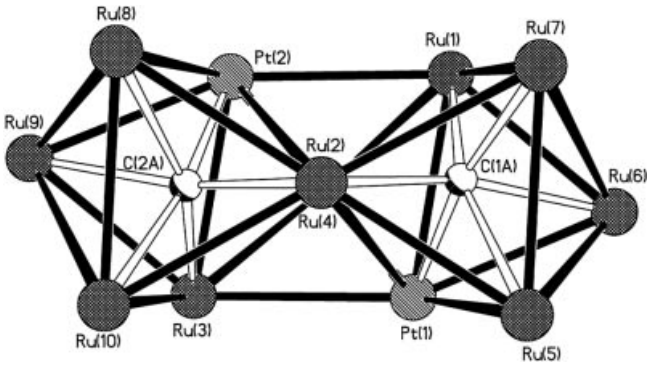

Figure 2. View down the C_2 axis passing through Ru(2) (top) and Ru(4) (bottom) atoms of the metal core of the dianion **2**

The structure of the dianion of **2** may be viewed in two different ways. The first considers the cluster core as three square-based pyramidal units [Pt(1)Ru(1)Ru(5)Ru(6)Ru(7), Pt(1)Pt(2)Ru(1)Ru(3)Ru(4), and Pt(2)Ru(3)Ru(8)-Ru(9)Ru(10)] sharing two edges [Pt(1)−Ru(1) and Pt(2)−Ru(3)] and bound together through the Ru(2) atom. The two outer pyramids correspond to Ru_4Pt units whereas the central pyramid accounts for Ru_3Pt_2. Alternatively, the structure may be viewed as three face-sharing octahedra with the two common edges — Ru(1)−Ru(2) and Ru(3)−Ru(2) — missing. The Ru(1)−Ru(2) (3.475 Å) and Ru(2)−Ru(3) (3.511 Å) distances indicate little or no direct metal-metal bonding. All Pt−Ru distances are within the expected range[5,6] with the shortest being Pt(1)−Ru(4) and Pt(2)−Ru(4) [2.7872(8) and 2.7905(9) Å, respectively] and the longest Pt(1)−Ru(2) and Pt(2)−Ru(2) [3.0800(9) and 3.1029(9) Å, respectively]. The Ru−Ru distances are similar to those reported previously for hexanuclear ruthenium clusters,[7−9] and lie between 2.7984(12) Å and 2.9333(12) Å, with the shortest being Ru(8)−Ru(9) [2.7984(12) Å] and Ru(5)−Ru(6) [2.8057(13) Å] and the longest Ru(9)−Ru(10) [2.9164(11) Å] and Ru(6)−Ru(7) [2.9333(12) Å], all these belonging to the outer pyramids. The bases of the two outer pyramids are inclined at an angle of 40° with respect to each other. The interstitial carbon atoms in each of these pyramids are shifted towards the Ru(2) atom and deviate from the plane of the base [by −0.244 Å and 0.269 Å for C(1a) and C(2a), respectively]. In agreement with the infrared data, eight carbonyl ligands are in bridging mode while the remaining twenty are terminally bonded. The Ru(2) atom bears only two bridging carbonyl ligands — the Ru(7) and Ru(10) atoms have each three terminal carbonyls — but all the other Ru atoms bear two terminal CO ligands and share two bridging CO ligands with neighboring Ru atoms. The platinum atoms are connected only to terminal carbonyls. The overall symmetry of the anion is C_2 with a twofold axis passing through Ru(2) and Ru(4) (Figure 2).

The cluster $[Ru_{10}Pt_2C_2(CO)_{28}]^{2-}$ (**2**) has a total of 166 valence electrons, which is four more than the 162 electrons predicted for three face-sharing octahedra, according to the condensed polyhedra approach proposed by Mingos. The four additional electrons might account for the two non-existing Ru−Ru bonds. This has also been noted in other Ru-Pt mixed-metal clusters, such as $[PtRu_5C(CO)_{13}(\mu\text{-}RC_2R)(\mu_3\text{-}RC_2R)]$ (R = Et,[6] Ph[10]) with a capped square-based-pyramidal metal core. These compounds have a total electron count of 88, which is two more than predicted by the PSEPT rules and is accounted for by the presence of two unusually long, and consequently weakened, Ru−Ru bonds.

The formation mechanism of compound **2** is unclear. The silica present in the reaction mixture is presumed to assist the formation of the active fragment $[Pt(MeCN)_2]^{2+}$, which undergoes addition to $[Ru_5C(CO)_{14}]^{2-}$ (by analogy with the reactions involving $[PtCl_2(COD)]$, see ref.[4]). The hypothetical monomer $[Ru_5PtC(CO)_{14}(MeCN)_2]$ is probably unstable and readily undergoes rearrangement to form compounds **1** and **2**. The fact that the ratio of the two metals in **2** is 10:2 is consistent with this view involving as it does prior formation of a Ru_5Pt adduct. The same product, $[Ru_{10}Pt_2C_2(CO)_{28}]^{2-}$, was obtained when $[PPN]_2[Ru_5C(CO)_{14}]$ was reacted with $[PtCl_2(PhCN)_2]$ in dichloromethane in the presence of silica. Its identity was proven by infrared spectroscopy and mass spectrometry. This result further supports our view on the mechanism of formation of **2**.

If the reaction leading to the formation of **2** does follow the proposed mechanism, then the formation of $[Ru_5PtC(CO)_{16}]$ (**1**) would be dependent upon the availability of CO that could substitute the acetonitrile in the intermediate (the simple adduct formed initially). Therefore, a reaction of $[Ru_5C(CO)_{14}]^{2-}$ with $[PtCl_2(MeCN)_2]$ was carried out under an atmosphere of carbon monoxide. Indeed, compound **1** was isolated in 11% yield, to compare with 1.7% obtained from the reaction carried out under N_2. The second product isolated was identified as $[PPN]_2[Ru_{10}Pt_3C_2(CO)_{32}]$. The detailed synthesis and structure of this compound will be reported elsewhere.[11]

Similarly, in an alternative set of experiments, we find that when the salt $[PPN]_2[Ru_6C(CO)_{16}]$ is treated with the same platinum compound, $[PtCl_2(MeCN)_2]$, in dichloromethane, in the presence of silica, a high nuclearity cluster is

also obtained. In this case the product was found to be $[\{Ru_6C(CO)_{16}\}_2Pt(MeCN)_2]$ (**3**) on the basis of a single crystal X-ray structure determination. In its infrared spectrum, bands attributable to both terminal (2076 and 2002 cm^{-1}) and bridging CO ligands (1869 and 1844 cm^{-1}) were observed. In the ^1H NMR spectrum, recorded in CD_2Cl_2, two peaks, at δ = 1.32 (3 H) and 0.89 (3 H) ppm, may be assigned to the two MeCN ligands. In the mass spectrum, a molecular peak was not observed, but instead a peak at m/z = 1096 corresponding to $[Ru_6C(CO)_{17}]$ was found. Crystals suitable for X-ray diffraction structure determination were grown by slow diffusion of hexane into a solution of **3** in dichloromethane. The structure obtained is shown in Figure 3 and relevant bond lengths and angles are listed in Table 2.

The asymmetric unit of the crystal structure contains two independent but structurally similar molecules. The overall molecular structure of **3** consists of two $[Ru_6C(CO)_{16}]$ octahedra linked by a single Pt atom and one bridging acetonitrile ligand (Figure 4). This MeCN ligand forms an unusual triple bridge, linked through its nitrogen atom to the platinum and one ruthenium atom [Ru(10)], and through the carbon to a second ruthenium atom [Ru(1)]. A second acetonitrile ligand is terminally bound to the platinum atom through its nitrogen lone pair. The Ru(2)−Ru(3) distance in one of the Ru_6 octahedra is beyond the range usually considered as a Ru−Ru bond. A compound in which two Ru_3 cluster subunits are linked by a single platinum atom has been previously reported but is of lower nuclearity (Ru_3-Pt-Ru_3).[12] The geometry of the two $[Ru_6C(CO)_{16}]$ moieties in **3** is not unusual, except for the "missing" Ru-Ru edge. The two carbide atoms lie at the centre of the octahedra. The Ru−Ru bond lengths range from 2.806(2) to 3.114(2) Å in molecule 1 and from 2.803(2) to 3.085(2) Å in molecule 2. These span a wider range than those found in $[Ru_6C(CO)_{17}]$ [2.827(5)−3.034(5) Å], but average to the same value (ca. 2.90 Å).[5] Three carbonyl ligands bridge Ru-Ru edges in the first Ru_6 unit [containing the long Ru(2)−Ru(3) bond], while only two occupy a bridging position in the second Ru_6 unit. All the other carbonyl ligands are terminal and almost linear. The Ru-Ru edges spanned by bridging CO ligands are amongst the shortest. The longest Ru-Ru edges are associated with the Ru atoms bonded to the bridging acetonitrile ligand [Ru(1) and Ru(10)], which is presumably due to the increased electron density on these atoms. The Ru-Pt distances vary from 2.7412(14) to 2.8734(12) Å in molecule 1 and from 2.7562(12) to 2.8897(13) Å in molecule 2. As such there are two short and one longer Ru−Pt bonds. These distances are very similar to the mean value (2.789 Å) that can be calculated over all the compounds containing a Ru−Pt bond that have been characterised crystallographically. The MeC-N bond length in the acetonitrile ligand bound in a terminal fashion is 1.16(2) Å in molecule 1 and 1.17(2) Å in molecule 2. These values are typical of a C≡N triple bond (theoretical value: 1.16 Å) and fall within the range [1.03(7)−1.22(8) Å] reported for a number of "end-on" nitrile complexes characterised by X-ray crystallography.[13] The second acetonitrile ligand is not linear: the Pt−N−C angle is 133.9(10)° in molecule 1 and 131.6(10)° in molecule 2, while the N−C−CH_3 angle is 120.1(13)° in molecule 1 and 120.5(12)° in molecule 2. The MeC-N distance of 1.28(2) Å in both molecules is

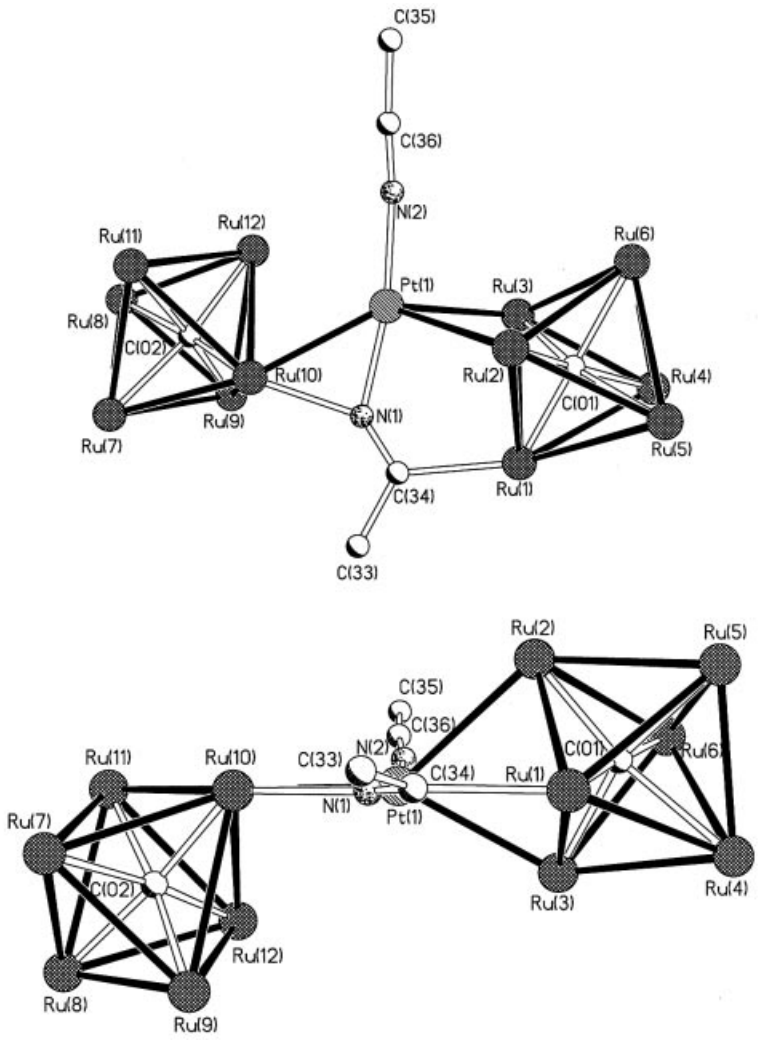

Figure 4. Side views of the structure of $[\{Ru_6C(CO)_{16}\}_2Pt(MeCN)_2]$ (**3**), emphasising the coordination of both MeCN ligands (top) and the planarity of the bridging acetonitrile ligand (bottom); carbonyl ligands are omitted for clarity

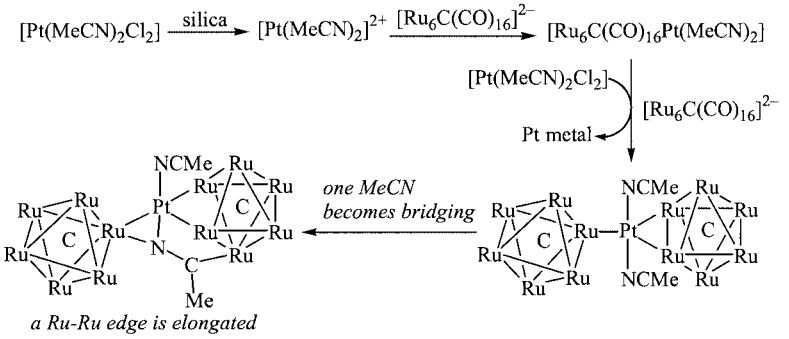
typical of a C=N double bond (theoretical value: 1.28 Å). These angles (close to the ideal 120° value) and bond length indicate that the C(34) and N(1) atoms are sp^2 rehybridised in the bridging MeCN. Indeed, the N-C atoms of the ligand are coplanar with the bridged platinum and two ruthenium atoms. The view shown in Figure 4 (bottom) emphasises the planarity of the bridging acetonitrile.

This type of triply bridging nitrile ligand has been reported only in one previous instance, in the compound $[Os_6Pt(CO)_{17}(NCMe)(COD)]$.[14] The C−N bond length in that case was intermediate between a triple and a double bond [1.22(3) Å], and the distribution of metal-metal bonds between the atoms bridged by the MeCN unit was different. The bridging nitrile was considered to be a four-electron donor. The shift of the second MeCN ligand in $[\{Ru_6C(CO)_{16}\}_2Pt(MeCN)_2]$ (**3**) from a terminal to a triply bridging bonding mode is thus accompanied by a change from a two-electron donor to a four-electron donor capacity. This additional pair of available electrons might explain the observed lengthening of one Ru−Ru distance in one of the octahedra. The Ru_6 unit displaying this elongated Ru−Ru distance is associated with the greatest number of interactions with the platinum fragment (two Ru−Pt bonds and one Ru−N bond, as opposed to one Ru−Pt and one Ru−N bond for the other Ru_6 unit). The coordination geometry at the platinum atom can be described either as a distorted trigonal bipyramid [N(1) and N(2) axials] or a distorted square pyramid [Ru(2) axial]. A five-coordinate Pt atom is indicative of the metal centre being in the +2 oxidation state,[15] and non-planar Pt^{II} usually respects the 18-electron rule. Indeed, in **3**, eight electrons are provided by the platinum, and each of the three Pt−Ru bonds accounts for two electrons, as do each of the two Pt−N bonds, reaching a total of 18 around the Pt atom. The oxidation state of the platinum is thus unchanged during the course of the reaction. If the reaction is considered as the addition of two $[Ru_6C(CO)_{16}]^{2-}$ "ligands" to the $[Pt(MeCN)_2]^{2+}$ fragment, the resulting adduct should be doubly negatively charged. An oxidation of one $[Ru_6C(CO)_{16}]^{2-}$ unit to $[Ru_6C(CO)_{16}]$ must have occurred, probably at the expense of some $[PtCl_2(MeCN)_2]$ undergoing reduction to platinum(0). This would explain the low



Scheme 1. Suggested mechanism for the reaction leading to $[\{Ru_6C(CO)_{16}\}_2Pt(MeCN)_2]$ (**3**); carbonyl ligands are omitted for clarity

yield of the reaction. Scheme 1 summarises our view on the mechanism of the reaction leading to the formation of $[\{Ru_6C(CO)_{16}\}_2Pt(MeCN)_2]$ (**3**).

Conclusions

In this paper we have reported the synthesis of two high nuclearity Ru-Pt clusters, obtained by reacting $[Ru_5C(CO)_{14}]^{2-}$ or $[Ru_6C(CO)_{16}]^{2-}$ with $[PtCl_2(MeCN)_2]$ in the presence of silica. The idea that $[Ru_5C(CO)_{14}]^{2-}$ and $[Ru_6C(CO)_{16}]^{2-}$ may serve as simple bidentate ligands (for the platinum) in a conventional sense is attractive and has certainly been of benefit previously in our interpretation of the chemistry of certain Ru-Sn systems.[16] Here this view is complicated by further reaction, leading to rearrangement of the cluster core in **2** and the formation of a triply bridging MeCN ligand in **3**. Additionally, in these reactions, the role of the silica is crucial and its net action is to remove Cl^-. High yields of other Ru-Pt clusters of predictable nuclearity were obtained following this method,[4] while the use of more conventional chloride scavengers (such as $AgBF_4$) did not prove as efficient. No reaction is observed in the absence of silica, leading to the conclusion that an initial reaction of $[PtCl_2(MeCN)_2]$ with surface Si−OH occurs, resulting in surface-bonded and stabilised $[Pt(MeCN)_2]^{2+}$ units, that can then react with the ruthenium clusters in a controlled way. This aspect is under further exploration.

Experimental Section

All the reactions were carried out using standard Schlenk techniques, under water- and oxygen-free nitrogen. All solvents were dried and distilled immediately before use. Reactants and chemicals were purchased from Aldrich Chemicals and used without further purification. The silica used in reaction media was Silica gel 60 (0.040−0.063 mm) for column chromatography purchased from Merck. The clusters $[PPN]_2[Ru_5C(CO)_{14}]$[17] and $[PPN]_2[Ru_6C(CO)_{16}]$[8] were synthesised following literature procedures.

All chromatographic separations were performed on the open bench without any precaution to exclude air. Thin-layer chromatography (TLC) was carried out using glass plates (20 × 20 cm) coated with a layer of silica gel 60 F_{254}, supplied by Merck. The eluents used were standard grade laboratory solvents.

Infrared spectra were collected in dichloromethane solution using a NaCl liquid cell (0.5 mm path length) supplied by Specac Ltd., on a Perkin−Elmer Paragon 1000 FT-IR spectrometer. The mass spectra were obtained on a Kratos Concept spectrometer (*) using electron impact ionisation (EI) in positive mode or on a Micromass Quattro-LC spectrometer using the electrospray ionisation technique (ESI) in negative mode (‡). The ^1H NMR spectrum was recorded on a Bruker DPX-400 instrument. The elemental analyses were performed by the microanalysis service of the department.

Preparation of $[Ru_5PtC(CO)_{16}]$ (1) and $[PPN]_2[Ru_{10}Pt_2C_2(CO)_{28}]$ (2): $[PPN]_2[Ru_5C(CO)_{14}]$ (100 mg, 0.050 mmol) was dissolved in dichloromethane (20 mL). A slight excess of $[PtCl_2(MeCN)_2]$ (20 mg, 0.057 mmol) and two spoons of silica (ca. 1 g) were added, inducing an immediate darkening of the solution. After five hours stirring at room temperature, the mixture was filtered, and the solvent evaporated. The residue was separated into its component compounds by thin layer chromatography, using hexane/acetone/dichloromethane (50:5:45, v/v) as eluent. The top orange band was identified as $[Ru_5PtC(CO)_{16}]$ (**1**), obtained in very low yield (1 mg, 1.7%), and $[PPN]_2[Ru_{10}C_2Pt_2(CO)_{28}]$ (**2**) (17 mg, 21%) was isolated from the bottom. Compound **2** can also be isolated as its $[Ph_4P]^+$ salt.

$[Ru_5PtC(CO)_{16}]$ (1): IR (CH_2Cl_2): ν_{CO} 2065.0(s), 2049.7(vs), 2003.0(w, sh), 1873.1(vw, br) cm^{-1}. EI-MS (*): m/z = 1163 (calcd. for $Ru_5PtC(CO)_{16}$: 1162, M^+), followed by loss of 16 CO ligands.

$[Ph_4P]_2[Ru_{10}Pt_2C(CO)_{28}]$ (2): IR (CH_2Cl_2): ν_{CO} 2026vs (br), 2002m (sh), 1964w (sh), 1823m (br), 1789m (br) cm^{-1}. ESI-MS (‡): m/z = 1104.7 (calcd. for $[Ru_{10}Pt_2C_2(CO)_{28}]^{2-}$: 1104.6, $M^{2-}/2$), 2209.4 (calcd. for $[Ru_{10}Pt_2C_2(CO)_{28}]^-$: 2209.2, M^-). $C_{78}H_{40}O_{28}P_2Pt_2Ru_{10}$ (2888.0): calcd. C 32.44, H 1.40; found C 32.26, H 1.56.

Reaction of $[PPN]_2[Ru_5C(CO)_{14}]$ with $[Pt(PhCN)_2Cl_2]$: $[PPN]_2[Ru_5C(CO)_{14}]$ (100 mg, 0.050 mmol) was dissolved in dichloromethane (20 mL). An equivalent of $[PtCl_2(PhCN)_2]$ (24 mg, 0.050 mmol) and two spoons of silica (ca. 1 g) were added, inducing an immediate darkening of the solution. After five hours stirring at room temperature, the mixture was filtered, and the solvent evaporated. The residue was separated into its component compounds by thin layer chromatography, using hexane/acetone/dichloromethane (40:20:40, v/v) as eluent. The top orange band was identified as $[Ru_5PtC(CO)_{16}]$ (**1**), obtained in very low yield (less than 1 mg), and $[PPN]_2[Ru_{10}C_2Pt_2(CO)_{28}]$ (**2**) (21 mg, 26%) was isolated from the bottom.

Reaction of $[PPN]_2[Ru_5C(CO)_{14}]$ with $[PtCl_2(MeCN)_2]$ under CO: One equivalent of $[PtCl_2(MeCN)_2]$ (18 mg, 0.05 mmol) and silica

(approx. 1 g) were added to a solution of $[PPN]_2[Ru_5C(CO)_{14}]$ (100 mg, 0.05 mmol) in CH_2Cl_2 (20 mL). The mixture was stirred for 3 hours under carbon monoxide and then left to stir overnight under nitrogen. Subsequently, the silica was filtered off and the solvent evaporated to dryness in vacuo. The crude product was dissolved in a minimum amount of CH_2Cl_2 and purified by TLC using a mixture of CH_2Cl_2/acetone/hexane (45:5:50, v/v) as eluent. The top red band was identified as $[PtRu_5C(CO)_{16}]$ (**1**) (11 mg, 0.009 mmol, 19% yield) and the bottom violet band was identified as $[PPN]_2[Pt_3Ru_{10}C_2(CO)_{32}]$ (4 mg, 0.001 mmol, 2.5% yield).

$[Ru_5PtC(CO)_{16}]$ (1): IR (CH_2Cl_2): ν_{CO} 2064.5(s), 2049.9(vs), 2004(w, sh), 1869(vw, br) cm^{-1}. EI-MS (*): m/z = 1162 (calcd. for $Ru_5PtC(CO)_{16}$: 1162, M^+), followed by loss of 16 CO ligands.

Preparation of $[\{Ru_6C(CO)_{16}\}_2Pt(MeCN)_2]$ (3): The reaction was performed in a similar fashion, starting from $[PPN]_2[Ru_6C(CO)_{16}]$ (100 mg, 0.0466 mmol) and $[PtCl_2(MeCN)_2]$ (16 mg, 0.0466 mmol) and purification by thin-layer chromatography, using hexane/dichloromethane (3:2, v/v) as eluent. The eluting brown fraction is $[\{Ru_6C(CO)_{16}\}_2Pt(MeCN)_2]$ (**3**), obtained in very low yield (3.4 mg, 3.03%).

$[\{Ru_6C(CO)_{16}\}_2Pt(MeCN)_2]$ (3): IR (CH_2Cl_2): ν_{CO} 2076(m), 2063(s), 2048(vs), 2018 (w, sh), 2002(w, sh), 1869(w, br), 1844(w, br) cm^{-1}. ^{1}H NMR (400 MHz, CD_2Cl_2, 25 °C): δ = 0.89 (s, 3 H, MeCN), 1.32 (s, 3 H, MeCN) ppm. EI-MS (*): m/z = 1096 (calcd. for $Ru_6C(CO)_{17}$: 1095), with CO losses. $C_{38}H_6N_2O_{32}Pt_1Ru_{12}$ (2410.4): calcd. C 18.94, H 0.25, N 1.16; found C 21.40, H 3.17, N 0.33. Crystals suitable for X-ray diffraction structure determination were grown by slow diffusion of hexane into a solution of **3** in dichloromethane.

Crystallography: Single crystal X-ray diffraction analyses were performed on a Nonius Kappa CCD system with a sealed-tube Mo-K_α source equipped with an Oxford Cryostream apparatus for low-temperature data collection. The structures were solved by direct methods using teXsan,[18] and refined by full-matrix least-squares on F^2 with the SHELXL-97[19] (**2**) and SHELXL-93[20] (**3**) software packages. In the case of **2**, all non-hydrogen atoms, apart from the solvent molecules and disordered groups (one of the Ph_4P cations is disordered over two positions), were refined with anisotropic atomic displacement parameters. In the case of **3**, only the Ru and Pt metal atoms were refined with anisotropic atomic displacement parameters. All hydrogen atoms were placed in idealised positions, assigned isotropic displacement parameters and allowed to ride on the parent carbons. The crystal data for **2** and **3** are summarised in Table 3.

CCDC-191419 (**2**) and 191420 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Lanthanide Chelates Based on Diethylenetriamine Fitted with *O*-Benzoic Acid Pendant Arms

Daniel Imbert,[a] Nicolas Fatin-Rouge,[a] and Jean-Claude G. Bünzli*[a]

Keywords: Carboxylate ligands / Lanthanides / Luminescence / Podand / Stability constant

A new polycarboxylate ligand H_5L has been synthesized by the attachment of five benzoate subunits onto a diethylenetriamine framework. Seven pK_a values have been determined by potentiometry, spectrophotometry and NMR spectroscopy as 1.9(2), 2.8(2), 3.87(5), 4.58(6), 4.87(6), 9.19(6) and 11.68(5), the first four corresponding to the carboxylic functions and the last three to amine sites. The interaction between H_5L and Ln^{III} ions in dilute aqueous solution has been examined by UV/Vis absorption and emission spectrometries, and has been found to result in monometallic complexes that are moderately stable in the pH range 3.7–7.5. Conditional stability constants at pH 5.3 are logK_{11} = 5.3(2), 6.6(1), 6.5(1) and 7.2(3) for La, Eu, Tb and Lu, respectively. In the case of Tb^{III}, the stability constants for $[Tb(HL)]^-$ and $[Tb(H_2L)]$ are logβ_{111} = 22.0(2) and logβ_{121} = 29.8(1), giving a pTb of 10.0. In the pH range 4–7, more than 90% of the Tb^{III} ions are in the form of the neutral species $[Tb(H_2L)]$. Lifetime determinations of the Eu($^5D_0$) and Tb($^5D_4$) excited levels in both H_2O and D_2O at pH 5.3 indicate 4.8 ± 0.5 (Eu) and 4.5 ± 0.5 (Tb) water molecules being bound in the inner coordination sphere of the Ln^{III}. The triplet state of the ligand in water lies at around 26000 cm^{-1}, resulting in a sizeable sensitisation of the Tb-centred luminescence (absolute quantum yield: φ_{abs} = 10.3%), while the luminescence of Eu^{III} is only poorly sensitised (φ_{abs} = 1.5%).

Introduction

Stable chelates of trivalent lanthanide ions are of interest as contrast enhancement agents in magnetic resonance imaging,[1] as catalysts for the cleavage of phosphodiester bonds in DNA and RNA,[2] as precursors for various functional materials,[3] including doped polymers for optical amplifiers,[4] or as luminescent probes for biomedical analysis,[5–7] for responsive analytical sensors[8] or for imaging of cancerous cells.[9] The main difficulty associated with the design of luminescent probes and sensors lies in overcoming the very low molar absorption coefficients of the Ln^{III} ions, due to the forbidden nature of the f-f transitions. To sensitise the metal ion efficiently, there are specific requirements for ligand molecules i.e. that they should be strong complexation agents, have large absorption coefficients and offer a series of photophysical properties allowing efficient energy transfer from the ligand onto the metal ion and minimization of quenching processes.[5]

Several synthetic strategies intended to meet all these requirements have been examined,[3] including the use of preorganised (macrocyclic)[10] or predisposed receptors,[11,12] leading to induced cavities; these receptors can also be obtained by self-assembly processes[13] or by the use of flexible podands.[14] These latter are readily available, cheap and are easy to derivatize. In this paper we attempt to combine the stability of Ln^{III} complexes with ligands derived from polyaminocarboxylates, such as dtpa,[15] with the large

sensitisation of Tb^{III} ion luminescence (and also other Ln^{III} ions) achieved by incorporation of the benzoate chromophore,[5,16] absolute quantum yields of 100 and 20% having been reported for Tb^{III} and Eu^{III}, respectively, in the solid state.[17] We have therefore synthesized the polydentate ligand H_5L [1,4,7-heptanetriamine-*N,N,N′,N′,N″*-pentakis-(2-methylbenzoic acid), Scheme 1] and investigated its complexation and sensitisation properties towards trivalent lanthanide ions.

Results and Discussion

Acidity Constants of the Ligand

The ligand H_5L was prepared in three steps (Scheme 1) in an overall yield of 31%. Its acidity constants were determined separately by potentiometry (Figure 1) and spectrophotometry (Figure 2) and further confirmed by ^1H NMR spectroscopy. The extracted pK_a values, defined by the following equations and obtained by titration in the 2−12 pH range, are summarized in Table 1.

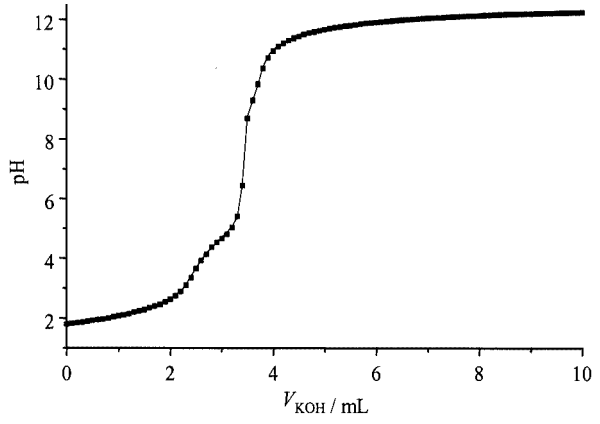

Figure 1. Potentiometric titration of H_7L^{2+} with OH^- in H_2O/CH_3OH (98:2 v/v); T = 20.0 ± 0.2 °C; μ = 0.1 M (KCl)

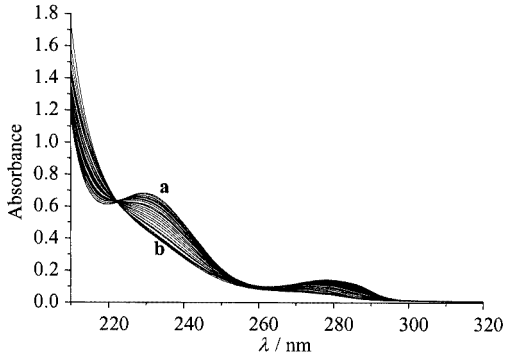

Figure 2. UV/Visible absorption spectra of H_7L^{2+} as a function of pH in H_2O/CH_3OH (98:2 v/v); T = 20.0 ± 0.2 °C; μ = 1 M (KCl): curve a (pH = 1.37), curve b (pH = 12.04)

[c] ^1H NMR spectroscopic data. $[L]_0 = 1.0\cdot10^{-3}$ M; T = 20 °C. [d] ^1H NMR spectroscopic data. I = 0.1 M (KNO_3); T = 25.0 °C.[34]

$$(H_{8-i}L)^{(3-i)+} \rightleftarrows (H_{7-i}L)^{(2-i)+} + H^+ \qquad (1)$$
$$pK_{ai}\ (i = 0-4, \text{carboxylic functions})$$

$$(H_{8-i}L)^{(3-i)+} \rightleftarrows (H_{7-i}L)^{(2-i)+} + H^+ \qquad (2)$$
$$pK_{ai}\ (i = 5-7, \text{amine functions})$$

The agreement between the values from various experimental techniques is quite good, and the dissociation constants display behaviour similar to that reported for dtpa: five pK_a values are in the 2 to 5 range while the last two are between 9 and 12. A fit of the data with eight pK_a values did not converge, indicating that pK_{a0}, corresponding to the deprotonation of a carboxylic group (see below, NMR spectra), probably lies below pH 2. However, the protolytic groups of H_5L are less acidic than those of dtpa. The first is only slightly less acidic ($\Delta\log K_a$ = 0.35), but the difference increases up to $\Delta\log K_a$ = 1.9 for pK_{a4}. The electron-donor ability of the benzene moieties and the larger number of bonds separating the nitrogen atoms from the carboxylate groups explain this trend.

^1H NMR spectra were measured from pH 12.2 to 1.1 in D_2O/CD_3OD (95:5) solutions (Figure 3), and the resonances were attributed on the basis of their chemical shifts, signal intensities and ^1H-^1H COSY experiments. In the aromatic region, because of superimposed signals, only the protons labelled (i) and (h) could be unambiguously assigned. The eight protons labelled (c) and the two protons labelled (d) appear to be equivalent, pointing to an averaged structure of the molecule on the NMR timescale. The (a) and (b) protons are nonequivalent and appear as two broad peaks because of spin coupling and conformational motions.

The variation of the chemical shifts with pH is shown at the bottom of Figure 3. At pH 12.2, corresponding to a solution containing mainly the totally deprotonated ligand L^{5-}, the resonances for the (c) and (d) protons have very similar chemical shifts, and this is also true for protons (a) and (b). A decrease in the pH to 10.4 by the addition of one equivalent of acid causes only slight variations in the

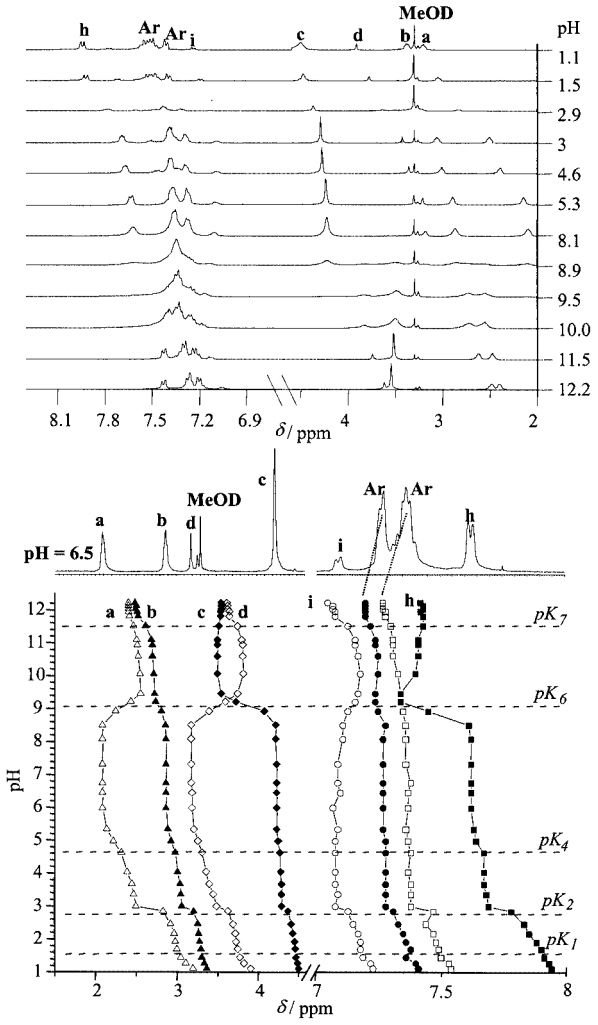

Figure 3. (Top) ^{1}H NMR spectra of $H_nL^{(5-n)-}$ vs. pH in D_2O/CD_3OD (95:5 v/v) at T = 20 °C, and (bottom) variation of the ^{1}H NMR chemical shifts vs. pH

shifts of the methylene protons, which become more shielded, except for protons (d), which become deshielded. Similarly, the aromatic protons undergo small positive shifts, except for protons (h), which become deshielded. Further addition of acid again results in relatively small changes until around pH 9, except that the shift tendency inverts for protons (d) and (i), which become more shielded. In the pH range 9 to 3, dramatic changes occur for the methylene protons and for protons (h); in particular, the resonances of protons (a) and (b) on one hand and (c) and (d) on the other become clearly separated. After a discontinuity at pH 3, all the protons, particularly protons (h), become more shielded upon further addition of acid.

The observed shift of the methylene protons is in fact an average value reflecting the mean time that each proton spends in a given chemical environment.[18] Quantitative analysis of the pH dependence of these chemical shifts can therefore be performed by assuming that the contributions to the shift of a given proton i (δ_i) are additive and linearly related to the fraction of time spent in each environment. As a result, the preferred protonation sites and the extent of protonation can be estimated from a simple model taking into account only the two closest protonation sites, where f is the fractional population of a given protonation site, C is the chemical shift increment caused by the presence of the proton in this site, and the indices α and β refer to the position of the protonated nitrogen atom relative to the resonant proton.

$$\delta_a = \delta_a^0 + f_1 \times C_{N\alpha} + f_2 \times C_{N\beta} \quad (3)$$

$$\delta_b = \delta_b^0 + f_2 \times C_{N\alpha} + f_1 \times C_{N\beta} \quad (4)$$

$$\delta_c = \delta_c^0 + f_2 \times C_{N\alpha} + f_3 \times C_{O3} \quad (5)$$

$$\delta_d = \delta_d^0 + f_1 \times C_{N\alpha} + f_4 \times C_{O4} \quad (6)$$

We have set C_{O3}, C_{O4}, C_O to be equal. The δ_i^0 values were taken as equal to the chemical shifts measured at pH 12.2. Finally, the f_i values were normalised by the following relationship, where n is the number of equivalents of acid added to the fully deprotonated ligand L^{5-}.

$$f_1 + 2f_2 + 4f_3 + f_4 = n \quad (7)$$

Values of f_1, f_2 and $C_{N\alpha}$, $C_{N\beta}$ were obtained only for n = 1 and 2, because the data become too imprecise beyond this amount of acid. For n = 0−2, f_3 and f_4 were set as equal to zero, which is a reasonable assumption. The best results for n = 1 were obtained at pH 1/2(pK_{a6} + pK_{a7}), and Equations (3), (4), (6) and (7) give f_1 = 0.22, f_2 = 0.39, $C_{N\alpha}$ = 0.59 ppm and $C_{N\beta}$ = 0.05 ppm. Generally speaking, the C values have large error margins because of the fairly small chemical shift changes. The calculated $C_{N\alpha}$ value is in good agreement with literature data for dtpa (0.75), but the value found for $C_{N\beta}$ is much lower than the reported value of about 0.35 ppm.[18] At pH 1/2(pK_{a4} + pK_{a3}), different values of n were again tested and n = 2 gave the best result, with Equations (3)−(5) and Equation (7) yielding f_1 = 0.38, f_2 = 0.81, $C_{N\alpha}$ = 0.82 ppm, and $C_{N\beta}$ = 0.77 ppm. These calculations offer evidence of the drastic change in the charge repartition on the three nitrogen atoms on going from n = 1 to n = 2, consistent with the data for dtpa.[18] At n = 2, for instance, the protons are mainly bound to the end nitrogen atoms N2, as a result of electrostatic repulsion. Further attempts to determine quantitatively the extent of protonation of the benzoate groups with pH failed. Nevertheless, the similar values of the three largest pK_a values for dtpa and for H_5L point to the protonation of L^{5-} occurring first on the three nitrogen atoms. However, distribution diagrams show that protonation of the benzoate sites starts while full protonation of the central nitrogen atom is not yet complete.

Interaction with Trivalent Lanthanide Ions

The interaction between Ln^{III} ions (Ln = La, Eu, Tb, Lu) and H_5L was first monitored in dilute aqueous solu-

tions by UV/Vis spectrophotometry at pH 5.3. The variation of the absorbance versus $R = [Ln^{III}]_{tot}/[H_5L]_{tot}$ (Figure 3) points to the presence of a single 1:1 complex species in the stoichiometry range investigated ($0 < R < 5$). This is in agreement with the ESI-MS spectra. The conditional stability constants extracted from these data amount to $\log K_{11} = 5.3(2)$, 6.6(1), 6.5(1) and 7.2(3), respectively (Figure S1, Supporting Information, see also the footnote on the first page of this article). The linear relationship between the magnitude of the binding constants and the charge density of the cation is a clear indication that there is no steric effect in the coordination of the metal ions. To determine the influence of the pH on the speciation, we titrated the ligand in the presence of one equivalent of Tb^{III} and monitored the experiment both by spectrophotometry (Figure 4) and by luminescence spectroscopy (Figure 5). Potentiometry could not be used because of precipitation of the metal complexes at concentrations greater than 10^{-3} M. The best model used to fit the titration data was fairly complex, with ten different $[Ln_i(OH)_jH_kL_l]^{(3i-j+k-5l)+}$ species: one hydroxide moiety ($i = 1$; $j = 3$; $k = l = 0$), six protonated forms of the ligand ($i = j = 0$) determined independently from the potentiometric titration described above, and two protonated 1:1 complexes ($i = 1$, $j = 0$, $k = 1$ and 2, $l = 1$). The absorption maxima of the different species are given in Table 2. The two proton-dependent stability constants refined amount to $\log\beta_{111} = 22.0(2)$ [Equation (8)] and $\log\beta_{121} = 29.8(1)$ [Equation (9)].

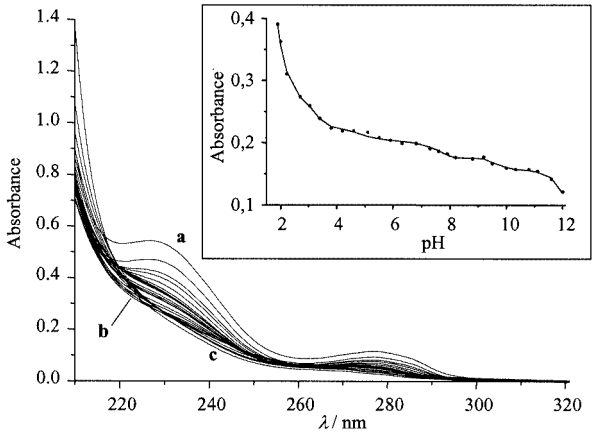

Figure 4. UV/Visible absorption spectra of H_7L^{2+} $2\cdot10^{-5}$ M in H_2O/CH_3OH (98:2 v/v), $\mu = 0.1$ M (KCl) in the presence of one equivalent of Tb^{III}, at $T = 20.0 \pm 0.2$ °C at various pH; curve a, b, and c: pH = 1.92, 9.22, and 12.0; the inset shows the absorbance variation at 240 nm

$$Tb^{3+} + H^+ + L^{5-} \overset{\beta_{111}}{\rightleftharpoons} [TbHL]^- \quad (8) \qquad (8)$$

$$Tb^{3+} + 2H^+ + L^{5-} \overset{\beta_{121}}{\rightleftharpoons} [TbH_2L] \quad (9) \qquad (9)$$

The calculated distribution curves from these stability constants are presented in Figure 6. In the pH range 3.5−7.5, the neutral species $[Tb(H_2L)]$ is clearly dominant,

which explains the difficulty in solubilising the metal complexes after their isolation as solid-state samples. At lower pH, competition with protons dissociates the complex, while very stable hydroxides are the major species at pH values higher than 8.5. Altogether, the metal complexes are moderately stable, as shown by the pTb value of 10.0,[19] calculated with $[Tb]_{tot} = 10^{-6}$ M, $[H_5L]_{tot} = 10^{-5}$ M and pH 7.4, in comparison with 19.2 for $[Tb(dtpa)]^-$ [20] and with 6.7 for terbium benzoate. This result is a clear indication that the nitrogen atoms of the H_5L ligand are most probably nonbonding and remain protonated in the metal complexes, as indicated by the unchanged values of the two highest apparent pK_a values upon addition of Ln^{III} ions.

Photophysical Properties of the Ligand and the $[LnH_2L]$ Complexes

In water, the ligand displays two main adsorption bands around 46080 (shoulder at 42370 cm^{-1}) and 39370 cm^{-1}. The high-energy band is slightly blue-shifted (ca. 400−500 cm^{-1}) in the Ln^{III} complexes. The photophysical properties of the ligand and of its 1:1 complexes with La, Lu, Eu and Tb in water (pH 5.3) and in frozen glycerol/water mixtures are summarized in Table 3. UV excitation in the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ absorption bands of the ligand results in a

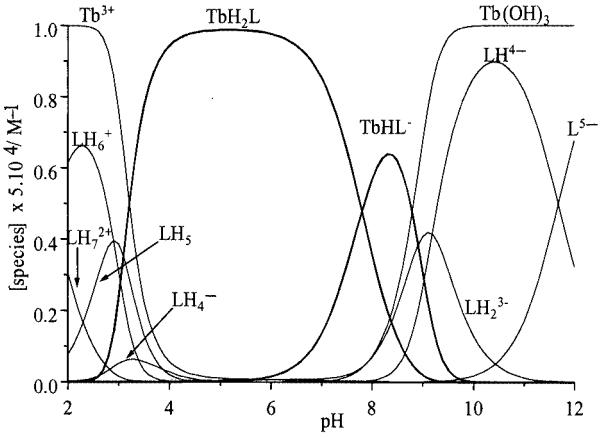

Figure 6. Corresponding formation curves of proton and terbium complexes, computed from the stability constants given in the text; $[L]_{tot} = [Tb^{III}]_{tot} = 2.0 \cdot 10^{-5}$ M; $\lambda_{exc} = 274$ nm; $T = 20$ °C

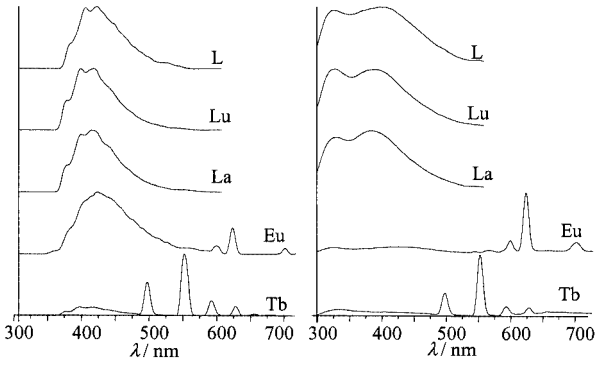

Figure 7. Emission spectra of the $[LnH_2L]$ complexes (Ln = La, Eu, Tb, Lu), pH = 5.3; (left) phosphorescence spectra in solutions of glycerol/water, 10:90% at 77 K; (right) fluorescence spectra at 295 K in water

ligand-centred emission displaying two overlapping bands assigned to emission from the $^1\pi\pi^*$ (33110 cm^{-1}) and $^3\pi\pi^*$ states (Figure 7). The absolute fluorescence quantum yield of the fully deprotonated ligand (L^{5-}) is small at 0.3%, a value that increases slightly for the $[Ln(H_2L)]$ complexes: 0.4 and 0.5% for La and Lu, respectively, at pH 5.3. At 77 K, the $^3\pi\pi^*$ state emission is structured with a vibrational progression of 1350 ± 30 cm^{-1}, corresponding to a ring breathing mode and its 0-phonon transition is located at 26520 cm^{-1}. The gap between the $^3\pi\pi^*$ and $^1\pi\pi^*$ states (ca. 6320 cm^{-1}) is favourable for a relatively efficient intersystem crossing process.[5] The emission spectra of the ligand and its complexes at room temperature are consistent with this finding, since they display emission from both the singlet and triplet states, although very weakly for Eu and Tb. The $^3\pi\pi^*$ lifetime amounts to 1.88 s, a value close to that obtained for benzoic acid ($\tau = 2$ s).[21] As would be expected from the relatively high energy of the $^3\pi\pi^*$ 0-phonon component, both the Eu^{III} ions, with $\Delta E(^3\pi\pi^* - {}^5D_0) \approx 9700$ cm^{-1}, and the Tb^{III} ions, with $\Delta E(^3\pi\pi^* - {}^5D_4) \approx 6500$ cm^{-1}, are reasonably well sensitised (Figure 7). This is in agreement with what has been observed for Tb^{III} poly(aminocarboxylates), for which the best antenna effect was observed for $^3\pi\pi^*$ states around 26000 cm^{-1}.[22]

The high-resolution excitation spectrum of a solid-state sample of $[EuH_2L]$ in the $^5D_0 \leftarrow {}^7F_0$ spectral range, obtained by analysis of the maximum on the $^5D_0 \rightarrow {}^7F_2$ transition at 10 K, displays a single broad and symmetrical peak at 17246 cm^{-1} with a full width at half height (fwhh) of 26.9 cm^{-1}, which is consistent with the presence of a single site for the Eu^{III} ion.

The metal-centred luminescence of diluted aqueous solutions is pH dependent, due to the distribution of the various species present in solution. The Tb complex displays emission over a large pH range, from pH 3.5 to 10.5 (Figure 4), with maximum intensity occurring in the pH range 5−8, in which $[TbH_2L]$ is the major species in solution. The average numbers of water molecules bound to the metal ions were determined from the experimental lifetimes at room temperature for solutions of $[LnH_2L]$ (Ln = Eu, Tb) in H_2O (pH 5.3) and D_2O (pD 5.7).[23,24] For the Eu complex, the measured lifetimes ($\tau = 1.41 \pm 0.04$ ms in D_2O and 0.20 ± 0.01 ms in H_2O) give $q = 4.8 \pm 0.5$, while $q = 4.5 \pm 0.5$ is obtained for the Tb podate ($\tau = 1.47 \pm 0.01$ ms in D_2O and 0.61 ± 0.01 ms in H_2O). The presence of at least eight OH oscillators in the inner coordination sphere is consistent with the reasoning, based on the stability constants, that at least four benzoate units are coordinated to the metal ions (in a monodentate fashion), but the nitrogen atoms are not. The large number of water molecules in the first coordination sphere explains the inability of the ligand to sensitise the luminescence of the Dy^{III}, Er^{III} and Tm^{III} ions. Despite this, the quantum yields of metal-centred luminescence in

[a] The most intense component is italicised. [b] Luminescence data and lifetimes for frozen solutions in glycerol/water 10:90% (77 K). [c] Electronic spectroscopic data at 295 K in water; energies are given for the maximum of the band envelope (sh: shoulder).

water at pH 5.3 remain sizeable, at 1.5 and 10.3% for the Eu and Tb podates, respectively (Table 4). This points to fairly efficient energy transfer from the ligand to the Tb($^5D_4$) level. It is noteworthy that the quantum yield of [Tb(H_2L)] increases significantly upon addition of HMPA, which is know to be a good complexation agent for Ln^{III} ions and which removes the water from the inner coordination sphere (2 eqs: +45%, 4, 10, 100 and 500 eqs: +105%). Moreover, a graph of the quantum yield of [Tb(H_2L)] vs. pH (Figure S2, Supporting Information) reflects the distribution curve of this species reasonably well.

Conclusion

The solution studies described in this paper show that podand H_5L gives stable Ln^{III} complexes in water that are resistant toward hydrolysis and show interesting photophysical properties. Thermodynamically stable 1:1 neutral podates [Ln(H_2L)] form in the pH range 3.7−8. No nitrogen atom is involved in the binding, as a result of the protonation of the amine functions, preventing the wrapping of the ligand around the metal ion. The emission lifetimes of the Eu^{III} and Tb^{III} complexes recorded in D_2O and H_2O point to four water molecules completing the coordination sphere of the metal ions. The luminescence study shows that the ligand exhibits a good antenna effect with respect to the Tb^{III} ion, due to efficient intersystem crossing ($^1\pi\pi^*$- to-$^3\pi\pi^*$) and ligand-to-metal energy transfer. Despite the large number of coordinated water molecules, the quantum yields of the metal-centred luminescence in the Tb^{III} (and Eu^{III}) complexes are encouraging and demonstrate that benzoate is a potentially interesting moiety for attachment onto a flexible receptor for Ln^{III} ions.

Experimental Section

Starting Materials and General Procedures: Analytical grade solvents and chemicals (Fluka AG) were used without further purification, except for acetonitrile, which was distilled from CaH_2. Solutions were prepared just before use with freshly boiled, doubly distilled water saturated with N_2. Stock solutions of $LnX_3{\cdot}nH_2O$ (X = ClO_4, CF_3SO_3) were prepared from lanthanide oxides (99.99%, Rhône Poulenc) and the corresponding acid. They were systematically acidified with HCl to a pH of about 4 before titration to avoid hydroxide precipitation. The concentrations were determined by complexometric titrations with a standardized Na_2H_2EDTA solution in urotropine-buffered medium and with xylenol orange as indicator.[25] Elemental analyses were performed by Dr. Eder, Microchemical Laboratory, University of Geneva.

1-D and 2-D NMR spectroscopic data were collected on Bruker DPX 400 or AM 360 spectrometers. ^1H NMR and ^{13}C NMR spectra were recorded in $CDCl_3$, D_2O or CH_3OD and their assignment was based on ^1H coupling and 2-D ^1H-^{13}C correlation spectra. The mass spectra were recorded in electrospray ionisation mode on a Finnigan quadrupole mass spectrometer (T_{matrix} = 240 °C). The instrument was calibrated with a horse myoglobin standard. The analyses were conducted in positive mode. The ion spray voltage was 4.6 kV. Assignment of the species was based on the isotopic distribution of the peaks. Electronic UV/Vis spectra were recorded on a Perkin−Elmer Lambda 900 spectrometer. Infra-red spectra were measured on a FT-IR Mattson Alpha Centauri spectrometer (4000−400 cm^{-1}, KBr pellets).

Syntheses (see Scheme 1). Methyl 2-(Bromomethyl)benzoate (1): This compound was synthesized by a known procedure.[26]

1,4,7-Heptanetriamine-*N,N,N′,N′,N″*-pentakis(methyl 2-methylbenzoate) (2): Potassium carbonate (10.04 g, 72.7 mmol) was added under nitrogen atmosphere to a solution of diethylenetriamine (500 mg, 4.9 mmol) in freshly distilled acetonitrile (100 mL). The resulting mixture was heated at reflux for 30 min, and a solution of **1** (6.08 g, 26.7 mmol) in dry acetonitrile (50 mL) was added over 2 h. The mixture was stirred and heated at reflux for an additional 12 h and filtered while hot. The solvents were then evaporated to give a black oil, which was dissolved in dichloromethane, washed with brine and dried with Mg_2SO_4, and the solvents were evaporated to dryness. The residue was purified by column chromatography (silica gel; 2% MeOH in CH_2Cl_2). Yield: 1.76 g (43%), orange foam. IR (KBr): $\tilde{\nu}$ = 1711 (C=O), 1452, 1384 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 2.46 (m, 8 H, CH_2), 3.72 (s, 8 H, CH_2), 3.76 (s, 2 H, CH_2), 3.82 (s, 12 H, CH_3), 3.86 (s, 3 H, CH_3), 7.21 (m, 5 H, ArH), 7.27 (dt, ^1J = 7.5, ^2J = 1.3 Hz, 1 H, ArH), 7.34 (dt, ^1J = 7.8, ^2J = 1.3 Hz, 4 H, ArH), 7.41 (d, J = 7.5 Hz, 1 H, ArH), 7.58 (d, J = 7.8 Hz, 4 H, ArH), 7.68 (dd, ^1J = 7.5, ^2J = 1.3 Hz, 1 H, ArH), 7.74 (dd, ^1J = 7.8, ^2J = 1.3 Hz, 4 H, ArH) ppm. ^{13}C NMR ($CDCl_3$): δ = 51.7, 51.8 (CH_3), 52.5, 52.6, 57.0, 57.6 (CH_2), 126.3, 129.3, 129.7, 129.9 (CH), 130.1, 130.4 (Cq), 131.3, 131.6 (CH), 141.4 (Cq), 168.2, 168.4 (C=O) ppm. ESI-MS (CH_3CN, H_2O, CH_3CO_2H): m/z = 844.3 (calcd. 844.3) $[M + H]^+$, 422.8 (calcd. 422.7) $[M + 2H]^{2+}$. $C_{49}H_{53}N_3O_{10}$ (843.97): calcd. C 69.73, H 6.33, N 4.98; found C 69.72, H 6.31, N 4.96.

1,4,7-Heptanetriamine-*N,N,N′,N′,N″*-pentakis(2-methylbenzoic acid) (H_5L): Compound **2** (500 mg, 0.59 mmol) was dissolved in a solution of methanol (200 mL) and KOH in water (1 M, 15 mL). The resulting mixture was heated at reflux for 4 h, and the solvents were evaporated. The residue was dissolved in water (400 mL), cooled to 0 °C and acidified to pH 2 with aqueous HCl. The yellow precipitate was collected, washed with water and then diethyl ether, and dried. Yield: 417 mg (91%), yellow solid. IR (KBr): $\tilde{\nu}$ = 3426 br (OH), 2606 br (OH), 1700 (C=O), 1590, 1552, 1451, 1381, 1295, 1145, 1085, 752 cm^{-1}. ^1H NMR (300 MHz, D_2O, 20 °C): δ = 2.8 (m, 4 H, CH_2), 3.3 (m, 4 H, CH_2), 3.63 (s, 2 H, CH_2), 4.44 (s, 8 H, CH_2), 7.2 (m, 1 H, ArH), 7.3−7.4 (m, 14 H, ArH), 7.74 (m, 1 H, ArH), 7.93 (m, 4 H, ArH) ppm. ^{13}C NMR (D_2O, 20 °C): δ = 51.1, 55.4, 56.7, 57.9, 58.1 (CH_2), 127.2, 129.6, 130.6, 130.8 (CH), 131.4, 131.6 (quat. C), 133.1, 134.4 (CH), 137.5 (quat. C), 170.7 (C=O) ppm. ESI-MS (CH_3CN, H_2O, CH_3CO_2H): m/z = 774.4 (calcd. 774.3) $[M + H]^+$, 387.8 (calcd. 387.7) $[M + 2H]^{2+}$. $H_5L{\cdot}H_2O$ $C_{44}H_{45}N_3O_{11}$ (791.85): calcd. C 66.74, H 5.73, N 5.31; found C 66.72, H 5.60, N 5.20.

Preparation of [Ln(H_2L)]·nH_2O Complexes (Ln = La, Eu, Tb, Lu): Freshly titrated $LnClO_4.nH_2O$ solutions (10^{-3} M, 0.039 mmol) were added over 4 h, at room temperature, to an aqueous solution of H_5L (40 mL, 0.039 mmol, 10^{-3} M, pH = 5.3, adjusted with HCl). The mixture was stirred for an additional 2 h and the resulting white precipitate was filtered, washed successively with water (several times) and diethyl ether, and further dried for 3 days at 65 °C and 0.01 Torr. These complexes being very hygroscopic, variable numbers of water molecules were found when performing microanalyses.

[La(H_2L)]·$5H_2O$ (75%): IR (KBr): $\tilde{\nu}$ = 3422 br (OH), 1554 and 1399 (ν_{as}, ν_s COO), 1606, 1498, 1449, 1294, 1203, 1151, 1120, 1089,

753 cm^{-1}. $C_{44}H_{50}LaN_3O_{15}$ (999.80): calcd. C 52.86, H 5.04, N 4.20; found C 52.27, H 4.50, N 4.27.
$[Eu(H_2L)]\cdot 3H_2O$ (89%): IR (KBr): $\tilde{\nu}$ = 3413 br (OH), 1556 and 1403 (ν_{as}, ν_s COO), 1607, 1490, 1449, 1294, 1202, 1150, 1120, 1094, 752 cm^{-1}. ESI-MS: a stoichiometric mixture of $Eu(ClO_4)_3\cdot xH_2O$ (x = 4.2) and H_5L 10^{-4} M in pure methanol gave $[EuH_3L]^+$ m/z = 923.4 (calcd. 923.4). $C_{44}H_{46}EuN_3O_{13}$ (976.81): calcd. C 54.10, H 4.75, N 4.30; found C 53.65, H 4.59, N 4.30.
$[Tb(H_2L)]\cdot 7H_2O$ (84%): IR (KBr): $\tilde{\nu}$ = 3416 br (OH), 1556 and 1407 (ν_a, ν_s COO), 1608, 1491, 1450, 1295, 1203, 1151, 1120, 1087, 752 cm^{-1}. $C_{44}H_{54}N_3O_{17}Tb$ (1055.83): calcd. C 50.05, H 5.15, N 3.98; found C 49.16, H 4.78, N 3.72. Complexometry: calcd. Tb 15.05; found Tb 15.28 ± 0.28.
$[Lu(H_2L)]\cdot 4H_2O$ (92%): IR (KBr): $\tilde{\nu}$ = 3417 br (OH), 1561 and 1410 (ν_{as}, ν_s COO), 1608, 1491, 1450, 1294, 1203, 1152, 1120, 1088, 752 cm^{-1}. $C_{44}H_{48}N_3O_{14}Lu$ (1017.84): calcd. C 51.92, H 4.75, N 4.13; found C 51.98, H 4.41, N 4.14.

Physical Measurements. Potentiometric Titrations: H_7L^{2+} was titrated with a 5.1 mL sample ($[H_7L^{2+}]_{tot}$ = $3.7\cdot10^{-3}$ M, solvent: H_2O/CH_3OH 98:2 v/v) in a thermostatted (20.0 ± 0.1 °C) glass-jacketed vessel under an Ar atmosphere. The ionic strength was fixed with KCl (μ = 0.1 M). The solution was acidified to a pH of about 1.8 (HCl) 30 min before titration. Titrations were carried out with an automatic Metrohm Titrino 736 GP potentiometer linked to an IBM PS/2 computer (resolution 0.1 mV, accuracy 0.2 mV) and by use of constant volume addition (0.05 mL). An automatic burette (Metrohm 6.3013.210, 10 mL, accuracy 0.03 mL) was used, together with a Metrohm 6.0238.000 glass electrode. The standard base solution (KOH = 0.050 M, μ = 0.1 M, KCl) was added inside the solution through a capillary tip attached to the automatic burette. The data (200 points, drift < 1 mV/min) were mathematically treated by use of the program SUPERQUAD[27] with a Marquardt algorithm while the distribution of species was calculated with the program Haltafall.[28] Calibration of the pH meter and the electrode system was performed prior to each measurement with a standardized HCl solution (μ = 0.1 M, KCl) at 20.0 °C: 10 mL of the latter were titrated with a standardized 0.1 M KOH solution at a ionic strength of 0.1, and the electrode potential readings were converted to pH. The ion product of solvent (pK_w = 13.91) and electrode potential were refined by use of the program Scientist® by Micromath® (Version 2.0).

Spectrophotometric Titrations: Electronic spectra were recorded with a Perkin–Elmer Lamdba 900 spectrophotometer at 20 °C (210–350 nm, 60 nm min^{-1} scan speed, spectral width 2 nm) in 1 cm Suprasil® quartz cells. Titrations of 10 mL samples were performed in a thermostatted (20.0 ± 0.1 °C), glass-jacketed vessel filled with Ar, at μ = 1 M (KCl); H_7L^{2+} (pH, 2) was titrated with KOH (0.1 M), H_5L (pH, 5.3, HCl) with $Ln(ClO_4)_3$ (≈ $4.0\cdot10^{-3}$ M, Ln = La, Eu, Tb, Lu) at pH = 5.3, and $[Tb(H_2L)]$ $2.0\cdot10^{-5}$ M at pH_0 ≈ 2 by KOH (0.050 M). Aliquots of the titrant were added through a Socorex® micropipette. The pH values of the titrated solutions were monitored continuously. After a 15 min delay, 3 mL of solution was transferred into the quartz cell with a Teflon® syringe. The stability constants were computed by use of the Specfit program.[29] Differences between the measured and the computed absorbances were less than 7×10^{-3} absorbance unit at any wavelength and exhibited statistical behaviour.

NMR Titration: A solution of H_5L (11.6 mg, $7.3\cdot10^{-3}$ M) was prepared in 2 mL of a D_2O/CD_3OD (95:5, v/v) mixture, by addition of a concentrated KOD/D_2O aliquot (pD_0 ≈ 12). Samples with different pD values were prepared by addition of dilute D_2SO_4/D_2O (Fluka, puriss). Precipitation of ligand occurred at pD values lower than 3.2. The pH values of the solutions were determined with a Metrohm Titrino 736 GP potentiometer equipped with a calibrated Metrohm 6.0234.100 glass electrode in H_2O. Ionic strength was not adjusted. The pD values were obtained from the equation $pD = pH_{measd.} + 0.4$.[30]

Luminescence Titrations: The solutions {$[H_5L]_0$ = $2.0\cdot10^{-5}$ M, $[Tb(ClO_4)_3]_0$ = $2.0\cdot10^{-5}$ M, 10 mL, pH_0 ≈ 2; $[KOH]_{tit}$ = 0.050 M; μ = 0.1 M (KCl)} were identical to those used for the spectrophotometric pH-dependent titration described previously. After a 15 min delay, 3 mL of solution were transferred into a quartz cell and degassed with Ar for 5 min. Absorbance at the excitation wavelength was measured (A < 0.05) and emission (λ_{exc} = 285 nm) and excitation spectra were collected.

Luminescence Measurements: Low-resolution luminescence measurements (spectra and lifetimes) were recorded on a Perkin–Elmer LS-50B spectrofluorimeter. Phosphorescence lifetimes (τ) were measured with the instrument in time-resolved mode, on frozen glycerol/water (10:90%) solutions in a quartz capillary or a 1-cm Suprasil® cell. They are the average of at least three independent measurements, made by monitoring the decay at the maxima of the emission spectra, enforcing a 0.03–0.04 ms delay. The decays were mono-exponential and were analysed by use of the FLDM program (Perkin–Elmer). Solutions of $[Ln(H_jL)]^{(3+j-5)+}$ were prepared in water at pH = 5.3, with stock solutions of H_5L ($2.0\cdot10^{-3}$ M) and $Ln(ClO_4)_3\cdot xH_2O$ (x ≈ 4.5, Ln = La, Eu, Tb, Lu; ≈ $4\cdot10^{-3}$ M). Quantum yields of L^{5-} (10^{-5} M, pH = 12) and $[Ln(H_2L)]$ (Ln = La, Eu, Tb, Lu, 10^{-5} M in H_2O) were determined in degassed water relative to quinine sulfate in 0.05 M aqueous H_2SO_4 (absolute quantum yield: 0.546)[31] and cresol violet (absolute quantum yield: 0.52);[32] estimated error ±10%. The number of coordinated water molecules (q) for the Eu and Tb complexes were calculated from $q = A(\tau_H^{-1} - \tau_D^{-1} - k_{corr})$, where τ_H and τ_D are the lifetimes in H_2O and D_2O respectively, A = 1.2 (Eu) and 5.0 (Tb), and k_{corr} = 0.25 (Eu) and 0.06 (Tb) ms^{-1}.[24] High-resolution spectra were recorded on a previously described setup.[33]

Table 4. Absolute quantum yield of the ligand-centred fluorescence in $[L]^{5-}$ (pH = 12) and $[LnH_2L]$ (Ln = La, Lu) and of the metal-centred phosphorescence in $[LnH_2L]$ (Ln = Eu, Tb) measured in water at 295 K and pH = 5.3 (values in D_2O are italicised)

Compound	λ_{exc} (nm)	φ_{abs} (%)
$[L]^{5-}$	268	0.3
$[LuH_2L]$	273	0.4
$[LaH_2L]$	273	0.5
$[EuH_2L]$	270	1.5, *3.3*
$[TbH_2L]$	270	10.3, *18.9*

Acknowledgments

This work is supported through grants from the Swiss National Science Foundation and the Swiss Federal Office for Science and Education (COST Action D18). We thank Frédéric Gumy for his help in recording the high-resolution luminescence data.

Keywords: Amine ligands / Chelates / Ligand design / Stability constants

The protonation and metal complex formation of the branched pentaamine ligand 2,2,6,6-tetrakis(aminomethyl)-4-azaheptane (ditame, L) with Co^{II}, Co^{III}, Ni^{II}, Cu^{II}, Zn^{II}, and Cd^{II} have been studied. The crystal structures of $[Ni(ditame)(EtOH)]Br_2$, $[Co_2(ditame)_2(O_2)]Cl_4{\cdot}4H_2O$, and $[Co_2(ditame)_2(O_2)]Cl_2[ZnCl_4][ZnCl_3(H_2O)]{\cdot}H_2O$ were determined by X-ray diffraction analyses. The metal complexes showed octahedral coordination geometries with exclusive formation of six-membered chelate rings, the four primary amino groups being in equatorial positions and the secondary amino group (N^{sec}) apical. This geometry enforces a relatively short M–N^{sec} bond. Complex formation in aqueous solution was evaluated by potentiometric titration. The ditame ligand forms a surprisingly stable Ni^{II} complex with $\log K_{NiL} = 17.8$ (25 °C, 0.1 M KNO_3), and formation of protonated species $[Ni(H_n ditame)]^{(n+2)+}$ (n = 1, 2) is not significant. Different behavior is evident for Zn^{II} and Cd^{II}, with which protonated species are extensively formed, while the stability of $[ML]^{2+}$ is relatively low. Complex formation between ditame and Cu^{II} in the range $3 < pH < 7$ resulted in the formation of $[Cu(H_2ditame)]^{4+}$. In slightly alkaline solution, the dinuclear $[Cu_2(ditame)_2]^{4+}$ appears to be formed. The structural assignment of this dimer is based on its UV/Vis and EPR characteristics, with the EPR data indicating a $Cu^{II}\cdots Cu^{II}$ separation of about 5.9 Å. The redox behavior of the Ni and Co complexes was investigated by cyclic voltammetry. The mononuclear species showed quasi-reversible electron transfer for the $Ni^{II/III}$ and $Co^{II/III}$ couples. For the dinuclear peroxo/superoxo-bridged Co^{III} complexes, quasi-reversible electron transfer corresponding to oxidation/reduction of the O_2^{2-}/O_2^- bridge was observed.

Introduction

Ligand design is a well-established field in modern coordination chemistry.[1] Tailored complexing agents are of importance for the construction of catalysts,[2] and as building blocks for coordination polymers,[3,4] since they allow specific modulation of the electronic and steric properties of a metal complex.[5] Pentadentate chelators are of particular interest, since the high denticity often gives rise to high stability, while the binding of an additional ligand (e.g. a substrate) to the metal cation within an octahedral environment is still possible.[6–16] As regards complex formation with late transition metal cations, aliphatic polyamines are of particular relevance.[17,18] Various aliphatic and alicyclic pentaamines have been prepared and their coordination chemistry explored. They comprise a series of pentaaza macrocycles[19] as well as tetraaza and triaza macrocycles with pendant amine groups.[20] Macrobicyclic pentaaza ligands are also known,[19] and a number of open-chain, linear, and branched aliphatic pentaamines have been described.[6,7,21–25] The synthesis of the doubly branched 2,2,6,6-tetrakis(aminomethyl)-4-azaheptane, or ditame (Scheme 1), has recently been reported by some of us, and the structure and reactivity of its Co^{III} complex have been discussed in detail.[21] Metal complex formation by a related pyridine analogue has been published by Grohmann and

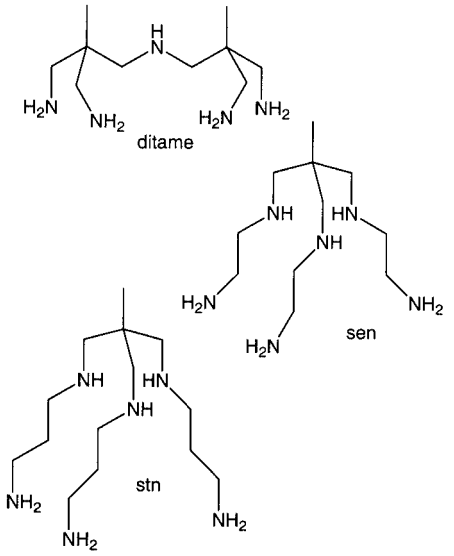
co-workers.[10−16] This investigation explores the stability of labile coordination complexes of ditame in comparison with the coordination chemistry of two related hexadentate ligands (Scheme 1), 1,1,1-tris(5-amino-2-azapentyl)ethane (stn) and 1,1,1-tris(4-amino-2-azabutyl)ethane (sen).[26]



Scheme 1

Results and Discussion

Protonation of ditame

Because of the fairly high charges of multiply protonated amines, increased electrostatic effects have to be taken into account. It is known that some cyclic, multiply protonated polyamines selectively bind suitable anions such as chloride or nitrate through hydrogen bonding.[19] Such interactions could influence the acidity constants of the ligand. Since precise pK_a values of the ligand are a prerequisite for conclusive analysis of metal complex formation in aqueous solution, a series of pK_a determinations was performed, with the nature and concentration of the inert electrolyte (KCl and KNO_3, 0.1 and 1.0 M) as well as the total concentration of ditame (1−10 mM) being varied. Inspection of the corresponding values (Table 1) reveals a significant dependence of the pK_a values on the ionic strength. The acidities of multiply protonated species decrease at higher salt concentrations, and this effect increases with increasing degree of protonation.[27] The effect of the anion (Cl^- versus NO_3^-) was negligible, so specific binding of these anions by the open-chained H_xL^{x+} appears not to be significant in aqueous solution. However, a weak but significant dependence of the pK_a values on total ligand concentration is evident, indicating some deviation from ideal behavior for solutions in which the ratio of total ditame to the ionic strength exceeds a value of 1:500.

Table 1. pK_a values of ditame (25 °C) for different inert electrolytes

Ionic strength [M]	0.1	0.1	1.0	1.0	1.0
Inert electrolyte	KCl	KNO_3	KCl	KCl	KNO_3
Total L [M]	0.001	0.001	0.002	0.010	0.010
p$K_{a,1}$[a]	–[b]	–[b]	1.7(1)	1.8(1)	1.8(1)
p$K_{a,2}$	6.77	6.83	7.32	7.36	7.40
p$K_{a,3}$	7.90	7.90	8.26	8.32	8.33
p$K_{a,4}$	9.47	9.44	9.61	9.72	9.76
p$K_{a,5}$	11.10	11.09	11.06	11.25	11.28

[a] $pK_{a,i} = -\log K_{a,i}$, $K_{a,i} = [H_{5-i}L] \times [H] \times [H_{6-i}L]^{-1}$, estimated standard deviations are 0.01 or less unless otherwise noted. [b] Value too low for determination by pH-metric methods.

A series of pD-dependent ^1H NMR spectra were measured in D_2O (Figure 1). These exhibit four signals for the H(−C) protons of the C_{2v}-symmetric[21] H_xL^{x+} entity, a singlet for the two homotopic methyl groups (X), an additional singlet (Y) for the enantiotopic methylene protons [$H^{(Y1)}$ and $H^{(Y2)}$], and an AB system for the diastereotopic protons $H^{(Za)}$ and $H^{(Zb)}$ of the four methylene groups (Z). Since the chemical shifts of $H^{(Za)}$ and $H^{(Zb)}$ differ only slightly over the entire pD range, a mean value corresponding to the center of the AB system (Z) is presented in Figure 1. The pD-dependence of these signals was modeled by minimization of $\Sigma(\delta_{obs} - \delta_{calc})^2$, assuming a rapid equilibrium with weighted averaged shifts (δ_{obs}) for the six macrospecies H_xL^{x+} ($0 \le x \le 5$, see Table S1).[28,29] The resulting pK_a values of 0.9, 7.2, 8.0, 9.3, and 11.0 agree well with the values obtained from potentiometric titrations. In the fully protonated and the fully deprotonated forms, the two types of methylene groups (Y and Z) have rather similar environments, with similar chemical shifts. For some of the intermediate forms H_xL^{x+} ($2 \le x \le 4$), however, the chemical shifts of Y and Z differ significantly. This observation is attributed to different tautomeric forms that have to be taken into account for the partially protonated species, with the secondary nitrogen atom either protonated or not protonated. Additionally, the four primary amino groups of H_2L^{2+} and H_3L^{3+} can be protonated in different ways, which results in the generation of further tautomers. However, since the four primary amino groups appear to be symmetry-equivalent on the NMR timescale, the latter type of tautomerism can be taken account of by means of an averaged, partial protonation of the NH_2 groups. A total of two microspecies for each of the partially protonated forms is thus sufficient for a suitable description of the NMR characteristics. A set of empirically derived deshielding parameters was used to elucidate the equilibrium between the different microspecies.[28,29] These parameters were determined by use of the well-established observation that protonation of an amino group generally results in a deshielding of nearby H(−C) protons, and that this effect decreases with increasing distance.[30,31] In the range $10 < pD < 12$, the related pD dependence of Y and Z is indicative of fairly unspecific binding of the first proton. The quantit-

ative analysis suggests 25% protonation at the secondary amino group in HL^+, approximately corresponding to a statistical distribution of the proton over the five basic sites. Obviously, there is no significant difference in basicity between the secondary and primary nitrogen donors. For H_2L^{2+}, protonation at the secondary nitrogen atom is < 10%, and in H_3L^{3+} and H_4L^{4+} the protons are exclusively bonded to the primary amino groups. Therefore, consecutive protonation of L up to H_4L^{4+} resulted in increasing protonation at the primary amino groups and decreasing protonation at the secondary amino group. Consequently, the chemical shifts of X and Z increase steadily with increasing protonation (Figure 1), whereas the methylene protons Y are less deshielded in H_2L^{2+} than in HL^+. A dramatic deshielding of Y is observed on final protonation of H_4L^{4+}. However, since H_4L^{4+} is a rather weak base, the exclusive presence of the fully protonated H_5L^{5+} is only observed in strongly acidic solutions (pD = 0).

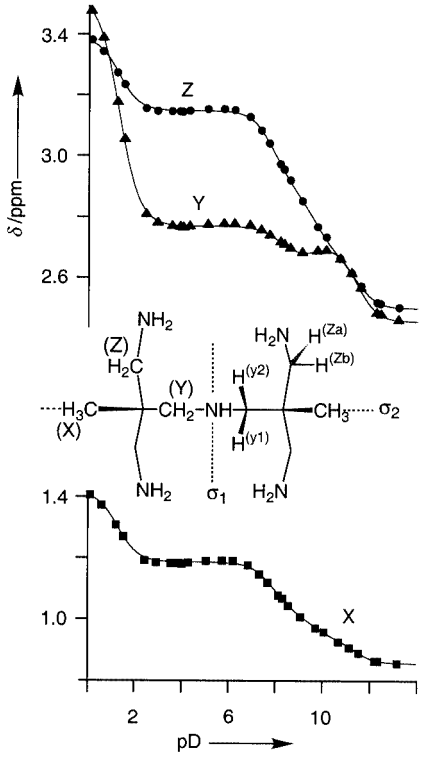


Figure 1. pD dependence of the ^1H NMR resonances of $H_x$ditame^{x+}; the points correspond to experimental values, the lines are calculated (least-squares), by assuming a rapid equilibrium; the values of Z correspond to the center of the AB system of Z^a and Z^b; the schematic formula indicates the observed C_{2v} symmetry with the mirror plane σ_1 and the pseudo mirror plane σ_2[21]

Crystal Structures

[Ni(ditame)(EtOH)]Br$_2$ (1Br$_2$)

The complex cations $\mathbf{1}^{2+}$ and the Br^- anions are arranged in linear chains along the crystallographic *b* axis through $Ni^{II}-N-H\cdots Br^-$ and $Ni^{II}-O-H\cdots Br^-$ hydrogen bonding. Two such chains, related through a crystallographic screw axis, form a double-chain structure. The $\mathbf{1}^{2+}$ cation (Figure 2) is situated on a crystallographic mirror plain, approximately corresponding to the molecular pseudo-plane σ_2 (Figure 1). However, the symmetry operation σ_2 requires either a planar geometry or rapid inversion of the pyramidal configuration for the secondary nitrogen atom. Obviously, neither requirement can be met in the metal complex, and the inherent violation of this symmetry has resulted in a characteristic disorder. The cation was thus refined by two superimposed, but completely independent models (mirror images) with occupancies of 50% each (Figure S1). A similar type of disorder has previously been reported for [Co(ditame)Cl][$ZnCl_4$].[21]

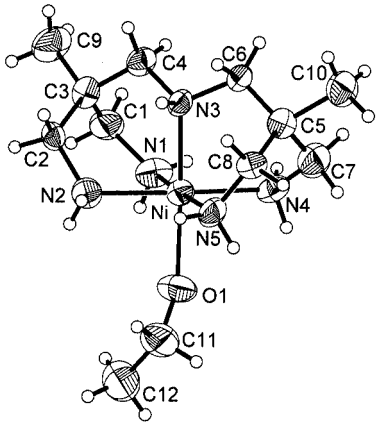

Figure 2. Molecular structure of $[Ni(ditame)(EtOH)]^{2+}$ ($\mathbf{1}^{2+}$); the atomic displacement ellipsoids are drawn at the 50% probability level; hydrogen atoms are shown as spheres of arbitrary size; selected bond lengths [A] and angles [°]: Ni−N1 2.111(7), Ni−N2 2.107(7), Ni−N3 2.050(5), Ni−N4 2.115(7), Ni−N5 2.113(7), Ni−O1 2.172(6); N1−Ni−N2 85.0(3), N1−Ni−N3 93.2(3), N1−Ni−N4 92.4(4), N1−Ni−N5 176.9(4), N1−Ni−O1 86.8(3), N2−Ni−N3 86.8(3), N2−Ni−N4 177.1(3), N2−Ni−N5 98.1(4), N2−Ni−O1 90.2(3), N3−Ni−N4 92.2(3), N3−Ni−N5 87.2(2), N3−Ni−O1 177.0(3), N4−Ni−N5 84.6(3), N4−Ni−O1 90.8(3), N5−Ni−O1 92.9(3)

[Co$_2$(ditame)$_2$(O$_2$)]Cl$_4$·4H$_2$O (2Cl$_4$·4H$_2$O)

The Co−O−O−Co group of the peroxo complex $\mathbf{2}^{4+}$ was located on a twofold rotational axis. It could be refined without problems, although considerable anisotropy for the atomic displacement of the primary nitrogen atoms indicated some conformational disorder within the ditame moieties (Figure 3). The dimeric cation $\mathbf{2}^{4+}$ and the counterions again form a chain structure. The chains are oriented parallel to *b* and coincide with the twofold rotational axes, forming a type of distorted hexagonal rod packing.

[Co$_2$(ditame)$_2$(O$_2$)]Cl$_2$[ZnCl$_4$][ZnCl$_3$(H$_2$O)]·H$_2$O {3Cl$_2$[ZnCl$_4$][ZnCl$_3$(H$_2$O)]·H$_2$O}

The centrosymmetric superoxo complex $\mathbf{3}^{5+}$ (Figure 4) was located and refined without problems, although the counter-ion and the water of crystallization showed some disorder. The positive charge of +2.5 in the asymmetric

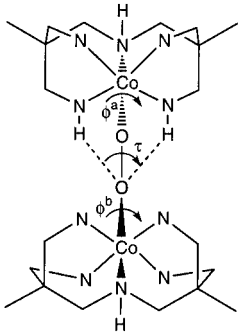
unit is balanced by a Cl^- anion and an additional tetrahedral ZnX_4 moiety. Three of these X positions could be unambiguously refined as Cl atoms; the fourth position exhibited two maxima in an electron density map with a separation of 0.69(2) Å. These two positions were refined as a Cl and an O atom, each with 50% occupancy. The corresponding distances to the Zn center, of 2.28(1) and 2.08(3) Å, are in agreement with a Zn−Cl and a Zn−OH_2 bond, respectively.[32,33] Obviously, the ZnX_4 positions are equally and randomly shared by $[ZnCl_4]^{2-}$ and $[ZnCl_3(OH_2)]^-$ anions; the simultaneous presence of these two anions has frequently been observed in solid-state structures.[33] An additional water molecule, located in proximity to two ZnX_4 moieties, was distributed over three positions with site occupancies of 28−36%. The zincate anions and the water molecule form chains of composition $[ZnCl_4]\cdots H_2O\cdots[ZnCl_3(H_2O)]\cdots$ along the crystallographic *c* axis. Additional chains along *c* were formed by $\mathbf{3}^{5+}$ and the Cl^- counter-ions. They are stabilized by Co−N−H···Cl^- hydrogen bonds.

Molecular Structures of the ditame Complexes

The crystal structures of two mononuclear Co^{III}(ditame) complexes have been reported previously.[21] The structures of $\mathbf{1}^{2+}$ and of the dinuclear $\mathbf{2}^{4+}$ and $\mathbf{3}^{5+}$ (Figures 2−4) each display a closely related coordination mode for the ditame ligand, with exclusive formation of six-membered chelate rings. The four primary nitrogen donors form an almost regular square, with a slight distortion towards an isosceles trapezium: The $N^{prim}\cdots N^{prim}$ distances in one tripodal tris(aminomethyl)ethane (= tame) cap are slightly shorter than corresponding distances between the nitrogen atoms belonging to different caps. Moreover, the inter-tame N···N distances are inequivalent, the N···N distance with a *cisoid* orientation towards the (N^{sec})−H hydrogen is longer than that with a *transoid* orientation. In all three complexes, the M(ditame) moiety exhibits approximate local C_s symmetry, although the corresponding mirror plain (σ_1 in Figure 1) never corresponds to a crystallographic symmetry element. The M−N^{sec} bond is always somewhat shorter than the corresponding bonds to the primary amino groups. This is also the case if a ligand with a significant *trans* influence[34−36] such as O_2^{2-} is bonded *trans* to N^{sec}, and it appears that the short M−N^{sec} bond is a consequence of the steric requirements of this particular ligand.[15]

The Co−O−O−Co structures of $\mathbf{2}^{4+}$ and $\mathbf{3}^{5+}$ exhibited characteristic differences. The O−O lengths of 1.495 and 1.341 Å are indicative of an O_2^{2-} and an O_2^- bridge, respectively. Corresponding distances for related monobridged (pentaamine)Co^{III} complexes are 1.42−1.53 Å for O_2^{2-} and 1.27−1.34 Å for O_2^-.[6−9,15,23,34−43] The presence of a peroxo bridge in $\mathbf{2}^{4+}$ is also indicated by the Raman data, with an O−O stretch vibration at 810 cm^{-1}.[7,15,35,44] The $Co^{III}-O_2^-$ bond of 1.917(5) Å in the superoxo complex $\mathbf{3}^{5+}$ is in good agreement with literature values, but the $Co^{III}-O_2^{2-}$ bond [1.951(7) Å] in $\mathbf{2}^{4+}$ is unusually long (reported range: 1.83−1.92 Å).[6,8,9,15,23,34−39] The Co^{III}−O−O angles and the average Co^{III}−N distances in both complexes are all normal. The superoxo complex $\mathbf{3}^{5+}$ has a planar, *transoid* Co−O−O−Co grouping with a torsional angle τ of 180°, whereas the Co−O−O−Co grouping in the peroxo complex $\mathbf{2}^{4+}$ is twisted with τ = 138.1°. In agreement with our findings, dinuclear, monobridged

Co^{III}(pentaamine)(superoxo) complexes reported to date are centrosymmetric[7,15,40−42] or nearly centrosymmetric[43] ($\tau = 175°$). For (pentaamine)Co^{III}(peroxo) complexes, both planar *transoid*[6,23,34,35,37,38] and bent[8,9,15,36,39] structures have been described, examples with $\tau = 180°$ predominating. The known non-centrosymmetric, bent structures have torsional angles τ of 146−177.5°.[45] Obviously, $\mathbf{2}^{4+}$ exhibits a particularly high degree of such torsional twist. It has been argued that the value of τ is strongly influenced by inter- and intramolecular hydrogen bonding. In particular, hydrogen bonds between the coordinated amino groups and the remote oxygen atom of the peroxo bridge have been proposed to be a major structure-determining factor.[15,23] However, the corresponding $N\cdots O^{remote}$ distances depend on the rotation around the Co−O bond rather than about O−O. A conclusive discussion of the different types of rotamers requires consideration of three torsional angles τ, φ^a, and φ^b (Scheme 2, φ^a and φ^b are defined as the torsional angles $O-O\cdots N^{sec}-H$). The symmetry types of the various conformers can be mapped as functions of these three parameters; *transoid* conformations ($\tau = 180°$) with $\varphi^a = \varphi^b = 180°$ or $\varphi^a = \varphi^b = 0°$ have the highest possible symmetry (C_{2h}).[42] Further *transoid* conformations have C_s ($\varphi^a = 0$, $\varphi^b = 180°$), C_i ($\varphi^a = -\varphi^b$), or C_2 ($\varphi^a = \varphi^b$) symmetry. For $\tau < 180°$ and $\varphi^a = \varphi^b$ the symmetry remains C_2. Evidently, all conformations with $0° < |\varphi^a| \neq |\varphi^b| < 180°$ are completely asymmetric (C_1). The prerequisite for the formation of four equal intramolecular $N-H\cdots O^{remote}$ hydrogen bonds is $|\varphi^a|, |\varphi^b| = 0$, 90, or 180°. Several of the symmetry types described above match these requirements (even C_1). Neither a centrosymmetric structure nor the *transoid* conformation is required.[23]



Scheme 2

In the crystal structures reported here, the superoxo and the peroxo complexes have a C_i ($\tau = 180°$, $\varphi^a = 86.2°$, $\varphi^b = -86.2°$) and a C_2 ($\tau = 138.1°$, $\varphi^a = -82.7°$, $\varphi^b = -82.7°$) structure, respectively. Only one strong $N-H\cdots O^{remote}$ hydrogen bond per Co(ditame) moiety is formed in each complex. Since the two Co(ditame) moieties are twisted against each other by an angle of almost 90°, the four methyl groups are not equivalent. In solution (D_2O, pD = 7), however, we observed only one single signal for these methyl groups in the ^1H and the ^{13}C NMR spectra of the peroxo complex $\mathbf{2}^{4+}$. The methylene groups exhibited three AB systems (six unique H atoms) in the ^1H NMR, and the ^{13}C NMR showed a total of five lines. These characteristics are only compatible with a C_{2h} structure. Variation in temperature did not produce any unusual line-broadening effect, and it appears that the barriers of rotation for the Co−O and the O−O bonds are − as would be expected − fairly small. The different values of τ reported in the literature are thus most probably based on the crystal packing and not on any electronic effect.

Evidence of the different conformations of $\mathbf{2}^{4+}$ in solution and in the solid state is also provided by UV/Vis spectroscopy. In solution the typical spectrum of a monobridged, centrosymmetric complex[46−48] with $\lambda_{max} = 296$ nm, $\log \varepsilon = 4.1$ (π_σ* CT), and shoulders around 420 and 520 nm has been observed. In the solid state, an intense CT band remained at about 300 nm, but an additional shoulder appeared at about 380 nm while the 420 and 520 nm bands gained in intensity. This behavior is clearly indicative of the diminished symmetry in the solid state, in which some transitions, symmetry-forbidden in the C_{2h} forms, become allowed. A more detailed discussion on the electronic properties of this complex will be given elsewhere.[49] The spectrum of the superoxo complex $\mathbf{3}^{5+}$ has maxima at 471 nm ($\log \varepsilon = 2.3$) and 695 nm ($\log \varepsilon = 2.9$). These values agree well with the characteristics reported for monobridged Co^{III}(pentaamine)(superoxo) complexes.[7,15,41,42,50]

Complex Formation of ditame (= L) with Co^{II}, Ni^{II}, Zn^{II}, and Cd^{II} in Aqueous Solution

Potentiometric measurements were performed to evaluate complex formation as a function of pH (Figure 5), and to determine the corresponding formation constants (Table 2). For Co^{II}, Ni^{II}, Zn^{II}, and Cd^{II} the predominant species at $8 < pH < 11$ is the 1:1 complex $[ML]^{2+}$. The observed order of stability $Co^{II} < Ni^{II} > Zn^{II}$ is in agreement with the well-established Irving−Williams series.[51] Differences between 0.1 M KNO_3 and 0.1 M KCl are generally small, with the exception of Cd, for which formation of chloro complexes must be taken into account.[28] The difference between Cd^{II} and Zn^{II} ($\Delta\log \beta_{110} = 2.8$ in 0.1 M KNO_3) is fairly large. Such an effect can be attributed to the formation solely of six-membered chelate rings, which is more favorable for the smaller cation.[52] Additional species of composition $[M(HL)]^{3+}$ and $[M(H_2L)]^{4+}$ appeared at lower pH values. Formation of such protonated components is almost negligible for Co^{II} and Ni^{II} but more significant for Zn^{II} and Cd^{II}. In these latter species, the donor set is necessarily only partially bonded to the metal cation, one or two nitrogen atoms of the primary amino groups remaining protonated. In the alkaline range, hydroxo complexes of composition $[ML(OH)]^+$ formed, thus indicating additional coordination of a solvent molecule which can be deprotonated. A corresponding octahedral NiN_5O structure has been established by X-ray analysis (Figure 2) and was confirmed in solution by the Vis spectrum of $[Ni(ditame)(H_2O)]^{2+}$, with bands at 338, 533, and 884 nm.[4] The pK_a values of the $[ML(H_2O)]^{2+}/[ML(OH)]^+$ couples can be calculated as $pK_a = \log \beta_{110} - \log \beta_{11-1}$. For the divalent cations, they

showed only minor differences: 11.7 (Co^{II}), 12.0 (Ni^{II}), 11.8 (Zn^{II}), and 11.7 (Cd^{II}). For the inert Co^{III}, the corresponding value was determined directly by acid-base titration. As was to be expected,[15,17,24] the water molecule bonded to this trivalent cation was considerably more acidic (pK_a = 6.38).

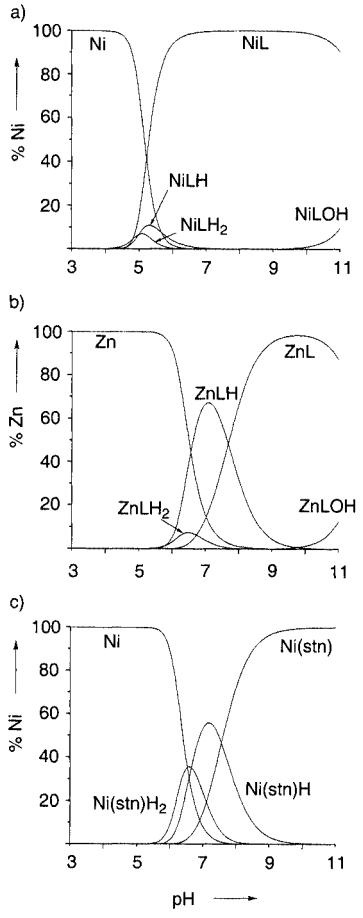


Figure 5. Species distribution plots for equilibrated aqueous solutions; a) Ni^{II} and ditame, b) Zn^{II} and ditame, c) Ni^{II} and stn; total metal and total ligand (L = ditame) concentrations are 1 mM; only metal-containing species are shown; the equilibrium constants listed in Tables 1 and 2 were used for the calculations

Stability constants for metal complexes with representative pentaamine ligands are given in Table 3. These values clearly show that ditame forms a surprisingly stable complex with Ni^{II}. The formation constant of the 1:1 complex has the same order of magnitude as those observed for corresponding complexes with the linear, open-chained tetren or the macrocyclic [16]aneN5. For Zn^{II} and Cd^{II} the situation is different; here the linear and the macrocyclic representatives form 1:1 complexes of higher stability. Obviously, the ditame geometry appears to be particularly suited for the accommodation of relatively small metal ions with a pronounced preference for an octahedral coordination. The particular metal-binding properties of ditame can be elucidated further by comparison with ligands representing different types of substructures with the ditame geometry (Table 4). It is particularly interesting that the addition of two aminomethyl branches to the linear 1,5,9-triazanonane (3,3-tri) ligand at the 3- and the 7-positions increases the stability of the Ni^{II} complex by almost nine orders of magnitude. Again, this effect is much less pronounced for Zn^{II} and Cd^{II}. Similarly, the fusion of two "tame" fragments to the ditame structure is particularly effective for Ni^{II}. Some examples listed in Tables 3 and 4 also support the notion that an increasing number of six-membered chelate rings usually results in a reduction in complex stability. Such destabilization is not observed for ditame, however, although this ligand forms six-membered chelate rings exclusively. The *penta*dentate ditame forms more stable complexes with Co^{II} and Ni^{II}, than the *hexa*dentate stn. This behavior is consistent with the observation that protonated Ni(ditame) complexes are minor species whereas $[Ni(Hstn)]^{3+}$ and $[Ni(H_2stn)]^{4+}$ are substantial components in neutral solution (Figure 5). Even the sen ligand, with three five-membered and three six-membered chelate rings, has a higher

See Tables S4 and S5 in the Supporting Information for further details. [f] 0.5 M KCl.[54] [g] A value $\log\beta_{110} = 17.0(1)$ is reported for 0.5 M KCl.[54]

proportion of such protonation products (Figure S2). The detachment of an amino group in $[Ni(ditame)(H_2O)]^{2+}$ is obviously a particularly unfavorable process, and ditame appears to be unique within the family of ligands forming exclusively six-membered chelate rings.

Formation of Cu^{II} Complexes in Aqueous Solution

Comparison of Ni^{II} and Cu^{II} complex formation with ditame in aqueous solution reveals significant differences. When a 1:1 mixture of $H_5ditame^{5+}$ and Ni^{II} is titrated with 5 equiv. of base, a single, continuous buffer region is observed, according to the reaction $H_5ditame^{5+} + Ni^{2+} + 5\ OH^- \rightarrow [Ni(ditame)]^{2+} + 5\ H_2O$. For Cu^{II}, two individual buffer regions are observed (Figure S3), corresponding to the abstraction of three and of two protons from $H_5ditame^{5+}$ in two sequential and separated steps. It is noteworthy that for the second buffer region, the curve of Cu^{II} lies above that of Ni^{II}, indicating that binding of subsequent amino groups to Ni^{II} is favored at this stage.

For further characterization of the Cu complexes formed, the titration was monitored photometrically. This method allowed the assignment of a spectrum to each individual colored species (Figure S4). The first buffer region could unambiguously be evaluated in terms of $[Cu(H_2L)]^{4+}$ formation (Figure 6). This protonated species predominated in the range $4 < pH < 6$. A meridional coordination mode with two detached $-CH_2-NH_3^+$ branches is proposed for this complex. This assignment is supported by the characteristics of the d-d band with $\lambda_{max} = 619$ nm in comparison to $\lambda_{max} = 616$ nm reported for $[Cu(3,3\text{-tri})]^{2+}$.[55] E. Prenesti et al. reported an empirically derived equation for the estimation of λ_{max} in equatorially coordinated Cu^{II}(amine) complexes,[56] yielding a value of 608 ± 10 nm for such a meridional triamine configuration.

A conclusive assignment for the species appearing in the second buffer region was more difficult. According to the potentiometric measurements, a species of composition Cu^{II}/ditame/H^+ = 1:1:0 was finally formed. The titrations could be interpreted by the assumption of the formation of the simple $[Cu(ditame)]^{2+}$ complex. The corresponding

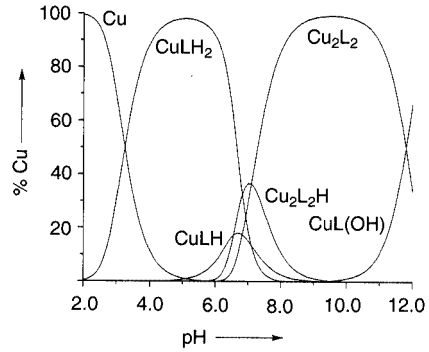

Figure 6. Species distribution plots for equilibrated aqueous solutions with total Cu and total ditame concentration of 10 mM; only metal-containing species are shown; the abundance is given in % of total Cu rather than the amount of species formed; the equilibrium constants listed in Tables 1 and 5 were used for the calculations

λ_{max} of 567 nm, however, is indicative of a tetraammine configuration with the four nitrogen atoms all equatorial.[57] For CuN_5 coordination with an additional nitrogen at the apex, a shift of about 50 nm to *longer* wavelengths would be expected ("pentaamine effect").[4,58] Interestingly, the spectral properties of this species strongly depend on the solvent. Addition of glycerol to a complex solution at pH = 9 resulted in a significant shift of λ_{max} to longer wavelengths (Figure S5). For a glycerol content of 20%, λ_{max} was found at 606 nm. Upon further addition of glycerol this value remained constant. This change can be interpreted as an equilibrium between two different complexes with a Cu^{II}/ditame/H^+ = 1:1:0 composition. An obvious choice for such an equilibrium is the dimerization $2\ [CuL]^{2+} \rightleftarrows [Cu_2L_2]^{4+}$, with the monomer having the square-pyramidal CuN_5 ($\lambda_{max} = 606$ nm) and the dimer a square-planar CuN_4 ($\lambda_{max} = 567$ nm) chromophore. Obviously, $\Delta G°$ for the dimerization is close to 0 under the experimental conditions and this equilibrium is sensitive to subtle changes in the solvent. A conceivable structure for such a dimer would consist of two Cu^{II} centers bonded to the primary amino groups of two ditame ligands. Various conformers of this type, with Cu···Cu separations of 4.0−7.5 Å, were analyzed

by Molecular Mechanics calculations.[59] The structure shown in Figure 7 was found to be of particularly low strain and so can be regarded as a possible model for such a dimer. A series of potentiometric titrations with variable total Cu concentration and variable total Cu/total ditame ratios was now performed, and these measurements could be interpreted well by assuming $[Cu_2L_2]^{4+}$, $[Cu_2L(HL)]^{5+}$, and $[Cu(HL)]^{3+}$ as relevant species (Table 5, Figure 6). The formation of some other Cu^{II} dimers with branched polyamine ligands has recently been described.[60] The spectra of the two dinuclear species $[Cu_2L_2]^{4+}$ and $[Cu_2L(HL)]^{5+}$ did not differ significantly. This is in keeping with the structure shown in Figure 7, in which one of the noncoordinating, secondary nitrogen atoms may be protonated, possibly through intramolecular N−H···N hydrogen bond formation.

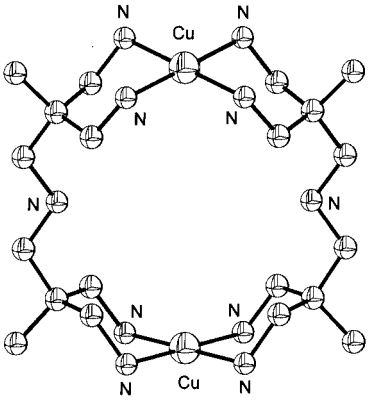

Figure 7. Minimum-energy structure (hydrogen atoms omitted for clarity), calculated by Molecular Mechanics,[59] for the $[Cu_2(ditame)_2]^{4+}$ complex with a square-planar arrangement of the tetraamine donor set; the possible binding of an additional solvent (= H_2O) molecule in the apical positions is omitted in this graphical representation

Table 5. Final model (log $\beta_{x\,y\,z}$) of the Cu(ditame) system (25 °C, 1.0 M KNO_3)

$x\ y\ z$	log $\beta_{x\,y\,z}$[a]
1 1 1	25.5
1 1 2	32.6
1 1 −1	7.1
2 2 0	39.8
2 2 1	46.9

[a] Estimated standard deviations are 0.1 or less.

Further addition of base to an aqueous $[Cu_2L_2]^{4+}$ solution resulted in formation of the hydroxo complex $[CuL(OH)]^+$. This species has a λ_{max} of 606 nm, which is in agreement with an elongated octahedral structure, with N^{sec} and the OH^- ligand in the apices.[58] A pK_a of about 11 was estimated for the $[CuL(OH_2)]^{2+} \rightleftarrows [CuL(OH)]^+ + H^+$ equilibrium. Obviously, $[CuL(OH_2)]^{2+}$ is a slightly stronger acid than the corresponding Co^{II}, Ni^{II}, Zn^{II}, and Cd^{II} complexes.

EPR Characteristics of $[Cu_2(ditame)_2]^{4+}$

For unambiguous identification of the dimer, a comprehensive EPR investigation was performed. The addition of DMSO to a Cu(ditame) complex solution at pH = 9, unlike that of glycerol, did not result in any spectral changes (λ_{max} remained at 567 nm). Most of the low-temperature experiments were therefore performed in frozen DMSO/water solutions. CW EPR measurements were performed primarily to verify the existence of dimers. Figure 8 shows the CW EPR spectra of frozen solutions (2.5 mM Cu) in H_2O with 10% DMSO at pH = 9 (**4**), 10% DMSO at pH = 12 (**5**), and 50% glycerol at pH = 9 (**6**) in the field ranges 260−360 mT (a) and 120−200 mT (b). Simulation parameters for the three samples are given in Table 6. The low-field signal of **4** belongs to the $\Delta M_s = \pm 2$ transitions and arises from magnetic dipole couplings between two Cu^{II} ions. The observation of this low-field spectrum unambiguously shows that sample **4** contains dimers. However, the lack of such a signal in the spectra of **5** and **6** does not necessarily mean that these copper complexes are monomers, since the $\Delta M_s = \pm 2$ transitions can be very low in intensity and difficult to detect. The ratio of the intensity of the forbidden $\Delta M_s = \pm 2$ to the allowed $\Delta M_s = \pm 1$ transitions can be used to estimate the Cu−Cu distance r by the expression[61] $r = [k/I_r(9.1/\nu)^2]^{1/6}$, where k is a constant of approximately 20, I_r is the relative intensity, and ν the microwave frequency. For the dimer of sample **4**, $I_r = 4.4 \cdot 10^{-4}$ yields a distance $r = 5.9$ Å. This estimate is consistent with the proposed structure of the dimer (Figure 7).

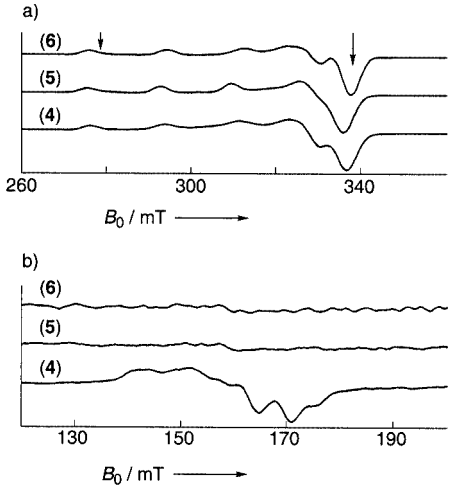

Figure 8. CW EPR spectra of Cu^{II}(ditame); (a) allowed transitions $\Delta M_s = \pm 1$ recorded at 120 K; (b) low-field forbidden transitions $\Delta M_s = \pm 2$ recorded at 10 K; samples: 2.5 mM Cu(ditame) in H_2O with 10% DMSO at pH = 9 (**4**), 10% DMSO at pH = 12 (**5**) and 50% glycerol at pH = 9 (**6**); the two arrows in (a) indicate the observer positions used in ENDOR and HYSCORE experiments

Further information on the coordination of ^{14}N and ^1H nuclei was achieved through ENDOR and HYSCORE experiments.[62] ENDOR spectra on all three samples showed signals from strongly coupled ^{14}N nuclei with hyperfine couplings A between 28 and 34 MHz overlapping with the

Table 6. Principal values of g and A^{Cu} of Cu(ditame) complexes derived from CW EPR

Sample	$g_{\parallel}$	$g_{\perp}$	$\lvert A_{\parallel}^{Cu}\rvert$ [MHz]	$\lvert A_{\perp}^{Cu}\rvert$ [MHz]
^{63}Cu(ditame) in H_2O with				
10% DMSO at pH = 9 (**4**)	2.227	2.051	550	45
10% DMSO at pH = 12 (**5**)	2.238	2.050	530	35
50% Glycerol at pH = 9 (**6**)	2.222	2.048	560	45

signals from weakly coupled ^{1}H nuclei. Spectra from the Cu/ditame dimer sample (Figure 8, sample **4**) taken at the two observer positions indicated in Figure 8a are shown in Figure 9. With weak and long microwave pulses the proton signals dominate, whereas with strong and short microwave pulses the signals of the weakly coupled ^{1}H nuclei are attenuated and the nitrogen signals centered at $A/2$ become clearly visible. The hyperfine couplings of the ^{14}N nuclei are typical for equatorially coordinated nitrogen nuclei with the unpaired electron in the $d_{x^2-y^2}$ orbital of the copper(II) ion.[63]

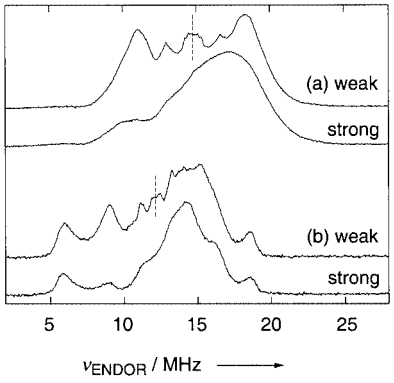

Figure 9. Davies-ENDOR spectra of 2.5 mM Cu(ditame) in H_2O with 10% DMSO at pH = 9 (**4**); spectra were recorded at $g_{\perp}$ (a) and $g_{\parallel}$ (b) by use of weak and strong microwave pulses, respectively (see arrows in Figure 8a); the dashed lines indicate the ^{1}H Larmor frequency

Figure 10 shows two HYSCORE spectra recorded at the high-field position indicated by the arrow in Figure 8a. The spectrum in Figure 10a was measured on the dimer sample **4** and shows large couplings from equatorial ^{1}H nuclei. The spectrum in Figure 10b was measured on sample **5**. In addition to the equatorial ^{1}H nuclei, signals from a ^{14}N nucleus are observed, as indicated in the Figure. Simulations of the ^{14}N HYSCORE spectra, measured at several field positions (Figure S6), resulted in the hyperfine couplings $A_{iso} = -5.6$ MHz, $A_{\parallel} - A_{iso} = 1.8$ MHz, $A_{\perp} - A_{iso} = -0.9$ MHz, and in the nuclear quadrupole coupling $|e^2qQ/h| = 1.3$ MHz with the asymmetry parameter $\eta = 0.4$. They allowed assignment to an axially coordinated ^{14}N nucleus, in agreement with the proposed structure for the monomeric complex. By use of the point-dipole model,[62] the hyperfine anisotropy is given by $T = (\mu_o/2\pi)(gg_n\beta_e\beta_n/hr^3)$. For $T = 0.9$ MHz, a distance of $r = 1.9$ Å between the nitrogen atom and the electron is calculated, a value consistent with expectations. The proton HYSCORE spectra for both complexes show hyperfine couplings of up to 13 MHz, consistent with the ENDOR data.

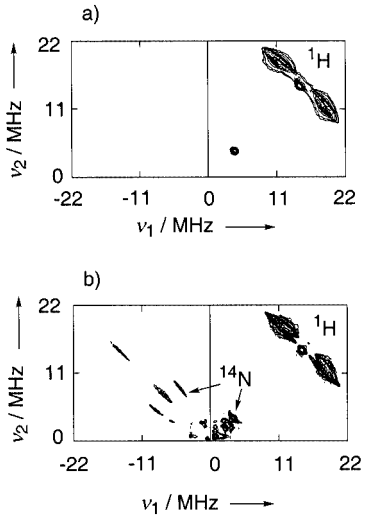

Figure 10. HYSCORE spectra recorded at the high-field position (arrow in Figure 8a) for: 2.5 mM Cu(ditame) in H_2O with 10% DMSO at pH = 9 (Figure 8, sample **4**) (a), 10% DMSO at pH = 12 (Figure 8, sample **5**) (b)

Electrochemistry

Cyclic voltammograms of $[Co(ditame)(H_2O)]^{3+/2+}$ were recorded by use of a hanging Hg drop electrode. Attempts to measure CVs with Au, Pt, or glassy carbon electrodes were not successful. CV scans in neutral and alkaline aqueous solutions showed one single redox step with a strongly pH-dependent potential $E_{obs}^{1/2}$, which decreased with increasing pH in the range $6 < pH < 13$. In aqueous 0.1 M KNO_3, the peak separation ΔE_P was 0.086 V at a scan rate v of 10 mV/s, increasing to $\Delta E_P = 0.162$ V at $v = 200$ mV/s (pH = 9). The ratio of the anodic and cathodic peak current I_{pa}/I_{pc} was 1.0, and I_{pc} depended linearly on $v^{0.5}$. All these observations are in agreement with quasi-reversible electron transfers. The pH dependence was interpreted in terms of a deprotonation of the coordinated water ligand. The species $[Co^{II}L(H_2O)]^{2+}/[Co^{II}L(OH)]^{+}$ ($pK_a^{II} = 11.75$) and $[Co^{III}L(OH_2)]^{3+}/[Co^{III}L(OH)]^{2+}$ ($pK_a^{III} = 6.38$) were taken into consideration. For $pK_a^{III} < pH < pK_a^{II}$, $E_{obs}^{1/2}$ corresponded to an intermediate between the values of the aqua and the hydroxo couples (Figure 11),[24] giving $E^{1/2} = -0.15(1)$ V for $[Co(ditame)(H_2O)]^{3+/2+}$ and $E^{1/2} = -0.47(1)$ V for $[Co(ditame)(OH)]^{2+/+}$ (vs. NHE). For comparison, the corresponding ammine and chloro complexes $[Co(ditame)(NH_3)]^{3+}$ and $[Co(ditame)Cl]^{2+}$ were also studied; they exhibited quasireversible redox behavior with $Co^{3+/2+}$ potentials of -0.41 and -0.20 V (Au electrode), respectively.

CV measurements were performed on the dinuclear Co^{III} complex by use either of the peroxo or of the superoxo forms as starting materials (1 M KCl, Au electrode). Quasireversible redox behavior was found with $E^{1/2} = 0.72$ V vs.

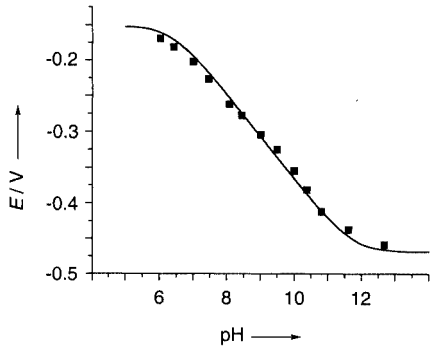

Figure 11. Observed redox potentials $E^{1/2}_{obs}$ for the $[Co(ditame)(OH_2)]^{3+/2+}$ – $[Co(ditame)(OH)]^{2+/+}$ system; squares represent the measured values; the line was calculated by use of the equation $E^{1/2}_{obs} = E^{1/2}{}_{Co^{III/II}L(H_2O)} - RT/F \times \ln\{(1 + K^{III}_a/[H^+])/(1 + K^{II}_a/[H^+])\}$ with $pK^{III}_a = 6.36$, $pK^{II}_a = 11.75$, and $E^{1/2}{}_{Co^{III/II}L(H_2O)} = -0.15$ V; $E^{1/2}{}_{Co^{III/II}L(OH)}$ can be calculated as $E^{1/2}{}_{Co^{III/II}L(H_2O)} - 2.303\ RT/F \times (pK^{II}_a - pK^{III}_a) = -0.47$ V

NHE. This value showed no significant pH dependence in the range $3 < pH < 8$. ΔE_P increased steadily with increasing v ($\Delta E_P = 70$ mV at $v = 10$ mV/s, $\Delta E_P = 120$ mV at $v = 200$ mV/s). I_{pc} was again found to depend linearly on $v^{0.5}$. I_{pa}/I_{pc} varied between 0.8 and 1.2. Similar behavior has been reported for other dinuclear, peroxo-bridged (pentaamine)Co^{III} complexes, with $E^{1/2}_{obs}$ being assigned to reversible oxidation of the O_2^{2-} bridge.[7,15,35,48,64]

In aqueous solutions of $[Ni(ditame)]^{2+}$ (0.1 M KNO_3), cyclic voltammetry indicated formation of an Ni^{III} species. A quasi-reversible one-electron transfer was observed, with $E^{1/2}_{obs} = 0.95$ V vs. NHE ($\Delta E_P = 79$ mV, $v = 5$ mV/s, Au electrode). ΔE_P again increased with increasing v. Unlike in the case of the Co complexes, I_{pa}/I_{pc} depended significantly on v, with $I_{pa}/I_{pc} < 1$ for $v < 100$ mV/s. At $v > 100$ mV/s the ratio was close to unity. $E^{1/2}_{obs}$ did not depend on H^+ concentration in the range $7 < pH < 11$. At higher pH values a significant drop in the potential was noted. Under these conditions, however, the reaction was no longer reversible, and deposition of solid materials on the surface of the electrode was observed. The electrochemical oxidation of Ni^{II}(polyamine) complexes to corresponding Ni^{III} species is well established.[65,66] For $[Ni(sen)]^{3+/2+}$, $E^{1/2}_{obs} = 0.92$ V has been reported.[66] The absence of any pH dependence for the $[Ni(ditame)]^{3+/2+}$ couple at $pH < 11$ is a clear indication that deprotonation of an acidic aqua ligand in the Ni^{III} species does not occur.[67,68] This could be attributable to the Jahn–Teller distortion caused by the low-spin d^7-electron configuration. The drastic drop in the potential at higher pH is coupled with decomposition. A possible explanation of this reactivity would be N–H deprotonation of a coordinated amino group, followed by an intramolecular oxidation of the ligand by Ni^{III}.[68,69]

Conclusions

The pentadentate ditame ligand (= L) forms $[NiLX]^{2+}$ complexes (X = solvent molecule) of surprisingly high stability and selectivity. We attribute the high selectivity to the peculiar ligand geometry, which appears to be particularly well suited for accommodation of late transition metal ions of fairly small size and a distinct preference for octahedral coordination. This conclusion is based on the following observations:

(i) ditame and stn (Scheme 1) can both be regarded as extensions of the tripodal tris(aminomethyl)ethane (tame), with exclusive formation of six-membered chelate rings. However, with respect to $[NiL]^{2+}$ formation, the complex with the *penta*dentate ditame is significantly more stable than the complex with the *hexa*dentate stn. The situation is different for Cd^{II}, for which the complex with stn is of slightly higher stability.

(ii) The favorable geometry of ditame for Ni^{II} binding is further demonstrated by the low capacity of $[Ni(ditame)]^{2+}$ to dissociate partially and to protonate an amino group. This type of reactivity is usually a feature of polyamine complexes with multiple six-membered chelate rings. For $[Zn(ditame)]^{2+}$, partial dissociation and partial protonation of the ligand is indeed extensively observed.

(iii) The geometry of ditame appears to induce a rather short $M-N^{sec}$ bond. This feature is most readily attained in complexes with an approximately octahedral structure. As a consequence, $[Cu(ditame)]^{2+}$ has a rather low stability, which does not fit normal Irving–Williams behavior. Two primary amino groups are readily detached and protonated, forming a meridional $[Cu(H_2ditame)]^{4+}$ complex, which appears to predominate in slightly acidic solutions. Furthermore, the EPR measurements provided unambiguous evidence that in slightly alkaline solution, in which the noncoordinating ammonium groups of $[Cu(H_2ditame)]^{4+}$ become deprotonated, the mononuclear species is in equilibrium with a dimer, $[Cu_2(ditame)_2]^{4+}$. In this dimer, Cu^{II} is probably bonded to the four primary amino groups with a square-planar arrangement.

From the high stability and the possibility for additional binding of a monodentate entity X (a "substrate"), octahedral complexes such as $[NiLX]^{2+}$ or $[CoLX]^{3+}$ would have ideal prerequisites for synthetic or even catalytic applications. The dimeric Co^{III}(peroxo)/(superoxo) complexes $\mathbf{2}^{4+}$ and $\mathbf{3}^{5+}$, in which reversible one-electron transfer was observed for the dioxygen bridge over a wide pH range (2–9), may be regarded as models for this type of reactivity.

Experimental Section

Materials and Instrumentation: ditame·5HCl,[21] [Co(ditame)Cl][$ZnCl_4$],[21] [Co(ditame)(NH_3)]Cl[$ZnCl_4$],[21] sen·6HCl,[26] and stn·6HCl[26] were prepared as described. Unless otherwise stated, all chemicals used for the synthetic work were commercially available products of reagent-grade quality. H_2O was distilled twice (quartz apparatus). Organic solvents were purified by distillation prior to use. For the potentiometric and spectrophotometric titrations, metal salts of the highest available quality (> 99.95%) were used. $^{63}CuCl_2$ (for EPR) was purchased (98.6% isotopically enriched) from CAMPRO Scientific (Berlin, Germany). Dowex 50 W-X2 (100–200 mesh, H^+ form) and Dowex 2-X8 (50–100 mesh,

Cl^- form) were purchased from Fluka. The anion resin was converted into the OH^- form or the NO_3^- form by use of 0.3 M aqueous NaOH or concd. KNO_3, respectively. UV/Vis spectra of the Ni^{II} complexes were measured with a Uvikon 941 spectrophotometer (H_2O, 25±3 °C), while a solid-state UV/Vis spectrum of **2**Cl_4·$4H_2O$ was recorded with sapphire plates and a Cary 5 spectrometer. IR spectra were recorded with a Bruker Vector 22 FT IR spectrometer equipped with a Golden Gate ATR unit. Raman spectra were measured with a Dilor-XY spectrometer, with an Ar^+/Kr^+-mixed gas laser used for excitation (λ = 647.1 nm). C,H,N analyses were performed by H. Feuerhake (Universität des Saarlandes).

Measurement and Interpretation of NMR Spectra: ^1H and $^{13}C\{^1H\}$ NMR spectra were measured in D_2O (28 °C) with a Bruker DRX 500 spectrometer (resonance frequencies: 500.13 MHz for ^1H and 125.9 MHz for ^{13}C). Chemical shifts (in ppm) are given relative to sodium [D_4](trimethylsilyl)propionate as an internal standard (δ = 0 ppm). A Hamilton SPINTRODE glass electrode, fitted with an internal Ag/AgCl reference (H_2O), was used within the NMR tube for a direct measurement of pD (corrected).[29] Least-squares calculations [$\Sigma(\delta_{obs} - \delta_{calc})^2$ = min] were performed with the computer program NMR-Tit,[70] the resulting parameters (pK_a and δ_{calc}) of the macro species are listed in Table S1. The constants P^α, S^α, P^χ, and S^χ were used to model the deshielding of the CH_2 and CH_3 protons in the individual microspecies caused by protonation of a primary (*P*) or the secondary (*S*) amine site, respectively. The distances between the protonated site and the hydrogen atom under consideration are indicated as α (N−C−H) and χ (N−C−C−C−H). Effects over longer distances were not considered. From symmetry arguments, the protonation of a primary amino group was always treated in a statistical manner by distributing the protons equally over all four sites. Because of the low number of observations (i.e., the resonances X, Y, Z in Figure 1), the same distance dependence was assumed for the primary and the secondary amine sites: $P^\chi/P^\alpha = S^\chi/S^\alpha = x$. From the data for the fully protonated and the fully deprotonated form one obtains: (i) $P^\alpha + xP^\alpha + xS^\alpha = 0.89$; (ii) $S^\alpha + 2x\,P^\alpha = 1.066$; (iii) $2xP^\alpha + x\,S^\alpha = 0.558$; and subsequently $P^\alpha = 0.495$, $S^\alpha = 0.748$, and $x = 0.32$. It is noteworthy that the value of 0.32 for *x* is significantly larger than corresponding ratios previously reported for methylene groups of macrocyclic polyamines.[31] The observed shifts of the macrospecies HL^+, H_2L^{2+}, H_3L^{3+}, and H_4L^{4+} were then interpreted as weighted averages of the two micro species (Table S2).

EPR: CW EPR measurements were performed with a Bruker ESP300 spectrometer (microwave frequency 9.43 GHz) equipped with a liquid nitrogen cryostat and a liquid helium cryostat from Oxford Inc. HYSCORE and ENDOR experiments[62] were carried out at X-band frequencies with a Bruker Elexsys spectrometer (microwave frequency 9.68 GHz) at 20 K. The HYSCORE experiments with the pulse sequence $\pi/2-\tau-\pi/2-t_1-\pi-t_2-\pi/2-\tau-$echo used 40-ns $\pi/2$ pulses, a 16-ns transfer π pulse, and an eight-step phase cycle. Two Davies-ENDOR experiments were measured by using the pulse sequence $\pi-T-\pi/2-\tau-\pi-$echo. One sequence employed a 120-ns π pulse and the second sequence employed a 32-ns π pulse to suppress weakly coupled proton nuclei. A radio frequency pulse with a length of 8 μs and a flip angle of π for the matrix protons was used. All measurements were carried out in frozen aqueous solutions with addition of DMSO or glycerol, using ^{63}Cu. Oxygen-free samples were obtained by degassing (freeze-pump-thaw method under vacuum). CW EPR and HYSCORE simulations were calculated with the EasySpin package[71] and the TRYSCORE program,[72] respectively.

Electrochemistry: Cyclic voltammograms of $[CoL(NH_3)]^{3+/2+}$, $[CoLCl]^{2+/+}$, $[NiL(H_2O)]^{3+/2+}$, and $[Co_2L_2(O_2)]^{5+/4+}$ (L = ditame) were recorded with a BAS C2 cell and a BAS 100B/W 2 potentiostat at ambient temperature (23±3 °C) with an Au working electrode, a Pt counter-electrode, and an Ag/AgCl reference. The $[CoL(H_2O)]^{3+/2+}$ couple was investigated by using an Hg (hanging drop) working electrode and $Na_2B_4O_7$·$10H_2O$ or 4-(2-hydroxyethyl)piperazin-1-propanesulfonic acid (HEPPS) as buffers. Potentials quoted were calculated relative to the normal hydrogen electrode (NHE), with a value of 0.46 V used for the $[Fe(CN)_6]^{3-/4-}$ couple (0.01 M NaOH).

Potentiometric Measurements: Potentiometric titrations (50 mL sample solution) were carried out under nitrogen at 25.0±0.1 °C as described previously.[4,29] Solid, analytically pure samples of ditame·5HCl, ditame·$5HNO_3$·$0.5H_2O$, stn·6HCl·$2H_2O$, or sen·6HCl were applied to determine the pK_a values of the ligands. Metal-containing samples (Co, Ni, Cu, Zn, Cd) were prepared from standardized aqueous stock solutions (w/w) of the metal chlorides or metal nitrates. Details of the various titrations are summarized in Tables S3−S5. Formation of Ni^{II} complexes with sen and stn proved to be too slow for continuous titration, and a batch method with individually sealed sample solutions was applied.

Spectrophotometric Titrations: The titration cell used for the potentiometric titrations was equipped with an immersion probe (HELLMA) connected to a diode array spectrophotometer (J&M, TIDAS-UV/NIR/100-1). An in-house computer program was used to control the addition of the titrant (1 M KOH) and to trigger a spectrum of the sample solution (0.01−0.02 M total Cu, 1 M KNO_3, 25.0±0.1 °C) prior to the addition of each aliquot of titrant.

Calculations of Equilibrium Constants: All equilibrium constants were calculated as concentration constants and the pH was defined as $-\log [H^+]$. The potentiometric data were evaluated by use of the computer program HYPERQUAD.[73] The pK_w (13.78 for μ = 0.1 M, 13.71 for μ = 1.0 M)[53] and the total concentrations of the reactants were treated as fixed values. Additionally, the protonation constants of the ligands were also fixed (Table 1) when refining formation constants of metal-containing species. The model for Cu(ditame) complexes was established by collective evaluation of several titration experiments with total Cu and total ditame concentrations ranging from 0.25 to 10.0 mM. The spectrophotometric data were evaluated by use of the computer program SPECFIT.[74] The spectrum of the free Cu^{2+} was measured separately and was not refined; ditame and its protonation products were regarded as colorless.

Crystal Structure Determination:[75] X-ray diffraction data of **1**Br_2, **2**Cl_4·$4H_2O$, and **3**$Cl_2[ZnCl_4][ZnCl_3(H_2O)]$·$H_2O$ were collected with a STOE imaging Plate Diffraction System by use of graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å) at 25(2) °C. Further details are summarized in Table 7. No indication of crystal decay was noted for any of the crystals during data collection. All data sets were corrected for Lorentz and polarization effects. *Specific comments for* **1***Br*$_2$ *and* **2***Cl*$_4$·$4H_2O$*:* The symmetries of diffraction patterns and systematic extinctions were consistent with space group types *Pnma* and $Pna2_1$ for **1**Br_2, and *I*2/*m*, *Im*, and *I*2 for **2**Cl_4·$4H_2O$. The structures were solved by direct methods.[76] Approximate positions of all the hydrogen atoms were found in different stages of refinements by full-matrix, least-squares calculations on F^2.[77] Refinements suffered from the high pseudosymmetry of the cations $\mathbf{1}^{2+}$ and $\mathbf{2}^{4+}$ and the possibility of disorder on sites of higher symmetry had to be taken into account with respect to their

shape and the symmetry of their solid-state environments. In both cases, none of the possible space groups allowed a complete set of physically reasonable atomic and anisotropic displacement parameters to be refined without use of appropriate weak restraints to overcome correlation problems. Consistent with E-statistics, significantly better results were observed for a model with 1:1 orientationally disordered cations on a site of symmetry *m* in centrosymmetric space group *Pnma* in the case of $\mathbf{1}Br_2$ ($S = 1.06$), and for a C_2-symmetric model on a site of corresponding symmetry in the chiral space group *I*2 in the case of $\mathbf{2}Cl_4{\cdot}4H_2O$ ($S = 1.07$).[77] The absolute structure of $\mathbf{2}Cl_4{\cdot}4H_2O$ could be determined reliably.[78] Anisotropic displacement parameters were refined for all non-hydrogen atoms with the exception of O4 and O5, representing disordered water molecules of $\mathbf{2}Cl_4{\cdot}4H_2O$ in partially occupied general positions (occupation 0.25 and 0.25). All H atoms were treated with fixed idealized O−H, N−H, or C−H distances. With idealized geometries assumed for the CH_3, CH_2, NH_2, and NH groups, the riding model was applied for the H atoms. In addition, the H atoms of methyl groups were allowed to move collectively around the neighboring C−C axis. The water molecules of $\mathbf{2}Cl_4{\cdot}4H_2O$ were treated as rigid groups with idealized bond lengths and angles. The orientation of the OH group of the ethanol ligand of $\mathbf{1}^{2+}$ was refined. Isotropic displacement parameters of H atoms were kept equal to 120% of the equivalent isotropic displacement parameters of the parent oxygen, nitrogen, and carbon atoms for the OH, NH, NH_2, and CH_2 groups and equal to 150% for the CH_3 groups and water molecules. *Specific comments for* $\mathbf{3}Cl_2[ZnCl_4]{\cdot}[ZnCl_3(H_2O)]{\cdot}H_2O$: The structure was solved by direct methods (SHELXS-97) and refined by full-matrix, least-squares calculations on F^2 by use of SHELXL-97.[76,77] One water molecule of crystallization (O2) was found to be distributed over three sites (O2A, O2B, O2B′, with O2B−O2B′ being related by $= -x, y, -z + 1/2$) with site occupancies of 0.28, 0.36, and 0.36. The O(4A)−Cl(4A) part of the two counter-ions $[ZnCl_4]^{2-}$and $[ZnCl_3(H_2O)]^-$ (which were related through a center of inversion), was also found to be disordered. Some preliminary isotropic refinement found an occupancy of 50±2% for O(4A) and Cl(4A). In the final refinement, the occupancy of these atoms was fixed at 50%, and anisotropic displacement parameters were used for all non-hydrogen atoms. The positions of the H atoms were calculated (riding model with $U_{iso} = 1.2 \times U_{eq}$ of the pivot atom).

Molecular Modeling Calculations: These were carried out with the commercially available program MOMEC97.[59]

[Ni(ditame)(EtOH)]Br_2: ditame·5HCl[21] (2.20 g, 5.50 mmol) was dissolved in H_2O (100 mL) and deprotonated with Dowex 2 (OH^- form). The solution was concentrated to dryness under reduced pressure. The oily residue was redissolved in H_2O (20 mL), and a solution of $NiBr_2{\cdot}3H_2O$ (1.47 g, 5.39 mmol) in H_2O (20 mL) was added dropwise. A color change to violet was noted. The solution was concentrated to dryness, and the residue was recrystallized from EtOH (40 mL)/H_2O (6 mL) at 5 °C. The resulting violet precipitate was washed with EtOH and Et_2O and dried in vacuo over P_2O_5 (1.07 g, 41%). $C_{12}H_{33}Br_2N_5NiO$ (482.0): calcd. C 29.91, H 6.90, N 14.53; found C 30.06, H 6.93, N 14.70. UV/Vis: λ_{max} (ε) = 338 (10.1), 533 (7.6), 884 (9.9) nm. Single crystals suitable for X-ray crystallography were grown by layering a concentrated aqueous complex solution with EtOH.

ditame·5HCl: A high-purity sample required for the potentiometric titrations was obtained from the Ni complex. [Ni(ditame)(EtOH)]Br_2 was recrystallized twice from EtOH/H_2O. The resulting, analytically pure, violet compound was dissolved in H_2O and heated to 50 °C. Concd. HCl was added to the solution in small portions until a color change to green was noted. The clear green solution was diluted with water to pH = 1 and sorbed on Dowex 50. The column was eluted with water and with 0.5 M HCl until all the Ni had been removed (checked with dimethylglyoxime). Elution with 6 M HCl yielded a colorless solution of ditame·5HCl, which was concentrated to dryness. The resulting white solid was recrystallized from concd. HCl/MeOH/EtOH (yield 72%). $C_{10}H_{32}Cl_5N_5$ (399.7): calcd. C 30.05, H 8.07, N 17.52; found C 30.06, H 8.19, N 17.30. ^{1}H NMR (D_2O, pD < 2): δ = 1.27 (s, 6 H), 3.06 (s, 4 H), 3.23 (AB system, 8 H) ppm. ^{13}C NMR (D_2O, pD < 2): δ = 20.1, 38.7, 46.4, 57.0 ppm.

ditame·5HNO$_3$·0.5H$_2$O: ditame·5HCl (1.40 g, 3.50 mmol) was dissolved in H_2O (1400 mL) and sorbed on Dowex 2 (NO_3^- form). The column was eluted *slowly* (over 24 h) with water and the resulting solution was concentrated to dryness. The oily residue was carefully dried in vacuo over P_2O_5, and recrystallized from MeOH/H_2O (yield 72%). $C_{10}H_{33}N_{10}O_{15.5}$ (541.4): calcd. C 22.18, H 6.14, N 25.87; found C 22.32, H 6.14, N 25.59. ^{1}H NMR (D_2O, pD < 2) identical with that of ditame·5HCl.

[Zn(ditame)(EtOH)]Br$_2$: The Zn complex was prepared by the same procedure as reported for the Ni complex and was obtained as a colorless, crystalline solid (38%). $C_{12}H_{33}Br_2N_5OZn$ (488.6): calcd. C 29.50, H 6.81, N 14.33; found C 29.31, H 6.73, N 14.52.

[Co$_2$O$_2$(ditame)$_2$]Cl$_4$·4H$_2$O: ditame·5HCl (800 mg, 2 mmol) was dissolved in H_2O (5 mL) and deprotonated on Dowex 2 (OH^- form). The alkaline eluent was concentrated to dryness under reduced pressure, and the oily residue was redissolved in H_2O (10 mL). $CoCl_2{\cdot}6H_2O$ (476 mg, 2 mmol), dissolved in H_2O (10 mL), was then added dropwise, and a stream of O_2 was passed through the solution over a period of 3 h. The color changed from yellow to deep brown. The solution was allowed to stand for 3 d at 5 °C, and the resulting brown solid was collected by filtration. The remaining clear, brown solution was concentrated to a volume of 20 mL, cooled, and allowed to stand for 3 d at 5 °C. After collection of a second fraction of the product, the two fractions were combined, washed with Et_2O, and dried in vacuo (367 mg, 47%). $C_{20}H_{62}Cl_4Co_2N_{10}O_6$ (798.5): calcd. C 30.09, H 7.83, N 17.54; found C 30.04, H 7.89, N 17.74. UV/Vis: λ_{max} (log ε) = 296 (4.1) nm. IR: $\tilde{\nu}$ = 3358, 3177, 3079, 2954, 2907, 2873, 1603, 1461, 1409, 1202, 1155, 1117, 1083, 1020, 969, 910, 735, 629, 562, 505 cm^{-1}. ^{1}H NMR (D_2O): δ = 0.86 (s, 12 H), 2.36 (4 H), 2.47 (8 H), 2.56 (8 H), 2.73 (4 H) ppm. ^{13}C NMR (D_2O): δ = 23.5, 42.3, 47.8, 49.2, 59.2 ppm. Single crystals suitable for X-ray crystallography were grown from a saturated aqueous solution by slow concentration at room temperature.

[Co$_2$O$_2$(ditame)$_2$]Cl$_5$·2H$_2$O: $[Co_2O_2(ditame)_2]Cl_4{\cdot}4H_2O$ (270 mg, 0.338 mmol) was suspended in H_2O (50 mL). $Ce(SO_4)_2{\cdot}4H_2O$ (140 mg, 0.346 mmol) was separately dissolved in H_2O (10 mL). Both solutions were acidified to pH = 1 with a few drops of 8 M HCl. The Ce^{IV} solution was added rapidly (within 1 min) to the suspension of the μ-peroxo complex, and the resulting deep green solution was stirred for 10 min. EtOH (200 mL) was added, and the mixture was allowed to stand for 72 h at 5 °C. The green precipitate was collected, washed carefully with EtOH and Et_2O, and air-dried (200 mg, 74%). $C_{20}H_{58}Cl_5Co_2N_{10}O_4$ (797.9): calcd. C 30.11, H 7.33, N 17.55; found C 30.25, H 7.30, N 17.16. UV/Vis: λ_{max} (log ε) = 312 (3.9), 471 (2.3), 695 (2.85) nm. Single crystals of composition $\mathbf{5}Cl_2[ZnCl_4][ZnCl_3(H_2O)]{\cdot}H_2O$ suitable for X-ray crystallography were grown at 5 °C from a saturated aqueous solution (10 mL) of the pentachloride salt after addition of a solution (10 mL) of HCl (8 M) and $ZnCl_2$ (1 g).

Table 7. Crystallographic data of $[Ni(ditame)(EtOH)]Br_2$ (**1**Br_2), $[Co_2(ditame)_2O_2]Cl_4{\cdot}4H_2O$ (**2**$Cl_4{\cdot}4H_2O$), and $[Co_2(ditame)_2O_2]Cl_2[ZnCl_4][ZnCl_3(H_2O)]{\cdot}H_2O$ (**3**$Cl_2[ZnCl_4][ZnCl_3(H_2O)]{\cdot}H_2O$)

[Co(ditame)(H_2O)](CF_3SO_3)$_3$: [Co(ditame)Cl][$ZnCl_4$][21] (100 mg, 193 μmol) was dissolved in H_2O (10 mL) and sorbed on Dowex 50. The column was washed with H_2O, 0.1 M HCl, 0.5 M HCl, and 1 M HCl (200 mL each). Further elution with 3 M HCl gave a dark red fraction, which was concentrated to dryness. The resulting solid was redissolved in H_2O (20 mL) and heated to 80 °C. A solution of $AgCF_3SO_3$ was added dropwise until the precipitation of solid AgCl was completed. The solid was removed by filtration (Celite) and the reddish-orange, clear solution was concentrated to dryness. (142 mg, 100%). $C_{13}H_{29}CoF_9N_5O_{10}S_3$ (741.5): calcd. C 21.06, H 3.94, N 9.44; found C 21.42, H 4.09, N 9.42. UV/Vis: λ_{max} = 345, 487 nm. ^{1}H NMR (D_2O): δ = 0.93 (s, 6 H), 2.06 (2 H), 2.33 (2 H), 2.45 (2 H), 2.62 (2 H) 2.74 (2 H), 2.77 (2 H) ppm. ^{13}C NMR (D_2O): δ = 22.8, 42.8, 47.1, 48.4, 57.7, 122.3 (q, *J* = 316 Hz) ppm.

[Ni(stn)]$Br_2{\cdot}2.5H_2O$: The procedure reported above for the ditame complex was applied, with $NiBr_2{\cdot}3H_2O$ (534 mg, 1.96 mmol) and crude[26] stn·6HCl·$2H_2O$ (1.09 g, 2 mmol). The resulting violet solid was recrystallized from H_2O (10 mL) and EtOH (20 mL) at 5 °C (70%). $C_{14}H_{41}Br_2N_6NiO_{2.5}$ (552.0): calcd. C 30.46, H 7.49, N 15.22; found C 30.52, H 7.48, N 15.19. UV/Vis: λ_{max} (ε) = 341 (13.9), 539 (10.6), 858 (8.3) nm.

stn·6HCl·$2H_2O$: A high-purity sample required for the titration experiments was prepared from crystalline, analytically pure [Ni(stn)]$Br_2{\cdot}2.5H_2O$ (570 mg, 1.03 mmol). The complex was decomposed by HCl and sorbed on Dowex 50 as described above for ditame·5HCl. The protonated polyamine was eluted with 8 M HCl, and the solution was concentrated to a total volume of 10 mL. MeOH (20 mL) was added slowly, and the mixture was allowed to stand at 5 °C for 72 h. The colorless, crystalline solid was removed by filtration, washed with EtOH and EtOEt, and dried in vacuo (81%). $C_{14}H_{46}Cl_6N_6O_2$ (543.3): calcd. C 30.95, H 8.53, N 15.47; found C 30.90, H 8.57, N 15.28. ^{1}H NMR (D_2O, pD < 3): δ = 1.39 (s, 3 H), 2.18 (m, 6 H), 3.12 (t, *J* = 8 Hz, 6 H), 3.26 (t, *J* = 8 Hz, 6 H), 3.38 (s, 6 H) ppm. ^{13}C NMR (D_2O, pD < 3): δ = 21.0, 26.7, 38.8, 39.6, 49.4, 55.4 ppm.

[Ni(sen)]Br_2:[66] The procedure reported above for the ditame complex was applied, with $NiBr_2{\cdot}3H_2O$ (545 mg, 2 mmol) and crude[26] sen·6HCl (930 mg, 2 mmol). The resulting violet solution was concentrated to a total volume of 10 mL. EtOH (50 mL) was added, and the solution was allowed to stand at 5 °C for 72 h. Violet needles (572 mg, 62%). $C_{11}H_{30}Br_2N_6Ni$ (464.9): calcd. C 28.42, H 6.50, N 18.08; found C 28.72, H 6.56, N 17.77. UV/Vis: λ_{max} (ε) = 337 (10.0), 522 (8.2), 803 (10.0) nm.

sen·6HCl: A high-purity sample required for the titration experiments was prepared from crystalline, analytically pure [Ni(sen)]Br_2 (1664 mg, 3.58 mmol). The complex was decomposed with HCl and sorbed on Dowex 50 as described above for ditame·5HCl. The protonated polyamine was eluted with 8 M HCl and the solution was concentrated to a total volume of 20 mL. MeOH (100 mL) and EtOH (50 mL) were added slowly, and the mixture was allowed to stand at 5 °C for 72 h. The colorless, crystalline solid was removed by filtration, washed with EtOH and EtOEt, and dried in vacuo (1.20 g, 72%). $C_{11}H_{36}Cl_6N_6$ (465.2): calcd. C 28.40, H 7.8, N 18.07; found C 28.30, H 7.86, N 17.69. ^{1}H NMR (D_2O, pD < 3): δ = 1.44 (s, 3 H), 3.47 (s, 6 H), 3.53 (m, 12 H) ppm. ^{13}C NMR (D_2O, pD < 3): δ = 21.1, 38.4, 39.3, 48.9, 55.1 ppm.

Supporting Information: Supporting information for this article is available (see footnote on the first page of this article). Tables S1−S5 list NMR parameters and potentiometric data. Figures S1−S6 show the disorder of [Ni(ditame)(EtOH)]Br_2, pH-dependent species distribution plots of the Co^{II}/ditame, Cd^{II}/ditame, and Ni^{II}/sen systems, titration curves of Cu^{2+}/Ni^{2+}/ditame·$5HNO_3$ solutions, and Vis and EPR data for the Cu(ditame) complexes.

Acknowledgments

The Raman and solid-state UV/Vis spectra were measured by Prof. Dr. Felix Tuczek (Kiel). MM calculations were carried out by Dr. Dirk Kuppert (Saarbrücken). Part of the synthetic work was performed by Anton Zaschka (Saarbrücken). X-ray diffraction data

for $\mathbf{5}Cl_2[ZnCl_4][ZnCl_3(H_2O)]\cdot H_2O$ were recorded by Dr. Volker Huch (Saarbrücken). We thank Stefan Steinhauser and Bernd Morgenstern (Saarbrücken) for valuable help and suggestions. Financial support from the Saarland (O. M.) and the Fonds der Chemischen Industrie (K. H.) is gratefully acknowledged.

Hydrothermal Synthesis and Characterization of Novel Lanthanide 2,2′-Diphenyldicarboxylate Complexes

Yi-Bo Wang,[a] Xiang-Jun Zheng,[a] Wen-Juan Zhuang,[a] and Lin-Pei Jin*[a]

Keywords: Hydrothermal synthesis / Lanthanides / Coordination polymer / X-ray diffraction

Lanthanide complexes with a one-dimensional chain, $[Ln_2(dpdc)_3(H_2O)_2]_n$ [Ln = La (**1**), Pr (**2**), Eu (**3**), Tb (**4**); dpdc = 2,2′-diphenyldicarboxylate] were obtained by hydrothermal reaction of lanthanide(III) chlorides and 2,2′-diphenyldicarboxylic acid, and characterized by X-ray diffraction. The crystal structure data reveal that they are isostructural. In the asymmetric unit, the two Ln^{3+} ions are both eight-coordinate but they have different coordination environments. Lanthanide ions arranged in a zigzag manner are bridged by the dpdc ligands into a 1-D chain, while the structure appears like a pinwheel viewed along the *c* axis. In these complexes, 2,2′-diphenyldicarboxylate anions exhibit tetradentate and pentadentate coordination modes. A laser-induced high-resolution spectrum (resolution: 0.2 cm^{-1}) of **3** was obtained, which shows two Eu^{3+} sites in **3**. This is in agreement with the results of single-crystal X-ray diffraction studies of **3**.

Introduction

The crystal engineering and synthesis of one-, two-, and three-dimensional coordination polymers have been areas of renewed interest and have undergone explosive growth in recent years.[1−11] In principle, the physical and chemical properties of polymer networks are decisively dependent on the properties of the individual molecular components and their distribution within the crystal lattice. In terms of molecular composition, the inorganic-organic coordination polymers have many advantages over simple inorganic and organic materials. This is because varieties of organic ligands coordinating to metal atoms construct coordination polymers with many fascinating structures, in which the metal atoms display many kinds of coordination geometries,[12−17] and these polymers may possess distinctive and attractive properties. Therefore, the choice of appropriate bridging ligands is a key step in forming interesting structures.

The coordination chemistry of aromatic polycarboxylic acids coordinated to metal atoms has been extensively investigated for their potential applications such as magnetic,[18−20] luminescent,[21,22] and microporous materials.[23,24] In constructing coordination polymers with networks or channels, 2,2′-diphenyldicarboxylic acid (H_2dpdc) is a useful starting material and possesses several interesting structural features. Two carboxyl groups may be partially or completely deprotonated, resulting in novel structures of coordination polymers by various coordination modes. Dpdc is a flexible ligand in which the carboxyl groups may not be coplanar with the phenyl ring due to steric hindrance in the coordination process. It can form an infinite variety of architectures in different directions. In the crystal structures of many reported transition metal complexes with 2,2′-diphenyldicarboxylate, the dpdc ligand exhibits diverse types of coordination modes[25−29] with multiple coordination sites. Owing to the higher coordination number and attractive luminescent properties, applied in fluorescent probes, the reactions of dpdc and lanthanide ions may generate polymers with different coordination modes and properties distinct from transition metal complexes of dpdc. To the best of our knowledge, lanthanide 2,2′-diphenyldicarboxylate complexes have never been reported.

To obtain the coordination polymers, reaction of the lanthanide chloride and sodium 2,2′-diphenyldicarboxylate was carried out by the conventional solution method. The uncharacterized precipitate is insoluble in water and common organic solvents. This led us to adopt hydrothermal synthesis to obtain single crystals suitable for X-ray structure analysis. It is well known that hydrothermal reactions are useful in the synthesis of zeolites, phosphates, phosphonates, and polyoxalkoxometalates.[30,31] Hydrothermal methods are also an effective approach to produce metastable compounds and promote the growth of crystals.[32] More recently, we have used this method in the synthesis of lanthanide coordination polymers. Herein, we report the synthesis and structural characterization of lanthanide 2,2′-diphenyldicarboxylate complexes.

Results and Discussion

Structural Description

The crystallographic data of **1**−**4** are shown in Table 1. The structural data show that the four coordination poly-

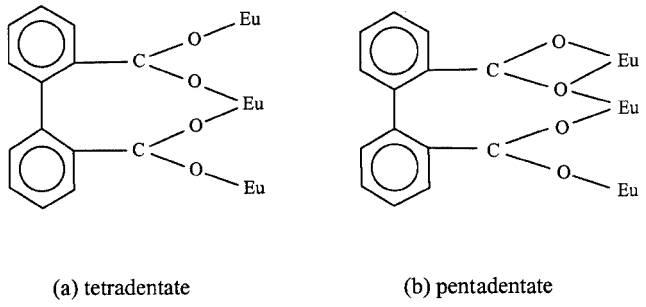
mers are isostructural. Each polymer can be regarded as a one-dimensional infinite chain composed of $[Ln_2(dpdc)_3(H_2O)_2]$ units. Herein, only complex **3** will be described in detail. Complex **3** is composed of one-dimensional chains of $[Eu_2(dpdc)_3(H_2O)_2]_n$. Two carboxylate groups of each dpdc ligand are deprotonated, and the dpdc ligands adopt two types of coordination modes, as shown in Scheme 1. $[Eu_2(dpdc)_3(H_2O)_2]$ consists of two crystallographically independent europium(III) ions as shown in Figure 1. Eu(1) is coordinated to eight oxygen atoms, two oxygen atoms [(O6A), (O6B)] from two bridging bidentate carboxylate groups of two tetradentate dpdc ligands, two oxygen atoms [O(3), O(3A)] from two bridging bidentate carboxylate groups of two pentadentate dpdc ligands, two oxygen atoms [O(1), O(1A)] from the two chelating-bridging tridentate carboxylate groups of the two pentadentate dpdc ligands, and two oxygen atoms [O(7), O(7A)] from two coordinated water molecules. The Eu(1)−O(carboxylate) bond lengths vary from 2.307 Å to 2.465 Å, and the Eu(1)−O(w) distances are both 2.521 Å. The O−Eu(1)−O bond angles range from 66.2° to 147.4°. Eu(2) is also ligated to eight oxygen atoms, two oxygen atoms [O(5), O(5A)] from two bridging bidentate carboxylate groups of a tetradentate dpdc ligand, four oxygen atoms [O(1), O(2), O(1B), O(2A)] from two chelating-bridging tridentate carboxylate groups of two pentadentate dpdc ligands, and two oxygen atoms [O(4A), O(4B)] from two bridging bidentate carboxylate groups of other two pentadentate dpdc ligands. The Eu(2)−O(carboxylate) distances fall in the range 2.318−2.594 Å, and the O−Eu(2)−O bond angles are in the range 35.8−150.7°. The results show that Eu(1) is surrounded by two tetradentate dpdc ligands, two pentadentate dpdc ligands, and two water molecules, while around Eu(2) there are one tetradentate dpdc ligand and four pentadentate dpdc ligands; the coordination environments of the two Eu^{III} ions are therefore different. However, the coordination geometries of the two Eu^{III} ions can both be described as slightly distorted triangular dodecahedra.



Scheme 1. Two coordination modes of dpdc ligand in **3**

Each carboxylate moiety of the dpdc ligands bridges two adjacent Eu^{III} ions, and each ligand bridges three adjacent Eu^{III} ions through carboxylate oxygen atoms of these bridging dpdc groups, resulting in one-dimensional infinite polymeric chains along the *c* axis (Figure 2). The Eu^{III} ions are arranged in a zigzag manner, and the distance between two adjacent Eu^{III} ions is 4.459 Å. The tetradentate dpdc ligands and pentadentate dpdc ligands are located around the $Eu^{III}\cdots Eu^{III}$ chain and the number of pentadentate dpdc ligands is double the number of tetradentate ones. From Figure 2, we can see that the coordination environments of Eu(1A), Eu(1B), and Eu(1C) are the same as Eu(1) in Figure 1, and those of Eu(2A), Eu(2B), and Eu(2C) are the same as Eu(2) in Figure 1. In a tetradentate dpdc ligand, the two phenyl rings are not coplanar, and the dihedral angle is 56.2°. In addition, each of the two carboxylic groups of a tetradentate dpdc ligand is not coplanar with the connected phenyl ring, and the dihedral angles are both 122.5°; the two carboxylic groups of the tetradentate dpdc ligand are, however, coplanar. In the pentadentate dpdc ligand, one of the two carboxylate groups adopts a chelating-bridg-

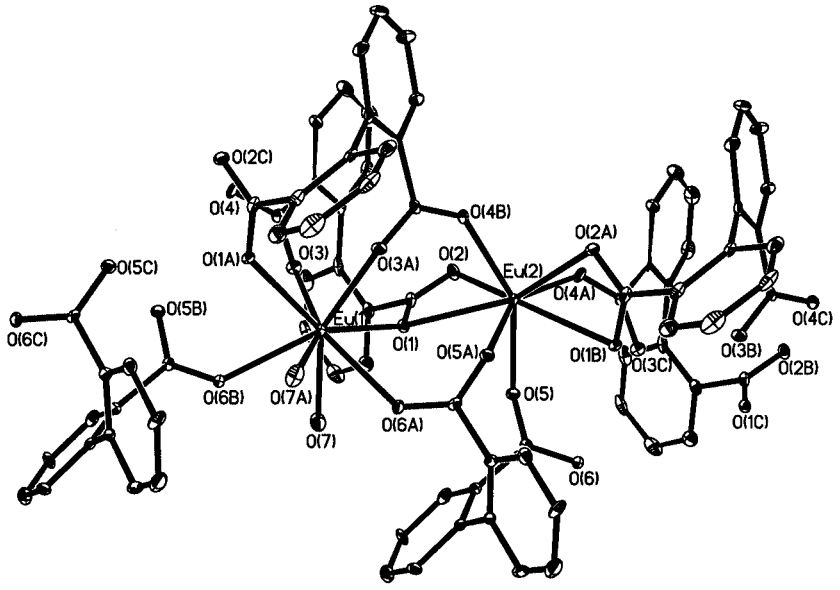


Figure 1. Coordination environment of the two Eu^{III} ions in **3** with thermal ellipsoids at 15% probability; all hydrogen atoms have been omitted for clarity

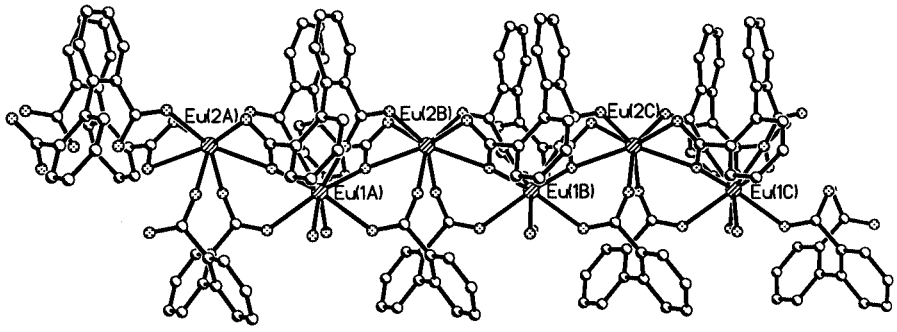

Figure 2. 1-D chain of **3** viewed along the *a* axis; all hydrogen atoms and uncoordinated water molecules have been omitted for clarity

ing tridentate mode, the other group adopts a bridging bidentate mode. Two oxygen atoms of the bridging bidentate carboxylate group coordinate to two Eu^{III} ions [Eu(1A), Eu(2B)], while two oxygen atoms of the other carboxylate group chelate to the third Eu^{III} ion [Eu(2A)] (see Figure 2) and, moreover, one oxygen atom of the chelating carboxylic group acts as a μ_2-O atom. In the pentadentate ligand, the bridging bidentate carboxylate group and the connected phenyl ring are not coplanar and the dihedral angle is 34.9°. The chelating-bridging tridentate carboxylate group and the connected phenyl ring are not coplanar either, and the dihedral angle is 67.4°. The two phenyl rings in a pentadentate dpdc ligand are not coplanar and the dihedral angle is 70.1°. This may result from the steric effect of the coordination. In the tetradentate ligand, the two bridging bidentate O−C−O bond angles are 124.6°, whereas the chelating-bridging tridentate O−C−O bond angles (122.6°) are all smaller than the bridging bidentate ones (123.9°) in the pentadentate ligand, as expected.

Every chain looks like a pinwheel viewed along the *c* axis (Figure 3). Eu^{III} ions reside at the centers of the pinwheel and are grouped into two parts, arranged in two rows. The ligands fall into three groups and are well distributed

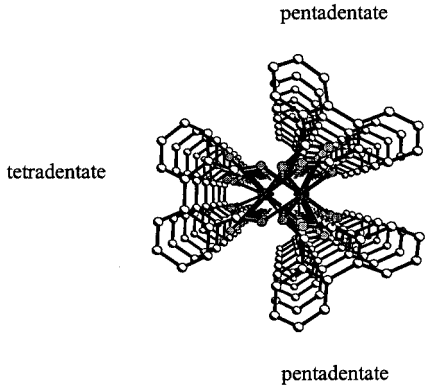

Figure 3. Pinwheel structure of **3**

around the centers of the Eu^{III} ions. The phenyl rings of the dpdc ligands belonging to the same group of a chain are all parallel to each other and the distances between the parallel phenyl rings are in the range of 6.4490 Å to 7.0314 Å.

The phenyl rings of dpdc ligands in adjacent 1-D chains of complex **3** are interdigitated, forming channels with a cavity of size 9.676 × 4.520 Å in the *c* direction (see Figure 4).

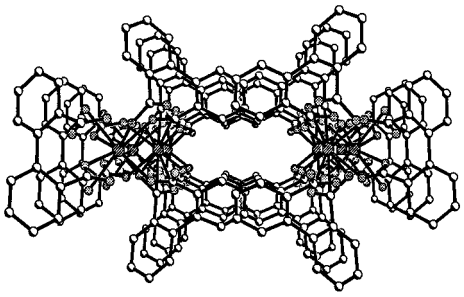

Figure 4. Packing of **3** viewed along the *c* axis

In the four lanthanide coordination polymers, the mean La−O(carboxylate), Pr−O(carboxylate), Eu−O(carboxylate), and Tb−O(carboxylate) distances are 2.501 Å, 2.470 Å, 2.413 Å, and 2.386 Å, respectively; the La−O(w), Pr−O(w), Eu−O(w), and Tb−O(w) distances are 2.633 Å, 2.579 Å, 2.521 Å, and 2.470 Å, respectively. The separations of La···La, Pr···Pr, Eu···Eu, and Tb···Tb are 4.555 Å, 4.529 Å, 4.459 Å, and 4.440 Å, respectively. We can thus conclude that the Ln^{III}−O and Ln···Ln distances decrease with the contraction of the ionic radii from La^{III} to Tb^{III} ions.

In the two reported isostructural complexes with 2,2′-diphenyldicarboxylic acid, $[M_2(O_2CC_{12}H_8CO_2)_2(H_2O)_8]$, [M = cobalt(II), nickel(II)],[25] the M−O distances of the two transition metal complexes are both shorter than those of complexes **1**−**4**. The coordination environments of the two transition metal ions are both slightly distorted octahedra, and the M^{II} ions are all six-coordinate, with two oxygen atoms from two carboxylate groups of a dpdc ligand and four oxygen atoms from four coordinated water molecules. Obviously, there are two more atoms coordinated to the Ln^{III} ion in **1**−**4**, producing an eight-coordinate metal center. The dihedral angles of the aromatic rings of the dpdc ligand in the two transition metal complexes are 85.96° and 87.2° for Co^{II} and Ni^{II}, respectively, which are larger than those in the tetradentate dpdc ligand and pentadentate dpdc ligand of **3** (56.2° and 70.1°, respectively). This may be a result of the higher coordination number of the lanthanide ions and thus the steric hindrance effect results in the formation of coordination polymers. Similarly, compounds **1**−**4** exhibit more complicated coordination modes than the transition metal dpdc complexes. This is due to the larger radii of Ln^{III} ions, and corresponding large coordination number, as well as the different coordination modes that are required by lanthanide ions.

Thermogravimetric Analyses

Thermogravimetric analyses of **1**−**4** were performed to observe their thermal behaviors. The thermogravimetric analysis data for **1**, **2**, **3**, and **4** are listed in Table 2. Loss of two coordinated water molecules of the four complexes was observed as the first weight loss. Their dehydration temperatures are in the range of 178.6 °C to 225.1 °C, and further decomposition processes begin at temperatures above 459 °C, giving the final products Ln_2O_3 (Ln = La, Eu), Pr_6O_{11}, and Tb_4O_7. Taking **1** as an example, the TGA curve shows that the process of first weight loss is between 178.6 and 221.5 °C with 3.5% total weight, which is in accordance with the removal of two water molecules per formula unit (calculated: 3.6%). Then, further decomposition of **1** begins at temperatures above 461.2 °C, giving rise to La_2O_3.

Photophysical Properties of 3

Complex **3** emits intense red fluorescence when it is irradiated by UV light. Figure 5 shows its high-resolution emission spectrum excited at a wavelength of 355 nm at 77 K, corresponding to $^5D_0 \rightarrow {}^7F_J$ (J = 0−4) transitions in

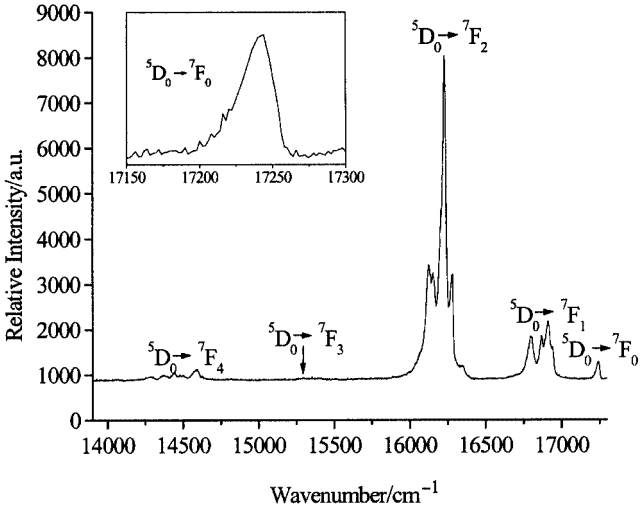

Figure 5. Emission spectrum of **3** corresponding to $^5D_0 \rightarrow {}^7F_J$ (J = 0−4) transitions at 77 K, λ_{exc} = 355 nm

Table 2. Thermogravimetric analysis data of **1**−**4**

	1	**2**	**3**	**4**
Dehydration temperature [°C]	178.6−221.5	197.6−208.3	209.1−225.1	199.3−215.3
Loss of water calcd. (found) [%]	3.6 (3.5)	3.5 (3.6)	3.4 (3.3)	3.3 (3.5)
Further decomposition temperature [°C]	461.2	460.9	459.5	463.8

the range 13900−17300 cm^{-1}. The $^5D_0 \rightarrow {}^7F_2$ transition is the induced electric dipole transition, which is greatly affected by the coordination environment, while the $^5D_0 \rightarrow {}^7F_1$ transition is the magnetic dipole transition, which is much less sensitive to the environment. The intensity ratio of $^5D_0 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1$ is 3.73, which shows that the Eu^{3+} ions are not at an inversion center. For the $^5D_0 \rightarrow {}^7F_J$ transition, the peak number should obey the $(2J + 1)$ rule. However, the broad and asymmetric spectrum of the $^5D_0 \rightarrow {}^7F_0$ transition (see inset in Figure 5), as well as the shoulder of the three peaks in the $^5D_0 \rightarrow {}^7F_1$ transition indicate that $2\times(2J + 1)$ partly overlapping signals are expected in the low-temperature luminescence spectrum of **3**, and thus the europium ions in **3** are not located in the same chemical environment. To further study the local structural characteristics, a selective excitation technique has been applied. Setting 16213 cm^{-1} and 16143 cm^{-1} as the analyzing wave number, respectively, the excitation spectra *a* and *b* arising from the $^5D_0 \leftarrow {}^7F_0$ transition were obtained, as shown in Figure 6. Obviously, there are two peaks located at 579.57 nm and 579.83 nm in both excitation spectra *a* and *b*, which confirms two Eu^{3+} ion sites in the complex **3**.[33] This is in good agreement with the results of the single-crystal X-ray diffraction. It can be concluded that there are two different La^{3+}, Pr^{3+}, and Tb^{3+} ion sites in the complexes **1**, **2**, and **4**, respectively.

Conclusion

The first examples of structural characterization of lanthanide coordination polymers with 2,2′-biphenyldicarboxylic acid were obtained. The dpdc ligands in **1**, **2**, **3**, and **4** have two coordination modes, tetradentate and pentadentate. Coordination polymers **1**−**4** are isostructural, and 1-D chains of **1**−**4** are composed of $Ln_2(dpdc)_3(H_2O)_2$ building blocks, in which the lanthanide(III) ions have two chemical environments. The Ln−O bond lengths and Ln···Ln separations show a lanthanide contraction over the series.

Experimental Section

Materials: $LaCl_3{\cdot}7H_2O$, $PrCl_3{\cdot}6H_2O$, $EuCl_3{\cdot}6H_2O$, and $TbCl_3{\cdot}6H_2O$ were prepared by dissolving their oxides in hydrochloric acid, and then drying. 2,2′-Diphenyldicarboxylic acid was purchased from Aldrich and used without further purification,while all the other reagents are commercially available and were used as received.

Instrumentation: Elemental analyses were performed on an Elementar Vario EL analyzer. The IR spectra were recorded with a Nicolet Avatar 360 FT-IR spectrometer using the KBr pellet technique. Thermogravimetric analyses were performed on a ZRY-2P Thermal Analyzer. The excitation light source was a YAG-Nd laser that emits at 1.064 μm, and the excitation wavelength was 355 nm. The sample was placed in a Dewar and cooled with liquid nitrogen. The fluorescence was collected at right angles through a Spex 1403 monochromator with a photomultiplier tube, then averaged by a Boxcar integrator, and finally data were transferred to a computer.

X-ray Crystallographic Study: The single-crystal X-ray data collections for complexes **1**, **2**, **3**, and **4** were performed on a Bruker Smart 1000 CCD diffractometer, using graphite-monochromated MoK_α radiation (λ = 0.71073 Å). Semiempirical absorption corrections were applied using the SADABS program. The structures were solved by direct methods and refined by full-matrix least-squares on $|F|^2$ using the SHELXTL-97 program.[34] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were generated geometrically and treated by a mixture of independent and constrained refinements.

CCDC 195399−195402 (**1**−**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at ww.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

$[La_2(dpdc)_3(H_2O)_2]_n$ (1): A mixture of $LaCl_3{\cdot}7H_2O$ (0.111 g, 0.3 mmol), 2,2′-diphenyldicarboxylic acid (0.109 g, 0.45 mmol), H_2O (10 mL), and an aqueous solution of NaOH (0.4 mL, 0.26 mmol) was sealed in a 25-mL stainless-steel reactor with a Teflon liner, heated to 170 °C for 72 h, and then slowly cooled to room temperature. The products were filtered, washed with ethanol, and then dried in air. Colorless transparent crystals of **1** were obtained in 70.4% yield (0.109 g). $C_{42}H_{28}La_2O_{14}$ (1034.44): calcd. C 48.77, H 2.73; found C 48.66, H 2.52. IR data (KBr pellet): $\tilde{\nu}$ = 3549(m) cm^{-1}, 1615(s), 1548(s), 1523(s), 1442(s), 1406 (s), 771(m), 760(m).

$[Pr_2(dpdc)_3(H_2O)_2]_n$ (2): A mixture of $PrCl_3{\cdot}6H_2O$ (0.107 g, 0.3 mmol), 2,2′-diphenyldicarboxylic acid (0.109 g, 0.45 mmol), H_2O (10 mL), and an aqueous solution of NaOH (0.3 mL, 0.20 mmol) was sealed in a 25-mL stainless-steel reactor with a Teflon liner, heated to 200 °C for 72 h, and then slowly cooled to room temperature. The products were filtered, washed with ethanol, and then dried in air. Light green crystals of **2** were obtained in 71.5% yield (0.111 g). $C_{42}H_{28}O_{14}Pr_2$ (1038.44): calcd. C 48.58, H 2.91; found C 48.67, H 2.43. IR data (KBr pellet): $\tilde{\nu}$ = 3550(m) cm^{-1}, 1617(s), 1548(s), 1522(s), 1442(s), 1406 (s), 771(m), 761(m).

$[Eu_2(dpdc)_3(H_2O)_2]_n$ (3): The synthesis of **3** was similar to that of **1**. The products were filtered, washed with ethanol, and then dried in air. Reddish brown transparent crystals of **3** were obtained in 67.4% yield (0.107 g). $C_{42}H_{28}Eu_2O_{14}$ (1060.64): calcd. C 47.54, H 2.66; found C 47.59, H 2.30. IR data (KBr pellet): $\tilde{\nu}$ = 3551(m) cm^{-1}, 1622(s), 1553(s), 1525(s), 1443(s), 1408(s), 772(m), 762(m).

$[Tb_2(dpdc)_3(H_2O)_2]_n$ (4): The synthesis of **4** was similar to that of **2**. The products were filtered, washed with ethanol, and then dried in air. Colorless transparent crystals of **4** were obtained in 68.9%

yield (0.111 g). Calcd. for $C_{42}H_{28}Tb_2O_{14}$ (1074.44): calcd. C 46.95, H 2.81; found C 46.97, H 2.38. IR data (KBr pellet): $\tilde{\nu}$ = 3552(m) cm^{-1}, 1624(s), 1555(s), 1527(s), 1443(s), 1409(s), 763(m).

Low-Valent Organobismuth Compounds with Intramolecular Coordination: *cyclo*-R_3Bi_3, *cyclo*-R_4Bi_4, $RBi[W(CO)_5]_2$, and R_4Bi_2 [R = 2-$(Me_2NCH_2)C_6H_4$]

Lucia Balazs,[a] Hans J. Breunig,*[a] Enno Lork,[a] and Cristian Silvestru[b]

Keywords: Bismuth / Metallacycles / Tungsten

The cyclobismuthanes R_nBi_n, [R = 2-$(Me_2NCH_2)C_6H_4$; n = 3 (**1a**), 4 (**1b**)] have been synthesised by reduction of $RBiCl_2$ with Na in liquid NH_3 or by reaction of R_2BiCl with $LiAlH_4$ in Et_2O. The reaction of **1a/b** with $W(CO)_5$·THF afforded the bismuthinidene complex $RBi[W(CO)_5]_2$ (**2**). R_2BiCl reacts with Mg in THF to give the dibismuthane R_4Bi_2 (**3**). Single-crystal X-ray structure analyses of **1b**, **2**, and **3** reveal intramolecular coordination of the pendant CH_2NMe_2 groups to the bismuth atom.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Relativistic effects[1] are expected to favour the lower oxidation states of bismuth and to stabilize singlet bismuthinidenes RBi. Known examples of Bi^I derivatives[2] are the dibismuthenes RBi=BiR [R = 2,4,6-$[(Me_3Si)_2CH]_3C_6H_2$,[3,4] 2,6-$(Me_3C_6H_2)_2C_6H_3$[5]], *cyclo*-R_nBi_n oligomers [n = 3, 4; R = $(Me_3Si)_2CH$,[6] $(Me_3Si)_3Si$[7] and n = 5; R = Me_3SiCH_2[8]], and a complex of R_2Bi_2 (R = Me_3SiCH_2), i.e. $[(RBi=BiR)\{W(CO)_5\}_2]$.[8] Monomeric bismuthinidenes have not been isolated, but RBi groups have been incorporated into *cyclo*-$[RBiFe(CO)_4]_2$ (R = Me,[9] Ph,[10] *i*Bu[11]). The oxidation state of bismuth in these complexes is, however, ambiguous. Bismuth(II) compounds are known as dibismuthanes R_4Bi_2.[12–16] All low-valent organobismuth compounds tend to decompose with formation of elemental Bi and R_3Bi, unless protected by bulky groups or stabilized by complexation. Usually, monodentate alkyl or aryl ligands are used for steric protection. We expected additional stabilization with substituents containing a pendant donor group available for internal coordination at Bi. Examples of compounds with internal coordination at Bi^{III} are the 2-(dimethylaminomethyl)phenyl derivatives R_2BiCl,[17] $RBiI_2$,[17] or R_3Bi[18] [R = 2-$(Me_2NCH_2)C_6H_4$]. We report here on arylbismuth(I) and -bismuth(II) compounds with internal nitrogen coordination of the 2-$(Me_2NCH_2)C_6H_4$ ligand.

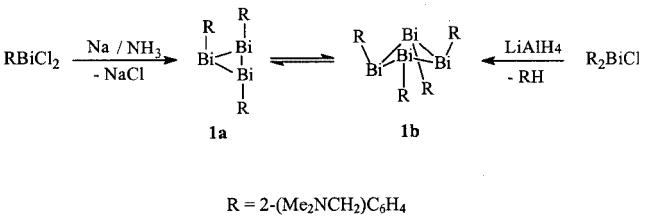
Results and Discussion

Both the reduction of $RBiCl_2$ with Na in liquid ammonia at −70 °C and the reaction of R_2BiCl with $LiAlH_4$ in Et_2O resulted in isolation of a black-green product (49 and 65% yield, respectively), which was identified as *cyclo*-R_nBi_n (**1**) by elemental analysis. A possible intermediate for the latter reaction is R_2BiH, which gives **1** by elimination of RH (Scheme 1). Three- (**1a**) and four-membered (**1b**) R_nBi_n rings were identified by NMR spectroscopy in solution, whereas the crystals of **1** consist of the four-membered ring **1b**, the structure of which was established by a single-crystal X-ray diffraction study.



Scheme 1

Crystals of **1b** are stable for a long time at room temperature under argon. Solutions of **1** in hydrocarbon solvents are more sensitive, however, and in sealed tubes at 25 °C the R_nBi_n rings decompose after several hours to R_4Bi_2 (**2**) and metallic bismuth. At −28 °C, however, they are stable for weeks. The colour of the crystals is dark green, while solutions in hydrocarbon solvents are dark red. Variable-temperature and concentration-dependent ^1H NMR spectra in $C_6D_5CD_3$ enable the rings **1a** and **1b** to be easily distinguished. Two sets of signals (1:2 intensity ratio) for the 2-(dimethylaminomethyl)phenyl group could be assigned to the *cyclo*-trimer **1a** in the *cis-trans* configuration. For the tetramer **1b** only one set of signals was observed, corre-

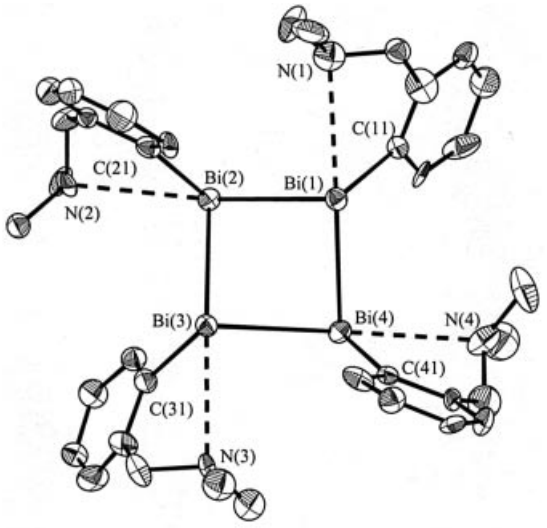
sponding to the *all-trans* configuration with equivalent substituents. Each set consists of two singlets, for the CH_3 and the CH_2 protons respectively, and a group of signals for the spin system of the aromatic protons. The ^{1}H NMR spectroscopic data suggest rapid reversible dissociation of the pendant CH_2NMe_2 arm in solution.

The relative concentration of **1a** and **1b** in solution depends on the temperature and the absolute concentration of the ring systems. Lower temperatures and higher concentrations favour the four-membered ring **1b** at the expense of the three-membered ring **1a**. Similar solution equilibria following the principle of Le Chatelier were also reported for *cyclo*-$[(Me_3Si)_2CH]_nBi_n$ (n = 3, 4)[6] and *cyclo*-$(Me_3SiCH_2)_nBi_n$ (n = 3, 5).[8] In contrast to the *cyclo*-$(Me_3SiCH_2)_nBi_n$ system, where the equilibrium between the trimer and the pentamer is frozen at −15 °C, the equilibrium between **1a** and **1b** occurs even at −45 °C. The equilibrium constant $K = [\mathbf{1a}]^4/[\mathbf{1b}]^3$ is 36±5 mol/L at 0 °C.

Additional signals for species containing equivalent R groups were observed at high dilution and high temperature. These signals can be assigned to [2-(Me_2NCH_2)-C_6H_4]Bi or [2-$(Me_2NCH_2)C_6H_4]_2Bi_2$.

Single crystals of **1b** suitable for X-ray diffraction studies were obtained by cooling a petroleum ether solution of a mixture of the rings to −28 °C. The molecular structure is depicted in Figure 1. The structure consists of a folded four-membered bismuth ring with the 2-$(Me_2NCH_2)C_6H_4$ substituents in the *all-trans* configuration, consistent with the NMR spectroscopic data in solution. The Bi_3-Bi_3 dihedral angles are 107.9 and 109.4°, respectively. The Bi−Bi bond lengths [3.0095(16)−3.0221(16) Å] compare well with the analogous values found in $[(Me_3Si)_2CH]_4Bi_4$ [2.970(5)−3.044(2) Å][6] and $[(Me_3Si)_3Si]_4Bi_4$ [3.013(1)−3.028(1) Å].[7] The Bi−C bonds [2.24(3)−2.30(3) Å] are shorter than the corresponding bonds in $[(Me_3Si)_2CH]_4Bi_4$ [2.33(2)−2.39(2) Å].[6] The 2-$(Me_2NCH_2)C_6H_4$ groups act as bidentate chelating ligands with weak N→Bi intramolecular interactions [2.97(3)−3.05(2) Å] *trans* to a Bi−Bi bond. The N−Bi distances lie between the sum of the covalent (2.2 Å) and van der Waals radii (3.7 Å) of N and Bi. Comparable interactions were observed in [2-$(Me_2NCH_2)C_6H_4]_3Bi$ [Bi−N 3.04(2)−3.11(3) Å][17] and [2-$(Me_2NCH_2)C_6H_4]_2BiCl$ [Bi−N 2.570(5), 3.047(5) Å].[18] The orientation of the aryl groups leads to a propeller-like arrangement. The geometry about the bismuth atoms is distorted pseudo-trigonal-bipyramidal with one of the neighbouring bismuth atoms and the nitrogen atom in axial positions [Bi−Bi−N 158.7(6)−163.5(5)°]. The second bismuth atom, the *ipso*-carbon atom and the lone pair of electrons are in equatorial positions. The Bi−Bi−Bi angles [76.79(4)−79.51(4)°] are similar to those found in *cyclo*-$[(Me_3Si)_2CH]_4Bi_4$ [78.97(8)−79.93(6)°].[6] The transanular Bi···Bi distances in **1b** [3.753(1), 3.857(1) Å] and *cyclo*-$[(Me_3Si)_2CH]_4Bi_4$[6] [3.834, 3.859 Å] are also similar.

Coordination of the bismuthinidene [2-(Me_2NCH_2)-C_6H_4]Bi was achieved by treatment of the **1a/1b** mixture with $W(CO)_5$·THF in at 0 °C affording the complex $RBi[W(CO)_5]_2$ (**2**) [Equation (1)].



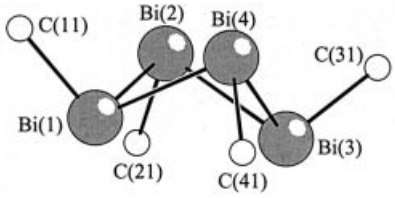


Figure 1. Structure of **1b** in the crystal; the ellipsoids represent 40% probability; selected bond lengths [Å] and angles [°]: Bi(1)−Bi(2) 3.0095(16), Bi(1)−Bi(4) 3.0206(16), Bi(2)−Bi(3) 3.0187(15), Bi(3)−Bi(4) 3.0221(16), Bi(1)−C(11) 2.24(3), Bi(2)−C(21) 2.30(3), Bi(3)−C(31) 2.28(3), Bi(4)−C(41) 2.28(3); Bi(2)−Bi(1)−Bi(4) 79.51(4), Bi(1)−Bi(2)−Bi(3) 77.01(4), Bi(2)−Bi(3)−Bi(4) 79.34(4), Bi(1)−Bi(4)−Bi(3) 76.79(4), Bi(2)−Bi(1)−C(11) 99.4(7), Bi(4)−Bi(1)−C(11) 98.6(7), Bi(1)−Bi(2)−C(21) 97.7(7), Bi(3)−Bi(2)−C(21) 93.2(7), Bi(2)−Bi(3)−C(31) 96.7(8), Bi(4)−Bi(3)−C(31) 101.7(7), Bi(1)−Bi(4)−C(41) 92.3(6), Bi(3)−Bi(4)−C(41) 94.4(7)

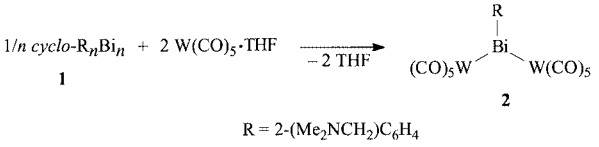

(1)

Red-orange crystals of **2** were obtained from a red toluene solution at −28 °C. The ^{1}H NMR spectrum of **2** shows the expected two singlets for the CH_3 and CH_2 groups, respectively, and the signals for the aryl protons. In the CI mass spectrum, the molecular ion peak of **2** was observed as the one with highest mass. The molecular structure of this bismuthinidene complex with intramolecular base coordination is depicted in Figure 2.

The [2-$(Me_2NCH_2)C_6H_4$]Bi group bridges two pentacarbonyltungsten fragments. The bismuth atom is tetra-coordinate in an irregular trigonal-pyramidal environment. The Bi−W bond lengths [2.8248(8) and 2.8362(8) Å] are similar to the values observed in $[Ph_3BiW(CO)_5]$ [2.8294(5) Å],[19] $[(Ph_3P)_2N][Ph_2Bi\{W(CO)_5\}_2]$ [2.891(2), 2.997(3) Å][20] and $[(Bi_2)W_2(CO)_8\{MeBiW(CO)_5\}]$ [2.851(2)−3.001(3) Å].[21]

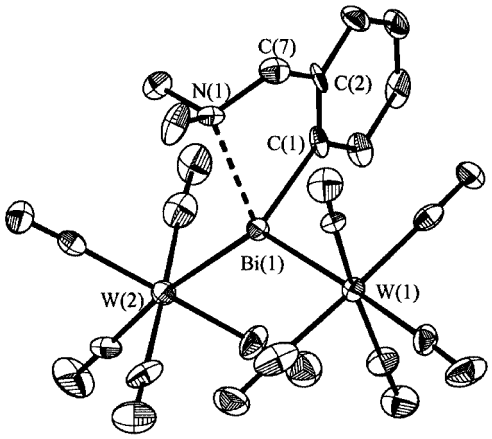

Figure 2. Structure of **2** in the crystal; the ellipsoids represent 40% probability; selected distances [Å] and angles [°]: Bi(1)−C(1) 222.3(16), Bi(1)−N(1) 2.435(12), Bi(1)−W(2) 2.8248(8), Bi(1)−W(1) 2.8362(8); C(1)−Bi(1)−N(1) 73.7(5), C(1)−Bi(1)−W(2) 108.8(3), N(1)−Bi(1)−W(2) 111.7(3), C(1)−Bi(1)−W(1) 105.7(3), N(1)−Bi(1)−W(1) 109.2(3), W(2)−Bi(1)−W(1) 132.13(3)

The intramolecular N−Bi distance [2.435(12) Å] in **2** is shorter than in R_2BiCl [2.570(5) Å][18] or $RBiI_2$ [2.503(6) Å],[18] [R = 2-$(Me_2NCH_2)C_6H_4$]. The W_2BiC framework of the Bi(*C,N*)W_2 core is almost planar (the sum of angles around Bi is 346.53°), with the Bi atom situated only 0.5 Å above the W_2C plane. Compound **2** can be described as a complex of an RBi ligand with two sp^2-orbitals containing lone pairs of electrons and an empty p-orbital at the bismuth atom. The filled orbitals are involved in the dative bonds to the tungsten atoms and the empty p-orbital accepts electron density from the amine group and the tungsten atoms. The structure is certainly also influenced by the constraints imposed by the five-membered chelate ring.

Analogous base-stabilized bismuthinidene complexes with donation of two lone pairs of electrons to two 16-electron complex fragments are unknown. Closely related compounds are the dinuclear complexes with phosphinidene, arsinidene, or stibinidene ligands, which have been studied by Huttner et al. They found that the tendency to form adducts with Lewis bases is considerably stronger for the heavier group-15 element ligands.[22] The formation of **2** does not prove unambiguously the presence of a monomeric bismuthinidene in the reaction solution. Alternatively, the reaction of the rings **1a** or **1b** with $W(CO)_5$·THF followed by splitting of the Bi−Bi bond might lead to **2**. It is remarkable that the analogous reaction of *cyclo*-$(Me_3SiCH_2)_nBi_n$ with $W(CO)_5$·THF, carried out under very similar conditions, gave the dibismuthene complex $[(RBi{=}BiR)\{W(CO)_5\}_2]$ (R = Me_3SiCH_2) instead of a bismuthinidene complex.[8]

The dibismuthane R_4Bi_2 (**3**) was synthesised by reduction of $[2\text{-}(Me_2NCH_2)C_6H_4]_2BiCl$ with Mg in THF at −40 °C [Equation (2)] and was isolated in 78% yield as a dark red hydrocarbon-soluble solid. Solutions of **3** are air-sensitive, but under an inert gas they are stable at room temperature for a long time ($\tau_{1/2}$ = 14 d). Crystals of **3** are stable in air for several hours.

$$2\ R_2BiCl + Mg \xrightarrow[-40\ ^\circ C]{THF} \underset{\mathbf{3}}{R_2Bi{-}BiR_2} + MgCl_2 \quad (2)$$

R = 2-$(Me_2NCH_2)C_6H_4$

The ^1H NMR spectrum of **3** shows one singlet for the methyl groups and an AB spin system for the CH_2 groups, indicating that all substituents are equivalent in solution. Variation of the temperature between +20 and −60 °C does not result in significant changes in the ^1H NMR spectrum. The EI mass spectrum of **3** displays a peak for the R_2Bi^+ fragment at highest mass. Single crystals of **3** were obtained from diethyl ether at −28 °C and the structure was determined by a single-crystal X-ray diffraction study. The molecular structure is depicted in Figure 3. Compound **3** is a dibismuthane exhibiting an antiperiplanar (*trans*) conformation [φ = lp−Bi−Bi−lp 132.18(1)°; lp = assumed position of the lone pair of electrons], which brings two organic groups on different metal atoms in an almost ecliptic position relative to each other [C(31)−Bi(2)−Bi(1)−C(11) 35.2(2)°]. This behaviour contrasts with the ideal *trans* conformation found in other dibismuthanes, $R_2Bi{-}BiR_2$ [R = Ph: φ = 180.00(5);[14] R = Me_3Si: φ = 180.00(3)[15]]. Intramolecular N−Bi coordination occurs through three of the four nitrogen atoms, the pendant arm carrying the N(1) atom being twisted far from the Bi(1) atom.

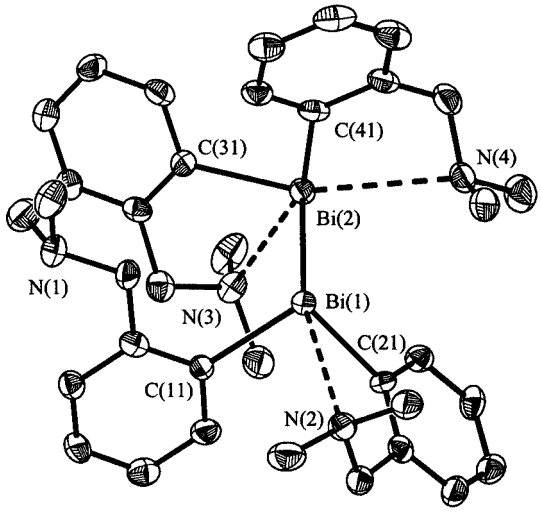

Figure 3. Structure of **3** in the crystal; the ellipsoids represent 40% probability; selected distances [Å] and angles [°]: Bi(1)−Bi(2) 3.0657(5), Bi(1)−C(11) 2.272(5), Bi(1)−C(21) 2.295(6), Bi(1)−N(2) 2.952(5), Bi(2)−C(31) 2.287(5), Bi(2)−C(41) 2.317(5), Bi(2)−N(3) 3.027(4), Bi(2)−N(4) 3.170(4); C(11)−Bi(1)−C(21) 96.29(19), C(11)−Bi(1)−N(2) 85.15(16), C(21)−Bi(1)−N(2) 67.39(18), C(11)−Bi(1)−Bi(2) 101.20(13), C(21)−Bi(1)−Bi(2) 96.04(15), N(2)−Bi(1)−Bi(2) 162.97(10), C(31)−Bi(2)−C(41) 94.3(2), C(31)−Bi(2)−N(3) 66.54(17), C(41)−Bi(2)−N(3) 159.83(18), C(31)−Bi(2)−Bi(1) 106.33(15), C(41)−Bi(2)−Bi(1) 81.77(14), N(3)−Bi(2)−Bi(1) 97.24(10), C(31)−Bi(2)−N(4) 159.31(17), C(41)−Bi(2)−N(4) 65.72(17), N(3)−Bi(2)−N(4) 133.92(13), Bi(1)−Bi(2)−N(4) 77.10(9)

This results in a wide range of Bi−Bi−C angles [81.77(14)−106.33(14)°] and different overall coordination geometries at the metal atoms. Bi(1) is in a distorted pseudo-trigonal-bipyramidal environment similar to that of the bismuth atoms in **1b**, with N(2) and Bi(2) in axial positions [N(2)−Bi(1)−Bi(2) 162.97(10)°].

The coordination geometry around Bi(2) is distorted tetragonal-pyramidal, with Bi(1) in the apical position and a C_2N_2 basal plane. The Bi−N distances [2.952(5), 3.027(4), and 3.170(4) Å] in the molecule of **3** are similar to the corresponding Bi−N bond lengths in **1b** [2.97(3)−3.05(2) Å], while the Bi−Bi distance in **3** [3.0657(5) Å] corresponds to a normal single bond as found in **1b** [3.0095(16)−3.0221(16) Å] or Ph_4Bi_2 [2.990(2) Å].[14] The Bi−Bi−C angles in **3** lie in the range between 81.77(14) and 106.33(15)°.

Conclusions

The present results show that the use of the 2-(dimethylaminomethyl)phenyl group stabilizes di- and *cyclo*-bismuthanes through intramolecular coordination of the pendant CH_2NMe_2 arm. The stabilizing effect is, however, not sufficient to allow the isolation of the monomeric 8-electron bismuthinidene species, RBi. This moiety was trapped by formation of a complex with pentacarbonyltungsten.

Experimental Section

General Comments: Syntheses were carried out under argon using dried solvents freshly distilled under argon. NMR spectra were recorded with a Bruker DPX 200 instrument. Mass spectra were recorded with a Finnigan MAT 8222 instrument and IR spectra with an FT-IR SPEKTRUM 1000. Compounds with the formulae $[2\text{-}(Me_2NCH_2)C_6H_4]_nBiCl_{3-n}$ were prepared according to the literature method.[17] The crystal structure measurement and refinement data for **1b**, **2**, and **3** are given in Table 1. Data for **1b** and **2** were collected with a Siemens P4 four-circle diffractometer. Data for **3** were collected with a STOE IPDS diffractometer. In both cases a graphite monochromator was used to produce a wavelength (Mo-K_α) of 0.71073 Å. The crystals were attached with Kel-F oil to a glass fibre and cooled under a nitrogen stream at 173 K. The structures were solved by direct methods (full-matrix least squares on F^2). All non-hydrogen atoms were refined with anisotropic thermal parameters. Structure solutions and refinements were carried out using the SHELX-97 software package.[23] Diagrams were created using the Diamond program by Crystal Impact GbR.[24] CCDC-195483 (**1b**), -195484 (**2**), and -195482 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html

Synthesis of [2-(Me_2NCH_2)C_6H_4]$_n$$Bi_n$ [*n* = 3 (1a), 4 (1b)]. Procedure 1: Na (1.0 g, 44.4 mmol) was dissolved in liquid ammonia (ca. 150 mL) and [2-(Me_2NCH_2)C_6H_4]$BiCl_2$ (9.0 g, 21.7 mmol) was added. The reaction mixture was stirred for 9 h and the liquid ammonia evaporated. The remaining black residue was extracted with petroleum ether (250 mL). After filtration, the petroleum ether was evaporated leaving a black-green solid (3.7 g, 49.5%). Compound **1b** [m.p. 53 °C (dec.)] separated as dark-green crystals from petroleum ether at −28 °C after a few weeks. ^{1}H NMR (200 MHz, 25 °C, $C_6D_5CD_3$, TMS): R_3Bi_3 (**1a**): δ = 2.29 (s, 12 H, *cis*-CH_3), 2.34 (s, 6 H, *trans*-CH_3), 3.38 (s, 4 H, *cis*-CH_2), 3.34 (s, 2 H, *trans*-CH_2), 6.42−6.99 (m, 9 H, 3−5-H), 7.57 (dd, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 1.3, 2 H, *cis*-6-H), 7.87 (dd, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 1.3, 1 H, *trans*-6-H); R_4Bi_4 (**1b**): δ = 1.91 (s, 24 H, CH_3), 3.43 (s, 8 H, CH_2), 6.68−6.99 (m, 12 H, 3−5-H), 8.93 (d, $^3J_{H,H}$ = 6.2, 4 H, 6-H). $C_{36}H_{48}Bi_4N_4$ (1372.70): calcd. C 31.50, H 3.52; found C 31.39, H 3.42. **Procedure 2:** $LiAlH_4$ (0.4 g, 10.7 mmol) was added with stirring to a solution of [2-(Me_2NCH_2)C_6H_4]$_2$BiCl (5.0 g, 9.7 mmol) in Et_2O (90 mL) at −78 °C. The reaction mixture was then warmed slowly to −30 °C. At −30 °C the solution was filtered through a precooled glass frit. The dark red filtrate was concentrated in vacuo at −30 °C leaving dark green crystals of **1b** (2.2 g, 65.9%). The identity of the product was established by ^{1}H NMR and X-ray diffraction (determination of the unit cell parameters).

Synthesis of [{2-(Me_2NCH_2)C_6H_4}Bi{$W(CO)_5$}$_2$] (2): A solution of [$W(CO)_5$THF] (2.3 g, 5.8 mmol) in THF (100 mL) was added to **1** (1.0 g, 0.7 mmol) in THF (40 mL) at 0 °C and the mixture was stirred for 3 h at 0 °C. After removal of the solvent in vacuo, the residue was extracted with toluene (100 mL) and then filtered through a glass frit covered with kieselguhr. The clear filtrate was concentrated and cooled to −28 °C to give orange-red crystals of **2** (1.6 g, 57.6%) (m.p. 82−85 °C). ^{1}H NMR (200 MHz, 25 °C, C_6D_6, TMS): δ = 1.99 (s, 6 H, CH_3), 3.07 (s, 2 H, CH_2), 6.88−7.21 (m, 3 H, 3−5-H), 7.58 (dd, $^3J_{H,H}$ = 7.2, 1 H, 6-H) ppm. ^{13}C NMR (50 MHz, 25 °C, C_6D_6, TMS): δ = 49.85 (s, CH_3), 72.73 (s, CH_2), 131.59 (s, C-4), 134.96 (s, C-3), 143.48 (s, C-5), 163.74 (s, C-6), 198.07 (s, CO_{eq}), 200.89 (s, CO_{ax}) ppm. IR (nujol): $\tilde{\nu}$ = 2072, 2054, 1940, 1908 cm^{-1} (C=O). MS (EI, 70 eV): *m*/*z* (%) = 990 (5) [M^+], 822 (2) [M^+ − 6 CO], 794 (3) [M^+ − 7 CO], 766 (2) [M^+ − 8 CO], 583 (10) [$RW(CO)_2^+$], 343 (60) [RBi^+], 134 (76) [R^+], 58 (100) [$Me_2NCH_2^+$]. $C_{19}H_{12}BiO_{10}W_2$ (990.98): calcd. C 23.03, H 1.22; found C 22.79, H 1.23.

Synthesis of [2-(Me_2NCH_2)C_6H_4]$_4$$Bi_2$ (3): A solution of [2-(Me_2NCH_2)C_6H_4]$_2$BiCl (7.0 g, 13.8 mmol) in THF (70 mL) was added dropwise at −40 °C to Mg (0.5 g, 21.4 mmol) activated with 1,2-dibromoethane (0.5 mL). The reaction mixture was stirred for 3 h and then the temperature was raised to 0 °C. The solvent was removed in vacuo leaving a dark red solid. After extraction with petroleum ether (150 mL) and filtration, the solvent was evaporated to dryness and the residue dissolved in Et_2O (20 mL). Cooling to −28 °C gave **3** (4.9 g, 78.3%) as red crystals (m.p. 69−79 °C). ^{1}H NMR (200 MHz, 25 °C, C_6D_6, TMS): δ = 1.93 (s, 6 H, CH_3), AB spin system with δ_A = 3.14 and δ_B = 3.32 ($^2J_{H,H}$ = 12.8, 2 H, CH_2), 6.99 (ddd, $^3J_{H,H}$ = 7.1, $^4J_{H,H}$ = 1.5, 1 H, 4-H), 7.13 (ddd, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 1.5, 5-H), 7.24 (dd, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 1.2, 1 H, 3-H), 8.67 (dd, $^3J_{H,H}$ = 7.1, $^4J_{H,H}$ = 1.5, 1 H, 6-H) ppm. ^{13}C NMR (50 MHz, 25 °C, C_6D_6, TMS): δ = 45.12 (s, CH_3), 69.13 (s, CH_2), 126.75 (s, C-4), 129.75 (s, C-3), 129.99 (s, C-5), 145.46 (s, C-6), 146.31 (s, C-1), 151.73 (s, C-2) ppm. MS (EI, 70 eV): *m*/*z* (%) = 477 (100) [R_2Bi^+], 342 (8) [RBi^+], 134 (50) [R^+]. $C_{36}H_{48}Bi_2N_4$ (954.74): calcd. C 45.29, H 5.07; found C 45.10, H 5.05.

Keywords: Peptides / Adsorption / Clays / NMR spectroscopy / X-ray diffraction

Two homopolypeptides, polylysine and polyglutamic acid, were adsorbed on a synthetic montmorillonite clay, in acidic medium. These organic-inorganic complexes can be heated up to 110 °C without any degradation of the polypeptide. ^{1}H-^{13}C CP-MAS NMR spectra show that these polypeptides, which exhibit a mixture of α-helical and random coil conformations in the bulk, tend to unfold and adopt a more extended random coil structure on adsorption on the phyllosilicate. The values of the basal spacing measured by X-ray diffraction on dehydrated samples clearly indicate that in the presence of adsorbed polypeptide, the silicate layers do not collapse. The incorporation of polypeptide fragments within the interlayer space is also revealed by the decrease in the specific surface areas measured by N_2-adsorption BET experiments.

Introduction

Specific interactions between polymers or proteins and clay mineral solid surfaces are at the basis of both natural processes and technological applications. In soil chemistry for instance, such organic-inorganic interactions are considered to be of prime importance in the regulation of the microbially mediated decomposition processes of soil organic matter.[1] Alternatively, membrane filtration[2] or advanced hybrid materials[3,4] are examples of the efficient use of the macromolecule-clay mineral interactions for new industrially relevant techniques. On the other hand, bentonites have been used for more than 60 years as adsorbents in winemaking, to remove proteins from musts and wines.[5] This particular affinity of proteins for phyllosilicates is based on the commonly high specific-surface areas associated with swelling and cation-exchange properties of the latter. Due to intralayer octahedral and/or tetrahedral substitutions, montmorillonites exhibit an overall negative surface charge that is balanced by hydrated cations such as sodium or calcium which are located within the interlayer spaces.[6] At pH values below their isoelectric points (i.e.p.), proteins are positively charged and their adsorption is basically seen as a cation-exchange process based on electrostatic, hydrophobic and/or hydrophilic interactions.[7]

To characterize the way in which proteins interact with solid surfaces, several studies have pointed out the important features arising from the modification of the conformation of interacting macromolecules. In particular, FTIR and enzymatic activity studies have emphasized the pH-dependent modification[8] and/or pH-dependent orientation[9] effects on the adsorbed enzymes, characterized by structural unfolding due to electrostatic interactions with montmorillonite. However, the mechanisms by which proteins are adsorbed on clay minerals are still subject to many questions.[10] A detailed description of the part of the protein that interacts with the mineral surface and the distance of interaction is required to understand the proteins/solid surface interactions.[11]

The aim of this study is to investigate model samples that can be considered as representative of protein−clay mineral complexes. This is accomplished through the analysis of the adsorption of two homopolypeptides, polylysine and polyglutamic acid (Scheme 1), on a synthetic montmorillonite,[12] using complementary approaches.

Thermal analyses (TG-DTA) can provide a rather accurate determination of the amount of adsorbed polypeptides on the solid surfaces,[13] and can also afford useful indirect information about the strength of the organic-inorganic interaction, from the decomposition temperature of the organic matter.[14]

Despite its low sensitivity, solid-state NMR spectroscopy has been successfully applied to the study of interfaces. In particular, this technique does not require any mechanical treatment and can provide, under certain circumstances, a direct three-dimensional picture of polypeptides in the bulk or in the adsorbed state.[13,15] Solid-state NMR spectroscopy has already been applied to the qualitative and/or quantitative characterization of soil organic matter,[16] but rarely to the characterization of adsorbed proteins on clay minerals.[17]

Several features can be obtained from powder X-ray diffraction patterns of smectites, e.g. the basal spacing, which is equal to the sum of the interlayer spacing and the thickness of the silicate layer, and which is given by the measurement of the (001) peak position.[18] Numerous studies have reported the d_{001} values of clay minerals onto which organic molecules such as amino acids[19] or alkylammonium ions[20] were adsorbed. These results provide a good basis for the comparison of values measured for polypeptide-adsorbed montmorillonite, either under controlled humidity or after dehydration.

Finally, one of the most interesting properties to explore when dealing with porous solids is the specific surface area and its variation resulting from the adsorption of organic molecules. However, measuring the actual specific surface area of montmorillonites corresponds to the determination of the surface area between the silicate layers which, in the absence of any adsorbed molecule, is theoretically equal to 760 m^2/g.[21] Such a result is classically obtained by the adsorption of a probe molecule such as methylene blue,[22] which can displace some interlayer species, and therefore cannot be used in the presence of previously adsorbed polypeptides. Consequently, nitrogen was used to determine the BET surface areas. It must be noted that the whole interlayer microporous surface of montmorillonites is theoretically not accessible to nitrogen molecules owing to the reversible collapse of the silicate layers on outgassing.

Results and Discussion

Thermal Analyses

The DTA curve (Figure 1, a) of the synthetic montmorillonite (**M**) is characterized by a major endothermic peak at 100 °C, which corresponds to interlayer dehydration, followed by a second weaker and broader endothermic peak, with a minimum at 650 °C, for the dehydroxylation of the layer.[12] On adsorption of polypeptides, the DTA curves (Figure 1, a) show additional exothermic signals in the range 260−700 °C, which correspond to the oxidative degradation of the adsorbed organic molecules. For **M/PL**, a strong exothermic peak occurs at 320 °C, and is followed by a second weaker exothermic peak at 600 °C. Two broader peaks are also observed for **M/PG**, but with weaker intensities and with the first peak occurring at a higher temperature than that for **M/PL**.

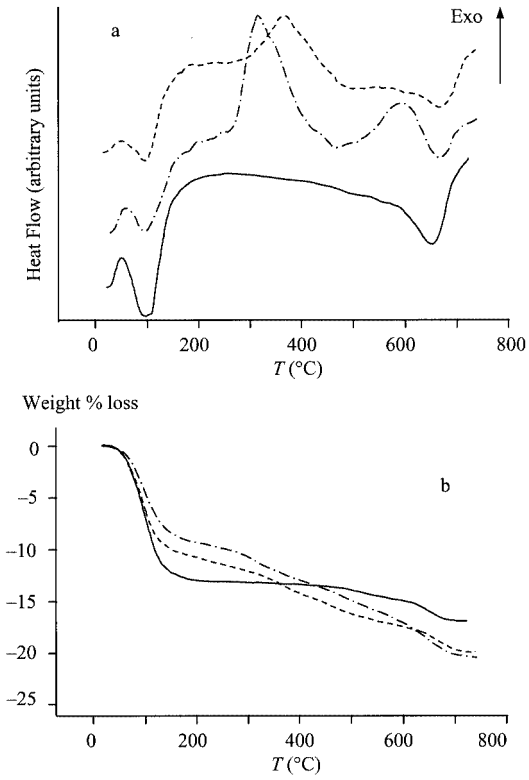

Figure 1. (a) DTA and (b) TG curves of **M** (plain line), **M/PL** (dashed dotted line) and **M/PG** (dotted line)

The amounts of adsorbed polypeptide were determined from the analysis of the TG curves (Figure 1, b), since the distinct exothermic peaks are solely due to the combustion of the organic matter. However, weight losses recorded at higher temperatures include the dehydroxylation process. The latter can be quantified from the experiment on **M** alone, and then subtracted from the weight losses determined for the organic-inorganic complexes. Table 1 gathers the calculated amounts of **PL**, **PG** and **PL/PG** adsorbed on **M**. For each separate adsorption (**M/PL** and **M/PG**), nearly all the polypeptide introduced is adsorbed. When both polypeptides are simultaneously introduced, and in higher quantities (**M/PL/PG**), they are also almost completely adsorbed (Table 1). In the case of **M/PL/PG**, the amount of **PL** introduced was set to present approximately 100 mequiv. of side chain NH_3^+ charges per 100 g of calcined

Table 1. Weight-percent amount, relative to dehydrated montmorillonite, of polypeptide introduced and adsorbed, from TG analyses; errors are ± 0.2

	M/PL	M/PG	M/PL/PG
Introduced	7.0	5.0	12.0 + 12.0
Adsorbed	7.0	4.7	21.0
After outgassing	4.6	3.3	20.3

montmorillonite, i.e. the initial cation exchange capacity of **M**.[12] Therefore, if **PL** is adsorbed via an electrostatic mechanism, in order to replace the Na^+ cations and balance the negative charge of **M**, **PG**, which does not bear positively charged side chains, is adsorbed via a different mechanism.

In order to assess the thermal stability of these organic-inorganic complexes, similar TG-DTA measurements were performed on the samples which had previously been outgassed under vacuum to a temperature of 110 or 150 °C, as required for nitrogen adsorption experiments. The corresponding weight losses are also given in Table 1. On outgassing at 150 °C under vacuum, both **M/PL** and **M/PG** have lost part of the initial amount of adsorbed organic matter. This loss of matter is higher for **M/PL** than for **M/PG**. In contrast, the total amount of adsorbed **PL** and **PG** is kept unchanged after having heated **M/PL/PG** to 110 °C, under vacuum. Furthermore, as shown below by ^{13}C NMR spectroscopy, the structure of the remaining adsorbed polypeptides is kept unchanged, which indicates that outgassing has basically lowered the amount of adsorbed matter, and that any decomposition products, volatile or not, have been outgassed.

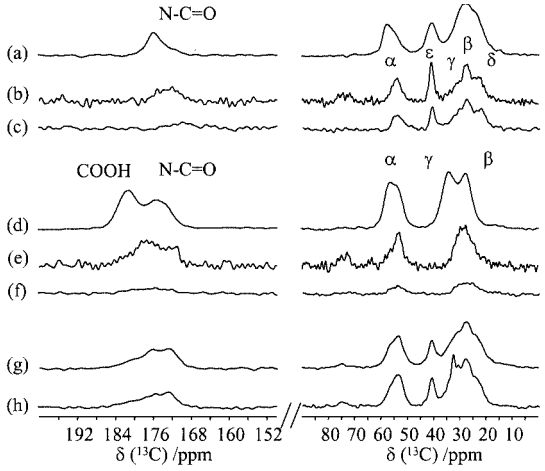

Figure 2. ^1H-^{13}C CP-MAS spectra of: (a) **PL**, (b) **M/PL**, (c) **M/PL** outgassed, (d) **PG**, (e) **M/PG**, (f) **M/PG** outgassed, (g) **M/PL/PG** and (h) **M/PL/PG** outgassed; contact time of 1 ms; only the peak regions are displayed

^{13}C NMR Chemical Shifts and Line Widths

^1H-^{13}C CP-MAS spectra of the bulk **PL** and **PG** samples, and the three polypeptide-adsorbed samples (**M/PL**, **M/PG** and **M/PL/PG**) are presented in Figure 2, with peak assignments taken from the literature.[23] The chemical shifts for the different resolved peaks along with their corresponding line widths are given in Table 2, and an example of deconvolution, for **PL** is given in Figure 3.

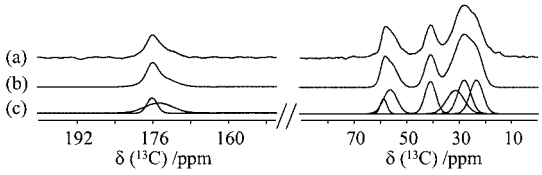

Figure 3. Deconvolution of the ^1H-^{13}C CP-MAS spectrum of **PL**: (a) experimental spectrum, (b) simulated spectrum and (c) individual components

The ^1H-^{13}C CP-MAS spectra of bulk **PL** (Figure 2, a) shows four distinct signals, which are composed of eight components (Figure 3 and Table 2): the backbone carbonyl (δ = 176.1 and 174.7 ppm), the backbone α-CH (δ = 58.3 and 55.8 ppm), the side chain ε-CH_2 (δ = 40.8 ppm), and the three remaining side chain methylene carbon atoms (δ = 31.3, 28.0 and 23.4 ppm) corresponding to the γ, β and δ-CH_2 carbon atoms, respectively. The distribution of the chemical shifts for both the carbonyl and the α-CH carbon atom clearly indicates the heterogeneous secondary structure of bulk **PL**. This is based on the well-established rule that the α-helix to β-sheet transformation in polypeptides is accompanied by a shift towards lower frequencies of the backbone α- and carbonyl carbon atoms, and a shift towards higher frequencies of the side chain β-carbon atom.[23] Intermediate shifts between these two extremes reflect the presence of random coils. For the α-CH group of **PL**, literature values of δ = 57.6 and 57.4 ppm are given for a helical conformation, and values of δ = 51.4 and 52.3 ppm for the β-sheet conformation.[23a,23c] Likewise, for the carbonyl group, literature values of δ = 175.7 and 171.5 ppm or δ = 170.4 ppm are given for the α-helix and the β-sheet, respectively.[23a] This indicates that **PL** displays a mixture of α-helical and random coil secondary structures

Table 2. ^{13}C chemical shifts (δ) and line widths (Δ) in ppm, of the different resolved peaks in the ^1H-^{13}C CP-MAS spectra; where possible, proportions of populations are indicated

	COO^-			NC=O			α-CH		ε-CH_2		γ-CH_2		β-CH_2		δ-CH_2	
	δ	Δ	%	δ	Δ	%	δ	Δ	δ	Δ	δ	Δ	δ	Δ	δ	Δ
PL			28	176.1	2.6	22	58.3	2.9	40.8	4.9	31.3	7.7	28.0	5.8	23.4	5.7
			72	174.7	6.8	78	55.8	6.1								
M/PL				173.0	5.9		54.1	4.3	40.8	2.2	30.5	6.3	27.5	2.7	23.3	5.6
PG	181.3	5.0	50	176.1	3.7	50	57.3	4.2			34.3	6.1	27.7	5.4		
			50	173.3	4.1	50	53.5	4.5								
M/PG	176.9	4.6		172.3	4.0	20	57.4	3.4			29.6	6.7	26.5	7.4		
	181.1	5.4				80	53.3	4.1								
M/PL/PG	181.0	5.8		176.5	3.2		57.4	3.4	40.7	3.0						
				173	5.9		53.3	4.1								

with proportions of about 25 and 75%, respectively (Table 2).

Similar observations can be made with regard to the **PG** ^{13}C chemical shifts (Figure 2, d). The backbone α-carbon resonance is clearly composed of two peaks at δ = 57.3 and 53.5 ppm, indicating the simultaneous α-helical and random coil secondary structures.[23a,23b] Likewise, two components are observed for the carbonyl resonance. From the deconvolutions of both the α-CH and the carbonyl resonances of **PG**, the α-helical and random coil conformations are in equal proportions (Table 2). As for **PL**, the heterogeneous nature of the **PG** secondary structure is in good agreement with the fact that the molecular weights of **PL** and **PG** are intermediate in value between low values, which favor β-sheet conformations and high values, which favor α-helices. The resonance of the carboxylic group at δ = 181.3 ppm is in the expected region for the Na salt form of the **PG** side chains.[24]

On adsorption of polylysine (sample **M/PL**, Figure 2, b), both the backbone carbonyl and α-CH peaks give rise to more symmetrical signals, shifted to lower frequencies at δ = 173.0 and 54.1 ppm, respectively. This directly reflects an overall loss of helicity of polylysine, and the adoption of a single more extended conformation. The α-helices are no longer detected. Besides, three different resolved signals are now observed for the γ, β and δ side chain methylene carbon atoms, which are shifted to lower frequencies (Table 2). This discrepancy is characterized by an apparent shielding of the three side chain −CH− carbon atoms, whereas the β-carbon peak, which should have shifted towards higher frequencies with the loss of helicity,[23a] can be directly correlated to the simultaneous approach of these carbon atoms near the negatively charged clay layer surface.[25] Furthermore, for **M/PL**, the three signals are narrower than for **PL**. The more significant narrowing occurs for the side chain ε-CH_2 peak, whose line width at half height (Δ) halves on adsorption (Table 2). This general line narrowing suggests an increase in the conformational order of these adsorbed polylysine side chain carbons within the clay interlayer space.

For **M/PG** (Figure 2, e), both the carbonyl and the α-CH peaks are shifted to lower frequencies (Table 2), indicating a similar loss of helicity. However, for the latter, a shoulder representing 20% of the signal is still observed at δ = 57.4 ppm, which indicates that the change in conformation is not complete, in contrast with **M/PL**. The side chain carboxylic peak shifts to lower frequencies, but a shoulder also remains at δ = 181.1 ppm, as in bulk **PG**. A shift to lower frequencies of the carboxylic isotropic chemical shift is in good agreement with the protonation of the side chain group.[24] Hence, on adsorption of **PG** onto **M**, most of the polyglutamic acid side chains are protonated, though a minor part remains unprotonated. Taken together with the conclusion drawn from the α-CH chemical shifts, these results confirm that **PG** side chains are directly involved in the adsorption process. However, unlike **PL** side chains, they do not have any positive charges at pH = 3.4. Therefore, to overcome the repulsion from the negative charges of the clay, carboxylic groups have to be protonated, as already shown for BSA adsorbed onto clays.[9b] Furthermore, the broadening of the $-CH_2-$ peaks (Figure 2, e) indicates that unlike for polylysine, adsorption of polyglutamic acid is not accompanied by an apparent increased ordering of the side chains.

The ^{1}H-^{13}C CP-MAS spectrum of **M/PL/PG** (Figure 2, g) displays both the characteristic ε-CH_2 signal (δ = 40.7 ppm) of **M/PL** and the characteristic carboxylic signal (δ = 181 ppm) of **M/PG**, indicating that the two polypeptides have been adsorbed. From the deconvolution of the carboxylic and carbonyl peaks and on the basis of the results of the deconvolutions on the spectra of **M/PL** and **M/PG**, an estimated ratio of 50:50 for the proportions of adsorbed **PL** and **PG** is found, which is consistent with the TG results. As for **M/PL** and **M/PG**, the carboxylic, the carbonyl and the α-CH peaks of **M/PL/PG** shift towards lower frequencies (Table 2). A part of the **PG** molecules retain the bulk secondary structure, as revealed by the carboxylic signal at δ = 181 ppm, and the α-CH signal is narrower than in bulk **PL**. Therefore, it seems that in terms of conformation, each polypeptide has been adsorbed as if the other one was not present.

When the samples were outgassed under vacuum, the ^{1}H-^{13}C CP-MAS spectra still exhibit comparable chemical shifts with those of the unheated samples (Figure 2 c, f, h), thus confirming that this high temperature treatment has not significantly modified the secondary structure of the adsorbed **PL** and **PG** molecules. This is more clearly seen for the **M/PL/PG** sample, which exhibits the highest amount of adsorbed organic matter. Only a weak modification of the conformation of some of the side chain $-CH_2-$ carbon atoms is observed, as suggested by the narrow peak at δ = 32 ppm (Figure 2, h). It must be noted that owing to the small quantities of samples left, spectra in Figure 2 c, f, h were recorded with a Bruker 2.5-mm probe, thus explaining the poor signal-to-noise ratio, particularly for **M/PG**.

X-ray Diffraction

The d_{001} peak region of each sample was recorded under controlled humidity (P/P_0 = 0.79) and after dehydration at 110 °C under vacuum (Figure 4). Unfortunately, we did not succeed in recording the diffractogram of **M/PG** after dehydration due to the lack of sample. The corresponding d_{001} values, which directly reflect the basal spacing of the samples, are presented in Table 3. This spacing is equal to the sum of the interlayer distance and the thickness of the layer, which is about 9.6 Å for a 2:1 phyllosilicate. As already reported, under a relative humidity of P/P_0 = 0.79, **M** exhibits a d_{001} value of 16.1 Å (Table 3).[12] On dehydration, the value falls to 10.5 Å, indicating the almost complete collapse of the layers, with interlayer cations partially inserted into hexagonal openings formed by the silicon tetrahedra.

Under a relative humidity of P/P_0 = 0.79, the d_{001} value of the two **PL**-containing samples (**M/PL** and **M/PL/PG**) is slightly higher (16.4 and 16.5 Å, respectively) than that

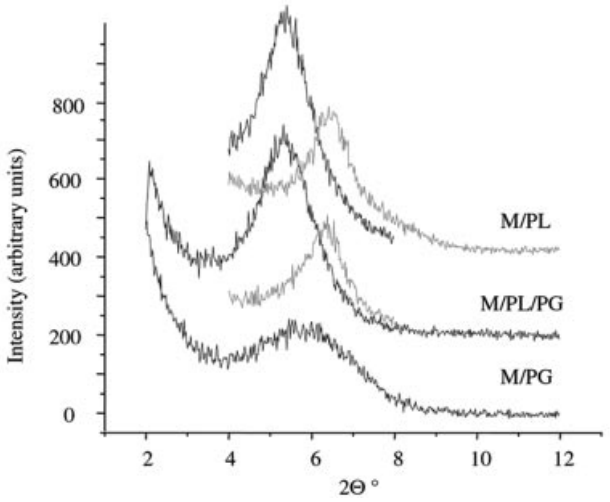

Figure 4. XRD patterns showing the d_{001} region for **M/PL** (top), **M/PL/PG** (center) and **M/PG** (bottom), under a relative humidity of 79% (black) and after dehydration (gray)

Table 3. XRD d_{001} values [Å]

	M	M/PL	M/PG	M/PL/PG
P/P_0 = 79%	16.1	16.4	15.4	16.5
Dehydrated	10.5	13.7		13.9

of **M**, whereas the d_{001} value of **M/PG** is slightly lower (15.4 Å), suggesting that the cumulative volume of adsorbed water molecules and polypeptide moieties is higher for **PL** than for **PG**. However, the highest value of 16.5 Å indicates that, in any case, only one layer of polypeptide moieties is intercalated within the interlayer space, which is consistent with the short length of the side chains of both **PL** and **PG**.[26] On dehydration, the d_{001} values for **M/PL** and **M/PL/PG** (13.7 and 13.9 Å, respectively) remain significantly higher than the thickness of the layers, and are conversely, in very good agreement with those reported for the monolayer adsorption of short chain length alkylammonium cations.[26] Therefore, only the polypeptide side chains appear to be adsorbed within the interlayer space of **M**.[11]

Nitrogen Adsorption

Nitrogen adsorption-desorption isotherms are given for samples **M** and **M/PL/PG** in Figure 5, a and are representative of the other samples. They both exhibit an important hysterisis loop, which is a mixing of type H3 and H4, characteristic of adsorbents containing slit-shaped pores.[27] The first part of these isotherms (P/P_0 between 0 and 0.2) clearly indicates a higher microporous character for **M** (type I isotherm) relative to **M/PL/PG** (type IIb isotherm), whereas the last part (P/P_0 above 0.7) reflects a higher swelling ability of **M** relative to **M/PL/PG**.

The specific surface areas calculated from the BET method are presented in Table 4, along with the corresponding proportions of microporous and external surfaces, as determined from the analyses of the *t*-plot (Figure 5, b).

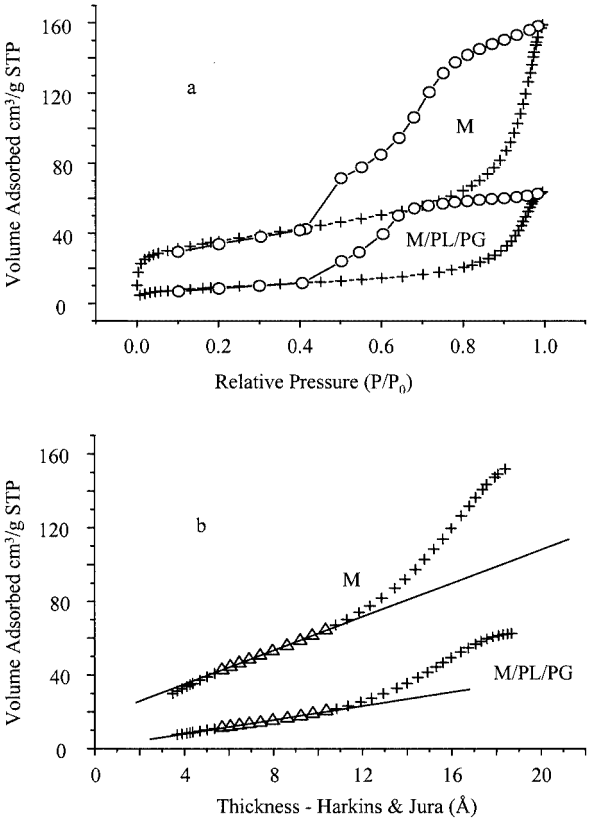

Figure 5. (a) Adsorption (+)-desorption (o) isotherms of nitrogen at 77 K on **M** and **M/PL/PG**; (b) *t*-plot representations for the same samples; triangles represent the experimental points considered for the analysis and the straight line represents the corresponding linear fit

Table 4. Specific surface areas determined from the BET measurements and proportions of external and microporous surface obtained from the *t*-plot analyses; values are expressed in m^2 per gram of dry montmorillonite and corrected for the mass of polypeptide adsorbed

	M	M/PL	M/PG	M/PL/PG
BET	128	110	92	41
External	72	63	63	37
Microporous	56	47	29	4

In the *t*-plots, the volume of nitrogen adsorbed is represented vs. the mean thickness of the adsorbed layer of nitrogen molecules,[28] and a positive intercept of the fitted linear region between ca. 5 and 10 Å directly reflects and quantifies the presence of micropores. Cumulative histogram plots (Figure 6) represent, for each sample, the sum of the microporous and external specific surface areas, which equals to the BET surface area. The above-mentioned microporosity has been attributed to the broken edge face of the particles due to the irregular stacking of the layers, which gives rise to slit-shaped pores.[29] Hence, this microporosity has been shown to be more accessible to hydration, for instance, than interlamellar porosity.[29] Therefore, although being external, this microporosity can be seen basically as interme-

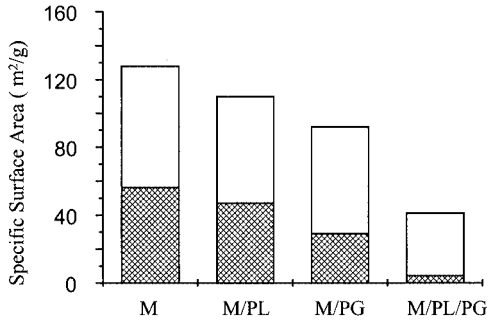

Figure 6. Cumulative histogram representing the microporous (bottom) and external (top) specific surface areas of the different samples; their sum corresponds to the BET surface for each sample

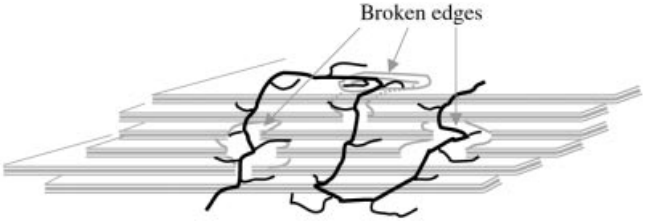
diate between the external surface of particles and the interlayer porosity.

Adsorption of polypeptides clearly leads to a decrease in the BET specific surface area of **M**, with the microporous component being the major contributor to this decrease (Figure 5, b and Figure 6). The higher BET value of **M/PL** compared with that of **M/PG** is in agreement with the thermal analyses, which have shown that on dehydration, **M/PL** has lost a more important proportion of the polypeptide than **M/PG**. In the case of **M/PL/PG**, where more polypeptides were initially adsorbed, nearly all the microporosity is lost. The external specific surface area also decreases on adsorption of the polypeptides, which indicates that the interparticle surface decreases.

Therefore, adsorption of these polypeptides can be described as a plugging process, more specifically, at the broken edges of the **M** particles, with side chains incorporated within the interlayer spaces (Scheme 2). This description agrees with all our results and explains the decrease in both the microporous character and the swelling ability of **M** on adsorption of polypeptides (Figure 5, a).



Scheme 2. Proposed description for the plugging of an unfolded polypeptide fragment at the broken edges of the **M** particles, with side chains pointing into the interlayer spaces

Conclusion

Understanding the mechanisms by which polypeptides and proteins adsorb on clay minerals is of major importance for several scientific areas, particularly in areas where this organic-inorganic interaction is at the basis of advanced composite materials. In this study, the use of complementary approaches has led to a more detailed description of the interaction between polylysine and polyglutamic acid with a synthetic montmorillonite. ^{13}C NMR chemical shifts of the backbone α- and carbonyl carbon atoms have shown that both polypeptides, which exhibit a mixture of α-helical and random coil conformations in the bulk, tend to unfold and adopt a more extended random coil structure on adsorption. Furthermore, analysis of the ^{13}C NMR line widths has shown that adsorption of the basic polylysine is accompanied by an increased ordering of the side chains, which is not the case for polyglutamic acid. However, in agreement with thermal analyses, the secondary structure of the adsorbed polypeptides is not significantly modified by heating at temperatures of up to 150 °C under vacuum. Based on this observation, we were able to compare the basal spacing of the polypeptide-adsorbed samples kept under controlled humidity ($P/P_0 = 0.79$) with that measured after dehydration under vacuum. The montmorillonite sheets collapse in the absence of adsorbed polypeptides, whereas they remain about 3.5 Å apart in their presence. Finally, nitrogen adsorption experiments, which are also based on dehydration under vacuum of the samples, were run to compare the accessible specific surface areas of the different samples. We observed that the higher the amount of polypeptide adsorbed, the lower the BET surface. The major contribution to this decrease in measured specific surface area is attributed to the microporous component of the external surface, as deduced from the analyses of the *t*-plots. All together, our results lead to the hypothesis that polypeptides are adsorbed at the periphery of the montmorillonite particles through specific interaction between the polypeptide side chains and the silicate sheets, whereas the polypeptide backbones do not enter the interlayer space.

Experimental Section

Samples: Poly-D-lysine (HBr salt) of average molecular weight 20900 and polydispersity 1.15, and poly-D-glutamic acid (sodium salt) of average molecular weight 19900 and polydispersity 1.3, were purchased from Sigma−Aldrich Chimie and used as received. Montmorillonite (**M**), whose synthesis and characterization is detailed elsewhere,[12] is a Mg-containing 2:1 dioctahedral clay with Na^+ cations in its interlayer space to balance the layer negative charge. Separate adsorption of each polypeptide was realized by mixing a solution of poly-D-lysine (**PL**) (ca. 30 mg), or poly-D-glutamic acid (**PG**) (ca. 30 mg), dissolved in a 15-mL acidic solution (pH = 3.4) with a solution of montmorillonite (**M**) (500 mg), initially suspended for 5 d in 25 mL of the same acidic buffer, at 10 °C for 6 h. Co-adsorption of the two polypeptides was realized under similar conditions by adding a solution of **PL** (50 mg) and **PG** (50 mg) dissolved in 50 mL of the acidic buffer to a solution of **M** (240 mg), initially suspended in 25 mL of the acidic buffer. After filtration through 0.45 μm filters and repeated washes with the buffer and deionized water, the three polypeptide-adsorbed samples **M/PL**, **M/PG** and **M/PL/PG** were dried overnight at room temperature in air and stored at 4 °C.

Thermal Analysis: TG-DTA measurements were carried out with a Setaram Labsys apparatus under air-flow condition, with a heating rate of 5 °C/min, from 18 to 750 or 800 °C.

X-ray Powder Diffraction: X-ray diffractograms were recorded with a STOE STADI-P powder X-ray diffractometer, equipped with a linear position-sensitive detector ($2\theta = 6°$) in Debye−Scherrer geometry and employing Ge-monochromated Cu-$K_{\alpha 1}$ radiation (λ = 1.5406 Å). Records, in the range $2\theta = 2-12°$, were performed on samples under controlled humidity ($P/P_0 = 0.79$) and on samples dehydrated at 110 °C under vacuum for 10 h. For the former, capillaries were filled with powder kept under controlled humidity, just before starting the experiment, whereas for the latter, capillaries were filled in a glove box under argon. In both cases, the capillaries were sealed immediately after filling up.

N_2 Adsorption: Complete nitrogen gas adsorption-desorption cycles were obtained with a Micromeritics ASAP 2001 apparatus. BET specific surface areas were determined from the initial part of the adsorption branches (typically in the range $P/P_0 = 0.04-0.2$), and the *t*-plot analysis of the adsorption permitted the determination of the microporous and external surface proportions. Prior to experiments, about 100 mg of each sample was outgassed to a residual pressure of less than 0.8 Pa at 110 or 150 °C for about 15 h.

Solid-State NMR Spectroscopy: ^{13}C NMR spectroscopic experiments were run with a Bruker DSX 400 spectrometer operating at frequencies of 100.6 MHz, and a Bruker MSL 300 spectrometer operating at a frequency of 75.4 MHz. ^1H-^{13}C Cross-Polarization-MAS (CP-MAS) experiments were performed using a Bruker double-channel 4-mm probe or a Bruker double-channel 2.5-mm probe. Hartmann−Hahn matching for the ^1H-^{13}C CP-MAS experiments was set on adamantane for ^1H and ^{13}C radio-frequency fields of ca. 60 kHz. Proton T_1 spin-lattice relaxation times ranged between 100 and 500 ms for the different proton species observed in the ^1H MAS spectra of mineral/polypeptide products. In the case of bulk polypeptides, rotors were packed in a glove box under argon in order to prevent interaction with ambient moisture. This resulted in higher ^1H T_1 values (ca. 1 s), mainly attributed to the absence of the paramagnetic O_2 relaxing agent. Chemical shifts for ^{13}C spectra were referenced to adamantane (δ_C = 29.47 ppm for the low-frequency peak). Deconvolution of the ^1H-^{13}C CP-MAS spectra was performed with the WINFIT software.[30]

Assembly of Hydrogen-Bonded Organic Layers with Macrocyclic Complexes Acting as Pillars

Myunghyun Paik Suh,*[a] Kil Sik Min,[a] Jung Woo Ko,[a] and Hye Jin Choi[a]

Keywords: Hydrogen bonds / Layered compounds / Macrocyclic ligands / Nickel / Self-assembly

Novel supramolecular networks of 2D $\{[Ni(cyclam)][C_6H_9(COOH)_2(COO)]_2\}_n$ (**1**) and 3D $\{[Ni(cyclam)][C_6H_3(OH)_2(COO)]_2\}_n$ (**2**) have been constructed by the self-assembly of $[Ni(cyclam)](ClO_4)_2$ with *cis,cis*-1,3,5-cyclohexanetricarboxylic acid (H_3CTC) and 3,5-dihydroxybenzoic acid (HDHB), respectively, in py/MeCN/H_2O. In the crystal structure of **1**, each nickel(II) macrocyclic complex binds two H_2CTC^- ions at the axial sites. The coordinated H_2CTC^- ions form hydrogen bonds with one another, which results in organic bilayers having macrocyclic complexes as pillars. In the crystal structure of **2**, each nickel(II) macrocyclic complex binds two DHB^- ions in the *trans* position. Two free hydroxyl groups and one carbonyl oxygen atom of the coordinated DHB^- ion are extensively hydrogen-bonded with the DHB^- ligand of the neighboring complexes, which results in a 3D network where 2D organic layers are linked by the macrocyclic complexes acting as pillars.

Introduction

Supramolecular solids with various network topologies and with interesting properties have been prepared by the self-assembly of transition metal ions and organic building blocks.[1,2] In the self-assembly of supramolecules, hydrogen bonding,[3] metal-ligand coordination,[4] and π-π interactions[5] are involved in multidimensional intermolecular interactions. In particular, directional hydrogen-bonding interactions are important for materials design[6] and molecular recognition.[7,8] It has been demonstrated that extensive hydrogen-bonding interactions in organic compounds result in remarkably robust three-dimensional networks.[9] In addition, frameworks with different topologies can be constructed by changing the hydrogen-bonding mode.[10,11] Macrocyclic complexes have been rarely employed as metal building blocks in the self-assembly of supramolecular networks.[12,13] Recently, a molecular floral lace with 1D channels, $[Ni(cyclam)(H_2O)_2]_3[C_6H_3(COO)_3]_2\cdot 24H_2O$ (**A**), was assembled by the extensive hydrogen-bonding interactions between the coordinated water molecules of $[Ni(cyclam)(H_2O)_2]^{2+}$ and 1,3,5-benzenetricarboxylate.[12]

Here we report 2D $\{[Ni(cyclam)][C_6H_9(COOH)_2(COO)]_2\}_n$ (**1**) and 3D $\{[Ni(cyclam)][C_6H_3(OH)_2(COO)]_2\}_n$ (**2**) supramolecular networks, which are assembled from $[Ni(cyclam)](ClO_4)_2$ with *cis,cis*-1,3,5-cyclohexanetricarboxylic acid (H_3CTC) and 3,5-dihydroxybenzoic acid (HDHB), respectively, in the presence of pyridine. Multidimensional networks **1** and **2** are generated by the extensive hydrogen-bonding interactions between the organic building blocks, giving rise to 2D layers with the macrocyclic complexes acting as pillars connecting the organic layers. To the best of our knowledge, this is the first example where macrocyclic complexes are involved as pillars linking the organic layers in the supramolecular networks. This synthetic strategy can be applied to construct hybrid materials that consist of alternately packed organic-inorganic layers.

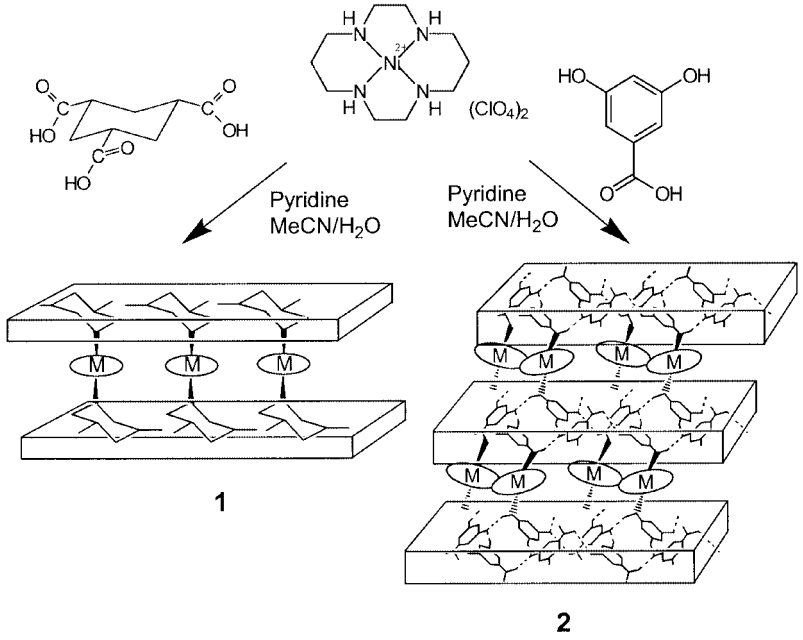

Scheme 1. Synthetic strategy for **1** and **2**

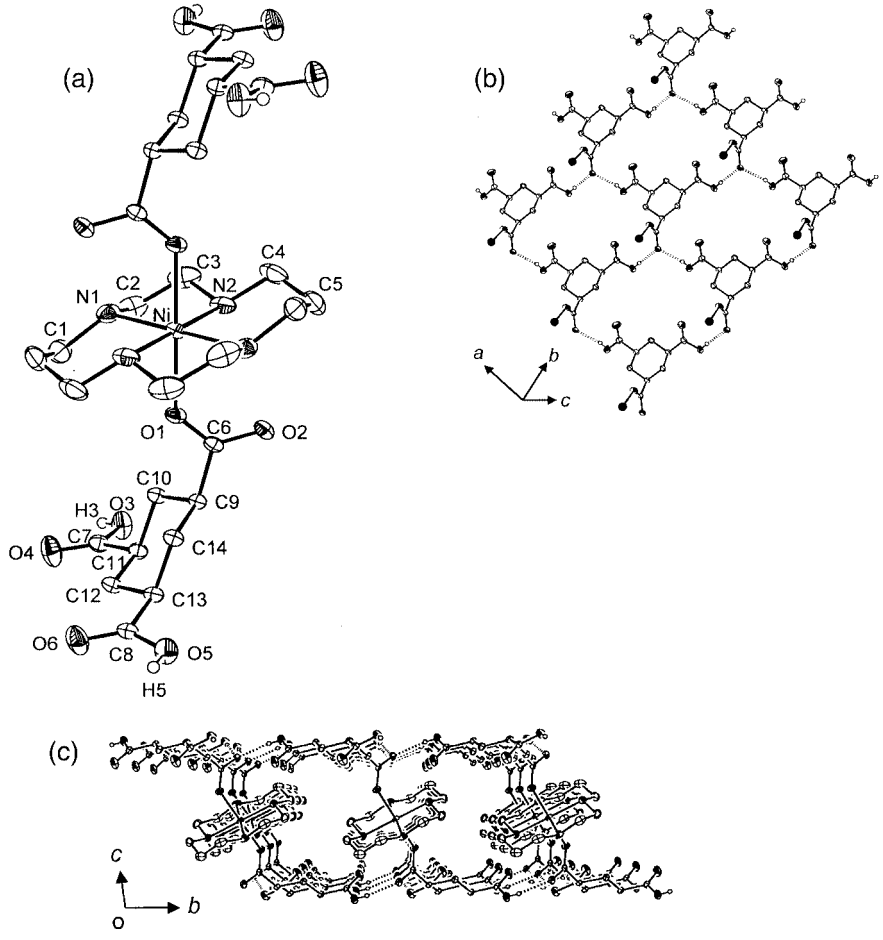

Figure 1. (a) An ORTEP view of **1** with atomic numbering scheme; the atoms are represented by 40% probability thermal ellipsoids; (b) the 2D organic layer, showing 26-membered supramolecular synthons constructed by the hydrogen bonding interactions between the coordinated H_2CTC^- ions; metal ions are indicated as filled black circles and intermolecular hydrogen bonds are indicated as dotted lines; (c) a view from the *bc* plane, showing the bilayer network where macrocyclic complexes act as pillars

tween organic ligands, which led to 2D organic layers with the macrocyclic complexes linking the organic layers as pillars. For this, $[Ni(cyclam)](ClO_4)_2$[14] and the carboxylate anions derived from *cis*,*cis*-1,3,5-cyclohexanetricarboxylic acid (H_3CTC) and 3,5-dihydroxybenzoic acid (HDHB) were used as the building blocks (Scheme 1).

When $[Ni(cyclam)](ClO_4)_2$ was reacted in MeCN/H_2O (1:1 v/v) with *cis*,*cis*-1,3,5-cyclohexanetricarboxylic acid (H_3CTC) in the presence of pyridine, only one proton of H_3CTC was removed and $[Ni(cyclam)]^{2+}$ was coordinated by two H_2CTC^- anions to form $\{[Ni(cyclam)][C_6H_9(COOH)_2(COO)]_2\}_n$ (**1**). When $[Ni(cyclam)](ClO_4)_2$ was reacted in MeCN/H_2O (1:1 v/v) with 3,5-dihydroxybenzoic acid (HDHB) in the presence of pyridine, the carboxylic acid group of HDHB was deprotonated and $[Ni(cyclam)]^{2+}$ was coordinated with two DHB^- anions to form $\{[Ni(cyclam)][C_6H_3(OH)_2(COO)]_2\}_n$ (**2**).

The supramolecular compounds **1** and **2** are pink and air-stable. They are insoluble in all solvents except water. In water, they are dissociated into the building blocks, as evidenced by the UV/Vis spectra, which exhibit the characteristic chromophore (λ_{max} = 445 nm) of the starting material $[Ni(cyclam)]^{2+}$. The diffuse reflectance spectrum measured for a powdered sample of **1** shows maximum absorptions at 332, 505, and 648 nm and that of **2** at 300, 511, and 661 nm, which correspond to the chromophores of nickel(II) ions coordinated by N_4O_2 donors.[15] The TGA and DSC traces of **1** and **2** (Figures S1 and S2) show that decomposition starts at 240 and 220 °C, respectively.

X-ray Crystal Structure of 1

An ORTEP[16] drawing of **1** is shown in Figure 1a. Table 1 shows selected bond lengths and angles. In the crystal structure of **1**, the nickel(II) ion of the macrocyclic complex $[Ni(cyclam)]^{2+}$ is coordinated to two carboxylate oxygen atoms of H_2CTC^- ions at the axial sites (Figure 1a). The complex has an inversion center at the nickel(II) ion. The average Ni−N bond length is 2.042(1) Å and the average Ni−O bond length is 2.171(1) Å, similar to those of open-framework **A**.[12] The coordinated H_2CTC^- ligands are linked to one another by the extensive hydrogen-bonding interactions. Each carbonyl oxygen atom of the coordinated carboxylate group of H_2CTC^- behaves as a hydrogen acceptor to form bifurcated hydrogen bonds with two carboxylic acid groups belonging to two different H_2CTC^- ions of the adjacent macrocyclic complexes [O2···O3′(x − 1, y, z): 2.701(2) Å; O2···H3′−O3′: 172.73°; O2···O5′′(x, y − 1, z): 2.700(2) Å; O2···H5′′−O5′′: 172.74°), and two free carboxylic acid groups of the H_2CTC^- ligand behave as hydrogen donors and form hydrogen bonds with the carbonyl oxygen atoms of the H_2CTC^- ligands belonging to two different adjacent complexes. The extensive hydrogen-bonding interactions between H_2CTC^- ligands construct 26-membered supramolecular synthons that propagate infinitely parallel to the crystallographic *ab* plane to give rise to a 2D organic network (Figure 1b). Due to the hydrogen-bonding interactions, the free C=O bond length of H_2CTC^- [C6−O2, 1.266(2) Å] is longer than that of the coordinated C−O bond length [C6−O1, 1.241(2) Å]. Since both of the H_2CTC^- ions coordinating a nickel(II) macrocyclic complex are involved in the formation of two different 2D organic layers, the structure becomes a bilayer containing nickel(II) macrocycles acting as pillars (Figure 1c). The interlayer distance within the bilayer is 5.692(4) Å and the shortest distance between two adjacent bilayers (C···O) is 3.399(3) Å.

X-ray Crystal Structure of 2

An ORTEP[16] drawing of **2** is shown in Figure 2a. Table 2 shows selected bond lengths and angles. In the crystal structure of **2**, the nickel(II) ion of the macrocyclic complex binds two carboxylate oxygen atoms of DHB^- ions at the axial sites (Figure 2a). The complex has an inversion center at the nickel(II) ion. The average Ni−N and Ni−O bond lengths are 2.065(1) and 2.130(1) Å, respectively, which are similar to those of **1**. The aromatic ring of the DHB^- ion is tilted with respect to the square coordination plane of the macrocycle [dihedral angle = 51.3(1)°]. The DHB^- ligand is not planar since the dihedral angle between the carboxylate group and the aromatic ring of DHB^- ion is 29.9(3)°. Within the molecule, there are hydrogen-bonding interactions between the carbonyl oxygen atoms of the carboxylate ions and the secondary amines of the macrocy-

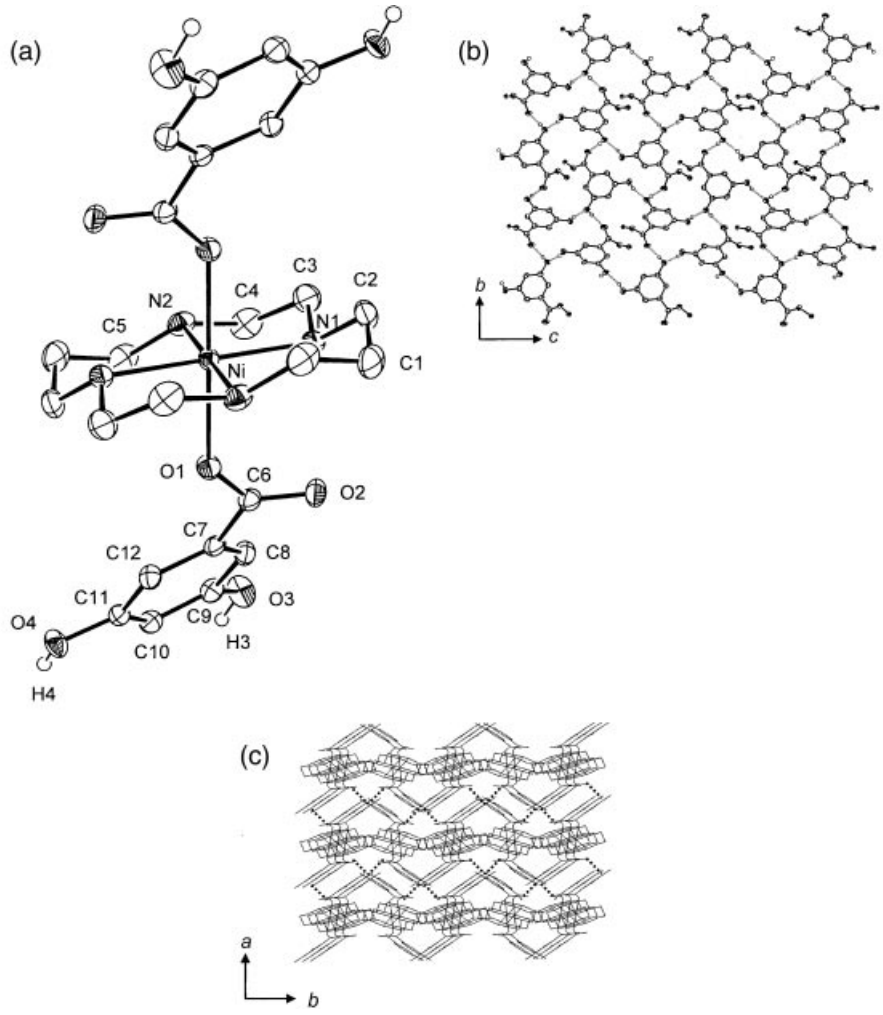

Figure 2. (a) An ORTEP view of **2** with atomic numbering scheme; the atoms are represented by 40% probability thermal ellipsoids; intramolecular hydrogen bonds are indicated as dotted lines; (b) a 2D organic layer constructed by the hydrogen-bonding interactions between the coordinated DHB^- ligands; (c) a view of the 3D network on the *ab* plane, showing how the thick 2D organic layers are linked by the macrocyclic complexes acting as pillars, interlayer hydrogen bonds are indicated as ·····

cle to form six-membered rings (O2···N1: 2.980(3) Å; O2···H1−N1: 162°). The six-coordinate nickel(II) macrocyclic complexes are linked together by extensive hydrogen-bonding interactions between the DHB^- ligands. Each DHB^- ion coordinating the metal above the plane forms hydrogen bonds with two neighboring DHB^- ligands, via hydroxyl groups [O3···O4(#1) (#1: x, $-y - 0.5$, $z + 0.5$): 2.763(2) Å; O3−H3(#1)···O4(#1): 164°], to build a 1D chain that extends along the crystallographic *c* axis, undulating in the *b* and *a* directions (Figure 2b; A in Scheme 2). Similarly, each DHB^- ligand coordinating a metal below the macrocyclic coordination plane also forms hydrogen bonds with two adjacent DHB^- ligands to construct another undulating 1D chain that also extends along the *c* direction (B in Scheme 2). These two kinds of chains are alternately aligned toward the *b* direction, and they are connected to one another by the hydrogen-bonding interactions via the free carbonyl oxygen atom of the coordinated carboxylate group of DHB^- belonging to one chain and the hydroxyl group of DHB^- belong to the other chain [O2···O4(#2) (#2 = $-x - 1$, $y + 0.5$, $-z + 0.5$): 2.610(2) Å; O2···H4(#2)−O4(#2): 175°]. There are π-π interactions between the phenyl rings of DHB^- belonging to the adjacent chains [centroid···centroid distance: 6.032 Å; closest C···C distance: 3.917(4) Å]. Since the interchain hydrogen-bonding interactions extend along the *b* direction and undulate in the *a* direction, the DHB^- ligands construct a

thick 2D organic layer (Figure 2b and 2c). The thickness of the organic layer is 4.872(3) Å. These thick 2D organic layers are linked by the macrocyclic complexes located on a plane parallel to the *bc* plane, and thus the whole structure can be viewed as a 3D network where macrocyclic complexes act as pillars (Figure 2c).

Conclusion

A 2D bilayered framework (**1**) and a 3D supramolecular network (**2**), where macrocyclic complexes behave as pillars linking 2D organic layers, have been prepared by the self-assembly of the nickel(II) macrocyclic complex $[Ni(cyclam)]^{2+}$ with *cis*,*cis*-1,3,5-cyclohexanetricarboxylate (H_2CTC^-) and 3,5-dihydroxybenzoate (DHB^-), respectively. The multi-dimensional networks are constructed by the extensive hydrogen-bonding interactions between the organic ligands coordinating the nickel(II) ions. The synthetic strategy can be applied to construct hybrid materials that consist of organic layers and layers of transition metal complexes packed alternately.

Experimental Section

General Remarks: All chemicals and solvents used in the synthesis were of reagent grade and used without further purification. $[Ni(cyclam)](ClO_4)_2$ was prepared according to the literature procedures previously reported.[14] Infrared spectra were recorded with a Perkin−Elmer 2000 FT-IR spectrophotometer. Elemental analyses were performed by the analytical laboratory of Seoul National University. UV/Vis diffuse reflectance spectra were recorded with a Cary 300 Bio UV/Vis spectrophotometer. Thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) were performed at a scan rate of 5 °C/min using a DuPont TGA 2050 and a DuPont DSC 2100 TA instrument, respectively.

Safety Note: *Perchlorate salts of metal complexes with organic ligands are often explosive and should be handled with great caution, although we have experienced no problem with the compounds reported in this work.*

$\{[Ni(cyclam)][C_6H_9(COOH)_2(COO)]_2\}_n$ (1): An MeCN solution (6 mL) of *cis*,*cis*-1,3,5-cyclohexanetricarboxylic acid (H_3CTC; 0.14 g, 0.76 mmol) mixed with pyridine (1 mL) was added dropwise to an MeCN/H_2O (1:1 v/v, 12 mL) solution of $[Ni(cyclam)](ClO_4)_2$ (0.17 g, 0.38 mmol). The yellow color of the nickel(II) solution turned to pale pink. The solution was allowed to stand at room temperature until pale pink crystals of $\{[Ni(cyclam)][C_6H_9(COOH)_2(COO)]_2\}_n$ formed, which were filtered, washed with MeCN/H_2O (1:1 v/v), and dried in air. There is no other form of aggregation present in the solution. Yield: 0.20 g (77%). $C_{28}H_{46}N_4NiO_{12}$: calcd. C 48.78, H 6.73, N 8.13; found C 48.60, H 6.55, N 8.50. FT-IR (Nujol mull): $\tilde{\nu}$ = 3300 (s), 3123 (s), 3084 (s), 1721 (s), 1548 (s), 1251 (s), 1177 (s), 954 (s), 870 (s), 730 (s), 649 (s) cm^{-1}. UV/Vis (diffuse reflectance spectrum): λ_{max} = 332, 505, 648 nm.

$\{[Ni(cyclam)][C_6H_3(OH)_2(COO)]_2\}_n$ (2): An MeCN solution (6 mL) of 3,5-dihydroxybenzoic acid (0.14 g, 0.88 mmol) and pyridine (1 mL) was added dropwise to an MeCN/H_2O (1:1 v/v, 12 mL) solution of $[Ni(cyclam)](ClO_4)_2$ (0.20 g, 0.44 mmol). The yellow color of the nickel(II) solution turned to pale pink. The solution was allowed to stand at room temperature until pale pink crystals of $\{[Ni(cyclam)][C_6H_3(OH)_2(COO)]_2\}_n$ formed, which were filtered off, washed with MeCN/H_2O (1:1 v/v), and dried in air. There is no other form of aggregation present in the solution. Yield: 0.19 g (75%). $C_{24}H_{34}N_4NiO_8$: calcd. C 51.00, H 6.06, N 9.91; found C 50.27, H 6.17, N 9.98. FT-IR (Nujol mull): $\tilde{\nu}$ = 3306 (s), 3200 (s), 3062 (s), 2554 (s, br), 1558 (s), 1393 (s), 1284 (s), 1156 (s), 1025 (s), 958 (s), 792 (s), 689 (s) cm^{-1}. UV/Vis (diffuse reflectance spectrum): λ_{max} = 248, 300, 511, 661 nm.

X-ray Crystallographic Study: Single crystals of **1** and **2** were mounted on an Enraf−Nonius CAD4 diffractometer. The unit-cell parameters were determined from 25 machine-centered reflections with $22° < 2\theta < 28°$ for **1** and $22° < 2\theta < 27°$ for **2**. Intensities were collected with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å), using the ω-2θ scan. Three standard reflections were measured every 2 h for the orientation and intensity control; no significant intensity decay was observed. The data were corrected for Lorentz and polarization effects. No absorption correction was made. For **1**, among 2618 reflections measured in the range $3.78 < 2\theta < 49.88$, 2552 were assumed to be observed [$F > 4\sigma(F)$]. For **2**, among 2193 reflections measured in the range $4.80 < 2\theta < 49.94$, 1842 were assumed to be observed [$F > 4\sigma(F)$]. The crystal structures were solved by direct methods[17] and refined by full-matrix least-squares methods using the SHELXL-97 computer program.[18] For **1** and **2**, the positions of all non-hydrogen atoms were refined with anisotropic displacement factors. The carboxylic acid protons and hydroxyl protons were located from the difference Fourier maps and refined with isotropic thermal parameters. The remaining hydrogen atoms were allowed to ride on their bonded atoms with the isotropic displacement factors fixed with values of 1.2-times those of the bonded atoms. ORTEP drawings were made

Five- and Six-Membered Cobaltocycles with C,P-Chelating Ligands through Regiospecific Cyclometalation of Mono(2-Substituted) Triphenylphosphane

Hans-Friedrich Klein,*[a] Robert Beck,[a] Ulrich Flörke,[b] and Hans-Jürgen Haupt[b]

Keywords: Chelates / Cobalt / Metalation / Metallacycles / Structure elucidation

Cyclometalation in the aliphatic ring occurs in the reaction between $[CoCH_3(PMe_3)_4]$ and 5-(diphenylphosphanyl)-1,2,3,4-tetrahydronaphthalene to give [{8-(diphenylphosphanyl)-1,2,3,4-tetrahydronaphthyl-(C^1,P)}tris(trimethylphosphane)cobalt] (**1**), containing a five-membered metallacycle as shown in the molecular structure. While 1-(diphenylphosphanyl)naphthalene reacts accordingly, affording [{8-(diphenylphosphanyl)naphthyl-(C^1,P)}tris(trimethylphosphane)cobalt] (**2**), 2-(diphenylphosphanyl)biphenyl yields *ortho*-metalated [{2-(diphenylphosphanyl)-3-phenylphenyl-(C^1,P)}tris(trimethylphosphane)cobalt] (**3**), containing a four-membered metallacycle**.** 1-**(**Diphenylphosphanyl)-8-methylnaphthalene is metalated in the aliphatic substituent to form [{[8-(diphenylphosphanyl)naphth-1-yl]methyl-(*C*,*P*)}tris(trimethylphosphane)cobalt] (**4**). The molecular structure shows a trigonal-bipyramidal configuration of the cobalt atom accommodating a six-membered metallacycle. 2-(Diphenylphosphanyl)styrene replaces two trimethylphosphane ligands to give [{2-(diphenylphosphanyl)styrene-(*C*,*C*-η^2,*P*)}methylbis(trimethylphosphane)cobalt] (**5**), avoiding metalation. Replacement of equatorial trimethylphosphane in compounds **1**–**3** by ethene gives π-ethene complexes **6**–**8**. In the molecular structure of **7** the C–C vector of the π-ethene ligand is arranged in the equatorial plane of a trigonal bipyramid. Under 1 bar of CO, compound **2** forms a monocarbonyl complex **9**, in which an equatorial carbonyl ligand is found in the molecular structure. Iodomethane transforms **2** into pentacoordinate [{2-(diphenylphosphanyl)naphthyl-(C^1,P)}iodobis(trimethylphosphane)cobalt] (**10**) with retention of the metallacycle.

Introduction

Cyclometalation reactions with mono(2-substituted) triphenylphosphanes and $[CoCH_3(PMe_3)_4]$ proceed with elimination of methane, whereby the selective product formation is rendered irreversible.[1] The observed regiospecificity, based on the orientation of C−H bonds situated in the vicinity of the metal atom, is sterically controlled by the preferred substrate conformation. Four-membered cobaltocycles have been found to originate from an *ortho*-metalation process, while in exceptional cases five-membered rings arise from attack in the side chain, although on the basis of C−H and C−Co bond energies the balance is believed to be less favorable for C(sp^3)−H bonds.[2] With the aim of selectively generating larger metallacycles we have metalated some pre-chelate phosphane ligands capable of forming five- and six-membered cobaltocycles (Scheme 1). An optional *ortho*-metalation route, disregarding the *ortho*-CH groups in the phenyl substituents, is also indicated for all four pre-chelate systems under investigation.

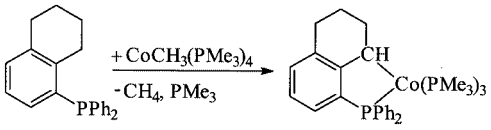
Results and Discussion

The $ArCH_3 \rightarrow ArCH_2 \rightarrow ArCH$ Line

Proximity of a C−H bond to the metal atom and a perpendicular orientation are believed to be necessary prerequisites for a cyclometalation reaction to occur. The unusual switching of selectivities from side-chain attack (2-methyl substituent) to *ortho*-metalation (2-ethyl substituent), which is steric in origin, prompted us to clarify the cyclometalation process further by restricting the proximity conformations. Rotational orientations of C−H bonds will be restricted in an aliphatic ring when 5-(diphenylphosphanyl)-1,2,3,4-tetrahydronaphthalene is chosen as a prechelate reactant. Reaction with $[CoCH_3(PMe_3)_4]$ proceeds below 20 °C [Equation (1)].



(1)

1

Red-brown crystals of **1**, melting with decomposition above 121 °C, were obtained from pentane. In the ^{31}P NMR spectrum, the observed coordination chemical shift of $\delta \approx 80$ ppm is only compatible with the PPh_2 group ($\delta = 64$ ppm) as part of a five-membered cobaltocycle. This configuration was confirmed in the molecular structure of **1** (Figure 1).

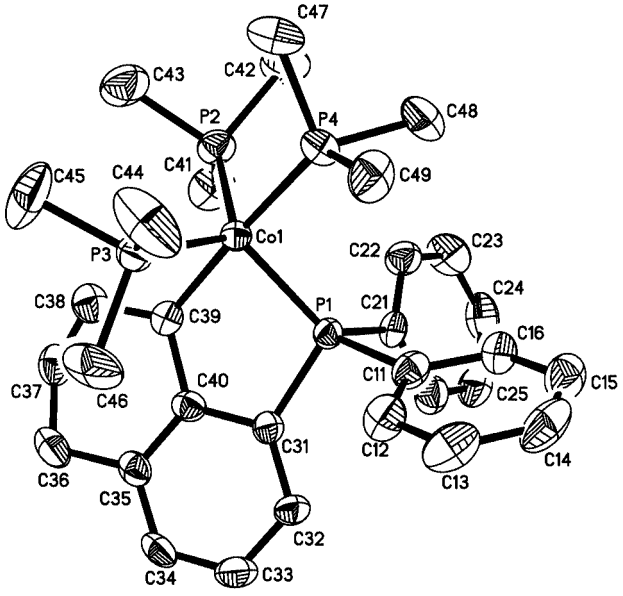


Figure 1. Molecular structure of **1** (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C39 2.082(6), Co−P1 2.1612(17), Co−P2 2.2189(17), Co−P3 2.1911(18), Co−P4 2.223(2), P1−C31 1.837(6), C31−C40 1.401(8), C39−C40 1.487(8); C39−Co−P1 81.18(17), C39−Co−P2 88.12(18), C39−Co−P3 85.34(19), C39−Co−P4 176.58(18), P1−Co−P2 120.50(7), P1−Co−P3 117.05(7), P1−Co−P4 95.56(6), P2−Co−P3 120.11(7), P2−Co−P4 94.45(7), P3−Co−P4 95.29(7), Co−P1−C31 105.26(19), P1−C31−C40 110.3(4), C31−C40−C39 117.8(5), Co−C39−C40 116.5(4)

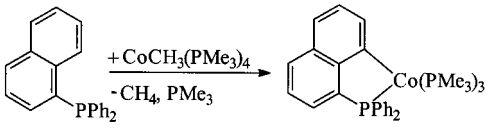
The cobalt atom is centered in a trigonal bipyramid with axial CH and PMe_3 groups and a five-membered metallacycle spanning C-axial and P-equatorial positions with a C39−Co−P1 bite angle of 81.18(17)°. The Co−C bond is unusually long [Co−C39 = 2.082(6) Å], and while the adjacent distance $C(sp^3)-C(sp^3)$ is shortened [C39−C38 = 1.422(8) Å] the $C(sp^3)-C(sp^2)$ distance is normal [C39−C40 = 1.487(8) Å]. A multiplet arising from multiple phosphorus coupling at $\delta = 1.08$ ppm (1 H) in the ^1H NMR spectrum at 296 K is attributable to the CoCH group, and there is nothing remarkable in the remaining cycloaliphatic proton signals ($\delta = 2.20-2.63$ ppm, 6 H). As there are no unusual anisotropic properties of the carbon atoms, and as split models for the atomic positions of C39 and C38 were found insufficient, the structural irregularity in the cycloaliphatic ring is attributed to packing forces.

Incorporation of the CH_2 group in a cyclohexenyl ring switches the cyclometalation reaction from *ortho*-metalation of a $C(sp^2)-H$ bond to side-chain attack at a $C(sp^3)-H$ bond.

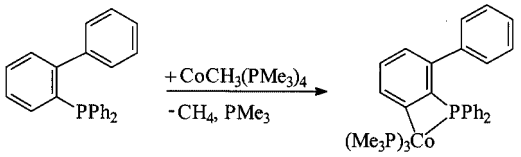
1-(Diphenylphosphanyl)naphthalene, providing two in-plane *ortho*-$C(sp^2)-H$ bonds, reacts with $[CoCH_3(PMe_3)_4]$ at −70 °C [Equation (2)] to afford **2** exclusively, isolated in 85% yield. The ^{31}P NMR chemical shifts and coupling constants at 193 K are found in positions and of an order expected for a five-membered cobaltocycle. The configuration of **2** was confirmed by monosubstitution with carbon monoxide to afford **9** (see below). Formation of a similar metallacycle starting from iridium(III) chloride was reported to require reflux conditions in 2-methoxyethanol.[3]



(2)

2

In order to address the matter of preference of six- or four-membered cobaltocycles, 2-(diphenylphosphanyl)biphenyl was treated with $[CoCH_3(PMe_3)_4]$ [Equation (3)].



(3)

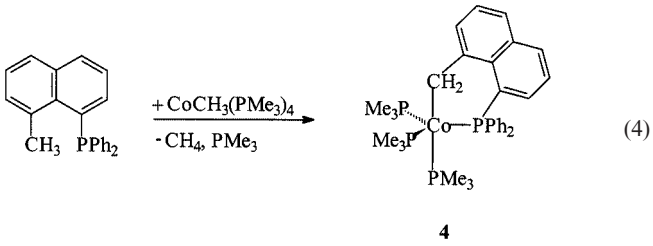
3

After evolution of gas, the mixture became red-brown in color and afforded **3** as a waxy solid, which was characterized by spectroscopy but gave no satisfactory elemental analysis. Evidence for the presence of a four-membered cobaltocycle was substantiated by its π-ethene derivative **8** (see below).

Metalation of the congested methyl group in 1-(diphenylphosphanyl)-8-methylnaphthalene should provide a six-

membered cobaltocycle, if not dominated by *ortho*-metalation (Scheme 1). The relative proximity effects at the cobalt center upon coordination of the anchoring PPh_2 group allow reaction with $[CoCH_3(PMe_3)_4]$ at −70 °C and evolution of methane to proceed within 5 min.

Metalation occurs specifically at the naphthylmethyl group, forming the six-membered metallacycle [Equation (4)]. Compound **4** was crystallized from pentane as short, dark brown rods. The ^{31}P NMR spectrum shows two doublets of triplets and a doublet of doublets, as in the five-membered cobaltocycles of **1** or **2**. The observed pattern is in agreement with axial CH_2 and PMe_3 groups and three P donor functions in equatorial positions. A six-membered chelate ring spanning axial C and equatorial P sites of a trigonal bipyramid is shown in the molecular structure of **4** (Figure 2).



(4)

4

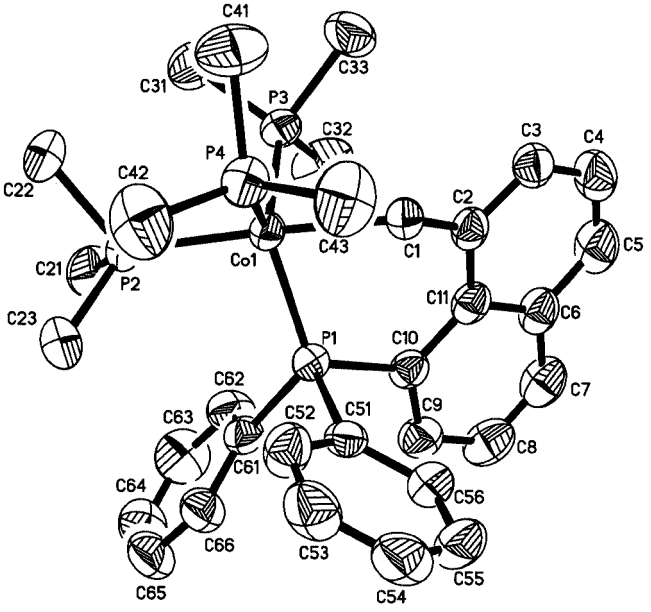


Figure 2. Molecular structure of **4** (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C1 2.090 (3), Co−P1 2.1438(9), Co−P2 2.1904(12), Co−P3 2.1932(10), Co−P4 2.2180(11), P1−C10 1.859(3), C10−C11 1.421(4), C2−C11 1.420(4), C1−C2 1.484(4); C1−Co−P1 79.72(9), C1−Co−P2 176.61(10), C1−Co−P3 88.32(10), C1−Co−P4 85.25(9), P1−Co−P2 98.60(4), P1−Co−P3 120.87(4), P1−Co−P4 121.21(4), P2−Co−P3 95.06(4), P2−Co−P4 93.18(4), P3−Co−P4 115.02(4), Co−P1−C10 117.05(10), P1−C10−C11 120.4(2), C2−C11−C10 123.5(2), C11−C2−C1 121.7(3), Co−C1−C2 123.4(2)

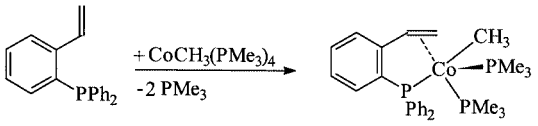
The cobalt atom is situated 109.5(1) pm above the best plane in the chelate ring. Bond lengths and angles show only minor deviations from the molecular structure of **1** (Figure 1).

Formation of all three ring sizes can be envisaged in 2-(diphenylphosphanyl)styrene (Scheme 1). However, treatment with $[CoCH_3(PMe_3)_4]$ failed to show evolution of gas, proceeding instead by substitution of two trimethylphosphane ligands [Equation (5)].



(5)

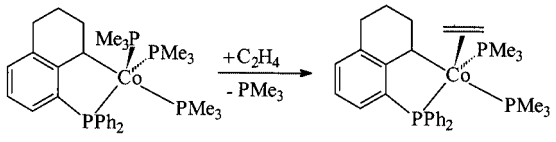
5

Compound **5** was obtained as an orange solid, decomposing above 152 °C under argon and stable in air under ambient conditions for at least 2 h. In the ^1H NMR spectrum at 296 K, a doublet of triplets at $\delta = -0.85$ ppm (3 H) represents the $CoCH_3$ group, while in the ^{31}P NMR spectrum at 233 K, two doublets of doublets for an axial and two anisochronic equatorial P-donor atoms indicate a tbp-coordinated cobalt atom with local C_s symmetry caused by an equatorial π-vinyl ligand. 2-(Diphenylphosphanyl)styrene appears to be trapped as a neutral chelating ligand[4] that does not undergo a metalation reaction.

Reactions with Ethene

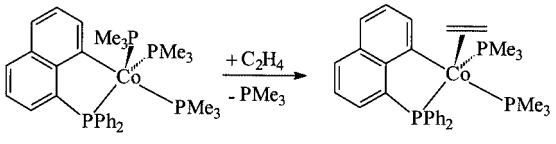
π-Olefin coordination in aryl(trimethylphosphane)cobalt(I) complexes is usually achieved through a smooth substitution reaction.[1a,5] Complex **6** was observed to crystallize much better under 1 bar of ethene than under argon.

The underlying replacement of dissociated trimethylphosphane by ethene [Equations (6) and (7)] converts **1** and **2** into π-ethene compounds that form orange plates (**6**) and short orange rods (**7**) from pentane solutions.



(6)

1 **6**



(7)

2 **7**

When the complexes are heated under argon, decomposition (**6**: > 101 °C; **7**: > 105 °C) proceeds with release of ethene, and no alteration in the five-membered metallacycle was indicated (IR) prior to deposition of cobalt. The expected tbp configuration was confirmed in the molecular structure of **7** (Figure 3).

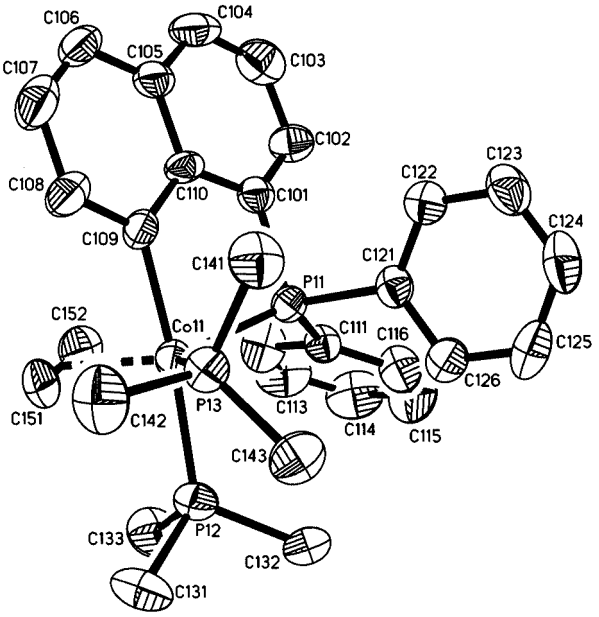


Figure 3. Molecular structure of **7** (molecule A) (QRTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C109 2.001(5), Co−C151 2.026(6), Co−C152 2.045(7), Co−P11 2.1830(16), Co−P12 2.2413(18), Co−P13 2.2097(17), P11−C101 1.821(6), C101−C110 1.409(7), C109−C110 1.432(7); C109−Co−P11 83.82(16), C109−Co−P12 174.07(16), C109−Co−P13 88.06(17), P11−Co−P12 99.20(6), P11−Co−P13 105.74(6), P12−Co−P13 95.98(7), Co−P11−C101 102.55(18), P11−C101−C110 111.0(4), C101−C110−C109 119.0(5), Co−C109−C110 118.5(4)

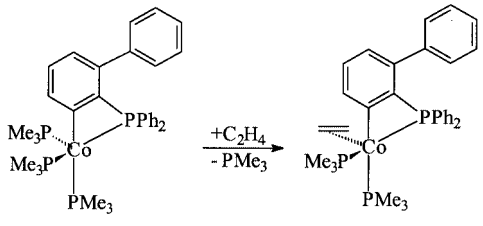
A cobalt atom is found in the central position of a trigonal bipyramid with axial C and PMe_3 donor groups and a side-on coordinated ethene ligand with its C−C vector arranged in the equatorial plane, although crowded by PPh_2 and PMe_3 groups. The chelate bite angle [C109−Co−P = 83.82(16)°] is only 2° larger than in **1**, and the axial P−Co distance [Co−P12 = 2.2413(18) Å] is again the longest in the molecule, due to the *trans* influence of the naphthyl ligand.

Irrespective of the ring size or the heteroatom in P,C-, P,N-, and P,O-cobaltocycles, coordination of ethene in tbp complex molecules is regioselective, due to a better overlap with the strongest π-acceptor ligand in an equatorial position.[6]

A smooth replacement of trimethylphosphane by ethene also proceeds [Equation (8)] with complex **3**, which contains a four-membered cobaltocycle.

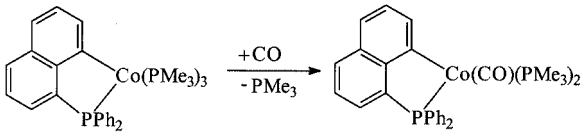


3 **8** (8)

Three doublets of doublets in the ^{31}P NMR spectrum of **8**, at δ = −11, 9, and 21 ppm, fall in the positions corresponding to a four-membered cobaltocycle expected from data for *ortho*-metalated compounds[1] and indicate an equatorial position of the π-ethene ligand.

Reaction with Carbon Monoxide

In solution under 1 bar of CO at 20 °C, **2** forms a monocarbonyl complexe **9** [Equation (9)].



2 **9** (9)

The dark red crystals of **9** are thermally about 30 K more stable than their parent trimethylphosphane compound and are less air-sensitive. ^{31}P NMR spectra obtained from THF solutions show a mixture of isomers with $J_{P,P}$ coupling constants consistent with tbp configurations in which a terminal carbonyl ligand resides either in an axial or in an equatorial position. In toluene solution, only the isomer with axial CO is observed.

The molecular structure of **9** (Figure 4) shows the tbp configuration of the isomer containing an equatorial carbonyl ligand and, in view of the otherwise similar infrared spectra, confirms the presence of a five-membered cobaltocycle in **2**. The chelate bite angle in **9** [C38−Co−P1 = 83.97(12)°] is as in **7**, and the sum of internal angles (534.7°) indicates little deviation from planarity. The Co−CO dis-

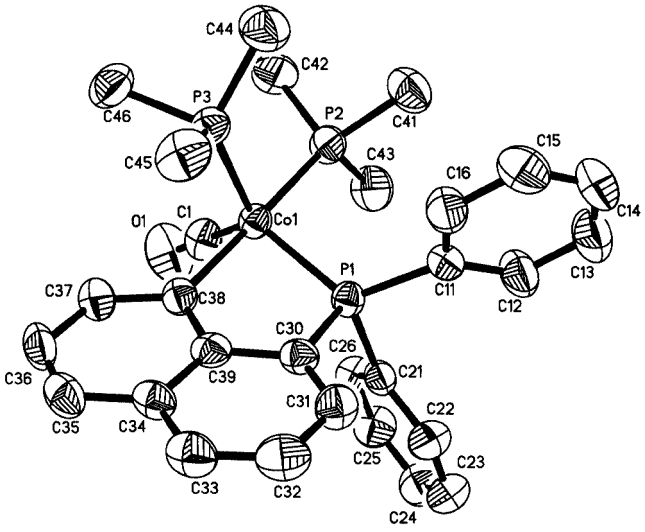


Figure 4. Molecular structure of **9** (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C38 1.996(4), Co−C1 1.720(5), Co−P1 2.1753(12), Co−P2 2.1935(13), Co−P3 2.2213(13), P1−C30 1.824(4), C30−C39 1.410(6), C38−C39 1.445(5); C38−Co−P1 83.97(12), C38−Co−P2 176.71(13), C38−Co−P3 85.07(12), P1−Co−P2 98.10(5), P1−Co−P3 113.16(5), P2−Co−P3 96.41(5), Co−P1−C30 103.09(14), P1−C30−C39 110.1(3), C30−C39−C38 119.6(4), Co−C38−C39 118.0(3)

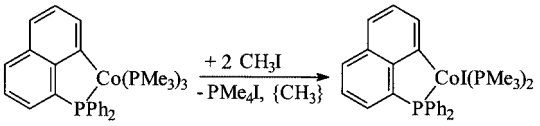
tance [Co−C1 = 1.720(5) Å] is at the short end of the range for monocarbonylcobalt(I) complexes although in most cases the CO ligand occupies an axial position.[7]

Reactions with Iodomethane

Iodomethane oxidizes **2** [Equation (10)] to form a cobalt(II) complex **10** without there being evidence of a cobalt(III) intermediate.[1a] Although the molecular geometry of **10** has not been clarified, the magnetic moment of 1.91 is as would be expected for a tbp configuration at the cobalt atom (d^7).[1a,8]



2 **10** (10)

Conclusion

The irreversible cyclometalation processes with $[CoCH_3(PMe_3)_4]$ appear to depend on the conformation of the 2-substituent when accommodated within the first coordination sphere of the metal atom. As soon as proximity to the electron-rich metal center is optimized, the product is formed by a sequence of fast steps involving oxidative addition of an aliphatic or an aromatic CH group, followed by elimination of methane. The ring size of the C,P-cobaltocycles in the product complex may be four, five, or six and does not dictate the regiospecificity of the cyclometalation reaction. Neither cobaltocycle inserts a π-coordinated ethene ligand into the Co−C bond and neither is expanded by CO uptake as with four-membered cobaltocycles.[1]

Experimental Section

General Procedures and Materials: All air-sensitive and volatile materials were handled by use of standard vacuum techniques and were kept under argon. Microanalyses: Kolbe Microanalytical Laboratory, Mülheim/Ruhr, FRG. Melting points/decomposition temperatures: sealed capillaries, uncorrected values. Chemicals (Merck/Schuchardt) were used as purchased. Literature methods were applied in the preparation of 1-iodo-8-methylnaphthalene,[9] 5-(diphenylphosphanyl)-1,2,3,4-tetrahydronaphthalene,[10] 2-(diphenylphosphanyl)biphenyl,[11] 2-(diphenylphosphanyl)stryrene,[12] and $[CoCH_3(PMe_3)_4]$.[13] IR: Nujol mulls between KBr discs, Bruker spectrophotometer type FRA 106. ^1H and ^{13}C NMR spectra (300 MHz and 75 MHz, respectively) were recorded with a Bruker ARX 300 spectrometer, ^{31}P NMR spectra (81 MHz) with a Bruker AM 200 instrument. ^{13}C and ^{31}P resonances were obtained with broad-band proton decoupling. Magnetic susceptibility data were obtained by the Faraday method with a Cahn D 200 torsion balance (Bruker) at 1.5 Tesla.

1-(Diphenylphosphanyl)-8-methylnaphthalene: *n*BuLi (9.7 mL 1.6 N in hexane, 15.7 mmol) was added slowly at −70 °C to 1-iodo-8-methylnaphthalene (4.20 g, 15.7 mmol) in 50 mL of diethyl ether, and the mixture was allowed to warm to −30 °C. After 2 h, chlorodiphenylphosphane (3.45 g, 15.7 mmol) was added, and the resulting suspension was stirred at 20 °C for 4 h. The volatiles were then removed in vacuo and the residue was extracted with two portions of methylcyclohexane (each 50 mL). On cooling of the combined extracts to 4 °C, white cubic crystals (1.89 g, 37%) were formed; m.p. 131−132 °C. ^1H NMR (300 MHz, CD_2Cl_2, 296 K): δ = 3.08 (d, $J_{P,H}$ = 4.2 Hz, 3 H, CH_3), 7.12 (ddd, ^3J = 6.5, $^4J_{P,H}$ = 5.0, ^4J = 1.5 Hz, 1 H, CH), 7.21−7.28 (m, 6 H, CH), 7.31−7.32 (m, 1 H, CH), 7.34 −7.38 (m, 6 H, CH), 7.73 (d, ^3J = 7.9 Hz, 1 H, CH), 7.85 (dd, ^3J = 8.1, ^4J = 1.4 Hz, 1 H, CH) ppm. ^{13}C NMR (75.4 MHz, CD_2Cl_2, 296 K): δ = 27.5 (d, $^1J_{P,C}$ = 32.0 Hz, CH_3), 125.2 (s, CH), 125.9 (s, CH), 126.6 (d, $^2J_{P,C}$ = 16.3 Hz, C), 128.5 (s, CH), 129.2 (d, $^2J_{P,C}$ = 16.5 Hz, CH), 131.3 (s, CH), 131.9 (s, CH), 132.2 (m, CH), 134.6 (d, $^3J_{P,C}$ = 20.4 Hz, CH), 135.5 (d, $^3J_{P,C}$ = 29.3 Hz, C), 135.9 (s, CH), 136.0 (s, C), 136.7 (s, C), 139.1 (d, $^2J_{P,C}$ = 14.0 Hz, C) ppm. ^{31}P NMR (81 MHz, CD_2Cl_2, 296 K): δ = −0.5 ppm. $C_{23}H_{19}P$ (326.2): calcd. C 84.64, H 5.87; found C 84.17, H 5.98.

[{8-(Diphenylphosphanyl)-1,2,3,4-tetrahydronaphthyl-(*C*^{1},*P*)}tris-(trimethylphosphane)cobalt(I)] (1): 5-(Diphenylphosphanyl)-1,2,3,4-tetrahydronaphthalene (685 mg, 2.16 mmol) in THF (50 mL) was mixed at −70 °C with $[CoCH_3(PMe_3)_4]$ (820 mg, 2.16 mmol) in THF (50 mL). On warming, the mixture turned red-brown and was stirred at 20 °C for 16 h. The volatiles were then removed in vacuo, and the waxy residue was extracted with pentane (two 50-mL portions). At 4 °C, the solution afforded deep-red octahedral crystals of **1**, suitable for X-ray diffraction. Yield 535 mg (41%); m.p. 121−123 °C. ^1H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.98 (d, $^2J_{P,H}$ = 6.3 Hz, 9 H, PCH_3), 1.08 (m, 1 H, CoCH), 1.25 (m, 18 H, PCH_3), 2.20 (m, 2 H, CH_2), 2.48 (m, 2 H, CH_2), 2.63 (dd, $^2J_{P,H}$ = 8.2, 7.6 Hz, 2 H, CH_2), 5.89 (m, 1 H, CH), 6.75−6.79 (m, 2 H, CH), 7.09−7.12 (m, 6 H, CH), 7.52−7.55 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 21.7 (m, PCH_3), 23.1 (m, CoCH), 23.9 (m, CH_2), 25.6 (m, CH_2), 27.4 (m, CH_2), 123.1(d, $^3J_{P,C}$ = 4.3 Hz, CH), 125.4 (s, CH), 126.1 (d, $^3J_{P,C}$ = 7.6 Hz, CH), 126.2 (s, CH), 126.5 (s, CH), 131.9 (d, $^2J_{P,C}$ = 13.0 Hz, CH), 133.6 (s, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = −3 (dd, $^2J_{Peq,Peq}$ = 97, $^2J_{Peq,Pax}$ = 53 Hz, 2 P, PCH_3), 24 (dt, $^2J_{Pax,Peq}$ = 53, $^2J_{Pax,Peq}$ = 53 Hz, 1 P, PCH_3), 64 (dt, $^2J_{Peq,Peq}$ = 97, $^2J_{Peq,Pax}$ = 53 Hz, 1 P, PPh_2) ppm. $C_{31}H_{47}CoP_4$ (602.5): calcd. C 61.79, H 7.86, P 20.56; found C 61.47, H 7.47, P 21.05.

[{8-(Diphenylphosphanyl)naphthyl-(*C*^{1},*P*)}tris(trimethylphosphane)-cobalt(I)] (2): 1-(Diphenylphosphanyl)naphthalene (710 mg, 2.27 mmol) in THF (50 mL) was mixed at −70 °C with $[CoCH_3(PMe_3)_4]$ (860 mg, 2.27 mmol) in THF (50 mL). On warming, the mixture turned red-brown and was stirred at 20 °C for 16 h. The volatiles were then removed in vacuo, and the waxy residue was extracted with diethyl ether (three 80-mL portions). At −27 °C, the solution afforded black rhombuses of **2**. Yield 1150 mg (85%); m.p. 107−109 °C (dec.). ^1H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 1.01 (d, $^2J_{P,H}$ = 6.4 Hz, 9 H, PCH_3), 1.09 (m, 18 H, PCH_3), 6.88 (t, ^3J = 7.6 Hz, 1 H, CH), 7.12 (m, 2 H, CH), 7.19−7.21 (m, 2 H, CH), 7.39−7.47 (m, 7 H, CH), 7.61−7.69 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 21.9 (dd, $^1J_{P,C}$ = 14.2, $^3J_{P,C}$ = 7.6 Hz, PCH_3), 22.5 (m, PCH_3), 117.6 (s, CH), 122.6 (s, CH), 122.8 (d, $^3J_{P,C}$ = 6.1 Hz, CH), 124.6 (s, CH), 126.2 (d, $^3J_{P,C}$ = 7.6 Hz, CH), 126.4 (s, CH), 127.2 (s, CH), 131.6 (d, $^1J_{P,C}$ = 15.2 Hz, C), 132.2 (d, $^2J_{P,C}$ = 12.2 Hz, CH), 139.8 (d, $^2J_{P,C}$ = 12.2 Hz, C), 142.3 (m, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = −3 (dd, $^2J_{Peq,Peq}$ = 100, $^2J_{Peq,Pax}$ = 54 Hz, 2 P, PCH_3),

24 (dt, $^2J_{Pax,Peq}$ = 54, $^2J_{Pax,Peq}$ = 54 Hz, 1 P, PCH_3), 64 (dt, $^2J_{Peq,Peq}$ = 100, $^2J_{Peq,Pax}$ = 54 Hz, 1 P, PPh_2) ppm. $C_{31}H_{43}CoP_4$ (598.5): calcd. C 62.21, H 7.24, P 20.70; found C 61.43, H 7.36, P 21.11.

[{2-(Diphenylphosphanyl)-3-phenylphenyl-(C^1,P)}tris(trimethylphosphane)cobalt(I)] (3): 2-(Diphenylphosphanyl)biphenyl (608 mg, 1.79 mmol) in THF (50 mL) was mixed at −70 °C with $[CoCH_3(PMe_3)_4]$ (680 mg, 1.79 mmol) in THF (30 mL). After warming, the dark red mixture was stirred at 20 °C for 5 h, and the volatiles were then removed in vacuo. The solid residue was extracted with pentane (80 mL). No crystallization was achieved either at 4 or at −27 °C from pentane, diethyl ether, THF, or mixtures of these solvents. Evaporation of solvent afforded **3** as a dark-red, waxy solid. Crude yield 940 mg. ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 1.05 (d, $^2J_{P,H}$ = 6.4 Hz, 9 H, PCH_3), 1.30 (t′, $|^2J_{P,H} + {}^4J_{P,H}|$ = 4.6 Hz, 18 H, PCH_3), 5.40−7.70 (m, 18 H, CH) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = −21 (dt, $^2J_{Peq,Peq}$ = 90, $^2J_{Peq,Pax}$ = 71 Hz, 1 P, PPh_2), −4 (dd, $^2J_{Peq,Peq}$ = 90, $^2J_{Peq,Pax}$ = 48 Hz, 2 P, PCH_3), 21 (dt, $^2J_{Pax,Peq}$ = 71, $^2J_{Pax,Peq}$ = 48 Hz, 1 P, PCH_3) ppm.

[{[8-(Diphenylphosphanyl)naphth-1-yl]methyl-(C,P)}tris(trimethylphosphane)cobalt(I)] (4): 1-(Diphenylphosphanyl)-8-methylnaphthalene (740 mg, 2.26 mmol) in THF (50 mL) was added at −78 °C to a solution of $[CoCH_3(PMe_3)_4]$ (857 mg, 2.26 mmol) in THF (50 mL). A rapid change of color from dark red to brown was observed as the solution warmed up. After 5 h, the solvent was removed in vacuo and the residue was extracted with pentane (two portions of 50 mL). Crystallization at 4 °C afforded dark brown cubes of **4**, suitable for X-ray diffraction. Yield 625 mg (45%); m.p. 146−148 °C (dec.). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 1.02 (s, 27 H, PCH_3), 1.92 (q, $^3J_{P,H}$ = 11.7 Hz, 2 H, $CoCH_2$), 6.72 (dt, ^3J = 7.5, ^4J = 0.8 Hz, 1 H, CH), 7.03 (dt, ^3J = 7.8, ^4J = 2.5 Hz, 2 H, CH), 7.16−7.21 (m, 6 H, CH), 7.31−7.33 (m, 2 H, CH), 7.42−7.47 (m, 4 H, CH), 7.67 (d, ^3J = 8.0 Hz, 1 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 11.6 (m, $CoCH_2$), 19.8 (m, PCH_3), 122.0 (d, $^3J_{P,C}$ = 4.3 Hz, CH), 125.4 (s, CH), 126.1 (d, $^3J_{P,C}$ = 7.6 Hz, CH), 126.2 (s, CH), 126.5 (s, CH), 131.9 (d, $^2J_{P,C}$ = 13.0 Hz, CH), 133.6 (s, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 203 K): δ = −3 (dd, $^2J_{Peq,Peq}$ = 102, $^2J_{Peq,Pax}$ = 40 Hz, 2 P, PCH_3), 20 (dt, $^2J_{Pax,Peq}$ = 46, $^2J_{Pax,Peq}$ = 40 Hz, 1 P, PCH_3), 48 (dt, $^2J_{Peq,Peq}$ = 102, $^2J_{Peq,Pax}$ = 46 Hz, 1 P, PPh_2) ppm. $C_{32}H_{45}CoP_4$ (612.5): calcd. C 62.75, H 7.40, P 20.23; found C 62.72, H 7.38, P 20.39.

[{2-(Diphenylphosphanyl)styrene-(C,C-η^2,P)}methylbis(trimethylphosphane)cobalt(I)] (5): 2-(Diphenylphosphanyl)stryrene (571 mg, 1.98 mmol) in diethyl ether (40 mL) was mixed at −70 °C with $[CoCH_3(PMe_3)_4]$ (750 mg, 1.98 mmol) in diethyl ether (40 mL). After warming, the orange mixture was stirred at 20 °C for 3 h, and the volume was then reduced to 40 mL. Pentane (50 mL) was added with vigorous stirring to precipitate **5** as a light brown solid. This was isolated by filtration and washing with pentane. Yield 652 mg (64%); m.p. 152−154 °C (dec.). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = −0.85 (dt, $^3J_{P,H}$ = 8.1, 1.8 Hz, $CoCH_3$), 0.78 (d, $^2J_{P,H}$ = 5.6 Hz, 9 H, PCH_3), 1.30 (d, $^2J_{P,H}$ = 5.5 Hz, 9 H, PCH_3), 1.80 (m, 2 H, $=CH_2$), 2.64 (m, 1 H, =CH), 6.86 (t, ^3J = 7.3 Hz, CH), 7.01 (dt, ^3J = 6.3, ^4J = 1.3 Hz, 1 H, CH), 7.18 (t, ^3J = 6.7 Hz, 1 H, CH), 7.26−7.31 (m, 6 H, CH), 7.31−7.33 (m, 1 H, CH), 7.38−7.41 (m, 2 H, CH), 7.77−7.83 (m, 2 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 17.6 (d, $^1J_{P,C}$ = 14.7 Hz, PCH_3), 18.9 (d, $^1J_{P,C}$ = 16.7 Hz, PCH_3), 50.8 (s, $=CH_2$), 62.1 (d, $^2J_{P,C}$ = 18.2 Hz, =CH), 121.7 (d, $^4J_{P,C}$ = 4.1 Hz, CH), 123.4 (d, $^2J_{P,C}$ = 112.6 Hz, CH), 126.4 (d, $^3J_{P,C}$ = 7.9 Hz, CH), 126.7 (d, $^3J_{P,C}$ = 7.7 Hz, CH), 127.3 (s, CH), 127.8 (s, CH), 130 (s, CH), 132.8 (d, $^2J_{P,C}$ = 10.5 Hz, C), 133.2 (d, $^2J_{P,C}$ = 9.8 Hz, CH), 137.8 (s, C), 138.4 (s, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = 9 (dd, $^2J_{Peq,Pax}$ = 44, $^2J_{Peq,Pax}$ = 26 Hz, 2 P, PCH_3), 71 (dd, $^2J_{Pax,Peq}$ = 26, $^2J_{Pax,Peq}$ = 44 Hz, 1 P, PPh_2) ppm. $C_{27}H_{38}CoP_3$ (514.2): calcd. C 63.04, H 7.45, P 18.06; found C 63.44, H 6.79, P 18.18.

[{8-(Diphenylphosphanyl)-1,2,3,4-tetrahydronaphthyl-(C^1,P)}-(ethene)bis(trimethylphosphane)cobalt(I)] (6): A sample of **3** (620 mg, 1.03 mmol) in diethyl ether (30 mL) was stirred under 1 bar of ethene for 1 h to provide an orange-red solution. The volatiles were removed in vacuo and the solid residue was extracted with pentane (40 mL). Crystallization at 4 °C afforded orange, hexagonal plates of **6**. Yield 490 mg (86%); m.p. 101−103 °C (dec.). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.98 (d, $^2J_{P,H}$ = 6.3 Hz, 9 H, PCH_3), 1.08 (m, 1 H, CoCH), 1.25 (br. s, 9 H, PCH_3), 2.19−2.21 (m, 2 H, CH_2), 2.48 (m, 2 H, CH_2), 2.63 (dd, ^3J = 8.2, ^3J = 7.6 Hz, 2 H, CH_2), 5.89 (m, 1 H, CH), 6.75−6.79 (m, 2 H, CH), 7.09−7.12 (m, 2 H, CH), 7.52−7.55 (m, 4 H, CH) ppm. ^{1}H NMR (300 MHz, [D$_8$]toluene, 296 K): δ = 0.53 (d, $^2J_{P,H}$ = 6.4 Hz, 9 H, PCH_3), 0.86 (m, 1 H, CoCH), 1.05 (d, $^2J_{P,H}$ = 5.0 Hz, 9 H, PCH_3), 1.88−2.54 (m, 6 H, CH_2), 1.90 (m, 2 H, $=CH_2$), 2.29 (m, 2 H, $=CH_2$), 5.35 (m, 1 H, CH), 6.42−6.59 (m, 2 H, CH), 6.92−7.03 (m, 2 H, CH), 7.61−7.84 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 16.3 (d, $^1J_{P,C}$ = 19.5 Hz, PCH_3), 19.1 (d, $^1J_{P,C}$ = 19.5 Hz, PCH_3), 23.4 (m, CoCH), 25.4 (m, CH_2), 27.6 (s, CH_2), 29.1 (s, CH_2), 39.2 (m, $=CH_2$), 40.9 (m, $=CH_2$), 121.1 (s, CH), 123.2 (d, $^3J_{P,C}$ = 5.2 Hz, CH), 124.7 (s, CH), 126.1 (d, $^2J_{P,C}$ = 12.3 Hz, C), 126.2 (d, $^1J_{P,C}$ = 15.1 Hz, C), 126.9 (d, $^2J_{P,C}$ = 12.7 Hz, CH), 127.2 (d, $^1J_{P,C}$ = 20.5 Hz, CH), 131.8 (d, $^1J_{P,C}$ = 16.3 Hz, C), 132. 4 (d, $^2J_{P,C}$ = 11.8 Hz, CH), 140.2 (s, C) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]toluene, 296 K): δ = 18.1 (d, $^1J_{P,C}$ = 18.4 Hz, PCH_3), 21.8 (d, $^1J_{P,C}$ = 19.3 Hz, PCH_3), 23.3 (m, CoCH), 26.8 (m, CH_2), 29.0 (s, CH_2), 30.5 (s, CH_2), 41.1 (d, $^2J_{P,C}$ = 18.2 Hz, $=CH_2$), 42.4 (d, $^2J_{P,C}$ = 16.4 Hz, $=CH_2$), 122.8 (s, CH), 124.7 (d, $^2J_{P,C}$ = 14.2 Hz, CH), 124.8 (s, CH), 127.6 (d, $^2J_{P,C}$ = 11.2 Hz, CH), 128.4 (s, C), 133.2 (d, $^3J_{P,C}$ = 10.5 Hz, CH), 133.5 (d, $^3J_{P,C}$ = 9.5 Hz, CH), 134.4 (d, $^2J_{P,C}$ = 16.1 Hz, C), 141.7 (d, $^2J_{P,C}$ = 22.6 Hz, CH), 155.0 (d, $^1J_{P,C}$ = 43.7 Hz, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 213 K): δ = 5 (dd, $^2J_{Peq,Pax}$ = 46, $^2J_{Peq,Peq}$ = 38 Hz, 1 P, PCH_3), 17 (dd, $^2J_{Pax,Peq}$ = 32, $^2J_{Pax,Peq}$ = 46 Hz, 1 P, PCH_3), 75 (dd, $^2J_{Peq,Pax}$ = 32, $^2J_{Peq,Peq}$ = 38 Hz, 1 P, PPh_2) ppm. $C_{30}H_{42}CoP_3$ (554.5): calcd. [{2-(Diphenylphosphanyl)-3-phenylphenyl-(*C*^{1},*P*)}(ethene)bis(trimethylphosphane)cobalt(I)] (8): A sample of **3** (940 mg, ca. 1.5 mmol) in THF (40 mL) was stirred under 1 bar of ethene for 3 h. The volatiles were removed in vacuo, and the oily residue was extracted with pentane (50 mL). Crystallization at 4 °C afforded short, orange rods of **8.** Yield 503 mg (58%); m.p. 95−97 °C (dec.). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.82 (d, $^2J_{P,H}$ = 6.3 Hz, 9 H, PCH_3), 1.10 (d, $^2J_{P,H}$ = 5.9 Hz, 9 H, PCH_3), 1.66 (m, 1 H, =CH), 1.91 (m, 2 H, $=CH_2$), 2.31 (m, 1 H, =CH), 6.51 (m, 1 H, CH), 6.72 (dd, ^3J = 5.0, ^4J = 1.5 Hz, 2 H, CH), 7.15 (dd, ^3J = 6.8, ^4J = 1.6 Hz, 1 H, CH), 7.17 (dd, ^3J = 8.3, ^4J = 1.3 Hz, 1 H, CH), 6.85 (m, 3 H, CH), 6.95 (dd, ^3J = 7.3, ^4J = 1.4 Hz, 1 H, CH), 7.16 (dd, ^3J = 7.2, ^4J = 1.5 Hz, 1 H, CH), 7.21 (m, 6 H, CH), 7.41(dd, ^3J = 9.4, ^4J = 1.5 Hz, 1 H, CH), 7.42 (m, 2 H, CH), 7.68 (dd, ^3J = 9.4, ^4J = 1.9 Hz, 1 H, CH), 7.70 (dd, ^3J = 5.8, ^4J = 2.6 Hz, 1 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 16.5 (d, $^1J_{P,C}$ = 18.1 Hz, PCH_3), 20.3 (d, $^1J_{P,C}$ = 18.4 Hz, PCH_3), 32.5 (d, $^2J_{P,C}$ = 10.4 Hz, $=CH_2$), 38.8 (d, $^2J_{P,C}$ = 18.1 Hz, $=CH_2$), 121.5 (s, CH), 124.7 (s, CH), 125.9 (s, CH), 126.6 (d, $^2J_{P,C}$ = 8.8 Hz, CH), 127.1 (s, CH), 127.8 (s, CH), 128.2 (s, CH), 128.6 (d, $^1J_{P,C}$ = 15.2 Hz, C), 131.9 (d, $^2J_{P,C}$ = 12.1 Hz, CH), 132.2 (d, $^2J_{P,C}$ = 12.2 Hz, CH), 135.6 (d, $^1J_{P,C}$ = 16.4 Hz, CH), 136.9 (s, C), 139.1 (d, $^1J_{P,C}$ = 17.5 Hz, C), 140.7 (d, $^3J_{P,C}$ = 4.3 Hz, C), 146.4 (s, C), 153.0 (m, CoC) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = −11 (dd, $^2J_{Peq,Pax}$ = 47, $^2J_{Peq,Peq}$ = 51 Hz, 1 P, PPh_2), 9 (dd, $^2J_{Pax,Peq}$ = 31, $^2J_{Pax,Peq}$ = 47 Hz, 1 P, PCH_3), 21 (dd, $^2J_{Peq,Pax}$ = 31, $^2J_{Peq,Peq}$ = 51 Hz, 1 P, PCH_3) ppm. $C_{32}H_{40}CoP_3$ (576.2): calcd. C 66.67, H 6.99, P 16.22; found C 66.45, H 7.41, P 16.14.

[(Carbonyl){2-(diphenylphosphanyl)naphthyl-(*C*^{1},*P*)}bis(trimethylphosphane)cobalt(I)] (9): A sample of **2** (770 mg, 1.28 mmol) in THF (40 mL) was stirred under 1 bar of CO for 1 h to provide a light red solution. The volatiles were removed in vacuo, and the solid residue was extracted with pentane (three 70-mL portions). Crystallization at −27 °C afforded short, orange rods of **9** suitable for X-ray diffraction. Yield 616 mg (87%); m.p. 112−114 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1905 cm^{-1} (C≡O). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): CO-eq isomer (12%): δ = 0.68 (d, $^2J_{P,H}$ = 6.3 Hz, 18 H, PCH_3), 1.12 (d, $^2J_{P,H}$ = 7.9 Hz, 18 H, PCH_3), 7.01−8.02 (m, 16 H, CH) ppm; CO-ax isomer (88%): δ = 0.69 (d, $^2J_{P,H}$ = 6.3 Hz, 9 H, PCH_3), 1.00 (t′, $|^2J_{P,H} + {}^4J_{P,H}|$ = 6.8 Hz, 18 H, PCH_3), 1.19 (d, $^2J_{P,H}$ = 7.9 Hz, 9 H, PCH_3), 7.08 (d, ^3J = 6.6 Hz, 1 H, CH), 7.10 (t, ^3J = 7.4 Hz, 1 H, CH), 7.26−7.29 (m, 8 H, CH), 7.43−7.49 (m, 4 H, CH), 7.61 (d, ^3J = 6.9 Hz, 1 H, CH), 7.70 (d, ^3J = 6.9 Hz, 1 H, CH), 7.84 (d, ^3J = 7.0 Hz, 1 H, CH), 7.97 (d, ^3J = 8.2 Hz, 1 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K) CO-ax isomer (88%): δ = 19.8 (m, PCH_3), 120.5 (s, C), 125.5 (d, $^3J_{P,C}$ = 5.4 Hz, CH), 125.8 (s, CH), 126.5 (s, C), 128.6 (d, $^1J_{P,C}$ = 15.5 Hz, C), 128.8 (d, $^2J_{P,C}$ = 8.4 Hz, CH), 129.4 (s, CH), 130.4 (s, CH), 132.6 (d, $^2J_{P,C}$ = 12.7 Hz, CH), 133.3 (s, C), 134.7 (d, $^1J_{P,C}$ = 14.3 Hz, C), 138.9 (m, CH), 141.6 (s, C), 142.0 (s, C), 203.2 (s, CO) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K) CO_{ax} isomer (12%): δ = 5 (d, $^2J_{Peq,Peq}$ = 96 Hz, 2 P, PCH_3), 63 (t, $^2J_{Peq,Peq}$ = 96 Hz, 1 P, PPh_2) ppm; CO_{eq} isomer (88%): δ = −1 (dd, $^2J_{Peq,Peq}$ = 81, $^2J_{Peq,Pax}$ = 48 Hz, 1 P, PCH_3), 23 (dd, $^2J_{Pax,Peq}$ = 48, $^2J_{Pax,Peq}$ = 48 Hz, 1 P, PCH_3), 70 (dd, $^2J_{Peq,Peq}$ = 81, $^2J_{Peq,Pax}$ = 48 Hz, PPh_2) ppm. $C_{29}H_{34}CoOP_3$ (550.4): calcd. C 63.28, H 6.23, P 16.88; found C 62.67, H 5.78, P 17.30.

[{2-(Diphenylphosphanyl)naphthyl-(*C*^{1},*P*)}iodobis(trimethylphosphane)cobalt(II)] (10): A sample of **2** (670 mg, 1.12 mmol) in diethyl ether (50 mL) was mixed at −70 °C with iodomethane (365 mg, 2.57 mmol, slight excess). After 1 h at 20 °C, the mixture was filtered and the solution was kept at 4 °C to afford dark-brown crystals of **10**. The solid was extracted with diethyl ether (two 80-mL portions) to give a second fraction of **10**, which was combined with the first. Yield 421 mg (58%); m.p. 158−160 °C (dec.). Magnetic moment: μ_{eff} = 1.91 μ_B. $C_{28}H_{34}CoIP_3$ (649.3): calcd. C 51.79, H 5.28, P 14.31; found C 51.78, H 5.41, P 14.26.

Crystal Structure Analyses: Crystal data are presented in Tables 1 and 2. Complex **1**: A crystal was sealed under argon in a glass capillary and mounted on a Bruker AXS P4 diffractometer. Reflections were collected (ω-scans) by use of graphite-monochromated Mo-K_α radiation; a Lorentz polarization correction and an absorption correction based on ψ-scans were applied. The structure was solved by direct and conventional Fourier methods. All non-hydrogen atoms were treated anisotropically, hydrogen atoms were treated with a riding model in idealized positions. Complex **4**: Crystal mounting, data collection, structure solution, and refinement as for **1**. Complex **7**: Crystal mounting, data collection, structure solution, and refinement as for **1**. Two independent molecules per asymmetric unit. Complex **9**: Crystal mounting, data collection, structure solution, and refinement as for **1**. CCDC-184425 (**1**), -184426 (**4**), -184427 (**7**), and -184428 (**9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

A Comparison of Analogous 4f- and 5f-Element Compounds: Syntheses and X-ray Crystal Structures of the Mixed Sandwich Complexes $[M(\eta\text{-}C_8H_8)(L)\{OP(NMe_2)_3\}]$ (M = Nd or U; L = $\eta\text{-}C_5Me_5$ or $\eta\text{-}C_4Me_4P$)

Sophie M. Cendrowski-Guillaume,*[a][‡] Gildas Le Gland,[a] Martine Nierlich,[a] and Michel Ephritikhine*[a]

Keywords: Cyclopentadienyl ligands / P ligands / Lanthanides / Actinides / Sandwich complexes

The series of complexes [M(COT)(L)(HMPA)] {M = Nd or U; COT = $\eta\text{-}C_8H_8$; L = $\eta\text{-}C_5Me_5$ (Cp^*) or $\eta\text{-}C_4Me_4P$ (tmp), HMPA = $OP(NMe_2)_3$} have been synthesized. [Nd(COT)(Cp^*)(HMPA)] (**1b**) was prepared by substitution of the THF ligand of [Nd(COT)(Cp^*)(THF)]; [Nd(COT)(tmp)(HMPA)] (**3**) was prepared by reaction of the neodymium cation $[Nd(COT)(THF)_4][BPh_4]$ with Ktmp followed by the addition of HMPA to the dimeric compound $[Nd(COT)(tmp)]_2$ (**2**); [U(COT)(Cp^*)(HMPA)] (**4**) was isolated from the reaction of the uranium cation $[U(COT)(HMPA)_3][BPh_4]$ with KCp^*, and $[U(COT)(tmp)(HMPA)_2]$ (**5**) was obtained upon reduction of the uranium(IV) cation of $[U(COT)(tmp)(HMPA)_2][BPh_4]$ with sodium amalgam. The X-ray crystal structures of **1b**, **3**, and **4** have been determined. In the isostructural compounds **1b** and **4**, the differences between the U–C and Nd–C bond lengths are smaller than those predicted from the ionic radii of the trivalent ions; in particular, the average M–C(Cp^*) distances are equal to 2.77 Å for both M = Nd and U.

Introduction

The differentiation of trivalent lanthanide (Ln) and actinide (An) ions should be facilitated by the precise knowledge of the metal−ligand bond and the respective role of the 4f- and 5f-electrons. Such a discrimination between Ln^{III} and An^{III} complexes represents an important problem for both its fundamental aspects and its applications, especially in the management of nuclear wastes.[1] In this context, much attention is currently focused on highlighting the possible significant variations in the structural parameters of analogous Ln^{III} and U^{III} coordination complexes.[2−5]

Recently, we reported the synthesis and structural characterization of the unique cyclooctatetraenyllanthanide cation $[Nd(COT)(L)_x][BPh_4]$ {COT = $\eta\text{-}C_8H_8$; L = THF and x = 4; L = $OP(NMe_2)_3$ (HMPA) and x = 3},[6,7] of the first cationic monocyclooctatetraenyluranium(III) complex, the analog $[U(COT)(HMPA)_3][BPh_4]$,[7] and of the first organometallic dication of an f-element, $[U(COT)(HMPA)_3][BPh_4]_2$.[8] These cationic compounds form the $[M(COT)(HMPA)_3]^{n+}$ series (M = Nd and n = 1; M = U and n = 1 or 2), which allowed a direct structural comparison of the Nd^{III}/U^{III} and U^{III}/U^{IV} analogous derivatives.[7] These investigations revealed that the variations in the metal−ligand bond lengths were proportional to the differences in the ionic radii of the metals.

In contrast to the numerous mixed cyclooctatetraenyl-/cyclopentadienyllanthanide complexes characterized by X-ray crystallography,[9] the only such compound of actinide(III) is [U(COT)(Cp*)(Me_2bpy)] (Cp* = $\eta\text{-}C_5Me_5$; Me_2bpy = 4,4′-dimethyl-2,2′-bipyridine).[10] While phospholyl derivatives of the f-elements are well known,[11−13] a few mixed cyclooctatetraenyl/phospholyl complexes of Nd^{III}, Sm^{III},[14] and U^{III} [15] have been recently isolated; the crystal structures of [Nd(COT)(Dsp)(THF)] {Dsp = 3,4-dimethyl-2,5-bis(trimethylsilyl)phospholyl}[14] and [U(COT)(tmp)(BH_4)(THF)] (tmp = $\eta\text{-}C_4Me_4P$)[15] have been determined.

Here we present the syntheses and X-ray crystal structures of the analogous neutral complexes in the mixed COT/Cp* or tmp series, [M(COT)(L)(HMPA)] with M = Nd or U and L = Cp* or tmp.

Results and Discussion

Synthesis and Characterization

The borohydride and cationic compounds $[Nd(COT)(BH_4)(THF)]_2$,[6a] and $[Nd(COT)(THF)_4][BPh_4]$,[6,7] proved to be valuable precursors for the synthesis of monocyclooctatetraenyllanthanide derivatives;[6,7,16] they are also at the origin of the neodymium

complexes studied in the present work. The mixed COT/Cp* sandwich derivative [Nd(COT)(Cp*)(THF)] was prepared in high yield from either the neutral or cationic parent complex, the procedure using the cation being more efficient and more selective.[6] Exchanging the THF solvent molecule for HMPA gave the green derivative [Nd(COT)(Cp*)(HMPA)$_2$] (**1a**) in 93% yield; green crystals of [Nd(COT)(Cp*)(HMPA)] (**1b**) were obtained by crystallization from THF/pentane. These complexes are the only examples among the [Ln(COT)(Cp*)] series (Ln = Sc, Y, La, Pr, Sm, Gd, Tb, Dy, Er, Lu) that have not been prepared by a metathesis reaction from a lanthanide chloride precursor.[9] Addition of Ktmp to a THF solution of [Nd(COT)(THF)$_4$][BPh$_4$] afforded the mixed COT/tmp compound [Nd(COT)(tmp)]$_2$ (**2**), which was obtained as a green powder in 75% yield. Considering that the Nd(COT)(Cp*) species was isolated as the THF adduct [Nd(COT)(Cp*)(THF)], it is very likely that the isosteric moiety Nd(COT)(tmp), which is less electron-rich because the tmp group is less electron-donating than the Cp* ligand,[12] adopts in the solid state a dimeric structure ensured by a μ-η^5,η^1-bridging tmp ligand. The ability of the phospholyl ligand to bridge two metal centers through the available lone pair on the P atom is well documented, and can be illustrated with the structures of the U^{III} complexes [U(tmp)$_2$(BH$_4$)]$_2$ and [U(tmp)(Cp*)(BH$_4$)]$_2$.[13] Complex **2** certainly forms monomeric adducts in coordinating solvents and with Lewis bases; in the presence of HMPA, it was readily transformed into the dark green derivative [Nd(COT)(tmp)(HMPA)] (**3**), which crystallized from THF/pentane.

Treatment of [U(COT)(HMPA)$_3$][BPh$_4$] with KCp* led to the formation of [U(COT)(Cp*)(HMPA)] (**4**), which was isolated as dark brown crystals in 70% yield. The adducts U(COT)(Cp*)(L) (L = THF, Me$_2$bpy) have been synthesized in THF from the reaction of [U(Cp*)I$_2$(THF)$_2$] and K$_2$COT, in the presence of Me$_2$bpy for the latter.[10] The dark brown powder of [U(COT)(tmp)(HMPA)$_2$] (**5**) was obtained in 57% yield after reduction of the uranium(IV) cation [U(COT)(tmp)(HMPA)$_2$][BPh$_4$] with sodium amalgam. A similar reduction of a cationic tetravalent cyclooctatetraenyluranium compound was already performed to make [U(COT)(HMPA)$_3$][BPh$_4$] from [U(COT)(HMPA)$_3$][BPh$_4$]$_2$.[7] Complex **5** is the first mixed cyclooctatetraenyl/phospholyl complex of uranium(III). Unfortunately, no crystals suitable for X-ray diffraction analysis could be obtained. The synthesis of **4** and **5** provide further examples of the usefulness of cationic uranium compounds as precursors of derivatives in the +3 oxidation state.

As previously observed with [U(COT)(tmp)(BH$_4$)(THF)] and [U(COT)(tmp)(HMPA)$_2$][BPh$_4$],[15] protonation of the tmp ligand of **2** and **5** with NEt$_3$HBPh$_4$ afforded the parent cationic complexes. Thus, **2** was transformed in THF into [Nd(COT)(THF)$_4$][BPh$_4$], while **5** also underwent oxidation to give [U(COT)(HMPA)$_3$][BPh$_4$]$_2$ (NMR spectroscopic experiments). Protonolysis of the U−P bond was also observed with the phosphido complex [U(NEt$_2$)$_3$(PPh$_2$)], which was transformed into [U(NEt$_2$)$_3$][BPh$_4$] by reaction with (NEt$_3$H)BPh$_4$.[17]

Complexes **1**−**5** were characterized by elemental analyses (except **4**) and ^{1}H NMR spectra. The crystal structures of **1b**, **3** and **4** have been determined.

Crystal Structures of [Nd(COT)(Cp*)(HMPA)], [Nd(COT)(tmp)(HMPA)], and [U(COT)(Cp*)(HMPA)]

The two analogous neodymium and uranium COT/Cp* complexes **1b** and **4** are isostructural; the crystal structure of **4** is shown in Figure 1. The crystal structure of **3**, the tmp analog of **1b**, is shown in Figure 2. Selected bond lengths and angles of the three complexes are listed in Table 1.

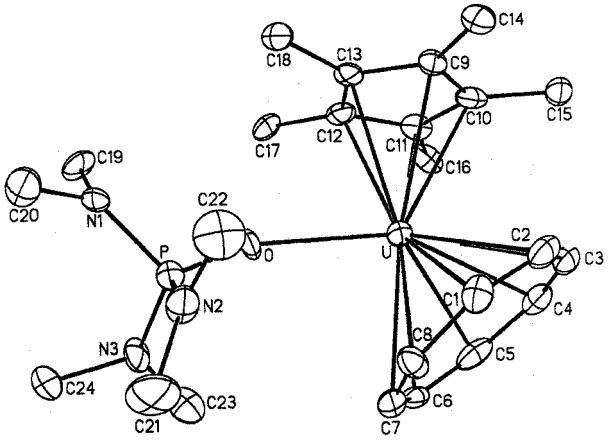

Figure 1. View of the crystal structure of [U(COT)(Cp*)(HMPA)] with thermal ellipsoids drawn at the 30% probability level

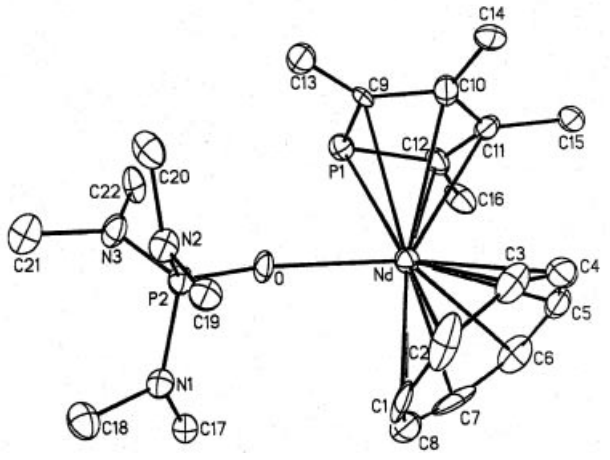

Figure 2. View of the crystal structure of [Nd(COT)(tmp)(HMPA)] with thermal ellipsoids drawn at the 30% probability level

These complexes adopt the same trigonal configuration as that encountered in [Nd(COT)(Dsp)(THF)][14] and [Gd(COT)(η-C$_5$H$_9$C$_5$H$_4$)(THF)],[18] considering the COT, Cp*, and tmp ligands as monodentate. Coordination of the COT ligand in **1b** and **3** is similar to that found in other monocyclooctatetraenylneodymium complexes; the Nd−COT(centroid) distances of 1.99(2) Å in **1b** and 1.97(1)

Table 1. Selected bond lengths [Å] and angles [°] for the complexes

Å in **3** can be compared with those measured in $[Nd(COT)(\eta\text{-}C_5H_9C_5H_4)(THF)_2]$ (2.011 Å),[18] [Nd(COT)(Dsp)(THF)] (1.94 Å),[14] and $[Nd(COT)(HMPA)_3][BPh_4]$ [1.984(5) Å].[7] The Cp* ligation in **1b** is also unexceptional; the Nd−Cp*(centroid) distance of 2.49(2) Å is similar to that of 2.48 Å in $[Nd(Cp^*)I_2(pyridine)_3]\cdot C_7H_8$.[19] In the crystal structure of **3**, the Nd−tmp(centroid) distance of 2.59(1) Å compares well with the corresponding value of 2.57 Å in [Nd(COT)(Dsp)(THF)];[14] the Nd−P bond length is equal to 3.0195(4) Å in the latter and to 2.968(8) Å in **3**. As previously observed in other analogous tmp and Cp* compounds,[12] the Nd−tmp(centroid) distance in **3** is longer, by 0.1 Å, than the Nd−Cp*(centroid) distance in **1b**. The Nd−O distances in **1b** and **3**, 2.441(3) and 2.434(8) Å, are longer than the average Nd−O bond length of 2.36(3) Å in $[Nd(COT)(HMPA)_3][BPh_4]$[7] while the Nd−C(COT) distances are practically the same. This feature likely results from the more positive charge on the cationic Nd^{III} center, which induces a stronger interaction with the Lewis base.

The structural parameters of the U(COT)(Cp*) unit in **4** are quite similar to those determined in $[U(COT)(Cp^*)(Me_2bipy)]$.[10] The U−COT(centroid) distance is equal to 2.01(1) Å in both compounds while the U−Cp*(centroid) distances are 2.50(1) and 2.49 Å, respectively. The U−O bond length of 2.46(1) Å in **4** is, here again, longer than the average U−O distance of 2.40(6) Å in the cation $[U(COT)(HMPA)_3][BPh_4]$[7] while the U−C(COT) distances are identical, reflecting the weaker interaction between the metal center and the oxygen donor ligand.

More interesting is the comparison of the crystal structures of the Nd^{III} and U^{III} analogs **1b** and **4**. In contrast to what was observed in the cations $[M(COT)(HMPA)_3]^+$ (M = Nd, U),[7] where the differences <U−O> − <Nd−O> and <U−C> − <Nd−C> perfectly reflect the +0.04 Å difference between the ionic radii of the trivalent uranium and neodymium ions,[20] it seems that the average U−O, U−C(COT), and U−C(Cp*) distances in **4** are shorter than those expected from a purely ionic model, the <U−X> − <Nd−X> differences (X = C or O) being lower than 0.04 Å. Most notably, there is no difference between the mean U−C(Cp*) and Nd−C(Cp*) bond lengths which are both equal to 2.77(3) Å. Similar small deviations (0.02−0.05 Å) between the differences in metal−ligand bond lengths and the differences in metal ionic radii, which must be considered with caution in view of the experimental errors, have previously been detected in the crystal structures of analogous uranium and lanthanide complexes with polydentate nitrogen ligands: $[M(Mentb)_2]X_3$ {M = La and X = ClO_4, M = U and X = I; Mentb = tris(*N*-methylbenzimidazol-2-ylmethyl)amine},[2] $[MI_3(tpa)(C_5H_5N)]$ {M = La or U; tpa = tris[(2-pyridyl)methyl]amine},[2] $[MI_3(bipy)(C_5H_5N)]$ (M = Ce or U; bipy = 2,2′-bipyridine),[3] and $[M(terpy)_3]I_3\cdot 2MeCN$ (M = La, Ce, Nd, U; terpy = 2,2′:6′,2″-terpyridine).[4] A difference of +0.047 Å was also measured between the average La−S and U−S distances in the complexes $[M(1,4,7\text{-trithiacyclononane})I_3(MeCN)_2]$ (M = La, U),[5] while the ionic radius of the U^{III} ion is only 0.01 Å shorter than that of the La^{III} ion.[20] It is solely in the phosphorous complexes $[M(\eta\text{-}C_5H_4Me)_3L]$ {M = Ce or U; L = PMe_3 or $P(OCH_2)_3CEt$}[21] and in the tris(btp) compounds $[M(btp)_3]I_3\cdot n C_5H_5N$ {M = Ce or U; btp = 2,6-bis(5,6-dialkyl-1,2,4-triazin-3-yl)pyridine}[4] that the U−P and U−N bond lengths were found to be significantly shorter, by 0.1 Å, than the Ce−P and Ce−N distances, while the ionic radius of the U^{III} ion is 0.01 Å longer than that of the Ce^{III} ion.[20] In all these pairs of analogous Ln^{III} and U^{III} complexes, the deviations of the U−X distances

(X = N, P, S) from the ionic bonding model have been explained by a stronger π back-bonding interaction between the metal atom and the ligand that is much less likely in the lanthanide analogs. If significant, the variations observed in the crystal structures of **1b** and **4**, especially the apparent shortening of the U−C(Cp*) bonds, could also be accounted for by a metal to ligand π back-donation which, as expected,[22] is more important and detectable than in the cationic parent compounds $[M(COT)(HMPA)_3][BPh_4]$ (M = Nd, U).

Conclusion

The synthesis of the mixed cyclooctatetraenyl/cyclopentadienyl or phospholyl compounds **1**−**5** further demonstrate the utility of cationic complexes as precursors in organo-f-element chemistry.[6−8,23] The crystal structures of the isostructural neodymium and uranium complexes **1b** and **4** revealed that the differences between the U−C and Nd−C bond lengths are smaller than those predicted from the ionic radii of the trivalent ions; in particular, the mean M−C(Cp*) distances are equal in both compounds. These structures would provide a unique example in which the more covalent character of the uranium−ligand bond is observed primarily with an anionic hydrocarbon ligand, and not a neutral Lewis base. Further studies on analogous Ln^{III} and U^{III} organometallic compounds are necessary to confirm these observations.

Experimental Section

General: All manipulations and reactions were carried out under argon (less than 3 ppm of oxygen and water) using standard Schlenk and vacuum-line techniques or in a glove box. Solvents were thoroughly dried and deoxygenated by standard methods and distilled immediately prior to use. Deuterated solvents were dried with Na/K alloys. The ^{1}H NMR spectra were recorded with a Bruker DPX 200 instrument and were referenced internally using the residual protio solvent resonances relative to tetramethylsilane (δ = 0). Elemental analyses were performed by the Analytische Laboratorien at Lindlar (Germany). $[Nd(COT)(THF)_4][BPh_4]$,[6] [Nd(COT)(Cp*)(THF)],[6] $[U(COT)(HMPA)_3][BPh_4]$,[7] and [U(COT)-(tmp)$(HMPA)_2$]$[BPh_4]$[15] were synthesized as previously reported.

Synthesis of [Nd(COT)(Cp*)$(HMPA)_2$] (1a): HMPA (10 μL, 10.3 mg, 57.48 μmol) was added to a solution of [Nd(COT)(Cp*)-(THF)] (13.03 mg, 28.60 μmol) in THF (5 mL). After 45 min, the green solution was concentrated to dryness. After washing with toluene (5 mL), the green powder of **1a** was dried under vacuum (19.7 mg, 93%). ^{1}H NMR ([D$_8$]THF): δ = 6.12 (br. s, $w_{1/2}$ = 27 Hz, 15 H, Cp*), 3.56 (br. s, $w_{1/2}$ = 21 Hz, 36 H, HMPA), −13.52 (br. s, $w_{1/2}$ = 67 Hz, 8 H, COT) ppm. $C_{30}H_{59}N_6O_2P_2Nd$ (741): calcd. C 48.56, H 8.01, N 11.32, P 8.35; found C 48.30, H 7.94, N 11.07. Green single crystals of **1b** were obtained at 20 °C within a week from a THF solution of [Nd(COT)(Cp*)(THF)] (24.1 mg, 52.88 μmol) and HMPA (28 μL, 28.8 mg, 160.94 μmol, 3.04 equiv.), layered with pentane.

Synthesis of [Nd(COT)(tmp)]$_2$ (2): A flask was charged with $[Nd(COT)(THF)_4][BPh_4]$ (160.1 mg, 187.02 μmol), Ktmp (33.2 mg, 186.40 μmol) and THF (25 mL). After stirring for 3 h at 20 °C, the green solution was filtered and the solvents evaporated to dryness.

[a] $R_1 = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$ (observed reflections). [b] $wR_2 = [\Sigma w(||F_o| - |F_c||)^2/\Sigma w(|F_o|)^2]^{1/2}$ (observed reflections).

The resulting product was further extracted with THF (15 mL) and after evaporation of the solvent, the green powder of **2** was washed with toluene (5 mL) and dried under vacuum (54.0 mg, 75%). ^{1}H NMR ([D$_8$]toluene): δ = 11.01 (br. s, $w_{1/2}$ = 42 Hz, 6 H, Me), 1.20 (br. s, $w_{1/2}$ = 40 Hz, 6 H, Me), −15.62 (br. s, $w_{1/2}$ = 95 Hz, 8 H, COT) ppm. ^{1}H NMR ([D$_8$]THF): δ = 10.64 (br. s, $w_{1/2}$ = 20 Hz, 6 H, Me), 2.70 (br. s, $w_{1/2}$ = 22 Hz, 6 H, Me), −15.0 (br. s, $w_{1/2}$ = 50 Hz, 8 H, COT) ppm. $C_{16}H_{20}PNd$ (387): calcd. C 49.59, H 5.20, P 7.99; found C 49.32, H 5.33, P 8.13.

Synthesis of [Nd(COT)(tmp)(HMPA)] (3): HMPA (64.0 μL, 65.9 mg, 0.37 mmol), was added to a solution of **2** (118.4 mg, 0.153 mmol) in THF (30 mL); the initial green solution became darker. After stirring at 20 °C for 2 h, the solution was concentrated to dryness, leaving a dark green powder of **3** (159.4 mg, 92%). ^{1}H NMR ([D$_8$]THF): δ = 12.30 (br. s, $w_{1/2}$ = 20 Hz, 6 H, Me), 5.68 (br. s, $w_{1/2}$ = 62 Hz, 18 H, HMPA), −2.32 (br. s, $w_{1/2}$ = 27 Hz, 6 H, Me), −12.20 (br. s, $w_{1/2}$ = 53 Hz, 8 H, COT) ppm. $C_{22}H_{38}N_3OP_2Nd$ (660): calcd. C 46.62, H 6.76 N 7.41, P, 10.93; found C 46.41, H 6.86, N 7.55, P 10.67. Green crystals of **3** were grown from a saturated THF solution layered with pentane.

Synthesis of [U(COT)(Cp*)(HMPA)] (4): Addition of KCp* (22.5 mg, 129.1 μmol) to [U(COT)(HMPA)$_3$][BPh$_4$] (153.6 mg, 128.1 μmol) in THF (40 mL) induced a color change of the solution from dark green to dark brown within 30 min. After stirring at 20 °C for 2 h, the solution was filtered and the solvents were evaporated to dryness to give a brownish solid that was then extracted with toluene (10 mL). After concentration to dryness, the dark brown solid was crystallized from THF/pentane, affording brown crystals of **4** (60.1 mg, 70%). ^{1}H NMR ([D$_8$]toluene): δ = 1.67 (d, 7 Hz, 18 H, HMPA), −10.07 (s, 15 H, Cp*), −50.18 (s, 8 H, COT) ppm. ^{1}H NMR ([D$_8$]THF): δ = 1.97 (d, 9 Hz, 18 H, HMPA), −8.45 (s, 15 H, Cp*), −48.94 (s, 8 H, COT) ppm.

Synthesis of [U(COT)(tmp)(HMPA)$_2$] (5): Reduction of [U(COT)(tmp)(HMPA)$_2$][BPh$_4$] (303.3 mg, 261.7 μmol) with 2% Na(Hg) (596.5 mg, 518.7 μmol of Na) in THF (40 mL) over 24 h afforded a dark brown suspension. After filtration and concentration to dryness, the crude product was extracted with toluene (3 × 15 mL) and then precipitated upon addition of pentane, affording a dark brown powder of **5** (125.5 mg, 57%). ^{1}H NMR ([D$_8$]toluene): δ = 1.87 (s, 36 H, HMPA), −3.91 (s, 6 H, Me), −25.57 (s, 6 H, Me), −43.16 (s, 8 H, COT) ppm. ^{1}H NMR ([D$_8$]THF): δ = 3.07 (s, 36 H, HMPA), −1.15 (br. s, $w_{1/2}$ = 60 Hz, 6 H, Me), −22.39 (br. s, $w_{1/2}$ = 90 Hz, 6 H, Me), −41.44 (br. s, $w_{1/2}$ = 55 Hz, 8 H, COT) ppm. $C_{28}H_{56}N_6O_2P_3U$ (839): C 40.05, H 6.72, N 10.01, P 11.07; found C 39.94, H 6.63, N 9.79, P 10.80.

Reactions of 2 and 5 with (NEt$_3$H)BPh$_4$. a) An NMR tube was charged with **2** (8.1 mg, 10.45 μmol) and (NEt$_3$H)BPh$_4$ (9.0 mg, 21.35 μmol) in [D$_8$]THF (0.3 mL). After 45 min at 20 °C, the spectrum of the green solution showed the formation of [Nd(COT)(THF)$_4$][BPh$_4$] as the sole organometallic product. **b)** An NMR tube was charged with **5** (7.3 mg, 8.64 μmol) and (NEt$_3$H)BPh$_4$ (5.0 mg, 11.8 μmol) in [D$_8$]THF (0.3 mL). Precipitation of an orange solid was immediate. The precipitate was identified as [U(COT)(HMPA)$_3$][BPh$_4$]$_2$ by its ^{1}H NMR spectrum in pyridine.

X-ray Crystallography of 1b, 3, and 4: Diffraction collections were carried out with a Nonius Kappa-CCD diffractometer. The lattice parameters were determined from 10 images recorded with 2° Φ-scans and later refined on all data. A 180° Φ range was scanned with 2° steps and 10 s of exposure time per frame with a crystal-to-detector distance fixed at 30 mm. Data were corrected for Lorentz polarization and absorption effects.[24] The structures were solved by the heavy-atom method and refined by full-matrix least squares on F^2 with anisotropic thermal parameters for all non-hydrogen atoms. H atoms were introduced at calculated positions as riding atoms with an isotropic displacement parameter equal to 1.2 (CH, CH$_2$) or 1.5 (CH$_2$, CH$_3$) times that of the parent atom. All calculations were performed with an O2 Silicon Graphics Station using the SHELXTL package.[25] Crystal data and details of data collection and refinement are given in Table 2. CCDC-195294 (**1b**), -195292 (**3**), and -195293 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Two New Dinuclear Sterically Crowded Cu^{II} Complexes as Catalyst Precursors for the Oxidative Coupling of 2,6-Dimethylphenol

Guillem Aromí,[a] Patrick Gamez,[a] Huub Kooijman,[b] Anthony L. Spek,[b] Willem L. Driessen,[a] and Jan Reedijk*[a]

Keywords: Copper / N ligands / Homogeneous catalysis / Oxidations

The molecular structure and spectroscopic properties of the first two bis(μ-η^1-nitrato)-bridged, dinuclear Cu complexes containing 4,4′-biimidazole ligands are presented. ^{1}H NMR, EPR, and UV/Vis spectroscopy indicate that their solid-state structure is not retained in solution. Dioxygen uptake measurements show that the presence of a methyl group at the 2-position of the imidazole rings leads to a dramatic increase of the rate of the catalytic polymerization of 2,6-dimethylphenol. Detailed examination of the molecular structures of both catalyst precursors in the crystalline state suggests that this may either be caused by the difference in basicity of the biimidazole ligands or by a small but important steric effect of the 2-Me groups affecting the coplanarity of equatorial Cu^{II} ligands and the orientation of the axial nitrate ligands.

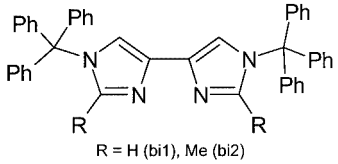
Introduction

Our longstanding interest in the preparation and spectroscopic study of copper coordination compounds with azole-based ligands[1−6] originates from two main driving forces. First, it is well established that many important enzymes hold a copper-active site mainly by means of the imidazole moieties from protein histidine amino acids.[7] Second, the unique characteristics of the Cu^{II}/Cu^{I} redox couple render many of their complexes especially suited for the catalysis of organic oxidation reactions, in some cases with industrial relevance.[8]

Since its discovery in 1959,[9] the oxidative polymerization of 2,6-dimethylphenol (DMP) catalyzed by Cu complexes of N-based ligands has been used on an industrial scale. The product, poly(1,4-phenylene ether) (PPE), is a valuable thermoplastic with vast worldwide applications thanks to its excellent mechanical properties and chemical resistance.[10,11] An unwanted side product of this reaction is diphenoquinone (DPQ), which results from the C−C coupling and subsequent oxidation of two DMP units. Considerable research effort has been dedicated to improve the performance and selectivity of the reaction and to elucidate its mechanism. For example, we have recently found conditions that have led to a dramatic increase of the reaction rates compared with those still encountered in large-scale production.[12] Although the exact mechanism of the reaction remains a matter of discussion, several hypotheses have been put forward. Early proposals favored a pathway involving phenoxy radicals as key intermediates.[13,14] More recently, the presence of a dinuclear phenolate-bridged Cu^{II} complex has been suggested.[15−17] Quite diverse approaches have been adopted to obtain mechanistic details of the reaction. These include kinetic studies using various kinds of ligands,[18−24] the use of different substrates such as oligomers,[16] ab initio calculations,[25] or changing the proportions between the various components (Cu, ligand, base, water, substrate) and studying the influence on the catalytic activity.[12,19,26] Another strategy has been to examine the molecular structure of various catalyst precursors or potential reaction intermediates to establish possible correlations between geometric parameters and activity. In this context, we decided to explore the coordination properties of the two chelating 4,4′-biimidazole (bi) ligands shown in Scheme 1.[27]



Scheme 1

In sharp contrast to their isomeric 2,2′-analogues, 4,4′-biimidazole chelates have not been found as part of any structurally characterized coordination compound, most likely owing to the difficulty in preparing these ligands. In

this paper we report synthetic procedures to prepare the complexes $[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi)]_2$ [bi = bi1 (**1**), bi2 (**2**)], the first examples containing 4,4′-biimidazole ligands. Their catalytic activity during the oxidation of DMP into PPE is examined and discussed in the light of their single-crystal X-ray structure and their solution properties.

Results and Discussion

Complexes **1** and **2** both crystallize from acetonitrile directly from reaction mixtures containing the stoichiometric amount of the appropriate components. In both cases, well-formed crystals collapse immediately upon exposure to air, probably reflecting loss of lattice solvent, which is detected crystallographically, but not from microanalysis (see below). The fact that the complexes are hygroscopic is reflected in repeated experiments of elemental analysis.

Description of the Structures

Crystallographic data for $[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi1)]_2$ (**1**) and $[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi2)]_2$ (**2**) are collected in Table 4. Selected interatomic distances and angles for complexes **1** and **2** are listed in Table 1 and the respective molecular structures are represented in Figures 1 and 2.

Table 1. Selected interatomic distances [Å] and angles [°] for $[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi1)]_2$ (**1**) and $[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi2)]_2$ (**2**)

$[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi1)]_2$ (1)

The structure of **1** shows a dinuclear centrosymmetric complex consisting of two Cu^{II} ions bridged by two monodentate $\mu\text{-}\eta^1\text{-}NO_3^-$ ligands. This bridging mode is relatively uncommon for nitrate,[28] which usually bridges Cu ions in a didentate fashion. The bridging nitrate ligand is bound to the Cu centers through a short [1.975(2) Å] and a long bond [2.360(2) Å], which occupy an equatorial and an axial position, respectively, of the nearly square-pyramidal coordination environment observed around the Cu centers ($\tau = 0.03$, where τ is 0 and 1 for the perfect square-pyramidal and trigonal-bipyramidal geometries, respectively).[29] The remaining equatorial positions of each metal ion are completed by the N donors of one chelating bi1 ligand [at distances of 1.973(2) and 1.978(2) Å, respectively] and by one O atom of a terminal NO_3^- ligand [1.963(2) Å]. A second O atom of the latter lays 2.697(2) Å apart from the Cu^{II} ion. The intermetallic Cu···Cu distance is 3.4106(8) Å. The crystal packing shows no unusual features. Complexes **1** and **2** (vide infra) are the first crystallographically characterized complexes of a 4,4′-biimidazole ligand.

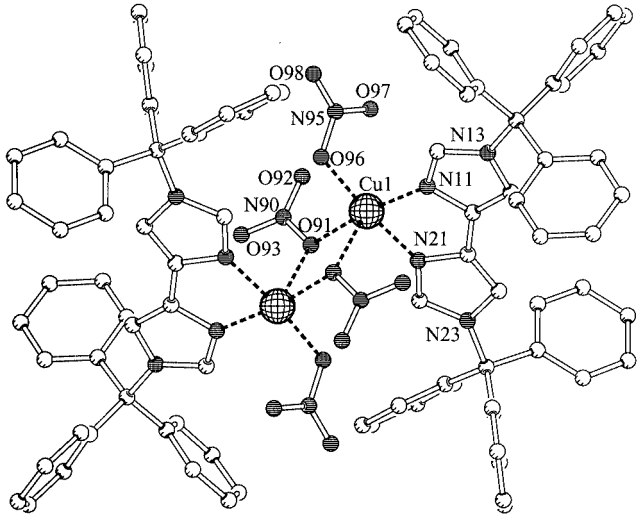

Figure 1. PLATON[38] representation of $[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi1)]_2$ (**1**)

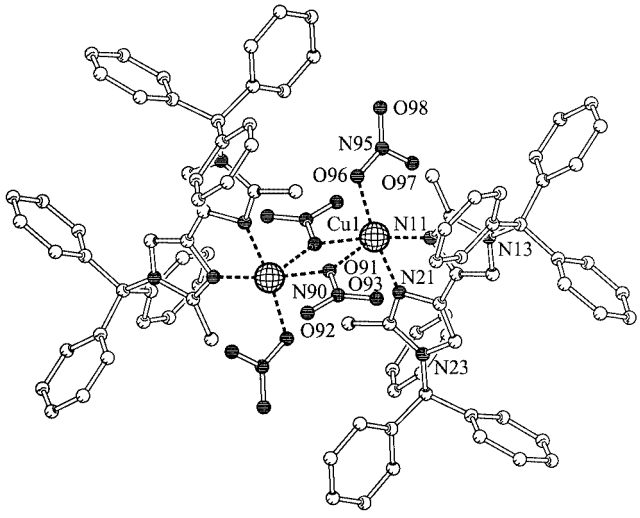

Figure 2. PLATON[38] representation of $[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi2)]_2$ (**2**)

$[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi2)]_2$ (2)

Complex **2** is isostructural with complex **1**. The presence of a methyl substituent at the 2- and 2′-positions of the imidazole rings does not appear to affect significantly the

overall structure of the complex. The metal centers maintain the square-pyramidal coordination geometry (with $\tau = 0.02$), and are slightly more separated [Cu···Cu = 3.530(1) Å] than in **1**. The bridging nitrate ligand is bound to the Cu centres at 1.996(3) and 2.403(3) Å, and the oxygen donor of the terminal nitrate group is separated from the metal ion by 1.970(3) Å. The long O···Cu contact featured by this ligand is 2.643(5) Å. The orientations of the nonbridging nitrato groups do differ from complex **1**, which is ascribed to the steric effect of the 2-Me group. The chelating ligands display Cu−N distances of 1.996(3) and 2.002(3) Å.[30,31] The packing in this structure is also uneventful and involves mainly van der Waals forces.

Spectroscopic Studies

The infrared (IR) spectra of complexes **1** and **2** were measured in the solid state. Both compounds exhibit a strong absorption (1279 and 1282 cm^{-1}, respectively) in the region characteristic for ν(NO) of monodentate-coordinated nitrates.[32]

The electronic spectra of **1** and **2** were collected from polycrystalline samples, using the diffuse reflectance technique. Both spectra have the same qualitative appearance, with the bands of complex **1** being slightly red-shifted with respect to those of **2**. One broad absorption band is observed (Table 2) in the 712−770-nm range (14000−12900 cm^{-1}) that can be assigned to d−d transitions involving the Cu^{II} ion in a square-pyramidal environment.[33,34] Near-ultraviolet absorption bands at ca. 400 nm (25000 cm^{-1}, shoulder; **1**) and 452 nm (22000 cm^{-1}; **2**) were also detected, and are assigned as charge-transfer transitions from a nitrate nonbonding orbital to the copper ion. In addition, both spectra display LMCT transitions from the chelating ligands at ca. 320 and 261 nm (31100 and 38100 cm^{-1}; **1**) and at ca. 320 and 274 nm (31100 and 36300 cm^{-1}; **2**). The electronic spectra of both compounds where also measured in CH_2Cl_2 solution. The above-mentioned various bands were found at very similar positions, but a dramatic decrease of intensity of the visible absorptions with respect to the ultraviolet bands was evident. This could be due to a change of the dipolar integral for some transitions, caused by an alteration of the symmetry within the complex upon dissolution or by dissociation. Furthermore, a new band could be seen at very high energy (227 nm, i.e. 43800 cm^{-1} for both complexes), most probably corresponding to an intra-ligand transition.

Complexes **1** and **2** were studied by paramagnetic ^1H NMR in $CDCl_3$ solution (Figure 3). A list of the chemical shifts of the different observed resonances is included in Table 2. Both complexes show a unique set of three paramagnetically broadened signals in the range δ = 6−8 ppm, corresponding to the phenyl rings of the biimidazole ligands. Complex **2** also displays a very broadened and shifted resonance at δ ≈ −9 ppm attributed to the methyl substituents on the imidazole rings of the ligand bi2. The signals corresponding to the protons directly on the imidazole rings were broadened beyond detection. Thus, the spectra of **1** and **2** show that both complexes exhibit higher symmetry in solution than in the solid state. This could be due to a rapid fluxional process rendering both halves of the ligand equivalent, or to the dissociation of the dimers in solution, leading to more symmetric mononuclear species. The second hypothesis was supported by a variable temperature ^1H NMR study, conducted down to ca. 110 K, in which no sign of any de-coalescence process could be observed (data not shown).

The solid-state and solution X-band EPR spectra of **1** and **2**, respectively, were compared at room temperature and ca. 77 K. The solution (CH_2Cl_2/toluene, 2:1) spectrum

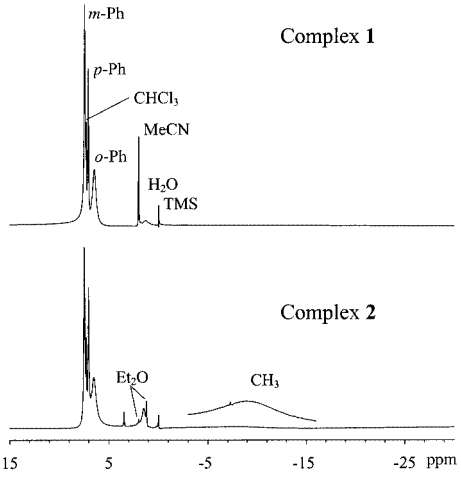

Figure 3. 300 MHz ^1H NMR spectra of complexes **1** and **2** in $CDCl_3$; the labels used for the top spectrum apply also to the bottom spectrum

at room temperature (not shown) displays for both species a band typical for mononuclear Cu^{II}, with g_{iso} = 2.15/2.16 (**1**/**2**). Both bands are split into four signals (A_{iso} = 68/62 G) due to hyperfine coupling of the spin with the Cu nuclei ($I = {}^3/_2$). In frozen solution, both compounds feature typical axial spectra (Figure 4) where $g_{\|}$ = 2.30/2.31 and $g_{\perp}$ = 2.07/2.07. From these values, the isotropic g constants reported above can be calculated from $g_{iso} = 1/3(2\times g_{\perp} + g_{\|})$. The parallel resonance in both compounds display hyperfine splitting due to the coupling with Cu ($A_{\|}$ = 166/150 G). Also, both spectra show superhyperfine splitting of the perpendicular signal due to interaction with the ^{14}N nuclei of the biimidazole ligands. These spectra are consistent with the presence of mononuclear species in solution. A possible distribution of species could be tetragonally elongated [Cu-$(NO_3)_2(bi)_2$] along with solvated $Cu(NO_3)_2$. Because $A_{\|}$ in **1** is slightly higher than in **2** the first type of species may well be EPR-active in both systems, the complex of **2** experiencing a larger distortion from planarity at the equatorial plane caused by the methyl substituents of bi2. A much broader signal underlying the spectra (especially visible in the frozen solution spectrum of **2**) could be attributed to the second type of species. The solid-state EPR spectra of **1** and **2** are also very similar to each other and distinct from the corresponding solution spectra. In both cases, a broad, isotropic signal is observed at g = 2.05/2.11. These bands could be ascribed to a triplet state, and the dramatic difference with the frozen solution spectra clearly indicates that the dinuclear structure of **1** and **2** observed in the solid state is not maintained in solution. No attempts were made to analyze the triplet signals in detail.

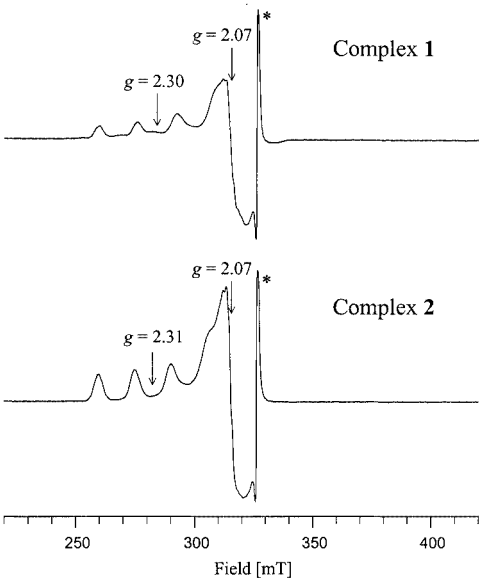

Figure 4. X-band EPR spectra of complexes **1** and **2** at 77 K in CH_2Cl_2/toluene (2:1) frozen solution; the signal labeled "*" corresponds to the reference radical used for calibration (see Exp. Sect.)

Catalytic Properties

$[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi1)]_2$ (**1**) and $[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi2)]_2$ (**2**) were tested as catalysts for the polymerization of 2,6-dimethylphenol (DMP) to ascertain the influence of the ligand derivatives on the catalytic activity of these precursors, in relation to their structural properties. Interestingly, the catalytic activity of complex **2** (which contains the 2,2′-dimethylbiimidazole ligand) is more than ten times faster than that of **1** (Table 3). This confirms the results achieved with ligands Meim and Dmeim (1-methylimidazole and 1,2-dimethylimidazole, respectively), where a methyl group on the 2-position of the imidazole ring led to a dramatic enhancement of activity[18] (see Table 3). The crystal structures of complexes **1** and **2** (see above) have revealed that the presence of methyl groups at the 2,2′-positions of the imidazole rings has almost no influence on the metric parameters of the rest of the complex. This suggests that the main reason for the difference in activity is the differential basicity of the ligands. It has been proposed that the N-based ligands of the catalyst might act as a Brønsted base during the catalytic cycle. In such a case the pK_b of the ligand could affect the rate of conversion. In this particular system the structural factors influencing the catalytic activity might be dominated by the much larger triphenylmethyl substituents common to both compounds. It would be interesting to expand the present study using the corresponding ligands 4,4′-biimidazole and 2,2′-dimethyl-4,4′-biimidazole. Here, however, an influence of the steric properties on the catalytic activity cannot be completely excluded, since no structural details of intermediates containing the reaction substrate, DMP, are known.

Conclusion

Single-crystal X-ray diffraction has revealed the solid-state molecular structure of the two copper dimeric com-

Table 3. Catalytic activity of Cu^{II} with didentate ligands bi1 and bi2 during the polymerization of DMP in acetonitrile, compared with that with Meim and Dmeim[18]

Ligand L	L/Cu	Conversion [%]	Reaction time [h]	R_0 [10^{-5} molL^{-1}s^{-1}]	PPE [%]
bi1	1	68	1.50	3	95.1
bi2	1	43	0.30	31	95.0
Meim[a]	4	68	0.08	142	> 95
Dmeim[b]	4	76	0.08	200	> 95

[a] Meim = 1-methylimidazole. [b] Dmeim = 1,2-dimethylimidazole.

plexes $[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi1)]_2$ (**1**) and $[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi2)]_2$ (**2**) are similar, despite the fact that the 2-Me group of the latter is close to the coordination sphere of Cu^{II}. These are the first crystallographically characterized coordination compounds featuring 4,4′-biimidazole ligands. Spectroscopic studies indicate that the solid-state structure of compounds **1** and **2** is not preserved in solution. The various data suggest that dissociation into mononuclear species takes place. Complexes **1** and **2** have been used as catalyst precursors for the oxidative coupling of DMP into PPE. In view of the solid-state molecular structure of both precursors, their dramatic difference in activity is interpreted in terms of the difference in ligand basicity. The EPR solution spectra, however, indicate that the presence of an Me group might distort the mononuclear complexes present in solution, thereby affecting their catalytic activity. The preparation and crystallographic characterization of additional catalyst precursors for this reaction will establish any correlations between structural parameters and the catalytic activity of these species.

Experimental Section

General Remarks: The biimidazole ligands 1,1′-bis(triphenylmethyl)-4,4′-biimidazole (bi1) and 2,2′-dimethyl-1,1′-bis(triphenylmethyl)-4,4′-biimidazole (bi2) were prepared according to the method reported by Pyne et al.[27] Solvents and chemicals were commercially available and were used as received unless otherwise indicated. The syntheses of all organic compounds were performed under argon and their purification was commonly performed in air. Infrared spectra were collected with a Perkin−Elmer Paragon 1000 spectrophotometer equipped with a Golden Gate Diamond ATR as a sample support. ^1H NMR spectra were recorded with a 200 MHz Jeol JNM FX-200 instrument and a 300 MHz Bruker DPX 300 spectrometer. Vis/NIR spectra where measured with a Perkin−Elmer Lambda 900 spectrophotometer in CH_2Cl_2 solution or using the diffuse reflectance technique, with MgO as a reference. X-band EPR spectra were recorded with a JEOL ESR spectrometer equipped with an Esprit 330 data system at room temperature and at 77 K, with dpph as an internal reference ($g = 2.0036$). Elemental analyses were performed at the Microanalytical Laboratory of the University College, Dublin, Ireland or at the Mikroanalytisches Labor Pascher, Remagen-Bandorf, Germany.

Dioxygen Uptake Measurements: In a typical quantitative, time-resolved dioxygen-uptake experiment, one compartment of a special in-house made two-compartment reaction vessel was filled with 5 mL of a 0.01 M Cu^{II}/ligand solution, and the other with 10 mL of the substrate (3 mmol) solution. Intense shaking in under dioxygen combined these solutions and started the reaction. The resulting reaction mixture was 3.33 mM in Cu and 0.2 M in DMP (**3**). The polymerization reactions were performed at 25 °C under pure dioxygen at atmospheric pressure. In this particular case, a ligand/Cu ratio of 1 and an NaOMe/Cu ratio of 2 were used. The catalytic activity was determined from the initial dioxygen-uptake rate R_0. A detailed description of the dioxygen-uptake experiments and the processing of the experimental data have been previously published.[35]

$[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi1)]_2$ (1): A slurry of bi1 (62 mg, 0.1 mmol) in MeCN (5 mL) was added to a stirred blue solution of $Cu(NO_3)_2{\cdot}3H_2O$ (26 mg, 0.1 mmol) in MeCN (5 mL). The ligand dissolved completely upon reaction. After a few minutes, the blue solution was left unperturbed and the solvent was allowed to slowly evaporate for a few days. After this time, blue block-shaped crystals suitable for X-ray crystallography had deposited. The crystals were collected by filtration and dried in vacuo. The yield was 44%. IR (neat): $\tilde{\nu}$ [cm^{-1}] = 1511.8 m, 1490.0 m, 1471.6 s, 1445.7 m, 1278.9 vs, 1214.0 m, 1085.8 m, 1002.1 m, 947.3 w, 845.8 w, 744.6 vs, 697.7 vs, 659.4 vs, 638.8 m, 374.0 w, 345.3 m, 316.6 w. $C_{88}H_{68}Cu_2N_{12}O_{12}(H_2O)_2$ (1648.72): calcd. C 64.11, H 4.40, N 10.19; found C 63.86, H 4.12, N 9.96.

$[Cu(\mu\text{-}\eta^1\text{-}NO_3)(NO_3)(bi2)]_2$ (2): A slurry of bi2 (259 mg, 0.4 mmol) in MeCN (10 mL) was added to a stirred blue solution of $Cu(NO_3)_2{\cdot}3H_2O$ (96 mg, 0.4 mmol) in MeCN (20 mL). After a few minutes, the resulting green solution was filtered with paper and the filtrate was left unperturbed for the slow evaporation of the solvent. After a few days, green needles suitable for X-ray crystallography were obtained. The solid was collected by filtration and turned gray upon contact with air. The sample was dried in vacuo (yield 31%). IR (neat): $\tilde{\nu}$ [cm^{-1}] = 1489.7 s, 1446.0 m, 1394.1 w, 1281.8 vs, 1232.9 m, 1149.5 w, 1010.1 m, 747.9 vs, 700.1 vs, 668.2 m, 655.7 w, 637.9 m, 586.0 w, 499.4 w, 398.2 w, 336.4 w. $C_{92}H_{76}Cu_2N_{12}O_{12}(H_2O)$ (1686.81): calcd. C 65.51, H 4.66, N 9.96; found C 65.67, H 4.78, N 9.48.

X-ray Crystallography: Crystals of complexes **1** and **2** were mounted on Lindemann glass capillaries and transferred into the cold nitrogen stream of a Nonius KappaCCD diffractometer on a rotating anode, (Mo-K_α radiation, graphite monochromator, λ = 0.71073 Å, T = 150 K). Pertinent data for the structure determinations are collected in Table 4. Structures were solved with direct methods using SHELXS86.[36] Refinement on F^2 was performed with SHELXL-97-2.[37] The hydrogen atoms were included in the refinement on calculated positions riding on their carrier atoms. The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were refined with a fixed isotropic displacement parameter related to the value of the equivalent isotropic displacement parameter of their carrier atoms. The structures of both **1** and **2** contain an area filled with acetonitrile. In **1** the solvent could be described with an ordered model, albeit with relatively high displacement parameters. In **2** the volume of the solvent area was significantly larger, and no satisfactory model could be constructed. Therefore, for this complex, the contribution to the structure factors associated with the solvent was taken into account using the SQUEEZE procedure as incorporated in PLATON.[38] A total of 126 electrons were found in a system of channels running parallel to a and c of 600 Å^3 per unit cell, corresponding to approximately six molecules of acetonitrile. The nitrate ions and one of the phenyl rings of **2** displayed high anisotropy in their displacement factors. Mild rigid bond restraints were applied to ensure realistic values for the displacement parameters. Neutral atom scattering factors and anomalous dispersion corrections were taken from the International Tables for Crystallography.[39] Geometrical calculations and illustrations were performed with PLATON.[38] CCDC-194207 (**1**) and -194208 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Studies of Pyridinyl-Containing 14-Membered Macrocyclic Copper(II) Complexes

Sabrina Autzen,[a] Hans-Gert Korth,[a] Roland Boese,[b] Herbert de Groot,*[c] and Reiner Sustmann*[a]

Keywords: Macrocyclic ligands / Copper / Enzyme models / Superoxide dismutase

Six copper(II) complexes of tetracoordinating, pyridinyl-containing 14-membered macrocycles with varying ratios of nitrogen and oxygen donor atoms were prepared and characterized by IR, UV/Vis, and EPR spectroscopy and cyclic voltammetry. A distorted tetragonal coordination of the copper center in the solid-state was established by X-ray crystallography for the tetraazamacrocyclic complex **Cu-3** carrying a methoxybenzyl pendent arm and the trioxaaza complex **Cu-6**. The superoxide dismutase-like activity of the Cu^{II} complexes was investigated by inhibition of NADH oxidation. Although the UV/Vis and EPR spectra of the complexes were strongly affected when the coordinating nitrogen atoms were successively replaced by oxygen atoms, no significant change in their reactivity towards superoxide was observed. In all cases a 1:1 or 1:2 stoichiometry for the reaction with superoxide was found, with the exception of the methoxybenzyl-substituted tetraaza complex, which showed a low catalytic activity with a turnover number of about 10.

Introduction

Our present studies are concerned with the preparation of transition metal complexes of 14-membered, pyridine-containing macrocycles and the examination of their spectroscopic properties to elucidate their potential enzyme-mimetic qualities. We have recently reported the catalase-mimetic activity of some non-heme iron(III) complexes.[1] Copper is another biologically significant metal, being found in various enzymes, such as the important Cu-Zn superoxide dismutase (Cu_2Zn_2-SOD), which is used in living organisms to detoxify the superoxide radical anion, $O_2^{\cdot -}$, [Equation (1)].[2]

$$2\,O_2^{\cdot -} + 2\,H^+ \xrightarrow{SOD} H_2O_2 + O_2 \qquad (1)$$

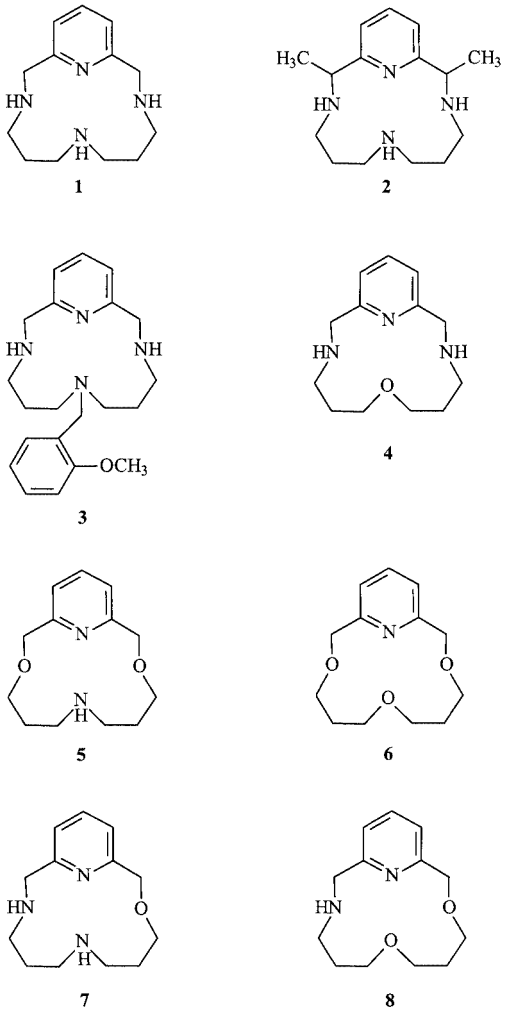
Numerous transition metal (preferably Cu, Fe, Mn) complexes of various kinds have been investigated with regard to their reactivity toward superoxide. The use of copper complexes as SOD mimics has been reviewed.[3,4] Although several investigated compounds exhibit good SOD-like activities, systematic studies concerning the factors which govern the enzyme-mimicking reactivities are scarce.[5] We report here on the copper(II) complexes **Cu-1**−**Cu-6** of ligands **1**−**6** in which the sp^3-nitrogen atoms of the parent macrocycle **1** are successively replaced by oxygen atoms. Spectroscopic properties were compared to determine the influence of the coordinating atoms on the SOD-like activities of the complexes. Complexes **Cu-1** and **Cu-2** have previously been described,[6−9] but their SOD activity was not investigated. Complex **Cu-3**, carrying a methoxybenzyl pendent arm, was included in this study to determine whether a possible coordination by the phenolic oxygen atom to the fifth coordination site at the copper atom might influence the catalytic activity. Coordination of phenolate groups to the fifth position in square-planar Cu^{II} complexes has been reported before;[10] however, to the best of our knowledge, coordination of phenyl ether substituents to the axial position has not been reported. There is, however, a recent report[11] in which phenyl ether moieties within the chain of a 20-membered macrocyclic ligand bind to the axial position of a tetra-*N*-coordinated copper(II) complex. X-ray crystal structures of the copper(II) complexes **Cu-3** and **Cu-6** are presented. X-ray structures of eight 14-membered *endo*-pyridine Cu^{II} complexes, including the PF_6^- salt of

Cu-1,[9] can be found in the Cambridge Structural Database.[12]

Results and Discussion

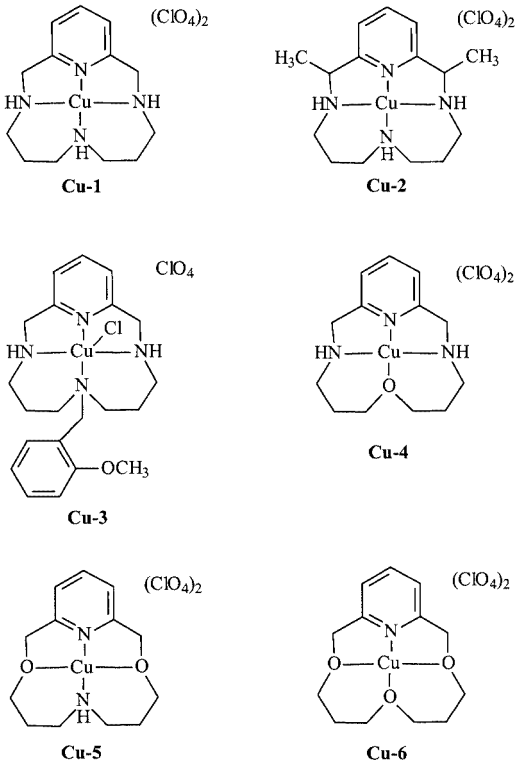
Synthesis

Macrocycle **2** was prepared from its nickel complex as described by Karn and Busch.[13] Compound **5** was prepared from ditosylated pyridine-2,6-diyldimethanol and the alkanediol, compound **6**[14] from pyridine-2,6-diyldimethanol and the appropriate alkanediyl ditosylate. Macrocycles **1**[6] and **3**[1] were prepared according to literature procedures in a copper-template reaction. The preparation of ligands **1**, **3** and **4** was devised starting from pyridine-2,6-dicarbaldehyde, which was treated with the appropriate diamine in a copper-template reaction to give the macrocycle. Diimine reduction by sodium borohydride and removal of copper(II) as sulfide provided the free ligands. Unfortunately, attempts to prepare the macrocycles **7** and **8**, in which the position of the nitrogen and oxygen atoms was exchanged with respect to compounds **4** and **5**, respectively, were not successful (Scheme 1).



Scheme 1

Facile formation of the copper(II) complexes was achieved by addition of an equimolar ethanolic solution of copper(II) perchlorate to an ethanolic solution of the ligands at room temperature and subsequent crystallization. As expected, for the ligands **1**, **2**, and **4**−**6** the corresponding copper complexes **Cu-1**, **Cu-2**, and **Cu-4**−**Cu-6** (Scheme 2) with two perchlorate counterions were obtained.



Scheme 2

Unexpectedly, X-ray structural and elemental analysis revealed that the copper complex **Cu-3** of ligand **3** contained one chloride ion as a counterion, although no chloride was involved in any steps of the synthesis. Thus, perchlorate must have been reduced during complex formation. Although perchlorate (which is a weakly chelating, relatively large anion) is a strong oxidant it is generally kinetically stable to reductants and is therefore frequently used to regulate the ion strength in kinetic and thermodynamic studies.[15] Because perchlorate reduction was not observed in the preparation of the related complexes **Cu-1** and **Cu-2**, it is very likely that the methoxybenzyl side chain of **3** facilitated this reduction. This conclusion is supported by the rapid formation of a Cu^{II}+**3** complex of 1:2 stoichiometry, $[Cu^{II}(\mathbf{3})_2](ClO_4)_2$, after mixing of copper(II) perchlorate and **3** (see Exp. Sect.). When kept in the reaction mixture, this complex slowly (within 12 h) converted into complex **Cu-3**. We propose that the initial 1:2 complex may have been formed by a kinetically controlled, exocyclic complexation, probably involving the oxygen atom of the methoxybenzyl

substituent. In solution, this exocyclic complex then rearranges to the thermodynamically more stable complex **Cu-3**, thereby re-releasing one ligand molecule. Concomitantly, partial reduction of perchlorate to chloride takes place. Given the rather mild reaction conditions used here it is not clear how the perchlorate might have been reduced, i.e. which chemical entity would have been the reductant. The copper(II) ion is unlikely to be oxidized under the applied conditions (compare the inertness of **Cu-1**, **Cu-2**), whereas the electron-rich phenyl group of the side arm might be a chemically reasonable target. A reduction of perchlorate to chloride during the preparation of a macrocyclic iron complex has been described by Goedken et al.[16] who discussed the formation of an unspecified, yet very reactive, intermediate. Elucidation of the mechanism of this interesting reaction is beyond the scope of this paper and will be the subject of a separate study.

Crystal Structure

The crystal structure of **Cu-1** with two PF_6^- counterions instead of perchlorate has been reported.[9] The crystal structures and the unit-cell diagrams of **Cu-3** and **Cu-6** are displayed in Figures 1 and 2. Selected bond lengths and angles are listed in the captions. It can be seen that in **Cu-3** copper(II) has a fivefold coordination environment. The four in-plane distances are of lengths commonly found in square-based pyramidal structures, with the $Cu-N_{pyr}$ distance (1.94 Å) being somewhat shorter than the other C−N distances (2.02−2.05 Å). This bond-length pattern seems to be characteristic of complexes of tetraazamacrocyclic ligands containing a pyridine moiety (see refs.[1,9] and references cited therein). The copper(II) ion in **Cu-3** is lifted out of the plane of the four coordinating ligand atoms by ρ(**Cu-3**) = 0.311 Å with a $Cu^{II}-Cl$ distance of 2.564 Å. The tetrahedral distortion of 0.311 Å is significantly increased compared with that in **Cu-1**·$(PF_6)_2$ (ρ = 0.133 Å),[9] which may be related to the coordination of Cl^-. The methoxybenzyl group, C(15)−C(21) and O(1), with the riding hydrogen atoms and the methylene hydrogen atoms H(14A/14B) is disordered over two sites with occupancies of 0.6 and 0.4 together; O(31) and C(32) of the methoxy group are disordered over two sites with occupancies of 0.5. In the crystal, the oxygen atom of the 2-methoxybenzyl group is not coordinated to the central ion. The second counterion is essentially noncoordinating perchlorate. Unlike **Cu-3**, in **Cu-6** the copper atom is essentially located in-plane [ρ(**Cu-6**) = 0.003 Å], with a Cu−N distance of 1.89 Å and Cu−O lengths of 1.93−1.96 Å. One of the perchlorate anions is

coordinated to two Cu^{II} centers as a bridging ligand with Cu^{II}−O distances of 2.425 and 2.433 Å, respectively, in a range (2.2−2.9 Å) commonly observed for axial Cu−O bond lengths.[17] Thus, the coordination geometry of **Cu-6** is essentially tetragonal-octahedral. Oxygen atom O(5) is disordered over two sites with occupancies of 0.68−0.32. In both complexes, the pyridine ring adopts an offset face-to-face orientation.

Infrared Spectra

The spectra of the free ligands **1**−**5** show sharp, medium-intensity bands at 3250−3300 cm^{-1} for the N−H valence vibrations. All ligands showed two bands around 1590 cm^{-1} for the C=N valence vibration of the pyridine ring (Table 2). On Cu^{II} complexation, the N−H valence bands are shifted by about 15−150 cm^{-1} to lower frequencies. For **Cu-1** and **Cu-2** two N−H valence vibrations are observed,

[a] Assignment ambiguous due to superposition with $\tilde{\nu}$(C−O).

in line with the different chemical environment of the NH groups located in *cis* and *trans* positions with respect to the pyridine nitrogen atom. As the higher wavenumber vibration is missing in the spectra of **Cu-3** and **Cu-4** but found in **Cu-5** (for which the lower wavenumber is absent), we assign this band to the *trans*-oriented NH group. In the complexes, the pyridine ν(C=N) bands are uniformly shifted to higher frequencies by 10−20 cm^{-1}, but virtually unaffected by the variation of the coordinating ring atoms.

The typical ν_3 (antisymmetric stretch) and ν_4 (antisymmetric bent) modes of noncoordinated perchlorate give rise to single, strong absorptions. In complexes **Cu-1**−**Cu-6** the perchlorate absorption at about 1100 cm^{-1} (ν_3) is split into two or three components, whereas the sharp strong band at 620 cm^{-1} (ν_4) remained a singlet. Thus, in the solid state, the symmetry of the perchlorate ions in these complexes is lowered.[7] However, it is not certain whether this is the result of coordination or of crystal packing effects. The latter appears to be more likely because the X-ray structure of **Cu-3** revealed that here the perchlorate is not coordinated to Cu^{II}.

Electronic Absorption

Complexes **Cu-1**−**Cu-6** show broad electronic absorptions in the 550−800-nm region (Table 3), typical for d−d transitions of Cu^{II} in a weak tetragonal field.[24] The absorption maxima show a red-shift (i.e. decreasing ligand-field strength) with increasing number of coordinating oxygen atoms, ranging from λ_{max} = 560 nm for the tetra-*N*-substituted complexes **Cu-1**−**Cu-3** to 793 nm for the tris-O complex **Cu-6**. This red-shift is accompanied by a similar decrease of the molar extinction coefficient ε. With respect to the parent complex **Cu-1**, the methyl and methoxybenzyl substituents in **Cu-2** and **Cu-3**, respectively, have virtually no effect on the absorption maxima but appear to decrease slightly the molar extinction. However, the red-shift of the absorption maxima is markedly different for the various positions with respect to the pyridine ring. Replacement of the nitrogen atom *trans* to the pyridine ring by an oxygen atom, viz. **Cu-1**−**Cu-3** → **Cu-4** and **Cu-5** → **Cu-6**, shifts the absorption maximum by $\Delta\lambda \approx 40$ nm^{-1} toward longer wavelengths, whereas replacement of the *cis* nitrogen atoms, viz. **Cu-1**−**Cu-3** → **Cu-5** and **Cu-4** → **Cu-6**, induces an approximate fivefold stronger shift of $\Delta\lambda \approx 190-200$ nm^{-1}. This discontinuity in the λ_{max} values on *cis*-N→O replacement is paralleled by a decrease of the extinction coefficient ε and a "jump" in the *g* values of the EPR spectra (see below), both indicating a significant change of the coordination geometry from a distorted tetragonal (square-based pyramidal) to a more octahedral tetragonal structure. In line with the stronger effect exerted by a *cis*-oxygen atom, the Cu^{II}-EDTA complex, having a *cis*-2N-2O coordination arrangement, shows a λ_{max} value of ca. 730 nm.[19] For the observed dependencies of the d−d transitions on the ligand substitution pattern, possible Cu^{II} complexes of the hitherto unknown ligands **7** and **8** should have absorption maxima around 700 and 740 nm, respectively.

ous solutions (Figure 4, Table 5). The spectra show the expected characteristics of distorted (axially elongated) tetragonal coordination of Cu^{II} ($S = 1/2$) with $g_\parallel > g_\perp$,[18,22] thus indicating a $d_{x^2-y^2}$ ground state. EPR data for Cu^{II}-EDTA and Cu_2Zn_2-SOD are given for comparison. In liquid solution, **Cu-1**−**Cu-3** show virtually identical, nearly isotropic EPR spectra with a well-resolved $^{63/65}$Cu hyperfine splitting in the range of 8 mT (Figure 3), confirming that the additional ring substituents in **Cu-2** and **Cu-3** have only a marginal effect on the spectral properties, in agreement with the absorption spectral properties.

Replacement of the *trans*-nitrogen atom by an oxygen atom in **Cu-4** yields a similarly resolved spectrum with only the apparent *g* factor slightly shifted to higher values. Replacement of the *cis*-nitrogen atoms by oxygen atoms (**Cu-5**), however, results in both a stronger *g* shift to higher values and an increased anisotropy of the spectra, as well as a reduced copper splitting [$a(^{63/65}Cu) \approx 4.9$ mT]. These effects are further pronounced for **Cu-6**. Thus, a replacement of a *cis*-N by O has a stronger effect on the *g* factor than replacement of the *trans*-N by O. These observations strikingly parallel the above-mentioned shifts of the UV/Vis absorption maxima. In addition, the apparent *g* factor of Cu^{II}-EDTA,[23] which has a 2N-2O coordination pattern similar to the arrangement in the macrocycle **8**, lies in between the *g* factors of **Cu-1**−**Cu-4** and **Cu-5** and **Cu-6**. The small spectral features between 330 and 370 mT in the EPR spectrum of **Cu-6** are probably due to a Cu^{II}-containing impurity. Because these signals could not be diminished by repeated recrystallization, they might belong to a copper complex formed from, and in equilibrium with, **Cu-6** in the aqueous phase. The uncommonly low *g* value of about 1.951 [$a(^{63/65}Cu) \approx 8.9$ mT] of this feature would indicate a d_z^2 ground state ($g_\perp > g_\parallel \approx 2$)[18,22] for this species.

In frozen (77 K) aqueous solution (Figure 4) a $^{63/65}$Cu hyperfine splitting can no longer be resolved in any of the spectra. The spectra of **Cu-1**−**Cu-3**, **Cu-5**, and **Cu-6** all consist of a single, broad line with apparent *g* values as given in Table 5. The spectral resolution could not be improved by tenfold dilution and lower microwave power and modulation settings, in agreement with observations by Costa and Delgado[8] who noted for **Cu-1** and related complexes the loss of resolution in solutions of low ionic strength (Table 5, footnote[b]). The anisotropic parameters (Table 5) were evaluated by spectral simulation and are approximate values because of the low resolution. Nevertheless, they are typical for Cu^{II} in a distorted tetragonal environment. As was observed for liquid aqueous solution, the apparent *g* factors are shifted to higher values, from 2.085 to about 2.140, with increasing number of oxygen atoms in the macrocyclic ring. However, two distinct differences compared with the liquid-phase spectra are apparent. First, the spectra of **Cu-5** and **Cu-6** now show approximately the same apparent *g* factor (ca. 2.134−9), similar to that of Cu-EDTA; second, the spectrum of **Cu-4** displays a clear separation of the parallel and perpendicular components of the *g* tensor and also has a smaller linewidth than the other spectra. We have no straightforward explanation for this unique feature of **Cu-4**. As the spectrum of **Cu-4** is strikingly similar to those observed for polycrystalline samples of **Cu-2** and related complexes at ambient temperature,[4] it might indicate that the coordination sphere in frozen water is very similar to that in the solid state.

Electrochemical Properties

Cyclic voltammograms of complexes **Cu-1**−**Cu-4** and **Cu-6** were examined in oxygen-free aqueous solution at room temperature. Potassium chloride was employed as supporting electrolyte to achieve a better correspondence with the conditions of the SOD activity measurements (see below). All complexes showed a quasi-reversible redox wave (E^1) in the range +0.37 to +0.42 V vs. NHE and an apparent irreversible cathodic peak (E^2_{pc}) between −0.13 and −0.36 V (Table 6). The latter potential might be quasi-reversible but the corresponding anodic peak was overlayed by a strong adsorption peak which appeared between 0 and +0.15 V on the subsequent oxidation cycle. Very similar voltammograms were obtained for hydrated Cu^{II} ions from solutions of copper(II) perchlorate and copper(II) sulfate un-

der the same conditions. The data of Table 6 display no dramatic variation of the potentials with the nature of the ligands. The quasi-reversible potentials $E^1_{1/2}$ of **Cu-1**−**Cu-3** differ only by 10 mV, the cathodic peak potentials E^2_{pc} by ca. 50 mV. Replacement of N by O in the macrocyclic ligand (**Cu-4**, **Cu-6**) shifted the E^1 potentials toward slightly (20−40 mV) more positive values, approaching the values for $CuSO_4$ and $Cu(ClO_4)_2$. The same is true for E^2_{pc} with the exception of **Cu-4** for which a cathodic shift of ca. 200 mV was observed. However, inspection of Table 6 clearly reveals that neither the E^1 nor the E^2_{pc} potential would account for the unique, though low SOD activity of **Cu-3** (see below, Table 7), as its anodic redox potential does not differ from those of **Cu-1** and **Cu-2**, and, also, the SOD activities of all copper compounds (see below) do not parallel the variation of the E^2_{pc} values. Thus, the redox potentials of the Cu^{II} complexes are not essentially associated with their SOD activities.

Table 6. Cyclic voltammetric data [V vs. NHE] of the copper(II) complexes

Compound[a]	E^1_{pa}	E^1_{pc}	$E^1_{1/2}$[b]	E^2_{pc}[c]
Cu-1	0.439	0.322	0.381	−0.164
Cu-2	0.438	0.317	0.378	−0.138
Cu-3	0.465	0.287	0.376	−0.214
Cu-4	0.491	0.318	0.405	−0.358
Cu-6	0.466	0.366	0.416	−0.056
$Cu(ClO_4)_2$	0.463	0.335	0.400	−0.068
$CuSO_4$	0.446	0.314	0.414	−0.005

[a] At 1 mM and a scan rate of 0.1 V s^{-1}. [b] Quasi-reversible, $E_{1/2} = (E_{pa} + E_{pc})/2$. [c] Irreversible or quasi-reversible.

Superoxide Dismutase Activity

Copper(II) complexes **Cu-2**−**Cu-4**, and **Cu-6** were examined with regard to their Superoxide Dismutase (SOD) mimetic activity by the method of Paoletti et al.[25] For comparison purposes, hydrated Cu^{II} [employed as $Cu(ClO_4)_2$] was also investigated. The applied method is based on the oxidation of β-nicotinamide adenine dinucleotide (β-NADH) by mercaptoethanol/EDTA/Mn^{2+} at pH = 7.4. In the presence of molecular oxygen, this system generates superoxide ($O_2^{\cdot -}$), which, in turn, oxidizes NADH to NAD^+. Based on the kinetics of the oxidation of NADH in the presence and absence (control) of copper(II) complexes, the SOD-mimetic potential was determined. Addition of SOD or a SOD-active compound inhibits the oxidation of NADH, which is monitored UV-spectroscopically by the retarded decay of the absorption of NADH at 340 nm. After an initially progressive course, the decline of the absorption follows apparent zero-order kinetics (Figure 5, inset). These parts of the decay traces were used for the subsequent evaluation of the rates. To determine the SOD activity, the percentage of the rate of inhibition of NADH oxidation (control: absence of SOD-mimic = 100%) was plotted against the initial concentration of the copper complexes (Figure 5). For all complexes the inhibition of the oxidation rate is not proportional to the concentrations of copper complexes but rather follows an exponential dependence. The IC_{50} value, that is the amount of complex reducing the rate of the NADH oxidation by 50%, was extracted from the graphs (Table 7). Since catalase does not interfere in the above reaction, this enzyme was used to remove the produced hydrogen peroxide so as to determine whether the peroxide and/or its possible reaction products affect the assay. As the catalytic activity in the presence of catalase[26] did not change, inhibition by hydrogen peroxide and its possible products can be excluded.

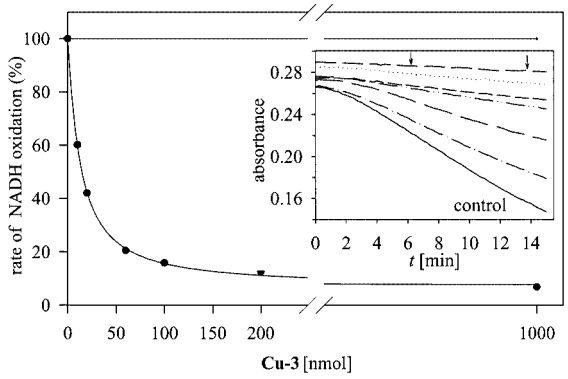

Figure 5. Inhibition of NADH oxidation as a function of **Cu-3** concentration; inset: kinetic traces of NADH oxidation monitored at 340 nm at different concentrations of **Cu-3**

Table 7. Comparison of superoxide dismutase activity at 296 K

Compound	IC_{50} [μM]	Cu/NADH ratio
Cu-2	247	1:1.07
Cu-3	28	1:9.46
Cu-4	206	1:1.29
Cu-6	126	1:2.10
$Cu(ClO_4)_2$	247	1:1.07

The IC_{50} values and the Cu/NADH ratios listed in Table 7 reveal that complexes **Cu-2** and **Cu-4** do not show any true catalytic activity, rather, they convert $O_2^{\cdot -}$ in a roughly 1:1 stoichiometric ratio, similar to copper(II) perchlorate. Likewise, **Cu-6** does not appear to be a catalyst, reacting with $O_2^{\cdot -}$ in a 1:2 stoichiometry. Hence, simple exchange of the coordinating atoms, i.e. N vs. O, in the macrocyclic ring does not effect the SOD-like activity of this type of Cu^{II} complexes. However, for complex **Cu-3**, which carries a methoxybenzyl pendent arm, a low but unequivocal catalytic activity is found. The data indicate a turnover of about 10, i.e. one molecule of the complex decomposes about ten molecules of superoxide before being deactivated.

Investigation of the SOD-mimetic activity of complexes by employing indirect methods like the one chosen here are frequently hampered because "free" (hydrated) Cu^{II} ions also react with $O_2^{\cdot -}$, as is demonstrated here by $Cu(ClO_4)_2$. Thus, the question arises as to whether the present copper complexes or low amounts of free Cu^{II} ions, deriving from dissociation of the complexes or impurities, are responsible for the observed reaction. The latter possibility can be ex-

cluded on the basis of the control experiments with copper(II) perchlorate. Further, the stability of our complexes was confirmed by EPR experiments in which a tenfold excess of EDTA added to aqueous solutions of the complexes produced no detectable changes in the EPR spectra of **Cu-1**−**Cu-6**.

The catalytic activity of **Cu-3** is rather surprising as the above spectroscopic and electrochemical data do not indicate any unique physicochemical properties in solution compared with the analogues **Cu-1** and **Cu-2**. Indeed, the oxygen-substituted systems **Cu-4**−**Cu-6** which indeed show marked variations in their UV/Vis and EPR spectra, behave very similarly to **Cu-1** and **Cu-2**. Exploratory experiments were performed with regard to the mechanistic background for the enhanced activity of **Cu-3**. In complex **Cu-3**, the fifth coordination site in the solid state is occupied by a chloride ion, whereas in the nonactive complexes **Cu-2**, **Cu-4**, and **Cu-6** this site is occupied by a second perchlorate ion. Thus, the chloride coordination might be responsible for the catalytic activity of **Cu-3**. Experiments were, therefore, performed in which large amounts (50 mM) of potassium chloride were added to the reaction mixture. However, no changes in the catalytic activities of all complexes were detected. As neither contamination by "free" Cu^{II} nor different coordinating counterions account for the different activity of **Cu-3**, it appears that the methoxybenzyl side chain in **Cu-3** is responsible. The X-ray structure of **Cu-3** showed that the methoxybenzyl substituent is not coordinated via the oxygen atom to the copper center but rather directed outward (Figure 3). Such an arrangement would make a significant influence of the pendent arm on the SOD activity very unlikely. However, in solution the situation might change due to free rotational movement of the methoxybenzyl group. Trial PM3(tm) calculations indeed favor (at least in the gas phase) an arrangement of the substituent where the methoxy oxygen atom is coordinated to the central Cu^{II} ion (Figure 6).

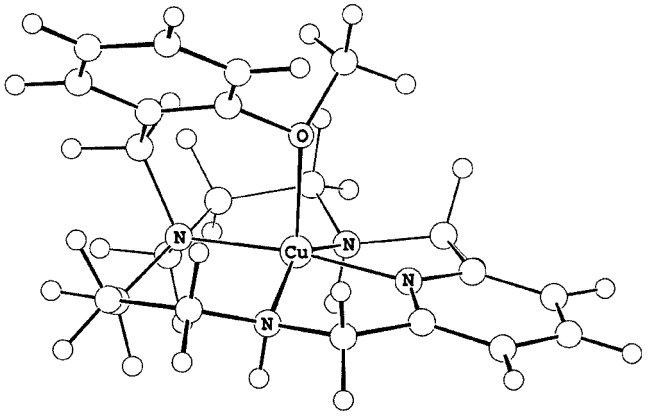

Figure 6. Optimized PM3 structure for **Cu-3**

Therefore, in aqueous solution the methoxybenzyl substituent might "protect" one of the axial positions against further, deactivating reactions (e.g. from attack of a second superoxide molecule) when the substrate superoxide has associated to the opposite side. Such a blocking function might be a crucial feature for the catalytic activity of the complex. However, from the currently available data, no further conclusions concerning the reaction mechanism can be made. Further work is necessary for a deeper insight into the mechanism of superoxide dismutation.

Experimental Section

Instrumentation: ^1H and ^{13}C NMR spectra: Bruker DRX 500 and Varian Gemini 200. Melting points (uncorrected): Elektrothermal 9100. IR: Bio-Rad Series FTS 135 FT-IR. UV/Vis: J&M TIDAS Detector NMC 301. EPR: Bruker ESP 300E. Elemental analysis: Carlo Erba 1010 CHNSO. Cyclic voltammetry: ECO-Chemie Autolab GPES.

Materials: The following compounds were prepared according to published procedures: pyridine-2,6-dicarbaldehyde,[27] 3,7,11,17-teraazabicyclo[11.3.1]heptadeca-1(17),13,15-triene (**1**),[6] {2,12-dimethyl-3,7,11,17-tetraazabicyclo[11.3.1]heptadeca-1(17),2,11,13,15-pentaene}nickel(II) perchlorate,[13] {2,12-dimethyl-3,7,11,17-tetraazabicyclo[11.3.1]heptadeca-1(17),13,15-triene}nickel(II) perchlorate,[13] (2*R*,12*S*)-2,12-dimethyl-3,7,11,17-tetraazabicyclo[11.3.1]-heptadeca-1(17),13,15-triene monohydrate (**2**),[28,29] *N*,*N*-bis(2-cyanoethyl)-2-methoxybenzylamine, *N*,*N*-bis(3-aminopropyl)-2-methoxybenzylamine,[1] 7-(2-methoxybenzyl)-3,7,11,17-tetraazabicyclo[11.3.1]heptadeca-1(17),13,15-triene (**3**),[1] 2,6-bis[(tosyloxy)methyl]pyridine,[30] dipropanolamine,[31] 4-oxa-1,7-heptanediol,[14] 4-oxaheptane-1,7-diyl ditosylate,[14] 3,7,11-trioxa-17-azabicyclo[11.3.1]heptadeca-1(17),13,15-triene (**6**).[14] Reduced adenine dinucleotide (β-NADH, disodium salt) and diethyleneaminotetraacetic acid (EDTA) were obtained from Sigma, while manganese(II) chloride dihydrate and 2-mercaptoethanol were supplied by Merck and 3,3′-oxydipropionitrile by Fluka. Reagents and solutions: triethanolamine/diethanolamine (Tea-Dea) buffer (100 mM each, pH = 7.4); NADH (7.5 mM); EDTA/$MnCl_2$ (100 mM/50 mM); mercaptoethanol (10 mM).

3,3′-Oxydipropaneamine: The literature synthesis[32] was improved as follows: Raney nickel (3 g) was added to a solution of 3,3′-oxydipropionitrile (2.06 g, 16.6 mmol), dissolved in methanol (40 mL), containing anhydrous ammonia (5.2 g, 0.31 mol). The nitrile was hydrogenated under pressure (8 bar) at room temperature, until no drop in pressure was observed (10 h). The residue was filtered off and the product obtained by distillation under reduced pressure (2.0 g, 15.1 mmol, 91%). ^1H NMR (500 MHz, CD_3OD): δ = 1.66 (m, 4 H, 2 × CH_2), 2.66 (t, ^3J = 6.5 Hz, 4 H, 2 × CH_2), 3.44 (t, ^3J = 6.2 Hz, 4 H, 2 × CH_2) ppm. ^{13}C NMR (75 MHz, CD_3OD): δ = 33.77 (2 × CH_2), 40.11 (2 × CH_2), 70.13 (2 × CH_2) ppm.

7-Oxa-3,11,17-triazabicyclo[11.3.1]heptadeca-1(17),13,15-triene (4): A solution of pyridine-2,6-dicarbaldehyde (3.25 g, 24.0 mmol) in ethanol was added to a stirred solution of copper nitrate trihydrate (5.80 g, 24.0 mmol) in water (65 mL), resulting in a pale green mixture. A solution of 3,3′-oxydipropioamine (3.24 g, 24.5 mmol) in ethanol (10.0 mL) was then added dropwise with rapid stirring over 30 min and the resulting dark blue solution was refluxed for 2 h, then cooled to 5 °C in an ice/brine bath and sodium borohydride (2.30 g, 60.4 mmol) added. After 30 min, the solution was stirred at room temperature for 2 h, heated at 60 °C for 1 h, and stirred further at room temperature for several hours. The copper(II) was removed by treating the mixture with sodium sulfide nonahydrate (14.41 g, 60 mmol) followed by stirring at 60 °C for 1 h, and the solution was then cooled and the copper(II) sulfide removed by

filtration through Celite. Ethanol was evaporated, the residue extracted three times with dichloromethane, and the combined extracts dried with $MgSO_4$. After removal of the dichloromethane by evaporation, the resultant light brown residue was purified by chromatography (chloroform, neutral aluminium oxide). The product was obtained as a colourless solid (3.16 g, 13.4 mmol, 56%). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 1.82 (m, 4 H, CH_2), 2.59 (t, ^3J = 5.5 Hz, 4 H, CH_2), 3.54 (t, ^3J = 5.5 Hz, 4 H, CH_2), 3.70 (s, 2 H, N*H*), 3.89 (s, 4 H, CH_2), 6.99 (d, ^3J = 7.6 Hz, 2 H, C*H*), 7.52 (dd, 1 H, ^3J = 7.6 Hz, C*H*) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 29.28 (*C*H$_2$), 45.39 (*C*H$_2$), 53.91 (*C*H$_2$), 68.34 (*C*H$_2$), 120.81 (*C*H), 136.72 (*C*H), 158.53 (*C*) ppm. $C_{13}H_{21}N_3O$ (235.33): calcd. C 66.35, H 8.99, N 17.86; found C 66.05, H 9.17, N 17.61.

3,11-Dioxa-7,17-diazabicyclo[11.3.1]heptadeca-1(17),13,15-triene (5): Macrocycle **5** was prepared from (1.81 g, 4.0 mmol) 2,6-bis[(tosyloxy)methyl]pyridine and dipropanolamine (0.54 mg, 4.0 mmol) in a similar fashion to the procedure of Bradshaw et al.[14] The product thus obtained was a colourless solid (0.51 g, 2.16 mmol, 54%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.91 (m, 4 H, CH_2), 3.05 (br. m, 8 H, CH_2), 4.67 (s, 4 H, CH_2), 7.20 (d, 2 H, C*H*), 7.68 (dd, 1 H, C*H*) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 30.12 (*C*H$_2$), 49.15 (*C*H$_2$), 65.83 (*C*H$_2$), 72.72 (*C*H$_2$), 117.12 (*C*H), 123.52 (*C*H), 158.88 (*C*) ppm. $C_{13}H_{20}N_2O_2$ (236.31): calcd. C 66.07, H 8.53, N 11.86; found C 66.33, H 8.55, N 11.92.

Copper Complexes Cu-1−Cu-6: The preparation of **Cu-1**[6] and **Cu-2**[7] has been reported before. All solid complexes were obtained in good yields (> 65%) by mixing ethanolic solutions of the appropriate ligands with equimolar solutions of cupric perchlorate hexahydrate in ethanol at room temperature. The precipitated complexes were isolated by filtration and purified by washing several times with cold ethanol. Whereas complexes **Cu-1**, **Cu-2**, and **Cu-4−Cu-6** were instantaneously formed on mixing of the reactants, addition of an equimolar amount of copper(II) perchlorate in ethanol to an ethanolic solution of ligand **3** initially led to rapid formation of a yellow precipitate which according to elemental analysis and EPR spectroscopy represented a Cu^{II}−ligand complex of 1:2 stoichiometry, $[Cu^{II}(\mathbf{3})_2](ClO_4)_2$ (60% yield relative to **3**). When the reaction mixture without prior separation of this complex was allowed to stand for 12 h at ambient temperature, violet crystals of complex **Cu-3** were obtained in 68% yield.

CAUTION: Metal perchlorate salts containing organic ligands are potentially explosive, and should be handled with care!

Characterization of Complexes Cu-1−Cu-6

Cu-1: Blue-purple powder (0.39 g, 68%). IR (KBr): $\tilde{\nu}$ = 3242 (NH), 3084 (CH_{Ph}), 2936 (CH_{aliph}), 624 (ClO_4) cm^{-1}. $C_{13}H_{22}Cl_2CuN_4O_8$ (496.80): calcd. C 31.43, H 4.46, Cu 12.79, N 11.28; found C 31.14, H 4.41, Cu 12.58, N 10.99. UV (water): λ_{max} (lg ε) = 565 (2.56) nm.

Cu-2: Violet-blue powder (0.76 g, 76%), decomp. 254 °C. IR (KBr): $\tilde{\nu}$ = 3223 (NH), 3094 (CH_{Ph}), 2943 (CH_{aliph}), 624 (ClO_4) cm^{-1}. $C_{15}H_{26}Cl_2CuN_4O_8$ (524.86): calcd. C 34.33, H 4.99, Cu 12.11, N 10.68; found C 34.29, H 4.97, Cu 11.84, N 10.39. UV (water): λ_{max} (lg ε) = 254 (3.90), 560 (2.29) nm.

Cu-3: Violet-blue crystals (0.39 g, 68%), decomp. 231 °C. IR (KBr): $\tilde{\nu}$ = 3226 (NH), 3068 (CH_{Ph}), 2934 (CH_{aliph}), 2893 ($CH_{methyl\ ether}$), 1600 (NH), 1248 ($CO_{aryl\ alkyl\ ether}$), 622 (ClO_4) cm^{-1}. $C_{21}H_{30}Cl_2CuN_4O_5$ (553.73): calcd. C 45.61, H 5.47, Cu 11.49, N 10.13; found C 45.31, H 5.55, Cu 11.41, N 9.84. FAB (glycerol): *m/z* (%) = 516 (3), 417 (15), 355 (34). UV (water): λ_{max} (lg ε) = 256 (3.89), 563 (2.13) nm.

Cu-4: Blue crystals (0.83 g, 73%), decomp. 290 °C. IR (KBr): $\tilde{\nu}$ = 3242 (NH), 3092 (CH_{Ph}), 2951 (CH_{aliph}), 1608 (NH), 1108 (COC), 624 (ClO_4) cm^{-1}. $C_{13}H_{21}Cl_2CuN_3O_9$ (497.78): calcd. C 31.37, H 4.25, Cu 12.77, N 8.44; found C 31.72, H 4.26, Cu 12.66, N 8.52. FAB (glycerol): *m/z* (%) = 397 (22), 298 (30). UV (water): λ_{max} (lg ε) = 255 (3.82), 603 (2.15) nm.

Cu-5: Light blue crystals (0.24 g, 65%), decomp. 291 °C. IR (KBr): $\tilde{\nu}$ = 3078 (CH_{Ph}), 2957 (CH_{aliph}), 1605 (NH), 627 (ClO_4) cm^{-1}. $C_{13}H_{20}Cl_2CuN_2O_{10}$ (498.76): calcd. C 31.31, H 4.04, Cu 12.74, N 5.62; found C 30.98, H 3.94, Cu 12.89, N 5.47. UV (water): λ_{max} (lg ε) = 757 (1.42) nm.

Cu-6: Turquoise crystals (0.36 g, 72%), decomp. 292 °C. IR (KBr): $\tilde{\nu}$ = 3084 (CH_{Ph}), 2957 (CH_{aliph}), 621 (ClO_4) cm^{-1}. $C_{13}H_{19}Cl_2CuNO_{11}$ (499.73): calcd. C 31.24, H 3.83, Cu 12.72, N 2.80; found C 31.52, H 3.82, Cu 12.43, N 2.99. FAB (glycerol): *m/z* (%) = 300 (100), 238 (83). UV (water): λ_{max} (lg ε) = 264 (3.59), 793 (1.36) nm.

Aqueous solutions of the complexes all had pH values between 7 and 8.

Kinetic Measurements: The principle of the method is based on the oxidation of NADH, mediated by superoxide radical, in a purely chemical system developed by Paoletti et al.[25] To monitor the assay we added the following solutions (see materials) into a cuvette (1-mm cell): 400 μL Tea-Dea buffer (100 mM each), 20 μL NADH solution (7.5 mM), 12.5 μL EDTA/$MnCl_2$ solution (100 mM/50 mM) and 50 μL of sample or buffer were mixed thoroughly. In a second series of experiments the reaction mixture was supplemented with 50 mM KCl. The reaction was started by rapid mixing with 50 μL of mercaptoethanol (10 mM). Rates of NADH oxidation, observed at 340 nm, were initially low, then increased progressively to yield good linear kinetics and an 8-min window was used for our calculations. The maximal rates obtained are expressed as a percentage of the control and plotted against the complex concentracion. One unit of the SOD-mimic is the amount of copper complex capable of inhibiting by 50% the rate of NADH oxidation observed in the control.

EPR Spectroscopy: X-band (9.5 GHz) EPR spectra were recorded from 1−3 mM solutions of the complexes in oxygen-free, deionized water in a TM_{110} wide-bore cavity (Bruker). For liquid solutions, a 0.4 mm inner diameter quartz flat cell (Wilmad) was used; measurements at 77 K were performed in 4 mm Suprasil quartz tubes immersed in a liquid nitrogen dewar insert. Spectral simulations were carried out with the Simfonia program (Bruker). The concentration of the copper complexes in liquid and frozen solution was checked by numerical double integration (WinEPR software, Bruker) of the EPR spectra and comparison with the integrated EPR signal of a 1 mM Cu^{II}-EDTA solution. In all cases the integration accounted for > 90% purity of the complexes.

Cyclic Voltammetry: Cyclic voltammetric measurements were performed at 20 °C in aqueous solution under nitrogen. Complex concentrations of 1 mM were employed, and 100 mM KCl was used as supporting electrolyte. A 3 mm diameter glassy-carbon working electrode, an Ag/AgCl reference electrode, and a Pt-wire counter electrode were used. Scan rates were varied from 0.01 to 1.0 V s^{-1}. Electrochemical potentials were converted into the normal hydrogen electrode (NHE) scale by addition of 0.222 V.

X-ray Crystallographic Study: CCDC-188550 (**Cu-3**) and -188551 (**Cu-6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at

www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Direct Synthesis of $(PhSe)_4Ge$ and $(PhTe)_4Ge$ from Activated Hydrogenated Germanium − Crystal Structure and Twinning of $(PhTe)_4Ge$

Sabine Schlecht*[a] and Karen Friese[b]

Keywords: Germanium / Tellurium / Van der Waals interactions / Active metals

The germanium chalcogenolates $(PhSe)_4Ge$ and $(PhTe)_4Ge$ were synthesized from activated hydrogenated germanium (Ge*) and diphenyldiselenide or diphenylditelluride, respectively. $(PhTe)_4Ge$ is the first homoleptic organotellurolate of germanium. It was characterized spectroscopically and by X-ray crystal structure analysis. $(PhTe)_4Ge$ crystallizes in the monoclinic space group $P2_1/c$ with a = 12.8018(14), b = 9.1842(9), c = 23.690(3) Å and β = 105.458(8)°. The molecules show a tetrahedral $GeTe_4$ core. Weak Te-Te interactions connect neighbouring tetrahedra to infinite helices along [010].

Introduction

In the last two decades, organochalcogenolates of group 14 elements have gained increasing importance as molecular precursors for IV/VI semiconductors.[1−3] In the case of the homoleptic series $(RCh)_4E$ with Ch = Se, S and E = Ge, Sn only rather elaborate and low-to-medium yield synthetic routes are known in the literature.[4−6] Analogous tellurolates $(RTe)_4E$ with E = Ge or Sn have not been described so far.

Hence, a direct synthesis of this class of compounds from R_2Ch_2 (R = alkyl, aryl; Ch = Se, Te) and the group 14 element is highly desirable, especially in the case of the tellurium compounds.

Results and Discussion

Commercially available elemental germanium or tin powder does not react with diorganodichalcogenides at temperatures below the decomposition temperature of these organoelement compounds. Thus, a chemical activation of germanium is necessary in order to make such a direct reaction feasible.

We used solvochemically produced hydrogenated germanium, which is highly reactive and a good reductand and can be obtained from $GeCl_2$·dioxane and $Li[Et_3BH]$ in THF according to Equation (1).[7]

$$GeCl_2\cdot\text{dioxane} + 2\,Li[Et_3BH] \rightarrow \underset{\mathbf{1}}{Ge^*} + 2\,Et_3B + 2\,LiCl + H_2 + \text{dioxane} \quad (1)$$

The activated germanium thus obtained indeed inserted into the Se−Se bond and Te−Te bond of Ph_2Se_2 and Ph_2Te_2 at surprisingly low temperatures to give homoleptic $(PhSe)_4Ge$ (**2**) at 65 °C and $(PhTe)_4Ge$ (**3**) at room temperature [Equation (2) and (3)].

$$\underset{\mathbf{1}}{Ge^*} + 2\,Ph_2Se_2 \rightarrow \underset{\mathbf{2}}{Ge(SePh)_4} \quad (2)$$

$$\underset{\mathbf{1}}{Ge^*} + 2\,Ph_2Te_2 \rightarrow \underset{\mathbf{3}}{Ge(TePh)_4} \quad (3)$$

The same type of direct reaction with Ph_2Se_2 has also been observed for activated nanocrystalline tin and also yielded the homoleptic product $(PhSe)_4Sn$.[8]

In the reaction of Ge* (**1**) with diphenyldiselenide at 65 °C in THF solvent, the selenolate **2** is obtained in 92% yield. This yield is significantly higher than the 60−65% yield that could be obtained in reactions of LiSePh with $GeCl_4$.[4,5] In addition, our direct synthesis from activated germanium and Ph_2Se_2 does not produce any by-products in significant amounts and therefore no separation procedure is required.[5]

The reaction of **1** with Ph_2Te_2 is less straightforward, but tellurolate **3** was obtained in 26% yield as a deep red solid. Although all suspended Ge* was consumed after two hours of stirring at room temperature and a clear red solution had formed, we were not able to isolate pure **3** from that solution. Instead, a mixture of Ph_2Te_2, amorphous brownish

germanium and product **3** was obtained after removal of the tetrahydrofuran. This mixture was re-dissolved in diethyl ether and the amorphous germanium was separated by filtration. The filtrate was evaporated to dryness and Ph_2Te_2 and **3** were separated by an extraction with ice-cold diethyl ether in which only Ph_2Te_2 is soluble. The deep-red product that remained was pure **3** and was recrystallized at room temperature by slow evaporation of a concentrated solution in diethyl ether.

The X-ray crystal structure of germanium tellurolate **3** is depicted in Figure 1. Details of the crystal structure determination are given in Table 1, and atomic coordinates can be found in Table 2.

The structure of the molecule is similar to that of $(PhSe)_4Ge$ and $(PhSe)_4Sn$, of which an orthorhombic and a monoclinic polymorph are known.[5] The germanium centre is surrounded by an almost regular tetrahedron of tellurium atoms. The Ge−Te bond lengths span from 257.5 pm to 258.2 pm (Table 3) and are similar to the distances

Table 3. Selected bond lengths [pm] and bond angles [°] of **3**

Ge−Te1	257.51(10)	Te1−C1	211.6(10)
Ge−Te2	257.75(11)	Te2−C7	211.7(8)
Ge−Te3	258.24(10)	Te3−C13	213.8(10)
Ge−Te4	258.17(13)	Te4−C19	213.4 (9)
Te3−Te4′	393.23(8)		
Te1−Ge−Te2	112.95(4)	Ge−Te1−C1	93.8(2)
Te1−Ge−Te3	111.54(3)	Ge−Te2−C7	94.8(3)
Te1−Ge−Te4	104.39(4)	Ge−Te3−C13	93.1(2)
Te2−Ge−Te3	104.76(4)	Ge−Te4−C19	93.7(3)
Te2−Ge−Te4	113.32(4)		
Te3−Ge−Te4	110.03(4)		

found in the literature for other $GeTe_4$ tetrahedra (e.g. K_2GeTe_4: 250.8−264.0 pm;[9] Ag_8GeTe_6: 254.4 pm;[10] Cs_4GeTe: 253.7−262.3 pm[11]).

The angles around the four symmetrically independent tellurium atoms range from 93.1° to 94.8° and are generally more oblique than in the related selenium compounds [$(PhSe)_4Ge$ (**2**): 96.2−96.7°; orthorhombic $(PhSe)_4Sn$: 95.9−96.4°]. Only in monoclinic $(PhSe)_4Sn$ are similar angles (93.5−95.6°) observed.

The main difference between $(PhTe)_4Ge$ (**3**) and the other related compounds becomes evident when looking at the spatial arrangement of the molecules. In the orthorhombic compounds the molecules are arranged in such a way that the tetrahedral cores are relatively isolated from each other and, consequently, the intertetrahedral Se−Se distances are significantly longer than the intratetrahedral distances [$(PhSe)_4Ge$: intratetrahedral distances: 374.7−397.4; shortest intertetrahedral distance: 468.5 pm; orthorhombic $(PhSe)_4Sn$: intratetrahedral distances: 403.2−424.6 pm; shortest intertetrahedral distance: 434.9 pm]. In the monoclinic polymorph of $(PhSe)_4Sn$ some of the intertetrahedral distances (the shortest is 382.3 pm) are shorter than the intratetrahedral distances (404.1−414.4 pm), yet still too long to assume Se−Se interactions. In $(PhTe)_4Ge$ (**3**) the shortest intertetrahedral Te−Te distance is 393.2 pm, which is significantly shorter than all intratetrahedral distances (407.44−431.0 pm). Furthermore, this distance is well below the sum of the van der Waals radii (440 pm)[12] and in this case it is indeed reasonable to assume weak, attractive Te−Te interactions. These interactions connect Te atoms of neighbouring tetrahedra and lead to the formation of helical chains consisting of germanium and tellurium atoms along the crystallographic *b* direction (see Figure 2 and 3). The type of helix that is formed by the tellurium and germanium atoms in the backbone of the chain resembles the anionic chain of tetrahedra in K_2GeTe_4[9] and the chain of tellurium atoms found in the tellurium subchloride Te_3Cl_2,[13] except for the differences in the bond angles. The observed Te−Te distance in **3** is similar to that observed in other compounds, for example in $Te[N(SiMe_3)_2]_2$ (377 pm),[14] with van der Waals interactions between the tellurium atoms. These distances are longer than the interchain distance in elemental tellurium (350 pm),[15] but they are again similar to the Te−Te distances at the van der Waals gap of extended layered tellurides such as Ta_2Te_3,[16] where a value of 373 pm was found.

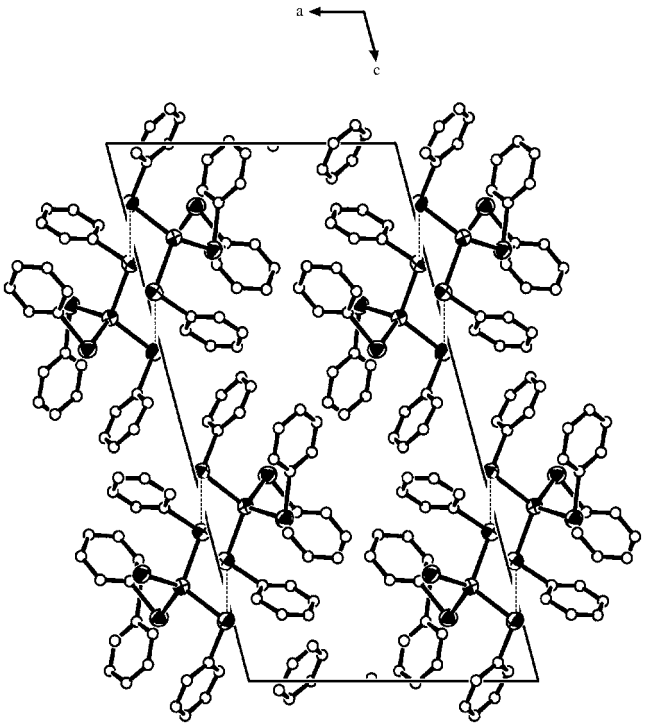

Figure 2. Projection of the crystal structure of **3** along [010]; Te−Te interactions are indicated as dashed lines (ORTEP representation[19]); thermal ellipsoids are represented at a 50% probability level

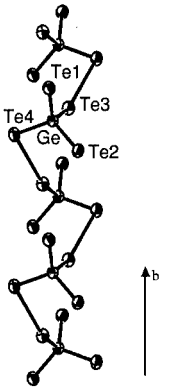

Figure 3. Helical chain of interconnected tetrahedra of $GeTe_4$ units (ORTEP representation[19]); thermal ellipsoids are represented at a 50% probability level

Conclusion

Activated hydrogenated germanium **1** allows the direct one-step synthesis of $(PhSe)_4Ge$ (**2**) and $(PhTe)_4Ge$ (**3**) from Ph_2Se_2 or Ph_2Te_2 and **1** in an oxidative addition leading directly to the tetravalent germanium species. The homoleptic tellurolate **3** shows short intertetrahedral Te−Te contacts that lead to the formation of helical chains consisting of germanium and tellurium atoms in this compound. The easy accessibility of $(PhSe)_4Ge$ (**2**) and $(PhTe)_4Ge$ (**3**) makes these compounds ideal candidates for molecular precursors leading to IV/VI semiconductors. Investigations on the low-temperature synthesis of germanium(II) chalcogenides from $(PhSe)_4Ge$ and $(PhTe)_4Ge$ are currently under way.

Experimental Section

All manipulations were carried out under dry, oxygen-free argon, except where stated otherwise. $Li[Et_3BH]$ (1 M in THF), diphenylditelluride, diphenyldiselenide and tetrahydrofuran were purchased from Aldrich. $GeCl_2$·dioxane was purchased from ABCR. THF

was dried over CaH_2 under argon atmosphere and freshly distilled prior to use. The reactions were carried out in standard Schlenk glassware. Activated hydrogenated germanium (**1**) was prepared as described in the literature.[7]

$(PhSe)_4Ge$ (2): $GeCl_2$·dioxane (232 mg, 1.0 mmol) was reduced to Ge* (**1**) by 2.0 mL of a 1.0 M solution of $Li[Et_3BH]$ in THF as described previously.[7] The resulting **1** was suspended in 60 mL of THF and Ph_2Se_2 (624 mg, 2.0 mmol) was added. The reaction mixture was heated to gentle reflux for 4 h and a clear yellow solution was obtained. This was allowed to cool to room temperature and then the THF was removed under vacuum. The yellow solid obtained was washed with 10 mL of hexane and dried again. The product was identified as $(PhSe)_4Ge$ (**2**)[5] by ^1H, ^{13}C and ^{77}Se NMR spectroscopy, elemental analysis and powder diffraction data. Yield: 641 mg (92%).

$(PhTe)_4Ge$ (3): $GeCl_2$·dioxane (232 mg, 1.0 mmol) was reduced with 2.0 mL of a 1 M solution of $Li[Et_3BH]$ in THF as described above. The resulting **1** was suspended in 60 mL of THF and Ph_2Te_2 (818 mg, 2.0 mmol) was added. The reaction mixture was stirred at room temperature for 2 h and a clear red solution formed. The THF was quickly evaporated under vacuum and an orange-red powder remained. Diethyl ether (40 mL) was added and the solution was filtered. The filtrate was evaporated to dryness under vacuum and the remaining mixture of Ph_2Te_2 and **3** was extracted with 3 × 5 mL of ice-cold diethyl ether. A dark red solid remained. Yield: 232 mg (26%). ^1H NMR (300 MHz, CD_2Cl_2, 25 °C): δ = 7.19 (t, 8 H), 7.38 (t, 4 H), 7.61 (t, 8 H) ppm. ^{13}C NMR (75 MHz, CD_2Cl_2, 25 °C): δ = 129.1, 130.0, 141.5 ppm. IR (nujol mull): $\tilde{\nu}$ 1573 cm^{-1} (w), 1153 (w), 1014 (w), 996 (w), 688 (m), 450 (m, νTe-C), 252 (m, νGe-Te), 238 (m, νGe-Te), 178 (w). MS (EI, 70 eV): *m/z* (%) = 766 (2) $[(PhTe)_2Ge(Te)(TeC_2H_3)]^+$, 561 (10) $[(PhTe)Ge(Te)(TeC_2H_3)]^+$, 410 (20) $[Ph_2Te_2]^+$, 305 (50) $[(PhTe)Ge(C_2H_3)]^+$, 206 (30) $[PhTeH]^+$, 154 (42) $[TeC_2H_3]^+$, 77 (100) $[Ph]^+$. $C_{24}H_{20}GeTe_4$ (891.01): calcd. C 32.32, H 2.24; found C 32.03, H 2.51.

X-ray Crystallographic Study: The overall distribution of intensities in the diffraction pattern of $Ge(TePh)_4$ (**3**) can be explained assuming a monoclinic lattice with a = 12.8018(14), b = 9.1842(9), c = 23.690(3) Å and β = 105.458(8) and an additional twinning operation (Figure 4). Two twin individuals of different volume fractions have to be taken into account. The twinning can be classified as twinning by reticular merohedry. The two individual lattices have the *hk*0 plane in common and generally all reflections $l = 7n$ overlap completely, while reflections $l \neq 7n$ correspond to reflections of a single individual. This implies that it is inevitable to consider the twinning operation in the refinement process. If the two twin individuals were of equal volume, orthorhombic Laue symmetry 2/*m*2/*m*2/*m* would be simulated for the overall diffraction pattern. The reduction of the symmetry of one individual to Laue class 2/*m* leaves the remaining four symmetry operations $2'/m'-2'/m'$ as possible choices for the twinning operation. We chose the mirror plane perpendicular to a^* as twin law corresponding to the matrix (−1 0 0 | 0 1 0 | −2/7 0 1).

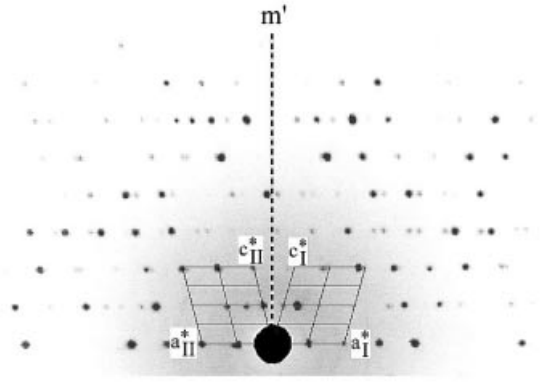

Figure 4. h0l plane of the reciprocal space of $(PhTe)_4Ge$; unit cells of the two different twin individuals and the twinning operation are indicated

Although in the structure solution process (with the program SIR97[17]) all reflections were taken into account (i.e. also the overlapping ones) no problems were encountered and the positions of all heavy atoms were easily identified. Structure refinement employing the above -described twin law was carried out with the program Jana2000.[18] Hydrogen atoms were taken from the difference Fourier synthesis map.

Arylcalcium Hydrides as Precursors to Alkoxides and Aryloxides of Calcium

John P. Dunne,[a] Matthias Tacke,*[a] Carola Selinka,[b] and Dietmar Stalke[b]

Keywords: Calcium / C−H activation / Cocondensation / Hydrides

Calcium atoms react with +I-substituted benzene derivatives under cocondensation conditions to yield arylcalcium hydrides. With toluene, *tert*-butylbenzene, and trimethyl(phenyl)silane the reaction showed no selectivity for C–H activation, resulting in the formation of each of the three possible isomers, while with *m*-xylene the reaction resulted in selective activation of the bond *meta* to the CH_3 groups. Treatment of (*tert*-butylphenyl)calcium hydride with di- and trisubstituted phenols such as 2,6-di-*tert*-butylphenol, 2,6-di-*tert*-butyl-4-methylphenol, and 2,4,6-tri-*tert*-butylphenol resulted in the formation of calcium aryloxides in yields > 95%. $[Ca(2,4,6\text{-}tBu_3C_6H_2O)_2(THF)_3]$ crystallises from a THF solution as a distorted trigonal bipyramid, with two THF ligands in the *trans*-axial positions and the third THF ligand and both aryloxide groups in equatorial positions. The $Ca–O_{Aryl}$ bond length was found to average at 2.181(3) Å. The $Ca–O–C_{Aryl}$ angles are almost linear, with Ca1–O1–C1 and Ca1–O2–C19 being 173.9(3)° and 178.8(3)°, respectively, while the O1–Ca1–O2 angle was determined as 152.04(12)°. A reaction between (*tert*-butylphenyl)calcium hydride and triphenylmethanol resulted in the formation of the corresponding monomeric calcium bis(alkoxide) $Ca(OCPh_3)_2(THF)_4$ in 95% yield. The structure was determined as a distorted octahedron with the alkoxide ligands in a *cis*-equatorial arrangement. The Ca–O bond length was determined at 2.1609(17) Å. The $Ca–O–C_{Aryl}$ angle of 177.46(16)° is almost linear, while the O1–Ca1–O1A angle was determined at 110.12(19)°.

Introduction

Until the mid 1980s, complexes of calcium were among the longest known, yet least understood class of compounds. Since the early 1990s, however, there has been renewed interest in this field.[1] The reasons for this slow development have been due to numerous factors. Firstly, calcium complexes have rather poor solubility in hydrocarbon solvents and many are thermally unstable.[1] Secondly, there are only a limited number of starting reagents and preparative techniques for the formation of calcium compounds.[1]

The most popular preparative technique is to use non-elemental forms of calcium (as shown in Figure 1), utilising a salt such as CaI_2 or calcium bis(trimethylsilyl)amide as the source of calcium. Another method is by deprotonation with an activated hydrocarbon, as shown in Equation (C) in Figure 1.

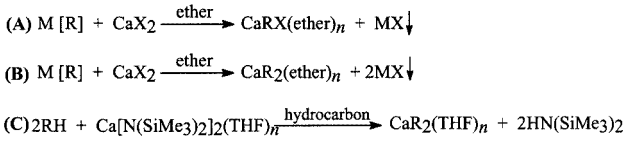

Figure 1. Reactions using non-elemental forms of calcium

Another synthetic method is to use bulk calcium metal for reaction, but a major difficulty encountered with this technique is its relative inertness to reaction. There are a number of different methods to activate the bulk metal, including the formation of an activated powder by displacement of calcium by potassium from a calcium dihalide (Rieke calcium),[2] or by decomposition of alkaline earth metal/anthracene complexes (Bogdanovic method).[3] Alternatively, the metal can be dissolved in liquid ammonia[4] or dispersed in THF.[5]

Metal vapour synthesis (MVS) takes a different approach to the above methods to overcome the inertness of bulk calcium metal. The above procedures are in reality a cleaning of the metal surface. Metal atom techniques are different, in that they utilise the vaporisation enthalpy of calcium as the reaction enthalpy. This technique has received only sporadic attention to date. In the late 1980s, MVS was used to prepare $[Ca(cot)(THF)_n]$[6] and the bis(cyclopentadienyl)-calcium complex $[Ca\{\eta\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2\}_2(THF)]$,[7] and more recently $[Ca\{CH(SiMe_3)_2\}_2(THF)_3]$,[8] while in the mid 1980s Mochida et al.[9] reported the C−H bond activation of benzene by calcium atoms to form PhCaH, which was not isolated but characterised by its organic products as outlined in Figure 2. In these systems the high reactivity of calcium atoms is stored in the products' highly reactive bonds.

Recently performed theoretical work showed that the molecule "PhCaH" should be able to exist in donor solv-

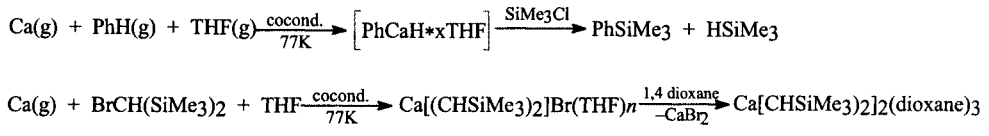

Figure 2. Cocondensation reactions with calcium atoms

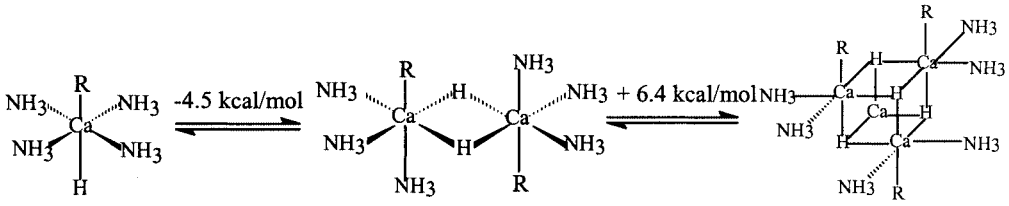

Figure 3. Calculated structures for PhCaH in donor solvents

ents such as THF in different aggregation states.[10] As a means of developing a convenient theoretical model for arylcalcium hydride in donor solvents, ammonia was used to simulate an amine and the elimination of H_2 was suppressed. These calculations show that a concentration-dependent equilibrium exists in donor solvents (as outlined in Figure 3). At low concentrations of "PhCaH", a monomeric species is energetically favoured, while at higher concentrations a tetrameric species with triply bridging hydride ligands exists. However, at average concentrations of "PhCaH" the energetically favoured structure is a dimer.

Calcium alkoxides are used as CVD precursors and for sol-gel synthesis.[1,11] As well as this, alkaline earth metal alkoxides are noted for their rich variety of structures and reactions.[1] This is due to the conformational and bonding flexibility of the alkoxide ligand (e.g., μ^1-, μ^2-, and μ^3-bonding modes are known). Crystallographically identified structural types range from discrete monomeric species such as $[Ca(BHT)_2(THF)_3]$ (BHT = 2,6-*tert*-butyl-4-methylphenolate)[12] to large polynuclear aggregates such as $[Ca_9(OCH_2CH_2OMe)_{18}(HOCH_2CH_2OMe)_2]$.[13]

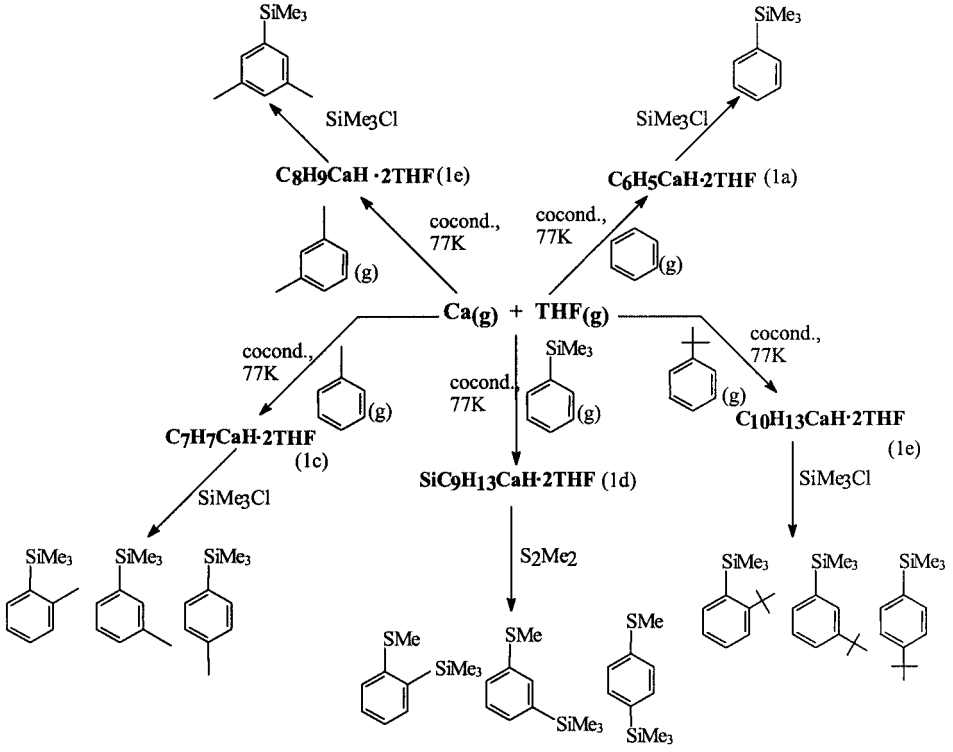
The aim of this work was firstly to use calcium atoms to activate the aromatic C−H bonds of +I-substituted benzene derivatives, thus forming arylcalcium hydrides, and secondly to use these arylcalcium hydrides as starting reagents for the formation of calcium alkoxides and aryloxides. To date, relatively few examples of monomeric alkoxides and aryloxides have been structurally characterised [examples include $[Ca(BHT)_2(THF)_3]$ and $[Ca(cox)_2(THF)_3]$·THF {cox = $C(Ph)_2(CH_2C_6H_4Cl\text{-}4)$}.[12] The reasons for this arise from difficulties in preventing oligomerisation or polymerisation of the calcium alkoxides and their low solubilities in most solvents. For this purpose a series of sterically bulky alcohols and phenols were chosen, in order to prevent oligomerisation and increase solubility in hydrocarbons.

Results

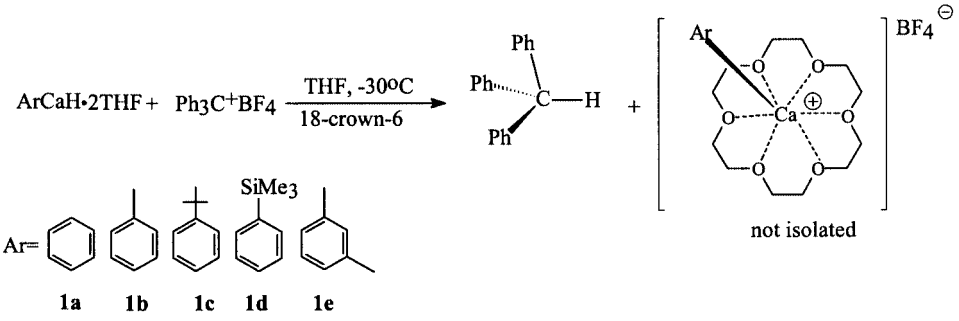
Experimental Study

Under cocondensation conditions, calcium atoms react with +I-substituted benzene derivatives to form extremely air- and moisture-sensitive, dark red solids in yields ranging from 78 to 97%. When calcium atoms were cocondensed with benzene in the presence of THF (as outlined in Scheme 1), a dark red, pyrophoric solid of composition PhCaH·2THF was obtained in a yield of 78%. An IR spectrum in Nujol mull showed a strong vibration at 1094 cm^{-1} and a weaker signal at 1031 cm^{-1}. We assign these as the Ca−H vibration at 1094 cm^{-1} and C−H bond deformations of the phenyl ring at 1031cm^{-1}, based on similar trends seen in our DFT-modelled vibrations. Because of the low solubility of the product in organic solvents and its extremely high sensitivity to air and moisture, however, NMR spectroscopic data were not obtained for this or any other arylcalcium hydride species. Instead, **1a** was treated at −30 °C with $SiMe_3Cl$ (as shown in Scheme 1) and the organic derivative trimethyl(phenyl)silane was identified by GC MS and NMR techniques. Further characterisation to show the presence of the hydride moiety was performed by treatment of **1a** with the hydride-abstracting agent $Ph_3C^+BF_4^-$. The product isolated from this reaction was triphenylmethane, as shown in Scheme 2.

A change of the aromatic compound from benzene to toluene resulted in a higher yield of 97%. The elemental analysis of the solid compound showed that it was composed of a C_7H_7CaH·2THF moiety. As with the benzene cocondensation product, a Ca−H vibration was found at 1092 cm^{-1}. In order to ascertain which C−H bond was activated, **1b** was converted into an organic compound by treating it with chlorotrimethylsilane. In this case, GC MS detected the presence of three different isomers in similar abundances. In conjunction with NMR spectroscopic data,



Scheme 1. Cocondensation of calcium atoms with +I-substituted benzene derivatives in the presence of THF



Scheme 2. Reaction of arylcalcium hydrides with $Ph_3C^+BF_4^-$

these were identified as the *ortho*, *meta*, and *para* isomers of trimethyl(methylphenyl)silane, as outlined in Scheme 1.[14–16] As before, **1b** was treated with $Ph_3C^+BF_4^-$, resulting in the isolation of triphenylmethane as outlined in Scheme 2. No attack at the thermodynamically favoured benzyl position was detected.

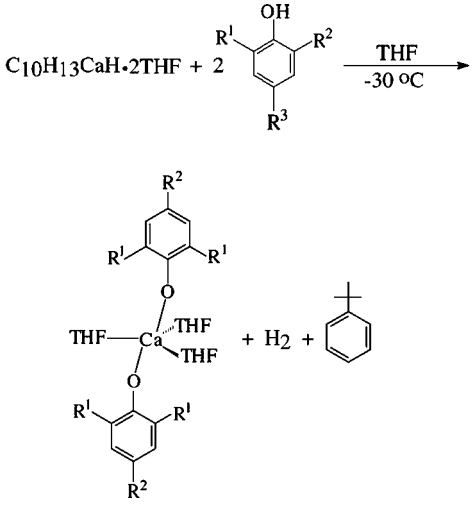
When *tert*-butylbenzene was used instead of toluene (as outlined in Scheme 1), a slightly lower yield of 93% was obtained. Like the previous cocondensation products, elemental analysis showed it to be composed of a $C_{10}H_{13}CaH{\cdot}2THF$ moiety, and a Ca–H vibration was found at 1094 cm^{-1}. As in the toluene cocondensation, **1c** was treated with chlorotrimethylsilane to identify which C–H bonds were activated. As in the case of the toluene reaction product, GC MS and NMR showed the presence of *ortho*, *meta*, and *para* isomers of (*tert*-butylphenyl)trimethylsilane in similar abundances, as outlined in Scheme 1.[17–19] As in the previous cocondensations, **1c** was treated with $Ph_3C^+BF_4^-$ to form triphenylmethane, thus indicating the presence of a hydride ligand, as outlined in Scheme 2.

A change of the +I benzene derivative to *m*-xylene resulted in a lower yield of 85%. As in the previous cocondensation products, elemental analysis shows the product to be of the composition $C_8H_9CaH{\cdot}2THF$, and the Ca–H vibration was detected at 1095 cm^{-1}. To confirm the regiochemistry of this reaction, **1d** was again treated with chlorotrimethylsilane. Unlike in the toluene and *tert*-butylbenzene cocondensations, though, GC MS and NMR showed that a single species had been formed, and this was identified as (3,5-dimethylphenyl)trimethylsilane, as outlined in Scheme 1.[20] Treatment of **1d** with $Ph_3C^+BF_4^-$ as outlined in Scheme 2 confirmed the presence of the hydride ligand.

When trimethyl(phenyl)silane was cocondensed with calcium atoms in the presence of THF, a similar lack of selectivity was observed. The isolated dark red solid (86% yield) had the composition $C_9H_{13}SiCaH{\cdot}2THF$. As in the previous cocondensation products, a Ca–H vibration was found

at 1094 cm^{-1}. For ease of characterisation, **1c** was treated with dimethyl disulfide rather than chlorotrimethylsilane in order to elucidate the selectivity of this reaction. GC MS measurements showed the presence of three different isomers in similar abundances. In conjunction with NMR spectroscopic data, these were identified as the *ortho*, *meta*, and *para* isomers of trimethyl[4-(methylthio)phenyl]silane, as outlined in Scheme 1.[17,19] As in all the previous cocondensations, **1c** was treated with $Ph_3C^+BF_4^-$ (as outlined in Scheme 2) to confirm the presence of a hydride ligand.

These arylcalcium hydrides can be redissolved in THF and utilised as reagents for the formation of new calcium compounds. When arylcalcium hydrides were treated at room temperature with bulky phenols (**3a**−**3c**), the corresponding bis(aryloxides) were formed in excellent yields (all > 95%), as outlined in Scheme 3. IR and NMR techniques identified all species as bis(aryloxides) of calcium. A characteristic ^{13}C NMR signal for the *ipso*-carbon atom (C−O^-) can be seen at δ ≈ 164.4 (for **3a**), 163.9 (for **3b**) and 163.4 ppm (for **3c**). The calcium aryloxides **3b** and **3c** have been reported previously and the NMR and IR data agree with the literature.[12,21] However, no crystal structure for **3c** had been reported in the literature. Integration of the THF signals in the ^1H NMR shows that **3a** has a coordination number of six, while **3b** has the lower coordination number of five.



3a: $R^1 = t$Bu, R^2 = H
3b: $R^1 = t$Bu, $R^2 = CH_3$
3c: $R^1 = t$Bu, $R^2 = t$Bu

Scheme 3. Synthesis of calcium aryloxides using **1c**

A single crystal of **3c** suitable for X-ray diffraction was grown over 5 d at +5 °C in THF. The result of the structure determination is depicted in Figure 4. The coordination number for the calcium is five, with two aryloxide and three THF ligands arranged in a distorted trigonal-bipyramidal coordination polyhedron around the calcium centre. Two and a half further uncoordinated THF molecules could be detected as lattice solvent. Bond lengths and angles are listed in Table 1.

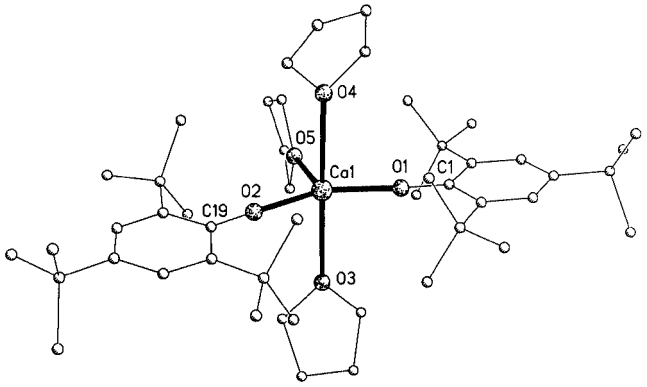


Figure 4. Crystal structure of Ca[2,4,6-tBu$_3$C$_6$H$_2$O]$_2$(THF)$_3$ (**3c**)

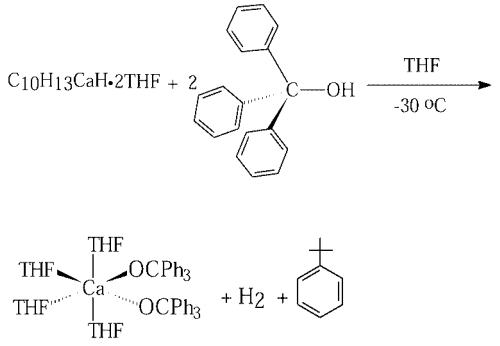
Table 1. Selected bond lengths [Å] and angles [°] for **3c**

Bond	Bond length [Å]	Angle	[°]
Ca1−O1	2.180(3)	O3−Ca1−O4	177.78(12)
Ca1−O2	2.183(3)	O1−Ca1−O2	152.08(12)
Ca1−O3	2.399(3)	O1−Ca1−O5	103.39(10)
Ca1−O4	2.395(3)	O2−Ca1−O5	104.45(11)
Ca1−O5	2.393(3)	C1−O1−Ca1	173.8(3)
O1−C1	1.325(5)	C19−O2−Ca1	178.7(3)
O2−C19	1.336(5)		

The calcium aryloxide **3c** crystallises as a monomer with two aryloxide ligands and a single THF donor molecule in the equatorial plane and two THF donors in axial positions. The Ca atom and three equatorial oxygen atoms are located in a plane with a mean deviation of 0.03 Å. The axial (THF)O−Ca−O(THF) angle of 177.78(12)° is almost linear, but the equatorial ArO−Ca−OAr angle of 152.08(12)° is markedly widened from the expected 120° for an ideal trigonal bipyramid. As a consequence, the angles for the other equatorial ligands are smaller [103.93(10)° for O1−Ca1−O5 and 104.45(11)° for O2−Ca1−O5]. The C_6 planes of the aryl ligands intersect at an angle of 8.2°. The two calcium−oxygen ($^-$OAr) bond lengths of 2.183(3) Å (av.) are almost identical. The Ca−O(THF) bonds are almost invariant at 2.395(3) Å. The carbon−oxygen bonds in the alkoxide ligands are identical within estimated standard deviations [1.324(5) Å for O1−C1 and 1.336(5) Å for O2−C19], and hence considerably shorter than standard C−O single bonds (1.43 Å).[22] In addition, the Ca−O−C angles of 173.8(3)° for Ca1−O1−C1 and 178.7(3)° for Ca1−O2−C19 are almost linear. Similar bond shortening and linearity was found in the analogous complex {[Ca(BHT)$_2$(THF)$_3$]·THF[12] and in the thiolate complex [Ca(SMes)$_2$(THF)$_4$] (Smes = 2,4,6-tBu$_3$C$_6$H$_2$S)}.[23]

The arylcalcium hydride **1c** also reacts with alcohols to form the corresponding bis(alkoxides) of calcium. When triphenylmethanol was allowed to react with **1c**, it produced the previously unrecorded calcium alkoxide **4** in 94% yield, as shown in Scheme 4. A single crystal of **4** was grown for X-ray diffraction over 10 d at +5 °C in THF. The coordina-

tion polyhedron around the central calcium atom is made up of six oxygen atoms, two of the Ph_3CO^- anions in adjacent equatorial positions and four of THF molecules in the remaining equatorial and axial positions (Figure 5). An additional THF molecule is found uncoordinated in the crystal lattice. Bond lengths and angles are described in full in Table 2.



4

Scheme 4. Synthesis of **4** using **1c**

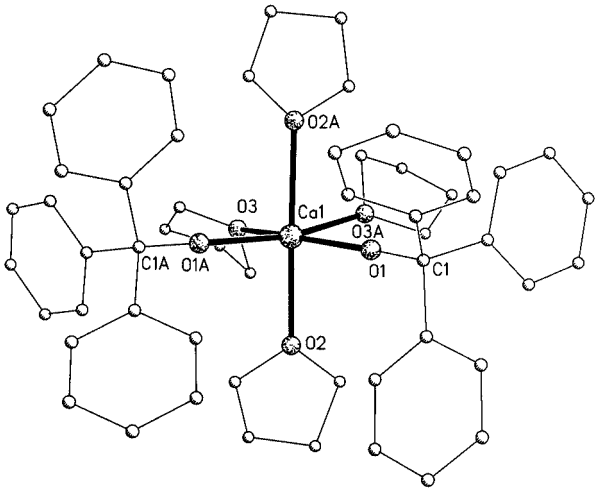


Figure 5. Crystal structure of $Ca[OCPh_3]_2(THF)_4$

Table 2. Selected bond lengths [Å] and angles [°] for **4**

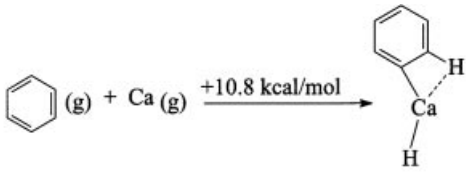
Bond	Bond length [Å]	Angle	[°]
Ca1−O1	2.1609(16)	O1−Ca1−O1A	110.16(9)
Ca1−O2	2.440(2)	O1−Ca1−C3A	87.9(2)
Ca1−O3	2.482(7)	O3−Ca1−O3A	76.3(4)
O1−C1	1.375(2)	O2−Ca1−O2A	166.67(8)
C1−C2	1.565(3)	C1−O1−Ca1	177.47(13)
C1−C8	1.550(3)		
C1−C14	1.565(3)		

The distorted octahedral arrangement is evident from the deviation from linearity of the angle O2−Ca1−O2A, at 166.67(8)°. The calcium atom and four equatorial oxygen atoms are located in a plane with a mean standard deviation of 0.22 Å. The angle O1−Ca1−O1A between the two triphenylmethoxy ligands and the calcium atom is 110.16(9)°, while the angle between the two equatorial THF ligands at the calcium atom is considerably smaller at 76.3(4)°. This deformation in the octahedral geometry can clearly be attributed to the greater steric demand of the alkoxide ligands than of the THF ligands. Both axial THF ligands are bent away from the alkoxide ligands. Again, the angle $Ca-O-C_{Aryl}$, at 177.47(13)°, indicates near linearity. The Ca−O bond length in the alkoxide ligand is 2.1609(16) Å, and hence almost as long as in **3c**. The $O-C_{Aryl}$ single bonds in **4** − at 1.375(2) Å − are slightly longer than in **3c**.

Theoretical Study

In order to gain further insight into the proposed compositions of the arylcalcium hydrides a series of theoretical calculations were performed. As in previous reported theoretical work,[10] the AKR4/6-31g** basis set combination was used. This has proved to give reasonable geometries without greatly increasing the calculation time. As before, ammonia was chosen as a model Lewis base to decrease calculation time.

The aim of this theoretical study was to examine a possible mechanism for this reaction. The first step examined was the direct insertion of calcium atoms into the C−H bond. This is unlikely, since the calculated reaction enthalpy of +10.8 kcal/mol for the formation of PhCaH (**8**) is too large to occur at 77 K (outlined in Figure 6). This would indicate that a highly endothermic reaction is occurring at such a low temperature. The calculated Ca−H bond length for **8** was 2.037 Å and the Ca−C bond length was found to be 2.324 Å. The optimised structure **8** (as shown in detail in Table 3) showed an agostic interaction between the calcium atom and the *ortho* C−H bond of the phenyl ligand. This agostic bond length was calculated as 2.534 Å and the angle between the phenyl ligand, the calcium atom and the hydride ligand (C−Ca−H angle) was found to be 144.8°. This bending of the C−Ca−H angle in conjunction with an agostic C−H bond indicates coordinative unsaturation of the calcium centre in **8**. This is to be expected, since a coordination number of two for calcium is extremely low, particularly in view of the lack of steric bulk in the phenyl and hydride ligands. It would be reasonable to expect that, in the presence of donor solvents such as THF, a higher coordination number would be achieved through the coordination of donor solvent molecules.



8

Figure 6. Reaction of calcium atoms with benzene

In a previous theoretical study,[10] it was reported that phenylcalcium hydride exists in donor solvents as a hydride-bridged dimer with a coordination number of six. Here it is extended to show that the *trans* "$PhCaH\cdot3NH_3$" dimer

Table 3. Comparison of bond lengths and IR frequencies in calculated arylcalcium hydride species

	PhCaH	*trans*-PhCaH·3NH$_3$	*cis*-PhCaH·3NH$_3$
Ca−H [Å]	2.037	2.305	2.318
Ca−C [Å]	2.324	2.552	2.528
Ca−N [Å]	N/A	2.569	2.575
Ca−Ca [Å]	N/A	3.461	3.532
ν_s(Ca−H) [cm^{-1}]	N/A	991 (sym)	849 (sym)
ν_{as}(Ca−H) [cm^{-1}]	N/A	1048 (antisym)	930 (antisym)

species **9** has a reaction enthalpy −13.9 kcal/mol lower than that of the *cis* dimer species **10**, as described in Figure 7. For the *trans* species **9**, the calculated Ca−H bond length is 2.305 Å, the Ca−C bond length is 2.552 Å and the Ca−N bond length is 2.569 Å; these values are outlined in Table 3. The Ca−H antisymmetric vibration, which is IR-active, is calculated as 1078 cm^{-1}. Slightly different values (as shown in Table 3) are seen for **10**. The calculated Ca−H bond (2.318 Å) is slightly longer than in **9**, while the Ca−C bond length was found to be 2.528 Å, shorter than in **9**. The Ca−H antisymmetric vibration in **10** is 930 cm^{-1}. This value is lower than that of **9** (1078 cm^{-1}). It should be possible to distinguish whether "solvated PhCaH" exists in either *cis* or *trans* form in solution by IR methods.

Figure 7. Energy difference between *cis* and *trans* isomers of PhCaH·3NH$_3$

Discussion

Composition of Arylcalcium Hydrides

Mochida originally proposed that the product from the reaction between benzene and calcium atoms was "PhCaH",[9] but he failed to isolate this compound. Instead, it was allowed to react with D_2O and $SiMe_3Cl$. On repeating this experiment in THF, we isolated a dark red, air- and moisture-sensitive solid in 78% yield, as shown in Scheme 1. This is an extremely high yield for an MVS experiment, and it appears moreover that the loss in yield stems from a relatively high-melting matrix in the vessel, which hinders collection of the entire sample. In the benzene cocondensation, for example the matrix is a benzene/THF mixture. The melting point of benzene is 5.5 °C and the melting point of THF is −103 °C. However, the toluene cocondensation has a lower melting matrix of toluene/THF (melting point of toluene −95 °C) and hence a higher yield. This reaction type was expanded to include other +I-substituted benzene derivatives, as in the similar lithium atom reaction.[20] Calcium atoms were able to activate the C−H bonds of toluene, *tert*-butylbenzene, trimethyl(phenyl)silane, and *m*-xylene, as outlined in Scheme 1. It is clear from the derivatisation reactions with chlorotrimethylsilane (as shown in Scheme 1) and $Ph_3C^+BF_4^-$ (shown in Scheme 2) that the backbone of **1a** is composed of the anionic ligands Ph^- and H^-. However, the elemental analysis indicates that the composition is (PhCaH·2THF)$_x$: The existence of coordinated Lewis base molecules such as THF is a well-known facet of calcium chemistry.[1]

Theoretical calculations show the tendency towards oligomerisation through hydride bridging and the uptake of THF to fill the coordination sphere of the calcium atom. These calculations showed that the formation of PhCaH is energetically unfavourable by +10.8 kcal/mol and that an aggregated state through hydride bridging is favoured over a monomeric species.[6] These calculations also showed that the favoured coordination number is six and that a solvent-dependent equilibrium exists in donor solvents. The calculations show that the aggregation state can be elucidated from the IR data on the Ca−H vibration. The calculated IR frequency for a terminal hydride ligand (e.g., monomeric PhCaH·4NH$_3$) is 897 cm^{-1}. When the hydride ligand is bridging, as in a dimeric species, the calculated Ca−H vibration is higher, at 1048 cm^{-1}. The calculated data for this dimeric species are in good agreement with the experimentally measured value of 1094 cm^{-1}. However, the possibility of higher aggregates such as tetramers (in which the hydride ligand would be triply bridging) or an oligomeric species through mixed bridging of the phenyl and hydride ligands cannot be gauged from these data.

Selectivity of C−H Activation with Calcium Atoms

Lithium atoms have been reported to activate aromatic C−H bonds of +I-substituted benzene derivatives selectively in the *para* position.[24] By use of an approach similar to Mochida's and by treatment of the "ArCaH" with chlorotrimethylsilane at −30 °C, easy identification of the activated positions on the aromatic ring by NMR and GC MS is possible. On expanding this reaction type to other aromatic compounds [e.g., toluene, *tert*-butylbenzene, trimethyl(phenyl)silane, and *m*-xylene], it was expected that selective C−H bond activation in the *para* position would be observed, in a reaction series analogous to that of lithium atoms.[20] However, this was not observed; instead, a lack of selectively was noted. All benzene derivatives except xylene experienced the activation of the *ortho*, *meta*, and *para* C−H bonds. This lack of selectivity is different to the case of the lithium atom reaction, in which the *para* position was selectively attacked.[24] Another difference was that xylene, which had failed to react with lithium atoms, reacted with calcium atoms. [Calcium atoms react with mesitylene, which does not react with lithium atoms, to yield an extremely pyrophoric, insoluble, red solid.]

One similarity to the lithium atom reaction is that the reaction between calcium atoms and toluene does not result in the activation of the thermodynamically favoured benzyl position. In the case of lithium atoms, it was shown the a key intermediate was the formation of a π complex between

the benzene ring and an Li_2 cluster, which favours the activation of the aromatic C−H bonds.[24]

Reactions of Arylcalcium Hydrides

These arylcalcium hydrides can be redissolved in THF and allowed to react with sterically bulky phenols and alcohols to form bis(aryloxides)/-(alkoxides) of calcium in improved yields (all > 95%).[12]

The structure of **3c** is similar to those of **5** and **7**, which are shown in Figure 8 and have been reported previously.[12,23] It is monomeric, in a distorted trigonal-bipyramidal arrangement, with the Ca−O(phenolate) bond length of 2.182(3) Å av. for **3c** being shorter than that for **5** at 2.197 Å. Like those in **5** and **7**, the aryloxide ligands in **3c** are in the equatorial positions. Another similarity between **3c** and **5** is the almost linear Ca−O−C angle. It is not clear what causes this linearity (and shortened Ca−O bond) in calcium aryloxides.[12] One possible explanation is the steric load on the ligands in both **3c** and **5**; another might lie in π-bonding.[25,26] This is not as unreasonable as it appears, since aryloxides are good π-donor ligands and it has been shown that calcium possesses low-lying d orbitals that influence the structure of molecules.[27−29] It can be very difficult to separate steric and electronic effects.[30] It has been demonstrated that the M−O−C angle has no simple correlation with the degree of π-bonding.[25] A similar comparison can be made between the calcium alkoxide **4** and the previously reported species **6** and **8**.[12,31] There is a pronounced difference between the structures. In **4**, the crystal was grown from THF and crystallised as a monomer of coordination number six, while compounds **6** and **8** were grown from toluene and crystallised as dimers with lower coordination numbers of four and three, respectively. The Ca−O bond length for the terminal alkoxide in **6** is 2.105 Å, shorter than the same Ca−O bond length, of 2.1609(17) Å, in **4** and more akin to the Ca−O bond lengths found in the aryloxide species **3d** [2.182(3) Å] and **8** (2.121 Å). Unlike those in the above species **3c**, **4**, and **5**, the Ca−O−C angle in **6** is bent at 167.4°, while in **4** the Ca−O−C angle is 177.46(14)°. This is almost linear and similar in value to those in the aryloxide species **3c** and **5**.

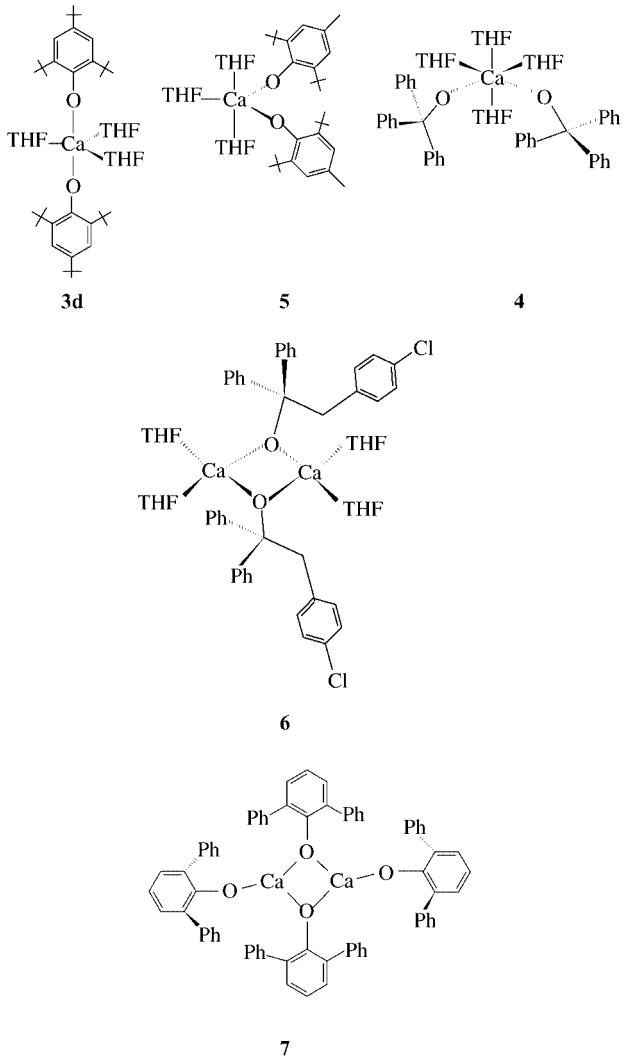

Figure 8. A comparison of some selected group-II bis(alkoxides)

Conclusion

Calcium atoms react unselectively with toluene, *tert*-butylbenzene and trimethyl(phenyl)silane to form the *ortho*, *meta*, and *para* isomers of each arylcalcium hydride. However, when *m*-xylene was cocondensed with calcium atoms in the presence of THF, selective C−H bond activation in the position *meta* to the methyl groups was observed. These arylcalcium hydrides are useful reagents for the formation of calcium bis(alkoxides). The reactions between (*tert*-butylphenyl)calcium hydride and different *tert*-butyl-substituted phenols resulted in the formation of the corresponding aryloxides in high yields. In $Ca(2,4,6\text{-}tBu_3C_6H_2O)_2(THF)_3$ the five oxygen atoms furnish a distorted trigonal-bipyramidal coordination polyhedron with the sterically bulky aryloxide ligands in the equatorial positions. In a similar reaction, triphenylmethanol yielded the alkoxide $[Ca\{OC(C_6H_5)_3\}_2(THF)_4]$ in a similar high yield. This compound shows a distorted octahedron of six oxygen atoms around the central metal atom and the two alkoxide ligands in a *cis* equatorial geometry.

Experimental Section

General: All experimental procedures were performed by use of standard Schlenk techniques under dry argon. Solvents such as THF, benzene, toluene, *m*-xylene, and *tert*-butylbenzene were dried and distilled prior to use from sodium benzophenone ketyl under argon. Trimethyl(phenyl)silane was dried and distilled from calcium dihydride under argon. Pentane was dried and distilled prior to use from sodium/potassium amalgam under argon. The solvents were then degassed by three freeze-pump-thaw cycles. Triphenylcarbenium tetrafluoroborate and 18-crown-6 were purchased from Aldrich and dried under high vacuum for 2 d. Celite was stored in an oven at 120 °C overnight and was dried under vacuum for 3 h before use. Approximately 6 cm of Celite was used for each filtra-

tion. ^{1}H and ^{13}C NMR spectra were obtained with either a Varian 300 MHz or a Varian 500 MHz NMR machine. All chemical shifts are reported in ppm and are referenced to TMS. All the GC MS samples were run as ethyl acetate solutions with a Finnigan Trace GC MS, on a room temp. X-5MS 15-m column. Warwick Analytical Service, Warwick, UK, performed the elemental analysis.

Typical Cocondensation Experiment: Calcium (1.5 g, 0.0375 mol) was vaporised from an alumina crucible over 90 min (5.6 V and 56 A) and cocondensed with a mixture of the aromatic compound (20 mL) and THF (80 mL). The pressure measured at the bottom of the cocondensation vessel was kept below 10^{-5} mbar to avoid gas-phase reactions between the metal atoms and reactants. The apparatus used has been described previously.[24] At the end of the experiment, the frozen matrix was allowed to warm up under argon. The molten mixture flowed through an internal drain into a Schlenk tube. The solution was filtered through 6 cm of Celite and the solvent was evaporated under reduced pressure to yield a dark red, pyrophoric solid $\{(ArCaH{\cdot}2THF)_x\}$ in yields ranging from 78 to 97%.

Cocondensation of Benzene with Calcium Atoms in THF: This cocondensation yielded a dark red, pyrophoric solid $\{(PhCaH{\cdot}2THF)_x\}$(**1a**) in 78% yield. $C_6H_5CaH{\cdot}2THF$ (262.4): calcd. C 64.1, H 8.4, Ca 15.3; found C 63.5, H 7.9, Ca 15.2. IR (Nujol mull; major peaks): $\tilde{\nu}$ = 3369 (s), 1285 (m), 1224 (s), 1094 (vs), 1031 (w), 981 (m), 905 (s), 837 (s), 751 (m), 726 (m), 696 (m) cm^{-1}.

Cocondensation of Toluene with Calcium Atoms in THF: This cocondensation yielded a brown, pyrophoric solid $\{(C_7H_7CaH{\cdot}2THF)_x\}$ (**1b**) in 97% yield. $C_7H_7CaH{\cdot}2THF$ (276.4): calcd. C 65.2, H 8.8, Ca 14.5; found C 64.4, H 8.8, Ca 14.3. IR (Nujol mull; major peaks): $\tilde{\nu}$ = 3368 (s), 1285 (m), 1223 (s), 1093 (vs), 1032 (w), 986 (m), 908 (s), 837.9 (s), 752 (m), 728 (m), 691 (m) cm^{-1}.

Cocondensation of *tert*-Butylbenzene with Calcium Atoms in THF: This cocondensation yielded a dark red, pyrophoric solid $\{(C_{10}H_{13}CaH{\cdot}2THF)_x\}$ (1c) in 93% yield. $C_{10}H_{13}CaH{\cdot}2THF$ (318.5): calcd. C 67.9, H 9.5, Ca 12.6; found C 67.0, H 9.2, Ca 12.3. IR (Nujol mull; major peaks): $\tilde{\nu}$ = 3370 (s), 1264 (s), 1112 (s), 1094 (vs), 1033 (w), 982 (m), 835 (s), 761.6 (m), 723 (m), 697 (m) cm^{-1}.

Cocondensation of *m*-Xylene with Calcium Atoms in THF: This cocondensation yielded a dark red, pyrophoric solid $\{(C_8H_9CaH{\cdot}2THF)_x\}$ (**1d**) in 85% yield. $C_8H_9CaH{\cdot}2THF$ (290.5): calcd. C 66.2, H 9.0, Ca 13.8; found C 65.9, H 8.7, Ca 13.6. IR (Nujol mull; Major peaks): $\tilde{\nu}$ = 3372 (s), 1288 (m), 1220 (s), 1096 (vs), 10323 (w), 989 (m), 912 (s), 838.4 (s), 757 (m), 732 (m), 686 (m)cm^{-1}.

Cocondensation of Trimethyl(phenyl)silane with Calcium Atoms in THF: This cocondensation yielded a dark red, pyrophoric solid $\{(C_9H_{13}CaH{\cdot}2THF)_x\}$ in 86% yield. $C_9H_{13}SiCaH{\cdot}2THF$ (334.6): calcd. C 61.0, H 9.0, Ca 12.0, Si 8.4; found C 59.8 H 8.8, Ca 12.3, Si 8.0. IR (Nujol mull; major peaks): $\tilde{\nu}$ = 3372 (s), 1591 (w), 1306 (w), 1260 (s), 1206 (m), 1114 (m), 1094 (vs), 1034 (m), 1019 (s), 837 (m), 801 (br), 751 (m), 725 (s), 698 (m), 618 (m) cm^{-1}.

Typical Derivatisation of the Arylcalcium Hydride with Chlorotrimethylsilane: Chlorotrimethylsilane (0.06 mL, 0.73 mmol) in THF (5 mL) was added dropwise at −30 °C to a stirred solution of arylcalcium hydride (1.0 g, dissolved in 50 mL of THF). The dark red colour turned yellow over a period of 5 min. After this time, the stirring was continued, while the solution was allowed to warm to room temperature. Water (15 mL) was added to this solution. The organic layer was separated and dried with magnesium sulfate, and the solvent was removed under reduced pressure to yield the corresponding substituted silane as a dark red oil.

Derivatisation of 1b with Chlorotrimethylsilane: All three possible trimethyl(methylphenyl)silane isomers were detected by GC MS ([M$^+$]: *m*/*z* = 164.1). Trimethyl(2-methylphenyl)silane: ^{1}H and ^{13}C NMR spectroscopic data agree with literature values.[14] Trimethyl(3-methylphenyl)silane: ^{1}H and ^{13}C NMR spectroscopic data agree with literature values.[15] Trimethyl(4-methylphenyl)silane: ^{1}H and ^{13}C NMR spectroscopic data agree with literature values.[16]

Treatment of 1c with Chlorotrimethylsilane. All three possible (*tert*-butylphenyl)trimethylsilane isomers were detected by GC MS ([M$^+$]: *m*/*z* = 206.4). (2-*tert*-Butylphenyl)trimethylsilane: ^{1}H and ^{13}C NMR spectroscopic data agree with literature values.[17] (3-*tert*-Butylphenyl)trimethylsilane: ^{1}H and ^{13}C NMR spectroscopic data agree with literature values.[18] (4-*tert*-Butylphenyl)trimethylsilane: ^{1}H and ^{13}C NMR spectroscopic data agree with literature values.[19]

Treatment of 1e with Chlorotrimethylsilane: Only one compound was detected by GC MS ([M$^+$]: *m*/*z* = 178.4), corresponding to (3,5-dimethylphenyl)trimethylsilane as identified by ^{1}H and ^{13}C NMR data.[20]

Treatment of 1d with Dimethyl Disulfide: Dimethyl disulfide (0.07 mL, 0.73 mmol) in THF (5 ml) was added dropwise at −30 °C to a stirred solution of **1d** (1.0 g, 0.091 mmol, dissolved in 50 mL of THF). The workup was performed as for the derivatisation above. All three isomers of trimethyl[(methylthio)phenyl]-silane were detected by GC MS ([M$^+$]: *m*/*z* = 196.4). Trimethyl[2-(methylthio)phenyl]silane: ^{1}H NMR ($CDCl_3$): δ = 0.33 (s, 9 H, $SiMe_3$), 2.52 (s, 3 H, SCH_3), 7.31 (2 H, Ar-H), 7.5 (2 H, ArH) ppm.^{13}C NMR ($CDCl_3$): δ = −1.1 ($SiMe_3$), 15.6 (SCH_3), 124.4 ($C_{meta'}$), 125.9 (C_{meta}), 129.0 (C_{para}), 132.5 ($C_{ortho'}$), 138.1 (C_{ipso} $CSiMe_3$), 144.1 (C_{ortho} CSMe). Trimethyl[3-(methylthio)phenyl]silane: ^{1}H and ^{13}C NMR spectroscopic data agree with literature values.[17] Trimethyl[4-(methylthio)phenyl]silane: ^{1}H and ^{13}C NMR spectroscopic data agree with literature values.[19]

Typical Hydride Abstraction Reaction of the Arylcalcium Hydride with Ph_3CBF_4: The appropriate arylcalcium hydride (0.52 g, 1.9 mmol) was dissolved in toluene (30 mL) and 18-crown-6 (0.5 g, 1.9 mmol) and placed in a pressure-equalising dropping funnel. This solution was added slowly at −30 °C and with vigorous stirring to a suspension of triphenylcarbenium tetrafluoroborate (0.65 g, 1.9 mmol) in toluene (20 mL). After completion of the addition, the dark red solution was stirred at −30 °C for 1 h. Any unchanged solid was removed by filtration and the toluene solvent was removed in vacuo to yield triphenylmethane.

Typical Synthesis of Calcium Bis(alkoxides) by Use of 1c: Compound **1c** (1.27 g, 0.001 mol) was dissolved in THF (150 mL). The substituted alcohol or phenol (0.008 mol), dissolved in THF (50 mL), was added dropwise to this solution over 15 min at −30 °C. The solution was kept at −30 °C with vigorous stirring until the evolution of H_2 had ceased. The solution was then allowed to warm up slowly to room temperature. The solvent was removed under vacuum to yield a beige, moisture-sensitive solid. This was washed twice with pentane and the remaining solid was dried under vacuum to yield the corresponding bis(alkoxide) of calcium in high yields ranging from 95 to 98%.

Synthesis of $[Ca(2,6\text{-}tBu_2C_6H_2O)_2(THF)_3]$ (3a): This reaction yielded 0.53 g (96% yield) of **3a** as an off-white solid. ^{1}H NMR

(500 MHz, C_6H_6) δ = 7.3 (d, 4 H), 6.7 (t, 2 H), 3.4 (s, 12H THF), 1.9 (s, 12 H, THF), 1.4 (s, 36 H, CH_3) ppm. ^{13}C NMR (500 MHz, C_6H_6) 164.4 (C_{ipso}), 137.4 C_{ortho}), 125.0 (C_{meta}), 112.8 (C_{para}), 69.1 (THF), 35.4 $(CCH_3)_3$, 31.4 (CH_3), 25.1 (THF) ppm. IR (Nujol mull; major vibrations): $\tilde{\nu}$ = 2887 (m), 1416 (m) 1382 (s), 1228 (m), 1037 (s), 898 (m), 809 (m), 519 (m) cm^{-1}.

Synthesis of [Ca(2,6-*t*Bu$_2$-4-MeC$_6$H$_2$O)$_2$(THF)$_3$] (3b): This reaction yielded 0.55 g (98% yield) of **3b** as an off-white solid. ^1H and ^{13}C NMR spectroscopic data (500 MHz C_6H_6) agree with literature values.[12]

Synthesis of [Ca(2,4,6-*t*Bu$_3$C$_6$H$_2$O)$_2$]·3THF (3c): This reaction yielded 0.59 g (97%) of **3c** as an off-white solid. ^1H and ^{13}C NMR (500 MHz C_6H_6) agree with literature values.[32] X-ray quality crystals were grown from a concentrated THF solution at +5 °C over a period of one week.

Synthesis of [Ca{OC(C$_6$H$_5$)$_3$}$_2$(THF)$_3$] (4): This reaction yielded 0.77 g (95%) of **4** as a pale white solid. A colourless single crystal of **4** for X-ray diffraction studies was grown from a concentrated THF solution at +5 °C over 10 d. ^1H NMR (500 MHz, C_6H_6) δ = 7.30 (d, 12 H, CH C_6H_5), 7.10−7.01 (m, 18 H, C_6H_5), 3.41 (m, 16 H, THF), 1.36 (m, 16 H, THF) ppm. IR (Nujol mull; major bands): $\tilde{\nu}$ = 3056 (s), 2919 (m), 1490 (m), 1444 (m), 1230 (s), 1031 (vs), 1015 (s), 823 (m), 776 (m), 754 (m), 727 (m), 700 (s), 671 (m), 617 (m), 512 (m) cm^{-1}.

X-ray Crystallographic Study of 3c and 4: The data for **3c** and **4** were collected at 173(2) K from shock-cooled crystals with a BRUKER SMART-APEX diffractometer (graphite-monochromated Mo-K_α radiation, λ = 71.073 pm), equipped with a low-temperature device.[32] The crystal data are summarized in Table 4. The structure was solved by direct methods (SHELXS-NT97)[33] and refined by full-matrix, least-squares methods against F^2 (SHELXL-NT97).[34] R values defined as $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$, $w = [\sigma^2(F_o^2) + (g_1P)^2 + g_2P]^{-1}$, $P = 1/3[\max(F_o^2,0) + 2F_c^2]$. SADABS 2.0 was employed as a program for empirical absorption correction.[35] In addition to the calcium complex **3c**, the unit cell also contained 2.5 noncoordinating THF molecules. The THF molecule (O7−C57) is disordered and was refined to split occupancies of 0.68/0.32. The disordered *tert*-butyl moiety (C12−C14) was refined to a split occupancy of 0.65/0.35. All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were geometrically idealised and refined with a riding model. In addition to the calcium complex **4**, the unit cell also contains one noncoordinating THF molecule. The coordinated THF molecule (O3−C27) was disordered and could be refined to split occupancies of 0.73/0.27. Bond length and similarity restraints were used in the refinement of the disorder. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were geometrically idealised and refined with a riding model. CCDC-190905 (**3c**) and -190906 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Theoretical Methods: For determination of the structures, spectroscopic data, and reaction enthalpies of intermediates in the reaction mechanisms, the application of theoretical methods has proven advantageous. For this purpose the program package GAUSSIAN98[36] implemented on a DEC Alpha workstation (500 MHz CPU/256 MB RAM) or an Origin 200 eight-processor cluster (SGI, 180 MHz CPU/2 GB RAM) was used. Ab initio calculations were performed at the DFT level of theory (B3LYP) with the 6-31G** basis set for C, H, and N. The chosen general basis set for calcium was AKR4, which was used by us in another study on organocalcium complexes.[6] Harmonic vibrational frequencies, calculated at the same level, characterised stationary points and gave the zero-point energies. The difference in the sum of the electronic and the zero-point energies were interpreted as reaction enthalpies at 0 K.

Table 4. Crystallographic data for [Ca{2,4,6-*t*Bu$_3$C$_6$H$_2$O}$_2$(THF)$_3$] (**3c**) and [Ca(OPh$_3$)$_2$(THF)$_4$] (**4**) at T = 173 K

A Facile Direct Synthesis of Bimetallic $Cu^{II}Zn^{II}$ Complexes with Ethylenediamine Revealing Different Types of Chain Crystal Structures

Oksana V. Pryma,[a] Svitlana R. Petrusenko,*[a] Volodymyr N. Kokozay,[a] Brian W. Skelton,[b] Oleg V. Shishkin,[c] and Tetyana S. Teplytska[c]

Keywords: Heterometallic complexes / Copper / Zinc / N ligands

Unactivated copper metal powder and zinc oxide readily react with ethylenediamine (en) in nonaqueous [methanol, dimethylformamide (dmf), dimethyl sulfoxide (dmso), acetonitrile] solutions of ammonium salts under ambient conditions producing, in high yields, a series of heterobimetallic complexes of general formula $[Cu(en)_2ZnX_4]\cdot(Solv)$, where X = Cl, Br, NCS, CH_3COO (OAc); Solv = dmf, dmso, CH_3CN, H_2O. The single-crystal X-ray analysis of the complexes reveals chain structures, which are based on the completion of the octahedral coordination of Cu^{II} by two bridging X atoms from ZnX_4^{2-}. The ZnX_4^{2-} is shown to be a distorted tetrahedron (Cl, Br, NCS) or a very distorted octahedron (OAc) and to behave as a one- or two-linking centre bridging ligand. The chains are found to be zigzag $[Cu(en)_2ZnCl_4]\cdot$dmso (**1**), $[Cu(en)_2ZnCl_4]\cdot$dmf (**2**), $[Cu(en)_2Zn(NCS)_4]\cdot CH_3CN$ (**3**), quasi linear $[Cu(en)_2Zn(OAc)_4]$ (**4**), or helical, $[Cu(en)_2Zn(NCS)_4]\cdot 0.5H_2O$ (**5**), depending on the nature of the anion and solvent. Complex **4** represents the first compound containing $Zn(OAc)_4^{2-}$ to be crystallographically authenticated.

Introduction

The one-pot synthesis of metal complexes using elemental metals as starting materials, the so called "direct synthesis of coordination compounds" (DS),[1] has become an active research field and is undergoing rapid progress. Among the various methods of DS — cryosynthesis, electrochemical synthesis, mechanosynthesis — the oxidative dissolution of unactivated coarse-grain metal powders in solutions of ligands is one of the most important because of its simplicity and versatility. This method has provided a route to the synthesis of almost all the main types of monometal coordination compounds.[1,2]

Recently we have expanded this approach to the preparation of mixed-metal complexes that are of current interest due to their promising physical and biological properties. The synthetic procedure shown in Scheme 1 has been used to produce a series of new heterobimetallic Cu^{II}/M^{II} (M = Co, Ni, Zn, Pb) complexes with amino alcohols (HL).[2–8]

$$Cu^0 - M^0/MX_2 \text{ - HL - Solv (in air)}$$

Scheme 1

The synthetic route (Scheme 1) is effective when using proton-donating ligands. In this paper we suggest developing DS for the use of aprotic ligands (L). The essence of the proposed approach is to use ammonium salts as both proton- and anion-donating reagents (Scheme 2).

$$Cu^0 \text{ - } M^0/MO \text{ - L - } NH_4X \text{ - Solv (in air)}$$

Scheme 2

Ethylenediamine was employed in our synthesis as an aprotic ligand. It has been shown that ethylenediamine can take part in the activation of the metal surface and also in electron transfer in the reacting system.[9] Moreover, it is a strong coordinating agent that is efficiently applied in supramolecular design.[10–13]

Exploiting this approach (Scheme 2), we have synthesized a number of $Cu^{II}Zn^{II}$ complexes with ethylenediamine, which have the general formula $[Cu(en)_2ZnX_4]\cdot n$ Solv (X = Cl, Br, SCN, OAc; Solv = dmf, dmso, CH_3CN, and H_2O which is produced in the reaction; n = 0, 0.5, 1). The reactions proceed in the following way:

$$Cu^0 + ZnO + 2\,en + 4\,NH_4X + 1/2\,O_2 + n\,Solv \rightarrow [Cu(en)_2ZnX_4]\cdot n\,Solv + 4\,NH_3 + 2\,H_2O$$

In each case the reactions were conducted in air, at 50–60 °C and with stirring for 1–2 h. The yields of the products were up to 90%.

Details of the syntheses, crystal structures and IR spectroscopic investigations of the complexes are reported.

Results and Discussion

Zigzag CuZn Chain Structures of $[Cu(en)_2ZnCl_4]\cdot$dmso (1), $[Cu(en)_2ZnCl_4]\cdot$dmf (2), and $[Cu(en)_2Zn(NCS)_4]\cdot CH_3CN$ (3)

All the titled complexes possess the same type of crystal structure. The tetrahedral ZnX_4^{2-} anions behave as one-linking centre bridging ligands, spanning the square planar $Cu(en)_2^{2+}$ cations in the *trans* positions with the Cl (in **1**, **2**) or S (in **3**) atoms, building up one-dimensional networks (Figure 1). The unusual coordination mode of ZnX_4^{2-} in these complexes is most probably due to the set of hydrogen bonds (ca. 3.0−3.2 Å) between the amino groups of ethylenediamine and the donor atoms of the nonbridged X ligands. Usually, the coordination is two-linking for similar complexes, as in $[ZnL_2][ZnCl_4]$ (L = diacetone alcohol).[14] Additionally the structure is supported by the guest dimethyl sulfoxide, dimethylformamide or acetonitrile molecules accommodated in the interchain space and hydrogen bonded through the O (dmso, dmf) or N (CH_3CN) atoms to the NH_2 groups (Figure 1). The lengths of the en-solvate hydrogen bonds show the strongest connection in case of dmso molecule [$d(N\cdots O_{dmso})$ are 2.95(1) and 2.94(1) Å (**1**), $d(N\cdots O_{dmf})$ are 3.171(7) and 2.973(8) Å (**2**), $d(N\cdots N)$ are 3.13(2) and 3.07(2) Å (**3**)].

The chains of Cu−Zn atoms have a zigzag shape with the Cu−Zn−Cu angle [89.06(2)° (**1**), 82.88(2)° (**2**), 66.05(3)° (**3**)] being dependant on both the nature of the X ligands in the ZnX_4^{2-} anion and the nature of the solvate molecule. The Cu···Cu distances within the chains are 5.910(1), 5.5130(5) and 6.308(3) Å for **1**, **2** and **3**, respectively.

Bond lengths in the en ligands and Cu−N distances (Table 2) are in accordance with those found in the literature for similar copper(II) complexes.[15,16] The axial Cu−X distances are 3.117(3) and 3.085(4) Å (Cu−Cl, **1**), 2.9285(8) Å (Cu−Cl, **2**), 3.202(4) Å and 3.232(4) Å (Cu−S, **3**). These are quite long but do occur in complexes that have an elongated tetragonal or rhombic octahedral stereochemistry of the copper(II) ion, e.g. the $Cu-Cl_{ax}$ distances of ca. 3.0−3.2 Å are found in $Cs_3[Cu_2Cl_7(H_2O)_2]$,[17] $(Me_3NH)_2[Cu_4Cl_{10}]$,[18] $[Pt(NH_3)_4CuCl_4]$,[19] and the $Cu-S_{ax}$ of 3.00 and 3.27 Å in $[Cu(NH_3)_4(SCN)_2]$[20] and $[Cu(en)_2(SCN)_2]$,[21] respectively. The geometrical parameters of ZnX_4^{2-}, namely nonequivalence of the Zn−Cl and Zn−N bond lengths (Table 2), lend additional support to the conclusion that the complex anions are weakly or *semi*-coordinated[22] to the copper(II) ion and not just positioned by van der Waals forces.

Quasi Linear CuZn Chain Structure of $[Cu(en)_2Zn(OAc)_4]$ (4)

Although the main building blocks of the acetate complex $Cu(en)_2^{2+}$ and $Zn(OAc)_4^{2-}$ show a formal resemblance

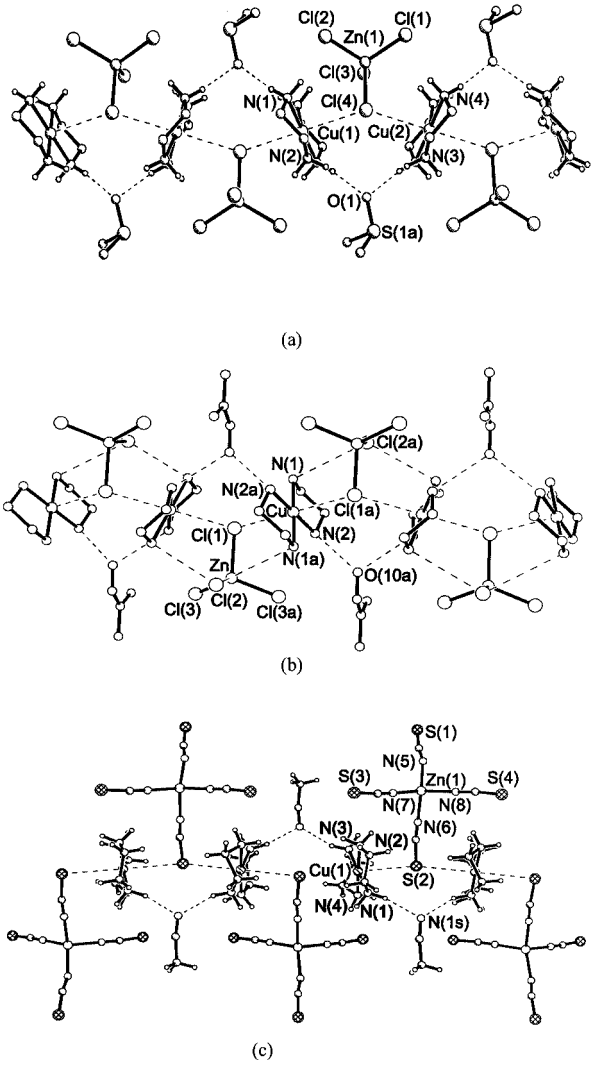

Figure 1. Structures of zigzag CuZn chains in (a) $[Cu(en)_2ZnCl_4]\cdot$dmso (**1**), (b) $[Cu(en)_2ZnCl_4]\cdot$dmf (**2**), (c) $[Cu(en)_2Zn(NCS)_4]\cdot CH_3CN$ (**3**), with atomic numbering

to **1**−**3**, the differences in their crystal structures are quite significant. Most importantly, the Zn atom in the tetraacetatozincate ion is not four- but now six-coordinate through two asymmetrically chelating and two monatomic bridging bidentate acetate groups (Figure 2). The octahedron ZnO_6 is very distorted: the Zn−O distances and O−Zn−O angles vary from 2.00−2.41 Å and 57.0−154.4°, respectively (Table 2). Because no crystallographic data was found for $Zn(OAc)_4^{2-}$ a structural comparison was made with $M(OAc)_4^{2-}$ (M = Cu, Cd)[23] and $Zn(NO_3)_4^{2-}$.[24] In these complexes the symmetry of the resulting coordination polyhedron is approximately D_{2d} and depicted as a distorted dodecahedron. The differences in the bond lengths M−O within a chelate carboxylate group or nitrate ring are very significant [Cu−O(OAc) = 1.97−2.79 Å and Zn−O(NO_3) = 2.03−2.52 Å]. In the case of the tetranitratozincate complex the distortions observed were explained by the tendency of the Zn^{II} ion to undergo tetrahedral coor-

dination; this explanation may also be applicable in our case.

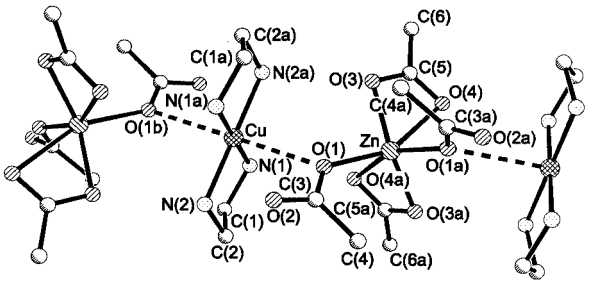

Figure 2. Structure of quasi linear CuZn chain in $[Cu(en)_2Zn(OAc)_4]$ (**4**) with atomic numbering.

It is worth noting that the absence of data on the crystal structure of $Zn(OAc)_4^{2-}$ may not be accidental but due to its low thermodynamic stability. A search for isomorphous crystals of $CaCu(OAc)_4{\cdot}6H_2O$ was undertaken by Langs and Hare,[23] but all attempts to substitute the Zn atoms for Cu atoms were met with failure. The existence of the $Zn(OAc)_4^{2-}$ in **4** is presumably stabilized by the $Cu(en)_2^{2+}$ cation, which is apt to the formation of numerous hydrogen bonds. Indeed, all the acetate oxygen atoms [except O(1), which is bridging the Cu and Zn atoms] take part in hydrogen bonding (Table 3).

The arrangement of the Cu and Zn atoms is almost linear, with the angle at the Cu atom (on an inversion centre) being 180° and that at the Zn atom, 170.25(2)°. The Cu···Zn distances are 4.1064(7) Å.

Helical CuZn Chain Structure of $[Cu(en)_2Zn(NCS)_4]{\cdot}0.5H_2O$ (5)

One of the more interesting structures is given in Figure 3 where a helical type of chain crystal structure is presented. A comparison of the structures of **3** and **5** demonstrates seemingly insignificant changes in composition, such as the replacement of an included acetonitrile molecule for a water molecule, associated with dramatic changes in the supramolecular structure. In contrast to **3**, in the hydrate complex a $Zn(NCS)_4^{2-}$ ion acts as a two-linking centre bridging ligand connecting the $Cu(en)_2^{2+}$ moieties in an infinite bimetallic spiral. The spirals, running along the *a* axis, form channels filled with uncoordinated water molecules (Figure 3, see b).

The Zn^{II} coordination environment closely approximates tetrahedral symmetry, the N−Zn−N bond angle being 107−112°. The thiocyanato groups are almost linear with a mean value of the N−C−S angles of 177(2)°. The Zn−N−C linkages are bent with angles varying from 159(1)° to 177(2)°; those with maximal deviations from linearity have the NCS^- groups bridging Zn and Cu atoms with the minimal values being those of the N(6)C(6)S(2) group, which bridges the Zn atoms such that the Zn-NCS···Zn′ atoms are essentially linear [the S(2)···Zn distance and C(6)S(2)Zn angle are ca. 3.64 Å and 171° respectively] (Figure 3, see a). The S−C average distance of 1.62(2) Å, and C−N average distances of 1.14(2) Å are in accordance with the values observed in other thiocyanato-containing metal complexes.[25,26]

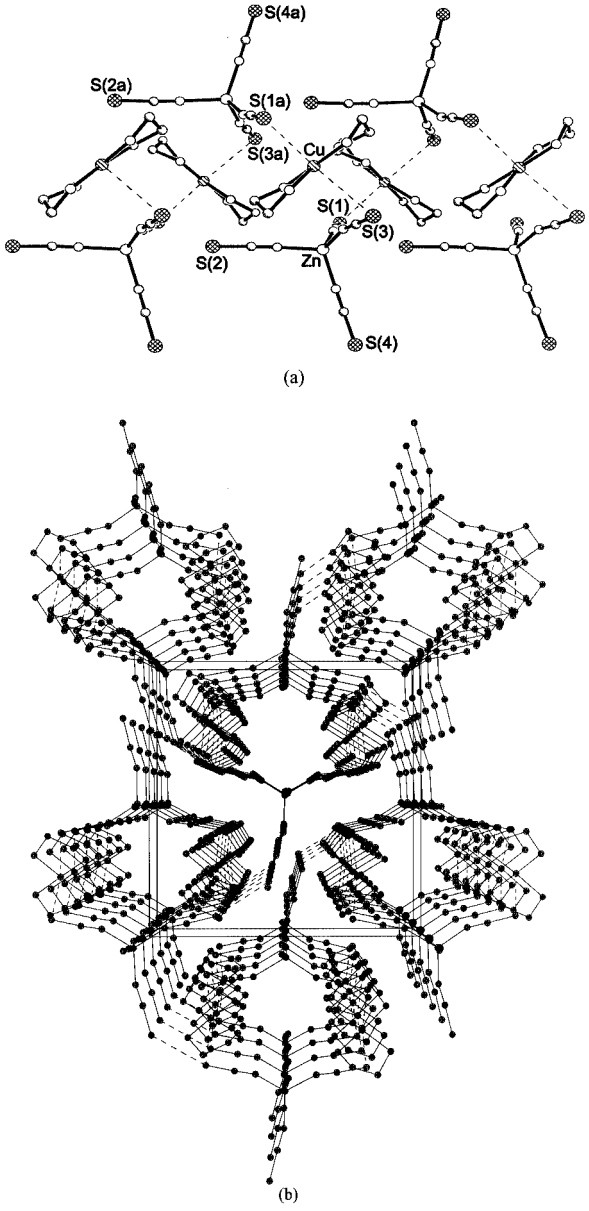

Figure 3. (a) Structure of helical CuZn chain in $[Cu(en)_2Zn(NCS)_4]{\cdot}0.5H_2O$ (**5**) with atomic numbering; (b) packing diagram of **5** revealing the channels down the a axis; hydrogen atoms and water molecules are omitted for clarity.

The Cu^{II} ion has asymmetric (4+1+1) surroundings; the axial positions are occupied by the S(1) and S(3) atoms from the thiocyanate groups: Cu−S(1) = 2.921(6) and Cu−S(3) = 3.218(5) Å; the S(1)−Cu−S(3) angle is 170.7(1)°. The CuN_4 fragment is largely planar and its geometrical parameters are consistent with those normally observed.[16]

IR Spectroscopic Measurements

The infrared spectra for complexes **1**−**5** contain characteristic ν(N−H), ν(C−H), δ(HNH), ν(C−N) and ν(C−C)

frequencies for ethylenediamine in the ranges 3325−3130, 2990−2890, 1605−1580 (in **4** the corresponding mode of en is obscured by stretching vibrations of the carboxylate group), 1105−1053 and 990−980 cm^{-1}, respectively. Evidence for the coordination of en is provided by the shift of asymmetrical and symmetrical NH stretching frequencies of ca. 30−100 cm^{-1} to lower values and CH stretching frequencies of ca. 50−80 cm^{-1} to higher values compared with corresponding ones for en itself [3355, 3270 cm^{-1} − ν(NH); 2925, 2855 cm^{-1} − ν(CH)].[27,28] Two strong and broad absorption bands found for the acetate groups in complex **4** (1630− 580 and 1430−1390 cm^{-1}) lead to the Δ value [$\Delta = \nu_{as}(COO) - \nu_s(COO)$] in the range 150−240 cm^{-1}. This value is consistent with bridging unidentate or asymmetrical chelate (''pseudo-unidentate'') carboxylate coordination.[29] The coordinated thiocyanate groups in **3** and **5** are confirmed by the presence of the intense absorption at 2090 cm^{-1} attributed to $\nu_{as}(C\equiv N)$ and the weak ν(CS) absorption at 835 cm^{-1}.[26] The presence of the solvate molecules in **1**−**3** can be identified by the peaks at 1020 and 950 cm^{-1} (for dmso, **1**), 1650 cm^{-1} (for dmf, **2**), and 2250 cm^{-1} (for CH_3CN, **3**). It should be noted that the peaks of ν(SO) and ν(CO) found in **1** and **2** are typical for coordinated dmso and dmf[26] but in our case the shift of the frequencies to lower values can be explained by the participation of the solvates in hydrogen bonding.

Conclusion

This paper describes a novel synthetic method for the preparation of bimetallic Cu/Zn complexes with ethylenediamine using zerovalent copper in powdered form. We consider that such an approach can also be used for the synthesis of other mixed-metal compounds, e.g. Cu/Cd, Cu/Ni and Cu/Co, with ethylenediamine or related ligands (diethylenetriamine, triethylenetetramine). Further work in this direction is in progress and will be presented in subsequent papers.

metals were performed by atomic absorption spectroscopy, by standard titrimetric methods for anions and with a Carlo Erba Strumentazion Analyser (for C, H and N). Thermogravimetric analyses (TGA) were performed on polycrystalline samples *ca.* 150 mg in air at a scan speed of 10 °C/min on a derivatograph "Q−1500". Infrared spectra were recorded with KBr discs and in Nujol mulls on a UR−10 spectrophotometer in the 4000−400 cm^{-1} region using conventional techniques.

$[Cu(en)_2ZnCl_4]$·dmso (1): Copper powder (0.32 g, 0.005 mol), zinc oxide (0.41 g, 0.005 mol), ammonium chloride (1.54 g, 0.02 mol), dmso (20 cm^3) and ethylenediamine (0.7 cm^3, 0.01 mol) were placed in a flask in the above order, heated to 60 °C and magnetically stirred until total dissolution of Cu^0 and ZnO was observed (110 minutes). The dark-violet crystals suitable for X-ray crystallography formed immediately after cooling the resulting solution. The crystals were filtered out and dried in vacuo at room temperature. Mass collected 2.1 g, yield 89%. $C_6H_{22}Cl_4CuN_4OSZn$ (469.05): calcd. C 15.36, H 4.74, N 11.95, Cu 13.55, Zn, 13.94, Cl 30.23; found C 15.2, H 4.63, N 11.9, Cu 13.9, Zn, 14.3, Cl 29.9. TGA results indicated that **1** exhibited a weight loss of 41.71% in the temperature range 170−340 °C (calcd. 42.28% for the loss of one dmso and two ethylenediamine molecules per formula unit). IR (cm^{-1}): $\tilde{\nu}$ = 3315 s, 3260 s, 3145 s, 2990 w, 2950 sh, 1605 s, 1580 m, 1450 w, 1285 w, 1185 m, 1090 s, 1045 vs, 1020 vs, 975 w, 950 s, 710 s, 540 m. The compound is soluble in water, dmso and dmf.

$[Cu(en)_2ZnCl_4]\cdot$dmf (2): This complex was obtained in a similar manner to **1**, except for the use of dmf (20 cm^3) instead of dmso. Mass collected 1.9 g, yield 82%. $C_7H_{23}Cl_4CuN_5OZn$ (464.04): calcd. C 18.12, H 5.01, N 15.12, Cu 13.71, Zn, 14.11, Cl 30.60; found C 18.3, H 4.9, N 16.0, Cu 14.0, Zn, 13.5, Cl 29.2. TGA results showed an initial weight loss of 15.03% in the temperature range 110−190 °C (calcd. 15.75% for the loss of one dmf molecule per formula unit). IR (cm^{-1}): $\tilde{\nu}$ = 3310 s, 3260 s, 3160 w, 2980 w, 2895 w, 1650 vs, 1600 s, 1585 sh, 1455 w, 1410 w, 1385 m, 1325 w, 1285 w, 1250 w, 1095 m, 1045 vs, 975 w, 705 m, 660 w, 535w, 475w, 420w. The compound is soluble in water, dmso and dmf.

$[Cu(en)_2Zn(NCS)_4]\cdot CH_3CN$ (3): This complex was obtained in a similar manner to **1**, except for the use of NH_4NCS instead of NH_4Cl in CH_3CN (25 cm^3). Mass collected 1.62 g, yield 62%. $C_{10}H_{19}CuN_9S_4Zn$ (522.49): calcd. C 22.99, H 3.67, N 15.12, Cu 13.71, Zn14.11; NCS 50.14; found C 22.7, H 3.5, N 15.3, Cu 13.7, Zn, 13.7; NCS 49.9. TGA results showed a weight loss of 8.00% in the temperature range 50−130 °C (7.86% for the loss of one CH_3CN molecule per formula unit). IR (cm^{-1}): $\tilde{\nu}$ = 3325 m, 3270 m, 3235 m, 3155 w, 2955 w, 2890 w, 2250 w, 2090 vs, 1585 m, 1460 w, 1385 w, 1370 w, 1360 w, 1325 w, 1280 w, 1180−1150 br, 1095 m, 1045 s, 1010 w, 980 w, 880 w, 690 w, 535 w, 520 w, 480 w. The compound is insoluble in water but soluble in dmso and dmf.

$[Cu(en)_2Zn(CH_3COO)_4]$ (4): This complex was obtained in a similar manner to **1**, except for the use of CH_3COONH_4 instead of NH_4Cl. Mass collected 0.95 g, yield 39%. $C_{12}H_{28}CuN_4O_8Zn$ (485.29): calcd. C 29.69, H 5.83, N 11.55, Cu 13.09, Zn 13.47; found C 29.3, H 6.1, N 11.6, Cu 13.3; Zn, 13.5. TGA results showed an initial decomposition of **4** at 40 °C but no well-separated weight loss steps were observed. IR (cm^{-1}): $\tilde{\nu}$ = 3340−3305 br, 3275 sh, 3140 s, 2985−2955 br, 2900 w, 1625 sh, 1575 vs, 1425 vs, 1405 sh, 1340 m, 1280 w, 1185−1165 br, 1105 w, 1050 vs, 1020 m, 985 w, 915 m, 735 w, 660 s, 615 w, 550 w, 525 w, 480 w, 415 w. The compound is soluble in water, dmso and dmf.

$[Cu(en)_2Zn(NCS)_4]\cdot 0.5\ H_2O$ (5): This complex was obtained in a similar manner to **1**, except for the use of NH_4NCS instead of NH_4Cl in CH_3OH (25 cm^3). Mass collected 0.47 g, yield 19%. $C_8H_{17}CuN_8O_{0.5}S_4Zn$ (490.47): calcd. C 19.59, H 3.50, N 20.54, Cu 11.65, Zn 11.98; NCS 42.59; found C 20.1, H 3.4, N 21.5, Cu 11.5, Zn 12.2; NCS 39.5. The presence of water molecules in **5** is clearly indicated in the TGA results, which exhibited an initial weight loss of 1.99% in the temperature range 180−205 °C [calcd. 1.84% for the loss of half a water molecule per formula unit]. IR (cm^{-1}): $\tilde{\nu}$ = 3320 m, 3290 sh, 3230 m, 3130 w, 2980−2950 br, 2930 sh, 2885 w, 2090 vs, 1580 s, 1455 w, 1320 w, 1275 w, 1165 w, 1090 m, 1040 s, 1010 w, 980 w, 830 w, 690 m, 520 w, 475 w. The compound is insoluble in water and soluble in dmso and dmf.

X-ray Data Collection and Processing: Well-shaped crystals of **1**−**5** were suitable for X-ray analysis. Crystal data and details of structure solutions are summarized in Table 1 and selected bond lengths and angles in Table 2.

The data were corrected for Lorentz-polarisation effects and for the effects of absorption by the gausian for **1** and multiscan methods for **2**. The non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms (except those of the water molecule in **5**) were located in Fourier difference syntheses or assigned at geometrically calculated positions and refined using a riding model (**1**, **4**) or fixed (**2**, **3**, **5**). The structures were solved by direct methods and refined by full-matrix least-squares methods using the SHELXL−93, SHELXL-97[30−32] and XTAL3.4 programs.[33] For **1**, the dmso S atom and Me groups were modelled as being disordered over two sites.

CCDC-174059−174063 contains the supplementary crystallographic data for this paper. Structural Manipulation of Hydrogen Bond Networks Using Sulfonated Phosphane Ligands and Their Complexes: Competition and Interplay Between Strong and Weak Hydrogen Bonds

Andrew D. Burrows,*[a] Ross W. Harrington,[a] Mary F. Mahon,[a] and Simon J. Teat[b]

Keywords: Crystal engineering / Phosphane ligands / Hydrogen bonds / X-ray crystal structures

Using the sulfonated phosphane $[PPh_2(C_6H_4\text{-}m\text{-}SO_3)]^-$, $\mathbf{L}^-$, we have demonstrated that metal centres can readily be incorporated into guanidinium sulfonate (GS) hydrogen-bonded networks, and that the increase in steric bulk on going from $[C(NH_2)_3][\mathbf{L}]$ (**1**) to $[C(NH_2)_3][AuCl(\mathbf{L})]$ (**2**) leads to a flattening of the GS sheets. The crystal structures of $[C(NH_2)_3][\mathbf{LS}]$ **3** and $[C(NH_2)_3][\mathbf{LSe}]$ **4** ($\mathbf{LS}^- = [SPPh_2(C_6H_4\text{-}m\text{-}SO_3)]^-$, $\mathbf{LSe}^- = [SePPh_2(C_6H_4\text{-}m\text{-}SO_3)]^-$) reveal disorder in both the sulfonate groups and the guanidinium cations, which is a consequence of *pseudo*-sixfold phenyl embraces between the anions. These interactions, identical to those observed in Ph_3PS and Ph_3PSe, position the sulfonate groups too close together for regular quasihexagonal hydrogen bonding motifs to be formed. The regular GS hydrogen bonding patterns can also be disrupted by using an anion containing two sulfonate groups such as that in $[C(NH_2)_3]_2\{cis\text{-}[PdCl_2(\mathbf{L})_2]\}$ (**5**). In this case the incorporation of two sulfonate groups from each anion into the same hydrogen-bonded sheet also serves to constrain the distance between the sulfur atoms to a value incommensurate with that enabling a guanidinium cation to hydrogen bond to both groups. In this case irregular GS sheets are formed involving fewer N–H···O hydrogen bonds than in **1** and **2**.

Introduction

The use of intermolecular interactions in the design and synthesis of solid-state structures — a process often referred to as crystal engineering — has attracted enormous interest over the past few years.[1] Previously, we have reported the use of multiple hydrogen bonds to control the aggregation of metal complex cations and anions containing complementary hydrogen bonding groups.[2] The incorporation of two hydrogen bond donors (D) on each cation face and two hydrogen bond acceptors (A) on each anion face, giving an overall DD:AA interaction, ensures that secondary interactions are all favourable, thus enhancing the total energy of the interaction.

The guanidinium sulfonate (GS) system is another case in which the cations and anions are linked together by pairs of hydrogen bonds in the DD:AA arrangement, though, since both cations and anions contain three hydrogen bonding faces, the hydrogen bond interactions in this system lead to quasihexagonal arrays and the formation of infinite two-dimensional sheets.[3,4] These GS sheets are particularly robust to changes in the steric and electronic properties of the sulfonate substituents, and bilayer or pillared-brick structures incorporating disulfonates can be used to include many guest molecules.[5] In this paper we show how monosulfonated triphenylphosphane $[PPh_2(C_6H_4\text{-}m\text{-}SO_3)]^-$, $\mathbf{L}^-$, a ligand initially prepared for biphasic catalysis,[6] can be incorporated into GS arrays, therefore providing a means of introducing metal centres into hydrogen-bonded networks in which two dimensions are controlled by the hydrogen bonds. A recent communication from Kathó and coworkers[7] using guanidinium to crystallise sulfonated phosphanes has prompted us to report our findings.[8] To this end, the syntheses and crystal structures of $[C(NH_2)_3][\mathbf{L}]$ (**1**), $[C(NH_2)_3][AuCl(\mathbf{L})]$ (**2**), $[C(NH_2)_3][\mathbf{LS}]$ (**3**), $[C(NH_2)_3][\mathbf{LSe}]$ (**4**) and $[C(NH_2)_3]_2\{cis\text{-}[PdCl_2(\mathbf{L})_2]\}$ (**5**) are reported ($\mathbf{LS}^- = [SPPh_2(C_6H_4\text{-}m\text{-}SO_3)]^-$, $\mathbf{LSe}^- = [SePPh_2(C_6H_4\text{-}m\text{-}SO_3)]^-$). Analysis of the structures reveals that predetermination of the relative positions of the sulfonate groups, either through interactions between the triphenylphosphane groups or through coordination of two phosphane ligands to a metal centre, can lead either to disruption of the quasihexagonal hydrogen bonding motif or to disorder in the GS sheets.

Results and Discussion

Metathesis of Na[**L**] with guanidinium chloride in methanol gave colourless crystals of $[C(NH_2)_3][\mathbf{L}]$ (**1**) suitable for analysis by X-ray crystallography. The asymmetric unit of

1 showed the presence of two independent guanidinium cations and two independent triphenylphosphane sulfonate anions. Hydrogen bond interactions between the cations and anions lead to the formation of the anticipated quasihexagonal GS arrays [Figure 1 (top)], despite the steric bulk of the triphenylphosphane group. A single-layer sheet structure is adopted, with PPh_3 groups located on both sides of the GS sheets. The sheets are corrugated, with a "hinge" between hydrogen-bonded ribbons [Figure 1 (bottom)], and this is reflected in an inter-ribbon angle of 103°, based on the angle between guanidinium planes in neighbouring ribbons. Similar distortions to GS sheets have been observed previously,[3] and occur as a means of minimising void space within the structure.

The single-layer sheet structure ensures that triphenylphosphane groups from neighbouring sheets project into the inter-sheet space. The major interaction between these groups involves pairs of $[\mathbf{L}]^-$ anions, based on P(1) and P(2) in neighbouring sheets, which adopt sixfold phenyl embraces (6PEs).[9] Two C−H···O interactions are also evident [C(8)···O(1) 3.548(10), H(8)···O(1) 2.66(1) Å, C(8)−H(8)···O(1) 160.8(5)°; and C(36)···O(6) 3.639(10), H(36)···O(6) 2.75(1) Å, C(36)−H(36)···O(6) 161.0(5)°].

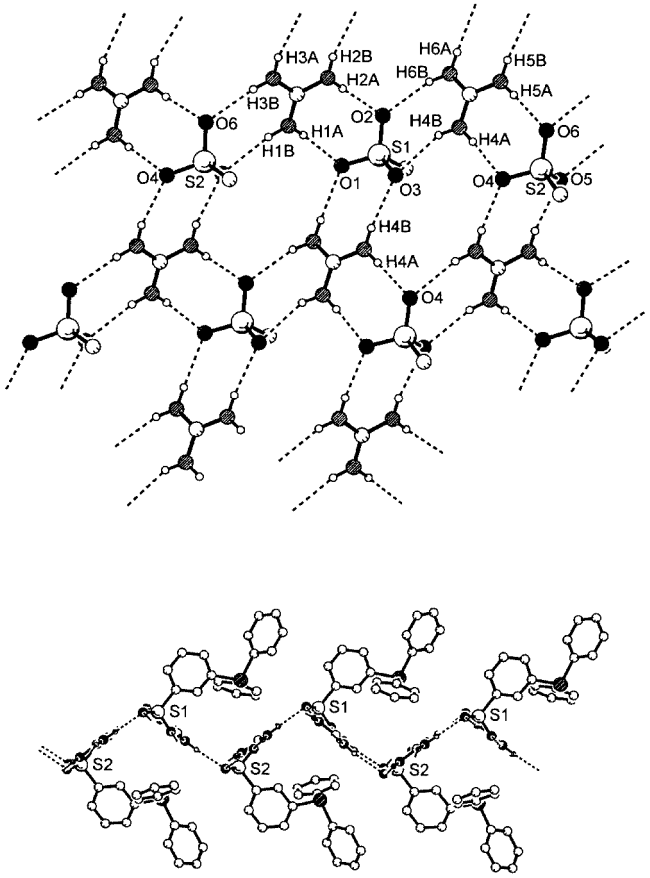

Figure 1. (top) Quasihexagonal hydrogen-bonded GS sheets in the crystal structure of $[C(NH_2)_3][\mathbf{L}]$ (**1**); hydrogen bond lengths (Å) and angles (°): N(1)···O(1) 2.974, H(1A)···O(1) 2.12, N(1)−H(1A)···O(1) 176; N(1)···O(5) 3.056, H(1B)···O(5) 2.24, N(1)−H(1B)···O(5) 158; N(2)···O(5) 3.010, H(2A)···O(5) 2.16, N(2)−H(2A)···O(5) 170; N(2)···O(2) 3.008, H(2B)···O(2) 2.15, N(2)−H(2B)···O(2) 176; N(3)···O(4) 3.061, H(3A)···O(4) 2.20, N(3)−H(3A)···O(4) 177; N(3)···O(6) 3.038, H(3B)···O(6) 2.20, N(3)−H(3B)···O(6) 165; N(4)···O(3) 3.050, H(4A)···O(3) 2.21, N(4)−H(4A)···O(3) 167; N(4)···O(4) 3.053, H(4B)···O(4) 2.20, N(4)−H(4B)···O(4) 175; N(5)···O(6) 2.981, H(5A)···O(6) 2.12, N(5)−H(5A)···O(6) 174; N(5)···O(3) 3.046, H(5B)···O(3) 2.20, N(5)−H(5B)···O(3) 166; N(6)···O(2) 3.021, H(6A)···O(2) 2.18, N(6)−H(6A)···O(2) 166; N(6)···O(1) 2.981, H(6B)···O(1) 2.13, N(6)−H(6B)···O(1) 171; (bottom) side-on view of one of the GS sheets in the structure of **1**

The gold complex $Na[AuCl(\mathbf{L})]$ was formed from the reaction of $[AuCl(SC_4H_8)]$ and $Na[\mathbf{L}]$ in acetone, and recrystallised from methanol. Metathesis of $Na[AuCl(\mathbf{L})]$ with guanidinium chloride in methanol gave colourless crystals of $[C(NH_2)_3][AuCl(\mathbf{L})]$ (**2**) which were suitable for X-ray crystallography. The structural analysis of **2** showed the presence of one guanidinium cation and one $[AuCl(\mathbf{L})]^-$ anion in the asymmetric unit. As in **1**, the sulfonate groups form quasihexagonal hydrogen-bonded arrays through N−H···O interactions with guanidinium cations, and these lead to the formation of GS sheets [Figure 2 (top)]. Although the interactions within the sheets are similar to those in **1**, there are two main differences. Firstly, the presence of the AuCl group coordinated to each phosphane serves to flatten the sheets, and the inter-ribbon angle in **2** is increased to 161° [Figure 2 (bottom)]. In other GS sheet structures, increase in steric bulk or inclusion of guest molecules can have the effect of reducing the degree of distortion from planarity, hence the AuCl group can be regarded as a "guest" within the $[C(NH_2)_3][\mathbf{L}]$ lattice, albeit one with a directional coordination binding site. Secondly, the quasihexagonal sheets are distorted such that the intra-ribbon S···S distance is increased to 8.105 Å, equal to the unit cell parameter *a*. In simple guanidinium sulfonate structures[3,4] closest S···S distances within the GS sheets range from 6.57 to 7.77 Å. The distortion of the GS sheets in **2** is also apparent in the values of the N−H···O angles.

These distortions are related to the interactions between the (triphenylphosphane)gold chloride units. Dance and Scudder have shown[10] the importance of interactions between multiple phenyl groups in the crystal structures of PPh_3 complexes. In **2**, *pseudo*-sixfold phenyl embraces serve to link the $AuCl(PPh_3)$ units into chains running perpendicular to the direction of the hydrogen-bonded ribbons (Figure 3). In these *pseudo*-sixfold phenyl embraces, the AuCl unit acts in a similar manner to a phenyl group, so that each embrace involves three phenyl rings on one anion and two phenyl rings and the AuCl group on the other. These interactions bring the phosphorus atoms on closest phosphane groups to within 6.49 Å of each other, and position sulfur atoms from the same sheet at 11.29 Å, equal to the unit cell parameter *b*, from each other. *Pseudo*-sixfold phenyl embraces in which gold-containing groups are involved have been shown to be recurrent structural motifs in the crystal structures of gold-PPh_3 complexes.[11] Au···Au interactions have previously been exploited as crystal engineering tools in conjunction with hydrogen bond networks.[12] However, in the crystal structure of **2** there are no aurophilic interactions, the shortest Au···Au distance being 7.35 Å.

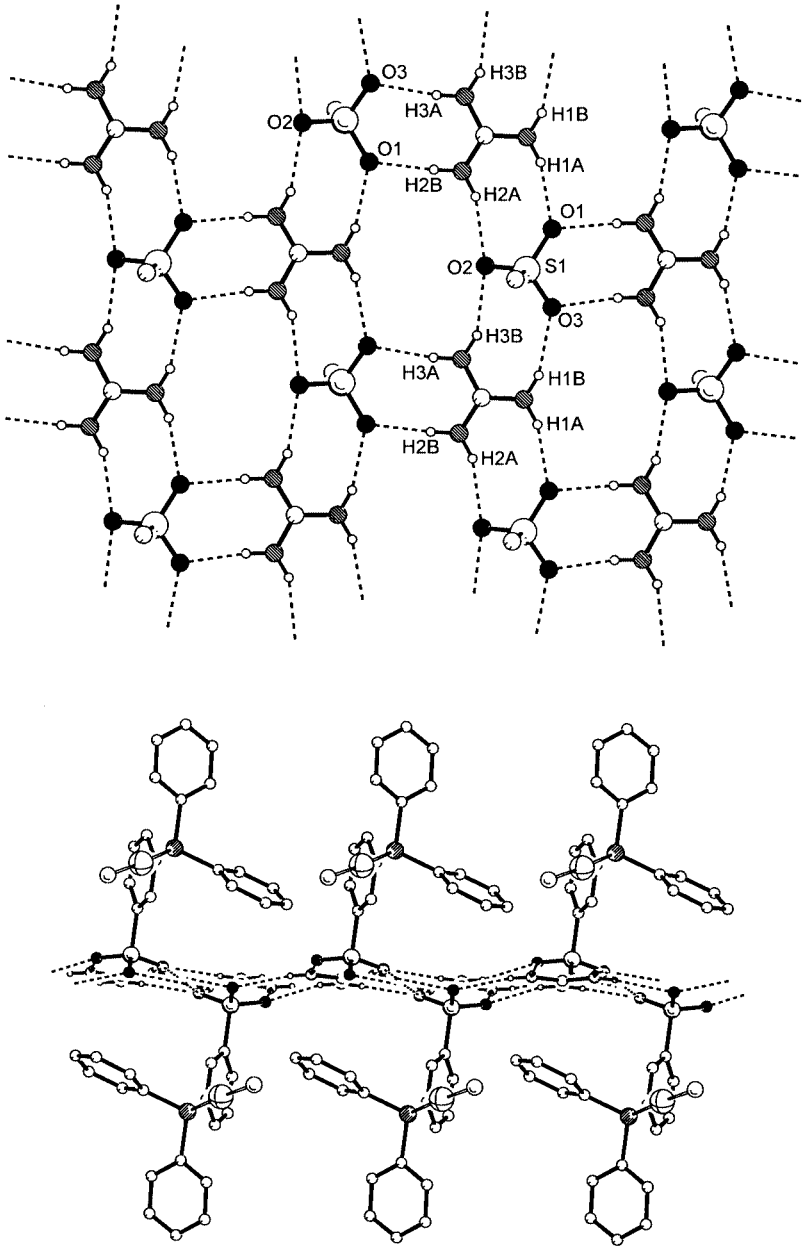

Figure 2. (top) Quasihexagonal hydrogen-bonded GS sheets in the crystal structure of $[C(NH_2)_3][AuCl(\mathbf{L})]$ (**2**); hydrogen bond lengths (Å) and angles (°): N(1)···O(1) 2.988, H(1A)···O(1) 2.16, N(1)−H(1A)···O(1) 157; N(1)···O(3) 3.030, H(1B)···O(3) 2.19, N(1)−H(1B)···O(3) 160; N(2)···O(2) 3.024, H(2A)···O(2) 2.19, N(2)−H(2A)···O(2) 159; N(2)···O(1) 2.907, H(2B)···O(1) 2.03, N(2)−H(2B)···O(1) 175; N(3)···O(3) 2.913, H(3A)···O(3) 2.05, N(3)−H(3A)···O(3) 169; N(3)···O(2) 3.049, H(3B)···O(2) 2.23, N(3)−H(3B)···O(2) 155; (bottom) side-on view of one of the GS sheets in the structure of **2**

The compounds Na[**L**S] and Na[**L**Se] were prepared from the oxidation of Na[**L**] with elemental sulfur or selenium in methanol. Metathesis with $[C(NH_2)_3]Cl$ in methanol gave colourless crystals of $[C(NH_2)_3][\mathbf{L}S]$ (**3**) and $[C(NH_2)_3][\mathbf{L}Se]$ (**4**) respectively. X-ray structural analyses of **3** and **4** showed that both compounds possess one cation and one anion in their asymmetric units, and that they are essentially isostructural. Both **3** and **4** are disordered with regard to the sulfonate oxygen atom positions (1:1 ratio between two sets of positions) and the guanidinium cations (2:1:1 ratio between three positions in **3**, 50:37:13 between similar positions in **4**). Although GS sheets are formed [Figure 4 (top)], the presence of this disorder makes an unambiguous evaluation of the inter-ribbon angle impossible, though estimated values of 150° for **3** and 153° for **4** suggest that, as anticipated, the Group 16 atom is less sterically demanding than the AuCl fragment [Figure 4 (bottom)]. The disorder in these structures can be rationalised by consideration of the interactions between the triphenylphosphane sulfide (or selenide) units.

In a similar manner to the (triphenylphosphane)gold chloride units in **2**, the triphenylphosphane sulfides and selenides form *pseudo*-sixfold phenyl embraces involving three phenyl rings on one anion and two phenyl rings and the

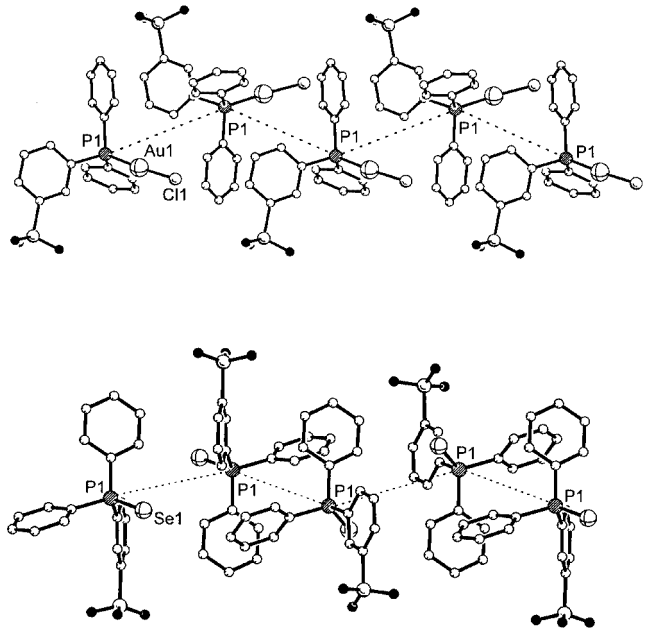

Figure 3. *Pseudo*-sixfold phenyl embraces linking the anions into chains in the crystal structures of $[C(NH_2)_3][AuCl(\mathbf{L})]$ (**2**) and $[C(NH_2)_3][\mathbf{L}Se]$ (**4**)

Group 16 atom on the other. These embraces lead to the formation of chains running in the same direction as the hydrogen-bonded ribbons, which possess closest P···P distances of 6.17 Å for **3** and 6.27 Å for **4** (Figure 3). This chain formation ensures that sulfonate groups within the same sheet are positioned with S···S distances of 9.27 Å for **3** and 9.49 Å for **4**, in both cases equal to the respective unit cell parameter *b*. In addition to these interactions, each triphenylphosphane sulfide or selenide unit forms a second *pseudo*-sixfold phenyl embrace, approximately perpendicular to the first, in this case arising from neighbouring centrosymmetrically related pairs of anions, and involving two phenyl rings and the Group 16 atom. This interaction leads to P···P distances of 5.75 Å and 5.90 Å for **3** and **4**, respectively. Both types of *pseudo*-sixfold phenyl embrace are also observed in the crystal structures of Ph_3PS[13] and Ph_3PSe,[14] and together they serve to dictate the relative positions of the sulfonate groups in **3** and **4**. These groups are too close together for the guanidinium cations to form regular hydrogen bonding patterns, and as a consequence the cations are disordered. In one of the three orientations, N−H groups are directed out of the plane of the GS sheets, and form N−H···S or N−H···Se hydrogen bonds to the sulfide or selenide together with $R_2^1(6)$ rings [N(1B)···S(1) 3.35(1), H(1B2)···S(1) 2.52(1) Å, N(1B)−H(1B2)···S(1) 157(1)° and N(3B)···S(1) 3.41(1), H(3B1)···S(1) 2.61(1) Å, N(3B)−H(3B1)···S(1) 151(1)° for **3**; N(1B)···Se(1) 3.29(2), H(1B1)···Se(1) 2.46(2) Å, N(1B)−H(1B1)···Se(1) 158(1)° and N(3B)···Se(1) 3.44(3), H(3B2)···Se(1) 2.67(2) Å, N(3B)−H(3B2)···Se(1) 148(2)° for **4**].

The complex $Na_2\{cis\text{-}[PdCl_2(\mathbf{L})_2]\}$ was formed from the reaction of $[PdCl_2(cod)]$ with Na[**L**] in acetonitrile/methanol. Metathesis of this sodium salt with guanidinium nitrate in the same solvent mix gave several products including small, yellow crystals of $[C(NH_2)_3]_2\{cis\text{-}[PdCl_2(\mathbf{L})_2]\}$ (**5**) suitable for analysis at the SRS facility. The structural analysis of **5** showed the presence of GS sheets [Figure 5 (top)], with both of the sulfonate groups from each complex anion incorporated into the same sheet. The hydrogen bonding patterns in **5** are less regular than those observed in **1** and **2**. Only two of the six independent guanidinium faces are involved in DD:AA interactions. Of the remaining faces, two form $R_2^1(6)$ rings with sulfonate oxygen atoms whereas another forms bifurcated N−H···O hydrogen bonds. The final guanidinium face is not involved in any N−H···O hydrogen bonding, instead forming N−H···Cl interactions to the metal-bound chlorides.[15] The distortions from the regular pattern observed for **1** and **2** are a consequence of the distance constraint imposed by virtue of the two sulfonate groups arising from the same anion (S···S 9.21 Å) coupled with the triangular shape of the guanidinium cation. It is not possible to orientate the cation to enable it to form two N−H···O hydrogen bonds with both sulfonates as the groups are too far apart.

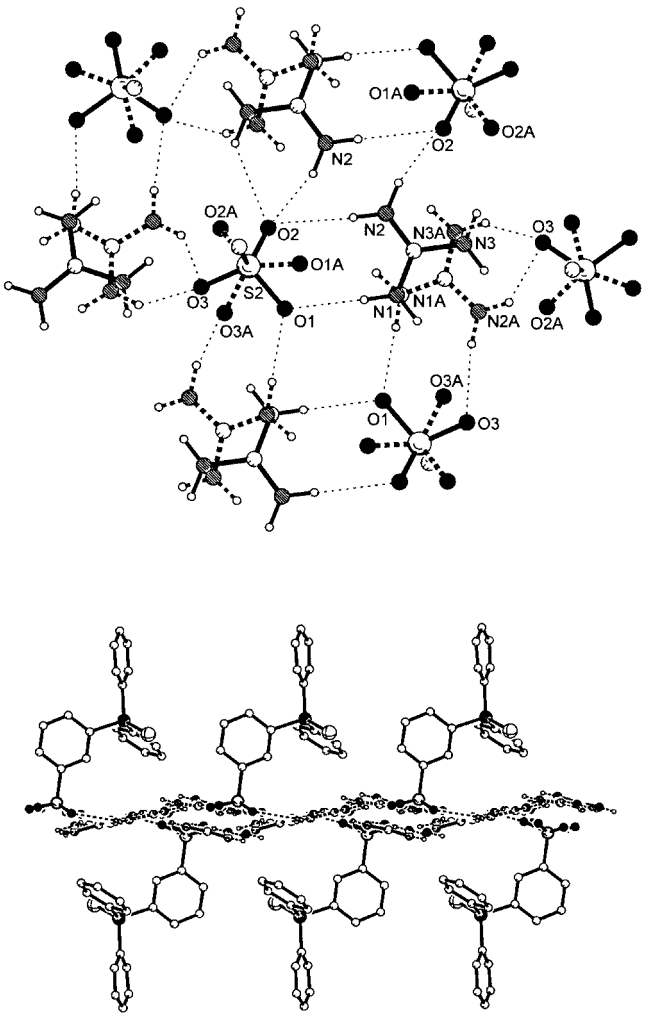

Figure 4. (top) GS sheet formation in $[C(NH_2)_3][\mathbf{L}S]$ (**3**); for the guanidinium cations only two of the three positions are shown for clarity; (bottom) side-on view of one of the GS sheets in the structure of **3**

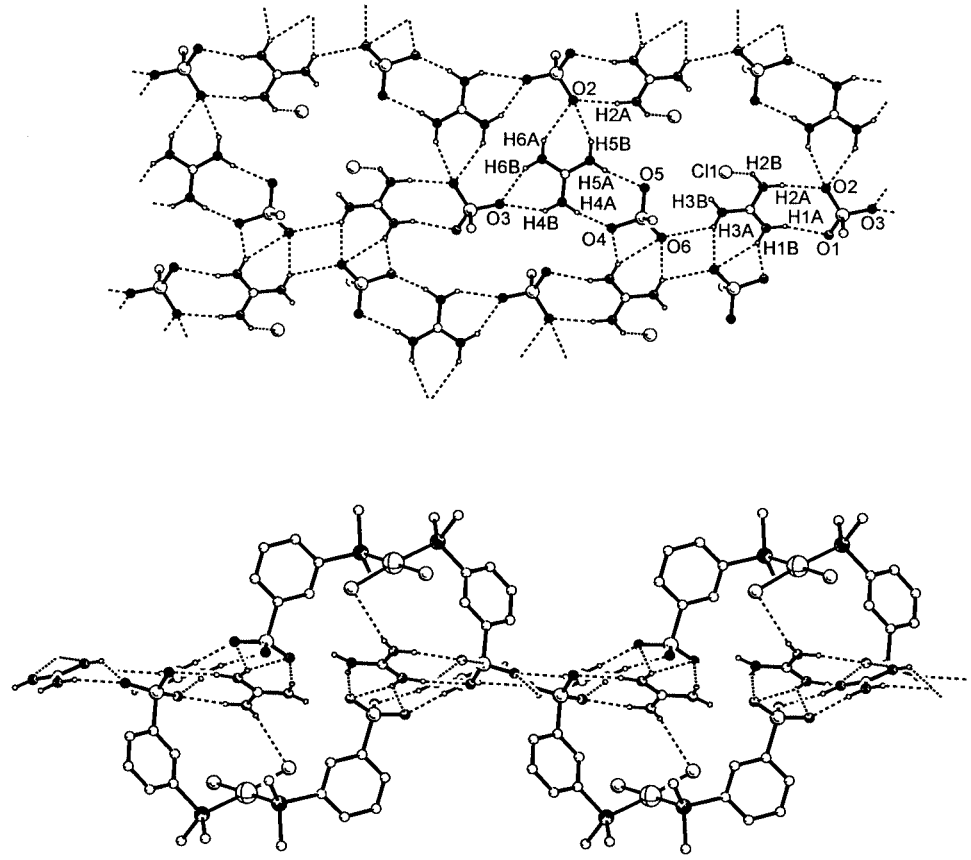

Figure 5. (top) GS sheet formation in $[C(NH_2)_3]_2\{cis\text{-}[PdCl_2(\mathbf{L})_2]$ (**5**); hydrogen bond lengths (Å) and angles (°): N(1)···O(1) 2.911, H(1A)···O(1) 2.06, N(1)−H(1A)···O(1) 162; N(1)···O(4) 2.893, H(1B)···O(4) 2.12, N(1)−H(1B)···O(4) 146; N(1)···O(6) 3.219, H(1B)···O(6) 2.43, N(1)−H(1B)···O(6) 150; N(2)···O(2) 2.902, H(2A)···O(2) 2.04, N(2)−H(2A)···O(2) 168; N(2)···Cl(1) 3.253, H(2B)···Cl(1) 2.56, N(2)−H(2B)···Cl(1) 136; N(3)···O(6) 3.140, H(3A)···O(6) 2.32, N(3)−H(3A)···O(6) 154; N(3)···O(6) 3.003, H(3A)···O(6) 2.50, N(3)−H(3A)···O(6) 117; N(4)···O(4) 2.810, H(4A)···O(4) 1.94, N(4)−H(4A)···O(4) 168; N(4)···O(3) 2.855, H(4B)···O(3) 2.11, N(4)−H(4B)···O(3) 142; N(5)···O(5) 2.923, H(5A)···O(5) 2.05, N(5)−H(5A)···O(5) 171; N(5)···O(2) 2.994, H(5B)···O(2) 2.19, N(5)−H(5B)···O(2) 153; N(6)···O(2) 3.079, H(6A)···O(2) 2.30, N(6)−H(6A)···O(2) 147; N(6)···O(3) 2.927, H(6B)···O(3) 2.21, N(6)−H(6B)···O(3) 139; (bottom) side-on view of one of the GS sheets in the structure of **5**; for clarity only the *ipso* carbon atoms on the unfunctionalised phenyl rings are shown

As with compounds **1**−**4**, the phosphanes are located on either side of the GS sheets [Figure 5 (bottom)]. Parallel fourfold phenyl embraces (P4PEs) link centrosymmetrically related pairs of phosphanes based on P(1), and pairs of phosphanes based on P(2), and, as in the structures of **2**−**4**, these interactions serve to constrain the distances between sulfonate groups.

The structures reported in this paper clearly demonstrate that sulfonated phosphane ligands and their metal complexes can be incorporated into hydrogen-bonded networks based on guanidinium sulfonate sheets. This system is sufficiently robust to cope with the increased steric bulk that accompanies inclusion of a coordination centre. The interactions between phosphane groups − involving C−H···π interactions and *pseudo*-sixfold phenyl embraces − observed in the crystal structures of molecules such as Ph_3PS and Ph_3PSe can be preserved in their guanidinium sulfonate adducts, and these are important in determining the relative positions of the sulfonate groups. Although the GS motif is flexible to a range of S···S distances, if the sulfonates are positioned too closely to each other, guanidinium cations are unable to form regular hydrogen bonding patterns, and disorder in both the cation and the anion sulfonate groups is observed. In contrast, when the S···S distance is constrained by having two sulfonate groups from the same complex incorporated into the same sheet, significant distortions from the quasihexagonal array may result.

Taken together, these structural analyses demonstrate that supramolecular interactions that are generally considered weak can compete effectively with strong hydrogen bonds in determining gross structures. Clearly, the disorder and the distortions observed in the GS networks in **3**, **4** and **5** occur with loss of some, but not all, of the stabilisation energy. Non-disordered structures in the cases of **3** and **4** would involve either steric clashes or voids within the structure, both of which are energetically unfavourable. Similarly, non-distorted GS sheets in **5** would result in unfavourable bond lengths and/or angles within the anions, which would also be energetically less favourable than the loss of hydrogen bonding in the distorted GS network.

We are currently exploring the use of bis(phosphane) complexes containing unsaturated metal centres to bridge between GS sheets with a view to exploring the reversible coordination of small molecules.

Experimental Section

Synthesis of metal complexes of [**L**]$^-$ were routinely carried out using Schlenk-line techniques under pure dry dinitrogen using dioxygen-free solvents. Metathesis reactions were carried out with no special precautions to exclude air. Microanalyses (C, H and N) were carried out by Mr. Alan Carver (University of Bath Microanalytical Service). Infrared spectra were recorded on a Nicolet Nexus FT-IR spectrometer as KBr pellets. The compounds Na[**L**][16] and [AuCl(SC_4H_8)][17] was prepared according to the literature methods.

Synthesis of Na[AuCl(L)]: Na[**L**] (0.182 g, 0.50 mmol), dissolved in acetone (10 cm^3) was added to a solution of [AuCl(SC_4H_8)] (0.158 g, 0.50 mmol) in acetone (10 cm^3). The resultant solution was stirred for 2 h, filtered, and the solvent removed in vacuo. Recrystallisation from methanol gave a colourless crystalline material. Yield 0.188 g (64%). ^{31}P NMR (CD_3OD): δ = 46.0 (s) ppm. IR: ν(SO_3) 1670s cm^{-1} (br).

Synthesis of Na[AuCl(LS)]: An excess of elemental sulfur was added to a solution of Na[**L**] (0.200 g, 0.55 mmol) in wet methanol (30 cm^3) and the mixture stirred vigorously for 3 h. Unreacted sulfur was removed by filtration, then the solvent was removed in vacuo and the crude solid recrystallised from methanol. Yield 0.191 g (88%). ^{31}P NMR (CD_3OD): δ = 46.3 (s) ppm.

Na[AuCl(**L**Se)] was prepared in an analogous manner using elemental selenium.

Synthesis of Na$_2$\{*cis*-[PdCl$_2$(L)$_2$]\}: A solution of Na[**L**] (0.276 g, 0.70 mmol) in methanol (25 cm^3) was added dropwise with stirring to a solution of [$PdCl_2$(cod)] (0.100 g, 0.35 mmol) in acetonitrile (30 cm^3) giving a slight darkening of colour. Stirring was continued for 45 min, and then the solvent was removed in vacuo and the crude yellow-orange solid recrystallised from methanol. Yield 0.235 g (74%). ^{31}P NMR (CD_3OD): δ = 25.6 (s) ppm. IR: ν(SO_3) 1641s cm^{-1} (br), 1536s.

Synthesis of [C(NH$_2$)$_3$][L] (1): Na[**L**] (0.100 g, 0.27 mmol) and [$C(NH_2)_3$]Cl (0.026 g, 0.27 mmol) were dissolved in methanol (10 cm^3), and the solvent allowed to slowly evaporate. After two weeks colourless crystals were harvested. Yield 0.077 g (70%). $C_{19}H_{20}N_3O_3PS$ (401.4): calcd. C 56.9, H 5.02, N 10.5; found C 57.2, H 4.99, N 10.0. IR: ν(NH) 3380s cm^{-1} (br), 3195s (br); ν(SO_3)/δ(NH_2) 1684s, 1571s, 1431m.

Synthesis of [C(NH$_2$)$_3$][AuCl(L)] (2): Na[AuCl(**L**)] (0.100 g, 0.17 mmol) and [$C(NH_2)_3$]Cl (0.016 g, 0.17 mmol) were dissolved in methanol (10 cm^3), and the solvent allowed to slowly evaporate. After one week colourless crystals were harvested. Yield 0.085 g (80%). $C_{19}H_{20}AuClN_3O_3PS$ (633.8): calcd. C 36.0, H 3.18, N 6.63; found C 36.0, H 3.16, N 6.44. IR: ν(NH) 3400s cm^{-1} (br), 3273s, 3202s; ν(SO_3)/δ(NH_2) 1684s, 1569m, 1479m.

Synthesis of [C(NH$_2$)$_3$][LS] (3): Na[**L**S] (0.100 g, 0.25 mmol) and [$C(NH_2)_3$]Cl (0.024 g, 0.23 mmol) were dissolved in methanol (10 cm^3), and the solvent allowed to slowly evaporate. After two weeks colourless crystals were harvested. Yield 0.085 g (80%). $C_{19}H_{20}N_3O_3PS_2$ (433.5): calcd. C 52.2, H 4.65, N 9.70; found C 52.6, H 4.51, N 9.60. IR: ν(NH) 3388s cm^{-1} (br), 3208s (br); ν(SO_3)/δ(NH_2) 1664s, 1577s, 1431s.

Crystals of [$C(NH_2)_3$][**L**Se] **4** were prepared in a similar manner from Na[**L**Se] and [$C(NH_2)_3$]Cl.

Synthesis of [C(NH$_2$)$_3$]$_2$\{*cis*-[PdCl$_2$(L)$_2$]\} (5): Na$_2$\{*cis*-[$PdCl_2$(**L**)$_2$]\} (0.050 g, 0.045 mmol) in methanol (5 cm^3) was added to [$C(NH_2)_3$]NO_3 (0.013 g, 0.10 mmol) in acetonitrile (5 cm^3). The solvent was allowed to slowly evaporate, and after two weeks small yellow crystals were obtained.

Crystallography

Single crystals of compounds **1**−**5** were prepared by the methods above. Data were collected using a Enraf−Nonius CAD4 automatic four-circle diffractometer for **1** and a Nonius Kappa CCD diffractometer for **2**, **3** and **4**. Crystals of **5** were too small to ana-

lyse at Bath so data were collected at Station 9.8 of the SRS, Daresbury. Corrections for Lorentz and polarisation were implemented in all cases, with extinction corrections being merited for **2** and **3**. All atoms were refined anisotropically. Absorption corrections were also applied to data for **2** and **4**. In **2**, the largest residual peak and hole are proximate to C(11) (1.54 Å) and Au(1) (0.84 Å) respectively. These are artifacts of the data and are not chemically significant. Details of the data collections and structure solutions are given in Table 1.

As mentioned above, the structures of **3** and **4** were subject to considerable disorder. In **3**, there was 1:1 disorder of sulfonate oxygens between O(1)−O(3) and O(1A)−O(3A). Threefold disorder was also observed in the guanidinium moiety (ratio 2:1:1) between atoms labelled therein without suffix, atoms with suffix "A" and atoms with suffix "B" respectively. These fragments were refined subject to being flat, and atomic displacement parameters therein were also constrained. Compound **4**, which is isostructural with **3**, was treated similarly during refinement, with the exception of the occupancies assigned to the disordered guanidinium fragments. All structures were solved using SHELXS-97 and refined using SHELXL-97.[18] Hydrogen atoms were readily located in the penultimate difference Fourier maps for the non-disordered structures **1**, **2** and **5** but in the final least-squares cycles they were included at calculated positions throughout.

CCDC-191297 (**1**), -191298 (**2**), -191299 (**3**), -191300 (**4**) and -191301 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterization of Five-Coordinate Gallium and Indium Complexes Stabilized by Tridentate, Substituted Pyrrole Ligands

Pei-Cheng Kuo,[a] Jui-Hsien Huang,*[a] Chen-Hsiung Hung,[a] Gene-Hsiang Lee,[b] and Shie-Ming Peng[b]

Keywords: Gallium / Indium / N ligands / Bridging ligands

Five-coordinate gallium and indium complexes stabilized by tridentate, substituted pyrrole ligands have been synthesized and characterized. The reaction of MCl_3 with 1 equiv. of $Li[NC_4H_2(CH_2NMe_2)_2\text{-}2,5]$ in diethyl ether affords $[\{NC_4H_2(CH_2NMe_2)_2\text{-}2,5\}MCl_2]$ [M = Ga (**1**), In (**2**)] in high yield. Reaction of **1** with 2 equiv. of MeLi in diethyl ether at −78 °C followed by heating to reflux for 30 min affords the alkylated product $[\{NC_4H_2(CH_2NMe_2)_2\text{-}2,5\}GaMe_2]$ (**3**). Similarly, the reaction of **2** with 2 equiv. of MeLi or *n*BuLi affords the dialkylated complexes **4** and **5**, respectively. Complex **2** is a strong Lewis acid which readily absorbs H_2O forming $[\{[C_4H_2N(CH_2NMe_2)_2\text{-}2,5]InCl_2\}_2(\mu\text{-}OH_2)]$ (**6**). Complexes **3**, **4**, and **6** have been characterized by X-ray crystallography.

Introduction

Lewis acids catalyze a wide range of reactions. The reactivity and selectivity of these reactions are often related to the Lewis acid's electronic and steric properties.[1] Among the Lewis acid catalysts derived from group-13 metals, those of aluminum are well known for serving as catalysts in organic synthesis, and more recently for polymerization reactions.[2−4] The number of metal complexes reported, however, declines upon descending the group from aluminum to indium. Indium-mediated organometallic reactions have received considerable attention recently, due to their tolerance of polar solvents, including water.[5−11] Lewis acidic indium complexes are dominated by a low coordination number at the metal center (three or four)[12−14] but a few complexes of higher coordination number (five and six) have been reported.[15−21]

We have been interested in the chemistry of group-13[22−23] and early transition metal complexes[24−25] stabilized by bi- or tridentate substituted pyrrole ligands.[26−27] These complexes are Lewis acids with the potential to serve as catalysts in organic synthesis or for the polymerization of olefins. We report here the syntheses, intramolecular rearrangement, and X-ray crystal structures of Ga and In complexes.

Results and Discussion

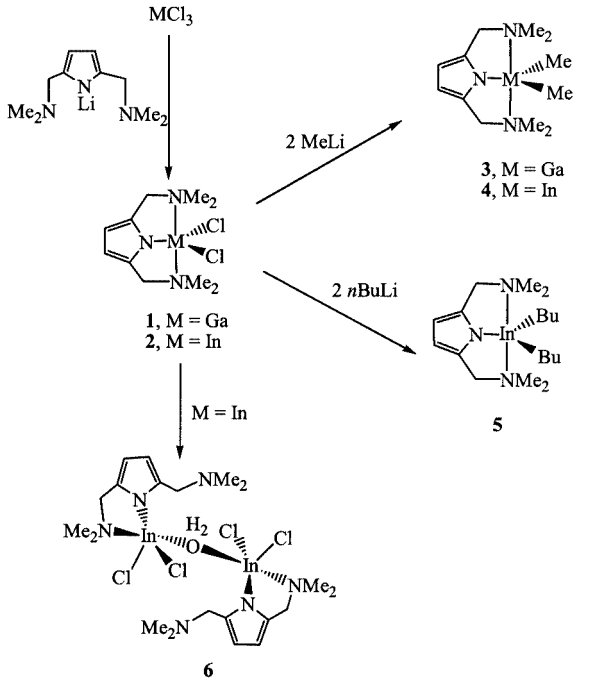
Synthesis and Characterization

Reaction of $Li[NC_4H_2(CH_2NMe_2)_2\text{-}2,5]$ with MCl_3 (M = Ga, In) in diethyl ether affords $[\{NC_4H_2(CH_2NMe_2)_2\text{-}2,5\}MCl_2]$ [M = Ga (**1**), In (**2**)] in yields of 98 and 81%, respectively (Scheme 1). However, suitable crystals of complexes **1** and **2** could not be obtained. The ^1H and ^{13}C NMR spectra of both **1** and **2** show the signals of one type of CH_2 and NMe_2 units at $\delta \approx 3.6$ and 2.5 ppm, respectively, which are consistent with symmetrical structures.

Reaction of complex **1** with 2 equiv. of 1.6 M methyllithium in diethyl ether solution at −78 °C followed by heating to reflux for 30 min afforded the dimethylgallium complex $[\{NC_4H_2(CH_2NMe_2)_2\text{-}2,5\}GaMe_2]$ (**3**) in 75% yield. The ^1H NMR spectrum of **3** shows signals of one set of CH_2, NMe_2, and GaMe units at $\delta = 3.47$, 2.29, and −0.37 ppm, respectively.

Similarly, treatment of **2** with 2 equiv. of MeLi or *n*BuLi in a diethyl ether solution at −78 °C, allowing to warm to room temperature, and then heating to reflux for 30 min generated the pure dimethyl complex **4** and the dibutyl complex **5** in yields of 61 and 65%, respectively. Complexes **3**, **4**, and **5** are thermally robust and show no decomposition upon heating in toluene at 100 °C for over 12 h.

Complex **2** is very Lewis acidic and reacts readily with moisture upon exposure to air. During recrystallization of **2** from a toluene solution at −20 °C, the Schlenk flask was occasionally opened to air resulting in the deposition of the water-bridged complex $[\{[C_4H_2N(CH_2NMe_2)_2\text{-}2,5]InCl_2\}_2(\mu\text{-}OH_2)]$ (**6**). The procedure was carried out several times in both toluene and diethyl ether, and the same result was obtained. Attempts to let **2** react with 0.5 equiv. of H_2O



Scheme 1

in either toluene or diethyl ether afforded a mixture, from which only a small amount of **6** was isolated. Similarly, diffusion of H_2O vapor into a toluene solution of **2** yielded the same results. The ^1H NMR spectrum of **6** in CD_2Cl_2 at room temperature indicates an asymmetric arrangement, which is consistent with the X-ray crystal structure (vide infra). Complex **6** gives rise to three methyl resonances for the two NMe_2 units at $\delta = 2.50$, 2.59, and 2.84 ppm in the ratio of 1:1:2. Four doublets for the two AB systems of the CH_2N units were observed at $\delta = 3.16$, 3.70, 4.56, and 4.72 ppm in the ratio of 1:1:1:1. Selective homonuclear decoupling of the ^1H NMR spectrum of **6** revealed that one AB pattern of a CH_2N unit gives rise to the resonances at $\delta = 3.16$ and 4.56 ppm while the other unit can be attributed to the resonances at $\delta = 3.70$ and 4.72 ppm.

Solid-State Structures of Complexes 3, 4, and 6

Crystals of **3** suitable for X-ray structure determination were obtained from a saturated diethyl ether solution stored at −20 °C. Crystals of **4** were obtained by sublimation from a flask in the glove box under nitrogen. Details of the data collections for **3** and **4** are summarized in Table 2 with selected bond lengths and angles listed in Table 1. The ORTEP diagram of complex **3** is depicted in Figure 1. The gallium atom is surrounded by two methyl groups and three nitrogen atoms of the tridentate pyrrolyl ligand, $[NC_4H_2(CH_2NMe_2)_2\text{-}2,5]$, forming a distorted trigonal-bipyramidal structure. The tridentate pyrrolyl ligand is arranged at the meridional positions, with the pyrrolyl nitrogen atom occupying the equatorial position and the two NMe_2 units occupying the axial positions. The axial N(1)−Ga−N(3) angle of 146.68(6)° deviates from linearity

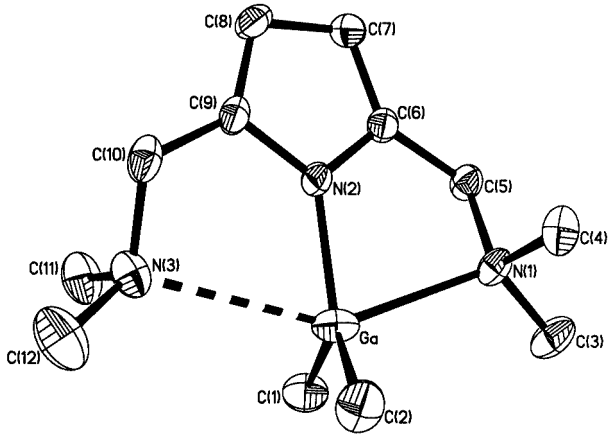

Figure 1. ORTEP diagram of complex **3**; thermal ellipsoids at the 50% probability level and hydrogen atoms are omitted for clarity

by 33.32° due to the geometrical constraints of the two fused five-membered rings. It is noteworthy that the N(1)−Ga and N(3)−Ga bond distances of 2.307(2) and 2.736(2) Å, respectively, are significantly different. The unit cell of **4** contains two independent molecules and the structure of one of these is shown in Figure 2. The structure of **4** is very similar to that of complex **3**. However, the difference of 0.14 Å in the metal-to-axial-nitrogen bond lengths In(1)−N(1) [2.519(5) Å] and In(1)−N(3) [2.661(6) Å] is smaller in **4** than in the corresponding gallium species. This is consistent with the larger atomic radius of indium. The axial angle, N(1)−In−N(3) [140.96(19)°], deviates from linearity by 39.04° due to the steric constraints imposed by the two fused five-membered rings.

Crystals of complex **6** were obtained by dissolving **2** in toluene and cooling to −20 °C. The reaction of **2** with moisture was effected by slowly exposing the solution to air occasionally. This caused crystals of **6** to appear in the flask. The crystals were collected and characterized by ^{1}H NMR spectroscopy and a single-crystal X-ray diffraction study. Details of the data collection for complex **6** are summarized in Table 2 with selected bond lengths and angles listed in Table 1. The ORTEP diagram of **6** is shown in Figure 3. The structure of **6** can be described as corner-sharing bis(square-pyramidal), in which the oxygen atom acts as the corner atom with Cl(1) and Cl(3) occupying the apical positions. A view of the coordination spheres of the two indium centers is shown in Figure 4, where the two square planes are joined by the oxygen atom. The In(1) and In(2) atoms are displaced from the planes defined by N(1)−N(2)−O(1)−Cl(2) and N(4)−N(5)−O(1)−Cl(4) by 0.4717 and 0.3389 Å, respectively. The question has been raised as to whether the oxygen-containing bridging groups should be viewed as water molecules or dianionic oxo groups. Although the hydrogen atoms of the bridging group were not found either in the ^{1}H NMR spectrum or in the X-ray crystal structure, three points support the water-bridged formulation for the dinuclear indium complex: (1) In both **4** and **6**, both pyrrolyl groups exist as σ-coordinated ligands with similar In−N distances [2.108(5) vs. 2.17 Å]. Furthermore, accommodation of the two methyl groups results in an oxidation state of +3 for the In center. These data suggest that the oxygen atom is coordinated to the indium

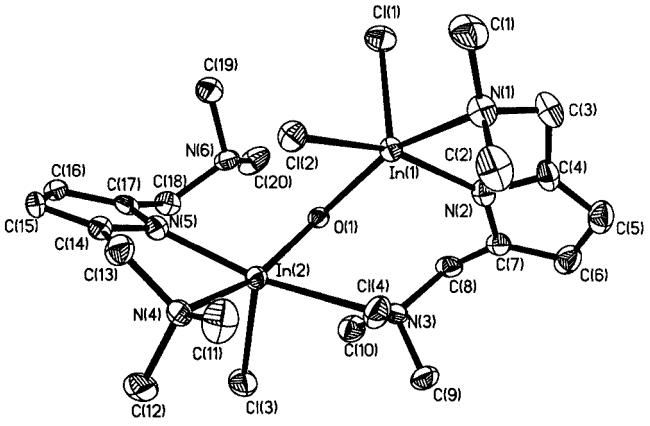

Figure 3. ORTEP diagram of complex **6**; thermal ellipsoids are at the 50% probability level and hydrogen atoms are omitted for clarity

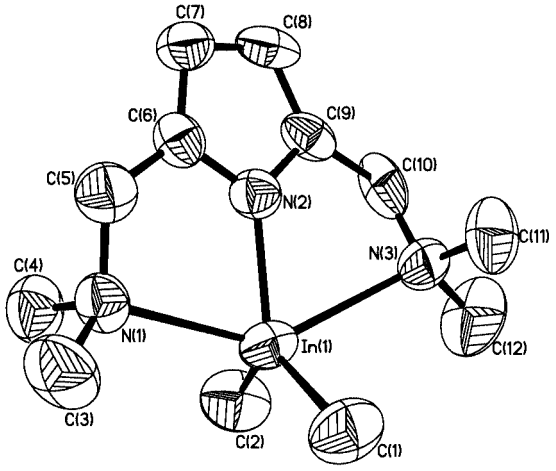

Figure 2. ORTEP diagram of complex **4**; thermal ellipsoids are at the 50% probability level and hydrogen atoms are omitted for clarity

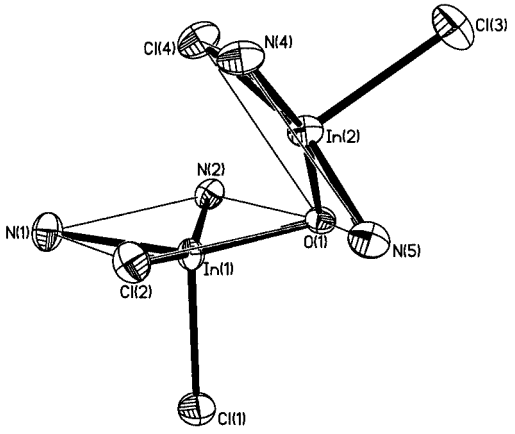

Figure 4. View of the coordination spheres of complex **6** showing only atoms coordinated to the indium atom; thermal ellipsoids are at the 50% probability level

atom via a lone pair of electrons. (2) The bond angle subtended by In(2)−O(1)−In(1) in complex **6** is 108.6(2)°, which is very close to the sp^3 bonding angle of 109.28. (3) Finally, an IR spectrum of **6** supports the existence of the bridged H_2O molecule, since a broad characteristic OH stretching peak was observed at 3460 cm^{-1}. Oxygen-atom-bridged dinuclear indium complexes have been observed often,[28−30] however, water-bridged diindium complexes have not been reported.

Experimental Section

General Procedures: All reactions were performed under dry nitrogen using standard Schlenk techniques or a glove box. Toluene, diethyl ether, and tetrahydrofuran were dried by heating to reflux in the presence of sodium benzophenone ketyl. CH_2Cl_2 was dried with P_2O_5. All solvents were distilled and stored under nitrogen in solvent reservoirs containing 4-Å molecular sieves. ^1H and ^{13}C NMR spectra were recorded with a Bruker AC 200 spectrometer. Chemical shifts for ^1H and ^{13}C spectra were recorded in ppm relative to the residual protons of the solvent or the ^{13}C resonances of the deuterated solvent: $CDCl_3$ (δ = 7.24, 77.0 ppm), C_6D_6 (δ = 7.15, 128.0 ppm), or CD_2Cl_2 (δ = 5.24, 54.0 ppm). Elemental analyses were performed with a Heraeus CHN-OS Rapid Elemental Analyzer at the Instrument Center, NCHU. $[C_4H_3N(CH_2NMe_2)_2$-2,5] and Li$[C_4H_2N(CH_2NMe_2)_2$-2,5] were prepared according to previously reported procedures.[23−25] $InCl_3$ (Strem) and MeLi (Aldrich) were used as received.

[{$C_4H_2N(CH_2NMe_2)_2$-2,5}$GaCl_2$] (1): A 100-mL Schlenk flask was charged with a solution of $GaCl_3$ (5.0 g, 28.57 mmol) in diethyl ether (30 mL). This solution was added dropwise to a suspension of Li$[C_4H_2N(CH_2NMe_2)$-2,5] (5.34 g, 28.57 mmol) in diethyl ether (20 mL) with stirring at −78 °C. The mixture was allowed to warm to room temperature and stirred for 5 h. The resultant suspension was filtered through Celite. The filtrate was concentrated to dryness and the resultant solid was recrystallized from diethyl ether to afford **1** (9.0 g, 98%). ^1H NMR ($CDCl_3$): δ = 2.52 (s, 12 H, N*Me*$_2$), 3.63(s, 4 H, CH_2N), 5.95 (s, 2 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 47.0 (q, $J_{C,H}$ = 136 Hz, N*Me*$_2$), 58.8 (t, $J_{C,H}$ = 139 Hz, *C*H_2N), 105.2 (d, $J_{C,H}$ = 167 Hz), 128.0 (s) ppm. $C_{10}H_{18}Cl_2GaN_3$ (320.90): calcd. C 37.43, H 5.65, N 13.09; found C 36.93, H 5.68, N 12.55.

[{$C_4H_2N(CH_2NMe_2)_2$-2,5}$InCl_2$] (2): This complex was prepared in a similar way to that described for **1**, starting from $InCl_3$ (3.0 g, 13.6 mmol) and Li$[C_4H_2N(CH_2NMe_2)$-2,5] (2.53 g, 13.6 mmol). Yield: 4.03 g (81%). ^1H NMR ($CDCl_3$): δ = 2.54 (s, 12 H, N*Me*$_2$), 3.65 (s, 4 H, CH_2N), 5.99 (s, 2 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 46.5 (q, $J_{C,H}$ = 137 Hz, N*Me*$_2$), 59.3 (t, $J_{C,H}$ = 138 Hz, *C*H_2N), 106.4 (d, $J_{C,H}$ = 167 Hz), 129.5 (s) ppm. $C_{10}H_{18}Cl_2InN_3$ (365.99): calcd. C 32.82, H 4.96, N 11.48; found C 32.26, H 4.54, N 10.92.

[{$C_4H_2N(CH_2NMe_2)_2$-2,5}$GaMe_2$] (3): A 50-mL Schlenk flask was charged with diethyl ether (20 mL) and **1** (2.0 g, 6.23 mmol) and the resultant solution was cooled to −78 °C. To this solution was added MeLi (1.4 M in diethyl ether, 4.45 mL, 12.5 mmol) via syringe. The mixture was stirred at room temperature for 5 h, and the resultant suspension was heated to reflux for 30 min and filtered through Celite. The filtrate was concentrated to dryness affording **3** in 75% yield (1.30 g). ^1H NMR ($CDCl_3$): δ = −0.37 (s, 6 H, Ga*Me*), 2.29 (s, 12 H, N*Me*$_2$), 3.48 (s, 4 H, CH_2N), 5.89 (s, 2 H) ppm. ^{13}C NMR ($CDCl_3$): δ = −9.32 (q, $J_{C,H}$ = 121 Hz), 45.9 (q, $J_{C,H}$ = 137 Hz, N*Me*$_2$), 58.9 (t, $J_{C,H}$ = 136 Hz, *C*H_2N), 103.0 (d, $J_{C,H}$ = 163 Hz), 131.9 (s) ppm. $C_{12}H_{24}GaN_3$ (280.06): calcd. C 51.46, H 8.64, N 15.00; found C 49.802, H 8.036, N 14.51. The error in the elemental analysis may be due to traces of LiBr in the final product.

[{$C_4H_2N(CH_2NMe_2)_2$-2,5}$InMe_2$] (4) and [{$C_4H_2N(CH_2NMe_2)_2$-2,5}$InBu_2$] (5): A similar procedure described for the preparation of complexe **3** was applied for the preparation of **4** and **5**. The yield of **4** was 61% (0.54 g, based on 1.0 g of **2**). ^1H NMR ($CDCl_3$): δ = −0.31 (s, 6 H, In*Me*), 2.31 (s, 12 H, N*Me*$_2$), 3.47 (s, 4 H, CH_2N), 5.91 (s, 2 H) ppm. ^{13}C NMR ($CDCl_3$): δ = −10.6 (q, $J_{C,H}$ = 126 Hz), 46.1 (q, $J_{C,H}$ = 135 Hz, N*Me*$_2$), 59.4 (t, $J_{C,H}$ = 135 Hz, *C*H_2N), 103.0 (d, $J_{C,H}$ = 164 Hz), 131.9 (s) ppm. $C_{12}H_{24}InN_3$ (325.16): calcd. C 44.33, H 7.44, N 12.92; found C 44.92, H 6.96, N 12.65. For **5** the yield was 65% (0.73 g, based on 1.0 g of **2**) of a brown viscous liquid after removing all volatiles. Due to the viscosity of complex **5**, it could not be purified by recrystallization or distillation. ^1H NMR ($CDCl_3$): δ = 0.66 (t, 4 H, In*CH*$_2$CH$_2$CH$_2$CH$_3$), 0.89 (t, 6 H, InCH$_2$CH$_2$CH$_2$*CH*$_3$), 1.31 (m, 4 H, InCH$_2$*CH*$_2$CH$_2$CH$_3$), 1.57 (m, 4 H, InCH$_2$CH$_2$*CH*$_2$CH$_3$), 2.34 (s, 12 H, N*Me*$_2$), 3.45 (s, 4 H, CH_2N), 5.91 (s, 2 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 13.2 (t, $J_{C,H}$ = 140 Hz), 13.7 (q, $J_{C,H}$ = 123 Hz), 28.8 (t, $J_{C,H}$ = 125 Hz), 30.3 (t, $J_{C,H}$ = 128 Hz), 46.8 (q, $J_{C,H}$ = 137 Hz, N*Me*$_2$), 60.0 (t, $J_{C,H}$ = 135 Hz, *C*H_2N), 103.0 (d, $J_{C,H}$ = 164 Hz), 132.7 (s). No elemental analysis was performed due to a small amount of impurity present in the product.

[{[$C_4H_2N(CH_2NMe_2)_2$-2,5]$InCl_2$}$_2$(μ-OH_2)] (6): The same procedure was applied for the preparation of **6** as that used to synthesize **2**, with the exception that during recrystallization of complex **2** from a toluene solution at −20 °C the Schlenk flask was periodically opened to air. This resulted in the deposition of **6** on the bottom of the flask (1.03 g,13%, based on 5 g of $InCl_3$). ^1H NMR (CD_2Cl_2): δ = 2.50 (br. s, 6 H, N*Me*$_2$), 2.59 (br. s, 6 H, N*Me*$_2$), 2.84 (br. s, 12 H, N*Me*$_2$), 3.16 (d, 4 H, CH_2N), 3.70 (d, 4 H, CH_2N), 4.56 (d, 4 H, CH_2N), 4.72 (d, 4 H, CH_2N), 6.01 (d, 2 H), 6.26 (d, 2 H) ppm. ^{13}C NMR (CD_2Cl_2): 47.8 (q, $J_{C,H}$ = 136 Hz, N*Me*$_2$), 49.6 (q, $J_{C,H}$ = 135 Hz, N*Me*$_2$), 50.2 (q, $J_{C,H}$ = 135 Hz, N*Me*$_2$), 60.6 (t, $J_{C,H}$ = 139 Hz, *C*H_2N), 61.3 (t, $J_{C,H}$ = 145 Hz, *C*H_2N), 106.3 (d, $J_{C,H}$ = 167 Hz), 114.9 (d, $J_{C,H}$ = 164 Hz), 122.5 (s), 136.0 (s). A small amount of complex **2** was present in **6** (less than 3% by ^1H NMR spectroscopy), which prevented a reasonable elemental analysis from being obtained.

X-ray Structure Determination of Complexes 3, 4, and 6: Crystals were mounted on a glass fiber using epoxy resin and transferred to the goniostat. Data collections were preformed at 150 K under liquid nitrogen vapor for complexes **3** and **6** and at 293 K for complex **4**. Data were collected with a Bruker SMART CCD diffractometer with graphite-monochromated Mo-K_α radiation. Structural determinations were carried out using the SHELXTL package of programs. All refinements were carried out by the full-matrix least-squares method using anisotropic displacement parameters for all non-hydrogen atoms. All the hydrogen atoms were placed in calculated positions. The crystal data are summarized in Table 2. CCDC-185057 and -185059 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Manganese in Precipitated Hydroxyapatites

Isaac Mayer,*[a] Orit Jacobsohn,[a] Tamara Niazov,[a] Jacques Werckmann,[b] Monica Iliescu,[b] Mireille Richard-Plouet,[b] Olaf Burghaus,[c] and Dirk Reinen[c]

Keywords: Manganese / Hydroxyapatite / EPR spectroscopy / Thermal properties

The synthesis of Mn-containing hydroxyapatite (HA) samples was carried out by precipitation from an aqueous solution with and without carbonate at pH 5.8–6.0. Chemical analyses have shown that Mn uptake (about 70%) is proportional to the amount of initially added Mn. The molar Ca/P ratios of the samples (1.53–1.63) indicate the formation of nonstoichiometric HA, with the higher values being obtained for the carbonated samples. Powder X-ray diffraction (XRD) and IR spectroscopy have shown well-defined patterns with structural data characteristic of HA. The calculated lattice constants were found to be similar to those known for HA, without any effect of the varying Mn content. High temperature treatment of selected samples was studied by XRD and IR and showed that the apatite structure is stable up to 400 °C for all samples. At 600 °C samples with low carbonate content transform partially, and at 800 °C completely, to β-$Ca_3(PO_4)_2$, while for samples with higher carbonate content (3.5–6.0%) the apatite structure is stable up to 800 °C, and a colour change to blue occurs. EPR spectroscopy reveals that manganese is divalent in all precipitated samples and present in a cubic impurity phase. After heating above 600 °C it is partially oxidized to Mn^V in the samples with high carbonate content and enters the HA lattice as the blue MnO_4^{3-} ion. In the carbonate-poor solids Mn^{2+} seems to partly occupy the Ca^{2+} sites in β-$Ca_3(PO_4)_2$ when sintered at temperatures above 400 °C.

Introduction

Various calcium hydroxyapatites (HA) containing Mn^{2+} ions were prepared in the course of a project dealing with the surface improvement of metal implants. HA is frequently used in implant materials for orthopaedic applications because of its biocompatibility. The addition of Mn^{2+} ions to HA in the present work was due to the fact that divalent Mn^{2+} has been linked to the activation of integrins,[1] a family of receptors which mediate cellular interactions with extracellular matrix and cell-surface ligands. In the presence of Mn^{2+} ions the ligand affinity of integrin increases and cell adhesion is promoted.

It is well-known that Mn^{2+} may enter the divalent M^{II} metal positions of apatites at the doping level, preferentially the M(I) site on a C_3 axis and with the coordination number 9 with respect to oxygen. The EPR spectra of Mn^{2+} in the Ca(I) position of the fluoride apatite $Ca_5(PO_4)_3F$ have been reported, indicating an axial lower-symmetry ligand field according to a zero-field splitting, D, of 428 G (about four times larger than the hyperfine splitting A).[2] Single crystal spectra of Mn^{2+}-doped $Cd_5(PO_4)_3Cl$ yield rather similar values ($D \approx 457$ G; $A \approx 92$ G).[3] Manganese may also enter the tetrahedral positions in the (+V) oxidation state, however, and a series of detailed single-crystal and powder studies centred on the optical and EPR properties have been published.[4]

Results

Chemical Analyses

Table 1 is a partial list of the analytical results of the synthesised samples (for preparation see Exp. Sect.). The molar Ca/P ratios found were in the range of 1.51−1.62, lower than the ratio for stoichiometric HA (1.67), thus indicating that under the experimental conditions used nonstoichiometric HA is obtained. Higher values of Ca/P are usually obtained for carbonate-containing samples. The Mn contents found in the samples were proportional to the initial amounts of Mn ions added and were about 70% of the original percentages.

Crystal Phase Analyses

Powder XRD patterns of the samples consisted of well defined reflections with the characteristic $P6_3/m$ hexagonal structure of apatites and with no additional crystal phases. The calculated lattice constants are listed in Table 1, and

are close to those of pure HA. The amount of Mn added during precipitation has no apparent effect on the lattice constant values.

The IR spectra of the samples display the characteristic phosphate, hydroxide and water bands of HA. The carbonate bands appear around 1420 and 1470 cm^{-1}, indicating the replacement of phosphate by carbonate (B-type). In samples without carbonate HPO_4^{2-} could be detected by a band at around 866 cm^{-1}.

Thermal Properties

The thermal properties of selected samples were studied by heating them during four hours in the temperature range of 400−800 °C in 200 °C intervals. The samples were then analysed by XRD. The results of this thermal treatment are summarised in Table 2. The XRD patterns of the samples heated up to 800 °C display very sharp and well-defined peaks, an indication of improved crystallinity. The samples show no change in their crystal structure after heating up to 400 °C, and only one crystal phase − the apatite structure − is present. At 600 °C the apatite structure is still the only crystal phase found for the samples containing more than 4% carbonate. The XRD powder patterns of all the other samples have, in addition to the apatite phase, the diffraction peaks of β-$Ca_3(PO_4)_2$ (β-TCP),[5] indicating the partial transformation of HA to β-TCP. At 800 °C samples without, or with up to 2%, carbonate transform almost completely to β-TCP. The samples with a carbonate content equal to or higher than 4% do not decompose at all during thermal treatment but their colour turns to blue above 600 °C. This colour change is most pronounced in samples with low Mn content (around 0.1%); above 1.0% Mn, part of the crystallites are brownish. No such colour changes were observed for the samples which transform to β-TCP.

EPR Spectroscopy

Figure 1 shows the Q-band spectrum and the second derivative of a sample after precipitation and drying. The spectrum is characteristic of Mn^{2+} in a cubic environment, with a well-resolved sextet due to the hyperfine interaction with the manganese nucleus. A significant zero- field splitting, indicating lower-symmetry crystal field components − which should be observable if Mn^{2+} substitutes into the Ca^{2+} position of the apatite lattice[3] − cannot be detected. Apparently, Mn^{2+} is present as an impurity phase (oxidic or hydroxy), sometimes with manganese clustering, which shows up in an only partly resolved hyperfine structure of many samples.

Annealing at 400 °C leads already to distinct changes in the environment of part of the Mn^{2+} ions, obviously induced by the onset of migration of manganese into the apatite lattice. This is deduced from the Q-band spectrum in Figure 2 (top), for example, where new lines beside the original sextet appear, but even more distinctly in the X-band region, where more or less pronounced additional absorptions, in particular at lower magnetic fields, supplement the original broad signal around 3300 G (Figure 2; bottom). However, more precise information is obtained by looking

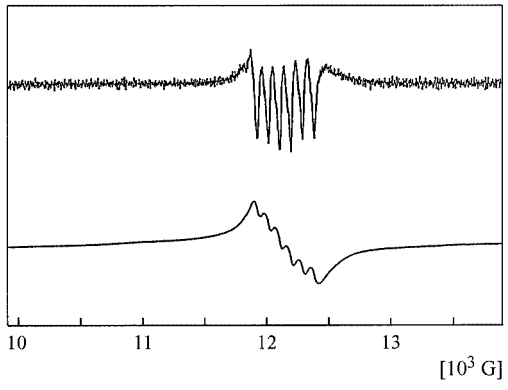

Figure 1. Q-band spectrum of the non heated sample HAMn61 (33.99 GHz, 298 K); the second derivative spectrum is also shown (above)

at the EPR spectra samples after heat treatment at 600 °C and 800 °C. The Q-band spectrum in Figure 3 depicts the typical situation for compounds with vanishingly small or very low CO_3^{2-} contents, which transform to β-TCP when heated to higher temperatures. This spectrum is typical for zero-field effects, displaying a centrosymmetric intensity distribution; the fine structure transitions are broad and not resolved into hyperfine sextets, except in the central part. The optical spectra give no evidence for oxidation states of manganese beyond +II, in agreement with the white colour. A moderate zero-field splitting *D* of about 500 G is estimated, which is near to the value for Mn^{2+} doped into the Cd^{2+} position of the $Cd_5(PO_4)_3Cl$ apatite.[3] One can easily follow this argument by direct comparison. The group of lines five (I–V) due to the zero-field splitting, which is induced by the non-cubic ligand-field component, are each nicely resolved into the six hyperfine components in the case of Mn^{2+}-doped $Cd_5(PO_4)_3Cl$ (powdered single crystals); they are also present in the β-TCP sample, however, as broad absorptions — presumably because of Mn^{2+} clustering in the host. We therefore conclude that Mn^{2+} has partly entered one of the five Ca^{2+} positions in β-TCP – presumably Ca(5) with a pseudo-octahedral coordination.[6]

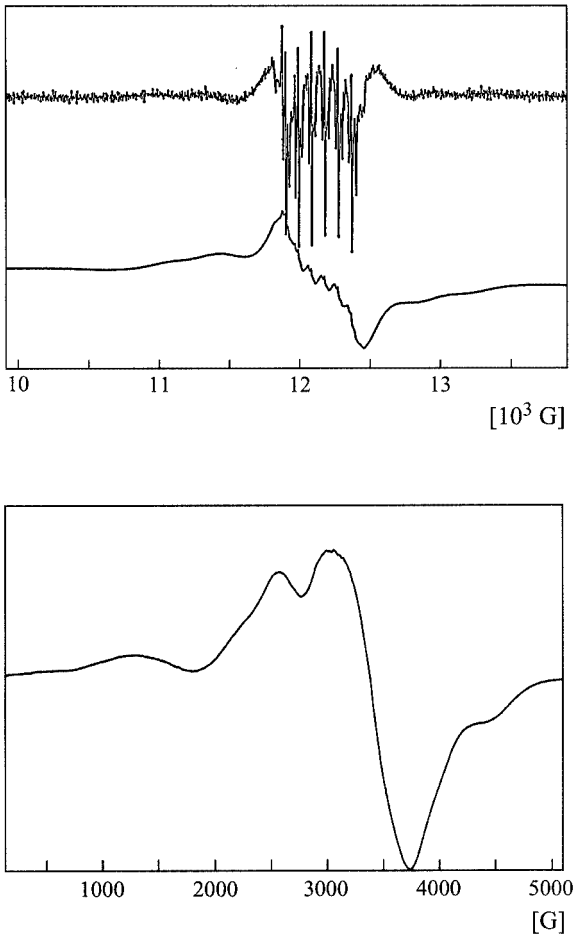

Figure 2. Q-band spectrum and second derivative of sample HAMn21, annealed at 400 °C (33.98 GHz, 298 K; top) and X-band spectrum of the same sample (9.23 GHz, 120 K; bottom)

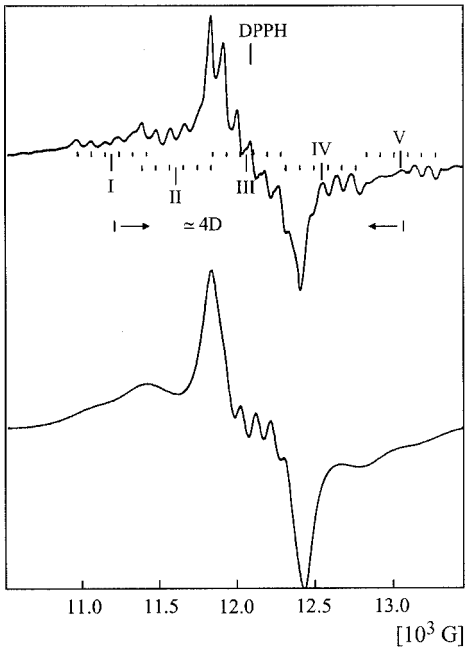

Figure 3. Q-band spectrum of sample HAMn28 with low carbonate content and annealed at 800 °C (33.98 GHz, 298 K; bottom) in comparison with the Q-band spectrum of Mn^{2+}-doped $Cd_5(PO_4)_3Cl$ (adapted from ref.;[3] top)

A different situation arises when looking at the samples with higher carbonate content, heated to temperatures above 400 °C. They turn bluish and the optical spectra indicate $Mn^{V}O_4$ tetrahedra; the split and intensity-dominating $^3A_2(e^2) \rightarrow {}^3T_1(\approx e^1t_2^1)$ transition shows the same structure and appears at the same energy (Figure 4) as the colour-determining band of Mn^{V}-doped apatites synthesised by high-temperature solid-state reactions.[7a,7b] Correspondingly, a diverse spectral intensity distribution becomes apparent in the EPR spectra, with a considerably larger fine

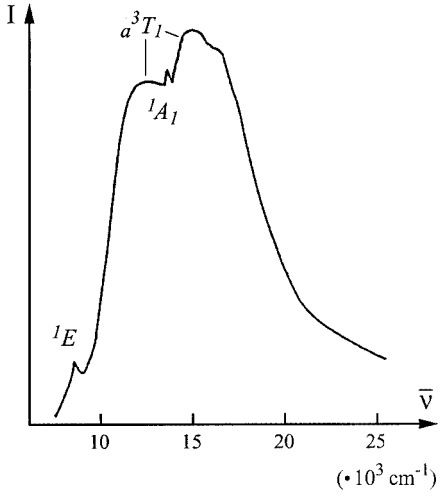

Figure 4. The optical powder reflection spectrum of sample HAMn69, heated at 800 °C, between 8000 and 28000 cm^{-1}; besides the allowed $^3A_2 \rightarrow {}^3_aT_1$ band around 12000 to 15000 cm^{-1} the characteristic narrow spin-forbidden transitions $^3A_2 \rightarrow {}^1E$, $^1A_1$ within the e^2 ground-state configuration are seen at 8700 and 13500 cm^{-1}, respectively

structure splitting. This is particularly observable in the X-band spectra, where signal groups extend down to 700 G, in contrast to the former case with low carbonate content (Figure 5). The described features roughly correspond to those typical for tetrahedral Mn^{V} in apatites.[7a] Apparently part of the manganese present has been oxidized and has entered the apatite lattice. A reaction where CO_3^{2-} is positioned on a PO_4^{3-} lattice position and OH^- is a constituent of the apatite host [depicted in Equation (1)] would offer an explanation for these spectral findings.

$$Mn^{II}(OH)_2 + CO_3^{2-} + OH^- + 3/4O_2 \rightarrow Mn^{V}O_4^{3-} + CO_2 + 3/2H_2O \quad (1)$$

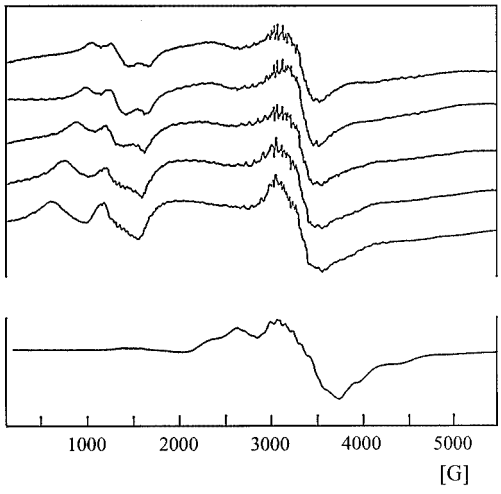

Figure 5. X-band spectra (9.21 GHz) of sample HAMn69, after heating to 800 °C, at temperatures 340, 293, 280, 170 and 117 K (above) and of sample HAMn86 (below), after heating to 800 °C, at 298 K

EDX Analysis and TEM Electron Microscopy

The results of the EDX analysis of two representative samples, HAMn23 and HAMn61, are shown in Figure 6 and 7. The Ca/P ratios and the Mn content obtained at different locations within the samples show that the Ca/P ratio is relatively constant, while Mn is not homogeneously dispersed in the samples.

The results of the TEM analysis of selected samples have shown that in the samples with and without carbonate and with Mn, crystals appear in the form of sticks and platelets. Figure 8 and 9 are TEM pictures of samples HAMn2 (no CO_3, 0.56% Mn) and HAMn61 (2.6% CO_3, 0.44% Mn). Sticks and plates appear in both and in the case of HaMn61 fibres can also be seen. In Figure 9 (sample HAMn59) wider sticks and plates appear, but no fibres are present, which indicates that Mn may play a role in the formation of fibres. The main morphological observations obtained are summarised in Table 3.

Discussion

The main aim of this work was to prepare precipitated HA samples in the presence of Mn^{2+} and to investigate their properties. The analytical data concerning the chemical composition of the samples, as well as their XRD and FTIR data, prove that apatite-type HA samples were obtained with their typical structural characteristics. The non-stochiometry of the samples, with molar Ca/P ratios of less than 1.67, is most probably due to the presence of HPO_4^{2-}

ions which occupy a small part of the anion sites of the compounds together with the PO_4^{3-} ions. Such an assumption is in good agreement with the structural and spectroscopic findings discussed below. The Ca/P ratios found by EDX analysis locally, and by global analyses as well, are close to the chemical analysis results. EPR spectroscopy shows that Mn is in the divalent state in all the samples. Mn^{2+} is present as a cubic (oxidic or hydroxy) impurity phase, which is not homogeneously distributed over the samples, as is clearly indicated by EDX analysis and also suggested by EPR spectroscopy.

TEM observations have shown that the morphology of the crystals is that of platelets, sticks and fibres. Platelets and sticks have also been found in HA samples precipitated in the presence of Zn[8] and Al.[9] In the present work fibre-like crystals were also observed. Apparently, further studies are needed to determine the role of Mn in the formation of fibre-type crystals.

Two types of high temperature behaviour have been observed: HA samples without or with carbonate contents up to about 3.5% transform partially or completely above 600 °C to β-TCP; samples with carbonate contents higher than 4% retain the apatite structure and their colour changes to blue above 600 °C. There is definite spectroscopic evidence that $Mn^{V}O_4^{3-}$ ions – generated by oxidation of Mn^{2+} and presumably substituting CO_3^{2-} ($+OH^-$) [cf. Equation (1)] in the HA structure – are responsible for this colour. In contrast manganese in the samples with low carbonate content remain in the (+II) oxidation state and partly migrate into Ca^{2+} positions of β-TCP and of HA as well, when heated to temperatures from 400 °C to 800 °C.

The simultaneous effect of $HPO_4^{2-}$and CO_3^{2-} ions on the thermal transformation of HA to β-TCP was discussed in a previous work[10] and it was shown that HPO_4^{2-} ions support this transformation; the CO_3^{2-} ions in carbonate-containing apatites prevent the incorporation of HPO_4^{2-} ions. The assumption of HPO_4^{2-} substituting PO_4^{3-} in the apatite lattice as the cause of the lower molar Ca/P ratios is well in agreement with the high temperature properties of precipitated HA samples. As Equation (2) indicates for an extreme case the presence of vacancies in the Ca^{2+} sublattice and the release of water on heating – which leaves the OH^- positions unoccupied – destabilizes the apatite structure and favours the structural transformation to β-TCP. Indeed, such a transformation is often observed for HA samples with small molar Ca/P ratios. On the other hand, the presence of larger amounts of carbonate, which is known to replace phosphate in HA to a certain extent, prevents the formation of β-TCP on annealing,[10] as Equation (3) – again for an extreme case – illustrates nicely.

$$\square_{0.5}Ca_{4.5}(PO_4)_2(HPO_4)OH \rightarrow 1.5\,Ca_3(PO_4)_2 + H_2O \quad (2)$$

$$\square_{0.5}Ca_{4.5}(PO_4)_2(HPO_4)_{0.7}(CO_3)_{0.3}OH \rightarrow 0.9Ca_5(PO_4)_3OH + 0.3CO_2 + 0{\cdot}4H_2O \quad (3)$$

It is clearly the basic character of CO_3^{2-} that stabilizes the apatite lattice, as well as the fact that the substitution of PO_4^{3-} by CO_3^{2-} in the lattice raises the Ca/P ratio towards that characteristic for stoichiometric apatite (Table 1). The basic (O^{2-} donor) properties of CO_3^{2-} are

also needed for the oxidation from Mn^{II} to Mn^{V} [Equation (1)]. If the manganese concentration becomes too high, such an oxidation process is only partly possible; most of the manganese is oxidized to Mn^{IV} in that case − where O^{2-} donors are not needed − as indicated by the brownish colour (MnO_2 impurities).

In a very recent EPR study[11] it was suggested that in precipitated HA (carbonate-free, manganese presence), heated to 400 °C, Mn^{2+} has partly migrated into the Ca^{2+} position − in perfect agreement with the results presented here.

Experimental Section

Sample Preparation and Characterisation

Samples of HA with Mn (0.1−2.0%), and with (1.0−6.0%) and without carbonate, were prepared by a precipitation method described in more detail elsewhere.[12] A phosphate solution [3.7 g of $(NH_4)_2HPO_4$ in 200 mL of triply distilled water (TDW)] was added dropwise to a calcium solution [9.47 g $Ca(NO_3)_2{\cdot}4H_2O$ in 200 mL TDW]. Carbonate was added [5.0, 10.0, 15.0 and 20.0 mL] from a 1 M $NaHCO_3$ stock solution. These additions were designed to give 2.5−3.5 and 3.5−6.0% carbonate in the final sample. The amount of Mn added was 0, 2.5, 5.0, 10, 15.0, 20.0 and 25.0 mL per sample from a 0.025 M $MnCl_2$ solution.

For the preparation of HA samples with Mn^{2+} the pH of 5.8−6.0 was chosen because it was found that at this pH Mn^{2+} is not oxidized to a higher valence state. The pH was maintained constant during precipitation by adding NaOH solution using a Mettler pH-stat automatic titrator. The precipitation was carried out during 2 h, and following this the temperature was raised to boiling point and the system was refluxed for 2 h. The sample was then washed with TDW and dried overnight in air at 120 °C.

The Ca, P and Mn contents of the samples were determined by ICP-atomic emission spectroscopy with a precision of ±0.1, ±0.5, and ±0.3% for Ca, P and Mn respectively.

Powder X-ray Diffraction (XRD) was used for crystal phase and lattice constant determination. The X-ray diffraction analyses were made by a Philips Automatic Diffractometer using Cu-K_α radiation. The samples were scanned in the 2θ range of 20−55°. The lattice parameters were calculated by a least-square computer program. The maximum deviation of the lattice constants was ±0.003 Å.

The characterisation of the samples by infrared spectroscopy (IR) was performed by a Nicolet FTIR spectrometer. Samples of approx. 1 mg were pressed into pellets with approx. 150 mg KBr. The carbonate content of the samples was estimated by IR analysis using the extinction ratio of the carbonate (1420 cm^{-1}) and phosphate (575 cm^{-1}) bands. Carbonate is determined by this method with an accuracy of ±5%.[13]

Thermal analyses of selected samples were carried out by heating in porcelain crucibles up to 800 °C in an electric furnace.

EPR measurements were performed at X- and Q-band frequencies between 300 and 80 K with a Bruker ESP-300 spectrometer. UV/Vis spectra were recorded using the powder diffuse-reflection technique with a Zeiss PMQII spectrometer.

Samples were also examined by EDX analysis and by TEM electron microscopy. For this purpose they were ground and sonicated in ethanol. The thus-obtained suspension was deposited onto a carbon-coated grid. In local analysis of the samples the beam diameter was 18 nm, in global analysis 15 μ and 56 and 700 nm.

Cyclopropanation of Olefins with Diazoalkanes, Catalyzed by Co^{II}(porphyrin) Complexes − A Synthetic and Mechanistic Investigation and the Molecular Structure of $Co^{III}(TPP)(CH_2CO_2Et)$ (TPP = Dianion of *meso*-Tetraphenylporphyrin)

Andrea Penoni,[a] Riccardo Wanke,[a] Stefano Tollari,[b] Emma Gallo,[a] Danilo Musella,[a] Fabio Ragaini,[a] Francesco Demartin,[c] and Sergio Cenini*[a]

Dedicated to Prof. Mauro Graziani on the occasion of his 65th birthday

Keywords: Cobalt / Cyclopropanation / Olefins / Porphyrinoids

Cobalt(II) porphyrin complexes catalyze reactions between ethyl diazoacetate (EDA) and styrenes to give the corresponding cyclopropanes with *trans* selectivity. The reactions of other diazoalkanes and other olefins have also been carried out, and the mechanism of the reaction has been investigated. Kinetic data and stoichiometric reactions support the formation of a diazoalkane cobalt-porphyrin complex that reacts with the olefins to generate the cyclopropane. Diethyl maleate and fumarate are not formed in the presence of an excess of olefin. On treatment of EDA with Co^{II}(TPP) (TPP = dianion of *meso*-tetraphenylporphyrin) in the absence of the olefin, an alkyl cobalt(III) complex $Co^{III}(TPP)(CH_2CO_2Et)$ was isolated, and its structure has been solved by X-ray diffraction.

Introduction

A vast number of investigations into metal complex-catalyzed cyclopropanations of alkenes with diazo compounds have recently been reported.[1] A variety of transition metal compounds have been employed as catalysts for diazo decomposition, and the most efficient compounds have been found to be based on copper[2] and rhodium.[3]

In the last few years, transition metal-porphyrin complexes of iron,[4] rhodium,[5] osmium,[6] and ruthenium[7−9] have been extensively employed as catalysts in the cyclopropanation of olefins and, in the case of ruthenium, excellent enantioselectivity was obtained in this reaction.

The mechanism of the metal−porphyrin-catalyzed reactions has also been investigated. Carbene complexes have always been implicated, and the molecular structures of these carbene complexes have in several cases been determined by X-ray diffraction. Carbene complexes of ruthenium-,[7,9b,10] iron-,[4a,11] and osmium-porphyrins[10b,12] are known. In the case of rhodium, while no stable carbene complex has been isolated from reactions involving diazo compounds, one has been spectroscopically characterized and its reactivity investigated.[13] A stable rhodium-porphyrin carbene complex has been obtained by a different route and crystallographically characterized, but its reactivity with olefins was not investigated.[14]

Recently we have reported on the catalytic activity of cobalt(II) porphyrin complexes in the amination reactions of olefins[15] and benzylic C−H bonds,[16] with aromatic azides as aminating agents. Since diazo compounds are isoelectronic with aryl azides, we considered that cobalt(II) porphyrin complexes may also act as catalysts for the cyclopropanation reaction, and the results of our studies are reported here.

To the best of our knowledge, this is the first time that cobalt(II) porphyrin complexes have been used as catalysts for cyclopropanation reactions, though cobalt(II) Schiff bases[17,18] and dioximato complexes[19] are excellent catalysts for the cyclopropanation of olefins. Several reports concerning stoichiometric reactions between cobalt porphyrins and diazo compounds have been published.[20−22] Both cobalt(III) and cobalt(II) porphyrin complexes have been used as substrates, but in the latter case the reactions were always performed in $CHCl_3$ and in air, so chloride-containing cobalt(III) complexes were obtained as products in any case. The chloride anion clearly derives from a radical activation of the solvent, and in the only reaction employing

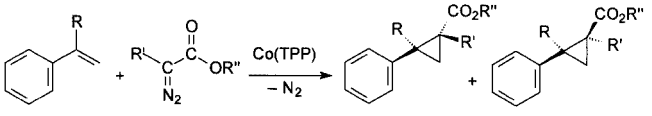
Co^{II}(OEP) and ethyl diazoacetate with exclusion of air, the same cobalt(III) chloride complex was obtained as in the presence of air, although after a longer time and in a lower yield.[20a] The identity of the major product depends on the amounts of the reagents and the identity of the diazo compound, but with ethyl diazoacetate the primary product from Co(OEP)[20a] or Co(TPP)[20b] was Co^{III}(porphyrin)-(Cl)(CHCOOEt), with a carbene group bridging cobalt and one of the pyrrole nitrogen atoms. Relevantly to this work, all attempts to trap the carbene group by treatment with an olefin failed, indicating that the cobalt(III) carbene complex is not an active species in cyclopropanation reactions. No cyclopropanation activity has been reported even for the other complexes obtained under different experimental conditions or with other diazo compounds or porphyrins.

Results and Discussion

Catalytic Reactions

Ethyl diazoacetate reacts with an excess of olefin, in the presence of catalytic amounts of Co(porphyrin) complexes (1%), to give the corresponding cyclopropanes in good yields [Equation (1)]. The results are listed in Table 1. Fumaric and maleic acid esters were never detected in these reactions, consistently with literature data, which show that these by-products are not generally formed when catalytic systems based on cobalt complexes are employed.[17–19] It is also important to note that no polystyrene was formed either, as evidenced by the lack of any signal in the $-CH_2-$ region in the ^1H NMR spectra of reactions run in deuterated solvents (see also later).



(1)

The reaction between styrene (R = H) and EDA (R′ = H, R′′ = Et) in refluxing CH_2Cl_2, catalyzed by Co(TPP) (TPP = dianion of *meso*-tetraphenylporphyrin), gave a mixture of *trans*- and *cis*-cyclopropanes (**1**) in 85:15 ratio (Table 1, entry 1).

The most active catalyst for the synthesis of cyclopropanes, although slightly less diastereoselective as far as the *trans*/*cis* ratio is concerned, is Co(*p*-ClTPP) (*p*-ClTPP = dianion of *meso*-tetra-*p*-chlorophenylporphyrin) (entry 2). Co(*p*-OMeTPP) (*p*-OMeTPP = dianion of *meso*-tetra-*p*-methoxyphenylporphyrin) and Co(OEP) (OEP = dianion of *beta*-octaethylporphyrin) are also effective catalysts (entries 3 and 4).

With methyl phenyldiazoacetate (MPhDA, R′ = Ph, R′′ = CH_3) as the diazoalkane and again with styrene as the olefin and Co(*p*-ClTPP) as catalyst, a slower reaction was observed, as would be expected in view both of the greater stability of the starting diazo compound and of the steric hindrance of the derived carbene. The cyclopropane (**2**) was obtained in a 40% yield. Surprisingly, the most abundant cyclopropane isomer is the one with two phenyl groups in a *cis* arrangement (39:61 *trans*/*cis* ratio). The use of MPhDA will be investigated further, because many metal catalysts afford excellent *trans* selectivities,[2b,3,23] but only a few examples showing *cis* selectivity have been reported.[24]

With other diazoalkanes such as ethyl diazoacetacetate (EDAA, R′ = $COCH_3$, R′′ = Et) and with the diethyl ester of diazomalonic acid (EDM, R′ = COEt, R′′ = Et) we did not observe any reaction.

Other olefins were also tested. The reaction between 1,1-diphenylethylene (R = Ph) and EDA (R′ = H, R′′ = Et), catalyzed by Co(TPP), was fast and gave high yields of the cyclopropane (**3**, entry 5). With this olefin the most efficient catalyst appears to be Co(TPP), while Co(*p*-XTPP) (X = Cl, OMe) and Co(OEP) were less active and less selective. However the differences are not marked enough to allow any speculation about the electronic effects of the porphyrin ring. Again, with a hindered and more stable diazoalkane such as EDAA, a slower reaction was observed (**4**, 42% yield).

Table 1. Reactions of EDA with olefins catalyzed by Co^{II}(porphyrin)

Entry[a]	Substrate	Catalyst	*t*/h[b]	Cyclopropane yield%[c]	*trans*/*cis* ratio[d]
1	styrene	Co(TPP)	21	62 (**1**)	85:15
2	styrene	Co(*p*-ClTPP)	22	99 (**1**)	75:25
3	styrene	Co(*p*-OMeTPP)	22	80 (**1**)	76:24
4	styrene	Co(OEP)	24	71 (**1**)	83:17
5	1,1-diphenylethylene	Co(TPP)	7	99 (**3**)	–
6	1,1-diphenylethylene	Co(*p*-ClTPP)	10	88 (**3**)	–
7	1,1-diphenylethylene	Co(*p*-OMeTPP)	19	85 (**3**)	–
8	1,1-diphenylethylene	Co(OEP)	20	65 (**3**)	–
9	α-methylstyrene	Co(TPP)	19	95 (**5**)	70:30
10	α-methylstyrene	Co(*p*-ClTPP)	17	91 (**5**)	75:25
11	α-methylstyrene	Co(*p*-OMeTPP)	20	72 (**5**)	77:23
12	α-methylstyrene	Co(OEP)	21	65 (**5**)	85:15

[a] Reaction carried out in refluxing dichloromethane (10 mL), with $1.2 \cdot 10^{-3}$ mmol of catalyst and a catalyst/diazoalkane/styrene ratio of 1:100:500. [b] Time required to reach complete conversion of EDA. [c] Isolated yields, calculated with respect to the initial amount of the diazoalkane. [d] Determined by ^1H NMR spectroscopy.

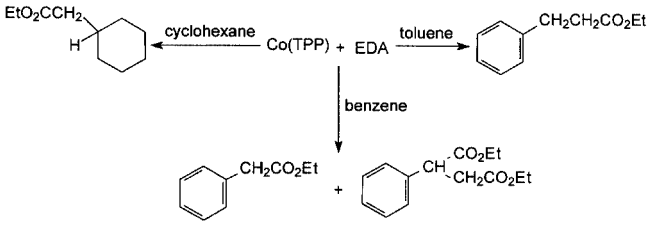
The reaction between α-methyl styrene (R = CH_3) and EDA, catalyzed by Co(TPP), gave good yields of the cyclopropanes (**5**, entry 9). The dominant isomer is the cyclopropane with the phenyl and the $-CO_2Et$ groups *trans* to each other. Small variations were observed on using the other porphyrin complexes as catalysts, while the use of the more hindered and stable EDAA gave slower reactions both when using Co(TPP) (**6**, 29% yield, 62:38 = *trans*/*cis* ratio) and when using Co(*p*-ClTPP) (**6**, 40% yield, 60:40 = *trans*/*cis* ratio).

The reactions between other olefins, such as norbornene and indene, and EDA with Co(*p*-ClTPP) as catalyst gave the corresponding cyclopropanes in low yields in mixtures with other compounds.

With 1-octene and cyclohexene, Co(*p*-ClTPP) as catalyst and EDA as the diazoalkane, we observed no derivatives originating from the attack of the carbene moiety on the alkene. On the other hand, we observed the products of coupling of two carbene units − that is, diethyl maleate and fumarate − for the first time. The formation of these coupling products when unreactive olefins are employed is in line with the results of the mechanistic study described below.

Preliminary studies were carried out with 2,3-dimethyl-1,3-butadiene as a representative diene. The efficiency of the catalytic system was checked under the same reaction conditions, and we observed the complete consumption of the EDA. Analysis of the ^1H NMR of the crude product verified the formation only of the monocyclopropanation derivative, and no coupling products were detected

Finally, when a 4:1 ratio between EDA and Co(TPP) was used, the products of the attack of the carbene on C−H bonds of the organic compounds used as solvent were observed in low amounts by GC-MS (Scheme 1).



Scheme 1

Intermolecular C−H activation by highly reactive metal carbenoid intermediates formed from diazo compounds has already been reported,[25] but alkylation of a C−H bond as stable as the one in benzene is rare.[26] These reactions will be investigated further.

Mechanistic Studies

The mechanism of the reaction between diazoalkanes and olefins with cobalt-porphyrins as catalysts was investigated by use of styrene as the olefin, EDA as the carbene precursor, and Co(TPP) as the catalyst. We first describe the experimental results and discuss them together in the end.

A series of kinetic measurements was performed; the reactions were followed by IR spectroscopy (disappearance of the absorptions of the diazo group at 2108 cm^{-1}), in benzene as solvent, at 50 °C. Some reactions showed an excellent first order dependence of the rate on the EDA concentration up to its complete consumption, but in several cases deviation from first order was observed after a variable time. We thus decided to calculate the kinetic constants for all reactions by the initial rates method (see also the Exp. Sect.). In all those cases in which first order behavior was observed throughout the reaction, good agreement was observed between the values obtained by the initial rates method and those obtained by fitting log[EDA] versus time for all the data points. The collected data show that the reaction rate is first order in EDA and in the catalyst (Figure 1 and Figure 2, see Exp. Sect.). In the latter case, the straight line in the plot of $k_{obsd.}$ versus the concentration of Co(TPP) showed an intercept on the axis of the concentration. The dependence of the reaction rate on the styrene concentration is more complex and has a bell shape, with styrene concentrations over 0.125 M inhibiting the reaction (Figure 3). Moreover, it has been observed that the diazoalkane is not completely consumed for concentrations of EDA higher than 0.05 mol/L.

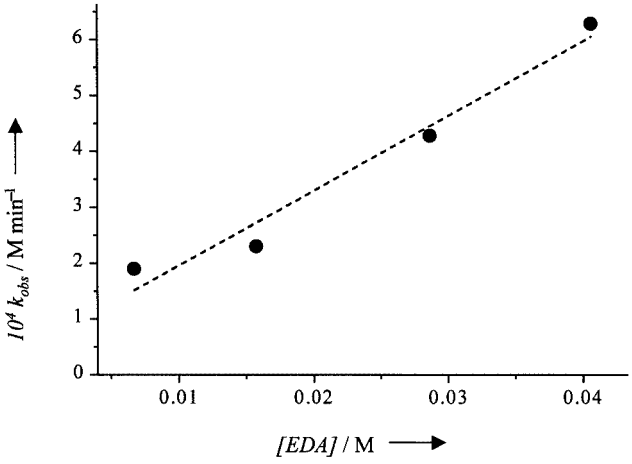


Figure 1. Dependence of the initial reaction rate on the initial EDA concentration; $k_{obsd.} = \{[EDA]_0 - [EDA]_t\}/t$, $R = 0.990$

One of the previously described experiments ($k_{obsd.}$ = 0.0149 min^{-1}) was repeated in the presence of several compounds capable of interfering with the formation of the cyclopropanes. In the presence of diethyl maleate ($k_{obsd.}$ = 0.0139 min^{-1}), diethyl fumarate ($k_{obsd.}$ = 0.0132 min^{-1}), and diethyl succinate ($k_{obsd.}$ = 0.0133 min^{-1}) the reaction rate is about 10% lower, but the reaction is still first order in EDA. This is probably due to the interaction of the metal center with the ester group of the added compound. In the absence of styrene, diethyl maleate reacts with EDA in the presence of Co(TPP) to give the corresponding cyclopropane in low yields. This last reaction is noteworthy, since it has never been reported with other catalytic systems based on metal-porphyrin complexes and it is usually performed with cobalt(0) or nickel(0) complex as catalyst.[27] On the

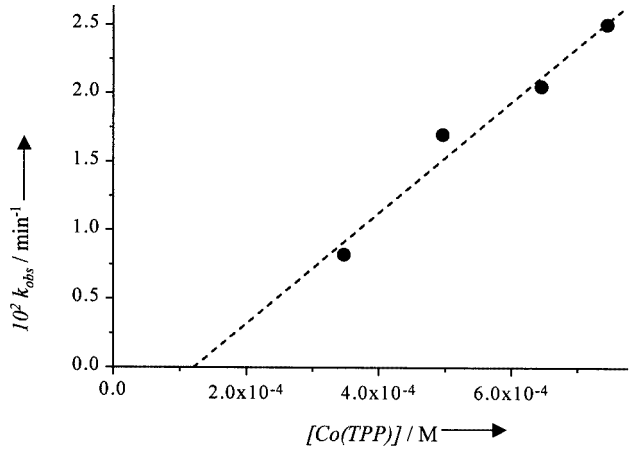

Figure 2. Dependence of the initial reaction rate on the initial Co(TPP) concentration; $k_{obsd.} = \{[EDA]_0 - [EDA]_t\}/[EDA]_0 \cdot t$, $R = 0.982$

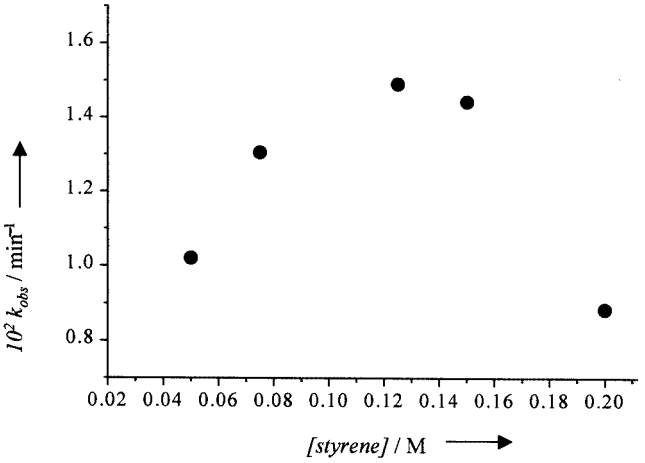

Figure 3. Dependence of the initial reaction rate on the initial styrene concentration; $k_{obsd.} = \{[EDA]_0 - [EDA]_t\}/[EDA]_0 \cdot t$

other hand, when dimethyl fumarate is used as substrate, only the cyclopropane derivative obtained from diethyl maleate (formed by carbene coupling from EDA) is obtained. This result emphasizes the importance of steric effects in this reaction. When we repeated the catalytic cyclopropanation reactions in the presence of the free radical trap TEMPO (2,2,6,6-tetramethylpyperidine-oxyl), we did not observe complete conversion of EDA, and a very slow reaction occurred. Since no irreversible reaction occurs between Co(TPP) and TEMPO alone,[16] this indicates that some intermediates in which unpaired spin density is present on the organic moiety must be formed during the reaction, although this should not be taken as an evidence of the formation of free organic radicals. An analogous outcome was observed for related amination reactions.[15,16]

Several reactions were performed in order to clarify the reaction mechanism. In the absence of the olefin and with use of a Co(TPP)/EDA ratio of 1:100, 35% of the EDA reacts to form diethyl maleate and a complex that has been identified as $Co^{III}(TPP)(CH_2CO_2Et)$ (**7**). A different synthesis of this complex has previously been reported in the literature,[28] but the product was then only characterized spectroscopically. We have now unequivocally characterized complex **7** by X-ray crystallography, and its structure is described in the next section. It is important to note that **7** is inactive as a catalyst. It may be this species that explains why an intercept on the axis of the concentrations is observed on the plot of $k_{obsd.}$ versus the concentration of Co(TPP).

By carrying out the catalytic reaction in a ^1H NMR tube, with a Co(TPP)/EDA/styrene ratio of 1:10:50, we observed that if EDA is added first and then styrene, diethyl maleate is immediately formed, followed by the cyclopropane derivatives. On the other hand, if styrene is added first to the Co(TPP) solution and then EDA, only the cyclopropanes can be detected.

The stoichiometric reaction between Co(TPP) and EDA in the absence of styrene and at 50 °C in benzene was followed by IR spectroscopy, a spectrum being recorded every 10 minutes. It was possible to observe the steady disappearance of EDA ($\nu_{CO} = 1685\ cm^{-1}$) and, after 30 minutes, the formation of an absorption at 1722 cm^{-1}. This new signal is attributable to an unstable intermediate (**8**), since it gradually disappeared and at the end of the reaction only the absorptions due to diethyl maleate ($\nu_{CO} = 1730$, 1750 cm^{-1}) and $Co^{III}(TPP)(CH_2CO_2Et)$ (**7**) ($\nu_{CO} = 1710\ cm^{-1}$) were detected (Figure 4).

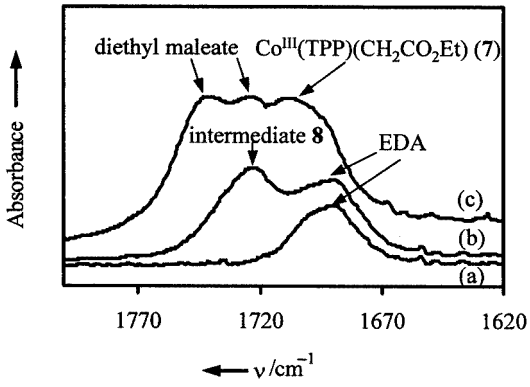

Figure 4. IR spectra of the reaction between Co(TPP) and EDA (stoichiometric ratio = 1:3); a) EDA; b) 30 min after the addition of Co(TPP); c) after 60 min (end of the reaction)

The absorption due to the diazo group at 2108 cm^{-1} gradually disappears, but no shift of this signal was detected. Even spectra subtraction techniques (Figure 5) failed to find any absorption attributable to a diazo group associated with the intermediate absorbing at 1722 cm^{-1}.

When the same reaction was run in C_6D_6 and followed by ^1H NMR spectroscopy, it was possible to observe the formation of a new paramagnetic species of cobalt(II) (δ = 22.2 ppm) in the range from δ = 25 to 10 ppm while the signals of Co(TPP) (13.2, 16.3 ppm) gradually disappeared (Figure 6).

As with the experiment followed by IR spectroscopy, only the signals of $Co^{III}(TPP)(CH_2CO_2Et)$ (**7**) and diethyl maleate were observed at the end of the reaction. From these

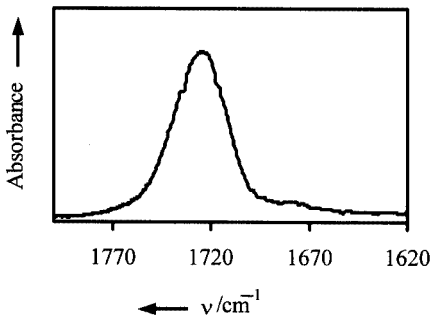

Figure 5. IR spectrum of the intermediate **8** obtained by subtracting spectrum (a) in Figure 4 from spectrum (b)

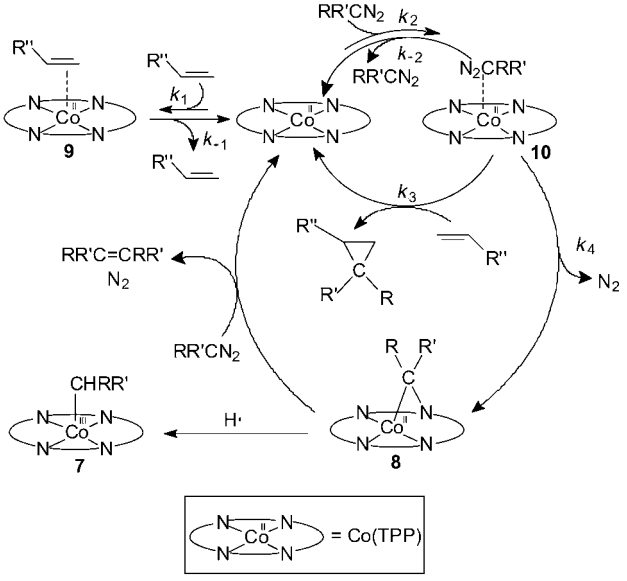
observations, we suggest that an intermediate carbene complex, $Co^{II}(TPP)(CHCO_2Et)$ (**8**), is formed. However, it was not possible to isolate it, since a fast reaction with EDA (to give diethyl maleate) occurs. We propose that the carbene group should be bridging between the cobalt and a pyrrole nitrogen atom, rather than being terminally bound only to cobalt, because related cobalt(III) complexes display this bonding mode,[20−22] and Tatsumi and Hoffmann's theoretical treatment of metalloporphyrin-carbene complexes[29] shows that an increase in the electron count on the metal stabilizes the bridging mode with respect to the terminal one. The bridging mode should thus be even more favorable for a cobalt(II) complex than for the cobalt(III) analogues. It should be noted that terminal cobalt(II) carbene complexes have been proposed as intermediates in cyclopropanation reactions catalyzed by cobalt Schiff base and dioximato ligands,[17−19] but these are different ligands and the formation of bridged complexes was apparently not taken into consideration.

The kinetic and reactivity data collected is not unequivocal in indicating the correct reaction mechanism. Given the observation of a transient carbene complex **8,** it is very tempting to point to this as the intermediate responsible for the production of both cyclopropane (by reaction with an olefin molecule) and diethyl maleate (by reaction with another EDA molecule). If this is the case, however, it is difficult to explain the bell-shaped dependence of the rate of cyclopropanation with the styrene concentration. The descending part of the curve may be due to competitive formation of a $Co^{II}(TPP)$(styrene) complex (**9**), inactive as catalyst, a mechanism for which there are precedents in related copper chemistry.[2a,30,31] In this case, however, explanation of the ascending part of the curve would require that the reaction between **8** and styrene proceed at a rate slower than, or at least comparable with, that of the formation of **8** itself. If this did not occur and the reaction between **8** and styrene were much faster than the formation of **8** from Co(TPP) and EDA, then the reaction rate should not depend on the styrene concentration and only the previously mentioned inhibiting effect should be observed. However, the assumption of a slow reaction between **8** and styrene contrasts with the failure to observe **8** in the presence of that olefin. We also tried to fit the kinetic data quantitatively to a model of this kind by a multivariate regression, but the results were inconsistent. In recent work in our laboratories[16] we have investigated the mechanism of the amination reaction of benzylic hydrocarbons by aryl azides. It turned out that the species responsible for the activation of the hydrocarbon is a reversibly formed complex in which the aryl azide is still coordinated as such, rather than a nitrene complex. By analogy, we can propose the mechanism shown in Scheme 2 for the cyclopropanation reaction.



Scheme 2

As shown in Scheme 2, the starting Co(TPP), which is in equilibrium with the catalytically inactive complex **9**, reacts with EDA to form the unstable intermediate **10**. This last complex can either react with the olefin to afford the cyclopropane derivative or lose dinitrogen to give the observed intermediate **8**. This is then responsible for the formation of diethyl maleate by reaction with an additional EDA molecule. The reaction with the olefin is much faster than the

loss of dinitrogen, and the formation of the maleate is unobservable in the presence of an excess of olefin. Both of these reactions regenerate the active Co(TPP). Alternatively, complex **8** can be oxidized to the catalytically inactive Co^{III}(TPP)(CHRR′) (**7**). The source of the "hydrogen radical" necessary to transform **8** into **7** is uncertain, but it may be connected with a decomposition reaction of EDA. Indeed, **7** is formed more easily when a larger amount of EDA is present. We recall that incomplete consumption of the diazoacetate is observed at EDA concentrations higher than 0.05 M. This appears to be related to the formation of the catalytically inactive **7**. In this scenario styrene can either promote the reaction, by trapping the reversibly formed **10**, or inhibit it, by coordinating to Co(TPP) to form **9**. Formation of the cyclopropane even by reaction between the carbene complex **8** and styrene cannot be excluded, but it should not be the only route for its production.

To derive a kinetic equation for the process in Scheme 2 we can make the following assumptions:

a) The steady state approximation can be applied to intermediate **10**.

b) Coordination and de-coordination of the olefin are fast in comparison with the overall reaction. We call $K_{eq} = k_1/k_{-1}$.

c) The total concentration of cobalt at the beginning of the reaction (where data have been determined) is essentially the sum of the concentrations of Co(TPP) and **9**: $[Co]_{tot} = [Co(TPP)] + [\mathbf{9}]$.

d) The process associated with k_4 is slow with respect to that associated with k_3, in agreement with the selectivity data, and so can be neglected.

Under these assumptions the following kinetic equation is derived:

$$-d[EDA]/dt = k_2k_3[Co]_{tot}[EDA][styrene]/(k_{-2} + k_3[styrene])(K_{eq}[styrene] + 1)$$

which is in qualitative agreement with the observed trends, although the number of parameters and the limited number of data points available did not allow a more quantitative fitting.

Although Scheme 2 justifies all of the observed data, we must admit that a quite different mechanism is also consistent with the kinetic data. In this new scenario the intermediate reacting with ethyl diazoacetate would be Co(TPP)(styrene), presumably in equilibrium with both Co(TPP) and an inactive diolefin complex Co(TPP)$(styrene)_2$. A similar mechanism has been shown to operate in the case of a rhodium(III) porphyrin catalyst.[13c,13d] In the case of our system, we view the alternative mechanism as less likely, since no data, either collected by us or reported in the literature, supports the formation of a Co^{II}(porphyrin) complex with two olefins.

X-ray Structure of Co^{III}(TPP)(CH_2CO_2Et) (7)

An ORTEP view of the Co^{III}(TPP)(CH_2CO_2Et) (**7**) molecule with the atom numbering used is shown in Figure 7. Selected interatomic distances and angles are reported in Table 2.

The complex consists of neutral molecules in which the trivalent cobalt atom is pentacoordinate through the four nitrogen atoms of the divalent TPP anion and one carbon atom of the -CH_2CO_2Et moiety, and displays a distorted square-pyramidal coordination geometry. The four nitrogen atoms are coplanar within ± 0.08 Å, and the cobalt atom is displaced from this plane 0.108(1) Å towards the axial −CH_2CO_2Et ligand. The average Co−N bond length is 1.957 Å, and is consistent with the range of nitrogen-cobalt bond lengths observed in five-coordinate organocobalt(III) com-

plexes (1.948−1.969 Å).[32] The porphyrin core shows significant displacements of the atoms from the mean plane of the 24-atom core. The pattern of displacements conforms to an idealized D_{2d} symmetry with the pseudo-twofold axes passing through the methine carbon atoms C(2), C(12) or C(7), C(17) and the pseudo-dihedral mirror planes passing through N(1), Co, N(3) and N(2), Co, N(4).

The Co−C bond is 2.013(4) Å. Tetrahedral geometry is maintained at C(21) with a Co−C(21)−C(22) angle of 110.0(3)°; a significant distortion with respect to the ideal trigonal geometry is observed at C(22), the carbonyl carbon atom [C(21)−C(22)−O(2) 112.6(3)°, C(21)−C(22)−O(1) 128.8(4)°, O(1)−C(22)−O(2) 118.6(4)°], but the four-atom moiety is planar and the plane also includes atom C(23). The conformation of the -CH_2CO_2Et axial appendage is such that the C(21)−C(22) bond almost projects onto the Co−N(1) bond. This orientation produces a C(21)−Co−N(1) angle [103.6(1)°] substantially larger than the other three C(21)-Co-N angles (see Table 2). A similar feature has also been observed in, for instance, (acetonyl)-Co(TPP).[33]

Experimental Section

General Procedures: Unless otherwise specified, all reactions and manipulations were performed under a N_2 atmosphere by use of standard Schlenk apparatus and magnetic stirring. Solvents were dried and distilled by standard procedures and stored under dinitrogen. TPP, *p*-ClTPP, *p*-MeOTPP[34] and their cobalt complexes[35] were synthesized by methods reported in the literature. All other starting materials, including Co(OEP), were commercial products and were used as received. Alkenes, EDA, EDAA, and EDM were purchased from Aldrich. MPhDA[36] was prepared as reported in the literature. Products **1**,[37] **2**,[38] **3**,[39] and **5**[40] have previously been reported in the literature and were characterized by comparison of their analytical data with those reported in the literature or obtained from independently synthesized samples. Gas chromatographic analyses were performed on a Dani 8610 capillary gas chromatograph equipped with a PS 255 column. Ri values (Ri = response factor, relative to naphthalene as an internal standard) were determined by the use of solutions of the compounds of known concentrations. GC-MS analyses were performed on a Shimadzu GCMS-5000 instrument. NMR spectra were recorded on a Bruker AC 300 FT machine (300 MHz) at room temp. IR spectra were recorded on a Bio Rad FTS-7 FT-IR spectrophotometer. Elemental analyses and mass spectra were recorded in the analytical laboratories of Milan University.

Catalytic Reactions

The olefin (6.31 mmol) was added under an inert atmosphere to a solution of the diazo compound (1.26 mmol) and cobalt porphyrin catalyst ($1.26 \cdot 10^{-3}$ mmol) in CH_2Cl_2 (10.0 mL). The solution was heated at reflux with magnetic stirring. The reaction was run to complete consumption of the diazo compound (TLC analysis). The solvent was evaporated in vacuo and the products were purified by flash chromatography on silica gel. The determination of the molar ratio of the two diastereoisomers was carried out by ^{1}H NMR spectroscopy.

Compound 4: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.45−7.22 (m, 10 H), 4.31 (q, *J* = 7.2 Hz, 2 H), 2.38 (s, 3 H), 2.21 (s, 1 H), 1.65 (s, 1 H), 1.24 (t, *J* = 7.2 Hz, 3 H)

Compound 6 *cis*: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.36−7.20 (m, 5 H), 4.19 (q, *J* = 7.2 Hz, 2 H), 2.40 (s, 3 H), 2.25 (s, 1 H), 1.60 (s, 1 H), 1.27 (s, 3 H), 1.24 (t, *J* = 7.2 Hz, 3 H)

Compound 6 *trans*: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.38−7.24 (m, 5 H), 4.02 (q, *J* = 7.2 Hz, 2 H), 2.37 (s, 3 H), 2.10 (s, 1 H), 1.81 (s, 1 H), 1.25 (s, 3 H), 1.21 (t, *J* = 7.2 Hz, 3 H)

Kinetic Measurements

Co(TPP), styrene, and EDA were introduced in that order, under N_2, into a Schlenk flask. The flask was capped with a rubber septum and immediately placed in an oil bath, preheated at 50 °C. The solution was stirred for one minute to dissolve all reagents and a 0.20 mL sample of the solution was withdrawn for IR analysis. The consumption of EDA was monitored by IR spectroscopy (ν_{N2} = 2108 cm^{-1}). The apparent kinetic constants were calculated

by use of the initial rate method. The data for different initial EDA concentrations were fitted to the equation $[EDA]_0 - [EDA]_t = k_{obs}\cdot t$, where $[EDA]_0$ and $[EDA]_t$ are the initial molar concentration of EDA and the molar concentration of EDA at the time t. The data for the series at different Co(TPP) or different styrene concentrations were fitted to the equation: $([EDA]_0 - [EDA]_t)/[EDA]_0 = k_{obs}\cdot t$.

i) Determination of the Kinetic Order with Respect to EDA: Co(TPP) (10.0 mg, $1.49\cdot10^{-2}$ mmol) was dissolved in benzene (30.0 mL) together with EDA (21 μL, 0.20 mmol) and styrene (0.430 mL, 3.75 mmol). The resulting red solution was heated at 50 °C. The consumption of EDA was monitored by recording an IR spectrum every 10 min ($k_{obsd.} = 1.90\cdot10^{-4}$ M min^{-1}). The same reaction was repeated three more times with three different amounts of EDA [a) 50 μL, 0.48 mmol, $k_{obsd.} = 2.30\cdot10^{-4}$ M min^{-1}; b) 90 μL, 0.86 mmol, $k_{obsd.} = 4.28\cdot10^{-4}$ M min^{-1}; c) 128 μL, 1.22 mmol, $k_{obsd.} = 6.29\cdot10^{-4}$ M min^{-1}].

ii) Determination of the Kinetic Order with Respect to Co(TPP): Co(TPP) (15.0 mg, $2.23\cdot10^{-2}$ mmol) was dissolved in benzene (30.0 mL) together with EDA (157 μL, 1.49 mmol) and styrene (0.430 mL, 3.75 mmol). The resulting red solution was heated at 50 °C. The consumption of EDA was monitored by recording an IR spectrum every 10 min ($k_{obsd.} = 2.62\cdot10^{-2}$ min^{-1}). The same reaction was repeated three more times with three different amounts of Co(TPP) [a) 13.0 mg, $1.94\cdot10^{-2}$ mmol, $k_{obsd.} = 1.85\cdot10^{-2}$ min^{-1}; b) 10.0 mg, $1.49\cdot10^{-2}$ mmol, $k_{obsd.} = 1.49\cdot10^{-2}$ min^{-1}; c) 7.0 mg, $1.0\cdot10^{-2}$ mmol, $k_{obsd.} = 0.76\cdot10^{-2}$ min^{-1}].

iii) Determination of the Kinetic Order with Respect to Styrene: Co(TPP) (10.0 mg, $1.49\cdot10^{-2}$ mmol) was dissolved in benzene (30.0 mL) together with EDA (157 μL, 1.49 mmol) and styrene (0.172 mL, 1.50 mmol). The resulting red solution was heated to 50 °C. The consumption of EDA was monitored by recording an IR spectrum every 10 min ($k_{obsd.} = 1.02\cdot10^{-2}$ min^{-1}). The same reaction was repeated four more times with four different amounts of styrene [a) 0.260 mL, 2.25 mmol, $k_{obsd.} = 1.31\cdot10^{-2}$ min^{-1}; b) 0.430 mL, 3.75 mmol, $k_{obsd.} = 1.49\cdot10^{-2}$ min^{-1}; c) 0.520 mL, 4.54 mmol, $k_{obsd.} = 1.44\cdot10^{-2}$ min^{-1}; d) 0.680 mL, 5.94 mmol, $k_{obsd.} = 0.88\cdot10^{-2}$ min^{-1}].

Typical Procedure for the ^{1}H NMR Analysis of the Reaction Progress: Co(TPP) (3.1 mg, $4.6\cdot10^{-3}$ mmol) was dissolved in C_6D_6 (0.75 mL) in an NMR tube. The substrates were added and the solution was then heated to 50 °C inside the probe. An NMR spectrum was recorded every five minutes.

i) EDA (4.7 μL, $4.5\cdot10^{-2}$ mmol) was added to a C_6D_6 solution of Co(TPP), and an NMR spectrum was immediately recorded, showing the presence of diethyl maleate (δ = 5.83 ppm, s 2 H, -*CH*=*CH*-). Styrene (26 μL, $2.3\cdot10^{-1}$ mmol) was then added to the mixture and the reaction was run to complete consumption of EDA. The progress of the reaction has already been described in the results and discussion section.

ii) Styrene (26 μL, $2.3\cdot10^{-1}$ mmol) was added to a C_6D_6 solution of Co(TPP), and an NMR spectrum was immediately recorded. No new peaks were detected, nor was any shift of those of Co(TPP) and styrene. EDA (4.70 μL, $4.47\cdot10^{-2}$ mmol) was then added to the mixture and the reaction was run to complete consumption of EDA. The progress of the reaction has already been described in the results and discussion section.

Stoichiometric Reaction between Co(TPP) and EDA

i) IR Analysis: Co(TPP) (10.0 mg, $1.49\ 10^{-2}$ mmol) and EDA (4.7 μL, $4.5\ 10^{-2}$ mmol) were dissolved in benzene (5 mL) at room temperature. The solution was heated at 50 °C and the consumption of EDA was monitored by recording an IR spectrum every 5 min. The progress of the reaction has already been described in the results and discussion section.

ii) ^{1}H NMR Analysis: Co(TPP) (3.2 mg, $4.8\ 10^{-3}$ mmol) was dissolved in C_6D_6 (0.75 mL) with CH_2Cl_2 (6.0 μL) as an internal standard. EDA (2.5 μL, $2.4\ 10^{-2}$ mmol) was then added to the mixture. The solution was heated at 50 °C and an NMR spectrum was recorded every 5 min. The progress of the reaction has already been described in the results and discussion section.

Preparation of Co^{III}(TPP)(CH_2CO_2Et) (7): EDA (15.7 μL, $1.49\cdot10^{-1}$ mmol) was added under an inert atmosphere to a solution of Co(TPP) (100 mg, $1.49\cdot10^{-1}$ mmol) in CH_2Cl_2 (15.0 mL). The resulting red solution was stirred for 12 h at room temperature, by which time EDA had been completely consumed. The solution was evaporated to dryness under vacuum and the crude product was purified by chromatography on silica gel with CH_2Cl_2/*n*-hexane = 4:6 as eluent (68 mg, 60% yield). The analytical data (^{1}H NMR, IR, elemental analysis) are in agreement with the data reported in the literature.[22] Crystals suitable for X-ray analysis were obtained by crystallization from CH_2Cl_2/*n*-hexane.

X-ray Structure Determination of Co^{III}(TPP)(CH_2CO_2Et) (7): Crystal data: $C_{48}H_{35}CoN_4O_2$, f.w. 758.73, monoclinic, space group $P2_1/c$ (no. 14), $a = 13.098(1)$, $b = 24.840(3)$, $c = 12.552(1)$ Å, β = 116.11(1) °, $Z = 4$, $d_{calc} = 1.374$ Mg·m^{-3}, μ = 5.156 cm^{-1}, $F(000)$ 1576. A crystal sample of dimensions 0.14 × 0.15 × 0.25 mm, obtained by diffusion of *n*-hexane into a CH_2Cl_2 solution of the complex, was mounted on a glass fiber in air at room temperature on a Siemens SMART CCD area-detector diffractometer. Graphite monochromatized Mo-K_α radiation (λ = 0.71073 Å) was used, with the generator working at 50 *k*V and 35 mA. 31789 intensity data were measured in the full sphere (ω scan method) with sample-detector fixed at 5 cm, of which 6648 were independent; 2100 frames (20 s per frame, Δω = 0.3°) were collected and the first 100 frames were recollected for monitoring of crystal decay, which was not observed. An absorption correction was applied by use of the SADABS routine.[41] Transmission factors are in the 0.84−1.00 range. The structure was solved by direct methods (SIR, 97)[42] and refined with full-matrix, least- squares (SHELX93)[43] on the basis of 3113 independent reflections with $I > 2\sigma(I)$; $R = 0.036$, $R_{all} = 0.072$. Anisotropic displacement parameters were assigned to all non-hydrogen atoms. Hydrogens were riding on their carbon atoms. CCDC-190083 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Phosphorus-Selenium Heterocycles from the Tetraphospholane $(PhP)_4CH_2$

Petr Kilian,[a] Pravat Bhattacharyya,[a] Alexandra M. Z. Slawin,[a] and J. Derek Woollins*[a]

Keywords: Phosphanes / Heterocycles / Isomers / Phosphorus / Selenium

Two new heterocyclic and one acyclic species were prepared by reduction/deselenation of the five-membered heterocycle $PhP(Se)CH_2PhP(Se)Se_2$ (containing a $PCPSe_2$ ring sequence). Deselenation with Me_3SiCN led to the four-membered heterocycle $PhP(Se)CH_2PPh(Se)Se$ (containing a PCPSe ring sequence), whereas reaction with Bu_3P afforded the five-membered heterocycle $PhP(Se)CH_2PhP(Se)SePPh$ (ring sequence PCPSeP) and reduction with K metal afforded the dipotassium salt of methylene-bis(diselenophenylphosphinic) acid $[K_2(PhPSe_2)_2CH_2]$. The new compounds were characterised by a combination of NMR, MS and FT IR spectroscopic techniques; their structures were confirmed by single crystal X-ray analyses.

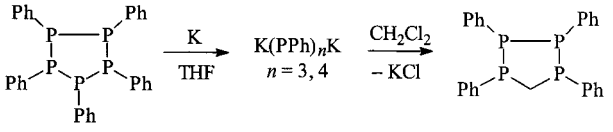
Introduction

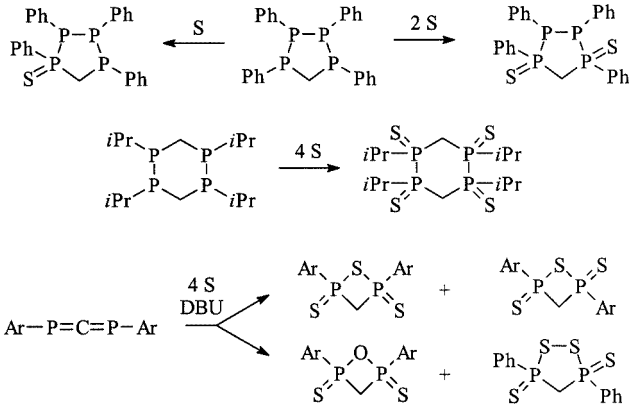
The chemistry of organophosphorus-sulfur and -selenium heterocycles is rich and varied.[1] The common ring sizes are four and five, although larger or smaller rings are not unusual.[2,3] The constitutional variability found in pseudo-binary heterocycles $(RP)_xE_y$ (R = organics, E = S, Se) can be explained by two factors: i) the ease with which their divalent building blocks can rearrange [illustrated, for example, by self-rearrangements of oligomeric $(RP)_5$, $(RP)_4$ and $(RP)_6$], and ii) an ability to form kinetically stable short "homoatomic" chains such as -S-S-, -Se-Se-Se- or, as mentioned above, $(RP)_n$. Cyclophosphanes $(RP)_n$ together with diphosphenes R-P=P-R are important precursors here. In particular, cyclophosphanes with aromatic substituents are frequently studied, due to their stabilizing (kinetic) effect against undesired oxidation or hydrolysis, and, in the case of very bulky organyl groups such as supermesityl, because of their ability to stabilize unusually low phosphorus coordination states.

The chemistry of cyclocarbaphosphanes $[(PR)_x(CR'_2)_y]$ with one or more RP units substituted by carbon functionalities seems to be much less developed than that of the parent cyclophosphanes. Cyclocarbaphosphanes are generally prepared from metallated oligophosphanes and geminal dichloro compounds[4] (Scheme 1); in a similar manner they are also obtained as relatively stable by-products during the synthesis of bifunctional phosphane ligands.[5,6]

Other methods employing Me_3Si-(tBuP)$_4$-$SiMe_3$ [7] or $(i\text{PrPCl})_2CH_2$ [8] have also been reported. Reports on reactions of cyclocarbaphosphanes and related systems with sulfur are scarce (Scheme 2); no report on reactions with selenium was found in the literature.



Scheme 1. Synthetically useful route to cyclocarbaphosphanes



Scheme 2. Reported reactions of carbacyclophosphanes and related systems with sulfur;[9–11] DBU is 1,8-diazabicyclo[5,4,0]undec-7-ene

The results summarised in Scheme 2 show that, unlike the homo-cyclophosphanes $(PR)_x$,[12] the addition of S to $(RP)_x(CH_2)_y$ does not proceed with cleavage of any P–P bond. On the other hand, the treatment of $(PPh)_5$ with vari-

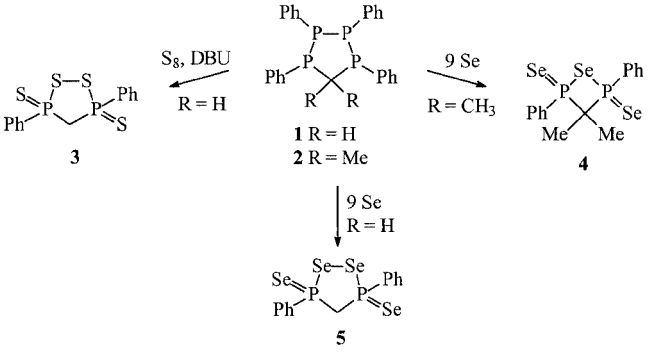
E-mail: jdw3@st-andrews.ac.uk

ous ratios of grey Se commonly leads to ring rupture and reorganization.[13] Obviously no rules of thumb have been laid down concerning the product structures obtained with varying ratios of $(RP)_n$ or $(RP)_x(CR'_2)_y$ to S/Se, or the effect of the electronic structure of R and R′, thus it seemed interesting to study these − to some extent unpredictable − systems.

We have reported reactions of $(PPh)_4CR_2$ (R = H, Me) with excess sulfur and selenium in a previous communication (Scheme 3).[14]

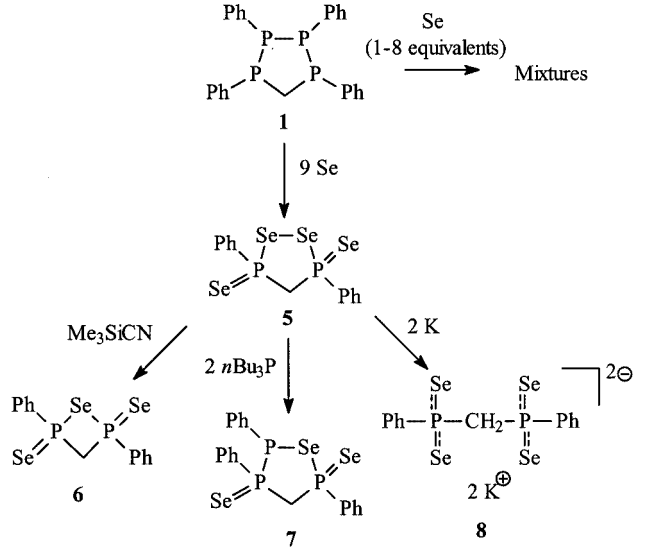


Scheme 3. Heterocycles from $(PPh)_4CR_2$ (R = H, Me)[14]

Herein we report a series of new species obtained by reductive ring-rearrangements of diselenadiphospholane (**5**); as in the case of the products shown in Scheme 3, the P−C−P motif is retained throughout the transformation to the new heterocycles as well as an acyclic dianion.

Results and Discussion

Application of a common strategy − oxidation of tetraphospholane **1** with various ratios of elemental selenium − led in all but one of the ratios studied to complicated mixtures. Attempts to separate these mixtures by flash chromatography on dried silica or alumina as well as by size-exclusion chromatography resulted in poor separation and oxidation/hydrolysis of separated species with deposition of red selenium. The only exception, where a single product was obtained, was the reaction of **1** with an excess of selenium, from which diselenadiphospholane (**5**) was obtained in very good yield and purity without the need for chromatographic separation.[14] This led us to test another tactic for the preparation of products with a lower Se/P ratio; as a starting material heterocycle **5** was used and it was treated with various reducing/deselenating agents such as Ph_3P, nBu_3P, Me_3SiCN and potassium metal. This afforded two new heterocyclic species **6** and **7** and the new dianion **8** (Scheme 4).



Scheme 4. New P−Se compounds obtained from tetraphospholane **1**

PSePC Heterocycle 6

The ^{31}P NMR spectra of crude reaction mixtures of **1** with seven or eight equivalents of Se indicated that two compounds are present in the solution after heating the two components in toluene. Compound **5** was identified as a major product [singlet with ^{77}Se satellites (2 × AXX′ pattern), δ_P = 43 ppm; ^1J (PSe_{exo}) = 775, ^3J (PSe_{exo}) = 11, ^1J (PSe_{endo}) = 342, ^2J (PSe_{endo}) = 13, ^2J (PP) = 34 Hz], whilst the pattern of the ^{77}Se satellites of a minor singlet at δ_P = −4.1 ppm suggests that the second compound is a four-membered heterocycle **6**. As attempts to separate it from the reaction mixture were unsuccessful, the abstraction of Se from **5** with Ph_3P, nBu_3P or Me_3SiCN was tested. ^{31}P NMR spectroscopy indicated that rather complicated mixtures resulted, although a substantial amount of the four-membered heterocycle **6** was present in the mixtures after the reaction with between one and two equivalents of a reducing agent. Me_3SiCN proved to be the reagent of choice, as the by-product, $Me_3SiCNSe$, is easily removable in vacuo (b.p. 65 °C/20 Torr). However, even after refluxing of **5** with two equivalents of Me_3SiCN in toluene, a small amount of starting material **5** was still present in the mixture, together with the product of further deselenation (vide infra). Attempts to separate the components of the mixture by flash chromatography were unsuccessful. The purification of **6** by recrystallisation was complicated by its similar solubility to **5**, as well as its instability in the solution (substantial decomposition to **5** and further unidentified products was observed when a solution of pure **6** in $CDCl_3$ or toluene was kept for one day at ambient temperature). The ease of self-reorganization of **6** in solution is surprising considering the stability of the dimethyl congener **4**, which was obtained as a sole product by the reaction of **2** with an excess of selenium.[14]

However, a small amount of the pure yellow solid **6** was obtained by repeated crystallisation of the crude product from CH_2Cl_2 and toluene; it was characterised by ^{31}P, ^1H and ^{13}C NMR and IR spectroscopy and EI-MS, the purity was assessed by elemental analysis. The small amount of compound available did not allow its characterisation by ^{77}Se NMR spectroscopy.

The $^{31}P\{^1H\}$ NMR spectrum of **6** (in $CDCl_3$) consists of a singlet (δ_P = −4.1 ppm) with two sets of ^{77}Se satellites,

arising from two distinct isotopomers with one ^{77}Se atom in the *exo*- or *endo*-position of the ring. These two sets are A_2X (Se_{endo}) and AA′X (Se_{exo}) systems (A, A′ = ^{31}P, X = ^{77}Se), the simulation of the latter subspectra allowed the determination of $^1J_{P,P}$ (26 Hz). The magnitudes of $J_{P,Se}$ are as expected (see Exp. Sect.). The ^1H NMR spectrum of **6** consists of the signals of Ph protons and a triplet due to the CH_2 group with $^2J_{H,P}$ = 12.0 Hz, which collapses into a singlet in the $^1H\{^{31}P\}$ spectrum. The $^{13}C\{^1H\}$ NMR spectrum also confirmed the identity of **6**, although the weak signal of the *ipso* carbon was not identified with certainty due to the small amount of sample available. The endocyclic carbon gave a triplet at δ_C = 63.7 ppm with $^1J_{C,P}$ = 32.8 Hz, a similar low magnitude of $^1J_{C,P^v}$ of 27.3 Hz was observed in heterocycle **5**.[14]

Crystallographic analysis (Figure 1, Table 1 and 5) confirms the formation of a four-membered PCPSe heterocycle with a *trans*-geometry of the exocyclic phenyl and seleno substituents. Two independent molecules with approximately the same geometry are present in the asymmetric unit of **6** (Table 1). In both molecules the positions of atoms Se13 and CH_2 group are partially disordered. Each independent molecule possesses only approximate C_2 symmetry, with the C_2 axis passing through the C14 and Se13 atoms. The central four-membered ring is very slightly folded (1.4 and 2.3° along the Se···C diagonal). Despite the symmetric substitution pattern, the geometries at P1 and P2 are slightly different, probably as a result of packing effects.

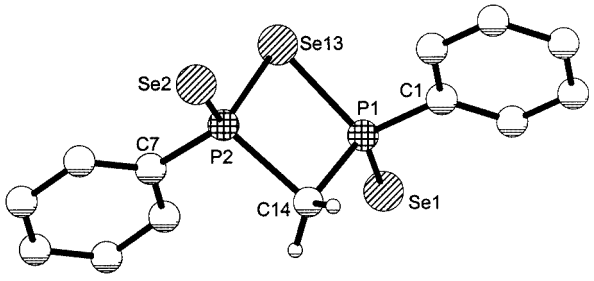


Figure 1. Structure of one of the two independent molecules present in unit cell of **6**; phenyl H atoms are omitted for clarity; the positions of the Se13 atom and CH_2 group are partially disordered

We have published the first structural characterisation of a PCPSe ring (compound **4**) in a recent communication.[14] In contrast to **6**, the presence of two methyl groups bonded to the ring carbon atom in **4** causes significant folding of the heterocycle (17 and 28° along the Se···C diagonal for each of the two molecules in the unit cell). The flattening of the central ring in **6** results in significantly reduced PCP angles in both independent molecules [87.8(2) and 83.3(3)°] with respect to the value found in **4** [96.9(3)°] and, as expected, also to the value found in the five-membered PCPSeSe ring of **5** [116.7(4)°].[14] The terminal Se atoms and the phenyl ring carbon atoms fit an approximate plane, which is nearly perpendicular to the central PCPSe heterocycle.

In summary, an interesting difference in the reactivity of **1** and **2** was observed. Whilst **1** (CH_2 derivative) reacts with a slight excess of selenium in boiling toluene to give the five-membered ring **5** and the formation of only a small amount of the four-membered ring product **6** was observed, compound **2** (CMe_2 derivative), under identical conditions, gives exclusively the four-membered ring product **4**.[14] Furthermore, a spontaneous reorganization of pure **6** in the solution, leading to **5** and unidentified products, was observed. On steric grounds we would predict that **2** should be more likely to give large rings than **1**. We observed the opposite effect and have to conclude that the electronic factors are more significant here. The electron-donating Me groups in **2** appear to favour smaller ring formation.

P_3CSe Heterocycle (Four Diastereomers 7a-d)

The reaction of **5** with two to three equivalents of nBu_3P or Ph_3P resulted in rather complicated mixtures as shown by $^{31}P\{^1H\}$ NMR spectroscopy. nBu_3P proved to be better suited for the synthetic purposes as the by-product nBu_3PSe is easily removed by washing the oily residue remaining after evaporation of solvent with warm acetonitrile; the separation of Ph_3PSe is not as straightforward. The solid remaining after extraction with acetonitrile was recrystallised from a small amount of toluene, giving a yellow crystalline material. An X-ray analysis was performed at this stage, showing that the product is the toluene-solvated five-membered P_3CSe heterocycle **7a** (Figure 2; a single diastereomer formed from a racemic mixture of its two enantiomers).

The uniformity of shape of the crystals suggested initially that they all consist of one diastereomeric form (**7a**), however the $^{31}P\{^1H\}$ NMR spectrum measured shortly after dissolving the crystalline material was rather complex, although at 121.4 MHz all signals are of first order and are nonfluxional. Following the analysis of spin-spin coupling systems and a P-P COSY experiment the signals were assigned to four distinct diastereomeric forms **7a**−**7d** (Scheme 5), in agreement with the presence of three centres of chirality per molecule (P atoms). The relative amount of isomers changes slightly with time after dissolving in

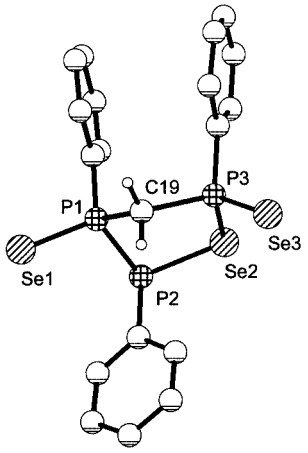

Figure 2. Molecular structure of **7a** (single diastereomer) in the crystal; toluene solvate molecule (0.25 per molecule) and phenyl H atoms are omitted for clarity

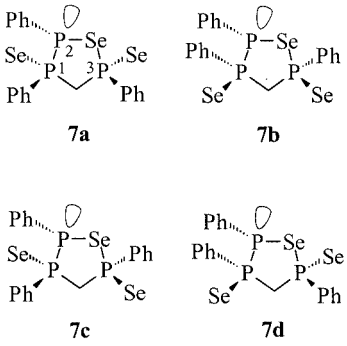

Scheme 5. Structural formulae and numbering of diastereomers **7a**−**7d**

$CDCl_3$, and the equilibrium ratio of 24:26:40:10 was established after several days at ambient temperature. A tentative mechanism explaining the observed inversion of configuration at the P-centres takes into account the fact that a detectable amount of **6** (^{31}P NMR) is always present in the solution as an impurity, even after dissolving crystalline material. We suppose that the change of configuration at the chiral P-centres may involve a ring contraction reaction of the five-membered ring **7a**−**d** to the four-membered ring **6**. The change of configuration may occur during reinsertion of the "PPh" group.

A tentative assignment of the ^{31}P NMR spectroscopic data to the distinct isomers was performed as shown in Table 2 and Scheme 5. Two assumptions were made: (i) that the least abundant isomer in solution possesses the configuration with all Ph substituents positioned in one direction with regard to the central heterocycle (all-*cis*, **7b**); and (ii) that the most abundant isomer in solution will have the least sterically hindered configuration **7c**. This corresponds to the fact that the intensity of signal assigned to **7c** increases steadily with time after preparation of sample until it reaches the major intensity shown above. To assign the remaining two isomers, the most configuration-sensitive chemical shift of P2 was considered. The higher-field P2 signal probably corresponds to isomer **7d**, with a *cis* configuration of Ph groups on atoms P1 and P2 (the same relative configuration as in isomer **7b**).

As expected, the ^1H NMR spectrum (300 MHz) of the mixture of **7a**−**7d** is very complex, and apart from the Ph signals and toluene protons a complicated multiplet ranging from δ = 3.0 to 4.5 ppm arising from CH_2 protons was observed. Employing ^{31}P broadband decoupling of the ^1H NMR spectrum offered partial simplification of the very complex overlapping signals of CH_2 groups from different diastereomers, although an analysis of the coupling constants was still not possible. Nor did measurement of H-P HMQC and H-H COSY experiments allow assignment of these signals to the individual diastereomers. No attempts were made to measure the ^{13}C and ^{77}Se NMR spectra due to the expected complexity.

A molecular ion was observed in the MS spectrum of the mixture of **7a**−**d** using ESI- ionization, whilst pronounced fragmentation was observed in EI+ and CI+ (ionizing gas NH_3) modes, the highest abundant fragments having *m*/*z* values 452 (EI) and 453 (CI).

The solid consisting of **7a**−**d** was further characterised by IR spectroscopy and its purity was assessed by microanalysis.

Crystallographic analysis of **7a** (0.25 toluene solvate, Figure 2, Table 3 and 5) reveals that the central P_3CSe heterocycle in **7a** adopts an envelope conformation with atom P1 lying 0.86 Å out of the plane defined by the other ring atoms (mean deviation of this plane is 0.04 Å), which results in dihedral angles P3−Se2−P2−P1 [19.3(1)°] and Se2−P3−C19−P1 [34.2(1)°]. The bond lengths within the central heterocycle are as expected, although the geometries at P1 and P3 including the inner P−C bond lengths differ slightly as a result of the asymmetry in the molecule. The P−C−P angle in **7a** [109.4(4)°] is slightly lower than the corresponding value [116.6(8)°] found in parent molecule

Table 2. ^{31}P NMR (121.4 MHz, $CDCl_3$) chemical shifts (ppm) and magnitudes of coupling constants (Hz) for four diastereomers **7a**−**7d**; for numbering of atoms see Figure 2 and Scheme 5

Isomer	δ_{P1} [ppm]	δ_{P2} [ppm]	δ_{P3} [ppm]	$^1J_{P1,P2}$ [Hz]	$^2J_{P2,P3}$ [Hz]	$^2J_{P1,P3}$ [Hz]	Abundance[a] [%]

[a] Approximate relative equilibrium abundance in $CDCl_3$ solution.

1.[12] The phenyl substituents on the neighbouring P1 and P2 atoms alternate above and below the central ring (trans arrangement), all three Ph substituents occupy axial positions. Only two examples of heterocycles with a PPCPSe atomic sequence in cyclic arrangement have been reported previously.[16–18] The first example (**10**, Figure 3), prepared by insertion of Se into a cage phosphane does not offer many structural similarities due to its rigid cage structure.[16] The second known compound containing the PPCPSe ring sequence (**11**, Figure 3) was prepared by the action of carbon disulfide on the product of the reaction of lithium selenide (obtained from $LiHBEt_3$ and Se) with phenyl dichlorophosphane.[18] Interestingly, the substitution pattern as well as the configuration of substituents in **11** is nearly identical to those in **7a** – the P atoms directly bonded to the C atom bear exocyclic Se atoms and the configuration of Ph substituents on two neighbouring P atoms is *trans*. Furthermore, the central heterocycle in **11** adopts an envelope shape, the out-of-plane P atom being the one corresponding to P1 in **7a**. There are differences in the ring conformation in **11** and **7a** though, as the carbon ring atom is formally double bonded in **11** (and there is substantial delocalisation of π-character over all three P–C bonds) to the P atom of the central heterocycle. Thus the dihedral angles corresponding to P3–Se2–P2–P1 and Se2–P3–C19–P1 in **7a** are 30.2 and 8.4 in **11**.

Dipotassium Salt 8

The reaction of **5** with two equivalents of potassium metal did not proceed with elimination of potassium selenide as expected, instead a quantitative formation of the dipotassium salt of methylene-bis(diselenophenylphosphinic) acid (**8**) was observed. The colourless solid **8**, isolated by filtration, is surprisingly stable towards water, however on contact with air it slowly decomposes with deposition of red selenium. Recrystallisation of **8** from THF gives crystals of the 0.5THF solvate, as indicated by ^1H NMR spectroscopy. After prolonged drying in vacuo at room temperature partial desolvation took place, as shown by microanalysis data, indicating that the composition changed slightly to give **8** 0.4THF. Compound **8** was fully characterised by ^{31}P, ^1H, ^{13}C and ^{77}Se NMR, IR, ESI-MS (including accurate mass measurement), microanalysis as well as by X-ray crystallography.

The $^{31}P\{^1H\}$ NMR spectrum of **8** in D_2O consists of a singlet (δ_P = 10.7 ppm) with a symmetric set of ^{77}Se satellites. Their analysis allowed determination of magnitudes of $^2J_{P,P}$ (34 Hz), $^1J_{P,Se}$ (588 Hz) and $^3J_{P,Se}$ (2 Hz). The magnitude of $^1J_{PSe}$ was reconfirmed also by measurement of the $^{77}Se\{^1H\}$ NMR spectrum (d, δ_{Se} = 49.9 ppm). The pattern of the ^{31}P and ^{77}Se NMR spectra, together with the magnitudes of $J_{P,Se}$ – lying between the usual values for single and double bonded selenium – clearly indicate that delocalization of the negative charge in the molecule occurs, as shown in the structural formula in Scheme 4. Further, simulation of the C_i second order signal in the $^{13}C\{^1H\}$ NMR spectrum of **8** confirmed the magnitude of $^2J_{P,P}$ (34 Hz); the signal due to the CH_2 group appears in the $^{13}C\{^1H\}$ NMR spectrum as a triplet with $^1J_{C,P}$ = 20 Hz. Dianion **8** represents the first example of the acyclic $Se_2P–C–PSe_2$ moiety; no sulfur analogue is known.

Crystallographic analysis of **8** confirmed the ring-opening reaction of **5** leading to the formation of the potassium salt of the acyclic dianion (Figure 4, Table 4 and 5). Crystals for analysis were grown from acetonitrile, from which compound **8** crystallises as **8**·0.75 MeCN; the position of one of the phenyl substituents is disordered as shown in Figure 4, the angle between Ph planes in the two alternating positions being ca. 45°. Despite the symmetric substitution pattern of the anion, no approximate symmetry element can be found in its structure in the crystal. The low symmetry results mainly from the mutual synclinal configuration of the two P environments, which is adopted by the dianion in order to decrease the steric strain resulting from facing negatively charged bulky Se atoms (the shortest intramolecular Se···Se distance is 3.94 Å). As expected, the P–C–P angle is broader in acyclic **8** [124.4(3)°] than in the parent ring system **5** [116.7(4)°][14] and neutral acyclic $Ph_2P(Se)CH_2P(Se)Ph_2$ [117.9(6)°].[19] The delocalization of the negative charge and π-character in the P–Se bonds was mentioned in the NMR discussion, in the crystal this phenomenon results in the P–Se bond lengths in **8** [2.143(2)–2.165(2) Å] being intermediate between the typical single- and double-bonded P-Se distances [usual distinct values of 2.10 Å (P=Se) and 2.25 Å (P–Se) were found in **5**]. The anion and the K^+ cations interact with the Se atoms with K···Se distances in the range 3.29–3.54 Å; the nitrogen atom of the acetonitrile solvate molecules coordinate to K^+ cations.

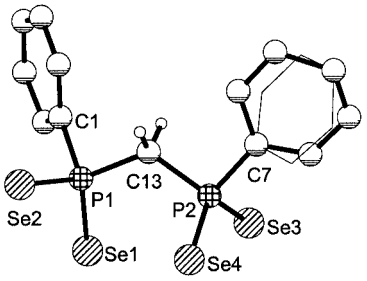

Figure 4. Structure of dianion **8** in the crystal; countercations $2K^+$, acetonitrile solvate molecule (0.75 molecule per dianion) and phenyl H atoms are omitted for clarity; the Ph ring bonded to P2 is disordered, in half of the molecules being in positions as shown in the picture, position in a second half of molecules is indicated by thin lines

Conclusion

Two new heterocyclic and one acyclic compound with rare structural motifs are reported. In all the products described the P−C−P moiety is preserved. The ^{31}P NMR spectra of the mixtures after heating of $(PhP)_4CH_2$ (**1**) with various ratios of Se indicated that further P−Se heterocycles may exist, however the complexity of mixtures and tendency to reorganization (observed in reported heterocycles **6** and **7a**−**d**) may complicate significantly their isolation in a pure form.

Experimental Section

General Remarks: Compound **1** was prepared from $(PPh)_5$ as described earlier.[4] Compound **5** was prepared by the reaction of **1** with an excess of grey selenium, followed by recrystallisation from hot toluene.[14] All manipulations (unless stated otherwise) were performed under a dry, oxygen-free nitrogen atmosphere using standard Schlenk technique. Solvents and other reagents were dried by standard methods. In vacuo refers to a pressure of ca. 13 Pa. NMR spectra were recorded on Varian Gemini 2000 (300 MHz), Varian Unity (500 MHz) and Bruker Avance (300 MHz) spectrometers and are referred to 85% H_3PO_4 (external reference for ^{31}P) or TMS or deuterated solvent peaks (^1H and ^{13}C). Infrared spectra were recorded as KBr discs.

P_2SeC Heterocycle (4): Me_3SiCN (0.24 mL, 1.80 mmol) and a suspension of **5** (0.50 g, 0.92 mmol) in toluene (10 mL) were heated under reflux for 2 hours. The solvent and volatile by-products were evaporated in vacuo with slight heating. The resulting solid was recrystallised from 3 mL of CH_2Cl_2 and then from hot toluene (2 mL). Further recrystallisations were sometimes needed to obtain product free from starting material **2**. Crystals suitable for an X-ray diffraction study were obtained from dichloromethane. Yield 39 mg (9%). $C_{13}H_{12}P_2Se_3$ (467.1): calcd. C 33.4, H 2.6; found C 33.7, H 2.3. M.p. 183−185 °C. IR (KBr): $\tilde{\nu}$ = 1434vs, 1088vs, 747s, 711s, 563m [ν(P=Se)], 499vs cm^{-1}. ^1H NMR ($CDCl_3$) (300.0 MHz): δ = 5.25 (t, $^2J_{H,P}$ = 12.0 Hz, 2 H, CH_2), 7.60−7.68 (m, 6 H, *m*- and *p*-Ph), 8.50−8.60 (m, 4 H, *o*-Ph) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz): δ = 63.7 (t, $^1J_{C,P}$ = 32.8 Hz, CH_2), 129.1 (m, *m*-C), 132.6 (m, *o*-C), 133.2 (s, *p*-C) ppm; the small amount of sample available did not allow identification of the *ipso*-C signal. $^{31}P\{^1H\}$ NMR (121.4 MHz): δ = −4.1 (s) ppm; analysis of the ^{77}Se satellites showed $^2J_{P,P}$ = 26, $^1J_{P,Se_{exo}}$ = 810, $^1J_{P,Se_{endo}}$ = 221, $^3J_{P,Se_{exo}}$ = 7 Hz. MS (EI+): *m*/*z* = 470 [M^+], 390 [M − Se], 310 [M − 2Se].

P_3CSe Heterocycle (7a): nBu_3P (1.07 mL, 4.29 mmol) was added with stirring to an externally cooled (0 °C) suspension of **5** (1.00 g, 1.83 mmol) in toluene (20 mL). The mixture was kept at 0 °C for 30 min, then it was left to warm to room temperature and stirred for another 12 hours, followed by filtration and evaporation of the solvents from the filtrate in vacuo. The resulting oil was washed with *n*-hexane (15 mL) and with warm acetonitrile (2 × 10 mL) to remove the nBu_3PSe. The solid obtained was recrystallised from hot toluene (4 mL). Yield 0.23 g (30%) of **7a**−**d** (mixture of diastereomers, each containing approximately half a molecule of toluene) in the form of yellow crystals, some of which were suitable for X-ray analysis. The following analytical and spectroscopic data were obtained from the mixture of four diastereomeric forms **7a**−**d**: $C_{19}H_{17}P_3Se_3 \cdot 1/2C_7H_8$: calcd. C 43.5, H 3.4; found C 43.1, H 3.0. M.p. 143−145 °C. IR (KBr): $\tilde{\nu}$ = 1434s, 1101s, 736vs, 683vs, 567s [ν(P=Se)], 524vs cm^{-1}. ^1H NMR ($CDCl_3$, 300 MHz): δ = 2.25 (s, ≈1.5 H, CH_3 toluene), 4.5−3.0 (set of multiplets, 2 H, CH_2), 8.5−6.9 (set of multiplets, ≈17.5 H, 3.5×Ph) ppm. $^{31}P\{^1H\}$ NMR: see text and Table 2. MS (ESI−): *m*/*z* = 577 [M − H; correct isotopic pattern], 499 [M − Se + 1], 469 [M − P − Se], 299 [PhP_2Se_2, base peak].

Potassium salt (8): Potassium metal (0.07 g, 1.84 mmol) was added to a stirred suspension of **5** (0.50 g, 0.92 mmol) in THF (7 mL). The stirring was continued for 48 hours after which time a white solid precipitated and was filtered off using a sintered glass frit. The product obtained after drying in vacuo was of sufficient purity (assessed by ^{31}P NMR spectroscopy), however it can be recrystallised from cold THF. Yield 540 mg (ca. 85%, before recrystallisation) of 0.5 THF solvated **8** in the form of a colourless solid. Compound **8** is hygroscopic, it is soluble in THF, acetonitrile and water, and decomposes with deposition of red selenium on contact with air. Crystals suitable for X-ray work were obtained from acetonitrile as **8** 0.75MeCN solvate. The following analytical and spectroscopic data were obtained with **8** in the form of its 0.4THF solvate: $C_{13}H_{12}K_2P_2Se_4 \cdot 0.4C_4H_8O$: calcd. C 26.8, H 2.3; found C 26.8, H 2.1. Decomp. above 150 °C. IR (KBr): $\tilde{\nu}$ = 1434vs, 1091s, 738vs, 689s, 524vs, 482vs cm^{-1}. ^1H NMR (D_2O, 300 MHz): δ = 3.68 and 1.82 (2 × m, variable, THF), 4.33 [t, $^2J_{H,P}$ ≈ 11.5 Hz, 2 H, CH_2], 7.31−7.13 (2 × m, 6 H, *m*- and *p*-Ph), 7.79 (m, 4 H, *o*-Ph) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz): δ = 25.1 (s, THF), 54.8 [t, $^1J_{C,P}$ = 19.5 Hz, CH_2), 68.0 (s, THF), 127.8 [t (virtual), $^3J_{P,C}$ = 6.5 Hz, C_m], 130.6 (s, C_p), 131.5 [t (virtual), $^2J_{P,C}$ = 5.4 Hz, C_o], 136.8 [m (second order), $^1J_{P,C}$ = 62.0, $^3J_{P,C}$ < 2 Hz, C_i] ppm. $^{31}P\{^1H\}$ NMR (121.4 MHz): δ = 10.7 (s) ppm; analysis of ^{77}Se satellites showed $^2J_{P,P}$ = 34.0, $^1J_{P,Se}$ = 588, $^3J_{P,Se}$ = 2.0 Hz;

$^{77}Se\{^1H\}$ NMR (57.2 MHz): δ = 49.9 [d, $^1J_{P,Se}$ = 588 Hz] ppm. MS (ESI−): *m*/*z* = 587 [anion + K], 274 [(anion)$^{2-}$], both had correct isotopic pattern; accurate mass measurement on $^{12}C_{13}{}^1H_{12}{}^{39}K^{31}P_2{}^{77}Se_4$ requires 588.6712, found 588.6716 (error of 0.7 ppm).

Crystal Structure Analyses: Data for **6** and **7a** were collected at 293 K on a Bruker SMART CCD diffractometer; data for **8** were collected at the same temperature on a Rigaku Mercury CCD using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). Absorption corrections were performed on the basis of multiple equivalent reflections. The structures were solved by direct methods. Structural refinements were performed with the full-matrix least-squares method on F^2 using the program SHELXTL (Version 5.10, Bruker AXS, 1997). The non-hydrogen atoms were refined anisotropically, the hydrogen atoms were idealised and refined isotropically using a riding model. CCDC-19036 (**6**), -19037 (**7a**) and -19038 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows two views of $Ba_5Fe_4Ti_{10}O_{31}$ type structure. Barium atoms are shown as yellow spheres, iron tetrahedra are depicted in red, iron trigonal bipyramids in gold, and titanium octahedra in blue. On the left side is a full unit cell stack of 18 layers, on the right side, the unique 9-layer repeat unit is shown. Details are discussed in the Microreview by T. Siegrist and T. A. Vanderah on p. 1483 ff.

Combining Magnets and Dielectrics: Crystal Chemistry in the $BaO-Fe_2O_3-TiO_2$ System

Theo Siegrist*[a][‡] and Terrell A. Vanderah[b]

Keywords: Dielectric properties / Magnetic properties / Perovskite phases / Solid-state structures / Titanates / Ferrites

Phases observed in the $BaO–Fe_2O_3–TiO_2$ system are classified and described in terms of the framework of close-packed {O,Ba/O} layers, with the transition metal atoms either in octahedral (titanium and iron) or in tetrahedral (iron only) sites. The resulting crystal chemistry features new combinations of structural features intermediate between the magnetic barium hexaferrites and the dielectric barium polytitanates, and thus gives rise to phases with potentially useful magnetic/dielectric properties.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

1. Overview

The crystal chemistry in the $BaO-Fe_2O_3-TiO_2$ phase diagram is surprisingly rich. A recent study of the system found a large number of new phases,[1] with structures featuring moieties from both the polytitanates and hexaferrites, as well as new building blocks showing a mixture of features from both. The observed structural features organize the composition space into regions containing phases with common building units. These regions in the phase diagram, as indicated in Figure 1, include those featuring framework-type structures (e.g., hollandites, indicated in yellow), the perovskite derivatives and polytitanates (light blue), the hexaferrites (dark blue), and intermediate phases with new structural units (red). Magnetic multilayer compounds are in the violet/gray area. The areas are defined by bisecting existing tie lines and are a guide to the eye.

As can be seen, three distinct "structural end members" ($BaO-TiO_2$, $Fe_2O_3-TiO_2$, and $BaO-Fe_2O_3$) dominate along the binary subsystems. The framework-type structures such as hollandite dominate the lower left corner of

Theo Siegrist was born in Winterthur, Switzerland. He received his diploma in physics (Dipl.-Phys. ETH) from the Federal Institute of Technology (ETH) in Zürich in 1979. He then enrolled in the Ph.D. program at the Laboratory for Solid State Physics at ETH, working in the area of rhenium intermetallic compounds with F. Hulliger. He was awarded the Dr. sc. nat. in 1982. In 1983 he joined the group of F. Holtzberg at the IBM T. J. Watson Research Center as a postdoctoral fellow, working on thin films of semimagnetic semiconductors. In 1985 he became a research associate at the National Research Council of Canada in Ottawa, in the Solid State Chemistry department. There he investigated rare earth intermetallics and heavy fermion uranium compounds. He joined Bell Laboratories in New Jersey, USA in 1986, where he entered the field of high T_c superconductors based on copper oxides. He investigated the crystal chemistry of this new class of compounds and related phases. Further work was done on C_{60} and its compounds, various oxides, and intermetallic phases. From 1998 he spent two years as Professor of Solid State Chemistry at Lund University/Lund Institute of Technology, where he investigated new phases with mixed anion lattices. From 2000 he has once again been at Bell Labs, working on the structural characterization of organic electronic materials and on the crystal chemistry of new phases.

Terrell Vanderah received a B.S. in Chemistry from the University of Maryland in 1977 and a Ph.D. in Inorganic (Solid State) Chemistry from the University of Connecticut in 1985, with Prof. B. L. Chamberland. From 1985 to 1993 she worked as a research chemist at the Naval Weapons Center in China Lake, California, in the area of non-oxide optical ceramics and high-temperature superconductors. In 1994 she moved to the National Institute of Standards and Technology in Gaithersburg to become the group leader for Phase Equilibria. Her research interests include the solid-state chemistry and phase equilibria of oxide systems of electronic interest and the interrelationships of crystal structure, chemical composition, and properties.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

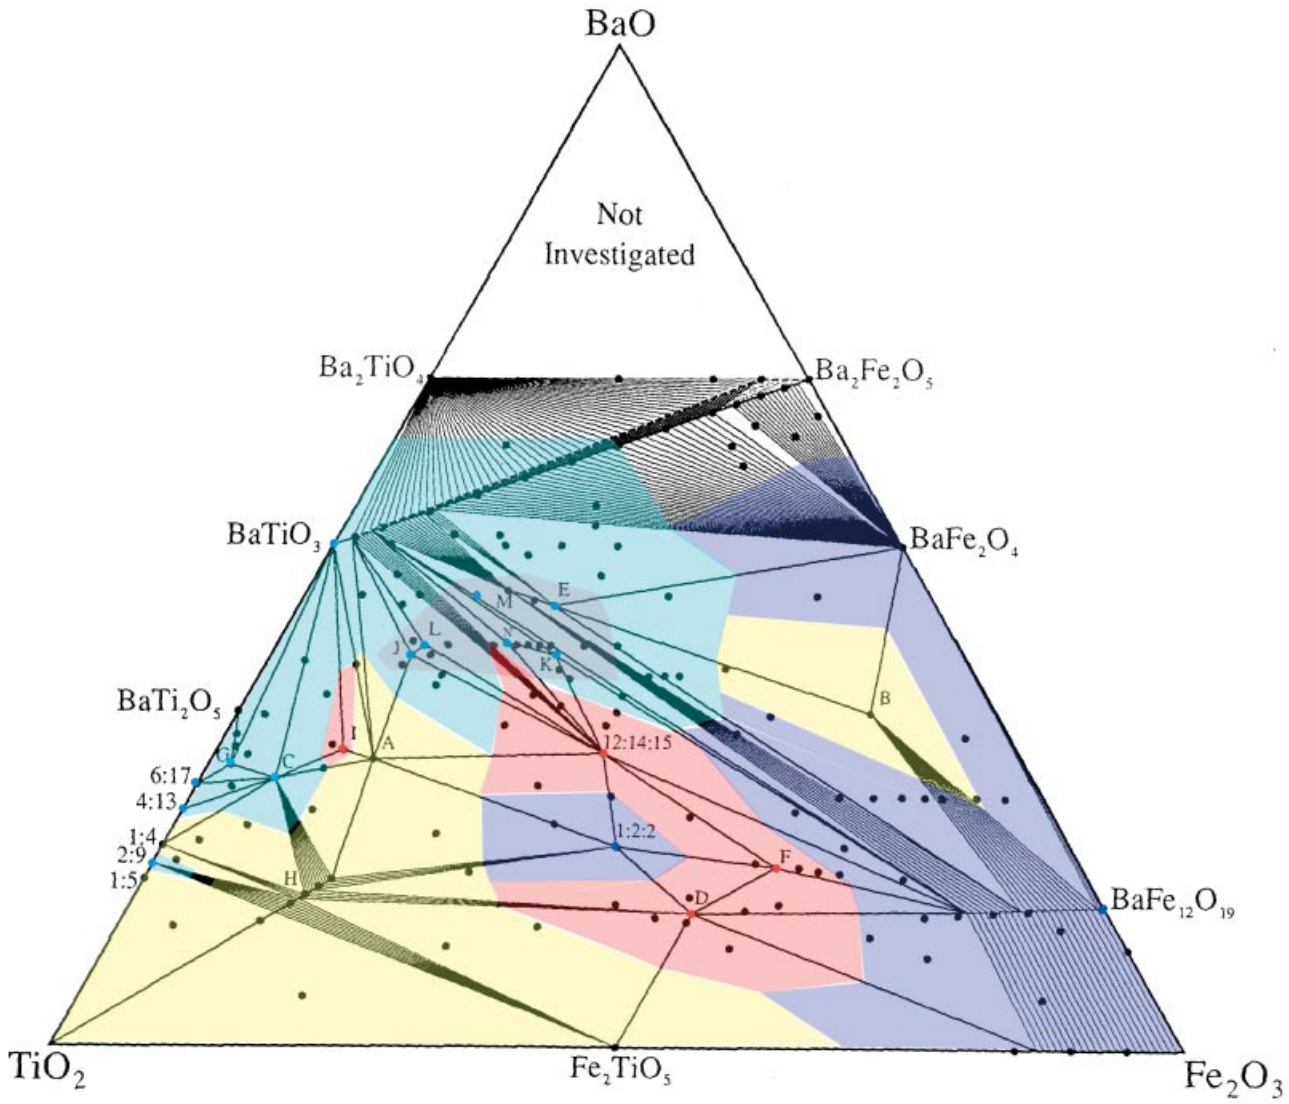

Figure 1. $BaO-Fe_2O_3-TiO_2$ phase diagram with regions of structurally related phases indicated in color; yellow: framework-type phases; light blue: hexagonal polytitanates; dark blue: hexaferrites; violet/gray: magnetic multilayer systems (based on hexagonal perovskite and hexaferrite); red: new "mixed" phases

the phase diagram nearest TiO_2. The other two structural "end members", the polytitanates/perovskites (Ti-rich side) and hexaferrites (Fe-rich side), both feature close-packed {O,Ba/O} layers and would therefore be expected to form numerous "blended" structures. Indeed, in the transition area indicated in red, the phases found are based on seven new types of close-packed {O,Ba/O} layers intermediate between the layers present in the hexaferrites and in the polytitanates. The stacking of the different layers gives rise to a variety of phases, extending from the iron-rich to the titanium-rich side. Phases in this region based on hexagonal $BaTiO_3$ with Fe ordering in distinct layers reveal superstructures with periodicities of around 100 Å. Disorder in stacking is often seen, but their structural features are similar to the other intermediate phases.

Phases indicated in violet/gray include blocks of hexagonal $BaTiO_3$ and often disordered layers mainly comprised of $BaO-Fe_2O_3$.[2] These phases are part of the red area of new structures.

The structural features observed in the $BaO-Fe_2O_3-TiO_2$ system are presented below, and some of the new phases found are discussed. The combination of high dielectric and ferri-/ferromagnetic systems produces potentially useful materials for microwave applications, such as nonreciprocal devices.[3,4] The dielectric properties of some of the phases are discussed in terms of the Clausius–Mosotti theory. Furthermore, the iron valence has to be stabilized at Fe^{3+} to ensure low microwave losses. The phases discussed below are based on Fe^{3+} and Ti^{4+}.

2. Background

High dielectric materials have been key in the miniaturization of microwave devices (i.e. high frequencies of the

order of 50 MHz to 22 GHz). Use of a dielectric material allows the size of a microwave device to be scaled by $\varepsilon^{-1/2}$. Requirements for materials used in microwave applications are a high dielectric constant and low microwave losses, together with a negligible temperature dependence of these properties. Materials in common use are based on mixtures of barium titanates, in which dielectric constants of the order of 28, together with small temperature dependencies, are observed. Furthermore, microwave losses can be reduced such that high-quality filters with Q of the order of 45k and higher can be realized. The loss mechanisms are often related to defects in the material; the presence of reduced titanium, Ti^{3+}, for instance, correlates with increased loss. Careful synthesis of the material to ensure fully oxidized titanium is key to performance.

The addition of a static magnetic field affects the propagation of the electromagnetic wave in such a material, allowing the construction of nonreciprocal devices such as isolators, phase shifters, circulators, etc. Such ceramic magnetic oxides are key components in a wide variety of electronic applications; communication systems, for instance, utilize coaxial circulators and isolators that contain ceramic magnets.[3,4] Materials in current use include spinels, garnets, and hexaferrites, the last of these based on the magnetoplumbite-type structure. Improved materials would exhibit higher dielectric constants and high saturation magnetization, while retaining low-loss behavior in the microwave region. In addition, a small or negligible temperature dependence of the dielectric and magnetic properties is highly desirable. For this reason, a thorough study of the phase equilibria in the $BaO-Fe_2O_3-TiO_2$ system was recently carried out.[1] In particular, combinations of the high dielectric materials based on polytitanates with magnetic Fe_2O_3 were of interest. Since the materials in use today are often based on mixtures of several different crystallographic phases, detailed knowledge of the phase diagram is key to understanding the processing of multicomponent materials with engineered properties. The interface of the barium hexaferrites with the barium polytitanates is discussed below, and the structural relationships emphasized.

The pseudo-binary systems have been examined previously, and corresponding phase diagrams were produced in "Phase Equilibria Diagrams" (formerly "Phase Diagrams for Ceramists"),[5] in Figures 1:208, 4:5130, 91:009, 1:213, 3:4302, 4:5135, 11:9211–13, 93:016, 12:10036, and references cited therein.

The crystal chemistries both of the barium polytitanates[6] and of the barium hexaferrites[7] have been extensively studied in the past. These systems are based on close-packed oxygen lattices, with barium atoms substituting for oxygen atoms while retaining the close-packed arrays. Titanium and iron atoms occupy interstitial sites. The resulting structures obey a metric determined by the close-packed lattice, usually based on a hexagonal unit cell, with layers approximately 2.35 Å thick and in-plane base hexagonal lattice parameters of the order of $a = b = 5.75$ Å. Ordering of the transition metal atoms in interstitial sites and of the barium atoms which are substituted for oxygen atoms often reduces symmetry from hexagonal or rhombohedral to orthorhombic or monoclinic, and correspondingly changes the in-plane lattice parameters. The similar unit cell metrics of the two systems allow the formation of mixed or "blended" phases that would be expected to contain structural motifs both from the polytitanates and from the hexaferrites, giving rise to new structures. Furthermore, new structural motifs combining features of both end systems may also occur.

Only one phase is stable in the pseudobinary $Fe_2O_3-TiO_2$ system: pseudobrookite-type Fe_2TiO_5. It may be regarded as a framework-type structure with edge-sharing octahedra only.

The barium polytitanates may be described as $(BaO)_m(TiO_2)_n$. Of the six phases stable above 1200 °C in the $BaO-TiO_2$ system, $Ba_2Ti_9O_{20}$,[8] $BaTi_4O_9$,[9] $Ba_4Ti_{13}O_{30}$,[10] $Ba_6Ti_{17}O_{40}$,[11] $BaTiO_3$,[12,13] and Ba_2TiO_4,[14] only the last is not based on a close-packed {O,Ba/O} layer system. It contains isolated TiO_4 tetrahedra, making it quite distinct in the series. The phase $Ba_2Ti_5O_{12}$ was found to be stabilized by small amounts of impurities, and is therefore not a true polytitanate.[15] The framework structure of $Ba_4Ti_{11}O_{26}$ is related to the mineral jeppite,[16] but with partial occupancy of titanium to achieve charge balance (also referred to as $Ba_2Ti_{5.5}O_{13}$).[17]

The barium hexaferrite system and spinels differ markedly from the polytitanates in that Fe occupies both octahedral and tetrahedral interstitial sites in the close-packed lattice. This results in sixfold octahedral and fourfold tetrahedral coordination, as well as fivefold trigonal-bipyramidal coordination in the case of the hexaferrites. This last form is obtained when two tetrahedral interstitial sites share a face. The occupying iron atom is usually shifted out of the basal plane into either one of the tetrahedral interstitial sites.

In the case of the hexaferrites, various superstructures based on hexagonal lattices with the *c* axis approaching 1000 Å have been reported.[18] Other phases in the $BaO-Fe_2O_3$ system may adopt structures that are not based on a close-packed lattice. $BaFe_2O_4$, for instance, adopts a "stuffed tridymite"-type structure,[19] while $Ba_2Fe_2O_5$ is reported to occur in a distorted perovskite-type superstructure.[20] $Ba_2Fe_6O_{11}$ may be regarded as intermediate between the tridymite-type structures and the close-packed structures, as a layer of edge-shared octahedra alternate with a partial stuffed tridymite-like framework of tetrahedra.[21]

The spinels and hexaferrites are used in nonreciprocal microwave devices. However, they have considerably lower dielectric constants than the barium polytitanates.

Combinations of the barium polytitanates and barium hexaferrites are of potential interest since they offer the possibility of high dielectric constants in a magnetic system. Depending on the concentration of Fe^{3+}, paramagnetic to ferri- or ferromagnetic systems would be expected. At low iron concentrations, good dielectric materials based on polytitanates, but with weak magnetism, would be likely. In contrast, a high iron concentration would be expected to

yield magnets, albeit with reduced dielectric constants. Superexchange, the prevalent magnetic interaction in insulating oxides,[22] produces antiferromagnetic spin alignments, reducing the overall possible magnetic moment of the material. Since the X-ray contrast between Fe and Ti is small, investigations studying the ordering of Fe and Ti may

need the use of synchrotron radiation tuned to the Fe or Ti absorption edge, or neutron diffraction experiments. High-resolution electron microscopy may also be utilized to study the ordering of Fe in such pseudo-quaternary phases.[23]

3. Structural Units

The structural motifs observed in the hexaferrites and the barium polytitanates are few, and so allow classification of the large variety of structures observed in these systems. Stacking sequences, on the other hand, may extend over many layers in one direction. Table 1 compiles the unit cell parameters and stacking sequences for various phases present in the $BaO-Fe_2O_3-TiO_2$ system. The structural motifs observed in the pseudobinary systems are briefly discussed here.

The following color scheme has been adopted for the representation of structures: barium atoms: green or yellow spheres; tetrahedral iron: red tetrahedron; pentagonal iron: gold bipyramid; octahedral iron: dark blue octahedron; octahedral titanium: light blue octahedron.

3.1. Spinel-Type Layers (S-Block)

The spinel-type structure of Fe_3O_4 is based on a close-packed oxygen lattice, with iron present in tetrahedral and octahedral interstitial sites. It should be noted that Fe_3O_4 is a mixed valent system, and so does not meet the criterion of Fe^{3+} ions only. However, since its structural features are prominent, it is described separately here. The layer stacking is $(c)_n$. There are two distinct layers: one with edge-sharing octahedra (sP1 layer), and the other with a 1:2 combination of octahedra and tetrahedra, connected through the corners (sP2 layer) (Figure 2). Three layers, stacked sP2−sP1−sP2, form an "S-block", of Fe_3O_4 stoichiometry with an average layer thickness of 2.33 Å.

3.2. Magnetoplumbite-Type Layers (R-, T-, and Q-Block)

Barium hexaferrite $BaFe_{12}O_{19}$, crystallizes in the magnetoplumbite-type structure,[7,24] containing spinel-type S- and R-blocks. The R-block incorporates pentagonal iron, found in a trigonal bipyramid sandwiched between spinel (sP1) layers. The position of the iron atom in the basal plane of the pyramid is unstable, resulting in displacements that move the iron atom into one of the oxygen tetrahedra in a random way. Two face-sharing FeO_6 octahedra and one barium atom complete the R-block unit. The close-packed oxygen lattice in the R-block has an $(h)_3$ stacking sequence, which gives an overall stacking sequence for the magnetoplumbite-type of $(hhhcc)_2$ (ten-layer structure) with an average layer thickness of 2.318 Å. The individual layers are shown in Figure 2. $BaFe_{12}O_{19}$ is also referred to as hexaferrite M, on the basis of phase diagram studies by Smit and Wijn.[25,7]

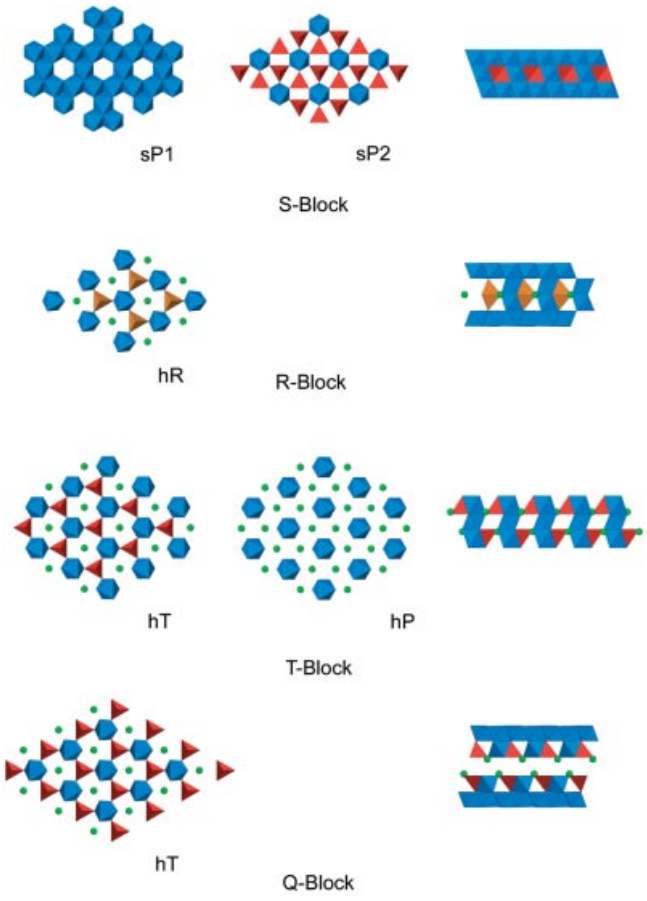

Figure 2. Close-packed layers found in spinel and hexaferrite phases; barium atoms are shown as green spheres, iron octahedra are indicated in dark blue, iron tetrahedra in red, and trigonal bipyramids in gold; the hexaferrites are made up of five different layers only

In hexaferrite Y, $Ba_2Fe_{14}O_{22}$ ($Ba_2Zn_2Fe_{12}O_{22}$),[25] a combination of S-blocks and T-blocks is observed. The T-blocks are made up of three close-packed layers (see Figure 2) containing columns of three face-sharing octahedra. The iron−iron distances in these columns are of the order of 2.84 Å, so iron atoms are moved out of their ideal positions. These iron−iron contacts allow only three face-sharing octahedra, since shifts in a fourth octahedron would be too large. The hT layer (Figure 2) may be regarded as a spinel sP2 layer in which all of the down-pointing tetrahedra have been removed, and a barium atom replaces the apical oxygen. The middle layer hP, containing Ba and octahedra only, is of the same type as observed in the cubic and hexagonal perovskite. The T-block may also be described as a modified R-block, in which the two tetrahedra forming the bipyramids are separated by a layer of octahedra, and are rotated by 60°.

The Q-block, found in iron and chromium ferrites, is related to the T-block in such a manner that the octahedral interstitial sites in the middle layer are not occupied (Figure 2).[26,27] A large number of hexaferrite phases can be described on the basis of the combinations of Q-, R-, S-, and T-blocks. Apart from $BaFe_{12}O_{19}$ (M),[28] for instance,

the hexaferrite phases $BaFe_{18}O_{27}$ (W), $Ba_2Fe_{14}O_{22}$ (Y), $Ba_3Fe_{26}O_{41}$ (Z), and $Ba_2Fe_{30}O_{46}$ (M_2S)[7] have been reported. With the exception of $BaFe_{12}O_{19}$, they show reduced iron valence, and are stabilized by the introduction of divalent atoms such as zinc, magnesium, or cobalt, or of mixtures such as Li^{1+}/Fe^{3+}. Some of these phases, with their stacking sequences and combinations of R-, S-, and T-blocks, are illustrated in Figure 3. For instance, $Ba_2Fe_{30}O_{46}$ is structurally a combination of $BaFe_{12}O_{19}$ and $BaFe_{18}O_{27}$, representing the M2S member, with block arrangement ($RSRS_2$).

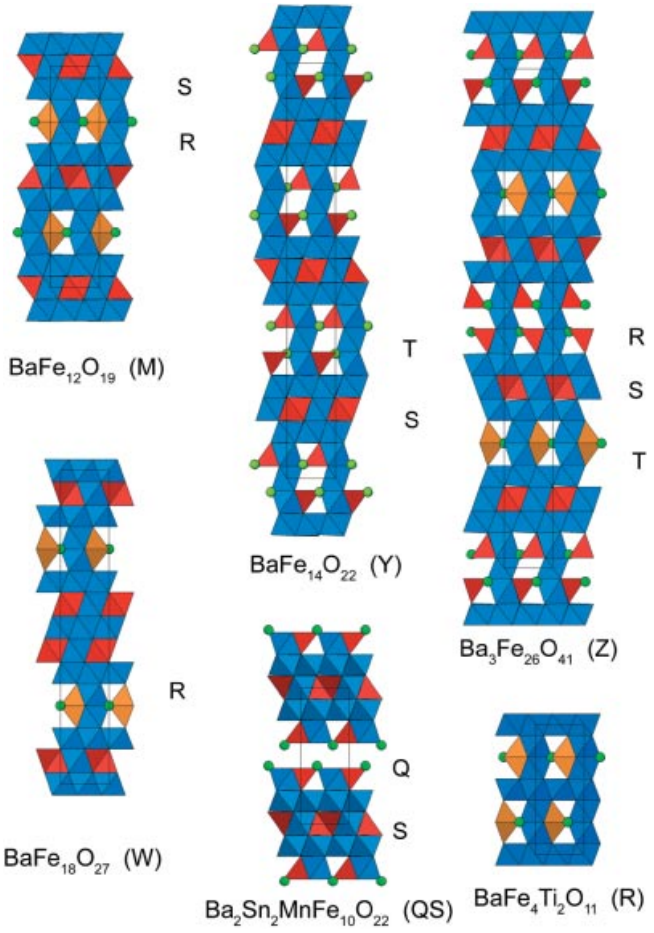

Figure 3. View of stacking sequences of hexaferrite phases M, W, Y, Z, and QS; barium atoms are shown as spheres, iron octahedra are indicated in blue, tetrahedra in red, and bipyramids in gold; hexaferrite building blocks shown in Figure 2 are indicated

The long-period superstructures observed may be described as stacking of different blocks in various ways, combinations, and periodicities.

3.3. Barium Polytitanates

The $BaO-TiO_2$ system contains a large number of phases, nearly all of which feature structures based on close-packed {O,Ba/O} lattices.[6] Mixed-valent barium titanate phases containing Ti^{3+}/Ti^{4+} mixtures have also been prepared and characterized; examples are the hollandite-type $Ba_2Ti_6O_{13}$[29] and the hexagonal 6L $Ba_2Ti_{13}O_{22}$.[22,30]

Only the cubic and hexagonal barium polytitanates are considered below, since these systems are based on close-packed {O,Ba/O} layers and tetravalent titanium in octahedral interstitials. Reduced titanium, Ti^{3+}, detrimentally affects the microwave properties. Barium titanate phases are compiled in Table 1.

The simplest structure present in the $BaO-TiO_2$ system is the well-known cubic perovskite $BaTiO_3$.[12] It may be regarded as a cubic stacking of close-packed layers with a thickness of 2.306 Å, a value expected to be close to the lower limit, since only corner-connected octahedra are present. Projection of the structure along one of the four close-packed stacking directions {111} shows the titanium octahedra well separated by barium atoms (Figure 4), and the same as the hP layer observed in the hexaferrite T-block.

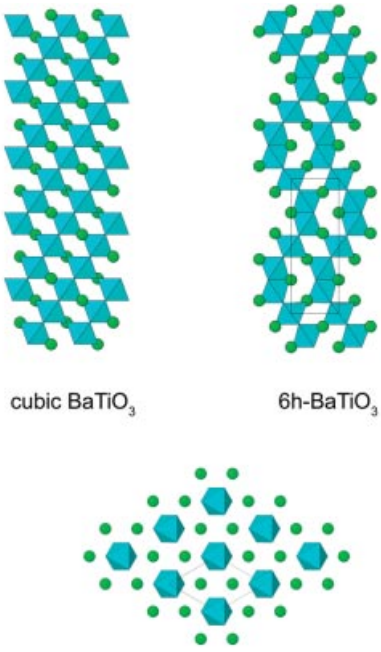

Figure 4. View of the stacking sequence for the cubic and hexagonal perovskite $BaTiO_3$; below is a depiction of a single perovskite layer, common to both structures; barium atoms are shown as green spheres, titanium octahedra are light blue, oxygen is found at the corners of the octahedra

The hexagonal 6H-$BaTiO_3$ structure[13,31] (Figure 4) has a stacking sequence $(cch)_2$ with an average layer thickness of 2.327 Å. It can be viewed as a cubic perovskite type, in which units of three layers are rotated by 180° and stacked on top of the previous layer, resulting in face-sharing titanium octahedra. The titanium−titanium distance in this double layer is increased from 2.327 to 2.69 Å, and so the metal atoms are moved away from the center of the octahedra. In general, face-sharing octahedra in titanates are observed in pairs, unlike in ruthenates, platinates, or nickelates, in which longer face-sharing chains of metal octahedra are found.[22] In an extended face-sharing arrangement, short Ti−Ti contacts of the order of 2.35 Å would be expected from the average layer thickness imposed by the oxygen−oxygen contacts, making such extended systems unstable.

The phases in the $BaO-TiO_2$ system may be written as $(BaO)_m(TiO_2)_n$, with $m = n = 1$ representing the simple $BaTiO_3$, with all tetravalent Ti. Alkaline earth rich titanates are not abundant, with Ba_2TiO_4 being the ($m = 2$, $n = 1$) phase, in which Ti is in tetrahedral coordination.[14] In contrast, a whole series of phases with ($m = 1$, $n = 2$, 4, 5, 6), ($m = 2$, $n = 5$, 9), ($m = 4$, $n = 11$, 13), and ($m = 6$, $n = 17$) have been reported and structurally characterized.[6] Most of these are based on close-packed {O,Ba/O} layers, with Ti in octahedral sites. The octahedra are connected through corners, edges, or faces, giving various stacking sequences. The framework structures of $BaTi_2O_5$, $BaTi_4O_9$, and $Ba_2Ti_{6-x}O_{13}$ (reduced) were discussed further by Tillmanns,[6] and are not considered further here.

Figure 5 shows the different close-packed layers found in $Ba_6Ti_{17}O_{40}$, $Ba_4Ti_{13}O_{30}$, $Ba_2Ti_9O_{20}$, $BaTi_5O_{11}$, and $BaTi_6O_{13}$.[6] The average layer thickness in these compounds is of the order of 2.34 Å. All these systems can be described in terms either of two or of three distinct topological layers. They combine edge- and corner-sharing octahedra only, without any face-sharing octahedra observed. The layers are often complementary in such a way that two or three layers cover an entire plane with octahedra by merging with shear, as for instance in $BaTi_6O_{13}$ and $BaTi_5O_{11}$, thus avoiding face-sharing octahedra.

It is interesting to note that $Ba_4Ti_{13}O_{30}$ [10] is the only phase in which the close-packed layers consist of discrete building blocks that do not form an extended unit. All the other phases have at least one close-packed layer with a one-dimensional chain-type building unit. The discrete building units within each plane are all of the same type; no combination of different units within a plane is observed for the polytitanates.

4. The $BaO-Fe_2O_3-TiO_2$ System

In contrast to the barium polytitanates, the barium hexaferrites show extended, two-dimensionally connected polyhedron arrays, generally resulting in higher symmetry structures. In combinations of the two systems, new types of intermediate structural building blocks would be expected. Indeed, exhaustive study of the $BaO-Fe_2O_3-TiO_2$ phase diagram revealed several new phases.[1] The nomenclature introduced in the phase diagram study is used below (Figure 1).

The five regions identified in the phase diagram are composed of: I. hollandites and framework structures (yellow); II. polytitanate-based systems (light blue); III. magnetic multilayer systems (blended hexagonal perovskite/hexaferrites(violet/gray); IV. hexaferrites and related phases, such as 1:2:2 (dark blue), and V. new family of mixed $BaO-Fe_2O_3-TiO_2$ phases (red).

4.1. Hollandites and Framework Structures (Yellow)

The systems based on framework-type structures are located near the titanium-rich corner of the phase diagram. The hollandite-type phases are in equilibrium with the framework-type phases 1:4 and A, the hexagonal systems 2:9, C and D, the pseudobrookite Fe_2TiO_5, and the hexaferrite-related 1:2:2.

4.2. Polytitanate-Based Systems (Light Blue)

The new phases C and G are in equilibrium with complex polytitanates, such as the phases 6:17 and 4:13, as well as with the cubic and hexagonal perovskites. Furthermore, phases C and G are in equilibrium with each other, which is reflected in the close structural relationship between them.

The layer stacking of phase C, $Ba_4Fe_2Ti_{10}O_{27}$,[32] and phase G,[33] $Ba_{11}Fe_2Ti_{26}O_{66}$,[34] is shown in Figure 6. The 8L structure of $Ba_4Fe_2Ti_{10}O_{27}$ is expanded into the 10L structure of $Ba_{11}Fe_2Ti_{26}O_{66}$ by repetition of the starting layer of every four-layer block. Phase G, $Ba_{11}Ti_{28}O_{66+x}$,[34] containing trivalent Fe, may be written as $Ba_{11}Fe_2Ti_{26}O_{66}$, but is likely to be intermediate, depending on preparation conditions such as oxygen partial pressure. It is easy to see that the close structural relationship of these two systems allows formation of intergrowths. Ordered superstructures based on the regular arrangement of blocks of four and five layers can produce a potentially large number of long-period superstructures. Further electron microscopy studies may reveal the presence of such ordered superstructures. In addition, both phases C and G introduce new close-packed layers in which, unlike in the pseudo-binary systems, two different building blocks are present within a layer. Isolated TiO_6 octahedra coexist with either Ti_5O_9 units or Ti_3O_{14} units.

4.3. Magnetic Super-Lattices (Blended Hexagonal Perovskites/Hexaferrites) (Violet/Gray)

The cubic and hexagonal perovskites $BaTiO_3$ are in equilibrium with the ternary phases A, C, E, G, I, J, K, L, M, N, and 12:14:15, as well as titanium-substituted barium hexaferrite. The new phases E, K, L, M, and N have previously been studied by high-resolution electron microscopy,[2] and further structural information is available for phases J and M. Alternating stacks of hexagonal perovskites and of layers preferentially occupied by Fe are common features in these phases. For instance, phase M, $Ba_{11}Fe_8Ti_9O_{41}$[35] (Figure 7), is a 26L structure with stacking sequence $[(cch)_3(ch)_2]$. As indicated, three hexagonal perovskite (*cch*) stacks alternate with four modified layers consisting of two octahedral layers and two spinel-related layers. All four of these modified layers preferentially contain Fe. Separated by nine hexagonal perovskite layers, this phase forms a natural magnetic super-lattice.[2,36] In the case of phase M, the magnetic layers are located around $z = 1/4$ and 3/4, spaced approximately 30.7 Å apart, with a hexagonal perovskite separation stack of the order of 21 Å in thickness. The iron-rich layers, however, show strong disorder. For instance, the layer containing tetrahedra, octahedra, and Ba may be described as an overlay of the hP and hT layers. The apparent densely packed layer of edge-sharing octahedra shows reduced metal occupancy, and may be regarded as a combination of spinel sP1 and hP layers.

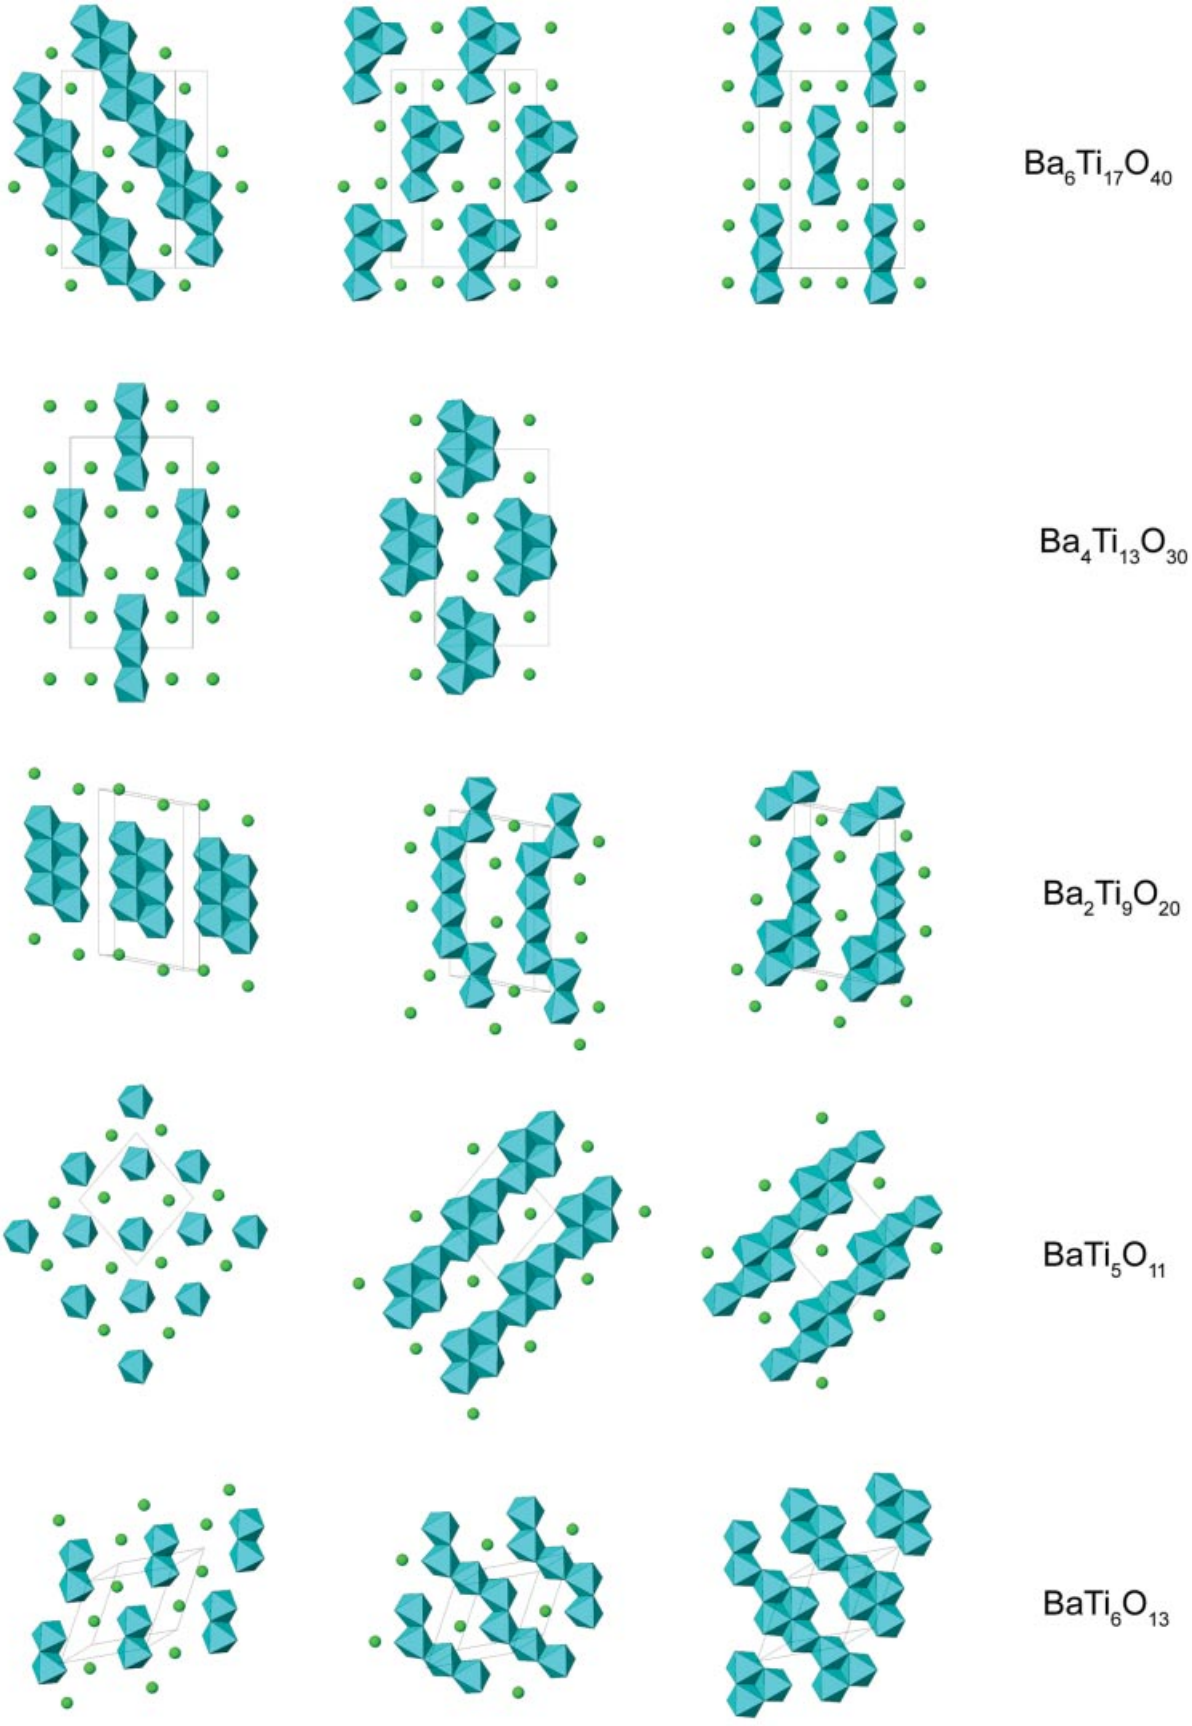

Figure 5. Compilation of the close-packed layers observed in hexagonal polytitanates; titanium octahedra are indicated in light blue and barium atoms are shown as green spheres; only $Ba_4Ti_{13}O_{30}$ has no extended building block

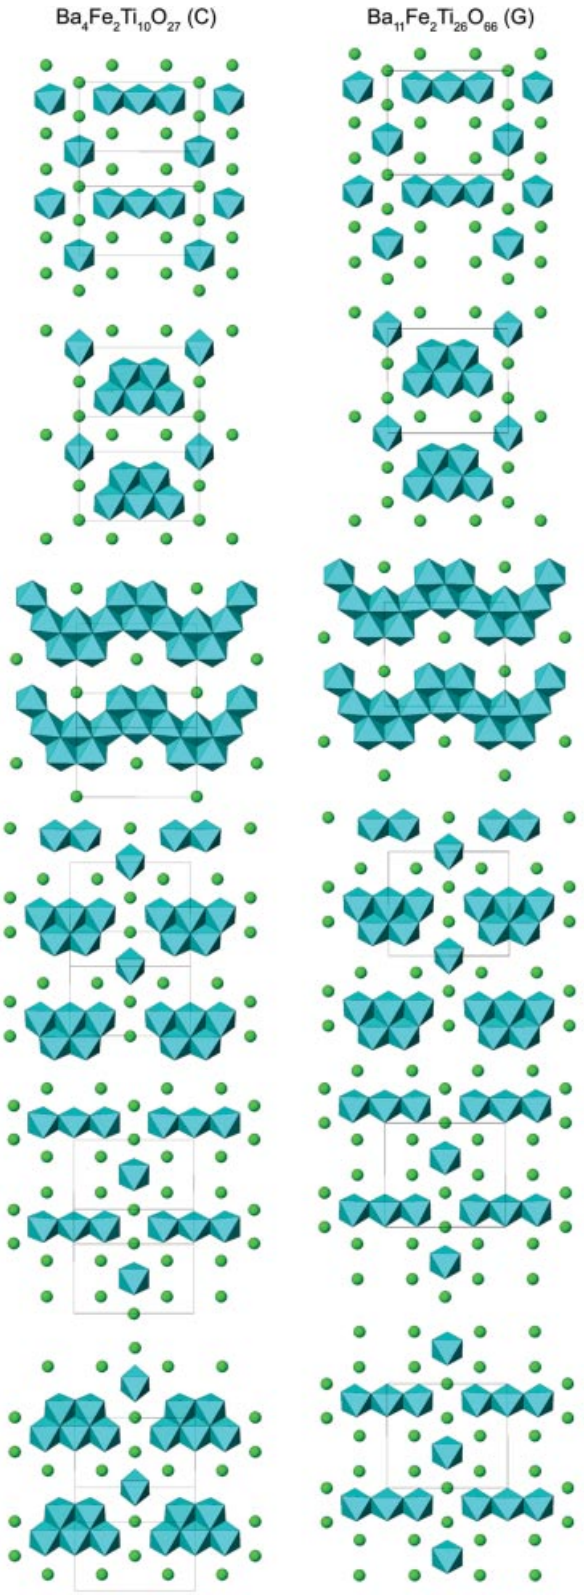

Figure 6. Close-packed layers of $Ba_4Fe_2Ti_{10}O_{27}$ (phase C) and $Ba_{11}Fe_2Ti_{26}O_{66}$ (phase G); the 8L structure of C is expanded into the 10L structure of G by repeating the starting layer in every four-block unit of phase C

Similarly, phase J (Figure 8), $Ba_{27}Fe_{16}Ti_{33}O_{117}$,[37] is based on the same building principle. It is a 54L structure with a $(cchcchhhhcchhhhcch)_3$ stacking sequence, previously described as an 18L monoclinic *C*-centered structure. Like phase M, it is a system with disorder and, to some extent, variable iron stoichiometry. As the stacking sequence indicates, the structure incorporates hexagonal perovskite (*cch*) blocks, alternating with iron-containing nine-layer blocks. Disorder similar to that in M, $Ba_{11}Fe_8Ti_9O_{41}$, is confined to those nine layers.[23,37] Furthermore, diffuse superstructure reflections observed in electron microscopy studies[2,36] indicate a possibly larger supercell.

While the structural characterization of phase E is not yet complete, preliminary investigations show that a hexagonal perovskite unit with a (*cch*) stacking sequence is again present, alternating with iron-containing layers. Furthermore, phases K, L, and N show similar building principles according to electron microscopy studies.[2] While the details of the structures need further elucidation, the overall building principle is well established, producing systems with magnetic iron blocks well separated by hexagonal perovskite blocks. These natural magnetic super-lattices may furthermore produce large supercells in which different blocks may be arranged in various ways. For instance, since J and L, as well as E and M, are in equilibrium, intergrowths are possible for these pairs of phases, giving rise to possible superstructures with *c* axes beyond 100 Å.

4.4. Hexaferrites and Related Phases (Dark Blue)

Phase 1:2:2, $BaFe_4Ti_2O_{11}$, is a hexaferrite-related system consisting of R-blocks only.[38] It is in equilibrium with phase 12:14:15, the framework-type phase A, the hollandites, and phases D and F. Interestingly, the magnetoplumbite $BaFe_{12}O_{19}$ is not in equilibrium with 1:2:2, despite the close structural relationship. Since the iron-only R-block $BaFe_6O_{11}$ has a net charge, the inclusion of two tetravalent titanium atoms renders the block neutral, resulting in the formation of phase 1:2:2. Similar stabilization might be expected from substitution of Zr^{4+} or Hf^{4+} for Fe.

Magnetoplumbite-type $BaFe_{12}O_{19}$ (hexaferrite M) has a solid solution range with TiO_2. It is in equilibrium with $BaFe_2O_4$, a hexagonal phase containing tetrahedral Fe only, Fe_2O_3, phases B, E, M, $Ba(Fe,Ti)O_3$, K, 12:14:15, D, and F. In Figure 1, the connection from the hexaferrites via the magnetic superlattice phases to the hexagonal perovskites is clearly seen. The large number of different types of hexaferrites, however, are not seen in the phase diagram since most of them require slightly reducing conditions upon preparation. The exception is phase 1:2:2, which is neutral. Intergrowths are to be expected on crystal chemical grounds, but are not observed in the phase diagram.

4.5. New Family of Ternary $BaO-Fe_2O_3-TiO_2$ Phases (Red)

New structures are found in the general transition-metal-rich part of the phase diagram, with an iron/titanium ratio ranging approximately from 4:1 to 1:2. These phases are characterized by the presence of fourfold tetrahedral and also fivefold bipyramidal Fe in new arrangements. The

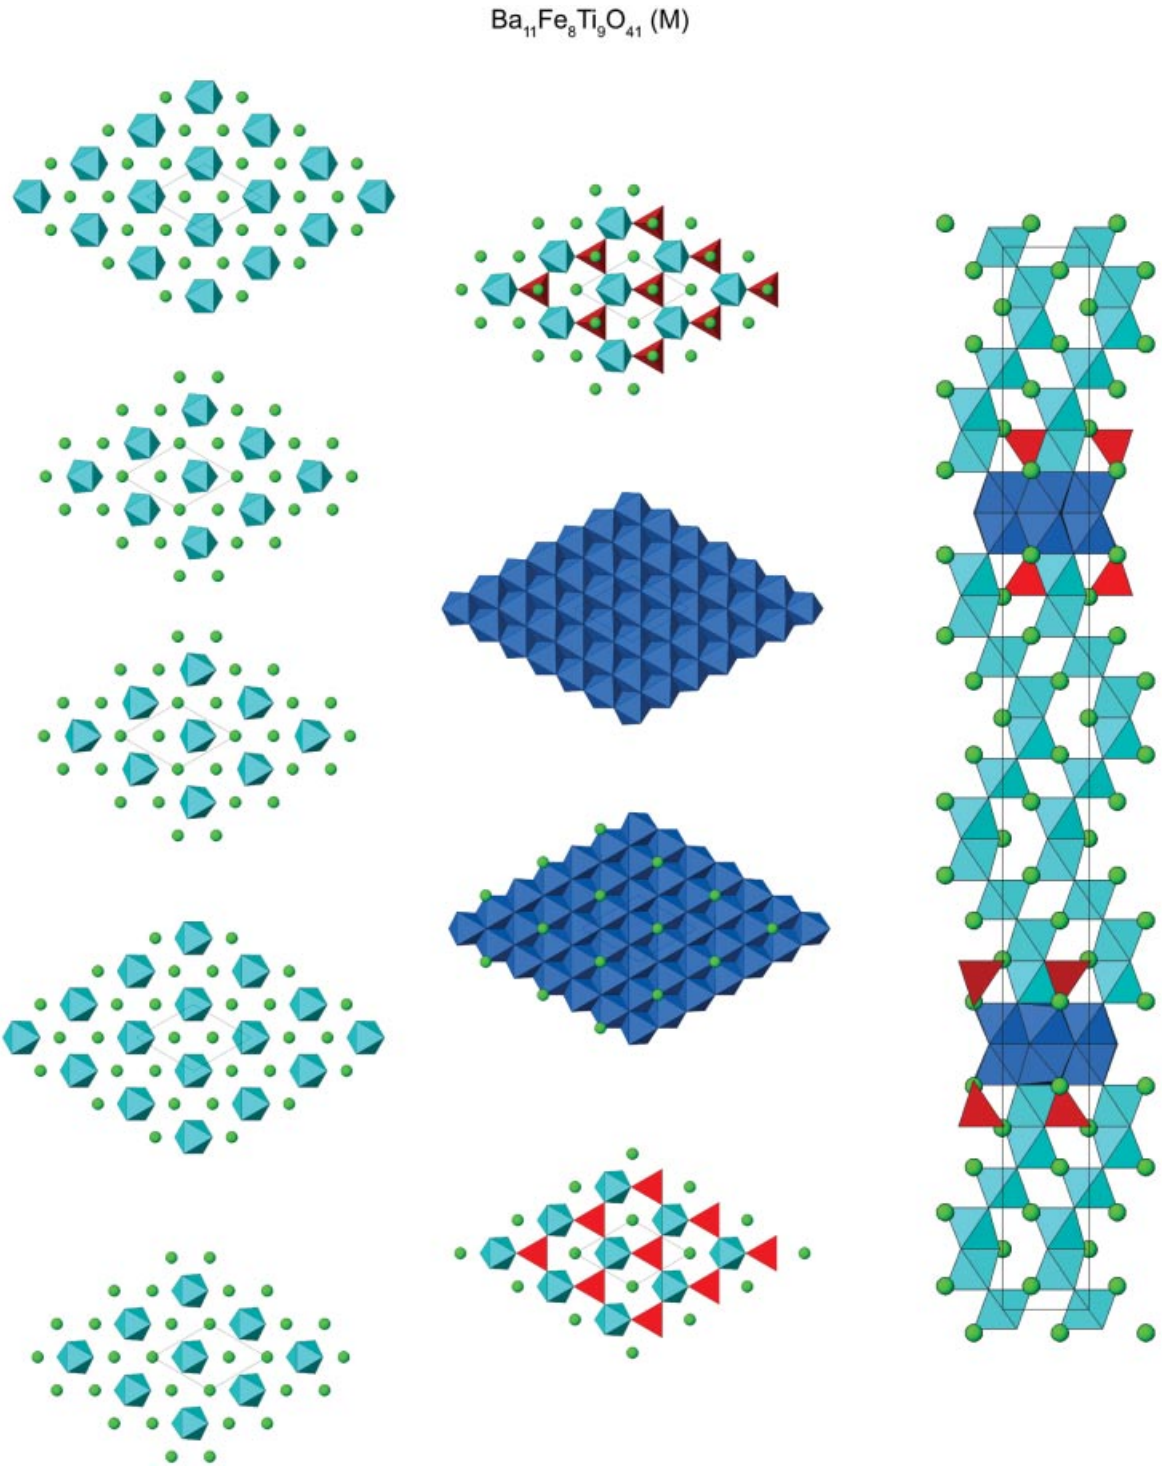

Figure 7. View of the close-packed layers and stacking arrangement of $Ba_{11}Fe_8Ti_9O_{41}$ (phase M), a 26L natural magnetic super-lattice in which iron-containing layers are separated by the hexagonal perovskite motif; disorder is confined to the iron-containing layers only, in which barium atoms randomly replace oxygen atoms; adjacent iron atoms show reduced occupancy corresponding to the barium occupancy factor

structural features show a strong relationship to spinel and magnetoplumbite. In the case of $Ba_{12}Fe_{28}Ti_{15}O_{84}$[39] there are five distinct layers, shown in Figure 9. There is a modified spinel-type layer (sP2) in which two tetrahedra are replaced by barium atoms (layer S1), and one in which five tetrahedra are replaced by barium atoms (layer S2). The latter may also be regarded as an hT layer in which two thirds of the tetrahedra have been removed. Layers containing octahedra only show symmetrical Ti_6O_{22} clusters made up of six edge-sharing octahedra (layer T1). Further,

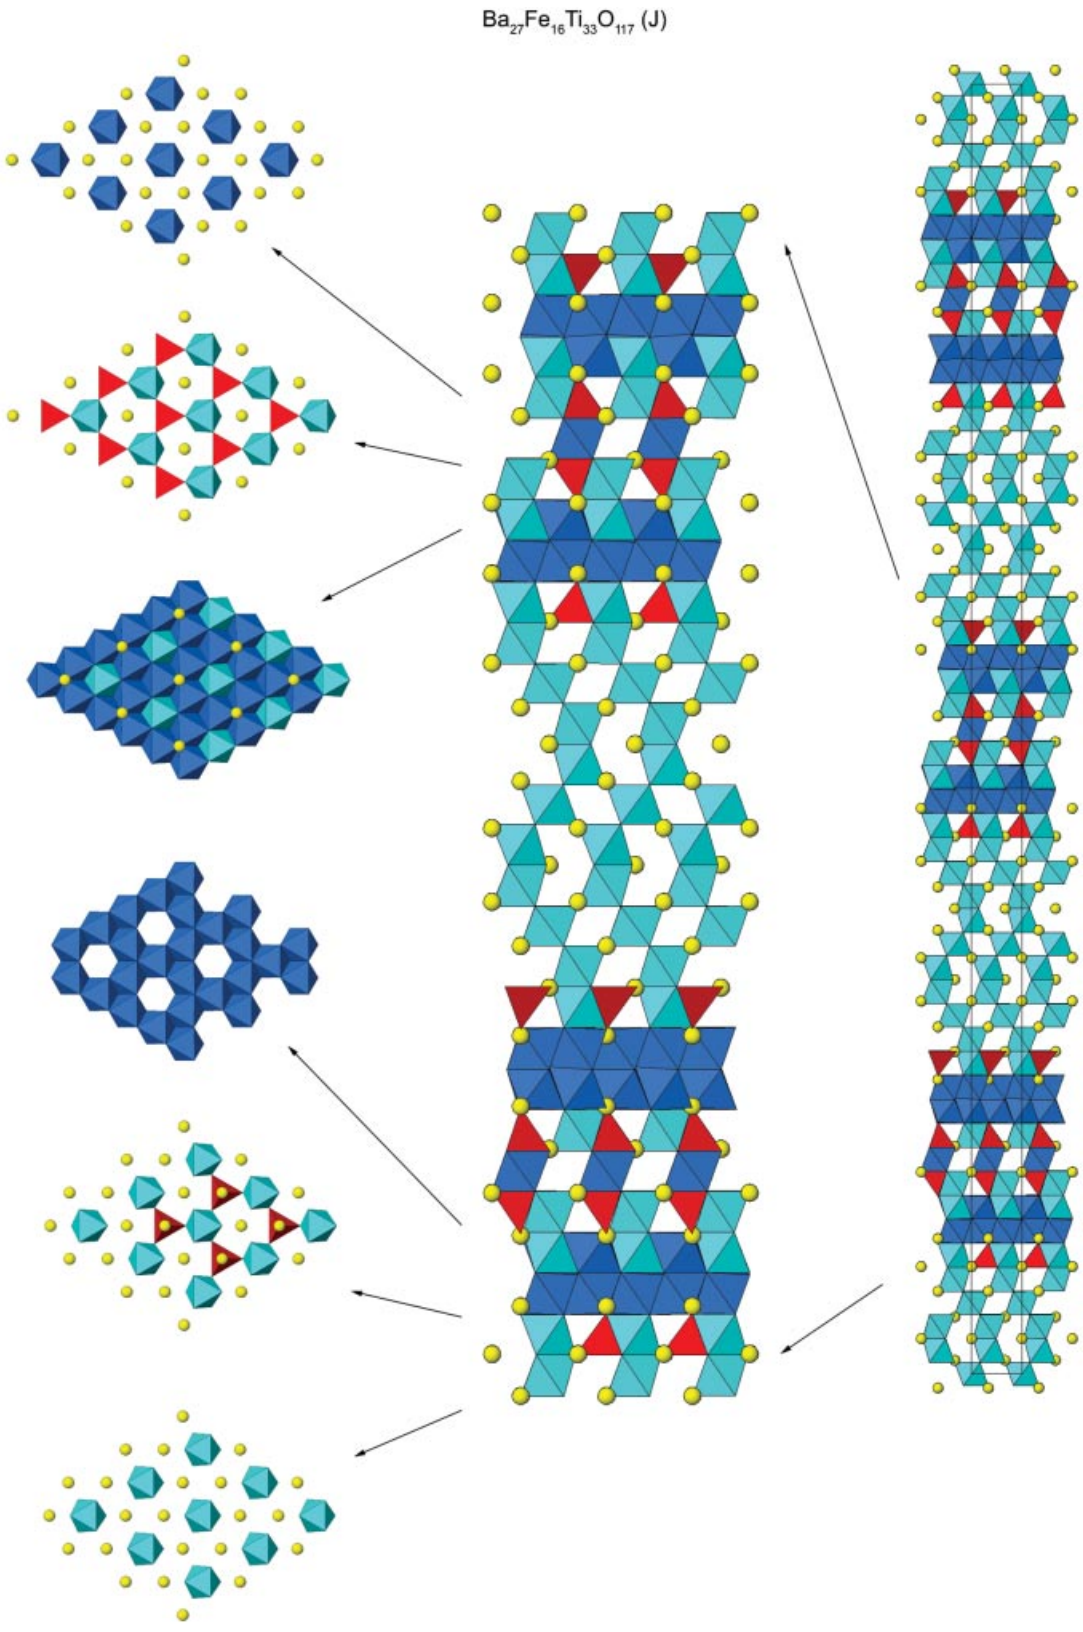

Figure 8. View of the close-packed layers and stacking arrangement of $Ba_{27}Fe_{16}Ti_{33}O_{117}$ (phase J), a 54L natural magnetic super-lattice; the rhombohedral structure has an 18L unique substructure with the hexagonal perovskite motif; disorder similar to that in phase M is observed in the iron-containing layers

layers with extended octahedron frameworks (T2), and finally hP perovskite-type-related layers in which half of the octahedra have been removed (layer P) make up the structure. These five different layer types produce the observed

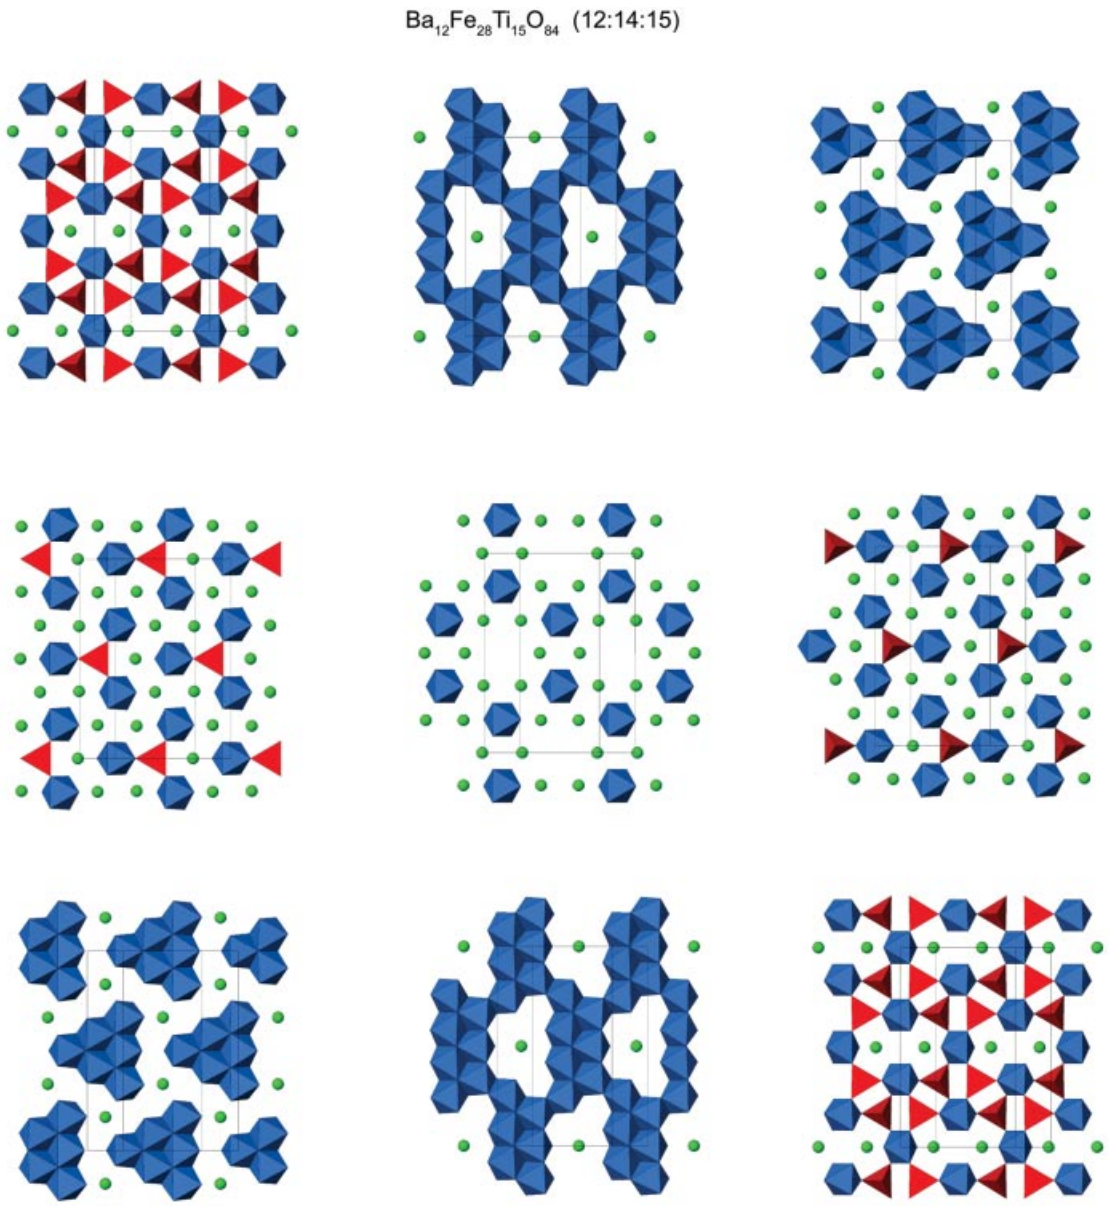

Figure 9. View of the close-packed layers of $Ba_{12}Fe_{28}Ti_{15}O_{84}$ (phase 12:14:15); four new layer types, intermediate between hexaferrite/spinel and polytitanate layers, are observed

8L structure with an {S1−T2−T1−S2−P−S2−T1−T2−S−...} stacking sequence.

The layers S1, T1, and T2 are again present in phase F, $Ba_4Fe_{28}Ti_5O_{56}$ (Figure 10),[40] in an {S1−T2−T1−T1−T2−S1−...} stacking sequence. Two modifications with this stacking were observed, the layers showing different relative orientations. The hexagonal symmetry of the T1 layer allows the orientation of the subsequent T2 layer to be changed by 120°. Superstructures with complicated stacking sequences are therefore possible for these systems. For instance, a more symmetrical unit cell may be produced by the stacking of 15 layers, with subsequent rotation of each five-layer block by 120°. Indeed, a unit cell indicating a 15L structure was previously observed for phase F.[1]

A further layer type is found in phase I, $Ba_5Fe_4Ti_{10}O_{31}$[41] (Figure 11), in equilibrium with $BaTiO_3$ and $Ba_2Fe_2Ti_4O_{13}$, as well as with $Ba_4Fe_2Ti_{10}O_{27}$ (phase C). Phase I is closely related to $Ba_{12}Fe_{28}Ti_{15}O_{84}$, with the S2 and T1 layers present, together with a modified T2′ layer. The T2′ layer derives from the T2 layer by removal of one octahedron to render the layer more symmetric. The combination of the T1 and T2′ layer again shows the principle of full plane coverage with two distinct layers, A new modified R-block of two close-packed layers R1 completes the 9L substructure found in this hexagonal 18L system. The modified R-block R1 shows a similar feature of substitution of barium for a tetrahedron, or, in this case a trigonal bipyramid. The resulting layers show a two-dimensional framework more open than the corresponding hexaferrite R-block.

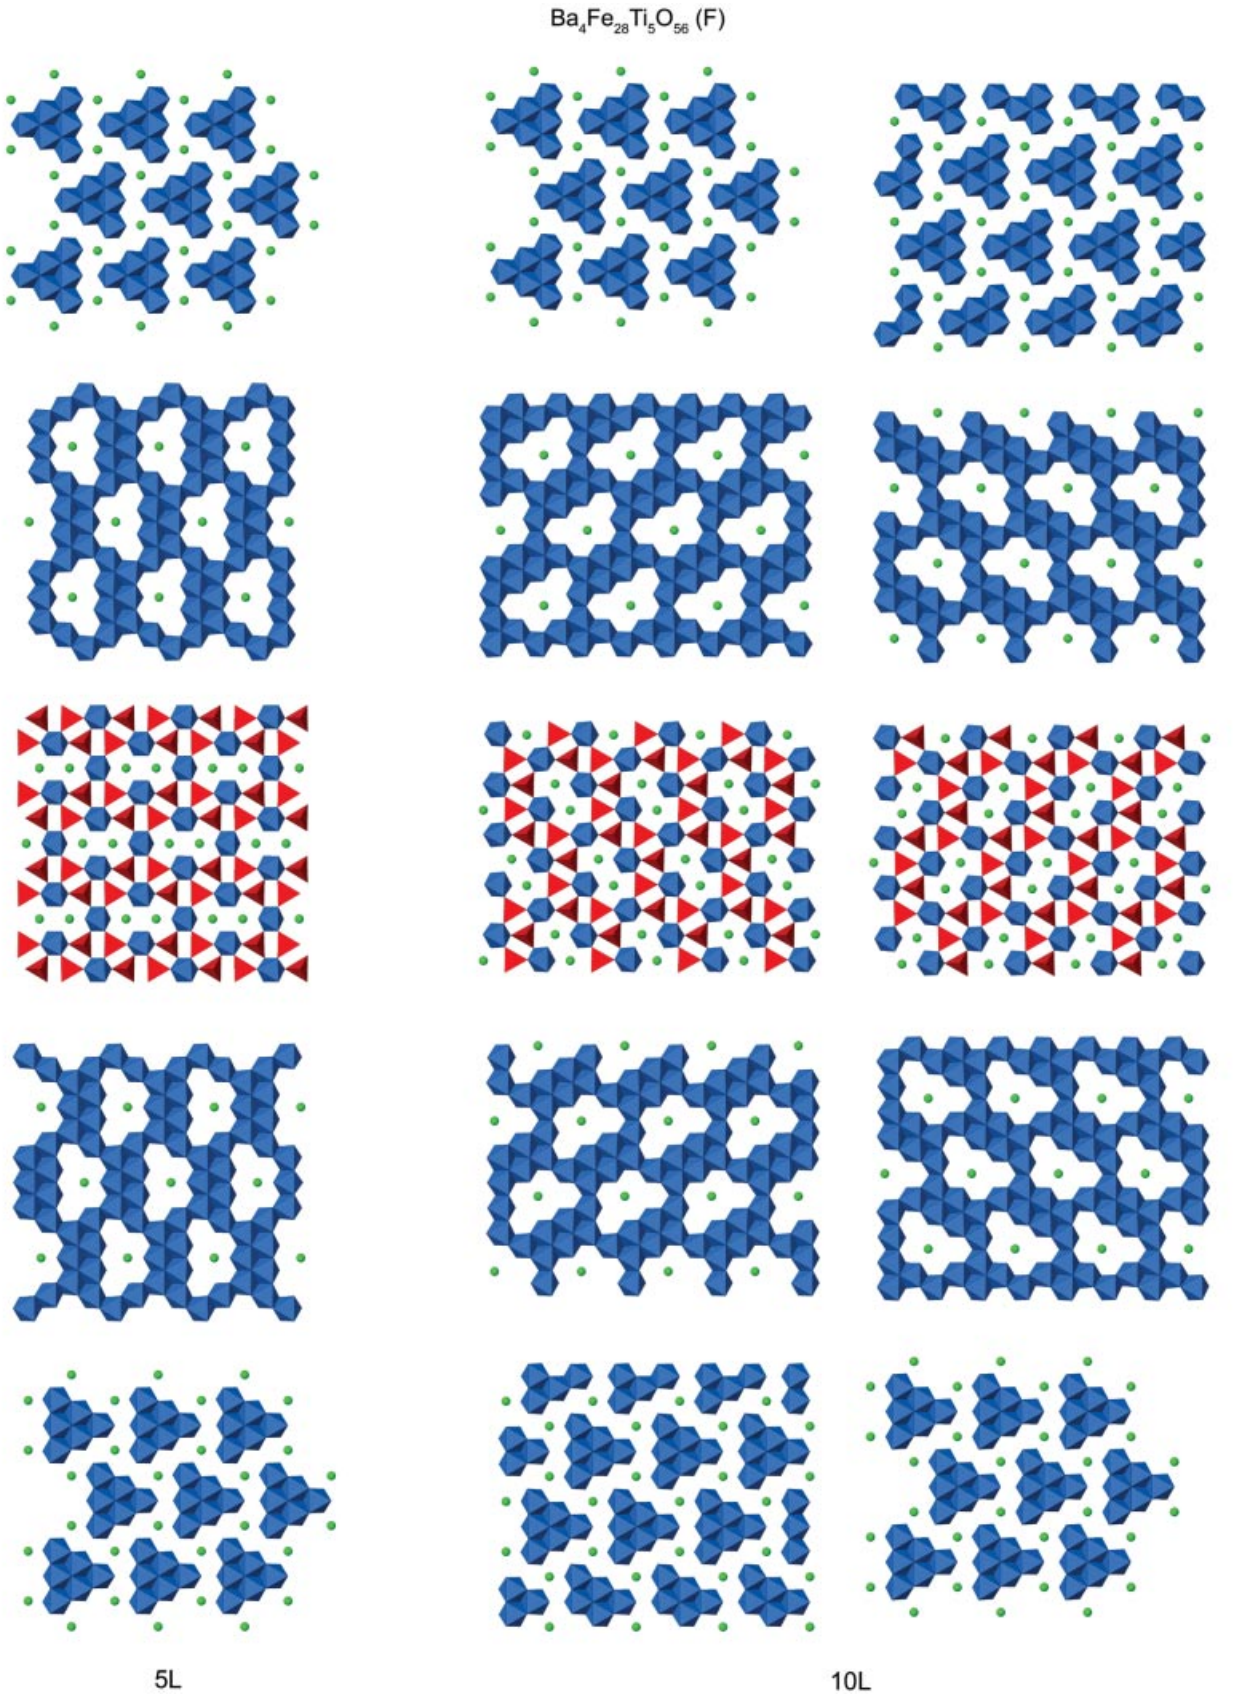

Figure 10. View of the close-packed layers of $Ba_4Fe_{28}Ti_5O_{56}$ (phase F); the 10L superstructure (right) can be derived from the 5L substructure (left) by rotation of the second layer depicted by 120°; only three of the five different layers of $Ba_{12}Fe_{28}Ti_{15}O_{84}$, are present, in the same relative arrangement

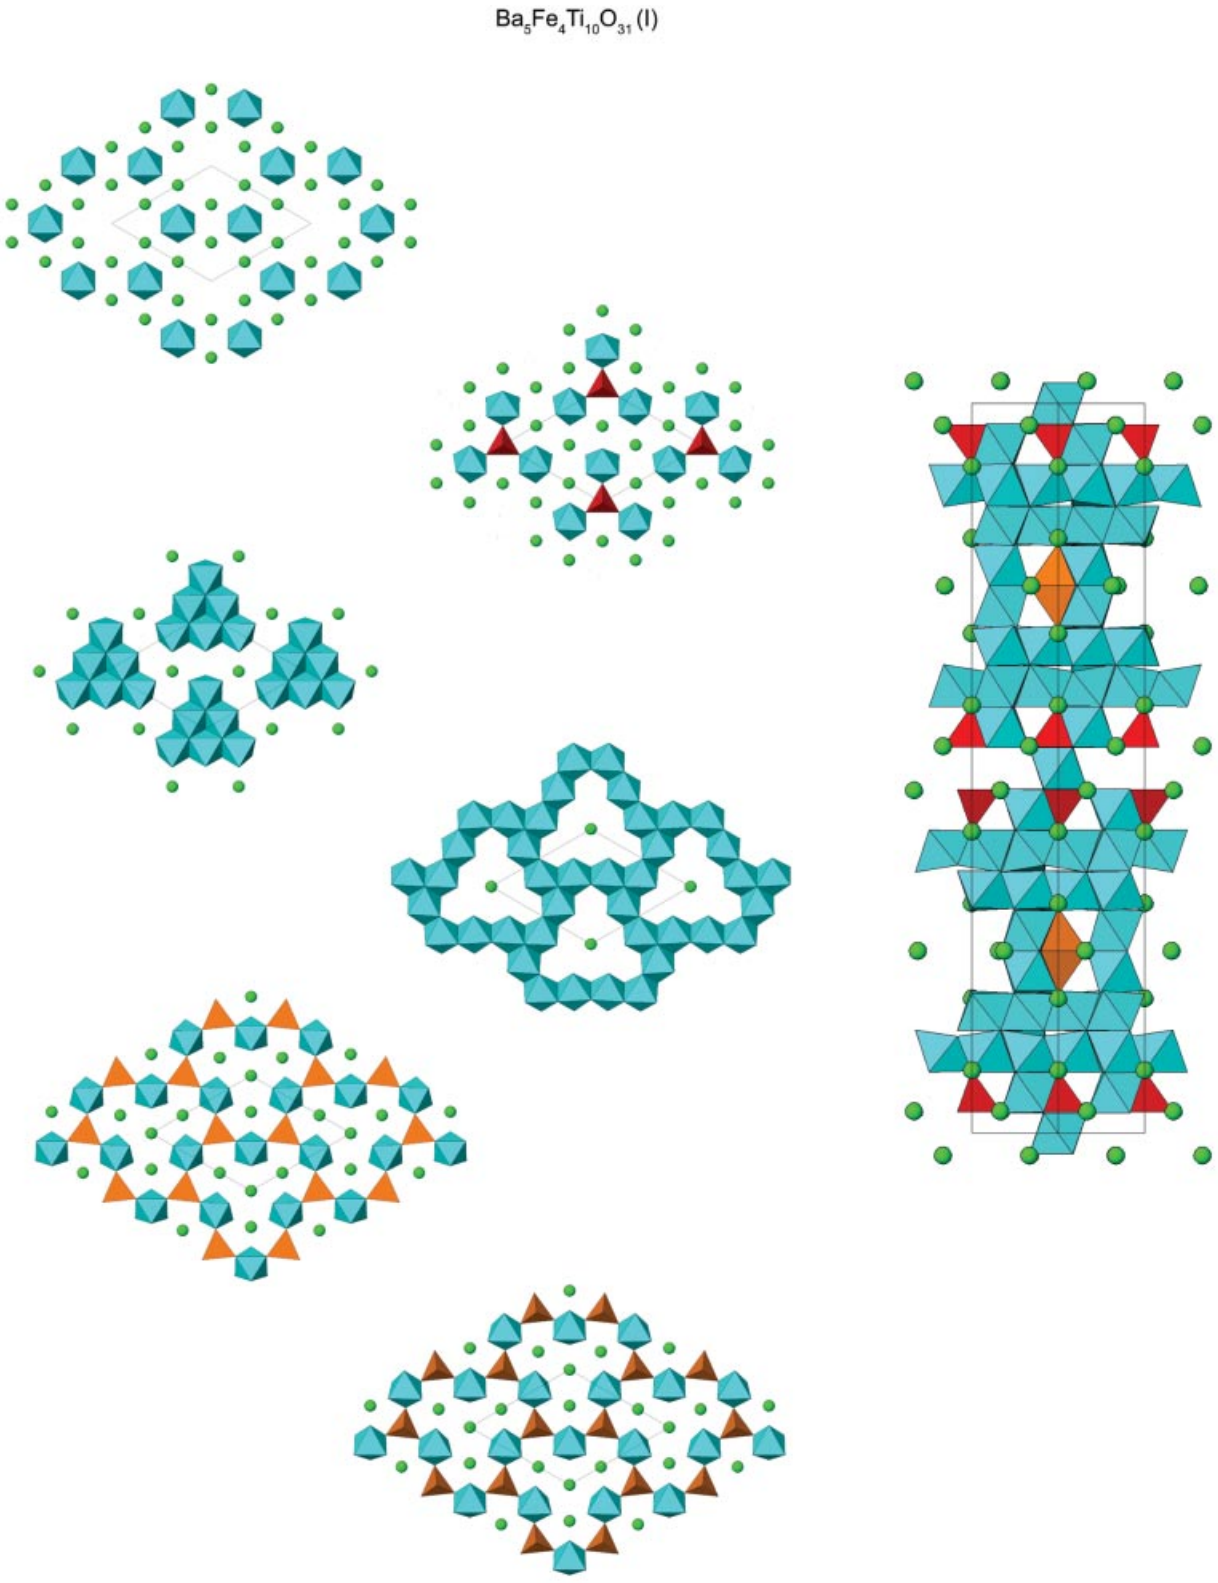

Figure 11. View of the close-packed layers and stacking arrangement of $Ba_5Fe_4Ti_{10}O_{31}$ (phase I); three of the six layers are identical to layers found in $Ba_{12}Fe_{28}Ti_{15}O_{84}$; furthermore, a modified R-block is seen

The stacking sequence in phase I is very similar to that in $Ba_{12}Fe_{28}Ti_{15}O_{84}$. In phase I, it is {P−S2−T1−T2′−R1−T2′−T1−S2−P−...}, in comparison with {P−S2−T1−T2−S1−T2−T1−S2−P−...}. In this respect, phase I ($Ba_5Fe_4Ti_{10}O_{31}$) may be regarded as a modified version of 12:14:15, $Ba_{12}Fe_{28}Ti_{15}O_{84}$. Unlike in

$Ba_{12}Fe_{28}Ti_{15}O_{84}$, the hexagonal symmetry is retained in $Ba_5Fe_4Ti_{10}O_{31}$, due to the higher symmetry of the R1 and T2′ layers, and the absence of the lower symmetric S1 layer. Even though the two structures are closely related in their crystal chemistry, they are not in equilibrium, and so intergrowth of the two would not be expected to occur under the given growth conditions. Interestingly, phase I displays an unusual barium coordination of 9+3 oxygen atoms in which the barium atom is shifted out of the close-packed plane, creating three short bonds of 2.74 Å and three long bonds of 3.50 Å.

A potentially large number of superstructures based on the various S1, S2, T1, T2, T2′, P1, and R1 layers (shown in Figure 12), may be envisioned. Furthermore, possible intergrowth structures produced under different growth conditions allow some degree of stoichiometric variation. Indeed, observed unit cells show lattice parameters up to about 40 Å, and larger superstructures are possible.

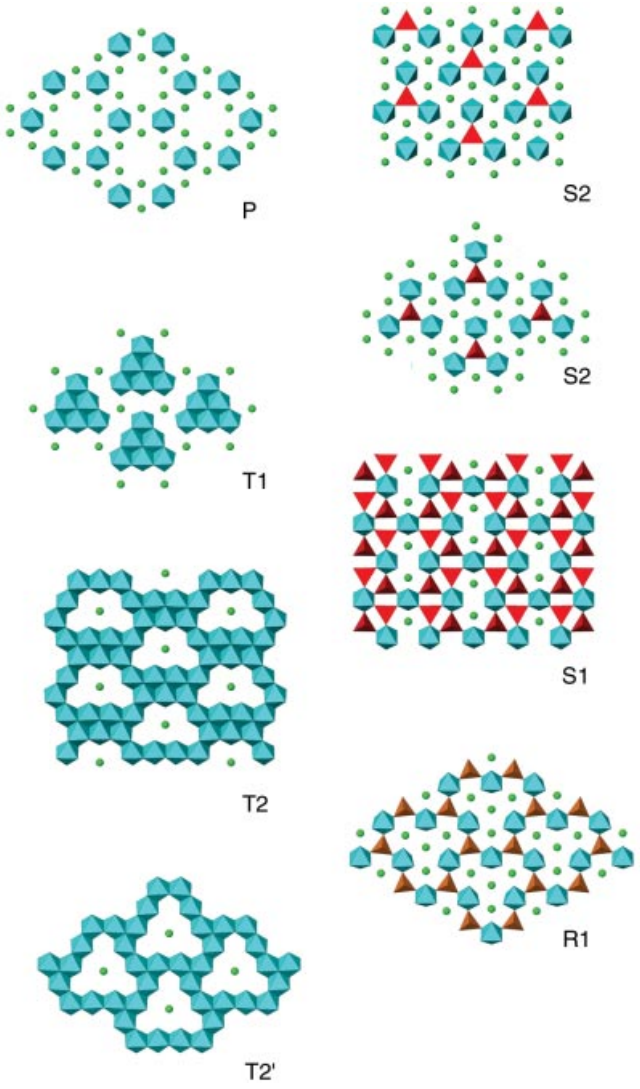

Figure 12. View of the seven different close-packed layers found in the new $BaO-Fe_2O_3-TiO_2$ phases; the close relationship to the T2 and T2′ layers can clearly be seen; the S1 and S2 layers are related to spinel-type layers, as are T2 and T2′ layers; the P and T1 layers are related to perovskite-type layers, and the R1 layers is related to the R-block layers in hexaferrite

Phases D, $Ba_6Fe_{45}Ti_{17}O_{106}$ and D′, $BaFe_{11}Ti_3O_{23}$, which are related,[42] are shown in Figure 13. The two distinct close-packed layers in phase D show a new building principle: the combination of different building units as described above within a single layer. For instance, a hexaferrite T-block layer composed of tetrahedra, octahedra, and Ba is combined with the previously described "ring" structure from a T2′ layer. Every second row of rings in the T2′ layer is split and expanded by the width of one octahedron to accommodate the three tetrahedra around an octahedron and the barium atom. In a similar way, the second layer is made up of the Ti_6O_{22} motif from the T1 layer in combination with the spinel-type sP1 layer of connected octahedra. In this respect, phase D may be regarded as a special intergrowth of the spinel-type structure and phase I, in which the combination is within the close-packed layers.

Phase D′, $BaFe_{11}Ti_3O_{23}$, is also composed only of two distinct layers (Figure 13). The structural motifs are related to the spinel-type structure, in which, in addition to Ba, the sP1 and sP2 layers are combined. As a result, phase D′ contains one-dimensional chains within a close-packed layer based on the substitution of barium for tetrahedra.

5. Dielectric Behavior

The dielectric response of a material may be described by use of the Clausius−Mosotti theory. This approach is valid for frequencies well below typical phonon frequencies in a solid-state material, and far from possible resonances due to magnetic atoms. In the case of the $BaO-Fe_2O_3-TiO_2$ system, Fe does not show resonance behavior up to frequencies of a few GHz. The dielectric constant ε of a material is related to the polarizability α and the molar volume V_m, with α being the sum over all the individual polarizabilities of the atoms in the molar volume ($\alpha = \Sigma_i \alpha_i$), according to Equation (1).

$$\varepsilon = \frac{1+\frac{8\pi\alpha}{3V_m}}{1-\frac{4\pi\alpha}{3V_m}} \quad (1)$$

The individual polarizabilities have been tabulated,[43] and give reasonable values for the dielectric constant ε. To achieve a high dielectric constant, it is therefore necessary to pack large atoms that are easily polarized in as small a volume as possible. As a guide, the value of $(4\pi\alpha/3V_m)$ should be close to 1.0. In the case of cubic $BaTiO_3$, this expression is approximately 0.9975, giving a calculated ε value of 1200. If $(4\pi\alpha/3V_m)$ is exactly 1.0, the expression diverges, giving a nonphysical value, and values larger than 1.0 would result in negative dielectric constants. The temperature dependence of the dielectric constant is related to the thermal expansion coefficient, since, to first order, only

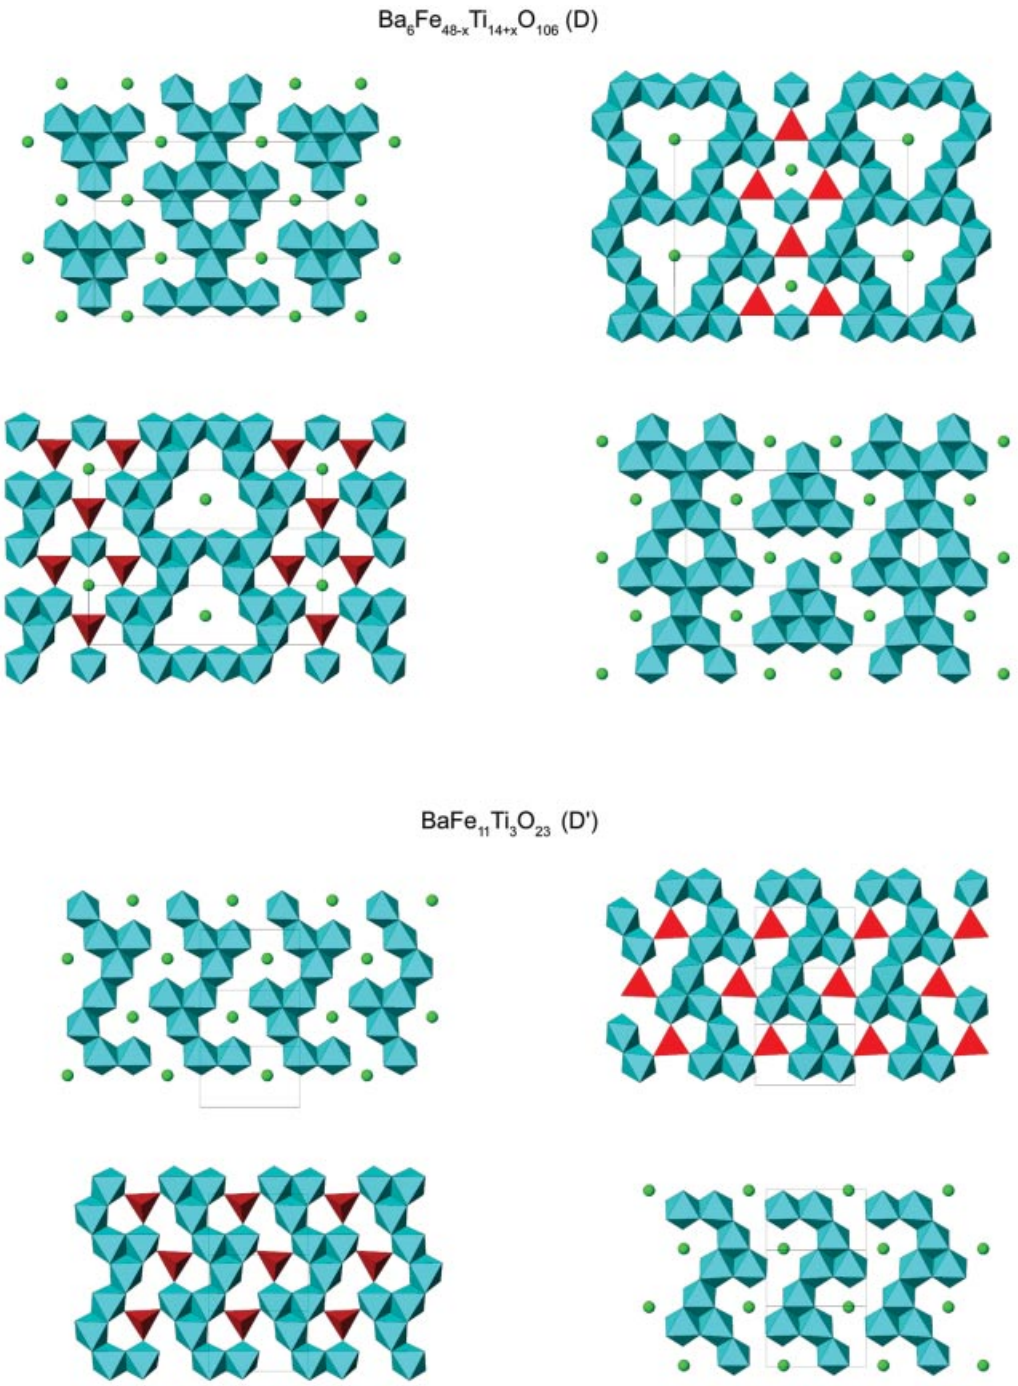

Figure 13. View of the close-packed layers in $Ba_6Fe_{48-x}Ti_{4-x}O_{106}$ (phase D, above) and $BaFe_{11}Ti_3O_{23}$ (phase D′, below); different building blocks are combined within a single close-packed layer; for instance elements of the T1 layer combines with the T2 layers, and elements of the T2′ layer combine with sP1 spinel-type layers in $Ba_6Fe_{48-x}Ti_{14+x}O_{106}$ (phase D); similarly, the combination of spinel-type elements and barium atoms within single layers are also observed for $BaFe_{11}Ti_3O_{23}$

the molar volume V_m has a temperature dependence of the form $V(T) = V_0(1 + \beta T)$. For technological use, a vanishing temperature dependence of ε is desirable, therefore excluding isotropic materials. Lower symmetry systems offer the opportunity of smaller temperature dependence of the molar volume, in which an expansion in one direction may be offset by a contraction in an other direction, resulting in a small or even zero overall thermal volume expansion coefficient. The values for atomic polarizabilities given are:[43] barium (Ba^{2+}) 6.40 Å^3; iron (Fe^{3+}) 2.29 Å^3; titanium (Ti^{4+}) 2.93 Å^3; oxygen (O^{2-}) 2.01 Å^3.

With these values, reasonable estimates of the dielectric constants of the phases found in the $BaO-Fe_2O_3-TiO_2$ system are obtained, assuming that the transition elements are in their expected valence states (i.e., no reduced titanium or reduced/oxidized iron atoms are present).

Estimated dielectric constants ε of a few selected compositions are given in Table 2. The values for the various compounds indicate the expected trend of lower dielectric constant with higher iron concentration, due to the reduced polarizability of iron versus titanium. Furthermore, higher barium concentrations would also be expected to increase the dielectric constant, as is reflected in the higher ε seen in phase M, $Ba_{11}Fe_8Ti_9O_{41}$, for which the estimated ε is of the order of 46. However, these values represent an approximation and do not take into account any loss mechanisms that may arise from mixed iron valence or reduction of titanium during the synthesis of the material.

Table 2. Estimated dielectric constants of selected compositions

Compound	$\varepsilon_{est.}$
$BaFe_4Ti_2O_{11}$ (1:2:2)	30
$Ba_{12}Fe_{28}Ti_{15}O_{84}$ (12:14:15)	26
$Ba_2Fe_2Ti_4O_{13}$ (A)	11
$Ba_3Fe_{10}TiO_{20}$ (B)	10
$Ba_4Fe_2Ti_{10}O_{27}$ (C)	27
$Ba_6Fe_{45}Ti_{17}O_{106}$ (D)	25
$BaFe_{11}Ti_3O_{23}$ (D′)	23
$Ba_4Fe_{28}Ti_5O_{56}$ (F)	23
$Ba_{11}Fe_2Ti_{26}O_{66}$ (G)	31
$Ba_5Fe_4Ti_{10}O_{31}$ (I)	33
$Ba_{27}Fe_{16}Ti_{33}O_{117}$ (J)	46
$Ba_{11}Fe_8Ti_9O_{41}$ (M)	47

It is clear from the above that systems based on channel structures are in general less efficiently packed than close-packed structures, and so polarizabilities per molar volume tend to be smaller for the channel-type structures.

Since the polarizability of barium is roughly twice that of titanium and almost three times that of iron, it is possible to increase the dielectric constant by substituting Ba in place of an iron tetrahedron. This substitution principle has been observed in the phases discussed above, and is reflected in the higher dielectric constants, both estimated and observed, for the barium-rich systems. The highest concentration of Ba would be expected for BaO (cubic rock salt type), but the estimated dielectric constant is only of the order of 15. Here, the molar volume is markedly larger than in comparable $BaO-Fe_2O_3-TiO_2$ phases, due to the lattice contraction (reduction in molar volume) produced by the higher charge on the transition metal atoms in interstitial sites.

6. Magnetic Behavior

The magnetic properties of the new phases in the $BaO-Fe_2O_3-TiO_2$ system are not yet fully established. However, the ferrimagnetic behavior of the hexaferrites is well known and documented.[25]

In the $BaO-Fe_2O_3-TiO_2$ phases as prepared, iron is present as Fe^{3+}, the desired valence state for low loss behavior. Free trivalent Fe is in a $^6S_{5/2}$ state, with a free magnetic moment of 5.92 μ_B. In cases of spinels and hexaferrites, the individual magnetic moments for trivalent iron are the full spin-only moment of 5.92 μ_B, but the magnetic superexchange produces antiferromagnetic coupling between the iron sub-lattices, reducing the net magnetic moment. Superexchange tends to produce antiferromagnetic spin alignments, although more complicated spin structures are possible.[22] Furthermore, the crystal field may produce low-spin iron. All these effects tend to reduce the overall magnetic moment per formula unit. Dilution of iron with nonmagnetic titanium induces changes in the magnetic coupling while reducing the number of spins. In special cases, an increase in the magnetic moment is possible if strong antiferromagnetic coupling is reduced.

At low iron concentrations, paramagnetic behavior with antiferromagnetic interactions would be expected, as observed, for instance, in the case of $Ba_5Fe_4Ti_{10}O_{31}$. Here, paramagnetic behavior was observed at room temperature, with cooperative interactions apparent below 250 K, but without magnetic order at low temperatures.[41] The effective magnetic moment per iron atom, obtained from the high-temperature susceptibility, is 5.12 μ_B, close to the free-atom value. The negative Weiss constant of $\Theta = -190$ K indicates that the dominant interactions are antiferromagnetic in nature. Furthermore, possible magnetic cluster formation is reflected in the behavior of the susceptibility.

Similarly, $Ba_6Fe_{45}Ti_{17}O_{106}$ (phase D) shows Curie–Weiss behavior, with a high-temperature effective magnetic moment of 34 μ_B per formula unit (45 iron atoms), and $\Theta = -806$ K, indicating strong antiferromagnetic interactions. A magnetic transition below 100 K was observed, and was attributed to a small amount of a strongly magnetic impurity, such as $BaFe_{12}O_{19}$. In comparison with $Ba_{12}Fe_{28}Ti_{15}O_{84}$,[39] a phase with less overall iron that shows a ferromagnetic Curie temperature well above room temperature, $Ba_6Fe_{45}Ti_{17}O_{106}$ is an exceptionally weak magnet. Appropriate chemical substitutions would be likely to improve magnetic properties by reducing the antiferromagnetic coupling between different sub-lattices.

The natural magnetic super-lattices found in the regions with low overall iron content merit further investigation, since the iron atoms are preferentially found near to one another. In this way, magnetic interactions within the layers may occur at higher temperatures than might be expected from the overall iron concentration alone. In addition, the two-dimensional character of the structure should be reflected in its magnetic behavior.

7. Conclusions and Outlook

The $BaO-Fe_2O_3-TiO_2$ system shows a wealth of new phases with interesting structural, dielectric, and magnetic properties. The crystal chemistry of a majority of the phases in this system is based on close-packed structures made up of {O,Ba/O} layers. With relatively few distinct types of layers, combining octahedra, tetrahedra, trigonal bipyramids, and barium atoms, a rich variety of stacking sequences with different combinations of the various layers

are found. In the polytitanate-related phases, new types of layers with complexity intermediate between that of the hexaferrites and that of polytitanates form. As in the hexaferrites, superstructures with long periodicities develop, all based on a few common types of layers (Figures 2, 5, and 12). Furthermore, preferential ordering of Fe in distinct layers well separated from each other produces natural magnetic super-lattices. Relationships between structures, based on the stacking arrangement of similar layers in various ways, can be identified in the $BaO-Fe_2O_3-TiO_2$ system. In contrast to the barium polytitanates, which often show low crystallographic symmetry, the mixed barium hexaferrites tend to exhibit higher symmetries based on hexagonal features.

The polarizability of iron is smaller than that of titanium, and substitution of Fe for Ti reduces the overall dielectric constant. This is offset in part by the ability of Fe to occupy tetrahedral interstitial sites, allowing a higher concentration. Phases with high dielectric constants are therefore observed in the mixed iron/titanium systems.

Most microwave materials in use today are composite materials, so knowledge of the phase diagram provides crucial processing information. Combination of hexaferrites and barium polytitanates in a composite process should produce phases described above. Since properties are additive in ceramic composites, knowledge of physical and chemical properties is crucial for tailoring of a material to maximize its performance.

The large number of new phases observed in the $BaO-Fe_2O_3-TiO_2$ phase diagram has produced new insights into the crystal chemistry of these phases. Since the cut of the phase diagram was carried out at 1275 °C, more phases are likely under different preparation conditions. So far, the presence of Fe^{3+} has been needed for microwave applications. However, reduced oxygen pressures may stabilize other new, as yet unknown phases. The rich crystal chemistry observed in this system may be expected to extend into related phases, prepared under different synthesis conditions.

Efficient Energy Transfer in Supramolecular, Hydrogen-Bonded Polypyridylruthenium-Osmium Complexes

Sven Rau,*[a] Bernhard Schäfer,[a] Sebastian Schebesta,[a] André Grüßing,[a] Wolfgang Poppitz,[a] Dirk Walther,[a] Marco Duati,[b] Wesley R. Browne,[b] and Johannes G. Vos[b]

Keywords: Ruthenium / Osmium / Supramolecular chemistry / Photosynthesis

Hydrogen bond association between ruthenium bibenzimidazole and carboxylated polypyridylosmium complexes results in stable supramolecular aggregates. The determined stability constant of $\log K \approx 6 \pm 0.3$ allows efficient energy transfer from the ruthenium to the osmium moiety.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Primary processes in natural photosynthesis consist of photon absorption and fast, directional and highly efficient energy transfer along chains of chlorophyll molecules. The efficiency and directionality of the energy-transfer processes are determined by the spatial orientation of the individual chromophores, which is defined by supramolecular forces such as hydrogen bonding and by minute variations of their chemical environment.[1] Artificial systems are most often based on polypyridylruthenium and -osmium complexes, which, due to their photophysical and electrochemical properties, are ideal models. The vast majority of investigations in this area have been generated with covalently linked systems, which are based on highly complicated ligand synthesis.[2] This distinct contrast between natural building principles employing relatively simple components and artificial model components has, to the best of our knowledge, only been overcome in one principle example where hydrogen-bonded ruthenium and osmium complexes have been investigated.[3] The association between both components was accomplished by exploiting the complementary base-pairing of cytosine and guanine, however the complicated ligand synthesis together with relatively low stability constants are serious disadvantages which leave room for considerable improvement. Recently, we have found that the cis diamine moiety of cationic bibenzimidazole ruthenium complexes is an ideal hydrogen bond donor, especially for carboxylate groups.[4] On the basis of this observation it is our intention to develop stable, supramolecular hydrogen-bonded systems where we can study the dependence of the efficiency and directionality of energy-transfer processes on the type of supramolecular association and the modification of the chemical composition of the components. Here we describe the investigation of the first example of these systems based on a novel dicationic ruthenium bibenzimidazole complex as hydrogen-bond donor and a monocationic osmium bipyridine carboxylate[5] as hydrogen-bond acceptor.

Results and Discussion

The investigation was conducted using a bis(2,2′-bipyridine)(4,4′,5,5′-tetramethyl-2,2′-

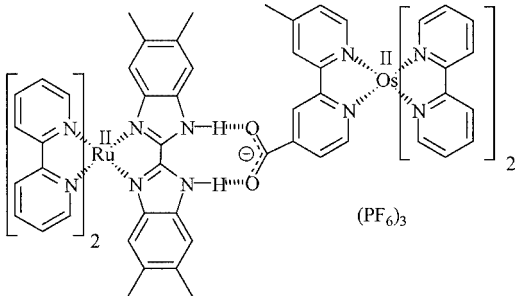

Figure 1. Supramolecular aggregate consisting of bis(2,2′-bipyridine)(4,4′,5,5′-tetramethyl-2,2′-bibenzimidazole)ruthenium(II), Ru(biH_2), and bis(2,2′-bipyridine)(4-carboxy-4′-methyl-2,2′-bipyridine)osmium(II), Os(mcbpy)

bibenzimidazole)ruthenium(II) complex, Ru(biH$_2$), as donor and a bis(2,2′-bipyridine)(4-carboxy-4′-methyl-2,2′-bipyridine)osmium(II) complex, Os(mcbpy), as acceptor (Figure 1). It is known that the biimidazole complex is fully protonated in solution and the carboxylate function fully deprotonated,[4,5] which should facilitate the hydrogen bond formation. The synthetic accessibility of the mononuclear components is relatively straightforward and has been described previously.[4,6–9]

In order to investigate the potential of this approach the emission intensity of Ru(biH$_2$) was investigated in the presence of different polypyridylosmium compounds. As reference $[Os(bpy)_3]^{2+}$, containing no carboxylate function, was used. It did not significantly alter the observed emission spectrum of Ru(biH$_2$), as depicted in Figure 2a. In contrast the carboxylated derivative Os(mcbpy) induced a significant decrease in emission intensity of Ru(biH$_2$), which suggested that an intermolecular energy transfer took place, Figure 2b.

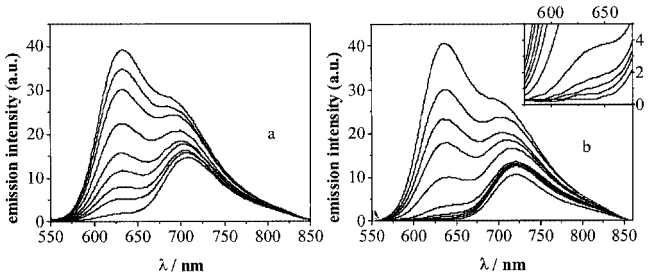

Figure 2. a) Emission spectra of the mixtures of Ru(biH$_2$) and Os(bpy)$_3$ in dichloromethane at various concentrations of Ru(biH$_2$); b) emission spectra of the mixtures of Ru(biH$_2$) and Os(mcbpy) in dichloromethane at various concentrations of Ru(biH$_2$); inset: zoom of region between 575 and 675 nm showing the changes for x between 0.1 and 1 [c(Os complex) = 0.95×10^{-6} mol/L, c[Ru(biH$_2$)] = x * c(Os complex), x = 0.1, 0.33, 0.5. 0.67, 1, 1.5, 2, 2.5, 3, 4]

A more detailed analysis of the obtained data clearly shows that the emission intensities of Ru(biH$_2$) and $Os(bpy)_3^{2+}$ are independent of their respective ratio, whereas the Ru(biH$_2$)-based emission is quiet effectively quenched in the presence of Os(mcbpy). The titration of the luminescence intensities of Ru(biH$_2$) in the presence of Os(mcbpy) yields valuable information about the supramolecular association in solution. The quantity of ruthenium donor was varied, beginning with one-tenth of the Os(mcbpy) concentration to reach, in regular steps, a one to one ratio of donor and acceptor. The concentration of Ru(biH$_2$) was further increased until the final concentration of Ru(biH$_2$) in the last solution was four times higher than the Os(mcbpy) concentration. The results are depicted in Figure 3, all emission spectra consist of the sum of the Ru(biH$_2$)- and Os(mcbpy)-based emissions because a selective excitation of the two fragments is not possible. It is evident from Figure 3 that Os(mcbpy) efficiently quenches the Ru(biH$_2$)-based emission until the concentration of Ru(biH$_2$) exceeds the one to one ratio with respect to Os(mcbpy), whereas $Os(bpy)_3^{2+}$ does not influence the emission of Ru(biH$_2$).

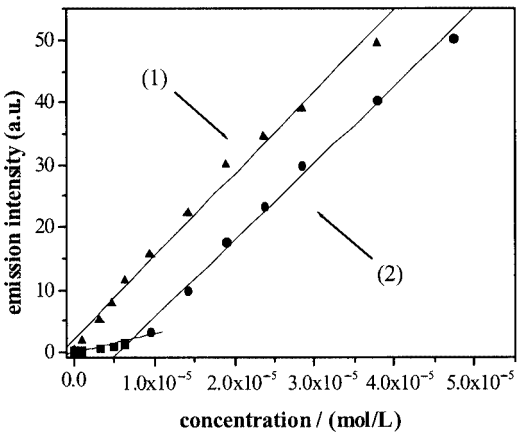

Figure 3. Emission intensity vs. concentration of Ru(biH$_2$) spectra with Os(bpy)$_3$ (1) and Os(mcbpy) (2) in dichloromethane [c(Os complex) = 0.95×10^{-6} mol/L, c[Ru(biH$_2$)] = x * c(Os complex), x = 0.1, 0.33, 0.5. 0.67, 1, 1.5, 2, 2.5, 3, 4]

These results suggest that the ruthenium bibenzimidazole complex interacts with the monocarboxylated osmium complex in such a way that intermolecular energy transfer may occur and that the carboxylate function is essential for this interaction, as depicted in Figure 1.

A careful examination of the obtained data shows that the ruthenium-based phosphorescence in the H-bonded dimer is not completely quenched. One possibility to explain this is a thermodynamic equilibrium between the two free complexes — Ru(biH$_2$) and Os(mcbpy) — and the supramolecular dimer [Ru(biH$_2$)Os(mcbpy)].

On the other hand, it has to be considered that the quenching of the ruthenium-based emission is perhaps not fast enough and, consequently, an emission of a very low intensity level is detected. In order to obtain more detailed information on this process, time-resolved photophysical investigations were performed. Ru(biH$_2$) has an absorption maximum at 482 nm and an emission maximum at 630 nm. Os(mcbpy) has an absorption maximum at 487 nm and an emission maximum at 717 nm. Due to the large separation of nearly 90 nm between both emission maxima it is therefore possible to monitor the emission intensities or lifetimes of the excited states of both complexes independently in the same solution without interference. To gain more insight into this problem luminescence lifetime measurements of the titrated solution were carried out. Figure 4a shows the decay of a one to two mixture of Ru(biH$_2$) and Os(mcbpy) in dichloromethane monitored close to the emission maximum of Ru(biH$_2$) to avoid any Os(mcbpy) signal.

If we compare the decay of the mixture with the decay of the pure donor solution, it is obvious that in the mixture a shorter lived component causes biexponential decay. The lifetime of the short component lies under 10 ns and the unbound Ru(biH$_2$) donor has the same lifetime as in the solution containing no Os(mcbpy) acceptor. Figure 4b depicts the data monitored at the Ru(biH$_2$)-based emission

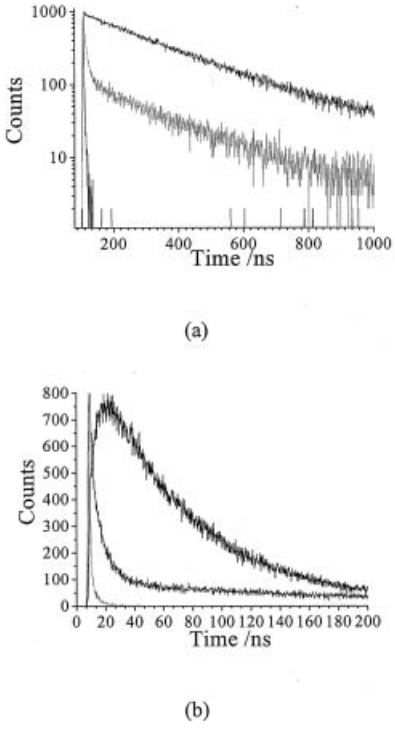

Figure 4. a) Overlay of $Ru(biH_2)$ (top), $Ru(biH_2)$/Os(mcbpy) (ratio 1:2; middle) and IRF (Instrument Response Function; bottom) monitored at 620 nm; b) overlay of $Ru(biH_2)$ (top, monitored at 620 nm) and Os(mcbpy) (middle, monitored at 750 nm) in a 1:2 ratio, IRF (Instrument Response Function; bottom, monitored at 620 nm)

wavelength and at the Os(mcbpy)-based emission. The shape of the Os(mcbpy)-based decay monitored at 750 nm, where $Ru(biH_2)$ does not emit, leads to the conclusion that as long as the short component of $Ru(biH_2)$ dominates its decay for approximately 30 ns the counted number of photons emitted by Os(mcbpy) increases to reach a maximum. After the maximum is passed, the exhibited decay is similar to that observed for free Os(mcbpy). A possible explanation for this behaviour is that the population of the emitting ^{3}MLCT state of Os(mcbpy) is rising. It is evident that the increase of counted photons has to be due to an additional population of these states. A plausible source of this extra population is energy transfer from the $Ru(biH_2)$ ^{3}MLCT state

The obtained results show that a hydrogen-bonded heterodinuclear associate is formed, that efficient energy transfer occurs and that the supramolecular associate is in equilibrium with its unbound components, according to $Ru(biH_2)$ [A] and Os(mcbpy) [B] in equilibrium with Ru(biH_2)Os(mcbpy) [A-B] [Equation (1) and (2)].

$$[A] = ([A_0]\cdot I_Q)/I_{NQ} \quad (1)$$

$$K = ([A_0] - [A])/[A]([B_0] - [A_0] + [A]) \quad (2)$$

Within all these assumptions it is possible to determine the equilibrium constant as $\log K \approx 6 \pm 0.3$ using Equation (2).

Conclusion

The results of the initial investigations presented here clearly show that the perfectly tailored geometrical parameters of the hydrogen-bond interaction groups together with the reduced coulombic repulsion between a monocationic Os(mcbpy) and a dicationic $Ru(biH_2)$ lead to stable supramolecular model compounds for photosynthetic light harvesting complexes. Barigelletti and Ward reported a log(K) $\leq$ 3.7 for the formation of a mixed cytosine-modified ruthenium and guanine-substituted osmium complex exhibiting a detectable change of luminescence properties indicative of Ru $\rightarrow$ Os energy transfer.[3] The difference in the association constants of the system described in this work compared to the one reported by Barigelletti et al. is extraordinarily high. The equilibrium constant is about two to three orders of magnitude higher although there is only a double instead of a triple chelating effect of H-bonding interactions involved within the biimidazole carboxylate system. Furthermore, the structure of the moieties connected by H-bonding in this study appears almost simple in contrast to the synthetic effort made to yield the nucleobase-modified polypyridyl complexes. The application of these construction principles should lead to more advanced compounds which might be used to gain more detailed insight into processes occurring in natural photosynthesis.

Experimental Section

Materials

All solvents used for spectroscopic measurements were of Uvasol (Merck) grade. All other reagents were HPLC grade. *cis*-$[RuCl_2(bpy)_2]\cdot 2H_2O$,[10] *cis*-$[OsCl_2(bpy)_2]\cdot 2H_2O$,[11] and $[Os(mcbpy)(bpy)_2](PF_6)$[6] were prepared by standard procedures. All reagents for synthesis, $RuCl_3\cdot 3H_2O$ (ABCR), 2,2′-bipyridine, trichloroacetic acid, 4,5-dimethyl-1,2-phenylenediamine, and 4,′4-dimethyl-2,2′-bipyridine (Aldrich) were used as received without further purification.

The synthesis of 5,5′,6,6′-tetramethyl-2,2′-bisbenzimidazole was a modification of the method of Reedijk et al.[12] 4-Carboxy-4′-methyl-2,2′-bipyridine was prepared according to literature procedures.[13]

UV/Visible spectra were obtained using a Shimadzu UV 3100 UV/Vis-NIR spectrophotometer. Emission spectra were obtained using a Perkin−Elmer LS50 luminescence spectrometer; at room temperature the measurements were taken using an excitation slide of 10 nm and emission slit of 10 nm. The NMR spectra were recorded on a Bruker 400 MHz spectrophotometer. The mass spectrometry was carried out on a SSQ 170, Finnigan Mat. The Electrospray mass spectrometry was performed on a Finnigan MAT 95 XL double focussing sector field instrument (Thermo Finnigan GmbH, Bremen, Germany) adjusted to a mass resolution of about 2000. The two complexes were first dissolved in a small amount of acetonitrile and then diluted with dichloromethane to a final concentration of 3×10^{-6} M respectively. This solution was introduced into the ion source at a flow rate of 40μL/min. The spray voltage was 4.5 kV and nitrogen was used as sheath gas.

Luminescence lifetime measurements were obtained using an Edinburgh Analytical Instruments (EAI) time-correlated single-photon counting apparatus (TCSPC) comprised of two model J-yA monochromators (emission and excitation), a single photon photomultiplier detection system model 5300, and a F900 nanosecond flashlamp (N2 filled at 1.1 atm pressure, 40 kHz) interfaced with a personal computer via a Norland MCA card. A 500 nm cut-off filter was used in emission to attenuate scatter of the excitation light (337 nm); luminescence was monitored at 640 nm. Data correlation and manipulation was carried out using EAI F900 software version 5.1.3.

Emission lifetimes were calculated using a single-exponential fitting function, Levenberg−Marquardt algorithm with iterative deconvolution (Edinburgh instruments F900 software). The reduced χ^2 and residual plots were used to judge the quality of the fits. Samples were of low concentration (2×10^{-5} M) dissolved in a small amount of dichloromethane at room temperature. The lifetimes of the complexes in equilibrium was measured in aerated dichloromethane. The lifetime errors are estimated to be less than 8%.

The following assumptions were made for the determination of the stability constant *K*. [A_0] [initial concentration of Ru(biH$_2$)] and [B_0] [initial concentration of Os(mcbpy)] of the solutions are determined from the weighted masses of donor and acceptor. The ratio of [*A*] to [A_0] might be expressed by the quotient of the intensities of I_{NQ} to I_Q ($I_{NQ/Q}$ emission intensity for different concentration for not quenched and quenched case) at the maximum of the ruthenium donor (λ_{max} = 630 nm). In order to determine the I_{NQ} correctly the emission intensity of Ru(biH$_2$) was determined in the presence of non-binding $[Os(bpy)_3]^{2+}$. At the monitored emission wavelength of 630 nm the absorption of the two osmium complexes, the binding Os(mcbpy) and $[Os(bpy)_3]^{2+}$, is different. Therefore we have to consider a correcting factor x for I_{NQ}, the concentration [*A*] may therefore be determined using Equation (1) and the corrected I_{NQ}.

Synthesis of [Ru(tmbbiH$_2$)(bpy)$_2$](PF$_6$)$_2$, Ru(biH$_2$): [RuCl$_2$(bpy)$_2$]·2H$_2$O (0.19 mmol) and 5,5′,6,6′-tetramethyl-2,2′-bisbenzimidazole (0.19 mmol) were suspended in a mixture of EtOH/H$_2$O (1:1 v/v, 30 mL) and stirred and refluxed overnight. The reaction mixture was allowed to cool to room temperature and filtered. The volume of the solution was reduced (to ca. 10 mL) by rotary evaporation, and the product was precipitated as the PF$_6$ salt. The crude product was washed with water and diethyl ether, and chromatographed on silica with an eluent formed of THF, CH$_3$CN, KNO$_3$ (saturated aqueous solution) (12:4:0.5, v/v/v). The first peak (main band) contained the desired compound, which was finally obtained by recrystallisation from acetone and water. $[C_{38}H_{34}F_{12}N_8P_2Ru]^{2+}$ (993.7): calcd. C 45.93, H 3.45, N 11.28; found C 46.44, H 3.41, N 10.98. ESI-MS: *m/z* = 704.0 $[C_{38}H_{34}N_8Ru]$, 352.3 $[C_{38}H_{34}N_8Ru]^{2+}$. ^{1}H NMR (CD$_3$CN): δ = 8.54 (d, 2 H), 8.44 (d, 2 H), 8.16 (dd, 2 H), 8.05 (d, 2 H), 7.97 (dd, 2 H), 7.93 (d, 2 H), 7.49 (dd, 2 H), 7.47 (s, 2 H), 7.34 (dd, 2 H), 5.39 (s, 2 H), 2.65 (s, 6 H), 2.15 (s, 6 H) ppm. ^{13}C NMR (CD$_3$CN): δ = 20.37, 20.55, 114.66, 116.07, 124.61, 125.01, 128.08, 128.47, 134.53, 135.46, 137.16, 137.85, 138.34, 141.31, 144.44, 153.70, 154.16, 158.36, 160.07 ppm. UV/Vis (CH$_2$Cl$_2$): λ_{max} = 482 nm (ε = 9200 $M^{-1}cm^{-1}$). Emission (CH$_2$Cl$_2$): λ_{max} = 630 nm. Lifetime of excited state (CH$_2$Cl$_2$): τ = 238 ns.

The First Azaindatrane and Unprecedented Structural Features

Pavel L. Shutov,[a] Sergey S. Karlov,*[b] Klaus Harms,[a] Oleg Kh. Poleshchuk,[c] Jörg Lorberth,*[a] and Galina S. Zaitseva[b]

Keywords: Azametallatranes / Indium / Tripodal ligands

The reaction between $[In(NEt_2)_3]_2$ and $N(CH_2CH_2NMeH)_3$ yields the *N*,*N*′,*N*′′-trimethylazaindatrane dimer $[N(CH_2CH_2NMe)_3In]_2$ (**1**). The composition and structure of **1** were established by ^1H and ^{13}C NMR spectroscopy as well as by an X-ray diffraction study. The X-ray structure shows that both indium atoms are pentacoordinate, with widely differing In–N distances. The structural parameters of **1** were compared with those obtained from a computational study.

Introduction

Compounds containing intramolecular interactions have found widespread application for the stabilisation of low-valent species or for achieving unusual molecular geometries. Of particular interest are metallatranes of the type $[N(CH_2CH_2Y)_3M-X$, where X = substituent, electron lone pair or nothing and Y = O, NR, CH_2, S] containing tetradentate, c_3-symmetric ligands such as tris(alkoxyamine) groups $[N(CH_2CH_2O)_3]^{3-}$ and tris(amidoamine) groups $[N(CH_2CH_2NR)_3]^{3-}$.[1−3] These ligands bind to various main-group elements or transition metals in a tridentate or tetradentate manner to form complexes. The latter are usually characterised by a transannular N→M interaction. The strength of this N→M interaction depends on the nature of the central atom M and the equatorial substituents Y.

Verkade et al. have recently prepared azametallatranes of boron, aluminium, and gallium,[4−7] but, to the best of our knowledge, no azaindatranes have been reported yet. However, it should be noted that the chemistry of indium-nitrogen compounds, especially indium amides, has been the focus of much interest during the last two decades for their importance in the preparation of nitride ceramic materials and semiconductors.[8]

In this paper we report on the synthesis of the *N*,*N*′,*N*′′-trimethylazaindatrane dimer $[N(CH_2CH_2NMe)_3In]_2$ (**1**). Details of the X-ray crystal and molecular structures of **1** are also described. Our aim was to prepare the first azaindatrane **1** and to compare its structure with the structures of closely related derivatives of Al and Ga (**2** and **3**, respectively).

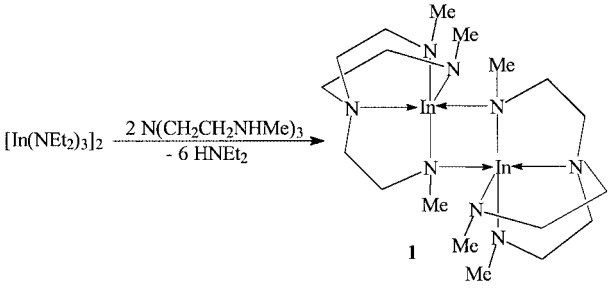
Results and Discussion

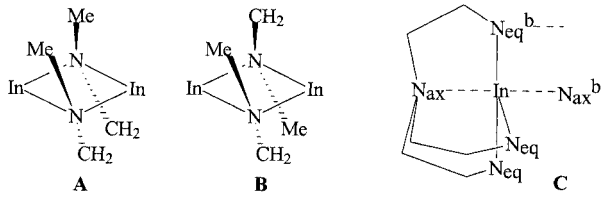
Treatment of $[In(NEt_2)_3]_2$ with equimolar amounts of $N(CH_2CH_2NMeH)_3$ (Me_3-tren) in toluene afforded azaindatrane **1** in high yield [Equation (1)]. The crystals of compound **1** contain variable amounts of toluene, which could not completely be removed.



(1)

The NMR spectroscopic data (^1H, ^1H COSY and ^{13}C) of **1** are consistent with its formulation as a dimer $[N(CH_2CH_2NMe)_3In]_2$: compound **1** exists in solution as one of two geometrical isomers of the In_2N_2 core [**A** (cis) and **B** (trans); Scheme 1] analogous to the previously described complexes $[N(CH_2CH_2NMe)_3M]_2$ [M = Al (**2**), Ga (**3**)].[7] This is supported by the appearance of three singlets for the Me groups and 12 partially overlapping multiplets for each of the non-equivalent hydrogens of six methylene groups for both atrane moieties in the ^1H NMR spectrum

of **1**. Nine signals of the atrane skeleton were found in the ^{13}C NMR spectrum of **1**; however, according to Verkade et al. NMR spectroscopy alone is not suitable for the unambiguous attribution of a cis or a trans structure to the $(In-N)_2$ core.[5]



Scheme 1

The dimeric structure of **1** in the solid state was established by an X-ray diffraction study. The molecular structure of **1**·0.5toluene (one of two independent molecules) is shown in Figure 1. Important atomic distances and bond angles are summarised in Table 1. Similarly to both **2** and **3** (M = Al, Ga) molecules of **1** possess a conformation of type **A**, which is unusual for solid-state structures of Group 13 elements.[9] The central $(In-N)_2$ units are non-planar for both independent molecules and form a puckered rectangle (153.0° and 151.1°) with a pseudo-twofold axis through its centre, analogously to both **2** and **3**. The coordination polyhedron of the indium atoms in **1** is a distorted trigonal bipyramid (**C**, Scheme 1).

The transannular bonded nitrogen atoms (N_{ax} and N^b_{ax}) are in axial positions and the covalently bonded nitrogen atoms (two of N_{eq}, and N^b_{eq}) in the equatorial sites. The indium atoms are displaced by 0.36−0.46 Å from a plane defined by the three equatorial nitrogen atoms towards the bridging nitrogen atom of another atrane part of the dimeric structure (N^b_{ax}). The $N_{ax}-In-N^b_{ax}$ angles [150.3(1)−157.77(9)°] are smaller than those for other closely related $[N(CH_2CH_2NMe)_3M]_2$ complexes [average:

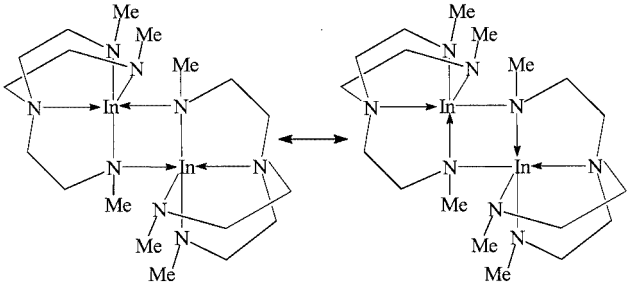
160.3°, M = Al (**2**) and 162.3°, M = Ga (**3**)].[7] It should be noted that in contrast to both **2** and **3**, there is an unusual set of In−N distances in **1** (Table 1). It is very surprising that the transannular bond lengths In(1)−N(4) and In(1)−N(14) are similar to the values of In−N covalent bonds found in monomeric indium amides [2.02(1)−2.166(4) Å][10,11] and, to the best of our knowledge, these are the shortest transannular In−N distances found to date. Other values of transannular In−N distances in **1** are within the typical range [2.20−2.62 Å],[12,13] although the In(4)-N(43) distance is rather long. Interestingly, values for $In\leftarrow N_{ax}$ distances of three known indium atranes investigated are 2.39(1) Å for $N(CH_2CH_2S)_3In$,[14] 2.386(6) Å for $N(CH_2$-*o*-C_6H_4-$S)_3In$·1-Me-imidazole, 2.345(9) Å for $N(CH_2$-*o*-C_6H_4-$S)_3In$·DMF, and 2.29(1) Å for $N[2\text{-}CH_2$-$(4,6\text{-}Me_2C_6H_2)$-$O]_3In$·$(1\text{-Me-imidazole})_2$.[15]

The nonbridging covalent distances $In-N_{eq}$ in compound **1** are within the range 1.960(3)−2.350(3) Å and are therefore markedly different from those found in indium tris(amides) [2.049(1)−2.130(4) Å].[16,17] In a similar manner, the bridging covalent bonds $In-N^b_{eq}$ in compound **1** also vary from 2.073(2) Å to 2.456(3) Å, the previously reported values lie in the range 2.199(7)−2.305(3) Å.[12,18]

The geometry of the N_{ax} atoms is a distorted tetrahedron with $C-N_{ax}-C$ and $C-N_{ax}-In$ angles ranging from 97.0(2)° to 121.0(3)° for **1**. The same situation was observed for N^b_{eq} [$C-N_{ax}-C$ and $C-N_{ax}-In$: 89.1(1)−121.6(2)°]. The environment of the nonbridged N_{eq} is a pyramid with a sum of bond angles from 334.9° to 352.6°. All five-membered rings of the atrane skeleton in **1** adopt an "envelope"-like conformation. For both **1** and **3**, all carbon atoms in the β-positions to the N_{ax} atom occupy "flap" sites, while the C-α atoms form the base of these envelope planes.

In order to get a better understanding of the structural trends for compound **1** we have carried out a computational study on **1** using the Gaussian 98W program.[19,20] A geometry optimisation of *cis*-**1** leads to the expected parameters of the coordination environment at the indium atoms. Both calculated $N_{ax}-In-N^b_{ax}$ angles (154.9 °) are in good agreement with our X-ray data. The calculated $In\leftarrow N_{ax}$ distances (2.342 Å) are appreciably longer than those in $In\leftarrow N^b_{ax}$ (2.179 Å) and especially than those of covalent

bonds: In−N^{b}_{eq} (2.293 Å) and In−N_{eq} (2.043 and 2.030 Å). Thus, the unusual geometry of the indium atoms in the solid state is probably due to a strong influence of crystal field forces, as is normal in atrane structural chemistry.[21] However, it should be noted that compound **1** may exist as two mesomeric forms (Scheme 2), which could also be a possible reason for the unusual geometry of **1**.



Scheme 2

Conclusion

We have presented the synthesis of *N*,*N*′,*N*′′-trimethylazaindatrane (**1**). Its dimeric structure was confirmed by X-ray diffractometry and by ^{1}H and ^{13}C NMR spectroscopy. The In−N distances in the solid state for this compound show an unusual variety. Further studies on the synthesis of azaindatranes and an investigation of their structure are in progress.

Experimental Section

General Remarks: All manipulations were performed under a dry, oxygen-free argon atmosphere using standard Schlenk techniques. Solvents were dried by standard methods and distilled prior to use. The starting materials Me_3-tren[22] and $[In(NEt_2)_3]_2$ [23] were prepared according to the literature procedures. C_6D_6 was obtained from Deutero GmbH and dried over sodium. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AC 300 spectrometer. ^{1}H and ^{13}C chemical shifts are reported in ppm relative to Me_4Si as external standard.

***N*,*N*′,*N*′′-Trimethylazaindatrane Dimer (1):** A solution of Me_3-tren (1.92 g, 10.20 mmol) in 15 mL of toluene was added dropwise via cannula within 10 min to a solution of $[In(NEt_2)_3]_2$ (3.38 g, 10.20 mmol) in 15 mL of toluene at room temperature. The reaction mixture was stirred for 48 h and then all volatiles were removed under reduced pressure. The crude product was washed with *n*-pentane (3 × 10 mL). After recrystallisation (toluene/*n*-pentane) **1** (2.23 g, 73%) was obtained as colourless crystals. ^{1}H NMR (C_6D_6, 300.130 MHz): δ = 1.73−3.54 (m, 24 H, $12CH_2$), 2.75 (s, 6 H, $2CH_3$), 3.26 (s, 6 H, $2CH_3$), 2.32 (s, 6 H, $2CH_3$) ppm. ^{13}C NMR (C_6D_6, 75.47 MHz): δ = 42.03, 44.61, 45.56 (CH_3); 48.72, 53.03, 53.34, 54.13, 54.20, 55.90 (CH_2) ppm.

X-ray Crystallographic Study

Crystal Data for 1: $C_{43}H_{93}In_4N_{16}$, M = 1293.61, triclinic, a = 12.4845(7), b = 15.3700(8), c = 15.1624(10) Å, α = 78.938(5), β = 85.708(5), γ = 76.988(4)°, V = 2780.6(3) Å^3, space group $P\bar{1}$, Z = 2, d_{calc} = 1.545 g·cm^{-3}, F(000) = 1318, μ(Mo-K_α) = 1.682 mm^{-1}, colourless block with dimensions ca. 0.45 × 0.45 × 0.30. Total of 36385 reflections (11919 unique, R_{int} = 0.0449) were measured on a Stoe IPDS diffractometer (graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å) at 193(2) K. Data were collected in the range 1.68 < θ < 30.50 (−15 ≤ h ≤ 15, −19 ≤ k ≤ 19, −19 ≤ l ≤ 19). The structure was solved by direct methods[24] and refined by full-matrix least-squares on F^2 [25] with anisotropic thermal parameters for all non-hydrogen atoms. All H atoms were placed in calculated positions and refined using a riding model. The final residuals were: R_1 = 0.0271, wR_2 = 0.0808 for 10623 reflections with I > 2σ(I) and 0.0323, 0.0940 for all data and 607 parameters. Goof = 1.101, maximum shift/e.s.d. = 0.002, maximum Δρ = 0.685 e·Å^{-3}. CCDC-194359 contains the supplementary crystallographic data for this paper. Sequential Nucleophilic−Electrophilic Reactions Selectively Produce Isomerically Pure Nona-*B*-Substituted *o*-Carborane Derivatives

Gemma Barberà,[a] Francesc Teixidor,[a] Clara Viñas,*[a] Reijo Sillanpää,[b] and Raikko Kivekäs[c]

Keywords: Boron / Clusters / Iodinated compounds / Methylated compounds / Electrophilic reactions

Nine equal substituents on the intensively studied *o*-carborane have been obtained for the first time by a combined nucleophilic-electrophilic reaction sequence. Iodine and methyl groups have been introduced to prove the generality of the method.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

During the last decade there has been a great deal of interest in introducing a large number of substituents on boron in icosahedral boranes and heteroboranes.[1−6] The possibility of generating weakly coordinating anions,[3,6,7] X-ray contrast agents,[8] camouflaged boron clusters,[5] the attainment of molecules comparable in size to C_{60} [9] and the generation of stable radicals[4] are some of the goals that have stimulated this research. Substitutions have been achieved with a good degree of success for cluster anions, but there are few examples for the dicarbaboranes. This is surprising considering that the chemistry of the latter has become one of the most intensively investigated areas in the field of boranes and heteroboranes.[10] The paucity of reported examples is in agreement with the relative rates of halogenation, which decrease in the order $[B_{12}H_{12}]^{2-} > [CB_{11}H_{12}]^{-} > C_2B_{10}H_{12}$.[11] Thus, methods to introduce substituents on the well studied *o*-carborane cluster need to be investigated. The *o*-carborane, 1,2-dicarba-*closo*-dodecaborane, contains four distinct types of boron atoms that may be ordered according to their distance from the C atoms, with B(9,12) being the farthest away, followed by B(8,10), B(4,5,7,11), and B(3,6), which are adjacent to both carbon atoms. Those farthest from the carbon atoms are the more electron-rich and those closest are the more electron-poor. It is generally accepted that icosahedral carboranes are aromatic[12] and undergo electrophilic substitution reactions, making this method attractive for the introduction of iodine into the cage molecules.[10] Whereas perfluorination[13] and perchlorination[14] of dicarbaboranes has been achieved, perbromination has not been accomplished. Indeed, only a maximum of four bromine atoms have been incorporated in dicarboranes to date. Periodination of *o*-carborane has not been achieved. Before 1996 the maximum number of iodines in *o*-carborane was two, occupying the 9- and 12-positions.[1,15] Little information exists on higher substitution although reference has been made to 8,9,10,12-tetraiodo-*o*-carboranes.[16] Major progress was recently achieved with the synthesis of the eight iodine 4,5,7,8,9,10,11,12-octaiodo-1,2-dicarba-*closo*-dodecaborane.[8] The carbons adjacent to the B(3,6) positions are resistant to electrophilic methods, although with the extremely powerful electrophiles F^+ and Cl^+ full substitution has been achieved. However, with the milder electrophiles Br^+ and I^+ this has not been possible.

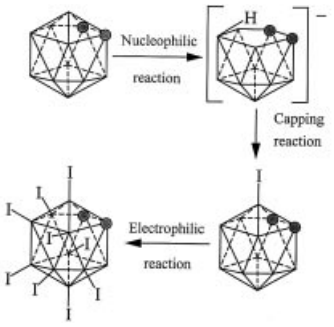
Results and Discussion

We based our work on the hypothesis that the first introduced group in the cluster determines the subsequent reactivity of the cluster towards further substitution causing, in cases such as the reaction of *o*-carborane with mild electrophiles, persubstitution to be impossible. To attain such substitution more than one type of reaction is necessary: an

electrophilic reaction for the electron-rich boron atoms and a nucleophilic reaction for the electron-poor B(3,6) atoms. With this aim, we devised the sequence of reactions shown in Scheme 1.



Scheme 1. Synthesis of 3,4,5,7,8,9,10,11,12-nonaiodo-1,2-dicarba-*closo*-dodecaborane (*closo*-**1**) from *o*-carborane

The first step consists of producing 3-I-1,2-$C_2B_{10}H_{11}$. This is achieved by a nucleophilic reaction to remove one boron adjacent to the two carbon atoms followed by a capping reaction with BI_3 to give 3-I-1,2-$C_2B_{10}H_{11}$.[1] The next step consists of an electrophilic reaction with $AlCl_3$ and CH_3I. The presence of one B(3)−I will provide information on the susceptibility of the second boron, B(6), adjacent to both carbons, to electrophilic attack.

In a typical experiment 3-I-1,2-$C_2B_{10}H_{11}$ (3.7 mmol) was mixed with triflic acid[17] (66.5 mmol) and ICl (6.0 mL, 111 mmol). Following heating at 90 °C for three days, and after workup, a 94% yield of 3,4,5,7,8,9,10,11,12-nonaiodo-1,2-dicarba-*closo*-dodecaborane (*closo*-**1**) was obtained. The $^{11}B\{^1H\}$ NMR shows a 2:1:1:1:2:2:1 pattern spanning from δ = −4.2 to −22.1 ppm. Only the resonance at δ = −11.1 ppm, of intensity 1, shows splitting due to proton coupling in the ^{11}B NMR spectrum, indicating that all of the boron atoms, except B(6), have an exo-cluster iodine substituent. This was confirmed by X-ray diffraction analysis of *closo*-**1**·EtOAc (Figure 1).[18] Consequently, the pre-introduced B(3)−I does not labilize B(6)−H.

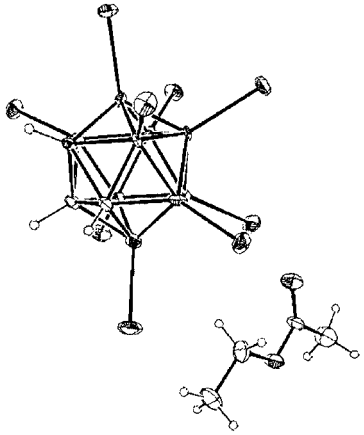


Figure 1. Perspective view of *closo*-**1**·EtOAc with 30% ellipsoids; H atoms have been omitted for clarity; selected bond lengths (Å): C(1)−C(2) 1.637(14), B−I 2.113(6)−2.166(11)

The method is successful for mildly electron-withdrawing elements, posing the question: could it be applicable for the introduction of Me substituents?

A good target was the long sought after 3,4,5,7,8,9,10,11,12-nonamethyl-1,2-dicarba-*closo*-dodecaborane (*closo*-**2**). The strategy for its synthesis was also a combination of nucleophilic and electrophilic attacks, the first producing 3-CH_3–1,2-$C_2B_{10}H_{11}$,[19] followed by reaction with $AlCl_3$ and CH_3I at reflux temperature for two days to produce *closo*-**2** (98%) after subsequent workup. The $^{11}B\{^1H\}$ NMR spectrum shows a 2:1:1:5:1 pattern indicating the geometrical similarity of *closo*-**1** and *closo*-**2**. The B(6) resonance is observed at δ = −17.16 ppm and again shows an exo-terminal proton coupling. As before, the pre-introduced B(3)−CH_3 does not labilize B(6)−H, thus maintaining the *closo* structure.

Conclusion

To summarize, a combined nucleophilic and electrophilic sequential process has allowed for the first time the introduction of nine equal substituents onto the well-studied *o*-carborane species. Iodine and methyl groups have been introduced to prove the generality of the method.

Experimental Section

General Remarks: Elemental analyses were performed using a Carlo Erba EA1108 microanalyser. IR spectra were recorded from KBr pellets on a Shimadzu FTIR-8300 spectrophotometer. ^1H and $^1H\{^{11}B\}$ NMR (300.13 MHz), $^{13}C\{^1H\}$ NMR (75.47 MHz) and ^{11}B NMR (96.29 MHz) spectra were recorded with a Bruker ARX 300 instrument equipped with the appropriate decoupling device. Chemical shift values for ^{11}B NMR spectra were referenced to external $BF_3{\cdot}OEt_2$ and those for ^1H, $^1H\{^{11}B\}$ and $^{13}C\{^1H\}$ NMR spectra were referenced to $SiMe_4$. Chemical shifts are reported in units of parts per million downfield from the reference with all coupling constants in Hz.

Unless otherwise noted, all manipulations were carried out under a dinitrogen atmosphere using standard vacuum line techniques. Iodine monochloride, aluminium trichloride and triflic acid were purchased from Aldrich.

***closo*-1:** Triflic acid (10.0 g, 66.5 mmol) and then ICl (6.0 mL) were added, under nitrogen flow, to 3-iodo-1,2-dicarba-*closo*-dodecaborane (1.0 g, 3.7 mmol). The mixture was heated at 90 °C for three days and then allowed to cool to room temperature. Cold water (10 mL) and then aqueous $NaHSO_3$ were added to the mixture. The resultant precipitate was filtered and then immediately dissolved in 125 mL of hot EtOAc and Zn added until the solution became colourless. The colourless solution was filtered and the solvent evaporated with a water pump. The solid obtained was recrystallized from EtOAc. (4.5 g, 94% yield). $C_2H_3B_{10}I_9$ (1277.1): calcd. C 1.88, H 0.23; found C 1.97, H 0.20. IR: $\tilde{\nu}$ = 3012 ($C_{cluster}$-H), 2650 (B-H) cm^{-1}. ^1H NMR (CD_3COCD_3): δ = 6.98 (br. s, $C_{cluster}$-H, B-H) ppm. ^{11}B NMR (CD_3COCD_3): δ = −4.2 (s, 2B), −9.7 (s, 1B), −11.1 [1B, B(6)], −12.6 (s, 1B), −17.2 (s, 2B), −20.3 (s, 2B), −22.1 (s, 1B) ppm. $^{13}C\{^1H\}$ NMR (CD_3COCD_3): δ = 72.5 (s, $C_{cluster}$) ppm. MALDI-TOF-MS: *m*/*z* = 1277.0 [M^+]. The $^1H\{^{11}B\}$

NMR of crystals of *closo*-**1**·EtOAc was run in CD_3COCD_3: δ = 6.98 (d, $^3J_{H,H}$ = 3.8 Hz, 2 H, $C_{cluster}$-H), 6.98 (br. s, 1 H, B-H), 4.06 (q, $^2J_{H,H}$ = 7.1 Hz, 2 H, CH_2), 3.54 (s, 3 H, CH_3), 1.20 (t, $^2J_{H,H}$ = 7.1 Hz, 3 H, CH_3) ppm.

***closo*-2:** MeI (6.4 mL) was added to a mixture of 3-methyl-1,2-dicarba-*closo*-dodecaborane (0.7 g, 4.4 mmol) and $AlCl_3$ (1.2 g, 8.8 mmol). The mixture was refluxed for 2 days after which the unchanged MeI was distilled off. The residue was hydrolyzed and extracted with pentane. The combined organic phases were treated with $Na_2S_2O_3$ and dried over $MgSO_4$. The final compound was purified by flash silica gel chromatography using pentane as the eluting solvent to give 3,4,5,7,8,9,10,11,12-nonamethyl-1,2-dicarba-*closo*-dodecaborane. (1.2 g, 98% yield). $C_{11}H_{30}B_{10}$ (270): calcd. C 48.89, H 11.11; found C 48.98, H 11.25. IR: $\tilde{\nu}$ = 3056 ($C_{cluster}$-H), 2945, 2905, 2833 (C-H), 2590 (B-H) cm^{-1}. $^1H\{^{11}B\}$ NMR ($CDCl_3$): δ = 0.32 (br. s, 3 H, CH_3), 0.13 (br. s, 6 H, CH_3), 0.05 (br. s, 6 H, CH_3), 0.01 (br. s, 3 H, CH_3), −0.12 (br. s, 3 H, CH_3), −0.23 (br. s, 6 H, CH_3), 2.89 (d, $^3J_{H,H}$ = 43 Hz, 2 H, $C_{cluster}$-H), 1.86 (br. s, 1 H, B-H) ppm. ^{11}B NMR ($CDCl_3$): δ = 5.4 (s, 2B), −2.1 (s, 1B), −4.2 (s, 1B), −8.8 (s, 5B), −17.2 (d, $^1J_{B,H}$ = 161 Hz, 1B) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = −3.02 (br., CH_3), 54.25 (s, $C_{cluster}$) ppm. MALDI-TOF-MS: *m*/*z* = 270.1 [M^+].

X-ray Crystallographic Study: CCDC-185388 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

A Three-Dimensional Framework of Novel Vanadium Clusters Bridged by $[Ni(en)_2]^{2+}$: $Ni(en)_3\{V^{IV}_{11}V^{V}_{5}O_{38}\ Cl\ [Ni\ (en)_2]_3\}\cdot 8.5H_2O$

Keywords: Polyoxometalates / Hydrothermal synthesis / Cluster compounds / Crystal structure

The hydrothermal reaction of V_2O_5, $H_2C_2O_4\cdot 2H_2O$, KOH, en and $NiCl_2\cdot 6H_2O$ yields a new three-dimensional open-framework solid. The extended structure consists of a three-dimensional network of $[V_{16}O_{38}Cl]^{8-}$ cages, with each cage connected to six other neighboring units through $[Ni(en)_2]^{2+}$ bridging groups.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

The systematic construction of specific architectures from molecular building blocks has been an area of active research over the past few years.[1] Examples range from coordination polymers [2] to larger cluster-based building blocks.[3] The mechanism of the formation of polyoxometalates (POMs) is still not yet fully understood and is often described as self-assembly. What appears to be evident in exploiting suitable molecular building blocks is to employ polyoxoanions linked through some kinds of tethers to form extended structures. While a synthetic method leading to rational design remains a challenging topic, there seems to be an increasing use of a combination of hydrothermal synthesis and structure-directing templates. Small changes in the synthetic technique, such as solvent, pH value or counterion, can lead to different products.[4] However, once structure principles are recognized, the synthesis of targeted species can be designed, as has been demonstrated by the work of Müller and co-works with the large polymolybdates. Zubieta and co-workers have reported one- and two-dimensional polymeric oxometalates in several organic-inorganic hybrid materials.[3a] On-going research has demonstrated that transition metal (e.g. Fe, Co, Ni, Cu, Zn, and Mn) coordination complexes may serve as inorganic bridging ligands linking polyanion clusters into one-, two- and three-dimensional networks.[5]

POMs are an important subclass of metal oxide cluster with an exceptional capacity to form mixed-valence compounds that exhibit rich electronic and magnetic properties and have relevance to catalysis, medicine, and in materials science.[6] Polyoxovanadates have been extensively studied, with many structurally characterized examples now known, such as $[V_4O_{12}]^{4-}$, $[V_5O_{14}]^{3-}$, $[V_6O_{19}]^{8-}$, $[V_{10}O_{28}]^{6-}$, $[V_{12}O_{32}]^{4-}$, $[V_{13}O_{34}]^{3-}$, $[V_{15}O_{36}]^{5-}$, $[V_{15}O_{42}]^{9-}$, $[V_{17}O_{42}]^{4-}$ and $[V_{18}O_{42}]^{12-}$, $[V_{19}O_{49}]^{9-}$ and $[V_{34}O_{82}]^{10-}$.[7] Although polyoxovanadate clusters emerging as discrete ions are common, synthetically prepared examples of extended structures with polyoxoanions are relatively rare. Some new mixed-valance vanadium oxide layers have also been observed in $[Ni(en)_2][V_6O_{14}]$,[8] $[Zn(en)_2][V_6O_{14}]$, $[Cu(en)_2]$-$[V_6O_{14}]$, $[Cu(en)_2][V_{10}O_{25}]$[9] and $[Cd(enMe)_2][V_8O_{20}]$.[10] Khan et al. have reported several three-dimensional frameworks which consist of spherical $[V_{18}O_{42}\ (XO_4)]$ clusters linked by bridging $[M(H_2O)_4]$ groups (X: V, S; M: Fe, Co, Mn, Zn).[5a] At present, we are making a systematic investigation of POMs of group V transition elements for finding the best strategies to design and synthesize metal oxide clusters with new structures. Here, we report an entirely new type of mixed-valence ion $[V_{16}O_{38}Cl]^{8-}$ as a building block, which is bridged by $[Ni(en)_2]^{2+}$ leading to the three-dimensional network $Ni(en)_3\{V^{IV}_{11}V^{V}_{5}O_{38}Cl[Ni(en)_2]_3\}\cdot 8.5H_2O$ (**1**). As far as we are aware, compound **1** is composed of a new type of mixed-valance vanadium-oxygen cluster $[V_{16}O_{38}Cl]^{8-}$ as structural motif, unlike most of the known materials with extended structures, which are composed of well-characterized metal-oxygen cluster types.

The X-ray structure analysis reveals that the extended structure of **1** (Figure 1), consists of a three-dimensional network of $[V_{16}O_{38}Cl]^{8-}$ cages, with each cage connected to six other neighboring units through $[Ni(en)_2]^{2+}$ bridging groups. This generates a network of $\{$-$[V_{16}O_{38}Cl]$-$[Ni(en)_2]$-$[V_{16}O_{38}Cl]$-$\}_n$ arrays running along two mutually non-perpendicular directions, so the overall topology of the six-connected network is simple cubic. The building block in the structure of **1** may be viewed as a "rugby ball"-like $[V_{16}O_{38}Cl]$ shell encapsulating a Cl^- ion at its center, as has been reported by Müller in the polyoxovanadate $[V_{15}O_{36}Cl]^{6-}$.[7g] Indeed, an unusual property of reduced polyoxovanadates is their tendency to form cages encapsulating a guest atom. To the best of our knowledge, there

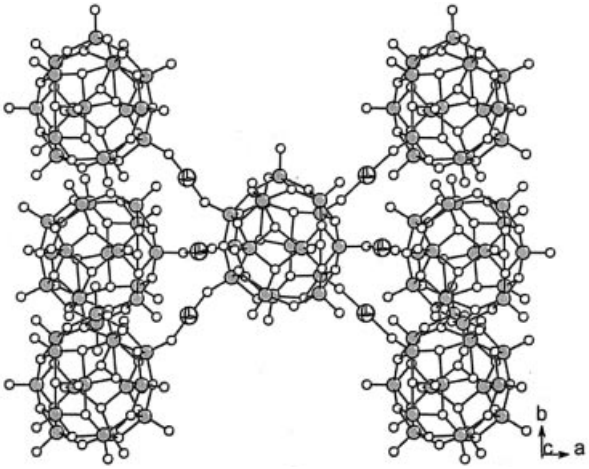

Figure 1. View of the extended structure of $Ni(en)_3\{V_{16}O_{38}Cl[Ni(en)_2]_3\}\cdot 8.5H_2O$, showing nets of $[V_{16}O_{38}Cl]$ clusters interconnected through $[Ni(en)_2]^{2+}$ bridging groups like reticular framework; H_2O, Cl^-, en and $[Ni(en)_3]^{2+}$ groups have been omitted for clarity

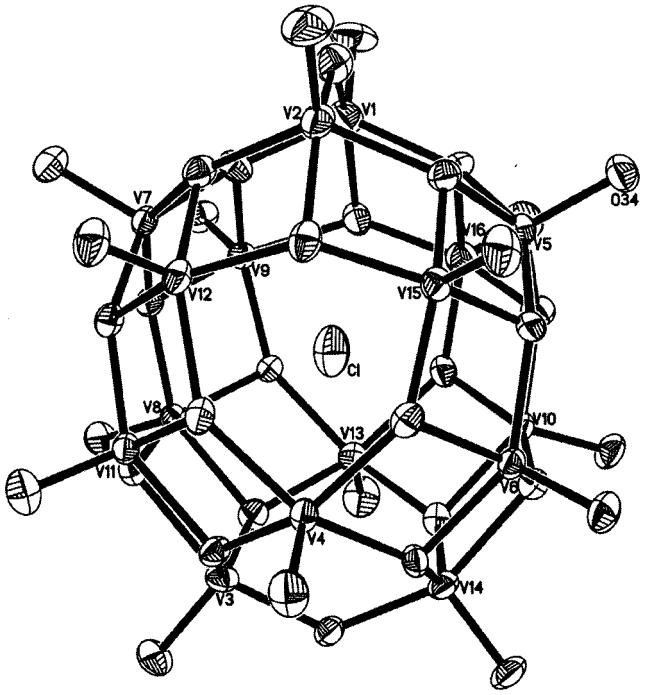

Figure 2. Structure of the $[V_{16}O_{38}Cl]^{8-}$ anion showing a novel cage; selected distances (Å) are as follows: V−O_t 1.584(6)−1.619(6), V−μ_2-O(−Ni) 1.620(5)−1.641(6), V−μ_2-O(−V) 1.760(6)−1.898(7), V−μ_3-O 1.846(5)−2.242(5), Ni−O 2.062(6)−2.131(6)

are no examples where a $[V_{16}O_{38}Cl]$ cage forms a three-dimensional network by $[Ni(en)_2]^{2+}$ bridging.

The $[V_{16}O_{38}Cl]^{8-}$ unit is a novel type of polyoxovanadate cage, as shown in Figure 2. The new vanadium exhibits only one type of coordination i.e. pyramidal. The host shell is made up of 16 VO_5 square pyramids sharing edges through 20 μ_3-oxygen atoms, 8 μ_2-oxygen atoms, and 10 μ_1-oxygen atoms. All the average bond lengths in the cluster are within normal ranges.[7] Fivefold-coordinated VO_5 units are interconnected to form polyoxovanadate $[V_{16}O_{38}]$ units, and the environment around V1 is defined by three μ_3-oxygen groups, a μ_2-O, and an apical O1 moiety. Interestingly, O34 is also bonded to the Ni center of one of the six $Ni(en)_2$ bridges that interlink the other $[V_{16}O_{38}Cl]^{8-}$ clusters; the six-coordination of Ni^{2+} is completed by four N and two O atoms. Furthermore, each surface of the cluster supports six $[Ni(en)_2]^{2+}$ groups which connect different cages by μ_2-oxygen, leading to a three-dimensional network. To the best of our knowledge, the $[V_{16}O_{38}Cl]^{8-}$ cluster in **1** is the first observation of a hexadecavanadium structure containing an included Cl^- anion.

The assignment of the oxidation state of the vanadium is consistent with the coordination geometry and was confirmed by bond valence sum calculations (BVS).[11] The room temperature EPR spectrum of a crystalline sample of compound consists of one signal ($g = 2.002$), indicating the presence of V^{IV}. According to bond valence sum calculations and charge balance, compound **1** is formulated as $Ni(en)_3\{V^{IV}_1V^{V}_5O_{38}Cl[Ni(en)_2]_3\}\cdot 8.5H_2O$.

Each terminal oxygen of the six VO_5 pyramids (V5−V10) in compound **1** is linearly bonded to the nickel(II) center, in contrast to the $[M(en)_2][V_6O_{14}]$ (M = Cu, Zn)[9] structures where the V=O oxygen atoms of the VO_4 tetrahedron are bonded to the metal cations. The octahedral geometry around each nickel is completed by two en groups. The bridging Ni^{2+} ions exhibit strong covalent attachments to the two adjacent clusters with an average Ni−O distance of 2.087 Å, which is much shorter than that in $[M(en)_2][V_6O_{14}]$ (Cu−O: 2.53 Å; Zn−O: 2.54 Å).

The structure of highly reduced polyoxovanadate bridged by $[Ni(en)_2]^{2+}$ in the compound allows us to predict the existence of magnetic exchange coupling. The variable temperature magnetic susceptibility of **1** was measured between 5 and 300 K. The effective magnetic moment of **1** at room temperature (300 K), determined by the equation $\mu_{eff} = 2.83(\chi_M T)^{1/2}$, where χ_M is the molar magnetic susceptibility per formula unit, is 8.72 μ_B, and is therefore smaller than the value expected for the total spin-only value of 11 uncoupled $S = 1/2$ spins of V^{4+} atoms and four uncoupled $S = 1$ spins of Ni^{2+} atoms. Figure 3 shows that the effective magnetic moment of **1** increases as the temperature decreases from 300 to 14 K, which is in agreement with a Weiss constant of $\theta > 0$, indicating the presence of a weak ferromagnetic exchange interaction in compound **1**. In the range 14−5 K, the effective magnetic moment decreases with the temperature decreasing, showing there is antiferromagnetic coupled interaction in **1** in this temperature range. Because no suitable theoretical model is available in the literature[12] for such a complex system, further studies on the magnetic properties of similar systems are ongoing in our lab.

Hydrothermal techniques exploit the principle of "self-assembly" of a metastable solid phase from soluble precur-

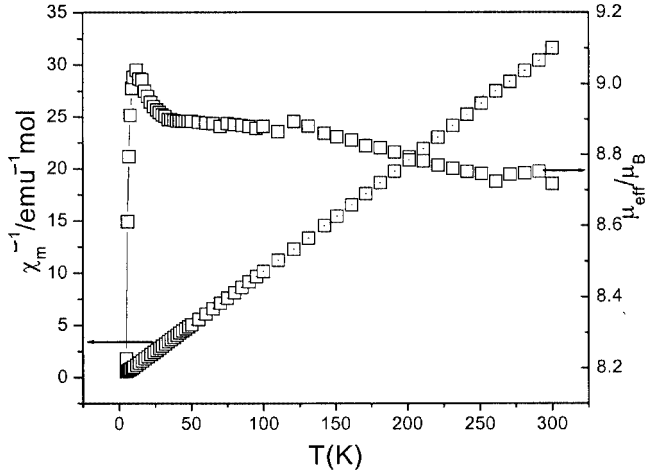

Figure 3. A plot of the effective magnetic moment μ_{eff} and inverse molar susceptibility vs. temperature for compound **1**

sors.[5b] Complex **1** is synthesized from V_2O_5 by exploiting the reducing ability of $H_2C_2O_4{\cdot}2H_2O$ and en. The presence of $H_2C_2O_4$ and en are absolutely essential for product formation. Under more reducing conditions the fully reduced V^{IV} clusters are isolated. V^{IV} and V^{IV}/V^{V} clusters are cryptands and tend to form spherical structures. This feature is evident in the class of reduced and mixed-valence polyoxovanadates described by Zubieta et al.[13] However, this result may originate from the nature of the transition metal ions employed. The nickel ion favors a six-coordinate octahedral geometry. It should be noted that the pH value of the starting mixture has a big influence on the resulting products. Crystals of **1** can only be prepared in a system with pH values in the range from 8.5 to 9.5. The Ni−O−V linkages play a critical role in constructing the chain structure. Although the architecture of a one-, two- and three-dimensional network could not be predicted, we managed to synthesize the compound and obtain high productivity.

Experimental Section

Synthesis of 1: The raw materials used in the synthesis are V_2O_5, $H_2C_2O_4{\cdot}2H_2O$, KOH, $NiCl_2{\cdot}6H_2O$, en, and distilled water. In a typical synthesis of compound **1**, 0.82 g of V_2O_5, 0.5 g of KOH and 1.24 g of $H_2C_2O_4{\cdot}2H_2O$ were first added to 12 mL of distilled water, and then 0.95 g of $NiCl_2{\cdot}6H_2O$ and 0.8 mL of en were added whilst stirring. The reaction mixture, with a pH value about 9.0, was sealed in a 20 mL Teflon-lined autoclave and heated under autogenous pressure at 160 °C for four days. The crystalline product was filtered, washed with distilled water, and dried at ambient temperature to give 0.46 g of **1**. IR: 1582(s) cm^{-1}, 1458(m), 1394(w), 1369(w), 1327(w), 1277(w), 1142(w), 1103(w), 1022(s), 967(s), 650(s), 512(s). $C_{18}H_{89}ClN_{18}Ni_4O_{46.5}V_{16}$ (2387.4): C 9.05, H 3.73, N 10.56; found C 7.36, H 2.08, N 12.94. The TGA of **1** showed that water is lost first, followed by the en molecules in the range 250−469 °C, and a weight gain at 469−583 °C, consistent with the oxidation from V^{IV} to V^{V}.

X-ray Crystallography: Crystal data for $C_{18}H_{89}ClN_{18}Ni_4O_{46.5}V_{16}$, dimensions 0.52 × 0.46 × 0.42 mm, monoclinic, space group $P2_1/n$, a = 21.953(4), b = 15.896(3), c = 25.086(5) Å, β = 109.39(3)°, V = 8258(3) Å^3, Z = 4, Dc = 1.920 g/cm^3, μ(Mo-K_α) = 2.726 mm^{-1}, T = 293(2) K, $R[I < 2\sigma(I)]$ = 0.0754] and the goodness-of-fit on F^2 is 1.007.

An Unusual Bonding Situation in a Novel Au^I-Phosphido Complex with a Planar Au_3P_3 Framework

Ulf Vogel,[a] Perumal Sekar,[a] Reinhart Ahlrichs,[b] Uwe Huniar,[b] and Manfred Scheer*[a]

Dedicated to Professor A. Zschunke on occasion of his 65th birthday

Keywords: Metathesis / Cyclopentadienyl ligands / Chromium / P ligands / Gold

Reaction of the mono-deprotonated derivative of $[\{Cp(CO)_2Mo\}_2(\mu\text{-}PH_2)(\mu\text{-}H)]$ (**1**) leads to the novel complex $[\{Cp(CO)_2Mo\}_2(\mu\text{-}H)\{\mu_3\text{-}P(H)Au(PPh_3)\}]$ (**2**). In contrast the reaction of the analogous Cr derivative $[\{Cp(CO)_2Cr\}_2(\mu\text{-}PH_2)(\mu\text{-}H)]$ (**1a**) leads under identical conditions to a planar Au_3P_3 cluster $[\{CpCr(CO)_2\}_6(P_3Au_3)]$ (**3**). Both complexes were completely structurally and spectroscopically characterised. Density functional calculations have shown that **3** is characterised by P–Cr–Au multicentre and Cr-P multiple bonding.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Polynuclear Au^I complexes are a fascinating field of chemistry[1] as there are, for example, planar, wheel-like mixed metal clusters of the type $[M\{Au(mes)\}_5]X$ (M = Cu, Ag; X = PF_6, ClO_4; mes = 2,4,6-trimethylphenyl)[2] and the larger class of chalcogenido-bridged clusters.[3] Among the latter ones are compounds possessing luminescence properties.[4] However, phosphanido (R_2P^-) substituted Au^I complexes are rare,[5] and for Au^I complexes containing the phosphido (P^{3-}) ligand, only the series of phosphorus-centred homoleptic gold clusters of Schmidbaur et al. exists. These complexes — $P(AuPR_3)_4^+$, $P(AuPR_3)_5^{2+}$, $P(AuPR_3)_6^{3+}$, $(R_3P)_2AuP(AuPR_3)_4^{2+}$, $(R_3PAu)_4PAuP(AuPR_3)_4^{3+}$ — were synthesized by the reaction of PH_3 or $P(SiMe_3)_3$ and $P_2(SiMe_3)_4$, respectively, with R_3PAu^+.[6] Interestingly, due to their instability no X-ray structural analysis exists so far for the tetrahedrally coordinated phosphido complex of the monocation $P(AuPR_3)_4^+$.

Lately, an unusual route to naked[7] phosphorus-containing ligands was presented by Mays et al., who reacted $[\{Cp(CO)_2Mo\}_2(\mu\text{-}PH_2)(\mu\text{-}H)]$ (**1b**)[8] with group 15 trichlorides ECl_3 (E = P, As, Sb) to form the novel mixed group 15 element-containing tetrahedrane complexes $[\{Cp(CO)_2Mo\}_2(\mu,\eta^2\text{-}PE)]$ by elimination of LiCl and HCl.[9] The chromium analogue $[\{Cp(CO)_2Cr\}_2(\mu\text{-}PH_2)(\mu\text{-}H)]$ (**1a**) had not been described in the literature until we found an efficient method for its synthesis by the reaction of $[\{Cp(CO)_2Cr\}_2(\mu,\eta^2\text{-}P_2)]$ with superhydride ($LiBEt_3H$).[10a] Herein we report on the remarkable differences in the reaction behaviour of the corresponding anions of **1a** and **1b** with the transition metal electrophile $[(Ph_3P)AuCl]$ and the formation of the first phosphido-containing mixed metal Au^I complex in an unusual multi-centre bonding situation.

Results and Discussion

Both neutral complexes **1a** and **1b** were converted into the corresponding anions under identical conditions using KH (Scheme 1). Subsequent reaction with $[(Ph_3P)AuCl]$ leads, in the case of the molybdenum complex **1b**, to substitution of a hydrogen atom by a $AuPPh_3$ moiety to form $[\{Cp(CO)_2Mo\}_2(\mu\text{-}H)\{\mu_3\text{-}P(H)Au(PPh_3)\}]$ (**2**). However, for the chromium homologue **1a** a rearrangement of the $[CpCr(CO)_2P]$ units is observed with formation of the novel trinuclear Au cluster **3** with a $Au_3Cr_6P_3$ core.

Complex **2** forms orange and **3** brown crystals, which are slightly soluble in hexane and readily soluble in toluene, CH_2Cl_2 and THF. In their IR spectra the CO stretching frequencies are observed in the typical range for terminal CO ligands. Additionally, a P−H stretching frequency is found for **2** at 2243 cm^{-1}. In the EI mass spectrum of **2** only characteristic fragment ion peaks could be detected, whereas for **3** no such fragments were found. Due to the quadrupolar moment of the ^{197}Au nucleus only two broad singlets at δ = 41.0 and 73.1 ppm are observed in the $^{31}P\{^1H\}$ NMR spectrum of **2** and one for **3** at δ = 38 ppm.

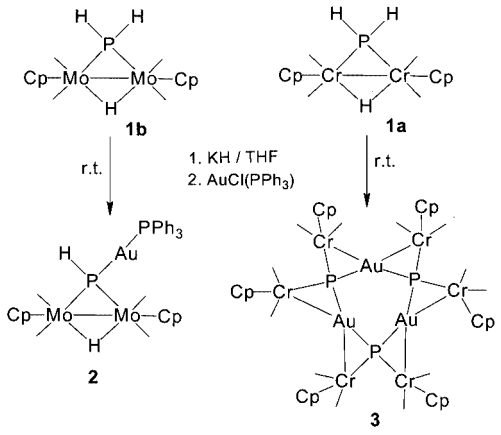

Scheme 1. Different reaction behaviour of dinuclear complexes [{$Cp(CO)_2M$}$_2$(μ-PH_2)(μ-H)] [M = Cr (**1a**), Mo (**1b**)] with $AuCl(PPh_3)$ (CO ligands are represented by bond lines)

The ^{1}H NMR spectrum of **2** shows a characteristic peak at high field ($\delta = -11.73$ ppm) for the bridging hydride ligand. This signal is split into a doublet due to the coupling with the phosphorus atom ($^2J_{H,P} = 29$ Hz). The PH proton also splits into a doublet which is detected at $\delta = 6.12$ ppm ($^1J_{H,P} = 282$ Hz). Two discrete singlets for the Cp protons at $\delta = 4.84$ and 5.04 ppm suggest a *trans* arrangement of the two Cp ligands as found in the solid-state structure of **2**.

The dinuclear [$Mo_2(CO)_4Cp_2$] fragment of **2** (Figure 1) is bridged by a hydrido and a PH($AuPPh_3$) ligand. The Au atom is almost linearly surrounded by its substituents (P1−Au−P2 179.15(7)°]. The Mo−Mo distance is 3.266(2) Å and is similar to that in the neutral complex **1b** [3.282(1) Å].[8b] The Mo−P bond lengths of 2.450(2) and 2.434(2) Å in **2** are only slightly longer than that in the starting material **1b** [2.402(1) Å]. The Au−P distances in **2** are almost identical [Au−P1 2.309(2) Å; Au−P2 2.324(2) Å]. Similar bond lengths are found in the structurally related compounds [$(CO)_8M_2$(μ-H)(μ_3-PCy)Au(PPh_3)] [M = Mn, Re; Cy = cyclohexyl; M = Mn: Au−P1 2.306(1) Å and Au−P2 2.317(1) Å; M = Re: Au−P1 2.313(4) Å, Au−P2 2.303(4) Å].[11]

The X-ray structure analysis of **3** (Figure 2) reveals a planar Au_3P_3 six-membered ring (mean deviation of the atoms from the plane: 0.077 Å), where each of the distorted tetrahedrally surrounded phosphido ligands are bound to two Au atoms as well as to two $CpCr(CO)_2$ moieties. The Au atoms by themselves form an isosceles triangle with the closest distances between the atoms Au2 and Au3 of 3.284(1) Å; the other distances are 3.454(1) and 3.482(1) Å indicating essentially no Au···Au interaction.[6,12] The Au−P bond lengths of **3** are between 2.405(4) Å and 2.440(4) Å and are therefore longer than those found in the square pyramidal-coordinated P atoms of $P(AuPR_3)_5^{2+}$ [13] [2.295(3) Å for the axial P−Au bond and 2.356(3)−2.379(3) Å for the other] and $(R_3PAu)_4PAuP(AuPR_3)_4^{3+}$ [14] [2.293(7) Å (axial) and 2.369(3) Å for the other]. The Au−Cr distances of **3** [2.707(2)−2.748(3) Å] are in the range of those distances found in linear-coordinated

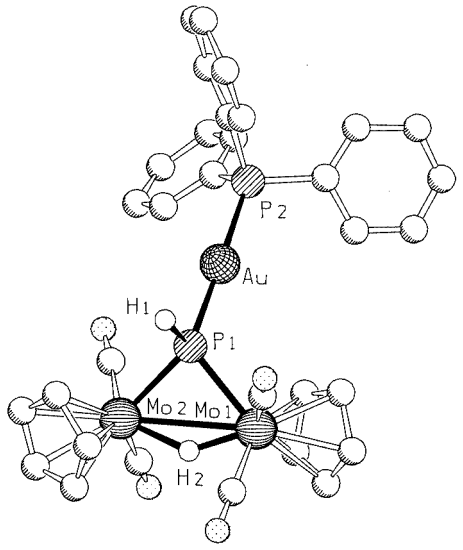

Figure 1. Molecular structure of **2**; hydrogen atoms of the Ph and Cp substituents are omitted for clarity; selected bond lengths [A] and angles [°]: Mo(1)−Mo(2) 3.266(2), Mo(1)−P(1) 2.434(2), Mo(2)−P(1) 2.450(2), Au−P(1) 2.309(2), Au−P(2) 2.324(2); P(1)−Au−P(2) 179.15(7), Mo(1)−P(1)−Mo(2) 83.92(7), Mo(1)−P(1)−Au 119.24(9), Mo(2)−P(1)−Au 127.7(1)

Au−$CrCp(CO)_3$-containing complexes.[15] Significant structural features of **3** are the very short Cr−P bond lengths of 2.135(5)−2.168(4) Å, which are much shorter than the average Cr−P bond lengths in the related complexes [{$Cp(CO)_2Cr$}$_2$(μ-PH_2)$_2$] (2.381 Å),[10b] [$(CO)_4CrP(CH_3)_2$]$_2$ (2.318 Å)[16] and in [{$Cp(CO)_2Cr$}$_2$(μ,η^2-P_2)] (2.409 Å),[17] [{$Cp(CO)_2Cr$}$_2$(μ,η^2-P_2){$Cr(CO)_5$}] (2.405 Å)[18] and [{$Cp(CO)_2Cr$}$_2$(μ,η^2-P_2){$Cr(CO)_5$}$_2$] (2.411 Å).[19] They are

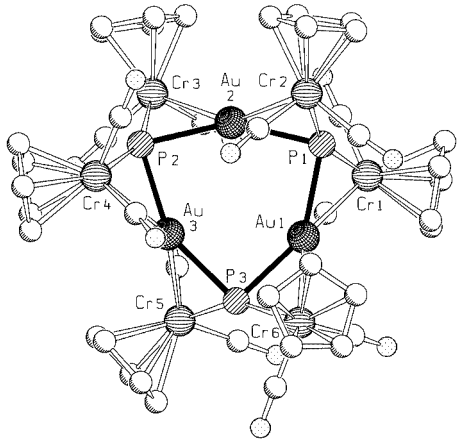

Figure 2. Molecular structure of **3**; hydrogen atoms are omitted for clarity; selected bond lengths [A] and angles [°]: Au(1)−P(1) 2.413(3), Au(1)−P(3) 2.405(4), Au(2)−P(1) 2.399(4), Au(2)−P(2) 2.382(4), Au(3)−P(2) 2.408(4), Au(3)−P(3) 2.440(4), Au(1)−Cr(1) 2.725(3), Au(1)−Cr(6) 2.723(3), Au(2)−Cr(2) 2.730(3), Au(2)−Cr(3) 2.726(2), Au(3)−Cr(5) 2.707(2), Au(3)−Cr(4) 2.748(3), Cr(1)−P(1) 2.135(5), Cr(2)−P(1) 2.154(4), Cr(3)−P(2) 2.168(4), Cr(4)−P(2) 2.163(4), Cr(5)−P(3) 2.167(4), Cr(6)−P(3) 2.171(5); Au(1)−P(1)−Au(2) 91.75(12), Au(2)−P(2)−Au(3) 86.58(12), Au(1)−P(3)−Au(3) 91.96(12), P(1)−Au(1)−P(3) 143.92(13), P(2)−Au(2)−P(1) 153.13(12), P(2)−Au(3)−P(3) 151.00(12), Cr(1)−P(1)−Cr(2) 154.9(2), Cr(4)−P(2)−Cr(3) 154.2(2), Cr(5)−P(3)−Cr(6) 150.8(2)

even shorter than the Cr−P bond length in **1a** [2.266(1) and 2.271(1) Å],[10a] where the Cr−Cr bond is additionally clamped by the μ-H ligand.

Due to these remarkable structural features of **3**, including the unexpected existence of the Au−Cr bonding in this Au^I complex together with the fact that the phosphido atoms of **3** are substituted by only two 15 valence electron $Cp(CO)_2Cr$ units, we first speculated about the existence of additional H bridges between the Au and Cr atoms. Since we found no spectroscopic indication for this, we decided to perform density functional calculations[20] of a hypothetical complex $[\{Cp(CO)_2Cr\}_6(\mu\text{-}H)_6\{(\mu_4\text{-}P)_3Au_3\}]$ (**3a**) with a tentative X-ray structure and various other structures as starting points. This led to a large distribution of hydrogen positions showing Cr−H, Au−H, P−H and Cp−H bonds for different minimum structures of similar energies (some within 20 kJ/mol). The approximate C_3 symmetry of the $(AuP)_3$ ring was always heavily distorted and the bond lengths deviated considerably from the experimental values [d(Au−P) = 2.40−2.72 Å; d(Cr−P) = 2.14−2.39 Å; d(Au−Cr) = 2.75−2.98 Å]. We thus examined the structure of **3** by DFT calculations which resulted in close agreement with the experimental data [d(Au−P) = 2.49−2.56 Å; d(Cr−P) = 2.16−2.19 Å; d(Au−Cr) = 2.75−2.81 Å]. The computed bond lengths exceed the experimental values as is typical for the BP86 functional method, particularly for weak bonds involving Au atoms. The latter are stabilised by attractive dispersion forces, which are not accounted for in DFT.

The bond lengths in **3** and the Cr−P−Cr angle (151−155°) together with the electron count of Cr point to an unusual electronic structure, which is difficult to disentangle due to the low molecular symmetry. Mullikan occupancies[20f] for the valance orbitals 3p(P), 3d(Cr) and 6s(Au) are all close to one (0.8−1.2), which implies that they are all involved in bonding. The three-centre shared electron number[20g,20h] PCrAu = 0.16 indicates pronounced multicentre bonding. These facts may be rationalised by the following simplified picture: the 3p orbitals of (formal) P^{3-} are delocalised to form partial σ- and π-bonds to Cr with π-bonds delocalised into 6s(Au), leading to short P−Cr, relatively long Au−P and weak Au−Cr bonds.

Conclusions

The reported results confirm our observations in the reactivity studies of the tetrahedral P_2-containing complexes $[\{Cp(CO)_2M\}_2(\mu,\eta^2\text{-}P_2)]$ [M = Cr (**4a**), Mo (**4b**)] towards inorganic and organometallic complexes, where we found significant differences due to the lability of the Cr−Cr bond in **4a**[21] in comparison to the more stable Mo−Mo bond of **4b**.[22] Moreover, the molybdenum complex **1b** follows its general reactivity pattern towards transition metal electrophiles of the type $[L_nM'X]$ [X = Cl, Br; L_nM' = $Cp(CO)_3Mo$, $Cp(CO)_3W$, $Cp(CO_2)Fe$, $(CO)_5Mn$] to give complexes of the type $[\{Cp(CO)_2M\}_2(\mu\text{-}H)(\mu_3\text{-}PH)M'L_n]$ in which transition metal phosphorus bonds are formed while retaining the Mo−Mo bond.[23] However, due to the high lability of the Cr−Cr bond in **1a** this complex appears to be a good synthon for the generation of flexible $[PCr(CO)_2Cp]$ units, and thus is a valuable starting material in cluster chemistry.

Experimental Section

General Remarks: All manipulations were performed under an atmosphere of dry N_2 using standard Schlenk techniques. The solvents were dried by common methods and freshly distilled prior to use. The starting materials $[\{Cp(CO)_2Mo\}_2(\mu\text{-}PH_2)(\mu\text{-}H)]$[24] $[\{Cp(CO)_2Cr\}_2(\mu\text{-}PH_2)(\mu\text{-}H)]$[10a] and $[(Ph_3P)AuCl]$[25] were prepared according to literature methods. NMR: Bruker AC 250 (^1H, 250.13 MHz; ^{31}P, 101.256 MHz); standard Me_4Si (^1H), 85% H_3PO_4 (^{31}P). MS: Finnigan MAT 311 ADF at 70 eV. IR: Bruker IFS 28 FT−IR spectrometer.

$[\{Cp(CO)_2Mo\}_2(\mu\text{-}H)(\mu_3\text{-}PH)Au(PPh_3)]$ (2): KH (0.04 g, 1.00 mmol) was added to a solution of $[\{Cp(CO)_2Mo\}_2(\mu\text{-}PH_2)(\mu\text{-}H)]$ (**1b**; 0.35 g, 0.75 mmol) in 25 mL of THF and the solution was stirred at room temperature for 30 minutes. During this time the solution turned deep purple due to the formation of the anion $[\{Cp(CO)_2Mo\}_2(\mu\text{-}PH_2)]^-$. After filtration, $[(Ph_3P)AuCl]$ (0.37 g, 0.75 mmol) was added to the filtrate and the reaction mixture was stirred for another 14 hours. The solvent was then removed completely in vacuo, and the residue was dissolved in a small quantity of CH_2Cl_2. Separation of the reaction mixture by TLC (hexane/CH_2Cl_2 2:1) in a glove box yielded an orange fraction containing a small amount of starting material **1b** and a red fraction of **2**. Recrystallisation from CH_2Cl_2 yielded **2** as orange crystals (0.21 g, 33%). ^1H NMR (300 MHz, [D$_6$]benzene, TMS): δ = −11.73 (d, $^2J_{H,P}$ = 29 Hz, 1 H, MoHMo), 4.84 (s, 5 H, Cp), 5.04 (s, 5 H, Cp), 6.12 (d, $^2J_{H,P}$ = 282 Hz, 1 H; PH), 7.93−7.47 (m, 15 H, PPh_3) ppm. $^{31}P\{^1H\}$ NMR (101 MHz, [D$_6$]benzene, H_3PO_4): δ = 41.0 (s, br), 73.1 (s, br) ppm. MS (EI, 140 °C): *m/z* (%) = 467 (22) $[M^+ - AuPPh_3]$, 443 (1) $[M^+ - AuPPh_3 - CO]$, 406 (9) $[Mo_2(CO)_3Cp_2^+]$, 378 (24) $[Mo_2(CO)_2Cp_2^+]$, 350 (51) $[Mo_2(CO)Cp_2^+]$, 322 (16) $[Mo_2Cp_2^+]$, 262 (100) $[PPh_3^+]$. IR (KBr): ν(PH) = 2243 (w), ν(CO) = 1916 (vs), 1831 (vs) cm^{-1}.

$[\{Cp(CO)_2Cr\}_6\{(\mu_4\text{-}P)_3Au_3\}]$ (3): A solution of $[\{Cp(CO)_2Cr\}_2(\mu\text{-}PH_2)(\mu\text{-}H)]$ (**1a**; 0.46 g, 1.21 mmol) in 15 mL of THF was added to a solution of KH (0.12 g, 3.02 mmol) in 10 mL of THF and the mixture was stirred for 2 h at room temperature. The colour changed from dark green to bluish green due to the formation of the anion $[\{Cp(CO)_2Cr\}_2(\mu\text{-}PH_2)]^-$. The unchanged KH was filtered off and the filtrate was stirred with $[(PPh_3)AuCl]$ (0.6 g, 1.21 mmol) for 3 h. The solvent was then removed in vacuo. Chromatographic separation on a silica gel column (35 × 2.5 cm) with *n*-hexane/toluene (2:1) gave a dark green fraction containing unchanged $[\{Cp(CO)_2Cr\}_2(\mu\text{-}PH_2)(\mu\text{-}H)]$ (**1a**) (0.15 g, 33%). Elution with *n*-hexane/CH_2Cl_2 (1:10) yielded a reddish brown fraction of $[\{Cp(CO)_2Cr\}_6\{(\mu_4\text{-}P)_3Au_3\}]$ (**3**) (0.13 g, 40%). IR (CH_2Cl_2): ν(CO) = 1930 (s), 1903 (vs) cm^{-1}. ^1H NMR (300 MHz, [D$_6$]benzene, TMS): δ = 4.29 (s, 30 H, C_5H_5) ppm. $^{31}P\{^1H\}$ NMR (101 MHz, [D$_6$]benzene, H_3PO_4): δ = 38 ($\omega_{1/2}$ = 1200 Hz) ppm. $C_{42}H_{30}Au_3Cr_6O_{12}P_3$ (1722.49): calcd. C 29.29, H 1.76; found C 28.98, H 1.83.

X-ray Crystallographic Study

2: $C_{32}H_{27}AuMo_2O_4P_2$, M = 926.32, crystal dimensions 0.20 × 0.20 × 0.05 mm^3, triclinic, space group $P\bar{1}$ (No. 2); a = 8.8953(18), b = 13.989(3), c = 14.925(3) Å, α = 63.72(3)°, β = 83.99(3)°, γ = 72.64(3)°, T = 200(1) K, Z = 2, V = 1588.6(6) Å^3, D_c = 1.937 Mg/m^3, μ(Mo-K_α) = 5.519 mm^{-1}, 9502 independent reflexes (R_{int} = 0.1125, $2\theta_{max}$ = 48°), 378 parameters, R_1 = 0.0573 for 4310 observed reflections with $F_o = 4\sigma(F_0)$, wR_2 = 0.1486 for all reflections.

3: $C_{42}H_{30}Au_3Cr_6O_{12}P_3$, M = 1722.47, crystal dimensions 0.08 × 0.04 × 0.02 mm^3, monoclinic, space group $P2_1$ (No. 4); a = 12.268(3), b = 15.996(3), c = 13.010(3) Å, β = 117.32(3)°, T = 193(1) K, Z = 2, V = 2268.4(8) Å^3, D_c = 2.522 Mg/m^3, μ(Mo-K_α) = 11.206 mm^{-1}, 11802 independent reflexes (R_{int} = 0.0621, $2\theta_{max}$ = 51.94°), 591 parameters, R_1 = 0.0474 for 7060 observed with $F_o = 4\sigma(F_0)$, wR_2 = 0.1152 for all reflections.

Crystal structure analyses of **2** and **3** were performed on a STOE IPDS diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods with the program SHELXS-97,[26a] and full-matrix least-squares refinement on F^2 in SHELXL-97[26b] was performed with anisotropic displacements for non-H atoms, except for the C14 atom of **3**. Hydrogen atoms at the carbon atoms were located in idealised positions and refined isotropically according to the riding model. The hydrogen atoms at the phosphorus and molybdenum atoms of **2** were refined freely. Although different crystals of **3** from different reactions were measured the same results were obtained to refine the data sets of **3** in the acentric space group $P2_1$ as inversion twins in an occupancy ratio of 53:47. All attempts to refine the structure in the centric space groups $P2_1/m$ or $P2_1/c$ failed.

CCDC-194528 (**2**) and CCDC-194529 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.uk/retrieving.htlm [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK (fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

DFT Calculations

All calculations were carried out using the BP86[20a] functional and the RI-J technique[20b] of the program package TURBOMOLE.[20c] C_1 symmetry and the SV(P)[20d] basis set were used throughout. Calculations with the TZVP[20e] basis set showed similar results.

Self-Assembly of Supramolecular Structures from Palladium Chloride and Guanidinium Salts of Pyridinecarboxylic Acids − A Dramatic Change on Passing from the *para*- to the *meta*-Substituted Acid

Alessia Bacchi,*[a] Gian Paolo Chiusoli,[b] Mirco Costa,*[b] and Emmanuele Giacobbi[b]

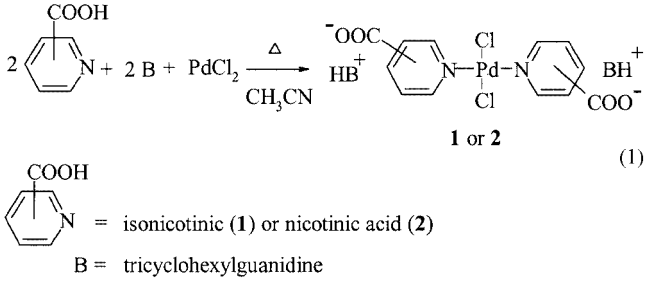
Dedicated to the late Prof. Salvatore Castellano

Keywords: Crystal engineering / Hydrogen bonds / Self-assembly / Multicomponent systems

Supramolecular structures **1** and **2** were obtained in the solid state from the reaction between palladium chloride and guanidinium salts of *p*- and *m*-pyridinecarboxylic acid, respectively. The pyridinecarboxylate anions were *trans*-coordinated to palladium dichloride through nitrogen, and the carboxylate groups formed hydrogen bonds with guanidinium cations. The present paper describes a remarkable change in the stoichiometry and structural organization of the solid **3** derived from the *meta*-substituted acid **2**, triggered by the elimination of one guanidine molecule as hydrochloride per molecule of palladium chloride, during crystallization from methanol. The corresponding isonicotinate **1** structure appears to be stable under the same conditions. As shown by the analysis of the crystal structures, the guanidinium nicotinate organic salt **4** turns out to be preorganized to host palladium chloride both in **2** and **3**.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Interest in the solid-state structures of hybrid materials organised by cooperative interactions of different strength, directionality and range of action (coordinative, electrostatic, lipophilic, hydrogen bonds) is rapidly increasing in the field of crystal engineering.[1] In the framework of a programme aimed at the incorporation of metal salts into supramolecular organic structures, we studied the reaction of palladium chloride with tricyclohexylguanidinium (BH^+) salts of *p*-pyridinecarboxylic acid (isonicotinic acid) or *m*-pyridinecarboxylic acid (nicotinic acid). The formation of supramolecular assemblies self-organized in the solid state according to different stoichiometries showed a hydrogen bond distribution involving both the carboxylic group and the nitrogen base.

Equation (1) indicates the stoichiometry of the reaction of $PdCl_2$ with isonicotinic or nicotinic acids and tricyclohexylguanidine in refluxing acetonitrile, which resulted in the precipitation of yellow solids in both cases. Recrystallisation from a methanol/acetonitrile mixture (1:1) at room temperature led to crystals of the respective palladium complexes (**1** and **2**) of analogous stoichiometry.



Surprisingly, recrystallisation of **2** from pure methanol gave a crystalline compound (**3**) with one less guanidine molecule per molecule of $PdCl_2$. This behaviour was not observed with complex **1**, which was recovered unchanged from methanol after crystallisation. The proposed course of the reaction leading from **2** to **3** (Scheme 1) is based on the products isolated (see Exp. Sect.). A reasonable interpretation is that during crystallisation one molecule of the Pd^{II} complex is reduced to Pd^0 by methanol (which is oxidized to formaldehyde dimethyl acetal, as confirmed experimentally) with concomitant expulsion of guanidine hydrochloride and nicotinic acid. A second molecule of complex **2** then loses one molecule of guanidine as its nicotinic acid salt, forming complex **3**. It is worth noting that mixing one

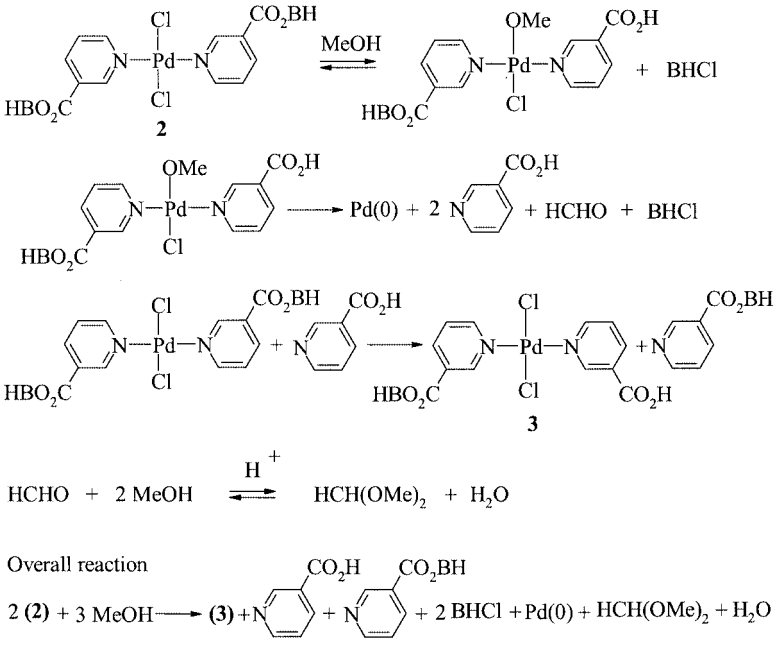

Scheme 1. Proposed course of formation of **3** from **2**

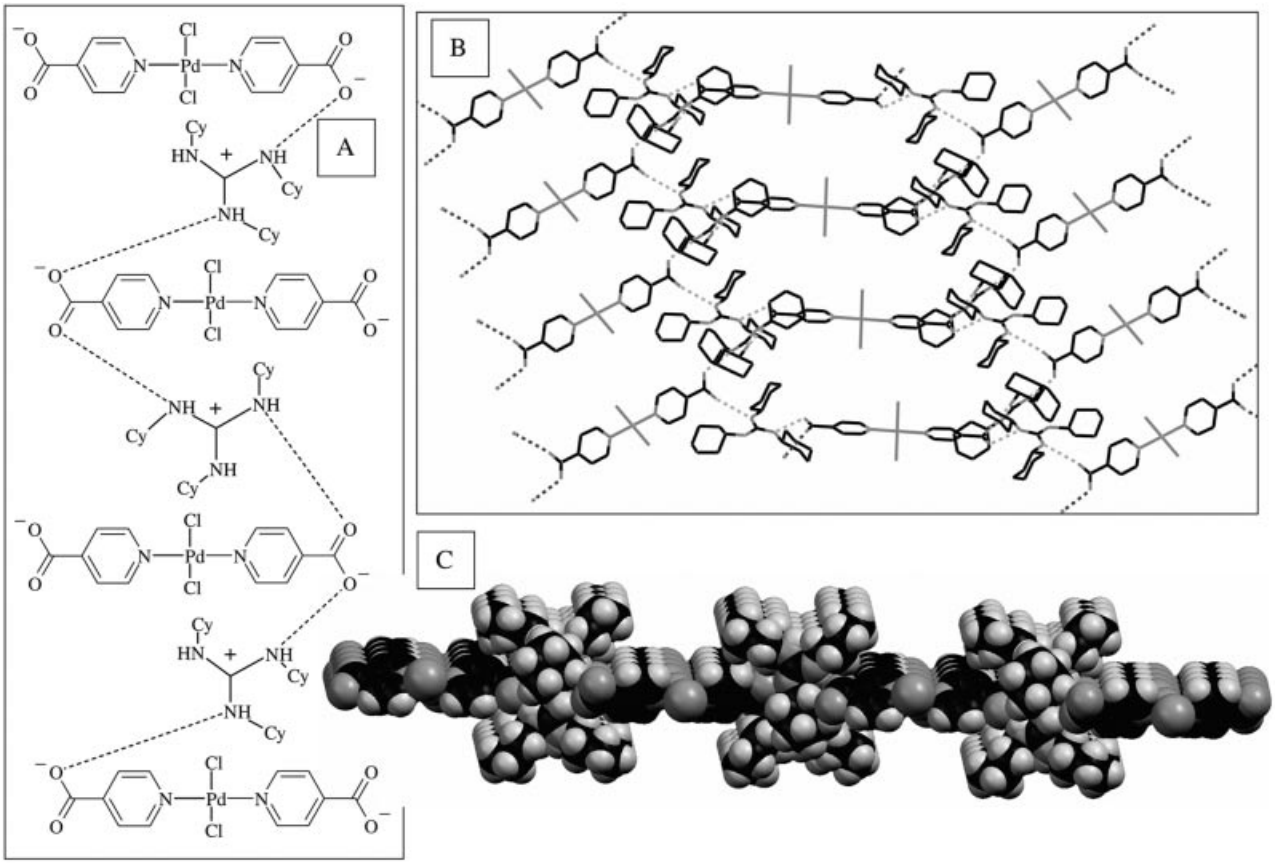

Figure 1. Solid-state arrangement of compound **1**: (A) chains built by NH···O hydrogen bonds between cations and anions, one NH is not involved in the chain formation, Cy = cyclohexyl; (B) the chains are assembled in sheets by coordination of $PdCl_2$ to the dangling pyridinic nitrogen atoms; (C) space-filling view of the section of the sheets; the ridges are formed by the protruding cations; the free NH groups point out of the ridges, to fit in the chlorine array of the adjacent sheets, with consequent staggering of the layers

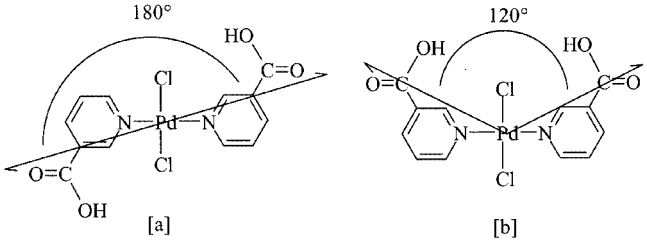
molecule of guanidine with two molecules of nicotinic acid and one of $PdCl_2$ led to a solid precipitate with stoichiometry corresponding to compound **3**, which was not analysed by X-ray diffraction since its crystallinity was not satisfactory. The direct addition of dry CF_3COOH to **2** also failed to afford suitable crystals, although the stoichiometry of the solid obtained was in agreement with that of complex **3**.

In order to elucidate the structural reasons for the diverse behaviour of the two chemically similar systems **1** and **2**, the crystal structures of **1**, **2** and **3** were determined. In **1** cations and anions are assembled in chains built by $-NH^+\cdots{}^-O_2C-$ hydrogen bonds involving two guanidinic NH donors and both the carboxylate oxygen acceptors [N···O = 2.791(7), 2.935(9) Å] (Figure 1a). The chains are covalently linked in sheets by the inorganic $PdCl_2$ spacers through the pyridinic nitrogens, thus defining a ladder motif in which the rung width, 14 Å, depends on the length of the $[trans\text{-}PdCl_2(i\text{nic-}COO)_2]^{2-}$ spacer. The resulting bidimensional network is formed by meshes with a section of 9 × 20 $Å^2$ (dimensions are expressed as atom-atom distances) rimmed by four anions and four cations (Figure 1b). The sheets are assembled so that the -NH ridges of one sheet match the hollows of the adjacent sheets, corresponding to the $PdCl_2$ sites, thus blocking the development of channels or three-dimensional pores perpendicular to the sheets (Figure 1c).

The local structural perturbation introduced by changing the position of the N donor on the pyridinecarboxylate ring greatly affects the self-assembly of the multicomponent system, showing how the crystal organization depends critically on the shape of the *trans*-$PdCl_2L_2$ unit. With L = nicotinic acid this unit could give rise to a *syn* and an *anti* arrangement (Scheme 2).

Only the latter, however, is present in **2**, where the structural organization of **1** is retained, the only difference being that all the NH groups are involved in intra-chain hydrogen bonds [$NH^+\cdots O^-$ = 2.764(6), 2.901(6), 2.990(6) Å] (Figure 2a). The skew $PdCl_2L_2$ units (length = 13 Å) link paral-



Scheme 2. Geometry and shape of the $PdCl_2L_2$ spacers in: (a) compound **2**, *anti* isomer, linear; and (b) compound **3**, *syn* isomer, bent

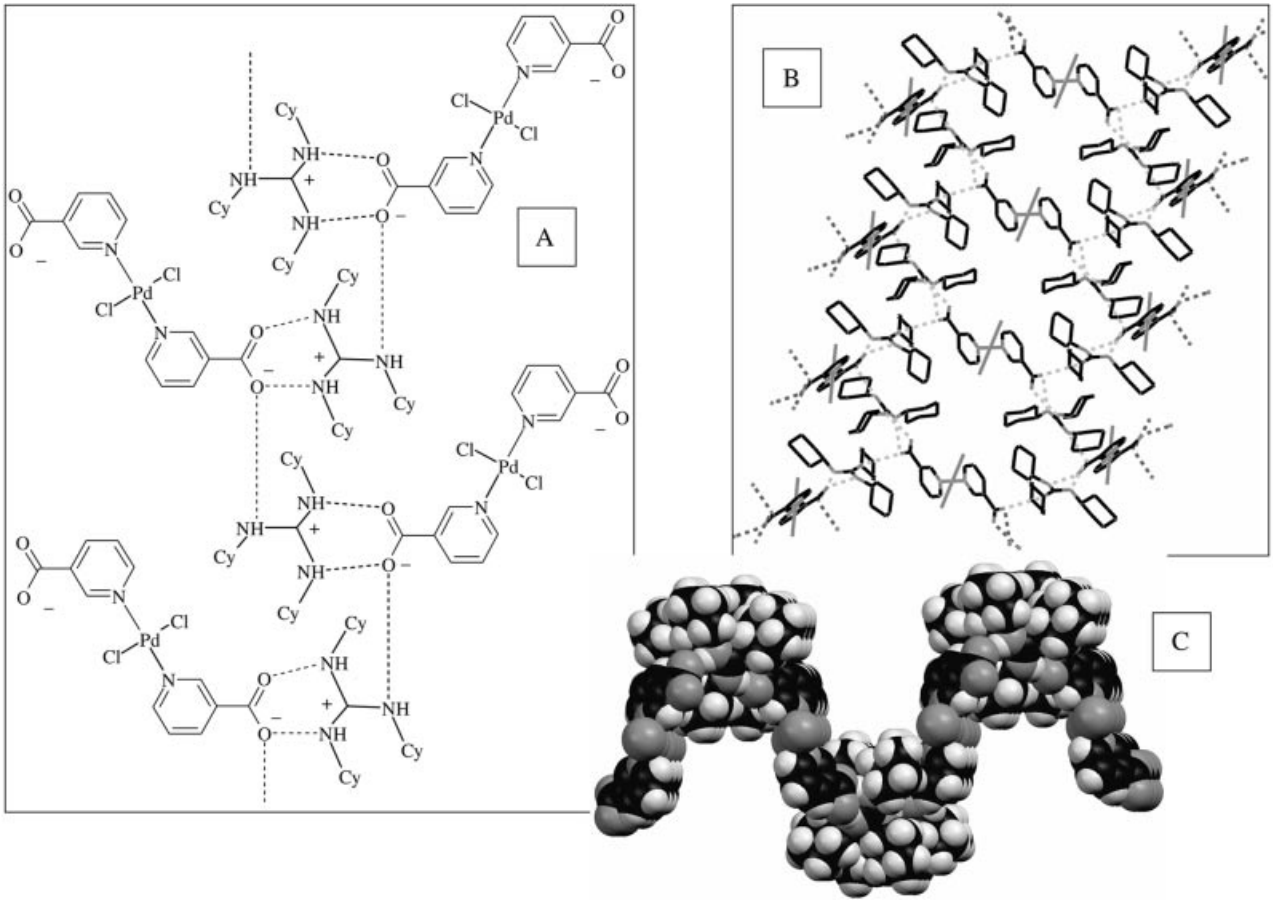


Figure 2. Solid-state arrangement of compound **2**: (A) chains built by NH···O hydrogen bonds as in **1**, all NH groups are involved in the chain formation, Cy = cyclohexyl; (B) sheets organization as in **1**; (C) space-filling view of the section of the sheets; the sheets are corrugated due to the shape of the inorganic spacer

lel chains, forming 10 × 17 Å^2 meshes defined by four anions and four cations (Figure 2b). Due to the shape of the *anti* complex, the sheets are corrugated and assemble in three dimensions in a bump-hollow arrangement (Figure 2c). In both **1** and **2** the bidimensional structural assembly is controlled by coordination bonds and hydrogen bonds resulting in a robust network with wide meshes, promising for the building up of nanometre-sized pores in the third dimension. However, the stacking of the porous sheets is controlled by the close packing principle, and the voids are filled by means of multiple weak dispersive interactions. The largest cavities in structures **1** and **2** are 10 and 33 Å^3, respectively.

A bent *syn*-$PdCl_2L_2$ unit is present in **3**, and this is accompanied by a dramatic change in the stoichiometry and structure of the supramolecular complex, as shown by the X-ray crystal structure. The cations and anions are arranged in hydrogen-bonded chains [N···O = 2.97(1), 2.82(2) Å] generated by translation and the complex is aligned with the direction of the chain (Figure 3a). Only one oxygen on each carboxylate interacts with a nitrogen of the cation, while the other is employed in O−H···O$^-$ strong interactions [O···O = 2.43(2) Å] between chains related by a 2_1 operation (Figure 3b), generating a double-strand motif (Figure 3c). This requires that each complex is monodeprotonated, and causes the observed change in the stoichiometry. The polymeric motif consisting of -CO_2H···$^-$OOC- hydrogen-bonded chains is quite common in the structure of monodeprotonated dicarboxylic acids, and has a stabilising nature.[2] Examples of crystalline salts of monodeprotonated dicarboxylic acids with protonated nitrogen bases where the structure is built through a network of O−H···O$^-$ and N$^+$−H···O$^-$ interactions have recently been reported.[3] In our case the special arrangement of complex **3** is reached through an unusual series of events: protonation of one carboxylate group of **2** (Scheme 1) triggers the supramolecular polymerisation of [$PdCl_2$(nic-COO)(nic-COOH)]$^-$, and induces the precipitation of the *syn*-isomer of the monoanionic complex, which can form chains appropriately arranged in double strands.

The fact that guanidine expulsion occurs with the nicotinic rather than isonicotinic complex points to a favourable arrangement of the former. As a matter of fact the comparison with the structure of guanidinium nicotinate **4** shows that the latter is pre-organised for hosting palladium chloride. The crystal packing of **4** is based on catemers of hydrogen bonds linking cations and anions with the same topology as in **1** and **2** (Figure 4a). The pyridinic N is used to connect adjacent chains through NH···N interactions with the third guanidinium NH. In the crystal, the hydro-

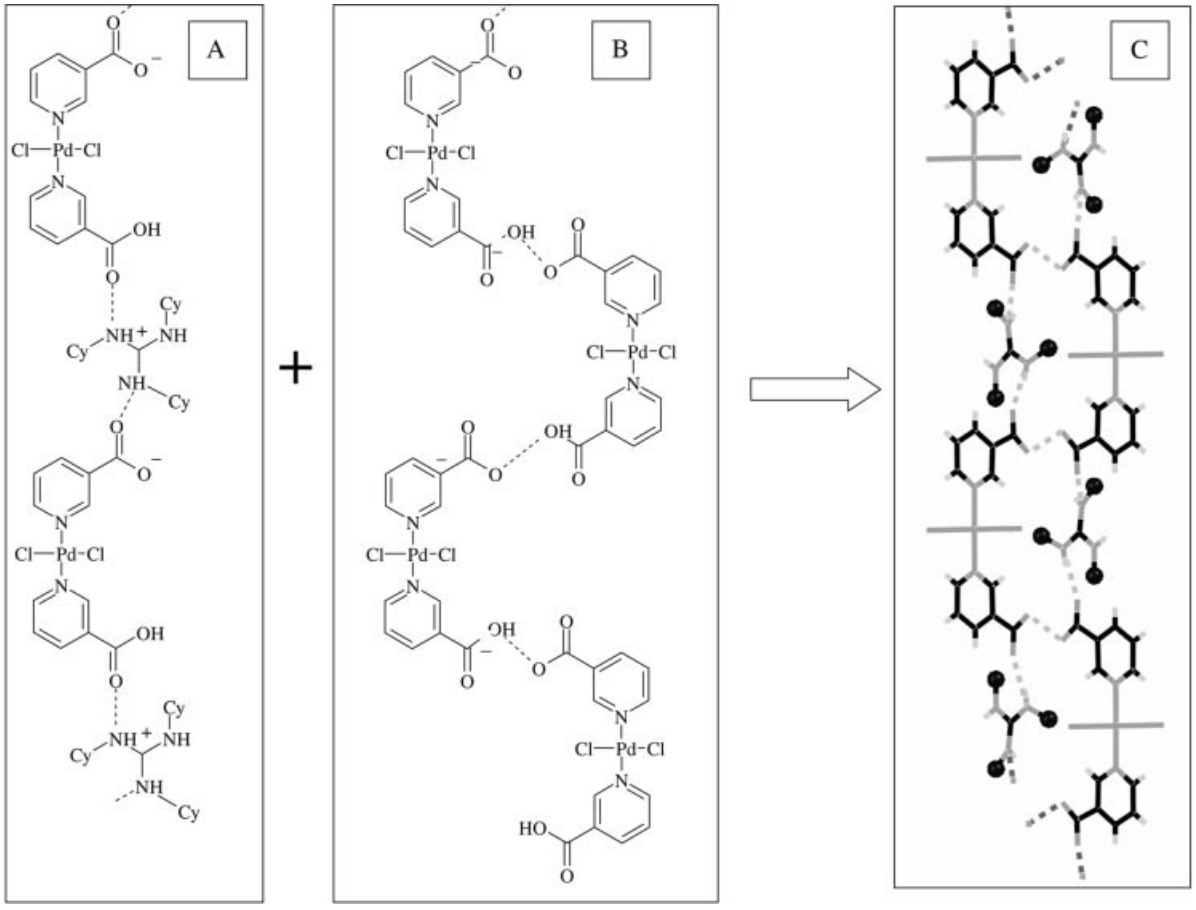

Figure 3. Crystal organization of **3**: (A) chain motif generated by hydrogen bonding between cations and monoanionic complexes, Cy = cyclohexyl; (B) association between pairs of chains via OH···O hydrogen bonds; (C) double strand obtained by assembling a pair of catemers by O−H···O hydrogen bonds; cyclohexyls are represented as solid balls

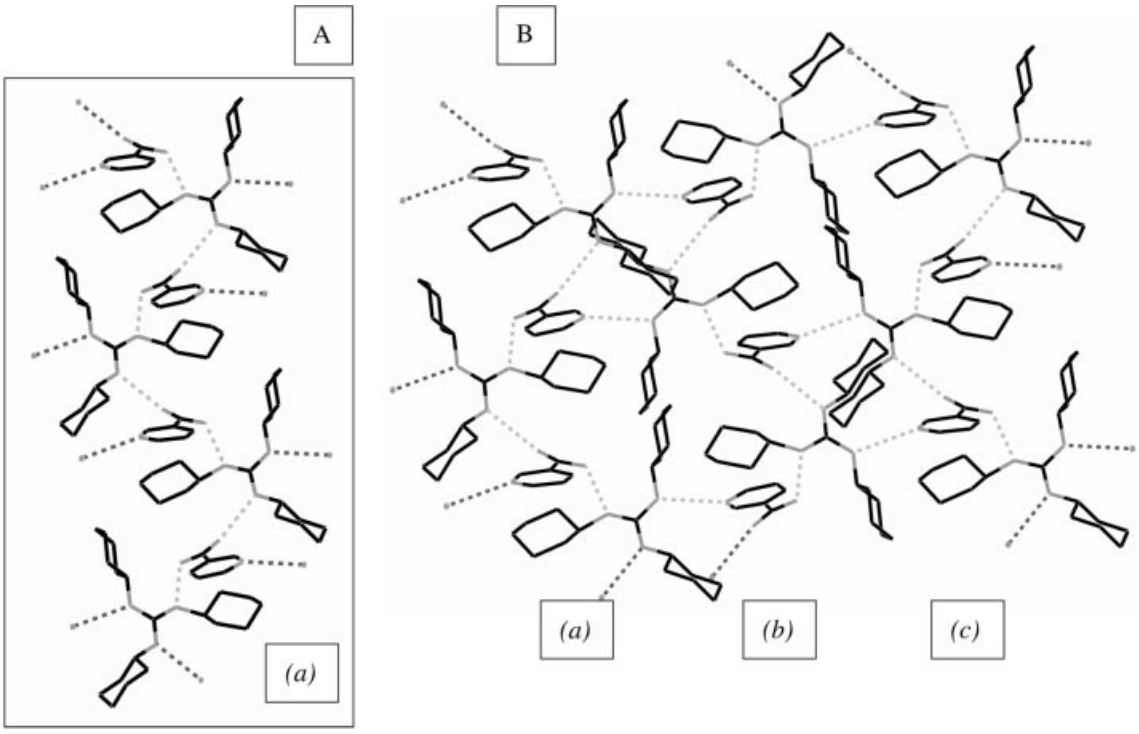

Figure 4. (A) Chain motif in **4**, generated by hydrogen bonds between alternating cations and anions as in **1** and **2**; (B) the chains (*a, b, c*) are arranged in sheets by hydrogen bonding between pyridinic nitrogens and one NH group of the cations

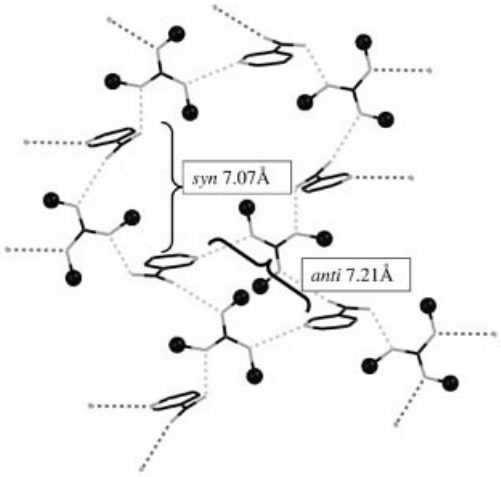

Figure 5. Spatial preorganization of **4** showing how a slight rotation of pyridinic rings can accommodate the $PdCl_2$ unit, giving the structural motif observed either in **2** (*anti* isomer), by sliding of the chains, or in **3** (*syn* isomer) by release of a neutral guanidine; cyclohexyls are represented as solid balls

gen bond of **4** plays the same function as the N−Pd−N covalent link in **1** and **2** in forming bidimensional sheets (Figure 4b). In **2** and **3** the coordination of the incoming Pd requires a concerted rotation of the aromatic rings, to bring the pyridine N atoms into a favourable arrangement. Depending on the mutual position of the pair of pyridinic N atoms, the inorganic spacer orients itself either perpendicular to the organic chains (**2**, *anti* spacer) or parallel to them (**3**, *syn* spacer; Figure 5), in this case causing the release of the guanidine bridging the pair of anions involved in complexation. Guanidine expulsion leaves free -O^- acceptors and -OH donors regularly spaced on the newly formed metal-containing chain, favouring the association of two chains in the observed double strands. The versatile preorganization of the organic salt **4** justifies the remarkable differences in the solid-state organization of the *anti*- and *syn*-spacers and explains how the release of guanidine can occur with a modest expense in terms of structural rearrangement to **3**. Nevertheless guanidine is not expelled spontaneously and liberation of HCl as shown in Scheme 1, is needed.

In conclusion we have reported novel supramolecular arrays held together both by nitrogen coordination to palladium and hydrogen bonds. The structure derived from a guanidine salt of nicotinic acid readily responds to dissolution in methanol by guanidine expulsion and formation of a new structure where the original $NH^+\cdots OOC^-$ bonds are replaced by $NH^+\cdots$OOC-COOH bonds. This type of response can be expected to offer a new tool for working out supramolecular architectures sensitive to chemical stimulation. Work in progress has already shown that similar structures can be obtained with other bi- and tetrasubstituted guanidines.

Experimental Section

Tricyclohexylguanidinium isonicotinate and nicotinate were both prepared in almost quantitative yield by dissolving the pyridinecarboxylic acid (0.73 g, 6 mmol) and tricyclohexylguanidine (1.83 g, 6 mmol) in 20 mL of acetonitrile and refluxing the solution for 6

hours under argon. The corresponding $PdCl_2$ complexes **1** and **2** were prepared in 88% and 86% yield, respectively, by dissolving the guanidinium salt (0.43 g, 1 mmol) and $PdCl_2$ (0.09 g, 0.5 mmol) in 11 mL of acetonitrile. The solutions were refluxed at 70 °C for 6 hours. After cooling and filtering, the precipitates were recrystallised from a 1:1 mixture of methanol and acetonitrile at room temperature to obtain crystals suitable for X-ray analysis. Analogous results were obtained by allowing $PdCl_2$, nicotinic or isonicotinic acid and tricyclohexylguanidine (1:2:2 molar ratio) to react in refluxing CH_3CN for 6 hours. Satisfactory elemental analysis were obtained (available as supporting information).

In order to investigate the process leading from **2** to **3**, complex **2** (0.103 mg 0.1 mmol) dissolved in the smallest quantity of MeOH was left to crystallise. Yellow crystals of complex **3** (24 mg 0.035 mmol) were selected for X-ray analysis. The residue, consisting of crystals of guanidine hydrochloride, nicotinic acid, guanidine nicotinate and palladium(0), was treated with Et_2O to remove formaldehyde dimethylacetal.

The above-described procedure was used for the direct synthesis of complex **3**. Thus $PdCl_2$ (0.044 g, 0.25 mmol), nicotinic acid (0.062 g, 0.50 mmol) and tricyclohexylguanidine (0.076 g 0.25 mmol) were refluxed under argon in dry CH_3CN (4.0 mL) for 6 hours. The mixture was filtered and the yellow precipitate was recrystallised from CH_3OH/CH_3CN (1:1). The solid precipitate gave a satisfactory elemental analysis but was not suitable for single crystal X-ray diffraction.

Treatment of Complex 2 with CF_3COOH: CF_3COOH (0.023 mL, 0.3 mmol) was added to crystals of complex **2** (0.31 g, 0.3 mmol) suspended in dry CH_3CN (6 mL) at 0 °C. After stirring for 2 hours the mixture was filtered and a yellow solid was dried and recrystallised from CH_3CN/CH_3OH (1:1). The solid precipitate gave a satisfactory elemental analysis in agreement with the composition of complex **3**, but was not suitable for single crystal X-ray analysis.

Crystallographic Analysis: Mo-K_α radiation (λ = 0.71073 Å), T = 293 K for **1**, **3** (Siemens AED diffractometer) and **2** (SMART AXS 1000 CCD diffractometer), and Cu-K_α (λ = 1.54178 Å), T = 173 K for **4** (Enraf−Nonius CAD4 diffractometer). Lorentz and polarisation corrections were applied. The structures were solved by direct methods using SIR97[4] and refined by full-matrix least-squares on all F^2 using SHELXL-97.[5] Hydrogen atoms were introduced in calculated positions, and refined riding on their carrier atoms. Anisotropic displacement parameters refined for all non-hydrogen atoms.

1: 0.4 × 0.2 × 0.1 mm, monoclinic, space group $P2_1/c$, a = 12.743(5), b = 9.725(5), c = 22.345(7) Å, β = 105.76(5)°, V = 2665(2) Å^3, ρ = 1.289 Mg·m^{-3}, 5232 unique reflections, 1459 observed [$I > 2\sigma(I)$], 307 parameters, R = 0.0592, R_w = 0.1401. The palladium is on a crystallographic inversion centre.

2: 0.3 × 0.2 × 0.1 mm, monoclinic, space group $P2_1/a$, a = 10.565(2), b = 22.739(3), c = 11.509(2) Å, β = 94.785(2)°, V = 2755.3(1) Å^3, ρ = 1.247 Mg·m^{-3}, 2288 unique reflections, 1636 observed [$I > 2\sigma(I)$], 307 parameters, R = 0.0332, R_w = 0.0823. The palladium is on a crystallographic inversion centre.

3: 0.1 × 0.2 × 0.2 mm, monoclinic, space group $C2/m$, a = 22.786(5), b = 17.730(5), c = 10.405(5) Å, β = 108.31(5)°, V = 3991(2) Å^3, ρ = 1.213 Mg·m^{-3}, 4093 unique reflections, 1077 observed [$I > 2\sigma(I)$], 274 parameters, R = 0.0698, R_w = 0.1825. The metal and the chlorine atoms are on a crystallographic symmetry plane, as well as the carbocationic C atom of guanidinium. The cation is disordered over two equivalent orientations, which do not alter the hydrogen bonding scheme.

4: 0.2 × 0.2 × 0.4 mm, triclinic, space group $P\bar{1}$, a = 16.843(5), b = 14.612(5), c = 11.156(5) Å, α = 66.54(5), β = 103.29(5), γ = 104.70(5)°, V = 2410(1) Å^3, ρ = 1.181 Mg·m^{-3}, 9138 unique reflections, 4436 observed [$I > 2\sigma(I)$], 583 parameters, R = 0.1108, R_w = 0.2668. Two independent molecules are present in the asymmetric unit.

Application of Gel-Phase ^{195}Pt NMR Spectroscopy in a Novel Solid-Phase Synthesis of a Primary Amine Dichloroplatinum(II) Complex

Marc S. Robillard,[a] Jason S. Leith,[a] Gijs A. van der Marel,[a] Jacques H. van Boom,[a] and Jan Reedijk*[a]

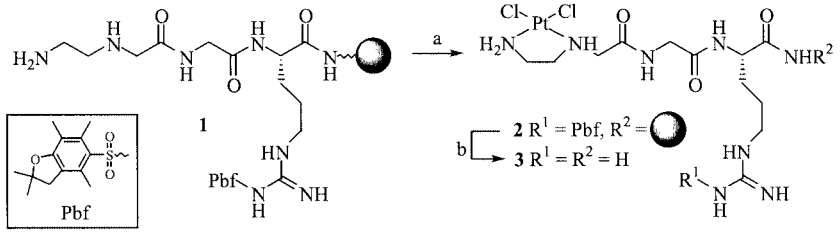
Keywords: Peptides / Platinum / Solid-phase synthesis / NMR spectroscopy / Bioinorganic chemistry

Gel-phase ^{195}Pt NMR spectroscopy of dichloroplatinum peptide complexes attached to a solid support is described. The observed ^{195}Pt chemical shifts of the support-bound platinum complexes are in good agreement with the solution-state ^{195}Pt NMR spectra of the soluble and deprotected analogs. This non-destructive analytical method for on-resin-compound analysis was applied in the optimization of the solid-phase synthesis of the primary amine dichloroplatinum complex **6**, which represents a new class of platinum complexes now available via solid-phase synthetic chemistry.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Both combinatorial chemistry and parallel synthesis have embraced solid-phase synthesis (SPS) as one of their fundamental tools. The advantages involved are also likely to pertain to the preparation of libraries of anticancer platinum drugs. Earlier we reported the construction of a dichloroplatinum(II) tripeptide complex (compound **3** in Scheme 1) via a solid-phase approach in nearly quantitative conversion.[1] The rich coordination chemistry of platinum has still not been fully exploited in a solid-phase combinatorial approach. Reactions on a solid support usually require different conditions than in solution, and further explorations in this field would clearly profit from an analytical method that allows the on-resin monitoring of a desired coordination reaction. Standard analytical techniques (MS, HPLC, TLC, NMR) for resin reaction optimization are available once a reaction product is cleaved from the solid support. However, this process is still time consuming, and may alter the desired species or preclude observation of unstable intermediates. This drawback has been widely recognized by solid-phase chemists and, as a result, a plethora of non-destructive analytical methods have been used for on-resin analysis.[2,3] Gel-phase NMR spectroscopy is regarded as one of the more powerful and information rich methods.[4–7] Although on-resin evaluation of metal coordination using NMR spectroscopy, particularly in the field of immobilized catalysts, is of increasing interest,[8–13] only two examples of gel-phase metal NMR spectroscopy have been reported,[12,13] namely for the ^{119}Sn nucleus.

It was envisaged that the diamagnetic ^{195}Pt ($S = 1/2$) nucleus could be applied for monitoring platinum coordination reactions on a solid support using gel-phase NMR spectroscopy. Such an approach would circumvent the need to study the "outer sphere" of an immobilized platinum complex by gel-phase ^{1}H, ^{13}C or ^{31}P NMR spectroscopy, as it is possible to observe the "core" itself.



Scheme 1. Solid-phase synthesis of platinum complex **3**; reagents and conditions: a) K_2PtCl_4 (5 equiv., 0.05 M), DMF/H_2O (9:1, v/v), 24 h in the dark; b) TFA/H_2O (95:5, v/v), 1 h

This paper reports on the feasibility of gel-phase ^{195}Pt NMR spectroscopy, using the immobilized dichloroplatinum peptide complex **2** (Scheme 1). The potential of this technique for assessing the success of an unknown com-

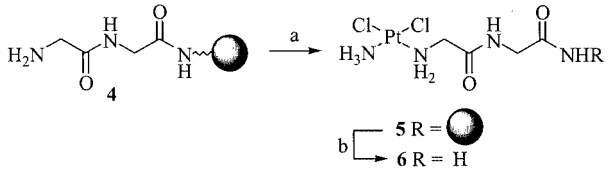
plexation reaction will be illustrated in a novel solid-phase synthesis of the primary amine dichloroplatinum complex **6** (Scheme 2).



Scheme 2. Solid-phase synthesis of platinum complex **6**; reagents and conditions: a) $[PPh_4][PtCl_3(NH_3)]$ (5 equiv., 0.1 M), DMF/H_2O (9:1, v/v) or DMF, 24 h in the dark; b) TFA, 1 h

Results and Discussion

The immobilized peptide dichloroplatinum complex **2** (Scheme 1) was prepared using our previously published method.[1] Gel-phase ^{195}Pt NMR spectroscopy of **2**, preswollen in [D_7]DMF in a 5 mm NMR tube, using standard solution-state parameters, revealed a clear, albeit broad, signal at $\delta = -2336$ ppm (Figure 1A).

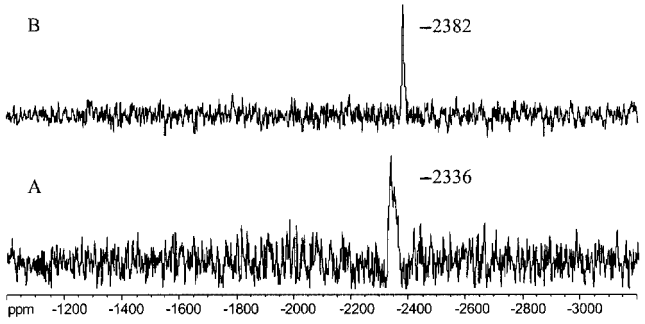


Figure 1. Gel-phase ^{195}Pt NMR spectrum of **2** ([D_7]DMF, 200 mg, 71 μmol) (A), and solution ^{195}Pt NMR spectrum (D_2O) of cleaved and deprotected platinum complex **3** (B)

The gel-phase ^{195}Pt NMR spectrum of **2** not only exhibits a significantly broader signal than the corresponding cleaved and deprotected peptide dichloroplatinum complex **3** dissolved in D_2O (Figure 1B), but is also shifted 46 ppm downfield from the solution-state signal at $\delta = -2382$ ppm. The line width at half-height of **2** is 19.3 ppm, as opposed to a line width at half-height of 6.7 ppm for **3**, indicating that the signal of **2** corresponds to a polymer-bound species. Indeed, when the [D_7]DMF layer was separated from the resin and subjected to ^{195}Pt NMR spectroscopy, no signal appeared. The main factors contributing to line broadening in the gel-phase NMR spectra of polymer-bound species are known to be limited motional freedom, increased correlation time, and magnetic susceptibility variations within the sample.[5,7] The optimal mobility of **2** was attained through the use of DMF, which ensures a high degree of swelling of the polystyrene-based Rink amide resin, as well as solvation of the appended complex with its arginine residue still protected by the apolar Pbf group. Chemical shift studies have indicated that regardless of whether compounds are bound to resins or in solution, the chemical shifts are both virtually identical.[14,15] A conflicting report recently suggested[3] that compounds bound to the solid support exhibit a downfield shift compared to solution-state NMR spectra, due to the high density of aromatic rings within the polymer matrix. However, in the present case the observed, small downfield shift is most likely due to the solvent change, as it has been established that the solvent has a large effect on the chemical shift of platinum (up to a few hundred ppm).[16]

The gel-phase ^{195}Pt NMR technique was subsequently used to optimize the synthesis of a novel type of dichloroplatinum complexes on the solid support. The target molecule **6** (Scheme 2) encompasses a glycine-glycine dipeptide coordinated in a *cis*-configuration to a monoamminedichloroplatinum moiety.

Complex **6** is more cisplatin-like than the dichloroethylenediamineplatinum derivative **3**, as it lacks the ethylene bridge and has a primary amine and a molecule of ammonia as ligands. Gel-phase ^{195}Pt NMR spectroscopy opens the way to investigate whether or not the lack of the ethylenediamine chelating ligand (present in **3**) affects the stability of the primary amine complex on the support. The route of synthesis of target compound **6** (Scheme 2) comprises platination[17,18] of the primary amine of immobilized dipeptide **4** with $[PPh_4][PtCl_3(NH_3)]$, and subsequent release from the solid support with trifluoroacetic acid (TFA). First, dipeptide **4** was reacted with $[PPh_4][PtCl_3(NH_3)]$ (0.1 M, 5 equiv.) in DMF/water (9:1) for one day. The platination conditions were similar to those used for the preparation of **2**, except for the starting platinum salt (K_2PtCl_4 vs. $[PPh_4][PtCl_3(NH_3)]$). After washing the resin with water, DMF, and dichloromethane, a gel-phase ^{195}Pt NMR spectrum was recorded in [D_7]DMF (Figure 2A). The signal at $\delta = -2150$ ppm, with a line width at half-height of 20.9 ppm, corresponds to immobilized **5**, indicating that the solution synthesis method[17,18] is compatible with solid-phase chemistry. However, the signal at $\delta = -1786$ ppm (line width at half-height of 17.8 ppm) was unexpected and is ascribed to hydrolysis of the dichloroplatinum functionality in **5** by the water (10%) present in the reaction mixture.[19] Indeed, subsequent platination in the absence of water afforded a gel-phase ^{195}Pt NMR spectrum devoid of a hydrolysis signal with only the expected $PtCl_2N_2$ chromophore at $\delta = -2147$ ppm (line width at half-height of 15.6 ppm, Figure 2B). This finding indicates that **5** is more susceptible to hydrolysis than the dichloroethylenediamineplatinum derivative **2**, since no hydrolysis signal was observed on the support for the latter after similar reaction conditions. Acidolyis of **5** in TFA and subsequent purification of the product using gel permeation chromatography (HW-40, 0.01 M HCl in water/methanol) gave **6** in 32% yield. The recorded solution-state ^{195}Pt NMR spectrum in D_2O (Figure 2C) shows the $PtCl_2N_2$ chromophore at $\delta = -2200$ ppm, demonstrating roughly the same solvent-induced shift of 53 ppm, as shown for complex **3**.[20] The line width at half-height of **6** (9.6 ppm) is similar to that ob-

served for **3** and considerably smaller than that observed for its immobilized analog **5**.

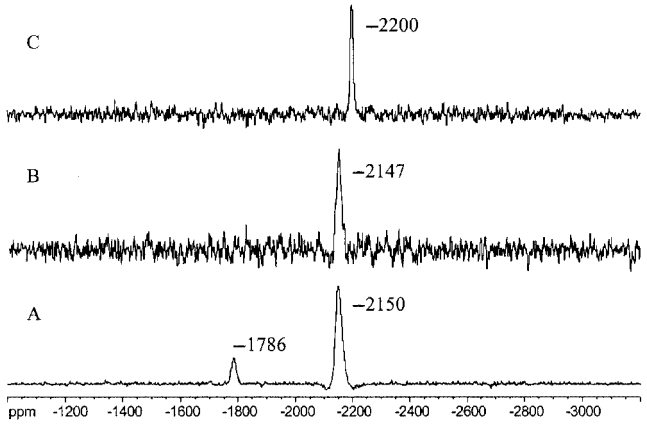

Figure 2. Gel-phase ^{195}Pt NMR spectrum of **5** ([D_7]DMF, 100 mg, 34 μmol) after reaction in DMF/H_2O (9:1) (A), and after reaction in DMF (B); solution-state ^{195}Pt NMR spectrum (D_2O) of cleaved complex **6** (C)

Conclusion

In summary, it has been demonstrated that gel-phase NMR spectroscopy can be applied to the ^{195}Pt nucleus of an immobilized platinum complex. Aided by this technique, the monoamminedichloroplatinum bis-glycine complex **6** has been successfully prepared, representing a new class of platinum complexes now available via solid-phase chemistry. The observed chemical shift of the resin-bound platinum complexes discussed in this paper are in good agreement with the solution-state ^{195}Pt NMR spectra of the soluble and deprotected analogs. As a result of the high receptivity of ^{195}Pt (19.1 times ^{13}C), simple spectra (one signal per nonequivalent Pt) and a wide spectral dispersion (some 15000 ppm, resulting in a high sensitivity to structural perturbations), well-resolved spectra are obtained within hours, without any need for magic-angle spinning. The solvents, polymer backbone and the immobilized ligand are transparent to the technique, eliminating a rigorous drying procedure and suppression techniques. The use of gel-phase ^{195}Pt NMR spectroscopy will be valuable for monitoring a variety of transformations on the resin, aiding the development of novel platinum structures readily available on the solid support, thus facilitating the preparation of new libraries of anticancer platinum complexes.

Experimental Section

General Remarks: All solvents and reagents were of commercial grade and used without purification. Solvents and reagents used in the automated peptide synthesis were of peptide synthesis grade and were purchased from Biosolve. Amino acids and the Rink Amide MBHA resin were purchased from NovaBiochem. K_2PtCl_4 was obtained as a loan from Johnson−Matthey. [PPh_4][$PtCl_3(NH_3)$] was synthesized according to a previously published procedure.[18] Gel permeation chromatography was executed on a HW-40 column (26 mm × 600 mm) at 1.5 mL/min. Mass spectra were recorded on a PE SCIEX API 165 instrument.

NMR Spectroscopy: (Gel-phase) NMR spectra were recorded on a Bruker DPX 300 spectrometer with a 5-mm multi-nucleus probe. The temperature was kept constant at 295 K by a variable temperature unit. ^{1}H NMR spectra were measured using TMS as an external reference at δ = 0 ppm. ^{195}Pt NMR spectra were calibrated with respect to external K_2PtCl_4 at δ = −1614 ppm. Gel-phase ^{195}Pt NMR samples of **2** and **5** were prepared by swelling respectively 200 mg (71 μmol) and 100 mg (34 μmol) of platinated, washed and dried resin in 1 mL of [D_7]DMF in a 5 mm NMR tube. The number of scans used for the gel-phase experiments varied from 89262 to 1243681.

***cis*-Amminedichloro(glycylglycine-NH_2)platinum(II) (6):** Dipeptide **4** was assembled on Rink amide resin with an ABI 433A (Applied Biosystems, division of Perkin−Elmer) peptide synthesizer, employing a FastMoc® peptide synthesis protocol. Immobilized **4** (100.0 mg, 37.9 μmol) was reacted with [PPh_4][$PtCl_3(NH_3)$] (124.6 mg, 189.4 μmol, 0.1 M in DMF) in the dark for one day, washed with water, DMF and dichloromethane and dried in vacuo. Cleavage of the solid support was effected by treatment of **5** with TFA for 1 h, after which the reaction mixture was precipitated with diethyl ether. The resulting solid was washed with diethyl ether, water was added, the mixture was filtered and the resin was washed with water. Subsequently, the combined water fractions were lyophilized, yielding crude **6** as a yellow powder. Purification by gel permeation chromatography (HW-40, 0.01 M HCl in water/methanol, 1:1, v/v) afforded **6** (5.0 mg, 12.0 μmol) in 32% yield, based on **4**. ^{1}H NMR (D_2O): δ = 3.85 (s, 2 H, αGly), 3.83 (s, 2 H, αGly) ppm. ^{195}Pt NMR (D_2O): δ = −2200 ppm. ESI-MS: *m/z* = 449 [M + H + HCl]$^+$.

Keywords: Boranes / Carboranes / NMR spectroscopy / Rearrangement / N ligands

Deprotonation of the eleven-vertex tricarbaborane zwitterions 7-L-*nido*-7,8,9-$C_3B_8H_{10}$ [**1**: L = H_3N (**1a**), *t*BuH_2N (**1b**), Me_2HN (**1c**)], followed by reactions with metal reagents [FeI_2, $NiCl_2$, and $Ni(C_5H_5)_2$] at higher temperatures and in situ acidification, led to the 7 → 8 rearrangement of the *N*-substituted cage carbon atom to yield a series of 8-amino-substituted derivatives of *nido*-7,8,9-$C_3B_8H_{12}$. These were characterized as 8-R-*nido*-7,8,9-$C_3B_8H_{11}$ [**2**: R = H_2N (**2a**), *t*BuHN (**2b**), Me_2N (**2c**)]. A possible rearrangement mechanism for their formation has been proposed. Deprotonation of compound **2a** with proton sponge [PS = 1,8-bis(dimethylaminonaphthalene)] generated the [8-*t*BuHN-*nido*-7,8,9-$C_3B_8H_{10}]^-$ (**2b**$^-$) anion, which can be reprotonated to give the original compound **2b** and not the tautomeric zwitterion 8-*t*BuH_2N-*nido*-7,8,9-$C_3B_8H_{10}$ (**3b**). All compounds were characterized by high-field (^{11}B and ^1H) NMR and IR spectroscopy, and mass spectrometry. The molecular structures of the neutral carbaborane **2b** and its salt PSH$^+$**2b**$^-$were determined by single-crystal X-ray diffraction analyses.

Introduction

Over the last decade, there has been a growing interest in the chemistry of ten- and eleven-vertex tricarbaboranes.[1−6] The first representatives of the eleven-vertex family (tricarbollides), ligand derivatives 7-L-*nido*-7,8,9-$C_3B_8H_{10}$ (L = amines)[2,6] and the parent tricarbollides *nido*-7,8,9-$C_3B_8H_{12}$ and [*nido*-7,8,9-$C_3B_8H_{11}]^-$, were discovered in 1995.[3,6] An extension of this chemistry has led to the isolation of the isomeric [*nido*-7,8,10-$C_3B_8H_{10}]^-$ anion,[3] its 7-substituted (alkyl and aryl)[4a] and amine-ligand derivatives,[2,4b,4c,6] and finally to the synthesis of isomeric 7-R-*nido*-2,7,10-$C_3B_8H_{11}$ (R = alkyl and aryl)[5] compounds. Later efforts in this area were directed to the exploration of metal complexation properties since $[C_3B_8H_{11}]^-$-type anions can be regarded as cyclopentadienide analogues.[6−12] This research led, in turn, to the isolation of a whole series of metallatricarbollides in which the tricarbaborane core acts as an η^5-coordinating ligand.[6−12] We report herein that, with certain metal reagents, the expected complexation reaction of the [7-R-7,8,9-$C_3B_8H_{10}]^-$ anions (R = H_2N, *t*BuHN, and Me_2N) fails, leading instead to an unexpected 7 → 8 migration of the R−C(cage) carbon atom with the formation of new 8-R-*nido*-7,8,9-$C_3B_8H_{11}$ compounds in moderate to good yields. These are 8-amino-substituted derivatives of *nido*-7,8,9-$C_3B_8H_{12}$ [2,3] and are tautomeric with regards to the nonexistent zwitterions of the 8-L-*nido*-7,8,9-$C_3B_8H_{10}$ compounds. The numbering system for the eleven-vertex compounds used in this work can be seen in Schemes 1 and 2, and in Figures 1−3. The unmarked vertices in Schemes 1 and 2 denote cage BH units.

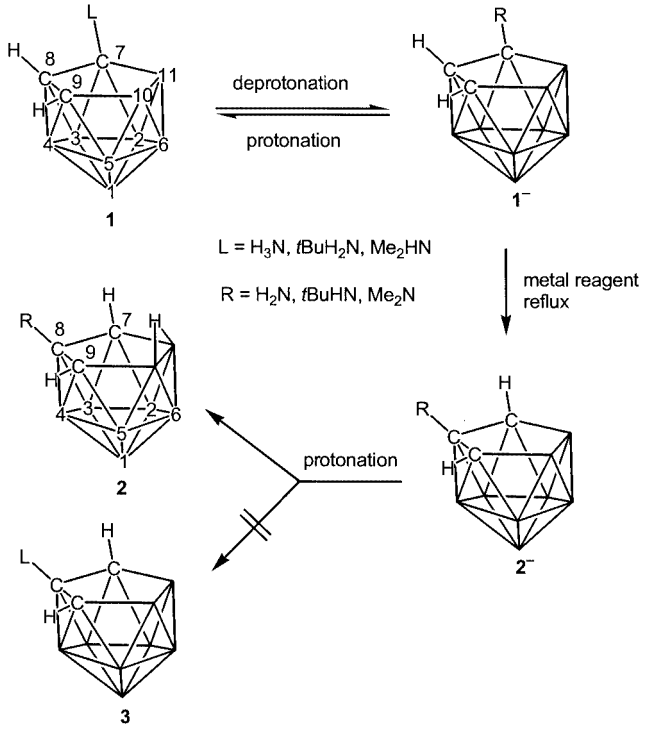
Results and Discussion

Syntheses

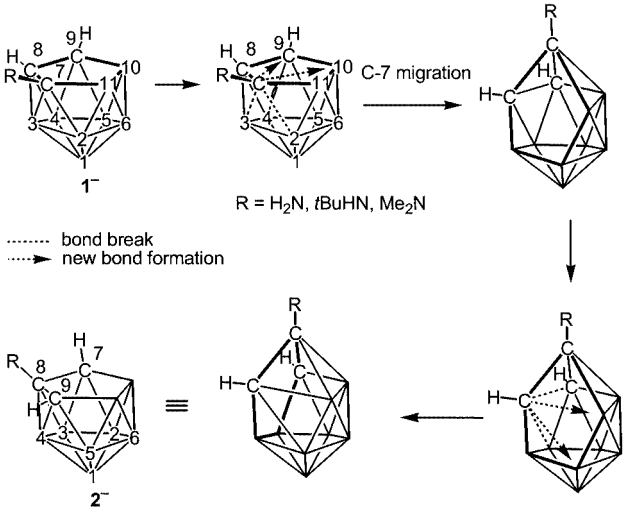
As shown in Scheme 1, selected zwitterionic compounds of the type 7-L-*nido*-7,8,9-$C_3B_8H_{10}$ [**1**: L = H_3N (**1a**), *t*BuH_2N (**1b**), Me_2HN (**1c**)] were deprotonated in situ at the exoskeletal N site by gentle heating with sodium hydride in DME (1,2-dimethoxyethane) or diethylene glycol dimethyl ether (diglyme) (see Table 1) to give the anions [7-R-*nido*-7,8,9-$C_3B_8H_{10}]^-$ [**1**$^-$: R = H_2N (**1a**$^-$), *t*BuHN (**1b**$^-$), Me_2N (**1c**$^-$)]. These were treated with selected metal reagents [FeI_2, $NiCl_2$, $NiCp_2$ (Cp = $C_5H_5^-$)] at elevated temperatures (95−140 °C, see Table 1) to give the isomeric anions [8-R-*nido*-7,8,9-$C_3B_8H_{10}]^-$ [**2**$^-$: R = H_2N (**2a**$^-$), *t*BuHN (**2b**$^-$), Me_2N (**2c**$^-$)]. Final acidification of the reaction mixture gave a series of neutral compounds of general formulation 8-R-*nido*-7,8,9-$C_3B_8H_{11}$ [**2**: R = H_2N (**2a**), *t*BuHN (**2b**), Me_2N (**2c**)]. As seen from Scheme 1, the net result of

these reactions is, instead of the expected metal complexation, an unusual migration of the amine functionality into the adjacent C-8 position. When compared to structures **1**, compounds **2** thus formed, have lost their original zwitterionic character, being transformed into the tautomeric 8-amino-substituted derivatives of the neutral tricarbaborane *nido*-7,8,9-$C_3B_8H_{12}$.[3] It should be noted that the reactions do not proceed without deprotonation of compounds **1** preceding the reaction with individual metal reagents. The role of the metal reagents is quite obscure, as no sign of complex formation is observed during the reactions, nevertheless, the reactions do not proceed in the absence of the metal reagent. Moreover, the reactions never come to completion (see Table 1) and the starting compounds can easily be recovered by chromatography.



Scheme 1

Although there is no direct evidence on the reaction mechanisms, the formation of anions of type $\mathbf{2}^-$ from anions of type $\mathbf{1}^-$ is consistent with a simple C-7 vertex-swing mechanism outlined in Scheme 2. The mechanism is similar to that proposed recently by Sneddon et al.[5] and involves the formation of two new bonds together with a cleavage of two original bonds around the C-7 vertex. The new system, thus formed, has one of the skeletal carbon atoms in an unfavorable high-connectivity position and is therefore rearranged in a similar manner to the isomeric anions $\mathbf{2}^-$.



Scheme 2

An interesting aspect is the final protonation of the $\mathbf{2}^-$ anions as there are two ways in which the proton can be added (see Scheme 1). In contrast to the anions $\mathbf{1}^-$, the protonation of $\mathbf{2}^-$does not occur on the exoskeletal nitrogen atom with the anticipated formation of the 8-L-*nido*-7,8,9-$C_3B_8H_{10}$ zwitterions (compounds of type **3**), but exclusively on the open-face B-10−B-11 edge to give the tautomeric 8-R-*nido*-7,8,9-$C_3B_8H_{11}$ (**2**) compounds, 8-substituted derivatives of the parent tricarbollide 7,8,9-$C_3B_8H_{12}$ (**4**).[3]

As demonstrated by a separate experiment, the deprotonation of compound **2b** with PS (see also Scheme 1) proceeds by abstraction of the μ_{10-11} bridging proton with the formation of anion $\mathbf{2b}^-$, which by reprotonation returns to the original compound **2b**, and not the zwitterionic compound **3b**.

Structural Studies

The structures of the neutral compound **2b** and the corresponding salt $PSH^+\mathbf{2b}^-$ were determined by single-crystal

Table 1. Conditions for the formation of 8-amino-substituted derivatives of type **2**

Starting compound	Metal reagent	Conditions	Product	Yield (%)
1a	FeI_2	DME, reflux, 2 h	**2a**	43 (50)[a]
1b	FeI_2	diglyme, 120 °C, 16 h	**2b**	48 (67)[a]
1b	$NiCl_2$	DME, reflux, 16 h	**2b**	51 (64)[a]
1b	$NiCl_2$	diglyme, 140 °C, 16 h	**2b**	60
1b	$NiCp_2$	diglyme, 140 °C, 24 h	**2b**	30
1c	$NiCl_2$	DME, reflux, 42 h	**2c**	18 (66)[a]

[a] Yields based on recovered starting compounds **1** in parentheses.

X-ray diffraction analyses (see Figures 1−3). The molecular structure of the latter salt shows that the arrangement of the substituent at the C8 site and the whole cage remain unaltered by deprotonation. Both structures confirm the adjacent position of all three of the cage carbon atoms in the *nido* cage and the substitution on the central C8 atom. Two symmetrically independent molecules in the unit cell of **2b** differ only slightly in the orientation of the *t*Bu moiety. Selected interatomic distances and angles for both species (see Table 2) show all expected features, with the shortest distances between carbon atoms. The longest interboron distances are those between the open-face B10−B11 vertices. This distance is even more elongated by the presence of the hydrogen bond in **2b** [1.841(3) Å] in comparison with the corresponding separation in PSH^+**2b**$^-$ [1.727(2) Å]. The latter distance is similar to that found for B10−B11 in the zwitterionic compound 7-*t*BuHMeN-7,8,9-$C_3B_8H_{10}$ [1.725(3) Å].[2b]

The structures of all remaining amino derivatives **2a** and **2c** were proposed from the structurally determined com-

pound **2b**, on the basis of close similarities in their NMR spectroscopic shielding behavior. The comparison revealed (see Figure 4) straightforward similarities between corresponding ^{11}B and ^{1}H resonances for all amino derivatives of **2**. The observed NMR spectroscopic data for this class of compounds (see Exp. Sect.), together with the results of mass spectrometry, are in excellent agreement with their formal descriptions as 8-amino-substituted derivatives of the previously reported parent tricarbaborane **4**.[3] All the cluster ^{11}B and ^{1}H resonances were interrelated by [^{11}B-^{11}B]-COSY[13] and/or ^{1}H{^{11}B(selective)}[14] experiments, which permitted complete assignments and thence comparisons with the known, but isomeric, 7-*t*BuMeN-10-Me-7,8,9-$C_3B_8H_{10}$ and 7-*t*BuMeN-10,11-Me_2-7,8,9-$C_3B_8H_9$ amine derivatives.[2b]

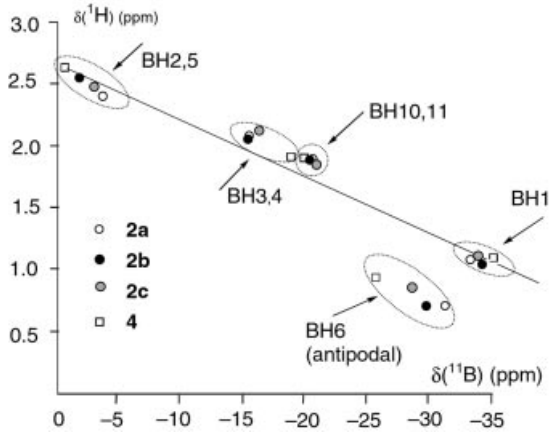

Figure 4. Graphical correlation between the ^{1}H and ^{11}B NMR chemical shifts for compounds **2a**, **2b**, and **2c**, and for the parent tricarbaborane **4**

As shown in Figure 4, the most significant feature of the compounds **2** is the 2:2:2:1:1 patterns of the ^{11}B resonances. These are very similar to those of the parent compound **4**, which is of the same C_s symmetry,[3] the most remarkable feature being the upfield shift of resonances assigned to the antipodal B-6 vertex. A similar effect was also observed in the spectrum of 8-Me-7,8,9-$C_3B_8H_{11}$,[3] the only 8-substituted derivative of **4** isolated so far. The ^{11}B NMR spectrum of PSH^+**2b**$^-$, showing (2+2+1):2:1 patterns of doublets (incidental overlap), is consistent with the same C_s symmetry. As expected, most of the peaks are markedly shifted upfield in comparison with adequate resonances observed for **2b** due to the absence of hydrogen bonding. This correlates closely with the observed bridge effect found in the ^{11}B NMR spectra for the couple of unsubstituted compounds **4** and [7,8,9-$C_3B_8H_{11}$]$^-$ (**4**$^-$).[3] Moreover, ^{1}H NMR spectra of compounds **2a**−**2c** clearly reveal, besides the 7,9-H resonance of intensity 2, a broad high-field singlet due to the presence of the μ_{10-11} bridging proton. As demonstrated graphically in Figure 4, there is an approximately linear correlation between the ^{11}B and ^{1}H chemical shifts for all derivatives of **2**, with the exception of data points for the antipodal B-6-H positions.

Mass spectrometric results along with similar chromatographic and solubility properties are all consistent with the proposed structures of the neutral derivatives of type **2**. Across the series, enhanced solubility in less polar solvents and higher R_f values were observed for **2** in comparison with the corresponding characteristics of the starting zwitterions of structure **1**.

Conclusions

It was shown that the zwitterionic tricarbollides **1** undergo an unusual metal-promoted cage rearrangement upon deprotonation and reaction with some metal reagents to generate isomeric compounds of type **2**. The net result of the rearrangement is a shift of the amine functionality to the adjacent position without changing the configuration of the cage carbon atoms. In contrast to the starting zwitterionic compounds of **1**, the rearranged compounds adopt the tautomeric neutral configuration of **2** and *not* the zwitterionic structure of **3** (see Scheme 1). The relation between structures **2** and **3** falls into the category of H-tautomerism as the two forms differ only in the positioning of the extra hydrogen atom. In structure **2** this hydrogen atom resides in the bridging open-face position, while in the zwitterionic structure **3** it would reside on the exoskeletal nitrogen atom. This interesting aspect of tautomerism in the eleven-vertex tricarbaborane series was encountered for the first time in the 7-substituted series of compounds of the general form 7-*t*BuMeN-10,11-R^1R^2-7,8,9-$C_3B_8H_9$ (R^1, R^2 = H or Me). For R^1 = R^2 = H these compounds exist exclusively in the zwitterionic form 7-*t*BuMeHN-7,8,9-$C_3B_8H_{10}$ (**1d** for L = *t*BuMeHN), while the formally *B*-mono- and *B*,*B*-dimethylated derivatives of **1d**, exist only in the neutral tautomeric forms 7-*t*BuMeN-10-Me-7,8,9-$C_3B_8H_{10}$ and 7-*t*BuMeN-10,11-Me_2-7,8,9-$C_3B_8H_9$.[2b] It seems highly probable that both the electron density on the nitrogen center and the type of substitution of the tricarbaborane core play decisive

roles in determining the preferences for individual tautomeric forms. It is also highly probable that compounds of the general structure **2**, isolated in this work, act as intermediates in the metal complexation reactions of anions of type $\mathbf{1}^-$.[6−12] We are currently studying the aspects of tautomerism and associated rearrangements of tricarbaborane cages occurring during the metal complexation process in more detail. Studies on further interesting rearrangement reactions of compounds of the type **2** and $\mathbf{2}^-$, at high temperatures, are also in progress.

Experimental Section

General Procedures: All reactions were carried out with the use of standard vacuum or inert gas techniques as described by Shriver,[15] although some operations, such as preparative LC, were carried out in air. The starting compounds **1** were prepared according to the literature.[2] The Aldrich DME and diglyme were dried with sodium metal and freshly distilled from sodium diphenylketyl or NaH. Hexane and benzene were dried with CaH_2, CH_2Cl_2 and P_2O_5 and then freshly distilled prior to use. Other chemicals were reagent grade and used as purchased. Preparative liquid chromatography was carried out using Aldrich silica gel (60−230 mesh) as the stationary phase under nitrogen. Analytical TLC on Macherey−Nagel plates with a UV indicator (silica gel on aluminium foil; detection by UV at 254 nm followed by 2% aqueous $AgNO_3$ spray) was used to check the purity of individual chromatographic fractions. Melting points were measured in sealed capillaries and are uncorrected. Elemental analyses were performed in the IIC analytical laboratories using standard procedures. Low-resolution mass spectra were obtained using a Finnigan MAT MAGNUM ion trap quadrupole mass spectrometer equipped with a heated inlet option, as developed by Spectronex AG, Basle, Switzerland (70 eV, EI ionization). Proton (^{1}H) and boron (^{11}B) NMR spectroscopy was performed at 11.75 Tesla with a Varian UNITY-500 instrument. The [^{11}B-^{11}B]-COSY[13] and ^{1}H{^{11}B(selective)}[14] NMR experiments were essentially as described in other related papers from our laboratories.[16] Chemical shifts are given in ppm to high-frequency (low field) of Ξ = 32.083971 MHz (nominally $F_3B{\cdot}OEt_2$ in $CDCl_3$) for ^{11}B (quoted ± 0.5 ppm) and Ξ = 100 MHz ($SiMe_4$) for ^{1}H (quoted ± 0.05 ppm), Ξ being defined as in ref.[17] Residual solvent ^{1}H resonances were used as internal secondary standards. Coupling constants $^1J_{BH}$ are taken from resolution-enhanced ^{11}B NMR spectra with a digital resolution of ± 8 Hz and are given in Hz.

General Conditions for the Synthesis of the 8-R-*nido*-7,8,9-$C_3B_8H_{11}$ Derivatives 2 [R = H_2N (2a), *t*BuHN (2b), Me_2N (2c)]: A slurry of the starting compound **1** (reaction scale 1.5 mmol), NaH (3.15 mmol) and solvent (DME or diglyme, 20 mL) was stirred at room temperature for 1 h and then heated at 90 °C (bath) for an additional hour whilst stirring. Excess metal reagent (see Table 1) (reaction scale 4.5 mmol) was then added and the mixture was stirred under the conditions given in Table 1. The solvent was rotaevaporated and the residue treated with a mixture of Et_2O (20 mL) and water (20 mL), and the aqueous layer was acidified with dilute hydrochloric acid to pH = 3.0 under cooling. The organic layer was then separated and the aqueous phase extracted with additional portions of Et_2O (2 × 20 mL). The combined ethereal extracts were concentrated and the residue treated with CH_2Cl_2 (15 mL) and silica gel (10 g). The solvent was evaporated, the solids were placed on top of a silica gel column (25 × 2 cm) and eluted with a CH_2Cl_2/pentane (1:1, v/v) mixture. The purity of individual fractions was checked by analytical TLC (for R_F values see Table 1). Essentially pure compounds of type **2** were obtained by concentration of the corresponding chromatographic fractions and the products were repurified by crystallization from hexane. Compound **2b** was purified by vacuum sublimation at 120 °C. Subsequent elution with CH_2Cl_2 or its mixtures with CH_3CN (up to 1:1 composition) recovered, in most cases, the starting compounds of type **1**. Reaction conditions for individual derivatives and yields are summarized in Table 1.

2a: R_f (CH_2Cl_2) = 0.40; m.p. 132 °C. ^{11}B NMR ($CDCl_3$): δ = −4.1 (d, $^1J_{B\text{-}H}$ = 159 Hz, 2 B, B-2,5), −15.5 (d, $^1J_{B\text{-}H}$ =171 Hz, 2 B, B-3,4), −20.4 (d, $^1J_{B\text{-}H}$ = 183 Hz, 2 B, B-10,11), −31.4 (d, $^1J_{B\text{-}H}$ = 153 Hz, 1 B, B-6), −32.8 (d, $^1J_{B\text{-}H}$ = 150 Hz, 1 B, B-1) ppm, all theoretical [^{11}B-^{11}B]-COSY cross-peaks observed. ^{1}H{^{11}B} NMR ($CDCl_3$): δ = 2.93 (s, 2 H, 7,9-H), 2.39 (s, 2 H, 2,5-H), 2.16 (br. s, 2 H, NH_2), 2.05 (s, 2 H, 3,4-H), 1.86 (s, 2 H, 10,11-H), 1.18 (s, 1 H, 1-H), 0.62 (s, 1 H, 6-H), −1.92 (s, 1 H, 10,11-μ-H). MS (70 eV, EI): *m*/*z* (%) = 151 (16) $[M]^+$, 150 (100) $[M - H]^+$. $C_3H_{13}B_8N$ (149.6): calcd. B 57.80; found 57.54.

2b: R_f (CH_2Cl_2) = 0.62; m.p. 95 °C. ^{11}B NMR ($CDCl_3$): δ = −1.5 (d, $^1J_{B\text{-}H}$= 162 Hz, 2 B, B-2,5), −15.4 (d, $^1J_{B\text{-}H}$ = 171 Hz, 2 B, B-3,4), −19.9 (d, $^1J_{B\text{-}H}$ = 192 Hz, 2 B, B-10,11), −29.9 (d, $^1J_{B\text{-}H}$ = 147 Hz, 1 B, B-6), −32.6 (d, $^1J_{B\text{-}H}$ = 150 Hz, 1 B, B-1).) ppm, all theoretical [^{11}B-^{11}B]-COSY cross-peaks observed. ^{1}H{^{11}B } NMR ($CDCl_3$): δ = 3.28 (s, 2 H, 7,9-H), 2.66 (s, 2 H, 2,5-H), 2.56 (br. s, 1 H, NH), 2.04 (s, 2 H, 3,4-H), 1.94 (s, 2 H, 10,11-H], 1.19 (s, 9 H, *t*Bu), 1.08 (s, 1 H, 1-H), 0.71 (s, 1 H, 6-H), −2.34 (s, 1 H, 10,11-μ-H) ppm. IR (KBr): $\tilde{\nu}$ = 2579 (B−H) cm^{-1}. MS (70 eV, EI): *m*/*z* = 207 (15) $[M]^+$, 206 (100) $[M - H]^+$. $C_7H_{21}B_8N$ (205.7): calcd. B 42.04, found 41.92.

2c: R_f (CH_2Cl_2) = 0.50; m.p. 75 °C. ^{11}B NMR (CD_3CN): δ = −3.76 (d, $^1J_{B\text{-}H}$ = 158 Hz, 2 B, B-2,5), −16.4 (d, $^1J_{B\text{-}H}$ = 168 Hz, 2 B, B-3,4), −20.6 (d, $^1J_{B\text{-}H}$ = 195 Hz, 2 B, B-10,11), −30.6 (d, $^1J_{B\text{-}H}$ = 140 Hz, 1 B, B-6), −33.6 (d, $^1J_{B\text{-}H}$ = 153 Hz, 1 B, B-1) ppm, all theoretical [^{11}B-^{11}B]-COSY cross-peaks observed. ^{1}H{^{11}B} NMR (CD_3CN): δ = 3.00 (s, 2 H, 7,9-H), 2.43 (s, 2 H, 2,5-H), 2.36 (s, 2 H, 3,4-H), 2.16 (m, 6 H, Me), 1.98 (s, 2 H, 10,11-H), 1.02 (s, 1 H, 1-H), 0.72 (s, 1 H, 6-H), −1.98 (s, 1 H, 10,11-μ-H) ppm. IR (KBr): $\tilde{\nu}$ = 2556 (B−H) cm^{-1}. MS (70 eV, EI): *m*/*z* = 179 (18) $[M]^+$, 178 (100) $[M - H]^+$. $C_5H_{17}B_8N$ (177.7): calcd. B 48.67; found 48.34.

PSH^+[8-*t*BuHN-7,8,9-$C_3B_8H_{10}$]$^-$ (PSH^+2b$^-$): A solution of PS (107 mg, 0.5 mmol) in hexane (15 mL) was added dropwise to a stirred solution of **2b** (100 mg, 0.48 mmol) in hexane (15 mL) over a period of 10 min. The mixture was stirred for an additional 30 min and a white, voluminous precipitate formed. The precipitate was isolated by filtration, washed with hexane (3 × 5 mL) and vacuum-dried to yield 188 mg (92%) of $PSH^+\mathbf{2b}^-$, which was identified by NMR spectroscopy. **PSH^+2b$^-$:** ^{11}B NMR (CD_3CN): δ = −18.5 (d, $^1J_{B\text{-}H}$ = 170 Hz, 2 B, B-10,11), −19.7 (d, $^1J_{B\text{-}H}$ =158 Hz, 5 B, B-2,3,4,5,6), −47.7 (d, $^1J_{B\text{-}H}$ = 139 Hz, 1 B, B-1) ppm, all theoretical [^{11}B-^{11}B]-COSY cross-peaks observed. ^{1}H{^{11}B } NMR (CD_3CN): δ = 18.81 (s, 1 H, PSH^+), 7.35−9.96 (m, 6 H, PS-aromatic), 3.21 (br. s, 6 H, PS-Me), 2.66 21 (br. s, 6 H, PS-Me), 2.17 (s, 2 H, 7,9-H), 1.30, 1.53, 1.80 (s, 1 H, 2 H, 2 H, 2,3,4,5,6-H), 1.13 (s, 9 H, *t*Bu), 0.97 (s, 2 H, 10,11-μ-H), 0.17 (s, 1 H, 1-H) ppm.

Protonation of PSH^+[8-*t*BuHN-7,8,9-$C_3B_8H_{10}$]$^-$ (PSH^+2b$^-$): A solution of $PSH^+\mathbf{2b}^-$ (126 mg, 0.3 mmol) in CH_2Cl_2 (20 mL) was treated with several drops of concentrated H_2SO_4 whilst stirring for 1 h and cooling to 0 °C. The organic layer was then separated and

the solvents were evaporated to give 59 mg (96%) of **2b**, which was identified by NMR spectroscopy by comparison with the characteristics of an authentic sample.

X-ray Crystallography: The crystal of **2b** was obtained by slow vacuum sublimation of the tricarbaborane at 120 °C and that of the $PSH^+\mathbf{2b}^-$ salt by slow concentration of the $CHCl_3$ solution in a glass tube. The colorless crystals of **2b** and $PSH^+\mathbf{2b}^-$ of dimensions 0.4 × 0.3 × 0.17 and 0.3 × 0.27 × 0.22 mm, respectively, were mounted on glass fibers with epoxy cement and measured with a four-circle diffractometer Nonius Kappa CCD equipped with a CCD area detector at 150(2) K with Mo-K_α radiation. The crystallographic details for both compounds are summarized in Table 3. The structures were solved by the direct method (SIR97)[18] and that of $PSH^+\mathbf{2b}^-$ was refined by a full-matrix least-squares procedure based on F^2 (SHELXL-97).[19] However, the crystal of **2b** underwent pseudomerohedral twinning, as discovered during the structure solution. The phase problem was therefore solved using the $P2_1$ space group and the model was later transformed into the $P2_1/c$ space group. The symmetry of the diffraction pattern is consistent with the orthorhombic space group $C222_1$ as the result of twinning due the matrix:

h' 0 0 1 h
k' 0 1 0 k
l' 1 0 0 l

The data were corrected accordingly during the refinement by a full-matrix least-squares procedure based on F^2 (SHELXL-97),[19] which yielded a ratio of twin parts 0.472/0.528. The absorption was neglected. All hydrogen atoms, except for those of the methyl groups, were localized on a difference Fourier map and refined isotropically. For $PSH^+\mathbf{2b}^-$, hydrogen positions of the methyl groups and those of the PSH^+ CH moieties were recalculated into idealized positions (riding model) and assigned temperature factors $H_{iso}(H) = 1.2\ U_{eq}$(pivot atom) or $1.5\ U_{eq}$ for the methyl moiety, others were localized on a difference Fourier map and refined isotropically. The final difference maps for both compounds had no peaks of chemical significance. Scattering factors were those implemented in the SHELX programs. CCDC-184057 and -190913 contain the supplementary crystallographic data for compounds **2b** and $PSH^+\mathbf{2b}^-$, respectively. These can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors gratefully acknowledge Drs. J. Fusek, Z. Plzák, and E. Večerníková from the Institute of Inorganic Chemistry, ASCR for providing NMR, mass, and IR spectra. The work was supported by the Ministry of Education of the Czech Republic (project no. LN 00A028) and Grant Agency of the Czech Republic (grant nos. 203/00/1042 and 203/99/M037, the latter is appreciated for the purchase of the Kappa CCD equipment).

New Mononuclear Manganese(III) Complexes with Hexadentate (N_4O_2) Schiff Base Ligands: Synthesis, Crystal Structures, Electrochemistry, and Electron-Transfer Reactivity towards Hydroxylamine

Anangamohan Panja,[a] Nizamuddin Shaikh,[a] Shankareswar Gupta,[a] Ray J. Butcher,[b] and Pradyot Banerjee*[a]

Keywords: Cyclic voltammetry / Electron transfer / Kinetics / Manganese

Four new manganese(III) complexes of hexadentate Schiff base ligand obtained from *N*,*N*′-bis(3-aminopropyl)ethylenediamine and salicylaldehyde, or salicylaldehyde derivatives having N_4O_2 donor sets – [Mn(sal-N-1,5,8,12)]ClO_4 (**1**), [Mn(5-Cl-sal-N-1,5,8,12)]ClO_4 (**2**), [Mn(5-Br-sal-N-1,5,8,12)]-ClO_4 (**3**), and [Mn(3-methoxy-sal-N-1,5,8,12)]ClO_4·H_2O (**4**) – have been synthesized and characterized. The crystal structures of **1** and **4** have been determined, and the kinetics of the electron-transfer reactions between these complexes and hydroxylamine hydrochloride have been followed spectrophotometrically in the 5.5–8.0 pH range. Similar kinetic reactivities of all the complexes towards a particular species of the reductant were noted. Hydrogen-bonded adduct formation between the reactants prior to electron transfer seems to be a possible reaction pathway, according to analysis of the experimental data.

Introduction

An important area of investigation in the bioinorganic chemistry of manganese is the study of the structures and reactivities of manganese(III) complexes incorporating biologically relevant heteroatom donor ligands. In this regard, syntheses and characterization of manganese(III) complexes with polydentate Schiff base ligands[1–6] have been an ongoing theme. In this communication we report the synthesis of a series of manganese(III) complexes with hexadentate Schiff base ligands possessing N_4O_2 donor sets (Scheme 1): [Mn(sal-N-1,5,8,12)]ClO_4 (**1**), [Mn(5-Cl-sal-N-1,5,8,12)]-ClO_4 (**2**), [Mn(5-Br-sal-N-1,5,8,12)]ClO_4 (**3**), and [Mn(3-methoxy-sal-N-1,5,8,12)]ClO_4·H_2O (**4**). Of these compounds, **1** and **4** have been characterized by X-ray crystallography. A kinetic study of these complexes with hydroxylamine in aqueous solution has been carried out in order to determine the electron-transfer reactivity of these complexes. The mechanistic versatility noted in the reaction behavior of hydroxylamine is attractive in that it can act both as an oxidant or a reductant,[7] and can coordinate through either the N- or the O-end.[8] The estimated bond dissociation energy for the N–H moiety[9] in hydroxylamine (92 kcal·mol^{-1}) is similar to that of the O–H group of tyrosine (85.5 kcal·mol^{-1}),[10,11] and so proton movement – as observed with tyrosine in PSII – may have some relevance to the observed reactions with hydroxylamine.

atoms are in a *trans* configuration, and the two coordinating ONN ligand halves are facial. The mean deviations of the manganese atom from the equatorial plane are 0.10 Å in **1** and 0.08 Å in **4**. The bond lengths are quite similar (Tables 1 and 2), the Mn−O(phenolic) lengths being 1.869(4) and 1.878(4) Å in **1** and 1.869(15) and 1.873(15) Å in **4**, the Mn−N(imine) bond lengths being 2.098(4) and 2.102(4) in **1** and 2.054(19) and 2.104(2) Å in **4**, and the Mn−N(amine) lengths being 2.207(4)/2.239(5) and 2.163(2)/2.174(2) Å, respectively. These are consistent with those reported for manganese(III) Schiff base complexes.[1,3−5] Both the lattices are hydrogen bonded, although the hydrogen bonding is less extensive in **1**. The intramolecular hydrogen bonding here involves the N−H moiety and the phenolic oxygen of the ligand and O of the perchlorate anion. The N−H···O(phenolic) distances are 3.199(12) and 3.387(12) Å, whereas N−H···O(perchlorate) is 3.098(18) Å. In **4**, on the other hand, the coordinated water molecule, together with the phenolic oxygen, amine nitrogen (N−H), and perchlorate anion, constitute a network (Figure 3). Both intra- and intermolecular hydrogen bonding are observed, the O(1W)−H···O(phenolic) distances being 2.858(3) and 2.837(7) Å, whereas the O(1W)−H···O(perchlorate) distances are 2.638(10), 3.196(8), and 3.227(7) Å. The amine hydrogen also enters into intramolecular hydrogen bonding with the oxygen of $-OCH_3$ in the aromatic ring, as well as with the H_2O molecule.

UV/Visible and IR Spectroscopy

The electronic absorption spectra for all the complexes **1−4** were recorded in acetonitrile, and data are given in Table 3. All the complexes exhibit similar spectral features. There are four important regions in the UV/Vis spectra for this set of complexes. The least intense bands appear in the 630−660 nm range, while another band of higher intensity is observed in the 510−540 nm range. The UV/Vis spectra

of all the complexes show ligand to metal charge-transfer bands in the 330−370 nm region. These bands are similar to those reported for hexacoordinate [Mn^{III}(BBPEN)](PF_6) [H_2BBPEN = *N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-methylpyridyl)ethylenediamine] with N_4O_2 donor sets.[12] The intense higher-energy bands in the region 220−280 nm are usually attributed to intraligand π→π* transitions, as observed previously for manganese(III) ions in octahedral environments.[6,12−15] It is interesting to note that all the bands are affected by the benzene ring substitution, which indicates that the frontier molecular orbitals of the high-spin manganese(III) complexes possess significant contribution from the ligands.

In order to provide some insight into the nature of redox and spectroscopically relevant orbitals, extended Hückel MO calculations, using the crystallographic parameters of **1** and **4**, were performed with the aid of the CACAO program (Figure S1 and Figure S2 in the Supplementary Material, see footnote on the first page of this article).[16] The lowest unoccupied molecular orbital (LUMO) of **1** was found to be strongly delocalized, with 61% metal contribution and 29% ligand contribution. The HOMO, on the other hand, is predominantly metal-based (84%), with little contribution from the ligand (6%). The closely spaced (ΔE = 0.036 eV) HOMO-1 also has the same character, but with less contribution from the metal orbitals (72% metal and 17% ligand). In **4**, the LUMO is also strongly delocalized, with a little more contribution from the ligand (58% metal and 33% ligand) relative to **1**. Two closely spaced (ΔE = 0.071 eV) HOMO (83% metal and 7% ligand) and HOMO-1 (64% metal and 30% ligand) orbitals are also delocalized, with a greater contribution from the metal in the former than in the latter.

The EHMO calculations indicate that the frontier molecular orbitals are predominantly metal-based, but with significant contributions from the ligands. The bands in the 630−660 nm range can therefore be assigned as predominantly d-d with some admixed MLCT character. These bands are similar to those reported previously for manganese(III)−Schiff base complexes.[6,12,13,17] The bands in the 510−540 nm range have previously been attributed to phenolato-to-manganese(III) LMCT for similar Mn^{III} complexes.[8,14,15,17] The EHMO calculations, however, indicate that all the frontier MOs are predominantly metal-based with significant contribution from the ligands, so the above assignment is not unambiguous. From the X-ray crystal data, the observed Mn^{III}−O(phenolate) average bond lengths are 1.873 Å for **1** and 1.871 Å for **4**, which is quite short in comparison with the reported values for manganese(III) complexes.[5,14,15,18] The shift of the 510−540 nm bands to much lower energy compared to those (ca. 480−490 nm) reported earlier indicates stronger interaction between the phenolato(O) and manganese(III) center[12] and supports the assignment of the 510−540 nm bands as LMCT from phenolato-to-Mn^{III}.

All the complexes show similar IR spectral features, each exhibiting a strong band attributable to ν(CN) between 1620−1627 cm^{-1}. All of them also show broad unsplit bands at 1081−1095 cm^{-1}, together with bands at 626−627 cm^{-1} indicative of the presence of a noncoordinated perchlorate counterion. As well as these, **4** exhibits a broad band at 3550 cm^{-1} due to the presence of a non-coordinated water molecule in the crystal, which is consistent with the molecular structure.

Electrochemical Studies

Cyclic voltammograms of all the Mn^{III} complexes were recorded in acetonitrile solution with TEAP as supporting electrolyte in the potential range from −1.2 to +1.2 V vs. SCE. The results are summarized in Table 4. As the cyclic voltammetric features of all the complexes are similar, a representative profile for **3** is shown in Figure 4. A notable feature for all the complexes is that an electrochemically quasi-reversible anodic wave and two well defined irreversible cathodic waves are detected. The anodic process corresponds to the Mn^{IV}/Mn^{III} couple, and the peak-to-peak separation lies between 80 mV to 120 mV, slightly above the value expected for a one-electron electrochemically reversible process.[19] The first irreversible cathodic process can be attributed to the Mn^{III}/Mn^{II} couple, in line with previously reported complexes of similar ligand environment.[1,13] The irreversibility of the Mn^{III}/Mn^{II} couple might be due to the

Table 4. Cyclic voltammetric results[a] for manganese(III) complexes at 298 K

Complex[a]	Mn^{IV}/Mn^{III} E_{pa}/V	Mn^{III}/Mn^{II} E_{pc}/V	ΔE_p/V	$(E_{1/2})$/V	E_{pc}/V
1	0.66	0.54	0.12	0.60	−0.60
2	0.78	0.68	0.10	0.67	−0.52
3	0.78	0.70	0.08	0.70	−0.54
4	0.64	0.55	0.09	0.59	−0.58

[a] Solvent: acetonitrile; working electrode: platinum; reference electrode: SCE; E_{pa} and E_{pc} are anodic and cathodic peak potentials respectively; $E_{1/2} = 0.5(E_{pa} + E_{pc})$; $\Delta E_p = E_{pa} - E_{pc}$; scan rate: 50 mV·s^{-1}.

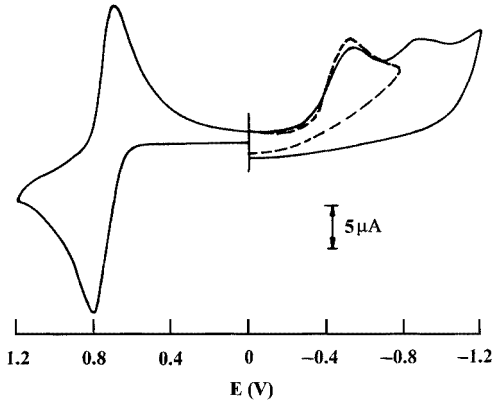

Figure 4. Cyclic voltammogram (scan rate 50 mV·s^{-1}) of complex **3** in acetonitrile at a platinum electrode with ferrocene as internal standard and TEAP as supporting electrolyte

instability of the formally Mn^{II} species.[20] The second cathodic process is very difficult to assign. It has been observed that the cyclic voltammogram of the free ligands features an irreversible reduction at about −1.0 V. The more negative (ca. −0.88 V) cathodic process in the complex is close to that observed for the free ligand. This chemical environment is not suitable to stabilize the Mn(I) state, and Mn^{II}/Mn^{I} couples are not usually observed for this type of complexes.[14] Because of the instability of the formally Mn^{II} species, there might be free ligand (probably protonated) available in the solution, resulting in the second irreversible cathodic wave.[20] The electrochemical results are consistent with those observed previously for manganese(III) complexes.[1,12,21] In the group of complexes at hand, both the E_{pc} and $E_{1/2}$ values are sensitive to substitution, both increasing with increasing electron-withdrawing power of the substituents. The standard extended Hückel MO calculation indicates that the frontier molecular orbitals are predominantly metal-based with significant contribution from the ligands. The ligand contribution both to the HOMO and to the LUMO is reflected in the change in the redox potentials with substitution in the benzene ring.

Electron-Transfer Reactivity

The electron-transfer reactivities of all four complexes were studied in the 5.5−8.0 pH range, with hydroxylamine as the reducing agent. The redox chemistry of hydroxylamine in solution is very complicated, due to its oxidation to various products depending upon the nature of the oxidants. It has been observed that the most common oxidation products of hydroxylamine are N_2O and N_2,[8,22−24] oxidation of hydroxylamine to NO_2^-, NO_3^-, and NO[22−24] being relatively rare.

Stoichiometry

Because of the formation of various products and the complicated redox chemistry involved, variable stoichiometry has usually been encountered for the oxidation of hydroxylamine by various oxidants.[8,22,23] The stoichiometry was therefore examined very carefully in the presence both of excess reductant and of excess oxidant. In the presence of excess hydroxylamine over the complexes, the stoichiometry was determined by bromatometric estimation of the unchanged reductant,[25] whereas in the presence of excess oxidant, the stoichiometry was measured spectrophotometrically with the aid of the known extinction coefficient of the complex (λ_{max} = 517 nm, ε = 820 dm^3 mol^{-1}·cm^{-1} for complex **3**). The results in Table 5 also imply a variable stoichiometry in our system. Thus, under the kinetic reaction conditions, the "putative first step" of the reaction may be given as shown in the following equations.

Table 5. Stoichiometry of the reduction of complex **3** by hydroxylamine hydrochloride (all concentrations are in mmol·dm^{-3}) at 30 °C

[Complex]	pH	$[NH_2OH]$	Δ[complex]/$\Delta[NH_2OH]$
3.00	5.50	30.0	1.05
3.00	5.50	15.0	0.97
20.0	5.50	2.00	1.95
10.0	5.50	2.00	1.75
3.00	8.00	30.0	1.03
3.00	8.00	12.0	1.20
20.0	8.00	2.00	1.98

$$Mn^{III}L + NH_2OH \rightarrow Mn^{II}L + 1/2\ N_2 + H^+ + H_2O \quad (1)$$

and with an excess of Mn^{III}

$$2\ Mn^{III}L + NH_2OH \rightarrow 2\ Mn^{II}L + 1/2\ N_2O + 1/2\ H_2O + 2\ H^+ \quad (2)$$

The appearance of a six-line EPR signal in the g = 2.0 region indicates that at least some complex is in the +2 state in the final form, thus supporting the above mechanism. The electrochemical study shows that the formally $Mn^{II}L$ species formed upon reduction of the parent complexes are unstable and readily decompose. The decomposed species may be hydrated Mn^{2+} ion in aqueous solution, together with free ligand. The formulation of the reduced product as $Mn^{II}L$ is therefore not unambiguous. However, externally added Mn^{2+} ion in the form of

$Mn(ClO_4)_2 \cdot 6H_2O$ was found to exert no effect on the rate of the reactions, indicating that the reduced product of the complexes has no influence on the electron transfer rate.

Kinetics and Mechanism

The kinetics of the oxidation of NH_2OH were observed under pseudo first-order conditions, with the reductant being maintained in large excess over the complex. At a fixed hydrogen ion concentration and ionic strength (pH = 6.0, I = 0.2 mol·dm^{-3} (NaCl), [phosphate] = 0.05 mol·dm^{-3}, temperature = 30 °C and λ = 360 nm), the observed rate constants ($k_{obsd.}$/s^{-1}) [Table 6] follow rate saturation kinetics at higher values of [NH_2OH] for all the complexes **1**−**4**. These observations are consistent with the theoretical rate law in Equation (3).

Table 6. Pseudo-first order rate constants ($k_{obsd.}$/s^{-1}) for the oxidation of NH_2OH by the complexes **1**−**4** at a fixed pH of 6.0 {kinetic conditions: [complex] = 5−6 ×10^{-5} mol·dm^{-3}, I = 0.20 mol·dm^{-3} (NaCl), [buffer] = 0.05 mol·dm^{-3} (phosphate), 30 °C}

10^3 [NH_2OH] [mol·dm^{-3}]	[NaCl][a] [mol·dm^{-3}]	mol % D_2O	10^3 $k_{obsd.}$ [s^{-1}] **1**	**2**	**3**	**4**
0.6		0	2.86	3.88	4.01	1.36
0.6		50	2.85			
0.6		90	2.82

3.0			6.63	6.61	7.68	3.25
5.0			7.68	7.99	9.29	3.88
7.0			7.88	8.93	9.57	4.05
10			8.31	9.68	11.1	4.33

[a] I = 1.0 mol·dm^{-3} ($NaNO_3$).

$$k_{obsd.} = (k\,Q\,[NH_2OH])/(1 + Q\,[NH_2OH]) \quad (3)$$

where Q is the association constant between the complex and the reductant prior to the electron-transfer reaction, and the parameters derived by fitting the experimental data to above equation at pH 6.0 are:

(i) k = (9.4±0.1) ×10^{-3} s^{-1} and Q = (791±37) for **1**

(ii) k = (1.03±0.05) ×10^{-2} s^{-1} and Q = (820±130) for **2**

(iii) k = (1.20±0.05) ×10^{-2} s^{-1} and Q = (792±98) for **3**

(iv) k = (5.20±0.1) ×10^{-3} s^{-1} and Q = (527±39.8) for **4**

The effect of pH on the rate of reaction was studied at a constant concentration of NH_2OH (6·10^{-4} mol·dm^{-3}) at which a strict first-order dependence is valid. The observed rate constants decrease with increasing pH (Table 7). Figure 5 shows the plot of k_{ox} vs. [H^+]. The observations are not unprecedented, similar findings having been made in the reaction between this reductant and several mononuclear and polynuclear manganese complexes reported previously,[9,26,27] and have been attributed to the generation of more reactive aquated derivatives of the complexes. The complexes **1**−**4** are octahedral, with all the coordination sites occupied by the four N atoms and the two O atoms of the ligand. An effort was made to examine the electrochemistry of the complex at different pH values in an acetonitrile/water medium, but no variance was seen. There was also no noticeable change in the electronic spectra of the complexes when recorded at different pH values. The conclusion that can be drawn from these observations is that either only one species of the Mn^{III} complexes is present, or that the reactivity of the protonated species is identical to that of the parent species, if one exists, over the pH range studied. The pH variation results are also inconsistent with those expected from the thermodynamic potential values of the reductants. It is well documented that the deprotonated forms of the reductants are more reactive than the protonated species, due to the changed oxidation potential.[28] On protonation, the oxidation potential of the reductant decreases significantly from +3.04 V for NH_2OH to +1.87 V for NH_3OH^+, according to[29]

Table 7. Pseudo-first order rate constants ($k_{obsd.}$/s^{-1}) for the oxidation of NH_2OH by the complexes **1**−**4** at different pH values (kinetic conditions: [NH_2OH] = 6 × 10^{-4} mol·dm^{-3}, [complex] = 5−6 ×10^{-5} mol·dm^{-3}, I = 0.20 mol·dm^{-3} (NaCl), [buffer] = 0.05 mol·dm^{-3} (phosphate), 30 °C)

pH	10^4 $k_{obsd.}$/s^{-1} **1**	**2**	**3**	**4**
5.50	61.3	64.2	69.9	28.8
5.75	41.7	41.1	55.3	19.0
6.00	28.6	40.0	42.7	13.6
6.25	23.5	32.3	31.6	11.2
6.50	19.0	27.9	25.6	9.10
7.00	9.80	14.4	16.7	6.50
7.50	5.50	9.00	4.50	3.00
8.00	3.40	5.00	2.50	1.20

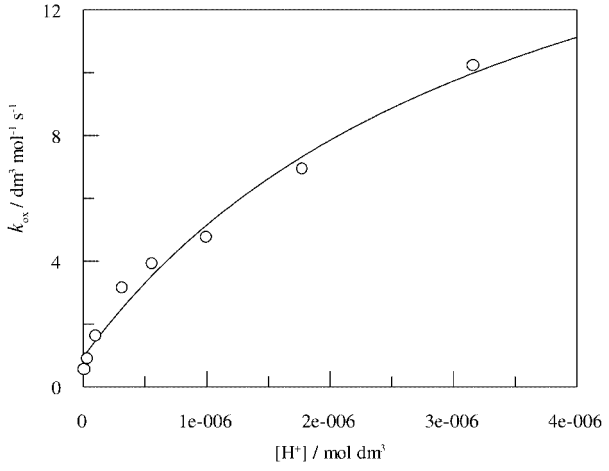

Figure 5. Plot of k_{ox} vs. [H^+] for the oxidation of hydroxylamine by **1** at 30 °C, I = 0.2 mol·dm^{-3} (NaCl), 0.05 mol·dm^{-3} phosphate buffer

$2\,NH_2OH \rightleftarrows N_2 + 2\,H^+ + 2\,H_2O + 2\,e$; E^0 = +3.04 V

$2\,NH_3OH^+ \rightleftarrows N_2 + 4\,H^+ + 2\,H_2O + 2\,e$; E^0 = +1.87 V

It is therefore unlikely that the observed decrease in $k_{obsd.}$ at higher pH values is due to the greater kinetic activity of NH_3OH^+ over NH_2OH. Rate saturation at higher [NH_2OH], however, with high association constant values, and also the leveling off of rates at higher [H^+], are clear indications of some sort of association between the complex and the reductant prior to the electron-transfer act. The self-exchange rate constant of the NH_2OH/NH_2OH^+ couple is very low (5×10^{-13} M^{-1}·s^{-1}), with $E^0 = +0.42$ V.[9,22] In the absence of any accurately determined potential value for the NH_3OH^+/NH_2OH^+ couple the self-exchange rate constant may be taken roughly as that for the NH_2OH/NH_2OH^+ couple.[9] The very low self-exchange rate constant value for the NH_3OH^+/NH_2OH^+ couple and the poor reducing character of the protonated reductant disfavors the outer sphere electron-transfer path. The structure of the complex also discounts the possibility of the formation of a seven-coordinated adduct with the Mn^{III} center, so formation of a hydrogen-bonded adduct (HA) is more reasonable to conceive. The EHMO calculations indicate that the lowest unoccupied molecular orbitals in all the complexes are predominantly metal-based, with significant contribution from the phenoxo ligand. Initial association between the reductant and the complex could involve an interaction with the metal center in addition to hydrogen bonding with the ligand prior to the electron transfer, and would be conducive for an inner sphere mechanism. The following sequence of reactions may be proposed to explain the observed kinetics.

$$NH_2OH + H^+ \overset{K_a}{\rightleftharpoons} NH_3OH^+ \quad (4)$$

$$Mn^{III}L + NH_3OH^+ \overset{Q_1}{\rightleftharpoons} (HA)_1 \xrightarrow{k_1} Mn^{II}L + NH_2O^{\cdot} + 2\,H^+ \quad (5)$$

$$Mn^{III}L + NH_2OH \overset{Q_2}{\rightleftharpoons} (HA)_2 \xrightarrow{k_2} Mn^{II}L + NH_2O^{\cdot} + H^+ \quad (6)$$

The termination of the free radicals for the consumption of a 1:1 ratio was reported to occur as in Equation (7).

$$2\,NH_2O^{\cdot} \xrightarrow{\text{fast}} N_2 + 2\,H_2O \quad (7)$$

The rate law derived from the above sequence of reactions can be given as:

$$k_{ox} = (k'_1\cdot[H^+] + k'_2\cdot K_a)/(K_a + [H^+]) \quad (8)$$

where $k_{ox} = k_{obsd.}/[NH_2OH]$, $k'_1 = k_1Q_1$, and $k'_2 = k_2Q_2$.

The derived kinetic parameters for all the complexes are: $k'_1 = 20.32\pm4.5$ dm^3·mol^{-1}·s^{-1}, $k'_2 = 0.95\pm0.29$ dm^3·mol^{-1}·s^{-1} and $K_a = (3.61\pm0.80) \times10^{-6}$ for **1**; $k'_1 = 13.0\pm1.5$ dm^3·mol^{-1}·s^{-1}, $k'_2 = 1.16\pm0.42$ dm^3·mol^{-1}·s^{-1}, and $K_a = (1.03\pm0.42) \times10^{-6}$ for **2**; $k'_1 = 15.29\pm1.5$ dm^3·mol^{-1}·s^{-1}, $k'_2 = 0.76\pm0.39$ dm^3·mol^{-1}·s^{-1}, and $K_a = (1.18\pm0.45) \times10^{-6}$ for **3**; $k'_1 = 10.00\pm3.4$ dm^3·mol^{-1}·s^{-1}, $k'_2 = 0.56\pm0.18$ dm^3·mol^{-1}·s^{-1}, and $K_a = (4.14\pm0.9) \times10^{-6}$ for **4**.

The pK_a values obtained from kinetic experiments are in good agreement with that reported for NH_2OH (pK_a = 6.0).[30] The composite parameters obtained from the above rate equation are indicative of the similar kinetic reactivity of all the complexes towards a particular species of the reductant. This is also reflected in the potential values of the complexes, which fall in a narrow range. The hydrogen-bonding association between the complex and the reductant species probably occurs through the phenoxo-O of the Schiff base and the hydrogen atom of the reductant. The low association constant ($Q = 5.27 \times 10^2$) encountered in complex **4** is probably a reflection of hindered hydrogen bonding involving the phenoxo-O and the reductant species.

Effect of Chloride Ions

Salem[27] observed that rate of the reaction between hydroxylamine and Mn^{III}-salen complex decreases considerably with increasing chloride ion concentration. It has been claimed that this is due to the lowering of redox potential as well as to the common ion effect, both of which shift the equilibrium according to Equation (9) to the left-hand side.

$$NH_3OH^+Cl^- \rightleftarrows NH_3OH^+ + Cl^- \quad (9)$$

To examine any influence of chloride ions in our systems, we varied its concentration at a fixed ionic strength but no [Cl^-] effect was observed (Table 6). We also carried out some kinetic experiments with hydroxylamine nitrate in place of hydroxylamine hydrochloride; the rate constant values were found to be unaffected. The lowering of redox potential is quite understandable for Mn^{III}-salen complex, since the Cl^- ion can occupy the axial position of Mn^{III} and produce an effect on redox potential, but this is impossible in the hexacoordinate complexes under study.

Solvent Isotope Effect

The rate saturation kinetics and pH dependence on the rate of the reaction indicate the formation of hydrogen-bonded precursor complexes between the Mn^{III} complexes and the reductant prior to the electron-transfer process. These facts prompted us to examine whether the electron-transfer path is coupled with proton movement, as in the case of tyrosine in PS II. We measured the rate constants in aqueous medium partially substituted with D_2O at a fixed concentration of NH_2OH and pH {[NH_2OH] = $6\cdot10^{-4}$ mol·dm^{-3}, pH = 6.0, [buffer] = 0.05 mol·dm^{-3} (phosphate), I = 0.2 mol·dm^{-3} (NaCl) and temp. 25 °C}. The observed rate constants in pure water are almost the same as those in a 90% D_2O/water mixture (Table 6), which rules out proton-coupled electron-transfer paths in this study.

Conclusions

The synthesis and characterization of four new manganese(III) complexes with hexadentate Schiff base ligands

with N_4O_2 donor sets − derived from *N*,*N*′-bis(3-aminopropyl)ethylenediamine and salicylaldehyde, or salicylaldehyde derivatives − are reported. Two of them have been characterized by X-ray crystallography, which shows two phenolic oxygen atoms in *trans* configurations and the two coordinating ONN ligand halves facial. Both the lattices are stabilized through extended hydrogen bonding. The ligand contribution both to the HOMO and to the LUMO is reflected in the change in the redox potentials as well as the shifting of UV/Vis spectra with substitution in benzene ring. The electron-transfer reactivities of all the complexes towards hydroxylamine in the 5.5−8.0 pH range are almost identical, as reflected in the evaluated kinetic parameters. It is also notable that the hydrogen-bonding association between the manganese(III) complexes and the reductant species probably occurs through the phenoxo-O of the Schiff base and the hydrogen atom of hydroxylamine. Chloride ion has no effect on the electron-transfer act, which contrasts with Salem's observations[27] for an almost identical reaction with hydroxylamine. Since the estimated bond dissociation energy for the N−H of hydroxylamine is similar to that of the O−H in tyrosine, an attempt was made to examine the possibility of proton movement during the electron-transfer act. The results of solvent isotope effect studies with variable mixtures of D_2O and water do not indicate any proton-coupled electron-transfer path.

Experimental Section

Materials: Hydroxylamine hydrochloride, *N*,*N*′-bis(3-aminopropyl)ethylenediamine, salicylaldehyde, 5-bromosalicylaldehyde, 5-chlorosalicylaldehyde, and *o*-methoxysalicylaldehyde were of analytical reagent grade (Aldrich) and were used without further purification. All other chemicals − manganese perchlorate hexahydrate, NaCl, NaH_2PO_4, acetonitrile, methanol, sodium hydroxide, and hydrochloric acid − were of reagent grade. Solvent isotope effects were examined with deuterium oxide, 99 atom% D (Aldrich).

Syntheses: All the complexes reported here were synthesized by air oxidation of solutions made up from $Mn(ClO_4)_2{\cdot}6H_2O$ and the Schiff base, by the same general procedure. A typical preparation is outlined below. (***Caution!*** Although no problems have been encountered in this work, perchlorates are potentially explosive and should be handled with care and only in small quantities).

[Mn(sal-N-1,5,8,12)]ClO_4 (1): *N*,*N*′-Bis(3-aminopropyl)ethylenediamine (1.74 g, 0.01 mol) was added to an ethanol (30 cm^3) solution of salicylaldehyde (2.44 g, 0.02 mol). The yellowish orange solution was brought to reflux for 1 h and then allowed to cool to room temperature, which was followed by the dropwise addition of $Mn(ClO_4)_2{\cdot}6H_2O$ (3.61 g, 0.01 mol) dissolved in ethanol (20 cm^3). The resulting dark brown solution was heated at reflux for 30 min. On subsequent cooling to room temperature, a microcrystalline compound separated out and was collected by filtration, washed with cold ethanol and diethyl ether, and dried under vacuum. Yield: 4.54 g, 85%. $C_{22}H_{28}ClMnN_4O_6$ (534.9): calcd. C 49.35, H 5.23, N 10.46; found C 49.21, H 5.26, N 10.28%. FTIR (KBr, cm^{-1}): ν(C=N) 1625, ν(C−O) 1280, ν(ClO_4^-) 1095 and 627. μ_{eff} 4.91 BM.

[Mn(5-Cl-sal-N-1,5,8,12)]ClO_4 (2): Yield: 4.94 g, 82%. $C_{22}H_{26}Cl_3MnN_4O_6$ (603.8): calcd. C 43.74, H 4.31, N 9.28; found C 43.63, H 4.49, N 9.19%. FTIR (KBr, cm^{-1}): ν(C=N) 1624, ν(C−O) 1281, ν(ClO_4^-) 1088 and 626. μ_{eff} 4.89 BM.

[Mn(5-Br-sal-N-1,5,8,12)]ClO_4(3): Yield: 5.54 g, 80%. $C_{22}H_{26}Br_2ClMnN_4O_6$ (692.7): calcd. C 38.13, H 3.75, N 8.09; found C 38.23, H 3.76, N 7.89%. FTIR (KBr, cm^{-1}): ν(C=N) 1627, ν(C−O) 1283, ν(ClO_4^-) 1088 and 627. μ_{eff} 4.94 BM.

[Mn(3-methoxy-sal-N-1,5,8,12)]$ClO_4{\cdot}H_2O$(4): Yield: 5.08 g, 83%. $C_{24}H_{34}ClMnN_4O_9$ (612.9): calcd. C 47.02, H 5.55, N 9.14; found C 47.13, H 5.49, N 9.01%. FTIR (KBr, cm^{-1}): ν(C=N) 1621, ν(C−O) 1281, ν(ClO_4^-) 1082 and 627, ν(O−H) 3550. μ_{eff} 4.92 BM.

Physical Measurements: Microanalysis (CHN) was performed in a Perkin−Elmer 240C elemental analyzer. Magnetic susceptibility measurement was carried out on a PAR 155 vibrating sample magnetometer. The EPR spectra were obtained on a Varian model 109 E-line X-band spectrometer equipped with a low-temperature quartz Dewar for measurements at 77 K. pH measurements were made with a Systronics digital pH meter (model 335, India). The observed pH was corrected by using the relationship, $pH = -\log[H^+] = pH_{obsd.} \pm 0.02$. IR spectra were obtained on a Nicolet, MAGNA-IR 750 spectrometer with samples prepared as KBr pellets. Cyclic voltammetry (scan rate of 0.05 $V{\cdot}s^{-1}$) was performed at a platinum electrode with an EG&G PARC electrochemical analysis system (model 250/5/0) in acetonitrile under dry nitrogen atmosphere in conventional three-electrode configurations.

Kinetic Measurements: Spectral and kinetic measurements were performed in an UV/Vis spectrophotometer (UV-2100, Shimadzu, Japan) with thermostatted cell compartments. The disappearance of the complex peak was monitored at 360 nm as a function of time. All the measurements were made under pseudo first-order conditions with use of an excess of hydroxylamine and a constant ionic strength of 0.2 $mol{\cdot}dm^{-3}$ (NaCl) with 0.05 $mol{\cdot}dm^{-3}$ phosphate buffer at 30 °C. The corresponding rate constants were evaluated by means of a suitable nonlinear curve fit program with data taken for at least three half-lives of the reactions. Every rate constant reported here represents the mean value of at least three determinations that fall within ±5%.

Crystal Structure Determination and Structural Refinements of Complexes 1 and 4: Single crystals of **1** were grown from acetonitrile/ethanol solution, and single crystals of **4** were obtained from acetonitrile/methanol solution. Each crystal was then mounted on an automatic Bruker P4 diffractometer equipped with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). Unit cell dimensions and intensity data were measured at 296 K. The structure was solved by direct methods and refined by full-matrix, least-squares based on F^2 with anisotropic thermal parameters for non-hydrogen atoms by use of Bruker SHELXTL (data reduction), SHELXS[31] (structure solution), and SHELXL[32] (structure refinement). The hydrogen atoms were included in structure factor calculations in their idealized positions. Information concerning crystallographic data collection and refinement of the structures is compiled in Table 8.

CCDC-191275 and -191276 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Crystallographic and Spectroscopic Studies of Dimeric Cu^{I} Complexes with Schiff-Base-Containing Triazole Ligands

Krzysztof Drabent,*[a] Zbigniew Ciunik,[a] and Piotr J. Chmielewski[a]

Keywords: Copper / Schiff bases / N ligands / Dimers / Self-assembly

New Cu^{I} complexes of the Schiff-base-containing triazole ligands *N*-[(*E*)-(4-chlorophenyl)methylidene]-4*H*-1,2,4-triazol-4-amine (ClPhtrz) and *N*-[(*E*)-phenylmethylidene]-4*H*-1,2,4-triazol-4-amine (Phtrz) have been synthesised and characterised. Depending on the reaction conditions ClPhtrz forms two different dimeric complexes **1** and **2**. X-ray crystallography revealed that each copper centre exhibits a planar trigonal coordination in **1**, while the tetrahedral coordination sphere of the copper centre in **2** is completed by a solvent molecule. In dimeric complex **3** the tetrahedral coordination of the Cu^{I} ions is formed by two monodentate and two bidentate (bridging) Phtrz ligands. Complexes **1**–**3** are unstable and easily lose coordinating and/or solvating acetonitrile molecules giving **4** (from **1** and **2**) and **5** (from **3**). On the basis of ESI MS and ^{1}H NMR and UV/Vis spectroscopy, it was shown that dimeric complexes **1**–**5** do not survive upon dissolution and dissociate rapidly forming mainly a 1:2 monomeric complex, along with a minor 1:1 complex.

Introduction

Binuclear and multinuclear transition metal complexes containing two or more metal centres bridged by multidentate ligands have been the subject of great interest in coordination chemistry.[1] Particular interest has been focused on five-membered aromatic nitrogen heterocycles (azoles) as ligands because of their ability to form complexes in which two metal centres are bridged by one, two or three azole groups.[1,2] The most studied bridging ligand of this type is the pyrazolate anion.[3,4] Recently, copper(I) complexes containing pyrazolate ligands have been extensively studied due to their ability to act as selective catalysts in the oxidation of organic substrates such as aliphatic and aromatic amines.[5,6] Different pyrazoles modified by introducing substituents on the heterocyclic ring have been involved in these studies.[5–7] Depending on the ring substituent copper(I) forms a large series of derivatives: neutral 1-D polymers $[Cu(pz)]_{\infty}$ for unsubstituted pyrazole,[8] cyclic trimers $[Cu(pz')]_3$ [pz′ = 3,5-dimethyl-4-nitropyrazole (Hdmnpz),[6] 3,5-dimethylpyrazole (Hdmpz),[9] 3,5-diphenylpyrazole (Hdppz),[10] 3,4,5-trimethylpyrazole (tmpzH)[11]] and cyclic neutral $[Cu(dppz)]_4$ [5] and anionic tetramers $[Cu_4(dmnpz)_6]^{-2}$.[6] However, the most frequently observed structure is a dimer $[Cu_2(pz'')_2X_n]$ [where pz″ = dmpz, dcmpz, dppz, dmnpz (Hdcmpz = 3,5-dicarbomethoxy pyrazole); X = isocyanide, pyridine, PPh_3].[5–8,12] The common feature of all these compounds is that pyrazole ligands are always connected to two adjacent copper(I) ions in an N^1,N^2-bridging mode.

Similar coordination properties could be expected for N^4-substituted 1,2,4-triazole as a ligand. In fact, a number of coordination compounds with this group of ligands coordinated to transition metal ions have been reported.[2] However, to the best of our knowledge, Cu^{I} complexes of N^4-substituted 1,2,4-triazoles are unknown. A limited number of structurally characterised systems based on copper(I) and deprotonated 1,2,4-triazolates have been reported.[13,14] In these systems the nitrogen atoms of the triazolate anion are coordinated to three different Cu^{I} ions, forming polynuclear species; copper(I) complexes with a 1,2,4-triazole moiety as a part of an organic ligand have also been reported.[15–18]

In this work we describe the synthesis of dimeric copper(I) complexes with Schiff-base-containing triazole ligands (Scheme 1). The complexes were characterised by X-ray crystallography. The results are compared with those reported for pyrazole-bridged Cu^{I} dimers. We also report the results of our study on the behaviour of these systems upon dissolution in acetonitrile.

Results and Discussion

Depending on the experimental conditions two products were obtained from the reaction between $[Cu(CH_3CN)_4](ClO_4)$ and *N*-[(*E*)-(4-chlorophenyl)methylidene]-4*H*-1,2,4-triazol-4-amine (ClPhtrz) in acetonitrile. Colourless, needle-shaped crystals of $[Cu_2(ClPhtrz)_4](ClO_4)_2\cdot 2CH_3CN$ (**1**) were grown overnight from a concentrated solution. When the crystallisation was carried on from a very dilute solution light-yellow, prismatic crystals of $[Cu_2(ClPhtrz)_4$-

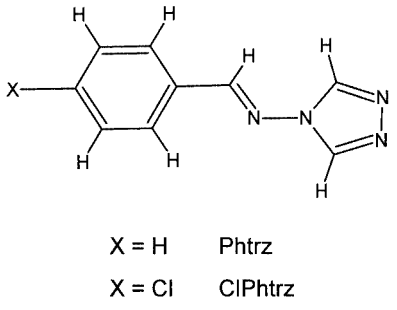
E-mail: drab@wchuwr.chem.uni.wroc.pl



Scheme 1

$(CH_3CN)_2](ClO_4)_2 \cdot CH_3CN$ (**2**) were formed after a much longer time (about 1 month).

The main difference between dimers **1** and **2** is the coordination mode around each copper atom: in **1** the metal ion is coordinated by three triazole ligands whereas in **2** additional coordination of an acetonitrile molecule gives a tetrahedral environment for the copper(I) ion.

The procedure described above is valid for a 1:2 metal-to-ligand ratio or with an excess of ligand in solution. When an excess of metal ion is used only **2** is formed. In the case of $[Cu_2(Phtrz)_6](ClO_4)_2 \cdot 2CH_3CN$ (**3**) the complex is formed in any metal-to-ligand molar ratio. When crystals of **1**−**3** are removed from acetonitrile solution they rapidly lose acetonitrile molecules (within a few minutes; see Exp. Sect.). In this way crystals of **1** and **2** give $[Cu_2(ClPhtrz)_4](ClO_4)_2$ (**4**), whereas **3** gives $[Cu_2(Phtrz)_6](ClO_4)_2$ (**5**). Crystals of **1**−**3** were characterised crystallographically, while complexes **4** and **5** were studied by spectroscopic methods (UV, ^1H NMR, ESI-MS).

Structural Studies

X-ray Structure of 1

The molecular structure of **1** is shown in Figure 1. It consists of a discrete binuclear copper(I) centre bridged by two N^1,N^2-coordinated ClPhtrz ligands. Surprisingly, an additional triazole ligand is bound to the Cu^I ion in a monodentate fashion. This unprecedented coordination mode results in almost *planar* tricoordinate, trigonal coordination environment with a small deviation [0.073(2) Å] of the metal centre from the plane defined by the N11, N12A and N21 atoms. The non-bonding Cu···Cu distance is equal to 3.508(1) Å. A slight deviation from planarity toward a chair-like configuration is observed due to the asymmetric triazole ligands forming a six-membered Cu-$[N\text{-}N]_2$-Cu ring. The copper atoms are located only 0.202(6) Å off the mean plane defined by four triazole nitrogens, well below the value reported for the Cu^I-pyrazole system (0.62 Å).[5] Furthermore, the Cu-N-N-Cu dihedral angle of 13.8(4)° is considerably smaller than that observed (41.7°) for the pyrazole-containing complex $[Cu(dppz)(RNC)]_2$ with the same conformation.[5] In the latter compound it has been suggested that the large value of the dihedral angle is due to the presence of steric interactions between the phenyl groups in the 3,5-positions of the ligand and the cyclohexyl isocyanide groups attached to the copper ions.

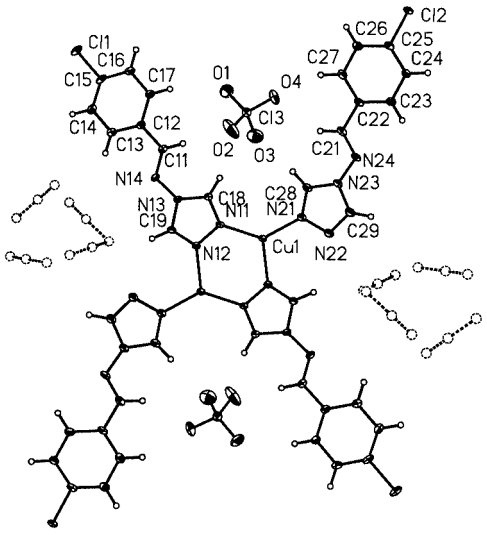


Figure 1. Molecular structure of the dimeric compound **1**; selected bond lengths [Å] and angles [°]: Cu1···Cu1a 3.508(1), Cu1−N11 1.948(3), Cu1−N21 1.937(3), Cu1−N12a 2.012(3); N21−Cu1−N11 131.57(13), N21−Cu1−N12 113.12(13), N11−Cu1−N12 114.89(12), Cu1−N11−N12−Cu1 13.8(4)

Because all the ClPhtrz ligands are coordinated in an almost planar *E* configuration the resulting binuclear unit can be described as an X-shaped dimer. These X-shaped dimers strongly influence the packing of the discrete units in the crystal (Figure 2). The dimers form sheets with an average distance of 3.04 Å between the planes. The chlorine atoms of the ligands (see Scheme 1) are located above and below each copper(I) ion [Cu···Cl = 3.129(1) and 3.242(1) Å, respectively; Cl···Cu···Cl = 158.44(3)°] and are believed to stabilise the packing. As a result rhomboidal channels, defined by the separation of the centre of Cu-$[N\text{-}N]_2$-Cu fragments, are observed parallel to the crystallographic [100] direction with a cross-section of about 15 × 15 Å. The ClO_4^- anions and solvent (acetonitrile) molecules are positioned in these channels (see Figure 2). Location of the non-coordinating solvent molecules in the channels makes them potentially labile and easy to remove from the crystals. The free-pore volume of the unit cell was estimated to be 696 $Å^3$ (25.2% of the total) with the PLATON[19] program (squeeze).

A trigonal environment of Cu^I such as that observed in **1** is rare for dinuclear compounds, but not unknown, and has been reported previously for complexes with pyrazole bridges.[5−7,12,20] However, in all those systems at least one other ligand coordinates to the copper ion. Three-coordinate copper(I) has also been detected in polymeric systems with different ligands.[14,21,22] The dimers derived from tris(pyrazolyl)borate[23] and tris(imidazole)methoxymethane[24] are rare examples of tricoordinate Cu^I complexes without bridges between the metals.

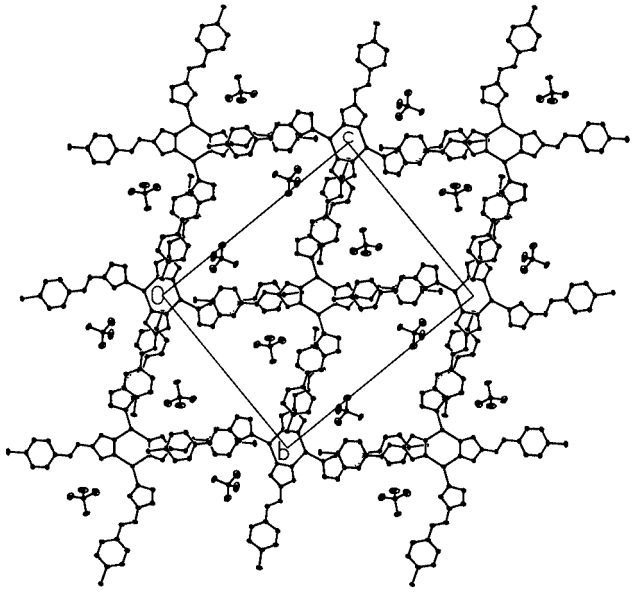

Figure 2. View of **1** along the crystallographic axis *a* illustrating the channels; the disordered acetonitrile molecules have been omitted for clarity

X-ray Structure of 2

When a dilute solution of $[Cu(CH_3CN)_4](ClO_4)$ and ClPhtrz ligand in acetonitrile was allowed to stand for a long time (about one month) light-yellow crystals of **2** were formed. The molecular structure of **2** is shown in Figure 3. The crystals of **2** contain discrete dimeric complexes of Cu^I bridged by two ClPhtrz ligands. Another triazole ligand is bonded in a monodentate fashion to each copper atom, as was observed for **1**. A molecule of acetonitrile completes the distorted tetrahedral coordination geometry. The increased steric crowding around the metal atoms considerably disturbs the planarity of the six-membered cycle defined by two copper and the four nitrogen atoms of bridging ligands. The observed chair-like conformation in **2** is more pronounced than in **1** and the Cu-N-N-Cu torsion angle is 34.2(3)°. The copper atoms are located 0.516(5) Å out of the plane defined by the four nitrogens of the bridging triazole ligands. Each metal ion is moved towards the coordinated acetonitrile molecules. The observed Cu−N distances [1.990(3) to 2.083(3) Å] lie well within the range for tetracoordinate copper(I) complexes[6,25] and are about 0.1 Å longer than the Cu−N bond lengths observed in **1** and other tricoordinate Cu^I structures.[5−8,12] The nonbonding Cu···Cu distance increases from 3.508(1) Å in **1** to 3.685(1) Å in **2**. The same tendency was reported previously for tri- and tetracoordinate pyrazole-containing dimers of Cu^I.[6]

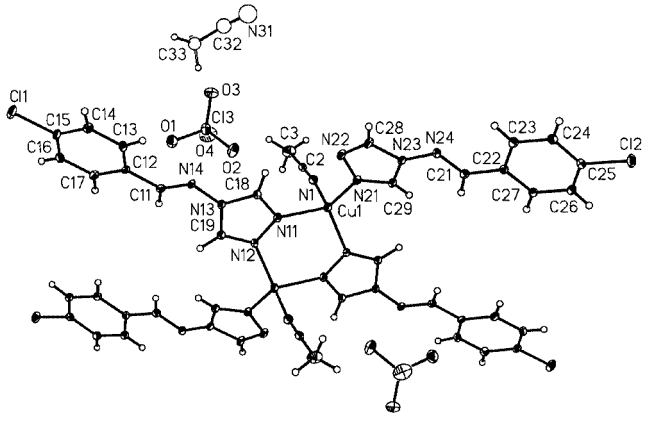

Figure 3. Molecular structure of the dimeric compound **2**; selected bond lengths [Å] and angles [°]: Cu1···Cu1a 3.685(1), Cu1−N11 2.082(3), Cu1−N21 1.991(3), Cu1−N12a 2.028(3), Cu1−N1 2.013(3); N21−Cu1−N1 116.02(11), N21−Cu1−N12 120.68(10), N1−Cu1−N12 102.33(10), N21−Cu1−N11 106.58(10), N1−Cu1−N11 100.12(10), N12−Cu1−N11 109.16(10), Cu1−N11−N12−Cu1 34.2(3)

X-ray Structure of 3

Another tetracoordinate complex **3** was obtained when the 4-chlorophenyl group in the triazole ligand was replaced by a phenyl substituent. A view of the molecule is shown in Figure 4. Compound **3** is a dinuclear Cu^I complex containing two bridging triazole groups as in the case of **1** and **2**. Surprisingly two additional triazole ligands are coordinated to each copper(I) ion in a monodentate fashion to give a coordination number of four, with all four coordination sites being occupied by triazole ligands. The more-regular tetrahedral surrounding of the Cu^I centres causes a less-pronounced chair-like configuration of the Cu-$[N\text{-}N]_2$-Cu ring and, in fact, the copper atoms are located only 0.152(3) Å out of the plane defined by the bridging triazole nitrogens. It is worth noting that this value matches well

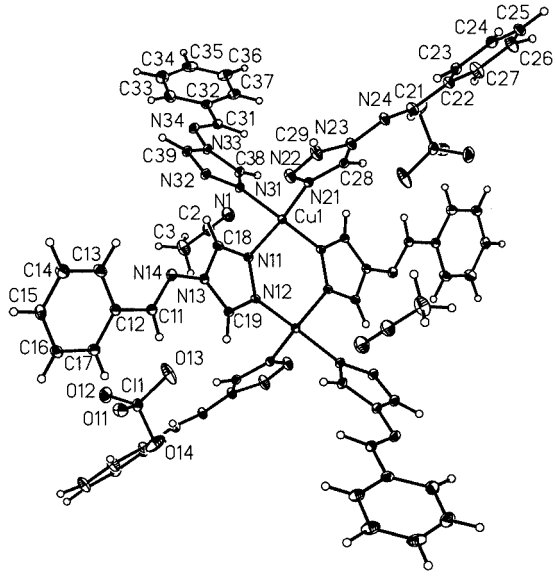

Figure 4. Molecular structure of the dimeric compound **3**; selected bond lengths [Å] and angles [°]: Cu1···Cu1a 3.6606(5), Cu1−N11 2.0737(15), Cu1−N21 2.0376(16), Cu1−N31 2.0220(16), Cu1−N12 1.9923(15); N12−Cu1−N31 119.72(6), N12−Cu1−N21 113.46(6), N31−Cu1−N21 107.02(6), N12−Cu1−N11 112.01(6), N31−Cu1−N11 102.58(6), N21−Cu1−N11 99.71(6), Cu1−N11−N12−Cu1 −10.3(2)

with the value observed in the tricoordinate compound **1**, although the Cu−N bond lengths [1.992(2) to 2.074(2) Å] and the nonbonding Cu···Cu distance [3.6606(5) Å] are closer to those observed in **2**.

Solution Studies

Mass Spectrometry

Formation of monomeric 1:2 and 1:1 complexes from the dimer has been observed by ESI mass spectrometry upon dissolution of original samples of **1**, **2** or **4**. Peaks at *m*/*z* (%) = 475.3 (100), 309.9 (70), 206.6 (10) and 144.5 (10) are observed in the ESI mass spectra independently of the sample used (see above). The isotopic peaks are separated by 1.0 amu, revealing a charge state of +1 for the corresponding ions. Therefore, the peaks at 475.3 and 309.9 correspond to $[Cu(ClPhtrz)_2]^+$ and $[Cu(ClPhtrz)(CH_3CN)]^+$ species, respectively. No peaks characteristic of the dimer entities could be detected in the ESI-MS spectra. The formation of the 1:2 and 1:1 complexes from the pure dimeric complexes should be accompanied by the release of both free ligand and free Cu^{I} cation. Indeed, weak peaks at 206.6 (for $[ClPhtrz]^+$) and at 144.5 (for $[Cu(CH_3CN)_2]^+$) are observed during the ESI-MS analysis.

Unexpected ESI-MS spectra were obtained for complexes **3** and **5**. Despite the different metal to triazole ligand ratio in dimer **3** (2:6) than in dimers **1** and **2** (2:4) the fragmentation led to the same pattern in the mass spectrum, i.e. a monomeric 1:2 species at 406.9 (attributed to $[Cu(Phtrz)_2]^+$) and a 1:1 species at 276.2 (attributed to $[Cu(Phtrz)(CH_3CN)]^+$). Dissociation of the parent dimer results in two additional peaks at 172.2 and 144.1 corresponding to free ligand $[Phtrz]^+$ and solvated copper(I) cation $[Cu(CH_3CN)_2]^+$, respectively

On the basis of the electrospray mass spectrometry results it can be concluded that the dimeric complexes $[Cu_2(ClPhtrz)_4]^{+2}$, $[Cu_2(ClPhtrz)_4(CH_3CN)_2]^{+2}$, and $[Cu_2(Phtrz)_6]^{+2}$ do not survive upon dissolution and dissociate rapidly to mainly form a 1:2 monomeric complex, along with a minor 1:1 complex. Similar phenomena have been observed for other Cu^{I} dimers.[23,24,26]

Spectroscopic Studies

The competitive equilibria related with dissociation of the complexes can also be observed by UV/Vis and ^1H NMR spectroscopy. The UV spectra of **4** or **5** in acetonitrile consist of two major bands: one centred at 210 nm and the other at 283 nm. Both bands contain several shoulders. Comparison of the spectrum obtained for the complex with that of the free ligand reveals a close similarity of the lower energy bands for each of the systems under study. In fact, these spectra are superimposable in this region after normalisation of the absorbance. The band at 210 nm can be reproduced by a superposition of the spectra of an appropriate free ligand and that of $[Cu(CH_3CN)_4]^+$ (Figure 5). Evidently, at the concentration level of electronic spectroscopy the overwhelming excess of acetonitrile ligand causes the complete substitution of Phtrz or ClPhtrz by CH_3CN in the first coordination sphere of the copper(I) ion.

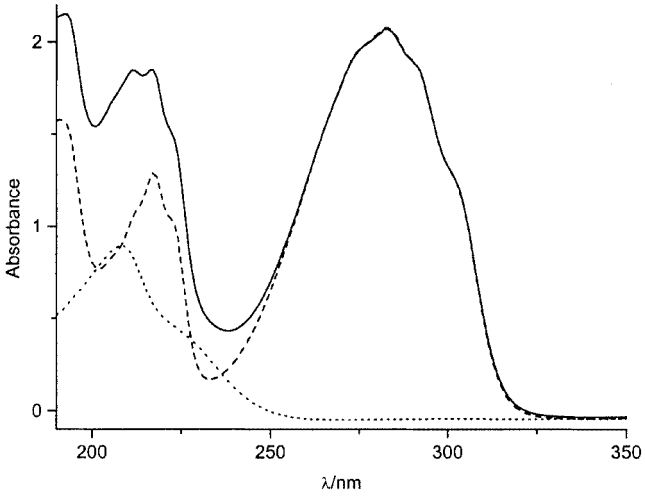

Figure 5. Electronic spectra of acetonitrile solutions of **4** (solid line), ClPhtrz (dashed line), and $[Cu(CH_3CN)_4]ClO_4$ (dotted line)

The ^1H NMR spectra of saturated solutions of the complexes in CD_3CN are consistent with the labile character of the complexes and also reveal the dissociation of the dimers upon dissolution in acetonitrile. The number of signals indicates the degeneracy of the respective resonances, i.e. there is only one peak for the azomethine group (N=CH), the triazole (trz) ring and each type of aryl ring proton (Figure 6). Differentiation of the chemical shifts is expected particularly for these protons that are in the vicinity of the coordination sites if the solid-state structure of the complex is retained in solution. Although the number of peaks is the same for both the complex and for the appropriate free ligand, the positions of the peaks differ considerably [**5** (Phtrz): δ = 8.869 (8.844) ppm (N=CH), 8.864 (8.791) (trz); **4** (ClPhtrz): δ = 8.845 (8.825) (N=CH), 8.838 (8.777) (trz) ppm; CD_3CN, 233 K]. This suggests an equilibrium between coordinated and free ligand in solution. Such an equilibrium, which is fast on the NMR timescale, causes an averaging of the chemical shifts. The considerable broadening of the triazole signal of the complex at low temperature is also consistent with the presence of a fast chemical exchange between coordinated and uncoordinated ligand. Titration of the complex solution with free ligand does not result in the appearance of any additional signals. Instead, it gradually shifts the position of all the peaks to those of the free ligand (Figure 6).

Conclusion

The results discussed here demonstrate that reaction between $[Cu(CH_3CN)_4](ClO_4)$ and Schiff-base-containing triazole ligands in acetonitrile gives various dimeric copper(I) complexes. The composition and geometry of these complexes depend on the reaction conditions (compounds

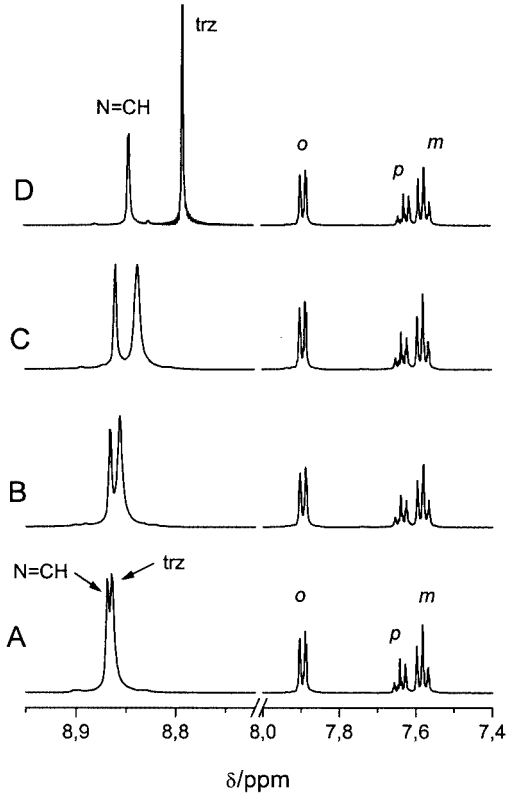

Figure 6. ^{1}H NMR spectra (500 MHz, CD_3CN, 233 K) of a saturated solution of **5** (A), mixtures of **5** and Phtrz (B and C) and Phtrz (D); assignments: N=CH − azomethine proton, trz − triazole protons, *o*, *m*, *p* − *ortho*, *meta*, *para* protons of phenyl substituent

1 and **2**) and/or type of ligand used (**3**), as confirmed by single-crystal X-ray diffraction. Our studies show that Schiff-base-containing triazole ligands coordinate simultaneously in the monodentate and bidentate mode. The latter results in them bridging two metal centres. This is in contrast with pyrazolylcopper(I) complexes, in which a pyrazole molecule acts solely as a bridging ligand. All studied crystals are unstable and lose acetonitrile molecules (coordinated and solvated) forming **4** (from **1** and **2**) and **5** (from **3**). Regardless of the stoichiometry, the complexes dissociate rapidly to form monomeric species upon dissolution, unlike the pyrazole-bridged dimers, which retain their dimeric structure in solution.

Experimental Section

General Remarks: ESI MS were performed on a Finnigan Mat type TSQ700 mass spectrometer. ^{1}H NMR spectra were recorded on a Bruker AM500 spectrometer in CD_3CN. UV spectra were recorded on a Hewlett Packard 8453 diode array spectrophotometer. Elemental analyses were carried out at the Microanalytical Laboratory of this University.

Starting Materials: Commercially available solvents, hydrazine monohydrate, formic acid, 4-chlorobenzaldehyde and benzaldehyde (Fluka) were used without further purification. $[Cu(CH_3CN)_4](ClO_4)$,[27] 4-amino-1,2,4-triazole,[28] and *N*-[(*E*)-(4-chlorophenyl)-methylidene]-4*H*-1,2,4-triazol-4-amine (ClPhtrz)[29] were prepared according to literature procedures. All reactions with Cu^I were carried out under a dry nitrogen atmosphere using standard Schlenk techniques.

Caution. *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small quantities of the compound should be prepared and handled with much care!*

***N*-[(*E*)-(phenyl)methylidene]-4*H*-1,2,4-triazol-4-amine (Phtrz):** An ethanolic solution (20 mL) of benzaldehyde (2.12 g, 20 mM) was added to a warm ethanolic solution (25 mL) of 4-amino-1,2,4-triazole (1.69 g, 20 mM) and the resulting solution was refluxed for four hours. The reaction mixture was then cooled to room temperature. The solution was evaporated to dryness under reduced pressure, and the crude product was recrystallised from ethanol/diethyl ether. The resultant white solid was filtered off, washed with diethyl ether and dried under vacuum. Yield 2.55 g, 74%; M.p. 144 °C (subl.). $C_9H_8N_4$ (172.2): calcd. C 62.78, H 4.68, N 32.54; found C 62.71, H 4.66, N 32.54. MS: *m*/*z* = 173 $[MH]^+$. ^{1}H NMR (500 MHz, CD_3CN, 298 K): δ = 8.84 (s, 1 H, N=CH) 8.74 (s, 2 H, triazole) 7.92 (m, 2 H, *ortho*) 7.64 (m, 1 H, *para*) 7.59 (m, 2 H, *meta*) ppm.

$\{[Cu_2(ClPhtrz)_4](ClO_4)_2\}\cdot 2CH_3CN$ (1): A solution of $[Cu(CH_3CN)_4](ClO_4)$ (164 mg, 0.5 mmol) in acetonitrile (5 mL) was added dropwise to an acetonitrile solution (15 mL) of ClPhtrz (207 mg, 1 mmol). The colourless solution was stirred for 15 min, then the volume of the solution was reduced by half over 4 hours in a stream of N_2. The resultant solution was allowed to stand overnight at room temperature, affording colourless, needle-shaped crystals of **1** which were collected by filtration, washed with acetonitrile and diethyl ether. The crystal used in the X-ray structure determination was selected from this sample. The molecular formula for **1** was established on the basis of X-ray crystallographic measurement (see Table 1). Elemental analysis data: vide infra.

$\{[Cu_2(ClPhtrz)_4(CH_3CN)_2](ClO_4)_2\}\cdot CH_3CN$ (2). ***Method A*:** The compound was obtained as described for **1**, but no reduction of solvent volume was done. The colourless solution was allowed to stand at room temperature for about one month. During this time light-yellow, prismatic crystals of **2** were formed.
***Method B*:** The compound was obtained as described in *method A*, but ClPhtrz (104 mg, 0.5 mmol) and $[Cu(CH_3CN)_4](ClO_4)$ (164 mg, 0.5 mmol) were used. After standing overnight at room temp. light-yellow, prismatic crystals were formed. The measured lattice parameters for the crystals obtained by *method B* were identical to those detected for **2** obtained by *method A*. The molecular formula for **2** was established on the basis of X-ray crystallographic measurement (see Table 1). Elemental analysis data: vide infra.

$\{[Cu_2(Phtrz)_6](ClO_4)_2\}\cdot 2CH_3CN$ (3): A solution of $[Cu(CH_3CN)_4](ClO_4)$ (164 mg, 0.5 mmol) in acetonitrile (10 mL) was added to an acetonitrile solution (10 mL) of Phtrz (172 mg, 1 mmol). The resultant light-yellow solution was stirred for 15 min, then about 4 mL of solvent was removed under a stream of dinitrogen. After 4 hours light-yellow crystals of **3** had formed. The crystals were filtered off, washed with acetonitrile and diethyl ether. The molecular formula for **3** was established on the basis of X-ray crystallographic measurement (see Table 1). Elemental analysis data: vide infra.

During the storage of the complexes even in a sealed vial under a dinitrogen atmosphere cracking of the crystals of **1** and **3** was detected, whereas crystals of **2** undergo complete powdering and become white. The analysis of the resulting products **4** and **5** indicated the loss of acetonitrile molecules, either independently solvated (**1** and **3**) or coordinated (**2**).[30] For **4**: $C_{36}H_{28}N_{16}Cl_6Cu_2O_8$ (1152.5):

calcd. C 37.52, H 2.45, N 19.44; (obtained from **1**) C 37.74, H 2.45, N 19.39; (obtained from **2**) C 37.38, H 2.47, N 19.43. For **5**: $C_{54}H_{48}Cl_2Cu_2N_{24}O_8$ (1359.1): calcd. C47.72, H 3.56, N 24.73; found C47.63, H 3.66, N 24.41. The elemental analytical data for **1** and **2** were analogous to that obtained for **4**, while elemental analysis showed that dried **3** and **5** were the same species.

X-ray Crystallographic Study: Crystal data of **1**−**3** are given in Table 1, together with refinement details. All measurements of crystals were performed at low temperature using an Oxford Cryosystem device on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo-K_α radiation. The crystals were positioned 65 mm from the CCD camera. 612 frames were measured at 0.75° intervals with a counting time in the range 10−20 sec. Accurate cell parameters were determined and refined by least-squares fit of 1900 to 3100 of the strongest reflections. Data reduction and analysis were carried out with the Oxford Diffraction (Poland) (formerly Kuma Diffraction Wrocław, Poland) programs. The data were corrected for Lorentz and polarisation effects. An analytical absorption correction was also applied for **3**. Data reduction and analysis were carried out with the Oxford Diffraction (Poland) Sp. z o. o. (formerly Kuma Diffraction Wrocław, Poland) programs. The structures were solved by direct methods (program SHELXS-97[31]) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL-97[32] programs. In the studied crystals the acetonitrile solvent molecules are disordered, with occupancy parameters of 0.25 in **1**, and 0.5 in **2**, whereas in **3** one molecule has two different orientations in an 0.84:0.16 ratio. The ClO_4^- ion in **3** is also slightly disordered, with two distinct orientations approximately in a 0.93:0.07 ratio. Non-hydrogen atoms were refined with anisotropic displacement parameters except for the disordered solvent molecules in **1** and **2** and the minor components of the disordered acetonitrile molecule and perchlorate ion. Hydrogen atoms were included from the geometry of the molecules and Δρ maps. During refinement their parameters were fixed.
CCDC-198765−198767 (**1**−**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The Electronic Absorption Characteristics of Mixed Phthalocyaninato Porphyrinato Rare Earth(III) Triple-Deckers $M_2(TPyP)_2(Pc)$

Xuan Sun,[a] Xuegui Cui,[a] Dennis P. Arnold,*[b] Michael T. M. Choi,[c] Dennis K. P. Ng,[c] and Jianzhuang Jiang*[a]

Keywords: Phthalocyanines / Porphyrins / Sandwich complexes / Lanthanides

Mixed phthalocyaninato tetrakis(4-pyridyl)porphyrinato rare earth triple-decker complexes $M_2(TPyP)_2(Pc)$ [M = La (**1**), Eu (**2**)] have been prepared by condensation between M(TPyP)acac generated in situ and $M(Pc)_2$. Their symmetrical structure (TPyP)M(Pc)M(TPyP) was verified by ^1H NMR (1D and 2D) spectra in $CDCl_3$ solutions. The electronic absorption spectra of these two compounds were recorded in the UV/Vis and near-IR region. A weak absorption in the near-IR region at 860 and 942 nm for **1** and **2**, respectively, was observed as the lowest energy band and is attributed to the electronic transition from HOMO to LUMO for these mono(phthalocyaninato) bis(porphyrinato) rare earth complexes. Their electrochemical properties were investigated by cyclic voltammetry (CV) and differential pulse voltammetry (DPV). Analysis of the relationship between the optical and redox properties of $M_2(TPyP)_2(Pc)$ reveals that the HOMO and LUMO of $M_2(TPyP)_2(Pc)$ have both porphyrin and phthalocyanine character.

Introduction

Sandwich-type phthalocyaninato and/or porphyrinato metal complexes have been intensively studied.[1−3] These species comprise two or three aromatic macrocyclic ligands held in close proximity by eight-coordinate metal ions in the +3 or +4 oxidation state. They exhibit a wide range of intriguing physical and chemical properties which render them useful in molecular (semi)conductors, molecular electronics and electrochromic displays.[4−5] Although heteroleptic and mixed tetrapyrrole ring complexes containing different phthalocyaninato and porphyrinato ligands have aroused increasing interest in recent years, relatively little is known about their optical, electrochemical and functional properties.[3] As part of our continuing exploration of this novel class of compounds, we have developed several effective pathways for preparing heteroleptic bis(phthalocyaninato) rare earth and mixed (na)phthalocyaninato porphyrinato rare earth double- and triple-deckers and systematically investigated their structural, electrochemical and spectroscopic (both electronic and vibrational) properties.[6−8]

Electronic absorption is one of the most powerful methods to characterize sandwich-type tetrapyrrole metal complexes. With regard to the optical properties of mixed phthalocyaninato porphyrinato rare earth sandwich complexes, it is worth pointing out that we have been intrigued by the significant difference in the appearance of the electronic absorption spectra of $(Por)M^{III}(Pc)M^{III}(Por)$ (for a list of abbreviations, see Table 1) from those of $[M^{III}(Por)(Pc)]^-$ since the very beginning of our research in this field.[9,10]

Table 1. List of abbreviations for ligands

Abbreviation	Ligand
P	general phthalocyaninato or porphyrinato
Pc	phthalocyaninato
Por, Por′	general porphyrinato
TPyP	5,10,15,20-tetrakis(4-pyridyl)porphyrinato
TPP	5,10,15,20-tetraphenylporphyrinato
TClPP	5,10,15,20-tetrakis(4-chlorophenyl)porphyrinato
TBPP	5,10,15,20-tetrakis(4-*tert*-butylphenyl)porphyrinato
TOMPP	5,10,15,20-tetrakis(4-methoxyphenyl)porphyrinato
OEP	2,3,7,8,12,13,17,18-octaethylporphyrinato
Nc	2,3-naphthalocyaninato (linearly annelated tetrabenzophthalocyaninato)

It is well known that an absorption band in the near-IR region is the most prominent feature in the electronic

absorption spectra of all the neutral homoleptic and heteroleptic tetrapyrrole double-decker rare earth(III) complexes. Such complexes contain an unpaired electron on one ring thus can be depicted as a monoanion radical $P^{\cdot -}$ (P = Por, Pc).[1,2] This near-IR band has been attributed to the ring-to-ring intramolecular charge transfer (RRCT) from the dianion P^{2-} electron donor to the monoanion radical $P^{\cdot -}$ electron acceptor.[3,11] In the spectra of the one-electron reduced form $[M^{III}(Por)(Pc)]^-$, no absorption band has ever been observed in the near-IR region beyond 800 nm, presumably due to the absence of an unpaired electron.[1−3] The reduced mixed ring complexes $[M^{III}(Por)(Pc)]^-$ display electronic absorption features common to both $[M^{III}(Por)_2]^-$ and $[M^{III}(Pc)_2]^-$ or $[M^{IV}(Pc)_2]$.[9,11−13] Thus, except for a weak absorption at ca. 480 nm assigned to a new π-π* transition arising from molecular orbitals delocalized over both rings, the porphyrin Soret band in $Li[M^{III}(TPyP)(Pc)]$ (M = Eu, Gd) appears at ca. 411 nm, whereas the phthalocyanine Soret and Q bands appear at ca. 330 and 584, 635, and 800 nm, respectively.[9]

The electronic absorption spectra of mixed phthalocyaninato porphyrinato rare earth triple-decker compounds $M^{III}_2(Por)_2(Pc)$ [having the constitution (Por)M(Pc)M(Por)] (Por = TPP, TClPP, TBPP, TOMPP) are usually recorded in the region of 300−800 (at most to 900) nm.[10] As these compounds are composed of two $[M^{III}(Por)(Pc)]^-$ moieties, which possess a common Pc^{2-} unit strongly interacting with two outer Por^{2-} rings, their absorption features should be easily understood on the basis of the electronic absorption spectra of $[M^{III}(Por)(Pc)]^-$. However, due to the increased ring-ring separation and consequently decreased ring-ring interaction in triple-deckers $M^{III}_2(Por)_2(Pc)$, all the absorption bands are expected to shift to the red as compared with those in the reduced double-decker counterparts $[M^{III}(Por)(Pc)]^-$. The absorptions at ca. 354 and 420 nm for $Eu_2(Por)_2(Pc)$ (Por = TPP, TClPP, TBPP, TOMPP) can be assigned to the phthalocyaninato and porphyrinato Soret bands, respectively. The band at around 490 nm has been compared to the similar weak absorption at ca. 480 nm for $Li[M^{III}(TPyP)(Pc)]$ (M = Eu, Gd) and similarly assigned to the π-π* transition arising from molecular orbitals delocalized over both rings. The remaining absorptions in the visible region at 539−551 and 603−605 nm for the various $Eu_2(Por)_2(Pc)$ complexes are mainly contributed by the Q bands of the phthalocyanine ring. Apparently, no absorption band similar to that at ca. 800 nm for reduced double-decker $Li[M^{III}(TPyP)(Pc)]$ has been found in the electronic absorption spectra of these triple-deckers. It is this phenomenon that has appeared anomalous to the primary authors of our group for a long time.

Researchers in this field including ourselves have not paid sufficient attention to the characteristic absorption of (Por)-$M^{III}(Pc)M^{III}(Por)$ in the near-IR region beyond 800 nm. One reason for this oversight is the hypothesis that there would be no absorptions in the near-IR region because there is no unpaired electron (hole) in such sandwich triple-deckers. Another reason for overlooking absorption in the near-IR region is the very low intensity of this absorption band (see below), which might be related to the decreased ratio of phthalocyanine to porphyrin in this kind of triple-deckers as well as the generally very weak absorption of porphyrins in the near-IR region. The last reason for missing the near-IR absorption is that the work in mixed phthalocyaninato porphyrinato rare earth triple-deckers thus far has mainly focused on the complexes of Sm, Eu, and Gd,[10] whose lowest energy absorption in the near-IR region is beyond 900 nm.

Our recent work on the 2,3-naphthalocyanine-containing mixed ring sandwiches revealed that $M_2(OEP)_2(Nc)$ $[(OEP)M^{III}(Nc)M^{III}(OEP)]$[8a] complexes exhibit a rather intense near-IR absorption (1000−1100 nm) associated with the HOMO−LUMO electron transition. This encouraged us to re-investigate the electronic absorption characteristics of triple-decker compounds $(Por)M^{III}(Pc)M^{III}(Por)$ and finally led to the discovery of the weak near-IR absorption band in the region of 860−960 nm for the mixed ring triple-decker complexes $M_2(TPyP)_2(Pc)$ (M = La, Eu). Herein we report these results, together with associated electrochemical and NMR characterization data.

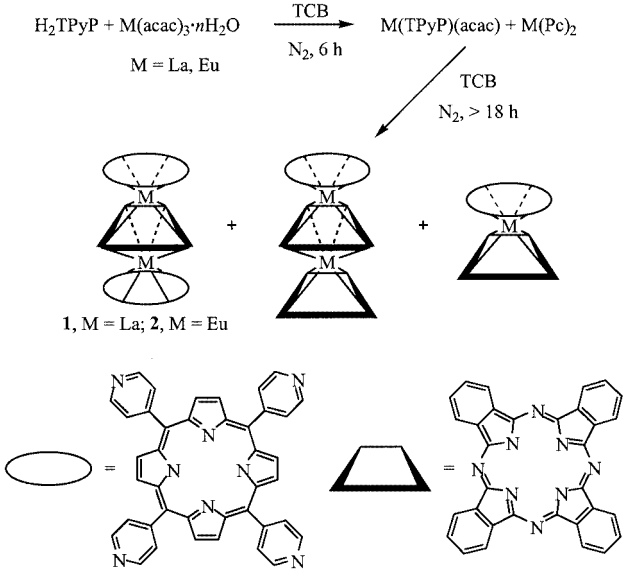
Results and Discussion

Synthesis

There are several possible synthetic pathways to rare earth(III) triple-decker complexes with mixed tetrapyrrole ligands $M_2^{III}(Por)_2(Pc)$.[1,3] The most commonly used method involves direct condensation between $H_2(Por)$ and $Li_2(Pc)$ in the presence of $M(acac)_3{\cdot}nH_2O$. However, in addition to the target mixed ring triple-deckers M_2^{III}-$(Por)_2(Pc)$, double-decker $M^{III}(Por)(Pc)$ together with another form of triple-decker $M_2^{III}(Por)(Pc)_2$ were also isolated by this method. The second familiar route is the so-called raise-by-one-story method in which the mono(porphyrinato) compound M(Por)acac generated in situ is treated with mixed ring double-decker M(Por)(Pc). By using this synthetic route, both homo- and heterodinuclear metal triple-deckers $M_2^{III}(Por)_2(Pc)$ or $(Por)M(Pc)M'(Por')$ can be isolated.[14] The third path to $M_2^{III}(Por)_2(Pc)$ developed recently by our group involves the tetramerization of phthalonitriles on the template of mono(porphyrinato) rare earth complex M(Por)acac in *n*-octanol catalyzed by the organic base DBU.[15]

However, it is worth mentioning that none of the above-mentioned procedures works for the tetrakis(4-pyridyl)porphyrin ligand. No $M_2(TPyP)_2(Pc)$ has ever been isolated for rare earths other than cerium thus far. The condensation between H_2TPyP and Li_2Pc with $M(acac)_3{\cdot}nH_2O$ (M = Eu, Gd) usually leads to the formation and isolation of reduced mixed ring double-deckers Li[M(TPyP)(Pc)] together with trace amounts of $M_2(TPyP)(Pc)_2$.[9] In the recent work in which we tried to prepare the mixed ring triple-decker $Eu_2(TPyP)(Pc)_2$ starting with H_2TPyP and $Eu(Pc)_2$ in the presence of $Eu(acac)_3{\cdot}nH_2O$ in refluxing TCB, unexpectedly the triple-decker $Eu_2(TPyP)_2(Pc)$ (**2**) was isolated as the primary product after refluxing the mixture for 18 h. Later it

was found that the other form of triple-decker $Eu_2(TPyP)(Pc)_2$ could only be isolated as the main product after a relatively short reaction time, say less than 12 h. Moreover, pre-preparation of the mono(porphyrinato) compound M(TPyP)acac was found to be unnecessary. More systematic and careful studies revealed that the one-pot reaction of H_2TPyP, $M(Pc)_2$ and $M(acac)_3{\cdot}nH_2O$ could lead directly to the formation of $M_2(TPyP)_2(Pc)$, $M_2(TPyP)(Pc)_2$ and some M(TPyP)(Pc) (M = La, Eu), the relative yields of which were determined by the refluxing time. This indicates that the neutral double-decker M(TPyP)(Pc) produced by degradation of the triple-decker $M_2(TPyP)(Pc)_2$ formed in the first step (Scheme 1) is the intermediate. The neutral double-decker reacts further with M(TPyP)acac formed in situ to generate the mono(phthalocyaninato) bis(porphyrinato) triple-decker compound $M_2(TPyP)_2(Pc)$. This postulate is supported by the isolation of a large amount of $Eu_2(TPyP)(Pc)_2$ when the mixture of H_2TPyP, $Eu(Pc)_2$ and $Eu(acac)_3{\cdot}nH_2O$ is refluxed for a short time (6 h) and relatively high yield of neutral double-decker Eu(TPyP)(Pc) after reflux for a relatively long time (10 h). The fact that Li[M(TPyP)(Pc)] (M = Eu, Gd) could not directly form triple-deckers $M_2(TPyP)_2(Pc)$ seems to suggest that the reduced double-decker Li[M(TPyP)(Pc)] is quite stable and the lithium cation is located on the top of the Pc ring, which prevents the reduced double-decker from reacting further with M(TPyP)acac. The relatively high stability of the reduced form of TPyP-containing double-deckers $[M^{III}(TPyP)(Pc)]^-$ is further confirmed by the isolation of protonated mixed [tetrakis(4-pyridyl)porphyrinato]-(phthalocyaninato) rare earth double-deckers HM^{III}-(TPyP)(Pc) (M = Eu, Gd, Y) formed by tetramerization of phthalonitrile on the template of the mono(porphyrinato) compound M(TPyP)acac.[13]



Scheme 1. Synthesis of rare earth triple-deckers

It has been found that among the whole series of rare earth metals, only the lighter rare earths with large enough ionic radius could connect three OEP rings to form homoleptic triple-deckers $M_2(OEP)_3$ (M = La, ..., Tb except for Pm).[1,16,17] This is also true for the formation of mixed ring triple-deckers $M_2(TPyP)_2(Pc)$ as will be detailed elsewhere. The lower yield of $Eu_2(TPyP)_2(Pc)$ (**2**) than $La_2(TPyP)_2(Pc)$ (**1**) is thus rationalized by the smaller ionic size of Eu.

These two compounds were fully characterized by various spectroscopic methods. The MALDI-TOF mass spectrum of **2** and the predicted isotope pattern are shown in the Electronic Supporting Information. However, satisfactory elemental analysis results could not be obtained for these two compounds as is usual for sandwich-type phthalocyaninatoand/or porphyrinato metal complexes and has been reported by different research groups.[15,18]

^{1}H NMR Spectra of $M^{III}_2(TPyP)_2(Pc)$ [M = La (1), Eu (2)]

The molecular structures of the newly prepared triple-decker complexes were clearly demonstrated to be of the form (TPyP)M(Pc)M(TPyP) (M = La, Eu) by their NMR spectra recorded in $CDCl_3$. The chemical shift data for the TPyP β-pyrrole, pyridyl, and Pc α- and β-protons are collected in Table 2, together with the T_1 values for protons in **2**. The assignments of the spectra for both the diamagnetic lanthanum complex and the weakly paramagnetic europium complex were achieved by virtue of the resolved multiplicity in the signals for the Pc α- and β-protons, the availability of spectra for related triple-deckers[10,15,19,20] and the 2D spectra. The positions on the pyridyl rings are labeled *ortho* and *meta* with respect to the bond to the porphyrin *meso*-carbon atom, and the terms *exo* and *endo* refer to the two possible environments with respect to the neighboring (inner) Pc ring. The *exo*/*endo* positions are exchanged by rotation about the bond between the pyridyl *ipso*-carbon atom and the porphyrin *meso*-carbon atom, but at room temperature, rotation is slow enough, as usual for *meso*-tetraarylporphyrins, that the usual AA′XX′ pattern is split into two pairs of signals. We show the ^{1}H NMR spectra of **1** and **2** in Figure 1 and the COSY spectrum of **1** in the Electronic Supporting Information. The sequence of assignments was as follows. The Pc proton signals could be readily identified by their integrals, their characteristic downfield positions, and the double-doublet signals (for **1**) at δ = 9.40 and 8.50 ppm for the α- and β-protons, respectively. The β-porphyrin signal was obvious as a unique 8-proton singlet at δ = 7.35 ppm. The *endo*- and *exo*-*ortho*- and *endo*- and *exo*-*meta*-proton signals appear as broad peaks and were readily assigned as *ortho*/*meta* pairs according to the COSY spectrum. At 30 °C the β-Pc signal overlaps with one of the py signals. For the paramagnetic Eu complex **2**, the assignment of the pair of *ortho*-protons is obvious from measurement of T_1 − faster relaxation is consistent with average proximity to the paramagnetic ion. In addition, an NOESY experiment with short mixing time (150 ms), showed positive cross peaks relating the protons in chemical exchange (EXSY), confirming these assignments. The only remaining ambiguity is the assignment of *exo*/*endo* for each pair of resonances. This has yet to be confirmed and will

Table 2. ^{1}H NMR spectroscopic chemical shifts (T_1 [ms] for Eu complex) for the triple-deckers (TPyP)M(Pc)M(TPyP) in $CDCl_3$ (300 MHz, 30 °C)

Complex[a][b]	Por β	*endo,ortho*	*endo,meta*	*exo,ortho*	*exo,meta*	Pc α	Pc β
1 La,La	7.36 s	9.52 b	9.11 b	6.48 b	8.51 b[c]	9.40 dd	8.50 dd
2 Eu,Eu	3.97 s	11.41 d	10.29 d	4.91 d	8.14 d	12. 56 d	10.73 d
	(150)	(190)	(760)	(190)	(760)	(140)	(390)

[a] Multiplicities: s = singlet, d = doublet, dd = double doublet, b = broad. [b] Assignments of *endo*/*exo* tentative (see text). [c] Signal overlapped with that of the Pc β-proton signals.

require variable-temperature ROESY experiments. The present assignments for **2** are based on the expected strong downfield pseudo-contact shift near the coordinated ion, i.e. on the *endo* side of the py ring. The assignments for **1** have been aligned with those for **2**. In the spectrum of compound **2**, the Pc α- and β-proton signals are less resolved than in analogue **1** because of broadening due to the paramagnetic europium ion. Conversely, the signals of the pyridyl protons of **2** are narrower than those in triple-decker **1** despite the presence of the paramagnetic europium ion. This is attributed to the slower rotation of pyridyl groups about the bond between the pyridyl *ipso*-carbon atom and the porphyrin *meso*-carbon atom associated with the smaller Eu^{III} ion and thus shorter ring−ring distance in compound **2**.

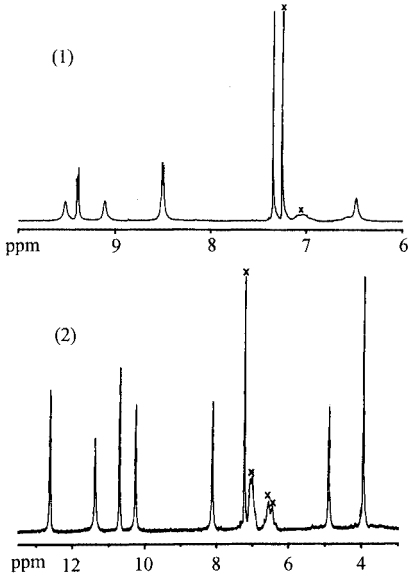


Figure 1. ^{1}H NMR spectra of $La_2(TPyP)_2(Pc)$ (**1**) and $Eu_2(TPyP)_2(Pc)$ (**2**) in $CDCl_3$

$M_2(Por)_2(Pc)$ (Por = TPP, TClPP, TOMPP, TBPP).[10] However, in the near-IR region, a weak absorption band was also observed at 860 and 942 nm for **1** and **2**, respectively. It is noteworthy that re-examination of the electronic absorption spectra of previously reported $M_2(Por)_2(Pc)$ (M = Ce, Sm, Eu, Gd; Por = TPP, TClPP, TOMPP, TBPP) showed that this near-IR absorption at 860−960 nm is common for these mixed ring triple-decker compounds although it had been ignored by most previous studies for the reasons mentioned in the Introduction. After carefully re-examining the documents in this field, the sole work that ever mentioned this absorption before the present report appears to be that of Tran-Thi, who drew the absorption of $Ce_2(TPP)_2(Pc)$ at 890 nm in a schematic representation of the electronic absorption bands for this compound.[12] However, this band was not discussed further.

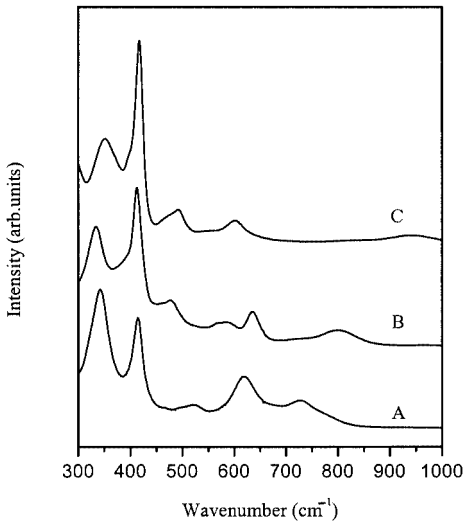

Figure 2. Electronic absorption spectra of (A) $Eu_2(TPyP)(Pc)_2$ in $CHCl_3$, (B) Li[Eu(TPyP)(Pc)] in MeOH, and (C) $Eu_2(TPyP)_2(Pc)$ (**2**) in $CHCl_3$

Electronic Absorption Spectra of $M^{III}_2(TPyP)_2(Pc)$ [M = La (1), Eu (2)]

The electronic absorption spectra of the mixed phthalocyaninato porphyrinato rare earth triple-decker compound **2** together with that of Li[Eu(TPyP)(Pc)] and the related triple-decker $Eu_2(TPyP)(Pc)_2$ are displayed in Figure 2. $M^{III}_2(TPyP)_2(Pc)$ shows similar features in the region from 300 to 800 nm to those of previously reported analogues

As expected, since compound $Eu_2(TPyP)_2(Pc)$ (**2**) consists of two units of $[(TPyP)Eu(Pc)]^-$, **2** indeed exhibits very similar electronic absorption spectrum to the corresponding double-decker Li[Eu(TPyP)(Pc)].[9] The Pc^{2-} and Por^{2-} Soret bands of **2** appear at 351 and 417 nm, respectively. The Pc^{2-} Q bands, which also contain some contributions from the Por ligands, appear at 602 and 942 nm, respectively. The absorption assigned to another π-π* transition

arising from molecular orbitals delocalized over both Pc and Por macrocycles is located at 492 nm. Compared with the spectra of the corresponding double-decker Li[Eu(TPyP)(Pc)], all of the corresponding absorption bands in **2** have been found to red-shift to some extent, indicating the decreased ring-ring interaction in the triple-decker because of the increased ring-ring distance.

For the purposes of comparison, the electronic absorption spectrum of another mixed tetrapyrrole triple-decker species $Eu^{III}_2(TPyP)(Pc)_2$ [(TPyP)Eu(Pc)Eu(Pc)] is also shown in Figure 2. This compound can be regarded as composed of $[(TPyP)Eu(Pc)]^-$ and $[(Pc)Eu(Pc)]^-$. However, the absorption spectrum is not simply a superposition of the spectra of the constituent double-decker species $[(TPyP)Eu(Pc)]^-$ and $[(Pc)Eu(Pc)]^-$, indicating apparent ring−ring interaction between the one Por and the two Pc moieties. The Soret bands of $Eu^{III}_2(TPyP)(Pc)_2$ appear to be composed of two peaks at 340 and 415 nm, which are mainly derived from Pc and TPyP Soret bands, respectively. The prominent Q bands appear at 621 and 740 nm, respectively. Based on similarities in the appearance as well as the relative absorption intensities of these two absorptions to those of phthalocyaninato rare earth triple-decker compounds $M_2(Pc')_3$ at 630−650 and 680−710 nm,[20] these two Q bands are considered to arise mainly from the two neighboring Pc chromophores connected by one europium cation $[(Pc)Eu(Pc)]^-$. Comparison between the electronic absorption spectra of $Eu^{III}_2(TPyP)(Pc)_2$ and $Eu^{III}_2(TPyP)_2$-(Pc) (**2**) clearly reveals that the remaining weak band in the spectrum of the former compound at ca. 520 nm is mainly contributed by $[(TPyP)Eu(Pc)]^-$.

Correlation between Optical and Redox Properties of $M^{III}_2(TPyP)_2(Pc)$ [M = La (1), Eu (2)]

The redox properties of mixed phthalocyaninato porphyrinato rare earth triple-decker compounds $M^{III}_2(Por)_2(Pc)$ [M = La (**1**), Eu (**2**)] were investigated by cyclic voltammetry (CV) and differential pulse voltammetry (DPV) in CH_2Cl_2. The half-wave redox potentials vs. SCE are summarized in Table 3. The cyclic voltammetry of compounds **1** and **2** is similar to that of known analogues.[10] Both these triple-deckers undergo two quasi-reversible one-electron oxidations and two quasi-reversible one-electron reductions under the present conditions. By analogy with the electrochemical properties of related sandwich complexes, especially (na)phthalocyaninato and/or porphyrinato rare earth sandwich complexes, all these processes can be attributed to successive electron removal from or addition to the ligand-based orbitals which are represented by the following five redox states: $[M_2(TPyP)_2(Pc)]/[M_2(TPyP)_2$-$(Pc)]^+$, $[M_2(TPyP)_2(Pc)]^+/[M_2(TPyP)_2(Pc)]^{2+}$, $[M_2(TPyP)_2$-$(Pc)]/[M_2(TPyP)_2(Pc)]^-$, and $[M_2(TPyP)_2(Pc)]^-/[M_2$-$(TPyP)_2(Pc)]^{2-}$.

The potential difference between the first oxidation and the first reduction process, $\Delta E^\circ_{1/2}$(oxd.1−red.1), is an important value for sandwich phthalocyaninato and/or porphyrinato complexes. As the first oxidation step and first reduction step, respectively, involve the HOMO and the LUMO of the molecule, the energy difference between these two redox processes corresponds to the electrochemical molecular band gap. The value $\Delta E^\circ_{1/2}$(oxd.1−red.1) should reflect the energy necessary for the transition of an electron from the HOMO to the LUMO of respective sandwich species and therefore should correlate with the lowest energy optical transition. The equation $\Delta E^\circ_{1/2}$(oxd.1−red.1) − hν = 0.01 eV was established between the redox characteristics and the lowest energy bands of monomeric metalloporphyrins M(Por).[21] According to this equation and the $\Delta E^\circ_{1/2}$(oxd.1−red.1) values of 1.71 and 1.51 V for **1** and **2**, respectively, these two triple-decker compounds should show the lowest energy band at 729 and 827 nm, respectively. However, these results are far away from the observed maxima of 860 and 942 nm for **1** and **2**, respectively, perhaps indicating the significant contribution from the phthalocyanine ring to the frontier orbitals of $M^{III}_2(Por)_2$-(Pc). Moreover, the discrepancy between the experimental and calculated data for these two triple-deckers $M_2(TPyP)_2(Pc)$ is larger than that for double-deckers $[M^{III}(Por)(Pc)]^-$,[11] which seems to suggest that the frontier molecular orbitals of $M_2(TPyP)_2(Pc)$ contain more phthalocyanine contribution. This appears difficult to understand at first glance as the ratio of phthalocyanine to porphyrin in triple-decker $M_2(TPyP)_2(Pc)$ is lower than in double-decker $[M^{III}(Por)(Pc)]^-$. However, this result could be rationalized by the fact that the central Pc ring interrupts direct interaction between the two TPyP ligands in $M_2(TPyP)_2(Pc)$ and the Por and Pc ring-to-ring distance in triple-deckers is larger than in double-deckers. It may also be that such a correlation is inappropriate for sandwich complexes in general. However, it is noteworthy that the maxima of the lowest energy electronic band for naphthalocyanine-containing mixed ring triple-decker analogues $M_2(OEP)_2(Nc)$ correspond well with the calculated values based on their redox data according to the above equation.[8a] This correspondence may well be fortuitous due to the similar redox properties of OEP and Nc rings and is unlikely to mean

Table 3. Electrochemical data for the triple-decker complexes

Compound[a]	$E^\circ_{1/2}$(oxd.2)	$E^\circ_{1/2}$(oxd.1)	$E^\circ_{1/2}$(red.1)	$E^\circ_{1/2}$(red.2)	$\Delta E^\circ_{1/2}$(oxd.1−red.1)
$La_2(TPyP)_2(Pc)$ (**1**)	1.42	0.97	−0.74	−1.27	1.71 V

[a] Recorded with $[Bu_4N][PF_6]$ as electrolyte in CH_2Cl_2 (0.1 M) at ambient temperature. Potentials were determined by cyclic voltammetry with a scan rate of 100 mV s^{-1}, and are expressed as half-wave potentials ($E_{1/2}$) in volts relative to SCE.

that the molecular orbitals, especially the HOMO and LUMO of $M_2(OEP)_2(Nc)$, possess only porphyrin character.

Conclusion

In summary, the HOMO and LUMO of mixed ring triple-deckers $M_2(TPyP)_2(Pc)$ (M = La, Eu) consist of contributions from both macrocycles. However, the research into this subject for mixed phthalocyaninato porphyrinato metal derivatives is relatively undeveloped at this stage due to the lack of systematic investigation into the optical and redox properties of such kinds of compounds. It is clear that the unexpected existence of near-IR absorption for neutral mixed ring triple-deckers warrants further experimental and theoretical attention, and work in this regard is in progress.

Experimental Section

General: $CHCl_3$ and CH_3OH were used as received from Beijing Chemical Reagents. H_2TPyP was purchased from Aldrich. $M(acac)_3{\cdot}nH_2O$[22] and $M(Pc)_2$[23] were prepared according to published procedures. The electronic absorption spectra were recorded with Hitachi U-3300 and Hitachi 3100 spectrophotometers. ^1H NMR spectra were recorded with a Bruker Avance 400 spectrometer at the Centre for Molecular Architecture, Central Queensland University, in $CDCl_3$ solutions at ca. 30 °C. Electrochemical measurements were carried out with a BAS CV-50 W voltammetric analyzer. The cell comprised a platinum-sphere working electrode, a silver-wire counter electrode, and an $Ag/AgNO_3$ (0.1 M in MeCN) reference electrode, which was connected to the solution by a Luggin capillary whose tip was placed close to the working electrode. Typically, a 1.0 mM sample solution containing 0.1 M $[Bu_4N][ClO_4]$ in CH_2Cl_2 was purged with nitrogen for 20 min, then the voltammograms were recorded at ambient temperature. Potentials were referenced to the Ag/Ag^+ couple in MeCN, which was taken as +0.31 V vs. SCE as determined for this system previously using ferrocene as an internal standard.[24]

Preparation of Triple-Decker $La_2(TPyP)_2(Pc)$ (1): A mixture of $La(acac)_3{\cdot}nH_2O$ (15 mg, 0.03 mmol), H_2TPyP (18 mg, 0.03 mmol) and $La(Pc)_2$ (23 mg, 0.02 mmol) in 1,2,4-trichlorobenzene (TCB) (4 mL) was refluxed overnight (> 18 h) under nitrogen to give a dark-blue solution. The volatiles were then removed under reduced pressure and the residue was chromatographed on a silica gel column with $CHCl_3$ to remove trace amounts of unchanged $La(Pc)_2$ as the first fraction. The column was then eluted with $CHCl_3$/MeOH (100:1−5) to elute triple-decker $La_2(TPyP)(Pc)_2$ and the desired triple-decker $La_2(TPyP)_2(Pc)$ as the second and third fractions, respectively. The crude product was repeatedly purified by the same chromatographic procedure, followed by recrystallization from a mixture of $CHCl_3$ and MeOH to afford dark blue microcrystals. Yield 14 mg (47%). MS (MALDI-TOF): an isotopic cluster peaking at m/z = 2025 $[M + H]^+$. IR (KBr): $\tilde{\nu}$ = 1328 cm^{-1} (Pc^{2-}).

Preparation of Triple-Decker $Eu_2(TPyP)_2(Pc)$ (2): This compound was prepared by the above procedure with $Eu(acac)_3{\cdot}H_2O$ (15 mg, 0.03 mmol), H_2TPyP (18 mg, 0.03 mmol) and $Eu(Pc)_2$ (23 mg, 0.02 mmol) as starting materials. Yield 16 mg (51%). MS (MALDI-TOF): an isotopic cluster peaking at m/z = 2051 $[M + H]^+$. IR (KBr): $\tilde{\nu}$ = 1331 cm^{-1} (Pc^{2-}).

Structures of Carbonato and Bicarbonato Complexes of Bis(1,10-phenanthroline)Zinc(II): Experiment and Theory

Hans Erras-Hanauer,[a,b] Zong-Wan Mao,[a,c] Günter Liehr,[a] Timothy Clark,*[b] and Rudi van Eldik*[a]

Keywords: Density functional calculations / Zinc / Carbonate complexes / Bicarbonate complexes

We report experimental and theoretical studies on the structure and properties of carbonato and bicarbonato complexes of bis(1,10-phenanthroline)zinc(II). The complex $[Zn(phen)_2O_2CO]$ has been synthesized and DFT calculations have been performed based upon its X-ray structure. The carbonate ligand coordinates in a bidentate binding mode to the metal centre with Zn–O distances of 2.130 and 2.092 Å in the X-ray structure and 2.027 Å for both distances in the calculated gas-phase structure. Because of the fundamental role of (bicarbonato)Zn^{II} complexes, especially in different carbonic anhydrases, the structures and properties of the experimentally unknown bicarbonato complexes of this kind were investigated using DFT with different basis sets up to the Ahlrichs triple zeta basis set with additional polarization functions. The bidentate bicarbonato complex $[Zn(phen)_2O_2C(OH)]^+$ was found to be about 8.2 kcal·mol^{-1} (SHAsvp), 6.4 kcal·mol^{-1} (Ahlrichs triple zeta with polarization functions) and 3.5 kcal·mol^{-1} (Ahlrichs triple zeta) more stable than the quasi-monodentate bicarbonato complex $[Zn(phen)_2O(OH)CO]^+$.

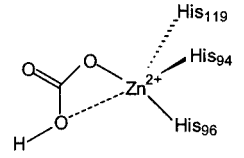
Introduction

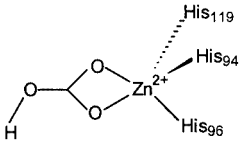
Knowledge of the structures of bicarbonato complexes of Zn^{II} is essential to understand the mechanism of human carbonic anhydrase (HCA),[1−12] an enzyme that catalyzes the hydration of CO_2 and dehydration of HCO_3^- according to the overall reaction given in Equation (1).

$$CO_2 + H_2O \rightarrow HCO_3^- + H^+ \quad (1)$$

Two contrasting structural types have been proposed for these important bicarbonato complexes. The Lindskog structure involves a characteristic monodentate bicarbonate binding mode, i.e., one of the carboxylate oxygen atoms is bound to the zinc ion, whereas the hydroxy oxygen atom is only weakly coordinated to the metal centre. The Lipscomb structure involves a characteristic bidentate bicarbonate binding mode, i.e., both the carboxylate oxygen atoms are utilized as ligands for the zinc centre.[10−12] Two X-ray structures involving monodentate bicarbonate binding to different carbonic anhydrases, i.e. a bicarbonate-HCAI intermediate and a mutant intermediate of bicarbonate-HCAII (Thr-200→His-200), have been determined and taken to support the Lindskog structure.[13,14] However, calculations suggest that the bidentate coordination mode of bicarbonate contributes significantly towards the effective catalytic activity of the enzymes.[15,16] The structure of bicarbonate bound to Co^{II}-substituted carbonic anhydrase closely resembles the bidentate Lipscomb bicarbonate structure with the two bicarbonate oxygen atoms at between 2.3 and 2.5 Å from the Co^{II} ion.[17] However, bicarbonato complexes of Zn^{II} are unstable and have only recently be identified structurally.[18−23]



Lindskog structure



Lipscomb structure

To gain more insight into the possible coordination geometries of bicarbonate to related metal centres, we recently isolated and characterized the first stable bicarbonato complexes of bis(1,10-phenanthroline)copper(II).[24] Two complexes of the type $[Cu(phen)_2OCO_2H]ClO_4$ and $[Cu(phen)_2O_2COH]ClO_4$, in which bicarbonate is bound in monodentate and bidentate modes, respectively, could be characterized (Figure 1). The structures reported resemble

$[Cu(phen)_2OCO_2H]ClO_4$

Figure 1. X-ray structure of the two $Cu(phen)_2$ bicarbonate complexes

Lipscomb- and Lindskog-like intermediates closely with respect to the coordination mode of bicarbonate, but not with respect to the coordination geometry of the metal centre.

We could not isolate similar bicarbonato complexes of Zn^{II}, obtaining instead only $[Zn(phen)_2O_2CO]$ under all experimental conditions. In this structure, carbonate is bound in a bidentate mode − structural details are reported here. Therefore, we have used density functional theory (DFT) to calculate the structures and stabilities of the two possible bicarbonato complexes of Zn^{II}.

Results and Discussion

$[Zn(phen)_2(CO_3)]\cdot 7H_2O$ (1)

Structural and crystallographic data for this complex are reported in Tables 1 and 7. Figure 2 shows that the N_4-coordinated Zn^{II} ion is coordinated by carbonate in a bidentate mode. The bond lengths for Zn−O1 and Zn−O2 are 2.129(2) and 2.091(2) Å, respectively. The coordination polyhedron of the zinc atom can be described as a distorted octahedron. By comparison, in $[Cu(phen)_2(CO_3)]\cdot 7H_2O$ the

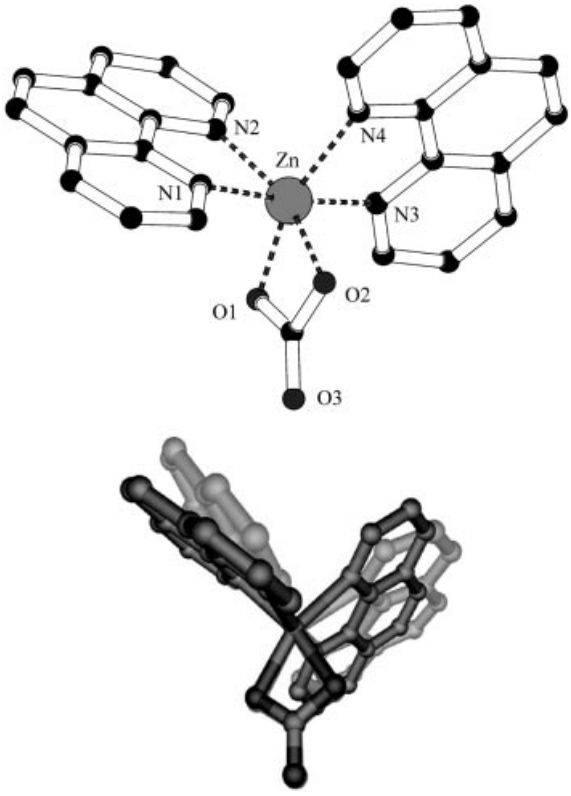

Figure 2. X-ray structure (top) and calculated structure (superimposed on the X-ray structure, bottom) of the $[Zn(phen)_2(O_2CO)]$ complex

Cu−O1 and Cu−O2 bond lengths are 2.421(3) and 1.972(3) Å, respectively,[25] i.e. the carbonate ligand forms a stronger bidentate coordination mode in the Zn^{II} complex than in the corresponding Cu^{II} complex. This behaviour differs from that in monodentate-coordinated nitrate or binuclear carbonate complexes of Zn^{II} reported before.[21,26] Therefore, the bidentate distortion of bicarbonate/carbonate Zn^{II}/Cu^{II} complexes is not only determined by the metal centre, but also by the geometry of the metal complexes.

^{13}C NMR Spectra

^{13}C NMR spectra of the labelled complex **1** were recorded in C_2D_5OD. The $[Zn(phen)_2{}^{13}CO_3]\cdot 7H_2O$ complex revealed a medium peak at $\delta = 171.1$ ppm for the bidentate binding of the carbonate group and a strong peak at $\delta = 163.3$ ppm for free HCO_3^-. Due to the low solubility of complex **1** in water, ^{13}C NMR spectra of 10 mM $[Zn(phen)_2(H_2O)](NO_3)_2$ in the presence of 30 mM $NaH^{13}CO_3$ were also recorded in D_2O/[D_6]DMSO (1:1). The spectra revealed a weak multiplet peak at $\delta = 167.5-171.1$ ppm for the various binding forms of the carbonate group, i.e. polynuclear carbonato complexes, a strong peak at $\delta = 161.5$ ppm for free HCO_3^- and a medium peak at $\delta = 126.4$ ppm for free CO_2. The chemical shift for the bidentate carbonate group lies within the values reported for other (carbonato)zinc complexes.[21,27,28]

Computational Details

Calculations were performed using the Gaussian98[29] program package with the B3LYP[30–32] combination of functionals and both the Schäfer, Horn, Ahlrichs split valence (SHAsv)[33] and the Ahlrichs triple zeta basis sets.[34] These levels of theory are referred to as B3LYP/SHAsv and B3LYP/Ahlrichs_tz, respectively. Calculations with additional polarization functions,[35,36] referred to as SHAsvp and Ahlrichs_tzp, respectively, were also performed. The latter is the highest level of theory used in this study. Due to the large number of basis functions, the use of these basis sets was restricted to the centres of interest, viz. the Zn^{2+} centre, the carbonate ligand and the N atoms of the phenanthroline ligands. For the remaining atoms of the phenanthroline chelates, the SHAsv basis set was used. The following discussion is based on the highest level of calculations, except where stated mentioned. Minimizations used the Berny algorithm along with redundant internal coordinates.[37,38] All structures were verified as local minima on the potential energy hypersurface by frequency analyses, and the zero-point vibrational energies obtained were used unscaled to correct the total energies. The DFT calculations started with the X-ray structure of the $[Zn(phen)_2(CO_3)]$ complex as shown in Figure 2. All geometries of the complexes $[Zn(phen)_2O_2CO]$, $[Zn(phen)_2O(OH)CO]^+$, and $[Zn(phen)_2O_2COH]^+$ were fully optimized without any constraints.

The structure for the carbonate complex was first calculated in C_1 symmetry corresponding to the original X-ray data, followed by further optimization in C_2 symmetry

(SHAsv). Both structures were verified as local minima, and were found to be very similar and practically of the same energy (Table 2). However, the structure with C_2 symmetry was used as the starting structure for the higher level calculations. All calculations were performed for the gas phase, and therefore neither solvent nor crystal effects, nor the influence of counterions was considered. As expected for a molecule in two different states of aggregation, this results in minor structural differences between the calculated and X-ray structures of the unprotonated carbonate complex. Thus, in the calculated structure the carbonate ligand is 0.068 Å closer to the metal centre with a Zn−C distance of 2.437 Å, and the calculated bond lengths for Zn−O1 and Zn−O2 of 2.027 Å are about 0.065 and 0.103 Å shorter than the corresponding bond lengths of 2.092 and 2.130 Å, respectively, found in the X-ray structure. The calculated angle for O1−C−O2 of 112.5° is 2.1° smaller, whereas the O1−Zn−O2 angle is 4.6° larger than in the X-ray structure, viz. 66.7° compared with 62.1°. The C−O1 and C−O2 distances were calculated to be 1.340 and 1.341 Å, respectively, i.e. 0.051 and 0.045 Å longer than in the X-ray structure. A comparison of selected bond lengths from the X-ray and theoretical structures is given in Table 3.

The arrangement of the coordinated phenanthroline ligands depends on the solid or gas phase state of the complex. The dihedral angle between the two ring systems decreases from 125.4° in the crystal to 113.5° in the gas phase structure owing to the more ordered and stacking arrangement of the ligands and the presence of seven water molecules in the crystal structure. Consideration of the two water molecules near the carbonate ligand in the calculations (see below) leads to an almost unchanged dihedral angle of 113.6°. The calculated Zn−N distances show two short Zn−N(1) and Zn−N(3) bonds of 2.185 Å for each, and two long bonds for Zn−N(2) and Zn−N(4) of 2.277 and 2.278 Å. In the X-ray structure a short bond [Zn−N(1) = 2.146 Å] and a long one [Zn−N(4) = 2.189 Å] and two almost equal [Zn−N(2,3) ≈ 2.157 Å] bond lengths for the phenanthroline ligands were found.

In this study the importance of the selected basis set on the bond lengths, especially for Zn^{2+}, could be confirmed. As shown in Table 3, for both basis sets the best agreement between X-ray and calculated structures was obtained without adding additional polarization functions to these basis sets. This paradoxically suggests that these basis sets give larger errors because they cannot reproduce the differences between gas phase and solid state structures. The calculations with the SHAsvp basis set lead to a shortening of between 0.02 and 0.03 Å of all bonds in which O atoms are involved. The corresponding effect on the Zn−N distances is more distinctive. The Zn−N2/N4 bond length is enlarged from 2.211 to 2.380 Å. Thus, with this basis set, the coordination sphere for Zn is strongly distorted in comparison with that found in the X-ray structure. This discrepancy did not occur with the Ahlrichs_tz basis set. The Zn−N bonds are found to be 2.184 and 2.240 Å. All C−O and Zn−O bonds are longer than the SHAsvp results, but almost identical to those found with SHAsv. We included two additional water molecules in our calculations to study their influence on the Zn−O bond lengths, which are too short for all basis sets used. The location of these water molecules was chosen according to the X-ray data. In the optimized structure (Figure 3) the O(carbonate)−O(water) distance averages as 2.643 and 2.648 Å. We used the SHAsvp basis set in a balance between accuracy and computational effort for the optimization. This was performed in C_1 symmetry without any constraints. Summarized bond lengths are given in Table 3. At this level of theory the Zn−O bond length was calculated to be 2.024 Å, which is 0.020 Å (1%) longer than in the corresponding structure without the water molecules. Transferred to the SHAsv and Ahlrichs_tz levels, an elongation of 1% means a Zn−O bond length of about 2.061 and 2.047 Å, respectively, and results in a slightly better agreement with the X-ray structure.

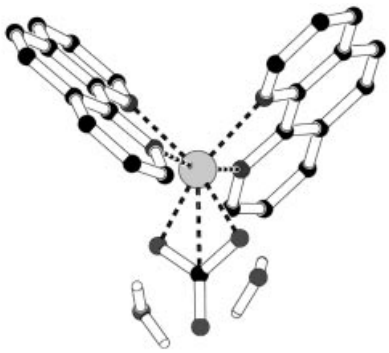

Figure 3. Calculated structure of $[Zn(phen)_2(O_2CO)]$ with two water molecules

The agreement between the X-ray and calculated Ahlrichs_tzp structure is such that the structures and relative energies of the bicarbonate complexes for which experimental data are not available can be satisfactorily calculated. The Lipscomb bicarbonate structure is represented in this model by protonation of O(3) and the Lindskog structure by protonation of O(1). The energies and properties of the calculated structures are summarized in Table 2.

The bicarbonate complex **A** clearly shows a bidentate binding mode with Zn−O bond lengths of 2.156 and 2.228 Å. The former is about 0.2 Å and the latter 0.13 Å shorter than in the related Cu complex,[24] and 0.129 and 0.201 Å, respectively, longer than in the Zn carbonate structure. The C−O(3) distance is elongated to 1.350 Å, whereas the C−O(1) and C−O(2) distances are shortened to 1.267 and 1.260 Å, respectively. As expected, the influence of protonation of O(3) on the structure of the phenanthroline ligands is small. All Zn−N bond lengths decrease to 2.159, 2.169, 2.158, and 2.166 Å, respectively, and the dihedral angle increases by 3.9° on protonation. The coordination sphere of the metal centre is best described as distorted octahedral (Figure 4). Structural details for the different basis sets are given in Table 4. The bicarbonate structure **A** was found to be the most stable bicarbonate complex. Its energy is about 8.2 kcal·mol^{-1} (SHAsvp), 3.5 kcal·mol^{-1} (Ahlrichs_tz) and 6.4 kcal·mol^{-1} (Ahlrichs_tzp) lower

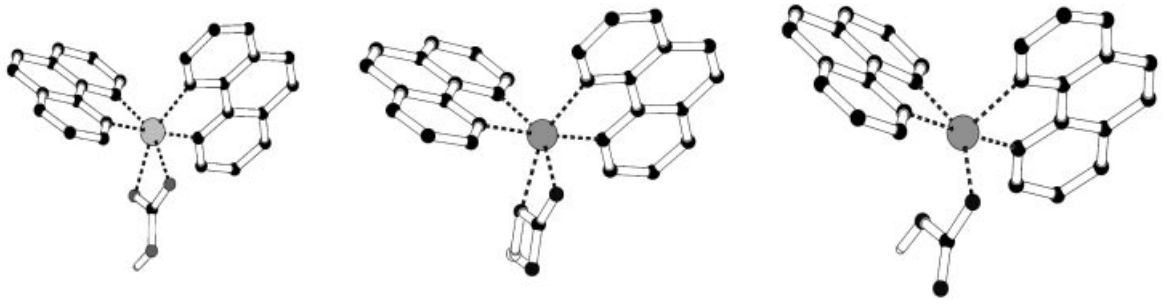

Figure 4. Structures of $[Zn(phen)_2O_2COH]^+$ (**A**), $[Zn(phen)_2O(O\cdots H)CO]^{+\#}$ (transition state for proton transfer), and $[Zn(phen)_2O(OH)CO]^+$ (**B**), respectively

than the bicarbonate complex with the proton bound to O(1) (Table 2).

In the calculated structure of **B**, a strong Zn−O(2) bond of 1.973 Å, which is only 0.051 Å shorter than the 2.024 Å in the bidentate bicarbonate structure, and a weak binding of O(1) to the metal centre with a Zn−O(1) bond length of 2.698 Å, were found. This is consistent with the calculation for the related copper complex (see below). Therefore, the binding mode has a somewhat bidentate character in comparison with the X-ray data of the analogous copper complex, which clearly binds the bicarbonate ligand in a monodentate binding mode. This behaviour shows a distinct dependence on the basis set. The Zn−O(1) distance varies from 2.542 Å (SHAsvp) to 2.980 Å (Ahlrichs_tz). The calculated C−O(1) bond length averages 1.421 Å, whereas the C−O(2) bond length averages 1.283 Å. In terms of the carbonate structure, the third C−O bond, C−O(3), remains, at 1.211 Å, almost unchanged. The structural changes on the phenanthroline ligands concern the Zn−N bond lengths, for which the values are between 2.121 and 2.177 Å, and the dihedral angle of 120.5° is 3.4 and 7.8° larger than in the bicarbonate **A** and in the carbonate structures, respectively. With the SHAsv basis set, in contrast to all other basis sets used, this bicarbonate structure was found to be lower in energy. However, this basis set gives acceptable structures, except for the Zn−O(1) distance, but the calculated energies must be treated with care. Structural details are given in Table 4.

Although, due to the significantly different coordination sphere, these complexes cannot be seen as model complexes for the active site of carbonic anhydrase, the energy of activation for the proton transfer reaction from O1 to O2 is of interest. It was possible to calculate the transition state for this reaction using the QST2 method. In the resulting structure the proton is located almost centrally between O1 and O3 with distances of 1.263 and 1.339 Å, respectively. The binding mode of the bicarbonate ligand changes from monodentate to more bidentate with Zn−O bond lengths of 2.054 and 2.409 Å, respectively. The C−O3 bond is shortened to 1.274 Å, whereas the C−O1 distance remains practically unchanged. Frequency analysis clearly shows a single imaginary frequency almost solely due to the displacement of the hydrogen atom. The activation energy for the proton transfer was calculated to be 37.6 kcal·mol^{-1}, which is close to values found previously for the uncatalyzed proton transfer reactions in related Zn complexes.[39,40]

To validate the methods used here, additional calculations were performed on the related copper bicarbonate complexes for which X-ray data are available.[24] For the $[Cu(phen)_2O(OH)CO]^+$ complex, the structural agreement between experimental and theoretical data is similar to that for the $[Zn(phen)_2(O_2CO)]$ complex. The C−O1 and C−O2 bonds in the calculated structures, viz. 1.295 and 1.397 Å, respectively, are longer than in the X-ray structure (1.264 and 1.364 Å), and the C−O3 bond is 0.012 Å too long. The results for the Cu−O distances are somewhat different. The Cu−O2 bond was calculated to be 1.939 Å, which is 0.059 Å shorter than the X-ray data, but of the same order as found for all metal−O2 bond lengths calculated here for this type of complexes. It was therefore not surprising that the Cu−O1 bond was found to be significantly shorter, viz. 2.720 Å compared with 3.045 Å in the X-ray data, which is similar to the Zn−O1 distances in the $[Zn(phen)_2O(OH)CO]^+$ complex. As already mentioned, this effect depends strongly on the basis set employed. A summary of structural details is given in Table 5. Similar structural differences were obtained between gas phase and solid state structures for the $[Cu(phen)_2O_2COH]^+$ complex. The C_2 symmetry found in the X-ray data is lowered to C_1 in the calculated structure with bond lengths of 1.988 and 2.488 Å, respectively, in contrast to 2.359 Å for both bond lengths in the X-ray structure. In this case, an additional factor to the basis set effects mentioned above is the absence of the perchlorate anion in the calculations. In the X-ray structure, the ClO_4^- anion is positioned like a cap over the bicarbonate ligand with a distance of 2.575 Å between $O(HCO_3^-)$ and $O(ClO_4^-)$. This indicates two hydrogen bonds between the bicarbonate and the perchlorate ions, which leads to a more symmetric arrangement of the bicarbonate ligand with respect to the metal centre. All calculated C−O distances are elongated between 0.037 and 0.103 Å and the Cu−N bonds are in the range of 2.074, 2.098, 2.113, and 2.330 Å. The former values are significantly shorter than those found in the Zn complexes, whereas the last value has the same magnitude as found for the $[Zn(phen)_2(O_2CO)]$ complex (without considering the additional two water molecules). According to our calculations,

[a] Absolute energy [hartree]. [b] Zero point energy [kcal·mol^{-1}]. [c] Difference in energy between the two bicarbonate complexes [kcal·mol^{-1}].

the $[Cu(phen)_2O_2COH]^+$ complex is about 3.8 kcal·mol^{-1} more stable than the corresponding $[Cu(phen)_2O(OH)CO]^+$ complex.

Based on the optimized structures obtained with the Ahlrichs_tzp basis set, the ^{13}C NMR shielding factors were calculated using the same basis set and compared with the experimental values obtained for complex **1**. The results (Table 6) demonstrate a good agreement between the experimental and theoretical values. The predicted values for the two bicarbonate complexes demonstrate that protonation of the chelated carbonate ligand (**A**) does not have a significant effect on the chemical shift, in contrast to the ring-opened protonated species (**B**). In fact, in the latter case the chemical shift is very close to that of uncoordinated bicarbonate, suggesting that the bicarbonate ligand is only weakly coordinated to the Zn centre.

The optimized theoretical structures clearly demonstrate the feasibility of stable bicarbonato complexes of bis(phenanthroline)zinc(II), even if these could not be isolated from solution. This, along with the recently identified structures of stable monodentate and bidentate (bicarbonato)Zn^{II} complexes[23] and the results of DFT studies for the conversion of carbon dioxide into bicarbonate with the $[(NH_3)_3Zn(OH)]^+$ model catalyst,[40,41] shows that stable bicarbonato complexes can form part of the overall catalytic cycle of carbonic anhydrase. According to our calculations the ring-closed complex **A** is 8.2 kcal·mol^{-1} (SHAsvp), 6.4 kcal·mol^{-1} (Ahlrichs_tzp), and 3.5 kcal·mol^{-1} (Ahlrichs_tz) more stable than the ring-opened complex **B**. This relatively small difference in energy is in good agreement with reactivity models for a series of zinc complexes.[41]

Experimental Section

$[Zn(phen)_2CO_3]\cdot 7H_2O$ (1): A mixture of (0.284 g, 0.5 mmol) of $[Zn(phen)_2(H_2O)](NO_3)_2$ and (0.336 g, 4.0 mmol) of $NaHCO_3$ was dissolved in 20 mL of water and stirred for 5 min at room temperature. The solution was filtered and allowed to stand in air for slow concentration. After a few days, colourless block crystals (0.212 g; 69.5%) suitable for X-ray analysis were obtained. IR cm^{-1} (KBr pressed pellet): $\tilde{\nu}$ = 1342 (s, CO_3^{2-}). $C_{25}H_{30}N_4O_{10}Zn$ (611.92): calcd. C 49.07, H 4.94, N 9.16; found C 49.05, H 4.88, N 8.96.

Table 6. NMR shielding values for the carbonate and bicarbonate ligands in the Zn phenanthroline complexes

	Calculated (absolute)[a] [ppm]	Calculated (relative to TMS)[a] [ppm]	Experimental [ppm]
TMS	183.3	–	0
$[Zn(phen)_2O_2CO]$	6.9	176.4	171.1
$[Zn(phen)_2O_2COH]^+$	8.6	174.7	–

Spectral Measurements: Infrared spectra were recorded with a Nicolet 5SX instrument using the KBr pellet method. ^{13}C NMR spectra were recorded with a Bruker DPX 300 MHz spectrometer.

X-ray Structure Analysis: Analyses on block single crystals of complex **1** were performed with a Philips PW1100/10 diffractometer. Intensity data were collected using the ω/2θ-scan technique and corrected for Lorentz and polarization effects. The structure of complex **1** was solved by direct methods using the SIR-92 program[42] and refined by full-matrix least-squares methods on F^2 using the SHELXL-93 program.[43] Hydrogen atoms were located partially from a difference synthesis and refined with an overall isotropic thermal parameter. Crystallographic data and data collection parameters are summarized in Table 7, and selected bond lengths and bond angles are given in Table 1. A labelled diagram of **1** is shown in Figure 2. CCDC-175269 for $[Zn(phen)_2(CO_3)]\cdot 7H_2O$ (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336 033; E-mail: deposit@ccdc.cam.ac.uk].

Ethylene Polymerization by Self-Immobilized Neutral Nickel Catalysts Bearing Allyl Groups

Dao Zhang,[b] Guo-Xin Jin,*[a,b] and Ning-Hai Hu[b]

Dedicated to Professor Fo-Song Wang on the occasion of his 70th birthday

Keywords: Nickel / N,O ligands / Immobilization / Polymerizations

[Ni(Ph)(PPh_3)(N,O)] complexes containing phenylimino-phenolato ligands (N,O) (**1**: N,O = **A**; **2**: N,O = **B**; **3**: N,O = **C**; **4**: N,O = **D**; **5**: N,O = **E**) have been synthesized and characterized. The molecular structure of **4** was determined by single-crystal X-ray analysis. Complexes **2**–**5** bearing allyl groups have been investigated as self-immobilized catalysts for ethylene polymerization without the use of co-catalysts. The high ethylene polymerization activities of ca. 10^5 g·PE mol^{-1} Ni·h^{-1} and high molecular weight ($M_w \approx 10^5$) of polyethylene could be accomplished by changing the ligand structures and reaction conditions. The self-immobilization of catalysts brings about a dramatic increase in the catalytic activities of ethylene polymerization.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The polymerization of ethylene with late-transition-metal catalysts has attracted much interest because they not only catalyze the polymerization or oligomerization of ethylene and α-olefins, but they can also co-polymerize ethylene with α-olefins containing functional groups.[1−12] More recently, Grubbs et al. reported a new family of neutral late-transition-metal catalysts that are capable of polymerizing ethylene to high-molecular-weight linear polyethylene, even in the presence of a broad range of polar additives .[13] At the same time, this new family of catalysts based on neutral Ni^{II} complexes of substituted salicylaldiminato N,O ligands are highly active systems that can polymerize functionalized olefins. More importantly, the neutral, single-component nickel(II) catalysts require no co-catalysts, such as MAO, $B(C_6F_5)_3$ or $Ni(COD)_2$. The substantial cost incurred in the hyper-purification of the monomer feed in the production of polyolefin along with the use of co-catalysts has gone. People have been attracted by the potential for using them as active polymerization catalysts as a result of their low cost and ready availability.[1,2,14,15]

In order to be applied in conventional gas-phase or slurry reactors, homogeneous catalysts have to be heterogenized because soluble catalysts cause "fouling" which means that the polyolefin that is formed is deposited on the reactor walls and causes a "boiler scale effect". Inorganic supports such as silica or alumina[16a] and also organic supports such as polystyrene and starch,[16] have been used to heterogenize soluble polymerization catalysts. Many research groups have reported on the heterogenization of metallocene catalysts.[16] As a different heterogenization strategy, Alt et al. developed the self-immobilization of metallocene catalysts, which is the synthesis of metallocene catalysts with an olefin or alkyne functional group that can be used as a co-monomer in the polymerization process.[17] Recently, our group[18] and also Herrmann et al.[19] reported the self-immobilization of Ni and Fe catalysts, respectively, for olefin polymerization. The homogenous self-immobilized catalyst can be transferred to a heterogeneous catalyst by itself during the ethylene polymerization. Herein, we report on neutral (benzaldehyde-phenylimine)nickel(II) complexes with allyl groups as self-immobilized catalysts, which exhibit excellent activities in ethylene polymerization, without co-catalysts, resulting in linear polymers.

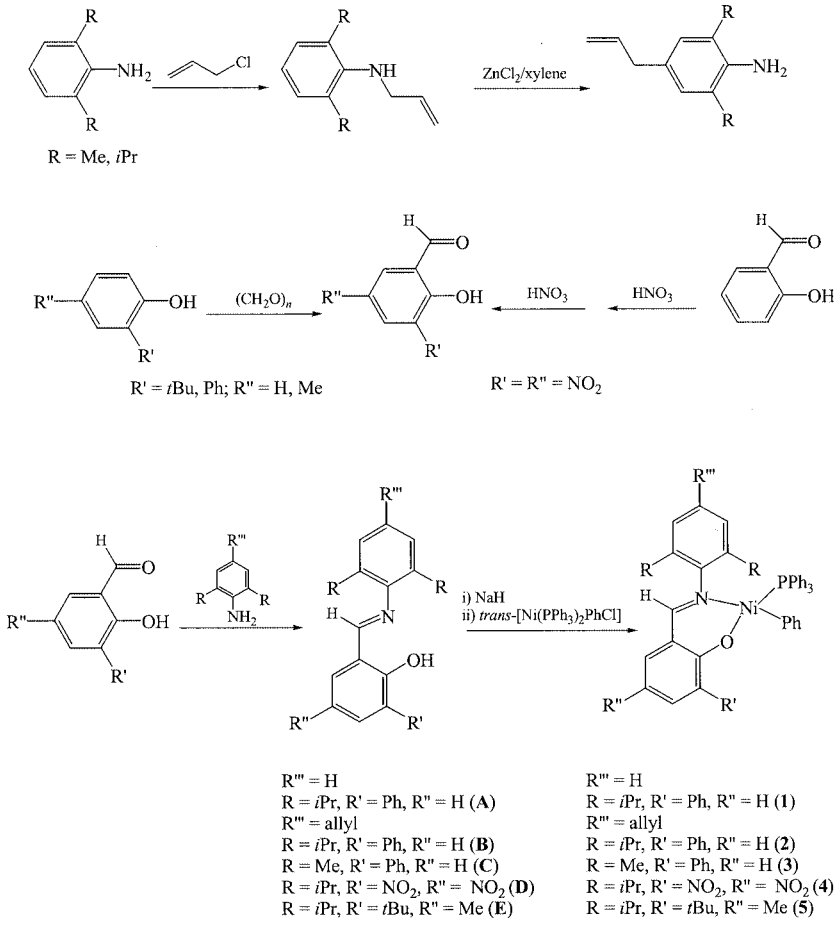
Results and Discussion

Synthesis of Nickel Complexes as Self-Immobilized Catalysts

In this study, we utilized nickel complexes that possess phenylimino-phenolato chelate ligands bearing allyl groups. A general synthetic route for these complexes is shown in Scheme 1. The allyl group was introduced in dialkylaniline



Scheme 1. Preparation of allyl-functionalized (phenylimino-phenolato)nickel complexes

by treating it with allyl chloride, giving *N*-allyl-dialkylaniline. The colorless oil was rearranged to 4-allyl-2,6-dialkylaniline in refluxing xylene in the presence of zinc chloride. Treatment of a phenol derivative with paraformaldehyde in the presence of tin(IV) chloride produced an *ortho*-formylated phenol in high yields. However, phenols containing electron-withdrawing groups barely reacted at all. Dinitrobenzaldehyde was obtained by performing the nitrogenation of benzaldehyde twice.

Ligands **B**−**E** were produced by the condensation of benzaldehyde derivatives with an equimolar amount of the allyl-substituted aniline derivative in alcohol in the presence of formic acid.[15,24,25] All phenylimino-phenolato ligands were characterized by ^{1}H NMR spectroscopy.

The (phenyl)(phenylimino-phenolato)nickel(II) complexes **1**−**5** (Scheme 1) were synthesized according to known procedures.[15,24] The phenylimino-phenolato ligand was dissolved in THF and treated with an excess of NaH. The sodium salt of the corresponding ligand was obtained in benzene and then combined with *trans*-[NiCl(Ph)(PPh_3)$_2$] to form the (benzaldehyde-phenylimine)(phenyl)nickel(II) complex in high yield. The ^{1}H NMR spectroscopic characterization and elemental analyses of complexes **2**−**5** have confirmed the composition of the complexes. The EI mass spectra generally contain the peaks of the molecular ion $[M]^+$. A particularly intense signal is observed for the $[Ni(L)(Ph)]^+$ ion which has lost the two-electron ligand PPh_3.

Molecular Structure

An X-ray crystallographic structure analysis was carried out for catalyst **4** (Figure 1). The unit cell in the solid state contains two crystallographically independent, but chemically similar molecules (**4a** and **4b**) that are related by a non-crystallographic pseudo-inversion center. Table 1 summarizes selected bond lengths and angles.

Complex **4** contains a chelating phenylimino-phenolato ligand, a triphenylphosphane group and a phenyl group. The Ni atoms are arranged in a distorted square-planar geometry made up of four atoms of the ligands (P1, O1, N1, C1 and P2, O6, N4, C47). The PPh_3 group and the imine nitrogen atom are *cis* to one another. The distances between Ni and the imine-N {phenoxy-O} are shorter [1.883(14)−1.967(15) Å] {1.912(12)−1.917(13) Å} than those in other complexes with N−O bidentate ligands [1.926(6)−1.945(4) Å] {1.911(5)−1.931(3) Å}[26b] and N−N bidentate ligands [2.010(5)−2.022(5) Å],[26a] while the distance between Ni and PPh_3 [2.207(5)−2.121(6) Å] is much

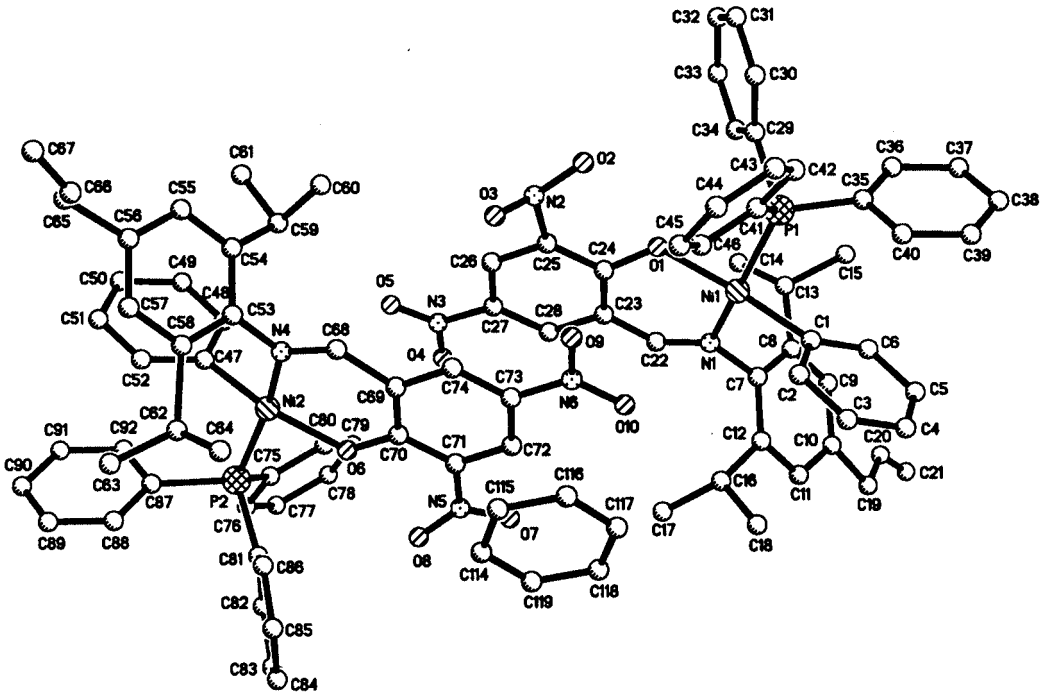


Figure 1. View of the molecular structure of complex **4**; hydrogen atoms have been omitted for clarity

Table 1. Selected bond lengths [Å] and bond angles [°] for **4** (**4a** and **4b**, respectively) with estimated standard deviations

	Bond lengths [Å]			Bond angles [°]	
	4a	**4b**		**4a**	**4b**
Ni−P	2.207(5)	2.121(6)	C(1)−Ni−N(1)	95.1(6)	94.8(6)
Ni−N	1.883(14)	1.967(15)	C(1)−Ni−O(1)	164.9(7)	160.2(6)
Ni−C	1.883(11)	1.857(10)	N(1)−Ni−O(1)	91.9(6)	93.4(6)
Ni−O	1.912(12)	1.917(13)	C(1)−Ni−P	89.0(4)	86.5(4)
N−C(imine)	1.23(2)	1.369(19)	N(1)−Ni−P	164.6(6)	164.3(5)
N−C(Ph)	1.451(16)	1.389(16)	O(1)−Ni−P	87.8(4)	90.5(4)
O−C	1.313(13)	1.324(13)	Ni−N(1)−C(22)	121.0(14)	125.6(13)
C(20)−C(21)	1.182(9)	1.194(9)	Ni−O−C	125.7(9)	130.5(9)

longer than those in other complexes [2.148(2)−2.163(2) Å,[26b] 2.172(2) Å[24]]. However, the dihedral angles defined by the C24 phenyl ring and N3−O4−O5 and also the C69 phenyl ring and N6−O9−O10 are 6.6° and 7.3°, respectively, which indicates that each nitro group is coplanar with its corresponding phenyl ring. At the same time, the dihedral angle of the C24 phenyl ring and C69 phenyl ring is only 4.9° and the distances between the atoms of the nitro groups of **4a** and the phenyl ring plane of **4b** are in the range 3.240−3.510 Å, which means that there is some interaction between the nitro group and the phenyl ring (Figure 2).

Catalysis

The (phenyl)(phenylimino-phenolato)nickel(II) complexes **1**−**5** were tested for ethylene polymerization without any co-catalysts. A significant difference in the activities was observed for the different complexes (Table 2). For example, complex **2** displays an activity of $1.8\cdot10^5$ g PE·mol^{-1} Ni·h^{-1} while complex **5** shows no activity for ethylene polymerization. Attachment of a methyl group (complex **3**), which is sterically smaller than an isopropyl group, at the R position, dramatically decreases the activity. The reason for this is that the bulky substituents surrounding the active center shield the axial faces and retard chain termination. Complex **4**, which contains electron-withdrawing groups such as the nitro groups, shows an enhanced catalytic activity.

As expected a self-immobilization effect,[17−19] similar to that found for metallocenes, could be observed during the polymerization processes. The self-immobilized catalyst **2** bearing allyl substituents displays an ethylene polymerization activity of $1.8\cdot10^5$ g PE·mol^{-1} Ni·h^{-1}, while complex **1**, without allyl group, only exhibits an ethylene polymerization activity of $0.10\cdot10^5$ g PE·mol^{-1} Ni·h^{-1} under the same polymerization conditions. When ethylene was applied

5	0	–	–

[a] Polymerization conditions: 65.4 μmol of the appropriate catalyst, toluene (120 mL), 27 °C, 500-mL autoclave reactor, 4.0 bar ethylene pressure, reaction time 1 h. [b] 10^5 g PE·mol^{-1}Ni·h^{-1}. [c] *M*w ($\times 10^{-3}$) and *M*w/*M*n values were determined by GPC measurement. [d] Polymerization in the presence of 3 mL of methacrylate (MA). [e] Not determined.

to the solution of the self-immobilized catalysts **2**−**5**, the ethylene was polymerized and the catalyst molecules were simultaneously incorporated into the growing chain of polyethylene due to their allyl functions (Scheme 2). At the beginning the color of the reaction mixture became deep and soon a large number of dark-red particles appeared in the polymerization system. These particles still displayed high activities after they were separated to be re-used as heterogeneous catalysts. That is to say, the homogenous catalysts were transformed into heterogeneous systems without any supports. Thus, active centers distributed along the polymer chain prevent catalysts from losing their effectiveness and help to make their catalytic activities more efficient. When complex **1** was used in the polymerization the "self-immobilization" of the nickel catalysts did not occur.

Complex **2** showed a slight drop in activity of ethylene polymerization when 3 mL of methyl acrylate (MA) was added to the polymerization system. This indicates that the self-immobilized neutral nickel catalysts are tolerant towards polar monomers. The IR spectra show that the methyl acrylate was not incorporated into the polymer chain, which suggests that the addition of MA does not destroy the catalytic activity.

Influence of the Polymerization Conditions with Self-Immobilized Catalyst 2

It is well known that the conditions of the polymerization reaction influence the productivity of the self-immobilized catalyst system and the nature of the polymer produced. To study these effects, we carried out polymerization over ranges of catalyst concentration, ethylene pressure, reaction temperature, polymerization time and solvent, employing the self-immobilized catalyst **2**. The results are summarized in Table 3.

To examine the effect of the catalyst concentration on the polymerization of ethylene, we carried out several tests in which the amount of catalyst **2** was systematically varied from 65.4 to 11.3 μmol. At 65.4 μmol of catalyst a broad molecular weight distribution (12.8) was observed, centered at 67213 (M_{pk}s). As the amount of catalyst is decreased to 32.7 μmol, a narrow distribution (9.9) is observed, with an

[a] Polymerization conditions: 500-mL autoclave reactor, 120 mL of toluene, 800 rpm stirring, reaction time 1 h. [b] 10^5 g PE·mol^{-1}Ni·h^{-1}. [c] M_v ($\times 10^{-3}$) was determined with an Ubbelohde viscometer in decalin at 135±0.1 °C. [d] 120 mL of hexane was used instead of toluene. [e] Reaction time 36 min.

M_{pk}s of 71968. At 15.1 μmol the distribution (3.1) becomes very narrow with an M_{pk}s of 138061.

The ethylene pressure also has an effect on both the activity and the molecular weight distribution of the polyethylene. For example, employing 65.4 μmol of catalyst **2** at 2.0 bar of ethylene, a polymer with a distribution of 7.471 and a peak centered at 73042 was produced. On increasing the pressure to 4.0 bar, a broad distribution (12.8) was observed.

A series of experiments was undertaken to determine the effect of temperature variation on the performance of the catalyst. First, polymerization performed at 47 °C had a higher activity of $2.23 \cdot 10^5$ g PE·mol^{-1} Ni·h^{-1} than those at 27, 37, 57, and 67 °C. These results parallel the effect observed by Grubbs et al.[13] Secondly, with the increase of temperature, the molecular weight M_η varied from 238000 at 27 °C to 4400 at 67 °C, while the molecular weight distribution of PE decreased from 4.2 to 2.3. Moreover, as the reaction time increased from 36 to 60 min the activity decreased slightly from $3.70 \cdot 10^5$ g PE·mol^{-1} Ni·h^{-1} due to partial loss of catalytic activity. The solvent used for the polymerization had a slight influence, for example, when toluene solvent was replaced by hexane the activity decreased from $1.26 \cdot 10^5$ g PE·mol^{-1} Ni·h^{-1} to $1.14 \cdot 10^5$ g PE·mol^{-1} Ni·h^{-1} and M_η increased from 196400 to 247300.

Characterization of the Polyethylene Products

The ^{13}C NMR spectra of polyethylene produced by the self-immobilized catalysts **2**, **3**, and **4** have similar resonances, which can be seen in Table 4. Methyl branches were identified by the resonances at δ = 30.1 (CH_2), 20.1 (CH_3), 30.3 (CH), 37.7 (α-CH_2), 30.5 (γ-CH_2), and 27.6 ppm (β-CH_2).[27,13] The methyl branches were estimated as 0.41% (catalyst **2**), 0.55% (catalyst **3**), and 0.65% (catalyst **4**) in the spectra of PE. No other types of short branches are observed in the ^{13}C NMR spectra. The similar microstructures of polyethylene indicate that the self-immobilized catalysts keep the same arrangement around the active center as that of the original catalysts. The bulk densities of the PE produced by these self-immobilized catalysts are in the range of 0.148−0.278 g·cm^{-3}, which suggests that self-immobilization can improve the morphology of polymer products. The DSC results for the PE produced by catalysts **2**, **3**, and **4**, indicate that the self-immobilized catalysts convert ethylene to linear polyethylene with high crystallinity. The melting point temperatures (Tm [°C]) of the polyethylene produced are 131 °C (catalyst **2**), 130 °C (**3**), and 129 °C (**4**), indicating the high-density nature of the polyethylene.

Conclusion

In this study, we have demonstrated that neutral nickel complexes bearing allyl groups as self-immobilized single-component catalysts display very high ethylene polymerization activities. The activities can be improved by changing the substituents of the benzaldehyde-phenylimine ligand and the polymerization reaction conditions. The results clearly indicate that self-immobilized neutral nickel complexes possess great potential as new olefin polymerization catalysts.

Experimental Section

General: All experiments with metal complexes and phenyliminophenolato ligands were carried out under argon using standard Schlenk and vacuum-line techniques. Solvents were dried by re-

Table 4. ^{13}C NMR spectroscopic data of polyethylene employing self-immobile catalysts **2**, **3**, and **4**

fluxing with appropriate drying agents (sodium/benzophenone for toluene, benzene, diethyl ether, THF, and hexane; CaH_2 for dichloromethane; magnesium for methanol) and distilled under argon prior to use. ^1H NMR spectra were recorded with a Varian Unity-400 spectrometer. NMR multiplicities are abbreviated as follows: s = singlet, d = doublet, q = quadruplet, m = multiplet, br = broad. IR spectra of the complexes were measured with a Bio-Rad FTS135 spectrometer. EI-MS spectra were recorded with a Finnigan MAT 8500 spectrometer (electron energy 70 eV) and elemental analyses were performed with a Perkin−Elmer Series II CHN/O Analyzer 2400. The ^{13}C NMR spectroscopic data for polyethylene were obtained using *o*-dichlorobenzene as the solvent with an FX-100 NMR spectrometer at 130 °C. The intrinsic viscosity [η] was measured in decalin at 135 °C using an Ubbelohde viscometer. The viscosity average molecular weight (M_v) was calculated by the following equation $[\eta] = 67.7 \cdot 10^{-3} M_v^{0.67}$. Average molecular weight (M_w) and molecular weight distribution (M_n/M_w) values of polyethylene products were determined using a PL GPC-220 gel permeation chromatograph at 150 °C using a narrow standards calibration and equipped with three PL gel columns (sets of PL gel 10 μm MIXED-B LS). Trichlorobenzene was employed as a solvent at a flow rate of 1.00 mL/min. Melting points were determined by DSC with a Perkin−Elmer 7 Series Thermal Analysis System. The starting materials 3-*tert*-butyl-5-methylbenzaldehyde and 3-phenylbenzaldehyde,[20] 3,5-dinitrobenzaldehyde,[21] 4-allyl-2,6-dimethylaniline,[22] *trans*-[Ni(PPh$_3$)$_2$(Ph)Cl][23] and complex **1**[13] were prepared according to literature procedures and characterized by ^1H NMR spectra. Other commercially available reagents were purchased and used without purification.

General Procedure for Ethylene Polymerization: A 500-mL autoclave was charged with 100 mL of toluene under argon. A solution of the self-immobilized nickel(II) complex (10−65 μmol) in toluene (20 mL) was added. After three times of ethylene gas exchange, the ethylene pressure was raised to the specified value and maintained for a certain time. The polymerization was terminated by the addition of methanol and dilute HCl (10%). The solid polyethylene was filtered, washed with methanol and dried at 40 °C in vacuo.

Preparation of Complex 2. (a) Ligand Synthesis: 4-Allyl-2,6-diisoproylaniline was prepared from 2,6-diisoproylaniline by an analogous method according to ref.[22] The colorless liquid product was collected at 98.5 °C/0.6 Torr in 35% yield. ^1H NMR(400 MHz, $CDCl_3$): δ = 6.85 (s, 2 H, H-Ar), 5.98 (m, 1 H, CH=C), 5.09 (d, 1 H, C=CH$_{(E)}$), 5.03 (d, 1 H, C=CH$_{(Z)}$), 3.6 (br, 2 H, NH_2), 3.30 (d, 2 H, CH_2C=C), 2.92 [m, 2 H, CH(Me)$_2$], 1.26 [d, 12 H, C(CH$_3$)$_2$]. Formic acid (0.25 mL) was added to a methanol solution (5 mL) containing 4-allyl-2,6-diisopropylphenylamine (1.302 g, 6.0 mmol) and 3-phenylbenzaldehyde (1.148 g, 5.8 mmol). After stirring at room temperature for 12 h, the reaction mixture was poured into distilled water (25 mL), extracted with diethyl ether (25 mL × 2), washed with deionized water (25 mL × 2) and dried overnight with anhydrous sodium sulfate. After the solvent was removed by rotary evaporation a yellow solid was separated and dried under vacuum to afford 2.187 g of **B** in 95% yield. ^1H NMR ($CDCl_3$, 400 MHz): δ = 13.68 (s, 1 H, OH), 8.35 (s, 1 H, N=CH), 7.71−7.05 (m, 8 H, Ar−H), 7.00 (s, 2 H, C=N−Ar−H), 6.00 (m, 1 H, CCH=C), 5.11 (q, 2 H, C=CH$_2$), 3.39 (d, 2 H, CH_2C=C), 2.99 (m, 2 H, CHMe$_2$), 1.16 (d, 12 H, CH_3 of *i*Pr). **(b) Complex Synthesis:** Sodium hydride (0.2 g, 5 mmol) was added to a solution of the ligand **B** (0.596 g, 1.5 mmol) in THF (20 mL). The mixture was stirred at room temp. for 2 h, and then centrifuged after which the upper clear solution was transferred and concentrated in vacuo to afford a pale-yellow solid residue. After washing with hexane (20 mL), the sodium salt of the corresponding ligand was obtained. A solution containing the sodium salt of **B** (0.629 g, 1.5 mmol) and *trans*-[Ni(PPh$_3$)$_2$(Ph)Cl] (1.0 g, 1.44 mmol) in benzene (20 mL) was stirred at room temp. After 6 h, the reaction mixture was separated by filtration to remove NaCl. Hexane was slowly added to the top of the filtrate. Complex **2** was obtained as a yellow-orange solid. Yield: 0.95 g (83%). ^1H NMR (400 MHz, C_6D_6): δ = 8.13 (d, 1 H, N=CH), 7.89−6.34 (m, 30 H, Ar-H), 6.02 (m, 1 H, CH=), 5.11 (m, 2 H, =CH$_2$), 4.23 (m, 2 H, CHMe$_2$), 3.32 (d, $J_{H,H}$ = 6.4, 2 H, CH_2), 1.35 (d, $J_{H,H}$ = 6.8 Hz, 6 H, CH_3), 1.27 (d, $J_{H,H}$ = 6.8 Hz, 6 H, CH_3) ppm. EI-MS: *m*/*z* = 717 [M − Ph]$^+$, 455 [M − Ph − PPh$_3$]$^+$. $C_{52}H_{50}NNiOP$ (794.64): calcd. C 78.60, H 6.34, N 1.76; found C 78.88, H 6.22, N 1.73.

Complex 3: Ligand **C** as a yellow solid in 90% yield. ^1H NMR ($CDCl_3$, 400 MHz): δ = 13.71 (s, 1 H, OH), 8.39 (s, 1 H, N=CH), 7.69−7.01 (m, 8 H, Ar-H), 6.93 (s, 2 H, C=N−Ar−H), 5.98(m, 1 H, CCH=C), 5.09(q, 2 H, C=CH$_2$), 3.37(d, 2 H, CH_2C=C), 2.19(s, 6 H, CH_3). **3** as a red crystalline solid. Yield: 0.95 g (86%). ^1H NMR (400 MHz, C_6D_6): δ = 8.07 (d, $J_{P,H}$ = 8.4 Hz, 1 H, N=CH), 7.78−6.44 (m, 30 H, Ar-H), 6.01 (m, 1 H, CH=), 5.10 (d, $J_{H,H}$ = 1.6, 2 H, =CH$_2$), 3.19 (d, $J_{H,H}$ = 6.4 Hz, 2 H, CH_2), 2.53 (s, 6 H, CH_3) ppm. EI-MS: *m*/*z* = 662 [M − Ph]$^+$, 400 [M − Ph − PPh$_3$]$^+$. $C_{48}H_{42}NNiOP$ (738.53): calcd. C 78.06, H 5.73, N 1.90; found C 77.99, H 5.73, N 1.91.

Complex 4: Ligand **D** as yellow-gold crystals in 95% yield. ^1H NMR ($CDCl_3$, 400 MHz): δ = 16.27 (s, 1 H, OH), 9.07 (s, $^4J_{P,H}$ = 3.2 Hz, 1 H, N=CH), 8.50 (s, $^4J_{H,H}$ = 2.8 Hz, 1 H, Ar-H), 8.26 (s, 1 H, Ar-H), 7.10 (s, 2 H, C=N−Ar−H), 5.97 (m, 1 H, CCH=C), 5.16 (q, 2 H, C=CH$_2$), 3.43 (d, 2 H, CH_2C=C), 2.95 (m, 2 H, CHMe$_2$), 1.24 (d, 12 H, CH_3 of *i*Pr). **4** as a red solid. Yield: 1.05 g (90%). ^1H NMR (400 MHz, C_6D_6): δ = 8.34 (d, $J_{H,P}$ = 2.8 Hz, 1 H, N=CH), 7.84−6.34 (m, 24 H, Ar-H), 6.02 (m, 1 H, CH=), 5.12 (m, 2 H, =CH$_2$), 3.96 (m, 2 H, CHMe$_2$), 3.28 (d, $J_{H,H}$ = 6.0, 2 H, CH_2), 1.29 (d, $J_{H,H}$ = 6.8 Hz, 6 H, CH_3), 1.12 (d, $J_{H,H}$ = 6.8 Hz, 6 H, CH_3) ppm. EI-MS: *m*/*z* = 807 [M$^+$], 545 [M − PPh$_3$]$^+$. $C_{46}H_{44}N_3NiO_5P$ (808.53): calcd. C 68.33, H 5.48, N 5.20; found C 68.97, H 5.41, N 5.10.

Complex 5: Ligand **E** as a yellow-green oil in 92% yield. ^1H NMR ($CDCl_3$, 400 MHz): δ = 13.41 (s, 1 H, OH), 8.12 (s, 1 H, N=CH), 7.26−6.98 (m, 4 H, Ar-H), 6.02 (m, 1 H, CCH=C), 5.10 (q, 2 H, C=CH$_2$), 3.39 (d, 2 H, CH_2C=C), 2.99 (m, 2 H, CHMe$_2$), 2.32 (s, 3 H, CH_3Ar), 1.48 (s, 9 H, CH_3 of *t*Bu), 1.16 (d, 12 H, CH_3 of *i*Pr). **5** as a yellow-orange solid. EI-MS: *m*/*z* = 787 [M]$^+$. $C_{51}H_{56}NNiOP$ (788.67): calcd. C 77.67, H 7.16, N 1.78; found C 77.90, H 7.03, N 1.88.

X-ray Crystal Structure Determination of Complex 4: The crystallographic data for **4** (**4a**/**4b**) are summarized in Table 5. Dark-red single crystals were grown in toluene/hexane (1:1) at −15 °C. The crystal was sealed in a thin-walled glass capillary under argon. The intensity data were collected at 293 K with a Siemens P4 diffractometer using Mo-K_α radiation (λ = 0.71073 Å, graphite monochromator). The stability of the primary beam was controlled by monitoring three check reflections every 100 reflections. Corrections for absorption based on the ψ-scan technique were applied. The structure was solved by direct methods using the SHELXTL-97 program and refined by full-matrix least-squares on F_o^2 using

Intercalation of Amino Alcohols into α-$Zr(HPO_4)_2 \cdot H_2O$

Ludvík Beneš,*[a] Klára Melánová,[a] Vítězslav Zima,[a] Pasquale Patrono,[b] and Paola Galli[c]

Keywords: Layered compounds / Intercalations / Amino alcohols / Zirconium / Phosphate

The formation of phases during the intercalation of amino alcohols (2-aminoethanol, 3-aminopropanol, 4-aminobutanol, 5-aminopentanol, and 6-aminohexanol) into α-$Zr(HPO_4)_2 \cdot H_2O$ was studied. The existence of three phases with general formula α-$Zr(HPO_4)_2 \cdot xNH_2(CH_2)_nOH \cdot zH_2O$ (x = 0.5, 1, 2; n = 2–6; z = 0.2–1.2) depends on the molar ratio of the starting compounds in the reaction mixture. The compounds α-$Zr(HPO_4)_2 \cdot 2NH_2(CH_2)_nOH \cdot 1.2H_2O$ (n = 5 and 6) lose water and one molecule of amino alcohol upon heating to about 200 °C, as observed by thermal X-ray diffraction measurements.

Introduction

α-$Zr(HPO_4)_2 \cdot H_2O$, hereafter α-ZrP, is a layered compound generated by the packing of two-dimensional macromolecular units that interact weakly with each other. Due to the presence of ionogenic P-OH groups on the surface of the layers, and to the easily accessible interlayer region, this compound is able to act as a host for cationic or molecular polar guest species. The host-guest chemistry of α-ZrP has been summarized in several reviews[1–3] and books.[4–6]

The intercalation of strong bases such as alkylamines is driven by the acid-base interaction between the amino group of the amine and the P-OH groups of the layer. The intercalation of aliphatic monoamines and diamines has been investigated by several groups.[7–12] The intercalation process usually occurs in well-defined steps, indicating the presence of two or more solid phases, and the final products contain one water and two monoamine molecules or one water and one diamine molecules per formula unit. The amine is usually protonated during the intercalation.

A homologous series of 1-alkanols or 1,ω-alkanediols with chain lengths ranging from 2 to 18, or 2 to 10 carbon atoms, respectively, was intercalated into α-ZrP, finely dispersed with the guest species, by exposing the reaction mixture to microwave radiation.[13] Thermogravimetric analysis showed that the intercalation compounds contain a maximum of two mols of alkanol or one mol of alkanediol per mol of zirconium phosphate.

The intercalation of amino alcohols was performed by titrating α-ZrP with their aqueous solution.[6] Fully intercalated products contain two molecules of amino alcohol per formula unit, forming a bilayer with the carbon chain axis almost perpendicular to the host layers. These compounds undergo thermal decomposition leading to phases with one and 0.6 amino alcohol molecules per formula unit.

This paper reports on the intercalation of amino alcohols into α-zirconium hydrogenphosphate. The work is focused on a study of phase formation as a function of reaction time and the ratio of the starting compounds (amino alcohol/α-ZrP, hereafter denoted as y).

Results and Discussion

Amino alcohol molecules enter between the host layers and the decrease of concentration of basic amino alcohol molecules in solution is accompanied by a decrease of pH, which can be observed. A plot of the pH value as a function of time is given in Figure 1. 3-Aminopropanol was added to an aqueous suspension of α-ZrP in an amount corresponding to the α-ZrP/aminopropanol ratios of 1:1 and 1:2 at time t = 2 min (see inset in Figure 1). The decrease in the amount of amino alcohol is indicated by an exponential decrease of pH. As is obvious from Figure 1, the decrease of pH proceeds for several hours. This means that a relatively long time is needed to reach equilibrium. This time increases with increasing length of the carbon chains.

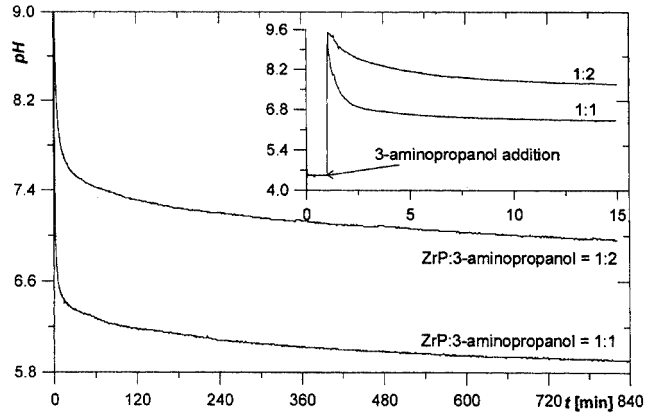

Figure 1. Time course of pH after addition of stoichiometric amount of 3-aminopropanol to an α-ZrP water suspension

For the titration of the aqueous suspensions of α-ZrP, a 100 min time interval between addition of 0.2 mL doses of amino alcohol was chosen, so that a constant pH value was reached (see Figure 2). For the 6-aminohexanol intercalations, 200 min intervals between 0.4 mL doses were used. Titration curves for the titration of α-ZrP with 2-aminoethanol, 3-aminopropanol, 4-aminobutanol, 5-aminopentanol, and 6-aminohexanol are given in Figure 3. In the case of 2-aminoethanol, the reaction occurs in well-resolved steps and plateaus, indicating the presence of three phases. Each step leads to the formation of the given intercalation compound with a characteristic value of the basal spacing that differs from the others in a higher amino alcohol content. The steps become less pronounced for longer amino alcohols.

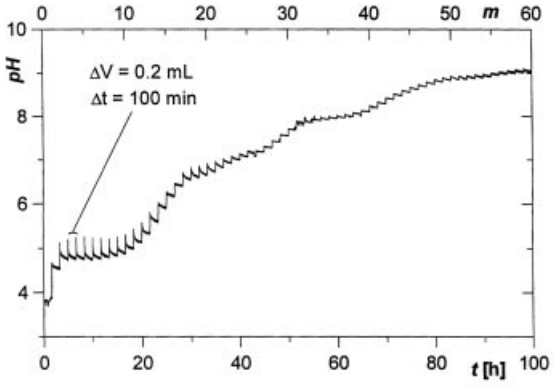

Figure 2. Time dependence of pH during potentiometric titration of an α-ZrP/water suspension with 2-aminoethanol solution; the number of additions of aminoethanol is given in the upper *x* axis

Three phases with different basal spacings were found in the samples during the intercalation (see Figure 4). They are formed consecutively, with a maximum relative ratio at amino alcohol contents *x* of 0.5, 1, and 2 (hereafter denoted as phases 0.5, 1, and 2). The 0.5 phase forms rapidly with amino alcohols having shorter chains (from 2-aminoethanol

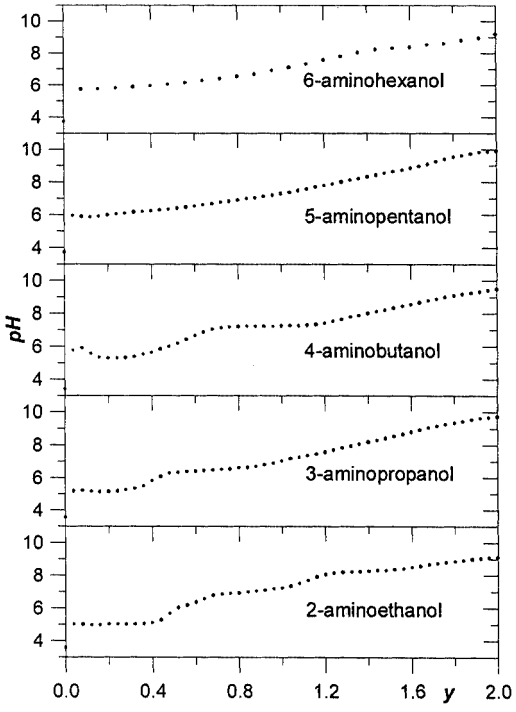

Figure 3. Potentiometric titration curves; *y* = amino alcohol:Zr ratio

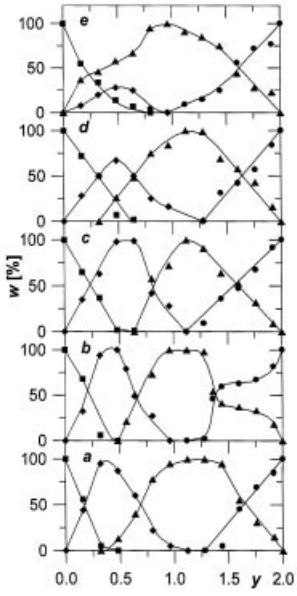

Figure 4. Dependence of relative phase content *w* on stoichiometric quotient *y* of: 2-aminoethanol (a), 3-aminopropanol (b), 4-aminobutanol (c), 5-aminopentanol (d), and 6-aminohexanol (e)

to 4-aminobutanol) and can be prepared in a pure form. In the case of 5-aminopentanol, this phase forms less readily, although it still represents a significant part of the reaction product. On the other hand, only a small amount of the 0.5 phase was observed in the intercalate with 6-aminohexanol, in which it accompanies the 1 phase. While a plateau corresponding to the 1.5 phase is observed on the titration curve for 2-aminoethanol, no such phase was observed for any

amino alcohol in the diffraction spectra of the corresponding intercalates. A moderate consecutive change of the basal spacing of phases 1 and 2 is observed when the ratio of the starting compounds y is changed from 1 to 2. It can be presumed that the amino alcohol content x in these phases is variable within a certain range.

The pure phases $Zr(HPO_4)_2 \cdot xNH_2(CH_2)_nOH \cdot zH_2O$ were prepared by the reaction of α-ZrP with a stoichiometric amount of the corresponding amino alcohol. Their composition was determined by thermogravimetric and elemental analysis. The found compositions (Table 1) are in good agreement with the presumed values ($x = 0.5$, 1.0, and 2.0). The TG curves of all prepared pure intercalate phases of 4-aminobutanol are given in Figure 5. The intercalated water is released up to 200 °C, 4-aminobutanol is released at around 300 °C, and a slow weight decrease at 350−550 °C corresponds to the removal of condensation water and the formation of pyrophosphate ZrP_2O_7. A further slow decrease of the weight is given by the combustion of carbon formed by the decomposition of the amino alcohol. The final product of the heating to 1200 °C is gray and contains some residual carbon.

Table 1. Composition of intercalates $Zr(HPO_4)_2 \cdot xNH_2(CH_2)_nOH \cdot zH_2O$

n	Phase 0.5		Phase 1		Phase 2

5	—[a]	—	0.95	1.2	1.90	1.2
6	—[a]	—	0.90	0.2	1.93	1.2

[a] Pure compounds were not prepared.

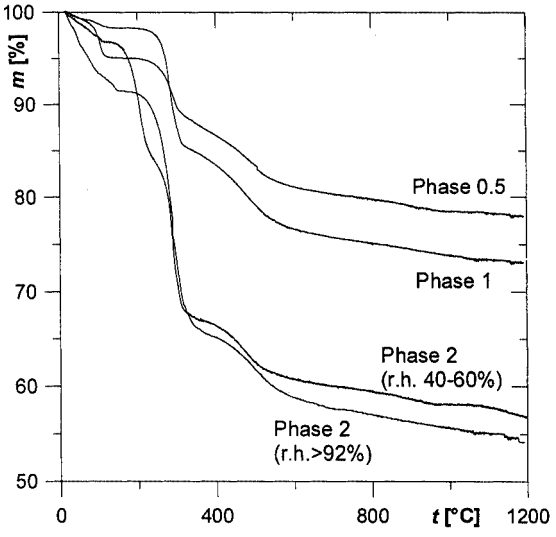

Figure 5. TGA of 4-aminobutanol intercalates

The dependence of the basal spacing of the intercalates prepared on the carbon chain length is given in Figure 6. This dependence is linear for the phases 0.5, with a slope of 0.407.

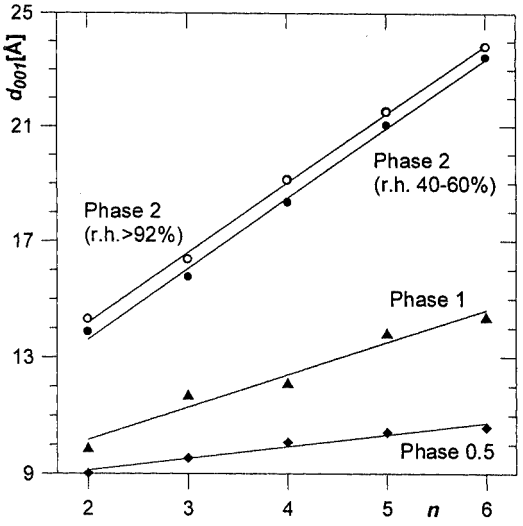

Figure 6. Dependence of the basal spacing d_{001} on the number of carbon atoms n in the amino alcohol chain

For the phases 1, the increment of the basal spacing alternates regularly when a homologous series of amino alcohols is used. The basal spacing increases by about 1.8 Å when going from an amino alcohol with an even number of carbon atoms to an amino alcohol with the chain one carbon atom longer. When we go from an amino alcohol with an odd number of carbon atoms to an amino alcohol with the chain one carbon atom longer, the increase of basal spacing is about 0.5 Å. This alternation can be explained by a different water content in the intercalates (see Table 1). The average increment of the basal spacing is 1.11 Å. As was found by XRD measurements at different relative humidities (*r.h.*), the basal spacing of the 2-aminoethanol, 4-aminobutanol, and 6-aminohexanol intercalates remains constant at *r.h.* > 92% and basal spacing of 3-aminopropanol and 5-aminopentanol intercalates does not change at *r.h.* < 11%. The water content in these intercalates does not depend on the relative humidity of ambient air, as was found by TG measurements.

On the other hand, the water content of the fully intercalated products (phases 2) does depend on the relative humidity. Under ambient conditions (*r.h.* = 40−60%), the intercalates contain about one water molecule per formula unit. The linear dependence of the basal spacing on n has a slope of 2.356. At high relative humidity (*r.h.* > 92%), these intercalates contain two water molecules and their basal spacings increase by about 0.62 Å, although the slope of the dependence of the basal spacing on n is practically the same as under ambient conditions.

The 5-aminopentanol and 6-aminohexanol intercalates (phases 2) were studied by thermal X-ray measurements. A small decrease of the basal spacing (about 0.25 Å) was ob-

served at about 50 °C; this may be caused by water released from the interlayer space. Formation of phases 1 was observed at about 160 °C and the phases 2 disappeared at 200 °C. This is in good agreement with Costantino's results.[6] The temperatures of dehydration and loss of one molecule of amino alcohol determined by TG (79 and 220 °C for 6-aminohexanol) are higher than those determined by XRD. This difference is caused by the insensibility of TG to crystal structure changes which occur during the release of the guest from the interlayer space before its evaporation from the sample.

As follows from the calculated slopes, the molecules of amino alcohols in the interlayer space are less tilted relative to the host layers with an increasing degree of intercalation, so that they form a bimolecular film with chains tilted at an angle of 67° in the fully intercalated phases.

Experimental Section

Well-crystallized α-ZrP, of formula α-$Zr(HPO_4)_2 \cdot H_2O$, was obtained according to the method reported by Alberti and Torracca.[14] A clear solution was prepared by dissolving 10.1 g of $ZrOCl_2 \cdot 8H_2O$, 8 mL of hydrofluoric acid (40% w/w) and 92 mL of H_3PO_4 (85% w/w) in 160 mL of water. The solution was heated at 80 °C for 4 days, maintaining a constant volume by continuously adding water. The α-ZrP precipitate was washed with deionized water and dried in air.

Intercalation of 2-aminoethanol, 3-aminopropanol, 4-aminobutanol, 5-aminopentanol and 6-aminohexanol into α-ZrP was studied. Three types of experiment were carried out:
1) α-ZrP (0.25 g, 0.83 mmol) suspended in 50 mL of H_2O was titrated with a 0.166 M solution of the corresponding amino alcohol. In each step, 0.2 mL of amino alcohol was added at 100 min intervals. The pH values were followed as a function of time.
2) The successive formation of the phases was followed on the samples prepared by the reaction of the suspension of 0.125 g of α-ZrP in 50 mL of H_2O with 0.4, 0.8, 1.2, 1.6, 2.0, 2.4, 2.8, 3.2, 3.6, 4.0, 4.4, 4.8 and 5.0 mL of a 0.166 M solution of the corresponding amino alcohol. After the amino alcohol addition, the samples were stirred for 24 h and the solvents evaporated to dryness at 50 °C.
3) The pure phases $Zr(HPO_4)_2 \cdot xNH_2(CH_2)_nOH \cdot zH_2O$ (x = 0.5, 1.0 and 2.0; z = 0.4−1.2) were prepared by reaction of α-ZrP with a stoichiometric amount of corresponding amino alcohol. The basal spacing and content of water as a function of relative humidity of the atmosphere was followed.

X-ray powder diffraction (XRPD) patterns of the intercalates were obtained with an X-ray diffractometer (HZG-4, Germany) using Ni-filtered Cu-K_α radiation. The Cu-$K_{\alpha 2}$ intensities were removed from the original data. Silicon (a = 5.43055 Å) was used as internal standard. Diffraction angles were measured from 2θ = 1.5° to 2θ = 50°. XRPD patterns at different temperatures, from 20 to 250 °C, were taken on samples heated on a sintered alumina ceramic plate equipped with a thermocouple.[15]

The compositions of the pure phases were calculated from thermogravimetry measurements (Stanton Redcroft STA-801, heating rate 5 °C/min, Pt crucible, Pt-Pt/Rh thermocouples, air flow) and elemental analysis. The weight of the gray residue obtained by heating to 1200 °C was corrected for the carbon remaining in the sample, which was determined by elemental analysis. The difference between the original weight of the sample and the corrected weight of the sample after heating is the weight of the organic substance, hydration water, and condensation water (water released by formation of pyrophosphate ZrP_2O_7). From the corrected weight of the heated sample, the amount of zirconium pyrophosphate was calculated and found to correspond to the amount of condensation water. The amount of hydration water corresponded to the weight loss observed to about 200 °C. The amount of the organic substance was calculated as the difference between the total weight loss and the amount of water. From the amount of the organic substance one can calculate the N, C, and H content of the sample and compare it with the results from elemental analysis. From these considerations the general formula of the intercalation compounds $Zr(HPO_4)_2 \cdot xNH_2(CH_2)_nOH \cdot zH_2O$ was determined.

Acknowledgments

Research was carried out in the framework of the Agreement for Scientific Cooperation between the Italian C.N.R. and the Academy of Sciences of the Czech Republic. K. M., L. B., and V. Z. wish to thank the Grant Agency of the Czech Republic (Grant No. 202/01/0520) for funding.

A Study of the Equilibrium and Kinetics of Urea Binding by a Biomimetic Dinickel(II) Complex

Sergey V. Kryatov,[a] Elena V. Rybak-Akimova,*[a] Franc Meyer,*[b] and Hans Pritzkow[c]

Dedicated to Professor George M. Sheldrick on the occasion of his 60th birthday

Keywords: Enzyme models / Nickel / N ligands / Kinetics / Thermodynamics

The equilibrium and kinetics of urea binding by model dinickel complexes have been studied, which is relevant to the activity of the urease enzyme. The pyrazolate-based, O_2H_3-bridged dinuclear nickel(II) complex $[LNi_2(OH)(H_2O)]^{2+}$ (**1**) binds urea reversibly in organic solvents with the formation of an *N*,*O*-bridged urea anion complex $[LNi_2[OC(NH_2)NH)]^{2+}$ (**2**) and two water molecules. The equilibrium constant has been measured as 4.3(4) in acetone, 2.7(5) in acetonitrile, and 3(1) in methanol at 25 °C. Upon dissolving **1** in anhydrous methanol, the O_2H_3 bridge is substituted for an O_2Me_2H bridge to give $[LNi_2(OMe)(MeOH)]^{2+}$ (**4**),which has been crystallized as **4**·$(ClO_4)_2$ and characterized by X-ray diffraction. Both Ni^{II} ions in **4** are five-coordinate with geometries intermediate between square-pyramidal and trigonal-bipyramidal. The H atom in the Me_2O_2H bridging unit is located in an asymmetric position. The exchange of water and methanol ligands in complexes **1** and **4** is very fast in solution at 25 °C ($k_{obsd.} > 10^3$ s^{-1}). Binding of urea by complexes **1** and **4** are slower reactions ($k_{obsd.} \approx 10^{-1}$ to 10^1 s^{-1} under the concentration conditions used) and can be monitored by stopped-flow techniques. Detailed kinetic studies indicate that binding of urea is a multi-step process. Steady-state intermediates of the tentative formula $[LNi_2(OR)(urea)_n]^{2+}$ (n = 1, 2) are formed in fast preequilibrium with the starting complexes **1** (R = H) and **4** (H = Me), respectively. The bidentate *N*,*O*-coordination and deprotonation of an *O*-bound urea ligand constitute the overall rate-limiting step. The kinetic data suggest that both mono- and bis(urea) complexes participate in the formation of the chelate **2**, and that the latter are substantially more reactive. The bis(urea) pathway was unexpected because only one urea molecule is incorporated into the final product **2**. Reactive intermediates $[LNi_2(OH)(urea)_n]^{2+}$ are close analogs of the reactive intermediate of urease, which also has the hydroxide and urea ligands bound at a dinickel core. However, the reactivities of the intermediates are different. The hydroxide ligand in our model complex acts as a base towards urea, and the urea anion complex **2** is formed. In urease, the hydroxide ligand attacks urea as a nucleophile leading to the hydrolysis of urea.

Introduction

Urease is an exceptional metallohydrolase that is present in various plants, fungi and bacteria. It contains two proximate nickel ions within its active site and efficiently catalyzes the hydrolysis of urea to finally give carbon dioxide and 2 equiv. of ammonia.[1,2] This is a very remarkable reaction because urea has a very high resonance energy and hence is an extremely stable molecule. In fact, the uncatalyzed hydrolysis of urea has never been observed, while in aqueous solution urea slowly decomposes by an elimination pathway to yield ammonium cyanate.[3] Since the first X-ray crystal structure of microbial urease was published in 1995,[4] accumulating crystallographic evidence has provided a detailed picture of the enzyme active site and a reliable background for understanding its mechanism of catalysis.[5–7] Based on the crystal structures of urease inhibited by either phosphate or diamidophosphate, as well as on the basis of recent model calculations and the mechanistic studies of enzyme inhibition, the process outlined in Scheme 1 now seems most probable.[7,8] It implies that urea first coordinates to one nickel ion through its carbonyl oxygen atom, followed by a transition towards a bridging binding mode and concomitant nucleophilic attack by the bridging hydroxide ligand. The exact sequence of the latter events remains unclear, but work on synthetic model compounds suggests that urea becomes quite acidic (down to pK_a = 3 in aqueous solution) and tends to deprotonate upon *N*-

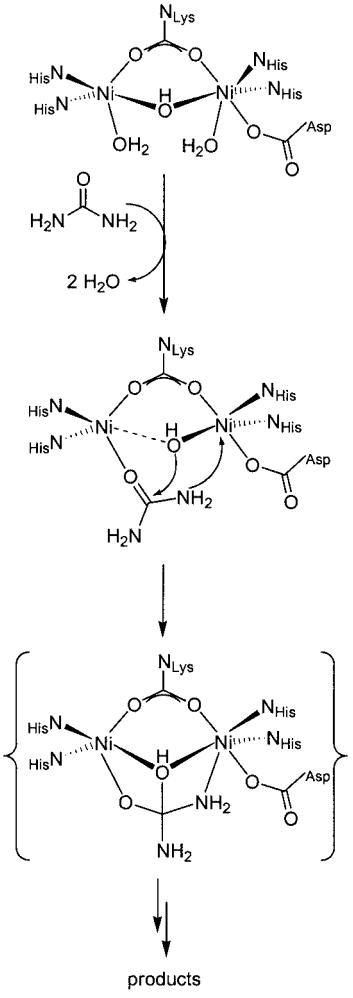
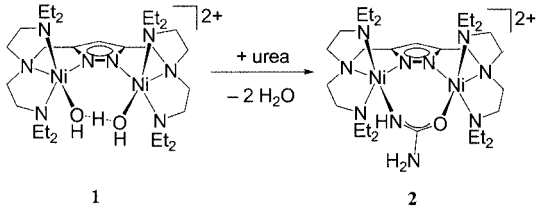
coordination.[9] This should be even more pronounced upon bidentate *N,O*-binding to two metal ions, thereby rendering the substrate more resistant to hydrolysis under the optimal pH conditions of urease (pH = 4−8).[10] It thus seems likely that one of the Ni−OH bonds is weakened upon initial binding of the substrate, and that formation of the bridging Ni−N_{urea} bond and nucleophilic attack occur simultaneously.[7,8,11]



Scheme 1

Several synthetic dinickel model complexes have been prepared to mimic structural or functional features of the urease active site.[11−16] In most model systems where urea coordination has been structurally verified, the substrate is bound through its carbonyl O atom, which is the preferred urea binding mode.[14] In the very few systems showing a dinickel site with a bidentate *N,O*-bridging urea,[11,15,16], the substrate is deprotonated as a ureate anion. Clearly, elucidation of the details of substrate binding is a prerequisite for a comprehensive understanding of urease activity. Likewise, control of urea binding in dinickel model complexes is crucial for achieving urease-like reactivity.

We have therefore carried out an in-depth analysis of the equilibrium and kinetics of urea binding by the active dinickel compound **1**, which was shown to give ureate-bridged **2** in an acid/base reaction according to Scheme 2.[15] The bridging pyrazolate in **1** and **2** was anticipated to most closely resemble the bridging carboxylate of the native enzyme (i.e. a carboxylated lysine residue), since both bridging units are monoanionic and can support similar metal−metal distances (from 3.3 to 4.6 Å for pyrazolate-bridged complexes).[11,12e,13,14d,15,16,17,19,20] Short pendant arms (such as in complex **1**) enforce larger M−M separations. Complex **1** was chosen to specifically investigate the reactivity of an *Ni*-bound hydroxide ligand that can not bridge the two Ni centers. In urease, both terminal and bridging hydroxide ligands are present. Complex **1** possesses an intramolecular O_2H_3 bridge that can be described as a hydrated form of an active *Ni*-bound hydroxide ligand. This terminal hydroxide ligand is expected to be much more reactive as a base compared with a bridging hydroxide ligand. The latter is prevented in **1** due to the large Ni···Ni separation (4.5 Å, as compared to 3.5 Å in urease) enforced by the compartmental pyrazolate ligand scaffold.[13,17] Urea incorporation by the diiron(III) complex $[Fe_2(tpa)_2(\mu\text{-}O)(O_2H_3)]^{3+}$ has recently been shown to proceed by a reversible multistep process.[18] To the best of our knowledge, no quantitative data on the stability of nickel urea complexes or on the kinetics of their formation in solution have been reported.



Scheme 2

Results and Discussion

Equilibrium Studies

Initially, the behavior of **1** in various solvents and the equilibrium of urea binding (Scheme 2) were studied by UV/Vis spectroscopy.

Acetone

Complex **1** ($[LNi_2(OH)(H_2O)]^{2+}$) has been shown to react with urea in acetone solution according to Scheme 2,[15] with an equilibrium constant given by K_1 [Equation (1)].

$$[LNi_2(OH)(H_2O)]^{2+} + OC(NH_2)_2 \rightleftarrows [LNi_2\{OC(NH_2)\text{-}NH\}]^{2+} + 2\,H_2O$$
$$K_1 = \{[LNi_2\{OC(NH_2)NH\}][H_2O]^2\}/\{[LNi_2(OH)(H_2O)]\text{-}[OC(NH_2)_2]\} \quad (1)$$

The UV/Vis spectrum of complex **1** in acetone at 25 °C is independent of the water content in the range 0.002−0.2 M H_2O (Table 1). The species $[LNi_2(OH)(H_2O)]^{2+}$ (**1**) ap-

Table 1. UV/Vis data of the complexes

pears to be unchanged upon dissolving in such a weakly coordinating solvent as acetone, and no hydration or dehydration occurs in the solution.

Addition of urea to the solution of **1** in acetone elicits a moderate change in the UV/Vis spectrum, with the most sensitive region being 370−470 nm (Figure 1). The absorbance maximum in this region shifts from 405 to 409 nm. The change is cleanly reversed by the addition of water (Figure 2), showing that the reaction between **1** and urea is reversible. Spectrophotometric titrations performed at different concentrations of urea and water showed conserved isosbestic points (at 370 and 410 nm) and conserved extremum points in differential spectra (at 392 and 430 nm; Figure 2), suggesting that only two colored species were at equilibrium. The spectrophotometric titration data obtained in acetone at 25 °C can be fitted satisfactorily by a simple model based on Equation (1) with K_1 = 4.3(4) M, confirming that urea replaces two water molecules in complex **1**.

Acetonitrile

The UV/Vis spectrum of complex **1** in acetonitrile is susceptible to the content of water. The spectrum of **1** in anhydrous acetonitrile (water content < 0.002 M) has an absorbance maximum at 402 nm and is different from that in acetone (Table 1). The addition of water systematically changes the spectrum: the absorbance maximum drifts from

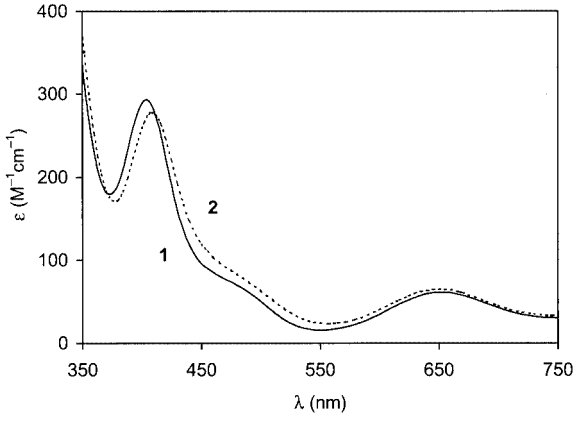

Figure 1. UV/Vis spectra of complexes **1** (solid line) and **2** (dashed line) in acetone

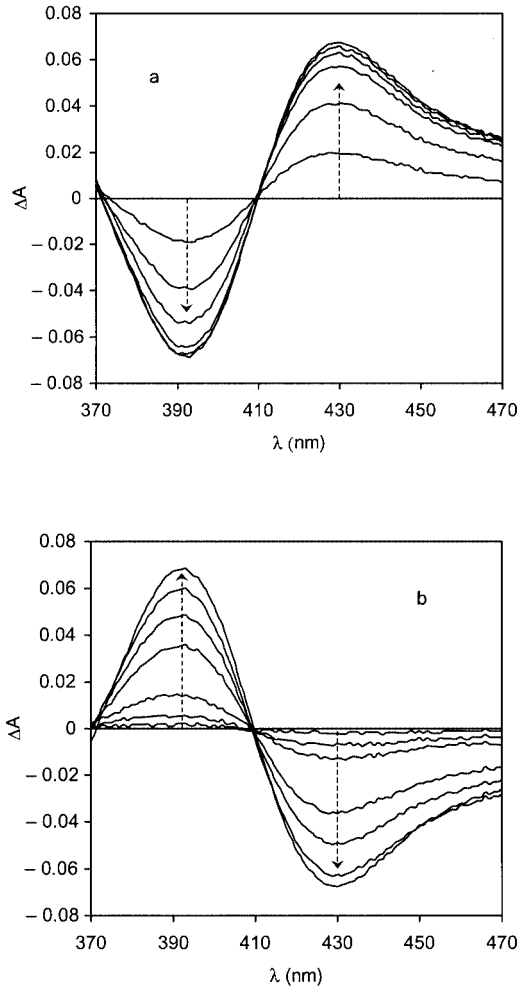

Figure 2. Differential UV/Vis spectra: (a) 2.0 mM solution of **1** in anhydrous acetone titrated with urea: 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0 mM urea; (b) resulting solution titrated with water: 9, 18, 36, 112, 187, 337 mM water, the final line is for the starting complex **1**

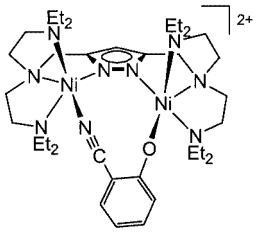
402 to 405 nm. At $[H_2O] \geq 0.1$ M the spectrum in acetonitrile is almost congruent to that in acetone. Based on the known reactivity of complex **1** with nitriles,[13] it can be hypothesized that acetonitrile substitutes a molecule of water to form the complex $[LNi_2(OH)(MeCN)]^{2+}$. Such species resemble the crystallographically characterized complex **3**.[19]



3

The dehydration of complex **1** in acetonitrile solution can be written as Equation (2). The equilibrium constant is estimated as $K_2 = 0.05(2)$ M. It should be noted that regular commercial acetonitrile contains about 0.1 M H_2O, in which medium the dehydration of complex **1** is insignificant.

$$[LNi_2(OH)(H_2O)]^{2+} + MeCN \rightleftarrows [LNi_2(OH)(MeCN)]^{2+} + H_2O$$
$$K_2 = \{[LNi_2(OH)(MeCN)][H_2O]\}/\{[LNi_2(OH)(H_2O)]\} \quad (2)$$
(in MeCN)

Addition of urea to the solution of complex **1** in acetonitrile with controlled water content, $[H_2O] \geq 100$ mM, causes changes in the UV/Vis spectrum that are very similar to those observed in acetone solution (Table 1). With excess urea the spectrum is very similar to that of complex **2** in acetone. The equilibrium constant of Equation (1) in acetonitrile at 25 °C was determined as $K_1 = 2.7(5)$ M, close to that in acetone.

Methanol

The UV/Vis spectrum of complex **1** dissolved in aqueous methanol (> 2 M H_2O) is very similar to those in acetone or aqueous acetonitrile. However, the spectrum is different in anhydrous methanol (Table 1). Spectrophotometric titration of the methanol solution of **1** with water showed two consecutive isosbestic points, suggesting that three species are at equilibrium with significantly different consecutive stability constants. As methanol and water are quite similar as ligands, it is reasonable to assume that these species are $[LNi_2(OH)(H_2O)]^{2+}$ (**1**), $[LNi_2(OH)(MeOH)]^{2+}$ and $[LNi_2(OMe)(MeOH)]^{2+}$ (**4**).

$$[LNi_2(OH)(H_2O)]^{2+} + MeOH \rightleftarrows [LNi_2(OH)(MeOH)]^{2+} + H_2O$$
$$K_3 = \{[LNi_2(OH)(MeOH)][H_2O]\}/\{[LNi_2(OH)(H_2O)]\} \quad (3)$$
(in MeOH)

$$[LNi_2(OH)(MeOH)]^{2+} + MeOH \rightleftarrows [LNi_2(OMe)(MeOH)]^{2+} + H_2O$$
$$K_4 = \{[LNi_2(OMe)(MeOH)][H_2O]\}/\{[LNi_2(OH)(MeOH)]\} \quad (4)$$
(in MeOH)

Indeed, the experimental data can be well fitted to the model based on Equations (3) and (4) with the consecutive equilibrium constants $K_3 = 0.040(5)$ M and $K_4 = 0.6(1)$ M at 25 °C (Scheme 3). Previous work showed that the intramolecular O_2H_3 bridging unit in type **1** complexes is rather labile, allowing for the exchange of water by other ligands, e.g. methanol.[13,20] Formation of complex **4** has been confirmed by its isolation and structural characterization (vide infra).

Addition of urea to the solution of complex **1** in anhydrous methanol elicits changes in the UV/Vis spectrum. The spectrum recorded for large excess of urea is very similar to that of the ureate complex **2** in other solvents (Table 1). Assuming that **4** is the dominant species in the solution of complex **1** in anhydrous methanol, the reaction can be written as Equation (5).

$$[LNi_2(OMe)(MeOH)]^{2+} + OC(NH_2)_2 \rightleftarrows [LNi_2\{OC(NH_2)NH\}]^{2+} + 2\,MeOH$$
$$K_5 = [LNi_2\{OC(NH_2)NH\}]\}/\{[LNi_2(OMe)(MeOH)][OC(NH_2)_2]\} \quad (5)$$
(in MeOH)

Data from spectrophotometric titration fit this assumption well. The equilibrium constant is $K_5 = 130(10)$ M^{-1} at 25 °C. A combination of equilibrium constants K_3, K_4 and K_5 allows us to calculate $K_1 = K_3K_4K_5 = 3(1)$ M in methanol at 25 °C (Scheme 3), which compares well with the values obtained in other solvents (Table 2).

Solid-State Structure of 4

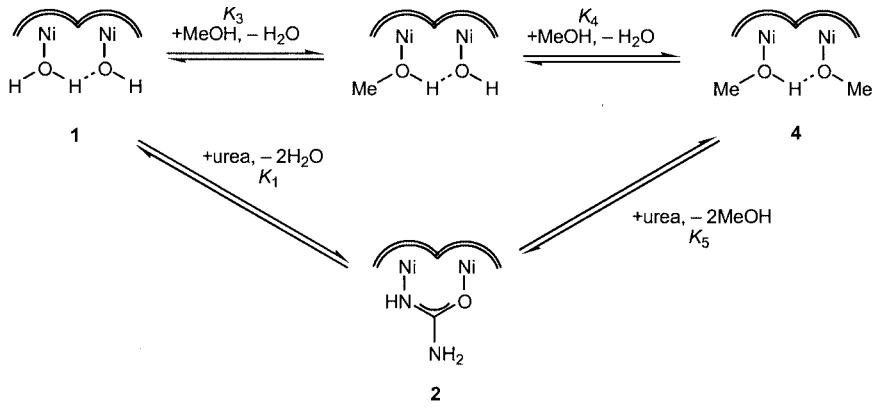
Single crystals of **4**·$(ClO_4)_2$ were obtained by dissolving complex **1**·$(ClO_4)_2$ in anhydrous methanol and subsequent slow diffusion of diethyl ether into the solution. One such crystal was analyzed by X-ray crystallography; the molecular structure of the cation is depicted in Figure 3, together with selected atom distances and bond angles.

The overall structure of **4** is very similar to that of the related O_2H_3-bridged dinickel complex **1**·$(ClO_4)_2$.[20a] As anticipated, complete exchange of water by methanol has occurred, corroborating that the intramolecular O_2H_3 bridge is labile and that binding of substrate molecules should proceed by substitution reactions within the dimetallic pocket of **1**. Both the Ni1···Ni2 and O1···O2 distances are slightly longer in **4** (4.552/2.426 Å in **4** versus 4.380/2.410 Å in **1**[20a]). The coordination is very similar for both Ni1 and Ni2 and is intermediate between square-pyramidal and trigonal-bipyramidal ($\tau = 0.66$ for Ni1 and 0.62 for Ni2; the respective values for complex **1** are 0.38 and 0.82).[21] The bridging hydrogen atom H1, located in the crystallographic analysis, was found in an asymmetric position between the two O atoms with d(O1−H1) = 0.972 Å and d(O2−H1) = 1.457 Å, but the two Ni−O bond lengths are almost identical.

The structure determination of **4** corroborates the conclusions drawn from the solution UV/Vis experiments, i.e. the O_2H_3-bridged complex **1** is transformed into the O_2Me_2H-bridged species **4** in anhydrous methanol.

Kinetic Studies

Initial kinetic experiments were performed on the exchange of methanol and water ligands in complexes $[LNi_2(OR)(ROH)]^{2+}$ (R = H, Me) using rapid-scanning



Scheme 3. Equilibrium processes studied

stopped-flow spectrophotometry. The solution of complex **4**, $[LNi_2(OMe)(MeOH)]^{2+}$, in anhydrous methanol was mixed with the solutions of water in methanol. Equilibrium studies (vide supra) showed that complex **4** is converted predominantly into $[LNi_2(OH)(MeOH)]^{2+}$ at $[H_2O]$ = 0.1 M and $[LNi_2(OH)(H_2O)]^{2+}$ at $[H_2O]$ = 2 M. The first scan, taken 10 ms after mixing, already revealed the hydrated species upon the introduction of the respective amounts of water (Table 1). In a control experiment, mixing the methanol solution of **4** with the anhydrous solvent did not cause any spectral changes other than dilution. The reaction was reversed, by mixing solutions of **1** and methanol in acetone, and the first spectrum, recorded in 10 ms, was that of $[LNi_2(OH)(MeOH)]^{2+}$ (the formation of **4** in acetone solution could not be observed because of concentration limitations). Thus, the exchange of water and methanol ligands in complexes **1** and **4** is very fast. Substitution of neutral monodentate ligands at high-spin nickel(II) centers is usually a rather quick process, with rate constants on the order of 10^3 to 10^4 s^{-1}.[22]

The reaction between complex **1**, $[LNi_2(OH)(H_2O)]^{2+}$, and urea to form complex **2**, $[LNi_2\{OC(NH_2)NH\}]^{2+}$, proceeds according to Equation (1) in a broad range of reagent concentrations in acetone as a solvent. In acetonitrile and methanol the reaction is complicated by solvation of the starting complex **1**. We performed kinetic studies in both acetone and methanol using single-wavelength stopped-flow spectrophotometry.

Acetone

Wavelengths 392 and 430 nm were chosen as the most susceptible to the transformation of complex **1** into **2** (Figure 2). Mixing the acetone solutions of **1** and urea under conditions of excess urea at 25 °C leads to simple first-order kinetic traces as monitored by spectrophotometry on 3–5 half-lives (Figure 4). Very similar values of the rate constant were observed on the rise and the fall of optical absorbance, at 430 and 392 nm, respectively. The initial and final optical absorbances measured in the kinetic experiments were identical to those determined by conventional spectrophotometry in the equilibrium studies, within the accuracy of determination.

Pseudo-first order rate constants k_{obs} were experimentally determined at 23 different concentrations of urea (0.0080–0.0275 M) and water (0.010–0.100 M). The concentrations were chosen to make the formation of complex **2** almost irreversible [yield > 95% according to Equation (1)].

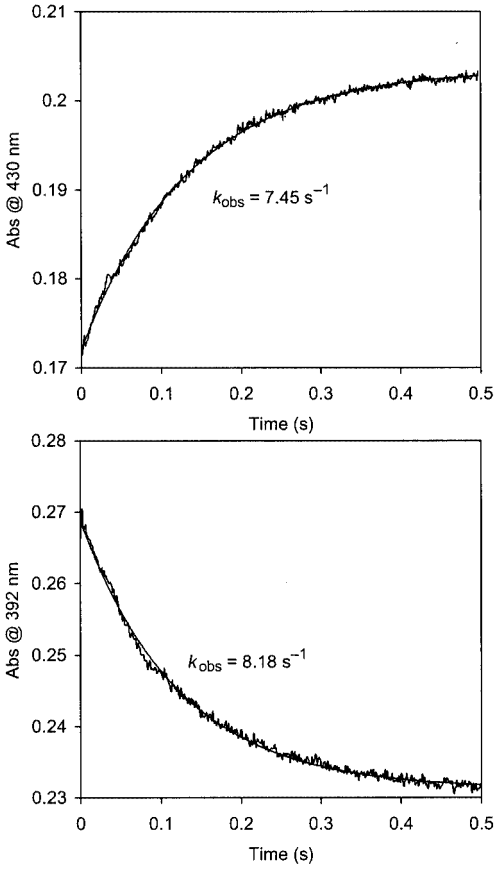

Figure 4. Representative kinetic traces of the reaction between complex **1** and urea in acetone, obtained by stopped-flow spectrophotometry, superimposed with single-exponential fits; conditions: T = 25 °C, $[\mathbf{1}]_0$ = 1.05 mM, $[urea]_0$ = 27.5 mM, and $[H_2O]_0$ = 10 mM

The transformation of complex **1** into complex **2** under these conditions was not a very fast process, with k_{obs} in the range 0.3−8 s^{-1}. The reaction is accelerated by urea and decelerated by water (Figure 5). From the shapes of the concentration dependencies, k_{obs} versus [urea] at constant $[H_2O]$, the reaction order in urea is evidently higher than one. Several kinetic equations were tested to fit the experimental data, and only those with both first- and second-order terms in [urea] gave satisfactory fits (see Supporting Information for details; see also the footnote on the first page of this article). Equation (6) gave the best fit, and also a plausible mechanistic interpretation (vide infra).

$$k_{obs} = \{k'K'[urea] + k''K'K''[urea]^2\}/\{[H_2O] + K'[urea]\} \quad (6)$$

Optimization of Equation (6) by non-linear weighed least-squares method gave k' = 0.39 s^{-1}, K' = 0.29, and $k''K''$ = 650 M^{-1}·s^{-1} with an average relative deviation of 2.7% and a satisfactory coverage of all experimental points (Figure 5).

Additional experiments were made to check if the reaction between **1** and urea is influenced by an external base. Addition of 2,6-dimethylpyridine (1−100 equiv.) to the solution of either complex **1** or **2** in acetone does not change the UV/Vis spectra. Also, the kinetics are constant for the reaction between complex **1** and urea in the presence of up to 10-fold excess of 2,6-dimethylpyridine versus complex **1** in acetone solution.

Methanol

As previously mentioned, complex $[LNi_2(OH)(H_2O)]^{2+}$ (**1**) is converted into $[LNi_2(OMe)(MeOH)]^{2+}$ (**4**) upon dissolution in anhydrous methanol. To minimize the interference from water, solutions of solid **4**·$(ClO_4)_2$ in anhydrous methanol were used. Complex **4** reacts with excess urea to yield complex **2**, as found by the equilibrium studies (vide supra). The formation of **2** from **4** and urea in anhydrous methanol is almost two orders of magnitude slower than from **1** and urea in anhydrous acetone at the same urea concentration. Fortunately, the solubility of urea in methanol is also much higher, allowing a wider range of

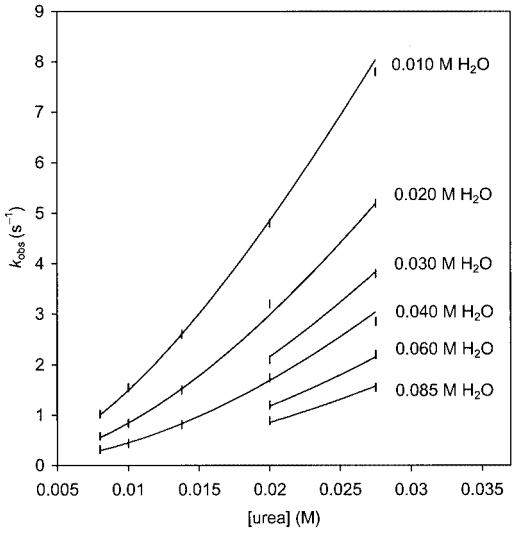

Figure 5. Pseudo first-order rate constants of the reaction between complex **1** and urea in acetone versus urea concentration in the series with constant water concentrations; lines represent the fits with Equation (6)

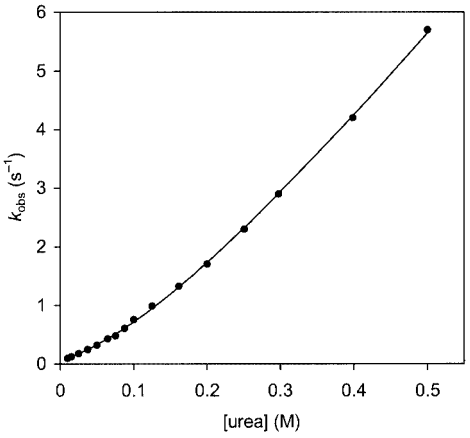

Figure 6. Pseudo first-order rate constants of the reaction between complex **4** and urea in methanol versus urea concentration (T = 25 °C); experimental points superimposed with the fitting line [Equation (7)]

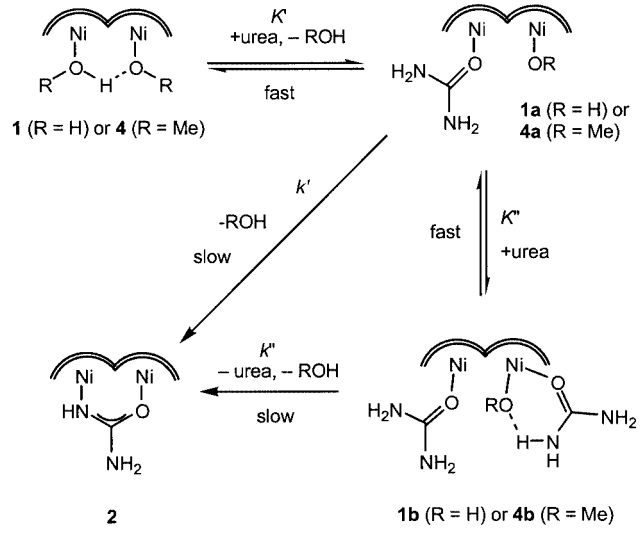
available urea concentrations. Kinetic traces of the reaction between **4** and excess urea fit perfectly with a single-exponential function in all performed experiments. The reaction accelerates with increasing in urea concentration (Figure 6). As in the reaction of **1** with urea in acetone, the kinetic data for the reaction in methanol can be fit satisfactorily only by kinetic equations with both first- and second-order terms in [urea]. Equation (7), which is very similar to Equation (6), gave the best fit for the dependence of k_{obs} versus [urea] and allowed for a similar mechanistic interpretation (vide infra).

$$k_{obs} = \{k'K'[\text{urea}] + k''K'K''[\text{urea}]^2\}/\{1 + K'[\text{urea}]\} \quad (7)$$

Optimization of Equation (7) gave $k' = 1.5\ s^{-1}$, $K' = 2.7\ M^{-1}$, and $k"K'' = 16.5\ M^{-1}\cdot s^{-1}$ with an average relative deviation of 1.1% (Figure 6).

Proposed Mechanism

As mentioned above, the experimental data for the formation of complex **2** in acetone and methanol could be fit satisfactorily only with kinetic equations having both linear and quadratic terms in urea concentration. This result strongly suggests the existence of two reactive pathways, involving one and two urea molecules, respectively. The bis(urea) pathway is dominant at all studied urea concentrations in acetone, and becomes dominant at higher urea concentrations (> 0.08 M) in methanol. The bis(urea) pathway is unexpected, because only one urea molecule is incorporated into the product **2**. A mechanism shown in Scheme 4 can account for the experimental observations.



Scheme 4. Kinetic processes studied (formation of **2** was almost irreversible under the concentration conditions used)

The starting complexes **1** (in acetone) or **4** (in methanol) contain easily exchangeable solvent molecules at the LNi_2 core. Therefore, it is reasonable to assume the formation of intermediate urea complexes, $[LNi_2(OR)(urea)]^{2+}$ [**1a** (R = H) or **4a** (R = Me)] and $[LNi_2(OR)(urea)_2]^{2+}$ [**1b** (R = H) or **4b** (R = Me)] in a fast preequilibrium with the starting complex **1** or **4**, respectively (Scheme 4). Fast exchange of monodentate ligands within the LNi_2 core has been observed for water and methanol in this work.

Steady-state mono(urea) intermediates **1a** and **4a** are formed upon the substitution of a neutral coordinated water or methanol molecule for a molecule of urea, which agrees with the kinetic Equations (6) and (7). The Ni^{II} ions in **1a** and **4a** are probably five-coordinate, as found in most complexes with the LNi_2 core and different additional ligands.[13,19] Coordination of the neutral urea ligands in these putative intermediates is most likely *O*-monodentate, as found in most structurally characterized nickel–urea complexes.[12,14] The equilibrium constants for the formation of **1a** and **4a** can be estimated from the kinetic data as $K'_{1a} = 0.30$ (in acetone) and $K'_{4a} = 2.7\ M^{-1}$ (in methanol). These values are reasonable, as urea is generally known to form relatively weak complexes with nickel(II) and other dipositive 3d metal cations.[23] The substitution of a solvent molecule for urea should activate the *Ni*-bound HO^- (or MeO^-, respectively), which in **1** and **4** is present in the stabilized solvated form. The reactivity of the intermediate $[LNi_2(OH)(urea)]^{2+}$ ($k'_{1a} = 0.39\ s^{-1}$) is lower than that of $[LNi_2(OMe)(urea)]^{2+}$ ($k'_{4a} = 1.5\ s^{-1}$), in agreement with the more basic nature of the methoxide ligand. The calculated steady-state yields of intermediates **1a** and **4a** are significant (up to 40%) only at the highest used concentrations of urea, according to the kinetic data (see Supporting Information). An attempt to confirm the rapid formation of intermediate **1a** from **1** in anhydrous acetone at the high urea concentration by rapid scanning spectrophotometry was inconclusive. Upon mixing the acetone solutions of **1** and urea, the first registered spectrum (10 ms) could not be distinguished from that of the starting complex **1**. The spectral changes upon ligand substitution at the LNi_2 core are usually small, and rapid scanning gives UV/Vis spectra of relatively poor quality. Therefore, the formation of intermediates **1a** and **4a** should be considered as the most probable hypothesis.

Intermediates **1b** and **4b** are formed in solution upon binding of a second urea molecule (Scheme 4). Their yield is very small and could not be evaluated from the kinetic data. Because ligand L is quite bulky and usually limits the coordination number of the nickel(II) cations in the LNi_2 core to five,[13,19] intermediates **1a** and **4a** may bind a second urea molecule only weakly (e.g., by sterically unfavorable expansion of the coordination number of a Ni^{II} cation to six, or the substitution of a diethylamino arm of ligand L, or hydrogen bonding). Nevertheless, the bis(urea) pathway is dominant at all studied urea concentrations in acetone and becomes dominant at [urea] > 0.08 M in methanol. Therefore, bis(urea) complexes **1b** and **4b** are much more reactive than their mono(urea) counterparts **1a** and **4a**.

A possible explanation for the unique reactivity of the putative bis(urea) intermediates is as follows. If **1b** and **4b** are formed upon *O*-coordination of two urea molecules to two different Ni^{II} centers at the LNi_2 core, then the HO^- and $OC(NH_2)_2$ ligands bound to the same Ni center may

form an intramolecular hydrogen bond as a part of six-membered pseudo-chelate cycle (Scheme 4). Such O···H−N bonding would make the N atom of urea more nucleophilic than in free or *O*-bound $OC(NH_2)_2$. As a consequence, an intramolecular nucleophilic attack of the urea N atom on the second Ni^{II} cation and a proton transfer from the urea to the HO^- ligand may proceed as simultaneous or closely related events, followed by the loss of water and unproductively bound urea ligands (Scheme 4). The formation of a hydrogen bond between hydroxide and urea ligands bound to different Ni atom in mono(urea) intermediates **1a** and **4a** is less probable. In this picture, the first urea molecule is required to activate the *Ni*-bound HO^- (or MeO^-, respectively) which in **1** and **4** is present in a stabilized solvated form, and the second urea molecule is the actual precursor of the ureate in **2**. The second urea molecule may also cause uncoordination of a diethylamino arm of the dinucleating ligand L,[13,19] in which case the strongly basic free amino arm may play a catalytic role in the intramolecular proton transfer and the formation of the ureate anion at the LNi_2 core. Alternatively, if the second urea molecule is bound to the $[LNi_2(OR)(urea)]^{2+}$ core via hydrogen bonds it may act as a proton shuttle and facilitate the formation of the final ureate complex **2** (see Supporting Information for details).

The rate-limiting step in the formation of **2** for both mono- and bis(urea) pathways involves the bidentate *N*,*O*-coordination and deprotonation of an *O*-coordinated urea. The deprotonation of urea is apparently intramolecular, since Equations (1) and (5) are first-order in the dinickel complexes **1** and **4**, respectively, and the addition of an external base has no influence on the rate of Equation (1). It is not clear whether deprotonation or *N*-coordination of urea occurs first, but these events should be closely related. The amide N-atoms of neutral urea are very poor donors because of their involvement in the resonance with the carbonyl group. However, the N-atoms become very good donors upon deprotonation and the formation of an amide anion. Conversely, *N*-bound urea becomes much more acidic than *O*-bound or free urea, and its deprotonation is facilitated.[9]

In summary, the reactive complexes **1a**, **4a**, **1b**, and **4b** with neutral urea ligands may be formed in solution in a fast preequilibrium and low yield. Formation of the final urea anion complex **2** is different. Thermodynamically, the urea anion $H_2NC(O)NH^-$ has a much higher affinity to the dinickel core than neutral urea, water, methanol, or even hydroxide or methoxide ions, because of the chelate effect and the presence of a deprotonated amide N-donor atom. Kinetically, the formation of **2** is relatively slow, because substitution of several donor atoms at the Ni^{II} centers and a proton transfer are involved. It should be noted that under the concentration conditions used in the kinetic study, the formation of the ureate complex **2** was irreversible (Scheme 4). The bridging *N*,*O*-coordinated urea anion at a dimetal core is quite stable and is not activated for hydrolysis.[11,13,18] Urease avoids the deprotonation of urea at its catalytic dinickel site. In the enzyme, urea undergoes a nucleophilic attack from the hydroxide ligand, which eventually leads to hydrolysis (Scheme 1). This supports the view that nucleophilic attack and *N*-binding of the substrate have to occur simultaneously in urease. The specific action of the enzyme is probably caused by the involvement of additional groups in the stabilization of a tetrahedral intermediate and subsequent general acid/base catalysis.[2,5] Another difference between the reactivity of urease and model complex **1** towards urea is the existence of two parallel reactive pathways for the model complex. While complexes **1** and **2** are not functional models for urease, a detailed investigation of these complexes reveals valuable insight into the binding of urea at a dinickel core.

Conclusion

The equilibrium and kinetics of urea binding by model dinickel complexes have been studied for the first time. Complexes $[LNi_2(OR)(ROH)]^{2+}$ (R = H, Me) with a dinucleating pyrazole-based ligand L react reversibly with urea in solution to form complex $[LNi_2[OC(NH_2)NH)]^{2+}$ with an *N*,*O*-bridging urea anion. Kinetic studies revealed several reaction steps in which, initially, urea substitutes the solvent molecule in $[LNi_2(OR)(ROH)]^{2+}$ to form steady-state intermediates $[LNi_2(OR)(urea)_n]^{2+}$ (n = 1, 2) in a fast pre-equilibrium. The subsequent bidentate *N*,*O*-coordination and deprotonation of an *O*-bound urea ligand constitute the rate-limiting step. Reactive complexes $[LNi_2(OH)(urea)_n]^{2+}$ are close analogs of the reactive intermediate of urease, which also has the HO^- and urea ligands bound at a dinickel core. However, the reactivities of the intermediates are different. In the urease enzyme, the HO^- ligand attacks urea as a nucleophile, leading to the hydrolysis of urea. The HO^- ligand in our model complex acts a base towards urea, and the dinickel complex with urea anion is formed. The present study helps in understanding the factors that govern the pathway of the reaction between the HO^- and urea ligands at a dinickel core, which is a prerequisite for the design of a fully functional synthetic model of urease.

Experimental Section

Caution: Although no problems were encountered, transition metal perchlorate complexes are potentially explosive and should be handled with proper precautions!

General: Complex **1**·$(ClO_4)_2$ was prepared as described previously.[13] Urea (Acros) was recrystallized three times from hot water and dried in vacuo over Drierite for 48 h before use. Anhydrous acetone (Acros), acetonitrile and methanol (Aldrich) were used as received. Solutions of the nickel complexes and urea in the anhydrous solvents were prepared and handled in a dry box. UV/Vis spectra were taken with a Hitachi U-2000 spectrophotometer at 25 °C.

Kinetic Studies: Kinetic experiments were carried out by using a Hi-Tech Scientific (Salisbury, UK) SF-43 stopped-flow apparatus with stainless steel lines. The concentrations of stock solutions were

1−4 mM **1**·$(ClO_4)_2$ in acetone, 8−55 mM urea in acetone, 1−4 mM **4**·$(ClO_4)_2$ in methanol, and 20−1000 mM urea in methanol. The stock solutions of a nickel complex and urea were mixed in a 1:1 ratio. Urea was always taken in at least eightfold excess to allow pseudo first-order conditions.

Urea Solubility: The solubility of urea in acetonitrile and acetone in the range of 0−30 °C was determined by gravimetric measurements. The molar solubility of urea in anhydrous acetonitrile (water content $[H_2O] \leq 0.002$ M) is expressed by $\ln S = 6.2372 - 2615/T$; 0.079 M at 298 K. The molar solubility of urea in anhydrous acetone (water content $[H_2O] \leq 0.002$ M) is expressed by $\ln S = 6.2628 - 2733/T$; 0.055 M at 298 K. The molar solubility of urea in regular commercial acetone (water content $[H_2O] \approx 0.2$ M) can be satisfactorily expressed by $\ln S = 5.6253 - 2465/T$; 0.071 M at 298 K.

Synthesis of 4·$(ClO_4)_2$: A solution of **1**·$(ClO_4)_2$ (0.25 g, 0.84 mmol) in anhydrous MeOH (1 mL) was layered with diethyl ether; green crystals of **4**·$(ClO_4)_2$ gradually formed. To ensure complete replacement of water by methanol, crystallization should be carried out in the presence of predried molecular sieves. $C_{31}H_{68}Cl_2N_8Ni_2O_{10}$ (901.22): calcd. C 41.32, H 7.60, N 12.43; found C 40.40, H 7.45, N 12.41.

X-ray Crystallographic Study: Data collection for **4**·$(ClO_4)_2$ was carried out with a Bruker AXS CCD diffractometer at 173 K by using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). Structures were solved by direct methods (SHELXS-97) and refined by full-matrix least-squares techniques based on F^2 (SHELXL-97).[24] Atomic coordinates and thermal parameters of the non-hydrogen atoms were refined in fully anisotropic models. Hydrogen atoms, except those of the disordered ethyl group, were located in difference Fourier maps and refined isotropically. One of the ethyl groups is disordered over two positions (3:1). $C_{31}H_{68}Cl_2N_8Ni_2O_{10}$, $M = 901.2$, orthorhombic, space group $Pna2_1$, $a = 25.6829(5)$, $b = 13.4179(3)$, $c = 11.9614(2)$ Å, $V = 4122.0(2)$ Å^3, $Z = 4$, $\rho_{calcd.} = 1.452$ g cm^{-3}, μ (Mo-K_α) = 1.104 mm^{-1}, $3.2° < 2\theta < 56.7°$, 40935 measured reflections, 9727 unique ($R_{int} = 0.047$), 8177 observed [$I > 2\sigma(I)$], 743 parameters, final $R1[I > 2\sigma(I)] = 0.032$, $wR2$(all data) = 0.073, goodness of fit on $F^2 = 1.049$, largest diff. peak +0.48/−0.34 e·Å^{-3}. CCDC-191806 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html or from CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterization of New Transplatinum Complexes Containing Phosphane Groups − Cytotoxic Studies in Cisplatin-Resistant Cells

Francisco J. Ramos-Lima,[a] Adoración G. Quiroga,[a] José M. Pérez,[a] Mercé Font-Bardía,[b] Xavier Solans,[b] and Carmen Navarro-Ranninger*[a]

Keywords: Antitumor agents / Bioinorganic chemistry / Crystal structure / Phosphanes / Platinum

In this paper we report the synthesis and characterization of novel *trans* platinum(II) complexes of general formula *trans*-[$PtCl_2$(L)(PPh_3)], where L is $NH_2CH(CH_3)CH_2CH_3$ (complex **1**), (*R*)-$NH_2CH(CH_3)CH_2CH_3$ (complex **2**), (*S*)-$NH_2CH(CH_3)CH_2CH_3$ (complex **3**) and $NH_2CH(CH_3)_2$ (complex **4**). The new complexes contain phosphane ligands *trans* to the amine group. X-ray crystal structure determinations of complexes **1** and **3** confirmed their *trans* configurations. The cytotoxic activity of these complexes have been evaluated and compared with the activity of *trans* platinum complexes already viewed as potential drugs.

Introduction

Current platinum-based drug research is moving towards the development of new agents capable of overcoming the problem of acquired resistance to cisplatin in order to be active against a wider range of cancer types.[1,2] For decades, platinum complexes of *trans* geometry were not regarded as potential drugs because transplatin is an inactive isomer. Over the last ten years, however, transplatinum complexes have been developed as new drugs.[3,4] We have recently shown that *trans* amino complexes such as *trans*-[$PtCl_2$(dimethylamine)(isopropylamine)] are able to circumvent *cis*-DDP resistance in tumour cells transformed by *ras* oncogenes (Pam212-*ras*), and are also able to kill these cells through apoptosis.[5] In addition, we found in the literature a wide range of active platinum complexes containing aminophosphane,[6,7] triphos ligand[8] and phosphorus derivative ligands.[9] Following these results we thought that the study of the effect of the phosphane in the *trans* configuration could help to extend understanding of the cytotoxic activity of *trans* platinum complexes.

In this paper we report the synthesis and characterization of *trans*-[$PtCl_2$(L)(PPh_3)] complexes, where L is $NH_2CH(CH_3)CH_2CH_3$ (**1**), (*R*)-$NH_2CH(CH_3)CH_2CH_3$ (**2**), (*S*)-$NH_2CH(CH_3)CH_2CH_3$ (**3**) and $NH_2CH(CH_3)_2$ (**4**). As far as we know, these complexes are the first Pt complexes with phosphane groups and chiral amines in *trans* configurations. Moreover, they have chloride leaving groups, which may facilitate comparison with some previously reported *trans* platinum complexes, such as *trans*-[$PtCl_2$(dimethylamine)(isopropylamine)].[4]

Results and Discussion

The new *trans*-Pt complexes with phosphane groups are prepared in three different steps. In the first step, K_2PtCl_4 reacts with PPh_3 to produce the *cis* isomer. In a second step, direct treatment of the *cis* isomer with $PtCl_2$ affords the dimer complexes [(μ-Cl)PtCl(PPh_3)]$_2$. Further addition of the desired amine splits the chloro-bridged complex to afford the final *trans* complex *trans*-[$PtCl_2$L(PPh_3)]. A scheme of the synthesis pathway is depicted in Figure 1.

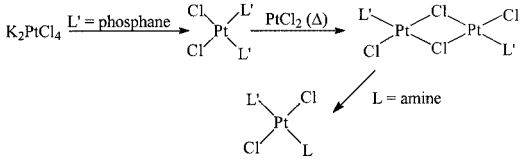

Figure 1. Chart of the synthesis pathway for the complexes **1**, **2**, **3** and **4**

The characterization of these complexes was carried out by IR and ^{195}Pt, ^{31}P, ^{1}H and ^{13}C NMR. The IR spectra show information in the low region in which ν(Pt−Cl) bands are detected.[10] As would be expected for a *trans*-Pt geometry, complexes **1**, **2** and **3** each show only one ν(Pt−Cl) band, at 346 cm^{-1}.[11] Complex **4** also shows a single ν(Pt−Cl) band, but located at 344 cm^{-1}. The ν(Pt−N) band in complexes **1**, **2**, **3** and **4** appears at 430

cm^{-1}. These ν(Pt−N) bands are lower than the ν(Pt−N) band found in *trans*-[$PtCl_2$(dma)(ipa)],[5] probably due to the greater *trans* influence of the phosphorus atom, while the Pt−Cl stretching band is virtually independent of this substitution.[11] This effect is also observed in the X-ray structure discussed below.

The *cis*- and *trans*-platinum complexes can readily be distinguished by comparison of the $^1J(^{31}P\text{-}^{195}Pt)$ values, measured from the ^{195}Pt satellites on the high-field and low-field doublets.[12] We found in the literature that complexes such as *cis*-[$PtCl_2(PPh_3)_2$] show a larger coupling constant than the *trans* isomer between ^{195}Pt and ^{31}P , but any decrease in the covalency of the Pt−P bond will also reduce the coupling.[11] Complexes **1**, **2**, **3** and **4**, in which the P atom is *trans* to the N atom, each show a value of 3600 Hz, normal for a ^{31}P atom *trans* to an N donor.[7,11,13]

The structures of complexes **1** and **3** were determined by X-ray analysis. Selected bond lengths (Å) and angles (°) for complex **1** and **3** are summarized in Table 1 and Table 2, respectively.

Table 1. Selected bond lengths (Å) and angles(°) for complex **1**

Pt−Cl(1)	2.295(3)	Pt−Cl(2)	2.287(3)
Pt−P	2.243(2)	Pt−N	2.144(8)

A view of the complex **1**, *trans*-{$PtCl_2[NH_2CH(CH_3)CH_2CH_3](PPh_3)$}, is shown in Figure 2. The space group for the complex **1** is centrosymmetric, so this compound is an equimolar mixture of the *S* and *R* enantiomers. The crystal structure of this compound consists of discrete molecules in which PPh_3 and $NH_2CH(CH_3)CH_2CH_3$ groups are σ bonded to the platinum atom in *trans* configuration. The platinum atom has a square-planar environment with typical angles for square-planar platinum complexes.[4,11,14] The Pt−N distance is similar to that found in complexes with planar amines *trans* to the triethylphosphane ligand, while the Pt−P distance is slightly longer.[14] This difference is probably due to the steric effect of the different bulks and the different electronic effects of the

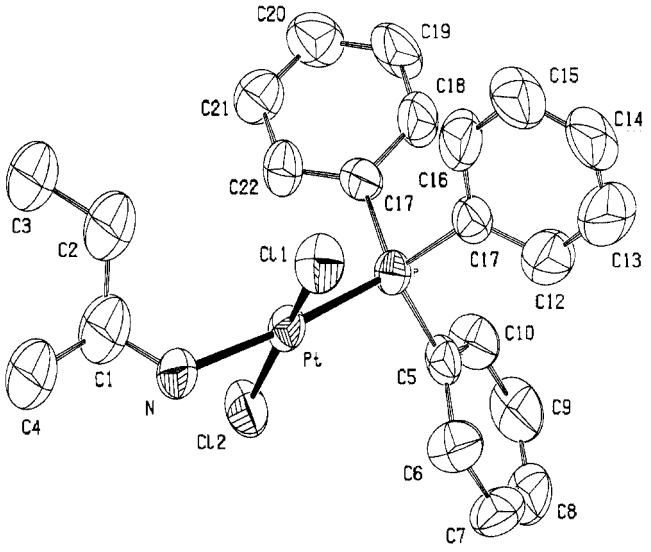

Figure 2. Ortep view of complex **1**

phenyl substituent in the phosphane group.[15] No significant differences in the Pt−Cl *trans* distances are found in comparison with *trans*-[$PtCl_2$(benzoquinoline)(PEt_3)][14] and platinum complexes such as *trans*-[$PtCl_2$(dma)(ipa)].[5] Only the Pt−N distance is significantly longer than those in the complexes mentioned, which is consistent with the greater *trans* influence of phosphane ligands relative to aliphatic amine ones.

The H22(C22)−Pt distance is fairly short [2.97(14) Å] and the distance H2(C2)−Pt is even shorter, in comparison with those found in the references (see Table 3).[12] The data reported in the literature also support the idea of a weak interaction between H and Pt atoms when such a distance is from 2.3 to 2.9 Å, which includes the distance here.[14]

Table 3. Distances (Pt, X) (Å) for complex **1**

d(Pt, X)	Atom X
3.064(13)	C(1)
3.344(9)	C(17)
3.374(13)	C(2)
3.401(8)	C(5)
3.457(12)	C(22)
3.469(8)	C(11)
2.4443	H(1A)
2.8679	H(2)
2.97(14)	H(22)
3.1334	H(1A)
3.1546	H(1)
3.31(6)	H(6)

A view of the complex **3**, which contains the enantiomerically pure amine moiety (*S*)-$NH_2CH(CH_3)CH_2CH_3$, is shown in Figure 3. The crystal structure of this compound consists of two different discrete molecules in which PPh_3 and (*S*)-$NH_2CH(CH_3)CH_2CH_3$ groups are σ bonded to platinum in a *trans* configuration. Although both molecules look like very similar, the main difference between them is the C−H···ring π interaction between C(214)−H(214) and

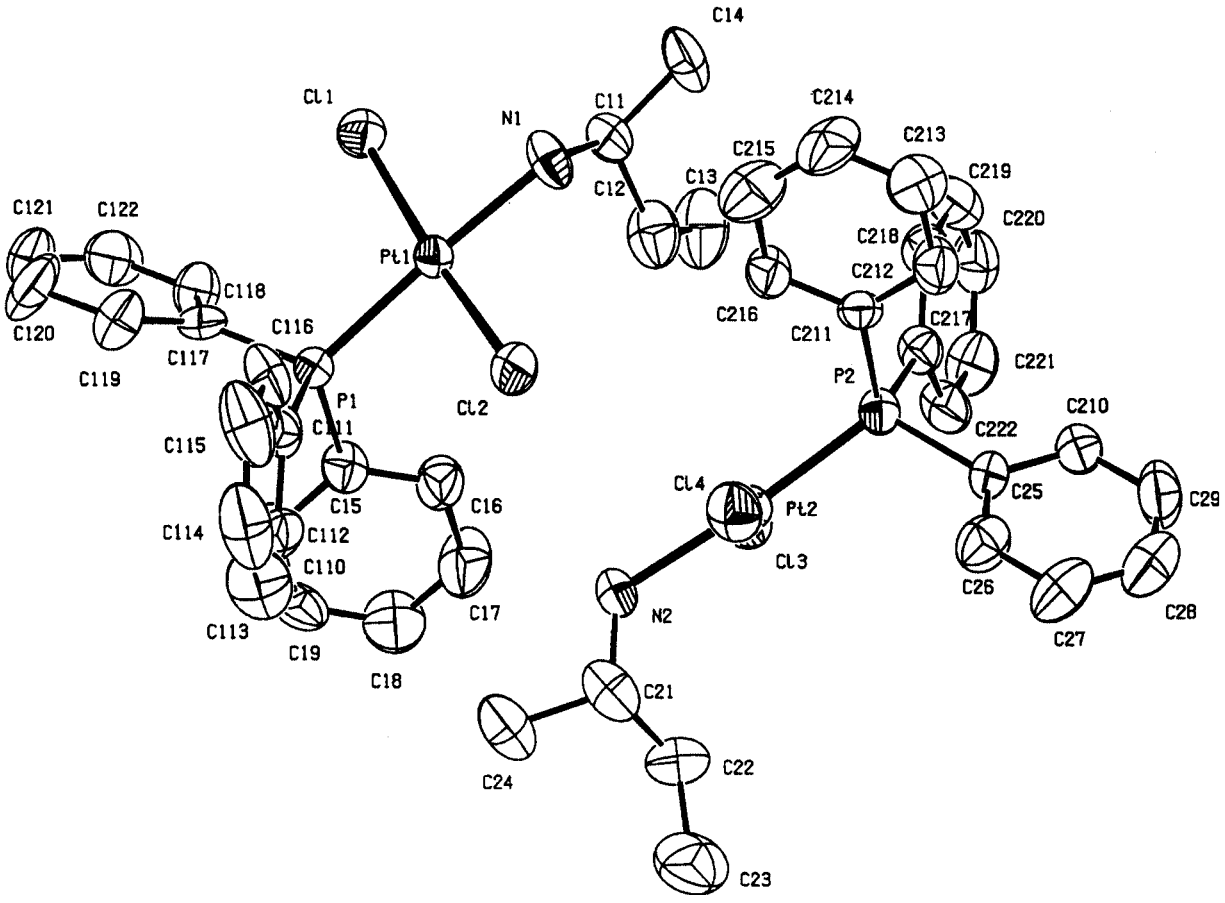

Figure 3. Ortep view of complex **3**

the phenyl represented by C(25), C(26), C(27), C(28), C(29) and C(210) (symmetry code for phenyl ring: $1 + x,y,z$). The distance from H(214) to the aromatic ring centre is 2.635 Å. This π interaction produces a short lengthening of the P(2)−C(25) bond [1.831(12) Å, while this distance is 1.811(12) Å in the equivalent bond in the other molecule] and a shortening of the Pt(2)−P(2) bond [2.211(3) Å, while this value is 2.261(3) Å in the other molecule]. This effect is reflected in the Pt(2)−N(2) distance, which is longer than Pt(1)−N(1) or other bond lengths described in the literature for similar complex such as *trans*[$PtCl_2$(benzoquinoline)-(PEt_3)].[14] These lengthening and shortening interactions could be interpreted in terms of a high *trans* influence in the molecule of Pt(2). The variation in Pt(1)−Cl(1) or Pt(2)−Cl(3) in both structures is related to the value of the Cl(1 or 3)−Pt(1 or 2)−P bond angles. The widening of this angle increases the lengthening of the Pt−Cl bond, so this variation is attributable to steric effects.

The H16(C16)−Pt(1) distance in complex **3a** is fairly short (2.9758 Å) and is similar to the equivalent distance found in complex **1**.

Complex **1** shows a weak hydrogen bond. The hydrogen bonds are: N−H(1A)···Cl(1) (symmetry code for Cl(1) = $1 - x, -y, 1 - z$) with bond lengths N−H = 0.8594 Å, H···Cl = 2.6738 Å, and N···Cl = 3.496(9) Å. On the other hand, hydrogen bonding was not detected for complex **3**, although the only difference with complex **1** is the chirality of the amine.

We determined the cytotoxic activities of complexes **1**, **2**, **3** and **4** against the Pam 212-*ras* line, which are cisplatin-resistant cells through overexpression of H-*ras* oncogene. The cytotoxicities of these complexes were evaluated by using the MTT cell survival assay. The IC_{50} values were defined as the concentration of compound producing 50% of cell death. As shown in Figure 4, the lowest IC_{50} values

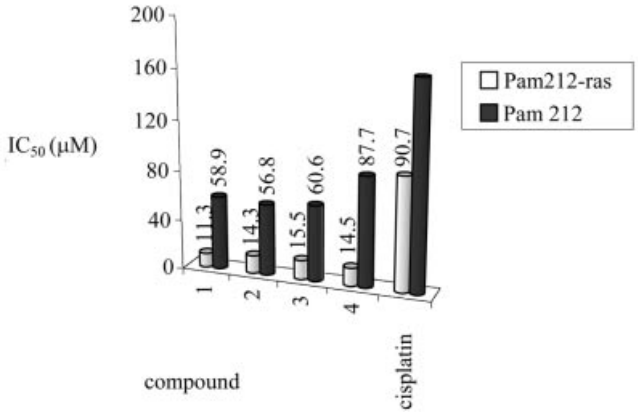

Figure 4. IC_{50} values (μM) for cisplatin and *trans* phosphane platinum derivatives (**1**, **2**, **3** and **4**) in Pam 212 and Pam 212-*ras* cell lines

were obtained with the compounds prepared from the racemic and enantiomerically pure *R* ligand and the *S* isomer (IC_{50} values of 56.84, 58.9 and 60.66 μM). However, the isopropylamine derivative (compound **4**) seems to be less cytotoxic to Pam 212-*ras* cells than compounds **1**, **2** and **3** (IC_{50} value of 87.73 μM) although this compound is still more active than cisplatin (IC_{50} value of 164 μM).

In order to compare the molecular and cellular pharmacological properties of these complexes with those of *trans*-[Pt(dma)(ipa)Cl_2], which is also active against cisplatin-resistant cell lines by induction of apoptotic cell death,[16] we analysed the status of the genomic DNA of Pam 212-*ras* cells after treatment with the novel *trans*-Pt complexes with phosphane ligands. It is known that the final biochemical hallmark of apoptosis is the digestion of genomic DNA into DNA fragments corresponding to multiples of the oligonucleosome unit ("DNA laddering").[17] In addition, it is also known that certain antitumor drugs may achieve a therapeutic index by selective killing of transformed cells without provoking severe toxicity of wild-type cells. Moreover, it has been proposed that this ability may be related with the induction of tumour cell death through apoptosis at drug concentrations lower than those needed to kill normal cells.[18]

Figure 5 shows the electrophoresis in agarose gel of genomic DNA extracted from Pam 212-*ras* cells treated for 24 hours with quantities of complexes **1**, **2**, **3** and **4** corresponding to their IC_{50} or 2 × IC_{50} values. The lanes are: 2 and 3 (complex **2**), 4 and 5 (complex **3**), 6 and 7 (complex **1**) and lane 8 (complex **4**). It may be observed in lanes 2 to 8 that the genomic DNA of Pam 212-*ras* cells appears as a continuous smear and not as a ladder of DNA bands, which would be indicative of apoptosis induction.[17] This leads us to believe that these new platinum complexes have modes of activity against Pam 212-*ras* cells different to those of the previously published isopropylamine derivatives, which induced DNA laddering in these cisplatin-resistant cell lines.[16] It is therefore likely that *trans*-Pt complexes with phosphane ligands may induce cell death through necrotic pathways and/or unfinished apoptotic processes.[19] As reported previously, treatment of Pam 212-*ras* cells with a quantity of *cis*-DDP corresponding to the IC_{50} value did not produce a DNA ladder either, in agreement with the fact that cisplatin is only able to kill this resistant cell line through necrosis and at high drug concentrations.[16]

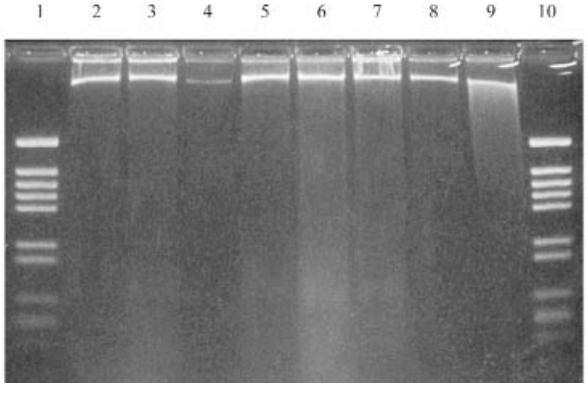

Figure 5. Agarose gel electrophoresis of genomic DNA extracted from Pam 212-*ras* cells treated with quantities corresponding to the IC_{50} values of: complex *R* (**2**), lanes 2 and 3; compound *S* (**3**), lanes 4 and 5; racemic complex (**1**), lanes 6 and 7; complex (**4**), lane 8; and *cis*-DDP, lane 9: − lanes 1 and 10: controls of Φ_{29}-HindIII digested DNA

On the other hand, DNA-binding experiments of complexes **1**, **2**, **3** and **4** with pBR322 plasmid were carried out to determine the molar ratio of bound Pt per nucleotide (r_b) at an input molar ratio of Pt per nucleotide (r_i) of 0.1. Total reflection X-ray fluorescence (TXRF) data showed that binding of compounds **1** to **4** to pBR322 is much lower than that of cisplatin (see Table 4). In fact at r_i = 0.1, the r_b for cisplatin was 0.09, while the r_b values for compounds **1**, **2**, **3** and **4** were 0.002, 0.008, 0.009 and 0.002, respectively, so the binding of complexes **1**−**4** to pBR322 plasmid DNA is 10 to 45 times lower than that of cisplatin.

Table 4. TXRF data for binding of compounds **1** to **4** to pBR322 plasmid DNA. r_i = input molar ratio of Pt per nucleotide; r_b = molar ratio of bound Pt per nucleotide

	r_i	r_b
Cisplatin	0.1	0.09
Complex **1** (racemic)	0.1	0.002
Complex **2** (chiral *R*)	0.1	0.008
Complex **3** (chiral *S*)	0.1	0.009
Complex **4** (isopropylamine)	0.1	0.002

Further experiments with pBR322 showed that complexes **1**−**4** do not alter the electrophoretic mobility either of the oc (open circular) form or of the ccc (covalently closed circular) form of plasmid DNA (see Figure 6). In contrast, we have previously reported that, at r_i = 0.1, both *cis*-DDP and *trans*-[Pt(dma)(ipa)Cl_2] decreases the mobility of the ccc form and increases in the mobility of the oc form in pBR322 DNA.[5] Consequently, the electrophoretic results, in combination with the r_b data obtained by TXRF, suggest that complexes **1**−**4** do not induce relevant structural changes in the double helix, due to their low levels of binding to DNA.

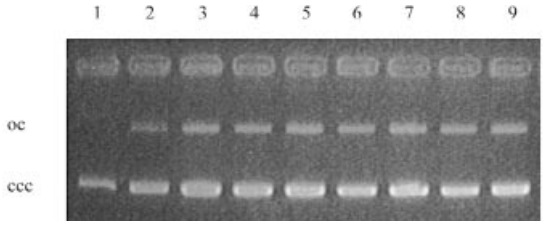

Figure 6. Agarose gel electrophoresis of pBR322 plasmid treated with the *trans* phosphane platinum complexes; lane 1: DNA of control plasmid; lanes 2 to 9, plasmid DNA incubated with complexes **4**, **1**, **2** and **3** at r_i = 0.05 and 0.1 respectively; oc = open circular DNA form; ccc = covalently closed circular DNA form

Conclusions

Replacement of the two amine groups of transplatin by aliphatic amine and phosphane groups results in circumvention of cisplatin resistance. Moreover, these new *trans*-Pt complexes probably achieve this circumvention in a different way from the *trans*-platinum complexes with mixed aliphatic amines that we have previously reported.[5,16] In fact, the *trans*-Pt complexes with phosphane groups do not provoke DNA laddering, which is the final hallmark of the apoptotic process. Overall, the results indicate that, relative to the extent of platinum binding to DNA, these new *trans*-Pt complexes are disproportionately more potent than cisplatin in the induction of cytotoxicity in Pam 212-*ras* cells. As recently suggested for the circumvention of cisplatin resistance by the antitumor drug oxaliplatin, it is likely that the induction of cell death by necrotic pathways and/or unfinished apoptotic programs, possibly enhanced by a contribution of targets other than DNA (such as proteins), may be an important factor in the mechanisms of action of complexes **1−4.** We think that the hydrophobic PPh_3 ligand in complexes **1−4** might also, similarly to the 1,2-diaminecyclohexane ligand in oxaliplatin, direct drug reactivity toward cellular proteins with sulfhydryl groups in hydrophobic pockets that may be poorly reactive with *cis*-DDP, which is polarized.[20]

Experimental Section

Infrared spectra were recorded in Nujol mulls on CsI windows and KBr pellets in the 4000−200 cm^{-1} range with a Perkin−Elmer Model 283 spectrophotometer. NMR spectra were recorded on a Bruker AMX 300 (300 MHz) spectrometer in [D_6]acetone solution. Elemental analysis were performed on a Perkin−Elmer 2400 Series II microanalyzer.

Structural Determination and Refinement of the Complex 1: A prismatic crystal (0.1 × 0.1 × 0.2 mm) was selected and mounted on a MAR345 diffractometer with image plate detector. Unit cell parameters were determined from automatic centring of 5289 reflections ($3 < \theta < 3.1°$) and refined by the least-squares method. Intensities were collected with graphite monochromatized Mo-*K*α radiation. 5329 reflections were measured in the range $2.42 \leq \theta \geq 24.99$, 3170 of which were non-equivalent by symmetry [*R*int(on *I*) = 0.021). 2896 reflections were assumed as observed on application of the condition $I > 2\ \sigma(I)$. Lorentz-polarization and absorption corrections were made. The structure was solved by direct methods, with the SHELXS computer program[21] and refined by the full-matrix, least-squares method, with the SHELX97 computer program,[21] using 3170 reflections (very negative intensities were not assumed). The function minimized was $\Sigma w\ ||F_o|^2 - |F_c|^2|^2$, where $w = [\sigma^2(I) + (0.0723\ P)^2 + 4.1899P]^{-1}$, and $P = (|F_o|^2 + 2\ |F_c|^2)/3$, *f*, *f′* and *f″* were taken from the International Tables of X-ray Crystallography.[22] Ten H atoms were located from a difference synthesis and refined with an overall isotropic temperature factor, and sixteen H atoms were computed and refined with a riding model, with an isotropic temperature factor equal to 1.2 times the equivalent temperature factor of the linked atom. The final *R*(on *F*) factor was 0.042, *wR*(on $|F|^2$) = 0.107 and goodness of fit = 1.082 for all observed reflections. The number of refined parameters was 286. Max. shift/esd = 0.00, Mean shift/esd = 0.00. Max. and min. peaks in final difference synthesis was 0.848 and −0.874 e·Å^{-3}, respectively. The details of the data collected and the structural analyses are summarized in Table 5.

Structural Determination and Refinement of the Complex 3: A prismatic crystal (0.1 × 0.1 × 0.2 mm) was selected and mounted on a MAR345 diffractometer with a image plate detector. Unit cell parameters were determined from automatic centring of 9961 reflections ($3 < \theta < 31°$) and refined by the least-squares method. Intensities were collected with graphite monochromatized Mo-*K*α radiation. 16358 reflections were measured in the range $2.40 \leq \theta \geq 25.01$, 3747 of which were non-equivalent by symmetry [*R*int(on *I*) = 0.038). 3460 reflections were assumed as observed, by application of the condition $I > 2\sigma(I)$. Lorentz-polarization and absorption corrections were made.

The structure was solved by direct methods, with the SHELXS computer program[21] and refined by the full-matrix, least-squares method with the SHELX97 computer program,[21] using 3747 reflections (very negative intensities were not assumed). The function minimized was $\Sigma w\ ||F_o|^2 - |F_c|^2|^2$, where $w = [\sigma^2(I) + (0.0214\ P)^2 + 11.378P]^{-1}$, and $P = (|F_o|^2 + 2\ |F_c|^2)/3$, *f*, *f′* and *f″* were taken from the International Tables of X-ray Crystallography.[22] The chirality of the structure was defined from the Flack coefficient, which is equal to 0.035(12) for the given results.[23] All H atoms were computed and refined with a riding model, with an isotropic temperature factor equal to 1.2 times the equivalent temperature factor of the radiator, which are linked. The final *R*(on *F*) factor was 0.030, *wR*(on $|F_c|^2$) = 0.065 and goodness of fit = 1.083 for all observed reflections. The number of refined parameters was 487. Max. shift/esd = 0.00, Mean shift/esd = 0.00. Max. and min. peaks in final difference synthesis was 0.601 and −0.676 e·Å^{-3},

respectively. The details of the data collected and the structural analyses are summarized in Table 6.

Synthesis and Characterization

***cis*-[$PtCl_2(PPh_3)_2$]:** A PPh_3 (1.263 g, 4.82 mmol) solution in ethanol (2.5 mL) was added to K_2PtCl_4 (1.0 g, 2.4 mmol) solution in water (2.5 mL) and the mixture was stirred in darkness at room temperature for 24 h. The product, a yellow pale precipitate, was collected and washed with water, ethanol and diethyl ether. The solid was then washed with chloroform, and a white precipitate (*cis* isomer) and a yellow solution (*trans* isomer) were obtained. The yellow solution produced a white precipitate on storage in chloroform. This isomerization of yellow *trans*-[$PtCl_2(PPh_3)_2$] to its white *cis* isomer is catalysed by light irradiation.[24]

White solid, yield: 98% (1.859 g). ν(Pt−Cl): 317 cm^{-1} and 292 cm^{-1}, ν(Pt−P): 464 cm^{-1} and 445 cm^{-1}. $C_{36}H_{30}Cl_2P_2Pt$ (790.6): calcd. C 54.60, H 3.82; found C 54.05, H 3.73. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C) (ppm): 7.49 (m, 6 H, *ortho*); 7.32 (m, 3 H, *para*), 7.25 (m, 6 H, *meta*) ppm. ^{31}P NMR (300 MHz, $CDCl_3$, 25 °C) (ppm): 14.81 (J_{P-Pt}= 3673 Hz)

[(μ-Cl)PtCl(PPh_3)]$_2$: This synthesis was based on F. R. Hartley's method[25] and also on R. J. Goodfellow's method.[26] Goodfellow's method, with some modifications, affords the highest yield.

The complex *cis*-[$PtCl_2(PPh_3)_2$] (0.38 mmol, 0.300 g) and $PtCl_2$ (0.4 mmol, 0.106 g) were finely ground with naphthalene in a mortar. The mixture was transferred into a flask. The mixture was then heated at reflux with stirring at 150 °C for 15 min. After cooling, the solid mixture was transferred to a Soxhlet thimble and washed with light petroleum to remove the naphthalene. The crude product was then extracted with dichloromethane to obtain a yellow-orange solution, which was taken to dryness under reduced pressure. The solid was partially dissolved in chloroform to obtain a orange precipitate and a yellow solution. When the yellow solution was warmed in chloroform it turned orange, with precipitation of the orange isomer (*trans* isomer).

Deep orange solid, yield: 98% (0.394 g). ν(Pt−Cl_μ): 321 and 260 cm^{-1}. ν(Pt−Cl_T): 355 cm^{-1}. $C_{36}H_{30}Cl_4P_2Pt_2$ (1056.6): calcd. C 40.93, H 2.86, Cl 13.47; found C 40.96, H 2.79, Cl 13.36. ^{1}H NMR (300 MHz [D_3]acetonitrile, 25 °C) (ppm): 7.71 (m, 6H), 7.67 (m, 6H), 7.46 (m, 3H).^{31}P NMR (300 MHz [D_3]acetonitrile, 25 °C) (ppm): 3.60 (J_{P-Pt} = 4100.26 Hz)

***trans*-[$PtCl_2$L(PPh_3)]:** Complexes **1**, **2**, **3** and **4** were obtained Chatt's method, with variations.[27] [(μ-Cl)PtCl(PPh_3)]$_2$ (0.142 mmol, 150 mg) was partially dissolved in acetone, together with the stoichiometry quantity of amine ligand (L), at room temperature. A solution was immediately formed, and this was generally accompanied by a lightening in colour. The acetone was removed under reduced pressure. Diethyl ether was added and the *trans*-[$PtCl_2$L(PPh_3)] was dissolved. The solution was filtered to remove the insoluble impurities. The *trans*-[$PtCl_2$L(PPh_3)] solution in diethyl ether produced crystals or a yellow precipitate on storage.

Yellow compounds, yields: 72% (complex **1**, 0.123 g), 61% (complex **2**, 0.104 g) and 50% (complex **3**, 0.085 g). ν(Pt−Cl): 346 cm^{-1}, ν(Pt−P):449 cm^{-1}, ν (Pt−N): 430 cm^{-1}. $C_{22}H_{26}Cl_2NPPt$ (601.4): calcd. Biochemical Probes

Biologicals and Drugs: 100 mm culture and microwell plates were obtained from NUNCLON (Roskilde, Denmark). MTT was purchased from Sigma Co., FCS was supplied by GIBCO-BRL, and ethanol was obtained from Merck. *cis*-Diamminedichloroplatinum(II), cisplatin or *cis*-DDP, was synthesized from K_2PtCl_4 supplied by Johnson Matthey. *cis*-DDP was dissolved in $NaClO_4$ (10 mM). The *trans* platinum phosphane complexes were dissolved in acetone as 1 mg/ml solutions. These solutions were freshly prepared before use.

Cell Lines and Culture Conditions: Pam 212, a normal cell line of murine keratinocytes, and Pam 212-*ras*, a transformed murine keratinocytes cell line overexpressing the H-*ras* oncogene, were cultured in DMEM (Dulbecco modified Eagle's medium), supplemented with FCS (foetal calf serum, 10%), glutamine (2 mM), peni-

cillin (100 units/mL) and streptomycin (100 μg/mL) at 37 °C in an atmosphere of 95% air and 5% CO_2. All cultures were passaged twice weekly, showing a doubling time between 16−24 hours.

Cytotoxicity Assays: Cell survival was evaluated by use of a system based on the tetrazolium compound MTT, which is reduced by living cells to yield a soluble formazan product that can be detected colorimetrically.[28] Cells were platted in 96-well sterile plates at a density of 10^4 cells/well in 100 μL of medium and were incubated for 3−4 h. The compounds were added to final concentrations from 0 to 200 μM in a volume of 100 μL/well. Twenty-four hours later, 50 μL of a MTT solution (1/5 in culture medium) freshly diluted to a concentration of 1 mg/ml were pipetted into each well, and the plate was incubated for 5 h at 37 °C in a humidified 5% CO_2 atmosphere. After the periods specified, the cell viability was evaluated by measurement of the absorbance at 520 nm, by use of a Whittaker Microplate Reader 2001. IC_{50} values (compound concentration that produces 50% of cell growth inhibition) were calculated from curves constructed by plotting (%) cell survival versus drug concentration. The therapeutic index (T.I.) of every compound was calculated as the ratio of the IC_{50} in normal cells versus the IC_{50} in transformed cells. In control experiments it was observed that 10% acetone did not have any effect on cell growth. This was the highest percentage of acetone present in the cell cultures after addition of 200 μM of the compounds. All experiments were made in quadruplicate.

DNA Fragmentation Assay: Pam212-ras cells (5×10^5 cells/mL) were platted in 100 mm sterile dishes. The cells were treated with the compounds for 24 h to a final concentration of the IC_{50} under the conditions described above.[28] The fraction of detached cells was collected by centrifugation of the culture media and washed twice with PBS. The cell pellet was disrupted with 700 μL of lysis buffer (150 mM Tris, tris(hydroxymethyl)aminomethane, pH 8.0; 100 mM NaCl; 100 mM EDTA, ethylenediamine tetracetate). The fraction of non-detached cells was also washed twice with BPS and lysed by addition of 700 μL of lysis buffer to the plate. Both cell fractions were joined and the whole cell lysate was treated with proteinase K (500 μg/mL) for 2 h at 55 °C. Afterwards, samples were exposed to RNase A (50 μg/mL) for 16 h at 37 °C. The DNA was first extracted with phenol, followed by phenol/chloroform/isoamyl alcohol (25:24:1) and a chloroform/isoamyl alcohol (24:1) phase. Subsequently, the DNA was precipitated overnight at −20 °C in 2.5 volumes of cold 100% ethanol/150 mM potassium acetate. After centrifugation at 12,000 rpm for 15 min to recover the precipitated DNA, the supernatant was discarded and the pellet was washed with 70% ethanol. Samples were dried on a SAVANT Speed Vac Concentrator and then resuspended in distilled water. The DNA concentration was calculated by determining the OD_{260}. Electrophoresis of DNA (10 μg/well) was performed for 16 h at 75 V in 1.8% agarose gel with TAE (40 mM Tris-acetate, 1 mM EDTA, pH 8.0) as running buffer. The bands were viewed by ethidium bromide staining for 16 h and UV transillumination. DNA bands were analysed by laser densitometry with a Molecular Dynamics densitometer.

Determination of Platinum Binding to pBR322 Plasmid DNA by TXRF: pBR322 DNA aliquots (50 μg/mL) were incubated with the platinum compounds in a buffer solution containing 50 mM NaCl, 10 mM Tris.HCl (pH 7.4) and EDTA (0.1 mM) at $r_i = 0.1$ (input molar ratio of Pt per nucleotide). Incubations were performed in the dark at 37 °C. After 24 hours of incubation, the DNA of the samples was precipitated with 0.1 volumes of sodium acetate (pH 4.7) and 2.5 volumes of absolute ethanol to eliminate unchanged drug. The DNA content in each sample was measured by UV spectrophotometry at 260 nm in a Shimadzu UV-240 spectrophotometer, and platinum bound to DNA was determined by total reflection X-ray fluorescence (TXRF). Experiments were carried out in triplicate.

TXRF Measurements: The analysis by TXRF was performed with a Seifert Extra-II spectrometer (Seifert, Ahrensburg, Germany). TXRF determinations were carried out by a previously reported procedure.[29] Briefly, a 100 μL sample of the DNA precipitated from the solutions of pBR322 incubated with the platinum complexes was introduced into a 2 mL test tube. This solution was standardised with 100 ng/mL vanadium [Merck (Darmstadt, Germany) ICP vanadium standard solution]. Afterwards, the sample was introduced into a high-purity nitrogen flow concentrator at a temperature of 70 °C until the volume had been reduced five times. An aliquot of 5 μL was then taken, deposited on a clean quartz reflector and dried on a ceramic plate at a temperature of 50 °C. The entire process was carried out in a laminate flow chamber (Model A-100). The samples were analysed by following the X-ray molybdenum line under working conditions of 50 *k*V and 20 mA with a live-time of 1000 s and a dead time of 35%. Spectra were recorded between 0 and 20 keV. The following 15 elements were analysed simultaneously: P, S, K, Ca, V, Fe, Cu, Zn, As, Br, Rb, Sr, Ni, Mn and Pt, in order to obtain a correct deconvolution of profiles associated with the general spectrum. The Pt line was used for Pt quantification. The analytical sensitivity of the TXRF measurements was 0.3 to 22.4 ng Pt in a solution volume of 100 μL, with repeatability between 2 and 8% (the number of determinations was $n = 3$).

Gel Electrophoresis of Drug:pBR322 Complexes: pBR322 DNA aliquots (50 μg/mL) were incubated with the platinum compounds in a buffer solution containing 50 mM NaCl, 10 mM Tris.HCl (pH 7.4) and EDTA (0.1 mM) at several r_i values (0.5 and 0.1). Incubations were performed in the dark at 37 °C. 20 μL aliquots of the drug:DNA complexes containing 1 μg of DNA were subjected to 1.5% agarose gel electrophoresis for 16 h at 25 V in TAE buffer (Tris-acetate 40 mM, EDTA 2 mM pH 8.0). The DNA was stained in the same buffer containing ethidium bromide (0.5 μg/mL). The gels were photographed with a MP-4 Polaroid camera with a 665 Polaroid film and an orange filter.

Synthesis and Dynamic Features of (Chloro)zirconocene Cations Stabilised by Pendant (Diarylphosphanyl)alkyl and (Dimethylamino)alkyl Substituents at Their Cyclopentadienyl Ring Systems

Steve Döring,[a] Vasily V. Kotov,[a] Gerhard Erker,*[a] Gerald Kehr,[a] Klaus Bergander,[a][‡] Olga Kataeva,[a][‡] and Roland Fröhlich[a][‡‡]

Keywords: Cations / Metallocenes / N ligands / P ligands / Zirconium

Treatment of the substituted (diarylphosphanyl)methyl group-4 metallocene complexes $[(C_5H_4–CR^1R^2–PAr_2)_2ZrCl_2]$ (**2**: R^1/R^2 = CH_3/CH_3, H/CH_3, H/aryl) with $Li[B(C_6F_5)_4]$ in dichloromethane solution results in chloride ligand abstraction (with LiCl precipitation) to yield the complexes $[(C_5H_4–CR^1R^2–PAr_2)_2Zr–Cl^+]$ (**5**), with both phosphanyl groups internally coordinated to the metal centre. Three possible diastereoisomers are observed in the case of **5c** (R^1 = H; R^2 = CH_3), while bulkier R^2 substituents give higher selectivities. The thermally induced (reversible) cleavage of the Zr–phosphane linkage results in dynamic NMR behaviour. Gibbs activation energies of $\Delta G^{\neq}$(298 K) = 14.8 ± 0.5 and 14.5 ± 0.5 kcal/mol were obtained for these intramolecular equilibration processes in the complexes *trans*-**5d** (R^1 = H; R^2 = Ph) and *trans*-**5e** (R^1 = H; R^2 = ferrocenyl), respectively. Treatment of the substituted (dimethylamino)methyl metallocene complexes $[(C_5H_4–CR^1R^2–NMe_2)_2ZrCl_2]$ (**6a**, **6b**) with $Li[B(C_6F_5)_4]$ proceeds analogously to yield the cation systems $[\{C_5H_4–C(CH_3)_2–NMe_2\}_2ZrCl^+]$ (**12a**) and $[\{C_5H_4–CH(CH_3)–NMe_2\}_2ZrCl^+]$ (**12b**, three possible diastereoisomers). Both complexes have their pairs of amino groups coordinated to the metal centre. The complexes exhibit dynamic NMR spectra. Selective equilibration of the diastereotopic $N(CH_3)^A(CH_3)^B$ resonances of complex **12a** is observed [$\Delta G^{\neq}$(233 K) = 11.5 ± 0.2 kcal/mol], whereas the adjacent $C(CH_3)^A(CH_3)^B$ methyl groups remain diastereotopic. The dynamic equilibration of the latter was observed at a markedly higher temperature [$\Delta G^{\neq}$(333 K) = 17.3 ± 0.2 kcal/mol]. Treatment of $[\{C_5H_4–C(CH_3)_2–NMe_2\}CpZrCl_2]$ (**10**) with $Li[B(C_6F_5)_4]$ resulted in the formation of complex $[\{C_5H_4–C(CH_3)_2–NMe_2\}CpZr–Cl^+]$ (**11**), which shows the internal $–N(CH_3)^A(CH)^B$ equilibration proceeding with a markedly higher activation barrier [$\Delta G^{\neq}$(333 K) = 17.6 ± 0.2 kcal/mol] than in **12a**, and a stereochemical memory effect indicative of solvent coordination to the metal centre of the resulting highly electrophilic chlorozirconocene cation intermediate. Complex **11** was characterised by an X-ray crystal structure analysis, which shows the internal Zr←amine coordination.

Introduction

Alkylzirconocene cations are regarded as the active species in homogeneous Ziegler−Natta olefin polymerisation.[1a−1e] Some of such complexes can very easily be prepared, a typical example being the parent compound $[Cp_2ZrCH_3^+]$ (**1**), readily available from the neutral precursor $[Cp_2Zr(CH_3)_2]$ by a variety of methods.[2a,2b,3−5] The cation **1** is stabilised by tight ion pair formation with its anion.[6] Alternatively, it adds a variety of simple neutral donor ligands such as tetrahydrofuran to form pseudotetrahedral adducts (e.g., $[Cp_2ZrCH_3(THF)^+]$ or its respective "outer-sphere" or "solvent-separated" ion pair).[7,8] $[^RCp_2ZrCl^+]$ complexes are much less stable. Their syntheses are often less straightforward and they require stronger donor ligand stabilisation. A typical example is shown in Scheme 1. Treatment of the (diarylphosphanyl)alkyl-substituted $[^RCp_2Zr(CH_3)_2]$ derivatives with $B(C_6F_5)_3$ as a suitable methyl anion abstractor[9,10] results in the clean formation of the corresponding $[^RCp_2ZrCH_3^+]$ cation (**3**).[11] Treatment of this in turn with a second equivalent of $B(C_6F_5)_3$ in the presence of a chloride source then gives rise to subsequent formation of the doubly internally phosphane-stabilised $[^RCp_2ZrCl^+]$ cation derivative **5** (via **4**, see Scheme 1).[11,12]

It would be interesting to have the corresponding (dimethylamino)alkyl-substituted Cp systems available in order to study the stabilising influence of the tertiary amine donor ligands relative to the stabilising phosphanes. However, their synthesis from **6** by an analogous pathway is precluded by a preferred internal C−H activation process that rapidly takes place at the stage of the intermediate **8** (see Scheme 2).[13−16] We therefore had to devise an alternative pathway to make the (dimethylamino)alkyl−Cp-containing

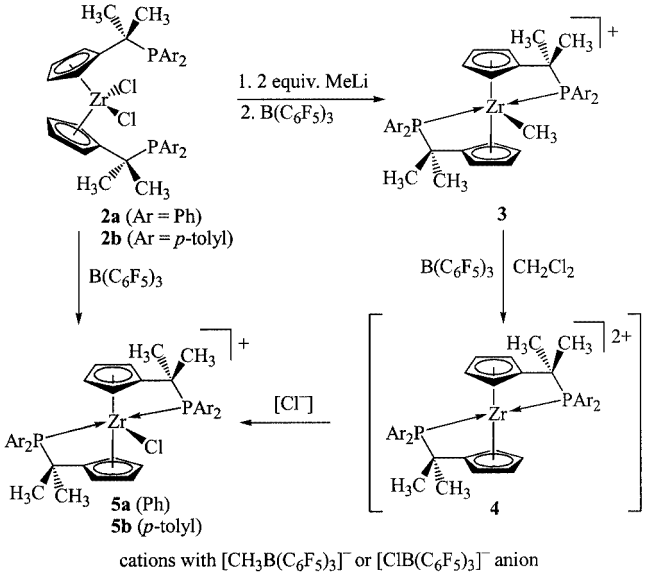
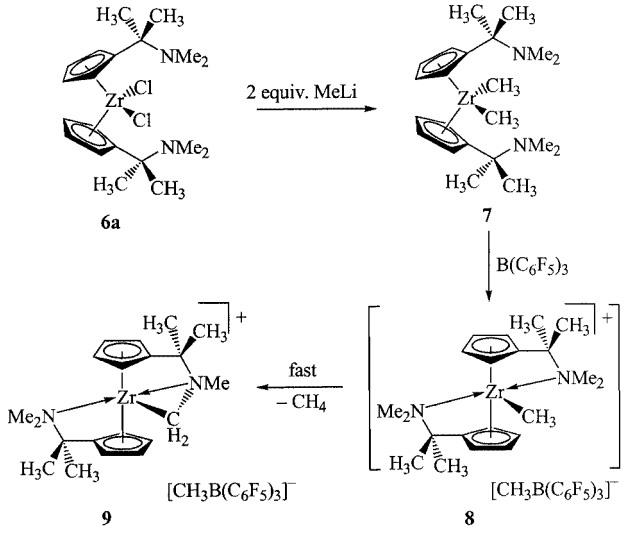


Scheme 1

[$^{R}Cp_2Zr-Cl^+$] cation systems synthetically available. Such a selective preparative route is described in this paper. The dynamic NMR behaviour of the resulting complexes allowed for an estimate of the internal stabilisation of such strongly electrophilic group-4 metallocene cations by tertiary amine donor ligands.

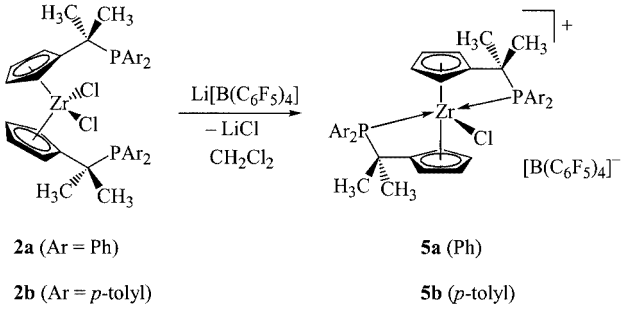


Scheme 2

Results and Discussion

Synthesis and Characterisation of [Chlorobis{[(diarylphosphanyl)alkyl]cyclopentadienyl}zirconium] Cation Complexes

We had previously prepared a series of [{(Ar_2PCMe_2)C_5H_4}$_2$$ZrCl^+$] cation systems by a three-step synthesis via the dication intermediate **4**, as outlined in Scheme 1 [**5a**′: Ar = Ph; **5b**′: Ar = *p*-tolyl, with [$CH_3B(C_6F_5)_3^-$] anion; **5a**′′: Ar = Ph, with [$ClB(C_6F_5)_3^-$] anion].[11] In one case (**5a**′′) we succeeded in preparing the substituted chlorozirconocene cation directly by means of chloride abstraction by the strong organometallic Lewis acid $B(C_6F_5)_3$.[11,12] This result indicated to us that chloride abstraction by more powerful reagents, such as $Li[B(C_6F_5)_4]$,[17,18] might provide a suitable direct route to this general class of internally donor ligand stabilised chlorozirconocene cation systems. Initial tests were therefore carried out with the substituted [{[(diarylphosphanyl)methyl]C_5H_4}$_2$$ZrCl_2$] systems **2a** (Ar = Ph) and **2b** (Ar = *p*-tolyl), which were each treated with 1 mol-equiv. of the $Li[B(C_6F_5)_4]$ reagent in dichloromethane solution at room temperature. After ca. 1 h, the chloride abstraction was complete. The resulting LiCl precipitate was removed by filtration and the corresponding chlorometallocene cation products **5a** and **5b** were isolated in 55 and 67% yields, respectively (both with [$B(C_6F_5)_4^-$] anion, see Scheme 3).

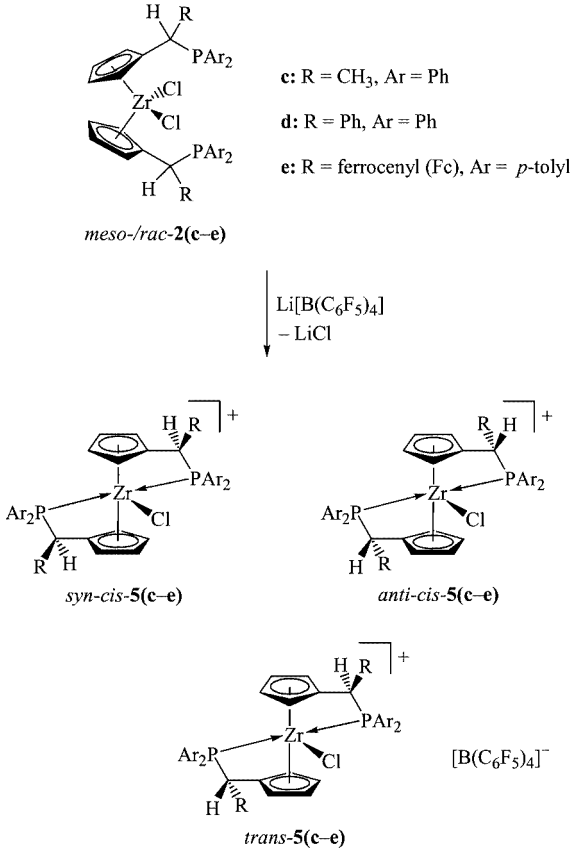


Scheme 3

We have also used the previously described complexes [($C_5H_4-CHR-PAr_2$)$_2$$ZrCl_2$] **2c** (R = CH_3; Ar = Ph), **2d** (R = Ph; Ar = Ph) and **2e** (R = ferrocenyl; Ar = *p*-tolyl)[11,12,30] as neutral substrates for the chloride abstraction reaction with $Li[B(C_6F_5)_3]$ to give the new metallocene cation complexes **5c**−**e** (see Scheme 4).

The complexes **2c**−**e** each contain two stereogenic carbon centres and were each employed in the Cl^- abstraction reaction as ca. 1:1 *meso*-/*rac*-**2(c−e)** mixtures of diastereoisomers. The doubly phosphorus-coordinated products **5c**−**e** can each form three diastereoisomers: two complexes in which the substituents at the pair of stereogenic metallacyclic ring carbon centres are oriented *cis* (*syn*- or *anti*-oriented relative to the Zr−Cl vector,[19] thus giving rise to the formation of compounds *syn-cis*-**5c**−**e** and *anti-cis*-**5c**−**e**, respectively), together with the *trans* diastereoisomers (*trans*-**5c**−**e**) (see Scheme 4).

In the case of **5c** (R = CH_3; Ar = Ph) a near to statistical mixture of the three diastereoisomers was actually obtained (isolated in 54% yield). This is evident from inspection of typical NMR spectra of the organometallic salt **5c**. The ^{31}P NMR spectrum (at 253 K) shows singlets at δ = −36.2 and −45.9 ppm corresponding to the pairs of symmetry-equivalent phosphorus nuclei of the complexes *syn-cis*-**5c** and *anti-cis*-**5c** (no absolute assignment was achieved) and an AB pattern at δ = −38.1 ppm and δ = −47.2 ppm with a $^2J_{P,P}$



Scheme 4

coupling constant of 110 Hz, attributable to the *trans*-**5c** diastereoisomer (see Figure 1).

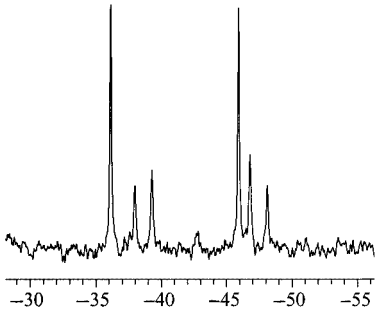


Figure 1. $^{31}P\{^{1}H\}$ NMR spectrum of the close to statistical mixture of the *syn-cis*-**5c**, *anti-cis*-**5c** and *trans*-**5c** diastereomers (in CD_2Cl_2 solution)

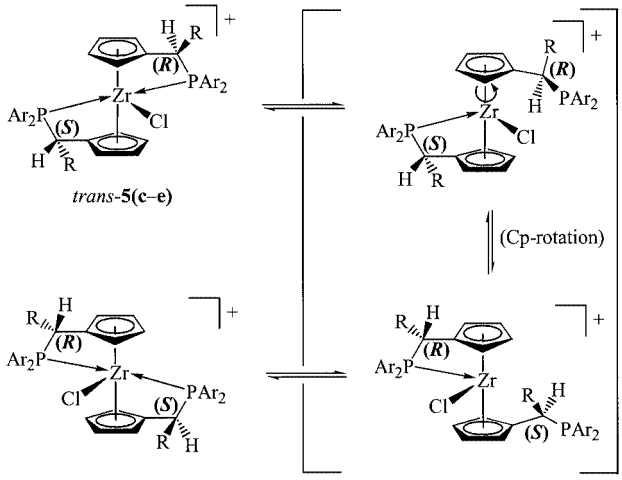
As would be expected, each *cis*-**5c** isomer exhibits a set of four methine $^{1}H/^{13}C$ NMR signals of the pair of symmetry-equivalent C_5H_4 ligand units. In contrast, the (C_5H_4−CHMe−[P]) ligands of the *trans*-**5c** isomer are diastereotopic. Consequently, complex *trans*-**5c** shows a set of eight Cp signals of equal intensity (for numerical values see the Exp. Sect.), a pair of C_α−*H* multiplets (δ = 4.21 and 4.47 ppm), each of 1 H relative intensity, and two methyl ^{1}H NMR resonances at δ = 1.25 and 1.50 ppm.

Treatment of complex [(C_5H_4−CHPh−PPh_2)$_2ZrCl_2$] (**2d**) with the Li[$B(C_6F_5)_4$] reagent cleanly resulted in the formation of the chlorozirconocene cation complex **5d**. Again, diastereomeric complexes are formed, but the ^{31}P NMR spectrum of **5d** shows the presence only of the *trans*-**5d** isomer (AB system at δ = −18.4 and −41.8 ppm, $^{2}J_{P,P}$ = 108 Hz) and of *one* of the *cis*-**5d** isomers, in a ca. 1:1 ratio.

Complex *trans*-**5d** shows two ^{1}H NMR Cp−C*H*R signals at δ = 5.65 and 5.57 ppm. An increase in the temperature results in coalescence of the signals of pairwise diastereotopic groups of *trans*-**5d**, including these Cp−C*H*R resonances with a Gibbs activation energy of $\Delta G^{\neq}$(298 K) = 14.8 ± 0.5 kcal/mol.[11,20,21] The NMR signals of the *cis*-**5d** isomers remain unaffected by the dynamic behaviour of *trans*-**5d**. We therefore assign a process as depicted in Scheme 5 to account for this characteristic behaviour, in which a consecutive dissociation of *both* Zr←P linkages takes place in *trans*-**5d**, followed by rotation around the Zr−Cp vector and reformation of the stabilising intramolecular Zr←phosphane interactions.



Scheme 5

Complex **5c** shows similar dynamic NMR features at elevated temperatures. We have found indications for an intramolecular equilibration process of *trans*-**5c**, analogous to that described above for **5d**, *and* a separate equilibration between the two *cis*-**5c** isomers. Unfortunately, the coalescence temperatures could not be reached cleanly in this case because of a rapid thermal decomposition of the systems.

Complex **5e** was obtained as a similar mixture of a single *cis*-**5e** diastereomer and the *trans*-**5e** diastereomer. Complex *trans*-**5e** exhibits a total of eight C_5H_4 resonances [at δ = 7.18, 6.92, 6.17, 6.06 ppm (ring A), and δ = 6.65, 6.06, 6.00, 5.94 ppm (ring B)] and a pair of CpC*H*R ^{1}H NMR resonances at δ = 5.06 and 5.12 ppm. From the coalescence of these last two signals at T_c = 298 K, a Gibbs activation energy of $\Delta G^{\neq}(T_c)$ = 14.5 ± 0.5 kcal/mol was obtained. Again, the *cis*-**5e** isomer is not involved in this dynamic process. It shows a single ^{31}P NMR resonance (δ = −18.2

ppm) and four C_5H_4−R ^{1}H NMR multiplets at δ = 7.15, 6.42, 6.35, and 6.22 ppm.

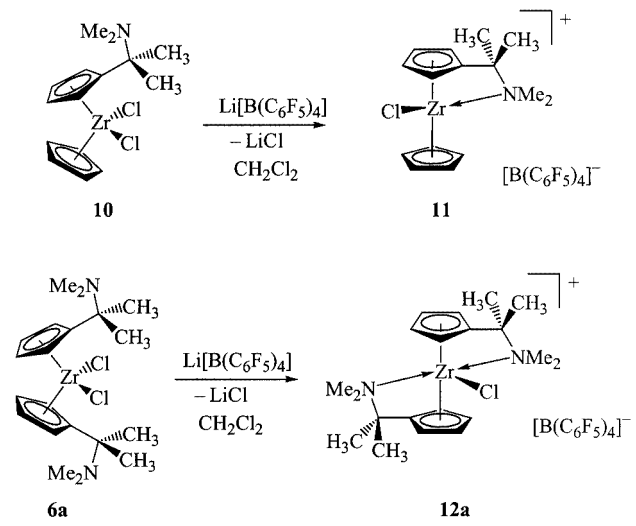
Synthesis and Characterisation of [Chlorobis{[(dimethylamino)alkyl]cyclopentadienyl}zirconocene] Cation Complexes

The starting materials for the preparation of the related [(dimethylamino)alkyl−C_5H_4]zirconium complexes (**6a**,**b** and **10**) were also prepared by a fulvene route,[22] as described previously by us.[14−16] The synthesis started from 6-(dimethylamino)-6-methylfulvene.[23] Hydride addition gave the Li[C_5H_4−CHMe−NMe_2] reagent,[24] which was then transmetallated with zirconium to yield a *meso*/*rac* mixture of [$(C_5H_4$−CHMe−$NMe_2)_2ZrCl_2$] (**6b**). Methyllithium addition to 6-(dimethylamino)-6-methylfulvene[25] gave Li[C_5H_4−CMe_2−NMe_2]. Transmetallation by treatment with [$ZrCl_4(THF)_2$] [26] furnished [$(C_5H_4$−CMe_2−$NMe_2)_2ZrCl_2$] (**6a**), whereas treatment with $CpZrCl_3$ [27] gave [$(C_5H_4$−CMe_2−$NMe_2)CpZrCl_2$] (**10**).

Complex **10** was treated with 1 mol-equiv. of Li[$B(C_6F_5)_4$] in dichloromethane to yield the cation complex **11** (> 70% isolated) (see Scheme 6). Single crystals of **11** suitable for an X-ray crystal structure analysis were obtained when liquid pentane was allowed to diffuse slowly into a CH_2Cl_2 solution of the organometallic salt. Cations and anions of **11** are independent in the solid state. The zirconium atom in **11** is pseudotetrahedrally coordinated by two η^5-cyclopentadienyl rings, the chloride ligand and the nitrogen atom of the pendant −CMe_2−NMe_2 group attached to one of the C_5H_4 ligands (Figure 2). The resulting N−Zr−Cl angle is fairly large at 106.0(1)°, whereas the Zr−N bond length is short at 2.369(3) Å [the respective Zr−N(Me_2) distance in **9**, for example (see Scheme 2), amounts to 2.469(1) Å].[14−16] The framework of the metallacyclic ring system in complex **11** is reasonably unstrained, with bond angles C1−C6−N = 100.7(3)° and C6−N−Zr = 99.6(2) [bond lengths C1−C6 1.528(5) Å, C6−N 1.541(5) Å]. The C1−C6 vector at the C1 to C5 Cp ring is oriented slightly out of the C_5H_4 ring plane toward the zirconium centre (161.5°).

The internal (dimethylamino)alkyl coordination to the electron-deficient zirconium centre also shows up in the ^{15}N NMR shift of **11**.[28] The cation complex **11** exhibits a ^{15}N NMR resonance at δ = −359.8 ppm, which is Δδ > −20 as compared to its neutral precursor **10**,[14−16] for which an open, noncoordinating geometry of the −CMe_2−NMe_2 substituent was found by X-ray diffraction.[14−16]

The *meso*-**6b**/*rac*-**6b** mixture also reacts cleanly with Li[$B(C_6F_5)_4$] in dichloromethane at ambient temperature to yield **12b** (Scheme 7). The NMR spectra at room temperature are quite complicated, due to the dynamics of the system and some signal overlap. At 213 K a clean separation of most resonances is achieved, and it was shown that a ca. 1:2:1 mixture of three diastereoisomers was obtained. These show the same overall characteristics as seen earlier for the related phosphorus complexes (see above). Consequently, it should also be assumed here that two *cis*-configured cation complexes have been obtained, namely *syn*-*cis*-**12b** and *anti*-*cis*-**12b**, and their diastereoisomer *trans*-**12b**. Each of the *cis* complexes shows four ^{1}H/^{13}C NMR methine resonances of their symmetry-equivalent pairs of C_5H_4 ligands, whereas the C_5H_4 ligands of *trans*-**12b** are diastereotopic and hence give rise to the observation of eight respective methine NMR signals. Similarly, we have observed a total of four −C*H*Me− signals in the mixture (one each of *syn*- and *anti*-*cis*-**12b** and two of *trans*-**12b**) as well as four −CH(CH_3)− ^{1}H NMR doublets. Both nitrogen centres in the complexes **12b** are coordinated to the zirconium atom. This follows from the observed ^{1}H and ^{13}C NMR patterns, *and* is clearly demonstrated by the observed *four* ^{15}N NMR resonances[28] (again, two for the pair of *cis*-**12b** isomers and the remaining pair originating from *trans*-**12b**), all of which are charac-



Scheme 6

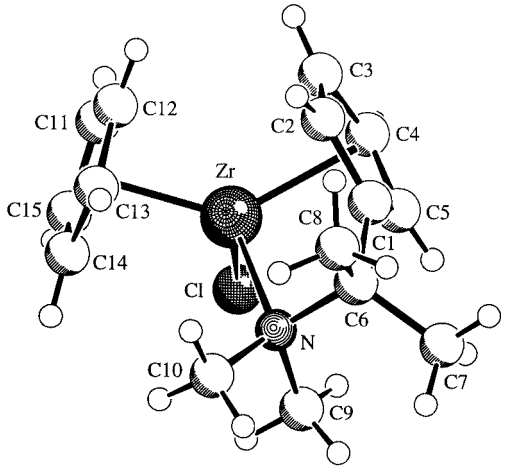


Figure 2. A view of the molecular geometry of **11** in the crystal (only the cation is depicted); selected bond lengths [Å] and angles [°]: Zr−N 2.369(3), Zr−Cl 2.426(1), Zr−C 2.398(4) to 2.502(4), C1−C6 1.528(5), C6−N 1.541(5), C6−C7 1.527(6), C6−C8 1.527(6), N−C9 1.491(5), N−C10 1.480(5); N−Zr−Cl 106.0(1), Zr−N−C6 99.6(2), Zr−N−C9 101.0(2), Zr−N−C10 123.5(2), C9−N−C6 112.8(3), C10−N−C6 115.1(4), C9−N−C10 104.2(3), N−C6−C1 100.7(3), N−C6−C7 112.6(3), N−C6−C8 111.0(4), C7−C6−C1 112.7(4), C8−C6−C1 109.8(4), C7−C6−C8 109.7(4)

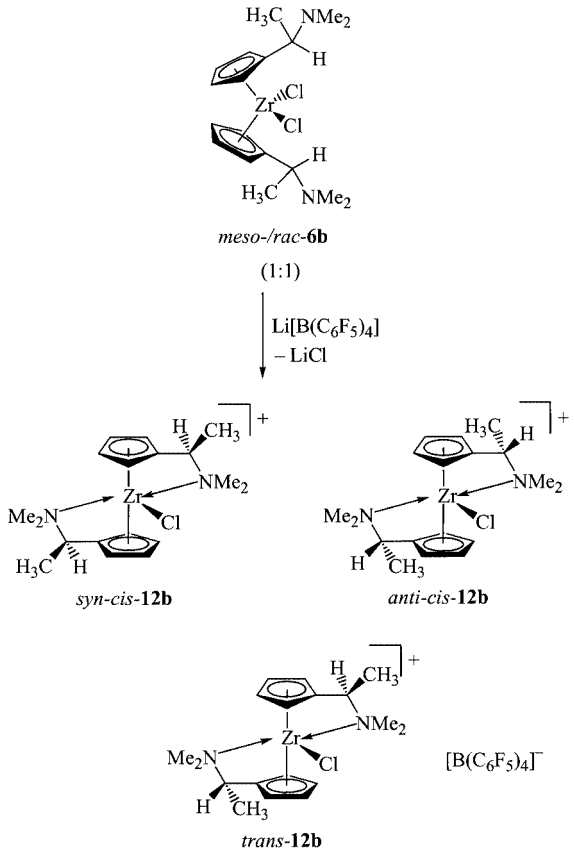
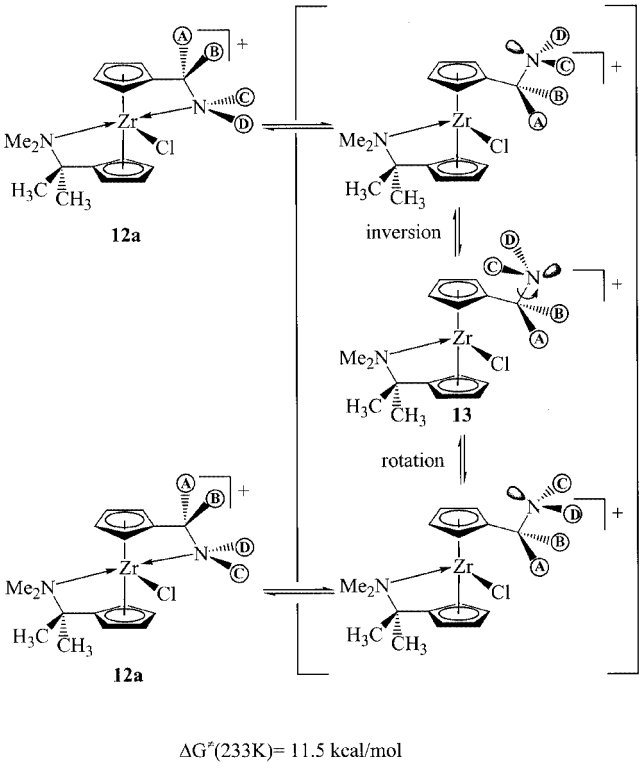
teristically shifted to more negative δ values (by $\Delta\delta \approx -30$) relative to the open, noncoordinated amino groups of the starting material **6b** (^{15}N NMR: **12b**: δ = −369.6, −369.3, −364.7, −367.1 ppm vs. **6b**: δ = −337.6 ppm). Because of the complexity of the system, with many overlapping NMR resonances at higher temperature, the dynamic NMR features of the metallocene cation isomers of **12b** were not further analysed.



Scheme 7

Treatment of $[(C_5H_4{-}CMe_2{-}NMe_2)_2ZrCl_2]$ (**6a**) with $Li[B(C_6F_5)_4]$ cleanly resulted in chloride abstraction with formation of the complex **12a** (Scheme 6; 78% yield, isolated). Again, the ^{15}N NMR spectra indicate that both $-NMe_2$ groups were coordinated to the central zirconium atom (^{15}N NMR: **12a**: δ = −358.6 vs. **6a**: δ = −337.4 ppm).

The dynamic features of complex **12a** are slightly different from those of the phosphorus-containing cations **5**. At 298 K the ^{1}H NMR spectrum of **12a** shows a 1:1 pair of signals for the $Cp{-}C(CH_3)_2$ methyl groups, indicating their chemical differentiation into *syn*- and *anti*-CH_3 substituents relative to the central Zr−Cl vector. At the same time we observe only a double intensity ^{1}H NMR singlet of the $-N(CH_3)_2$ groups of **12a** at ambient temperature. This indicates that, at room temperature, a rapid equilibration of the diastereotopic methyl groups of the amino function (marked C and D in Scheme 8) is taking place in a process that does not involve a similar exchange of the corresponding (A and B) methyl groups at the adjacent α-carbon atom. This indicates that a rapid dynamic process involving cleavage of the $Zr{-}N(Me)_2$ linkage, inversion at the nitrogen atom, rotation around the $N{-}C(Me_2)$ vector and ring closure by reformation of the Zr−N bond is taking place in the complexes **12**; this process must take place *without* concomitant rotation around the Zr−Cp vector, since no CMe^AMe^B interconversion is observed under these conditions.



Scheme 8

This isolated dynamic process of the $Zr{-}NMe_2$ moiety in **12a** can be slowed on the ^{1}H NMR timescale and eventually frozen (see Figure 3). Below a decoalescence temperature of T_c = 243 K, a 1:1 pair of $N(CH_3)_2$ ^{1}H NMR resonances is observed, and a Gibbs activation energy of $\Delta G^{\neq}(233\ K) = 11.5 \pm 0.2$ kcal/mol was calculated[20,21] for this characteristic dynamic process of **12a**, which probably involves a rate-determining (reversible) rupture of the zirconium−nitrogen linkage (Scheme 9).

A considerable increase in the monitoring temperature eventually also results in a broadening of the pair of CMe^AMe^B ^{1}H NMR signals and subsequently in their coalescence (see Figure 3). In 1,2-dideuteriotetrachloroethane solvent a Gibbs activation energy of $\Delta G^{\neq}(333\ K) = 17.3 \pm 0.2$ kcal/mol was obtained for this second dynamic process of **12a**. Unlike the "low-temperature" NMe^CMe^D exchange in **12a** (see above), this "high-temperature" intramolecular CMe^AMe^B equilibration requires rupture of *both* Zr−N linkages to take place at some time. We therefore have to assume the involvement of a chlorozirconocene intermedi-

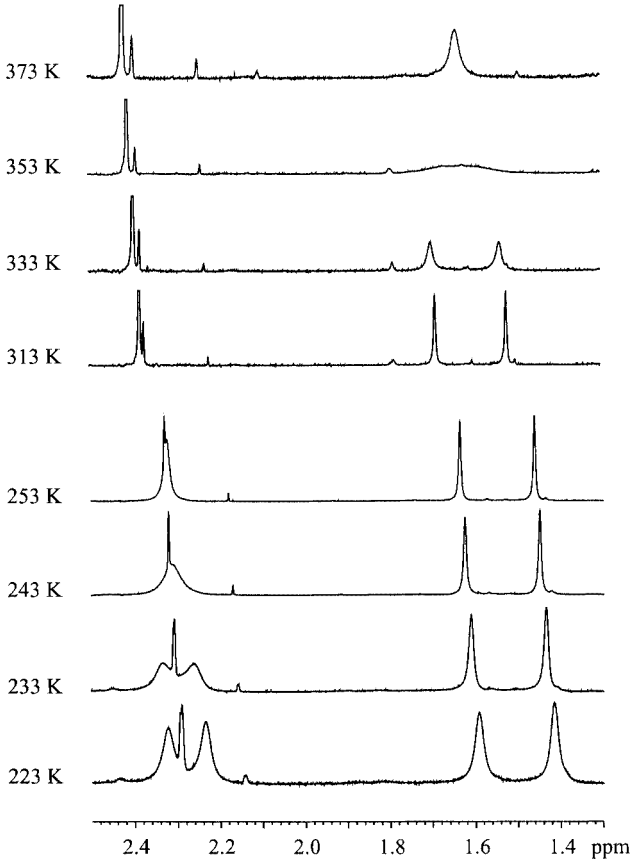


Figure 3. Dynamic ^{1}H NMR spectra of **12a** (600 MHz, $C_2D_2Cl_4$) showing the rapid equilibration of the diastereotopic $-NMe_2$ methyl resonances (left) followed by a markedly slower diastereotopic signal exchange at the adjacent $-CMe_2-$ moieties (right)

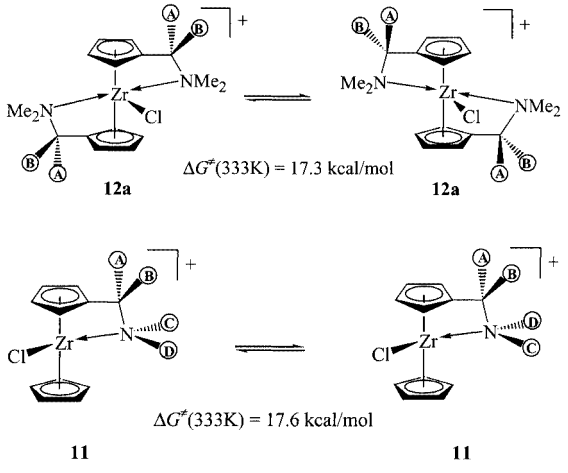
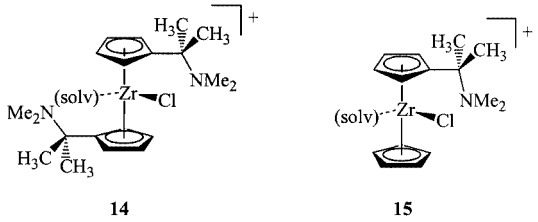


Scheme 9

ate (such as **14**, see Scheme 10) that lacks any favourable internal amine donor stabilisation.

Analogous dynamic behaviour is observed for complex **11**, which at *low* temperature (223 K) shows two $-C(CH_3)-$ ^{1}H NMR singlets (in CD_2Cl_2, 600 MHz) at δ = 1.60 and 1.55 ppm *and* a pair of $-N(CH_3)_2$ singlets (δ = 2.61, 2.33 ppm), of which only the latter displays coalescence with increasing NMR monitoring temperature. This again indicates that rapid (on the NMR timescale) breaking of the Zr−N bond takes place, followed by inversion at the nitrogen atom without equilibration of the remaining groups of signals, but that the activation barrier of this process is substantially higher [**11**: $\Delta G^{\neq}$(333 K) = 17.6 ± 0.2 kcal/mol] than in **12**.



Scheme 10

It is remarkable that the internal NMe^CMe^D equilibration of **11** is observed without a concomitant equilibration of the adjacent CMe^AMe^B moiety. We must assume that the $-NMe_2$ group in the respective intermediate (e.g., **15**; see Scheme 10) is not coordinated to the zirconium atom. Nevertheless, a complete rotation of the $C_5H_4-CMe_2NMe_2$ ligand around the Zr−Cp vector cannot be operative, since this would result in an inversion at the stereogenic zirconium centre,[19] which would be registered as a CMe^AMe^B interconversion on the NMR timescale. This is not observed by dynamic NMR spectroscopy in the experimentally accessible temperature range: the dynamic cation system **11** shows a remarkable stereochemical memory effect. We assume that stereoselective solvent coordination at the reactive intermediate stage (e.g., **15** in Scheme 10) might account for this observation. A similar stabilising solvent coordination of the intermediate **14** derived from the "more symmetrical" system **12a** would in principle also be in accord with the observed dynamic features of that system.

The systems **5a**[11] and **12a** are suitable for comparison of the stabilising features of $-PAr_2$ and $-NMe_2$ groups in a chlorozirconocene cation system, since these two complexes exhibit the same type of dynamic CMe^AMe^B equilibration process requiring rupture of *both* Zr−N/P linkages. Our experiments show that $-NMe_2$ and $-PAr_2$ stabilisation in these [Zr]−Cl^+ systems are about equal, as judged from the respective enantiomerisation barriers of the two systems [$\Delta G^{\neq}_{enant}$(358 K) = 17.5 ± 0.5 kcal/mol (**5a**[11]), $\Delta G^{\neq}_{enant}$(298 K) = 17.3 ± 0.5 kcal/mol (**12a**)]. In addition, comparison of the two nitrogen-stabilised chlorozirconocene cation systems **12a** and **11** shows a fairly substantial difference in the $\Delta G^{\neq}$ values of their internal $-NMe^CMe^D$ equilibration processes. As would be expected, the corresponding activation barrier of **11** is markedly higher because the chloro zirconocene cation resulting from Zr←NR_2- dissociation now lacks any internal stabilisation (but probably benefits from some solvent or anion interaction). In this case, the observed $\Delta G^{\neq}$(**12a**)/$\Delta G^{\neq}$(**11**) differ-

ence of $\Delta\Delta G^{\neq} \approx 6$ kcal/mol for internal $-NMe^{C}Me^{D}$ equilibration should probably be regarded as a lower limit of the stabilisation energy of such an electrophilic zirconocene cation by an amine donor ligand.

Experimental Section

General Remarks: Reactions were carried out under argon in Schlenk-type glassware or in a glovebox. Solvents (including the deuterated solvents used for NMR spectroscopy) were dried and distilled under argon prior to use. The following instruments were used for characterisation of the synthesised compounds: Bruker AC 200 P NMR spectrometer (^{1}H 200 MHz, ^{13}C 50 MHz) at 298 K or a Varian Unity Plus NMR spectrometer (^{1}H 600 MHz, ^{13}C 150 MHz) at variable temperature (most NMR assignments were secured by 2D NMR experiments);[29] a Nicolet 5 DXC FT-IR spectrometer; a Micromass Quattro LC-Z mass spectrometer; elemental analyses were carried out with a Fross−Heraeus CHN-rapid elemental analyser or a Vario El III micro elemental analyser. $[\{C_5H_4(CMe_2)PPh_2\}_2ZrCl_2]$ (**2a**),[11] $[\{C_5H_4(CMe_2)P(tolyl)_2\}_2ZrCl_2]$ (**2b**),[11] $[\{C_5H_4(CHMe)PPh_2\}_2ZrCl_2]$ (**2c**),[12] $[\{C_5H_4(CHPh)PPh_2\}_2ZrCl_2]$ (**2d**),[12] $[\{C_5H_4(CHFc)P(tolyl)_2\}_2ZrCl_2]$ (**2e**),[30] $[\{C_5H_4(CMe_2)NMe_2\}_2ZrCl_2]$ (**6a**),[14−16] $[\{C_5H_4(CHMe)NMe_2\}_2ZrCl_2]$ (**6b**),[14−16] $[\{C_5H_4(CMe_2)NMe_2\}\{Cp\}ZrCl_2]$ (**10**),[14−16] tris(pentafluorophenyl)borane $[B(C_6F_5)_3,]$[9,10] lithium [tetrakis(pentafluorophenyl)borate] $[Li\{B(C_6F_5)_4\}]$[17a][17b,18] were prepared by literature methods.

$[C_5H_4(CHFc)P(tolyl)_2]Li(THF)$:[30] This compound was obtained from (p-tolyl)$_2$PH (2.8 g, 13.0 mmol), nBuLi (8.0 mL, 13.0 mmol) and 6-ferrocenylfulvene (3.9 g, 14.8 mmol), 5.4 g (75%) isolated. ^{1}H NMR (200.1 MHz, C_6D_6/[D$_8$]THF, 298 K): δ = 1.07 (m, 4 H, THF), 1.94, 2.01 (s, each 3 H, Me of p-tolyl), 2.05 (m, 4 H, THF), 3.60, 3.84, 4.05 (m, 4 H, C_5H_4 of Fc), 4.09 (s, 5 H, C_5H_4 of Fc), 4.62 (d, $^2J_{PH}$ = 6.1 Hz, 1 H, CHFc), 6.24 (br. s, 2 H of C_5H_4), 6.30, 6.58 (br. s, each 1 H of C_5H_4), 6.82, 6.89 (m, each 2 H, p-tolyl), 7.31 (m, 2 H, p-tolyl), 7.65 (m, 2 H, p-tolyl) ppm. ^{31}P{^{1}H} NMR (81.0 MHz, C_6D_6/[D$_8$]THF, 298 K): δ = −0.9 ppm.

$[\{C_5H_4(CHFc)P(tolyl)_2\}_2ZrCl_2]$ (2e):[30] **2e** was obtained from $[C_5H_4(CHFc)P(tolyl)_2]Li(THF)$ (5.0 g, 9.0 mmol) and $[ZrCl_4(THF)_2]$ (1.69 g, 4.5 mmol), and isolated as a yellow solid (4.3 g, 81%) as a 1:1 mixture of diastereoisomers. IR (KBr): $\tilde{\nu}$ = 3111, 3091, 2918, 2850, 1595, 1497, 1468, 1456, 1394, 1266, 1185, 1105, 1090, 1039, 1027, 1018, 998, 813, 734, 512, 503, 500, 486, 423 cm^{-1}. ^{1}H NMR (200.1 MHz, C_6D_6, 298 K): δ = 2.02, 2.06 (s, each 6 H, Me of p-tolyl), 3.83 (m, 2 H, Fc), 3.92−3.93 (m, 4 H, Fc), 4.33 (d, J_{PH} = 0.5 Hz, 10 H, Fc), 4.47 (m, 2 H, Fc), 5.04 (d, $^2J_{PH}$ = 1.5 Hz, 2 H, C*H*Fc), 4.65, 4.82, 5.73, 6.32 (m, each 2 H, C_5H_4), 6.83 (pd, $J_{H,H}$ = 8 Hz, 4 H, p-tolyl), 6.93 (pd, $J_{H,H}$ = 7 Hz, 4 H, p-tolyl), 7.10 (pt, $J_{H,H}$ = 8 Hz, 4 H, p-tolyl), 7.46 (dd, $J_{H,H}$ = 6, 8 Hz, 4 H, p-tolyl) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, C_6D_6, 298 K): δ = 21.1, 21.3 (Me of p-tolyl), 42.2 (d, $J_{P,C}$ = 28.9 Hz, *C*HFc), 66.3 (d, $J_{P,C}$ = 2.2 Hz, Fc), 68.2 (Fc), 69.6 (d, $^3J_{P,C}$ = 6.1 Hz, Fc), 70.1 (d, $J_{P,C}$ = 4.4 Hz, Fc), 71.1 (d, $J_{P,C}$ = 5.4 Hz, Fc), 89.9 (d, $J_{P,C}$ = 15.7 Hz, Fc), 105.8, 110.9, 113.8, 125.7 (C, C_5H_4), 129.1 (d, $J_{P,C}$ = 8.8 Hz, p-tolyl), 129.7 (d, $J_{P,C}$ = 4.4 Hz, C, p-tolyl), 131.8 (d, $J_{P,C}$ = 23 Hz, p-tolyl), 131.9 (d, $J_{P,C}$ = 16.6 Hz, C, p-tolyl), 135.7 (d, $J_{P,C}$ = 17.5 Hz, p-tolyl), 137.3 (d, $J_{P,C}$ = 24.5 Hz, p-tolyl), 137.7 (p-tolyl), 138.0 (d, $J_{P,C}$ = 8.8 Hz, C_5H_4), 140.0 (p-tolyl) ppm. ^{31}P{^{1}H} NMR (81.0 MHz, C_6D_6, 298 K): δ = 12.1, 12.8 ppm.

General Procedure for the Preparation of $[\{C_5H_4(CR^1R^2)PAr_2\}_2ZrCl]^+[B(C_6F_5)_4]^-$, $[\{C_5H_4(CR^1R^2)NMe_2\}_2ZrCl]^+[B(C_6F_5)_4]^-$ or $[\{C_5H_4(CMe_2)NMe_2\}\{Cp\}ZrCl]^+[B(C_6F_5)_4]^-$: Dichloromethane (or CD_2Cl_2 or $C_2D_2Cl_4$) was added at room temperature to a mixture of equimolar amounts of the cyclopentadienyl complex (**2a−e, 6a−b, 10**) and the chloride anion abstractor $Li[B(C_6F_5)_4]$. The reaction mixture was stirred for 1 h. The precipitated LiCl was removed by filtration. The filtrate was concentrated in vacuo or used directly. The product was washed twice with pentane and dried in vacuo.

$[\{C_5H_4(CMe_2)PPh_2\}_2ZrCl]^+[B(C_6F_5)_4]^-$ (5a): 5a was obtained from **2a** (3.72 g, 5.0 mmol) and $Li[B(C_6F_5)_4]$ (3.43 g, 5.0 mmol), and isolated as a yellow-brown solid (3.82 g, 55%). IR (KBr): $\tilde{\nu}$ = 3015, 2919, 2856, 1601, 1497, 1443, 1184, 1094, 1018, 802, 514, 492 cm^{-1}. ^{1}H NMR (200.1 MHz, CD_2Cl_2, 300 K): δ = 1.55−2.19 (br. s, 12 H, CH_3), 6.15−6.47 (br. m, 8 H, C_5H_4), 7.32−7.60 (m, 20 H, Ph) ppm. ^{31}P{^{1}H} NMR (81.0 MHz, CD_2Cl_2, 300 K): δ = −29.1 ppm. ^{11}B{^{1}H } NMR (64.2 MHz, CD_2Cl_2, 300 K): δ = −16.6 ($w_{1/2}$ = 32 Hz) ppm. $C_{64}H_{40}BClF_{20}P_2Zr$ (1388.42): calcd. C 55.37, H 2.90; found C 55.33, 3.36.

$[\{C_5H_4(CMe_2)P(tolyl)_2\}_2ZrCl]^+[B(C_6F_5)_4]^-$ (5b): 5b was obtained from **2b** (4.0 g, 5.0 mmol) and $Li[B(C_6F_5)_4]$ (3.43 g, 5.0 mmol), and isolated (2.68 g, 67%) as a beige solid. IR (KBr): $\tilde{\nu}$ = 3030, 3005, 2939, 1621, 1507, 1451, 1287, 1200, 1105, 802, 534 cm^{-1}. ^{1}H NMR (200.1 MHz, CD_2Cl_2, 300 K): δ = 1.55, 1.76 (m, each 6 H, CH_3), 2.41 (s, 12 H, CH_3 of p-tolyl), 6.13, 6.22 (m, each 4 H, C_5H_4), 7.25−7.55 (m, 16 H, p-tolyl) ppm. ^{31}P{^{1}H} NMR (81.0 MHz, CD_2Cl_2, 300 K): δ = −31.0 ppm. ^{11}B{^{1}H} NMR (64.2 MHz, CD_2Cl_2, 300 K): δ = −13.6 ($w_{1/2}$ = 48 Hz) ppm. $C_{68}H_{48}BClF_{20}P_2Zr$ (1444.53): calcd. C 56.54, H 3.35; found C 56.34, 3.72.

$[\{C_5H_4(CHMe)PPh_2\}_2ZrCl]^+[B(C_6F_5)_4]^-$ (5c): 5c was obtained from **2c** (3.58 g, 5.0 mmol) and $Li[B(C_6F_5)_4]$ (3.43 g, 5.0 mmol), and isolated (3.67 g, 54%) as a beige solid. IR (KBr): $\tilde{\nu}$ = 2965, 2810, 1621, 1479, 1453, 1110, 1088, 1015, 802, 685, 554 cm^{-1}. SiO_2-CaO Vitreous Films Deposited onto Ti6Al4V Substrates

Isabel Izquierdo-Barba,[a] Agustina Asenjo,[b] Luis Esquivias,[c] and María Vallet-Regí*[a]

Keywords: Thin films / Sol-gel processes / Gels / Glasses / Amorphous materials

A sol-gel dipping method has been utilised to deposit SiO_2-CaO films onto Ti6Al4V alloy substrates. These layers were prepared by the dip-coating technique from a series of precursor solutions with different concentrations of glassy $xSiO_2$-(1 – x)CaO (x = 0.8 mol) diluted with absolute ethanol. The characterisation of the films by a variety of techniques reveals differences in the textural properties and in the films' thicknesses depending on the sol concentration in the precursor solution. Concentrated precursor solutions yield porous layers with a higher thickness and surface roughness than those obtained from the dilute ones.

Introduction

Titanium and its alloys are widely used in the aerospace, chemical and sporting equipment industries. It was not until the 1960s, however, that Ti6Al4V alloy began to be used as a surgical implant material because of its excellent mechanical properties (tensile strength of 860 MPa and yield strength of 790 MPa), and its lightness (specific gravity of 4.5 g/cm^3). Ti-based alloys are not the best from a biological point of view, however, since they corrode away when implanted; this disadvantage led to the discontinuation of the use of Ti6Al4V alloys for load-bearing applications.[1,2] It is commonly believed that this is due to their poor tribomechanical properties under certain physiological conditions, which could cause a local build-up of low pH acidity and high Cl^- ion concentration.

An interesting alternative for protection of metal surfaces against corrosion phenomena is to employ ceramic coatings. Several attempts have been made in this sense, using sophisticated deposition techniques such as PVD and CVD, ion implantation, reaction-assisted and laser coating.[3−5]

The dipping method is a much simpler, versatile and cost effective option which, combined with the sol-gel chemical method, allows the coating of metal surfaces with ceramic layers. The quality of these coatings is strongly determined by the chemical synthesis of the starting sols. In this initial stage, the control of viscosity, ageing and/or solvent allows the determination, at least indirectly, of the roughness, the porosity and thickness of the deposited ceramic layer.[6,7]

Using this method, layers of hydroxyapatite have been deposited onto metallic substrates of the Ti6Al4V alloy.[8] As an alternative solution to the deposition of hydroxyapatite onto titanium alloys, the deposition of bioactive glasses yields an additional advantage: besides its role as a barrier against corrosion, it could improve the bonding with tissues by means of a bioactive interphase.

The aim of this work is to deposit glassy coatings onto Ti6Al4V alloy. The glass chosen for this type of coating is SiO_2-CaO, which our group produces in bulk forms[9,10] and

where in vitro and in vivo studies have confirmed the bioactivity of such a composition. The films are characterised by X-ray diffraction (XRD), scanning electron microscopy (SEM), X-ray dispersive energy spectroscopy (EDS), reflection ellipsometry and scanning force microscopy (SFM).

It is our purpose to define the production method for these coatings. Their potential applications go beyond the clinical field, and therefore special care is devoted to the control of thickness, roughness and porosity of the deposited layer, through the synthesis conditions, in order to tailor those parameters to the specific application proposed.

Results and Discussion

Five SiO_2-CaO vitreous films were deposited onto Ti6Al4V substrates by the dip-coating method from a series of precursor solutions with different concentrations of glassy $x SiO_2$-$(1-x)$CaO (x = 0.8 mol) diluted with absolute ethanol. The X-ray diffraction patterns show, for all the synthesised films, a broad peak between $15 < 2\theta < 30°$ that could correspond to amorphous silica. Sharp peaks that correspond to the substrate are only observed for 2θ values between 35.1 and 53.0. Figure 1 shows that the intensity of these diffraction maxima decreases as the ethanol volume used in the sol preparation decreases.

SEM, SFM and reflection ellipsometry observations manifest the differences in the textural properties, which depend on to the solution used for coating.

Figure 2 shows the SEM micrographs and EDS spectra of the coatings obtained from the different precursor solutions and the substrate. Film 1 (obtained from the 1:2 sol) presents large pores of different sizes. The pore size ranges between 150 ± 50 nm and 875 ± 50 nm. In film 2 (from the 1:4 sol) the number of pores with a 150 ± 50 nm diam-

eter with regard to those of 875 ± 50 nm is higher than in film 1. The micrograph corresponding to film 3 (1:6 sol) shows a film with a noticeably different structure, consisting of crossed grains. Furthermore, the films 4 (1:8 sol) and 5 (1:12) present a rough structure. Consequently, when the precursor solution has a low ethanol content (films 1 and 2) the films are porous, while as ethanol volume rises the films become more compact (films 3, 4 and 5).

The EDS analyses of the surfaces show that Si and Ca are present in the coatings, while Ti, Al and V, constituents of the substrate, can also be detected. Differences between the relative intensities of substrate (Ti, Al, V) and deposited elements (Ca, Si) are observed. The higher the alcohol content in the precursor solution, the higher the intensity of Ti, Al, V. The Si and Ca content measured by EDS in all cases are 81.2 and 18.8 atom %. These elements have been found homogeneously distributed throughout every sample. These results indicate that the composition does not depend on the sol concentration.

In Figure 3, thickness and refraction indexes of the films obtained by reflection ellipsometry are plotted as a function of the precursor solution concentration. Thickness, ranging from 240 to 1639 nm, decreases as the alcohol content increases as can be expected since the amount of sol drawn also lessens. These data are corroborated by the intensity of the diffraction peaks and EDS observations (see Figure 1 and inset in Figure 2). The refraction index, on the other

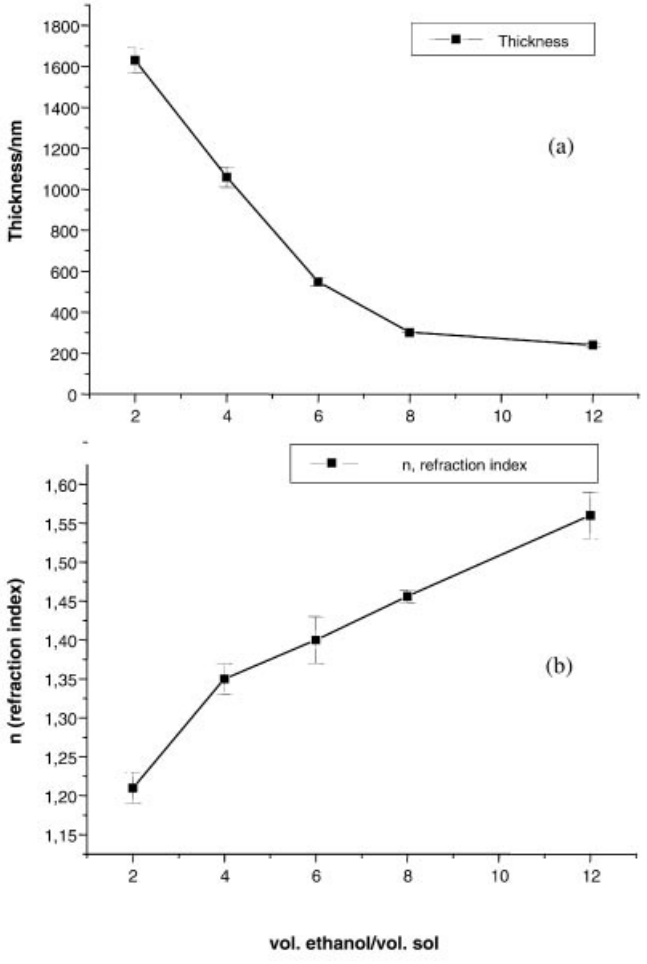

Figure 3. (a) Thickness and (b) refraction index of the films as function of the concentration of the precursor solutions

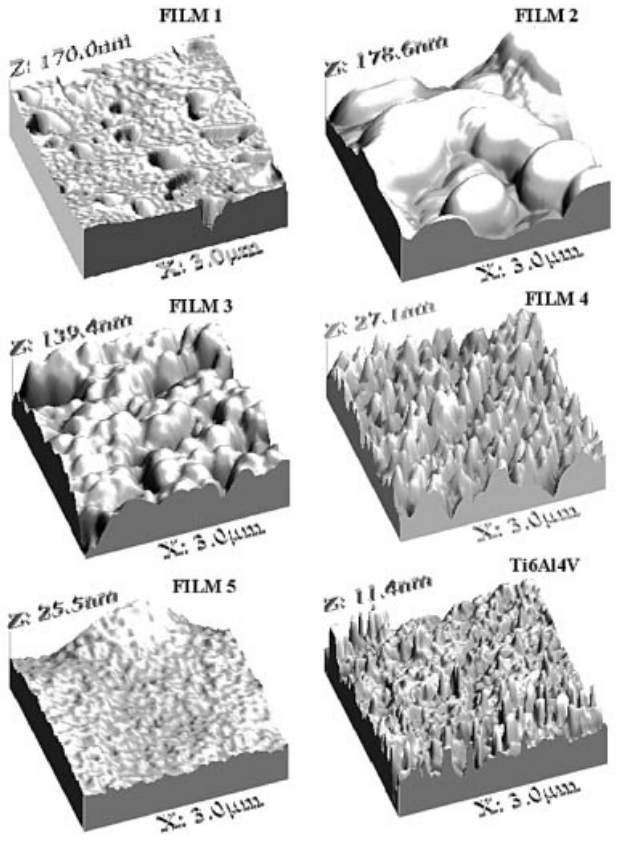

Figure 4. SFM images of the substrate and films; image size: 3 μm × 3 μm

Table 1. Nomenclature, porosity, roughness and grain size of the films obtained

Nomenclature	Precursor solutions (Vol sol:Vol Ethanol)	% Porosity $\rho = (n^2 - n_p^2)/(n^2 - 1)$	Roughness (nm)	Grain size (nm)
Film 1	Sol 1:2	65.6 ± 3.0	25	–
Film 2	Sol 1:4	42.6 ± 3.4	36	800
Film 3	Sol 1:6	34.4 ± 5.3	26	400
Film 4	Sol 1:8	26.2 ± 1.5	6	190
Film 5	Sol 1:12	9.8 ± 6.0	2	90

hand, increases as the precursor concentration decreases. The refraction index, on the other hand, increases as the precursor concentration increases: 1.21 and 1.55 for films 1 and 5, respectively. These results agree with the diminished porosity observed by SEM because the refraction index (n) is related to porosity by the equation shown in the Exp. Sect. Accordingly, n increases as the porosity decreases (see Table 1).

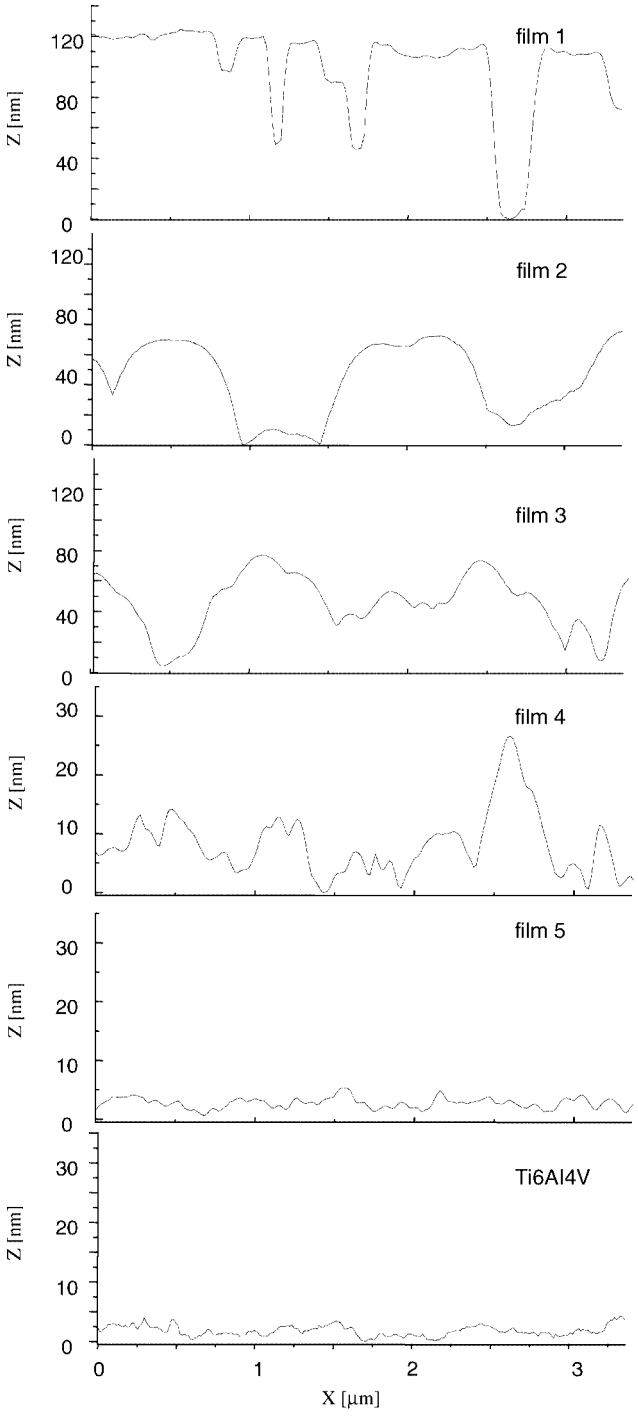

Figure 5. Profiles obtained from the SFM images performed in the different films; note that the profiles corresponding to films 1, 2 and 3 have the same scale, and that the profiles corresponding to films 4, 5 and substrate are presented at a higher magnification

The SFM images shown in Figure 4 are in agreement with the SEM images presented in Figure 2. The advantages in the use of SFM lie in the real 3D information offered, which allows us to study the evolution of the surface roughness versus the precursor concentration. In particular, the roughness (rms) values have been calculated for the different films. The rms values range from 2 nm to 25 nm as shown in Table 1. The lower roughness corresponds to film 5 and an increase of the rms value is observed when the precursor concentration increases. The evolution of the film structure can also be deduced from the analysis of the profiles in Figure 5 obtained from the SFM data. In addition, the SFM images show the increase of the grain size as the precursor concentration increases (see Table 1). Moreover, we have found that, for a precursor concentration of 1:4, the grains start to coalesce, giving an almost continuous film for 1:2 precursor concentrations.

It should also be noted that the structure as well as the roughness of the thicker film, shown in Figure 6, differ from those observed on the other films. This almost continuous film 1 has pores with discrete depth values of 20 nm, 40 nm, 60 nm, 80 nm and 100 nm.

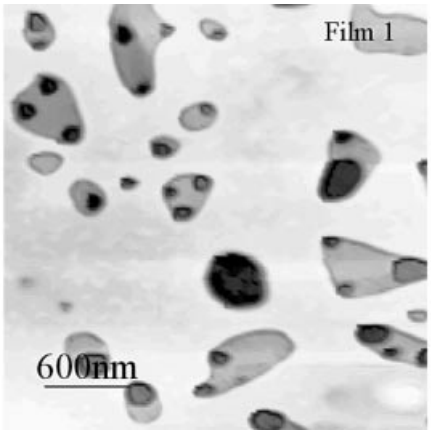

Figure 6. Top view SFM image of film 1; image size: 3 μm × 3 μm

The effect of increasing the alcohol concentration on the sol kinetics is that of slowing down its polymerisation.[6,7,11] Accordingly, the polymerisation of 1:2 sol is faster (and exhibits higher viscosity) than in 1:12 sol. In the latter case, the Si-O-Si aggregates are smaller and easily packed, forming more compact and homogeneous films of lower thickness.

Conclusions

SiO_2-CaO films have been deposited onto Ti6Al4V metal alloy wafers by dip-coating in precursor solutions, a cost-effective and controllable method.

The films are noncrystalline, and are independent of the dipping solution characteristics. In addition, the actual compositions of films do not depend on the precursor solution concentration. However, thickness and texture of surfaces depend on the precursor solution concentration.

The porosity, roughness, grain size and thickness depend on the amount of ethanol present in the dipping solutions. Concentrated dipping solutions yield porous films with higher thickness and surface roughness. Less concentrated precursor solutions produce dense films with higher refraction indexes and lower surface roughness and grain size. The thicker coating shows a continuous film with well-defined pore depths.

In summary, the dip-coating deposition method allows us to tailor the thickness, surface roughness and porosity of the obtained product that can be useful for a variety of applications in the materials science field.

Experimental Section

Dipping Solution Preparation: A SiO_2-CaO, [Si]/[Ca] = 4, sono-sol was elaborated by hydrolysis and polycondensation of tetraethylorthosilane (TEOS) and $Ca(NO_3)_2{\cdot}4H_2O$ under acidic conditions (pH [HNO_3] = 0.5) with R_w = [TEOS]/[H_2O] = 8. Ultrasound waves of 20 MHz were generated by a sonicator device (Sonic & Materials Vibracell), delivering 15 $W{\cdot}cm^{-3}$ of ultrasound power to this liquid mixture for three minutes.

This sol, diluted with different amounts of alcohol (99.99% purity), was distributed in five different containers to obtain the precursor sols named as follow: 1:2 Sol, 1:4 Sol, 1:6 Sol, 1:8 Sol and 1:12 Sol (the figures indicating the sol to ethanol volumes ratio). The sols were aged for 30 days at room temperature before starting to prepare the films.

Films Preparation: Before film deposition, Ti6Al4V metal wafers, provided by IQL (Industrias Quirúrgicas de Levante S.L., Biomet Merck), 13 mm diameter and 1 mm thick, were polished with SiC of 220, 500, 800 and 1200 grit and then with 3−1 μm diamond paste. Finally, the polished discs were washed for 5 min in an ultrasound bath distilled water, alcohol and acetone.

The coating procedure was carried out in a device which allows the control of the substrate extraction at a rate between 50 and 2550 μm/s. Metal substrates were grasped by dipping tweezers, dipped into one of the previously prepared solutions, and then taken out at a constant speed of 1500 μm/s. After muffling the pieces with a thin cloak of sol, they were dried in air at room temperature for 10 minutes and afterwards in an oven at 100 °C for 20 minutes. The samples were stabilised at 550 °C for 10 minutes. This process was repeated six times. Finally, the wafers were washed in an ultrasound bath for five minutes.

Film Characterisation: The resulting films were characterised by X-ray diffraction (XRD), scanning electron microscopy (SEM), X-ray dispersive energy spectroscopy (EDS), reflection ellipsometry and scanning force microscopy (SFM).

X-ray diffraction experiment were carried out using Cu-K_α radiation (λ = 1.54056 Å) in an automatic powder diffractometer (Philips X′Pert MPD) with a thin-film attachment. Scanning measurements at grazing incidence were done in the range $10° < 2\theta < 60°$. The fixed incidence angle was 0.5° for all samples.

SEM and EDS observations were performed on a JEOL 6400 microscope equipped with a Pentajet inper ATW system analyser microscope.

The measurements of reflection ellipsometry were carried out with a PLASMOS SD-2300 automatic ellipsometer with a spot size of 2 mm^2 and a wavelength of 632.8 nm. The ellipsometry angles, Ψ and Δ, were obtained at the same point, under multiple incidence angles (MIA), and are correlated with film thickness and reflective index, n, by means of McCrackins routines[12,13] by interactive calculus with software provided by PLASMOS.

The film porosity, ρ, (as shown in Table 1) was estimated from the refraction indexes calculated by Equation (1),[14]

$$\rho \equiv \frac{n^2 - n_p^2}{n^2 - 1} \quad (1)$$

where n_p is the refraction index of the film measured by reflection ellipsometry and n the refraction index of SiO_2-CaO bulk glass, n = 1.61, calculated as the weighted average of the tabulated indexes for SiO_2 and CaO.[15]

The topography of the samples was obtained by using an Autoprobe-CP SFM from Park Scientific Instruments working in contact mode. Cantilevers with a 0.4 N/m force constant and conical tip were used.

Ruthenium-Catalysed Selective Transetherification of Substituted Vinyl Ethers To Form Acetals and Aldehydes

Mustapha Saoud,[a] Antonio Romerosa,*[a] Sonia Mañas Carpio,[a] Luca Gonsalvi,[b] and Maurizio Peruzzini*[b]

Keywords: Ruthenium / Allenylidenes / Vinyl ethers / Homogeneous catalysis / Acetals

The water-soluble ruthenium allenylidene complex [{RuCl(μ-Cl)(C=C=CPh$_2$)(TPPMS)$_2$}$_2$]Na$_4$ catalyses the selective transformation of substituted linear and cyclic vinyl ethers with MeOH, under mild non acidic conditions, to give acetals, while aldehydes and ketones are obtained in a CHCl$_3$/H$_2$O mixture, which allows for easy recycling of the catalyst. NMR studies showed that the reaction follows a transetherification mechanism rather than simple acid-catalysed hydrolysis.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Unsaturated transition-metal carbene complexes, M=C=(C)$_n$=C, such as vinylidenes (n = 0)[1] and allenylidenes (n = 1),[2] are a ubiquitous class of organometallic compounds whose use in catalysis has gained an increasing consideration during the last decade.[3] In this regard, particular emphasis has been placed on ruthenium vinylidene complexes, which have been shown to catalyze several important processes targeting the elaboration of linear and cyclic organic compounds.[3,4] More recently, ruthenium allenylidene species have also started attracting interest as catalysts or catalyst precursors and have been employed to achieve important metal-mediated reactions such as alkene ring closing metathesis (RCM),[5a−5e] ring opening metathesis polymerisation[5f,5h] and propargylation of aromatic compounds.[6]

In a previous communication we have described the first example of a water-soluble transition metal allenylidene complex of formula [{RuCl(μ-Cl)(C=C=CPh$_2$)-(TPPMS)$_2$}$_2$]Na$_4$ (**1**) [TPPMS = Ph$_2$P{2-OS(O)$_2$-C$_6$H$_4$}$^-$}].[7] As a first exploratory assessment of its catalytic activity, we have demonstrated that this ruthenium(II) complex may be successfully used in the selective ring-opening metathesis (ROM) of cyclic olefins with methylacrylate as chain-transfer reagent. In order to further evaluate the catalytic activity of this water-soluble unsaturated carbene complex, we decided to investigate its behaviour under the conditions of RCM of acyclic dienes,[8−11] a reaction which is well-known with several Grubbs-type ruthenium catalysts,[12,13] including the few that are soluble in water.[14]

However, in spite of our expectations, the reaction of **1** in a biphasic CHCl$_3$/H$_2$O system with representative substrates such as diethyl diallylmalonate and *N*,*N*-diallyltosylamide failed to give any RCM reaction. Thus, when 1,4-butanediol vinyl ether (**2**) was chosen as substrate, we observed that, although not affording RCM products as reported for other Ru-carbene species,[15] complex **1** was still endowed with catalytic activity, bringing about the selective formation of ethanal and 1,4-butandiol, followed by their intermolecular condensation to generate 2-methyl-[1,3]dioxepane (**3**) in almost quantitative yield. When the same reaction was carried out in methanol, the isolated products were 1,1-dimethoxyethane and 1,4-butanediol (Scheme 1). Although this catalytic method is of little synthetic interest, and the reaction under scrutiny can be performed without the need for expensive transition-metal catalysts, this serendipitous discovery nevertheless represents a completely new reaction to the best of our knowledge, and on this basis we decided to study its general applicability and tried to unravel its mechanism.

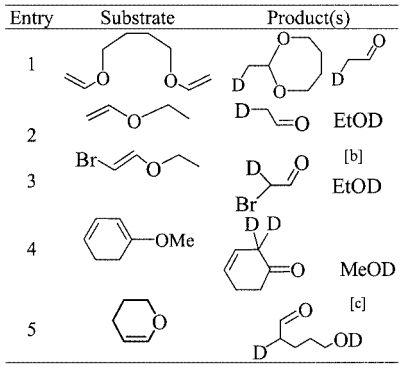
Results and Discussion

In order to explore the scope of the reaction, we applied our catalytic system to a series of linear and cyclic vinyl ethers bearing different functional groups. The nature of the final products depends strictly on whether the reactions are run under monophasic (MeOH) or biphasic ($CHCl_3$/H_2O) conditions. All the tests were run under very mild conditions (47 °C). The results are summarised in Table 1 and 2 for biphasic and monophasic conditions, respectively. Our protocol is highly specific for vinyl ethers, as diallyl, diethyl, dibenzyl and allylpropargyl ethers were recovered intact after the catalytic tests. This indicates a high tolerance of the method for a wide variety of organic substrates and suggests a potential application for the selective deprotection of masked aldehydes protected as vinyl ethers, such as acid sensitive β-hydroxy aldehydes. However, only trivial products were obtained from the ethers of choice as these were deliberately chosen for screening purposes only.

Table 1. Catalytic reactions of linear and cyclic vinyl ethers in the presence of **1** in $CDCl_3/D_2O$[a]

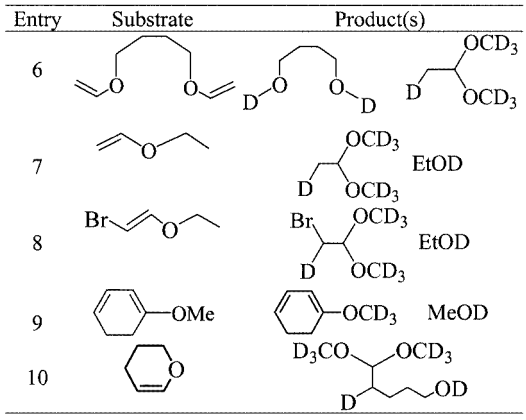


[a] Reaction conditions: substrate (0.1 mmol), **1** (0.005 mmol), $CDCl_3$ (0.5 mL), D_2O (0.5 mL), 47 °C, 2.5 h, in NMR tube (5 mm) under Ar. [b] Bromoacetaldehyde is not stable under the reaction conditions and cyclotrimerizes to 2,4,6-tris(bromodeuteromethyl)-1,3,5-trioxane (see Exp. Sect.). [c] The aldehyde 5-hydroxypentanal intramolecularly condenses to 3-deuterotetrahydro-2*H*-pyran-2-deuterol, equilibrium yield 84% (see Exp. Sect.).

The reactions were carried out on an NMR-tube scale at first and then repeated in bulk to check for reproducibility and to isolate the products. For all reactions the two methods gave similar results, showing that NMR-scale tests can be representative of the actual catalytic test under the same conditions. Under NMR tube reaction conditions, at 47 °C with a 1:1 $CDCl_3/D_2O$ mixture, all vinyl substrates were smoothly converted within three hours, reaching complete selectivity for the products described in Table 1, as determined by NMR spectroscopy and GC-MS techniques. The deep-red coloured catalytically active species remains confined to the water phase and can be recycled up to four times without significant loss of activity (see Exp. Sect.).

An interesting reaction is the selective deuteration of 1-methoxy-1,3-cyclohexadiene to yield 2,2-dideuterocyclohex-3-en-1-one (Table 1, entry 4) where the selective double deuteration at the 2-position follows from H/D exchange via a keto-enol equilibrium (see Scheme 4 in the Exp. Sect.). For linear vinyl ethers the formation of CD_3-diacetals was observed, resulting from the condensation of acetaldehyde and CD_3OD by cleavage of the vinyl carbon-oxygen bond. For example, 2-bromovinyl ethyl ether was converted into 2-bromo-2-deutero-1,1-bis(trideuteromethoxy)ethane (Table 2, entry 8). For cyclic vinyl ethers such as dihydropyran, ring opening and acetalization occur to give the protected 5-trideuteroxy-2-deuteropentan-1-al (Table 2, entry 10). 1-Methoxy1,3-cyclohexadiene was converted into the deuterated OCD_3 analogue (kinetic product) instead of the corresponding diacetal (Table 2, entry 9) which forms only after a week at 47 °C.

Table 2. Catalytic reactions of linear and cyclic vinyl ethers in the presence of **1** in CD_3OD[a]



[a] Reaction conditions: substrate (0.1 mmol), **1** (0.005 mmol), CD_3OD (1.0 mL), 47 °C, 17 h, in NMR tube (5 mm) under Ar

We chose 1,4-butanediol vinyl ether (**2**) to test the effect of catalyst concentration on the rate and selectivity of the reaction. In $CDCl_3/D_2O$, the reaction reached completion in 2.5 hours with 5 mol % of catalyst **1**, 8 h with 1 mol % and 20 h with 0.2 mol %, in all cases with selectivity higher than 99%. In CD_3OD, the reaction is slower (17 h) and normally 5 mol % of **1** are required to complete the reaction in a comparable time scale. The nature of the ruthenium precursor was also found to be crucial for the reaction. A series of precursors was tested for the reaction of **2** under standard conditions; the results are summarised in Table 3. Remarkably, while the classic Grubbs catalyst does not work under these reaction conditions, the water-soluble phenylvinylidene complex $[RuCl_2\{C{=}C(H)Ph\}(TPPMS)_2]Na_2$ (**4**)[7] shows a similar reactivity to **1** in promoting the acetalization of **2**. These results are significant and indicate that ruthenium, TPPMS and *unsaturated carbenes* are necessary ingredients in this reaction either as molecular complexes or to form the catalytic species in situ (Table 3, entries 18 and 19). However, catalytic tests with isolated samples of **4** were not systematically evaluated due to the lower stability and difficulty of isolation of **4** compared to **1**.[7]

Table 3. Blank reactions and effect of Ru precursor on the conversion of **2** to 1,4-D-butanediol and 1,1-D-dimethoxy-2-D-ethane[a]

Entry	Precursor	Yield (%)	Time (h)
11	None	–	70
12	TPPMS	–	70
13	$[RuCl_2(CHPh)(PCy_3)_2]$	–	20
14	$[Cp^*Ru(PEt_3)_2Cl]$	–	20
15	$[RuCl_2(PPh_3)_3]$	–	20
16	$[RuCl_2(TPPMS)_2]_2$	80	1 month
17	$[RuCl_2(PPh_3)_3]$ + 4 TPPMS	30	18

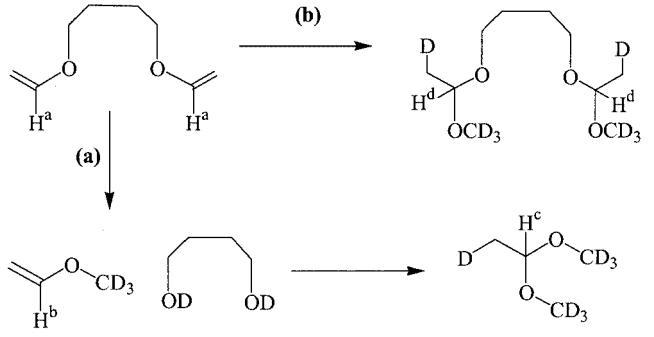
19	$[RuCl_2(PPh_3)_3]$ + 4 TPPMS + HC≡CC(OH)Ph_2	95	17

[a] Reaction conditions: substrate (0.1 mmol), precursor (0.005 mmol), CD_3OD (1.0 mL), 47 °C, 17 h, in NMR tube (5 mm) under Ar

We obtained evidence for a transetherification mechanism by monitoring the reaction of **2** with **1** in CD_3OD by ^1H and $^{13}C\{^1H\}$ NMR spectroscopy at 47 °C. The decrease in the intensity of the signal at δ = 6.49 ppm (dd, $J_{H,H}$ =



Scheme 2. NMR mechanistic experiments: (a) **2**, 0.1 mmol; **1**, 0.005 mmol. CD_3OD 1.0 cm^3; 47 °C; 24 h, in NMR tube (5 mm) under Ar; (b) **2**, 0.1 mmol; HOTs, 0.01 mmol. CD_3OD 1.0 mL; 47 °C; 24 h, in NMR tube (5 mm) under Ar

14.3, 7.0 Hz) due to the vinyl proton H^a (Scheme 2a) was accompanied by an increase in the intensity of a new signal at δ = 6.51 ppm (dd, $J_{H,H}$ = 14.2, 6.8 Hz) that we attribute to H^b, which in turn decreases in intensity with the appearance of the signal due to H^c at δ = 4.56 ppm (dt, $J_{H,H}$ = 5.2, $J_{H,D}$ = 1.8 Hz) belonging to the final product. A parallel experiment, carried out replacing **1** with HOTs, ruled out the possibility of acid-catalysed hydrolysis of the substrate (Scheme 2b).[16–18] Under these conditions, **2** is immediately converted into a new species that does not contain a vinyl group, is stable and is plausibly the product of addition of CD_3OD to the vinyl double bond as evidenced by the diagnostic H^d signal at δ = 4.66 ppm (dt, $J_{H,H}$ = 5.4, J_{HD} = 1.6 Hz). Although a detailed mechanism cannot be proposed on the basis of the NMR study alone, these latter experiments suggest that the reaction occurs as a two-step transformation of the vinyl substrate by exchange of the ether substituent, followed by addition of alcohol to the C=C double bond with regioselective deuteration of the β-carbon. $^{31}P\{^1H\}$ NMR monitoring of the biphasic reaction shows that **1** quantitatively transforms into an unknown ruthenium species (singlet at δ = 21.4 ppm), which remains catalytically active over more than four runs.

Conclusion

In summary, our study provides an insight into the reactivity of vinyl ethers in the presence of a Ru-allenylidene complex and an alternative method for the production of acetals, aldehydes and ketones from a wide choice of vinyl ether precursors.[19] Although the present method is certainly not convenient for routine applications, it is important to stress that this protocol affords catalytic solvolysis of vinyl ethers under mild conditions at neutral pH in aqueous phase or anhydrous organic phase, with high tolerance for a variety of functional groups. As a consequence, the present ruthenium catalyst might deserve application in particular cases where the vinyl ether functionality is coupled with acid-sensitive groups. We are currently investigating more interesting applications of the catalytic protocol, such as the synthesis of polyacetals[20] and podands. Preliminary experiments showed that our system is active in the selective catalytic synthesis of a variety of linear polyethers by acetalization of vinyl ethyl ether with various glycols.

Experimental Section

General Remarks: Complex **1** was prepared as described previously.[7] ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on Varian VXR300, or Bruker AVANCE DRX300 spectrometers operating at ca. 300 MHz (^1H) and ca. 75.4 MHz (^{13}C). Peak positions are relative to tetramethylsilane and were calibrated against the residual solvent resonance (^1H) or the deuterated solvent multiplet (^{13}C). $^{31}P\{^1H\}$ NMR spectra were recorded on the same instruments operating at ca. 121 MHz. Chemical shifts were measured relative to external 85% H_3PO_4 with downfield values taken as positive. A Shimadzu GC-14A/GCMS-QP2000 instrument was employed for GC-MS investigations.

Bulk-Scale Experiments: In a typical macro scale experiment, 3 mmol of substrate were added under argon to 2 mL of MeOH together with 0.03 mmol of **1**. After 2 h whilst stirring at 47 °C the solvent was removed giving the 1,1-dimethoxy-substituted product. When a biphasic system was used, 3 mmol of vinyl ether and

0.03 mmol of **1** were dissolved into 1 mL of $CHCl_3$ and 1 mL of H_2O under argon. The mixture was kept at 47 °C for 1 h under vigorous stirring, then the organic phase was separated and dried over $MgSO_4$. The aldehyde or ketone was obtained in nearly quantitative yield by evaporation at reduced pressure of the solvent.

Typical Experimental Procedure for NMR-Tube Tests. (a) Monophasic Conditions: Compound **1** (11 mg, 5×10^{-3} mmol) was introduced into a 5 mm NMR tube, which was repeatedly evacuated and filled with argon. The substrate (20 equiv., typically 15−18 μL) was then added together with 0.5 mL of CD_3OD, to obtain an orange-red homogeneous solution. The tube was kept in an oil bath at 47 °C for typically 15−17 hours after which ^1H and ^{13}C NMR spectra were collected.
(b) Biphasic Conditions: As above, except for solvent (a mixture of $CDCl_3$, 0.5 mL and D_2O, 0.5 mL was used) and reaction time (typically 3 h). The tube was shaken thoroughly after mixing of the reagents and before taking the NMR spectra.

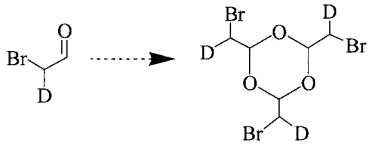
Experimental Procedure for Catalyst Recycling Tests: An NMR tube was charged with **1** (12.5 mg, 5.7×10^{-3} mmol), **2** (18 μL, 0.114 mmol), 0.5 mL of $CDCl_3$ and 0.5 mL of D_2O. The tube containing two separate phases was kept at 47 °C for 3 h, during which time it was shaken approximately every 20 min. After separation of the organic phase, the aqueous phase, which contained the catalyst, was proved to be active in the catalytic reaction during three additional runs carried out by adding 18 μL of **2** to 0.5 mL of $CDCl_3$ (a 100% conversion of **2** was achieved after 2.3 h in the first catalytic run, after 2.5 h in the second catalytic test and after 2.75 h in the third run). Only in the fourth catalytic run was a significant decrease of the catalytic activity observed — the reaction time to transform all of the substrate rose to about 4 h.

NMR and GC-MS Product Characterisation

2-Deuteromethyl-[1,3]dioxepane: (Table 1, entry 1). ^1H NMR (300.13 MHz, $CDCl_3$, room temp.): δ = 1.32 (dt, $J_{H,H}$ = 5.16, $J_{H,D}$ = 1.8 Hz, 2 H, CH_2D), 1.70 (m, 4 H, OCH$_2$CH_2), 3.67 (m, 2 H, OC*H*H), 3.93 (m, 2 H, OCH*H*), 4.95 (t, $J_{H,H}$ = 5.16 Hz, OC*H*O) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, room temp.): δ = 28.9 (s, OCH$_2$*C*H$_2$), 66.4 (2 O*C*H$_2$), 100.4 (s, O*C*HO), 31.7 (t, $J_{C,D}$ = 18.5 Hz, *C*H$_2$D) ppm. GC/MS: *m*/*z* (%) = 117 (5) [$C_6H_{11}O_2D$], 101 (43) [$C_5H_9O_2$], 71 (87) [C_4H_7O], 55 (53) [C_4H_7], 43 (100) [C_2H_3O].

Deuteroacetaldehyde: (Table 1, entries 1, 2). ^1H NMR (300.13 MHz, $CDCl_3$, room temp.): δ = 9.79 (br. t, $J_{H,H}$ = 2.80 Hz, 1 H, CHO), 2.19 (dt, $J_{H,H}$ = 2.80, $J_{H,D}$ = 2.25 Hz, 2 H, CH_2D) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, room temp.): δ = 200.89 (s, *C*HO), 21.49 (t, $J_{C,D}$ = 19.5 Hz, *C*H$_2$D) ppm. GC/MS: not registered.

Bromodeutero Acetaldehyde: (Table 1, entry 3). Bromoacetaldehyde, which selectively forms from the reaction of **1** with 1-bromo-2-ethoxyethene, is not stable under the reaction conditions and cyclotrimerizes spontaneously to 2,4,6-tris(bromodeuteromethyl)-1,3,5-trioxane (see Scheme 3 below). The NMR analysis of the reaction mixture reveals the presence of both the aldehyde (minor component) and the cyclotrimer. ^1H NMR (300.13 MHz, $CDCl_3$, room temp.): bromoacetaldehyde: δ = 9.55 (d, $J_{H,H}$ = 2.5 Hz, C*H*O), 3.86 (dt, $J_{H,H}$ = 6.8, $J_{H,D}$ = 2.5 Hz, C*H*DBr) ppm; 2,4,6-tris(bromodeuteromethyl)-1,3,5-trioxane: δ = 4.68 (d, $J_{H,H}$ = 5.5 Hz, C*H*OO), 3.61 (dt, $J_{H,H}$ = 5.5, $J_{H,D}$ = 1.9 Hz, C*H*DBr) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, room temp.): bromoacetaldehyde: δ = 191.9 (s, *C*HO), 52.2 (t, $J_{C,D}$ = 18.5 Hz, *C*HDBr) ppm. 2,4,6-tris(bromodeuteromethyl)-1,3,5-trioxane: δ = 101.36 (s, *C*HOO), 51.7 (t, $J_{C,D}$ = 18.5 Hz, *C*HDBr) ppm. GC/MS: not registered.

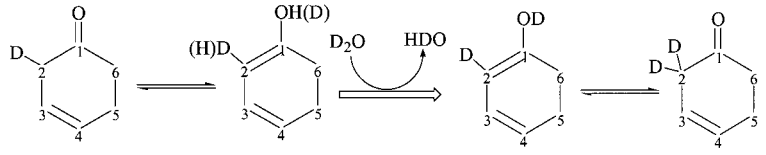


Scheme 3

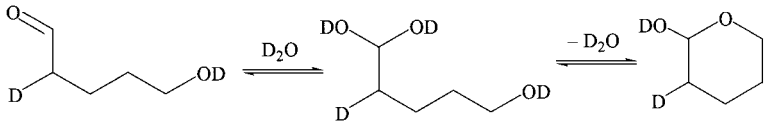
2,2-Dideuterocyclohex-3-enone: (Table 1, entry 4). The product probably forms by selective incorporation of deuterium in position 2 following H/D exchange. The latter is likely to be promoted by the keto-enol equilibrium depicted in Scheme 4.
^1H NMR (300.13 MHz, $CDCl_3$, room temp.): δ = 2.34 [m, 4 H, $CH_{2(5)}CH_{2(6)}$], 6.03 [dt, $J_{H,H}$ = 10.3, $J_{H,H}$ = 1.9 Hz, 1 H, $CH_{(4)}$], 6.97 [dm, $J_{H,H}$ = 10.3 Hz, 1 H, $CH_{(3)}$] ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, room temp.): δ = 205.2 [$C_{(1)}$],130.9 [s, $C_{(4)}$], 128.2 [s, $C_{(3)}$], 41.9 [s, $C_{(6)}$], 38.0 [quin., $J_{C,D}$ = 19.7 Hz, $C_{(2)}$], 22.6 [s, $C_{(5)}$] ppm. GC/MS: *m*/*z* (%) = 98 (18) [$C_6H_6D_2O$], 82 (5)[$C_6H_6D_2$], 70 (100%) [$C_5H_6D_2$].

2-Deutero-5-deuteroxypentanal: (Table 1, entry 5). The aldehyde that forms selectively from the cyclic vinyl ether 3,4-dihydro-2*H*-pyran, undergoes acetalization under the present reaction conditions and intramolecularly condenses to yield 3-deuterotetrahydro-2*H*-pyran-2-deuterol. The NMR analysis indicates the formation of an equilibrium mixture with about 84% of the cyclic compound (Scheme 5).
^1H NMR (300.13 MHz, $CDCl_3$, room temp.): 2-deutero-5-deuteroxypentanal: δ = 9.79 (s, 1 H, CHO), 3.46 (m, 2 H, CH_2OD), 1.5−2.1 [m, 5 H, C*H*(D)CH_2CH_2] ppm; 3-deuterotetrahydro-2*H*-pyran-2-deuterol: δ = 4.27 [m, 1 H, OC*H*(OD)], 3.53 (t, $J_{H,H}$ = 7.4 Hz, 2 H, CH_2O), 1.5−2.0 (m, CH_2CH_2 + *C*HD) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, room temp.): 2-deutero-5-deuteroxypentanal: δ = 200.1 (s, *C*HO), 62.2 (s, *C*H$_2$OD), 30.4 (t, $J_{C,D}$ = 19.5 Hz, CHD), 27.2 (s, *C*H$_2$CH$_2$OD), 19.6 (s, CHD*C*H$_2$) ppm; 3-deuterotetrahydro-2*H*-pyran-2-deuterol: δ = 94.5 [s, O*C*H(OD)], 62.9 (s, *C*H$_2$O), 29.7 (t, $J_{C,D}$ = 36.3 Hz, CHD), 25.2 (s, *C*H$_2$CH$_2$O), 20.1 (s, *C*H$_2$CHD) ppm. GC/MS: *m*/*z* (%) = 103 (23) [$C_5H_7O_2D_2$], 85 (10) [C_5H_7OD], 58 (100) [C_3H_4OD], 42 (60) [C_3H_4D].

1,4-Butandeuterol: (Table 2, entry 6). ^1H NMR (300.13 MHz, $CDCl_3$, room temp.): δ = 3.67 (m, 4 H, 2 × O*C*H$_2$), 1.64 (m, 4 H,



Scheme 4



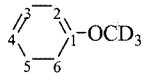
Scheme 5

2 × OCH_2CH_2) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, room temp.): δ = 30.2 (s, 2 × OCH_2CH_2), 62.6 (s, 2 × OCH_2) ppm. GC/MS: *m/z* (%) = 92 (2) [$C_4H_8O_2D_2$], 86 (5) [$C_4H_6O_2$], 71 (18) [C_4H_7O], 57 (11) [C_3H_5O], 42 (100) [C_2H_2O].

2-Deutero-1,1-bis(trideuteromethoxy)ethane: (Table 2, entries 6,7). ^1H NMR (300.13 MHz, $CDCl_3$, room temp.): δ = 4.56 [t, $J_{H,H}$ = 5.2 Hz, 1 H, $CH(OCD_3)_2$], 1.26 (dt, $J_{H,H}$ = 5.2, $J_{H,D}$ = 1.8 Hz, 2 H, CH_2D) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, room temp.): δ = 101.2 [s, $CH(OCD_3)_2$], 47.5 (sept, $J_{C,D}$ = 21.3 Hz, OCD_3), 17.2 (t, $J_{C,D}$ = 18.7 Hz, CH_2D) ppm. GC/MS: *m/z* (%) = 96 (5) [$C_4H_3O_2D_7$], 81 (53) [$C_3HO_2D_6$], 63 (100) [$C_2HO_2D_3$], 44 (27) [CO_2].

1-Bromo-1-deutero-2,2-bis(trideuteromethoxy)ethane: (Table 2, entry 8). ^1H NMR (300.13 MHz, $CDCl_3$, room temp.): δ = 4.55 [d, $J_{H,H}$ = 5.2 Hz, 1 H, $CH(Ocd_3)_2$], 3.40 (m, 1 H, CHDBr) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, room temp.): δ = 103.1 [s, $CH(Ocd_3)_2$], 29.8 (t, $J_{C,D}$ = 23 Hz, CHDBr) ppm. GC/MS: *m/z* (%) = 176 (6) [$C_4H_2O_2D_7Br$], 142 (30) [$C_3H_2OD_4Br$], 108 (5) [C_2H_2DBr], 81 (100) [HBr].

1-Trideuteromethoxy-1,3-cyclohexadiene: (Table 2, entry 9). ^1H NMR (300.13 MHz, $CDCl_3$, room temp.): δ = 5.86 [m, 1 H, $CH_{(3)}$], 5.40 [br. d, $J_{H4,H3}$ = 7.9 Hz, 1 H, $CH_{(4)}$], 4.97 [d, $J_{H,H}$ = 5.1 Hz, 1 H, $CH_{(2)}$], 2.21 [m, 4 H, $CH_{2(5)}CH_{2(6)}$] ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, room temp.): δ = 127.8 (s, C3), 120.1 (s, C1), 113.4 (s, C4), 76.7 (s, C2), 54.8 (sept, $J_{C,D}$ = 21.3 Hz, OCD_3), 25.1 (s, C5), 22.2 (s, C6) ppm. GC/MS: *m/z* (%) = 114 (40) [$C_8H_7O_2D_7$], 96 (100) [C_6H_8O], 80 (62) [C_6H_8].



4-Deutero-5,5-bis(trideuteromethoxy)pentan-1-deuterol: (Table 2, entry 10). ^1H NMR (300.13 MHz, $CDCl_3$, room temp.): δ = 4.50 [br. s, 1 H, $CH(OCD_3)_2$], 3.68 (br. t, $J_{H,H}$ = 6.2 Hz, CH_2OD), 1.53−1.80 (m, 5 H, $CHDCH_2CH_2$) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, room temp.): δ = 99.8 [s, $CH(OCD_3)_2$], 61.7 (s, CH_2OD), 48.1 (sept, $J_{C,D}$ = 21.8 Hz, OCD_3), 29.8 (t, $J_{C,D}$ = 19.7 Hz, CHD), 18.9 and 25.1 (all s, CH_2CH_2) ppm. GC/MS: *m/z* (%) = [$C_7H_8O_3D_8$] not observed, 120 (30) [$C_6H_6O_2D_5$], 86 (70) [C_5H_8OD], 57 (100) [C_4H_7D], 42 (60) [C_3H_4D].

Oligomerisation of Ethylene to Linear α-Olefins by new C_s- and C_1-Symmetric [2,6-Bis(imino)pyridyl]iron and -cobalt Dichloride Complexes

Claudio Bianchini,*[a] Giuseppe Mantovani,[a] Andrea Meli,[a] Fabio Migliacci,[a] Fabrizio Zanobini,[a] Franco Laschi,[b] and Anna Sommazzi[c]

Keywords: Cobalt / Ethylene / Iron / N ligands / Oligomerisation

A new family of C_s- and C_1-symmetric 2,6-bis(imino)pyridyl ligands has been synthesised. These ligands, which differ from their known counterparts in the contemporaneous presence of alkyl and aryl substituent at the ketimine nitrogen atoms, form stable, five-coordinate complexes with $FeCl_2$ and $CoCl_2$. All ligands and catalysts have been fully characterised both in the solid state and in solution. A single-crystal X-ray analysis of $[CoCl_2\{2\text{-}[CMe{=}N\text{–}(2,6\text{-dimethylphenyl})]\text{-}6\text{-}(CMe{=}N\text{–}C_6H_{11})C_5H_3N\}]\cdot H_2O$ shows the metal centre to adopt a highly distorted square-pyramidal geometry. In combination with methylaluminoxane (MAO), both iron and cobalt compounds act as effective and selective (> 99%) catalysts for the oligomerisation of ethylene to a Schulz–Flory distribution of α-olefins, with the α factor ranging from 0.61 to 0.91. The iron catalysts exhibit TOFs as high as $7\cdot10^5$ mol C_2H_4 (mol of cat × h)$^{-1}$ and are much more active than their cobalt analogues. Experiments at different ethylene pressures with the iron catalysts showed that both the propagation rate and the chain transfer rate are first order in ethylene pressure.

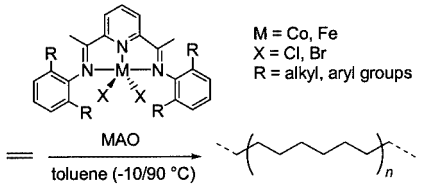
Introduction

In 1998, Brookhart and Gibson independently discovered that [2,6-bis(arylimino)pyridyl]iron and -cobalt dihalides, when activated by MAO, are effective catalysts for the polymerisation of ethylene to high-density polyethylene (PE) with productivities as high as those of the most efficient metallocenes (Scheme 1).[1]



Scheme 1

The advantages of these late transition metal systems over other types of single-site Ziegler–Natta catalysts (e.g., metallocenes, constrained-geometry early transition metal complexes) are multiple, ranging from their ease of preparation and handling to the use of low-cost metals with negligible environmental impact. Another intriguing feature of [bis(arylimino)pyridyl]iron and -cobalt precursors is provided by the facile tuneability of their polymerisation activity by simple modification of the ligand architecture. Indeed, previous studies have shown that the size and regiochemistry of the substituents in the iminoaryl groups are of crucial importance in controlling the polymerisation and oligomerisation of ethylene, and also the isospecific polymerisation of propene.[1–3] In particular, the presence of substituents in both *ortho* positions on each aryl group results in the formation of high molecular weight PE with molecular weights depending upon the size of these substituents.[1] In contrast, the presence of one *ortho* substituent generates catalysts that selectively oligomerise ethylene to Shultz–Flory distributions of α-olefins.[2] Experimental and theoretical studies agree in identifying restricted rotation around the two nitrogen–aryl bonds as the key factor responsible for disfavouring chain transfer over chain propagation.[1,3c,4] Only when the aryl groups are very large (e.g., naphthyl, pyrenyl, 2-benzylphenyl) does restricted rotation apparently operate without the need for two *ortho* substituents, PE being formed.[5]

In this paper we demonstrate that the presence of two arylimino groups in the bis(imino)pyridyl backbone is not a mandatory condition to generate a ligand capable of oligomerising ethylene to α-olefins in conjunction with $FeCl_2$/

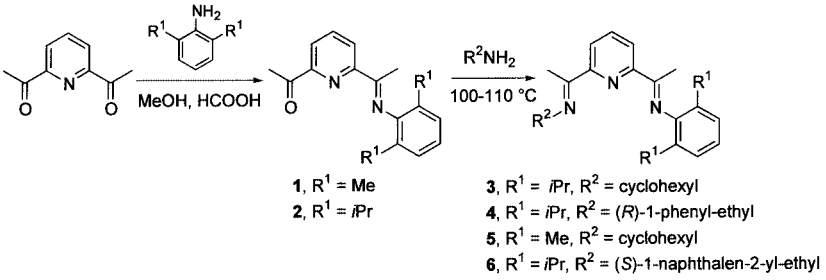


Scheme 2

MAO or $CoCl_2$/MAO. In fact, an aryl group can be replaced by an alkyl group and the resultant [2-(alkylimino)-6-(arylimino)pyridyl]Fe^{II} or -Co^{II} dichloride complexes will oligomerise ethylene as efficiently and selectively as the 2,6-bis(arylimino)pyridyl congeners. It is also shown here that the size of the alkyl group can control both the catalyst productivity and the Schulz−Flory parameters.

Results

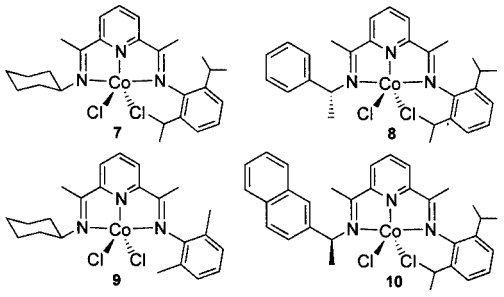
Synthesis and Characterisation of Ligands

The 2-(alkylimino)-6-(arylimino)pyridyl ligands **3**−**6** have been synthesised via keto-imine intermediates obtained by treatment of 2,6-diacetylpyridine with the appropriate aniline (0.9 equiv.) in MeOH with formic acid as promoter (Scheme 2).

An important contribution to the selectivity of this reaction was made by the low solubility of the monoimine products, which precipitated upon formation and so suppressed further condensation with the aniline. The bis(imino)pyridine products were indeed obtained in low amounts (2−4%), however, and so the crude reaction products were purified by repeated extraction of the (imino)pyridyl ketones with boiling ethanol. Once purified, these products were treated with the appropriate neat primary amine at 100−110 °C, in the presence neither of solvent nor of acid promoter, to give the expected 2,6-bis(imine)pyridyl ligands. Under these mild conditions, the bis(imino) compounds were obtained selectively.

Synthesis and Characterisation of the Cobalt(II) Complexes

The [2,6-bis(imino)pyridyl]Co^{II} complexes illustrated in Scheme 3 were prepared in acceptable yields by heating of an *n*BuOH solution containing equimolar amounts of anhydrous $CoCl_2$ and ligand at reflux for ca. 10 min. Crystalline compounds were obtained upon cooling to room temperature. Complexes **7** and **9** exhibit C_s symmetry, while complexes **8** and **10** are C_1-symmetric by virtue of the simultaneous presence of 2,6-disubstituted aryl and chiral alkyl groups at the imine nitrogen atoms.



Scheme 3

All complexes are green, crystalline solids and are fairly soluble in polar organic solvents such as THF, dichloromethane, and 1,2-dichloroethane, in which they behave as non-electrolytes. Their solubilities in toluene and other hydrocarbons are very low. All compounds are reasonably thermally stable and air-stable both in the solid state and in solution. For caution's sake, however, their preparation and manipulation in solution were carried out under dry N_2.

Magnetic data at room temperature and relevant IR and UV/Vis absorptions for each complex are reported in the Exp. Sect. The IR spectra of all the compounds each show a red shift of ν(C=N) by ca. 50−60 cm^{-1} relative to the corresponding free ligand, which reflects the coordination of the imine nitrogen atoms to the cobalt atom.

All the complexes are high-spin in the solid state, with μ_{eff} at room temperature ranging from 4.6 to 4.8 BM, which is typical for high-spin cobalt(II) five-coordinate complexes with 2,6-bis(imino)pyridyl ligands.[6] In principle, five-coordinate metal complexes may adopt either square-pyramidal or trigonal-bipyramidal geometries. In idealised C_{4v} and D_{3h} symmetries, a d^7 metal ion may have either a low- or a high-spin configuration, according to whether the energy separation between the two highest orbitals in each symmetry is higher or lower than the spin-pairing energy. A donor atom set consisting of three nitrogen and two chlorine atoms has invariably been found to stabilise the high-spin configuration of cobalt(II).[6] As shown by a single-crystal X-ray analysis on the cyclohexyl/2,6-dimethylphenyl

derivative **9**·H_2O (see below), the presence of the rigid chelating 2,6-bis(imino)pyridyl ligand causes important distortions from the idealised geometries. However, these are apparently not so significant as to favour spin pairing and give a doublet ground state (S = 1/2).

An ORTEP drawing of the molecular structure of **9**·H_2O is shown in Figure 1. Perusal of the bond angles around the metal centre shows that the coordination geometry in **9**·H_2O is greatly distorted from any idealised five-coordinate structure, and may be roughly described as a square pyramid with one chloride ion (Cl1) occupying the apical position. The presence of two chemically different imine nitrogen atoms in **9**·H_2O contributes substantially to the observed stereochemical distortions. Noticeable asymmetries affect the Co−N(imine) distances in fact: Co1−N1 is unusually short [2.185(6) Å] and Co1−N2 is exceedingly long [2.348(6) Å]. These differences are most probably due to the higher nucleophilicity of the alkyl-substituted nitrogen atom N1 relative to the aryl-substituted N2. Indeed, the N1−Co1−N2 angle of 149.3(2)° allows one to invoke *trans* influence effects. In contrast, due to the substantial departures from idealised square-pyramidal geometry, these effects cannot account for the Co−Cl distances, which (although less pronouncedly) are significantly different from one another [Co1−Cl1 2.243(2); Co1−Cl2 2.269(2) Å]. As would be expected,[1d−1e][2b][3c] the M−N(pyridyl) bond [Co1−N3 2.032(6) Å] is shorter than both the M−N(imino) bonds, which have retained the imine C=N double bond character [N1−C1 1.266(10) Å, N2−C3 1.276(9) Å]. The deviation of the metal from the N_3 ligand plane is 0.06 Å. The plane of the 2,6-dimethyl-substituted aryl ring is oriented essentially orthogonally to the plane of the backbone [86.5(2)°].

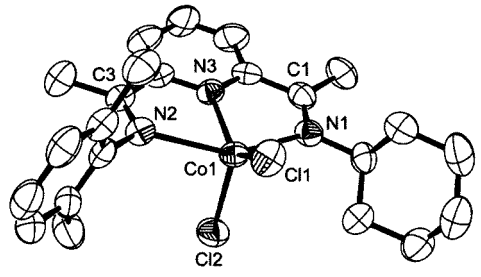


Figure 1. ORTEP drawing of **9**·H_2O (hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co1−N1 2.185(6), Co1−N2 2.348(6), Co1−N3 2.032(6), Co1Cl1 2.243(2), Co1−Cl2 2.269(2); N3−Co1−N1 76.7(2), N3−Co1−Cl1 131.87(18), N1−Co1−Cl1 99.91(18), N3−Co1−Cl2 107.58(18), N1−Co1−Cl2 99.80(17), Cl1−Co1−Cl2 120.12(9), N3−Co1−N2 73.4(2), N1−Co1−N2 149.3(2), Cl1−Co1−N1 94.88(15), Cl2−Co1−N2 95.72(16)

The reflectance and solution UV/Vis spectra of the [2,6-bis(imino)pyridyl]Co^{II} complexes are similar to one another, indicating that the primary stereochemistry is the same both in the solid state and in solution: intermediate between the square pyramid and the trigonal bipyramid.[6b] Although the spectra show some changes in band shape and frequency as the substituents at the imine nitrogen atoms vary, these are not sufficient for them to be due to substantial differences in structure. Such differences are probably due to the different steric bulks of the substituents in the complexes.

The presence of three unpaired electrons (S = 3/2) in each complex molecule makes all the Co^{II} compounds X-band-EPR-silent at room temperature both in the solid state and in CH_2Cl_2 solution. A low-temperature EPR study of the X-band was carried out on derivative **8** in CH_2Cl_2 (Scheme 3). At 4 K the spectrum displays a broad and poorly resolved rhombic structure with g_1 = 5.06(8) > g_2 = 3.03(8) > g_3 = 1.95(8) ≠ g_{elect} [<g> = 3.35(8); a_1 40(8) G, a_2 80(8) G, a_3 94(8) G; <a> 71(8) G], which is typical of an "S" = 1/2 fictitious spin (Figure 2). Indeed, the spectrum may be interpreted in terms of an "S" = 1/2 effective spin Hamiltonian occasioned by large Zero Field Splitting (ZFS) effects.[7−11] In fact, we observed a reversible temperature dependence of the signal intensity, which rules out the occurrence of a spin transition. This behaviour is not unusual for $S > 1/2$ paramagnetic metal species affected by important ZFS effects (S = 3/2) as well as noticeable spin-orbit coupling in highly distorted coordination geometries.[7,8,11] All g_i regions show hyperfine structure apparently due to magnetic interaction with the ^{59}Co nucleus (S = 7/2). However, the poor resolution and the presence in each region of more than eight bands, as expected for coupling to cobalt, do not rule out either interactions with other spin-active nuclei in the molecule (e.g., ^{14}N) or the presence of different geometric isomers.

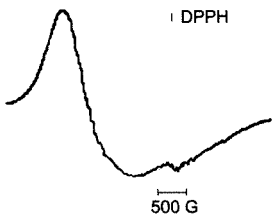

Figure 2. X-band EPR spectrum of cobalt(II) complexes **8** in CH_2Cl_2 at 4 K

The ^1H NMR spectrum of complex **7** was acquired in oxygen-free CD_2Cl_2 solution at 21 °C on a 500 MHz instrument (Figure 3). All protons resonate at chemical shifts significantly different from those of the corresponding protons in the free ligands, which is consistent with the paramagnetic nature of the compound. Analysis of the ^1H NMR resonances suggests that the isotropic shift (i.e., the difference between the observed chemical shift and the reference diamagnetic shift) is almost completely attributable to a Fermi contact contribution.[12] Unambiguous signal assignment was achieved on this basis (Table 1). Overall, the NMR spectrum is similar to that reported by Gibson and co-workers for {2,6-bis[1-(2,6-diisopropylphenylimino)-ethyl]pyridine}cobalt dichloride.[1d] As in the spectrum of this more symmetric complex, the 3-, 4-, and 5-hydrogen atoms of the central pyridine ring and the C*H*Me_2 hydrogen atom exhibit remarkable paramagnetic shifts and line

broadening as well. The strong coordination of the cyclohexyl-substituted imine arm to the cobalt atom, given in evidence in the X-ray structure, is confirmed by the large downfield shift (δ = 143.42 ppm) of the NC*H* resonance as well as its broad linewidth. Similarly, the coordination of both imine nitrogen atoms is demonstrated by the chemical shifts of the N=C*Me* methyl groups. The presence of two signals for the CH*Me* protons is consistent with hindered rotation of the aryl ring about the N−C axis.[1d]

A cyclic voltammetry study in CH_2Cl_2 was performed on complex **9**, containing cyclohexyl and 2,6-dimethylphenyl groups on the imine nitrogen atoms (Figure 4a). The complex undergoes one irreversible one-electron oxidation at E_p = +1.18 V and another irreversible one-electron reduction at E_p = −0.99 V even at very high scan rates.

Synthesis and Characterisation of the Iron(II) Complexes

Like the cobalt(II) derivatives, the iron(II) complexes could be conveniently prepared by heating of a solution containing anhydrous $FeCl_2$ and 1 equiv. of the ligand at reflux in *n*BuOH for ca. 10 min (Scheme 4). Crystalline compounds were obtained upon cooling to room temperature.

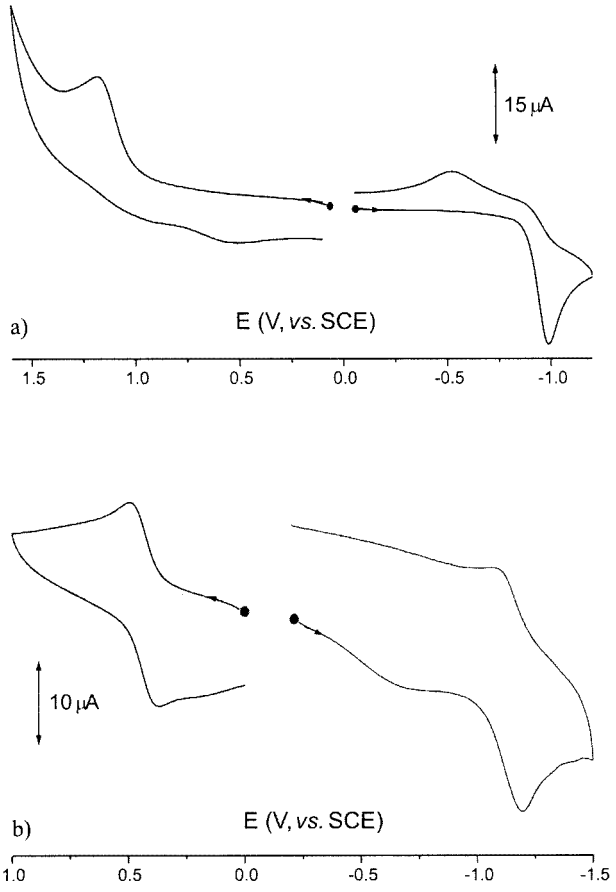

Figure 4. Cyclic voltammograms of the cobalt(II) and iron(II) complexes **9** (a) and **13** (b) in CH_2Cl_2 [$6\cdot10^{-4}$ M, scan rate 0.2 $V\cdot s^{-1}$; Bu_4NPF_6 (0.2 M as supporting electrolyte)]

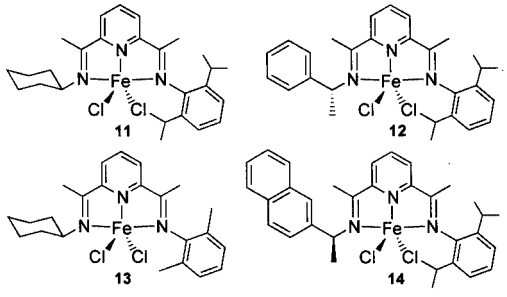

Scheme 4

All compounds are only sparingly soluble in aromatic hydrocarbons, while dissolving fairly well in THF, MeCN, CH_2Cl_2, and 1,2-dichloroethane. In the last of these they behave as non-electrolytes. The solids are fairly air-stable, whereas they decompose in solution unless protected by dinitrogen or argon.

Magnetic data at room temperature and relevant IR absorptions for the [2,6-bis(imino)pyridyl]Fe^{II} compounds are provided in the Exp. Sect. As in the IR spectra of the Co^{II} derivatives, ν(C=N) is generally red-shifted by ca. 50−60 cm^{-1} relative to the corresponding free ligand, reflecting the coordination to the metal centre.

All the compounds are dark blue and exhibit high-spin electronic configurations, as shown by their magnetic moments μ_{eff}, which range from 5.5 to 5.7 BM and are similar to those reported for several high-spin iron(II) five-coordinate complexes with quintuplet ground states.[1,6] The quintuplet ground state makes the complexes EPR-silent even at 4 K and irrespective of the EPR frequency.

Like the [2,6-bis(imino)pyridyl]Co^{II} complexes, the Fe^{II} derivatives might adopt either square-pyramidal or trigonal-bipyramidal structures with various degrees of geometrical distortion. In either geometry, a d^6 metal ion may assume a singlet, a triplet or a quintuplet ground state, depending on the nature of the donor atom set.[14] A donor atom set comprising three nitrogen and two chlorine atoms generally stabilises the high-spin quintuplet configuration for iron(II), as is in fact observed for these bis(imino)pyridyl complexes.[6,13]

None of the [2,6-bis(imino)pyridyl]Fe^{II} complexes described in this work has been studied by X-ray diffraction methods, but the molecular structures of several Fe^{II} derivatives bearing aryl substituents on the imine nitrogen atoms are available from the literature.[1a,1d,2,3c] In most cases the geometry at the iron centre can be described as distorted trigonal-bipyramidal with the pyridyl nitrogen atom and the two chloride ligands forming the equatorial plane; only when the aryl rings on the imine nitrogen atoms bear two bulky substituents − as in {2,6-[2,6-(*i*Pr)$_2$C$_6$H$_3$NCMe]$_2$-C$_5$H$_3$N}iron dichloride − does iron tend to adopt a distorted square-pyramidal coordination geometry.[1c]

The [2,6-bis(imino)pyridyl]Fe^{II} complexes studied here exhibit either C_1 or C_s symmetry by virtue of the simultaneous presence of substituted aryl groups and either chiral [CH(Me)Ph] or cyclic (C_6H_{11}) alkyl groups at the imine nitrogen atoms. The combined action of the ketimine group and the two *o*-alkyl substituents should lock the aryl ring in an orthogonal conformation with respect to the N_3 ligand plane both in the solid state and in solution, while the alkyl group at the other imine nitrogen atom should rotate freely about the C−N axis in solution (vide infra).

Trigonal-bipyramidal structures for all these iron(II) complexes are supported by the UV/Vis spectra in CH_2Cl_2 solution. Some detailed studies of the electronic spectra of five-coordinate Fe^{II} complexes with N_3Cl_2 donor atom sets were reported in the late 1960s, mainly by Ciampolini and coworkers.[14] On the basis of these studies, a band in the 7000−8400 cm^{-1} region, common to all Fe^{II} complexes investigated in this work, can be unambiguously correlated with a spin-allowed transition in trigonal-bipyramidal high-spin Fe^{II} complexes such as [Fe(dienMe)Cl_2] or [Fe(trenMe)Cl]Cl [dienMe = bis(2-dimethylaminoethyl)methylamine; trenMe = tris(2-dimethylaminoethyl)amine].[15] Those complexes also each showed a band at ca. 4000 cm^{-1}, not detectable for our compounds due to the measuring limit of our spectrophotometer. Unlike the trenMe and dienMe complexes, the spectra of **11**−**14** each contain a band at ca. 20000 cm^{-1} that may be attributable to a metal-to-ligand charge transfer (MLCT). Absorption bands at ca. 14500 cm^{-1} have been reported by Gibson for C_{2v}-symmetric [2,6-bis(imino)pyridyl]Fe^{II} complexes and also attributed to MLCT.[1d] In general, MLCT bands fall at higher energy than those observed by Gibson, but a reduction in frequency may occur for highly π-conjugated ligand systems, which may be the case for C_{2v}-symmetric 2,6-bis(imino)pyridyl ligands.[6b]

The reflectance spectra of **11**−**14** are similar to one another and fully comparable with the solution spectra, which indicates that the primary stereochemistry of the Fe^{II} complexes is the same both in the solid state and in solution. As an example, the spectra of **12** in the solid state and in CH_2Cl_2 solution are given in Figure 5.

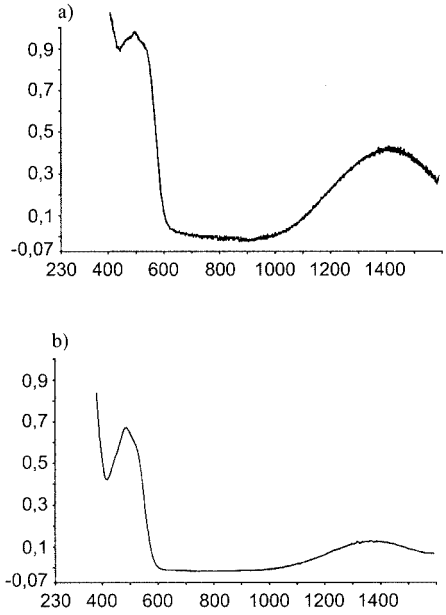

Figure 5. Reflectance spectrum of **12** (a); electronic spectrum of **12** (b) in CH_2Cl_2 solution

The ^{1}H NMR spectrum of **11** was acquired in deaerated CD_2Cl_2 solutions at 21 °C (Figure 6). All protons resonate at chemical shifts significantly different from the corresponding protons in the free ligands, which is consistent with the paramagnetic nature of the compounds. Band assignments are given in Table 2.

Despite the presence of the same ligand, the ^{1}H NMR spectrum of the iron(II) complex **11** is notably different from that of the cobalt(II) analogue **7** (Figure 3), which reflects a structural divergence in solution. In particular, the resonances of four hydrogen atoms of the cyclohexyl group are shifted to high field (ca. −30 and −37 ppm) and have very broad linewidths, which suggests that this cyclohexyl ring is spatially very close to the paramagnetic iron centre on the NMR timescale. No such linewidth broadening for the cyclohexyl resonances was observed for the Co^{II} analogue **7**. The presence of two relatively narrow signals for the *i*Pr groups confirms the hindered rotation of the aryl group.

Unlike the cobalt analogue **9**, the iron complex **13** can be reversibly oxidised ($E^{0\prime}$ = +0.43 V) to give the yellow iron(III) derivative [$FeCl_2${2-[CMe=N(2,6-dimethylphenyl)]-6-(CMe=NC$_6$H$_{11}$)C$_5$H$_3$N}]$^+$, which is stable in CH_2Cl_2

Cy	−2.99 (s, 2 H), −7.85 (s, 2 H), −29.10 (s, 2 H), −37.18 (br. s, 2 H), 1.28 (s, 1 H), −4.72 (s, 1 H), −6.74 (s, 1 H)

solution, although no attempt was made to isolate it in the solid state (Figure 4b). Stable C_2-symmetric [2,6-bis(arylimino)pyridyl]Fe^{III} dihalide complexes have been prepared by Gibson and shown to have the same activity as the Fe^{II} precursors in the oligomerisation of ethylene, as a consequence of instantaneous Fe^{III} reduction to Fe^{II} by MAO.[1d,16] Figure 4b also shows that the Fe^{I} derivative, obtained by a partially reversible one-electron reduction of **13** (at $E^{0\prime} = -1.15$ V), has a relatively short lifetime ($t_{1/2}$ = 0.5 s).

Oligomerisation of Ethylene by the Cobalt(II) and Iron(II) Dichloride Complexes, Activated by MAO

The [bis(imino)pyridyl]cobalt (**7**−**10**) and -iron (**11**−**14**) complexes, in combination with the activator MAO, were evaluated as catalysts for the oligomerisation of ethylene in toluene.

Table 3 reports on the results of reactions carried out under a variety of experimental conditions. In all cases the addition of ethylene to the catalyst/co-catalyst mixture resulted in a rapid exothermic event, indicative of no induction period. Initially, all catalysts were tested at 4.1 bar C_2H_4 pressure and 25 °C for 15 min, with 250 equiv. of MAO as both co-catalyst and reactor scavenger. Catalyst activities [mol of C_2H_4 converted (mol of M × h)$^{-1}$] were calculated from the GC readings, by use of extrapolated values for 1-butene.

Table 3. Ethylene oligomerisation with the iron(II) and cobalt(II) catalysts

Entry[a]	Pre-catalyst	Pressure [bar]	TOF [10^{-5}][b]	α	β

[a] Reaction conditions: complex (12 μmol), toluene (100 mL), MAO (250 equiv.), 15 min, 25 °C. [b] TOF: mol of C_2H_4 converted (mol of M × h)$^{-1}$. [c] 80 °C. [d] Only butenes.

The four iron complexes **11**−**14** were all active catalysts for the production of α-olefins with Schulz−Flory distributions.[17] No appreciable formation either of internal olefins or of odd carbon oligomers was observed (Figure 7).

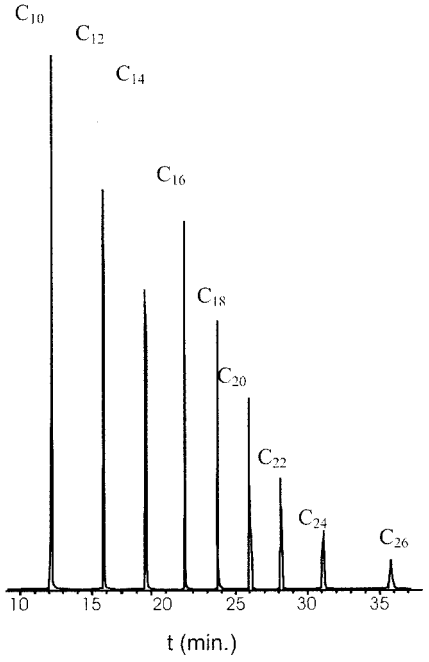

Figure 7. GC trace relative to Entry 1 in Table 3, showing the α-olefins distribution from C_{10} to C_{26}

The catalytic activity increased with the bulkiness of the alkyl substituent at the imine carbon atom (Entries 1, 2, 4), but decreased with the size of the substituents on the aryl ring (Entries 1, 3). The naphthyl group containing catalyst was as active as the C_2-symmetric [2,6-bis(arylimino)pyridyl]iron(II) precursors described by Brookhart and Gibson.[2] Notably, the probability of propagation, indicated by the

Schulz−Flory parameter α,[17] increased steadily with the overall steric hindrance of the imine substituents.

Experiments with precursor **13** in the C_2H_4 pressure range from 4.1 to 10.3 bar showed a linear dependence of activity on the pressure, while the α factor did not vary substantially (Entries 3, 5−7). No isomeric oligomer formed either by alkene isomerisation or by reincorporation of α-olefin products into oligomers later in the reaction was observed. The absence of reincorporation mechanisms was confirmed by independent experiments in which the oligomerisation of ethylene with **13** was carried out in the presence of an excess of 1-undecene. In fact, no odd-numbered carbon oligomer was formed in the temperature range from 25 to 80 °C.[2a] Similarly, these catalysts did not promote head-to-head dimerisation of α-olefins to internal olefins, a reaction that [2,6-bis(arylimino)pyridyl]iron complexes are able to catalyse.[18]

Experiments at relatively high temperature (80 °C) with precursor **13** showed a slight decrease in productivity and α factor as well. Both phenomena have precedent for [2,6-bis(arylimino)pyridyl]iron precursors.[1d] In particular, the decrease in productivity with temperature has been ascribed to the combined effects of faster catalyst degradation and lower ethylene solubility.[1d]

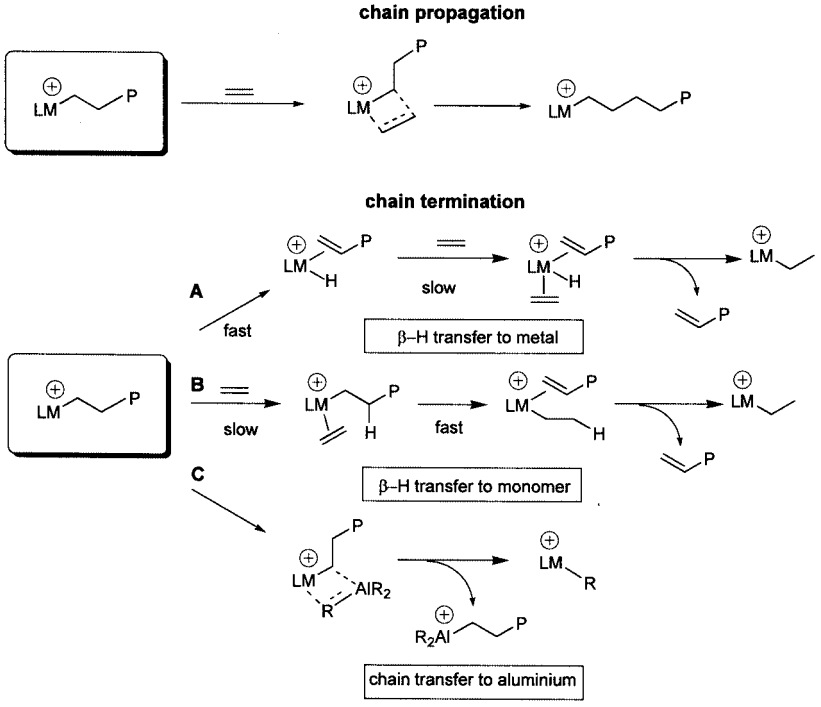
The activities of the cobalt catalysts **7**−**10** (Entries 9−12) were approximately one order of magnitude lower than those of the analogous iron(II) derivatives. The sensitivity to steric effects was even higher for cobalt than for iron, as shown by the catalyst precursors containing the cyclohexyl substituent (Entries 9, 11), which gave only small amounts of 1-butene, indicating a prevalence of chain transfer over chain propagation.

Discussion

The nature and statistical distribution of the α-olefins produced with the [2-(alkylimino)-6-(arylimino)pyridyl]iron and -cobalt catalysts described in this work are consistent with a mechanism involving: (i) metal−alkyl initiators produced by the action of MAO on the dichloride precursors, (ii) propagation by migratory insertion of Co(alkyl)(ethylene) (Cossee−Arlman mechanism), and (iii) termination by chain transfer (Scheme 5).[2,19]

In line with the large majority of catalytic systems for Schulz−Flory oligomerisations of ethylene, the rates of propagation and chain transfer exhibited by the iron catalysts do not differ significantly, the β parameter ($\beta = r_{transfer}/r_{propagation}$) varying between 0.10 and 0.52. It has been found that the activity of the iron catalysts shows a linear dependence on the ethylene pressure, while α is independent of the pressure. Accordingly, both chain propagation and chain transfer are first-order in monomer concentration, as previously observed for [2,6-bis(arylimino)pyridyl]Fe^{II} and -Co^{II} oligomerisation catalysts.[2]

Late transition metal catalysts may undergo chain transfer in ethylene polymerisation by three main mechanisms: β-hydrogen transfer to the metal atom (**A**), β-hydrogen transfer to the monomer (**B**), and chain transfer to aluminium (**C**) (this generally occurs at low pressure) (Scheme 5).[1d,20] The last mechanism can safely be ruled out in the oligomerisation reactions reported here, as only α-olefins were produced, with no saturated hydrocarbon. It is therefore very likely that chain transfer proceeds either by path **A**, involving an associative displacement step followed by β-hydrogen transfer to the metal atom, or by path



Scheme 5. Chain propagation and chain transfer mechanisms proposed for polymerisation of ethylene by late transition metal catalysts

B, involving direct β-H transfer to the incoming monomer with no formation of metal hydride. The exclusive production of α-olefins with no appreciable formation of internal olefins might be taken as indirect evidence for the occurrence of path **B**, as it does not involve the formation of the metal hydride necessary for isomerisation. Moreover, calculations suggest its involvement in ethylene polymerisation by late transition metal systems.[20] We wish to stress, however, that the chain transfer mechanisms **A** and **B** are kinetically indistinguishable, and so no preference is allowed; nor may one exclude their simultaneous occurrence.

Overall, the performances of these C_s- and C_1-symmetric iron and cobalt catalysts do not diverge substantially from those of the 2,6-bis(arylimino) complexes studied by Brookhart and Gibson, which means that the presence of aryl groups on both ketimine nitrogen atoms is not a necessary condition to produce an ethylene oligomerisation catalyst in conjunction with iron or cobalt dihalides and MAO. Actually, these catalysts polymerise ethylene only when the aryl rings are 2,6-substituted by alkyl groups. As a general trend, α-olefins are produced with one alkyl substituent, while the presence of two alkyl groups results in the formation of PE with molecular weight increasing with the size of these alkyl moieties.[1,2] It has been experimentally and theoretically demonstrated that the steric interaction between the ketimine methyl group and the alkyl substituents increases the barrier to aryl rotation and effectively locks the rings in an orthogonal conformation with respect to the N_3M plane on the timescale of polymerisation.[1d][3c] The steric protection provided by the orthogonal aryl rings contributes to retard the chain transfer, which − irrespective of the mechanism − requires access to the metal centre above or below the N_3M plane.[4] Apparently, one 2,6-substituted aryl moiety is sufficient to slow down the chain-transfer rate and allow oligomer formation. The high α value (0.91) obtained with the naphthyl-substituted catalysts (Table 3, Entries 4 and 12) suggests that polymerisation to high molecular weight PE might be achieved by further increasing the size of the C=N−alkyl group. Studies in this direction are currently being carried out in our laboratory.

The thorough chemical-physical study of the catalyst precursors described in this work suggests that cobalt(II) prefers to be square-pyramidal, while iron(II) prefers to be trigonal-bipyramidal. This behaviour of cobalt(II) and iron(II) metal ions is amply recognised in the literature.[6a,21] With no intention of minimising the importance of electronic effects related to the different d-electron count, it is possible that these structural differences (with implications on the metal spin state),[6a] if maintained during catalysis, may contribute to rendering the cobalt catalysts less active than the iron ones. Square-pyramidal coordination, for example, generally produces less steric congestion at the metal centre than trigonal-bipyramidal coordination and requires less energy to attain the octahedral geometry that seems to feature in relevant transition states in ethylene polymerisation catalysed by five-coordinate [2,6-bis(arylimino)pyridyl]Fe^{II} and -Co^{II} complexes.[4]

Conclusion

C_1- and C_s-symmetric 2-(alkylimino)-6-(arylimino)pyridyl ligands, readily prepared by condensation of chiral and achiral primary amines with 2-(acetyl)-6-(arylimino)pyridine intermediates, coordinate to iron(II) and cobalt(II) dichlorides to give monomeric, paramagnetic complexes. The cobalt complexes adopt distorted square-pyramidal structures both in the solid state and in solution, while the coordination geometries of the iron catalysts can be better described as trigonal-bipyramidal. All the complexes can be activated with MAO to give ethylene oligomerisation catalysts with complete selectivity for α-olefins. Unlike [2,6-bis(arylimino)pyridyl]iron precursors, no head-to-head dimerisation of α-olefins to internal olefins was observed. Iron-based catalysts can be more than one order of magnitude more active than cobalt-based systems. The catalytic activity increases with the bulkiness of the alkyl substituent and decreases with the size of the substituent on the aryl ring. The Schulz−Flory oligomer distribution factor α is not sensitive to the metal centre, but it increases with the size of the alkyl and aryl groups. Both chain propagation and chain transfer are first order in ethylene concentration, and chain transfer proceeds exclusively by β-H transfer.

Experimental Section

General Procedures: All air- and water-sensitive reactions were performed in flame-dried flasks under dinitrogen. Solid compounds were collected on sintered glass frits and washed with appropriate solvents before being dried in a stream of dinitrogen. Anhydrous THF and Et_2O were obtained by distillation from sodium/benzophenone ketyl, while CH_2Cl_2 and MeOH were distilled from CaH_2 and Mg, respectively. All the other reagents and solvents were used as purchased from commercial suppliers. Analytical TLC was performed on pre-coated silica gel 60 F_{254} and/or neutral Al_2O_3 N/UV_{254} plates and developed in an appropriate solvent system. The products were viewed with the aid of UV light (254 nm), I_2 vapour, 2.5% $(NH_4)_6Mo_7O_{24}$ + 1% $(NH_4)_4Ce(SO_4)_4$ in 10% H_2SO_4 and warming. Deuterated solvents for NMR measurements were dried with molecular sieves. ^1H and $^{13}C\{^1H\}$ NMR spectra were obtained with a Bruker ACP 200 instrument working at 200.13 and 50.32 MHz, respectively. All chemical shifts are reported in ppm (δ) relative to tetramethylsilane, referenced to the chemical shifts of residual solvent resonances (^1H and ^{13}C). The multiplicity of the $^{13}C\{^1H\}$ NMR spectra were determined by the DEPT 135 technique and are quoted as: CH_3, CH_2, CH, and C for primary, secondary, tertiary, and quaternary carbon atoms, respectively. Two-dimensional ^1H and ^{13}C NMR spectra were recorded at 21 °C with a Bruker Avance DRX 500 spectrometer operating at 500.132 and 125.77 MHz, respectively, and equipped with a variable-temperature control unit accurate to ±0.1 °C. This instrument was also employed to study the paramagnetic metal complexes. Chemical shifts are relative to 0.03% (v/v) tetramethylsilane. The assignments of the signals was achieved with the aid of 1D spectra, 2D ^1H DQF-COSY, ^1H NOESY, and proton detected ^1H,^{13}C correlations (HMQC and HMBC) using non-spinning samples. 2D NMR spectra were recorded with pulse sequences suitable for phase-sensitive representations by TPPI. ^1H DQF-COSY experiments[22] were recorded with 1024 increments of size 2 K (with 16 scans each) cover-

ing the full range in both dimensions and with a relaxation delay of 1.5 s. ^{1}H NOESY measurements[23] were recorded with 1024 increments of size 2 K (with 16 scans each) covering the full range in both dimensions and with mixing times of 800 ms and a relaxation delay of 1.5 s. ^{1}H,^{13}C HMQC correlations[24] were recorded by use of the standard sequence with no decoupling during acquisition, 1024 increments of size 2 K (with 16 scans each) were collected, covering the full range in both dimensions with a relaxation delay of 1 s. ^{1}H,^{13}C HMBC correlations[25] were recorded by the standard sequence with no decoupling during acquisition and a low-pass *J*-filter to suppress one-bond correlations, 1024 increments of size 2 K (with 32 scans each) were collected, covering the full range in both dimensions, with a relaxation delay of 0.8 s. EPR spectra were recorded for all the compounds at the X-band frequency (9.23 GHz) with a Varian ESR9 spectrometer equipped with a continuous-flow ^{4}He cryostat to work at 4 K. Elemental analyses were performed with a Carlo Erba Model 1106 elemental analyzer. UV/Vis spectra were recorded with a Perkin−Elmer Lamda 9 spectrophotometer. Infrared spectra were recorded with a Perkin−Elmer 1600 Series FT-IR spectrophotometer with samples mulled in Nujol between KBr plates. GC analyses were performed with a Shimadzu GC-14 A gas chromatograph equipped with a flame ionisation detector and a 30-m (0.25 mm i.d., 0.25 μm film thickness) SPB-1 Supelco fused silica capillary column. GC/MS analyses were performed with a Shimadzu QP 5000 apparatus equipped with a column identical to that used for GC analysis. Molar susceptibility analyses were performed with a Sherwood Scientific MSB AUTO balance. Materials and apparatus for electrochemistry have been described elsewhere.[26] Potential values are referred to the Saturated Calomel Electrode (SCE). Under the adopted experimental conditions the one-electron oxidation of ferrocene occurs at $E^{0\prime} = +0.39$ V.

1-{6-[(2,6-Dimethylphenyl)ethanimidoyl]-2-pyridinyl}-1-ethanone (1): Formic acid (50 μL) was added by syringe at 0 °C to a stirred solution of 2,6-diacetylpyridine (0.490 g, 3.0 mmol) and 2,6-dimethylaniline (0.33 mL, 0.327 g, 2.7 mmol) in MeOH (7 mL). Stirring was stopped, and the resulting solution was maintained at 0 °C for 24 h. The desired product precipitated as large, yellow crystals, which were separated by filtration (0.447 g, 1.680 mmol). A second crop (0.148 g, 0.556 mmol) was obtained from the mother liquor after cooling to 0 °C for 48 h. Overall yield 75%. M.p. 117−118 °C. IR: $\nu_{(C=N)}$ 1645 cm^{-1}, $\nu_{(C=O)}$ 1698 cm^{-1}. ^{1}H NMR (200.13 MHz, CD_2Cl_2): δ = 2.02 (s, 6 H, CH_3), 2.22 [s, 3 H, C(NAr)CH_3], 2.76 [s, 3 H, C(O)CH_3], 6.89−6.97 (m, 1 H, CH Ar), 7.05−7.10 (m, 2H CH Ar), 7.96 (m, 1H CH Ar), 8.10 (dd, *J* = 7.7, 1.2 Hz, 1 H, CH Ar), 8.56 (dd, *J* = 7.7, 1.2 Hz, 2 H, CH Ar) ppm. ^{13}C{^{1}H} NMR (50.32 MHz, $CDCl_3$): δ = 17.0 [1 C, C(NAr)*C*H$_3$], 18.6 (2 C, CH_3), 26.4 [1 C, C(O)*C*H$_3$], 123.3 (1 C, CH Ar), 123.9 (1 C, CH Ar), 125.2 (1 C, CH Ar), 126.0 (2 C, C Ar), 128.6 (2 C, CH Ar), 138.0 (1 C, CH Ar), 149.2 (1 C, C Ar), 153.1 (1 C, CH Ar), 156.2 (1 C, C Ar), 167.3 [1 C, *C*(NAr)CH$_3$], 200.7 [1 C, *C*(O)CH$_3$] ppm. $C_{17}H_{18}N_2O$ (266.34): calcd. C 76.67, H 6.81, N 10.53; found C 76.45, H 6.54, N 10.41.

1-{6-[(2,6-Diisopropylphenyl)ethanimidoyl]-2-pyridinyl}-1-ethanone (2): Formic acid (150 μL) was added by syringe at room temperature to a stirred solution of 2,6-diacetylpyridine (1.630 g, 10.0 mmol) and 2,6-diisopropylaniline (1.70 mL, 1.596 g, 9.0 mmol) in MeOH (15 mL). After 12 h, a yellow solid had formed, and this was filtered off and washed with cold (0 °C) MeOH. The precipitate was characterised as a mixture of the expected product (97%) and the corresponding 2,6-bis(imino)pyridyl compound (3%) (^{1}H NMR integration). The solid was suspended in refluxing ethanol and the resulting mixture was filtered while still hot. The solvent was removed from the filtrate under reduced pressure to give pure **1** as pale yellow crystals in 67% yield (2.17 g, 6.73 mmol). M.p. 182−184 °C. IR: $\nu_{(C=N)}$ 1648 cm^{-1}, $\nu_{(C=O)}$ 1698 cm^{-1}. ^{1}H NMR (200.13 MHz, $CDCl_3$): δ = 1.16 [d, *J* = 6.9 Hz, 6 H, CH(CH_3)(CH$_3$)], 1.17 [d, *J* = 6.9 Hz, 6 H, CH(CH$_3$)(CH_3)], 2.28 [s, 3 H, C(NAr)CH_3], 2.74 [sept, *J* = 6.9 Hz, 2 H, C*H*(CH$_3$)(CH$_3$)], 2.81 [s, 3 H, C(O)CH_3], 7.08−7.22 (m, 3 H, C*H* Ar), 7.96 (t, *J* = 7.8 Hz, 1 H, CH Ar), 8.16 (dd, *J* = 7.7, 1.2 Hz, 1 H, CH Ar), 8.58 (dd, *J* = 7.9, 1.2 Hz, 1 H, CH Ar) ppm. ^{13}C{^{1}H} NMR (50.32 MHz, $CDCl_3$): δ = 17.7 [1 C, C(NAr)*C*H$_3$], 23.5 [2 C, CH(*C*H$_3$)(CH$_3$)], 23.9 [2 C, CH(CH$_3$)(*C*H$_3$)], 26.4 [1 C, C(O)*C*H$_3$], 29.0 [2 C, *C*H(CH$_3$)(CH$_3$)], 123.2 (1 C, CH Ar), 123.7 (2 C, CH Ar), 124.4 (1 C, CH Ar), 125.2 (1 C, CH Ar), 136.4 (2 C, C Ar), 138.4 (1 C, CH Ar), 142.9 (1 C, C Ar), 153.1 (1 C, CH Ar), 156.2 (1 C, C Ar), 167.8 [1 C, *C*(NAr)CH$_3$], 200.8 [1 C, *C*(O)CH$_3$] ppm. $C_{21}H_{26}N_2O$ (322.45): calcd. C 78.22, H 8.13, N 8.69; found C 78.39, H 8.17, N 8.84.

***N*-{(*E*)-1-[6-(Cyclohexylethanimidoyl)-2-pyridinyl]ethylidene}-2,6-diisopropylaniline (3):** A mixture of **1** (0.170 g, 0.53 mmol) and cyclohexylamine (0.910 mL, 0.789 g, 7.95 mmol) was heated at 100 °C without stirring for 20 h. Elimination of excess cyclohexylamine by distillation under reduced pressure gave an oily material that was dissolved in 3−4 mL of MeOH and cooled to 0 °C. After 6 h, yellow crystals of the desired product were isolated by filtration (0.153 g, 0.38 mmol, yield 72%). M.p. 186−188 °C. IR: $\nu_{(C=N)}$ 1636 cm^{-1}. ^{1}H NMR: (200.13 MHz, CD_2Cl_2): δ = 1.16 [d, *J* = 6.9 Hz, 12 H, CH(CH_3)$_2$], 1.25−1.95 (m, 10 H, CH_2), 2.26 (s, 3 H, CH_3), 2.45 (s, 3 H, CH_3), 2.77 [sept, 2 H, *J* = 6.9 Hz, C*H*(CH$_3$)$_2$], 3.55−3.66 (m, 1 H, CH), 7.05−7.25 (m, 3 H), 7.81 (t, *J* = 7.8 Hz, 1 H, CH Ar), 8.21 (dd, *J* = 7.8, 1.1 Hz, 1 H, CH Ar), 8.36 (dd, *J* = 7.8, 1.1 Hz, 2 H, CH Ar) ppm. ^{13}C{^{1}H} NMR (50.32 MHz, $CDCl_3$): δ = 14.1 [1 C, C(N-alkyl)*C*H$_3$], 17.8 [1 C, C(N-Ar)*C*H$_3$], 23.6 [2 C, CH(*C*H$_3$)(CH$_3$)], 23.9 [2 C, CH(CH$_3$)(*C*H$_3$)], 25.48 (2 C, CH_2), 25.49 (1 C, CH_2); 28.50 [2 C, *C*H(CH$_3$)(CH$_3$)], 34.1 (2 C, CH_2); 61.0 (1 C, CH), 121.9 (1 C, CH Ar), 122.7 (1 C, CH Ar), 123.7 (2 C, CH Ar), 124.1 (1 C, CH Ar), 136.5 (2 C, C Ar), 147.2 (1 C, CH Ar), 155.4 (1 C, CH Ar), 157.8 (1 C, C Ar), 164.4 [1 C, *C*(N-alkyl)CH$_3$], 167.8 [1 C, *C*(N-Ar)CH$_3$] ppm. $C_{27}H_{37}N_3$ (403.61): calcd. 2,6-Diisopropyl-*N*-[(*E*)-1-(6-{[(1*R*)-1-phenylethyl]ethanimidoyl}-2-pyridinyl)ethylidene]aniline (4): A mixture of **1** (0.170 g, 0.53 mmol) and (*R*)-(+)-(1-phenylethyl)amine (0.473 mL, 0.450 g, 3.71 mmol) was heated at 100 °C without stirring for 18 h. Elimination of the excess of amine by distillation under reduced pressure gave an oily material that was dissolved in 3−4 mL of MeOH and cooled to 0 °C. After 2 d, yellow microcrystals of the product were isolated by filtration (0.153 g, 0.36 mmol, yield 68%). M.p. 91−93 °C. IR: $\nu_{(C=N)}$ 1633, 1644 cm^{-1}. ^{1}H NMR (200.13 MHz, $CDCl_3$): δ = 1.14−1.19 [m, 12 H, CH(CH_3)$_2$], 1.58 (d, *J* = 6.6 Hz, 3 H, CHCH_3), 2.26 (s, 3 H, CH_3), 2.50 (s, 3 H, CH_3), 2.73 (m, 2 H, CH), 4.97 (q, *J* = 6.6 Hz, 1 H, C*H*CH$_3$), 7.07−7.77 (m, 8 H, CH Ar), 7.85 (m, 1 H, CH Ar), 8.36−8.39 (m, 2 H, CH Ar) ppm. ^{13}C{^{1}H} NMR (50.32 MHz, $CDCl_3$): δ = 14.4 [1 C, C(N-alkyl)*C*H$_3$], 17.9 [1 C, C(N-Ar)*C*H$_3$], 23.6 [2 C, CH(*C*H$_3$)(CH$_3$)], 23.9 [2 C, CH(CH$_3$)(*C*H$_3$)], 25.5 (1 C, CH_3), 29.0 [2 C, *C*H(CH$_3$)(CH$_3$)], 61.0 (1 C, *C*H), 122.2 (1 C, CH Ar), 122.9 (1 C, CH Ar), 123.7 (2 C, CH Ar), 124.2 (1 C, CH Ar), 127.4 (1 C, CH Ar), 127.4 (2 C, CH Ar), 129.1 (2 C, CH Ar), 136.5 (2 C, C Ar), 137.4 (2 C, CH Ar), 146.7 (1 C, CH Ar), 147.3 (1 C, CH Ar), 155.4 (1 C, CH Ar), 157.5 (1 C, C Ar), 165.4 [1 C, *C*(N-alkyl)CH$_3$], 167.8

[1 C, *C*(N-Ar)CH_3] ppm. $C_{29}H_{35}N_3$ (425.62): calcd. C 81.83, H 8.29, N 9.87; found C 82.04, H 8.47, N 9.85.

***N*-{(*E*)-1-[6-(Cyclohexylethanimidoyl)-2-pyridinyl]ethylidene}-2,6-dimethylaniline (5):** A mixture of **2** (0.131 g, 0.49 mmol) and cyclohexylamine (0.485 g, 4.9 mmol) was heated at 100 °C without stirring for 24 h. Elimination of the excess of cyclohexylamine by distillation under reduced pressure gave an oily material that was dissolved in 2 mL of MeOH and cooled to −24 °C. After 3 d, small yellow needles of the product were isolated by filtration (0.13 g, 0.38 mmol, yield 78%). M.p. 98−100 °C. IR: $\nu_{(C=N)}$ 1634 cm^{-1}. ^1H NMR (200.13 MHz, CD_2Cl_2): δ = 1.25−1.95 (m, 10 H, CH_2), 2.01 (s, 6 H, CH_3), 2.20 (s, 3 H, CH_3), 2.42 (s, 3 H, CH_3), 3.55−3.66 (m, 1 H, CH), 6.88−7.08 (m, 3 H, CH Ar), 7.81 (m, 1 H, CH Ar), 8.18 (dd, *J* = 7.7, 1.1 Hz, 1 H, CH Ar), 8.34 (dd, *J* = 7.7, 1.1 Hz, 1 H, CH Ar) ppm. $^{13}C\{^1H\}$ NMR (50.32 MHz, $CDCl_3$): δ = 14.1 [1 C, C(N-alkyl)*C*H_3], 17.8 [1 C, C(N-Ar)*C*H_3], 18.6 (2 C, CH_3), 25.5 (2 C, CH_2), 26.5 (1 C, CH_2); 34.2 (2 C, CH_2); 61.0 (1 C, CH), 121.9 (1 C, CH Ar), 122.8 (1 C, CH Ar), 123.6 (1 C, CH Ar), 126.1 (2 C, C Ar), 128.5 (2 C, CH Ar), 137.3 (1 C, CH Ar), 149.5 (1 C, C Ar), 155.3 (1 C, CH Ar), 157.8 (1 C, C Ar), 164.4 [1 C, *C*(N-alkyl)CH_3], 168.1 [1 C, *C*(N-Ar)CH_3] ppm. $C_{23}H_{29}N_3$ (347.50): calcd. C 79.50, H 8.41, N 12.09; found C 79.78, H 8.65, N 12.15.

2,6-Diisopropyl-*N*-{(*E*)-1-[6-{[(1*S*)-1-(2-naphthyl)ethyl]-ethanimidoyl}-2-pyridinyl]ethylidene}aniline (6): A mixture of **1** (0.170 g, 0.53 mmol) and (*S*)-(−)-(1-naphthalenylethyl)amine (0.33 mL, 0.350 g, 2.04 mmol) was heated at 100 °C without stirring for 17 h. The resulting mixture was diluted with 2−3 mL of MeOH and cooled to 0 °C. After 5 h, pale yellow microcrystals of the product were isolated by filtration (0.118 g, 0.36 mmol, yield 69%). M.p. 66−69 °C. IR: $\nu_{(C=N)}$ 1643 cm^{-1}. ^1H NMR (200.13 MHz, CD_2Cl_2): δ = 1.10−1.17 [m, 12 H, $CH(CH_3)_2$], 1.72 (d, *J* = 6.5 Hz, 3 H, $CHCH_3$), 2.26 (s, 3 H, CH_3), 2.50 (s, 3 H, CH_3), 2.73 [m, 2 H, $CH(CH_3)_2$], 5.67 (q, *J* = 6.5 Hz, 1 H, $CHCH_3$) 7.03−7.20 (m, 3 H, CH Ar), 7.45−7.77 (m, 7 H, CH Ar), 7.88 (m, 1 H, CH Ar), 8.32−8.43 (m, 2 H, CH Ar) ppm. $C_{33}H_{37}N_3$ (475.68): calcd. C 83.32, H 7.84, N 8.83; found C 83.64, H 7.82, N 8.77.

Synthesis of Metal Complexes: All iron(II) and cobalt(II) complexes with the 2,6-bis(imino)pyridyl ligands were prepared by the following procedure. The ligand (1.0 equiv.) was added under nitrogen to a solution of the metal halide (1.2 equiv.) in *n*BuOH and the resulting mixture was heated at reflux for 10 min. After the mixture had cooled to room temperature, a crystalline solid was obtained within 30−60 min. This was filtered through a sintered-glass frit, washed with *n*BuOH and petroleum ether and then dried in a stream of nitrogen.

[*N*-{(*E*)-1-[6-(Cyclohexylethanimidoyl)-2-pyridinyl]ethylidene}-2,6-diisopropylaniline]cobalt Dichloride (7): This complex was obtained as green microcrystals. Yield 70%. IR: $\nu_{(C=N)}$ 1590, 1587 cm^{-1}. μ_{eff} = 4.82 BM (25 °C). Diffuse reflectance spectra (40000−5550 cm^{-1}): 25000 sh, 17000 sh, 15600, 10500, 8200, 5700. Solution spectra (CH_2Cl_2, 28500−6250 cm^{-1}): 25000 sh, 17000 sh, 14950 (ε 830), 11100 (ε 67), 7800 (ε 100). $C_{27}H_{37}Cl_2CoN_3$ (533.45): calcd. C 60.79, H 6.99, N 7.88; found C 60.55, H 7.01, N 8.72.

[2,6-Diisopropyl-*N*-{(*E*)-1-[6-{[(1*R*)-1-phenylethyl]ethanimidoyl}-2-pyridinyl]ethylidene}aniline]cobalt Dichloride (8): This complex was obtained as green crystals. Yield 85%. IR: $\nu_{(C=N)}$ 1590 cm^{-1}. μ_{eff} = 4.95 BM (25 °C). Diffuse reflectance spectra (40000−5550 cm^{-1}): 25000 sh, 17200 sh, 15500, 10500, 8300, 5600. Solution spectra (CH_2Cl_2, 28500−6250 cm^{-1}): 25000 sh, 17100 sh, 14800 (ε 710), 10500 (ε 40), 8000 (ε 75). $C_{29}H_{35}Cl_2CoN_3$ (555.46): calcd. C 62.71, H 6.35, N 7.57; found C 62.80, H 6.29, N 7.60.

[*N*-{(*E*)-1-[6-(Cyclohexylethanimidoyl)-2-pyridinyl]ethylidene}-2,6-dimethylaniline]cobalt Dichloride (9): This complex was obtained as green crystals. Yield 84%. IR: $\nu_{(C=N)}$ 1590 cm^{-1}. μ_{eff} = 4.85 BM (25 °C). Diffuse reflectance spectra (40000−5550 cm^{-1}): 25000 sh, 16950, 15400, 10500, 8150, 5700. Solution spectra (CH_2Cl_2, 28500−6250 cm^{-1}): 25000 sh, 17000 (ε 460), 15450 (ε 740), 11000 (ε 42), 7800 (ε 90). $C_{23}H_{29}Cl_2CoN_3$ (477.34): calcd. C 57.87, H 6.12, N 8.80; found C 57.61, H 6.25, N 8.61.

[2,6-Diisopropyl-*N*-{(*E*)-1-[6-{[(1*S*)-1-(2-naphthyl)ethyl]-ethanimidoyl}-2-pyridinyl]ethylidene}aniline]cobalt Dichloride (10): This complex was obtained as green crystals. Yield 88%. IR: $\nu_{(C=N)}$ 1592 cm^{-1}. μ_{eff} = 4.87 BM (25 °C). Diffuse reflectance spectra (40000−5550 cm^{-1}): 25100 sh, 17400 sh, 15600, 10300, 8000, 5650. Solution spectra (CH_2Cl_2, 28500−6250 cm^{-1}): 25000 sh, 17300 sh, 14900 (ε 700), 10350 (ε 40), 7800 (ε 90). $C_{33}H_{37}Cl_2CoN_3$ (477.34): calcd. C 65.46, H 6.16, N 6.90; found C 65.58, H 6.03, N 6.93.

[*N*-{(*E*)-1-[6-(Cyclohexylethanimidoyl)-2-pyridinyl]ethylidene}-2,6-diisopropylaniline]iron Dichloride (11): This complex was obtained as dark blue microcrystals. Yield 81%. IR: $\nu_{(C=N)}$ 1589, 1580 cm^{-1}. μ_{eff} = 5.72 BM (25 °C). Diffuse reflectance spectra (40000−5550 cm^{-1}): 18200 sh, 7400. Solution spectra (CH_2Cl_2, 28500−6250 cm^{-1}): 20230 (ε 240), 7170 (ε 6). $C_{27}H_{37}Cl_2FeN_3$ (530.36): calcd. C 61.15, H 7.03, N 7.92; found C 60.97, H 6.91, N 7.88.

[2,6-Diisopropyl-*N*-{(*E*)-1-[6-{[(1*R*)-1-phenylethyl]ethanimidoyl}-2-pyridinyl]ethylidene}aniline]iron Dichloride (12): This complex was obtained as a blue powder. Yield 87%. IR: $\nu_{(C=N)}$ 1584 cm^{-1}. μ_{eff} = 5.56 BM (25 °C). Diffuse reflectance spectra (40000−5550 cm^{-1}): 18000 sh, 14600, 8100. Solution spectra (CH_2Cl_2, 28500−6250 cm^{-1}): 20300 (ε 250), 7700 (ε 8). $C_{29}H_{35}Cl_2FeN_3$ (552.37): calcd. C 63.06, H 6.39, N 7.61; found C 62.68, H 6.28, N 7.59.

[*N*-{(*E*)-1-[6-(Cyclohexylethanimidoyl)-2-pyridinyl]ethylidene}-2,6-dimethylaniline]iron Dichloride (13): This complex was obtained as dark blue crystals. Yield 81%. IR: $\nu_{(C=N)}$ 1589 cm^{-1}. μ_{eff} = 5.68 BM (25 °C). Diffuse reflectance spectra (40000−5550 cm^{-1}): 18800 sh, 8330 cm^{-1}. Solution spectra (CH_2Cl_2, 28500−6250 cm^{-1}): 19050 (ε 230), 8350 (ε 12). $C_{23}H_{29}Cl_2FeN_3$ (474.26): calcd. C 58.25, H 6.16, N 8.86; found C 58.13, H 6.29, N 8.68.

[2,6-Diisopropyl-*N*-{(*E*)-1-[6-{[(1*S*)-1-(2-naphthyl)ethyl]-ethanimidoyl}-2-pyridinyl]ethylidene}aniline]iron Dichloride (14): This complex was obtained as blue microcrystals. Yield 79%. IR: $\nu_{(C=N)}$ 1590 cm^{-1}. μ_{eff} = 5.77 BM (25 °C). Diffuse reflectance spectra (40000−5550 cm^{-1}): 18300 sh, 8000. Solution spectra (CH_2Cl_2, 28500−6250 cm^{-1}): 20000 (ε 240), 7900 (ε 8). $C_{33}H_{37}Cl_2FeN_3$ (602.43): calcd. C 65.79, H 6.19, N 6.98; found C 65.90, H 6.10, N 6.84.

Oligomerisation Reactions: A 0.5-L stainless steel reactor was heated at 100 °C under vacuum for 3 h, solid precatalyst (12 μmol) was introduced into the autoclave at room temperature, and the system was evacuated. A solution of oxygen-free toluene (100 mL) and MAO (sol. 10% w/w, 1.6 mL) was then introduced into the reactor and the mixture was stirred at room temperature for 10 min. The system was then heated or thermostatted to the desired temperature, pressurised with ethylene, and stirred at 1500 rpm. The reaction was terminated by cooling to 5 °C and slow depressurisation, followed by addition of MeOH (2 mL) and *n*-heptane (internal standard, 200 μL).

X-ray Structure Determination of 9·H_2O: Single crystals of 9·H_2O were grown by slow diffusion of *n*-hexane into a CH_2Cl_2 solution of **9**. A summary of crystal and intensity data is presented in Table 4.

Experimental data were recorded at 20 °C with an Enraf−Nonius CAD4. A set of 25 carefully centred reflections in the range $8° \leq \theta \leq 10.25°$ was used for determining the lattice constants. As a general procedure, the intensity of three standard reflections were measured periodically every 200 reflections for orientation and intensity control. This procedure did not reveal any appreciable decay in intensities. The data were corrected for Lorentz and polarisation effects. Atomic scattering factors were those tabulated by Cromer and Waber,[27] with anomalous dispersion corrections taken from ref.[28] An empirical absorption correction was applied by use of the program XABS with correction factors in the range 1.3518−0.394. The computational work was carried out by intensive use of the program WINGX. Final atomic coordinates of all atoms and structure factors are available on request from the authors and are provided. A dark green parallelepiped crystal with dimensions 0.375 × 0.300 × 0.225 mm was used for the data collection. The structure was solved by direct methods by use of the SIR97 program.[29] Refinement was performed by full-matrix, least-squares calculations, initially with isotropic thermal parameters and then with anisotropic thermal parameters for all the atoms other than the oxygen atoms. In the final stage of the refinement, two atoms were detected and were assigned as oxygen of solvent molecules and successfully refined. The phenyl ring was treated as a rigid body with D_{6h} symmetry, and the hydrogen atoms were allowed to ride on the attached carbon atoms. Hydrogen atoms were introduced at calculated positions. CCDC-195274 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 4. Selected crystallographic data for **9**·H_2O

Empirical formula	$C_{23}H_{31}Cl_2CoN_3O$
Formula mass	495.36
T [K]	293(2)
Crystal system	orthorhombic
Space group	*Pcab* (No. 61)

Mn and Fe *K*-edge XAS Spectra of Manganese and Iron Nitrido Compounds

Rainer Niewa,*[a] Zhiwei Hu,[b] and Rüdiger Kniep[a]

Keywords: X-ray absorption spectroscopy / Nitrides / Iron / Manganese

We performed a Mn *K*-edge XAFS study of a number of highly moisture-sensitive nitridomanganates with manganese in different oxidation states and in various surroundings: $Li_2[(Li_{1-x}Mn^{I}_{x})N]$ [x = 0.75(1)], $Li_{24}[Mn^{III}N_3]_3N_2$, and $Li_7[Mn^{V}N_4]$. For reference purposes Mn, MnO and θ-Mn_6N_{5+x} [x = 0.26(1)] were measured. The energy positions of the pre-edge maxima are almost independent of the electronic state of Mn, while the intensity is sensitive to the geometric arrangement of the coordination of Mn. The main-edge is sensitive to the oxidation state – a clear shift to higher energies with increasing oxidation state can be seen. This shift is smaller than the shift observed for the corresponding oxides, due to the lower electronegativity of nitrogen compared to oxygen, and corresponds to a higher covalency of the Mn–N bond. Similar results can be taken from the Fe *K*-edges of $Li_2[(Li_{1-x}Fe^{I}_{x})N]$ with x = 0.20(1) and $Li_3[Fe^{III}N_2]$ in comparison to metallic Fe, $Fe^{II}SO_4\cdot 7H_2O$ and α-$Fe^{III}_2O_3$. The results are consistent with the presence of an unusual oxidation state (+1) for the transition metals in the phases of the general composition $Li_2[(Li_{1-x}M_x)N]$.

Introduction

XAS spectroscopy at the thresholds is an element-specific tool that can provide valuable information on the oxidation state and the electronic configuration of most atomic components of both crystalline and amorphous materials. The shape and energy position of the absorption spectrum in its near-edge region is closely related to the electronic structure, and is partly also influenced by the magnetic state, the local symmetry, and the coordination environment of the nuclei, while the oscillation observed in the high energy region of the spectrum is associated with the arrangement of the atoms, i.e. the local surrounding.

A wide range of oxidation states is known for Mn: in inorganic oxide compounds manganese covers the whole range of oxidation states from +2 to +7, and in carbonyl complexes the oxidation states −1, 0 and +1 are also known. In nitride chemistry, the highest reported oxidation state for manganese is +5, while the lower oxidation states are predominately stabilized (as generally in 3d nitridometalates):[1] oxidation states below +2 are frequently observed. The oxidation state +5 is known only for $Li_7[MnN_4]$,[2] with a high ratio of electropositive elements to manganese, while in binary manganese nitrides even +3 has not been reached so far. MnN reported in the literature always exhibits a nitrogen deficiency and belongs to the θ-Mn_6N_{5+x} phase region.[3] The situation is similar for lithium nitridoferrates: $Li_3[FeN_2]$ contains iron in its highest oxidation state (+3) observed so far in nitride chemistry.[4] $Li_4[Fe^{II}N_2]$[5] and $Li_2[(Li_{1-x}Fe^{I}_{x})N]$[6,7] are formed as decomposition phases from $Li_3[Fe^{III}N_2]$ at elevated temperatures.

In XAS at the transition metal *K*-edge an M 1s core-electron is excited to the 4p orbitals (dipole allowed), at higher energy the M 1s core-electron is excited to the continuum. In general, XAS spectra of the first-row transition metals have a weak pre-edge structure about 10 eV below the absorption edge, a feature that was assigned as originating from a 1s→3d transition.[8−10] For compounds with the transition metal in a centrosymmetric environment, a 1s→3d transition is electric dipole-forbidden by parity considerations. (The fact, that dipole selection rules hold only in systems with an inversion center is known in spectroscopy as Laporte's rule[11]). However, a weak pre-edge feature is still observed experimentally. In the case of non-centrosymmetric local surroundings M-4p-wavefunctions can mix into the 3d orbitals which provides some electric dipole-allowed 1s→4p character to the transition. All this may lead to a significant pre-edge feature that is more intense for local symmetries lacking an inversion center. In particular, the features in the region of the 1s→3d transition have been shown to be sensitive to the oxidation state and coordination geometry of a 3d transition metal.[10]

X-ray absorption probes the unoccupied part of the electronic structure of the system. Thus, for all discussions it should be mentioned that information on the ground state is concluded from excited states with an M 1s hole, a conclusion which might not be uncritical. This situation is

moderated for metallic compounds, since, as a general rule, the core holes in metals are better screened than in insulators, therefore many-body effects involving both the core hole and the excited electron are less important for metals.[8] We chose to measure *K*-edge spectra, because: i) the relevant energies make it possible to work in transmission mode, hence to use fully encapsulated samples (necessary for the strongly sensitive compounds), and ii) the valence state can be taken directly from the energy shift of the main absorption edge, while in $L_{2,3}$ XAS spectra the edge of oxidized 3d metals can lie at higher or lower energies than those of the corresponding metallic elements. The latter fact is due to strong multiplet interactions in the final state effects.[12,13]

Results and Discussion

The striking features of the presented data are the pre-edge peaks visible for all investigated nitrides, although their shape and their intensity are significantly different. As can be seen from Figure 1, for the manganese compounds the most pronounced and best separated pre-edge features are visible for $Li_7[Mn^{V}N_4]$ and $Li_{24}[Mn^{III}N_3]_3N_2$ around 6539 eV. This pre-edge peak was assigned to a 1s→3d transition.[8–10] In the spectra of the other nitrides the pre-edge is observed only as a shoulder of the main absorption edge, which itself reflects a 1s→4p transition. The positions of the pre-edge feature exhibit only a slight change in energy in the presented data. Therefore, the pre-edge peak becomes more visible when the main absorption edge shifts to higher energies. It was observed earlier that the pre-edge peaks are shifted to higher energy with increasing oxidation state for chromium oxides.[14,15] Such a shift can only be confirmed for the well-separated strong pre-edge signals in the spectra of $Li_7[Mn^{V}N_4]$ and $Li_{24}[Mn^{III}N_3]_3N_2$, indicating the difference in oxidation state (about 1 eV). The intensity of the pre-edge peak can be related directly to the local symmetry of the manganese coordination in the different nitrido compounds: $Li_7[Mn^{V}N_4]$: tetrahedral, lacking centrosymmetry,[2] $Li_{24}[Mn^{III}N_3]_3N_2$: trigonal, slightly non-planar, lacking centrosymmetry,[2] $Li_2[(Li_{1-x}Mn^{I}_x)N]$: linear by N, and thus centrosymmetric, but with Li-Mn disorder in the basal plane perpendicular to the Mn−N bond (second coordination sphere assembled from six Li or Mn) breaking the symmetry,[2] θ-Mn_6N_{5+x}: octahedral, centrosymmetric, but with some degree of N-vacancies breaking the local symmetry.[3]

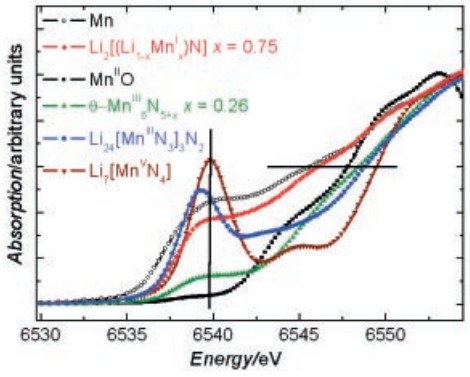

Figure 1. Near-edge XAS spectra of Mn, $Li_2[(Li_{1-x}M_x^{I})N]$ (x = 0.75), $Mn^{II}O$, θ-Mn_6N_{5+x} (x = 0.26), $Li_{24}[Mn^{III}N_3]_3N_2$ and $Li_7[Mn^{V}N_4]$; the strong pre-edge peak for the compounds lacking local centrosymmetry at the Mn-center and the shift of the main absorption edge to higher energies with increasing oxidation state are clearly visible

Unfortunately, the inflection point of the main absorption edge in many spectra is overlapped by the pre-edge feature. However, the general trend of the increasing absorption edge levels at about 0.6 of the full edge jump from elemental Mn and the Mn^{I}-phase $Li_2[(Li_{1-x}Mn^{I}_x)N]$ to $Mn^{II}O$ is still visible (Figure 1). The inflection point of θ-Mn_6N_{5+x} (x = 0.26) lies slightly lower than that of $Li_{24}[Mn^{III}N_3]_3N_2$, indicating the lower oxidation state of Mn in the binary nitride due to the nitrogen deficiency in the crystal structure compared to the ideal composition for a manganese(III) nitride. The edge of $Li_7[Mn^{V}N_4]$ lies at the highest energy, as was to be expected. The absorption edge of $Mn^{II}O$ is much closer to that of the manganese(III) nitrido compounds than to that of the nitridomanganate(I). This is easily understood from the lower electronegativity of the nitrogen ligands compared to oxygen. As observed earlier, the absorption edge is shifted to higher energies with increasing electronegativity of the ligands.[16]

Larger degrees of vacancies and, thus, increased oxidation states of the transition metals in the sense of $Li_{2-y}[(Li_{1-x}M_x)N]$, have been discussed for the analogues substitution series of M = Cu, Ni and Co.[17–19] The small shift of the absorption edge of the manganese(I) compound compared to the manganese foil proves that the oxidation state of manganese in $Li_2[(Li_{1-x}Mn_x)N]$ is close to +1, indicating that the vacancy concentration in this phase (y in $Li_{2-y}[(Li_{1-x}Mn_x)N]$) is small. This is in agreement with our single crystal and magnetic susceptibility investigations.[2] Similar results were also obtained for the M = Cu, Ni, Co substitution phases from XAS spectroscopy, indicating oxidation states close to +1.[20]

The main absorption edge is determined by the threshold of the electron dipole transition from the manganese 1s orbital to the continuum of p-like states above the Fermi energy. The shift of the edge position is correlated with the length of the Mn−N bonds: the shorter it is, the larger the overlap between the electron wavefunctions originating from Mn and N. This results in an increase of the energy of the outer states relative to the energy of the core levels, and thus in a higher-energy shift of the absorption edge. Higher oxidation states generally lead to shorter bond lengths considering the same coordination geometry, thus adding to the effect of the positive edge shift. In our study lower coordination numbers (*CN*) in phases with lower oxidation states of M partly counteract these effects: $\bar{d}$(Mn−N): $Li_2[(Li_{1-x}Mn_x)N]$ [x = 0.75(1)] with *CN*(Mn) = 2: 191 pm;[2] $Li_{24}[MnN_3]_3N_2$ with *CN*(Mn) = 3: 178 pm;[2] $Li_7[MnN_4]$ with *CN*(Mn) = 4: 182 pm;[2] θ-Mn_6N_{5+x} (x = 0.26) with *CN*(Mn) = 5,6: 218 pm[3]. The effect of Li−Mn−disorder, i.e. the size of the substitution parameter

x, on the average bond length $\bar{d}$(Li,Mn−N) in $Li_2[(Li_{1-x}Mn_x)N]$ is negligible.[21]

Figure 2 plots the Fe K-edges of $Li_3[Fe^{III}N_2]$ and $Li_2[(Li_{1-x}Fe^{I}_x)N]$ [x = 0.20(1)] together with reference compounds and the element. As discussed for the manganese compounds, good separation of the pre-edge feature is only reached for $Li_3[Fe^{III}N_2]$ with Fe in tetrahedral (non-centrosymmetric) coordination. The main absorption edge taken at 0.6 of the total edge jump shifts only slightly from metallic Fe to $Li_2[(Li_{1-x}Fe^{I}_x)N]$ [x = 0.20(1)] indicating the oxidation state of iron in the latter phase is close to unity. The absorption edges of $Fe^{II}SO_4{\cdot}7H_2O$ and $Li_3[Fe^{III}N_2]$ nearly coincide for the same reason of electronegativity difference of nitrogen and oxygen as discussed above, while the Fe K-edge of α-$Fe^{III}_2O_3$ is clearly shifted to higher energies.

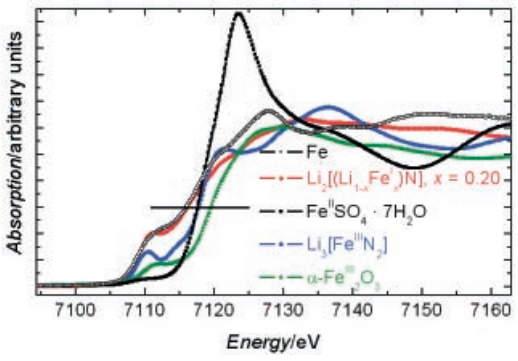

Figure 2. Near-edge XAS spectra of Fe, $Li_2[(Li_{1-x}Fe^{I}_x)N]$ (x = 0.20), $Fe^{II}SO_4{\cdot}7H_2O$, $Li_3[Fe^{III}N_2]$, and α-$Fe^{III}_2O_3$; the shift of the main absorption edge to higher energies with increasing oxidation state is clearly visible

Experimental Section

Samples of the compounds under investigation were prepared and characterized as described previously.[2,3,7,22] For the XAS measurements the air-sensitive compounds $Li_7[Mn^{V}N_4]$, $Li_{24}[Mn^{III}N_3]_3N_2$, $Li_2[(Li_{1-x}Mn^{I}_x)N]$ [x = 0.75(1)], $Li_3[Fe^{III}N_2]$ and $Li_2[(Li_{1-x}Fe^{I}_x)N]$ [x = 0.20(1)] were handled in an Ar-filled glove box with $p(O_2, H_2O) < 1$ ppm. All powder samples were mixed with three times their volume of dry B_4C to produce homogenous absorbers. The air-sensitive samples were loaded in steel capsules equipped with Be windows (0.5 mm). Due to the extreme moisture sensitivity of these samples and the necessary way of handling, thickness effects in the resulting XAS spectra are basically inevitable.[23,24] Non-sensitive samples (MnO, θ-Mn_6N_{5+x}, α-Fe_2O_3) were prepared on mylar films. $Fe^{II}SO_4{\cdot}7H_2O$ was also loaded into a steel capsule to prevent dehydration in vacuo.

The M K-edge measurements were performed in transmission geometry at the E4 bending magnet beamline located at the DORISIII storage ring in the HASYLAB laboratory (Hamburg, Germany). The X-ray beam outgoing from the bending magnet and formed with the toroidal and plane golden mirrors was monochromatized using a double crystal monochromator, equipped with a Si(111) crystal. This resulted in an experimental resolution of about 1.5 eV (FWHM) at the studied thresholds. For detectors ionization chambers were used. The absorption spectra were measured simultaneously with the spectrum of metallic manganese or iron foil, respectively, serving as references for energy calibration. Typical scan times were 30 min with smaller step size and longer measurement times in the range of the main-edge.

Acknowledgments

We wish to thank Dr. K. Klementiev for his support at the E4 beamline.

Synthesis and Characterization of $(PTU)I_2$ (PTU = 6-*n*-propyl-2-thiouracil) and $(CMBZT)I_2$ (CMBZT = 5-chloro-2-mercaptobenzothiazole) and Possible Implications for the Mechanism of Action of Anti-Thyroid Drugs

Keywords: Bioinorganic chemistry / Charge transfer / Iodine / S ligands / Nitrogen heterocycles

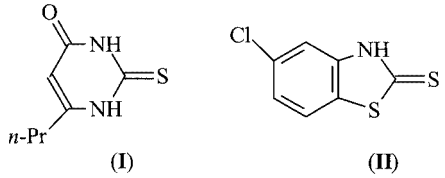
Direct reaction of 6-*n*-propyl-2-thiouracil (PTU), a widely used anti-thyroid drug against hyperthyroidism (Graves' disease), or 5-chloro-2-mercaptobenzothiazole (CMBZTH) with iodine in a molar ratio of 1:1 resulted in the formation of the charge-transfer (CT) complexes $[(PTU)I_2]$ (**1**) or $[(CMBZT)I_2]$ (**2**). All reactions were carried out in dichloromethane and water solutions. Compounds **1** and **2** were characterized by elemental analyses, FT-Raman, FT-IR, UV/Vis and ^1H NMR spectroscopy. The crystal structures of both complexes were determined by X-ray diffraction at 120(1) K (**1**) and 293(2) K (**2**). The charge-transfer nature of the bonds in the adducts **1** and **2** was verified by the lengthening of the I–I bond lengths as compared to the S–I bond lengths and by the characteristic CT bands observed in the UV spectra of the complexes. Compound **1** $[(C_7H_{10}N_2OS)I_2]$ [monoclinic with space group $P2_1/c$ and a = 9.8501(7), b = 10.3101(7), c = 12.0287(8) Å, β = 99.707(6)°, Z = 4] consists of a propylthiouracil ligand bonded with an iodine atom through sulfur. Extended intermolecular N–H···O contacts link the molecules forming a supramolecular assembly. Compound **2** $\{(C_7H_4ClNS_2)I_2\}$ [orthorhombic, space group $P2_12_12_1$, a = 4.1650(10), b = 9.691(2), c = 28.471(6) Å, Z = 4] consists of a 5-chloro-2-mercaptobenzothiazole ligand bonded with an iodine atom through sulfur. An extended intermolecular linkage via I···H–N bonds leads to the formation of an extended structure. Attempts to draw conclusions on the behavior of a thioamide — when used as an anti-thyroidal drug — towards iodine have been made.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The most commonly employed anti-thyroidal drugs for the treatment of hyperthyroidism (Graves' disease) are 6-*n*-propyl-2-thiouracil (PTU), *N*-methylimidazoline-2-thione (methimazole) (MMI) and 3-methyl-2-thioxo-4-imidazoline-1-carboxylate (carbimazole) (CBZ).[1–2] They have been found to inhibit the formation of 3,5,3′-triiodothyronine (T3) and 3,5,3′,5′- tetraiodothyronine (T4) hormones by blocking the metabolism of iodine (Scheme 1).[3] Therefore, there is an increasing interest in the study of charge-transfer (CT) complexes of iodine with thioamides or thiones,[2,4–7] not only for the clarification of the iodine binding mechanism but also for the development of new anti-thyroidal agents.

Although much work has been carried out with these drugs, structural data on their CT complexes with I_2 were only reported very recently for the complex with MMI.[8] Herein we report the structural and spectroscopic characterisation of two new iodine complexes with the heterocyclic thioamides 6-*n*-propyl-2-thiouracil (PTU, I) and 5-chloro-2-mercaptobenzothiazole (CMBZT, II) $[(PTU)I_2]$ (**1**) and $[(CMBZT)I_2]$ (**2**). PTU is used in the treatment of hyperthyroidism while CMBZT was used for comparison purposes.



(I) (II)

Results and Discussion

Dark crystals of the complexes, suitable for single crystal analysis by X-ray crystallography, were grown by slow evaporation of the filtrates resulting from the reaction of iodine with the appropriate thioamide in 1:1 or 2:1 molar ratios in

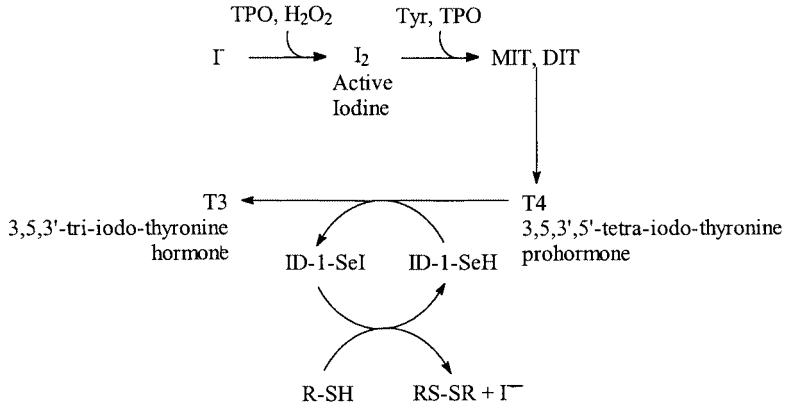

Scheme 1. Mechanism of TPO-catalyzed iodination reactions (MIT = 3-monoiodotyrosine and DIT = 3,5-diiodotyrosine)

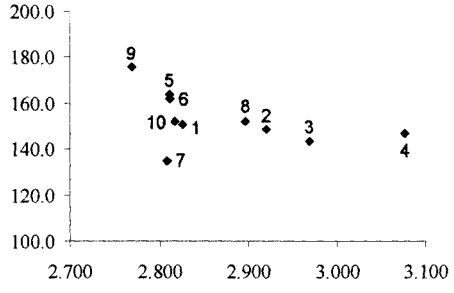

Figure 1. Correlation between ν(I-I) Raman bands of the adducts [{(bztzdtH)I_2}·I_2][7a] (**3**; bztzdtH = benzothiazole-2-thione) ν(I-I)= 143.7 cm^{-1}; [(bztzdtH)I_2][7a] (**4**) ν(I-I) = 147 cm^{-1}, [ptc·I_2][5a] (**5**; ptc = 1,3-dithiacyclohexane-2-thione) ν(I-I)= 164 cm^{-1}; [ttb·I_2][5a] (**6**; ttb = 4,5-ethylenedithio-1,3-dithiole-2-thione) ν(I-I) = 162 cm^{-1}; [mdtt·I_2][5c] [**7**; mdtt = 4,5-bis(methylsulfanyl)-1,3-dithiole-2-thione] ν(I-I) = 136 cm^{-1}; [mbit·I_2][6a] [**8**; mbit = 1,1-methylenebis(3-methyl-4-imidazoline-2-thione)] ν(I-I) = 152 cm^{-1}; [bzoxtH·I_2][6b] (**9**; bzoxtH = benzoxazole-2-thione) ν(I-I) = 176 cm^{-1}; [dmimdtH·I_2][6d] (**10**; dmimdtH = 5,5-dimethylimidazoline-2,4-dithione) ν(I-I) = 152 cm^{-1} and compounds **1** and **2**

dichloromethane. The reactions were also carried out in H_2O. The insoluble dark brown powders obtained were recrystallized from dichloromethane.

The structure of compound **1** shows that the PTU ligand, with anti-thyroidal activity, is able to retain one iodine molecule. The formulae of complexes **1** and **2** were first deduced from elemental analysis and spectroscopic data. Both complexes are highly soluble in organic solvents and their crystals are stable in air, although they were stored in darkness in a refrigerator.

Spectroscopy

Vibrational Spectroscopy

New bands appearing at 153 and 152 cm^{-1} in the far-IR spectra of compounds **1** and **2**, respectively, were assigned to the ν(I−I) stretching vibration modes.[7a] The ν(I−S) bond vibration for the [{(bztzdtH)I_2}·I_2],[7a] [(bztzdtH)I_2][7a] and [{(bzimtH)I_2}$_2$·I_2·H_2O][7a] complexes was observed at 281−280 cm^{-1} and 255−254 cm^{-1}. Here, new bands appear at 250 and 247 cm^{-1} for compounds **1** and **2**, respectively, which can be assigned similarly.

The Raman spectra of complexes **1** and **2**, recorded in the 300−50 cm^{-1} region, show an intense band at 150.9 cm^{-1} for **1** and 148.9, 123.9 cm^{-1} for **2**; these bands are attributed to the ν_1(I−I) vibration of coordinated I_2 moieties.[7a] Iodine gives a band at 180 cm^{-1} ν(I-I) in the solid state.[7a] This shifts to lower frequencies upon coordination to a donor atom because of the reduction of the I−I bond strength. According to Deplano's classification[5a] compound **1** can be classified as being of type **A**, with a weak sulfur-iodine interaction (D···I−I), while compound **2** is of type **B**, with a stronger such interaction (D−I−I). Additionally, complexes **1** and **2** confirm the linear correlation of the d(I−I) bond lengths vs. ν(I-I) FT-Raman frequencies proposed by Deplano et.al.[9] (Figure 1).

UVIVis Spectroscopy

The visible spectra of the thione-iodine adducts in dichloromethane or chloroform exhibit one distinct absorption band at 495−505 nm, assigned to the "blue shift" band of I_2,[6h] which appears at 504 nm in free I_2 in CH_2Cl_2.[6e]

A shoulder in the range 310−360 nm could be assigned to a charge-transfer band from the HOMO of the donor to the iodine LUMO (σ_π*).[2a,5a,5d,6a] It should be noted that the CT (charge transfer) bands are not recognizable for complexes **1** and **2**, as they are most probably covered by the intra-ligand transitions ($\pi^* \leftarrow \pi$ or $\pi^* \leftarrow$ n) occurring at almost the same wavelength. The bands, however, are enhanced in intensity, with increased coefficients, in the complexes. The absorption bands at 285.5 nm in the spectrum of complex **1** and at 336 nm in the case of complex **2** were attributed to intra-ligand ($\pi^* \leftarrow \pi$) transitions.

Thermal Analysis

Thermal analysis in flowing nitrogen shows that complex **2** decomposes in two stages. The TGA and DTA data curves for complex **2** show that the first stage of its decomposition (90−120 °C) is connected with an endothermic effect and involves a 54.7% mass loss consistent with the loss of iodine (calculated mass loss 55.7%). The second stage of its decomposition (180−200 °C) connected

with an endothermic effect and involving a 31.1% mass loss is consistent with the loss of the thione.

Crystal and MolecularStructures of $[(PTU)I_2]$ (1) and $[(CMBZT)I_2]$ (2)

ORTEP diagrams of molecules **1** and **2**, as well as selected bond lengths and angles, are shown in Figure 2 and 3, respectively.

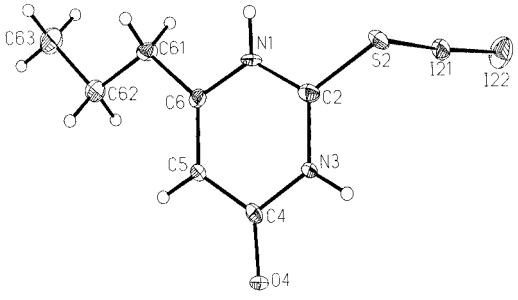

Figure 2. ORTEP diagram of molecule **1** together with the atomic numbering scheme; selected bond lengths (Å), angles [°] and torsion angles [°]: I(21)−I(22) 2.8264(4), S(2)−I(21) 2.7805(10), C(2)−S(2) 1.696(4), C(2)−N(3) 1.358(4), N(1)−C(2) 1.342(5), N(1)−C(6) 1.382(4), N(3)−C(4) 1.396(4) C(4)−O(4) 1.244(4), C(4)−C(5) 1.430(5), C(5)−C(6) 1.362(5); C(2)−S(2)−I(21) 96.05(12), S(2)−I(21)−I(22) 175.85(2), N(3)−C(2)−S(2)−I(21) 85.0(3), N(1)−C(2)−S(2)−I(21) −95.9(3), C(2)−S(2)−I(21)−I(22) −177.0(3)

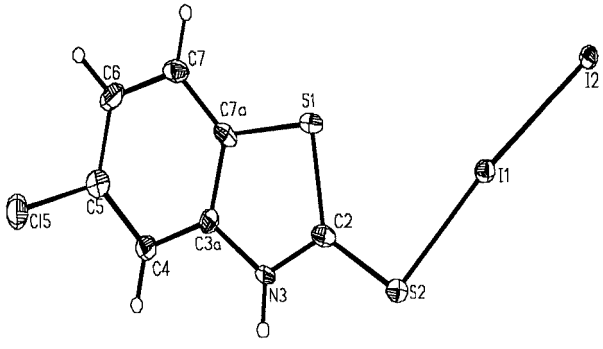

Figure 3. ORTEP diagram of molecule **2** together with the atomic numbering scheme; selected bond lengths (Å), angles [°] and torsion angles [°]: I(1)−I(2) 2.9205(7), I(1)−S(2) 2.634(2), S(2)−C(2) 1.680(6), N(3)−C(2) 1.344(7), S(1)−C(2) 1.746(5), S(1)−C(7A) 1.753(5); S(2)−I(1)−I(2) 173.78(4), C(2)−S(2)−I(1) 105.07(19), I(2)−I(1)−S(2)−C(2) −157.1(4), I(1)−S(2)−C(2)−N(3) 167.9(4), I(1)−S(2)−C(2)−S(1) −13.7(4)

The crystal structures of **1** and **2** consist of a thione ligand bonded to an iodine atom through sulfur, with S−I values of 2.7805(10) Å in **1** (Figure 2), and2.634(2) Å in **2** (Figure 3). The corresponding I−I bond lengths [2.8264(4) Å in **1** and 2.9205(7) Å in **2**] are longer than in iodine itself [gas phase: 2.677 Å;[6e] crystal: 2.715 Å at 110 K[6e]] as a result of the S···I interaction.

Extended intermolecular hydrogen bonding N(1)−H(1)···O(4)#1 [1.96 Å, with N(1)···O(4)#1 = 2.791(4) Å (x, $-y + 1/2$, $z - 1/2$)] and N(3)−H(3)···O(4)#2 [2.02 Å, with N(3)···O(4)#2 = 2.881(4)#2 Å ($-x + 1$, $-y$, $-z + 1$)] is found in complex **1** (Figure 4a). The absence of I···H−N hydrogen bonding in complex (**1**) is due to the perpendicular arrangement of iodine towards the plane of the C=S bond of PTU (vide infra). Since the presence of I···H−N hydrogen bonding in methimazole (MMI) and other related anti-thyroid drugs such as thiazolidine-2-thione (tzdtH) has been shown to play a crucial role in the inhibition[7a,8] this indicates that the inhibition of tyrosil iodination by anti-thyroid drugs should be different in the case of PTU than MMI or thzdtH. In the case of complex **2**, an intermolecular I(2)#2···H(3)−N(3) interaction [2.76 Å, with I(2)#2···N(3) = 3.573(4) Å ($-x + 1$, $y + 1/2$, $-z + 3/2$)] leads to the formation of a supramolecular assembly (Figure 4b).

The X−C=S···I torsion angles for the complexes are N(1)−C(2)−S(2)−I(21) = −95.9(3)° and N(3)−C(2)−S(2)−I(21) = 85.0(3)° for **1**, and I(1)−S(2)−C(2)−S(1) = −13.7(4)° and I(1)−S(2)−C(2)−N(3) = 167.9(4) for **2**. Thus, compound **1** can be considered to contain an almost perpendicular arrangement of iodine atoms with respect to the X−C=S plane. To the best of our knowledge this is the second structurally characterised molecule with such an arrangement, the second being [mbit·I_2].[6a] Examples include {I-S-C-S = −2.3(12)° and I-S-C-N = 174.7(13) in [{(bztzdtH)I_2}·I_2];[7a] I-S-C-S = −15.6(14)° and I-S-C-N = 166.5(15)° in [(bztzdtH)I_2];[7a] I-S-C-N = 3.0(19)° and I-S-C-N′ = −179.7(13)° in [{(bzimtH)I_2}$_2$·I_2·H_2O];[7a] I-S-C-X = −1.5(9)° in [mdtt·I_2];[5c] and I-S-C-X = −96.4(4)° in [mbit·I_2][6a]}. Compound **2**, on the other hand, can be considered as having an almost co-planar arrangement. Finally, the values for the S−I−I angles also imply an almost linear arrangement [S(2)−I(21)−I(22) = 175.85(2)° in (**1**) and S(2)−I(1)−I(2) = 173.78(4)° in (**2**)].

According to the value of the I−I bond order (n) defined by Pauling's equation:[10a]

$$d(\mathrm{I-I}) = d_o - 0.85 \cdot \log(n)$$

where d_o is the I−I bond length of I_2 in the gas phase (2.67 Å),[10b] Bigoli et al.[6a] have classified I_2 adducts into three classes: types **A**, **B** and **C**. When the value of the I−I bond order (n) is greater than or equal to 0.6 [d(I−I) < 2.85 Å] the adduct is classified as type **A**, while if n is less than or equal to 0.4 [d(I−I) > 3.01 Å] the compound is of type **C**;[6a] compounds with intermediate values are of type **B**.[6a] The I−I bond-order values calculated for the complexes studied in this work are 0.654 and 0.507 for complexes **1** and **2**, respectively. Therefore, complex **1** can be classified as type **A**, with a weak S−I interaction, while complex **2** is of type **B**. This is consistent with the classification derived from the spectroscopic data above. Thus, PTU forms a weak CT complex with iodine, in contrast to CMBZT or thiazolidine-2-thione (tzdtH). TzdtH has also been used as anti-thyroidal agent.[1] This molecule reacts with iodine in a molar ratio of 1:2 to form the strong CT

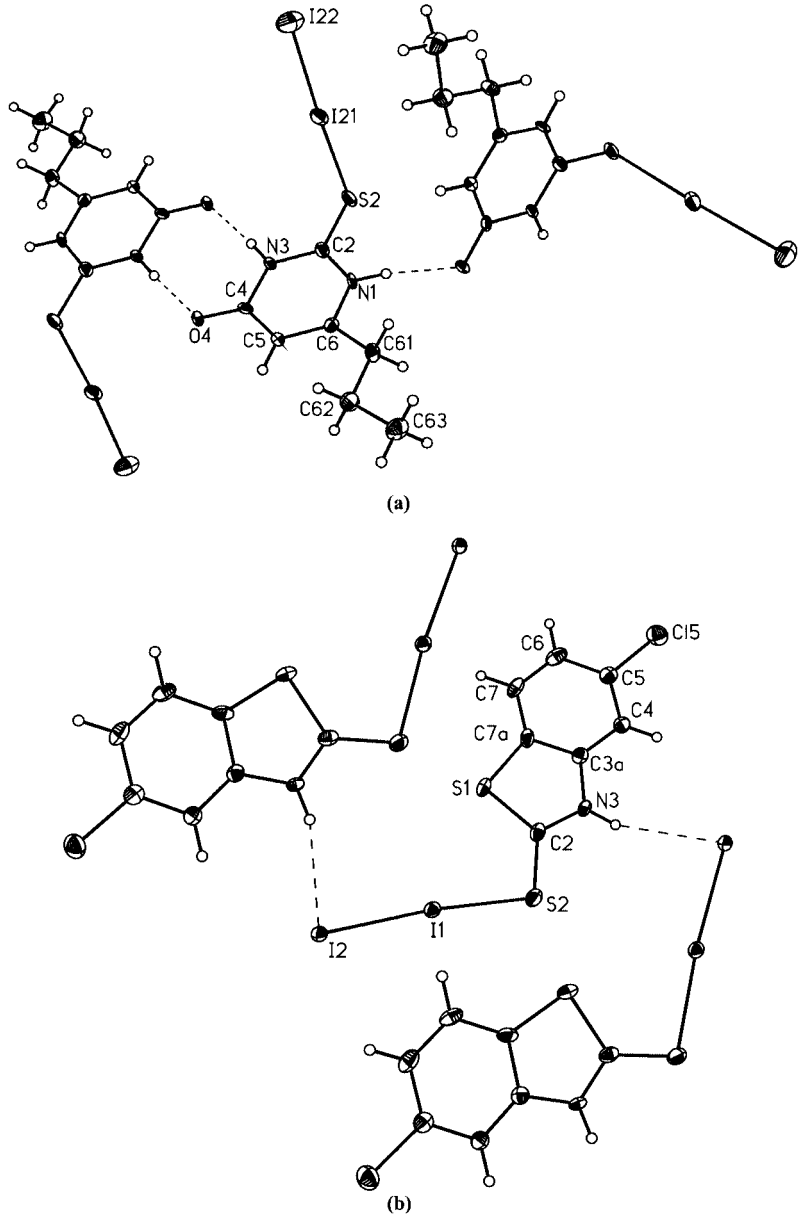

Figure 4. Intramolecular linkages via: (a) N−H···O interactions in **1** and (b) N−H···I interactions in **2**

complex $[\{(tzdtH)_2I^+\}\cdot I_3^-\cdot 2I_2]$,[7a] and is able to retain a total of four iodine molecules per two ligand molecules. On the other hand, MMI reacts with iodine to yield a CT complex which consists of the dication of the disulfite of MMI and I_8^{2-} counteranions $[(C_4H_6N_2S)_2]I_8$.[8] These findings also confirm that the inhibition of tyrosil iodination by anti-thyroid drugs should be different in the case of PTU than MMI or tzdtH, as proposed by Nakataka et.al.[11]

Conclusions

In conclusion, thioamides exhibiting anti-thyroidal activity against hyperthyroidism (Graves' disease) can be classified into two categories: (i) thioamides, such as MMI[8] or tzdtH,[7a] which are strong donors to iodine and form ionic salts, and (ii) thioamides like PTU, which are able to form weak charge-transfer molecules with iodine. Thioamides with intermediate donor activity to iodine — CMBZT, benzothiazole-2-thione (bztdtH)[7a] or benzimidazole-2-thione (bzimtH)[7a] — are able to bind only one I_2 molecule strongly and show no anti-thyroid activity. Thus, it seems that whereas drugs like MMI etc. interfere with the iodination mechanism by forming active iodine species in competition with the tyrosil residues of thyroglobuline[8,12,13] (Scheme 1), drugs like PTU appear to interfere either in the formation of the thyroid peroxide (TPO)-iodonium complex[12,13] or inhibit the activity of iodothyronine deiodinase (ID-1-SeH), an enzyme responsible for the monodeiodination of the **T4** prohormone to the **T3** hormone, as proposed by Berry et al.[13a] and later supported by du Mont et al.[13b] (Scheme 1). This is in agreement with

the proposal of Nakataka et al.,[11] supporting the difference in the inhibition mechanism of these type of drugs.

Experimental Section

Synthesis and Crystallisation of the Molecules: Complexes **1** and **2** were prepared by mixing dichloromethane solutions of iodine with a suspension of the appropriate thione in dichloromethane solution in molar ratios of 1:1 or 2:1, in air, at 0 °C, with continuous stirring, for 24 hours. The mixtures were then filtered and the resulting clear solutions were kept in the refrigerator for several days. Dark crystals of the complexes suitable for single-crystal analysis by X-ray crystallography were then grown and isolated by filtration. The reactions were also carried out in H_2O. The insoluble dark brown powders obtained were recrystallized from dichloromethane to yield the same products as previously.

Complex 1: Yield 0.085 g, (20%); m.p. 144−146 °C. $C_7H_{10}N_2I_2OS$ (424.0): calcd. C 19.83, H 2.37, N 6.61, S 7.56; found C 20.29, H 2.43, N 6.68, S 7.79. UV/Vis (CH_2Cl_2): λ_{max} (logε) = 512.5 nm (3.12), 287.5 (4.25). ^{1}H NMR ($CDCl_3$): δ = 10.05 [s, 1 H, HN(3)−C(2)], 9.74 [s, 1 H, HN(1)−C(2)], 2.41−2.35 [t, 2 H, $H_2C(61)$-C(6) of *n*-Pr], 1.73−1.26 [m, 2 H, $H_2C(62)$-C(61) of *n*-Pr], 1.06−1.00 [t, 3 H, $H_3C(63)$-C(62) of *n*-Pr] ppm.

Complex 2: Yield 0.050 g, (22%); m.p. 160−165 °C. $C_7H_4ClI_2NS_2$ (455.5): calcd. C 18.46, H 0.88, N 3.08, S 14.08; found C 17.90, H 0.63, N 2.80, S 14.07. UV/Vis (CH_2Cl_2): λ_{max} (logε) = 504 nm (2.93), 336 (4.36), 229 (4.41). ^{1}H NMR ($CDCl_3$): δ = 8.02 (s, 2 H, NH), 7.41−7.31 (m, 4 H, aromatic) ppm.

Crystal Data: Data were collected by the ω-scan technique in the $\theta-2\theta$ range 3.53 to 29.30° for **1** and 3.55 to 29.24° for **2** on a KUMA KM4CCD four-circle diffractometer[14a] with CCD detector, using graphite-monochromated Mo-K_α (λ = 0.71073 Å). Cell parameters were determined by a least-squares fit.[14b] All data were corrected for Lorentz-polarization effects and absorption.[14b] The structures were solved by direct methods with SHELXS-97[15] and refined by full-matrix least-squares procedures on F^2. All non-hydrogen atoms were refined anisotropically, hydrogen atoms were located at calculated positions and refined as a "riding model" with isotropic thermal parameters fixed at 1.2-times the U_{eq}'s of the appropriate carrier atom.

1: $C_7H_{10}I_2N_2OS$, mol. wt. = 424.03, monoclinic space group $P2_1/c$, a = 9.8501(7), b = 10.3101(7), c = 12.0287(8) Å, β = 99.707(6)°, V = 1204.09(14) Å^3, Z = 4, T = 120(1) K, ρ(calcd.) = 2.339 g cm^{-3}, μ = 5.365 mm^{-1}, reflections collected 2997. Final R indices [$I > 2\sigma(I)$]: $R1$ = 0.0323, $wR2$ = 0.0745.

2: $C_7H_4ClI_2NS_2$, mol. wt. = 455.48, orthorhombic space group $P2_12_12_1$, a = 4.1650(10), b = 9.691(2), c = 28.471(6) Å, V = 1149.2(4) Å^3, Z = 4, T = 293(2) K, ρ(calcd.) = 2.633 g cm^{-3}, μ = 6.023 mm^{-1}, reflections collected 7301. Final R indices [$I > 2\sigma(I)$]: $R1$ = 0.0275, $wR2$ = 0.0528.

The Human Telomeric Sequence $(T_2AG_3)_n$ is Efficiently Cross-Linked by AN1 Binding to the Platinum of a *trans*-$Pt(NH_3)_2$ Chelate of an Antisense Oligo-2′-*O*-Methylribonucleotide

Sandrine Perrier,[a] Frank Seela,[b] Annie Schwartz,[c] Marc Leng,[c][†] and Jean-Claude Chottard*[a]

Keywords: Platinum / DNA / RNA / Chelates / Bioinorganic chemistry

In order to irreversibly cross-link an antisense oligonucleotide to the human telomeric sequence $(T_2AG_3)_n$, the inter-strand bridging rearrangement described by Leng et al. was investigated on (21-mer antisense) (20-mer target) duplexes: (G*NG*)(TA) → (G*NG)(TA*), G*NG* being a *trans*-[$Pt(NH_3)_2$\{1,3-(GNG)-*N7*-G,*N7*-G\}] chelate with N = U or T. Three different duplexes were studied, confirming first that for a DNA target strand the rearrangement was faster with a platinated oligo-2′-*O*-methylribonucleotide than with a deoxy oligonucleotide as antisense strand. Second, a telomeric DNA target strand was cross-linked faster than an all-purine oligonucleotide containing a single TA doublet. Accordingly, the half time of formation of the cross-linked hybrid duplex [2′-OMe-r(CCCUAACCCG*UGACCCUAACCC)]·[$d(T_2AG_3)_2(TTA*G_3)(T_2AG_3)$] is one minute, compared with the nine days required for the complete formation of the bridged d(CTCCTG*TGTCTC)·d(GAGATA*AGGAG) duplex. The NMR analysis of the latter showed that the platinum cross-link involves the A*N1 moiety as ligand. The timescale difference between the two reactions raised the question of an eventual kinetic cross-link which might isomerize to the final one observed. This question was addressed using 1-deazaadenine in the TA doublet of the three target strands of this work. No cross-linking reaction was observed, proving that AN1 is the bridging atom in all the cases studied so far.

Introduction

Transplatin *trans*-diamminedichloroplatinum(II) is clinically ineffective, as opposed to its stereoisomer cisplatin *cis*-diamminedichloroplatinum(II).[1−4] Nevertheless it reacts with both single- and double-stranded DNA. On the former, it gives an intra-strand *trans*-[$Pt(NH_3)_2$\{1,3-d(GNG)-*N7*-G,*N7*-G\}] platinum chelate (named G*NG*) with the sequences d(GNG), N being any nucleotide but G.[5] Such adducts were found to be stable in single-stranded oligonucleotides, except that formed on the d(CG*NG*) sequence, which rearranges into the 1,4-d(C*GNG*)-*N3*-C,*N7*-G chelate.[6,7] Upon pairing with the complementary strands, the G*NG* chelates rearrange into inter-strand adducts. In DNA/DNA duplexes and DNA/RNA hybrids, inter-strand cross-links are formed slowly and involve mainly the N7 atom of the 5′ guanine of the initial chelate and the N3 atom of its complementary cytosine.[8−10]

The discovery of this reaction allowed the conception of a new tool for antisense strategy, although therapeutic applications would require cross-linking reactions with short half times compared to most mRNA half-lives, which are of the order of minutes.[11] An investigation of the influence of the series and of the bases of the antisense and target strands led to the selection of hybrid duplexes between a platinated oligo-2′-*O*-methylribonucleotide and a target RNA containing a 5′-pyrimidine/adenine doublet in place of the triplet complementary to the GNG sequence. In these cases, the inter-strand cross-link is formed between the N7 atom of the 5′-G* of the intra-strand chelate and the facing A on the opposite strand after a few minutes.[12,13] The antisense platinated oligo-2′-*O*-methylribonucleotides can be relatively resistant to nucleases. They can enter the cells where they bind specifically and irreversibly to mRNA. The platinum complex bridging both oligonucleotides resists translating ribosomes and leads to inhibition of mRNA expression.[12,14,15] All these results were obtained with purine-rich target strands, suggesting that the platinated oligonucleotides could also bind irreversibly to the human telomeric sequence $(T_2AG_3)_n$ and therefore become potential inhibitors of telomerase activity.[16−18]

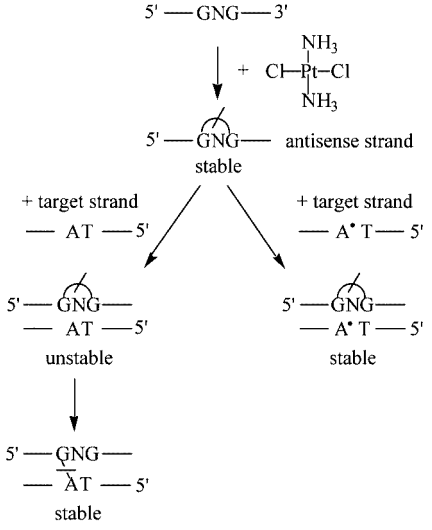
[†] Deceased May 2000

As already reported with target r-UA oligonucleotides,[12,13] we found that the most efficient platinated antisense strands belong to the 2′-*O*-methylribonucleotide series, with the G*NG* triplet facing a d-TA doublet. The fast cross-linking of the platinated ribonucleotide with the telomeric sequence (timescale of a few minutes) compared to that observed in the case of the bridged d(CTCCTG*TGTCTC)·d(GAGATA*AGGAG) duplex (timescale of a few days) raised the question of the possibility of two bridging pathways and/or the existence of a kinetic and a final products. For the cross-linked deoxy duplex, NMR spectroscopy has shown the presence of a *trans*-G*(*N7*)-Pt$(NH_3)_2$-A*(*N1*) bridge.[19] The presence of the 1,3-chelate, the base mismatch, the hybrid pairing and the missing nucleotide on the target strand could allow adenine N7 and/or N1 nucleophilic attack on platinum. This prompted us to check the AN1 involvement in our reactions. We have replaced adenine by 1-deazaadenine (A˙) in the (TA˙) target DNA strand of three duplexes where the G*NG* chelate belongs to DNA or 2′-OMe-RNA strands. No inter-strand cross-link was formed in any of the (G*NG*)(TA˙) duplexes containing 1-deazaadenine, showing the generality of the AN1 involvement (Scheme 1).



Scheme 1. Inter-strand cross-linking reaction, within a duplex structure, between the adenine of the TA target strand and the platinum atom of the G*NG* intra-strand chelate of the antisense strand; G*NG* = *trans*-[Pt$(NH_3)_2${1,3-(GNG)-*N7*-G,*N7*-G}], G* indicates an *N*7-bound guanine; the bridging reaction is not observed when A in the target strand is replaced by 1-deazaadenine A˙

Results and Discussion

The four antisense oligonucleotides used in this work were 21-mers − either DNA or 2′-OMe-RNA − with a G*NG* intra-strand *trans*-Pt$(NH_3)_2$ chelate in a central position (Figure 1). All of them were ^{32}P labelled at the 5′ position. The (G*NG*) strand was mixed with an equal amount of a (TA) or (TA˙) 20-mer target strand. In two cases, this target strand was the human telomeric $(T_2AG_3)_3$ sequence. Solid-phase synthesis of the oligonucleotides containing 1-deaza-2′-deoxyadenosine was performed in Dr. F. Seela's laboratory (Osnabrück University, Germany). The incorporation of the synthesized 1-deaza-2′-deoxyadenosine was checked by HPLC analysis of the nucleoside composition after enzymatic hydrolysis of the oligomers.[20,21] The duplex oligonucleotides (2 μM) were incubated at 37 °C for 165 minutes. Aliquots were withdrawn at regular time intervals and analyzed by polyacrylamide gel electrophoresis under denaturing conditions. As shown in Figure 2, when the G*NG* chelate is facing the 5′-TA doublet, a new band appears at the expense of that of the platinated single-stranded DNA or 2′-OMe-RNA. This new band migrates slower than that of the antisense strand. It corresponds to the antisense and target strands cross-linked by the *trans*-[Pt$(NH_3)_2${(*N7*-G),d(A)}] bridge as shown by Maxam−Gilbert footprinting, in agreement with previous results.[8,10,13] At the end of the incubation period (165 min), about 90% and 100% of the platinated antisense strand

1	5′ UCUCCUCUG*UG*UCUCCUUCUU AGAGGAGA A T AGAGGAAGAA 5′	2′-OMe-RNA DNA
2	5′ AACCCTAACCCG*TG*ACCCTAA TTGGGATTGGG A T TGGGATT 5′	DNA DNA
3	5′ AACCCUAACCCG*UG*ACCCUAA TTGGGATTGGG A T TGGGATT 5′	2′-OMe-RNA DNA
4	5′ CCCUAACCCG*UG*ACCCUAACCC GGGATTGGG A T TGGGATTGGGATT 5′	2′-OMe-RNA DNA

Figure 1. The paired oligonucleotides **1**−**4** of this study; at the rearrangement site, the intra-strand cross-link G*NG* (G* denotes an *N*7 platinated guanine; N = T or U) faces the 5′-TA doublet; in the text the intra-strand platinated 21-mer is called the (G*NG*) antisense strand, and the target 20-mer either the (TA) or (TA˙) strand according to the presence of adenine or 1-deazaadenine

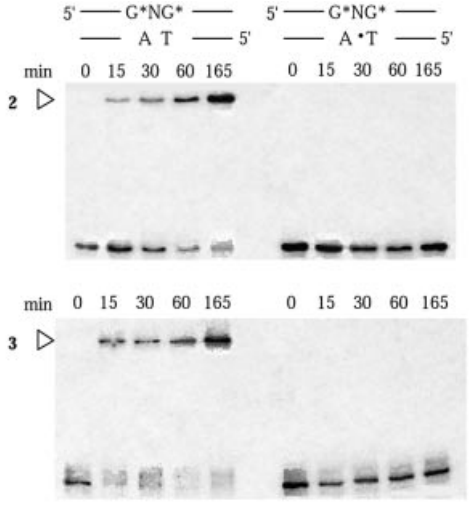


Figure 2. Cross-linking reactions within the DNA/DNA (**2**) and 2′-OMe-RNA/DNA (**3**) duplexes monitored by electrophoresis on a denaturing 20% polyacrylamide gel; the (G*NG*) strands were ^{32}P 5′-end labelled and paired with their complementary telomeric DNA target strand containing either TA or TA˙ (A˙ = 1-deazaadenine); the duplexes were incubated at 37 °C in 150 mM NaCl, 5 mM phosphate buffer, pH 7.5 and 0.2 mM EDTA; incubation times (in minutes) are given above the lanes; the inter-strand adduct is indicated by an arrowhead on the left

were cross-linked to the target strand within the platinated DNA/DNA duplex **2** and 2′-OMe-RNA/DNA hybrids **3** and **4**, respectively (Figure 2), with respective $t_{1/2}$ values of 40 minutes for the former and one minute for the latter two. The half reaction time for the platinated 2′-OMe-RNA/DNA hybrid **1** is 18 minutes. It is noteworthy that the rearrangement is faster when the platinated antisense strand is a 2′-OMe-ribonucleotide (see **2** vs. **3**), as already found.[12,13] Moreover, it is faster when the target deoxyoligonucleotide is the human telomeric sequence $(T_2AG_3)_n$ (see **1** vs. **3** and **4** in Figure 3).

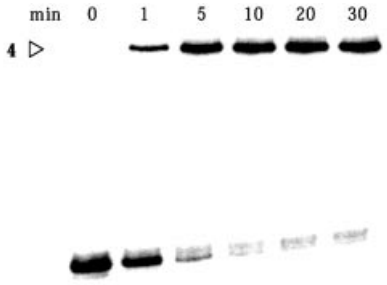

Figure 3. Cross-linking reaction within the 2′-OMe-RNA-(CCCUAACCCG*UG*ACCCUAACCC)/DNA$(T_2AG_3)_4$ hybrid **4**; autoradiogram of a denaturing 20% polyacrylamide gel; the (G*UG*) strand was ^{32}P 5′-end labelled; the hybrid was incubated at 37 °C in 0.2 M NaCl, 5 mM phosphate buffer, pH 7.5 and 0.2 mM EDTA; incubation times (in minutes) are given above the lanes; the inter-strand adduct is indicated by an arrowhead on the left

Replacing the adenine of the TA doublet by a 1-deazaadenine (TA$^{\cdot}$) suppresses the inter-strand cross-linking within any of the three paired sequences **1**−**3**. It must be noted that after 165 minutes, a product migrating like two cross-linked strands was present in a very small amount, accounting for ca. 1% of the total radioactivity for the systems **1** and **2**, and 4% for **3**. This product might result from a slow cross-linking reaction involving the A$^{\cdot}$N7 atom. To check further an eventual rearrangement of the 1,3-intra-strand chelate facing a 1-deazaadenine within the systems studied, the incubation was extended by 48 h for the platinated DNA/DNA duplex **2** (not shown). Some products appeared, with migration similar to that of as two cross-linked strands, and accounting for less than 2% of the total radioactivity. The amount of isolated material was too small to allow any further characterization. These data suggest that the N7 atom of the TA adenine, facing the G*NG* platinum chelate, is not competitive with the N1 atom of the same adenine when binding to the metal and cross-linking the antisense and target strands.

These results agree with the very slow rate of isomerization observed when the UA doublet of a target strand is replaced by UG at the rearrangement site.[12] They also agree with the NMR analysis of the *trans*-Pt(NH_3)$_2$ cross-linked DNA/DNA duplex d(CTCCTG*TGTCTC)·d(GAGATA*AGGAG), which showed that the A*N1 atom is bound to platinum.[19] It is noteworthy that the much longer time needed for the bridging of this duplex (nine days for complete conversion) compared to the speed of our reactions (one minute), shows that the AN1 binding to the platinum is a common feature of all these rearrangements, whatever their efficiency, and can be compared to the (G*NG*)(CN′C) → (G*NG)(CN′C*) cross-linking involving the 3′-CN3 of the target strand. Within a B-DNA the AN1 and CN3 atoms occupy similar positions and this might be retained in the (G*NG*)(CN′C) and (G*NG*)-(TA) duplexes despite the mispairing and the missing nucleotide at the rearrangement core. This could be favored by the stabilizing effect of the 2′-OMe-ribonucleotide nature of the (G*NG*) strand.[13]

In conclusion, we have shown that a platinated 2′-OMe-RNA-antisense strand efficiently cross-links a $(T_2AG_3)_n$ telomeric target with a one minute half-reaction time. This irreversible binding to telomeric sequences might inhibit telomerase activity. Moreover, our results suggest that all the rearrangements involving the G*NG*/TA core involve the AN1 atom of the target strand acting as a bridging ligand to platinum, independently of the nature of the antisense strand and of the cross-linking rate.

Experimental Section

Materials and Methods: The oligodeoxyribonucleotides and oligo-2′-*O*-methyl ribonucleotides (from Eurogentec Belgium) were purified by ion-exchange chromatography (monoQ column, Pharmacia) as described previously.[12,13] The 1-deaza-2′-deoxyadenosine phosphoramidite was synthesized and employed in solid-phase oligonucleotide synthesis.[20−23] The purified oligonucleotides containing 1-deazaadenine were checked by hydrolysis with snake-venom phosphodiesterase followed by alkaline phosphatase yielding the monomeric nucleosides. The presence of the modified nucleotide was controlled by HPLC analysis of the nucleoside composition. The T4 polynucleotide kinase was purchased from Boehringer Mannheim and the radioactive products from Amersham. All other chemicals were purchased from Merck, except *trans*-diamminedichloroplatinum(II), which was a gift of Johnson Matthey (UK).

Platination: The single-stranded oligonucleotides containing a single GNG triplet were reacted with transplatin as described previously.[12,13] The platinated oligonucleotides were incubated in the presence of thiourea to remove the monofunctional adducts[6] and were purified on a monoQ column. The formation of the *trans*-[Pt(NH_3)$_2$\{1,3-(GNG)-*N7*-G,*N7*-G\}] intra-strand chelates was verified by the non-reactivity of the platinated G residues with dimethylsulfate.[10,13]

Linkage Isomerization Reaction: The 5′[^{32}P]-labelled platinated oligonucleotides (2 μM) were mixed at 0 °C with their complementary strands and then incubated at 37 °C in 5 mM phosphate buffer at pH 7.5, 150 mM NaCl and 0.2 mM EDTA. Aliquots were withdrawn at various times and analyzed on electrophoresis gel under denaturing conditions (20% polyacrylamide/7 M urea). The disappearance of the labelled strands containing the intra-strand chelate was monitored by quantitation of the gel bands with a Molecular Dynamics PhosphorImager using ImageQuant software version 3.3 for data processing. The location of the inter-strand cross-link was deduced from Maxam−Gilbert footprinting.[8]

Acknowledgments

We are indebted to the EC Biomed programme "Modulation of gene expression by platinated oligonucleotides" (BMHA CT 97-

2485) and Ministère de la Recherche (doctoral fellowship for S.P.) for financial support. We thank Johnson-Matthey, Inc. for a generous loan of *trans*-diamminedichloroplatinum(II).

COVER PICTURE

The cover picture shows a schematic illustration of the unusual inorganic-organic hybrid structures (upper right) formed by linking of the inorganic building units through organic linkers. The structures of two different compounds (bottom) containing the inorganic cadmium chloride chains (upper left corner) linked by oxalate and piperazine moieties into two and three dimensions are also shown. Color scheme: Cd – yellow; Cl – green; O – red; N – violet; C – blue. Details are discussed in the article by C. N. R. Rao et al. on p. 1675 ff.

Phosphane-Substituted Selenido−(carbonyl)iron and −(carbonyl)ruthenium Clusters: Structures, Fluxionality and Reactivity

Claudia Graiff,[a] Giovanni Predieri,[a] and Antonio Tiripicchio*[a]

Keywords: Crystal structures / Fluxional behaviour / Iron clusters / Ruthenium clusters / Selenium compounds

Selenium-transfer reactions from tertiary phosphane and diphosphane selenides to the carbonyl clusters $[M_3(CO)_{12}]$ (M = Fe or Ru) provide a simple, stepwise synthetic route to phosphane-substituted, mono- and diselenido–(carbonyl)iron and –(carbonyl)ruthenium clusters. Four families of clusters are generally obtained: (*i*) the $M_2Se_2L_6$ tetrahedral species (only for iron), (*ii*) the M_3SeL_{10} capped triangular species, (*iii*) the $M_3Se_2L_9$ square-pyramidal *nido* species (for iron and ruthenium), and (*iv*) the $M_4Se_2L_{11}$ octahedral *closo* species (only for ruthenium), with L being a phosphane or carbonyl ligand. When the tertiary phosphane selenide contains heterocyclic fragments, the reaction is not only limited to the transfer of the selenium atom, but proceeds by P–C and, sometimes, C–H bond cleavages, affording new selenidophosphido carbonyl clusters bearing coordinated heterocyclic fragments. Many clusters show fluxional behaviour in solution because of either ligand mobility or M–M bond migration. Furthermore, dimetallic substituted carbonyl clusters have been prepared by two different synthetic approaches: (1) MM′ + PSe (reactions between preformed dimetallic clusters and tertiary phosphane selenides) and (2) MSeP + M′ [cluster growth reactions from preformed chalcogenido–(carbonyl)metal clusters and suitable organometallic fragments]. In particular, from the tetrahedral clusters $[HMCo_3(CO)_{12}]$ (M = Fe or Ru) monoselenido clusters $[MCo_2(\mu_3\text{-Se})]$ with a tetrahedral core have been obtained. The second type of approach has been applied to the open-triangular *nido* clusters $[Ru_3(\mu_3\text{-Se})_2(CO)_{9-n}L_n]$ (L = tertiary phosphane, n = 1 or 2), which can add zero-s.e.p.'s organometallic fragments, such as $M(CO)_3$ (M = Mo or W), giving the corresponding *closo* clusters $[MRu_3(\mu_4\text{-Se})_2(CO)_{12-n}L_n]$.

I. Introduction

Transition metal species may combine with main group elements or related molecular fragments to afford a variety

Claudia Graiff obtained her PhD degree in chemistry in 1999 at the University of Parma under the supervision of Prof. Giovanni Predieri and Antonio Tiripicchio. Since 1999 she has been a researcher at the University of Parma. Her current research interests concern the synthesis and characterization of chalcogenido−(carbonyl)metal clusters substituted by phosphane ligands.

Giovanni Predieri obtained his degree in Chemistry from the University of Parma in 1972 and was a postdoctoral fellow in 1981 and 1984 at the Laboratoire de Chimie de Coordination of the University of Strasbourg. In 1988 he received the "Arturo Miolati" award from the Italian Chemical Society for his research in Inorganic Chemistry. He is now a full professor of General and Inorganic Chemistry at the Faculty of Science of the University of Parma. His current research interests are in the area of inorganic chemistry, including the synthesis of new transition metal clusters, the design of hybrid organic-inorganic materials by the sol-gel process and, very recently, the production of chelated metal complexes for use in animal nutrition.

Antonio Tiripicchio has been full professor of General and Inorganic Chemistry at the Faculty of Science of the University of Parma since 1980. He is the author of more than 500 papers in international journals and of about 180 communications at national and international symposia and conferences. His current research interests are: synthesis, structure, and reactivity of homo- and heterometallic clusters and their use as precursors of catalysts and materials; characterization of inorganic-organic hybrid materials prepared by sol-gel processes and their use in catalysis; new synthetic routes for the synthesis of organometallic selenides. Presently he is Past-President of the Inorganic Chemistry Division of the Italian Chemical Society of which he was President from 1997 to 1999 and Director of the Interuniversity Consortium on "Chemical Reactivity and Catalysis"

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

of interesting cluster compounds. Apart from their fundamental significance as a class of complexes owning peculiar chemical and structural properties, the growing interest in these species derives from their potential applications as catalysts, electrocatalysts and precursors for semiconductors.[1−3] Very recently, chalcogenido−ruthenium derivatives have shown interesting catalytic activity in oxygen reduction reactions in polymer electrolyte fuel cells (PEMFC),[4−7] suggesting their application as cathodes for these devices. The presence of chalcogenide species, in particular Se, appears to catalyse processes that lead to reduction of oxygen through the formation of selenido−transition metal cluster materials.[8] In addition, it is well known that sulfur and selenium atoms are found in active sites of a large number of proteins.[9]

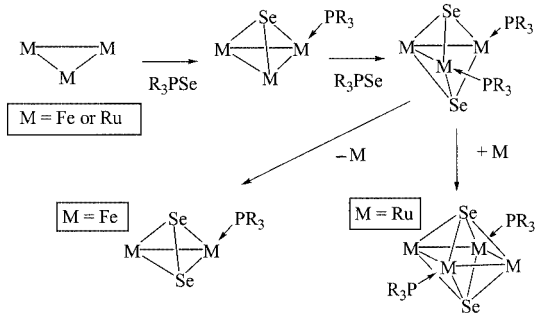
The availability of substituted chalcogenido−metal clusters offers the opportunity to exert a stoichiometric control in those processes that lead from molecular metal chalcogenides, such as $[M_xE_y(PR_3)_z]$, to extended inorganic solids, like M_xE_y. The stoichiometric control, combined with kinetic control, which derives from low activation energies of these processes, often allows the preparation of otherwise inaccessible solid phases or microinhomogeneous materials, such as nanocomposites.[10]

Different synthetic routes are presently available for the preparation of selenido−transition metal clusters, such as those involving diphenyl diselenide,[11,12] phenylselenyl chloride,[13] selenophene,[14] trialkylsilyl selenides,[15−17] polyselenide anions,[18,19] and phosphane selenides [20−23] as starting materials. Furthermore, small selenido clusters, such as $[M_2(\mu\text{-}Se_2)(CO)_6]$ and $[M_3(\mu_3\text{-}Se)_2(CO)_9]$, can be used conveniently to prepare larger mono- and dimetallic species.[24,25]

II. Synthesis of Selenido Clusters from Phosphane Selenides

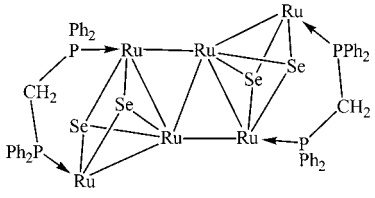
The reactions of tertiary phosphane selenides with (carbonyl)metal species provide a simple synthetic procedure to form selenido clusters through transfer of selenium atoms to low-valent metal centres, taking advantage of the frailty of the P=Se bond. Despite the synthetic potential of the phosphane selenides, their reactions with (carbonyl)metal compounds have been explored only to a limited extent prior to the last few years. For this reason, we began studying the reactions of tertiary phosphane and diphosphane selenides with $[M_3(CO)_{12}]$ (M = Fe or Ru)[26,27] with the aim to obtain new phosphane-substituted selenido carbonyl clusters, whose structural characterization, fluxional behaviour and reactivity are the central issues of this Microreview.

The carbonyl clusters $[M_3(CO)_{12}]$ (M = Fe or Ru) react with tertiary phosphane selenides through transfer of selenium atoms to the metal cluster, giving a variety of phosphane-substituted selenido carbonyl clusters, whose structural frameworks are shown in Scheme 1. The open-triangular, variously substituted, *nido* clusters with the M_3Se_2 core are the major products for both metals, but significant amounts of clusters with dinuclear M_2Se_2, trinuclear M_3Se, and tetranuclear M_4Se_2 cores are also obtained. The product distribution is strongly dependent on the reaction conditions, on the nature of the phosphane and on the cluster/phosphane molar ratio. In the case of iron, the reaction takes place rapidly upon gentle warming, whereas, in the case of ruthenium, the presence of Me_3NO as a decarbonylation reagent is required to increase the reaction rate. Most of those clusters are air-stable and can be separated and recognized by silica gel chromatography[28] and recovered by TLC.



Scheme 1

Moreover, the reactions with bis(diphenylphosphanyl)-methane diselenide ($dppmSe_2$) lead to the formation of other less common compounds, which can be obtained by condensation processes, such as the hexanuclear clusters containing M_6Se_4 cores[29] shown in Scheme 2 and the compound $[Ru_4(\mu_3\text{-}Se)_4(CO)_{10}(dppm)]$, shown in Figure 1, which is the first reported 72-electron Ru_4Se_4 cubane-like cage complex.[30] This complex should be regarded as a secondary product, probably formed by the self-assembly of two dinuclear Ru_2Se_2 groups, derived from *nido*-Ru_3Se_2 by loss of a mononuclear metal fragment. Despite the presence of the bridging diphosphane, the overall geometry of the Ru−Se cubane is very similar to those of the unsubstituted Fe−S and Fe−Se cubanes $[Fe_4E_4(CO)_{12}]$ (E = S, Se).[31,32]



Scheme 2

On the basis of our results we have suggested that the reactions between $[M_3(CO)_{12}]$ and R_3PSe proceeds through two consecutive steps. The monoselenido clusters $[Ru_3(\mu_3\text{-}Se)(\mu_3\text{-}CO)(CO)_8PR_3]$, obtained by the stoichiometry-controlled reaction of phosphane selenide R_3PSe with $[Ru_3(CO)_{12}]$, undergo a second attack by R_3PSe affording the corresponding diselenido derivatives $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(PR_3)_2]$. To demonstrate the stepwise selenium transfer,

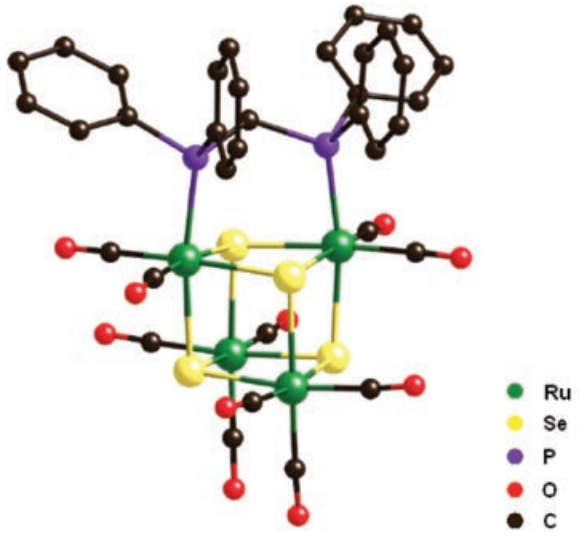

Figure 1. Perspective view of cage compound $[Ru_4(\mu_3\text{-}Se)_4(CO)_{10}(dppm)]$

we have treated the monoselenido clusters with another equivalent of phosphane selenide, obtaining the corresponding diselenido species quantitatively.[33] The process, occurring at 60−70 °C, in the presence of Me_3NO, can be monitored by IR spectroscopy.

The structure of the monoselenido-disubstituted cluster $[Ru_3(\mu_3\text{-}Se)(\mu_3\text{-}CO)(CO)_7(PPh_3)_2]$ is shown in Figure 2. The triangle of ruthenium atoms is capped on one side by a selenium atom and on the other by a carbonyl group. The two PPh_3 ligands coordinate through the P atoms to two Ru atoms in pseudo-equatorial and pseudo-axial positions, respectively. The μ_3-Se ligand is practically equidistant from the three Ru atoms, whereas the μ_3-CO group bridges, in a slightly asymmetrical way, the two shortest Ru−C distances involving the ruthenium atoms coordinated by the two phosphane groups. This slight asymmetry has also been observed in the case of the unsubstituted cluster $[Ru_3(\mu_3\text{-}S)(\mu_3\text{-}CO)(CO)_9]$.[34]

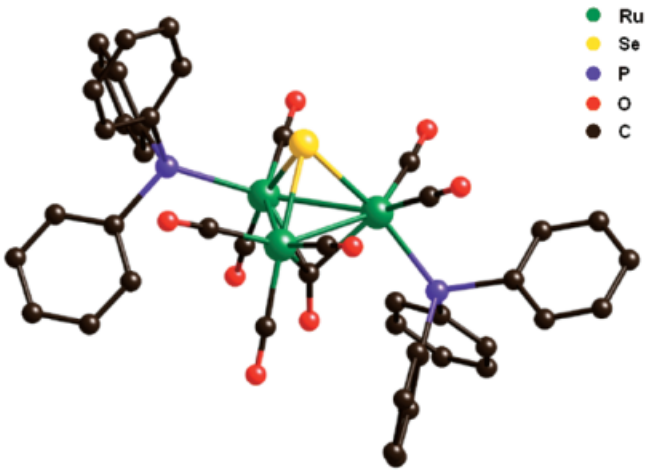

Figure 2. Perspective view of cluster $[Ru_3(\mu_3\text{-}Se)(\mu_3\text{-}CO)(CO)_7(PPh_3)_2]$

The structure of the diselenide cluster $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(dppy)_2]$ [dppy = diphenyl(pyridyl)phosphane] (Figure 3) contains an Ru_3Se_2 core that can be described as a square pyramid with one Ru atom at the apex and two Ru and Se atoms alternating at the base. In this structure, the two phosphane groups coordinate the Ru atoms in pseudo-equatorial and pseudo-axial positions, as in the triphenylphosphane derivative,[35] although, with other ligands, we have obtained analogous clusters with both phosphane groups in equatorial positions.[36] The values of the Ru−P bond lengths, 2.326(3) and 2.371(4) Å, differ remarkably because of the influences of the *trans* Ru−Ru and Ru−Se bonds.

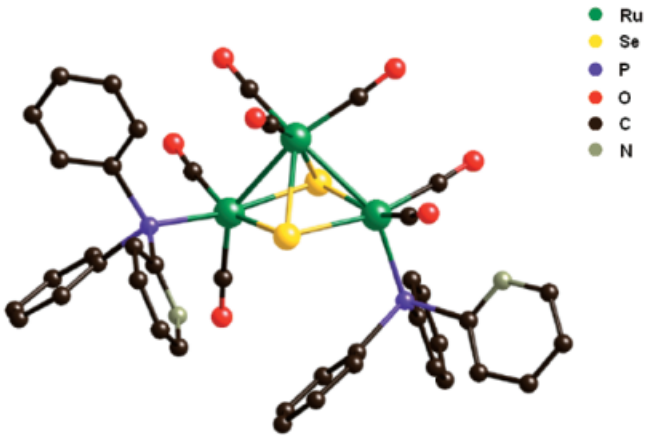

Figure 3. Perspective view of cluster $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(dppy)_2]$

III. Multiple Fragmentation of the Phosphane Selenide Leading to Selenido-Phosphido Clusters

Recently, we observed that tertiary phosphane selenides bearing heterocyclic fragments, such as 2-thienyl (th),[37] 2-pyridyl (py),[38] and 5-(2-pyridyl)-2-thienyl (pyth),[39] (see Scheme 3) can undergo P−C bond cleavage by reaction with (carbonyl)iron and -ruthenium compounds, affording selenido-phosphido clusters. In fact, the heterocyclic moiety was introduced to drive new reactivity patterns in cluster-growing processes, because of the possible release of heterocyclic fragments and the coordinating ability of the heteroatoms.

The cluster $[Ru_3(\mu_3\text{-}Se)(\mu\text{-}PPh_2)(CO)_6(\mu\text{-}\eta^1{:}\eta^2\text{-}C_4H_3S)\{P(C_4H_3S)Ph_2\}]$, obtained by reaction between $[Ru_3(CO)_{12}]$ and diphenyl(2-thienyl)phosphane selenide, was identified only after the determination of its crystal structure by diffraction methods because of its structural singularity. In the structure, shown in Figure 4, the Se atom caps the metal triangle, two sides of which are bridged by a phosphido and a thienyl ligand, which derive from the multiple fragmentation of the parent diphenyl(2-thienyl)-phosphane selenide.

The bonding of the thienyl group is rather unusual, since it interacts through the double bond forming a σ-bond with

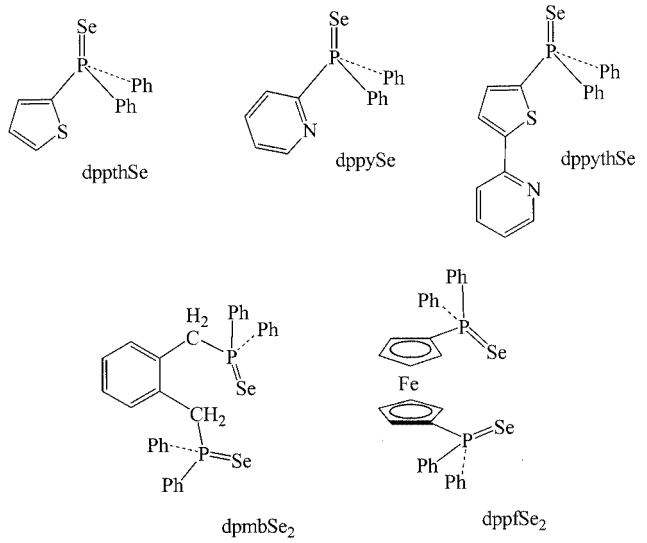
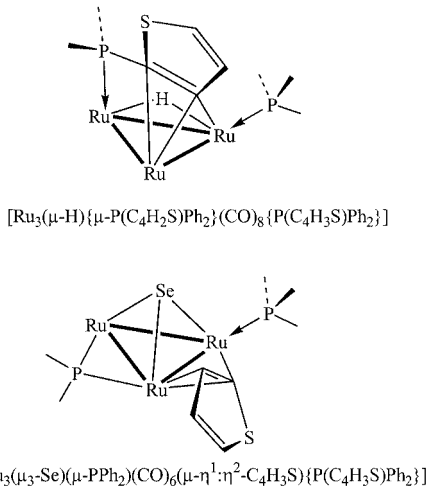


Scheme 3



Scheme 4

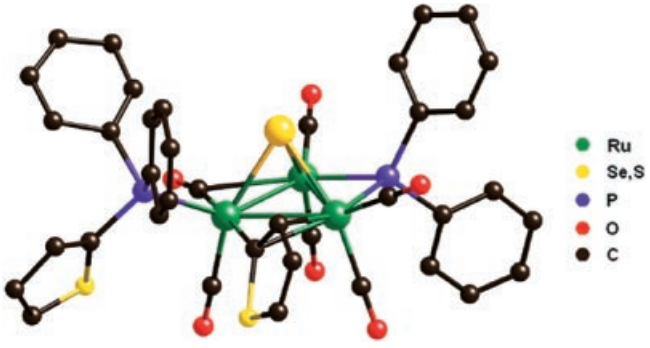


Figure 4. Perspective view of cluster $[Ru_3(\mu_3\text{-}Se)(\mu\text{-}PPh_2)(CO)_6(\mu\text{-}\eta^1{:}\eta^2\text{-}C_4H_3S)\{P(C_4H_3S)Ph_2\}]$

an Ru atom and a π-bond with another Ru atom. The coordination mode (μ-η^1:η^2) of the 2-thienyl fragment is similar to that observed in $[Ru_3(\mu\text{-}H)\{\mu\text{-}P(C_4H_2S)Ph_2\}(CO)_8\{P(C_4H_3S)Ph_2\}]$ for the $Ph_2(C_4H_3S)P$ ligand.[40] The most important difference, however, between the two coordination modes is the position of the bridging thienyl moiety with respect to the metal triangle. In fact, in $[Ru_3(\mu\text{-}H)\{\mu\text{-}P(C_4H_2S)Ph_2\}(CO)_8\{P(C_4H_3S)Ph_2\}]$ the thienyl ring overhangs the metal triangle, whereas in $[Ru_3(\mu_3\text{-}Se)(\mu\text{-}PPh_2)(CO)_6(\mu\text{-}\eta^1{:}\eta^2\text{-}C_4H_3S)\{P(C_4H_3S)Ph_2\}]$ it approaches the triangle laterally, in such a way that the α-carbon atom is almost lying in the cluster plane, as shown in Scheme 4.

The structure of the cluster $[Ru_3(\mu_3\text{-}Se)(\mu\text{-}PPh_2)(CO)_6(\mu\text{-}pyth)\{P(pyth)Ph_2\}]$, obtained by reaction between $[Ru_3(CO)_{12}]$ and diphenyl[5-(2-pyridyl)-2-thienyl]phosphane selenide, is very similar to that with the thienyl ligand.

In the case of the pyridyl group, the ligand $Ph_2(2\text{-}C_5H_4N)PSe$ undergoes multiple fragmentation by reaction with $[Ru_3(CO)_{12}]$ to afford the cluster $[Ru_3(\mu_3\text{-}Se)(\mu\text{-}PPh_2)_2(\mu\text{-}C_5H_4N)(\mu_3\text{-}C_5H_4N)(CO)_6]$ that does not contain any Ru−Ru bond and is built up through the unique synergy of five bridging ligands. The structure of this polynuclear species (Figure 5) is characterized by the presence of a nearly planar array of eleven atoms forming two roughly coplanar fused rings; i.e., the heptaatomic RuPRuPRuCN cycle and one pyridyl ring [dihedral angle 6.9(1)°].

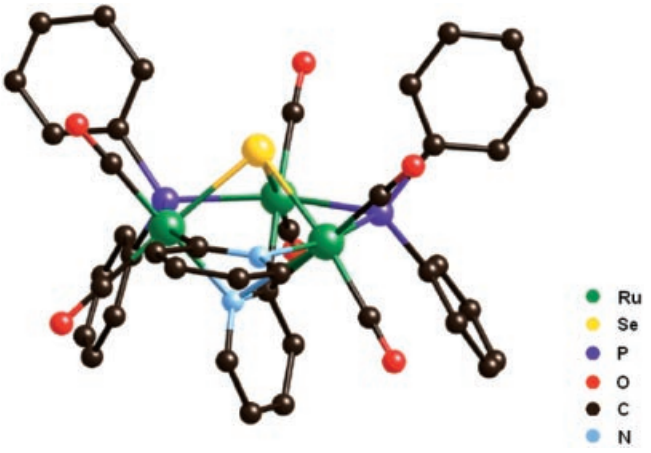

Figure 5. Perspective view of compound $[Ru_3(\mu_3\text{-}Se)(\mu\text{-}PPh_2)_2(\mu\text{-}C_5H_4N)(\mu_3\text{-}C_5H_4N)(CO)_6]$

The μ_3-Se bridging mode, connecting three non-interacting ruthenium atoms, has only a few precedents in other trinuclear ruthenium derivatives.[38] This cluster has been obtained from $Ph_2(2\text{-}C_5H_4N)PSe$ through P=Se and P−C(Py) bond cleavages. It contains two differently bridging pyridyl groups, the former connects two Ru atoms through σ bonds, lying on the plane defined by the three metal atoms, the latter is σ-bonded to the same two Ru atoms, being nearly perpendicular to the metal plane, in such a way that it appears to be involved in a weak π interaction with the third metal atom, which completes its coordination sphere. Moreover, if we consider that the capping pyridyl group donates two π electrons to Ru(1), the whole set of ligands contributes 30 electrons to the structure, attaining the expected count of 54 electrons. This arrange-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ment would be an unprecedented type of bridging mode for the pyridyl group.

Multiple fragmentations involving P−Se and P−C bond cleavages have been observed also with the two following diphosphane diselenides: the 1,2-bis[(diphenylphosphanyl)-methyl]benzene diselenide[41] ($dpmbSe_2$) and the 1,1′-bis(diphenylphosphanyl)ferrocene diselenide[42] ($dppfSe_2$) (see Scheme 3). The reactions between $[M_3(CO)_{12}]$ (M = Ru or Fe) and the 1,2-bis[(diphenylphosphanyl)methyl]benzene diselenide were carried out with the aim of investigating the use of $dpmbSe_2$ as an effective precursor for selenido−(carbonyl)ruthenium and −(carbonyl)iron clusters containing the scarcely studied 1,2-bis[(diphenylphosphanyl)methyl]benzene ligand. The reaction of $[Ru_3(CO)_{12}]$ with $dpmbSe_2$ in hot toluene affords a variety of phosphane-substituted selenido carbonyl clusters. Along with substituted clusters with Ru_3Se_2, Ru_3Se, and Ru_2Se_2 cores, we have obtained workable amounts of an unprecedented and interesting complex $[Ru_3(\mu_3\text{-}Se)(\mu_3\text{-}H)\{\mu_2\text{-}PPh_2\}(CO)_6(\mu_2\text{-}CHC_6H_4CH_2PPh_2)]$ with an Ru_3Se core bound to phosphido, hydrido, and carbene moieties, whose structure (Figure 6) has been fully elucidated by X-ray diffraction methods.

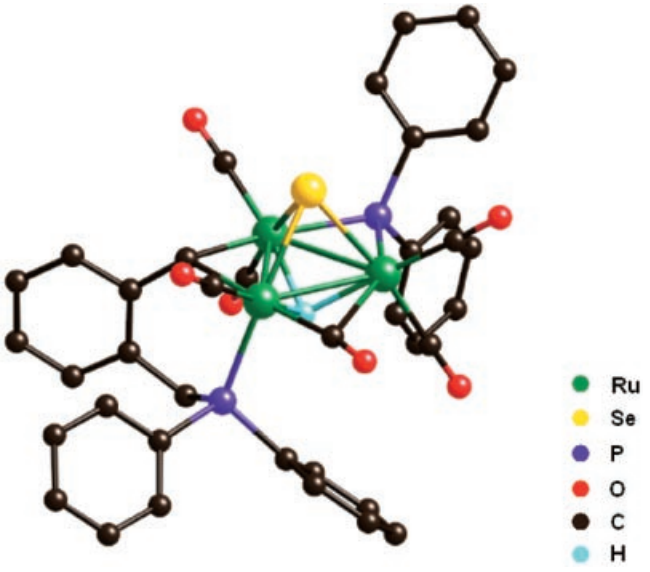

Figure 6. Perspective view of cluster $[Ru_3(\mu_3\text{-}Se)(\mu_3\text{-}H)\{\mu_2\text{-}PPh_2\}(CO)_6(\mu_2\text{-}CHC_6H_4CH_2PPh_2)]$

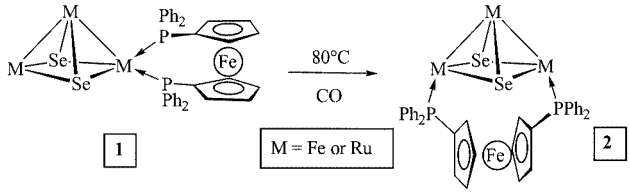
This cluster is the first example of a triruthenium triangular cluster capped on one side by a μ_3-Se unit and on the other by a μ_3-H atom. The diphosphane has undergone multiple fragmentations, namely P=Se, P−C, and C−H activations. This fragmentation produces a bridging carbene on an Ru−Ru edge resulting from a hydride migration from the Ar-CH_2 group to the cluster. (Carbene)ruthenium complexes have been used widely in the last few years as models, precursors and effective catalysts for olefin metathesis, ring-opening polymerization and alkyne oligomerization.[43] The $^{31}P\{^1H\}$ NMR spectrum, recorded at room temperature, shows two sharp singlets for the σ-coordinated phosphorus atoms and the phosphide group bridging one side of the metal triangle, respectively. The complete proton assignment has been achieved by two-dimensional NMR experiments (COSY, NOESY, TOCSY). The μ_3-hydride signal is found as a doublet of doublets at δ = −14.62 ppm, because of coupling with the two non-equivalent phosphorus atoms. From the 2D NOESY spectrum, a correlation is detected between the hydride and a proton of a methylene group, which, in the solid-state structure, points towards the hydride group at a distance of 2.67(6) Å. The carbene hydrogen atom gives a sharp singlet at δ = 10.13 ppm.

The reactions between $dppfSe_2$ at 60 and 110 °C afford the two isomeric *nido* clusters $[Ru_3(\mu_3\text{-}Se)_2(dppf)(CO)_7]$ (**1**) and $[Ru_3(\mu_3\text{-}Se)_2(\mu\text{-}dppf)(CO)_7]$ (**2**) which contain dppf as chelating and bridging ligand, respectively. Clusters **1** and **2** belong to the family of numerous open-triangular phosphane-substituted Ru_3Se_2 *nido* clusters, which are the primary products of the attack of 2 equiv. of P=Se groups to the starting triangular cluster. The chelated derivative **1**, obtainable under kinetic control, can be converted into the more stable bridged cluster **2** by thermal treatment in toluene solution as shown in Scheme 5. This conversion can be monitored by IR spectroscopy.[42]



Scheme 5

The cluster $[Ru_3Se\{\mu\text{-}P(Ph)C_5H_4FeC_5H_4PPh_2\}(\mu\text{-}OCPh)(CO)_6]$ (whose structure is depicted in Figure 7) was isolated as a minor product in the reaction between $[Ru_3(CO)_{12}]$ and $dppfSe_2$ at 60 °C.[42] The core consists of a metal triangle capped by a selenium atom and bridged on two sides by a phosphido ligand and by a benzoyl group, respectively, both deriving from multiple fragmentation of dppf diselenide and migratory insertion of a Ph ring into an Ru−C bond of a terminal carbonyl group.

Because of the loss of a phenyl ring, the phosphane-phosphido ligand is coordinated to one side of the Ru−Ru bond in an unusual manner: the phosphido P atom bridges two Ru atoms asymmetrically and participates with the other P atom in the chelation of one of them. The migratory insertion of a phenyl ring into a carbonyl group causes the formation of a benzoyl ligand that bridges two Ru atoms in a $\mu_2\text{-}\eta^1\text{:}\eta^1$-fashion through the C and O atoms. Only few examples are known of a μ_2-benzoyl group bridging two metal atoms in the same $\mu_2\text{-}\eta^1\text{:}\eta^1$-fashion.[42]

IV. Fluxional Behaviour

Two types of fluxional behaviour have been observed: (*i*) ligand mobility and (*ii*) M−M bond migration.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

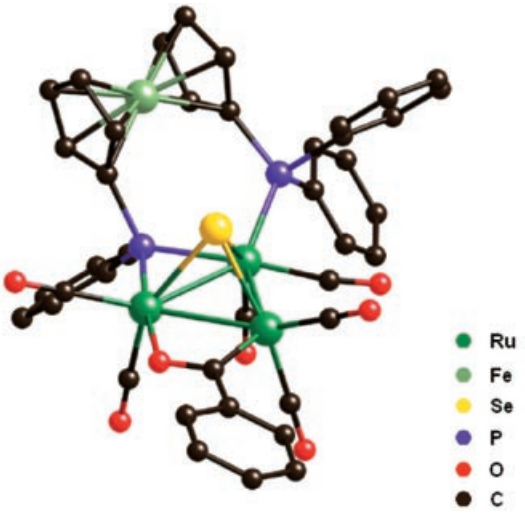


Figure 7. Perspective view of cluster $[Ru_3Se\{\mu\text{-}P(Ph)C_5H_4FeC_5H_4PPh_2\}(\mu\text{-}OCPh)(CO)_6]$

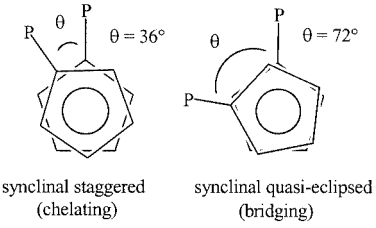
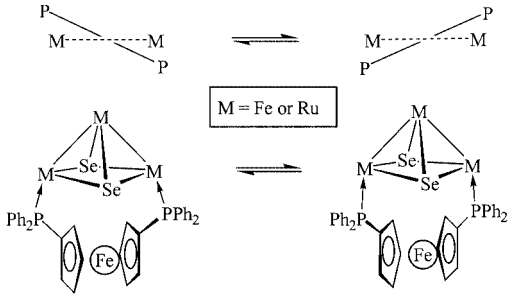
The ferrocenediphosphane ligand can assume different coordination modes in cluster chemistry. This feature derives from the possibility of the cyclopentadienyl rings twisting about their axis. In fact, the P···P separation between the two donor atoms depends on the θ torsional angle, ranging from 3.30 (θ = 0°) to 6.90 Å (θ = 180°). Scheme 6 shows the preferred conformations adopted in the case of chelating (θ = 36°) and in the case of bridging (θ = 72°) over one side of a (carbonyl)metal cluster. To gain an insight into the structures of these molecules in solution, we performed ^{1}H NMR investigations on clusters $[M_3(\mu_3\text{-}Se)_2(\mu\text{-dppf})(CO)_7]$. At room temperature, the proton pattern of $[Fe_3(\mu_3\text{-}Se)_2(\mu\text{-dppf})(CO)_7]$ shows a featureless broad band in the cyclopentadienyl region, suggesting the onset of a fluxional behaviour. At 258 K, four singlets are visible in the same region, which indicate the equivalence of the two cyclopentadienyl rings. It has been demonstrated that the fluxional behaviour consists of the concerted twisting of the two equivalent rings around their axis ($\Delta G^{\ddagger}$ = 58.2 kJ·mol^{-1}, T_c = 303 K)[44] as shown in Scheme 7.



Scheme 6

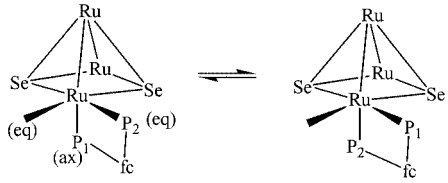
The pattern of the signals of the protons of the Ru analogue parallels that of the corresponding Fe derivative at 273 °C, indicating that the fluxional behaviour of the ligand, observed for the Fe species, exhibits a higher energy barrier in the Ru congener.

The dynamic behaviour of $[Ru_3(\mu_3\text{-}Se)_2(dppf)(CO)_7]$ (**1**) is quite different (see Scheme 8). At room temperature the



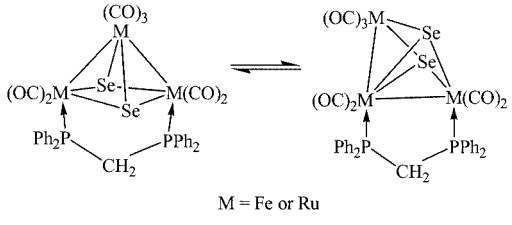
Scheme 7

^{1}H NMR spectrum exhibits four singlets for the Cp protons, indicating the equivalence of the two rings. At 213 K, the two rings become inequivalent, with the proton spectrum showing eight singlets that were assigned by 2D NMR spectra. The fluxional behaviour of **1** consists of the localized scrambling of the chelating ligand around Ru, namely the exchange of the axial and equatorial positions of the two $Ph_2(C_5H_4)P$ moieties. This dynamic behaviour makes the two rings equivalent, but the four protons of each ring remain unequal.[44]



Scheme 8

The cluster $[Ru_3(\mu_3\text{-}Se)_2(\mu\text{-dppm})(CO)_7]$ has the well-known bicapped open-triangular 50-electron core and is the expected primary product of the attack of $dppmSe_2$ on the starting carbonyl cluster. The structure in the solid state is the same as that observed for other phosphane-disubstituted Ru_3Se_2 derivatives, which exhibit two P donor groups coordinated (in axial positions) to the two non-bonded, basal metal atoms. Nevertheless, its NMR spectra in solution suggest fluxional behaviour. In fact, the ^{31}P NMR spectrum shows a singlet and two doublets at lower frequency. The ^{13}C NMR spectra, as well as the ^{77}Se NMR spectra, show a couple of signals, consistent with the presence of two isomers in solution: the first is the symmetrical cluster with the two phosphorus atoms equivalent, as found in the solid state, and the other is that obtained by migration of the M−M bond from a side of the square pyramid to the base, as depicted in Scheme 9.[29]



Scheme 9

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

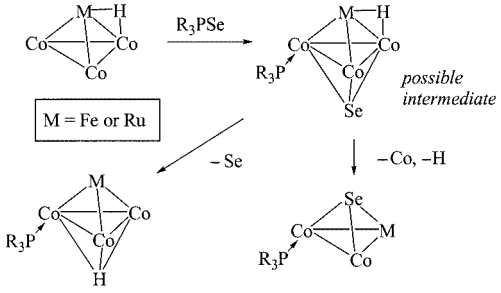
Also, the disubstituted Ru_3Se_2 clusters with monophosphanes exhibit ^{31}P NMR spectra in solution indicative of the same fluxional motion observed for the dppm.[35,36]

V. Dimetallic Clusters

Recently, we have extended our interest in the search for new synthetic routes to phosphane-substituted selenido−mixed-metal clusters by considering that the presence of different metals can influence the selectivity of certain processes and can lead to the formation of compounds presenting new, and not always easily predictable, structures.

Two different synthetic strategies have been developed for the synthesis of dimetallic substituted carbonyl clusters: (1) MM′ + PSe (reactions between preformed dimetallic clusters and tertiary phosphane selenides) and (2) MSeP + M′ [cluster growth reactions from preformed chalcogenido−(carbonyl)metal clusters and suitable organometallic fragments].

As a first approach for the synthesis of dimetallic selenido clusters, we have treated different phosphane selenides with the tetrahedral clusters $[HMCo_3(CO)_{12}]$ (M = Fe or Ru) and obtained two classes of products:[45] (*i*) trinuclear selenido clusters possessing an $MCo_2(\mu_3\text{-Se})$ core and (*ii*) tetranuclear hydrido clusters with an $HMCo_3$ core obtained by simple substitution of carbonyl groups by phosphane ligands (Scheme 10).



Scheme 10

Both classes are *nido* species and probably are derived from a trigonal-bipyramidal intermediate. While compounds of type (*ii*) have been reported already in the literature, the triangular dimetallic clusters of type (*i*), capped by a μ_3-selenide unit and substituted by a phosphane ligand, have been obtained and fully characterized for the first time. One possible hypothesis for the formation of these clusters is that the reactions proceed first with an addition of the phosphane selenide, giving an intermediate species in which the phosphane group and the selenium atom are coordinated. This intermediate would then loose a cobalt atom and a hydride ligand or a selenium atom to afford type (*i*) or (*ii*), respectively.

As an example of the structure of type (*i*), Figure 8 shows the structure of $[RuCo_2(\mu_3\text{-Se})(CO)_7(\mu\text{-dppy})]$ in which an MCo_2 triangle is capped by a μ_3-Se ligand. The bidentate phosphane ligand bridges the Co−Co edge through the phosphorus and nitrogen atoms. The bidentate bridging phosphane group forms a five-membered ring that is fused with the metal triangle on one side and with the pyridyl ring on the other.

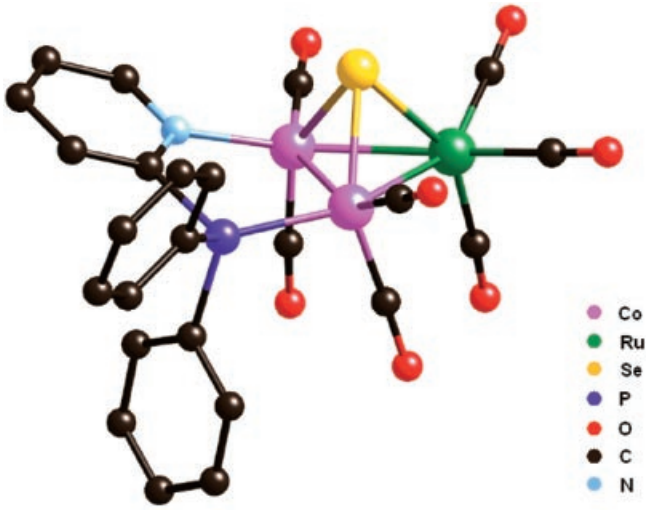


Figure 8. Perspective view of cluster $[RuCo_2(\mu_3\text{-Se})(CO)_7(\mu\text{-dppy})]$

The structure of $[HRuCo_3(CO)_7(\mu\text{-CO})_3(\mu\text{-dppy})]$ (Figure 9) shows a tetranuclear $RuCo_3$ core of type (*ii*) in which two carbonyl groups have been replaced by the dppy ligand bridging two cobalt atoms through the P and N atoms. Perhaps because of the steric hindrance resulting from this coordination, the hydride ligand has migrated from its original μ_3-capping position to the Ru−Co edge.

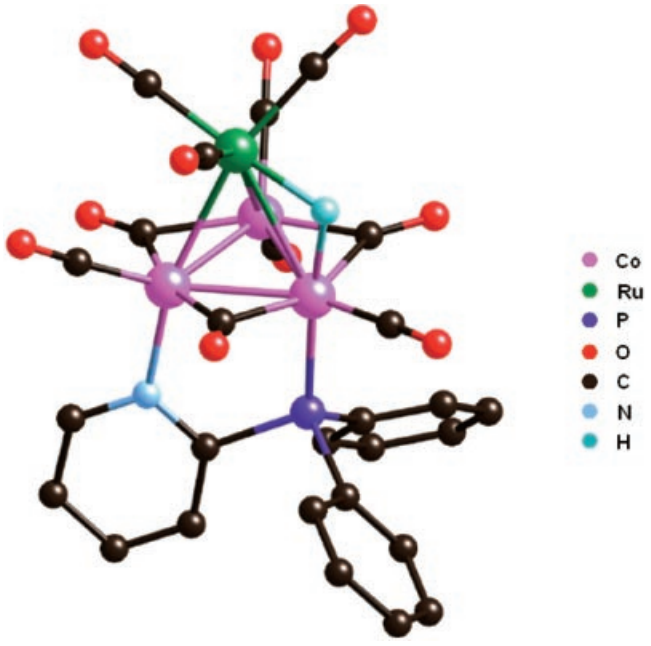

Figure 9. Perspective view of cluster $[HRuCo_3(CO)_7(\mu\text{-CO})_3(\mu\text{-dppy})]$

The linear trinuclear complex $[Pt\{Fe(CO)_3(NO)\}_2(PhCN)_2]$ was chosen for the reaction with phosphane sel-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

enides, by considering that its open geometry and the lability of the PhCN ligands could possibly result in an easy attack of the P=Se moiety to the cluster core. Actually, the reaction of the $PtFe_2$ complex with diphenyl(2-pyridyl)phosphane selenide occurs even at low temperature, affording a variety of compounds.[46] One of them was recognized as the 46-electron cluster $[(CO)_3Fe(\mu_3\text{-}Se)\{Pt(CO)P(2\text{-}C_5H_4N)Ph_2\}_2]$. It exhibits a butterfly framework consisting of two FePtSe wings sharing the common Fe−Se hinge (Figure 10). The value of the Fe−Se bond length, 2.337(1) Å, is slightly smaller than the average one, 2.37 Å, found in several clusters with a *nido*-Fe_3Se_2 core.[27] The two Pt atoms are definitely non-bonded since the Pt···Pt separation is rather large at 3.167(9) Å. By considering the two Fe−Pt bonds, the coordination about the Pt atoms is almost square-planar, with the CO and phosphane ligands being *trans* to the selenium and iron atoms, respectively.

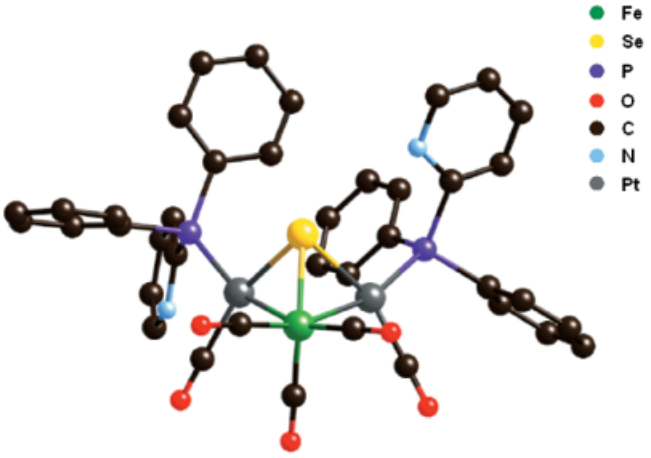

Figure 10. Perspective view of cluster $[(CO)_3Fe(\mu_3\text{-}Se)\{Pt(CO)P(2\text{-}C_5H_4N)Ph_2\}_2]$

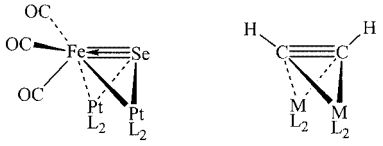
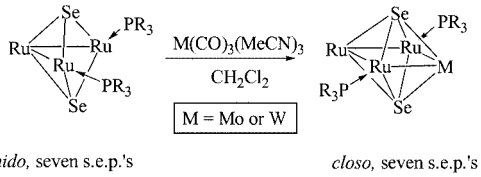
There are only a few known examples of the cluster typology found in $[(CO)_3Fe(\mu_3\text{-}Se)\{Pt(CO)P(2\text{-}C_5H_4N)Ph_2\}_2]$. The structure can be described also as a $(CO)_3Fe{\equiv}Se$ group (a legitimate, but unknown, 18-electron species) stabilized by the double bridging interaction with two PtL_2 fragments, a system analogous to the well-understood $L_2M(\mu\text{-acetylene})ML_2$ systems, as shown in Scheme 11.



Scheme 11

The chemical bonding in this cluster, and in similar systems, has been analysed through density functional theory (DFT) and qualitative MO approaches, considering the $(CO)_3Fe{\equiv}X$ unit as being equivalent to RC≡CR molecules by isolobal analogy.[46]

The second approach for the synthesis of phosphane-substituted, selenido−mixed-metal clusters consists of the reaction of preformed selenido species with organometallic fragments. This approach was chosen by considering the availability of workable amounts of complexes $[Ru_3(\mu_3\text{-}Se)_2(CO)_{9-n}L_n]$ (n = 1 or 2; L = tertiary phosphane). Compounds of this kind are open-triangular, *nido* clusters with 7 skeletal electron pairs. As a consequence, they could be prone to add a zero-s.e.p. fragment, such as $M(CO)_3$ (M = Mo or W), giving the hypothetical *closo* clusters $[MRu_3(\mu_4\text{-}Se)_2(CO)_{12-n}L_n]$. The reactions of various $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(L)_2]$ clusters with $W(CO)_3(CH_3CN)_3$ afford the dimetallic *closo* clusters $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6L_2]$,[36] as shown in Scheme 12.



Scheme 12

In their crystal structures, most of these clusters lie on a crystallographic centre, so a disorder exists that involves the mutually opposite Ru and M (M = W or Mo) atoms of the *closo* core of the cluster, resulting in a disordered $Ru_3M(\mu_4\text{-}Se)_2$ cluster core. This disorder caused us to formulate these clusters erroneously in a previous note as $Ru_2W_2Se_2$ electron-deficient species.[47] These complexes belong to the family of diselenide tetranuclear *closo* clusters. They could be described as distorted octahedra in which the three ruthenium atoms and the M atom lie on the basal plane and two selenium atoms at the apices. Two phosphane ligands coordinate the *trans* ruthenium atoms through the phosphorus atoms. Four carbonyl groups bridge the Ru−Ru and Ru−M edges asymmetrically. The crystal structure of compound $[Ru_3M(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(t4mpp)_2]$ [t4mpp = tris(*p*-methoxyphenyl)phosphane] is reported in Figure 11.

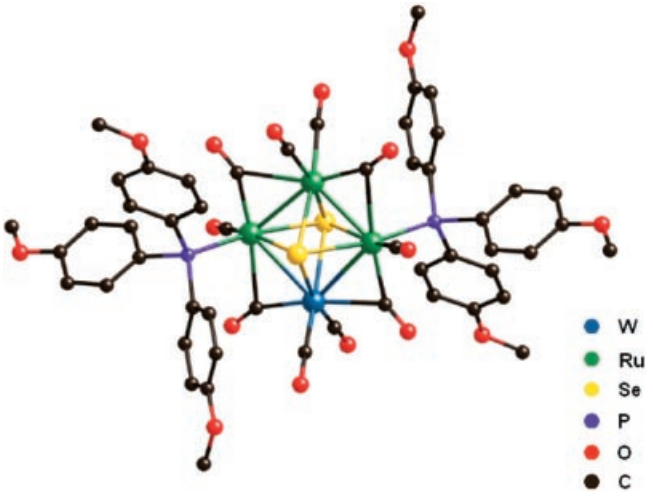


Figure 11. Perspective view of cluster $[Ru_3M(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(t4mpp)_2]$

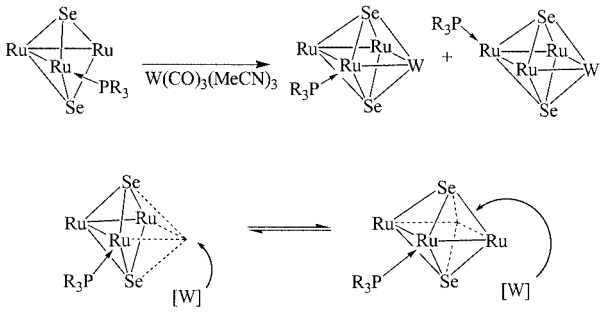
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

When the starting reagent is the monosubstituted $[Ru_3(\mu_3\text{-}Se)_2(CO)_8L]$ (L = tertiary phosphane) the reaction product is the expected dimetallic *closo* cluster $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_7L]$, which was fully characterized in solution as well as in the solid state. Two isomers were obtained depending on whether the position of the tertiary phosphane on the ruthenium atom is *cis* or *trans* to the tungsten atom (see Scheme 13).



Scheme 13

A possible explanation for the synthesis of the two isomers is derived from the fluxional behaviour of the $Ru_3(\mu_3\text{-}Se)_2$ core clusters: when the Ru−Ru bond is localized on the pyramid edge, the $W(CO)_3$ fragment can fit in the *cis* position with regard to the phosphane ligand; when the Ru−Ru bond is localized on the basal plane, the unique position in which the fragment fits is the *trans* one (see Scheme 13).

In the case of the reaction between $W(CO)_3(MeCN)_3$ and $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(dpbz)_2]$ (dpbz = diphenylbenzylphosphane), the compound $[Ru_3(\mu_3\text{-}Se)(\mu_4\text{-}Se)(CO)_7(dpbz)_2W(CO)_5]$ (Figure 12) was obtained. This cluster can be considered as the product of a donor−acceptor interaction between the fragment $W(CO)_5$ and a selenido atom of $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(dpbz)_2]$.

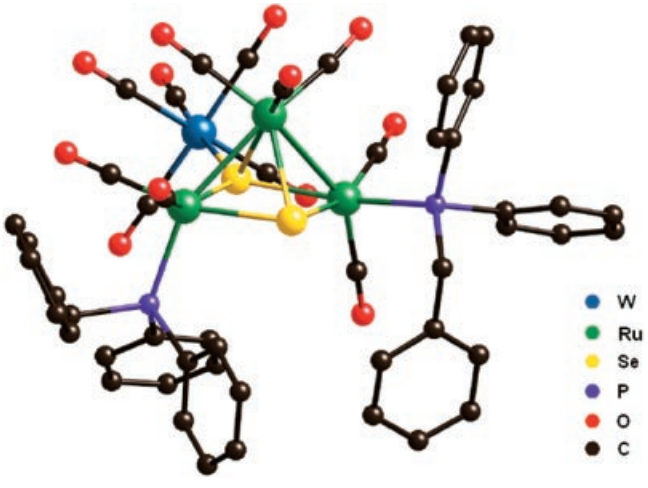


Figure 12. Perspective view of cluster $[Ru_3(\mu_3\text{-}Se)(\mu_4\text{-}Se)(CO)_7(dpbz)_2W(CO)_5]$

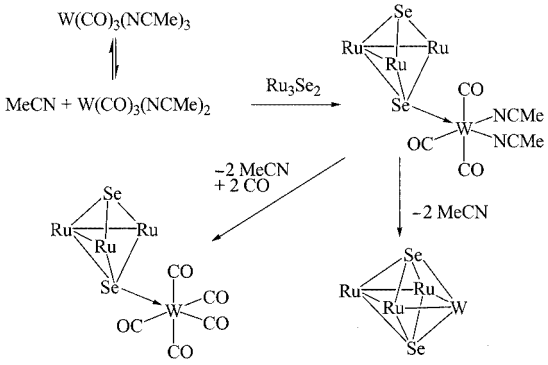
A possible mechanism for the production of this compound involves the formation of the labile intermediate $[Ru_3(\mu_3\text{-}Se)(\mu_4\text{-}Se)(CO)_7(dpbz)_2W(CO)_3(CH_3CN)_2]$ (Scheme 14) that could undergo easily the substitution of two acetonitrile groups with two carbonyl groups. If the loss of the two acetonitrile groups is followed by saturation of the coordinative vacancy on the basal plane of the pyramid, the previously described *closo* cluster is obtained.



Scheme 14

Concluding Remarks

Systematic investigations on the reactions of tertiary phosphane and diphosphane selenides towards (carbonyl)iron and -ruthenium clusters have achieved the following results: (*i*) The reaction provides a simple, stepwise synthetic route to phosphane-substituted, small-nucleus selenido carbonyl clusters, through transfer of selenium atoms; (*ii*) it leads, in some cases, to the formation of new species, such as the cubane-like cage complex $[Ru_4(\mu_3\text{-}Se)_4(CO)_{10}(\mu\text{-}dppm)]$, that are not easily attainable by other routes; (*iii*) when the tertiary phosphane selenide bears heterocyclic fragments, the reaction is not only limited to the transfer of the chalcogenido atom, but proceeds with P−C and/or C−H bond cleavages, affording selenido-phosphido carbonyl compounds; (*iv*) some clusters display particular physico-chemical characteristics, such as the fluxional behaviour in solution involving ligand exchange as well as M−M bond migration; (*v*) certain compounds exhibit specific activity in cluster-growth reactions, such as the *nido* clusters with the $Ru_3(\mu_3\text{-}Se)_2$ core, which reacts with $M(CO)_3$ fragments (M = Mo or W), leading to the corresponding dimetallic *closo* octahedral species $[Ru_3M(\mu_4\text{-}Se)_2(CO)_{12-n}L_n]$ (L = tertiary phosphane, n = 1 or 2). For the synthesis of dimetallic substituted carbonyl clusters we have also investigated another strategy: treatment of different phosphane selenides with the dimetallic tetrahedral clusters $[HMCo_3(CO)_{12}]$ (M = Fe or Ru) and with the linear trinuclear complex $[Pt\{Fe(CO)_3(NO)\}_2(PhCN)_2]$ obtaining new selenido−mixed-metal clusters substituted by tertiary phosphanes.

The Dicopper(II) Complex of the Novel Asymmetric Dinucleating Ligand Hpy3asym as a Structural Model of Catechol Oxidase

Iryna A. Koval,[a] Daniel Pursche,[b] Arno F. Stassen,[a] Patrick Gamez,[a] Bernt Krebs,[b] and Jan Reedijk*[a]

Keywords: Copper / Cyclic voltammetry / Enzyme models / Ligand design / Magnetic properties

The new asymmetric dinucleating ligand 2-{[bis(2-pyridinylmethyl)amino]methyl}-4-methyl-6-{[(2-pyridinylmethyl)amino]methyl}phenol (Hpy3asym) has been designed in order to model the type-3 active site of the copper proteins. This phenol-based "end-off" compartmental ligand has one tridentate and one didentate arm attached to the 2- and 6-positions of the phenolic ring, respectively. A dinuclear copper(II) nitrate complex with this ligand $[Cu_2(py3asym)(H_2O)_{1.5}(NO_3)_2]NO_3$ has been obtained and structurally characterized. In this complex both copper ions have a distorted octahedral geometry and are endogenously bridged by the phenolic oxygen atom of the deprotonated ligand. The complex shows a donor-atom asymmetry that consists of an N_3O_3 donor set for the Cu1 ion and an N_2O_4 donor set for the Cu2 ion. The electrochemical, magnetic behavior and spectral properties of the complex are discussed.

Introduction

The copper proteins with the type-3 active site, such as hemocyanins, tyrosinases and catechol oxidases, have attracted the attention of scientists due to their ability to process primary dioxygen under ambient conditions.[1−3] The latter two enzymes use it to perform selective oxidations of organic substrates, such as tyrosine and catechol, to produce various melanins, whereas hemocyanin is the dioxygen transport and storage protein in some arthropods and molluscs.

The type-3 active site is characterized by a dicopper core where each of the metal ions is surrounded by three histidine residues. In the met-Cu^{II}-Cu^{II} form two copper ions are antiferromagnetically coupled via the μ-OH bridge, resulting in an EPR-silent active site.

The determination of the crystal structure of catechol oxidase from sweet potatoes (*Ipomoea batatas*) by some of us[4] offered new insight into the catalytic mechanism of the enzyme with the possibly different functions of the two copper ions. Taking our inspiration from the natural molecule, our attention has turned to the deliberate design of novel model systems of the type-3 active site, where the two copper ions would have distinctively different coordination surroundings. The site specificity of the copper ions may help to answer an important question concerning the binding of the substrate in the natural enzyme, i.e. is the catechol substrate forming a bridge between the two copper(II) centers rather than binding to only one of them?

Dinucleating phenol-based "end-off" compartmental[5] ligands have previously been successfully used for modeling dimetallic biosites.[6−8] In this paper, the synthesis of the novel phenol-based ligand 2-{[bis(2-pyridinylmethyl)-amino]methyl}-4-methyl-6-{[(2-pyridinylmethyl)amino]-methyl}phenol, Hpy3asym, is reported. This dinucleating ligand was designed to hold two copper ions in close proximity and to provide them with different coordination surroundings, thus making one of the two copper ions more readily accessible for the binding of the substrate. This was achieved by substituting the 2- and the 6-positions of the phenol ring by tridentate and didentate arms, respectively, containing nitrogen donor atoms. The reaction of Hpy3asym with copper(II) nitrate yields the new dinuclear asymmetric complex, which is regarded as a structural model of the type-3 active site. The dinuclear copper core exhibits a donor-atom asymmetry in the solid state, comprised of an N_3O_3 donor set for the Cu1 ion and an N_2O_4 donor set for the Cu2 ion. The crystal structure, spectroscopy, electrochemical and magnetic behavior of the complex are reported below.

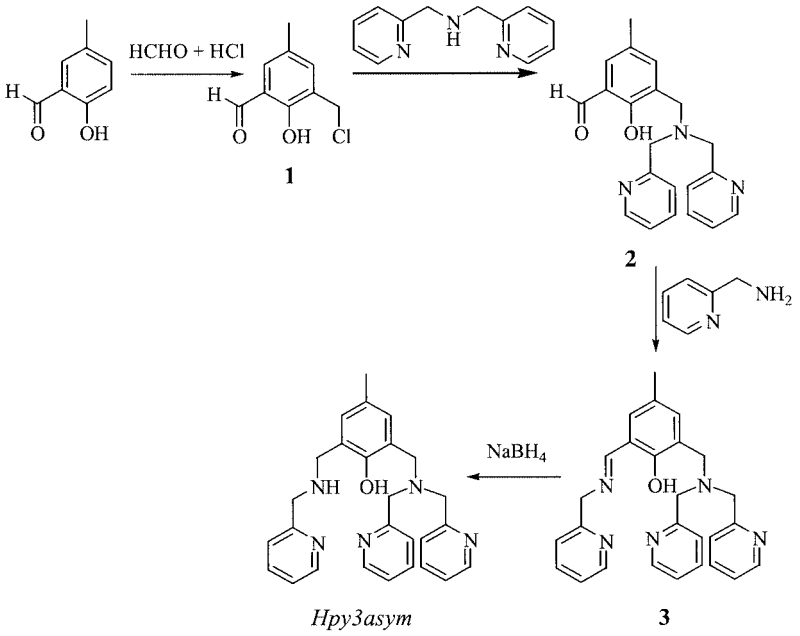

Figure 1. The reaction scheme of the synthesis of the phenol-based compartmental "end-off" ligand Hpy3asym

Results and Discussion

Ligand Design

Hpy3asym was synthesized in three steps (Figure 1) from commercially available 5-methylsalicylaldehyde. The first step includes the introduction of the dichloromethane group in the 3-position of the phenol ring. The chloride atom was subsequently substituted by di(2-picolyl)amine. Finally, the reductive amination of the aldehyde group by 2-aminomethylpyridine and sodium borohydride led to the desired ligand.

Crystal Structure Description

Very small green rectangular crystals of $[Cu_2(py3asym)(H_2O)_{1.5}(NO_3)_2](NO_3)$ were obtained by slow evaporation of the solvent from an acetonitrile solution of the complex. The Platon[9] projection of the complex is depicted in Figure 2. The compound crystallizes in the space group $P2_1/n$. Both copper ions have distinctively different coordination surroundings, showing a donor-atom asymmetry. An endogenous phenolato bridge is present in the dinuclear core, but there is no exogenous bridge. The N_3O_3 coordination sphere around the Cu1 ion can be regarded as a very distorted octahedron. The equatorial plane is formed by the *tert*iary amine nitrogen atom N1 at a distance of 2.0182(18) Å, two *trans* located nitrogen atoms N2 and N3 from two pyridine rings at a distance of 1.9860(17) Å and 1.9760(18) Å, respectively, and the oxygen atom from a water molecule at a distance of 1.9701(16) Å. One of the axial positions is occupied by the bridging phenolate oxygen atom O1 at a relatively long distance of 2.3070(13) Å. The second apical position has a weak O-donor ligand, which was refined for 50% to be water and for 50% a disordered nitrate anion. The oxygen atom O20 (occupancy 0.4886) from the water molecule is at a distance of 2.535(3) Å. The loosely bound oxygen atom O10 (occupancy 0.5114) from the disordered nitrate counteranion [the Cu1−O10a distance is 3.007(6) Å] is at a much larger distance, which, however, still matches the range of bond lengths observed for copper-oxygen bonds along the Jahn−Teller axis.[10−13] The in-plane *cis* angles around the Cu1 ion vary over quite a broad range, viz. 83.92(8)° for the N1−Cu1−N3 angle and 96.92(7)° for the O2−Cu1−N2 angle. Their sum amounts to 357.76°. The O−Cu1−O angle along the Jahn−Teller axis is equal to 173.85(8)° for the O1−Cu1−O20 angle and 165.46(10)° for the O1−Cu1−O10 angle, thus indicating a significant distortion from a regular octahedral geometry.

The coordination sphere around the second copper ion Cu2 can also be described as a distorted octahedron, but with an N_2O_4 donor set. The equatorial plane around the Cu2 ion is formed by two *cis* located nitrogen atoms N4 from the secondary amine [the Cu2−N4 distance is 1.9838(17) Å], N5 from the pyridine ring [the Cu2−N5 distance is 2.0181(17) Å], and two *cis* oxygen atoms, O1 from the bridging phenolate [the Cu2−O1 distance is 1.9353(14) Å] and O3 from the chelating nitrate anion [the Cu2−O3 distance is 1.9910(14) Å]. The second oxygen atom O5 from the chelating nitrate anion and the oxygen atom O6 from the monocoordinated nitrate anion occupy the axial positions, thus adjusting the coordination sphere around the copper ion to a very distorted octahedron [the distances Cu2−O5 and Cu2−O6 are equal to 2.5431(16) Å and 2.5982(16) Å, respectively]. The in-plane *cis* angles vary in the range 87.36°−94.64°. The angle O5−Cu2−O6, which should be equal to 180° in the regular octahedron, is only 157.37(5)°, indicating an even greater distortion from a regular octahedral geometry than observed in the case of the Cu1 ion.

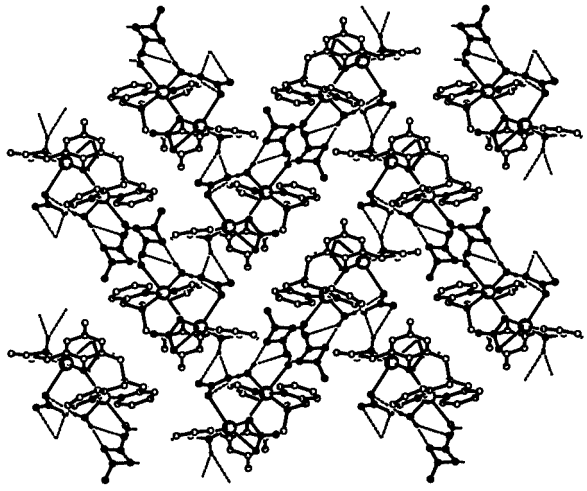

Figure 3. The Platon[9] projection of the "herring bone" packing arrangement along the crystallographic *a* axis; all hydrogen atoms, except for those participating in hydrogen bonding, are omitted

The absence of the exogenous bridge between the two copper ions promotes the large copper-copper separation of 3.9003 Å, which is significantly longer than the distances observed for similar complexes with two types of bridges between the copper ions.[7,8,14] It is interesting to note that potentially bridging nitrate anions are present in the complex; however, they fail to bridge the two copper ions, instead being coordinated as monodentate and didentate chelating ligands. The distribution of charged and neutral ligands in the complex is also remarkable: 1.5 neutral water molecules are coordinated to the Cu1 ion, whereas two charged nitrate anions are coordinated to the Cu2 ion.

The crystal packing is stabilized by an extensive net of intra- and intermolecular hydrogen bonds (see Table 1). In particular, a bifurcated intramolecular hydrogen bonding is realized between the proton H2b of the water molecule coordinated to the Cu1 ion and the two oxygen atoms O6 and O7 of the monodentate nitrate anion coordinated to the Cu2 ion, giving an impression of an exogenous pseudo-bridge between the two copper ions. Furthermore, each formula unit is connected via intermolecular hydrogen bonds to three neighboring units. The Platon[9] projection of the crystal packing along the crystallographic *a* axis is shown in Figure 3. As can be seen, the molecules are assembled by means of hydrogen bonds to form a "herring bone" pattern.

Physical Characterization

Besides the crystal structure determination, the complex was characterized spectroscopically and magnetically. The electrospray mass spectrum (ESI-MS) of the complex performed in acetonitrile reveals one major peak at $m/z = 688$, corresponding to $[Cu_2(py3asym)(NO_3)_2]^+$. The theoretical isotope pattern calculated for the empirical formula $C_{27}H_{28}Cu_2N_7O_7$ is in agreement with the experimentally found one. Thus, the 1.5 water molecules coordinated to the Cu1 ion, observed in the solid state, are lost during the measurement. The UV/Vis spectrum of the solid exhibits two peaks at 456 and 640 nm. The first peak is assigned to an LMCT transition between the bridging phenoxo group and copper ions,[14] whereas the second one is characteristic for Cu^{II} d-d transitions.[15] The positions of these bands do not significantly change when the spectrum of the complex is taken in acetonitrile solution, suggesting no important modifications in the copper-ligand chromophores.

A cyclic voltammogram of the complex recorded in acetonitrile, when scanning towards the negative region of potentials, shows two successive one-electron electrochemical signals. The first one, at −0.13 V vs. Ag/AgCl, is assigned to the $Cu_2^{II,II}/Cu_2^{II,I}$ redox couple. The second one, at −0.33 V, is attributed to the formation of $Cu_2^{I,I}$ species. They both appear to be irreversible. In addition, a very

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

broad peak at ca. −0.7 V suggests the reduction of both copper ions to Cu^0 and the deposition of the free metal on the electrode surface. On the reverse scan, an additional sharp anodic peak is observed at −0.27 V. This is the so-called stripping peak, caused by the redissolution of the metallic copper. This peak is absent if the potential sweep is reversed at ca. −0.5 V, before the reduction to Cu^0 can take place. The anodic part of the cyclic voltammogram is characterized by three successive fully irreversible oxidation waves at 1.16, 1.48 and 1.68 V, apparently corresponding to the oxidation of the ligand and/or water molecules.

Magnetic Properties

In Figure 4, the magnetic susceptibility of the complex $[Cu_2(py3asym)(H_2O)_{1.5}(NO_3)_2]NO_3$ is shown, plotted as both χ^{-1} and χ versus the temperature. The compound displays a weak ferromagnetic coupling with a Curie temperature θ of 0.87 K and a Curie−Weiss constant C of 0.39 $cm^3 \cdot K \cdot mol^{-1}$. The value for μ is 1.10 B.M.

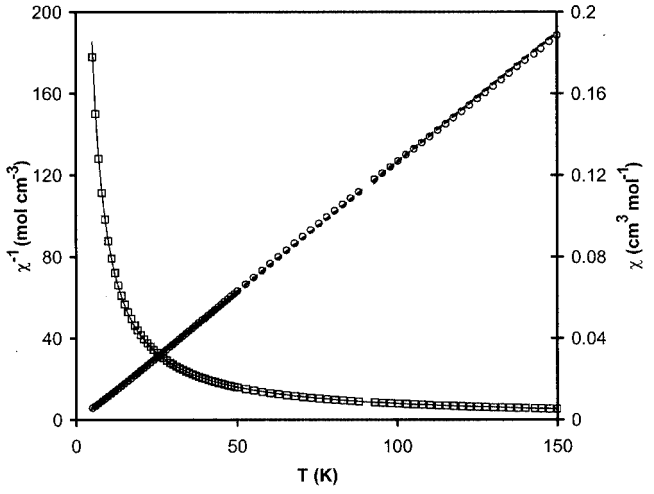

Figure 4. Magnetic susceptibility plotted as χ^{-1} versus T (O) and as χ versus T (□); the dashed line is the Curie−Weiss plot from near field theory and the solid line is the theoretical curve according to the Bleany-Bowers equation

The magnetic properties of this dinuclear copper(II) complex have been interpreted in terms of the Bleaney−Bowers equation [Equation (1)], where g is the magnetic field splitting factor, J is the exchange integral of magnetic theory and N_α is the temperature-independent paramagnetism of one mol of copper(II) ions.[16,17]

$$\chi_M = \frac{g^2 N\beta^2}{3kT}\left(1+\frac{1}{3}e^{J/kT}\right)^{-1} + N\alpha \quad (1)$$

The fit was accomplished by minimization of the reliability factor, defined as $R = \Sigma(\chi_m T_{calc} - \chi_m T_{obs})^2/(\chi_m T_{obs})^2$, by a least-squares procedure. The best fit was obtained for the exchange integral $J = -4.6\ cm^{-1}$, the magnetic field splitting factor $g = 2.02$ and $R = 2.9 \times 10^{-3}$.

Conclusion

The asymmetric phenol-based "end-off" compartmental ligand 2-{[bis(2-pyridinylmethyl)amino]methyl}-4-methyl-6-{[(2-pyridinylmethyl)amino]methyl}phenol forms a dinuclear asymmetric copper(II) nitrate complex which can be regarded as a new structural model of the type-3 active site of the copper proteins. The ligand holds a tridentate and a didentate arms attached to the 2- and 6-positions of the phenol ring. In the solid state the complex possesses donor-atom asymmetry, constituted by an N_3O_3 donor set for the Cu1 ion bound to a tridentate arm, and an N_2O_4 donor set for the Cu2 ion bound to a didentate arm. The magnetic behavior of the complex was interpreted in terms of weak ferromagnetic coupling between the two copper ions, with the exchange integral $J = -4.6\ cm^{-1}$, and a Curie−Weiss temperature θ of 0.87 K.

Experimental Section

General Remarks: Most of the synthetic work was carried out using standard Schlenk techniques. All chemicals were commercially available and used without further purification. 5-Methylsalicylaldehyde was purchased from Fluka, 2-(aminomethyl)pyridine from Acros, and di(2-picolyl)amine from Aldrich. 3-Chloro-5-methylsalicylaldehyde (**1**) was prepared according to the procedure described by Lock.[18] Tetrahydrofuran and methanol were dried by refluxing over sodium. Water was demineralized prior to use. C,H,N determinations were performed on a Perkin−Elmer 2400 Series II analyzer. NMR spectra were recorded on a JEOL FX-200 (200 MHz) FT NMR spectrometer. Solid-state ligand field spectra (300−2000 nm, diffuse reflectance) and in solution were taken on a Perkin−Elmer 330 spectrophotometer equipped with a data station. IR spectra were recorded of pure solids on a Perkin−Elmer FT-IR Paragon 1000 spectrophotometer with a Specac single-reflection diamond ATR P/N 10500, using the diffuse reflectance technique (4000−300 cm^{-1}, res. 4 cm^{-1}). Electrospray mass spectra (ESI-MS) were recorded on the Thermo Finnigan AQA apparatus. Cyclic voltammetry measurements were performed with an Autolab PGSTAT 10 cyclic voltammeter, using a Pt working electrode and a Ag/AgCl reference electrode in acetonitrile (10^{-3} M), with tetrabutylammonium perchlorate as supporting electrolyte, at a scan rate of 0.1 mV/s. DC magnetic susceptibility measurements (5−150 K) were carried out at 0.1 Tesla using a Quantum Design MPMS-5 5T SQUID magnetometer. Data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants.[19]

3-{[Bis(2-pyridinylmethyl)amino]methyl}-2-hydroxybenzaldehyde (2): A solution of di(2-picolyl)amine (1.08 g, 5.4 mmol) and triethylamine (1.09 g, 10.8 mmol) in 50 mL of dry THF was added dropwise with stirring to a solution of **1** (1 g, 5.4 mmol) in 250 mL of dry THF under an Ar atmosphere. After completion of the addition, the resulting white suspension was refluxed for two hours and cooled to room temperature. After the removal of the triethylamine hydrochloride salt by filtration, the resulting solution was evaporated under reduced pressure, yielding a yellow oil, from which compound **2** crystallized within a few minutes. Recrystallization from a methanol/diethyl ester mixture gave slightly yellowish crystals of the pure compound **2**. Yield: 1.55 g, 4.5 mmol (82%). ^1H NMR ($CDCl_3$, 200 MHz): δ = 10.42 (s, 1 H, aldehyde proton),

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

8.56 (d, 2 H, 6′py-*H*), 7.63 (td, 2 H, 4′py-*H*), 7.40 (t, 2 H, 5′py-*H*), 7.20 (d, 2 H, 3′py-*H*), 7.15 (s, 1 H, 2′phenol-*H*), 7.13 (s, 1 H, 5′phenol-*H*), 3.89 [s, 4 H, N-(CH_2py)$_2$], 3.80 (s, 2 H, phenol-CH_2-N), 2.23 (s, 3 H, CH_3) ppm.

2-{[Bis(2-pyridinylmethyl)amino]methyl}-4-methyl-6-{[(2-pyridinylmethyl)imino]methyl}phenol (3): A solution of 2-pyridylmethylamine (0.39 g, 3.6 mmol) in 50 mL of dry methanol was added dropwise with stirring to a solution of **2** (1.26 g, 3.6 mmol) in 250 mL of dry methanol under argon. After the addition was complete, the resulting bright yellow solution was heated for two hours at 50 °C. The successful formation of the imine derivative was verified by NMR spectroscopy. The imine was reduced in situ to the respective amine with sodium borohydride. ^{1}H NMR (CDCl$_3$, 200 MHz): δ = 8.51 (d, 3 H, 6′py-*H*), 8.34 (s, 1 H, C*H*=N), 7.62 (td, 3 H, 4′py-*H*), 7.33 (t, 3 H, 5′py-*H*), 7.26(d, 2 H, 3′py-*H*), 7.09 (s, 1 H, 3′phenol-*H*), 7.03 (2, 1 H, 5′phenol-*H*), 4.92 (s, 2 H, CH=N-CH_2), 3.88 [s, 4 H, N-(CH_2py)], 3.80 (s, 2 H, phenol-CH_2-N), 2.29 (s, 3 H, CH_3) ppm.

2-{[Bis(2-pyridinylmethyl)amino]methyl}-4-methyl-6-{[(2-pyridinylmethyl)amino]methyl}phenol (Hpy3asym): $NaBH_4$ (0.41 g, 10.9 mmol, 3 equiv./CH=N) was added in situ to a solution of **3** in methanol. After the hydrogen evolution stopped, the resulting colorless solution was refluxed for two hours and the solvent was evaporated under reduced pressure. The residue was dissolved in acidified water and washed three times with dichloromethane. The water layer was made alkaline (pH ≈ 9) by addition of concentrated ammonia. The resulting white suspension was extracted three times with dichloromethane. The organic layers were collected and dried over Na_2SO_4. After evaporation under reduced pressure, the pure compound was obtained as a clear yellow oil. Yield: 1.54 g, 3.5 mmol (96%). ^{1}H NMR (CDCl$_3$, 200 MHz): δ = 8.55 (d, 3 H, 6′py-*H*), 7.59 (td, 3 H, 4′py-*H*), 7.36 (d, 3 H, 3′py-*H*), 7.14 (t, 3 H, 5′py-*H*), 6.93 (s, 1 H, 3′phenol-*H*), 6.84 (s, 1 H, 5′phenol-*H*), 3.95 (s, 2 H, NH-CH_2-py), 3.91 (s, 2 H, phenol-CH_2-NH), 3.85 [s, 4 H, N(CH_2-py)$_2$], 3.75 (s, 2 H, phenol-*N*-CH_2), 2.22 (s, 3 H, CH_3) ppm. ^{13}C NMR (CDCl$_3$, 200 MHz): δ = 159.35, 154.80, 147.32, 136.17, 128.35, 126.35, 124.00, 123.11, 122.85, 121.67, 59.06, 56.12, 54.65, 50.95, 26.22 ppm.

[Cu$_2$(py3asym)(H$_2$O)$_{1.5}$(NO$_3$)$_2$](NO$_3$): The bulk sample was prepared by dissolving Hpy3asym (0.076 g, 0.17 mmol) and Cu(NO$_3$)$_2$·3H$_2$O (0.09 g, 0.37 mmol) in 10 mL of an acetonitrile/water mixture (1:1). The resulting solution was stirred for one hour at room temperature and the solvents evaporated to dryness under reduced pressure. After washing with a small amount of acetone, 0.08 g (0.1 mmol, 59% yield) of the pure compound was obtained as a dark green powder. $C_{27}H_{31}Cu_2N_8O_{11.5}$ (778.68): calcd. C 41.7, H 3.9, N 14.7; found C 41.3, H 4.0, N 14.4. MS(ESI): *m*/*z* = 688 ([Cu$_2$(py3asym)(NO$_3$)$_2$]$^+$). IR: $\tilde{\nu}$ = 3600−3200, broad band (H$_2$O, asymmetric and symmetric OH stretching), 3184 (N−H stretching), 1613 (HOH bending), 1484 (chelating didentate NO$_3^-$, N=O stretching), 1396 (monodentate NO$_3^-$, NO$_2$ asymmetric stretching), 1290 (monodentate NO$_3$-, symmetric NO$_2$ stretching, and chelating didentate NO$_3^-$, asymmetric NO$_2$ stretching).[20]

Single crystals of the complex, suitable for X-ray crystal structure determination, were obtained by slow evaporation of the solvent from an acetonitrile solution containing stoichiometric amounts of Cu(NO$_3$)$_2$·3H$_2$O and the ligand.

X-ray Crystallographic Study: A single crystal of [Cu$_2$(py3asym)(H$_2$O)$_{1.5}$(NO$_3$)$_2$](NO$_3$) was mounted at 100 K on a Bruker AXS SMART 6000 diffractometer equipped with Cu-K_α radiation (λ = 1.54184 Å). $C_{27}H_{31}Cu_2N_8O_{11.5}$, M = 778.68 g mol^{-1}, rectangular green needles, 0.17 × 0.08 × 0.07 mm, a = 10.3731(2), b = 22.1430(4), c = 14.2325(2) Å, β = 105.709(10)°, Z = 4, V = 3146.98(9) Å^3, $\rho_{calcd.}$ = 1.644 g cm^{-3}, μ = 2.322 cm^{-1}, absorption correction: SADABS,[21] monoclinic, space group $P2_1/n$ (no. 14), reflections collected: 18421, independent reflections: 5871 (R_{int} = 0.0314). The structure was solved by direct methods and refined using the SHELX program package.[22,23] All hydrogen atoms were placed at idealized positions riding on the carrier atom, with isotropic thermal parameters, except for two hydrogen atoms located close to O20. They were assigned to rest electron density on the electron density map. The final cycle refinement, including 475 parameters, converted to $R1$ = 0.0312 ($R1$ = 0.0388 all data) and $wR2$ = 0.0800 ($wR2$ = 0.0826 all data) with a maximum (minimum) residual electron density of 0.463 (−0.293) e·Å^{-3}.

Solvothermal Synthesis of a Layered Open-Framework Chlorocadmium Oxalate, $Cd_2(C_2O_4)_{0.5}Cl_3NaCl{\cdot}4H_2O$

R. Vaidhyanathan,[a] Srinivasan Natarajan,[a] and C. N. R. Rao*[a]

Keywords: Materials science / Cadmium / Solvothermal synthesis / Metathesis

The metathesis reaction between $CdCl_2{\cdot}2H_2O$ and sodium oxalate in *n*-hexanol under solvothermal conditions yields a hybrid compound of formula $Cd_2(C_2O_4)_{0.5}Cl_3NaCl{\cdot}4H_2O$. It consists of one-dimensional chains formed by Cd and Cl atoms, containing μ_2(Cl) and μ_3(Cl) bridges, and cross-linked by oxalate units to give a layered structure. The Na^+ ions and water molecules occupy the interlamellar spaces.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

A variety of inorganic open-framework compounds containing extra-framework alkali metal ions and other cations have been synthesized in recent years.[1−3] Intercalation of cations and anions in cages and cavities (cryptands, spherands, siderands, coronates) is also well documented in host-guest chemistry.[4] Thus Na^+, K^+, Cl^- and NO_3^- have been incorporated into inorganic host compounds. Interestingly, extended structures of alkali halides such as KCl, RbCl, and CsBr, of varying dimensionalities, have been recently incorporated in host lattices of cadmium oxalate.[5−8] The $NH_4^+Cl^-$ ion-pair has been introduced in the cage formed by the anionic cluster of isopolyvanadate and phenylphosphonate units.[9] The use of solvothermal techniques to prepare hybrid organic-inorganic solids has resulted in materials inaccessible by other means.[10−13] In our efforts to synthesize hybrid open architectures incorporating alkali halides and other inorganic guests by means of solvothermal routes, we have obtained a two-dimensional cadmium oxalate of the composition $Cd_2(C_2O_4)_{0.5}Cl_3NaCl{\cdot}4H_2O$ (**I**), wherein the NaCl unit is accommodated in the cadmium oxalate structure. The synthesis of **I** seems to have become possible because of the solvothermal conditions employed by us with *n*-hexanol as the solvent; **I** is not obtained under hydrothermal conditions.

Results and Discussion

The asymmetric unit of **I** consists of 14 non-hydrogen atoms with two crystallographically distinct, octahedrally coordinated Cd atoms. Whilst Cd(1) is linked by three chlorine atoms, two oxalate oxygens and one bonded water molecule, Cd(2) is connected by six chlorine atoms. The average Cd(1)−O/Cl and Cd(2)−Cl distances are 2.459 Å and 2.631 Å, respectively (Table 1). The framework structure of **I** is formed by linkages involving $Cd(1)O_3Cl_3$, $Cd(2)Cl_6$ and oxalate units. The Cd(2) atoms are connected to each other through chloride bridges, giving rise to infinite one-dimensional chains, and the Cd(1) atoms are connected to these chains by μ_2(Cl)- and μ_3(Cl)-type chloride bridges (Figure 1). These one-dimensional building units are cross-linked by oxalate units giving rise to a layered architecture (Figure 2). Adjacent layers are shifted by 1/2 the unit cell length along the [1 0 1] direction, giving rise to ABAB-type layer stacking. Extra-framework Na^+ ions occupy spaces in the interlamellar regions along with water molecules (Figure 3). The environment around the Na^+ ion in **I** can be considered to be octahedral with five water molecules (av. Na−O = 2.411 Å) and a chloride, which is also attached to two Cd atoms. The Na−Cl distance is 2.999 Å, slightly longer than the distance in bulk NaCl (2.814 Å). Selected bond lengths and angles in **I** are presented in Table 1.

The one-dimensional $CdCl_2$ chain in **I** is similar to the double chain in ABX_3.[14] The structure of **I** can therefore be considered as originating from $CdCl_2$, which under the non-aqueous conditions employed for the synthesis can give rise to $NaCdCl_3$ chains. Cross-linking of the chlorocadmium chains by the oxalate units would then yield the layer present in **I**, the process being somewhat similar to the assembly of molecular metal clusters by organic linkers described by Yaghi and co-workers.[15] The cadmium chloride chains in **I** are also related to the infinite one-dimensional chains formed by the pyramidal β-$[AsS_4]^{3-}$ units observed in the potassium tin thioarsenide compound $KSnAsS_5$.[16] One can visualize the structure of **I** to be arising from the replacement of the $[AsS_4]^{3-}$ units by $[Cd(C_2O_4)Cl_2(H_2O)]^{2-}$ units and simultaneously replacing the Sn^{4+} by Cd^{2+} units, as represented schematically on the next page.

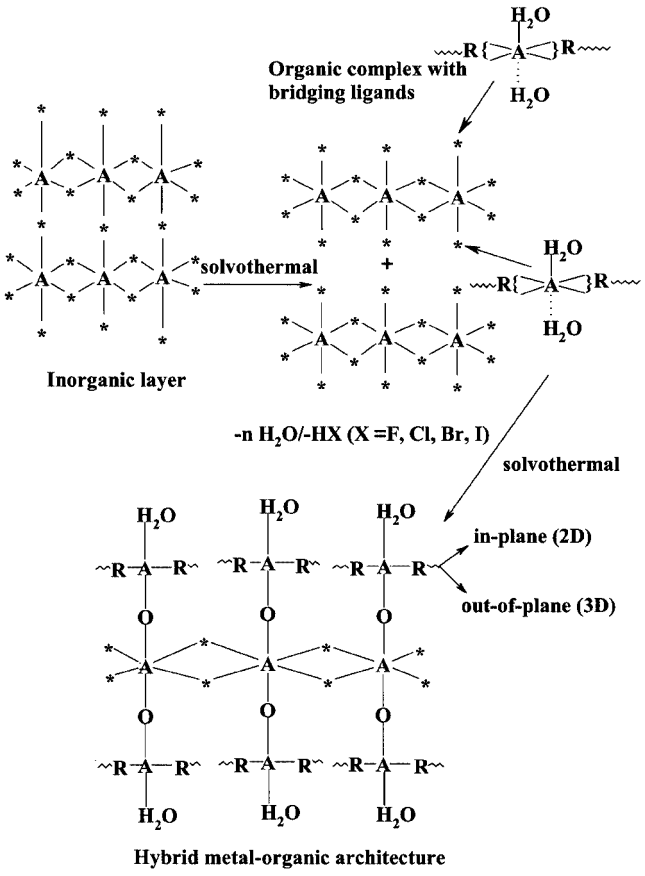

Scheme 1. A general scheme illustrating the building up of complex hybrid metal-organic architectures by aligning the lower-dimensional structures of metal halides/hydroxides by replacing the Cl^- or OH^- ions with metal complexes possessing organic ligands capable of bridging these lower dimensional inorganic structures. Depending on the mode of linking that the organic linkers provide the hybrid metal-organic structures can either be two- or three-dimensional. The probable generation of the low-dimensional structures by the partial disintegration of the higher dimensional parent structure under suitable reaction conditions has also been indicated. A = any metal; * = F, Cl, Br, I, -OH, H_2O; R = dicarboxylate, bipyridyl, nicotinate etc. Note that the one-dimensional inorganic chains can be introduced directly into the reaction medium

The above schematic suggests a new strategy for designing hybrid metal-organic frameworks, wherein one inorganic anion is replaced by another anion possessing an organic ligand, which in turn facilitates the extension of the structure into higher dimensions. A more general schematic representing this notion to illustrate the building up of three-dimensional hybrid metal-organic frameworks by aligning the lower-dimensional structures of metal halides and metal hydroxides by the introduction of metal complexes with organic ligands (dicarboxylate, bipyridyl, nicotinate etc.) capable of bridging the lower dimensional inorganic structures is presented in Scheme 1. Depending on the mode of linking of the organic linkers, the hybrid metal-organic structures can either be two- or three-dimensional. The possibility that the lower-dimensional structures can be generated by the partial disintegration of the higher dimensional parent structure under suitable reaction conditions is also indicated in Scheme 1. This possibility can be realized by observing the close structural relationships among some of the well-known lower-dimensional inorganic structures shown in Scheme 2. A similar notion has been proposed by Wood and co-workers[17−19] to describe the possible building of the cobalt squarate framework from the parent cobalt hydroxide with a brucite structure. Notably, the structural relationship between the Cd(OH)Cl and Cu(OH)Cl to brucite has been noted recently.[20]

It is likely that many such hybrid metal-organic structures with open-architectures can be made by employing other different organic linkers. In this context, we should draw attention to a new three-dimensional, open-framework, neutral and anhydrous chlorocadmium compound $[CdCl_2(C_4H_8N_2)]$ (**II**),[21] synthesized using solvothermal route by us, wherein the amine performs the role of linking the one-dimensional chlorocadmium chains into three-dimensions (Figure 4). Interestingly, in **II**, the channels are hydrophobic and empty. Assembling such predetermined polymeric units via organic pillars or linkers provides an interesting methodology for combining the dimensionality of the electronic exchange pathways and the open frameworks.[22]

The framework structure of **I** has certain unusual features which merit discussion. The position of the chloride, Cl(2), in **I** provides an interesting comparison with the layered chlorocadmium oxalate, $[Rb_2Cd(NO_3)(Cl)(C_2O_4)(H_2O)]$,[6] chlorozinc phosphate, $[C_6NH_{14}][ZnCl(HPO_4)]$[23] and the tin(II) phosphate, $[C_3H_{12}N_2]2[SnPO_4]$.[24] Although the Cl(2) atom in **I** is a bridging chloride its position is similar to that of the pendant Cl atoms in the chlorocadmium oxalate, chlorozinc phosphate and the lone pairs in the Sn^{II} phosphate (Figure 5a−d). The lone-pair of electrons in $[C_3H_{12}N_2]2[SnPO_4]$ and the chlorine atoms in $[C_6NH_{14}][ZnCl(HPO_4)]$ and $[Rb_2Cd(NO_3)(Cl)(C_2O_4)(H_2O)]$ point in a direction perpendicular to the plane of the layer, with the charge-compensating organic amine mol-

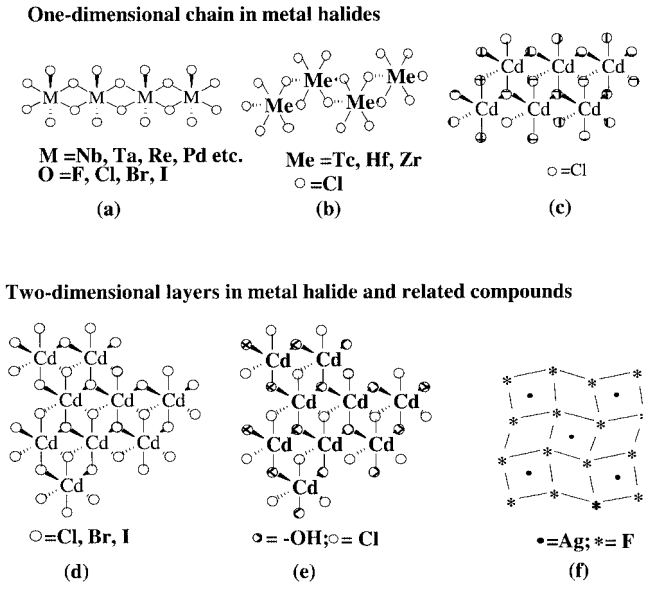

Scheme 2. Some of the low-dimensional structures of metal halogen and related inorganic solids; (a) the *cis*-oriented 1-D chains in NbI_4, $TaCl_4$, WCl_4; (b) the *trans*-oriented 1-D chains in $TcCl_4$, $ZrCl_4$, $PtCl_4$; (c) the $CdCl_3$ double chain present in NH_4CdCl_3; (d) the structure of CdX_2 (X = Cl, Br, I); (e) a layer in Cd(OH)Cl; (f) the layer in AgF. Note the similarity in the structure of the double chain in (c) and the cadmium chloride chain in **I** and also the structural relationship existing among the structures shown here

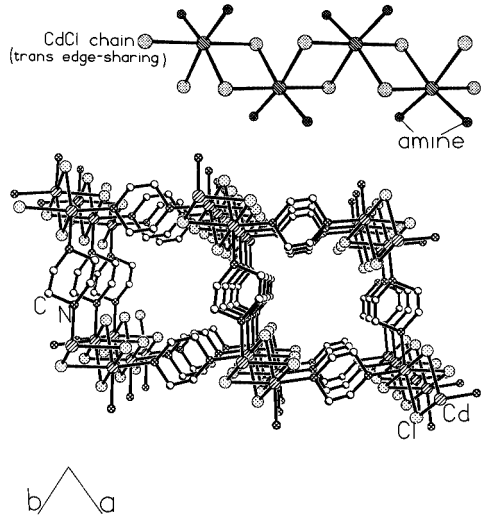

Figure 4. Structure of $[CdCl_2(C_4N_2H_8)]$ (**II**) showing the square hydrophobic channels present along the *a* axis formed by alignment of the Cd-chloro chains by the piperazine units; the inset shows the one-dimensional Cd-chloro chains formed by trans-edge sharing between the $CdCl_4N_2$ octahedra

ecule or the cation situated in the inter-lamellar space. In **I**, Cl(2) points into the inter-lamellar region occupied by the sodium (Figure 5a). Both the Cl atoms and the lone pairs orient themselves perpendicular to the plane of the metal oxalate layer and, satisfying their steric requirements, protrude into the interlayer spaces, making them available for chemical exploitation. Incorporation of halide ions, hydroxy groups or lone pairs in designed compounds, wherein they are made to occupy specific positions with predetermined orientations (based on stereochemical requirements) may enable the formation of materials possessing high chemospecificity.

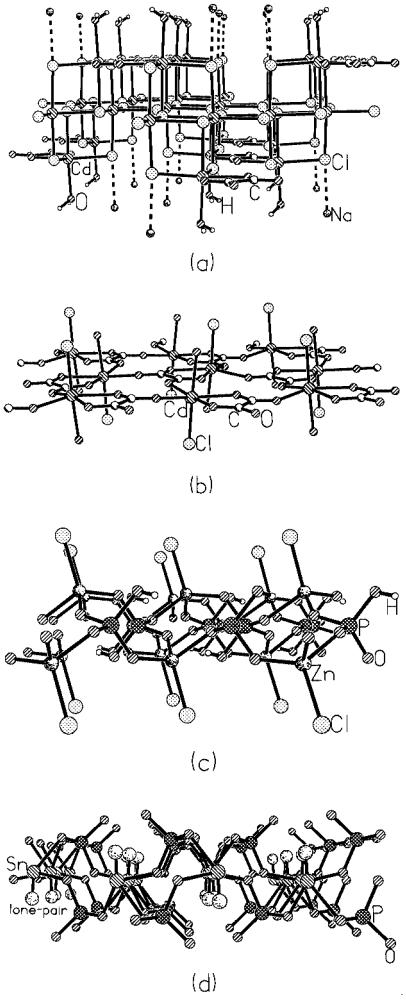

Figure 5. (a) Structure of **I**, showing the Cl(2) atoms pointing to the interlamellar region and the Na···Cl interaction (shown in dotted bonds) between the framework Cl(2) and the guest Na atoms; (b) structure of $[Rb_2Cd(NO_3)(Cl)(C_2O_4)(H_2O)]$, showing the pendant Cl atoms pointing into the interlayer regions; (c) structure of $[C_6NH_{14}][ZnCl(HPO_4)]$, showing the pendant Cl atoms protruding into the interlayer space; (d) structure of $[N_2C_3H_{12}]2[SnPO_4]$, with the pendant Cl atoms protruding into the interlamellar space

The arrangement of the extra-framework Na^+ cations gives rise to certain noteworthy features. The octahedrally coordinated sodium shares an edge with neighboring NaO_5Cl octahedra via bridging water molecules, forming an $Na_2O_8Cl_2$ dimer. These dimers are oriented in such a manner as to form strong O(w)−H···O(w) hydrogen bonds [O(w) = water oxygen] with the adjacent dimer, giving rise to a hydrogen-bond-stabilized one-dimensional ladder (Figure 6). Such low-dimensional structures formed by the guest species, involving weak interactions, contribute to the overall stability of these structures.[25]

In summary, the synthesis and structure of a new open-framework two-dimensional chlorocadmium oxalate compound (**I**) has been achieved. The formation of **I** could be

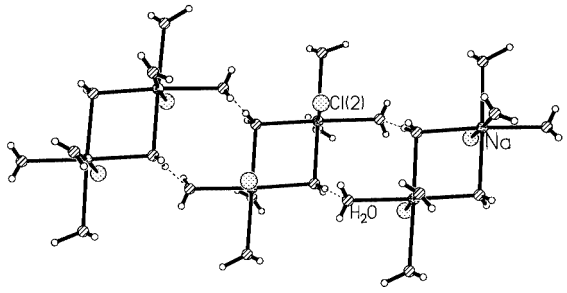

Figure 6. Figure shows the one-dimensional ladder-like structure formed by the $Na_2O_8Cl_2$ dimers *via* O(w)−H···O(w) hydrogen-bond interactions

the result of incomplete dissociation of the starting $CdCl_2$ under solvothermal conditions, facilitating the facile cross-linking by the oxalate units. It is likely that other such unusual structures can be formed under solvothermal conditions by employing other linkers.

Experimental Section

$Cd_2(C_2O_4)_{0.5}Cl_3NaCl{\cdot}4H_2O$ (**I**) was synthesized by the metathesis reaction between $CdCl_2{\cdot}2H_2O$ and sodium oxalate under solvothermal conditions. Typically, sodium carbonate (0.026 g) and oxalic acid (0.1879 g) were dissolved in 3 mL of dry *n*-hexanol. The mixture was stirred for two hours at room temperature. $CdCl_2{\cdot}2H_2O$ (0.20 g) and 0.07 mL of glacial acetic acid were added to the mixture and the contents were stirred to homogeneity (45 mins). The final mixture of the composition $CdCl_2{\cdot}2H_2O$:Na_2CO_3:$H_2C_2O_4{\cdot}2H_2O$:CH_3COOH:*n*-$C_6H_{13}OH$ (1:0.25:1.5:1.2:24) was sealed in a 23 mL PTFE-lined stainless steel autoclave and heated to 150 °C for 60 h. The product — colorless hexagonal plate-like and/or rod-like crystals — was filtered, washed with deionized water and dried under ambient conditions. Both type of crystals with different morphologies were identified to be compound **I**. The role of acetic acid is not clear to us. The water molecules present in **I** could have come from the use of $CdCl_2{\cdot}2H_2O$ and $H_2C_2O_4{\cdot}2H_2O$. The same reaction when carried out in the presence of water (hydrothermally) did not yield **I**. The EDAX studies resulted in an Na:Cd:Cl ratio of 1.0:1.9:4.1, which is in agreement with the calculate values (1.0:2.0:4.0); the elemental microanalysis showed: $Cd_2(C_2O_4)_{0.5}Cl_3NaCl{\cdot}4H_2O$ (**I**): calcd. C 2.4, H 1.6; found C 2.7, H 1.5.

Initial characterization of **I** was carried out by powder X-ray diffraction, thermogravimetric analysis (TGA), IR spectroscopy, elemental microanalysis and EDAX studies. The powder XRD patterns indicated that the products were new materials and were entirely consistent with the structures determined using the single-crystal X-ray diffraction (see Supporting Information). A least-squares fit (Cu-K_α) of the XRD patterns, using the *hkl* indices generated from the single-crystal structure gave the following lattice parameters: a = 12.216(8), b = 17.2104(10), c = 11.834(8) Å, β = 101.507(9) for **I**. IR spectra (KBr pellet) showed characteristic features of the dicarboxylate units.[26] The various bands are: ν_{as}(C=O) at 1646(s) cm^{-1} and ν_s(C=O) at 1417(w) cm^{-1}; ν_s(C-O) + δ(O-C=O) at 1312(s) cm^{-1}; δ(O-C=O)+ ν(MO) at 790(m) cm^{-1}; ν(MO) + ν(C-C) at 516(m) cm^{-1}; ν(MO) + ring def. at 438(w) cm^{-1}. A broad band appears in the 3550−3300 cm^{-1} region due to the presence of water molecules in the structure.

TGA studies of **I** indicate two distinct mass losses. A gradual mass loss in the range 100−300 °C (obsd. 14.3%) due to the loss of four water molecules (14.2%). The second mass loss of 15.7% in the range of 350−450 °C is due to the loss of the oxalate moiety (calcd. 17.4%). Above 500 °C, a gradual loss was observed due to the slow evaporation of the Cd compound.

Single-Crystal Structure Determination: A suitable single crystal of **I** was selected under a polarizing microscope and glued at the tip of a thin glass fiber with cyanoacrylate (superglue) adhesive. Structure determination by X-ray diffraction was performed on a Siemens Smart-CCD diffractometer equipped with a normal focus, 2.4 kW sealed-tube X-ray source (Mo-K_α radiation, λ = 0.71073 Å) operating at 50 kV and 40 mA. A hemisphere of intensity data was collected at room temperature in 1321 frames with ω scans (width of 0.30° and exposure time of 20 s per frame) in the θ range 2.07 to 23.30°. Pertinent experimental details for the structure determinations are presented in Table 2.

The structure was solved and refined by using SHELXTL-PLUS[27] suite of programs. An absorption correction based on symmetry equivalent reflections was applied using the SADABS program.[28] The last cycles of refinement included atomic positions for all the atoms and anisotropic thermal parameters for all the atoms. Full-matrix least-squares structure refinement against $|F^2|$was carried out using the SHELXTL-PLUS package of programs. Details of the crystal data and final refinements are given in Table 2. Selected bond lengths and angles for compound **I** are presented in Table 1. CCDC-203041 (**I**) and CCDC-203042 (**II**) contain the supplementary crystallographic data for this paper. These data can be ob-

Synthesis of C_1-Symmetric Tripod Ligands Containing a P,P,N Donor Set – η^2-Coordination in d^8-Metal Complexes

Ralf Faissner,[a] Gottfried Huttner,*[a] Elisabeth Kaifer,[a] and Peter Rutsch[a]

Dedicated to Professor Horst Kisch on the occasion of his 60th birthday

Keywords: Mixed donor sets / Nickel / Palladium / Rhodium / Tripodal ligands

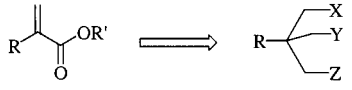
Tripod ligands $RC(CH_2X)(CH_2Y)(CH_2Z)$ (X, Y, Z = NR_2, PR_2) are accessible from α,β-unsaturated esters $R(=CH_2)COOR'$. The key steps in this synthetic approach are Michael additions of amines and phosphanes to produce $RCH(COOR')(CH_2X)$ (X = NR_2, PR_2) (**2** and **3**), followed by hydroxymethylation with paraformaldehyde to result in $RC(COOR')(CH_2OH)(CH_2X)$ (X = NR_2) (**4**). Standard transformations of this C_1-symmetric precursor allow for the synthesis of tripod ligands such as $PhC(CH_2pz)(CH_2PPh_2)(CH_2PMes)$ (**11**). Coordination of these ligands with d^8-metal ions [nickel(II), palladium(II), rhodium(I)] results in square-planar complexes with the chelate cycles in half-chair, twist-boat or boat conformations, depending on the specific substitution pattern. Coordination through two phosphane donors with the nitrogen donor acting as a dangling arm is generally preferred throughout. Detail preparative procedures and complete characterisation by analytical methods, including X-ray analysis of the coordination compounds, are given.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

While tripod ligands $CH_3C(CH_2PR_2)_3$ have been known for a long time,[1] the synthesis of chiral tripodal ligands $CH_3C(CH_2X)(CH_2Y)(CH_2Z)$ (X, Y, Z = donor groups) has only been developed in the last decade.[2,3] Different synthetic procedures were found to allow access to these compounds. It was observed, however, that the introduction of nitrogen donors in one or more of the X, Y, Z positions called for quite specific procedures, dependent both on the specific precursor and on the specific type of the NRR′ function to be introduced.[2b,2d,3g,3h,4] A general drawback of the strategies so far published for the synthesis of $RC(CH_2X)(CH_2Y)(CH_2Z)$ resides in the fact that there is no free choice of the kind of the group R fixed at the backbone of the tripodal ligand. Only ligands with R = H,[5] CH_3,[1–3] and CH_2OR'[6] are easily available by the published routes, while other functions such as benzyl, alkyl or alkenyl groups have to be introduced into appropriate ligand precursors by specific reactions,[7] which do not, however, in general allow for the consequent introduction of three different donor groups X, Y, and Z.

In search of a solution for both of these problems we studied α,β-unsaturated esters $RC(=CH_2)COOR'$ as potential precursors (see Scheme 1). We now report that the transformation of these precursors into tripod ligands is achieved with different kinds of groups R as well as different kinds of donor functions X, Y, Z including NRR′.

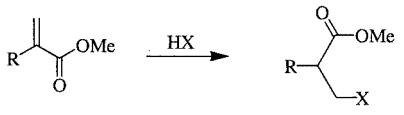


Scheme 1

Results and Discussion

Ligand Synthesis

α,β-Unsaturated esters $RC(=CH_2)COOR'$ are known to undergo 1,4-addition reactions with different types of HX compounds, including RR′NH[8] and R_2PH.[9] By applica-



1 **2, 3**

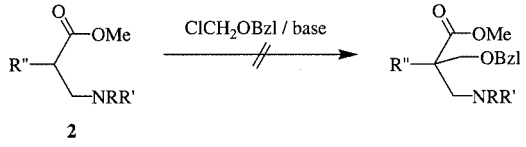
E-mail: g.huttner@indi.aci.uni-heidelberg.de

tion of this strategy, compounds **2** and **3** are obtained from compounds **1** in high yields (see Scheme 2 and Exp. Sect.).

The ester function in compounds **2** offers itself for transformation into a CH_2X' donor entity in later steps of the reaction. In order to obtain tripod ligands, an additional functionalisable CH_2X'' group has to be added to the central position of **2** in such a way that it forms the third "leg" of the desired tripod ligand. Hydroxymethylation is the obvious solution. Reactions of this type are generally quite efficient, but only in the absence of a CH_2NRR' substituent and with aldehyde or ketone functions, rather than an ester function as present in **2**.[10] Unactivated esters of the general type of framework as present in **2** – that is, disubstituted in the α,α′-position – are only rarely found to be suitable precursors for hydroxymethylation.[11] Hydroxymethylation is generally only successful if they are activated by an additional electron-withdrawing group, such as in malonic ester derivatives, and this type of reaction has accordingly been used as a key step for the construction of specific tripod ligands.[3d,7b,7c]

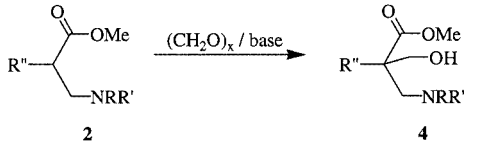
With compound **2**, however, it was found that even substitution under basic conditions by chloromethyl benzyl ether failed (see Scheme 3).



2

Scheme 3

While the direct introduction of a CH_2OH group in the form of formaldehyde or paraformaldehyde is reported to be less efficient[10,12] than the synthesis of its protected form by use of $ClCH_2OBzl$, it still proved possible to find suitable conditions for the synthesis of **4** from **2** by just this route (Scheme 4). The key to obtaining the necessary reactivity was the nature of the deprotonation of **2**; such deprotonation to afford the corresponding enolate is possible with NaH/DMF at 20 °C or LDA/THF at −70 °C. The choice of either one of these bases depends on the nature of R′′ and NRR′ in **2** (see Exp. Sect.), while KO*t*Bu was found to be ineffective in this kind of reaction.



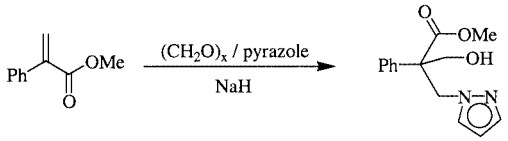
2 **4**

2a R" = Ph NRR' = $N(CH_2)_5$ **4a** R" = Ph NRR' = $N(CH_2)_5$
2b R" = CH_3 NRR' = NEt_2 **4b** R" = CH_3 NRR' = NEt_2
2c R" = CH_3 NRR' = $N(CH_2)_5$ **4c** R" = CH_3 NRR' = $N(CH_2)_5$

Scheme 4

The yields of the transformations of **2** into **4** are between 45 and 65% and correspond well to yields reported for the hydroxymethylation of RCH_2COR' by paraformaldehyde.[10]

In the case of **1a**, Michael addition and hydroxymethylation could be performed in a one-pot reaction with pyrazole as the HNRR′ reagent (see Scheme 5),[13] compound **4d** being obtained in 65% yield in this way. This type of one-pot reaction was, however, only successful with **1a** as the Michael acceptor and pyrazole as the Michael donor, and so only **4d** – and not **4a**–**4c** – is accessible by this simple route.

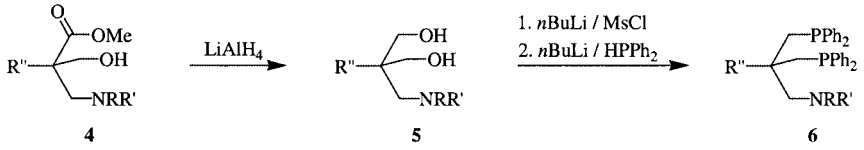


1a **4d**

Scheme 5

The compounds **2**–**4** have been fully characterised by elemental analysis, mass spectrometry and ^1H and ^{13}C NMR spectroscopy (see Tables 4, 6, 7 and Exp. Sect.).

Reduction of the ester function in **4** afforded the diols **5**, which – after activation by mesyl chloride – could be transformed into the diphosphanes **6** (see Scheme 6). These diphosphanes are tripod ligands containing two P and one N donor functions. Their identity was established by their elemental analyses, mass spectra and NMR spectra (see



4 **5** **6**

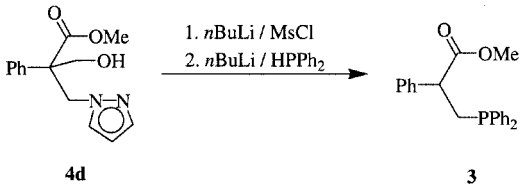
Tables 5−7 and Exp. Sect.) and by the formation of tripod metal complexes (see Coordination Chemistry).

Since compounds **4** already contain three different functionalities, their transformation into chiral racemic tripod ligands should be possible. The activation of the OH group of **4** by mesyl chloride was found to be quite inefficient in this respect: either the yields were very low or, as in the case of **4d**, formal elimination of the CH_2pz group occurred, to give **3** as the main product (see Scheme 7).



Scheme 7

The mechanism of this reaction has not yet been studied, but $MePPh_2$ and $MeP(=O)Ph_2$ have been observed (^{31}P NMR, GC/MS) as accompanying products.

In contrast, activation by means of the Appel reaction[14] transformed **4** into **7** in fair yields (see Scheme 8). The direct substitution of the chloride function of **7** by diphenylphosphide was successful for **7a**, while with **7b**, with its pyrazolyl functionality, sluggish reactivity, and partial decomposition was observed. For **7a**, with its diethylamine function, a clear transformation into **8** (63% yield) was accomplished (see Scheme 8).

A more general route is based on the reduction of the ester group as the first step. The activation of the resulting alcohol function by mesyl chloride was followed by the substitution of the mesylate by diarylphosphide. The remaining chlorine function could then be substituted by a different diarylphoshide. The reaction sequence has been fully worked out for the transformation **7b** → **9** → **10** → **11** (see Scheme 9). The two phosphide substitution steps give yields normal for this type of process, with an overall yield of **11** of 35% based on **7b**. To avoid unwanted side reactions during these substitution steps (internal cyclization) the reaction temperatures have to be thoroughly controlled (see Exp. Sect., for elemental analysis, NMR spectra, and mass spectra of compounds **7−11**, see Tables 4−7).

Coordination Chemistry

Tripod ligands containing nitrogen and phosphorus donor functions in one and the same ligand are known to form tripodal coordination compounds. This has been demonstrated with $Mo(CO)_3$ as the coordinated entity.[3g,3h] With d^8-ions as the metal constituents, square-planar coordination of the metal ion is generally preferred and is exclusively observed for tripod ligands containing a P,P,N donor set.[4b,15] With this type of η^2-coordination of a tripod ligand containing different types of donor functions, it is not clear a priori which kinds of donor functions will be coordinated.

Compounds **6**, **8**, and **11** offer the opportunity to address this question. The coordination behaviour of this type of compounds with respect to nickel(II), palladium(II), and rhodium(I) was therefore analysed.

	R"	PAr_2	NRR'

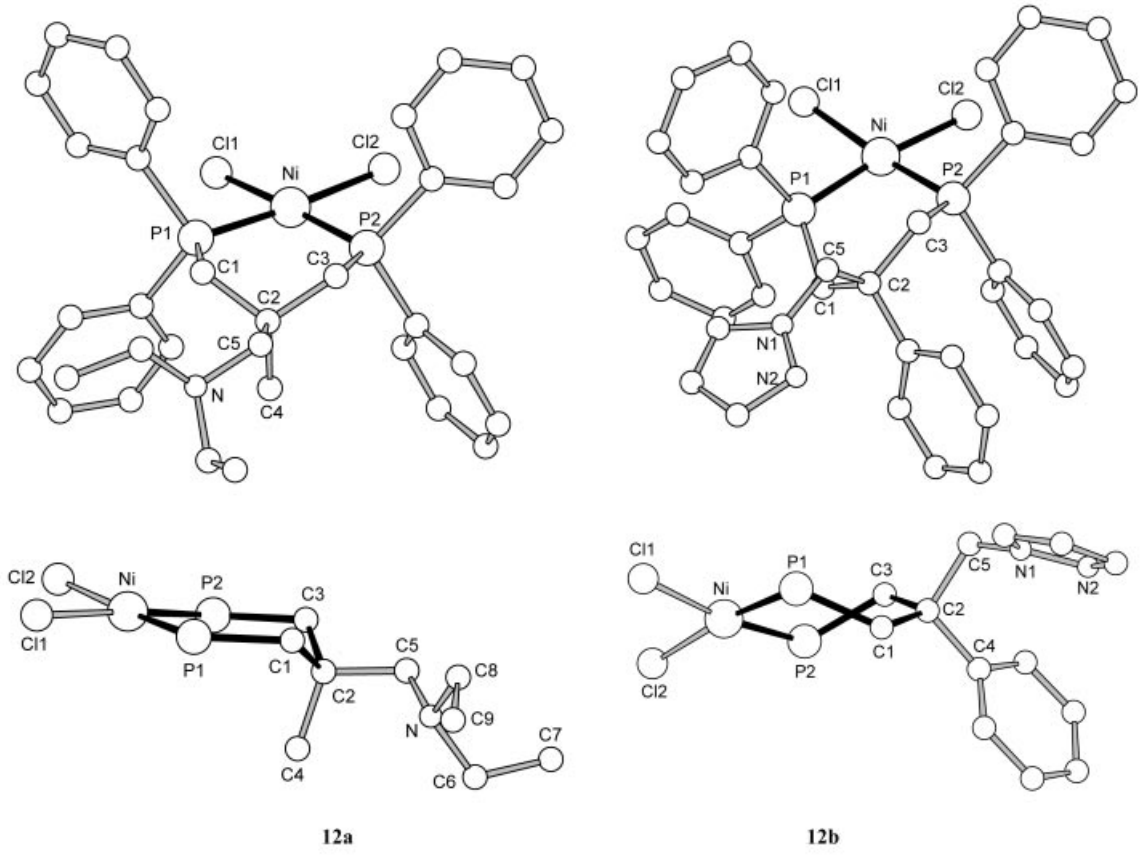

Figure 1. Two views of the X-ray structure of compound **12a** (left, half-chair conformation) and **12b** (right, twist-boat conformation); top: general view; bottom: view showing the conformation of the six-membered chelate cycle (phenyl groups are not shown for the sake of clarity)

Tripod ligands **6a**, **6b**, and **11** each contain a P,P,N donor set. Complexation with aqueous $NiCl_2$ resulted in orange to red, square-planar nickel(II) complexes **12** in which the two phosphane functions are coordinated exclusively while the nitrogen-functionalised "leg" is a dangling substituent (see Scheme 10). The same type of coordination behaviour has already been observed for other ligands of the type $RC(CH_2PPh_2)_2(CH_2X)$. Phosphorus coordination is preferred over coordination of ligand groups X such as NRR′, OH, OMe, and SR.[3e,16]

The structures of **12a** and **12b** as determined by X-ray crystallography are shown in Figure 1.

Interestingly, the conformations of the chelate cycles are different for the two compounds − being a half-chair form in **12a** and a twist-boat form in **12b** (see Table 1). The relative stability of these types of conformations has recently been analysed thoroughly.[17]

Compound **8** has three different potential donor substituents within the tripodal framework: coordination is conceivable for the PPh_2, the NEt_2 and the ester groups. Compound **8** was found to react with $(dme)NiCl_2$ to give a violet, paramagnetic compound, which − due to its insufficient crystallisation properties − could not be obtained in analytically pure form. In contrast, palladium(II), introduced by use of $(cod)PdCl_2$, and rhodium(I), introduced by use of $[(nbd)RhCl]_2$, give the readily crystallised, diamagnetic compounds **13** (yellow) and **14·PF$_6$** (orange) (Scheme 11).

NMR (^1H, ^{13}C, ^{31}P) spectra of **13** reveal the expected resonances as sharp signals even at 30 °C (see Tables 4 and 6). The ethyl groups of the NEt_2 entity are diastereotopic, consistent with the proposed structure. Diastereotopic differentiation of the ethyl groups in **14·PF$_6$** is only observable below −30 °C (see Tables 4 and 6), while above this temperature some dynamic process gives rise to considerable broadening of the peaks such that the diastereotopic differentiation is no longer observable. The dynamic process is presumably due to a change in the conformation of the chelate cycle.[17,18]

X-ray analysis of **13** establishes the square-planar coordination of the palladium atom and reveals that the chelate cycle has a twist-boat conformation (see Figure 2, Table 1). The X-ray structure of **14$^+$** similarly establishes the pseudo-square-planar coordination of the rhodium atom. The chelate cycle is found to have the unconventional boat form, with the sterically more demanding methoxycarbonyl group axial and the methyl group in the equatorial position (see Figure 2, Table 1). The methoxycarbonyl group is orientated such that the normal to its plane points toward the rhodium centre (see Figure 2). The distance between the

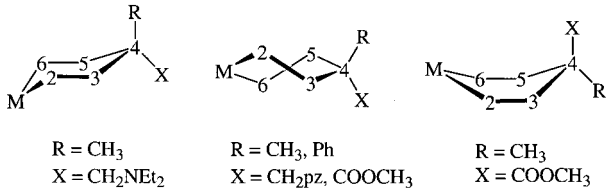

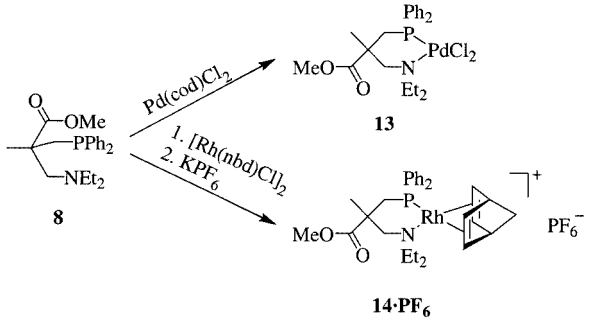

Scheme 11

rhodium atom and the carboxy group (Rh−O: 348.7 pm and 350.2 pm) is too large to be interpreted in terms of any direct bonding between these partners while it is short enough for some type of secondary interaction to be assumed (see Table 2).

Boat conformations as observed for **14**$^+$ have not yet been found in crystal structures of rhodium complexes with six-membered phosphorus-containing saturated chelate cycles, while their inherent relative stability in some cases has been indicated by a thorough molecular dynamics analysis.[17b] With the dynamic behaviour of six-membered phosphorus-containing saturated chelate cycles in mind,[17,18] equilibria between different ring conformations are the most probable explanation for the temperature dependence of the behaviour of the NMR spectra of **14·PF$_6$**.

Conclusion

It has been shown that α,β-unsaturated esters RC(=CH_2)COOR′ may serve as starting materials for the synthesis of tripod ligands RC(CH_2X)(CH_2Y)(CH_2Z). The procedure allows for the incorporation of different types of substituents R in the backbone and also allows the introduction of donor functions X = NR_2 in the presence of different potential phosphorus donor functions (Y, Z).

Ligands of this type − containing a P,P,N donor set − coordinate to d^8-metal ions through their two phosphorus donor groups, resulting in a square-planar coordination with the amine function acting as a dangling arm.

Ligands containing a P,N,O donor set (O = part of a carboxy group) form complexes in which P,N donors serve as ligands in six-membered chelate cycles. For the d^8-metal ions Pd^{II} and Rh^{I} the coordination is square-planar. The O donor is not involved in direct bonding to the metal atom but may engage in secondary interaction with it.

[a] Standard deviations in units of the least significant digit are given in each case.

The conformations of the six-membered chelate cycles comprise the conventional half-chair and twist-boat forms as well as the unconventional boat form.

Experimental Section

General Remarks: All manipulations involving phosphanes were carried out under argon by use of standard Schlenk techniques. All solvents were dried by standard methods[19] and distilled under argon. The solvents $CDCl_3$ and CD_2Cl_2 used for NMR spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried over 4 Å molecular sieves. NMR: Bruker Advance DPX 200 at 200.12 MHz (^{1}H); 50.323 MHz (^{13}C{^{1}H}); 81.015 MHz (^{31}P{^{1}H}); T = 303 K unless stated otherwise; chemical shifts (δ) with respect to $CDCl_3$ (^{1}H: δ = 7.27; ^{13}C: δ = 77.0 ppm) and CD_2Cl_2 (^{1}H: δ = 5.32 ppm; ^{13}C: δ = 53.5 ppm) as internal standards. ^{31}P chemical shifts (δ) with respect to 85% H_3PO_4 (^{31}P: δ = 0 ppm) as external standard. FT-IR: Biorad Excalibur FTS 3000 spectrophotometer (samples in solutions between CaF_2 windows). MS: Finnigan MAT 8230. EI (70 eV). FAB (xenon; matrix: 4-nitrobenzyl alcohol). Melting points: Gallenkamp MFB-595010; uncorrected values. Elemental analyses: Microanalytical Laboratory of the Organic-Chemical Institute, University of Heidelberg.

Crystallographic Structure Determinations: Suitable crystals were taken directly out of the mother liquor, immersed in perfluorinated polyether oil, and fixed to a glass capillary. The measurements were carried out with an Enraf−Nonius Kappa CCD diffractometer, with graphite-monochromated Mo-K_α radiation used throughout.

The data were processed with the standard Nonius software,[20] and the calculations were performed with the SHELXT PLUS software package. Structures were solved by direct methods with the SHELXS-97 program and refined with the SHELXL-97 program.[21] Graphical handling of the structural data during solution and refinement was performed with XMPA.[22] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix, least-squares calculations. Data relating to the structure determinations are collected in Table 3. Figures 1 and 2 were prepared with WinRay-32.[23] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-191480 to -191483. Copies of the data can be obtained free of charge

on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Materials: Silica gel (Kieselgel 32−63 μm, ICN Biomedicals GmbH) used for chromatography was degassed at 1 mbar for 24 h and saturated with argon. A solution of *n*BuLi in hexane (2.5 M) was used for deprotonations. $HPPh_2$,[24] $HPMes_2$[25] and methyl 2-phenylacrylate (**1a**)[26] were prepared according to or by adaptation of literature procedures. All other chemicals were obtained from commercial suppliers and used without further purification. Boiling range of the petroleum ether used: 40−60 °C. For ^{1}H NMR data see Tables 4 and 5, for ^{13}C NMR data see Table 6, and for analytical data see Table 7.

Ligand Syntheses

General Procedure for the Synthesis of 2: The α,β-unsaturated ester **1a** or **1b** (0.5 mol) was mixed with the secondary amine (1.1 equiv.), and hydroquinone (1.0 g) in the case of **1b**. The solution was heated and, after cooling, the crude product was distilled under reduced pressure through a 15-cm Vigreux column, yielding the β-amino esters **2** as colourless liquids.

Methyl 2-Phenyl-3-(1-piperidino)propanoate (2a): Starting materials: **1a**, piperidine. The mixture was heated to 70 °C for 1 h. Yield: 103.8 g (0.42 mol, 84%), b.p. 84 °C (0.1 mbar). ^{1}H NMR ($CDCl_3$): δ = 1.43−2.61 ppm (m, 10 H, piperidine-H), 2.50−2.61 (m, 1 H, CH_2N), 3.21 (dd, $^2J_{H,H}$ = 12.6, $^3J_{H,H}$ = 10.2 Hz, 1 H, CH_2N), 3.71 (s, 3 H, OCH_3), 3.90 (dd, $^3J_{H,H}$ = 4.6, $^3J_{H,H}$ = 10.2 Hz, 1 H, PhC*H*), 7.31−7.35 (m, 5 H, aromat. H). ^{13}C NMR ($CDCl_3$): δ = 24.8 ppm, 26.5, 55.0 (3 × s, piperidine-C), 50.4 (s, Ph*C*H), 52.3 (s, OCH_3), 62.9 (s, CH_2N), 127.7−138.3 (m, aromat. C), 174.4 (s, C=O).

Methyl 3-(Diethylamino)-2-methylpropanoate (2b): Starting materials: **1b**, diethylamine. The mixture was heated under reflux for 72 h. Yield: 41.6 g (0.24 mol, 48%), b.p. 29 °C (0.2 mbar). ^{1}H NMR ($CDCl_3$): δ = 0.93 ppm (t, 6 H, NCH_2CH_3, $^3J_{H,H}$ = 7.0 Hz), 1.08 (d, 3 H, $CHCH_3$, $^3J_{H,H}$ = 7.1 Hz), 2.30 (dd, $^2J_{H,H}$ = 12.7, $^3J_{H,H}$ = 6.3 Hz, 1 H, CH_2NEt), 2.34 (q, $^3J_{H,H}$ = 7.0 Hz, 4 H, NCH_2CH_3,), 2.50−2.73 (m, 2 H, $CHCH_3$ and CH_2NEt), 3.62 (s, 3 H, OCH_3). ^{13}C NMR ($CDCl_3$): δ = 12.3 ppm (s, NCH_2CH_3), 15.8 (s, $CHCH_3$), 39.4 (s, $CHCH_3$), 47.8 (s, NCH_2CH_3), 51.7 (s, OCH_3), 57.3 (s, CH_2NEt), 177.0 (s, C=O).

Methyl 2-Methyl-3-(1-piperidino)propanoate (2c): Starting materials: **1b**, piperidine. The mixture was heated to 90 °C for 6 h. Yield: 76.0 g (0.41 mol, 82%), b.p. 54 °C (0.2 mbar). ^{1}H NMR ($CDCl_3$): δ = 1.10 ppm (d, $^3J_{H,H}$ = 7.0 Hz, 3 H, $CHCH_3$), 1.35−2.33 (m, 10 H, piperidine-H), 2.21 (dd, $^2J_{H,H}$ = 12.3, $^3J_{H,H}$ = 6.3 Hz, 1 H, CH_2N), 2.53 (dd, $^2J_{H,H}$ = 12.3, $^3J_{H,H}$ = 8.3 Hz, 1 H, CH_2N), 2.62 (sext, 1 H, $^3J_{H,H}$ = 7.1 Hz, $CHCH_3$), 3.63 (s, 3 H, OCH_3). ^{13}C NMR ($CDCl_3$): δ = 16.0 ppm (s, $CHCH_3$), 24.8, 26.3, 55.0 (3 × s, piperidine-C), 38.3 (s, $CHCH_3$), 51.7 (s, OCH_3), 62.7 (s, CH_2N), 177.0 (s, C=O).

Methyl 2-Methyl-3-(1-pyrazolyl)propanoate (2d): Starting materials: **1b**, pyrazole. The mixture was heated under reflux for 60 h. Yield: 68.4 g (0.41 mol, 82%), b.p. 48 °C (0.2 mbar). ^{1}H NMR ($CDCl_3$): δ = 1.07 ppm (d, $^3J_{H,H}$ = 7.1 Hz, 3 H, $CHCH_3$), 3.02 (sext, 1 H, $^3J_{H,H}$ = 7.1 Hz, $CHCH_3$), 3.57 (s, 3 H, OCH_3), 4.08 (dd, $^2J_{H,H}$ = 13.7, $^3J_{H,H}$ = 6.5 Hz, 1 H, CH_2N), 4.34 (dd, $^2J_{H,H}$ = 13.7, $^3J_{H,H}$ = 7.5 Hz, 1 H, CH_2N), 6.11, 7.30, 7.40 (t, 2×d, 3 H, $^3J_{H,H}$ = 2.0 Hz, pyrazole-H). ^{13}C NMR ($CDCl_3$): δ = 15.1 ppm (s, $CHCH_3$), 41.0 (s, $CHCH_3$), 52.2 (s, OCH_3), 54.5 (s, CH_2N), 105.6, 130.2, 140.0 (3 × s, pyrazole-C), 174.9 (s, C=O). For further analytical data of **2a**−**2d**, see Table 7.

Methyl 3-(Diphenylphosphanyl)-2-phenylpropanoate (3): Compound **1a** (1.62 g, 10 mmol) and diphenylphosphane (1.86 g, 10 mmol) were dissolved in DMF (30 mL). NaH (60% dispersion in mineral oil, 200 mg, 5 mmol) was added, and the reaction mixture was stirred at 25 °C for 18 h and then quenched by addition of deoxygenated water (10 mL). The product was extracted with diethyl

ether (4 × 20-mL portions), the organic portion was separated, and solvent was removed in vacuo. The resulting viscous oil was purified by chromatography on silica gel with petroleum ether/diethyl ether (6:1; R_f = 0.43) as eluent to afford **3** (2.30 g, 6.6 mmol, 66%) as a colourless oil. ^1H NMR ($CDCl_3$): δ = 2.59 ppm (d, $^2J_{H,H}$ = 13.6 Hz, 1 H, CH_2P), 2.96 (d, $^2J_{H,H}$ = 13.6 Hz, 1 H, CH_2P), 3.60−3.71 (m, 1 H, PhC*H*), 3.66 (s, 3 H, OCH_3), 7.33−7.48 (m, 15 H, aromat. H). ^{13}C NMR ($CDCl_3$): δ = 33.2 ppm (d, $^1J_{C,P}$ = 14.7 Hz, CH_2P), 49.0 (d, $^2J_{C,P}$ = 19.3 Hz, Ph*C*H), 52.5 (s, OCH_3), 127.9−139.8 (m, aromat. C), 174.3 (d, $^3J_{C,P}$ = 4.6 Hz, C=O). ^{31}P NMR ($CDCl_3$): δ = −20.9 (s). For further analytical data, see Table 7.

Methyl 3-Hydroxy-2-phenyl-2-[(1-piperidino)methyl]propanoate (4a): Compound **2a** (5.00 g, 20 mmol) and paraformaldehyde (2.70 g) were suspended in DMF (100 mL). Upon addition of NaH (60% dispersion in mineral oil, 900 mg) to the cooled (0 °C) suspension, the reaction mixture became clear within minutes. The reaction mixture was allowed to warm up to 25 °C and was stirred for 18 h. The reaction was quenched by the addition of brine (150 mL). The aqueous phase was extracted with diethyl ether (4 × 100-mL portions). The combined organic phases were washed with brine, dried with $MgSO_4$, filtered, and concentrated by rotary evaporation. The resulting viscous oil was purified by chromatography on silica gel with petroleum ether/diethyl ether (1:1; R_f = 0.39, strong tailing) as eluent to afford **4a** (3.60 g, 13.0 mmol, 65%) as a viscous fluid. For analytical data see Tables 4, 6 and 7.

Methyl 2-(Diethylaminomethyl)-3-hydroxy-2-methylpropanoate (4b): A solution of lithium diisopropylamide[27] (110 mmol) in THF (100 mL) was added at −78 °C to a suspension of **2b** (17.3 g, 100 mmol) and paraformaldehyde (10.5 g, 350 mmol) in THF (200 mL). The mixture was stirred for 1 h at −78 °C and then for 4 h at 25 °C, quenched by the addition of water (50 mL) and partitioned between diethyl ether and water. The aqueous layer was extracted with diethyl ether (3 × 50 mL), and the combined organic phases were washed with brine, dried with $MgSO_4$, and concentrated by rotary evaporation. Distillation of the residue under reduced press-

ure afforded **4b** (8.8 g, 43 mmol, 43%) as a colourless liquid, b.p. 62 °C (0.2 mbar). For analytical data, see Tables 4, 6 and 7.

Methyl 3-Hydroxy-2-methyl-2-[(1-piperidino)methyl]propanoate (4c): Starting material: **2c** (18.5 g, 100 mmol). This compound was prepared analogously to **4b**. Yield: 11.1 g (51.6 mmol, 52%), b.p. 99 °C (0.2 mbar). For analytical data, see Tables 4, 6 and 7.

Methyl 3-Hydroxy-2-phenyl-2-[(1-pyrazolyl)methyl]propanoate (4d): Pyrazole (5.10 g, 75 mmol) was deprotonated at 0 °C with sodium hydride (1.00 g, 25 mmol, 60% dispersion in mineral oil) in DMF (50 mL). This solution was slowly added at 0 °C to a mixture of **1a** (8.14 g, 50 mmol) and paraformaldehyde (4.50 g, 150 mmol) in DMF (50 mL). When a clear, colourless solution had formed, the reaction mixture was stirred at 25 °C for 1 h. The reaction was quenched by the addition of brine (150 mL), and the aqueous phase was extracted with diethyl ether (4 × 100-mL portions). The combined organic phases were washed with brine, dried with $MgSO_4$, filtered, and concentrated by rotary evaporation. The resulting viscous oil was purified by chromatography on silica gel with petroleum ether/diethyl ether (1:3; R_f = 0.42) as eluent to afford **4d** (8.10 g, 31.0 mmol, 62%) as a colourless oil. For analytical data, see Tables 4, 6 and 7.

General Procedure for the Synthesis of 5 and 9: A solution of the substituted ester (**4** or **7b**; 20 mmol) in THF (50 mL) was slowly added at 25 °C to a stirred suspension of $LiAlH_4$ (30 mmol per OH group) in THF (200 mL). The mixture was stirred for 15 h and hydrolysed by dropwise addition of water. The precipitate was filtered off and washed five times with ethyl acetate. The combined organic phases were dried with $MgSO_4$ and the solvents were evaporated to dryness to yield the corresponding alcohols.

2-(Diethylaminomethyl)-2-methylpropane-1,3-diol (5a): Starting material: **4b**. Yield: 3.45 g (19.7 mmol, 99%) of a viscous oil.

2-Phenyl-2-[(1-pyrazolyl)methyl]propane-1,3-diol (5b): Starting material: **4d**. Yield: 4.52 g (19.5 mmol, 97%) of a microcrystalline powder, m.p. 86 °C.

2-(Chloromethyl)-2-phenyl-3-(1-pyrazolyl)propan-1-ol (9): Starting material: **7b**. Yield: 4.81 g (19.2 mmol, 96%) of a microcrystalline powder. For further analytical data of **5a**, **5b**, and **9**, see Tables 5−7.

General Procedure for the Synthesis of 6 and 10: The substituted alcohol (**5** or **9**; 10.0 mmol, 1 equivalent) in THF (50 mL) was deprotonated at −30 °C with *n*BuLi (1.2 equiv. per OH group). The resulting solution was then allowed to warm to 25 °C, stirred for 30 min and subsequently recooled to −30 °C. Methanesulfonyl chloride (1.2 equiv. per OH group) was then added slowly, and the reaction mixture was stirred at 0 °C for 2 h. In a separate vessel diphenylphosphane (1.2 equiv. per OH group) in THF (50 mL) was deprotonated with *n*BuLi (1.2 equiv. per OH group). The resulting red lithium diphenylphosphide solution was added to the reaction mixture at −30 °C. After the mixture had been stirred for 15 h at 25 °C, all volatiles were removed in vacuo. The remaining residue was purified by chromatography on silica gel.

{2,2-Bis[(diphenylphosphanyl)methyl]propyl}diethylamine (6a): Starting material: **5a**. Yield: 3.34 g (6.5 mmol, 65%) of a viscous oil, R_f = 0.43 (petroleum ether/diethyl ether, 3:1). ^{31}P NMR ($CDCl_3$): δ = −27.1 ppm (s).

1-{2,2-Bis[(diphenylphosphanyl)methyl]-2-phenylethyl}-1*H*-pyrazole (6b): Starting material: **5b**. Yield: 3.91 g (6.9 mmol, 69%) of a microcrystalline powder, R_f = 0.65 (petroleum ether/diethyl ether/CH_2Cl_2, 2:1:1), m.p. 145 °C. ^{31}P NMR ($CDCl_3$): δ = −26.8 ppm (s).

1-[2-(Chloromethyl)-3-(diphenylphosphanyl)-2-phenylpropyl]-1*H*-pyrazole (10): Starting material: **9**. Yield: 2.32 g (5.5 mmol, 55%) of a microcrystalline powder, R_f = 0.43 (petroleum ether/diethyl ether, 3:1), m.p. 119 °C. ^{31}P NMR ($CDCl_3$): δ = −26.9 ppm (s). For further analytical data of **6a**, **6b**, and **10**, see Tables 5−7.

General Procedure for the Synthesis of 7: A solution of anhydrous PPh_3 (15.7 g, 60 mmol) in CCl_4 (80 mL) was heated under reflux for 90 min, during which the colour of the solution changed from colourless to light red. The substituted β-hydroxy ester **4** (30 mmol), dissolved in CCl_4 (30 mL), was added rapidly to the boiling reaction mixture from a dropping funnel. The solution discoloured immediately and a brown precipitate of $O{=}PPh_3$ was formed. The mixture was heated under reflux for another 12 h and afterwards cooled to 25 °C. The precipitate was filtered off and washed five times with diethyl ether. The combined organic solutions were concentrated by rotary evaporation.

Methyl 2-(Chloromethyl)-3-(diethylamino)-2-methylpropanoate (7a): Starting material: **4b**. Kugelrohr distillation of the residue under reduced pressure afforded **7a** (7.3 g, 32.9 mmol, 55%) as a viscous oil, b.p. 100 °C (0.2 mbar).

Methyl 3-Chloro-2-phenyl-2-[(1-pyrazolyl)methyl]propanoate (7b): Starting material: **4d**. The remaining residue was purified by chromatography on silica gel with petroleum ether/diethyl ether (2:1; R_f = 0.53) as eluent to afford **7b** (9.4 g, 33.7 mmol, 56%) as a colourless powder, m.p. 100 °C. For analytical data of **7a** and **7b**, see Tables 4, 6 and 7.

General Procedure for the Synthesis of 8 and 11: The substituted alkyl chloride (**7b** or **10**; 10 mmol, 1 equiv.) was dissolved in DMSO (25 mL). In a separate vessel, diarylphosphane (1.2 equiv.) in DMSO (40 mL) was deprotonated at 25 °C with KO*t*Bu (1.2 equiv.). The resulting red potassium diarylphosphide solution was stirred for 20 min and then added dropwise to the solution of the alkyl chloride. The reaction mixture was stirred for 15 h and hydrolysed by dropwise addition of water (50 mL). The aqueous phase was extracted with diethyl ether (4 × 40-mL portions). The combined organic phases were washed with brine and dried with $MgSO_4$, and the solvents were evaporated to dryness. The remaining residue was purified by chromatography on silica gel.

Methyl 3-(Diethylamino)-2-[(diphenylphosphanyl)methyl]-2-methylpropanoate (8): Starting material: **7b**. Yield: 2.32 g (6.3 mmol, 63%) of a viscous oil, R_f = 0.43 (petroleum ether/diethyl ether, 3:1). FT-IR (CH_2Cl_2): $\tilde{\nu}$ = 1726 cm^{-1} vs (CO), 1434 m (PPh). ^{31}P NMR ($CDCl_3$): δ = −24.3 ppm (s).

1-{2-[(Dimesitylphosphanyl)methyl]-3-(diphenylphosphanyl)-2-phenylpropyl}-1*H*-pyrazole (11): Starting material: **10**. Yield: 2.32 g (6.3 mmol, 63%) of a microcrystalline powder, R_f = 0.47 (petroleum ether/diethyl ether, 4:1), m.p. 120 °C. ^{31}P NMR ($CDCl_3$): δ = −34.1 ppm (d, $^4J_{P,P}$ = 10 Hz, $PMes_2$), −26.1 (d, $^4J_{P,P}$ = 10 Hz, PPh_2). For further analytical data of **8** and **11**, see Tables 5−7.

Coordination Chemistry Compounds

General Procedure for the Synthesis of 12: A solution of the respective tripod ligand (1.05 mmol) in ethanol (10 mL, with some THF added to increase the solubility if necessary) was added rapidly to a solution of $NiCl_2{\cdot}6H_2O$ (1.0 mmol, 240 mg) in ethanol (10 mL). The colour of the reaction mixture immediately changed to red and within a few minutes the nickel complexes precipitated. After the mixture had been stirred at 25 °C for 1 h, the precipitate was fil-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tered, washed with diethyl ether (3 × 10-mL portions), and dried in vacuo.

[(6a-κ²*P*)NiCl₂] (12a): Starting material: **6a**. Recrystallisation from CH_2Cl_2/diethyl ether afforded **12a** (525 mg, 0.82 mmol, 82%) in the form of red crystals suitable for X-ray structure analysis, m.p. 212 °C (decomposition). ^{31}P NMR (CD_2Cl_2, −40 °C): δ = 10.7 ppm (s).

[(6b-κ²*P*)NiCl₂] (12b): Starting material: **6b**. Recrystallisation from CH_2Cl_2/diethyl ether afforded **12b** (650 mg, 0.93 mmol, 93%) in the form of red crystals suitable for X-ray structure analysis, m.p. 248 °C (decomposition). ^{31}P NMR (CD_2Cl_2, −40 °C): δ = 15.6 ppm (s).

[(11-κ²*P*)NiCl₂] (12c): Starting material: **11**. Removal of the solvent afforded **12c** (585 mg, 0.75 mmol, 75%) in the form of an orange, microcrystalline solid. ^{1}H NMR and ^{13}C NMR: no sharp signals could be detected, due to a dynamic process. ^{31}P NMR (CD_2Cl_2, −40 °C): δ = −4.5 ppm (d, $^2J_{P,P}$ = 95 Hz, $PMes_2$), 4.0 (d, $^2J_{P,P}$ = 95 Hz, PPh_2).

For crystallographic data of **12a** and **12b**, see Table 3; for further analytical data of **12a**−**12c**, see Tables 5−7.

[(8-κ²*N*,*P*)PdCl₂] (13): A solution of ligand **8** (210 mg, 0.5 mmol) in ethanol (15 mL) was added rapidly to a suspension of (η⁴-cod)$PdCl_2$ (145 mg, 0.5 mmol) in ethanol (10 mL). Within a few minutes the yellow reaction mixture became clear. After the mixture had been stirred at 25 °C for 12 h, all volatiles were removed in vacuo. The residual yellow solid was washed with diethyl ether (3 × 10-mL portions) and dried in vacuo. Recrystallisation from CH_2Cl_2/diethyl ether afforded **13** (180 mg, 0.33 mmol, 66%) in the form of yellow crystals suitable for X-ray structure analysis. FT-IR (CH_2Cl_2): $\tilde{\nu}$ = 1732 cm^{-1} vs (CO), 1438 m (PPh). ^{31}P NMR (CD_2Cl_2): δ = 19.6 ppm (s). For crystallographic data, see Table 3; for further analytical data, see Tables 4, 6 and 7.

[(8-κ²*N*,*P*)(η⁴-nbd)Rh]PF₆ (14·PF₆): [(η⁴-nbd)RhCl]$_2$ (230 mg, 0.5 mmol) was dissolved in acetone (5 mL). In a second flask, potassium hexafluorophosphate (195 mg, 1.05 mmol) was dissolved in acetone (5 mL, 0.1 mL of water added). This solution was added to the orange rhodium(I) solution. A colourless KCl precipitate formed over 5 min, while the colour of the reaction mixture faded. A solution of ligand **8** (370 mg, 1.0 mmol) in CH_2Cl_2 (5 mL) was then added. After the mixture had been stirred at 25 °C for 1 h, all volatiles were removed in vacuo. The residue was taken up in acetone (20 mL) and dried with $MgSO_4$. The insoluble KCl was removed by filtering the solution through Kieselguhr. Removal of the solvent in vacuo and recrystallisation from CH_2Cl_2/diethyl ether afforded **14·PF₆** (640 mg, 0.9 mmol, 90%) in the form of orange crystals suitable for X-ray structure analysis, m.p. 203 °C (decomposition). FT-IR (CH_2Cl_2): $\tilde{\nu}$ = 1725 cm^{-1} vs (CO), 1437 m (PPh). ^{31}P NMR (CD_2Cl_2): δ = −144.2 ppm (sept, $^1J_{P,F}$ = 711 Hz, PF_6^-), 29.8 (d, $^1J_{Rh,P}$ = 174 Hz, PPh_2). For crystallographic data, see Table 3; for further analytical data, see Tables 4, 6 and 7.

Acknowledgments

We are indebted to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support. One of us (R. F.) is indebted to the local Graduiertenkolleg "Selektivität in der organischen und metallorganischen Synthese und Katalyse" for a scholarship. The technical support by T. Jannack (mass spectrometry) and the Microanalytical Laboratory of the Institute of Organic Chemistry is gratefully acknowledged. We are indebted to Dr. J. Scherer and Dr. K. Heinze for their advice and help in solving the crystal structure of **14·PF₆**.

Cu^{II} Ion Coordination to an Unprotected Pentadecapeptide Containing Two His Residues: Competition Between the Terminal Amino and the Side-Chain Imidazole Nitrogen Donors

Chiara Conato,[a] Wojciech Kamysz,[b] Henryk Kozłowski,*[c] Marek Łuczkowski,[c] Zbigniew Mackiewicz,[b] Francesca Mancini,[d] Piotr Młynarz,[d][‡] Maurizio Remelli,*[a] Daniela Valensin,[d] and Gianni Valensin[d]

Keywords: Copper / Peptides / Coordination chemistry / Bioinorganic chemistry

The complex-formation equilibria of the pentadecapeptide TLEGTKKGHKLHLDY, the 114–128 protein fragment of SPARC, with the Cu^{II} ion have been investigated, at I = 0.1 mol·dm^{-3} (KNO_3) and T = 298.2 K. Protonation and complex-formation constants have been determined potentiometrically, and formation enthalpies measured by direct solution calorimetry; the complex-formation model and species stoichiometry have been carefully checked by means of UV/Vis absorption, CD and EPR spectroscopy. The structure hypotheses of the complex species are also based on detailed study of the ^{1}H and ^{13}C NMR spectra of the ligand in both the absence and presence of copper ions. The involvement in complex-formation of both the terminal amino and imidazole groups has been suggested and their specific behaviour at different pH values elucidated.

Introduction

SPARC (Secreted Protein, Acidic and Rich in Cysteine) is a 32 kD calcium-binding matricellular protein[1] secreted by many types of cells. It mediates the cell−matrix interactions without covering any primarily structural role:[2,3] it has counter-adhesive properties, thus altering the cell shape, it modulates growth factor activity and influences the cell-cycle. SPARC is the product of a single-copy gene; its sequence has been highly conserved both during vertebrate evolution and among species.[4] It is highly expressed during embryonic development while its expression in the adult is associated with tissue remodelling or renewal, also in response to injury. SPARC is a major product of many tumours,[5] most likely owing to its activity, and that of its fragments, in angiogenesis,[6] both in their free form and as copper complexes.[7]

Human SPARC consists of 286 amino acids, belonging to three distinct modules.[8] The *N*-terminal module (residues 1−52, after a 17 amino-acid signal sequence) is an acidic region, which binds 5−8 calcium ions with low affinity. It interacts with hydroxyapatite, being involved in the mineralization of cartilage and bones. The second module is a Cys-rich, follistatin-like domain (residues 53−137), in which all the 10 Cys residues are disulfide-bonded. A carbohydrate moiety is *N*-linked at Asn99. This module contains two bioactive peptides (residues 55−74 and 114−130), which enable SPARC to bind the copper ion.[7] The latter fragment, corresponding to the strongest Cu^{II}-binding site of the protein, contains the sequence Gly-His-Lys (GHK) (residues 121−123). GHK, a liver-cell growth factor,[9] is a well recognised Cu^{II} binding peptide;[10] it is present in the human serum and it most likely derives from SPARC hydrolysis.[7] Cu^{II}/GHK complexes proved to have angiogenic activity and to play an important role in wound healing.[9] Module III (residues 138−286) is largely α-helical and contains the extracellular high-affinity calcium binding sites. It is globular and contains two EF-hand motifs.

Recent investigations[11,12] into the complex-formation equilibria of protected $SPARC_{114-128}$ (Ac-TLEGTKKGHKLHLDY-NH_2), $SPARC_{122-126}$ (Ac-HKLHL-NH_2), $SPARC_{121-126}$ (Ac-GHKLHL-NH_2) and

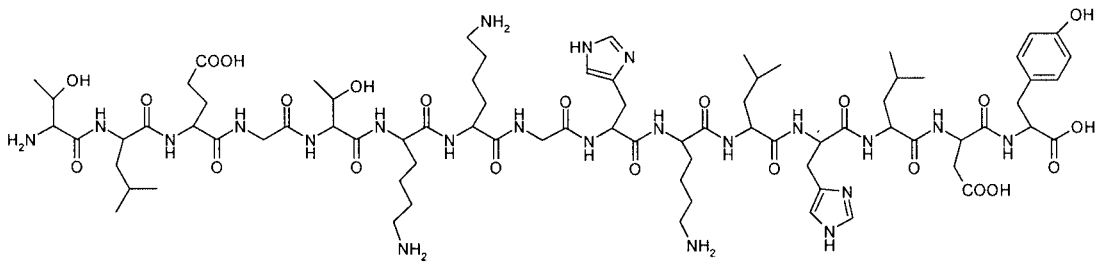

Figure 1. Structure of the ligand TLEGTKKGHKLHLDY.

$SPARC_{120-126}$ (Ac-KGHKLHL-NH_2) fragments with the Cu^{II} ion have shown the central role played by ^{122}His and ^{125}His at acidic pH. The copper-promoted deprotonation of three amido nitrogens has also been reported, at alkaline pH. Here the Cu^{II} complex-formation equilibria of the unprotected TLEGTKKGHKLHLDY pentadecapeptide (see Figure 1) have been investigated, at I = 0.1 mol·dm^{-3} (KNO_3) and T = 298.2 K, to gain new information on the role played in metal ion complexation by His residues belonging to relatively short peptides. In such cases the imidazole nitrogens can compete or cooperate with the terminal amino group for binding copper. In this context, an interesting recent report concerns the Prion Peptide fragment 106−126 ($PrP_{106-126}$),[13] which is neurotoxic in vitro and its activity is highly sensitive to the presence of copper, zinc or iron ions. In that system, the formation of a macrochelate structure at physiological pH has been suggested in which Cu^{II} is bound to both the terminal amino nitrogen and the imidazole ring of the ^{111}His residue. TLEGTKKGHKLHLDY is also a good model for the $PrP_{106-126}$ fragment. Protonation and complex-formation constants have been determined potentiometrically; formation enthalpies have been measured by direct solution calorimetry; complex-formation model and species stoichiometry have been carefully checked by means of UV/Vis absorption, CD and EPR spectroscopy. The proposed structures of the complex species are also based on a detailed study of the ^{1}H and ^{13}C NMR spectra of the ligand both in the absence and in the presence of copper ions.

Results

Ligand protonation constants are shown in Table 1 along with the corresponding thermodynamic quantities determined by calorimetry. It was not possible to distinguish between the two His or the three Lys residues. The terminal carboxylic group is deprotonated over the explored pH range and the corresponding equilibrium is not considered throughout. The thermodynamic results are in good agreement with literature data on analogous ligands,[11,12,14,15] within experimental errors.

Table 1 also shows the whole set of thermodynamic parameters for complex-formation equilibria between the Cu^{II} ion and the pentadecapeptide. Ten mono complexes were detected in the explored pH range; all with different protonation degrees. The corresponding distribution diagram is reported in Figure 2. The ligand starts to bind the Cu^{II} ion at pH 3.5, forming the species MLH_6 and MLH_5. At pH > 4, MLH_4 is formed: it dominates the acidic pH range and is the main species at physiological pH. In the alkaline pH range (7.0−10.5) up to seven protons are subsequently lost by the MLH_4 complex due to deprotonation of some amido nitrogens and of basic side chains of Lys and Tyr residues.

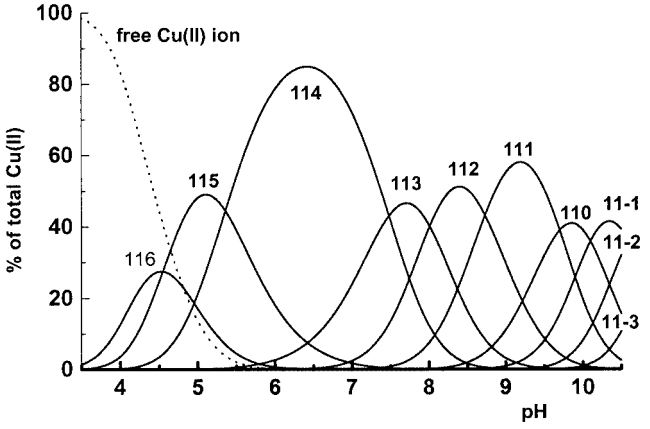

Figure 2. Distribution diagram of Cu^{II}/TLEGTKKGHKLHLDY complexes, at 298.2 K; I = 0.1 mol·dm^{-3} (KNO_3); [Cu^{II}] = 1.0 × 10^{-3} mol·dm^{-3}; [TLEGTKKGHKLHLDY] = 1.2 × 10^{-3} mol·dm^{-3}

Electronic spectra (Figure 3 and Table 2) confirm the presence of a complex species at a pH as low as 4: in fact at pH 4 the wavelength of maximum absorption is already lower than 800 nm. With increasing pH the d−d absorption band shifts towards lower wavelength values. This behaviour is typical of the coordination of successive nitrogen

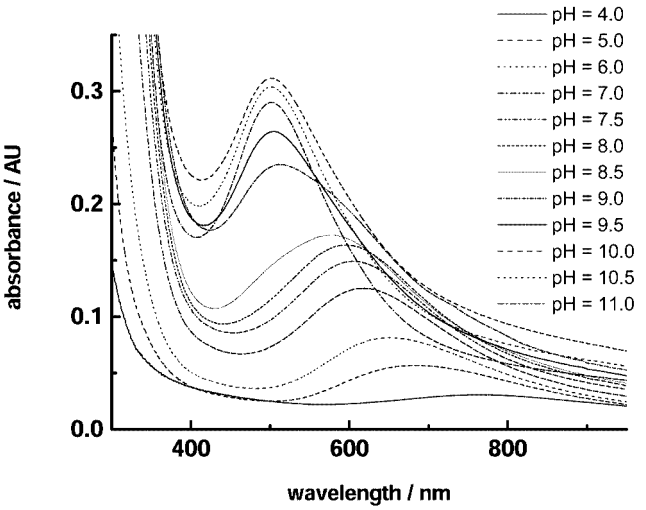

Figure 3. Absorption spectra of Cu^{II}/TLEGTKKGHKLHLDY solutions. [Cu^{II}] = 1.0 × 10^{-3} mol·dm^{-3}, [TLEGTKKGHKLHLDY] = 1.2 × 10^{-3} mol·dm^{-3}, T = 298.2 K, I = 0.1 mol·dm^{-3} (KNO_3).

atoms to the metal ion. A noticeable change in the absorption spectrum is seen between pH 8.0 and 9.5, with the onset of a new absorption band with a maximum close to 500 nm.

The CD spectra show some typical absorption bands (Figure 4 and Table 2). A double band is present in the d−d region, from pH 5 on, which is typical of Cu^{II}/His coordination.[16] The two bands at 250−256 and 350 nm can be ascribed to a charge-transfer transition from imidazole π_2 and π_1 to copper.[17] The positive band at 316−320 nm is most likely due a charge-transfer transition from a deprotonated amido nitrogen to copper:[17] this band is clearly detected from pH 6.0 on.

$A_{\parallel}$ and $g_{\parallel}$ parameters of the EPR spectra are reported in Table 2. At pH 6 they are typical of a 2N complex; at pH 8 those of a 3N complex. From pH 10, the EPR data be-

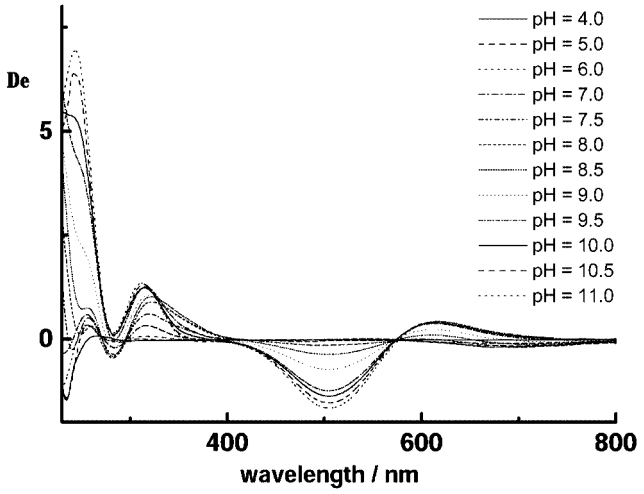

Figure 4. Circular dichroism spectra of Cu^{II}/TLEGTKKGHKLHLDY solutions. $[Cu^{II}] = 1.0 \times 10^{-3}$ mol·dm^{-3}, [TLEGTKKGHKLHLDY] = 1.2×10^{-3} mol·dm^{-3}, $T = 298.2$ K, $I = 0.1$ mol·dm^{-3} (KNO_3).

come typical of a 4N complex characterised by a strong ligand field. No evidence of binuclear species has been found over the whole pH range.

The ^{1}H NMR spectrum of TLEGTKKGHKLHLDY was recorded at both pH ≈ 6 and pH ≈ 10. At pH > 7, most amide protons were removed from the spectrum by chemical exchange. Thus, NMR studies at pH 10.4 were carried out in deuterium oxide (99.95%).

The complete assignment of the peptide at lower pH is reported in the Supplementary Material. None of the NMR spectroscopic data (temperature coefficients of the chemical shifts of amide protons, intramolecular NOEs and HN-H_α coupling constants) was consistent with the presence of secondary structure elements. Only the amide proton of ^{15}Tyr (see Supplementary Material), exhibits a different temperature coefficient compared to the other amide protons ($\Delta\delta/\Delta T = -4.3$ ppb/K), which is very close to values typical of a proton engaged in direct intramolecular or water-mediated hydrogen-bonding (head−tail interaction).

The complete assignment of the ^{13}C NMR spectrum of the peptide, recorded at alkaline pH, is given in the Supporting information (see footnote on the first page of this article).

Upon addition of copper, chemical shifts, line widths and spin−lattice relaxation rates were selectively affected. However, such effects could be observed only at relatively high Cu^{II}/peptide ratios (especially at pH > 7.0), much higher than is usual in NMR experiments on Cu^{II} complexes. As shown in Figure 5, the paramagnetic effects at pH 5.6 were mainly detected on ^{9}His and ^{12}His aromatic protons, on the His H_β and on the ^{14}Asp H_β.

To observe signal broadening at pH 10.4 a large amount of copper was added to the system (Figure 6). The signals that underwent the largest broadening were those of His and ^{1}Thr residues, but, to a lesser extent, the ^{14}Asp, ^{6,7,10}Lys, and ^{15}Tyr residues were also affected. Similarly, the most affected relaxation rates were those of the His resi-

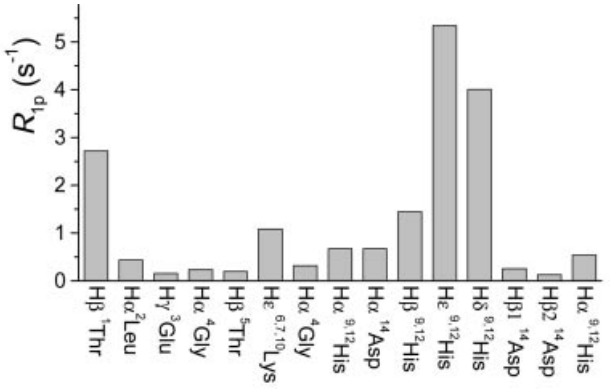

Figure 7. R_{1p} for selected protons of TLEGTKKGHKLHLDY (4.0×10^{-3} mol·dm^{-3}) in deuterium oxide at pH 10.5 after the addition of Cu^{II} (8.0×10^{-4} mol·dm^{-3}).

dues and the H_α, H_β of ^{1}Thr, with slight changes for protons of the ^{14}Asp, ^{6,7,10}Lys and ^{15}Tyr residues (Figure 7). The ^{1}H (Figure 6) and ^{13}C NMR spectra (see Supplementary Material) support the fact that copper perturbs two molecular regions: the *N*-terminal part of the peptide and the His regions. Overlapping ^{1}H NMR signals prevented differentiation of the ^{9}His and ^{12}His residues.

Discussion

TLEGTKKGHKLHLDY contains two different binding sites for copper ions: the terminal amino group and the two side-chain imidazole of its ^{9}His and ^{12}His residues. When the former is protected the two His residues behave as "anchoring" sites for copper at pH < 4.[11,12] Conversely, unprotected peptides can bind copper at approximately the same pH with their terminal amino and neighbouring carbonyl groups.[18] In both cases the metal can promote amido nitrogen ionisation, at pH < 7. The present ligand has both of the above capabilities: the two sites compete to bind copper, and binuclear species could also be formed. How-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ever, in the present study, where nearly equimolar concentrations of copper and TLEGTKKGHKLHLDY have been used, neither potentiometric nor spectroscopic evidence was found for binuclear species formation. To favour such complexes an excess of copper could have been used, but this was beyond the aim of the present work. However, reports of polynuclear copper/peptide complex formation are common, even in the presence of an excess of ligand.[10]

First of all it is interesting to compare the overall binding ability of the present peptide with that of its protected analogue.[11] The competition diagram reported in Figure 8 shows that the copper complexes with the unprotected peptide are favoured over the whole pH range. This suggests that the terminal amino group plays an important role in determining the behaviour of TLEGTKKGHKLHLDY as a copper ligand. In addition, the wavelength of maximum absorption in the electronic spectra is always slightly lower for the unprotected peptide (Table 2) compared with the protected one,[11] indicating a higher mean coordination number for the former ligand.

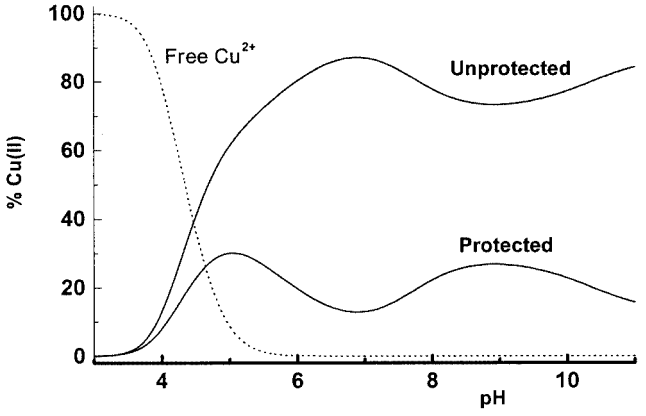

Figure 8. Competition diagram for Cu^{II} complex formation with TLEGTKKGHKLHLDY and Ac-TLEGTKKGHKLHLDY-NH_2. The concentrations were calculated by using the stability constants of Table 1 and ref.[11] at 298.2 K, I = 0.1 mol·dm^{-3} (KNO_3) and identical concentration of the three reagents: 1.0×10^{-3} mol·dm^{-3}.

The species detected at the most acidic pH is the MLH_6 complex (see Figure 2). EPR and UV/Vis data suggest that this is a 1N species where the metal ion is either bound to the terminal NH_2 or to one of the imidazole nitrogens; the three acidic groups (Asp and Glu side chains and terminal carboxylic) are deprotonated. Experimental data favour the second hypothesis. In fact, the computed step constant $\log\beta_{116} - \log\beta_{016} = 4.6$ (see Table 1), corresponding to the coordination of a protonated ligand to the Cu^{II} ion, is very close to that reported for the Cu^{II}/imidazole system (4.2) under the same experimental conditions.[15] Moreover, $\log\beta_{116}$, once the contribution due to terminal-NH_2 protonation has been subtracted (59.8−7.3 = 52.5, Table 1), is very close to the corresponding $\log\beta_{115}$ reported[11] for the protected ligand (52.0). Conversely, a 1N species where the Cu^{II} ion is chelated by the terminal-NH_2 and the neighbouring carbonyl groups could also be hypothesized. However, upon subtracting the constants for protonated sites from $\log\beta_{116}$ a value of 6.0 is obtained (see Table 1), which is significantly higher than the corresponding $\log\beta_{110}$ for the Cu^{II}/penta-alanylamide complex (4.9).[19] Finally, the wavelength of maximum absorption at pH 4 (765 nm, Table 2) is closer to that expected[20] for a $Cu-N_{Im}$ species (758 nm) than the mean value found[20] for a $Cu-N_{amino}$ complex (743 nm).

MLH_5 complex formation starts immediately after that of the MLH_6 species discussed above, at pHs still lower than 4. This complex reaches its highest concentration around pH 5, when it is the most abundant species in solution. The wavelength of maximum absorption in the UV/Vis spectra is blue-shifted with respect to pH 4, and the change in EPR parameters also point to a complex with additional nitrogen atoms bound to copper; the enthalpy of formation, minus the protonation contribution ($\Delta H^\circ_{115} - \Delta H^\circ_{015} = -34$ kJ·mol^{-1}, Table 1), is compatible with a 2N complex. Other structural hypotheses can be put forward for this species, the most likely of which is that TLEGTKKGHKLHLDY binds the metal ion with both imidazole nitrogens, as do its protected analogue[11] and its shorter fragments[12]. The corresponding log$K$ (4.6, Table 1) is close to that already reported for the above systems and is compatible with deprotonation of the second imidazole nitrogen, promoted by the copper ion. CD spectra at pH 5 clearly show a positive band at 256 nm attributable to a π_2 charge-transfer transition from imidazole to copper.[17] The d−d band in the electronic spectra has its maximum at 685 nm (at pH 5), exactly the value expected for a $Cu-(N_{Im})_2$ complex.[20] Subtracting log$K$ for the terminal amino group (7.3, Table 1) from $\log\beta_{115}$ gives 47.9, a value only slightly higher than that reported for the corresponding complex with the protected analogue (47.1).[11] This hypothesis is also in excellent agreement with the NMR spectroscopic data discussed below.

From pH 4.5 on a new species forms in solution: the MLH_4 complex, which reaches its maximum at pH 6.5, when it is almost the only species in solution. It is also the most abundant complex at neutral pH. Even though the EPR data remain those of a 2N complex a relevant blue-shift is registered in the electronic spectra when the pH changes from 5 to 7, suggesting the coordination of a further nitrogen atom, or at least the substitution of one nitrogen donor with another giving a higher ligand field. CD spectra show the onset of two new bands at 283 and 317 nm, which can be ascribed to a π_1 charge-transfer transition from imidazole to copper and to a charge-transfer transition from a deprotonated amido nitrogen to copper, respectively.[17] The log$K$ (5.4, Table 1) is compatible with the deprotonation of both an amido and an amino nitrogen[18] promoted by the copper ion. It is difficult, at this point, to suggest a unique complex structure with the stoichiometry 114 that accounts for all of the above experimental results. EPR data suggest the simultaneous presence of different species with comparable concentrations. One pos-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sible structure is that already proposed for the corresponding complex formed by Ac-TLEGTKKGHKLHLDY-NH_2:[11] one imidazole and one neighbouring amido nitrogens bound to the equatorial plane of the copper complex. The second N_{Im} should be free, for steric reasons. This would explain the wavelength of maximum absorption in the electronic spectra (652 nm at pH 6, Table 2), which is close to the computed[20] value for this type of coordination (658 nm). This hypothesis also agrees with the EPR results. The complex stoichiometry requires that the terminal amino group is protonated. The $\Delta H°_{114}$ value, once the terminal amino group protonation is subtracted ($-247 + 36 = -211$ kJ·mol^{-1}, Table 1), becomes nearly identical to that found for the protected peptide (-212 kJ·mol^{-1}, ref.[11]). However, the MLH_4 complex formed by the unprotected ligand is much more stable than that reported for the protected peptide.[11] This can deduced by examining the competition diagram of Figure 8 and comparing $\log\beta_{114} - \log K_{amino}$ (42.5, Table 1) with the stability of the corresponding complex with the protected ligand (40.1, ref.[11]). The can be explained by the simultaneous formation, in the present system, of an additional complex species with the same stoichiometry but a different structure, i.e. involving the terminal amino group. The ligand should then form a macrochelate ring with at least one N_{Im} and the terminal amino group simultaneously bound to copper. Such a structure is similar to that previously reported for the $PrP_{106-126}$ peptide.[13]

The first complex to be formed in the alkaline pH range is MLH_3, which becomes the main complex at approximately pH 7.6. Four protons have already been released by the ligand at this stage, in addition to those of the acidic side chains: two from the imidazole side chains, one amido and the terminal amino. EPR data again suggest the presence in solution of two species. The corresponding log*K* (7.5, Table 1) is very close to that found for the protonation of the terminal amino group (7.3, Table 1), but it is also compatible with an amido nitrogen deprotonation, promoted by copper. No new important signal appears in CD spectra when the pH is raised from 6.0 to 7.5; the N_{amido}–copper binding is confirmed by the band at 319 nm. The wavelength of maximum absorption at pH 7.5 (604 nm) is not far from the computed[20] average value for 3N complexes with various combinations of nitrogen atoms bound to copper (581–615 nm). The $-\Delta H°_{113}$ value also suggests a 3N coordination. Again, the simultaneous formation of two complex species with the same MLH_3 stoichiometry best explains the experimental results. One of the complexes should have the metal ion located at the His site of the ligand, as with the protected analogue,[11] with the terminal amino group not protonated and free. The second should be a macrochelate where the terminal amino, one imidazole and one amido nitrogen simultaneously bind the copper ion.

At more basic pHs the complex loses other protons, giving rise to species from MLH_2 to MLH_{-3}. The first two steps (species MLH_2 and MLH) are most likely due to the subsequent deprotonation of two further amido groups which bind the metal ion. The corresponding thermodynamic parameters support this hypothesis. The spectroscopic parameters are typical of a 4N species. The four last protons probably derive from the basic side chains of the ^{15}Tyr, ^{6}Lys, ^{7}Lys and ^{10}Lys residues. The corresponding log*K*s are practically identical to those of the free ligand (Table 1), while the spectroscopic data do not change from pH 10 on. These results suggest that no binding interaction is present in solution between the latter residues and the metal ion, as already found for the protected peptide.[11] It is worth noting that on raising the pH from 9 to 10 big changes are observed in all the registered spectra. In particular, in the CD spectrum the charge-transfer $N_{Im} \rightarrow Cu^{II}$ bands are no longer observed while a new intense band appears at 242–245 nm, which can be ascribed to a charge-transfer transition from the terminal amino group to copper. This result strongly suggests that complex structure in the most alkaline pH range is that typical[20] of any unprotected peptide: "four nitrogens, one amino and three deprotonated peptide nitrogens, occupy the four tetragonal positions about Cu^{2+}". Only weak interactions with other donor atoms should be present in the apical position. In such a structure the two imidazole rings should be free. Once again, the presence of another 4N species, where one N_{Im} and three amido nitrogens are bound to copper, cannot be excluded (see also below). However, this species, the main complex at alkaline pH in the case of the protected peptide,[11] should be present here only in lower amounts.

The effect of paramagnetic Cu^{II} on spin–lattice relaxation rates is measured by the value of the observed relaxation rates R_{1m} in presence of the metal ion. They are defined as:[21]

$$R_{1m} = \frac{p_f}{R_{1f}^{-1}} + \frac{p_b}{R_{1M}^{-1} + \tau_m} \quad (1)$$

where R_{1f} is the rate calculated in the absence of the metal, τ_m is the exchange lifetime from the bound to the free state and p_f and p_b are the molar fraction of the free and bound ligand, the relaxation of which is described by R_{1M}. Since the ligand occurs in the bulk and in the metal coordination sphere, exchange has to be considered. If the metal-bound ligand is much less concentrated than its free form a $p_f \approx$ of **1** can be assumed. Equation (1) can then be reduced:

$$R_{1m} - R_{1f} = R_{1p} = \frac{p_b}{R_{1M}^{-1} + \tau_m} \quad (2)$$

R_{1M} is usually accounted for by the Solomon equation[22] and is proportional to the inverse sixth power of the metal–nucleus distance. The obtained R_{1p} values are consistent with τ_m not dominating Equation (2), but the relatively high Cu^{II}/peptide ratios that can be reached without severe alteration of NMR parameters demonstrate that τ_m contributes to R_{1p} and, therefore, that an intermediate exchange region occurs ($\tau_m \approx R^{-1}{}_{1M}$). Although the NMR spectroscopic data refer to a slight excess of ligand, and they

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cannot be directly transferred to the equimolar solutions discussed above, the distinct effect of Cu^{II} ions on the protons of both His residues (see Figure 5) strongly supports the involvement of two imidazoles in the metal coordination at acidic pHs. The obtained complex is similar to that formed by the protected peptide,[11] except for the involvement of the negatively charged carboxylate of adjacent ^{14}Asp in the coordination sphere. In addition, molecular mechanics calculations[23] performed on the Cu^{II}/TLEGTKKGHKLHLDY complex with the suggested $\{2N_{Im}, O^-\}$ donor set gave the low energy structures shown in Figure 9.

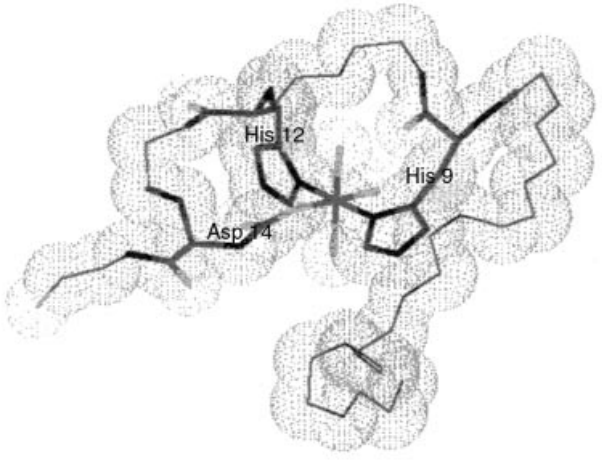

Figure 9. HYPERCHEM structure hypothesis for the Cu^{II}/TLEGTKKGHKLHLDY complex at pH 5.6.

At pH 10.4, ratios as high as 1:25 or 1:5 can be reached, which are consistent with slower off-rates arising from a more complicated exchange process. The observed spin−lattice relaxation rate enhancements (Figure 7) and line broadenings observed on the ^{1}H (Figure 6) and ^{13}C NMR spectra (see Supplementary Material) suggest the presence of two different complexes. In the first complex, copper is bound to ^{9}His and coordination takes place in the *N*-terminal direction, thus involving the ^{8}Gly and ^{7}Lys residues in the same way as with the protected peptide.[11] In the second complex the *N*-terminal group acts as an anchoring point and copper is bound to the amino nitrogen of ^{1}Thr and to the three amide nitrogens of the following residues (^{2}Leu, ^{3}Glu, ^{4}Gly). Moreover the effects measured on R_{1p} of ^{12}His, ^{14}Asp and ^{15}Tyr may result from the accumulation of the negative charges on the C-terminal side of the peptide (Tyr-O^-, Asp-COO^-) and their proximity to paramagnetic centre.

Experimental Section

TLEGTKKGHKLHLDY was synthesised manually on a 0.1 millimol scale by the solid-phase method, using the Fmoc/But amino acids,[24,25] according to the following procedure: (i) 5 and 15 min deprotection steps using 20% piperidine in DMF in the presence of 1% Triton; (ii) coupling reactions carried out with the protected amino acid diluted in DMF/NMP (NMP = *N*-methylpyrrolidone) (1:1, v/v) in the presence of 1% Triton, using DIC (1,3-diisopropylcarbodiimide) as the coupling reagent in the presence of HOBt (Fmoc-AA/DIC/HOBt, 1:1:1) for 1.5 h. The completeness of each coupling reaction was monitored by the chloranil and the ninhydrin tests.[26] The protected peptidyl resin was treated with a mixture of 95% trifluoroacetic acid (TFA), 2.5% water and 2.5% TIS (triisopropylsilane) for 1 h. The cleaved peptide was precipitated with diethyl ether and lyophilised. It was then purified by the solid-phase extraction (SPE) as described previously.[27] The product was homogeneous according to TLC and was judged to be more than 98% pure by HPLC (see Supplementary Material, Figure 3). The molecular weight was checked by FAB MS, using an AMD-604 spectrometer. The ion source was equipped with a Cs^+ gun. The energy of the Cs^+ ions was 12 keV.

Aliquots (2.5 cm^3) of sample solution, containing suitable amounts of the metal ion, the ligand, HNO_3 (when the initial pH value needed to be lowered) and KNO_3 (to adjust the ionic strength to 0.1 $mol{\cdot}dm^{-3}$) were titrated potentiometrically with standard NaOH in a thermostatted potentiometric vessel (pH range: 3.5−11.0; T = 298.2 K). The metal ion concentration was close to $1{\cdot}10^{-3}$ $mol{\cdot}dm^{-3}$ and the metal-to-ligand ratio was 1:1.2. Two pairs of potentiometric titrations, for both protonation and complex-formation, were performed. Further experimental details, equipment and software used are reported elsewhere.[14] Thermodynamic data are given with an estimated accuracy reported as the uncertainty on the last significant figure.

CD, EPR and UV/Vis spectra were recorded on a JASCO J 715, on a Bruker ESP 300E (at, 120 K and 9.4 GHz) and on a Beckman DU 650 spectrometer, respectively. Sample solutions had the same composition as above; the pH was varied by addition of suitable amounts of standard NaOH or HCl, under potentiometric control. Spectra were recorded every 0.5 pH units.

Calorimetric titrations were performed with an Isoperibolic Calorimeter (Tronac) at 298.2 K, by addition of standard HNO_3 to a sample solution (2.5 cm^3) of the same composition as above. For each system two pairs of calorimetric titrations containing not less than 250 experimental points were used to calculate the thermodynamic quantities.

NMR spectra were performed at 14.1 T with a Bruker Avance 600 MHz Spectrometer at controlled temperatures (±0.1 K). Two different peptide solutions were prepared: the first with deionized water containing D_2O (10%), the second with deuterium oxide (99.95% from Merck), and both were carefully deoxygenated through a freezing/vacuum pumping/sealing/thawing procedure. The pH was adjusted to the desired values with either DCl or NaOD, and the required concentration of copper ions was achieved by using a stock solution of copper nitrate (Sigma Chemical Co.) in deuterium oxide. TSP-d_4, 3-(trimethylsilyl)-[2,2,3,3-d_4] propansulfonate, sodium salt, was used as an internal reference standard. The assignment of the spectra was accomplished with TOCSY, COSY, and NOESY 2D experiments. TOCSY spectra were recorded with a total spin-locking time of 75 ms using a MLEV-17 mixing sequence; NOESY spectra were obtained with standard pulse sequences at mixing times ranging between 50 and 400 ms. During all 2D experiments, water suppression was achieved by the Watergate method.[28] The spectral width of homonuclear 2D experiments was typically 6000 Hz in both F_1 and F_2 dimensions. Spin−lattice relaxation rates were measured with inversion recovery pulse sequences. The same sequence was also used to measure the single- or double-selective relaxation rates by means of suitably

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

shaped π-pulses instead of the usual non-selective π-pulse. All rates were calculated by regression analysis of the initial recovery curves of longitudinal magnetization components, leading to errors not larger than ±3%. 2D $^{1}H-^{13}C$ shift correlation methods were used to detect and assign ^{13}C NMR spectra at relatively low concentrations. HMBC (multiple-bond heteronuclear multiple-quantum coherence) spectra were obtained with standard pulse sequences, over a spectral width of 6000 Hz in the F_2 dimension and 31700 Hz in the F_1 dimension a total of 1024 points were used in F_2 and 256 in F_1, which was zero filled once before processing; 8 transients were accumulated with a relaxation delay of 2.0 s for each of the 256 increments. A 5-mm broad-band probe was used to perform the ^{13}C NMR spectra, which were acquired with a FID composed of 32768 data points over a spectral width of 28700 Hz (acquisition time 0.570 s), a 90° pulse of 8.5 μs, relaxation delay of 5.0 s; the WALTZ16 broad-band decoupling method was used.[29,30]

Molecular structures were generated by the HYPERCHEM software package[23] implemented on a Pentium 120 MHz PC by using the ZINDO-1 semi-empirical method for charge calculations and the MM+ force field for molecular mechanics and dynamics calculations.

Heterotrinuclear Complexes of the Platinum Group Metals with 2,2′-Biimidazole as a Bridging Ligand

Andrey Mayboroda,[a] Peter Comba,*[a] Hans Pritzkow,[a] Gerd Rheinwald,[b] Heinrich Lang,[b] and Gerard van Koten[c]

Keywords: Osmium / Platinum / Palladium / Heterometallic complexes / Cyclic voltammetry / Hydrogenation

The novel trinuclear complexes $[(Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\})_2(\mu\text{-}Hbiim)_2Os(O{=}PPh_3)_2](NO_3)(SO_3CF_3)_2$ [$C_6H_3(CH_2NMe_2\text{-}2,6)_2$ = pincer ligand, H_2biim = 2,2′-biimidazole] and $[(PdL)_2(\mu\text{-}biim)_2Os(O{=}PPh_3)_2](NO_3)_3$ (L = cod, 1,5-cyclooctadiene or L = en, ethylene-1,2-diamine) were prepared by the reaction of the mononuclear complex $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ with $[Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\}](SO_3CF_3)$, or with $PdL(NO_3)_2$ (L = cod or L = en), in the presence of a base. The exchange reaction between $[Os(Hbiim)_2(O{=}PPh_3)_2](NO_3)_3$ and $[Me_2NH_2][RhCl_4(NHMe_2)]$ led to the formation of $[Os(Hbiim)_2(O{=}PPh_3)_2][RhCl_4(NHMe_2)]$. The solid-state structures of $[Os(Hbiim)_2(O{=}PPh_3)_2][RhCl_4(NHMe_2)]$ and $[(Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\})_2(\mu\text{-}Hbiim)_2Os(O{=}PPh_3)_2](NO_3)(SO_3CF_3)_2{\cdot}4H_2O$ were determined by single-crystal X-ray diffraction. The crystals of $[Os(Hbiim)_2(O{=}PPh_3)_2][RhCl_4(NHMe_2)]$ are triclinic with a space group $P\bar{1}$, with a = 10.4293(5), b = 10.6365(6), c = 13.0287(7) Å, β = 91.6840(10), γ = 109.8540(10)°, V = 1316.14(12) Å^3, Z = 1. The crystals of the complex $[(Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\})_2(\mu\text{-}Hbiim)_2Os(O{=}PPh_3)_2](NO_3)(SO_3CF_3)_2{\cdot}4H_2O$ are triclinic with a space group $P\bar{1}$, with a = 12.604(3), b = 13.471(3), c = 14.347(3) Å, β = 77.530(5), γ = 66.613(4)°, V = 2005.6(7) Å^3, Z = 1. Deprotonation of 2,2′-biimidazole in the mononuclear osmium complex, followed by coordination to an additional transition metal fragment leads to a modification of the ligand field and a variation of the redox properties of the Os^{III} center. $[\{Pd(cod)\}_2(\mu\text{-}biim)_2Os(O{=}PPh_3)_2](NO_3)_3$ shows significant catalytic activity towards hydrogenation of terminal and cyclic alkenes.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Oligonuclear complexes in which the transition-metal centers are bridged by π-conjugated ligands have attracted much attention as model compounds for the study of cooperative effects in, for example, homogeneous catalysis.[1] Mechanisms have been postulated which involve more than one catalytically active metal center within the oligometallic array.[2] Generally, however, only one of the metal centers plays a dominant role in the catalytic cycle, while the other(s) influence the molecular architecture and support the catalytically active center as a donor or acceptor of electron density. An enhancement of the reactivity results from changes in the ligand field or from intramolecular electronic communication between the transition-metal centers.[1b]

Much attention has been focused on the metal-binding ability of the ligand 2,2′-biimidazole (H_2biim) and its derivatives.[3−9] Anionic moieties, e.g. $Hbiim^-$ and $biim^{2-}$, have successfully been used as bridging ligands for the synthesis of homo- and heterometallic oligonuclear complexes. Dinuclear 2,2′-biimidazolate complexes of Rh^I,[3] Ir^I,[3] Cu^{II},[4] Pd^{II},[5,6] Ru^{II},[7] Ru^{II}-Os^{II},[8] and $Ru^{II}-Rh^I$ [9] have been prepared and characterized. An example of a trinuclear heterometallic species of the structural type **A** is $[\{Au(PPh_3)\}_2(\mu\text{-}bbzim)Rh(cod)](ClO_4)$ (bbzim = 2,2′-bibenzimidazole).[9] However, so far there are no examples of trinuclear complexes of types **B** and **C** (Figure 1).

Here, we report on the synthesis and characterization of the $Pt^{II}-Os^{III}-Pt^{II}$ and $Pd^{II}-Os^{III}-Pd^{II}$ complexes, with 2,2′-biimidazolate ($Hbiim^-$, $biim^{2-}$) as the bridging ligands (structural types **B** and **C**). The solid-state structures of $[Os(Hbiim)_2(O{=}PPh_3)_2][RhCl_4\{NH(CH_3)_2\}_2]$ (**2b**) and $[(Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\})_2(\mu\text{-}Hbiim)_2Os(O{=}PPh_3)_2](NO_3)(SO_3CF_3)_2{\cdot}4H_2O$ (**7**) are reported (for the numbering of the complexes, see Scheme 1, cod = 1,5-cyclooctadiene, en = ethylene-1,2-diamine). The electrochemical behavior of compounds **7**−**9** was studied, using cyclic voltammetry, and the catalytic activity of **7**−**9**, in the homogeneous hydrogenation of 1-hexene and cyclohexene, is also reported.

Results and Discussion

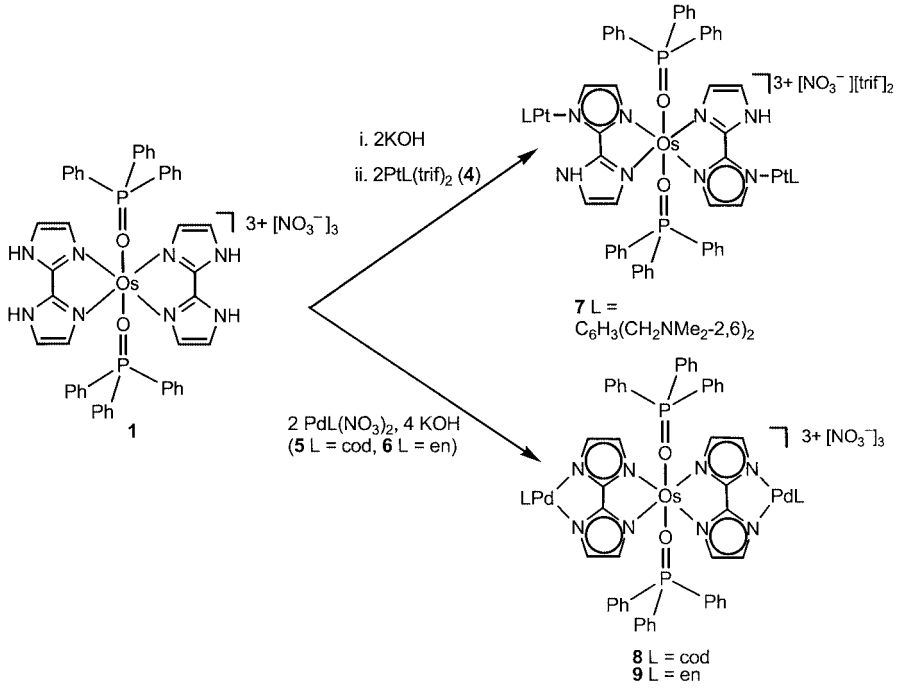
Synthesis and Spectroscopy

The mononuclear osmium(III) complex $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**1**),[10] was used as a starting material in the synthesis of the trimetallic $OsPt_2$ and $OsPd_2$ complexes **7**−**9**. Complex **1** is a polybasic acid and was successfully deprotonated by KOH, affording $[Os(Hbiim)_2(O{=}PPh_3)_2](NO_3)$ (**2**),[10] and $[Os(biim)_2(O{=}PPh_3)_2]^-$ (**3**, not isolated as a solid). Complexes **2** and **3** are reactive building blocks ("metal complex as the ligand"), which smoothly reacted with various transition-metal complexes, producing the trimetallic compounds **7**−**9** in high yields (Scheme 1). After appropriate workup, complexes **7**−**9** were isolated as red (**7**) or dark green (**8**, **9**) air-stable solids, which gradually decompose at temperatures higher than 150 °C. They are insoluble in tetrahydrofuran, acetone, diethyl ether and aromatic hydrocarbons, only moderately soluble in methanol and dichloromethane, but very soluble in a mixture of these solvents, e.g., in 80% of dichloromethane and 20% of methanol.

We were also interested in the structural properties of mononuclear osmium(III) complexes with a partially deprotonated 2,2′-biimidazolate ligand. Attempts to crystallize $[Os(Hbiim)_2(O{=}PPh_3)_2](NO_3)$ (**2a**) from dichloromethane/methanol were unsuccessful. However, in the presence of the rhodium(III) salt $[Me_2NH_2][RhCl_4\{NH(CH_3)_2\}_2]$ (**10**) single crystals of $[Os(Hbiim)_2(O{=}PPh_3)_2][RhCl_4(NH(CH_3)_2)_2]$ (**2b**), suitable for X-ray structure determination, could be obtained (see below).

The UV/Vis spectra of **7**−**9** have an absorbance maximum at approx. 350 nm, which can be assigned to a metal-to-ligand charge-transfer transition {for comparison, the parent complex $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**1**) has two transitions at 360 and 388 nm[10]}. In the visible region, a broad absorbance of low intensity at approx. 550 nm is also observed for **8** and **9**, and these are assigned to d-d transitions. It is worth noting that the mononuclear Os^{III} complex **1**, as well as the Pt^{II} and Pd^{II} complexes **4**−**6**, have no transitions in this region.

The infrared spectrum of 2,2′-biimidazole shows a strong absorption band at around 3100 cm^{-1}, which is assigned to the N−H stretching vibrations. This band is also found in the infrared spectrum of **7** (at 3075 cm^{-1}), however, it is not observed in the infrared spectra of **8** and **9**. This implies that complete deprotonation of the 2,2′-biimidazole bridging ligands occurs in the trinuclear compounds **8** and **9**.



Scheme 1

The effective magnetic moments of the trinuclear complexes [μ_{eff} = 1.87 (**7**), 1.45 (**8**), 1.58 (**9**) BM; powders, 298 K] are as expected for Os^{III} complexes (one unpaired electron, 1.73 BM). Complex **7** could not be characterized by NMR spectroscopy, owing to its magnetic properties. The paramagnetism of complexes **8** and **9** leads to considerable broadening of the NMR signals, but these spectra are sufficiently resolved to be interpreted. The ^1H NMR spectra of [{Pd(cod)}$_2$(μ-biim)$_2$Os(O=PPh$_3$)$_2$](NO$_3$)$_3$ (**8**) and [{Pd(en)}$_2$(μ-biim)$_2$Os(O=PPh$_3$)$_2$](NO$_3$)$_3$ (**9**) show a multiplet between δ = 7.5 and 7.8 ppm, due to the superimposition of the signals resulting from the Ph$_3$PO and biim fragments. The resonance signals at δ = 2.5 and 5.5 ppm, also observed in the ^1H NMR spectrum of **8**, can be assigned to the CH and CH$_2$ groups, respectively, of the coordinated cyclooctadiene. They are slightly shifted to a lower field compared to those in the spectrum of the metal-free ligand. In the spectrum of complex **9**, the resonance signal for the CH$_2$ groups of the en ligands is observed at δ = 2.96 ppm, while in the spectrum of metal-free en, the signal of these protons appears at δ = 2.85 ppm. The carbon resonance signals of the terminal cod (δ = 28.4, 76.4 ppm) and en units (δ = 47.3 ppm), observed in the $^{13}C\{^1H\}$ NMR spectra of **8** and **9**, respectively, are also shifted to a lower field, when compared with the spectra of the corresponding metal-free ligands. As a result of the deprotonation of H$_2$biim and the addition of the PdL complex fragments, the ^{13}C resonances of 2,2′-biimidazole are shifted to a lower field in comparison with **1**. The signal for the C atoms in the 2, 2′-position is observed at δ = 152.1 ppm (**8**) and at δ = 152.6 ppm (**9**), while this resonance is found at δ = 141.2 ppm for **1**. The variation of the terminal ligand coordinated to the palladium center does not affect the chemical shifts of the C atoms in the 2,2′-biimidazolate bridging ligands.

In the $^{31}P\{^1H\}$ NMR spectra of **8** and **9**, the signal for the phosphorus atom of the triphenylphosphane oxide group is seen at δ = 32.6 ppm. Relative to [Os(H$_2$biim)$_2$(O=PPh$_3$)$_2$](NO$_3$)$_3$ (**1**) this ^{31}P signal is shifted to a higher field by approx. 3.8 ppm and this indicates an increase of electron density at the Os^{III} center due to better electron donation of the deprotonated 2,2′-biimidazole ligand.

Electrochemistry

Cyclic voltammetric studies of **1** and **7**−**9** were carried out in methanol at 25 °C. The mononuclear complex [Os(H$_2$biim)$_2$(O=PPh$_3$)$_2$](NO$_3$)$_3$ (**1**) has a reversible one-electron step at $E_{1/2}$ = −1.01 V (vs. $FeCp_2^+/FeCp_2$, Figure 2, a). This is attributed to the Os^{II}/Os^{III} redox couple. Complex **1** also has an irreversible Os^{III}/Os^{IV} oxidation at 0.92 V. In contrast to this, the trinuclear complexes **7**−**9** have a single quasi-reversible voltammetric response (Figure 2, b shows the cyclic voltammogram of **8** as an example). Since [Pt{C$_6$H$_3$(CH$_2$NMe$_2$-2,6)$_2$}](SO$_3$CF$_3$) (**4**), [Pd(cod)(H$_2$biim)](NO$_3$)$_2$ (**5**) and [Pd(en)(H$_2$biim)](NO$_3$)$_2$ (**6**) do not have a cyclic voltammetric response in the potential range −1.2 to +1.2 V, the processes observed in the cyclic voltammograms of **7**−**9** are attributed to the Os^{III}/Os^{IV} redox couple. Electrochemical data are given in Table 1.

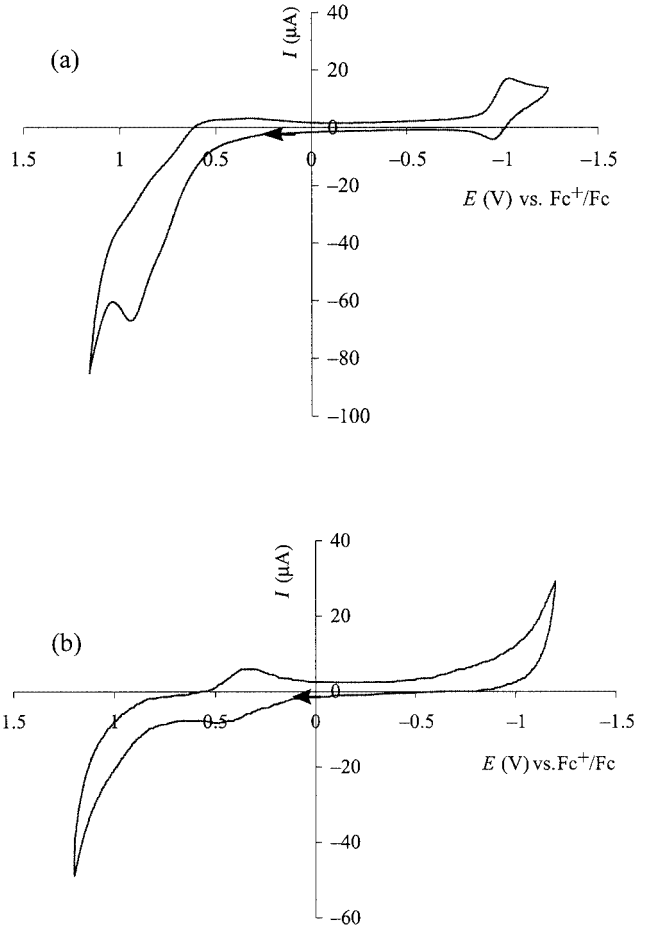


Figure 2. Cyclic voltammograms of (a) [Os(H$_2$biim)$_2$(O=PPh$_3$)$_2$](NO$_3$)$_3$ (**1**) and (b) [{Pd(cod)}$_2$Os(μ-biim)$_2$(O=PPh$_3$)$_2$](NO$_3$)$_3$ (**8**)

Table 1. Electrochemical data of **1** and **7**−**9**

Complex[a]	$E_{1/2}(Os^{III}/Os^{IV})$ [V]
[Os(H$_2$biim)$_2$(O=PPh$_3$)$_2$](NO$_3$)$_3$ (**1**)	0.92
[{Pt[C$_6$H$_3$(CH$_2$NMe$_2$-2,6)$_2$]}$_2$Os(μ-Hbiim)$_2$-(O=PPh$_3$)$_2$](NO$_3$)(SO$_3$SF$_3$)$_2$·4H$_2$O (**7**)	0.53
[{Pd(cod)}$_2$Os(μ-biim)$_2$(O=PPh$_3$)$_2$](NO$_3$)$_3$ (**8**)	0.41
[{Pd(en)}$_2$Os(μ-biim)$_2$(O=PPh$_3$)$_2$](NO$_3$)$_3$ (**9**)	0.23

[a] CH$_3$OH, 25 °C, vs. $E(Fc/Fc^+)$ = 0.00 V.

The addition of transition-metal fragments such as $[Pd(cod)]^{2+}$ or $[Pd(en)]^{2+}$ to **3** leads to a significant cathodic shift of the Os^{III}/Os^{IV} couple (Table 1). For **9**, this occurs at a more negative potential ($E_{1/2}$ = +0.23 V) than that for **8** ($E_{1/2}$ = +0.41 V). However, NMR spectroscopy shows that substitution of cod by en in PdL does not affect the chemical shifts of the C atoms in the biimidazolate bridging

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

group, and the chemical shifts of the P atoms in $Ph_3P{=}O$ in **8** and **9** are also almost identical. Therefore, it is not appropriate to attribute the difference in the redox potentials of **8** and **9** to an effect of the terminal ligand (cod, en) on the osmium center. Possible reasons for the shift in the redox potential are a variation of the adsorption properties of the complex cation at the electrode or of the electron transfer between the electrode and the osmium complex as a function of the terminal ligands.

Solid-State Structures

Slow concentration of dichloromethane/methanol solutions of $[Os(Hbiim)_2(O{=}PPh_3)_2][RhCl_4\{NH(CH_3)_2\}_2]$ (**2b**) and $[(Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\})_2(\mu\text{-}Hbiim)_2Os(O{=}PPh_3)_2](NO_3)(SO_3CF_3)_2{\cdot}4H_2O$ (**7**) led to the formation of red crystals of **2b** and pale pink crystals of **7**, respectively. Both **2b** and **7** crystallize in triclinic space groups $P\bar{1}$. The coordination geometry around the osmium center in the two complexes is approximately octahedral. The polyhedron is defined by the four nitrogen atoms of two $Hbiim^-$ ligands and the two oxygen atoms of the $Ph_3P{=}O$ units, which are in the axial positions.

Figure 3 shows the ZORTEP[11] plot of complex **2b**; structural parameters are given in Table 2. The $[Os(Hbiim)_2(O{=}PPh_3)_2]^+$ cation and the $[RhCl_4\{NH(CH_3)_2\}_2]^-$ anion have a center of inversion, located at the osmium and rhodium centers, respectively; the symmetry-generated atoms are identified with the suffix a. The Os(1)−N(1) and Os(1)−N(3) distances in **2b** (bonds to the mono-deprotonated 2,2′-biimidazolate ligands), are nearly identical to those in $[Os(H_2biim)_2(O{=}Ph_3)_2](NO_3)_3$ (**1**) [**2**: Os(1)−N(1) = 2.076(2), Os(1)−N(3) = 2.080(2); **1**: Os(1)−N(1) = 2.0651(19) Å[10]]. The deprotonated imidazolate sites in **2b** are *trans*-oriented. The Os(1)−O(1) bond [2.056(2) Å] is significantly longer than that observed in **1** and in other osmium complexes with a triphenylphosphane oxide, e.g., $[Os(OEP)(O{=}PPh_3)_2]$ (Os−O = 2.036 Å, OEP = octaethylporphyrin).[12] The bite angle N(1)−Os(1)−N(3) [77.78(6)°] is almost identical to that found in **1** [77.14(8)°] and is typical for bite angles in biimidazole and biimidazolato transition-metal complexes, e.g., $[H(CO)(PPh_3)_2Ru(\mu\text{-}biim)Rh(cod)]$ [N−Ru−N = 79.2(2) Å][9] and $[OsCl(\eta^2\text{-}H_2)(H_2biim)_2(P\mathit{i}C_3H_7)_2]Cl$ [N−Os−N = 75.6(3)°] .[13] The Rh^{III} ion in the counterion $[RhCl_4(NHMe_2)_2]^-$ in **2b** has a slightly distorted octahedral coordination geometry, where the chloride ions are situated in the equatorial positions and the amine groups are occupying the axial positions. The Rh(1)−Cl(1) [2.3597(5) Å] and Rh(1)−N(5) [2.106(2) Å] distances are in agreement with the bond lengths observed in similar octahedral Rh^{III} complexes, e.g., $[ImH][RhCl_4(Im)_2]$ (Im = imidazole), with Rh−Cl = 2.326(2) Å and Rh−N = 2.039(4) Å.[14] In the $[RhCl_4(NHMe_2)_2]^-$ anion, the four chloride ligands form an almost ideal quadrangle around the Rh atom [Cl(1)−Rh(1)−Cl(2) = 92.979(2)°].

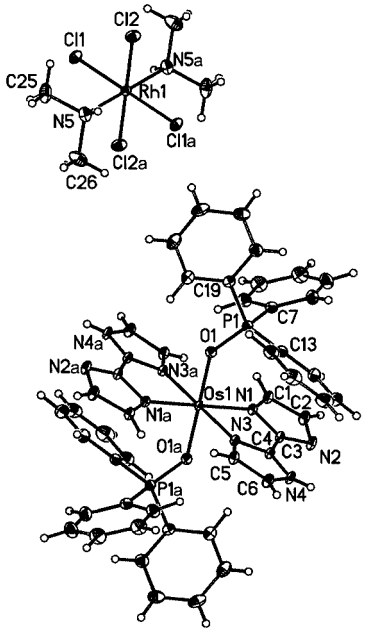

Figure 3. ZORTEP[11] diagram of $[Os(Hbiim)_2(O{=}PPh_3)_2][RhCl_4\{HN(CH_3)_2\}_2]$ (**2b**) (50% probability level); symmetry transformations used to generate equivalent atoms: $a = -x+1, -y+1, -z+1$; $b = -x+2, -y, -z+2$

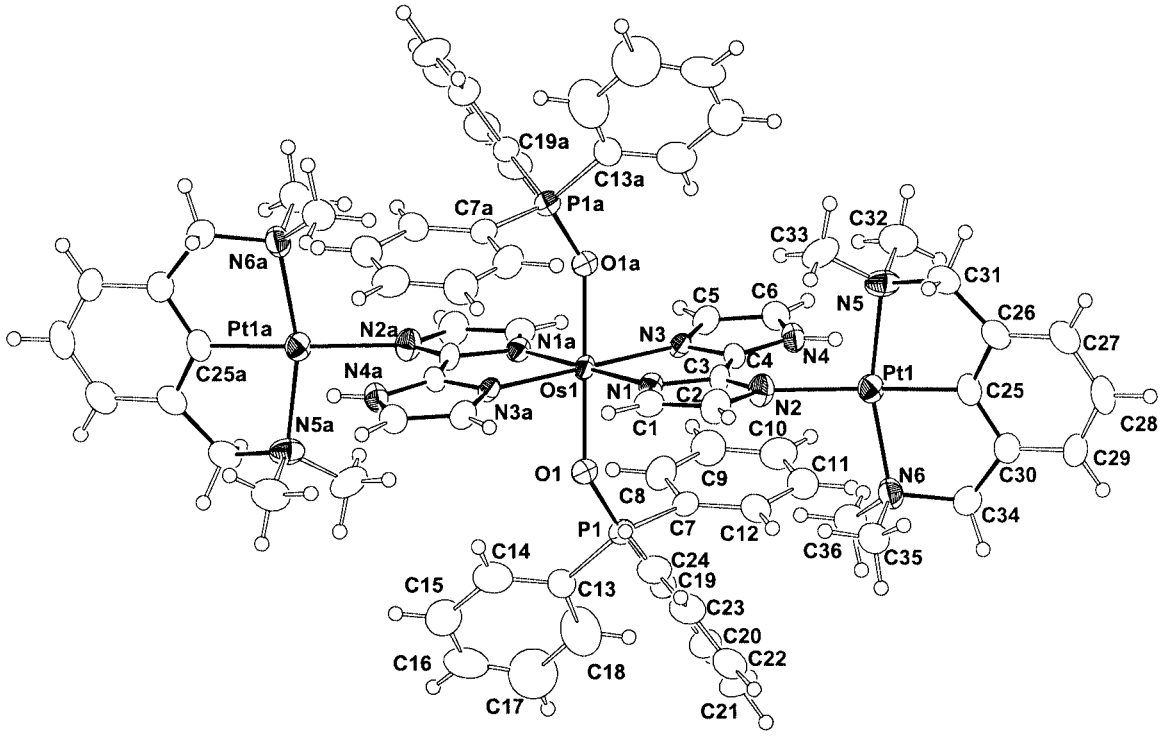

Figure 4. ZORTEP[11] drawing of the complex cation $[(Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\})_2Os(\mu\text{-}Hbiim)_2(O{=}PPh_3)_2]^{3+}$ of **7** (50% probability level; NO_3^-, $SO_3CF_3^-$ and H_2O are omitted for clarity); symmetry transformation used to generate equivalent atoms: $a = -x + 1, -y + 1, -z$; $b = -x + 2, -y, -z$

four water molecules in the unit cell. A plot of the molecular cation with the atom numbering scheme is given in Figure 4, selected bond lengths and angles are listed in Table 2. The molecular cation **7** has a center of inversion situated at the osmium atom; symmetry-generated atoms are identified with the suffix a.

Each $Hbiim^-$ bridging ligand in **7** is planar [root mean squares deviation rms = 0.0547 Å]. The Os(1)−N(1) and Os(1)−N(2) distances are slightly shorter than in **2b**, the bite angles of the Os−biim fragment are, as expected, nearly identical to those in **2b**. However, some changes are observed in the geometry of the triphenylphosphane oxide ligands. The Os(1)−O(1) distance in **7** is shorter than that in **2b** by 0.026 Å, and the P(1)−O(1)−Os(1) angle is larger than that in **2b** by 9.06°. The rigid biimidazole ligand is not affected. The PtL entities are planar [rms deviation = 0.0389 Å, Pt(1)−N(2)−N(5)−N(6)−C(25)] and are *trans*-disposed, similar to the deprotonated sites in $[Os(Hbiim)_2(O{=}PPh_3)_2]^+$ in **2b** (see Figure 3). The platinum centers have a slightly distorted square-planar coordination geometry. The N(5)−Pt(1)−N(6) angle is 163.1(4)°, which is in the typical range for NCN pincer complexes.[15] The PtL units are perpendicular to the imidazole rings [interplanar angle between Pt(1)−N(2)−N(5)−N(6)−C(25) and N(1)−N(2)−C(1)−C(2)−C(3) = 89.14(25)°].

Catalytic Activity

The catalytic properties of the trimetallic complexes **7**−**9** were investigated through the homogeneous hydrogenation of 1-hexene and cyclohexene in dichloromethane solutions at 25 °C, and under a hydrogen pressure of 5 bar. The yields of the catalytic hydrogenation reactions are summarized in Table 3. Complex **7**, as well as its homodinuclear analog $[\{Pt(C_6H_3(CH_2NMe_2\text{-}2,6)_2)\}_2'(\mu\text{-}Hbiim)](SO_3CF_3)_2$ (**11**)

Table 3. Homogeneous hydrogenation of 1-hexene and cyclohexene catalyzed by complexes **1**, **7**−**9** and **11**

Catalyst	Hydrogenation of 1-hexene		Hydrogenation of cyclohexene	
	Time [h]	Yield of hexane (%)	Time [h]	Yield of cyclohexane (%)

have a low catalytic activity. This is probably due to the inertness of these coordinatively saturated complexes towards ligand exchange. With $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**1**) as a catalyst, 11% of hexane was obtained from 1-hexene, but no hydrogenation was observed with cyclohexene. The most active catalyst in the series is $[\{Pd(cod)\}_2Os(\mu\text{-}biim)_2(O{=}Ph_3)_2](NO_3)_3$ (**8**) (Table 3). A probable mechanism for the catalytic cycle involves hydrogenation of 1,5-cyclooctadiene and the formation of a coordinatively unsaturated palladium center as the catalytically active species. This could explain the lower activity of $[\{Pd(en)\}_2Os(\mu\text{-}biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**9**) since the chelating ligand en is not easily substituted by substrate molecules. An attempt to use the mononuclear complex $[Pd(H_2biim)(cod)](NO_3)_2$ (**12**) as a homogeneous catalyst under identical conditions was unsuccessful, as it decomposes under hydrogen with the formation of palladium metal. This adequately demonstrates the increased stability of the Pd(cod) fragment in the trinuclear compound **8** relative to the mononuclear precursor **12**.

Conclusions

Deprotonation of the 2,2′-biimidazole building block in $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**1**) provides a powerful route towards the preparation of the trimetallic $Pt^{II}-Os^{III}-Pt^{II}$ and $Pd^{II}-Os^{III}-Pd^{II}$ complexes **7**–**9**. The solid-state structural analysis of $[(Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\})_2(\mu\text{-}Hbiim)_2Os(O{=}PPh_3)_2](NO_3)(SO_3CF_3)_2{\cdot}4H_2O$ (**7**) demonstrates that the two $[Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\}]^+$ moieties are *trans* to each other, as expected from the *trans*-deprotonated sites of the 2,2′-biimidazolato ligands in the starting material, as shown in the solid-state structure of $[Os(Hbiim)_2(O{=}PPh_3)_2][RhCl_4\{NH(CH_3)_2\}_2]$ (**2b**). Cyclic voltammetric studies demonstrate that deprotonation of 2,2′-biimidazole and the coordination to a second metal ion result in a modification of the redox properties of the central osmium ion, and this is probably due to a change in the ligand field. The $OsPd_2$ complex $[\{Pd(cod)\}_2(\mu\text{-}biim)_2Os(O{=}PPh_3)_2](NO_3)_3{\cdot}H_2O$ (**8**) is shown to have considerable catalytic activity towards the homogeneous hydrogenation of linear and cyclic alkenes, e.g. 1-hexene and cyclohexene.

Experimental Section

Materials and Measurements: The complex $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3{\cdot}H_2O{\cdot}0.5CH_3OH$ (**1**) was prepared by a published method.[10] $[Os(Hbiim)_2(O{=}PPh_3)_2](NO_3){\cdot}2H_2O$ (**2**) was obtained by reaction of **1** with KOH in methanol/dichloromethane.[10] $[Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\}(H_2O)](SO_3CF_3)$ (**4**) was prepared from $[Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\}Cl]$[15] (addition of $AgSO_3CF_3$ in methanol). $[Me_2NH_2][RhCl_4(HNMe_2)_2]$[16] was obtained as described elsewhere. ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded with a Bruker AC 250 spectrometer, chemical shifts (^1H and ^{13}C) in ppm are quoted relative to $SiMe_4$. ^{31}P chemical shifts are given in ppm with respect to 85% H_3PO_4 (^{31}P: $\delta = 0$) as an external standard. Infrared spectra (KBr pellets) were recorded with a Perkin–Elmer 16PC FT-IR instrument. UV/Vis spectra were obtained with a Cary 1E spectrophotometer. Magnetic measurements were carried out with an Alfa MK 1 magnetic susceptibility balance. Electrochemical measurements (CV) were performed in methanol solutions containing $[nBu_4N]PF_6$ (0.1 mol·dm^{-3}) at 293 K, using a BAS 100B system with a glassy carbon working electrode, a platinum auxiliary electrode and an Ag/AgCl reference electrode. All potentials are referenced to the ferrocene/ferrocenium couple (E = 0.0 V). GC-MS analyses were performed with a Fison GC 8000/MD 800 series instrument, equipped with a ZB-1 (Zebron) column. Melting (decomposition) points were determined with a Gallenkamp MFB 595 010 M melting point apparatus. Organic solvents (methanol, dichloromethane) were freshly distilled before use. Microanalyses were obtained from the microanalytical laboratory of the chemical institutes of the University of Heidelberg or the Technische Universität Bergakademie Freiberg.

X-ray Crystallography: X-ray quality crystals of $[Os(Hbiim)_2(O{=}PPh_3)_2][RhCl_4\{HN(CH_3)_2\}_2]$ (**2b**) and $[(Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\})_2(\mu\text{-}Hbiim)_2Os(O{=}PPh_3)_2](NO_3)(SO_3CF_3)_2$ (**7**) were obtained by slow concentration of solutions of the complexes in a dichloromethane/methanol (4:1) mixture at 25 °C. Experimental crystal data are listed in Table 4 and geometric details are presented in Table 2. X-ray structural data were collected with a Bruker SMART CCD diffractometer. The unit cell parameters were checked for the presence of higher lattice symmetry.[17] Data were corrected for absorption using SADABS.[18] The structures were solved by direct methods (SHELX-97/2).[19] Refinement was carried out by full-matrix least-squares techniques on F^2 (SHELXL-97/2).[19] Hydrogen atoms were located from the difference Fourier map. All hydrogen atoms were fully refined. All non-hydrogen atoms were refined anisotropically.

Catalytic Hydrogenation of 1-Hexene and Cyclohexene: All experiments were performed in a 100-mL stainless steal autoclave with an inner polytetrafluorethylene vessel. In a typical experiment, 0.016 mmol of catalyst was placed as a solid in the autoclave, supplied with a magnetic stirring bar. Under stirring, the catalyst was dissolved in 6 mL of dichloromethane (complexes **7**, **8** and **11**) or in a mixture (90:10, 6 mL) of dichloromethane and methanol (complex **9**). 1-Hexene or cyclohexene (0.16 mmol; purity checked by GC-MS) was added to the solution of the catalyst. The autoclave was evacuated three times and filled with hydrogen. The pressure of hydrogen was increased to 5 bar. The reaction mixture was stirred for 5 h. The autoclave was then degassed and all volatile materials were evaporated from the reaction mixture using an oil-pump vacuum, and condensed (liquid nitrogen). The resulting solution was analyzed by GC-MS.

Synthesis of $[Os(Hbiim)_2(O{=}PPh_3)_2][RhCl_4(HNMe_2)_2]$ (2b): $[Os(Hbiim)_2(O{=}Ph_3)_2](NO_3){\cdot}2H_2O$ (**2**)[10] (100 mg, 0.09 mmol) was treated with $[Me_2NH_2][RhCl_4(HNMe_2)_2]$ (33 mg, 0.09 mmol) in 20 mL of a dichloromethane/methanol (4:1) mixture at 25 °C. Slow evaporation of the solvent resulted in a mixture of solid products. This contained some of the starting materials, $Me_2NH_2NO_3$ and red crystals of **2b**, which were hand-picked and suitable for X-ray crystal structural analysis. Due to the very low yield, no further spectroscopic characterization was possible.

Synthesis of $[(Pt\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\})_2(\mu\text{-}Hbiim)_2Os(O{=}PPh_3)_2](NO_3)(SO_3CF_3)_2{\cdot}4H_2O$ (7): $[Os(Hbiim)_2(O{=}Ph_3)_2](NO_3){\cdot}2H_2O$ (**2**, 200 mg, 0.18 mmol) was dissolved at 25 °C in 15 mL of a dichloromethane/methanol mixture (4:1). $[Pt(\{C_6H_3(CH_2NMe_2\text{-}2,6)_2\}(H_2O)](SO_3CF_3)$ (199 mg, 0.36 mmol), dissolved in methanol (5 mL), was added to the solution. Catalytic Aziridination of Styrene with Copper Complexes of Substituted 3,7-Diazabicyclo[3.3.1]nonanones

Peter Comba,*[a] Michael Merz,[a] and Hans Pritzkow[a]

Keywords: Copper / N ligands / Catalysis

The copper(II) complexes of five bispidine-type ligands {3,7-diazabicyclo[3.3.1]nonanone; three tetradentate ligands with 2-pyridyl (L^1), 6-methyl-2-pyridyl (L^2) or 2-imidazolyl-3-methyl (L^3) substituents in 2,4-positions; two pentadentate derivatives of L^1 with an additional 2-methylpyridine substituent at N3 (L^4) or N7 (L^5)} have, with one co-ligand (Cl^-), a ligand-enforced square pyramidal ($L^{1,2,3}$) or octahedral ($L^{4,5}$) geometry. The main structural properties of three of the five $[Cu(L)(Cl)]^+$ complexes ($L^{1,2,3}$) are very similar, with Cu–N3 < Cu–N7 and Cu–Cl ≈ 2.25 Å (*trans* to N3); with L^2 Cu–N3 ≈ Cu–N7 and Cu–Cl = 2.22 Å (*trans* to N7); with L^5 Cu–N3 < Cu–N7 and Cu–Cl = 2.72 Å (*trans* to N7). These structural patterns lead to considerable differences in ligand field and electrochemical properties (range of $E°$ of approx. 500mV), and the reactivities of the copper(II) complexes as aziridination catalysts (styrene, PhINTs, CH_3CN) are strikingly different. While the complex with L^2 is very efficient, the activities of those with L^1 and L^3 are reduced to approx. 50% and 30%, respectively, and those with L^4 and L^5 are inactive. The fact that the maximum TON (maximum turnover number) of $Cu^{II}L^2$ (19) is much smaller than the maximum TON of $Cu^{I}L^2$ (47) suggests that in the active form the catalysts are in the Cu^I oxidation state, and that the differences in reduction potentials are of major importance for catalysis. The result that $CuL^{4,5}$ have no activity in the Cu^{II} state and only a small activity in the reduced form indicates that, apart from the reduction potentials, steric effects might also be of importance.

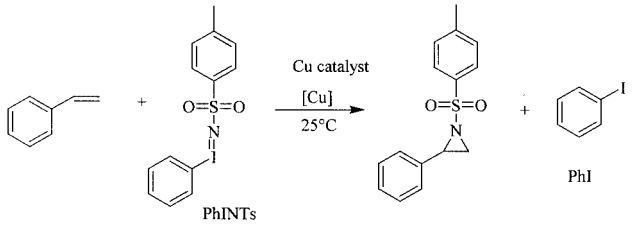
Introduction

Aziridines, the nitrogen analogues of epoxides, are attractive intermediates in organic synthesis,[1,2] and various aziridine-containing natural products have cytotoxic properties.[3,4] Their synthesis, mediated by copper powder, has been known for many years,[5] and transition metal-catalyzed procedures have recently attracted much attention (Scheme 1).[6] Since their discovery[7–9] copper-catalyzed processes have been studied extensively, and various enantioselective catalysts have been developed.[7–12] PhINTs {[*N*-(*p*-toluenesulfonyl)imino]phenyliodinane} is the most frequently used nitrene source in copper-catalyzed aziridination reactions, but others have also been described.[13–15] An interesting observation is that both copper(I) and copper(II) complexes have been found to be active catalysts. Two possible general mechanisms have been discussed, one which involves the copper complexes as Lewis acid catalysts (activation of the coordinated iodinane without electron transfer) and, in analogy to cyclopropanation, a process with a discrete copper-nitrene intermediate (electron transfer).[11,12] Recent experimental evidence[11,16,17] and theoretical studies[17] indicate that there is a discrete nitrene intermediate, and that the copper(I) complexes are the active catalysts, leading to a copper(I)-nitrene or a copper(III)-imido species; the copper(II) pre-catalysts may enter the catalytic cycle via reduction by PhINTs to the corresponding copper(I) complexes.[17] Interesting questions related to this latter mechanism are the electronic structure, spin state and copper oxidation state of the catalytically active intermediate, i.e., whether it is best formulated as a copper(I)-nitrene or a copper(III)-imido species, and the coordination mode of the nitrene donor, derived from PhINTs, which generally is formulated as a monodentate ligand and recently has been proposed to coordinate as a bidentate with the sulfonyl oxygen atom being an additional donor.[17]



Scheme 1

Copper(II)-catalyzed reactions are of particular interest since, in contrast to copper(I), the catalysts are air-stable. A

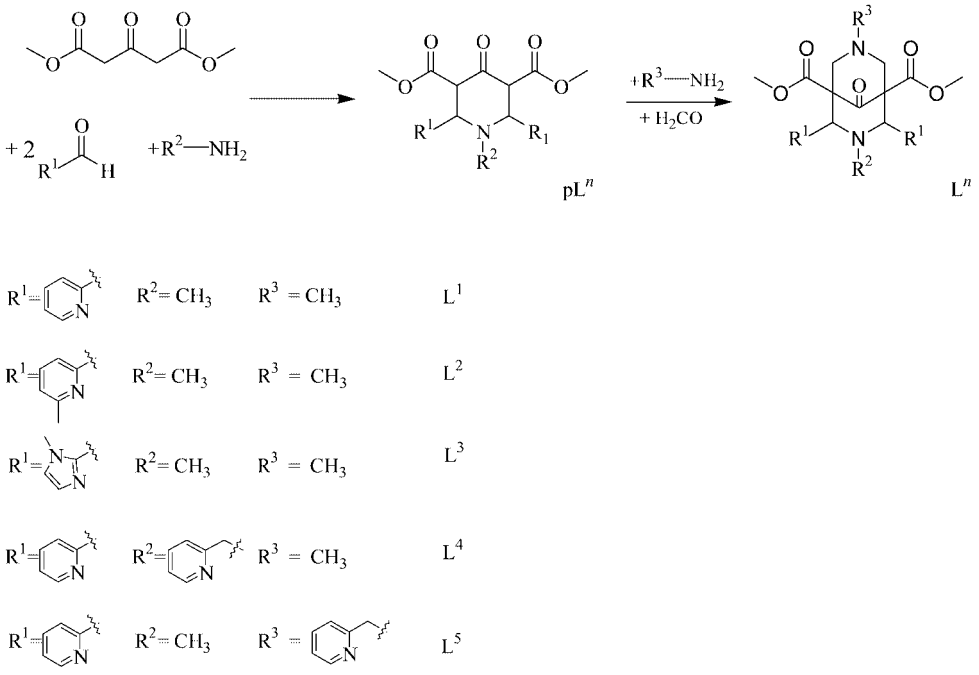

Scheme 2

series of classical copper(II) coordination compounds have recently been reported to efficiently catalyze olefin aziridination.[18–20] Of interest was the observation that the efficiency and, specifically, the reaction rate can be increased significantly when the denticity of the co-ligands is reduced from four to three.[19] The ligands discussed in those studies involve two tertiary amine and one or two pyridine donors, leading to a planar geometry of the putative nitrene intermediate with the copper-nitrene bond in-plane; the reduced reactivity of the tetradentate ligand complexes was believed to be due to a pre-equilibrium, involving copper-pyridine bond breaking.[19,20] This is in agreement with the above mentioned theoretical studies which indicate that the formation of the nitrene intermediate is the rate determining step of the catalytic cycle. Note however that the DFT calculations were done with different and only bidentate ligands.[17]

The copper complexes of the bispidine ligands, reported here (see Scheme 2), are of interest because most of these tetra- and pentadentate ligands enforce an in-plane and strong coordination of the substrate, with one of the tertiary amines as a relatively weak axial donor.[21] This leads to copper complexes with interesting and unprecedented properties,[22–25] and subtle changes in the ligand backbone induce significant structural variation and predictable changes of the redox and electronic properties, as well as the reactivities.[26]

Results and Discussion

Syntheses and Structural Properties: The five bispidone ligands L^{1-5} studied here are all prepared in moderate to high yield, according to the general procedure given in Scheme 2, by variation of the aldehyde and the amine components in the two Mannich condensation steps. As observed before, the coordination to copper(II) leads to hydration of the keto function if the reaction is not done in strictly anhydrous conditions.[22,23,27] The molecular structures of the copper(II) chloro complexes are presented in Figure 1. Table 1 gives selected structural parameters {the structures of $[Cu(L^1)(Cl)]^+$ and $[Cu(L^2)(Cl)]^+$, also included in Figure 1 and Table 1, have been published before[22,23]}.

The bispidine ligands are very rigid. In the present structures this is best seen in the constant N1···N2 distances (N3, N7 according to the IUPAC numbering; the crystallographic numbering used throughout is defined in Figure 1); this is a general feature observed for all transition metal-bispidine complexes.[27] In contrast to this rigidity of the ligand there is a considerable elasticity of the coordination sphere,[26] and this is responsible for appreciable differences in the relative bond lengths, primarily to the tertiary amine donors (see Cu–N1 vs. Cu–N2 in Table 1). This is the result of a dislocation of the copper(II) center within the bispidine cavity, enforced by specific changes at the ligand backbone (see below), and this is a major tool for modifying the properties of the corresponding complexes.

L^1 is highly complementary for copper(II), i.e., $[Cu(L^1)(Cl)]^+$ is a very stable complex {log $K[Cu^{II}(L^1)]$ is approx. 20} ,[28] the stability is similar to that of copper(II) complexes with tetraazamacrocyclic ligands; see also electrochemical and spectroscopic properties below).[21,28,29] An intriguing feature is that the Cu–Cl bond is very short and strong (approx. 2.2 Å vs. approx. 2.5 Å for CuN_4Cl^+ chromophores with axial Cl^-, see also complex with L^5 with a CuN_5Cl^+ chromophore). This is as expected from theoreti-

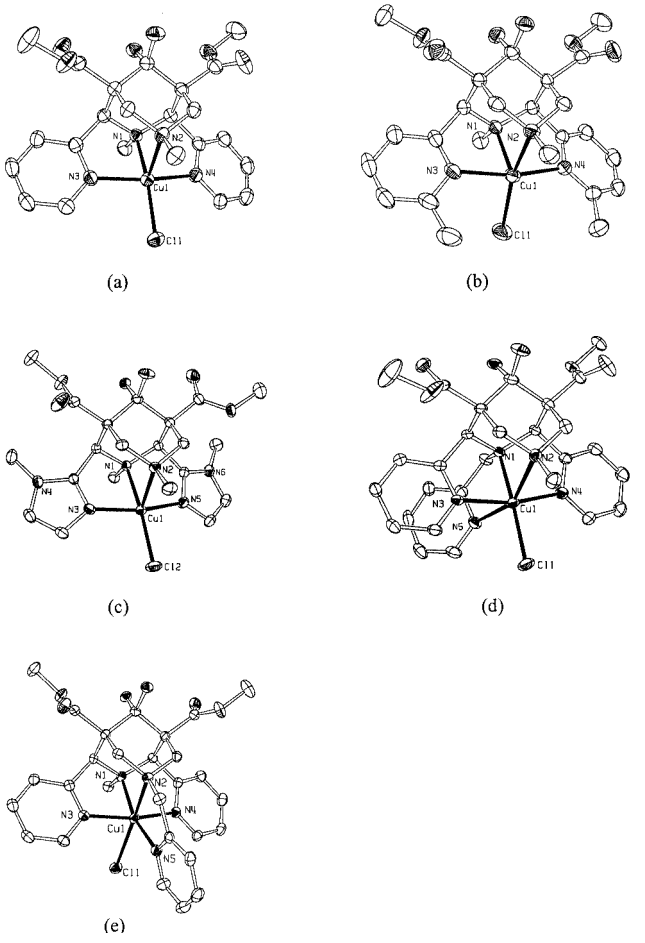

Figure 1. ORTEP[34] plots of (a) $[Cu(L^1)(Cl)]^+$,[19] (b) $[Cu(L^2)(Cl)]^+$,[20] (c) $[Cu(L^3)(Cl)]^+$, (d) $[Cu(L^4)(Cl)]$, (e) $[Cu(L^5)(Cl)]^+$

cal considerations[21] and translates to generally strongly bound and highly activated substrates (peroxide, catecholate)[22–25] and an unprecedented high stability constant for chloride.[29] The main structural features of $[Cu(L^3)(Cl)]^+$ and $[Cu(L^4)(Cl)]^+$ are, as expected, similar to those of $[Cu(L^1)(Cl)]^+$ (see Cu–N1, Cu–N2, Cu–Cl, Figure 1, Table 1). The structural differences of the aromatic five- vs. six-membered ring (L^1 vs. L^3) and the small differences in donor strength between imidazole and pyridine (strong σ-donors, pK_a(pyridine) = 5.3, pK_a(imidazol) = 7.1, weak π-acids) lead only to minor structural variations. The addition of a third pyridine donor *trans* to N2 (L^4, additional pyridine donor in the "Jahn–Teller" axis, 2.5 vs. 2.0 Å) also leads to only small over-all structural changes (Cu–Cl = 2.25 Å, similar to $L^{1,3}$).

More important and interesting are the structural changes enforced by L^2 (α-methyl substitution of the pyridine donors, steric crowding) and L^5 (ligand-enforced coordination of the substrate in the "Jahn–Teller" axis, *trans* to N2). In the latter case (L^5) the structural features are obvious and as expected: the distance to the third pyridine donor is similar to that of the other two (Cu–N3 ≈ Cu–N4 ≈ Cu–N5, note the differences to the structure with L^4), and Cu–Cl = 2.72 Å (in contrast to all the other complexes discussed here, but similar to the usual CuN_5Cl^+ (and CuN_4Cl^+) chromophores, see above).

The most interesting structure, however, is probably that of the complex with L^2. The methyl substitution enforces the coordination of bulky co-ligands (substrates) such as Cl^- *trans* to N2 (note that the sterically less demanding $NCCH_3$ donor is coordinated *trans* to N1[23]). The resulting structure is best described as square pyramidal with the two pyridine donors, Cl^- and N2 in-plane, and N1 as the axial donor (see Figure 2). The main structural differences be-

Table 1. Selected bond lengths (Å) and angles (deg) of the molecular cations of the copper(II) complexes

[a] For $[Cu(L^3)(Cl)]^+$ N4 in this table corresponds to the crystallographic label N5 (see Figure 1).

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tween $[Cu(L^1)(Cl)]^+$ and $[Cu(L^2)(Cl)]^+$ are then (i) a rotation of the pyridine rings out of the *xy* plane with the methylated ligand L^2; this leads to a destabilization of the entire complex and of the Cu−Cl bond,[21] and (ii) a quenching of the Jahn−Teller-type electronic stabilization due to steric constraints from the bispidine backbone (Cu−N1 ≈ Cu−N2), again leading to destabilization.[26] The stability constant with L^2 is not yet available. However, it is known[30] that differences in the potential of copper(II/I) couples are strongly correlated with the complex stabilities of the corresponding copper(II) complexes. The difference in the reduction potential between $Cu^{II}L^1$ and $Cu^{II}L^2$ of approx. 300 mV (see below) leads to a difference in total energy of approx. 30 kJ·mol^{-1}. The computed energy difference (DFT)[21] is approx. 20 kJ·mol^{-1}, and some of this difference (approx. 10 kJ·mol^{-1}) might be due to the quenching of the Jahn−Teller effect, which was not included in the DFT study (model compound with monodentate ligands).[21] Note, however, that some of these data refer to gas phase calculations and that the co-ligand is not the same in all the studies referred to, i.e., the quoted energies have to be considered with care. Interestingly, the two Cu−Cl bond lengths in the structures with L^1 and L^2 are similar (see Table 2), supporting the interpretation of the structure as square pyramidal with an in-plane Cu−Cl bond, and the short bond is probably also due to less repulsion between Cl^- and the ligand backbone of L^2 (see Figure 2). The theoretically expected decrease in bonding energy[21] is paralleled by a decrease in Cu−Cl stability by an experimentally observed factor of approx. 2.[29]

Also relevant for the aziridination catalysis are the corresponding copper(I) structures. A number of solid state structures have been reported,[23,25,27] and these are similar to the corresponding copper(II) structures. An interesting feature is that with L^1 four- and five-coordinated complexes are known, which differ by one of the pyridine donors (N3 or N4) either being coordinated or not.[23] The dynamics in solution are not yet fully understood but the structural data and a qualitative interpretation of the solution NMR spectra suggest that an equilibrium which also involves a reduced coordination number species is feasible.

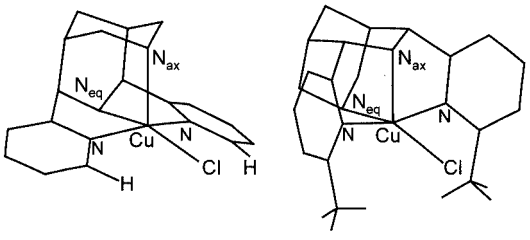

Figure 2. Plots of the crystal structures of $[Cu(L^1)(Cl)]^+$ [22] and $[Cu(L^2)(Cl)]^+$, [23] visualizing the square pyramidal structure of $[Cu(L^2)(Cl)]^+$

Spectroscopy and Electrochemistry: Electronic spectra of the copper(II) complexes of the five bispidine ligands L^{1-5} have been recorded as the chloro complexes (chloride salts) and with a coordinated solvent molecule (tetrafluoroborate salts), each in two different solvents (acetonitrile and methanol), see Table 2. The data of the chloro complexes indicate that chloride remains coordinated, i.e., the spectra are close to identical in the two solvents and different from the spectra of the corresponding tetrafluoroborate salts, which differ for each solvent. This was expected from the strong bonds (see above and ref.[21]), the high stability constants,[29] and is also supported by conductometric experiments with $L^{1,2}$.[25] Worth noting is the strongly different chromophore of the copper(II) complexes with L^4 (generally very weak ligand field), which might be due to the considerable angular distortion of the hexacoordinate complex (N2−Cu−N5 = 155°) and/or subtle changes in π-bonding. The solvent-dependent shift of the dd transitions of the copper(II) complexes with L^2 is much larger than it is for the other complexes and suggests some significant structural changes. For the co-ligands Cl^- and $NCCH_3$ this was expected, i.e., the former coordinates *trans* to N2, the latter *trans* to N1.[23]

Preliminary EPR spectroscopic data are also included in Table 2. The expected trends (*g* vs. ligand field strength, *g* vs. *A*) are observed but the differences are not significant enough, and the lack of resolution in the ligand field spectra, as well as the lack of a thorough assignment do not warrant further interpretation at present. An interesting feature is that, in the EPR spectrum of $[Cu(L^1)Cl]^{2+}$ (in MeOH or DMF/H_2O, frozen solution), there is a well resolved fine-structure in the g_{xy} region of the spectrum; a less well resolved but clearly observable fine-structure is also apparent in the g_z region, and in the g_{xy} region of $[Cu(L^4)Cl]^{2+}$. A more detailed interpretation of these and other spectroscopic features will be given elsewhere.

The reduction potentials are also given in Table 2. These are a measure of the stabilities of the copper(II) complexes

Table 2. Spectroscopic and electrochemical properties of the copper(II) complexes of L^{1-5}

Compound	dd Transitions (nm)				EPR (X = Cl^-[a]/X = CH_3CN[b])			$E°$ (X = CH_3CN)[a]
	X = Cl^- [a]	X = MeOH[b]	X = CH_3CN[b]	X = H_2O[b]	$g_\parallel$	$g_\perp$	$A_\parallel$	(mV vs. $Ag/AgNO_3$)

(see above).[30] As expected from the structural data (see above) the electrochemically deduced stabilities of the copper(II) complexes of $L^{1,3,4}$ (coordinated $NCCH_3$) are similar (-489 mV $< E^\circ < -417$ mV). That of the complex with L^5 is significantly larger ($E^\circ = -603$ mV; pentadentate ligand; in L^4 the third pyridine donor is only weakly coordinated and leads to a significant distortion of the chromophore, see spectroscopic data). The difference in E° between the complexes of L^1 and L^4 suggests that in solution the latter remains hexacoordinate. The reduction potential of the complex with L^2 is considerably smaller ($E^\circ = -98$ mV); i.e., the stability of the copper(II) complex is significantly smaller. Note again that, in CH_3CN, the co-ligand with L^2 is coordinated *trans* to N1, while other donors (specifically PhINTs) are expected to coordinate *trans* to N2.

Aziridination Catalysis: The efficiency of the aziridination catalytic reactivity of the copper(II) and copper(I) complexes of L^{1-5} are summarized in Table 3. Note that the aziridines were isolated and their yield determined by weight (see Exp. Sect.). This might lead to a loss of product of up to approx. 5%. The reaction time was not optimized but it appears that the reactions with L^2 and those with copper(I) catalysts are considerably faster than the others.

In a first set of experiments the copper(II) catalysts of L^{1-5} were tested with standard conditions (entries 1,2,5,6,8).[20] Under these conditions, the pentadentate ligands $L^{4,5}$ do not lead to active copper(II) pre-catalysts, and ligands $L^{1,3}$ lead to catalytic systems of similar activities to those observed recently with other tetradentate ligand systems with two tertiary amine and two pyridine donors.[20] An interesting feature is that the activity of the copper(II) catalyst with methyl-substituted pyridine donors (L^2) is enhanced by a factor of at least 2. In a second series of experiments the maximum turnover number (TON) of the most active copper(II) catalyst (L^2) was evaluated (entry 3). A third series of experiments was done to compare the performance of the catalytic systems with copper in the oxidation states (II) and (I) (entries 4,7,9). It appears that the copper(I) forms are generally more efficient. This is supported by the observation that the TONs of the copper(II) systems with the tetradentate ligands L^{1-3} (entries 1,2,5) are qualitatively correlated to the corresponding reduction potentials (Table 2). The fact that ligands $L^{4,5}$ do not lead to active copper(II) pre-catalysts indicates that the ease of reducing the pre-catalysts is not the only property related to the catalytic activity (the reduction potential of $Cu^{II}(L^4)X$ is not much different from those with ligands $L^{1,3}$). Therefore, another important factor might be that the inner-sphere reduction by PhINTs (as proposed in the literature[17]) is, for steric reasons, not possible with the pentadentate ligands. This is supported by the fact that the copper(I) complexes with $L^{4,5}$ show some catalytic activity, but this is marginal.

Based on the current data we assume that electronic and steric effects are both responsible for the observed differences in reactivity. Based on the proposal that the copper(II) pre-catalysts enter the catalytic cycle after reduction by PhINTs to the corresponding copper(I) complexes,[17] the destabilization of the oxidized form by L^2 might be an important driving force for the higher activity (note again here the ambiguity of the site of coordination of substrates to the complex with L^2). PhINTs is a sterically demanding donor, and this is true for a terminal or a chelated copper(I)-nitrene or copper(III)-imido species (with the sulfonyl oxygen atom also coordinated[17]). Therefore, it is not unexpected that its rate-determining formation with the pentadentate ligand L^4 is unfavorable. With L^5, coordination of the substrate to copper(II) is along the Jahn–Teller axis and probably does not lead to a stable interaction, also, this redox potential is extremely negative. Significant differences in steric crowding between the copper-$L^{1,2}$ fragments emerge from Figure 2, the two square pyramidal chromophores are very similar but the L^1 substrate coordination (Cl^- in Figure 2) is hindered by the α-CH groups of the pyridine donors; the corresponding methyl groups are not sterically efficient in L^2. The differences in reactivity between L^1 and L^3 (the repulsion due to the α-CH groups in L^3 is, for geometric reasons, reduced) indicate that electronic factors (reduction potentials) are also of importance in this case.

Conclusion

Subtle changes on the bispidine backbone have been shown to lead to strikingly different structural and electronic properties of the corresponding copper(II) complexes, and these are transferred to strong differences in the activi-

Table 3. Results of the catalytic aziridination of styrene in CH_3CN (for detailed conditions see text)

Entry	Catalyst	[PhINTs] (mol)	[Catalyst] (mol %)	Yield (%)	TON
1	$[Cu^{II}(L^1)](BF_4)_2$	0.4	5	41	9 ± 1
2	$[Cu^{II}(L^2)](BF_4)_2$	0.4	5	94	19 ± 1
3	$[Cu^{II}(L^2)](BF_4)_2$	0.6	3.5	67	19 ± 1
4	$[Cu^{I}(L^2)](BF_4)$	0.9	1.7	80	47 ± 2
5	$[Cu^{II}(L^3)](BF_4)_2$	0.4	5	29	6 ± 0.5
6	$[Cu^{II}(L^4)](BF_4)_2$	0.4	5	0	0
7	$[Cu^{I}(L^4)](BF_4)$	0.4	1.7	7	7.5 ± 1
8	$[Cu^{II}(L^5)](BF_4)_2$	0.4	5	0	0
9	$[Cu^{I}(L^5)](BF_4)$	0.4	1.7	6	5.5 ± 1

ties of these complexes as aziridination catalysts. It appears that the differences in catalytic activities are due to steric effects and to the destabilization of the copper(II) oxidation state. Bond breaking to one of the pyridine donors in the copper(I) state might facilitate the formation of the copper(I)-nitrene intermediate, and this type of dynamic process with bispidine ligands has been described before.[23] Further ligand modifications might shed more light on the relative importance of all these factors and lead to more efficient catalytic systems.

Experimental Section

Measurements and Materials: Chemicals for the syntheses and solvents were of the highest degree of purity and used without further purification. The piperidone precursors pL^1 for $L^{1,2,5}$, the ligands L^1, L^2, and the corresponding copper(II) complexes (Cl^-, BF_4^- salts) were prepared using published procedures (see Scheme 1).[23]

IR spectra (KBr pellets) were measured with a Perkin−Elmer 16C FT-IR instrument. NMR spectra were recorded with a Bruker AS 300 spectrometer (^1H, 300.13 MHz; ^{13}C, 75.47 MHz); chemical shifts (δ, ppm) are relative to TMS or solvent. Electronic absorption spectra were measured from solutions (approx. 10^{-3} M, CH_3CN), using 1-cm quartz cells, on a Varian Cary 1E instrument. EPR spectra were recorded on a Bruker ELEXSYS E500 spectrometer as approx. 10^{-3} M frozen solutions (liquid nitrogen temperature MeOH, CH_3CN or DMF/H_2O). XSophe, version 1.0.2β, on a Linux workstation was used for the computer simulation of the spectra.[31,32] Electrochemical measurements (cyclic voltammetry, 10−500 mV/s, 2×10^{-3} M complex solutions; 0.1 M tetrabutylammonium hexafluorophosphate in acetonitrile) were obtained from a BAS100B system (data analysis with Digisim) with a glassy carbon working, a Pt-wire auxiliary and a $Ag/AgNO_3$ reference electrode; the potential of the Fc^+/Fc couple at a scan rate of 100 $mV \cdot s^{-1}$ lies at 87 mV with $\Delta E = 64$ mV. Mass spectra were recorded with a Finnigan 8400 spectrometer with a nitrobenzyl alcohol matrix for the FAB spectra. Elemental analyses were obtained from the microanalytical laboratory of the University of Heidelberg.

Ligand Syntheses. Piperidones. pL^3: Methylamine (1.9 mL, 22.7 mmol, 40%, in water) and dimethyl acetonedicarboxylate (3.95 g, 22.7 mmol) were added to a cold solution (4 °C) of 1-methylimidazole-2-carbaldehyde (5.0 g, 45.4 mmol) in methanol (40 mL). After stirring at 4 °C for 4 h a yellowish white solid occurred, which was collected by filtration and washed with methanol. Yield 5.63 g (14.4 mmol, 63%) of a white solid. $C_{18}H_{23}N_5O_5$ (389.4): calcd. C 55.52, H 5.95, N 17.98; found C 55.36, H 5.97, N 17.72. ^1H NMR (300 MHz, $CDCl_3$): δ = 1.79 (s, 3 H, N−CH_3), 3.70 (s, 6 H, N_{Im}−CH_3), 3.72 (s, 6 H, OCH_3), 4.47 (d, $^3J_{H,H}$ = 11.5 Hz, 2 H, CH), 4.84 (d, $^3J_{H,H}$ = 11.4 Hz, 2 H, CH-Im), 6.85 (d, $^3J_{H,H}$ = 1.1 Hz, 2 H, CH_{Im}), 6.92 (d, $^3J_{H,H}$ = 1.1 Hz, 2 H, CH_{Im}) ppm. ^{13}C NMR (75.47 MHz, $CDCl_3$): δ = 30.1 (Im−CH_3), 32.6 (NCH_3), 52.4 (NCH), 53.7 (OCH_3), 59.6 (CH), 122.0 (CH_{Im}), 127.6 (CH_{Im}), 143.8 (C_{Im}), 168.7 (Ester), 199.4 (C=O) ppm. FAB^+MS(NBA): *m*/*z* = 412.2 [M + Na^+], 390.2 [MH^+].

pL^4: The piperidone precursor for L^4 {3,5-dimethyl-2,6-dipyridyl-*N*-[2-(pyridyl)methylene]-4-piperidone-3,5-dicarboxylate} was obtained by a dropwise addition of pyridin-2-aldehyde (9.6 mL, 100 mmol), and then picolylamine (5.1 mL, 50 mmol) to an ice-cold solution of dimethyl acetonedicarboxylate (7.2 mL, 50 mmol) in MeOH (30 mL). After 5 min the orange solution was stored in a freezer (−18 °C). The crystallized product was collected after several days, washed with cold EtOH, and recrystallized from ethanol; a further crop could be obtained by evaporation of the filtrate. Total yield (recrystallized) 19.3 g (42 mmol, 84%).

Bispidones. L^3: An aqueous solution of methylamine (40%, 1.1 mL, 13.0 mmol) and aqueous formaldehyde (37%, 2.1 mL, 26 mmol) were added to a suspension of pL^3 (4.84 g, 12.4 mmol) in ethanol (200 mL) . The suspension was stirred under reflux for 2 h and a clear yellow solution emerged. The solvent was removed under low pressure and the remaining yellow-white solid was recrystallized from ethanol. Yield 3.57 g (8 mmol, 65.2%) of a white solid. $C_{21}H_{28}N_6O_5$ (444.5): calcd. C 56.75 , H 6.35 , N 18.90; found C 56.56 , H 6.48 , N 18.48. ^1H NMR (300.13 MHz, $CDCl_3$): δ = 1.67 (s, 3 H, NCH_3), 2.49 (s, 3 H, NCH_3), 3.62 (s, 6 H, OCH_3), 3.72 (s, 6 H, N_{Im}-CH_3), 3.73 (d, $^2J_{H,H}$ = 13.9 Hz, 2 H, N−CH_2−), 4.03 (s, 2 H, NC*H*), 4.63 (d, $^2J_{H,H}$ = 11.7 Hz, 2 H, N−CH_2−), 6.76 (s, 2 H, Im-*H*), 6.96 (s, 2 H, Im-*H*) ppm. ^{13}C NMR (75.47 MHz, $CDCl_3$): δ = 32.7 (NCH_3), 37.0 (NCH_3), 45.2 (NCH_2), 52.3 (OCH_3), 59.5 ($C_{q,Alkyl}$), 63.6 (N*C*H), 120.9 (Ar-*C*), 127.0 (Ar-*C*), 143.9 (Ar-*C*), 169.9 (ester), 202.0 (C=O) ppm.

L^4: Aqueous methylamine (40%, 4.8 mL, 56.7 mmol) and formaldehyde (37%, 9.2 mL, 113.4 mmol) were added to a suspension of pL^4 (21.79 g, 47.3 mmol) in ethanol (250 mL). The suspension was stirred under reflux for 3 h, and a deep-brown solution occurred. The solvent was removed under low pressure and the remaining brown-green solid was recrystallized from ethanol. Yield 6.58 g (12.7 mmol, 27.5%) of a white solid. $C_{28}H_{29}N_5O_5$ (515.6): calcd. C 65.23, H 5.67, N 13.58; found C 64.86, H 5.60, N 13.41. ^1H NMR (300 MHz, $CDCl_3$): δ = 2.20 (s, 3 H, N−CH_3), 2.56 (d, $^2J_{H,H}$ = 11.8 Hz, 2 H, −CH_2−), 2.98 (d, $^2J_{H,H}$ = 11.8 Hz, 2 H, −CH_2−), 3.72 (s, 8 H, OCH_3 + CH_2-Py), 5.42 (s, 2 H, CH-Py), 6.76 (d, $^3J_{H,H}$ = 7.7 Hz, 1 H, Py-H), 6.97 (t, $^3J_{H,H}$ = 5.7 Hz, 1 H, Py-H), 7.13 (t, $^3J_{H,H}$ = 6.0 Hz, 2 H, Py-H), 7.38 (t, $^3J_{H,H}$ = 7.6 Hz, 2 H, Py-H), 7.68 (t, $^3J_{H,H}$ = 7.6 Hz, 2 H, Py-H), 8.06 (d, $^3J_{H,H}$ = 7.6 Hz, 1 H, Py-H), 8.43 (d, $^3J_{H,H}$ = 4.6 Hz, 1 H, Py-H), 8.47 (d, $^3J_{H,H}$ = 4.4 Hz, 2 H, Py-H) ppm. ^{13}C NMR (75.47 MHz, $CDCl_3$): δ = 44.3 (N−CH_3), 52.3 (O−CH_3), 57.2 (CH_2-Py), 60.7 (CH_2−N), 62.3 (CH-Py), 70.2 ($C_{q,Alkyl}$), 121.5, 122.5, 123.7, 124.3, 135.4, 135.7, 148.9 ($C_{Ar,C-N}$), 149.0 ($C_{Ar,C-N}$), 156.5 ($C_{q,Ar}$), 158.8 ($C_{q,Ar}$), 168.6 (ester), 203.4 (C=O) ppm. FAB^+MS (Nibeol): *m*/*z* = 538.3 [M + Na^+], 516.3 [MH^+].

L^5: 2-(Aminomethyl)pyridine (4.3 g, 39.7 mmol) and aqueous formaldehyde (37%, 6.5 mL, 79.4 mmol) were added to a suspension of pL^1 (12.71 g, 33.1 mmol) in ethanol (200 mL). The suspension was stirred under reflux for 30 min and a clear brown solution occurred. The solvent was removed under low pressure, and the remaining green/brown solid was recrystallized from ethanol. Yield 4.2 g (8.1 mmol, 25.2%) of a white solid. $C_{28}H_{29}N_5O_5$ (515.6): calcd. C 65.23, H 5.67, N 13.58; found C 64.95, H 5.62, N 13.48. ^1H NMR (300 MHz, $CDCl_3$): δ = 1.94 (s, 3 H, N−CH_3), 2.68 (d, $^2J_{H,H}$ = 12.1 Hz, 2 H, −CH_2−), 3.14 (d, $^2J_{H,H}$ = 11.9 Hz, 2 H, −CH−), 3.57 (s, 2 H, CH_2-Py), 3.76 (s, 6 H, OCH_3), 4.66 (s, 2 H, CH-Py), 7.09 (t, $^3J_{H,H}$ = 1.5 Hz, 2 H, Py-H), 7.21 (t, $^3J_{H,H}$ = 6.0 Hz, 1 H, Py-H), 7.33 (d, $^3J_{H,H}$ = 7.6 Hz, 1 H, Py-H), 7.50 (t, $^3J_{H,H}$ = 1.7 Hz, 2 H, Py-H), 7.66 (t, $^3J_{H,H}$ = 7.5 Hz, 1 H, Py-H), 7.92 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, Py-H), 8.45 (d, $^3J_{H,H}$ = 4.0 Hz, 2 H, Py-H), 8.62 (d, $^3J_{H,H}$ = 4.8 Hz, 1 H, Py-H) ppm. ^{13}C NMR (75.47 MHz, $CDCl_3$): δ = 42.9 (N−CH_3), 52.3 (O−CH_3), 58.5 (CH_2−N), 62.1 (CH-Py), 63.3 (CH_2-Py), 73.6 ($C_{q,Alkyl}$), 122.2, 122.7, 123.6, 124.3, 136.1, 148.9 ($C_{Ar,C-N}$), 149.3 ($C_{Ar,C-N}$), 156.7

($C_{q,Ar}$), 158.2 ($C_{q,Ar}$), 168.3 (ester), 203.2 (C=O) ppm. FAB^+MS (Nibeol): m/z = 538.3 [M + Na^+], 516.3 [MH^+].

Syntheses of the Copper(II) Compounds. General Method: A solution of the metal salt (1 mmol) in methanol (1 mL) was added to a solution of of the ligand (1 mmol) in acetonitrile (1 mL) . The mixture was stirred for 24 h, the solvent was then evaporated to dryness and the resulting solid washed twice with EtOAc, and dried in vacuo. Note that the ε values given below, specifically for the BF_4^- salts, are not necessarily of pure compounds, with various coordinated solvent molecules, e.g. OH_2, OMe, see text.

[Cu(L^3)(Cl)]Cl: $C_{21}H_{28}Cl_2CuN_6O_5{\cdot}2H_2O$ (614.97): calcd. C 41.01, H 5.24, N 13.63; found C 41.33, H 5.30, N 13.89. FAB^+MS (NBA): m/z = 542.1 ([Cu(L^3)(Cl)]H^+), 560.1 ([Cu(L^3)(Cl)(H_2O)]H^+). IR: ν̃ = 3198 (m, OH), 3096 (w), 2948 (m), 1732 (s), 1540 (w), 1500 (m), 1282 (s), 1272 (s), 1070 (m), 760 cm^{-1} (w). UV/Vis (MeOH): λ (ε, $cm^2{\cdot}mol^{-1}$) = 638 (96), 279 (2520), 237 nm (2340).

[Cu(L^3)](BF_4)$_2$: M.p. 181 °C. $C_{21}H_{28}B_2CuF_8N_6O_5{\cdot}2H_2O$ (717.67): calcd. C 35.14, H 4.49, N 11.71; found C 35.15, H 4.94, N 11.15. FAB^+MS (NBA): m/z = 525.3 ([Cu(L^3)(H_2O)]H^+). $E_{1/2}$ (MeCN) = −440 mV. IR: ν̃ = 3502 (s), 3400 (s), 3136 (m), 2958 (m), 1728 (s), 1544 (w), 1504 (m), 1452 (m), 1274 (s), 1040 (s), 758 cm^{-1} (m). UV/Vis (MeOH): λ (ε, $cm^2{\cdot}mol^{-1}$) = 668 (51), 334 (299), 260 (1088), 237 nm (2289).

[Cu(L^4)(Cl)]Cl: $C_{28}H_{29}Cl_2CuN_5O_5{\cdot}H_2O$ (668.03): calcd. C 49.51, H 4.62, N 10.69; found C 49.53, H 4.89, N 11.05. FAB^+MS (NBA): m/z = 631.2 ([Cu (L^4)(Cl)(OH_2)]H^+). IR: ν̃ = 3376 (s, OH), 3101 (w), 2952 (m), 1724 (s), 1603 (m), 1465 (m), 1423), 1247 (s), 1046 (m), 789 (m), 647 (w), 532 cm^{-1} (w). UV/Vis (MeOH): λ (ε, $cm^2{\cdot}mol^{-1}$) = 714 (29), 260 nm (3035).

[Cu(L^4)](BF_4)$_2$: $C_{28}H_{29}B_2CuF_8N_5O_5{\cdot}2H_2O$ (788.75): calcd. C 42.64, H 4.22, N 8.88; found C 42.86, H 4.32, N 9.01. $E_{1/2}$ = −489 mV in acetonitrile. IR: ν̃ = 3386 (s), 3098 (w), 2952 (m), 1726 (s), 1605 (m), 1465 (m), 1423 (m), 1247 (s), 1046 (m), 786 (m), 645 (w), 534 cm^{-1} (w). UV/Vis (MeOH): λ (ε, $cm^2{\cdot}mol^{-1}$) = 704 (69), 260 nm (3135).

[Cu (L^5)(Cl)]Cl: $C_{28}H_{29}Cl_2CuN_5O_5{\cdot}2H_2O$ (686.04): calcd. C 49.02, H 4.85, N 10.21; found C 49.06, H 4.81, N 10.27. FAB^+MS (NBA): m/z = 631.1 ([Cu(L^5)(Cl)(H_2O)]H^+). UV/Vis (MeOH): λ (ε, $cm^2{\cdot}mol^{-1}$) = 633 (55), 262 (2694), 242 nm (2535).

[Cu(L^5)](BF_4)$_2$: $C_{28}H_{29}B_2CuF_8N_5O_5{\cdot}2H_2O$ (788.75): calcd. C 42.64, H 4.22, N 8.88; found C 42.37, H 4.32, N 8.80. FAB^+MS(NBA): m/z = 596.3 ([Cu(^{5})(OH_2)]H^+).

$E_{1/2}$ (MeCN) = −603 mV. IR: ν̃ = 3444 (s), 3084 (m), 2956 (m), 1730 (s), 1608 (m), 1460 (w), 1438 (m), 1256 (s), 1040 (vs), 764 cm^{-1} (m). UV/Vis (MeOH): λ (ε, $cm^2{\cdot}mol^{-1}$) = 621 (71), 262 (3483), 247 nm (3337).

Catalysis: The aziridination reactions were performed by stirring mixtures of PhINTs (0.4, 0.5, 0.6 mmol), styrene (1.0 mL) and the copper catalyst (5, 3.5, 1.7 mol % vs. PhINTs) in anhydrous CH_3CN (2.0 mL) under a dry argon atmosphere at 25 °C (the catalyst and PhINTs concentrations were varied to determine the maximum TON, see Results and Discussion; all results reported are averages of at least three experiments). For the studies with the Cu^I catalysts care was taken to do the experiments under strictly anaerobic conditions. After 7 h the green solutions were passed through a short column of neutral alumina to remove the copper species, eluted with EtOAc (20 mL), and the elutes were evaporated to yield oily residues. These crude mixtures were recrystallized with hexane to produce the pure aziridine products. $C_{15}H_{15}NO_2S$ (273.3): calcd. C 65.91, H 5.53, N 5.12; found C 65.84, H 5.56 , N 5.14. ^1H NMR (300 MHz, $CDCl_3$): δ = 2.34−2.42 (m, 4 H), 2.98 (d, $^3J_{H,H}$ = 7.2 Hz, 1 H), 3.77 (dd, $^3J_{H,H}$ = 4.7, $^2J_{H,H}$ = 2.3 Hz, 1 H), 7.10−7.34 (m, 7 H), 7.88 (d, $^3J_{H,H}$ = 6.7 Hz, 2 H) ppm.

Crystal Structure Determination: Crystal data and details of the structure determinations are listed in Table 1. Intensity data were collected at low temperature on a Bruker AXS Smart 1000 diffractometer (Mo-K_α, λ = 0.71073 Å, ω-scan). Absorption corrections were performed (multiple scans of equivalent reflections, SADABS). The structures were solved by direct methods and refined by full-matrix least-squares against F^2 of all data, using SHELXTL 5.1.[33]

All non-hydrogen atoms were refined with anisotropic temperature factors. Hydrogen atoms were located in difference Fourier syntheses and refined isotropically. In [Cu(L^3)(Cl)]Cl one of the ester groups (at C-5) of the bispidine ligand is disordered. [Cu(L^4)(Cl)]Cl crystallizes with a disordered acetonitrile molecule.

Cyanide-Bridged Oligonuclear Complexes Containing Ni-CN-Cu and Pt-CN-Cu Linkages

Marie-Louise Flay[a] and Heinrich Vahrenkamp*[a]

Keywords: Nickel / Platinum / Copper / Cyanide

The central building blocks $Ni(CN)_4^{2-}$ and $Pt(CN)_4^{2-}$ can be combined with one, two or four $Cu^{II}L$ units (L = tren, Me_6tren, tpa) to form di-, tri- and pentanuclear complexes with Ni-CN-Cu and Pt-CN-Cu linkages. Structure determinations of these and the side product [(tren)-Cu–CN–Cu(tren)] $(ClO_4)_2$ reveal mostly linear M-C-N-Cu arrays and *cis*-, *trans*- and star-like arrangements of the CN-Cu units around the central Ni or Pt ions. The $\tilde{\nu}$(CN) IR data for the bridging cyanides show a characteristic hypsochromic effect compared to the data for the free $M(CN)_4^{2-}$ complexes. The absorption bands in the visible spectra of the oligonuclear complexes are shifted to shorter wavelengths than those of the free LCu^{II}-X complexes. The Cu^{II}/Cu^{I} redox steps in the cyclic voltammograms allow the conclusion that there is electronic communication between the external CuL units when they are arranged in a *trans*-orientation at Pt^{II}, but not Ni^{II}, centers.

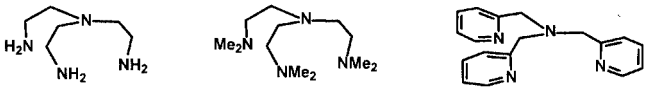
Introduction

In a series of papers[1–6] and a review article[7] we have outlined and justified our research work on cyanide-bridged oligonuclear complexes with chain-like arrangements of metal ions and cyanide ligands. This work, which has also been pursued by the research groups of Haim,[8] Connelly,[9] Vogler,[10] Scandola[11] and Denning,[12] originates from the observation that a bridging cyanide is a good conductor of electronic interactions between the metallic groups attached to it. In this context it is not so much the bulk properties like magnetism, luminescence or electrical conductivity that interest us, but the phenomena which result from metal-metal charge transfer like multi-redox steps, mixed valence and long-range electronic interactions.

For this purpose we have synthesized a series of compounds in which the number of cyanide-bridged metal atoms, their ligation patterns and redox properties, the orientation of the bridging ligand (CN versus NC) and the geometry at the interconnected metal atoms (cis, trans, tetrahedral, square planar, octahedral) have been varied. So far we, like others, have been unable to fully characterize chains with more than three CN-linked metal atoms. The best, though not the only, arrangement for long-range metal-metal interactions was found in trans-configured central $M(CN)_2$ or $M(NC)_2$ units derived from square-planar L_2MX_2 or octahedral L_4MX_2 building blocks. Of these, linear arrays M′(μ-CN)Pt(μ-CN)M′ of organometallic L_nM' units attached to $Pt(CN)_2$ centers were the best objects of study due to their inertness and favourable redox properties.[2]

Based on this we have focused our synthetic work on the complexes $[Pt(CN)_4]^{2-}$ and $[Ni(CN)_4]^{2-}$ as starting materials, to which various external redox-active complex units were to be attached. For the present work we chose copper-containing external units in which copper is in a trigonal-bipyramidal ligand environment due to the fact that both Cu^{I} and Cu^{II} are reasonably stable in this environment. The uncharged tripodal ligands tren, Me_6tren and tpa were used to support the trigonal bipyramidal geometry at copper. While the main purpose of the work was to study linear Cu-NC-Ni-CN-Cu and Cu-NC-Pt-CN-Cu arrays, we were also interested in finding out whether all possible modes of attachment of the copper units to the $M(CN)_4$ centers (one to four such units and cis or trans arrays for two of them) could be realized.



tren Me_6tren tpa

Results and Discussion

$Ni(CN)_4$-Centered Complexes

The first experiments in this series yielded an unexpected result: when $(PPN)_2[Ni(CN)_4]$ was treated with four equiva-

lents of $[Cu(tren)H_2O](ClO_4)_2$ in dimethylformamide, cyanide transfer occurred and the dicopper complex **1** was obtained. It turned out that cyanide transfer is a common feature in these compounds, and could be avoided by using not too polar solvents. Complex **1** with PF_6 counterions has already been described, but not structurally characterized.[13] In addition, the analogous complexes with Me_3tren and Me_6tren ligands have been fully characterized.[14,15]

$$[(tren)Cu-CN-Cu(tren)](ClO_4)_3$$
1

Compound **1** can be considered a reference compound here for structural and spectroscopic comparisons. Its $\tilde{\nu}$(CN) IR absorptions (2182 and 2163 cm^{-1} in KBr) occur at the upper end of the frequency range of all copper compounds described here, and they are also higher than all other reported values for dinuclear M-CN-M′ complexes with organometallic constituents.[1] This means that the $(tren)Cu^{II}$ unit at the C terminus of the cyanide (the only such unit in this paper) is a very poor π-backdonator. The fact that two $\tilde{\nu}$(CN) bands are observed is explained by the existence of two independent complex units in the asymmetric unit of the crystals' unit cell (see below). The spread of the two bands for identical species may serve as a caveat against too detailed discussions of $\tilde{\nu}$(CN) variations in such complexes.

The intended attachment of two L·Cu units to the $Ni(CN)_4$ center could be achieved by adjusting the conditions for (tren)Cu, (Me_6tren)Cu and (tpa)Cu. All three resulting complexes **2**, **3** and **4** were obtained as *trans*-$Ni(CN)_2X_2$ species, i.e. they contain the linear Cu-NC-Ni-CN-Cu arrays. In one case, however, the use of $K_2[Ni(CN)_4]$ instead of $(PPN)_2[Ni(CN)_4]$, and a slight variation of the reaction conditions, yielded a small amount of the *cis*-oriented complex **5**. In contrast to all other new compounds in this paper, which are blue, **5** is blue-green. In one case, namely for L·Cu = (tpa)Cu, the attachment of four L·Cu units was possible: $(PPN)_2[Ni(CN)_4]$ and four equivalents of $[Cu(tpa)CH_3CN](ClO_4)_2$ yielded the pentanuclear complex **6**.

6

$Pt(CN)_4$-Centered Complexes

The chemistry of the $Pt(CN)_4$-centered complexes was not fully analogous to that of the $Ni(CN)_4$-centered ones. For platinum the attachment of only one L·Cu unit was possible, resulting in the dinuclear complex **7**. Complex **7** corresponds to several such dinuclear complexes obtained from $L_2Pt(CN)_2$ species and organometallic building blocks. Its low symmetry is reflected by the occurrence of four $\tilde{\nu}$(CN) bands (see Exp. Sect.) of which the highest one at 2179 cm^{-1} can be assigned to the bridging cyanide.

$$[(tpa)Cu\text{-}NC\text{-}Pt(CN)_3]$$
7

The attachment of two L·Cu units to the $Pt(CN)_4$ center occurred in the trans fashion in all three cases, yielding the trinuclear complexes **8**, **9** and **10**. As expected, these complexes have a higher thermal stability than their nickel-containing analogues **2**, **3** and **4**. Attempts to attach three L·Cu fragments to $[Pt(CN)_4]^{2-}$ failed, despite the fact that such complexes with Cp(dppe)Fe and $Cp(PPh_3)_2Ru$ fragments are known.[16] In the case of (tpa)Cu, however, four such units could again be attached, resulting in pentanuclear **11**. As in the nickel case, all these compounds are blue, and despite their high perchlorate content, specifically in **6** and **11**, none of the compounds was found to be explosive.

Structure Determinations

Dinuclear Complexes

The structure of the dinuclear cation of **1** is shown in Figure 1. The asymmetric unit of the orthorhombic crystals contains two independent half-molecules, each of which is related to the other half by a twofold rotation. This makes C and N of the bridging cyanide indistinguishable and a discussion of the bond lengths for the bridging ligand irrelevant. Yet these bond lengths are close to those in the related complexes with Me_3tren and Me_6tren ligands.[14,15] The most notable feature in the structure of **1** is the bending of the Cu-C-N (or Cu-N-C) arrays, which is moderate yet significant, with angles of 164.7(3) and 170.2(3)°.

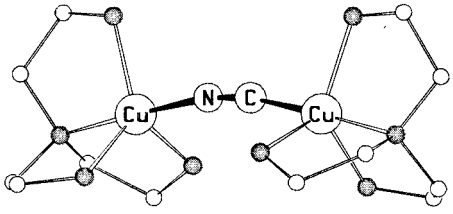

Figure 1. Structure of one of the two independent dinuclear cations of complex **1**; relevant bond lengths: Cu−C or Cu−N 2.008(9) or 1.956(9); C−N 1.134(18) or 1.138(18) Å

The neutral complex **7** also has two formula units in the asymmetric unit and shares the low crystal quality, which is obvious from the high *R* value, and an irregular spread of Pt−C, C−N and Cu−N bond lengths. Thus the structure is mainly a proof of the identity of the complex (Figure 2). Again, there is a slight bending along the Pt-C-N-Cu sequence with Pt−C−N angles of 174(2)° and Cu−N−C angles of 169(2)°. Again there is a closely related and structurally similar reference compound: $[(NH_4)_3Cu\text{-}NC\text{-}Pt(CN)_3]$.[17]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

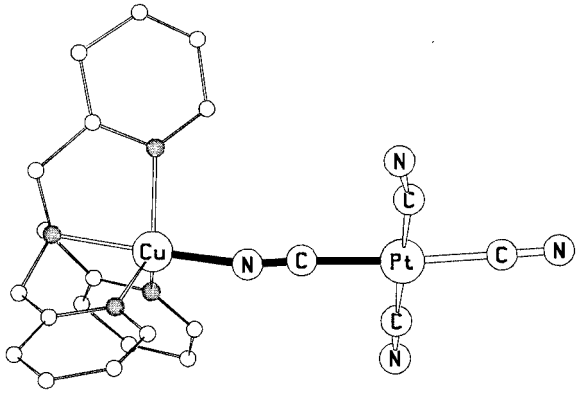

Figure 2. Structure of one of the two independent complex molecules of **7**; relevant bond lengths: Pt−C 1.91(2) and 2.02(2); Cu−N 1.95(2) and 1.94(2); C−N 1.19(3) and 1.09(3) Å.

Trinuclear Complexes

According to our experience the attachment of two ML_n units to $[Ni(CN)_4]^{2-}$ or $[Pt(CN)_4]^{2-}$ leads to trans arrays for steric reasons.[2,16] The *cis*-trinuclear complex **5** is a singular exception to this rule. The complex cation (Figure 3) has twofold symmetry. It is noteworthy that the Ni−C as well as the C−N bond lengths are identical for the terminal and the bridging cyanides. In this complex the bending of the Ni-C-N-Cu array is a means of identifying the C and N atoms of the bridging cyanide: characteristically[1−6] the Ni−C−N angle is close to 180° while the Cu−N−C angle (169°) deviates noticeably from linearity.

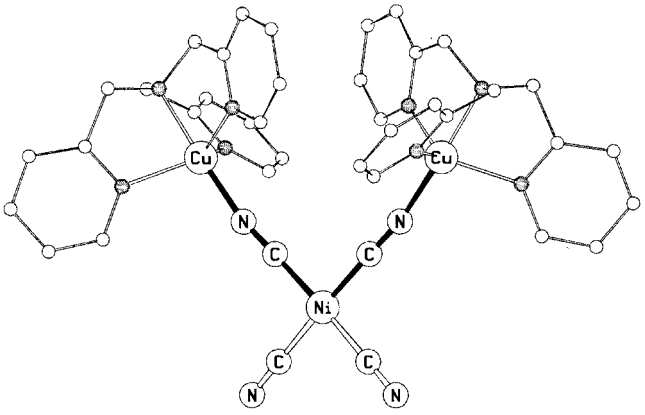

Figure 3. Structure of the trinuclear cation of **5**; relevant bond lengths (Å) and angles (°): Ni−C(term) 1.845(2), Ni−C(br) 1.842(2), C−N(term) 1.163(7), C−N(br) 1.161(7), Cu−N 1.938(5), Ni−C−N(br) 177.5(7), Cu−N−C 168.9(5)

The two $PtCu_2$ complexes **8** and **10** (Figure 4 and 5) can be discussed together. Both contain the Pt center in a virtually ideal square-planar environment, both have the platinum atom on a center of symmetry, both have nearly linear Pt−C−N(bridge) arrays, and in both cases the Cu-N-C array is significantly bent. Again the Pt−C distances are the same for the terminal and the bridging cyanides which seems to indicate that the L·Cu units have rather low σ-acceptor properties. This is reflected by the identical C−N bond lengths for the terminal and bridging cyanides in **10**. These bond lengths differ by 0.08 Å in **8**, which however, like in **7**, may be a reflection of low crystal quality. Most of these features correspond to those of the *trans*-$Pt(CN)_4$ complex with terminal FeCp(dppe) units.[2]

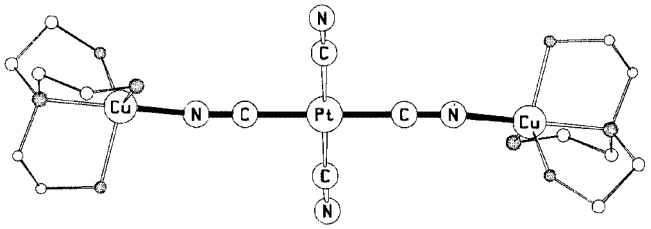

Figure 4. Structure of the trinuclear cation of **8**; relevant bond lengths (Å) and angles (°): Pt−C(term) 1.96(1), Pt−C(br) 1.96(1), C−N(term) 1.12(2), C−N(br) 1.20(2), Cu−N 1.92(1); Pt−C−N(br) 179(1), Cu−N−C 169(1)

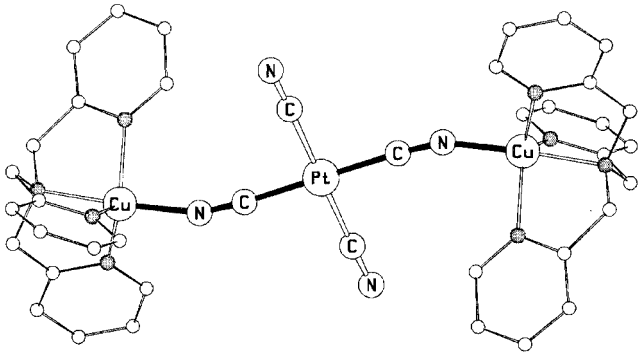

Figure 5. Structure of the trinuclear cation of **10**; relevant bond lengths (Å) and angles (°): Pt−C(term) 1.987(7), Pt−C(br) 1.988(6), C−N(term) 1.142(8), C−N(br) 1.146(8), Cu−N 1.953(5); Pt−C−N(br) 176.0(6), Cu−N−C 160.0(5)

Pentanuclear Complexes

Complexes **6** (Figure 6) and **11** (Figure 7) seem to be the first derivatives of $[Ni(CN)_4]^{2-}$ and $[Pt(CN)_4]^{2-}$ in which all four cyanide ligands are bridging. There are, however, numerous star-like complexes of the type $M(\mu\text{-}CN\text{-}M'L_n)_x$,[7] and the closest relative of **6** and **11** is $[Fe\{CN\text{-}Cu(tpa)\}_6]^{8+}$.[18] While the low crystal quality of **6** renders its structure determination only useful as a product identification, the good crystal quality of **11** allows a meaningful discussion of its molecular dimensions. Complexes **6** and **11** are not isostructural, and only in **6** is the central metal on a center of symmetry. Nevertheless the general appearance of both complexes is quite similar: there is only a small spread of the Ni−C, Pt−C, C−N and Cu−N bond lengths, and these bond lengths correspond closely to those in the trinuclear complexes. There is, however, a variable degree of bending in the Cu-N-C-M-C-N-Cu chains. In **6** one of these chains is linear to a good approximation, the other shows severe bending in a wave-like fashion, as expressed by the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Cu−N−C angle of 162°. In **11** the Cu−N−C angles vary progressively from 176 to 165°, the Pt−C2−N2−Cu2 array is closest to linearity and the Pt−C1−N1−Cu1 array is most distorted.

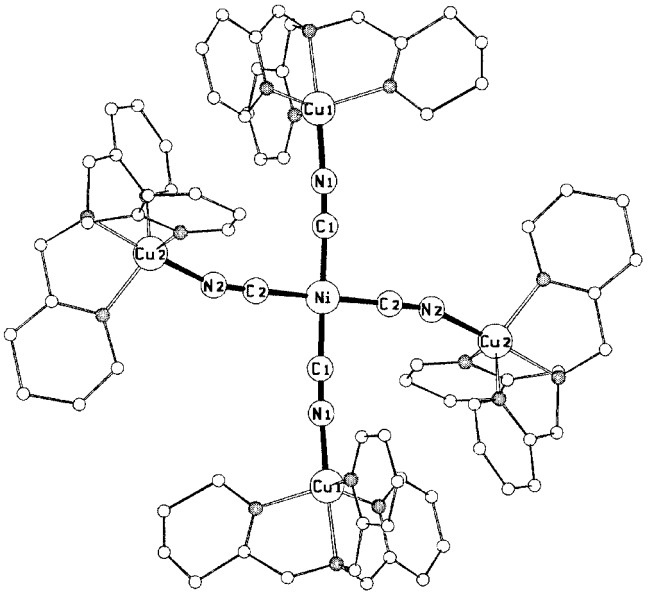

Figure 6. Structure of the pentanuclear cation of **6**; relevant bond lengths (Å) and angles (°): Ni−C1 1.84(2), Ni−C2 1.86(2), C1−N1 1.16(2), C2−N2 1.16(2), Cu1−N1 1.92(2), Cu2−N2 1.94(2); Ni−C1−N1 176.7(14), Ni−C2−N2 178.0(15), Cu1−N1−C1 176.0(18), Cu2−N2−C2 161.9(17)

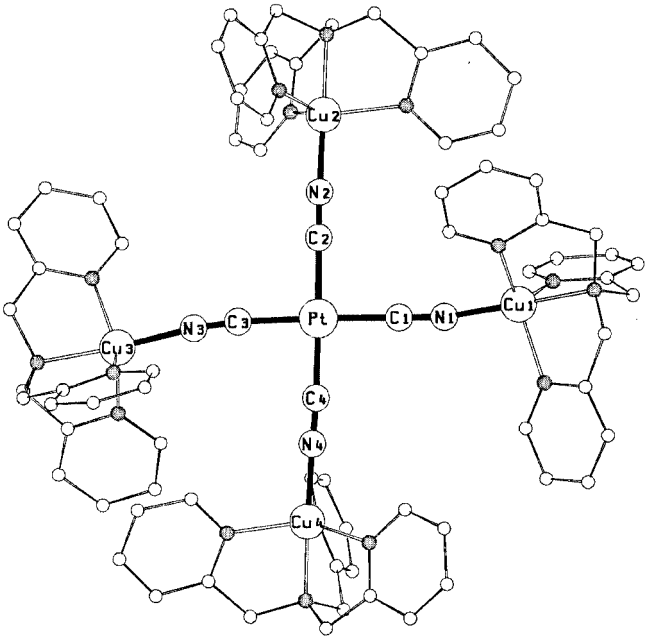

Figure 7. Structure of the pentanuclear cation of **11**; relevant bond lengths (Å) and angles (°): Pt−C1 2.004(6), Pt−C2 1.997(7), Pt−C3 1.995(7), Pt−C4 1.970(7), C1−N1 1.121(8), C2−N2 1.135(8), C3−N3 1.112(8), C4−N4 1.139(8), Cu1−N1 1.940(6), Cu2−N2 1.935(6), Cu3−N3 1.949(6), Cu4−N4 1.948(6); Pt−C1−N1 179.4(7), Pt−C2−N2 179.0(6), Pt−C3−N3 174.0(6), Pt−C4−N4 176.0(7), Cu1−N1−C1 165.2(6), Cu2−N2−C2 176.2(6), Cu3−N3−C3 173.8(6), Cu4−N4−C4 170.4(7)

Altogether it must be stated that the structures of these copper-containing complexes yield only few data for comparative discussions, unlike those of the organometallic complexes that we investigated previously.[1−6] None of the pertinent bond lengths Pt−C, Ni−C, C−N or Cu−N varies significantly with the number of bridging cyanides or the geometry of the complexes. This seems to indicate that the copper(II) ion in those compounds is neither a good π-donor nor a strong σ-acceptor. Thus the Ni−C and Pt−C π-backbonding, which is reflected in the Ni−C, Pt−C and C−N bond lengths, does not vary much, accounting for the similar features of all complexes which were structurally characterized here.

IR Spectroscopy

IR spectroscopy is a more sensitive probe than structure determination for bonding variations in M-CN-M′ arrays. Previously we had observed for $L_2Pt(\text{-CN-M}')_2$ systems with organometallic building blocks M′ that the increase of $\tilde{\nu}$(CN) upon coordination of the second metal (which is a general phenomenon due to the kinematic effect) is modulated in a typical way by the π-donor and σ-acceptor properties of the attached metals.[1,2] As a rule the electron withdrawal by the σ-acceptor at the CN's N terminus is compensated by an increased π-donation from the metal at the C terminus, resulting in a reduction in the increase in $\tilde{\nu}$(CN).[2] Table 1 shows that similar effects are also observed here.

Table 1. IR data for the tri- and pentanuclear complexes [in KBr; $\tilde{\nu}$(CN) in cm^{-1}]

Complex	Backbone	CN_{bridge}	$CN_{term.}$
$[Ni(CN)_4]^{2-}$			2112
$[Pt(CN)_4]^{2-}$			2123
2	*trans*-$Ni(CN\text{-}Cu)_2$	2176	2125
3	*trans*-$Ni(CN\text{-}Cu)_2$	2172	2135
4	*trans*-$Ni(CN\text{-}Cu)_2$	2159	2126
5	*cis*-$Ni(CN\text{-}Cu)_2$	2158	2137, 2126
6	$Ni(CN\text{-}Cu)_4$	2175	
8	*trans*-$Pt(CN\text{-}Cu)_2$	2165	2139
9	*trans*-$Pt(CN\text{-}Cu)_2$	2182	2147
10	*trans*-$Pt(CN\text{-}Cu)_2$	2169	2137
11	$Pt(CN\text{-}Cu)_4$	2196	

For all tri- and pentanuclear complexes the IR bands of the terminal and bridging CN ligands can be clearly discerned. The band positions for the terminal cyanides are only slightly different from those of the $[M(CN)_4]^{2-}$ complexes. In contrast, $\tilde{\nu}$(CN) for the bridging cyanides rises considerably, in fact much more than for the analogous complexes with external organometallic building blocks.[2,16] The number of the CN absorptions corresponds to the symmetry of the complexes. This is also the basis for the assignment of the *trans*-symmetry for **4**, while the *cis*-symmetry of its isomer **5**, which was confirmed by the structure determination, is also reflected in the higher number of its $\tilde{\nu}$(CN) IR bands.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The $\tilde{\nu}$(CN) values due to the CN bridges can be interpreted satisfactorily by a variable degree of π back-donation from the Ni and Pt centers. Compared to the $[M(CN)_4]^{2-}$ references the values are raised by 42−64 cm^{-1} for the trinuclear and by 63 and 73 cm^{-1} for the pentanuclear complexes. In the pentanuclear complexes the π-backbonding capacity of the central metals has to be shared by four CN ligands and hence their $\tilde{\nu}$(CN) values are lowered to a lesser degree than those of the trinuclear complexes (after the raising due to the kinematic effect). Among the trinuclear complexes those with the Cu(tpa) units have (on average) the lowest $\tilde{\nu}$(CN) values. This sheds light on the origin of the variable π-backdonation: the aromatic tripod tpa provides less electron density to the copper ions than the aliphatic tripods tren and Me_6tren. Hence the Cu(tpa) unit is a better σ-acceptor, which in turn forces the central metal to provide more π back-donation. As mentioned above, these effects are smaller here than for the analogous complexes with organometallic constituents.[2,16] Yet, unlike the data from the structure determinations, they have yielded a consistent interpretation of the electronic situation of the various M-CN-Cu groupings.

Electronic Spectra

Cu^{II} in a trigonal-bipyramidal ligand environment gives rise to two d-d transitions in the visible or NIR range which are the origin of its bluish colours.[19] In practice one broad band at 700−800 nm with a more or less pronounced shoulder on the higher energy side is observed.[20] This is also the case here. Table 2 lists the data for the main absorption bands.

4	*trans*-Ni(CN-Cu)$_2$	755(550)
5	*cis*-Ni(CN-Cu)$_2$	745(670)
10	*trans*-Pt(CN-Cu)$_2$	840(2100)
6 Ni(CN-Cu)$_4$		760(1100)
11 Pt(CN-Cu)$_4$		840(2100)

Three features are noticeable. First, all absorptions for the cyanide-bridged complexes occur at higher energies than those for the cyanide-free L·Cu-X reference compounds. Second, nickel induces a much stronger band shift than platinum. Third, the band positions are independent of the number of L·Cu units attached to the $M(CN)_4$ center. A detailed discussion of these phenomena would require quantum mechanical calculations. Qualitatively, it can be stated, however, that the cyanide ligand, even in its isocyanide orientation, exerts a moderately strong ligand field to the L·Cu unit and that this ligand field is modulated strongly by the central metal. In terms of long-range metal-metal interactions there seems to be no effect, since only the type of connectivity (e.g. Ni-CN-Cu) but not the number of such connectivities determines the energy of the electronic transition.

Considering the fact that the Cu/Pt complexes contain Pt^{II} as a reducing and Cu^{II} as an oxidizing metal, one might envisage the occurrence of a Pt^{II} to Cu^{II} MMCT absorption. Actually the reverse charge transfer, with Pt^{IV} as acceptor, has been observed in related Fe/Pt complexes.[21] However, in the measurement window from 300 to 2500 nm no feature indicative of such a MMCT could be observed.

Electrochemistry

Cyclic voltammetry is the best method for evaluating remote metal-metal interactions in ligand-bridged systems. It has allowed us to show for the first time that there is directionality in such interactions, i.e. in $L_2Pt(CN\text{-}M')$ systems they occur for the linear [*trans*-$Pt(CN)_2$], but not for the bent [*cis*-$Pt(CN)_2$] array.[2] This was one of the reasons for the present study: it could be expected that the inert $[M(CN)_4]^{2-}$ centers would ensure electrochemical stability for their oligonuclear derivatives, and one could hope to obtain isomeric cis and trans complexes. Both expectations were fulfilled, albeit only partially. Table 3 lists the electrochemical data that were obtained.

Table 3. Electrochemical data for the Cu(tpa) complexes (in CH_3CN, scan rate 100 mV/s, potentials vs. Ag/AgCl)

Complex	Backbone	$E_{1/2}$ (red)
$[Cu(tpa)CH_3CN](ClO_4)_2$		−0.05 (rev.)
4	*trans*-Ni(CN-Cu)$_2$	−0.30 (irrev.)
5	*cis*-Ni(CN-Cu)$_2$	−0.24 (irrev.)
10	*trans*-Pt(CN-Cu)$_2$	−0.13, −0.26 (rev.)
6 Ni(CN-Cu)$_4$		−0.10, −0.33 (quasirev.)
11 Pt(CN-Cu)$_4$		−0.10, −0.29 (rev.)

It turned out that the tren and Me_6tren complexes decomposed during the cyclovoltammetric experiments. The tpa complexes yielded satisfying cyclic voltammograms, the most informative of which is shown in Figure 8. All oligonuclear complexes are more difficult to reduce than the mononuclear reference compound, corresponding to the fact that the cyanometalate "ligand" $[M(CN)_4]^{2-}$ increases the electron density at copper. Likewise, the nickel-containing complexes are more difficult to reduce than the platinum-containing ones, which may reflect the different electron-releasing properties of these two metals. Although one might want to discuss cis-trans effects for the two isomeric

nickel complexes **4** and **5**, the irreversible nature of their redox processes prevents this.

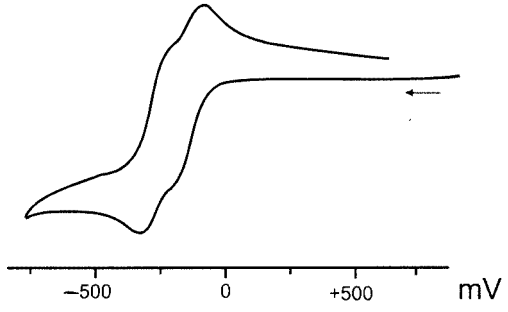

Figure 8. Cyclic voltammogram of complex **10** (in CH_3CN, scan rate 100 mV/s, potentials vs. Ag/AgCl)

The most important observation from the electrochemical measurements is the splitting of the redox wave of the *trans*-Pt(CN-Cu)$_2$ complex **10**. This is proof of the long-range interaction between the two copper ions across two cyanide bridges over a distance of about 10 Å. The number of proven such interactions is still quite small, as they require a redox-inert central metal.[1−12] So far we have observed this interaction only for *trans*-configured trinuclear complexes with central L_2Pt,[2] (Pc)Fe[4] and (salen)M units [M = Cr^{III} or Co^{III}].[6] Like **10**, the pentanuclear complexes **6** and **11** show two redox steps in the reduction of their four Cu(tpa) units. Their separation is larger than the typical one for M′-NC-M-CN-M′ systems (0.05−0.15 V), and the two steps must each represent two-electron reductions. We propose that this again reflects remote metal-metal interactions, both along the two linear Cu-NC-M-CN-Cu arrays, and that the larger potential separation reflects the fact that two electrons are already injected in the first redox step. However, it cannot be excluded that in the first step both copper ions of one linear Cu-NC-M-CN-Cu array are reduced and then the remaining two.

The splitting of the redox waves for **6**, **10** and **11** raised hopes that mixed-valent species might be obtained by partial reduction of the complexes, which might then be investigated for long-range MMCT by UV/Vis-NIR spectroscopy. So far, however, our attempts to achieve this have been unsuccessful.

Conclusions

This work has again shown that square-planar tetracyanometalates are good building blocks for oligonuclear cyanide-bridged complexes that show long-range metal-metal interactions. Between one and four external L·Cu units could be attached to the Ni(CN)$_4$ and Pt(CN)$_4$ centers, and the resulting star-like M(CN-Cu)$_4$ complexes are the first of their kind. The structure determinations have shown that the Cu-NC-M-CN-Cu arrays have a good degree of linearity, but in some cases are noticeably bent at the nitrogen atoms.

The IR absorptions of the C≡N vibrations have allowed some conclusions to be drawn on the electronic situation of the M-CN-Cu arrays. The L·Cu units seem to be both weaker σ-acceptors and π-donors than the organometallic units investigated previously. As a result the kinematic effect is the dominating one in determining the $\tilde{\nu}$(CN) values, and π-backbonding from platinum or nickel to the CN ligands is small, with the effect that the CN IR bands occur at rather high energies.

The electrochemical measurements have again proved the presence of remote metal-metal interactions due to the fact that the complexes containing Cu(tpa) units yield useful cyclic voltammograms. As observed previously, the light central metal (Ni) does not allow the detection of long-range Cu−Cu interactions by means of a splitting of the Cu^{II}/Cu^{I} redox waves. With platinum at the center, however, this splitting occurs. Its order of magnitude corresponds to that previously observed for trinuclear complexes with external organometallic units, thereby supporting the reasonable notion that it is the central and not the external metal unit which controls the long-range metal-metal interactions.

Experimental Section

General: The general working and measuring procedures and the syntheses of the cyanometalates are listed in refs.[1,2] The copper reagents [Cu(tren)H_2O](ClO$_4$)$_2$ (**A**),[22] [Cu(Me$_6$tren)H_2O](ClO$_4$)$_2$ (**B**)[22] and [Cu(tpa)CH_3CN](ClO$_4$)$_2$ (**C**)[23] were prepared as described.

1: A solution of complex **A** (140 mg, 0.33 mmol) in 20 mL of dimethylformamide was added droppwise with stirring into a solution of (PPN)$_2$[Ni(CN)$_4$] (100 mg, 0.08 mmol) in 20 mL of dimethylformamide. The mixture was stirred for 2 h, evaporated to 10 mL and layered with diethyl ether. After one week 45 mg (68%) of **1** had separated as blue crystals, m.p. 180 °C (dec.). $C_{13}H_{36}Cl_3Cu_2N_9O_{12}$·DMF (743.93 + 73.10): calcd. C 23.52, H 5.30, N 17.14; found C 23.48, H 5.28, N 17.18.

2: A solution of complex **A** (96 mg, 0.23 mmol) in 20 mL of methanol was added dropwise with stirring into (140 mg, 0.11 mmol) of (PPN)$_2$[Ni(CN)$_4$] in 20 mL of methanol, upon which a blue precipitate was formed. After 2 h the precipitate was filtered off and washed with dichloromethane and then dissolved in a minimum amount of dimethylformamide. Layering with diethyl ether yielded, within one week, 53 mg (60%) of **2** as a blue powder, m.p. 190 °C (dec.) (the crystalline raw product lost its solvent of crystallization upon drying). $C_{16}H_{36}Cl_2CuN_{12}NiO_8$ (781.23): calcd. C 24.59, H 4.64, N 21.52; found C 24.51, H 4.40, N 21.29.

3: A solution of complex **B** (100 mg, 0.194 mmol) in 20 mL of acetonitrile was added dropwise with stirring to a solution of (PPN)$_2$[Ni(CN)$_4$] (120 mg, 0.97 mmol) in 20 mL of acetonitrile. After 10 h of stirring the solvent was removed in vacuo and the residue washed with dichloromethane. Workup as before for **2** yielded 15 mg (15%) of **3** as a blue powder, m.p. 175 °C (dec.). $C_{28}H_{60}Cl_2Cu_2N_{12}NiO_8$·DMF (949.33 + 73.10): calcd. C 36.41, H 6.60, N 17.80; found C 36.33, H 6.84, N 16.49.

4: A solution of complex **C** (96 mg, 0.16 mmol) in 30 mL of methanol was added dropwise with stirring to a solution of (PPN)$_2$[Ni(CN)$_4$] (100 mg, 0.08 mmol) in 20 mL of methanol at 0

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

°C. After 2 h of stirring the resulting precipitate was filtered off and dried in vacuo. Dissolving in acetonitrile and layering with diethyl ether yielded, within one week, 30 mg (35%) of **4** as blue crystals, m.p. 215 °C (dec.). $C_{40}H_{36}Cl_2Cu_2N_{12}NiO_8$ (1069.49): calcd. C 44.92, H 3.39, N 15.71; found C 45.10, H 3.14, N 15.71.

5: A solution of complex **C** (255 mg, 0.43 mmol) in 50 mL of methanol was added dropwise slowly with stirring to a solution of $K_2[Ni(CN)_4]$ (104 mg, 0.43 mmol) in 40 mL of water/methanol (1:1). After 2 h of stirring at 0 °C and subsequent filtration the filtrate was evaporated to dryness. The residue was dissolved in acetonitrile, filtered and the solvents evaporated to dryness again. Dissolving the residue in a minimum amount of acetonitrile and layering with diethyl ether produced, within one week, a mixture of blue-green and colourless crystals. The blue-green crystals were separated manually, and recrystallized again from acetonitrile layered with diethyl ether, resulting in 20 mg (4%) of **5** as blue-green crystals, m.p. 230 °C (dec.). $C_{40}H_{36}Cl_2Cu_2N_{12}NiO_8$ (1069.49): calcd. C 44.92, H 3.39, N 15.71; found C 44.25, H 3.85, N 15.38.

6: Like **4** from $(PPN)_2[Ni(CN)_4]$ (30 mg, 0.24 mmol) and **C** (57 mg, 0.96 mmol). Yield 32 mg (61%) of **6** as blue crystals, m.p. 255 °C (dec.). $C_{76}H_{72}Cl_6Cu_4N_{20}NiO_{24}$ (2175.12): calcd. C 41.97, H 3.34, N 12.88; found C 41.85, H 3.18, N 12.44.

7: A solution of complex **C** (22 mg, 0.04 mmol) in 10 mL of methanol was added dropwise with stirring to a solution of $(PPN)_2[Pt(CN)_4]$ (51 mg, 0.04 mmol) in 10 mL of dichloromethane. After 12 h of stirring the solvent was removed in vacuo, the residue washed with dichloromethane and dried in vacuo. Dissolving in a minimum amount of acetonitrile and layering with diethyl ether yielded, within one week, 9 mg (37%) of **7** as blue crystals, m.p. 204 °C. $C_{22}H_{18}CuN_8Pt$ (653.06): calcd. C 40.46, H 2.78, N 17.16; found C 39.15, H 2.45, N 16.78.

8: A solution of complex **A** (143 mg, 0.34 mmol) in 20 mL of methanol was added dropwise with stirring to a solution of $(PPN)_2[Pt(CN)_4]$ (213 mg, 0.17 mmol) in 20 mL of methanol. After 2 h of stirring the resulting precipitate was filtered off, washed with dichloromethane and dissolved in 5 mL of dimethylformamide, which was layered with diethyl ether. After one week **8** had separated as blue crystals, which crumbled upon drying in vacuo. 100 mg (66%) of solvent-free **8** remained as a blue powder, m.p. 190 °C (dec.). $C_{16}H_{36}Cl_2Cu_2N_{12}O_8Pt$ (917.70): calcd. C 20.94, H 3.95, N 18.32; found C 20.70, H 3.81, N 17.92.

9: Like **3** from **B** (237 mg, 0.45 mmol) and $(PPN)_2[Pt(CN)_4]$ (294 mg, 0.21 mmol). Yield 45 mg (18%) of **9** as a blue powder, m.p. 180 °C (dec.). $C_{28}H_{60}Cl_2Cu_2N_{12}O_8Pt{\cdot}DMF$ (1085.93 + 73.10): calcd. C 32.13, H 5.83, N 15.71; found C 32.41, H 5.73, N 14.47.

10: Like **4** from **C** (129 mg, 0.22 mmol) and $(PPN)_2[Pt(CN)_4]$ (150 mg, 0.11 mmol). Yield 75 mg (57%) of **10** as blue crystals, m.p. 275 °C. $C_{40}H_{36}Cl_2Cu_2N_{12}O_8Pt$ (1205.88): calcd. C 39.84, H 3.01, N 13.94; found C 39.83, H 2.99, N 13.87.

11: Like **4** from **C** (97 mg, 0.16 mmol) and $(PPN)_2[Pt(CN)_4]$ (54 mg, 0.04 mmol). Yield 62 mg (64%) of **11** as blue crystals, m.p. 200 °C (dec.). $C_{76}H_{72}Cl_6Cu_4N_{20}O_{24}Pt{\cdot}2CH_3CN$ (2311.51 + 82.10): calcd. C 40.14, H 3.25, N 12.87; found C 40.05, H 3.13, N 12.85.

Structure Determinations:[24] Crystals were obtained from the reaction mixtures. Diffraction data were recorded at room temp. with a Bruker Smart CCD diffractometer fitted with a molybdenum tube (Mo-K_α, λ = 0.7107 Å) and a graphite monochromator and subjected to empirical absorption corrections. The structures were solved by direct methods and refined anisotropically with the SHELX program suite.[25] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5-times those of

Metal-Controlled Stereoselectivity in Complex Formation: Assembly of Tetranuclear Copper(I) Complexes with Four Stereogenic Nitrogen Donor Functions in all-(*R*) and all-(*S*) Configurations

Jörg Schneider,[b,c] Martin Köckerling,[b] Rodion Kopitzky,[b] and Gerald Henkel*[a]

Dedicated to Professor Dieter Sellmann

Keywords: Copper / Chirality / N ligands / S ligands / Metal-controlled stereoselectivity

The reaction of *N*,*N*′-dialkyl-3,7-diazanonane-1,9-dithiolate ($N_2^RS_2$) ligands (R = Me, Et) with monovalent copper resulted in the formation of the chiral complexes $[Cu_4(N_2^{Me}S_2)_2]$ (**1**) and $[Cu_4(N_2^{Et}S_2)_2]$ (**2**) which were characterised by means of X-ray diffraction and spectroscopic techniques. They contain copper atoms in both linear {S–Cu–S} fragments, which act as linkers between mononuclear $[Cu(N_2^RS_2)]^-$ subsites, and in $\{CuS_2N_2\}$ units within these building blocks, which can be described as incomplete coordination octahedra of unusual design. Due to favourable interplay between the spatial demands of the ligand system and the electronic requirements of the copper atom, the nitrogen donor atoms within the $[Cu(N_2^RS_2)]^-$ metallo ligands are restricted to identical absolute configurations. The combination of two $[Cu(N_2^RS_2)]^-$ metallo ligands with two further Cu^I ions to give the tetranuclear complexes **1** or **2** via S–Cu–S bridges underlies stereochemical control, resulting in optically active systems with (*R*,*R*,*R*,*R*) and (*S*,*S*,*S*,*S*) configurations. Consequently, metallo ligands in their enantiomeric forms cannot combine via S–Cu–S bridges to form optically inactive *meso* complexes with the (*R*,*R*,*S*,*S*) configuration.

Introduction

For most aerobic organisms the enzyme "cytochrome-c oxidase" is involved in the final step of cell respiration. This enzyme contains the heterodimetallic Cu_B-Fe_{a3} and the homodimetallic mixed-valence Cu_A centre. The copper atoms of the latter are coordinated by two bridging cysteinyl groups and one terminally bonded histidine residue each. Additional weakly bonded terminal S(Met) and O(Glu) donor functions complete the coordination spheres around the copper atoms, which are ca. 2.45 Å apart.[1] Dinuclear copper complexes containing N/S donor sets have been synthesised as models for specific properties of the Cu_A centre.[2]

This subject has stimulated our investigations on heteroleptic copper thiolate complexes with ligands containing both sulfur and prochiral nitrogen donor functions.[3] The work described here focuses on the reactions of *N*,*N*′-dialkyl-3,7-diazanonane-1,9-dithiolate ($N_2^RS_2$), which is widely used to stabilise square-planar N_2S_2 [4] or trigonal-bipyramidal N_2S_2S'[5] ligand fields, with Cu^I (a metal known to avoid such coordination situations) resulting in the formation of tetranuclear complexes.

Herein we present the first report of two pathways for the preparation of tetranuclear Cu^I thiolate complexes with $N_2^RS_2$ ligands that stabilise severely distorted pseudo-tetrahedral N_2S_2 ligand fields. Their metal atom frameworks can be derived from the frequently observed regular metal tetrahedron present, for example in $[Cu_4(SCH_2CH_2S)_3]^{2-}$,[6] by elongation of one M−M edge, leading to a completely planar situation yet unknown in copper thiolate chemistry though other derivatives with two elongated edges[7] or with more general rhombohedral[8] or less regular quadrilateral shapes[9] are known. Both $[Cu_4(N_2^{Me}S_2)_2]$ (**1**) and $[Cu_4(N_2^{Et}S_2)_2]$ (**2**), with coordination numbers of 2 and 4 for the metal atoms resulting in CuS_2 and CuN_2S_2 coordination sites, have been synthesised and characterised by means of X-ray structure analysis and spectroscopic techniques.

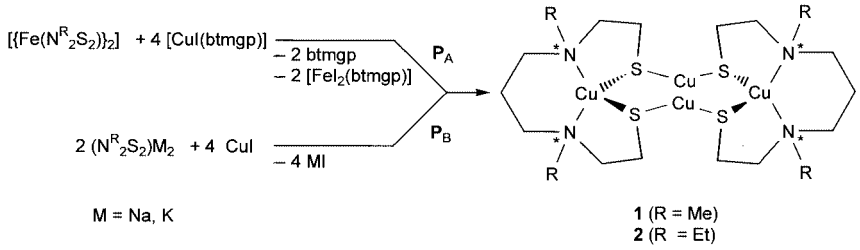

Scheme 1. Pathways for the synthesis of the complexes **1** and **2** [btmgp = 1,3-bis(*N*,*N*,*N*′,*N*′-tetramethylguanidino)propane]

Results and Discussion

Synthetic Pathways

The *N*,*N*′-dialkyl-3,7-diazanonane-1,9-dithiolate ($N^R_2S_2$) ligands used here (R = Me, Et) are accessible from the corresponding diaminodithiols, which can be synthesised by reaction of *N*,*N*′-dialkyl-1,3-diaminopropanes with ethylene sulfide in toluene in sealed glass tubes under strictly anaerobic conditions at high pressure according to the procedure reported by Corbin et al.[10]

The diamino dithiols, isolated after filtration and removal of the solvent, can be purified by distillation before use. A small excess of ethylene sulfide was used to avoid the survival of unchanged diamines. In these reactions, the small amounts of polyethylene thioethers obtained as side products are less soluble and therefore easily removed by filtration. The use of racemic propylene sulfide instead of ethylene sulfide leads to chiral ligands that are reported elsewhere.[3,11]

The $[Cu_4(N^R_2S_2)_2]$ complexes **1** and **2** described here have been prepared by different pathways ($\mathbf{P_A}$ and $\mathbf{P_B}$, Scheme 1).

The reaction of the dinuclear compound $[\{Fe(N^{Me}_2S_2)\}_2]$[5a] with the mononuclear complex [CuI(btmgp)][12] in a molar ratio of 1:4 in MeCN (pathway $\mathbf{P_A}$) leads by ligand exchange to the tetranuclear complex **1** in fairly good yields. In a more straightforward approach (pathway $\mathbf{P_B}$), **2** is accessible by reaction of CuI with $M_2(N^{Et}_2S_2)$ (M = K or Na) in almost quantitative yields. The $M_2(N^R_2S_2)$ precursors are obtained by reaction of sodium or potassium methanethiolate with the diaminodithiol and successive removal of the methane thiol formed in this reaction step.

Both complexes **1** and **2** are soluble in THF and other aprotic solvents such as dichloromethane or chloroform, which allows solution studies (NMR, CV, and UV/Vis). Moreover, the complexes contain four nitrogen donor functions that are chiral centres with identical configurations. Within crystals, both enantiomers [all-(*R*) and all-(*S*)] are present.

Crystal Structures

Complex **1** crystallises together with acetonitrile molecules in a 1:1 molar ratio (Table 1). The molecular structure of **1** within these crystals is shown in Figure 1 [all-(*S*) configuration]. Selected interatomic distances and angles are given in Table 2. The four copper atoms are arranged in a planar rhomboidal fashion with Cu···Cu distances of 2.685 Å for the edges (averaged value) and 2.726 and 4.625 Å for the diagonals. The edges of the rhomb are bridged by thiolate-S atoms (average Cu−S distance: 2.217 Å) that reside in opposite pairs above and below the copper plane at an average distance of 1.369 Å.

With the exception of the four methyl and the eight methylene groups bonded to nitrogen atoms, all other non-H atoms of the complex follow in fairly good approximation the symmetry requirements of three twofold rotation axes, two of which pass through the diagonals of the Cu_4 rhomb and the third being normal to this plane. The overall point symmetry of **1** comes very close to C_2 with the twofold axis passing through Cu(2) and Cu(4). Both deprotonated ligand molecules are wrapped around Cu(1) and Cu(3), defining S_2N_2 coordination polyhedra for these two metal atoms, which are neither square-planar nor tetrahedral but

		S(2)−Cu(4)−S(3)	163.6(1)

can be derived from a (distorted) $S_2N_2L_2$ octahedron (Figure 1) with sulfur and nitrogen atoms at opposite (slightly bent towards L, mean S−Cu−S angle 145.8°) and neighbouring corners (mean N−Cu−N angle 96.2°), respectively, by removal of L. They are central constituents of mononuclear subunits that act as ligands towards Cu(2) and Cu(4), resulting in slightly bent S−Cu−S coordination sites with valence angles of 162.7(1)° for Cu(2) and 163.6(1)° for Cu(4). As the subunits lack molecular symmetry, the formation of two isomeric forms is possible but only one could be isolated. The other isomer can be obtained by rotating one of the mononuclear subunits of **1** around an axis that passes through Cu(1) and Cu(3). Within the tetranuclear complexes the nitrogen atoms are in identical configurations [all-(*R*) or all-(*S*), respectively]. The average Cu−N distance is 2.202 Å, and the valence angles for Cu(1) and Cu(3) range from 88.0(1)° [S(4)−Cu(3)−N(4)] to 146.7(1)° [S(1)−Cu(1)−S(2)], showing significant distortions if compared with a regular tetrahedron. Moreover, the angles between the planes defined by the CuS_2 and CuN_2 fragments are calculated to be 73.3 and 71.7° for Cu(1) and Cu(3), respectively, demonstrating significant planarisation tendencies within the coordination polyhedra. The methylene groups connecting the nitrogen atoms in the $N_2^{Me}S_2$ ligand fit into six-membered chelate rings that adopt the chair conformation.

In contrast to the methylated complex **1**, the ethylated variant **2** could be isolated in both isomeric forms (**2a** and **2b**, vide supra). Their structures, in the all-(*R*) configurations, are depicted in Figure 2.

Similar to **1**, both isomers are assembled from identical dissymmetric mononuclear subunits with significantly distorted defect-octahedral CuN_2S_2 coordination sites that act as ligands towards additional copper ions. The structure of **2a** (Figure 2, bottom) is closely related to that of **1**. The molecule occupies a twofold rotation axis that passes through Cu(2) and Cu(2a) and is crystallographically imposed. For the other isomeric form (**2b**; Figure 2, top) a twofold rotation axis of crystallographic origin passes through the centre of the Cu_4 rhomb normal to the metal plane. Crystals of **2** contain both isomers in a disordered fashion. The superposition of two conformationally different molecules with twofold rotation axes that are normal to each other results in the crystallographic site symmetry 222. This overall symmetry is reduced towards 2 for the individual complex molecules. The existence of potentially possible conformers with at least one mononuclear subunit possessing twofold symmetry can be excluded from geometric considerations: for all these cases, the valence angle at the central carbon atom of the propylene chain [C(4)] must adopt a value of ca. 132°, which is much too large to be physically meaningful. For both **2a** and **2b**, the Cu···Cu distances are 2.647(1) Å for the edges of the Cu_4 rhomb and 2.675(1) and 4.570(1) Å for the short and long diagonals, respectively. These values compare nicely with those of **1**, as do the Cu−S and Cu−N distances and the overall metal coor-

Spectroscopic Properties

Infrared and Raman Spectra

In the region above 1350 cm^{-1}, the IR spectra of **1** and **2** show strong ν_{as}/ν_s and δ_{as}/δ_s bands of the CH_2 and CH_3 groups. The bands between ca. 1300 cm^{-1} and 1200 cm^{-1} should be attributed to wagging modes of the CH_2 groups, the high intensities being consistent with their great number. A complicated pattern in the range of 1150 to ca. 1000 cm^{-1} with only small differences in frequencies between **1** and **2** is probably a superposition of ν_{C-N} bands, frequencies originating from C−C vibrations and bands associated with the rocking mode of the CH_3 groups (969 cm^{-1}). The bands between 800 and 1000 cm^{-1} can be traced back to C−C stretching and CH_3 rocking vibrations. In the expected region for the ν_{C-S} vibration, four bands are observed. The infrared and Raman spectra of **2** are compared in Figures 3 and 4.

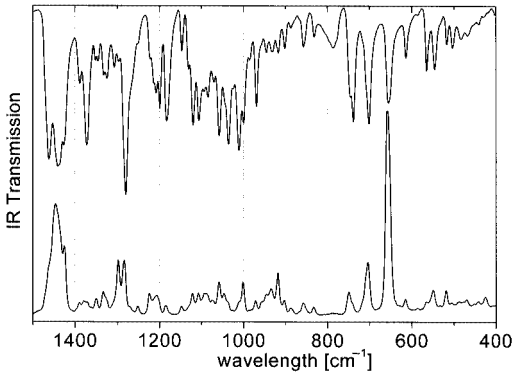

Figure 3. Infrared (top) and Raman (bottom) spectra of **2** (MIR region)

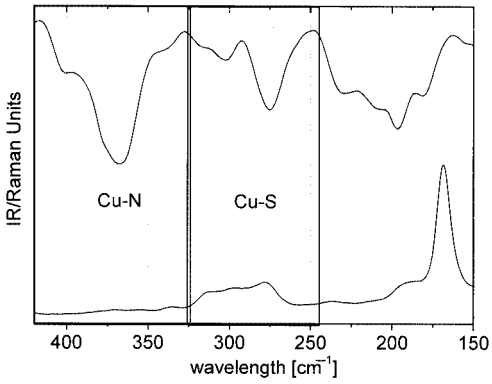

Figure 4. Infrared (top) and Raman (bottom) spectra of **2** (FIR region)

The strong Raman line at 656 cm^{-1} is assigned to the fully symmetric stretch of the C−S groups. This line can be correlated with a weak band in the infrared spectrum which is shifted by 3 cm^{-1}.

As expected for these compounds, in the region down to 400 cm^{-1}, several deformation modes of the heterocyclic five- ($CuSC_2N$) and six-membered ($CuNC_3N$) chelate rings are observed.

Based on the infrared and Raman spectra of **2**, the ν_{Cu-N} and ν_{Cu-S} frequencies can be allocated as illustrated in Figure 4. The ν_{Cu-N} frequencies occur in the range from 325 to 420 cm^{-1} (central frequency at 368 cm^{-1}), whereas the ν_{Cu-S} frequencies are assigned to bands in the range 250−325 cm^{-1} (main frequencies at 276 and 303 cm^{-1}), especially in the Raman spectra. This assignment agrees with the observed relative intensities of the ν_{Cu-S} and the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ν_{Cu-N} bands, which can be correlated with the higher polarizability of sulfur compared with nitrogen.

NMR Spectra

As a representative example, complex **2** was investigated by NMR spectroscopy. Because different conformers were detected in the crystalline state, a mixture of chemically different states should also be present in solution. Accordingly, the ^{1}H NMR spectrum is very complicated, and so no attempts to allocate signals have been made. Nevertheless, two predominant forms can be identified by different resonances of their methyl groups in accordance with the crystal structure. At room temperature, two overlapping triplets with significant differences in their intensities and coupling constants are resolved ($\Delta^3J \approx 0.2$ Hz), whereas at higher temperatures (333 K) these differences vanish.

Consistent with this assumption, two sets (each of six signals) of carbon atoms are observed in the ^{13}C NMR spectrum for **2**. The signals at $\delta = 8.43$ and 8.54 ppm can be assigned to the methyl groups (positive signal in DEPT-135) of the conformers.

Electrochemistry

Cyclic voltammetry measurements of complex **2**, dissolved in THF, show only irreversible oxidation and reduction events at +610 and −90 mV (vs. GKE), respectively.[13]

Discussion

As the $Cu_4N_4S_4$ cores of the conformers **2a** and **2b** are identical, we shall use **2** here instead of **2a** or **2b**. Both tetranuclear complexes **1** and **2** contain identical mononuclear subunits with the copper atom in a distorted N_2S_2 environment which can be derived from an $N_2S_2L_2$ octahedron by removal of L (vide supra). This spatial arrangement is controlled by the steric requirements of the alkylene spacers connecting the donor functions, which do not allow for a more regular tetrahedral situation. The deviation from tetrahedral symmetry is best reflected by the S−Cu−S valence angle, which is as large as 149.1° in **2** and of comparable size in **1**. Similar analogies between **1** and **2** with respect to other structural features of their $Cu_4N_4S_4$ cores also exist. For clarity, numerical values of **1** are omitted in the following discussion. The vector which passes through the copper atoms of both subunits bisects the S−Cu−S and N−Cu−N triangles. Both CuN_2S_2 polyhedra within each tetranuclear molecule are rotated against each other by ca. 90° around this Cu−Cu vector in such a way that the CuS_2 fragment of one subunit and the CuN_2 fragment of the other are coplanar. As both CuN_2S_2 polyhedra face each other via their S_2 edges, the sulfur atoms form a distorted tetrahedron with opposite edges being 4.382, 4.262 and 4.858 Å in lengths, respectively. The edges that belong to individual CuN_2S_2 polyhedra are bridged by Cu(1). From geometrical considerations, the arrangement of the sulfur atoms should allow for the incorporation of a total of four additional copper atoms into places defined by the centres of the edges of the S_4 tetrahedron that connect the CuN_2S_2 units. For the complexes described here, only one half of these positions are occupied by copper [Cu(2) and Cu(4) in **1**, Cu(2) in **2**] in such a way that planar metal arrangements are formed. This half is associated with the shorter S···S edges of the S_4 tetrahedron, resulting in distorted linear S−Cu−S units. It is noteworthy that these additional copper atoms are shifted from the centres of the S···S edges towards the centroid of the S_4 tetrahedron and approach each other at 2.675 Å, a distance that is only marginally longer than that observed between Cu(2) and Cu(1) (2.647 Å), indicating some degree of attractive Cu···Cu interactions.

As has already been pointed out, the distorted "tetrahedral" CuN_2S_2 coordination sites are characterised by extremely wide S−Cu(1)−S valence angles of 149.1°. This situation can therefore alternatively be regarded as a first-order distorted linear S−Cu−S coordination with additional secondary bonds to nitrogen atoms. In this picture, four of the six edges of the S_4 tetrahedron are occupied by copper atoms, two of which are displaced towards the centroid whereas the remaining ones are shifted in the opposite direction to avoid Cu···Cu interactions that are too short to be stable.

The complex $[Cu_4\{SC_6H_2(i\text{Pr})_3\}_4]$ has recently been identified by Schröter-Schmidt and Strähle as containing a polycyclic Cu_4S_4 framework similar to that of **1** and **2**.[8b] In this case, however, the S_4 tetrahedron is drastically flattened if compared with those in **1** and **2**, and the short diagonal of the Cu_4 rhomb (3.383 Å) is much longer than the edges (2.700 Å). Though secondary Cu−N bonds are lacking in this example, two of the copper atoms are also displaced away from the centroid of the S_4 polyhedron (Cu···Cu 4.207 Å), whereas the others are shifted towards each other at a distance of 3.383 Å. Comparable geometrical features have also been found by Becker et al. and by Block et al. in the tetranuclear thiolate complexes $[Cu_4\{SSi(Ot\text{Bu})_3\}_4]$[8c] and $[Cu_4\{SC_6H_3(2,6\text{-}SiMe_3)_2\}_4]$,[8a] respectively.

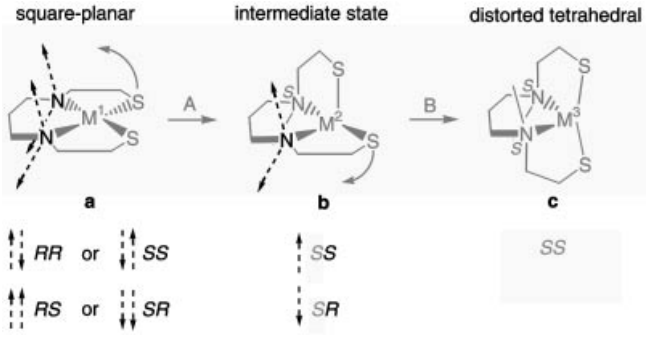
Coordination principles in tetranuclear thiolate complexes with planar copper frameworks that are different from those observed in **1** and **2** have been found in $[Cu_4\{SC_6H_2(2,4,6\text{-}i\text{Pr})_3\}_4(\text{bipy})_2]$[14] and $[Cu_4(St\text{Bu})_4(PPh_3)_2]$,[15] respectively. In both cases, two mononuclear $[Cu(SR)_2L]$ subunits with tetrahedral CuN_2S_2 or trigonal-planar $CuPS_2$ coordination sites act as ligands towards "naked" Cu^I ions, forming linear S−Cu−S units within cyclic Cu_4S_4 frames. Due to the non-linearity of the S−Cu−S fragments within the CuN_2S_2 and $CuPS_2$ coordination sites, these frames contain sulfur atoms in planar arrangements. Both frames differ in the magnitude of their Cu-S−Cu angles. For $[Cu_4\{SC_6H_2(2,4,6\text{-}i\text{Pr})_3\}_4(\text{bipy})_2]$,[14] both acute and obtuse angles are present, whereas only acute angles are observed in $[Cu_4(St\text{Bu})_4(PPh_3)_2]$.[15]

Of more general importance is the new finding that ligands derived from 3,7-dialkyl-3,7-diazanonane-1,9-dithiol-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ate stabilise complexes of coordination number 4 with a nonplanar ligand field. In principle, the spatial arrangement of the ligand donor functions fits perfectly well into a square-planar coordination geometry. This coordination mode has frequently been observed for Ni^{II} and, to a lesser extent, also for Cu^{II} and Pd^{II}.[4] In all these cases, the absolute configurations of the two nitrogen donor atoms are mirror images, resulting in optically inactive *meso* complexes. In contrast, the mononuclear subunits of **1** and **2** should be optically active as the stereogenic nitrogen atoms are in the same absolute configuration. The observed nonplanar arrangement of the N_2S_2 donor set can be derived from a planar case by rotation of the CuS_2 fragment around the bisector of the S−Cu−S angle. This rotation is accompanied by a drastic widening of the S−Cu−S valence angle induced by the restricted S···N bite distance.

To analyse the stereochemical consequences of this rotation with respect to the individual absolute configurations of the nitrogen atoms within the monomeric subunits, we will discuss a hypothetical stepwise mechanism (Scheme 2) starting from the square-planar arrangement.



Scheme 2. Metal-controlled stereochemistry (M^1 = Ni^{II}; M^2 = Mn^{II}, Fe^{II}; M^3 = Cu^{I}); the possible positions for the alkyl substituents are indicated by dashed arrows

In this situation (Scheme 2, **a**), each nitrogen atom can, principally, adopt both (*R*) or (*S*) conformations independently. In step A, we shift one of the sulfur atoms into a position such that the Cu−S bond is normal to the remaining CuN_2S plane. Such arrangements have been observed in the dinuclear complexes $[\{Fe(N_2^{Me}S_2)\}_2]$[5] and $[\{Mn(N_2^{Et}S_2)\}_2]$.[5] This procedure has stereochemical consequences with respect to the absolute configuration of the nitrogen atom directly connected with the shifted sulfur atom. If we look from the midpoint of the N···N edge to the copper atom and we shift the sulfur atom of the left-hand side upwards, the nitrogen atom on the same side has to adopt the (*S*) configuration. The absolute configuration of the other nitrogen atom is not restricted by this procedure. Thus, both diastereomeric forms, namely those with (*S*,*S*) and (*R*,*S*) configurations, should be possible (Scheme 2, **b**). In fact, the complex $[\{Fe(N_2^{Me}S_2)\}_2]$[5] is an example of a system which adopts the (*R*,*S*) configuration, whereas in $[\{Mn(N_2^{Et}S_2)\}_2]$,[5] the (*S*,*S*) configuration is observed. In the next step (B), the second sulfur atom is shifted into the opposite direction such that both Cu−S bonds are more or less parallel (Scheme 2, **c**). Both nitrogen atoms are now restricted to adopt the (*S*,*S*) configuration. This situation holds for both **1** and **2**. In the complex $[MoO_2(N_2^{Me}S_2)]$, a related situation has been observed.[16] The same process based on opposite shifts finally leads to the (*R*,*R*) configuration.

As a consequence of the spatial restrictions induced by the alkylene spacers of the polyfunctional ligands, a tetrahedral coordination geometry which requires S−Cu−S valence angles in the order of 109° cannot be achieved, and the rotation process is expected to converge against a limiting angle that is smaller than 90°, in accordance with our observations.

In both complexes **1** and **2** all of the four N atoms of the diamino dithiolate ligands are stereogenic centres with identical absolute configurations. The crystals are racemic mixtures of the two enantiomers [all-(*R*) and all-(*S*)], whereas diastereomers (*R*,*R*,*S*,*S*) have not been observed. The combination of monomeric subunits that are mirror images to tetranuclear complexes (in their *meso* forms) via bridging Cu ions is not possible due to steric requirements of the thiolate-S functions, which cannot form additional S−Cu bonds with suitable geometries. As an important consequence of this spatial control, tetranuclear complexes of the type described above must be optically active, and the assembly of any optically inactive form (with *meso* configuration) is therefore strictly forbidden.

Racemic mixtures of the type described here may play an important role as auxiliaries if it is possible to activate or deactivate one enantiomer selectively by a further chiral component.[17]

Conclusions

Here we have gained control of the stereochemistry of nitrogen donor functions in N_2S_2 ligands by adjusting the spatial demands with metal-specific coordination properties. For Cu^{I}, the coordination of N_2S_2 ligands can only be achieved if both nitrogen atoms adopt the same absolute configuration [(*R*,*R*)or (*S*,*S*)]. These mononuclear chiral CuN_2S_2 units have been found to act pairwise as bifunctional sulfur donor ligands towards monovalent copper ions, forming stable tetranuclear complexes with planar metal frames. The observation that this step is absolutely stereoselective, allowing only combinations of units with identical configurations, should be of more general importance. The stereochemical control can be traced back to an interplay between the coordination properties of the sulfur donor functions of the metallo ligand and the bonding requirements of the bridging copper ions. Consequently, the combination of units with opposite configurations, leading to optically inactive *meso* complexes (*R*,*R*,*S*,*S*), is strictly forbidden. These novel complexes might find applications in chemical and catalytic processes.

Experimental Section

General Remarks: All manipulations were performed under pure dinitrogen using Schlenk techniques or a glove box using abs. sol-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

vents. *N*,*N*′-Diethyl-3,7-diazanonane-1,9-dithiole is readily accessible by procedures described in the literature.[10] The complexes used as starting materials, [{Fe(N_2S_2Me)}$_2$] and [CuI(btmgp)], were synthesised by reaction of [Fe{N[Si(Me)$_3$]$_2$}$_2$] with stoichiometric amounts of *N*,*N*′-diethyl-3,7-diazanonane-1,9-dithiole and addition of btmgp to CuI, respectively.

Physical Measurements: All measurements were performed under strictly anaerobic conditions. IR spectra were obtained using a Bio-Rad FTS-7 (**1**) and a Bruker IFS 66v (**2**) spectrometer. ^{1}H NMR spectra for **2** were obtained with a Bruker Avance DRX 500 spectrometer and solvent signals were used as an internal standard [calibrated on δ = 7.240 (^{1}H), 77.00 (^{13}C)].

X-ray Crystallographic Studies: Single crystals of **1**·MeCN were obtained as yellow blocks by slow cooling of a solution of **1** in MeCN. Suitable yellow crystals of **2** were obtained by slow diffusion of diethyl ether into a MeCN solution of the complex. Crystals were sealed in a glass capillary (**1**) under an inert gas or mounted on top of a glass capillary with silicon grease (**2**). Diffraction data were collected at room temperature (**1**) with a Siemes-Stoe-AED-2 or at 150 K (**2**) with a Siemens P4RA four-circle diffractometer utilizing monochromated Mo-K_α radiation. The data were corrected for absorption (ψ-scan method), as well as for Lorentz and polarisation effects. The structures were solved by direct methods (SHELXS-86).[18] Refinements were done by full-matrix least-squares methods on F^2 with anisotropic thermal displacement parameters for all non-hydrogen atoms using the SHELXL-97 program suite.[19] Hydrogen atoms were fixed on idealised positions and refined with a common isotropic temperature factor. Crystals of **2** are composed of individual complex molecules **2a** and **2b** which occupy the same crystallographic position in a statistical manner. A summary of relevant crystal data is given in Table 1. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication numbers CCDC-203954 (**1**) and -203955 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation of Compounds

[$Cu_4(N_2S_2Me)_2$] (1) (Pathway A): A solution of [CuI(btmgp)] (0.175 g, 0.38 mmol) in MeCN was added dropwise, at room temperature, to a suspension of [{Fe(N_2S_2Me)}$_2$] (0.105 g, 0.19 mmol) in MeCN (15 mL). The mixture was refluxed for 30 min and then filtered. On slow cooling of the filtrate, **1** was obtained as light yellow crystals. Yield: 0.168 g; 60%, based on Cu^{I}. IR (KBr): ṽ = 2957−2920 s, 2841−2799 vs, 2247 m (ν_{CN}), 1458 vs, 1381 m, 1362 m, 1314 m, 1294 s, 1260 m, 1229 s, 1200 vs, 1152 m, 1088 m, 1053 s, 1044 vs, 1032 vs, 993 vs, 959 m, 936 m, 910 m, 893 m, 870 m, 760 vs, 723 vs, 652 m, 600 w, 550 w, 525 w, 467 m, 426 m, 368 m cm^{-1}.

[$Cu_4(N_2S_2Et)_2$] (2) (Pathway B): *N*,*N*′-Diethyl-3,7-diazanonane-1,9-dithiole (0.501 g, 2 mmol) was dissolved in tetrahydrofuran (15 mL) and treated with a slurry of potassium methanethiolate (0.345 g, 4 mmol) in tetrahydrofuran (10 mL). The yellow slurry was stirred at 40 °C for 30 min and the solvent removed in vacuo. The resultant colourless residue was suspended in tetrahydrofuran (20 mL) and again stirred for 30 min at the same temperature. After removal of the solvent under reduced pressure the obtained colourless residue was treated with a solution of copper(I) iodide (0.762 g, 4 mmol) in acetonitrile (25 mL) and the resulting mixture refluxed for 20 min. The solvent was then removed in vacuo and the residue resuspended in tetrahydrofuran (70 mL). After stirring for 16 h, the mixture was filtered and **2** obtained as yellow crystals by slow diffusion of diethyl ether into the clear yellowish filtrate. Yield: 0.413 g; 55%, based on Cu^{I}. $C_{31}H_{59}CuN_6S$ (751.06): calcd. C 35.18, H 6.44, N 7.46, S 17.09; found C 35.31, H 6.45, N 7.48, S 16.92. IR (KBr): ṽ = 2957 vs, 2922 vs, 2824 vs, 1441 s, 1373 m, 1324 m, 1281 vs, 1199 m, 1183 m, 1120 m, 1085 m, 1036 m, 1011 s, 969 m, 917 w, 902 w, 857 w, 787 m, 739 m, 701 m, 656 m, 614 w, 565 m, 503 w, 483 w cm^{-1}. FIR (polyethylene pellet): ṽ = 565 vs, 546 s, 517 m, 503 s, 484 m, 471 m, 451 vw, 438 w, 401 m, 368 vs, 303 w, 276 m, 229 m, 197 s, 181 m, 145 w, 120 m, 110 m, 89 m, 66 m cm^{-1}. Raman (capillary): ṽ = 2922 vs, 2873 m, 2851 m, 2730 w, 1446 w, 1333 vw, 1298 w, 1206 w, 1121 vw, 1093 vw, 1059 w, 1002 w, 934 vw, 918 w, 858 vw, 832 vw, 749 vw, 704 w, 658 m, 615 vw, 550 vw, 519 vw, 471 vw, 425 vw, 278 m, 237 w, 169 m, 120 m, 84 w cm^{-1}. ^{1}H NMR (500 MHz, $CDCl_3$, 298 K): δ = 1.08 (*t*, ^3J = 7.08 Hz, CH_3), 1.10 (*t*, ^3J = 7.26 Hz, CH_3, **2b**), 1.67 ("quint", ^3J = 5.09 Hz, CH_2−CH_2 CH_2−), 2.06 ("quint", ^3J = 6.9 Hz), 2.33 (m), 2.50 (m), 2.64 (m), 2.69 (m), 2.77 (m), 2.93 (*t*, ^3J = 7.08 Hz, H) ppm. ^{13}C NMR (125.75 MHz, $CDCl_3$, 298 K): δ = 8.43 (*C*H$_3$, **2a**), 8.54 (*C*H$_3$, **2b**), 21.89 (C, **2b**), 27.66 (C, **2a**), 27.85 (C, **2b**), 29.18 (C, **2a**), 46.82 (C, **2a**), 50.28 (C, **2b**), 53.09 (C, **2a**), 53.99 (C, **2b**), 56.13 (C, **2a**), 56.87 (C, **2b**) ppm. DEPT-135, ^{1}H^{13}C-COSY, ^{1}H^{1}H-COSY were used for allocation of the signals.

Synthesis, Structure, and Catalytic Activity of New μ-Oxo-Bridged Diiron(III) Complexes

Éva Balogh-Hergovich,[a] Gábor Speier,*[b] Marius Réglier,[c] Michel Giorgi,[c] Ernő Kuzmann,[d] and Attila Vértes[d]

Keywords: Iron / Tripodal ligands / Peroxides / Oxidation

The preparation and characterisation of two dinuclear iron(III) complexes with tripodal ligands 1,3-bis(2′-pyridylimino)isoindoline (indH) are presented. The μ-oxo-bridged diiron(III) complex [{FeCl(ind)}$_2$O] (**2**) has been prepared by reacting $FeCl_3 \cdot 6H_2O$ with indH in methanol solution. Compound [{Fe(ind)(OAc)}$_2$O] (**3**) was obtained from the reaction of **2** with CH_3CO_2Ag in THF. Both compounds were characterised by elemental analysis and UV/vis, IR, and Mössbauer spectroscopy. The X-ray structure analysis of [$Fe_2O(ind)_2Cl_2$]·THF (**2**·THF) revealed a distorted trigonal bipyramidal (τ = 0.88) coordination geometry around the iron(III) ion. More importantly, **2** is a good functional model for the activation of small molecules as its 5-coordinate iron ions can easily coordinate such molecules. This is confirmed by the high catalase-like activity of **2**, transforming 87% of the excess of H_2O_2 into O_2 in 1 min. The complexes exhibited monooxygenase-like activity using H_2O_2 as the oxidant and oxidise alkanes to alcohols and ketones in acetonitrile in moderate yields.

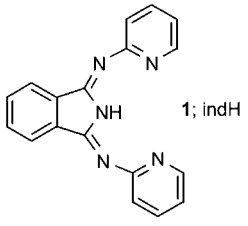
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Oxo-bridged dinuclear Fe^{III} complexes have been recently extensively studied owing to their presence in a class of non-heme iron proteins that include hemerythrin, ribonucleotide reductase, methane monooxygenase and purple acid phosphatase.[1] The soluble methane monooxygenase, sMMO, isolated from methanotropic organisms catalyses the transformation of methane into methanol using molecular oxygen as the oxidant in the presence of a source of electrons.[2] Several intermediates in the catalytic cycle of sMMO have been characterised but the mechanism of catalytic hydroxylation of unactivated C−H bonds is not fully understood.[3] Spectroscopic studies implicate high-valent (μ-oxo)diiron species as intermediates in the oxidation chemistry of the diiron centres in methane monooxygenase.[4] In the last decade several artificial sMMO systems have been developed using μ-oxo-diiron(III) complexes derived from various supporting ligands, and oxidants such as ROOH,[5] H_2O_2,[6] *m*-chloroperbenzoic acid,[7] and O_2 (+ electron source).[8] For this class of iron complexes the reactivity can be tuned by modifying the ligand around the metal centre.

Hydrogen peroxide may be the best oxidant to functionalise hydrocarbons as it is less expensive, and gives only water as a by-product. However, its use is limited, since a number of diiron complexes have catalase activity.[9]

We report here the preparation and characterisation of μ-oxo-bridged diiron(III) complexes with the tripodal ligand 1,3-bis(2′-pyridylimino)isoindoline (**1**, indH) and their monooxygenase- and catalase-like activity.



1; indH

Results and Discussion

Synthesis and Characterisation of the Complex [{FeCl(ind)}$_2$O]

Complex [{FeCl(ind)}$_2$O] (**2**) was prepared from equimolar amounts of the ligand and $FeCl_3 \cdot 6H_2O$. In its infrared spectrum the absorptions at 1638 and 1584 cm^{-1} indicate

that the complex contains the deprotonated isoindoline ligand.[10] The band at 792 cm^{-1} is characteristic of the asymmetric stretch of the Fe−O−Fe moiety, while the symmetric stretch occurs at 478 cm^{-1}.[3a,11,12] In the electronic spectrum the band at 238 nm can be assigned to π−π* transitions in the aromatic groups of the ligand, those in the oxo dimer region (388, 473 nm) to a weak oxo-to-iron LMCT transition. The less intense band at 473 nm is assigned to the $^6A_1 \rightarrow (^4A_1, 4E)$ transition and is the signature of the Fe−(μ-O)−Fe motif, independent of the bridging angle.[13,14] Another important characteristic of the μ-oxo core is expected in the 550−700 nm region, which is strongly dependent on the Fe−(μ-O)−Fe angle: the lower the angle, the less energetic and/or the more intense the band.[15] The broad, weak band at 615 nm indicates a bent structure with a low angle, in agreement with X-ray data.

Synthesis and Characterisation of the Complex [{Fe(ind)(OAc)}$_2$O]

Complex [{Fe(ind)(OAc)}$_2$O] (**3**) was prepared by the reaction of [{FeCl(ind)}$_2$O] with CH_3CO_2Ag in THF. Infrared spectrum absorptions at 1638 and 1577 cm^{-1} indicate that the complex contains the deprotonated isoindoline ligand (absence of a strong band at 1100 cm^{-1} and absorptions in the range 1600−1660 cm^{-1}). Complexes with the deprotonated isoindoline ligand exhibit a weak band above 1600 cm^{-1}.[10] The band at 752 cm^{-1} is characteristic of the asymmetric stretch of the Fe−O−Fe moiety, the symmetric stretch occurs at 510 cm^{-1}.[3a,11,12] The ν(CO_2) bands at 1570 and 1430 cm^{-1} suggest a bridged coordination of the acetate groups. In the electronic spectrum of **3**, the band at 237 nm can be assigned to π−π* transitions in the aromatic groups of the ligand, and bands in the oxo dimer region (385, 475 nm) assigned to an oxo-to-iron charge transfer transition. Finally a broad, weak band was observed in the low-energy visible region (720 nm). The considerable red-shift of this band, compared with λ_{max} assigned for the transition in **2**, indicates a smaller Fe−(μ−O)−Fe angle. This supports the binding mode of the acetate as a bidentate bridging ligand between the two iron atoms. From the spectroscopic data for compound **3** the [Fe(ind)(μ-O)(μ-OAc)$_2$(ind)Fe] structure was proposed; however, the [Fe(ind)(OAc)(μ-O)(OAc)(ind)Fe] structure could not be excluded.

Mössbauer Spectroscopy

The Mössbauer spectrum of complex [{FeCl(ind)}$_2$O] is shown in Figure 1 and the parameters are given in Table 1. The relatively low value of the isomer shift (IS) of **2** is due to the high population of 4s orbital of Fe^{III} and it can be explained by the s bonding between Fe^{III} and N(1) and N(6) donor atoms. The large quadrupole splitting (QS) is the consequence of the distorted trigonal bipyramidal geometry around the iron atom.[16,17] The Mössbauer parameters of **3** represent a typical iron(III) with octahedral environment (Table 1). Namely, the higher coordination number results in a higher population of 3d orbital of iron and, at the same time a lower s-electron density at the nucleus of Fe^{III} (higher IS) and a higher symmetry around iron atom than the trigonal bipyramidal coordination in [{FeCl(ind)}$_2$O]. The later effect is the origin of the smaller quadrupole splitting in the complex [{Fe(ind)(OAc)}$_2$O].

Line width	0.274	0.284	0.318	0.360

[a] T_N is the temperature of liquid nitrogen.

X-ray Crystal Structure of [{FeCl(ind)}$_2$O]·THF

The molecular structure of complex [{FeCl(ind)}$_2$O]·THF is shown in Figure 2, and selected bond lengths and angles are listed in Table 2. The complex is a μ-oxo dimer, the two iron atoms have a distorted trigonal bipyramidal geometry with $\tau = 0.88$. For perfect square pyramidal and trigonal bipyramidal geometries the values of τ are zero and unity, respectively; τ being an index of the degree of trigonality within the structural continuum between square pyramidal and trigonal bipyramidal geometries.[18] Oxygen and chlorine atoms and one N of the tridentate isoindolinate ligand are in basal positions, while two further N atoms of the ligand occupy apical positions. The metal−metal distance of 3.283 Å is shorter than in other five-coordinated μ-oxo monobridged diiron complexes.[12] Moreover, the Fe−O−Fe angle is significantly shorter than is usually found in similar complexes.[5b,6a,12] These values are close to those in μ-oxo complexes with an additional bridging ligand,[12] and also in dinuclear iron proteins.[1a,1b,3a] The Fe−O bond lengths are within the range reported for (μ-

oxo)diiron(III) complexes[12] and the Fe−N bond lengths are similar to those obtained for $[FeCl_2(ind)]$.[19] The Fe−N distances involving the pyridine nitrogen atoms, N1 and N3, are significantly longer than for the pyrrole nitrogen atom, N5. The same bond length pattern has been observed in Cu^{II} [20] and Ni^{II} [21] complexes of the isoindolinate ligand. The Fe−Cl bond lengths are similar to those of $[Fe_2O(TPA)_2Cl_2]^{2+}$.[5b]

Catalase-Like Activity

The H_2O_2 dismutation activity of complexes **2** and **3** was tested by measuring the dioxygen evolution in acetonitrile with a complex/H_2O_2 ratio of 1:100. As expected, H_2O_2 decomposed to give O_2 gas and water, a reaction competing with the oxidation of cyclohexane. As shown in Figure 3, complex **2** exhibited rather high activity for the decomposition of hydrogen peroxide with about 80 initial turnovers per min at 25 °C (turnover is mmol of O_2 per mmol of complex). The yield of O_2 was 87% based on H_2O_2 after 1 min of reaction. The residual hydrogen peroxide (measured by iodometric titration) was compared with the amount of dioxygen formed and showed good agreement with the stoichiometry of the dismutation reaction. Complex **3** showed much lower dismutation activity.

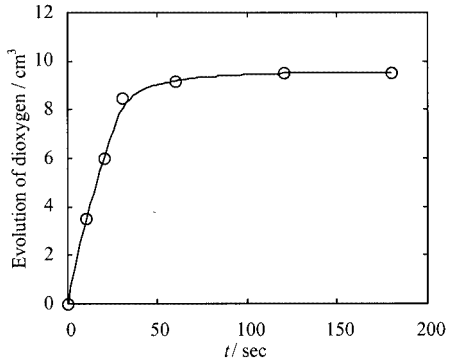

Figure 3. Evolution of dioxygen from H_2O_2 catalysed by $[\{FeCl(ind)\}_2O]$; [**2**] = 1.75 mol·dm^{-3}, $[H_2O_2]$ = 0.175 mol·dm^{-3}

Kinetic measurements of H_2O_2 decomposition in the presence of **2** were performed in acetonitrile at 25 °C under pseudo-first-order conditions. To determine the rate dependence on the two reactants, runs were performed at various $[\{FeCl(ind)\}_2O]$ and H_2O_2 concentrations. The straight line obtained by plotting the initial reaction rate against the initial catalyst concentration indicates a reaction order of one with respect to **2**. The first-order dependence of the reaction rate against $[H_2O_2]$ was established by plotting the initial reaction rate against the $[H_2O_2]$. On the basis of the kinetic data the rate law (1) could be derived. The second-order rate constant k was found to be 9.2 ± 0.6 mol^{-1}·dm^3·s^{-1}.

$$\text{Reaction rate} = k\cdot[H_2O_2][\mathbf{2}] \quad (1)$$

UV/vis spectra of a solution of $[\{FeCl(ind)\}_2O]$ recorded immediately after addition of the oxidant show drastic changes (Figure 4). The final spectrum is very similar to that obtained in the reaction of some other (μ-oxo)diiron(III) complexes with H_2O_2.[6b] This may indicate that in the reaction with hydrogen peroxide the original bent μ-oxo structure decomposes to form a linear μ-oxo type or a mononuclear complex.

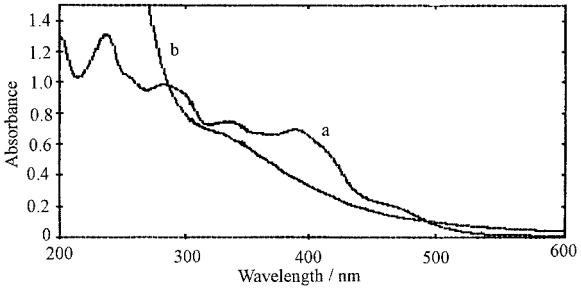

Figure 4. UV/vis spectra of (a) $[\{FeCl(ind)\}_2O]$, (b) **2** with 100 equiv. of H_2O_2 added. [**2**] = 4.02 10^{-5} mol·dm^{-3}, CH_3CN, 25 °C

Table 3. Oxidation of cyclohexane

Catalyst[a]	Oxidant	Yield [%][b] Cyclohexanol	Cyclohexanone	$tBuO_2$/cyclohexane	*TN*[c][d]
[{FeCl(ind)}$_2$O]	H_2O_2	14.6	14.8	–	29.4
[{FeCl(ind)}$_2$O]	H_2O_2	15.3	13.8	–	29.1[d]
[{FeCl(ind)}$_2$O]	H_2O_2	12.2	13.6	–	25.8[e]
[{Fe(ind)(OAc)}$_2$O]	H_2O_2	4.5	8.4	–	12.9
[$FeCl_2$(ind)]	H_2O_2	4.3	6.6	–	10.9
[{FeCl(ind)}$_2$O]	$tBuO_2H$	7.2	7.2	0.5	14.9
[{Fe(ind)(OAc)}$_2$O]	$tBuO_2H$	7.2	7.4	0.6	15.2

[a] Reaction conditions: cyclohexane (3.5 mmol), oxidant (3.5 mmol), catalyst (35 μmol), acetonitrile (10 cm^3), Ar, 25 °C, 10 h. [b] Based on the oxidant. [c] *TN* (turnover numbers) = mol of product per mol of catalyst. Total yield and TN values take into account that 2 equivalents of oxidant are required to make 1 equivalent of ketone. [d] Under O_2. [e] 1 cm^3 CCl_4 added.

Oxygenation of Alkanes

The monooxygenase-like activity of complexes [{FeCl(ind)}$_2$O] (**2**), [{Fe(ind)(OAc)}$_2$O] (**3**) and [$FeCl_2$(ind)] was tested in the oxidation of alkanes. We checked first the activity of (**2**) in the oxidation of cyclohexane by different oxidants and in different solvents (MeOH, CH_2Cl_2, CH_3CN). Catalytic oxidations were effective only with H_2O_2 and $tBuO_2H$. No oxidation products could be detected with di-*tert*-butyl peroxide and iodosylbenzene. The results (Table 3) show that the best yields were obtained with H_2O_2 in acetonitrile. Under our experimental conditions the molar ratio of iron complex/hydrogen peroxide/substrate is 1:100:100. The oxidation of cyclohexane yielded cyclohexanol and cyclohexanone in a 2:1 ratio. The total turnover number (mmol product per mmol catalyst) was 29.4, and the alcohol + ketone yield was 29.4% after 10 h. In comparison, the yield was 14.9% with $tBuO_2H$ and a small amount of *tert*-butyl cyclohexyl peroxide was also formed. Moreover, the catalyst obtained by replacing the chlorine ligands with acetate was less active. The mononuclear iron(III) complex, [$FeCl_2$(ind)], showed a catalytic activity similar to that of **2**.

As shown in Table 4, complex **2** also catalyses the oxygenation of methylcyclohexane, adamantane, and ethylbenzene. With methylcyclohexane as substrate, the reactivity at the tertiary position is 6 times higher than that at the secondary position, and no oxygenation was observed at the primary position. The normalised reactivity ratio of the tertiary C−H to secondary C−H in the oxygenation of adamantane is 4.0. The adamantane C3/C2 selectivity ratio is in the range found for other systems, including model studies of sMMO by using dinuclear iron complexes,[5a] and also for the MMO enzyme (3.0, normalised).[22] These results show that the regio-selectivity in the alkane hydroxylation catalysed by [{FeCl(ind)}$_2$O] follows the order tertiary > secondary > primary carbon. From the time dependence of the reaction (Figure 5) it seems that cyclohexanone and cyclohexanol were always formed in approximately constant ratios, showing that cyclohexanol is not the precursor of cyclohexanone. Experiments were also performed under dioxygen to elucidate the role of O_2. The almost constant yields of the oxidation products, whether the reaction was carried out under argon or dioxygen, suggest that O_2 is not involved in this reaction (Table 2). When 2,6-di-*tert*-butyl-4-methylphenol, as a free radical trap, was added to the oxidation of cyclohexane prior to H_2O_2 addition in the case of complex **2** there was no significant lowering of the yields of oxidation products. The oxidation reaction of cyclohexane was also performed after addition of CCl_4 to the reaction mixture. No formation of bicyclohexyl and cyclohexyl chloride was observed. Any free cyclohexyl radical present would undergo dimerisation to give bicyclohexyl, and would also abstract Cl from CCl_4 to give cyclohexyl chloride.[23]

Table 4. Oxygenation of alkanes catalysed by [{FeCl(ind)}$_2$O]

Substrate[a]	Product	Yield [%][b]	*TN*[c]
Methylcyclohexane	1-methylcyclohexanol	4.2	
	2-methylcyclohexanol	0.4	
	3-methylcyclohexanol	1.8	15.4
	3-methylcyclohexanone	6.2	
	4-methylcyclohexanone	2.8	
Adamantane[d]	1-adamantanol	9.2	
	2-adamantanol	6.3	16.7
	adamantanone	1.2	
Ethylbenzene	1-phenylethanol	2.5	16.1
	acetophenone	13.6	

[a] Reaction conditions: substrate (3.5 mmol), oxidant (3.5 mmol), **2** (35 μmol), acetonitrile (10 cm^3), Ar, 25 °C, 10 h. [b] Based on the oxidant. [c] *TN* (turnover numbers) = mol of product per mol of catalyst. Total yield and *TN* values take into account that 2 equiv. of oxidant are required to make 1 equiv. of ketone. In our study the coordinatively unsaturated iron(III) in [{FeCl(ind)}$_2$O] can easily bind H_2O_2, and an iron-peroxo species, observed also during other H_2O_2 dependent reactions,[24−26] may be a transient precursor of a metal-based oxidative species. Our observations suggest that the reaction proceeds via heterolytic scission of the peroxide bond, resulting in high-valent oxo metal intermediates, rather than via a radical mechanism. The same reaction also occurs with [$FeCl_2$(ind)]. It is likely that the mononuclear [$FeCl_2$(ind)] in solution is converted into the oxo-bridged dimer (**2**), the thermodynamic sink for the Fe^{III} state, and this will be the active catalyst of the reaction. Compound **2** could also be prepared by stirring [$FeCl_2$(ind)] in hot methanol. In [{Fe(ind)(OAc)}$_2$O], obtained by replacing chlorine ligands by acetate bridges, the six-coordinated iron(III) has no vacant site for the coordination of H_2O_2, which results in lower activity. Further spectroscopic studies are needed to elucidate the structure of the intermediate complexes.

Conclusion

Two new μ-oxo-diiron(III) complexes with 1,3-bis(2′-pyridylimino)isoindoline ligands, [{FeCl(ind)}$_2$O] (**2**), [{Fe(ind)(OAc)}$_2$O] (**3**), have been prepared and then characterised by elemental analysis and UV/vis, IR, and Mössbauer spectroscopy. X-ray structure analysis of the complex [Fe_2O(ind)$_2Cl_2$]·THF revealed that the coordination geometry around the iron(III) ion is distorted trigonal bipyramidal ($\tau = 0.88$). In complex **3** the iron(III) has an octahedral environment. Moreover **2** is a good functional model for the activation of small molecules, since each iron ion is five-coordinate and, thus, small substrate molecules can be coordinated easily. Both complexes were effective catalysts for the oxidation of alkanes utilising hydrogen peroxide as oxygen source; however, their use is limited due to their ability to dismutate H_2O_2. Complex **2** exhibits a rather high activity for the decomposition of hydrogen peroxide, transforming 87% of the excess of H_2O_2 into O_2 in 1 min.

Experimental Section

General Remarks: All manipulations were performed under a pure dinitrogen or argon atmosphere unless otherwise stated, using standard Schlenck-type inert-gas techniques.[27] 1,3-Bis(2′-pyridylimino)isoindoline,[28] and [$FeCl_2$(ind)][19] were prepared according to literature methods. Methanol and acetonitrile were purified in the usual manner and stored under argon.[29] All other chemicals were commercial products and were used as received without further purification.

Physical Measurements: Infrared spectra were recorded on a Specord 75 IR (Carl Zeiss) spectrophotometer using samples mulled in Nujol between KBr plates or in KBr pellets. GC analyses were performed on a HP 583OA gas chromatograph equipped with a flame ionisation detector and a 25 m (0.2 mm i.d., 0.25 μm FT) CP-SIL-8CB fused silica capillary column. GC-MS analyses were performed on a HP 5890II/5971 GC/MSD apparatus equipped with a column identical to that used for GC analyses. UV/vis spectra were recorded on a Shimadzu UV-160 spectrophotometer by using quartz cells. The Mössbauer spectroscopy measurements were carried out at room temp. or at liquid nitrogen temperature (T_N) and in zero applied magnetic field using a conventional Mössbauer spectrometer in constant acceleration mode. The γ-rays were provided by a ^{57}Co(Rh) source of 10^9 Bq activity. All isomer shift data are given relative to α-Fe. For the spectrum evaluation we used the MössWinn program package.[30]

Synthesis of [{FeCl(ind)}$_2$O] (2): $FeCl_3$·$6H_2O$ (0.270 g, 1 mmol) was dissolved in methanol (10 cm^3), then 1,3-bis(2′-pyridylimino)isoindoline (0.299 g, 1 mmol) in methanol (20 cm^3) was added and the reaction mixture stirred under argon at 60° for 8 h. After cooling, a dark brown powder of [{FeCl(ind)}$_2$O] precipitated, which was filtered off, washed with acetonitrile and dried under vacuum (0.34 g, 85%). Recrystallisation of the product from THF gave dark brown crystals. M.p. 354−356 °C. IR (KBr): $\tilde{\nu}$ = 1638 w, 1602 w, 1584 s, 1549 m, 1536 s, 1468 s, 1428 m, 1360 w, 1306 w, 1265 m, 1197 m, 1150 w, 1095 w, 1061 s, 1007 m, 898 w, 851 w, 792 m, 783 s, 722 m, 702 m, 641 w, 539 w, 514 w, 478 w, 437 w cm^{-1}. UV/vis (CH_3CN): λ_{max} (log ε/dm^3·mol^{-1}·cm^{-1}) = 238 (4.78), 282 (4.65), 388 (4.51), 473 (3.99), 615 (3.57) nm. $C_{36}H_{24}Cl_2Fe_2N_{10}O$ (795.2): calcd. C 54.36, H 3.04, Cl 8.91, Fe 14.04, N 17.61; found C 54.68, H 3.12, Cl 8.54, Fe 13.44, N 17.34.

Synthesis of [{Fe(ind)(OAc)}$_2$O] (3): [{FeCl(ind)}$_2$O] (1.067 g, 1.34 mmol) in THF (80 cm^3) was treated with CH_3CO_2Ag (0.447 g, 2.68 mmol) at 60 °C for 8 h. The resultant light brown precipitate was filtered off and the solution condensed under vacuum to 30 cm^3. Upon cooling (−10 °C), a dark brown solid was deposited, which was filtered off, washed with acetonitrile and dried under vacuum (0.75 g, 65%). M.p. > 320 °C. IR (KBr): $\tilde{\nu}$ = 1638 w, 1597 w, 1577 s, 1570 s, 1530 s, 1468 s, 1430 s, 1367 w, 1272 m, 1190 m, 1150 w, 1061 s, 1000 m, 878 w, 802 m, 797 s, 752 m, 539 w, 510 w, 430 w cm^{-1}. UV/vis (THF): λ_{max} (log ε/dm^3·mol^{-1}·cm^{-1}) = 237 (4.51), 363 (4.32), 385 (4.35), 409 (4.28), 475 (3.84) 720 (2.45) nm. $C_{40}H_{30}Fe_2N_{10}O_5$ (842.4): calcd. C 57.02, H 3.58, Fe 13.25, N 16.63; found C 56.74, H 3.60, Fe 12.97, N 16.57.

X-ray Structure Determination of 2: Suitable crystals of [{FeCl(ind)}$_2$O]·THF were obtained from THF. The intensity data were collected with a Nonius Kappa CCD single-crystal diffractometer, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) and φ scan technique at 293 K. Details of the crystal structure determination are shown in Table 5. The structure was solved by direct and difmap methods (SIR92),[31] and refined on F^2 by using full-matrix least-squares methods.[32,33] CCDC-195083 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Oxidation Reactions: Standard oxidation reactions were carried out under an inert atmosphere of argon. The complex (35 μmol) was dissolved in acetonitrile (10 cm^3) containing 3.5 mmol of substrate. The reaction was then started by adding 3.5 mmol of H_2O_2 or tBuO$_2$H. After stirring for 10 h at 25 °C the products were determined by GC analysis. The structures of the products were confirmed by GC-MS spectrometry, and by comparison with authentic samples.

Catalase-Like Reactions: All reactions were carried out at 25 °C under an argon atmosphere in a thermostatted reactor with stirring. To start the reaction hydrogen peroxide (0.875 mmol, 97 μL) was added through a septum to a stirred solution of the complex (8.75 mmol, 7 mg) in acetonitrile (5 cm^3). The volume of evolved dioxygen was read periodically by using a gas burette. In the kinetic measurements the hydrogen peroxide concentration was first kept constant ([H_2O_2] = 0.175 mol·dm^{-3}) and the concentration of **2** was varied from 0.525 to 3.52 mol·dm^{-3}. To determine the rate dependence on the H_2O_2, the catalyst concentration was kept constant ([**2**] = 1.75 mol·dm^{-3}) and the [H_2O_2] varied in the range 0.0618−0.3088 mol·dm^{-3}.

Cobalt(III) Tetraazamacrocyclic Complexes with Pendant Amino Groups: Synthesis, Structure and Electrochemical Properties

Bohdan Korybut-Daszkiewicz,*[a] Joanna Taraszewska,*[b] Katarzyna Zięba,[b] Krzysztof Woźniak,[c] and Daniel Kamiński[c]

Keywords: Macrocyclic ligands / N ligands / Cobalt / Electrochemistry

Two isomeric *cis*-2,9-bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane (**1** and **2**) and two 2-aminomethyl-2-methyl-1,4,8,11-tetraazacyclotetradecane (**3** and **4**) cobalt(III) complexes have been prepared and characterised. During the synthesis of **2** a minor oxidation product **5** was formed. The structures of **3**, **4** and **5** have been determined by X-ray crystallography, and the UV/Vis spectra of **1**–**5** have been analysed. The average Co–N distances in **1** and **2** have been estimated from the correlation between the average Co–N bond lengths and position of the maximum absorption for hexaamine complexes given in literature. The electrochemical behaviour of **1**–**5** in neutral and acidic solutions has been studied by cyclic voltammetry. In complexes displaying electronic maxima at higher energy, cobalt(III) was reduced at more negative potentials. Small differences in the conformation of ligand between **3** and **4** explain the different behaviour of these complexes in acidic solutions.

Introduction

Compounds containing the sarcophagine group − consisting of the cyclam unit with a single diamine strap bridging the apical sites of the macrocycle[1] − belong to the most extensively studied Co^{III} macrocyclic hexaamine complexes. In these compounds the hexaaza ligand can completely surround the metal ion coordinated in an octahedral manner. Another approach is realised in pendant arm macrocycles, which usually occupy four equatorial sites around coordinated metal ion, and simultaneously, via pendant coordinating amine groups, are bound at one or both axial positions. The synthesis and physico-chemical properties of macrocyclic Co^{III} tetraamines with pendant amine groups have been extensively studied in recent years.[2−6] Recently Bernhardt et al.[7] synthesised the hexaamine with five secondary amine groups in the macrocyclic ring and one pendant primary amine group to give hexadenate octahedral complexes with Co^{III} and other cations. Macrocyclic Co^{III} tetraamines with one pendant amine group coordinated in one axial position and anion coordinated in the second axial position have also been extensively studied[8−12] Such complexes present a different ligand field environment to that found in the neutral hexaamine complexes.

Here we describe the synthesis, characterisation and electrochemical studies of Co^{III} *C*-functionalised cyclam derivatives containing two or one aminomethyl side arms that are able to interact with the metal ion in the central cavity. In two isomeric Co^{III} complexes of *cis*-2,9-bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane (**1** and **2** respectively), the coordination of two pendant amino groups forces the ring to adopt a folded conformation. It was interesting to compare the behaviour of these complexes with their Ni^{II} analogues studied by us recently[13] and with other Co^{III} hexaamine complexes.

The crystallographic data for two isomeric Co^{III} complexes of 2-aminomethyl-2-methyl-1,4,8,11-tetraazacyclotetradecane (**3** and **4**) revealed that both complexes possess the *trans* configuration with the macrocyclic ring occupying the equatorial plane and the apical positions occupied by a pendant NH_2 group and a chloride ion in the *trans* configuration. They differ only in configuration at the secondary amine groups resulting in different conformations of the macrocyclic ring.

A goal of this study was to examine the influence of the macrocyclic ligand conformation on the properties of the synthesised complexes. The structures of the complexes studied are presented in Figure 1.

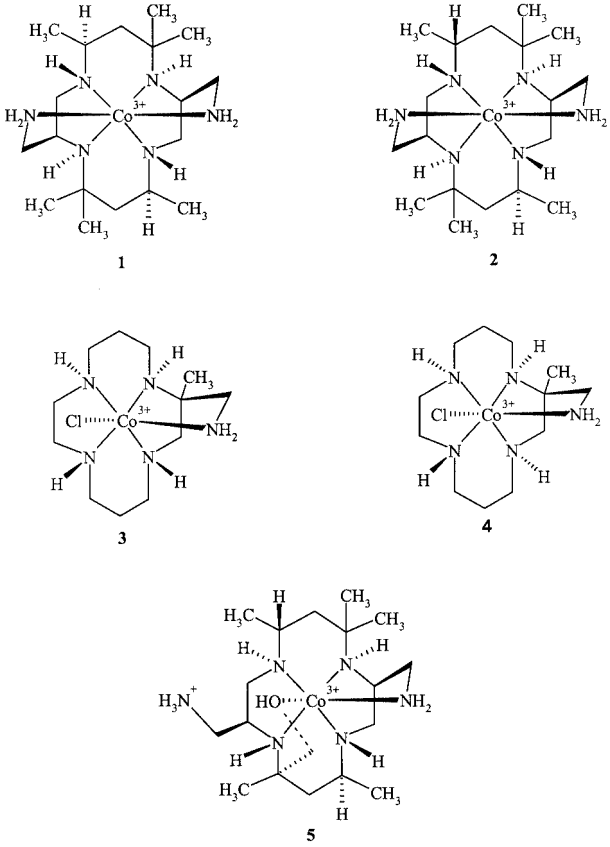

Figure 1. Schematic structures of studied complexes

Results and Discussion

Synthesis and Structure

Cobalt(III) complexes **1** and **2** were prepared by the reaction of free *cis*-2,9-substituted isomeric ligands with $CoCl_2 \cdot 6H_2O$ followed by aerial oxidation. The ^1H and ^{13}C NMR spectra of complexes **1** and **2** are consistent with that expected for the *cis*-fivefolded conformation of ligands – previously observed in their octahedral Ni^{II} complexes.[14]

During the synthesis of **2** (5,12-*trans*) an additional minor oxidation product **5** was formed and isolated by chromatography on a SP Sephadex C-25 column. X-ray analysis (Figure 2) revealed that complex **5** was formed by the oxidation of one of the geminal methyl groups attached to C-5 and located *trans* to the substituents at C-7 and C-10. The macrocyclic ring in complex **5** adopts a *trans*-III planar conformation with the 2-aminomethyl and 5-hydroxymethyl groups coordinated on opposite sides of the macrocycle. The remaining protonated 10-aminomethyl group occupies an equatorial position. A similar dioxygen oxidation of one of the *gem*-dimethyl substituents to a coordinated hydroxymethyl group in *C-meso*-5,7,7,12,12,14-hexamethyl-1,4,8,11-tetrazacyclotetradecane have been reported by House et al.[15]

The *N*-isomeric cobalt(III) complexes **3** and **4** were similarly obtained and separated by chromatography on a Dowex 50WX2 cation-exchange column. Slow evaporation of acetonitrile–methanol (9:1) solutions gave crystals suitable for X-ray crystal analysis.

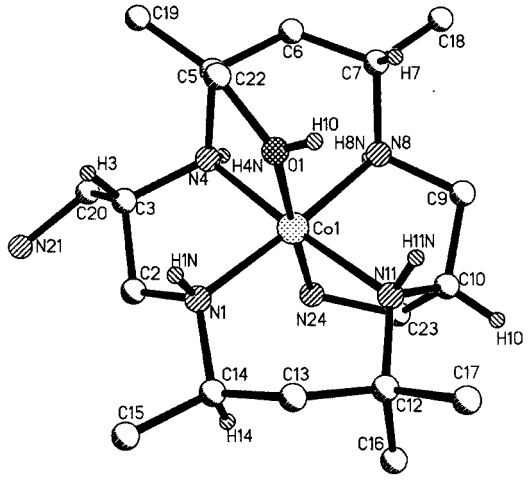

Figure 2. Molecular structure and labelling of atoms for the complex **5**; selected bond lengths (Å) are: Co(1)–O(1) 1.920(3), Co(1)–N(1) 1.957(4), Co(1)–N(4) 1.959(3), Co(1)–N(8) 1.983(3), Co(1)–N(11) 1.961(3), Co(1)–N(24) 1.936(4)

The molecular structures of cations **3** and **4** are shown in Figure 3 and 4, respectively. Both cations have irregular octahedral Co^{III} coordination spheres with the macro-cycle coordinated in a planar conformation and the pendant amino group in the apical position. The sixth coordination position is occupied by a chloride anion; *trans*-III (1*RS*,2*RS*,4*RS*,8*SR*,11*SR*) and *trans*-II (1*RS*,2*RS*,4*SR*,8*RS*,11*RS*) ligand configurations were established for **3** and **4**, respectively. The chloride anion in isomer **4** is coordinated on the same side of the macrocycle as three secondary amino group protons. The Co–Cl bond is longer [2.265(2) and 2.258(3) Å for two independent molecules] in the isomer **4** than in **3** [2.249(2) Å]. The two six-membered endomacrocyclic chelate rings in the cation **3** adopt the chair conformation, whereas one of them in isomer **4** [N(11)–N(1)] exists in the twist-boat conformation. The five-membered chelate rings exist in an envelope conformation in both isomers.

Solution Properties

Electronic Spectroscopy of Complexes

The aqueous solution UV/Vis electronic spectra of complexes **1**−**5** are presented in Table 1.

The spectra of complexes **1** and **2** exhibit two spin-allowed d−d transitions characteristic of low-spin d^6 ion in a pseudooctahedral ligand field. The transitions $^1T_{2g}\leftarrow{}^1A_{1g}$ and $^1T_{1g}\leftarrow{}^1A_{1g}$ in both complexes occur at lower energies than those in Co^{III} complexed with *cis*-6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane-6,13-diamine (*cis*-diammac) and other Co^{III} hexaamine complexes.[4] The electronic spectrum of complex **1** displays electronic maxima at higher energies than those of **2**. Spectra of the complexes **3** and **4** exhibit three bands that are similar to those of other complexes of this type.[8,9,11,12] The appearance of the three bands is connected with the lower symmetry of the both complexes in comparison with hexaamine with two pendant NH_2 groups. The transition maxima occur at higher energies for **3** than for **4**. For complexes **1**−**4**, for each pH value, the electronic spectra were unchanged after 5 h, proving the lack of protonation of the amine groups in **1** and **2** and the lack of hydrolysis of the chloro-ligands in the complexes **3** and **4**.

For complex **5** in a neutral solution, the first band was observed as a shoulder at about 340 nm, due to overlap with a strong absorption band in the UV region. The second band appeared at 489 nm. In acidic medium the shoulder and the second band appeared at 338 nm and 469 nm, respectively. This indicates that in neutral solution the pendant amino group substitutes the hydroxy group in the coordination sphere of the central metal ion. In the acidic medium the amino group is protonated and the reverse process takes place.

A correlation has been reported[16] between the Co−N bond length and the position of the absorption maxima in $[Co(N)_6]$ complexes. Unfortunately, for the complexes **1** and **2** we have no crystallographic data. To estimate the average Co−N distance in these complexes we plotted (Figure 5) the λ_{max} values for $^1T_{2g}$ and $^1T_{1g}$ transitions against the average Co−N bond lengths for hexaamine complexes **6**−**12** taken from the literature (Table 1). The structures of complexes **6**−**12** are presented in Figure 6. The open circles and squares in Figure 5 are for complexes **1** and **2**, respectively. The estimated average Co−N distances from this correlation are 1.989 and 2.010 Å for **1** and **2**, respectively.

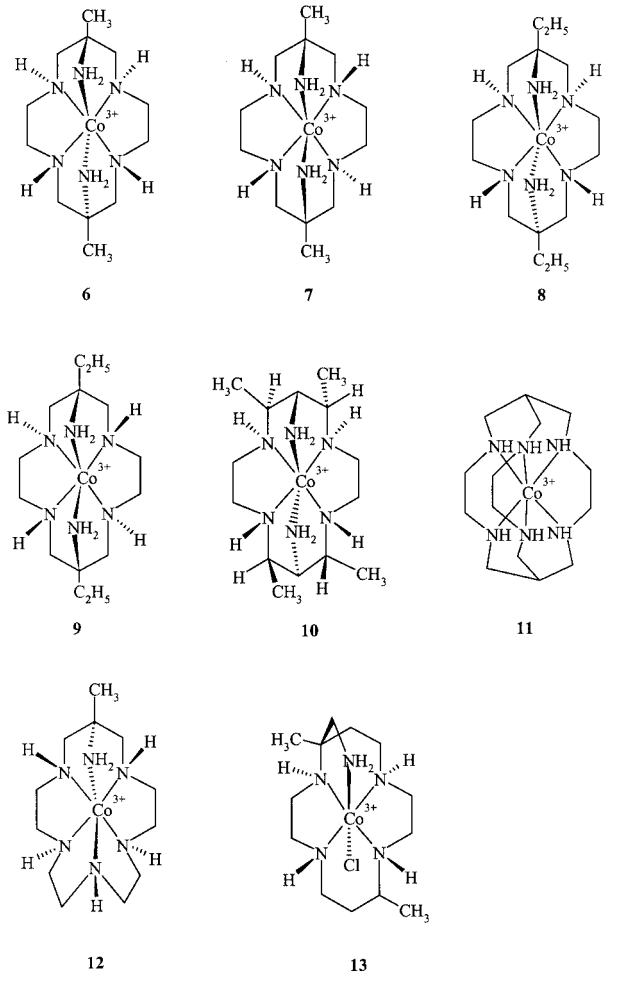

Figure 6. Schematic structures of Co^{III} hexaamine complexes **6**−**11**,[4] **12**[7] and chloro-pentaamine complex **13**[9]

Redox Properties of Complexes and Acid−Base Equilibria

The voltammetric behaviour of **1**−**4** was studied in aqueous solutions containing 0.1 M NaCl as the supporting electrolyte. The redox process Co^{III}/Co^{II} in all complexes was reversible or quasi-reversible. The values of formal potentials E_f, calculated as midpoints between the corresponding cathodic and anodic peaks, are −0.52, −0.48, −0.43 and −0.37 V for complexes **1**−**4**, respectively.

In **1** the ratio i_c/i_a was less than 1 which suggests that the larger Co^{II} ion cannot be well accommodated in the macrocyclic cage and the complex starts decomposing. This is supported by the smaller estimated average Co−N distance for **1** compared with **2**. On the C.V. curves recorded at higher scan rates (1 V s^{-1}) the ratio i_c/i_a was 1.

In comparison with other hexaamine complexes,[4] the redox potentials of the complexes **1** and **2** are shifted to less negative values. Replacement of one -NH_2 group by chloride causes a further positive shift. Comparison of the spectrophotometric and electrochemical parameters for **1**−**5** with those from literature revealed a very good correlation between E_f and λ_{max} (Figure 7). Consequently, for complexes displaying electronic maxima at higher energy, Co^{III} is reduced at more negative potentials. A similar correlation was found for Ni^{II} hexaamine complexes by Gavrish and Lampeka.[17]

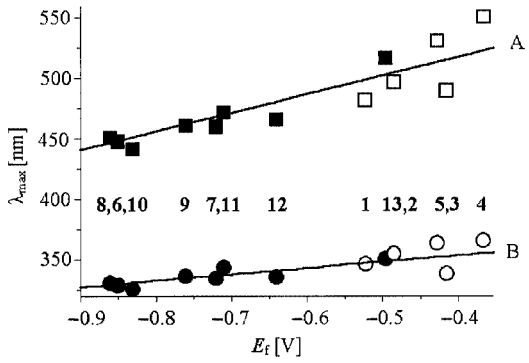

Figure 7. Plots of λ_{max} against formal potentials E_f for Co^{III} complexes **6**−**13**. Open circles and squares refer to complexes **1**−**5**; A for $^1T_{1g} \leftarrow {}^1A_{1g}$ and B for $^1T_{2g} \leftarrow {}^1A_{1g}$ transitions, respectively

The presence of a charged Cl^- donor instead of neutral primary amine group clearly changes both the charge and electronic effects in the complex. As the average Co−N distances in **3** and **4** are similar, the main reason for the difference in E_f values is that the Co−Cl distances are ca. 2.249(2) Å in **3**, and 2.265(2) and 2.258(3) Å in **4**. The longer Co−Cl distance in **4** diminishes the electronic density on the central ion and facilitates reduction of the Co^{III} complex. The shorter Co−NH_2 distance in complex **4** than in **3** seems to play a minor role.

The behaviour of Co^{III} in complexes **1**−**3**, in acidic solutions was similar. Up to the lowest value, pH 1, Co^{III} was reduced at the same potential as in neutral solutions and the reduction currents remained constant, indicating that the pendant NH_2 groups are not protonated. Upon lowering of pH from 7 to 1, the redox process Co^{III}/Co^{II} in **1** and **2** become less reversible ($\Delta E \approx 100$ mV) and the anodic peaks continuously diminished. In **3** up to pH 2.5, the redox process was quasi-reversible with $i_{pa}/i_{pc} = 1$. At lower pHs the anodic current started to diminish due to the protonation of the NH_2 group. The presence of two axial protons from the secondary amino groups in the macrocyclic ring in the neighbourhood of the protonated NH_3^+ group may explain why Co^{II} cannot coordinate either a H_2O molecule or a Cl^- anion. Therefore, this complex is electrochemically inactive. Similarly, the lack of the oxidation of Co^{II} in the protonated form of **2** may be connected with the presence of many methyl groups in the macrocyclic ring, which prevent access of axial ligands.

With increasing solution acidity, the behaviour of the complex **4** was different than that of **3** (Figure 8), indicating that even small differences in structure can significantly influence the electrochemistry. With decreasing pH, the reduction potential of Co^{III} shifts towards less negative values. However, the height of the peak remains constant, which means that the −NH_2 group in this complex is not protonated. The shift of the Co^{III} reduction potential may be connected with the competition between protons from solution and the metal centre for chloride ion, which is at

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

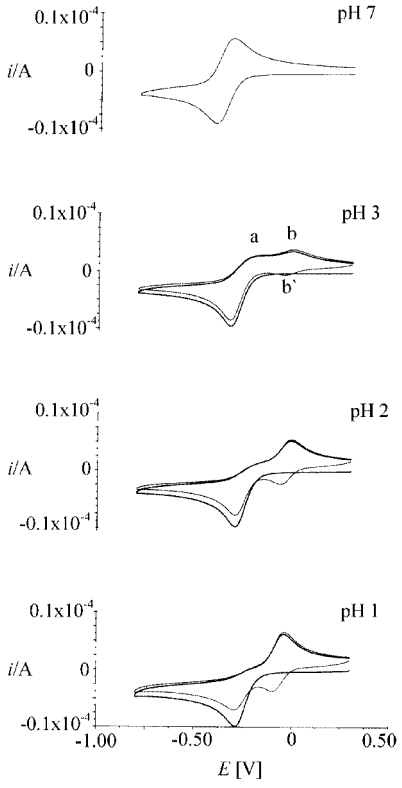

Figure 8. Cyclic voltammograms of 5×10^{-4} M of complex **4** recorded at the GC-20 electrode in aqueous 0.1 M NaCl solution at various pH, scan rate 0.05 V s^{-1}

a longer distance than in **3**. This weakens its coordination ability and decreases the charge density on Co^{III}, making the reduction process easier.

In the anodic scan at pH 3, the anodic peak *a* diminishes as in the other complexes and a new anodic peak *b* appears at about 0.0 V. The product formed at this potential is subsequently reversibly reduced at a potential of peak *b′* in the second scan. The heights of peaks *b* and *b′* increase with lowering pH. The formal potential $E_f = -0.07$ V of this process is similar to that corresponding to the redox process Co^{III}/Co^{II} in $[Co^{III}\text{-cyclam}Cl_2]Cl$[9] (about −0.11 V). Therefore, we can assume that, after protonation of the NH_2 group, Co^{II} in **4** coordinates the Cl^- ion and the second pair of peaks is connected with the Co^{III}/Co^{II} redox process from complex **4** with two chloride ions coordinated to the metal centre. In an experiment performed in 0.1 M $HClO_4$ solution the second pair of peaks appeared at positive potentials (E_f about +0.11 V), which suggests that, after protonation of the -NH_2 group, the ligand at the second apical position was replaced by a water molecule.

In **5**, the reduction potential of Co^{III} is shifted with decreasing pH towards less negative values. For example, from −0.46 V at pH 7 to −0.31 V at pH 1. This is in agreement with the postulated substitution of the coordinated hydroxy group in a neutral solution by the pendant -NH_2 group, protonation of it at low pH values, and subsequent replacement by the OH group.

Conclusion

Structural properties such as ring size and conformation of the ligands studied by us are very selective in the stabilisation of the Co^{II} cations. The effect of the ring size was particularly evident in the case of Co^{II} in the complex **1**. This complex decomposed because Co^{II} could not be well accommodated in the macrocyclic cavity. The redox process in hexaamine complexes **1** and **2** was recorded at more negative potentials than in the complexes **3** and **4** with an axially coordinated Cl donor instead of a neutral primary amine group. The longer Co−Cl distance in complex **4** facilitated the reduction of Co^{III}. Small differences in the ligand conformation between **3** and **4** caused different behaviour of these complexes in acidic solutions.

Experimental Section

Syntheses: The preparation of 2-aminomethyl-2-methyl-1,4,8,11-tetraazacyclotetradecane and isomeric (2*RS*,5*RS*,9*RS*,12*RS*)- and (2*RS*,5*SR*,9*RS*,12*RS*)-2,9-bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecanes has been described elsewhere.[14]

Instrumentation: Cyclic voltammograms of complexes **1**−**5** were measured at a glassy carbon (GC-20) electrode, with a Pt plate as the counter electrode. The reference electrode, a 1 M NaCl aqueous calomel electrode (MCE), was connected to the electrolytic cell via an intermediate vessel filled with the solution under investigation. Solutions were deaerated by flushing with pure argon. An Autolab (EcoChemie) measuring system was used. Electronic spectra were recorded using a Cary 1 (Varian) spectrophotometer. The NMR spectra were obtained on a Bruker AM 500 spectrometer.

(2*RS*,5*RS*,9*RS*,12*RS*)-2,9-Bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecanecobalt(III) Trichloride (1): A solution of free ligand (0.34 g, 0.001 mol) in methanol (10 cm^3) was added to a solution of $CoCl_2 \cdot 6H_2O$ (0.24 g, 0.001 mol) in methanol (20 cm^3) and aerated overnight, diluted with water (100 cm^3) and absorbed on the SP Sephadex C-25 column. The column was eluted with a 0.1 M solution of sodium sulfate. The single orange band was collected, absorbed on a Dowex 50WX2 cation-exchange column (H^+ form) that was washed with 1 M HCl and eluted with 3 M HCl. An orange eluate was evaporated to dryness and the residue dissolved in a methanol−acetonitrile mixture. Upon evaporation of methanol, orange crystals were obtained. Yield 0.34 g (70%). $C_{18}H_{42}Cl_3CoN_6 \cdot 2H_2O$ (543.9): calcd. C 39.8, H 8.5, Cl 19.6, N 15.5; found C 39.9, H 8.7, Cl 20.1, N 15.8. ^1H NMR (500.13 MHz, D_2O + DCl): δ = 1.41 (s) and 1.44 (s, 7,14-CH_3), 1.37 (d, 5,12-CH_3), 3.05 (m, 5,12-CH), 2.59 (d) and 3.06 (m, 2,9-CH_2NH_2), 3.54 (m, 2,9-CH), 1.73 (m) and 1.75 (m, 6,13-CH_2) 3.08 (m) and 3.18 (m, 3,10-CH_2), 4.70 (1,8-NH), 5.93 (4,11-NH), 4.92 and 5.49 (NH_2) ppm. ^{13}C NMR (125.8 MHz, D_2O +DCl): δ = 28.0 and 30.8 (7,14-CH_3), 22.0 (5,12-CH_3), 46.9 (2,9-CH_2NH_2), 66.1 (2,9-C), 60.2 (3,10-C), 59.9 (5,12-C), 47.9 (6,13-C), 59.0 (7,14-C) ppm.

(2*RS*,5*SR*,9*RS*,12*RS*)-2,9-Bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecanecobalt(III) Trichloride (2) and 2-Aminomethyl-9-ammoniummethyl-7-hydroxymethyl-5,7,12,14,14-pentamethyl-1,4,8,11-tetraazacyclotetradecanecobalt(III) Tetrachloride (5): These complexes were obtained from the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(2*RS*,5*SR*,9*RS*,12*RS*) isomer of the macrocyclic ligand by the same procedure. The minor red ligand oxidation product **5** was isolated as the first band eluted from a SP Sephadex C-25 column. Yield 60% and 8% of **2** and **5**, respectively.

Complex 2: $C_{18}H_{42}Cl_3CoN_6 \cdot 3H_2O$ (561.9): calcd. C 38.5, H 8.6, Cl 18.9, N 14.9; found C 38.9, H 8.2, Cl 18.6, N 14.6. ^{1}H NMR (500.13 MHz, D_2O): δ = 1.35 (s), 1.42 (s), 1.43 (s) and 1.47 (s, 7,14-CH_3), 1.27 (d) and 1.37 (d, 5,12-CH_3), 3.05 (m) and 3.20 (m, 5,12-CH), 2.71 (d), 3.00 (bd) and 2.66 (d), 3.00 (bd, 2,9-CH_2NH_2), 3.53 (t) and 3.59 (t, 2,9-CH), 1.56 (d), 2.16 (dd) and 1.62 (dd), 1.68 (dd, 6,13-CH_2) 3.29 (d), 3.14 (m) and 2.73 (d), 3.12 (m, 3,10-CH_2) ppm. ^{13}C NMR (125.8 MHz, D_2O): δ = 25.3, 27.8, 31.5 and 35.4 (7,14-CH_3), 21.2 and 22.3 (5,12-CH_3), 46.1 and 48.6 (2,9-CH_2NH_2), 64.8 and 64.8 (2,9-C), 50.8 and 61.3 (3,10-C), 52.9 and 59.8 (5,12-C), 45.2 and 47.7 (6,13-C), 59.8 and 61.1 (7,14-C) ppm.

Complex 5: $C_{18}H_{43}Cl_4CoN_6O \cdot 2H_2O$ (596.4): calcd. C 36.3, H 7.9, N 14.1; found C 36.6, H 7.9, N 13.6. ^{1}H NMR (500.13 MHz, D_2O): δ = 1.34 (s), 1.41 s, 1.58 (s) (7,14-CH_3), 1.34 and 1.50 (d, 5,12-CH_3), 3.35 (s, 7-CH_2OH) ppm. ^{13}C NMR (125.8 MHz, D_2O): δ = 20.0, 20.6, 21.3, 25.1, 32.5 (CH_3), 43.0, 47.8, 49.2, 52.1, 53.1, 55.4, 56.9, 57.1, 57.5, 59.7, 62.1, 70.5, 71.3 ppm.

Isomeric 2-Aminomethyl-2-methyl-1,4,8,11-tetraazacyclotetradecanecobalt(III) Trichlorides (3 and 4): A solution of 2-aminomethyl-2methyl-1,4,8,11-tetraazacyclotetradecane (1.0 g, 0.004 mol) in methanol (40 cm^3) was added to solution of $CoCl_2 \cdot 6H_2O$ (1.0 g, 0.004 mol) in methanol (60 cm^3) and aerated overnight, acidified with concentrated HCl (1 cm^3), diluted with water (500 cm^3) and then absorbed on a Dowex 50WX2 cation-exchange column (H^+ form). The column was washed with 1 M HCl and eluted with 2 M HCl. Two deep red bands were separated and the solvents evaporated to dryness. The residues were dissolved in small volumes of methanol and diluted with acetonitrile. Upon evaporation deep red crystals were obtained from both fractions. Yield 0.7 g (41%) of **3** (first fraction) and 0.6 g (35%) of **4** (second fraction).

Complex 3: $C_{12}H_{29}Cl_3CoN_5 \cdot 2H_2O$ (444.72): calcd. C 32.4, H 7.4, Cl 23.9, N 15.8; found C 32.1, H 7.4, Cl 24.5, N 15.8. ^{1}H NMR (500.13 MHz, D_2O + DCl): δ = 1.36 (s, 2-CH_3), 2.78 (m) and 2.86 (m, pendant-CH_2), 4.00 (m), 4.04 (m, NH_2), 6.52 (1-NH), 2.95 (3-CH, ax), 3.00 (3-CH, eq.), 5.56 (4-NH), 3.19 (5-CH, ax), 2.48 (5-CH, eq.), 1.97 (6-CH, ax), 2.05 (6-CH, eq.), 2.67 (7-CH, ax), 2.96 (7-CH, eq.), 6.00 (8-NH), 2.58 (9-CH, ax), 3.06 (9-CH, eq.), 2.56 (10-CH, ax), 3.01 (10-CH, eq.), 6.12 (11-NH), 2.65 (12-CH, ax), 2.85 (12-CH, eq.), 1.82 (13-CH, ax), 2.20 (13-CH, eq.), 2.30 (14-CH, ax), 2.93 (14-CH, eq.) ppm. ^{13}C NMR (125.8 MHz, D_2O +DCl): δ = 16.5 (2-CH_3), 48.8 (pendant-CH_2), 71.4 (2-C), 63.7 (3-C), 48.9 (5-C), 29.2 (6-C), 51.0 (7-C), 54.3 (9-C), 55.9 (10-C), 50.6 (12-C), 28.8 (13-C), 46.1 (14-C) ppm, assignments established on the basis of ^{1}H−^{1}H and ^{1}H−^{13}C correlation experiments.

Complex 4: $C_{12}H_{29}Cl_3CoN_5 \cdot H_2O$ (426.70): calcd. C 33.8, H 7.3, Cl 24.9, N16.4; found C 33.6, H 7.3, Cl 25.2, N 16.1. ^{1}H NMR (500.13 MHz, D_2O + DCl): δ = 1.33 (s, 2-CH_3), 2.67 (m) and 2.88 (m, pendant-CH_2), 3.97 (m, NH_2), 6.27 (bd, 1-NH), 3.34 (m, 3-CH, ax), 2.69 (m, 3-CH, eq.), 6.47 (bt, 4-NH), 2.58 (5-CH, ax), 2.94 (5-CH, eq.), 1.83 (6-CH, ax), 2.17 (bd, 6-CH, eq.), 2.90 (7-CH_2), 6.28 (8-NH), 2.67 (m, 9-CH, ax), 2.98 (m, 9-CH, eq.), 2.45 (m, 10-CH, ax), 3.09 (m, 10-CH, eq.), 5.89 (bt, 11-NH), 2.59 (12-CH, ax), 2.91 (12-CH, eq.), 2.09 (m, 13-CH, ax), 2.25 (m, 13-CH, eq.), 2.53 (14-CH, ax), 2.88 (14-CH, eq.) ppm. ^{13}C NMR

X-ray Crystallography: Crystal structure data for**3**, **4** and **5** are given in Table 2, together with refinement details. All measurements of crystal were performed on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo-K_α radiation. The crystal was positioned at 65 mm from the KM4CCD camera. For complex **3**: 4 runs of 575 frames each were measured at 0.2° intervals with a counting time of 37 s. For complex **4**: 4 runs of 153 frames each were measured at 0.75° intervals with a counting time of 30 s. For complex **5**: 4 runs of 153 frames each were measured at 0.75° intervals with a counting time of 30 s. The data were corrected for Lorentz and polarisation effects. No absorption correction was applied. Data reduction and analysis were carried out with the Kuma Diffraction (Wrocław) programs (KM4CCD and KM4RED).

The structures were solved by direct methods[18] and refined using SHELXL.[19] The refinement was based on F^2 for all reflections except those with very negative F^2. Weighted R factors wR and all goodness-of-fit S values are based on F^2. Conventional R factors are based on F with F set to zero for negative F^2. The $F_o^2 > 2s(F_o^2)$ criterion was used only for calculating R factors and is not relevant to the choice of reflections for the refinement. The R factors based on F^2 are about twice as large as those based on F. Most hydrogen atoms were located from differential maps and refined isotropically but some were fixed at ideal geometrical positions. For **4**, we were unable to find one hydrogen atom belonging to the disordered water molecule. One of the water molecules in **4** occupies a special position. Refinement of the solvent molecules is slightly worse. Scattering factors were taken from Tables 6.1.1.4 and 4.2.4.2 in ref.[20]

CCDC-187666, CCDC-187667 and CCDC-187668 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/etrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The X-ray measurements were undertaken at the Crystallographic Unit of the Physical Chemistry Laboratory at the Chemistry Department of the University of Warsaw.

Novel P,N Ligands Derived from (*R*)- and (*S*)-1-Phenylethylamine with (2*R*,5*R*)-2,5-Dimethylphospholanyl Groups (DuPHAMIN) for Asymmetric Catalysis

David J. Brauer,*[a] Konstantin W. Kottsieper,[a] Stefan Roßenbach,[a] and Othmar Stelzer[a][†]

Keywords: Asymmetric catalysis / N,P ligands / Rhodium

Novel P,N chelating ligands with three stereogenic centres in positions α to the donor atoms have been prepared in good yields and high enantiomeric purity by a series of reactions beginning with either (*R*)- or (*S*)-1-phenylethylamine. These isomers were first lithiated with *t*BuLi and converted into aminophosphanes **3a** by treatment with $(Et_2N)_2PCl$. They were transformed into the enantiomeric primary phosphanes **4** by quantitative solvolysis with ethanol to give the phosphonous acid esters **3b** and subsequent reduction with $LiAlH_4$. Stepwise treatment of **4** with *n*BuLi and the cyclic sulfate of (*S*,*S*)-2,5-hexanediol gave the isomeric tertiary phosphanes (*R*,*RR*)-**5** and (*S*,*RR*)-**5**. Treatment of the aminophosphane (*R*)-**3a** with (*R*)-2,2′-binaphthol yielded the aminophosphonite (*R*,*R*)-**6** in high yields. Cationic (COD)Rh complexes of **5** were prepared by treatment with $[Rh(COD)Cl]_2$, the PF_6^- salts **7a** being isolated. Analogous (2,5-norbornadiene)Rh complexes **7b** were prepared similarly. The chelate nature of the P,N ligands in these salts is indicated by their NMR spectra in solution and is confirmed by the crystal structures of (*R*,*RR*)-**7a** and (*S*,*RR*)-**7a**. With the exception of (*S*,*RR*)-**7a**, the complexes **7a** and **7b** are shown to catalyse the asymmetric hydrogenation of methyl acetamidocinnamate at room temperature. Differences in the catalytic activity of the complexes are related to the different dynamic behaviour detected by the ^1H EXSY spectra for the COD ligands of **7a**.

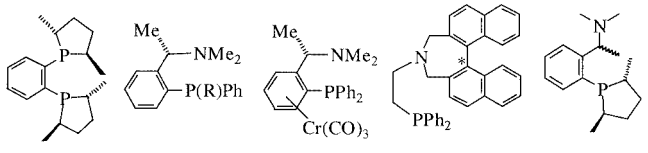
Introduction

Chiral chelates containing phosphorus and an electronically different donor atom can be highly effective coligands in a variety of transition-metal-catalysed asymmetric reactions. The enantioselectivities achieved in these systems[1] may well be comparable with those obtained by use of the established C_2-symmetrical diphosphanes of the DuPHOS type[2] (**1a**), attributed to the electronic asymmetry in the vicinity of the metallic coordination centre. For instance, the different *trans* effects of the coordinating atoms may enhance the steric influence exerted by the chiral substituents on the optical induction. The application of the concept of electronic disparity[3] has in the last decade resulted in the development of novel bidentate P,N hybrid ligands such as **1b**−**1d**[4] for enantioselective catalysis.[5]



1a **1b** **1c** **1d** **1e**

Ligands of type **1b** are derived from the cheap, commercially available (*R*)- and (*S*)-1-phenylethylamine. We wondered whether it is possible to introduce chiral 2,5-dialkylated phospholane units in place of the P(R)Ph groups of **1b**. Such a synthesis would yield hitherto unknown P,N hybrid ligands **1f** (“DuPHAMIN”) with three stereogenic centres in positions α to the donor atoms P and N. Their catalytic activity would be of particular interest because the interaction of the different types of chiral groups should give “matching” and “mismatching” effects[6] and potentially offer control over stereoselectivity in catalytic reactions.

Results

Lithiation of (*R*)-(+)-**2** with *t*BuLi[7] and subsequent treatment of the organolithium product with $(Et_2N)_2PCl$ gave the aminophosphane (*R*)-(+)-**3a** in 74% yield. (*S*)-(−)-**3a** was analogously derived from (*S*)-(−)-**2**. Solvolysis with ethanol quantitatively formed the corresponding phosphonous acid esters (*R*)-(+)- and (*S*)-(−)-**3b** (Scheme 1). These were reduced with $LiAlH_4$ to yield the two enantiomeric primary phosphanes **4**. The polyphosphane **4b** and the diphosphane **4a** were formed as side products, and these gave further primary phosphane **4** on treatment with potassium and subsequent hydrolysis {(*R*)-**4**: $[\alpha]_D^{20} = 73.3$ (*c* =

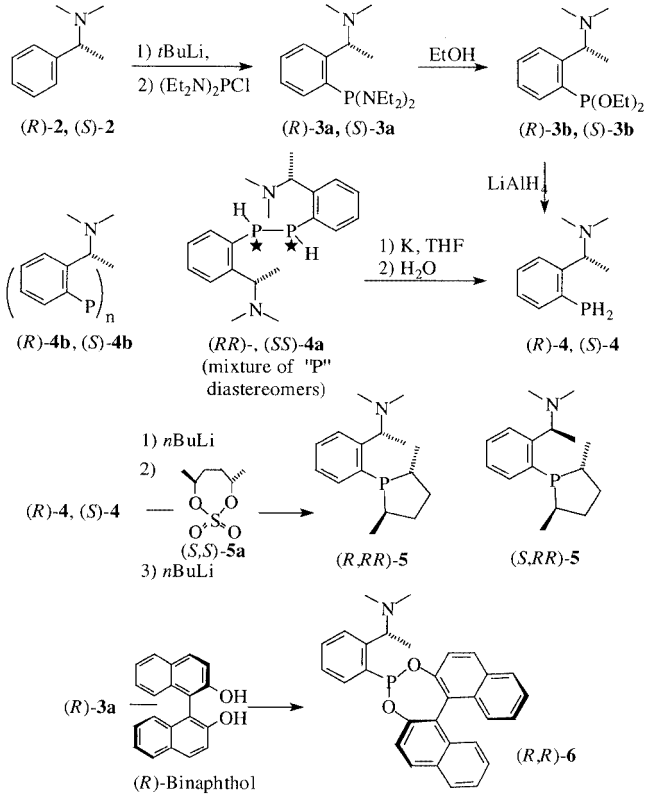
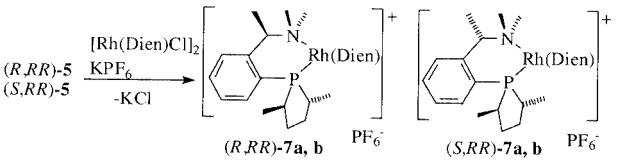
1.1, CH_2C1_2); (*S*)-**4**: $[\alpha]_D^{20} = -74.4$ (c = 1.1, CH_2C1_2)}. Enantiomers **4** each show a triplet in the $^{31}P\{^1H\}$ NMR spectrum at $\delta_P = -121.95$ ($^1J_{PH}$ = 200.5 Hz). No enantiomerically pure phenylphosphane derivatives of type **4** have previously been reported in the literature. They are synthons of broad applicability for the preparation of chiral P,N ligands by structural variation at the reactive PH_2 group. Thus, stepwise treatment of (*R*)-(+)-**4** with *n*BuLi and cyclic sulfate (*S,S*)-**5a**[8] resulted in the formation of the isomeric tertiary phosphanes (*R,RR*)-**5** in 82% yield, while (*S,RR*)-**5** was obtained analogously in 68% yield. They show singlets at $\delta = -7.10$ or -4.53 ppm, respectively, in the $^{31}P\{^1H\}$ NMR spectrum, no signals that might indicate the presence of additional diastereomers being detected. From the optical purity of the starting materials and the unlikelihood of simultaneous inversion of all three stereogenic centres, the enantiomeric purity of the phosphane ligands of type **5** should exceed 98%. The ^1H NMR spectra of (*R,RR*)-**5** and (*S,RR*)-**5** were analysed completely, and the ^1H NMR spectrum of the phospholane group was simulated as an $ABCDMNQ_3R_3X$ spin system {A, B, C, D = ^1H (C_2H_4); M, N = ^1H [C*H*(Me-P); Q, R = ^1H [CH(*Me*-P)]; X = ^{31}P}. As expected, fifteen resonances were observed in the $^{13}C\{^1H\}$ NMR spectra of both (*R,RR*)-**5** and (*S,RR*)-**5**, in part showing $^nJ_{PC}$ doublet fine structure (n = 1−3) (see Exp. Sect.).



Scheme 1. Syntheses of the chiral P,N ligands

Like (*R*)-**4** and (*S*)-**4**, the aminophosphanes (*R*)-**3a** and (*S*)-**3a** may also be employed as starting materials for the modular synthesis of P,N hybrid ligands based on commercially available (*R*)-and (*S*)-1-phenylethylamine. Treatment of (*R*)-**3a** with (*R*)-2,2′-dihydroxy-1,1′-binaphthyl afforded the novel, axially chiral aminophosphonite ligand (*R,R*)-**6** in high yield.

Treatment of each isomer of **5** with [Rh(1,5-cyclooctadiene)Cl]$_2$ or [Rh(2,5-norbornadiene)Cl]$_2$ and subsequent metathesis with KPF_6 gave the stable Rh^I complexes (*R,RR*)-**7a/b** and (*S,RR*)-**7a/b** (Scheme 2). The observation of two resonances for the diastereotopic Me groups of the NMe_2 unit in the ^1H NMR indicates the P,N coordination of both isomers of **5** in the Rh complexes in solution. This is corroborated by the ^{31}P-^{13}C-coupling fine structure [$^3J_{PC}$ = 2.5 Hz, (*R,RR*)-**7a**; 3.4 Hz, (*S,RR*)-**7a**] of one of the $^{13}C\{^1H\}$ NMR signals of the NMe_2 groups.[9] These observations rule out a rapid dissociation of the N donor of **5** on the NMR time scale.



Scheme 2. Syntheses of the complexes (*R,RR*)-**7a**, (*R,RR*)-**7b**, (*S,RR*)-**7a**, and (*S,RR*)-**7b**

Crystal Structures

The crystal structures of (*R,RR*)-**7a** and (*S,RR*)-**7a** have been determined by X-ray diffraction, and drawings of the cations are displayed in Figures 1 and 2. As shown by the distances and angles listed in Tables 1 and 2, good agreement is found for the Rh coordination in the two compounds. The studies confirm the P,N coordination of the novel ligands, the (*R*) configurations of the two carbon atoms α to the phospholane unit and the respective (*R*) and (*S*) configurations of the carbon atom α to the two $CH(Me)NMe_2$ groups.

Inspection of the bottom drawings in Figures 1 and 2 reveals that the inversion of configuration of the benzylic carbon atom is associated with a marked change in the conformation of the $Rh^a-P-C-C-C-N^b$(Rh^a-N^b) chelate ring. Cremer−Pople analysis[10] of their geometries shows that the puckering amplitude of (*S,RR*)-**7a** (0.673 Å) is greater than that of (*R,RR*)-**7a** (0.566 Å). The conformation of the former lies near the half-boat form with the N atom displaced by 0.873(3) Å (rms deviation 0.055 Å) from the plane defined by the other five ring atoms. In contrast, the screw-boat form appears to be the best description of the conformation of the chelate ring in the other isomer, the P1 and α-carbon C1 atoms deviating from the best plane (rms deviation 0.068 Å) of the other four ring atoms by 0.140 and 0.667 Å, respectively.

The methyl group at the α-carbon atom in each structure is found to occupy a pseudoaxial position on the chelate ring, thus avoiding close contact with the neighbouring

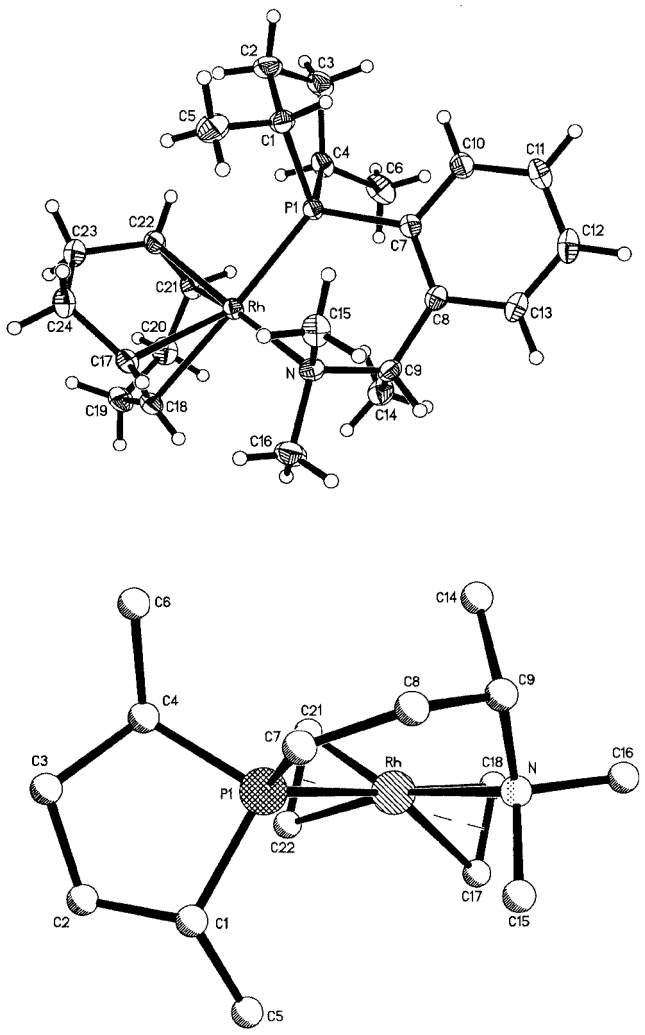

Figure 2. Structure of the cation of (*S*,*RR*)-**7a** (top); front view, showing the orientation of the phospholane group and the chelate ring of (*S*,*RR*)-**7a** (bottom); hydrogen atoms have been omitted for clarity

phenylene hydrogen atom. In (*R*,*RR*)-**7a** this methyl substituent C2 lies on the same side of the chelate ring as the phospholane methyl group C15, which is directed towards the COD ligand. Although these methyl groups are separated by six bonds, they are brought into contact distance [3.823(5) Å] by the screw-boat conformation adopted by the chelate ring. The corresponding methyl groups in (*S*,*RR*)-**7a** lie on opposite sides of the chelate ring. Here, the inwardly directed phospholane methyl group C5 makes a van der Waals contact with the pseudoaxial *N*-methyl group C15 [3.901(8) Å].

The centroids M1 (*trans* to P1) and M2 (*trans* to N) of the C=C double bonds do not lie in the P1−Rh−N plane. The dihedral angle formed by the normals to the M1−Rh−M2 and P1−Rh−N planes is significantly smaller in (*S*,*RR*)-**7a** (14.4°) than in (*R*,*RR*)-**7a** (21.4°). As an inspection of Figures 1 and 2 reveals, the sense of the out-of-plane twist of the COD ligands is the same in the two compounds. Apparently, the orientation of the COD ligands in the solid state reflects the arrangement of the phospholane ring more than it does the disposition of the NMe_2 group. While a similar value was found for this angle in [(COD)Rh{(*R*,*R*)-2,4-bis[(*R*,*R*)-2,5-dimethylphospholano]pentane}]OTf (mean value: 19.3°), a significantly smaller angle (mean 2.6°) was reported for the corresponding (*S*,*S*;*R*,*R*) isomer.[11]

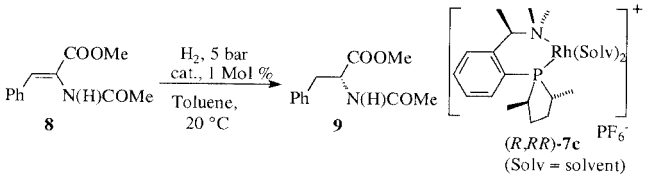
Catalytic Properties

The hydrogenation of methyl (*Z*)-α-acetamidocinnamate (**8**) at 20 °C is catalysed by (*R*,*RR*)-**7a**. Under a hydrogen pressure of 5 bar, the (*R*) isomer of **9** was formed with 95% *ee*. (Scheme 3). No reaction was observed when (*S*,*RR*)-**7a** was employed as the catalyst under these conditions. At higher temperature (60 °C) the (*R*) isomer of **9** is formed with 60% *ee*.



Scheme 3. Hydrogenation of methyl (*Z*)-α-acetamidocinnamate

The difference in the activities of the isomers of **7a** indicates that the catalytically active species **7c** is formed more rapidly in the case of (*R*,*RR*)-**7a**. This is supported by the observation that (*R*,*RR*)-**7a**, on treatment at room temperature with hydrogen, yields cyclooctane, identified by ^{1}H NMR spectroscopy, while (*S*,*RR*)-**7a** did not react. The COD ligand in the latter isomer is obviously bound to the transition metal atom much more tightly than in (*R*,*RR*)-**7a**. This is also indicated by the different dynamic behaviour of the COD ligands in the two isomers as derived from the 400 MHz ^{1}H NOESY spectrum of the olefinic hydrogen atoms. While (*R*,*RR*)-**7a** shows EXSY peaks,[12] these are not observed in the case of (*S*,*RR*)-**7a** (Figure 3). This may be interpreted as a result of diolefin rotation[13] causing a rapid exchange of the CH=CH groups *trans* to the N and P atoms.

A simple mechanism for diolefin rotation at our square-planar d^8 transition metal centre is by cleavage of one Rh−olefin bond, rotation around the remaining Rh−olefin bond and recoordination of the free olefin to Rh either *cis* to the nitrogen atom or *cis* to the phosphorus atom. We assume that the addition of dihydrogen in (*R*,*RR*)-**7a** is favoured only during the short interval in which an olefin either is not coordinated or is in a distorted complex geometry. In this case, addition of dihydrogen to (*S*,*RR*)-**7a** at 20 °C may be much slower than that to the (*R*,*RR*) diastereomer because of the absence of diolefin rotation in the former under these conditions.

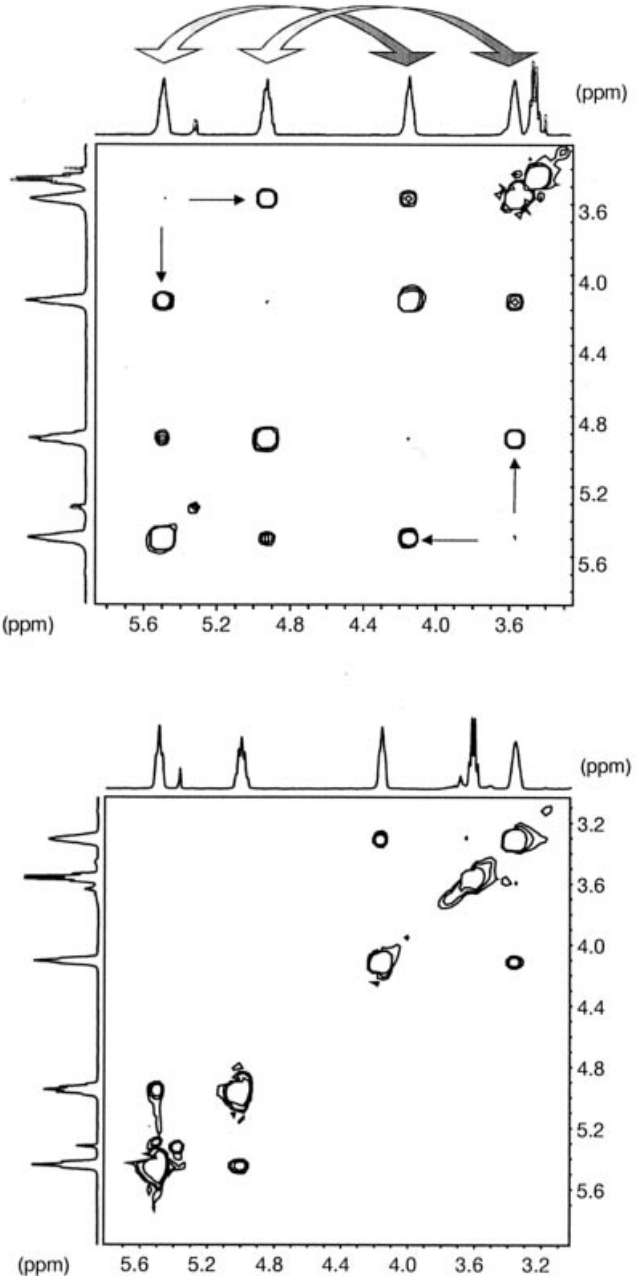


Figure 3. 400 MHz ^{1}H-NOESY spectra at 300 K in CD_2Cl_2 of (*R*,*RR*)-**7a** (top) and (*S*,*RR*)-**7a** (bottom); signals caused by chemical exchange are indicated with arrows; a mixing time of 1.0 s was used

Both norbornadiene complexes (*R*,*RR*)-**7b** and (*S*,*RR*)-**7b** were more active than the corresponding COD complexes. Differences between norbornadiene and COD complexes have also been reported in the literature for related catalytic complexes.[14] With (*R*,*RR*)-**7b** as the pre-catalyst, (*R*)-**9** was formed in 96% *ee*, which is similar to the yield obtained with (*R*,*RR*)-**7a**, while with (*S*,*RR*)-**7b** the hydrogenation product was obtained in only 60% *ee*.

Experimental Section

General: All reactions were performed under nitrogen by use of standard Schlenk techniques. Diethyl ether and pentane were distilled from $LiAlH_4$, THF and toluene from potassium under nitrogen. Dry CH_2Cl_2, methanol and ethanol were purchased from Aldrich in 99.9% purity and used without further purification. (*S*)- and (*R*)-1-Phenylethylamine (> 98% *ee*) were purchased from Aldrich and converted into the *N*,*N*-dimethyl derivatives by literature methods.[15] Enantiomerically pure (*S*,*S*)-2,5-hexanediol (> 99% *ee*) was purchased from Jülich Fine-Chemicals. The cyclic sulfate was prepared by the method described by Sharpless.[16]

NMR: Spectra were recorded with a Bruker ARX 400 MHz NMR spectrometer with use of standard pulse programs for HH-gs-NOESY measurements, spectra with various mixing times (0.1−1.0 s) being recorded. Positive ^1H, ^{13}C, or ^{31}P NMR chemical shifts are upfield from external Me_4Si or H_3PO_4 (85%).

Synthesis of (*R*)- and (*S*)-4

(*R*)-4: A solution of *t*BuLi (1.6 M, 29.0 mL) was added to a solution of (*R*)-**2** (6.91 g, 46.3 mmol) in *n*-pentane (50 mL) and the mixture was stirred at 20 °C for 14 h. The reaction mixture obtained was added at 0 °C to a solution of chlorobis(diethylamino)phosphane (8.86 g, 42.1 mmol) in dry diethyl ether (30 mL). The LiCl produced was removed by filtration, the solvent was evaporated, and the residue was distilled in vacuo (92 °C, 0.1 mbar). The aminophosphane (*R*)-**3a** (yield: 11.1 g, 74%) was dissolved in EtOH (40 mL) and the solution was heated at 60 °C for 48 h. All volatiles were then evaporated, leaving an oily residue, which was distilled in vacuo (76 °C, 0.1 mbar). Yield: 8.96 g (98%) of (*R*)-**3b**. Compound **3b**, as obtained above, was reduced with $LiAlH_4$ (1.18 g, 31.0 mmol) in THF at −30 to 20 °C. After hydrolytic workup of the reaction mixture with water (10.0 mL), the organic phase was separated and the solvent was evaporated. The remaining residue was dissolved in THF (20 mL), potassium (2.42 g, 62.0 mmol) was added, and the reaction mixture was heated at reflux for 4 h. Methanol (10 mL) was then added and the mixture was stirred for 1 h. All volatiles were removed in vacuo and the residue was distilled in vacuo (69 °C, 0.1 mbar). Yield: 4.59 g (76%), $[\alpha]_D^{20} = 73.3$, $c = 1.14$, CH_2Cl_2. (*S*)-**4** was obtained in an analogous manner from (*S*)-**2** as starting material. Yield: 4.21 g (76.0%). $[\alpha]_D^{20} = -74.4$, $c = 1.1$, CH_2Cl_2. ^1H NMR (C_6D_6): 1.13 (d, $J = 6.7$ Hz, 1 H, Me), 2.01 (s, 6 H, NMe), 3.48 (q, $J = 6.7$ Hz, 3 H, CH), 3.91 (dd, $J = 10.8$, 201.4 Hz, 1 H, PH_2), 4.02 (dd, $J = 10.8$, 198.9 Hz, 1 H, PH_2), 6.94 (m, 1 H, arom. H), 7.09 (m, 1 H, arom. H), 7.23 (m, 1 H, arom. H), 7.41 (m, 1 H, arom. H) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 15.14 (Me), 41.20 (NMe), 63.65 (d, $J = 6.1$ Hz, CH), 126.66 (d, $J = 2.0$ Hz, arom. C), 126.92 (d, $J = 3.05$ Hz, arom. C), 128.20 (s, arom. C), 130.66 (d, $J = 11.2$ Hz, arom. C), 136.45 (d, $J = 4.1$ Hz, arom. C), 148.55 (d, $J = 11.2$ Hz, arom. C) ppm. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −121.95 (d, $J = 200.5$ Hz) ppm. MS (EI): $m/z = 181$ [M^+]. $C_{10}H_{16}NP$ (181.2): calcd. C 66.28, H 8.90, N 7.73; found C 65.62, H 8.70, N 7.60.

Synthesis of (*R*,*RR*)- and (*S*,*RR*)-5

(*R*,*RR*)-5: *n*BuLi (1.6 M solution in *n*-hexane, 10 mL) was added at 0 °C to a solution of (*R*)-**4** (2.87 g, 15.8 mmol) in THF (70 mL) and the reaction mixture was stirred at ambient temperature for 30 min. After addition of (*SS*)-**4a** (2.88 g, 15.8 mmol, dissolved in 10 mL of THF), the mixture was stirred for 30 min. Further *n*BuLi (1.6 M solution in *n*-hexane, 15 mL) was added and the reaction mixture was stirred for another 30 min. To remove excess *n*BuLi, methanol (10 mL) was added to the reaction mixture. All volatiles were then removed in vacuo and the remaining residue was distilled in vacuo (98−101 °C, 0.1 mbar) to afford (*R*,*RR*)-**5** as a colourless liquid. Yield 3.40 g (82%). $[\alpha]_D^{20} = +57.5$, $c = 1.1$, CH_2Cl_2. The isomer (*S*,*RR*)-**5** was synthesised in an analogous manner from (*S*)-**4**. Yield: 1.10 g (68%). $[\alpha]_D^{20} = -158.7$, $c = 1.5$, CH_2Cl_2.

(*R*,*RR*)-5: ^1H NMR (C_6D_6): δ = 0.80 (dd, $J = 6.9$, 9.32 Hz, 3 H, Me), 1.26 (m, $J = 2.8$, 6.3, 9.9, 11.6, −13.1 Hz, 3 H, CH_2), 1.28 (dd, $J = 7.2$, 18.7 Hz, 3 H, Me), 1.29 (d, $J = 6.6$ Hz, 6 H, Me), 1.53 (m, $J = 4.7$, 6.0, 10.5, 11.6, −12.8 Hz, 1 H, CH_2), 1.88 (m, $J = 2.6$, 6.3. 6.5, 8.9, −12.8 Hz, 1 H, CH_2), 2.08 (m, $J = 2.6$, 6.0, 7.3, −13.1, 15.0 Hz, 1 H, CH), 2.21 (s, 6 H, NMe), 2.23 (m, $J = 6.5$, 6.9, 10.5, 23.3 Hz, 1 H, CH), 2.52 (m, $J = 5.9$, 7.2, 7.3, 9.9 Hz, 1 H, CH), 4.68 (dq, $J = 6.6$, 9.1 Hz, 1 H, CH), 7.08 (m, $J = 1.5$, 7.4, 7.8 Hz, 1 H, arom. H), 7.22 (m, $J = 1.4$, 7.3, 7.8 Hz, 1 H, arom. H), 7.36 (m, $J = 1.5$, 1.7, 7.5 Hz, 1 H, arom. H), 7.71 (m, $J = 1.4$, 3.6, 7.9 Hz, 1 H, arom. H) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 16.44 (d, $J = 1.5$ Hz, Me), 20.99 (d, $J = 36.1$ Hz, Me), 21.11 (s, Me), 34.84 (d, $J = 13.2$ Hz, CH), 36.63 (d, $J = 3.1$ Hz, CH_2), 37.08 (d, $J = 12.2$ Hz, CH), 37.12 (CH_2), 43.48 (Me), 61.11 (d, $J = 26.4$ Hz, CH), 126.07 (arom. C), 127.53 (d, $J = 5.1$ Hz, arom. C), 129.03 (arom. C), 133.27 (d, $J = 3.1$ Hz, arom. C), 135.92 (d, $J = 31.0$ Hz, arom. C), 152.93 (d, $J = 23.4$ Hz, arom. C) ppm. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −7.10 ppm. MS (EI): $m/z = 263$ [M^+]. $C_{16}H_{26}NP$ (263.4): calcd. C 72.97, H 9.95, N 5.32, P 11.76; found C 72.74, H 10.00, N 5.31, P 11.51.

(*S*,*RR*)-5: ^1H NMR (C_6D_6): δ = 0.84 (dd, $J = 7.0$, 9.1 Hz, 3 H, Me), 1.27 (dd, $J = 7.2$, 18.6 Hz, 3 H, Me), 1.27 (d, $J = 6.6$ Hz, 3 H, Me), 1.30 (m, $J = 3.4$, 6.1, 9.5, 11.2, −13.0 Hz, 1 H, CH_2), 1.53 (m, $J = 5.6$, 5.8, 9.7, 11.2, −12.6 Hz, 1 H, CH_2), 1.92 (m, $J = 3.4$, 6.1, 6.7, 8.8, −12.6 Hz, 1 H, CH_2), 2.07 (m, $J = 3.4$, 5.8, 7.3, −13.0, 14.7 Hz, 1 H, CH_2), 2.15 (s, 6 H, NMe), 2.34 (m, $J = 6.7$, 7.0, 9.7, 23.6 Hz, 1 H, CH), 2.49 (m, $J = 5.4$, 7.2, 7.3, 9.5 Hz, 1 H, CH), 4.53 (dq, $J = 6.8$, 6.9 Hz, 1 H, CH), 7.09 (m, $J = 1.6$, 7.4, 7.6 Hz, 1 H, arom. Rh^I Complexes 7a and 7b: Either (*S*,*RR*)-**5** or (*R*,*RR*)-**5** (0.10 g, 0.38 mmol) was added to a solution of [Rh(1,5-cyclooctadiene)Cl]$_2$ (93.7 mg, 0.19 mmol) or [Rh(2,5-norbornadiene)Cl]$_2$ (87.6 mg, 0.19 mmol) in dichloromethane (5 mL). The reaction mixture was stirred at ambient temperature for 20 min. A solution of KPF_6 (105 mg, 0.57 mmol) in water (5 mL) was added with stirring after 1 h. The aqueous phase was separated and the organic phase was washed with three aliquots of water (10 mL). After addition of a tenfold amount of diethyl ether, the Rh complexes were precipitated as red, crystalline solids in 90−95% yield. Crystals of (*S*,*RR*)- and (*R*,*RR*)-**7a** suitable for X-ray structural analysis could be obtained by slow concentration of the dichloromethane solutions.

Isomer (*S*,*RR*)-7a: $[\alpha]_D^{20}$ = 13.7 (c = 1.1, CH_2Cl_2). ^1H NMR (CD_2Cl_2): δ = 0.91 (dd, J = 6.4, 15.0 Hz, 3 H, Me), 1.81 (m, 1 H, CH_2), 1.82 (dd, J = 6.9, 18.1 Hz, 3 H, Me), 1.97 (m, 1 H, CH_2), 2.20 (m, 2 H, CH/CH_2), 2.26 (d, J = 6.5 Hz, 3 H, Me), 2.34 (s, 3 H, NMe), 2.40 (m, 1 H, CH), 2.53 (m, 1 H, CH_2), 2.70 (s, 3 H, NMe), 2.75 (m, 1 H), 2.87 (m, 1 H,), 3.31 (m, 1 H, olef. Asymmetric Hydrogenation Reactions: A 100-mL glass autoclave was charged with a solution of methyl (*Z*)-α-acetamidocinnamate (**8**, 0.40 g, 1.8 mmol) in methanol (15 mL). After repeated vacuum/H_2 cycles, the catalyst (ca. 1 mol %) was added and the autoclave was pressurised to 5 bar with hydrogen. The reactions were allowed

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to continue either at 20 °C or at 60 °C and the progress of the hydrogenation was monitored by ^{1}H NMR spectroscopy. After 10−12 h, all volatiles were removed in vacuo, and the residue was dissolved in chloroform (2−3 mL). To remove rhodium catalyst the solutions were filtered through silica gel and the filtrate was concentrated to dryness. Methyl *N*-acetylphenylalaninate (**9**) was obtained as a colourless powder. The *ee* values were determined by HPLC (CHIRACEL, *n*-heptane/2-propanol, flow rate 0.8 mL/h, UV detector) and ^{1}H NMR spectroscopy [chiral shift reagent Eu(hfc)$_3$]. Results are summarised in Table 3.

Table 3. Hydrogenation of methyl (*Z*)-α-acetamidocinnamate (**8**)

Catalyst	*T* [°C]	Time [h]	Yield (%)	*ee* (%)[a]
(*R*,*RR*)-**7a**	20	12	95	96
(*S*,*RR*)-**7a**	60	12	90	60
(*R*,*RR*)-**7b**	20	10	96	95
(*S*,*RR*)-**7b**	20	12	95	60

[a] The (*R*) configuration of **9** was found to be in excess in each case.

X-ray Crystallographic Studies: Crystals were glued to glass fibres and transferred to a Siemens P3 diffractometer, which employed Mo-K_α radiation (0.71073 Å) and was equipped with a graphite monochromator. Intensities were determined at 22 °C by a profile analysis of ω-scans and were corrected for absorption, the correction being made empirically for (*R*,*RR*)-**7a** and by integration for (*S*,*RR*)-**7a**. The structures were solved by direct methods and refined conventionally. Hydrogen atoms were positioned geometrically with the riding model, except for the olefinic hydrogen atoms of (*S*,*RR*)-**7a**, which were refined isotropically. An extinction correction was necessary only for the latter structure. Both structures were solved, refined and depicted with the aid of the SHELXTL program package. Crystal data are summarized in Table 4. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-166313 and -174251 for (*R*,*RR*)-**7a** and (*S*,*RR*)-**7a**, respectively. Copies of the data may be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Exchange Coupling in Metal Complexes of the Second Transition Series: A Theoretical Exploration

Cédric Desplanches,[a][‡] Eliseo Ruiz,*[a] and Santiago Alvarez[a]

Keywords: Density functional calculations / Electronic structure / Magnetic properties / Molybdenum / Ruthenium

Theoretical methods based on density functional theory using hybrid functionals provide good estimates of the exchange coupling constants for complexes with metals of the second transition series, with accuracy similar to that previously obtained for complexes with lighter transition metals. The influence of the basis set and effective core potentials has been analyzed. The more diffuse nature of the 4d orbitals, in comparison with the 3d ones, considerably modifies the electronic structure and, consequently, the magnetic properties enhancing the antiferromagnetic contributions.

Introduction

In the field of molecular magnetism, the metals of the second and third transition series have been considered to be less useful than their lighter congeners due to their tendency to form low-spin complexes that in many cases are diamagnetic.[1] The heavier transition metals also tend to form complexes with strong M−M bonds that usually also present diamagnetic behavior.[2] They are also employed because of their large spin-orbit coupling that may give rise to interesting magnetic properties, although rare earth metals have been preferred in this regard.[3] For all these reasons, little is known about the magnetic properties of di- and polynuclear complexes of second and third transition series elements, even if the more diffuse character of the 4d orbitals compared to the 3d ones, the possibility of reaching higher oxidation states and the tendency to adopt larger coordination numbers should make us expect that the heavier metals have very different magnetic behavior.[2] However, during the last five years special attention has been devoted to the magnetic behavior of some complexes, mainly with molybdenum and ruthenium.[4−8]

There have been few theoretical studies of the magnetic properties of these kinds of complexes using ab initio methods. We can mention the work of Bencini et al. devoted to study of the magnetic properties of dioxobenzene-bridged Mo^V complexes using DFT methods.[9] Other open-shell molecules, the d^3-d^3 $[M_2Cl_9]^{3-}$ and $[M_2Cl_{10}]^{4-}$ systems (M = Cr^{3+}, Mo^{3+} and W^{3+}), have been exhaustively studied by Stranger et al. using DFT methods.[10−13] Semiempirical methods have been employed to analyze the exchange coupling through the Hay−Thibeault−Hoffmann model.[14] We can mention one example of complexes with second transition series elements, in this case, Koelle et al., using the extended Hückel method, analyzed the exchange coupling in $[Ru_2(\mu\text{-}Cl)_2Cp_2]$ dinuclear complexes.[15]

During the last years, we have successfully employed theoretical methods based on Density Functional Theory[16] to study the exchange coupling in several complexes containing first transition series metals.[17−20] The goal of this work is to analyze the differences in the magnetic behavior between the complexes of first and second transition series elements and to check if the accuracy in the estimation of the *J* values is similar to that obtained in the case of lighter transition metals.

Computational Methodology

The computational strategy adopted in previous theoretical studies on exchange-coupled dinuclear complexes has been used. For the evaluation of each coupling constant *J*, two separate DFT calculations are carried out, one for the highest spin state and another one for a broken-symmetry singlet state. The *J* values are obtained using Equation (1), where S_1 and S_2 are the total spins of the paramagnetic centers and $S_1 > S_2$ has been assumed for heterodinuclear complexes.[20]

$$E_{HS} - E_{BS} = -(2S_1S_2 + S_2)J \quad (1)$$

The hybrid B3LYP method[21] has been used in all calculations as implemented in Gaussian-98.[22] We have previously found that, among the most common functionals,

[‡] Present address: Institut de Chimie de la Matière Condensée de Bordeaux,

[a] Departament de Química Inorgànica, and Centre Especial de Recerca en Química Teòrica (CeRQT), Universitat de Barcelona,
Diagonal 647, 08028 Barcelona, Spain

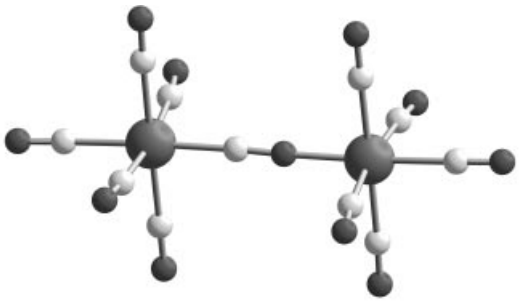
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200200457

the B3LYP method combined with the broken-symmetry treatment provides the best results for calculating coupling constants.[17,20] We had also found that, when using DFT-based wavefunctions, a reasonable estimate of the low spin state energy can be obtained directly from the energy of a broken-symmetry solution. This fact is due to the inclusion of the non-dynamic correlation effects in the commonly used exchange functionals. If spin projection is applied in addition, a cancellation of such effects results, as discussed recently by Polo et al.[23]

In previous calculations of complexes with transition metal atoms we have usually employed all electron basis sets. Due to the importance of the relativistic effect of the second and third transition series elements, pseudopotentials including relativistic effects are an interesting alternative to the all-electron basis sets. We employed five different basis sets as a benchmark for a dinuclear cyano-bridged Mo^{III} complex, four of them using pseudopotentials for the Mo atoms and one with the double-ζ all-electron basis set proposed by Rappe and Goddard[24] (keyword MSV in the Jaguar code[25]). The four combinations of pseudopotentials and basis sets are as follows: (1) Stoll−Preuss quasi-relativistic pseudopotentials[26] (indicated as SDD in the Gaussian code, we also performed a test calculation with the corresponding nonrelativistic pseudopotentials for molybdenum atoms) combined with the triple-ζ all-electron basis set proposed by Ahlrichs et al.[27] for the other elements; (2) the small-core Hay−Wadt pseudopotential[28] for the Mo atom combined with the D95 all-electron basis set[29] for the first-row elements (indicated in the Gaussian code as LANL2DZ); (3) core potentials proposed by Stevens et al. for all the atoms, using a double-ζ basis set for the valence orbitals[30,31] (called CEP-31G in the Gaussian code) and, (4) the same pseudopotentials as in (3) but with a triple-ζ basis set for the valence shell[30,31] (referred to as CEP-121G in Gaussian). For the other systems with Ru and Mo atoms we have employed option (2) corresponding to the LANL2DZ basis set. Finally, for the calculations of the chromium complex we employed the same basis sets as for the cyano-bridged molybdenum complex along with a triple-ζ all-electron basis set proposed by Ahlrichs (keyword TZV in Gaussian)[27] including two p polarization functions for the chromium atom, usually done by us for first transition series metal atoms.

Results of Benchmark Systems

In order to check the accuracy of the methodology employed previously for complexes with lighter transition metals, we selected a cyano-bridged dinuclear Mo^{III} complex $[Mo_2(CN)_{11}]^{5-}$ with tetraethylammonium as a counterion, recently synthesized by Long et al.[32] (see **1**). This complex is especially interesting because the Mo^{III} cation shows a very unusual octahedral coordination, with $S_1 = S_2 = 3/2$, while Mo^{III} usually adopts structures with coordination numbers of seven or eight with the cyanide ligands.[4]



1

The calculated exchange coupling constants for the experimental structure of complex **1** are indicated in Table 1. All calculated values are in excellent agreement with the experimental ones. The all-electron basis set gives results similar to those obtained with effective core potentials (ecp). Thus, it seems that the relativistic corrections incorporated in the ecp are not crucial for the calculation of exchange coupling constants in these types of complexes, probably because we are calculating an energy difference and relativistic corrections of about the same magnitude affect the two spin states. This conclusion is confirmed by the value of -226 cm^{-1} obtained by using the Stoll−Preuss non-relativistic pseudopotentials for molybdenum atoms (and TZV basis set for the other atoms). This also shows the small effect of the relativistic corrections. The values of the exchange coupling constant calculated with the effective core potential are very similar, independent of the quality of the basis set employed.

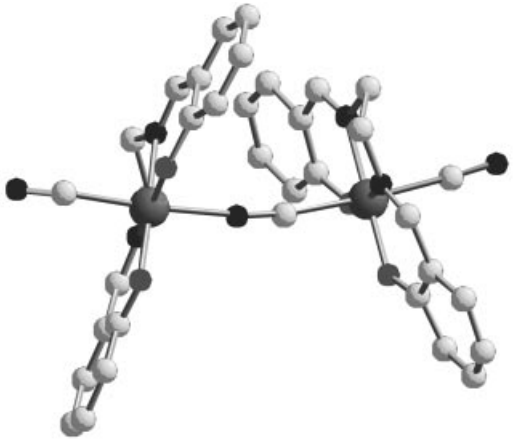
Table 1. Calculated exchange coupling constants (in cm^{-1}) for complex **1** and for an equivalent symmetric Cr^{III} dinuclear complex with different basis sets and effective core potentials (ecp), together with the available experimental data[32]

	Mo^{III}	Cr^{III}
all-electron MSV	−217	−29
all-electron TZV	–	−31
ecp − SDD + TZV	−242	−27
ecp − LANL2DZ	−225	−25
ecp − CEP-31G	−247	−30
ecp − CEP-121G	−247	−29
exp.	−226	–

One of the goals of this study is to analyze the differences between the complexes of the elements of the first and second transition metal series. For this reason, we performed calculations on a symmetric cyano-bridged Cr^{III} dinuclear complex with a fixed structure (Cr−C = 2.06; Cr−N = 2.14; C−N = 1.14 Å) and the resulting J values can be seen in Table 1. The calculated values using pseudopotentials and an all-electron basis set are very similar as are those of the molybdenum complex, but the most remarkable result is the decrease, by an order of magnitude, of the exchange coupling constant compared to that of the Mo^{III} complex. It is also interesting to point out that the effect of using pseudopotentials is similar for Cr and Mo. Similar Cr^{III} complexes have not been reported in the literature, there

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is only a well-characterized cyano-bridged Cr^{III} dinuclear complex (**2**) having one salycilenealdiminato ligand per Cr^{III} cation and a terminal cyanide ligand to complete an octahedral coordination sphere.[33] We have calculated the exchange coupling constant of this complex using the all-electron basis set to check the accuracy of our calculations, and we obtain a value of $-13.7\ cm^{-1}$ to be compared with the experimental result of $-11.4\ cm^{-1}$. The good agreement makes us confident about the *J* values reported for the Cr^{III} dinuclear model and confirms the weaker coupling of the Cr^{III} complexes compared to the Mo^{III} ones.



2

In order to rationalize these results, we have analyzed the contributions to the exchange coupling constant by using the Hay−Thibeault−Hoffmann[14] (HTH) and Kahn−Briatt[34,35] (KB) models [Equations (2) and (3), respectively].

$$J = 2K_{ab} - \frac{(\varepsilon_1 - \varepsilon_2)^2}{J_{aa} - J_{ab}} \quad (2)$$

$$J = 2K_{ab} + 4h_{ab}S_{ab} \quad (3)$$

In both models, we can consider, in a rough approximation, that an antiferrromagnetic contribution (second term) depends on the square of the energy gap between the orbitals bearing the unpaired electrons (HTH model) or on the overlap between the "magnetic" orbitals (KB model). We as well as other authors[36,37] have recently shown that such magnetic orbitals are well represented by the localized orbitals of the broken-symmetry solution (we call them BS-OMSO[38]). The overall energy splitting of the six t_{2g}-type orbitals in the high-spin solution is 0.73 eV for the Mo^{III} complex and only 0.32 eV for the Cr^{III} complex. A similar result is found if we employ the KB model: the overlap between each pair of BS-OMSOs directed towards the π-system of the bridging ligand (one of them is shown in Figure 1) is 0.22 for the Mo^{III} complex and 0.05 for the Cr^{III} one. The overlap between the remaining t_{2g} orbital pair is negligible because these orbitals are perpendicular to the exchange pathway. Thus, both models predict a stronger antiferromagnetic contribution for the Mo^{III} complex, if we assume that the other terms in Equations (2) and (3) are similar. The origin of such differences can probably be found in the more diffuse character of the 4d orbitals compared with the 3d ones. To verify this assertion, we have analyzed the overlap integrals between d atomic orbitals of the metal atoms and p atomic orbitals of neighboring carbon or nitrogen atoms. We find that the overlap integrals involving the Mo atom are about one order of magnitude larger than those for Cr, both for the σ- and π-systems.

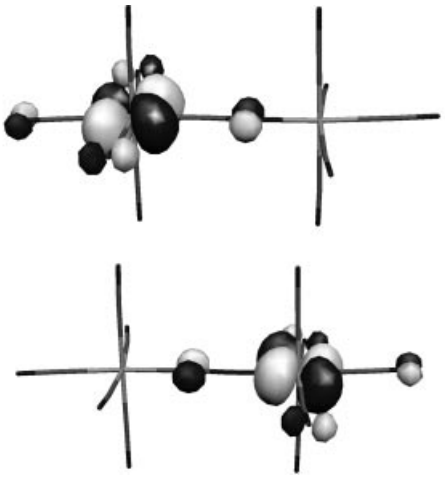


Figure 1. Broken-symmetry orbitals corresponding to one combination of the t_{2g} orbital pairs of $[Mo_2(CN)_{11}]^{5-}$ calculated at the B3LYP level

The spin population distribution also shows significant differences between the complexes of Mo^{III} and Cr^{III}. The spin population at each Mo atom is around 2.8 electrons, but 3.2 at the Cr atoms in the analogous complex. The orbital analysis shows that in both cases there is a small spin population in the formally empty e_g metal orbitals due to spin polarization of the metal−ligand bonding molecular orbitals of the same symmetry,[39] thus accounting for the spin population being larger than the number of unpaired electrons in the Cr compound. The substitution of Cr by Mo, with more diffuse atomic orbitals, results in a larger delocalization that is responsible for a smaller spin population at the molybdenum atoms.

Results of the Full Structures

We have selected two full structures to analyze the accuracy of the DFT methodology proposed for the calculation of the exchange coupling constant. The first structure corresponds to a pyrazino-bridged Ru^{III} dinuclear complex[40] (see **3**) related to the Creutz−Taube mixed-valence complex.[41] The interaction of the π-system of the pyrazine with one of the t_{2g} orbitals produces the largest stabilization due to the π-acid character of the pyrazine ligands while the one that combines slightly with the σ-system remains at an intermediate energy. Each Ru^{III} cation is low-spin d^5, and the unpaired electron is placed in the only t_{2g} orbital that

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

interacts neither with the π-system of the bridging ligand, nor with the σ-system (see Figure 2). Therefore, the two combinations of the orbitals bearing the unpaired electron cannot have large contributions towards the bridging ligand and we expect a small energy splitting between the in-phase and out-of-phase combinations of such d orbitals and, consequently, a small exchange coupling constant for this complex. Experimentally, the authors proposed a maximum negative value for the coupling constant of -6 cm^{-1} from magnetic susceptibility measurements,[42] in very good agreement with the presently calculated value at the B3LYP level of -2.6 cm^{-1}.

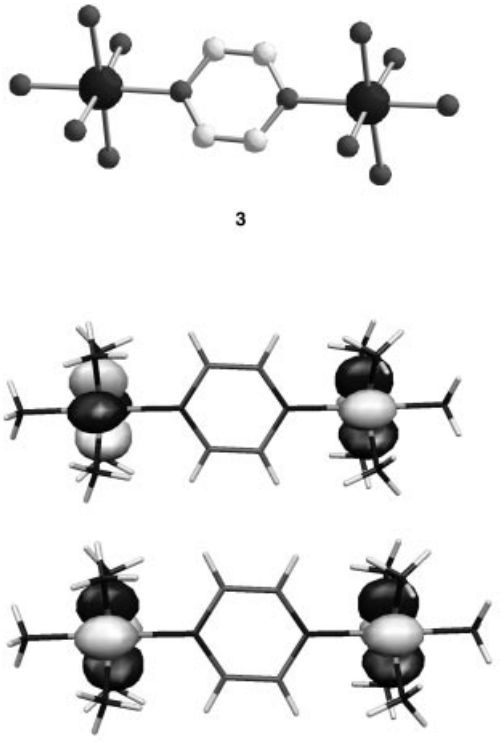

Figure 2. Orbitals bearing the unpaired electrons in the triplet state of the pyrazino-bridged Ru^{III} dinuclear complex **3** calculated at the B3LYP level

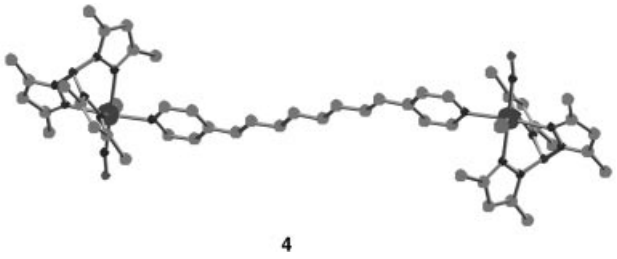
The second full structure that we have chosen is a very interesting system because it shows a strong antiferromagnetic exchange coupling between two paramagnetic centers over a long distance. It is an Mo^{V} complex with a very long dipyridylpolyene bridging ligand, complemented with nitrosyl, chloro and tris(pyrazolyl)borato ligands to complete an octahedral coordination sphere at each metal ion (see **4**).[43] The Mo−Mo distance is 20.76 Å and the exchange coupling constant between the two d^1 cations is -82 cm^{-1}, rather large considering the long distance. The authors also proposed a J value of -115 cm^{-1} using the g value obtained from EPR spectroscopy for the fitting of the magnetic susceptibility data. The problem with the experimental data is that it was only measured between 80 and 300 K. We have calculated a somewhat smaller value of -31 cm^{-1}, which nevertheless shows the ability of the present calculations to correctly describe the nature (antiferromagnetic) and approximate magnitude of exchange interactions at very long distances between two Mo^{V} centers.



Along the same lines, we have recently predicted with the same methodology that some transition metal complexes with long dicyanamidobenzene-type bridging ligands can show very strong ferromagnetic or antiferromagnetic coupling depending on the isomer and substituents of the bridging ligand.[44] In the same study we have analyzed, from an orbital point of view, the exchange coupling for systems with long conjugated bridging ligands that have usually only been analyzed in terms of the so-called spin polarization mechanism using a McConell model.[45] Our conclusions indicated that usually for a symmetric bridging ligand with an even number of atoms in the exchange pathway, such as that in complex **4**, the two ligand orbitals that combine with the two metal orbitals have different energies. Thus, the two molecular orbitals corresponding to the whole molecule show a sizeable energy splitting, resulting in a large antiferromagnetic contribution, according to the HTH model (see Figure 3). If the bridging ligand has an odd number of atoms, the orbitals remain nearly degenerate and the coupling would be ferromagnetic. For the dipyridylpolyene ligand, the calculated orbital energies are non-degenerate (energy splitting of 0.07 eV equivalent to 550 cm^{-1}) due to different π-bonding or antibonding character at the central C−C bond of the two orbitals, confirming those rules.

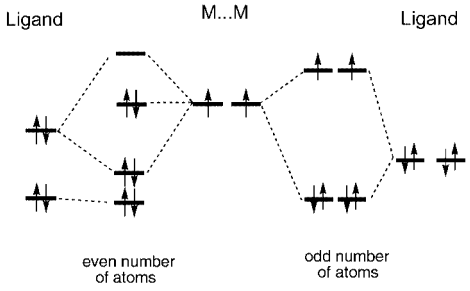


Figure 3. Scheme of the orbital interaction of a dinuclear transition metal complex through a bridging ligand depending on the number of atoms of the bridging ligand

Conclusions

The exchange coupling constants for different complexes of second series transition elements have been calculated using a theoretical method based on density functional theory. The use of the hybrid B3LYP functional, as in previous

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

studies devoted to complexes with metals of the first transition series, offers very good results. The influence of the basis set and different effective core potentials on the calculated J value is very small and results obtained with all-electron basis sets or with pseudopotentials are quite similar. The comparative analysis of the electronic structures of the $[Mo_2(CN)_{11}]^{5-}$ and $[Cr_2(CN)_{11}]^{5-}$ complexes reveals the importance of the more diffuse nature of the 4d orbitals of the molybdenum atoms. This fact results in a larger antiferromagnetic contribution that can be understood using the Hay−Thibeault−Hoffmann or Kahn−Briatt models, i.e., a larger energy splitting of the orbitals bearing unpaired electrons or a larger overlap between the localized "magnetic" orbitals, respectively. The study of the spin population distribution also shows a considerably larger delocalization in the case of the Mo^{III} complex due to the more diffuse character of the 4d orbitals.

Organotin-Drug Interactions. Organotin Adducts of Lornoxicam, Synthesis and Characterisation of the First Complexes of Lornoxicam

Angeliki Galani,[a] Mavroudis A. Demertzis,[a] Maciej Kubicki,[b] and Dimitra Kovala-Demertzi*[a]

Keywords: Antitumour agents / Tin / Supramolecular chemistry / Drug delivery

The synthesis and spectral characterisation of novel organotin complexes [$SnMe_2$(lorn)] (**1**) and [S*n*Bu_2(lorn)] (**2**) of the potent and widely used anti-inflammatory drug lornoxicam, H_2lorn, are reported. Crystal structure determinations of complexes**1** and **2** showed that the ligand is doubly deprotonated at the oxygen and amide nitrogen atoms and is coordinated to the SnR_2 fragment via four- and six-membered chelate rings. The monomers of **1** are linked through intermolecular hydrogen bonds of C–H--O type and through C–H–π intermolecular interactions. There are two similar molecules in the asymmetric unit of **2**. The dimers of **2** are arranged in polymers with a stacking of alternate parallel chains and are linked through intermolecular hydrogen bonds of C–H--O type, and through C–H–π intermolecular interactions. An extended network of Sn–O–Sn, C–H--O and C–H--π contacts lead to aggregation and a supramolecular assembly.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Lornoxicam (6-chloro-4-hydroxy-2-methyl- 2-pyridyl-2*H*-thieno[2,3-*e*]-1,2-thiazine-3- amide-1,1-dioxide) is a new non-steroidal antiflammatory drug (NSAID) with marked analgesic properties that chemically differs from tenoxicam by the presence of a single chloro-substituent in the 8-position.[1] Lornoxicam's principal mode of action is the inhibition of the enzyme cyclooxygenase and thus of prostaglandin synthesis from arachidonic acid.[2] It does not cause shunting of arachidonic acid to the lipoxygenase cascade, and therefore does not increase production of leukotrienes. In vitro experiments have demonstrated that lornoxicam is more than 100 times more potent than tenoxicam and 40 times more potent than piroxicam in its ability to inhibit cyclooxygenase.[1,2] Lornoxicam is a yellow crystalline substance with a pK of 4.7 and a partition coefficient of 1.8 (determined in octanol−phosphate buffer, pH 7.4). The acid−base behaviour of lornoxicam has also been studied and the apparent pK_a-values reported.[3]

Organotin(IV) compounds are important and have received increasing attention in recent years, not only because of their intrinsic interest, but also owing to the importance of tin-based anti-tumour drugs. Some examples find wide applications as catalysts and stabilizers, and certain derivatives are used as biocides, as antifouling agents and for wood preservation. Recent tests on their anti-tumour activity have revealed that several diorganotin adducts, as well as triorganotin species, show potential as antineoplastic and antituberculosis agents.[4,5]

We are interested in the coordination chemistry and anti-inflammatory properties of non-steroidal anti-inflammatory drugs with transition[6] and non-transition metal[7] ions, and report here the interaction of SnR_2O (R is methyl or butyl) with lornoxicam (H_2lorn) and the crystal structure of the complexes [$SnMe_2$(lorn)] and [S*n*Bu_2(lorn)]. These are the first reported structures of a lornoxicam complex.

Results and Discussion

Molecular Structures

The molecular structures of complexes **1** and **2**, along with the atom numbering scheme, are shown in Figure 1 and Figure 2 and crystal data are given in Table 1, together with refinement details. Bond lengths and angles are given in Table 2. Complexes **1** and **2** have a 1:1 Sn/lorn stoichiometry and the doubly deprotonated ligand, lorn, is coordinated as a tridentate ligand via the enolic oxygen O(4) and the amide N(31) and pyridyl N(1′) nitrogen atoms. Two carbon atoms complete the fivefold coordination at the diorganotin(IV) fragments. There are two similar molecules in the asymmetric unit of **2**.

Analysis of the shape-determining angles using the approach of Reedijk and co-workers[8] yields $\tau[(\alpha-\beta)/60]$ val-

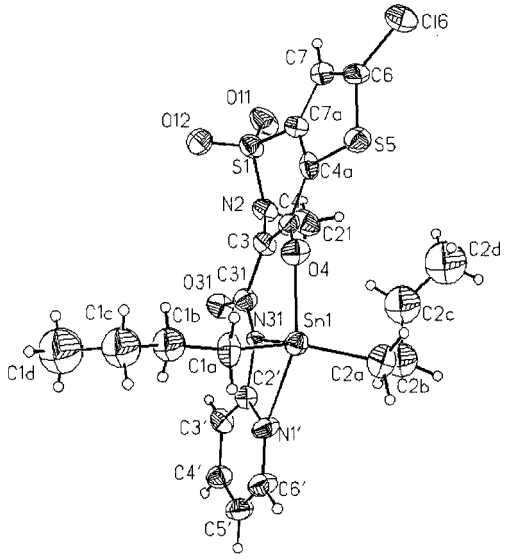

Figure 2. ORTEP representation of **2** with the atom numbering scheme.

ues of 0.01 for both tin centres, Sn(1a) and Sn(1b) for **2**, and 0.29 for **1** (τ = 0.0 and 1.0 for *sp* and *tbp* geometries respectively). The metal coordination geometry is therefore described as square pyramidal with N(31) occupying the apical positions. The donors N(31) are chosen as apices by the simple criterion that neither should be any of the four donor atoms that define the two largest angles, α and β. The coordinated ligand is composed of five rings and the donor atoms NNO are included in three rings, one heterocyclic and two chelates. The heterocyclic ring (I) is planar, the largest deviation from the mean plane being 0.016(6) for C(2′) for **1** and 0.008(12)° for C(5′A) for molecule (1) and 0.015(11) for C(3′B) for molecule (2), respectively, for complex **2**. For **1** the dihedral angles between the planes of the rings I and II, II and III, and I and III are 3.4(3), 3.8(2) and 6.9(2), respectively. For **2** the dihedral angles between the planes of the rings I and II, II and III, and I and III are 0.8(5), 6.1(4) and 6.8(4) for the first molecule Sn(1a), and 2.7(5), 5.2(4) and 7.1(4) for the second molecule Sn(1b), indicating that the ligand as a whole deviates from planarity, the largest deviations arising from the expected puckering of the sulfonamide rings which contain the pyramidal saturated N atoms. The C(31)−O(31) bond lengths indicate strongly that these bonds are ketonic − also supported by the coplanarity of the three bonds to C(31). The di-anionic, tridentate ligand has an *EZZ* configuration about the bonds C(2′)−N(31), N(31)−C(31) and C(31)−C(3) for **1** and **2**. The *EZZ* configuration differs from the *ZZZ* isomer only by a 180° rotation of the pyridyl ring. The deprotonation of amide nitrogen is being one of the principal effects, which favour *EZZ* configuration.

Molecules of **2** are joined into dimers in a head-to-tail fashion by intermolecular bonds between tin and the neighbouring ketonic oxygen atom, with distances of Sn(1a)--O(31B)^i 2.954 (2) and Sn(1b)--O(31A)^i 2.971 (2). Intermolecular distances for Sn--O of 2.61−3.02 Å have been confidently reported for intramolecular bonds, indicating Sn−O bonding here.[9b] For **2** the dimers of Sn(1a) and Sn(1b) are arranged in polymers with a stacking of alternate parallel chains. The dimers of Sn(1a) and Sn(1b) are linked through intermolecular hydrogen bonds of the C−H--O type,[9a] O(12B)l···H22A−C(2AA). Inter- and intra- C−H-π molecular interactions[9b] and intra- and intermolecular hydrogen bonds stabilize this structure. For **1** the distance between

Sn(1) and the neighbouring ketonic oxygen atom is 3.562(4), and the monomers of Sn(1) are linked through intermolecular hydrogen bonds of C−H--O type,[9a] O(12)axial···H6′−C(6′), O(11)eq···H13A−C(1A) and O(31)···H23A−C(2A) (Figure 3). Further, C−H−π interactions[9a] and intramolecular hydrogen bonds stabilize the structure. Although the numerous contacts, of many different types, are remarkable, the interactions themselves are consistent with known guidelines for hydrogen bond formation.[9c] In these two cases molecular recognition of the hydrogen bonds and intermolecular contacts lead to aggregation and a supramolecular assembly. These interactions and other close approaches of the type C−H--π, and some intermolecular interactions are listed in Table 3.

The negative charge on the atoms in a molecule with several donor centres can be used to study its formation of a donor−acceptor bond with a metal. In H_2lorn the four oxygen atoms exhibit the maximum electron density and negative charge. The highest effective charge and the highest electron density values for the four oxygen atoms and for the pyridyl and imine nitrogen in **1** and **2** evidently show strong electron-donor properties and could rationalize the coordination scheme and the extended network of inter-, intra- hydrogen, and non-hydrogen bonding. The optimised geometry in the gas phase for H_2lorn the total dipole moment and the enthalpy of formation of neutral, H_2lorn, and double deprotonated lornoxicam, lorn, in the gas state are shown in Figure 4.

Spectral and Electrochemical Characterisation

Infrared Spectroscopy

The ligand, H_2lorn, shows a broad absorption band centred at ca. 3500 and 3400 cm^{-1} that is characteristic of an O−H stretching vibration. The band at 3067 cm^{-1} for lornoxicam is attributed to the N−H stretching vibration. The low frequency of these two bands may be explained by inter- and intramolecular hydrogen bonds involving the nitrogen and two oxygen atoms of the secondary amide group.[11a] The sharp bands observed at 1647, 1619 cm^{-1} and the band at 1596 cm^{-1} in lornoxicam are assigned to the carbonyl ν(C=O) and the ν(C=N) vibrations of the secondary amide group −CO−NH−.[11] The ν(C=O) and the ν(C=N) bands are at lower frequencies in the complexes, at 1619, 1591 and 1567 cm^{-1} for **1** and at 1600, 1599, 1578 and 1549 cm^{-1} for **2**. For compounds **1** and **2**, bands assignable to ν_{asym} and ν_{sym} (Sn−C_2) are observed at 550, 473 and 551, 475 cm^{-1} respectively, indicating a non-linear Sn−C_2 moiety. The bands at 265 and 268 cm^{-1} are assigned to the ν(Sn−N_{pyr}) stretching mode for **1** and **2** respectively; and those at 221 and 215 cm^{-1} for **1**, and at 224 and 211 cm^{-1} for **2**, are assigned to ν(Sn−O) stretching modes.[7,11]

NMR Spectroscopy

^{1}H and ^{13}C NMR spectra were recorded for lornoxicam, **1** and **2**. Peak assignments were based on literature reports.[6,7] The main differences between the ^{1}H NMR spectrum of the free H_2lorn and the complexes are the disappearance of the downfield OH and NH signals. These changes confirm that loss of both hydrogens and metallation occurs, and that the structure of the complexes in the solid state persists in $(CD_3)_2SO$ or $CDCl_3$ solutions. The appearance of the OH peak downfield at δ = 14.02 ppm in $CDCl_3$ for H_2lorn indicates that OH is hydrogen-bonded. In complexes **1** and **2** deshielding of protons H6′, H3′ and the corresponding carbon atoms C(6′), C(3′) is observed, which should be related to the electrophilicity of the tin. A σ-charge donation from the N(1′)-donor to the tin centre removes electron density from the ligand and produces this deshielding, which will attenuate at positions remote from the metal. The upfield shift observed for H4′, H5′ and the corresponding carbon atom C(4′), C(5′) *meta* and *para* to the tin centre could be due to the flow of charge from the tin into the aromatic ring (π-back donation).[7] The signals corresponding to the imino and hydroxyl groups disappear upon interaction with the metal, indicating deprotonation of these atoms and possible coordination to the tin atom. A tridentate coordination via the enolic oxygen, the amide and the pyridyl nitrogen atoms has been recently observed for the first time in a similar complex of piroxicam, $[Bu_2Sn(Pir)]_n$, and tenoxicam, $[Bu_2Sn(ten)]_n$, where the ligand exists also in its doubly deprotonated form.[7] These

conclusions are confirmed by the ^{13}C NMR spectrum where the signal corresponding to C(4) disappears while the signals to C(3) and C(5) show downfield shift. The bond development of the N(1′) atom with the metal leads to a downfield shift by 6.0 ppm of the C(6′) and C(3′) while the C(4′) and C(5′) shift in the opposite direction by 2.0 ppm.

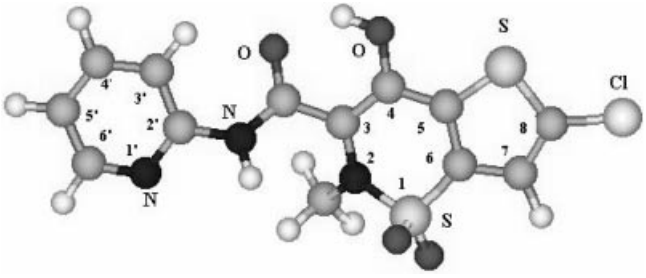

Figure 4. Fully AM1-optimised geometry of the neutral lornoxicam (ΔH_f = −48.28 kcal mol^{-1}; dipole moment = 3.98 Debye) in the gas state (Hyperchem 6.0[10]).

Electronic Spectroscopy

The electronic spectrum of H_2lorn in DMF solution exhibits two broad bands at ca. 398 and 273 nm. The band at 398 nm is assigned to a π → π* and that at 273 nm to a π → π* transition. The very broad band at ca. 400 nm is assignable to a HOMO → LUMO transition. The HOMO orbital (−10.972 eV) is composed of p_z orbitals from Cl 6% (+), C(8)p_z 12% (−), C(5)p_z 12% (+), C(6)p_z 11% (+), C(7)p_z 10% (−), C(4)p_z 6% (−), C(3)p_z 18% (−), N(2)p_z 8% (+) and the LUMO orbital (−9.261) is composed of p_z orbitals from C(6)p_z 5% (+), C(2′)p_z 11% (−), C(4′)p_z 14%

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(+), C(6′)p_z 6% (−), N(1′)p_z 11% (+), C(4) p_z 10% (−),C(10) p_z 17% (+). The HOMO orbital is π-centred on the sulfonamide and thiazine groups and the LUMO orbital is mainly π-centred on the pyridyl ring. H_2lorn and complexes **1** and **2** were studied by the extended-Hückel method using the CACAO PC Beta-Version 5.0 package geometry.[12] The molecular geometry was established by using the crystallographic coordinates of the complexes **1** and **2** and for H_2lorn by using the fully optimised in the gas state. The broad band centred at 376 and 373 nm respectively for **1** and **2** is assigned to a HOMO → LUMO transition. The extended-Hückel calculation using the crystallographic coordinates of **1** gives the following results: the HOMO orbital (−11.354eV) is composed of p_z orbitals from C(l6)p_z 5%(−), C(3)p_z 7%(+), C(6)p_z 9%(+), C(7)p_z 7%(+), C(7a)p_z 7%(−) and of p_y from C(3)p_y 11%(+); the LUMO orbital (−9.294 eV) is composed of p_y from C(4)p_y 10%(−), C(31)p_y 11%(+) and p_z orbitals from C(4) p_z 7%(−), C(7a)p_z 6%(+), C(31)p_z 9%(+). The extended-Hückel calculation using the crystallographic coordinates of **2** gives the following results: the HOMO for (−11.334 eV) is composed of p_x orbitals from C(3)p_x 10%(−), C(4a)p_x 6%(+), C(6)p_x 5%(−), C(7a)p_x 5%(+), C(7)p_x 5%(−) of p_z C(3)p_z 8%(+), C(4a)p_z 11%(−), C(6)p_z 8%(+), C(7a)p_z 5%(−), C(7)p_z 6%(+); the LUMO (−9.322 eV) is composed of p_x from C(4)p_x 10%(−), C(7a)p_x 4%(+), C(31)p_x 13%(+) and p_z orbitals from C(4)p_z 10%(+), C(6)p_z 3%(+), C(7a)p_z 5%(−), C(31)p_z 14%(−). The HOMO energy is isolated, suggesting that the assignment of the lowest energy electronic transition can be assigned to the computed HOMO−LUMO. Also, the similarity of the HOMO−LUMO gap from the calculations (2.060 and 2.012 eV for **1** and for **2** respectively) is reflected in the similarity of the first absorption band energy at ca. 375 nm in the complexes.

The HOMO−n (n = 1−6) levels for **1** are similar in energy, and are more stabilized (by ca. 1.4 eV) relative to the HOMO. The molecular orbital HOMO−6 has components of p_y (7%) and p_z (8%) from Sn, and p atomic orbitals from C(1a) and C(2a). Also, the molecular orbital HOMO-4 for **2** is stabilized by 1.01 eV relative to the HOMO and has components of p_x 6%(−) from Sn and p atomic orbitals from N(1′), C(3′), C(4′), C(5)′ and C(1b) This is consistent with a back donation from the metal to the π* orbitals of the ligand moieties.[13] The broad band at 292 and 295 nm for **1** and **2** is assigned to a combination of π → π* and M → L transitions. It has been found that the interaction of C−Sn σ orbitals and neighbouring p-type orbitals increases the HOMO level, which in turn favours electron transfer. Such σ-π interaction, σ−n and σ−σ interactions enjoy versatile applications in the field of electron transfer.[14]

Electrochemical Measurements

The ability of the complexes to either gain or to lose electrons was studied in anhydrous DMF solution by cyclic voltammetry. The ligand exhibits irreversible reduction peaks at −1.143 and −1.543 V. Irreversible reductions are seen at −0.764 and −1.267 V for **1**, and at −1.135 and 1.792 V for **2**. The electrochemical data suggest that the reduction of **1** and **2** might be regarded as being more or less centred on the ligand system. The electron transfers from the platinum cathode and is directed to the π* LUMO orbital. The reduction potential of **1** is less negative, while that of **2 is** more negative for the corresponding ligand and decreases in the order **1** < **H_2lorn** < **2**, indicating that the reduction process is more easily accomplished for 1 than for either free **H_2lorn** or **2**. The oxidation wave for **H_2lorn** is observed at +0.610 and that for **1** and **2** at 0.483 and 0.842 V, respectively. The oxidation is also associated with a ligand-based process and oxidized products are formed. The oxidation potentials of **1**, **2**, and **H_2lorn** increase in the order **2** > **H_2lorn** > **1**. Thus, both the reduction and oxidation processes in complex **1** are more easily accomplished than in either **2** or the parent drug. However, in the range from +1.5 to −2.5 V additional peaks are observed.

Experimental Section

All the chemicals used were of high purity and purchased from Fluka, Merck and Aldrich. Solvents were purified and dried according to standard procedures. Tenoxicam was a gift from "NYCOMED" NYCOMED DENMARK A/S and was recrystallised twice from ethanol. Elemental analyses were performed on a Carlo Erba EA (model 1108). Infrared and far-infrared spectra were obtained in KBr or polyethylene discs on a Perkin−Elmer Spectrum JX FT-IR spectrophotometer. A Jasco UV/Vis/NIR V 570 series spectrophotometer was used to obtain the electronic absorption spectra. ^{1}H (250.13 MHz) and ^{13}C (62.90 MHz) NMR spectra were recorded with a Bruker AMX-400 spectrometer at room temperature and referenced to DMSO or $CHCl_3$. UV spectra were recorded on a JASCO V-570 spectrophotometer. Electrochemical measurements were made using an AUTOLAB PGSTAT30 potentiostat with a platinum microsphere as working electrode, a platinum wire auxiliary electrode and an Ag/AgCl reference electrode in a three-electrode configuration. Ferrocene was added at the end of each experiment and used as an internal standard. All potentials are reported relative to an Ag/AgCl reference electrode and ferrocenium/ferrocene (Fe^+/Fc, $E_{1/2}$ = 0.173 V in DMF). Experiments were carried out on 1×10^{-3} M solutions of complex, under a nitrogen atmosphere, with Et_4NClO_4 (0.1 M) as supporting electrolyte (scan rate 100 mV s^{-1}).

Preparations

[$SnMe_2$(lorn)]$_n$ (1): $SnMe_2O$ (0.066 g, 0.4 mmol) was added to a solution of lornoxicam (H_2lorn) (0.150 g, 0.4 mmol) in benzene (25 cm^3) and the reaction mixture was refluxed for 7 h under a Dean−Stark trap. The resultant clear solution was rotary evaporated under vacuum to a small volume, chilled and triturated with diethyl ether to give a yellow solid that was redissolved (suspended) in dry diethyl ether and the same procedure was repeated twice. The final yellow product was filtered off and dried in *vacuo* over silica gel. (**1**) m.p. 260−262 °C; Yield 90%. $C_{15}H_{14}ClN_3O_4S_2Sn$ (518.6): calcd. C 34.31, H 2.70, N 8.10, S 9.92; found C 34.88, H 2.65, N 8.30, S 10.3. Crystals of **1** suitable for X-ray analysis were obtained by slow evaporation of a fresh EtOEt/CH_2Cl_2 solution.

[Sn(*n*-C_4H_9)$_2$(Hlorn)$_2$] (2): Sn(*n*-C_4H_9)$_2$O (0.099 g, 0.4 mmol) was added to a solution of lornoxicam (H_2lorn) (0.150 g, 0.4 mmol) in

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

benzene (25 cm^3) and the reaction mixture was refluxed for 27 h under a Dean−Stark trap. The resultant clear solution was rotary evaporated under vacuum to a small volume, chilled and triturated with hexane to give a yellow solid that was redissolved (suspended) in hexane and the same procedure was repeated twice. The final light yellow product was filtered off and dried in *vacuo* over silica gel (**1**). M.p. 174−176 °C; Yield 66%. $C_{21}H_{26}ClN_3O_4S_2Sn$ (602.7): calcd. C 41.84, H 4.32, N: 6.97, S 10.65; found C 42.10, H 4.56, N 6.65, S 10.38. Crystals of **2** suitable for X-ray analysis were obtained by slow evaporation of a fresh C_6H_{12}/C_6H_6 solution.

Crystal Structure Determination of Complexes 1 and 2

X-ray diffraction data were collected on a KUMA KM4CCD κ-geometry diffractometer with a CCD detector,[15] by using graphite-filtered Mo-K_α radiation (λ = 0.71073 Å). The unit cell dimensions were calculated from the least-squares fit of 2163 (**1**) and 1450 (**2**) most intense reflections from the whole experiment. Relevant crystallographic data, together with data collection and structure refinement details, are listed in Table 1. The measurements were performed in six separate runs, four runs consisted of 133 frames, and two of 125 frames (ω width of each frame was 0.75°). The θ, κ and angles for the runs were chosen so as to cover the appropriate part of the Ewald sphere. Two reference frames were measured after every 50 frames of experiment; neither the geometry nor the intensity of the reflections in these frames changed significantly during the data collection. Intensity data were corrected for Lorentz and polarisation effects and converted into F^2's. These data were corrected for absorption and averaged with respect to the point group symmetry with SORTAV program.[15b] The structures were solved with SHELXS-97,[16] and SHELXL-97[16] was used for full-matrix least-squares refinement. The function $\Sigma w(0.5F_o1/2^2 - 0.5F_c1/2^2)^2$ was minimised, with $w^{-1} = [\sigma^2(F_o)^2 + A{\cdot}P^2 + B{\cdot}P]$ (where P = [max. (F_o^2, 0) + $2F_c^2$]/3). Final values for A and B are listed in Table 1. In **1** all the non-hydrogen atoms were refined anisotropically, in **2** − due to the large thermal motion of the butyl groups − only the first atoms of these groups (connected to Sn) were refined anisotropically, while the other three atoms from each butyl groups were refined isotropically, with fixed values for U_{iso}. The (relatively weak) constrains were also applied to the geometry of these groups. The attempts to resolve the apparent disorder of butyl groups were not successful. In both structures, hydrogen atoms were placed in calculated positions and refined as "riding mode", i.e. they followed the movements of their carrier atoms. The isotropic displacement parameters for hydrogen atoms were calculated as 1.2 times equivalent displacement parameters for respective carrier non-hydrogen atoms.

Calculations

A computational study with a AM1 parameterization scheme utilizing the Steepest Descent algorithm, as implemented in the HYPERCHEM 6.0 program, was used to investigate the prevailing isomer of free H_2lorn in the gas phase.[10] H_2lorn and the complexes **1** and **2** were studied by the extended-Hückel method using the CACAO PC Beta-Version 5.0 package geometry.[12] The molecular geometry was established by using the crystallographic coordinates of complexes **1** and **2** and for H_2lorn by using the fully optimised in the gas state.[12]

Exchange Interactions and Covalency in Dinuclear Complexes of Iron(III) and Gallium(III) Containing the Redox-Noninnocent Ligand 1,2-Bis(3,5-di-*tert*-butyl-2-hydroxyphenyl)oxamide

Udo Beckmann,[a] Eckhard Bill,[a] Thomas Weyhermüller,[a] and Karl Wieghardt*[a]

Keywords: Iron / Gallium / EPR spectroscopy / Moessbauer spectroscopy / Radicals / Magnetic properties / Exchange interactions

The dinucleating ligand 1,2-bis(3,5-di-*tert*-butyl-2-hydroxyphenyl)oxamide [H_4(bbpo)] has been synthesized. From its reaction with $GaCl_3$ or $FeCl_3$ in CH_3OH/NaOH the salts $[N(nBu)_4]_2[M_2^{III}(bbpo)Cl_4]$ [M = Ga (**1**), Fe (**2**)] have been isolated as crystalline solids upon addition of $[N(nBu)_4]Cl$. Complexes **1** and **2** have been characterized by single-crystal X-ray crystallography. Cyclic voltammetry established that both species undergo two successive, reversible one-electron oxidations in CH_2Cl_2 {0.10 M $[N(nBu)_4]PF_6$} which are shown to be ligand-centered: one and then two *N*,*O*-coordinated *o*-iminobenzosemiquinonate π-radicals form which couple antiferromagnetically with the high-spin ferric ions in **2**. Thus, the monoanion of **2** has an $S_t = {}^1/_2$ ground state. The complexes have been characterized by Mössbauer, UV/Vis, and EPR spectroscopy.

1. Introduction

In a recent series of publications[1−6] we have shown that *o*-aminophenolates and their ring-substituted derivatives are redox-noninnocent ligands in coordination chemistry. In particular, we established that high-quality X-ray crystallography allows the unequivocal determination of the protonation and oxidation level of a given *N*,*O*-coordinated ligand in a transition metal complex and that it is possible to discern between an *N*,*O*-coordinated *o*-iminophenolate(−), $(L^{IP})^{2-}$, and its one-electron oxidized form, the *o*-iminobenzosemiquinonate(1−) π-radical, $(L^{ISQ})^{-}$.

When such a radical ligand ($S_{rad} = {}^1/_2$) is coordinated to a paramagnetic transition metal ion with an incompletely filled t_{2g} subshell, very strong intramolecular antiferromagnetic exchange coupling between the radical spin and the t_{2g}^n configuration is observed. Thus, $[Cr^{III}(L^{ISQ})_3]$,[3] containing a Cr^{III} ion with t_{2g}^3 configuration and three $(L^{ISQ})^{1-\cdot}$ radical anions, possesses an $S_t = 0$ ground state, whereas its cobalt(III) analogue[1] (t_{2g}^6) possesses an $S_t = {}^3/_2$ ground state because the three ligand spins couple ferromagnetically.

Here we describe the synthesis of a new dinucleating ligand that contains two *o*-aminophenolate units, which, in principle, should be oxidizable to two *o*-iminobenzosemiquinonate units. The ligand is the tetraanion of 1,2-bis(3,5-di-*tert*-butyl-2-hydroxyphenyl)oxamide [H_4(bbpo)], shown in Scheme 1. If both bound metal ions are paramagnetic, e.g. high-spin Fe^{III}, exchange coupling between these ions and the ligand π-radicals and coupling between the two metal ions containing units, which are bridged by an oxamide unit, should lead to various ground states. As we will show here, this is indeed the case.

2. Results and Discussion

2.1. Synthesis and Characterization of Complexes 1 and 2

The reaction of 3,5-di-*tert*-butyl-2-(hydroxyamino)benzene (2 equiv.) [7] with oxalyl chloride (1 equiv.) in diethyl ether in the presence of the base triethylamine (2 equiv.) affords the ligand 1,2-bis(3,5-di-*tert*-butyl-2-hydroxyphenyl)oxamide [H_4(bbpo)] in good yields (Scheme 1).

From the reaction of deprotonated H_4(bbpo) in CH_3OH/NaOH solution and 2 equiv. of $GaCl_3$ or $FeCl_3$ the yellow and green crystalline salts of $[N(nBu)_4]_2[M_2^{III}(bbpo)Cl_4]$ [M = Ga^{III} (**1**), Fe^{III} (**2**), respectively] were obtained upon addition of $[N(nBu)_4]Cl$.

In accord with the structures shown in Scheme 1 for the dianions of **1** and **2** the infrared spectra do not show ν(N−H) or ν(OH) stretching frequencies but prominent ν(C=O) stretching frequencies at 1633 cm^{-1} for **1** and at 1611 cm^{-1} for **2**.

The electro spray mass spectra of **1** and **2** in CH_3OH in the negative ion detection mode display peaks at $m/z = 737$ for **1** and at $m/z = 709$ for **2**, corresponding to the monoanions $[M_2^{III}(bbpo)Cl_3]^-$ (M = Ga, Fe, respectively). Both peaks display the correct isotope pattern.

Our attempts to synthesize a pure sample of the paramagnetic heterodinuclear complex $[N(nBu)_4]_2[Ga^{III}$-

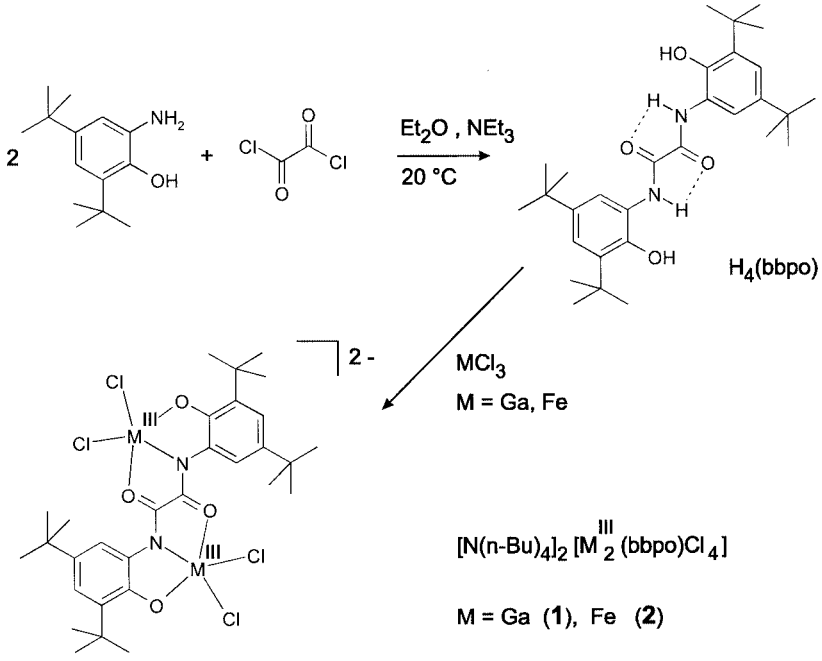

Scheme 1

$Fe^{III}(bbpo)Cl_4$], which would reveal the rhombicity, *E*/*D*, of a single high-spin ferric site in its EPR spectrum, yielded samples contaminated by **1** and **2**. Nevertheless, we found that in equimolar methanolic solutions of **1** [the pure gallium(III) species] and $FeCl_3$ the heterodinuclear species $[Ga^{III}Fe^{III}(bbpo)Cl_4]^{2-}$ is generated as well as **2**. The ESI (negative ion) mass spectra of such solutions clearly show the presence of $[GaFe(bbpo)Cl_3]^-$ at m/z = 724 (Z = 1) and of $[GaFe(bbpo)Cl_4]^{2-}$ at m/z = 379.5 (Z = 2). Both peaks display the correct isotope pattern. The signals of the corresponding homodinuclear monoanions $[M_2^{III}(bbpo)Cl_3]^-$ (M = Ga and Fe) are also present. Addition of $[N(nBu)_4]Cl$ to such solutions initiated the precipitation of a mixture of **1**, **2**, and $[N(nBu)_4]_2$ $[GaFe(bbpo)Cl_4]$. The latter is isomorphous and isostructural with **1** and **2** as was established by X-ray crystallography of a hand-picked, brown single crystal that contained a Ga/Fe ratio of ca. 1:1 (X-ray fluorescence analysis).

2.2. Crystal Structures of 1 and 2

The crystal structures of **1** and **2** have been determined at 100(2) K by single-crystal X-ray crystallography using

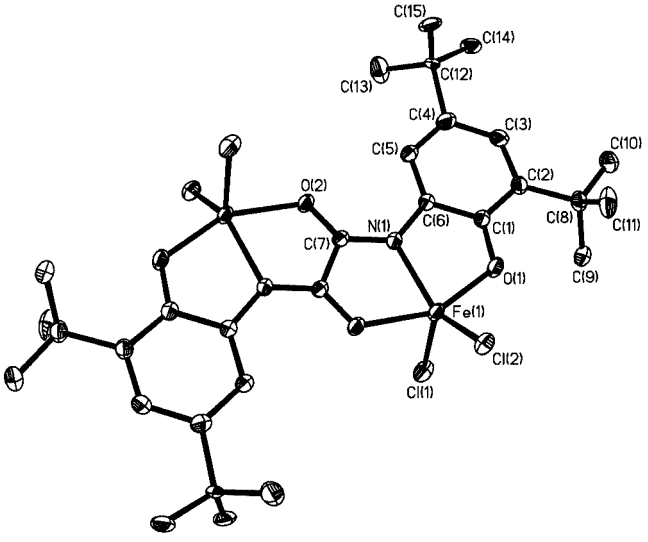

Figure 1. ORTEP representation of the structure of the dianion $[Fe^{III}_2(bbpo)Cl_4]^{2-}$ in crystals of **2**; that of the dianion in **1** is similar and not shown.

Both structures consist of well-separated tetra-*n*-butylammonium cations and dinuclear dianions (ratio 2:1).

The metal ions Ga^{III} and Fe^{III} in **1** and **2**, respectively, are five-coordinate with a distorted trigonal-bipyramidal MCl_2NO_2 polyhedron, where the two chloride ions and the nitrogen donor N1 occupy basal positions whereas the two oxygen donors O1 and O2 are in the remaining two axial sites. The Fe−Cl, Fe−N and Fe−O bond lengths are quite long and indicate a high-spin d^5 configuration at the ferric ions in **2**. The corresponding bonds in **1** are similar since the ionic radii of five-coordinate Ga^{III} and high-spin Fe^{III}, 0.69 and 0.72 Å, respectively, are also similar.[9]

We note that the metrical details of the coordinated *o*-aminophenolate parts of the ligand $(bbpo)^{4-}$ clearly indicate the presence of two *N*,*O*-coordinated *o*-iminophenolato(2−) halves.[5] The six C−C bond lengths of the phenyl rings are, within experimental error, equidistant; no evidence for a quinoid-type distortion typical for *o*-iminobenzosemiquinonato(1−) π-radicals was detected.[1−6] Similarly, the C1−O1 bonds at ca. 1.35 Å are long and typical for phenolates. The two corresponding C6−N1 bonds at 1.40 Å are also long, indicating single bonds.

2.3. Magnetic Properties of 2

The diiron complex **2** has been studied by magnetometry and applied-field Mössbauer spectroscopy. In contrast to the diamagnetic digallium analog **1**, which shows a "normal" ^{1}H NMR spectrum without paramagnetically shifted lines (see Exp. Sect.), the iron compound has a substantial magnetic moment at ambient temperature. Figure 2 (top) displays the temperature dependence of the magnetic moment of solid **2** recorded in the range 2−300 K using a SQUID magnetometer and an external field of 1 T. The molar susceptibilities were corrected for underlying diamagnetism by use of tabulated Pascal constants ($\chi_{dia} = -825 \times 10^{-6}$ cm^3·mol^{-1}). The magnetic moment decreases monotonically from ca. 7 μ_B at 300 K to about 0.5 μ_B at 4 K. The solid line in Figure 2 represents a best fit of the data using the spin Hamiltonian in Equation (1) with $S_1 = S_2 = {}^5/_2$, $J = -9.7 \pm 0.5$ cm^{-1}, $g = 2.016$, $|D| = 1.6 \pm 0.3$ cm^{-1}, and $E/D = 0.33$ for both identical iron sites.

$$H = -2J\,\vec{S}_1 \cdot \vec{S}_2 + \sum_{i=1,2}\{D_i[S^2_{z,i} - \tfrac{1}{3}S_i(S_i+1) + {}^{E}\!/_{D}(S^2_{x,i} - S^2_{y,i})] + g_i\mu_B\vec{S}_i \cdot \vec{B}\} \quad (1)$$

Thus, the spins of the two ferric ions in **2** are weakly antiferromagnetically coupled; the complex possesses an EPR-silent $S_t = 0$ ground state which, however, is not very well isolated from paramagnetic excited states. Thus, the applied field can induce a weak magnetic moment even at 2 K. This is best observed in multi-field measurements with variable-temperature data sampled on a $1/T$ scale (inset of Figure 2). The increasing level of magnetization with increasing field at low temperatures (arrows in the inset) indicates multiplet-mixing by competing exchange and single-ion zero-field splitting (ZFS). Increasing temperature (to the left in the inset) leads to Boltzmann population of the excited S = 1, 2 states and increasing magnetization. The decline of M_{mol} below $\mu_B B/kT = 0.1$ represents the usual $1/T$ behavior

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

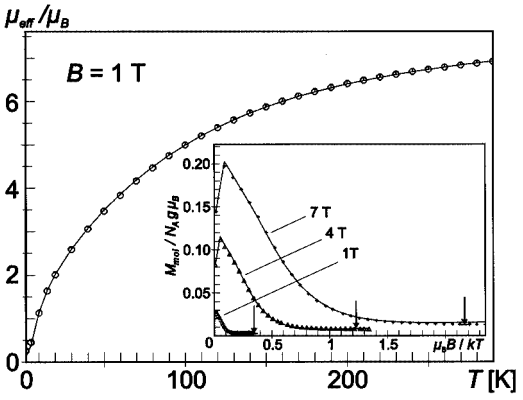

Figure 2. Temperature dependence of the magnetic moment, μ_{eff}, of **2** measured at $B = 1$ T; inset: variable-temperature variable-field plot of magnetization of **2**; the arrows indicate the induced magnetization of "$S_t = 0$" at low temperatures; see text for simulation parameters (solid lines)

at high temperatures due to equal population of the magnetic M_s sublevels. Systematic simulations of the temperature dependence at multiple fields yields a sensitive and unique measure of the exchange coupling constant, $J = -9.7 \pm 0.5$ cm^{-1}, and the ZFS parameter, $|D| = 1.6 \pm 0.3$ cm^{-1}. A similar but weaker antiferromagnetic coupling has been reported for the μ-oxalato-bridged dinuclear species $[Fe^{III}_2(\mu\text{-ox})(ox)_4]^{4-}$, with J established as -3.3 cm^{-1}.[8] The rhombicity parameter E/D in the analysis above was taken from an X-band EPR spectrum of the mixed-metal in complex $[Ga^{III}Fe^{III}(bbpo)Cl_4]^{2-}$ in CH_3OH solution, which selectively probes the Fe^{III} moiety in the bbpo ligand. The spectrum measured at 15 K shows the $g = 4.27$ signal (Figure 3) that is typical of Fe^{III}, $S = {}^5/_2$ with full rhombicity, $E/D = 0.33$. Note that at 15 K both "contaminants" of the Ga/Fe complex, **1** and **2**, are EPR-silent.

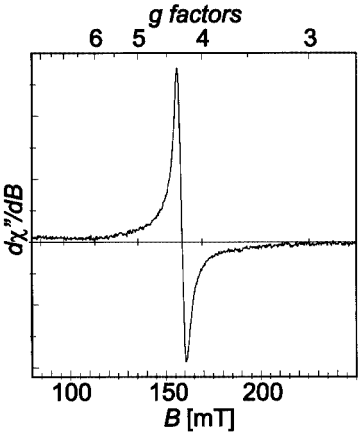

Figure 3. X-band EPR spectrum of $[Ga^{III}Fe^{III}(bbpo)Cl_4]^{2-}$ in CH_3OH solution at 15 K (conditions: frequency 9.4637 GHz; power 20.1 μW; modulation frequency 100 kHz; modulation amplitude 2.49 mT)

The zero-field Mössbauer spectrum of solid **2** at 80 K displays an asymmetric doublet with an isomer shift of 0.45 mm·s^{-1} and a quadrupole splitting of 0.97 mm·s^{-1} that are typical for high-spin ferric ions (Figure 4, top). The lines are broadened by residual spin relaxation close to the limit of fast rates. Magnetically perturbed spectra recorded at 1.8 K with fields of 3 and 7 T applied perpendicular to γ (Figure 4, center and bottom) show almost diamagnetic appearances, as expected for an electronic $S_t = 0$ ground state. The presence of induced magnetization can be visualized from the small but significant deviation of a diamagnetic simulation with "$S = 0$" from experiment (dotted lines). A spin Hamiltonian simulation based on Equation (1) with the above parameters gives a slightly better fit of the 3 and 7 T measurements. As expected, the small internal field in the latter case is opposite to the applied field. The corresponding Mössbauer parameters are summarized in Table 3.

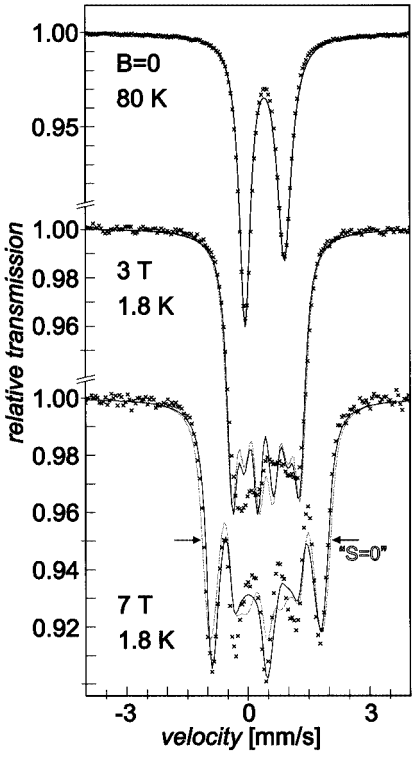

Figure 4. Zero- and applied-field Mössbauer spectra of solid **2**; parameters of the spin-Hamiltonian simulations based on Equation (1) (solid lines) are given in Table 3; the dotted lines represent an alternative diamagnetic simulation ($S = 0$) with the same electric hyperfine parameters

Hence, the magnetic Mössbauer spectra also demonstrate the effect of competing ZFS and exchange interaction for the low-lying spin multiplets of **2**. In addition, the symmetry of the splitting pattern reveals a large asymmetry parameter, $\eta = 0.9 \pm 0.1$, for the electric field gradient (efs) tensor, in agreement with the large rhombicity of the sites. The Mössbauer data agree fully with the electronic structure of **2** consisting of two identical, antiferromagnetically coupled high-spin ferric ions.

2.4. Electro- and Spectroelectrochemistry

The cyclic voltammograms (CV) of complexes **1** and **2** were recorded at 20 °C in CH_2Cl_2 solutions (0.10 M

$[N(n\mathrm{Bu})_4]PF_6$) at a glassy carbon working electrode and an $Ag/AgNO_3$ reference electrode. Ferrocene was used as an internal standard; all potentials are referenced versus the ferrocenium/ferrocene couple (Fc^+/Fc). Figure 5 displays the CVs of **1** (top) and **2** (bottom).

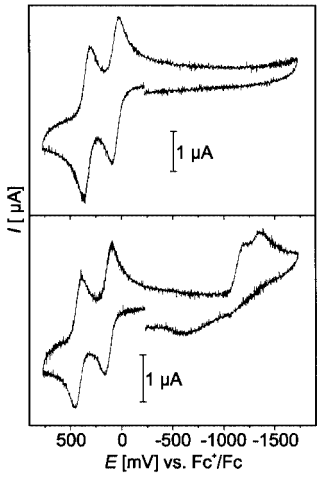

Figure 5. Cyclic voltammograms of **1** (top) and **2** (bottom) in CH_2Cl_2 {0.10 M $[N(n\mathrm{Bu})_4]PF_6$} at 248 K at a scan rate of 100 mV s^{-1} (glassy carbon working electrode; $Ag/AgNO_3$ reference electrode; ferrocene internal standard)

Both **1** and **2** display two reversible one-electron transfer waves in the potential range −0.5 to +0.75 V. The two redox potentials $E^1_{1/2}$ and $E^2_{1/2}$ are observed at +0.077 and +0.354 V for **1**; and at +0.156 and 0.454 V for **2**. Coulometric measurements at appropriately fixed potentials established that both processes correspond to two successive one-electron oxidations of **1** and **2**, respectively, as shown in Equation (2). We will show below that both oxidations are ligand-centered processes that generate the mono- and diradicals $(bbpo^{ox1})^{3-}$ and $(bbpo^{ox2})^{2-}$ shown in Scheme 2.

$$[M^{III}_2(bbpo)Cl_4]^{2-} \underset{+e}{\overset{-e}{\rightleftharpoons}} [M^{III}_2(bbpo)^{ox1\cdot}Cl_4]^{1-} \underset{+e}{\overset{-e}{\rightleftharpoons}} [M^{III}_2(bbpo)^{ox2\cdot-}Cl_4]^{0} \qquad (2)$$
$$E^1_{1/2} \qquad E^2_{1/2}$$

Upon increasing the potential range scanned to −1.7 V the resulting CV of **1** did not show an additional redox process but **2** displayed two successive, irreversible, probably metal-centered reductions: $Fe^{III} \rightarrow Fe^{II}$ at ca. −1.1 and ca. −1.4 V.

Since the coulometric measurements had established that the monoanions, and to a lesser degree the neutral forms of **1** and **2**, are stable in solution their electronic spectra were recorded. The neutral species of **2** proved to be unstable. Figure 6 shows the electronic spectrum of **1** and of its one-electron oxidized form in CH_2Cl_2. As expected, the spectrum of **1** is featureless at $\lambda > 500$ nm but shows an intense absorption at 405 nm (8.6×10^3 M^{-1}·cm^{-1}) which decreases and splits into two bands upon oxidation [393 (7.1×10^3), 412 (7.5×10^3)]. Remarkably, oxidation also yields a broad absorption at 908 nm (730 M^{-1}·cm^{-1}) that is typical for the *o*-iminobenzosemiquinonate(1−) radical.[2]

Electrochemical oxidation the monoanion to the neutral species $[Ga_2(bbpo^{ox2})\ Cl_4]$ is shown in Figure 6 (bottom). Roughly, the absorption maxima of the monoanion double their intensity: 382 sh (7.2×10^3), 402 (8.9×10^3), 414 sh, 421 (9.7×10^3), 466 (3.7×10^3), 506 (2.3×10^3), 727 sh, 874 nm (1.4×10^3 M^{-1}·cm^{-1}), indicating that a second *o*-iminophenolate moiety of the ligand is converted into the corresponding π-radical (Scheme 2). Figure 7 shows the electronic spectra of the di- and monoanions, $[Fe^{III}_2(bbpo)Cl_4]^{2-}$ and $[Fe^{III}_2(bbpo^{ox1})Cl_4]^{-}$, respectively. The spectrum of the dianion displays a typical phenolate-to-iron(III) charge-transfer band at 648 nm (5.0×10^3 M^{-1}·cm^{-1}) and two ligand-based CT bands at 379 (1.5×10^4 M^{-1}·cm^{-1}) and 342 nm (1.7×10^4 M^{-1}·cm^{-1}). The spectrum of the monoanion is similar: 366 sh (1.5×10^4 M^{-1}·cm^{-1}), 406 (1.5×10^4 M^{-1}·cm^{-1}), 492 sh (5.6×10^3 M^{-1}·cm^{-1}), 697 nm (5.0×10^3 M^{-1}·cm^{-1}).

2.5. X-band EPR Spectra of *Oxidized* 1 and 2

The X-band EPR spectra of the electrochemically generated monoanion and the neutral complex of **1** have been recorded at 298 K (Figure 8 top and bottom, respectively). Both spectra display typical S = $^1/_2$ signals at g = 2.004 for the monoanion and at g = 2.005 for the neutral species, with clearly discernible Ga hyperfine splitting (I = $^3/_2$) with a_{Ga} = 13.1 MHz for $[Ga_2^{III}(bbpo^{ox1})Cl_4]^{1-}$ and 13.9 MHz

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for $[Ga_2^{III}(bbpo^{ox2})Cl_4]^0$. In both cases the unpaired spin couples only to a single Ga nucleus. This indicates that the spin in the monoanion $[Ga_2^{III}(bbpo^{ox1})Cl_4]^-$ is not delocalized over the whole bridging π-radical ligand $(bbpo^{ox1})^{3-}$ but is localized on one *o*-iminobenzosemiquinonato part. There is no or only very weak electronic coupling through the oxamide C−C bond. This notion is nicely corroborated by the EPR spectrum of the neutral species, which shows virtually the same hyperfine pattern as the monoradical and thus clearly indicates that there are two equivalent (*o*-iminobenzosemiquinonato)gallium(III) ($S = {}^1/_2$) units present without significant exchange interaction. Preliminary simulations (not depicted) suggest that the weak line broadening observed for the diradical species might be consistent with a coupling constant of the order $J = 20$ MHz (7×10^{-4} cm^{-1}).

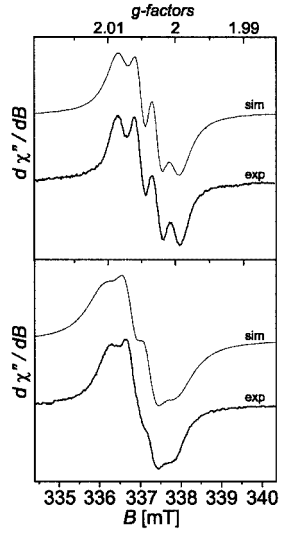

Figure 8. X-band EPR spectra of electrochemically generated monoanion of **1** (top) and of the two-electron oxidized form **1** (bottom) at ambient temperature in fluid solution; simulation parameters are given in the text; conditions: top spectrum (bottom spectrum): frequency 9.4485 GHz (9.4534 GHz); power 7 mW (10 mW); modulation frequency 100 kHz (100 kHz); modulation amplitude 0.08 mT (0.2 mT)

The X-band EPR spectrum of the electrochemically generated monoanion of **2** in frozen CH_2Cl_2 {0.10 M $[N(nBu)_4]PF_6$} at 10 K (Figure 9) clearly establishes that $[Fe_2^{III}(bbpo^{ox1})Cl_4]^-$ possesses an $S_t = {}^1/_2$ ground state since a rhombic signal with $g_x = 1.998$, $g_y = 1.944$, and $g_z = 1.825$ is observed. This $S_t = {}^1/_2$ ground state is assumed to be attained via a relatively strong intramolecular antiferromagnetic coupling, *J*, between an *o*-iminobenzosemiquinonate radical and an high-spin ferric ion, yielding S* = 2, which in turn couples weakly antiferromagnetically to the second high-spin ferric ion, *J′*, as shown in Scheme 3. Electronic coupling between this second ferric ion and the ligand radical is assumed to be either negligibly small or zero.

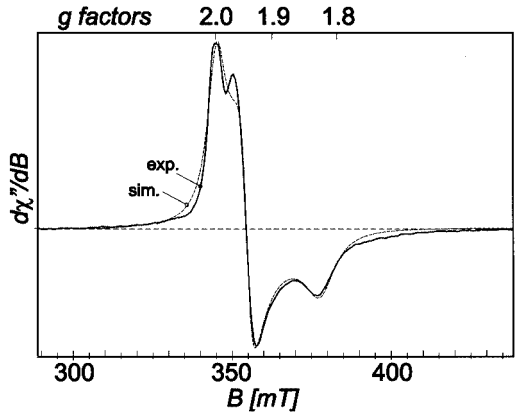

Figure 9. X-band EPR spectrum of electrochemically generated monoanion of **2** in frozen CH_2Cl_2 {0.10 M $[N(nBu)_4]PF_6$} solution at 10 K; the line widths for the simulation are: $W_x = 5.6$; $W_y = 3.4$; $W_z = 13.9$ mT ($g_x = 1.998$; $g_y = 1.944$; $g_z = 1.825$); conditions: frequency 9.6500 GHz; power 100 μW; modulation frequency 100 kHz; modulation amplitude 1.28 mT

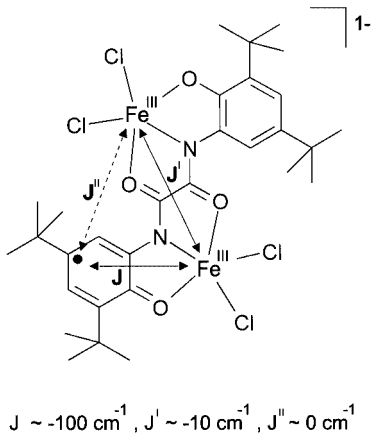

Scheme 3

The *g* values of the $S_t = {}^1/_2$ ground state of oxidized **2** deviate significantly from $g = 2.0$, in contrast to what can be expected from the single-ion properties of the ^6S state of high-spin Fe^{III} or a ligand radical. This does *not* necessarily indicate the formation of Fe^{IV}; the large *g* shifts owe their origin to level mixing of the ground state doublet with excited quadruplet due to competing exchange and ZFS, similar to what was found for **2**. This situation resembles moderately strong coupled high-spin Fe^{III}/Fe^{II} dimers ($S_1 = {}^5/_2$, $S_2 = 2$) as found in the OH-bridged diiron cores of purple-acid phosphatases, methane monooxygenase, and related model compounds[10] where the *g* values span the large range 1.5−2. We achieved a quantitative interpretation of the *g* values of oxidized **2** from a corresponding spin-Hamiltonian approach based on the simplified coupling scheme shown in Scheme 3 by using Equation (1) with $S_1 = {}^5/_2$ for an Fe^{III} site and a fictitious spin $S_2 = S^* = 2$. The latter is the spin of the pair formed by one iron(III) and the very strongly coupled ligand π-radical. This allowed us to probe the effect of ligand oxidation on the electronic properties of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the respective Fe^{III} site even if their spin coupling is too strong to measure. A reasonable fit of the experimental *g* values was obtained with $D_1 = 1.6\ cm^{-1}$, $E/D_1 = 0.33$ (fixed to the values taken from nonoxidized **2**) and $D_2 = 2.4\ cm^{-1}$, $E/D_2 = 0.33$ (fixed), and $J = -11.5\ cm^{-1}$. (We refrained from introducing local g anisotropies or Euler rotations of the principal axes systems.) The values of D_2 and *J* are convincingly close to what is obtained theoretically for *unperturbed* iron sites by converting the local values of non-oxidized **2** into the oxidized system with $S_2 = S^* = S_{Fe} + S_{rad}$ using spin projection techniques[11]: $D_2 = 2.13\ cm^{-1}$ ($= {}^4/_3\ D_{Fe}$). $E/D_2 = 0.33$, $J = -11.3\ cm^{-1} = {}^7/_6\ J$ ($S_1 = {}^5/_2$, $S_2 = {}^5/_2$). Hence, the unusual EPR *g* values of oxidized **2** are fully consistent with the concept of ligand oxidation and the simplified coupling scheme for the spin ground state with "infinitively" strong Fe^{III}−radical coupling.

2.6. Mössbauer Spectra of *Oxidized* 2

The zero- and applied-field Mössbauer spectra of oxidized **2** were obtained by using the following protocol. The monoanion of **2** was generated coulometrically in CH_2Cl_2 solution {0.10 M $[N(nBu)_4]PF_6$} at 248 K and then frozen to 80 K and transferred to a Mössbauer cup. Subsequently, the solvent CH_2Cl_2 was removed by evaporation under reduced pressure at −30 °C within 2 h and then the sample was rapidly cooled to 80 K. In a parallel experiment the remaining solution was monitored at −30 °C spectrophotometrically to check the redox stability of the monoanion. No decomposition was detected after 2 h.
