthalocyanine complexes have also

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

been shown to dimerise and oligomerise in LDI mass spectrometry,[12] although no MS/MS experiments have been conducted on the gas-phase products, which would help to confirm their identity.

Using AP-LDI, the mass spectrum of manganese phthalocyanine showed four main peaks, the parent ion $[Mn(phthalocyanine)]^+$ at $m/z = 567$ and the dimeric species $[\{Mn(phthalocyanine)\}_2]^+$ at $m/z = 1134$, (Figure 3). In addition, a peak centred at $m/z = 1153$ corresponds to two overlapping species, these being the hydroxide $[\{Mn(phthalocyanine)\}_2(OH)]^+$ and $[\{Mn(phthalocyanine)\}_2(H_3O)]^+$, and the peak at $m/z = 1168$ corresponds to $[\{Mn(phthalocyanine)\}_2(O_2H_3)]^+$, (i.e. probably an adduct with both OH and H_2O interactions). Oxidation products such as these are not unexpected for these types of compounds.[13] These products result from the presence of oxygen and water in the source, which are removed in conventional MALDI since it operates under high vacuum. In Figure 3 spectrum (ii) was obtained using exactly the same conditions, except the source was purged with nitrogen for five minutes before acquiring the data, and during data acquisition. The amount of products resulting from reactions with oxygen and water is reduced considerably. MS/MS of the simple dimer product resulted in regeneration of the parent ion only (**A**; Figure 3) indicating that the aggregate is held together by noncovalent interactions.

The same compound was analysed by MALDI quadrupole ion-trap time-of-flight (MALDI-QIT-TOF) mass spectrometry without matrix. Like the AP-MALDI experiment, a parent ion peak was observed at $m/z = 567$; however, a dimer was observed at $m/z = 1132$, which corresponds to the dimer with loss of two hydrogen atoms, probably corresponding to the formation of a C−C bond. This hypothesis is given greater weight as the MS/MS of the dimer does not result in the reformation of the monomer, but instead, a complicated series of fragmentation products are observed.

Again, the differences between the LDI-QIT-TOF and AP-LDI experiments may be attributed to the differences in pressure at which these experiments take place (see above).

Overall, the new techniques described herein cannot be applied to a wide range of coordination and organometallic compounds; APPI and PAESI give good spectra for any compound that can be analysed by APCI and ESI mass spectrometry, respectively. In addition, LDI-QIT-TOF can also be applied to any sample which is amenable to LDI, whereas AP-LDI is only suited to compounds with very strong chromophores. These various photoionisation techniques also give rise to some interesting features not accessible with other techniques currently used. For example, certain gas-phase products that form can be deciphered using the ion-trap, which allows information to be gained that would otherwise be inaccessible. We also found that for best results with AP-MALDI it is essential that the source is purged with nitrogen or another inert gas in order to reduce gas-phase reactions with oxygen or other reactive contaminants in the atmosphere. As yet, we have not evaluated in detail the influence of matrices in AP-MALDI and it is possible that their application may increase the range of compounds that can be studied.

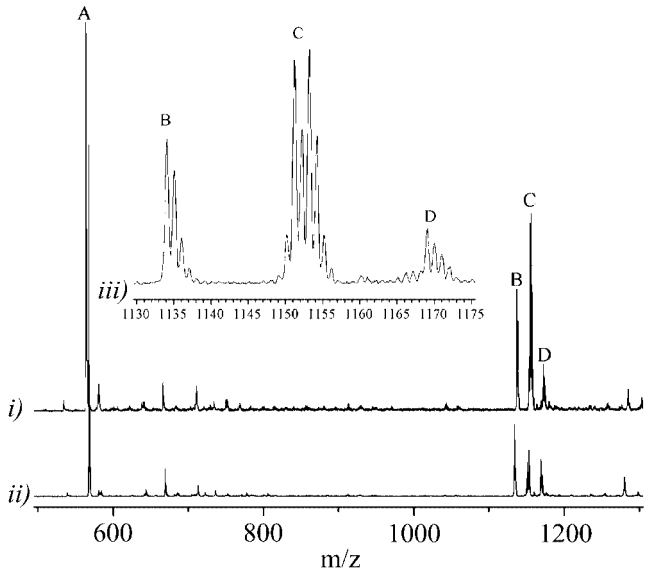

Figure 3. The positive ion AP-MALDI mass spectrum of Mn(phthalocyanine): (i) corresponds to the spectrum recorded under ambient atmospheric pressure, (ii) is the spectrum recorded when the source is purged with N_2: **A** corresponds to $[Mn(phthalocyanine)]^+$, **B** to $[\{Mn(phthalocyanine)\}_2]^+$, **C** to two overlapping ions $[\{Mn(phthalocyanine)\}_2(O)(H)]^+$ and $[\{Mn(phthalocyanine)\}_2(H_3O)]^+$, **D** to $[\{Mn(phthalocyanine)\}_2(O)(H_3O)]^+$; note that the amount of oxide and H_3O adducts reduced when the system is purged with N_2; trimers of low relative intensity are also observed (not shown)

Experimental Section

The compounds evaluated $[Fe(\eta\text{-}C_5H_5)_2]$, $[Fe(\eta\text{-}C_5H_5)(\eta\text{-}C_5H_4BOH_2)]$, $[Ru(\eta\text{-}C_5H_5)_2]$, $[Zr(\eta\text{-}C_5H_5)_2Cl_2]$, $[RhCl(PPh_3)_3]$, $[IrCl(CO)(PPh_3)_2]$, $[Ru(\eta\text{-}p\text{-cymene})(dppe)]^+$,[14] $[RuCl_2(\eta\text{-}p\text{-cymene})(pta)]$,[15] $Mo(CO)_6$ and $M_2(CO)_{10}$ (M = Mn or Re), $M_3(CO)_{12}$ (M = Fe, Ru or Os), $[Cr(\eta\text{-}C_6H_6)(CO)_3]$, $[Cr(\eta\text{-}C_{16}H_{16})(CO)_3]$,[16] $[Cr(\eta\text{-}C_7H_{10})(CO)_3]^+$, $Rh(Me)O_3$, [phthalocyanito manganese(II)], [chloro(5,10,15,20-tetraphenylporphyrinatok^4-$N^{21,22,23,24}$)iron(III)], [(5,10,15,20-tetraphenylporphyrinato-$k^4N^{21,22,23,24}$)nickel(II)], [(5,10,15,20-tetraphenylporphyrinato-$k^4N^{21,22,23,24}$)zinc(II)], *cis*-$PtCl_2(NH_3)_2$, auranofin (ICN Biomedicals Inc), ruthenium(II)tris(2,2′-bipyridyl-4,4′-dicarboxylato) dichloride (Solaronix), ruthenium(II)*cis*-bis(isocyanato)(2,2′-bipyridyl-4,4′-dicarboxylato) (Solaronix), tris(isothiocyanato)-ruthenium(II)-2,2′:6′,2"-terpyridine-4,4′,4"-tricarboxylic acid (Solaronix), ruthenium(II)*cis*-bis(isothiocyanato)bis(2,2′-bipyridyl-4,4′-dicarboxylato) (Solaronix) and tris(isothiocyanato)-ruthenium(II)-2,2′:6′,2"-terpyridine-4,4′,4"-tricarboxylic acid (Solaronix) were obtained from commercial sources (indicated when not a common supplier) or prepared by literature methods (indicated). Mass spectra were collected on a ThermoFinnigan LCQ DecaXP Plus quadrupole ion-trap instrument (APPI, APCI, PAESI and AP-MALDI) or a Shimadzu AXIMA-QIT (MALDI-OTI-TOF) mass spectrometer.

APPI, APCI and PAESI: All sources are commercially available from Thermo-Finnigan, although the PAESI must be constructed by combining the PI lamp with the ESI source. This is straightforward given the similar designs of the APCI and ESI sources. The

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

PI lamp is based on a photo-Mate ion source using a Krypton lamp which emits photons at 10.0 and 10.6 eV. Samples were infused directly into the source at 5 μL·min^{-1} using a syringe pump with nitrogen as drying gas. For the ESI source the temperature was set to 50 °C and the cone voltage within the range 4.50−5 kV. The MS detector was tuned automatically on the base peak, which optimised the remaining parameters. Samples were prepared by dissolving the complex (10−100 mg) in the appropriate mobile phase (1 mL).

AP-MALDI and MALDI-QIT-TOF: Samples were dissolved in dichloromethane solvent and deposited onto the sample probe. The solvent was allowed to evaporate leaving a thin layer of the pure sample. Several layers were added in this manner. The laser power was optimised for each sample. The spectra were recorded under air or N_2 at atmospheric pressure.

Peaks were assigned from the *m*/*z* values and from the isotope distribution patterns which were simulated using the ISOTOPE program.[17] The *m*/*z* values given are for the most intense peak in the envelope in each case.

Acknowledgments

We thank Dr. Rachel Martin (Shimadzu, Manchester, UK) for conducting the LDI-QIT-TOF experiment and the referees for their helpful comments. We thank the EPFL and Swiss National Science Foundation for financial support and JSM thanks Trinity and Newnham Colleges (Cambridge) for a college lectureship.

Non-Oxo Vanadium(IV) Complexes of Aminebis(phenolate) [O,N,O] Donor Ligands and Solution Studies of Isostructural V^{IV} and Mn^{IV} Complexes

Tapan K. Paine,[a] Thomas Weyhermüller,[a] Eckhard Bill,[a] Eberhard Bothe,[a] and Phalguni Chaudhuri*[a]

Keywords: Vanadium / Manganese / EPR spectroscopy / Cyclic voltammetry / Isomerism

Mononuclear non-oxo vanadium(IV) complexes, $[V^{IV}L^{Me}_2]$ (**1**) and $[V^{IV}LtBu_2]$ (**2**), with a tridentate bis(phenol) ligand H_2L bearing the O_2N donor atoms and with either dimethyl or di-*tert*-butyl substituents have been synthesized and the X-ray structures of **1** and **2** are reported. Additionally, **3**, an Mn^{IV} complex $[Mn^{IV}L^{Me}_2]$, and **4**, the anion containing the Mn^{III} center $[Mn^{III}L^{Me}_2]^-$, are discussed. The X-ray structure of **4** present as an anion in **4a**, $[(Me_3tacn)_2Mn^{II}_2(\mu\text{-}OOCCH_3)_3][Mn^{III}L^{Me}_2]$, where Me_3tacn = 1,4,7-trimethyl-1,4,7-triazacyclononane, confirms the magnetic susceptibility results of the high-spin d^4 nature of the manganese center in **4**. The compounds were characterized by elemental analysis, IR, UV/Vis, mass spectrometry, EPR spectroscopy, electrochemical and variable-temperature (2–295 K) magnetic susceptibility measurements. The electrochemical results of **1** and **2** suggest the metal-centered oxidation, i.e. the generation of a V^V–phenolate species, prior to the second oxidation attributable to the formation of a V^V–phenoxyl radical species. Isomerization of the meridional form for the bis(ligand)-metal species to the facial form has been observed for **1** and **3** in solution. The EPR spectroscopic data of **1** and **2** clearly show a considerable increase in the in-plane π bonding, as is expected for a phenolate ligand.

Introduction

We have been exploring the feasibility of using tridentate bis(phenol) ligands,[1] which comprise the three donor atoms [O,X,O], where X = S, Se, P, P=O or N for generating novel transition metal complexes.[2] These types of bis(phenol) ligands are expected to yield homoleptic bis(ligand) non-oxo vanadium(IV) complexes, whose relevance to bioinorganic chemistry has been mentioned quite often in the literature.[3]

It is now well established that vanadium occurs in a variety of biological systems,[3] e.g. in amavadin, a compound isolated from the mushroom *Amanita muscaria*. Amavadin has been shown to contain an eight-coordinate V^{5+} ion without oxo ligands; so-called "bare" or non-oxo vanadium species are still scarce.[4] Non-oxo vanadium centers have also been reported for the cofactor in vanadium nitrogenase. Although the chemistry of oxovanadium(IV) and -(V) complexes is well developed,[5] far less information is available for non-oxo (so-called "bare") complexes, particularly the EPR spectroscopic properties. The vanadyl ion ranks among the most stable of diatomic cations and dominates the chemistry of vanadium. Here we describe two mononuclear octahedral vanadium(IV) complexes ML_2, **1** and **2**, with the ligands H_2L^{Me} and H_2L^{tBu} (X = N) which are depicted in Scheme 1. Our expectation of non-oxo vanadium(IV) complexes was confirmed, as is authenticated by structure determinations, the results of which together with the EPR spectroscopic and electrochemical investigations are described herein. The solution properties of complex **1** and the manganese(IV) complex **3** with the same ligand are also discussed in comparison with the Mn^{III} anion complex **4**. Complex **3** and the anion complex **4** have recently been reported by us.[1c] As the structural characterization of **4** was lacking,[1c] we report it to be the same as the anion in **4a**. Scheme 1 shows the complexes to be described with their labels and the ligands.

Results and Discussion

The general method for the synthesis of complexes **1** and **2** involves an anaerobic reaction of $[V^{III}(THF)_3Cl_3]$ with the ligands H_2L and Et_3N as a base in dry acetonitrile. Exposing the resulting solution to air for a while ensures the conversion of V^{iii} to V^{IV} and subsequent storage of the solution under an argon stream, to avoid further oxidation and to concentrate the solution, yields the desired product. The reactions are clean, affording large quantities of pure crystalline products in good yield (50−80%).

$$2\ H_2L^x + V(THF)_3Cl_3 + 4\ Et_3N \xrightarrow[\text{ii) Air}]{\text{i) } CH_3CN,\ Ar} V^{IV}L^x{}_2 + 4\ Et_3NH^+ + 3\ Cl^- + 1\ e^- + 3\ THF$$

X = Me (**1**), *t*Bu (**2**)

Scheme 2

Selected IR data for complexes **1** and **2** are given in the Exp. Sect. There are several strong bands in the region 3000−2800 cm^{-1} due to the ν(C−H) stretchings of the *tert*-butyl or methyl groups. Absence of a strong ν(V=O) stretch at ca. 950 cm^{-1} in **1** and **2** indicates that the complexes are non-oxo species.

EI and ESI mass spectrometry were found to be very important analytical techniques for the characterization of complexes **1** and **2**. The EI mass spectrum of **1** shows a molecular ion peak at *m*/*z* = 645 with only 42% abundance. The base peak at *m*/*z* = 377 is a fragmentation product. The ESI (positive ion mode in CH_2Cl_2) mass spectrum for **2** clearly confirms the composition of the complex showing *m*/*z* (%) = 981 (100).

The electronic spectra (250−1200 nm) of complexes **1** and **2** in CH_2Cl_2 solution primarily consist of two transitions: a band at ca. 550 nm and the second band at ca. 400 nm. The lowest energy band at 550 nm is assigned to phenolate-to-vanadium(IV) CT transitions, by analogy with other reported "bare" vanadium(IV) complexes.[4a−4o] The higher energy transitions at ca. 400 nm, which are absent in the free ligands, are also assigned to the phenolate-to-vanadium(IV) CT transition. There is also a shoulder at ca. 700 nm for complexes **1** and **2**.

Single Crystal X-ray Diffraction Studies

Complexes **1** and **2** are structurally very similar and hence detailed structural aspects of only **1** are discussed here. The molecular structure of **3** has recently been reported.[1c] The structural parameters for the anionic unit **4** are obtained from the structural characterization of $[(Me_3tacn)_2Mn^{II}{}_2(\mu\text{-}OOCCH_3)_3][Mn^{III}L^{Me}{}_2]$ (**4a**), where Me_3tacn represents 1,4,7-trimethyl-1,4,7-triazacyclononane. The cation $[(Me_3tacn)_2Mn^{II}{}_2[\mu\text{-}OOCCH_3)_3]^+$ has been structurally characterized previously.[6]

Molecular Structure of 1

Single crystals of deep blue *mer-trans*-(*N*,*N*)-$[VL^{Me}{}_2]\cdot{}^2/_3CH_3CN$ were obtained from acetonitrile solution by slow evaporation of the solvent. As no substantial differences in bond lengths and angles are found between the crystallographically nonequivalent molecules, only one ORTEP diagram for the structure of compound **1** is displayed in Figure 1, while selected bond lengths and angles are summarized in Table 1.

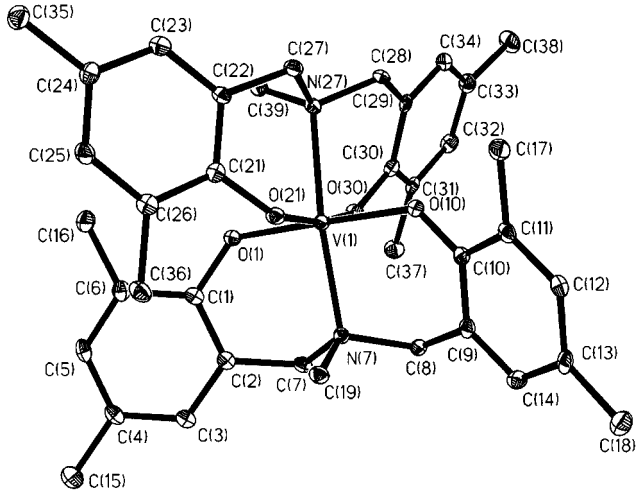

Figure 1. Molecular structure of $[VL^{Me}{}_2]\cdot{}^2/_3CH_3CN$ (**1**)

The overall geometry around the vanadium ion V(1) is best described as a distorted octahedron with *trans*-positioned nitrogen atoms N(7) and N(27) of the two amine bis(phenolate) ligands. The doubly deprotonated ligand with an [O,N,O] donor set is bound in a meridional manner.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

All the phenyl rings attached to the phenolate oxygen atoms are found to be planar, indicating that upon coordination the aromaticity of the phenyl rings is retained. The small distortion from octahedral geometry is mainly caused by the bite angles between the phenolate O atom and the N atom of the $[ONO]^{2-}$ ligand: N(7)−V(1)−O(10) 88.00(11)°, N(7)−V(1)−O(30) 93.31(11)°. The O(30)−V(1)−O(21) and O(10)−V(1)−O(1) angles are 168.88(11) and 178.51(11)°, respectively, while the corresponding N(27)−V(1)−N(7) angle at 173.88(11)° deviates from linearity. All the C−O bond lengths found in compound **1** are normal, the average being 1.345(4) Å. The average V−O and V−N distances of 1.879(3) and 2.185(3) Å fall in the range reported for other structurally characterized mononuclear vanadium(IV) complexes; the V−O bond is a little shorter.[4a] The V−N and V−O bond lengths are in agreement with those of a d^1 V^{IV} complex,[4] which also corroborate with the EPR measurements.

Molecular Structure of 2

This complex is isostructural with complex **1** having overall distorted octahedral geometry around the vanadium ion with two meridionally spanning ligands and two *trans* positioned nitrogen atoms. The ORTEP plot with the atom labeling scheme is shown in Figure 2. The structural parameters are given in Table 2.

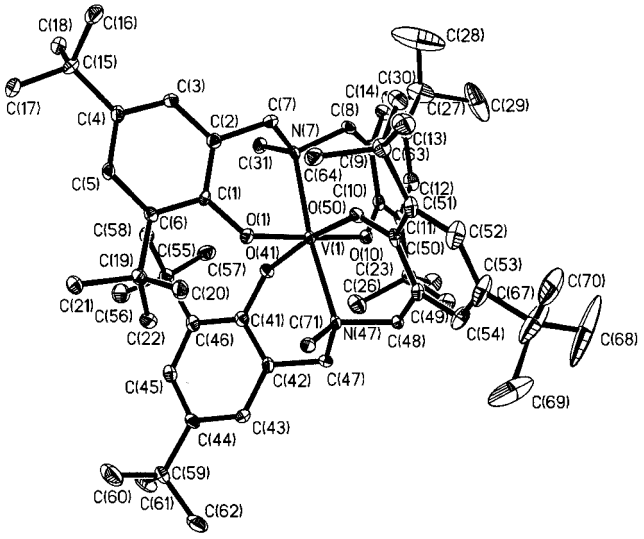

Figure 2. ORTEP representation of $[VLtBu_2]$ (**2**)

Molecular Structure of Complex 4a

The lattice of the crystal used for structural determination consists of discrete $[(Me_3tacn)_2Mn_2(\mu\text{-}OOCCH_3)_3]^+$ and $[ML^{Me}{}_2]^-$ ions. The bond lengths and angles in the cation $[(Me_3tacn)_2Mn_2(\mu\text{-}OOCCH_3)_3]^+$ are comparable (Table 3) with the reported values[6] and hence we have not described the cation in detail. An ORTEP diagram of the anion, **4** in **4a** with the atom labeling scheme is shown in Figure 3. Selected bond parameters are listed in Table 4.

O(32)−Mn(1)−N(29)	87.66(9)	O(21)−Mn(1)−N(29)	90.10(9)
N(29)−Mn(1)−N(9)	175.43(9)		

Each ligand acts as a facial [O,N,O] donor. In terms of angles within the coordination sphere, MnN_2O_4 is very close to an ideal octahedron. The ranges of *cis* and *trans* angles at the manganese center Mn(1) are 87.5(1)−92.4(1)° and 175.4(1)−176.5(1)°, respectively. The MnO_4 fragment is planar within experimental error, the mean deviation is 0.046 Å.

That the manganese center Mn(1) is in the +3 oxidation state is evident from the axial elongation of the octahedron along the N(29)−Mn(1)−N(9) axis with Mn(1)−N(29) 2.322(3) and Mn(1)−N(9) 2.317(2) Å as is expected for a Jahn−Teller distorted high-spin d^4 ion. The Mn−O [average 1.920(6) Å] and Mn−N [average 2.319(3) Å] distances fall in the range reported for the structurally characterized d^4 Mn^{III} complexes.[7] As expected, the average distances Mn(1)−O and Mn(1)−N are significantly longer than the corresponding bond lengths in complex **3** containing a +4 charged manganese center.[1c]

The anion **4**, being one of the numerous structurally characterized bis(homoleptic) manganese(III) complexes,[7] does not warrant any other special discussion.

Magnetic Susceptibility Studies

Magnetic susceptibility data for polycrystalline samples of complexes **1**, **2** and **4a** were collected over the temperature range 2−290 K in an applied magnetic field of 1 T. Above 10 K the temperature-independent magnetic moments of solids **1** and **2** are 1.69 (± 0.05) μ_B, and 1.70 (± 0.04) μ_B, respectively. These results are consistent with the formulation of the complexes as vanadium(IV) d^1 species (spin-only μ_{eff} = 1.73 μ_B) with no or very small intermolecular coupling and are in complete agreement with the X-ray and EPR spectroscopy results. Simulations (Figure S1 of Supporting Information; see also the footnote on the first page of this article) of the experimental magnetic moment data yield g_v = 1.89, temperature-independent paramagnetism (TIP) = 145 × 10^{-6} emu for **1** and g_v = 1.92, TIP = 200 × 10^{-6} emu for **2**. We note that the *g* values thus evaluated differ from those obtained from the EPR spectroscopic studies (see later).

The magnetic behavior of **4a**, $[(Me_3tacn)_2Mn_2(\mu\text{-}OOCCH_3)_3]^+[MnL_2^{Me}]^-$, is characteristic of an antiferromagnetically coupled complex (Figure 4). At 290 K the μ_{eff} value of 9.24 μ_B ($X_M{\cdot}T$ = 10.686 $cm^3{\cdot}K{\cdot}mol^{-1}$) decreases monotonically with decreasing temperature until it reaches a value of 4.12 μ_B ($X_M{\cdot}T$ = 2.127 $cm^3{\cdot}K{\cdot}mol^{-1}$) at 2 K; this is a clear indication of exchange coupling between two paramagnetic Mn^{II} centers present in the cation of **4a**, with a residual spin moment of ca. 4 μ_B due to the presence of the mononuclear $[MnL_2^{Me}]^-$ anion. The experimental magnetic data were simulated using a least-squares fitting computer program[8] involving three spins $S_1 = {}^5/_2$, $S_2 = {}^5/_2$ and $S_3 = {}^4/_2$ and applying a model in which the coupling between the S_1 and S_2 spins is only prevailing, and there is no exchange interactions between the S_3 and S_1 or S_2 spins. We use the Heisenberg spin-Hamiltonian in the form $\hat{H} = -2J\,\hat{S}_1{\cdot}\hat{S}_2$ for an isotropic exchange coupling between two spins $S_1 = S_2 = {}^5/_2$. The solid line in Figure 4 represents the best fit with the following parameters: J_{12} = −2.14 cm^{-1}, g_1 = g_2 = $g_{Mn^{II}}$ = 2.00, g_3 = $g_{Mn^{III}}$ = 1.95 and *TIP* = 185 ×

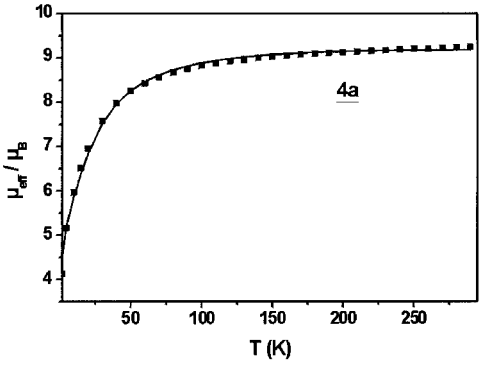

Figure 4. Plots of μ_{eff} vs. *T* for solid **4a**; the solid line represents the best fit of the data to the exchange coupling model

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

10^{-6} $cm^3 \cdot K \cdot mol^{-1}$. The evaluated antiparallel exchange coupling is very similar to that observed earlier[6] for the cation $[(Me_3tacn)_2Mn_2(\mu\text{-}OOCCH_3)_3]^+$. Thus, the magnetic susceptibility study also corroborates with the structural data of **4a**, whose anion contains the bis(ligand) manganese(III) unit (**4**) with a d^4 high-spin ion.

Electrochemical Results

Cyclic voltammograms (CVs) of complexes **1** and **2** have been measured in CH_2Cl_2 solutions containing 0.1 M nBu$_4$NPF$_6$ as supporting electrolyte at a glassy carbon working electrode and an Ag/AgNO$_3$ reference electrode. Ferrocene (Fc) was used as an internal standard, and the potentials are referenced vs. the ferrocenium/ferrocene couple (Fc^+/Fc). From the voltammograms redox potentials $E_{1/2}$ of the complexes were obtained and are compiled in Table 5.

Table 5. Redox potentials $E_{1/2}$ [V] (vs. Fc^+/Fc) of complexes **1** and **2**, obtained from cyclic voltammograms in CH_2Cl_2 solutions

Complex	$E_{1/2}^{red}$	$E_{1/2}^{ox1}$	$E_{1/2}^{ox2}$
1	−0.882	+0.177	+0.950
2	ca. −0.85[a]	+0.226	+0.875

[a] Slow heterogeneous electron transfer; electrochemically quasi-reversible.

The cyclic voltammogram of **1** displays two reversible and one irreversible wave, whereas that of **2** displays three reversible waves (Figure 5). Coulometric experiments show that the waves are due to one-electron transfer processes. The redox potentials $E_{1/2}$ for the reductions are observed in a narrow range (−0.85 to −0.88 V), irrespective of the nature of the heterodonor, i.e. N, S, Se or P [2] and since, moreover, phenolato ligands are not reduced in this potential range we assign all of these reductions to metal-centered reductions, the V^{III} form of the complexes.

For complexes **1** and **2** we performed controlled potential coulometric experiments at appropriate potentials (at −25 °C) in order to generate the reduced and oxidized forms of the complexes and recorded their electronic spectra. In each of the experiments referring to $E_{1/2}^{red}$ and $E_{1/2}^{ox1}$ the current dropped to background levels when one electron per molecule had passed. The stability of the oxidized and reduced forms was confirmed by recording a CV after the electrolysis or by the recovery of the starting material's electronic spectrum upon voltage reversal. The stabilities of the species were sufficient for the coulometric experiments (duration ca. 30 min at −25 °C).

In all reductions it was found that the broad absorption band which extends from 400 to 700 nm greatly diminishes during electrolysis. Likewise, the changes in the UV/Vis spectra during oxidations exhibit similar features for complexes **1** and **2**: new and very intense absorption grows in two regions, viz. at ca. 300−370 nm (for **1**) or 407 nm (for **2**) and in a second very broad range which extends typically from 500 to 1100 nm. These similarities of the spectral

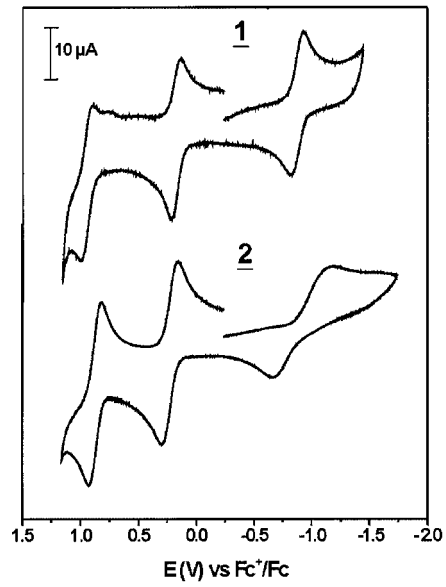

Figure 5. Cyclic voltammograms of complexes **1** and **2** in CH_2Cl_2 solution containing ca. 1 mM complex and 0.1 M nBu$_4$NPF$_6$ (scan rate = 0.2 V/s)

changes provide evidence that the oxidation mechanism is the same for compounds **1** and **2**. Since all monocations (oxidized species) were found to be EPR-silent in the temperature range 2−30 K two mechanisms appear to be feasible: a metal-centered oxidation to a V^V species or formation of an antiferromagnetically coupled V^{IV}−phenoxyl radical system.

However, phenoxyl radicals exhibit a very characteristic electronic spectrum: a band at 400−420 nm and often a single broad band at longer wavelengths with lower intensity. In the present monocations these features are not present: most of the low wavelength bands are at 300−370 nm, they are spread over a much broader range and the bands at higher wavelengths are very intense. Therefore we assign the cations to V^V species.

To gain information about the oxidation mechanism represented by $E_{1/2}^{ox2}$ we performed a $2e^-$ coulometric oxidation on **2**. During the coulometry the current approached a constant value, which indicates that the dication is not stable and there is a concomitant formation and decay of the $2e^-$-oxidized species. However, after two electrons had passed, the frozen solution showed an almost isotropic EPR signal (Figure 6) typical for an organic radical ($S = {}^1/_2$; no vanadium hyperfine coupling; $g_x = g_y = 2.0078$, $g_z = 2.0027$, $\langle g_{iso} \rangle = 2.0061$). Therefore the second oxidation represents the formation of a V^V−phenoxyl radical species.

Solution Properties and EPR Spectroscopy

Although the crystallographically characterized complex was found to be meridional in nature, complex **1** {$[VL_2^{Me}]$}separated out, from the acetonitrile reaction solution, as a mixture of two isomers (*fac* and *mer*). The solid isolated from the reaction solution after 75 h also exists in

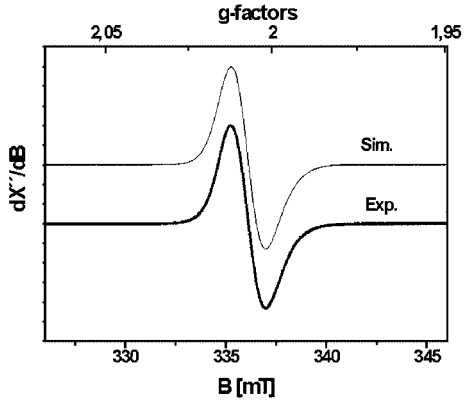

Figure 6. X-band EPR spectrum for the electrochemically $2e^-$-oxidized species of complex **2** at 30 K in CH_2Cl_2; experimental conditions (—): microwave frequency 9.44 GHz, microwave power 0.16 mW, modulation amplitude 6 G; simulations (---): g_{iso} = 2.0061; Gaussian line with angular-dependent line width W = {18, 22, 26} G

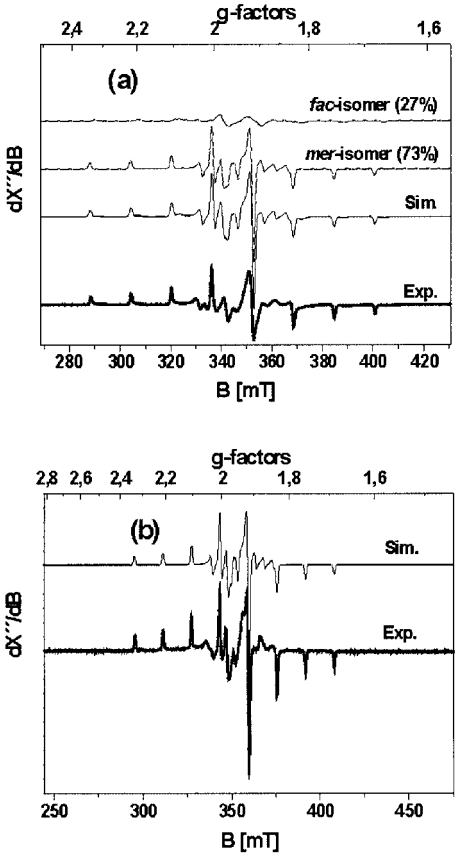

Figure 7. X-band EPR spectra of complex **1** at t = 0, T = 9.9 K (a) and at t = 90 h in CH_2Cl_2 + toluene, T = 33.8 K (b); experimental conditions (—): microwave frequency 9.44 GHz (a), 9.64 GHz (b); microwave power 0.01 μW (a), 0.2 μW (b); modulation amplitude 5 G (a), 5 G (b); simulations for spectrum (a) (---): g = {1.930, 1.960, 1.940}, A = {44, 14, 147} × 10^{-4} cm^{-1} (*fac* isomer); g = {1.932, 1.966, 1.958}, A = {44, 14, 147} × 10^{-4} cm^{-1} (*mer* isomer); Gaussian line with frequency-dependent line width W_f = 80 G (*fac*) and 30 G (*mer*)

two isomeric forms in CH_2Cl_2 solution. When the complex obtained after 75 h was dissolved in CH_2Cl_2 at room temperature followed immediately by LC analysis, both *fac* and *mer* isomers were seen. The LC analyses were performed as a function of time to monitor the change of the relative isomer percentage of **1** in solution.

With time the percentage of the *fac* isomer decreases whereas that of the *mer* isomer increases. 100% *mer* isomer is obtained after 90 h. The LC-MS, clearly indicating the two isomers present in the solution at initial or intermediate times, confirms the presence of only the *mer* form after ca. 90 h. For a qualitative comparison, the UV/Vis spectra of *mer* and *fac* isomers obtained from the LC analyses are provided as Supporting Information (Figure S2).

This change can also be observed in the solution EPR spectra recorded at low temperature. At the very beginning, the spectrum shows a mixture of two isomers, whereas at t = 90 h, only one isomer is seen. The spectrum taken at the beginning can be simulated by considering two isomers in the ratio obtained from the LC analysis (*fac*/*mer* = 27:73). On the other hand, the EPR spectrum of the same solution after 90 h shows only one isomer (meridional) in 100% and can be simulated as seen in Figure 7. The parameters found after simulations with the components x, y and z, respectively, are: g = {1.930, 1.960, 1.940} and A = {44, 14, 147} × 10^{-4} cm^{-1} for the facial isomer and g = {1.932, 1.966, 1.958} and A = {44, 14, 147} × 10^{-4} cm^{-1} for the meridional isomer. The same set of parameters for the meridional isomer was found from the simulation of the EPR spectrum taken after 90 h, containing 100% of the meridional form. Complex **2** on the contrary remains only in the *mer* form presumably due to steric reasons. The EPR spectrum of **2** was simulated with the parameters: g = {1.920, 1.945, 1.954} and A = {50, 10, 146} × 10^{-4} cm^{-1}.

Complexes **1** and **2** belong to the class with a $(d_{xy})^1$ ground state. Six-membered ring formation and steric availability favors the coordination of the ligands in a meridional manner. This results in a small increase in the equatorial σ bonding but considerable increase in the in-plane π bonding.

On the other hand, complex **3**, the Mn^{IV} complex, shows solution behavior in which the nature of the change is the opposite. When complex **3** is dissolved in methanol and the LC analysis is performed, only one isomer is found (100%). This is the *mer* isomer as confirmed from the solid-state crystal structure analysis. But with time the percentage of the *mer* isomer decreases and that of a second isomer (*fac*) increases (Figure 8). After 80 min, there is no more change and the percentage of the two isomers becomes constant with a *fac*/*mer* ratio of 1:4. At this stage the two isomers equilibrate in solution with the K_{eq} value found to be 4.

$$fac \rightleftharpoons mer$$

$$K_{eq} = [mer]/[fac] = 4$$

The isomerization processes for the isostructural **1** and **3** can be rationalized on the basis of the effective ionic radii for V^{IV} and Mn^{IV}. V^{IV}, with a larger ionic radius (0.58 Å)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

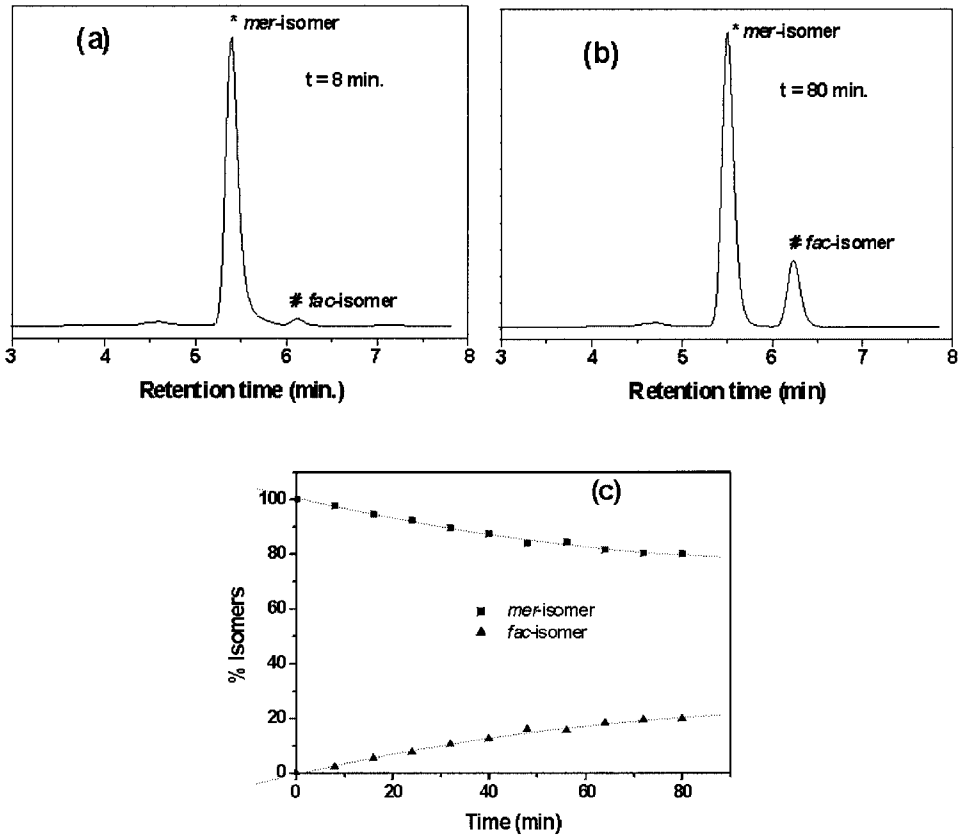

Figure 8. Liquid chromatograms of **3** (a) at t = 8 min and (b) at t = 80 min and (c) change of the isomer percentage with time for complex **3** in CH_2Cl_2 solution; the percentage of isomers is obtained from LC analysis

than that of Mn^{IV} (0.53 Å),[9] is prone to changing the coordination mode of the ligand from facial to meridional because of the steric availability in the meridional form.

This line of argument is in agreement with the observation that the Mn^{III} anion complex **4**, whose structure determination in the solid state shows the presence of only the facial form, also remains facial in solution. Mn^{III} has the largest ionic radius of 0.65 Å amongst these three ions and thus stabilizes the more sterically demanding facial form.

Conclusions

To conclude, the following points of this study deserve particular attention:

(i) The tridentate aminebis(phenolate) ligands with different substituents are capable of generating non-oxo vanadium(IV) complexes, VL_2, in which the ligands are coordinated to the V^{IV} metal center mainly meridionally. A similar geometrical isomer, i.e. meridional, is obtained with the manganese(IV) ions. On the contrary, manganese(III) exclusively yields the facial form. A rationale based on the metal ionic radii has been forwarded to explain the difference in geometrical isomers.

(ii) The investigation emphasizes the observation of the presence of two geometrical isomers, meridional and facial, in solution, albeit the structure determined in the solid state to be meridional.

(iii) Electrochemical measurements indicate that the reversibility of the redox processes is profoundly affected by the substituent on the ligand. Thus, the ligand with *tert*-butyl groups yields reversible redox behavior for the metal complexes. No stabilization of the V^{IV}–phenoxyl radical species has been observed. On the other hand, the formation of a V^{V}–phenoxyl radical complex has been clearly shown by an EPR spectroscopic experiment.

Experimental Section

Materials and Physical Measurements: Commercial grade chemicals were used for the synthetic purposes and solvents were distilled and dried before use. Fourier transform IR spectroscopy on KBr pellets was performed with a Perkin–Elmer 2000 FT-IR instrument. Solution UV/Vis spectra were measured with a Perkin–Elmer Lambda 19 spectrophotometer. Mass spectra were recorded either in the EI or ESI (in CH_2Cl_2) mode with a Finnigan MAT 95 or 8200 spectrometer. Magnetic susceptibilities of the polycrystalline samples were recorded with a SQUID magnetometer (MPMS, Quantum Design) in the temperature range 2–290 K with an applied field of 1 T. The resulting volume magnetization from the sample had its diamagnetic contribution compensated and was recalculated as volume susceptibility. Diamagnetic contributions were estimated for each compound by using Pascal's constants.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Cyclic voltammetry and coulometric experiments were performed using an EG&G potentiostat/galvanostat. X-band EPR spectra were recorded with a Bruker ESP 300E spectrometer equipped with a helium flow cryostat (Oxford Instruments ESR 910), an NMR field probe (Bruker 035M), and a microwave frequency counter HP5352B. Spin-Hamiltonian simulations of the EPR spectra were performed with a program that was developed from the routines of Gaffney and Silverstone[10] and that specifically makes use of the resonance-search procedure based on a Newton−Raphson algorithm as described therein. LC experiments were performed with HPLC instrumentation using a Gilson M305 pump, and the Diode Array Detector (DAD) SPDM 10 AV(Shimadzu Corporation). CH_3OH (0.8 mL/min) was used as eluent through a Nucleodor-5μ-(100A)-C18 column. LC-MS was performed using the above column with a mass spectrometer having a mass-selective detector.

X-ray Crystallographic Data Collection and Refinement of the Structures: Single crystals of **1**, **2** and **4a** were coated with perfluoropolyether, picked up with glass fibers, and mounted on a Nonius Kappa-CCD diffractometer equipped with a cryogenic nitrogen cold stream operating at 100(2) K. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used. Intensity data were corrected for Lorentz and polarization effects. The intensity data set of **1** was corrected for absorption with the use of the program Gaussian face-indexed and that for **2** and **4a** were not corrected. The Siemens SHELXTL software package (G. M. Sheldrick, Universität Göttingen[13] was used for solution, refinement, and artwork of the structure, and neutral atom scattering factors of the program were used. All structures were solved and refined by direct methods and difference Fourier techniques. Non-hydrogen atoms were refined anisotropically, and hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters. Details of data collection and structure refinements are summarized in Table 6. CCDC-211067 (**1**), -211068 (**2**) and -211069 (**4a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033. E-mail: deposit@ccdc.cam.ac.uk].

Ligand Synthesis: The ligands H_2L^{Me},[1c,11] and H_2LtBu[11] were synthesized according to the published procedure. Syntheses of the complexes **3** and the complex anion **4** have recently been reported by us.[1c]

General Method for the Synthesis of V^{IV} Complexes 1 and 2: $V(THF)_3Cl_3$ (0.5 mmol, 0.186 g) was dissolved in a degassed CH_3CN solution (40 mL) of ligand (1 mmol). Et_3N (0.5 mL) was added to the violet solution and the resulting solution was refluxed under argon for 0.5 h. After cooling to room temperature, the solution was opened to air and stirred for 5 min. The solution was then concentrated by passing argon over the surface of the solution to yield a crystalline solid.

Complex $[VL^{Me}_2]\cdot{}^2/_3CH_3CN$ (1): Yield: 0.23 g (68%). $C_{38}H_{46}N_2O_4V\cdot{}^2/_3CH_3CN$ (673.1): calcd. C 70.19, H 7.19, N 5.55, V 7.57; found C 69.9, H 7.1, N 5.5, V 8.7. Kinetics of Oxidation of Azide by [Ethylenebis(biguanide)]silver(III) in Aqueous Acidic Media

Prabir Bandyopadhyay,[a] Basab Bijayi Dhar,[a] Jhimli Bhattacharyya,[a] and Subrata Mukhopadhyay*[a]

Keywords: Kinetics / Mechanisms / Redox chemistry / Silver / Azides

In aqueous acidic media sodium azide and the orange-yellow title complex react quantitatively generating N_2 gas along with a colourless solution of Ag^+ ion and the ligand, ethylenebis(biguanide). The parent complex, $[Ag(H_2L)]^{3+}$, and one of its conjugate bases, $[Ag(HL)]^{2+}$, participate in the reaction with N_3^- as the kinetically reactive reductant. Ag^+ has no catalytic effect. At 25.0 °C, I = 1.0 M ($NaNO_3$), rate constants for the reactions $[Ag(H_2L)]^{3+} + N_3^-$ and that for $[Ag(HL)]^{2+} + N_3^-$ are (12.3±0.5) and (3.8±0.6) $M^{-1}\cdot s^{-1}$, respectively. The high rate constants along with the very low equilibrium constant (10^{-15} M^{-1}) calculated for the first reaction strongly suggest inner-sphere redox mechanism.

Introduction

Ethylenebis(biguanide)silver(III) (Figure 1) represents the simplest cationic complex[1−3] of Ag^{III} stable in aqueous solution over a wide pH range against dechelation and intramolecular redox decomposition.[4] The square-planar acyclic tetraaza ligand imparts fascinating thermodynamic stability[5] to the Ag^{III} state and renders the title complex a milder oxidant[6] than Ag^+. It is a potential inner-sphere oxidant,[7−11] which may bind a reducing ligand in its vacant axial coordination sites. But in this strong-field d^8 system such ligand binding is likely to be weak or at best moderate. Hence, outer-sphere reactions may be energetically more favourable[12,13] for weakly basic but strongly reducing ligands with the Ag^{III} complex. In redox reactions the complex may act as either a one-[7] or a two-electron[10] oxidant. In solution the title complex undergoes ligand-based protic equilibria.[14] Also, the Ag^{III}-bound ligand, H_2L may form hydrogen bonds with a suitable reducing agent, like $HC_2O_4^-$ and lead to a dead-end adduct in the electron-transfer pathway.[15] The mechanistic versatility of oxidations of various organic and inorganic species by the title Ag^{III} complex is an outcome of such properties as discussed above.

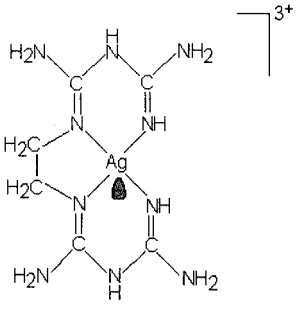

Figure 1. Structure of $[Ag(H_2L)]^{3+}$; the gray-shaded area represents a weakly bonded ClO_4^- ion at the axial site

Kirschenbaum et al. studied[16] the oxidation of N_3^- by $Ag(OH)_4^-$ in strongly alkaline media. They found that the N_3^- ion replaced a coordinated hydroxide ion in $Ag(OH)_4^-$ and the azido complex so produced underwent subsequent redox decay with another N_3^- ion. Sengupta et al. proposed an analogous mechanism[17] for the oxidation of N_3^- by $[Ag(H_2TeO_6)_2]^{5-}$, again in strongly alkaline media. We are not aware of any mechanistic study of azide oxidation by higher valent silver species in acidic media. The exceptional stability of the title complex towards redox decomposition in acidic media affords a good chance to examine for the first time the reactivity of HN_3 and N_3^- towards a cationic Ag^{III} complex in acidic solutions. Moreover, the ligand H_2L in $[Ag(H_2L)]^{3+}$ is substitution-inert so that Ag^{III} never comes free in solution to open up extra, complicating pathways in its kinetics.

Results and Discussion

Preliminary Observations

In the absence of any external buffer, the media pH before and after the reactions did not change by more than 0.05 units. Autodecomposition of the Ag^{III} complex was insignificant under the experimental conditions of pH and temperature. No Ag^+ catalysis (studied up to 0.01 M) was found in the reactions. We did not extend the reaction pH

> ca. 4.05, as reaction mixtures above pH ≈ 4.2 turn turbid probably due to formation of insoluble silver azide after ca. 30% decrease in their initial absorbances, thus seriously interfering with the kinetic measurements.

Stoichiometry and Reaction Products

Stoichiometric measurements yielded $\Delta[Ag^{III}]_T/\Delta T_R = 0.52\pm0.05$. The principal conversion can thus be represented by Equation (1).

$$Ag^{III} + 2\ N_3^- \rightarrow Ag^{I} + 3\ N_2 \quad (1)$$

The oxidation of azide to dinitrogen was qualitatively confirmed by GC analysis. Immediately after completion of the reaction (absorbance < 0.01 at 380 nm), the solution pH was raised to ca. 5 by adding NaOH solutions when all Ag^+ was precipitated as AgN_3 and removed by filtration. From the filtrate, the free ligand ethylenebis(biguanide) was quantitatively isolated[18] as the sparingly soluble [ethylenebis(biguanide)]copper(II) sulfate, and the amount of Cu^{II} thus held was estimated iodometrically after decomposing the Cu^{II} complex. The results showed that more than 95% of the free ligand (H_2L) was recovered.

Kinetics

No immediate spectral changes were observed on mixing the reactants over the entire experimental range of pH. But the absorbance of the reaction mixtures at $\lambda \geq 380$ nm gradually decreased to less than 0.01 and the $\log_{10}$(absorbance)/time plots were found to be linear to 90% completion of the reactions. The first-order rate constants, k_{obs}, defined by Equation (2) were obtained from least-squares slopes of these plots.

$$-d[Ag^{III}]/dt = k_{obs}[Ag^{III}] \quad (2)$$

Averages of the k_{obs} values (Table 1) from at least three independent runs were taken and the average coefficients of variation (CV) for these measurements were within 3%.

The reaction was found to be first-order in T_R (= $[HN_3] + [N_3^-]$) and there is no T_R-independent term. The following changes of the reaction conditions had, within the limits of experimental uncertainties, no influence on the values of k_{obs}: a fivefold variation in $[Ag^{III}]$ from 0.10 to 0.50 mM, addition of $AgNO_3$ up to 0.01 M, addition of ethylenebis(biguanide) up to 1.0 mM, occasional shaking of the spectrophotometer cell, presence or absence of dissolved oxygen and diffused light, and a variation in the monitoring wavelength in the range 380−480 nm.

No polymer formed when 6% (v/v) acrylonitrile was added to the reaction mixture and the entire reaction course was EPR-silent. These experiments therefore indicate that free radicals or other paramagnetic species like Ag^{II} do not accumulate in the reaction media in concentrations detectable by either of these two methods.

The value of k_{obs} sharply decreases with increasing $[H^+]$. A plot of k_{obs} versus $[H^+]^{-1}$ at a fixed T_R (Figure 2) is a

[a] [complex] = 0.20 mM, T = 25.0 °C, I = 1.0 M ($NaNO_3$). Calculated k_{obs} values are given in parentheses. [b] CV was measured using the relation: CV = sd × 100/x, where sd = standard deviation of the measurements of k_{obs} and x = average k_{obs}. See ref.[19], p. 1123. [c] 10^4 k_{obs} [s^{-1}] values are 91.0, 97.0 and 106 at I = 0.5, 0.2 and 0.1 M respectively.

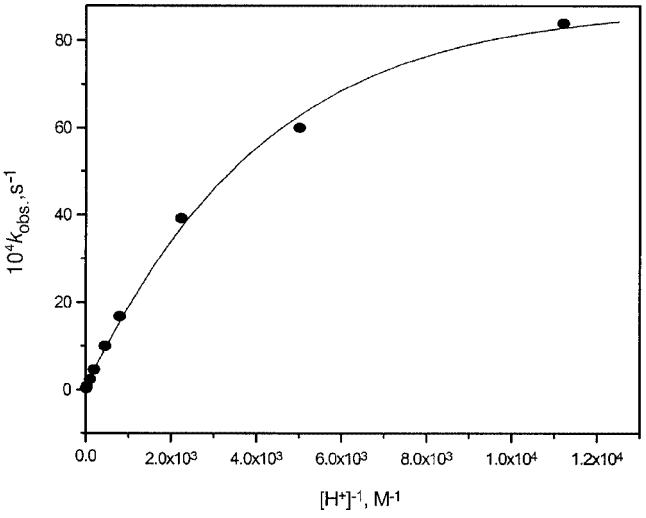

Figure 2. Plot of k_{obs} versus $[H^+]^{-1}$ at T_R = 3.0 mM; the solid line represents the fit of Equation (7)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

good straight line for pH ≤ 2.9 ($[H^+] \geq 1.26\cdot10^{-3}$ M) with zero intercept but droops at higher $[H^+]^{-1}$. Such $[H^+]$ dependence of k_{obs} indicates that the conjugate base form of one of the reactants is more reactive while that of the other is less reactive than the parent acid. We infer that N_3^- is much more reactive than HN_3 while $[Ag(H_2L)]^{3+}$ is more reactive than its conjugate base, $[Ag(HL)]^{2+}$. This is expected from known kinetic behaviour[11,12,19,20] of these species and the fact[21,22] that protonation generally increases the reactivity of metal complex oxidants whereas the anionic forms of protolytic reductants are much more reactive than the uncharged molecular compounds.[23–25] The near-zero value for k_{obs} at high $[H^+]$ further suggests that kinetic activity of HN_3 is negligible for the present system. The scheme in Equations (3) to (6) most simply accommodates the kinetic observations and the known acid/base equilibria K_{a1} and K_a.

$$[Ag(H_2L)]^{3+} \overset{K_{a1}}{\rightleftharpoons} [Ag(HL)]^{2+} + H^+ \quad (3)$$

$$HN_3 \overset{K_a}{\rightleftharpoons} H^+ + N_3^- \quad (4)$$

$$[Ag(H_2L)]^{3+} + N_3^- \xrightarrow{k_1} \text{Products, } Ag^+ + H_2L + N_2 \quad (5)$$

$$[Ag(HL)]^{2+} + N_3^- \xrightarrow{k_2} \text{Products, } Ag^+ + HL + N_2 \quad (6)$$

The derived rate-law for this scheme is Equation (7).

$$k_{obs}(K_{a1} + [H^+])(K_a + [H^+])/T_R = k_1K_a[H^+] + k_2K_{a1}K_a \quad (7)$$

A plot of the left hand side of Equation (7) versus $[H^+]$ is a good straight line (Figure 3, $r = 0.99$) with slope = $(8.0\pm0.3) \times10^{-4}$ s^{-1} and intercept = $(3.9\pm0.6) \times10^{-8}$ M·s^{-1}. Using known K_a (= $6.5\cdot10^{-5}$ M)[26] and K_{a1} (= $1.585\cdot10^{-4}$ M)[14] values, these lead to $k_1 = (12.3\pm0.5)$ $M^{-1}\cdot s^{-1}$ and $k_2 = (3.8 \pm 0.6)$ $M^{-1}\cdot s^{-1}$. These rate constants reproduced all experimental k_{obs} values satisfactorily (Table 1).

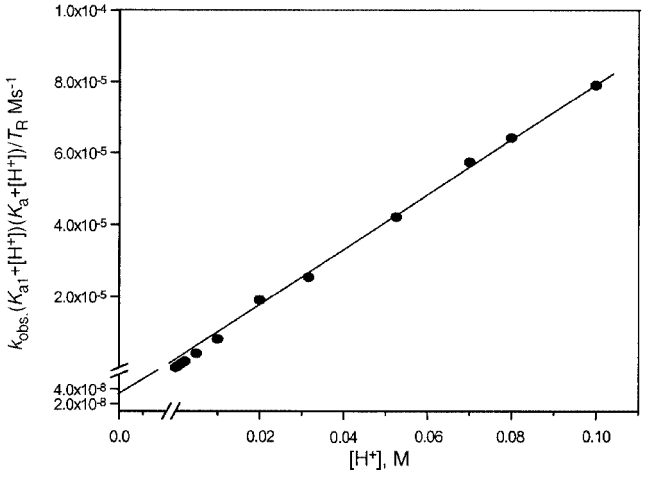

Figure 3. Plot of $k_{obs}(K_{a1} + [H^+])(K_a + [H^+])/T_R$ versus $[H^+]$; the solid line represents the fit of Equation (7)

Mechanism

The redox potentials for the couple $[Ag(H_2L)]^{3+/2+}$ and that for N_3^-/N_3 are 0.43 V[27,6] and 1.33 V,[28] respectively. The self-exchange rate constant[28] for N_3^-/N_3 is $4\cdot10^4$ $M^{-1}\cdot s^{-1}$ and the upper limit for the self-exchange rate for $[Ag(H_2L)]^{3+/2+}$ has been estimated[27] to be $10^{6.6}$. With these values and using the Marcus cross-relation,[29] $k_{12} = (k_{11}k_{22}K)^{1/2}$, the calculated maximum value of the outer-sphere oxidation rate of N_3^- by $[Ag(H_2L)]^{3+}$ is 10^{-4} $M^{-1}\cdot s^{-1}$, considerable less (10^5 times) than k_1 and we therefore propose an inner-sphere mechanism for the k_1 path. An inner-sphere mechanism appears very likely for the k_2 path, too. Indeed, the very high thermodynamic price for the oxidation of N_3^- to N_3 essentially requires strong oxidants[30,31] like $[Ni(bipy)_3]^{3+}$ or $[CoW_{12}O_{40}]^{5-}$ for outer-sphere reactions to occur.

Coordination of the azide ion to the metal centers[16,17,32–34] in $[Ag^{III}(OH)_4]^-$, $[Ag^{III}(H_2TeO_6)_2]^{5-}$, $[Cu^{III}(H_2TeO_6)_2]^{5-}$, $[Mn^{III}(bipy)_2(OH)]^{2+}$, $[Mn^{III}(edta)(H_2O)]^-$, or in Mn_{aq}^{3+} are well documented with the formation constants of azido complexes lying in the range 10^{-1} to 10^2. A similar azide binding is likely for the Ag^{III} complex under investigation. X-ray photoelectron spectroscopic measurements[35] have shown that the silver(III) centre in the title complex has a high degree of positive charge resulting in a high electron affinity of the Ag^{III} ion. Expectedly, therefore, structural[36–38] and kinetic studies[8,9,11] indicated axial coordination by Ag^{III} with low molecular weight alcohols, H_2O_2, SO_4^{2-}, NO_3^-, or even ClO_4^-. The kinetic steps (5) and (6) are therefore most likely to proceed via intermediate adduct formations between Ag^{III} and N_3^- followed by intramolecular redox decomposition to form the final products. The present results cannot straightaway eliminate the possibility of proton-ambiguous paths like

$$[Ag(H_2L)]^{3+} + HN_3 \rightleftarrows \{[Ag(H_2L)]^{3+}\cdot N_3^-\} + H^+;$$
$$\{[Ag(H_2L)]^{3+}\cdot N_3^-\} \rightarrow \text{Products, etc.}$$

Nevertheless, the observed increase in reaction rate with decreased ionic strength of the reaction media does not fit into this alternative reaction scheme, rather it directs the reaction between oppositely charged ions. Also, it has been established that N_3^- is kinetically far more reactive than HN_3 and may exhibit overwhelming kinetic dominance over HN_3[30,39] even for redox reactions in 1 M acid.

In the lower pH range (pH ≤ 2.9), where $[Ag(H_2L)]^{3+}$ is the only active and sole oxidant, the rate law simplifies to $k_{obs}/T_R = kK_a/[H^+]$. The observed linearity of the k_{obs} versus $[H^+]^{-1}$ plot at higher $[H^+]$ demands a maximum value of the order of 10^1 M^{-1} for preequilibrium formation of any adduct between $[Ag(H_2L)]^{3+}$ and N_3^-. $[Ag(HL)]^{2+}$, a possible weaker Lewis acid than its conjugate acid should bind N_3^- even less tightly.

The present kinetic observations cannot unambiguously settle the question of one- or two-electron transfer. The immediate one-electron oxidation product[28,40–44] of azide is N_3, as firmly established by pulse radiolysis, flash photolysis or by molecular beam studies. The azidyl radical (N_3)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

may decay to N_2 in several ways, like by fragmentation[45] to N_2 and N, the process, although spin-forbidden, is close to thermoneutral[46] with a rate constant[47,48] around 10^6 s^{-1}. In yet another possibility, N_3 can combine with N_3^- forming[49−51] N_6^- (however, attempts to observe the radical dimer N_6^- using pulse radiolysis met with no success,[48b] but nanosecond laser flash photolysis[50,51] and kinetic evidences[16] suggest involvement of N_6^- in some instances) and then rapid reaction of N_6^- with the oxidant species or a rapid direct reaction of two mol of N_3 radical could produce three mol of N_2 ($2\ N_3 \rightarrow 3\ N_2$, $2k = 9\cdot10^9$ $M^{-1}\cdot s^{-1}$).[28] The absence of EPR evidence for Ag^{II} or N_3 radicals in our study cannot conclusively eliminate the formation of such species as it may only indicate that such species are formed but decayed too rapidly before they can diffuse into the bulk solvent sufficiently quickly to permit detection. For example, Equations (8) to (12) are one conceivable expansion for the k_1 path.

$$[Ag(H_2L)]^{3+} + N_3^- \overset{K}{\rightleftharpoons} \{[Ag(H_2L)]\cdot N_3\}^{2+} \quad (8)$$

$$\{[Ag(H_2L)]\cdot N_3\}^{2+} \xrightarrow{k_1'} [Ag^{II}(H_2L)]^{2+} + N_3 \quad (9)$$

$$[Ag^{II}(H_2L)]^{2+} + N_3^- \xrightarrow{fast} Ag^I + H_2L + N_3 \quad (10)$$

$$N_3 \xrightarrow{k_d} N_2 + N \quad (11)$$

$$2\ N \xrightarrow{fast} N_2 \quad (12)$$

Reaction (9) requires a very high thermodynamic price and is as such unfavourable. Yet, the very high protonation constants[52] of the ligand H_2L drag the overall reaction to completion in acidic media.

An alternative for the assigned fate of the azidyl radical could be the dimerisation to produce N_6 that ultimately produces N_2. But, this appears unlikely here as, if it were the actual pathway, then sufficient accumulation of N_3 to cause appreciable reversal of reaction (9) and hence rate retardation (deviation from simple first-order kinetics) could be anticipated.[48b,53] No such retardation could be detected and thus the dimerisation pathway is neglected in the present study.

Though the silver(III) complex under investigation is far more stable than $[Ag(OH)_4]^-$ or $[Ag(TeO_4)_2(OH)_4]^{5-}$, it oxidises N_3^- at a faster rate. This can be attributed to a difference in mechanism operating in these oxidations, for example, two-electron transfer in $[Ag(OH)_3N_3]^-$ or in $[Ag(TeO_4)_2(OH)_3(N_3)]^{5-}$ and the proposed one-electron transfer in our inner-sphere adducts. A reactive species ambiguity (HN_3 versus N_3^-) may also be a reason for obtaining a higher rate in the present investigation. However, of these two alternatives, the first appears more logical but the proton-ambiguity situation is unresolvable. The tetraaza ligand is expected to stabilise Ag^{II} much more than that by hydroxide or tellurate.

Direct two-electron changes in these redox steps to form N_3^+ which reacts with N_3^- forming N_6 and ultimately decays to N_2 cannot be ruled out in principle. Formation of N_3^+ has been proposed for the thermal decomposition[54] of $[Mn(N_3)_2]^{2+}$ and photoinduced reductive decomposition of *cis*-$[Pt(N_3)_2(PPh_3)_2]$ has provided distinct spectral evidence for the intermediate formation[55] of neutral cyclic hexazine, N_6.

Experimental Section

Materials: The silver(III) complex, $[Ag(H_2L)]^{3+}$, was prepared by a known procedure.[3,56] Sodium azide (G. R., E. Merck) solutions were standardised by Ce^{IV} titration.[57] $NaNO_3$ (G. R., E. Merck) solutions were standardised by passing an aliquot through a Dowex 50W X-8 strong cation exchange resin in the H^+ form and titrating the liberated acid with standard NaOH to a phenolphthalein endpoint. To avoid any possible interaction of azide with oxides of nitrogen,[58] the stock HNO_3 solutions were purged with argon before use. All measurements were made at 25.0 °C and I = 1.0 M ($NaNO_3$). All solutions were prepared in water which was deionised and then doubly distilled.

Physical Measurements and Kinetics: UV/Vis spectra were recorded with a Shimadzu (1601 PC) spectrophotometer using 1.00-cm quartz cells. Kinetics were generally monitored at 380 nm in situ in the thermostatted (25.0±0.1 °C) cell-housing (CPS, 240A). For faster reactions sodium azide solutions (adjusted to the desired pH) were directly injected into the spectrophotometer cell containing other components of the reaction mixture at the same pH. The desired concentrations of the complex and the reducing agent were achieved after mixing which was immediately followed by automatic monitoring of the change in absorbance with time. We used capped quartz cells with minimum vacant space left and thus avoided escape of volatile HN_3. The solution pH (1.00−4.05) was measured with a Systronics (India) pH meter (model 335) with electrodes calibrated as described earlier.[59] All such pH measurements were done quickly to ensure minimum evaporation of volatile HN_3. Spectrophotometric determination[60] of azide in blank experiments indicated a near quantitative (≥ 97%) recovery of total azide under our experimental conditions. Excess reducing agent, T_R (= $[HN_3] + [N_3^-]$), 1.5−30.0 mM over the complex (0.20 mM) was used in all kinetic runs.

Stoichiometry and Reaction Products: The reaction stoichiometry was determined under kinetic conditions in the pH range 3.5−4.0 by estimating unchanged azide spectrophotometrically. Excess azide was mixed with the complex solutions and stored until the reaction mixtures turned colourless indicating complete reduction of Ag^{III} to Ag^I. $Fe(NO_3)_3$ solution in 0.5 M HNO_3 was then added to the product mixtures[60] to achieve $[Fe^{III}]/T_R$ in the final solutions within the range 1.5−2.5. The pH of the solutions was then adjusted[60] to 1.5−2.0 using HNO_3 or NaOH, as needed. A red complex, $[Fe(H_2O)_5N_3]^{2+}$, generated within minutes. Its absorbance at 460 nm yielded the concentration of unchanged azide from a calibration curve constructed under comparable conditions (ε = 3570 $M^{-1}\cdot cm^{-1}$, literature value,[60] 3680 $M^{-1}\cdot cm^{-1}$). We verified that Ag^+ or the ligand, ethylenebis(biguanide), do not interfere with the measurement of the azide concentration. The gaseous product formed during the reactions was collected over a saturated sodium chloride solution as described earlier[61] and analysed by gas chromatography using a Chemito (India) GCHT 8610 equipped with TCD, a Porapack Q and molecular sieves 13 X column. Splitless mode injection of 500 μL of sample was used. The oven temperature, injector and detector temperature were kept at 40, 55, and 100 °C, respectively. The carrier hydrogen gas flow was adjusted to 30 mL/min.

η^1-Vinylidene to η^2-Alkyne Isomerization of Tungsten and Molybdenum Complexes

Junes Ipaktschi,*[a] Javad Mohsseni-Ala,[a] and Sascha Uhlig[a]

Keywords: Vinylidene ligands / Alkyne ligands / Isomerization / Kinetics / Isotope effects

The thermal isomerizations of η^1-vinylidene complexes [(η^5-C_5H_5)(CO)(NO)W=C=CHR] [**5a**, R = $Si(CH_3)_2C(CH_3)_3$; **5c**, R = $C(CH_3)_3$] as well as [(η^5-C_5H_5)(CO)(NO)Mo=C=CHC$(CH_3)_3$] (**8**), to the corresponding η^2-1-alkyne complexes [(η^5-C_5H_5)(CO)(NO)W(η^2-H–C≡C–R)] [**7a**, R = $Si(CH_3)_2C(CH_3)_3$; **7c**, R = $C(CH_3)_3$] and [(η^5-C_5H_5)(CO)(NO)Mo{η^2-H–C≡C–CHC$(CH_3)_3$}] (**9**) has been investigated. Activation parameters for the isomerization of **5a** in [D_6]benzene and **8** in [D_8]toluene and [D_5]ethanol were determined. In [D_8]toluene η^1-vinylidene complex **5a** undergoes a single step 1,2-shift of the silyl group from C_β to C_α. However, complex **8** shows dichotomous behavior. The isomerization **8** → **9**, dependent upon the solvent applied, occurs by means of two different pathways: in a nonpolar solvent, **8** tautomerizes via the 1,2-migration of the hydrogen atom to **9** and in ethanol this tautomerization proceeds by a multi-step process via deprotonation-protonation and subsequent reductive elimination.

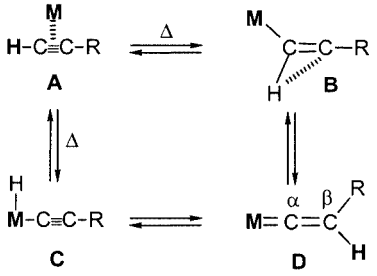
Introduction

A great deal of attention has been devoted to the isomerization of transition metal η^1-vinylidene and η^2-1-alkyne complexes over the past two decades.[1] Thus, it is now well established that the thermodynamic stabilities and properties of such derivatives are essentially a function of the nature of both the metal center and its ancillary ligands.[1,2] It is well-known that η^1-vinylidene complexes of electron-rich transition metals are thermodynamically more stable than the corresponding η^2-1-alkyne derivatives.[1,3] This fact is widely used in the preparation of η^1-vinylidene complexes.[4]

The mechanism of the η^2-1-alkyne → η^1-vinylidene rearrangement has been extensively studied both experimentally and theoretically.[2,4,5–8] Two alternative pathways are discussed so far in the literature (Scheme 1): via either an intramolecular 1,2-hydrogen shift (A–B–D)[2,4e,6a,6b] or by the formation of a hydride alkynyl species C and concomitant 1,3-hydrogen shift.[4a,4c,4d,4f,5a,8,6b] Electron-rich metal complexes favor the A–C–D[4a,4d,8b] pathway whereas electron poor complexes prefer the A–B–D[4e,5a,6a] pathway.

The reaction order for the 1,3-hydrogen shift is also a matter of active debate. Recent experimental and theoretical studies demonstrated a bimolecular mode for this process[4c,4a,4d,9] while others support a unimolecular reaction.[2]

The isomerization of η^1-vinylidene transition metal complexes into the corresponding η^2-alkyne complexes has rarely been described in the literature.[5] Bly et al.[5g,5h] have observed the isomerization of the cationic complexes [Fe(=C=CR^1R^2)(η^5-C_5H_5)$(CO)_2]^+OTf^-$ to the corresponding η^2-alkyne derivatives [Fe(η^2-R^1C≡CR^2)(η^5-C_5H_5)-$(CO)_2]^+OTf^-$ by an alkyl shift from the β- to α-carbon atom. In the same way, Connelly et al.[5b,5g,5i] have observed η^1-vinylidene → η^2-alkyne rearrangements induced by one-electron oxidation of the 18-electron complexes [M=C=$C(SiMe_3)_2$(η^6-C_6R_6)$(CO)_2]^+$ (M = Cr, Mo).



Scheme 1. Alternative pathways for the η^2-1-alkyne → η^1-vinylidene rearrangement

To shed some light on the mechanism of the η^1-vinylidene → η^2-alkyne isomerization we have studied the thermal isomerization of the tungsten η^1-vinylidene complexes **5a–c**, as well as of the molybdenum derivatives **8**.

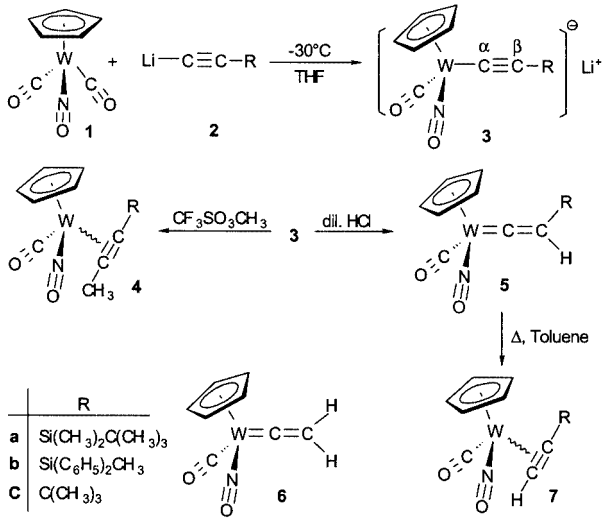
Results

Synthesis and Characterization of 5a,b

The reaction of the tungsten carbonyl complex **1** with lithium alkynyl **2a,b** in THF at −30 °C led to a deep green

[a] Institute of Organic Chemistry, Justus-Liebig University, Heinrich-Buff-Ring 58, 35392 Giessen, Germany
Fax: (internat.) +49-(0)641-9934309
E-mail: junes.ipaktschi@org.chemie.uni-giessen.de

solution of the lithium metalate **3a,b** (Scheme 2). Treatment of this solution with dilute HCl resulted, after purification through chromatography, in the formation of the η^1-vinylidene complexes **5a,b** as a mixture of two rotamers. It is interesting to note that, after protonation the C−Si bond is cleaved, in the course of the reaction of **3b**, yielding the η^1-vinylidene complex **6** (21% yield).[10] This behavior has precedents in the literature, i.e., the formation of [CpRu=C=CH_2(dippe)][BPh_4] from [CpRuCl(dippe)] with H−C≡C−$SiMe_3$,[4g] and the formation of [CpFe=C=CH_2(dppm)][BF_4] from [CpFe−C≡C−$SiMe_3$(dppm)].[11]



Scheme 2. Synthesis of vinylidene complexes **5** and **6** from the tungsten complexes **1**

Compound **5a** is an orange crystalline solid, whereas **5b** is a dark red oil. These η^1-vinylidenes can be stored under argon at −20 °C for several months. Their unequivocal characterization was achieved by means of standard spectroscopic techniques and, in particular, by the ^{13}C NMR signal at δ = 331−335 ppm that is characteristic for the α-carbon atom of the η^1-vinylidene moiety.

Upon treatment of the deep green solution of lithium metalate **3a,b** with methyltrifluoromethanesulfonate at −30 °C, the η^2-alkynes **4a,b** were obtained (Scheme 2). We suppose that the alkylation of the metalate anion occurs at the β-carbon atom generating the corresponding η^1-vinylidene complexes, which then isomerize by migration of the silyl group to **4a,b**. Structural assignment of the η^2-alkynes **4a,b** are based on NMR spectroscopic data and by the characteristic C≡C stretching vibration in IR spectra, respectively.[12]

Isomerization of η^1-Vinylidene Complexes

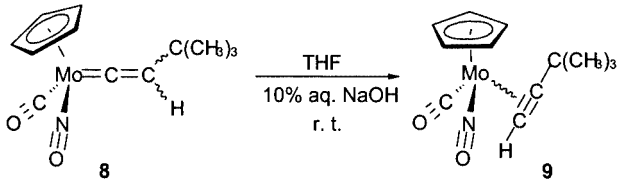
Molybdenum-vinylidene complex **8** and tungsten derivatives **5a,b** rearrange under refluxing toluene to the corresponding η^2-alkyne complexes **9** and **7a,b**. Whereas the tungsten η^1-vinylidene complex **5c** with a *tert*-butyl group at the β-carbon atom, is much more stable than **5a,b** and **8** and rearranges very poorly upon heating at 110 °C to the corresponding η^2-alkyne complex **7c**. The η^1-vinylidene/η^2-alkyne ratios of the interconversion of **8**, **5a,b** and **5c** after heating in toluene for 24 h are reported in Table 1. Longer reaction times lead to the decomposition of **5b** and **5c**. Interestingly the isomerization rate of **8** is highly dependent on the nature of the solvent. In ethanol as the solvent the transformation occurs quantitatively after heating for 2 h at 79 °C.[13]

Table 1. Product ratios of the thermal interconversion of the η^1-vinylidenes **8, 5a−c** after 24 h at 110 °C

η^1-Vinylidene complexes	Product ratio[a] η^2-alkyne: η^1-vinylidene[b]
[Mo{=C=CHC(CH_3)$_3$}(η^5-C_5H_5)(CO)(NO)] (**8**)	100:0
[W{=C=CHSi(CH_3)$_2$C(CH_3)$_3$}(η^5-C_5H_5)(CO)(NO)] (**5a**)	79:21
[W{=C=CHSi(C_6H_5)$_2$$CH_3$}($\eta^5$-$C_5H_5$)(CO)(NO] (**5b**)	63:37
[W{=C=CHC(CH_3)$_3$}(η^5-C_5H_5)(CO)(NO)] (**5c**)	6:94

[a] All reactions were carried out in toluene. [b] The product ratios were determined by measuring the relative peak integration of the ^1H NMR signals of the η^2-alkyne and η^1-vinylidene complexes in the crude product spectra.

Also a quantitative isomerization to **9** is observed by treating the THF solution of **8** at room temperature with 10% aqueous NaOH for 20 min (Scheme 3).



Scheme 3. Base-catalyzed isomerization of vinylidene complexes **8**

Kinetic Studies

a) Isomerization in a Nonpolar Solvent

The isomerization rates of **8** to **9** were measured at fixed temperatures between 80 °C and 140 °C in [D_8]toluene while the rate of transformation of **5a** to **7a** was measured between 130 °C and 150 °C in [D_6]benzene by varying the starting concentration of the η^1-vinylidene complexes.[14] The results indicate that the η^1-vinylidene → η^2-alkyne isomerization is first-order. The first-order rate constants measured at five different temperatures are listed in Table 2 and 3. From the Eyring plot, we derived the activation parameters for **8** → **9**: $\Delta H^{\#}$ = 29.0 ± 0.5 (kcal·mol^{-1}) and $\Delta S^{\#}$ = −1.8 ± 0.2 (cal/mol·K) and for **5a** → **7a**: $\Delta H^{\#}$ = 27.2 ± 0.4 (kcal·mol^{-1}) and $\Delta S^{\#}$ = −9.7 ± 0.9 (cal/mol·K). For the rearrangement of [RuCp(H−C≡C−Me)(PMe_3)$_2$]PF_6 to [RuCp(=C=CHMe)(PMe_3)$_2$]PF_6 the kinetic study in CH_3CN by Bullock gave $\Delta H^{\#}$ = 23.4 ± 0.3 kcal·mol^{-1} and $\Delta S^{\#}$ = 3.9 ± 0.9 (cal/mol·K).[15]

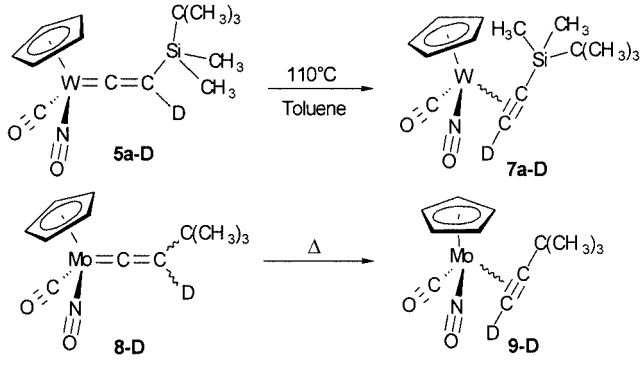
					average: 2.00 ± 0.2

[a] Correlation coefficient for the first-order plot.

Principally the isomerization of **5a** to **7a** can occur either by migration of the silyl group or of the hydrogen atom from C_β to C_α, however, a priori it is not possible to differentiate between one or the other reaction path. In order to distinguish between these two possibilities, we determined the kinetic deuterium isotope effect for the conversion of $[(\eta^5\text{-}C_5H_5)(CO)(NO)W{=}C{=}CDSi(CH_3)_2C(CH_3)_3]$ (**5a-D**) to $[(\eta^5\text{-}C_5H_5)(CO)(NO)W\{\eta^2\text{-}DC{\equiv}CSi(CH_3)_2C(CH_3)_3\}]$ (**7a-D**) and as a comparison the kinetic deuterium isotope effect for the transformation **8-D** to **9-D** (Scheme 4).



Scheme 4. Thermal isomerization of **5a-D** and **8-D**

The $k_{\mathbf{5a\rightarrow 7a}}/k_{\mathbf{5a\text{-}D\rightarrow 7a\text{-}D}}$ in [D_8]toluene was found to be 1.20 ± 0.03 and $k_{\mathbf{8\rightarrow 9}}/k_{\mathbf{8\text{-}D\rightarrow 9\text{-}D}}$ = 2.00 ± 0.2 (Table 2 and 3), both effects show very minor temperature dependency. The kinetic isotope effect for the former reaction is in the range of normal secondary isotope effects,[16] and is the result of a hybridization change from sp^2 to sp of the C_β of the η^1-vinylidene ligand in the transition state during the migration of the silyl group. Contrary, for the later isomerization, k_H/k_D suggests that the bond to the isotopically substituted hydrogen atom is being broken in the rate-determining step. The 1,2-shift of the silyl group is also supported by the comparison of the isomerization ability of **5a** and **5b** versus **5c** where the reaction rate decreases in the order: $Si(CH_3)_2C(CH_3)_3 > Si(C_6H_5)_2(CH_3) > C(CH_3)_3$.[17]

b) Isomerization in Ethanol

In order to obtain more information on the mechanism of the η^1-vinylidene → η^2-alkyne isomerization we examined the isomerization of **8** in ethanol as the solvent. The isomerization rate of **8** in C_2D_5OH, measured in a 0.1 M solution at fixed temperatures between 60 °C and 100 °C, is much faster than the reaction rate in [D_8]toluene. The pseudo first-order rate constants are listed in Table 4. From Eyring plots we have obtained the activation parameters for the isomerization **8** → **9** in C_2D_5OH, $\Delta S^{\#} = -21.3 \pm 0.5$ (cal/mol·K) and $\Delta H^{\#} = 19.6 \pm 1.6$ kcal·mol^{-1}. Compared to the isomerization in [D_8]toluene, the most striking point of the thermodynamics of the reaction, is the high negative value of $\Delta S^{\#}$ in C_2D_5OH. This leads one to suppose, that in toluene and ethanol two different mechanisms govern the reaction. This presumption is further strongly supported by the large differences of the kinetic isotope effect for $k_{\mathbf{8\rightarrow 9}}$ measured in C_2D_5OH and $k_{\mathbf{8\text{-}D\rightarrow 9\text{-}D}}$ in C_2D_5OD versus the $k_{\mathbf{8\rightarrow 9}}/k_{\mathbf{8\text{-}D\rightarrow 9\text{-}D}}$ measured in [D_8]toluene as the solvent. The $k_{\mathbf{8\rightarrow 9}}/k_{\mathbf{8\text{-}D\rightarrow 9\text{-}D}}$ ratio also shows a large temperature dependency in ethanol contrary to the value in toluene. From extrapolation of the reaction rate the values k_H/k_D = 15.7 at 60 °C and k_H/k_D = 7.1 at 100 °C, are obtained.

Table 4. Rates of the isomerization and kinetic deuterium isotope effect of **8** to **9** in [D_5]ethanol and **8-D** to **9-D** in [D_6]ethanol (k_H/k_D = 15.7 at 60 °C and 7.1 at 100 °C)

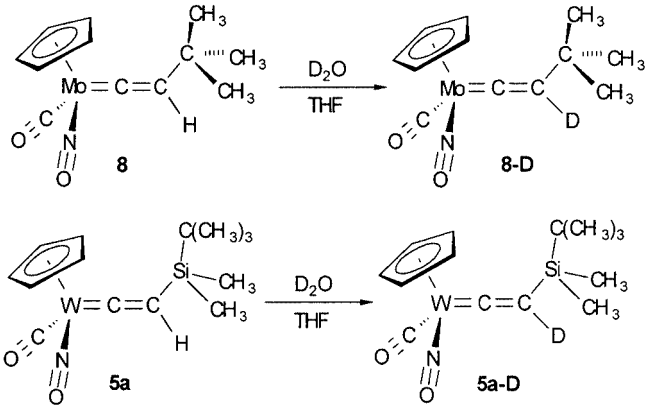
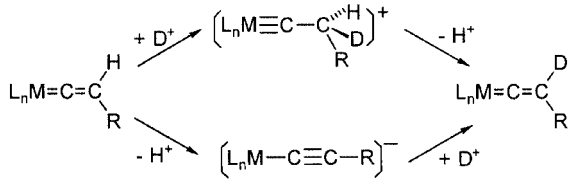
H/D Exchange

The η^1-Vinylidene derivatives **8** and **5a** undergo H/D exchange at the C_β atom without isomerization. Treatment of tetrahydrofuran solutions of **5a** at room temperature and **8** at 45 °C with D_2O produces the corresponding deuterated derivatives **8-D** and **5a-D** (Scheme 5).



Scheme 5. H/D exchange of vinylidene complexes **8** and **5a**

Besides the deprotonation-deuteration pathway, it is conceivable that the H/D exchange occurs by the prior addition of deuterium to yield a carbyne derivative (Scheme 6).



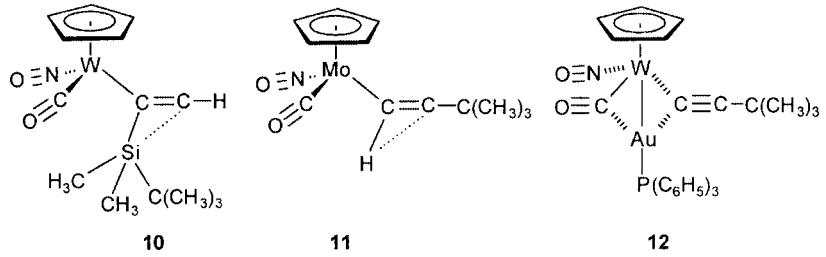
Scheme 6. Alternative mechanisms for the H/D exchange of vinylidene complexes

Theoretical studies on vinylidene transition metal complexes have identified the electron density on the C_β atom,[18] and the protonation of vinylidene complexes to the carbyne derivatives occurs via another mechanism.[9,19] In order to distinguish between these two possibilities we investigated the exchange rate in the presence of D_2O and C_6D_5OD, respectively. While after 3 h at 45 °C the H/D exchange in 10 molar D_2O/[D_8]THF was complete, no exchange occurred in the presence of C_6D_5OD. The result of this experiment clearly shows that the H/D exchange occurs by a dissociative pathway.

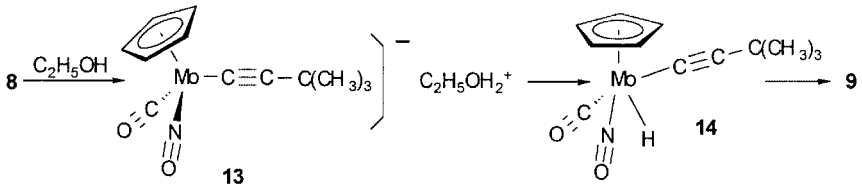
Discussion

Our kinetic study of the isomerization of **8** → **9** and **5a** → **7a** suggests that the η^1-vinylidene → η^2-alkyne isomerization of the molybdenum and tungsten complexes studied here, follows two different pathways.

In nonpolar solvents such as toluene or benzene, starting from the η^1-vinylidene **5a**, a 1,2-shift of the silyl group takes place by forming the transition state **10** (Scheme 7). Slippage processes of the silyl group as well as the metal, followed by C−Si σ bonding and π coordination of the metal center generated the η^2-alkyne complexes **7**. The magnitude of the kinetic isotope effect and the activation entropy observed for the isomerization **5a** → **7a** are in good agreement with an isomerization mechanism of least motion; namely, the 1,2-silyl group shifts in a concerted fashion.[20,21] In the same manner the thermal tautomerization of **8** in nonpolar solvents occurs by a 1,2-migration of the hydrogen atom leading to the transition state **11**, followed by a slippage of the metal to yield the η^2-1-alkyne complex **9**. The observed kinetic isotope effect supports the isomerization pathway, **D**→**B**→**A** (Scheme 1) with an asymmetrically bonded transition state in a single-step hydrogen or silyl transfer reaction for both transformations depicted as **10** and **11**.[22,23]



Scheme 7. Postulated transition states **10** and **11** and structure of gold complexes **12**



Scheme 8. Postulated mechanism for the isomerization of vinylidene complexes **8** in ethanol

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Additionally we have recently synthesized and structurally characterized the gold-tungsten complex **12** which has similar structural features to **10** and **11** and shows a fluxional behavior.[24]

Contrary to the isomerization in nonpolar solvents, the kinetic data of the isomerization **8** → **9** in ethanol suggests a two-step dissociation-addition process (Scheme 8). The high value of $k_{\mathbf{8}\rightarrow\mathbf{9}}/k_{\mathbf{8\text{-}D}\rightarrow\mathbf{9\text{-}D}}$ and its temperature dependency supports this mode of isomerization and suggests that it is even more likely that a tunneling process takes place for this reaction.[22,23] According to this data we suppose that the tautomerization of **8** occurs via a deprotonation step generating the η^1-alkynyl complex **13** followed by the protonation on molybdenum to the hydrido-alkynyl complex **14** which undergoes reductive elimination to the η^2-1-alkyne isomer **9**. The NaOH catalyzed isomerization of **8** (see Scheme 3) is in agreement with this hypothesis as it supports a deprotonation-protonation process. All attempts to isolate the hydrido-alkynyl complex were unsuccessful.

The tautomerization of η^2-1-alkyne via hydrido-alkynyl complexes is often postulated in the literature as a concerted 1,3-hydrogen shift.[1,4f] However, this mechanism was found to be, in general, energetically too costly.[4b,4h] Our results, however, support the findings that isomerization via a hydrido-alkynyl complex proceeds in a nonconcerted fashion.

Experimental Section

General Remarks: All reactions were carried out under argon (99.99%, by Messer−Griesheim) with the use of standard Schlenk techniques. Solvents were purified by standard methods and distilled under argon prior to use. Literature methods were used to prepare $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(NO)]$ and $[(\eta^5\text{-}C_5H_5)W(CO)_2(NO)]$,[25] (*tert*-butyldimethylsilyl)acetylene,[26] (methyldiphenylsilyl)acetylene,[26] $[(\eta^5\text{-}C_5H_5)(CO)(NO)Mo{=}C{=}CHC(CH_3)_3]$ (**8**);[12] **7c**, and **5c**[12] and $[(\eta^5\text{-}C_5H_5)(CO)(NO)W{=}C{=}CHSi(CH_3)_2C(CH_3)_3]$ (**5a**).[27] All other compounds were commercially available. NMR spectra were obtained with a Bruker AM 400 spectrometer (^{1}H NMR, 400.13 MHz. ^{13}C NMR, 100.61 MHz). Proton and carbon chemical shifts are reported in ppm relative to the residual proton resonance (δ = 7.24 ppm) or the carbon multiplet (δ = 77.0 ppm) of the NMR solvent $CDCl_3$. When [D$_6$]benzene is used as solvent for a ^{1}H NMR spectrum, the shifts are reported in ppm relative to the residual proton resonance at δ = 7.17 ppm. ^{13}C DEPT experiments were run with the Bruker AM 400 spectrometer. MS measurements (70 eV) were performed with a Varian MAT 311-A. IR spectra were recorded with a Bruker FT-IR IFS 85. Microanalyses were done with a Carlo Erba 1104 elemental analyzer.

Synthesis of the Vinylidene Complexes. $[(\eta^5\text{-}C_5H_5)(CO)(NO)W{=}C{=}CHSi(C_6H_5)_2CH_3]$ (5b): At −78 °C *n*BuLi (3 mL, 4.5 mmol; a solution of 1.5 mmol/mL in hexane) was added to a solution of (methyldiphenylsilyl)acetylene (1.00 g, 4.5 mmol) in THF (10 mL). This solution was added dropwise to $[(\eta^5\text{-}C_5H_5)(CO)_2(NO)W]$ (1.0 g, 3.0 mmol) in THF (60 mL) at −30 °C, whereby the color changed from orange to deep green. The reaction mixture was stirred for 4 h at −30 °C. Addition of 1 mL of concentrated HCl diluted with 20 mL of water led to a dark red solution. After the reaction mixture was allowed to reach room temperature, the THF was removed under reduced pressure. The residue was extracted with diethyl ether, washed with saturated aqueous sodium chloride and dried with magnesium sulfate. The dark red oil was filtered through silica gel (*n*-pentane/diethyl ether, 5:1) to remove decomposition products. Chromatography on silica gel (*n*-pentane/diethyl ether, 5:1) yielded 341 mg (21%) of **5b** as dark red oil and 230 mg (15%) of the unsubstituted vinylidene complex **6** as orange crystals.[12]

Compound 5b: Two rotamers (5:2) were found in the NMR spectra. ^{1}H NMR ($CDCl_3$, 25 °C): δ = 7.65−7.38 (m, 10 H, C_6H_5), 6.02 and 5.93 (2 s, 2:5, 1 H, $C_\beta H$), 5.73 and 5.40 (2 s, 2:5, 5 H, Cp), 0.71 and 0.69 (2 s, 5:2, 3 H, CH_3) ppm. ^{13}C NMR ($CDCl_3$, 25 °C): δ = 334.9 and 333.6 [$^1J_{C-W}$ = 183.1 Hz, C_α], 212.3 ($^1J_{C-W}$ = 202.6 Hz), 212.0 (CO), 136.0−127.9 (C_6H_5), 118.3 and 117.2 [$^2J_{C-W}$ = 34.5 Hz, C_β], 95.4 and 95.3 (Cp), −2.0 and −2.2 (CH_3) ppm. IR (KBr): $\tilde{\nu}$ = 1990 (s, C=O), 1636 (s, N≡O), 1595 (s, C=C) cm^{-1}. MS (70 eV): *m*/*z* = 529 [M$^+$, ^{184}W], 501 [M$^+$ − CO], 471 [M$^+$ − CO − NO]. $C_{21}H_{19}NO_2SiW$: calcd. C 47.65, H 3.62, N 2.65; found C 47.28, H 3.32, N 2.89. High-resolution mass spectrum: *m*/*z* calcd. for $C_{21}H_{19}NO_2Si^{182}W$ [M$^+$] 527.0668, found 527.0667.

Compound 6: ^{1}H NMR ($CDCl_3$, 25 °C): δ = 5.87 (s, 5 H, Cp), 5.28 ($^3J_{W-H}$ = 6 Hz), 5.21 [2 d, 2 H, $^2J_{H,H}$ = 19 Hz, CH_2] ppm. ^{13}C NMR ($CDCl_3$, 25 °C): δ = 341.2 (C_α), 209.9 (CO), 112.2 (C_β), 96.3 (Cp) ppm. IR (KBr): $\tilde{\nu}$ = 1998 (CO), 1635 (NO), 1591 (C=C) cm^{-1}. IR (CCl_4): $\tilde{\nu}$ = 2008 (CO), 1654 (NO), 1618 (C=C) cm^{-1}. MS (70 eV): *m*/*z* = 333 [M$^+$, ^{184}W], 305 [M$^+$ − CO], 275 [M$^+$ − CO − NO]. $C_{14}H_{11}NO_2W$: calcd. C 28.86, H 2.12, N 4.21; found C 29.17, H 1.74, N 4.29. High-resolution mass spectrum: *m*/*z* calcd. for $C_{14}H_{11}NO_2{}^{186}W$ [M$^+$] 335.0021, found 335.0027.

$[(\eta^5\text{-}C_5H_5)(CO)(NO)W{=}C{=}CDSi(CH_3)_2C(CH_3)_3]$ (5a-D): A solution of vinylidene **5a** (300 mg) in THF (5 mL) and D_2O (5 mL) was stirred for 2 h at room temperature. After removal of THF and D_2O under reduced pressure, the residue was dried under vacuum for several hours. Spectroscopically pure orange crystals of **5a-D** were obtained (m.p. 60 °C). $C_{14}DH_{20}NO_2SiW$: calcd. C 37.51, H 4.50, N 3.12; found C 37.32, H 4.53, N 3.28. Two rotamers were found in the NMR spectra. ^{1}H NMR ($CDCl_3$, 25 °C): δ = 5.76 (s, 5 H, Cp), 0.91 and 0.89 [2 s, 3:2, 9 H, $C(CH_3)_3$], 0.13, 0.10 and 0.09 (3 s, overlapping, diastereotopic methyl groups, 6 H, $Si[CH_3)_2C(CH_3)_3]$ ppm. ^{13}C NMR ($CDCl_3$, 25 °C): δ = 333.0 and 331.0 (C_α), 213.8 and 212.0 (CO), 118.5 ($^1J_{C-D}$ = 20.8 Hz) and 117.5 ($^1J_{C-D}$ = 22.2 Hz) (C_β), 95.4 and 95.2 (Cp), 26.1 [$C(CH_3)_3$], 17.6 and 17.1 [$C(CH_3)_3$], −4.4, −4.5 and −4.8 [$Si(CH_3)_2C(CH_3)_3$] ppm. IR (KBr): $\tilde{\nu}$ = 1999 and 1975 (s, C=O), 1635 and 1617 (s, N≡O), 1584 (s, C=C) cm^{-1}. MS (70 eV): *m*/*z* = 448 [M$^+$, ^{184}W], 420 [M$^+$ − CO]. High-resolution mass spectrum: *m*/*z* calcd. for $C_{14}DH_{20}NO_2Si^{182}W$ [M$^+$] 446.0887, found 446.0884.

Synthesis of the η^2-Alkyne Complexes. $[(\eta^5\text{-}C_5H_5)(CO)(NO)W\{\eta^2\text{-}H_3C{-}C{\equiv}C{-}Si(CH_3)_2C(CH_3)_3\}]$ (4a): The preparation of **4a** is analogous to that of **5a**, but, instead of diluted HCl, (0.5 mL, 4.5 mmol) trifluoromethanesulfonate was used. This solution was stirred for 1 h at −30 °C. After usual workup the dark red oil was chromatographed on silica gel (*n*-pentane/diethyl ether, 3:1) to yield 927 mg (67%) of **4a** as orange crystals (m.p. 119 °C). $C_{15}H_{23}NO_2SiW$: calcd. C 39.06, H 5.03, N 3.04; found C 39.02, H 4.73, N 2.78. Two rotamers were found in the NMR spectra. ^{1}H NMR ($CDCl_3$, 25 °C): δ = 5.65 and 5.60 ppm (2 s, 6:1, 5 H, Cp), 2.92 and 2.87 (2 s, 1:6, 3 H, $C{\equiv}CCH_3$), 0.96 and 0.90 [2 s, 6:1, 9 H, $C(CH_3)_3$], 0.30 ($^2J_{H-Si}$ = 6.3 Hz), 0.24 and 0.16 [3 s, overlapping,

Chromatography on silica gel with 10:1 *n*-pentane/diethyl ether yielded 24 mg (2%) of **7c** as light orange crystals and 563 mg (56%) of the starting material **5c** as orange crystals. $C_{12}H_{15}NO_2W$: calcd. C 37.04, H 3.89, N 3.60; found C 37.32, H 3.70, N 3.40. Two rotamers were found in the NMR spectra. ^1H NMR ($CDCl_3$, 25 °C): δ = 7.45 ($^2J_{H-W}$ = 8.0 Hz) and 6.98 ($^2J_{H-W}$ = 9.2 Hz) (2 s, 1:6, 1 H, C≡CH), 5.77 and 5.68 (2 s, 6:1, 5 H, Cp), 1.35 and 1.32 [2 s, 6:1, 9 H, $C(CH_3)_3$] ppm. ^{13}C NMR ($CDCl_3$, 25 °C): δ = 215.5 (CO), 133.7 ($^1J_{C-W}$ = 52.0 Hz) and 124.4 ($^1J_{C-W}$ = 13.6 Hz) (alkyne C), 96.4 and 96.0 (Cp), 91.0 ($^1J_{C-W}$ = 43.1 Hz) and 88.1 ($^1J_{C-W}$ = 8.9 Hz) (alkyne C), 36.4 and 34.6 [$C(CH_3)_3$], 31.9 and 31.0 [$C(CH_3)_3$] ppm. IR (KBr): $\tilde{\nu}$ = 1977 (s, C=O), 1736 (m, C≡C), 1556 (s, N≡O) cm^{-1}. MS (70 eV): *m/z* = 389 [M^+, ^{184}W], 361 [M^+ − CO]. High-resolution mass spectrum: *m/z* calcd. for $C_{12}H_{15}NO_2{}^{182}W$ [M^+] 387.0585, found 387.0553.

Isomerization of 8 to 9 with NaOH: 10% aqueous NaOH (3 mL) was added to a solution of **8** (0.4 mmol) in THF (10 mL). After the reaction mixture was stirred for 20 min at room temperature, the organic layer was separated and the solvent was removed under reduced pressure. The residue was dissolved in diethyl ether and dried with $MgSO_4$. The diethyl ether was removed under reduced pressure, and the ^1H NMR spectrum of the residue was collected. **8** was 100% isomerized to **9**.

Treatment of 8 with D_2O and C_6D_5OD: 8 (0.6 mL, 0.1 mmol) and D_2O (0.2 mL, 10 mmol) in [D_8]THF (1 mL) were heated at 45 °C. At regular time intervals the probe was cooled to −20 °C, which was followed by the measuring of the relative peak integration of the ^1H NMR $C_\beta-H$ signal [([D_8]THF) δ = 5.93 and 5.91 ppm] of **8**. After 3 h the H/D exchange was complete. The same experiment with perdeuterated phenol (C_6D_5OD) instead of D_2O showed no exchange.

[(η⁵-C_5H_5)(CO)(NO)Mo{η²-H-C≡C-$C(CH_3)_3$}] (9): At −30 °C, a solution of 7.5 mmol of (*tert*-butylethynyl)lithium in THF (15 mL) was added dropwise to an orange solution of (η⁵-C_5H_5)Mo(CO)₂(NO) (1.24 g, 5 mmol) in THF (50 mL). The progress of the reaction was monitored by IR spectroscopy. After complete disappearance of [(η⁵-C_5H_5)Mo(CO)₂(NO)], at 5 °C, saturated aq. sodium carbonate (30 mL) was added to the deep green reaction mixture, whereby the color changed to red. The solution was concentrated under vacuum and extracted with diethyl ether. The organic layer was dried with $MgSO_4$. The diethyl ether was removed under reduced pressure and the residue was chromatographed (silica gel, pentane) to yield 714 mg (47%) of **9**, as orange crystals, m.p. 71−72 °C (dec, pentane:dichloromethane, 10:1). $C_{12}H_{15}MoNO_2$: calcd. C 47.85, H 5.02, N 4.65; found C 47.84, H 4.83, N 4.72. Two rotamers (ratio 1:5). ^1H NMR ($CDCl_3$, 25 °C): δ = 6.69 and 6.09 ppm (2 s, 1:5, 1 H, C≡CH), 5.65 and 5.55 (2 s, 5:1, 5 H, Cp), 1.37 and 1.34 [2 s, 5:1, 9 H, $C(CH_3)$]. ^{13}C NMR ($CDCl_3$, 25 °C): δ = 226.7 (C=O), 128.0 (C≡C), 97.0 and 96.7 (Cp), 80.5 (C≡C), 35.8 [$C(CH_3)_3$], 32.2 and 31.3 (CH_3) ppm. IR (KBr): $\tilde{\nu}$ = 1982 (C=O), 1785 (C≡C), 1581 (N=O) cm^{-1}. MS (70 eV): *m/z* = 301 [M^+, ^{96}Mo], 273 [M^+ − CO], 243 [M^+ − CO − NO]. High resolution mass spectrum calcd. for $C_{12}H_{15}{}^{92}MoNO_2$ [M^+]: *m/z* = 297.0171, found *m/z* = 297.0141.

Kinetic Studies of the η¹-Vinylidene → η²-Alkyne Isomerization of 8 → 9; 8-D → 9-D in [D₈]Toluene and 5a → 7a and 5a-D → 7a-D in [D₆]Benzene: A typical experiment was done in the following way. **8** or **8-D** (0.8 mL, 0.1 M) in [D_8]toluene as well as a weighted amount of the vinylidene **5a** or **5a-D** (in the range of 20−120 mg) in [D_6]benzene (0.8 mL) (measured with a gas-tight syringe) were placed in a dried sealable NMR tube. The solution was freeze-pump-thaw degassed and the NMR tube was sealed under vacuum. The sample was then placed into a thermostat at a fixed temperature (reproducibility ± 0.1 °C). At regular time intervals, the tube was removed and the reaction quenched at room temperature. The reaction time was followed by measuring the relative peak integration of the ^{1}H NMR of the cyclopentadienyl signals of **8** (δ = 5.18 and 5.16 ppm); **9** (δ = 5.06 and 4.92 ppm); **8-D** (δ = 5.18 and 5.16 ppm); **9-D** (δ = 5.06 and 4.92 ppm); *tert*-butyl signals of **5a** (δ = 0.95 ppm); **7a** (δ = 1.01 and 0.99 ppm); **5a-D** (δ = 0.94 ppm) and **7a-D** (δ = 1.01 and 0.99 ppm).

First-order rate constants were derived from least-squares best-fit lines of the ln(%) versus time plots. The uncertainty in the isomerization rate constants was derived from the slope of the best-fit line. Uncertainties in the activation enthalpies and entropies were calculated from the uncertainties in the slope of the best-fit line of the Eyring plot.

Kinetic Studies of the η¹-Vinylidene → η²-Alkyne. Isomerization of 8 → 9 in [D₅]Ethanol and 8-D → 9-D in [D₆]Ethanol: The kinetic studies of isomerization of **8** → **9** in [D_5]ethanol and **8-D** → **9-D** in [D_6]ethanol are analogous to that for the isomerization of **8** → **9** and **8-D** → **9-D** in [D_8]toluene. The time course of the reaction was followed by measuring the relative peak integration of the ^{1}H NMR of cyclopentadienyl signals **8** [(C_2D_5OH) δ = 5.83 and 5.81 ppm], **9** [(C_2D_5OH) δ = 5.70 and 5.60 ppm], **8-D** [(C_2D_5OD) δ = 5.82 and 5.81 ppm] and **9-D** [(C_2D_5OD) δ = 5.67 and 5.59 ppm]. Uncertainties in the activation enthalpies and entropies were calculated from the uncertainties in the slope of the best-fit line of the Eyring plot.

2,3-Bis(diarylphosphanyl)-1,4-diazadienes: P,P Coordination of Pd^{II}, Pt^{II} and a Nickelacyclopentanone with Subsequent Formation of Quinoxalines by a Ring-Closure Reaction at the Periphery

Dirk Walther,*[a] Stefan Liesicke,[a] Reinald Fischer,[a] Helmar Görls,[a] Jennie Weston,[b] and Ariadna Batista[b]

Keywords: Chelates / Cycloadditions / Metallacycles / N,P ligands / Transition metals

The solid-state structures of several 2,3-bis(phosphanyl)-1,4-diazadiene ligands of the general formula RN=C(PPh_2)–C(PPh_2)=NR (**B**: R = 4-tolyl; **C**: R = 4-*tert*-butylphenyl; **D**: R = mesityl) were determined by single-crystal X-ray diffraction. The ligands **B** and **C** are nonplanar and lie between the (*E*) and the (*Z*) form (N=C–C=N is 99.5° in **B**, 94.0° in **C**, and 128.2° in **D**). In the presence of air, **B** is oxidized to its corresponding phosphane oxide. Reaction of **D** with elemental sulfur yields the corresponding phosphane sulfide. Furthermore, ligand **C** reacts with [$PtCl_2$(cod)] and [$PdCl_2(CH_3CN)_2$] to form mononuclear complexes (**1** and **2**, respectively) in which the two P atoms are bound to the metal center. X-ray structural analysis showed that in both complexes the 1,4-diazadiene functionality at the periphery had undergone a ring-closure reaction with one of the aromatic N-substituents thus resulting in a quinoxaline ring. The bulkier ligand **D** reacts with [$PdCl_2(CH_3CN)_2$] to form the mononuclear complex **3**. In the solid state, the two phosphorus atoms are coordinated to the metal center in a five-membered chelate ring. In contrast to **1** or **2**, a cyclohexadiene system is formed as result of a cycloaddition reaction of one aromatic N-substituent with the 1,4-diazadiene system. The nickel complex [Ni(tmeda)(C_2H_4COO)] reacts with **D** by displacement of tmeda to form a mononuclear complex **4a** with P,P coordination. A subsequent ring-closure reaction (cycloaddition) at the periphery does not occur in **4a**. If the ligand is sterically less demanding (**B** or **C**), a cycloaddition between the 1,4-diazadiene system and one aromatic substituent takes place in the nickel complex to form complexes of the type **5** containing a quinoxaline ring. This reaction could be monitored by ^{31}P NMR spectroscopy for ligand **C**.

Introduction

2,3-Bis(phosphanyl)-1,4-diazadienes contain perhaps the two most important chelating functionalities, a conjugated 1,4-diazadiene and a 1,2-bis(phosphanyl)ethane, within the same ligand. Both of these structural units are known to form stable five-membered metal chelate ring systems which have general importance in organometallic and coordination chemistry. Numerous catalysts for homogeneous reactions are, for example, based on these chelate complexes.[1–16]

In an initial communication, we reported a synthetic procedure for obtaining hitherto unknown 2,3-bis(diarylphosphanyl)-1,4-diazadienes.[17] These are the first experimentally accessible representatives that unify the two functionalities mentioned above. As one would expect, they react readily with Ni^{II}, Cu^{I}, and Mo^{0} fragments thus giving rise to a rich complex chemistry. Some of these chelating ligands chelate by P,P complexation with nickel(II) bromide and then subsequently undergo a rather unusual ring-closure reaction at the periphery of the ligand to form a quinoxaline.[17] This opens a simple route for the synthesis of bis(diphenylphosphanyl)ethylenes containing a quinoxaline backbone. Continuing with our investigations, we now report an alternative synthesis for obtaining these ligands. We have further investigated their structural and electronic properties as well as their behavior towards oxygen and sulfur. In order to gain a deeper understanding of their coordination behavior, as well as their interesting peripheral ring-closure reaction, we have extended the palette of metal fragments employed to include Pd^{II} and Pt^{II} as well as an organometallic derivative of Ni^{II}.

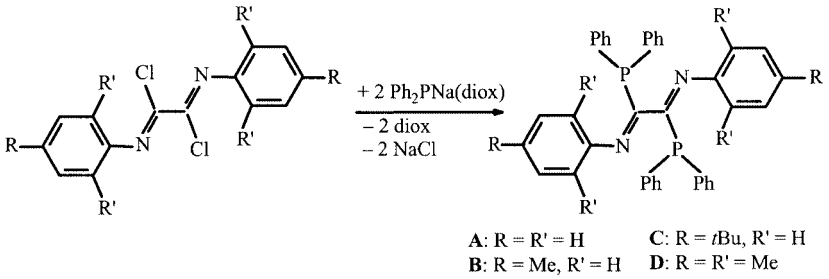
Results and Discussion

Synthesis of the Bis(diarylphosphanyl)-1,4-diazadienes A–D

In analogy to the previously reported 2,3-bis(diarylphosphanyl)-1,4-diazadienes **B**–**D**,[17] we succeeded in preparing



Scheme 1

the 2,3-bis(diphenylphosphanyl)-1,4-diphenyl-1,4-diazadiene (**A**) in 40% yield from sodium diphenylphosphide and the corresponding imidoyl chloride in THF (Scheme 1).

This new ligand has one singlet $^{31}P\{^1H\}$ resonance (δ = 4.7 ppm) in the same spectral region as the ^{31}P NMR signals of ligands **B**–**D**. The ^1H and ^{13}C NMR spectra of **A** are very simple, typical for a symmetrical structure in solution, and are directly comparable with those reported for the ligands **B**–**D**.[17]

An alternative route to **D** is the reaction of the corresponding imidoyl chloride with diphenyl(trimethylsilyl)phosphane (Scheme 2).

This preparative route leads to pure **D** in a much higher yield (64%) without the time-consuming necessity of purifying the raw material. The reaction mixture for this alternative route contained, in addition to **D**, a small amount of the hitherto unknown 2-(diphenylphosphanyl)-1,4-dimesityl-1,4-diazabutadiene (**G**) which could be isolated as yellow crystals and fully characterized by NMR spectroscopy and X-ray diffraction analysis.

The Structure and Electronic Properties of Ligands A–D

Single crystals of **B**–**D** suitable for an X-ray diffraction analysis could be grown from a solution in either toluene or chloroform. All of these ligands possess the same structural motif in the solid state. As a representative example, Figure 1 illustrates the molecular structure of compound **D**, which co-crystallizes with 1 equiv. of $CHCl_3$. Selected geometrical parameters can be found in the figure caption.

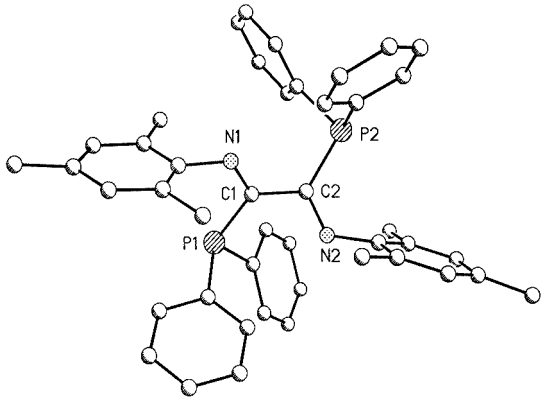


Figure 1. Solid-state structure of compound **D**; selected bond lengths [Å] and bond angles [°]: C1–P1 1.874(2), C1–N1 1.280(2), C1–C2 1.517(2), C2–P2 1.875(2), C2–N2 1.266(2); P1–C1–N1 119.5(1), P2–C2–N2 121.7(1), P1–C1–C2 125.4(1), N1–C1–C2 114.9(1), P2–C2–C1 124.7(1), N2–C2–C1 113.5(1)

The central C−C bond in **D** is a typical single bond (1.517 Å) and the C−N bond lengths are typical of double bonds (1.280 and 1.266 Å). The bulky PPh_2 group results in large P−C−C bond angles (125.4 and 124.7°); the N−C−C angles (114.9 and 113.5°) are rather small due to the effect of the lone pair on the nitrogen atom. Perhaps the most unusual feature of ligand **D** is that, in spite of the 1,4 diazabutadiene unit, it is not planar and assumes a twisted (*E*) conformation (the N−C−C−N dihedral angle is 128.2°). The twist angle is even larger in **B** (N−C−C−N = 99.5°) and **C** (N−C−C−N = 94.0°), leading to an almost orthogonal conformation. A conformational search for **D** at the B3LYP/lanl2dz level of theory confirmed that this nonplanar geometry is the global minimum (and the only stable conformation on the hypersurface). All calculated geometrical parameters agree quite satisfactorily with the solid-state values. An NBO analysis for **D** showed that a residual delocalization between the two C=N double bonds is present [$\pi_{C=N} \rightarrow \pi^*_{C=N}$ = 10.2 kcal/mol] in spite of the relatively large twist angle.

The by-product 2-(diphenylphosphanyl)-1,4-dimesityl-1,4-diazabutadiene (**G**, Scheme 2), which lacks the bulk of a second PPh_2 group, assumes a planar (*E*) conformation in the solid state (not depicted; the N−C−C−N torsion angle is 158.8°). This prompted us to explore the rotational process about the central C−C bond in the absence of steric hindrance (Figure 2).

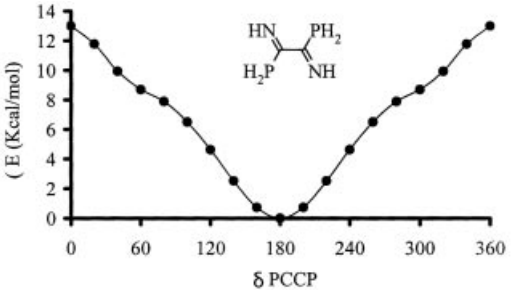

Figure 2. Torsional potential for rotation about the central C−C bond in a simple diphosphanyl-diazabutadiene, calculated at the B3LYP/6-311++G(3df,3pd) level of theory

The (*E*) conformation (P−C−C−P = 180°) is the only stable minimum on the hypersurface of this bifunctional chelating unit. The (*Z*) conformer is the transition structure for rotation about the C−C bond due to strong electronic repulsions between the lone electron pairs on the nitrogen atom in this orientation. It is interesting that two inflection points occur in the rotational barrier at ca. 60 and 300°. In the neighborhood of these points, the repulsion between the lone pairs of the nitrogen atoms is becoming quite weak and a $\pi_{C=N} \rightarrow \pi^*_{C=N}$ delocalization is beginning to appear. This delocalization is responsible for the preferred (E) conformation. If bulky substituents on P are introduced, these inflection points are stabilized and become minima on the hypersurface at the expense of the planar (E) conformation.

There are several possibilities for the coordination of **D** to a metal ion (P,P, N,N and two P,N modes) but, as discussed below, P,P coordination is generally favored. In each case, a lone pair on the heteroatom functions as a donor orbital to the metal ion. The NBO analysis of **D** (Table 1) shows that the lone pair orbital on P lies significantly higher in energy (−7.7 eV) than on N (−8.6 eV). This difference is probably responsible for the observed preference of a P,P coordination mode since the lone electron pair on P can interact more effectively with low-lying unoccupied orbitals on the metal ion.

Table 1. Selected electronic properties of ligand **D**, calculated at the B3LYP/6-31+G(d,p)//B3LYP/lanl2dz level of theory

Atomic charge		Orbital	Occupancy	Energy [eV]
q_C	0.05	n_N	1.82	−8.6
q_N	−0.46	n_P	1.80	−7.7
q_P	+0.76			

Reactivity towards Oxygen and Sulfur

The ligands **B**−**D** all decompose in the presence of water and are oxidized by air to yield the corresponding phosphane oxides. We succeeded in isolating the phosphane oxide **E**, resulting from the reaction of **B** with hydroperoxide or with oxygen, as single crystals. Its solid-state structure and relevant geometrical parameters can be found in Figure 3.

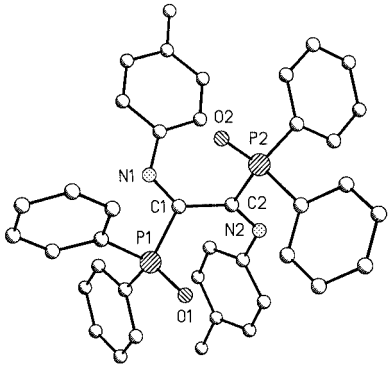

Figure 3. Solid-state structure of compound **E**; selected bond lengths [Å] and bond angles [°]: P1−O1 1.484(2), P1−C1 1.857(3), C1−N1 1.285(3), C1−C2 1.522(4), P2−O2 1.483(2), P2−C2 1.857(3), C2−N2 1.280(3); O1−P1−C1 112.1(1), O2−P2−C2 111.1(1), P1−C1−N1 113.0(2), P2−C2−N2 116.4(2), P1−C1−C2 115.9(2), N1−C1−C2 130.9(3), P2−C2−C1 115.9(2), N2−C2−C1 127.2(3)

Ligand **E** also assumes a nonplanar conformation. Rather than being almost orthogonal, the torsion angle (N−C−C−N = 118.6°) is significantly shifted towards an (*E*) conformation (N−C−C−N in **B** is 99.5°). This may possibly be due to the higher coordination number and thus increased steric bulk of the phosphorus functionalities which force them to be (*E*) to each other.

Adding elemental sulfur to a solution of **D** resulted in the formation of the corresponding disulfide **F**, which could then be characterized by MS and NMR spectroscopy. In the $^{31}P\{^1H\}$ NMR spectrum of **F**, a singlet at δ = 34.9 ppm (shifted downfield relative to **D**) was observed. In the ^{13}C NMR spectrum at room temperature, all expected 11 sig-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nals were detected. Surprisingly, the resonance of the P−C=N carbon atoms occurs at δ = 159.3 ppm as a broad signal, thus suggesting the presence of a hindered rotation about the central PNC−CNP single bond.

Pd^{II} and Pt^{II} Complexes of These Ligands

We observed in our initial investigation that a ring-closure reaction at the periphery of a metal-complexed 2,3-bis(diarylphosphanyl)-1,4-diazadiene unit only occurred when P,P coordination is present and only when the metal ion was Ni^{II}.[17] Corresponding Cu^{I} or $Mo(CO)_4$ complexes did not promote this reaction. This fact prompted us to investigate the coordination chemistry of the related d^8 metal ions Pd^{II} and Pt^{II}.

Ligand **C** reacts with $[PtCl_2(cod)]$ to yield the mononuclear complex **1** as the only product. The two phosphorus atoms are nonequivalent as can be seen from two resonances (δ = 25.0 and 20.0 ppm) in the $^{31}P\{^1H\}$ spectrum of **1**. In addition, the ^1H and ^{13}C NMR spectra of **1** in $[D_8]$THF are in agreement with the unsymmetrical structure shown in Scheme 3.

For example, two different signals, each integrating to nine protons, were observed at δ = 1.05 and 1.24 ppm for the two *tert*-butyl groups. The NMR spectroscopic data suggest that **1** is the product of a ring-closure reaction between the 1,4-diazadiene system at the periphery of the complex with one *tert*-butylphenyl substituent of a nitrogen atom yielding a quinoxaline system by subsequent tautomerization (Scheme 3).

Figure 4 shows the solid-state structure of **1**, which confirms the existence of a mononuclear complex in which a ring-closure reaction to form a quinoxaline ring has occurred. The coordination geometry of the platinum center is square-planar with two *cis*-chloro ligands. The two phosphorus donor atoms form a five-membered chelate ring. Typical for this structure is the C1−C2 double bond (1.342 Å). As expected, the C−C bond lengths in the peripheral benzene ring are equivalent to each other within experimental errors and correspond to typical C−C bond lengths in aromatic systems. The C1−N1 and the C3−N1 bond lengths are those of typical single bonds [1.448(6), and 1.449(7) Å]. In contrast, the C2−N2 and C4−N2 bonds [1.380(7), 1.404(6) Å] are slightly shortened, indicating

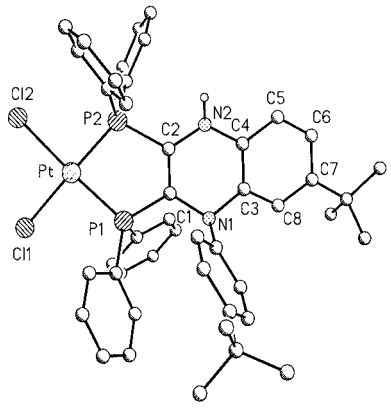

Figure 4. Solid-state structure of complex **1**; selected bond lengths [Å] and bond angles [°]: Pt−Cl1 2.361(1), Pt−Cl2 2.360(1), Pt−P1 2.214(1), Pt−P2 2.206(1), P1−C1 1.795(6), C1−C2 1.342(8), C1−N1 1.448(6), N1−C3 1.449(7), P2−C2 1.830(5), C2−N2 1.380(7), N2−C4 1.404(6), C4−C3 1.387(8), C4−C5 1.390(8), C5−C6 1.390(8), C6−C7 1.392(8), C7−C8 1.391(8), C8−C3 1.399(7); Cl1−Pt−Cl2 91.31(5), Cl1−Pt−P1 91.42(5), Cl1−Pt−P2 178.48(5), Cl2−Pt−P1 177.04(6), Cl2−Pt−P2 89.77(5), P1−Pt−P2 87.48(5)

charge delocalization in the C1−C2−N2−C4 part of the quinoxaline ring. Consequently, N1 is pyramidal and N2 is planar. This difference may be explained by steric reasons: N1 bears an aryl substituent in the neighborhood of the Ph_2P group whereas N2 bears the much smaller hydrogen substituent.

Ligand **C** also reacts with $[PdCl_2(CH_3CN)_2]$ to form the mononuclear complex **2** even if an excess of the palladium compound was employed. Analogous to the Pt compound, the $^{31}P\{^1H\}$ spectrum show that the two phosphorus atoms are unsymmetrical (two doublets at δ = 43.5 and 37.6 ppm). The ^1H and ^{13}C NMR spectra also indicate that a ring-closure reaction has taken place (see Exp. Sect.). Brown crystals of the palladium complex **2** could be isolated from THF. However, their quality was insufficient for the exact determination of bond lengths and bond angles in the solid state. Only the structure motif of the planar complex containing a peripheral quinoxaline ring could be unequivocally confirmed in the solid state.

Ligand **D** contains, in contrast to **C**, methyl groups in both *ortho* positions of the N substituents. This effectively prevents tautomerization to form a benzene ring. Coordi-

nation of a metal ion to both phosphorus atoms, followed by a peripheral ring closure, must then stop at the cyclohexadiene stage of the reaction.[17]

Ligand **D** does indeed react with $[PdCl_2(CH_3CN)_2]$ in THF to form the mononuclear complex **3**. ^1H, ^{13}C, and $^{31}P\{^1H\}$ NMR spectra are in complete agreement with a 1,3-cyclohexadiene ring at the periphery of the metal complex. The solid-state structure of **3** confirmed the presence of the expected 1,3-cyclohexadiene ring with its typically alternating bond lengths (Figure 5). The N1−C3 bond length (1.300 Å) is that of a double bond and therefore much shorter than the corresponding bond length in the N1−C1 single bond of **1** (1.448 Å). Bond lengths and angles in the (P,P)Pd chelate ring are very similar to those in **1**.

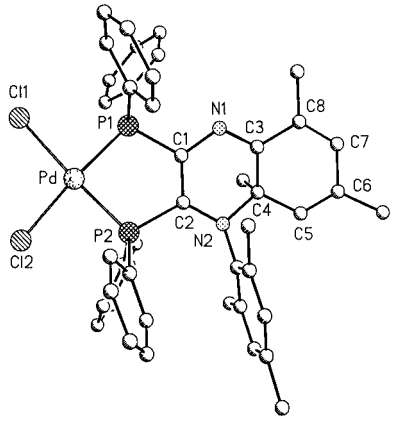

Figure 5. Solid-state structure of complex **3**; selected bond lengths [Å] and bond angles [°]: Pd−Cl1 2.354(1), Pd−Cl2 2.346(1), Pd−P1 2.194(1), Pd−P2 2.227(1), P1−C1 1.789(5), C1−N1 1.394(7), C1−C2 1.350(7), N1−C3 1.300(7), C2−N2 1.386(7), N2−C4 1.530(7), C4−C3 1.520(7), C4−C5 1.460(7), C5−C6 1.331(8), C6−C7 1.447(9), C7−C8 1.331(8), C8−C3 1.459(8); Cl1−Pd−Cl2 95.26(6), Cl1−Pd−P1 89.62(6), Cl1−Pd−P2 176.20(6), Cl2−Pd−P1 174.31(6), Cl2−Pd−P2 88.07(6), P1−Pd−P2 87.14(5), P1−C1−N1 116.8(4), P2−C2−N2 125.0(4), P1−C1−C2 120.9(4), P2−C2−C1 114.8(4), N1−C1−C2 122.0(5), N2−C2−C1 120.1(5)

These results allow us to conclude that bromides and chlorides of d^8 systems (Ni^{II}, Pd^{II}, and Pt^{II}) generally favor P,P coordination with 2,3-bis(phosphanyl)-1,4-diazadienes over P,N or N,N coordination. The formation of a mononuclear complex is then directly followed by an unusual peripheral ring-closure reaction to form a quinoxaline derivative, independent of the size of the metal ion.

Reaction of These Ligands with a Nickelacycle

We then modified the metal fragment employed to find out if the peripheral ring-closure reaction depends on the nature of the additional ligand(s) coordinated to the metal ion. Our metal fragment of choice was the nickelacycle [Ni(tmeda)(C_2H_4COO)], which contains a doubly negatively charged 1-oxo-2-nickelacyclopentan-5-one chelate ring on one side of the square-planar complex. On the other side is the neutral chelating ligand *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmeda). Displacement of tmeda by either **B**, **C**, or **D** should result in the initial formation of an [Ni{2,3-bis(diarylphosphanyl)-1,4-diazadiene}(C_2H_4COO)] complex. If the ring closure is affected by the additional metal ligands, one would expect a different reactivity of this complex compared to the related $NiBr_2$ complex, which undergoes a fast ring-closure reaction.

Treatment of the nickelacycle with the bulk ligand **D** in a solution of DMF followed by removal of tmeda by distillation in vacuo resulted in the expected organometallic complex [Ni(**D**)(C_2H_4COO)] (**4a**; Scheme 4) which turned out to be dark red. There are theoretically four possibilities for the coordination of **D** to the nickelacyclic fragment in this compound (P,P, N,N, and two P,N coordination modes). NMR spectroscopic data show that both phosphorus donor atoms coordinate to the nickelacycle in a different chemical environment (double signal sets for the mesityl groups in the ^1H NMR spectrum and two doublets at δ = 19.8 and 44.8 ppm in the $^{31}P\{^1H\}$ NMR spectrum of **4a**). Isolation of single crystals of **4a** from benzene and subsequent X-ray diffraction analysis (Figure 6) showed that both phosphorus atoms are coordinated to the nickel center (square-planar P,P mode) in the solid state. In addition, an oxygen and a carbon atom of the C_2HC_4COO moiety are bound to the nickel center. The 1,4-diazadiene unit of **D** is not involved in coordination. A ring-closure reaction of the 1,4-diazadiene and one mesityl substituent at the nitrogen atom to yield a quinoxaline ring *did not take place* upon coordination of the diphosphane unit to the nickelacycle.

The diazabutadiene unit in ligand **D** is not planar (N−C−C−N torsional angle is 52.4°) but is definitely closer to a (*Z*) arrangement than to the *twist*-(*E*) conformation of the free ligand **D** (N−C−C−N = 128.2°). Ligand bond lengths do not differ significantly between the free ligand **D** and the coordinated complex **4a**.

The less bulky ligand **B** also reacted with the nickelacycle [Ni(tmeda)(C_2H_4COO)] to yield an orange chelate complex, which could be isolated in good yields (54%) from dichloromethane as an adduct of the composition "[Ni(**B**)(C_2H_4-COO)(CH_2Cl_2)]". Analogous to **4a**, the $^{31}P\{^1H\}$ NMR spectrum of this complex in $CDCl_3$ shows a low-field shift relative to the free ligand and indicates a P,P coordination mode but, in this case, *two* sets of two doublets are observed at δ = 28.3 [d, $^2J(^{31}P^{31}P)$ = 19.0 Hz], 39.0 [d, $^2J(^{31}P^{31}P)$ = 24.2 Hz], 46.1 [d, $^2J(^{31}P^{31}P)$ = 24.2 Hz], and 48.9 [d, $^2J(^{31}P^{31}P)$ = 19.0 Hz] ppm.

This is not compatible with the "open coordination form" observed for **4a** but can be rationalized by an unsymmetrical chelate ring system formed by ring-closure reaction between the 1,4-diazadiene unit and an aromatic N-substituent to form the regioisomers **5b/5b′** (Scheme 4).

The ^1H NMR spectroscopic data support this conclusion. In the ^1H NMR spectrum two sets of signals for the CH_3 protons at δ = 1.84, 1.91, 2.11, and 2.15 ppm were found whereas the CH_2 protons of the metallacyclic ring appear as multiplets. The $^{13}C\{^1H\}$ NMR spectrum is very complicated due to the ^{31}P coupling pattern of the ^{13}C signals of the two very similar regioisomers. Therefore, not all expected signals could be resolved (see Exp. Sect.).

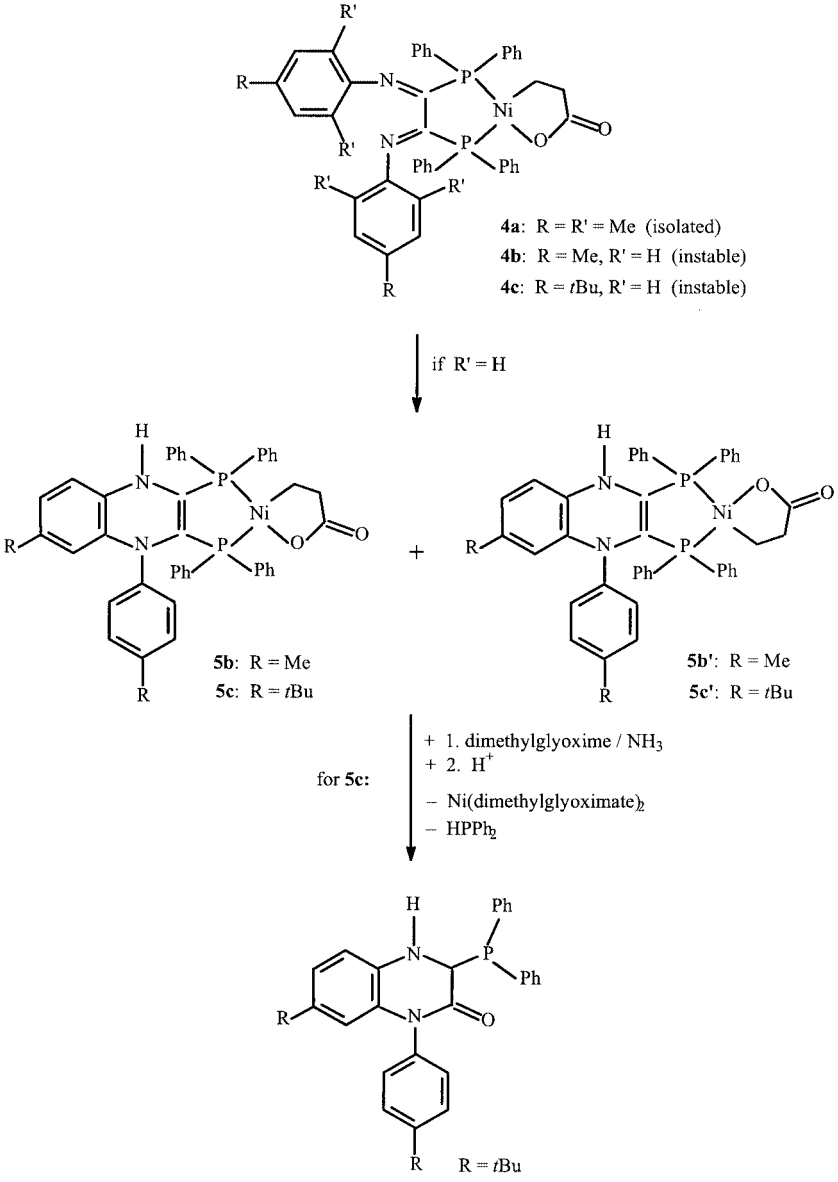

Scheme 4

The formation of a quinoxaline system at the periphery was confirmed by X-ray diffraction analysis. Figure 7 shows the molecule structure of a single crystal of the regioisomer **5b·CH_2Cl_2** grown from dichloromethane. Unfortunately, the quality of the crystals was insufficient for satisfactory refinement of all parameters.

Ligand **B** thus behaves in a fundamentally different way to ligand **D**. This clearly demonstrates the subtle dependence of the ring-closure reaction upon ligand environment and identity in the metal complex. Both the nature of the metal and the coordination geometry of the complex formed in the first step of the complex formation, and the nature of the other ligands surrounding the metal center, influence the subsequent cycloaddition reaction at the periphery.

When the closely related ligand **C** was treated with the nickelacycle [Ni(tmeda)(C_2H_4COO)], an initial intermediate was formed which could be monitored by time-resolved $^{31}P\{^1H\}$ NMR spectroscopy at 5 °C. The "open coordination form", characterized by two doublets at δ = 42.7 and 60.9 ppm, could be assigned to this intermediate [Ni(**C**)(C_2H_4COO)] (**4c**; Scheme 4).

As the reaction progressed, two sets of two doublets appeared at δ = 30.5/51.0 and 37.7/49.0 ppm and grew in intensity over time. The signals assigned to the "open form" intermediate **4c** completely disappeared after 2 h at room temperature, and, except for a very small amount of the free ligand, only the two sets of two doublets were observed, which we concluded was the "quinoxaline form" **5c/5c′** resulting from the peripheral ring-closure reaction. A com-

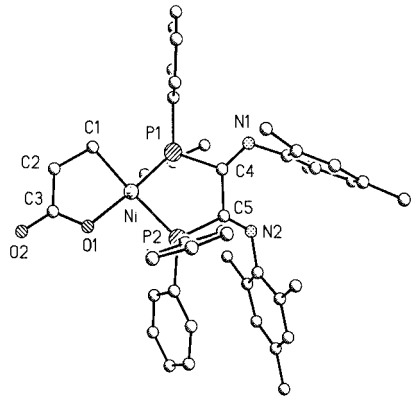

Figure 6. Solid -state structure of complex **4a**; selected bond lengths [Å] and bond angles [°]: Ni−P1 2.096(1), Ni−P2 2.170(1), Ni−O1 1.882(3), Ni−C1 1.952(4), C1−C2 1.526(6), C2−C3 1.512(6), C3−O1 1.306(5), C3−O2 1.227(5), P1−C4 1.853(4), P2−C5 1.864(4), C4−C5 1.530(5), C4−N1 1.271(5), C5−N2 1.267(5); P1−Ni−P2 90.30(4), P1−Ni−O1 170.55(9), P1−Ni−C1 88.6(1), P2−Ni−O1 96.00(9), P2−Ni−C1 171.5(1), O1−Ni−C1 86.2(1), P1−C4−N1 120.9(3), P2−C5−N2 133.4(3), P1−C4−C5 110.1(2), P2−C5−C4 110.4(2), N1−C4−C5 128.9(3), N2−C5−C4 115.0(3)

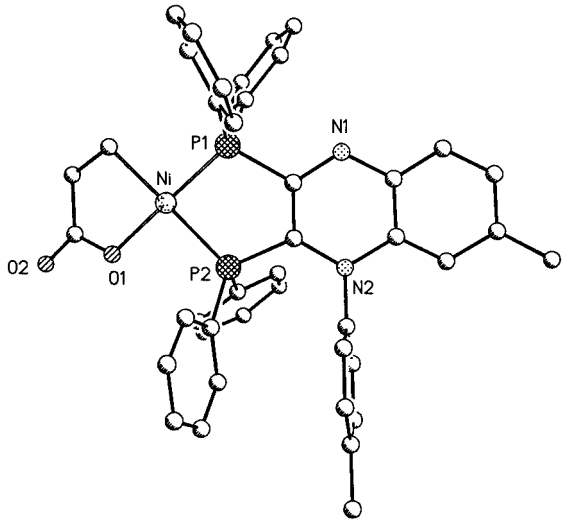

Figure 7. Solid-state structural motif of complex **5b** (the solvent CH_2Cl_2 has been omitted for clarity)

parison of the ^{31}P NMR spectrum of the closely related complex pair **5b/5b′** completely supports this assignment. There is no evidence for any other stable intermediate occurring during the ring-closure reaction.

In order to separate the quinoxaline ligand from the nickelacycle, the reaction mixture was treated with a solution of dimethylglyoxime in ethanol and aqueous ammonia. After separation of bis(dimethylgyoximato)nickel(II), thin white needles of 4-(*p*-*tert*-butylphenyl)-9-*tert*-butyl-3,4-dihydro-3-(diphenylphosphanyl)-1*H*-quinoxalin-2-one were isolated from the mother liquor, and were identified by IR measurements, mass spectra, ^1H, ^{13}C, and ^{31}P NMR spectra. The formation of this product can easily be explained by hydrolysis of the free 1,2-bis(diphenylphosphanyl)quinoxaline according to Scheme 4.

Experimental Section

General: ^1H, ^{13}C, and $^{31}P\{^1H\}$ NMR spectra were recorded at ambient temperature with a Bruker AC 200 MHz spectrometer unless otherwise stated. All spectra were referenced to TMS or deuterated solvent as an internal standard. FAB mass spectra were obtained with a Finnigan MAT SSQ 710 system (2,4-dimethoxybenzyl alcohol as matrix), ESI mass spectra were recorded with a Finnigan MAT, MAT 95 XL. IR measurements were carried out with a Perkin−Elmer System 2000 FT-IR. All manipulations were carried out by using Schlenk techniques under argon. Prior to use, tetrahydrofuran, diethyl ether, and toluene were dried with potassium hydroxide and distilled from Na/benzophenone. $[PtCl_2(cod)]$ and $[PdCl_2(CH_3CN)_2]$ (Aldrich) were used as received. Oxalic imidoyl chlorides R−N=C(Cl)−C(Cl)=N−R,[18,19] $NaPPh_2$(dioxane) and $K(PPh_2)(dioxane)_n$,[20] and the nickelacycle [Ni{(tmeda)-C_2H_4COO}][21] were prepared according to the literature.

Computational Methods: All calculations reported in this article were performed using the Gaussian 98[22] program package using the gradient-corrected B3LYP[23−25] density functional. Default convergence criteria were used for all optimizations. The size of ligand **D** limited optimizations and frequency calculations to the lanl2dz basis set developed by Hay and Wadt[26] as implemented in Gaussian 98. Atomic charges, orbital and hyperconjugative interaction energies were obtained at the B3LYP/6-31+G(d,p)//B3LYP/lanl2dz level using the natural bond orbital (NBO) analysis of Reed et al.[27] as implemented in Gaussian 98. The torsional barrier of diphosphanyl-diazabutadiene (Figure 2) was calculated using the very large 6-311++G(3df,3pd) basis set.

Crystal Structure Determination: The intensity data for the compounds were collected with a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-K_α radiation. Data were corrected for Lorentz and polarization effects, and (only for **1**) for absorption effects.[28,29] The structures were solved by direct methods (SHELXS[30]) and refined by full-matrix least-squares techniques against F_o^2 (SHELXL-97[31]). For the molecules **B**, **C**, **D**, **E**, and **G**, the hydrogen atoms were located by difference Fourier synthesis and refined isotropically. All other hydrogen atoms were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[4] Since the quality of the data of compounds **2** and **5c** was too low, we will only publish the conformation of **5b** and the crystallographic data of **2** and **5b**. We have not deposited the data in the Cambridge Crystallographic Data Centre. XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations.

Crystal Data for 2: $C_{46}H_{46}Cl_2N_2P_2Pd{\cdot}3C_4H_8O$, M_r = 1082.40 g·mol^{-1}, brown prism, size 0.18 × 0.12 × 0.10 mm, monoclinic, space group $P2_1/n$, *a* = 18.5913(3), *b* = 14.0835(4), *c* = 21.5903(6) Å, β = 104.930(1)°, *V* = 5462.2(2) Å^3, *T* = −90 °C, *Z* = 4, $\rho_{calcd.}$ = 1.316 g·cm^{-3}, μ(Mo-K_α) = 5.41 cm^{-1}, *F*(000) = 2264, 20954 reflections in *h*(−23/24),*k*(−17/18),*l*(−28/28), measured in the range 1.84° ≤ Θ ≤ 27.49°, completeness to Θ_{max} 99.2%, 12444 independent reflections, R_{int} = 0.077.

Crystal Data for 3:[32] $C_{44}H_{42}Cl_2N_2P_2Pd{\cdot}1.5C_4H_8O$, M_r = 946.19 g·mol^{-1}, yellow prism, size 0.18 × 0.12 × 0.10 mm, monoclinic, space group $P2_1/n$, *a* = 14.4502(6), *b* = 24.9850(10), *c* = 14.6521(5) Å, β = 112.360(3)°, *V* = 4892.2(3) Å^3, *T* = −90 °C, *Z* = 4, $\rho_{calcd.}$ = 1.285 g·cm^{-3}, μ(Mo-K_α) = 5.91 cm^{-1}, *F*(000) = 1960, 13135 reflections in *h*(−16/16),*k*(−28/28),*l*(−16/16), measured in the range 1.73° ≤ Θ ≤ 24.09°, completeness to Θ_{max} 96.7%, 7502 independent reflections, R_{int} = 0.037, 4810 reflections with $F_o > 4\sigma(F_o)$, 508 parameters, 8 restraints, $R1_{obs}$ = 0.057, $wR2_{obs}$ = 0.165, $R1_{all}$ = 0.081, $wR2_{all}$ = 0.177, GOOF = 0.953, largest difference peak/hole 1.069/−0.475 e·Å^{-3}.

Crystal Data for 4a:[32] $C_{47}H_{46}N_2NiO_2P_2{\cdot}0.5C_6H_6$, M_r = 830.56 g·mol^{-1}, red prism, size 0.10 × 0.10 × 0.08 mm, monoclinic, space group $P2_1/n$, *a* = 12.6055(3), *b* = 16.4881(4), *c* = 20.9493(6) Å, β = 99.186(2)°, *V* = 4298.3(2) Å^3, *T* = −90 °C, *Z* = 4, $\rho_{calcd.}$ = 1.283 g·cm^{-3}, μ(Mo-K_α) = 5.68 cm^{-1}, *F*(000) = 1748, 45176 reflections in *h*(−15/16),*k*(−21/21),*l*(−22/27), measured in the range 2.39° ≤ Θ ≤ 27.42°, completeness to Θ_{max} 98.6%, 9656 independent reflections, R_{int} = 0.115, 6543 reflections with $F_o > 4\sigma(F_o)$, 499 parameters, 0 restraints, $R1_{obs}$ = 0.069, $wR2_{obs}$ = 0.162, $R1_{all}$ = 0.114, $wR2_{all}$ = 0.191, GOOF = 1.055, largest difference peak/hole 1.412/−0.611 e·Å^{-3}.

Crystal Data for 5b: $C_{43}H_{38}N_2NiO_2P_2{\cdot}2CH_2Cl_2$, M_r = 904.70 g·mol^{-1}, prism, size 0.20 × 0.18 × 0.12 mm, monoclinic, space group $P2_1/c$, *a* = 8.8883(3), *b* = 26.1761(9), *c* = 19.3778(6) Å, β = 95.384(2)°, *V* = 4488.6(3) Å^3, *T* = −90 °C, *Z* = 4, $\rho_{calcd.}$ = 1.391 g·cm^{-3}, μ(Mo-K_α) = 8.4 cm^{-1}, *F*(000) = 1936, 16022 reflections in *h*(−11/11),*k*(−33/31),*l*(−25/25), measured in the range 2.89° ≤ Θ ≤ 27.46°, completeness to Θ_{max} 93.9%, 9655 independent reflections, R_{int} = 0.101.

Preparation of the Ligands

Ph−N=C(PPh$_2$)−C(PPh$_2$)=N−Ph (Ligand A): A solution of $NaPPh_2$ (7.17 mmol 15% excess) in 10 mL of cold THF (−78 °C) was added dropwise to a solution of diphenyloxalylimidoyl chloride (0.9 g, 3.24 mmol) in 50 mL of THF at −78 °C. The reaction mixture was then allowed to warm to room temperature. After removing the solvent in vacuo and recrystallization from toluene 0.75 g (40%) of **A** was isolated as a light yellow powder. ^{1}H NMR ([D$_8$]THF, 25 °C, 200 MHz): δ = 7.04 (m, CH-phenyl) ppm. $^{31}P\{^1H\}$ NMR ([D$_8$]THF, 25 °C, 81 MHz): δ = 4.59 (s) ppm. MS (CI): 577 (basic peak $[M+1]^+$ ($C_{38}H_{30}N_2P_2 + H^+$), 499 ($[M+1]^+ - C_6H_6$, 3%), 409 ($[M+1]^+ - C_{12}H_{12}N$, 3%), 393 ($[M+1]^+ - C_{12}H_9P$, 16%), 288 ($[M+1]^+ - C_{19}H_{16}NP$, 37%), 185 ($[M+1]^+ - C_{26}H_{21}N_2P$, 15%).

Mes−N=C(PPh$_2$)−C(PPh$_2$)=N−Mes·CHCl$_3$ [D(CHCl$_3$)]

a) From Mes−N=CCl−CCl=N−Mes and KPPh$_2$: A solution of dimesityloxalylimidoyl chloride (2.7 g, 7.5 mmol) and $Pd(OAc)_2$ (85 mg, 0.038 mmol) in 100 mL of toluene was cooled to −40 °C in a three-necked flask equipped with a stirrer and a dropping funnel. Over 1 h, a solution of $KPPh_2$ (15.0 mmol) in 42 mL of dioxane/THF (1:1) was added. The color of the solution turned from yellow to dark red. The dry-ice bath was then removed and the reaction mixture was kept at room temperature overnight. The precipitated KCl was then filtered off. The solvent was removed in vacuo and the residue dissolved in hexane. The mixture was then filtered through Celite and the filtrate concentrated to dryness. The

residue is a slowly crystallizing oil. Recrystallization from chloroform/hexane gave 3.96 g (80%) of **D(CHCl$_3$)** as yellow crystals. M.p. 170 °C. $C_{45}H_{43}N_2P_2Cl_3$ (780.1): calcd. C 69.28, H 5.56, Cl 13.63, N 3.59; found C 69.97, H 5.67, Cl 13.18, N 3.55. ^{1}H NMR ($CDCl_3$, 200.13 MHz, 298 K): δ = 1.42 (s, 12 H, *o*-CH_3), 2.17 (s, 6 H, *p*-CH_3), 6.45 (s, 4 H, *m*-H, Mes), 7.19−7.21 (m, 12 H, Ph), 7.50−7.54 (m, 8 H, Ph) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 50.32 MHz, 298 K): δ = 17.7 [t, $J(^{13}C^{31}P)$ = 2.5 Hz, CH_3), 20.6 (CH_3), 124.4 (C), 128.1 (CH), 128.1 [d, $J(^{13}C^{31}P)$ = 8.3 Hz, CH], 128.8 (CH), 132.8 (C), 133.8 [br., d, $J(^{13}C^{31}P)$ = 10.5 Hz, C], 135.2 [br., d, $J(^{13}C^{31}P)$ = 23.4 Hz, C], 145.3 [br., d, $J(^{13}C^{31}P)$ = 9.3 Hz, C], 175.2 [dd, $J(^{13}C^{31}P)$ = 58.1, $J(^{13}C^{31}P)$ = 4.5 Hz, C] ppm. ^{31}P{^{1}H} NMR ($CDCl_3$, 81.01 MHz, 298 K): δ = 9.0 (s) ppm. MS (EI): *m*/*z* = 660 [M^+], 330 [M^+/2]. **G** was separated by column chromatography (Florisil, hexane, toluene) as the most nonpolar compound from the residue of the mother liquor. Yield: 0.18 g (5%) of yellow crystals. The yield can be increased up to 44% by addition of $HPPh_2$ *before* $KPPh_2$. ^{1}H NMR ($CDCl_3$, 200.13 MHz, 298 K): δ = 1.55 (s, 6 H, *o*-CH_3), 2.02 (s, 6 H, *o*-CH_3), 2.14 (s, 3 H, *p*-CH_3), 2.17 (s, 3 H, *p*-CH_3), 6.65 (s, 2 H, *m*-H), 6.73 (s, 2 H, *m*-H), 7.34−7.64 (m, 11 H, Ph, =CH−) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 50.32 MHz, 298 K): δ = 17.5 (CH_3), 17.6 (CH_3), 20.6 (CH_3), 124.4 [d, $J(^{13}C^{31}P)$ = 1.8 Hz, C], 126.7 (C), 128.4 [d, $J(^{13}C^{31}P)$ = 18.8 Hz, CH], 128.4 (*m*-CH, Mes), 128.6 (*m*-CH, Mes), 129.1 (CH), 132.7 (C), 133.8 (C), 134.4 [d, $J(^{13}C^{31}P)$ = 6.6 Hz, C], 135.0 (CH), 135.2 (CH), 135.1 [d, $J(^{13}C^{31}P)$ = 20.1 Hz, C], 157.5 [d, $J(^{13}C^{31}P)$ = 23.4 Hz, C], 175.5 [d, $J(^{13}C^{31}P)$ = 14.2 Hz, C] ppm. ^{31}P{^{1}H} NMR ($CDCl_3$, 81.01 MHz, 298 K): δ = 2.4 (s) ppm. ^{31}P{^{1}H} NMR (C_6D_6, 81.01 MHz, 298 K): δ = 5.7 (s) ppm. MS (EI): *m*/*z* = 446 [M^+], 330 [$Ph_2PCNMes^+$], 146 [$MesNCH^+$].

b) From Mes−N=CCl−CCl=N−Mes and Me$_3$Si−PPh$_2$: A mixture of dimesityloxalylimidoyl chloride (2.25 g, 6.23 mmol) and diphenyl(trimethylsilyl)phosphane (3.25 g, 12.58 mmol) was held at 100 °C in a water bath for 12 h. Trimethylsilyl chloride was then distilled off the reaction mixture, which became more and more solid. The residue was then extracted with *n*-hexane. Yield: 2.63 g (64%) of **D** as yellow crystals. M.p. 170 °C.

Phosphane Oxide E by Oxidation of B: A solution of **B** in THF was treated with an equimolar amount of hydrogen peroxide at room temperature and a few milligrams of $CuSO_4$ were added. After 6 h, the solvent was removed and the residue was treated with chloroform. The organic phase was separated and dried with $NaSO_4$. After removing the solvent, a yellow product was isolated. White single crystals of **E** were obtained from THF at −20 °C. Similarly, the oxidation can also be carried out with air in the presence of a copper salt. MS (EI): *m*/*z* = 636 [$M^+ = C_{40}H_{34}N_2O_2P_2$], 402 [$(Ph_2PO)_2$], 318 [$M^+$/2], 201 [$Ph_2PO$]. ^{31}P{^{1}H} NMR ($CDCl_3$, 81.01 MHz, 298 K): δ = 23.56 ppm. ^{1}H NMR ($CDCl_3$, 200.13 MHz, 298 K): δ = 2.14 (s, 6 H, *p*-CH_3), 6.62. 6.78 (AA′BB′, 8 H, CH-tolyl), 7.24−7.70 (m, phenyl, solvent) ppm.

Phosphane Sulfide F by Oxidation of D with Sulfur: A solution of **D(CHCl$_3$)** (1.01 g, 1.30 mmol) in toluene was treated with sulfur (85 mg, 2.65 mmol) and stirred at room temperature for 24 h. The solution slowly turned dark red. The signal of **D** in the ^{31}P{^{1}H} NMR spectrum of the reaction mixture disappeared and a new signal at δ = 33.8 ppm appeared. The solvent was removed in vacuo. Recrystallization of the crude product from diethyl ether gave 0.60 g of Mes−N=C[P(S)Ph$_2$]−C[P(S)Ph$_2$]=N−Mes (**F**) (63.6%) as dark red thin plates. M.p. 242−243 °C. $C_{44}H_{42}N_2P_2S_2$ (724.8): calcd. C 72.90, H 5.84, N 3.86, S 8.85; found C 72.55, H 6.08, N 3.83, S 8.43. IR (nujol mull): ν(C=N) = 1640 cm^{-1}. ^{1}H NMR ($CDCl_3$, 200.13 MHz, 298 K): δ = 1.74 (s, 12 H, *o*-CH_3), 1.97 (s, 6 H, *p*-CH_3), 6.20 (s, 4 H, *m*-H), 1.74 (s, 12 H, *o*-CH_3), 7.17 (m, 8 H, *m*-H), 7.24 (m, 4 H, *p*-H), 7.81 (m, 8 H, *o*-H) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 50.32 MHz, 298 K): δ = 19.0 (*o*-CH_3), 20.3 (*p*-CH_3), 123.5 (*o*-C), 127.8 (m, *o*-CH), 129.1 (*i*-C), 130.5 (*p*-CH), 131.5 (m, *m*-CH), 132.4 (*p*-C), 133.2 (*m*-CH), 142.5 (m, *i*-C), 159.3 [br., t, *J* ≈ 29 Hz, $(N=C-P)_2$] ppm. ^{31}P{^{1}H} NMR ($CDCl_3$, 81.01 MHz, 298 K): δ = 34.9 (s) ppm. MS *m*/*z* = 725 [M^+ + H].

Complex 1 [PdCl$_2$(C$_{46}$H$_{46}$N$_2$P$_2$)]: A solution of **C** (0.873 mmol, 0.601 g) in 25 mL of THF was added dropwise to a solution of $[PdCl_2(CH_3CN)_2]$ (0.873 mmol, 0.226 g) in 25 mL of THF whilst stirring. Shortly after warming the solution up to 60 °C, complex **1** precipitated almost quantitatively. After filtration, the compound was dried in vacuo at room temperature. It is only very slightly soluble in organic solvents. $C_{50}H_{54}Cl_2N_2OP_2Pd$ [**1(THF)**] (938.26): calcd. C 64.01, H 5.80, N 2.99; found C 63.25, 62.94, H 6.24, 5.98, N 2.89. ^{1}H NMR ([D$_8$]THF, 25 °C, 200 MHz): δ = 1.06, 1.15 (s, 18 H, CH_3-*t*Bu), 6.79−7.67 (m, 28 H, Ph) ppm. ^{31}P{^{1}H} NMR ([D$_8$]THF, 25 °C, 81 MHz): δ = 37.67 (d), 43.54 (d) ppm.

Complex 2 [PtCl$_2$(C$_{46}$H$_{46}$N$_2$P$_2$)]: A solution of **B** (0.32 mmol) in 10 mL of THF was added to [PtCl$_2$(cod)] (0.32 mmol, 0.12 g), dissolved in 10 mL of THF. Shortly after warming the solution up to 60 °C, complex **2** crystallized in more than 95% yield. $C_{50}H_{54}Cl_2N_2OP_2Pt$ [**2(THF)**] (954.82): calcd. C 58.48, H 5.30, N 2.73; found C 58.44, H 5.61, 5.44, N 2.65. ^{1}H NMR ([D$_8$]THF, 27 °C, 200 MHz): δ = 1.11, 1.15 (s, 18 H,CH_3), 6.38−8.01 (m, 25 H, Ph and NH); ^{31}P{^{1}H} NMR ([D$_8$]THF, 27 °C, 81 MHz): δ = −1.49 (d), 4.38 (d), 20.16 (d, *J* = 12 Hz), 25.05 (d, *J* = 13 Hz), 41.82 (d), 45.80 (d) ppm. MS (DEI): 953 [$M^+ = C_{46}H_{46}N_2P_2Cl_2Pt$], 918 [$M^+$ − Cl], 784 [$M^+ - C_{10}H_{13}Cl$], 696 [$M^+ - C_{12}H_{11}PCl_2$].

Complex 3 [PdCl$_2$(C$_{44}$H$_{42}$N$_2$P$_2$)]: A solution of 1.17 mmol of **D** in 20 mL of THF was added dropwise to a solution of [PdCl$_2$(acetonitrile)$_2$] (1.17 mmol, 0.292 g) in 25 mL of THF whilst stirring at room temperature. The complex precipitated after a short time in almost quantitative yield. After filtration, the product was washed with cold THF and dried in vacuo. $C_{48}H_{50}Cl_2N_2OP_2Pd$ [**3(THF)**] (910.21): calcd. C 63.34, H 5.53, N 3.08; found C 63.37, H 6.06, N 3.12. ^{1}H NMR ([D$_8$]THF, 27 °C, 200 MHz): δ = 0.89, 0.99, 1.46, 1.59; 1.89, 2.17 (s, each 3 H, CH_3), 5.13, 5.97 (s, each 1 H, olefin-H), 6.08, 6.70 (s, each 1 H, mesityl-CH), 7.06−8.30 (m, 20 H, Ph), ^{31}P{^{1}H} NMR ([D$_6$]DMSO, 25 °C, 81 MHz): δ = 46.86 (d, *J* = 46 Hz), 53.63 (d, *J* = 46 Hz) ppm. MS (EI): *m*/*z* = 802 [$C_{44}H_{42}N_2P_2ClPd = M^+ - Cl$].

Ligand Exchange Reaction of [Ni(C$_2$H$_4$COO)(tmeda)] with B, C, and D

[Ni{Mes−N=C(PPh$_2$)−C(PPh$_2$)=N−Mes}(C$_2$H$_4$COO)] (4a): [Ni(tmeda)(C_2H_4COO)] (1.05 g, 4.26 mmol) and **D** (2.82 g, 4.26 mmol) in 20 mL of DMF were stirred for 20 min. During this time, the solution (initially light green) turned dark red. The volatile part of the reaction mixture was then removed at 50 °C in vacuo. The residue was washed with diethyl ether, extracted with benzene and crystallized at 5 °C by addition of diethyl ether. Yield 1.22 g (33.5%) red crystals of **4a(C$_6$H$_6$)$_{0.5}$**. ^{1}H NMR ($CDCl_3$, 200.13 MHz, 298 K): δ = 0.91 (m, 2 H, Ni−CH_2), 1.33 (s, 6 H, CH_3), 1.37 (s, 6 H, *o*-CH_3), 1.74 (s, 3 H, *p*-CH_3), 2.10 (s, 3 H, *p*-CH_3), 2.10 (m, 2 H, COO-CH_2), 5.67 (s, 2 H, CH Mes), 6.56 (s, 2 H, CH Mes), 7.20−7.64 (m, 20 H, Ph) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$, 81.01 MHz, 298 K): δ = 19.8 [br. d, $^2J(^{31}P^{31}P)$ = 19.3 Hz], 44.8 [br. d, $^2J(^{31}P^{31}P)$ = 19.3 Hz] ppm.

Preparation of [Ni($C_{40}H_{34}N_2P_2$)(C_2H_4COO)] (5b/5b′): A mixture of [Ni(tmeda)(C_2H_4COO)] (0.76 g, 3.08 mmol) and **B** (1.85 g, 3.08 mmol) in 20 mL of THF was warmed up until both compounds dissolved. A few minutes later, an orange-colored compound precipitated. Recrystallization from dichloromethane gave 1.36 g (54%) of **5b/5b′(CH_2Cl_2)** as orange crystals. This compound loses dichloromethane very easily in vacuo. $C_{43}H_{38}N_2NiO_2P_2$ (735.4): calcd. C 70.22, H 5.21, N 3.81; found C 69.83, H 5.61, N 3.74. IR (nujol): ν(C=O) = 1606 cm^{-1} (s), ν(N−H) = 3140 cm^{-1} (w). ^1H NMR ($CDCl_3$, 200.13 MHz, 298 K): δ = 0.70 (m, 2 H, CH_2-Ni), 1.84 (s, 3 H, CH_3), 1.91 (s, 3 H, CH_3), 2.11 (s, 3 H, CH_3), 2.15 (s, 3 H, CH_3), 2.20 (m, 2 H, CH_2−COO) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 50.32 MHz, 298 K): δ = 20.6 (CH_3), 20.8 (CH_3); CH: δ = 128.2 [d, $J(^{13}C^{31}P)$ = 2.4 Hz], 128.2 [d, $J(^{13}C^{31}P)$ = 2.4 Hz], 129.3 [d, $J(^{13}C^{31}P)$ = 4.9 Hz], 129.4 [d, $J(^{13}C^{31}P)$ = 4.9 Hz], 129.5 (s), 129.9 [d, $J(^{13}C^{31}P)$ = 2.4 Hz], 130.4 (s), 132.5 [d, $J(^{13}C^{31}P)$ = 1.8 Hz], 132.7 (s), 132.8 [d, $J(^{13}C^{31}P)$ = 4.7 Hz], 133.1 [d, $J(^{13}C^{31}P)$ = 5.9 Hz]; C: δ = 113.4 (s), 113.6 (s), 117.7 (s), 119.6 (s), 123.7 (s), 124.4 (s), 127.5 (s), 131.4 [t, $^1J(^{13}C^{31}P)$ = 22.0 Hz, $(NPC=)_2$], 133.3 [d, $J(^{13}C^{31}P)$ = 8.2 Hz], 136.3 (s), 136.7 (s), 137.2 (s), 139.8 (s), 142.0 (s) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 81.01 MHz, 298 K): δ = 28.3 [d, $^2J(^{31}P^{31}P)$ = 19.0 Hz], 39.0 [d, $^2J(^{31}P^{31}P)$ = 24.2 Hz], 46.1 [d, $^2J(^{31}P^{31}P)$ = 24.2 Hz], 48.9 [d, $^2J(^{31}P^{31}P)$ = 19.0 Hz] ppm.

In situ Preparation of 5c/5c′ and Reaction with Dimethylglyoxime and Aqueous Ammonia: A mixture of [Ni(tmeda)(C_2H_4COO)] (175 mg, 0.71 mmol) and **C** (484 mg, 0.70 mmol) in 20 mL of THF was stirred at 5 °C for 30 min. All of the starting materials dissolved and the color of the solution changed from light green to yellow. The complete ring-closure reaction of the intermediate [Ni(**C**)(C_2H_4COO)] to the orange-colored product [Ni($C_{46}H_{46}N_2P_2$)(C_2H_4COO)] was monitored by $^{31}P\{^1H\}$ NMR spectroscopy. $^{31}P\{^1H\}$ NMR (C_6D_6/THF, 81.01 MHz, 298 K): δ = 30.5 [d, $^2J(^{31}P^{31}P)$ = 18.7 Hz], 37.7 [d, $^2J(^{31}P^{31}P)$ = 24.7 Hz], 49.0 [d, $^2J(^{31}P^{31}P)$ = 24.7 Hz], 51.0 [d, $^2J(^{31}P^{31}P)$ = 18.7 Hz] ppm. Intermediate [Ni{*p*-*t*Bu−Ph−N=C(PPh_2)−C(PPh_2)=N−Ph-*p*-*t*Bu}(C_2H_4COO)]: $^{31}P\{^1H\}$ NMR (C_6D_6/THF, 81.01 MHz, 298 K): δ = 42.7 [d, $^2J(^{31}P^{31}P)$ = 23.0 Hz], 60.9 [d, $^2J(^{31}P^{31}P)$ = 23.0 Hz] ppm.

9-*tert*-Butyl-4-(*p*-*tert*-butylphenyl)-3,4-dihydro-3-(diphenylphosphanyl)-1*H*-quinoxalin-2-one: A solution of dimethylgyoxime (165 mg, 1.42 mmol in 20 mL of methanol), followed by 10 drops of concentrated aqueous ammonia, were added dropwise to a solution of [Ni($C_{46}H_{46}N_2P_2$)(C_2H_4COO)] (0.70 mmol in 5 mL THF). Red bis(dimethylglyoximato)nickel(II) precipitated from the reaction mixture and was then filtered off. The filtrate was distilled to dryness in a rotary condenser and the residue recrystallized from alcohol/chloroform. Yield 0.21 g (57%) of 9-*tert*-butyl-4-(*p*-*tert*-butylphenyl)-3,4-dihydro-3-(diphenylphosphanyl)-1*H*-quinoxalin-2-one. M.p. 288−292 °C. $C_{34}H_{37}N_2OP$ (520.6): calcd. C 78.43, H 7.16, N 5.38; found C 77.88, H 6.83, N 5.34. IR (nujol): ν(C=O) = 1663 cm^{-1}. ^1H NMR ($CDCl_3$, 200.13 MHz, 298 K): δ = 1.18 (s, 9 H, *t*Bu), 1.35 (s, 9 H, *t*Bu), 6.70 (s, 1 H), 7.14−7.70 (m, 16 H), 8.00 (br., 1 H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 50.32 MHz, 298 K): δ = 30.8 (*t*Bu), 30.9 (*t*Bu), 34.8 (C, *t*Bu), 35.2 (C, *t*Bu), 112.0 (CH), 121.2 (CH), 127.0 (C), 127.3 [d, $J(^{31}P^{13}C)$ = 42.3 Hz], 127.8 (CH), 128.3 [d, $J(^{31}P^{13}C)$ = 5.5 Hz, CH], 128.9 (CH), 129.7 (CH), 132.0 (CH), 132.2 [d, $J(^{31}P^{13}C)$ = 9.7 Hz], 132.6 (CH), 133.5 (C), 134.5 (C), 134.7 (CH), 152.3 (C), 154.0 (C) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 81.01 MHz, 298 K): δ = 0.0 (br) ppm. MS (CI) (m/z): 519 $[M-1]^+$.

Synthesis and Reaction of Mn^{II} Iodides Bearing the β-Diketiminate Ligand: the First Divalent Manganese N-Heterocyclic Carbene Complexes [{HC(CMeNAr)$_2$}MnI{C[N(*i*Pr)CMe]$_2$}] and [{HC(CMeNAr)$_2$}MnNHAr{C[N(*i*Pr)CMe]$_2$}] (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$)

Keywords: Manganese / Iodine / N ligands / Heterocycles / Carbene ligands

The manganese mono-iodide [HC(CMeNAr)$_2$]MnI(THF) (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$) (**3**) was prepared in good yield from the reaction of [HC(CMeNAr)$_2$]K with MnI_2 in THF. Treatment of **3** under reflux in toluene and removing all the volatiles in vacuo afforded the dimeric compound [{HC(CMeNAr)$_2$}-Mn]$_2$(μ-I)$_2$ (**4**). Displacement of the coordinated THF in **3** by a strong Lewis base C[N(*i*Pr)CMe]$_2$ or by adding C[N(*i*Pr)CMe]$_2$ to the toluene solution of **4** readily gave the N-heterocyclic carbene adduct [{HC(CMeNAr)$_2$}]MnI{C-[N(*i*Pr)CMe]$_2$} (**5**). Reduction of **5** with sodium/potassium alloy at room temperature unexpectedly resulted in the formation of the monomeric compound [{HC(CMeNAr)$_2$}]MnNHAr{C[N(*i*Pr)CMe]$_2$} (**6**). Alternatively **6** was obtained by the salt elimination reaction of **5** with LiNHAr. Compounds **5** and **6** are the first examples of divalent manganese N-heterocyclic carbene adducts and the first manganese non-carbonyl carbene complexes. The single crystal X-ray structural analyses reveal that compounds **3** and **6** are monomeric and compound **4** is dimeric in the solid state. The manganese centers in these compounds exhibit a distorted tetrahedral geometry.

Introduction

Manganese carbene complexes are important due to their applications in organic synthesis, synthetic methodology and theoretical implications and have been studied extensively.[1−4] N-Heterocyclic carbenes have attracted great attention in ligand design and homogeneous catalysis since Arduengo et al. reported the first stable crystalline N-heterocyclic carbene in 1991.[5−8] A variety of transition metal N-heterocyclic carbene complexes have been synthesized and isolated and some of them have been successfully applied as catalysts in a number of organic reactions such as iridium-catalyzed transfer hydrogenation,[6] ruthenium-catalyzed olefin metathesis, and especially palladium-catalyzed C−C coupling reactions: the Heck, Suzuki and Kumada reactions.[7,9] However, manganese N-heterocyclic carbene complexes are rare and have not attracted much attention to date.[9a] To the best of our knowledge, only a few monovalent manganese N-heterocyclic carbene complexes are known, including [$MeC_5H_4(CO)_2MnC(NMeCH_2)_2$],[10] [$(CO)_3MnBr\{C(NMeCH_2)_2\}_2$][10] and [$(CO)_5MnC\{N(BH_3)CMeCMeNMe\}$][11] and so far no higher oxidation state manganese N-heterocyclic carbene complexes have been reported. Furthermore, no X-ray structural data of manganese N-heterocyclic carbene complexes are available.

Organometallic iodide complexes have unique chemical properties due to their labile M−I bond compared to the M−Cl congener.[12] Recent results in our group proved that aluminum diiodide bearing a β-diketiminate ligand [AlI_2\{HC(CMeNAr)$_2$\}] (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$) is a good starting material for some interesting reactions such as reduction and hydrolysis. For instance, we reported the monomeric [Al\{HC(CMeNAr)$_2$\}] as a stable carbene analogue by reduction of [AlI_2\{HC(CMeNAr)$_2$\}] with potassium.[13a] Furthermore, the aluminum dihydroxide complex [$Al(OH)_2$\{HC(CMeNAr)$_2$\}], with terminal OH groups, was obtained by hydrolysis of [AlI_2\{HC(CMeNAr)$_2$\}] using a liquid NH_3/toluene two-phase system.[13b] Consequently we became interested in transition metals and investigated the behavior of Mn iodides bearing a β-diketiminate ligand. However, our efforts to reduce [{HC(CMeNAr)$_2$}Mn(μ-I)$_2$Li(OEt$_2$)$_2$] were unsuccessful with sodium or potassium due maybe to the existence of the stable lithium salt.[14] Herein we report the preparation of manganese iodides bearing β-diketiminate ligand free of lithium salt of composition [LMnI(THF)] (**3**), [(LMn)$_2$(μ-I)$_2$] (**4**) and [LMnI\{C[N(*i*Pr)CMe]$_2$\}] (**5**) [L = HC(CMeNAr)$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$] and the derivative [LMnNHAr\{C-[N(*i*Pr)CMe]$_2$\}] (**6**), in which compounds **5** and **6** are the

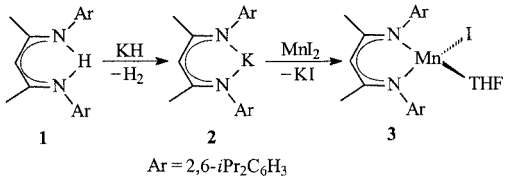
first examples of divalent manganese N-heterocyclic carbene adducts and the first manganese non-carbonyl carbene complexes. Compound **6** is the first structurally characterized manganese N-heterocyclic carbene complex.

Results and Discussion

Synthesis of Compounds 2−6

KL (**2**) was prepared from the reaction of HL (**1**) with $KN(SiMe_3)_2$ in relatively low yield (27%).[15] Herein we report that this compound can be conveniently obtained as a crystalline solid in good yield (87%) by the reaction of HL with KH in diethyl ether at room temperature (Scheme 1). The ^1H NMR spectrum and elemental analysis are identical with those of the literature.[15] Compound **2** is stable under an inert atmosphere and can be kept for a long time without obvious decomposition.



Scheme 1

The reaction of MnI_2 with one equiv. of $[LiL(Et_2O)]$ in diethyl ether afforded the heterobimetallic complex $[LMn(\mu\text{-}I)_2Li(OEt_2)_2]$.[14] Attempts to remove the coordinated lithium salt from the manganese center were unsuccessful. However, the reaction of MnI_2 with one equiv. of **2** in THF easily gave the monomeric compound [LMnI(THF)] (**3**) in high yield (87%) with a coordinated THF at the metal center. EI-MS of **3** exhibits $[LMnI]^+$ (m/z = 599, 100%) without the coordinated THF. The formula of **3** was confirmed by the crystal structure (Figure 1).

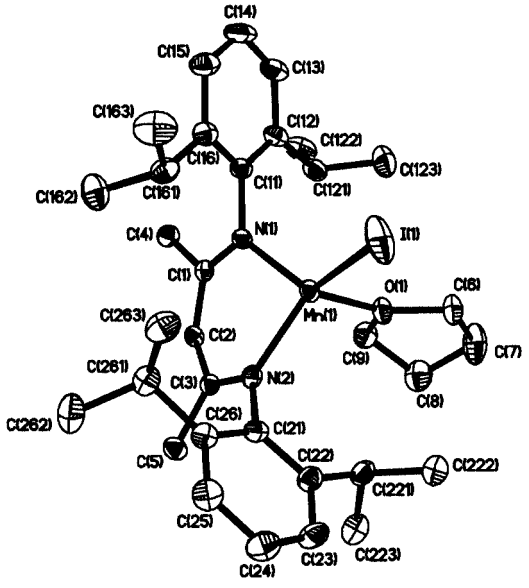


Figure 1. Molecular structure of **3** (30% probability thermal ellipsoids); hydrogen atoms are omitted for clarity

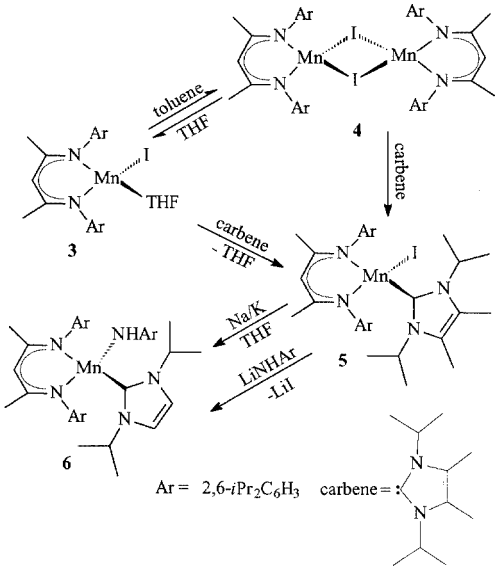
Attempts to prepare the di-β-diketiminato complex by using two equiv. of **2** were unsuccessful.

Refluxing of **3** in toluene for 0.5 h and removing all the volatiles in vacuo afforded the dimeric compound $[(LMn)_2(\mu\text{-}I)_2]$ (**4**). Crystals suitable for X-ray analysis were obtained by recrystallization from toluene. EI-MS of **4** did not give the molecular ion peak M^+ whereas half of the molecular mass $[LMnI]^+$ is observed at m/z = 599 (100%), which shows that **4** is monomeric in the gas phase, and no indication of fragments containing a Mn−Mn species, which is consistent with the X-ray structural analysis. Compound **3** can easily be obtained by dissolving **4** in THF (Scheme 2).



Scheme 2

Compound **3** can be considered as an adduct of a Lewis acid LMnI and a weak Lewis base THF. Displacement of the THF by a strong Lewis base $[C\{N(i\text{Pr})CMe\}_2]$ readily afforded the N-heterocyclic carbene adduct $[LMnI\{C[N(i\text{Pr})CMe]_2\}]$ (**5**), which can also be obtained by adding $[C\{N(i\text{Pr})CMe\}_2]$ to a solution of **4** in toluene. On the other hand we were not able to prepare **4** by removing the carbene in **5**, which shows that the N-heterocyclic carbene is a much stronger σ-donor ligand. Compounds **3**, **4**, and **5** are all soluble in polar solvents such as THF and CH_2Cl_2 and have poor solubility in hydrocarbon solvents.

The chemistry of organometallic dinuclear complexes containing a metal-metal bond is a burgeoning field.[16] We are interested in preparing L′MML′ (L′ = ligands, M = metal) type compounds by reduction of L′MX (X = halide). The first three-coordinate dinuclear manganese(I) compound LMnMnL [L = $HC(CMeNAr)_2$, Ar = 2,6-$i\text{Pr}_2C_6H_3$] has been successfully synthesized by reduction of **4** with sodium/potassium alloy.[17] However, further reduction of **5** by sodium/potassium alloy at room temperature, unexpectedly resulted in the formation of the monomeric compound $[LMnNHAr\{C[N(i\text{Pr})CMe]_2\}]$ (**6**) in low yield. The efforts to identify other species were unsuccessful. Given that Mn^{II} complexes are used as radical initiators

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for radical polymerisation processes,[18] it is tempting to propose that the formation of compound **6** is due to the partial decomposition of the intermediate radical [LMnC{N(*i*Pr)CMe}$_2$], which cannot aggregate due to the presence of the bulky N-heterocyclic carbene. In the mass spectrum, [LMnNHAr]$^+$ was observed at m/z = 648 (52%), followed by [LMn]$^+$ (m/z = 472, 100%). The elemental analyses are consistent with the solid-state structure. Compound **6** can also be prepared in good yield (76%) by the reaction of **5** with LiNHAr.

X-ray Diffraction Analyses for 3, 4, and 6

The single-crystal X-ray diffraction analyses for compounds **3**, **4**, and **6** have been undertaken. For **3** and **4**, there are two molecules in the unit cell, one of which is shown in Figures 1 and 2, respectively. The structure of **6** is presented in Figure 3. Crystallographic data for **3**, **4**, and **6** are given in Table 1 and selected bond lengths and angles in Table 2.

The X-ray structural analyses reveal that the [LMnI(THF)] (**3**), [LMnNHAr{C[N(*i*Pr)CMe]$_2$}] (**6**) are monomeric and [(LMn)$_2$(μ-I)$_2$] (**4**) is dimeric in the solid state (Figures 1−3). In all three compounds the manganese centers are four-coordinate and display a distorted tetrahedral geometry. The backbone of the chelating ligand is nearly planar and the manganese atom in all the reported compounds is out of the C_3N_2 plane (0.62 Å in **3**, 0.43 Å in **4**, 0.78 Å in **6**). The N(1)−Mn(1)−N(2) angle in **6** [88.94(7)°] is significantly smaller than the corresponding angles in **3** [93.56(13)°] and **4** [95.57(14)°], while the Mn(1)−N(1) and Mn(1)−N(2) bond lengths in **6** [2.166(2) and 2.133(2) Å] are obviously longer than those in **3** [2.079(3) and 2.070(3) Å] and **4** [2.067(2) and 2.067(2) Å], which indicates that the metal center in **6** is more weakly bonded to the chelating ligand possibly due to the different substituents that cause a stronger trans effect.

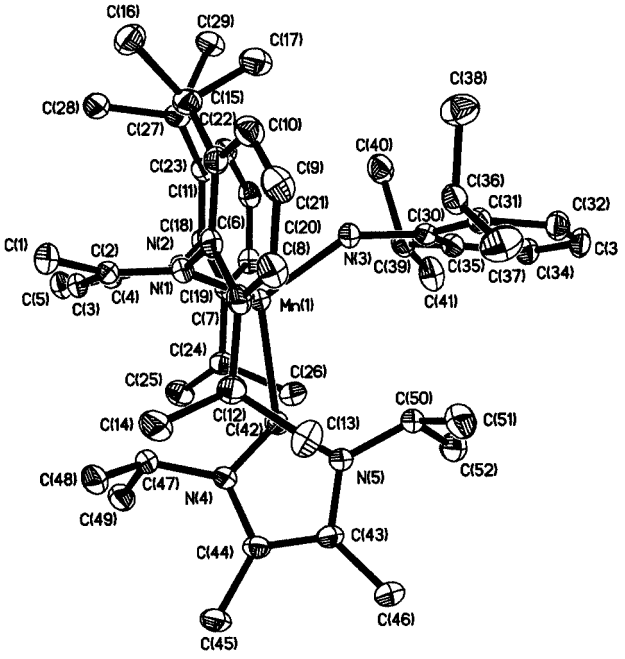


Figure 3. Molecular structure of **6** (30% probability thermal ellipsoids); hydrogen atoms are omitted for clarity

The terminal Mn(1)−I(1) distance [2.6272(8) Å] in **3** is similar to the reported values for the terminal Mn−I bond such as those in [MnI(sima)$_2$] [2.6233(6) Å] [sima = N(SiMe$_3$)C(Ph)N(SiMe$_3$)][19] and [MnI$_2$(PEt$_3$)$_2$] [av. 2.666(2) Å],[20] which is significantly shorter than the bridging Mn−I bond length in **4** [2.7688(7) and 2.7484(8) Å] and [LMn(μ-I)$_2$Li(OEt$_2$)$_2$] [2.716(9) and 2.733(9) Å].[14] The two manganese atoms are bridged by two iodine atoms in **4** and the distance between two manganese atoms is 3.615 Å, which is out of the range of a Mn−Mn bond. The Mn$_2$I$_2$

four-membered ring is exactly planar, bisecting and perpendicular to the two chelating ligands around them.

[LMnNHAr{C[N(*i*Pr)CMe]$_2$}] (**6**) is, to the best of our knowledge, the first structurally characterized manganese N-heterocyclic carbene complex. The Mn−C(carbene) distance [2.270(2) Å] is in the normal range of those in the manganates [Li(TMEDA)]$_2$[MnR$_4$] [2.22(6)−2.28(1) Å] (R = Me, Et, Bu or CH_2SiMe_3, TMEDA = tetramethylethylenediamine).[21] However, it is significantly longer than the Mn−C (carbene) distance in extensively studied manganese carbonyl carbene complexes [CpMn(CO)$_2$CXY] [X = Y = Me, 1.872(10) Å;[22] X = Y = Ph, 1.885(2) Å;[23] X = F, Y = Ph, 1.830(5) Å;[24] X = OEt, Y = Ph, 1.865(14) Å[25]]. This could result from two reasons: one is the steric repulsion between the bulky substituents; the other is the very weak Mn→C back bonding in **6** due to the relatively high energy of the formal empty p(π) orbital of the N-heterocyclic carbene carbon, which is increased by the N→C bond.[9a,26] In this respect N-heterocyclic carbenes are different from the usual carbenes, which have rather strong M→C(carbene) back bonding.[25,27] The manganese atom in **6** is out of the carbene plane (0.41 Å) and the dihedral angle between the carbene plane and the chelating ligand plane is 108.8°. The Mn(1)−N(3) bond length in **6** is 2.055(2) Å, which is close to that reported in Mn^{II} amide.[28]

Conclusion

As an extension of our previous work, manganese iodides bearing β-diketiminate ligand free of lithium salt, and their derivatives, were successfully synthesized and characterized. Compounds **5** and **6** are the first examples of divalent manganese N-heterocyclic carbene adducts and the first manganese non-carbonyl carbene complexes. The structure of **6** shows that the Mn−C (carbene) bond length in **6** is significantly longer than that of a "real" manganese carbene bond and π-backbonding is considered to be negligible in this system.

Experimental Section

General: All reactions were performed using standard Schlenk and dry box techniques. Solvents were appropriately dried and distilled under dinitrogen prior to use. Elemental analyses were performed by the Analytisches Labor des Instituts für Anorganische Chemie der Universität Göttingen. Mass spectra were obtained on a Finnigan Mat 8230. IR spectra were recorded on a Bio-Rad Digilab FTS-7 spectrometer as Nujol mulls between KBr plates. HL (**1**) [L = $HC(CMeNAr)_2$, Ar = 2,6-*i*$Pr_2C_6H_3$][29] and $C[N(iPr)CMe]_2$[30] were prepared by literature procedures.

KL (2): A suspension of KH (0.18 g, 4.5 mmol) and **1** (1.67 g, 4 mmol) in diethyl ether (50 mL) was stirred at room temperature for 3 days. After filtration the light yellow filtrate was concentrated to ca. 10 mL and kept at −26 °C for 24 h to afford crystalline solid. Yield: 1.59 g (87%). The ^1H NMR spectrum and elemental analyses are identical with those of the literature.[15]

[LMnI(THF)] (3): A solution of **2** (0.91 g, 2 mmol) in THF (10 mL) was added to a suspension of MnI_2 (0.62 g, 2 mmol) in THF (35 mL) at −78 °C. The mixture was allowed to warm to room temperature and stirred for 14 h. The precipitate was removed by filtration. The yellow filtrate was concentrated to ca. 5 mL and kept at −26 °C for 24 h to give yellow crystals. Yield: 1.17 g (87%). M.p. 379−381 °C. $C_{33}H_{49}IMnN_2O$ (670.84): calcd. C 59.03, H 7.30, N 4.17; found C 58.95, H 7.24, N 4.16. EI-MS: *m*/*z* (%) = 599 (100) $[LMnI]^+$. IR (KBr, Nujol mull): $\tilde{\nu}$ = 1624 cm^{-1} (w), 1552 (w), 1520.62 (m), 1314 (m), 1262 (m), 1174 (w), 1100 (w), 1024 (m), 935 (w), 870 (w), 852 (w), 794 (m), 757 (w), 721 (w), 600 (vw), 524 (w), 468 (vw).

[$(LMn)_2(\mu\text{-}I)_2$] (4): A solution of **3** (1.34 g, 2 mmol) in toluene (40 mL) was refluxed for 0.5 h. All volatiles were removed in vacuo and bright yellow micro crystals were obtained. Yield: 1.15 g (96%). M.p. 271−273 °C (dec). $C_{58}H_{82}I_2Mn_2N_4$ (1197.68): calcd. C 58.11, H 6.84, N 4.67; found C 58.34, H 6.92, N 4.85. EI-MS: *m*/*z* (%) = 599 (100) $[LMnI]^+$. IR (KBr, Nujol mull): $\tilde{\nu}$ = 1657 cm^{-1} (w), 1625 (w), 1552 (w), 1262 (m), 1097 (m), 1023 (m), 875 (w), 800 (m), 722 (w), 659 (vw), 536 (w), 468 (w).

[LMnI{C[N(*i*Pr)CMe]$_2$}] (5): A solution of $C[N(iPr)CMe]_2$ (0.18 g, 1 mmol) in THF (10 mL) was added to a THF (20 mL) solution of **3** (0.67 g, 1 mmol) at room temperature. The resulting mixture was stirred for 1 h. After removal of all volatiles in vacuo, a yellow solid was obtained. Yield: 0.76 g (98%). M.p. 271 °C (dec). $C_{40}H_{61}IMnN_4$ (778.8): calcd. C 61.63, H 7.83, N 7.19; found C 61.78, H 8.02, N 7.20. EI-MS: *m*/*z* (%) = 599 (100) $[LMnI]^+$. IR (KBr, Nujol mull): $\tilde{\nu}$ = 1625 cm^{-1} (m), 1552 (s), 1505 (m), 1318 (m), 1261 (s), 1232 (w), 1218 (vw), 1190 (vw), 1171 (m), 1105 (m), 1071 (vw), 1020 (m), 936 (w), 929 (w), 793 (s), 763 (m), 758 (m), 722 (m).

[LMnNHAr{C[N(*i*Pr)CMe]$_2$}] (6). Method a: A solution of **5** (0.78 g, 1 mmol) in THF (20 mL) was added to a suspension of sodium/potassium alloy (Na, 0.01 g, 0.5 mmol; K 0.04 g, 1 mmol) in THF (10 mL). The mixture was stirred for 6 days at room temperature. All volatiles were removed in vacuo and the residue was extracted with *n*-hexane (10 mL). Yellow crystals were obtained after cooling for one week at 4 °C. The crystals were collected by filtration and the mother liquor was concentrated to ca. 4 mL and kept at 4 °C for 4 days to give yellow crystals. Total yield: 0.19 g (23%). M.p. 170−172 °C. $C_{52}H_{79}MnN_5$ (829.14): calcd. C 75.26, H 9.53, N 8.44; found C 74.84, H 9.92, N 8.85. EI-MS: *m*/*z* (%) = 472 (100) $[LMn]^+$, 648 (52) $[LMnNHAr]^+$. IR (KBr, Nujol mull): $\tilde{\nu}$ = 3173 cm^{-1} (vw), 1633 (w), 1588 (w), 1543 (w), 1512 (m), 1420 (s), 1406 (m), 1316 (m), 1261 (m), 1169 (m), 1102 (w), 1019 (w), 929 (w), 886 (vw), 841 (w), 794 (m), 758 (w), 737 (m), 722 (m), 600 (vw), 565 (vw), 543(vw).

Method b: A THF (10 mL) solution of LiNHAr (0.18 g, 1 mmol) was added to a THF (20 mL) solution of **5** (0.78 g, 1 mmol) at −78 °C. The mixture was allowed to warm to room temperature and stirred for 14 h. After removal of all volatiles in vacuo, the residue was extracted with diethyl ether (10 mL). After filtration, the yellow filtrate was concentrated to ca. 5 mL and stored at −26 °C for 3 days to give yellow crystals. Yield: 0.63 g (76%). The spectroscopic characterization of the compound is identical to that of the compound prepared by method a.

X-ray Crystallography: Crystallographic data for **3** and **4** were collected on a Stoe−Siemens−Huber four-circle diffractometer coupled to a Siemens CCD area detector and for **6** on a Stoe IPDS II-array detector system. In both cases graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used. All structures were solved by direct methods (SHELXS-97)[31] and refined against F^2 using SHELXL-97.[32] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were included at geometrically calculated positions and refined using a riding model. Atomic coordinates, thermal parameters, bond lengths and angles. CCDC-207299 (**3**), -207298 (**4**), and -207297 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Dedicated to Professor G. Ourisson for his outstanding contributions to chemistry

Keywords: N ligands / Ammonolysis / Tin

Triaminostannanes of secondary amines have been known since 1977 and are widely used in tin organic chemistry. However, the corresponding nitrogen substituted stannanes of primary amines are not cited in the literature. Herein we report on the ammonolysis reaction of $[(Me_3Si)_3CSnCl_3]$ with $tBuNH_2$ in the presence of a strong base and the X-ray structural analysis of $[(Me_3Si)_3CSn(NHtBu)_3]$, the first monomeric triaminostannane containing protons at the nitrogen atoms.

Introduction

Hydrolysis as well as ammonolysis of mono-organotrihalides of the heavier group 14 elements has been a topic of interest for a long time. In the case of silicon there are many compounds of composition $RSi(OH)_3$ and $RSi(NH_2)_3$ (R = organic substituent) known, which can be used as precursors for generating molecular building blocks of heterosilicates or zeolite-like materials. These systems containing silicon, nitrogen and various metal atoms are often much more stable than the oxygen-based ceramics.[1]

Although hydroxy-substituted compounds of the congener tin are widely used in organic synthesis,[2] there is only one example known of a structurally characterized mono-organotin acid, the trimeric $[TsiSn(OH)O]_3$ [Tsi = $C(SiMe_3)_3$].[3] A monomeric trihydroxystannane has not been reported so far.

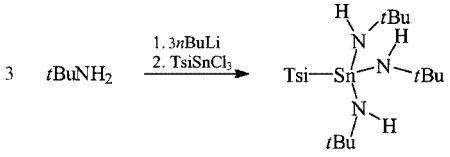
The corresponding isoelectronic nitrogen compounds of tin $[RSn(NH_2)(NH)]_3$ and $RSn(NH_2)_3$ are not reported in the literature, whereas tin compounds of composition $RSn(NR'_2)_3$ have been known since 1977 and are widely used as precursors in organometallic reactions.[4] Moreover, tin compounds of primary amines such as $RSn(NHR')_3$ are also unknown.

Finally a computer-based literature search showed that there are no known tin-nitrogen compounds with four-coordinate tin atoms, containing substituted NH groups. This fact indicates the instability of those compounds against condensation reactions.

The successful recently published hydrolysis reaction of $TsiSnCl_3$, which yields the trimeric mono-organotin acid chloride $[TsiSn(Cl)O]_3$,[3] showed that the so-called trisyl ligand[5] is able to stabilise unusual tin organic compounds.

Results and Discussion

Previously we tried ammonolysis reactions under mild conditions with liquid ammonia, but we were not able to isolate any products except the starting material $TsiSnCl_3$. However, the reaction of $TsiSnCl_3$ with an excess of $tBuNH_2$ in toluene containing three equivalents of nBuLi yields the first monomeric, triaminostannane $[TsiSn(NHtBu)_3]$ (**1**), with four-coordinate tin bound to primary amine groups. Compound **1** is stable against condensation reactions (Scheme 1).



Tsi = $C(SiMe_3)_3$ **1**

Scheme 1

We were able to confirm the tetrahedral coordination site of the tin atom in compound **1** by characteristic resonances in the ^{119}Sn NMR spectrum ($\delta = -94.7$ ppm). There are similar ^{119}Sn NMR resonances reported in the literature.[6] Crystallisation of the crude product from *n*-pentane resulted in single crystals of **1**, which could be characterized

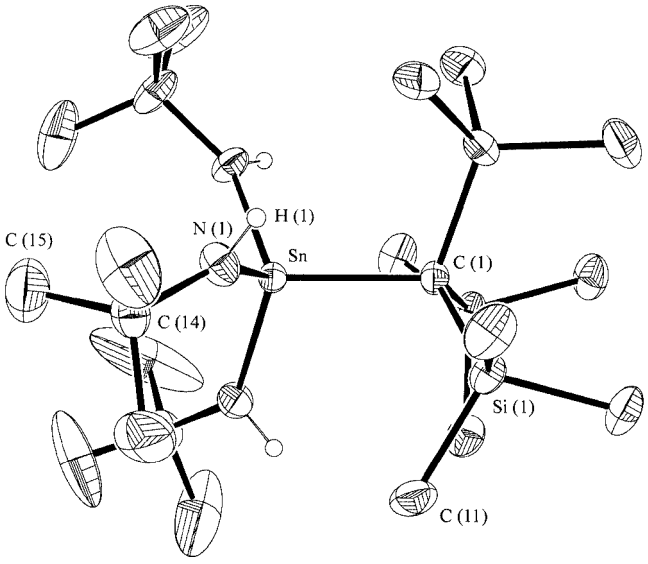

Figure 1. Molecular structure of **1** [ORTEP drawing[8] thermal ellipsoids (30% probability)]; the methyl groups are omitted for clarity; selected bond lengths [Å] and angles [°]: Sn(1)−N(1) 2.028(4), Sn(1)−C(1) 2.212(4), N(1)−C(14) 1.466(6), C(1)−Si(1) 1.895(5); N(1)−Sn(1)−C(1) 107.4(16), Sn(1)−C(1)−Si(1) 109.5(2), N(1)−Sn(1)−N(2) 110.2(17), C(1)− Si(1)−C(11) 113.4(2), Si(1)−C(1)−Si (2) 110.4(2), C(14)−N (1)−Sn (1) 135.0(3), C(15)−C (14)−N (1) 110.8(5)

for the first time by single-crystal X-ray structural analysis (Figure 1).[7]

Compound **1** exhibits a very high symmetrical arrangement and is built up by two staggered tetrahedral centers of carbon and tin. The angles between the C, N and Sn atoms range from 135.0 to 137.9° whereas the others are close to 108° (103.8−113.9°). This finding demonstrates distinctly the high symmetry of **1**. The tin-nitrogen bond lengths range from 2.017 to 2.028 Å and are similar to those in known tin-nitrogen systems of the type $[RSn(NR'R'')_3]$.[9] The Sn(1)−C(1) bond length amounts to 2.212 Å and could be compared with that in $[TsiSn(OH)O]_3$.[3] The N−C bond lengths range from 1.466 to 1.510 Å. They are similar to those in *tert*-butyl-substituted organometallic nitrogen compounds.[10]

Interactions between two molecules of **1** through hydrogen bonding were not observed. This crystallographic observation could be additionally supported by the determination of the molecular mass of **1** in liquid toluene, which is close to the calculated value for **1**. The mass spectrum shows a characteristic signal at $m/z = 567$. Furthermore the ^{1}H NMR investigation exhibits one resonance for the three nitrogen-bonded, chemically identical *tert*-butyl groups. The NH resonance was assigned as a singlet at $\delta = 0.5$ ppm, whereas in the IR spectrum the NH stretching frequency was observed at 3371 cm^{-1}.

Conclusion

The herein presented synthesis and single-crystal X-ray analysis of the monomeric, four-coordinate triaminostannane $[TsiSn(NHtBu)_3]$ (**1**) is the first example of a tetrahedral tin-nitrogen system with N-bonded protons. Now we are looking forward to a multitude of new reactions with this compound. Presently we are studying the chemistry of **1** using this compound as a precursor for preparing zeolite-like materials, but based on nitrogen and tin instead of silicon and oxygen.

Experimental Section

General Remarks: Solvents were dried and distilled under nitrogen prior to use. All reactions were carried out under dry nitrogen, using standard Schlenk techniques. NMR spectra were recorded using a Bruker Avance 200, Bruker MSL 400 or a Bruker Avance 500 spectrometer and referenced to the resonances of the residual protons in deuterated benzene. ^{1}H NMR: internal standard C_6D_6, external standard TMS. ^{13}C NMR: internal standard C_6D_6, external standard TMS. ^{29}Si NMR: internal standard C_6D_6, external standard TMS. ^{119}Sn NMR: internal standard C_6D_6, external standard $SnMe_4$. Infrared spectra were recorded on a BIO-RAD Digilab FTS 7 spectrometer as solution in *n*-pentane. The starting material $TsiSnCl_3$ was prepared as described in the literature.[3]

[Tris(trimethylsilyl)methyl]tri(*tert*-butylamino)stannane (1): At 0 °C tBuNH$_2$ (2.26 mL, 21.5 mmol) was dissolved in toluene (30 mL) and a solution of *n*BuLi in hexane (2 M, 2.60 mL, 6.45 mmol) was slowly added. The mixture was stirred for 0.5 h at this temperature to complete the lithiation reaction. A solution of $TsiSnCl_3$ (0.98 g, 2.15 mmol) in toluene (30 mL) was added to the resulting fine suspension of LiNH*t*Bu. After the addition was complete, the reaction mixture was allowed to warm to room temperature and was stirred for an additional 48 h. While warming the solution, the mixture was intensively yellow colored and a gel-like consistence resulted. After the reaction was completed a colorless liquid was obtained. Finally all volatile components were removed in vacuo and the residue was dissolved in *n*-pentane. The insoluble components were removed by filtration and the resulting colorless solution was concentrated under reduced pressure. The concentrated solution was stored for 2 days at −26 °C and **1** crystallised as a colorless solid (1.16 g, 2.04 mmol, 95%). M.p. 132−136 °C. ^{1}H NMR (C_6D_6, 300 K, 500 MHz): δ = 0.42 [s, 27 H, $(H_3C)_3Si$], 0.50 (br., 3 H, N*H*), 1.42 [s, 27 H, $(H_3C)C$]. ^{13}C NMR (C_6D_6, 300 K, 125 MHz): δ = 6.27 [s, $(H_3C)_3Si$], 11.34 [s, $\{(H_3C)_3Si\}_3C$], 35.68 [s, $(H_3C)_3C$], 53.94 [s, $(H_3C)_3C$]. ^{29}Si NMR (C_6D_6, 300 K, 99 MHz): δ = −1.66 [s, $(H_3C)_3Si$]. ^{119}Sn NMR (C_6D_6, 300 K, 186 MHz): δ = −94.7. $C_{22}H_{57}N_3Si_3Sn$ (566.65): calcd. C 46.6, H 10.1, N 7.4; found C 46.8, H 10.0, N 7.6. IR (*n*-pentane) $\tilde{\nu}$ = 468 w cm^{-1}, 615 w, 660 w, 676 w, 718 w, 800 w, 852 vs, 970 s, 1024 w, 1096 w, 1190 s, 1257 s, 1358 vs, 3371 w. MS (70 eV): *m*/*z* (%) = 567 (3) [M$^+$], 494 (10) [M$^+$ − TMS], 479 (8) [M$^+$ − TMS − Me], 422 (100) [M$^+$ − TMS − Me − *t*Bu].

Crystal Data for 1: A colorless crystal of compound **1** was mounted onto a STOE Siemens Huber Diffractometer System equipped with a four-circle goniometer and a graphite monochromator. Data collection was performed at 200 K using Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods and refined using full-matrix least-squares on F^2 with SHELX-97.[11a] The hydrogen atoms were included in calculated positions and treated as riding atoms using the SHELXL-97 default parameters.[11b] Monomeric, space group $P2_1/n$, a = 9.6292(15), b = 32.260(3), c = 11.006(3) Å, α = 90, β = 113, γ = 90°, V =

High Molecular Weight Phosphazene Copolymers Having Chemical Functions Inside Chiral Pockets Formed by (*R*)-(1,1′-Binaphthyl-2,2′-dioxy)phosphazene Units

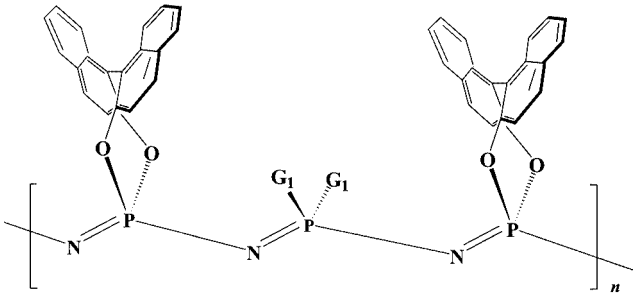
Gabino A. Carriedo,*[a] Francisco J. García Alonso,[a] and Alejandro Presa-Soto[a]

Keywords: Polymers / Polyphosphazenes / Ligand effects / Chirality

The polyphosphazene $\{[NPCl_2]_x[NP(O_2C_{20}H_{12})]_{1-x}\}_n$ ($O_2C_{20}H_{12}$ = 1,1′-binaphthyl-2,2′-dioxy) reacted in refluxing THF in the presence of Cs_2CO_3 with HOC_5H_4N or *para*-substituted phenols HOC_6H_4R to give the random copolymers $\{[NP(OC_5H_4N)_2]_x[NP(O_2C_{20}H_{12})]_{1-x}\}_n$ (**1**) or $\{[NP(OC_6H_4R)_2]_x[NP(O_2C_{20}H_{12})]_{1-x}\}_n$ [R = CN (**2**), COMe (**3**), CO_2nPr (**4**), PPh_2 (**5**)] and with H_2NnBu to give $\{[NP(NHnBu)_2]_x[NP(O_2C_{20}H_{12})]_{1-x}\}_n$ (**6**). The reaction of the polymer $\{[NPCl_2]_x[NP(O_2C_{20}H_{10}Br_2)]_{1-x}\}_n$ ($O_2C_{20}H_{10}Br_2$ = 6,6′-dibromo-1,1′-binaphthyl-2,2′-dioxy) with $HOC_6H_4PPh_2$ and Cs_2CO_3 gave $\{[NP(OC_6H_4PPh_2)_2]_x[NP(O_2C_{20}H_{10}Br_2)]_{1-x}\}_n$ (**7**). Those polymers have a very high glass-transition temperature (*Tg*) and a chemical function or ligand that is in the interior of a chiral pocket.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Due to their growing interest in materials science, the chemistry of linear polyphosphazenes $(N{=}PX_2)_n$ containing halogen, pseudohalogen, alkoxy, aryloxy, amino, alkyl or aryl group have been very extensively reviewed.[1] Recently, a new type of phosphazene polymer was discovered containing cyclic repeating units with biphenyldioxy[2] $[NP(O_2C_{12}H_8)]_n$ or binaphthyldioxy[3] $[NP(O_2C_{20}H_{12})]_n$ groups. The latter could be obtained as isotactic chiral (*R*) or (*S*) polymers, or as (*R*/*S*) copolymers with different proportions of both chiral units.[3] The structural data of those polymers revealed that both in solution[4,5] and in the solid state[6] their chains are helicoidal and therefore they are a new type of interesting synthetic helical polymers.[7] These results led us to attempt the preparation of well-defined copolymeric phosphazenes of the general type $\{[NPX_2]_x[NP(O_2C_{20}H_{12})]_{1-x}\}_n$, where the X group supports a chemical functionality, useful as precursors for other derivatives or as ligands for transition metal complexes. As shown in Scheme 1, these polymers contain their chemical functions within a chiral environment that could be considered as a chiral pocket,[8] and therefore they may be potentially useful as supported catalysts (soluble or insoluble) for enantiomeric synthesis. From our previous knowledge[2,3] we anticipated that these polymers would have very high transition temperatures, i.e. they are stereochemically very rigid and the efficiency to induce chirality of the pocket could be modified by using derivatized binaphthols. Herein we describe the synthesis and full characterization of several chiral copolymers having (binaphthyldioxy)- or (dibromobinaphthyldioxy)phosphazene units and pyridine, nitrile, ketone, ester, phosphane or amine functions.



Scheme 1

Results and Discussion

According to the partial substitution method previously described by us for functionalized phosphazene copolymers with biphenyldioxy[2,3] or binaphthyldioxy[4] units, the poly(dichlorophosphazene) $[NPCl_2]_n$ was treated first with *x* equiv. of (*R*)-(+)-1,1′-binaphthyl-2,2′-diol in the presence of Cs_2CO_3 [9] to give a THF solution of the intermediate $\{[NPCl_2]_x[NP(OC_{20}H_{12})]_{1-x}\}_n$ (see Scheme 2). The addition of 4-hydroxypiridine, a 4-substituted phenol HOC_6H_4R, or *n*-butylamine H_2NnBu, led to the new functionalized phosphazene random copolymers $\{[NP(OC_5H_4N)_2]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}\}_n$ (**1**), $\{[NP(OC_6H_4R)_2]_x[NP(O_2C_{20}H_{12})]_{1-x}\}_n$ [R = CN, *x* = 0.15 (**2**); R = COMe, *x* = 0.2 (**3**); R = CO_2nPr, *x* = 0.2 (**4**);

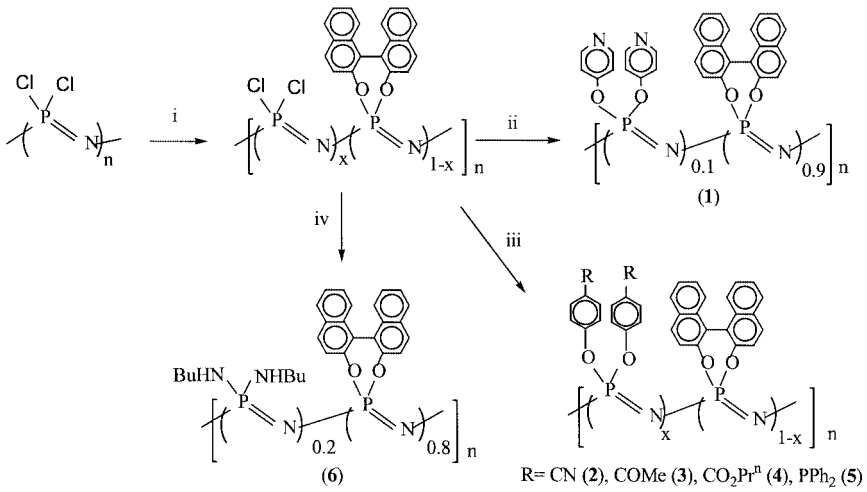

Scheme 2. i) (*R*)-(+)-$C_{20}H_{12}(OH)_2$, Cs_2CO_3; ii) HOC_5H_4N, Cs_2CO_3; iii) HOC_6H_4R, Cs_2CO_3; iv) H_2NnBu; for conditions see text

R = PPh_2, x = 0.1 (**5**)] and {$[NP(NHnBu)_2]_{0.2}[NP(O_2C_{20}H_{12})]_{0.8}\}_n$ (**6**) (see Scheme 2, Table 1).

The actual x values observed in the isolated materials (see below) were close to the 0.2:0.8 ratio initially intended. The deviations in the cases of **1**, **2** and **5** are within the limits normally encountered in the synthesis of this kind of copolymer.[4]

The average *Mw* values, as determined by GPC, were of the order of 10^6. That of the amine derivative **6** was lower, however, in agreement with previous observations,[10] and this is due to some degradation of the chains during the aminolysis step. On the other hand, polymer **7** (Scheme 3) exhibits a higher *Mw*, namely 1.7×10^6. In all cases the specific rotation of the isolated polymers revealed their optical activity (Table 2).

All the spectroscopic data of the new polymers (Exp. Sect., Tables 2 and 3) are in agreement with their formulation and confirmed their expected stereochemical rigidity. The IR spectra (in KBr pellets) show, along with the expected bands of the $[NP(O_2C_{20}H_{12})]$ units, the specific absorptions corresponding to the other $[NP(OC_5H_4N)_2]$, $[NP(OC_6H_4R)_2]$ or $[NP(NHnBu)_2]$ repeating units (see Exp. Sect.). No significant changes on either group of frequencies were observed when compared with those of the $[NP(O_2C_{20}H_{12})]_n$ homopolymer (given in the Exp. Sect.) or other copolymers containing similar pyridinoxy[11] or (diphenylphosphanyl)phenoxy groups.[12] However, a rather conspicuous difference was observed between the ν(NH) stretching frequency in **6** (3396 cm^{-1}), and that normally found in poly[(dibutylamino)phosphazenes] (3330 cm^{-1}).[13] This might be due to the effects of the environment on the NPNHBu groups provided by the two binaphthoxyphosphazene units surrounding them, but it could also indicate that, being more isolated within the chains, their participation in H-bonding interactions is precluded. In fact, the ν(NH) band in **6** is rather sharp in contrast with the broad one observed in the poly[(dibutylamino)phosphazenes] previously reported by us.[10]

The ^1H, ^{13}C and ^{31}P NMR spectra are broad, as expected for these types of polymers, but they sharpen significantly upon heating above 110 °C in [D_6]DMSO. The integration of the ^1H and ^{31}P NMR spectra at high temperature confirmed the chemical composition of the copolymer and allowed the quantitative determination of the relative amounts of the two repeating units. In those cases where x could be obtained form both the ^1H and the ^{31}P NMR spectra (i.e. polymers **3** and **4**), the results were practically identical. Moreover, in the case of the high-temperature ^{31}P NMR spectrum (Figure 1) the distribution of the chemical shifts of the phosphorus atom bearing the $[NP(O_2C_{20}H_{12})]$ units along the chain ($\delta \approx -5$ ppm) was clearly evidenced by two distinct main signals, one sharper (units mainly surrounded by the same units) and another much broader (units nearer the other repeating units).

Similarly, the high-temperature ^1H and ^{13}C NMR spectra show the main signals for the statistical distribution of the (binaphthoxy)phosphazene units and, among them, the much weaker signals corresponding to the other aryl groups present in the chain (see Exp. Sect.). Only in the

[a] The signals A correspond to $NP(OAr)_2$ groups, where Ar = C_5H_4N or C_6H_5-R. The signals B are due to $NP(O_2C_{20}H_{12})$ units surrounded by $NP(OAr)_2$ groups. The peaks C correspond to $NP(O_2C_{20}H_{12})$ units which are located between other $NP(O_2C_{20}H_{12})$ units. [b] At δ = −6.2 $[OC_6H_4P(C_6H_5)_2]$, 28.3 $[OC_6H_4P\{O\}(C_6H_5)_2]$ ppm. [c] At δ = −4.4 $[OC_6H_4P(C_6H_5)_2]$, 25.1 $[OC_6H_4P\{O\}(C_6H_5)_2]$ ppm. [d] Polymer **6** exhibits a very broad signal with two maxima at δ = −2.7 and −1.6 ppm in its $CDCl_3$ spectrum, measured at room temp.; in $[D_6]$DMSO at 120 °C its spectrum shows a very broad peak centered at δ = −3.4 ppm. [e] At δ = −6.3 $[OC_6H_4P(C_6H_5)_2]$, 28.0 $[OC_6H_4P\{O\}(C_6H_5)_2]$ ppm. [f] At δ = −4.4 $[OC_6H_4P(C_6H_5)_2]$, 25 $[OC_6H_4P\{O\}(C_6H_5)_2]$ ppm.

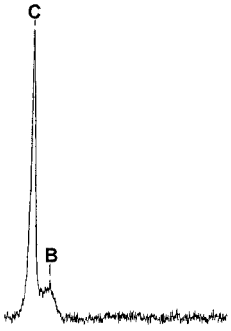

Figure 1. $^{31}P\{^1H\}$ NMR spectrum of $\{[NP(O_2C_{20}H_{12})]_{0.85}[NP(OC_6H_4CN)_2]_{0.15}\}_n$ (**2**) in $[D_6]$DMSO at 110 °C; δ_A = −26.6, −26.0, −25.4 ppm; δ_B = −5.4 ppm; δ_C = −4.0 ppm (see Table 3)

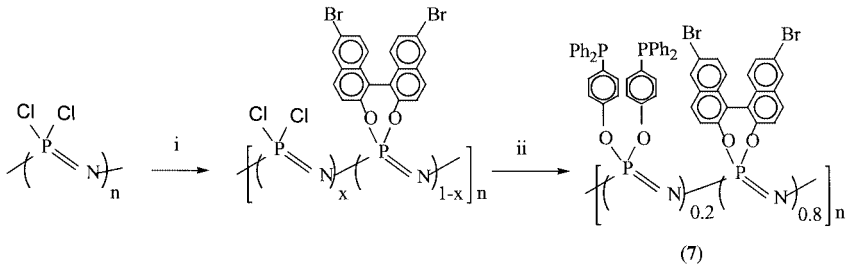
case of **6** are significant differences found between the signals corresponding to the butyl protons of NHBu (δ = 2.2, 0.6 and 0.4 ppm) and those observed in other poly-[(dibutylamino)phosphazene] polymers (δ = 3.0, 1.5 and 1.05 ppm).[10] However, the shift of the amine proton PNHR in **6** (δ = 2.6 ppm), which was unambiguously identified by its disappearance in the presence of D_2O, is very similar to that of the other aminophosphazenes (e.g., δ = 2.67 ppm in ref.[10]).

The *n*-butyl group was also easily detected in the ^{13}C NMR spectrum by the signals at δ = 15, 21, 35 and 42 ppm, of decreasing intensity, that are very close to those published for other polymers containing (butylamino)phosphazene units.[14]

The ^1H and ^{13}C NMR spectra also showed that all the isolated materials were perfectly free of any solvents, a fact that was confirmed by the TGA analysis (see below). This is important since poly(binaphthoxyphosphazene) polymers tend to retain solvent molecules even after having been dried in vacuo at 70 °C.[3,4] The only impurity present was a very small amount of the cyclic trimer $[N_3P_3(O_2C_{20}H_{12})_3]$ that in no case was higher than one molecule of the trimer for every 100 polymeric units [to be exact 1 (**1**), 0.5 (**2**), 0 (**3**), 1 (**4**), 1 (**5**), 0 (**6**), and 0.1 (**7**) molecules of the trimer].

In the case of the phosphane derivative **5**, the ^{31}P NMR spectrum (Table 3) revealed that 20% of the PPh_2 groups had been oxidized to $P(O)Ph_2$. Therefore, the exact chemical formula of **5** would be $\{[NP(OC_6H_4PPh_2)_{1.6}$-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3

$(OC_6H_4POPh_2)_{0.4}]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}\}_n$. The formation of oxidized phosphane sites also noted in other similar phosphazene polymers with PPh_2 ligands could not be prevented even under careful workup.[15]

All the polymers exhibit an increase in C_p corresponding to the glass transition at rather high temperatures ranging from 227 to 296 °C (Table 2) in their DSC thermograms. In fact, the *Tg* of **1** (296 °C) is the highest glass transition recorded for a phosphazene high molecular weight polymer [up to now the highest reported *Tg* is 220 °C for a poly(aminophosphazene)].[16] This, together with the broad NMR spectra at room temperature and the observed sharpness upon heating evidenced the high stereochemical rigidity of the polymeric chains, which, in principle, is helpful in their potential use as ligands to support catalysts for asymmetric reactions.

In order to synthesize similar polymers with a chiral pocket with different electronic and steric characteristics, we extended the reactions of Scheme 2 to the preparation of the polymer **7** (see Scheme 3), which is a brominated derivative of **5**. The data of the isolated product are in agreement with the formula given in the Scheme 3. In spite of the presence of the Br atoms in the binaphthyl units, the *Tg* of **7** (256 °C) is not higher than that of **5**. However, this is due to the lower content of binaphthyl groups — 0.8 in **7** and 0.9 in **5**. The oxidized phosphanes make up 12.5% of the PPh_2 groups, and therefore the exact formula is $\{[NP(OC_6H_4PPh_2)_{1.75}(OC_6H_4POPh_2)_{0.25}]_{0.2}[NP(O_2C_{20}H_{10}Br_2)]_{0.8}\}_n$.

The TGA thermograms show that the copolymers **1**−**3**, **5** and **7** have a high thermal stability, losing weight around 500 °C, near to the decomposition temperature of the poly(binaphthoxy) homopolymer $[NP(O_2C_{20}H_{12})]_n$ (540 °C).[3] The polymer **4** has two further losses at 380 and 440 °C. On the other hand, polymer **6** shows a stepped and continuous loss of weight starting at ca. 150 °C (see Exp. Sect.), which is typical of the poly(phosphazene)s containing amino side groups.[17] The final residues at 800 °C, of the order of 50−65%, are comparable or higher than the 50% residue observed for $[NP(O_2C_{20}H_{12})]_n$ under the same experimental conditions.[3]

Experimental Section

General: All the reactions were carried out under nitrogen. Cs_2CO_3 (Aldrich) was dried at 140 °C prior to use. THF (VWR International) was treated with KOH and distilled twice from Na in the presence of benzophenone. Hexane (VWR intern), (*R*)-(+)-1,1′-bis(2-naphthol) [(*R*)-(+)-$C_{20}H_{10}(OH)_2$], HOC_5H_4N, and the phenols HOC_6H_4R (R = CN, COMe and CO_2nPr) were used as purchased (Aldrich); the amine H_2NnBu (Aldrich) was distilled from CaH_2. The starting polymer $[NPCl_2]_n$ was prepared as described by Magill et al.[18] The phosphane $HOC_6H_4PPh_2$ [12] and (*R*)-(+)-6,6′-dibromo-1,1′-binaphthalene-2,2′-diol [(*R*)-(+)-$C_{20}H_{10}Br_2(OH)_2$][19] were prepared as described previously. The IR spectra were recorded with a Perkin−Elmer FT Paragon 1000 spectrometer. NMR spectra were recorded with Bruker AC-200, AV-300 and DPX 300 instruments, using $CDCl_3$ as solvent unless otherwise stated. Chemical shifts (^1H and $^{13}C\{^1H\}$) are given in δ relative to TMS. $^{31}P\{^1H\}$ NMR values are given in δ relative to external 85% aqueous H_3PO_4. C, H, N analyses were performed with a Perkin−Elmer 2400 microanalyzer. Chlorine analyses were performed by Galbraith Laboratories. GPC were measured with a Perkin−Elmer equipment with a Model LC 250 pump, a Model LC 290 UV, and a Model LC 30 refractive index detector. The samples were eluted with a 0.1% by weight solution of tetra-*n*-butylammonium bromide in THF through Perkin−Elmer PLGel (Guard, 10^5, 10^4 and 10^3 Å) at 30 °C. Approximate molecular weight calibrations were obtained using narrow molecular weight distribution polystyrene standards. *Tg* values were measured with a Mettler 3000 differential scanning calorimeter DSC. Thermal gravimetric analyses were performed with a Mettler TA 4000 instrument. The polymer samples were heated at a rate of 10 °C/min from ambient temperature to 800 °C under a constant flow of nitrogen. The specific rotation [α] was measured with a Perkin−Elmer 343 or 241 in $CHCl_3$ at c = 1 at 20 °C using the Na-D or the 578-nm Hg lines, respectively. The colour, analytical, *Mw* (GPC), glass transition and specific rotation data for the polymers are given in Table 2. The IR spectra (KBr pellet) of all the copolymers **1**−**6** showed the expected bands of the $[NP(O_2C_{20}H_{12})]$ units. These were identical to those found in the homopolymer $[NP(O_2C_{20}H_{12})]_n$: $\tilde{\nu}$ = 3054 cm^{-1} [w, ν_{CH} aromatic), 1622 w, 1590 m,1507 w, 1465 sh, 1433 sh,1403 w, 1362 m (aryl rings), 1318 (s, ν_{C-OP}), 1267 sh, 1220 vs (ν_{NP}), 1190 sh, 1155 w, 1072 (m, ν_{P-OC}), 964, 946 sh, (s, δ_{POC}), 896 w, 868 m, 812 (s, δ_{PNP}), 772 w, 746 m, 714 m, 695 w, 655 w, 571 (s, δ_{NPO}), 531 w, 487 w. The specific absorptions corresponding to the other repeating units present in the copolymers are given below. The ^{31}P NMR spectroscopic data are given in Table 3. The ^1H and ^{13}C NMR and TGA data for each compound are given below.

Preparation of $\{[NP(OC_5H_4N)_2]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}\}_n$ (1): (*R*)-(+)-$(HO)_2(C_{20}H_{12})$ (8.16 g, 28.50 mmol) and Cs_2CO_3 (46.4 g, 142.5 mmol) were added to a solution of $[NPCl_2]_n$ (4.13 g, 35.65 mmol) in THF (440 mL) and the mixture was refluxed with vigorous mechanical stirring for 35 h. Then, the pyridone HOC_5H_4N (2.03 g, 21.34 mmol) was added and the refluxing was maintained for another 48 h. The resulting mixture was poured into water (1.5 L) to give a solid residue that was extracted at room

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

temperature in THF (500 mL) for 4 h. The mixture was filtered and concentrated into a viscous liquid that was poured slowly into water (1.5 L). The product was reprecipitated in the same way from THF/IPA (isopropyl alcohol), and THF/hexane. Finally, the product was dried under vacuum at 70 °C for 7 d to give the polymer **1** as a white solid. Yield [5.41 g (47%)]. IR (KBr): $\tilde{\nu}$ = 1580 w cm^{-1} (ν_{CC}-ν_{CN}, OC_5H_4N) (seen as a shoulder of the band at 1591 cm^{-1} of the binaphthoxy group). ^{1}H NMR ($CDCl_3$, 25 °C): δ = 5.5−8.0 (very br. m, aromatic rings) ppm. ^{1}H NMR ([D$_6$]DMSO, 110 °C): δ = 6.7, 6.8, 7.1, 7.6 (br. m, $O_2C_{20}H_{12}$), 6.9, 7.9 (br. m, OC_5H_4N-4) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C): δ = 118 (C-3 of OC_5H_4N), 153 (C-2 of OC_5H_4N), 159 (NPO*C*, OC_5H_4N), 124, 128−131, 133−135 (br. peaks, naphthalene rings), 150 (NPO$C_{\text{naphthalene ring}}$) ppm. TGA: −48% (500 °C); residue at 800 °C (52%).

Preparation of {[NP(OC$_6$H$_4$R)$_2$]$_x$[NP(O$_2$C$_{20}$H$_{12}$)]$_{1-x}$}$_n$ [R = CN, *x* = 0.15 (2); R = COMe, *x* = 0.20 (3); R = CO$_2$*n*Pr, *x* = 0.20 (4); R = PPh$_2$, *x* = 0.10 (5)]: The following procedure for **2** is representative for all the polymers using the data given in Table 1. (*R*)-(+)-$(HO)_2(C_{20}H_{12})$ (2.96 g, 10.34 mmol) and Cs_2CO_3 (16.87 g, 51.78 mmol) were added to a solution of $[NPCl_2]_n$ (PDCP) (1.5 g, 12.94 mmol) in THF (200 mL), and the mixture was refluxed for 4 h (t_1) with vigorous mechanical stirring. After that, the phenol HOC_6H_4CN (0.92 g, 7.72 mmol) was added and the refluxing was continued for another 18 h (t_2). The resulting mixture was poured into water (1.5 L) and the precipitate was washed with water (3 × 0.5 L), IPA (2 × 0.2 L) and diethyl ether (2 × 0.2 L). This crude product was purified from THF/H_2O, THF/IPA, and THF/hexane as explained for **1**. Finally, the product was dried under vacuum at 70 °C for 1 d (DT) to give the polymer as a pale creamy solid. Yield [3.2 g 77 (%)].

{[NP(OC$_6$H$_4$CN)$_2$]$_{0.15}$[NP(O$_2$C$_{20}$H$_{12}$)]$_{0.85}$}$_n$ (2): IR (KBr): $\tilde{\nu}$ = 2227 w cm^{-1} (ν_{CN}). ^{1}H NMR ($CDCl_3$, 25 °C): δ = 6.0−8.0 (very br. m, aromatic rings) ppm. ^{1}H NMR ([D$_6$]DMSO, 110 °C): δ = 6.6, 6.8, 7.1, 7.6 (br. m, $O_2C_{20}H_{12}$), 7.2, 7.8 (br. m, OC_6H_4CN) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C): δ = 107, 119 (OC_6H_4CN), 154 (NPO*C*, OC_6H_4CN), 122, 125−130, 132−133 (br. peaks, aromatic C), 148 (NPO$C_{\text{naphthalene ring}}$) ppm. TGA: −45.5% (530 °C); residue at 800 °C 54.5%.

{[NP(OC$_6$H$_4$COMe)$_2$]$_{0.2}$[NP(O$_2$C$_{20}$H$_{12}$)]$_{0.8}$}$_n$ (3): IR (KBr): $\tilde{\nu}$ = 1683 m cm^{-1} (ν_{CO}), 1266 s, 1164 m. ^{1}H NMR ($CDCl_3$, 25 °C): δ = 1.9 (3 H, CO*CH*$_3$), 6.0−9.0 (very br. m, aromatic rings) ppm. ^{1}H NMR ([D$_6$]DMSO, 110 °C): δ = 2.1 (3 H, CO*CH*$_3$), 6.7, 6.8, 7.2, 7.6 (br. m, $O_2C_{20}H_{12}$) 7.4, 7.8 (br. m, $OC_6H_4COCH_3$) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 29 (CO*C*H$_3$), 157 (NOP*C*, OC_6H_4-$COCH_3$), 199 (*C*OMe), 125, 128−132, 133, 134, (br. peaks, aromatic rings), 150 (NPO$C_{\text{naphthalene ring}}$) ppm. TGA: −34.5% (485 °C); residue at 800 °C: 65.5%.

{[NP(OC$_6$H$_4$CO$_2$*n*Pr)$_2$]$_{0.2}$[NP(O$_2$C$_{20}$H$_{12}$)]$_{0.8}$}$_n$ (4): IR (KBr): $\tilde{\nu}$ = 2964 w cm^{-1}, 2877 w (ν_{CH} alkylic), 1717 (s, ν_{CO}), 1109 s. ^{1}H NMR ($CDCl_3$, 25 °C): δ = 0.8 (3 H, $OCH_2CH_2CH_3$), 1.5 (2 H, $OCH_2CH_2CH_3$), 4.0 (2 H, $OCH_2CH_2CH_3$), 6.0−8.0 (very br. m, aromatic rings) ppm. ^{1}H NMR ([D$_6$]DMSO, 110 °C): δ = 0.8 (3 H, $OCH_2CH_2CH_3$), 1.5 (2 H, $OCH_2CH_2CH_3$), 4.0 (2 H, $OCH_2CH_2CH_3$), 6.7, 6.8, 7.1, 7.5 (br. m, $O_2C_{20}H_{12}$), 7.3, 7.8 (br. m, OC_6H_4COO) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 11 ($OCH_2CH_2CH_3$), 23 ($OCH_2CH_2CH_3$), 67 ($OCH_2CH_2CH_3$), 121 [$OC_6H_4C(O)OPr$], 155 (NPO*C*, $OC_6H_4C(O)OPr$], 166 (*C*OOPr), 122, 125−130, 132, 133 (br. peaks, aromatic rings), 148 (NPO$C_{\text{naphthalene ring}}$) ppm. TGA: −13.5% (380 °C), −11.5% (440 °C), −32% (516 °C); residue at 800 °C: 43%.

{[NP(OC$_6$H$_4$PPh$_2$)$_2$]$_{0.1}$[NP(O$_2$C$_{20}$H$_{12}$)]$_{0.9}$}$_n$ (5): IR (KBr): $\tilde{\nu}$ = 1490 cm^{-1} sh, 1434 m, 694 m. ^{1}H NMR ($CDCl_3$, 25 °C): δ = 5.5−8.5 (very br. m, aromatic rings). ^{1}H NMR ([D$_6$]DMSO, 110 °C): δ = 6.4 (br. m, OC_6H_4P), 7.0 [br. m $P(C_6H_5)_2$], 6.6, 6.7, 7.0, 7.6 (br. m, $O_2C_{20}H_{12}$) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 128, 138 [$P(C_6H_5)_2$], 122, 127, 128, 131, 132, 134, (br. peaks, naphthalene and phosphane rings), 148 (NPO$C_{\text{naphthalene ring}}$) ppm. TGA: −42% (509 °C); residue at 800 °C: 58%.

Preparation of {[NP(NH*n*Bu)$_2$]$_{0.2}$[NP(O$_2$C$_{20}$H$_{12}$)]$_{0.8}$}$_n$ (6): (*R*)-(+)-$(HO)_2(C_{20}H_{12})$ (2.73 g, 9.54 mmol) and Cs_2CO_3 (29.24 g, 24.86 mmol) were added to a solution of $[NPCl_2]_n$ (1.38 g, 11.91 mmol) in THF (150 mL), and the mixture was refluxed with vigorous mechanical stirring for 21 h. After that, *n*-butylamine (H_2NnBu) (3.28 mL, 2.43 g, 33.22 mmol) was added at 0 °C and stirring was continued at room temp. for 54 h. The mixture was then poured into water (1.5 L) giving a white solid which was purified by re-precipitating it from THF/H_2O, THF/IPA, and THF/hexane. The resulting white polymer was dried under vacuum at 70 °C for 1 d and later at 90 °C for 2 d. Yield 3 g, 84%. IR (KBr): $\tilde{\nu}$ = 3396 w cm^{-1} (ν_{NH} amine), 2952 m, 2927 m, 2868w (ν_{CH} alkyl), 1508 m, 1094 w. ^{1}H NMR ([D$_8$]THF, 25 °C): δ = 0.36, 0.58 (br., $NHCH_2CH_2CH_2CH_3$), 2.2 (very br., $NHCH_2CH_2CH_2CH_3$), 2.6 (br., N*H*Bu), 7.3, 7.8 (very br. m, aromatic rings) ppm. ^{1}H NMR ([D$_6$]DMSO, 120 °C): δ = 0.4 (br., $NHCH_2CH_2CH_2CH_3$), 0.7 (br., $NHCH_2CH_2CH_2CH_3$), 2.3 (very br., $NHCH_2CH_2CH_2CH_3$), 2.9 (br., N*H*Bu), 7.2, 7.3, 7.6, 7.7 (br. m, aromatic rings) ppm. ^{13}C{^{1}H} NMR ([D$_8$]THF, 25 °C): δ = 15 (br., $NHCH_2CH_2CH_2CH_3$), 21 (br., $NHCH_2CH_2CH_2CH_3$), 35 (br., $NHCH_2CH_2CH_2CH_3$), 42 (br., $NHCH_2CH_2CH_2CH_3$), 123, 126, 127, 128, 130, 132, 133, 134 (br. peaks, naphthalene rings) 150 (NPO$C_{\text{naphthalene ring}}$) ppm. TGA: −4% (210 °C), −12% (370 °C), 28% (507 °C); residue at 800 °C: 56%.

Preparation of {[NP(OC$_6$H$_4$PPh$_2$)$_2$]$_{0.2}$[NP(O$_2$C$_{20}$H$_{10}$Br$_2$)]$_{0.8}$}$_n$ (7): (*R*)-(+)-$(HO)_2(C_{20}H_{10}Br_2)$ (6.4 g, 14.41 mmol) and Cs_2CO_3 (23.5 g, 72.13 mmol) were added to a solution of $[NPCl_2]_n$ (2.09 g, 18.03 mmol) in THF (300 mL), and the mixture was refluxed with vigorous mechanical stirring for 14 h. After that, the phenol ($HOC_6H_4PPh_2$) (3 g, 10.78 mmol) was added and refluxing was continued for 30 h. The mixture was then poured into water (1.5 L) giving a yellow solid which was washed with water (2 × 1 L) and then purified by re-precipitating it from THF/H_2O, THF/IPA, and THF/hexane. The resulting yellow polymer was dried under vacuum at 70 °C for 1 d. Yield 6.86 g, 74%. IR (KBr): $\tilde{\nu}$ = 3052 (w, ν_{CH} aromatic) cm^{-1}, 1585 m, 1493 m, 1434 w, 1396 w, 1354 w (aryl rings), 1317 (m, ν_{C-OP}), 1255 sh, 1217 (vs, ν_{NP}) 1186 sh, 1170 sh, 1066 (m, ν_{P-OC}), 960 (s, δ_{POC}), 942 s, 874 m, 826 m, 807 (m, δ_{PNP}), 778 w, 742 w, 728 w, 692 w, 655 w, 601 w, 570 (m, δ_{NPO}), 533 w, 493 w, 472 w. ^{1}H NMR ($CDCl_3$, 25 °C): δ = 5.5−9.5 (very br. m, aromatic rings). ^{1}H NMR ([D$_6$]DMSO, 110 °C): δ = 6.4 (br. m, OC_6H_4P), 7.0 (br. m, $P(C_6H_5)_2$], 6.4, 6.8, 7.4, 7.7 (br. m, $O_2C_{20}H_{10}Br_2$) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C): δ = 120 (br., Br*C*), 121−122, 129−134 (br. peaks, naphthalene and phosphane rings), 148 (NPO$C_{\text{naphthalene ring}}$), 129, 138 [$P(C_6H_5)_2$], 152 [NPO*C*, $P(C_6H_5)_2$] ppm. TGA: −48% (477 °C); residue at 800 °C: 52%.

Synthesis, Structure, and Biological Activity of New Azine-Bridged Dinuclear Platinum(II) Complexes − a New Class of Anticancer Compounds

Ganna V. Kalayda,[a] Seiji Komeda,[a] Kyoko Ikeda,[b] Takaji Sato,[b] Masahiko Chikuma,[b] and Jan Reedijk*[a]

Keywords: Platinum / Antitumor agents / Structure-activity relationships / Cytotoxicity / Apoptosis / Guanine binding

A recently described new class of dinuclear platinum anticancer compounds, represented so far by the isomeric azine-bridged complexes [{*cis*-Pt(NH_3)$_2$Cl}$_2$(μ-pzn)]Cl_2 (**1**) (pzn = pyrazine), [{*cis*-Pt(NH_3)$_2$Cl}$_2$(μ-pmn)]Cl_2 (**2**) (pmn = pyrimidine) and [{*cis*-Pt(NH_3)$_2$Cl}$_2$(μ-pdn)](NO_3)$_2$ (**3**) (pdn = pyridazine), has been added to. Three new dinuclear complexes of this type, [{*cis*-Pt(NH_3)$_2$Cl}$_2$(μ-2,5pzn)]Cl_2 (**4**) (2,5pzn = 2,5-dimethylpyrazine), [{*cis*-Pt(NH_3)$_2$Cl}$_2$(μ-qzn)]Cl_2 (**5**) (qzn = quinazoline), and [{*cis*-Pt(NH_3)$_2$Cl}$_2$(μ-pht)](NO_3)$_2$ (**6**) (pht = phthalazine), have been newly synthesized and characterized by ^{1}H and ^{195}Pt NMR spectroscopy. The interaction of the new compounds with 2 equiv. of 9EtG in D_2O at 310 K has been investigated. Complexes **4** and **5** undergo substitution of both chloride ligands by 9EtG similarly to the related complexes **1** and **2**, respectively. The methyl substituents on the pyrazine ring induce steric hindrance in **4** resulting in a slower reaction rate as compared to **1**. Similarly to the case of **3**, interaction of complex **6** with 9EtG results in cleavage of the Pt–N(pht) bond and subsequent formation of the polymeric species. A cytotoxicity assay of **4**–**6** has been performed on seven human tumor cell lines and on L1210 murine leukemia cell lines, sensitive and resistant to cisplatin. Compounds **4** and **5** exhibit lower cytotoxicity than the analogous complexes with unsubstituted azines. Complex **6** is more active: its cytotoxicity in the L1210 cell lines is similar to that of cisplatin. Analysis of nuclear DNA fragmentation in L1210 cells treated with the azine-bridged complexes **1**–**6** has been carried out. The results clearly indicate induction of apoptosis by all the compounds, implying considerable anticancer potential. The structure-activity relationship for this class of dinuclear platinum(II) complexes is discussed.

Introduction

cis-Diamminedichloroplatinum(II), usually referred to as cisplatin, has been used in cancer chemotherapy ever since its approval for the treatment of testicular cancer in 1978.[1] At present, it is one of the most widely utilized antitumor drugs, with especially high efficacy against solid tumors, such as testicular and ovarian cancer.[2] However, several problems have been encountered in clinical use. Firstly, cisplatin treatment is accompanied by severe side effects, e.g. nausea, vomiting, and nephrotoxicity. Secondly, cisplatin anticancer activity is limited to a relatively narrow range of tumors. Besides, some tumors develop resistance after repeated cisplatin administrations.[3,4] These drawbacks have stimulated intensive search for new potential antitumor drugs.

One of the most successful approaches in platinum-based anticancer drug design is the synthesis of polynuclear platinum complexes with bridging linkers.[5] Its success is based on the ability of such complexes to form DNA adducts, which are structurally different from those of cisplatin. The major product of cisplatin interaction with genomic DNA is a 1,2-intrastrand cross-link, which induces a kink on a DNA double helix.[6−9] These conformational changes are believed to play an important role in the development of cisplatin resistance.[10] Thus, the compounds capable of binding to DNA in a significantly different way are expected to overcome the resistance problem. Some of the polynuclear (mostly dinuclear) antitumor active platinum(II) complexes described in the literature contain flexible bridging ligands,[11−15] while others possess rigid linkers together with bridging leaving groups.[16−19] The complexes with flexible linkers (for instance, aliphatic diamines) are designed to form long-range cross-links on DNA,[20,21] and the complexes possessing rigid bridging ligands, such as hydrazine and azoles, are developed to minimize distortion of the DNA double helix in a 1,2-intrastrand cross-link.[22]

Recently, we described a new class of dinuclear platinum(II) complexes with azines as bridging ligands.[23] These complexes present a combination of the two above-mentioned types of compounds: they utilize rigid aromatic rings of azines as linkers between two platinum atoms, featuring

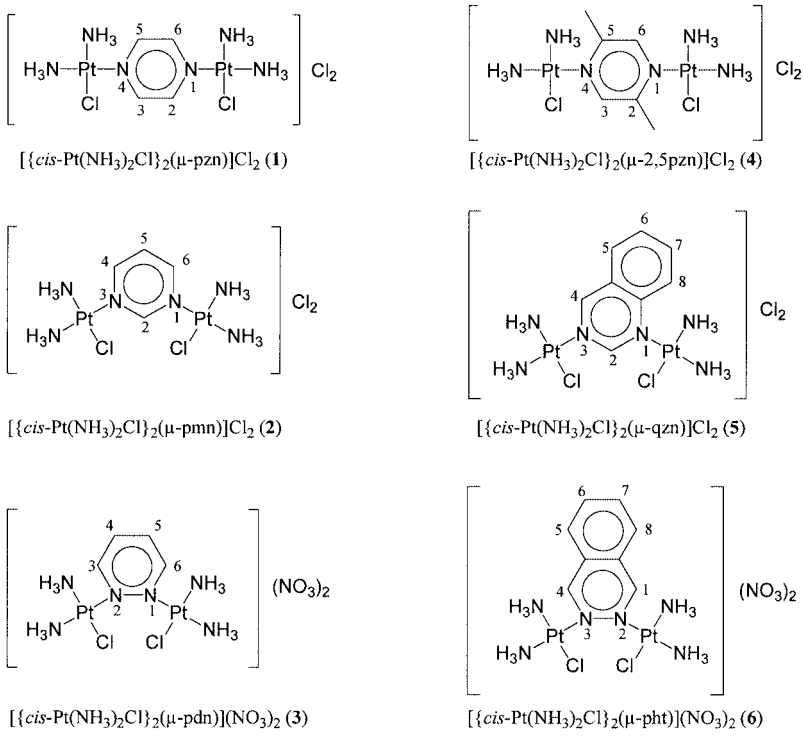

Figure 1. Schematic representation of the azine-bridged dinuclear platinum complexes [{*cis*-$Pt(NH_3)_2Cl\}_2$(μ-pzn)]Cl_2 (**1**), [{*cis*-$Pt(NH_3)_2Cl\}_2$(μ-pmn)]Cl_2 (**2**), [{*cis*-$Pt(NH_3)_2Cl\}_2$(μ-pdn)]$(NO_3)_2$ (**3**), [{*cis*-$Pt(NH_3)_2Cl\}_2$(μ-2,5pzn)]Cl_2 (**4**), [{*cis*-$Pt(NH_3)_2Cl\}_2$(μ-qzn)]Cl_2 (**5**), and [{*cis*-$Pt(NH_3)_2Cl\}_2$(μ-pht)]$(NO_3)_2$ (**6**)

at the same time non-bridging chloride ions as leaving groups. These compounds exhibit considerable activity in vitro in several human tumor cell lines. The complex [{*cis*-$Pt(NH_3)_2Cl\}_2$(μ-pzn)]Cl_2 (pzn = pyrazine) overcomes cisplatin resistance in the L1210/DDP murine leukemia cell line (Figure 1). We have now extended this new class of dinuclear platinum complexes applying other azines, such as quinazoline (qzn), phthalazine (pht), and 2,5-dimethylpyrazine (2,5pzn), as bridging ligands. These azines have different streric and electronic properties caused by substituents on the aromatic ring. In this paper, we describe the synthesis and characterization of three new azine-bridged dinuclear platinum(II) complexes, their interaction with 9-ethylguanine (9EtG), the results of cytotoxicity tests for these compounds, and the analysis of nuclear DNA fragmentation induced by the azine-bridged complexes. Structure-activity correlations for azine-bridged dinuclear platinum(II) complexes are presented.

Results

Synthesis and Characterization of the Complexes

The synthetic procedure used for the preparation of the new azine-bridged dinuclear platinum(II) complexes is similar to the previously described method for the synthesis of **1**−**3**.[23] In all cases the formation of the desired compounds was accompanied by a series of side reactions, and repeated recrystallizations were necessary to purify the complexes.

The complexes were characterized by ^1H and ^{195}Pt NMR spectroscopy (Table 1) and elemental analysis. ^1H NMR spectra show a downfield shift of the signals of the aromatic protons of the ligands as compared to the respective signals for the free azines. ^{195}Pt NMR shifts are in the range typical for an $[N_3Cl]$ coordination environment around the platinum atom.[24] The smaller upfield shift of **6** (δ = −2232 ppm) compared to the shifts of the two other platinum complexes (δ ≈ −2330 ppm) might result from the close proximity of the platinum atoms in **6**. Thus, NMR spectroscopy presents clear evidence of the formation of the desired dinuclear platinum(II) complexes.

Interaction with 9EtG

^1H NMR spectra, run over the course of the reaction, of the complexes **1** and **4**−**6** with 2 equiv. of 9EtG in 0.1 M $NaClO_4$ solution in D_2O at 310 K are shown in Figure 2, a−d, respectively. The ^1H and ^{195}Pt NMR spectroscopic data for the final products are given in Table 2.

Complex 1

As the reaction proceeds, the intensity of the 9EtG signal (δ = 7.82 ppm) decreases, and a signal at δ = 8.27 ppm from the H8 protons of the guanines in the disubstituted product **I** increases in intensity (Figure 2, a). The structure of **I** was confirmed by ^{195}Pt NMR spectroscopy: the ^{195}Pt chemical shift of the product is typical of the $[PtN_4]$ unit.[19,25] In the first hours of interaction of **1** with 9EtG a signal at δ = 8.34 ppm corresponding to the intermediate

[a] Not observed.

The half-life of 9EtG was determined graphically based on relative integration values of the H8 proton, and is presented in Table 3. As compared to the reaction with GMP [$t_{1/2}$(GMP) = 100 min] previously described,[23] binding of 9EtG to **1** is slower than GMP binding to this complex. A certain amount of the monosubstituted complex was observed in the case of 9EtG, indicating a slower substitution of the second chloride ion as compared to the reaction with GMP.

Table 3. The times of disappearance of 50% 9EtG ($t_{1/2}$) during the reactions of **1** and **4** with 2 equiv. of 9EtG in 0.1 M $NaClO_4$ solution in D_2O at 310 K

Complex	$t_{1/2}$ [min]
1	160
4	210

Complex 4

The substitution of the first chloride ion by a 9EtG molecule yields an intermediate complex **IVa** (see Scheme 1). As the reaction proceeds further, two new signals at δ = 8.08 and 8.18 ppm appear and gradually increase in intensity. One of them was initially tentatively assigned to the hydrolyzed intermediate **IVb**. However, no peaks corresponding to the platinum nucleus in the [N_3O] coordination environment[19,23,25] were found in the ^{195}Pt NMR spectrum. Thus, **IVb** is not present in the reaction mixture, and the signals at δ = 8.08 and 8.18 ppm can only be assigned to the non-equivalent H8 protons of the two guanine bases in the disubstituted product **IV**. In contrast to **I** where free rotation around Pt−N bonds is present, complex **IV** is sterically hindered, and it might exist in a certain thermo-

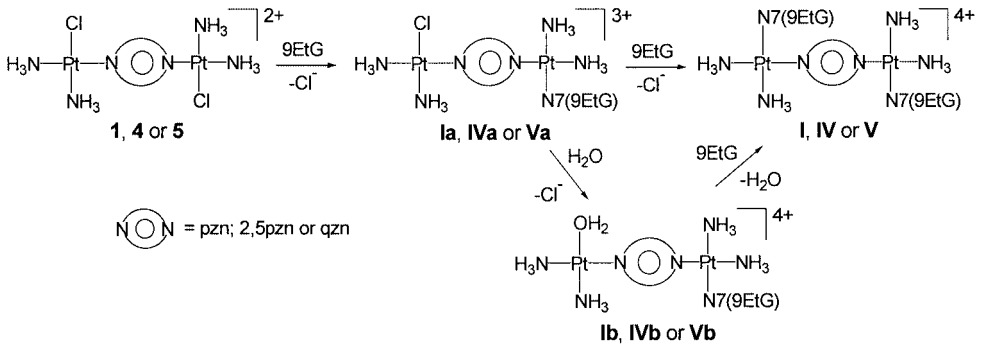

Scheme 1. The reaction scheme for the interaction of complexes **1**, **4**, and **5** with 2 equiv. of 9EtG in aqueous solution

dynamically favored conformation, in which the two guanine molecules have a different configuration with respect to the CH_3 groups.

The half-life of 9EtG was determined graphically based on relative integration values of the H8 proton, and is given in Table 3. As is clear from Table 3, complex **4** reacts much slower with 9EtG than the analogous complex **1**, without methyl substituents on the azine ring. It has been shown previously that the rate-limiting step of guanine binding to the azine-bridged complexes is a direct substitution of the chloride ion by N7 of a guanine base, and therefore the reaction rate is mainly determined by steric factors.[23] Apparently, methyl groups of the 2,5-dimethylpyrazine in **4** hamper chloride substitution by 9EtG, resulting in a much slower interaction as compared to **1**.

Complex 5

The reaction of **5** with 9EtG provides the disubstituted complex **V** as confirmed by ^1H and ^{195}Pt NMR spectroscopy (Table 2). An interesting feature of **V** is that the H8 protons of the two guanine molecules in this complex are not equivalent. This is not unexpected, as one of them is shielded by an aromatic ring of quinazoline and its signal is, therefore, shifted upfield. Complex **5** reacts with guanine via the intermediate species **Va**. This is clearly seen from the signals of the $H8_{(qzn)}$ proton of the quinazoline. As the reaction proceeds, the intensity of the peak corresponding to the starting complex **5** ($\delta = 9.56$ ppm) decreases, and at first the signal of the $H8_{(qzn)}$ proton of the intermediate **Va**, at $\delta = 9.42$ ppm, increases in intensity. Later in the course of the reaction the intensity of this signal diminishes, while the peak ($\delta = 9.63$ ppm) corresponding to the $H8_{(qzn)}$ proton of the final product **V** builds up in intensity. It should be noted that only one intermediate was observed, whereas two different intermediates would be expected due to the asymmetry of the starting complex. This indicates that the least hindered chloride ion is substituted first. The substitution of the second chloride ion is more difficult for steric reasons and is, therefore, slower. It may be concluded that the reaction of 9EtG with complex **5** proceeds slower than the same reaction with the related compound **2**. However, no quantitative confirmation was possible due to an overlap between the signals of the aromatic protons of quinazoline and H8 signals of the guanine bases of the products.

Complex 6

Complex **6** interacts with 9EtG in a similar manner to that previously found for the reaction of the related compound **3** with GMP,[23] i.e. with the cleavage of the Pt−N(pht) bond and subsequent polymerization. First, the N7,O6-platinated 1:1 complex $[\{cis\text{-}Pt(NH_3)_2\}_2(\mu\text{-}9EtG\text{-}N7,O6)(\mu\text{-}pht)]^{4+}$ is formed. Binding of another 9EtG molecule to this complex breaks the Pt−N(pht) bond, yielding two mononuclear fragments, $[cis\text{-}Pt(NH_3)_2(pht)(9EtG\text{-}N7)]^{2+}$ (**VIa**) and $[cis\text{-}Pt(NH_3)_2(9EtG)(H_2O)]^{2+}$. The latter species polymerizes to form product **VI**, $[\{cis\text{-}Pt(NH_3)_2\}(\mu\text{-}9EtG\text{-}N7,O6)\{cis\text{-}Pt(NH_3)_2\}(\mu\text{-}9EtG\text{-}N7,O6)]_n$ (see Scheme 2).

In contrast to the previously described reaction of **3** with GMP, in the case of interaction between **6** and 9EtG the second guanine molecule predominantly attacks the platinum atom bound to O6 of the bridging guanine. The Pt−N7(9EtG) bond of the initially formed 1:1 complex $[\{cis\text{-}Pt(NH_3)_2\}_2(\mu\text{-}9EtG\text{-}N7,O6)(\mu\text{-}pht)]^{4+}$ remains intact, and therefore, the mononuclear complex $[cis\text{-}Pt(NH_3)_2(pht)(9EtG\text{-}O6)]^{2+}$ was not observed. This phenomenon appears to be related to the guanine base rather than to the bridging azine, as during the reaction of **3** with 9EtG no species $[cis\text{-}Pt(NH_3)_2(pdn)(9EtG\text{-}O6)]^{2+}$ was detected (spectra not shown).

The structures of the products were confirmed by ^1H and ^{195}Pt NMR spectroscopy, mass spectrometry and pH titration. The ^1H NMR spectrum of **VIa** shows an asymmetric profile of the pht ligand. The ^{195}Pt shift of this complex is typical of $[N_4]$ coordination surrounding a platinum atom.[18,23,25] A signal assigned to $[cis\text{-}Pt(NH_3)_2(pht)(9EtG)]^+$ was observed in the mass spectrum of **VIa**. ^1H NMR spectroscopic data for **VI** confirm the absence of phthalazine. The H8 signal of this complex is shifted by 0.26 ppm downfield compared with free 9EtG, indicating an inductive effect of platinum coordinated to guanine. As in the case of the similar complex $[\{cis\text{-}Pt(NH_3)_2\}(\mu\text{-}GMP\text{-}N7,O6)\{cis\text{-}Pt(NH_3)_2\}(\mu\text{-}GMP\text{-}N7,O6)]_n$,[23] no signal was found in the ^{195}Pt NMR spectrum of **VI**. This phenomenon

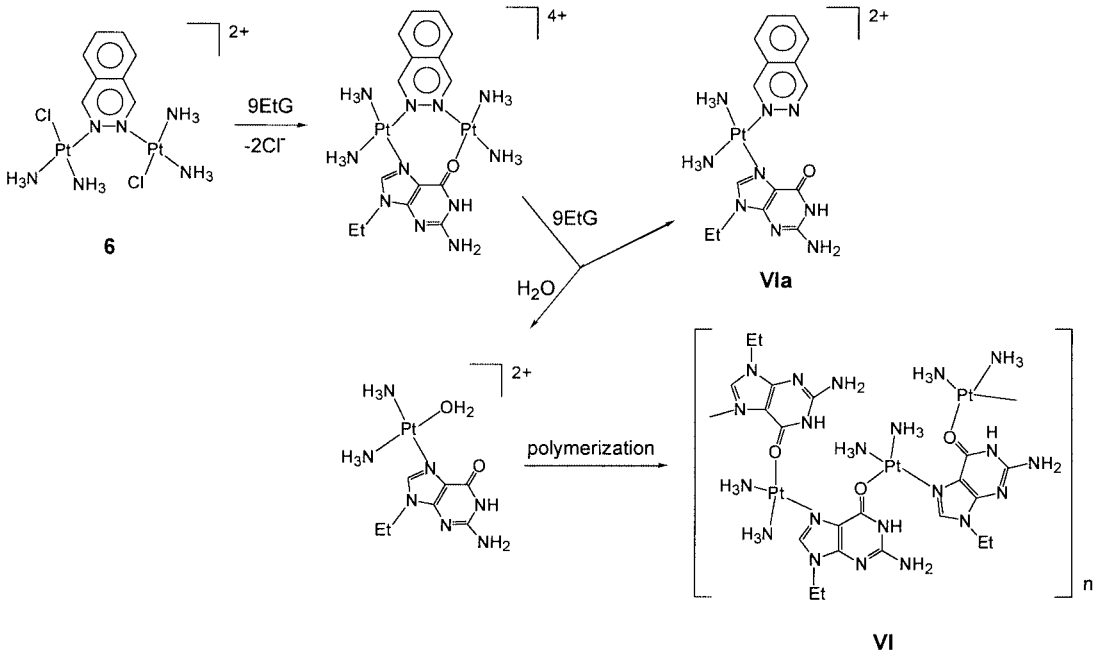

Scheme 2. The proposed reaction scheme for the interaction of **6** with 2 equiv. of 9EtG in aqueous solution

is a result of ^{195}Pt relaxation, and is often observed in the case of polymerized compounds.[26] The mass spectrum of complex **VI** gives a signal, which corresponds to $[Pt(\mu\text{-}9EtG)Pt(NH_3)]^+$.

Thus, the close proximity of the platinum atoms does not allow coordination of two 9EtG ligands to the Pt−(μ-pht)−Pt moiety resulting in cleavage of the Pt−N(pht) bond upon binding of the second 9EtG, followed by polymerization. It should be noted that this is the first example of the formation of polymeric species in the reactions involving platinum complexes with 9EtG.

pH Titrations

The chemical shift of the signal of the H8 proton of 9EtG is strongly dependent on (de)protonation of the heterocyclic nitrogen atoms. Therefore, a pH titration is a very convenient method of determining the platinum binding position of the guanine.[27,28] The pH titration was performed on the final products of the reaction of 9EtG with compounds **1** and **4**−**6**. The plots of the chemical shifts of the signal of the H8 protons as a function of pD are shown in Figure 3. For all the products analyzed, the N7 (de)protonation in the acidic area, as it is known for free 9EtG, is absent. This clearly indicates that in all of these compounds the platinum atoms are bound to the guanines at the N7 position. The N1 (de)protonation in basic solution was observed for **I**, **IV**, and **VIa**, confirming the proposed structures. Complex **V** was found to be unstable at pD > 8.5, therefore, the (de)protonation process at N1 in the basic region could not be detected.

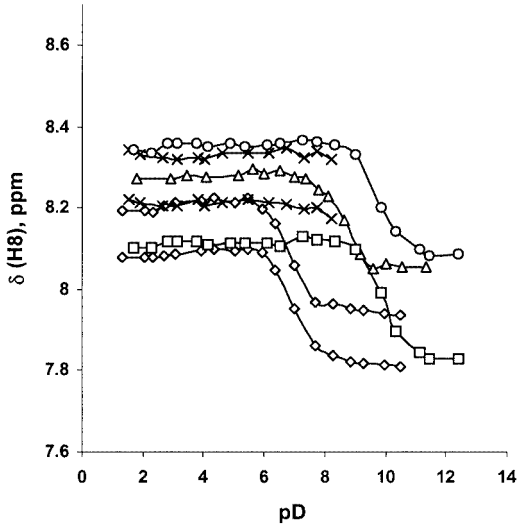

Figure 3. Plots of the chemical shift of H8 protons vs. pD for **I** (triangle), **IV** (diamond), **V** (cross), **VI** (square), and **VIa** (circle); pH titrations were performed in 0.1 M $NaClO_4$ solutions in D_2O at 298 K; pD was adjusted with 1 M and 0.1 M DCl, 1 M and 0.1 M NaOD

The results from the pH titration of **VI** present evidence of the binding positions of the platinum atoms in this complex. For **VI**, the N7 (de)protonation process was not observed indicating that platinum binds to guanine at the N7 position. Another platinum atom can possibly be bound to either N1 or the O6 position. N1 (de)protonation was detected upon pH titration of **VI**, strongly suggesting that the binding position of another platinum atom is the O6 atom of a guanine ligand.

In vitro Cytotoxicity Assay in Human Tumor Cell Lines

The cytotoxicity of **4**−**6**, and cisplatin as a reference, in several human tumor cell lines, MCF and EVSA-T (breast cancer), WIDR (colon cancer), IGROV (ovarian cancer), M19 (melanoma), A498 (renal cancer), and H226 (non-small cell lung cancer), is summarized in Table 4. All three azine-bridged complexes were found to be in the active range in all the cell lines, except for **4** in A498. Among the three dinuclear compounds tested, **4** was the least cytotoxic in all of the cell lines, and **6** exhibited a slightly higher activity than **5** in five cell lines. The cytotoxicity of the complexes is lower than that of cisplatin. However, similarly to the related complexes **1**−**3**,[23] compounds **4**−**6** show a high specificity for the IGROV cell line. They are approximately half as cytotoxic as cisplatin in this cell line, whereas their activity compared to cisplatin in the other cell lines is 4−5 times lower.

Table 4. In vitro cytotoxicity assay of complexes **4**−**6** and cisplatin on human tumor cell lines

Test compound	IC_{50} [μM]						
	A498	EVSA-T	H226	IGROV	M19	MCF-7	WIDR
4	11.9	6.3	19.6	1.1	8.4	9.0	5.4

6	> 88.3	16.7	53.7	3.2	23.5	23.4	7.5
Cisplatin	5.7	1.4	4.5	0.4	1.8	1.4	1.8

In vitro Cytotoxicity Assay in L1210 Cell Lines Sensitive and Resistant to Cisplatin

The cytotoxicity tests of complexes **4**−**6** were performed on L1210 murine leukemia cells, sensitive (L1210/0) and resistant (L1210/DDP) to cisplatin. Cisplatin and the azine-bridged complexes **1**−**3** were included as reference compounds. The results are presented in Table 5. The IC_{50} values for the reference complexes **1**−**3** correlate with the previously reported data.[23] Complex **4** exhibits significantly lower activity compared with the related compound **1** in both L1210/0 and L1210/DDP cell lines. Compound **5** is half as active as the analogous complex **2**. Both **4** and **5** are approximately 5 times less cytotoxic than cisplatin. Nevertheless, these complexes are still in the active range. Compound **6** was found to be twice as active as the related complex **3**. Its cytotoxicity is similar to that of cisplatin. As expected, in the resistant cell line cisplatin is significantly less active, with the resistance factor (*RF*) equal to 4.7. The resistant factors of the azine-bridged complexes are lower (around 3) indicating that they partially circumvent cisplatin resistance.

Table 5. In vitro cytotoxicity assay of complexes **1**−**6** and cisplatin on L1210 murine leukemia cell lines, sensitive (L1210/0) and resistant (L1210/DDP) to cisplatin

Test compound	IC_{50} [μM] L1210/0	L1210/DDP	*RF*[a]

Cisplatin	2.0±0.2	9.4±0.8	4.7

[a] *RF* − resistance factor, $RF = IC_{50}(L1210/DDP)/IC_{50}(L1210/0)$.

Induction of Apoptosis by the Platinum Complexes in L1210/0 Cells

One potentially important manner by which platinum−DNA adducts may kill the cells is by induction of programmed cell death or apoptosis. Activation of apoptosis results in nuclear disintegration and eventual fragmentation of the dying cell. Irreversible cleavage of nuclear DNA into nucleosomal oligomers is a distinct feature of apoptotic cell death.

The L1210/0 cells were exposed to the azine-bridged complexes **1**−**6** and cisplatin for 48 h at the concentrations equal to their IC_{50}. The low-molecular weight DNA extracted from the cells was taken for agarose electrophoresis. As shown in Figure 4, DNA fragmentation with a characteristic laddering pattern was observed for all the compounds. DNA laddering is a frequently used indicator of apoptosis.[29,30] Therefore, it can be concluded that all the azine-bridged complexes as well as cisplatin trigger apoptotic pathways in L1210/0 cells.

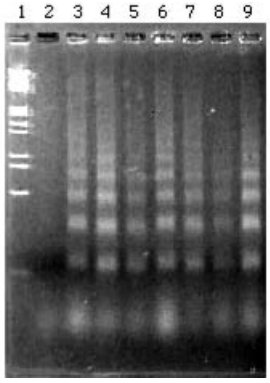

Figure 4. Analysis of nuclear DNA fragmentation induced by the azine-bridged dinuclear platinum complexes **1**−**6** and cisplatin; gel analysis was carried out as described in the Exp. Sect.; cells were incubated for 48 h with cisplatin (lane 3) and compounds **1**−**6** (lane 4−9, respectively) at the concentrations equal to their IC_{50}; lane 1: DNA marker; lane 2: control

Discussion

Compared to the previously described azine-bridged dinuclear complexes **1**−**3**, the newly synthesized complexes **4**−**6** possess additional substituents (e.g. additional aromatic ring or methyl groups) on the azine ligand. Investigation of their interaction with 9EtG shows that the steric hindrance induced by additional groups hampers the substitution of chloro ligands by guanine molecules. Binding

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of these complexes to DNA is supposed to be sterically even more restricted, and they might prefer to react with relatively flexible protein molecules than with rather rigid dsDNA. Therefore, a very small amount of Pt−DNA adducts is expected to be formed resulting in a lower cytotoxicity as compared to the parent compounds. This was observed for complexes **4** and **5**, which were found to be less active than their analogues **1** and **2**, respectively. The methyl groups of 2,5-methylpyrazine in **4** induce steric hindrance on both platinum atoms, while in the case of **5** only the second substitution step is supposed to be affected by the presence of an additional aromatic ring. This difference reflects on the activity of the complexes: **4** is much less cytotoxic than **5**.

In the case of **6**, the close proximity of two platinum atoms rather than the presence of an additional aromatic ring determines the outcome of the interaction with 9EtG. In contrast to the reaction with 9EtG, it is unlikely that complex **6** would form an N7,O6-platinated complex [{*cis*-$Pt(NH_3)_2$}$_2${μ-G(dsDNA)-N7,O6}(μ-pht)] on double-stranded DNA, because the O6 atom of the guanine is involved in Watson−Crick base paring. As suggested earlier for the related complex **3**,[23] the initial substitution of the first chloride ion will probably be followed by the Pt−N(pht) bond cleavage upon nucleophilic attack of the neighbouring guanine molecule. This will result in the formation of the two mononuclear fragments, [*cis*-$Pt(NH_3)_2$-(pht){G(dsDNA)-N7}] and [*cis*-$Pt(NH_3)_2${G(dsDNA)-N7}(H_2O)]. The latter one is expected to coordinate to another nucleobase producing cross-links on DNA similarly to cisplatin. The former will apparently stay as a monofunctional adduct as in the case of the analogous complex **3**. Since in this monofunctional adduct the phthalazine ligand occupies the *cis* position with respect to the guanine base, it might act as an intercalator on DNA improving the cytotoxicity of **6** compared with complex **3**, which cannot provide any additional interaction with nuclear DNA.

The azine-bridged dinuclear platinum(II) complexes present a new class of platinum anticancer compounds. In human tumor cell lines they exhibit cytotoxic profiles, which differ from that of cisplatin, and some of them largely or partly circumvent the cross-resistance with cisplatin in murine leukemia cells, due to the formation of DNA adducts different from those of cisplatin. Our results clearly show that the azine-bridged complexes induce apoptosis in L1210/0 cells. Apoptosis in cancer cells is more difficult to trigger because of their ability to either block pro-apoptotic pathways or stimulate anti-apoptotic ones. Thus, induction of apoptosis in tumor cells by the azine-bridged complexes presents clear evidence of considerable anticancer activity of these compounds.

Conclusion

In this paper, we have described the synthesis of three new azine-bridged dinuclear platinum complexes, their interaction with 9EtG, and biological activity of these compounds. The structure-activity relationship within this class of dinuclear platinum anticancer compounds has been established. The complexes possessing additional groups in the azine ring, which induce steric hindrance and hamper binding of the complex to nuclear DNA, are less cytotoxic than the complexes with unsubstituted azines. The substituents on the ligand, that can provide additional interaction with DNA such as intercalation, significantly improve antitumor properties of the complex. In this study, we have also shown that all the azine-bridged dinuclear platinum complexes are able to induce apoptosis in tumor cells indicating a considerable anticancer potential of this class of compounds.

Experimental Section

General: K_2PtCl_4 was used as obtained from Johnson&Matthey (Reading, U.K). Silver nitrate was purchased from Acros, 2,5-dimethylpyrazine, quinazoline, and phthalazine were received from Aldrich, 9EtG was purchased from Sigma, and further purification was not carried out. *cis*-$[Pt(NH_3)_2Cl_2]$ was synthesized according to a literature method.[31] The dinuclear platinum complexes [{*cis*-$Pt(NH_3)_2Cl$}$_2$(μ-pzn)]Cl_2 (**1**), [{*cis*-$Pt(NH_3)_2Cl$}$_2$(μ-pmn)]Cl_2 (**2**), [{*cis*-$Pt(NH_3)_2Cl$}$_2$(μ-pdn)]$(NO_3)_2$ (**3**) were prepared as described previously.[23]

Instrumentation: All NMR spectra were recorded with a 300-MHz Bruker DPX300 spectrometer with a 5-mm multi-nucleus probe. The temperature was kept constant by a variable-temperature unit. ^1H and ^{195}Pt chemical shifts were referenced to TSP and $Na_2[PtCl_6]$ (δ = 0 ppm), respectively. C, H, and N analyses were performed with a Perkin−Elmer 240B microanalyzer. Mass spectrometric measurements were performed with a ThermoFinnigan AQA spectrometer using an Electrospray Interface ionization technique.

***cis*-$[Pt(NH_3)_2Cl(dmf)](NO_3)$:** A solution of $AgNO_3$ (0.08 g, 0.47 mmol) in 3 mL of dimethylformamide (DMF) was added dropwise over 3 h to a stirred solution of *cis*-$[Pt(NH_3)_2Cl_2]$ (0.15 g, 0.5 mmol) in DMF (7 mL) at room temperature in the dark. The mixture was stirred overnight in the dark, and the AgCl precipitate was then filtered off. The resulting pale-yellow DMF solution of *cis*-$[Pt(NH_3)_2Cl(dmf)](NO_3)$ was used as a starting material for the preparation of each azine-bridged dinuclear platinum(II) complex described below.

[{*cis*-$Pt(NH_3)_2Cl$}$_2$(μ-2,5pzn)]Cl_2 (4): 2,5pzn (23.0 mg, 0.21 mmol) in DMF (1 mL) was added dropwise to the stirred DMF solution of *cis*-$[Pt(NH_3)_2Cl(dmf)](NO_3)$, obtained as above. The resulting solution was stirred at room temperature for 6 h in the dark, then concentrated in a rotary evaporator, and the residue was washed with diethyl ether. A crude product was recrystallized twice from a minimal amount of 0.5 M aqueous solution of LiCl yielding a pale-yellow powder of **4**, which was washed with MeOH and diethyl ether, dried in vacuo. Yield: 0.03 g (17%). $C_6H_{20}Cl_4N_6Pt_2$ (708.2): calcd. C 10.18, H 2.85, N 11.87; found C 10.13, H 2.82, N 11.94. ^1H NMR (D_2O): δ (2,5pzn resonance) = 3.09 (s, 6 H), 9.11 (s, 2 H) ppm. ^{195}Pt NMR (D_2O): δ = −2346 ppm.

[{*cis*-$Pt(NH_3)_2Cl$}$_2$(μ-qzn)]Cl_2 (5): qzn (28.3 mg, 0.22 mmol) in DMF (1 mL) was added dropwise to the stirred DMF solution of *cis*-$[Pt(NH_3)_2Cl(dmf)](NO_3)$, obtained as above. The resulting solution was stirred at room temperature for 6 h in the dark. This solution was then concentrated in a rotary evaporator, and the resi-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

due was washed with diethyl ether. The crude product was dissolved in a minimal amount of 1 M aqueous solution of LiCl, then excess of MeOH was added. The volume of the resulting solution was reduced to yield a yellow precipitate, which was purified in the same way once more to obtain a yellow precipitate of **5**. This precipitate was collected, washed with MeOH and diethyl ether, and dried in a dessicator over KOH. Yield: 0.05 g (25%). $C_8H_{18}Cl_4N_6Pt_2$ (730.2): calcd. C 13.16, H 2.48, N 11.51; found C 13.02, H 2.27, N 11.41. ^{1}H NMR (D_2O): δ (qzn resonance) = 8.13 (t, 1 H), 8.41 (d, 1 H), 8.53 (t, 1 H), 9.56 (d, 1 H), 10.09 (s, 1 H), 10.21 (s, 1 H) ppm. ^{195}Pt NMR (D_2O): δ = −2317, −2339 ppm.

[{*cis*-Pt(NH$_3$)$_2$Cl}$_2$(μ-pht)](NO$_3$)$_2$ (6): pht (28.3 mg, 0.22 mmol) in DMF (1 mL) was added dropwise to the stirred DMF solution of *cis*-[Pt(NH$_3$)$_2$Cl(dmf)](NO$_3$), obtained as above. The resulting solution was stirred overnight in the dark at room temperature. Then it was concentrated in a rotary evaporator and the residue extracted with MeOH (15 mL). The extract was filtered, concentrated in a rotary evaporator, and extracted again with MeOH (15 mL). The resulting extract was filtered, concentrated in a rotary evaporator, and the residue washed with a small amount of EtOH, and thoroughly washed with diethyl ether to obtain a yellow powder of **6** which was dried in a dessicator over KOH. Yield: 0.06 g (30%). $C_8H_{18}Cl_2N_8O_6Pt_2$ (783.3): calcd. C 12.27, H 2.32, N 14.30; found C 12.22, H 2.40, N 14.40. ^{1}H NMR (D_2O): δ (pht resonance) = 8.36 (m, 2 H), 8.41 (m, 2 H), 10.08 (s, 2 H) ppm. ^{195}Pt NMR (D_2O): δ = −2232 ppm.

Reactions with 9EtG: The reactions of the complexes **1**, **4**, **5**, and **6** (4 mM) with 2 equiv. of 9EtG (8 mM) were monitored over 14 h at 310 K by ^{1}H NMR spectroscopy in a 0.1 M $NaClO_4$ solution in D_2O (pD ≈ 7). The reactions of **1** and **4** with 9EtG were quantified using relative integration values of the signals of the H8 protons.

pH Titrations: The pH titrations were carried out in 0.1 M $NaClO_4$ solutions in D_2O by adjustment of the pD with 0.1 M and 1 M DCl, 0.1 M and 1 M NaOD. The pD values were measured at 298 K using a PHM 80 pH meter (Radiometer) before and after each ^{1}H NMR measurement. The pH values were not corrected for H/D isotope effects.

In vitro Cytotoxicity Assay in Human Tumor Cell Lines: In vitro cytotoxicity assays in human tumor cell lines were performed at the Dr. Daniel den Hoed Kliniek (Rotterdam Cancer Institute), Department of Medical Oncology (Rotterdam, the Netherlands). The seven well-characterized cell lines used were MCF7 and EVSA-T (breast cancer), WIDR (colon cancer), IGROV (ovarian cancer), M19 (melanoma), A498 (renal cancer), and H226 (non-small cell lung cancer). All cell lines were maintained in a continuous logarithmic culture in RPMI 1640 medium with Hepes and phenol red (Paisley, Scotland). The medium was supplemented with 10% FCS (Paisley, Scotland), penicillin 100 IU/mL and streptomycin 100 μg/mL (Sigma). Cisplatin and the dinuclear platinum complexes **4** and **5** were dissolved in water (1 mg/200 μL), complex **6** was dissolved in DMSO (1 mg/200 μL) and finally diluted in full medium. After 48 h of preincubation of the tumor cells in 96-well flatbottom microtiter plates, the solutions of the test compounds were added. The plates were incubated at 37 °C, 8.5% CO_2 for 120 h. IC_{50} values were determined using the microculture sulforhodamine-B test (SRB).[32]

In vitro Cytotoxicity Assay in L1210 Cell Lines Sensitive and Resistant to Cisplatin: The L1210/0 murine leukemia cell line (JCRB 9026) was obtained from the Health Science Research Resources Bank (Osaka, Japan). The cisplatin-resistant L1210/DDP cell line was obtained by exposure of L1210/0 cells to cisplatin at the concentration of 10 μM over a period of 3 months and subsequent cloning. L1210/0 and L1210/DDP were cultured in a suspension in RPMI 1640 medium (Sigma) supplemented with 10% heat-inactivated fetal calf serum and no antibiotics. The cells were grown at 37 °C in a 5% CO_2 humidified atmosphere. Cell growth inhibition was determined by an MTT assay [MTT = 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide].[33] In brief, the cells were divided into 96 well plates at the concentrations of 10^5 cells/mL in 100 μL of growth medium and were allowed to attach for 16 h at 37 °C in a 5% CO_2 humidified atmosphere. Then the cells were incubated with the platinum complexes at various concentrations for 48 h. Following exposure to the drugs, 10 μL of a 5 mg/mL MTT solution was added to each well, and the cells were incubated for 4 h. Then the culture media were removed, and the plates were washed with PBS. 200-μL aliquots of 2-propanol containing 0.04 M HCl were pipetted into each well. The absorbance was measured at 570 nm using a Biorad 550 microplate reader. The IC_{50} values were defined as the drug concentrations that reduced the absorbance by 50% compared to the drug-free control.

Induction of Apoptosis by the Platinum Complexes in L1210/0 Cells: The cells were exposed to the concentrations equal to IC_{50} of each azine-bridged complex. For the analysis of DNA fragmentation, DNA of a low molecular weight extracted from the cells was taken for agarose electrophoresis. The cells were cultured at the concentrations of 10^5 cells/mL in 24 mL for 16 h, followed by incubation with complexes **1**−**6** for 48 h. The cells (10^7 cells) were then harvested by centrifugation and resuspended in 0.1 mL of lysis buffer [0.5% Triton X-100, 1 mM EDTA, 10 mM Tris-HCl buffer (pH = 7.4)]. Afterwards the suspension was incubated at 4 °C for 10 min. In order to remove DNA of a high molecular weight, the suspension was centrifuged at 16300 rpm at 4 °C for 5 min. Then 10 μL of RNase A (10 mg/mL) in Tris-EDTA buffer [1 mM EDTA, 10 mM Tris-HCl buffer (pH = 8.0)] was added to the supernatant and incubated at 37 °C for 1 h. 10 μL of Proteinase K solution (10 mg / mL) was then added, and further incubation was performed at 50 °C for 30 min. Afterwards 20 μL of 5 M NaCl and 120 μL of 2-propanol were added, and the resulting mixture was left overnight at −20 °C. After centrifuging at 16300 rpm at 4 °C for 15 min, the DNA pellet was obtained and subsequently resuspended in 100 μL of 10 mM loading buffer [2 mM EDTA, 90 mM Tris-boric acid buffer (pH = 8.0)]. The DNA was loaded onto a 2% agarose gel, and electrophoresis was carried out in a loading buffer at 100 V for 1 h. The DNA was observed by ethidium bromide solution staining (1 μg/mL, 20 min). The photographs were obtained under UV illumination by a Kodak EDAS-120 system.

Acknowledgments

The authors are grateful to Johnson & Matthey (Reading, UK) for their generous donation of K_2PtCl_4 and to PCN/Pharmachemie BV (Haarlem, The Netherlands) for cytotoxicity tests. Also the support and sponsorship concerted by COST Actions D20/0001/00, D20/0002/00, and D20/003/01 is kindly acknowledged. This work has been performed under the auspices of the joint BIOMAC Research Graduate School of Leiden University and Delft University of Technology.

Keywords: Tin / Phosphorous / NMR spectroscopy / Cluster compounds

The trinuclear organotin–oxo cluster $[Ph_2P(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2][O_3SCF_3]$ (**6**), was prepared in good yield by the consecutive reaction of $(tBu_2SnO)_3$ with F_3CSO_3H and Ph_2PO_2H, and adopts a common tricyclic $ESn_3O_3X_2$ structural motif with E = P; X = OH, similar to those found in the recently reported species $[M(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2]$ [M = Ph_2Si (**1**), Me_2Si (**2**), CO (**3**), MesB (**4**)] and $[Ph_2Si(OSntBu_2)_2O{\cdot}tBu_2SnF_2]$ (**5**) where E = Si, C, B and X = OH, F. Compound **6** was characterized by multinuclear NMR spectroscopy, IR spectroscopy, electrospray mass spectrometry and single-crystal X-ray diffraction analysis. A natural population analysis (NPA) performed on the B3LYP/LANL2DZ level of theory for the molecular structures of the isoelectronic species $[Ph_2Si(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2]$ (**1**) and $[Ph_2P(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2]^+$ (**6a**) suggests that the positive charge of the latter is partially delocalised over the phenyl rings.

Introduction

In the last two decades there has been considerable interest in the chemistry of organotin−oxo clusters,[1] and particularly in those with Sn−O−P linkages.[1−8] In this regard, we and others have reported a variety of trinuclear organotin−oxo clusters $[M(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2]$ [M = Ph_2Si (**1**),[9] Me_2Si (**2**),[10] CO (**3**),[11] and MesB (**4**)[12]] and $[Ph_2Si(OSntBu_2)_2O{\cdot}tBu_2SnF_2]$ (**5**)[13] that adopt a common tricyclic, almost planar $ESn_3O_3X_2$ (E = Si, C, B; X = OH, F) structural motif (Scheme 1). It was proposed that further examples of this class of compound might be accessible upon replacement of E by other organometallic fragments.[13]

We now describe the synthesis and structure of $[Ph_2P(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2](O_3SCF_3)$ (**6**), which features a cation, $[Ph_2P(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2]^+$ (**6a**), that is isoelectronic to **1** and possesses a $PSn_3O_3(OH)_2$ structural motif in solution and in the solid state. The existence of the cation **6a** was recently suggested on the basis of a prominent mass cluster found in the electrospray mass spectrum of the eight-membered heterocycle *cyclo*-$[Ph_2P(OSntBu_2O)_2PPh_2](O_3SCF_3)_2$.[7]

Results and Discussion

The consecutive reaction of di-*tert*-butyltin oxide with triflic acid and diphenylphosphinic acid provided the trinuclear organotin−oxo cluster $[Ph_2P(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2](O_3SCF_3)$ (**6**) in good yield [Equation (1)].

$$(tBu_2SnO)_3 + F_3CSO_3H + Ph_2PO_2H \longrightarrow [Ph_2P(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2](O_3SCF_3)\ \mathbf{6} \quad (1)$$

Compound **6** comprises air-stable colourless crystals that are readily soluble in most common organic solvents. The ^{119}Sn NMR spectrum of **6** in $[D_3]MeCN$ reveals a singlet at $\delta = -240.4$ and a doublet at $\delta = -269.1$ with a $^2J(^{119}Sn\text{-}O\text{-}^{31}P)$ coupling constant of 134 Hz, with an integral ratio of 1:2. The ^{119}Sn chemical shifts are consistent with pentacoordinate tin atoms. The ^{119}Sn NMR spectrum of **6** in

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200300401

[D_8]toluene shows almost identical signals at δ = −243.3 and −271.9 ppm [$^2J(^{119}Sn\text{-}O\text{-}^{31}P)$ = 140 Hz], which apparently suggests that acetonitrile is not involved in strong coordination to the tin atoms. High temperature ^{119}Sn NMR measurements (T = 90 °C) in [D_8]toluene indicate the high configurative stability of **6**, which contrasts with the tendency of [$Ph_2Si(OSn{t}Bu_2)_2O{\cdot}{t}Bu_2Sn(OH)_2$] (**1**) to undergo a reversible dissociation in chloroform into [$Ph_2Si(OSn{t}Bu_2)_2O$], ($t$$Bu_2SnO)_3$ and water, even at room temperature.[9] The ^{31}P NMR spectrum of **6** in [D_3]MeCN shows a signal at δ = 33.1 ppm with unresolved tin satellites [$^2J(^{31}P\text{-}O\text{-}^{119/117}Sn)$ = 136 Hz]. The electrospray mass spectrum (positive mode, cone voltage 20 V) of **6** displays two intense mass clusters at 965.2 and 700.1 Da that were unambiguously assigned to the organotin cations $[Ph_2P(OSn{t}Bu_2)_2O{\cdot}{t}Bu_2Sn(OH)_2]^+$ (**6a**) and $[Ph_2P(OSn{t}Bu_2)_2O]^+$ (**6b**), respectively. A conductivity measurement (372 μS cm^{-1}; c = 3.33 mmol·L^{-1}, Λ = 112 S cm^2 mol^{-1}) of **6** confirms the electrolytic dissociation into **6a** and triflate anions in MeCN.[14]

Solid-State Structure of $[Ph_2P(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2][O_3SCF_3]$ (6)

The molecular structure of $[Ph_2P(OSn{t}Bu_2)_2O{\cdot}{t}Bu_2Sn(OH)_2](O_3SCF_3)$ (**6**) is shown in Figure 1; selected bond lengths and angles are collected in Table 1. Like its closely related stannasiloxane derivatives [$Ph_2Si(OSn{t}Bu_2)_2O{\cdot}{t}Bu_2SnX_2$] [X = OH (**1**),[9] F (**5**)[13]], the [$PSn_3O_3(OH)_2$] structural motif of **6a** is almost planar, the largest deviation from the plane being 0.033(3) Å. All three tin atoms show slightly distorted trigonal bipyramidal configurations [geometrical goodness[15] ΔΣ(θ) = 89.0° for Sn(1), 89.6° for Sn(2), 90.1° for Sn(3)], in which two carbon atoms and an oxygen atom occupy the equatorial positions [C(10), C(20) and O(1) for Sn(1); C(30), C(40) and O(1) for Sn(2); C(50), C(60) and O(1) for Sn(3)]. The axial positions are occupied by O(2) and O(4) for Sn(1), O(3) and O(5) for Sn(2), and O(4) and O(5) for Sn(3).

The effects of the variation of E and X upon the overall geometry of the tristannoxane motif of [$Ph_2E(OSn{t}Bu_2)_2O{\cdot}{t}Bu_2Sn(X)_2$] [E = P^+, X = OH (**6a**); E = Si, X = OH (**1**); E = Si, X = F (**5**)] is shown in Table 2 and can be summarized as follows: (*i*) The Sn(1)−O(1) and Sn(2)−O(1) distances show only marginal differences. The Sn(3)−O(1) distances decrease in the order **6** > **1** > **5**. (*ii*) The Sn(1)−X(1) and Sn(2)−X(2) distances increase on going from **6** to **1** and then **5**, which is consistent with the dissociation of compound **1** in solution, as shown by variable temperature ^{119}Sn NMR spectroscopy.[9] (*iii*) The Sn(1)−O(2) and Sn(2)−O(3) distances also decrease in the order **6** > **1** > **5**. (*iv*) The geometrical goodness ΔΣ(θ)[15] of the trigonal bipyramidal configurations for Sn(1) and Sn(2), is best for compound **6**. For the Sn(3) atom there is almost no difference between compounds **1**, **5** and **6** .

Consistent with the ^{119}Sn chemical shifts in solution and the molecular structure established by X-ray diffraction, the ^{119}Sn MAS NMR spectrum of **6** shows two signals at δ =

−246.1 and −277.9 with an integral ratio of 39:61 and accompanying sets of spinning sidebands. The sets of spinning sidebands were used to perform a tensor analysis according to the method of Herzfeld and Berger;[16] the results are collected along with those of the stannasiloxane **1** in Table 3. In view of the similar molecular structures of compounds **1** and **6**, it is not surprising that the anisotropy (ζ) and asymmetry (η) parameters are also comparable. With the data at hand, it appears that the anisotropy (ζ) somewhat correlates with an increasing geometrical goodness $\Delta\Sigma(\theta)$; however, this tentative observation may be subject to revision when more examples are available for comparison. The individual P−O bond lengths of the organotin phosphinate **6** [1.493(3), 1.509(3) Å] differ only slightly.

Table 3. Selected ^{119}Sn MAS NMR parameters for **1** and **6**.

	δ_{iso} [ppm][a]	%	ζ [ppm]	η	σ_{11} [ppm]	σ_{22} [ppm]	σ_{33} [ppm]
1[9]	−265.7	33	471	0.61	−115	175	737
	−273.7	67	417	0.68	−78	207	692
6	−246.1	39	508	0.45	−123	106	755
	−277.9	61	522	0.60	−140	174	800

[a] Definitions: $\delta_{iso} = -\sigma_{iso} = -(\sigma_{11} + \sigma_{22} + \sigma_{33})/3$; $\zeta = \sigma_{33} - \sigma_{iso}$ and $\eta = \sigma_{22} - \sigma_{11}/\sigma_{33} - \sigma_{iso}$ where σ_{11}, σ_{22} and σ_{33} are the principal tensor components on the shielding anisotropy (SA), sorted as follows $\sigma_{33} - \sigma_{iso} > \sigma_{11} - \sigma_{iso} > \sigma_{22} - \sigma_{iso}$.

In the crystal lattice, the cations **6a** are associated with the triflate anions through O(4)-H(4)···O(6) and O(5)-H(5)···O(7a) hydrogen bonds giving rise to the formation of an infinite chain (symmetry operation: $a = -x, y - 1/2, -1/2 - z$), as shown in Figure 2. The O(4)···O(6) and O(5)···O(7a) distance of 2.789(6) and 2.791(6) Å, respectively, and the position of the corresponding OH stretching vibration ν(OH) at 3338 cm^{-1} in the IR spectrum of **6** are indicative of medium-strength hydrogen bonding.[17] The fact that the triflate anions are not involved in coordination to tin atoms is also reflected by IR spectroscopy. Generally, for the free triflate anion (C_{3v} symmetry) the asymmetric SO_3 stretching vibration $\nu_{as}(SO_3)$ is doubly degenerate, whereas in the presence of sufficiently large cation−anion interactions the axial symmetry is diminished (C_s symmetry), and the asymmetric SO_3 stretching vibration $\nu_{as}(SO_3)$ splits into two components.[18] Thus, for $[Ph_2P(OSn\textit{t}Bu_2)_2O{\cdot}\textit{t}Bu_2Sn(OH)_2](O_3SCF_3)$ (**6**), the non-coordinating triflate anion gives rise to only one IR absorption (KBr) for the asymmetric SO_3 stretching vibration $\nu_{as}(SO_3)$ at 1285 cm^{-1}. The symmetric SO_3 stretching vibration $\nu_s(SO_3)$ is found at 1034 cm^{-1}.

Charge Distribution in $[Ph_2E(OSn\textit{t}Bu_2)_2O{\cdot}\textit{t}Bu_2Sn(OH)_2]$ [E = Si (1), P^+ (6a)]

Considering the structural similarity of $[Ph_2E(OSn\textit{t}Bu_2)_2O{\cdot}\textit{t}Bu_2Sn(OH)_2]$ with E = Si (**1**) and E = P^+ (**6a**), the question arises as to where the positive charge of **6a** is situated. In an effort to answer this question a natural population analysis (NPA)[19] was performed at the B3LYP/LANL2DZ level of theory and the atomic charges are given in Scheme 2. Somewhat unexpected, the atomic charges of the Si and P atoms are almost alike at about 2.2 (variation < 0.1). Moreover, the atomic charges of all Sn atoms are almost identical at about 2.5 for both compounds (variation < 0.05). However, this result is essentially in agreement with the results obtained by single-crystal X-ray structure determination. In compound **1** the Sn(1)−O(2) and Sn(2)−O(3) bond lengths of 2.020(2) and 2.018(3) Å, respectively, are somewhat shorter than the corresponding values of 2.192(3) and 2.200(3) Å in **6a**. The Sn−O bonding situation is reversed for the Sn(1)−X(1) and Sn(2)−X(2) bond lengths [2.261(3) and 2.264(3) Å in **1**; 2.138(2) and 2.134(3) Å in **6a**]. A minor difference of +0.26 is found for the atomic charges of the two E−O oxygen atoms (E = Si, P). A more significant change of +0.48 is observed for the group atomic charges of the two phenyl groups on going from **1** to **6a**. The remainder of the atomic charge difference of +0.24 is almost equally divided over the six *tert*-butyl groups (variation per *tert*-butyl group smaller than 0.05). Thus, it appears that the largest fraction of the positive charge in **6a** is delocalised over the polarisable phenyl groups. Apparently, this observation provides a reasonable explanation for the absence of strong cation−anion interactions in **6**, which is in marked contrast to the related eight-membered heterocycle *cyclo*-$[Ph_2P(OSn\textit{t}Bu_2O)_2PPh_2](O_3SCF_3)_2$.[7]

Experimental Section

General Remarks: (tBu$_2$SnO)$_3$ was prepared according to the literature.[20] F_3CSO_3H and Ph_2PO_2H were purchased from Aldrich. The solution NMR spectra (conc. 50 mg/300 μL; 25 °C) were measured using a Jeol Eclipse Plus 400 spectrometer [at 399.78 MHz (^{1}H) 100.54 (^{13}C) 161.84 (^{31}P) 149.05 (^{119}Sn)] and were referenced against $SiMe_4$, aqueous H_3PO_4 (90%) and $SnMe_4$. The solid-state NMR spectra were measured using the same instrument equipped with a 4 mm MAS probe. Crystalline $NH_4H_2PO_4$ (δ = 0.95 ppm) and c-Hex$_4$Sn (δ = −97.35 ppm) were used as secondary references. The ^{119}Sn MAS NMR spectra were obtained using cross polarization (contact time 5 ms, recycle delay 10s). The isotropic chemical shifts δ_{iso} were determined by comparison of two acquisitions measured at sufficiently different spinning frequencies. The tensor analyses were performed using the method of Herzfeld and Berger[16] implemented in DmFit 2002.[21] The IR spectrum was recorded using a BioRad FTIR spectrometer. The ESMS spectrum was obtained with a Platform II single quadrupole mass spectrometer (Micromass, Altrincham, UK) using an acetonitrile mobile phase. MeCN solutions (0.1 mM) were injected directly into the spectrometer with a Rheodyne injector equipped with a 50 μL loop. A Harvard 22 syringe pump delivered the solutions to the vaporisation nozzle of the electrospray ion source at a flow rate of 10 μL min^{-1}. Nitrogen was used both as a drying gas and for nebulization with flow rates of approx. 200 mL min^{-1} and 20 mL min^{-1} respectively. The pressure in the mass analyser region was usually about 4×10^{-5} mbar. The conductivity measurement was performed using a CDM80 Conductivity Meter equipped with a CDC104 Conductivity Cell (Radiometer Copenhagen, DK) at 25 °C. Microanalysis was carried out by CMAS, Belmont, Australia.

[Ph$_2$P(OSntBu$_2$)$_2$O·tBu$_2$Sn(OH)$_2$](O$_3$SCF$_3$) (6): F_3CSO_3H (150 mg, 1.00 mmol) was added to a suspension of (tBu$_2$SnO)$_3$ (747 mg, 1.00 mmol) in MeCN (20 mL) whilst stirring at room temperature. After 10 min, solid Ph_2PO_2H (218 mg, 1.00 mmol) was added, and the mixture heated at 85 °C for 12 h. The solvent was removed in vacuo, to yield a white powder, which was recrystallized from $CHCl_3$/MeCN to give colourless crystals of **6** [959 mg, 0.86 mmol, 86%; m.p. 220 °C (dec)].

^{119}Sn NMR ([D$_3$]MeCN): δ = −240.4 (1Sn), −269.1 [d, 2Sn; ^2J(^{119}Sn-O-^{31}P) = 134 Hz] ppm. ^{119}Sn NMR ([D$_8$]toluene): δ = −243.3 (1Sn), −271.9 [d, 2Sn; ^2J(^{119}Sn-O-^{31}P) = 140 Hz] ppm. ^{31}P NMR ([D$_3$]MeCN): δ = 33.1 [^2J(^{31}P-O-$^{119/117}$Sn) = 136 Hz] ppm. ^{13}C NMR ([D$_3$]MeCN): δ = 133.0, 131.0, 129.9, 127.4, 119.2, 41.8, 38.9, 28.7, 28.5 ppm. ^{1}H NMR ([D$_3$]MeCN): δ = 8.00−7.50 (m,

IR (KBr): $\tilde{\nu}$ = 3338 br, 3064 w, 2976 m, 2947 m, 2853 s, 1466 m, 1441 w, 1396 w, 1366 w, 1285 s, 1253 s, 1224 w, 1166 s, 1131 vs, 1048 s, 1034 m, 1014 m, 998 w, 941 w, 802 w, 756 w, 721 m, 698 w, 665 w, 638 m, 548 m, 532 m, 448 m cm^{-1}. $C_{37}H_{66}F_3O_8PSSn_3$ (1115.16): calcd. C 39.85, H, 5.97; found C 39.82, H 6.00. ES MS (positive mode, cone voltage 20 V): *m*/*z* = 700.1 $[Ph_2P(OSntBu_2)_2O]^+$, 965.2 $[Ph_2P(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2]^+$. Conductivity measurement (MeCN; *c* = 3.33 mmol·L^{-1}): 372 μS cm^{-1}.

X-ray Crystallographic Study: Single crystals of $[Ph_2P(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2](O_3SCF_3)$ (**6**) suitable for X-ray crystallography were obtained by slow evaporation of a CH_2Cl_2/*n*-hexane solution. Data and structure solution at *T* = 293(2) K: $C_{37}H_{66}F_3O_8PSSn_3$, (1115.00), orthorhombic, $P2_12_12_1$, crystal dimensions: 0.20 × 0.25 × 0.45 mm^3, *a* = 10.7376(6), *b* = 17.9769(10), *c* = 25.4598(14) Å, *V* = 4914.5(5) $Å^3$, *Z* = 4, $\rho_{calcd.}$ = 1.507 Mg·m^{-3}, *F*(000) = 2240, μ = 1.640 mm^{-1}. Intensity data were collected on a Bruker SMART Apex CCD diffractometer fitted with Mo-K_α radiation (graphite crystal monochromator, λ = 0.71073 Å) to a maximum of θ_{max} = 27.52° via ω scans (completeness 99.6% to θ_{max}). Data were reduced and corrected for absorption using the programs SAINT and SADABS.[22] The structure was solved by direct methods and difference Fourier synthesis using SHELX-97 implemented in the program WinGX 2002.[23] Full-matrix least-squares refinement on F^2 using all data was carried out with anisotropic displacement parameters applied to all non-hydrogen atoms. The hydrogen atoms H(4) and H(5) were located in the Fourier density map and refined isotropically, whereas all other hydrogen atoms were included in geometrically calculated positions using a riding model and were refined isotropically. One phenyl group is disordered over two positions with occupancies of 0.8 [C(80) to C(85)] and 0.2 [C(80′) to C(85′)], which were refined as regular hexagons (AFIX66). One carbon atom of a *tert*-butyl group is also disordered and was refined over two sites with occupancies of 0.7 C(61) and 0.3 C(61′). The weighting scheme employed was of the type $w = [\sigma^2(F_o^2) + (0.0404\ P)^2 + 0.6740\ P]^{-1}$ where $P = (F_o^2 + 2\ F_c^2)/3$. R_1 = 0.0284 for 10422 [$I > 2\sigma(I)$] reflections and wR_2 = 0.0692 for 11216 independent reflections; GooF = 1.035. The Flack parameter was −0.002(17).[24] The max. and min. residual electron densities were 0.900/−0.233 e·$Å^{-3}$. CCDC-213484 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

MO Calculation: Single point calculations based on the coordinates of the molecular structures of $[Ph_2E(OSntBu_2)_2O{\cdot}tBu_2Sn(OH)_2]$ with E = Si (**1**) and E = P^+ (**6a**) were performed at the B3LYP/LANL2DZ level of theory using Gaussian 98.[25] Natural bond orbital charges were obtained using NBO 5.0.[26]

Acknowledgments

The Australian Research Council (ARC) and the Deutsche Forschungsgemeinschaft (DFG) are thanked for financial support. Dr. Jonathan White (The University of Melbourne) is gratefully acknowledged for the X-ray crystallography data collection.

Keywords: Ligand design / Phosphanes / Coordination modes / Structure elucidation / Transition metals

A series of easily accessible diphosphane compounds **1**–**4**, based on bisphenol A derived backbones, has been prepared. A straightforward two-step synthetic route has been employed to obtain these new ligands in good yields from cheap starting materials. Molecular structures for both compound **2** and its oxidized form (**5**·H_2O) have been determined and are discussed in detail. The coordination of ligand **2** to palladium, platinum, and rhodium precursors has been studied by NMR spectroscopy as well as X-ray crystallography. The molecular structures of the face-to-face dimeric species [{$PdCl(CH_3)$(**2**)}$_2$] (**6**), [{$PtCl_2$(**2**)}$_2$] (**7**), and [{$RhCl(CO)$(**2**)}$_2$] (**8**) are described in detail.

Introduction

The coordination chemistry of diphosphane ligands with a variety of transition metals has been widely studied and several types of coordination modes have been established over the years.[1,2] Numerous families of novel ligands have been synthesized,[3] with emphasis on *cis*-chelation to form monomeric metal complexes. As well as designing ligands based on desired behaviour towards transition metals and the catalytic activity of the resultant systems, the approach of modular design and availability from cheap resources has gained significant importance.

We have chosen Bisphenol A as a somewhat neglected yet promising starting material for the synthesis of a new ligand class.[4,5] A wide range of these bisphenols is commercially available at low price since they are used as components in epoxy resins. Generic structures are easily available by simple acid catalyzed condensation of a ketone with two molecules of a phenol.[6] Based on these versatile compounds we employed a straightforward two-step synthetic route to novel P-containing compounds (Scheme 1).

In the first step, the phenol groups were protected by methylation with iodomethane. Subsequently, selective *ortho*-lithiation of both phenyl rings was followed by reaction with the phosphane source $ClPPh_2$. Filtration and evaporation of the solvent followed by washing of the crude product with methanol afforded the pure compounds in overall yields of 40−50%. Using this method, we obtained compounds **1**−**3** based on derivatives of the Bisphenol A backbone. Furthermore, the silicon derivative **4** was synthesized in good yield starting from 4-bromoanisole and dichlorodimethylsilane via a modified two-step route. Compounds **1**−**4** were characterized by ^1H, ^{13}C, and ^{31}P NMR spectroscopy, as well as by elemental analysis. We have previously reported this synthetic route, focussing on the synthesis and catalytic applicability of a ligand derived from 1,2-diphenylbenzene as the backbone.[5]

We were able to obtain single crystals, suitable for X-ray analysis, for compounds **1**−**3**, by recrystallization of the pure solids from hot 1-propanol or hot acetonitrile. Only the molecular structure of compound **2** is depicted in Figure 1, while selected bond lengths and bond angles for all three compounds are summarized in Table 1.

Because of the rotational freedom of the aromatic rings in the backbone, the diphenylphosphane groups are not constrained to any particular mutual orientation. Compound **2** shows approximate C_2 symmetry. The bond distances between the *ipso*-carbons of the backbone with the phosphorus atoms are normal at around 1.84 Å [P^1-C^3 1.840(2) Å and P^2-C^9 1.845(2) Å]. The central-carbon (C^{15}) of the backbone is clearly tetrahedrally surrounded. The through-space P^1-O^1 and P^2-O^2 distances are around 2.8−2.9 Å. The intramolecular P−P distance is 9.7664(8) Å.

To obtain the corresponding diphosphane oxide, we reacted compound **2** with hydrogen peroxide to yield compound **5**. In the ^{31}P NMR spectrum a singlet was observed at $\delta = 27.7$ ppm which is a typical value for a phosphane oxide.[7] We were able to obtain single crystals, suitable for

X-ray analysis, from a THF solution. The molecular structure is depicted in Figure 2, with selected bond lengths and angles listed in Table 2.

The structure of compound **5** represents the diphosphane oxide of **2** but with an additional molecule of water present. There is hydrogen-bonding between the oxo groups of compound **5** and the hydrogen atoms of the water molecule.[8] The O−H···O(P) contacts are almost equivalent with $H^{\#}-O(P)$ bond lengths of 1.99(5) Å ($H^{\#}-O^3$) and 2.01(5) Å ($H^{\#}-O^4$), which are much smaller than the calculated sum of the van der Waals radii of 2.72 Å. The $O^5-O(P)$ distances are 2.835(7) Å (O^3-O^5) and 2.822(7) Å (O^4-O^5) and the $O^5-H^{\#}-O(P)$ angles are 166(5)° (P^1) and 168(6)° (P^2), respectively. Furthermore, the orientation of the two phosphorus atoms is dramatically altered relative to the structure of the free ligand (vide supra). Due to the template effect of the water molecule, both P-atoms are located on the same side of the molecule with the oxygen atoms pointing towards one another. This leads to a decreased P^1-P^2 distance of 6.579(2) Å. The bond lengths between the phosphorus and carbon atoms of the ligand backbone (P^1-C^3 and P^2-C^9) are slightly shorter than the corresponding distances in compound **2**, due to a decrease of electron density on the phosphorus atoms in the oxidized state. The P−O bond lengths found for both phosphane oxide moieties, 1.491(4) Å (P^1-O^3) and 1.492(5) Å (P^2-O^4), are similar to those found in triphenylphosphane oxide hemihydrate[8] and tris(*p*-tolyl)phosphane oxide[9] but slightly lower in comparison with the mono oxide of

BINAP.[10] We are currently investigating the inclusion of other molecules capable of forming hydrogen bonds in order to form three-dimensional networks. The coordination behaviour of the phosphane oxide, which is still a weakly coordinating group,[11] has also been studied.

We were interested in the coordination of the novel diphosphane compounds to various transition metals and, in particular, whether the chelate ring size of 9 atoms (including the two P-atoms) would have implications for the mode of coordination and if bidentate mononuclear complexes would be formed.

Rauchfuss et al. have already investigated the monophosphane (diphenylphosphanyl)anisole and they concluded that coordination to a metal, such as palladium and platinum, took place only through the phosphorus.[12] In order to study the coordination chemistry of the new family of BPphos ligands to Pd, Pt, and Rh, we used ligand **2** as a representative example. Marty et al. have reported some experimental evidence for the formation of a monomeric, *trans*-coordinated $PdCl_2$ complex using 3,3′-oxybis[(diphenylphosphanyl)methyl]benzene, which is structurally related to compounds **1**−**4**.[13]

From the reaction of **2** with [$PdClCH_3$(cod)] as a starting material, only a singlet at δ = 25.0 ppm was observed in the ^{31}P NMR spectrum. In the ^1H NMR spectrum, a broad triplet was present at δ = −0.05 ppm and a singlet at δ = 3.8 ppm was seen in the ^{13}C NMR spectrum. These observations are clear indications that a *trans*-coordinated species is present, either monomeric or dimeric. For monomeric *trans*-coordinated [$PdClCH_3$(Xantphos)] complexes, Zuideveld et al. have reported proton methyl signals at around δ = −0.2 ppm.[14] Upon slow evaporation of the deuterated solvent, yellow block-shaped single crystals, suitable for X-ray analysis, were obtained for this compound. The crystallographic study undertaken, indicated formation of the dimeric macrocyclic complex **6** which did indeed display a *trans*-coordination for each of the two phosphorus atoms and two bridging palladium atoms. The molecular structure of complex **6** is depicted in Figure 3, while Table 3 contains selected bond lengths and bond angles.

The complex is centrosymmetric and the geometry around the palladium atoms is distorted square planar, as indicated by the corresponding angles listed in Table 2. The P^1-Pd-P^2 angle is 172.94(3)°, while the $C^1-Pd^1-Cl^1$ angle is 171.64(13)°. The Pd−P bond lengths of 2.3250(9) Å ($Pd-P^1$) and 2.3248(9) Å ($Pd-P^2$) are typical for triarylphosphanes[15,16] as are the lengths of the palladium to chlorine and palladium to methyl bonds.[17] The P^1-P^{2a} distance was found to be 7.4470(13) Å. Other binuclear palladium complexes with a face-to-face structure that have been described in literature most often have two chlorine ligands coordinated to the metal center instead of one

chlorine and one methyl ligand.[18,19] Davies et al. have described the face-to-face dimer [$Pd_2Cl_2(CH_2NO_2)$(μ-dmpm)$_2$] (dmpm = $Me_2PCH_2PMe_2$). The bond lengths between the palladium and the chlorine or the carbon atom of the nitromethyl group turned out to be slightly shorter than in the case of complex **6**, due to the electronic withdrawing effect of the nitro unit.[20] Only very recently the group of James published the synthesis and structural characterization of the Pd_2Cl_4 derivative of dmpm.[20b] Kemmitt and co-workers quite recently reported various dimeric palladium-diphosphane complexes with a chlorine and a phenyl group attached to the palladium atoms.[16]

In order to verify if the formation of face-to-face dimeric complexes is always favoured, regardless of the transition metal, we decided to study the complexation of ligand **2** with a platinum precursor. After reaction with [$PtCl_2(CH_3CN)_2$], an off-white solid was obtained. After dissolving this compound in acetone and slow evaporation of the solvent, one product could be isolated as yellow single crystals in good yield. The ^{31}P NMR spectrum of this compound showed a singlet at δ = 15.8 ppm, flanked by ^{195}Pt-satellites, and a coupling constant J_{Pt-P} of 2705 Hz. This clearly indicates a *trans*-coordination of two phosphorus atoms.[21] These block-shaped crystals turned out to be suitable for X-ray analysis. The molecular structure for complex **7** is depicted in Figure 4. Selected bond lengths and bond angles are listed in Table 4.

Pt^1-Pt^{1a}	8.6391(5)		

Like the palladium complex **6**, the molecular structure of complex **7** also turned out to be dimeric and centrosymmetric. The geometry around the platinum atoms is distorted square planar, with a P^1-Pt-P^2 angle of 176.78(7)° and a $Cl^1-Pt-Cl^2$ angle of 171.77(7)°. The geometry around the central atom C^{15} of the ligand backbone is nearly perfectly tetrahedral, as indicated by the angle of 108.9(7)° for both phenyl rings. Interestingly, the P^1-P^{2a} distance of 8.627(3) Å is larger than in the palladium-dimer **6**. The P−Pt and Cl−Pt bond lengths are in their expected ranges, compared with similar structures previously reported.[22,23] Wood et al. showed that the reaction of 2,6-bis(diphenylphosphanyl)pyridine with $PtCl_2$ yielded a *cis*-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dimer. When the chlorine-ligands were substituted for iodine-ligands, however, the phosphorus atoms were coordinated in a *trans*-fashion.[24]

To further understand the formation of these face-to-face dimers, we chose the rhodium precursor [{Rh(μ-Cl)$(CO)_2$}$_2$]. Complexes prepared from this metal source normally exhibit a *trans*-coordination for the phosphorus atoms. After reaction of this rhodium species with ligand **2**, a doublet was observed in the ^{31}P NMR spectrum at δ = 23.7 ppm, with a coupling constant J_{Rh-P} of 128.3 Hz. This value is typical of those seen in rhodium diphenylphosphane complexes.[25] In the carbonyl region of the IR spectrum (ATR-mode) obtained from the solid product, the CO-stretching vibration was present at ν_{CO} = 1976 cm^{-1}. This is in good agreement with the value of ν_{CO} = 1974 cm^{-1} reported for [RhCl(CO){P(*o*-An)Ph_2}] (An = anisole).[26] Compared with the value of ν_{CO} = 1982 cm^{-1} found for [RhCl(CO){$PPh_2(C_6F_5)$}][27] and ν_{CO} = 1980 cm^{-1} for [Rh(Cl)(CO)$(PPh_3)_2$][28], the value found for our Rh complex is slightly low. *Note:* Moloy and Petersen have touched upon the discrepancy arising in literature with respect to the CO stretching frequency for [Rh(Cl)(CO)$(PPh_3)_2$]. Their own experiments showed a single band at ν_{CO} = 1965 cm^{-1} in CH_2Cl_2.[29] The value of 1976 cm^{-1} demonstrates that the ligands from the BPphos family are slightly more basic than the aforementioned two ligand systems. However the value is signifcantly higher than that found for Rh(Cl)(CO) complexes with alkyldiarylphosphanes such as those described by Zhang et al.[30] and by the group of Dilworth (ν = 1957 cm^{-1}).[31]

By slow diffusion of acetonitrile into a dichloromethane solution of the compound, single crystals could be grown that were suitable for an X-ray crystallographic study. The molecular structure for centrosymmetric complex **8** is shown in Figure 5. Similar to the Pd and Pt complexes, a face-to-face dimeric structure can be observed. Selected bond lengths and bond angles are listed in Table 5.

The geometry around the rhodium atoms is distorted square planar, with a P−Rh−P angle of 171.01(3)° and a Cl−Rh−C(O) angle of 176.99(7)°. These distances are in the expected range with an average Rh−P bond length of 2.32 Å. The Rh−Cl and Rh−C(O) bond lengths are 2.3795(5) Å and 1.810(2) Å, respectively. The C−O distance is typical at 1.145(2) Å.[30−34] The P^1-P^{2a} distance of 8.8150(12) Å as well as the corresponding Rh−Rh distance of 9.0005(11) Å are in the range found for the palladium and platinum complexes.

Many *trans*-[RhCl(CO)] complexes with (di)phosphane ligands have been described in the literature, yet most of these systems are solely mononuclear. Relatively few examples are known where a dimeric compound has been formed exclusively and subsequently structurally characterized by X-ray crystallography.[35−39]

In summary, we have described the easy synthesis of a new class of diphosphane ligands based on commercially available, cheap raw materials derived from Bisphenol A and in good overall yields. In addition to NMR spectroscopy, X-ray crystallography has been used to study the structural differences between compound **2** and its oxidised form, **5**. In the structure of the latter compound, water acts as a template orientating both phosphorus-atoms to the same side of the molecule in the same direction. Complexation studies undertaken with ligand **2** yielded face-to-face dimeric macrocycles with palladium, platinum and rhodium, as was shown by NMR spectroscopy as well as X-ray crystallography.

We are currently investigating the options available for modifying the ligand backbone to further control and enforce a certain orientation of the phosphane-moieties as well as the modification of these ligands in order to gain access to chelating variants.

Experimental Section

Chemicals were purchased from Aldrich, Acros, and Merck and used as received. All preparations were carried out under an argon

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

atmosphere using standard Schlenk techniques. Solvents were distilled from sodium/benzophenone (THF, diethyl ether, toluene, hexanes, and ethanol) or calcium hydride (CH_2Cl_2 and $CDCl_3$) prior to use. $[PdCl_2(cod)]$,[40] $[PdClMe(cod)]$[41] and $[PtCl_2(cod)]$[42] were synthesized according to literature procedures. All glassware was dried by heating under vacuum. The NMR spectra were recorded on a Varian Mercury 400 spectrometer (^1H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$). Chemical shifts are given in ppm referenced to the deuterated solvent (^1H, $^{13}C\{^1H\}$) or 85% H_3PO_4 ($^{31}P\{^1H\}$).

2,2-Bis(4-methoxyphenyl)propane (A): This is a modification of the literature procedure.[43] To a solution of Bisphenol A [2,2′-bis(4-hydroxyphenyl)propane] (11.48 g, 0.050 mol) in acetone (120 mL) were added K_2CO_3 (27.69 g, 0.20 mol) and CH_3I (21.69 g, 0.15 mol) as well as NBu_4I (0.88 g, 2.38 mmol). The heterogeneous mixture was stirred for 16 h under reflux. The suspension was filtered through celite and poured into a mixture of diethyl ether (100 mL) and a 15 w% aqueous KOH solution (100 mL). The organic phase was further washed with saturated brine (100 mL) and water (50 mL) after which $MgSO_4$ was added and the organic phase stirred for about 10 h. After filtration through Celite the solvent was removed in vacuo and ethanol (40 mL) was added to the remaining oil. After stirring, the ethanol was removed in vacuo to yield a pure off-white powder (9.44 g, 36.8 mmol) (73%). ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = 1.65 (s, 6 H, CCH_3), 3.79 (s, 6 H, OCH_3), 6.81 (d, ^1J = 8.8 Hz, 4 H, *m*-H^2), 7.15 (d, ^1J = 8.8 Hz, 4 H, *o*-H^1) (Numbering scheme see Figure 6). ^{13}C NMR (100 MHz, $CDCl_3$, 300 K, ppm): δ = 31.1, 41.6, 55.2, 113.2, 127.7, 143.1, 157.4.

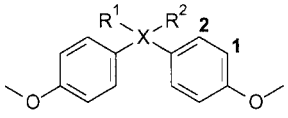

Figure 6. Numbering scheme for protons H^1 and H^2 of compounds **A**−**D**

1,1-Bis(4-methoxyphenyl)cyclohexane (B): This is a modification of the literature procedure.[44] Starting from Bisphenol *Z* [1,1-bis(4-hydroxyphenyl)cyclohexane] (28.8 g, 0.11 mol), compound **B** was obtained as a white crystalline solid, using the same procedure as described for **A**. Yield 83.5% (27.7 g, 93.5 mmol). ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = 1.55 (m, 6 H, *m*-,*p*-CH_2, *c*-C^6), 2.23 (m, 4 H, *o*-CH_2, *c*-C^6), 3.77 (s, 6 H, OCH_3), 6.81 (d, ^1J = 8.8 Hz, 4 H, *m*-H^2), 7.18 (d, ^1J = 8.8 Hz, 4 H, *o*-H^1). ^{13}C NMR (100 MHz, $CDCl_3$, 300 K, ppm): δ = 22.9, 26.4, 37.4, 45.0, 55.1, 113.4, 128.0, 141.0, 157.1.

2,2-Bis(4-methoxyphenyl)ethylbenzene (C): This is a modification of the literature procedure.[45] Starting from Bisphenol AP {[2,2-bis(4-hydroxyphenyl)ethyl]benzene} (20.0 g, 68.9 mmol), compound **C** was obtained as a pure off-white powder, using the same procedure as described for **A**. Yield 64% (13.92 g, 43.7 mmol). ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = 2.14 [s, 6 H, $C(CH_3)$], 3.79, (s, 6 H, OCH_3), 6.79 (d, ^1J = 8.8 Hz, 4 H, H^2), 7.00 (d, ^1J = 8.8 Hz, 4 H, H^1), 7.09 (m, 2 H, *o*-CH, Ph), 7.20 (m, 1 H, *p*-CH, Ph), 7.26 (m, 2 H, *m*-CH, Ph). ^{13}C NMR (100 MHz, $CDCl_3$, 300 K, ppm): δ = 30.7, 55.2, 113.1, 125.8, 127.8, 128.6, 129.7, 141.5, 157.6.

Bis(4-methoxyphenyl)dimethylsilane (D): This is a modification of the literature procedure.[46] 4-Bromoanisole (5.79 g, 0.031 mmol) was dissolved in THF (100 mL) and the solution was cooled to −78 °C whereupon *n*BuLi (2.5 M solution in hexanes) (12.4 mL, 31.0 mmol) was added dropwise by syringe. The reaction mixture was stirred for 1 h followed by addition of $SiCl_2(CH_3)_2$ (2.0 g, 31.0 mmol) by syringe. The reaction mixture was allowed to warm up to room temp. and stirring was continued for about 10 h. Solvents were removed in vacuo and the crude product was dissolved in CH_2Cl_2 (30 mL). Washing with distilled water (40 mL) afforded a turbid white organic layer. The organic phase was separated and the solvent removed in vacuo to leave a yellow oil. Upon addition of hexanes (25 mL), a brown precipitate was formed. The solution was isolated and dried with $MgSO_4$. After filtration and subsequent removal of solvent, an off-white solid was obtained. Yield 71% (3.00 g, 22.0 mmol). ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = 0.54 [s, 6 H, $Si(CH_3)$], 3.83 (s, 6 H, OCH_3), 6.93 (d, ^1J = 8.8 Hz, 4 H, H^2), 7.48 (d, ^1J = 8.8 Hz, 4 H, H^1). ^{13}C NMR (100 MHz, $CDCl_3$, 300 K, ppm): δ = −2.0, 55.0, 113.5, 129.4, 135.6, 155.0. 160.4.

2,2-Bis[(3-diphenylphosphanyl-4-methoxy)phenyl]propane (1): TMEDA (12.95 g, 0.11 mol) was added to *n*BuLi (2.5 M solution in hexanes) (44.6 mL, 0.11 mol). At −15 °C a solution of **A** (13.29 g, 0.052 mol) in diethyl ether (75 mL) was added dropwise over a period of 1.5 h. The mixture was allowed to slowly warm up to room temp. and was stirred for about 10 h to yield a yellow suspension. At 0 °C $ClPPh_2$ (24.6 g, 0.11 mol) in hexanes (30 mL) was added dropwise over a period of 1 h. Solvents were removed in vacuo and CH_2Cl_2 (60 mL) was added together with saturated brine (50 mL). The organic phase was separated and dried with $MgSO_4$. After filtration through celite, the solvents were removed in vacuo to yield a pink oil that solidified on standing for about 10 h at room temp. under argon. Ethanol (40 mL) was added to give an orange solution and a white precipitate. The solid was washed with ethanol, filtered, and dried. Yield 54% (17.46 g, 28.1 mmol). ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = 1.24 (s, 6 H, CCH_3), 3.73 (s, 6 H, OCH_3), 6.40 (dd, ^1J = 5.2, ^2J = 2.4 Hz, 2 H, H^1), 6.73 (dd, ^1J = 8.8, ^2J = 4.8 Hz, 2 H, H^2), 7.04 (dd, ^1J = 8.8, ^2J = 2 Hz, 2 H, H^3), 7.24 (m, 20 H, PPh_2) (Numbering scheme see Figure 7). ^{13}C NMR (100 MHz, $CDCl_3$, 300 K, ppm): δ = 30.3 [$C(CH_3)_2$], 41.6 [$C(CH_3)_2$], 55.7 (OCH_3), 109.5, 124.3, 128.2 (d, $J_{P,C}$ = 6.8 Hz), 128.3, 128.4, 132.4, 133.7 (d, $J_{P,C}$ = 19.8 Hz), 136.9 (d, $J_{P,C}$ = 10.7 Hz), 143.0, 159.0 (d, $J_{P,C}$ = 14.5 Hz). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 300 K, ppm): δ = −14.8 (s). $C_{41}H_{38}O_2P_2$: calcd. C 78.83, H 6.13; P, 9.92; found C 78.65, H 6.08; P, 9.98.

4 H, *o*-CH_2, *c*-C^6), 3.71 (s, 6 H, OCH_3), 6.47 (dd, ^1J = 5.6, ^2J = 2.4 Hz, 2 H, H^1), 6.72 (dd, ^1J = 8.8, ^2J = 4.8 Hz, 2 H, Ar-H^2), 6.99 (dd, ^1J = 8.8, ^2J = 2.4 Hz, 2 H, H^3), 7.24 (m, 20 H, PPh_2). ^{13}C NMR (100 MHz, $CDCl_3$, 300 K, ppm): δ = 22.7, 26.2, 37.0, 45.2, 55.6, 109.8, 125.7, 128.2, 128.3 (d, $J_{P,C}$ = 13.0 Hz), 128.8, 132.9, 133.7 (d, $J_{P,C}$ = 19.8 Hz), 137.0, 140.9, 159.0 (d, $J_{P,C}$ = −15.2 (s). $C_{44}H_{42}O_2P_2$: calcd. C 79.50, H 6.37; P, 9.32; found C 79.39, H 6.39; P, 9.31

2,2-Bis[(3-diphenylphosphanyl-4-methoxy)phenyl]ethylbenzene (3): Starting from **C** (12.4 g, 38.9 mmol), compound **3** was obtained as a white powder using the same procedure as described for compound **1**. Yield 61% (16.5 g, 23.7 mmol). ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = 1.74 (s, 3 H, CCH_3), 3.72 (s, 6 H, OCH_3), 6.33 (dd, ^1J = 5.6, ^2J = 2.4 Hz, 2 H, H^1), 6.67 (dd, ^1J = 8.8, ^2J = 4.8 Hz, 2 H, H^2), 6.81 (m, 2 H, *o*-CH, Ph), 6.91 (dd, ^1J = 8.8, ^2J = 2.4 Hz, 2 H, H^3), 7.07 (m, 3 H, *m*-,*p*-CH, Ph), 7.18 (m, 20 H, PPh_2). ^{13}C NMR (100 MHz, $CDCl_3$, 300 K, ppm): δ = 30.0, 51.2, 55.6, 109.3, 124.2 (d, $J_{P,C}$ = 13.0 Hz), 125.5, 127.6, 128.2 (d, $J_{P,C}$ = 6.8 Hz), 128.3 (d, $J_{P,C}$ = 3.1 Hz), 130.2, 133.6 (d, $J_{P,C}$ = 19.8 Hz), 134.1, 136.7 (d, $J_{P,C}$ = 10.7 Hz), 141.3, 149.0, 159.1 (d, $J_{P,C}$ = 14.5 Hz). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 300 K, ppm): δ = −15.3 (s). $C_{46}H_{40}O_2P_2$: calcd. C 80.45, H 5.87; P, 9.02; found C 80.52, H 5.76; P, 9.05.

Bis[(3-diphenylphosphanyl-4-methoxy)phenyl]dimethylsilane (4): Starting from **D** (3.00 g, 0.011 mol), compound **4** was obtained as a white powder using the same procedure as described for compound **1**. Yield 65% (4.58 g, 7.20 mmol). ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = 0.09 [s, 6 H, $Si(CH_3)$], 3.75 (s, 6 H, OCH_3), 6.69 (dd, ^1J = 8.0, ^2J = 4.4 Hz, 2 H, H^1), 6.81 (dd, ^1J = 8.0, ^2J = 4.4 Hz, 4 H, H^2, H^3), 7.28 (m, 20 H, PPh_2). ^{13}C NMR (100 MHz, $CDCl_3$, 300 K, ppm): δ = −2.6, 55.5, 109.7, 124.7, 128.2 (d, $J_{P,C}$ = 6.8 Hz), 128.5, 129.5, 133.8 (d, $J_{P,C}$ = 19.8 Hz), 136.3, 136.7 (d, $J_{P,C}$ = 9.9 Hz), 139.5, 161.9 (d, $J_{P,C}$ = 15.9 Hz). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 300 K, ppm): δ = −16.1 (s). $C_{40}H_{38}O_2P_2Si$: calcd. C 74.98, H 5.98; P, 9.67; found C 75.06, H 5.93; P, 9.63.

Bis(2,2′-methoxy-5,5′-cyclohexyl)diphenylphosphane Oxide (5): Ligand **2** (0.65 g, 0.98 mmol) was dissolved in CH_2Cl_2 (25 mL) and H_2O_2 (30 wt% aqueous solution) (0.20 mL, 1.96 mmol) in H_2O (20 mL) was added dropwise at 0 °C after which the two-phase system was stirred for about 10 h at room temp. The organic layer was washed with 0.1 M NaOH solution (20 mL) and water (20 mL). After drying with $MgSO_4$ and subsequent filtration, the solvent was removed in vacuo to leave a white powder. Yield 85% (0.58 g, 0.83 mmol). ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = 1.46 (s, 6 H, *m*,*p*-CH_2, *c*-C^6), 2.18 (s, 4 H, *o*-CH_2, *c*-C^6), 3.55 (s, 6 H, O*C*H_3), 6.81 (dd, ^1J = 8.8, ^2J = 5.6 Hz, 2 H, H^1), 7.32 (dd, ^1J = 8.8, ^2J = 2.4 Hz, 2 H, H^2), 7.41 (dt, ^1J = 8.0, ^2J = 2.4 Hz, 8 H, *o*-CH, PPh), 7.51 (dt, ^1J = 8.4, ^2J = 1.2 Hz, 4 H, *p*-CH, PPh), 7.65 (d, ^1J = 2.4 Hz, 2 H, H^3), 7.69 (q, ^1J = 4.8 Hz, 8 H, *m*-CH, PPh). ^{13}C NMR (100 MHz, $CDCl_3$, 300 K, ppm): δ = 22.7, 26.1, 37.0, 45.3, 55.2, 111.3 (d, $J_{P,C}$ = 7.6 Hz), 128.0 (d, $J_{P,C}$ = 12.3 Hz), 131.3 (d, $J_{P,C}$ = 10.8 Hz), 132.8, 133.2, 133.9, 141.0, 158.6 (d, $J_{P,C}$ = 3.7 Hz). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 300 K, ppm): δ = 27.7 (s). $C_{44}H_{42}O_4P_2$: calcd. C 75.85, H 6.08; found C 76.04, H 6.14.

***trans,trans*-[$PdClCH_3$-2]$_2$, Complex 6:** Ligand **2** (40.2 mg, 60.5 μmol) and [$PdClCH_3$(cod)] (13.9 mg, 52.4 μmol) were dissolved in $CDCl_3$ (0.5 mL) and the solution was stirred for 2 h before the solution was analyzed by NMR spectroscopy. Single crystals were obtained by slow evaporation of the solvent from the NMR solution. ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = −0.05 (t, 6 H, PdCH_3), 1.26 (br. s, 12 H, *m*,*p*-CH_2, *c*-C^6), 1.80 (br. s, 8 H, *o*-CH_2, *c*-C^6), 3.61 (s, 12 H, OCH_3), 6.71 (d, ^1J = 8.0 Hz, 4 H, H^3), 7.04 (d, ^1J = 8.0 Hz, 8 H, H^1, H^2), 7.30 (m, 24 H, PPh_2), 7.71 (br. s, 16 H, PPh_2). ^{13}C NMR (100 MHz, $CDCl_3$, 300 K, ppm): δ = 3.8, 22.8, 26.3, 37.1, 45.1, 55.5, 110.8, 119.0, 119.2, 127.5, 129.2, 130.9, 131.6, 133.3, 135.0, 140.4, 157.9. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 300 K, ppm): δ = 25.0 (s). $C_{90}H_{90}Cl_2O_4P_4Pd_2$: calcd. C 65.78, H 5.52; found C 65.60, H 5.46.

***trans,trans*-[$PtCl_2$-2]$_2$, Complex 7:** $PtCl_2$ (170.3 mg, 640.5 μmol) was heated to reflux in acetonitrile (10 mL) until the solid had completely dissolved. Ligand **2** (425.8 mg, 640.5 μmol) was added and the mixture stirred under reflux for about 10 h. After cooling to room temp., the solvent was evaporated in vacuo to leave a yellow powder. Single crystals were obtained from acetone, by slow evaporation of the solvent. ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = 1.23 (m, 12 H, *m*,*p*-CH_2, *c*-C^6), 1.71 (br. s, 8 H, *o*-CH_2, *c*-C^6), 3.63 (s, 12 H, OCH_3), 6.67 (d, ^1J = 8.0 Hz,4 H, H^1), 7.00 (br. s, 4 H, H^2), 7.09 (d, ^1J = 8.8 Hz, 4 H, H^3), 7.37 (br. m, 24 H, PPh_2), 7.73 (q, ^1J = 5.6 Hz, 16 H, PPh_2). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 300 K, ppm): δ = 15.8 (s, J_{Pt-P} = 2705 Hz). $C_{88}H_{84}Cl_4O_4P_4Pt_2$: calcd. C 56.78, H 4.55; found C 56.65, H 4.45.

***trans,trans*-RhCl(CO)-2, Complex 8:** [$RhCl(CO)_2$]$_2$ (170.3 mg, 640.5 μmol) and ligand **2** (425.8 mg, 640.5 μmol) were dissolved in CH_2Cl_2 (10 mL) and the mixture was stirred for 2 h. Evaporation of the solvent in vacuo yielded a yellow solid. Single crystals were obtained by slow diffusion of CH_3CN into a CH_2Cl_2 solution of the solid. ^1H NMR (400 MHz, $CDCl_3$, 300 K, ppm): δ = 1.20 (br. s, 12 H, *m*,*p*-CH_2, *c*-C^6), 1.64 (br. s, 8 H, *o*-CH_2, *c*-C^6), 3.61 (s, 12 H, OCH_3), 6.65 (d, ^1J = 8.8 Hz, 4 H), 6.87 (br. s, 4 H), 7.00 (d, ^1J = 6.4 Hz, 4 H), 7.38 (t, ^1J = 7.2 Hz, 16 H, PPh_2), 7.46 (q, ^1J = 7.2 Hz, 8 H, PPh_2), 7.82 (br. s, 16 H, PPh_2). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 300 K, ppm): δ = 23.7 (d, J_{Rh-P} = 128 Hz). IR (ATR mode, solid, carbonyl region, cm^{-1}): $\tilde{\nu}$ = 1976 (Rh*CO*). $C_{90}H_{84}Cl_2O_6P_4Rh_2$: calcd. C 65.03, H 5.09; found C 64.88, H 4.96.

Molecular Structures of 1−3 and 5−8: The data were collected on a Nonius−Kappa CCD diffractometer with a rotating anode. The structures were solved by direct methods using SHELXS-97 (**2**, **3**)[47] or DIRDIF99 (**1**, **6**−**8**)[48] and refined by least-squares procedures on F^2 using SHELXL-97.[49] All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were constrained to idealized geometries and allowed to ride on their carrier atoms with an isotropic displacement parameter related to the equivalent displacement parameter of their carrier atoms. Compound **3** contained one phenyl ring on one of the phosphanes which is disordered over two positions. Compound **6** contained four molecules of $CDCl_3$ in the unit cell. Compound **7** contained two acetone molecules which were disordered over two positions. Compound **8** contained disordered dichloromethane molecules. Their contribution was taken into account using the PLATON/SQUEEZE procedure. Structure validation and molecular graphics preparation were performed with the PLATON package.[50] Crystal data are given in Tables 6 and 7. CCDC-213681 (**1**), -213682 (**2**), -213683 (**3**), -213684 (**5**), -213685 (**6**), -213686 (**7**), and -213687 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html [or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Investigation of the Crystallization Stages of LTA-Type Zeolite by Complementary Characterization Techniques

Monique Smaihi,*[a] Olivier Barida,[a] and Valentin Valtchev[b]

Keywords: Zeolites / Hydrothermal synthesis / NMR spectroscopy / Crystal growth

This paper reports on the physicochemical reorganizations, at 40 °C, of a template-free aluminosilicate system yielding an LTA-type zeolite. The events that take place in the system during the transformations of the amorphous material into a crystalline material were monitored by various characterization techniques which provide information from the molecular to the micrometer scale. High-resolution solid-state ^{29}Si and ^{27}Al MAS NMR spectroscopy, small-angle X-ray scattering (SAXS), X-ray diffraction (XRD), and scanning electron microscopy (SEM) were used in order to achieve a better understanding of the structural properties of the precursor gel and its transformation into a crystalline zeolite-type material. The experimental results show that the first crystallization stage proceeds by reorganization of the amorphous aluminosilicate units formed during the mixing of the precursors. This reorganization involves an ordering of the Si–O–Al bond angles and operates on aggregates of constant volume. The crystallization process takes place in the volume of the aggregates by propagation through the gel phase. This propagation through the gel continues to complete the transformation of the particles into crystalline zeolite Na-A nanocrystals with a rough surface. After this stage, the growth in the system is dominated by the solution-mediated transport, which leads to the formation of well-shaped zeolite A crystals.

Introduction

Zeolites are crystalline solids that have a highly regular and open microporous structure.[1] More than 130 microporous structure types are known,[2] each with its own distinct pore size, shape, and interconnectivity. The sizes of these pore openings range from 0.3 to 1 nm. The framework composition (Si/Al ratio) can give rise to different ion-exchange properties, to a hydrophilic or hydrophobic character of the material, and to acid sites with different strengths and densities.

Owing to its excellent ion-exchange capacity and consequent use as a water-softening agent in modern-day washing powders, zeolite A boasts the greatest world-wide industrial tonnage of any zeolite. Besides the important industrial applications, zeolite A attracts the interest of researchers with its relatively simple composition and fast crystallization kinetics, which makes it very useful for fundamental studies.

Many techniques have been used to gain an insight into the complex processes occurring during the nucleation and subsequent crystal-growth processes.[3−26] Recently, the use of various non-intrusive and in-situ techniques have provided evidence to support the theory of zeolite crystallization through gel transformation, even for situations considered before as homogeneous.[20,22] The presence of aluminosilicate nanoparticles in the early stages of nucleation of zeolite A has been confirmed by quasi-elastic light scattering and SAXS,[11] dynamic light scattering (DLS),[17,18] TEM,[8] and AFM.[7,14] SAXS observations[19−21] have suggested that some physical rearrangements occur within the amorphous aluminosilicate particles during the nucleation process. A number of studies on the transformations occurring on a molecular scale during the nucleation and crystal-growth processes were based on Nuclear Magnetic Resonance (NMR) spectroscopy.[22−25] Such a spectroscopic method is complementary to those presented above; it fills the gaps in the information needed between the molecular scale entities and the crystal structure formed. Several studies[23−26] showed how the initial reactant sources greatly affect the intermediates observed during the crystallization process. These investigations showed the complexity of the zeolite nucleation/crystallization process, which is dependent on the overall composition of the initial system and the silica and alumina sources used.

Although it was proven that the nucleation of zeolite A is related to the presence of aluminosilicate gel, many questions concerning different stages of evolution of the system remain to be met. The crystal growth can take place by propagation through the gel phase or by solution-mediated transport. In a particular reaction system, the true mechanism could lie somewhere between these two extremes, where one of those might be dominant at a certain stage. In

order to highlight the mechanism that controls the zeolite formation in a particular system, a link between events taking place on an atomic and on a large scale has to be established. Therefore, valuable information on the mechanism governing crystal growth could be obtained only by a combination of methods which provide information from the molecular to the micrometric scale.

The goal of the present study was to distinguish different stages of zeolite A formation at low temperature, and to investigate the mechanism controlling each of these stages for a conventional organic-free system. The experiments were performed at 40 °C in order to slow down crystal growth so as to distinguish different stages of zeolite formation. High-resolution solid-state ^{29}Si and ^{27}Al MAS NMR spectroscopy, SAXS, X-ray diffraction (XRD), and scanning electron microscopy (SEM) were used to provide information from the molecular to the micrometer scale, and thus to achieve a better understanding of the structural properties of the solid gel phase and its transformation into a crystalline LTA-type material.

Results

The XRD patterns of the samples after different crystallization times are shown in Figure 1. Traces of crystalline LTA-type material were detected after 14 h of hydrothermal synthesis, whereas after 16 h, the XRD pattern showed all the characteristic peaks of zeolite A. A gradual increase in the crystallinity was observed between 14 and 20 h. Further increase in the synthesis time did not yield material with higher X-ray crystallinity.

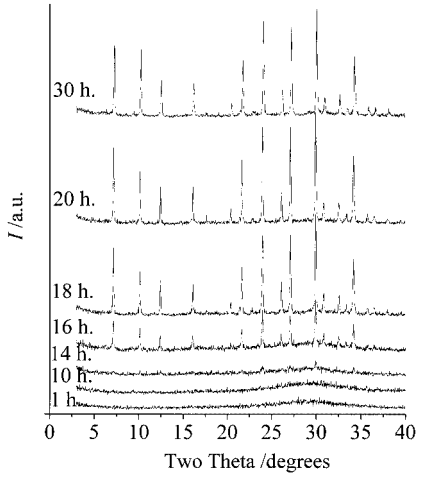

Figure 1. X-ray diffractograms of samples prepared at 40 °C for various heating times: a) 1 h; b) 10 h; c) 14 h; d) 16 h; e) 18 h; f) 20 h; g) 30 h

The electron micrographs shown in Figure 2 represent the morphological features of the materials taken after 1, 16, and 20 h of hydrothermal treatment. The micrograph of the material taken after 1 h shows that the material does not have a crystalline appearance. However, isometric particles of similar sizes, which form large aggregates can be seen. The sizes of these primary particles are in the range 40−100 nm. The micrograph of the sample taken after 16 h shows isolated particles with a round shape and sizes from 40 to 300 nm. All samples that were treated hydrothermally for more than 18 h contained crystals that are of similar sizes, with cubic morphology typical of zeolite A. The sizes of the crystals are in the range 300−400 nm. A small fraction of 40−100 nm crystallites can also be seen.

The morphologies and interfaces of the samples crystallized for different periods of time were characterized by SAXS. The SAXS data provide information on the presence of different particle populations, and on some of their properties such as particle-size distribution, their shape and the type of interactions they are involved in. The intensity of the small-angle X-ray scattering, $I(Q)$, is given by the general equation

$$I(Q) = \varphi P(Q)S(Q)$$

where φ is the number density of the particles in the sample and Q is the momentum transfer [$Q = 4\pi\cdot\lambda^{-1}\cdot\sin(\theta/2)$, θ the scattering angle, λ the X-ray wavelength]. The form factor $P(Q)$ reflects the distribution of the scattering material in the scattering particle, and the structure factor $S(Q)$ is related to the spatial distribution of the scattering particles in the material. The relation between a scattering spectrum and the species responsible for the scattering is shown schematically in Figure 3. On the scale of the primary building units (Porod region, $QR_g >> 1 >> Qa$, where a is the monomer size), the form factor of the primary building units becomes dominant in the scattering pattern, thus providing information about the surface structure of these particles. In many cases, the concept of fractal geometry[27] is used to describe scattering curves in the Porod region. Basi-

cally, all fractals show a power law dependence of the scattered intensity I on the scattering vector Q: $I(Q) \propto Q^{-x}$. For 3-dimensional objects with fractal surfaces,[28] $x = 6 - D_s$, where D_s is the fractal dimension of the surface ($2 \leq D_s \leq 3$). D_s provides a quantitative measure of the roughness; if the roughness of the surface increases, D_s will increase. Thus, $D_s = 2$ represents a classical smooth surface. The $I(Q)$ curves (Figure 4) are similar for all samples with slopes ranging from -3.8 (± 0.05) for samples with "short" synthesis time (1−14 h) to -4 (± 0.05) for those obtained after

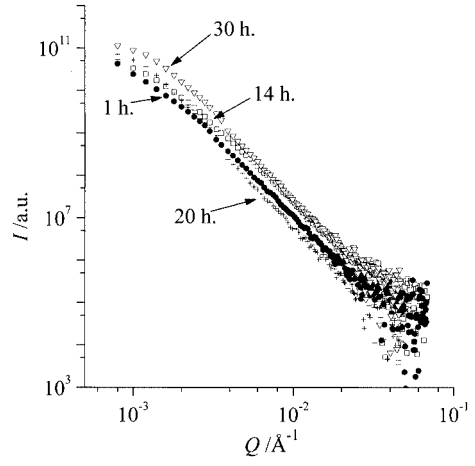

Figure 4. SAXS profiles of samples obtained after different synthesis times at 40 °C

20−30 h of thermal treatment. The initial decay of the intensity in the Guinier region also varies slightly with hydrothermal treatment of the samples.

The molecular organization in the samples was studied by ^{29}Si and ^{27}Al NMR spectroscopy. The ^{29}Si NMR and ^{27}Al NMR spectra of the precursor solutions were recorded in order to characterize the initial species before mixing. Each spectrum presents a single line at $\delta = -72.2$ and 79.5 ppm, which are assigned to the monomeric $Si(OH)_4$ and $Al(OH)_4^-$ species, respectively. The ^{29}Si and ^{27}Al NMR chemical shifts (δ) and line-widths ($\Delta\nu_{1/2}$) recorded for all solid samples are summarized in Table 1. The ^{29}Si MAS NMR spectra of samples obtained after a short synthesis time exhibit broad signals between $\delta = -78$ and -92 ppm (Figure 5). Sample 1 (Table 1) presents a relatively broad signal (half-width = 668 Hz) with a chemical shift of the peak maximum at $\delta = -83.5$ ppm. With increasing synthesis time, the resonance signal becomes narrower and also shows a change in the chemical shift distribution. After 8 h of synthesis, the resonance signal is centered at $\delta = -85.9$ ppm, and after 14 h of thermal treatment, an additional shoulder appears at $\delta = -88.4$ ppm. The latter increases with synthesis time at the expense of the higher frequency resonances. After 20 h of synthesis, the spectrum presents a single narrow signal centered at $\delta = -89.5$ ppm, which does not change with further thermal treatment. The ^{27}Al MAS NMR spectra have been recorded using the same samples (Figure 6). They all present a single signal centered at $\delta = +58$ ppm. The width of this resonance signal then decreases with the time of thermal treatment. The spectrum collected after 1 h of synthesis presents a broad signal (half-width = 1197 Hz), whereas the spectrum recorded after 20 h presents a narrow signal (half-width = 400 Hz) which does not change with further thermal treatment.

Discussion

The TEM study of the initial gel showed that the 40−100 nm particles formed non-uniform gel aggregates (Figure 7). The large-scale changes observed by SEM show that aggregates composed of nanoparticles with a random form are seen in the system during the induction period. The characteristic morphological features of the product did not change substantially after 14 h of hydrothermal treatment, when traces of crystalline LTA-type material were detected in the XRD pattern of the product. In the sample crystallized for 16 h, which displayed a relatively high crystallinity (approximately 30%) (Figure 2, B), particles without the specific morphological features of LTA-type zeolite were observed. All these data show that the first stage of the crystallization process is not coupled with substantial morphological changes in the solid. This result could be considered as reasonable if the crystallization takes place in the volume of the gel phase. Bearing in mind the mass of the crystallites at this stage, and the fact that the density of the zeolite and the gel is about 2.0 and 1.0,

respectively, a substantial decrease in the volume could not be expected. On the other hand, if the zeolite nuclei are released by the gel phase and grown in the mother liquor, at 30% conversion, the formation of new particles would be observed in the product.

Complementary information on the morphological changes in the course of the transformation of the initial gel into crystalline zeolite A was obtained by the SAXS investigation. From the initial decay of the SAXS intensity in the Guinier region, the electronic radius of gyration, Rg, can be deduced using the Guinier approximation for scattering particles $I(Q) = N{\cdot}n^2{\cdot}\exp(-Q^2{\cdot}\mathrm{Rg}^2/3)$, where N is the number density of particles and n the number of excess electrons in each particle.

The Guinier radius (Figure 8) is about 100 nm and does not drastically vary with the time of thermal treatment. In spite of the limitations of the Guinier method due to the restricted Q range and the possible interference effects due to multiple particle scattering, the obtained values for samples that were heated for up to 20 h are not unreason-

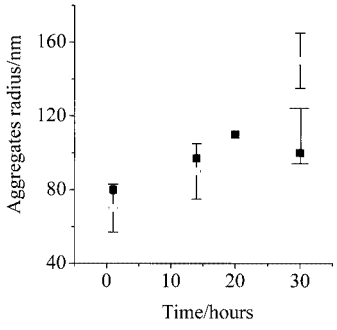

Figure 8. Aggregates radius obtained from SAXS profiles (solid squares), SEM micrographs (open circles) as a function of heating time at 40 °C

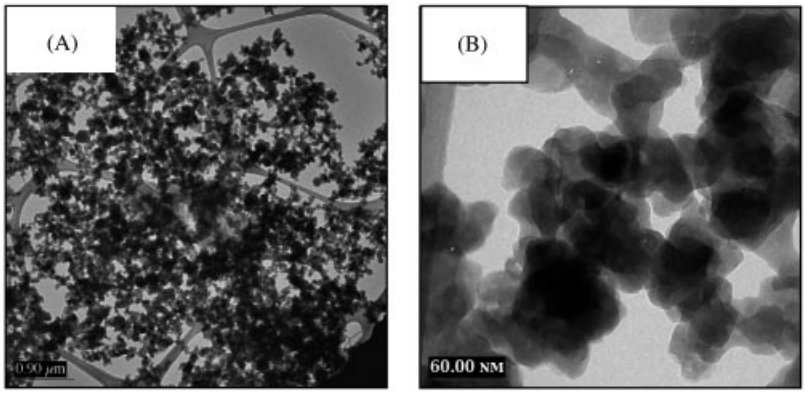

Figure 7. Low (A) and high (B) magnification TEM images of the zeolite A precursor gel

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

able and the estimated errors are ±10 nm. For crystalline samples (30 h of thermal treatment), the restricted Q range of the experimental set-up may underestimate the Guinier radius of particles larger than 250 nm, and leads to larger experimental errors (±30 nm). However, the sizes observed by SEM are consistent with the Guinier radii for all samples treated for up to 30 h, and similarly do not significantly vary during the first 14 h of thermal treatment.

Porod plots for all samples (Figure 4) show a single region with a slope of about −3.8 for the noncrystalline samples and −4 for the crystalline samples. The SAXS profiles observed for all samples are rather similar and insensitive to the crystallization stage. The observed Porod slopes of about −4 indicate that the particle surfaces are smooth. Several studies have been devoted to the characterization of silicate networks obtained under different conditions, and show that the scattering curves display fractal dimensions varying from −2 to −4 depending on the polymerization conditions.[28b,28c] Further, with regard to the specific case of zeolite crystallization, there have been many studies involving the crystallization of silicalite under different conditions.[29] Slopes observed during crystallization of these systems ranged between −2 and −4, depending on the composition of the system and the aging of the system.

In our case, it can be concluded that the SAXS investigation is in agreement with the SEM observation, i.e. on the morphological scale there were no changes during the first stage of zeolite formation. In other words, as the SAXS measurements did not detect the formation of new particles, the nucleation and the subsequent growth of the nuclei takes place in the volume of the gel. Thus, it appears that the nucleation and subsequent crystallization occur with aggregates of constant size. A close association of the initially formed nuclei with the gel particles has already been described by Gora et al.[17] However, it is difficult, to discuss the transport of the nutrient during this stage.

On a molecular scale amorphous highly disordered species were detected during this stage. The broad resonance observed between δ = −78 and −92 ppm in the ^{29}Si MAS NMR spectra of sample 1 is typical of amorphous aluminosilicates.[30] This broadness is mainly caused by the overlapping of individual peaks with slightly different δ values, due to the small differences in the structural arrangements in the SiO_4 tetrahedra of the gel skeleton. The ^{29}Si and ^{27}Al NMR spectra of aluminosilicate solutions, pertinent to zeolite synthesis, indicate the formation of Si−O−Al linkages by the appearance of up to four peaks assigned to the Al(OSi), $Al(OSi)_2$, $Al(OSi)_3$, and $Al(OSi)_4$ species.[31] For solid samples, characteristic ^{29}Si NMR chemical shift ranges for the five $Q^4(m\text{Al})$ [i.e. $Si(OSi)_{4-m}(OAl)_m$] units in framework silicates have been established by comparison between calculated and experimental chemical shifts.[32] They range from δ = −112 to −94 ppm for $1 \leq m \leq 4$. Thus, the presence of such units in our samples can be excluded. Further, hydroxylated units, such as $HOSi(OAl)_3$, for which chemical shift values may be expected in the range of the observed signal, should be present only in minor amounts since no noticeable signal enhancement is observed in the ^{1}H-^{29}Si cross-polarization spectrum.

For sample 6 (20 h, 40 °C), the chemical shift of δ = −89.5 ppm reveals that the framework of the gel consists mainly of $Si(OAl)_4$ building units, i.e. of silicon atoms linked by oxygen bridges to four tetrahedral aluminum atoms. This chemical shift is consistent with the presence of crystalline zeolite Na-LTA (Si/Al = 1).[33]

Since the ^{29}Si NMR spectra can be analyzed quantitatively (the total area of the peaks corresponds to 100% of the observed nuclei), the signal centered at δ = −89.5 ppm corresponding to $Si(OAl)_4$ units in crystalline Na-A zeolite can be deconvoluted from the spectra in order to follow the kinetics of the formation of these units. Figure 9 presents the proportion of $Si(OAl)_4$ crystalline units as a function of crystallization time. This curve shows an "induction" period of about 10 h, which precedes a steep rise. After 20 h of synthesis (t/t_c = 1), 95% of the silicon species are $Si(OAl)_4$ crystalline units. Nevertheless, an increase in the size of the crystals and the formation of crystals with well-defined crystal morphology was observed after this period.

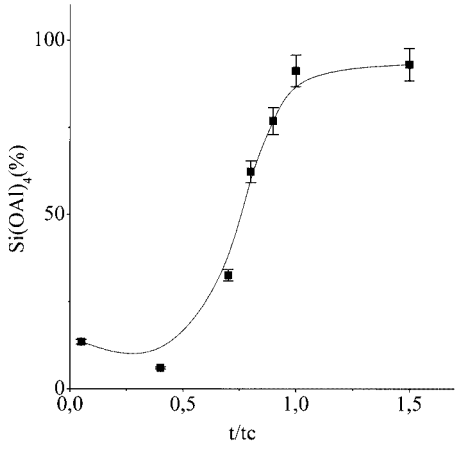

Figure 9. Proportion of crystalline $Si(OAl)_4$ units as a function of crystallization time (t_c: time needed to obtain pure crystalline Na-A zeolite)

The single signal centered at δ = +58 ppm in the ^{27}Al MAS NMR spectra is typical of $Al(OSi)_4$ units. The highly symmetrical line shape indicates that the presence of hydroxylated AlO_4 species is unlikely. Moreover, no signals corresponding to octahedral AlO_6 or tetrahedral $Al(OAl)_4$ aluminate species are detected. For the latter two units, ^{27}Al NMR chemical shifts of δ ≈ 0 and +75 ppm, respectively, were found in previous studies.[34] The observed line broadening is probably caused by residual quadrupolar interactions due to slight symmetry distortions in the vicinity of the Al atoms. However, these quadrupolar interactions are small enough such that they do not modify the line shape.

Short-range ordering in the samples can also be estimated from the line-widths of the ^{29}Si and ^{27}Al NMR resonance signals. The most likely contributing factor to the line-width ($\Delta\nu_{1/2}$) is the structural disorder which involves

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a large number of slightly different environments around nominally equivalent $Q^n(m\text{Al})$ type silicon atoms, thus leading to many overlapping lines with slightly different chemical shifts. The different environments are created by distortion of bond angles and bond lengths due to lattice imperfections. Hence, very broad signals ($\Delta\nu_{1/2} \approx 10-20$ ppm) are observed for highly disordered systems such as amorphous materials, whereas narrow peaks ($\Delta\nu_{1/2} \approx 0.2-3$ ppm) are obtained for perfectly ordered systems. Figure 10 presents the evolution of the ^{29}Si and ^{27}Al MAS NMR signal line-width as a function of the synthesis time for the $Si(OAl)_4$ and $Al(OSi)_4$ species. Both curves present two regions where a slight decrease in the line-width is observed for up to 14 h, followed by a significant decrease in the line-width after 16 h of synthesis.

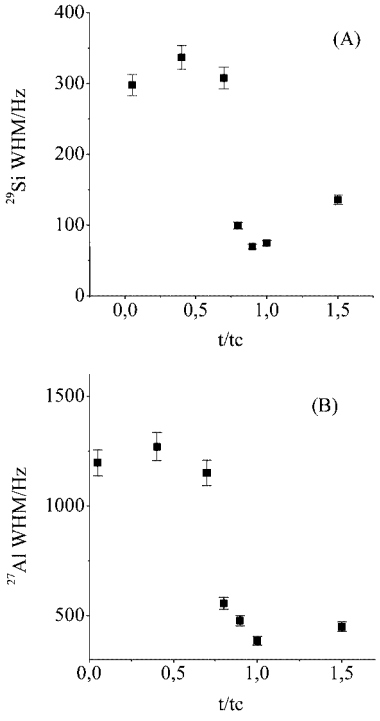

Figure 10. Width at half maximum of the $Si(OAl)_4$ (A) and $Al(OSi)_4$ (B) resonance signals of the ^{29}Si and ^{27}Al MAS NMR spectra, respectively, as a function of crystallization time at 40 °C (t_c: time needed to obtain pure crystalline Na-A zeolite)

Thus, the information collected on the molecular scale shows that during the first 16 h, while no large-scale morphological changes were observed, the first crystallization stage involves a rearrangement of the Si−O−T bonds in the amorphous phase formed after precursor mixing prior to crystallization. After this induction period when a product with zero crystallinity was observed, the above-mentioned transformation in the system takes place. This stage includes the time period 12−16 h, when the increase in the crystallinity is not coupled with large-scale changes in the system, i.e. the crystalline particles retain the size and morphology of the initial amorphous gel precursors. Obviously, during this first stage, the dominant mechanism of crystal growth is propagation through the gel. Growth by propagation through the gel network has already been observed in the formation of zeolite L.[16] During this first stage, the solid is about 30% crystalline, according to the XRD measurements (Figure 1). The nutrients for the crystal growth are provided mainly by the amorphous gel phase, although an extensive exchange between the solid and liquid parts of the system is likely.

After the first stage, a very rapid increase in crystallinity was observed which was coupled with significant changes in the size and morphological features of the particles. Well-shaped zeolite A crystals in the product indicate a change in the crystal growth process. This distinct change in the system occurred during the period 16−18 h, when the crystallinity is about 50%. At this stage, a substantial part of the amorphous material is consumed and crystallites are either released by the gel or are in contact with the mother liquor.[34] The SEM study of the 18-h product does not show much material with an amorphous appearance. At this stage the product already contains well-distinguished individual particles. During this latter stage, a solution-mediated growth mechanism seems to be dominant in the system. This crystallization stage, where a layer growth mechanism controls the zeolite A formation, has been studied and described in detail by Agger et al.[7] The nutrients for this crystallization stage are provided by the amorphous part of the gel and the less stable zeolite nanoparticles. The crystallization during this second stage was completed between 16 and 20 h, and further hydrothermal treatment did not influence the morphology nor the crystallinity of the product. The disappearance of the small crystallites and the increase in the size of the well-shaped cubic crystals were observed during the 20−30-h period, thus resembling Ostwald ripening.

Conclusions

The present study reports on the results obtained during the formation and transformations of precursor particles for the whole course of the template-free Na-A zeolite crystallization process at 40 °C, using various characterization techniques that provide information from the molecular to the micron scale.

The experimental results showed that in the system under investigation the crystallization process could be subdivided into two stages, during which the crystallization process is controlled by different crystallization mechanisms. After the formation of viable nuclei, the first stage of the crystal growth process proceeded by reorganization of the amorphous homogeneous aluminosilicate phase formed during the mixing of the initial precursors. This reorganization involves an ordering of the Si−O−Al bond angles of the $Si(OAl)_4$ units and operates on aggregates of constant volume to form nanocrystals with a rough surface at the end of the process. The zeolite formation in the system was

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

completed by the second crystallization stage when a fully crystalline product containing well-shaped zeolite crystals was obtained. A layer growth, where a solution-mediated transport of nutrients dominates, is the controlling mechanism during the second stage.

Experimental Section

Samples Preparation: The Na-A zeolite samples were prepared from an initial gel with the following composition: $7.5Na_2O/0.5Al_2O_3/SiO_2/200H_2O$. Sodium silicate solution (overall composition $SiO_2/7.5NaOH/102H_2O$) was prepared by dissolving sodium silicate (2.22 g, $Na_2Si_3O_7$, 27% SiO_2, 17% NaOH, Aldrich) and sodium hydroxide (2.69 g) in H_2O (17.1 g). A sodium aluminate solution (overall composition $Al_2O_3/15NaOH/197H_2O$) was prepared by dissolving sodium aluminate (0.963 g, $NaAlO_2$, 53% Al_2O_3, 42% Na_2O, Riedel−de Haën) and sodium hydroxide (2.465 g) in H_2O (17.69 g). The solutions were stirred in closed polyethylene bottles at room temperature until complete dissolution of the solid. After mixing of the initial solutions, the resultant mixture was stirred vigorously for 15 min. During mixing, the solution became opaque. The syntheses were performed at 40 °C for different periods of time ranging from 1 to 30 h. At this temperature, the crystallization of the zeolite A was relatively slow, but still fast enough to be achieved in a reasonable period of time. The solid phase was recovered after 5−8 cycles of centrifugation (8000 rpm, 15 min), decanting and ultrasonic redispersion in distilled water. The solid phase was dried over silica gel at room temperature for 48 h. The yield based on the silica conversion was ca. 70%. A similar (slightly higher) yield (76%) was obtained in the reference experiment performed with the same initial system at 90 °C for 5 h.

Samples Characterization: Scanning electron micrographs were obtained with a Hitachi S-4500 microscope. All samples were platinum-coated (2−3 nm) and mounted on aluminum mounts with carbon conducting tape. X-ray diffraction measurements were performed with a Bruker diffractometer D-5000 (Cu-$K_{\alpha 1}$ radiation, 0.154 nm). Small-angle X-ray scattering experiments were performed with an instrument that has an incident wavelength of 0.154 nm (Cu-$K_{\alpha 1}$ radiation) using a high-resolution Bonse-Hart camera. The monochromator was a three-reflection channel-cut scattered beam. These experimental parameters allow studies in a range of wave vectors Q from 0.02 to 1 nm^{-1}. The ^{29}Si and ^{27}Al NMR spectra of the precursor solutions were obtained at 49.68 and 65.17 MHz, respectively, with a Bruker spectrometer. The ^{29}Si spectra were recorded using a 12-μs pulse width (corresponding to a 60° flip angle), 10 s pulse repetition time and 128 scans. The ^{27}Al spectra were recorded using a 4-μs pulse width (corresponding to a 45° flip angle), 0.1 s pulse repetition time and 256 scans. The ^{29}Si MAS NMR spectra of the solid samples were recorded with a Bruker spectrometer at 39.73 MHz, using 4-μs single pulses (60° flip angle) with 60 s repetition rate, and employing high-power proton decoupling and magic-angle spinning at 3.5 kHz; 1000 scans were accumulated. The powder samples were filled into zirconia rotors of 4 mm diameter. The ^{27}Al MAS NMR spectra were measured at 104.26 MHz, using single pulses of 1 μs duration with 1 s repetition rate, and employing magic-angle spinning at 10 kHz; 512 scans were accumulated. All ^{27}Al and ^{29}Si chemical shifts were referenced to a 1% aqueous $Al(H_2O)_6^{3+}$ solution and tetramethylsilane (TMS), respectively.

Thermal Stability and Absorption Spectroscopic Behavior of (μ-Peroxo)dicopper Complexes Regulated with Intramolecular Hydrogen Bonding Interactions

Syuhei Yamaguchi,[a] Akira Wada,[a] Yasuhiro Funahashi,[a] Shigenori Nagatomo,[b] Teizo Kitagawa,[b] Koichiro Jitsukawa,*[a] and Hideki Masuda*[a]

Keywords: Copper / Peroxides / Tripodal ligands / Hydrogen bonding interactions

In order to clarify the effect of hydrogen bonding on the stabilities of (μ-peroxo)dicopper complexes with a *trans*-μ-1,2-peroxo form, novel copper complexes with intramolecular hydrogen bonding interaction sites have been synthesized, and their spectroscopic properties and thermal stabilities studied. The selected tripodal tetradentate ligands were tris(2-pyridylmethyl)amine (TPA) derivatives bearing pivalamido and amino groups at the 6-position of the pyridine ring in TPA, {[6-(pivalamido)pyrid-2-yl]methyl}bis(pyrid-2-ylmethyl)amine (MPPA) and [(6-aminopyrid-2-yl)methyl]bis(pyrid-2-ylmethyl)amine (MAPA). The single-crystal X-ray structure of a monomeric Cu^{II} complex with N_3^- namely $[Cu(mppa)N_3]ClO_4$ (**1a**), revealed an interligand hydrogen bonding interaction between the substituent NH group of MPPA and the azide nitrogen atom in the axial position. The Cu^I complexes of MPPA and MAPA were immediately oxygenated with dioxygen in acetone solution at –78 °C to give the μ-peroxo dinuclear copper(II) complexes $[\{Cu(mppa)\}_2(O_2)]^{2+}$ (**1b**) and $[\{Cu(mapa)\}_2(O_2)]^{2+}$ (**2b**). These complexes exhibited two kinds of characteristic absorption bands ($\pi^*_\sigma \rightarrow d_\sigma$, $\pi^*_v \rightarrow d_\sigma$) originating from the ligand–metal charge transfer (LMCT) of O_2^{2-} to Cu. Affected by the hydrogen bonding interaction, the $\pi^*_\sigma \rightarrow d_\sigma$ CT band shifted significantly to a higher energy region and the $\pi^*_v \rightarrow d_\sigma$ CT absorbance decreased due to stabilization of the π^*_σ orbital and restriction of the Cu–O bond rotation. The thermal stabilities of the (μ-peroxo)dicopper(II) complexes were estimated from their decomposition rates which decreased in the order, **2b** ≈ $[\{Cu(tpa)\}_2(O_2)]^{2+}$ (**3b**) > **1b** >> $[\{Cu(6\text{-}metpa)\}_2(O_2)]^{2+}$ (**4b**) {6-MeTPA = [(6-methylpyrid-2-yl)methyl]bis(pyrid-2-ylmethyl)amine}. The above findings indicate that the interligand hydrogen bonding interaction, although overcome to some extent by the adverse effect of the steric bulk of the NH group, is inclined to stabilize (μ-peroxo)dicopper(II) complexes.

Introduction

In biological systems, O_2 binding and its activation by metalloenzymes are important processes for respiratory and metabolic systems.[1] Detailed examinations using biomimetic model systems are required for understanding the natural processes, such as dioxygen transport, oxidation, oxygenation, and dehydrogenation.[1–3] These processes are catalyzed by heme iron,[4,5] non-heme iron[6,7] and copper centers[8–13] at the active sites of the metalloenzymes. In order to clarify the catalytic reaction mechanism of the dicopper-containing enzymes, dicopper–dioxygen adduct complexes have been investigated as biomimetic models.[14–35] The binding of dioxygen to dinuclear copper complexes has been previously found to result in (*trans*-μ-1,2-peroxo)dicopper(II),[14–25] [μ-(η^2:η^2)-peroxo]dicopper(II),[14,26–31] and [bis(μ-oxo)]dicopper(III) forms.[14,32–35] These coordination modes in dicopper sites are known to depend on the stereochemistry of the coordination environment. The geometries of dicopper–dioxygen complexes are likely to be regulated by the number of coordinating ligands;[14–35] (*trans*-μ-1,2-peroxo)dicopper(II) complexes[14–25] have been generally formed using tetradentate ligands and the structural and spectroscopic properties of (*trans*-μ-1,2-peroxo)dicopper(II) complexes were first systematically investigated by Karlin and co-workers.[16–23]

In biological catalysts, environmental factors such as the proximal effect of amino acid residues are frequently required for regulating reaction intermediates and activating substrates. We have demonstrated that the hydrogen bonding interaction can control the reactivity of metal–dioxygen species, and have succeeded in the preparation of the stable monomeric (hydroperoxo)copper(II) complex $[Cu^{II}(bppa)(OOH)]^+$ [BPPA = bis{[6-(pivalamido)pyrid-2-yl]methyl}-(pyrid-2-ylmethyl)amine].[36] The crystal structure of this

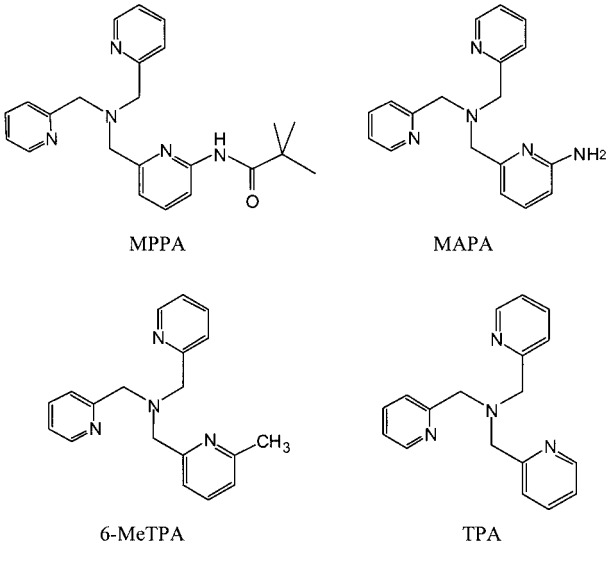
complex revealed a hydrogen bonding interaction between the pivalamido NH group of BPPA and the ligating hydroperoxo oxygen atom.[36] The remarkable stability of $[Cu^{II}(bppa)(OOH)]^+$ was acquired by the intramolecular hydrogen bonding interaction. From this point of view, it has been previously discussed that the interligand hydrogen bonding interaction can stabilize (superoxo)-, (alkylperoxo)-, and (hydroxo)metal complexes with tripodal tetradentate ligands.[37−43]

As an expansion of our previous research, tripodal ligands having the hydrogen bonding feature, such as {[6-(pivalamido)pyrid-2-yl]methy}bis(pyrid-2-ylmethyl)amine (MPPA) and [(6-amino-2-pyridyl)methyl]bis(pyrid-2-ylmethyl)amine (MAPA) (Scheme 1), have been newly prepared for complexation with copper ions. It was expected that these tetradentate ligands would form (*trans*-μ-1,2-peroxo)dicopper(II) complexes that would be dominated by their coordination numbers. In this paper, we describe details of the following: (i) the coordination structures and hydrogen bonding modes of copper complexes with MPPA and MAPA and (ii) formation of the corresponding μ-peroxo dinuclear copper complexes and their characteristic absorption spectroscopic behavior and thermal stabilities. We also discuss the intrinsic effect of the proximal hydrogen bonding interaction in μ-peroxo dinuclear copper complexes in detail and compare these with the cases of copper complex systems of TPA and Cu-6-MeTPA {6-MeTPA = [(6-methyl-2-pyridyl)methyl]bis(pyrid-2-ylmethyl)amine} without a hydrogen bonding site (Scheme 1).[44,45]



MPPA: {[6-(pivalamido)pyrid-2-yl]methyl}bis(pyrid-2-ylmethyl)amine
MAPA: [(6-aminopyrid-2-yl)methyl]bis(pyrid-2-ylmethyl)amine
6-MeTPA: [(6-methyl-2-pyridyl)methyl]bis(pyrid-2-ylmethyl)amine
TPA: tris(pyrid-2-ylmethyl)amine

Results and Discussion

Formation of $Cu^{II}-L-N_3$ Complexes (L = mppa, mapa, tpa, 6-metpa) and Their Spectroscopic Properties

$[Cu^{II}(mppa)](ClO_4)_2$ (**1**) [mppa = bis(pyrid-2-ylmethyl){[6-(pivalamido)pyrid-2-yl]methyl}amine] was synthesized by mixing equimolar amounts of $Cu^{II}(ClO_4)_2 \cdot 6H_2O$ and MPPA in methanol. Addition of NaN_3 to **1** in CH_3CN results in a color change of the solution from blue to green, indicating formation of $[Cu^{II}(mppa)(N_3)]^+$ (**1a**). $[Cu^{II}(L)(N_3)]^+$ complexes [L = mapa (**2a**), tpa (**3a**),[46] and 6-metpa (**4a**)] were also prepared in CH_3CN solution by a similar procedure and the azide complexes all showed almost the same spectroscopic properties corresponding to the analogous coordination geometries. Electronic absorption and ESR spectroscopic data for $[Cu^{II}(L)(N_3)]^+$, **1a**, **2a**, **3a** and **4a**, are listed in Tables 1 and 2, respectively. The electronic absorption spectrum of **1a** exhibited d-d transition bands centered at 647 nm (300 $M^{-1}cm^{-1}$) and 833 nm (220 $M^{-1}cm^{-1}$), and an intense absorption band at 395 nm (2700 $M^{-1}cm^{-1}$). The latter intense absorption band in the UV region can be assigned to LMCT since the other azide complexes, $[Cu(mapa)(N_3)]^+$ (**2a**) and $[Cu(tpa)(N_3)]^+$ (**3a**), exhibited intense LMCT bands between the bound N_3^- anion and the copper ion in the same region [at 403 nm (2940 $M^{-1}cm^{-1}$) [46] and 413 nm (2130 $M^{-1}cm^{-1}$), respectively] (Table 1).

$[Cu^{II}(6\text{-metpa})(N_3)]^+$ (**4a**) also showed the same characteristic LMCT band at 414 nm (2600 $M^{-1}cm^{-1}$), indicating that the azide ion is bound to the Cu^{II} center. The frozen solution ESR spectrum of the azide complex **1a** at 77 K gave signals typical for a Cu^{II} complex with a d_{z^2} ground state ($g_{\|} = 2.03 < g_{\perp} = 2.20$, $|A_{\|}| = 71$ G, and $|A_{\perp}| = 130$ G). Including other azide complexes, the ESR spectroscopic patterns of **1a**, **2a**, and **3a** are characteristic of a trigonal-bipyramidal geometry ($g_{\|} < g_{\perp}$) which agrees well with those speculated from their absorption spectroscopic features showing lower d-d transition energies (Table 2).

Crystal Structures of $[Cu(mppa)](ClO_4)_2$ (1) and $[Cu(mppa)(N_3)]ClO_4$ (1a)

$[Cu(mppa)](ClO_4)_2$ (**1**) and $[Cu(mppa)(N_3)]ClO_4$ (**1a**) were obtained as blue and green crystals, respectively, which were suitable for X-ray structural analysis. The molecular structures of the cationic parts of **1** and **1a** are shown in Figures 1 and 2, respectively. Selected bond lengths and angles around the copper cores are listed together in Table 3. The Cu^{II} ion in **1** is coordinated by three pyridine nitrogen atoms of MPPA [Cu−N(2) = 1.970(6) Å, Cu−N(3) = 2.062(6) Å, Cu−N(4) = 2.079(6) Å] in the trigonal plane and by one tertiary amine nitrogen and one pivalamido oxygen atom of MPPA [Cu−N(1) = 2.006(7) Å and Cu−O(1) = 1.940(6) Å] in the axial positions. The Cu^{II} ion in the azide complex **1a** has almost the same coordination mode as in **1** except for substitution of an azide ion for the pivalamido oxygen atom of MPPA. The copper

center is surrounded by three pyridine nitrogen atoms from MPPA [Cu−N(2) = 2.180(5) Å, Cu−N(3) = 2.050(5) Å, Cu−N(4) = 2.070(5) Å] in the trigonal plane and one tertiary amine nitrogen atom [Cu−N(1) = 2.010(5) Å] from MPPA and one azide nitrogen atom [Cu−N(6) = 1.936(5) Å] in the axial positions. Judging from the coordination geometric parameter τ around the Cu^{II} ion [$\tau = (\beta - \alpha)/60$, where α and β represent two basal angles ($\beta \geq \alpha$)],[47] the coordination structures for **1** (0.81) and **1a** (0.94) are both almost trigonal-bipyramidal as listed in Table 3. As shown by the above spectroscopic and structural results, it is clear that the Cu^{II} complexes with an azide group exhibit a trigonal-bipyramidal structure both in solution and in the solid state. In the molecular structure of **1a**, a hydrogen bond was observed between the pivalamido NH group of MPPA and the coordinated azide ion. The distance between N(5) and N(6) [2.893(6) Å] corresponds well to a hydrogen bonding interaction (Figure 2), which apparently contributes to the fixation of the azide ion, as found in the previously reported Cu-TPPA and Cu-BPPA complexes with the pivalamido group [TPPA: tris{[6-(pivalamido)pyrid-2-yl]methyl}amine; BPPA: bis{[6-(pivalamido)pyrid-2-yl]methyl}(pyrid-2-ylmethyl)amine].[36−41]

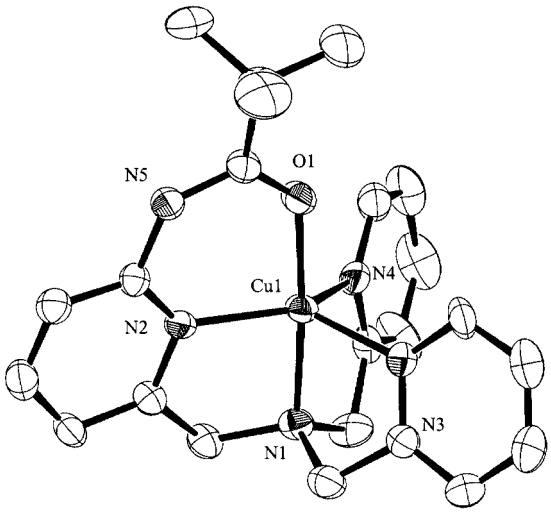

Figure 1. ORTEP plots of $[Cu(mppa)]^{2+}$ (**1**) with the atomic labeling scheme; hydrogen atoms have been omitted for clarity

Electrochemical Properties

In order to understand the electrochemical properties of the Cu^{II} complexes with tripodal tetradentate ligands, the cyclic voltammograms of the azide complexes were measured in MeCN under argon relative to the SCE. The cyclic voltammograms of **1a**, **2a**, **3a**, and **4a** showed a reversible one-electron redox potential wave. The redox potential values were converted into the NHE scale by adding 244.4 mV,[48] and the electrochemical data are listed in Table 4. The $E_{1/2}$ values of the azide complexes are significantly dif-

Reaction of Copper(I) Complexes with Dioxygen and Characterization of the Oxygenated Complexes

The reactions of the Cu^I-MPPA or -MAPA complexes with dioxygen were performed in acetone and EtCN solutions, which were monitored by spectroscopic methods such as electronic absorption, resonance Raman and ESR spectroscopy. Bubbling dioxygen into the solution of each Cu^I complex at −78 °C resulted in an intense color change from light yellow to violet. The absorption spectra of these violet species in acetone solution showed intense bands at 517 nm (ε = 5600 $M^{-1}cm^{-1}$) and 503 nm (ε = 7500 $M^{-1}cm^{-1}$) for the Cu-MPPA and Cu-MAPA systems, respectively. These bands exhibited shoulder bands around 600 nm (ε = 1500 $M^{-1}cm^{-1}$). The intense absorption bands in the visible region have been tentatively assigned as resulting from charge transfer (CT) transitions from the *trans*-μ-1,2-peroxo groups to the copper(II) centers.[14−25] A detailed interpretation of the spectroscopic features of these CT bands for the Cu-MPPA and Cu-MAPA systems will be discussed in the following section together with those of the Cu-TPA system.[16−23] The resonance Raman spectra of EtCN or acetone solutions containing these copper−dioxygen adduct complexes measured at −78 °C (514 nm laser excitation) showed a strong resonance enhanced Raman peak at 837 cm^{-1} for the Cu-MPPA system, which shifted to 792 cm^{-1} ($\Delta\nu$ = 45 cm^{-1}) when ^{18}O-labeled dioxygen was used and a corresponding peak for the Cu-MAPA complex was observed at 847 cm^{-1}, which shifted to 800 cm^{-1} ($\Delta\nu$ = 45 cm^{-1}) when $^{18}O_2$ was used. The frequencies and ^{18}O-isotope shifts of these bands are characteristic of (*trans*-μ-1,2-peroxo)dicopper(II) complexes.[14−25] The ESR spectra of these oxygenated complexes in solution were silent which also suggests that two copper(II) ions are bridged by a dioxygen molecule and are antiferromagnetically coupled.

On the basis of these spectroscopic observations, we conclude that the (*trans*-μ-1,2-peroxo)dicopper(II) complexes $[\{Cu(mppa)\}_2(O_2)]^{2+}$ (**1b**) and $[\{Cu(mapa)\}_2(O_2)]^{2+}$ (**2b**) have formed in solution.

Spectral Changes in the LMCT Bands of O_2 Adduct Complexes Affected by a Hydrogen Bonding Interaction

Bubbling dioxygen into an acetone solution containing $[Cu(L)]PF_6$ complexes with L = MPPA or MAPA afforded $[\{Cu(mppa)\}_2(O_2)]^{2+}$ (**1b**) or $[\{Cu(mapa)\}_2(O_2)]^{2+}$ (**2b**), respectively, as described above. The intense charge-transfer bands (LMCT) observed at 517 nm for the Cu-MPPA system and at 503 nm for the Cu-MAPA system can be attributed to the formation of a (*trans*-μ-peroxo)dicopper(II) core in each case. The absorption spectra of four kinds of μ-peroxide complexes namely **1b**, **2b**, $[\{Cu(tpa)\}_2(O_2)]^{2+}$ (**3b**),[16−23] and $[\{Cu(6\text{-}metpa)\}_2(O_2)]^{2+}$ (**4b**),[44] are shown in Figure 3 and Table 5. Interesting spectroscopic behavior was observed as follows: the LMCT bands of the complexes exhibited blue shifts in the order **4b** < **3b** < **1b** < **2b**. The intensities of the shoulder peaks of the LMCT bands observed in the former two complexes **1b** and **2b** at about 600 nm were quite weak compared with those in the latter two complexes **3b** and **4b**. In the following section we discuss this by use of Solomon's theoretical consideration.

Solomon et al. first explained the LMCT bands of copper(II) peroxide complexes using a mononuclear copper(II) model with a peroxide ion in the end-on mode (Figure 4).[49] The highest occupied molecular orbitals of the peroxide have two degenerate π* sets which split into two energy levels upon binding to the copper(II) ion. One π* orbital (π^*_σ) along the Cu−O bond has a larger overlap with the d_σ orbital of the copper ion and is critically stabilized by this interaction. The other π* orbital (π^*_v) perpendicular to the d_σ orbital undergoes a weaker d-π interaction. On the basis of this consideration, there are two types of CT transitions from the peroxide to the copper(II) ion, that is, the band in the shorter wavelength region (500−540 nm) corresponds to a $\pi^*_\sigma \rightarrow d_\sigma$ transition and the shoulder band at longer wavelength (≈ 600 nm) can be ascribed to a $\pi^*_v \rightarrow d_\sigma$ transition.

Firstly, considering the $\pi^*_\sigma \rightarrow d_\sigma$ transition wavelength region (500−540 nm), the LMCT band for **4b** was observed at 537 nm, indicating that the energy gap between the π^*_σ and the d_σ orbitals is relatively small in comparison with that of **3b** at 523 nm, as shown in Table 5. This low energy shift of the $\pi^*_\sigma \rightarrow d_\sigma$ transition band can be explained by a decrease in the energy splitting of the d orbitals because the

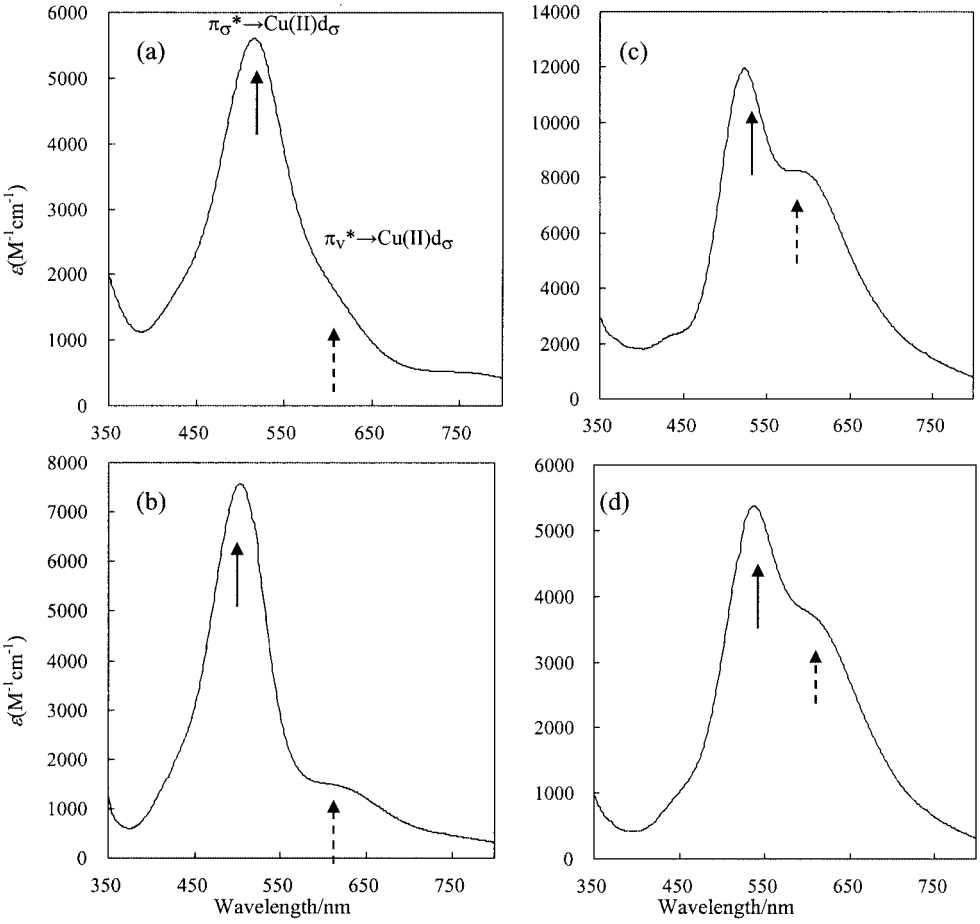

Figure 3. Absorption spectra of $[(CuL)_2(O_2)]^{2+}$ complexes in acetone at −78 °C [L = MPPA (a), MAPA (b), TPA (c), 6-MeTPA(d)]

Table 5. Absorption spectroscopic data for $[(CuL)_2(O_2)]^{2+}$ complexes

L (Ligand)	λ_{max}/nm (ε/M^{-1}cm^{-1})	Ref.
MPPA (**1b**)	517 (5600), 600 (1500)	this work
MAPA (**2b**)	503 (7500), 600 (1500)	this work
TPA (**3b**)	524 (12000), 600 (8000)	[16−23]
6-MeTPA (**4b**)	537 (5500), 600 (4000)	[44]

ligation of the pyridine nitrogen atoms to the copper(II) ion is weakened by the steric hindrance of the methyl group substituents at the 6-position of the pyridine ring.[44,45] On the other hand, the $\pi^*_\sigma\rightarrow d_\sigma$ CT bands of **1b** (517 nm) and **2b** (503 nm) were observed in a higher energy region than that of **3b** (523 nm) in spite of the larger steric hindrance of the 6-(pivalamido)- and 6-amino substituted derivatived. In these cases, the pivalamido and amino groups in the 6-positions of the pyridine ring in MPPA and MAPA can be considered to form intramolecular hydrogen bonding interactions with the ligating peroxide ion in the same mode as in the previously reported monomeric (hydroperoxo)-copper(II) complex $[Cu^{II}(bppa)(OOH)]^+$ [BPPA = bis{[6-(pivalamido)pyrid-2-yl]methyl}(2-pyridylmethyl)amine].[36] The electronic absorption spectra of the azide complexes,

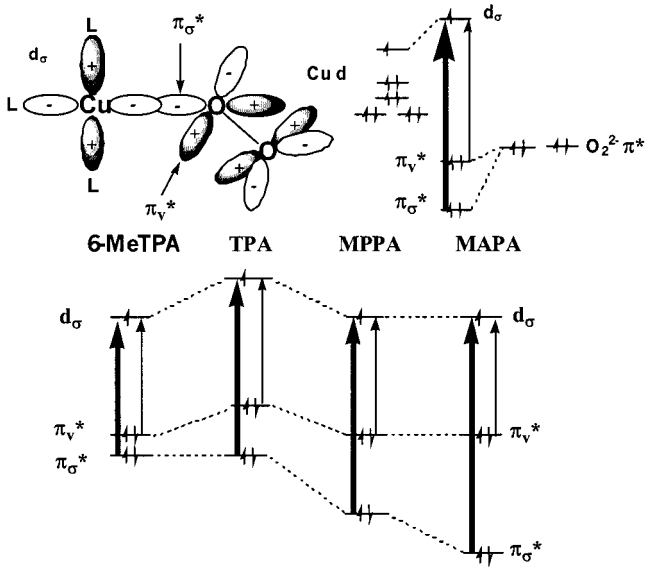

Figure 4. Schematic diagram of the energy levels of the molecular orbitals participating in the copper−peroxo bond

1a, **2a**, **3a and 4a**, also exhibited a similar tendency: the LMCT energies of the azide complexes with MPPA and MAPA detected at 395 and 403 nm are relatively larger than

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

those of the azide complexes with TPA and 6-MeTPA observed at 413 and 414 nm. Indeed, in the crystal structures of the azide complexes with MPPA and MAPA, **1a** and **2a**, the intramolecular hydrogen bonding interactions were clearly formed between the 6-amido/amino NH hydrogen and the axially bound azide nitrogen atoms. These findings suggest that similar hydrogen bonds can also be formed in the corresponding (peroxo)dicopper(II) complexes, **1b** and **2b**. Taking this into account, it can be understood that the higher energy shifts of the $\pi^*_\sigma \rightarrow d_\sigma$ CT bands in the (peroxo)dicopper(II) species, **1b** and **2b**, were caused by a stabilizing π^*_σ orbital energy level giving the larger $\pi^*_\sigma - d_\sigma$ CT energy gap.

In the $\pi^*_v \rightarrow d_\sigma$ transition wavelength region ($\approx$ 600 nm), the shoulder LMCT bands of **1b** and **2b** are broadened as shown in Figure 4. The shoulder LMCT absorbances of **1b** and **2b** at 600 and 600 nm (ε = 1500 and 1500 $M^{-1}cm^{-1}$) are smaller than those of **3b** and **4b** at 600 and 600 nm (ε = 8000 and 4000 $M^{-1}cm^{-1}$), respectively. The decrease in the $\pi^*_v \rightarrow d_\sigma$ CT absorbance would also be affected by the intramolecular hydrogen bonding interaction. In the case of **3b** and **4b** without a hydrogen bonding moiety, the π^*_v orbital of the peroxide can overlap well with the d_σ orbital of copper because of the free rotation of the Cu−O bond in these (peroxo)dicopper(II) complexes. In **1b** and **2b**, however, such a rotation around the Cu−O bond is apparently inhibited by the hydrogen bond formed between the groups in the 6-position of the pyridine ring and the ligating peroxide ion with the result that overlap of the π^*_v and the d_σ orbitals would become small enough so as to decrease the CT transition probability.

In summary, the absorption spectroscopic behavior of the (peroxo)dicopper(II) complexes in question can be interpreted in terms of the contribution of the hydrogen bonding ability of the NH group of the pivalamido or amino groups introduced into pyridine 6-position of the ligands.

Thermal Stability of the (μ-Peroxo)dicopper Complexes with Hydrogen Bonding Interaction Sites

In our previous report, we found that the copper(II) complex with pivalamido at the 6-position of pyridine ring in the ligand forms the stable (hydroperoxo)copper(II) complex, $[Cu^{II}(bppa)(OOH)]^+$ [BPPA = bis{[6-(pivalamido)pyrid-2-yl]methyl}(2-pyridylmethyl)amine][36] which remains stable in solution at room temperature for more than one month. The first crystal structure of a monomeric (hydroperoxo)copper(II) complex $[Cu^{II}(bppa)(OOH)]^+$ revealed that the pivalamido NH group of BPPA interacts with the ligated hydroperoxide oxygen atom by hydrogen bonding, thus promoting its thermal stability.[36] Based on this study, we expected that the hydrogen bond interaction might stabilize (μ-peroxo)dicopper(II) species generated from the Cu-MPPA and -MAPA systems. The thermal stability of these peroxo species at 183 or 213 K was established by monitoring the decrease in their LMCT absorbances. The reduction of the LMCT bands occurred with first-order kinetics, demonstrating the decomposition of the (μ-peroxo)dicopper(II) species. The decomposition rate constants are listed in Table 6. The effects on the thermal stabilities of the (μ-peroxo)dicopper(II) species as a result of substitution at the 6-position of pyridine ring are described in detail in the following discussion.

Table 6. Decomposition rate constants of $[(CuL)_2(O_2)]^{2+}$ complexes

L (Ligand)	λ_{max}/nm	$k_{obsd.}$/min^{-1} [a]	T/K
MPPA (**1b**)	517	0.2×10^{-3}	183
6-MeTPA (**4b**)	537	39.4×10^{-3}	183
MPPA (**1b**)	517	13.3×10^{-3}	213
MAPA (**2b**)	503	2.5×10^{-3}	213
TPA (**3b**)	523	2.9×10^{-3}	213

[a] The $k_{obsd.}$ values are estimated by following the decrease of absorption band (λ_{max}).

The (μ-peroxo)dicopper(II) complex **4b** is remarkably unstable and its decomposition rate is the fastest of all the complexes listed in Table 6 ($k_{obsd.}$ = 39.4×10^{-3} min^{-1} at 183 K). Unlike the other systems, the decomposition of **4b** at 213 K was too fast to allow estimation of the rate constant. This clearly indicates that the thermal stability of the (μ-peroxo)dicopper(II) complex is extensively decreased by the sterically hindered 6-methyl substituent around the metal center.[44,45] Substitution of the 6-pivalamido group in place of the 6-methyl substituent dramatically improves the thermal stability and stabilized the (μ-peroxo)dicopper(II) complex, **1b** ($k_{obsd.}$ = 0.2×10^{-3} min^{-1} at 183 K). Furthermore, the analogous 6-amino-substituted (μ-peroxo)dicopper(II) complex **2b** ($k_{obsd.}$ = 2.5×10^{-3} min^{-1}) is more stable than **1b** ($k_{obsd.}$ = 13.3×10^{-3} min^{-1} at 213 K) and its thermal stability was improved to the same extent as that of **3b** ($k_{obsd.}$ = 2.9×10^{-3} min^{-1}), although the amino group in the 6-position of pyridine ring is as bulky as the methyl group in **4b**.

The order of the thermal stability of these peroxo complexes can therefore be determined as follows: **2b** $\approx$ **3b** > **1b** >> **4b**.The (μ-peroxo)dicopper complexes are partially stabilized by the hydrogen bonding interaction, although the stability was reduced by the adverse effect of the steric bulk around the metal ion.

Conclusion

In order to examine the mode of the hydrogen bonding interaction and its effect on the (μ-peroxo)dicopper(II) species, we have prepared copper complexes with the tripodal tetradentate ligands MPPA and MAPA which bear a hydrogen bonding site . The crystal structures of the azide complexes **1a** and **2a** revealed that pivalamido and amino NH groups in 6-position of the pyridine ring can interact with the axially coordinated azide ion via the hydrogen bond. The tripodal ligands with a hydrogen bonding ability exerted significant influence on two LMCT bands of the (μ-peroxo)dicopper(II) species. The energy of the $\pi^*_\sigma \rightarrow d_\sigma$ CT transition was raised and the absorbance of the $\pi^*_v \rightarrow d_\sigma$ CT band was decreased. Such characteristic spectroscopic

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

behavior was interpreted in terms of stabilization of the π^*_σ orbital and restriction of rotation of the Cu−O bond by the hydrogen bond between the NH group and the axially coordinated peroxide groups of the copper complexes. Finally, the hydrogen bonding interaction was found to overcome the adverse effect of steric bulk and thus stabilize the (μ-peroxo)dicopper(II) complexes.

Experimental Section

Materials and Measurements: Reagents and solvents employed were of the highest grade available. All solvents for spectroscopy were further purified by distillation before use. Other chemicals were used without further purification. Tris(pyrid-2-ylmethyl)amine (TPA) and [(6-methylpyrid-2-yl)methyl]bis(pyrid-2-ylmethyl)amine (6-MeTPA) were prepared using literature methods.[16,44] Electronic absorption spectra were recorded at low temperature with a JASCO Ubest-35 spectrophotometer equipped with an Oxford Variable Temperature Liquid Nitrogen Cryostat Optistant. X-Band ESR spectra of frozen solutions were recorded at 77 K by using a JEOL RE-1X ESR spectrometer. ^{1}H NMR spectra were measured with a Bruker Avance-600 spectrometer with chemical shift values referenced relative to TMS as an internal standard. Cyclic voltammetric measurements were performed using a Bioanalytical Systems (BAS) CV-1B electrochemical analyzer. A three-electrode system was used with a 3-mm diameter glassy carbon electrode as the working electrode, a saturated calomel electrode (SCE) as the reference electrode and a Pt-wire electrode as the counter electrode in a glass cell having a working compartment of approximately 3 mL in volume. All measurements were made in solution at 25 °C under argon with tetra(*n*-butyl)ammonium tetrafluoroborate (0.1 M) as a supporting electrolyte at a scan rate of 100 mVs^{-1}. The potential of the regular ferrocene/ferrocenium (Fc/Fc^+) redox couple in acetonitrile was −0.33 V under our experimental conditions. In order to discuss the electrochemical values in comparison with other data, all the electrochemical potentials were converted into values with the normal hydrogen electrode (NHE) as a standard by adding 244.4 mV. Resonance Raman spectra were recorded with a liquid-nitrogen-cooled CCD detector (Model LN/CCD-1300-PB, Princeton Instrument) attached to a 100-cm single polychromator (Model MC-100DG, Ritsu Oyo Kogaku). The excitation was provided by the 476.5-nm line of an Ar laser (Model GLG3200, NEC). $^{16}O_2$ samples were prepared by bubbling dry dioxygen into acetone or EtCN solutions of the copper(I) complexes with tetradentate ligands at −78 °C. Isotopic substitution of the peroxo oxygen atoms bridged to the dicopper ions was accomplished by oxygenation of the copper(I) complexes with $^{18}O_2$. All measurements were carried out with a spinning cell maintained at −78 °C by a stream of liquid N_2 vapor.

Synthesis of Ligands

{[6-(Pivalamido)-2-pyridyl]methyl}bis(pyrid-2-ylmethyl)amine (MPPA): Reaction of the primary amine, 2-(aminomethyl)-6-(pivalamido)pyridine,[37,38] (2.80 g, 13.5 mmol) with 2 equiv. of 2-(chloromethyl)pyridine (5.25 g, 32.0 mmol) was carried out in a dioxane/H_2O (4:1) solution (300 mL) containing KOH (2.92 g, 52.0 mmol). The solution was stirred at 50 °C for 3 d followed by removal of the solvent by evaporation in vacuo. Dissolving the resultant crude brownish oil in diethyl ether and allowing it to stand at room temperature gave colorless needle-like crystals of MPPA (2.32 g, 45.9% yield). ^{1}H NMR ($CDCl_3$): δ = 1.33 (s, 9 H), 3.78 (s, 2 H), 3.89 (s, 2 H), 7.15 (m, 2 H), 7.28 (d, 2 H), 7.56 (d, 2 H), 7.66 (t, 3 H), 7.95 (b, 1 H), 8.06 (b,1 H), 8.10 (d, 1 H), 8.53 (d, 2 H) ppm.

[(6-Aminopyrid-2-yl)methyl]bis(pyrid-2-ylmethyl)amine (MAPA): To an ethanol solution (500 mL) of MPPA (3.89 g, 10.0 mmol) was added KOH (28.1 g, 0.50 mol). The solution was stirred at 50 °C for 1 week. After removal of the solvent from the reaction mixture by evaporation in vacuo, the resultant crude brownish oil was dissolved in dichloromethane (100 mL) which was washed with water and dried with $MgSO_4$. The resultant solution was concentrated in vacuo to give the crude product as an oil. Pure MAPA was obtained as colorless needle-like crystals by recrystallization from diethyl ether (2.13 g, 70.0% yield). ^{1}H NMR ($CDCl_3$): δ = 3.54 (s, 2 H), 3.76 (s, 4 H), 5.79 (s, 2 H), 6.30 (d, 1 H), 6.73 (d, 1 H), 7.24 (t, 2 H), 7.35 (t, 1 H), 7.62 (d, 2 H), 7.77 (t, 1 H), 8.48 (d, 2 H) ppm.

Synthesis of Cu Complexes

Preparation of [Cu(mppa)](ClO$_4$)$_2$: To a stirred MeOH solution (10 mL) of $Cu(ClO_4)_2 \cdot 6H_2O$ (74.1 mg, 0.2 mmol) was added MPPA (77.8 mg, 0.2 mmol). After the resultant mixture was allowed to stand at room temperature for a few days, blue crystals of $[Cu(mppa)](ClO_4)_2$, suitable for X-ray structural analysis, were obtained. Yield: 109 mg (85%). $C_{23}H_{27}Cl_2CuN_5O_9$ (651.94): calcd. C 42.37, H 4.17, N 10.73; found C 42.57, H 4.16, N 11.05.

Preparation of [Cu(mppa)(N$_3$)]ClO$_4$: To a stirred MeCN solution (10 mL) of $[Cu(mppa)](ClO_4)_2$ (151.9 mg, 0.2 mmol) was added NaN_3 (13.0 mg, 0.2 mmol). A green precipitate formed immediately. After filtration, recrystallization of the precipitate from MeCN gave plate-like green single crystals, suitable for X-ray structural analysis. Yield: 85 mg (71%). $C_{23}H_{27}ClCuN_8O_5$ (594.51): calcd. C 46.46, H 4.47, N 18.84; found C 46.38, H 4.47, N 19.15.

X-ray Structural Analysis of [Cu(mppa)](ClO$_4$)$_2$ and [Cu(mppa)(N$_3$)]ClO$_4$: Crystals suitable for X-ray diffraction measurements were mounted on glass fibers. The diffraction data were collected with a Rigaku Mercury diffractometer using graphite-monochromated Mo-K_α radiation at −100 °C with the oscillation technique. Crystal data and experimental details are listed in Table 7. All structures were solved by a combination of direct methods and Fourier techniques. Non-hydrogen atoms were anisotropically refined by full-matrix least-squares calculations. Hydrogen atoms were included but not refined. Refinements were continued until all shifts were smaller than one-third of the standard deviations of the parameters involved. Atomic scattering factors and anomalous dispersion terms were taken from the International Tables for X-ray Crystallography.[50] All calculations were carried out with a Japan SGI workstation computer using the teXsan crystallographic software package.[51] CCDC-211622 and -211623 contain the crystallographic data for this paper. This data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/ or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ [Fax: (internat.) + 44-1223-336-033; E-mail: depost@ccdc.cam.ac.uk].

Reaction of [Cu(L)]PF$_6$ (L = MPPA, MAPA, TPA, 6-MeTPA) with Dioxygen: Sample solutions of $[Cu(L)]PF_6$ (L = MPPA, MAPA, TPA, 6-MeTPA) were prepared by mixing $[Cu(MeCN)_4]PF_6$ (0.7 mg, 2.0 mmol) and each ligand (2.1 mmol) in acetone (4 mL) at room temperature under nitrogen. The resultant solutions containing $[Cu(L)]PF_6$ were oxygenated by bubbling dioxygen through them at −78 °C. The formation and decomposition of the peroxo intermediates were monitored by following the increase or decrease in their characteristic ligand−metal change transfer (LMCT) absorption bands at λ_{max} = 517, 503, 524, and 537 nm, for $[\{Cu(L)\}_2(O_2)]^{2+}$ [L = MPPA (**1b**), MAPA (**2b**), TPA (**3b**), 6-

MeTPA (**4b**)], respectively. The thermal stability of the peroxo species was examined under constant temperature (183 or 213 K) by following the absorption intensity at 5-min intervals for 12 or 24 h. The decomposition process of the respective complex was analyzed using first order kinetics in which $\ln([A]/[A_0])$ values were plotted according to the time course (where $[A_0]$ and $[A]$ are absorption intensities of the LMCT bands observed initially and at a given time). It was observed that decreasing of the LMCT bands exhibited good first-order kinetics for each peroxo complex.

Acknowledgments

This work was supported partly by a Grant-in-Aid for Scientific Research (No. 11228203, 12304039) from the Ministry of Education, Science, Sports, and Culture of Japan and in part by a grant from the NITECH 21st Century COE Program (S. Y. and H. M.) to which our thanks are due. A. W. is grateful to the Japan Society for the Promotion of Science for a JSPS Research Fellowship for Young Scientists.

Bis(*tert*-butoxyaluminum dihydride) $(t\text{BuOAlH}_2)_2$ decomposes on metal surfaces heated to 250 °C (Fe, Ni, Cu, Pt) and under reduced pressures of 0.01–0.1 atm with elimination of dihydrogen and isobutene to form a glasslike, amorphous film, which is composed of equimolar parts of hydrogen, aluminum and oxygen (elemental analysis, EDX analysis). The gases eliminated during this process were characterized by mass spectroscopy (H_2, isobutene) or by infrared matrix techniques (isobutene). The exclusive binding of hydrogen to aluminum is deduced from IR spectroscopy of the HAlO film and of its deuterated form DAlO. The HAlO layer (which shows no X-ray diffraction pattern), when heated to 450 °C or when exposed to a CO_2 laser, loses hydrogen and transforms to an almost stoichiometric composite with nanoscale crystalline aluminum and aluminum oxide (Al/Al_2O_3) as ingredients. This transformation may be followed by IR spectroscopy, by ^{27}Al MAS NMR or by XPS, the latter showing different signals (Al, 2p electrons, Mg-K_α, $\theta = 0°$) for HAlO (74.2 eV) and for the composite (Al: 72.1 eV, Al_2O_3: 75.3 eV). Microstructures that are characterized by different chemical compositions and different optical contrasts of the "drawing", relative to the surrounding matrix, may be generated with an X/Y-table and a CO_2 laser.

Introduction

Aluminum hydride (AlH_3)[1,2] and aluminum oxide (Al_2O_3)[3] are well-characterized, crystalline compounds. In the first case, the compound may be considered a coordination polymer from a molecular point of view. For aluminum oxide, several crystalline and amorphous phases, which are often described as ionic structures, are known.[4] Well-established compounds of aluminum simultaneously containing hydrogen and oxygen are aluminum hydroxide, $[Al(OH)_3$, for example: bayerite] and other oxohydroxides such as boehmite, AlO(OH).[5,6] It is interesting to note that no chemically pure compounds in which hydrogen is directly bound to aluminum have yet been described (for recent developments see the next paragraph). This is even more surprising because aluminum oxohalides with the general formula XAlO (where X = Cl, Br, I) have been well-established for many years and have been structurally characterized by X-ray diffraction[7–9] (and for molecular OAlX species in matrix by spectroscopy[10]).

We were intrigued by the possible existence of HAlO, a compound that may be derived from the oxohalide by formal substitution of the halide by hydride. Instead of using a classical solid-state reaction to synthesize this compound, we chose a molecular route, which seemed to open up the access to metastable compounds or phases. When revising the manuscript in June, we learned that R.J. Wehmschulte and his co-workers have described a powder, obtained in organic solvents, in which HAlO also seems to be present.[29] This mixed compound, which also contains some organic residues, is synthesized by treating AlH_3*NMe_3 with siloxanes [such as $(Me_2SiH)_2O$]; the oxygen is thus transposed from silicon to aluminum, while the hydride is partly transferred to silicon, forming Me_2SiH_2. Indeed, some of the spectroscopic data given in this paper[29] are similar to our results, while others seem to be different. This difference may also be due to the fact that we describe a layer, whereas the alternative route gives a powder.

Results and Discussion

Synthesis and Elemental Composition of HAlO

For the synthesis of HAlO, the gas-phase decomposition of $(t\text{BuOAlH}_2)_2$ on metallic substrates heated to 240–250

°C at low pressures (0.01−0.1 atm) was used.[11,12] HAlO is formed as a transparent layer on the metallic surface of the sample and may be separated as a glasslike film from the metal surface using cold shock in a liquid-nitrogen bath. Prior to the gas-phase process the whole apparatus is heated, flooded, and pumped several times with nitrogen, argon, or helium, in order to eliminate residual oxygen and water in the apparatus. The most simple way to generate HAlO layers is to direct a constant stream of $(t\text{BuOAlH}_2)_2$ on inductively heated copper, nickel, iron, or platinum substrates in a CVD cold-wall reactor, the principle construction of which was described earlier.[13] The obtained layers stick well to the metal surfaces if their thickness does not exceed 2−3 μm, and they are stable towards the atmosphere (H_2O, O_2, H_2S, CO_2) for longer periods of time. The synthetic route used has to be different from the route producing the composite Al/Al_2O_3, which requires distinctly higher temperatures (450−500 °C) at the surface of the metallic target, with $(t\text{BuOAlH}_2)_2$ as a precursor[14,15] (see also next chapters and reference [16]).

In order to get some insight in the thermal reaction discussed above and in order to analyze the gaseous products of the reaction, we ran the same process with the deuterated molecule $(t\text{BuOAlD}_2)_2$ parallel to $(t\text{BuOAlH}_2)_2$ (where D = ^{2}H). The mass spectra of the two reactions only differ in one mass peak at m/z = 3 (HD), which is the signal of highest intensity for the deuterated compound, whereas this peak is completely absent in the mass spectrum when $(t\text{BuOAlH}_2)_2$ is the precursor. A mass fragment m/z = 4 is not found in the case of $(t\text{BuOAlD}_2)_2$ (as long as 270 °C is not exceeded), and all signals in both spectra, besides hydrogen, are those of isobutene.

Conducting a constant stream of $(t\text{BuOAlH}_2)_2$ through a quartz tube heated to 300−700 °C and subsequent trapping of the gaseous products in a cold argon matrix leads exclusively to isobutene, in accordance with the mass spectrometry (see Figure 1).

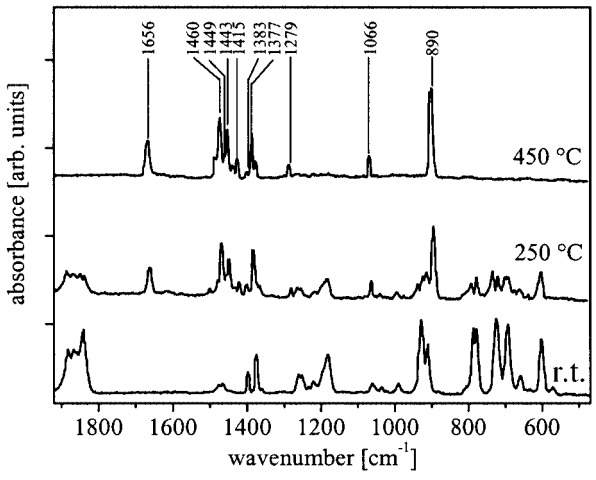

Figure 1. IR spectra of the argon matrix isolated isobutene with identification of the lines (spectrum obtained at 450 °C) and the precursor spectra of $(t\text{Bu−O−AlH}_2)_2$ obtained at room temperature (r.t.) and at 250 °C; already at 250 °C the evolution of isobutene, together with residual $(t\text{Bu−O−AlH}_2)_2$, is found

No $(HAlO)_n$ species or any other aluminum compound is trapped in the matrix under these experimental conditions. This observation is a first hint that HAlO must have a high molecular mass and perhaps a complex structure. On the basis of these findings, the reactions may be formulated as in Equation (1).

$$\begin{aligned}[H_3C-C(CH_3)_2-O-AlH_2]_2 &\rightarrow H-H + H_2C=C(CH_3)_2 \\ &\quad + 2/n\,(HAlO)_n \\ [H_3C-C(CH_3)_2-O-AlD_2]_2 &\rightarrow H-D + H_2C=C(CH_3)_2 \\ &\quad + 2/n\,(DAlO)_n\end{aligned} \quad (1)$$

The splitting off of dihydrogen from $(t\text{BuOAlH}_2)_2$ can be explained by the recombination of a partially negatively charged hydrogen at aluminum with a partially positively charged hydrogen in the *tert*-butyl group, forming isobutene as a complementary molecule (β-elimination). The observed reaction is very similar to the process when $[Mg\{(Ot\text{Bu})_2AlH_2\}_2]$ is transformed to $MgAl_2O_4$.[17]

Whereas the structural and analytical characterization of the gaseous products of Equation (1) is straightforward, the structure and composition of HAlO is not yet clear. From the EDX analysis, the Al to O ratio in HAlO is 0.96(3) to 1.00(3). The carbon content of the film determined by classical elemental analysis is C = 0.2(1)%, and the hydrogen content has a high standard deviation with a lower threshold value of 0.8% (see also below). The aluminum content, determined by complexometry, is found to be 60.5(1.0)% near to the 61.4% calculated for HAlO.

In order to make the elemental determination of hydrogen and its relation to the other elements more accurate, we developed a new analytical method. First we deposited a layer of HAlO (around 1.8 mg) on a thin platinum sheet of approximately 30 mg. The layer was then dissolved in a defined volume of 2 N HCl heated to 80 °C. To avoid hydrolysis of the aluminum ion, sodium fluoride was added to the solution. Some aliquots of the solution were taken to determine the former hydroxide content (after HCl addition and by back-titration with NaOH) and others for the determination of the aluminum content by complexometry. The hydrogen content can be deduced from volumetric measurements of the gas developed from the contact with the acid in a calibrated vessel [see also Equation (2)]. It should be pointed out that freshly prepared samples have to be used and that the HAlO layer should be produced at moderate temperatures (240−250 °C). If higher temperatures are used on the platinum sheet during the deposition process, slightly yellow layers with a significant decrease in the hydrogen content of the layer are obtained.[18]

$$\begin{aligned}1/n(H-AlO)_n + 3\,H_3O^+Cl^- + 6\,NaF &\rightarrow H_2 + 4\,H_2O \\ &\quad + 3\,NaCl + Na_3(AlF_6)\end{aligned} \quad (2)$$

From these analyses, the experimental molar ratio of the elements in the layers on platinum are H:Al:O = 0.95(8):0.95(8):1.0.

Properties of HAlO

The HAlO layers do not show any reflections when exposed to X-rays. In the infrared spectrum of HAlO (see Figure 2), two signals of different width are found in the 1100−2000 cm^{-1} region: one of these absorption bands at 1925 cm^{-1} is sharp while the other seems to be broad, with a shoulder around 1670 cm^{-1}.

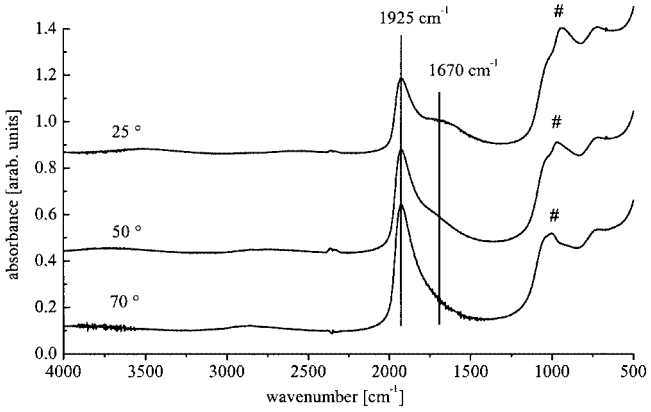

Figure 2. IR spectra of an HAlO layer deposited on a plain copper target in angle-dependent reflection (angles taken between the perpendicular line to the surface and the incoming beam); the signals indicated by # do not belong to the layer and are due to the spectrometer setting

In the deuterated sample DAlO, these absorption bands are found at 1400 and 1223 cm^{-1}, respectively (see Figure 3). The observed isotopic shifts are only understandable for vibrations in which hydrogen takes part, and the values indicate that terminal Al−H (higher wavenumbers) and bridging Al−H···Al entities are both present.[19,20] From the spectra, shown in Figures 2 and 3, obtained in the reflection mode on films deposited on plain metal substrates, it is evident that there is a correlation between the incident angle of the IR beam and the width and the intensities of the absorptions.

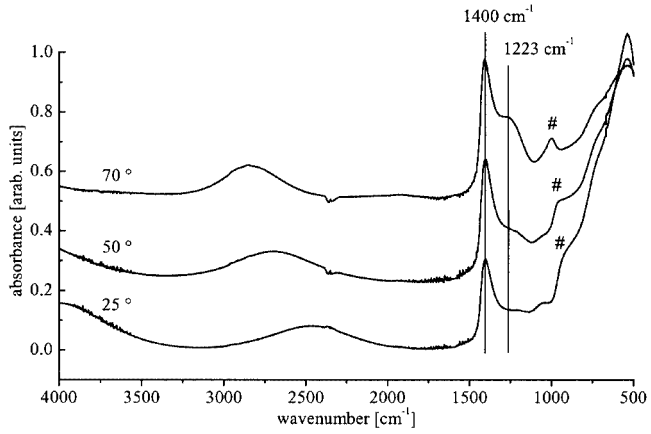

Figure 3. IR spectra of a DAlO layer in angle-dependent reflection with "wrings"; cf. the comments of Figure 2

Although we have not yet finished our systematic studies, we have noticed that, for example, the relative intensities of the hydrogen-based and oxygen-based vibrations (found in between 600−900 cm^{-1} with a characteristic shoulder at 730 cm^{-1}) change with the angle of incidence of the IR beam. This change could indicate different orientations between the Al−H and Al−O bonds with respect to the plain surface of the film.[18]

In the ^1H NMR (MAS) spectrum of the glassy HAlO film separated from the metal target by the shock technique (see above), a broad, structured absorption at approximately 4.0 ppm appears [hydride in $(t\text{BuOAlH}_2)_2$ at δ = 4.48 ppm].[12] In the ^{27}Al NMR spectrum [see spectrum (e) in Figure 4] absorption peaks are found at δ = 6 (sixfold), 30 (fivefold) and 58 ppm (fourfold coordinated aluminum) indicating an amorphous or complex structure for HAlO.[21] For comparison, ^{27}Al NMR spectra for amorphous Al_2O_3 {obtained from the thermolysis of $[(t\text{BuO})_2\text{AlH}]_2$ (a)}, for aluminum metal [obtained from the thermolysis of AlH_3 (b)] and for composites Al/Al_2O_3 [obtained from HAlO at 600 °C (c) and 450 °C (d)] are shown in Figure 4. The aluminum metal is nicely characterized through its Knight shift, whereas in the Al−O (Al−H) region (due to more, or less crystallinity and different compositions) the maxima of the peaks are of different intensities. These data, as well as the IR spectrum and the matrix-isolation experiments, indicate that HAlO is not a simple mixing of the distinct phases AlH_3 and Al_2O_3 (compare data in references [2,4,19,20,22]), but could be composed of different structural units.

The XPS analysis of an HAlO film obtained at 250 °C is consistent with the findings of the spectroscopic methods described so far. In Figure 5, the spectrum (2p-band of aluminum) of an HAlO layer (deposited at 250 °C) is compared to a surface of bulk aluminum that has been partly oxidized (lower part of the figure) and to an HAlO film

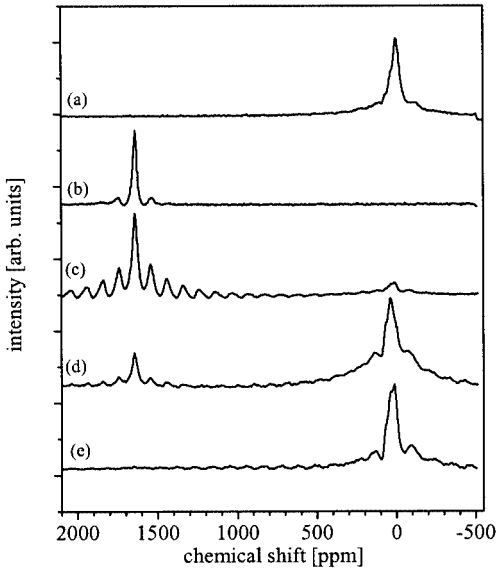

Figure 4. ^{27}Al NMR MAS spectra of (a) amorphous Al_2O_3 obtained from decomposition of $[(t\text{BuO})_2\text{AlH}]_2$, (b) aluminum obtained by decomposition of AlH_3, (c) solid phase after heating HAlO to 600 °C under argon, (d) solid phase after heating HAlO to 420 °C under argon, (e) HAlO obtained from $(t\text{BuOAlH}_2)_2$ at 250 °C

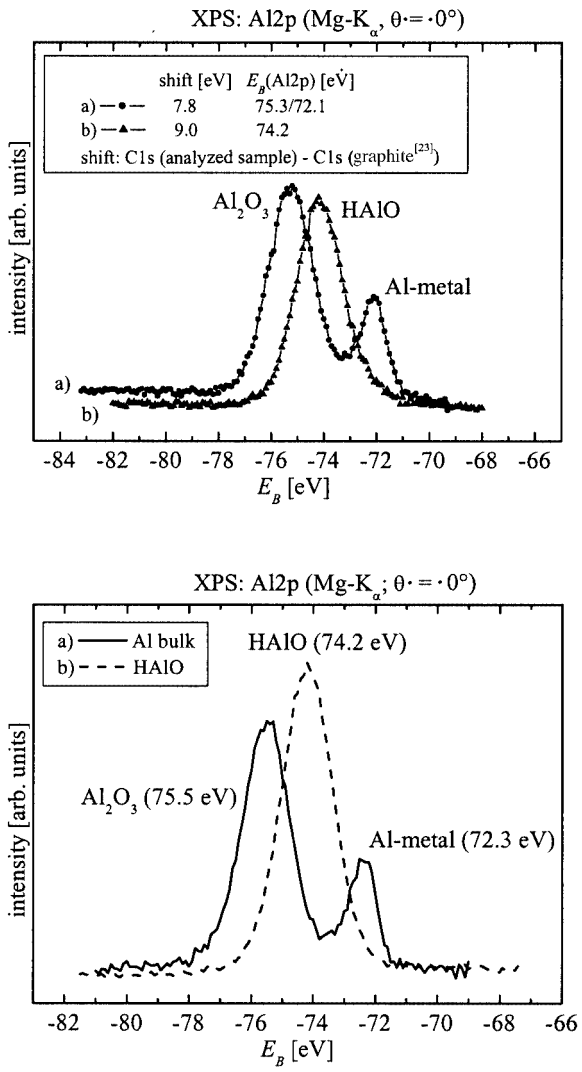

Figure 5. XPS spectra (measured in normal emission); top: the HAlO film obtained at 250 °C from (tBu−O−AlH_2)$_2$ (b) and an Al/Al_2O_3-composite, obtained by heating the HAlO film to 550 °C for comparison (a); bottom: the same HAlO film (b) and a partly oxidized aluminum sheet for comparison (a)

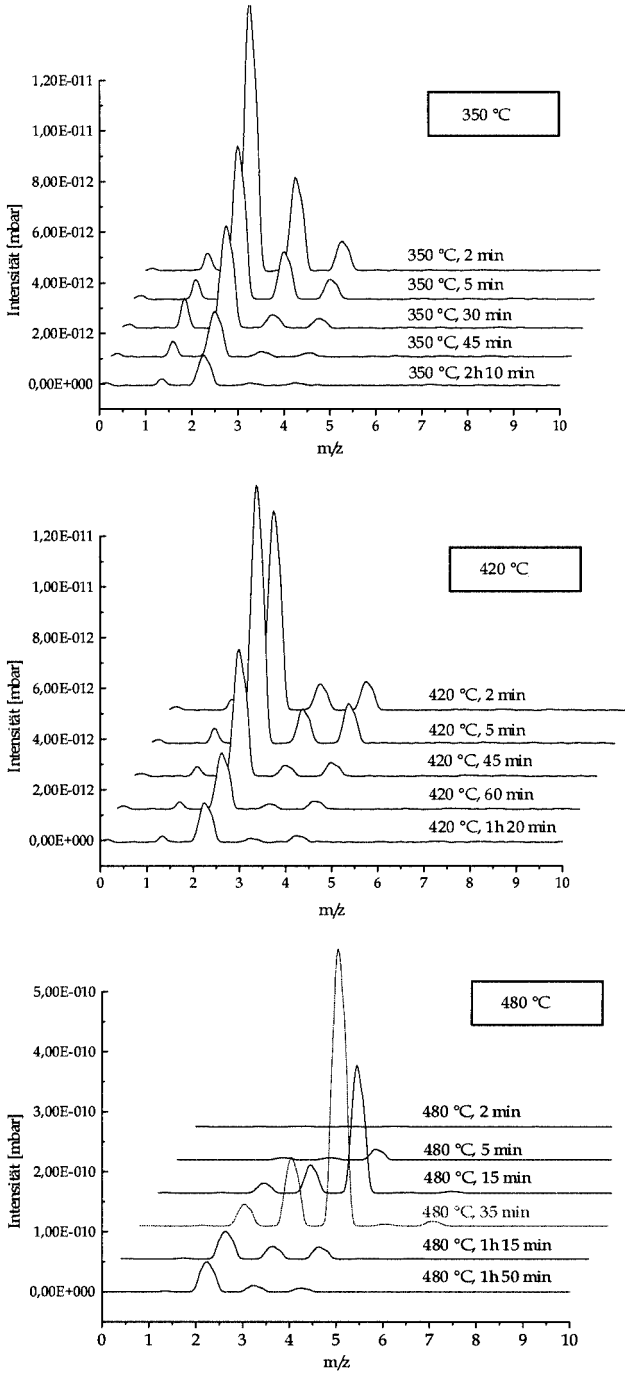

Figure 6. Evolution of H_2 or D_2 from H(D)AlO films (H:D = 8:92) heated at different temperatures, determined by mass spectrometry

that has been heated up to about 600 °C under exclusion of air (see also next paragraph). Compared to Al_2O_3 (Al, 2p-peak found at 75.3 eV), the Al atom in HAlO has a 2p-peak maximum at 74.2 eV, and is shifted towards the energy of the bulk Al metal (Al, 2p-band found at 72.1 eV in the corresponding samples), which is in accordance with the lower electronegativity of hydrogen compared to oxygen.

The bonding of hydrogen to aluminum and the metastable property of HAlO can be easily demonstrated by thermolysis of the film.[16,29] This experiment was repeated with DAlO containing approximately 8% HAlO. In the mass spectrum run simultaneously during decomposition, the evolution of the signal at m/z = 4(D_2) could be followed with increasing temperature and time (see Figure 6).

The hydrogen observed at the beginning may come from the HAlO mixing in the deuterated sample, or may be attributed to residuals on the surfaces of the sample and the apparatus. During the temper process, the color of the layer changed from transparent to black. The temperature- and time-dependent liberation of hydrogen may also be followed in the infrared spectrum of the film coated on the target, in which the Al−H valence vibration constantly decreases. At the end of the heating process the IR absorption at 1925 cm^{-1} had completely disappeared (see Figure 7).

At this stage the HAlO film had turned into a biphasic composite film of almost stoichiometric composition, Al/Al_2O_3. Figure 8 contains an X-ray powder diffractogram, which, apart from some non-indexed lines of low intensities

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

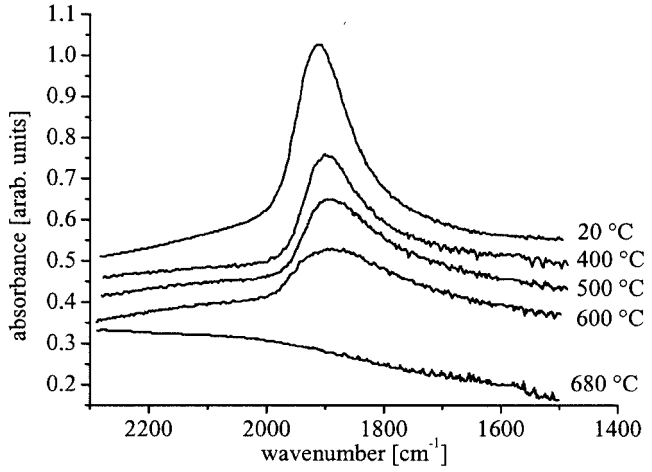

Figure 7. FT-IR spectra of HAlO layers in the 2200−1500 cm^{-1} region heated at different temperatures (heated for 3 minutes before the registration of each spectrum)

at low diffraction angles, consists of two phases: Al and γ-Al_2O_3 (aluminum forms nanoscale crystals; from the reflex profiles in the powder pattern 30−40 nm particles can be deduced;[24] compare also[14,15]).

The chemical equations for the tempering are assembled in Equation (3):

$$\begin{aligned} HAlO &\rightarrow 1/2\ H_2 + 1/3\ Al/Al_2O_3 \\ DAlO &\rightarrow 1/2\ D_2 + 1/3\ Al/Al_2O_3 \end{aligned} \quad (3)$$

The chemical equations in Equation (3) may be interpreted as follows: H (H_2) or D (D_2) is eliminated after breaking of the Al−H or Al−D bonds. The remaining "AlO" (with formal Al^{II}) seems to be unstable at the high processing temperatures and disproportionates to zero- and three-valent aluminum. Accordingly, the aluminum/oxygen ratio is maintained during the tempering process with an EDX analysis of the composite Al:O = 0.95(9):1.00 (similar to the precursor HAlO). In the classical CHN analysis, the carbon content remains 0.2(1)%, while no hydrogen can be detected.

Instead of transforming the whole surface by heating, locally defined regions may be tranformed using a 12.5-W CO_2 laser together with a motor driven *x*/*y*-table. By this technique various structures may be produced on the surface of the film.

In Figure 9, a 600 μm large letter, with a line width of approximately 70 μm, which is dark gray and is composed of Al/Al_2O_3 composite, is seen. The area around the letter is still made up of metastable HAlO, whereas in the infrared spectrum taken within the letter, no vibrations due to Al−H can be detected.

Conclusions

The formation of HAlO (DAlO) films by thermolysis of (tBuOAlH_2)$_2$ on hot metallic substrates has been shown to proceed via β-elimination of dihydrogen and isobutene. Although the HAlO layers are almost stoichiometric in hydrogen, aluminum and oxygen, their structure is not yet clear. Like in other amorphous glasses, there may be different structure entities present, which, according to NMR spectroscopy, seem to have four, five, and sixfold coordination sites around aluminum. HAlO films are metastable and lose hydrogen when heated. At a certain point disproportionation of intermediate Al(II) is observed, forming aluminum and aluminum oxide. From the infrared spectra, the presence of Al−H(D) bonding is beyond doubt; even under high reflection angles we have not yet been able to detect hydroxide on the surface of the films by infrared

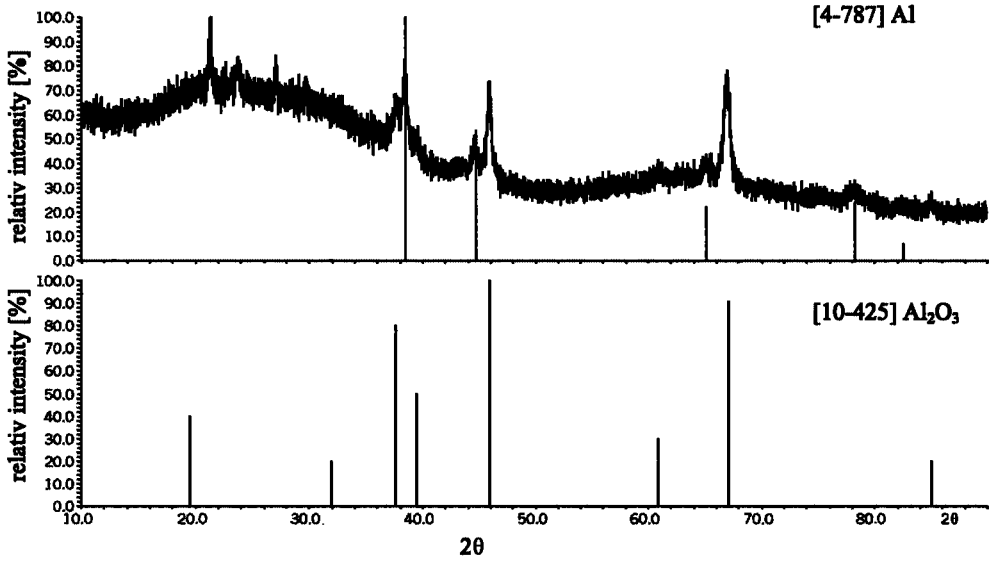

Figure 8. X-ray powder pattern of an HAlO layer on steel tempered at 510 °C; the reflections at lower 2-θ values seem to come from reactions of the iron surface, as they are almost absent on other metal surfaces; the reflections at higher angles can be indexed with Al[27] and γ-Al_2O_3[28]

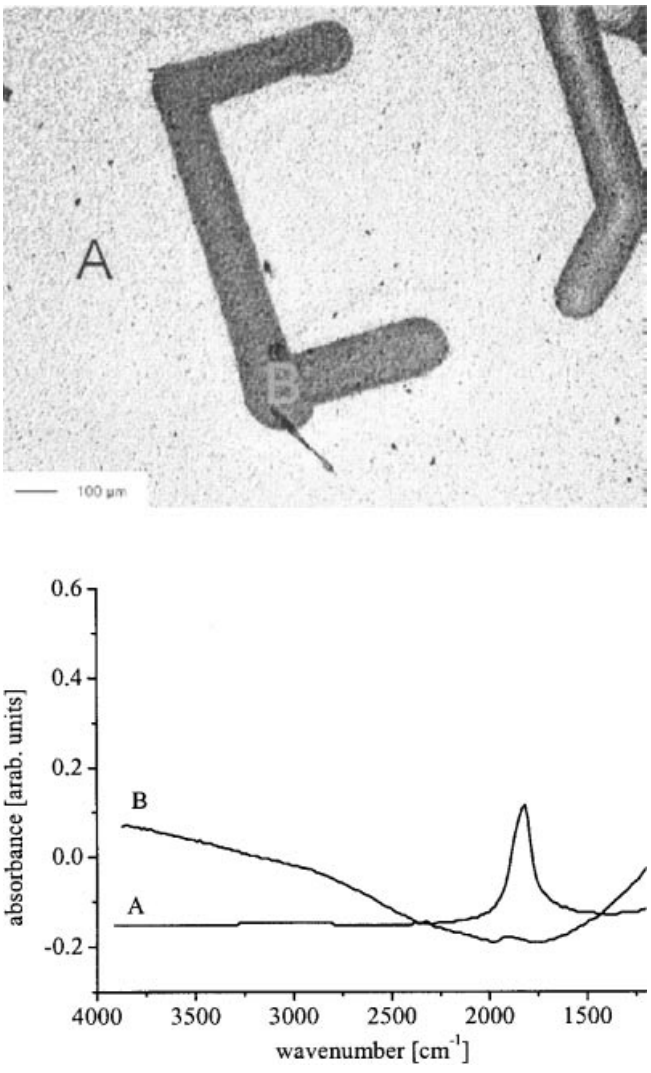

Figure 9. Light microscopy picture of a 3 µm thick HAlO layer, on which an Al/Al_2O_3-microstructure has been produced with a CO_2 laser (the sample was moved with respect to the laser beam with a velocity of 200 µm/s); the transparent (A) and the dark (B) spots show different absorptions in the Al−H region of the IR spectrum (reflection mode)

spectroscopy, although we cannot exclude it completely. More sophisticated measurements on the structure of HAlO are on the way.

Experimental Section

General Remarks: The precursor compound $(t\text{BuOAlH}_2)_2$ is synthesized following the routes described before[11,12] under dry N_2 using standard Schlenk techniques. The deuterated sample $(t\text{BuOAlD}_2)_2$ was obtained from $LiAlD_4$ instead of $LiAlH_4$. Solvents were dried by refluxing with appropriate drying agents and were distilled before being used. CVD was carried out in a cold-wall reactor as described in an earlier publication[13]. The CVD reactor consists of a cylindrical reaction tube in which the metal substrate is situated on a glass support. The substrate is heated inductively at temperatures ranging from 250−500 °C. The temperature of the substrate is measured by a thermocouple and is connected to the high frequency source to monitor the temperature. The quadrupole mass spectrometer is linked to the system and enables monitoring of the reaction gases.

Physical Measurements: The C, H analyses were carried out using a CHN analyzer from LECO™ Corporation, St. Joseph, MI., U.S.A. IR spectra of the produced solid film were obtained using a Bio-Rad FTS 165 with a mirror unit for direct reflection. ^{27}Al solid-state MAS NMR spectra were measured on a Bruker 200 MHz-MSL 200 with magic angle spinning (MAS). The powder X-ray diffraction measurements were performed in a glass capillary on a STOE diffractometer using Cu-K_α and a linear PSD detector. The XRD patterns of layer material were compared with literature values.[27,28] Electron microscopy and energy dispersive X-ray (EDX) analyses were performed on a scanning electron microscope CAMSCAN S4 with Si(Li)-semiconductor detectors and with thin windows (Cameca and Noran). The mass spectra of the pyrolysis gases were recorded on a quadrupole mass spectrometer QMS 200 (Balzer). The cryostat used for the matrix isolation of the pyrolysis gases and the deposition conditions are described in an earlier publication.[25,26] The IR spectra of the pyrolysis products were obtained with a Bruker IFS 113 v FT-IR spectrometer. The XPS spectra were recorded on a VG ESCA MKII spectrometer with a Mg-K_α-source (E_{kin} = 1253.6 eV, E_{Pass} = 10 eV, $\Delta E \approx$ 0.8 eV). The HAlO film was heated successively up to 600 °C on a micro-heating table TS 1400 (Linkham) under N_2 atmosphere. The tempering was monitored by IR spectrometry. Laser-structuring of the HAlO film was achieved by a CO_2laser (LC-25, DEOS) of 25 W. In the optical pathway between laser and film surface, layer gold-coated, optical lenses (f = 2.5 mm) were used for focussing, while the target was positioned by use of a micro-driven mechanical X/Y-table.

Preparation of Compounds

CVD Process of $(t\text{BuOAlH}_2)_2$ [$(t\text{BuOAlD}_2)_2$] and Synthesis of HAlO (DAlO): The thermal decomposition of the alkoxide precursor $(t\text{BuOAlH}_2)_2$ [$(t\text{BuOAlD}_2)_2$] was performed in a CVD apparatus. The experimental setup consists of a high vacuum line with Ar as the inert gas and a metal (steel, copper, nickel, platinum) support, which is inductively heated at 250 °C. The volatile precursor is transported to the substrate at pressures around 6.0×10^{-2} mbar. The volatile decomposition products (hydrogen, isobutene) were analyzed by online mass spectrometry. The precursor deposits on the substrate as a transparent HAlO layer. The CHN analysis of HAlO (43.989 g/Mol) gave a mean C value of 0.2(1), a range for H of 0.8 to 2.1% (calculated: 2.31%) and a value for N of 0(0.1)%. EDX analysis agrees with an Al/O ratio of 0.96(3):1.00(3). The titrimetric analysis of Al content (with titriplex as complexing ligand) gave a value of 60.5 (1.0) wt% (calculated Al in HAlO: 61.4 wt%). In order to determine the content of aluminum with respect to hydroxide in the same sample (after hydrolysis of HAlO, see also Equation 2), we used a known concentration of aqueous HCl and a standard solution of NaOH for back-titration. In a typical experiment, a layer of HAlO (1.212 mg, 0.0276 mMol) deposited on a platinum sheet gave 0.028(4) mMol aluminum and 0.087(4) mMol of hydroxide, consistent with a H:Al:O ratio of 1.05:1.01:1.05. The volumetric determination of the hydrogen evolved during hydrolysis in a calibrated tube (under standard conditions), gave typically 95% of the assumed hydrogen content. The reflectance IR spectra of the HAlO thin layer show an absorption at 1925 cm^{-1} (valence vibration for terminal Al−H groups), a shoulder at 1670 cm^{-1} for bridging Al−H···Al groups, and a broad band between 900 and 600 cm^{-1} with a typical shoulder at 730 cm^{-1} (Al-O groups). The ^1H-MAS solid NMR spectrum of HAlO shows a wide, structured absorption with a maximum at 4.0 ppm. The ^{27}Al-MAS solid NMR spectrum shows peaks at 6, 30 and 58 ppm. The binding

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

energy of the 2p-signal of aluminum in HAlO was found at 74.2 eV in the XPS spectrum.

Synthesis of Al/Al_2O_3 by Annealing of HAlO: The HAlO sample was tempered on a micro-heating table under N_2 atmosphere or was heated inductively in the CVD reactor under vacuum conditions (1×10^{-2} mbar). The annealing of the HAlO at 500 °C for one hour transforms the transparent layer into a black Al/Al_2O_3 composite. The XRD pattern of the Al/Al_2O_3 is shown in Figure 8. EDX analysis agrees with an Al/O ratio of 0.95(9):1.00. The CHN analysis of the composite gave a mean C value of 0.2(1)%, and almost no H and N. In the IR spectrum a broad absorption is found between 900 cm^{-1} and 600 cm^{-1}. During the temper process of HAlO (DAlO) the hydrogen elimination was detected online by a quadrupole mass spectrometer linked to the CVD apparatus (see also Figure 6). The XPS analysis shows the binding energies of two 2p-signals of aluminum: at 75.3 eV for Al_2O_3 and at 72.1 eV for Al, in agreement with the literature.[23] The peaks were shifted towards the C1s peak (E_B = 284.3 eV).

Synthesis of Al/Al_2O_3 by CO_2 Laser Treatment of HAlO: The HAlO sample was laser-treated by a CO_2 laser (12.5 W) in air. The transparent HAlO layer changes to display black Al/Al_2O_3 composite patterns. In the IR spectra (microscopic setup) of the Al/Al_2O_3 patterns, the Al−H valence bands at 1925 cm^{-1} and 1670 cm^{-1} disappear, whereas the broad absorption between 900 cm^{-1} and 600 cm^{-1} is maintained.

Synthesis, Structure and Magnetic Properties of a New Iron Arsenate, $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$, with a Layer Structure

Sandip Chakrabarti,[a] Swapan K. Pati,[b] Mark A. Green,[c] and Srinivasan Natarajan*[a]

Keywords: Iron / Arsenic / Solvothermal synthesis / N ligands

Through an unfortunate series of events, the Figures in this article[1] do not correspond with their captions. The correct version is given below.

The Editors

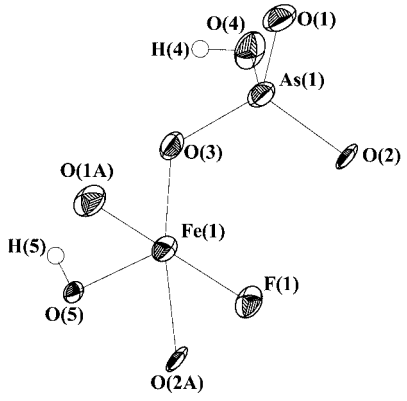

Figure 1. ORTEP diagram of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ showing the atoms that constitute the layer; thermal ellipsoids are given at 50% probability

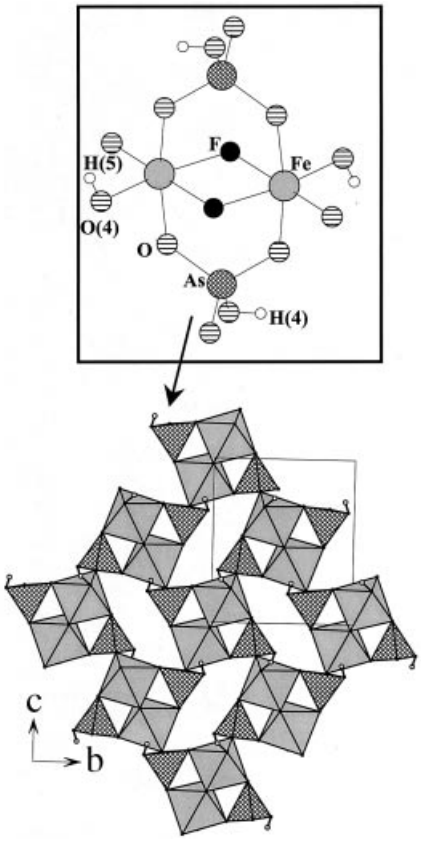

Figure 2. Polyhedral view of the structure of $[C_{10}N_4H_{28}]$-$[\{FeF(OH)(HAsO_4)\}_4]$ in the *bc* plane showing a single layer; the inset shows the SBU-4 units; the amine molecules are not shown

 DOI: 10.1002/ejic.200300838 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

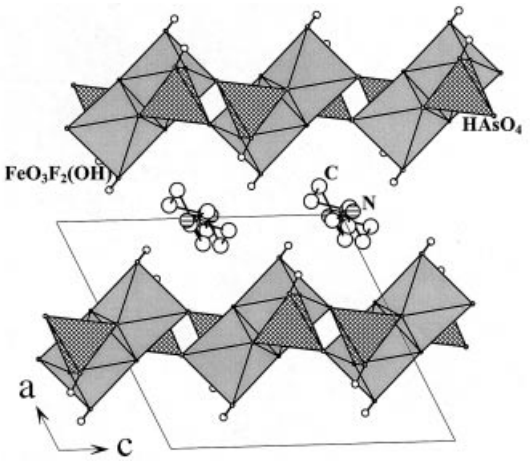

Figure 3. Polyhedral view of the structure of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ in the *ac* plane showing the arrangement of layers

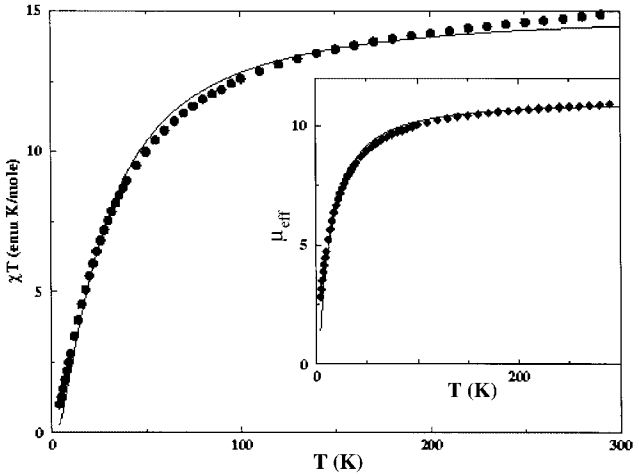

Figure 5. The variation of the χT as a function of temperature for $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$; the inset shows the variation of $\mu_{eff.}$ as a function of temperature; the solid line in both the cases shows the dimer-model fit to the experimental data

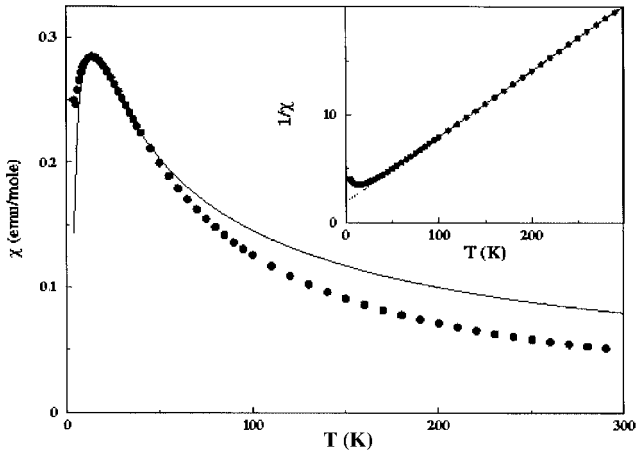

Figure 4. Thermal variation of the experimental magnetic susceptibility (χ) of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$; the solid line is a fit using the exponential form (see text); the inset shows the variation of inverse magnetic susceptibility (χ^{-1}) with temperature; the Curie−Weiss fit is shown as dotted lines

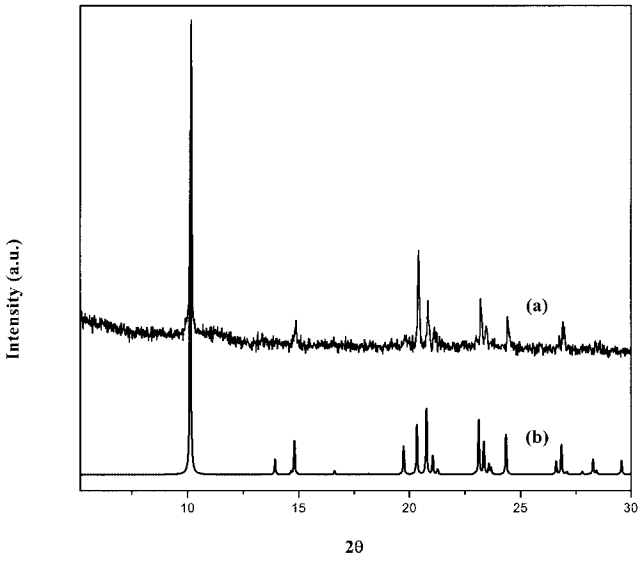

Figure 6. Powder XRD pattern of $[C_{10}N_4H_{28}]$-$[\{FeF(OH)(HAsO_4)\}_4]$ (a) experimental (Cu *Kα*) and (b) simulated

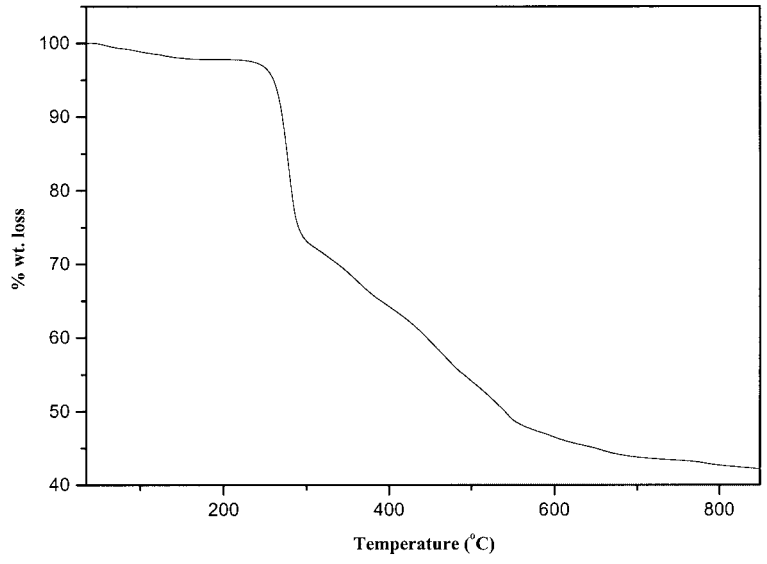

Figure 7. Thermogravimetric analysis (TGA) of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$

EurJIC
European Journal of Inorganic Chemistry

The Belgian, French, German, Greek, Italian, Netherlands, Portuguese and Spanish Chemical Societies, and the Hungarian Academy of Sciences together with the Hungarian Chemical Society have taken a significant step into the future by merging their traditional journals to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry*. Each one of the founding society owned journals brings decades of past excellence to this merger as a guarantee for future excellence. Three further European societies, those of Austria, the Czech Republic, and Sweden, are associate members.

E. L. Doyle, L. Riera, D. S. Wright*
Toroidal Main Group Macrocycles: New Opportunities for Cation and Anion Coordination
Eur. J. Inorg. Chem. **2003**, 3279−3289

A. E. H. Wheatley
The Directed Lithiation of Benzenoid Aromatic Systems
Eur. J. Inorg. Chem. **2003**, 3291−3303

M. Sundermeier, A. Zapf, M. Beller*
Palladium-Catalyzed Cyanation of Aryl Halides: Recent Developments and Perspectives
Eur. J. Inorg. Chem. **2003**, 3513−3526

M. Gómez
(Alkyl)(monocyclopentadienyl)niobium and -tantalum Complexes in Insertion Processes
Eur. J. Inorg. Chem. **2003**, 3681−3697

C. Den Auwer,* E. Simoni, S. Conradson, C. Madic
Investigating Actinyl Oxo Cations by X-ray Absorption Spectroscopy
Eur. J. Inorg. Chem. **2003**, 3843−3859

N. S. Hosmane,* J. A. Maguire
Recent Advances in the Chemistry of Metallacarboranes
Eur. J. Inorg. Chem. **2003**, 3989−3999

C. Belle,* J.-L. Pierre*
Asymmetry in Bridged Binuclear Metalloenzymes: Lessons for the Chemist
Eur. J. Inorg. Chem. **2003**, 4137−4146

W. Beck
The First Chemical Achievements and Publications by Justus von Liebig (1803−1873) on Metal Fulminates and Some Further Developments in Metal Fulminates and Related Areas of Chemistry
Eur. J. Inorg. Chem. **2003**, 4275−4288
