[a] General conditions: 0.5 mmol aryl bromide, 5 mol % $[Pd(PPh_3)_4]$, 1.2 equiv. cyanoboronate ester, 1.5 equiv. K_3PO_4, 5 mL THF, 50 °C. [b] Conversions determined by GC-MS, isolated yield in parentheses.

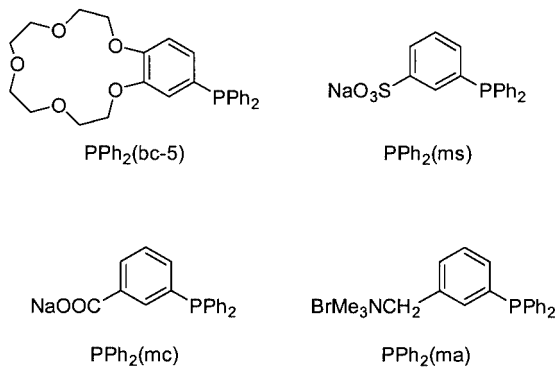

Figure 2. Ligands with phase-transfer catalyst properties

PPh_2(ms) as ligand requires the addition of $ZnCl_2$ and $NaBH_4$ in order to obtain satisfactory results (Table 5).

Unfortunately, using PPh_2(ms) as ligand just aryl iodides and electron-deficient aryl bromides can be cyanated in good yield, whereas bromobenzene is hardly converted. Without sodium borohydride, no catalytic activity at all is observed. The authors state that the hydride is needed for reduction of the catalyst precursor $[PdCl_2\{PPh_2(ms)\}_4]$,

[a] General conditions: 7.5 mmol aryl bromide, 3 equiv. NaCN, 0.33 mol % *trans*-[PhPdBr{PPh_2(bc-5)$_2$}], 0.66 mol % PPh_2(bc-5), 5 mL dioxane, reflux, 20 h. [b] Yields determined by GC-MS, isolated yield in parentheses.

however the reduction of catalytically nonactive cyanopalladium species, which result from catalyst deactivation processes in the presence of an excess of cyanide ions, has to be considered, too.

Anderson et al. studied the influence of solvent, cyanide source, co-catalysts, and the palladium source on the palladium-catalyzed cyanation of aryl halides.[55] Depending on the reaction conditions, potassium and sodium cyanide both gave satisfactory results. The choice of the right cyanide source is mainly influenced by the solvent. While KCN gives better results in THF, NaCN is preferable in ethyl acetate or acetonitrile. Furthermore, the authors discovered that copper salts were effective additives for the cyanation of 1-iodonaphthalene (Scheme 9, Table 6). In addition, aryl bromides and triflates can be coupled to the corresponding nitriles in good to very good yields.

Another new procedure has been described by Maligres et al.[56] They combined the palladium catalyst system introduced by Takagi ($Pd_2(dba)_3$/dppf)[47] with the use of zinc(II) cyanide as the cyanating agent (introduced by Tschaen et al.)[48] to get an efficient system for the palladium-catalyzed cyanation of aryl bromides (Scheme 10). Besides dppf several other phosphane ligands have also been tested, but with little success.

Palladium-Catalyzed Cyanation of Aryl Chlorides

Regarding costs and availability aryl chlorides are favorable substrates for catalytic refinement of aryl−X derivatives.[57−60] Because of their low reactivity, the cyanation of chloroarenes has been known prior to 2000 only with nickel catalysts[29,61−68] or with palladium catalysts for activated (hetero)aryl chlorides (e.g., pyrazines,[44] purines[46,49]). In 2000, Jin and Confalone reported the first general method for the palladium-catalyzed cyanation of aryl chlorides (Scheme 11).[69]

Table 5. Palladium-catalyzed cyanation of aryl halides using PPh_2(ms) as ligand

8			5	8
9			10	95

[a] General conditions: 10 mmol aryl halide, 1.3 equiv. NaCN, 1 mol % [$PdCl_2$[{Ph_2(ms)}$_4$], 50 mol % $ZnCl_2$, 20 mol % $NaBH_4$, 10 mL heptane, 10 mL water, reflux. [b] Yields determined by GC-MS, isolated yield in parentheses. [c] 13% Terephthalonitrile detected.

As shown in Table 7 the corresponding benzonitriles were obtained in good to very good yields by using 4 mol % of a palladium complex generated in situ from [tris(dibenzylideneacetone)dipalladium(0)] and [1,1′-bis(diphenylphosphanyl)ferrocene] (dppf). The use of zinc(II) cyanide as cyanide source and catalytic amounts of zinc powder to reduce palladium(II), which is formed to some extent in side reactions, is important for successful cyanation.

Despite its usefulness the procedure has some drawbacks such as the need for a comparatively high amount of catalyst (4 mol % palladium) and the use of zinc(II) cyanide as cyanide source, which leads to significant amounts of metal waste.

In a joint project with SKW Trostberg AG (now Degussa AG) we became interested in this topic in 1998. Based on our catalyst developments for Heck,[70−73] Suzuki[74−77] and amination[78,79] reactions of aryl chlorides, we were primarily attracted in finding more productive palladium catalyst

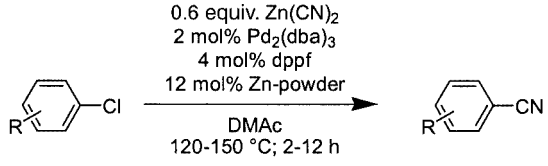

Scheme 11. Palladium-catalyzed cyanation of aryl chlorides according to Jin et al.

systems for the cyanation of aryl chlorides, which work in the presence of a cheap and readily available cyanide source (e.g., sodium or potassium cyanide). Initially, we studied the relation of various positive additives described for cyanations of aryl bromides using 4-chloro(trifluoromethyl)benzene as a model substrate. For example, we combined the known positive effect of crown ethers[53,54] with the use of inorganic bases like sodium carbonate or potassium hydroxide as co-catalysts.[39] Surprisingly, this combination of additives has never been tested before. As shown in Table 8 (Entries 1–3) a significant improvement of the product yield can be realized under these conditions.[80] Apart from additives the right choice of phosphane ligand is also important in order to obtain good results. Similar to carbonylation reactions of aryl chlorides,[81–85] the best results are observed in the presence of chelating phosphane ligands such as dppb and dpppe.

8	–	–	20	97	91

[a] General conditions: 2 mmol 4-chloro(trifluoromethyl)benzene, 1 equiv. potassium cyanide, 2 mol % palladium(II) acetate, 4 mol % 1,5-bis(diphenylphosphanyl)pentane, 2 mL toluene, 16 h, 160 °C. [b] Conversions and yields were determined by GC using an internal standard (diethylene glycol di-*n*-butyl ether). [c] Triphenylphosphane instead of 1,5-bis(diphenylphosphanyl)pentane.

As the combination of base and crown ether led to better results in the cyanation reaction, the question arose as to whether both properties could be combined into one single additive. *N*,*N*,*N*′,*N*′-Tetramethylethylenediamine (TMEDA) is a typical candidate for the desired type of substances. Therefore, we tried the cyanation reaction in the presence of various amounts of TMEDA. To our delight,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the addition of 20 mol % of TMEDA as co-catalyst (Table 8, Entries 5−8) gave excellent yield (91%) and selectivity (94%) of 4-trifluoromethylbenzonitrile. Somewhat surprisingly, the combination of TMEDA with sodium carbonate and 18-crown-6 gave lower yields than with TMEDA alone. In the presence of TMEDA and 18-crown-6 a disappointingly low yield (8%) of the desired nitrile was observed. The dramatic influence of these additives on selectivity and yield of the desired benzonitrile is explained by their effect on the cyanide concentration in solution. While a high concentration of cyanide ions leads to immediate catalyst deactivation, a low concentration of CN^- retards the reductive coupling of the aryl group and cyanide ions (see mechanistic discussion below). The general applicability of the new protocol is shown in Table 9.

Table 9. Scope and limitations of the palladium-catalyzed cyanation of aryl and heteroaryl chlorides in the presence of TMEDA

[a] General conditions: 2 mmol aryl or heteroaryl chloride, 1 equiv. potassium cyanide, 2 mol % palladium(II) acetate, 4 mol % 1,5-bis(diphenylphosphanyl)pentane, 20 mol % TMEDA, 2 mL toluene, 16 h, 160 °C. [b] Conversions and yields were determined by GC using an internal standard (diethylene glycol di-*n*-butyl ether). [c] Reaction conditions: 2 mmol aryl chloride, 1 equiv. potassium cyanide, 3 mol % palladium(II) acetate, 6 mol % 1,5-bis(diphenylphosphanyl)pentane, 30 mol % TMEDA, 2 mL toluene, 16 h, 160 °C. [d] Isolated yield in parentheses.

The catalyst system is applicable to activated aryl chlorides, which react with KCN to give the corresponding benzonitriles in high yields. Also *N*-heteroaryl chlorides such as 3-chloropyridine and 4-chloroquinaldine give the desired product in moderate to good yield. Unfortunately, deactivated and nonactivated aryl chlorides like chlorobenzene and 3-chlorotoluene lead to poor results under these conditions (Table 9, Entries 5−6).

The beneficial effect of TMEDA as co-catalyst prompted us to investigate the influence of other amines in the palladium-catalyzed cyanation of nonactivated chloroarenes. Here, chlorobenzene was used as a more suitable model system, which does not react efficiently with KCN under standard conditions, i.e., benzonitrile is obtained only in 13% in the presence of 0.2 equiv. of TMEDA and 2 mol % palladium catalyst. Selected examples of successful co-catalysts are shown in Scheme 12.[86]

Clearly, the reaction outcome is significantly influenced by the added amine. Among the various amines tested the best results were obtained in the presence of sparteine, 1,1′-methylenedipiperidine (MDP), 2,2′-bipyridine, and 1-adamantylamine. A closer look at the catalysis results reveals that there is no obvious connection of catalytic activity and any structural property of the amine (e.g., basicity or sterics). Because of the promising results using MDP, the reaction of other nonactivated, deactivated, or sterically hindered aryl chlorides and *N*-heteroaryl chlorides was investigated with this additive (Table 10).

In most cases we observed considerably improved results with MDP as co-catalyst compared to TMEDA. Almost all problematic substrates are converted into the desired benzonitriles in good to very good yields. This procedure

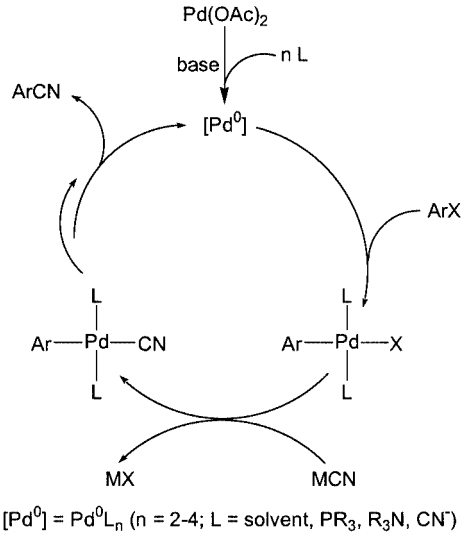
with either TMEDA or MDP as co-catalyst is until today the most efficient and widely applicable method for the palladium-catalyzed cyanation of aryl chlorides with readily available and cheap KCN.

Mechanistic Investigations into the Palladium-Catalyzed Cyanation of Aryl Halides

The catalysis results discussed above show that different amines have a positive effect on the palladium-catalyzed cyanation reaction. The question remains, however, which elementary steps are influenced by the addition of amine. Because of the high temperatures palladium colloids also have to be considered as potential catalysts. It is known that such colloids, or nanoparticles, are formed from unstable palladium phosphane complexes at high temperature and that they show catalytic activity in C−C coupling reactions.[87,88] However, the color of the reaction mixtures (typically pale yellow for palladium phosphane complexes) makes this unlikely.

In order to understand the effect of the organic co-catalyst in more detail, single steps of the generally accepted mechanism for such types of palladium-catalyzed C−C coupling reactions[89−92] were performed in the presence and absence of TMEDA. As shown in Scheme 13 the catalytic cycle starts with the oxidative addition of the aryl halide to a Pd^0 species. In case of aryl chlorides the activation of the C−X bond is more difficult than with aryl bromides, aryl iodides or aryl triflates.[93]



Scheme 13. Proposed mechanism of the palladium-catalyzed cyanation of aryl−X

Despite the simplicity and analogy to similar coupling reactions there should be some concern about the viability of the proposed mechanism, because so far there is no report known about the isolation of an arylpalladium(II) cyanide complex. Recent ^1H and ^{31}P NMR experiments concerning the oxidative addition of 4-bromo(trifluoromethyl)-benzene to $[Pd(PPh_3)_4]$ at different cyanide concentrations showed that excess cyanide ions not only deactivate palladium(II), but also turn off the activity of palladium(0) complexes.[86] It was suggested that only 1−2 equivalents of cyanide ions with respect to palladium are tolerated by the catalyst system.

In the presence of TMEDA deactivation of the palladium(0) complex is prevented, even in the presence of an overstoichiometric amount of cyanide (five equivalents). It was assumed that the amine is capable of substituting cyanide ions at the palladium center, thereby regenerating an active palladium catalyst. Interestingly, the in situ formed arylpalladium(II) halide complex reacts immediately with cyanide to give the corresponding benzonitrile and a pal-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ladium(0) complex. Hence, the second and third elementary steps in the catalytic cycle — transmetalation and reductive elimination — must be much faster than the oxidative addition. In stoichiometric oxidative addition reactions of 4-bromo(trifluoromethyl)benzene and Pd^0 it has also been shown that TMEDA increases the stability of the phosphane ligand towards ligand degradation (aryl-aryl scrambling[94−96]).

Improved Efficiency by Dosage of the Cyanide Source as a Result of the Mechanistic Studies

As discussed above various palladium species [palladium(0) as well as palladium(II) species] are deactivated by cyanide ions in solution. To overcome this problem it is necessary to control the concentration of cyanide at a predefined low level, which allows the reductive coupling to proceed efficiently but prevents catalyst deactivation at the same time. In the past, this was done by careful selection of a solvent, in which the solubility of the cyanide is low and can be increased by means of a phase-transfer catalyst (crown ether, amine, etc.). However, it is clear that the CN^- concentration is difficult to control and that reproducibility problems might arise.

A more elegant and promising approach is the defined dosage of cyanide to the reaction mixture. Unfortunately, dosage of a solid cyanide source like potassium or sodium cyanide is difficult. However, the continuous addition of a liquid cyanide source using a syringe pump is easy. One of the simplest soluble cyanide sources for such reactions is acetone cyanohydrin, which is cheap and commercially available on a large scale (Scheme 14).[97−99]

Scheme 14. Acetone cyanohydrin, a useful HCN equivalent

As shown in Table 11, the cyanation of 4-bromo(trifluoromethyl)benzene with acetone cyanohydrin is possible in a very efficient manner.[100] The convenient reaction conditions, the excellent nitrile selectivity and the low catalyst concentration (Table 11, Entry 10) are remarkable. So far the highest turnover number for palladium-catalyzed cyanation of aryl halides known has been reported by applying acetone cyanohydrin as cyanating agent (TON 1900).

The generality of this approach is shown in Table 12. Activated, nonactivated, and deactivated aryl bromides give very good results in the cyanation, as do heteroaryl bromides. Electron-deficient aryl chlorides also react under these conditions (Table 12, Entries 13−15). However, conversion of *ortho*-substituted aryl halides to their corresponding benzonitriles is not satisfactory.

Another useful liquid cyanating agent is trimethylsilyl cyanide (TMSCN).[101] It has been described for the palladium-catalyzed cyanation of aryl iodides, whereas conversion of aryl bromides and chlorides was not possible in the past.[43] Apparently, catalyst deactivation takes place. Recently, we observed that *trans*-bromo[4-(trifluoromethyl)-phenyl]bis(triphenylphosphane)palladium(II) (**1**) reacts readily with TMSCN yielding the corresponding benzonitrile even at 0 °C (Scheme 15).[102]

So it was not surprising that continuous dosage of TMSCN works well for aryl bromides. By using the corresponding oxidative addition product with additional phosphane ligand as catalyst system the cyanation reactions exhibited excellent yield and selectivity (Scheme 16).[102]

As outlined in Table 13, a plethora of aryl bromides can easily be transformed into the corresponding benzonitriles. Less-reactive aryl chlorides can be coupled only with moderate success under these conditions (Table 13, Entry 14). However, utilization of an autoclave with dosage equipment, which allows to work at temperatures significantly above the boiling point of TMSCN and the solvent, should provide a possibility to overcome this problem.

Microwave-Assisted Palladium-Catalyzed Cyanation of Aryl Bromides

For many reactions it is possible to enhance the reaction rate by applying microwaves. This holds also true for the palladium-catalyzed cyanation of aryl halides. Alterman

and Halberg have shown that microwave irradiation accelerates the rate of cyanation considerably. Reaction times could be reduced from hours to a few minutes in the case of aryl bromides. The corresponding benzonitriles were obtained in high yield and selectivity. Some examples of this methodology are given in Table 14.[103]

Conclusion

Significant progress with regard to substrate compatibility and catalyst efficiency has been achieved in the palladium-catalyzed cyanation of aryl halides. Hence, industrial realizations of this methodology in the area of fine chemical syntheses seem to be feasible in the near future. Based on mechanistic investigations it became clear that catalyst deactivation by excess cyanide ions is one of the main reasons for the low productivity and activity of palladium catalysts in the cyanation reaction of aryl halides when compared to other C−C-coupling reactions.[104−113] Hence, an important factor for further development of this reaction is the control of the concentration of cyanide ions in solution. One way to achieve this is the continuous dosage of cyanide to the reaction mixture. Another possibility is to apply a two-phase system (liquid-liquid or liquid-solid) and to control the cyanide concentration by use of phase transfer catalysts or by adjusting the solubility by choosing an appropriate solvent.

Because of the relatively mild reaction conditions and the broad scope, the palladium-catalyzed cyanation of aryl halides has become an interesting tool for the total synthesis of natural products and pharmaceuticals. Since the first total synthesis using this methodology (the synthesis of (+)-estradiol[114]), numerous biologically active substances have been synthesized including a palladium-catalyzed cyanation step (Fadrozol, Robalzotan, etc.).[5−7,45,115−118] In addition to active agents, other more complicated organic products, for example special calixarenes,[119] have also been synthesized by palladium-catalyzed cyanations. Obviously, further catalyst improvements will increase the usage of this methodology in organic synthesis.

Synthesis and Structural Elucidation of a "Free" Phosphinoamide Anion

Zhaofu Fei,[a] Rosario Scopelliti,[a] and Paul J. Dyson*[a]

Keywords: N,P ligands / Potassium / Crown ether / X-ray structure

The reaction of the aminophosphane C_6H_4(*o*-CN)$NHPPh_2$ with elemental potassium in the presence of 18-crown-6 affords the phosphinoamide-containing complex [C_6H_4(*o*-CN)N-PPh_2(THF)(18-Crown-6)K] which has been fully characterised in solution and the solid state. The potassium cation interacts with the nitrile substituent group and crown, but does not interact with the P–N bond. The anion appears to be considerably more reactive than related anions in which the cation interacts with the P-N unit, as demonstrated by the reaction with O_2/H_2O which affords [Ph_2P(:O)OK(18-Crown-6)] and C_6H_4(*o*-CN)NH_2. A co-crystal containing these two products was obtained and the structure has been elucidated by single-crystal X-ray diffraction analysis.

Introduction

The chemistry of aminophosphanes and their anionic derivatives (phosphinoamide anions) has been intensively explored over the years.[1] Phosphinoamide anions are frequently used as precursors in synthesis, including, for example, for the synthesis of compounds containing P−P bonds.[2] Detailed structural studies on these anions were first reported by Ashby in 1992,[3] and there are now numerous papers describing the synthesis, structure[4] and reactivity[5] of phosphinoamide anions. Much effort has been directed towards rationalising the nature of the P−N bond in these anions and various theoretical studies have been made.[6] The short P−N distance implies that the bond has mostly double-bond character with the negative charge located on the nitrogen centre; however, their reactivity often leads to different conclusions. For example, in [$Ph_2PNLiPh\cdot(Et_2O)]_2$, while there are both P−Li and N−Li interactions, reaction with Ph_2PCl quantitatively gives $(Ph_2P)_2NPh$. In contrast, the anion of the functionalised aminophosphane [$Ph_2PNLiC_6H_4$(*o*-CN)·(THF)]$_2$, which shows only a N−Li interaction in the solid state, reacts with Ph_2PCl to afford Ph_2P-PPh_2=NC_6H_4(*o*-CN) as the only product.[7]

As far as we are aware, there are no examples of phosphinoamide anions in which the P−N bond does not interact in some way with the cation. Free anions of other types of compounds have been isolated by incorporation of a crown ether during their synthesis which serves to separate the cation from the anion.[8] This strategy has also been used with phosphinoamide-type anions, but weak interactions with the P- and N-centres and the cation remain.[9] However, we proposed that it might be possible to isolate a free anion by combining the crown ether strategy with the use of an appropriate functional group attached to the aminophosphane precursor and we report on our findings in this communication.

Results and Discussion

The reaction of the aminophosphane C_6H_4(*o*-CN)-$NHPPh_2$ (**1**) with elemental potassium in the presence of 18-crown-6 gave the anion **2**. The reaction proceeds smoothly in toluene under ambient conditions. Tetrahydrofuran or diethyl ether can also be used in place of toluene, but the yield of **2** is somewhat lower, with side-products being formed in significant quantities. The ^{31}P NMR spectrum of the reaction mixture in THF exhibits a singlet at δ = 26.5 ppm as the main signal. A signal at δ = −19.1 ppm with low relative intensity (less than 5%) is also observed. Although many phosphinoamide anions have been reported in the last years, supporting ^{31}P and ^{7}Li NMR spectroscopic data are rare. In our experience, under inert conditions, these anions give sharp signals in THF. However, traces of moisture may cause the signals to broaden, sometimes to an extent that the signal is so broad it cannot be observed. The signal at δ = 26.5 ppm in the ^{31}P NMR spectrum of **2** is at slightly lower frequency than that of the parent aminophosphane **1** (δ = 28.5 ppm). In general, phosphinoamide anions give rise to signals at higher frequency than their precursor aminophosphanes.[4,7]

Compound **2** is stable in the solid state or in dry solution under an inert atmosphere and can be stored for weeks without any appreciable decomposition. Crystallisation of **2** from a solution of THF and diethyl ether yielded crystals that were analysed by single-crystal X-ray diffraction. The

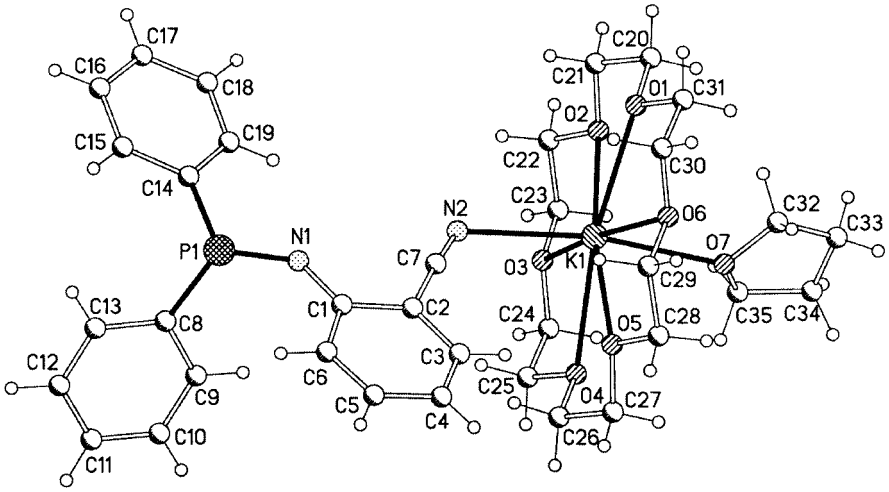

Figure 1. The molecular structure of **2** in the solid state (external THF has been omitted for clarity); key bond lengths (Å) and angles (°) include: P1−N1 1.675(5), N1−C1 1.353(7), N2−C7 1.145(7), K1−N2 2.862(5), N1−P1−C14 100.7(3), N1−P1−C8 106.0(3), C14−P1−C8 101.7(2), C1−N1−P1 118.3(4), C7−N2−K1 126.1(5)

molecular structure of **2** is shown in Figure 1 and key bond parameters are given in the caption. Compound **2** is monomeric, with both the crown ether and the nitrile functional group involved in coordinating to the potassium cation, leaving the P−N unit free. The P−N bond length is 1.675(5) Å, which is somewhat shorter than in the precursor C_6H_4(*o*-CN)NHPPh_2 **1** [1.7155(14) Å]; the N1−C1 bond is considerably shorter [1.353(7) vs. 1.393(2) Å].[7] The bond lengths associated with the P, N and the aromatic ring substituent show delocalization of the negative charge along the ring and, to some extent, towards the P centre.

In keeping with the distinct structural data in both solution and the solid state, the chemical behaviours of **2** differs from that of other phosphinoamide anions. Reaction of **2** with oxygen and water does not lead to the formation of the parent aminophosphane **1**, but results in cleavage of the P−N bond with the formation of [Ph_2P(:O)OK(18-crown-6)] (**3**) and C_6H_4(*o*-CN)NH_2.[10] Previously, re-protonation of phosphinoamide anions has been used to help establish their structure;[2c,2d] reformation of the aminophosphane takes place such that the P−N bond remains intact. For example, [Ph_2PNLiPh·(Et_2O)]$_2$ and [C_6H_4(*o*-CN)PNLiPh·(THF)]$_2$[7] react with O_2/H_2O to give the neutral aminophosphanes, as evidenced by ^{31}P NMR spectroscopy.[11]

The reaction of **2** with O_2/H_2O immediately gave two signals in the ^{31}P NMR spectrum at δ = 82.5 and 12.3 ppm, in approximately equal intensity, corresponding to Ph_2P−O−K[12] and **3**, respectively. After 48 hours, the signal at δ = 82.5 ppm disappears completely, and only the signal at δ = 12.3 ppm remains. There is no evidence for the formation of the original aminophosphane **1** or its oxide. The identity of **3** was confirmed by single-crystal X-ray diffraction analysis. The molecular structure of **3** is shown in Figure 2 and key bond parameters are given in the caption. The structure shows a heptacoordinate potassium cation coordinated to the crown ether and the Ph_2P(:O)O anion, similar structures to this latter unit are known.[13] The C_6H_4(*o*-CN)NH_2 by-product co-crystallises with **3** and interacts via hydrogen bonds with both O atoms of the anion [N1···O1, 3.072(10) Å; N1···O2, 3.270(11) Å] and with one oxygen of the crown ether [N1···O7, 3.195(13) Å].

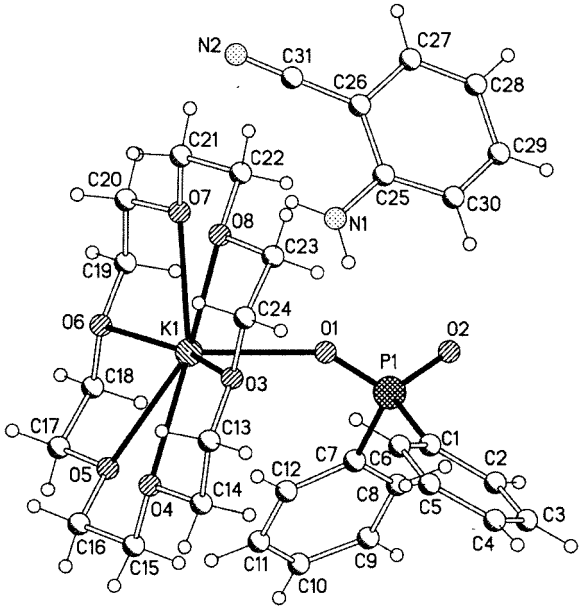

Figure 2. The molecular structure of **3**·C_6H_4(*o*-CN)NH_2 in the solid state; key bond lengths (Å) and angles (°) include: K1−O1 2.578(6), P1−O1 1.504(6), P1−O2 1.495(6), N1−C25 1.39(2), N2−C31 1.11(4), O2−P1−O1 119.7(4), P1−O1−K1, 148.2(3)

In conclusion, we have provided the first experimental example of a "free" phosphinoamide anion. The reactivity of the anion is also markedly different from that of lithium-coordinated anions, being considerably more reactive, although one cannot assume that the solution structure is the same as that observed in the solid state. However, this methodology, in which a crown ether and functional group are utilised in the synthesis of such anions, could lead to new phosphinoamide anion chemistry.

Experimental Section

The compound C_6H_4(*o*-CN)NHPPh_2 (**1**) was prepared by the literature method[7] and all other reagents were purchased from Aldrich and used as received. Solvents were dried using the appropriate reagents and distilled prior to use. NMR spectra were obtained at 20 °C on a Bruker DMX 200 instrument using $SiMe_4$ (for ^1H) and 85% H_3PO_4 (for ^{31}P) as external standards. ESI-MS spectra were recorded on a ThermoFinnigan LCQ Deca XP Plus quadrupole ion trap instrument using literature methods[14] with samples infused directly into the source at 5 μL min^{-1} using a syringe pump. Elemental analysis was carried out by the Institute of Molecular and Biological Chemistry (EPFL).

Synthesis of 2: Elemental potassium (0.078 g, 2.0 mmol) and dry toluene (10 mL) were heated to 100 °C for 5 min with stirring until the potassium was distributed as a fine suspension. After cooling to room temp. the suspension was transferred to a solution of **1** (0.604 g, 2.0 mmol) and 18-crown-6 (0.530 g, 2.0 mmol) in toluene (5 mL). After 5 h stirring at room temp. (heating should be avoided) the evolution of hydrogen gas was complete and all the potassium had disappeared completely. The solvent was removed under vacuum and the resulting solid was recrystallised from THF and diethyl ether. Yield: 1.150 g (81%). ^1H NMR ([D_8]THF): δ = 6.70−8.40 (m, aromatic H), 3.62 (m, OCH_2 of THF), 3.60 (s, OCH_2 of the crown), 1.75 (m, CH_2 of THF) ppm. ^{31}P NMR ([D_8]THF): δ = 26.5 (s) ppm. Positive ion ESI-MS: *m*/*z* = 303 $[C_{12}H_{24}O_6K]^+$. Negative ion ESI-MS: *m*/*z* = 301 $[(C_6H_5)_2PNC_6H_4(o\text{-}CN)]^-$.

Synthesis of 3: A solution of **2** (0.709 g, 1.0 mmol) in THF (10 mL) was exposed to moisture at room temp. for 48 h. The solvent was removed under vacuum and the resulting solid was crystallised from THF and diethyl ether to give the product as colourless crystals. Yield: 0.562 g; 88%. M.p: 101 °C. ^1H NMR ([D_8]THF): δ = 6.60−8.20 (m, aromatic H), 5.95 (broad signal, NH_2), 3.60 (s, OCH_2 of crown) ppm. ^{31}P NMR ([D_8]THF): 12.3 (s) ppm. Positive ion ESI-MS: *m*/*z* = 303 $[C_{12}H_{24}O_6K]^+$. Negative ion ESI-MS: *m*/*z* = 217 $[(C_6H_5)_2P(O)O]^-$. $C_{31}H_{40}KN_2O_8P$ (638.7): C 58.29, H 6.31, N 4.39; found C 58.43, H 6.46, N 4.33.

Crystal Data for 2: $C_{39}H_{54}KN_2O_8P$, *M* = 748.91, monoclinic, space group $P2_1/c$, *a* = 9.5723(6), *b* = 14.3422(12), *c* = 28.928(3) Å, β = 95.072(6)°, *V* = 3955.9(5) $Å^3$, *T* = 140(2) K, *Z* = 4, μ = 0.227 mm^{-1}, λ = 0.71073 Å, 22845 measured reflections, 6367 independent reflections, R_{int} = 0.0771, R_1 [$I > 2\sigma(I)$] = 0.0627, wR_2 (all data) = 0.1771.

Crystal Data for 3: C_6H_4(*o*-CN)NH_2: $C_{31}H_{40}KN_2O_8P$, *M* = 638.72, monoclinic, space group $P2_1/n$, *a* = 9.7036(13), *b* = 14.6000(19), *c* = 23.287(3) Å, β = 93.277(11)°, *V* = 3293.8(7) $Å^3$, *T* = 140(2) K, *Z* = 4, μ = 0.260 mm^{-1}, λ = 0.71073 Å, 19252 measured reflections, 5506 independent reflections, R_{int} = 0.1238, R_1 [$I > 2\sigma(I)$] = 0.0806, wR_2 (all data) = 0.2041.

CCDC-203628 (**2**) and -203629 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[10] In order to assess the influence of the CN group and the crown moiety, two more reactions were carried out: (1) The reaction of the unfunctionalised aminophosphane Ph_2PNHPh with elemental potassium in the presence of 18-crown-6 in a 1:1:1 ratio in THF under the same conditions gave an orange powder that was highly soluble in THF. Recrystallisation from THF and diethyl ether gave orange crystals, but not of sufficient quality for X-ray diffraction analysis. The ^{31}P NMR spectrum ([D_8]THF) of the orange compound displays a singlet at δ = 32.8 ppm. The ESI-MS (positive ion mode) exhibits a peak at *m*/*z* = 303 indicative of $[C_{12}H_{24}O_6K]^+$ (18-crown-6-K)$^+$, indicating that the potassium ion is coordinated to the crown moiety. The ESI-MS (negative ion mode) gives a low intensity peak corresponding to the anion at 276, with the main peak at 292, which is the oxidised product. Based on these data, we are not sure if the potassium is coordinated to the N. Reprotonation of this compound gave signals at δ = 81.3 (Ph_2P-O-K), 27 ($Ph_2P-NHPh$), −71 and −77 ppm (Ph_2P-K?) as the main signals. (2) The reaction of C_6H_4(*o*-CN)NHPPh_2 (**1**) and elemental potassium in a 1:1 ratio without 18-crown-6 gave a yellow powder with a chemical shift of δ = 32.7 ppm in the ^{31}P NMR spectrum. Re-protonation of this compound gave **1** in quantitative yield as indicated by a singlet at δ = 30.7 ppm in the ^{31}P NMR spectrum and a broad signal centred at δ = 5.5 ppm in the ^1H NMR spectrum.

The Water-Exchange Rate in Neutral Heptadentate DO3A-Like Gd^{III} Complexes: Effect of the Basicity at the Macrocyclic Nitrogen Site

Enzo Terreno,[a] Patrizia Boniforte,[a] Mauro Botta,[b] Franco Fedeli,[c] Luciano Milone,[a] Armando Mortillaro,[c] and Silvio Aime*[a]

Keywords: Gadolinium / Water exchange / Imaging agents / Kinetics

The rate of exchange of the two water molecules coordinated to a Gd^{III} centre in neutral complexes with heptadentate DO3A derivatives is modulated by the basicity of the macrocyclic nitrogen bearing the pendant group: a lower basicity results in a slower water-exchange rate.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The exchange rate (k_{ex}) of the metal-coordinated water protons in lanthanide(III) complexes plays a fundamental role in determining their efficiency as contrast agents (CA) for Magnetic Resonance Imaging (MRI) applications.[1] In the case of Gd^{III}-based agents the attainment of high relaxivity values is strongly dependent on k_{ex}. In fact, the paramagnetic relaxation of the water protons for a given Gd^{III} chelate reaches the maximum efficiency when k_{ex} is significantly larger than the longitudinal relaxation rate of the water protons bound to the Gd^{III} ion, i.e. $k_{ex} >> R_{1M}$. To this regard, it has been calculated that a k_{ex} value of about 5×10^7 s^{-1} at 298 K allows the attainment of the highest relaxivity (at 0.47 T) for a large-sized Gd^{III}-based system.[2] Conversely, a novel class of paramagnetic CAs based on saturation transfer, the so-called CEST (Chemical Exchange Saturation Transfer) agents, require much lower k_{ex} values.[3,4] In these Ln^{III} chelates (with Ln ≠ Gd) the contrast in the MR image arises from the decrease of the NMR signal intensity of the bulk water protons following the irradiation of the water protons coordinated to the Ln^{III} ion. Here, the condition $\Delta\omega > k_{ex}$ has to be fulfilled ($\Delta\omega$ is the chemical shift separation, in rad·Hz, between the free and metal-bound water protons) and, therefore, k_{ex} values of about two orders of magnitude smaller than the optimal values required for Gd^{III}-based agents are necessary for ensuring an efficient saturation transfer.

It is worth remembering that k_{ex} refers to the exchange of the water protons coordinated to the metal centre and not to the exchange of the whole water molecule ($k_{ex\text{-}w}$). Nevertheless, at pH values around neutrality the proton exchange is extremely slow (about 10^3 s^{-1}) when compared with the typical $k_{ex\text{-}w}$ values measured for Ln^{III} chelates. Thus, it is reasonable to assume that at physiological pH values k_{ex} corresponds to $k_{ex\text{-}w}$.

In the case of nine-coordinate Gd^{III} complexes, it has been established that the water-exchange process occurs through a dissociative pathway in which the transition state is represented by an eight-coordinate species.[5] Thus, the exchange rate is related to the free-energy difference, $\Delta G^{\#}$, between the transition and the ground states. Several factors contribute to the $\Delta G^{\#}$ value. $\Delta G^{\#}$ is usually dominated by the enthalpic term, $\Delta H^{\#}$, which mainly depends on the strength of the $Ln-O_{(water)}$ bond. The highly electrostatic nature of this bond accounts for the marked dependence of the water-exchange rate on the overall electric charge in isostructural Ln^{III} chelates. In fact, relatively fast and exceedingly slow exchange rates have been observed for anionic and cationic Gd^{III} complexes, respectively.[1] Moreover, the $\Delta H^{\#}$ term may be affected either by the steric crowding at the water coordination site or by the structural properties of the second hydration sphere of the metal ion.[6–8] The large number of parameters that contribute to determine the water-exchange process renders the assessment of the relative role played by each single contribution quite difficult. For this reason, the evaluation of the k_{ex} values for Gd^{III} complexes differing in only one main struc-

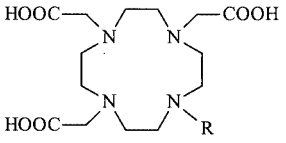
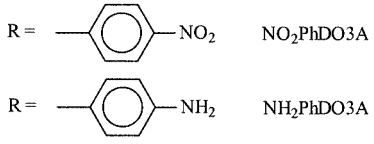
tural or electronic feature may be particularly useful. On this basis, it was deemed of interest to investigate the dependence of the water-exchange rate on the basicity of the macrocyclic nitrogen bearing the non-coordinating substituent in two neutral heptadentate DO3A-like Gd^{III} chelates. To this purpose, the ligands reported below, and their corresponding Eu^{III}, Gd^{III} and Yb^{III} complexes, have been synthesised. In spite of a very similar structure, the two Ln^{III} chelates have a noticeable difference in the electronic availability at the macrocyclic nitrogen bearing the phenyl group [$\sigma_{para}(NO_2) = 0.78$, $\sigma_{para}(NH_2) = -0.66$].





Results and Discussion

The synthesis of the ligands (see Exp. Sect.) was carried out by reacting 1,4,7,10-tetraazacyclododecane (TAZA) with *p*-nitrofluorobenzene (molar ratio 3:1) in acetonitrile. The purified mono-alkylated TAZA derivative was then exhaustively carboxymethylated with bromoacetic acid at pH 10. The NH_2PhDO3A ligand (pale brown) was obtained upon hydrogenation (Pd/C) of the nitro derivative. The synthesis of the Ln^{III} complexes was carried out in water at pH 7 by mixing equimolar amounts of the ligand and the corresponding Ln^{III} chloride.

Figure 1 shows the pH dependence of the relaxivity, r_1, for the two Gd^{III} complexes at 0.235 *T* (corresponding to a proton Larmor frequency of 10 MHz) and 298 K.

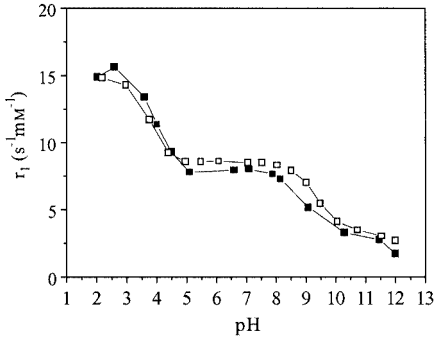


Figure 1. pH dependence of relaxivity for [Gd(NO_2PhDO3A] (■) and [Gd(NH_2PhDO3A] (□) at 298 K and 10 MHz

Qualitatively, both chelates behave similarly to other neutral heptadentate DO3A-like complexes.[9] r_1 is constant in the pH interval 5 and 8; at lower pH values r_1 increases owing to the acid-catalysed demetallation process, whereas at higher pH values the relaxivity decreases owing to the formation of ternary adducts with anionic species like carbonate (from dissolved CO_2) and hydroxide anions which displace the metal-bound water molecule(s). This behaviour, coupled with the relatively high r_1 values {8.0 and 8.5 $s^{-1}\cdot mM^{-1}$ at 298 *K* and pH = 7 for [Gd(NO_2PhDO3A)] and [Gd(NH_2PhDO3A)], respectively} provides a strong indication that the hydration sphere of the two complexes is closely analogous to that of the parent [Gd(DO3A)] complex,[10] i.e. characterised by the presence of two water molecules coordinated to the metal ion. Nevertheless, it is likely that the complexes are present in solution as a mixture of species which may differ in the conformation of the donor atoms wrapped around the metal centre (Δ/Λ and δδδδ/λλλλ isomerism)[11] or in the hydration state of the metal ion (equilibrium between nine- and eight-coordinate isomers).[10,12]

In principle, each species may have a different k_{ex} value[13] and thus the isomeric population of the two complexes has to be checked.

Figure 2 shows a comparison of the ^1H NMR high resolution spectra of the Eu^{III} chelates. In spite of the complexity of the spectra, it is evident that they are very similar in terms of chemical shift range and number and relative intensity of the resonances. Analogous conclusions can be drawn by analysing the ^1H NMR spectra of the corresponding Yb^{III} complexes.

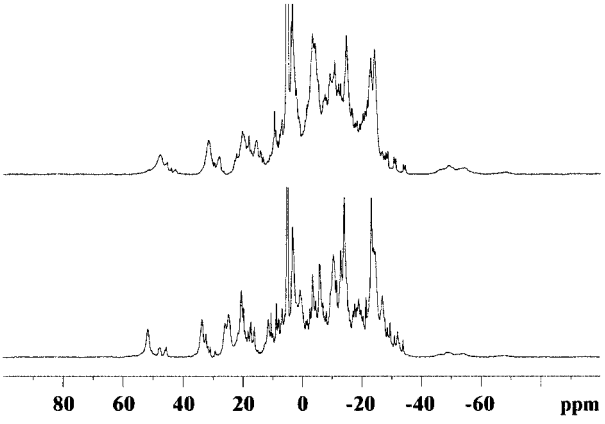

Figure 2. ^1H NMR spectra at 7.05 T, pH 7 and 275 K in D_2O of [Eu(NH_2PhDO3A)] (top) and [Eu(NO_2PhDO3A)] (bottom)

Further confirmation that the isostructurality between the two Ln^{III} chelates is retained for the Gd^{III} complexes was gained by the analysis of their NMRD (Nuclear Magnetic Relaxation Dispersion) profiles (Figure 3). Again, the two complexes display a very similar magnetic-field dependence of their r_1 values (measured at pH 7 and 298 K) even if the relaxivity of the *p*-nitro derivative is slightly lower over the entire range of magnetic-field strengths investigated.

Finally, the exchange rate of the water molecules coordinated to Gd^{III} has been determined through the well-established NMR method based on the analysis of the tempera-

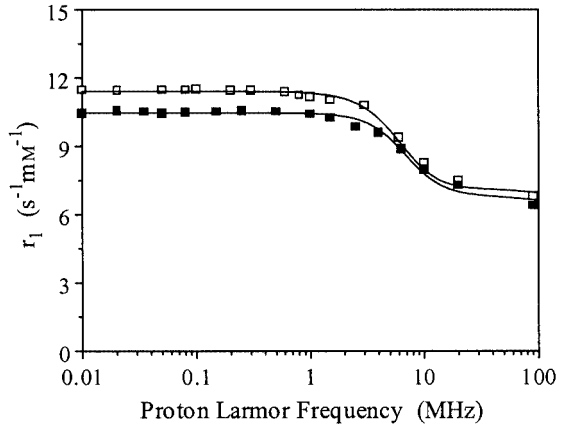

Figure 3. ^{1}H NMRD profiles for [Gd(NO_2PhDO3A)] (■) and [Gd(NH_2PhDO3A)] (□) at pH 7 and 298 K

ture dependence of the paramagnetic contribution to the transverse relaxation rate of the ^{17}O-water nuclei. Figure 4 reports the data obtained for the two complexes.

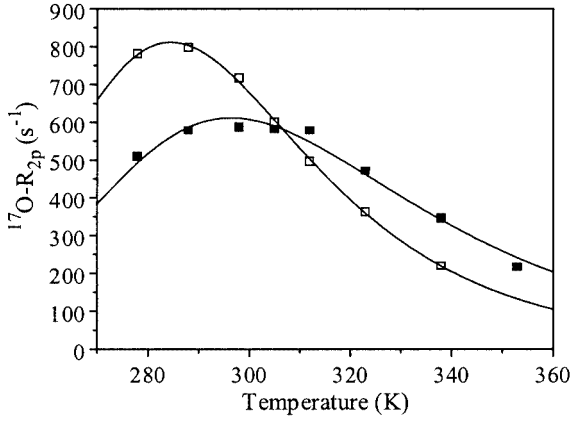

Figure 4. Temperature dependence of ^{17}O-R_{2p} for [Gd(NO_2PhDO3A)] (■) and [Gd(NH_2PhDO3A)] (□) at pH 7 and 7.05 T ([GdL] = 10 mM)

The profiles appear rather different, with the top of the bell-shaped curve shifted to lower temperature for the *p*-amino derivative. This behaviour suggests that k_{ex} is significantly influenced by the nature of the substituent at the macrocyclic nitrogen.

A quantitative analysis of the ^{17}O NMR spectroscopic data, according to the available theory,[5] confirms this effect. The result of the best-fitting procedure, on the assumption that the two labile water molecules have the same exchange rate, is reported in Table 1, along with the results obtained from the analysis of the NMRD profiles carried out according to the usual inner- and outer-sphere model.[1]

No relevant differences were obtained, within the same experimental data set, for the parameters controlling the electronic relaxation times Δ^2 and τ_V, which represent the mean energy of the transient zero-field splitting (ZFS) and its time modulation, respectively. Nevertheless, different Δ^2 and τ_V values were obtained depending on the experimental technique. It is likely that this discrepancy is due to the

Table 1. Best-fit parameters (at 298 K) obtained from the analysis of ^{17}O-R_{2p} versus T profiles and NMRD profiles of [Gd(NO_2PhDO3A)] and [Gd(NH_2PhDO3A)] at pH 7

	[Gd(NO_2PhDO3A)]		[Gd(NH_2PhDO3A)]	
	NMRD[a]	^{17}O-R_{2p} [b]	NMRD	^{17}O-R_{2p}
k_{ex} ($\times 10^6 s^{-1}$)	[c]	7.4 ± 1.2	[c]	17.6 ± 3.8
ΔH_M (kJ·mol^{-1})	[d]	33.8 ± 1.6	[d]	36.2 ± 2.8
Δ^2 ($\times 10^{19}$ s^{-2})	5.8 ± 0.5	11.6 ± 0.8	5.7 ± 0.4	9.8 ± 0.4
τ_V ($\times 10^{-12}$ s)	22.0 ± 0.3	13.0 ± 0.6	20.3 ± 0.7	15.0 ± 0.7
τ_R ($\times 10^{-12}$ s)	77.0 ± 0.4	[d]	81.1 ± 0.3	[d]

[a] The fitting of the NMRD profiles has been carried out by keeping fixed the following parameters: r = 3.1 Å, q = 2, a = 3.8 Å, $D = 2.25 \times 10^{-5}$ cm^2·s^{-1}. [b] The fitting of the temperature dependence of ^{17}O-R_{2p} has been performed by keeping fixed the following parameters: ΔH_v = 5.0 kJ·mol^{-1}, (A/ħ) = -3.8×10^6, q = 2. [c] This parameter has been fixed to the value obtained by the fitting of the data obtained with the other experimental technique. [d] This parameter cannot be obtained from the fitting.

limitations of the currently available theory for describing adequately the magnetic-field dependence of the electronic relaxation times, but, fortunately, this concern has only a small effect on the estimation of k_{ex}. Therefore, the relaxometric analysis indicates that the water exchange for the *p*-amino derivative occurs faster than the *p*-nitro complex.

It seems reasonable that such a difference could be accounted for in terms of the different electronic properties of the two *p*-substituents on the aromatic ring. The strong electron-withdrawing character of the *p*-nitro group makes the Gd−N bond much more polarised, thus increasing the positive charge at the metal centre. This effect results in a stabilisation of the nine-coordinate ground state of the complex, thus slowing down the rate of exchange of the coordinated water molecules. The opposite electronic effect of the *p*-amino group leads to a destabilisation of the $Gd^{III}-O_{(water)}$ bond and to a faster exchange rate.

Interestingly, the water-exchange regime reported for [Gd(DO3A)] (11.0×10^6 s^{-1})[10] is intermediate as expected on the ground of the basicity of the secondary amino group.

The results reported here might also help to rationalise the fast water-exchange rates (ca. 5.0×10^7 s^{-1} at 298 K) reported in the literature for several *N*-benzyl-DO3A derivatives[14] and support the hypothesis forwarded for explaining the relatively fast exchange rate observed in a cationic *N*-methyl DO3A derivative.[15] In fact, in these complexes a destabilisation of the $Gd^{III}-O_{(water)}$ bond is expected on the basis of the inductive effect (−I) of the alkyl group on the macrocyclic nitrogen.

Conclusion

In conclusion, the experimental evidence reported in this communication supports the view that the exchange rate of the water molecules coordinated to the Gd^{III} ion in a nine-coordinate DO3A-like arrangement may be successfully modulated through a proper choice of the electronic properties of the substituent on the macrocyclic nitrogen.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

However, whether the two water molecules exchange at the same rate and/or the substituent effect described herein affects the dissociation rate at the two coordination sites to a different extent still remain undefined.

Experimental Section

Synthesis of NO_2PhDO3A: This ligand was synthesised in two steps. First, a suspension of 1,4,7,10-tetraazacyclododecane, TAZA, (35.05 g, 0.2035 mol) in acetonitrile (500 mL) was dissolved whilst stirring at 60 °C by adding 50 mL of water. To this solution was then added dropwise 50 mL of a solution of acetonitrile containing 1-fluoro-4-nitrobenzene (9.57 g, 0.0678 mol). After 8 h at 60 °C the suspension was cooled down and filtered. The crude solid was dissolved in 1 L of boiling water and the resulting solution (obtained by filtration) was first diluted 1:1 with water, loaded onto a chromatographic column (Amberlite® XAD 1600) and then eluted with water in order to separate the unchanged TAZA. The 1-(4-nitrophenyl)-1,4,7,10-tetraazacyclododecane ligand (14.08 g; 0.048 mol, 70.8% yield) was obtained by eluting the column with methanol and subsequent evaporation of the solvent.

In the second step, 2-bromoacetic acid (22.23 g, 0.16 mol) was added whilst stirring to an aqueous solution of 1-(4-nitrophenyl)-1,4,7,10-tetraazaciclododecane (11.73 g, 0.04 mol in 50 mL of water). The pH of the solution was brought to 10 by adding 2 N NaOH. The solution was heated at 50 °C for 6 h by keeping the pH constant. The reaction mixture was cooled down, filtered and the filtrate was acidified at pH 3 with HCl. This solution was loaded onto a chromatographic column (Amberlite® XAD 1600) and then eluted first with water, in order to separate the bromide ions, and then with methanol. After evaporation of the solvent the NO_2PhDO3A ligand was obtained in the acid form as a yellow solid (16.38 g, 0.035 mol, 87.6% yield). ^{1}H NMR (D_2O, *t*BuOH as internal reference, 298 K): δ = 8.0 (d, 2 H), 6.65 (d, 2 H), 3.7 (s, 4 H), 3.45 (s, 4 H), 3.35 (s, 2 H), 3−3.2 (m, 12 H) ppm. $^{13}C\{^1H\}$ NMR (D_2O, *t*BuOH as internal reference, 298 K): δ = 173.2, 169.2, 153.9, 142.7, 124.2, 122.3, 55.1, 51.6, 50.9, 50.0, 47.7, 46.9 ppm. MS (MALDI-TOF): calcd. for $C_{20}H_{29}N_5O_8$ 467.47 uma; found 468.4 [MH^+].

Synthesis of NH_2PhDO3A: Ammonia solution (26%) was added to a suspension of NO_2PhDO3A in water (7.70 g; 0.02 mol in 50 mL of water) until the ligand dissolution was complete. Then, 0.7 g of 10% Pd/C, previously treated with 5 mL of water, was added to the solution and the catalytic hydrogenation was carried out at room temperature and pressure with hydrogen (1180 mL, 0.05 mol) produced electrochemically (Hydrogen generator HG 600; CLAIND). After 4 h the suspension was filtered in order to remove the catalyst. The filtrate (brown colour) was lyophilised and then redissolved in water acidified (pH 2.3) with HCl. 0.5 g of Carbopuron was then added in order to partially decolourise and stabilise the product. After filtration, the solution was re-lyophilised and the NH_2PhDO3A ligand was obtained in the acid form as a dark-brown solid (8.16 g; 0.016 mol, 80% yield). ^{1}H NMR (D_2O, *t*BuOH as internal reference, 298 K): δ = 7.15 (d, 2 H), 6.7 (d, 2 H), 3.6 (s, 4 H), 3.4 (s, 4 H), 3.3 (s, 2 H), 3.27 (s, 8 H), 3.1 (s, 4 H) ppm. $^{13}C\{^1H\}$ NMR (D_2O, *t*BuOH as internal reference, 298 K): δ = 176.8, 169.1, 143.6, 138.9, 124.8, 116.0, 55.7, 54.2, 51.0, 50.2, 49.5, 47.9 ppm. MS (MALDI-TOF): calcd. for $C_{20}H_{31}N_5O_6$ 437.5 uma; found 438.3 [MH^+].

Synthesis of the Ln^{III} Complexes: The Ln^{III} complexes (Ln = Gd, Eu and Yb) were synthesised in water at room temperature by adding an equimolar amount of $LnCl_3$ to the selected ligand. The pH was monitored during the synthesis in order to keep it in the 6−8 range. The final concentration of the metal chelates was checked by Evans' method.[16]

NMR Measurements: The high resolution NMR spectra and the ^{17}O-R_{2p} measurements were performed on a Bruker Avance 300 spectrometer (Karlsruhe, Germany) operating at 7.05 T (proton Larmor frequency of 300 MHz).

The water-proton longitudinal relaxation rates at 0.235 T (proton Larmor frequency of 10 MHz) as well as the NMRD profiles in the 0.000235−0.235 T range (0.01−10 MHz) were obtained from a Stelar Fast Field Cycling Relaxometer (Mede (Pv), Italy). The temperature was controlled with a Stelar VTC-91 air-flow heater equipped with a copper-constantan thermocouple (uncertainty of ±0.1 °C). The NMRD profile was completed with data obtained at 20 MHz and 90 MHz by using a Stelar Spinmaster and a JEOL EX-90 NMR spectrometer, respectively.

A Template-Interface Co-Reduction Synthesis of Hollow Sphere-like Carbides

Cun Li,[a,b] Xiaogang Yang,[a] Baojun Yang,[a] Yan Yan,[a] and Yitai Qian*[a]

Keywords: Nanostructures / Carbides / Titanium / Vanadium / Synthesis design

Hollow sphere-like carbides MC (M = Ti, V) with diameters of between 70 and 170 nm were synthesized via a template-interface co-reduction (TICR) route, in which MCl_4 and hexachlorobuta-1,3-diene (C_4Cl_6) were reacted with metallic sodium at 500 °C for 24 h. X-ray powder diffraction (XRD) patterns indicated the samples were single-phase NaCl-type carbides. Transmission electron microscopy (TEM) photographs showed the hollow spheres consisted of nanocrystalline carbides. The possible formation mechanism of hollow sphere-like carbides is discussed.

Introduction

The transition-metal carbides of groups IV and V possess unusual properties that make them desirable and useful engineering materials in industry.[1] Nanosized TiC and VC powders have promising applications in mechanical and tribological fields.[2] Recent research work has proved that some transition metal carbides have similar catalytic properties to those of the platinum-group metals. For instance, vanadium carbide is an active NH_3 decomposition catalyst.[3]

Hollow spheres consisting of nanoparticles are useful as fillers, coatings, catalysts, and encapsulating agents because of their low density, large specific surface area, and interesting optical properties.[4] Various hollow spheres including carbon,[5] polymers,[6] metals,[7] and inorganic oxides[8] have been synthesized by using spherical templates such as polystyrene beads or silica sol.[9] Several other methods have also been developed to fabricate hollow spheres, such as coaxial nozzle techniques,[10] microemulsion and reverse microemulsion methods,[11] exchange-resin methods,[12] self-organization,[13] and template-interface reactions.[14] Hollow sphere carbides may be promising materials in mechanical and catalyst fields. However, to the best of our knowledge, there are few reports on these compounds.[15]

Generally, transition metal carbides, including TiC and VC, are prepared by either direct element reaction,[16] carbothermal reduction,[17] self-propagating high-temperature synthesis (SHS)[18] or solid-state metathesis (SSM) [19] at elevated temperatures. Previously, we have developed a co-reduction method to synthesize nanocrystalline carbides by allowing CCl_4 and MCl_4 to react with metallic sodium at relatively low temperatures.[20]

Herein, we report a template-interface co-reduction (TICR) route to synthesize TiC and VC hollow spheres, using $TiCl_4$ or VCl_4 as the titanium or vanadium source, C_4Cl_6 as the carbon source and Na as reductant. $TiCl_4$ or VCl_4 and C_4Cl_6 are co-reduced by metallic Na at 500 °C. Metallic Na droplets generated in the co-reduction process may play a role as a template in the formation process of hollow sphere carbides. The formation of carbides can be expressed as shown in Equation (1):

$$4MCl_4 + C_4Cl_6 + 22Na \xrightarrow{500^\circ C} 4MC + 22NaCl\ (M = Ti, V) \quad (1) \qquad (1)$$

Results and Discussion

Figure 1 shows the XRD patterns of as-prepared samples. All the diffraction peaks in the XRD patterns can

be indexed as face-centered cubic (fcc) carbides. The shifts of the peak positions correspond to the different lattice constants of these two samples, due to the different ionic radii of Ti and V. The lattice parameters obtained from as-prepared products are $a = 4.322$ Å for TiC and $a = 4.169$ Å for VC, in good agreement with the values in the literature.[21]

The size and morphology of the carbides was studied by TEM. The TEM photographs and selected area electron diffraction (SAED) patterns of as-prepared carbides are shown in Figure 2a−d. From the TEM photographs it can be seen that there is an obvious contrast between the dark edge and the pale center of the samples, revealing that the core is hollow.[22] The hollow nature of the spheres is also supported by the observation of a TiC sphere with a broken shell [Figure 2a (inset)]. The as-prepared carbide spheres have diameters ranging from 70 to 120 nm; the thickness of the shell is about 10−20 nm for carbides. The SAED patterns of a single sphere of both samples show three clear ring patterns corresponding to the (111), (200) and (220) reflections of cubic TiC (Figure 2b) and VC (Figure 2d). The cell constants calculated from the radii of the diffraction rings confirm the results from the XRD patterns. No diffuse rings of amorphous carbon are observable. These results indicate that the hollow spheres are mainly composed of polycrystalline carbides. From the HRTEM photographs (Figure 2e and 2f), it can be seen that the shells of the carbide spheres are composed of nanoparticles of between 2 and 5 nm. FESEM micrographs of both carbides are shown in Figure 3. Besides some irregular particles, the portion of spheres with sizes of about 70−170 nm in the products is above 60%. It can be seen that a big sphere is usually found with a broken shell (indicated by an arrow in Figure 3a).

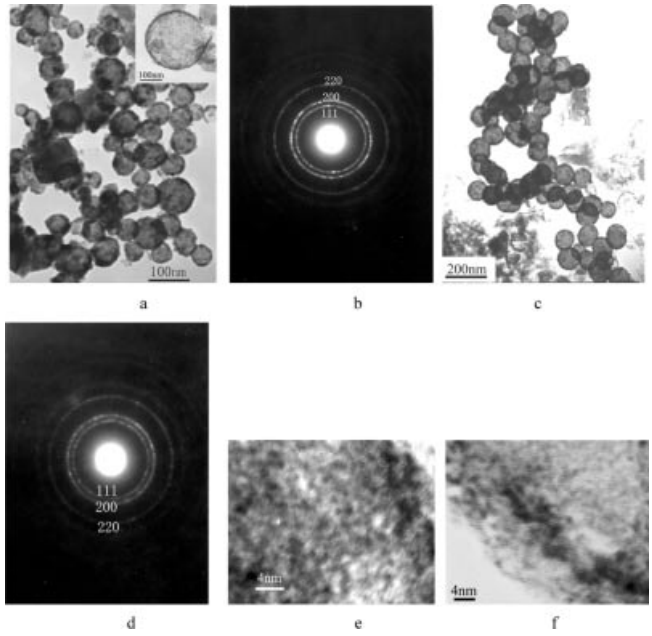

Figure 2. (a) (b) TEM micrograph and SAED pattern of TiC [(inset in a) single TiC hollow sphere with broken shell]; (c) (d) TEM micrograph and SAED pattern of VC; (e) HRTEM micrograph of the sphere shell of TiC; (f) HRTEM micrograph of the sphere shell of VC

Based on our previous experiment results,[20] the overall reaction [Equation (1)] might occur via a co-reduction route, which could be described by Equations (2)−(4):

$$C_4Cl_6 + 6Na \rightarrow 4C + 6NaCl \quad (2)$$

$$MCl_4 + 4Na \rightarrow M + 4NaCl\ (M = Ti, V) \quad (3)$$

$$M + C \rightarrow MC\ (M = Ti, V) \quad (4)$$

Similar to the reaction between CCl_4 and Na, C_4Cl_6 could be reduced by Na to generate carbon [Equation (2)], which should be a thermodynamically spontaneous and exothermic process concluded from the very high Gibbs energy of formation and enthalpy of NaCl ($\Delta_fG^o = -384.1$ kJ·mol^{-1}, $\Delta_fH^o = -411.2$ kJ·mol^{-1}).[23] The reaction in Equation (3) is highly exothermic ($\Delta H^o = -881.6$ kJ·mol^{-1} using $TiCl_4$ as reactant; $\Delta H^o = -1075.4$ kJ·mol^{-1} using VCl_4 as reactant).[23] The reaction in Equation (4), which produces TiC ($\Delta H^o = -92$ kJ·mol^{-1}) or VC ($\Delta H^o = -51$ kJ·mol^{-1}),[24] is also exothermic. Hence, the overall reaction in Equation (1) is highly exothermic.

In this synthetic system, metallic sodium may form droplets owing to reaction heat generated from the exothermic reactions, and these metallic Na droplets may act as templates in the formation process of hollow sphere carbides. This possible formation process is illustrated in Figure 4 and is similar to the mechanism of formation of CdS hollow spheres via a template-interface reaction.[14] In our experiment, upon increasing the reaction temperature to 500 °C C_4Cl_6 (b.p. 215 °C), $TiCl_4$ (b.p. 136.4 °C) and VCl_4 (b.p. 148 °C) begin to vaporize.[23] Strongly exothermic reactions then take place on the surface of the fused sodium (m.p. 97.82 °C),[23] raising the local temperature near the surface

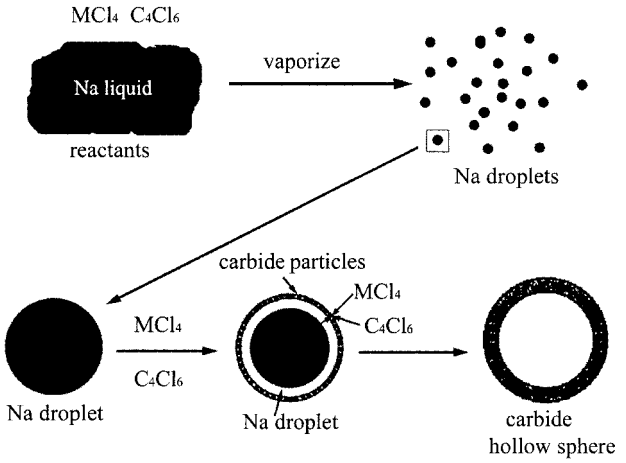

Figure 4. The formation mechanism of hollow carbide spheres

and hence causing the sodium to vaporize (b.p. 881.4 °C).[23] This sodium vapor could form many small droplets in the autoclave. Subsequently, the co-reduction reactions could occur on the surface of the Na droplets in the atmosphere of C_4Cl_6 and MCl_4, which may result in the formation of a carbide shell around the Na core. This is an important step in the formation of hollow spheres. Analogous to the synthesis of hollow spheres using emulsion droplets as templates,[25] the produced carbide shell could stabilize the sodium droplets, thus preserving the spherical shape. As the reaction continues the amount of sodium becomes depleted and the shell gradually thickens, resulting finally in hollow spheres with a polycrystalline carbide shell. In this co-reduction procedure the sodium droplets may serve as a template with the carbide shells being formed near the liquid-gas interface. We have therefore called it a template-interface co-reduction (TICR) route. We have not observed sodium encapsulated in carbides by TEM directly due to the high reactivity and air sensitivity of sodium. However, the formation of broken spheres may be ascribed to the presence of unconsumed sodium in the hollow sphere, which could react with water to blow out the hollow spheres due to gas evolution. This may be a supportive evidence for the proposed mechanism. In order to understand the formation process of hollow sphere carbides, further extensive studies are underway.

Conclusion

We have successfully prepared TiC and VC hollow spheres via a template-interface co-reduction (TICR) route. The TiC and VC hollow spheres have potential applications in catalysis and mechanical fields. A possible template-interface reaction mechanism for the formation of carbide spheres has been proposed. This TICR route may be applied to produce other carbide hollow spheres.

Experimental Section

All manipulations were carried out in a dry glovebox under N_2. In a typical synthetic procedure for TiC, 0.02 mol of $TiCl_4$ and 0.005 mol of C_4Cl_6 were syringed into a stainless steel autoclave of 50 mL capacity, and 0.12 mol of granular metallic Na was added. The autoclave was sealed and maintained at 500 °C for 24 h, then allowed to cool slowly to room temperature. The product was collected and washed successively with absolute ethanol, 1 M hydrochloric acid and distilled water. After drying in vacuo at 60 °C for 4 h, 0.98 g of black powder was obtained. Substitution of VCl_4 for $TiCl_4$ gave VC.

The samples were characterized by X-ray powder diffraction (XRD) on a Japan Rigaku Dmax-γA X-ray diffractometer with graphite-monochromated Cu-K_α radiation (λ = 1.54178 Å). Transmission electron microscopy (TEM) photographs and selected area electron diffraction (SAED) patterns were taken with a Hitachi Model H-800 transmission electron microscope. High resolution transmission electron microscopy (HRTEM) was carried out using a JEOL-2010 transmission electron microscope. Field-emission scanning electron microscopy (FESEM) images were taken with a JEOL JSM-6700F scanning electron microscope.

Halide abstraction of *trans*-[$RuCl_2${κ^4-(1*R*,2*R*)-PNNP}] {(1*R*,2*R*)-PNNP = (1*R*,2*R*)-*N*,*N*′-bis[2-(diphenylphosphanyl)-benzylidene]-1,2-diiminocyclohexane} and *trans*-[$RuCl_2${κ^4-(1*R*,2*R*)-P(NH)(NH)P}] {(1*R*,2*R*)-P(NH)(NH)P = (1*R*,2*R*)-*N*,*N*′-bis[2-(diphenylphosphanyl)benzylidene]-1,2-diaminocyclohexane} with $AgBF_4$ in acetonitrile at ambient temperature gave *cis*-[RuCl(CH_3CN){κ^4-(1*R*,2*R*)-PNNP}][BF_4] (**1**) and *cis*-[RuCl(CH_3CN){κ^4-(1*R*,2*R*)-P(NH)(NH)P}][BF_4] (**2**), respectively. When **1** was refluxed in pyridine (py), the coordinated CH_3CN was replaced by pyridine to form *cis*-[RuCl(py){κ^4-(1*R*,2*R*)-PNNP}][BF_4] (**3**). However, when **2** was refluxed in pyridine, one of the amino moieties (–CH_2–NH–)was oxidized to an imino moiety (–CH=N–) with concomitant displacement of the coordinated CH_3CN by pyridine to produce *cis*-[RuCl(py){κ^4-(1*R*,2*R*)-P(N)(NH)P}][BF_4] (**4**). The structures of **3** and **4** were ascertained by X-ray crystallography. Compounds **1**–**4** are effective catalysts for the epoxidation of various olefins with air. A turnover frequency of up to 733 h^{-1} and an enantiomeric excess of up to 24% were obtained for the epoxidation of styrene catalysed by **2**. Compound **2** can also catalyse the epoxidation, dehydrogenation and C–H activation of various olefins, alcohols and alkanes by *tert*-butyl hydroperoxide with high chemical selectivity.

Introduction

Diamino-, diimino- and diamidodiphosphanes are very versatile ligands. Their transition metal complexes are effective catalysts for asymmetric hydrogenation,[1] epoxidation,[2] cyclopropanation,[3] and allylic alkylation.[4,5] Thus, the synthesis of chiral diamino-, diimino- and diamidodiphosphane ligands and their applications as auxiliaries for the preparation of chiral catalysts have aroused considerable interest. We have investigated the preparation and chemistry of such phosphanes,[5−10] and reported the synthesis of (1*R*,2*R*)-*N*,*N*′-bis[2-(diphenylphosphanyl)benzylidene]-1,2-diiminocyclohexane [(1*R*,2*R*)-PNNP], (1*R*,2*R*)-*N*,*N*′-bis[2-(diphenylphosphanyl)benzylidene]-1,2-diaminocyclohexane [(1*R*,2*R*)-P(NH)(NH)P], and their Ru^{II},[8] Cu^{I} and Ag^{I} [9] complexes. Recently, we reported the synthesis, structure and catalytic activity of *trans*-[$RuCl_2${κ^3-(1*R*,2*R*)-P(NH)(NH)P}(PPh_3)][11] and its nonchiral analogue *trans*-[$RuCl_2${κ^3-P(NH)(NH)P}(PPh_3)] {P(NH)(NH)P = *N*,*N*′-bis[2-(diphenylphosphanyl)benzylidene]-1,2-diaminoethane}.[12] Here we describe the synthesis of *cis*-[RuCl(CH_3CN){κ^4-(1*R*,2*R*)-PNNP}][BF_4] (**1**), *cis*-[RuCl(CH_3CN)-{κ^4-(1*R*,2*R*)-P(NH)(NH)P}][BF_4] (**2**), *cis*-[RuCl(py){κ^4-(1*R*,2*R*)-PNNP}][BF_4] (**3**) and *cis*-[RuCl(py){κ^4-(1*R*,2*R*)-P(NH)NP}][BF_4] (**4**), and their applications in catalytic oxidation. The crystal structures of **3** and **4** are also presented.

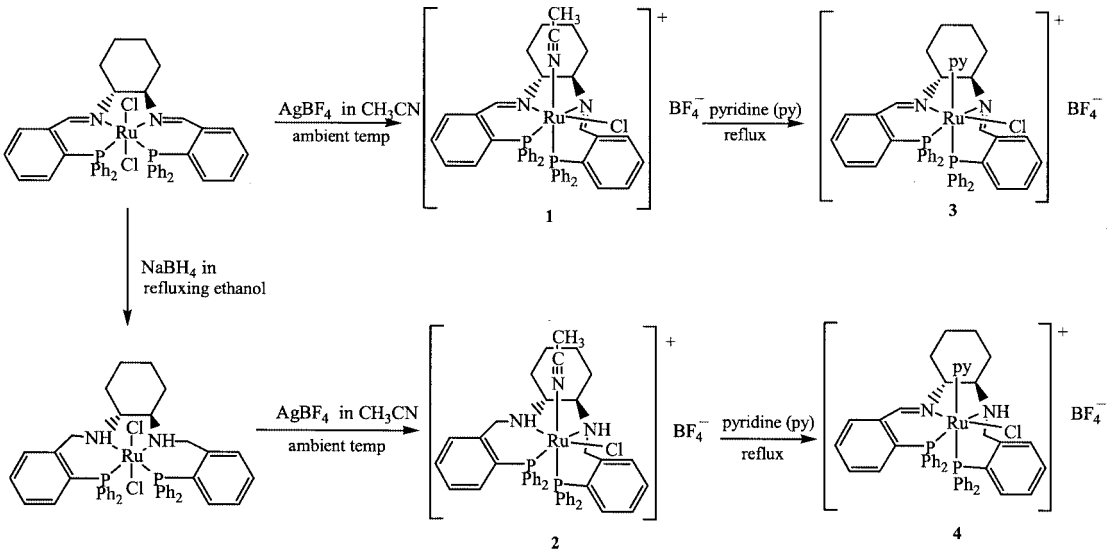
Results and Discussion

Synthesis and Characterisation of the Complexes

Scheme 1 summarises the reactions leading to complexes **1**−**4**. One chloride ion from *trans*-[$RuCl_2${κ^4-(1*R*,2*R*)-PNNP}] or *trans*-[$RuCl_2${κ^4-(1*R*,2*R*)-P(NH)(NH)P}] was abstracted by $AgBF_4$ in CH_3CN at ambient temperature to afford the solvent-coordinated complex *cis*-[RuCl(CH_3CN){κ^4-(1*R*,2*R*)-PNNP}][BF_4] (**1**) or *cis*-[RuCl(CH_3CN){κ^4-(1*R*,2*R*)-P(NH)(NH)P}][BF_4] (**2**), respectively. The coordination of CH_3CN in **1** and **2** was revealed by their FAB MS, ^{1}H NMR and IR data. The $^{31}P\{^1H\}$ NMR spectra of both **1** and **2** exhibit two doublets [δ = 44.0 ($^2J_{P,P}$ = 24.3 Hz) and 49.8 ppm ($^2J_{P,P}$ = 24.3 Hz) for **1**; δ = 37.3 ($^2J_{P,P}$ = 24.5 Hz) and 44.1 ppm ($^2J_{P,P}$ = 24.5 Hz) for **2**], implying a *cis*-[RuCl(CH_3CN)] arrangement, which is further supported by the X-ray structures of the pyridine derivatives of **1** and **2** (vide infra).



Scheme 1

When **1** was heated under reflux in pyridine the coordinated CH_3CN molecule was substituted by pyridine to give *cis*-[RuCl(py){κ⁴-(1*R*,2*R*)-PNNP}][BF_4] (**3**). The presence of the pyridine ligand was confirmed by FAB MS and ^1H NMR spectroscopic data. The $^{31}P\{^1H\}$ NMR spectrum of **3** exhibited two doublets at δ = 45.1 ($^2J_{P,P}$ = 29.5 Hz) and 46.7 ppm ($^2J_{P,P}$ = 29.5 Hz), suggesting two non-equivalent phosphorus atoms. The structure of **3** was ascertained by X-ray crystallography. A perspective drawing of the cation of **3** is shown in Figure 1. Selected bond lengths and angles are given in Table 1. The Ru atom adopts a distorted octahedral geometry with the chloro and pyridine ligands in a *cis* arrangement and the (1*R*,2*R*)-PNNP ligand behaving as a chelating tetradentate ligand. The chloro ligand is *trans* to the imino group N(1), whereas the pyridine group is

trans to the diphenylphosphanyl group P(2). The Ru−P, Ru−Cl and Ru−N distances are in the ranges expected for similar (diamino- and diaminodiphosphane)ruthenium complexes.[1,8,11−13] The relatively short Ru(1)−N(1) bond [2.0436(19) Å] is a reflection of the *trans* influence. The difference between Ru(1)−N(2) [2.1251(17) Å] and Ru(1)−N(3) [2.1799(17) Å] may be attributed to the chelating effect of the tetradentate diiminodiphosphane ligand. The N(1)−C(19) [1.283(3) Å] and N(2)−C(26) [1.260(3) Å] distances fall in the normal range observed for carbon−nitrogen double bonds.[11,12]

When **2** was heated under reflux in pyridine one of the two amino moieties (−CH_2−NH−) of the tetradentate diaminodiphosphane ligand was oxidized to an imino moiety

(−CH=N−) with concomitant displacement of the coordinated CH_3CN by pyridine to give *cis*-[RuCl(py){κ⁴-(1*R*,2*R*)-P(NH)NP}][BF_4] (**4**), whose structure was established by X-ray crystallography. A perspective drawing of the cation of **4** is shown in Figure 2 and selected bond lengths and bond angles are listed in Table 1. Structural analysis revealed that the κ⁴-(1*R*,2*R*)-P(NH)(NH)P ligand had been oxidized to a κ⁴-(1*R*,2*R*)-P(NH)NP ligand with the amino group *trans* to the chloride ion oxidized to an imino group. The N(1)−C(19) and N(2)−C(31) distances [1.296(6) and 1.480(6) Å] lie in the normal ranges observed for carbon−nitrogen double and single bonds, respectively. The Ru atom adopts a slightly distorted octahedral geometry with a *cis* arrangement of the chloro and pyridine ligands. The Ru−P, Ru−Cl and Ru−N distances are similar to those of **3**. The Ru−P bond [Ru(1)−P(1) 2.2835(11) Å] *trans* to the amino group N(2) is shorter than that [Ru(1)−P(2) 2.3133(11) Å] *trans* to the pyridine group N(3) due to the *trans* influence. The difference in Ru−N distances [Ru−N(1) 2.022(4) Å vs. Ru(1)−N(2) 2.162(3) Å] implies that the imino nitrogen atom, N(1), is more tightly bound to the Ru centre than the amino nitrogen atom, N(2), presumably due to dπ−pπ back donation to the imino group. The N(1)−Ru(1)−Cl(1) angle of 172.67(10)° indicates that the chloro ligand is *trans* to the imino nitrogen atom. This configuration is favoured over the alternative with *trans*-Cl−Ru−N(amine) as an imino nitrogen atom is a better π-acceptor than an amino nitrogen atom. The solid-state structure of **4** is consistent with its $^{31}P\{^1H\}$ and ^1H NMR, IR and FAB MS data. The $^{31}P\{^1H\}$ NMR spectrum shows two doublets at δ = 42.7 ($^2J_{P,P}$ = 28.8 Hz) and 52.7 ppm ($^2J_{P,P}$ = 28.8 Hz), which can be assigned to P(1) and P(2), respectively (Figure 2). The presence of the imino group is further supported by the ^1H NMR spectrum, which shows a broad singlet at δ = 9.42 ppm for the −C*H*=N− proton. The IR spectrum also shows the *ν*(C=N) absorption at 1657 cm^{-1}. Oxidation of the coordinated amino moiety to a coordinated imino moiety has been reported recently for related (diaminodiphosphane)ruthenium complexes. At room temperature, *trans*-[$RuCl_2${κ³-(1*R*,2*R*)-P(NH)(NH)P}(PPh_3)] was slowly oxidized by air to *trans*-[$RuCl_2${κ³-(1*R*,2*R*)-P(NH)NP}(PPh_3)],[11] and *trans*-[$RuCl_2${κ³-P(NH)(NH)P(O)}(PPh_3)] by H_2O_2 to *trans*-[$RuCl_2${κ³-P(NH)NP(O)}(PPh_3)].[12] In both cases one of the two coordinated amino moieties was oxidized to a coordinated imino moiety.

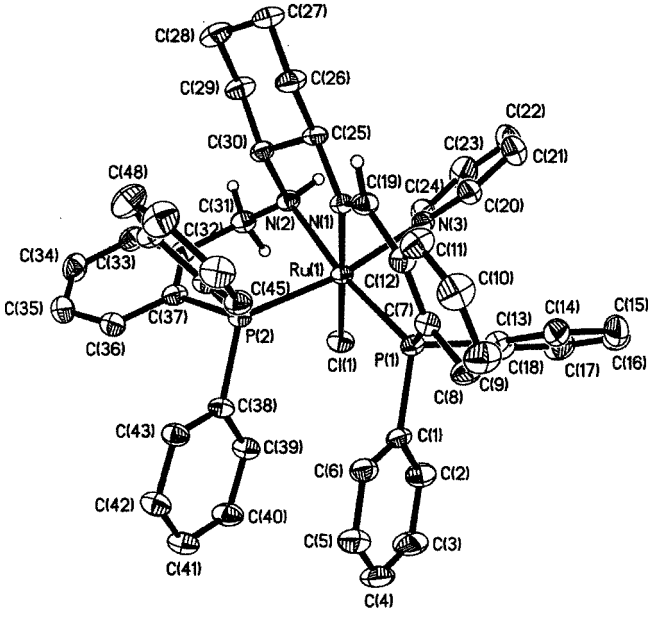

Figure 2. A perspective drawing of the cation of **4**, with the atoms shown at the 30% probability level; hydrogen atoms of the cyclohexyl, pyridine and phenyl rings are omitted for clarity

Catalytic Oxidation

Ruthenium-catalysed oxidation of alkenes with various oxidants has drawn considerable interest recently, but there are very few studies on aerobic oxidation.[11,12,14,15] In this work, air was chosen as one of the oxidants. Furthermore, complexes **1**−**4** were employed as the catalysts for the asymmetric oxidation of olefins. Styrene, the first substrate we used, gave three main products, namely styrene oxide, benzaldehyde and phenylacetaldehyde (Table 2). Nevertheless, with **4** as the catalyst, styrene was converted into styrene oxide with exceptionally high selectivity (80%). Presumably, epoxidation prevails over the oxidative cleavage of the C=C double bond. In addition, the enantioselectivity of all these catalytic epoxidation reactions is comparatively low. However, the highest TOF (733 h^{-1}) and the highest enantiomeric excess (*ee*) (24%) were obtained with **2**. Therefore, complex **2** was chosen to study the catalytic asymmetric oxidation of various olefins with air (Table 3). Although conversions of sterically crowded *cis*- and *trans*-stilbene were expected, and found, to be very low, those of α-methylstyrene and 1,2-dihydronaphthalene were as good as that of styrene. It is noteworthy that the catalytic oxidation of α-methylstyrene and 1,2-dihydronaphthalene with air using **2** selectively gave acetophenone and 1,2-dihydronaphthalene epoxide, respectively. Unfortunately, only a moderate *ee* was obtained from α-methylstyrene, which is attributed to the formation of a planar intermediate. In addition, the dependence of the asymmetric oxidation of styrene using **2** on various oxidants was investigated (Table 4). *tert*-Butyl hydroperoxide (TBHP) clearly gave the highest TOF and the highest selectivity for styrene oxide but only with poor enantioselectivity. The catalytic oxidation probably proceeds via a planar species, without the involvement of a chiral metal centre as an active intermediate. Investigation on the mechanism of the autoxidation of olefins is in progress.

The catalytic activity of **2** towards the oxidation of organic substrates with TBHP has also been studied (Table 5). In control experiments, no oxidized product was detected in the absence of either **2** or TBHP. Complex **2** catalysed the oxidation of styrene (Entry 1), with TBHP giving styrene oxide as the major product along with benzylaldehyde, possibly by C=C cleavage, and phenylacetaldehyde; α-methylstyrene (Entry 2) mainly afforded phenylacetalde-

hyde. Notably, *cis*- and *trans*-stilbene (Entries 3 and 4) were selectively oxidized to 2,3-diphenyloxirane whereas oxidation of 1,2-dihydronaphthalene (Entry 5) gave only naphthalene; we believe that the formation of a highly conjugated system provides the necessary driving force for the conversion. It is interesting that the oxidation of *cis*-cyclooctene (Entry 6) and of norbornene (Entry 7) produced predominantly 9-oxabicyclo[6.1.0]nonane and 2,3-epoxynorbornane, respectively, whereas oxidation of cyclohexene (Entry 8) afforded 2-cyclohexen-1-one as the major product. The oxidation of cyclohexene (Entry 9) was notably suppressed when 2,6-di-*tert*-butyl-4-methylphenol was added to the reaction mixture, which suggests a substantial radical character in the active intermediate.[16] When the terminal oxidant was changed from TBHP to cumene hydroperoxide (CHP), the product profile (Entry 10) is dominated by cumene, acetophenone and 2-phenyl-2-propanol, which are presumably generated by β-scission of cumyloxy radicals. The oxidation of cyclohexene by TBHP might involve abstraction of the allylic hydrogen atom from the relatively flexible six-membered ring to give an allylic free radical intermediate that can be stabilized by the π-system of the double bond; this is unlikely to occur with *cis*-cyclooctene and norbornene due to inefficient allylic stabilisation in the more rigid and nonplanar norbornenyl and cyclooctenyl radicals. Conversely, the epoxidation of norbornene and *cis*-cyclooctene could result from the homolytic addition of the *t*BuOO$^{\cdot}$ species to the more strained double bond, followed by homolytic cyclisation.[17−20] The homolytic mechanism accords with the absence of epoxidation with cyclohexene, which is less prone to addition of peroxy radicals. Indeed, the predominance of peroxy substitution follows from the ease with which H-atom abstraction occurs from the allylic position of cyclohexene.

Moreover, complex **2** would also be an efficient catalyst for the oxidation of alcohol with TBHP. In the presence of 2 equiv. of TBHP in benzene, complex **2** catalysed the oxidation of primary alcohols (Entries 11 and 12, Table 5) to the corresponding acid and/or ester, of secondary alcohols (Entries 13 and 14) to the corresponding ketones, and of phenol (Entries 15 and 16) to *p*-benzoquinone. Minisci and co-workers have reported (porphyrin)Fe^{III}-catalysed oxidation of phenol to *p*-benzoquinone by TBHP by a free

radical mechanism.[21] They found that addition of a nitrogen-containing base such as pyridine enhanced the production of *p*-benzoquinone by catalyzing the decomposition of the alkylperoxy intermediate. We used a similar strategy to test the involvement of reactive free radical species during catalysis and found that the rate of *p*-benzoquinone formation was enhanced by the addition of triethylamine, which is consistent with the formation of a *tert*-butylperoxy intermediate.[21]

Furthermore, complex **2** can catalyse the oxidation of unactivated saturated C−H bonds with TBHP. Alkanes (Table 5, Entries 17, 18 and 21) were oxidized to their corresponding ketones, alcohols or a mixture of both. In the presence of 2 equiv. of TBHP and a catalytic amount of **2**, *n*-octane was oxidized to a mixture of 2-octanone and 4-octanone, cyclohexane to a mixture of cyclohexanol and cyclohexanone, and adamantane to adamantan-1-ol and 2-adamantone. The results revealed that oxidation of *n*-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

octane proceeded by secondary C−H bond activation exclusively with no detectable products from primary C−H bond activation, and that adamantane preferentially gave a tertiary alcohol. Presumably, alkane oxidation proceeded by an H-atom abstraction pathway to give a relatively stable free radical intermediate. This is supported by the formation of cyclohexyl chloride (Entry 19) along with cyclohexanone and cyclohexanol upon catalytic oxidation of cyclohexane by TBHP in the presence of CCl_4. Moreover, copious formation of cumene, acetophenone and 2-phenyl-2-propanol (Entry 20) from cumene hydroperoxide also implies an alkylperoxy radical as the transient intermediate.[22] A similar mechanism has been proposed for the ruthenium-catalysed oxidation of alkanes with TBHP.[23] Under similar conditions, *n*-propylbenzene (Entry 22) was oxidized to 1-phenyl-1-propanone, ethylbenzene (Entry 23) to acetophenone, diphenylmethane (Entry 24) to benzophenone, cumene (Entry 25) to a mixture of 2-phenyl-2-propanol and acetophenone, and 1,3-diisopropylbenzene (Entry 26) to 2,4-diisopropylphenol. It is obvious that the activity of arylalkanes towards oxidation by **2** is higher than those of nonarylalkanes and it is consistent with the relative stability of the radicals generated by H-atom abstraction, i.e. aryl-substituted radicals are more stable than unsubstituted radicals. Experimental evidence suggests that free radicals are probably involved in the catalytic oxidation of various organic substrates. In general, the oxidation of a series of organic substrates with TBHP by complex **2** involves a free radical mechanism.

Conclusion

We have described the synthesis, characterisation and structural studies of a series of new chiral cationic (diimino- and diaminodiphosphane)ruthenium complexes. Detailed investigations of their catalytic properties in the asymmetric oxidations of various organic molecules show that these chiral complexes effectively catalyse the epoxidation of a range of alkenes with air; the data are compared to those using other oxidants. Experimental evidence suggests that free radicals are probably involved in the catalytic oxidation processes associated with these chiral complexes.

Experimental Section

General Remarks: Unless otherwise stated, all experiments were conducted under dry nitrogen. Solvents were dried by standard procedures, distilled and deaerated before use. Reagent grade chemicals were used and, where appropriate, degassed before use. All organic substrates were purified by literature methods, and their purities verified by GC or ^{1}H NMR analysis. Melting points were taken in sealed capillaries and are uncorrected. The compounds *trans*-[$RuCl_2${κ^4-(1*R*,2*R*)-PNNP}][8] and *trans*-[$RuCl_2${κ^4-(1*R*,2*R*)-P(NH)(NH)P}][11] were prepared according to literature methods. IR spectra (KBr pellets) were recorded with a Nicolet Nagna-IR 550 spectrometer and NMR spectra with a JEOL EX270 spectrometer. Chemical shifts of ^{1}H NMR spectra were referenced to internal deuterated solvents and then recalculated to TMS (δ = 0.00 ppm) and those of ^{31}P{^{1}H} NMR spectra were referenced to external 85% H_3PO_4. Low-resolution mass spectra were obtained with Finnigan MAT SSQ-710 and MAT 95 spectrometers in positive FAB mode and are reported as *m*/*z*. Gas chromatograms were obtained with an HP 5890 GC system equipped with an FID detector or an HP 6890−5972 GC-MSD system. An HP 5890 GC equipped with a WCOT fused silica capillary column (25 × 0.25 mm, 0.25-μm film, Varian) was used for chiral analyses. Microanalyses were performed by the Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences. The progress of all reactions was monitored by ^{31}P{^{1}H} NMR spectroscopy.

***cis*-[RuCl(CH_3CN){κ^4-(1*R*,2*R*)-PNNP}][BF_4] (1):** A red solution of *trans*-[$RuCl_2${κ^4-(1*R*,2*R*)-PNNP}] (0.260 g, 0.313 mmol) in acetonitrile (10 mL) was added dropwise to a solution of $AgBF_4$ (0.062 g, 0.318 mmol) in acetonitrile (10 mL). The mixture was then stirred at ambient temperature for 24 h to give an orange solution with a white precipitate. The solution was filtered and the solvents evaporated to dryness. The resultant orange residue was redissolved in CH_2Cl_2 and filtered. Diethyl ether was added and the mixture was then cooled to 0 °C to give an orange solid that was filtered off, washed with diethyl ether and *n*-hexane, and dried in vacuo. Yield: 0.220 g, 76%; m.p. 180−182 °C (dec). IR (KBr): $\tilde{\nu}$ = 3059 s, 2932 m, 2858 m, 1964 m, 1642 s, 1434 s, 1085 br, 749 s, 702 s, 527 s cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 1.20−2.31 (m, 8 H, CH_2CH_2), 2.53 (s, 3 H, CH_3CN), 3.71 (m, 2 H, NC*H*−C*H*N), 6.37−7.76 (m, 28 H, aryl *H*), 8.77 (d, $^3J_{P-H}$ = 10.0 Hz, 1 H, −C*H*=N−), 8.97 (d, $^3J_{P-H}$ = 8.6 Hz, 1 H, −C*H*=N−) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 44.0 (d, $^2J_{P,P}$ = 24.3 Hz), 49.8 (d, $^2J_{P,P}$ = 24.3 Hz) ppm. FAB MS: *m*/*z* = 836 [M − BF_4]$^+$, 795 [M − CH_3CN − BF_4]$^+$. $C_{46}H_{43}BClF_4N_3P_2Ru\cdot1.5CH_2Cl_2\cdot H_2O$ (1068.56): calcd. C 53.38, H 4.54, N 3.93; found C 53.01; H 4.62; N 4.11. $[\alpha]_D^{20}$ = −91.56 (*c* = 0.5, CH_2Cl_2).

***cis*-[RuCl(CH_3CN){κ^4-(1*R*,2*R*)-P(NH)(NH)P}][BF_4] (2):** *trans*-[$RuCl_2${κ^4-(1*R*,2*R*)-P(NH)(NH)P}] (0.400 g, 0.480 mmol) and $AgBF_4$ (0.100 g, 0.513 mmol) were dissolved in acetonitrile (40 mL) and the mixture stirred at ambient temperature for 24 h. A yellow solution with a white precipitate was obtained. The solution was filtered and the solvents evaporated to dryness in vacuo. The resultant yellow residue was then redissolved in CH_2Cl_2 and *n*-hexane was added to initiate the crystallisation of the product as a yellow solid. Yield: 0.400 g, 90%; m.p. 189−190 °C (dec). IR (KBr): $\tilde{\nu}$ = 3431 s, 3053 m, 2934 m, 1963 m, 1476 m, 1439 s, 1077 vs, 746 s, 700 s, 519 s cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 1.58−2.04 (m, 8 H, CH_2CH_2), 2.62 (s, 3 H, CH_3CN), 2.81−3.01 (m, 4 H, CH_2N), 3.65 (m, 2 H, NC*H*−C*H*N), 4.21 (m, 2 H, N*H*), 6.71−8.00 (m, 28 H, aryl *H*) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 37.3 (d, $^2J_{P,P}$ = 24.5 Hz), 44.1 (d, $^2J_{P,P}$ = 24.5 Hz) ppm. FAB MS: *m*/*z* = 840 [M − BF_4]$^+$, 799 [M − CH_3CN − BF_4]$^+$. $C_{46}H_{47}BClF_4N_3P_2Ru\cdot CH_2Cl_2\cdot 2H_2O$ (1048.14): calcd. General Procedure for Catalytic Oxidation by Air: A reaction mixture of organic substrate (3.0 g) and catalyst (0.001 mmol) was stirred in open air at 80 °C for 16 h. The resultant solution was analysed by GC, and the identity of the analytes verified by GC-MS and standard compounds (Tables 2 and 3). Control experiments were performed in the absence of catalyst under identical conditions.

General Procedure for Catalytic Oxidation by TBHP: A solution of organic substrate (1.5 mmol), TBHP (80% in di-*tert*-butyl peroxide, 3.2 mmol) and **2** (1.0 mg, 0.001 mmol) in benzene (3 mL) was stirred under nitrogen at ambient temperature for 16 h. The reaction mixture was then poured slowly into a 10% aqueous Na_2SO_3 solution (5 mL) to destroy any remaining TBHP and the resultant solution was extracted with dichloromethane (2 × 5 mL). The organic layer was separated, dried with anhydrous Na_2SO_4 and analysed by GC (Tables 4 and 5). The identity of the analytes was verified by GC-MS and standard compounds. Control experiments without either the catalyst or TBHP were performed under identical conditions.

General Procedure for Catalytic Oxidation by H_2O_2: Styrene (0.16 g, 1.5 mmol) and **2** (2.0 mg, 0.002 mmol) were dissolved in acetone (3 mL). Aqueous hydrogen peroxide [0.29 g, 35% (w/w), 3.0 mmol] was then added as one portion and the reaction mixture was stirred under nitrogen at ambient temperature for 16 h, and then slowly poured into a 10% aqueous Na_2SO_3 solution (5 mL) to destroy any remaining H_2O_2. The resultant solution was extracted with dichloromethane (2 × 5 mL) and the organic layer was separated, dried with anhydrous Na_2SO_4 and analysed by GC (Table 4). Control experiments without either the catalyst or H_2O_2 were performed under identical conditions.

General Procedure for Catalytic Oxidation by $NaIO_4$: Styrene (0.16 g, 1.5 mmol) and **2** (2.0 mg, 0.002 mmol) were dissolved in acetone (3 mL). $NaIO_4$ (0.64 g, 3.0 mmol) was then added as one portion and the reaction mixture was stirred under nitrogen at ambient temperature for 16 h. The resultant solution was analysed by GC (Table 4). Control experiments in the absence of either the catalyst or $NaIO_4$ were performed under identical conditions.

General Procedure for Catalytic Oxidation by NaOCl: Styrene (0.16 g, 1.5 mmol) and **2** (2.0 mg, 0.002 mmol) were dissolved in acetone (3 mL). An excess of aqueous NaOCl was added as one portion and the reaction mixture was stirred under nitrogen at ambient temperature for 16 h. The resultant solution was analysed by GC (Table 4). Control experiments in the absence of either the catalyst or NaOCl were performed under identical conditions.

were grown by slow concentration of solutions of **3** and **4** in CH_2Cl_2/*n*-hexane. The crystals were wrapped in epoxy glue, to prevent solvent loss, and mounted on a thin glass fibre. No decay in intensity was encountered during the data collection. Intensity data were collected at 293 K with a Bruker Axs SMART 1000 CCD area-detector diffractometer using graphite-monochromated Mo-K_α radiation. The collected frames were processed with the software SAINT[24] and an absorption correction was applied (SADABS)[25] to the collected reflections. The structures were solved by direct methods (SHELXTL™)[26] and refined against F^2 by full-matrix least-squares analysis. All non-hydrogen atoms were refined anisotropically. Except for the hydrogen atoms of the solvent molecules in **3** and **4**, which were not located, all other hydrogen atoms were generated in their idealised positions and allowed to ride on their respective parent carbon atoms. CCDC-204329 and -204330 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The Preparation and Study of Bis(2-quinolyl) and Bis(2-[1,8]naphthyridyl) Derivatives of Pyrimidine and Pyrazine as Bridging Ligands for Ru^{II}

Darren Brown,[a] Seema Muranjan,[a] and Randolph P. Thummel*[a]

Keywords: Bridging ligands / Ruthenium / N ligands

The 2:1 Friedländer condensation of 2-aminobenzaldehyde or 2-aminonicotinaldehyde with either 4,6-diacetylpyrimidine or 2,5-diacetylpyrazine leads to a family of four new bis(bidentate) bridging ligands. Subsequent complexation of these ligands with $[RuCl_2(bpy)_2]$ (bpy = 2,2′-bipyridine) leads to the corresponding mononuclear and dinuclear mixed-ligand Ru^{II} complexes. Analysis of the ^1H NMR spectra of these systems affords some insight into their conformational properties. Electronic spectra of the complexes evidence two long-wavelength absorption bands which correspond to typical metal-to-ligand charge transfer states. The energies of these states may be explained by electronegativities of the pendant rings on the bridging ligand as well as the substitution pattern on the central ring. For the dinuclear complexes the lowest energy absorption shows components associated with coordination to the pendant and the central rings. The appearance of two metal-based oxidations gives good evidence for strong intermetalic interaction and Koopman's theorem is obeyed for all systems.

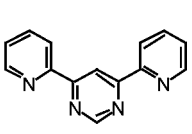
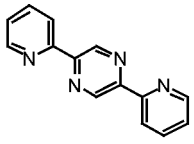
Introduction

One recurrent theme in the burgeoning field of supramolecular chemistry is the construction of organized assemblies through the judicious juxtaposition of appropriate ligands and metals. These systems take advantage of complementarity effects in the ligands as well as the principle of maximum occupation of sites to allow for the formation of a wide variety of multimetallic networks having interesting and often useful shapes. The bridging ligands used for this construction often have two equivalent bidentate chelating sites which allow the formation of linear assemblies as well as multidirectional dendritic structures.[1] Two such building blocks which have found considerable utility are 4,6-bis(2′-pyridyl)pyrimidine (**1**)[2] and 2,5-bis(2′-pyridyl)pyrazine (**2**).[3] Tris(complexation) of either ligand around a single Ru^{II} center leaves three equivalent bidentate sites available for further elaboration. If these sites are occupied by $[Ru(L)_2]^{2+}$ fragments where L = **1** or **2**, further branching is possible and polynuclear dendritic structures result. One reason for the strong interest in such systems is their potential to act as antennae where metal-based chromophores on the periphery could gather light energy and funnel it to a central, often different, metallic core.



1



2

There are several problems associated with these multimetallic dendritic systems. Firstly, the asymmetric chelating sites of the bridging ligands lead to metal-based stereocenters, Δ or Λ, so that the number of stereoisomers increases with the number of metal atoms in the system. The problems associated with separating and evaluating individual stereoisomers have been largely ignored since the photochemical properties of these very similar stereoisomers does not appear to differ substantially.[4] Nevertheless, impressive progress has been made in the construction of stereochemically discrete systems.[5] The other issue of concern is the directionality of energy or electron transfer. Photoexcitation of such dendritic systems often involves a metal-to-ligand charge transfer (MLCT) state in which the photoexcited electron is promoted from the metal atom to the most electronegative ligand.[6] Although **1** and **2** are more electronegative than 2,2′-bipyridine (bpy), their π*-states are not that much lower than that of bpy and it occurred to us that more electronegative analogues of these ligands might enhance the directionality of energy transfer.

In earlier work we have used the Friedländer condensation of 8-aminoquinoline-7-carbaldehyde with diacetyl derivatives of pyrimidine and pyrazine to afford bis([1,10]-phenanthrolinyl)diazines and we have examined the be-

[a] Department of Chemistry, 136 Fleming Building, University of Houston,
Houston, Texas 77204-5003, USA

havior of these ligands as bis(tridentate) chelators.[7] In this work we will utilize a similar Friedländer approach to prepare the 2-quinolyl and 2-[1,8]naphthyridyl derivatives of these same diazines (**3**−**6**) and examine the properties of their mono- and dinuclear Ru^{II} complexes.

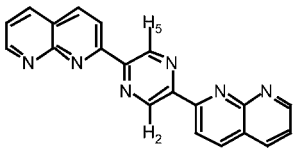
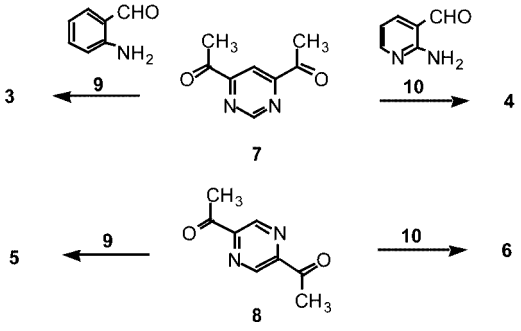
5



6

Results and Discussion

The ligands were synthesized by a Friedländer reaction[8] between 2 equiv. of 2-aminobenzaldehyde (**9**) or 2-aminonicotinaldehyde (**10**) and either 4,6-diacetylpyrimidine (**7**)[9] or 2,5-diacetylpyrazine (**8**).[10] The reactions proceed smoothly in refluxing ethanol to provide the ligands **3**−**6** in yields of 40−98%. The ligands were characterized by their ^1H NMR spectra which were readily assigned due to high symmetry. The quinoline and naphthyridine rings give characteristic and similar patterns with little variation between the pyrimidine and pyrazine systems. The central pyrimidine ring shows two singlets with 2-H appearing at δ = 9.48−9.51 ppm. The singlet of 5-H (being closer to the substituent rings) shows more variation appearing at δ = 9.78 ppm for the quinoline and at δ = 10.09 ppm for the naphthyridine derivatives. The central pyrazine ring shows only one singlet at δ = 9.95 ppm for **5** and at δ = 10.51 ppm for the more deshielded **6**.



Ru^{II} complexes were prepared by treating the ligands **3**−**6** with either 1 or 2 equiv. of $[Ru(bpy)_2Cl_2]$ in refluxing aqueous ethanol. The complexes were precipitated as their hexafluorophosphate salts and purified by chromatography on alumina (CH_3CN/toluene) or silica gel (CH_3CN/H_2O/satd. KNO_3, 5:4:1). Due to stereochemical complexities, only the ^1H singlets on the central diazine ring of the complexes could be confidently assigned.

The mononuclear complexes of **3** and **4** display two singlets, δ = 8.45 (2-H) and 9.81 (5-H) for **3** and δ = 8.63 (2-H) and 9.86 (5-H) for **4**. The coordination of $[Ru(bpy)_2]^{2+}$ disrupts the symmetry of **5** and **6** so that their mononuclear complexes also exhibit two singlets, δ = 8.86 (2-H) and 9.86 (5-H) for **5** and δ = 9.09 (2-H) and 9.93 (5-H) for **6.**

The dinuclear complexes of **3**−**6** possess two chiral octahedral centers and therefore exist as both *rac* (ΔΔ and ΛΛ) and *meso* (ΔΛ) diastereomers (Figure 1). The existence of two diastereomers, each having 22−24 unique protons, gives rise to rather complex ^1H NMR spectra. However, the protons on the central rings appear as singlets making them easier to identify and assign. For the dinuclear complex of **3**, two singlets are observed at δ = 7.53 and 9.54 ppm, which can be assigned, respectively, to 2-H and 5-H of the major diastereomer. The singlet assigned to 2-H is shifted upfield with respect to the mononuclear complex because this proton is now shielded by two pyridine rings. We assign the singlet at δ = 9.63 to 5-H of the minor diastereomer and thus integration of the two 5-H signals gives a diastereomeric ratio of 7:3. The dinuclear complex of **4** also shows two singlets at δ = 7.91 and 9.67 ppm which are assigned to 2-H and 5-H, respectively, of the major diastereomer. The two singlets at δ = 7.84 and 9.72 ppm are assigned to the minor diastereomer and a diastereomeric ratio of 4:1 was determined. For the dinuclear complexes involving pyrazine ligands **5** and **6**, 2-H and 5-H are equivalent so that only one singlet is observed for these protons, appearing at δ = 8.47 and 8.53 ppm for the major and minor diastereomers of $[(bpy)_2Ru(\mathbf{5})Ru(bpy)_2]^{4+}$ and at δ = 8.66 and 8.73 ppm for the major and minor diastereomers of $[(bpy)_2Ru(\mathbf{6})Ru(bpy)_2]^{4+}$. Due to the complexity of the spectra, clear diastereomeric ratios could not be determined.

The electronic absorption and luminescence spectra of the ligands **3**−**6** and their Ru^{II} complexes were determined in acetonitrile solution and the data are collected in Table 1. The ligands show low energy absorption bands in the range of 316−355 nm and several interesting correlations can be made involving the energies of these absorptions and structure. First, the ligands involving naphthyridine, **4** and **6**, absorb at longer wavelengths (324 and 355 nm) than their quinoline counterparts (316 and 340 nm) which agrees with increased electronegativity due to two additional nitrogen atoms. However, for the two isomeric quinoline systems, the one involving a central pyrazine ring (**5**) absorbs at 24 nm longer wavelength than the one involving a central pyrimidine ring (**3**). For the two isomeric naphthyridine systems the difference is 31 nm. This difference can be explained by considering the planar conformations available to the ligands. From a chelation point of view it is convenient to view them in their *syn*,*syn* conformation. However, this conformation involves unfavorable N−N lone pair interactions as well as some H−H congestion which can be relieved in the *anti*,*anti* conformation. For **3** and **4** the *anti*,*anti* form provides a less extended structure while for the pyrazine

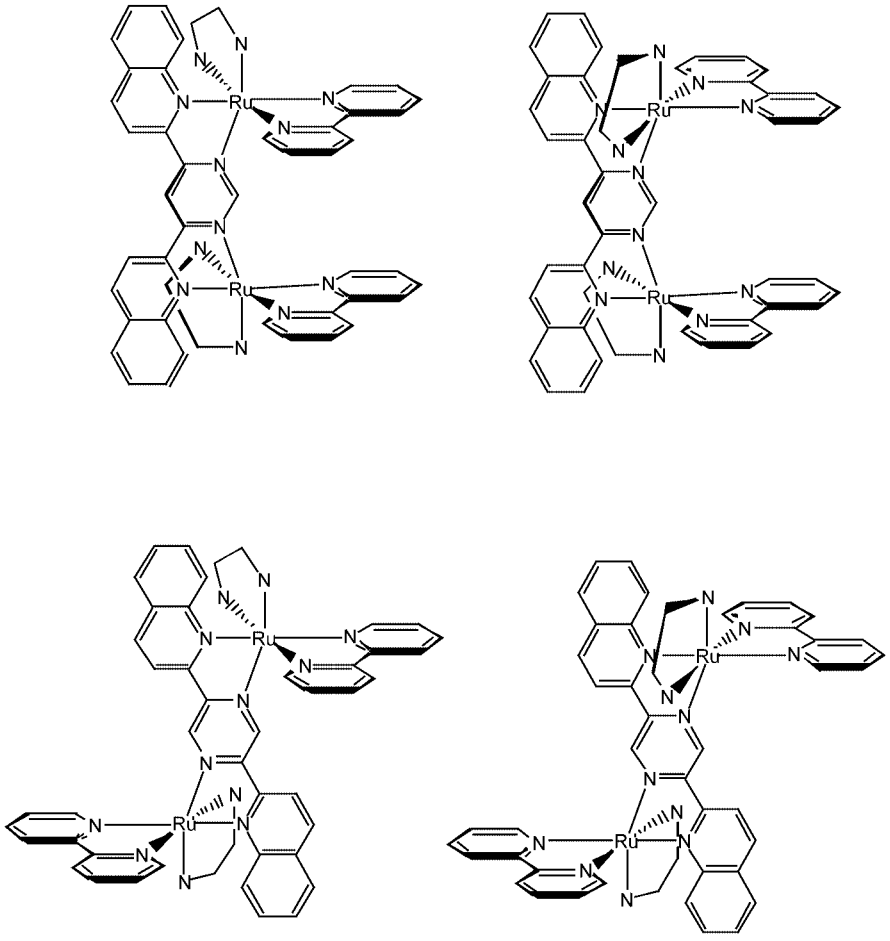

Figure 1. Stereochemical representation of the diastereomeric forms of $[(bpy)_2Ru(\mathbf{3})Ru(bpy)_2]^{4+}$ (top) and $[(bpy)_2Ru(\mathbf{5})Ru(bpy)_2]^{4+}$ (bottom)

systems **5** and **6** both conformations have a similar longitudinal arrangement, explaining the lower energy absorption. It is intriguing to speculate that a bulky C-2 substituent on either **3** or **4** would inhibit the normal bidentate coordination and one might expect to see some cyclometalation through the potential tridentate *anti*,*anti* conformation.

Table 1. Photophysical data for free ligands

Ligand	Absorption[a] λ_{max} [nm] (ε [$M^{-1}cm^{-1}$])	Emission[a] λ_{em} [nm] (rel. int.)
3	316 (24934), 250 (58052), 206 (53344)	406 (m)
4	324 (26776), 231 (43578)	430 (m)
5	340 (28140), 262 (26964), 207 (41490)	435 (s)
6	355 (27946), 253 (18544)	440 (m)

[a] 5×10^{-5} M in CH_3CN at 25 °C; s = strong, m = medium.

The absorption properties of the mononuclear complexes $[Ru(\mathbf{3}-\mathbf{6})(bpy)_2]^{2+}$ are well behaved and consistent with structure. Each complex shows two long-wavelength absorption bands which are associated with a metal-to-ligand charge transfer (MLCT) wherein a photoexcited electron is promoted from a metal d-orbital to the π*-orbital of a ligand (Figures 2 and 3). The longer wavelength band in the region of 510−559 nm correlates with MLCT to the more electronegative bridging ligand while the shorter wavelength band, in the much narrower range of 427−431 nm, correlates with MLCT to the auxiliary bpy ligand. The more

electronegative naphthyridine ligands have lower energy π*-states and thus absorb at lower energy with a difference from the corresponding quinoline ligands of 32 nm when the central ring is pyrimidine and 33 nm when the central ring is pyrazine.

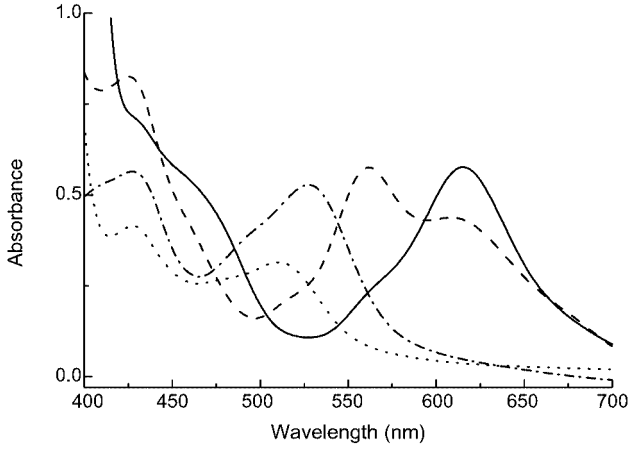

Figure 2. Long-wavelength portion of the electronic absorption spectra of the quinoline-containing systems $[Ru(\mathbf{3})(bpy)_2]^{2+}$ (dash-dot), $[Ru(\mathbf{5})(bpy)_2]^{2+}$ (dot), $[(bpy)_2Ru(\mathbf{3})Ru(bpy)_2]^{4+}$ (dash), and $[(bpy)_2Ru(\mathbf{5})Ru(bpy)_2]^{4+}$ (solid)

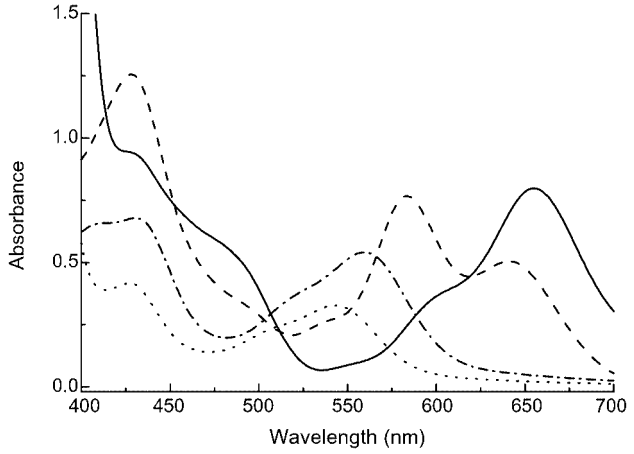

Figure 3. Long-wavelength portion of the electronic absorption spectra of the 1,8-naphthyridine-containing systems $[Ru(\mathbf{4})(bpy)_2]^{2+}$ (dash-dot), $[Ru(\mathbf{6})(bpy)_2]^{2+}$ (dot), $[(bpy)_2Ru(\mathbf{4})Ru(bpy)_2]^{4+}$ (dash), and $[(bpy)_2Ru(\mathbf{6})Ru(bpy)_2]^{4+}$ (solid)

It is especially interesting that the MLCT bands for the pyrimidine and pyrazine systems are reversed in energy when compared to the free ligands, with the pyrimidine complexes showing lower energy absorptions. The conformational effects cited for the free ligands are less important for the complexes. Rather the pendant, uncomplexed quinoline or naphthyridine may be considered as a substituent on the diazine portion of the bidentate chelator. For the pyrimidine systems this substituent is located in the 4-position where it will have a stronger resonance interaction with the coordinated metal atom. For the pyrazine systems, the substituent is in the 3-position and the delocalizing effect is weaker.

The absorption properties of the dinuclear complexes $[(bpy)_2Ru(\mathbf{3}-\mathbf{6})Ru(bpy)_2]^{4+}$ are somewhat unusual. Once again, there are long- and short-wavelength components to the MLCT absorption bands. All four systems show bands at 425−428 nm which correspond to charge transfer to the less electronegative bpy ligands. However, the long-wavelength component consists of two bands. For the naphthyridine systems these bands appear at longer wavelengths than for the quinoline systems. Charge transfer to the bridging ligands may involve either the pendant quinoline or naphthyridine moiety as the receptor or the central diazine ring as the receptor with the latter species being lower in energy. Thus, we observe that the long-wavelength contribution is more intense for the pyrazine systems where the *para* disposition of the metal centers on the pyrazine ring provides better communication and consequent delocalization than for the *meta*-substituted pyrimidine rings where charge transfer to the pendant groups is preferred.

The luminescence properties of the complexes were measured at room temperature in acetonitrile solution. As expected, the mononuclear complexes showed modest emission while the dinuclear complexes were less intense and completely quenched in the cases of $[(bpy)_2Ru(\mathbf{4}, \mathbf{6})Ru(bpy)_2]^{4+}$.

The half-wave redox potentials of the complexes were measured in acetonitrile and the data are collected in Table 2. For systems of this type, oxidations are typically associated with the removal of an electron from a metal d-orbital while reduction involves the addition of an electron to the π*-orbital of a coordinated ligand. In this regard the mononuclear complexes are well behaved. Metal-based $Ru^{II,III}$ oxidation occurs at +1.34−1.46 V. Pyrimidine is more basic than pyrazine and thus better able to stabilize a positive charge, which explains the lower oxidation potential of the complexes of **3** and **4**. Three reduction waves are observed for the mononuclear complexes, which can be associated with the addition of an electron to the π*-orbital of each of the three ligands around the metal atom. The first reduction for each system involves the ligands **3**−**6** and is more positive for the more electronegative ligands containing the naphthyridine ring. Plotting the lowest energy absorptions against the energy gap between the frontier redox couples gives a good linear relationship with a slope of 0.75 and a correlation coefficient of 0.9952 demonstrating good agreement with Koopman's theorem.

The dinuclear complexes show strong interaction between the two complexed metal centers as evidenced by two well-separated oxidation waves. Analogous with the mononuclear complexes, the naphthyridine-containing systems oxidize more readily, at less positive potentials, than the quinoline-containing systems. The separation between the two oxidations is greater for the pyrazines (+0.23 V) than for the pyrimidines (+0.14 to +0.15 V). Comproportionation constants may be calculated for all four complexes and fall in the range of 230−7730, in good agreement with previously reported systems involving **1** and **2**.[11]

$[(bpy)_2Ru(\mathbf{6})Ru(bpy)_2]^{4+}$	615 (14016), 573 (5702), 457 (11098), 428 (14276)	no emission	+1.34, +1.57	−0.31, −0.67, −1.49

[a] Solutions were 0.1 M TBAP in CH_3CN; the sweep rate was 200 mV/s. [b] 5×10^{-5} M in CH_3CN at 25 °C; m = medium, w = weak.

The dinuclear complexes exhibit 3−4 reduction waves with the first reductions falling in the range of −0.30 to −0.36 V and the second reductions in the range of −0.67 to −0.83 V. Both of these reductions are associated with the bridging ligand while the third reduction at −1.43 to −1.49 V is associated with one of the bpy ligands. The bridging ligand reductions are consistent with structure in that the naphthyridine-containing ligands reduce more readily than the quinoline containing ones.

Summary

Four bis(bidenate) bridging ligands have been prepared containing a central pyrimidine or pyrazine ring symmetrically substituted with either two 2-quinolyl or two 2-[1,8]naphthyridyl moieties. Mixed-ligand complexes of these ligands have been prepared by incorporating either one or two $[Ru(bpy)_2]^{2+}$ centers into the available bidentate sites. The resulting complexes possess one stereocenter at each metal atom resulting in an inseparable mixture of diastereomers for the dinuclear systems as evidenced by characteristic ^1H NMR singlets for protons on the central diazine ring. MLCT absorptions are observed for charge transfer to the bridging ligand in the range of 510−559 nm for the mononuclear complexes. For the dinuclear complexes this band splits into two components, at 562−612 and 613−655 nm, which are tentatively associated with the central and pendant rings on the bridging ligand. Charge transfer to the auxiliary bpy remains fairly constant for all complexes in the range of 425−431 nm. Clear splitting of the metal-based oxidation potential indicates interaction between two bound metal atoms with the pyrazine system showing the stronger coupling. Reduction potentials correlate well with electronegativities of the bridging ligand.

Experimental Section

General: Nuclear magnetic resonance spectra were recorded at 300 MHz for ^1H and at 75 MHz for $^{13}C\{^1H\}$ referenced to TMS in $CDCl_3$ and to the solvent peak in all other solvents (CD_3CN). Electronic spectra were obtained with a Perkin−Elmer Lambda 3B spectrophotometer. Emission spectra were obtained with a Perkin−Elmer LS-50 luminescence spectrometer. Cyclic voltammetry (CV) was carried out in a conventional three-electrode cell with a BAS-27 voltammeter and a Houston Instruments model 100 X-Y recorder according to a previously described procedure.[12] Mass spectra were obtained with an Applied Biosystems Voyager System 4160 MALDI-TOF spectrometer. Melting points were measured with a Hoover capillary melting point apparatus and are not corrected. Elemental analyses were performed by Quantitative Technologies Inc., P. O. Box 470, Whitehouse, NJ 08888, USA. 2,5-Diacetylpyrazine,[10] 4,6-diacetylpyrimidine,[9] 2-aminobenzaldehyde,[13] 2-aminonicotinaldehyde,[14] and $[Ru(bpy)_2Cl_2]$[15] were prepared according to published procedures.

4,6-Bis(2′-quinolinyl)pyrimidine (3): 50% ethanolic KOH (2 mL) was added to a stirred solution of 4,6-diacetylpyrimidine (50 mg, 0.30 mmol) and 2-aminobenzaldehyde (73 mg, 0.60 mmol) in EtOH (10 mL). The solution was allowed to reflux overnight. After cooling to room temperature, the precipitate was filtered and rinsed with EtOH. The product was purified by chromatography (silica gel, hexanes/EtOAc, 1:1) to give **3** (91 mg, 91%) as a white solid; m.p. 230−233 °C. ^1H NMR ($CDCl_3$): δ = 9.80 (s, 1 H), 9.49 (s, 1 H), 8.66 (d, J = 8.7 Hz, 2 H), 8.37 (d, J = 8.7 Hz, 2 H), 8.36 (d, J = 8.4 Hz, 2 H), 7.92 (d, J = 8.1 Hz, 2 H), 7.82 (t, J = 7.2 Hz, 2 H), 7.63 (t, J = 7.2 Hz, 2 H). ^{13}C NMR ($CDCl_3$): δ = 164.1, 158.6, 154.1, 148.1, 137.1, 130.3, 129.9, 128.9, 127.64, 127.61, 118.9, 115.0. MS: m/z = 334 [M^+]. $C_{22}H_{14}N_4 \cdot 0.5H_2O$ (343): calcd. C 76.97, H 4.37, N 16.32; found C 76.58, H 3.71, N 16.16.

4,6-Bis(2′-[1′,8′]naphthyridyl)pyrimidine (4): 50% ethanolic KOH (2 mL) was added to a stirred solution of 4,6-diacetylpyrimidine (100 mg, 0.61 mmol) and 2-aminonicotinaldehyde (164 mg, 1.34 mmol) in EtOH (10 mL). The solution was allowed to reflux overnight. After cooling to room temperature, the solvent was evaporated and the resulting solids were dissolved in $CHCl_3$ (50 mL). The organic phase was washed with water (50 mL), and brine (50 mL), dried ($MgSO_4$) and concentrated. The solid residue was purified by washing with cold EtOH until the washings ran clear to give **4** (84 mg, 41%) as a gray solid; m.p. > 280 °C. ^1H NMR ($CDCl_3$): δ = 10.07 (s, 1 H), 9.51 (s, 1 H), 9.24 (dd, J = 4.2, 1.8 Hz, 2 H), 8.78 (d, J = 8.4 Hz, 2 H), 8.42 (d, J = 8.7 Hz, 2 H), 8.22 (dd, J = 8.1, 1.8 Hz, 2 H), 7.57 (dd, J = 8.1, 4.2 Hz, 2 H). ^{13}C NMR ($CDCl_3$): δ = 163.8, 158.4, 157.1, 155.4, 154.2, 138.5, 137.2,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

123.7, 123.0, 120.1, 116.5. MS: m/z = 336 [M^+]. $C_{20}H_{12}N_6 \cdot 0.5H_2O$ (345): calcd. C 69.57, H 3.77, N 24.34; found C 69.59, H 3.26, N 24.39.

2,5-Bis(2′-quinolinyl)pyrazine (5): 50% ethanolic KOH (2 mL) was added to a stirred solution of 2,5-diacetylpyrazine (100 mg, 0.61 mmol) and 2-aminobenzaldehyde (155 mg, 1.27 mmol) in EtOH (20 mL). The solution was allowed to reflux overnight. After cooling to room temperature, the precipitate was filtered and rinsed with EtOH. The solid product was recrystallized from EtOH to give **5** (81 mg, 40%) as a light brown solid; m.p. 262−264 °C. ^{1}H NMR ($CDCl_3$): δ = 10.03 (s, 2 H), 8.64 (d, J = 8.7 Hz, 2 H), 8.2−8.5 (m, 4 H), 7.91 (d, J = 8.1 Hz, 2 H), 7.82 (t, J = 8.1 Hz, 2 H), 7.63 (t, J = 7.5 Hz, 2 H). ^{13}C NMR ($CDCl_3$): δ = 152.9, 149.3, 146.3, 142.0, 136.6, 129.3, 128.5, 127.5, 126.7, 126.6, 118.3. MS: m/z = 334 [M^+]. $C_{22}H_{14}N_4 \cdot 0.25CHCl_3$ (364): calcd. C 73.39, H 3.92, N 15.39; found C 73.25, H 3.33, N 15.33.

2,5-Bis(2′-[1′,8′]naphthyridyl)pyrazine (6): Solid KOH (200 mg) was added to a stirred solution of 2,5-diacetylpyrazine (400 mg, 2.44 mmol) and 2-aminonicotinaldehyde (625 mg, 5.12 mmol) in EtOH (10 mL). The solution was allowed to reflux for 5 h after which it was cooled to room temperature and the solids were collected by vacuum filtration. The solid product was purified by washing with cold EtOH until the washings ran clear to give **6** (820 mg, 98%) as a gray solid; m.p. > 280 °C. ^{1}H NMR ($CDCl_3$): δ = 10.15 (s, 2 H), 9.22 (dd, J = 3.9, 1.8 Hz, 2 H), 8.83 (d, J = 8.4 Hz, 2 H), 8.41 (d, J = 8.7 Hz, 2 H), 8.30 (dd, J = 8.1, 2.1 Hz, 2 H), 7.57 (dd, J = 8.1, 4.2 Hz, 2 H). ^{13}C NMR ($CDCl_3$): δ = 157.5, 155.8, 154.2, 150.4, 143.2, 138.2, 137.1, 123.3, 122.6, 120.5. MS: m/z = 336 [M^+]. $C_{20}H_{12}N_6 \cdot 0.25H_2O$ (341): calcd. C 70.48, H 3.67, N 24.67; found C, 70.24, H 3.36, N 24.27.

[Ru(3)(bpy)$_2$](PF$_6$)$_2$: A stirred suspension of **3** (20 mg, 0.06 mmol) and [Ru(bpy)$_2$Cl$_2$] (62 mg, 0.12 mmol) in EtOH/H_2O (3:1, 12 mL) was heated at reflux overnight after which the solution was cooled to room temperature, and filtered. NH_4PF_6 (20 mg) was added and the solution was concentrated. The product was purified by chromatography (silica gel, CH_3CN/H_2O/sat. KNO_3, 5:4:1) and the counterion was exchanged with satd. NH_4PF_6 to give [Ru(**3**)(bpy)$_2$](PF$_6$)$_2$ (38 mg, 66%) as a red solid. ^{1}H NMR (CD_3CN): δ = 9.81 (s, 1 H), 8.95 (d, J = 8.7 Hz, 1 H), 8.72 (d, J = 8.7 Hz, 1 H), 8.63 (d, J = 8.7 Hz, 2 H), 8.58 (d, J = 6.9 Hz, 2 H), 8.46 (s, 1 H), 8.39 (d, J = 8.1 Hz, 1 H), 8.32 (m, 2 H), 8.0−8.2 (m, 6 H), 7.9−8.0 (m, 3 H), 7.77 (t, J = 6.9 Hz, 2 H), 7.69 (t, J = 7.5 Hz, 2 H), 7.50 (m, 2 H), 7.2−7.4 (m, 4 H). MS: m/z = 893 [$M^+ - PF_6$], 748 [$M^+ - 2\ PF_6$].[16]

[(bpy)$_2$Ru(3)Ru(bpy)$_2$](PF$_6$)$_4$: A stirred suspension of **3** (34 mg, 0.033 mmol) and [Ru(bpy)$_2$Cl$_2$] (66 mg, 0.066 mmol) in EtOH/H_2O (3:1, 12 mL) was heated at reflux overnight after which the solution was cooled to room temperature, filtered, NH_4PF_6 (20 mg) was added and the solution was concentrated. The product was purified by chromatography (silica gel, CH_3CN/H_2O/satd. KNO_3, 5:4:1) and the counterion was exchanged with satd. NH_4PF_6 to give [(bpy)$_2$Ru(**3**)Ru(bpy)$_2$](PF$_6$)$_4$ (16 mg, 28%) as a green solid. The dinuclear complex exists as a mixture of diastereomers which were not further separated: ^{1}H NMR (CD_3CN): δ = 9.63 (s, 1 H), 9.54 (s, 1 H), 9.00 (2 overlapping d, J = 8.7 Hz), 9.73 (2 overlapping d, J = 9.0 Hz), 8.55 (d, J = 8.1 Hz), 8.41 (t, J = 7.5 Hz), 8.26 (t, J = 7.8 Hz), 7.8−8.3 (m), 7.6−7.8 (m), 7.1−7.6 (m), 7.00 (t, J = 7.2 Hz). MS: m/z = 1594 [$M^+ - PF_6$], 1452 [$M^+ - 2\ PF_6$], 1306 [$M^+ - 3\ PF_6$].[16]

[Ru(4)(bpy)$_2$](PF$_6$)$_2$: A stirred suspension of **4** (17 mg, 0.051 mmol) and [Ru(bpy)$_2$Cl$_2$] (27 mg, 0.051 mmol) in EtOH/H_2O (3:1, 12 mL) was heated at reflux overnight after which the solution was cooled to room temperature, and filtered. NH_4PF_6 (17 mg) was added and the solution was concentrated. The product was purified by chromatography (alumina, CH_3CN/toluene, 1:1) followed by recrystallization (CH_3CN/toluene, 1:1) to give [Ru(**4**)Ru(bpy)$_2$](PF$_6$)$_2$ (30 mg, 47%) as red crystals. ^{1}H NMR (CD_3CN): δ = 9.86 (d, J = 0.9 Hz, 1 H), 9.24 (dd, J = 4.2, 1.8 Hz, 1 H), 9.06 (d, J = 8.7 Hz, 1 H), 8.74 (d, J = 8.7 Hz, 1 H), 8.68 (d, J = 8.4 Hz, 1 H), 8.60−8.65 (m, 2 H), 8.55 (dd, J = 8.1, 4.8 Hz, 1 H), 8.49 (d, J = 8.1 Hz, 1 H), 8.37 (t, J = 6.9 Hz, 2 H), 8.16 (dd, J = 4.2, 1.8 Hz, 1 H), 8.12 (dd, J = 7.8, 1.8 Hz, 1 H), 8.0−8.1 (m, 2 H), 7.95 (td, J = 7.8, 1.5 Hz, 1 H), 7.80 (t, J = 4.8 Hz, 2 H), 7.67−7.77 (m, 3 H), 7.59 (dd, J = 8.4, 4.2 Hz, 1 H), 7.2−7.5 (m, 4 H). MS: m/z = 895 [$M^+ - PF_6$], 750 [$M^+ - 2\ PF_6$]. $C_{40}H_{28}F_{12}N_{10}P_2Ru \cdot 0.3PhCH_3 \cdot 1.0H_2O$ (1085): calcd. C 46.58, H 2.98, N 12.91; found C, 46.87, H 2.67, N 12.90.

[(bpy)$_2$Ru(4)Ru(bpy)$_2$](PF$_6$)$_4$: A stirred solution of **4** (30 mg, 0.089 mmol) and [Ru(bpy)Cl$_2$] (100 mg, 0.191 mmol) in EtOH/H_2O (3:1, 12 mL) was refluxed under argon overnight. The dark green solution was cooled, NH_4PF_6 (50 mg) was added and the solvent was evaporated to give a black solid. The material was purified by chromatography (silica gel, CH_3CN/H_2O/satd. KNO_3, 5:4:1) and the counterion was exchanged with saturated NH_4PF_6 to give [(bpy)$_2$Ru(**4**)Ru(bpy)$_2$](PF$_6$)$_4$ (90 mg, 58%) as a green solid: ^{1}H NMR (CD_3CN): δ = 9.66 (s), 9.13 (d, J = 8.7 Hz), 8.80 (d, J = 8.7 Hz), 8.2−8.6 (m), 7.9−8.2 (m), 7.0−7.7 (m). MS: m/z = 1596 [$M^+ - PF_6$], 1451 [$M^+ - 2\ PF_6$], 1306 [$M^+ - 3\ PF_6$], 1161 [$M^+ - 4\ PF_6$]. $C_{60}H_{44}F_{24}N_{14}P_4Ru_2 \cdot 0.5H_2O$ (1752): calcd. C 41.12, H 2.57, N 11.19; found C 40.79, H 2.52, N 10.96.

[Ru(5)(bpy)$_2$](PF$_6$)$_2$: A stirred suspension of **5** (30 mg, 0.08 mmol) and [Ru(bpy)$_2$Cl$_2$] (94 mg, 0.18 mmol) in EtOH/H_2O (3:1, 20 mL) was heated at reflux overnight after which the solution was cooled to room temperature, filtered, NH_4PF_6 (60 mg) was added and the solution was concentrated. Chromatography (silica gel, CH_2Cl_2/CH_3CN, 3:2) gave [Ru(**5**)(bpy)$_2$](PF$_6$)$_2$ (35 mg, 37%) as a red solid. ^{1}H NMR (CD_3CN): δ = 9.86 (s, 1 H), 8.86 (s, 1 H), 8.4−8.8 (m), 8.34 (m), 7.9−8.2 (m), 7.6−7.9 (m), 7.54 (AB pattern, J = 6.9 Hz), 7.48 (d, J = 8.4 Hz), 7.2−7.4 (m). MS: m/z = 893 [$M^+ - PF_6$], 748 [$M^+ - 2\ PF_6$]. $C_{42}H_{30}F_{12}N_8P_2Ru \cdot CHCl_3$ (1156): calcd. C 44.71, H 2.68, N 9.70; found C 44.86, H 2.16, N 9.64.

[(bpy)$_2$Ru(5)Ru(bpy)$_2$](PF$_6$)$_4$: A stirred solution of **5** (30 mg, 0.08 mmol) and [Ru(bpy)Cl$_2$] (94 mg, 0.18 mmol) in EtOH/H_2O (3:1, 20 mL) was refluxed under Ar overnight. The dark green solution was cooled, NH_4PF_6 (60 mg) was added and the solvent was evaporated to give a black solid. The material was purified by chromatography (silica gel, CH_2Cl_2/CH_3CN, 65:35) and the counterion was exchanged with satd. NH_4PF_6 to give [(bpy)$_2$Ru(**5**)Ru(bpy)$_2$](PF$_6$)$_4$ (35 mg, 22%) as a green solid. The dinuclear complex exists as a mixture of diastereomers which were not further separated. ^{1}H NMR (CD_3CN): δ = 8.73 (t, J = 7.8 Hz), 8.66 (t, J = 9.0 Hz), 8.52 (s) 8.4−8.5 (m) 8.2−8.4 (m), 8.11 (t, J = 7.8 Hz), 7.8−8.1 (m), 7.6−7.7 (m), 7.4−7.6 (m) 7.2−7.4 (m), 7.06 (t, J = 7.5 Hz). MS: m/z = 1594 [$M^+ - PF_6$], 1304 [$M^+ - 3\ PF_6$]. $C_{60}H_{44}F_{24}N_{14}P_4Ru_2 \cdot 0.1KPF_6$ (1754): calcd. C 39.28, H 2.47, N 8.26; found C 38.70, H 2.39, N 8.73.

[Ru(6)(bpy)$_2$](PF$_6$)$_2$: A stirred suspension of **6** (50 mg, 0.15 mmol) and [Ru(bpy)$_2$Cl$_2$] (79 mg, 0.15 mmol) in EtOH/H_2O (3:1, 12 mL) was heated at reflux overnight after which the solution was cooled to room temperature, filtered, NH_4PF_6 (49 mg) was added and the solution was concentrated. Chromatography (alumina, CH_3CN/toluene, 1:1) gave [Ru(**6**)(bpy)$_2$](PF$_6$)$_2$ (86 mg, 55%) as a red solid. ^{1}H NMR (CD_3CN): δ = 9.93 (s, 1 H), 9.0−9.2 (m, 2 H), 8.83 (d,

Study of the D→Sb (D = O, S) Transannular Interaction in Sb-Monohalogenated Dibenzostibocines − An Experimental and Theoretical Study

José G. Alvarado-Rodríguez,*[a] Noemí Andrade-López,[a] Simplicio González-Montiel,[a] Gabriel Merino,[b] and Alberto Vela[b]

Keywords: Antimony / Density functional calculations / Halogens / Hypervalent compounds / Structure elucidation

In order to gain a greater insight in the nature of the D→Sb transannular interaction in dibenzostibocines, a series of $D(C_6H_4S)_2SbHal$ complexes (D = S; Hal = Cl **1**, Br **2**, I **3**; D = O, Hal = Cl **4**) has been synthesised. X-ray structure determinations of complexes **1**–**4** reveal that the antimony atom is in a distorted ψ-bipyramidal geometry, acting as an acceptor atom. The eight-membered ring conformation in **1**, **2** and **4** can be described as a twist-boat, while in **3** it is approaching C_s symmetry. DFT calculations were carried out on **1** and **4**. Topological analysis of the electron density in **1** and **4** showed the presence of critical points in the D→Sb direction (D = O, S). The electron localisation function showed the presence of a lone pair located in an equatorial position on the antimony, and a lone pair of the donor along the D→Sb direction, confirming the presence of a dative bond in the system.

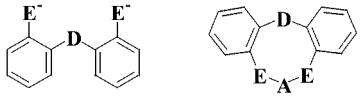
Introduction

The coordinating capabilities of ligands such as **I** (unsubstituted or benzene ring-substituted) have been extensively studied, particularly in the formation of dibenzoheterocycles **II** (Scheme 1). These studies have focused mainly on the synthesis of heterodinuclear compounds containing nickel and iron for modelling of active sites of [NiFe] hydrogenases,[1,2] and also on structural investigations devoted to understanding of the factors involved in the valence expansion of the acceptor atom A through formation of intramolecular transannular bonds with D and its relation with the adopted conformation of the central eight-membered ring.[3,4]



I **II**

A Lewis acid
D Lewis base
E O, S

Scheme 1

The coordination mode of **I** can mainly be di- or tridentate. In the first case, the lack of interactions results in atoms without valence expansion. The chemistry of the ligands with D = S and E = O is so far the most widely investigated. Metal complexes with *d*-block elements (Ti,[5] Zr,[6] V,[7] Co,[8] Cu,[9] W[10]) and light *p*-block elements, mainly phosphorus[11−13] and silicon,[4] acting as acceptor atoms A have been studied. Two spirocyclic germanium(IV) compounds containing ligands of type **I** (D = S, Se; E = O) have been crystallographically characterised. These compounds show the capabilities of **I** to expand the normal valence of the acceptor atom A.[14,15] In both cases, the germanium displays a distorted octahedral geometry with two transannular interactions D→Ge significantly shorter than the corresponding sums of the van der Waals radii.

For metal complexes **II** with D = S, and E = S, on the other hand, the chemistry is completely dominated by the *d*-block metals Fe,[16,17] Ni,[18−21] Pd[18−20] and Pt.[18,19] It is worth noting that, in the molecular structures determined in the solid state, the metal-sulfur (thioether) distance is always shorter than the metal-sulfur (thiolate) distance.

To the best of our knowledge, there are no reports of **II** complexes with heavier *p*-block elements, in particular complexes with antimony, in spite of the numerous studies carried out with similar stibocanes in which the presence of transannular D→A interactions and a large number of conformations of the eight-membered ring have been

observed.[22−26] Here we report an experimental and theoretical study of type **II** complexes with antimony as acceptor atom. These compounds are good models for further understanding of the nature of the D→Sb interaction. After the description of the synthesis of stibocine Sb-halogen complexes, NMR and X-ray crystallographic data are presented and discussed. Finally, density functional theory (DFT) calculations on the chloro complexes are discussed, together with an analysis of the bonding based on some molecular scalar fields.

Results and Discussion

Synthesis of $D(C_6H_4S)_2SbHal$ (D = O, S; Hal = Cl, Br, I)

The $S(C_6H_4SH)_2$ compound was obtained in a four-step, one-pot reaction by the method reported by Sellmann.[19] The $O(C_6H_4SH)_2$ compound was obtained in a similar way (see Exp. Sect. for details). Treatment of $S(C_6H_4SH)_2$ and $O(C_6H_4SH)_2$ with $SbCl_3$ in benzene yielded $S(C_6H_4S)_2SbCl$ (**1**) and $O(C_6H_4S)_2SbCl$ (**4**), respectively (see Scheme 2).

1 D = S
4 D = O

Scheme 2

Both complexes are air-stable, soluble in benzene and chloroform, and insoluble in pentane, hexane and 2-propanol. $S(C_6H_4S)_2SbI$ (**3**) was obtained from a halogen-exchange reaction between **1** and two equivalents of KI in hot toluene, yielding pale-yellow crystals. However, $S(C_6H_4S)_2SbBr$ (**2**) could not be obtained in a similar way. More drastic conditions were tested, and compound **2** was synthesized from **1** by treatment with two equivalents of KBr in a refluxing HBr/toluene mixture, giving **2** as colourless crystals.

Mass Spectra

The FAB mass spectra of all the compounds each exhibit a low intensity ion with the appropriate isotopic ratio representing the molecular ion; in all cases the $M^+ - Hal$ peak is assigned to the $D(C_6H_4S)_2Sb$ tricyclic moiety, confirming the binding of antimony to sulfur atoms. No more peaks could be assigned.

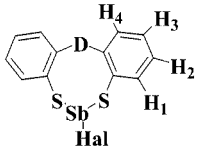
NMR Spectroscopy

NMR spectroscopic data are given in Table 1. At 25 °C, the ^1H NMR spectra of **1** and **3** in $CDCl_3$ and the ^1H spectrum of **2** in C_6D_6 each show four signals in an ABCD pattern, typical of *ortho*-substituted benzene rings. In **4**, the ^1H NMR spectrum in $CDCl_3$ at the same temperature shows two signals at δ = 7.55 and 7.13 ppm for protons H-4 and H-2, respectively, and one more at δ = 7.18 ppm for H-1 and H-3 (see Scheme 3). In solution, the two C_6H_4S halves are equivalent. In all complexes, protons H-2 and H-4 are shifted to higher frequencies with respect to the free neutral ligand.

Table 1. ^1H NMR chemical shifts (δ values, ppm) for **1−4**

Compound	D	Hal	H-1	H-2	H-3	H-4
1[a]	S	Cl	7.51	7.27	7.16	7.60
2[b]	S	Br	7.01	6.61	6.54	7.21
3[a]	S	I	7.44	7.27	7.17	7.60
4[a]	O	Cl	7.18	7.13	7.18	7.55

[a] In $CDCl_3$. [b] In C_6D_6.



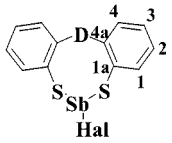
Scheme 3

The ^{13}C spectra of **1** and **3** in $CDCl_3$ at 25 °C each show the *ipso* carbons 1a (see Table 2, Scheme 4) at higher frequencies and the *ipso* carbons 4a at lower frequencies. An interesting observation in **3** is that the *ipso* carbon 1a is the most strongly shifted to lower frequencies. In **4**, the ^{13}C NMR spectrum in $CDCl_3$ at the same temperature shows C-1a and C-3 at 127.4 ppm; an APT experiment confirmed the previous result. The unequivocal assignment in **1** and **4** were performed by HETCOR and HMBC experiments.

Table 2. ^{13}C NMR chemical shifts (δ values, ppm) for **1−4**

Compound	D	Hal	C-1	C-1a	C-2	C-3	C-4	C-4a
1[a]	S	Cl	134.3	143.2	130.1	127.2	132.6	132.0
2[b]	S	Br	134.1	143.6	129.5	126.4	132.3	132.4
3[a]	S	I	134.8	141.9	129.9	127.2	132.2	132.1
4[a]	O	Cl	126.4	127.4	120.7	127.4	133.3	153.4

[a] In $CDCl_3$. [b] In C_6D_6.



Scheme 4

The ^1H and ^{13}C NMR spectra of **1** in $CDCl_3$ at −65 °C show only a very small displacement to higher frequencies (less than 0.1 and 0.5 ppm in ^1H and ^{13}C NMR, respectively), showing that any conformational equilibrium is too fast to be determined.

X-ray Structures of Compounds 1−4

The solid-state structures of **1**−**4** were determined by single-crystal X-ray diffraction analyses. The structures are depicted in Figure 1. The unit cell of **3** has two crystallographically independent molecules (**3a** and **3b**). Compounds **1** and **2** co-crystallised with benzene and toluene, respectively. Selected bond lengths and angles are given in Table 3.

If the covalent bonds are taken into consideration, the structure determination of all complexes reveals tricoordinate pyramidal antimony atoms. The Sb−S distances are in good agreement with those reported in other eight-membered heterocycles containing antimony-sulfur bonds.[22−26] The Sb−Hal distances (Hal = Cl, Br, I) are 1−5% longer than the corresponding sums of the covalent radii [Σ_{rcov} (Sb,Cl) = 2.39 Å; Σ_{rcov} (Sb,Br) = 2.54 Å; Σ_{rcov} (Sb,I) = 2.73 Å][27,28] and compare well with other distances found in similar eight-membered heterocycles. In addition to the expected bonding of the two sulfurs (thiolate) and the halogen ligands to the antimony atom, a short distance of the transannular D atoms to Sb is observed (D = S in **1**, **2** and **3**; D = O in **4**). These distances are longer than the corresponding sums of covalent radii but shorter than the sums of the corresponding van der Waals radii, and can be described as secondary interactions.[29] Moreover, the S···Sb distance in the complexes **1**−**3** decreases in the order of *trans* substituents, with the shortest distance in the iodo complex **3**.

If the secondary interactions are taken into account, the geometry of the coordination sphere of the antimony atom can be described as ψ-trigonal bipyramidal (TBP), in which the halogen and thioether-like sulfur atoms are in the axial positions, the two thiolate-like sulfur atoms occupy two equatorial positions and, in terms of the VSEPR model, we are tempted to envisage a stereochemical activity of the lone pair of the antimony(III) atom in the fifth position. Furthermore, the degree of TBP coordination can be determined by

a method used to describe structural displacements between pyramidal and trigonal bipyramidal idealised geometries.[30−32] In this method the degree of displacement from a lower (pyramidal) toward higher coordination geometry (TBP) is simply evaluated from the acceptor-donor atom distance and by how far this distance is displaced from the sum of the van der Waals radii (0% displacement) to the sum of covalent radii (100% displacement) of the acceptor-donor atoms. The results are presented in Table 4.

The eight-membered ring conformations of compounds **1**, **2** and **4** can be described as twist-boat (C_1 symmetry).[15] This description is based on the non-equivalence of the torsional angles, mainly those formed by the torsion of the carbon-sulfur (thioether) bond and the antimony-sulfur (thiolate) bond (Table 3). The ring conformation of compound **3** deserves some comments. In the **3a** molecule the conformation can also be described as twist-boat, but in **3b** the conformation could better described as boat-boat (C_s symmetry). This proposal is supported by the closer similitude between the torsion angles of the C−C−D−C and C−S−Sb−S atoms (ca. 10°).

DFT Calculation on Compounds 1 and 4

In order to analyse the bonding situation in the different molecules we performed a set of DFT calculations. The systems were fully optimised, and the nature of the chemical bonding was analysed in terms of the topology of the electronic density [$\rho(\mathbf{r})$[33]] and the electron localisation function [ELF($\mathbf{r}$)[34,35]].

All calculations were performed with the aid of Gaussian 98,[36] by use of the hybrid functional BHandHLYP. The selection of this hybrid functional was made for one reason. The half-and-half mixing of exact exchange and density-dependent exchange is justified by approximating the adiabatic connection formula.[37] For the geometry optimization, the 6-31++G(d,p) basis set was employed for all atoms, except for the antimony, for which a relativistic effective core potential (RECP) was used.[38] We denote these calculations as BHandHLYP/6-31++G(d,p) + RECP(Sb). All stationary points were characterised on the potential energy surface by a harmonic frequency analysis. For the generation of the molecular scalar fields, a double-ζ basis set with one polarisation function in all atoms (DZVP) was used.[39] The contractions of the DZVP basis set are (41/1*) for hydrogen, (621/41/1*) for carbon and oxygen, (6321/521/1*) for sulfur and chlorine, and (633321/53321/531*) for antimony. These calculations are denoted as BHandHLYP/DZVP. The Kohn−Shan orbitals were determined by BHandHLYP/DZVP//BHandHLYP/6-31++G(d,p) + RECP(Sb). The analysis of the electron density and the ELF were performed with the aid of the AIM2000[40] and the TopMod[41] programs, respectively.

A set of selected bond lengths and angles of the optimised structures are reported in Table 5. The calculated geometrical parameters are in good agreement with the crystallographic data. In relation to the initial structure in

[a] Experimental data. [b] Theoretical data.

the solid, the largest deviations are found in the D→Sb (D = O, S) and Sb−Cl bonds. The Sb−D bond length in the solid state is shorter than calculated for the gas phase. This behaviour is very common in donor-acceptor molecules and it is a consequence of the electrostatic dipole-dipole interactions (μ = 6.27 and 5.87 D in **1** and **4**, respectively).[42,43]

Of the possible isomers, the C_s structures (denoted as **1′** and **4′**, respectively) were considered, and their geometrical parameters are summarised in Table 5. These structures are transition states on the corresponding potential energy surface. Harmonic analysis shows one small imaginary frequency (−33 and −52 cm^{-1} in **1′** and **4′**, respectively). The relative energies of isomers **1′** and **4′** with respect to the unsymmetrical structures are ΔE = 3.2 and 4.2 kcal/mol, respectively. On the other hand, the Sb···D distances are smaller in the C_s structures than in unsymmetrical isomers. The largest bond length difference between the C_s and C_1 structures is the Sb···D distance (≈0.1 Å in **1** and ≈0.08 Å in **4**). It is worth noting that the Sb···D distances in the C_s structures are closer to the solid-state data and they have the largest dipole moment. This is in line with the model suggesting that donor-acceptor complex systems are stabilized by the dipole-dipole interactions.

To analyse the bonding in molecules **1** and **4**, the critical points of the electron density (CPs) and the gradient paths were determined. Here we focus the analysis mainly on the (3,-1) saddle points. Results of topological analysis of the electron density (TAED) are presented in Table 6, and the molecular graphs of **1** and **4** are depicted in Figure 2. All systems show bond critical points along the Sb···D directions, even though these distances are longer than the Sb−S(1) and Sb−S(2) bond lengths. The values of ρ_c(D···Sb) are smallest (≈0.027 a.u.) and $\nabla^2\rho_c$ are positive.

It is important to note that the L values of all bond critical points connecting Sb with its neighbours are negative, three interactions are stronger than the dative bond and have a very important ionic contribution.

The distribution of the lone pairs in the complexes is therefore a crucial question. In this sense, the electron localisation function is a good molecular scalar field with which to study this situation. The local maxima of this function define attractors corresponding to core, bonding and non-bonding electron pairs. The analysis of the ELF for molecules **1** and **4** are presented in Figure 3. The first important feature to note is the presence of a lone pair located on the antimony atom. At the same time, there are two basins around the equatorial sulfur atoms, which are related to the lone pairs on these atoms. However, the situation of the possible donor atom is special. In this case, the D atom has two basins, but one of them is found along the D→Sb interaction. On the other hand, one of lone pairs of the D atom is oriented towards antimony.

Figure 2. Molecular graphs of **1** and **4**; the small black and light grey spheres are the bond and ring critical points, respectively

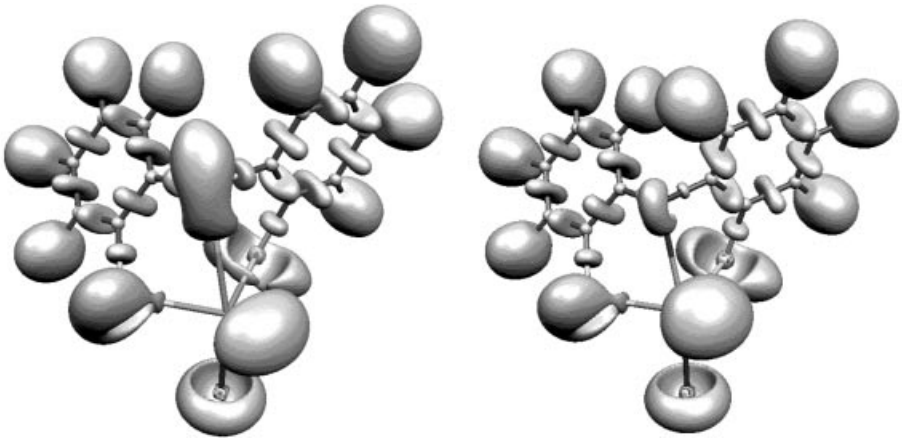

Figure 3. ELF isosurfaces [ELF(**r**) = 0.85] for **1** and **4**

The analyses presented above allow us to classify these molecules as intramolecular donor-acceptor complexes, in which Sb acts as an acceptor and the D atom as a donor.

Concluding Discussion

In the quest for good models with which to understand the nature of the D→Sb interactions, the complexes $D(C_6H_4S)_2SbHal$ **1**−**4** have been synthesised, structurally characterised and theoretically studied. All compounds display a distorted ψ-bipyramidal trigonal geometry of the antimony atom.

The X-ray analysis of the transannular Sb···S distances in the complexes **1**−**3** are 16.5−4.5% longer than the corresponding sums of the covalent radii and they indicate secondary bonding. This situation is different from that in *d*-block metals complexes in which the metal-sulfur (thioether) distance is shorter than the metal-sulfur (thiolate) distance. The Sb···S distance decreases as the electronegativity of the halogen ligand decreases. Moreover, there is a correlation between the symmetry of the eight-membered ring and the transannular distance: the higher the symmetry of the ring, the shorter the Sb···S distance, reflecting the flexibility of the $[S(C_6H_4S)_2]^{2-}$ ligand. In the chloro stibocine derivatives, the sulfur atom is a better donor that the oxygen atom. This is also consistent with the larger % TBP displacement determined in **1**.

The theoretical calculations predict a Sb···D bond length longer than in the solid state. This is a typical effect when a donor-acceptor complex is formed. On the other hand, the relative energies of the symmetrical isomers (**1′** and **4′**) with respect to unsymmetrical structures are ΔE = 3.2 and 4.2 kcal/mol, respectively, in agreement with the NMR results in which the conformational equilibria are too fast to be determined. Molecules **1** and **4** show bond critical points along the Sb···D directions. The topological descriptors allow us to classify the Sb···S interaction as a weak interaction. The ELF for the molecules **1** and **4** indicates the presence of a lone pair located on the antimony atom at the equatorial position. The D atoms (D = S, O in **1** and **4**, respectively) have two basins, one of them being found

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

along the D→Sb direction. These experimental and theoretical results allow us to classify these compounds as intramolecular donor-acceptor complexes in which the antimony atom acts as acceptor atom.

Experimental Section

General Methods: Unless noted otherwise, all reactions and operations were carried out under argon at room temperature with use of standard Schlenk techniques. Solvents were dried and distilled before use. Melting points were determined on a Melt-Temp II instrument and are uncorrected. Spectra were recorded with the following instruments. Mass spectra: for EI, a Hewlett Packard 5989A mass spectrometer was used. FAB+ mass spectra were recorded on a JEOL JMS-AX505HA by using a Xe beam at 6 keV, with nitrobenzyl alcohol (NBA) as matrix. Elemental analysis: Perkin-Elmer Series II CHNS/O Analyzer. The IR spectra were record in the 4000−400 cm^{-1} range on a Perkin−Elmer System 2000 FT-IR spectrometer, as KBr pellets or in CsI cuvettes. NMR: Jeol Eclipse 400 spectrometer; with the residual protio-solvent signal used as referenced for ^1H NMR spectra. $^{13}C\{^1H\}$ NMR spectra were referred through the solvent peaks. Chemical shifts are quoted on the δ scale (downfield shifts are positive) relative to tetramethylsilane (^1H, $^{13}C\{^1H\}$). Spectra were recorded at 25 °C. ^1H; 399.78 MHz, $^{13}C\{^1H\}$; 100.53 MHz. $S(C_6H_5)_2$, $O(C_6H_5)_2$, *n*BuLi (1.6 M, in hexanes), KI, KBr and HBr were purchased from Aldrich and Fluka. $SbCl_3$ was sublimed prior to use. The $S(C_6H_4SH)_2$ compound was prepared as reported.[19]

$O(C_6H_4SH)_2$: TMEDA (12.20 mL, 81.15 mmol), a solution of *n*BuLi in hexanes (1.6 M, 50 mL, 80 mmol) and diphenyl ether (6 mL, 37.85 mmol) were successively added at room temperature to 60 mL of hexanes. The solution was stirred for 24 h, in the course of which a beige solid precipitated. Elemental sulfur (3.46 g, 108.00 mmol) was added with vigorous stirring, and the resulting yellow suspension was stirred for 48 h and concentrated to dryness. The yellow residue was dissolved in THF (60 mL) and immersed in an ice bath, and $LiAlH_4$ (3.02 g, 84.85 mmol) was added in small portions. ***Caution: A vigorous reaction takes place and the reaction suspension starts to foam.*** Subsequently, the reddish-brown suspension was heated at reflux for 5 h, in the course of which the colour turned to light yellow green. The resulting mixture was cautiously added in small portions to a mixture of crushed ice (60 g) and concentrated hydrochloric acid (60 mL) immersed in an ice-bath. ***Caution: Vigorous evolution of H_2 and H_2S occurs, and this reaction must be carried out in a well ventilated fumehood.*** After the vigorous reaction had ceased, further concentrated hydrochloric acid (20 mL) was added, and the resulting suspension was extracted with CH_2Cl_2 (3 × 60 mL). The combined organic phases were washed with dilute HCl and passed through a column of Celite and Na_2SO_4, and evaporation of the solvent yielded a yellow oil. Yield: 3.0 g (34%) $O(C_6H_4SH)_2$. MS (EI, CH_2Cl_2): *m*/*z* = 234 [$M^{\cdot+}$ peak base], 200 [$M^{\cdot+}$ − H_2S]. ^1H NMR ($CDCl_3$): δ = 3.90 (s, 2 H, SH), 6.82 (dd, 2 H, C_6H_4), 7.04 (dt, 2 H, C_6H_4), 7.09 (dt, H, C_6H_4), 7.36 (dd, 2 H, C_6H_4) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 118.6, 123.7, 124.5, 126.7, 130.2, 152.1 ppm. IR (CsI): $\tilde{\nu}$ = 3052, 2555 (SH), 1582, 1446, 1426, 1036, 747 cm^{-1}. The neutral ligand was used further without purification.

$S(C_6H_4S)_2SbCl$ (1): A solution of freshly sublimed $SbCl_3$ (1.62 g, 7.10 mmol) in benzene (25 mL) was added dropwise to a solution of $S(C_6H_6SH)_2$ (1.76 g, 7.03 mmol) in benzene (25 mL). The yellow solution was stirred for 30 min, upon which a green solution resulted, and this was heated at reflux for 5 h. The solution was allowed to cool to room temperature. The resulting colourless crystals of **1**, as a benzene solvate, were separated by suction filtration and washed with *i*PrOH (40 mL). Yield: 2.40 g (84%) based on $S(C_6H_4S)_2SbCl$ free compound. FAB+: *m*/*z* (%) = 404 (4) [$M^{\cdot+}$], 369 (17) [$M^{\cdot+}$ − Cl]. M.p. 183−189 °C. $S(C_6H_4S)_2SbCl{\cdot}0.5C_6H_6$ (444.66): calcd. C 40.52, H 2.49; found C 39.29, H 2.36. ^1H NMR ($CDCl_3$): δ = 7.16 (ddd, 2 H, C_6H_4), 7.27 (ddd, 2 H, C_6H_4), 7.51 (dd, 2 H, C_6H_4), 7.60 (dd, 2 H, C_6H_4) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 127.17, 130.1, 132.0, 132.6, 134.3, 143.2 ppm. IR (KBr): $\tilde{\nu}$ = 3048, 1568, 1444, 1421, 1035, 744 cm^{-1}.

$S(C_6H_4S)_2SbBr$ (2): $S(C_6H_4S)_2SbCl{\cdot}0.5C_6H_6$·(**1**·$0.5C_6H_6$, 160 mg, 0.36 mmol), KBr (86 mg, 0.72 mmol) and HBr 48% (2 mL) were suspended in toluene (25 mL) and heated at reflux for 16 h. The water was removed from the resulting colourless solution by means of a Dean−Stark trap. The yellow solution obtained was dried by passage through a column of Celite and Na_2SO_4. The solution was left under an argon flow to provide yellow crystals of **2** as a toluene solvate, which were washed with hexanes (40 mL) and filtered by suction. Yield: 100 mg (62% based on free compound **2**). FAB+: *m*/*z* (%) = 448 (5) $[M]^+$, 369 (74) $[M - Br]^+$. M.p. 193−194 °C. $S(C_6H_4S)_2SbBr\ 0.5C_6H_5CH_3$ (496.13): calcd. C 37.52, H 2.44; found C 37.61, H 2.26. ^1H NMR (C_6D_6): δ = 6.54 (td, 2 H, C_6H_4), 6.62 (td, 2 H, C_6H_4), 7.01 (dd, 2 H, C_6H_4), 7.21 (dd, 2 H, C_6H_4) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 126.4, 129.5, 132.3, 132.4, 134.1, 143.6 ppm. IR (KBr): $\tilde{\nu}$ = 3046, 1568, 1443, 1420, 1245, 1036, 745 cm^{-1}.

$S(C_6H_4S)_2SbI$ (3): $S(C_6H_4S)_2SbCl\ 0.5C_6H_6$·(**1**·$0.5C_6H_6$, 160 mg, 0.36 mmol) and KI (120 mg, 0.72 mmol) were suspended in dry toluene (25 mL) and heated at reflux for 16 h. The yellow solution was dried by passage through a column of Celite and Na_2SO_4 whilst still warm, and was then allowed to cool to room temperature. On cooling, yellow crystals separated, and these were washed with *n*-hexanes (40 mL) and filtered by suction. Yield: 71 mg (40%). FAB+: *m*/*z* (%) = 496 (2) $[M]^+$, 369 (5) $[M - I]^+$. m.p. 200−204 °C. $S(C_6H_4S)_2SbI$ (497.05): calcd. C 29.00, H 1.62; found C 28.98, H 1.55. ^1H NMR ($CDCl_3$): δ = 7.17 (ddd, 2 H, C_6H_4), 7.27 (ddd, 2 H, C_6H_4), 7.44 (dd, 2 H, C_6H_4), 7.60 (dd, 2 H, C_6H_4) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 127.2, 129.9, 132.1, 132.2, 134.8, 141.9 ppm. IR (KBr): $\tilde{\nu}$ = 3045, 1569, 1447, 1415, 1247, 1034, 742 cm^{-1}.

$O(C_6H_4S)_2SbCl$ (4): A solution of $O(C_6H_6SH)_2$ (2.0 g, 8.54 mmol) in benzene (25 mL) was added to a solution of $SbCl_3$ (1.95 g, 8.54 mmol) in benzene (25 mL). The yellow solution was stirred for 30 min and was heated to reflux for 5 h. The solution was allowed to cool to room temperature. On cooling, colourless crystals separated, and these were washed with *i*PrOH (40 mL) and filtered by suction. Yield: 1.76 g (53%). FAB+: *m*/*z* (%) = 388 (2) $[M]^+$, 353 (5) $[M - Cl]^+$. m.p. 164−5 °C. $O(C_6H_4S)_2SbCl$ (389.54): calcd. C 37.00, H 2.07; found C 36.65. H 2.12. ^1H NMR ($CDCl_3$): δ = 7.11−7.20 (m, 6 H, C_6H_4), 7.53−7.58 m, 2 H, C_6H_4) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 120.7, 126.4, 127.4, 133.3, 153.41 ppm. IR (KBr): $\tilde{\nu}$ = 3055, 1584, 1458, 1435, 1054, 752 cm^{-1}.

X-ray Structure Analysis of $S(C_6H_4S)_2SbCl{\cdot}0.5C_6H_6$ (1·0.5C_6H_6), $S(C_6H_4S)_2SbBr{\cdot}0.5CH_3C_6H_5$ (2·0.5 $CH_3C_6H_5$), $S(C_6H_4S)_2SbI$ (3) and $O(C_6H_4S)_2SbCl$ (4)

Suitable single crystals of **1** were grown by slow evaporation of the solvent from a benzene solution, and crystals of **2** and **3** were grown similarly from toluene solutions. Single crystals of **4** were grown by slow diffusion of pentane into a **4**/toluene solution in a 5:1 solvent ratio

Suitable crystals were glued and mounted on fibre glass with the aid of epoxy resin. Intensity data were collected at room temperature on a CCD Smart 6000 diffractometer through the use of Mo-K_α radiation (λ = 0.71073 Å, graphite monochromator). Empirical absorption correction was applied for all complexes. The structures were solved by direct (**1**, **4**) or heavy atom (**2**, **3**) methods, and full-matrix, least-squares refinement was carried out on F^2 (SHELXTL NT 5.10).[44] All non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were kept fixed with a common isotropic displacement parameter. Selected crystallographic data are given in Table 7.[45]

Acknowledgments

JGAR gratefully acknowledges the CONACyT (Project J27919-E) for financial support for these investigations. We wish to thank Dra. Verónica García Montalvo (UNAM) for the recording of FAB+ Mass Spectra.

Synthesis, Structure, and Reactivity of Novel Intramolecularly Coordinated Organolead(II) Compounds[‡]

Klaus Jurkschat,*[a] Katja Peveling,[a] and Markus Schürmann[a]

Dedicated to Professor Jaroslaw Holeček on the occasion of his 70th birthday

Keywords: Lead / Chain structures / Carbene homologues / Phosphorus / Hypervalent compounds

The intramolecularly coordinated heteroleptic organolead(II) compounds {4-*t*Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}PbX (**2**, X = Cl; **3**, X = SPh) have been synthesized. Single-crystal X-ray analyses reveal that both compounds adopt polymeric chain structures by intermolecular Pb–X···Pb bridges, a structural motif previously unknown for organolead(II) derivatives. Compound **2** reacts with lithium diisopropylamide, *i*Pr$_2$NLi, and lithium bis(trimethylsilyl)methane, (Me$_3$Si)$_2$CHLi, respectively, to provide in situ the corresponding organolead(II) compounds {4-*t*Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}PbX (**4**, X = *i*Pr$_2$N; **5**, X = (Me$_3$Si)$_2$CH], which were identified by NMR spectroscopy but could not be obtained as analytically pure substances. Attempts to isolate the intramolecularly coordinated organolead(II) hexafluorophosphate {4-*t*Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}Pb$^+$PF$_6^-$ from the reaction of **2** with TlPF$_6$ also failed. Instead, the unprecedented salt [{5-*t*Bu-1,3-[P(O)(OEt)$_2$]$_2$C$_6$H$_3$}$_4$·(Pb$_2$F)] [PF$_6$]$_3$·4THF (**6**) was obtained, in which the [(Pb–F–Pb)]$^{3+}$ cation is stabilized by eight intermolecular P=O→Pb interactions. Compound **6** was characterized by single-crystal X-ray analysis and electrospray mass spectrometry.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Most of the extensive research on the chemistry of the heavier group-14 element carbene analogues ER$_2$ (E = Si, Ge, Sn, Pb; R = alkyl, aryl, alkoxide, thiolate, diorganoamide)[1] has focused on divalent tin[1] and germanium[1] compounds, with fewer studies on low-valent silicon[2–7] and organolead compounds.[1,4,8,9] Of the latter, compounds containing π-bonded ligands[10–17] and Pb–C σ-bonds have been investigated. Divalent lead compounds can be stabilized by bulky[18–33] intramolecularly coordinating substituents.[33–43] Unlike diorganolead compounds[18–31,34–41] there are few examples of RPbX heteroleptic plumbylenes {R = 2,6-[2,4,6-(*i*Pr)$_3$C$_6$H$_2$]$_2$C$_6$H$_3$, C(SiMe$_3$)$_3$, C(SiMe$_3$)$_2$(SiMe$_2$OMe), N(SiMe$_3$)C(Ph)C(SiMe$_3$)$_2$, C(SiMe$_3$)$_2$(SiMe$_2$C$_5$H$_4$N-2), C(SiMe$_2$Ph)$_3$, X = Br, Cl},[31–33,42,43] which are particularly interesting as they allow further derivatizations at the Pb–X function.

Recently, we reported the arylbis(phosphonic) esters 5-*t*Bu-1,3-[P(O)(OR)$_2$]$_2$C$_6$H$_3$ (**A**, R = Et; **B**, R = *i*Pr) and the application of their deprotonated monoanions to the synthesis of intramolecularly coordinated organosilicon(IV),[44–46] organotin(IV),[47–49] and organolead(IV)[50] compounds, and of intramolecularly coordinated heteroleptic stannylenes.[51] The latter, owing to intramolecular P=O→Sn coordination, show notably enhanced stability towards oxidation and thermal decomposition. We present here the synthesis and structure of the corresponding heteroleptic plumbylene and describe its reactivity towards nucleophiles.

Results and Discussion

The organolithium compound {4-*t*Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}Li (**1**)[47] reacts with PbCl$_2$ to give the heteroleptic plumbylene {4-*t*Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}PbCl (**2**) as colorless crystals in good yield [Equation (1)].

On contact with air and moisture, it slowly decomposes to give the protonated ligand **A** ($\delta^{31}P$ = 18.5 ppm) and unidentified products (10% decomposition after 4 d, 99% decomposition after 41 d). Under inert conditions and dissolved in C_6D_6, **2** is rather stable. No decomposition was observed after storage at 65 °C for 41 d.

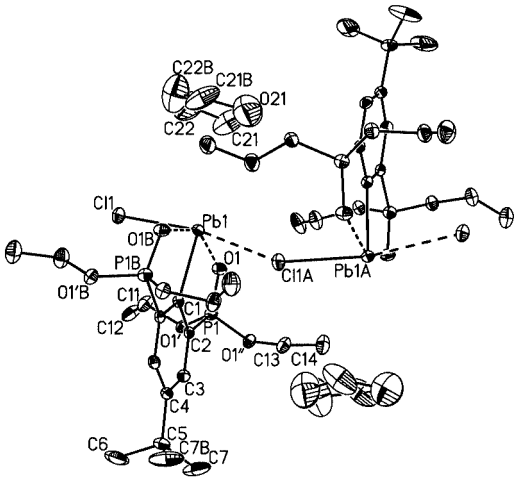

Figure 1. General view (SHELXTL) of two molecular units of **2**·THF showing 30% probability displacement ellipsoids and the atom numbering (symmetry transformations used to generate equivalent atoms: $a = -0.5 + x, y, -0.5 - z$; $b = x, 0.5 - y, z$; $c = 0.5 + x, y, -0.5 - z$)

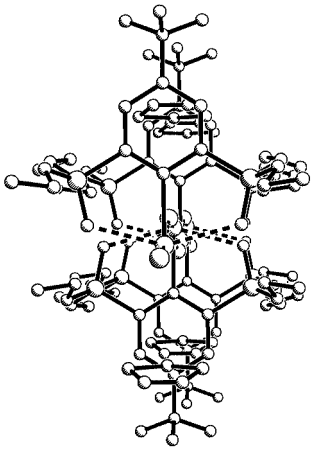

Figure 2. View along the Pb−Cl axis of **2**·THF

The molecular structure of **2**·THF (Figures 1 and 2), selected geometrical data (Table 1) and relevant crystallographic parameters (Table 2) are given here.

Unlike related heteroleptic plumbylenes $[C(SiMe_3)_2(SiMe_2C_5H_4N\text{-}2]PbCl$,[43] $[\{2,6\text{-}[2,4,6\text{-}(i\text{Pr})_3C_6H_2]_2C_6H_3\}PbBr]_2$,[31] $[(PhMe_2Si)_3CPbCl]_2$,[32,33] $\{[C(SiMe_3)_2(SiMe_2OMe)]PbCl\}_2$,[33] $\{[N(SiMe_3)C(Ph)C(SiMe_3)_2]PbCl\}_2$,[42] and $[(Me_3Si)_3CPbCl]_3$[33] being monomers, dimers and trimers, respectively, in the solid state, compound **2** forms an infinite zigzag chain via intermolecular, almost symmetrical Pb−Cl−Pb bridges (ΔPb−Cl 0.106 Å, Pb(1)−Cl(1)−Pb(1A) 155.96(6)°]. The Pb(1)−Cl(1) and Pb(1)···Cl(1A) distances of 2.795(1) and 2.901(1) Å, respectively, are in the range found in other monoorganoplumbylenes such as $[(PhMe_2Si)_3CPbCl]_2$ [Pb−Cl = 2.729(3) Å, Pb···Cl′ = 2.962(3) Å],[32,33] $[(Me_3Si)_3CPbCl]_3$ [Pb−Cl = 2.71(2) Å, 2.73(1) Å, 2.74(1) Å],[33] $\{[C(SiMe_3)_2(SiMe_2OMe)]PbCl\}_2$ [Pb−Cl = 2.680(5) Å, Pb···Cl′ = 2.868(5) Å],[33] $\{[N(SiMe_3)C(Ph)C(SiMe_3)_2]PbCl\}_2$ [Pb−Cl = 2.609(3) Å, Pb···Cl′ = 3.276(3) Å],[42] and $[C(SiMe_3)_2(SiMe_2C_5H_4N\text{-}2]PbCl$ [Pb−Cl = 2.647(3) Å].[43] The organic substituents at adjacent lead atoms in the heteroleptic plumbylene **2** are staggered with C(1)−Pb(1)···Pb(1A)−C(1A) = 180.0°.

The lead atom exhibits a ψ-octahedral configuration with O(1), O(1B), Cl(1) and Cl(1A) occupying the equatorial positions and C(1) being almost perpendicular to these atoms and *trans* to the lone pair. The stereochemical influence of the lone pair is mainly manifested by the Cl(1)−Pb(1)−Cl(1A), C(1)−Pb(1)−Cl(1), and C(1)−Pb(1)−Cl(1A) angles of 169.60(1), 89.1(1), and 80.5(1)°, respectively. The O(1)−Pb(1)−O(1B) angle of 149.5(1)° is close to the corresponding angle in the related heteroleptic stannylene {4-*t*Bu-2,6-[P(O)(O*i*Pr)$_2$]$_2$-C$_6$H$_2$}SnCl [O(1)−Sn(1)−O(2) 152.00(5)°][52] but much bigger than the O(1)−Pb(1)−O(2) of 119.36(5)° in the intramolecularly [4+2]-coordinated tetraorganolead(IV) derivative {4-*t*Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}PbPh$_3$.[50] In contrast to related organosilicon(IV),[44−46] organotin(IV),[47−49] and organolead(IV)[50] compounds containing the O,C,O-coordinating ligand {4-*t*Bu-2,6-[P(O)(OR)$_2$]$_2$C$_6$H$_2$}$^-$ (R = Et, *i*Pr), in the organoplumbylene **2** the P(O)(OEt)$_2$ groups and the lead atom are slightly displaced in the same direction from the plane defined by the aromatic ring [P(1)−C(2)−C(3)−C(4) = 177.5(3)°, Pb(1)−C(1)−C(2)−C(3) = 169.3(2)°]. The intramolecular Pb(1)−O(1) and Pb(1)−O(1B) distances of 2.518(2) Å are close to the intramolecular Pb−O [2.52(2) Å] reported for {2-[Ph$_2$P(O)CH$_2$]C$_6$H$_4$S}$_2$Pb.[53] The IR spectrum of **2** shows a band at $\tilde{\nu}$(P=O) = 1201 cm^{-1} which is similar to that for the related stannylene {4-*t*Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}SnCl [$\tilde{\nu}$(P=O) = 1192 cm^{-1}].[51]

The singlet at δ = 52.0 [J(^{207}Pb−^{31}P) = 127 Hz] ppm in the ^{31}P NMR (C$_6$D$_6$) spectrum of organolead(II) chloride **2** is at a higher frequency than for the corresponding organotin(II) compound {4-*t*Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}SnCl (in [D$_8$]toluene: δ = 39.1 ppm).[51] The solid-state ^{31}P NMR spectrum shows a broad resonance at δ = 54.5 ppm. No ^{207}Pb NMR chemical shift could be obtained, which accords with reported problems in recording ^{207}Pb NMR spectra of [(PhMe$_2$Si)$_3$CPbCl]$_2$,[32,33] [(Me$_3$Si)$_3$CPbCl]$_3$,[33] [{2,6-[2,4,6-(*i*Pr)$_3$C$_6$H$_2$]$_2$C$_6$H$_3$}PbBr]$_2$,[31] and [{2,6-[2,4,6-(*i*Pr)$_3$C$_6$H$_2$]$_2$C$_6$H$_3$}PbBr·py].[31]

Compound **2** reacts with sodium thiophenolate under nucleophilic substitution at the Pb−Cl function to give the corresponding organolead(II) thiophenolate **3** as a colorless crystalline solid that is stable at 20 °C under aerobic conditions for several days (Scheme 1).

lographic parameters (Table 2) are detailed here. As with organolead(II) chloride **2**, the organolead(II) thiophenolate **3** forms a polymeric zigzag chain with, however, a less symmetric intermolecular Pb−S···Pb bridge [ΔPb−S 0.5868 Å, Pb(1)−S(1)−Pb(1A) 18.72(1)°]. The torsion angle C(1)−Pb(1)···Pb(1a)−C(1a) is 170.9(1)°. The related organolead(II) thiophenolate derivative {2,4,6-$[(Me_3Si)_2CH]_3C_6H_2$}Pb{2,4,6-$[(Me_3Si)_2CH]_3C_6H_2S$},[54,55] however, is a monomer. As with compound **2**, the lead atom in the organolead(II) thiophenolate **3** shows a distorted ψ-octahedral configuration with O(1), O(2), S(1) and S(1A) occupying the equatorial positions and C(1) being almost perpendicular to these atoms. The stereochemical influence of the lone pair is shown by the S(1)−Pb(1)−S(1A) angle of 158.533(8)°. In contrast to the related organolead(II) chloride **2**, in **3** the intramolecular Pb(1)−O(1) and Pb(1)−O(2) distances differ [2.671(2) and 2.520(2) Å, respectively]. The non-equivalence of the two phosphorus atoms is also shown in the solid-state ^{31}P NMR spectrum by two resonances at δ = 50.4 and 45.0 ppm. The IR spectrum, however, is not sensitive enough to distinguish the two phosphonyl groups and shows only one band at $\tilde{\nu}$(P=O) = 1208 cm^{-1}. The O(1)−Pb(1)−O(2) angle of 148.70(6)° is again rather similar to the 152.48(7)° found in the related stannylene {4-*t*Bu-2,6-$[P(O)(OiPr)_2]_2C_6H_2$}SnSPh.[52] The Pb(1)−S(1) distance of 2.7090(9) Å lies in the range of Pb−S distances found in $([\{2,6\text{-}(iPr)_2C_6H_2\}S]_2Pb)_3$ [Pb−S = 2.554(4)−2.896(3) Å].[56] The Pb(1)···S(1A) distance [3.2958(9) Å] is in the range of lead−sulfur secondary bond lengths found in $_\infty[(S_2PPh_2)_2Pb]$ (Pb···S = 3.270−3.448 Å).[57] Compounds **2** and **3** appear to be the first organolead(II) derivatives to exhibit polymeric chain structures.

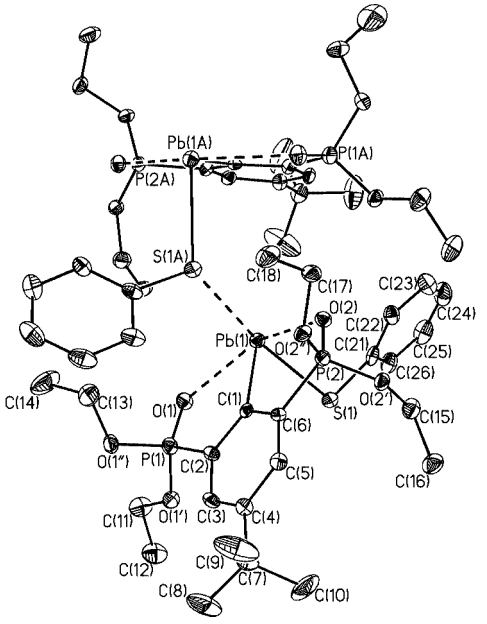

Figure 3. General view (SHELXTL) of two molecular units of **3** showing 30% probability displacement ellipsoids and the atom numbering (symmetry transformations used to generate equivalent atoms: $a = -0.5 - x, -0.5 + y, 0.5 - z$)

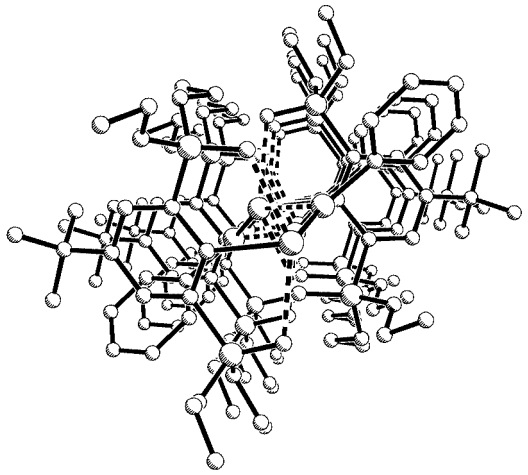

Figure 4. View along the Pb−S axis of **3**

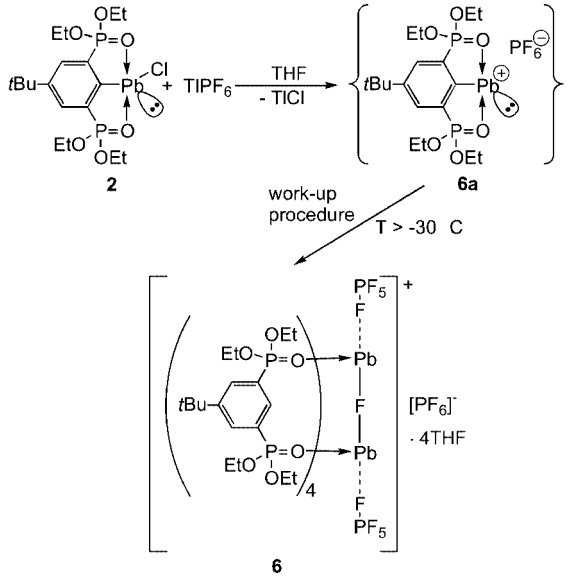
Osmometric molecular weight determinations in THF showed that plumbylenes **2** and **3** are monomeric in solution.

Compound **2** also reacts with lithium diisopropylamide and lithium bis(trimethylsilyl)methane by nucleophilic substitution at the Pb−Cl function to give, in situ, moderate yields of the heteroleptic plumbylenes {4-*t*Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2$}PbN*i*Pr_2 (**4**) and {4-*t*Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2$}$PbCH(SiMe_3)_2$ (**5**) (Scheme 1). Neither **4** nor **5** could be obtained analytically pure but their identity was confirmed by NMR spectroscopy (see Exp. Sect. and Supporting Information). Remarkably, the ^{207}Pb NMR chemical shift of **5** could be determined {δ = 6874 [$J(^{207}Pb$-$^{31}P)$ = 129 Hz] ppm}.

The reactions shown in Scheme 1 are always accompanied by Pb−C bond cleavage. No reaction between **2** and sulfur was observed even at 60 °C.

In an attempt to prepare the intramolecularly coordinated organolead(II) hexafluorophosphate [{4-*t*Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2$}Pb]$^+$ PF_6^- (**6a**), compound **2** was treated with $TlPF_6$ in THF at −78 °C (Scheme 2). The ^{31}P



Scheme 2

NMR spectrum of the crude reaction mixture showed signals (a) at δ = 18.0 (integral 27%, assigned to 5-*t*Bu-1,3-$[P(O)(OEt)_2]_2C_6H_3$) ppm and (b) at δ = 54.1 [$J(^{31}P$-$^{207}Pb)$ = 150 Hz, integral 73%] ppm. The latter signal is assigned with caution to the phosphonyl phosphorus atom in the salt **6a**.

After filtration under inert conditions through a diatomaceous earth filter, in the filtrate, the ratio of the ^{31}P NMR signals (a) to (b) changed to 88:12. From this filtrate, air- and moisture-sensitive single crystals of [{5-*t*Bu-1,3-$[P(O)(OEt)_2]_2C_6H_3\}_4$·$(Pb_2F)$] $[PF_6]_3$·4THF (**6**) were obtained.

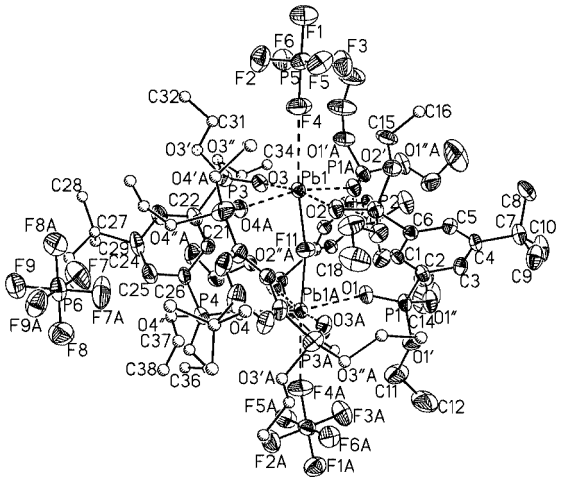


Figure 5. General view (SHELXTL) of a molecule of **6** showing 30% probability displacement ellipsoids and the atom numbering (symmetry transformations used to generate equivalent atoms: $-x$, y, $0.5 - z$)

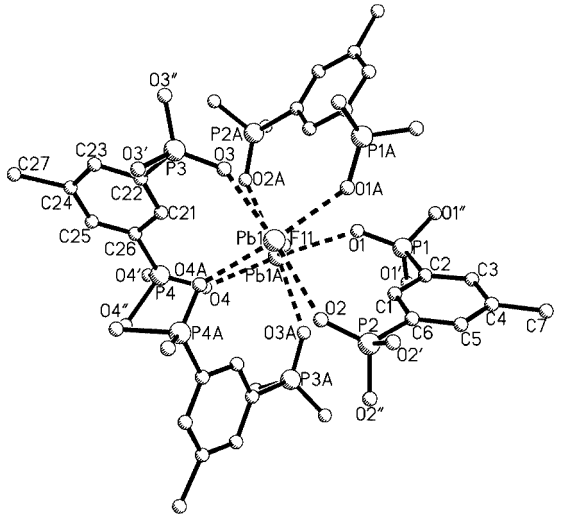

Figure 6. View along the Pb−F−Pb axis of **6**; methyl and ethyl groups, as well as THF and PF_6^-, are omitted for clarity

The molecular structure of **6** (Figures 5 and 6), selected geometrical data (Table 3), and relevant crystallographic parameters (Table 2) are given below.

The salt **6** consists of a $[(Pb-F-Pb)]^{3+}$ cation stabilized by eight intermolecular P=O→Pb coordinations of four 5-*t*Bu-1,3-$[P(O)(OEt)_2]_2C_6H_3$ molecules, three $[PF_6]^-$ anions, and four THF molecules. The cationic part of the structure has an axis of improper rotation. The three $[PF_6]^-$ anions are crystallographically non-equivalent. Two symmetry-related ones (P5/P5A) show a Pb(1)···F(4) distance of 3.075(5) Å whereas the third one (P6) is far from the lead atoms [Pb(1)···F(7) 8.437(6) Å]. The Pb(1)−F(11) distance of 2.2762(7) Å is rather short compared with Pb−F in α-PbF_2 [2.418(2), 2.439(8) Å][58] and β-PbF_2 (2.573 Å).[59] Lead−fluorine distances of 3.04(6) and 3.30 Å have been

reported for $Pb(dhfa)_2$ [Hdhfa = 1,5-bis(undecafluorocyclohexyl)pentane-2,4-dione][60] and bis(2,2-dimethyl-6,6,7,7,8,8,8-heptafluorooctane-3,5-dionato)lead,[61] respectively. The lead atom exhibits a distorted octahedral configuration with four P=O oxygen atoms equatorial and F(4), F(11) in axial positions. Distortion from the ideal geometry is manifested by F(4)−Pb(1)−F(11), O(2)−Pb(1)−O(3), and O(1A)−Pb(1)−O(4A) angles of 172.8(2), 170.2(1), and 163.3(1)°, respectively. The Pb−O distances lie between 2.426(4) [Pb(1)−O(4A)] and 2.550(4) Å [Pb(1)−O(1A)]. They are up to 0.245 Å shorter than the Pb−O distance in the intramolecularly coordinated organolead(II) chloride and thiophenolate **2** and **3**, respectively. The Pb(1)−F(11)−Pb(1A) angle amounts to 167.4(3)°. The electrospray mass spectrum of **6** in CH_3CN shows a cluster pattern at m/z = 1039, which is assigned to $\{(Pb + F + 2\ (5\text{-}t\text{Bu-}1,3\text{-}[P(O)(OEt)_2]_2C_6H_3)\}^+$. The IR spectrum (KBr pellet) of **6** shows a band at $\tilde{\nu}$(P=O) = 1197 cm^{-1}, indicating strong P=O→Pb coordination. The ^1H and ^{31}P NMR spectra of **6** exclusively show signals corresponding to the protonated ligand 5-*t*Bu-1,3-$[P(O)(OEt)_2]_2C_6H_3$ (**A**), THF, and PF_6^- anion.

Conclusion

We have demonstrated the capacity of the phosphorus-containing O,C,O-coordinating ligand 4-*t*Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2^-$ for the synthesis of stable heteroleptic organolead(II) compounds. This ligand or a modified version (replacement of ethyl groups by more bulky substituents) is also, probably, suitable to stabilize the corresponding germanium(II) and silicon(II) compounds. Although no rational synthesis for compound **6** has been developed yet, its serendipitous formation might help in developing concepts for the stabilization of di- and oligonuclear metal cations. Notably, Mews et al. have isolated and structurally characterized a compound that contains an $[(Sn-F-Sn)\cdot 4Ph_3PO]^{3+}$ cation.[62]

Experimental Section

General Remarks: All solvents were dried and purified by standard procedures. All reactions were carried out under argon using Schlenk techniques. Bruker DPX-300 and DRX-400 spectrometers were used to obtain ^1H, ^{13}C, ^{31}P, and ^{207}Pb NMR spectra. ^{31}P MAS NMR spectra were recorded with a Bruker MSL 400 spectrometer using cross-polarisation and high-energy proton decoupling. Two rotation frequencies (6000−9000 Hz) have been used to identify the isotropic shift. A repetition delay of 4.0 s and a 90.0° pulse of 5.0 μs were employed. ^1H, ^{13}C, ^{31}P, and ^{207}Pb NMR chemical shifts (δ) are given in ppm and referenced to Me_4Si, H_3PO_4 (85%), and $PbNO_3$ (saturated in D_2O) as appropriate. NMR spectra were recorded at room temperature unless otherwise stated. IR spectra were recorded with a Bruker IFS 28 spectrometer. UV measurements were performed with a Varian Cary 100. Elemental analyses were obtained with a LECO-CHNS-932 analyser. Molecular weight determinations were performed with a Knauer Osmometer K7000 in freshly distilled solvent and were referenced against benzil. Electrospray mass spectra were recorded in the positive mode with a Thermoquest-Finnigan instrument using CH_3CN as the mobile phase. The relevant compound was dissolved in CH_3CN to give an approximate solution concentration of $1\cdot10^{-4}$ mol·L^{-1}. The sample was then introduced via a syringe pump operating at 10 μL min^{-1}. The capillary voltage was varied between 7.0 and 8.7 V, while the cone-skimmer voltage was varied between 33.7 and 83.5 V. Identification of the inspected ions was assisted by comparison of experimental and calculated isotope distribution patterns. The m/z values reported correspond to the most intense peaks in the corresponding isotope pattern. {4-*t*Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2$}Li (**1**) was prepared as previously reported.[47]

[4-*tert*-Butyl-2,6-bis(diethoxyphosphonyl)phenyl]chloroplumbylene (2): $PbCl_2$ (3.32 g, 11.94 mmol) was added portionwise, at −78 °C, to a solution of [4-*tert*-butyl-2,6-bis(diethoxyphosphonyl)phenyl]lithium (**1**) (3.12 g, 7.57 mmol) in THF (150 mL). The reaction mixture was then stirred for 16 h (−78 °C to room temperature) and, after filtration, the solvent (50 mL) was evaporated. Crystallization at −6 °C afforded 4.42 g (81%) of **2**·THF as colorless crystals, m.p. 185 °C. After removal of THF by reduced pressure (11 Torr), **2** was characterized. ^1H NMR (400.13 MHz, C_6D_6): δ = 1.08 (t, 12 H, CH_3), 1.13 (s, 9 H, CH_3), 4.02−4.17 ($\nu_{1/2}$ = 32 Hz, 4 H, CH_2), 4.17−4.33 ($\nu_{1/2}$ = 36 Hz, 4 H, CH_2), 8.29 (complex pattern, 2 H, aromatics) ppm. $^{13}C\{^1H\}$ NMR (100.61 MHz, C_6D_6): δ = 16.4 (d, $^3J_{C,P}$ = 6 Hz, 4 C, CH_3), 31.0 (s, 3 C, CH_3), 34.9 (s, 1 C, C), 63.3 ($\nu_{1/2}$ = 23 Hz, 4 C, CH_2), 135.1 (dd, $^1J_{C,P}$ = 196, $^3J_{C,P}$ = 24 Hz, 2 C, C-2,6), 135.7 (dd, $^2J_{C,P}$ = 16, $^4J_{C,P}$ = 5 Hz, 2 C, C-3,5), 150.1 (t, $^3J_{C,P}$ = 12 Hz, 1 C, C-4), 250.7 (t, $^2J_{C,P}$ = 35 Hz, 1 C, C-1) ppm. $^{31}P\{^1H\}$ NMR (161.98 MHz, C_6D_6): δ = 52.0 (s, $J_{P,Pb}$ = 127, $^1J_{C,P}$ = 196 Hz ppm. $^{31}P\{^1H\}$ MAS NMR (161.98 MHz): δ = 54.6 ppm. IR (KBr): $\tilde{\nu}$(P=O) = 1201, 1179 cm^{-1}. UV/Vis (CH_3CN): λ = 217 nm, ε = 25309 L·mol^{-1}·cm^{-1}; λ = 279 nm, ε = 3122 L·mol^{-1}·cm^{-1}; λ = 286 nm, ε = 3039 L·mol^{-1}·cm^{-1}. Molecular weight determination (THF, 28 °C, c = 0.0147 mol·L^{-1}): 602.0 g mol^{-1}. $C_{18}H_{31}ClO_6P_2Pb$ (648.0): calcd. C 33.4, H 4.8; found C 33.4, H 4.8. MS: m/z (%) = 647 (45) [M − H], 612 (88) [M − Cl − H], 539 (52) [M − Cl − OEt − Et].

Investigations on the Stability of [4-*tert*-Butyl-2,6-bis(diethoxyphosphonyl)phenyl]chloroplumbylene (2). A: [4-*tert*-Butyl-2,6-bis(diethoxyphosphonyl)phenyl]chloroplumbylene (**2**) was exposed to light and atmospheric moisture on a watch glass. After t_1 = 4 d and t_2 = 41 d, respectively, representative portions were dissolved in C_6D_6 and analysed by NMR spectroscopy. $^{31}P\{^1H\}$ NMR (161.98 MHz, C_6D_6, t_1): δ = 19.0 [s, 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene, 10%], 52.5 (s, $J_{P,Pb}$ = 128 Hz, **2**, 90%) ppm; $^{31}P\{^1H\}$ NMR (161.98 MHz, C_6D_6, t_2): δ = 19.0 [s, 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene, 99%], 52.5 (s, $J_{P,Pb}$ = 128 Hz, **2**, 1%) ppm. **B:** [4-*tert*-Butyl-2,6-bis(diethoxyphosphonyl)phenyl]chloroplumbylene (**2**) (10 mg, $1.5\cdot10^{-5}$ mol) in C_6D_6 (0.4 mL) was sealed under inert conditions in an NMR tube at 65 °C for t_3 = 41 d. $^{31}P\{^1H\}$ NMR (161.98 MHz, C_6D_6, t_3): δ = 19.0 [s, 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene, 6%], 52.5 (s, $J_{P,Pb}$ = 128 Hz, **2**, 94%) ppm.

[4-*tert*-Butyl-2,6-bis(diethoxyphosphonyl)phenyl]thiophenolatoplumbylene (3): $NaSC_6H_5$ (0.16 g, 1.21 mmol) was added portionwise, at −78 °C, to a suspension of [4-*tert*-butyl-2,6-bis(diethoxyphosphonyl)phenyl]chloroplumbylene (**2**) (0.41 g, 0.63 mmol) in THF (100 mL). After the reaction mixture had been stirred for 16 h (−78 °C to room temperature), it was decanted from an insoluble residue. The solution was then kept at −6 °C to afford **3** [0.15 g (33%)] as colorless crystals, m.p. 86 °C. ^1H NMR (400.13 MHz, $[D_8]$thf): δ = 1.26 (t, 6 H, CH_3), 1.31 (t, 6 H, CH_3), 1.36 (s, 9 H,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

CH_3), 4.02−4.23 (complex pattern, 6 H, CH_2), 4.28−4.40 (complex pattern, 2 H, CH_2), 6.86 (t, 1 H, aromatics), 7.04 (t, 2 H, aromatics), 7.33 (d, 2 H, aromatics), 8.05 (complex pattern, 2 H, aromatics) ppm. $^{13}C\{^1H\}$ NMR (100.61 MHz, [D$_8$]thf): δ = 17.7 (d, $^3J_{C,P}$ = 6 Hz, 2 C, CH_3), 17.8 (d, $^3J_{C,P}$ = 6 Hz, 2 C, CH_3), 32.4 (s, 3 C, CH_3), 36.6 (s, 1 C, C), 63.9 (d, $^2J_{C,P}$ = 6 Hz, 2 C, CH_2), 65.0 (d, $^2J_{C,P}$ = 4 Hz, 2 C, CH_2), 124.8 (s, 2 C, C_p), 129.2 (s, 2 C, C_m), 135.2 (s, 2 C, C_o), 136.9 (dd, $^2J_{C,P}$ = 17, $^4J_{C,P}$ = 4 Hz, 2 C, C-3,5), 137.2 (dd, $^1J_{C,P}$ = 195, $^3J_{C,P}$ = 25 Hz, 2 C, C-2,6), 145.3 (s, 1 C, C_i), 151.4 (t, $^3J_{C,P}$ = 13 Hz, 1 C, C-4), 239.4 (t, $^2J_{C,P}$ = 35 Hz, 1 C, C-1) ppm. $^{31}P\{^1H\}$ NMR (161.98 MHz, [D$_8$]thf): δ = 47.8 (s, $J_{P,Pb}$ = 123 Hz) ppm. $^{31}P\{^1H\}$ MAS NMR (161.98 MHz): δ = 45.5, 50.4 ppm. IR (KBr): $\tilde{\nu}$(P=O) = 1208, 1183 cm^{-1}. UV/Vis (CH_3CN): λ = 215 nm, ε = 28695 L·mol^{-1}·cm^{-1}; λ = 259 nm, ε = 13211 L·mol^{-1}·cm^{-1}. Molecular weight determination (THF, 28 °C, c = 0.0069 mol·L^{-1}): 727.7 g mol^{-1}. $C_{24}H_{36}O_6P_2PbS$ (721.8): calcd. C 39.9, H 5.0; found C 40.0, H 5.1. MS: m/z (%) = 613 (100) [M − SPh], 391 (65) [M − SPh −3 OEt − Et − tBu], FAB-MS: m/z (%) = 613 (100) [M − SPh].

[4-*tert*-Butyl-2,6-bis(diethoxyphosphonyl)phenyl](diisopropylamino)-plumbylene (4). Method A: A solution of iPr$_2$NLi in hexane/diethyl ether (3:1) (37 mL, 0.75 M) was added, at −78 °C, to a solution of 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene (7.5 g, 18.5 mmol) in THF (120 mL) and the reaction mixture was stirred at this temperature for 5 h. $PbCl_2$ (3.85 g, 13.8 mmol) was added portionwise and the suspension stirred for 16 h (−78 to −30 °C). After filtration some of the solvent (75 mL) was evaporated. Crystallization at −6 °C afforded **2**·THF [1.98 g (20%)]. The solvent was then evaporated, and the residue dissolved in hexane (50 mL). After decantation from insoluble **2** and 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene, the solvent was removed in vacuo to give 4.18 g of a yellow oil containing **4** (yield 45%, purity 83%) and residues of **2** (δ^{31}P = 52.0 ppm, 5%) and 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene (δ^{31}P = 18.4 ppm, 12%). ^1H NMR (400.13 MHz, C_6D_6): δ = 0.98 (t, 6 H, CH_3), 1.13 (s, 9 H, CH_3), 1.22 (t, 6 H, CH_3), 1.53 [s, 6 H, C(H)(CH_3)$_2$], 1.55 [s, 6 H, C(H)(CH_3)$_2$], 3.68−3.79 (complex pattern, 2 H, CH_2), 3.86−3.97 (complex pattern, 2 H, CH_2), 4.17−4.34 (complex pattern, 4 H, CH_2), 5.12−5.28 (sept, 2 H, CH), 8.20 (complex pattern, 2 H, aromatics) ppm. $^{13}C\{^1H\}$ NMR (100.61 MHz, C_6D_6): δ = 16.4 (complex pattern, $^3J_{C,P}$ = 7 Hz, 4 C, CH_3), 30.1 [s, 3 C, C(CH_3)$_3$], 31.0 [s, 4 C, C(H)(CH_3)$_2$], 34.7 (s, 1 C, C), 53.7 (s, 2 C, CH), 62.1 (d, 2 C, $^2J_{C,P}$ = 5 Hz, CH_2), 62.3 (d, 2 C, $^2J_{C,P}$ = 6 Hz, CH_2), 134.8 (dd, $^2J_{C,P}$ = 17, $^4J_{C,P}$ = 4 Hz, 2 C, C-3,5), 136.1 (dd, $^1J_{C,P}$ = 197, $^3J_{C,P}$ = 26 Hz, 2 C, C-2,6), 148.9 (t, $^3J_{C,P}$ = 13 Hz, 1 C, C-4), 236.8 (t, $^2J_{C,P}$ = 38 Hz, 1 C, C-1) ppm. $^{31}P\{^1H\}$ NMR (161.98 MHz, C_6D_6): δ = 41.7 (s, $J_{P,Pb}$ = 116 Hz) ppm. IR (KBr): $\tilde{\nu}$(P=O) = 1203 cm^{-1}. **Method B:** A solution of LDA in hexane/diethyl ether (3:1) (0.4 mL, 0.75 M) was added, at −78 °C, to a suspension of [4-*tert*-butyl-2,6-bis(diethoxyphosphonyl)phenyl]chloroplumbylene (**2**) (0.187 g, 0.289 mmol) in THF (15 mL). After the reaction mixture had been stirred for 4 h at this temperature, it was characterized by ^{31}P NMR spectroscopy. $^{31}P\{^1H\}$ NMR (81.02 MHz, D_2O capillary): δ = 18.4 [s, 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene, 5%], 41.7 (s, $J_{P,Pb}$ = 122 Hz, **4**, 83%), 52.0 (s, **2**, 12%).

[4-*tert*-Butyl-2,6-bis(diethoxyphosphonyl)phenyl]{[bis(trimethylsilyl)]methyl}plumbylene (5): LiCH(SiMe$_3$)$_2$ (0.181 g, 1.09 mmol) was added portionwise, at −78 °C, to a suspension of [4-*tert*-butyl-2,6-bis(diethoxyphosphonyl)phenyl]chloroplumbylene (**2**) (0.679 g, 1.05 mmol) in THF (50 mL). After the reaction mixture had been stirred for 16 h (−78 to −30 °C), it was filtered. Evaporation of the solvent then afforded 0.20 g (25%) of **5** as a pale yellow oil. ^1H NMR (400.13 MHz, C_6D_6): δ = −0.60 [s, 1 H, CH(SiMe$_3$)$_2$], 0.39 (s, 18 H, SiMe$_3$), 0.95 (t, 6 H, CH_3), 1.16 (s, 9 H, CH_3), 1.20 (t, 6 H, CH_3), 3.66−3.76 (complex pattern, 2 H, CH_2), 3.83−3.93 (complex pattern, 2 H, CH_2), 4.07−4.24 (complex pattern, 4 H, CH_2), 8.10 (complex pattern, 2 H, aromatics) ppm. $^{13}C\{^1H\}$ NMR (100.61 MHz, C_6D_6): δ = 5.4 (s, 6 C, SiMe$_3$), 16.3 (complex pattern, 2 C, CH_3), 16.5 (complex pattern, 2 C, CH_3), 31.1 (s, 3 C, CH_3), 34.7 (s, 1 C, C), 62.3 (complex pattern, CH_2), 62.9 [s, 1 C, C(H)(SiMe$_3$)$_2$], 134.4 (dd, $^2J_{C,P}$ = 17, $^4J_{C,P}$ = 5 Hz, 2 C, C-3,5), 135.8 (dd, $^1J_{C,P}$ = 198, $^3J_{C,P}$ = 25 Hz, 2 C, C-2,6), 149.0 (t, $^3J_{C,P}$ = 13 Hz, 1 C, C-4), 231.8 (t, $^2J_{C,P}$ = 37 Hz, 1 C, C-1) ppm. $^{31}P\{^1H\}$ NMR (161.98 MHz, C_6D_6): δ = 42.1 (s, $J_{P,Pb}$ = 125 Hz) ppm. $^{207}Pb\{^1H\}$ NMR (83.72 MHz, C_6D_6): δ = 6874 (t, $J_{P,Pb}$ = 129 Hz) ppm. IR (KBr): $\tilde{\nu}$(P=O) = 1208 cm^{-1}. MS: m/z (%) = 613 (48) [M − C(H)(SiMe$_3$)$_2$], 406 (39) [M − C(H)(SiMe$_3$)$_2$ − Pb].

[{5-*t*Bu-1,3-[P(O)(OEt)$_2$]$_2$C$_6$H$_3$}$_4$·(Pb$_2$F)] [PF$_6$]$_3$·4THF (6): [4-*tert*-Butyl-2,6-bis(diethoxyphosphonyl)phenyl]chloroplumbylene (**2**) (0.107 g, 0.165 mmol) was added portionwise, at −78 °C, to a solution of $TlPF_6$ (0.055 g, 0.157 mmol) in THF (20 mL). The reaction mixture was then stirred at −78 °C under exclusion of light for 140 min. After storage at −35 °C for 5 d, the suspension was characterized by ^{31}P NMR spectroscopy. $^{31}P\{^1H\}$ NMR (81.02 MHz, D_2O capillary): δ = 18.0 [s, 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene, 27%], 54.1 (s, 73%). After the suspension had been filtered through a diatomaceous earth filter, the solution was once more characterized by ^{31}P NMR spectroscopy. $^{31}P\{^1H\}$ NMR (161.98 MHz, D_2O capillary): δ = 17.9 [s, 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene, 88%], 54.0 (s, 12%). Crystallization at −35 °C afforded 0.13 g (29%) of **6** as colorless crystals. ^1H NMR (400.13 MHz, C_6D_6): δ = 1.14 (s, 9 H, CH_3), 1.17 (t, 12 H, CH_3), 1.45 (m, 4 H, THF), 3.61 (m, 4 H, THF), 4.10−4.26 (complex pattern, 8 H, CH_2), 8.20 (d, 2 H, aromatics), 8.81 (t, 1 H, aromatics) ppm. $^{31}P\{^1H\}$ NMR (161.98 MHz, C_6D_6): δ = 18.8 [s, 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene], −142.3 (PF_6^-) ppm. IR (KBr, inert): $\tilde{\nu}$(P=O) = 1197 cm^{-1}, $\tilde{\nu}$(OH) not observed. ESMS: m/z = 1039 [Pb + F + 2 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene]$^+$; 713 [Pb + 3 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene]$^{2+}$; 510 [2 Pb + 4 1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene]$^{4+}$; 407 [1-*tert*-butyl-3,5-bis(diethoxyphosphonyl)benzene + H]$^+$. Elemental analysis and the melting point of **6** were obtained after THF had been removed under reduced pressure (11 Torr). $C_{72}H_{128}F_{19}O_{24}P_{11}Pb_2$ (2493.9): calcd. C 34.6, H 5.2; found C 34.2, H 5.0.

The ^1H, ^{13}C, and ^{31}P NMR spectra of compound **4** and the ^1H, ^{13}C, ^{31}P, and ^{207}Pb NMR spectra of compound **5** are available.[2]

X-ray Crystallographic Study: Intensity data for the colorless crystals were collected with a Nonius KappaCCD diffractometer with graphite-monochromated Mo-K_α (0.71073 Å) radiation at 173(1) K. The data collection covered almost the whole sphere of the reciprocal space with 3 collections at different k angles with 244 (**2**), 305 (**3**), and 260 (**6**) frames via w rotation (Δ/ω = 1°) at two times 15 s (**2**), 20 s (**3**), and 30 s (**6**) per frame. The crystal-to-detector distance was 3.4 cm. Crystal decay was monitored by repeating the initial frames at the end of the data collection. Analysis of the duplicate reflections revealed no indication of any decay. The structure was solved by direct methods SHELXS-97[63] and successive difference Fourier syntheses. Refinement was applied with full-matrix least-squares methods SHELXL-97.[64] H atoms were placed in geometrically calculated positions using a riding model with U_{iso} constrained at 1.2 for non-methyl and at 1.5 for methyl groups times U_{eq} of the carrier C atom. In **3** a disordered ethoxy group was found with occupancies of 0.6 [C(14)] and 0.4 [C(14′)]. In **6**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the *tert*-butyl and the ethoxy groups are disordered over two sites with occupancies of 0.4 [C(27′), C(28′), C(29′)], 0.5 [O(3′), O(3′′), O(4′), O(4′′), C(34), C(35), C(36), C(37), C(38), O(3′A), O(3′′A), O(4′A), O(4′′A), C(34′), C(35′), C(36′), C(37′), C(38′)] and 0.6 [C(27), C(28), C(29)]. The disordered groups, one solvent molecule [O(71) to C(75)], C(16), C(30), C(31), C(32) and C(33) were refined isotropically whereas C(73), C(74), C(73′), C(73′) are disordered over two positions with an occupancy of 0.5. All solvent molecules were refined with an occupancy of 0.5 except for the disordered atoms. Atomic scattering factors for neutral atoms and real and imaginary dispersion terms were taken from the International Tables for X-ray Crystallography.[65] The figures were created by SHELXTL.[66] Crystallographic data are given in Table 2, selected bond lengths and angles for **2** and **3** in Table 1, and for **6** in Table 3. CCDC-205058 (**2**), -205059 (**3**), and -205060 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/-retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

First Examples of Ternary Lanthanide 2,2′-Diphenyldicarboxylate Complexes: Hydrothermal Syntheses and Structures of Lanthanide Coordination Polymers of 2,2′-Diphenyldicarboxylic Acid and 1,10-Phenanthroline

Yibo Wang,[a] Xiangjun Zheng,[a] Wenjuan Zhuang,[a] and Linpei Jin*[a]

Keywords: Complexes / Hydrothermal synthesis / Lanthanides / Hydrogen bonds / X-ray diffraction

In the four new lanthanide coordination polymers $\{[La_2(2,2'\text{-dpdc})_3(phen)(H_2O)]\cdot 2H_2O\}_n$ (**1**), $[Eu_2(2,2'\text{-dpdc})_3(phen)(H_2O)_2]_n$ (**2**), $\{[Ln_2(2,2'\text{-dpdc})_3(phen)_2(H_2O)_2]\cdot 4H_2O\}_n$ [Ln = Tb (**3**), Yb (**4**)] (2,2′-dpdc = 2,2′-diphenyldicarboxylate, phen = 1,10-phenanthroline), prepared by hydrothermal synthesis, the 2,2′-dpdc dianion affords tetradentate, pentadentate, and hexadentate coordination modes. Complex **1** is a two-dimensional network of infinite 1-D chains assembled through π–π interactions, with nine- and ten-coordinate La^{3+}, and arranged in wave-like layers. In **2**, Eu^{3+} possesses nine- and ten-coordinate geometries bridged by 2,2′-dpdc ligands to give a 3-D structure. The isomorphous complexes **3** and **4**, in which Tb^{3+} and Yb^{3+} ions are both nine-coordinate, have two-dimensional structures of 1-D zigzag chains stacked via hydrogen bonds and π–π interactions of phen molecules. The high-resolution emission spectrum of **2** shows two Eu^{3+} ion sites, which is consistent with the results of the X-ray crystal structure analysis.

Introduction

The design and syntheses of one-, two-, three-dimensional coordination polymers is an attractive area of research due to their structural characteristics, such as diverse coordination modes, intriguing architecture, and porosity, and also to their tremendous potential as catalysts,[1,2] luminescent materials,[3−6] in reversible guest exchange,[7−10] and magnetism.[11−14] Coordination polymers are built by the rational selection of metal ions and the use of structurally interesting ligands with specific functionality to construct metal-organic frameworks. The synthesis of coordination polymers with fascinating structures requires careful selection of the organic ligands.

Hydrogen bonds are well suited for the design of polymeric arrangement and crystal engineering because of their important directional interactions, and because they can interlink 1-D, or 2-D structures into higher-dimensionality systems.[15,16] Ligands with aromatic rings may be assembled into a supramolecular structure via π−π interactions. As a building block to construct coordination polymers, 2,2′-diphenyldicarboxylic acid (2,2′-H_2dpdc) is considered because (1) it affords various coordination modes due to its multifunctional carboxylate groups, and it can bridge metal atoms; (2) as a flexible ligand it allows the formation of multi-dimensional structures constructed from different directions; (3) it displays high reactivity to d and f elements, especially lanthanides since the carboxyl group has a strong affinity for Ln^{3+}. A few transition metal coordination polymers using 2,2′-dpdc as bridging ligand have been reported.[17,18] The coordination modes of 2,2′-dpdc ligands in these polymeric complexes are shown in Scheme 1 (a). Lanthanide ions have larger radii and higher coordination numbers than transition metals, as well as luminescent properties for fluorescent probes, and so their introduction into metal-organic frameworks may generate polymers with a distinctive molecular structure and unusual properties. In addition, phen groups can enhance the luminescent properties of lanthanide complexes. However, to the best of our knowledge, there have been no systematic studies on lanthanide supramolecular coordination polymers with the 2,2′-dpdc ligand.

The hydrothermal method is effective for the crystal growth of many coordination polymers.[19,20] Under hydrothermal conditions, the properties of the reactants and the interactions between organic and inorganic partners are quite different from those under conventional conditions in water. Therefore, various simple precursors and metastable compounds may be produced by hydrothermal reactions, and it facilitates crystal growth from solution.[21,22] Thus, we chose the 2,2′-dpdc ligand as a reactant to build multidimensional architectures by a hydrothermal reaction. Our current focus on rational synthetic strategies for lanthanide coordination polymers, using the hydrothermal method, has yielded some fascinating crystal structures with luminescent properties.[23−25] Herein, we report the syntheses and struc-

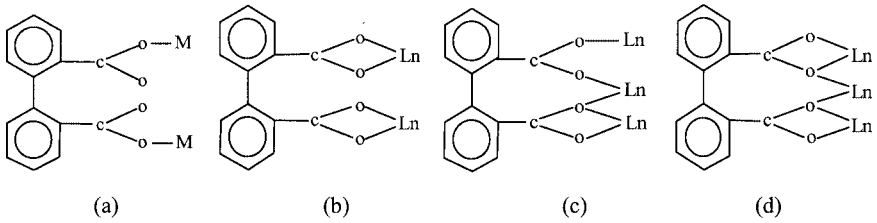

Scheme 1. Coordination modes of 2,2′-dpdc in transition metal 2,2′-dpdc complexes and complexes **1**−**4**

tures of four lanthanide complexes with 2,2′-dpdc ligand and phen ligand.

Results and Discussion

Crystal data of the title complexes (Table 1) and selected bond lengths and angles of **1**−**4** (Tables 2−4) are given here. The 2,2′-dpdc ligands are all completely deprotonated and afford three types of coordination modes (Scheme 1, b, c and d). The crystallographic analyses reveal a two-dimensional network (**1**, **3** and **4**) or a three-dimensional structure (**2**) made up of infinite 1-D chains, and that complexes **3** and **4** are isomorphous.

Crystal Structure of $\{[La_2(2,2'\text{-dpdc})_3(phen)(H_2O)]\cdot 2H_2O\}_n$ (1)

In the crystal structure of **1**, $[La_2(2,2'\text{-dpdc})_3(phen)(H_2O)]\cdot 2H_2O$, the 2,2′-dpdc ligands exhibit penta- and hexadentate coordination modes (Scheme 1, c and d). In an asymmetric unit, there are two types of environment for La^{3+} centers (Figure 1). La(1) is coordinated to ten atoms: eight carboxylate oxygen atoms (O1, O2, O1A, O4A, O5A, O6A, O11A, O12A) of three pentadentate 2,2′-dpdc ligands and one hexadentate 2,2′-dpdc ligand, and two nitrogen atoms (N1, N2) of one phen ligand. The mean La(1)−O(carboxylate) distance is 2.670 Å. La(2) is coordinated by eight carboxylate oxygen atoms (O3, O5, O7, O9, O10, O8B, O10B, O11B) of three pentadentate 2,2′-dpdc ligands and two hexadentate 2,2′-dpdc ligands, and one oxygen atom (O13) provided by a water molecule. The mean La(2)−O(carboxylate) distance is 2.568 Å. La(1) and La(2) are linked by a pentadentate 2,2′-dpdc ligand with an interatomic distance of 7.990 Å. Clearly, the steric hindrance around La(1) is greater than that around La(2) − La(1)−O(carboxylate) bonds are longer than La(2)−O(carboxylate) bonds. Influenced by the steric hindrance and coordination modes of the 2,2′-dpdc ligand and phen, the carboxylate planes of the pentadentate 2,2′-dpdc ligand connecting La(1) and La(2) deflect their aromatic rings with similar dihedral angles, 38.1° and 39.0°.

The one-dimensional chain of **1** (Figure 2) can be viewed as composed of an $\{[La_2(2,2'\text{-dpdc})_3(phen)(H_2O)]\cdot 2H_2O\}_2$ building block. In Figure 2, La1A and La1C (or La1B and La1D) are associated by two chelating-bridging carboxylate groups of two pentadentate 2,2′-dpdc ligands and are 4.487Å apart; La2C and La1A (La2D and La1B, La1C and La2A, or La1D and La2B) are linked by three carboxylate groups of two pentadentate 2,2′-dpdc ligands and one hexa-

dentate 2,2′-dpdc ligand through bridging or chelating-bridging coordination modes, and are 4.398 Å apart. La2A and La2D of two neighboring building blocks are connected by two bridging carboxylate groups of two pentadentate 2,2′-dpdc ligands and by two chelating-bridging carboxylate groups of two hexadentate 2,2′-dpdc ligands. Thus, the number of 2,2′-dpdc ligands linking two La^{3+} ions (4 for La2A and La2D, 3 for La2C and La1A, 2 for La1A and La1C, and 1 for La1A and La2A) increases with the decreasing distances between the two La^{3+} ions in the 1-D chain structure; the difference in La···La distances in **1** may be due to the different coordination modes and spatial arrangement of the 2,2′-dpdc ligands. In the chain of **1**, the lattice water molecules form strong hydrogen bonds with the carboxylate oxygen atoms of 2,2′-dpdc ligands and the coordinated water molecules simultaneously (Figure 2). The oxygen atoms of the carboxylate groups and coordinated water behave as H-bond acceptors. Thus, three types of hydrogen-bond interactions are observed (Figure 2): (1) between coordinated water (O13A) and lattice water (O15A), $O_w\cdots O_w$ (3.066 Å); (2) between lattice water (O15A) and carboxylate oxygen (O3A and O8BA), $O_w\cdots$O(carboxylate)

(3.003 Å), (3) another between lattice water (O14A) and carboxylate oxygen (O2B), $O_w\cdots O$(carboxylate) (3.033 Å). The phen molecules in a chain of **1** are parallel, but no π−π stacking interactions are found. However, the phen molecules of neighboring chains, which are stacked along the *a* axis, are parallel and 3.48 Å apart. Therefore, the chains packing in the *a* direction interdigitate to assemble into an extended network through π−π stacking interactions of phen molecules. The La^{3+} ions are arranged in a ruffled sheet parallel to the *ac* plane in waving pattern and the 2,2′-dpdc ligands and phen molecules run through the whole sheet.

Crystal Structure of $[Eu_2$ (2, 2′-dpdc)$_3$(phen)·$(H_2O)_2]_n$ (2)

Complex **2** is a 3-D structure of $[Eu_2$ (2,2′-dpdc)$_3$(phen)·$(H_2O)_2]_n$. Unlike **1**, the 2,2′-dpdc ligands in **2** present not only pentadentate and hexadentate coordination modes, but also a tetradentate one (Scheme 1, b, c, and d). The asymmetric unit of **2** also contains two crystallographically independent Eu^{3+} ions (Figure 3). Eu(1) is coordinated by three oxygen atoms (O5, O6 and O7) of two carboxylate groups of a pentadentate 2,2′-dpdc ligand, two oxygen atoms (O2, O3) of two carboxylate groups of one

hexadentate 2,2′-dpdc ligand in bridging mode, two oxygen atoms (O3A, O4A) of one carboxylate group of another hexadentate 2,2′-dpdc ligand in chelating mode, and two oxygen atoms (O11A, O12A) of a carboxylate group of a tetradentate 2,2′-dpdc ligand. The coordination sphere of Eu(2) differs from that of Eu(1) and is ten-coordinate. Around Eu(2), one tetradentate 2,2′-dpdc ligand chelates to Eu(2) through O9 and O10, one hexadentate 2,2′-dpdc ligand is simultaneously coordinated to Eu(1) and Eu(2) through O1 and O2 in chelating-bridging mode, and the pentadentate 2,2′-dpdc ligand is coordinated to Eu(1) and Eu(2) through O7 and O8 in the same mode. Of these oxygen atoms, O2 and O7 act as μ_2-oxygen atoms, connecting Eu(1) and Eu(2) with an Eu(1)···Eu(2) distance of 4.185 Å. Besides these six oxygen atoms, there are two nitrogen atoms (N1, N2) of one phen molecule and two oxygen atoms (O13, O14) of two coordinated water molecules to complete the ten-coordinate geometry of Eu(2). The mean Eu(2)−O(carboxylate) distance (2.575Å) is longer than Eu(1)−O(carboxylate) (2.465 Å), possibly because Eu(2) has a larger coordination number than Eu(1) [Eu(1) is nine-coordinate], resulting in a larger steric effect in the Eu(2) environment.

Unlike **1**, in the 1-D chain of **2**, every four Eu^{3+} (Eu2B, Eu1B, Eu1D, Eu2D), two tetradentate 2,2′-dpdc ligands, two pentadentate 2,2′-dpdc ligands and two hexadentate 2,2′-dpdc ligands fabricate one $\{[Eu_2(2,2'\text{-dpdc})_3(phen)]\cdot(H_2O)_2\}_2$ building block along the *a* axis (Figure 4). In each building block, two carboxylate groups of the hexadentate 2,2′-dpdc ligand are coordinated to

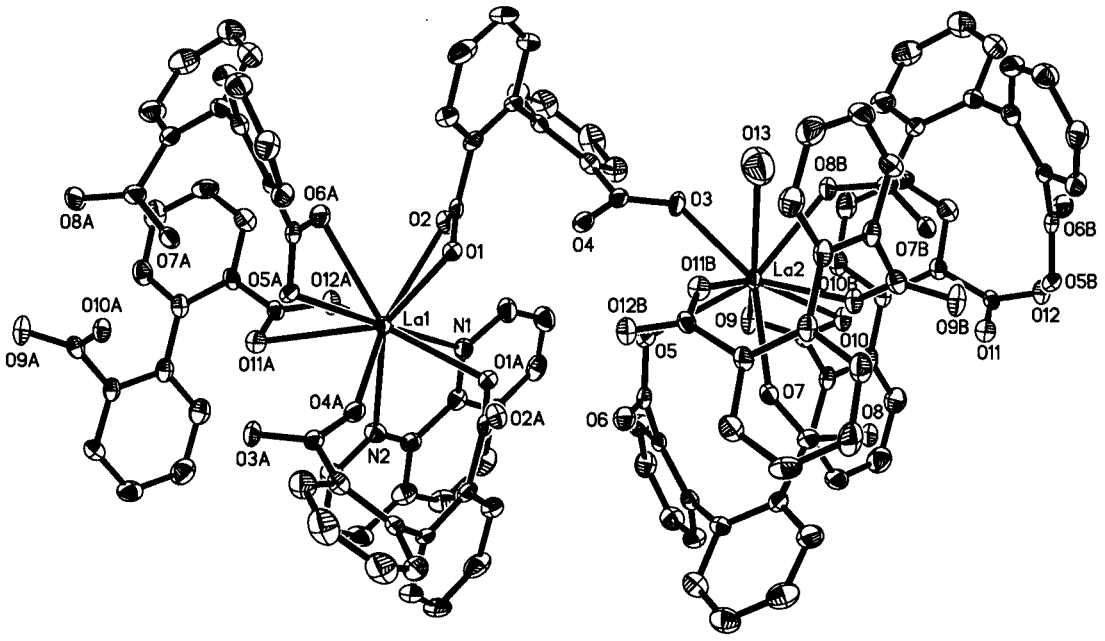

Figure 1. Coordination environment of the two La^{III} ions in **1** with thermal ellipsoids at 30% probability; all hydrogen atoms are omitted for clarity

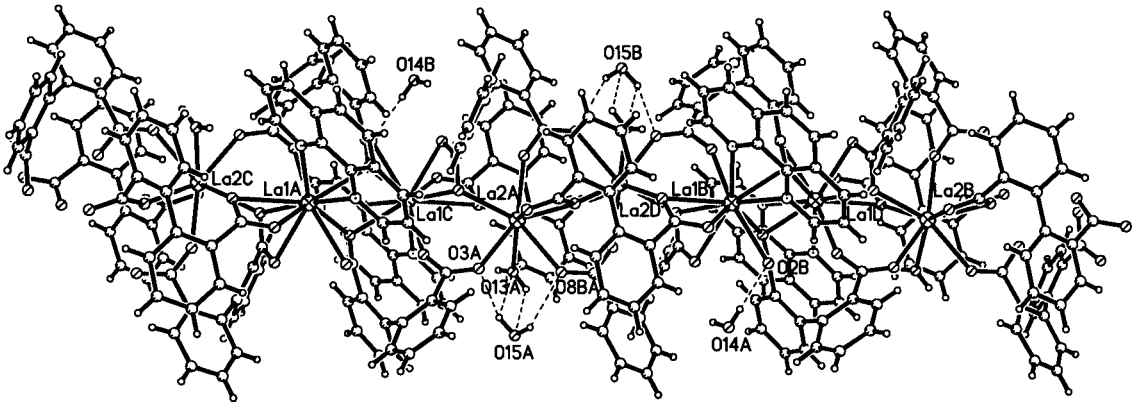

Figure 2. 1-D chain of **1** viewed along the *a* axis; hydrogen bonds containing lattice water are shown as dotted lines

three Eu^{3+} ions in chelating-bridging coordination mode. Each pentadentate 2,2′-dpdc ligand only links two Eu^{3+} ions belonging to the same asymmetric unit. Two pentadentate and two hexadentate 2,2′-dpdc ligands construct one building block through bridging four Eu^{3+} ions, while two carboxylate groups of each tetradentate 2,2′-dpdc ligand coordinate with two Eu^{3+} ions of two adjacent building blocks in chelating-bridging mode. Thus, it is tetradentate 2,2′-dpdc ligands that connect two adjacent building blocks, forming a 1-D infinite chain along the *a* axis. The phen molecules of adjacent chains are parallel and stacked next to each other (3.47 Å apart). The carbon atoms of these parallel phen molecules are also involved in weak C−H···O hydrogen bonds with the carboxylate oxygen atoms of 2,2′-dpdc ligands, and the C···O(carboxylate) distances are all 3.198 Å (Figure 5). Consequently, a three-dimensional supramolecular polymer is generated not only by coordination bonds but also by intermolecular hydrogen bonds and interchain π−π interactions.

Crystal Structure of $\{[Ln_2(2,2'\text{-dpdc})_3(phen)_2(H_2O)_2]\cdot 4H_2O\}_n$ [Ln=Tb (3), Yb (4)]

Since complexes **3** and **4** are isomorphous we will only describe the crystal structure of **3**. In **3**, each 2,2′-dpdc ligand shows the tetradentate coordination mode only (Scheme 1, b). Each Tb^{3+} is nine-coordinate and the coordination geometry is roughly a tricapped trigonal prism. Around each Tb center are two nitrogen atoms (N1, N2) of one phen, six carboxylate oxygen atoms (O1, O2, O3A, O4A, O6, O7) of three chelating carboxylate groups of three tetradentate bridging 2,2′-dpdc ligands, and one oxygen atom (O5) of coordinated water (Figure 6). The mean Tb−O(carboxylate) distance (2.453 Å) is longer than those in $[Tb_2(BDC)_3(H_2O)_4]_n$ [3] and $[Tb_2(oba)_3(2,2'\text{-bpy})_2]_n$,[27]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

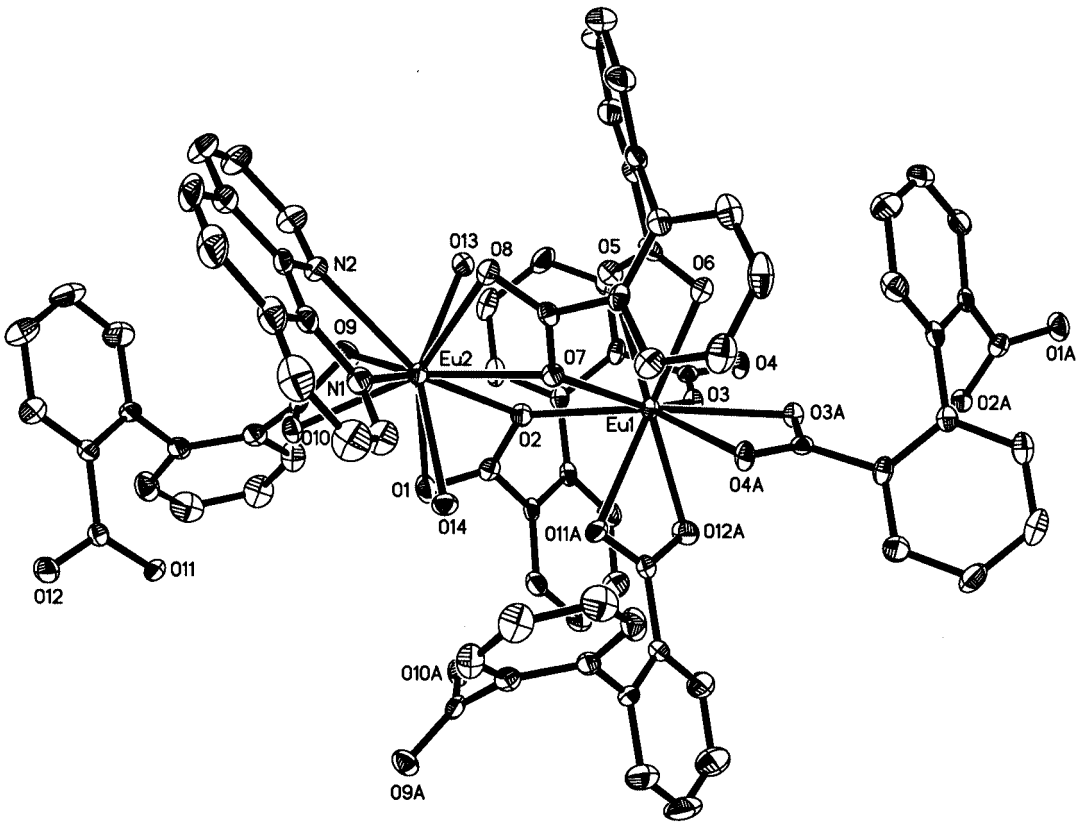

Figure 3. Coordination environment of the two Eu^{III} ions in **2** with thermal ellipsoids at 30% probability; all hydrogen atoms are omitted for clarity

which may be due to the larger steric hindrance of 2,2′-dpdc ligands and phen molecules. The coordination environment shows that there are three tetradentate 2,2′-dpdc ligands to chelate each Tb^{3+}, which is fewer than the 2,2′-dpdc ligands coordinated with La^{3+}. In addition, the 2,2′-dpdc ligand presents a tetradentate coordination mode to furnish the nine-coordinate coordination geometry in **3** and **4** because of the smaller radii of Tb^{3+} and Yb^{3+} ions.

In **3**, the dinuclear species $[Tb_2(2,2'\text{-dpdc})_3(phen)_2(H_2O)_2]\cdot 4H_2O$ is centrosymmetric, and these units are linked through 2,2′-dpdc ligands; a 1-D infinite zigzag chain is then constructed through coordination bonds. In each dinuclear motif, there are three chelating-bridging tetradentate 2,2′-dpdc ligands and two phen molecules coordinated to two Tb^{3+} ions. Two Tb^{3+} ions are linked by two chelating-bridging tetradentate 2,2′-dpdc ligands with a $Tb^{3+}\cdots Tb^{3+}$ distance of 6.992 Å. Two neighboring $[Tb_2(2,2'\text{-dpdc})_3(phen)_2(H_2O)_2]\cdot 4H_2O$ dinuclear motifs are connected by the third 2,2′-dpdc ligand by four $Tb^{3+}-O$(carboxylate) bonds. Two adjacent Tb^{3+} ions of two different dinuclear motifs are 6.317 Å apart.

In the 2-D network of **3**, there are hydrogen bonds between a coordination carboxylate atom (O7AD) and the C−H of a phen molecule (C8FC) of a neighboring chain, C···O(carboxylate) (3.313 Å). At the same time, the adjacent chains are stacked in a staggered fashion along the *b* axis through π−π interactions between phen molecules of two neighboring chains (3.434 Å apart). Hence, phen is crucial to the formation and stabilization of the structure of **3** because of its simultaneous participation in formation of the hydrogen bonds and π−π interactions. Thus, a two-dimensional layered supramolecular array parallel to the *bc* plane is constructed with the chains pulled together by a series of interchain hydrogen bonds and π−π interactions along the *b* axis (Figure 7). The Tb^{3+} ions are distributed on the layer in an undulating way and the Tb···Tb distance of neighboring chains is 12.104 Å. The 2,2′-dpdc ligands and phen interdigitate the whole undulating plane.

In terms of the structural characteristics and the formation of the supramolecular architecture of the title complexes, several parallels can be obtained: (1) Each complex has one or two coordinated water molecules to meet the high coordination number of Ln^{III} ions. (2) Much lattice water is held within the 1-D chains of **1**, **3** and **4**, therefore extensive intramolecular hydrogen bonds are formed among lattice water molecules, coordinated water molecules and carboxylate groups, which further stabilize the 1-D chain structure. Therefore, water molecules not only act as a reaction medium in the formation of these supramolecular structures, but also contribute positively to the interaction with 2,2′-dpdc ligands by hydrogen bonds. (3) The 2-D network (for **1**, **3** and **4**) and the 3-D structure (for **2**) are all constructed by 1-D chains linked through hydrogen bonds and packed by π−π interactions between phen molecules of adjacent chains (for **1**, **2**, **3**, and **4**). However, the title complexes also exhibit considerable differences with regard to

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

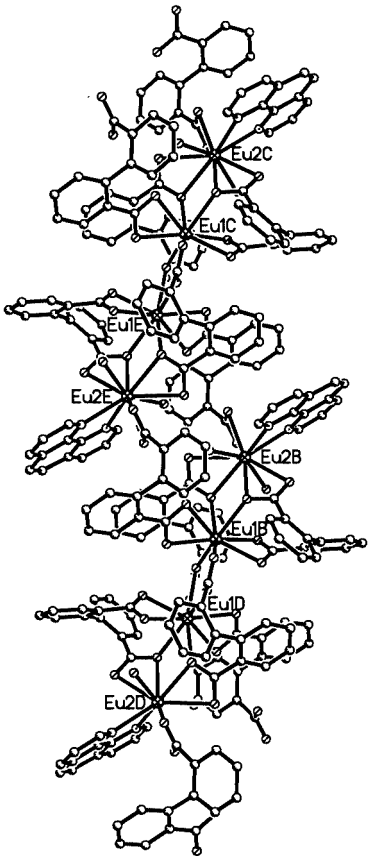

Figure 4. 1-D chain of **2** viewed along the *b* axis; all hydrogen atoms are omitted for clarity

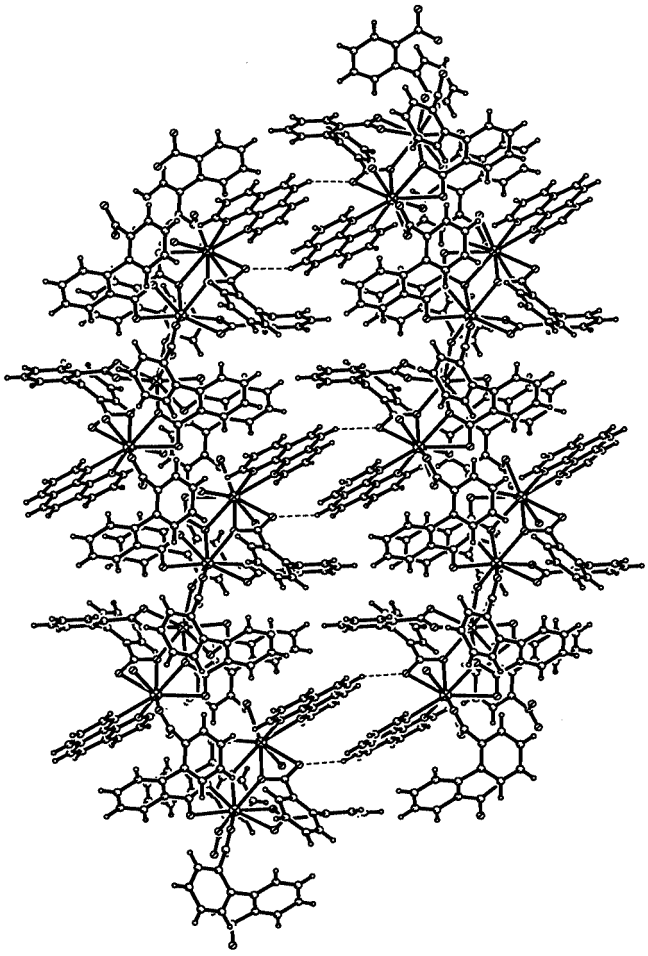

Figure 5. 2-D structure of **2** viewed along the *a* axis; hydrogen bonds are shown as dotted lines

the lattice water, hydrogen bonds, and π−π interactions. One difference is the absence of lattice water within the structure of **2** and, correspondingly, no O···H−O hydrogen bonds are observed. In addition, a 3-D network of **2** is formed by O···C−H (phen) hydrogen bonds and π−π interactions of phen from different orientations.

Lanthanide contraction clearly effects the formation and crystal structure of the title compounds. First, the Ln−O bond lengths decrease with increasing lanthanide atomic number: the mean Ln−O(carboxylate) distance follows the order La−O(carboxylate) > Eu−O(carboxylate) > Tb−O(carboxylate) > Yb−O(carboxylate); the mean Ln−O_w distances are 2.736, 2.466, 2.403, and 2.316 Å for La, Eu, Tb, and Yb, respectively. Similarly, the mean Ln−N distances are 2.768, 2.620, 2.540, and 2.478 Å for La, Eu, Tb, and Yb, respectively. Secondly, the coordination number and the number of 2,2′-dpdc ligands around Ln^{3+} all decrease with decreasing ionic radii of the lanthanides. Thirdly, the variations in coordination modes of 2,2′-dpdc ligands in these complexes are connected with the decreasing ionic radii of the La^{3+}, Eu^{3+}, Tb^{3+} and Yb^{3+} ions. As La^{3+} has the largest ionic radius in **1**−**4** the 2,2′-dpdc ligands adopt pentadentate and hexadentate coordination modes in **1** (Scheme 1, c and d). The tetradentate and pentadentate coordination modes of 2,2′-dpdc ligands in **2** (Scheme 1, b and c) and the tetradentate coordination modes of 2,2′-dpdc ligands in **3** and **4** reflect the decreasing

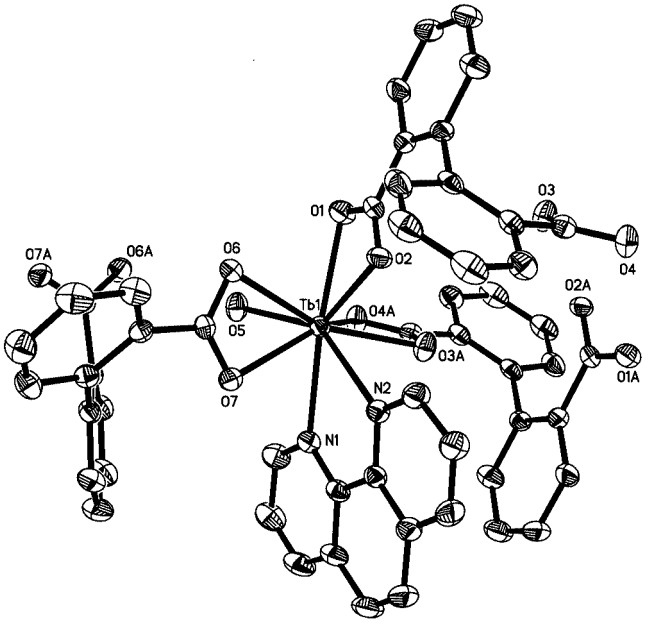

Figure 6. Coordination environment of the Tb^{III} ion in **3** with thermal ellipsoids at 30% probability; all hydrogen atoms are omitted for clarity

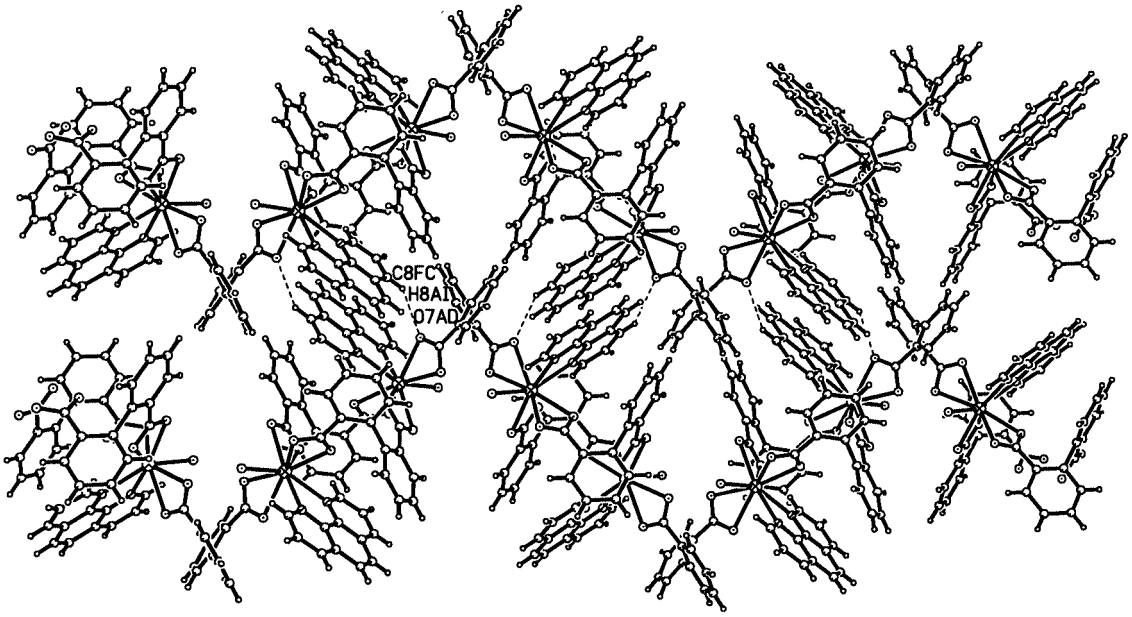

Figure 7. 2-D network of **3** viewed along the *a* axis

ionic radii of the respective lanthanides with increasing atomic number. These results are all in line with lanthanide contraction.

Contrasting the title complexes with binary lanthanide 2,2′-diphenyldicarboxylate complexes,[25] the mean Ln−O(carboxylate) distances for La, Eu and Tb in the title complexes are all longer than those in the binary complexes. Obviously, this is due to the steric hindrance of phen molecules. Similarly, because of the participation of phen molecules, the title complexes exhibit 2-D (**1**, **3** and **4**) or 3-D (**2**) supramolecular architectures constructed by 1-D chains through hydrogen bonds of neighbouring chains, while the binary complexes show 1-D chain structures. As regards 2,2′-dpdc ligands, there is a hexadentate coordination mode in the title complexes that is not present in the binary lanthanide complexes (Scheme 1, d). In addition, the tetradentate coordination mode of 2,2′-dpdc ligands in the binary complexes is quite different from that in the title complexes.

Photophysical Properties of 2

Eu^{3+} complexes can undergo characteristic Eu^{3+} ion emission when excited, and Eu^{3+} is usually regarded as a structural probe to determine the local ion sites based on its unique nondegenerate lowest emission level of $^5D_0$. In the asymmetric unit of the coordination polymer **2**, the two Eu^{3+} ions have obviously different coordination environments: one is coordinated by phen, while the other is not, which led us to probe its local structure in detail.

Figure 8 illustrates the emission spectrum of **2** corresponding to $^5D_0 \rightarrow {}^7F_J$ ($J = 0-4$) transitions in the range of 13900−17300 cm^{-1} at 77 K, in which the $^5D_0 \rightarrow {}^7F_3$ transition is too weak to be observed. The apparent four peaks corresponding to the $^5D_0 \rightarrow {}^7F_1$ transition and the

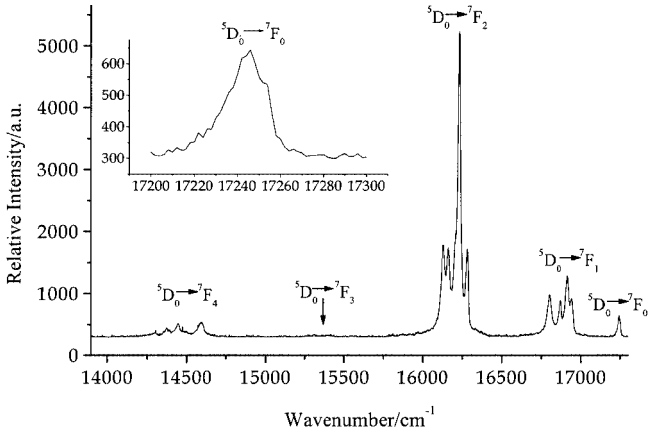

Figure 8. Emission spectrum of **2** corresponding to $^5D_0 \rightarrow {}^7F_J$ ($J = 0-4$) transitions at 77 K, $\lambda_{exc} = 355$ nm

shoulder at the peak (Figure 8, insert) corresponding to the $^5D_0 \rightarrow {}^7F_0$ transition both imply that there is more than one Eu^{3+} ion site in **2**. To further investigate the Eu^{3+} ion sites in the coordination polymer, selective excitation technology was applied. The excitation spectra (Figure 9, a and b) at 77 K were obtained by setting 16235 and 16204 cm^{-1} as the analyzing wavenumbers. Scanning in the range of 578.0−581.0 nm revealed two sharp excitation peaks, which show that there are two Eu^{3+} ion sites,[28] located at 579.58 nm and 579.84 nm, respectively, which is in good agreement with the results of X-ray diffraction.

Conclusion

Complexes **1**−**4** exhibit 2-D (**1**, **3**, and **4**) and 3-D (**2**) structures, and **3** and **4** are isomorphous. The 2,2′-dpdc li-

gands in these complexes adopt tetradentate, pentadentate and hexadentate coordination modes. The components of the building blocks for the title complexes, the coordination mode of the carboxylate groups, Ln−O and Ln−N distances, and the coordination number all clearly indicate the effect of lanthanide contraction on the formation and structure of the ternary lanthanide 2,2′-diphenyldicarboxylate complexes with 1,10-phenanthroline. Utilizing the characteristic emission of Eu^{3+} ions as a conformation probe, we confirm that there are two Eu^{3+} ion sites in **2**. Finally, the phen molecule clearly contributes to the formation of 2-D and 3-D structures in the title complexes.

Experimental Section

General: Materials: $LaCl_3·7H_2O$, $EuCl_3·6H_2O$, $TbCl_3·6H_2O$, and $YbCl_3·6H_2O$ were prepared by dissolving their respective oxides in hydrochloric acid followed by drying. 2,2′-Diphenyldicarboxylic acid was purchased from Aldrich and used without further purification. All the other reagents were commercially available and used as received. Instrumentation: Elemental analyses were performed with an Elementar Vario EL analyzer. The IR spectra were recorded with a Nicolet Avatar 360 FT-IR spectrometer as KBr pellets. For the emission studies, the excitation light source was a YAG-Nd laser that emits at 1.064 μm, and the excitation wavelength was 355 nm. The sample was placed in a Dewar, cooled with liquid nitrogen, and the fluorescence was collected at right angles through a Spex 1403 monochromator with a photomultiplier tube, then averaged by Boxcar integrator and, finally, the data were transferred to a computer.

X-ray Crystallographic Study: X-ray single-crystal data collection for complexes **1**, **2**, **3** and **4** was performed with a Bruker Smart 1000 CCD diffractometer, using graphite-monochromated Mo-K_α radiation (λ = 0.71073Å). Semiempirical absorption corrections were applied using the SADABS program. The structures were solved by direct methods and refined by full-matrix least-squares on $|F|^2$ using the SHELXTL-97 program.[26] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were generated geometrically and treated by a mixture of independent and constrained refinement. CCDC-201295 to -201298 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Syntheses

$\{[La_2(2,2'\text{-dpdc})_3(phen)(H_2O)]·2H_2O\}_n$ (1): A mixture of $LaCl_3·7H_2O$(0.111 g, 0.3 mmol), 2,2′-diphenyldicarboxylic acid (0.109 g, 0.45 mmol), phen·H_2O (0.059 g, 0.3 mmol), H_2O (10 mL), and an aqueous solution of NaOH (0.625 mL, 0.4 mmol) was heated in a stainless-steel reactor (23-mL capacity) with a Teflon liner at 170 °C for 3 d and then slowly cooled to room temperature by air cooling. The yellowish crystals so obtained were collected by filtration, washed with ethanol, and then air-dried to give a 57.9% yield (0.107 g). $C_{54}H_{38}La_2N_2O_{15}$ (1232.68): calcd. C 52.62, H 3.11, N 2.27; found C 52.85, H 2.68, N 2.09. IR (KBr pellet): $\tilde{\nu}$ = 3436 (m), 1600 (s), 1577 (s), 1544 (s), 1442 (s), 1406 (s), 756 (m), 730 (m) cm^{-1}.

$[Eu_2(2,2'\text{-dpdc})_3(phen)·(H_2O)_2]_n$ (2): A mixture of $EuCl_3·6H_2O$-(0.11 g, 0.3 mmol), 2,2′-diphenyldicarboxylic acid (0.109 g, 0.45 mmol), phen·H_2O (0.059 g, 0.3 mmol), H_2O (10 mL), and aqueous solution of NaOH (0.56 mL, 0.366 mmol) was heated in a stainless-steel reactor (23-mL capacity) with Teflon liner at 190 °C for 3 d and then slowly cooled to room temperature by air-cooling. The resultant flesh-colored crystals were collected by filtration, washed with ethanol, and then air-dried; 62.3% yield (0.116 g). $C_{54}H_{36}Eu_2N_2O_{14}$ (1240.77): calcd. C 52.27, H 2.93, N 2.26; found C 52.78, H 2.58, N 2.04. IR (KBr pellet): $\tilde{\nu}$ = 3551 (m), 1621 (s), 1552 (s), 1525 (s), 1442 (s), 1407 (s), 772 (m), 762 (m) cm^{-1}.

$\{[Ln(2,2'\text{-dpdc})_{1.5}(phen)(H_2O)]·2H_2O\}_n$ [Ln = Tb (3), Yb (4)]: The syntheses of complexes **3** and **4** followed the same procedure as for **2.** Colorless and pale yellow crystals of **3** and **4**, respectively, were obtained by filtration and washed with ethanol, then air-dried to give yields of 53.1% (0.061 g) and 58.3% (0.067 g), respectively. $C_{33}H_{26}N_2O_9Tb$ (**3**) (753.54): calcd. C 52.57, H 3.48, N 3.723; found C 52.54, H 3.01, N 3.43. IR (KBr pellet): $\tilde{\nu}$ = 3423 (m), 1600 (s), 1576 (s), 1544 (s), 1477 (s), 1408 (s), 766 (m), 728 (m) cm^{-1}. $C_{33}H_{26}N_2O_9Yb$ (**4**) (767.58): calcd. C 51.61, H 3.42, N 3.65; found C 51.46, H 3.24, N 3.60. IR (KBr pellet): $\tilde{\nu}$ = 3422 (m), 1600 (s), 1577 (s), 1546 (s), 1479 (s), 1412 (s), 766 (m), 726 (m) cm^{-1}.

Organic Functional Group Transformations in the Periphery of a Group-4 Metallocene Complex: 2*H*-Pyrrole Formation at a Pendant Boron Lewis Acid

Michael Hill,[a] Gerald Kehr,[a] Roland Fröhlich,[a][‡] and Gerhard Erker*[a]

Keywords: Boron / Hydroboration / Lewis acids / Tautomerism / Zirconium

The allyl-substituted *ansa*-zirconocene dichloride [$Me_2Si(C_5H_4)(C_5H_3CH_2CH{=}CH_2)ZrCl_2$] (**1**) cleanly adds the borane 9-BBN to the allyl C=C double bond to yield the corresponding hydroboration product **2**. The borane $HB(C_6F_5)_2$ (**3**) is also added regioselectively to **1** to yield [$Me_2Si(C_5H_4)\{C_5H_3(CH_2)_3B(C_6F_5)_2\}ZrCl_2$] (**4**). The strongly electrophilic boron Lewis acid in **4** adds 2-methyl-4,5-dihydrooxazole to yield **6**. Treatment of **4** with pyrrole results in the formation of the respective borane adduct **7** of the pyrrole tautomer 2*H*-pyrrole. The 2*H*-pyrrole ligand in **7** is deprotonated at C-2 upon treatment with pyridine, followed by proton transfer and replacement of pyrrole with formation of the corresponding pyridine adduct **12**. The complexes **1**, **4** and **7** were characterized by X-ray diffraction.

Introduction

There are numerous examples showing that typical organic functional group chemistry can be carried out at the Cp ligands of many transition metals from the middle and the right-hand side of the Periodic Table.[1] This is much more difficult to achieve in the case of the Group-4 metallocenes (and the corresponding complexes of the oxophilic f-block elements). Functional group chemistry here is usually carried out at the stage of the free ligand. Usually the functionalized Cp ligands are then subsequently attached to the respective metal centre.[2,3] Introduction of functional groups at the Cp rings of Cp_2ZrCl_2, for example, or conversion of functional groups at the zirconocene Cp rings is much more difficult, and consequently only a limited number of examples of such chemistry has so far been described in the literature. Noteworthy examples include Mannich-type enamine coupling reactions[4] and photochemical [2+2] cycloadditions,[5] both producing novel variants of *ansa*-metallocenes. The olefin metathesis reaction has been used for intra- and intermolecular carbon coupling reactions at bent metallocenes.[6] Moreover, various types of borylation[7] and hydroboration reactions[8] have been shown to be compatible with the general chemical features of many Group-4 metallocene complexes and related systems. We have now used such a reaction to attach a highly electrophilic borane at a Cp side chain of an *ansa*-metallocene and to carry out Lewis acid promoted reactions at the boron centre in the direct vicinity of the mildly electrophilic Group-4 metal centre. A first example is described in this article. We hope that our findings may contribute to the eventual development of novel bifunctional transition metal/main group element systems well suited for selective organic reactions, that may otherwise be hard to achieve, within such specific frameworks.

Results and Discussion

We had previously shown that [(allyl-C_5H_4)Cp] zirconium dichloride complexes can be cleanly hydroborated at the pendant allyl group.[8] Piers recently showed that similar $HB(C_6F_5)_2$[9] additions at such systems were feasible.[10] Such hydroboration reactions at open, unbridged Group-4 metallocenes (and at some related "constrained geometry" Zr complexes[10]) provided the synthetic basis for this work. We have now extended these reactions to the allyl-substituted rigid *ansa*-metallocene dichloride complex **1**. In contrast to the previously employed unbridged bent metallocenes,[8,10] the system **1** is no longer conformationally flexible but has its pendant functional group oriented towards the (chemically active) front side of the bent metallocene wedge.

Complex **1** was prepared as recently described by us[11] by adaptation of established literature procedures.[12] The X-ray crystal structure analysis of **1** was carried out and described previously.[11]

Treatment of **1** with 9-BBN was carried out in toluene at room temperature. The reaction was rather slow and required overnight stirring to go to completion. The hydroborated product **2** was isolated as a solid in almost quantitative yield. Complex **2** contains a chiral *ansa*-metallocene backbone, and therefore shows a total of seven ^1H NMR

methine signals of the two substituted Cp-type ligands [δ = 6.61, 5.91, 5.54 (C_5H_3), 7.02, 6.92, 5.98, 5.82 (C_5H_4) ppm] and a 1:1 intensity pair of Si−CH_3 signals (δ = 0.72, 0.69 ppm). It also shows three distinct ^{1}H NMR multiplets for the connecting trimethylene bridging unit (δ = 2.69, 1.75, 1.40 ppm) and the signals of the BBN residue.

Single crystals suitable for the X-ray crystal structure determination of **2** were obtained from a dichloromethane solution at −30 °C. In the solid state, complex **2** has a rigid *ansa*-metallocene framework. Because of the geometric constraints in such a system the Zr−C(Cp) bond lengths vary from 2.443(3) to 2.596(3) Å inside the C_5H_3 unit and from 2.471(3) to 2.535(3) Å inside the Zr(C_5H_4) moiety. The smaller values are found at the narrow backside of the bent metallocene wedge oriented toward the $SiMe_2$ unit. The C1−Si and C8−Si bond lengths are 1.866(3) and 1.862(3) Å, respectively. These (sp^2)C−Si bonds are slightly longer than the adjacent (sp^3)C−Si linkages [C6−Si 1.846(4) Å, C7−Si 1.849(4) Å], which is an additional indication that the *ansa*-metallocene framework is strained. The C1−Si−C8 angle is found at 93.6(1)° and the Cp(centroid)−Zr−Cp(centroid) angle in **2** is 126.0°. The Cl1−Zr−Cl2 angle is in the normal range at 99.60(4)°.

The attached −$(CH_2)_3$−BBN side chain is pointing toward the open front side of the bent metallocene wedge [C11−C13 1.499(5) Å] and is arranged at a maximum extension such as to bring the bulky −BBN group away from the $ZrCl_2$ unit (see Figure 1). This extended conformational arrangement is characterized by the corresponding dihedral angles C12−C11−C13−C14 −85.0(4)°, C11−C13−C14−C15 −179.2(3)°, and C13−C14−C15−B −172.3(4)°.

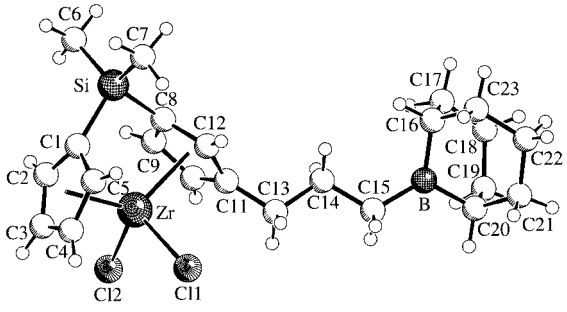

Figure 1. A view of the molecular geometry of complex **2**; selected bond lengths [Å] and angles (°): Zr−Cl1 2.431(1), Zr−Cl2 2.431(1), Si−C1 1.866(3), Si−C8 1.862(3), Si−C6 1.846(4), Si−C7 1.849(4), C11−C13 1.499(5), C13−C14 1.526(5), C14−C15 1.517(5), C15−B 1.555(6), B−C16 1.569(6), B−C20 1.566(6); Cl1−Zr−Cl2 99.60(4), C1−Si−C8 93.6(1), C1−Si−C6 112.6(2), C1−Si−C7 110.8(2), C8−Si−C6 112.7(2), C8−Si−C7 110.4(2), C6−Si−C7 114.8(2), C11−C13−C14 111.5(3), C13−C14−C15 113.6(3), C14−C15−B 118.3(3), C15−B−C16 126.3(4), C15−B−C20 122.5(4), C16−B−C20 111.1(4)

From its monomer/dimer equilibrium[9] the borane $HB(C_6F_5)_2$ (**3**) reacts much more rapidly with **1**. The hydroboration reaction was complete after ca. 30 min at room temperature in toluene solution, and the product **4** was isolated in a close to quantitative yield. It shows NMR spectroscopic features very similar to those of **2**, which let us assume that both complexes have similar structures. The chiral metallocene core shows a total of seven ^{1}H NMR methane signals, at δ = 6.56, 5.87, 5.47 (C_5H_3) and 7.00, 6.92, 5.96, 5.80 (C_5H_4) ppm. The ^{1}H NMR resonances of the trimethylene side chain of **4** occur at δ = 2.72, 1.96 and 1.80 ppm, with corresponding ^{13}C NMR features at δ = 32.3, 30.9 and 25.5 ppm. As would be expected, the pair of C_6F_5 groups at the boron atom behaves in symmetry-equivalent fashion in solution, producing a single set of *o*-, *p*- and *m*-^{19}F resonances at δ = −130.2, −148.6 and −160.8 ppm, respectively. The strongly electrophilic boron centre does not interact with the $ZrCl_2$ moiety in **4**. The ^{11}B NMR chemical shift of δ = 75.6 ppm ($\nu_{1/2} \approx 190$ Hz) indicates the presence of a coordinatively unsaturated tricoordinate boron centre [similarly to $B(C_6F_5)_3$:[13] δ(^{11}B) = 60.0 ($\nu_{1/2} \approx 400$ Hz); in contrast the dimeric $[HB(C_6F_5)_2]_2$ reagent features δ(^{11}B{^{1}H}) = 19.5 ($\nu_{1/2} \approx$ 320 Hz), as would be expected for a dimeric doubly H-bridged structure with two tetracoordinate boron atoms present].

Complex **4** reacts rapidly with a variety of two-electron donor ligands.[14] A typical product is the 2-methyl-4,5-dihydrooxazole adduct **6**, the molecular structure of which is depicted in Figure 2. Complex **6** was formed readily by treatment of **4** with the heterocyclic donor ligand in toluene solution at room temperature (see the Exp. Sect. for details). The attached trimethylene chain again adopts a fully extended "zigzag" conformation featuring a series of antiperiplanar conformational arrays [dihedral angles C11−C13−C14−C15 −175.4(2)°, C13−C14−C15−B −176.6(2)°]. This arrangement resembles the conformation of the side chain in **4** (see above and Figure 1), except that its torsional orientation relative to the adjacent Cp ring is quite different. In **4** (see above), the substituent chain is rotated *away* from the Cp plane, whereas in **6** it is rotated almost by 90° so that the w-shaped carbon skeleton of the side chain is now lying almost coplanar with its adjacent C8−C11 η^5-C_5H_4 ring [dihedral angle C10−C11−C13−C14 −25.8(3)°]. This brings the boron centre in the adduct **6** much closer to the zirconium atom (B···Zr separation in **6**: 6.395Å, in **2**: 7.621Å) and it brings the attached heterocycle almost in a direct opposition to the $ZrCl_2$ unit at the front side of the bent metallocene unit. The corresponding dihedral angles are −77.5(3)° (C14−C15−B−N1) and −2.8(4)° (C15−B−N1−C18). The bonding features of the dihydrooxazole heterocycle have not changed much upon complexation to the boron atom [N1−C16 1.277(3) Å, C16−O1 1.323(3) Å, N1−C18 1.507(4) Å].[15] The N1−B bond length is 1.626(4) Å, which is similar to the adjacent B−C bond lengths [B−C(aryl) 1.651(4) and 1.664(4) Å; B−C15 1.636(4) Å]. The N−B−C15 bond angle was found to be 110.1(2)°. The remaining bond angles at the boron atom were found to lie in a range between 105.0(2)° (N1−B−C31) and 114.0(2)° (C21−B−C31). With regard to their conformational orientation, the B−N vector is oriented almost coplanar with the C21−C26 aryl plane [dihedral angle C22−C21−B−N1 14.3(3)°] whereas it adopts a gauche orientation with the C31−C36 aryl ring [C32−C31−B−N1 −69.5(3)°].

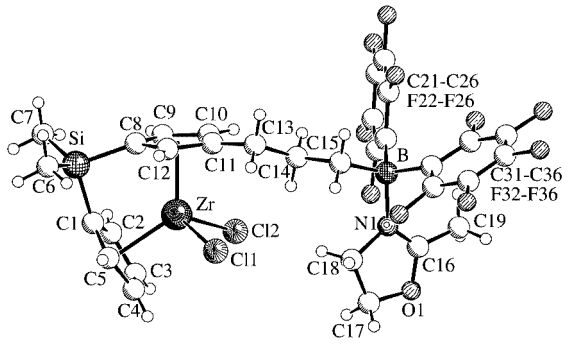

Figure 2. Molecular structure of the adduct **6**; selected bond lengths [Å] and angles [°]: Zr−Cl1 2.440(1), Zr−Cl2 2.445(1), Si−C1 1.868(2), Si−C8 1.877(2), Si−C6 1.847(3), Si−C7 1.846(3), C11−C13 1.501(3), C13−C14 1.527(3), C14−C15 1.528(3), C15−B 1.636(4), B−N1 1.626(4), B−C21 1.651(4), B−C31 1.664(4), N1−C16 1.277(3), N1−C18 1.507(4), C16−O1 1.323(3), C16−C19 1.467(4), O1−C17 1.451(4), C17−C18 1.491(4); Cl1−Zr−Cl2 95.56(3), C1−Si−C8 93.8(1), C1−Si−C6 110.9(1), C1−Si−C7 112.6(1), C8−Si−C6 112.7(1), C8−Si−C7 111.7(1), C6−Si−C7 113.5(1), C11−C13−C14 113.3(2), C13−C14−C15 114.1(2), C14−C15−B 115.8(2), C15−B−N1 110.1(2), C15−B−C21 106.4(2), C15−B−C31 110.1(2), N1−B−C21 111.2(2), N1−B−C31 105.0(2), C21−B−C31 114.0(2), B−N1−C16 128.9(2), B−N1−C18 123.4(2), C16−N1−C18 107.7(2), N1−C16−O1 116.5(3), N1−C16−C19 127.6(3), C19−C16−O1 115.9(2), C16−O1−C17 107.6(2), O1−C17−C18 105.3(2), C17−C18−N1 102.9(2)

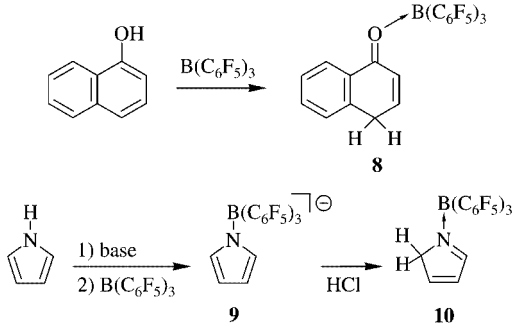
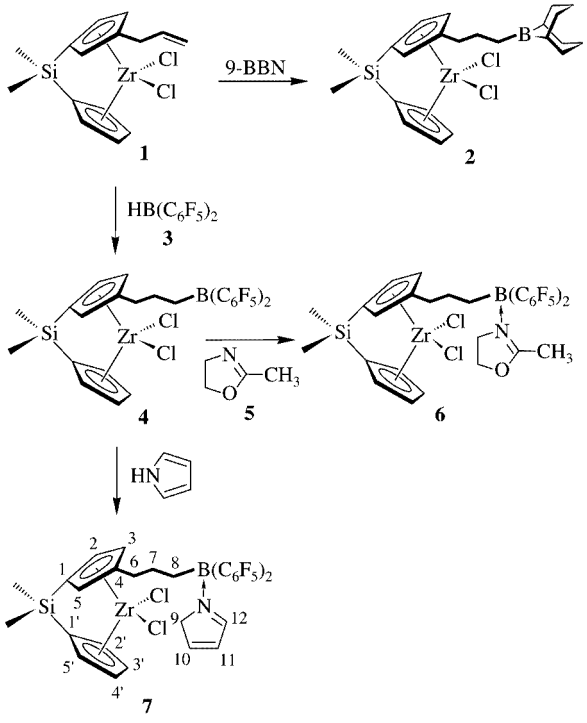
We had previously shown that unstable tautomers of a variety of aromatic and heteroaromatic compounds can be formed and stabilized by coordination to the strong organometallic Lewis acid $B(C_6F_5)_3$. The first examples included the α-naphthol/benzocyclohexadienone tautomerism (see Scheme 1).[16] We have also formed the 2*H*-pyrrole tautomer from its parent hetarene in the $B(C_6F_5)_3$ coordination sphere by a three-step procedure involving deprotonation at the nitrogen atom, attachment at the boron atom, and then protonation at the carbon atom to yield the 2*H*-pyrrole/$B(C_6F_5)_3$ adduct **10**.[17] Resconi has recently found a direct route yielding examples of the compound type **10** by treatment of pyrrole derivatives with $B(C_6F_5)_3$.[18]



Scheme 1

We were able to carry out such a pyrrole/2*H*-pyrrole tautomerism reaction at the *ansa*-zirconocene−trimethylene−$B(C_6F_5)_2$ complex **7**. A mixture of **4** and pyrrole was stirred in toluene/diethyl ether solution at room temperature for 18 h. During this time a close to quantitative conversion of the hetarene took place, with formation of the 2*H*-pyrrole adduct **7**. The coordination of the "isopyrrole tautomer" to the boron atom was apparent from the characteristic NMR spectra. The 2*H*-pyrrole moiety gave rise to a set of three methine ^{1}H NMR signals, one at rather low field (δ = 7.65 ppm, −N=C*H*−), the other two at δ = 6.42 ppm (10-H, see Scheme 2) and 5.61 (11-H) [corresponding ^{13}C NMR signals at δ = 169.3 (−N=*C*H−), 127.1 (C-11), 154.2 ppm (C-10)]. The remaining $N-CH_2$ group gives rise to a characteristic AB pattern at δ = 3.72 and 3.68 ppm ($^2J_{H,H}$ = 27 Hz, ^{13}C signal at δ = 65.0 ppm). The diastereotopic splitting of the 9-H/H′ ^{1}H NMR resonance of the 2*H*-pyrrole moiety is due to the chirality of the metal complex backbone. This also becomes evident in **7** in the partial splitting of the 7-H/H′ (δ = 1.52/1.36) and 8-H/H′ (δ = 1.36/1.21) signals of the bridging trimethylene unit (6-H/H′ ^{1}H NMR resonance at δ = 2.83 ppm). As would be expected, a 1:1 intensity pair of $SiMe_2$ ^{1}H NMR methyl resonances is observed for **7** (δ = 0.14 and 0.08 ppm). The diastereotopic splitting is even extended into the $B(C_6F_5)_2$ unit. The two pentafluorophenyl groups at the tetravalent boron centre [δ(^{11}B) = 4.7, $\nu_{1/2} \approx 414$ Hz)] have become diastereotopic. Consequently, we observed equal intensity pairs of ^{19}F NMR signals of the *ortho*- (δ = −158.1 and −158.2 ppm) and *para*-C_6F_5 signals (δ = −132.6 and −132.9 ppm). The *meta*-C_6F_5 resonances of the two diastereotopic C_6F_5 ligands are isochronous (δ = −163.3 ppm).



Scheme 2

Single crystals of **7** were obtained from a concentrated toluene solution at room temperature. The X-ray crystal

structure analysis confirms the formation of the 2*H*-pyrrole unit. The C_4H_5N moiety shows a short N=C bond inside the heterocyclic ring system [see Figure 3, N1−C16 1.294(4) Å], whereas the adjacent N1−C19 linkage [1.462(4) Å] denotes the presence of a single bond. The remaining framework of the five-membered nitrogen heterocycle exhibits a typical bond alternation [C16−C17 1.443(5) Å, C17−C18 1.326(5) Å, C18−C19 1.474(4) Å]. The N1−B bond length amounts to 1.612(4) Å, and the N1−B−C15 bond angle is found at 107.9(2)°. The remaining bond angles at the boron atom are within a range of 103.3(2) to 116.1(2)°.

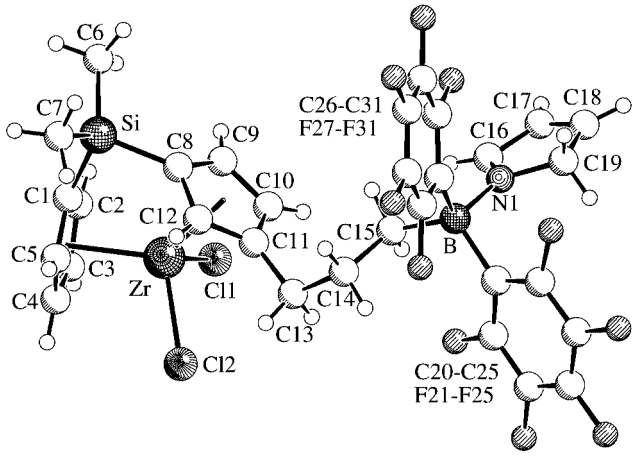

Figure 3. A projection of the molecular geometry of the 2*H*-pyrrole addition product **7**; selected bond lengths [Å] and angles [°]: Zr−Cl1 2.448(1), Zr−Cl2 2.414(1), Si−C1 1.877(3), Si−C8 1.875(3), Si−C6 1.845(4), Si−C7 1.857(4), C11−C13 1.506(4), C13−C14 1.541(4), C14−C15 1.531(4), C15−B 1.631(4), B−N1 1.612(4), B−C20 1.653(5), B−C26 1.651(4), N1−C16 1.294(4), N1−C19 1.462(4), C16−C17 1.443(5), C17−C18 1.326(5), C18−C19 1.474(4); Cl1−Zr−Cl2 98.76(4), C1−Si−C8 94.8(1), C1−Si−C6 112.5(2), C1−Si−C7 110.7(2), C8−Si−C6 110.6(2), C8−Si−C7 112.1(2), C6−Si−C7 114.5(2), C11−C13−C14 113.8(3), C13−C14−C15 113.1(3), C14−C15−B 115.9(2), C15−B−N1 107.9(2), C15−B−C20 116.1(2), C15−B−C26 108.4(2), N1−B−C20 103.3(2), N1−B−C26 108.8(2), C20−B−C26 112.0(2), B−N1−C16 126.9(3), B−N1−C19 125.3(2), C16−N1−C19 107.8(3), N1−C16−C17 111.8(3), C16−C17−C18 107.3(3), C17−C18−C19 108.7(3), C18−C19−N1 104.3(3)

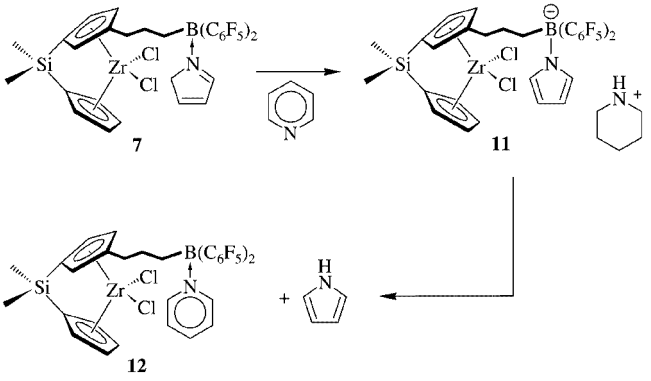
The 2*H*-pyrrole unit is oriented in plane with the B1−C15 vector [dihedral angle C16−N1−B−C15 2.5(4)°]. The connecting trimethylene chain between the *ansa*-metallocene framework and the borate section of **7** adopts a conformation different from those of the two complexes **2** and **6** (see above). As can be seen from the projection of **7**, depicted in Figure 3, the $-(CH_2)_3-$ chain in **7** contains an additional gauche conformation [C11−C13−C14−C15 −63.0(4)°]. The C13−C14−C15−B1 arrangement is antiperiplanar [θ = −165.9(3)°] and the C10−C11−C13−C14 dihedral angle [84.1(4)°] removes the borate end away from the centre of the metallocene unit. Consequently, the Zr···B separation in **7** (6.837Å) is smaller than in **2** (7.621Å) but larger than in **6** (6.395Å).

The methylene hydrogen atoms of the previously prepared and studied 2*H*-pyrrole/$B(C_6F_5)_3$ adduct **10** are rather acidic. The system **10** has been used as a Brønsted acid activator component for generating homogeneous Ziegler−Natta catalyst systems.[17] The 2*H*-pyrrole methylene hydrogen atoms are also acidic. Treatment with pyridine as a base removed one of these hydrogen atoms. We assume that salt **11** may be formed as an intermediate, and may then have reacted further in an acid/base reaction to yield the stable adduct **12** and free pyrrole (see Scheme 3).



Scheme 3

We next intend to try to make use of the specific coordinative features of such main group element/transition metal combinations and to investigate whether the zirconocene units in adducts such as **6** or **7** can be activated to undergo, for example, C−H or C−C activation reactions with substrates attached at their neighbouring electrophilic borane centre.

Experimental Section

General: All reactions were carried out under dry argon in Schlenk-type glassware or in a glove-box. Solvents, including deuterated solvents used for NMR spectroscopy, were dried and distilled prior to use. For additional general conditions, including a list of instruments used for a physical characterization of the compounds see ref.[6] Most NMR assignments were secured by carrying out a variety of 2D NMR experiments.[19]

X-ray Crystal Structure Analyses: Data sets were collected with a Nonius KappaCCD diffractometer, equipped with a Nonius FR591 rotating anode generator. Programs used: data collection COLLECT (Nonius B.V., **1998**), data reduction Denzo-SMN,[20] absorption correction SORTAV,[21] structure solution SHELXS-97,[22] structure refinement SHELXL-97,[23] graphics SCHAKAL.[24] CCDC-202081 to -202083 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation of the *ansa*-Zirconocene Dichloride Complex 1: Chilled toluene (250 mL, −78 °C) was added to a solid mixture of the reagent $[Me_2Si(3\text{-}C_5H_3CH_2CH{=}CH_2)(C_5H_4)Li_2]$ (3.47 g, 14.5 mmol) and $ZrCl_4$ (3.37 g, 14.5 mmol). The suspension immediately became yellow. It was allowed to warm to room temperature with stirring. After stirring overnight, the yellow suspension was filtered through Celite. Removal of the volatiles in vacuo pro-

vided the product (3.23 g, 57%) as a yellow solid. M.p. 104 °C. ^{1}H NMR ($CDCl_3$, 600 MHz): δ = 7.03 (m, 1 H, 4′-H), 6.93 (m, 1 H, 3′-H), 6.60 (m, 1 H, 3-H), 5.98 (m, 1 H, 2′-H), 5.92 (m, 3 H, 2-H, 7-H), 5.82 (m, 1 H, 5′-H), 5.54 (m, 1 H, 5-H), 5.06, 5.04 (each m, each 1 H, 8-H, 8-H′), 3.47, 3.38 (each m, each 1 H, 6-H, 6-H′), 0.72, 0.69 [each s, each 3 H, $Si(CH_3)_2$] ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 150 MHz): δ = 141.0 (C-4), 135.9 (C-7), 128.0 (C-3), 127.8 (C-3′), 127.7 (C-4′), 116.7 (C-8), 115.3 (C-2), 114.1 (C-2′), 113.6 (C-5′), 113.5 (C-5), 107.9 (C-1), 107.8 (C-1′), 34.3 (C-6), −5.1, −5.3 [$Si(CH_3)_2$] ppm. $C_{15}H_{18}Cl_2SiZr$ (388.5): calcd. C 46.37, H 4.67; found C 46.26, H 4.70.

Treatment of Complex 1 with 9-BBN; Preparation of Complex 2: 9-BBN (95 mg, 78.0 mmol) and **1** (302 mg, 78.0 mmol) were combined in a flask, and toluene (20 mL) was added at room temperature. The reaction mixture was stirred for 12 h. The solvent was removed in vacuo, which provided the product (381 mg, 97%) as a light yellow solid. Crystals suitable for an X-ray crystal structure analysis were obtained from a concentrated solution in dichloromethane at −30 °C. M.p. 155 °C. ^{1}H NMR ($CDCl_3$, 600 MHz): δ = 7.02 (m, 1 H, 4′-H), 6.92 (m, 1 H, 3′-H), 6.61 (m, 1 H, 3-H), 5.98 (m, 1 H, 2′-H), 5.91 (m, 1 H, 2-H), 5.82 (m, 1 H, 5′-H), 5.54 (m, 1 H, 5-H), 2.69 (m, 2 H, 6-H), 1.81, 1.64 (each m, each 4 H, 10-H), 1.81, 1.18 (each m, each 2 H, 11-H), 1.75 (m, 2 H, 7-H), 1.64 (m, 2 H, 9-H), 1.40 (t, $^3J_{H,H}$ = 7.8 Hz, 2 H, 8-H), 0.72, 0.69 [each s, each 3 H, $Si(CH_3)_2$] ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 150 MHz): δ = 143.9 (C-4), 127.9 (C-3), 127.7 (C-3′), 127.5 (C-4′), 115.2 (C-2), 113.9 (C-2′), 113.7 (C-5), 113.6 (C-5′), 107.6 (C-1), 107.5 (C-1′), 33.1 (C-6), 33.1 (C-10), 31.0 (br., C-9), 27.9 (br., C-8), 25.4 (C-7), 23.2 (C-11), −5.1, −5.2 [$Si(CH_3)_2$] ppm. $^{11}B\{^1H\}$ NMR ($CDCl_3$, 64 MHz): δ = 86.8 ($\nu_{1/2}$ = 320 Hz) ppm. $C_{23}H_{33}BCl_2SiZr$ (510.5): calcd. C 54.11, H 6.52; found C 53.09, H 6.54.

X-ray Crystal Structure Analysis of 2: Empirical formula $C_{23}H_{33}BCl_2SiZr$, M = 510.51, colourless crystal 0.40 × 0.25 × 0.05 mm, a = 8.175(1), b = 26.251(1), c = 11.251(1) Å, β = 98.13(1)°, V = 2390.2(4) Å^3, $\rho_{calcd.}$ = 1.419 g cm^{-3}, μ = 7.41 cm^{-1}, empirical absorption correction (0.756 ≤ T ≤ 0.964), Z = 4, monoclinic, space group $P2_1/n$ (no. 14), λ = 0.71073 Å, T = 198 K, ω and φ scans, 9625 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.65 Å^{-1}, 5428 independent (R_{int} = 0.028) and 4617 observed reflections [$I \geq 2\ \sigma(I)$], 255 refined parameters, R = 0.045, wR^2 = 0.105, max. residual electron density 1.27 (−0.68) e·Å^{-3} close to the $ZrCl_2$ core, hydrogen atoms calculated and refined as riding atoms.

Treatment of Complex 1 with $HB(C_6F_5)_2$ (3); Preparation of Complex 4: Bis(pentafluorophenyl)borane (254 mg, 73.0 mmol) and **1** (285 mg, 73.0 mmol) were combined in a flask, and toluene (50 mL) was transferred into the flask at 0 °C. The reaction mixture was stirred while being allowed to warm to room temperature, and the volatiles were removed in vacuo, resulting in the product (524 mg, 97%) as a light yellow solid. M.p. 142 °C. ^{1}H NMR ($CDCl_3$, 600 MHz): δ = 7.00 (m, 1 H, 4′-H), 6.92 (m, 1 H, 3′-H), 6.56 (m, 1 H, 3-H), 5.96 (m, 1 H, 2′-H), 5.87 (m, 1 H, 2-H), 5.80 (m, 1 H, 5′-H), 5.47 (m, 1 H, 5-H), 2.72 (m, 2 H, 6-H), 1.96 (m, 2 H, 7-H), 1.80 (m, 2 H, 8-H), 0.72, 0.66 [each s, each 3 H, $Si(CH_3)_2$] ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 150 MHz): δ = 146.8 (dm, $^1J_{C,F}$ = 246.1 Hz), 143.4 (dm, $^1J_{C,F}$ = 249.7 Hz), 137.4 (dm, $^1J_{C,F}$ = 258.0 Hz) (*o*-, *p*-, *m*-C_6F_5), 142.1 (C-4), 128.2 (C-3′), 127.8 (C-3), 126.9 (C-4′), 114.9 (C-2), 114.3 (C-5′), 113.8 (C-2′), 113.6 (C-5), 107.7 (C-1), 107.6 (C-1′), 32.3 (C-6), 30.9 (C-7), 25.5 (C-8), −5.6, −5.7 [$Si(CH_3)_2$] ppm. $^{11}B\{^1H\}$ NMR ($CDCl_3$, 64 MHz): δ = 75.6 ($\nu_{1/2}$ = 190 Hz). ^{19}F NMR ($CDCl_3$, 564 MHz): δ = −130.2 (m, *o*-C_6F_5), −148.6 (m, *p*-C_6F_5), −160.8 (m, *m*-C_6F_5) ppm. $C_{27}H_{19}BCl_2F_{10}SiZr$ (734.5): calcd. C 44.15, H 2.61; found C 43.23, H 2.56.

Treatment of 4 with 2-Methyl-4,5-dihydrooxazole; Formation of the Dihydrooxazole Adduct 6: A solution of 2-methyl-4,5-dihydrooxazole (9 mg, 104.8 mmol) in toluene (20 mL) was added at room temperature to a light yellow solution of **4** (77 mg, 104.8 mmol) in toluene (20 mL) and the mixture was stirred for 0.5 h. Removal of the volatiles in vacuo provided the product (85 mg, 99%) as a light yellow solid. Crystals suitable for an X-ray crystal structure analysis were obtained from a concentrated solution in benzene at room temperature. ^{1}H NMR (C_7D_8, 600 MHz): δ = 6.68 (m, 1 H, 4′-H), 6.67 (m, 1 H, 3′-H), 6.50 (m, 1 H, 3-H), 5.38 (m, 1 H, 2′-H), 5.37 (m, 1 H, 2-H), 5.33 (m, 1 H, 5′-H), 5.15 (m, 1 H, 5-H), 3.45/3.39 (each m, each 1 H, dihydrooxazole-CH_2), 3.38/3.26 (each m, each 1 H, dihydrooxazole-CH_2), 2.80/2.75 (each m, each 1 H, 6-H, 6-H′), 1.43/1.29 (each m, each 1 H, 7-H, 7-H′), 1.37/1.12 (each m, each 1 H, 8-H, 8-H′), 1.36 (s, 3 H, dihydrooxazole-CH_3), 0.13/0.06 [each s, each 3 H, $Si(CH_3)_2$] ppm. $^{13}C\{^1H\}$ NMR (C_7D_8, 150 MHz): δ = 174.4 (dihydrooxazole-C), 142.5 (C-4), 129.2 (C-3′), 128.4 (C-3), 125.8 (C-4′), 114.7 (C-5′), 114.6 (C-5), 113.6 (C-2), 112.4 (C-2′), 107.8 (C-1′), 107.2 (C-1), 67.9/51.3 (dihydrooxazole-CH_2), 33.1 (C-6), 26.9 (C-7), 22.9 (C-8), 13.1 (dihydrooxazole-CH_3), −5.7, −6.4 [$Si(CH_3)_2$]; 148.5 ($^1J_{C,F}$ = 239.7 Hz), 139.7 ($^1J_{C,F}$ = 240.6 Hz), 137.6 ($^1J_{C,F}$ = 253.9 Hz), 120.6 (*o*-, *p*-, *m*-, *ipso*-C_6F_5) ppm. $^{11}B\{^1H\}$ NMR (C_7D_8, 64 MHz): δ = −5.0 ($\nu_{1/2}$ = 290 Hz) ppm. ^{19}F NMR (C_7D_8, 564 MHz): δ = −133.2/−133.7 (each m, each 2 F, *o*-C_6F_5), −158.1/−158.4 (each t, each 1 F, $^3J_{FF}$ = 20.6/20.8 Hz, *p*-C_6F_5), −163.4/−163.5 (each m, each 2 F, *m*-C_6F_5) ppm. $C_{31}H_{26}BCl_2F_{10}NOSiZr$ (819.6): calcd. C 45.43, H 3.20, N 1.71; found C 45.15, H 3.05, N 1.65.

X-ray Crystal Structure Analysis of 6: Empirical formula $C_{31}H_{26}BCl_2F_{10}NOSiZr{\cdot}1/2C_6H_6$, M = 858.60, colourless crystal 0.30 × 0.15 × 0.10 mm, a = 8.017(1), b = 11.120(1), c = 20.434(1) Å, α = 87.13(1), β = 84.78(1), γ = 81.23(1)°, V = 1791.7(3) Å^3, $\rho_{calcd.}$ = 1.592 g cm^{-3}, μ = 5.71 cm^{-1}, empirical absorption correction (0.847 ≤ T ≤ 0.945), Z = 2, triclinic, space group $P\bar{1}$ (no. 2), λ = 0.71073 Å, T = 198 K, ω and φ scans, 10918 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.65 Å^{-1}, 7958 independent (R_{int} = 0.017) and 6149 observed reflections [$I \geq 2\ \sigma(I)$], 463 refined parameters, R = 0.037, wR^2 = 0.083, max. residual electron density 0.38 (−0.40) e·Å^{-3}, hydrogen atoms calculated and refined as riding atoms.

Treatment of 4 with Pyrrole; Formation of the 2*H*-Pyrrole Adduct 7: A solution of pyrrole (37 mg, 0.54 mmol) in toluene (10 mL) was added at room temperature to a light yellow solution of **4** (406 mg, 0.51 mmol) in toluene/diethyl ether (10:1, 20 mL), and the mixture was stirred for 18 h. Removal of the volatiles in vacuo provided the product (407 mg, 99%) as a light yellow solid. Crystals suitable for an X-ray crystal structure analysis were obtained from a concentrated solution in toluene at room temperature. ^{1}H NMR (C_7D_8, 600 MHz): δ = 7.65 (br. s, 1 H, 12-H), 6.72 (m, 1 H, 4′-H), 6.66 (m, 1 H, 3′-H), 6.48 (m, 1 H, 3-H), 6.42 (dq, $^3J_{10\text{-}H,11\text{-}H}$ = 5.5, $^4J_{10\text{-}H,12\text{-}H}$ = 0.9 Hz, 1 H, 10-H), 5.61 (dq, $^3J_{10\text{-}H,11\text{-}H}$ = 5.5, $^3J_{11\text{-}H,12\text{-}H}$ = 1.1, $^4J_{9\text{-}H,11\text{-}H}$ = 1.3 Hz, 1 H, 11-H), 5.43 (m, 1 H, 2′-H), 5.38 (m, 1 H, 2-H), 5.32 (m, 1 H, 5′-H), 5.17 (m, 1 H, 5-H), 3.72/3.68 (AB, $^2J_{H,H}$ = 26.7 Hz, each 1 H, 9-H, 9-H′), 2.83 (m, 2 H, 6-H, 6-H′), 1.52/1.36 (each m, each 1 H, 7-H, 7-H′), 1.36/1.21 (each m, each 1 H, 8-H, 8-H′), 0.14/0.08 [each s, each 3 H, $Si(CH_3)_2$] ppm. $^{13}C\{^1H\}$ NMR (C_7D_8, 150 MHz): δ = 169.3 (C-12), 154.2 (C-10), 143.1 (C-4), 128.7 (C-3′), 128.6 (C-3), 127.1 (C-11), 125.6 (C-4′), 114.2 (C-2), 114.0 (C-5), 114.0 (C-5′), 113.1 (C-

Preparation of Optically Active α-Amino[3]ferrocenophanes − Building Blocks for Chelate Ligands in Asymmetric Catalysis

Patrick Liptau,[a] Ludger Tebben,[a] Gerald Kehr,[a] Birgit Wibbeling,[a][‡] Roland Fröhlich,[a][‡] and Gerhard Erker*[a]

Keywords: Ferrocenes / Ferrocenophanes / Chelate ligands

Treatment of 1,1′-diacetylferrocene (**4**) with dimethylamine and $TiCl_4$ yielded the unsaturated dimethylamino-substituted [3]ferrocenophane product **5**. Its catalytic hydrogenation gave the corresponding saturated [3]ferrocenophane system **6** (*trans*/*cis* ≈ 7:1). The *rac*-[3]ferrocenophane amine **6** was partially resolved (to ca. 80% *ee*) by means of L- or D-*O*,*O*′-dibenzoyltartrate salt formation. Treatment of **4** with the pure (*R*)- or (*S*)-methyl(1-phenylethyl)amine (**8**)/$TiCl_4$ gave the corresponding optically active unsaturated [3]ferrocenophane amines (*R*)-(+)-**9** and (*S*)-(−)-**9**, respectively. Their catalytic hydrogenation again proceeded *trans*-selectively, giving the corresponding saturated diastereomeric [3]ferrocenophane amines (1*R*,3*R*,5*R*)-**10a** and (1*S*,3*S*,5*R*)-**10b** [starting from (*R*)-**9**], their enantiomers *ent*-**10a** and *ent*-**10b** were obtained from (*S*)-**9**, but with a poor asymmetric induction (**10a**/**10b** < 2:1). Quaternization of **6** (CH_3I) followed by amine exchange using (*R*)- or (*S*)-methyl(1-phenylethyl)-amine (**8**), respectively, proceeded with overall retention. Subsequent chromatographic separation gave the pure diastereoisomers (1*R*,3*R*,5*R*)-**10a** and (1*S*,3*S*,5*R*)-**10b** [from (*R*)-**8**, *ent*-**10a** and *ent*-**10b** from (*S*)-**8**] in > 60% yield. Subsequently, the benzylic (1-phenylethyl) auxiliary was removed from the nitrogen atom by catalytic hydrogenolysis to yield the enantiomerically pure (> 98%) ([3]ferrocenophanyl)-methylamines (1*R*,3*R*)-**11** and (1*S*,3*S*)-**11**, respectively, which were converted into the corresponding dimethylamino-substituted [3]ferrocenophanes (1*R*,3*R*)-**6** and (1*S*,3*S*)-**6**. Each enantiomer from the following enantiomeric pairs was isolated in its pure form and characterized by X-ray diffraction: (*R*)-**9**/(*S*)-**9**; (1*R*,3*R*,5*R*)-**10a**/(1*S*,3*S*,5*S*)-**10a**; (1*R*,3*R*,5*S*)-**10b**/(1*S*,3*S*,5*R*)-**10b**; (1*R*,3*R*)-**11**/(1*S*,3*S*)-**11**.

Introduction

Ferrocene-derived chelate ligands have found significant use in asymmetric catalysis.[1] A prime example is the "*Josiphos*" ligand (**1**) which has served as a very useful ligand especially in asymmetric hydrogenation.[2] Many variations of this ligand type have become known. Among them the [3]ferrocenophane systems may eventually find some specific use because of their very rigid framework. Based on early work by the Dijon group,[3] Weissensteiner et al. have developed synthetic pathways to optically active chelate bis(phosphanyl)[3]ferrocenophanes, such as **2**.[4,5] We had recently found an interesting complementary synthetic entry into such functionalized [3]ferrocenophane ligand systems that was based on the very readily available 1,1′-diacetylferrocene[6] (**4**) starting material. Treatment of **4** with e.g. dimethylamine in the presence of titanium tetrachloride probably gave the corresponding enamine[7] that was, however, not stable under the applied reaction conditions. It underwent an intramolecular Mannich-type condensation reaction to yield the unsaturated [3]ferrocenophane system **5**[8,9] (see Scheme 1). Subsequent (heterogeneous) catalytic hydrogenation in the presence of Pd/C gave a ca. 7:1 mixture of *trans*-**6**/*cis*-**6**. The major product of this surprisingly high *trans*-selective reduction (*trans*-**5**) was obtained in its pure

form after recrystallization.[10] The product *rac-trans*-**6** was then converted into a series of chelate ligands, especially to the bis(phosphanyl)[3]ferrocenophane *rac*-**3**, which was used to generate a very active Pd-based catalyst for the alternating CO/ethene copolymerization.[11,12]

So far our chemistry leading to **3** and a number of related compounds was carried out at the stage of the racemic compounds which were also used in the first catalytic test reactions.[11] We have now developed a viable synthetic entry to the amino-substituted [3]ferrocenophane enantiomers (1*R*,3*R*)-**6** and (1*S*,3*S*)-**6** and related systems that will eventually allow us to prepare both enantiomers of the chelate ligand **3** and other related [3]ferrocenophane-derived chelate systems. Several possible pathways were tested that will briefly be described in this account before the rather simple route was successfully established that led to the practically optically pure α-amino[3]ferrocenophanes. The essential products along this pathway had their structural assignments secured by X-ray diffraction.

Results and Discussion

Attempted Asymmetric Enamine Hydrogenation

The observation that the catalytic hydrogenation of the doubly unsaturated enamine **5** in the presence of palladium on charcoal proceeded predominantly with an overall *trans* stereochemistry[10] indicated a stepwise hydrogenation pathway with an active involvement of the amino group at the surface of the catalyst. Therefore, it needed to be tested whether the attachment of a chiral amino auxiliary would lead to a considerable asymmetric induction. For this reason we selected the secondary amine methyl(1-phenylethyl)-amine [(*R*)-**8**, (*S*)-**8**] as the amine component in the enamine formation/Mannich condensation sequence. The respective enantiomers of **8** were prepared starting from the optically active (1-phenylethyl)amine by $LiAlH_4$ reduction of their methyl carbamates (**7**).[13]

Right from the beginning the chosen reaction sequence proceeded unsatisfactorily. The Mannich coupling required a ca. 16 fold excess of the expensive amino component [(*R*)-**8** or (*S*)-**8**] to produce the corresponding [3]ferrocenophane derivatives [(*R*)-**9**, (*S*)-**9**], but even under these forced conditions the optically active aminoferrocenophane derivatives were only isolated in less than 20% yield. The enantiomers are characterized by an optical rotation of $[\alpha]_D^{20} = +44$ [(*R*)-**9**]. Figure 1 shows the CD spectrum of (*R*)-**9**, featuring a negative Cotton effect at the short wavelength edge of the spectrum [$\Delta\varepsilon$ (λ_{max}) = −0.37 (348), +0.11 (444)].

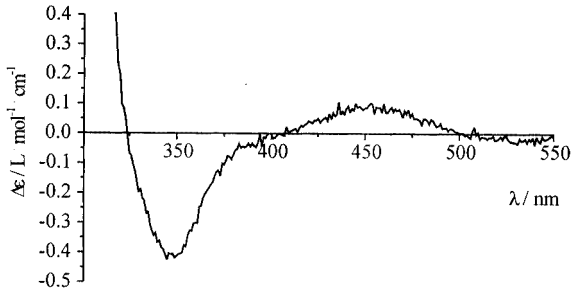

Figure 1. CD spectrum of the [3]ferrocenophane derivative (*R*)-**9** (8×10^{-4} g mL^{-1}) in CH_3CN

Single crystals that were suitable for characterization by X-ray diffraction were obtained for both enantiomers (*R*)-**9** and (*S*)-**9**. Figure 2 provides a view of the structures of the pair of enantiomers in the crystal. Since the solved structures are enantiomeric, only some of the data from enantiomer (*R*)-**9** will be given. The ferrocene framework of

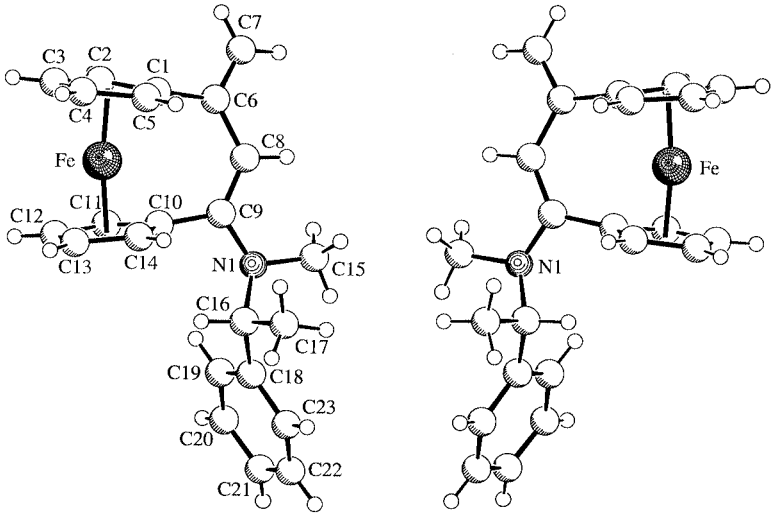

Figure 2. A view of the molecular geometries of the pair of the enantiomers (*R*)-(+)-**9** (left) and (*S*)-(−)-**9** (right) (with unsystematical atom numbering scheme), originating from different enantiomorphic crystals; selected bond lengths [Å] and angles [°] [values are from (*R*)-(+)-**9**]: C1−C6 1.491(5), C6−C7 1.333(5), C6−C8 1.471(5), C8−C9 1.362(4), C9−C10 1.477(5), C9−N1 1.408(4), N1−C15 1.455(4), N1−C16 1.481(4), C16−C17 1.526(5), C16−C18 1.525(5); C1−C6−C7 117.2(3), C1−C6−C8 122.3(3), C7−C6−C8 120.5(3), C6−C8−C9 129.0(3), C8−C9−C10 124.1(3), C8−C9−N1 121.4(3), C10−C9−N1 114.2(3), C9−N1−C15 117.9(3), C9−N1−C16 119.6(3), C15−N1−C16 114.1(3), N1−C16−C17 111.1(3), N1−C16−C18 109.3(3), C17−C16−C18 115.2(3)

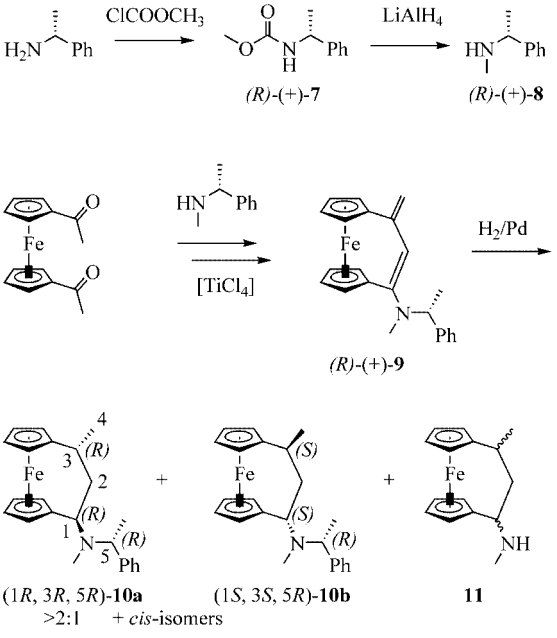
(*R*)-**9** is almost undistorted. The Cp(centroid)−Fe−Cp(centroid) angle amounts to 171.9°. Both Fe−C1/C10 [*ipso*-C(Cp)] linkages [2.001(4), 1.995(3) Å] are slightly shorter than the adjacent proximal Fe−CH(Cp) distances [ranging between 2.017(3) and 2.037(3) Å], which are in turn slightly shorter than the distal Fe−C(Cp) bonds [range: 2.045(3) Å for Fe−C4 to 2.062(4) Å for Fe−C12]. The substituted 1-aminobutadienediyl unit that bridges between the pair of Cp ligands in (*R*)-**9** is planar and features the expected bond alternation sequence[14] [C1−C6 1.491(5) Å, C6−C7 1.333(5) Å, C6−C8 1.471(5) Å, C8−C9 1.362(4) Å, C9−C10 1.477(5) Å, see Figure 2]. The bond angles inside the [3]ferrocenophane bridge amount to 122.3(3)° (C1−C6−C8), 129.0(3)° (C6−C8−C9), and 124.1(3)° (C8−C9−C10), which indicates a rather unstrained situation. The connecting C9−N bond is found at 1.408(4) Å, and the sum of the bonding angles at the nitrogen atom is 351.6°.[15]

The ^{1}H NMR spectrum of compound **9** shows the expected split signals of the butadienediyl $=CH_2$ terminus (δ = 4.99, 4.62 ppm; $^2J_{H,H}$ = 2.5 Hz) and a singlet of the corresponding central =CH− butadienediyl methine-H (δ = 5.52 ppm). The attached chiral amino substituents make the C_5H_4 methine CH groups pairwise diastereotopic. This is clearly resolved for the 2-H/5-H (δ = 4.30/4.29 ppm) and 2′-H/5′-H (δ = 4.35/4.32 ppm) pairs but not for their adjacent "distal" CH moieties.

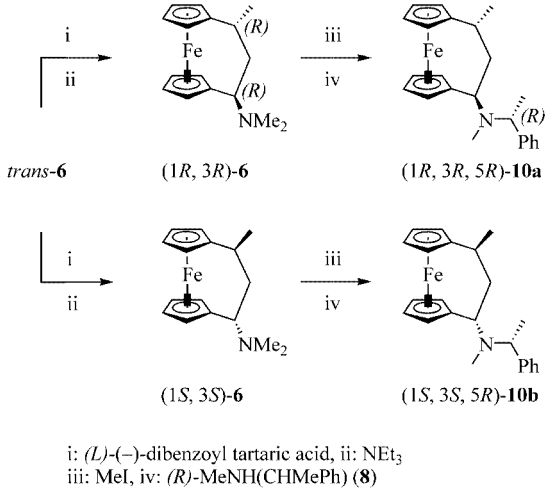
The catalytic hydrogenation of (*R*)-(+)-**9** was carried out in THF at room temperature and an atmospheric pressure of hydrogen in the presence of a heterogeneous Pd/C catalyst (Scheme 2). Workup after a typical reaction time of 2 h gave a complicated mixture of products. Since we had prepared the expected hydrogenation products separately as pure isomers (see below) it was possible to positively identify the major components of the mixture as the two saturated [3]ferrocenophane derivatives (1*R*,3*R*,5*R*)-**10a** and (1*S*,3*S*,5*R*)-**10b** (both of the *trans* series) and the product *trans*-**11**, which was derived from the *trans*-**10** compounds by hydrogenolytic removal of the benzylic-type "protective" group at the nitrogen atom.[16] In addition, there were several other [3]ferrocenophane products, probably the corresponding *cis* isomers or compounds derived from them. Most significantly, the ratio of the major products (1*R*,3*R*,5*R*)-**10a**/(1*S*,3*S*,5*R*)-**10b** was found as < 2:1. This meant that a significant enrichment had not been achieved in either of the expected diastereomers. Therefore, we decided to pursue other ways of preparing the diastereomerically and enantiomerically pure [3]ferrocenophanylamines.

Resolution of the trans-6 Enantiomers by Dibenzoyltartrate Salt Formation

The separation of the enantiomers of chiral (aminoalkyl)ferrocenes had previously been achieved by resolution via L- or D-*O*,*O*′-dibenzoyltartrate salt formation.[17] We therefore treated the racemate of the dimethylamino-substituted [3]ferrocenophane *trans*-**6** with L(−)-*O*,*O*′-dibenzoyltartaric acid. Salt formation in refluxing methanol followed by crystallization gave two fractions, a solid enriched in the dibenzoyltartrate of (1*R*,3*R*)-**6**, and a mother liquor that contained an excess of the respective salt of (1*S*,3*S*)-**6** (see Scheme 3). The resolution procedure was repeated once. The combined fractions of the respective enriched diastereomeric salts were then treated with excess triethylamine to liberate the free bases of **6**. The enantiomerically enriched compounds were obtained in almost equal amounts (total yield: 46%) and they are equally enriched as judged from their optical rotations {found: enriched (1*R*,3*R*)-**6**: $[\alpha]_D^{20}$ = +71; enriched (1*S*,3*S*)-**6**: $[\alpha]_D^{20}$ = −72}. The enantiomeric excess that was actually achieved by the dibenzoyltartrate resolution procedure was determined by converting samples of the enriched (1*R*,3*R*)-**6** material to their diastereomeric amine derivatives (1*R*,3*R*,5*R*)-**10** and (1*S*,3*S*,5*R*)-**10**, respectively, by an amine exchange reaction with (*R*)-methyl(1-phenylethyl)amine, subsequent to quat-



Scheme 2



Scheme 3

ernization with methyl iodide.[18] The ^{1}H NMR spectroscopic analysis showed the presence of a ca. 9:1 ratio of the (1*R*,3*R*,5*R*)-**10**/(1*S*,3*S*,5*R*)-**10** diastereoisomers in the resulting reaction mixture. The isolated product featured an optical rotation of $[\alpha]_D^{20} = +108$. We will see later that the pure (1*R*,3*R*,5*R*)-**10a** isomer has an optical rotation of $[\alpha]_D^{20} = +129$. Thus, from these measurements we must conclude that the resolution of *trans*-**6** via L(−)-*O*,*O*′-dibenzoyltartrate salt formation has resulted in a ca. 80% *ee* of (1*R*,3*R*)-**6** and (1*S*,3*S*)-**6**, respectively.

To achieve an independent absolute stereochemical assignment the partially resolved isolated complex (1*R*,3*R*)-**6** was treated with L-tartaric acid to form the respective salt **12** [i.e. L-tartrate·(1*R*,3*R*)-**6**], and the corresponding ca. 80% enantiomerically enriched (1*S*,3*S*)-**6** sample was treated with D-tartaric acid to give the salt *ent*-**12** [i.e. D-tartrate·(1*S*,3*S*)-**6**]. Single crystals of each of these independently prepared salts were obtained from methanol into which diethyl ether vapor was allowed to diffuse. The X-ray crystal structure analyses of the two sets of crystals confirmed the structural assignments to be correct (see Figure 3).

Inside the [L-tartrate·(1*R*,3*R*)-**6**] salt (**12**), the substituted symmetry-equivalent [3]ferrocenophane units attain a very typical conformation. The C8 methylene group is characteristically placed outside the C1−C6/C9−C13 plane, so that the substituents at the saturated C3 bridge [C1−C6 1.515(3), C6−C8 1.546(4), C8−C9 1.537(3), C9−C10 1.502(3) Å; C1−C6−C8 112.6(2), C6−C8−C9 112.5(2), C8−C9−C10 113.9(2)°] have become oriented pseudo-axially (CH_3 at C6) or pseudo-equatorially (NMe_2 at C9).[10] The corresponding dihedral angles of the [3]ferrocenophane framework amount to 63.8(3)° (C1−C6−C8−C9) and −79.0(2)° (C6−C8−C9−C10). The respective substituent positions at this framework are characterized by dihedral angles of −63.6(3)° (C7−C6−C8−C9) and 153.1(2)° (C6−C8−C9−N1). The C9−N1 bond length is 1.515(3) Å. The sum of C−N−C bonding angles at N1 is only 336.0°, which indicates that the amino nitrogen atom is protonated and connected to the tartrate oxygen O20 in the crystal by means of a hydrogen bond (N1−O20 distance 2.707Å). The tartrate dianion is bridging between a pair of protonated enantiomeric (dimethylamino)[3]ferrocenophane units. The tartrate conformation is as expected with the $-CO_2-$ groups arranged *antiperiplanar* (C18−C21−C21*−C18* −157.8(3)°] and the −OH substituents *gauche* (θ O22−C21−C21*−O22* −53.2(3)°].

Resolution of the Amino[3]ferrocenophanes by Separation of Covalent Diastereomeric Derivatives

It is well established that amine exchange by a suitable nucleophile at the α-carbon position at the ferrocene proceeds in a sequential two-step pathway with a neighboring group participation of the Fe metal center to result in overall stereochemical retention.[18,19] Early work by the Dijon group[3] supported by recent work e.g. by Weissensteiner et al.[4] has shown that this double inversion pathway also governs the stereochemical outcome of the respective substitution reactions at the [3]ferrocenophane framework.[11] We have therefore quaternized the (dimethylamino)[3]ferrocenophane system **6** by treating it with methyl iodide and then with a slight excess of the secondary amine (*R*)-methyl(1-phenylethyl)amine [(*R*)-**8**].[13] The amine exchange reaction was complete after 40 h of refluxing in acetonitrile in the presence of potassium carbonate. The mixture of the diastereomeric products (1*R*,3*R*,5*R*)-**10a** and (1*S*,3*S*,5*R*)-**10b**

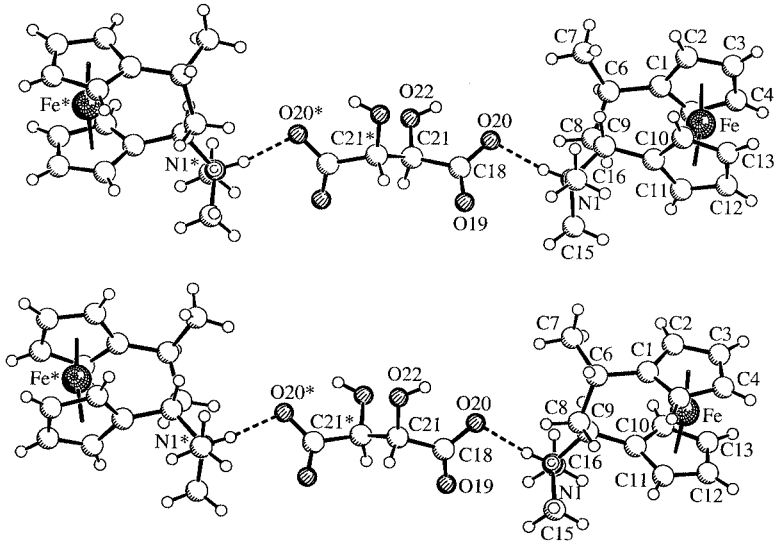

Figure 3. Views of the molecular structures of the independently prepared enantiomeric L-tartrate salt of (1*R*,3*R*)-**6** (**12**, top) and the D-tartrate salt of (1*S*,3*S*)-**6** (*ent*-**12**, bottom); selected bond lengths [Å] and angles [°] of the L-tartrate-derived enantiomer **12**: C1−C6 1.515(3), C6−C7 1.526(4), C6−C8 1.546(4), C8−C9 1.537(3), C9−C10 1.503(3), C9−N1 1.515(3), N1−C15 1.486(3), N1−C16 1.490(3), C18−O19 1.242(4), C18−O20 1.264(3), C18−C21 1.528(3), C21−C21* 1.524(5), C21−O22 1.412(3); C1−C6−C7 112.3(3), C1−C6−C8 112.6(2), C7−C6−C8 111.5(2), C6−C8−C9 112.5(2), C8−C9−C10 113.9(2), C8−C9−N1 110.6(2), C10−C9−N1 112.5(2), C9−N1−C15 114.8(2), C9−N1−C16 111.1(2), C15−N1−C16 110.1(2), O19−C18−O20 126.3(3), O19−C18−C21 117.6(3), O20−C18−C21 116.0(2), C18−C21−C21* 111.7(3), C18−C21−O22 113.0(2), O22−C21−C21* 111.7(2)

was obtained in a near to quantitative yield. Chromatographic separation of the diastereoisomers was achieved by column chromatography on silica gel using a mixture of cyclohexane, THF, and ethyl acetate in a ratio of 34:5:1 as an eluent. The two *trans* isomers [R_f = 0.83 for (1*S*,3*S*,5*R*)-**10a**;R_f = 0.74 for (1*R*,3*R*,5*R*)-**10b**] were clearly separated from each other and from residual reagent [(*R*)-**8**: R_f = 0.30]. The respective minor *cis* isomers were apparently lost during the separation and workup procedure; they could not be recovered. Subsequent recrystallization from diethyl ether gave the pure (1*R*,3*R*,5*R*)-**10a** and (1*S*,3*S*,5*R*)-**10b** isomers each in almost equal quantities (ca. 2 g, 66% yield). Their respective enantiomers were prepared analogously by amine exchange from **6** and the enantiomeric amine reagent (*S*)-**8** and the diastereoisomers *ent*-**10a** (1*S*,3*S*,5*S*) and *ent*-**10b** (1*R*,3*R*,5*S*) were separated accordingly. The (1*R*,3*R*,5*R*)-**10a** diastereomer is characterized by an optical rotation of $[\alpha]_D^{20}$ = +129 ($c = 4 \times 10^{-3}$ g mL^{-1}, CH_3CN), the (1*S*,3*S*,5*R*)-**10b** diastereomer by $[\alpha]_D^{20}$ = −49 ($c = 4 \times 10^{-3}$ g mL^{-1}, CH_3CN). Figure 4 shows the CD curves of the enantiomeric pair of the complexes **10b** (1*S*,3*S*,5*R*) and *ent*-**10b** (1*R*,3*R*,5*S*).

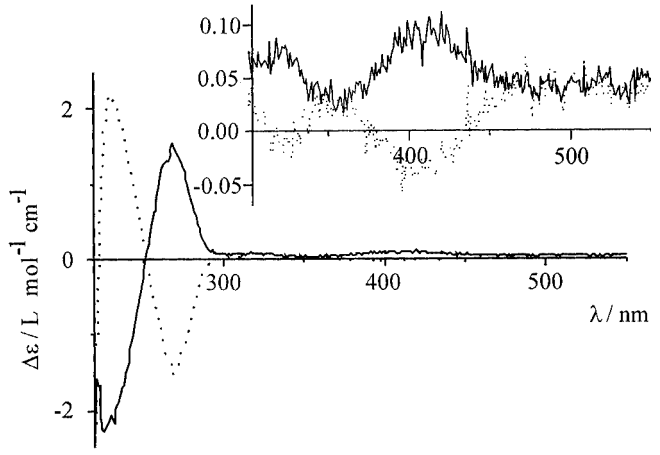

Figure 4. CD spectra of the enantiomeric pair of the complexes **10b** (solid line, 8×10^{-5} g mL^{-1}) and *ent*-**10b** (dotted line, 8×10^{-5} g mL^{-1}) in CH_3CN

The overall pattern of the NMR spectra of **10a** and **10b** are similar although distinctly different in detail. The ^{1}H NMR spectroscopic features of the 3-CH_3 group occur at δ = 0.91 (**10a**) and 1.16 (**10b**) ppm, respectively [corresponding ^{13}C NMR signals at δ = 16.8 (**10a**) and 17.3 (**10b**) ppm]. The 1-H, 2-H/H′ and 3-H signals of **10a** were found at δ = 3.39 (^{13}C: δ = 52.8 ppm), 2.55, 1.92 (^{13}C: δ = 47.9 ppm), and 2.65 ppm, whereas the corresponding **10b** NMR resonances were observed at δ = 3.57 (^{13}C: δ = 52.4 ppm), 2.42, 2.11 (^{13}C: δ = 45.6 ppm), and 2.76 ppm. Also, the NCH_3 (**10a**: δ = 2.25/33.8 ppm; **10b**: δ = 2.14/34.5 ppm) and the 5-CH_3 resonances inside the amino substituent (**10a**: δ = 1.24 ppm; **10b**: δ = 1.30 ppm) are sufficiently different to allow for an easy determination of the diastereomeric purity of the obtained samples. Within the limits of the 600 MHz ^{1}H NMR spectroscopic detection the isolated **10a** and **10b** diastereoisomers were > 99% isomerically pure. A close to complete isomeric separation was thus achieved (see Figure 5 for an illustration).

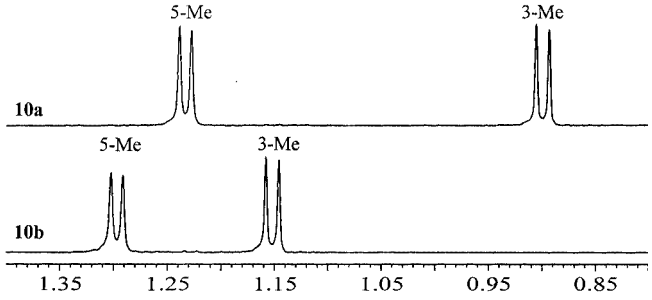

Figure 5. A comparison of the 3-CH_3 and 5-CH_3 ^{1}H NMR region of the (1*R*,3*R*,5*R*)-**10a** and (1*S*,3*S*,5*R*)-**10b** diastereoisomers isolated after chromatographic separation and recrystallization from diethyl ether

The absolute stereochemical assignment was again secured by X-ray diffraction. Single crystals were obtained from all stereoisomers (i.e. **10a**, *ent*-**10a**, **10b**, and *ent*-**10b**). Figure 6 shows the molecular structures of the enantiomeric pairs of both diastereoisomers.

The structural features of the two diastereomers are very similar. This may be illustrated by a comparison of some typical structural parameters of the [3]ferrocenophane frameworks of the complexes **10a** and *ent*-**10b** (values in parentheses), that both contain an (*R*)-configurated methyl(1-phenylethyl)amino substituent. The complexes feature almost identical bond lengths and angles of the central core, e.g. C1−C6 1.511(2) [1.508(2) Å], C6−C8 1.543(2) [1.549(2) Å], C8−C9 1.538(3) [1.545(2) Å], C9−N1 1.486(2) [1.487(2) Å], C9−C10 1.523(2) Å [1.511(2) Å]; C1−C6−C8 112.6(2) [112.8(1)°], C1−C6−C7 112.4(2) [112.2(1)°], C7−C6−C8 111.9(2) [112.1(1)°], C6−C8−C9 115.1(2) [114.3(1)°], N1−C9−C10 115.7(1) [115.8(1)°], N1−C9−C8 109.2(1)° [109.5(1)°]. However, there are a few conformational differences between the diastereomers with regard to the orientation of the methyl(1-phenylethyl)amino substituent. In **10a**, the phenyl group is rotated away from the central [3]ferrocenophane framework, whereas in *ent*-**10b** it is the adjacent methyl substituent that is rotated away. Typically this can be expressed by the characteristic differences in the C15−N1−C16−C17 dihedral angles of **10a** [−43.9(2)°] and *ent*-**10b** [179.6(2)°]. The remaining dihedral angles around the substituted nitrogen atom are again quite similar in both complexes, e.g. C10−C9−N1−C16 74.4(2) (**10a**), −65.7(2) (*ent*-**10b**); C9−N1−C16−C18: 67.7(2) (**10a**), −173.4(1) (*ent*-**10b**); C10−C9−N1−C15: −55.1(2) (**10a**), 59.3(2)° (*ent*-**10b**).

Conversion of the Enantiomerically Pure [3]Ferrocenophanes 10: Removal of the Chiral Auxiliary

We anticipated that the optically active systems **10** could be directly employed in the synthesis of chiral chelate ligands such as **3** in the enantiomerically pure form.[2a,11,20] However, it turned out that the specific systems **10** proved to be rather unreactive. Directed *ortho*-metalation[2,18] of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

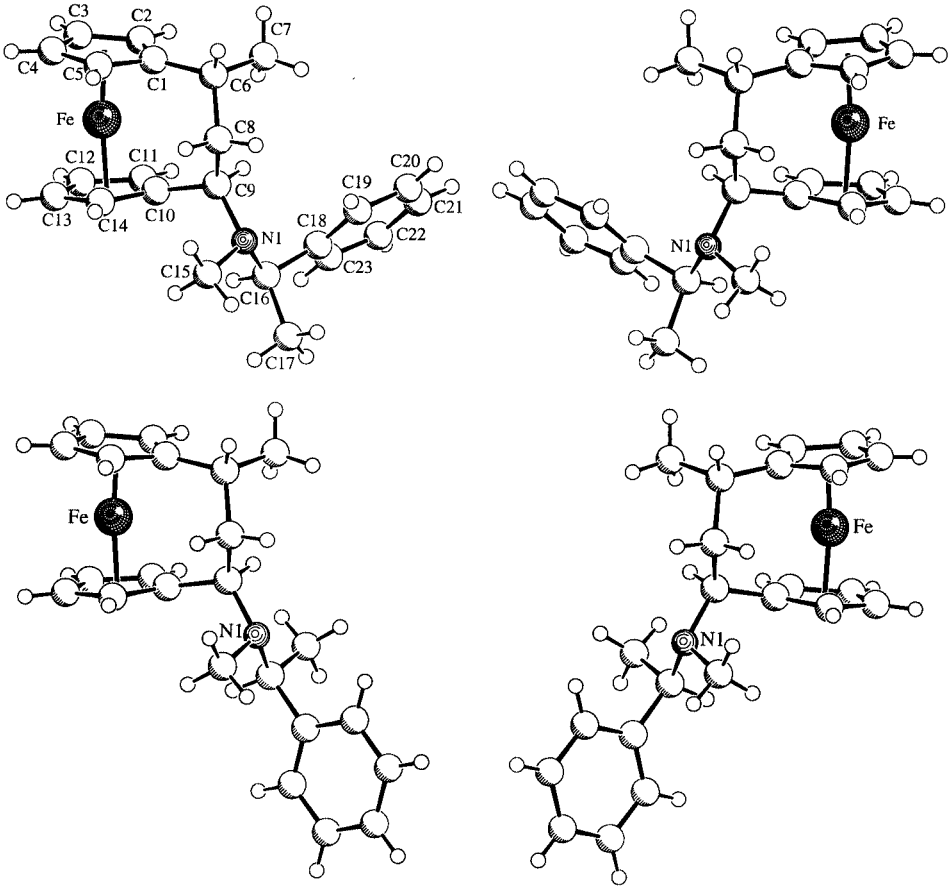

Figure 6. A comparison of the molecular geometries of the enantiomeric pairs (**10**/*ent*-**10**) of the diastereomers **10a** and **10b** [top left: **10a** (1*R*,3*R*,5*R*); top right: *ent*-**10a** (1*S*,3*S*,5*S*); bottom left: **10b** (1*R*,3*R*,5*S*); bottom right: *ent*-**10b** (1*S*,3*S*,5*R*)] (with unsystematical atom numbering scheme)

the adjacent Cp ring was unsuccessful. Moreover, the compounds **10** turned out to be unsuited for amine versus external nucleophile exchange, at least under the various conditions that we tried.

We therefore had to take a short detour to convert the complexes **10** into established building blocks for the synthesis of chiral [3]ferrocenophane-based chelate ligand systems. This was achieved by catalytic hydrogenolysis (see Scheme 4). The methyl(1-phenylethyl)amino substituent in this respect behaved as a typical benzylic amine.[16] Catalytic hydrogenolysis at ambient conditions in methanol (90 min) selectively removed the −CHMePh substituent from the nitrogen atom to yield the product **11** (isolated in ca. 90% yield). It shows the typical ^{1}H NMR spectroscopic features of the *trans*-1,3-disubstituted [3]ferrocenophane system with the framework hydrogen resonances appearing at δ = 3.28 (1-H), 2.00 (2-H$_{exo}$), 2.20 (2-H$_{endo}$) and 2.50 (3-H) ppm. The observed set of coupling constants [^3J(1-H,2-H$_{exo}$) = 3.0, ^3J(1-H,2-H$_{endo}$) = 8.0, ^3J(2H$_{exo}$,3-H) = 7.5, ^3J(2-H$_{endo}$,3-H) = 3.1, ^2J(2-H$_{exo}$,2-H$_{endo}$) = 13.6 Hz] shows that the 3-CH$_3$ group [δ = 1.21 ppm; $^3J_{H,H}$ = 7.3 Hz] attains a pseudo-axial orientation, whereas the NHCH$_3$ substituent is placed pseudo-equatorially at the non-planar saturated [3]ferrocenophane framework.

This was confirmed by X-ray diffraction. Single crystals of each of the enantiomers (1*R*,3*R*)-**11** and (1*S*,3*S*)-**11** were obtained from diethyl ether. Figure 7 shows a view of both structures. They feature the typical arrangement of the non-planar three-carbon containing bridge with the 3-CH$_3$ and 1-NH(CH$_3$) substituents in a *trans* position to one another. In the crystal the NHCH$_3$ group adopts a conformation that leads to maximum extension of the C6−C7−C8−N9−C16 chain (see Figure 7). The carbon−nitrogen bond lengths were found at 1.475(3) (C9−N1) and 1.462(3) Å (N1−C15); the C15−N1−C9 angle amounts to 113.3(2)°.

Each of the enantiomers of **11** was then subsequently *N*-methylated by treatment with formaldehyde/NaBH$_4$ (see Scheme 4) to yield the enantiomers (1*R*,3*R*)-**6** {$[\alpha]_D^{20}$ = +86 (c = 2 × 10^{-3} g mL^{-1}, CH$_3$CN)} and (1*S*,3*S*)-**6** {$[\alpha]_D^{20}$ = −85 (c = 2 × 10^{-3} g mL^{-1}, CH$_3$CN)} almost quantitatively. Their CD spectra are shown in Figure 8. The enantiomers (1*R*,3*R*)-*trans*-**6** and (1*S*,3*S*)-*trans*-**6** were thus prepared in a 5-step synthesis (plus one chromatographic separation), starting from 1,1′-diacetylferrocene and obtained in an overall yield of ca. 23% (out of a possible 50%). We will now use these compounds as building blocks for the preparation of optically active [3]ferrocenophane-derived

chelate ligands to study their potential for asymmetric catalysis.[11,21]

Experimental Section

General Methods: All reactions were carried out under dry argon in Schlenk-type glassware or in a glove-box. Solvents were dried and distilled prior to use. NMR spectra were recorded with a Varian UNITY*plus* 600 (^{1}H: 599.9 MHz; ^{13}C: 150.8 MHz) spectrometer. The atom numbering scheme used for the description of the NMR spectra in the Exp. Sect. deviates from the IUPAC nomenclature used in the text − it is equivalent as depicted in Figures 2, 3, 6, and 7. Most assignments were confirmed by 2D NMR spectra,[22] for details see the Supporting Information. The following instruments were used for additional physical characterization: IR spectroscopy: Nicolet 5DXC FT-IR spectrometer; melting points: DSC 2010 (TA instruments); elemental analyses: Foss Heraeus CHN-O-Rapid; optical rotation: Perkin−Elmer polarimeter 351; circular dichroism: Jobin Yvon-Spex CD-6 dichro-

Figure 7. graph. The following starting materials were prepared according to literature procedures: 1,1′-diacetylferrocene (**4**),[6] ferrocenophane **6**,[9] carbamate **7**,[13] methyl(1-phenylethyl)amine (**8**).[13]

X-ray Diffraction: Data sets were collected with a Nonius KappaCCD diffractometer, equipped with a rotating anode generator Nonius FR591. Programs used: data collection COLLECT (Nonius B.V., **1998**), data reduction Denzo-SMN,[23] absorption correction SORTAV[24], structure solution SHELXS-97,[25] structure refinement SHELXL-97,[26] graphics SCHAKAL.[27] CCDC-205072 to -205081 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation of 6 (from 11): A solution of (1*S*,3*S*)-**11** (100 mg, 0.37 mmol) in MeOH (4 mL) was cooled to 4 °C and treated with formaldehyde solution (4 mL, 37% in MeOH). After stirring at this temperature for 10 min, $NaBH_4$ (233 mg, 6.2 mmol) was added in small portions. The reaction mixture was stirred at room temperature for 1 h and then heated to 75 °C for 18 h. After removal of the solvent under reduced pressure, the residue was extracted with water/CH_2Cl_2. The organic phases were washed with water and brine and dried with $MgSO_4$. Evaporation of the solvent yielded (1*S*,3*S*)-**6** as a yellow solid (104 mg, 97%). $[\alpha]_D^{20} = -85$ ($c = 2 \times 10^{-3}$ g mL^{-1}, CH_3CN). CD: $\Delta\varepsilon$ (λ_{max}) = −3.70 (274), −0.15 (326), −0.28 (412), +0.15 (476) ($c = 4 \times 10^{-4}$ g mL^{-1}, CH_3CN). $C_{16}H_{21}FeN$ (283.20): calcd. C 67.86, H 7.47, N 4.95; found C 67.78, H 7.32, N 4.84. (1*R*,3*R*)-**6** was prepared analogously starting from (1*R*,3*R*)-**11** (443 mg, 1.65 mmol), yield: 453 mg (97%). $[\alpha]_D^{20} = +86$ ($c = 2 \times 10^{-3}$ g mL^{-1}, CH_3CN). CD: $\Delta\varepsilon$ (λ_{max}) = +3.33 (274), +0.14 (326), +0.28 (412), −0.15 (476) ($c = 4 \times 10^{-4}$ g mL^{-1}, CH_3CN). $C_{16}H_{21}FeN$ (283.20): calcd. C 67.86, H 7.47, N 4.95; found C 67.62, H 7.25, N 4.93.

Synthesis of 9: A suspension of 1,1′-diacetylferrocene (**4**) (4.0 g, 14.8 mmol) and either (*S*)- or (*R*)-**8** (35 mL, 240 mmol) in pentane (200 mL) was cooled to 4 °C. Over a period of 20 min a solution of $TiCl_4$ (2.0 mL, 18.2 mmol) in pentane (90 mL) was added dropwise. Afterwards, the reaction mixture was stirred at room temperature overnight. The resulting deep red suspension was filtered through Celite and the solvent removed in vacuo. Unchanged amine **8** could be regained by vacuum condensation of the product at 72 °C. The enantiomers (*S*)-**9** and (*R*)-**9** were each obtained as red to brown solids [(*S*)-**9**: 1.08 g, 20%; (*R*)-**9**: 1.03 g, 19%], m.p. 75 °C (DSC). IR (KBr): $\tilde{\nu}$ = 3855 (m), 3757 (m), 3085 (m), 2980 (s), 2868 (w), 2796 (w), 2380 (w), 1598 (vs), 1479 (vs), 1275 (vs), 1098 (vs), 1019 (vs), 907 (s), 802 (vs), 696 (vs) cm^{-1}. Crystals suitable for X-ray structure analysis were grown by slow diffusion of pentane into an Et_2O solution. ^{1}H NMR (599.9 MHz, CD_2Cl_2, 25 °C): δ = 1.35 [d, $^3J_{H,H}$ = 6.9 Hz, 3 H, C(17)−H], 2.47 [s, 3 H, C(15)−H], 4.13 [m, 2 H, C(2−4)−H], 4.21 [m, 2 H, C(11−14)−H], 4.28 [m, 1 H, C(2−4)−H], 4.29 [m, 1 H, C(2−4)−H], 4.31 [m, 1 H, C(11−14)−H], 4.34 [m, 1 H, C(11−14)−H], 4.64 [d, $^2J_{H,H}$ = 2.5 Hz, 1 H, C(7)−H$_{exo}$], 4.82 [q, $^3J_{H,H}$ = 6.9 Hz, 1 H, C(16)−H], 4.98 [d, $^2J_{H,H}$ = 2.5 Hz, 1 H, C(7)−H$_{endo}$], 5.50 [s, 1 H, C(8)−H], 7.21 (m, 1 H, Ph$_{para}$), 7.23 (m, 2 H, Ph$_{ortho}$), 7.30 (m, 2 H, Ph$_{meta}$) ppm. ^{13}C{^{1}H} NMR (150.8 MHz, CD_2Cl_2, 25 °C): δ = 15.6 [C(17)], 32.1 [C(15)], 56.4 [C(16)], 70.0 [C(2−4)], 70.1 [C(2−4)], 70.3 [C(11−14)], 70.4 [C(2−4)], 70.6 [C(2−4)], 71.8 [C(11−14)], 71.9 [C(11−14)], 84.2 [C(10)], 90.5 [C(1)], 109.0 [C(7)], 109.2 [C(8)], 127.0 (Ph$_{para}$), 127.3 (Ph$_{ortho}$), 128.4 (Ph$_{meta}$), 142.8 [C(6/9)], 142.9 (Ph$_{ipso}$), 146.2 [C(6/9)] ppm. X-ray Crystal Structure Analysis of (*R*)-(+)-9: Empirical formula $C_{23}H_{23}FeN$, M = 369.29, red crystal, 0.50 × 0.20 × 0.10 mm, a = 6.216(1), b = 12.121(1), c = 23.536(1) Å, V = 1773.3(3) Å^3, $\rho_{calcd.}$ = 1.383 g cm^{-3}, μ = 8.55 cm^{-1}, empirical absorption correction (0.675 ≤ T ≤ 0.919), Z = 4, orthorhombic, space group $P2_12_12_1$ (no. 19), λ = 0.71073 Å, T = 198 K, ω and φ scans, 8928 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.68 Å^{-1}, 4355 independent (R_{int} = 0.055) and 3156 observed reflections [$I \geq 2\sigma(I)$], 228 refined parameters, R = 0.049, wR^2 = 0.092, Flack parameter 0.01(2), max. residual electron density 0.44 (−0.43) e·Å^{-3}, hydrogen atoms calculated and refined as riding atoms.

X-ray Crystal Structure Analysis of (*S*)-(−)-9: Empirical formula $C_{23}H_{23}FeN$, M = 369.29, yellow crystal, 0.30 × 0.07 × 0.03 mm, a = 6.201(1), b = 12.119(1), c = 23.604(1) Å, V = 1773.8(3) Å^3, $\rho_{calcd.}$ = 1.383 g cm^{-3}, μ = 8.54 cm^{-1}, empirical absorption correction (0.784 ≤ T ≤ 0.975), Z = 4, orthorhombic, space group $P2_12_12_1$ (no. 19), λ = 0.71073 Å, T = 198 K, ω and φ scans, 12989 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.66 Å^{-1}, 4168 independent (R_{int} = 0.063) and 3222 observed reflections [$I \geq 2\sigma(I)$], 228 refined parameters, R = 0.051, wR^2 = 0.080, Flack parameter 0.02(2), max. residual electron density 0.51 (−0.26) e·Å^{-3}, hydrogen atoms calculated and refined as riding atoms.

Preparation of 10. a) By Hydrogenation: The Pd/C catalyst (10 mg, 10% Pd) was added to a solution of (*R*)-**9** (200.0 mg, 0.54 mmol) in THF (40 mL). Hydrogenation was carried out at ambient pressure under vigorous stirring for 2 h. The reaction mixture was filtered through Celite and the solvent removed in vacuo. An orange oil (179.0 mg) was obtained which was identified to be a complex mixture of all possible isomers of **10** and **11**. **b) By Amine Exchange:** A solution of *rac-trans*-**6** (6.00 g, 21.2 mmol) in CH_3CN (120 mL) was treated with CH_3I (84 mL) and stirred at room temperature for 1 h. Excess CH_3I was then removed in vacuo. K_2CO_3 (6.44 g, 46 mmol), (*R*)-**8** (3.8 mL, 26 mmol) and CH_3CN (300 mL) were added to the obtained trimethylammonium salt. The mixture was heated to reflux for 40 h. After removal of the solvent in vacuo, the residue was suspended in pentane (100 mL). Filtration through Celite and concentration of the filtrate yielded the crude product as a mixture of diastereomers (6.90 g, 87%). Purification was achieved by column chromatography (SiO_2; cyclohexane/THF/ethyl acetate, 34:5:1). (1*R*,3*R*,5*R*)-**10a**: R_f = 0.74; (1*S*,3*S*,5*R*)-**10b**: R_f = 0.83. Furthermore, the products were recrystallized from Et_2O.

(1*R*,3*R*,5*R*)-10a: orange solid, 2.01 g (34%) isolated from 6.0 g of crude product; m.p. 87 °C (DSC). IR (KBr): $\tilde{\nu}$ = 3855 (m), 3750 (m), 3085 (m), 3019 (w), 2973 (s), 2927 (s), 2881 (s), 2855 (s), 2796 (s), 2361 (w), 1664 (m), 1558 (m), 1460 (vs), 1032 (vs), 815 (vs), 769 (vs), 696 (vs) cm^{-1}. (793 mg, 1.12 mmol) of (1*S*,3*S*,5*R*)-**10b**, 720 mg (90%) isolated. $[\alpha]_D^{20} = -104$ ($c = 2 \times 10^{-3}$ g mL^{-1}, CH_3CN). CD: $\Delta\varepsilon$ (λ_{max}) = −0.86 (275), +0.09 (334), −0.38 (416), +0.09 (483) ($c = 4 \times 10^{-4}$ g mL^{-1}, CH_3CN). $C_{15}H_{19}FeN$ (269.17): calcd. C 66.93, H 7.11, N 5.20; found C 66.74, H 6.90, N 5.13.

X-ray Crystal Structure Analysis of (1*R*,3*R*)-11: Empirical formula $C_{15}H_{19}FeN$, $M = 269.17$, yellow crystal, 0.25 × 0.15 × 0.10 mm, $a = 7.420(1)$, $b = 10.017(1)$, $c = 8.255(1)$ Å, $\beta = 99.29(1)°$, $V = 605.5(1)$ Å^3, $\rho_{calcd.} = 1.476$ g cm^{-3}, $\mu = 12.20$ cm^{-1}, empirical absorption correction ($0.750 \le T \le 0.888$), $Z = 2$, monoclinic, space group $P2_1$ (no. 4), $\lambda = 0.71073$ Å, $T = 198$ K, ω and φ scans, 4068 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sinθ)/λ] = 0.66 Å^{-1}, 2503 independent ($R_{int} = 0.028$) and 2385 observed reflections [$I \ge 2\sigma(I)$], 159 refined parameters, $R = 0.026$, $wR^2 = 0.065$, Flack parameter 0.02(2), max. residual electron density 0.33 (−0.33) e·Å^{-3}, hydrogen atom at N1 from difference map, others calculated and all refined as riding atoms.

X-ray Crystal Structure Analysis of (1*S*,3*S*)-11: Empirical formula $C_{15}H_{19}NFe$, $M = 269.17$, yellow crystal, 0.30 × 0.30 × 0.20 mm, $a = 7.415(1)$, $b = 10.009(1)$, $c = 8.250(1)$ Å, $\beta = 99.26(1)°$, $V = 604.3(1)$ Å^3, $\rho_{calcd.} = 1.479$ g cm^{-3}, $\mu = 12.23$ cm^{-1}, empirical absorption correction ($0.711 \le T \le 0.792$), $Z = 2$, monoclinic, space group $P2_1$ (no. 4), $\lambda = 0.71073$ Å, $T = 198$ K, ω and φ scans, 3352 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sinθ)/λ] = 0.68 Å^{-1}, 2467 independent ($R_{int} = 0.030$) and 2349 observed reflections [$I \ge 2\sigma(I)$], 159 refined parameters, $R = 0.033$, $wR^2 = 0.088$, Flack parameter 0.00(2), max. residual electron density 0.50 (−0.62) e·Å^{-3}, hydrogen atom at N1 from difference map, others calculated and all refined as riding atoms.

(1*R*,3*R*)-11: The complex (1*R*,3*R*)-**11** was prepared analogously starting from (1*R*,3*R*,5*S*)-**10b** (1.00 g, 2.68 mmol), 0.65 g (91%) were isolated.

(1*S*,3*S*)-11: The complex (1*S*,3*S*)-**11** was prepared analogously starting from (1*S*,3*S*,5*S*)-**10a** (250 mg, 0.67 mmol), 175 mg (97%) were isolated.

Synthesis of 12: A solution of L-(−)-*O*,*O*′-dibenzoyltartaric acid (3.94 g, 11.0 mmol) in MeOH (21 mL) was heated to 60 °C and added to a solution of *rac*-*trans*-**6** (3.12 g, 11.0 mmol) in MeOH (11 mL) at this temperature. The mixture was heated to reflux for 1 h. Next, it was allowed to gradually cool to room temperature over the course of 4 h. After storage at 4 °C overnight, a yellow precipitate was collected and washed with cold MeOH. The mother liquor and the filtrates were combined and freed from solvent in vacuo. The precipitate and the residue were individually converted into the free bases by treatment with NEt_3 (1.6 mL, 11.5 mmol) and extraction with water/Et_2O. The organic phases were washed with water and brine and dried with $MgSO_4$. After removal of the solvent, the yield was 0.98 g (3.46 mmol) from the former precipitate and 1.01 g (3.57 mmol) from the former mother liquor. In a second resolution step, the free base from the former precipitate was again treated with L-(−)-*O*,*O*′-dibenzoyltartaric acid (1.24 g, 3.46 mmol) in MeOH (10.4 mL) under reflux (1 h) and processed as described above. Optically enriched (1*R*,3*R*)-**6** was obtained as a yellow solid (0.720 g, 2.55 mmol, 23%). $[\alpha]_D^{20} = +71$ ($c = 4 \times 10^{-3}$ g mL^{-1}, CH_3CN). Crystals of the L-tartrate salt (**12**) suitable for X-ray structure analysis were grown by reaction of a solution of optically enriched (1*R*,3*R*)-**6** (50 mg, 0.18 mmol) in MeOH (1 mL) with a solution of L-tartaric acid (26 mg, 0.18 mmol) in MeOH (1 mL). The reaction mixture was heated to 70 °C and slowly cooled to room temperature. The precipitate was collected, redissolved in MeOH (0.5 mL) and Et_2O was allowed to slowly diffuse into this solution. The free base from the former mother liquor was treated with D-(+)-*O*,*O*′-dibenzoyltartaric acid (1.28 g, 3.57 mmol) in MeOH (10.7 mL) under reflux (1 h) and processed as described above. Optically enriched (1*S*,3*S*)-**6** was obtained as a yellow solid (0.72 g, 2.55 mmol, 23%). $[\alpha]_D^{20} = +72$ ($c = 4 \times 10^{-3}$ g mL^{-1}, CH_3CN). Crystals of the D-tartrate salt (*ent*-**12**) suitable for X-ray structure analysis were grown by reaction of a solution of optically enriched (1*S*,3*S*)-**6** (50 mg, 0.18 mmol) in MeOH (1 mL) with a solution of D-tartaric acid (26 mg, 0.18 mmol) in MeOH (1 mL). The reaction mixture was heated to 70 °C and slowly cooled to room temperature. The precipitate was collected, redissolved in MeOH (0.5 mL) and Et_2O was allowed to slowly diffuse into this solution. Amine exchange with (*R*)-**8** (see **10**) followed by integration of suitable signals in the ^{1}H NMR spectrum showed an enantiomeric excess of 78% after the tartrate resolution.

X-ray Crystal Structure Analysis of (1*R*,3*R*)-12: Empirical formula $C_{16}H_{22}FeN{\cdot}0.5\ C_4H_4O_6$, $M = 358.23$, yellow crystal, 0.30 × 0.15 × 0.07 mm, $a = 16.234(1)$, $b = 8.513(1)$, $c = 12.723(1)$ Å, $\beta = 109.84(1)°$, $V = 1654.0(3)$ Å^3, $\rho_{calcd.} = 1.439$ g cm^{-3}, $\mu = 9.26$ cm^{-1}, empirical absorption correction ($0.769 \le T \le 0.938$), $Z = 4$, monoclinic, space group $C2$ (no. 5), $\lambda = 0.71073$ Å, $T = 293$ K, ω and φ scans, 5331 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sinθ)/λ] = 0.66 Å^{-1}, 3401 independent ($R_{int} = 0.027$) and 3154 observed reflections [$I \ge 2\sigma(I)$], 215 refined parameters, $R = 0.031$, $wR^2 = 0.068$, Flack parameter −0.01(2), max. residual electron density 0.32 (−0.42) e·Å^{-3}, hydrogen atom at N1 from difference map, others calculated and all refined as riding atoms.

X-ray Crystal Structure Analysis of (1*S*,3*S*)-12: Empirical formula $C_{16}H_{22}FeN{\cdot}0.5\ C_4H_4O_6$, $M = 358.23$, yellow crystal, 0.35 × 0.20 × 0.05 mm, $a = 16.168(1)$, $b = 8.457(1)$, $c = 12.715(1)$ Å, $\beta = 110.15(1)°$, $V = 1632.1(3)$ Å^3, $\rho_{calcd.} = 1.458$ g cm^{-3}, $\mu = 9.38$ cm^{-1}, empirical absorption correction ($0.735 \le T \le 0.955$), $Z = 4$, monoclinic, space group $C2$ (no. 5), $\lambda = 0.71073$ Å, $T = 198$ K, ω and φ scans, 5402 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sinθ)/λ] = 0.66 Å^{-1}, 3475 independent ($R_{int} = 0.029$) and 3324 observed reflections [$I \ge 2\sigma(I)$], 215 refined parameters, $R = 0.027$, $wR^2 = 0.061$, Flack parameter −0.01(1), max. residual electron density 0.29 (−0.28) e·Å^{-3}, hydrogen atom at N1 from difference map, others calculated and all refined as riding atoms.

Synthesis, Equilibrium and Kinetic Properties of Gd^{3+} Complexes of Three DTPA-Bis(Amide) Derivatives Containing Stable Nitroxide Free Radical Substituents

Zoltán Jászberényi,[a] Ernő Brücher,*[a] József Jekő,[b] Kálmán Hideg,[c] Tamás Kálai,[c] and Róbert Király[a]

Keywords: Chelates / Imaging agents / Kinetics / Lanthanides / Radicals

Two new DTPA-bis(amide) derivatives containing stable nitroxide free radicals, H_3L^2 and H_3L^3, were synthesized. The complexation properties of L^2 and L^3 with Gd^{3+} were compared with those of H_3L^1, synthesized earlier. The sums of the protonation constants $\Sigma\log K_i^H$ of the DTPA-bis(amide) derivative ligands with stable nitroxide free radicals are somewhat higher than that for DTPA-bis(methylamide) (H_3L^4). The ligands L^1, L^2, and L^3 form complexes with a metal-to-ligand ratio of 1:1 with Gd^{3+} (GdL), while the species formed with Zn^{2+} are ZnL, ZnHL, ZnH_2L, and Zn_2L. The formation of the dinuclear complex Zn_2L results in a lower selectivity of the ligands for Gd^{3+} over Zn^{2+} than was assumed for L^4. The relaxivities of the complexes GdL^1, GdL^2, and GdL^3 are close to the sums of the relaxivities of the complex GdL^4 and of the free ligands L^1, L^2, and L^3. The relaxivities of GdL^1, GdL^2, and GdL^3 are practically independent of temperature in the 7–30 °C range, which is probably a result of the relatively long lifetime of the water molecules in the inner spheres of the [$GdL(H_2O)$] complexes. The kinetic stabilities of the Gd^{3+} complexes were characterized by the rates of the exchange reactions taking place between the complexes GdL and Lu^{3+} or Zn^{2+}. The reactions occur through the proton-assisted dissociation of the complexes, with the formation of a protonated intermediate. Another pathway is the direct reaction between the Gd^{3+} complex and Lu^{3+} or Zn^{2+}, which occurs with the formation of a dinuclear intermediate, GdLM. The exchange reactions proceed about five times more rapidly with Zn^{2+} than with Lu^{3+}, indicating the importance of the formation of an intermediate containing an N–Zn^{2+} bond, which is stronger than the N–Lu^{3+} bond in an intermediate with similar structure. The exchange reactions of the complex GdL^3 formed with the disubstituted ligand L^3 are significantly slower than those of the complexes of the monosubstituted ligands L^1 and L^2.

Introduction

The Gd^{3+} complex of diethylenetriamine-*N*,*N*,*N*′,*N*′′,*N*′′-pentaacetic acid (H_5DTPA) is a clinically used contrast agent in magnetic resonance imaging (MRI). The negative charges on $Gd(DTPA)^{2-}$ are neutralized with methylglucosamine cations, so the osmotic pressure in the body fluids after intravenous administration of the contrast agent is relatively high.[1a−1c] Nonionic Gd^{3+} complexes are formed with the ligands obtained by replacement of two terminal carboxylates of DTPA with uncharged functional groups.[2] Of the uncharged functionalities investigated, the amide group has proven to be most suitable because it forms the strongest bonds with lanthanide(III) ions (Ln^{3+}).[3,4] The nonionic complexes [Gd(DTPA-BMA)] and [Gd(DTPA-BMEA)] are clinically used MRI contrast agents (H_3DTPA-BMA = H_3L^4 and H_3DTPA-BMEA = H_3L^5, see Scheme 1).[2,5−7] The stability constants of the Gd^{3+} complexes formed with the DTPA-bis(amide) derivative ligands are significantly lower than that of $[Gd(DTPA)]^{2-}$.[3,5−7] However, the selectivity of DTPA-BMA for Gd^{3+} over the endogenous Zn^{2+} was found to be significantly higher than that of DTPA, and as a consequence of the favorable selectivity, [Gd(DTPA-BMA)] is a safe contrast agent.[5]

The results of NMR spectroscopic and X-ray structural studies revealed that the octadentate DTPA-bis(amide) derivative ligands coordinate to Ln^{3+} through three amine nitrogen atoms, and three carboxylate and two amide oxygen atoms.[6−11] The ninth coordination site is occupied by an H_2O molecule, as found by fluorescence-lifetime measurements on the complexes of Eu^{3+}.[6,12] The rate of exchange of the H_2O molecule between the nonionic complexes [$Gd(DTPA\text{-}BMA)(H_2O)$] or [$Gd(DTPA\text{-}BMEA)(H_2O)$]

and bulk water, as studied by ^{17}O NMR spectroscopy, was found to be about 10 times lower than that for $[Gd(DTPA)(H_2O)]^{2-}$.[10,13,14]

The successful use of [Gd(DTPA-BMA)] as a nonionic contrast agent has resulted in growing interest in the synthesis and study of new DTPA-bis(amide) derivative ligands and their Gd^{3+} complexes. Through the use of different alkyl- and arylamines, a number of new ligands have been synthesized.[15−22] The structures and relaxation properties of the Gd^{3+} complexes formed with these ligands are similar to those of [Gd(DTPA-BMA)] and [Gd(DTPA-BMEA)].

Besides the paramagnetic metal complexes, nitroxide-stable free radicals are also known to increase the relaxation rates of water protons. The relaxation properties of several five-membered pyrrolidine and six-membered piperidine derived free radicals have been studied as potential contrast agents.[23−27] In order to increase the relaxation effect of Gd^{3+} complexes, Sosnovsky et al. synthesized a DTPA-bis(amide) derivative ligand (L^1 in Scheme 1) labeled with two piperidine-*N*-oxyl free radicals.[28] The increase in the relaxation effect of the complex GdL^1 was not significant, but attachment of GdL^1 to bovine serum albumin resulted in a spin-labeled macromolecule with high relaxivity.[29] As far as we know, however, the complexation properties of the ligands with stable nitroxide free radicals, the stability constants, and the kinetic stability of the Gd^{3+} complex have not yet been studied.

We recently synthesized two new DTPA-bis(amide) derivatives containing stable nitroxide free radical moieties (L^2 and L^3 in Scheme 1) and compared their complexation properties and their selectivities for Gd^{3+} over Zn^{2+} with those of L^1. The kinetic stabilities of the Gd^{3+} complexes were also studied by investigation of the rates of the exchange reactions between the Gd^{3+} complexes and Lu^{3+} or Zn^{2+}. We set out to obtain information on how the presence of bulky free radicals affects the equilibria and kinetic properties of the complexes.

Results and Discussion

Protonation and Stability Constants

The titration curves of L^1, L^2, and L^3 reveal two different buffer regions, in the pH ranges about 4−7 and 8−10. Typical titration curves of L^1 in the absence and in the presence of equivalent amounts of Gd^{3+} or Zn^{2+} are shown in Figure 1. The number of titration data points used to calculate the protonation constants of L^1, L^2, and L^3 were 213, 180, and 279, respectively. The protonation constants (K_i^H) are defined as described in Equation (1), where i = 1, 2, ... 5.

$$K_i^H = [H_iL]/\{[H_{i-1}L][H^+]\} \quad (1)$$

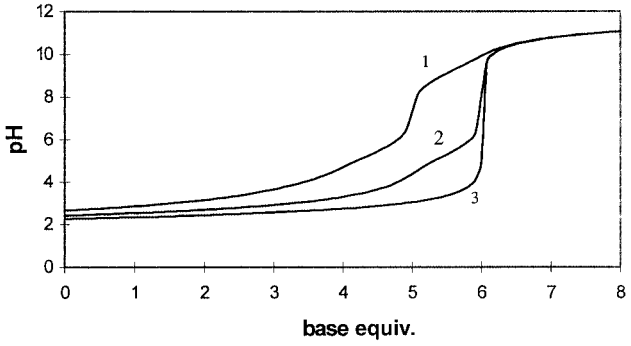

Figure 1. Titration curves of the ligand L^1 (1) alone or in the presence of Zn^{2+} (2) or Gd^{3+} (3), $[L^1] = [Zn^{2+}] = [Gd^{3+}] = 1 \times 10^{-3}$ M

The calculated protonation constants are presented in Table 1, which also gives the known protonation constants for L^4 and L^5 for comparison.

Table 1. Protonation constants of the ligands L^1, L^2, L^3 (25 °C, 0.1 M KCl), L^4 and L^5 (25 °C, 0.1 M $NaClO_4$)

	L^1	L^2	L^3	L^4 [a]	L^5[b]
$\log K_1^H$	9.13 (0.07)	8.99 (0.03)	9.46 (0.05)	9.37	9.40
$\log K_2^H$	5.40 (0.09)	5.07 (0.04)	5.82 (0.07)	4.38	6.22
$\log K_3^H$	3.87 (0.09)	3.81 (0.04)	4.21 (0.07)	3.31	3.99
$\log K_4^H$	2.90 (0.08)	2.57 (0.05)	3.01 (0.07)	1.43	2.26
$\log K_i^H$	21.30	20.44	22.50	18.49	21.87

[a] Ref.[6] [b] Ref.[7]

The first protonation constants of the different DTPA-bis(amide) derivative ligands are quite similar. The second protonation constants are somewhat lower for L^1 and L^2, containing two monosubstituted -C(O)NHR amide groups, than for L^3, containing two disubstituted -C(O)NR_2 amide groups. Similar results were found for L^4 and L^5, so the amide group does not decrease the $\log K_2^H$ value of the DTPA derivative so significantly if both amide hydrogens

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are replaced with alkyl (or aryl) groups.[7] This result was explained by the assumption of the formation of more hydrogen bonds in the ligands containing amide [-C(O)NHR] hydrogen atoms.[7]

The titration curves of the ligands obtained in the presence of equivalent amounts of Zn^{2+} (Figure 1) could be fitted with lower values of the standard deviations and fitting parameters (the difference between the experimentally ascertained and the calculated volumes of base needed to attain a given pH value) if formation of the species ZnL, ZnHL and ZnH_2L was assumed. The stability constants are defined as described in Equation (2), where $i = 0$, 1 or 2.

$$K_{MH,L} = [MH_iL]/\{[M][H_iL]\} \quad (2)$$

The stability constants, calculated by use of 214, 202, and 220 data points for L^1, L^2, and L^3, respectively, are presented in Table 2. The formation of mono- and diprotonated complexes is probably a consequence of the presence of more basic donor atoms in the ligands than the number of Zn^{2+} coordination sites. The complexes with Zn^{2+} are mainly formed in the pH range from 3−6, whereas the formation of Gd^{3+} complexes starts at pH values lower than 1.7 (the extent of complex formation at pH = 1.7 is about 50−60%) and it is completed at pH values around 3. Through the use of the titration data obtained in the pH range from 1.7−3 it was possible to calculate reliable stability constants, as indicated by the relatively low values of the standard deviations and fitting parameters. Similarly to the other DTPA−bis(amides) L^4 and L^5, the ligands L^1, L^2, and L^3 form only the species GdL, since the coordination number of Gd^{3+} practically agrees with the number of ligand donor atoms. This is probably the reason why the complexes GdL do not form dinuclear complexes in the presence of excess Gd^{3+}. In the ZnL^--Zn^{2+} systems, however, the formation of dinuclear complexes Zn_2L is possible because of the existence of free functional groups of the coordinated ligands. The differences between the titration curves obtained in the absence and the presence of excess Zn^{2+} clearly indicate the competition between H^+ and Zn^{2+} for the ZnL complexes. The stability constants of the dinuclear complexes Zn_2L [Equation (3)] were calculated from the titration data (42, 61 and 100 data points for the systems ZnL^1-Zn^{2+}, ZnL^2-Zn^{2+}, and ZnL^3-Zn^{2+}, respectively), and the $\log K_{M_2L}$ values are presented in Table 2.

$$K_{M_2L} = [M_2L]/\{[ML][M]\} \quad (3)$$

The formation of the dinuclear complexes Zn_2L results in more successful competition of Zn^{2+} with Gd^{3+} for the ligand, as found experimentally by Puttagunta et al.[30] These findings also mean that the selectivity of the DTPA-bis(amide) derivative ligands for Gd^{3+} over Zn^{2+} is lower than calculated by Cacheris et al.,[5] who assumed the formation only of the complexes ZnL and ZnHL.

The stability constants of the complexes of L^1, L^2, and L^3 with Gd^{3+} and Zn^{2+} are higher than those of the complexes with L^4 and L^5. This result can at least in part be interpreted in terms of the different media. In 0.1 M $NaClO_4$, Na^+ forms complexes with L^4 and L^5 more stable than those of K^+ with L^1, L^2, and L^3. The stronger competition of Na^+ with Gd^{3+} or Zn^{2+} for the ligand may result in some decrease in the stability constants in relation to the equilibrium constants observed in KCl solution.[31] Further, the basicity of L^1, L^2, and L^3 is higher than that of L^4 and L^5, as expressed in the values of the protonation constants.

Table 2. Stability constants ($\log K$) of the complexes Gd^{3+} and Zn^{2+} formed with the ligands L^1, L^2, L^3 (25 °C, 0.1 M KCl), L^4 and L^5 (25 °C, 0.1 M $NaClO_4$)

[a] Ref.[6] [b] Ref.[7]

Relaxivities of the Ligands and Complexes

The relaxivities of the ligands with stable nitroxide free radicals, measured at 9 MHz, are significantly lower than those of their Gd^{3+} complexes. For L^1, L^2, and L^3, the relaxivities were found to be 0.68, 0.57, and 0.88 $mM^{-1}\cdot s^{-1}$, respectively. The relaxivities of the five- and six-membered nitroxide stable free radicals are around 0.26 $mM^{-1}\cdot s^{-1}$ (25 °C, 9 MHz). Comparison of these values indicates that the relaxivities of L^1 and L^2 are a little higher than the sums of the relaxivities of the free radicals attached to the DTPA-bis(amide), while that of L^3 is somewhat lower (the error in the measurement of the relaxivities is ≤ 5%). On the basis of EPR studies, Sosnowsky et al. assumed a weak exchange interaction between the free radicals attached to EDTA or DTPA.[28]

The relaxivities of the complexes GdL^1, GdL^2, and GdL^3 are 7.46, 6.11, and 6.60 $mM^{-1}\cdot s^{-1}$, respectively. Since the relaxivity of [Gd-DTPA-BMA] is about 5.5 $mM^{-1}\cdot s^{-1}$ (25 °C, 9 MHz), the attachment of the nitroxide free radicals to the Gd-DTPA-bis(amide) complexes resulted in a weak increase in relaxivity. The interaction between the unpaired electron of the free radicals and Gd^{3+} must be negligible because the free radicals are not coordinated in the inner sphere of Gd^{3+} and some magnetic interaction is possible only if the free radical is in the inner sphere.[32]

The relaxivities of L^1, L^2, and L^3 decrease with increasing temperature. The temperature dependence of the relaxivity of the complex $[Gd(DTPA)]^{2-}$ is similar: the relaxivity decreases with increasing temperature (Figure 2). The relaxation effect of free radicals (and partly the Gd^{3+} complexes) arises from the translational diffusion of the water molecules near the paramagnetic centers, which results in the so-called outer-sphere contribution. An increase in temperature increases the rates of diffusion, which results in a decrease in the relaxivity values.[1a,1b] The exchange between the water molecule(s) coordinated in the inner sphere

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of Gd^{3+} complexes and the bulk water also produces an increase in the relaxivities. The contribution of the inner sphere effect is determined predominantly by the rotation correlation time of the complex at suitable rates of water exchange {e.g. for $[Gd(DTPA)]^{2-}$}. Increasing temperatures bring about decreases in the rotation correlation times and in relaxivities, as observed for $[Gd(DTPA)]^{2-}$.[1a,1b,10] However, the relaxivities of the complexes GdL^1, GdL^2, and GdL^3 in the 7−30 °C range exhibit practically no change with increasing temperature (Figure 2). Similarly, the relaxivities of GdL^4 were found to be practically independent of temperature.[10] An increasing temperature also results in decreases in the rotation correlation times for the Gd^{3+} complexes of the DTPA-bis(amide) derivatives. However, the rates of water exchange on the complexes of the DTPA-bis(amide) derivatives are about 10 times lower at 25 °C than those for $[Gd(DTPA)]^{2-}$, and the slower water exchange results in lower relaxivity values.[10,13,19,33] Increasing temperature causes an increase in the rate of water exchange, which would result in an increase of the relaxivity but this increase is compensated by the decrease in the relaxivity due to the shortening of the rotation correlation time. These results indicate that the Gd^{3+} complexes formed with the DTPA-bis(amide) derivatives containing stable nitroxide free radicals behave similarly to the complexes of the other DTPA-bis(amide)derivatives, which regularly display inner-sphere lifetimes of the water molecules longer than those seen for the ionic Gd^{3+} complexes such as $[Gd(DTPA)]^{2-}$ and $[Gd(DOTA)]^{-}$.[10,13,19,33]

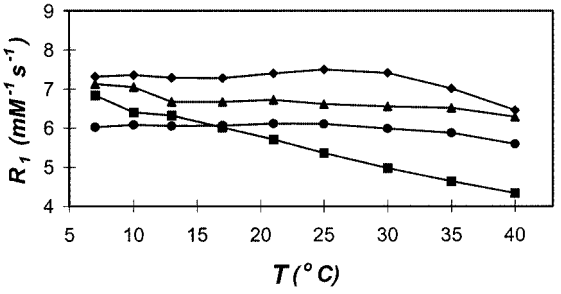

Figure 2. Temperature dependence of the relaxivities of the Gd^{3+} complexes (pH = 5, [GdL] = 1 × 10^{-3} M, 9 MHz) (◆ GdL^1, ● GdL^2, ▲ GdL^3, ■ $GdDTPA^{2-}$)

Kinetic Stabilities of Gd^{3+} Complexes

As far as the clinical use of Gd^{3+} complexes as MRI contrast agents is concerned, high kinetic stability is an important requirement. Since both Gd^{3+} and the aminopolycarboxylate ligand are toxic, the extent of dissociation of the complexes in the body has to be practically negligible. It has been proposed that the kinetic stabilities, measured in 0.1 M HCl (or $HClO_4$) are characterized by the rates of dissociation of the complexes.[34,35] In 0.1 M acid, the dissociation occurs predominantly through the proton-assisted dissociation of the complexes, and the role of direct reactions taking place through direct attack of the endogenous ions (e.g., Cu^{2+} or Zn^{2+}) on the complexes is neglected. In the dissociation of the DTPA and DTPA derivative complexes of Gd^{3+}, however, the direct reactions can be important, particularly at physiological pH values.[36,37]

The significance of the proton- and metal ion-assisted dissociation of complexes can be directly compared by study of the rates of the exchange reactions taking place between the Gd^{3+} complexes and some other Ln^{3+}, Cu^{2+} and Zn^{2+} species.[36,38] As the exchanging ion in this study we used Lu^{3+}, which forms more stable complexes than Gd^{3+} with L^1, L^2, and L^3, as indicated by the results of our preliminary experiments. Cu^{2+} could not be used as the exchanging ion because of its redox reactions with the free radicals. Of the endogenous ions, Zn^{2+} was used; this is present in the body fluids as an exchangeable species at relatively high concentrations.[39]

The rates of the exchange reactions were studied [in Equation (4), L = L^1, L^2 or L^3, and M = Lu^{3+} or Zn^{2+}].

$$GdL + M^{z+} \rightarrow ML^{(z-3)+} + Gd^{3+} \quad (4)$$

In the kinetic studies, the concentrations of the exchanging ions Lu^{3+} and Zn^{2+} were 20−60 times higher than the concentrations of the Gd^{3+} complexes. Under such conditions, the reactions can be regarded as pseudo-first order and the rates of the reactions can be expressed as in Equation (5), where k_p is a pseudo-first order rate constant, and $[GdL]_t$ is the total concentration of the Gd^{3+} complex.

$$-d[GdL]_t/dt = k_p [GdL]_t \quad (5)$$

The rates of the exchange reactions were studied at different concentrations of the exchanging Lu^{3+} and Zn^{2+} and at different pH values in the 4−5.2 range.

As can be seen in Table 2, the stability constants of the complexes ZnL formed with L^1, L^2, and L^3 are significantly lower than those of the respective Gd^{3+} complexes. Were only the complexes with a metal to ligand ratio of 1:1 formed, the extent of formation of Zn^{2+} complexes would be low. However, the relaxivities of the samples indicate that at equilibrium the Gd^{3+} is mostly present in the form of Gd^{3+}·aq species, which is possible only if some other Zn^{2+}-containing species is also formed besides the complexes ZnL, ZnHL, and ZnH_2L. This species is the dinuclear complex Zn_2L, as found in the equilibrium studies. In order to obtain reliable pseudo-first order rate constants, the rate data were used until about 60% conversion in the exchange reactions, and the k_p values were calculated by use of Equation (12). The relaxivities of the complexes GdL and the Gd^{3+}·aq ion were measured in separate experiments. The relaxivities of the complexes are presented above, while that of Gd^{3+}·aq is R_{Gd} = 16.9 mM^{-1}·s^{-1}. The pseudo-first order rate constants obtained are presented in Figure 3 and 4. The k_p values determined at different Lu^{3+} and Zn^{2+} concentrations are plotted against the H^+ concentration. As shown in Figure 3, the rates of the exchange reactions between the Gd^{3+} complexes and Lu^{3+} increase with rising H^+ concentration. The dependence can be expressed by a

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

second degree equation for the H^+ concentration. However, the k_p values increase very slightly with increasing Lu^{3+} concentration. For the reactions with Zn^{2+} (Figure 4) the k_p values are directly proportional to the H^+ concentration and increase with increasing Zn^{2+} concentration.

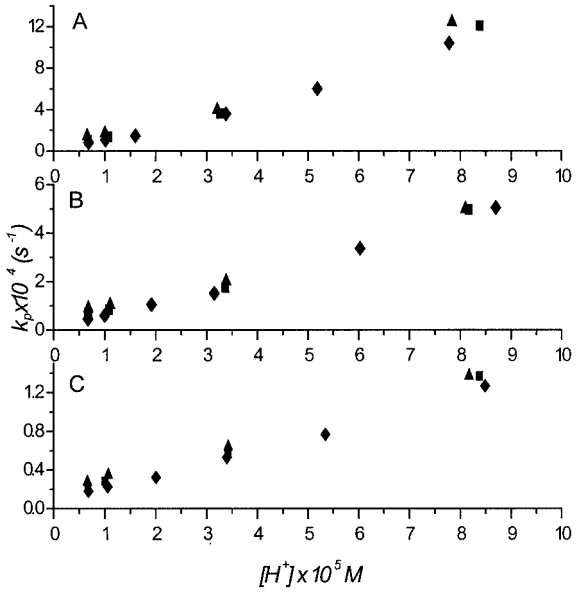

Figure 3. Rates of exchange reactions between Gd^{3+} complexes (5×10^{-4} M) and Lu^{3+}; $[Lu^{3+}] = 0.01$ M (◆), 0.02 M (■), and 0.03 M (▲) A: GdL^1; B: GdL^2, C: GdL^3 (25 °C, 1.0 M KCl)

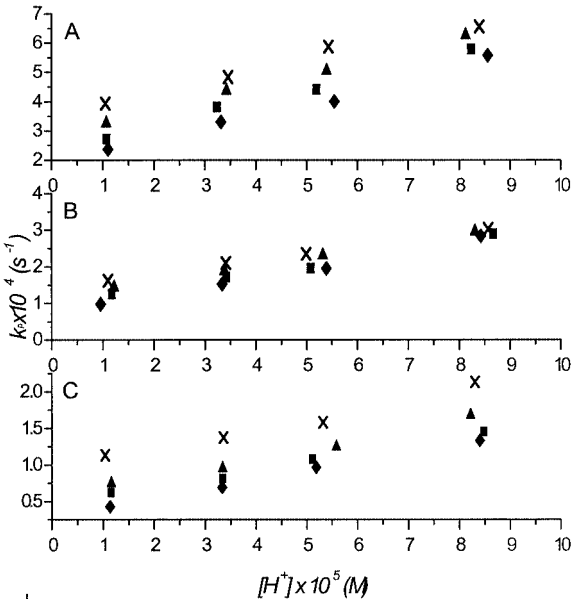

Figure 4. Rates of exchange reactions between Gd^{3+} complexes (5×10^{-4} M) and Zn^{2+}; $[Zn^{2+}] = 0.01$ M (◆), 0.015 M (■), 0.02 M (▲), and 0.03 M (×) A: GdL^1; B: GdL^2, C: GdL^3 (25 °C, 1.0 M KCl)

These findings are similar to those obtained for the exchange reactions of the DTPA and DTPA-mono(amide) complexes of Gd^{3+}.[36–38] The increases in the rates of the exchange reactions with increasing H^+ concentration can be interpreted in terms of the relatively slow, proton-assisted dissociation of Gd^{3+} complexes, which is followed by the fast reaction between the free ligand and the exchanging Lu^{3+} or Zn^{2+}. It can be assumed that H^+ protonates a carboxylate group of the ligand, which may be followed by the transfer of proton to a N atom when a glycinate functionality of the ligand becomes free, and the dissociation of the ligand can take place step by step.

The formation and dissociation of protonated complexes can be expressed as follows:

$$GdL + H^+ \overset{K_{GdHL}}{\rightleftharpoons} GdHL^+ \xrightarrow{k_{GdHL}} Gd^{3+} + HL^{2-} \quad (6)$$

The dissociation may occur more rapidly if a second proton is attached to the monoprotonated complex:

$$GdHL + H^+ \xrightarrow{k^H_{GdHL}} Gd^{3+} + H_2L^- \quad (7)$$

The increase in the exchange rate with increasing Lu^{3+} or Zn^{2+} concentration can be explained in terms of the direct attack of the exchanging metal ion on the complex, in which a dinuclear complex, GdLM, is formed, the ligand being transferred slowly, step by step, to the attacking ion:[36]

$$GdL + M^{z+} \overset{K_{GdLM}}{\rightleftharpoons} GdLM \xrightarrow{k_{GdLM}} ML + Gd^{3+} \quad (8)$$

From consideration of the reaction pathways [Equations (6)–(8)], the rates of the exchange reactions can be expressed as in Equation (9):

$$-d[GdL]_t/dt = k_{GdHL}[GdHL] + k^H_{GdHL}[GdHL][H^+] + k_{GdLM}[GdLM] \quad (9)$$

The pseudo-first order rate constant k_p can be expressed from Equations (5) and (9). By use of the expression for the total concentration of the complex, $[GdL]_t = [GdL] + [GdHL] + [GdLM]$, the equations defining the protonation constant $\{K_{GdHL} = [GdHL]/[GdL][H^+]\}$ and the stability constant of dinuclear complex $\{K_{GdLM} = [GdLM]/[GdL][M]\}$, k_p can be expressed as in Equation (10), where the rate constants $k_1 = k_{GdHL}K_{GdHL}$ and $k_2 = k^H_{GdHL}K_{GdHL}$ characterize the rates of the proton-assisted dissociation of the complexes, and $k_3 = k_{GdLM}K_{GdLM}$ is characteristic for the rates of exchange occurring through the direct attack of Lu^{3+} or Zn^{2+} on the complex:

$$k_p = \{k_1[H^+] + k_2[H^+]^2 + k_3[M]\}/\{1 + K_{GdLM}[M] + K_{GdHL}[H^+] \quad (10)$$

In the denominator of Equation (10), the term $K_{GdHL}[H^+]$ can be neglected since the protonation con-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stants of the Gd^{3+} complexes are very low (the formation of protonated complexes cannot be detected by pH potentiometry.)

The rate constants k_1, k_2, and k_3 and the stability constants K_{GdLM} were calculated by fitting the k_p values, obtained at different H^+ and exchanging metal concentrations, to Equation (10), and are given in Table 3. The K_{GdLM} values are relatively low and so could not be calculated for all the exchange reactions. Because of the low K_{GdLM} value in the denominator of Equation (10), $K_{GdLM}[M] << 1$ when the error in the calculated K_{GdLM} is high (in some cases the error was higher than the constant itself).

Table 3. Rate constants k_1 ($M^{-1}\cdot s^{-1}$), k_2 ($M^{-2}\cdot s^{-1}$) and k_3 ($M^{-1}\cdot s^{-1}$) characterizing the exchange reactions between the complexes GdL and Lu^{3+} or Zn^{2+} (25 °C, 1.0 M KCl)

Complex	Lu^{3+}	Zn^{2+}
GdL^1	$k_1 = 6.1\pm0.4$, $k_2=(9.6\pm0.7)\times10^4$, $k_3 = (3.3\pm0.2)\times10^{-3}$	$k_1 = 5.6\pm0.2$, $k_3 = (2.1\pm0.1)\times10^{-2}$, $K_{GdLZn} = 22\pm3$
GdL^2	$k_1 = 3.4\pm0.2$, $k_2=(2.9\pm0.4)\times10^4$, $k_3 = (2.4\pm0.2)\times10^{-3}$, $K_{GdLLu} = 3.0\pm1.8$	$k_1 = 3.1\pm0.1$, $k_3 = (9.2\pm0.4)\times10^{-3}$, $K_{GdLZn} = 27\pm3$
GdL^3	$k_1 = 1.4\pm0.1$, $k_3=(6.6\pm0.4)\times10^{-4}$	$k_1 = 1.2\pm0.1$, $k_3 = (3.1\pm0.1)\times10^{-3}$
$Gd(DTPA)^{2-}$[a]	$k_1 = 0.58$, $k_2 = 9.7\times10^4$, $k_3 = 4.9\times10^{-4}$, $K_{GdLEu}=20$	$k_3 = 5.6\times10^{-2}$
GdL^4 [a]		$k_1 = 12.7$, $k_3 = 7.8\times10^{-3}$

[a] Ref.[42]

The rate constants k_1 obtained for a given complex GdL in the reactions with Lu^{3+} and Zn^{2+} are practically equal, because the rates of the proton-assisted dissociation of the complexes are independent of the nature of the exchanging ion.

The exchange reactions occur more rapidly with Zn^{2+} than with Lu^{3+}. This is a result of the higher value of k_3, which is about five times greater for the reactions with Zn^{2+} than for Lu^{3+}. Zn^{2+} is more active than Lu^{3+} in the direct reaction because a $N-Zn^{2+}$ bond, which is stronger than the $N-Lu^{3+}$ bond, is formed in the dinuclear intermediate before the rate-determining step, and transfer of the other donor atoms from the Gd^{3+} to the Zn^{2+} is more probable.

Comparison of the values of k_1 and k_3 for the complexes GdL^1, GdL^2, GdL^3, and GdL^4 shows that the attachment of the free radicals to the DTPA-bis(amide) generally has only a slight effect on k_3. However, the k_1 values characteristic for the proton-assisted dissociation decrease by a factor of about 10 in the sequence GdL^4, GdL^1, GdL^2, and GdL^3. This sequence means that the kinetic stabilities are higher for the DTPA-bis(amide) derivative complexes containing free radicals.

The equilibrium and kinetic properties of the Gd^{3+} complexes indicate that the number of substituted amide hydrogens influences both the thermodynamic and kinetic stabilities. The stability constants of the Gd^{3+} complexes formed with the ligand L^3, containing two disubstituted amide groups, are higher than those of GdL^2, in which the ligand contains two monosubstituted amide groups. The trend in the kinetic stabilities is similar. The rate of proton-assisted dissociation is higher for GdL^2 than for GdL^3, so the complex formed with the disubstituted amide has the higher kinetic stability.

Experimental Section

Synthesis of the Ligands

DTPA dianhydride **2** (Scheme 1) was treated with paramagnetic amines RNHR′ **1** for L^1, L^2 and L^3 according to published procedures.[28,29,40,41] Since five-membered nitroxides are more stable than six-membered ones,[42] the syntheses were carried out with the five-membered ring nitroxide radical **1b** to give the biradical L^2. Since the preliminary results were promising, we tried to increase the number of the paramagnetic centers by treatment of DTPA dianhydride **2** with the biradical **1c** to yield the tetraradical L^3 (Scheme 1). For comparison, the ligand L^1 was synthesized by means of the reaction between **1a** and **2**, as carried out by Sosnowsky et al.[28]

A solution of the corresponding amine **1a**, **1b**, or **1c** (4.0 mmol) in dry DMF (30 mL) was added dropwise at 40 °C to a stirred solution of DTPA dianhydride **2** (758 mg, 2.2 mmol) in dry dimethylformamide (DMF, 60 mL), and the resulting mixture was stirred further at this temperature for 2 h. The mixture was left stand overnight and then filtered, and the filtrate was evaporated to dryness in vacuo. The residue was suspended in acetone (100 mL) and left stand at room temperature for 2 h. The turbid solution was then decanted from the residue, was again suspended in acetone (100 mL), and the mixture was left stand at 4 °C for 2 h. The resulting gummy material was filtered off and left stand over P_2O_5 in a vacuum desiccator overnight. The glassy semisolid was purified by flash column chromatography with $CHCl_3$/MeOH, 3:1, followed by $CHCl_3$/MeOH, 1:1 and $CHCl_3$/MeOH, 1:3. The effluents gathered with $CHCl_3$/MeOH, 1:1 and $CHCl_3$/MeOH, 1:3 were pooled and the solvents were evaporated to dryness. The crystalline residue was taken up in Et_2O (20 mL) and filtered, and the filter cake was washed with acetone (30 mL), then with a 1:1 mixture of acetone/Et_2O (30 mL), and air-dried.

DTPA-Bis(amide) H_3L^2: A yellow solid, 532 mg (38%); m.p. 130−133 °C; $R_f = 0.28$ (MeOH). IR (Nujol): $\tilde{\nu}$ = 3270, 1710, 1640, 1530 cm^{-1}. $C_{32}H_{53}N_7O_{10}$ (695.81): calcd. C 55.24, H 7.68, N 14.09; found C 55.05, H 7.86, N 14.00.

DTPA-Bis(amide) H_3L^3: Et_2O was used instead of acetone during the workup. A yellow solid, 800 mg (40%); m.p. 140−142 °C; R_f = 0.37 (MeOH). IR (Nujol): $\tilde{\nu}$ = 3400, 1710, 1650 cm^{-1}. $C_{50}H_{81}N_9O_{12}$ (1000.25): calcd. C 60.04, H 8.16, N 12.60; found C 60.19, H 8.14, N 12.74.

Melting points were determined with a Boetius micro melting point apparatus and are uncorrected. Elemental analyses (C, H, N, S) were performed with a Fisons EA 1110 CHNS elemental analyzer. The IR (Specord 75) spectra were in each case consistent with the assigned structure. Flash column chromatography was performed on Merck Kieselgel 60 (0.040−0.063 mm). Qualitative TLC was carried out on commercially prepared plates (20 × 20 × 0.02 cm)

coated with Merck Kieselgel GF_{254}. DTPA dianhydride **2** was purchased from Aldrich. Compounds **1b** and **1c** were prepared as published earlier.[43,44]

Equilibrium Measurements

For the preparation of $GdCl_3$ and $LuCl_3$ stock solutions, Gd_2O_3 and Lu_2O_3 (99.9%, Fluka) were dissolved in 1:1 HCl and the excess of acid was evaporated off. $ZnCl_2$ solution was prepared by dissolving $ZnCl_2$ in doubly distilled water. The concentrations of the metal chloride solutions were determined by complexometry with standardized K_2H_2edta, with xylenol orange as indicator (H_4edta = ethylenediaminetetraacetic acid).

The concentrations of the ligands L^1, L^2, and L^3 were determined by pH-potentiometry, on the basis of the titration curves obtained in the presence and absence of an excess of $CaCl_2$ ($c_{Ca}/cL \approx 40$, when all the dissociable protons of the ligands dissociate).

The protonation constants of the ligands were determined by pH-potentiometric titrations with a Radiometer PHM 93 Reference pH-meter, an ABU 80 autoburette, and PHG 211 glass and K 401 calomel electrodes. The titration vessel was thermostatted at 25 °C. The titrated solutions (15 mL, 1 mM) were stirred and N_2 was bubbled through them. The titrations were carried out in the pH range 1.7−11.5. For the calibration of the pH-meter, KH phthalate (pH = 4.008) and borax (pH = 9.180) buffers were used. The titrations were performed in 0.1 M KCl solutions with standardized KOH solution. To obtain H^+ concentrations from the measured pH values, the method proposed by Irving et al. was used.[45] A 0.01 M HCl solution (0.1 M for KCl) was titrated with standardized KOH solution. The differences between the measured and calculated pH values were used to calculate the H^+ concentrations from the pH values obtained in the titration experiments.

The stability constants of the complexes GdL and ZnL were determined by pH-potentiometry. The titrations were performed at metal to ligand ratios of 1:1 in 1.0 mM solutions (0.1 M KCl) in the pH range 1.7−11.5.

The formation equilibria of the dinuclear complexes Zn_2L were studied by pH-potentiometry. The solutions of ligands (1.5×10^{-3} M) were titrated with 0.2 M KOH in the presence of an excess of Zn^{2+} (3.1×10^{-3} M). In the knowledge of the stability constants of the complexes ZnL, ZnHL, and ZnH_2L and on the basis of the competition of H^+ and Zn^{2+} for ZnL, the stability constants of the complexes Zn_2L were determined.

The protonation and stability constants of the complexes were calculated with the program PSEQUAD.[46]

Measurement of Relaxation Times

The relaxation times of the water protons were measured at 9 MHz with an MS-4 NMR spectrometer. The temperature of the sample holder was controlled with a thermostatted air stream. The longitudinal relaxation times (T_1) were measured by the inversion recovery method (180°-τ-90°), with five to nine measurements at six to eight different τ values at 25 °C. In the study of the temperature dependence (7−40 °C) of the relaxation times, the concentration of the complexes GdL^1, GdL^2, and GdL^3 was 1.0 mM, while the concentration of the free radical ligands L^1, L^2, and L^3 was 10.0 mM. In the preparation of the solutions of complexes, a slight ligand excess was used. The pH of the solutions was around 5. To characterize the relaxation behavior of the free ligands and the complexes GdL, the water proton relaxation rates ($1/T_1$) were used as in Equation (11), where T_{1m} and T_{1w} are the relaxation times, measured in the presence and absence of the paramagnetic compound:

$$1/T_1 = 1/T_{1m} - 1/T_{1w} \quad (11)$$

The relaxivity (R_1) of the solutions is the increase in the relaxation rates observed on an increase in the concentration of the paramagnetic species (c_p) by 1.0 mM (i.e., $R_1 = (1/T_1) \times (1/c_p)$ $mM^{-1} \cdot s^{-1}$).

Kinetic Studies

The kinetic stabilities of the complexes (GdL) were characterized by the rates of the exchange reactions occurring between the paramagnetic complex and the diamagnetic Lu^{3+} or Zn^{2+}. The progress of the exchange reactions was followed by measurement of the relaxation rates, since the relaxivities of the complexes GdL and the ion Gd^{3+}.aq formed in the exchange reactions differ considerably. The exchanging metal ions were used in large excess in order to guarantee pseudo-first order conditions. The ionic strength of the solutions was kept constant (1.0 M for KCl). The exchange rates were studied in the pH range about 4−5.2. In the reactions with Zn^{2+} or Lu^{3+}, boric acid (0.01 M) − mannitol (0.04 M) or *N*-methylpiperazine (0.01 M) buffers were used, respectively. The pseudo-first order rate constants (k_p) were calculated by fitting the relaxation rate data to the Equation (12), where R_t is the relaxivity at time t, and R_0 and R_p are the relaxivities at the start of the reaction and at equilibrium, respectively.

$$R_t = (R_0 - R_p) \exp(-k_p t) + R_p \quad (12)$$

Lanthanide Complexes of 2,6-Dihydroxybenzoic Acid: Synthesis, Crystal Structures and Luminescent Properties of $[n\mathrm{Bu_4N}]_2[\mathrm{Ln(2,6\text{-}dhb)_5(H_2O)_2}]$ (Ln = Sm and Tb)

Paula C. R. Soares-Santos,[a] Helena I. S. Nogueira,[a] Filipe A. Almeida Paz,[c] Rute A. Sá Ferreira,[b] Luís D. Carlos,[b] Jacek Klinowski,[c] and Tito Trindade*[a]

Keywords: Lanthanides / O ligands / Luminescence / Triboluminescence

Lanthanide complexes of 2,6-dihydroxybenzoic acid (2,6-Hdhb), namely $[n\mathrm{Bu_4N}]_2[\mathrm{Ln(2,6\text{-}dhb)_5(H_2O)_2}]$ [Ln = Sm (**1**) and Tb (**2**)], were synthesized and their crystal structures determined by single-crystal X-ray diffraction studies. The 2,6-$\mathrm{dhb^-}$ ligand coordinates to the lanthanide cations through the carboxylate group in a monodentate or bidentate chelating coordination mode. The compounds were further characterised using IR, Raman, ^{1}H and ^{13}C NMR spectroscopy and elemental analysis. Photoluminescence measurements were performed on both compounds. In particular, the terbium complex **2** shows intense photoluminescence both in the solid state and in ethanolic solution. Compound **2** also exhibits triboluminescence.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Interest in the photophysical properties of lanthanide ion complexes has grown considerably in the last few years[1−3] since Lehn proposed that such complexes could be used as light conversion molecular device units (LCMDs).[4] Appropriate organic ligands can act as light collectors (antenna) and transfer absorbed energy to the coordinated lanthanide ion (emitter). These highly luminescent lanthanide complexes can act as functional units for the creation of luminescent devices on the nanoscale or molecular scale. We have been interested in the synthesis and characterisation of such complexes and in particular, lanthanide compounds containing aromatic ambidentate ligands in the first coordination shell.[5]

Complexes of Y^{3+}, La^{3+}, Pr^{3+}, Nd^{3+}, Sm^{3+} and Gd^{3+} with 2,6-dihydroxybenzoic acid (2,6-Hdhb) have been reported, along with their IR and UV/Vis spectra in ethanolic solutions, but their molecular formulae were not determined.[6] Brzyska et al. investigated the IR spectra and the thermal behaviour of 2,6-Hdhb complexes for a series of lanthanides including those of Y^{3+}, the series La^{3+} to Eu^{3+}[7] and Gd^{3+} to Lu^{3+},[8] with general formulae being proposed as $[\mathrm{Ln(C_7H_5O_4)_3}]\cdot n\mathrm{H_2O}$, where $n = 4$ for Ln = La^{3+} to Sm^{3+}, $n = 6$ for Eu^{3+}; $[\mathrm{Ln(C_7H_5O_4)_3(H_2O)_4}]\cdot 2\mathrm{H_2O}$ for Ln = Y^{3+} and Gd^{3+} to Lu^{3+}.[8] Glowiak et al. reported the crystal structures of the Tb^{3+} and Ho^{3+} complexes of 2,6-Hdhb,[9] confirming their molecular formula. 2,6-Hdhb complexes of the d-block metals have also been reported, namely those of Mo^{VI}, Os^{VI},[10] Re^{V},[10,11] Cu^{II} [12] and Ag^{I}.[13]

Here we report the synthesis and structural characterisation of new Sm^{3+} and Tb^{3+} complexes of 2,6-Hdhb. The 2,6-Hdhb ligand shows different coordination modes, either using both the carboxylate group and an adjacent hydroxy group in a salicylato-type chelate,[11] or utilising only the carboxylate group in a monodentate[12] or bidentate fashion.[9,14] The crystal structures of the complexes $[n\mathrm{Bu_4N}]_2[\mathrm{Ln(2,6\text{-}dhb)_5(H_2O)_2}]$ [Ln = Sm (**1**) and Tb (**2**)], were determined by single-crystal X-ray diffraction studies.

In complexes **1** and **2** the 2,6-$\mathrm{dhb^-}$ ligand coordinates both in a monodentate or chelating bidentate manner which is in contrast to that seen in similar compounds reported in the literature.[9] The photoluminescent behaviour of the complexes was investigated and the photophysical properties of the Tb^{3+} complex **2** were studied both in the solid state and in ethanolic solution. It was found that when compound **2** was subjected to mechanical force, luminescence was observed. This phenomenon is known as triboluminescence and the corresponding spectrum for compound **2** is presented and discussed. The compound $[\mathrm{Tb(2,6\text{-}dhb)_3(H_2O)_4}]\cdot 2\mathrm{H_2O}$ (**3**), previously reported by

Results and Discussion

Crystal Structures of $[n\mathrm{Bu_4N}]_2[\mathrm{Ln(2,6\text{-}dhb)_5(H_2O)_2}]$ Complexes

Single-crystal X-ray diffraction studies revealed similar crystal structures for the Sm^{3+} and Tb^{3+} complexes, which crystallise in the chiral and non-centrosymmetric $P2_1$ space group. The molecular formulae were calculated as $[n\mathrm{Bu_4N}]_2[\mathrm{Ln(2,6\text{-}dhb)_5(H_2O)_2}]$ [where Ln = Sm^{3+} (**1**) and Tb^{3+} (**2**)] (Table 1). Phase purity and homogeneity of the bulk samples were confirmed by elemental analyses and X-ray powder diffraction experiments. The crystal structures contain only one crystallographically unique metal centre coordinated to five 2,6-dhb$^-$ organic ligands and two water molecules, in a geometry which is best described as a distorted tricapped trigonal prism (Figures 1 and 2, Tables 2 and 3). The $[\mathrm{Ln(2,6\text{-}dhb)_5(H_2O)_2}]^{2-}$ complex anions (Ln = Sm^{3+} and Tb^{3+}) are chiral and the average Ln−O distance for the coordinated solvent molecules is 2.45 and 2.41 Å (for compounds **1** and **2**, respectively), in good agreement with reported results for other Ln complexes.[15] 2,6-dhb$^-$ appears as an *exo*-monodenate ligand forming two coordinative η^3-*syn*,*syn*-chelates and three *syn*-unidentate bonds to the lanthanide centres. All the carboxylate groups maintain the equivalence of the C−O bonds, with the distances being in the 1.26−1.28 Å range (Table 2). This is particularly unexpected for the unidentate groups, and can be explained by the presence of strong hydrogen bonds with the water molecules (Table 4).[16] The average O−C−O angles for the carboxylate groups (121.5 and 121.4° for **1** and **2**, respectively) are also close to the expected values.[16] An interesting feature of the crystal is the medium-intensity hydrogen bond between the O2 water molecule and the O14 hydroxy group of the neighbouring $[\mathrm{Ln(2,6\text{-}dhb)_5(H_2O)_2}]^{2-}$ complex ($O2\cdots O14^{i} \approx 2.9$ Å; symmetry code i: $x-1, y, z$), leading to the formation of a hydrogen-bonded metal chain which runs along the *a* direction of the unit cell (Figures 2 and 3, Table 4). Each hydroxy group of the 2,6-dhb$^-$ ligands is also involved in strong hydrogen bonding with the nearest oxygen atoms (Table 4).

Vibrational and NMR Spectra

Selected IR and Raman spectroscopic data for the free ligand 2,6-Hdhb, the tetrabutylammonium salt of the 2,6-dhb$^-$ ligand, $[n\mathrm{Bu_4N}]$[2,6-dhb], and the lanthanide complexes are shown in Table 5. Tentative assignments are based on those found in the literature for other 2,6-Hdhb complexes.[10,11] The IR spectra of the 2,6-dhb$^-$ tetrabutylammonium salt and of the lanthanide complexes both exhibit a broad band with a maximum in the region 3453−3419 cm^{-1} which can be assigned to the phenolic ν(O−H) stretch (3478 cm^{-1} in the free ligand) and to the coordinated water molecules. The corresponding δ(OH) bend is observed at 1351 cm^{-1} in the ligand, at 1345 cm^{-1} in the 2,6-dhb$^-$ tetrabutylammonium salt and at 1355 cm^{-1} in the complexes. The IR and Raman spectra of the free ligand both show a very strong band which may be assigned to the ν(C=O) at 1681 and 1674 cm^{-1}, respectively. In the

spectra of the complexes, the assymetric $\nu_{as}(CO_2)$ is shifted to a higher wavenumber by up to 11 cm^{-1} upon coordination, when compared with the tetrabutylammonium salt of the 2,6-dhb^- ligand (1633 cm^{-1}). The symmetric mode $\nu_s(CO_2)$ also shows shifts to a higher wavenumber upon coordination (1292 cm^{-1} in the complexes) when compared with the tetrabutylammonium salt of the ligand (1286 cm^{-1}). The band at 1241 cm^{-1} in the spectrum of the tetrabutylammonium salt of the ligand, assigned to the $\nu(C-O)_h$ stretch (at 1236 cm^{-1} in the free ligand) of the phenolic groups, shifts to 1228 cm^{-1} on coordination, possibly due to hydrogen bonding.

^1H and ^{13}C NMR spectroscopic data for the free ligand and its lanthanide complexes in deuterated dimethyl sulfoxide solution are given in Table 6 (see Scheme 1 for labelling and Table 6 for tentative assignments). In the ^1H NMR spectra, the line arising from H^3 and H^5 appears as a doublet, and the line arising from H^4 as a triplet, with relative intensities of 2:1, respectively, either in the free ligand or in the complexes. The resonances of these protons shift to higher field on coordination. The resonances due to the protons of the counterion can also be observed in the spectra of the complexes. The resonances of the aromatic protons in **2** show higher shifts when compared with the values obtained for **1**, which may be induced by the Tb^{III} ion. In the spectra of **1** and **2** we can also observe resonances due to the phenolic protons as a broad signal (at δ = 14.5 and 14.0 ppm), with relative intensities of 2:1 when compared with the line assigned to H^4.

^{13}C NMR spectroscopy shows the resonances of all the carbon atoms, both of the ligand and the counterion. The most relevant shifts are observed in the signal of the carboxylate atom C^7, which shifts to lower-field on coordination, showing that the ligand is bound to the lanthanide atom through the carboxylate oxygen atoms.

Luminescence Spectra

Figures 4 and 5 show the room-temp. photoluminescence (PL) features of compounds **1**, **2** and **3**, excited at 350, 344 and 342 nm, respectively. The emission spectrum of the Sm^{3+} complex (Figure 4) is composed of a large broad band between 380 and 500 nm and a series of straight lines assigned to intra-4f^5 transitions between the $^4G(4)_{5/2}$ and the $^6H_{5/2,7/2,9/2,11/2}$ levels. Apart from a red shift (2000 cm^{-1}), the large broad band was already observed in the emission spectrum of 2,6-Hdhb, as shown in the inset of Figure 4. In the emission spectra of the Tb^{3+} compounds **2** and **3** only the intra-4f^8 lines, corresponding to transitions between the $^5D_4$ and $^7F_{6-0}$ levels, could be detected (Figure 5). The fact that the ligand's broad band could not be observed, clearly indicates a more efficient energy transfer between the Tb^{3+} ions and the 2,6-dhb ligand than that involving the Sm^{3+} cations.

The Tb^{3+} emission of compound **2** was compared with that of compound **3** and with the emission arising from compound **2** in a 1.4 mM alcoholic solution (Figure 5). All the spectra display the typical Tb^{3+} lines resulting from $^5D_4 \rightarrow {}^7F_{6-0}$ transitions. The emission lines of the Tb^{3+} alcoholic solution are almost identical to the ones observed for the powdered compound **2** in terms of energy and full width at half maximum. However, the Tb^{3+} transitions in compound **3** are more structured, providing evidence for a higher number of Stark components. In order to evaluate accurately the PL differences between the two Tb^{3+} solid samples, the respective emission spectra were measured at 10 K (Figure 6, A and B).

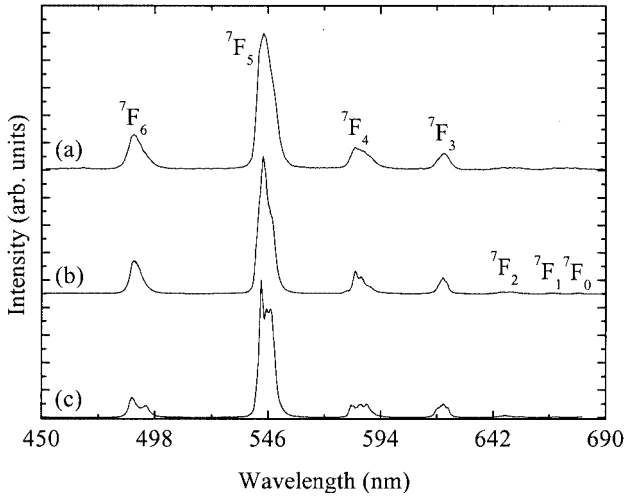

Figure 5. Room-temp. PL spectra of (a) 1.4 mM ethanolic solution of **2**, (b) compound **2** and (c) compound **3**

The most evident change with the decrease in temperature is related to the increase in the number of identified Stark components. For instance, in the most intense transition namely $^5D_4 \rightarrow {}^7F_5$, we can clearly distinguish 22 Stark components in both samples (Figure 6). Focusing our attention in the region of the $^5D_4 \rightarrow {}^7F_0$ transition, at least two lines, separated by 36 cm^{-1}, are undoubtedly discernable in the emission spectrum of **3**. For compound **2** the $^5D_4 \rightarrow {}^7F_0$ transition has a large value of 46 cm^{-1} for its full width at half maximum, suggesting the presence of more than one emission line. Since the Tb^{3+} ions lie in the same average local symmetry site (in agreement with the XRD data) and the $^7F_0$ is a non-degenerated level, the de-

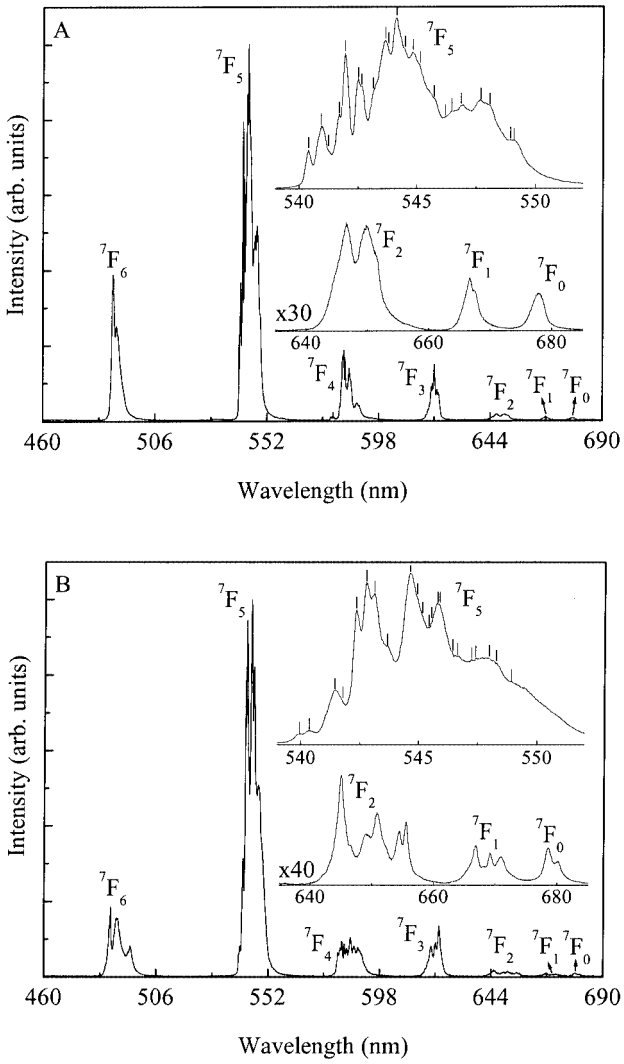

Figure 6. PL spectra, recorded at 10 K under 344 nm excitation wavelength of compound **2** (A) and compound **3** (B)

tection of more than one component in the $^5D_4 \rightarrow {}^7F_0$ region points to the thermal population of the upper $^5D_4$ levels. Even at 10 K, the emission from such levels, usually termed as hot lines, is not quenched making the emission spectra quite intricate.[17] These hot lines are responsible for the higher number of components perceived in the remaining transitions (Figure 6, A and B) and, thus, the observed local-field splitting of the $^5D_4 \rightarrow {}^7F_{1-6}$ transitions are in agreement with the point site symmetry group identified by XRD.

The differences observed between compounds **2** and **3** clearly indicate that the synthetic procedure results in different local coordination sites for the Tb^{3+} ions. On the contrary, dissolving the former compound in ethanol did not produce significant changes in the PL properties of the Tb^{3+}. This result suggests that the lanthanide ions are well shielded by the ligands from the incorporation of solvent molecules in the first coordination sphere which would contribute to the quenching of the emission intensity.

Figure 7 shows the room-temp. excitation (PLE) spectrum of the Sm^{3+} complex monitored around the cation's more intense line at 641 nm. The spectrum displays a large broad band between 250 and 420 nm, centred around 330 nm, and a series of sharp lines characteristic of the Sm^{3+} energy levels.

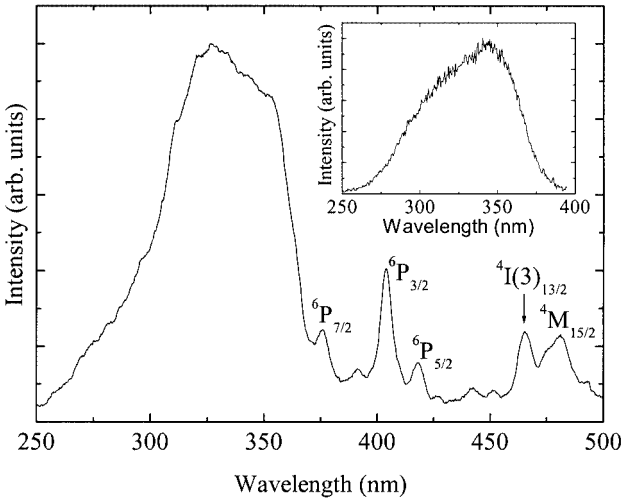

Figure 7. Room-temp. PLE spectrum of compound **1**; the inset shows the room-temp. PLE spectrum of the 2,6-Hdhb ligand detected around 480 nm

Figure 8 shows the PLE spectra of compounds **2** and **3** and of a 1.4 mM alcoholic solution of **2**. All the spectra exhibit a large broad band in the same spectral region of that observed in the PLE spectrum of the Sm^{3+}-based complex. The excited levels were only detected in the PLE spectrum of the Tb^{3+} solution. The large broad band is centred around 344, 342 and 327 nm, for **2**, **3** and the alcoholic solution, respectively. This band may be related to the ligand's excited states, since the PLE spectrum of the 2,6-

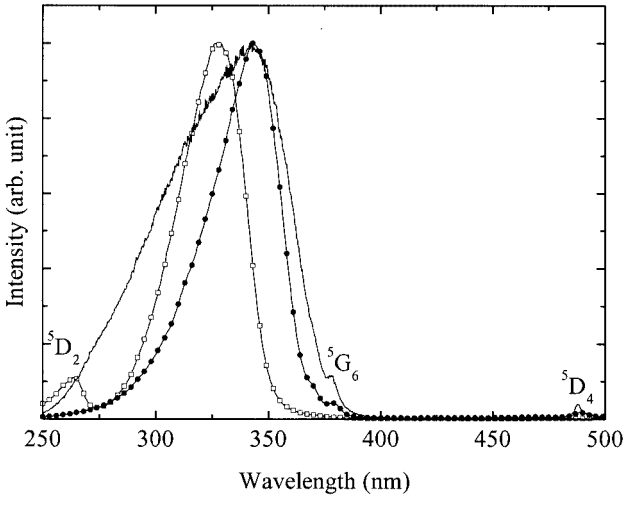

Figure 8. Room-temp. PLE spectra of compound **2** (solid line with solid circles), compound **3** (solid line) and a 1.4 mM ethanolic solution of **2** (solid line with open squares)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Hdhb ligand is characterized by a similar large broad band with peaks around 341 nm (inset of Figure 7).

The lifetimes of the $^5D_4$ Tb^{3+} excited levels were measured at room temperature under the excitation wavelength that maximizes their luminescent intensity for the two powdered complexes and for the ethanolic solution. The monitoring wavelength was set around the more intense emission line (544 nm). The lifetime of the $^4G(4)_{5/2}$ Sm^{3+} excited level could not be recorded since it lies in a time scale below our lower experimental detection limit (10^{-5} s). Figure 9 depicts the experimental data in a logarithmic scale for the three Tb^{3+}-based samples. All the data were well fitted by a single exponential function, confirming that all lanthanide ions occupy the same average local environment within each complex.

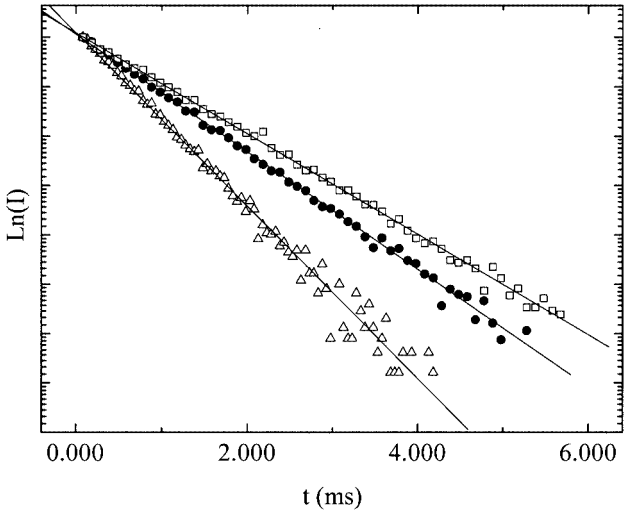

Figure 9. Room-temp. decay curves for compound **2** (solid circles), compound **3** (open triangles) and a 1.4 mM ethanolic solution of **2** (open squares); the solid lines represent the data best fits, assuming a single-exponential function ($r > 0.99$)

The $^5D_4$ lifetimes of **2** and the corresponding 1.4 mM ethanolic solution are 0.876 ±0.012 and 0.983 ±0.007 ms, respectively. Both values are similar, confirming the previous suggestion that solvation did not induce significant changes on the Tb^{3+} local environment, meaning that the ligands are efficiently shielding the lanthanide ions. The $^5D_4$ lifetime for **3** is smaller than the previous two values, being 0.562 ±0.001 ms. This decrease indicates that non-radiative pathways are more important in the latter complex. In fact, if we recall the local Tb^{3+} structure in both complexes, the lanthanide's first coordination sphere in **2** and **3** differs in the number of water molecules by two and four, respectively. It is well known that the presence of OH oscillators in the lanthanide first coordination sphere provides an efficient non-radiative path, so we can suggest that the observed decrease in the lifetime of the $^5D_4$ level is mainly related to an increase in non-raditive transitions due to the increase in the number of OH oscillators in the Tb^{3+} first coordination shell, which is in perfect agreement with the proposed structural results.

When ground by hand in daylight, single crystals of **2** exhibit green luminescence detectable by the naked-eye (Figure 10). The spectrum exactly matches that observed by excitation using UV light, indicating that triboluminescence (TL) involves the same Tb^{3+} excited-state deactivation as that observed in PL. The mechanisms behind TL are not well understood and predictions of this behaviour for a specific compound cannot be made. While TL behaviour of some compounds has been attributed to the piezoelectric properties of non-centrosymmetric crystals, many TL centrosymmetric crystals have also been reported.[18] Compound **2** is a non-centrosymmetric ionic complex and it has been suggested[18,19] that TL arises from charge separation by partial fracture along oppositely charged planes. Further work is under way to clarify the nature of the TL mechanism in this compound.

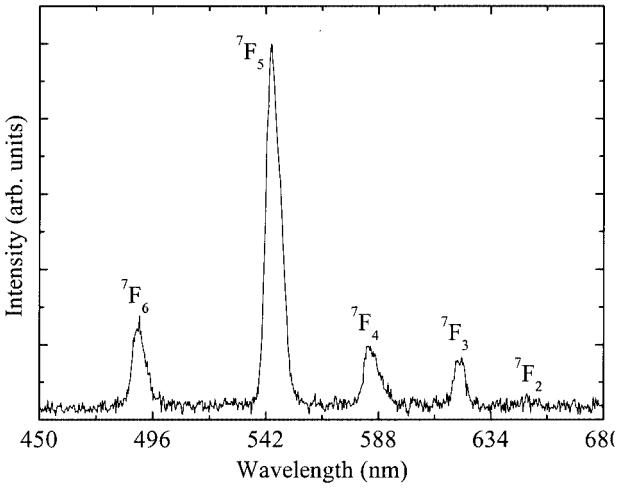

Figure 10. Room-temp. TL spectrum of compound **2**

Conclusion

New samarium and terbium complexes of 2,6-dihydroxybenzoic acid, each containing five 2,6-dhb$^-$ ligands coordinated to the metal centres and two tetrabutylammonium cations, have been synthesized and structurally characterized. The X-ray crystal structures show the carboxylate groups acting both as monodentate or bidentate chelating ligands; two water molecules complete the first coordination shell with a coordination number of nine. The luminescent properties of the Tb^{3+} complex with the 2,6-dhb$^-$ ligand are described here for the first time. The Tb^{3+} complex shows very high luminescence, even in an ethanolic solution. These particular luminescent properties may be explored in order to develop solution methods based on new luminescent materials in which this molecular unit could act as the active centre. Given its triboluminescent behaviour, the terbium compound is a potential candidate for the development of optical sensors.

Experimental Section

General: All chemicals were supplied by Aldrich and used without further purification. The terbium complex [Tb(2,6-dhb)$_3$(H$_2$O)$_4$]·2H$_2$O (**3**) was synthesized as described by Brzyska et al.[8]

Preparation of [*n*Bu$_4$N]$_2$[Ln(2,6-dhb)$_5$(H$_2$O)$_2$] [Ln = Sm (1) and Tb (2)]: The lanthanide complexes were prepared by adding an aqueous solution (ca. 20 mL) of the lanthanide salt Ln(NO$_3$)$_3$·5H$_2$O (Ln = Sm^{3+}, Tb^{3+}; 0.889 g, 2.00 mmol and 0.872 g, 2.00 mmol, respectively) to an aqueous solution (ca. 40 mL, pH = 3.0±0.1) containing 2,6-dihydroxybenzoic acid (1.23 g, 8.00 mmol) and KOH (0.448 g, 8.00 mmol). After stirring the mixture for 1 h, an aqueous solution (5 mL) containing tetrabutylammonium chloride hydrate (*n*Bu$_4$NCl·*n*H$_2$O, 1.11 g, 4.00 mmol) was added and a flocculant white solid was immediately formed. The supernant solution was decanted and the precipitate collected and washed with distilled water. Crystals of [*n*Bu$_4$N]$_2$[Ln(2,6-dhb)$_5$(H$_2$O)$_2$] [Ln = Sm^{3+} (**1**) and Tb^{3+} (**2**), respectively], suitable for single-crystal X-ray diffraction were obtained from the filtrate after 1 d.

Preparation of [*n*Bu$_4$N][2,6-dhb]: The 2,6-dhb$^-$ tetrabutylammonium salt, [*n*Bu$_4$N][2,6-dhb], was prepared by adding an aqueous solution (ca. 5 mL) of *n*Bu$_4$NCl·*n*H$_2$O (0.556 g, 2.00 mmol) to an aqueous solution (ca. 10 mL) containing 2,6-dihydroxybenzoic acid (0.308 g, 2.00 mmol) and KOH (0.112 g, 2.00 mmol). After stirring the mixture for 1 h, the white precipitate formed was filtered and washed with distilled water.

Characterisation: IR spectra were measured using KBr disks with a Mattson 7000 FT instrument. Raman spectra were recorded using a Bruker RFS100/S FT-Raman spectrometer (Nd:YAG laser, 1064 nm excitation). ^{1}H spectra were obtained using a Bruker AMX-300 spectrometer (^{1}H, 300 MHz; ^{13}C, 75.4 MHz) referenced to Si(CH$_3$)$_4$ or the solvent. Elemental analyses for carbon, nitrogen and hydrogen were performed with an Exeter Analytical CE-440 Elemental Analyser. The sample was combusted under oxygen at 975 °C for 1 min, with He as the purge gas. The lanthanide content in the complexes was measured by ICP (Analytical Laboratories, University of Aveiro). Powder X-ray diffraction patterns (PXRD) were recorded at ambient temperature using a Philips X'Pert instrument, operating with a monochromated Cu-K_α radiation source at 40 kV/50 mA. Data were collected using the step-counting method (step 0.01°, 7 s per step) in the $2° \leq 2\theta \leq 60°$ range. Theoretical PXRD calculations were performed using the STOE Win XPOW software package.[20] Photoluminescence (PL) spectra, measured between 10 K and room temp. were recorded using a Jobin Yvon-Spex spectrometer (HR, 460) coupled to an R928 Hamamatsu photomultiplier. An Xe arc lamp (150 mW) coupled to a Jobin Yvon monochromator (TRIAX 180) was used as the excitation source. All the spectra were corrected for the response of the detector. The lifetime measurements were carried out using a pulsed Xe arc lamp (5 mJ/pulse, 3 μs bandwidth) coupled to a Kratos GM-252 monochromator and a Spex 1934 C phosphorimeter. The room-temp. triboluminescence (TL) spectra were recorded with a plug-in high-sensitivity fibreoptic UV/Vis shortwave master spectrometer, fitted with a grating blazed at 500 nm with 600 grooves per mm, with a 2048-element linear CCD-array detector (PC, 2000, Ocean Optics, Inc.). A PC 2000 was mounted on a 1 MHz ISA-bus A/D card fitted directly into a desktop PC. The single-crystals of **2** were ground by hand using the plug-in high sensitivity fibre optic.

X-ray Crystallographic Studies: Suitable single crystals of **1** and **2** were mounted on glass fibres using perfluoropolyether oil.[21] Data were collected with a Nonius Kappa CCD diffractometer with Mo-K_α graphite-monochromated radiation (λ = 0.7107 Å). The structures were solved by direct methods and refined by full-matrix least squares on F^2 with anisotropic displacement parameters for all non-hydrogen atoms.[22,23] Multi-scan absorption corrections were also applied.[24] All hydrogen atoms were placed in calculated positions, and refined using a riding model with an isotropic displacement parameter fixed at x times U_{eq} for the atom to which they are bound (x = 1.5 for all the O−H and −CH$_3$ groups, and x = 1.2 for the remaining hydrogen atoms). Bond-length restraints were not applied, except for H atoms associated with the water molecules, for which the O−H and H−O−H distances were restrained to ensure a chemically reasonable geometry for the water molecule. Information concerning crystallographic data collection and structure refinement for **1** and **2** is summarised in Table 1, while selected bond lengths and angles are given in Tables 2 and 3, respectively. CCDC-201808 and -201809 contain supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre,12 Union Road, Cambridge CB2 2EZ, U.K.; Fax: (internat.) + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk)].

Acknowledgments

We are grateful to J. Soares for assistance in the triboluminescence measurements, to the University of Aveiro for a PhD research grant (P. C. R. S. S.), and to Fundação para a Ciência e a Tecnologia (Portugal), for financial support through the SFRH/BD/3024/2000 (F. A. A. P.) and SFRH/BPD/11480/2002 (R. A. S. F.), PhD and post-doc scholarships, respectively. We are also grateful for additional financial support from the FCT (grant contract: POCTI/35378/QUI/2000 and POCTI/33653/CTM/2000) supported by FEDER.

A Novel Mixed-Valence Cu^{I}/Cu^{II} Coordination Polymer: Solvothermal Synthesis, Crystal Structure, and Magnetic Properties of $Cu^{I}Cu^{II}$(2-Pyrazinecarboxylate)$_2$(H_2O)(ClO_4)

Cai-Ming Liu,*[a] De-Qing Zhang,*[a] Jian-Lin Luo,[b] Nan-Lin Wang,[b] Huai-Ming Hu,[a] and Dao-Ben Zhu*[a]

Keywords: Copper / Magnetic properties / N ligands / Solvothermal synthesis

The solvothermal reaction between $Cu(ClO_4)_2 \cdot 6H_2O$ and 2-pyrazinecarboxylic acid in methanol yields a novel mixed-valence Cu^{I}/Cu^{II} coordination polymer, $Cu^{I}Cu^{II}$(2-pyrazinecarboxylate)$_2$(H_2O)(ClO_4) (**1**), in which a three-dimensional supramolecular array with square channels (9.3 × 9.3 Å) is formed through crisscross arrangement of the one-dimensional $Cu^{I}Cu^{II}$(2-pyrazinecarboxylate)$_2$(H_2O)$^+$ coordination polymer cation chains in the adjacent layers. Complex **1** exhibits weak ferromagnetic interactions.

Introduction

Crystal engineering of coordination polymers has been one of the most rapidly developing areas in the past decade, due mainly both to theoretical aspects related to the topologies of novel frameworks and to the interesting physical and chemical properties of these rationally designed functional solids.[1] Their potential applications have been demonstrated in, for example, nonlinear optical,[2] electrical,[3] and magnetism materials.[4] Furthermore, because specific pore size, type, and functions of cavity have become designable, their implications in molecular recognition and host-guest chemistry,[5] and also as zeolite mimics,[6] are particularly attractive. Generally, treatment of transition metal ions with rigid or flexible polyfunctional ligands by self-assembly processes is one basic strategy to afford varied polymers with such features as diamondoid, honeycomb grid, square grid, ladder, brick wall, and octahedral frameworks.[3−7] Hydro(solvo)thermal techniques have also been developed for the preparation of a series of coordination polymers.[2,6d,6e,8] Here we present the solvothermal synthesis, crystal structure, and magnetic properties of a novel mixed-valence Cu^{I}/Cu^{II} coordination polymer: $Cu^{I}Cu^{II}$(2-pyrazinecarboxylate)$_2$(H_2O)(ClO_4) (**1**), in which the $Cu^{I}Cu^{II}$(2-pyrazinecarboxylate)$_2$(H_2O)$^+$ coordination polymer cation chains in adjacent layers are arranged in a cross-like fashion to generate a three-dimensional supramolecular array with square channels. In addition, the coordination polymer chain in complex **1** adopts an unusual *cis* configuration

Results and Discussion

Synthesis

Complex **1** was obtained as black blocks in 60% yield through a solvothermal reaction. A mixture of 2-pyrazinecarboxylic acid (0.4 mmol) and $Cu(ClO_4)_2 \cdot 6H_2O$ (0.4 mmol) in methanol (1 mL) was placed in a sealed thick Pyrex tube (ca. 20 cm long), which was kept at 80 °C under autogenous pressure for 2 d. The formation of Cu^{I} in **1** suggests that the methanol solvent and the 2-pyrazinecarboxylic acid may serve as effective reducing agents for Cu^{II} to Cu^{I} even under very mild solvothermal conditions. Similar trends have also been observed in the hydro(solvo)thermal syntheses of mixed-valence Cu^{I}/Cu^{II} tetranuclear complexes $[Cu_4(obpy)_4(tp)]$[9a] and $[Cu_4(ophen)_4(tp)]$[9a] (Hophen = 2-hydroxy-1,10-phenanthroline, Hobpy = 6-hydroxy-2,2′-bipyridine, tp = terephthalate) and mixed-valence Cu^{I}/Cu^{II} coordination polymers $[Cu_4\{1,4\text{-}C_6H_4(COO)_2\}_3(4,4'\text{-bipy})_2]_n$,[8a] $[Cu_2(ipO)(4,4'\text{-bpy})]$(ipOH = 2-hydroxyisophthalate),[9b] $Cu^{I}_2Cu^{II}(hedpH_2)_2(4,4'\text{-bpy})_2 \cdot 2H_2O$ (hedp = 1-hydroxyethylidenediphosphonate),[9c] but higher temperatures were required.

Crystal Structure

As shown in Figure 1 (top), the crystal structure of **1** consists of one-dimensional $Cu^{I}Cu^{II}$(2-pyrazinecarboxylate)$_2$(H_2O) cations and discrete perchlorate anions. Each Cu^{II}

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200300227

atom is situated in a distorted square-pyramidal environment, with the two oxygen atoms and the two nitrogen atoms from two chelating 2-pyrazinecarboxylate ligands at the equatorial positions, and a coordinated water molecule at the apical position. The coordination environment of Cu^{II} in complex **1** is similar to that in [Cu(2-methylpyrazine-5-carboxylate)$_2$(H_2O)]·3H_2O,[10] but quite different from that in Cu(2-pyrazinecarboxylate)$_2$(H_2O)$_2$,[11] which has a disordered octahedral coordination sphere. The Cu^{II} centers in linear Cu(2-pyrazinecarboxylate)$_2$[11] and three-dimensional [Cu(pyzca)$_2$]$_2$$Cd_4I_8$]$_n$[12] (pyzca = 2-pyrazinecarboxylate) also have octahedral configurations. The Cu−Ow bond length of 2.228(9) Å (see Table 1) is similar to that in [Cu(2-methylpyrazine-5-carboxylate)$_2$(H_2O)]·3H_2O [2.257(2) Å],[9] but shorter than that in Cu(2-pyrazinecarboxylate)$_2$(H_2O)$_2$ (2.39 Å).[11]

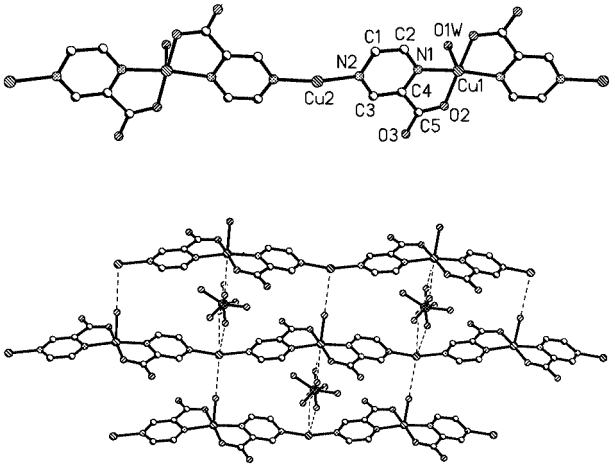

Figure 1. ORTEP figure of the cation chain in complex **1** at the 50% probability level showing the numbering scheme; all hydrogen atoms are omitted for clarity (top); illustration of the two-dimensional network layer formed by the mixed-valence Cu^{I}/Cu^{II} coordination polymer chains with Cu···$O_{perchlorate}$ short contacts (bottom)

Table 1. Selected distances [Å] and angles [°] for complex **1**; symmetry code: #1 $y-1, x+1, -z$; #2 $y, x, -z$

Cu(1)−N(1)	1.971(5)	Cu(1)−O(2)	1.941(3)
Cu(1)−O(2)#1	1.941(3)	Cu(1)−N(1)#1	1.971(5)
Cu(1)−O(1 W)	2.228(9)	Cu(2)−N(2)	1.949(5)
Cu(2)−N(2)#2	1.949(5)		
O(2)#1−Cu(1)−O(2)	176.0(3)	O(2)#1−Cu(1)−N(1)	96.39(16)
O(2)−Cu(1)−N(1)	83.18(16)	O(2)−Cu(1)−N(1)#1	96.39(16)
N(1)−Cu(1)−N(1)#1	167.7(4)	O(2)−Cu(1)−O(1 W)	92.02(13)
N(1)−Cu(1)−O(1 W)	96.2(2)	N(1)#1−Cu(1)−O(1 W)	96.2(2)
N(2)−Cu(2)−N(2)#2	161.2(3)		

The coordination sphere of the Cu^{I} site in complex **1** is defined by two crystallographically equivalent nitrogen donors from two Cu^{II}(2-pyrazinecarboxylate)$_2$(H_2O) molecules, with a Cu2−N2 distance of 1.949(5) Å. This coordination mode is quite similar to those of the Ag^{I} centers in Ag[Cu(2-methylpyrazine-5-carboxylate)$_2$(H_2O)$_2$]·(BF_4)[10] and Ag[Cu(2-methylpyrazine-5-carboxylate)$_2$(H_2O)$_2$]·(NO_3).[10] The N2−Cu2−N2^{i} (^{i} $y, x, -z$) bond angle of 161.2(3)° is a little smaller than the N2−Ag−N2 angle [165.7(2)°] in Ag[Cu(2-methylpyrazine-5-carboxylate)$_2$(H_2O)$_2$]·(BF_4),[10] but much larger than the N2−Ag−N2 angle [153.31(18)°] in Ag[Cu(2-methylpyrazine-5-carboxylate)$_2$(H_2O)$_2$]·(NO_3).[10]

The one-dimensional mixed-valence Cu^{I}/Cu^{II} cation chain is made up of alternating Cu^{I} centers and Cu^{II}(2-pyrazinecarboxylate)$_2$(H_2O) fragments. The intrachain Cu^{I}···Cu^{I}, Cu^{I}···Cu^{II}, and Cu^{II}···Cu^{II} distances are 13.203, 6.663, and 13.203 Å, respectively. Interestingly, all coordination water molecules in the same cation chain are arranged in a *cis* orientation. It is noteworthy that **1** is the first coordination polymer derived from 2-pyrazinecarboxylate known to adopt a *cis* configuration. Only a few examples of *cis* configurations in complexes of other carboxylate-substituted pyrazine derivatives are known, among them the two-dimensional {Cu_2(pzdc)$_2$(pyz)}$_n$ (pzdc = 2,3-pyrazinedicarboxylate, pyz = pyrazine),[13a] the one-dimensional {Co[pyz(COO)COOH]$_2$(H_2O)$_2$},[13b] and the mononuclear [NiL_2(H_2O)$_2$] (L = 1,4-dihydropyrazine-2,3-dione-5,6-dicarboxylate).[13c]

The disordered ClO_4^- anions are located between a Cu^{I} center and a Cu^{II} center of adjacent mixed-valence Cu^{I}/Cu^{II} cation chains (the related interchain Cu^{II}···Cu^{I} distance is 7.508 Å), with the shortest Cu^{I}···$O_{perchlorate}$ contact 2.684 Å and the shortest Cu^{II}···$O_{perchlorate}$ contact 2.865 Å (Figure 1, bottom). The chlorine atom of the ClO_4^- anion is a little closer to the Cu^{II} center than to the Cu^{I} center (the Cu···Cl contacts are 3.669 and 3.838 Å for Cu^{II} and Cu^{I}, respectively). The mixed-valence Cu^{I}/Cu^{II} coordination polymer chains are therefore bound to each other through ClO_4^- anions to generate a two-dimensional network layer parallel to the *ab* plane with the shortest interchain Cu^{II}···Cu^{I} distance 5.695 Å.

Within a layer, all mixed-valence Cu^{I}/Cu^{II} coordination polymer chains show the same orientation (along one of two diagonal lines of the *ab* plane). However, chains from each pair of adjacent layers are always crisscrossed through the Cu^{I}···$O_{carboxylate}$ short contacts of 2.464 Å and the Ow···$O_{carboxylate}$ hydrogen bond of 2.720 Å (Figure 2), resulting in a three-dimensional supramolecular array with square channels (9.3 × 9.3 Å) running along the *c* axis (Figure 3). This structure is quite different from those of the Ag[Cu(2-methylpyrazine-5-carboxylate)$_2$(H_2O)$_2$]·(BF_4)[10] and Ag[Cu(2-methylpyrazine-5-carboxylate)$_2$(H_2O)$_2$]·(NO_3),[10] in which all the Cu^{II}/Ag^{I} mixed-metal coordination polymer chains run in one direction, so square cavities cannot be generated. To the best of our knowledge, the only reported example of chains in adjacent layers being arranged in a cross-like fashion to generate a three-dimensional supramolecular array with channels is [Cu(4,4′-bipy)(H_2O)$_3$(SO_4)]·2H_2O,[14] in which the adjacent chains of Cu(4,4′-bipy)(H_2O)$_3$(SO_4) are arranged in a cross-like fashion at the midpoints of the 4,4′-bipy ligands, and so rhombic channels (11.12 × 11.12 Å) are formed.

Magnetic Properties

The variation in the molar magnetic susceptibilities χ was investigated for complex **1** in the 5−300 K temperature range in a 10 kG applied field. The inset of Figure 4 shows that the χT value continuously increases with cooling while going from 250 to 9 K, and then drops down to 5 K, indicating the presence of a ferromagnetic exchange interaction. The room-temperature χT value of 0.375 emu·K·mol^{-1} is in good agreement with that of **1**, uncoupled $S = 1/2$ spins of Cu^{2+} atom (≈ 0.375 emu·K·mol^{-1}; supposed $g = 2.0$ for Cu^{2+}), confirming that only half of the Cu atoms in complex **1** are Cu^{II} atoms. It was surprising to find that there is ferromagnetic exchange interaction between two Cu^{II} atoms 13.203 Å apart. Perhaps the uncoupled electron of the Cu^{II} atom is delocalized to some degree over the Cu^{II} and Cu^{I} centers. A quite recently reported mixed-oxidation-state Cu^{I}/Cu^{II} cluster complex $[(PAH)_4Cu^{II}_4Cu^{I}_2Br_{10}]$ (PAH = picolinamide hydrazone) also exhibited weak ferromagnetic exchange.[15] The temperature dependence of χ is interpreted in terms of a one-dimensional ferromagnetic chain,[16] by use of Equation (1) with $K = J/(2K_BT)$. The theoretical best fitting to the experimental data is obtained with $J/K_B = 1.80$ K and $C = 0.375$ emu·K·mol^{-1}. The deviation factor defined by $R = [(\chi_{obsd.} - \chi_{calcd.})^2/\chi_{obsd.}^2]^{1/2}$ is equal to 0.04437.

$$\chi = (C/T)[(1 + 5.7979916\,K + 16.902653\,K^2 + 29.376885\,K^3 + 29.832959\,K^4 + 14.036981\,K^5)/(1 + 1.27979916\,K + 7.0086780\,K^2 + 8.6538644\,K^3 + 4.5743114\,K^4)]^{2/3} \quad (1)$$

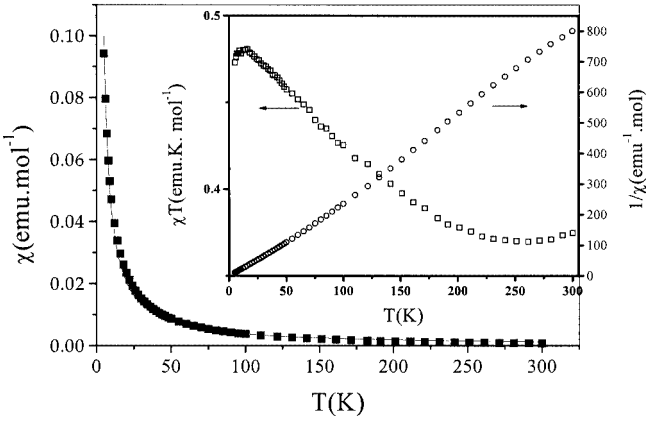

Figure 4. Temperature dependence of magnetic susceptibility of **1**: χ vs. T plots; inset, χT and/or χ^{-1} vs. T plots

IR and XPD Spectra

The strong and broad peak around 3454 cm^{-1} in the IR spectrum of complex **1** is mainly attributable to the presence of coordinated water molecules. The strong band at 1649 cm^{-1} is assignable to the antisymmetric C=O stretching vibration of the coordinated carboxylate group, while the strong band at 1120 cm^{-1} is typical of the uncoordinated perchlorate.

The powder XRD pattern of the complex and the pattern simulated on the basis of the single-crystal structure are presented in Figure 5. The diffraction peaks in both patterns correspond well in position, indicating the phase purity of the sample as synthesized.

In summary, this study illustrates that a three-dimensional supramolecular array with channels as exemplified by **1** can be achieved through crisscross arrangement of one-dimensional chains from parallel layers, and that solvothermal (or hydrothermal) synthesis is an effective method by which to obtain mixed-valence Cu^{I}/Cu^{II} coordination polymers.

Experimental Section

General: All chemicals purchased were of reagent grade and were used without further purification. Elemental analyses (C, H and N) were performed with a Heraeus CHN-Rapid elemental analyzer. IR spectra were recorded with a Perkin−Elmer 2000 spectrophotometer on pressed KBr pellets. UV/Vis spectra were run with a U-3010 spectrophotometer. Powder X-ray diffraction (XRD) data were obtained with a Rigaku D/max-2500 X-ray diffractometer with Cu-K_α radiation (λ = 1.5406 Å). Variable-temperature magnetic susceptibility data were collected with a crystalline sample (11.75 mg) from 5 to 300 K in a magnetic field of 10 kG after zero-field cooling with a SQUID magnetometer. Diamagnetic corrections were estimated from Pascal's constants.

Synthesis of 1: A mixture of 2-pyrazinecarboxylic acid (0.4 mmol) and $Cu(ClO_4)_2{\cdot}6H_2O$ (0.4 mmol) in methanol (1 mL) was placed in a thick Pyrex tube (ca. 20 cm long), and the tube was frozen with liquid N_2, evacuated under vacuum, and sealed with a torch. The tube was then heated at 80 °C under autogenous pressure for 2 d to give dark crystals of **1** in 60% yield. An unidentified blue polycrystalline material was formed as a by-product. $C_{10}H_6ClCu_2N_4O_9$ (488.72): calcd. C 24.58, H 1.24, N 11.46; found C 24.49, H 1.32, N 11.40. UV (1×10^{-4} M, DMF): λ_{max} = 273 nm (ε = 4.46×10^4 $M^{-1}cm^{-1}$), 691 nm (very broad peak, ε = 729 $M^{-1}cm^{-1}$).

Caution: *$Cu(ClO_4)_2{\cdot}6H_2O$ is potentially explosive and should be handled with care!*

X-Ray Crystallography Analysis: The data were collected with a Rigaku RAXIS RAPID IP imaging plate system by use of Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by the Patterson method and refined by a full-matrix, least-squares technique based on F^2 by use of the SHELXL 97 program. All non-hydrogen atoms except for the oxygen atoms of the perchlorate anion were refined anisotropically, and all hydrogen atoms other than those in coordinated hydrate molecule were allowed for as riding atoms. Crystal data for **1**: $C_{10}H_6ClCu_2N_4O_9$, tetragonal, space group $P4_12_12$, M = 488.72, $a = b$ = 9.3358(13), c = 20.835(4) Å, V = 1815.9(5) $Å^3$, Z = 4, $D_{calcd.}$ = 1.788 gcm^{-3}, T = 293(2)K, μ = 2.539 mm^{-1}, R_1 = 0.0494, wR_2 = 0.0863 for 1031 observed reflections[$I > 2\sigma(I)$] from 2071 independent reflections, GOF = 0.907. CCDC-187295 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Self-Assembly of Three Cd^{II}- and Cu^{II}-Containing Coordination Polymers from 4,4′-Dipyridyl Disulfide

Junhua Luo,[a] Maochun Hong,*[a] Ruihu Wang,[a] Daqiang Yuan,[a] Rong Cao,[a] Lei Han,[a] Yanqing Xu,[a] and Zhengzhong Lin[a]

Keywords: Cadmium / Coordination polymers / Copper / Fluorescence / Magnetic properties / N ligands

Three new organic/inorganic coordination polymers, $[\{Cu(4\text{-}DPDS)_2(H_2O)\}\cdot 2NO_3\cdot 3H_2O]_n$ (**1**), $[\{Cu(4\text{-}DPDS)_2(SO_4)\}\cdot 1.5H_2O\cdot CH_3OH]_n$ (**2**), and $[Cd(4\text{-}DPDS)_2Cl_2]_n$ (**3**), have been synthesized by using the flexible ligand 4,4′-dipyridyl disulfide (4-DPDS). Complex **1** crystallized in the *Ibca* space group: a = 10.5275(6), b = 20.2670(1), c = 27.235(1) Å, V = 5811.5(6) Å^3, Z = 16. Complex **2** crystallized in the *Pnna* space group: a = 10.547(2), b = 14.201(2), c = 19.667(3) Å, V = 2945.8(8) Å^3, Z = 8. Complex **3** crystallized in the $P2_1/c$ space group: a = 7.6146(3), b = 18.2606(8), c = 9.3203(2) Å, β = 100.26(1)°, V = 1275.24(8) Å^3, Z = 4. The three coordination polymers display a variety of structural architectures, ranging from double-stranded chains (**1**) to two-dimensional channels (**2**) and two-dimensional, puckered, grid-like arrays (**3**). Magnetic characterizations show that complex **1** exhibits antiferromagnetic interactions while **2** is ferromagnetic. Solid-state fluorescence results reveal that **3** exhibits fluorescence emissions at 418 and 575 nm (λ_{ex} = 314 nm).

Introduction

Self-assembly of organic ligands and inorganic metal ions is one of the most efficient and widely used approaches for the construction of supramolecular architectures. Owing to their potential as new functional solid materials, interest in self-assembled coordination polymers with interesting physical properties has grown rapidly.[1,2] An extensive amount of literature exists on networks crystallized from different dipyridyl ligands. A variety of architectures have been obtained over the past few years using the most simple of these ligands, i.e., 4,4′-bipyridyl.[3,4] The use of longer bis(pyridyl) spacers has afforded very interesting structural motifs, such as double helices,[5] multiple sheets,[6] interpenetrated ladders,[7] interpenetrated diamondoid nets,[8] and other noteworthy species.[9] Many of the architectures reported to date, however, are based upon rigid, linear, linker ligands, with only recent efforts being focused on the use of ligands showing conformational flexibility.[5,6,10,11] In addition, the design of coordination polymers from flexible ligands is highly influenced by factors such as the nature of coordination of the metal ion, the structural characteristics of the polydentate organic ligand, the metal:ligand ratio, and the possible influences of the counteranion and solvent. Thus, there is still a long way to go to rationalize the design of compounds with well-defined structures and useful functions by developing new architectures of coordination polymers using flexible spacers ligands.

In this report, we focus on 4,4′-dipyridyl disulfide (4-DPDS), in which the two pyridyl rings are bridged by the −S−S− group. Two enantiomeric conformers exist[12] (Scheme 1) with idealized dihedral angles (C−S−S−C) of 90° and the compound may assume a twisted conformation because of the flexible −S−S− group. Additionally, the bridging S atom has coordinating ability, which may lead to unique network structures because of its bonding ability to soft metal ions.[13] Several coordination polymers have been reported recently from the reaction of 4-DPDS with CuI,[14] $M(hfac)_2$ (M = Cu, Mn; hfac = 1,1,1,5,5,5-hexafluoroacetylacetone),[15] $Cd(NO_3)_2$,[16] platinum(II) subunits,[17] and various silver salts.[18] In this report, we describe the syntheses, structures, and properties of three new Cd^{II}- and Cu^{II}-containing coordination polymers, $[\{Cu(4\text{-}DPDS)_2(H_2O)\}\cdot 2NO_3\cdot 3H_2O]_n$ (**1**), $[\{Cu(4\text{-}DPDS)_2(SO_4)\}\cdot 1.5H_2O\cdot CH_3OH]_n$ (**2**), and $[Cd(4\text{-}DPDS)_2Cl_2]_n$ (**3**).

Results and Discussion

Crystal Structures

The energy-dispersive X-ray analyses confirm the presence of copper atoms in **1** and **2**, and cadmium atoms in **3**. On the basis of the results of single-crystal X-ray diffraction and elemental analyses, compounds **1**, **2**, and **3** are characterized as having the formulas $[\{Cu(4\text{-}DPDS)_2(H_2O)\}\cdot 2NO_3\cdot 3H_2O]_n$, $[\{Cu(4\text{-}DPDS)_2(SO_4)\}\cdot 1.5H_2O\cdot CH_3OH]_n$, and $[Cd(4\text{-}DPDS)_2Cl_2]_n$, respectively.

$[\{Cu(DPDS)_2(H_2O)\}\cdot 2NO_3\cdot 3H_2O]_n$ (1)

Figure 1 shows the ORTEP drawing of the copper center of **1**, with a numbering scheme, where the metal sites are in the crystallographic inversion center. The copper atom has a distorted square-pyramidal environment, which is surrounded by four nitrogen atoms from four 4-DPDS ligands in the base plane, and one oxygen atom from a water molecule occupying the axial position. The Cu−N(4-DPDS) bond lengths are 2.032(1) and 2.061(1) Å, and the Cu−O(water) distance is 2.305(1) Å. The *trans* N−Cu−N bond angles are 167.29(6) and 176.9(6)°, and the *cis* N−Cu−N and O−Cu−N bond angles range from 88.5(3) to 96.4(3)°, indicating the distorted square-pyramidal coordination environment of Cu center.

Each copper center is bridged by four 4-DPDS ligands to form a double-stranded chain (Figure 2). As in other double-stranded chain complexes,[20,21] two copper atoms and two 4-DPDS ligands in **1** form a metallacycle in which the non-bonded distance between the two copper atoms is ca. 10.528 Å. The two pyridyl rings of the 4-DPDS ligand are almost perpendicular, with a dihedral angle of 98.6°. The dimensions of the distorted square cavity are ca. 5 × 5 Å. The molecular box in **1** is twisted to make the enclosed cavity a small one, resulting from the flexibility of 4-DPDS and the pentacoordinate geometry of the Cu^{II} ion, and no solvent molecules are clathrated in the cavities.

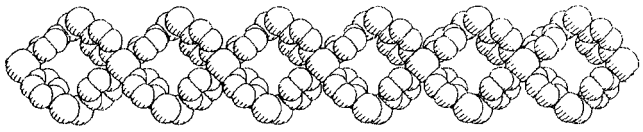

Figure 2. Space-filling representation of the double-stranded chain in **1**

It is interesting to note that in **1** the copper(II) ion has a pentacoordinate geometry and the water molecule occupies the axial position, and that all the axially coordinated water molecules are directed in the same direction. Two such chains lie reversibly and are linked into a ladder structure through hydrogen bonds between the axially coordinated water molecules and lattice water molecules (O1···O1W$^{\#1}$, 2.770 Å; O1···O1W$^{\#2}$, 2.770 Å; O1W···O1W$^{\#3}$, 2.785 Å; O1W···O2W$^{\#4}$, 2.769 Å; symmetry codes #1: $-x$, $-y$, $1-z$; #2: x, $y-1/2$, $1-z$; #3: $1/2-x$, y, $1-z$; #4: $1/2+$

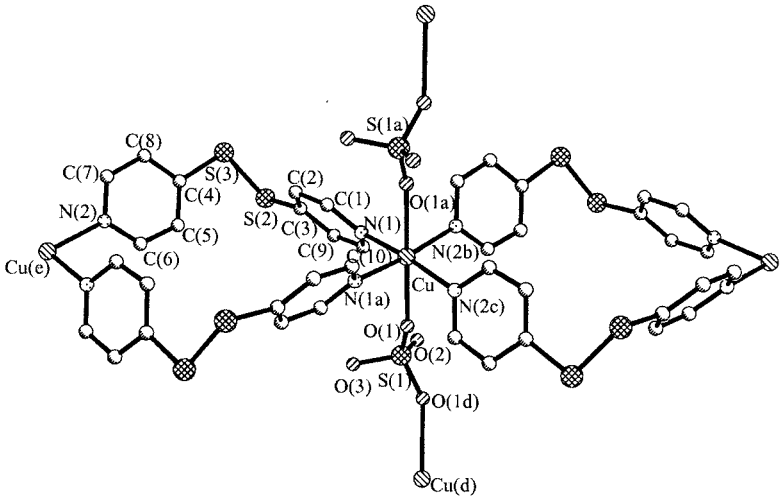

Figure 4. Drawing of the coordination environment of the Cu^{II} ion in **2**, and the atom numbering scheme

x, y, $1 - z$) and, furthermore, the ladders are linked into a bilayer through hydrogen bonds between free NO_3^- anions and the lattice water molecules (O1W···O5$^{\#1}$, 2.720 Å; O2W···O4$^{\#2}$, 2.893 Å; O2W···O4$^{\#3}$, 2.893 Å; symmetry codes #1: $1/2 + x$, y, $1 - z$; #2: $x - 1/2$, $1/2 - y$, $1 - z$; #3: $-x - 3/2$, $-y$, $z - 1/2$), as depicted in Figure 3.

$[\{Cu(DPDS)_2(SO_4)\}\cdot 1.5H_2O\cdot CH_3OH]_n$ (2)

Single-crystal X-ray crystallographic analysis of **2** revealed a two-dimensional assembly of Cu^{II} ions, wherein each Cu^{II} center is bonded to four different molecules of 4,4′-dipyridinedisulfide and two sulfate anions in a six-coordinate manner (Figure 4). Four nitrogen atoms from four 4-DPDS ligands coordinate to the copper(II) center in the base plane, and two oxygen atoms from two sulfate anions are located in the axial positions of the distorted octahedral geometry of the copper(II) center. The Cu−N(4-DPDS) bond lengths are 2.037(8) and 2.040(7) Å, which are similar to those of **1** and the 1D helical compound [4-DPDS·Cu(hfac)$_2$].[15] The *cis* N−Cu−N and O−Cu−N bond angles vary from 84.5(2) to 91.1(4)°, and the *trans* O(SO_4^{2-})−Cu−O(SO_4^{2-}) bond angle is 179.4(1)°.

Each copper ion is bridged by four 4-DPDS ligands to form a double-stranded chain. The sulfate anions take part in coordination and connect the double-stranded chains into a 2D sheet, as shown in Figure 5(a). The axial Cu−O(SO_4^{2-}) distance is 2.459(5) Å, which is similar to that found in other copper sulfate complexes,[22] and it is longer than the Cu−O(aqu) distance in **1**. The Cu···Cu separation through the sulfate anion is 7.118 Å, which is much shorter than the Cu···Cu separation through the bridge ligand 4-DPDS, which has a distance of 10.547 Å. Viewed along the *b* axis [Figure 5(b)], there are many one-dimensional channels in the 2D structure that are formed by the metallacycles $[Cu_2(4\text{-DPDS})_2]^{2+}$ linked by the sulfate anions, and these 1D channels are connected through the copper(II) centers to form the ultimate 2D sheets of **2**.

$[Cd(DPDS)_2Cl_2]_n$ (3)

The crystallographic analysis reveals that each cadmium(II) ion in **3** is coordinated by four nitrogen atoms from four 4-DPDS ligands and two chloride ions in a slightly distorted octahedral geometry (Figure 6). The four nitrogen atoms form the equatorial plane with the Cd center located in the plane, with the deviation of the Cd ion from the mean plane of [N(1b)N(1c)N(2a)] being 0.008(2) Å, and two Cl^- ions occupy the axial positions with a Cl−Cd−Cl(c) angle of just 180°.

Each 4-DPDS ligand acts as a single bridge to link two cadmium(II) ions through its two pyridine nitrogen atoms, and each cadmium(II) ion connects four 4-DPDS ligands to form an infinite two-dimensional structure with (4,4) topology, as shown in Figure 7. The cadmium(II) atoms, all of which are equivalent, serve as nodes and the ligands (L = 4-DPDS) as rods. Thus, the network is based upon squares $(CdL)_4$ formed by four 4-DPDS ligands and four quadruply connected cadmium(II) ions, forming 44-membered metallacyclic rings. Each of the four $(CdL)_4$ grids are joined together through sharing the cadmium apices to give the final two-dimensional layer structure consisting of puckered rhombus grids with dimensions of 12.265 × 12.265 Å based on the Cd···Cd distances. The most intriguing feature of the structure is that the basic grid is puckered (Figure 8), which is a different arrangement from that observed in previous grid-like structure in which the basic grids are usually coplanar or quasi-coplanar.[23] The puckered shape of the basic grid in **3** is understandable because the 4-DPDS unit may assume a twisted conformation because of the flexible -S−S- bridging group, which generates the non-linear grid sides and the puckered grids. The C−S−S angles of the 4-DPDS ligand are 105.1(2) and 106.3(2)°, the C−S−S−C torsion angle is 95.1°, and the two pyridine rings in each 4-DPDS ligand are almost perpendicular to one another with a dihedral angle of 81.9°. These data clearly depict the non-linear configuration of 4-DPDS in **3**. We note that the ulti-

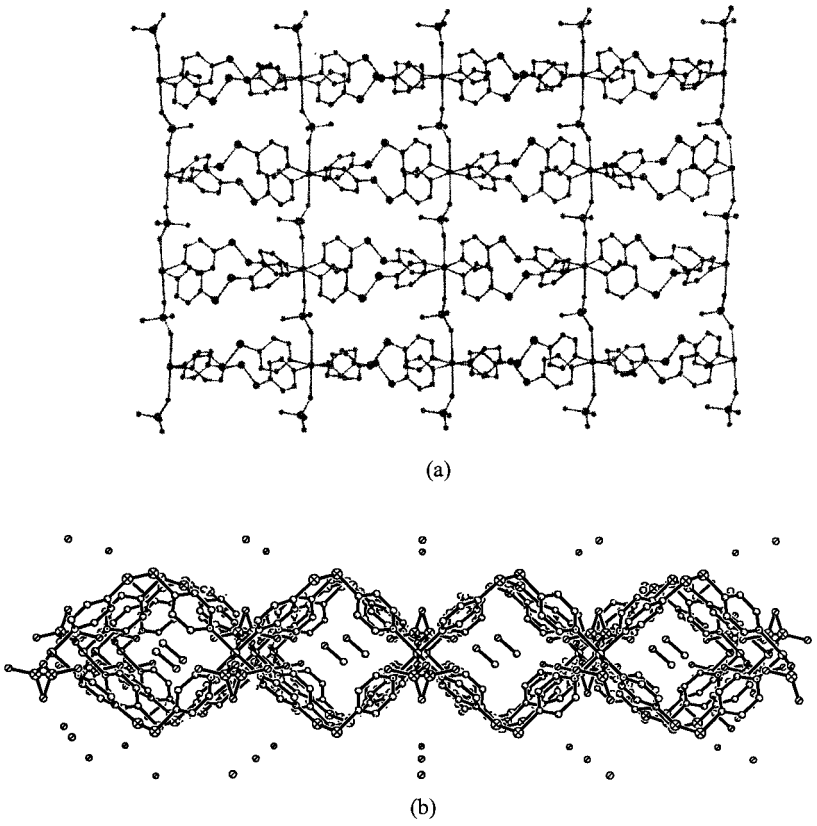

Figure 5. View of the 2D layer of **2** (a) along *a* axis and (b) along *b* axis

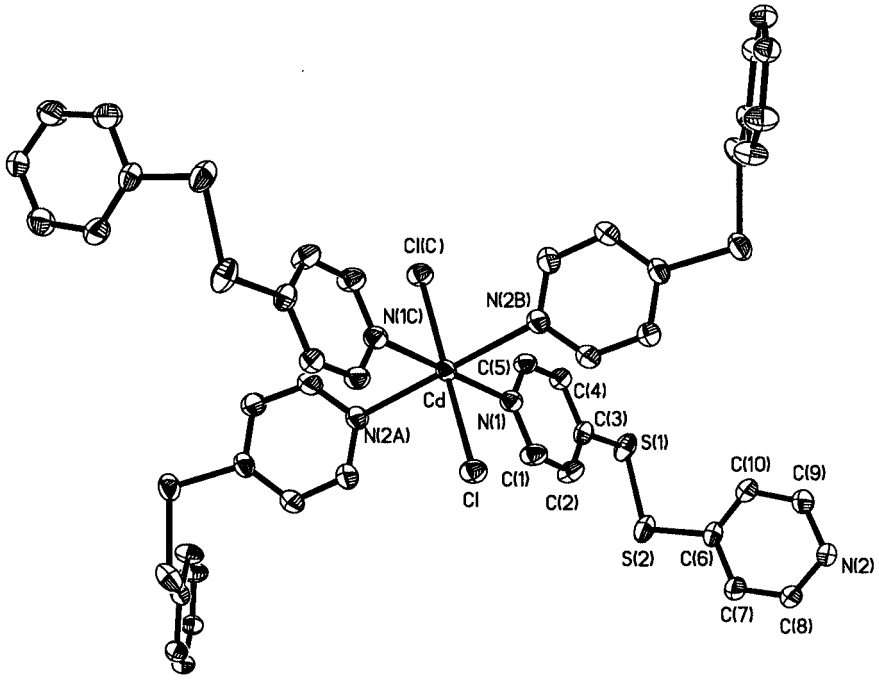

Figure 6. Drawing of the coordination environment of the Cd^{II} ion in **3**, and the atom numbering scheme

mate structure of the 2D layer is wave-like with a tightly puckered structure lacking any guest molecules.

The S−S bond length, the C−S−S−C torsion angles, and the dihedral angles of the two pyridyl rings in 4-DPDS in the three complexes **1**, **2**, and **3** are listed in Table 1. The S−S bond lengths are all ca. 2 Å, the C−S−S−C torsion angles are ca. 90° and the dihedral angles of the two pyridyl rings all show slight deviation from 90°. From these values

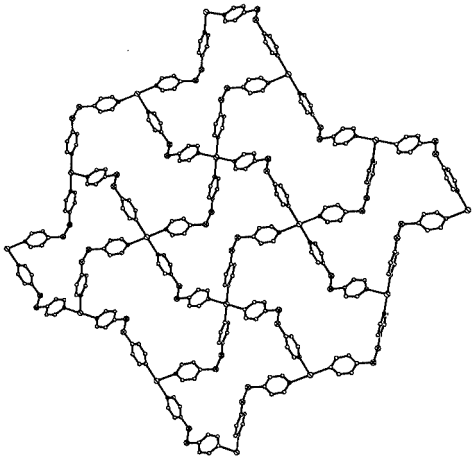

Figure 7. View of the 2D sheets of **3**

we see that the 4-DPDS ligand maintains its characteristic conformation despite the differences in the coordination schemes, but some notable differences exist between them. For the same metal ions, the M···M distances through the single 4-DPDS bridge are longer than those through the double 4-DPDS bridge (e.g., the Cd···Cd distance is 12.265 Å in **3**, but only 11.1 Å in the 1D structure $[Cd(4\text{-}DPDS)_2(H_2O)]\cdot 2NO_3\cdot 2EtOH\cdot 2H_2O$,[16] and the Cu···Cu separation is 11.26 Å in the single-helical chain complex $[4\text{-}DPDS\cdot Cu(hfac)_2]$,[15] while it is 10.528 Å in the double-stranded chain compound **1** and 10.547 Å in **2**). The most interesting differences in the present complexes are that the torsion angles of M−(4-DPDS)−M change from 15.1° in **1** and 15.0° in **2** to 37.9° in **3**, which we ascribed to the different coordination schemes of 4-DPDS. The 4-DPDS units in **1** and **2** link the metal ions to form double-stranded chains, but the 4-DPDS ligands in **3** connect the metal ions into a 2D grid-like sheet; the 4-DPDS ligand is more constrained in the double-stranded chains and more twisted in the 2D sheet because of steric factors.

Electronic Spectra

The reflectance spectra of the complexes in the solid state were recorded in the range 200−1100 nm. The visible reflectance spectra for **1** contain bands at $13.8\cdot10^3$ cm^{-1} with a shoulder $9.72\cdot10^3$ cm^{-1}, characteristic of a copper(II) $d_{xz},d_{yz} \rightarrow d_{x^2-y^2}$ transition[24] via ($^2B_1 \rightarrow {}^2E$) in a tetragonal ligand field, in which the copper(II) atom has a distorted square-based pyramidal coordination environment. The absorption of **2** at $14.97\cdot10^3$ cm^{-1} without a shoulder is assigned to copper(II) $d_{xz},d_{yz} \rightarrow d_{x^2-y^2}$ transitions[25] via ($^2B_{1g} \rightarrow {}^2E_g$) in a square-planar geometry (or elongated octahedron, due to the bridging sulfate anions), with the unpaired electron mainly located in the $d_{x^2-y^2}$ orbital. The d−d transition energy of complex **1** is lower than that of **2**, which is consistent with the crystal field splitting energy of the tetragonal ligand field when compared with that of the square planar ligand field in cases when there are similar or the same ligand field strengths of the donor ligands. The information obtained from the electronic spectra about the coordination configurations of the copper(II) ions in the two complexes is in agreement with that given by the structural data.

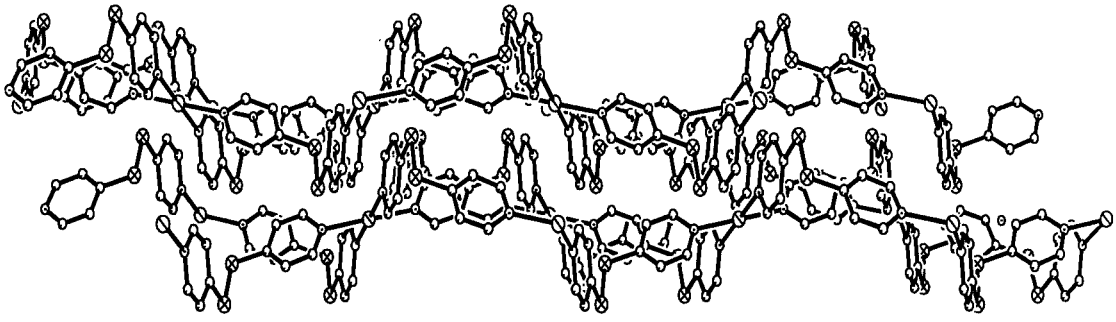

Figure 8. The tightly packed structure of **3**; only two layers are shown for clarity

Table 1. S−S bond lengths [Å] and C−S−S−C torsion angles [°], the dihedral angles of the two pyridyl rings [°] in the 4-DPDS ligands, and the M−[4-DPDS]−M torsion angles (°), for **1**, **2**, and **3**

Complexes	S−S distance (Å)	C−S−S−C torsion angle (°)	M···M separation through 4-DPDS (Å)	Dihedral angle of the two pyridyl rings (°)	M−(4-DPDS)−M torsion angle (°)
1	2.027(5)	89.8	10.528 (Cu···Cu)	98.6	15.1
2	2.033(5)	88.4	10.547 (Cu···Cu)	83.5	15.0

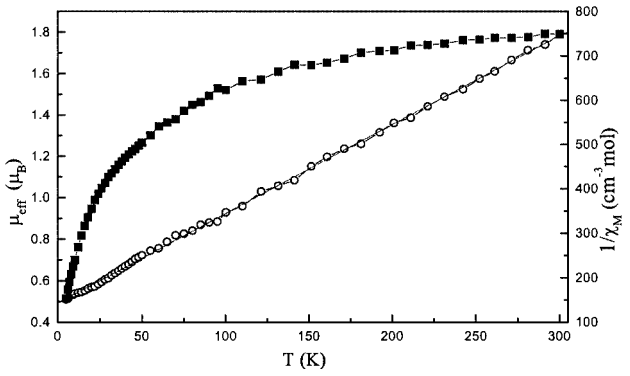

Figure 9. The plots for **1** of the effective magnetic moment μ_{eff} vs. T and $1/\chi_M$ vs. T

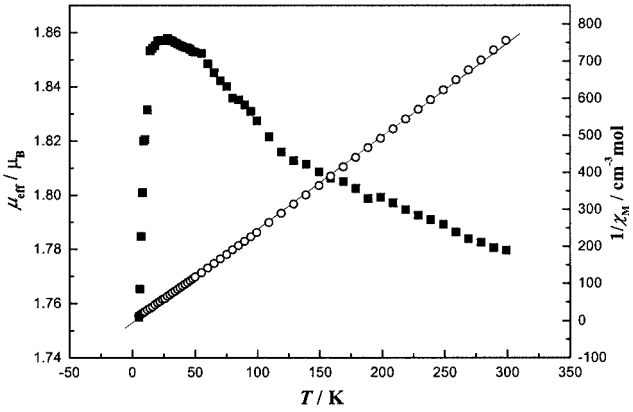

Figure 10. The plots for **2** of the effective magnetic moment μ_{eff} vs. T and $1/\chi_M$ vs. T

Magnetic Properties

Temperature-dependent magnetic susceptibility measurements for **1** and **2** were performed on the polycrystalline samples. The temperature dependence of $1/\chi_M$ and μ_{eff} [χ_M being magnetic susceptibility for one Cu^{II} ion, and $\mu_{eff} = (8\chi_M T)^{1/2}$] are shown in Figures 9 and 10, respectively. The value of μ_{eff} for **1** is 1.79 μ_B at room temperature, which is slightly larger than the spin-only value for an uncoupled Cu^{II} ion (g = 2.0, μ_{eff} = 1.73 μ_B). As the temperature decreases, the value of μ_{eff} decreases continuously and reaches 0.52 μ_B at 4 K, which indicates the occurrence of an antiferromagnetic interaction between the Cu^{II} ions in the double-stranded chain of **1**. A nonlinear fit of $\chi_M = C/(T - \Theta)$ to the data reveals a Curie−Weiss behavior, with the Weiss constant $\Theta = -2.27$ K. Taking into account the one-dimensional character of **1**, the magnetic susceptibility data were simulated by the Bonner−Fisher model[26] using the following polynomial expression:

$$\chi_M{}^J = \frac{N\beta^2 g^2 S(S+1)}{3kT}\frac{1+u}{1-u} \quad \left(u = \coth\left[\frac{JS(S+1)}{kT}\right] - \left[\frac{kT}{JS(S+1)}\right]\right) \qquad (1)$$

In this expression, $\chi = |J|/kT$ ($2J$ is the singlet−triplet splitting energy or the exchange integral in the spin Hamiltonian $H = -2J_{S1S2}$) and other symbols have their usual meanings. A satisfactory least-squares fitting of the observed data at 4−300 K led to g = 2.13 and $J/k = -2.5$ K. The small negative coupling constant imply the existence of a weak antiferromagnetic interaction between the copper(II) centers in the chain of **1**.

The value of μ_{eff} for **2** is 1.78 μ_B at room temperature, which is slightly larger than the spin-only value for an uncoupled Cu^{II} ion (g = 2.0, μ_{eff} = 1.73 μ_B). As the temperature decreases, the value of μ_{eff} increases gradually to 1.86 μ_B at 24 K, and then sharply decreases to 1.76 μ_B at 4 K, which implies the presence of ferromagnetic interactions between Cu^{II} ions in the 2D sheets of **2**. The nonlinear fit of $\chi_M = C/(T - \Theta)$ to the data reveals a Curie−Weiss behavior, with the Weiss constant Θ = 2.58 K. According to the structural data, the polymer may exhibit two types of Cu^{II}−Cu^{II} magnetic exchange interactions: type one is through a long double bridge, via 4-DPDS between copper centers in the double-stranded chain $[Cu(4\text{-}DPDS)_2]_n^{2n+}$, which is considered as the intrachain interaction; and type two is through a short bridge, via the sulfate groups between the adjacent chains, which is treated as the interchain interaction. The χ_M data are well interpreted based on the following expression:

A satisfactory least-squares fitting of the observed data at 4−300 K led to g = 2.10, $J/k = -2.3$ K, zJ'/k = 4.2 K. The value of J may be assigned to type one and that of zJ' to type two. The small negative J and small positive zJ'/k imply the existence of a weak intrachain antiferromagnetic interaction and a weak interchain ferromagnetic interaction. The interchain ferromagnetic interaction is stronger than the intrachain antiferromagnetic interaction, and **2** shows a overall weak ferromagnetic interaction between the copper(II) ions.

$$\chi_M{}^{J+J'} = \frac{\chi_M{}^J}{1-(2zJ'\times\chi_M{}^J/Ng^2\beta^2)}$$

$$\left(\chi_M{}^J = \frac{N\beta^2 g^2 S(S+1)}{3kT}\frac{1+u}{1-u};\ u = \coth\left[\frac{JS(S+1)}{kT}\right] - \left[\frac{kT}{JS(S+1)}\right]\right) \qquad (2)$$

The ESR spectra of **1** and **2** have been obtained at room temperature and 77 K, respectively; these spectra are almost the same. For **1** and **2**, both spectra exhibit the typical pattern, with the $d_{x^2-y^2}$ ground state [g (2.36) > $g_\perp$ (2.03) > 2.00 for **1**; g (2.14) > $g_\perp$ (2.06) > 2.00 for **2**], indicating the occupation of the unpaired d electron in the $d_{x^2-y^2}$ state.

Fluorescence Characterization

The diffuse reflectance UV/Vis spectra for 4-DPDS and the as-synthesized polymer of **3** (Figure 11) show different absorption features. There are two bands for the 4-DPDS ligand, with the longer- (332 nm) and shorter-wavelength (220 nm) absorptions corresponding to the intraligand n→π* and π→π* transitions, respectively. In comparison with the two bands for 4-DPDS, the shorter-wavelength

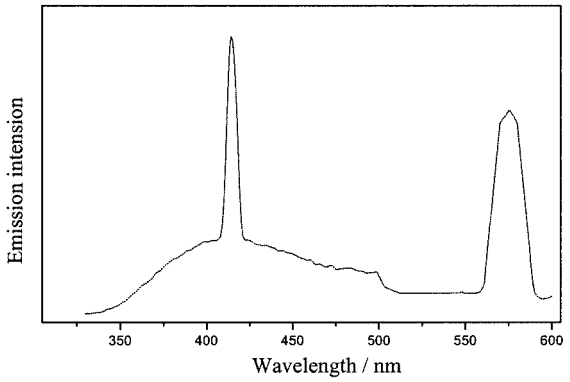

Figure 11. Solid-state emission spectra of **3** at room temperature

band for polymer **3** has the same energy, whereas the longer-wavelength band shifts to higher energy at 282 nm. This hypsochromic shift must be related to the coordination of Cd^{2+} to the 4-DPDS ligand, and it may arise from the same n→π* transitions. We note that the absorption intensity of **3** is markedly higher than that of the ligand. We attribute this increase in absorption intensity to the involvement of charge-transfer transitions from the N atoms of the ligands to the Cd^{2+} centers. The emission spectra of **3** show a broad emission band centered at 418 nm and a middle-intensity emission band occurring at 575 nm (λ_{ex} = 314 nm). The former may be assigned to the interligand transfer,[27] because the same emission appears also for the ligand 4-DPDS, and the latter may be due to the ligand-to-metal charge-transfer (LMCT) transition.[28]

Thermogravimetric Analysis

Thermogravimetric analysis (TGA) were performed to investigate the thermal stability of compounds **1**−**3**. All samples were heated under an N_2 atmosphere at a rate of 10 °C/min to 700 °C. The results show that **1** is stable up to 264 °C, although the first weight loss of 7.54% (calculated: 7.71), which corresponds to the loss of three lattice water molecules, occurred over the temperature range 65−128 °C. Complex **2** first lost one and a half water molecules and one CH_3OH molecule (obsd.: 8.68%; calcd.: 8.95%) and then gradually decomposed when the temperature reached 285 °C. Complex **3** is stable up to 302 °C, and above this temperature it decomposes.

Conclusions

Through the diffusion method, using different solvent systems, we acquired three coordination polymers (**1**, **2**, and **3**) derived from the flexible ligand 4-DPDS. The flexible ligand shows different coordination modes in the three complexes. In **1** and **2**, the 4-DPDS unit bridges the metal ions into double-stranded chains, but the 4-DPDS unit in **3** bridges the metal ions into a puckered (4,4) net sheet. The significant role of the anion is manifested in the dimension-

alities of the phases isolated, as well as the detailed coordination geometries about the copper(II) center in **1** and **2**. The configuration of the Cu^{II} atoms is a square-based pyramid in **1** and an elongated-octahedron in **2**. The anions in **1** are non-coordinated, but the anions in **2** act as bridges between the double-stranded chains and link the double-stranded chains into a 2D channel-type sheet. The UV-Vis reflectance spectra and ESR spectra are consistent with the crystal structures. Magnetic characterizations of **1** and **2** show that complex **1** exhibits antiferromagnetic interactions while **2** is ferromagnetic. Complex **3** displays an emission band at 575 nm that is due to ligand-to-metal charge transfer.

Experimental Section

General: $Cu(NO_3)_2{\cdot}3H_2O$, $CuSO_4{\cdot}5H_2O$, and $CdCl_2{\cdot}2.5H_2O$ were purchased commercially and used without further purification. 4,4′-Dipyridyl disulfide was purchased from Fluka. Elemental analyses of C, H, and N were determined on a Perkin−Elmer 240C analyzer. IR spectra were measured as KBr pellets on a Nicolet Magna 750 FT-IR spectrometer in the range 200−4000 cm^{-1}. Thermogravimetric analyses were performed on a NETSCHZ STA-449C thermoanalyzer under N_2 (over a 26−750 °C range) at a heating rate of 10°/min. Electronic reflectance spectra were recorded on a Lambda 35 spectrometer. ESR spectra were recorded on powdered samples at an X-band frequency of ca. 9.77 GHz at room temperature or liquid nitrogen temperature (77 K) using a Bruker ER420 automatic spectrometer. Variable-temperature magnetic susceptibilities were determined in the temperature range 5−300 K on a Quantum Design MPMS SQUID magnetometer at 10 T. Corrections were applied for diamagnetism calculated from Pascal constants. Effective magnetic moments were calculated by the equation $\mu_{eff} = 2.828(\chi_M T)^{1/2}$, where χ_M is the magnetic susceptibility per formula unit. Fluorescence characterization was performed on an Edinburgh F900 analytical instrument in Fuzhou University.

$[\{Cu(4\text{-}DPDS)_2(H_2O)\}{\cdot}2NO_3{\cdot}3H_2O]_n$ (1): A solution of $Cu(NO_3)_2{\cdot}3H_2O$ (0.12 g, 0.5 mmol) in a methanol/water mixture (5:1, 5 mL) was slowly added to a solution of 4,4′-dipyridyl disulfide (0.22 g, 1 mmol) in dichloromethane (4 mL). After 4 days, blue crystals (0.25 g, 72% yield based on copper nitrate) grew at the bottom of the test tube. $C_{20}H_{24}CuN_6O_{10}S_4$ (700.24): calcd. C 34.27, H 3.43, N 12.00; found C, 34.36, H 3.46, N 12.07%. IR (KBr): $\tilde{\nu}$ = 3408 cm^{-1} (br), 1589 (s), 1543 (m), 1477 (m), 1414 (s), 1385 (s), 1308 (w), 1213 (m), 1099 (m), 1057 (m), 798 (s), 715 (s), 499 (s) cm^{-1}.

$[\{Cu(4\text{-}DPDS)_2(SO_4)\}{\cdot}1.5H_2O{\cdot}CH_3OH]_n$ (2): A solution of $CuSO_4{\cdot}5H_2O$ (0.125 g, 0.5 mmol) in a methanol/water mixture(5:1, 5 mL) was allowed to diffuse slowly into a solution of 4,4′-dipyridyl disulfide (0.22 g, 1 mmol) in chloroform (5 mL). Immediately, a blue precipitate formed at the interface of the two layers. Blue single crystals (0.21 g, 64% base on the copper sulfate) were formed after 3 days. $C_{21}H_{23}CuN_4O_{6.5}S_5$ (659.28): calcd. C 38.22, H 3.49, N 8.49; found C, 38.31, H 3.52, N 8.57%. IR (KBr): $\tilde{\nu}$ = 3412 (br), 1596 (s), 1548 (m), 1481 (s), 1417 (s), 1245 (w), 1218 (m), 1071 (m), 1035 (m), 815 (s), 802 (s), 713 (s), 494 (s) cm^{-1}.

$[Cd(4\text{-}DPDS)_2Cl_2]_n$ (3): A colorless solution of $CdCl_2{\cdot}2.5H_2O$ (0.114 g, 0.5 mmol) in methanol/water (5:1, 5 mL) was carefully layered onto a solution of 4,4′-dipyridyl disulfide (0.22 g, 1 mmol) in acetonitrile (5 mL). Diffusion between the two phases over a period of 5 days produced light-yellow crystals (0.26 g, 84% yield based on cadmium chloride). $C_{20}H_{16}CdN_4Cl_2S_4$ (623.9): calcd. C 38.47, H 2.56, N 8.98; found C, 38.52, H 2.59, N 9.05%. IR (KBr): $\tilde{\nu}$ = 1585 (s), 1543 (m), 1479 (s), 1414 (s), 1321 (w), 1223 (m), 1063 (m), 1009 (m), 820 (s), 808 (s), 708 (s), 496 (s) cm^{-1}.

X-ray Crystallography: Suitable single crystals of **1**, **2**, and **3** were selected for X-ray diffraction studies. The unit cell parameters and intensities were collected at 299 K on a Siemens SMART CCD diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073Å) radiation. Measurements were made by using the ω scan mode in the range $1.50° < \theta < 20°$ for **1**, $1.77° < \theta < 20°$ for **2**, and $2.23° < \theta < 25.05°$ for **3** The structures were solved by direct methods and refined on F^2 by full-matrix least-squares procedures using SHELXTL software.[19] All non-hydrogen atoms were anisotropically refined. All H atoms were located theoretically and not refined. A summary of the crystallographic data of **1**, **2**, and **3** are presented in Table 2, and the selected bond lengths and bond angles are in Table 3.

Synthesis, Characterization, and DNA Binding Studies of a Chromium(III) Complex Containing a Tridentate Ligand

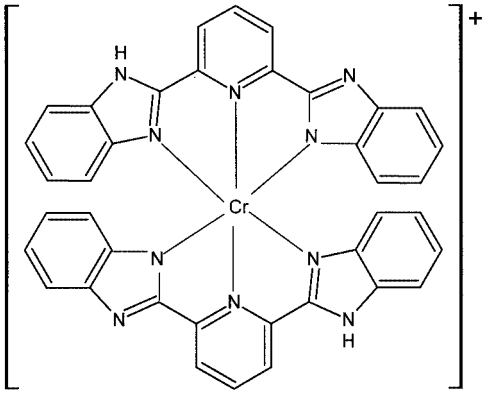
Vaidyanathan Ganesan Vaidyanathan[a] and Balachandran Unni Nair*[a]

Keywords: Chromium / Tridentate ligands / DNA cleavage / Radicals

[Cr(bzimpy)$_2$]Cl, where bzimpy is 2,6-bis(benzimidazol-2-yl)-pyridine, has been synthesized and characterized by ESI-MS, UV/Visible, and fluorescence spectra. Absorption titration and thermal denaturation experiments indicate that the complex binds to DNA with moderate strength, while viscosity measurements show that it may undergo surface binding. The fluorescence intensity of the complex increases with increasing DNA concentration, in contrast to [Cr(phen)$_3$]$^{3+}$ and [Cr(bpy)$_3$]$^{3+}$. The complex cleaves pBR322 DNA in the presence of H_2O_2.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

The interaction of metal complexes with biomolecules has been extensively studied in recent decades.[1−13] Several metal complexes, which bind to DNA through different modes, have been used as probes for DNA structure in solution, as agents for mediation of strand scission of duplex DNA and as chemotherapeutic agents.[14−16] [M(LL)$_3$]$^{n+}$ metal complexes, where LL is 1,10-phenanthroline (phen) or a modified phenanthroline ligand, are particularly attractive species to recognize and cleave DNA.[17−22] Some transition metal complexes that bind covalently to DNA function as anti-tumor agents.

There has been renewed interest in biological aspects of chromium, and its extensive use in the tanning and electroplating industries has aroused much environmental concern over effluents bearing Cr^{VI} and Cr^{III}. Epidemiological and animal studies have firmly established hexavalent chromium compounds as potent carcinogens.[23−25] Chromate can form several DNA lesions, including DNA, DNA−protein, and DNA−amino acid crosslinks, strand breaks and alkali labile sites, which are responsible for its mutagenic and carcinogenic effects.[26,27] The carcinogenic activity of Cr^{VI} is due to its reduction by intracellular reductants to generate Cr^{V} and Cr^{IV} intermediates and finally Cr^{III}. The chromium(V/IV) intermediates are proposed to cause DNA damage that leads ultimately to tumor development.[28−32] Chromium(III) is believed to be non-toxic and is an essential trace element for glucose and lipid metabolism.[33] While chromium(III) picolinate complex is a therapeutic in the treatment of adult-onset diabetes,[34−35] Wetterhahn and coworkers have demonstrated that Cr(pic)$_3$ causes chromosomal damage in Chinese hamster ovary cells (CHO).[36] Chromium(III) not only affects DNA replication but also inhibits enzymatic activity in the biosynthesis of nucleotide pools, which in turn is responsible for mutations in cells.[37−38] We have demonstrated that a chromium(III) complex of a Schiff base having a donor−acceptor group exhibits nuclease activity, while [Cr(salen)(H$_2$O)$_2$]$^+$ can cleave DNA only in the presence of peroxide.[39−40] Furthermore, Sudgen et al. showed that Cr^{III} aromatic bidentate amines that can enter cells are mutagenic agents in the Ames test, as such complexes can generate a Cr^{III}/Cr^{II} active redox center.[41] These observations indicate that modification of the ligand environment would alter the binding affinities and DNA cleaving properties of the metal complex. Our present study focuses on the interaction of DNA with chromium(III) complex **1** which has a pyridine-type tridentate ligand, bzimpy.



1

Results and Discussion

Compound **1** was synthesized in good yield by reaction of the ligand bzimpy with [Cr(dmso)$_6$]$^{3+}$ generated in situ.

The ESI mass spectrum shows the base peak at m/z = 672 due to $[Cr(bzimpy)]^+$. The ESI spectrum thus confirms the authenticity of the complex. It is noteworthy that the ligand behaves like a monoanion (through the loss of a proton from a −NH group). Similar behaviour has been observed in Mn^{II} complex of this ligand.[42] However, with $[Ru(bzimpy)_2]^{2+}$ the ligand coordinates as a neutral tridentate ligand without such a loss of a proton.[43] Despite our best efforts we could not grow diffraction quality crystals. However, the Mn^{II} complex of the same ligand has been crystallographically characterized and found to have a regular octahedral geometry.[42] The Cr^{III} complex reported here is expected to have a similar geometry. The cyclic voltammogram of the complex shows a reduction of Cr^{III} to Cr^{II} at a cathodic peak potential, E_{pc}, of −1.05 V versus SCE. Reoxidation of the Cr^{II} species occurred at −0.81 V upon reversal of the scan (Figure 1). The separation of anodic and cathodic peak potentials, ΔE_p = 240 mV for $[Cr(bzimpy)_2]^+$, indicates a quasi-reversible redox process. Such behavior is typical of many Cr^{III}/Cr^{II} couples because of the Jahn−Teller distortion expected for the Cr^{II} ion.

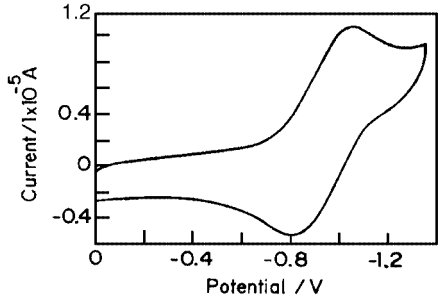

Figure 1. Cyclic voltammogram of $[Cr(bzimpy)_2]^+$

Absorption Titration

Absorption titration can monitor the interaction of a metal complex and DNA. In general, hypochromism and redshift are associated with the intercalative binding of the complex to the helix, due to strong stacking interactions between the aromatic chromophore of the complex and the base pairs of DNA. The chromium complex **1** shows an absorbance at 317 nm due to the intraligand (π−π*) transition of the ligand bzimpy. Binding of chromium(III) with DNA is expected to change markedly its electronic spectrum. Upon addition of CT DNA, the chromium(III) complex absorbance increases, and is accompanied by a small shift of 3 nm in λ_{max}, from 317 to 320 nm (Figure 2), that is consistent with groove binding, leading to small perturbations. Such a small increase in λ_{max} and hyperchromicity occurs with some porphyrin and copper complexes on their interaction with DNA.[44] This hyperchromism can be attributed to external contact (surface binding) with the duplex. The absorption data were analyzed to evaluate the intrinsic binding constant K_b, which can be determined from Equation (1), where ε_A corresponds to A_{obsd}/[Cr] and ε_F, and ε_B are the molar absorption coefficients for the free chromium complex and the chromium complex in the fully bound form, respectively.

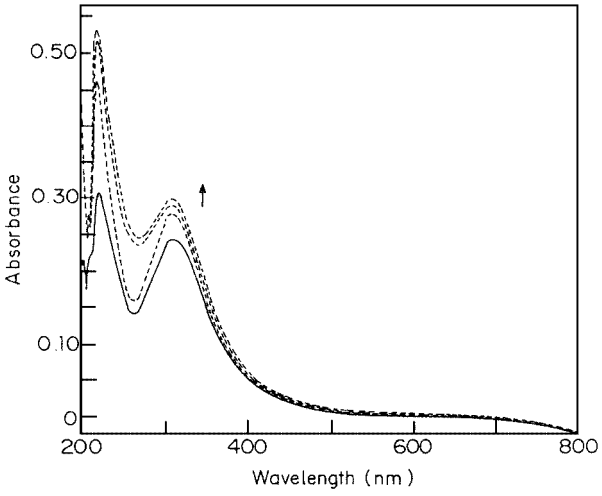

Figure 2. Electronic spectra of $[Cr(bzimpy)_2]^+$ in Hepes buffer upon addition of calf thymus DNA, [Cr] = 10 μM (—), [DNA] = 20−150 μM (- - -)

$$[DNA]/(\varepsilon_A - \varepsilon_F) = [DNA]/(\varepsilon_B - \varepsilon_F) + 1/K_b(\varepsilon_A - \varepsilon_F) \quad (1)$$

A plot of $[DNA]/(\varepsilon_A - \varepsilon_F)$ versus [DNA] revealed a moderate intrinsic binding constant K_b of $1.013 \pm 0.03 \times 10^4$ M^{-1}, which is similar to those observed for many other chromium and ruthenium complexes ($1-4 \times 10^4$ M^{-1}),[40,45] and is more in keeping with groove binding than intercalative binding. Further, since the complex is octahedral, and upon coordination the planarity of the ligand is lost, intercalative binding to DNA is highly unlikely.

Thermal Denaturation Studies

DNA melting is observed when double-stranded DNA molecules are heated and separate into two single strands; it occurs due to disruption in intermolecular forces such as π stacking and hydrogen bonding interactions between DNA base pairs. Here, a DNA melting experiment revealed that T_m of calf thymus DNA was 65±0.2 °C and 68±0.2 °C in the absence and presence of the complex, respectively. However, for the ligand alone, there is no change in DNA melting temperature. The ΔT_m of 3 °C indicates that the binding cannot be intercalative. Such a small ΔT_m is generally associated with surface binding of the metal complex. Generally one would expect a much larger increase in T_m for classical intercalators.[46−49] A small ΔT_m also indicates weak binding of the complex to DNA. This is also reflected in the binding constant.

Viscosity Measurement

Optical photophysical probes generally provide support for a binding model. Hydrodynamic measurements that are sensitive to length change are, in the absence of crystallographic data, regarded as the most critical tests of a binding model in solution. Intercalating agents are expected to destack the base pairs to accommodate the ligands, causing

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

elongation of the double helix and an increase in the viscosity of the DNA. However, some complexes, which bind through non-intercalative modes, decrease the viscosity initially and then increase it at higher concentrations. With chromium complex **1**, the viscosity of DNA showed a complicated dependence on complex concentration. The change in viscosity with the addition of the complex to DNA is shown in Figure 3. The viscometric data rules out classical intercalation. Similar behaviour has been observed on the addition of $[Cu(bcp)_2]^+$ to ST DNA.[50] The viscometric results could be explained in terms of a bridged structure to promote the extension of duplexes. Here the binding may involve inner-sphere complex formation via phosphate oxygen, indicating that the binding of Cr^{III} complex with DNA could be surface binding or by forming bridged adducts. Adducts formed by bridging duplexes are stabilized by hydrophobic interaction or coulombic interaction, as with $[Cu(bcp)_2]^+$ and $[Cu(dpsmp)_2(H_2O)]$.[51–53]

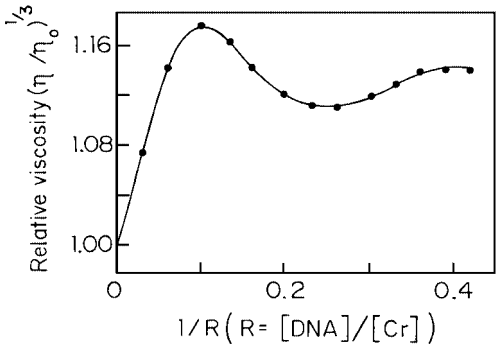

Figure 3. Effect of increasing amounts of $[Cr(bzimpy)_2]^+$ (–•–) on the relative viscosity of DNA

Fluorescence Spectroscopic Study

The emission spectra of $[Cr(bzimpy)_2]^+$ in the absence and the presence of CT DNA is shown in Figure 4. The luminescence spectrum of complex **1** shows an emission band at 717 nm when excited at 320 nm. The band at 717 nm is attributable to the $^2E_g \rightarrow {}^4A_{2g}$ transition of $[Cr(bzimpy)_2]^+$. Addition of DNA causes a gradual increase in the fluorescence intensity and the emission maximum also shifts by 2 nm to a longer wavelength. This is because, in the presence of DNA, the metal complex is bound in a relatively non-polar environment compared to water. Such an increase in fluorescence intensity has been reported for certain intercalators upon their binding to DNA. The increase observed here, however, is less than that observed for classical intercalators. In contrast, $[Cr(bpy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ show a decrease in luminescence intensity in the presence of DNA, indicating that the excited state of these complexes are strong oxidizing agents that could oxidize guanine base.[54–55] The excited state potential for complex **1** was calculated as 0.92 V from Equation (2), where $E_{0-0}(Cr^{3+}/{}^*Cr^{3+})$ is the one-electron potential corresponding to the zero-zero spectroscopic energy of the excited state.

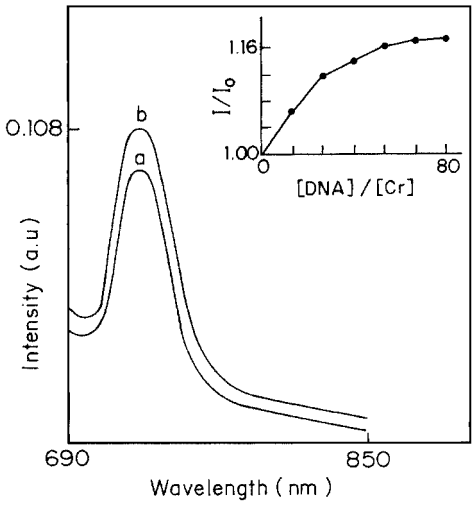

Figure 4. Emission spectra of $[Cr(bzimpy)_2]^+$ in aqueous solution in a) absence and b) presence of DNA. [Cr] = 10 mM, [DNA] = 200–800 mM. Inset: Relative emission intensity of $[Cr(bzimpy)_2]^+$ versus [DNA]/[Cr]

$$E^0({}^*Cr^{3+}/Cr^{2+}) = E^0(Cr^{3+}/Cr^{2+}) - E_{0-0}(Cr^{3+}/{}^*Cr^{3+}) \quad (2)$$

The reported excited state potentials of $[Cr(bpy)_3]^{3+}$ and $[Cr(phen)_3]^{3+}$ are 1.44 and 1.42 V, which are much greater than the 0.92 V in the present case. Hence, compared to $^*[Cr(bpy)_3]^{3+}$ and $^*[Cr(phen)_3]^{3+}$, the excited state of $[Cr(bzimpy)_2]^+$ is not a good oxidizing agent to oxidize the guanine base; as the excited state potential is low compared to that of guanine base.

DNA Cleavage by $Cr(bzimpy)_2^+$

The ability of $[Cr(bzimpy)_2]^+$ to serve as a metallonuclease has been examined. The reaction of $[Cr(bzimpy)_2]^+$ with pBR322 DNA was monitored by observing the conversion of supercoiled plasmid DNA (fastest migrating species) into the circular, nicked form (slowest migrating species). All reactions were evaluated by comparing the amount of circular plasmid to the amount present in plasmid controls. Neither relaxation nor nicking is observed in control reactions of DNA alone or with DNA and either $[Cr(bzimpy)_2]^+$ or hydrogen peroxide (Figure 5. lanes 1–3). However, with hy-

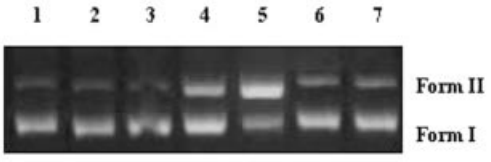

Figure 5. Nicking of pBR322 DNA by $[Cr(bzimpy)_2]^+$ over time. Lane 1, control DNA alone; lane 2, DNA + complex **1**; lane 3, DNA + H_2O_2; lanes 4 and 5, DNA + complex **1** + H_2O_2 incubated for 30 and 60 min, respectively. Lane 6, DNA + complex **1** + H_2O_2 + EtOH (1 M); lane 7, DNA + complex **1** + D-mannitol (500 mM)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

drogen peroxide, $[Cr(bzimpy)_2]^+$ relaxes supercoiled pBR322 DNA in a time-dependent manner (lanes 4,5). At longer times, the supercoiled form is completely converted into the open circular form (form II) in the presence of Cr^{III} complex. The time dependence of the reaction suggests that $[Cr(bzimpy)_2]^+$ acts as a catalyst. In the presence of Cr^{III} complex, H_2O_2 produces radical species, which cause the DNA cleavage. The addition of radical traps (1 M EtOH or D-mannitol) to reaction mixtures containing complex and H_2O_2 inhibited the cleavage of DNA (lanes 6 and 7 of Figure 6). Gel electrophoresis of similar DNA-cleaving experiments with CT DNA showed that complex **1** cleaved the CT DNA in a non-specific manner, in the presence of H_2O_2. The presence of hydroxyl radicals has been shown to lead to hydrolysis of *p*-nitrophenyl phosphate ester.[56] Treatment of p-nitrophenyl phosphate with complex **1** and H_2O_2 generates *p*-nitrophenol, which has an absorption at 404 nm (Figure 6). This confirms the formation of hydroxyl radicals from hydrogen peroxide in the presence of complex **1**.

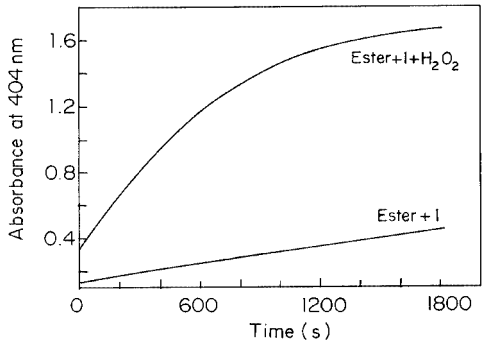

Figure 6. Kinetics of phosphate ester hydrolysis of *p*-nitrophenylphosphate by complex **1** in the presence of hydrogen peroxide

Conclusions

Chromium complexes having a tridentate ligand can bind DNA with moderate strength. Spectroscopic and viscosity measurements show that the Cr^{III} complex interacts with the DNA surface. A fluorescence study shows that the emission intensity of the complex increases on addition of DNA as the environment around the complex is more hydrophobic in the presence of DNA. The emission of both $[Cr(phen)_3]^{3+}$ and $[Cr(bpy)_3]^{3+}$ is quenched on binding to DNA. The emission of $[Cr(bzimpy)]^{2+}$, however, is not quenched by DNA as it has a lower excited state potential than that for guanine base. Gel electrophoresis shows that $[Cr(bzimpy)_2]^+$ nicks DNA in the presence of H_2O_2. The amount of nicked DNA formed increases with increasing incubation time of the Cr^{III} complex and H_2O_2 with DNA. The nicking of DNA is inhibited by radical scavengers such as ethanol and D-mannitol.

Experimental Section

Materials: *o*-Phenylenediamine, 2,6-pyridinedicarboxylic acid, and calf thymus DNA were obtained from Sigma chemicals, USA. Tris, Hepes, agarose, and pBR322 DNA were obtained from Bangalore Genei, Bangalore. All solvents were obtained from Ranbaxy, India. Milli Q water was used for preparing buffers.

Synthesis of $[Cr(bzimpy)_2]Cl$ (1): 2,6-Bis(benzimidazo-2-yl)pyridine was synthesized according to the published procedure.[57] An excess of DMSO was added to chromium(III) chloride salt (1 mmol, 0.267 g) and boiled under reflux for 1 h. The ligand bzimpy (2 mmol, 0.622 g) was then added to the resulting mixture, and refluxing was continued for a further hour. The volume of solvent was then minimised by rotary evaporation and a reddish orange precipitate was obtained on addition of diethyl ether. The precipitate was filtered off and dried in vacuo. The compound was then recrystallised from acetonitrile (yield 0.66 g, 75%); found C 64.33, H 3.34, N 19.80, Cr 7.32% calcd. for $C_{38}H_{24}ClCrN_{10}$ (M.wt. 707.5): C 64.43, H 3.41, N 19.78, Cr 7.34%. IR (KBr pellet): 3401 (N−H), 3057 (C−H), and 1615 (C=N) cm^{-1}.

Physical Measurements: UV/Visible spectra of the complex and DNA binding studies were recorded on a Perkin−Elmer Lambda 35 spectrophotometer at 25 °C. Elemental analysis was performed using a Heraeus-CHN-Rapid Analyzer at RSIC, IIT, Madras. The emission spectra were recorded on a Hitachi 650−40 spectrofluorimeter. The electrospray ionization (ESI) mass spectrum of the complex was recorded with a Hewlett−Packard 1100 mass spectrometer equipped with an electron spray source. The infrared spectrum of the complex was recorded on a Perkin-Elmer FT-IR spectrometer. Cyclic voltammetry was performed on an EG and G PAR 173 potentiostat/Galvanostat analyzer. Tetrabutylammonium perchlorate (TBAP) was used as supporting electrolyte. The sample in dried DMSO was purged with nitrogen prior to measurement. A standard three-electrode system consisted of a glassy carbon working electrode, platinum auxiliary electrode and a saturated calomel reference electrode (SCE).

DNA Binding Experiments: All experiments involving the interaction of the complex with DNA were carried out in Hepes buffer (10 mM, pH 7.5). A solution of calf thymus DNA in the buffer gave a ratio of UV absorbance at 260 and 280 nm of about 1.8−1.9:1, indicating that the DNA was sufficiently free from protein.[58] The DNA concentration per nucleotide was determined by absorption spectroscopy using the molar absorption coefficient (6600 $M^{-1}cm^{-1}$) at 260 nm.[59]

The electronic spectra of the Cr^{III} complex were monitored in both the presence and absence of DNA. The binding constant for the interaction of Cr^{III} complex **1** with DNA was obtained from absorption titration data. A fixed concentration of complex **1** (10 μM) was titrated with increasing amounts of DNA over the range 20−150 μM.

During measurement of the absorption spectra, an equal amount of DNA solution was added in both complex solution and reference solution to eliminate the absorbance of DNA itself.

Thermal denaturation studies were conducted in a Perkin−Elmer Lambda 35 spectrophotometer supplied with thermostatted cell holder. The temperature was controlled by a Peltier system (±0.1 °C). The absorbance at 260 nm was monitored for DNA (100 μM) in the absence and presence of the complex (10 μM).

Viscosity measurement was carried out on an Ostwald viscometer, immersed in a thermostatted water bath maintained at 28±0.1 °C.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The DNA concentration was kept constant (150 μM) and that of the metal complex was varied from 5 to 75 μM. The flow time was measured with a stop-watch operated manually, and each sample was measured five times and an average flow time calculated. Data are presented as $(\eta/\eta_o)^{1/3}$ versus [Cr]/[DNA], where η is the viscosity of DNA in the presence of complex, and η_o is the viscosity of DNA alone. Viscosity values were calculated from the observed flow time of DNA-containing solutions corrected for the flow time of buffer alone (t_o), $\eta = t - t_o$.[60]

In steady state fluorescence experiments, the complex concentration (10 μM) was fixed while that of DNA was varied (200−800 μM). The chromium(III) complex in the presence of DNA was excited at 320 nm and the fluorescence spectra were recorded between 650 and 850 nm.

Phosphate ester hydrolysis was monitored on a Perkin−Elmer Lambda 35 spectrophotometer at 25 °C by measuring the production of p-nitrophenol at 404 nm. The background reaction was carried out with the peroxide and ester alone. A reaction mixture containing Cr^{III} complex **1** (0.025 mM), peroxide (0.1 mM, freshly prepared) and *p*-nitrophenylphosphate (1 mM) in Hepes (10 mM, pH 7.0) was used to determine the rate of *p*-nitrophenol formation at 404 nm.

For gel electrophoresis experiments, supercoiled pBR322 DNA (800 ng) was treated with Cr^{III} complex (100 μM) in Tris-EDTA buffer (10 mM, pH 8.0) and the solution was incubated for 16 h at room temperature. H_2O_2 (500 μM) was then added and a timed assay was carried out. The reactions were quenched at various times by adding loading buffer. The samples were analyzed by electrophoresis for 4 h at 50 V on a 0.8% agarose gel in Tris−boric acid−EDTA buffer. The gel was stained with 0.5 μg/mL ethidium bromide and photographed under UV light.

Synthesis and Structural Characterization of Potassium Salts of Phosphane-Substituted (Cyclopentadienyl)iron Dicyanides, and Their Use as Bridging Ligands for Copper(I) Phosphane Derivatives

Donald J. Darensbourg,*[a] M. Jason Adams,[a] Jason C. Yarbrough,[a] and Andrea L. Phelps[a]

Dedicated to the memory of Professor Dieter Sellmann, a good friend and brilliant chemist

Keywords: Cyanides / Heterometallic complexes / Bridging ligands / Iron / Copper / Potassium

Phosphane-substituted $CpFe(CN)_2$ anions have been synthesized by photochemical decarbonylation of $KCpFe(CN)_2CO$ in the presence of various mono- and diphosphanes. The synthesis and characterization of uniquely bridged diphosphane derivatives, $[KCpFe(CN)_2]_2$-μ-$(Ph_2P)_2$–$(CH_2)_n$ (n = 2–4), are particularly noteworthy. These phosphane-substituted $CpFe(CN)_2^-$ units have afforded stable mixed-metal complexes upon reaction with Cu^I in the presence of tricyclohexylphosphane in acetonitrile solution. X-ray crystallography shows these derivatives to display two-dimensional diamond-shaped structures with copper(I) of the form $[Fe(CN)_2Cu]_2$, where the Cu^I centers exhibit both trigonal and tetrahedral geometries. Infrared data reveal that the withdrawal of electron density from the iron centers in these mixed metal cyanides via the cyanide ligands is enhanced upon replacing CO in $CpFe(CN)_2CO^-$ with phosphanes.

Introduction

The use of substitutionally inert organometallic cyanides as ligands to other metal ions has received much interest due to their ability to simplify studies utilizing cyanide as a bridging group.[1] Although, metal hexacyanide salts have long been known to complex other metal ions through bridging cyanide ligands, the resulting derivatives are often highly insoluble aggregates which are difficult to definitively characterize.[2] Organometallic derivatives having the three facial coordination sites occupied by an ancillary ligand, e.g., the cyclopentadienyl moiety, have been used to limit the degree of aggregation.[3] Substitution of the metal center by an additional strongly bonded ligand, such as a tertiary phosphane, further limits bridging in a multidimensional fashion. In addition to promoting solubility, phosphane adducts of these organometallic cyanides provide a convenient ^{31}P NMR probe for studying these complexes. Despite these advantages, relatively few studies have involved these simple metallocyanides.[4]

Vahrenkamp and co-workers have investigated neutral iron monocyanide complexes of the type CpFe(dppe)CN, where dppe = 1,2-bis(diphenylphosphanyl)ethane, as bridging ligands to other metal complexes.[5] The use of metal monocyanide derivatives is particularly beneficial at restricting the bridging capacity of the complex, and thus uncomplicating the study of the cyanide ligand as an electronic linkage between two metal centers. The chelated phosphane ligand serves to block any sites on the iron ion that a more labile ligand might leave open for substitution. Furthermore, the bulkiness of the phosphane ligand often aids in crystallization of the resulting multinuclear metal complexes. Indeed, this simple metallocyanide has allowed Vahrenkamp to examine in detail the redox chemistry of cyanide-bridged trimetallic complexes using cyclic voltammetry. One such study involved the effect of linear vs. bent bridging motifs in the Fe−CN−Pt−NC−Fe metallocyanide unit on electronic communication between the metal centers.[5,6]

A long standing focus in our research efforts involves the design of homogeneous catalysts for the copolymerization of epoxides and carbon dioxide to provide polycarbonates.[7] Relevant to this subject double metal cyanide derivatives, especially those of Fe(II and III) or Co^{III} and Zn^{II}, have received attention as heterogeneous catalysts for this process in the patent literature.[8] In our efforts to synthesize novel mixed-metal cyanides as models for these catalysts, a series of metal complex salts of the general formula $[K][CpFe(CN)_2PR_3]$ have been prepared and characterized both in solution and in the solid state. In addition, the employment of traditionally chelating phosphane ligands have extended the range of these salts to include diiron deriva-

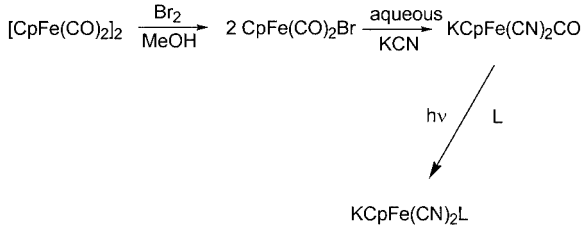
tives of the type $[K]_2[CpFe(CN)_2PR_2(CH_2)_nPR_2(CN)_2FeCp]$, where $n = 2-4$ and R = Ph, thereby affording unique bridging ligands with specific bite angles. Importantly, the electronic character of the cyanide ligands can be tailored by choosing phosphanes of the appropriate basicity. Examples of the viability of these anionic metallocyanide derivatives of iron as ligands towards copper(I) are demonstrated with the isolation and crystallographic characterization of the mixed-metal complexes $[CpFe(PPh_3)(\mu\text{-}CN)_2Cu(PCy_3)]_2$ and $Cu(PCy_3)[CpFe(\mu\text{-}CN)_2]_2Cu(PCy_3)_2$-μ-dppp [dppp = 1,2-bis(diphenylphosphanyl)propane].

Results and Discussion

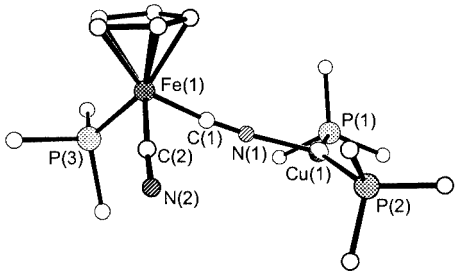
A series of phosphane (= L) substituted salts of $[K][CpFe(CN)_2L]$ has been prepared through photolytic decarbonylation of the parent $[K][CpFe(CN)_2CO]$ compound (Scheme 1). The impetus for these studies comes from our desire to synthesize well-defined double-metal cyanide (DMC) complexes to serve as soluble structural and reactivity models for those employed as heterogeneous catalysts for the polymerization of epoxides to polyols or epoxides and CO_2 to polycarbonates/cyclic carbonates. Relevant to these studies we have previously noted that upon treating analogous DMC complexes derived from the $CpFe(CN)_2CO^-$ anion with excess PCy_3, the reaction according to Equation (1) occurred over an extended reaction time. That is, the metal aggregate was disrupted to afford a trigonal copper(I) center and PCy_3 had displaced CO at the iron center (**A**).[9] Hence, an obvious concern is whether dimer disruption is a necessary structural prerequisite upon substitution of the CO ligand at the iron center with a sterically demanding phosphane ligand.



Scheme 1

$$[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)_2]_2 + 2\,PCy_3 \rightarrow 2\,CpFe(PCy_3)(CN)(\mu\text{-}CN)Cu(PCy_3)_2 + 2\,CO \quad (1)$$

In order to tailor the electronic and structural properties of the ancillary metal center we have photochemically substituted the CO ligand in the $KCpFe(CN)_2CO$ salt with various phosphane and diphosphane ligands. A mixture of methanol and acetonitrile was utilized to solubilize both the parent salt and in this instance PPh_3, respectively. Solubility of the reagents, especially the $KCpFe(CN)_2CO$ derivative, is



A

essential for complete conversion into product. This complex has alternatively been prepared thermally from $CpFe(CO)(PPh_3)I$ and KCN in refluxing ethanol by Reger.[4] The product, $KCpFe(CN)_2PPh_3$ (**1**), exhibited ν(CN) frequencies at 2055 vs, 2040 s, and 2028 sh cm^{-1} in methanol, which are shifted to lower wavenumbers when compared to the parent compound (see Table 1). This shift to lower frequencies is expected as the result of replacing the carbonyl ligand by primarily a donor phosphane ligand, thereby allowing the cyanide groups to be involved in greater π-backbonding with the iron center. The ^{31}P NMR spectrum of **1** displays a downfield chemical shift from that of the free ligand to δ = 86.9 ppm. The more basic methyldiphenylphosphane ligand was incorporated at the iron center for comparison with the PPh_3 analog, where the only other variance arises from its slightly reduced cone angle of 136 vs. 145° for PPh_3.[10–12] In this instance it was not necessary to employ a mixed-solvent system for the photolytic reaction since both the $KCpFe(CN)_2CO$ salt and PPh_2Me are soluble in methanol. As expected, the increased basicity of the monomethylated phosphane causes the ν(CN) vibrations in $KCpFe(CN)_2PPh_2Me$ (**2**) to shift to lower wavenumbers at 2050, 2034, and 2025 cm^{-1}. The ^{31}P NMR chemical shift in complex **2** appears at δ = 71.3 ppm. Interestingly, in an attempt to improve reaction yields, photolysis of the carbonyl salt with a fourfold excess of PPh_2Me afforded the bis(phosphane) neutral complex $CpFe(CN)(PPh_2Me)_2$ (**3**).

Table 1. Infrared and ^{31}P NMR spectroscopic data (all spectra were determined in methanol solution except for those of compound **3** which were determined in THF)

Compound	ν(CN) [cm^{-1}]	δ [ppm]
$KCpFe(CN)_2(CO)$	2095, 2084	N/A
$KCpFe(CN)_2(PPh_3)$ (**1**)	2055 vs, 2040 s, 2028 sh	86.9
$KCpFe(CN)_2(PPh_2Me)$ (**2**)	2050 vs, 2034 s, 2025 sh	71.3
$CpFe(CN)(PPh_2Me)_2$ (**3**)	2069	57.2
$[KCpFe(CN)_2]_2$ μ-dppe (**4**)	2050, 2032, 2025 sh	78.2
$[KCpFe(CN)_2]_2$ μ-dppp (**5**)	2050, 2032, 2025 sh	77.0
$[KCpFe(CN)_2]_2$ μ-dppb (**6**)	2050 vs, 2034 s, 2026 sh	76.5
$[KCpFe(CN)_2]_2$ μ-dppa (**7**)	2057 s, 2050 vs, 2032 sh	64.9

A number of bidentate phosphanes have been utilized as bridging ligands between two $CpFe(CN)_2$ anionic units. These derivatives were synthesized by photolysis of the parent salt $KCpFe(CN)_2CO$ in the presence of 0.5 equiv. of the

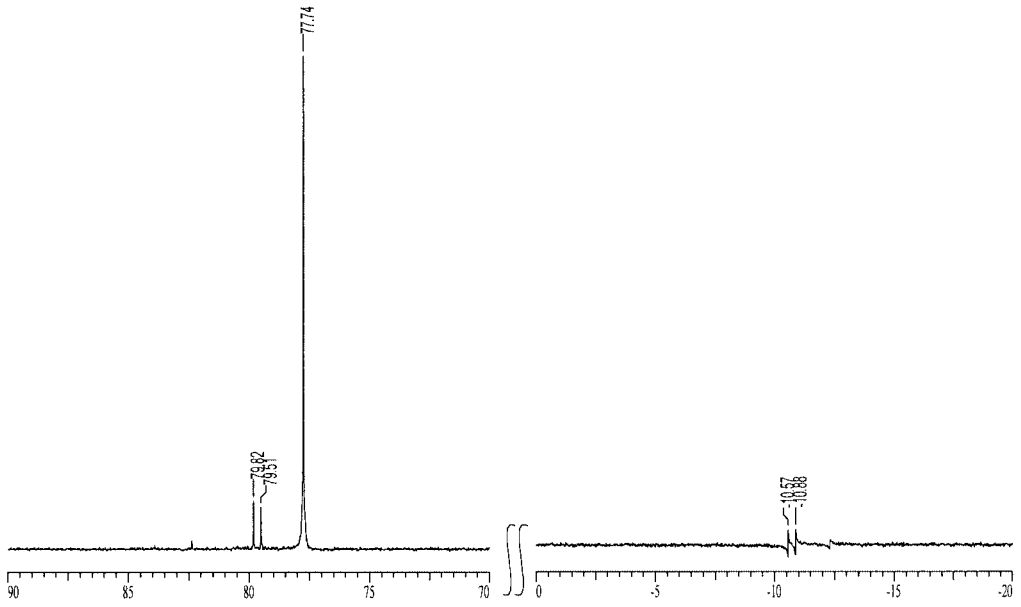

Figure 1. ^{31}P NMR spectrum of the crude product from the synthesis of $[KCpFe(CN)_2]_2$-μ-dppe (**4**) with baseline omitted from 0 to 70 ppm

corresponding diphosphane in a 1:1 mixture of acetonitrile/methanol. A small impurity of the singly bonded phosphorus derivative, such as $KCpFe(CN)_2$dppe, often accompanies these syntheses. Figure 1 depicts the ^{31}P NMR spectrum of the crude product resulting from the reaction of $KCpFe(CN)_2(CO)$ with 0.5 equiv. of dppe, where in addition to the desired product **4** ($\delta^{31}_P = 78.2$ ppm) two weak ^{31}P signals at $\delta = 79.7$ and -10.8 ppm with ^{31}P coupling constants of 38.3 Hz are observed corresponding to bound and free phosphane, respectively. Varying the number of $-CH_2-$ units linking the phosphorus donors from 2 to 4 allows for control of the orientation of the cyanide ligands with respect to one another (vide infra). As anticipated, the ν(CN) vibrational modes in complexes **4**, **5**, and **6** are virtually identical (see Table 1) since all of the bridging phosphane ligands are of similar basicity.

A more contrasting example of a bridging phosphane can be seen in the bis(diphenylphosphanyl)acetylene case, complex **7**. This short-chain bridging phosphane is comprised of a linear alkylene backbone, with diminished electron-donating ability compared to its dppe counterpart, **4**. The decrease in basicity is readily apparent in the ν(CN) values in complex **7** which are on average 10 cm^{-1} higher than those of complex **4**. Furthermore, the linear nature of the phosphane prohibits the cyanide ligands of the bis(iron) complex from interacting at the same metal center. One might imagine this bis(cyanometalate) behaving as a strut which links metal centers to form chain-like structures.

The solid-state structures of representative examples of these phosphane-substituted (cyclopentadienyl)iron dicyanide salts have been examined by X-ray crystallography. Single crystals of compounds **1** and **4** were grown from a concentrated methanol solution by slow concentration over several weeks at ambient temperature. Compound **6** was crystallized from THF/hexane at 10 °C, whereas single crystals of **3** were obtained by slow concentration of a hexane solution at room temperature. Selected bond lengths and angles of compounds **1**, **3**, **4**, and **6** are listed in Table 2.

Table 2. Selected bond lengths [Å] and angles [°] for compounds **1**, **3**, **4**, and **6**

	1	**3**	**4**	**6**
Fe(1)−C(6A)	1.880(8)	1.889(3)	1.871(12)	1.847(9)

P(1)−Fe(1)−P(2)	–	98.42(3)	–	–

The effect of replacing the carbonyl group with a phosphane donor can be seen in the metric data for the iron cyanide unit. Specifically, the iron−carbon(cyanide) distances in compounds **1**, **4**, and **6** are shorter than those seen in $KCpFe(CN)_2CO$, where an average Fe−CN distance of 1.911(8) Å was observed.[13,14] This subtle yet statistically relevant bond-length change is the result of replacing the good π-acceptor, CO, with a good donor ligand, phosphane. Concomitantly, the increase in bond order to the Fe−CN bond causes a decrease in the C−N triple-bond

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

character, where the C(6A)−N(1A) bond lengths in compounds **1**, **4**, and **6** are all longer than that determined in the CO analog [1.143(10) Å]. Although this is compelling crystallographic evidence, the decrease in the cyanide triple-bond order is more evident by observing the ν(CN) vibrational modes shift to lower frequencies as previously noted. As expected, the Fe−P bond lengths in compounds **1**, **4**, and **6** are quite similar, spanning the narrow range from 2.175(2) in **1** to 2.183(2) Å in **6**. In the diphosphane neutral derivative, **3**, there is a slight lengthening of the Fe−P bond where a distance of 2.2025(8) Å is observed. Although it is tempting to attribute the bond lengthening to an electronic effect, it might also be due to enhanced steric congestion about the iron center. Support for this latter explanation comes from the metric parameters obtained for the chelated CpFe(CN)(dppe) derivative. CpFe(CN)(dppe) was prepared by the method of Vahrenkamp and co-workers[5] and its solid-state structure defined by X-ray crystallography.[15] The average Fe−P bond length in this instance was found to be 2.1788(14) Å, which is indistinguishable from those seen in the anionic compounds **1**, **4**, and **6**. The thermal ellipsoid representations of these closely related neutral iron monocyanide derivatives, **3** and CpFe(CN)(dppe), are provided in Figure 2 and Figure 3. These drawings clearly illustrate the difference observed in the solid state of the orientation of the phenyl substituents of the phosphane ligands in **3** as compared with their imposed, sterically less demanding orientation seen in CpFe(CN)(dppe).

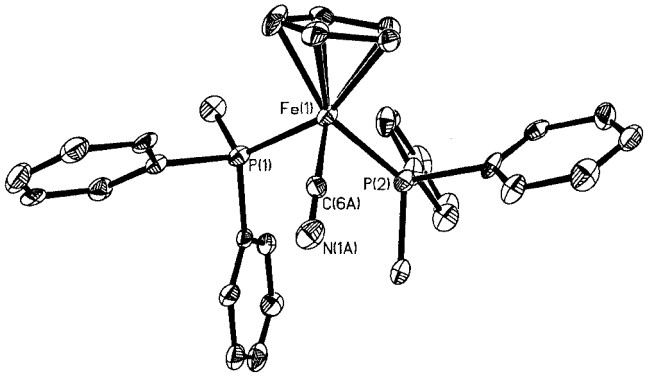

Figure 2. Thermal ellipsoid representation of CpFe(CN)-$(PPh_2Me)_2$ (**3**)

As noted in the thermal ellipsoid drawings in Figure 4, Figure 5 and Figure 6 of the salts, **1**, **4**, and **6**, in all instances the compounds pack in the crystal lattice so as to orient in such a manner as to maximize the number of cyanide−potassium interactions. These −CN−K interactions are either bridging or terminal in nature, with the two not being mutually exclusive. An instance of terminal interaction can be seen in Figure 4 between N(1A) and K(1), with an average distance of 2.847 Å. Potassium ions that bridge cyanide ligands on the same iron center, such as K(1) seen in Figure 5, display a stronger interaction with one of the cyanide nitrogen atoms. This is evidenced by a 0.1 Å

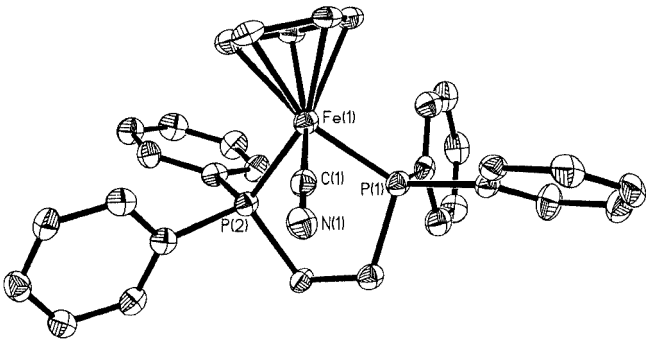

Figure 3. Thermal ellipsoid drawing of CpFe(CN)(dppe); selected bond lengths [A] and angles [°]: Fe(1)−P(2) 2.1747(14), Fe(1)−P(1) 2.1828(15), Fe(1)−C(1) 1.898(5), N(1)−C(1) 1.154(6); P(2)−Fe(1)−P(1) 84.76(6), C(1)−Fe(1)−P(2) 89.02(14), C(1)−Fe(1)−P(1) 88.43(14)

shorter interaction distance between N(1A) and K(1) as compared to that of N(2A)−K(1). In order to utilize these latter anionic metallocyanides as ligands towards other metal centers, the bridging diphosphane ligand must be flexible. That is, the orientation of the iron centers with respect to one another is controlled by the length of the chain between the Ph_2P- units. As is readily seen in Figure 5 of compound **4** the dppe bridge between the iron centers (n = 2) is sufficiently short so as to render it impossible for the four cyanide ligands on the two iron centers to become coplanar. The coplanarity of these four cyanide ligands is a requirement for providing mixed-metal diamond-shaped structures (vide infra). Upon lengthening the chain from n = 2 to n = 3 (**5**) or 4 (**6**) allows greater flexibility in the phosphane bridge, thereby, permitting the cyanide ligands to become coplanar in their chelation towards other metal centers (vide infra).

gands for the formation of double-metal cyanides. Specifically, the reaction of $KCpFe(CN)_2PPh_3$ with $Cu(CH_3CN)_4(BF_4)$ was carried out in acetonitrile to yield a fine yellow powder. This material was insoluble in all common organic solvents, which is in sharp contrast to its carbonylated analog.[16] In an effort to provide a soluble complex, a similar reaction was performed where an equivalent of PCy_3 was added to the copper(I) reagent prior to its addition to the iron dicyanide salt. This procedure led to the formation of a soluble double-metal cyanide derivative, complex **9**. Following the removal of acetonitrile, complex **9** was separated from the by-product KBF_4 salt by dissolution in dichloromethane. As anticipated for bridging cyanide ligands, the ν(CN) vibrational modes in complex **9** were shifted to higher frequencies compared to the corresponding values in the parent salt (see Table 1 and Table 3). Single crystals of **9** suitable for X-ray diffraction were grown by vapor diffusion of a CH_2Cl_2/hexane solution at 10 °C over a period of one week. A thermal-ellipsoid drawing of complex **9** is depicted in Figure 7, whereas selected bond lengths and angles are provided in Table 4.

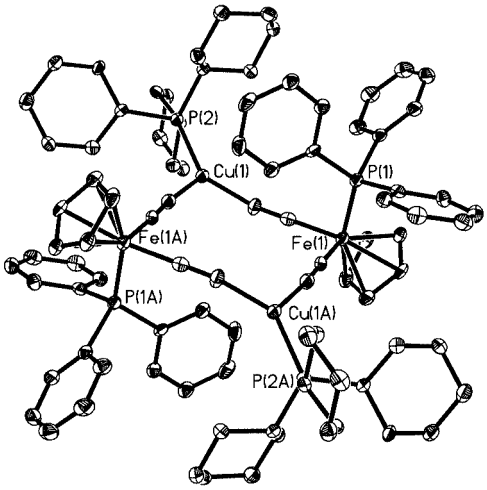

Figure 7. Thermal ellipsoid representation of $[CpFe(PPh_3)(\mu\text{-}CN)_2CuPCy_3]_2$ (**9**) with hydrogen atoms removed for clarity

The solid-state structure of complex **9** is similar to that seen for its $CpFe(CN)_2CO^-$-derived analog, $[\eta^5\text{-}C_5H_5Fe(CO)(\mu\text{-}CN)_2CuPCy_3]_2$.[16] That is, complex **9** exhibits a diamond-shaped motif composed of two $CpFe(PPh_3)$ fragments, two copper(I) centers, and four bridging CN^- ligands. The copper(I) centers display trigonal geometry as defined by the phosphorus and nitrogen donor groups. The iron-bound phosphane ligands lie on opposite sides of the metallacycle plane of the four metal atoms. The inversion center present in the structure of **9** demonstrates the metallacycle's high symmetry. Figure 8 illustrates the channels formed by the packing of complex **9** in the solid state, which

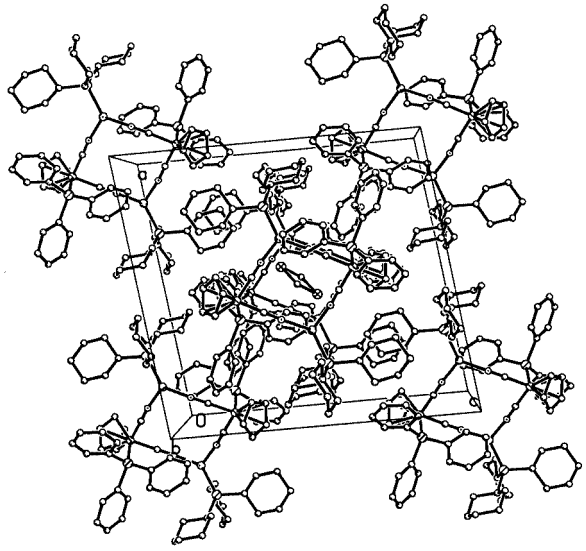

Figure 8. Crystal packing diagram of $[CpFe(PPh_3)(\mu\text{-}CN)_2CuPCy_3]_2$ (**9**), where the dichloromethane molecule is disordered

results in the inclusion of dichloromethane solvent molecules.

Utilization of two anionic $CpFe(CN)_2$ units bridged by diphosphanes containing three or four methylene linkers should afford particularly stable metallacycle derivatives with a second metal center as a result of the chelate effect. In a similar manner to the procedure employed in the synthesis of complex **9**, the iron cyanide salts (complexes **5** and **6**) were treated with $Cu(CH_3CN)_4(BF_4)$ in the presence of 2 equiv. of Cy_3P. The resulting mixed-metal cyanides **11** (dppp) and **12** (dppb) are soluble in dichloromethane, and as expected for bridging CN ligands, exhibit ν(CN) vibrational modes shifted to higher frequencies compared to the parent salts (see Table 1 and Table 3). The ^{31}P NMR spectra of both **11** and **12** display two broadened PCy_3 peaks indicative of two different phosphorus environments, with a single sharp signal for the iron-bound phosphorus atoms. The broadened phosphorus resonances for the PCy_3 ligands bound to Cu^I result from quadrupolar broadening i.e., for ^{63}Cu and ^{65}Cu, $I = 3/2$. Hence, spectroscopic data (IR and ^{13}P NMR) suggest the derivatives have similar structures.

Single crystals of **11** were grown by slow concentration of a concentrated hexanes solution of **11** over several days at ambient temperature, and were subjected to X-ray diffraction analysis. A thermal ellipsoid representation of complex **11** is shown in Figure 9, with selected bond lengths and angles given in Table 4. The crystal structure of **11** shows the familiar diamond-shaped motif with the bound phosphanes bridging the iron(II) centers. This phosphane-bridged form of the mixed-metal dimer forces both iron-bound phosphane ligands to be positioned on the same face

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

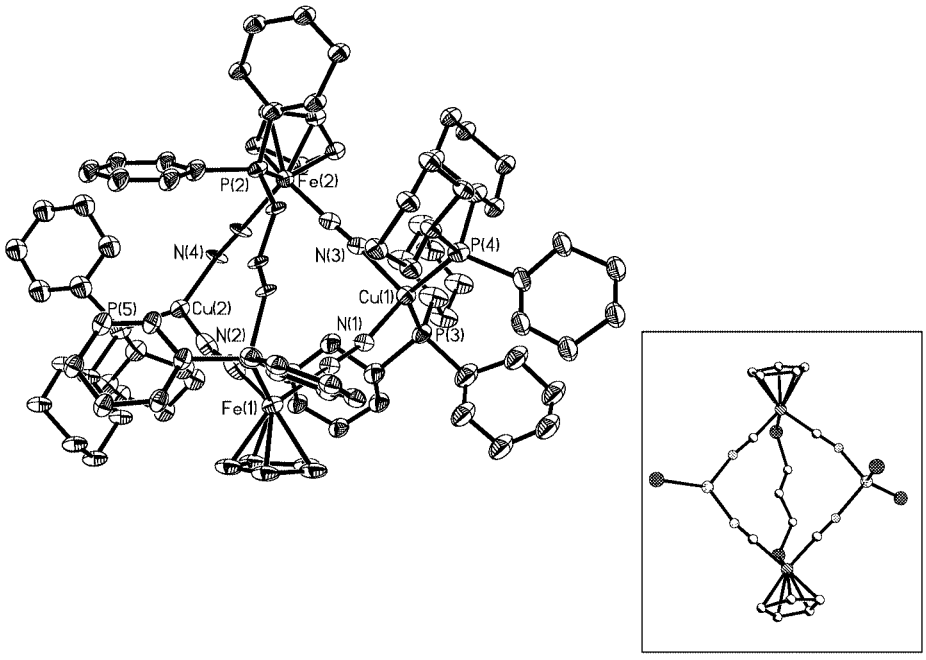

Figure 9. Thermal ellipsoid representation (drawn with 30% probability) of $Cu(PCy_3)[CpFe(\mu\text{-}CN)_2]_2Cu(PCy_3)_2$-μ-dppp (**11**); insert illustrates a ball-and-stick drawing of **11** where the substituents on the phosphane ligands are removed for clarity

of the metallacycle, with the two Fe−P distances being statistically equivalent at 2.174(6) and 2.177(7) Å. Interestingly, the basket shaped complex **11** crystallized with two PCy_3 ligands bonded to one Cu^I center, and one PCy_3 ligand attached to the other Cu^I center. This results in tetrahedral and trigonal-planar coordination geometries for the two copper centers, respectively. In addition to the differences in coordination geometries, the CN−Cu distances are shorter for Cu(2) as compared with Cu(1), i.e., the average CN−Cu(2) distance is 1.925(17) Å vs. the average CN−Cu(1) distance of 2.024(18) Å. This can be explained based on the higher Lewis acidity of Cu(2) resulting from fewer electron-donating PCy_3 ligands occupying its coordination sphere. The same effect is noted in the shorter Cu(2)−P(5) bond of 2.206(8) Å, as compared to the average Cu(1)−P bond length of 2.306(7)Å.

Unlike the $[Fe_2(CN)_4Cu_2]$ derivative containing a monodentate phosphane ligand bound to iron(II), as in complex **9**, complex **11** possesses *no* void channels for encompassing solvent molecules. This is best illustrated in their respective space-filling models depicted in Figure 10.

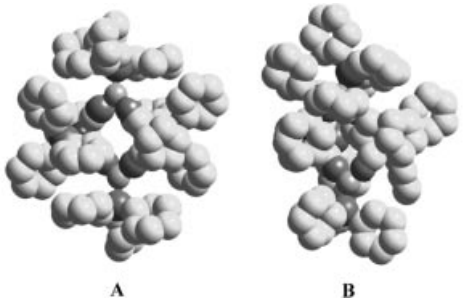

Figure 10. Space-filling model of: (A) $[CpFe(PPh_3)(\mu\text{-}CN)_2Cu(PCy_3)]_2$ (**9**) and (B) $Cu(PCy_3)[CpFe(\mu\text{-}CN)_2]_2Cu(PCy_3)_2$-μ-dppp (**11**)

Concluding Remarks

In summary, we have reported the syntheses and structures of several phosphane-substituted $CpFe(CN)_2$ salts obtained by photochemical decarbonylation of $KCpFe(CN)_2CO$ in methanol. The anions of these salts, which offer the opportunity for variation in steric and electronic modifications, were shown to serve as uninegative bridging ligands towards copper(I) centers. Unique among these derivatives was the preparation and characterization of the diphosphane-bridged iron species, $CpFe(CN)_2PPh_2-(CH_2)_n-PPh_2Fe(CN)_2Cp^{2-}$ ($n = 2-4$). These latter anions were shown to act as pincers to encapsulate (phosphane)copper(I) complexes, thereby leading to very stable diamond-shaped, two-dimensional $[Fe_2(CN)_4Cu_2]$, mixed-metal derivatives. These bridged (phosphane)metal anions may also serve to bind a variety of $M^{II}X^+$ or $M^{III}X_2^+$ ions in an analogous manner.[17]

Experimental Section

Methods and Materials: All manipulations were carried out using standard Schlenk techniques under argon unless otherwise stated. THF and hexane were dried by refluxing in the presence of sodium/benzophenone and distillation prior to use. Methanol was dried by distillation from magnesium turnings and iodine. Acetonitrile was dried by successive distillation from CaH_2 and P_2O_5. 1-Propanol was dried with molecular sieves and degassed by argon purge prior to use. All phosphanes were purchased from Strem Chemicals, ex-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cept for triphenylphosphane, which was purchased from Aldrich. Copper(I) oxide and nitrosyl tetrafluoroborate were obtained from Aldrich and Lancaster, respectively. $KCpFe(CN)_2(CO)$ was prepared by applying published procedures.[13,18] Unless otherwise stated, all photolysis reactions were performed using a mercury-arc 450-W UV immersion lamp purchased from Hanovia. The 200-mL water-cooled photolysis vessel was purchased from Ace Glass. CpFe(dppe)CN was synthesized according to the procedure described by Vahrenkamp and co-workers.[5] Copper tetrafluoroborate was prepared as described previously.[19]

Physical Measurements: All vibrational studies were carried out with a Mattson 6021 FTIR spectrometer, using a 0.1-mm CaF_2 sealed cell. ^1H and ^{31}P NMR were recorded with a 300-MHz Varian Unity Plus spectrometer (121.4 MHz, ^{31}P), with methanol as the solvent unless otherwise stated. Deuterated water was used as the lock solvent, and all spectra were referenced to an 85% phosphoric acid solution.

Synthesis of $KCpFe(CN)_2(PPh_3)$ (1): 100 mL of a 1:1 mixture of acetonitrile/methanol was added to $KCpFe(CN)_2(CO)$ (4.2 mmol, 1.0 g) and PPh_3 (4.2 mmol, 1.1 g) in a photolysis vessel. An argon purge was bubbled through the reaction slurry and the mixture was photolyzed for 2 h while monitoring the infrared spectra in the ν(CN) region at 30-min intervals to ensure complete replacement of CO. The crude orange product precipitated from the solution and the solvent was removed under vacuum. The isolated product was dissolved in 1-propanol and filtered through a frit containing Celite. The solvent was once again removed under vacuum, and the solid washed with pentane to give **1** in 88% yield (1.7 g). Single crystals of **1** were obtained by slow concentration of a methanol solution of **1** at room temperature over several days. $C_{25}H_{20}FeKN_2P{\cdot}CH_3CN$ (515.3): calcd. C 62.92, H 4.50, N 8.15; found C 62.54, H 4.67, N 8.03.

Synthesis of $KCpFe(CN)_2(PPh_2Me)$ (2): 100 mL of methanol was added to $KCpFe(CN)_2(CO)$ (1.0 mmol, 0.25 g) and PPh_2Me (1.0 mmol, 0.21 g) in a photolysis vessel and the solution was photolyzed with IR monitoring as described for the preparation of **1**. The reaction solution was concentrated to dryness under vacuum to yield an orange powder. The solid product was washed repeatedly with hexane and dried to provide **2** in a 70% yield (0.31 g). $C_{20}H_{18}FeKN_2P{\cdot}CH_3OH$ (444.3): calcd. C 56.77, H 4.99, N 6.30; found C 55.97, H 5.08, N 6.52.

Synthesis of $CpFe(CN)(PPh_2Me)_2$ (3): Photolysis of $KCpFe(CN)_2CO$ (1.8 mmol, 0.45 g) and PPh_2Me (7.4 mmol, 1.5 g) in 100 mL of methanol was carried out in a photolysis vessel under argon. Upon reaction completion, ca. 30 min as revealed by infrared spectroscopy in the ν(CO) region, the solution was concentrated to dryness under vacuum and the product was dissolved in hexane. The solution was filtered through a glass frit containing Celite to remove any remaining impurities and the product, complex **3**, was isolated upon removing the solvent under vacuum in a yield of 56% (0.52 g). Single crystals of **3** were grown by slow concentration of a hexane solution at ambient temperature. $C_{32}H_{31}FeNP$ (516.4): calcd. C 70.21, H 5.71; found C 69.92, H 5.86.

Synthesis of $[KCpFe(CN)_2]_2$-μ-$[Ph_2P-(CH_2)_n-PPh_2]$ [n = 2 (4), n = 3 (5), n = 4 (6), C≡C instead $(CH_2)_n$ (7)]: These four derivatives were prepared in a similar manner by photolysis of $KCpFe(CN)_2CO$ and the diphosphanes in a 1:1 mixture of acetonitrile/methanol over a 60-min reaction period in a photolysis vessel. After the photolysis, the reaction solution was concentrated to dryness under vacuum to produce an orange solid product. The crude product was dissolved in 1-propanol and filtered through a frit containing Celite. Subsequent to removal of solvent, the product was washed repeatedly with hexane and dried under vacuum. Specifics of reactions: $KCpFe(CN)_2CO$ (4.2 mmol, 1.0 g) and dppe (1.0 mmol, 0.40 g) provided **4** in an 85% yield (0.70 g). X-ray quality crystals were grown by slow concentration of a solution of **4** in methanol at ambient temperature over several weeks. $C_{40}H_{34}Fe_2K_2N_4P_2{\cdot}6CH_3OH$ (1014.5): calcd. C 54.44, H 5.76; found C 55.01, H 5.52. $KCpFe(CN)_2CO$ (4.6 mmol, 1.1 g) and dppp (1.6 mmol, 0.64 g) provided **5** in an 81% yield (1.08 g). Single crystals of **5** were grown as described for compound **4**. $C_{41}H_{36}Fe_2K_2N_4P_2{\cdot}6CH_3OH$ (1028.5): calcd. C 54.87, H 5.88, N 5.45; found C 55.10, H 5.55, N 5.70. $KCpFe(CN)_2(CO)$ (1.6 mmol, 0.40 g) and dppb (0.70 mmol, 0.30 g)provided **6** in a 61% yield (0.36 g). Single crystals of **6** were grown by vapor diffusion of hexane into a THF solution of **6** maintained at 10° for approximately one week. $C_{42}H_{38}Fe_2K_2N_4P_2{\cdot}2THF{\cdot}2H_2O{\cdot}CH_3OH$ (1062.6): calcd. C 58.51, H 5.97; found C 58.97, H 5.62. $KCpFe(CN)_2CO$ (3.1 mmol, 0.75 g) and dppa (1.0 mmol, 0.41 g) provided **7** in an 82% yield (0.67 g).

Synthesis of $[CpFe(PPh_3)(\mu\text{-}CN)_2Cu(CH_3CN)_2]_2$ (8): A solution of $Cu(CH_3CN)_4(BF_4)$ (0.08 g, 0.25 mmol) in 15 mL of CH_3CN was transferred via cannula to a Schlenk flask containing $KCpFe(CN)_2PPh_3$ (0.12 g, 0.25 mmol) in 10 mL of CH_3CN. The reaction mixture was stirred at ambient temperature for 1 h to afford a yellow precipitate. Upon removal of the solvent under vacuum a fine yellow powder was isolated. Among common organic solvents, only pyridine was found to solubilize the yellow solid product.

Synthesis of $[CpFe(PPh_3)(\mu\text{-}CN)_2Cu(PCy_3)]_2$ (9): $Cu(CH_3CN)_4(BF_4)$ (0.06 g, 0.19 mmol) in 15 mL of CH_3CN was transferred via cannula to a Schlenk flask containing 0.054 g (0.19 mmol) of PCy_3 in 10 mL of CH_3CN, and the solution was stirred at ambient temperature for 1 h prior to adding 0.091 g (0.19 mmol) of $KCpFe(CN)_2PPh_3$ in CH_3CN. The reaction mixture was stirred for an additional hour during which time a turbid yellow solution was observed. The solvent was removed under vacuum and the product was redissolved in dichloromethane, leaving behind a white precipitate of KBF_4 which was removed by filtration through a frit containing Celite. Evaporation of the solvent from the filtrate yielded a fine yellow powder in a yield of 62% (0.092 g). Single crystals of **9** were grown by vapor diffusion of CH_2Cl_2/hexane at 10 °C over a period of one week. $C_{86}H_{106}Cu_2Fe_2N_4P_4{\cdot}CH_2Cl_2$ (1651.1): calcd. C 63.58, H 6.62, N 3.41; found C 62.98, H 6.54, N 3.29.

Synthesis of $[CpFe(\mu\text{-}CN)_2Cu(CH_3CN)_2]_2$-μ-dppp (10): A solution of 0.1 g (0.32 mmol) of $Cu(CH_3CN)_4(BF_4)$ in 15 mL of CH_3CN was transferred via a cannula to a flask containing 0.133 g (0.16 mmol) of $[KCpFe(CN)_2]_2$-μ-dppp in 10 mL of CH_3CN. The solution was stirred at room temperature for 1.5 h to yield a yellow precipitate. The solvent was evaporated under vacuum to give a fine yellow powder. Among common organic solvents, only pyridine was found to solubilize the precipitate.

Synthesis of $Cu(PCy_3)[CpFe(\mu\text{-}CN)_2]_2Cu(PCy_3)_2$-μ-dppp (11): $Cu(CH_3CN)_4(BF_4)$ (0.03 g, 0.1 mmol) in acetonitrile (15 mL) was added via cannula to a Schlenk flask containing PCy_3 (0.054 g, 0.2 mmol). The solution was stirred at room temperature for 1 h. The mixture was transferred via cannula to a second flask containing $[KCpFe(CN)_2]_2$-μ-dppp (0.04 g, 0.05 mmol) in CH_3CN (10 mL), and the reaction mixture was stirred at room temperature for 1.5 h to afford a turbid yellow solution. The solvent was removed under vacuum and the product dissolved in dichlorometh-

ane. The salt by-product was removed by filtration through Celite, and the solvent evaporated to give a yellow powder of **11** in a yield of 54% (0.050 g). Crystals suitable for X-ray diffraction studies were obtained from hexanes by slow concentration at ambient temperature over several days. $C_{105}H_{159}Cu_2Fe_2N_4P_5$ (1871.2): calcd. C 67.40, H 8.57, N 2.99; found C 66.92, H 8.43, N 3.05.

Synthesis of $Cu(PCy_3)[CpFe(\mu\text{-}CN)_2]_2Cu(PCy_3)_2$-μ-dppb (12): $Cu(CH_3CN)_4(BF_4)$ (0.022 g, 0.07 mmol) in 15 mL of CH_3CN was transferred via cannula to a Schlenk flask containing PCy_3 (0.04 g, 0.14 mmol) in 10 mL of CH_3CN. The reaction mixture was stirred at room temperature for 1 h and transferred to a second flask containing 0.03 g (0.035 mmol) of $[KCpFe(CN)_2]_2$-μ-dppb in 10 mL of CH_3CN. The solution was stirred for 1.5 h to give a turbid yellow solution. Upon removal of the CH_3CN solvent under vacuum, the product was redissolved in dichloromethane and filtered through Celite to remove KBF_4. A yellow product of **12** was obtained in a yield of 39% (0.026 g) following the evaporation of solvent and was recrystallized from hexanes by slow concentration at ambient temperature. $C_{106}H_{161}Cu_2Fe_2N_4P_5$ (1885.2): calcd. C 67.54, H 8.61; found C 68.05, H 8.48.

X-ray Crystallography: Orange single crystals of compounds **1**, **3**, **4**, **6**, and CpFe(CN)(dppe), and yellow crystals of **9** and **11** were coated with paratone and mounted on a glass fiber using apiezon grease at ambient temperature. The crystals were placed on a Bruker SMART 1000 diffractometer equipped with a CCD detector. The crystals were placed in a nitrogen cold stream maintained at 110 K. More than a hemisphere of data was collected on each crystal over three batches of exposures using Mo-K_α radiation (λ = 0.71073 Å). A fourth set of data was measured and compared to the initial set to monitor and correct for decay, which was negligible in all cases. Details of crystal data for all compounds examined are found in Table 5. Systematic absences and intensity statistics were used in space-group determination. All structures were solved by direct methods. Anisotropic structure refinements were achieved using full-matrix least-squares techniques on all non-hydrogen atoms. All hydrogen atoms were placed in idealized positions based on hybridization, with isotropic thermal parameters fixed at 1.2 or 1.5 times the value of the attached atom. All atom scattering factors were obtained from the *International Tables for X-ray Crystallography*, vol. C. For all compounds, data collection and cell refinement, SMART;[20] data reduction, SAINTPLUS (Bruker[21]); programs used to solve structures, SHELXS-86 (Sheldrick[22]); programs used to refine structures, SHELXL-97 (Sheldrick[23]); molecular graphics and to prepare material for publication, SHLXTL-Plus version 5.0 (Bruker[24]). CCDC-211280 (**1**), -211281 (**3**), -211282 (**4**), -211283 (**6**), -211284 (**9**), -211285 (**11**) and -213786 [CpFe(CN)dppe] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Self-Organization of Dipolar 4,4′-Disubstituted 2,2′-Bipyridine Metal Complexes into Luminescent Lamellar Liquid Crystals

Daniela Pucci,*[a] Giovanna Barberio,[a] Alessandra Crispini,[a] Oriano Francescangeli,[b] Mauro Ghedini,[a] and Massimo La Deda[a]

Keywords: N ligands / Platinum / Zinc / Nickel / Metallomesogens

Mononuclear *cis*-dichloro complexes, [L^nMCl_2], with different metal centres (Pt^{II}, Ni^{II}, and Zn^{II}) and a series of palladium and platinum derivatives, [L^2MX_2], in which chloride groups are replaced with iodide, bromide, and azide ligands, have been synthesized from 4,4′-disubstituted-2,2′-bipyridines. Upon complexation of these non-mesogenic ligands, the peculiar structural arrangement, characterized by intermolecular associations of the new derivatives, induces mesomorphism in most [L^2MX_2] complexes, confirming the importance of coordination chemistry in metal-mediated formation of liquid crystals. Single crystal X-ray structures have been determined for dihexadecyl 2,2′-bipyridyl-4,4′-dicarboxylatopalladium and -zinc dichloride derivatives. Both the metal centres and the ancillary ligands have been varied to use dipole coupling as a tool to control molecular architecture: thermal, as well as spectroscopic properties, depend strongly upon molecular dipolar interactions. Tunable red and blue emitters based on Pd^{II} and Pt^{II}, both in solution and in the solid state, have been obtained.

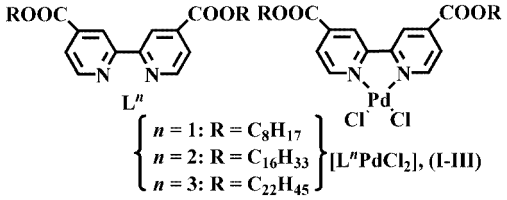
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

"Unconventional" metallomesogens form a new class of liquid crystals that exhibit novel structural and physical properties and numerous strategies have recently been developed for their design. Coordination chemistry has received increasing attention as a metal ion can induce mesomorphism in non-mesomorphic ligands.[1,2]

This phenomenon can be achieved through changes of molecular conformation, shape and structure induced both by complexation[3−6] and association phenomena of different natures, giving rise to supramolecular assemblies.[7−9] We are particularly interested in the so-called complementary shape approach, which is usually adopted to promote columnar mesophases, and we have looked at obtaining novel superstructures in calamitic mesophases by utilising attractive dimeric associations of small molecules with a large central dipole moment. 2,2′-Bipyridines are very attractive ligands because of their extensive coordination chemistry and their versatility: their spectroscopic and chemical properties can be tuned by the choice of metal centre and substituents.[10−14]

We recently reported the synthesis of a new family of non-mesomorphic dialkyl-2,2′-bipyridine-4,4′-dicarboxylates, L^n; the induction of a dipole moment, upon coordination with a $PdCl_2$ moiety, resulted in self-assembling dimers of metallomesogenic [L^nPdCl_2] species **I**−**III**, confirming the role of coordination chemistry in the metal-mediated formation of liquid crystals.[15]



Here we report the crystal structure characterization of the [L^2PdCl_2] (**II**) derivative. The head-to-tail arrangement of the single molecules of this class of complexes is confirmed and the packing and Pd···Pd intermolecular separation within the dimer and between dimers is discussed.

Liquid crystal displays (LCDs), which currently dominate flat panel technology, have severe limitations in brightness and energy efficiency due to the use of absorbing polarizers and color filters which convert a major amount (more than 80%) of the incident light into thermal energy.[16] Photoluminescent materials that act as "active" color filters and, therefore, might enhance the visual performance of LCDs.[17] Although luminescent platinum(II) complexes have attracted much attention recently as possible sen-

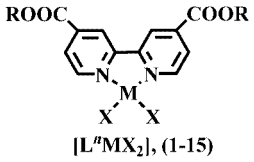
sors,[18] photochemical and electroluminescent devices,[19] there are few examples of emitters based on Pd^{II}.[20] Therefore, absorption and fluorescence measurements, in solution and in the condensed state, have been performed on the L^n ligands and the corresponding **I**−**III** palladium complexes. Moreover, to study systematically the effect of structural changes on the dipole moments, intermolecular stacking interactions and supramolecular arrangements, two new classes of the dialkyl 2,2′-bipyridine-4,4′-dicarboxylates metal derivatives have been prepared (**1**−**15**). This paper reports the synthesis and thermal and spectroscopic characterization of a family of *cis*-dichloro complexes $[L^nMCl_2]$ where M is Pt^{II}, Ni^{II}, and Zn^{II}. The crystal structure determination of $[L^2ZnCl_2]$ is also reported. In addition, a series of dihexadecyl 2,2′-bipyridyl-4,4′-dicarboxylate palladium and platinum derivatives $[L^2MX_2]$, in which the chlorine groups are replaced with iodide, bromide, and azide ligands, have also been prepared. Several novel complexes with potential applications as blue and red metallomesogens emitters have been obtained and the correlations between the self-assembling properties of these complexes and their photophysical properties are discussed.



$[L^nMX_2]$, (1-15)

Results and Discussion

Single-Crystal X-ray Diffraction for $[L^2PdCl_2]$ (II·2CHCl$_3$) and $[L^2ZnCl_2]$ (8) Complexes

The structure of **II**·2CHCl$_3$ is shown in Figure 1 and the bond lengths and angles are listed in Table 1.

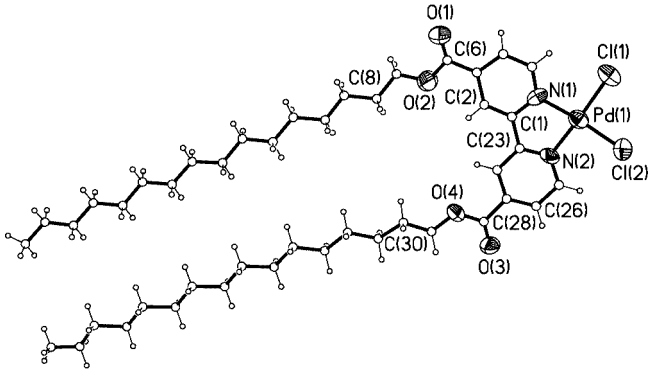


Figure 1. Molecular structure and atomic labeling scheme (50% probability thermal ellipsoids) of complex **II**·2CHCl$_3$

There are two cocrystallized chloroform molecules per complex molecule in the asymmetric unit. The Pd atom has a distorted square-planar geometry with a bite angle N(1)−Pd−N(2) of 81.6(4)°. The bond lengths and angles within the five-membered chelate ring agree well with those reported for other dichlorine palladium(II) species and various substituted 2,2′-bipyridine complexes.[21]

Table 1. Selected bond lengths [Å] and angles [°] for complex **II**·2CHCl$_3$

Pd(1)−N(1)	2.016(10)	Pd(1)−N(2)	2.041(10)
Pd(1)−Cl(1)	2.291(4)	Pd(1)−Cl(2)	2.281(4)
N(1)−Pd(1)−N(2)	81.6(4)	Cl(1)−Pd(1)−Cl(2)	90.7(2)
N(1)−Pd(1)−Cl(1)	95.3(4)	N(1)−Pd(1)−Cl(2)	86.4(2)
N(2)−Pd(1)−Cl(1)	176.8(4)	N(2)−Pd(1)−Cl(2)	92.4(4)

The five-membered chelate ring is essentially planar with a maximum deviation from planarity of 0.03(1) Å [C(1)]. The carboxylic oxygen atoms O(1) and O(3) of the dihexadecyl 2,2′-bipyridine-4,4′-dicarboxylate ligands point in opposite directions, with torsion angles C(2)−C(3)−C(6)−O(1) and C(24)−C(25)−C(28)−O(3) of 165 and 168°, respectively. Hence, the two carboxylic hydrocarbon chains are straight and parallel, and they both have a regular *anti* conformation, with mean torsion angles of 177(2) and 178(2)°, respectively.

The shortest Pd···Pd intermolecular separation of 3.487(2) Å was found between centrosymmetrically related molecules arranged in a head-to-tail fashion, which was approximately superimposed along the *a* axis (Figure 2, a).

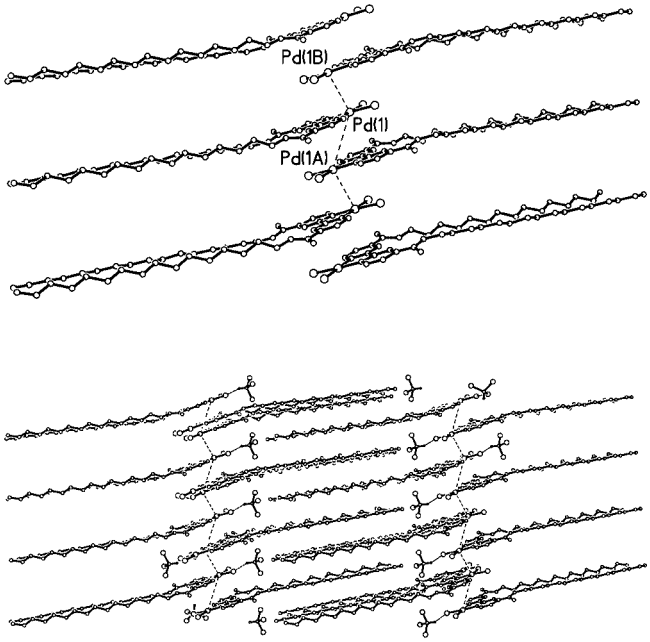

Figure 2. Ball and stick representation of the crystal packing of complex **II**·2CHCl$_3$ (b), viewed along the *b*-axis. Separate view (a) shows the alternating short and long Pd···Pd intermolecular contacts

This distance is similar to a polymorph of the (2,2′-bipyridine)dichloropalladium(II) complex (3.46 Å)[22] and is shorter than other similar complexes containing substituted 2,2′-bipyridine (found in the Cambridge Structural Database, CSD). Within the dimer the Pd···Pd vector deviates slightly from orthogonality to the coordination plane (9° angle with the plane normal), suggesting a very weak at-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tractive character for the Pd···Pd interaction. The coordinated portions of the bipyridine ligands are oriented in opposing directions and thus no significant aromatic π−π stacking within the dimer was observed. In fact, the pyridine rings have interplanar and centroid-centroid distances of 3.44 and 5.91 Å, respectively, and interplanar and displacement angles of 0.4 and 126°, respectively, and a horizontal slip of 4.81 Å.

A second rather longer Pd···Pd separation of 4.778 Å was found between the dimers. The Pd···Pd contacts alternate along a zig-zag chain with an off-set of 1.78 Å [Pd(a)−Pd−Pd(b) 127.5(2)°]. The 3D-space complex **II**·2$CHCl_3$ gives rise to a layered structure (Figure 2, b), where the planar cores (representing the polar, or at least polarizable, part of the molecule), superimposed along one direction, alternate with non-polar chains, confined to a non-polar region. The degree of interdigitation within the paraffinic sublayer is not as high as expected from the segregation effects of the alkyl chains, due to the chloroform molecules that fill the holes between the two sublayers. The resultant calculated interlayer spacing is 31.9 Å.

The overall structure of the analogous complex containing Zn^{II}, **8**, is completely different from the palladium one (Figure 3). As with [Zn(bipy)Cl_2][23] and [Zn(phen)Cl_2],[24] complex **8** is tetrahedral. Bond lengths and angles are listed in Table 2. The neutral complex has a C_2 symmetry axis passing through the zinc ion and the midpoint of the bipyridine ligand.

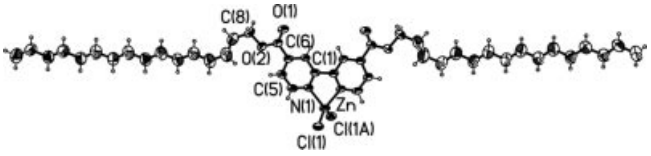

Figure 3. Molecular structure and atomic labeling scheme (50% probability thermal ellipsoids) of complex **8**

Table 2. Selected bond lengths [Å] and angles [°] for complex **8**

Zn−N(1)	2.064(3)	Zn−Cl(1)	2.211(1)
N(1)−Zn−N(1a)	79.5(2)	Cl(1)−Zn−Cl(1a)	123.1(1)
N(1)−Zn−Cl(1)	111.7(1)	N(1a)−Zn−Cl(1)	111.2(1)

The bond lengths and angles are similar to those for [Zn(bipy)Cl_2][23] and other Zn^{II} substituted 2,2′-bipyridine derivatives,[25] and [Zn(phen)Cl_2].[24] Because the zinc is tetrahedral, the $ZnCl_2$ moiety is not coplanar with the mean plane passing through the five-membered chelate ring. The dihedral angles Cl(1)−Zn−N(1)−C(1) and Cl(1a)−Zn−N(1)−C(1) are 107.9(3) and −110.3(3)°, respectively. The two carboxylic oxygen atoms O(1) and O(1a) point towards the internal part of the bipyridine ligand [torsion angle C(2)−C(3)−C(6)−O(1) 6.5(7)°].

Moreover, since O(2)−C(6)−C(7)−C(8) and C(8)−C(9)−C(10)−C(11) torsion angles are in a *gauche* conformation [54.6(7) and −85.2(8)°, respectively), the two carboxylic hydrocarbon chains run in opposite directions.

The dihedral geometry of the zinc ion prevented the formation of dimers in the crystal packing, as observed in the analogous complex **II**, and favour strong intermolecular contacts involving the bipyridine hydrogen atoms that are *ortho* and *meta* with respect to the $ZnCl_2$ moiety.

In fact, while H(4) participates in H···Cl contacts that are shorter than the sum of the van der Waals radii of hydrogen and chlorine atoms [Cl(1)···H(4b) = 2.863(1) Å, C(4b)−H(4b)···Cl(1) = 143.5(3)°, C(4b)···Cl(1) = 3.668(5) Å, b = x, 1 − y, z − 1/2), H(5) showed an hydrogen bond interaction with the carboxylic oxygen atom O(1) [O(1)···H(5c) = 2.424(3) Å, C(5c)−H(5c)···Cl(1) = 158.6(3)°, C(5c)···O(1) = 3.307(5) Å, c = x, 1 + y, z) (Figure 4, a).

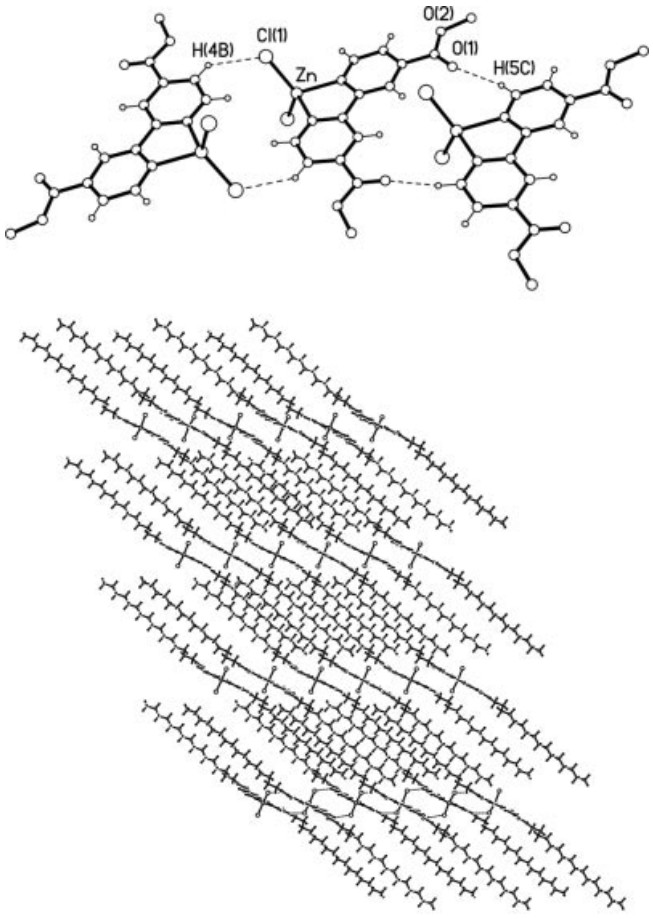

Figure 4. Ball and stick representation of the crystal packing of complex **8** (b), viewed along the *b* axis. Separate view (a) shows the C−H···X (X = Cl, O) intermolecular contacts within the *ac* plane

The crystal packing of **8** is characterized by a layered structure with a calculated interlayer spacing of 19.8 Å (Figure 4, b). Each carboxylic chain of a molecule of **8** is part of each paraffinic sub-layer, in which the segregation effects of the alkyl chains cause a high degree of interdigitation. The long molecular axis is tilted with respect to the layer normal by 56°.

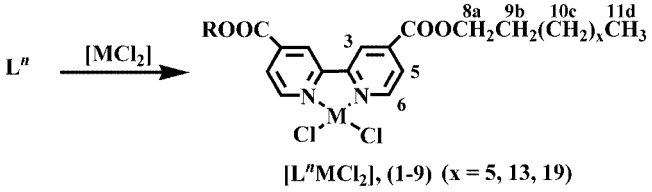
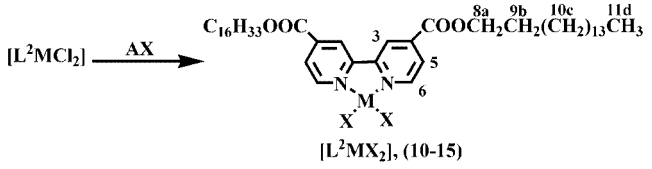
Synthesis

The [L^nMCl_2] complexes **1**−**9** were prepared by the reaction of an equimolar amount of the appropriate L^n ligands with [$Pt(PhCN)_2Cl_2$] (in toluene, under reflux), $NiCl_2$ (in ethanol, under reflux) or $ZnCl_2$ (in dichloromethane, at room temperature) (Scheme 1).



Scheme 1. Synthetic route to [L^nMCl_2] complexes **1**−**9** and related proton numbering scheme. *Reagents and conditions*: *i)* [MCl_2] = [$Pt(PhCN)_2Cl_2$], toluene, ΔT; *ii)* [MCl_2] = $NiCl_2$, ethanol, ΔT; *iii)* [MCl_2] = $ZnCl_2$, dichloromethane, room temp.

The dihexadecyl 2,2′-bipyridyl-4,4′-dicarboxylate palladium and platinum *cis*-dichloro complexes were transformed into the corresponding [L^2MX_2] derivatives by metathetical reactions with potassium iodide (**10**, **11**), potassium bromide (**12**, **13**), and sodium azide (**14**, **15**) (Scheme 2).



Scheme 2. Synthetic route to [L^2MX_2] complexes **10**−**15** and related proton numbering scheme. *Reagents and conditions*: *i)* AX = KI, acetone, room temp.; *ii)* AX = KBr, DMF, room temp.; *iii)* AX = NaN_3, acetone, room temp.

The structure and purity of all the compounds were confirmed using elemental analyses, IR and ^1H NMR spectroscopy, as reported in the Exp. Sect. For all of the investigated complexes, IR spectra showed ν(COO) absorptions for the carbonyls groups at higher wavenumbers (ca. 20 cm^{-1}) than for the free ligands. Moreover, the azide compounds **14** and **15** showed a strong band at 2043 and 2063 cm^{-1} respectively, due to the asymmetric N_3 stretching vibration, suggesting coordination of the ligand to the metal centre.[26] In the ^1H NMR spectra of the platinum and zinc [L^nMCl_2] complexes the resonance attributable to the $H^{6,6'}$ protons is low-field shifted by about 1 ppm with respect to the organic precursors. These observations confirm the coordination of bipyridines to the metal fragment. In the ^1H NMR spectra of the Ni^{II} complexes the signals are very broad, confirming the assumed distorted square-planar structure induced by the 4,4′ substituents of the bipyridine ligand. The few examples of crystal structures of dihalo disubstituted Ni^{II} complexes show a strong substituent effect on the geometry around the metal ion, with the promotion of distorted square-planar coordinations.[27−29]

Upon exposure to air, **4** and **5** are not stable as solids but gradually adsorbed water, as evidenced by the change from pale green to deep green, IR spectroscopy and elemental analysis.

The ^1H NMR resonance frequencies of the $H^{6,6'}$ protons of the palladium and platinum [L^2MX_2] complexes are very sensitive to the nature of the metal-bonded ancillary groups. This electronic effect of the ligand is seen for **10**−**13** where the $H^{6,6'}$ signal progressively moved downfield (Δδ of ca. 0.3 and 0.6 ppm for the bromo and iodo derivatives, respectively) as the electron-withdrawing power of the X-bridging ligand decreases. For complexes **14** and **15** the $H^{6,6'}$ proton resonances shifted upfield by ca. 0.7 ppm with respect to the homologous signals of the corresponding chloro precursors, as observed in related azido complexes of diimines.[14]

Liquid Crystalline Properties

[L^nMCl_2] Complexes

Although free 2,2′-bipyridine-4,4′-dicarboxylates (L^n) are not liquid crystals, most of their metal complexes [L^nMCl_2] show mesomorphism (investigated by polarized optical microscope and XRD); the phase diagram is shown in Figure 5. Thermal data, obtained using differential scanning calorimetry (DSC), are summarized in Table 3.

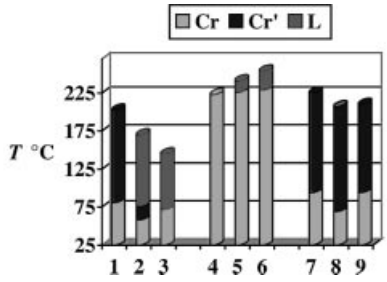


Figure 5. Bar graph showing the mesomorphic behaviour of [L^nMCl_2] (**1**−**9**) complexes

The *cis*-dichloro complexes with the shortest tail (R = C_8H_{16}) melted directly into an isotropic liquid at temperatures higher than for the corresponding free ligand, irrespective of the metal atoms.

The higher homologues of platinum, **2** and **3**, showed a mesophase with a mosaic-like texture (Figure 6), as observed in analogous palladium derivatives.[15]

As expected, the melting and clearing points decreased with aliphatic chain length, ranging from 16 to 22 carbon atoms, and, thus, complex **3** showed a more stable mesomorphism.

The X-ray diffraction (XRD) patterns of platinum complexes **2** and **3** in the mesophase were very similar to those of the analogous palladium complexes **II** and **III**.[15] The XRD pattern of **2** exhibits sharp inner reflections and diffuse outer halos that are consistent with a layered structure (Figure 7).

[a] Cr: crystal; L: lamellar; I: isotropic liquid.

Figure 6. Polarized optical micrograph of the mosaic texture for complex **2** at 150 °C.

In fact, the inner reflections consist of a set of *00n* peaks centred at $q = 2\pi n/d$ ($q = 2\pi\sin\theta/\lambda$ is the modulus of the scattering vector, 2θ is the scattering angle), where n is an integer ($n = 1-4$) and $d = 36.7$ Å is the layer spacing. The wide diffuse outer halo centred about $q = 1.3$ Å^{-1} is associated with the short-range liquid-like positional ordering of the hydrocarbon chains. Moreover, two additional peaks appeared, corresponding to $d_1 = 10.5$ Å and $d_2 = 3.4$ Å, which arise from Pt−Pt in-plane correlations along mutually-orthogonal directions which are parallel and orthogonal, respectively, to the long side of the molecular core (i.e. the axis of the benzene rings). This type of XRD pattern is consistent with an ordered smectic phase with one-dimensional ordering of the molecules within the layers as well as a lamello-columnar mesophase without positional correlation between the layers. Because the spacing of the layers in this compound is larger than the calculated molecular length in the fully extended configuration ($L \approx 28$ Å), but smaller than $2L$ ($d/L \approx 1.3$), if we assume that the arrangement is of a smectic type, the molecules are not arranged in single molecular layers but organized in semi-bilayers that are partially interdigitated, giving rise to a bilayered SmA$_d$ phase.[30] Here the semi-bilayer ordering is caused by dipole−dipole interactions and antiparallel correlations of nearest neighbour molecules, characterised by short intermetallic M···M distances (Figure 8).

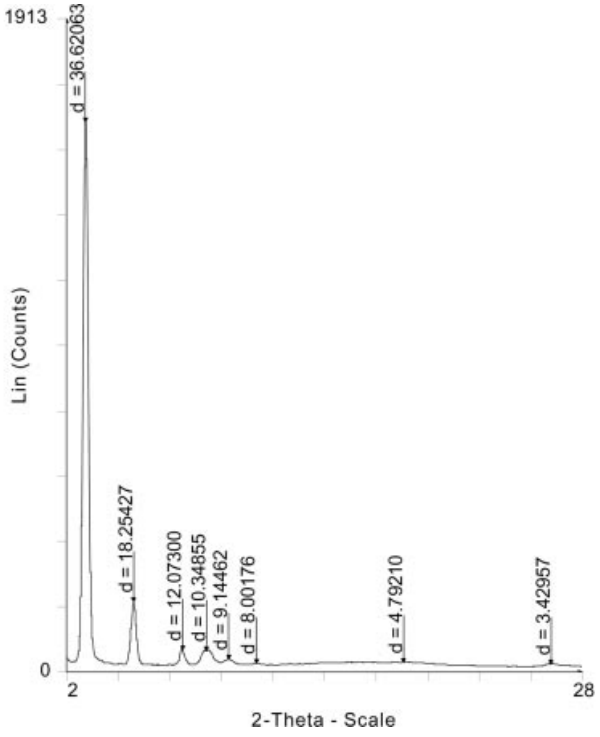

Figure 7. XRD pattern of the smectic phase of complex **2** recorded at $T = 140$ °C

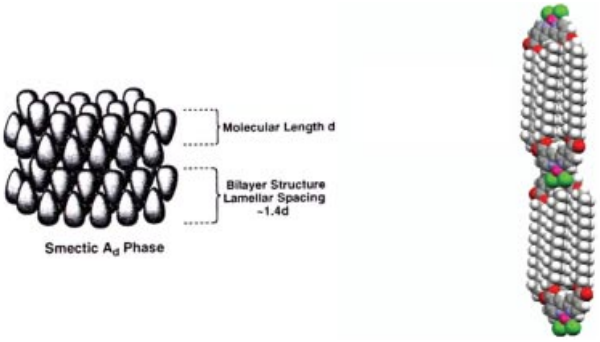

Figure 8. Idealized molecular arrangement for complex **2** in the SmAd phase

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

However, a very similar XRD pattern has been reported for *ortho*-palladated 5,5′-dialkyl-2,2′-bipyridines, where it was concluded that the mesophase, although showing a schlieren texture, was a lamello-columnar phase, with aromatic cores stacked in columns and in close contact with one another to form defined layers.[31]

Therefore, even for our complexes, the lamellar structure in the mesophase could be described as columnar. In this case the flat molecular cores of each molecule would be stacked along the *a* direction to form columns that would be in close contact with one another to form layers. The repetition of these layers (separated by the disordered aliphatic chains) along the *c* direction would give rise to a periodic structure (Figure 9).

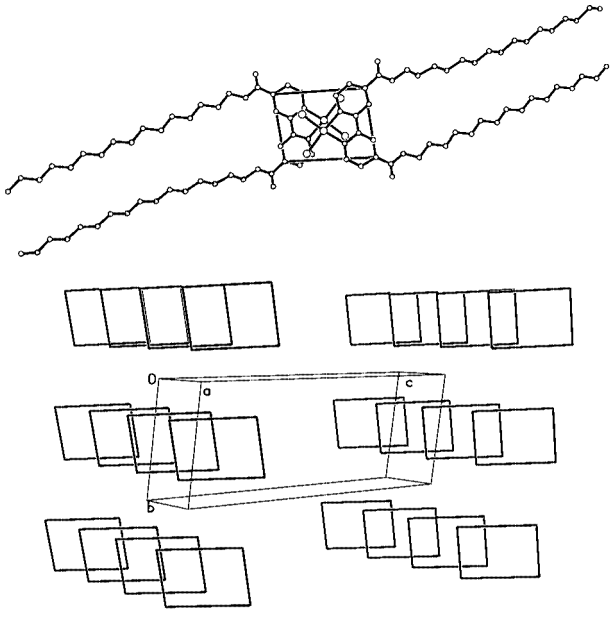

Figure 9. Schematic view of the molecular packing of complex **2** showing the stacking of the aromatic cores

In summary, since the XRD patterns of complexes **2** and **3** agree with both assignments (SmAd or lamello-columnar) and because the literature lacks a typical texture for the SmAd mesophase, while different textures are associated with a lamello-columnar phase,[31−33] we shall refer to this phase as L.

Ni^{II} compounds **5** and **6** showed a layered mesophase whose high transition temperatures prevented a complete identification by optical microscopy and X-ray powdered diffraction. Thermal analysis of Ni^{II} complexes on fresh samples and on samples stored in air for some days confirmed the addition of molecules of water. None of the zinc complexes were mesomorphic: after a crystal-to-crystal transition they melted into the isotropic liquid at temperatures much higher than the corresponding organic precursor. For **8** and **9** the total loss of liquid crystalline properties was ascribed to the tetrahedral coordination, which promoted strong intermolecular interactions in the crystal packing other than the metal−metal ones observed in the square-planar derivatives.

Both melting and clearing points, as expected, depended mostly on the aliphatic chains but were also very sensitive to the metal atom and the core interactions. Comparison of the thermal properties of complexes **1**−**6** with those reported for palladium(II)[15] shows that the melting temperatures, in each series, decreased in the order Pt < Pd < Ni whereas for the clearing points the trend was Pd < Pt < Ni, illustrating that the platinum derivatives have the largest mesomorphic range.

$[L^2MX_2]$ Complexes

All the dihexadecyl 2,2′-bipyridyl-4,4′-dicarboxylate palladium and platinum derivatives $[L^2MX_2]$ displayed enantiotropic liquid crystalline behaviour and were investigated by polarized optical microscope and XRD. The phase diagram is shown in Figure 10. The thermal data of $[L^2MX_2]$ complexes, as measured using DSC, are summarized in Table 4.

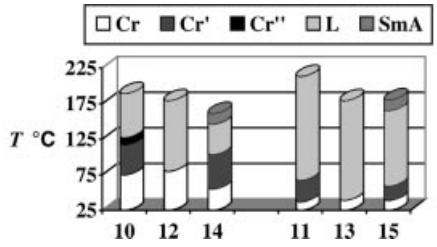

Figure 10. Bar graph showing the mesomorphic behaviour of $[L^2MX_2]$ (**10**−**15**) complexes

The phase sequence is notably dependent on the ancillary ligands overcoming the effect of the different metal atoms, which directly influence the thermal ranges. In particular, the iodo complexes **10** and **11**, after a crystal-to-crystal transition, gave rise to an L phase with the same mosaic texture as the chloro precursors. The thermotropic behaviour of the bromo derivatives **12** and **13** was also characterized as an L phase whose texture is retained, on cooling, in the solid state. The substitution of chloro for bromo atoms did not lead to crystal-to-crystal transitions. The mesomorphic properties were slightly changed when azide groups replaced the chloride ligands. When heated, complexes **14** and **15** gave, in addition to the crystal-to-crystal and the crystal-to-L transitions, an L-SmA transition phase, as confirmed by XRD analysis. For the chloro, iodo, and bromo complexes the layer thickness in the L phase increases with temperature due to an increase in molecular mobility and a progressive decrease in the degree of orientational order. This behaviour was magnified in the azide complexes. Indeed, in the high-temperature SmA phase the peaks corresponding to $d_1 \approx 10.5$ Å disappeared. These results suggest that, in this mesophase, thermal disorder within the layer weakened the intermolecular dipole interactions. In complexes **14** and **15**, on cooling the isotropic liquid, the SmA phase was observed, *via batonnets*, turning into a focal-conic texture and then homeotropic. On further cooling the L phase is restored, with a schlieren texture, which remained until solidification.

[a] Cr: crystal; L: lamellar; Sm: smectic; I: isotropic liquid. [b] Data by optical observation.

For all palladium and platinum complexes **10**−**15** the mesomorphic behaviour depends on the size of X and on the dipole moment associated with the M−X bond, irrespective of the metal atom. Indeed, the mesophase appeared at increasing temperatures in the order Br < I < Cl while the sequence for the clearing points was Cl < Br < I. However, with respect to the halo-compounds, the azide group promoted a lowering of both transition temperatures.

Finally, regardless of the X group, compared to the corresponding palladium compounds, the platinum complexes formed more stable mesophases, exhibiting, on average, much lower melting points and higher clearing temperatures.

Photophysical Studies − Absorption and Emission Spectroscopy

Uncomplexed Bipyridine Ligands

The absorption spectra of L^n ligands, in solution, were unaffected by their chain length, all showing a strong band at 300 nm with a shoulder at about 315 nm, attributed to a spin-allowed π→π* transitions involving the aromatic rings. At longer wavelengths a weakly absorbing tail at about 340 nm was assigned to an n→π* transition, probably involving pyridine nitrogens and ester fragments (Table 5). With respect to the unsubstituted bipyridine, the electron-withdrawing carboxylate groups induced a red-shift of the absorption bands, as determined by the LUMO stabilization.[34] The electronic spectra recorded from microcrystalline samples of L^n were identical to those in solution, indicating the absence of any relevant interactions in the solid state that can modify the energy states.

Table 5. Absorption data; MLCT bands are typed in bold

Compound	Solution (CH_2Cl_2) Abs., λ_{max}/nm (ε/M^{-1}·cm^{-1})	Solid (KBr pellet) Abs., λ_{max}/nm
L^2	300 (6700), 315 (sh), 340 (sh)	300

15	640	0.65	n.o.

[L^2MCl_2] Complexes

Preliminary investigation of the [L^nMCl_2] complexes revealed that the photophysical characteristics remained constant despite variation in the chain length of the ligands. Consequently, only the L^2 complexes will be discussed.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The absorption spectrum of **2** in solution (Figure 11 and Table 5) clearly showed two well-defined bands, centred at 300 and 422 nm, and a series of shoulders.

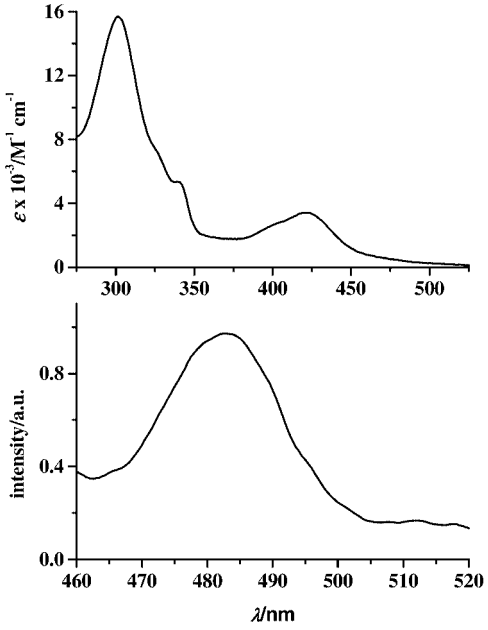

Figure 11. Absorption (top) and emission (down) spectra of complex **2** in dichloromethane solution

In accord with the literature,[35−37] the intense band at 300 nm, with a shoulder at about 320 nm, was attributed to spin-allowed ligand-centred transitions (^{1}LC). The band at 422 nm and its shoulder at about 430 nm could be attributed to ^{1}MLCT and ^{3}MLCT transitions, respectively.[38] A metal-perturbed LC transition could be give the band at 340 nm, while spin-allowed ligand field transitions (LF) produce weak shoulders at about 360 nm.[39]

The electronic spectrum of microcrystalline samples of **2** (Table 5) is not well resolved, due to the reflecting properties of the KBr support, which reduced signal intensity; it is possible to distinguish the principal maxima at 300 and 433 nm, with the first due to an ^{1}LC transition and the second to a ^{1}MLCT. The red-shift of this band was attributed to the environment sensitivity of this type of transition on passing from solution to the solid state.

As expected, the absorption spectrum of **II** (Table 5) did not show a MLCT band in the visible region, since the palladium(II) centre is more difficult to oxidize than the platinum(II) centre. Therefore, the observed UV-band at 355 nm could be assigned to a MLCT transition. The absorption spectrum of complex **II**, recorded from the KBr pellet, showed a 335 nm band corresponding to LC excitation.

The absorption spectra of **5** and **8** are very similar: in the near-UV region both exhibit two maxima at 314 and 324 nm in dichloromethane solution with a single peak at 322 nm in the solid state (Table 5). These features are assigned to the metal-perturbed ligand centred transition, showing two vibronic components in solution.

Complex **2** in dichloromethane solution has an emission band centred at 482 nm (Figure 11 and Table 6), as confirmed by the excitation spectrum.

This band can be attributed to a low-yield ($\Phi < 10^{-2}$ %) radiative deactivation from an ^{1}LF excited state. As expected, the analogous palladium complex **II**, in solution, did not emit, due to low-lying metal-centred excited states (MC), which can be populated easily by thermal activation and provide fast deactivation pathways via molecular distortion.[40]

The solid-state luminescence behaviours of **2** and **II** show interesting differences (Figure 12 and Table 6).

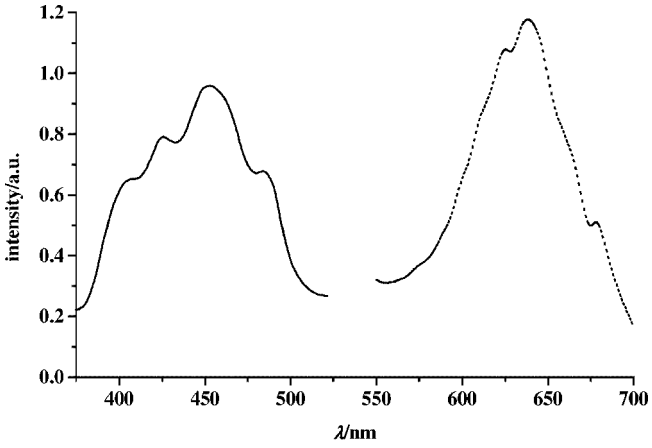

Figure 12. Emission spectra of complex **2** (dotted line) and complex **II** (solid line) in microcrystalline samples

Comparing the emission maximum of **2** in the solid state to that in solution, it is evident that d_z^2(Pt) orbital interactions in the stacked complexes in the microcrystalline sample are strong enough to affect the photophysical properties of the molecules. Therefore a Pt−Pt distance similar to the yellow form of (2,2′-bipyridine)dichloroplatinum(II) can be assumed.[41−43] The structured emission band at about 456 nm in the microcrystalline emission spectrum of **II** seems to indicate that the bipyridyl ligand is involved in the formation of the state responsible for the luminescence.[42] Moreover, the shortest Pd···Pd intermolecular separation of 3.487(2) Å, observed in the X-ray crystal structure determination, does not seem to be strong enough to affect the photophysical properties of the "isolated" molecules. This accounts for a small contribution of the metal in the electronic transition, in which LC character could be mixed with LF transitions. Further studies are necessary to clarify this crucial point.

[L^{n}MX$_2$] Complexes

The origin and position of the bands in the electronic spectra of [L^{2}MX$_2$] can be accounted for in the same way as for the [L^{2}MCl$_2$] spectra, irrespective of X. However, by modifying the donor character of X the MLCT state energy can be adjusted and, consequently, MLCT bands fall in the ranges 355−394 nm and 422−460 nm for the palladium and platinum derivatives, respectively. As discussed above,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the weak fluorescence of **2** in solution is due to the emission from a ^{1}LF state, while the ^{1}MLCT state was deactivated by intersystem crossing (i.s.c.) to the ^{3}MLCT state. For **11** and **13** no luminescence was observed in solution at room temperature. This may be ascribable to the heavy atom effect which, favouring i.s.c. to the ^{3}MLCT state, quenched the fluorescence more efficiently than in **2**. With the complex bearing the azide ligands, **15**, an interesting emission at 640 nm was recorded. This complex did not undergo i.s.c, and a spin-allowed emission from the ^{1}MLCT state was now observed, whereby the photoluminescence quantum yield is higher than that of the ^{1}LF emission (0.65 vs. 0.02 %, respectively).

Although emission was expected in microcrystalline **11**, by analogy with that reported for [(bipy)PtI_2] luminescence,[42] it was not possible to detect it as scattered light fell in the observed spectral range. Likewise, it was difficult to record a clear emission spectrum from the microcrystalline **15** sample, in which emission could be self-quenched by dimeric interactions.

Finally, it was very difficult to assign the low-energy band in the electronic spectrum of **10**, which showed a peak at 496 nm that probably resulted from a mixed triplet−singlet state, favouring spin−orbit coupling.[37] As expected, no emission was detected from solution and microcrystalline samples of palladium complexes **10**, **12**, **14** with X = Br, N_3, I, respectively.

Conclusions

We have further characterized a recently reported[15] series of non-mesogenic dialkyl 2,2′-bipyridine-4,4′-dicarboxylates, L^n, and their *cis*-dichloro palladium liquid crystalline derivatives. Preliminary XRD experiments on the mesophase of the [L^n$PdCl_2$] complexes led us to propose a model in which the promotion of a dipole moment upon complexation induces self-assembling in dimers with antiparallel disposition. The aggregation of each pair of molecules into a layered structure affords a lamellar L phase.[15] This arrangement in the crystalline state has been confirmed by single-crystal X-ray diffraction analysis of the [L^2$PdCl_2$] derivative, **II**. A relatively short Pd···Pd intermolecular separation of 3.487(2) Å is found between centrosymmetrically related molecules arranged in a head-to-tail fashion. Pd···Pd contacts of 4.778 Å between dimers, alternating along a zig-zag chain, give rise to a layered structure. The solid-state luminescence at room temperature of complex **II** is shifted to the violet region with respect to the corresponding ligand.

The synthesis and characterization of two new series of complexes are also described: the *cis*-dichloro compounds [L^nMCl_2], where the palladium is replaced with Pt, Ni, and Zn, and the dihexadecyl 2,2′-bipyridyl-4,4′-dicarboxylate palladium and platinum derivatives, [L^2MX_2], in which the chloride groups are replaced with iodide, bromide, and azide ligands. Careful choice of the molecular building blocks with suitable shapes and geometries enable control of the supramolecular structure, and prediction of the nature of the induced thermal behaviour. Most of the [L^nMX_2] complexes retained the enantiotropic lamellar L phase of the chloro palladium derivatives, while the thermal and spectroscopic behaviour depend on molecular assemblies and thus on electronic and steric factors. In particular, the appearance of mesomorphism is related to the length of the alkyl chains, with long chains (n = 12, 16) producing the global rod-like shape responsible for the liquid crystalline behaviour. Comparing the *cis*-dichloro derivatives containing the same aliphatic tails, their mesomorphic behaviour is directly related to the nature of the metal centre. A single-crystal X-ray structure has been determined for the dihexadecyl 2,2′-bipyridyl-4,4′-dicarboxylate zinc derivative **8**: the tetrahedral geometry prevented dimer formation in the crystal packing and favoured intermolecular contacts that are too strong to induce mesomorphic behaviour. Conversely, the distorted square-planar nickel complexes displayed a lamellar phase at temperatures higher than for the palladium and platinum homologous. For all square-planar complexes the ancillary ligands were varied to use dipole coupling as a tool of molecular architecture. All complexes exhibited the same L phase, but both thermal and spectroscopic properties appeared to depend strongly upon the molecular dipolar interactions.

New photoluminescent metallomesogens have been obtained that display highly desirable optical properties such as a good degree of tunability. The band due to the ^{1}MLCT transition red-shifts, increasing the π-donor capacity of the X ligands, and most of these compounds, including the palladium derivatives, exhibit excellent luminescence properties. Interestingly, the platinum compound bearing chloride ligands is a blue emitter in solution but a red emitter in the solid state. With the azide group, however, the platinum complex is a red emitter in solution but is not an emitter at all in the solid state.

Experimental Section

Materials and Methods: All chemical, reagents and solvents were used as received from commercial sources without further purification. Ligands (L^n) were synthesized as previously reported.[15]

Infrared spectra were recorded on a Perkin-Elmer FT 2000 spectrophotometer and the ^{1}H NMR spectra were recorded on a Bruker WH-300 spectrometer in $CDCl_3$ solution, with TMS as internal standard. Elemental analyses were performed with a Perkin−Elmer 2400 analyzer. The textures of the mesophases were studied with a Zeiss Axioscope polarizing microscope equipped with a Linkam CO 600 heating stage. The transition temperatures and enthalpies were measured on a Perkin−Elmer Pyris 1 Differential Scanning Calorimeter with a heating and cooling rate of 10 °C/min. The apparatus was calibrated with indium. Two or more heating/cooling cycles were performed on each sample.

Spectrofluorimetric grade solvent (Acros Organics) was used for the photophysical investigations in solution at room temperature. Solid-state spectra were obtained from microcrystalline samples on KBr pellets. Absorption spectra were recorded with a Perkin−Elmer Lambda 900 spectrophotometer; uncorrected emis-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sion spectra were obtained with a Perkin-Elmer LS-50B spectrofluorimeter. Fluorescence quantum yields in solution were measured by the method described by Demas and Crosby[44] using [Ru(bipy)$_3$]Cl$_2$ (bipy = 2,2′-bipyridine, $\Phi = 0.028$ in aerated water)[45] as standard. The experimental uncertainty on the band maximum for absorption and luminescence spectra is 2 nm; that on the luminescence intensity is 20% and that on the molar absorption coefficient is 10%. The free ligand and its metal complexes are fairly stable in CH_2Cl_2, as demonstrated by the constancy of their absorption spectra over a week.

The X-ray powder diffraction patterns were obtained using a Bruker AXS General Area Detector Diffraction System (D8 Discover with GADDS). Monochromatized Cu-$K\alpha$ radiation (λ = 1.54 Å) impinged on the about 1 mm thick sample, the temperature of which was controlled to ±0.1° by a hot stage containing electrical resistors.

Crystal Structure Studies: Pale yellow needles of [L^{2}PdCl$_2$] (**II**) with a relatively poor crystal habit were crystallized at room temperature from a chloroform/ethanol mixture. Different crystallization conditions gave no better results. A needle of suitable dimensions was mounted in a fiber glass capillary to avoid solvent evaporation during data collection. Crystal data of [L^{2}ZnCl$_2$] (**8**) were collected on a white, thin plate crystal obtained from a chloroform/ethanol mixture. In both cases diffraction measurements were carried out at room temperature on a Siemens *R3m/V* automated four-circle diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The data were corrected for Lorentz, polarization and X-ray absorption effects. For **8** an empirical absorption correction was applied using a method based upon azimuthal (Ψ) scan data.[46] With **II**·2CHCl$_3$ a slow loss of cocrystallized solvent prevented this type of data correction. Therefore the data were corrected for X-ray absorption effects using the *XABS2* program.[47] Details of the crystal data collections are listed in Table 7.

Both structure solutions (Patterson method) and full-matrix least-squares refinements based on F^2 were performed with *SHELXS*/*L* programs of the *SHELXTL-NT* software package (Version 5.10).[48]

For **II**·2CHCl$_3$, only palladium, chlorine (excluding the chlorine atoms of the two co-crystallized chloroform molecules), nitrogen and oxygen atoms were refined anisotropically, for **8**, however, all non-hydrogen atoms were refined anisotropically. In both cases hydrogen atoms were included as idealized atoms riding on the respective carbon atom hybridisation. The bipyridine hydrogen atoms of **8** were included in the refinement in their observed positions.

Synthesis of [L^{n}PtCl$_2$] Complexes 1−3: The [L^{n}PtCl$_2$] derivatives were prepared by the procedure described for the analogous palladium complexes,[15] starting from the suitable ligand and varying the solvent and reaction time for more energetic reaction conditions. The synthesis of [L^{1}PtCl$_2$] (**1**) is detailed below; all other homologues were prepared in a similar fashion and only yields, solvents, ^{1}H NMR, IR, and analytical data are reported.

(Dioctyl 2,2′-Bipyridyl-4,4′-dicarboxylate)platinum(II) Chloride ([L^{1}PtCl$_2$], 1): A solution of [Pt(PhCN)$_2$Cl$_2$] (0.1 g, 0.213 mmol) and dioctyl 2,2′-bipyridine-4,4′-dicarboxylate, L^1, (0.1 g, 0.213 mmol) in toluene (12 mL) was heated at reflux for 24 h. The solvent was then evaporated and the residue recrystallized from dichloromethane/methanol to give a yellow solid complex (0.092 g, 59%). Thermotropic behaviour: Table 3. ^{1}H NMR (300 MHz, CDCl$_3$, 25 °C, ppm): δ = 0.82 (m, 6 H, H$^{11d,11d'}$), 1.23 (m, 20 H, H$^{10c,10c'}$), 1.78 (m, 4 H, H$^{9b,9b'}$), 4.40 (t, ^3J = 6.8 Hz, 4 H, H$^{8a,8a'}$), 8.02 (dd, $^3J_{H,H}$ = 6.2, $^4J_{H,H}$ = 1.7 Hz, 2 H, H$^{5,5'}$), 8.54 (s, 2 H, H$^{3,3'}$), 9.77 (d, $^3J_{H,H}$ = 6.2 Hz, 2 H, H$^{6,6'}$). FTIR (KBr, cm^{-1}):

Synthesis of [L″NiCl₂] Complexes 4−6: The preparation of [L^1NiCl$_2$] (**4**) complex is detailed below; all other homologues were prepared in a similar fashion and only yields, solvents, ^{1}H NMR, IR, and analytical data are reported.

(Dioctyl 2,2′-Bipyridyl-4,4′-dicarboxylate)nickel(II) Chloride ([L¹NiCl₂], 4): A solution of $NiCl_2$ (0.041 g, 0.32 mmol) and dioctyl 2,2′-bipyridine-4,4′-dicarboxylate, L^1, (0.150 g, 0.32 mmol) in ethanol (25 mL) was heated at reflux for 48 h. The solvent was evaporated and the residue recrystallized from dichloromethane/diethyl ether to give a green solid (0.179 g, 94%). Thermotropic behaviour: Table 3. FTIR (KBr, cm^{-1}): ν(C=O) 1729. $C_{28}H_{40}Cl_2N_2NiO_4$ (598.24): calcd. C 56.22, H 6.74, N 4.68; found C 56.83, H 6.44, N 5.02.

(Dihexadecyl 2,2′-Bipyridyl-4,4′-dicarboxylate)nickel(II) Chloride ([L²NiCl₂], 5): 24 h. Yield: 0.159 g, 89%. Thermotropic behaviour: Table 3. FTIR (KBr, cm^{-1}): ν(C=O) 1725. $C_{44}H_{72}Cl_2N_2NiO_4$ (822.67): calcd. C 64.24, H 8.82, N 3.41; found C 64.34, H 8.94, N, 3.77.

(Didocosyl 2,2′-Bipyridyl-4,4′-dicarboxylate)nickel(II) Chloride ([L³NiCl₂], 6): 24 h. Yield: 0.130 g, 75%. Thermotropic behaviour: Table 3. FTIR (KBr, cm^{-1}): ν(C=O) 1725. $C_{56}H_{96}Cl_2N_2NiO_4$ (990.99): calcd. C 67.87, H 9.76, N 2.83; found C 67.77, H 9.09, N 2.90.

Synthesis of [L″ZnCl₂] Complexes 7−9: Compound [L^1ZnCl$_2$] (**7**) was prepared as detailed below; all other homologues were prepared in a similar fashion and only yields, solvents, ^{1}H NMR, IR, and analytical data are reported.

(Dioctyl 2,2′-Bipyridyl-4,4′-dicarboxylate)zinc Chloride ([L¹ZnCl₂], 7): Zinc chloride (0.02 g, 0.171 mmol) was added to a solution of dioctyl 2,2′-bipyridine-4,4′-dicarboxylate, L^1, (0.08 g, 0.171 mmol) in dichloromethane (10 mL). The resultant suspension was stirred at room temperature for 4 days. The solvent was then evaporated and the residue recrystallized from dichloromethane/diethyl ether to give a white solid (0.080 g, 78%). Thermotropic behaviour: Table 3. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, ppm): δ = 0.89 (t, ^3J = 6.6 Hz, 6 H, $H^{11d,11d'}$), 1.30 (m, 20 H, $H^{10c,10c'}$), 1.85 (m, 4 H, $H^{9b,9b'}$), 4.49 (t, ^3J = 6.6 Hz, 4 H, $H^{8a,8a'}$), 8.30 (d, ^3J = 4.7 Hz, 2 H, $H^{5,5'}$), 8.89 (s, 2 H, $H^{3,3'}$), 9.05 (d, ^3J = 4.7 Hz, 2 H, $H^{6,6'}$). FTIR (KBr, cm^{-1}): ν(C=O) 1732. $C_{28}H_{40}Cl_2N_2O_4Zn$ (604.92): calcd. C 55.40, H 6.66, N 4.63; found C 55.60, H 6.51, N 4.60.

(Dihexadecyl 2,2′-Bipyridyl-4,4′-dicarboxylate)zinc Chloride ([L²ZnCl₂], 8): Yield: 0.060 g, 72%. Thermotropic behaviour: Table 3. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, ppm): δ = 0.88 (t, $^3J_{H,H}$ = 6.8 Hz, 6 H, $H^{11d,11d'}$), 1.26 (m, 52 H, $H^{10c,10c'}$), 1.85 (m, 4 H, $H^{9b,9b'}$), 4.49 (t, $^3J_{H,H}$ = 6.8 Hz, 4 H, $H^{8a,8a'}$), 8.30 (dd, $^3J_{H,H}$ = 5.1, $^4J_{H,H}$ = 1.2 Hz, 2 H, $H^{5,5'}$), 8.89 (s, 2 H, $H^{3,3'}$), 9.04 (d, $^3J_{H,H}$ = 5.1 Hz, 2 H, $H^{6,6'}$). FTIR (KBr, cm^{-1}): ν(C=O) 1733. $C_{44}H_{72}Cl_2N_2O_4Zn$ (829.35): calcd. C 63.72, H 8.75, N 3.38; found C 63.15, H 8.48, N 3.11.

(Didocosyl 2,2′-Bipyridyl-4,4′-dicarboxylate)zinc Chloride ([L³ZnCl₂], 9): Yield: 0.084 g, 72%. Thermotropic behaviour: Table 3. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, ppm): δ = 0.88 (t, $^3J_{H,H}$ = 6.7 Hz, 6 H, $H^{11d,11d'}$), 1.25 (m, 76 H, $H^{10c,10c'}$), 1.85 (m, 4 H, $H^{9b,9b'}$), 4.49 (t, $^3J_{H,H}$ = 6.7 Hz, 4 H, $H^{8a,8a'}$), 8.30 (d, $^3J_{H,H}$ = 5.3 Hz, 2 H, $H^{5,5'}$), 8.89 (s, 2 H, $H^{3,3'}$), 9.04 (d, $^3J_{H,H}$ = 5.3 Hz, 2 H, $H^{6,6'}$). FTIR (KBr, cm^{-1}): ν(C=O) 1732. $C_{56}H_{96}Cl_2N_2O_4Zn$ (997.68): calcd. C 67.42, H 9.70, N 2.81; found C 67.32, H 9.41, N 2.79.

Synthesis of [L²MX₂] Complexes 10−15: The [L^2MX_2] complexes, starting from suitable precursors [L^2MCl_2] (M = Pd, Pt), were prepared by metathetical reactions with appropriate salts AX (X = I, Br, N_3). The synthesis of the [L^2PdI_2] (**10**) complex is described in detail; all other complexes were prepared in a similar fashion and only reagents, yields, solvents, ^{1}H NMR, IR, and analytical data are reported.

(Dihexadecyl 2,2′-Bipyridyl-4,4′-dicarboxylate)palladium(II) Iodide ([L²PdI₂], 10): KI (0.096 g, 0.58 mmol) was added to a yellow solution of [L^2PdCl_2], (**II**) (0.05 g, 0.058 mmol) in acetone (10 mL). The resultant suspension was then stirred at room temperature for 24 h. The so-obtained brown solid was filtered off and purified by recrystallization from chloroform/acetone to give the pure dark red product as a solid (0.050 g, 82%). Thermotropic behaviour: Table 4. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, ppm): δ = 0.88 (m, 6 H, $H^{11d,11d'}$), 1.26 (m, 52 H, $H^{10c,10c'}$), 1.86 (m, 4 H, $H^{9b,9b'}$), 4.48 (t, $^3J_{H,H}$ = 6.8 Hz, 4 H, $H^{8a,8a'}$), 8.14 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, $H^{5,5'}$), 8.70 (s, 2 H, $H^{3,3'}$), 10.18 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, $H^{6,6'}$). FTIR (KBr, cm^{-1}): ν(C=O) 1729. $C_{44}H_{72}I_2N_2O_4Pd$ (1053.30): calcd. C 50.17, H 6.89, N 2.66; found C 50.50, H 7.51, N 3.25.

(Dihexadecyl 2,2′-Bipyridyl-4,4′-dicarboxylate)platinum(II) Iodide ([L²PtI₂], 11): 10 equiv. of KI; three days. Red product obtained from chloroform/methanol (0.082 g, 86%). Thermotropic behaviour: Table 4. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, ppm): δ = 0.88 (t, $^3J_{H,H}$ = 6.9 Hz, 6 H, $H^{11d,11d'}$), 1.26 (m, 52 H, $H^{10c,10c'}$), 1.86 (m, 4 H, $H^{9b9b'}$), 4.48 (t, $^3J_{H,H}$ = 6.9 Hz, 4 H, $H^{8a,8a'}$), 8.12 (d, $^3J_{H,H}$ = 6.05 Hz, 2 H, $H^{5,5'}$), 8.63 (s, 2 H, $H^{3,3'}$), 10.51 (d, $^3J_{H,H}$ = 6.05 Hz, 2 H, $H^{6,6'}$). FTIR (KBr, cm^{-1}): ν(C=O) 1720. $C_{44}H_{72}I_2N_2O_4Pt$ (1141.96): calcd. C 46.28, H 6.36, N 2.45; found C 46.60, H 6.24, N 2.56.

(Dihexadecyl 2,2′-Bipyridyl-4,4′-dicarboxylate)palladium(II) Bromide ([L²PdBr₂], 12): 20 equiv. of KBr; DMF; three days. Yellow product obtained from chloroform/methanol (0.054 g, 80%). Thermotropic behaviour: Table 4. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, ppm): δ = 0.88 (t, $^3J_{H,H}$ = 6.7 Hz, 6 H, $H^{11d,11d'}$), 1.26 (m, 52 H, $H^{10c,10c'}$), 1.85 (m, 4 H, $H^{9b,9b'}$), 4.48 (t, $^3J_{H,H}$ = 6.7 Hz, 4 H, $H^{8a,8a'}$), 8.11 (d, $^3J_{H,H}$ = 6.1 Hz, 2 H, $H^{5,5'}$), 8.66 (s, 2 H, $H^{3,3'}$), 9.85 (d, $^3J_{H,H}$ = 6.1 Hz, 2 H, $H^{6,6'}$). FTIR (KBr, cm^{-1}): ν(C=O) 1722. $C_{44}H_{72}Br_2N_2O_4Pd$ (959.29): calcd. C 55.09, H 7.57, N 2.92; found C 54.79, H 7.11, N 2.43.

(Dihexadecyl 2,2′-Bipyridyl-4,4′-dicarboxylate)platinum(II) Bromide ([L^{2}PtBr$_2$], 13): 20 equiv. of KBr; DMF; four days. Yellow product obtained from chloroform/methanol (0.066 g, 76%). Thermotropic behaviour: Table 4. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, ppm): δ = 0.88 (t, $^3J_{H,H}$ = 6.6 Hz, 6 H, H$^{11d,11d'}$), 1.26 (m, 52 H, H$^{10c,10c'}$), 1.86 (m, 4 H, H$^{9b,9b'}$), 4.47 (t, $^3J_{H,H}$ = 6.6 Hz, 4 H, H$^{8a,8a'}$), 8.11 (d, $^3J_{H,H}$ = 5.8 Hz, 2 H, H$^{5,5'}$), 8.60 (s, 2 H, H$^{3,3'}$), 10.23 (d, $^3J_{H,H}$ = 5.8 Hz, 2 H, H$^{6,6'}$). FTIR (KBr, cm^{-1}): ν(C=O) 1730. $C_{44}H_{72}Br_2N_2O_4Pt$ (1047.95): calcd. C 50.43, H 6.93, N 2.67; found C 50.14, H 6.75, N 2.32.

(Dihexadecyl 2,2′-Bipyridyl-4,4′-dicarboxylate)palladium(II) Azide ([L^{2}Pd(N$_3$)$_2$], 14): 10 equiv. of NaN_3; 24 h. Yellow product obtained from chloroform/acetone (0.033 g, 65%). Thermotropic behaviour: Table 4. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, ppm): δ = 0.88 (t, $^3J_{H,H}$ = 6.5 Hz, 6 H, H$^{11d,11d'}$), 1.26 (m, 52 H, H$^{10c,10c'}$), 1.86 (m, 4 H, H$^{9b,9b'}$), 4.47 (t, $^3J_{H,H}$ = 6.5 Hz, 4 H, H$^{8a,8a'}$), 8.145 (d, $^3J_{H,H}$ = 5.5 Hz, 2 H, H$^{5,5'}$), 8.67 (s, 2 H, H$^{3,3'}$), 8.81 (d, $^3J_{H,H}$ = 5.5 Hz, 2 H, H$^{6,6'}$). FTIR (KBr, cm^{-1}): ν(C=O) 1728, ν(N_3) 2043. $C_{44}H_{72}N_8O_4Pd$ (883.53): calcd. C 59.82, H 8.21, N 12.68; found C 60.01, H 8.69, N 12.32.

(Dihexadecyl 2,2′-Bipyridyl-4,4′-dicarboxylate)platinum(II) Azide ([L^{2}Pt(N$_3$)$_2$], 15): 10 equiv. of NaN_3; 48 h. Orange product obtained from chloroform/methanol (0.036 g, 45%). Thermotropic behaviour: Table 4. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, ppm): δ = 0.88 (t, $^3J_{H,H}$ = 6.6 Hz, 6 H, H$^{11d,11d'}$), 1.26 (m, 52 H, H$^{10c,10c'}$), 1.86 (m, 4 H, H$^{9b,9b'}$), 4.47 (t, $^3J_{H,H}$ = 6.6 Hz, 4 H, H$^{8a,8a'}$), 8.10 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, H$^{5,5'}$), 8.63 (s, 2 H, H$^{3,3'}$), 9.14 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, H$^{6,6'}$). FTIR (KBr, cm^{-1}): ν(C=O) 1728, ν(N_3) 2063. $C_{44}H_{72}N_8O_4Pt$ (972.19): calcd. C 54.36, H 7.46, N 11.53; found C 54.04, H 7.20, N 11.40.

CCDC-208739 and CCDC-208740 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Intercalates of Vanadyl Phosphate with Benzonitrile and Tolunitrile

Ludvík Beneš,*[a] Víztězslav Zima,[a] Klára Melánová,[a] Jiří Dybal,[b] Miroslava Trchová,[c] and Pavel Matějka[d]

Keywords: Intercalations / X-ray diffraction / Vibrational spectroscopy / Ab initio calculations / Semiempirical calculations

Intercalates of vanadyl phosphate with benzonitrile and *p*-tolunitrile were prepared and characterized by X-ray powder diffraction, TG analysis, IR and Raman spectroscopy. Both intercalates contain one nitrile molecule per formula unit. The intercalates prepared are moisture sensitive and guest molecules are easily replaced by water molecules. The nitrile molecules are anchored to the host layers by an N–V donor-acceptor bond. Local structures and interactions appearing in the intercalates were suggested on the base of quantum chemical calculations. These calculations support the results of the IR and Raman spectroscopy, indicating the formation of a C≡N→V bond in the intercalates. The calculated basal spacings (11.32 Å for the benzonitrile and 13.00 Å for the tolunitrile intercalates) are in good agreement with the experimental values (11.22 and 13.19 Å, respectively).

Introduction

Vanadyl phosphate is able to accommodate various types of organic compounds having Lewis base character.[1] Less attention has been paid to intercalations of carboxylic acids[2] and their derivatives.[3−6] Intercalates of vanadyl phosphate with nitriles (acetonitrile, propionitrile, butyronitrile, valeronitrile, hexanenitrile)[5] and dinitriles (malononitrile, succinonitrile, glutaronitrile, adiponitrile, pimelonitrile, suberonitrile)[6] were prepared. The nitrile intercalates (except for acetonitrile) contain one nitrile molecule per formula unit. The dinitrile content in the intercalates decreases with increasing chain length. In contrast to most $VOPO_4$ intercalates with guest molecules containing aliphatic chains where the basal spacing increases with increasing chain length,[2,7−11] the basal spacings of all the nitrile and the dinitrile intercalates prepared are practically the same. This demonstrates that the aliphatic part of the guest molecules must be parallel to the host layers.

In this paper we report on the intercalation of benzonitrile and *p*-tolunitrile into vanadyl phosphate to complete the picture on the intercalation ability of vanadyl phosphate towards different nitriles.

Results and Discussion

Similarly to aliphatic nitriles and dinitriles, the aromatic nitriles analysed cannot be intercalated directly into anhydrous vanadyl phosphate and also a replacement of the water molecules in $VOPO_4 \cdot 2H_2O$ does not lead to an intercalation. The benzonitrile and *p*-tolunitrile intercalates can be prepared by replacing 2-propanol or 1-propanol in the corresponding $VOPO_4$ intercalates. While the 2-propanol molecules are replaced very easily, the replacement of the 1-propanol molecules is very slow and intermediate phases are formed. Therefore, it is necessary to repeat the reaction with a new amount of the corresponding nitrile.

The intercalates prepared are greenish-yellow crystalline solids, indicating that only a small part of vanadium(V) has been reduced to vanadium(IV). The diffractogram of the benzonitrile intercalate shows sharp (00*l*) and weak (200 and 201) reflections (Figure 1a). Reflections at 201, 202 and 310 are present in the diffractogram of the *p*-tolunitrile intercalate (Figure 1b). The low intensity of a few (*hkl*) lines in the intercalates suggests a turbostratic structure where the original tetragonal layers of the host are retained, but are shifted in the directions of the *x* and/or *y* axes. The lattice parameters of the tetragonal structures are $a = 6.21$ Å, $c = 11.22$ Å and $a = 6.21$ Å, $c = 13.19$ Å for the benzonitrile and tolunitrile intercalates, respectively.

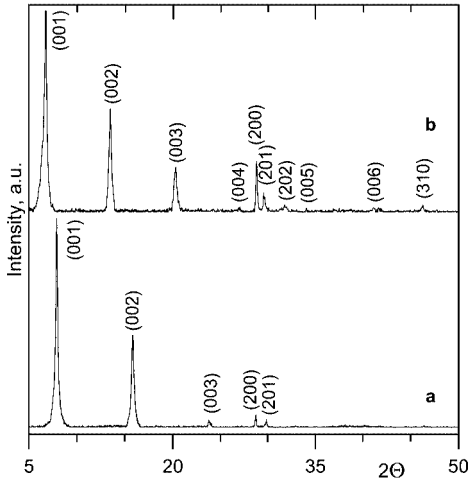

Figure 1. Diffractogram of benzonitrile (a) and *p*-tolunitrile (b) intercalated $VOPO_4$

The compositions of the intercalates were determined by thermogravimetric analysis (see Figure 2). During heating, nitriles are slowly released in two steps in the temperature range 100−550 °C. The second step is very slow and the DTA shows a broad exothermic peak probably due to the combustion of the nitriles. The product of the thermal decomposition is anhydrous vanadyl phosphate. Total weight losses correspond to the stoichiometric ratio $x = 1$, that is, one molecule of nitrile per formula unit (for the benzonitrile intercalate: calcd. 38.9%; found 38.1% and for the *p*-tolunitrile intercalate: calcd. 42.2%; found 40.9%).

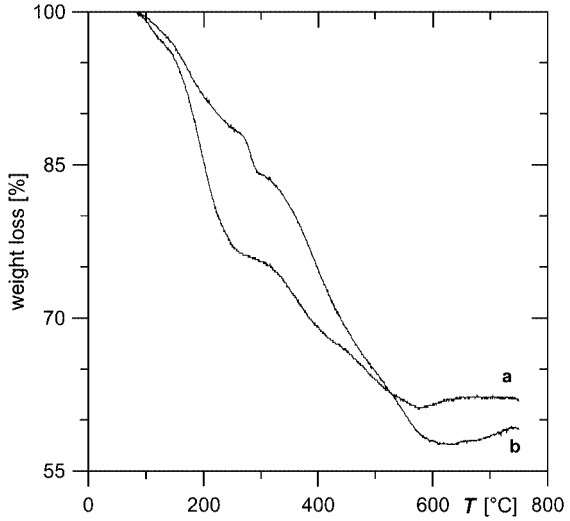

Figure 2. TG curves of the benzonitrile (a) and *p*-tolunitrile (b) intercalates

The benzonitrile and *p*-tolunitrile intercalates are more stable in air (at relative humidity 40−50%) than the nitrile intercalates[5] and less stable than the dinitrile intercalates.[6] The course of the hydration of both intercalates was followed by XRD. A small amount of dihydrate appeared after twenty minutes and the intercalates were completely decomposed after one day.

The character of the bonding between the guest and the host layers in the nitrile intercalates was studied by IR and Raman spectroscopy. From the point of view of the host-guest interaction, the most important position is that of the C≡N stretching vibration. The C≡N group can act either as a σ-donor, by donating nitrogen electrons to a metal, or as a π-donor, by donating electrons of a nitrile π-bond. The wavenumber of the C≡N stretching vibration is shifted to higher values in the case of σ-donation and to lower values in the case of π-donation.[12]

The IR spectra of pure benzonitrile and its $VOPO_4$ intercalate (KBr pellet and Nujol suspension), in the region from 2100 to 2400 cm^{-1}, are given in Figure 3. The strong C≡N stretching absorption band of pure benzonitrile is observed at 2228 cm^{-1}. In the spectrum of the benzonitrile intercalate, measured as a Nujol suspension, we observed two absorption bands at 2228 and at 2252 cm^{-1}. No shifted nitrile band was observed in the samples prepared as KBr pellets. The band with the same position as in the pure benzonitrile spectrum most probably corresponds to free benzonitrile molecules, which are present in the sample due to the instability of the intercalate in air. While preparing the KBr pellets the samples decomposed to free nitrile and vanadyl phosphate hydrate. In the case of the Nujol dispersion only a partial decomposition takes place. The shifted band observed at 2252 cm^{-1} in the IR spectrum of the Nujol suspension corresponds to coordinated benzonitrile. The observed shift indicates the formation of a C≡N→V bond in the intercalate.

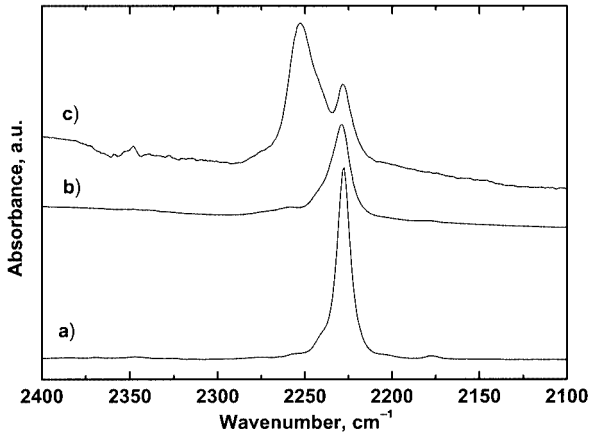

Figure 3. FTIR spectra of pure benzonitrile measured by the ATR technique (a) and of the benzonitrile intercalate measured as a KBr pellet (b) and as a Nujol suspension (c)

The Raman spectra of benzonitrile and its intercalate in the region from 400 to 4000 cm^{-1} are given in Figure 4. One can observe the intense band of the symmetric $\nu(PO_4)$ stretching vibration of a phosphate tetrahedron in the $(VOPO_4)_\infty$ layers. It is situated at about 941 cm^{-1} in the spectrum of the intercalate. Strong bands of aromatic vibrations at the same positions as in the spectrum of pure benzonitrile (1002, 1600 and 3078 cm^{-1}) are observed in the spectrum of the intercalate. The spectrum of the intercalate confirms that the structure of the original $VOPO_4$ layers

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

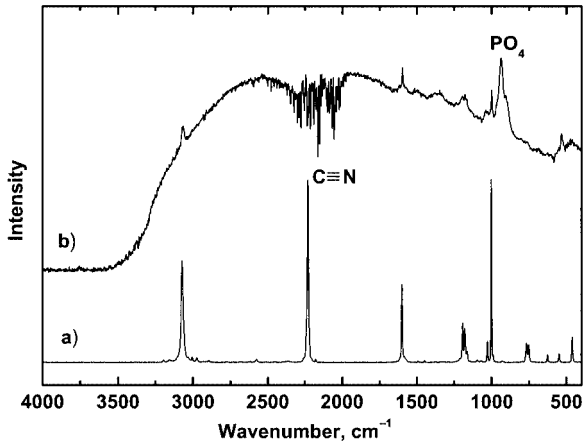

Figure 4. Raman spectra of liquid benzonitrile (a) and the benzonitrile intercalate (b)

remains unchanged and there are no significant changes in the guest molecules after intercalation. The vanadyl stretching band expected at about 1002 cm^{-1}, which appears to be especially sensitive to atoms coordinated to vanadium within an octahedral arrangement in the host-lattice structure, overlaps with one of the benzonitrile bands. The part of the Raman spectrum corresponding to the nitrile stretching vibration is strongly influenced by the baseline radiation. This is most probably due to the excitation of the benzonitrile molecules by the laser beam while the measurements were being performed.

The infrared spectra of pure tolunitrile and its intercalate in $VOPO_4$ (as a KBr pellet and as a Nujol suspension) in the region from 2100 to 2400 cm^{-1} are given in Figure 5. The strong C≡N stretching absorption band of pure tolunitrile is observed at 2228 cm^{-1}, exactly at the same position as for pure benzonitrile. There are three absorption bands at 2228, 2256 and 2269 cm^{-1} in the IR spectrum of the tolunitrile intercalate measured in the Nujol suspension. New shifted bands at 2256 and 2269 cm^{-1} correspond to two non-equivalent tolunitriles. From the fact that only one shifted nitrile band (2269 cm^{-1}) is observed in the IR spectrum of the tolunitrile intercalate dispersed in the KBr pellet, it follows that the bands at 2256 and 2269 cm^{-1} correspond to two (slightly different) arrangements of tolunitrile in the interlayer space.

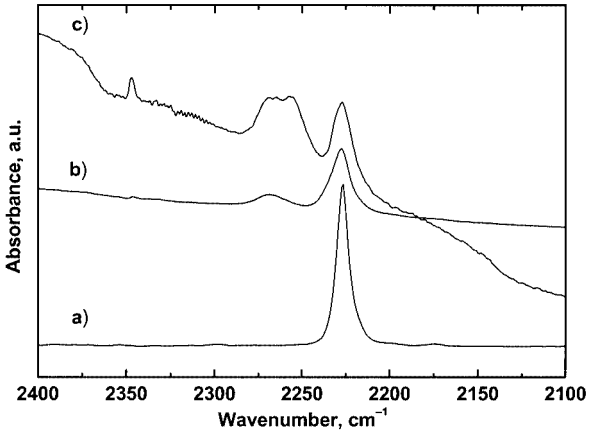

Figure 5. FTIR spectra of pure tolunitrile (a) and the tolunitrile intercalate measured as a KBr pellet (b) and as a Nujol suspension (c)

The Raman spectra of tolunitrile and its intercalate in the region from 400 to 4000 cm^{-1} are given in Figure 6. Only a part of the intercalate spectrum, including an intense band for the symmetric $\nu(PO_4)$ stretching vibration of the phosphate tetrahedron in the $(VOPO_4)_\infty$ layers situated at about 903 cm^{-1}, can be observed. The band for the aromatic vibration of tolunitrile is observed at about 1605 cm^{-1}. The part of the spectrum above 1800 cm^{-1} could not be measured due to the strong influence of the baseline radiation.

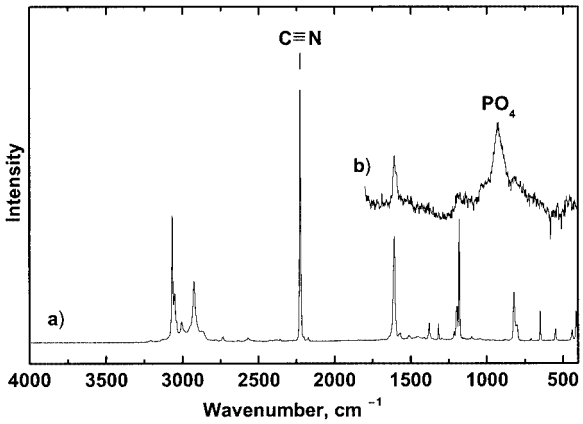

Figure 6. Raman spectra of liquid *p*-tolunitrile (a) and its intercalate (b)

The conclusions on the character of the bonding between the guest and the host layer in the nitrile intercalates are strongly supported by the results of quantum mechanical calculations and modeling. Figure 7 shows a DFT optimized structure of the molecular segment representing interactions of vanadyl phosphate with nitriles. In order to make the electronic structure in the segment close to the conditions appearing in the intercalates, free terminal oxygen atoms were substituted by OH groups and the total charge of the model compound was set to +3, the nitrile group being represented by acetonitrile. It was found that all the geometry optimizations, with various starting orientations for the acetonitrile with respect to the vanadyl group, lead to the structure displayed in Figure 7. Quantum chemical calculations thus support the results of the IR and Raman spectroscopy indicating the formation of the C≡N→V bond in the intercalates.

Because of the size and computational demand, the simulation of larger local intercalate structures, including two $VOPO_4$ layers, could only be done by using the semiempirical quantum-chemical method PM3. However, the model structure shown in Figure 7 was reoptimized with the PM3 method and only slight changes in optimized molecular parameters were found in comparison with a high precision DFT approach. This indicates that no serious artifacts are produced by the semiempirical PM3 method. The optimized geometries of the molecular segments, representing two

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

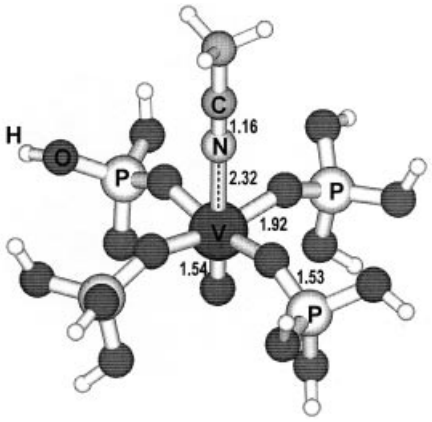

Figure 7. Optimized DFT structure of the molecular segment modeling the vanadyl phosphate-nitrile interaction, with indicated bond lengths (in Å)

layers of $VOPO_4$ and five molecules of benzonitrile and *p*-tolunitrile, intercalated between the two layers, are given in Figures 8 and 9, respectively. Free terminal oxygen atoms were substituted by OH groups and the total charge of the model compounds was set to −2. The coordination of the vanadium atoms to the nitriles in adjacent guest interlayer spaces was simulated by coordinating acetonitrile molecules, which are not shown in Figures 8 and 9. The initial geometrical parameters (bond lengths and angles) for the $VOPO_4$ layers were taken from the experimental X-ray diffraction data determined for $VOPO_4 \cdot 2H_2O$[13] and the initial basal spacings were set to the above given values of the lattice parameters c = 11.22 and 13.19 Å, determined by X-ray diffraction for the benzonitrile and *p*-tolunitrile intercalates, respectively. The first geometrical optimizations of the model structures were performed under various symmetry constraints and fixed parameters c. In the final energy minimization all the variables defining the positions of the atoms, both in the host and guest layers, were fully optimized, with the exception of the constraints arising from the symmetry conditions defining the polyhedra in the $VOPO_4$ layers and the relative orientations of four equivalent guest molecules in the interlayer space with respect to the $VOPO_4$ layer. The calculated basal spacings of 11.32 Å for benzonitrile and 13.00 Å for tolunitrile are in good agreement with the experimental values of 11.22 and 13.19 Å, respectively. The mutual position of the successive layers exhibits a shift that can be characterized by a vector with the components 0.12 and 0.14 Å for the benzonitrile and 0.08 and 0.06 Å for the tolunitrile intercalates.

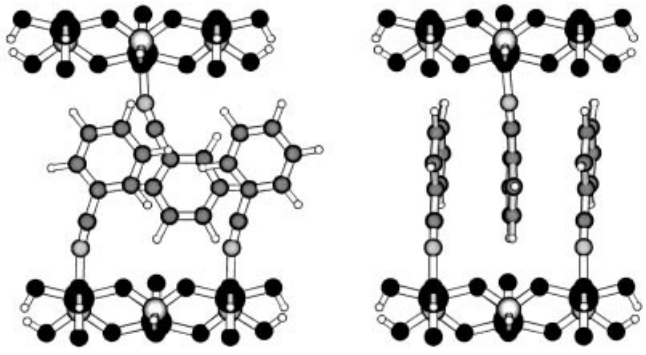

Figure 8. Side view of the PM3 optimized geometry of the molecular segment modeling the arrangement of benzonitrile molecules between the $VOPO_4$ layers

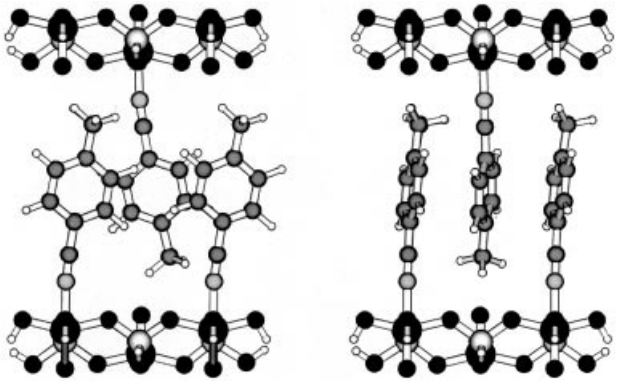

Figure 9. Side view of the PM3 optimized geometry of the molecular segment modeling the arrangement of *p*-tolunitrile molecules between the $VOPO_4$ layers

In the modeled structures one can observe cavities, which are larger for the tolunitrile intercalate than for the benzonitrile intercalate. The results of the model calculations indicate that water molecules, which are hydrogen-bonded to the oxygen atoms of the phosphate tetrahedron of the host layers, can be inserted into these cavities, in analogy with the second water molecules in vanadyl phosphate dihydrate.[14] Such water molecules can penetrate into the samples as soon as the latter are taken out of the ampoule. Amounts of incorporated water have been observed in the tolunitrile intercalate IR spectrum (as a Nujol suspension) at about 3500 and 3350 cm^{-1}, but they were not observed in the IR spectrum of the benzonitrile intercalate or of pure Nujol (see Figure 10). The overall (basic) crystalline structure of the intercalate is influenced by the presence of these water molecules only negligibly and thus the induced change is not observed in the diffractogram. However, the presence of the water molecules influences the coordination of the tolunitrile molecules in the vanadyl octahedron and

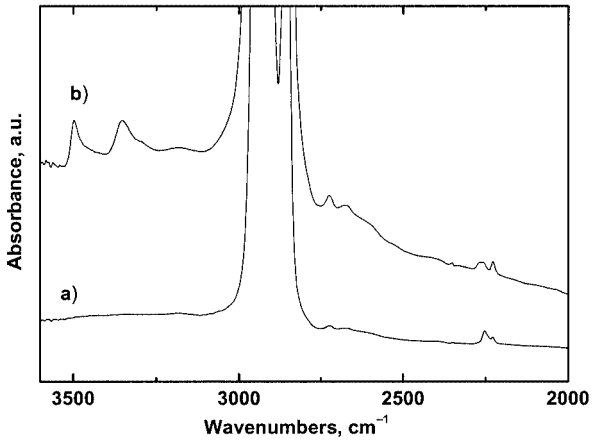

Figure 10. FTIR spectra of the benzonitrile (a) and tolunitrile (b) intercalates measured as a Nujol suspension

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the spectrum of the sample prepared as a Nujol suspension. This fact is probably shown by the presence of the second nitrile band at 2256 cm^{-1}, while the band at 2269 cm^{-1} corresponds to the original anhydrous tolunitrile intercalate structure. In the case of the KBr pellets we observe only a weak band of coordinated nitrile molecules in the hydrous intercalate, due to the decomposition of the sample by hydration during milling.

Conclusion

In contrast to aliphatic nitriles, molecules of aromatic nitriles are oriented perpendicularly to the host layers. The guest molecules are arranged in the interlayer space in an interdigitated manner, with the planes of the aromatic rings being parallel. This arrangement forms cavities between the guest molecules, especially in the *p*-tolunitrile intercalate. These cavities facilitate the incorporation of water molecules into the intercalates and thus reduce their stability. The assumption of the perpendicular arrangement of the guest molecules is supported by the fact that the basal spacing of the *p*-tolunitrile intercalate is about 2 Å higher than that of the benzonitrile intercalate. Quantum chemical calculations support the results of the IR and Raman spectroscopy indicating the formation of the C≡N→V donor-acceptor bond in the intercalates.

Experimental Section

Preparation: The intercalation compounds were obtained by a displacement reaction. The solid 2-propanol intercalate[10] was prepared in advance and used as a starting material for the reaction with the corresponding aromatic nitrile. The 2-propanol intercalate (0.5 g) was suspended in 10 mL of benzonitrile or molten *p*-tolunitrile and heated in a microwave field for 10 min. The samples were washed with toluene, dried in vacuo, and stored in a sealed evacuated ampoule.

XRD: Powder data were obtained with a D8 Advance X-ray diffractometer (Bruker AXS, Germany) using Cu-K_α radiation with a graphite secondary monochromator. Diffraction angles were measured from 5 to 50° (2θ). The samples were kept under a protection foil during the measurements and the signal of this foil in the diffractograms was compensated.

Thermogravimetry: The TG analyses were performed using a Derivatograph C (MOM Budapest, Hungary). The measurements were carried out in air between 20 and 700°C at a heating rate of 5 $K \cdot min^{-1}$.

IR Spectral Measurements: IR spectra in the range 400−4000 cm^{-1} were measured with a fully computerized Nicolet IMPACT 400 FTIR spectrometer (300 scans per spectrum at 2 cm^{-1} resolution). Measurements were performed in the transmission mode on a KBr pellet and a Nujol suspension for the intercalates and by the ATR technique on a ZnSe crystal for pure liquid guest-molecules. The spectra were corrected for the H_2O and CO_2 content in the optical path.

Raman Spectral Measurements: FT Raman spectra were collected using a Fourier transform near-infrared (FT-NIR) spectrometer Equinox 55/S (Bruker) equipped with FT Raman module FRA 106/S (Bruker) (128 interferograms were co-added per spectrum in the range 4000 to −1000 cm^{-1} at 4 cm^{-1} resolution).

Modeling: The strategy of the modeling was based on the quantum chemical geometry optimization of model compounds representing local structures and interactions appearing in the intercalates of vanadyl phosphate with nitriles. Quantum chemical calculations were carried out at the ab initio and semiempirical levels of theory employing the Gaussian 98[15] and MOPAC 2002[16] program packages, respectively. Local interactions and structures in intercalates of vanadyl phosphate with the nitrile group were studied at the DFT level using the B3LYP functional and 6-31G(d) basis set, geometrical optimization of larger structures including two vanadyl phosphate layers and five benzonitrile or *p*-tolunitrile molecules were performed at the semiempirical level using the PM3 method.

COVER PICTURE

The cover picture shows a chain of seven metal atoms parallel to a chain of Chinese friendship symbols (locks which people like to fix at high lookout points and then throw the keys down). The background photo was taken in the Chinese Huangshan mountains, but it relates to friendship grown in Fraiburg, Germany, and symbolizes a truly international scientific collaboration. As a result, the Chinese author of this paper has prepared the chainlike Fe–C–N–Ni–Ni–Ni–Ni–Ni–N–C–Fe complex, while the senior author is the godfather of his daughter, the energetic baby with the name Freia, pregnant with meaning. Details are discussed in the article by H. Vahrenkamp et al. on p. 3731 ff.

(Alkyl)(monocyclopentadienyl)niobium and -tantalum Complexes in Insertion Processes

Manuel Gómez[a]

Dedicated to Professor Pascual Royo on the ocassion of his 65th birthday

Keywords: Niobium / Tantalum / Cyclopentadienyl ligands / Insertions

Alkyl high-valent early transition metal compounds are important organometallic species, particularly because their reactions with unsaturated molecules, such as carbon monoxide and organic isocyanides, are relevant to several industrial stoichiometric and catalytic processes. Recently, we have reported several studies concerning (alkyl)(monocyclopentadienyl) derivatives of group-5 metals, including both synthetic aspects and chemical behaviour in insertion reactions. This Microreview is an account of this work, covering syntheses, structure, spectroscopic, and reactivity details that have been reported by us together with the most significant contributions from other authors.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The transfer of alkyl groups from transition metal atoms to coordinated unsaturated molecules,[1] such as carbon monoxide and isocyanides, is an important organometallic reaction that has been the subject of relevant synthetic, mechanistic and theoretical studies.[2] Further, the resulting η^2-acyl− and η^2-iminoacyl−metal functionalities constitute a powerful strategy for C−C bond formation under mild reaction conditions and are versatile reactive intermediates in many transition-metal-promoted stoichiometric and catalytic organometallic transformations.[3]

Compared with the η^2-acyl moiety, the reactivity of the η^2-iminoacyl group is even more versatile because it can be transformed into metallacyclic imines,[2d,2f,2h,2k] azaallyl complexes,[3i,3j,3k] and aminocarbyne derivatives[3f] or may participate in alkyne coupling processes[3g] and double[3e,3i,3j,3k] or multiple[3e,3i,3j,3k] isocyanide insertion reactions. It may also be transformed into azametallacyclopropane species, which give imido complexes[2e] by thermal decomposition. These reactions[2c,2d,2j,3g] are profoundly dependent on both the metal and the nature of its substituents, particularly on the number of metal-bound alkyl groups that can participate in the reaction. In this context, a systematic study[4] of isocyanide insertion reactions into methyl−tantalum bonds of different chloro(methyl)(pentamethylcyclopentadienyl) derivatives ($TaCp^*Cl_{4-x}Me_x$) led us to isolate a series of (η^2-iminoacyl)- ($x = 1$) and dichloroazatantalacyclopropane ($x = 2$) as well as chloro- and (methyl)(alkenylamido)(imido) ($x = 3, 4$) complexes.

This Microreview aims to systematically overview the synthetic methods of producing different alkyl(monocyclopentadienyl)niobium- and -tantalum(v) derivatives and also their behaviour in insertion reactions, as well as provid-

Manuel Gómez was born in Cieza (Murcia, Spain) in 1954. He received his Diploma in Chemistry at the University of Murcia in 1976 and his Ph.D. in 1981 from the University of Alcalá de Henares working in the field of coordination and organometallic chemistry with Professor Pascual Royo. He was a postdoctoral fellow at the University of Sheffield in 1982−1983 under the supervision of Professor Peter M. Maitlis. He subsequently joined the Inorganic Chemistry Department at the University of Alcalá de Henares where he is Professor of Inorganic Chemistry, a position he has held since 1985. His main research interests are in the field of organometallic chemistry, with an emphasis on synthesis, reactivity and applications of mono(cyclopentadienyl)niobium and -tantalum complexes.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

ing some data on intra- or intermolecular rearrangement processes of the insertion products.

Results and Discussion

Synthesis of Dichloro Complexes

The studies described here start with dichloro(imido)-, dialkyldichloro-, (alkyne)dichloro-, and (diazabutadiene)dichloro(monocyclopentadienyl)niobium and -tantalum complexes. Recent years have witnessed an extensive development of imido group-5 metal chemistry containing monofunctional,[5] tetradentate triamidoamine,[6] and cyclopentadienyl ligands in mono-[7] and dicyclopentadienyl-type[8] complexes. Protonated lithium amides[7b] have been extensively used to generate the imido ligand, but other synthetic strategies have been based on the deprotonation of cyclopentadiene by metal amides,[7e,8c] β-hydrogen elimination of amides and amines coordinated to metal(III) compounds[8a,8b] and oxidation of metal(III) complexes with azides.[8b] Related alkoxyimido and hydrazido(2−) derivatives have been reported[9] more recently.

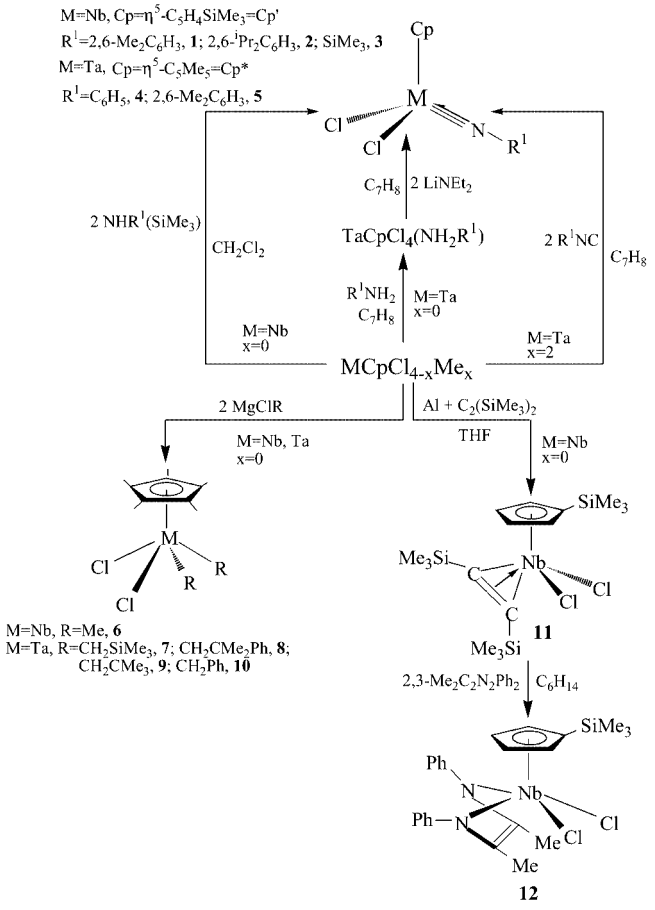
Pseudo-tetrahedral dichloro(imido) compounds **$MCpCl_2(NR^1)$** (M = Nb,[10] Cp = η^5-$C_5H_4SiMe_3$ = Cp′, R^1 = 2,6-$Me_2C_6H_3$, **1**; 2,6-*i*$Pr_2C_6H_3$, **2**; $SiMe_3$, **3**; M = Ta, Cp = η^5-C_5Me_5 = Cp*, R^1 = C_6H_5, **4**;[11] 2,6-$Me_2C_6H_3$, **5**[4]) can be easily obtained from the corresponding tetrachloro derivative $MCpCl_4$ (Scheme 1). Complex **5** was prepared by reacting $TaCp^*Cl_2Me_2$[12] with 2 equiv. of 2,6-$Me_2C_6H_3NC$ in toluene as described previously.[4c]

Dialkyldichloro complexes **$MCp^*Cl_2R_2$** (M = Nb, R = Me, **6**;[13c] M = Ta, R = CH_2SiMe_3, **7**;[13d] CH_2CMe_2Ph **8**;[13d] CH_2CMe_3, **9**;[13a,13b] CH_2Ph, **10**[13a,13b]) have been obtained by treating *n*-hexane suspensions of the MCp^*Cl_4 complex with stoichiometric amounts of the Grignard reagents MgClR (R = Me, CH_2SiMe_3, CH_2CMe_2Ph, CH_2Ph) or $Mg(CH_2CMe_3)_2(THF)_2$ under rigorously anhydrous conditions at room temperature (Scheme 1).

The (alkyne)dichloro complex **$NbCp'Cl_2(Me_3SiCCSiMe_3)$**, **11**[14] has been synthesized in high yield by treating $NbCp'Cl_4$ with an excess of aluminium powder and mercury(II) chloride in the presence of 1 equiv. of bis(trimethylsilyl)acetylene. Additionally, the reaction of **11** with 2,3-dimethyl-1,4-diphenyl-1,4-diazabuta-1,3-diene (Me,Ph-DAD) in hexane leads to the (diazabutadiene)dichloro complex **$NbCp'Cl_2$(Me,Ph-DAD)**, **12**[15] with elimination of $C_2(SiMe_3)_2$ (Scheme 1). Related DAD complexes[16] have been, essentially, isolated by treatment of the corresponding half-sandwich complexes $NbCpCl_4$ (Cp = η^5-C_5H_5, η^5-C_5Me_5) with a dilithium salt of the different DAD ligands.

Synthesis of Alkyl Complexes

Although the imido ligand has been employed as an ancillary group to support high-oxidation state metal centres,[17] these complexes can be made highly reactive in terms of synthesizing coordinatively unsaturated derivatives containing multiple π-bonded ligands. Further, an increasing number of complexes having reactive imido ligands have been shown to participate in C−H activation[18] and cycloaddition reactions.[19] Conversely, reactions based on carbon−carbon bond formation have led to many important synthetic applications of organo group-5 metal complexes by migration of methyl substituents to unsaturated isocyanide[4,20] and carbonyl[20a] ligands through the intermediate formation of (iminoacyl)- and (acyl)metal compounds, respectively. Whereas the chemistry of (cyclopentadienyl)(halo)(imido)niobium and -tantalum complexes is well defined, the alkyl derivatives are less well known although a great number of related amido and alkoxide complexes have been reported recently. Following our preliminary work on the dichloro- and chloro(methyl)(imido) derivatives[4b,20a] we reported a systematic study on the reactivity of (arylimido)(monocyclopentadienyl)niobium and -tantalum complexes towards alkylating reagents.



Scheme 1. Synthesis of dichloro complexes

Thus, the reactions of the dichloro complexes **1** and **5** with a stoichiometric amount of the alkylating reagent gave solutions from which the alkyl(chloro)imido complexes **$MCpClR(NR^1)$** [R^1 = 2,6-$Me_2C_6H_3$; M = Nb,[10] Cp = Cp′, R = Cp*, **13**; Me, **14**; M = Ta, Cp = Cp*, R = Me, **15**;[10] CH_2SiMe_3, **16**;[21] CH_2CMe_2Ph, **17**;[21] CH_2CMe_3, **18**;[21] $CH_2C_6H_5$, **19**;[21] 2-$(CH_2NMe_2)C_6H_4$, **20**;[21] Cp′,

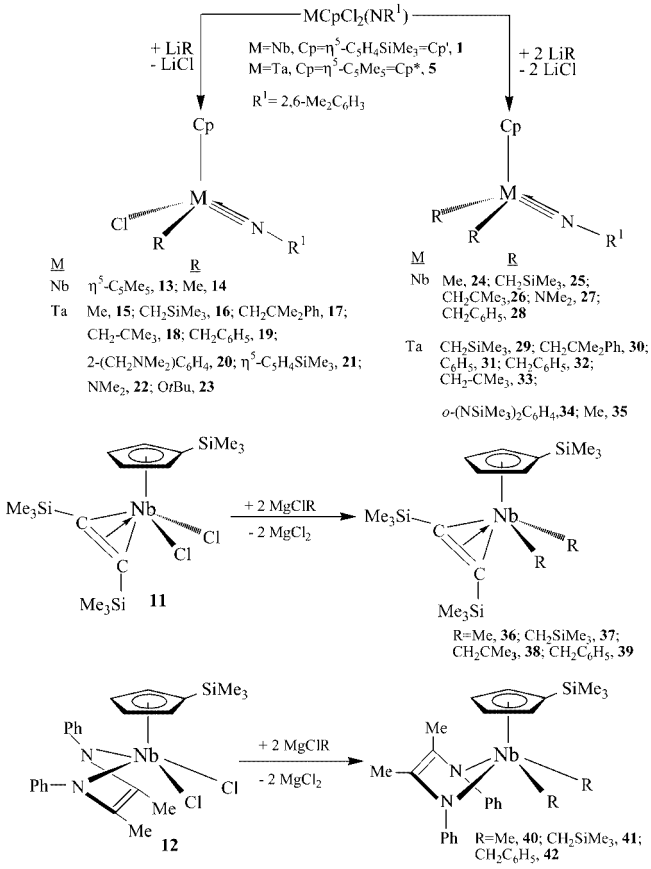
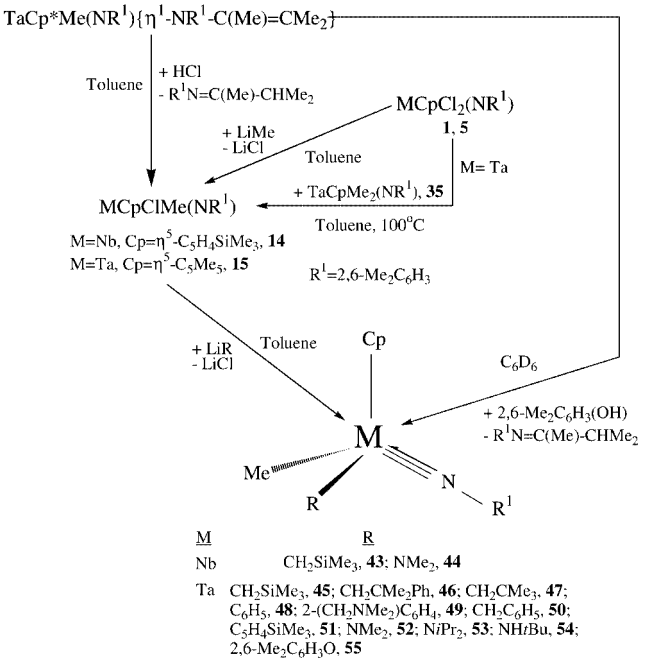
21;[21] NMe_2, **22**;[10] O*t*Bu, **23**[10]] and dialkyl(imido) complexes **$MCpR_2(NR^1)$** [R^1 = 2,6-$Me_2C_6H_3$; M = Nb,[10] Cp = Cp′, R = Me, **24**; CH_2SiMe_3, **25**; CH_2CMe_3, **26**; NMe_2, **27**; $CH_2C_6H_5$, **28**; M = Ta, Cp = Cp*, R = CH_2SiMe_3, **29**;[21] CH_2CMe_2Ph, **30**;[21] C_6H_5, **31**;[21] $CH_2C_6H_5$, **32**;[21] CH_2CMe_3, **33**;[21] *o*-$(NSiMe_3)_2C_6H_4$, **34**;[10] Me, **35**[20a]] were isolated. Alternatively, the chloro(methyl)(imido)tantalum derivative **15** can be prepared[21] by treating the (alkenylamido)imido(methyl) complex [TaCp*Me(NR^1){η^1-NR^1-C(Me)=CMe_2}] (R^1 = 2,6-$Me_2C_6H_3$)[4c] with HCl or by a redistribution[21] reaction between the corresponding dichloro- (**5**)[4c] and dimethyl- (**35**)[20a] (imido)tantalum derivatives (Scheme 2).



Scheme 2. Synthesis of alkyl(chloro) and dialkyl complexes

Conversely, dialkyl(alkyne) derivative **$NbCp'R_2(Me_3Si$-$CCSiMe_3)$**[14] (R = Me, **36**; CH_2SiMe_3, **37**; CH_2CMe_3, **38**; $CH_2C_6H_5$, **39**) and dialkyl(diazabutadiene) derivative **$NbCp'R_2(\eta^2$-$Ph_2N_2C_2Me_2$-2,3)**[15] (R = Me, **40**; CH_2SiMe_3, **41**; $CH_2C_6H_5$, **42**) were, respectively, isolated in good yields by alkylation of the dichloro complexes **11** and **12** with Grignard reagents in a 1:2 molar ratio (Scheme 2).

As shown in Scheme 3, the mixed alkylated imido compounds **MCpRMe(NR^1)** [R^1 = 2,6-$Me_2C_6H_3$; M = Nb,[10] Cp = Cp′, R = CH_2SiMe_3, **43**; NMe_2, **44**; M = Ta, Cp = Cp*, R = CH_2SiMe_3, **45**,[21] CH_2CMe_2Ph, **46**;[21] CH_2CMe_3, **47**;[21] C_6H_5, **48**;[21] 2-$(CH_2NMe_2)C_6H_4$, **49**;[21] $CH_2C_6H_5$, **50**;[21] Cp′, **51**;[21] NMe_2, **52**;[10] N*i*Pr_2, **53**;[10] NH*t*Bu, **54**;[10] 2,6-$Me_2C_6H_3O$, **55**[10]] were obtained from the starting chloro(methyl)imido complexes **14** and **15** by reactions with the corresponding alkylating reagent, except for the methyl(imido) phenoxide complex **55** which was synthesized by treating the alkenylamido(imido)methyltantalum derivative [TaCp*Me(NR^1){η^1-NR^1-C(Me)=CMe_2}] (R^1 = 2,6-$Me_2C_6H_3$)[4c] with 2,6-$Me_2C_6H_3$(OH). Related alkyl, amido, and imido alkoxide derivatives of different stoichiometries such as *monoalkyl compounds* MCpClR(NR^1) [M = Nb, Cp = η^5-C_5H_5, R = Me, R^1 = *t*Bu;[7c] 2,6-$Me_2C_6H_3$;[22d] 2,6-*i*$Pr_2C_6H_3$;[7c,22d] R = CH_2Ph, NH*t*Bu, R^1 = 2,6-*i*$Pr_2C_6H_3$;[22a,22d] R = NHR^1,[22d] R^1 = *t*Bu; 2,6-$Me_2C_6H_3$; R = NEt_2, R^1 = *t*Bu;[22d] R = $CH_2CH=CH_2$, $CH_2C(Me)=CH_2$, R^1 = *t*Bu;[22b] Cp = η^5-$C_5H_4SiClMe_2$;[7h,22c] η^5-$C_5H_4SiClMePh$,[7c] R = CH_2Ph, R^1 = *t*Bu; Cp = η^5-$C_5H_4SiMe_2NH$*t*Bu,[7h] R = CH_2Ph, NH*t*Bu, R^1 = *t*Bu; M = Ta,[22f] Cp = η^5-C_5Me_5, R = Me, NH*t*Bu, R^1 = *t*Bu], *dialkyl compounds* $MCpR_2(NR^1)$ (M = Nb, Cp = η^5-C_5H_5, R = NHR^1, R^1 = 2,6-$Me_2C_6H_3$;[22e] R = Ph, R^1 = 2,6-*i*$Pr_2C_6H_3$;[22a] R = *t*BuO; 2,6-Me_2-C_6H_3O, R^1 = Me;[7a] R = 2,6-*i*$Pr_2C_6H_3O$; 2,6-$Ph_2C_6H_3O$, R^1 = *t*Bu;[7a] Cp = η^5-C_5Me_5, R = Me,[7c] CH_2Ph,[22a] R^1 = 2,6-*i*$Pr_2C_6H_3$; Cp = η^5-$C_5H_4CMe_2C_9H_7$, R = NEt_2, R^1 = 2,6-*i*$Pr_2C_6H_3$;[22e] Cp = η^5-$C_5H_4SiMeXY$, X = Cl, CH_2Ph, Y = Me,Ph; X = Me, Y = NH*t*Bu; R = CH_2Ph, R^1 = *t*Bu;[7h] M = Ta, Cp = η^5-C_5Me_5, R^1 = *t*Bu;[2d] 2,6-*i*$Pr_2C_6H_3$[7c]) and *mixed alkyl* compounds $MCpRR'(NR^1)$ [M = Nb, Cp = η^5-C_5H_5, R = Me, R′ = NH*t*Bu, R^1 = 2,6-*i*$Pr_2C_6H_3$;[22d] R = NH*t*Bu, R′ = *n*Bu, NEt_2, σ-C_5H_5, R^1 = *t*Bu;[22d] R = Me, R′ = NHR^1, R^1 = 2,6-Me_2-C_6H_3;[22e] M = Ta, Cp = η^5-C_5Me_5, R = Me, R′ = NMe_2, NHMe, $OOCNMe_2$, OOCNH*t*Bu, R^1 = *t*Bu;[22g] R = Me, R′ = OMe, O*t*Bu, NH*t*Bu, R^1 = *t*Bu;[22f] R = Me, R′ = NPh_2, $N(SiMe_3)_2$ [22h]] have been reported.



Scheme 3. Synthesis of alkyl(methyl)imido complexes

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Complexes **1**−**55** are air- and moisture-sensitive and soluble in most organic solvents, including saturated hydrocarbons, except that dichloro(diazabutadiene) complex **12** is insoluble in hexane.

Imido complexes **1**−**5**, **13**−**35**, and **43**−**55** are monomers, pseudotetrahedral, and isostructural with other half-sandwich imido group-5 metal derivatives.[7a,23] The formulation as dichloro- **1**−**5**, (alkyl)chloro- **13**−**23**, dialkyl- **24**−**35**, and alkyl(methyl)- **43**−**55** -(imido) complexes is supported by analytical and spectroscopic data (IR, and ^{1}H and ^{13}C{^{1}H} NMR) that show the expected behaviour for such prochiral, chiral, prochiral and chiral species, respectively. Further, the molecular structure of **21** (Figure 1) shows a typical bent-metallocene moiety with the chlorine atom and the imido group lying in the equatorial plane. Although the two Cp rings differ, the distance from the tantalum atom to both centroids is the same, the angles between the equatorial plane and the mean Cp planes are also equivalent, and the bonding of both Cp rings to the metal centre is very similar. The Ta1−N1 distance of 1.803(4) Å is very similar to those of the closely related complexes [TaCp*$_2$X(NPh)] [X = Cl: 1.799(4) Å;[8a] X = H: 1.831(10) Å[9c]] and the Ta1−N1−C41 angle, 174.6(3)°, is almost linear. These data are consistent with a Ta−N bond order of about 2, in an 18-electron configuration at the metal centre,[24] and an sp nitrogen atom with a lone pair of electrons involved in bonding with the phenyl substituent centred on it.

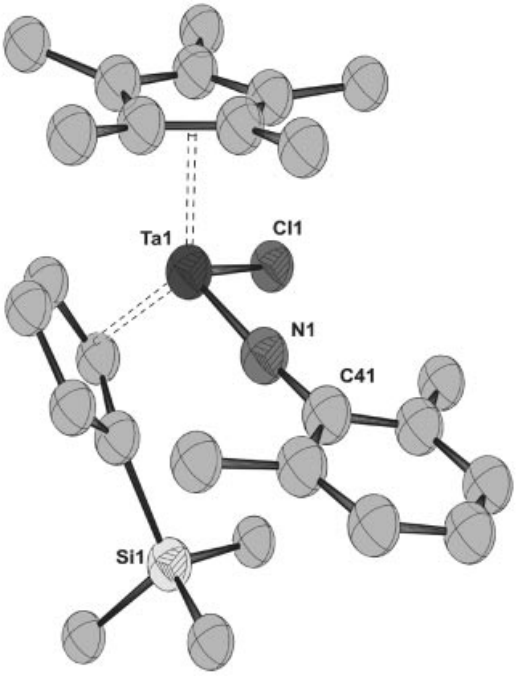


Figure 1. Molecular structure and atom labelling scheme for **[TaCp*Cp′Cl(NR^1)]** (Cp* = η^5-C_5Me_5; Cp′ = η^5-$C_5H_4SiMe_3$; R^1 = 2,6-$Me_2C_6H_3$, **21**)

The dichloro- **11** and dialkyl- **36**−**39** -(alkyne) complexes are monomers with a C_s symmetry and spectroscopic properties that are basically similar to those reported for metallacyclopropene derivatives[25,26] in which the alkyne ligand acts as a four-electron donor. The IR spectra show an absorption band for the stretching vibration $\nu_{(C=C)}$ ($\tilde{\nu} \approx$ 1582 cm^{-1}) in accordance with the hybridization change of the carbon atoms in the alkyne ligand,[26,27] whereas ^{13}C{^{1}H} NMR chemical shifts for the acetylenic carbon atoms appear to be $\delta \approx 244$.[28] Complex **37** (Figure 2) can be described as a monomer with a typical three-legged piano-stool environment for the niobium atom, assuming that the centroid of the alkyne ligand occupies a single coordination site. Notable are the perpendicular disposition of the alkyne ligand with respect to the $C_5H_4SiMe_3$ ring and the plane formed by the alkyl substituents at the niobium centre. The average Nb−C_{alkyne} distance is 2.090(6) Å and C41−C51 is 1.323(7) Å, values just within the range expected for a four-electron-donor alkyne ligand,[26,29] in which the C−C bond order is less than 3. Conversely, the DFT theoretical data[14] corresponding to the dichloro- and dimethyl(acetylene) compounds $NbCpR_2(HCCH)$ (R = Cl, Me) agree with a preferential disposition of the alkyne ligand lying perpendicular to the Cp plane, such as that observed for complex **37**.

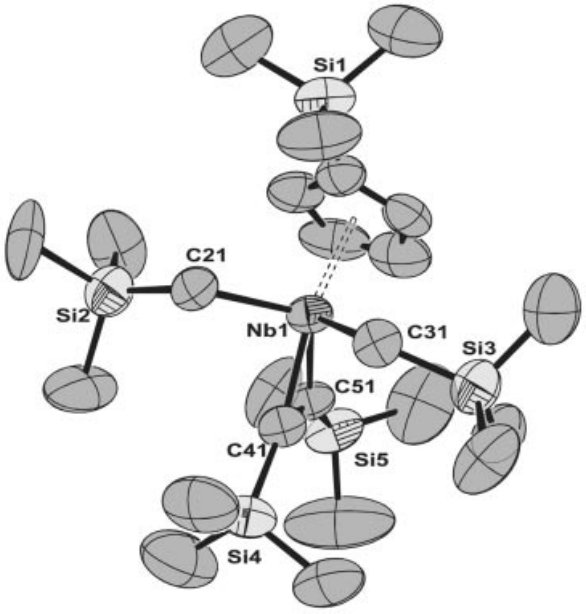

Figure 2. Molecular structure and atom labelling scheme for **[NbCp′R$_2$(Me$_3$SiCCSiMe$_3$]** (Cp′ = η^5-$C_5H_4SiMe_3$; R = CH_2SiMe_3, **37**)

The NMR spectroscopic data of complex **12** suggest that the (ene)diamido ligand adopts a *supine* conformation with respect to the (trimethylsilyl)cyclopentadienyl ring (Scheme 2), which accords with studies by Mashima et al.[30] on the geometric preferences of 1,4-diazadiene ligands in half-sandwich metallocene complexes of early transition metals. Furthermore, detailed DFT analysis of the fragment orbital interactions in the model complex $NbCpCl_2(HNCHCHNH)$ provides no evidence for positive overlap between the niobium centre and the inner carbon atoms of the DAD ligand.[15] The ^{1}H NMR spectrum of **40**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

displays a singlet at δ = 0.15 due to the Nb−Me, and shows an AB spin system for the diastereotopic α-CH_2 protons of alkyl groups in complexes **41** and **42**. The singlet δ = 1.75 due to the methyl substituents of the (ene)diamido ligand is at higher field than the δ = 1.84 ppm of the starting dichloro complex **12**. The ^{13}C resonances of the inner carbon atoms also show a high field displacement. These data, along with the preferential orientation discussed by Mashima et al.[30] in related complexes, suggest that the alkylation reactions of the dichloro complex involve an orientation change in the (ene)diamido ligand from the *supine* conformation in **12** to the *prone* form in the dialkyl derivatives **40**−**42**.[16d]

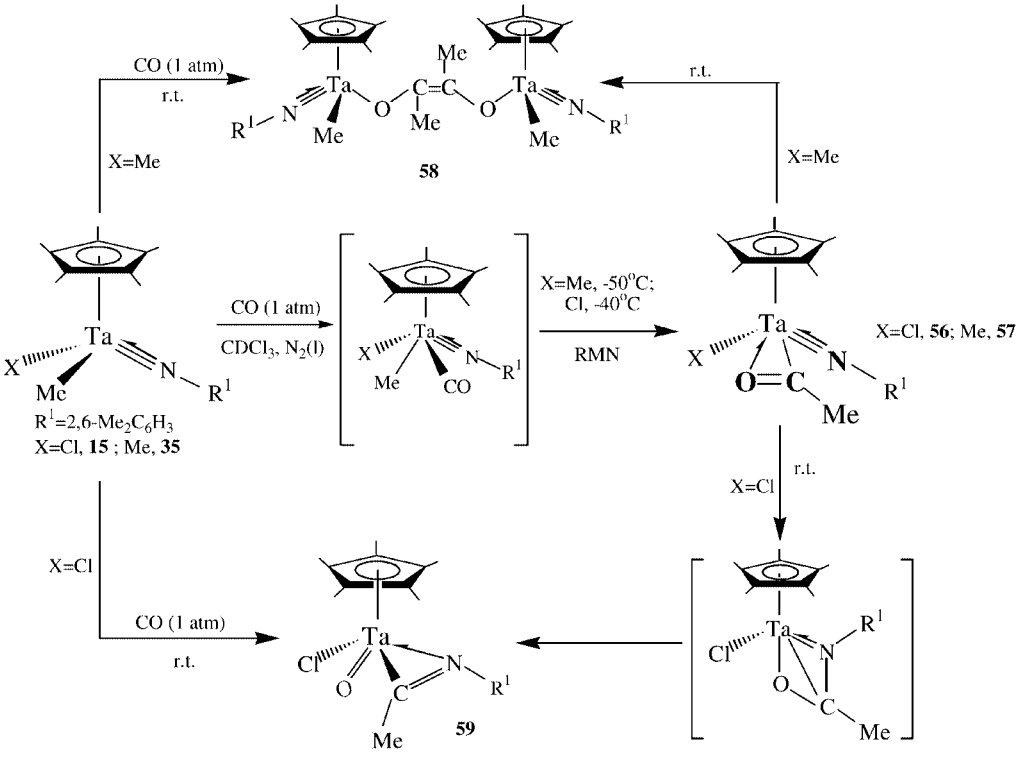
Insertion Processes

Reactions with Carbon Monoxide

Dimethyl(imido) complex **35** reacts with carbon monoxide (1 atm) at room temperature in toluene to give the dinuclear μ-enediolate complex **[{TaCp*Me(NR^1)}$_2${μ-η^2-OC(Me)=C(Me)O}]** (R^1 = 2,6-$Me_2C_6H_3$, **58**)[20a] in good yield. This takes place by intermolecular coupling between two acyl carbon atoms of the intermediate η^2-acyl(methyl)imido derivative **[TaCp*Me(NR^1){η^2-C(Me)=O}]** (R^1 = 2,6-$Me_2C_6H_3$, **57**),[20a] (Scheme 4) whose formation can be observed in situ by NMR spectroscopy[31] at low temperatures. Complex **57** is quantitatively transformed into the enediolate species **58** on heating to room temperature, preventing its isolation as a solid.

With the chloro(methyl)imido complex **15** as starting material the expected η^2-acyl(imido) derivative was not obtained, since it was spontaneously converted into the chloro(η^2-methyliminoacyl)oxo complex **[TaCp*Cl(O){η^2-C(Me)=NR^1}]** (R^1 = 2,6-$Me_2C_6H_3$, **59**).[20a] The formation of **59** can be explained (Scheme 4) by assuming the initial coordination of CO, followed by migration of the methyl group bonded to the metal atom to the electrophilic carbonyl carbon atom to give the scarcely stable intermediate η^2-acyl(chloro)imido complex **[TaCp*Cl(NR^1){η^2-C(Me)=O}]** (R^1 = 2,6-$Me_2C_6H_3$, **56**),[20a] which was identified in solution by NMR spectroscopy[31] at −40 °C. Nucleophilic attack of the imido nitrogen atom at the electrophilic acyl carbon atom leads to an unidentified intermediate species that spontaneously rearranges, breaking the C−O bond with simultaneous formation of M−C single and M=O double bonds to give the final chloro(η^2-methyliminoacyl)oxo compound **59**. Complex **59** is chiral and its structure (Figure 3) shows the tantalum centre in a three-legged piano-stool environment, assuming that the centroid of the Cp* ring and the centroid of the iminoacyl group is taken as occupying a single coordination site. The η^2-iminoacyl group is coordinated in a similar mode to that in related complexes[4c] with Ta−C1 and Ta−N1 distances of 2.133(9) and 2.132(7) Å, respectively, corresponding to single bonds, and a C1−N1 distance of 1.276(11) Å, which implies double-bond character. The oxygen ligand−tantalum atom bond of 1.731(7) Å is in the range reported for Ta=O double bonds.[32]

As well as alkyl (methyl) groups, the alkyl(chloro)- (**17**, **18**, **22**), dialkyl- (**29**−**33**), and alkyl(methyl)- (**46**, **47**, **49**) -imidotantalum complexes [TaCp*XR(NR^1)] (R^1 = 2,6-$Me_2C_6H_3$) also react with carbon monoxide (1 atm) at



Scheme 4. Insertion reactions of carbon monoxide

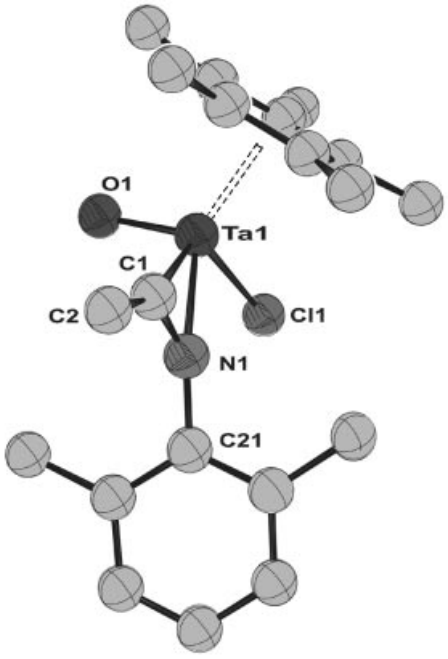

Figure 3. Molecular structure and atom labelling scheme for **[TaCp*Cl(O){η²-C(Me)=NR¹}]** (Cp′ = η⁵-C_5Me_5; R^1 = 2,6-$Me_2C_6H_3$, **59**)

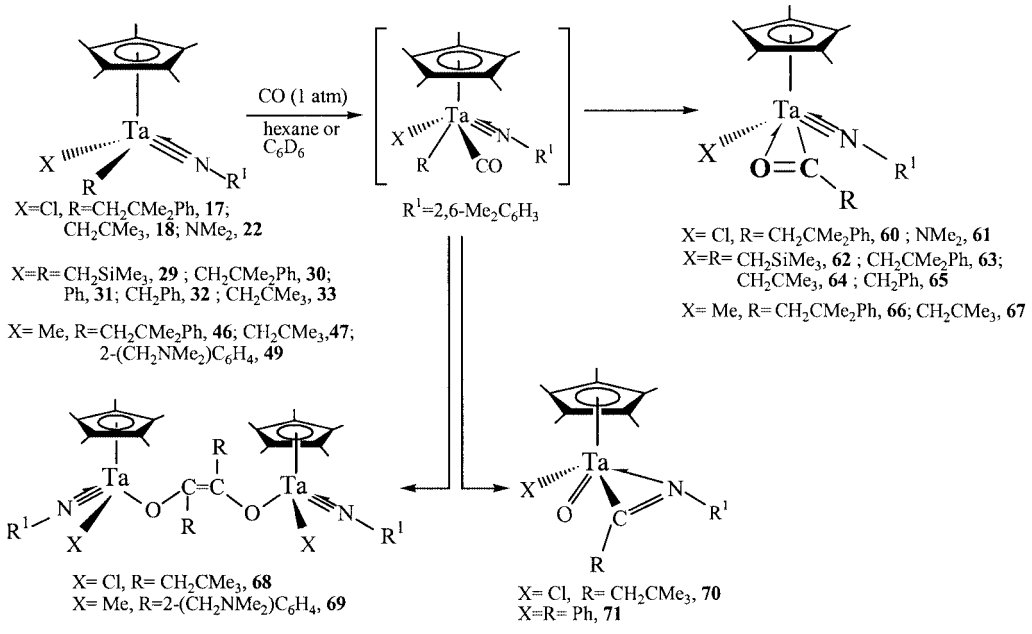
room temperature in hexane or [D_6]benzene (NMR tube scale) to give η²-acyl(chloro)- (X = Cl, R = CH_2CMe_2Ph, **60**), (η²-carbamoyl)chloro- (X = Cl, R = NMe_2, **61**), (η²-acyl)alkyl- (X = R = CH_2SiMe_3, **62**; CH_2CMe_2Ph, **63**; CH_2CMe_3, **64**; CH_2Ph, **65**), and (η²-acyl)methyl- (X = Me, R = CH_2CMe_2Ph, **66**; CH_2CMe_3, **67**) -imido complexes **[TaCp*X(NR¹){η²-C(R)=O}]** (**60**−**67**)[33] (Scheme 5), as result of migration of the alkyl group bonded to the metal atom to the electrophilic carbonyl atom of the previously coordinated CO ligand. The regioselective synthesis of the (η²-acyl)methyl complexes **66** and **67** reflects the preferential migration of CH_2CMe_2Ph and CH_2CMe_3 groups with respect to the methyl group, which accords with the sequence established for the isocyanide insertion process.[33]

When X = Cl, R = CH_2CMe_3 (**18**) and X = Me, R = 2-(CH_2NMe_2)C_6H_4 (**49**) the η²-acyl derivatives can neither be isolated nor detected by ^{1}H NMR spectroscopy due to their very low stability; however, the dinuclear μ-enediolate complexes **[{TaCp*X(NR¹)}₂{μ-η²-OC(R)=C(R)O}]** [R^1 = 2,6-$Me_2C_6H_3$; X = Cl, R = CH_2CMe_3, **68**; X = Me, R = 2-(CH_2NMe_2)C_6H_4, **69**] are easily obtained when the corresponding chloro- or methyl(alkyl)imido complex reacts with CO under the same conditions (Scheme 5), probably by intermolecular coupling between two acyl carbon atoms of the unstable intermediate η²-acyl complexes "[TaCp*X(NAr){η²-C(R)=O}]", which could not be observed in situ by ^{1}H NMR spectroscopy.[20a] The same reaction with CO but using [TaCp*XR(NR^1)] (R^1 = 2,6-$Me_2C_6H_3$; X = Cl, R = CH_2CMe_3, **18**; X = R = Ph, **31**) as starting materials failed to give the expected (η²-acyl)imido derivatives as they were spontaneously converted into the (η²-iminoacyl)oxo complexes **[TaCp*X(O){η²-C(R)=NR¹}]** after 35 d (X = Cl, R = CH_2CMe_3, **70**) and 12 h (X = R = Ph, **71**), respectively (Scheme 5); the formation of these products can be explained as with the analogous chloro(methyl)imidotantalum derivatives.[20a]

When X = Cl and R = CH_2SiMe_3, **16**; CH_2Ph, **19**; and X = Me and R = CH_2SiMe_3, **45**; Ph, **48**; CH_2Ph, **50** the reaction with CO leads to an unidentified mixture of products, whereas for X = Cl, R = 2-(CH_2NMe_2)C_6H_4, **20** there is no reaction, even on heating at 100 °C.

The dimethyl complexes [TaCp*Cl_2Me_2] (**72**)[12] and [NbCp′Me_2(Me,Ph-DAD)] (**40**) react with carbon monoxide (1 atm) at room temperature in [D_6]benzene and toluene



Scheme 5. Insertion reactions of carbon monoxide

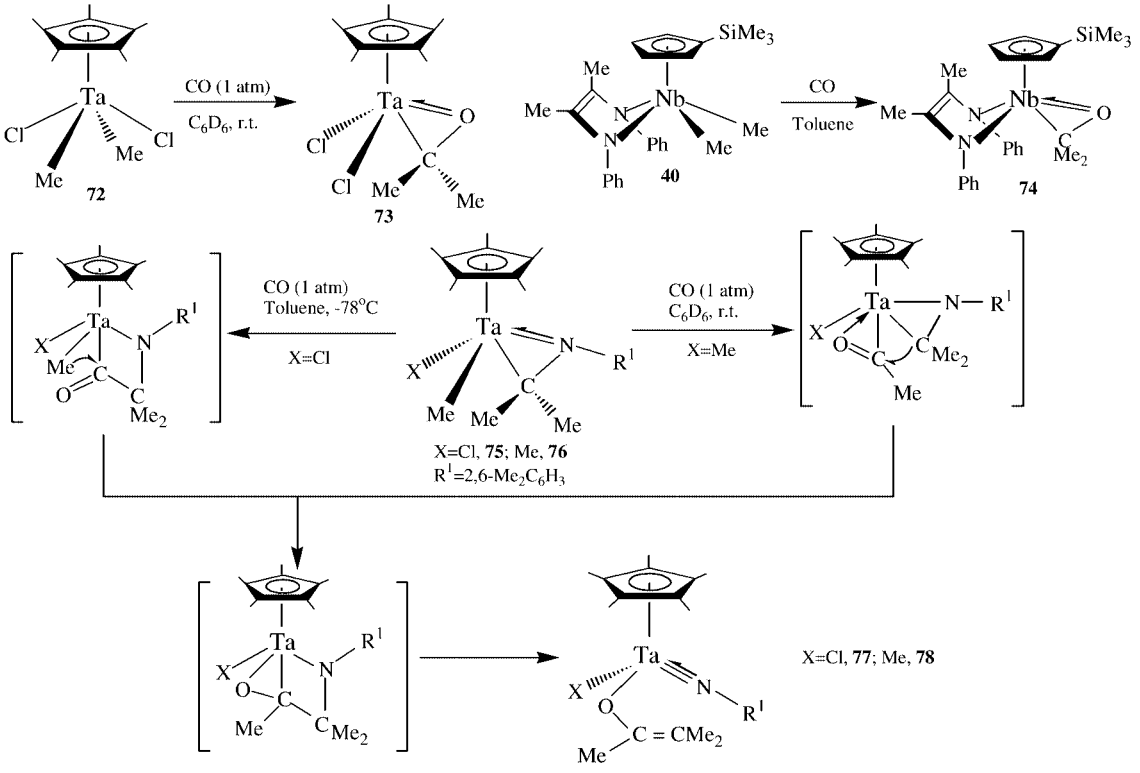

Scheme 6. Insertion reactions of carbon monoxide

to give the oxametallacyclopropane complexes **[TaCp*Cl_2(η^2-CMe_2-O)]** (**73**)[20a] and **[NbCp′(η^2-CMe_2-O)(Me,Ph-DAD)]** (**74**),[15] respectively, by double migration of two methyl groups, first to the electrophilic carbon atom of the coordinated CO ligand and then to the related η^2-acyl intermediate, which could not be detected (Scheme 6). The oxametallacyclopropane moiety, which is not further transformed, is analogous to that reported for the (acetone)tantalum complex [TaCp*Me_2(η^2-CMe_2-O)].[2d,34]

Conversely, the azatantalacyclopropane complexes [TaCp*XMe(η^2-CMe_2NR^1)] (R^1 = 2,6-$Me_2C_6H_3$; X = Cl, **75**; Me, **76**)[4b] react with 1 equiv. of CO, leading to the pseudotetrahedral enolate derivatives **[TaCp*X(NR^1){η^1-OC(Me)=CMe_2}]** (X = Cl, **77**; Me, **78**)[20a] (Scheme 6), probably by formation of intermediate species that could not be detected in situ by ^{1}H NMR spectroscopy.

All spectroscopic data for compounds **56**−**78** are consistent with their formulation. The (η^2-acyl)imido complexes **56**, **57** and **60**−**67** show $\nu_{Ta=N}$[7a,35] and $\nu_{C(R)=O}$[1d,36] at $\tilde{\nu} \approx$ 1327 and 1589 cm^{-1}, respectively. The C=O stretching vibration in η^2-acyl compounds ranges from 1453 to 1625 cm^{-1} and the lowest stretching frequencies occur for η^2-acyl complexes containing high-valent metal atoms (as we also found). This has been attributed to the participation of a "carbene-like" resonance form[37] or to the contribution of a "carbenium-ion-like" acceptor orbital on the undistorted η^2-acyl structure.[38] The η^2-acyl[39] and η^2-carbamoyl[40] (**61**) carbon resonances appear at $\delta \approx$ 317 and 228 ppm, respectively, in the typical ranges for both types of complexes. The η^2-acyl(methyl)imido complex **66** (Figure 4) is a monomer with a chiral tantalum atom in a typical four-legged piano-stool environment. The imido ligand is bonded to the metal centre in an almost linear disposition[4a,20a] with a Ta1−N1 bond length and a Ta1−N1−C21 bond angle of 1.815(11) Å and 172.2(10)°, respectively. The bonding system between the η^2-acyl moiety and the metal centre is similar to that of the trichloro derivative [TaCp*Cl_3\{η^2-C(CH_2CMe_3)=O\}],[41] but in our case the Ta1−C31 [2.126(14) Å] and Ta1−O1 [2.214(11) Å] bond lengths are slightly longer due to the different donor capacities and the *trans* influence of the chloride and imido ligands.

The μ-enediolates **58**, **68**−**69**, the (η^2-iminoacyl)oxo compounds **59**, **70**−**71**, the oxametallacyclopropanes **73** and **74**, and the enolate complexes **77** and **78** show the expected structural behaviour according to IR and NMR spectroscopy.

Reactions with 2,6-Dimethylphenyl Isocyanide

Several years ago we reported a systematic study[4] on the insertion of isocyanides into Ta−C(methyl) bonds of various chloro methyl derivatives, TaCp*$Cl_{4-x}Me_x$. When x = 2 azatantalacyclopropane species are formed in which the imine linkage typically binds strongly to the metal centre in an η^2-CN fashion.[2,42] These complexes have been postulated as intermediates in organometallic transformations[2a,2g,2i,20a] but few have been isolated and fully characterized.[4b,13d,43] Because of such high reactivity,[2b,4,42a,42d,44] we decided to extend our study to bulky alkyltantalum derivatives.

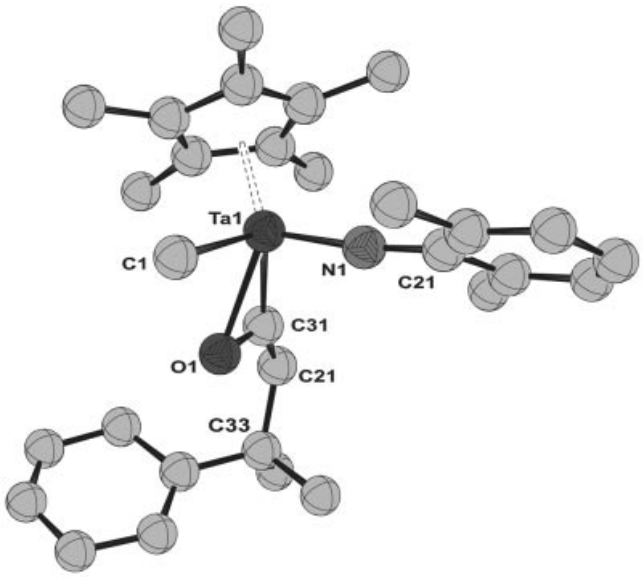

Figure 4. Molecular structure and atom labelling scheme for **[TaCp*Me(NR^1){η^2-C(CH$_2$CMe$_2$Ph)=O}]** (Cp′ = η^5-C$_5$Me$_5$; R^1 = 2,6-Me$_2$C$_6$H$_3$, **66**)

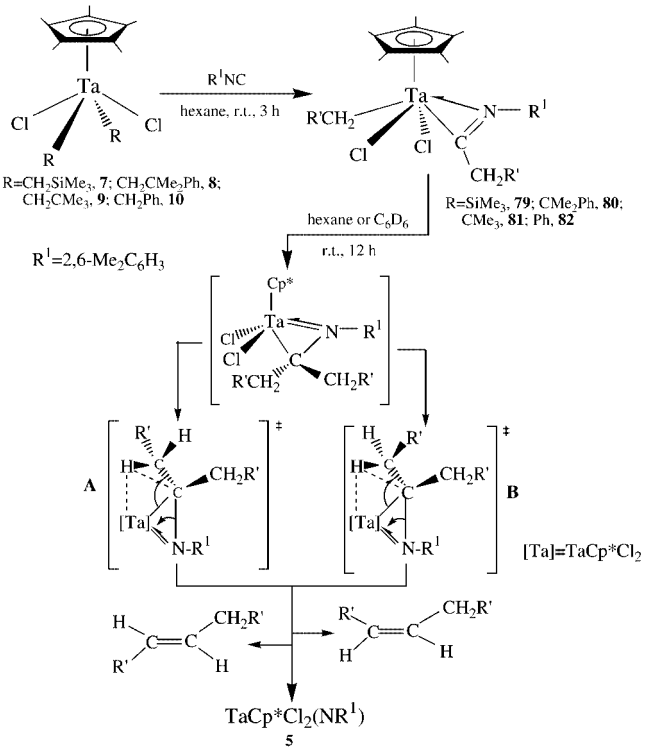
The complexes TaCp*Cl$_2$R$_2$ (R = CH$_2$SiMe$_3$, **7**;[13d] CH$_2$CMe$_2$Ph **8**;[13d] CH$_2$CMe$_3$, **9**;[13a,13b] CH$_2$Ph, **10**[13a,13b]) react with 1 equiv. of 2,6-Me$_2$C$_6$H$_3$NC in hexane under a rigorously dry inert gas to give reddish solutions, from which, after workup, the alkyldichloro(η^2-iminoacyl)tantalum complexes **[TaCp*Cl$_2$R{η^2-C(R)=NR^1}]** (R^1 = 2,6-Me$_2$C$_6$H$_3$; R = CH$_2$SiMe$_3$, **79**; CH$_2$CMe$_2$Ph, **80**; CH$_2$CMe$_3$, **81**; CH$_2$Ph, **82**)[13d] could be recovered (Scheme 7). This behaviour contrasts with that observed[4b] for the [TaCp*Cl$_2$Me$_2$] derivative, which with 1 equiv. of isocyanide gives a dichloroazatantalacyclopropane complex by a migration of the second methyl group to the electrophilic iminoacyl carbon atom of the dichloro(methyl)(η^2-iminoacyl) intermediate. In the present case, the remaining bulkier alkyl substituent does not migrate. Furthermore, the same η^2-iminoacyl complexes (**79**−**82**) are obtained by treating [D$_6$]benzene solutions of the starting dialkyldichloro compounds with 2 equiv. of isocyanide at room temperature, and no bis(η^2-iminoacyl) species are formed.

On the other hand, the η^2-iminoacyl complexes **79**−**82** slowly decompose at room temperature in [D$_6$]benzene or hexane solutions to give the dichloro(imido)tantalum compound **TaCp*Cl$_2$(NR^1)** (R^1 = 2,6-Me$_2$C$_6$H$_3$, **5**) together with a mixture of *cis* and *trans* olefins **R′-CH$_2$-CH=CH-R′** (R′ = SiMe$_3$, **79**o; CMe$_2$Ph, **80**o; CMe$_3$, **81**o; Ph, **82**o),[13d] probably via intermediate dialkylazatantalacyclopropane complexes (Scheme 7), which cannot be detected in situ by ^{1}H NMR spectroscopy. However, the azatantalacyclopropane structure favours agostic interactions between the β-hydrogen atoms of the alkyl groups and the tantalum atom, leading to concerted four-centre transition states **A** and **B**. Subsequent 2,1-migration of the hydrogen atom and back-rearrangements give the imido complex with elimination of the corresponding olefins.



R′	trans%	Olefin
SiMe$_3$	90	1,3-bistrimethylsilyl-propene, **79**o
CMe$_2$Ph	80	2,6-dimethyl-2,6-diphenyl-3-heptene, **80**o
CMe$_3$	66	2,2,6,6-tetramethyl-3-heptene, **81**o
Ph	100	1,2-diphenyl-propene, **82**o

Scheme 7. Insertion reactions of isocyanide

The spectroscopic data (IR and ^{1}H and ^{13}C{^{1}H} NMR) are consistent with the expected pseudooctahedral geometries of these η^2-iminoacyl complexes. Compound **80** (Figure 5) has a tantalum atom in a pseudooctahedral environment, with the centroid of the Cp* ring and the carbon atom of the iminoacyl ligand occupying the axial positions. The tantalum atom is 0.61(1) Å above the plane

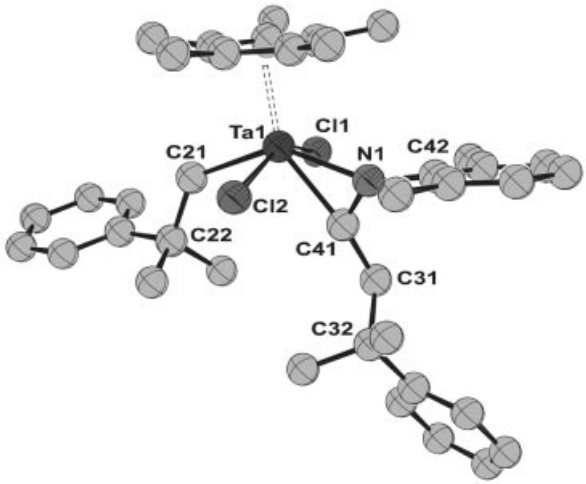


Figure 5. Molecular structure and atom labelling scheme for **[TaCp*Cl$_2$R{η^2-C(R)=NR^1}]** (Cp′ = η^5-C$_5$Me$_5$; R = CH$_2$CMe$_2$Ph; R^1 = 2,6-Me$_2$C$_6$H$_3$, **80**)

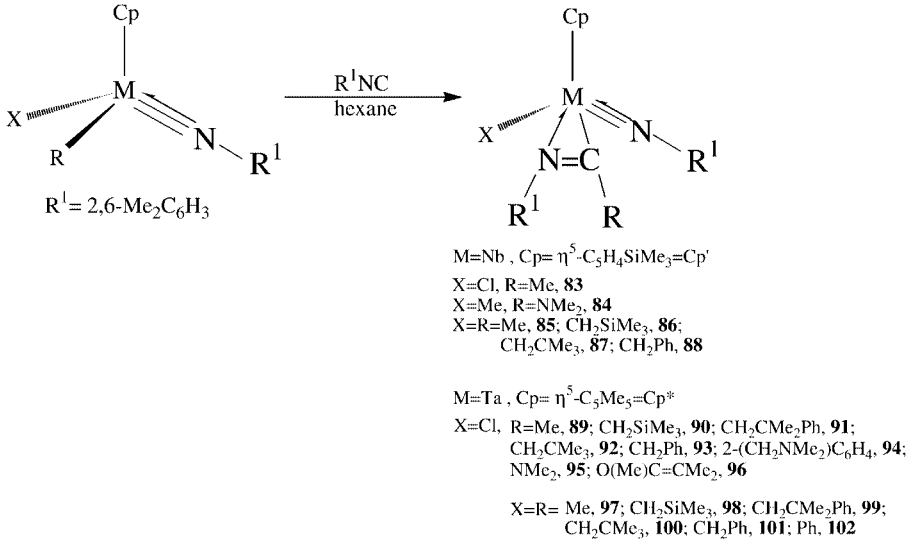
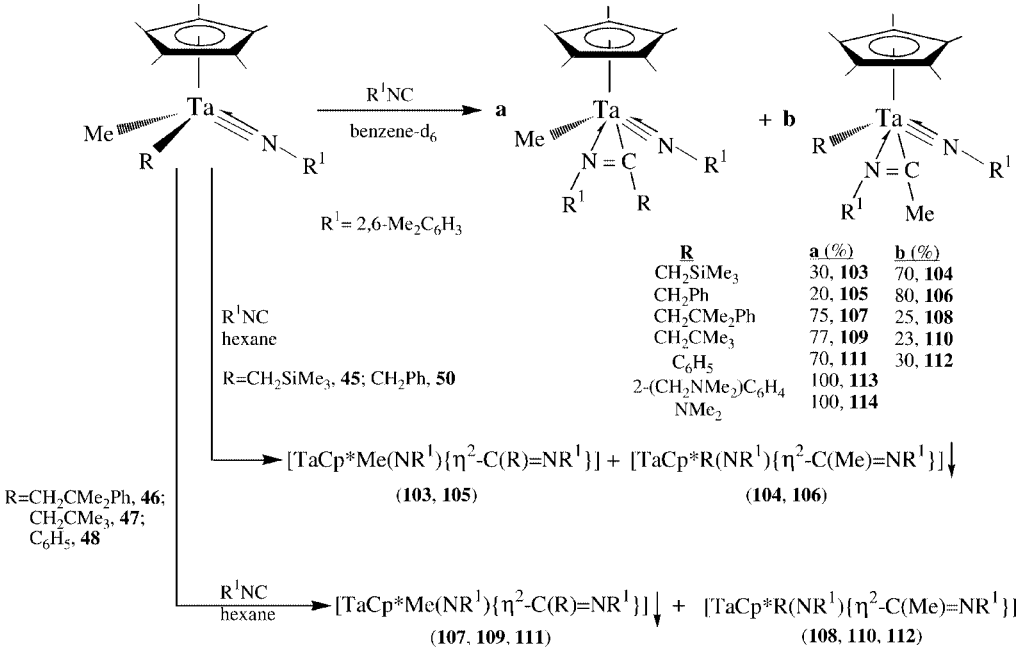


Scheme 8. Insertion reactions of isocyanide

formed by C21, Cl1, Cl2, and N1[45] and the C=N bond of the iminoacyl group is almost perpendicular to this plane.

When R^1NC is added to hexane solutions of the alkyl(chloro)- or dialkyl(imido) complexes $MCpXR(NR^1)$ (R^1 = 2,6-$Me_2C_6H_3$; M = Nb, Cp = η^5-$C_5H_4SiMe_3$=Cp′; M = Ta, Cp = η^5-C_5Me_5 = Cp*) in a 1:1 molar ratio an instantaneous insertion reaction gives the stable 18-electron chloro imido(η^2-iminoacyl) [M = Nb, Cp = Cp′, X = Cl, R = Me, **83**;[33] M = Ta, Cp = Cp*, X = Cl, R = Me, **89**;[20a] CH_2SiMe_3, **90**;[33] CH_2CMe_2Ph, **91**;[33] CH_2CMe_3, **92**;[33] $CH_2C_6H_5$, **93**;[33] 2-$(CH_2NMe_2)C_6H_4$, **94**;[33] O(Me)C=CMe_2, **96**[20]], alkyl(imido)η^2-iminoacyl (M = Nb, Cp = Cp′, X = R = Me, **85**;[33] CH_2SiMe_3, **86**;[33] CH_2CMe_3, **87**;[33] CH_2Ph, **88**;[33] M = Ta, Cp = Cp*, X = R = Me, **97**;[20a] CH_2SiMe_3, **98**;[33] CH_2CMe_2Ph, **99**;[33] CH_2CMe_3, **100**;[33] $CH_2C_6H_5$, **101**;[33] C_6H_5, **102**[33]], methyl- and chloro(imido)(η^2-iminocarbamoyl) (M = Nb, Cp = Cp′, X = Me, R = NMe_2, **84**;[33] M = Ta, Cp = Cp*, X = Cl, R = NMe_2, **95**[33]) derivatives **[MCpX(NR¹){η²-C(R)=NR¹}]** (R^1 = 2,6-$Me_2C_6H_3$, **83**−**102**) (Scheme 8).

For dialkyl derivatives (X = R = alkyl) the migration of the second alkyl group observed for $[TaCp^*Cl_2Me_2]$[4b] does not occur and an excess of isocyanide does not produce a second insertion reaction in the M−C(alkyl) or M−C(iminoacyl) bonds.[1d,3d,3i,3j] However, when X = OC(Me)=CMe_2 and R = Me the methyl group bound to



Scheme 9. Insertion reactions of isocyanide

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the tantalum atom migrates to the electrophilic carbon atom of the isocyanide ligand, which does not attack the terminal olefinic carbon atom of the enolate ligand, in contrast to when (alkenylamido)imido complexes[4c] are used.

The addition of 1 equiv. of 2,6-$Me_2C_6H_3NC$ to [D_6]benzene solutions of the alkyl(methyl)imido complexes [TaCp* RMe(NR^1)] under rigorously anhydrous conditions gives a mixture of (η^2-alkyliminoacyl)imido(methyl) **[TaCp* Me(NR^1){η^2-C(R)=NR^1}]** (R^1 = 2,6-$Me_2C_6H_3$; R = CH_2SiMe_3, **103**; CH_2Ph, **105**; CH_2CMe_2Ph, **107**; CH_2CMe_3, **109**; C_6H_5, **111**; 2-(CH_2NMe_2)C_6H_4, **113**; NMe_2, **114**)[33] and alkyl(η^2-methyliminoacyl)imido **[TaCp* R(NR^1){η^2-C(Me)=NR^1}]** (R^1 = 2,6-$Me_2C_6H_3$; R = CH_2SiMe_3, **104**; CH_2Ph, **106**; CH_2CMe_2Ph, **108**; CH_2CMe_3, **110**; C_6H_5, **112**)[33] complexes, in ratios determined from ^{1}H NMR spectra (Scheme 9).

The same reaction at room temperature using *n*-hexane as solvent in a dry box affords the insoluble microcrystalline (alkyl)imido(η^2-methyliminoacyl) (R = CH_2SiMe_3, **104**; CH_2Ph, **106**) and (η^2-alkyliminoacyl)methyl(imido) (R = CH_2CMe_2Ph, **107**; CH_2CMe_3, **109**. C_6H_5, **111**) complexes as solids, which are major components in the above-mentioned mixture. Further, when the resulting suspension of the above experiment is concentrated to dryness, the ^{1}H NMR spectrum in [D_6]benzene of the crude residue gave the same result. The yields reflect the relative ease of migration[46] of the various alkyl groups, such as 2-(CH_2NMe_2)C_6H_4 ≈ NMe_2 > CH_2CMe_2Ph ≈ CH_2CMe_3 > C_6H_5 > ***Me*** > CH_2SiMe_3 > CH_2Ph as compared with the methyl group. Our particular contribution also establishes the regioselective migration of the 2-[(dimethylamino)methyl]phenyl (**113**) and dimethylamido groups (**114**). The preferential migration of the NMe_2 moiety, for starting amido(methyl)niobium and -tantalum derivatives that give (η^2-iminocarbamoyl)methyl complexes **84** and **114**, is quite unusual because in similar alkyl- or methyl(amido)titanium,[47] -zirconium,[48] -tungsten[49] and -uranium[50] complexes the insertion occurs preferentially at the M−C_{alkyl} bond. More recent reports[22h] found similar behaviour in an almost instantaneous reaction of the amido(imido)methyl complexes [TaCp*MeX(N*t*Bu)] (X = NMe_2, NHMe) with 1 equiv. of R^1NC to give the corresponding η^2-iminocarbamoyl compounds [TaCp*Me(N*t*Bu){η^2-C(X)=NR^1}] (R^1 = 2,6-$Me_2C_6H_3$; X = NMe_2, NHMe). The authors justify, by DFT calculations, that coordination of the isocyanide ligand followed by nucleophilic attack initiates the insertion reaction, neither into Ta−NR_2 nor Ta−Me bonds, and is governed by kinetic factors. However, insertion into the Ta−Me bond is preferred for amido(imido)methyl [TaCp* Me(NR_2)(N*t*Bu)] (R = Ph, $SiMe_3$) complexes to give (amido)imido(η^1-iminoacyl) derivatives [TaCp*(NR_2)(N*t*Bu)-{η^1-C(Me)=NR^1}], whereas stereoselective insertion into the Ta−NR_2 bond occurs for related amido(methyl) derivatives, leading to (methyl)imido(η^2-iminocarbamoyl) complexes [TaCp*Me(N*t*Bu){η^2-C(X)=NR^1}] (X = NMe_2, NHMe).

The reaction of the starting mixed alkyl(imido)methyl derivatives with 2 equiv. of the isocyanide ligand in [D_6]benzene solutions at room temperature affords the same η^2-iminoacyl complexes **103**−**114**, and bis(η^2-iminoacyl) derivatives cannot be detected by ^{1}H NMR spectroscopy.

Structural studies[33] of the imido(η^2-iminoacyl) (**83**, **85**−**113**) and imido(η^2-iminocarbamoyl) (**84**, **95**, **114**) complexes agree with the expected pseudo-square-pyramidal geometry found for similar chiral niobium and tantalum derivatives.[20]

Early transition metal complexes[2f,42a,51] constitute a powerful component in carbon−carbon bond formation strategies in organic synthesis[52] and catalytic polymerization.[53] In particular, (alkyne)niobium and -tantalum complexes have provided convenient routes to carbonylic derivatives[54] and nitrile[55] coupling reactions via metallacyclic intermediates. Furthermore, (alkyne)niobium- and -tantalum(III) derivatives react with nitriles to give azatantalacyclopentene complexes that may participate in an intermolecular tautomerization process to enamines,[42c] and are also efficient catalysts for the oligomerization and polymerization of internal alkynes.[53]

In accord with this background, we recently reported a novel study[14] of the chemical behaviour of the (alkyl)alkyne[(trimethylsilyl)cyclopentadienyl]niobium complexes [NbCp′R_2($Me_3SiCCSiMe_3$)][14] (Cp′ = η^5-$C_5H_4SiMe_3$; R = Me, **36**; CH_2SiMe_3, **37**; CH_2CMe_3, **38**; $CH_2C_6H_5$, **39**) in insertion processes. Thus, when 1 equiv. of the isocyanide 2,6-$Me_2C_6H_3NC$ was added to [D_6]benzene solutions of the dialkyl(alkyne) derivatives **36**−**39**, under a rigorously dry inert gas in a sealed NMR tube, reddish solutions corresponding to (alkyl)alkyne(η^2-iminoacyl) complexes **[NbCp′R{η^2-C(R)=NR^1}($Me_3SiCCSiMe_3$)]**[14] (Cp′ = η^5-$C_5H_4SiMe_3$; R^1 = 2,6-$Me_2C_6H_3$; R = Me, **115**; CH_2SiMe_3, **116**; CH_2CMe_3, **117**) as the unique reaction products were obtained (Scheme 10). The insertion process is instantaneous and after coordination of the isocyanide ligand the migration of one alkyl group to the electrophilic isocyanide carbon atom produces an η^2-iminoacyl complex. With (alkyne)dibenzyl complex **39** the reaction takes place but, probably, the η^2-iminoacyl derivative is very unstable and decomposes to an unidentified product mixture. In the same reactions carried out in a Schlenk tube using hexane as solvent, only complex **116**, as a crystalline red solid, could be isolated. Both **115** and **117** are unstable at room temperature, and while **115** is partially transformed into an imidoniobacyclopent-3-ene complex (**118**) the alkyne(η^2-iminoacyl)neopentyl derivative **117** decomposes into an unidentified products mixture.

Alternatively, the imidoniobacyclopent-3-ene complex **[NbCp′(NR^1){η^4-CH($SiMe_3$)-C($SiMe_3$)=C(Me)-CH_2}]**[14] (Cp′ = η^5-$C_5H_4SiMe_3$; R^1 = 2,6-$Me_2C_6H_3$, **118**) can be prepared when the (alkyne)dimethyl derivative **36** is treated with 1 equiv. of isocyanide in hexane at 40−50 °C for 12 h (Scheme 11). Conversely, if the alkyne(trimethylsilylmethyl)-(η^2-iminoacyl) complex **116** is heated to 80 °C in hexane for 12 h it can be isolated as an imido(vinyl)niobacyclopropane derivative **[NbCp′(NR^1){η^4-CH($SiMe_3$)C($SiMe_3$)-C(CH_2SiMe_3)=CH($SiMe_3$)}]**[14] (Cp′ = η^5-$C_5H_4SiMe_3$; R^1 = 2,6-$Me_2C_6H_3$, **119**), a crystalline red solid, the struc-

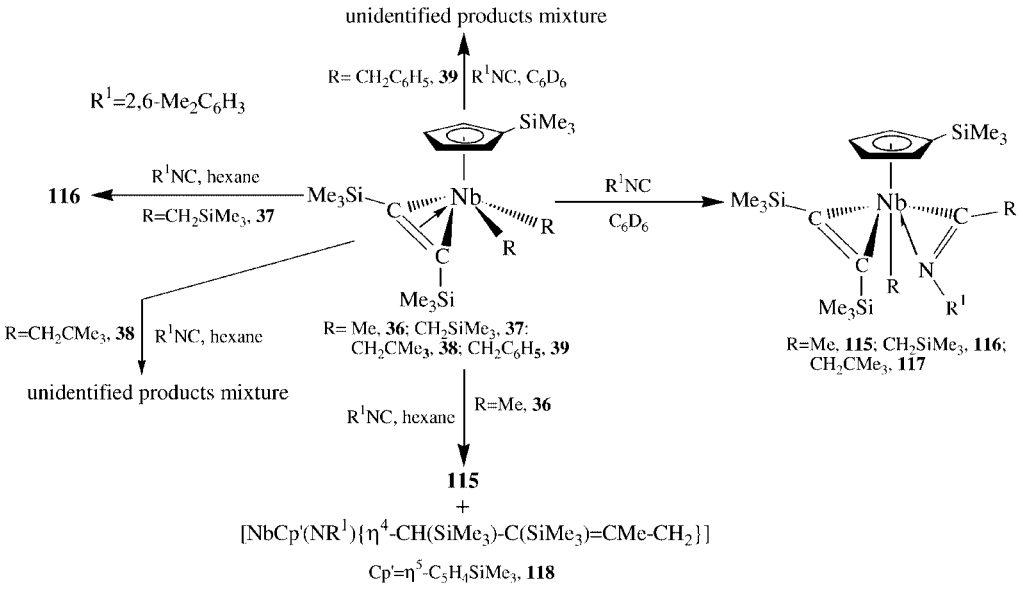
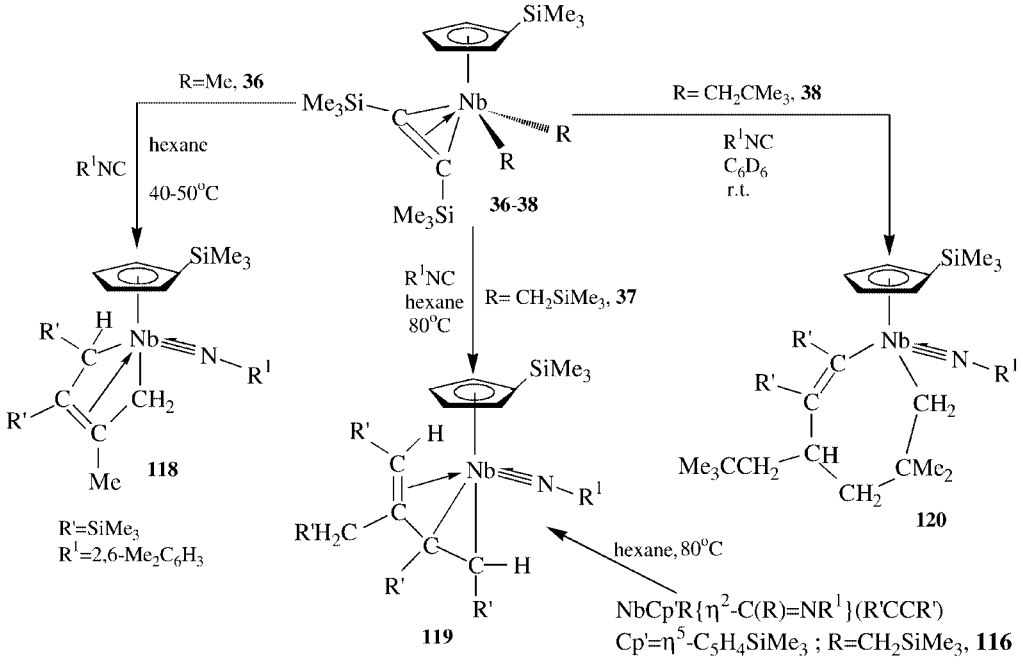


Scheme 10. Insertion reactions of isocyanide

ture of which was determined by X-ray diffraction methods. Identical results are obtained by thermally treating a mixture of **37** and 2,6-$Me_2C_6H_3NC$ (1:1 molar ratio). In contrast, the reaction between the (alkyne)bis(neopentyl) complex **39** and 2,6-$Me_2C_6H_3NC$ leads, in a first step, to an alkyne(η^2-iminoacyl)neopentyl complex (**117**) that is gradually transformed into the imidoniobacyclohept-2-ene complex **[NbCp′(NR¹){η²-$CH_2CMe_2CH_2CH(CH_2CMe_3)$C-($SiMe_3$)=C($SiMe_3$)}]**[14] (Cp′ = η^5-$C_5H_4SiMe_3$; R^1 = 2,6-$Me_2C_6H_3$, **120**), the structure of which may be proposed on the basis of NMR spectroscopic data.

On monitoring the formation processes of complexes **118**−**120** by ^{1}H NMR spectroscopy, only complex **118** was found to give an intermediate (alkyne)azaniobacyclopropane derivative, **[NbCp′{η²-C(CH_2R'')-NR¹}(Me_3SiCC-$SiMe_3$)]**[14] (Cp′ = η^5-$C_5H_4SiMe_3$; R^1 = 2,6-$Me_2C_6H_3$; R′′ = $SiMe_3$, **115i**). This transformation can be rationalized by migration of the second metal-bonded methyl group to the iminoacyl carbon center to give the intermediate **115i** (Scheme 12). Similar azametallacyclopropane species have been proposed and isolated by us in the reactions of dichlorodimethyl(pentamethylcyclopentadienyl)niobium[13d] and



Scheme 11. Insertion reactions of isocyanide

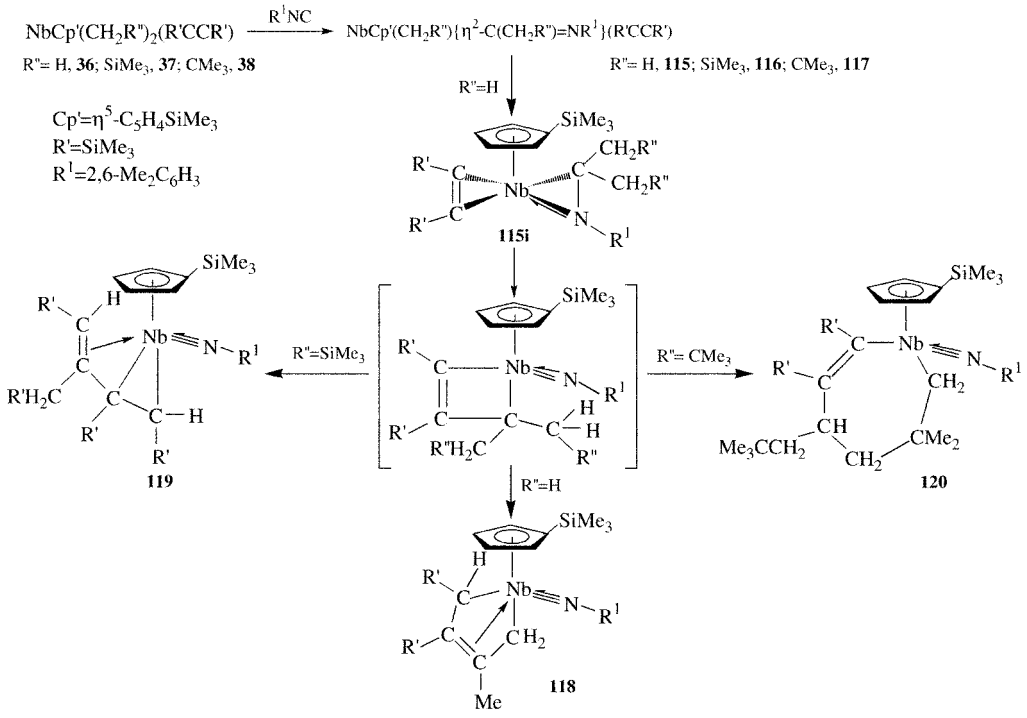

Scheme 12. Insertion reactions of isocyanide

-tantalum[4b] complexes and isocyanides and their structures confirmed by X-ray diffraction methods. Rearrangement of the intermediate **115i** is followed by migration of the hydrogen atom, and back-rearrangement gives the imidoniobacyclopent-3-ene complex **118**. Complexes **119** and **120** could be formed via imidoniobacyclobutene intermediates; when R′′ = $SiMe_3$, migration of the hydrogen atom and subsequent rearrangement leads to **119**, which is a niobacyclopropane complex with an η^2-coordinated vinyl substituent at the metal center. However, a different pathway may be proposed by the formation of azaniobacyclopentatriene species[3b,3g,56] as result of the intramolecular coupling between both alkyne and iminoacyl ligands. When R′′ = CMe_3, C−H activation of a methyl group of the *tert*-butyl fragment and back-rearrangement leads to the imidoniobacyclohept-2-ene complex **120**. This is probably due to the steric and electronic differences between $SiMe_3$ and CMe_3 groups. Thus, the lesser steric hindrance of the *tert*-butyl group permits a closer approach to the metal atom and the activation of a C−H bond gives the complex **120**.

Structural studies (IR, ^1H and $^{13}C\{^1H\}$ NMR)[14] of complexes **115**−**120** agree with the proposed structures. The pseudooctahedral complexes **115**−**117**, due to the chiral character of the metal center, show in their ^1H and $^{13}C\{^1H\}$ NMR spectra an ABCD spin system and five resonances, respectively, for the $C_5H_4SiMe_3$ moiety and, also, two inequivalent methyl groups for the 2,6-$Me_2C_6H_3$ ring, in accordance with the slow rotation of the aryl substituent around the N−C_{ipso}(aryl) bond. Complex **118** exhibits NMR behaviour that is consistent with a diene ligand in an *s-cis* conformation, as has been observed in other diene group-5 metal derivatives.[57] The unusual conformation of the diene ligand in complex **119** was deduced from detailed analysis of the NMR spectroscopic and X-ray diffraction data, which strongly suggest that the diene ligand is bonded

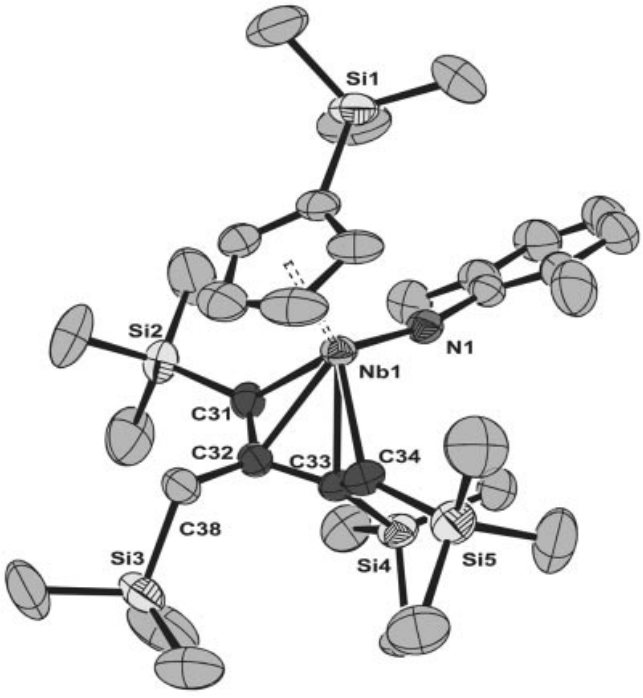

Figure 6. Molecular structure and atom labelling scheme for **[NbCp′(NR1){η4-CH(SiMe3)C(SiMe3)C(CH2SiMe3)=CH(SiMe3)}]** (Cp′ = η^5-$C_5H_4SiMe_3$; R^1 = 2,6-$Me_2C_6H_3$, **119**)

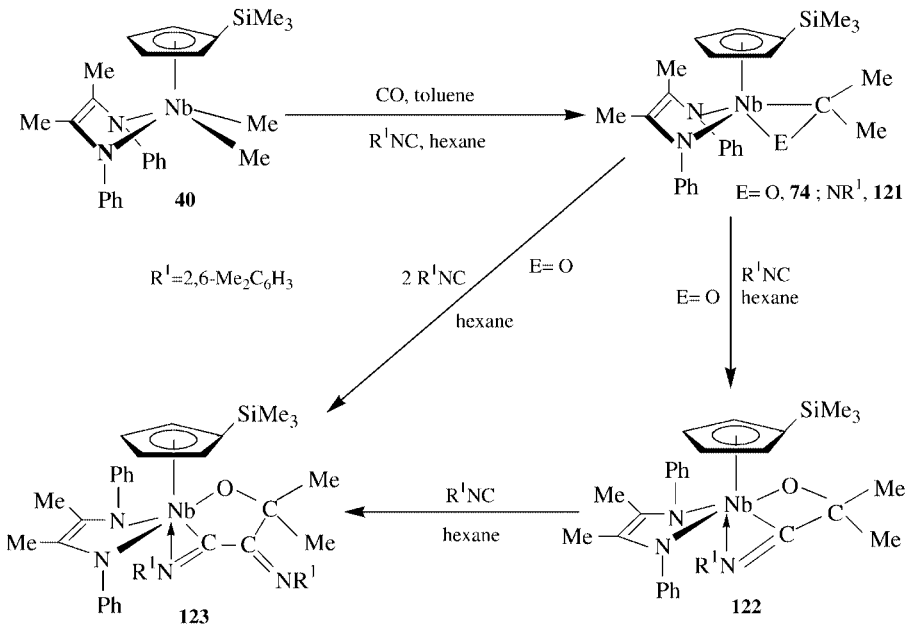

Scheme 13. Insertion reactions of carbon monoxide and isocyanide

in an η^2-niobacyclopropane fashion with a vinyl substituent η^2-coordinated to the metal center. This is the most relevant detail of the molecular structure (Figure 6) because, frequently, in diene mono(cyclopentadienyl)niobium and -tantalum complexes[57a,57d,58] the diene ligand forms a metallacyclopent-3-ene system with a preferred *supino* conformation, although there are examples with a *prono* conformation. Furthermore, the diene ligand can adopt an *s-trans* conformation, as observed in bis(cyclopentadienyl)zirconium,[59] mono(cyclopentadienyl)tantalum[60] and cationic bis(cyclopentadienyl)tantalum[61] complexes. In our case, the crystallographic data do not correspond to the same bonding system and, therefore, we propose a moiety consisting of a "diene" C31−C32−C33−C34 fragment linked to the metal atom through the C33−C34 atoms, forming a niobacyclopropane ring, and the donor vinyl substituent C31−C32.

Finally, when 2,6-$Me_2C_6H_3NC$ (1 equiv.) is added to a hexane solution of the dimethyl complex $NbCp'Me_2$(Me,Ph-DAD) (Cp′ = η^5-$C_5H_4SiMe_3$, **40**) under rigorously anhydrous conditions an orange solution is obtained, which after evaporation of the solvent produces the azaniobacyclopropane complex **[NbCp′(η²-CMe₂NR¹)(Me,Ph-DAD)]** (R^1 = 2,6-$Me_2C_6H_3$, **121**),[15] as the result of two consecutive steps (Scheme 13). The first step involves migration of one methyl group to the electrophilic isocyanide carbon atom to form an η^2-iminoacyl intermediate,[1d,2f,2h,2i,2j,2k,62] which could not be detected by ^1H NMR spectroscopy. Subsequent migration of the second methyl group to the iminoacyl carbon centre yields an azaniobacyclopropane.[2b,2c,4b,13d,63]

Dialkyl complexes **41** (R = CH_2SiMe_3) and **42** (R = $CH_2C_6H_5$) do not react with isocyanide at room temperature; when the solution is heated the reaction probably takes place simultaneously with the decomposition of the organometallic complex formed, leading to an unidentified product mixture. When **40** is treated with 2 equiv. of isocyanide the result is the same, in contrast to the behaviour of the azatantalacyclopropane derivatives [$TaCp^*Cl_2(\eta^2$-$CMe_2NR^1)$][4b] (R^1 = 2,6-$Me_2C_6H_3$; 2,4,6-$Me_3C_6H_2$), which in the presence of isocyanides give the corresponding dichloro(imido) complex [$TaCp^*Cl_2(NR^1)$] with elimination of the arylimine ketene $ArN{=}C{=}CMe_2$. However, the oxaniobacyclopropane [$NbCp'Cl_2(\eta^2$-CMe_2-O)(Me,Ph-DAD)] (**74**),[15] reacts with 1 or 2 equiv. of 2,6-$Me_2C_6H_3NC$ to give the expected insertion products **[NbCp′Cl₂{η²-OCMe₂(CNR¹)ₓ}(Me,Ph-DAD)]** (R^1 = 2,6-$Me_2C_6H_3$; x = 1, **122**; x = 2, **123**).[15] Complex **122** can be transformed into **123** by a simple isocyanide insertion reaction.

Conclusions

The review shows that direct alkylation of the corresponding chloro derivatives can afford dialkyldichloro [$MCp^*Cl_2R_2$] (**6**−**10**), alkyl(chloro)imido [$MCpClR(NR^1)$] (**13**−**23**), dialkyl(imido) [$MCpR_2(NR^1)$] (**24**−**35**), alkyl(methyl)imido [$MCpRMe(NR^1)$] (**43**−**55**), dialkyl(alkyne) [$NbCp'R_2(Me_3SiCCSiMe_3)$] (**36**−**39**), and dialkyl(diazabutadiene) complexes [$NbCp'R_2$(Me,Ph-DAD)] (**40**−**42**), whose reactivity has been studied in carbon monoxide and isocyanide insertion processes.

Imido(methyl) complexes [$TaCp^*MeX(NR^1)$] (R^1 = 2,6-$Me_2C_6H_3$; X = Cl, **15**; Me, **25**) react with carbon monoxide via the expected η^2-acyl derivatives [$TaCp^*X(NR^1)\{\eta^2$-C(Me)=O}] (X = Cl, **56**; Me, **57**) but lead to different products that depend on X. The higher carbenoid character of the η^2-acyl ligand when X = Me affords dinuclear μ-enedi-

olate complex **58**, whereas imido nitrogen attack at the more electrophilic acyl carbon atom when X = Cl gives the chloro (η^2-iminoacyl)oxo complex **59**.

Alkyl groups, other than methyl, as in alkyl(chloro)- (**17**, **18**, **22**) dialkyl- (**29**−**33**) and alkyl(methyl)- (**46**, **47**, **49**) -imidotantalum complexes react with CO (1 atm) to give (η^2-acyl)chloro (X = Cl, R = CH_2CMe_2Ph, **60**), (η^2-carbamoyl)chloro (X = Cl, R = NMe_2, **61**), (η^2-acyl)alkyl (X = R = CH_2SiMe_3, **62**; CH_2CMe_2Ph, **63**; CH_2CMe_3, **64**; $CH_2C_6H_5$, **65**), and (η^2-acyl)methyl (X = Me, R = CH_2CMe_2Ph, **66**; CH_2CMe_3, **67**) -imido derivatives [TaCp*X(NR^1){η^2-C(R)=O}] (R^1 = 2,6-$Me_2C_6H_3$) as result of a simple insertion process. The preferential migration of neophyl and neopentyl groups with respect to the methyl group determines the regioselective synthesis of complexes **66** and **67**, but when X = Cl, R = CH_2CMe_3 (**18**) and X = Me, R = 2-$(CH_2NMe_2)C_6H_4$ (**49**) the dinuclear μ-enediolate complexes **68** and **69** are formed through intermolecular coupling between two acyl carbon atoms of the unstable intermediate η^2-acyl complexes. For **18** and X = R = Ph (**31**) insertion of CO furnishes (η^2-iminoacyl)oxo complexes **70** and **71** by a mechanism similar to that proposed for the chloro(methyl)imidotantalum derivative **15**. However, the related dichlorodimethyl complex TaCp*Cl_2Me_2 (**72**) reacts with CO to give the oxametallacyclopropane derivative TaCp*Cl_2(η^2-CMe_2-O) (**73**) as result of a double migration of both methyl groups, whereas the azatantalacyclopropane complexes [TaCp*XMe(η^2-CMe_2NR^1)] (X = Cl, **75**; Me, **76**) lead to the pseudotetrahedral enolate derivatives [TaCp*X(NR^1){η^1-OC(Me)=CMe_2}] (R^1 = 2,6-$Me_2C_6H_3$; X = Cl, **77**; Me, **78**) by formation of unidentified intermediate species.

Dialkyldichloro complexes **7**−**10** react with R^1NC (1 equiv.) to give (alkyl)dichloro(η^2-iminoacyl) derivatives [TaCp*Cl_2R{η^2-C(R)=NR^1}] (R^1 = 2,6-$Me_2C_6H_3$; R = CH_2SiMe_3, **79**; CH_2CMe_2Ph, **80**; CH_2CMe_3, **81**; $CH_2C_6H_5$, **82**) in contrast to the related dichlorodimethyl compounds (M = Nb, **6**: Ta, **72**) which, under the same conditions, give a dichloroazametallacyclopropane system by migration of the second methyl substituent to the electrophilic iminoacyl carbon atom of the dichloro(η^2-iminoacyl)methyl intermediate species. Here, the remaining bulkier alkyl group does not migrate and no bis(η^2-iminoacyl) complexes are formed by treating the starting dialkyldichloro compounds with 2 equiv. of isocyanide. The η^2-iminoacyl complexes **79**−**82** slowly decompose at room temperature in [D_6]benzene solutions to give [TaCp*Cl_2(NR^1)] and a mixture of *cis*/*trans* olefins R′CH_2CH=CHR′ (**79**o−**82**o), probably via unidentified intermediate azatantalacyclopropane species.

Stable 18-electron η^2-iminoacyl derivatives, [MCpX(NR^1){η^2-C(R)=NR^1}] (**83**−**102**), are obtained by inserting 1 equiv. of R^1NC into the M−C(alkyl) bonds of alkyl(chloro) or dialkyl(imido) complexes. In contrast, alkyl(methyl)imidotantalum complexes react by migration of alkyl or methyl substituent to give a mixture of (η^2-alkyliminoacyl)methyl(imido) [TaCpMe(NR^1){η^2-C(R)=NR^1}] (**103**, **105**, **107**, **109**, **111**, **113**, **114**) and (alkyl)imido(η^2-methyliminoacyl) derivatives [TaCpR(NR^1){η^2-C(Me)=NR^1}] (**104**, **106**, **108**, **110**, **112**), respectively. When starting with {2-[(dimethylamino)methyl]phenyl}methyl and (dimethylamido)imido(methyl) complexes, insertion takes place with regioselective migration of 2-[(dimethylamino)-methyl]phenyl and dimethylamido groups.

The reaction of dialkyl(alkyne) derivatives **36**−**38** with 2,6-$Me_2C_6H_3NC$ (1 equiv.) occurs through initial formation of the (alkyl)alkyne(η^2-iminoacyl) compounds [NbCp′R-{η^2-C(R)=NR^1}($Me_3SiCCSiMe_3$)] (R^1 = 2,6-$Me_2C_6H_3$; R = Me, **115**; CH_2SiMe_3, **116**; CH_2CMe_3, **117**) but leads to different coupling products depending on R. When hexane solutions of **36** or **37** were treated with isocyanide (1 equiv.) at 40−50 °C (**36**) and 80 °C (**37**), respectively, imidoniobacyclopent-3-ene [NbCp′(NR^1){η^4-$CH(SiMe_3)C(SiMe_3)$=$C(Me)CH_2$}] (**118**) and imido(vinyl)niobacyclopropane [NbCp′(NR^1){η^4-$CH(SiMe_3)C(SiMe_3)C(CH_2SiMe_3)$=CH-$(SiMe_3)$}] (**119**) complexes are obtained, probably via azaniobacyclopropane intermediates. If R = CH_2CMe_3, after the initial formation of a non-stable η^2-iminoacyl complex (**117**), spontaneous conversion into the imidoniobacylohept-2-ene complex [NbCp′(NR^1){η^2-$CH_2CMe_2CH_2CH$-$(CH_2CMe_3)C(SiMe_3)$=$C(SiMe_3)$}] (**120**) occurs, but the intermediate species could not be observed by ^1H NMR spectroscopy. The NMR spectroscopic data of the coupling products confirmed an *s*-*cis* conformation for the diene ligand in complex **118**, while in complex **119** such a ligand presents an unusual coordination mode and forms, with the metal center, a niobacylopropane system with an η^2-vinyl substituent.

The dimethyl(diazabutadiene) complex **40** reacts with carbon monoxide and isocyanide to give oxa- and azaniobacyclopropane derivatives [NbCp′(η^2-CMe_2E)(Me,Ph-DAD)] (E = O, **74**; NR^1, **121**) due to migration of both methyl groups and, probably, via undetected η^2-acyl and η^2-iminoacyl intermediates. Successive isocyanide insertion reactions into the Nb−C bond take place in the oxaniobacyclopropane complex **74**, leading to insertion products **122** and **123**.

Acknowledgments

I am grateful to DGICYT (Project. No. PB 97-0761), to MCYT (Project No. BQU2002-03754) and to Universidad de Alcalá (Projects No. E009/98 and 2002-018) for financial support for this research. I also acknowledge P. Gómez-Sal and A. Martín for their help with X-ray studies, and A. Galindo and D. del Rio for DFT studies, and M. V. Galakhov for D NMR experiments and useful discussions. A. Castro, F. Sánchez, and P. Velasco as Ph.D. students carried out the experimental work.

A Room-Temperature Route to Bismuth Nanotube Arrays

Baojun Yang,[a,b] Cun Li,[a] Hanmei Hu,[a] Xiaogang Yang,[a] Qiaowei Li,[a] and Yitai Qian*[a]

Keywords: Bismuth / Nanostructures / Nanotubes / Synthesis design

A room-temperature aqueous-chemical route has been developed to synthesize a high proportion (above 80%) of bamboo-raft-like bismuth nanotube arrays using bismuth chloride and metallic zinc powder as reagents. The prepared Bi nanotubes have uniform diameters of approximately 3–5 nm and lengths from several hundred nanometers to several micrometers. HRTEM observations show that the axial direction of the prepared nanotubes is along the normal direction of the (012) lattice planes of the rhombohedral bismuth. The possible formation mechanism is discussed.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The discovery of carbon nanotubes[1] has initiated enormous interest in one-dimensional (1D) nanostructured materials, such as nanorods, nanowires, nanobelts and nanotubes, due to both their interesting physical properties and the wide range of their potential applications.[2] Over the past several years, various nanotubular materials, including oxides,[3] sulfides,[4] BN,[5] $NiCl_2$,[6] Te,[7] Au,[8] Ni,[9] Pt,[10] and Bi[11] have been successfully synthesized.

Bismuth (Bi) is a semimetal with a quasi-layered structure formally like that of rhombohedral graphite and black phosphorus.[12] The distances between one Bi atom and its three close neighbors in the same layer and the neighboring layers are 3.072 and 3.529 Å, respectively. Bismuth has unusual electronic properties that result from its highly anisotropic Fermi surface, low carrier concentration, small effective mass and long mean free path of the carriers.[13] These properties make Bi a good candidate to study quantum-confinement effects in 1D systems and very promising materials for thermoelectric applications. However, due to the relatively low melting point of Bi (273.1 °C), most of the existing high-temperature approaches, such as laser ablation, plasma-arc, or CVD (chemical vapor deposition) are inappropriate to synthesize 1D Bi nanomaterials. Hence, a low-temperature chemical approach may provide a more rational technique to prepare 1D Bi nanomaterials. Recently, Bi nanowires[14] (with a proportion of about 20%) have been solvothermally synthesized at 160 °C, using bismuth nitrate [$Bi(NO_3)_3{\cdot}5H_2O$] and ethylenediamine as starting materials. Bi nanotubes[11a] (with a proportion of about 30%) have been hydrothermally synthesized at 120 °C, using bismuth nitrate and aqueous hydrazine [$N_2H_4{\cdot}H_2O$] as starting materials. Bi nanotube arrays[11b] have been solvothermally synthesized at 200 °C, using bismuth oxide (Bi_2O_3) and ethylene glycol as starting materials.

Herein, we report a novel room-temperature aqueous-chemical route that has been developed in our synthesis of a high proportion (above 80%) of bamboo-raft-like bismuth nanotube arrays through the reduction of bismuth chloride by metallic zinc powder. The prepared bismuth nanotubes are arrayed side by side along the axial direction with uniform diameters of approximately 3−5 nm and lengths from several hundred nanometers to several micrometers. This method requires no complex apparatus or technique, and requires no catalyst or template.

Results and Discussion

Figure 1 shows a typical XRD pattern of a prepared sample. All of the sharp peaks can be indexed to a pure rhombohedral phase [space group: $R\bar{3}m$ (166)] of crystalline Bi. The calculated cell constants are a = 4.544 Å and c = 11.85 Å, which are in good agreement with the literature values of a = 4.547Å and c = 11.86 Å (JC,PDS 44-1246). This XRD pattern indicates that the reduction of Bi^{3+} to elemental Bi is complete and pure phase crystalline Bi products can be obtained under current synthetic conditions.

The morphologies and the size of the prepared Bi samples were characterized by TEM. As shown in Figure 2A and 2B, a high proportion (above 80%) of the

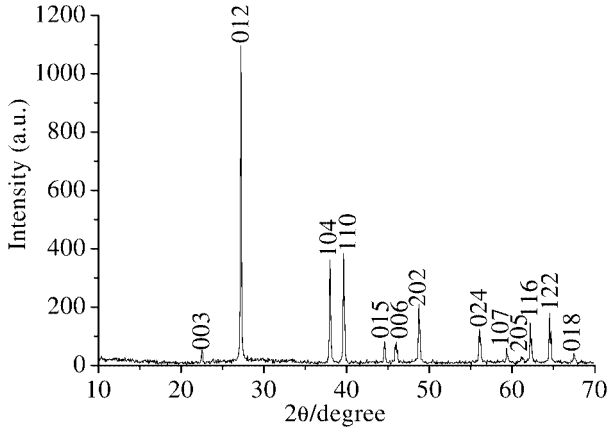

Figure 1. Typical XRD pattern of the prepared bismuth samples

sample dispersed on the TEM copper grids exhibits a nanotubular morphology. Small amounts of flake-like Bi were also observed. Interestingly, except for a small amount of individual Bi nanotubes (marked by the arrow in Figure 2A), almost all these bismuth nanotubes are arrayed like bamboo rafts. Each "bamboo raft" is comprised of several parallel straight bismuth nanotubes lying side by side along the axial direction. It can be seen that these Bi nanotubes have uniform diameters of approximately 3−5 nm and lengths from several hundred nanometers to several micrometers. Energy-dispersive X-ray spectrum (EDS) analysis (Figure 2D) shows that the prepared sample is pure bismuth. This result is consistent with the XRD pattern presented above, in which no impurity phase is observed.

The prepared samples are highly sensitive to electron beam irradiation during the TEM examination due to the relatively low melting point of Bi (273.1 °C), which makes it much more difficult to get clear HRTEM images. The TEM image of a prepared sample after several seconds of

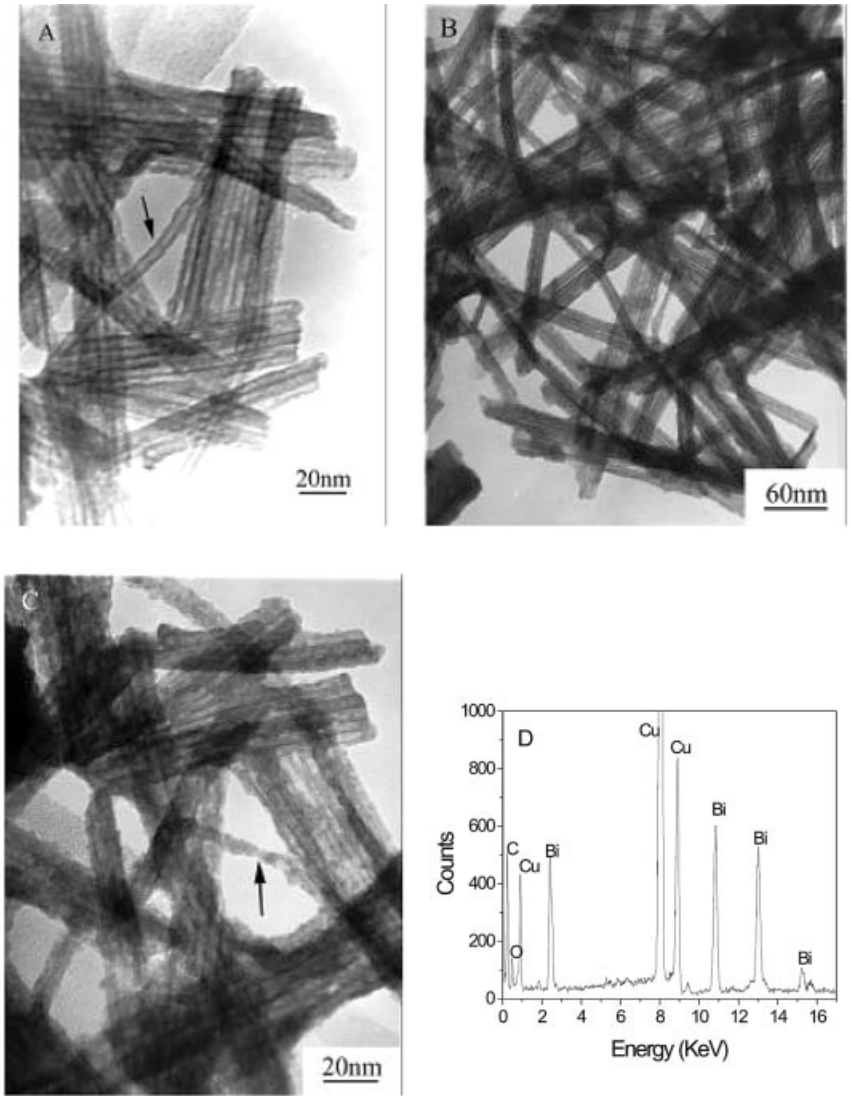

Figure 2. Typical TEM images (A-C) and EDS spectrum (D) of the prepared bismuth nanotubes

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

intensive electron beam irradiation is shown in Figure 2C. It can be seen that the morphologies of the bismuth nanotubes have become blurry, some individual Bi nanotubes have melted (marked by the arrow in Figure 2C) and transformed into polycrystalline nanowires. A similar phenomenon was also reported previously.[11a,15] However, some distinguishable HRTEM images have been obtained in our experiments. A representative HRTEM image of one section of a "bamboo raft" is shown in Figure 3. It can be seen that there are four Bi nanotubes which are lying side by side in the image. The discriminable lattice fringes, which are perpendicular to the axial direction of the nanotubes, illustrate that the prepared Bi nanotubes are single crystals in the area shown. The fringe spacing is about 3.2 Å, which is close to the interplanar spacing of the (012) lattice planes of the rhombohedral bismuth. This means that the axial direction of the prepared nanotubes is along the normal direction of the (012) lattice planes of the rhombohedral bismuth.

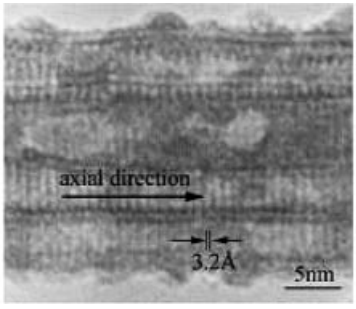

Figure 3. HRTEM image of a "bamboo raft" comprised of four parallel nanotubes

The overall reaction in our system can be simply formulated as shown in Equation (1):

$$2BiCl_3 + 3Zn \rightarrow 2Bi + 3ZnCl_2 \quad (1)$$

The reaction above includes two following steps formulated as Equations (2) and (3):

$$BiCl_3 + H_2O \rightarrow BiOCl + 2HCl \quad (2)$$

$$2BiOCl + 3Zn + 4HCl \rightarrow 2Bi + 2H_2O + 3ZnCl_2 \quad (3)$$

First, $BiCl_3$ hydrolyzes in water to form BiOCl, a white precipitate [Equation (2)], which is then reduced by metallic zinc powder to form metallic Bi. The reduction reaction [Equation (3)] is comprised of two half reactions [Equations (4) and (5)]:

$$BiOCl + 2H^+ + 3e^- \rightarrow Bi + H_2O + Cl^- \ (E^\circ = 0.170\ V) \quad (4)$$

$$Zn^{2+} + 2e^- \rightarrow Zn \ (E^\circ = -0.7626\ V) \quad (5)$$

According to the standard of the formal potential of half reactions (4) and (5), it can be seen that there is a strong tendency for reduction reaction (3) to the formation of metallic Bi. According to the added quantity of $BiCl_3$, the yield of metallic Bi is above 90% by weight.

The specific formation mechanism of the Bi nanotubes is not yet clear and warrants further investigation. Concerning the formation mechanisms for nanotubes, several models have been suggested. For instance, curving followed by seaming of molecular layers (CSML) has been proposed to be responsible for the tube-formation process of materials with layered structure.[16] Direct growth through concentration depletion at the surfaces of cylindrical seeds has been suggested to explain the formation process of Te nanotubes containing chain-like building blocks,[7a] and helical nanobelt-twist-join-growth has been suggested for the formation of Te nanotubes.[7b] Li and co-workers[11a] have described that the formation of metallic Bi nanotubes may be associated with the quasi-layered structure of metallic Bi. Similarly, the observation of tubular and flake-like structures of Bi strongly induce us to speculate that the formation of Bi nanotubes under our experimental conditions is closer to the CSML model, though further investigation about a reliable model for the structure and growth of nanotubes is necessary. As regards the formation of the "bamboo raft", we hypothesize that it might be due to the well-known surface effects of nanostructured materials. The small diameters and the high aspect ratios cause the surface of the newly formed bismuth nanotubes to have large numbers of surface atoms, a lack of atomic coordination and high surface energy. These may lead to a strong tendency of the newly formed bismuth nanotubes to get close to each other and then arrange side by side along the 1D direction (the axial direction), thus forming the bamboo-raft-like nanostructure. The observations that almost all of these nanotubes exhibit a bamboo-raft-like nanostructure, and only a small amount of tubes exist as individual nanotubes, may indirectly confirm the hypothesis described above. However, the intermediate process of the formation of the bamboo-raft-like Bi nanostructure is not yet clear.

The proper reducing agent is crucial for the formation of bismuth nanotubes. Further investigation shows that similar bamboo-raft-like bismuth nanotubes can also be obtained in alkaline solution at room temperature, using tin chloride dihydrate ($SnCl_2 \cdot 2H_2O$) as reducing agent (see Supporting Information). But we failed to get Bi nanotubes at room temperature by using sodium borohydride or aqueous hydrazine as reducing agent. The specific reasons for these observations are unknown.

Conclusion

In summary, we have described a room-temperature aqueous-chemical route to obtain a high proportion (above 80%) of bamboo-raft-like bismuth nanotubes, which are comprised of several parallel straight bismuth nanotubes lying side by side along the axial direction. HRTEM observations show that the axial direction of the prepared nanotubes is along the normal direction of the (012) lattice planes of the rhombohedral bismuth. The present study

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

may be advantageous over most of the previously reported approaches in terms of no requirement of complex apparatus or techniques, and the possibility of production on a large scale. In addition, as a tubular sacrificing template, the prepared Bi nanotubes might also be potentially converted into 1D nanostructures of many technologically important materials, such as Bi_2S_3, Bi_2Se_3, Bi_2Te_3, and so forth.

Experimental Section

All reagents used in our experiments were analytical pure grade, purchased from Shanghai Chemicals Co. (China), and were used without further purification. In a typical procedure, 2 mmol of $BiCl_3$ was added to 50 mL of distilled water whilst stirring with a magnetic stirrer to yield a white precipitate. Then, 4 mmol of metallic zinc powder (about 200 mesh) was added to the above system, and the mixture was continuously stirred at room temperature for 2−4 h. The obtained mixture was added to dilute hydrochloric acid (1 M) and left to react for several minutes to remove the excess metal zinc and by-products. The mixture was then filtered, washed with distilled water several times, and the resulting black powder was finally dried in a vacuum at 60 °C for 4 h.

The samples were characterized by X-ray powder diffraction data (XRD), which were recorded on a Japan Rigaku Dmax-γA X-ray powder diffractometer with graphite monochromated Cu-K_α radiation (λ = 1.54178 Å). Transmission electron microscopy (TEM) images and high-resolution transmission electron microscopy (HRTEM) images, accompanied by Energy-dispersive X-ray spectrum (EDS), were obtained with a JEOL-2010 transmission electron microscope, employing an accelerating voltage of 200 kV.

Acknowledgments

Financial support from the National Natural Science Funds and the 973 Projects of China is gratefully acknowledged. The author would like to thank Prof. Shuyuan Zhang for HRTEM observations and Dr. Maosong Mo for helpful discussions.

A Binuclear Copper(II) Acetate Complex Showing a 3D Supramolecular Network with Hydrophilic Pockets: Its Unusual Magnetic Behaviour

Matilde Fondo,*[a] Ana M. García-Deibe,[a] Jesús Sanmartín,[a] Manuel R. Bermejo,[a] Luis Lezama,[b] and Teófilo Rojo[b]

Keywords: 3D network / Copper / Magnetic properties / Bridging ligands / Intermolecular interactions

The binuclear complex $[Cu_2L(OAc)]\cdot 6H_2O$ (**1**) {H_3L = 2-(2-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-3-azabut-3-enyl]-1,3-imidazolidine} which shows an unusual magnetic superexchange behaviour, acts as a building block for a novel three-dimensional metal-organic framework, with hydrophilic pockets.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Coordination complexes that define unusual network topologies have attracted special interest not only because of their intriguing architectures, but also of their tremendous potential applications in a wide number of fields.[1−7] However, the assembly of inorganic materials from organic ligands and metal-ion building blocks to generate new supramolecular architectures is still a challenge. Supramolecular inorganic/organic hybrid materials have so far been constructed through two principal design philosophies. The most common approach is the assembly of transition metal complexes into coordination polymers using coordinative covalent bonds.[2−6,8−11] The second method makes use of weaker intermolecular forces (particularly π-π interactions and hydrogen bonding)[7,12−15] for connecting building blocks into a wide variety of extended networks.

In this work, a novel case of "one-pot" self-assembled 3D networks, by combination of coordinative and intermolecular interactions, with brick-wall shaped channels, is described (Figure 1). This topology has not been previously reported to the best of our knowledge. The binuclear copper complex, which acts as building block, shows an unfamiliar superexchange pathway, with a net ferromagnetic behaviour.

Results and Discussion

The reaction of 2-(2-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-3-azabut-3-enyl]-1,3-imidazolidine (H_3L)[16] with copper(II) acetate dihydrate in methanol/acetonitrile yields a deep green solution in air. Its slow evaporation leads to the isolation of crystals of $[Cu_2L(OAc)]\cdot 6H_2O$ (**1**), suitable for X-ray diffraction studies.

The crystal structure shows that **1** consists of binuclear $[Cu_2L(OAc)]$ units (Figure 2) with water molecules as solvates. The isolated units contain both copper atoms doubly bridged by a phenolate oxygen atom [O(103)] of the central ligand arm and by an oxygen atom from an acetate ligand [O(11)]. This gives rise to an intramolecular Cu(11)···Cu(12) separation of 3.1450(19) Å. The Cu−O distances [Cu(11)−O(103) and Cu(12)−O(103); Cu(11)−O(11) and Cu(12)−O(11)] reflect the asymmetry of both endogenous and exogenous bridges. The Cu(11)−O(103)−Cu(12) and Cu(11)−O(11)−Cu(12) bridging angles are 102.5(2)° and 91.8(2)° respectively. The geometry around both copper atoms can be described as highly distorted square pyramidal (τ = 0.43 and 0.35 for Cu(11) and Cu(12) respectively), with O(11) at the apex of both pyramids. As a result, the complex consists of two distorted square pyramids sharing one base-to-apex edge (Scheme 1, Type I). The distorted basal planes form an angle of 133.9°. Two other types of arrangements are described in the literature for square-pyramidal complexes containing a Cu_2O_2 core: a) square pyramids sharing one base-to-apex edge but with parallel basal planes (Scheme 1, Type II); b) square pyramids sharing one basal edge with coplanar basal planes (Scheme 1, Type III). To the best of our knowledge, the situation Type I has not been previously reported for this kind of complex. In addition, the nearly perpendicular orientation of the Cu−Oph−Cu ideal plane and the central phenyl ring (90.6°) is remarkable.

The $[Cu_2L(OAc)]$ units form an extended array by a combination of π···π, CH···π and C−H···O hydrogen bonds,[17] leading to the formation of a 3D network with hydrophilic channels along the (001) direction of ca. 11 × 7 Å^2 (Fig-

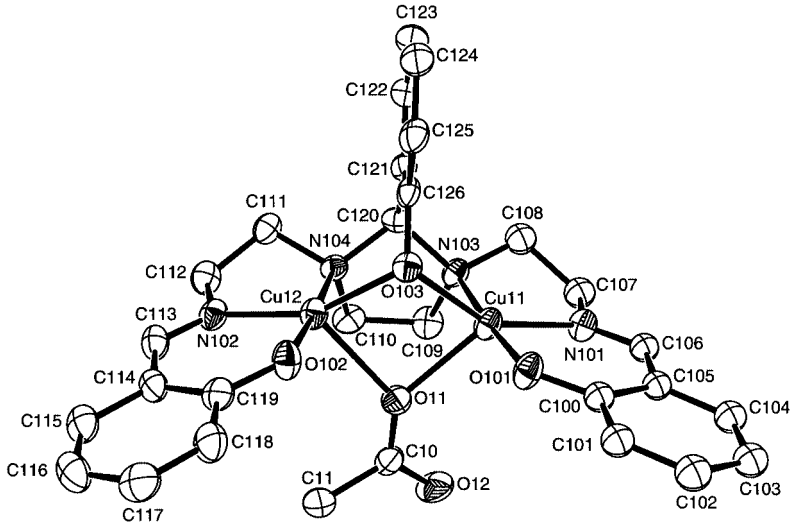

Figure 2. An ORTEP view of **1** showing 30% probability thermal ellipsoids (water molecules and hydrogen atoms are omitted for clarity); selected bond lengths and angles: Cu(11)−O(101) 1.909(6), Cu(11)−N(101) 1.950(7), Cu(11)−O(103) 2.042(6), Cu(11)−N(103) 2.076(7), Cu(11)−O(11) 2.171(6), Cu(12)−O(102) 1.919(6), Cu(12)−N(102) 1.931(7), Cu(12)−O(103) 1.991(5), Cu(12)−N(104) 2.076(7), Cu(12)−O(11) 2.208(6); O(101)−Cu(11)−N(103) 175.4(3), N(101)−Cu(11)−O(103) 149.5(3), N(101)−Cu(11)−O(11) 130.4(3), O(103)−Cu(11)−O(11) 79.5(2), O(102)−Cu(12)−N(104) 176.3(3), N(102)−Cu(12)−O(103) 155.2(3), N(102)−Cu(12)−O(11) 124.2(3), O(103)−Cu(12)−O(11) 79.7(2)

ure 1). Thus, the total void space, neglecting the solvent molecules, represents 34.2% of the cell volume. The water molecules occupy most of the void space and form an intricate hydrogen bond scheme. According to the structural data, they can be roughly assigned as: a) tightly bonded molecules, anchored to the network by one or more hydrogen bonds involving the phenol oxygen atoms or the uncoordinated acetate oxygen atom (O1w, O2w, O4w, O5w); b) loosely bonded molecules showing only contacts with other water molecules (the remaining solvent molecules).

ESR spectra for the title compound were recorded on powdered samples in the temperature ranges 4.2−300 K and 100−300 K operating at X- and Q-bands, respectively. Despite the extremely large observed signals, the spectrum

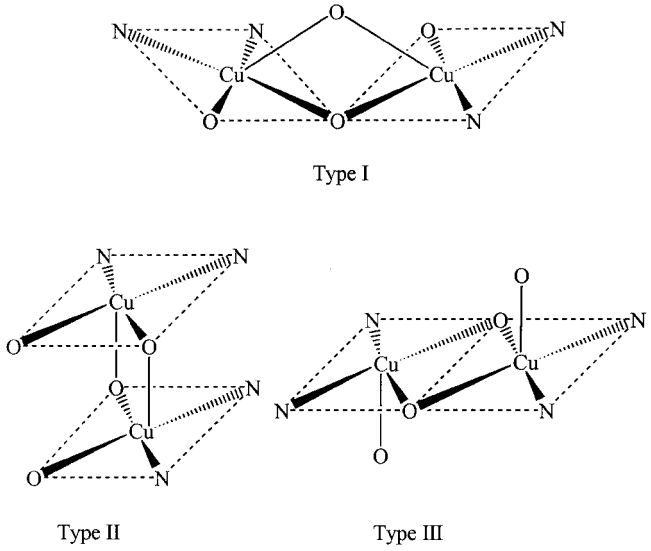

Scheme 1. Square pyramidal arrangements for Cu_2O_2 containing complexes

obviously corresponds to an $S = 1$ triplet state, as expected for an isolated binuclear Cu^{II} complex, with important zero-field splitting. The existence of a triplet state is confirmed by the presence of a "half-field" signal ($\Delta M_s = \pm 2$) in both X- and Q-band spectra. Unfortunately, the poor resolution of the spectra has precluded any unambiguous determination of the main components of the g and D tensors.

Magnetic susceptibility measurements have been performed between 5 and 300 K. Figure 3 shows the thermal evolution of the magnetic molar susceptibility, together with a plot of $\chi_m T$ vs T ($\chi_m T = \mu_{eff}^2/8$). Above 100 K, the data are well described by a Curie−Weiss law ($\chi_m = C_m/T-\theta$), with $C_m = 0.86$ cm^3 K/mol and $\theta = +12.6$ K. The positive θ value, as well as the overall appearance of the $\chi_m T$ vs. T curve, are indicative of the predominance of ferromagnetic interactions in this compound. The $\chi_m T$ product increases from 0.89 cm^{3}K/mol at room temperature to 1.13 cm^{3}K/mol at 5 K.

Taking into account the crystal structure of this compound, the susceptibility data have been fitted to the Bleaney−Bowers equation[18] derived from the Heisenberg spin Hamiltonian ($H = -2JS_1S_2$) for two coupled $S = 1/2$ ions:

$$\chi_m = \frac{2Ng^2\beta^2}{kT}\left[\frac{1}{3+\exp(-2J/kT)}\right] \quad (1)$$

The best least-squares fit (solid lines in Figure 3) is obtained with the parameter $2J = +49.2$ cm^{-1} ($J/k = +35.4$ K) and $g = 2.13$. Attempts to evaluate the possible interbinuclear interactions by means of a J' parameter treated in the molecular field approximation, led to extremely low values without any significant improvement of the fit.

As the geometry around both copper atoms is distorted square pyramidal, the $d_{x^2-y^2}$ magnetic orbitals (containing the unpaired electron) point towards the bridging phenolate oxygen atom. Therefore, the structure of complex **1** suggests that O(103) provides the likely pathway for coupling. The bridging acetate oxygen atom is at the common apical position of the square pyramidal chromophores, indicating that O(11) does not participate or shows negligible contribution to the superexchange pathway. Therefore, the magnetic behaviour of this complex is rather unusual. The main superexchange pathway is a phenolate oxygen atom, and binuclear copper complexes that share just one basal phenolate oxygen atom are usually antiferromagnetic.[19−23] In fact, just one binuclear copper of this type, which shows a square pyramidal arrangement of Type II, is described to be weakly ferromagnetic.[24] Besides, doubly bridged phenolate copper complexes usually show strong antiferromagnetic coupling.[25−29] The ferromagnetic behaviour of complex **1** can be attributed to its unusual structural features, detailed above.

In summary, this study reports the first complex containing a Cu_2O_2 core with a Type I arrangement, which shows an unfamiliar magnetic behaviour. Complex **1** acts as a building block to produce a 3D framework via weak intermolecular interactions. The network shows brick-wall shaped hydrophilic channels with unprecedented topology.

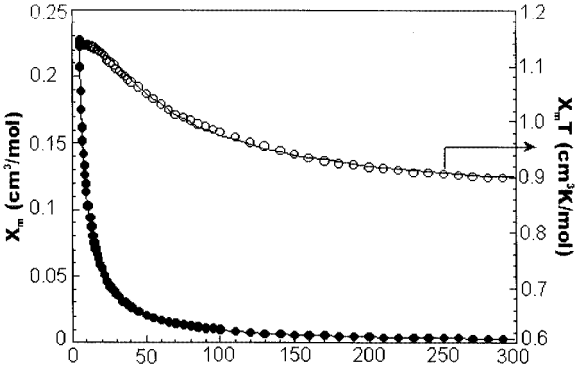

Figure 3. Magnetic data for **1** at 5−300 K

Experimental Section

General: Elemental analysis was performed on a Carlo Erba EA 1108 analyser. Infrared spectrum was recorded as KBr pellets on a Bio-Rad FTS 175 spectrophotometer in the range 4000−600 cm^{-1}. Electrospray mass spectrum was obtained on a Hewlett−Packard LC/MS spectrometer with methanol as solvent.

Synthesis of 1: A solution of copper acetate dihydrate (0.25 g, 1.25 mmol) in methanol (30 mL) was mixed with a solution of H_3L (0.287 g, 6.23 mmol) in acetonitrile (30 mL). The resultant green solution was stirred at room temperature for 4 h. Slow evaporation of the solution yielded crystals of **1** (Yield: 0.35 g, 74.6%). $C_{29}H_{42}Cu_2N_4O_{11}$ (749.75): calcd. C 46.5, H 5.6, N 7.5; found C 46.9, H 5.7, N 7.2. (KBr): ν(C=N) = 1634 cm^{-1} (s). ES-MS: $m/z = 581.1$ [Cu_2L^+].

X-ray Crystallography: Prism-shaped green crystals of **1** were grown as detailed above. Data were collected on a Smart-CCD-

1000 BRUKER diffractometer, using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å), operating at room temperature. The structure was solved by direct methods and refined by full-matrix least-squares based on F^2 using the SHELX-97 program package.[30] Absorption correction was carried out semi-empirically from equivalents using the SADABS program.[31] Crystal data: $C_{29}H_{42}Cu_2N_4O_{11}$, M_r = 749.75 g·mol^{-1}, monoclinic, space group $C2/c$, a = 31.831(11), b = 13.968(5), c = 20.754(7) Å, β = 126.359(19)°, V = 7431(4) Å^3, Z = 8, D_c = 1.340 Mg·m^{-3}, $F(000)$ = 3120, μ(Mo-K_α) = 1.201 mm^{-1}. 5367 Unique reflections were measured. Final $R1$ = 0.1480 on all data, conventional $R1$ = 0.0661 on [$I > 2\sigma(I)$].

CCDC-205980 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

EPR and Magnetic Measurements: A Bruker ESP300 spectrometer, operating at X- and Q-bands and equipped with standard Oxford low temperature devices, was used to record the ESR powder spectra of **1** at different temperatures. The magnetic field was calibrated by an NMR probe and the frequency inside the cavities was determined with a Hewlett−Packard 5352B microwave frequency counter. Magnetic susceptibility measurements were performed on powdered samples between 5 and 300 K with a Quantum Design MPMS-7 SQUID magnetometer. The magnetic field used in the experiments was 0.1 T, a value at which the magnetisation versus magnetic field curve was still linear at 5 K. Experimental susceptibility values were corrected for diamagnetic contributions and for temperature-independent paramagnetism.

Chiral Arene Ruthenium Complexes: Synthesis and Molecular Structure of the Enantiopure Cluster Cation (*S*)-$[H_3Ru_3\{C_6H_5[CH(CH_3)CH_2OH]\}(C_6Me_6)_2(O)]^+$

Ludovic Vieille-Petit,[a] Bruno Therrien,[a] and Georg Süss-Fink*[a]

Keywords: Arene ligands / Chirality / Cluster compounds / Ruthenium

The reaction of enantiopure (*R*)-(2-cyclohexa-1,4-dienyl)propan-1-ol with ruthenium chloride hydrate yields, without racemisation of the chiral ligand, the chloro-bridged dinuclear complex (*S*,*S*)-$[RuCl_2\{C_6H_5[CH(CH_3)CH_2OH]\}]_2$ (**1**). The dimer **1** reacts with triphenylphosphane to give the mononuclear complex (*S*)-$[RuCl_2\{C_6H_5[CH(CH_3)CH_2OH]\}(PPh_3)]$ (**2**). A single-crystal X-ray structure analysis of **2** reveals the absolute configuration of the asymmetric carbon atom to have remained, the change from (*R*) to (*S*) being due to the priority change caused by coordination; in the solid state, one-dimensional hydrogen-bonded chains are formed between the hydroxy functions and chloro ligands of neighbouring molecules. The mononuclear cationic complex (*S*)-$[Ru\{C_6H_5[CH(CH_3)CH_2OH]\}(H_2O)_3]^{2+}$, formed in situ from **1** in aqueous solution, reacts with the dinuclear complex $[H_3Ru_2(C_6Me_6)_2]^+$ to give a chiral trinuclear arene-ruthenium cluster, the cation (*S*)-$[H_3Ru_3\{C_6H_5[CH(CH_3)CH_2OH]\}(C_6Me_6)_2(O)]^+$ (**3**). This enantiopure cation has been isolated and characterised as its tetrafluoroborate salt. The single-crystal X-ray structure analysis of (*S*)-[**3**][BF_4] shows a strong intramolecular hydrogen bond between the μ_3-oxo cap and the hydroxy function, which also persists in acetone solvent, as demonstrated by NMR spectroscopy.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Recently, we found the water-soluble cluster cation $[H_3Ru_3(C_6H_6)(C_6Me_6)_2(O)]^+$ to efficiently catalyse the hydrogenation of benzene to give cyclohexane under biphasic conditions.[1,2] On the other hand, much attention has been given to the development of chiral arene-ruthenium complexes for the catalytic transfer hydrogenation of ketones[3−6] and for asymmetric Diels−Alder reactions.[7] Therefore, trinuclear ruthenium cluster cations with functional substituents at the η^6-moiety could give rise to homogeneous catalysts which display special solubility properties or can be immobilised on resins.[8]

Herein we report the synthesis and characterisation of a new chloro-bridged arene-ruthenium dimer, (*S*,*S*)-$[RuCl_2\{C_6H_5[CH(CH_3)CH_2OH]\}]_2$ (**1**), in which the η^6-arene ligand possesses a side-arm substituent incorporating an asymmetric carbon. The dimeric species is used to synthesise an enantiopure mononuclear complex, (*S*)-$[RuCl_2\{C_6H_5[CH(CH_3)CH_2OH]\}(PPh_3)]$ (**2**), as well as an enantiopure trinuclear cluster cation, (*S*)-$[H_3Ru_3\{C_6H_5[CH(CH_3)CH_2OH]\}(C_6Me_6)_2(O)]^+$ (**3**). NMR spectroscopy as well as single-crystal X-ray analyses show that the chiral centre is stable under various reaction conditions.[9]

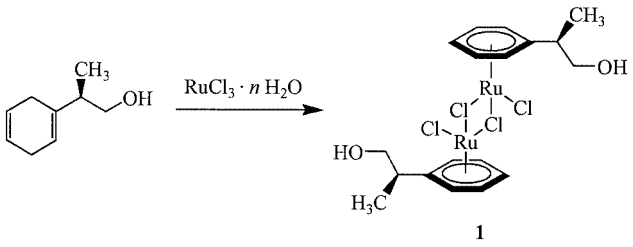
Results and Discussion

The reaction of (*R*)-(2-cyclohexa-1,4-dienyl)propan-1-ol, accessible from the Birch reduction[10] of commercially available (*R*)-(2-phenyl)propan-1-ol, with ruthenium(III) chloride hydrate, in refluxing ethanol, gives the new chiral chloro-bridged dimer (*S*,*S*)-$[RuCl_2\{C_6H_5[CH(CH_3)CH_2OH]\}]_2$ (**1**), which can be isolated quantitatively as an orange powder (Scheme 1). From enantiopure (2-cyclohexa-1,4-dienyl)propan-1-ol only the (*S*,*S*)-isomer is formed. There is no change in the absolute configuration of the asymmetric carbon atom, the change from (*R*) to (*S*) in the denomination is only due to the change in the priority (Cahn−Ingold−Prelog rules) by the coordination of the phenyl group to a ruthenium atom.



1

Scheme 1

Despite the strong acidic conditions during the dehydrogenation reaction, there is no evidence for racemisation of the (*R*)-(2-phenyl)propanol ligands. The ^1H and $^{13}C\{^1H\}$ NMR spectra of **1** show only one set of signals, the $^{13}C\{^1H\}$

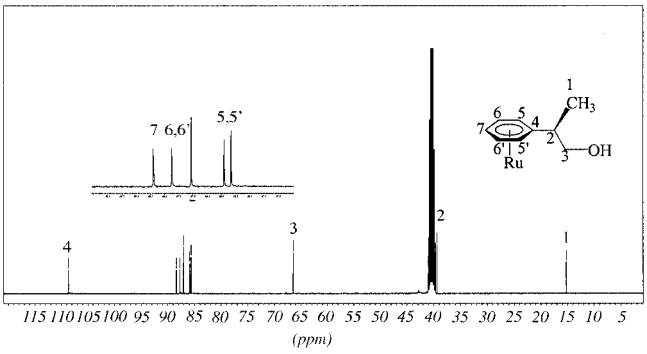


Figure 1. $^{13}C\{^1H\}$ NMR spectrum of **1** in $[D_6]$DMSO (400 MHz)

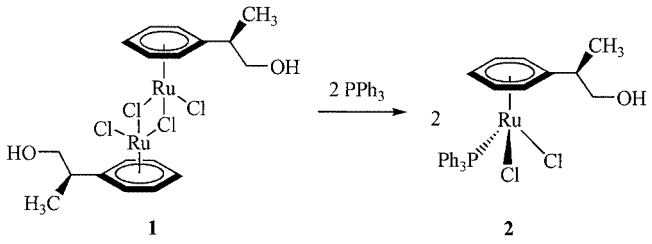

Scheme 2

NMR spectrum in $[D_6]$DMSO is presented in Figure 1. Except for the distinction between the two carbons at the *ortho* positions as well as the two carbons at the *meta* positions of the η^6-arene moiety, all diastereotopic carbons can be assigned unambiguously.

Cleavage of the chloro bridges of the dinuclear complex **1** with two equivalents of triphenylphosphane in CH_2Cl_2 gives the mononuclear complex (*S*)-$[RuCl_2\{C_6H_5$-$[CH(CH_3)CH_2OH]\}(PPh_3)]$ (**2**) in good yield (Scheme 2). The formation of **2** is conveniently monitored by $^{31}P\{^1H\}$ NMR spectroscopy, the $^{31}P\{^1H\}$ NMR signal being shifted downfield by 33.2 ppm (as compared to uncoordinated triphenylphosphane).

The orange air-stable compound was crystallised from a slow diffusion of hexane into a chloroform solution containing **2**. A single-crystal X-ray analysis was performed, confirming the molecular structure of **2** (Figure 2).

The ruthenium atom possesses a pseudo-octahedral geometry, and the metrical parameters around the metallic core compare well with those of similar three-legged pianostool $[RuCl_2(\eta^6$-arene$)(PPh_3)]$ complexes.[11−14] A distortion at the arene ligand is present, the Ru−C bond length *trans* to the phosphorous atom, Ru(1)−C(1) 2.274(4) Å, is elongated as compared to the other Ru−C bonds [ranging between 2.187(4) and 2.244(3) Å]. In the solid state, a series of hydrogen bonds between hydroxy functions and chloride

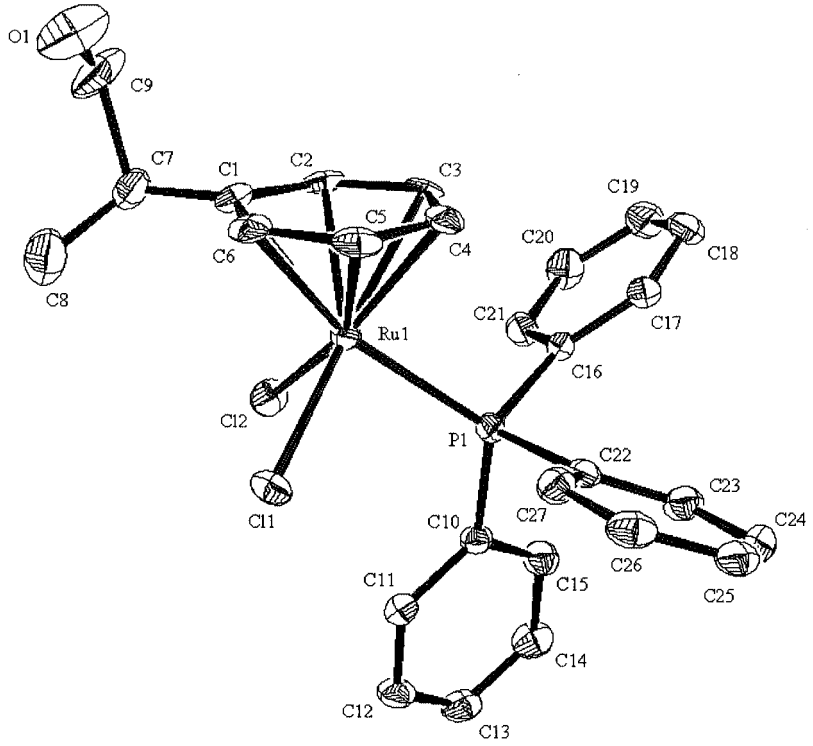

Figure 2. ORTEP view of **2**; displacement ellipsoids are drawn at the 50% probability level; hydrogen atoms and chloroform molecule are omitted for clarity; selected bond lengths (Å) and angles (°): Ru(1)−P(1) 2.3530(10), Ru(1)−Cl(1) 2.4134(9), Ru(1)−Cl(2) 2.3995(10), Ru(1)−C(1) 2.274(4), Ru(1)−C(2) 2.187(4), Ru(1)−C(3) 2.205(4), Ru(1)−C(4) 2.195(4), Ru(1)−C(5) 2.187(4), Ru(1)−C(6) 2.244(3); P(1)−Ru(1)−Cl(1) 91.81(3), P(1)−Ru(1)−Cl(2) 86.34(4), Cl(1)−Ru(1)−Cl(2) 86.62(4)

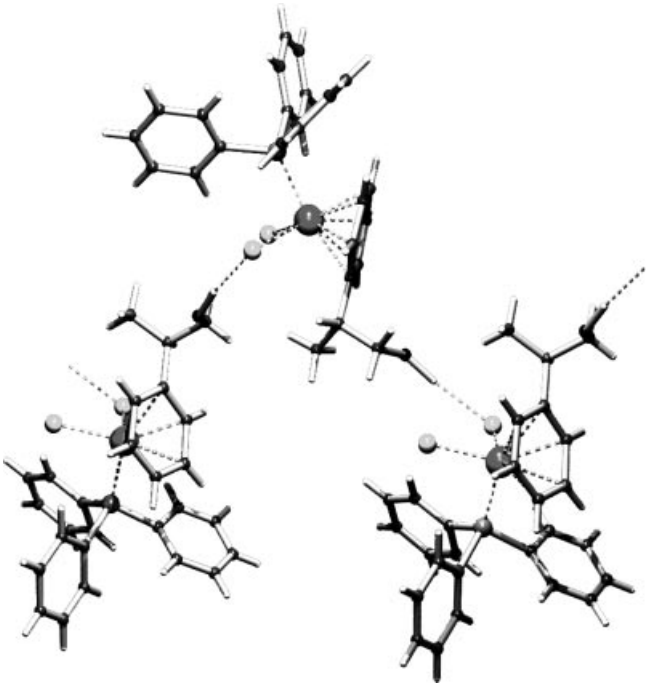

Figure 3. One-dimensional hydrogen bonded chains in the crystalline form of **2**

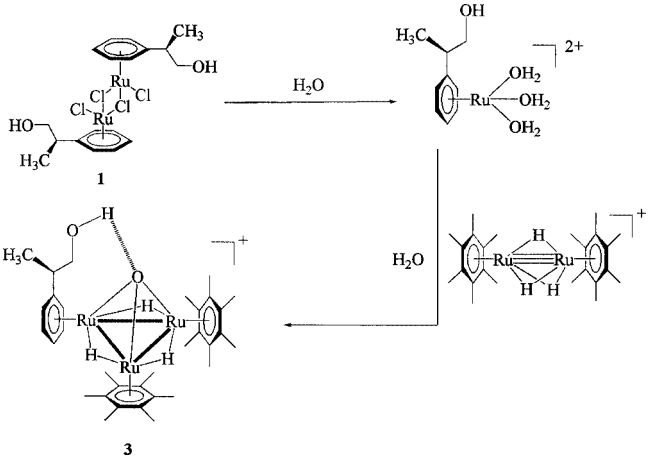
ligands of neighbouring molecules forms one dimensional chains through the crystal (Figure 3).

In aqueous solution, the dinuclear complex **1** forms the mononuclear complex $[Ru\{C_6H_5[CH(CH_3)CH_2OH]\}(H_2O)_3]^{2+}$, an analogue of the known cation $[(C_6H_6)Ru(H_2O)_3]^{2+}$,[15] which reacts in situ with the dinuclear complex $[H_3Ru_2(C_6Me_6)_2]^+$ [16,17] to give the chiral cluster cation (*S*)-$[H_3Ru_3\{C_6H_5[CH(CH_3)CH_2OH]\}(C_6Me_6)_2(O)]^+$ (**3**; Scheme 3).



Scheme 3

The enantiopure cation (*S*)-[**3**] has been isolated and characterised as its tetrafluoroborate salt. Whereas the known trinuclear ruthenium cluster cation analogues $[H_3Ru_3(\eta^6\text{-arene})(\eta^6\text{-arene'})_2(O)]^+$ [1,14,18,19] give rise to two hydride signals, a triplet and a doublet integrating for one and two protons, respectively, in the ^1H NMR spectra. The three hydrido ligands in **3** are all inequivalent and give rise to three independent signals. The ^1H NMR spectrum of **3** in [D_6]acetone shows three multiplets at high field centered at $\delta = -19.86$, -19.43 and -19.23 ppm, due to the presence of the asymmetric α-carbon on the side arm. In order to ascertain the retention of the chirality during the synthesis of **3**, a single crystal structure analysis of [**3**][BF_4] was performed.

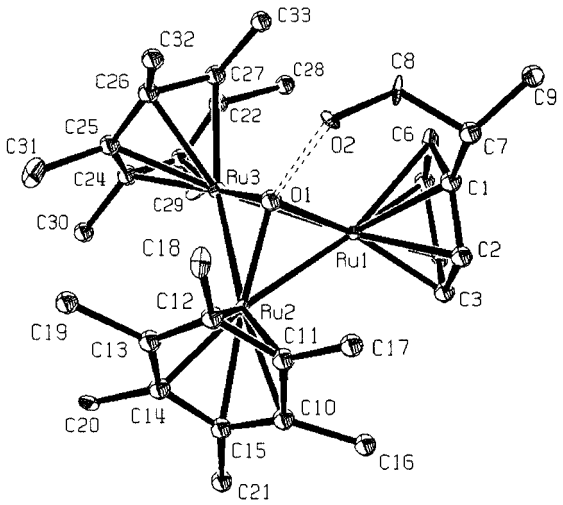


Figure 4. ORTEP view of [**3**]$^+$; displacement ellipsoids are drawn at the 35% probability level, hydrogen atoms, solvent, and the anion are omitted for clarity; selected bond lengths (A) and angles (°): Ru(1)−Ru(2) 2.751(3), Ru(1)−Ru(3) 2.749(3), Ru(2)−Ru(3) 2.785(2), Ru(1)−O(1) 2.058(16), Ru(2)−O(1) 1.935(18), Ru(3)−O(1) 1.971(16); Ru(1)−Ru(2)−Ru(3) 59.54(7), Ru(2)−Ru(3)−Ru(1) 59.62(7), Ru(3)−Ru(1)−Ru(2) 60.84(6), Ru(1)−O(1)−Ru(2) 87.0(6), Ru(1)−O(1)−Ru(3) 86.0(6), Ru(2)−O(1)−Ru(3) 90.9(5)

Poor quality crystals of [**3**][BF_4] were obtained by slow diffusion of benzene into an acetone solution of the salt. The asymmetric unit comprises two independent molecules of **3**, two BF_4 anions, and half a molecule of a disordered benzene. Only one molecule of **3** is shown in Figure 4. The two independent molecules show identical symmetrical data.

The metal core consists of three ruthenium atoms, the three Ru−Ru distances being in accordance with a metal-metal single bond. The three ruthenium atoms are capped by a μ_3-oxo ligand which is almost symmetrically coordinated. As shown by its molecular structure, the presence of the $CH(CH_3)CH_2OH$ side-arm allows **3** to form a strong intramolecular hydrogen bond with the μ_3-oxo cap. The distances between the two oxygen atoms involved in the intramolecular hydrogen bonds are 2.69(3) Å for molecule 1 and 2.66(2) Å for molecule 2.

The strong intramolecular hydrogen bond in **3**, found in the solid state, seems to persist also in acetone solution. The ^1H NMR spectrum of **3** in [D_6]acetone shows a well defined doublet of doublets centered at $\delta = 6.67$ ppm attributed to the proton of the OH group coupled to the two diastereotopic protons of the neighbouring CH_2 group.

Conclusion

The chiral chloro-bridged η^6-(*S*)-(2-phenyl)propan-1-ol ruthenium complex (*S*,*S*)-**1** can be synthesised by dehydrogenation of (*R*)-(2-cyclohexa-1,4-dienyl)propan-1-ol without racemisation. Cleavage of the chloro bridges with triphenylphosphane gives the enantiopure mononuclear complex (*S*)-**2** in good yield. The first water-soluble trinuclear arene-ruthenium cluster cation containing an asymmetric carbon atom tethered to an arene ligand was isolated as the tetrafluoroborate salt (*S*)-[**3**][BF_4]. NMR spectroscopy and X-ray analyses show that no racemisation is observed during the different steps of synthesis. The absolute configuration at the asymmetric α-carbon remains unchanged under the different reaction conditions: acidic conditions during the dehydrogenation to form **1**, basic conditions during the cleavage of the chloro bridges of **2** with triphenylphosphane, and aqueous conditions during the formation of **3**.

Experimental Section

General Remarks: All manipulations were carried out by routine methods under a nitrogen atmosphere. De-ionised water and organic solvents were degassed and saturated with nitrogen prior to use. NMR spectra were recorded using a Varian Gemini 200 BB spectrometer and a Bruker 400 MHz spectrometer. Microanalyses were carried out by the Laboratory of Pharmaceutical Chemistry, University of Geneva (Switzerland). Electro-spray mass spectra were obtained in positive-ion mode with an LCQ Finnigan mass spectrometer. The starting dinuclear dichloro complex [$RuCl_2(C_6Me_6)]_2$ was prepared according to known literature methods.[20] (*R*)-(2-Cyclohexa-1,4-dienyl)propan-1-ol was synthesised by sodium reduction of (*R*)-(2-phenyl)propan-1-ol in liquid ammonia.[21]

Complex 1: (*R*)-(2-Cyclohexa-1,4-dienyl)propan-1-ol (2.5 g, 18.1 mmol) was added to a solution of ruthenium trichloride hydrate (1.0 g, 3.8 mmol) in ethanol (70 mL), and the mixture was refluxed overnight. After cooling to room temperature, half of the solvent was evaporated. The orange precipitate was filtered, washed with diethyl ether, and dried under vacuum to give pure [$RuCl_2${C_6H_5[$CH(CH_3)CH_2OH$]}]$_2$. Yield: 1.90 g (81%). ^{1}H NMR (400 MHz, [D$_6$]DMSO): δ = 1.17 (d, ^3J = 6.92 Hz, 6 H, CH_3), 2.73 [m, 2 H, C*H*(CH_3)CH_2OH], 3.44 [dd, ^2J = 10.63, ^3J = 6.01 Hz, 2 H, $CH(CH_3)CH_2$OH], 3.55 [dd, ^2J = 10.63 Hz, ^3J = 5.38 Hz, 2 H, $CH(CH_3)CH_2$OH], 4.06 [br., 2 H, $CH(CH_3)CH_2O$*H*], 5.75 (m, 6 H, H_{arom}), 5.87 (m, 4 H, H_{arom}) ppm. ^{13}C{^{1}H} (100 MHz, [D$_6$]DMSO): δ = 15.24 (CH_3), 39.37 [*C*H(CH_3)CH_2OH], 66.43 [$CH(CH_3)$*C*H_2OH], 85.67, 85.90, 87.06, 87.75, 88.40, 108.63 (C_{arom}) ppm. MS (ESI, positive mode, dmso): *m*/*z* = 580.5 [M − Cl]$^+$ $C_{18}H_{24}Cl_4O_2Ru_2$ (616.3): calcd. C 35.08, H 3.92; found C 34.96, H 4.01.

Complex 2: Two equivalents of triphenylphosphane (170 mg, 0.6 mmol) was added to a suspension of **1** (200 mg, 0.3 mmol) in 30 mL of CH_2Cl_2. The mixture was stirred at room temperature during 2 hours and then filtered through celite to eliminate insoluble degradation materials. The product was purified on a silica gel column, eluting CH_2Cl_2/acetone (10:2) to give **2** as an orange-brown powder. Yield: 295 mg (80%). Orange crystals suitable for X-ray analysis were obtained by recrystallisation from $CHCl_3$/*n*-hexane. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.39 (d, ^3J = 5.98 Hz, 3 H, CH_3), 2.36 [m, 1 H, C*H*(CH_3)CH_2OH], 3.19 [br., 1 H, $CH(CH_3)CH_2O$*H*], 3.99 [m, 1 H, $CH(CH_3)$C*H*$_2$OH], 4.14 [m, 1 H, $CH(CH_3)$C*H*$_2$OH], 4.74 to 4.89 (m, 3 H, Ru-C_6H_5), 5.70 to 5.86 (m, 2 H, Ru-C_6H_5), 7.42 (m, 9 H, P-C_6H_5), 7.76 (m, 6 H, P-C_6H_5) ppm. ^{13}C{^{1}H} (50 MHz, $CDCl_3$): δ = 17.49 (CH_3), 39.06 [*C*H(CH_3)CH_2OH], 66.51 [$CH(CH_3)$*C*H_2OH], 84.10, 84.19, 84.37, 91.78, 92.99, 113.51 (Ru-C_6H_5), 128.48, 130.79, 133.54, 134.45 (P-C_6H_5) ppm. ^{31}P{^{1}H} (80 MHz, $CDCl_3$): δ = 28.93 ppm. MS (ESI, positive mode, CH_3OH): *m*/*z* = 535 [M − Cl]$^+$. $C_{27}H_{27}Cl_2OPRu$ (570.5): calcd. C 56.85, H 4.77; found C 57.02, H 4.71.

Complex 3: A mixture of [$RuCl_2(C_6Me_6)]_2$ (400 mg, 0.6 mmol) and Ag_2SO_4 (376 mg, 1.2 mmol) in water (40 mL) was stirred in the dark for 1 h. During this period the mixture was treated several times with ultrasound, until the orange solid was completely dissolved. The white precipitate (AgCl) was removed by filtration from the yellow solution containing [$Ru(C_6Me_6)(H_2O)_3]^{2+}$. An aqueous solution containing $NaBH_4$ (100 mg, 2.6 mmol, 10 mL H_2O) was then added dropwise to this yellow solution. The solution turned dark-red due to the formation of [$Ru_2(C_6Me_6)_2(\mu_2$-H)$_3]^+$. After filtration, solid [$RuCl_2${C_6H_5[$CH(CH_3)CH_2OH$]}]$_2$ (345 mg, 0.56 mmol) was added. The mixture was heated to 60 °C for 50 hours in a closed pressure Schlenk tube. The resulting red solution was filtered, and a large excess of $NaBF_4$ was added to precipitate [**2**][BF_4]. The precipitate was centrifuged, dissolved in CH_2Cl_2, filtered through celite to eliminate excess $NaBF_4$ and purified on silica-gel plates (eluent: CH_2Cl_2/acetone 2:1). Yield: 210 mg (40%). ^{1}H NMR (400 MHz, [D$_6$]acetone): δ = −19.86 (m, 1 H, hydride), −19.43 (m, 1 H, hydride), −19.23 (m, 1 H, hydride), 1.21 [d, ^3J = 7.03 Hz, 3 H, $CH(CH_3)CH_2OH$], 2.49 [m, 1 H, C*H*(CH_3)CH_2OH], 2.77 [s, 18 H, $C_6(CH_3)_6$], 2.78 [s, 18 H, $C_6(CH_3)_6$], 3.63 [m, 1 H, $CH(CH_3)CH_2OH$], 3.90 [m, 1 H, $CH(CH_3)CH_2OH$], 5.39 (m, 2 H, H_{arom}), 5.56 (m, 1 H, H_{arom}), 6.01 (m, 1 H, H_{arom}), 6.10 (m, 1 H, H_{arom}), 6.67 [dd, ^3J = 3.63, ^3J = 11.09 Hz, 1 H, $CH(CH_3)CH_2O$*H*] ppm. ^{13}C{^{1}H} (100 MHz, [D$_6$]acetone): δ = 17.46 [$CH(CH_3)CH_2OH$], 17.51 [$C_6(CH_3)_6$], 42.07 [*C*H(CH_3)CH_2OH], 66.77 [$CH(CH_3)$*C*H_2OH], 74.42, 76.72, 81.57, 84.59, 87.67, 95.29, 113.66 (C_{arom}) ppm. MS (ESI positive mode, acetone): *m*/*z* = 783 [M + H]$^+$. $C_{33}H_{51}BF_4O_2Ru_3$ (869.8): calcd. C 45.57, H 5.91; found C 45.41, H 6.07.

X-ray Crystallographic Study

X-ray Data for (*S*)-[2]·$CHCl_3$: $C_{28}H_{28}Cl_5OPRu$, *M* = 689.79 gmol^{-1}, monoclinic, *P*2$_1$ (no. 4), *a* = 9.6386(9), *b* = 13.5325(11), *c* = 11.4019(12) Å, β = 105.096(11)°, *U* = 1435.9(2) Å^3, *T* = 153 K, *Z* = 2, μ(Mo-K_α) = 1.088 mm^{-1}, 10215 reflections measured, 4654 unique (R_{int} = 0.0317) which were used in all calculations. The final wR_2 (F^2) was 0.0620 (all data).

X-ray Data for (*S*)-[3][BF_4]·C_6H_6: $C_{72}H_{108}B_2F_8O_4Ru_6$, *M* = 1817.62 gmol^{-1}, monoclinic, *P*2$_1$ (no. 4), *a* = 8.8158(9), *b* = 20.2561(14), *c* = 23.352(2) Å, β = 91.870(12)°, *U* = 4167.6(7) Å^3, *T* = 153 K, *Z* = 2, μ(Mo-K_α) = 1.118 mm^{-1}, 15789 reflections measured, 13603 unique (R_{int} = 0.0920) which were used in all calculations. The final wR_2 (F^2) was 0.3828 (all data).

The data were measured using a Stoe Image Plate Diffraction system equipped with a φ circle, using Mo-K_α graphite monochromated radiation (λ = 0.71073 Å) with φ range 0−200°, increment of respectively 1.6 and 1.0°, 2θ range from 2.0−26°, D_{max}-D_{min} = 12.45−0.81 Å. The structures were solved by direct methods using the program SHELXS-97.[22] The refinement and all further calculations were carried out using SHELXL-97.[23] The H-atoms were included in calculated positions and treated as riding atoms using the SHELXL default parameters. The non-H atoms were refined

2D Chiral Uranyl(VI) Coordination Polymers with Second-Harmonic Generation Response and Ferroelectric Properties

Yong-Rong Xie,[a] Hong Zhao,[a] Xi-Sen Wang,[a] Zhi-Rong Qu,[a] Ren-Gen Xiong,*[b] Xiang Xue,[a] Ziling Xue,[c] and Xiao-Zeng You[a]

Keywords: Chirality / Polymers / Uranium / Crystal engineering / SHG properties

The in situ hydrothermal reactions of $UO_2(NO_3)_2$ with 1-oxo-4-cyanopyridine (ocpy) and ethyl (*S*)-lactate (e-la) afforded two unprecedented chiral 2D neutral luminescent square grids, uranyl-bis(1-oxo-4-pyridylcarboxylate) $UO_2(opyca)_2$ (**1**) and homochiral uranyl-bis[(*S*)-lactate] (**2**). Their solid-state structures, preliminary optical and photoluminescent properties are reported.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The crystal engineering strategy has provided many advantages to construct chiral or polar supramolecular motifs with many useful physical properties, especially the nonlinear optical properties [second harmonic generation (SHG) response].[1,2] Enantiopure or homochiral metal-organic coordination polymers have found some applications in selective enantio-separation and asymmetric catalysis.[3] Apart from those achievements, however, as Ward et al. pointed out,[1a] the prediction of crystal structures based solely on the structure of their molecular components still remains unexplored and crystal engineering has not developed to the stage where a desired structure (or crystal symmetry) can be ensured. One of the foremost challenges not only in organic solid-state chemistry, but also in supramolecular materials design with SHG properties, essentially requires crystallization in noncentrosymmetric space groups (those lacking inversion symmetry). Moreover, a noncentrosymmetric polar packing arrangement is a requirement for a number of macro-physical properties, such as piezoelectricity, pyroelectricity, and ferroelectricity as well as SHG, which describes the capacity of a material to double the frequency of incident light. A ferroelectric material is one which can be switched rapidly between different states by means of an external electric field. Such materials may be useful in a variety of new technologies, such as electric-optical devices, information storage, switchable NLO (nonlinear optical) devices and light modulators. Recently, some polar and chiral metal-organic coordination polymers have been used as SHG materials with metal ions such as Zn^{2+}, Cd^{2+}, and Ag^{+}.[2] To this end, chiral or enantiopure organic-inorganic hybrid coordination polymers containing the uranium(VI) ion, to the best of our knowledge, remain unexplored and unknown, although there has been much current interest in multi-dimensional U^{VI} coordination polymers which have widespread properties such as fluorescence and zeolite-likeness.[4−6] To our surprise, the in situ hydrothermal reactions of $UO_2(NO_3)_2$ with 1-oxo-4-cyanopyridine (ocpy) and ethyl (s)-lactate(e-la) afford two unprecedented chiral 2D neutral luminescent square grids, uranyl-bis(1-oxo-4-pyridylcarboxylate) $UO_2(opyca)_2$ (**1**) and homochiral uranyl-bis[(*S*)-lactate] (**2**). Herein, we report their synthesis, solid state structures, fluorescent and optical properties (1).

Results and Discussion

The hydrolysis reaction of $UO_2(NO_3)_2$ with ocpy under hydrothermal reaction conditions gave **1**, as shown by the absence of the cyano group peak (ca. 2200 cm^{-1}) and appearance of a strong carboxylate peak at 1600 cm^{-1} in its IR spectrum. The hydrolysis reaction of $UO_2(NO_3)_2$ with e-la under hydrothermal reaction conditions yielded **2**, as confirmed by the appearance of the carboxylate peak (ca. 1600 cm^{-1}).

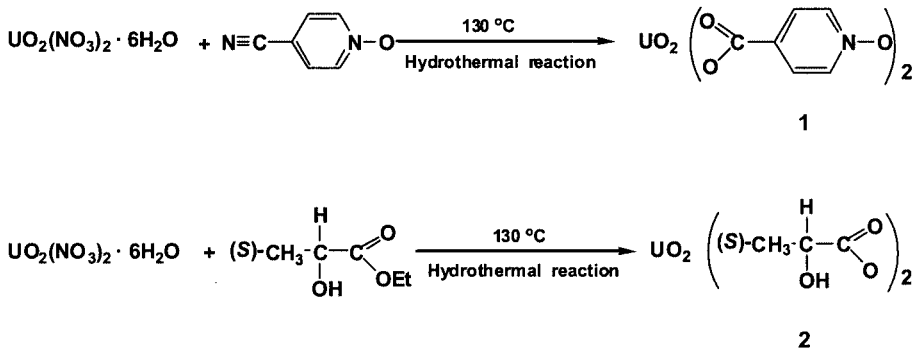

Scheme 1

These in situ hydrolysis reactions or in situ ligand syntheses provide an excellent route to novel metal-organic coordination polymer construction for chemists.[7]

The solid-state structure of **1** (Figure 1a) has a slightly distorted pentagonal bipyramid as the local coordination geometry around each U atom center, defined by seven oxygen atoms from two carboxylate groups, two N-oxide and two oxo groups. Thus, there are two kinds of opyca ligands, one serves as a tridentate spacer, and the other acts as a bidentate linker. Overall each opyca ligand bridges two U atom centers, resulting in the formation of a 2D square grid network with dimensions of 10.07 × 10.04 Å (Figure 1b). The relationship between two layers in the packing diagram in **1** should be an ABAB-type stack, as observed (Supporting Information). No interpenetration was observed in **1**. To the best of our knowledge, this is the first example of neutral square networks containing an U atom as the connecting node.[8]

Like **1**, the local coordination geometry around each U atom center in **2** can best be described as a distorted pentagonal bipyramid. However, there are two crystallographically different U centers (Figure 2a). There are also three kinds of lactate ligands: One serves as a bidentate ligand to chelate one U atom using two oxygens from one carboxylate and one hydroxy group; the second lactate ligand acts as a bidentate bridge to link two U atoms using one carboxylate group; the third lactate ligand is a monodentate terminal group with coordination of its carboxylate to one U atom. Such coordination results in the formation of a 2D brick-wall type grid network with approximate dimensions of 3 × 6.04 Å (Figure 2b). The relationship between two layers is also an ABAB-type stack (Supporting Information). No interpenetration was found in **2**.

Compounds **1** and **2** crystallize in the chiral space groups $P2_12_12_1$ and $P2_1$ respectively. These two space groups belong to the crystal classes 222 and 2, respectively, where their optical activity can occur as a specific physical effect. Preliminary experimental results show that **1** and **2** display powder SHG efficiencies ca. 0.4 and 0.1 times that of urea. Due to **2** having a polar point group (C_2) which theoretically can display potential ferroelectric property. However **1**, with a point group of D_2, fails to do that in principle.

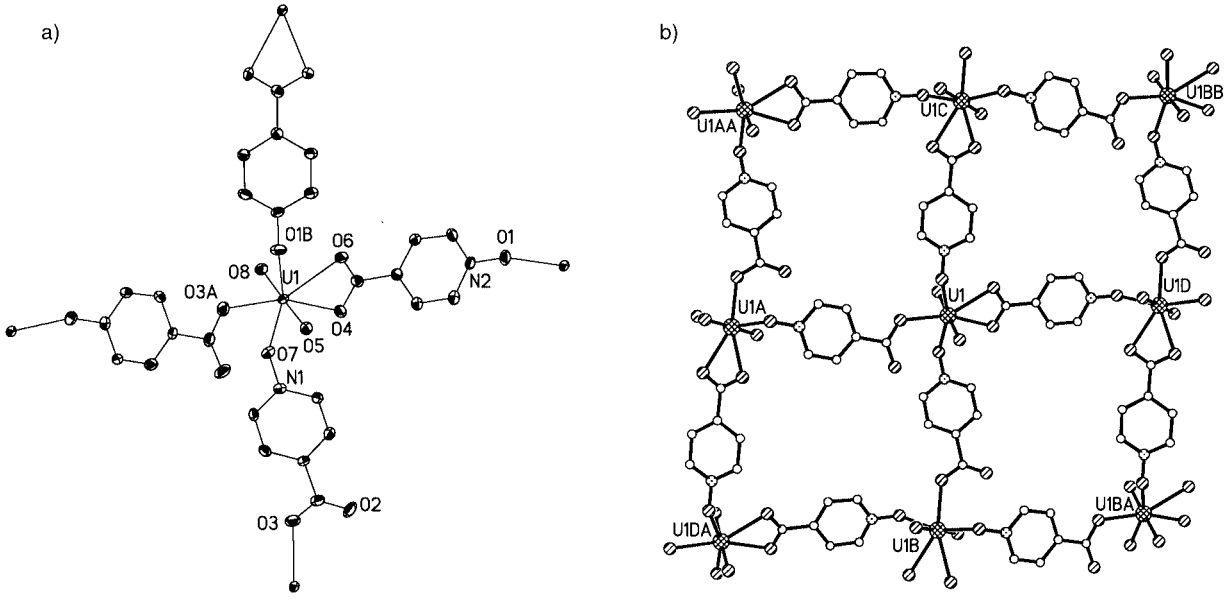

Figure 1. (a) An asymmetric unit of **1** in which thermal ellipsoids are drawn at the 30% probability level; (b) a 2D square grid representation of **1**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

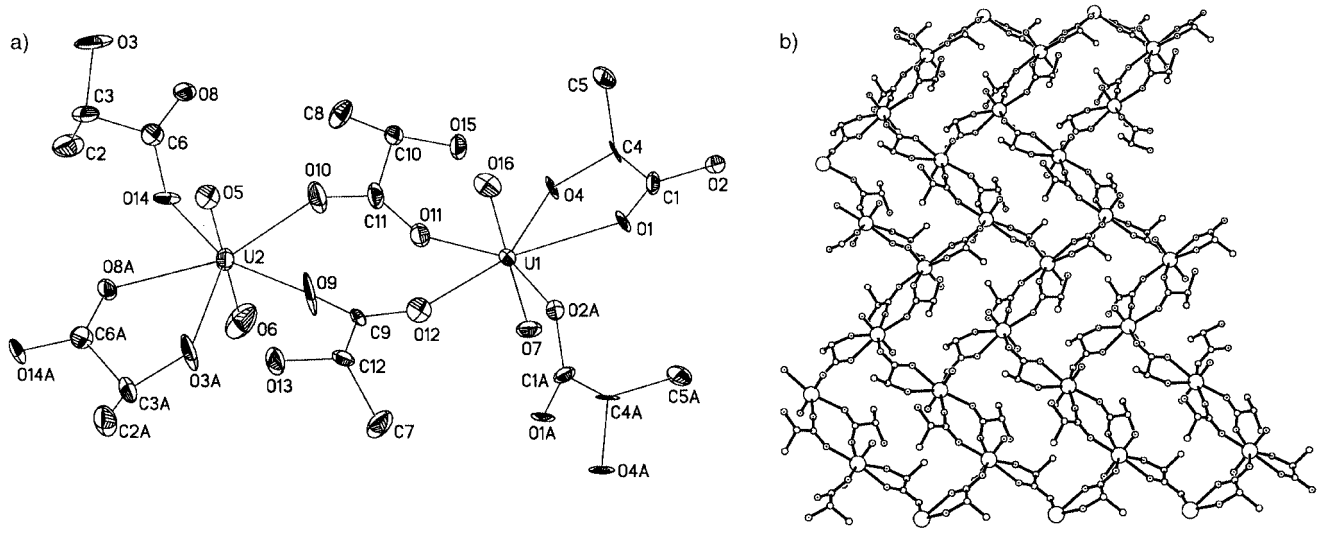

Figure 2. (a) An asymmetric unit of **2** in which thermal ellipsoids are drawn at 30% probability level; (b) a 2D brick-wall representation of **2**

Experimental results indicate that **2** exhibits a low ferroelectric behavior (Figure 3), while **1** does not [Figure 4 shows that there is a weak electric hysteresis loop which is a ferroelectric feature with a remanent polarization (Pr) of 0.12 $\mu C \cdot cm^{-2}$ and coercive field (Ec) of 5 $kVcm^{-1}$. The saturation spontaneous polarization (Ps) of **2** was not observed, probably due to current leakage]. Maybe H-bonds and the layered structure are responsible for **2**'s ferroelectric behavior.[9] Furthermore, **1** and **2** are thermally stable up to 250 and 300 °C, respectively, and are insoluble in common solvents. On the other hand, both **1** and **2** exhibit strong green fluorescent emission at room temperature (Figure 4), which is typical for the uranyl fluorescent spectrum. Thus, **1** represents the first neutral luminescent molecular box with uranyl.[10]

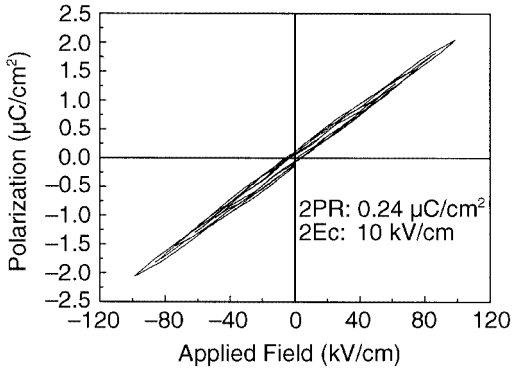

Figure 3. An electric hysteresis loop of **2** was observed by Virtual Ground Mode in a powdered sample in the form of a pellet using an RT6000 ferroelectric tester at room temperature while the sample was immerged in insulating oil; the measurement was performed using ac-pulse

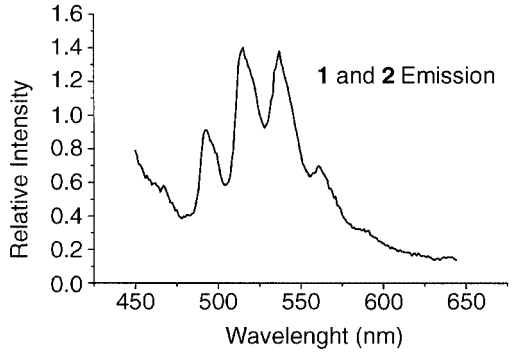

Figure 4. Fluorescent emission spectra of **1** and **2** in the solid state at room temperature

The synthesis of chiral or homchiral novel UO_2-coordination polymer self-assembled through in situ ligand hydrolysis is an extension of a crystal engineering strategy, which is very useful for functional materials design, while the properties of **1** and **2** perhaps make them potential candidates for fluorescent and opto-electronic information storage materials.

Experimental Section

Caution: Compounds containing UO_2^{2+} should be handled with great care (no skin contact or respiration).

Preparation of 1: Hydrothermal treatment of $U(NO_3)_2 \cdot 6H_2O$ (1.0 mmol, 0.502 g), 1-oxo-4-cyanopyridine (2.0 mmol, 0.240 g) and H_2O (2 mL) over 4 days at 130 °C yielded yellowish block crystals of **1** (0.355 g, only one pure phase) in 65% yield based on 1-oxo-4-cyanopyridine. $C_{12}H_8N_2O_8U$ (546.23): calcd. C 26.45, H 1.53, N 5.60; found C 26.36, H 1.47, N 5.13. IR spectrum (KBr): $\tilde{\nu}$ = 3449 cm^{-1} (w), 3112 (w), 3039 (w), 1644 (s), 1617 (w), 1583 (w), 1562 (w), 1540 (m), 1491 (w), 1425 (s), 1352 (s), 1226 (m), 1210 (s), 1177 (m), 1150 (w), 924 (m), 916 (s), 876 (m), 784 (m), 683 (w), 642 (m), 559 (w), 467 (w).

Preparation of 2: Hydrothermal treatment of $U(NO_3)_2 \cdot 6H_2O$ (1.0 mmol, 0.502 g) and ethyl (*S*)-lactate (2.0 mL, 17.6 mmol, 2.084 g) over 4 days at ca. 80−100 °C yielded yellowish block crystals of **2** (0.202 g, only one pure phase) in 45% yield based on $U(NO_3)_2 \cdot 6H_2O$. $C_6H_{10}O_8U$ (448.17): calcd. C 16.07, H 2.23; found

C 16.12, H 2.31. IR spectrum (KBr): $\tilde{\nu}$ = 3449 cm^{-1} (br., w), 2989 (w), 1620 (m), 1562 (br.,s), 1471 (m), 1432 (w), 1372 (w), 1314 (w), 1261 (m), 1118 (m), 1048 (m), 940 (s), 865 (w), 787 (w), 767 (w), 557 (m), 477 (w).

Crystal Data for 1: $C_{12}H_8N_2O_8U$, M_r = 546.23 g·mol^{-1}, orthorhombic, $P2_12_12_1$, a = 7.1116(5), b = 13.4060(10), c = 14.9176(11) Å, α = β = γ = 90.00°, V = 1422.22(18) $Å^3$, Z = 4, D_c = 2.551 Mg·m^{-3}, R_1 = 0.0240, wR_2 = 0.0659, T = 293 K, μ = 11.459 mm^{-1}, S = 0.518. The crystal was twinned.
Crystal Data for 2: $C_6H_{10}O_8U$, M_r = 448.17 g·mol^{-1}, monoclinic, $P2_1$, a = 8.2854(5), b = 8.1836(5), c = 15.1707(9) Å, α = γ =90°, β = 92.9830(10)°, V = 1027.25(1) $Å^3$, Z = 4, D_c = 2.898 Mg·m^{-3}, R_1 = 0.0660, wR_2 = 0.1732, T = 293 K, μ = 15.823 mm^{-1}, S = 1.333, Flack χ = 0.04(3).
The structures were solved by Direct methods using the program SHELXTL (Sheldrick, 1997).[11] All the non-hydrogen atoms were located from the trial structure and then refined anisotropically with SHELXTL using a full-matrix least-squares procedure. The hydrogen atom positions were fixed geometrically at calculated distances and allowed to ride on the parent carbon atoms. The final difference Fourier map was found to be featureless. CCDC-215386−215387 (**1** and **2** respectively) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Oxosulfido Complexes of Platinum — $(Ph_3P)_2Pt(S_2O)$ and $(Ph_3P)_4Pt_2(\mu\text{-}S)(\mu\text{-}SO)$ — Their Formation and Properties

Akihiko Ishii,*[a] Masami Murata,[a] Hideaki Oshida,[a] Kimiyo Matsumoto,[a] and Juzo Nakayama*[a]

Keywords: Platinum / S ligands / Oxo ligands

The platinum S_2O complex $[(Ph_3P)_2Pt(S_2O)]$ (**10**) was obtained by S_2O transfer reactions from tetrathiolane 2-oxide (**8**), tetrathiolane 2,3-dioxide (**5**), and pentathiane 3-oxide (**6**) to $[(C_2H_4)Pt(PPh_3)_2]$ (**4**). The S_2O complex **10** further reacts with **4** to give a novel binuclear platinum complex **16**, which is found to be a source of several platinum S_nO_m complexes. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

The coordination chemistry of organotransition metal compounds of sulfur oxides has been attracting considerable attention.[1−4] Among them, disulfur monoxide (S_2O) complexes **1** of several transition metals (Nb,[5] Mo,[6] Mn,[7−11] Re,[8] Rh,[2] Os,[12] Ir,[2,5,9,10,12,13] and Pt[14]) are known, in which platinum−S_2O complexes **2** (E = S, E′ = SO) were reported very recently by Tokitoh and co-workers.[14] They synthesized the platinum−S_2O and −Se_2O complexes, **2** by oxidation of the respective S_2 and Se_2 complexes,[15] which were prepared for the first time by taking advantage of bulky phosphane ligands ($TbtMe_2P$ and $BbtMe_2P$). Similarly, most of the other S_2O complexes were synthesized by oxidation of the corresponding S_2 complexes, and a few were prepared by S_2O transfer reactions from 4,5-diphenyl-3,6-dihydro-1,2-dithiin 1-oxide[6,9,10] or reaction with $S_2O(THF)_x$.[2] On the other hand, the chemistry of sulfido complexes of platinum bearing the Pt_2S_2 core (**3**) has also been drawing considerable interest.[16] Another recent topic in this field is oxidative additions of Pt^0 complex **4** to a thiosulfinate [−S−S(O)−] moiety in cyclic sulfur compounds.[17−21] We have been studying the synthesis and reactivities of cyclic polysulfides, and have reported on the chemistry of tetrathiolane 2,3-dioxide (**5**),[22,23] pentathiane 3-oxide (**6**),[24,25] and S_8O,[26] all of which act as S_2O transfer reagents.[27−30] Recently we also reported the reaction of dithiirane 1-oxides **7** with **4**.[31] Here, we report the reaction of **5**, **6**, and tetrathiolane 2-oxide (**8**)[23] with **4**, where an S_2O transfer took place giving rise to $[(Ph_3P)_2Pt(S_2O)]$ which further reacted with **4** to yield the binuclear platinum complex $[(Ph_3P)_4Pt_2(\mu\text{-}S)(\mu\text{-}SO)]$.

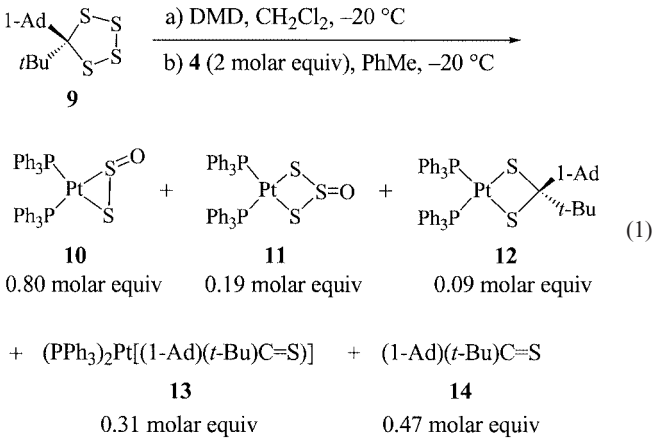
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim **DOI: 10.1002/ejic.200300348**



The structure of the S_2O complex **10** was determined by X-ray crystallography (Figure 1).[35] The crystal contained one molecule of benzene — the recrystallization solvent — per two molecules of **10**, and the $Pt(S_2O)$ moiety was disordered as shown in Figure 1a: the occupancies of the set A [Pt(1A)S(1A)S(2A)O(1A)] and the set B [Pt(1B)S(1B)S(2B)O(1B)] were almost equivalent (0.515 and 0.485, respectively). Figure 1b shows the whole of the molecule

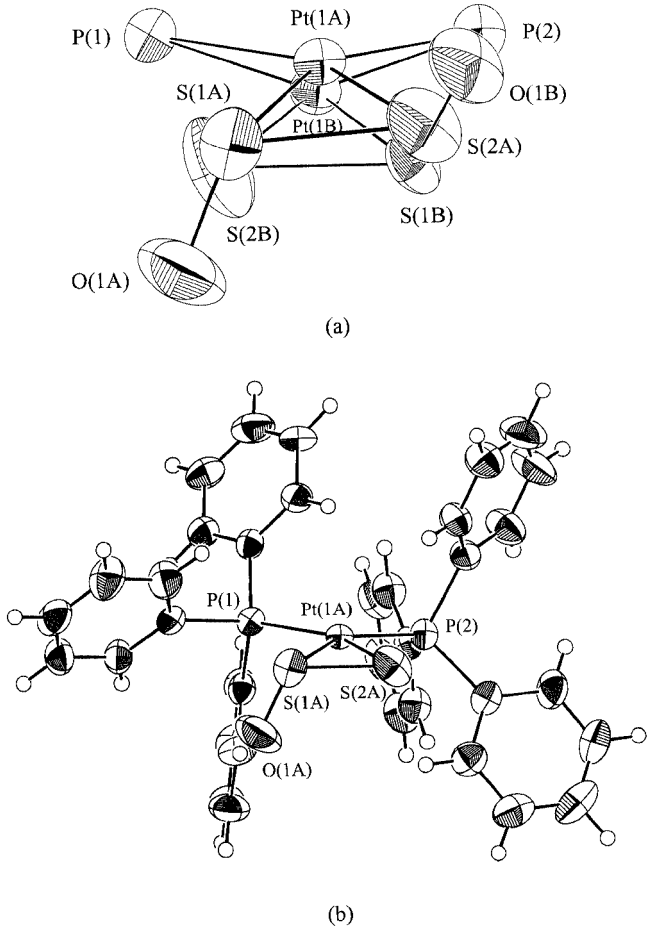


Figure 1. ORTEP drawings of $(Ph_3P)_2Pt(S_2O)$ (**10**) (50% ellipsoidal probability): (a) disorder of the $Pt(S_2O)$ moiety (phenyl groups are omitted for clarity), set A (0.515 occupancy) Pt(1A)S(1A)S(2A)O(1A), set B (0.485 occupancy) Pt(1B)S(1B)S(2B)O(1B); (b) the whole of **10** drawn with the set A

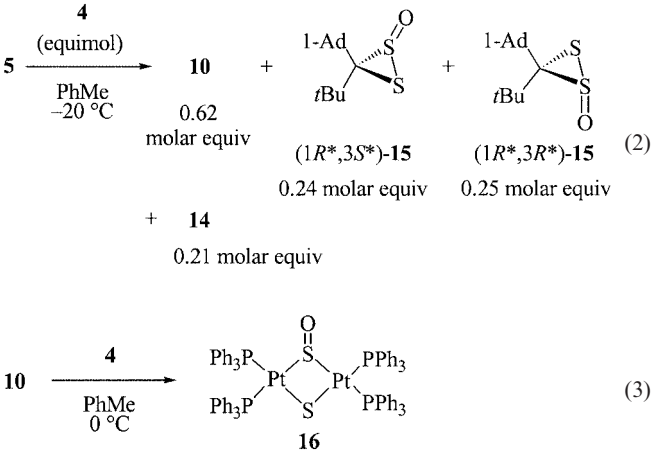
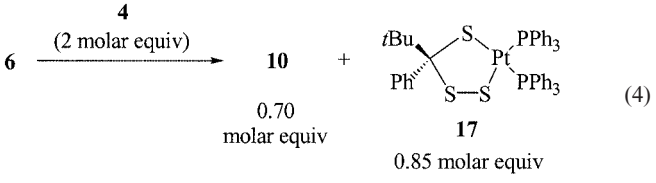
with only the set A. In the ^{31}P NMR spectrum, two doublets appear at $\delta = 18.2$ and 18.4 [$^2J_{P,P} = 7$ Hz] with satellite signals due to the ^{195}Pt nucleus [$^1J_{Pt,P} = 4364$ and 3410 Hz in $CDCl_3$, respectively]. These coupling constant values are quite similar to those of the S_2O complex **2** (Ar = Bbt, E = S, E′ = SO) [$^2J_{P,P} = 8$, $^1J_{Pt,P} = 4263$ and 3254 Hz].[14] Shaver reported that the S_3O complex **11** can be obtained by reaction of $[(PPh_3)_2Pt(SH)_2]$ with SO_2,[34] while we found that the reaction of S_8O with **4** yields **11** in good yield.[36]

The reaction of tetrathiolane 2,3-dioxide (**5**) with an equimolar amount of **4** yielded the S_2O complex **10** (0.62 molar equiv.) along with (1*R**,3*S**)- and (1*R**,3*R**)-dithiirane 1-oxides (**15**)[22,23] (0.24 and 0.25 molar equiv., respectively) and thioketone **14** (0.21 molar equiv.) [Equation (2)]. Interestingly, when two molar equivalents of **4** were employed, binuclear platinum complex **16** was obtained. Indeed, the isolated S_2O complex **10** reacted with **4** very quickly to give **16** in high yield [Equation (3)]. Insertion reactions of **4** into the S−S bond of cyclic oligosulfide oxides[17−21] and $Fe_2(\mu\text{-}S_2)(CO)_6$[37] have been reported. The properties of complex **16** will be described later in this paper.



Similarly, pentathiane 3-oxide (**6**) was treated with **4** (2 molar equiv.) to furnish the S_2O complex **10** and the dithiolato-thiolato complex **17** in 0.70 and 0.85 molar equiv., respectively [Equation (4)]. The structure of **17** was determined by X-ray crystallography (Figure 2).[35]



Interestingly, complex **17** decomposes in $CDCl_3$ at 65 °C (2 h) to give an alternative complex **18** (0.23 molar equiv.) and *t*Bu(Ph)C=S (0.23 molar equiv.) [Equation (5)]. Complex **18** exhibits a singlet at $\delta = 22.7$ ($^1J_{Pt,P} = 3939$ Hz) in the ^{31}P NMR spectrum of the mixture, and this $^1J_{Pt,P}$ value is quite similar to that of **2** (Ar = Bbt, E = E′ = S) ($\delta = -32.2$ ppm, $^1J_{Pt,P} = 3909$ Hz).[15] Thus, we tentatively as-

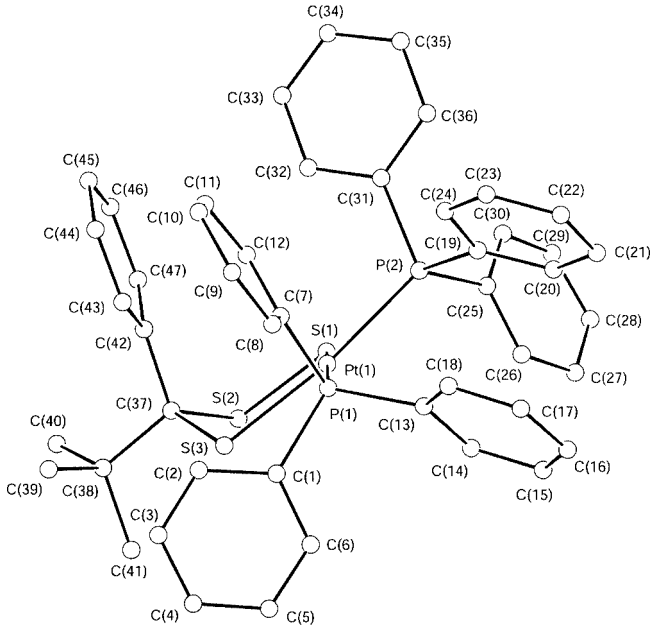

Figure 2. Molecular structure of $[(t\text{Bu})(\text{Ph})\text{CS}_3]\text{Pt}(\text{PPh}_3)_2$ (**17**); hydrogen atoms are omitted for clarity; selected bond lengths [A] and angles [deg]: Pt(1)−P(1) 2.2854(19), Pt(1)−P(2) 2.297(3), Pt(1)−S(3) 2.307(2), Pt(1)−S(1) 2.3350(18), S(1)−S(2) 2.061(4), S(2)−C(37) 1.837(9), S(3)−C(37) 1.837(8); P(1)−Pt(1)−P(2) 99.39(8), P(1)−Pt(1)−S(3) 86.99(8), P(2)−Pt(1)−S(3) 171.29(8), P(1)−Pt(1)−S(1) 174.65(9), P(2)−Pt(1)−S(1) 84.32(8), S(3)−Pt(1)−S(1) 89.74(8), S(2)−S(1)−Pt(1) 106.27(12), C(37)−S(2)−S(1) 100.5(3), C(37)−S(3)−Pt(1) 103.6(3), C(7)−P(1)−Pt(1) 114.7(3), C(13)−P(1)−Pt(1) 111.5(3), C(1)−P(1)−Pt(1) 115.4(3), C(31)−P(2)−Pt(1) 112.7(4), C(25)−P(2)−Pt(1) 112.4(3), C(19)−P(2)−Pt(1) 120.3(3), S(2)−C(37)−S(3) 105.3(5), C(42)−C(37)−C(38) 112.1(8)

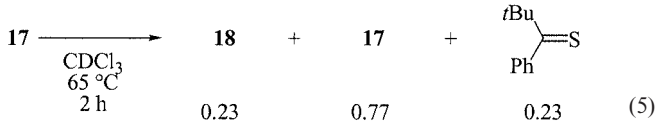
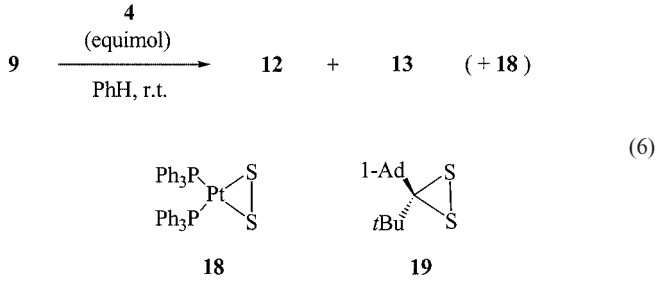
signed the S_2 complex structure **18** to this compound. However, the complex was not stable enough to be isolated; prolonged heating of the mixture or even allowing it to stand at room temperature for several hours led to complete disappearance of the signal. We also examined the reaction of tetrathiolane **9** with **4**. The reaction yielded mainly the dithiolato complex **12** and the thioketone complex **13**. In addition, ^{31}P NMR spectroscopy showed a small signal due to **18** [Equation (6)]. The dithiolato complex **12** was also formed by the reaction of dithiirane **19** with **4** in benzene.[38]

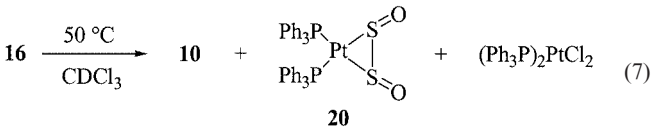


(5)



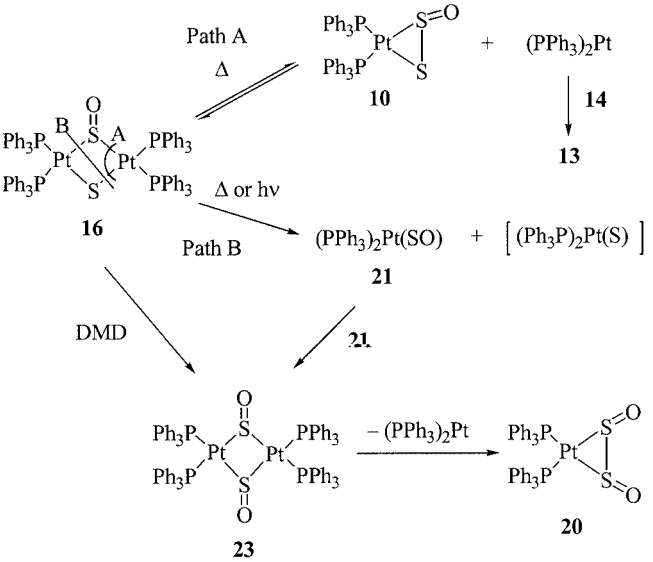
(6)

We tried to prepare the binuclear platinum complex **16** by oxidation of $[(\text{Ph}_3\text{P})_2\text{Pt}]_2(\mu\text{-S})_2$ (**3**: L = PPh_3).[39] It has been reported that oxidation of a binuclear platinum complex bridged by S gives the μ-SO complex.[40] However, **16** was not obtained because of the insolubility of $[(\text{Ph}_3\text{P})_2\text{Pt}]_2(\mu\text{-S})_2$ in the usual organic solvents. Complex **16** decomposes upon heating at 50 °C in CDCl_3 to yield the S_2O complex **10**, the S_2O_2 complex **20**,[41] and $[(\text{PPh}_3)_2\text{PtCl}_2]$ [Equation (7)]. The identification of the S_2O_2 complex **20** was done by comparison of the ^{31}P NMR spectrum of an authentic sample prepared by the reported method.[41] The decomposition in the presence of (1-Ad)(*t*Bu)C=S (**14**) in PhH yielded the thioketone complex **13** and the S_2O complex **10** as the main products in 0.66 and 0.61 molar equiv., respectively, along with the S_2O_2 complex **20** and recovered thioketone **14**. The formation of the thioketone complex **13** indicates the intervention of $(\text{PPh}_3)_2\text{Pt}$.



(7)

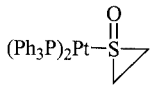
A plausible mechanism for the thermal decomposition of **16** is depicted in Scheme 1. Initially, **16** decomposes via two pathways: in Path A, it extrudes $(\text{PPh}_3)_2\text{Pt}$, which is trapped by thioketone **14** to yield **13**, to give the S_2O complex **10**; in Path B, **16** splits into the SO complex **21** and $[(\text{PPh}_3)_2\text{Pt(S)}]$. Lorenz and Kull have reported that an attempt to prepare the SO complex **21** by thermolysis of the episulfoxide complex **22** results in the formation of the S_2O_2 complex **20**.[41] We propose that the SO complex **21** dimerizes to give another binuclear platinum complex **23** that readily extrudes $(\text{PPh}_3)_2\text{Pt}$ to furnish the S_2O_2 complex **20**. This proposal is strongly supported by the fact that oxidation of **16** with



Scheme 1. Plausible mechanism for reactions of the platinum dinuclear complex **16**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

DMD yields the S_2O_2 complex **20** in high yield, probably via **23**. The fate of $[(PPh_3)_2Pt(S)]$ is unclear, but the formation of $[(PPh_3)_2PtCl_2]$ upon thermolysis in $CDCl_3$ implies the formation of $[(Ph_3P)_2Pt]_2(\mu\text{-}S)_2$ (**3**: L = PPh_3), which reportedly reacts with CH_2Cl_2 to give $[(PPh_3)_2PtCl_2]$.[16] Irradiation of **16** with light in $CDCl_3$ gave the S_2O_2 complex **20**, $[PtCl_2(PPh_3)_2]$, and $Ph_3P{=}X$ (X = O, S) indicating that Path B is dominant in the photolysis.



22

In summary, the platinum S_2O complex **10** was obtained by S_2O transfer reactions from tetrathiolane 2-oxide (**8**), tetrathiolane 2,3-dioxide (**5**) and pentathiane 3-oxide (**6**) to $[(PPh_3)_2Pt(C_2H_4)]$ (**4**). The S_2O complex **10** further reacts with **4** to give a novel binuclear platinum complex **16**, which is found to be a source of several platinum$-S_nO_m$ complexes.

Experimental Section

Reaction of Tetrathiolane 2-Oxide (8) with 4: An acetone solution of DMD (0.106 M, 0.30 mL, 0.032 mmol) was added to a solution of tetrathiolane **9** (10 mg, 0.031 mmol) in CH_2Cl_2 (2 mL) at −20 °C under argon. The mixture was stirred for 1 h at this temperature and then the solvent was removed in vacuo below −20 °C. The residue was dissolved in toluene (1 mL) at −20 °C and then treated with a solution of $[(PPh_3)_2Pt(C_2H_4)]$ (**4**; 48 mg, 0.062 mmol) in toluene (2 mL). After stirring for 10 min, the solvent was evaporated to dryness and the residue was subjected to column chromatography (silica gel, CH_2Cl_2/Et_2O, 5:1) to elute first a mixture of 1-adamantyl *tert*-butyl thioketone (**14**), the dithiolato complex (**12**), and $[(PPh_3)_2Pt\{(1\text{-Ad})(t\text{Bu})C{=}S\}]$ (**13**) and then $[(PPh_3)_2Pt(S_3O)]$ (**11**; 4.9 mg, 0.19 molar equiv.) and $[(PPh_3)_2Pt(S_2O)]$ (**10**; 19.7 mg, 0.80 molar equiv.) in this order. The mixture of **12**, **13**, and **14** was further subjected to gel permeation chromatography (GPC) with $CHCl_3$ as solvent to give a mixture (12.8 mg) of **12** (0.09 molar equiv.) and **13** (0.31 molar equiv.), and 1-adamantyl *tert*-butyl thioketone (**14**; 3.5 mg, 0.47 molar equiv.). The yields of **12** and **13** were estimated on the basis of the ^1H NMR integral ratio. The crude S_2O complex **10** was precipitated from a mixed solvent of dichloromethane and hexane, and the collected powder was washed with benzene several times to give the analytical sample. When the reaction was conducted using four molar equivalents of **4**, the thioketone complex **13** was not formed and the dithiolato complex **12** was isolated in nearly pure form after chromatographic purification. The crude dithiolato complex **12** was washed with ethanol several times to give the analytical sample.

10: Yellow powder, m.p. 200 °C (dec.). ^1H NMR (400 MHz, $CDCl_3$): δ = 7.15−7.23 (m, 12 H), 7.28−7.36 (m, 18 H) ppm. ^{31}P NMR (162 MHz, $CDCl_3$): δ = 18.2 (d, $^2J_{P,P}$ = 7, $^1J_{Pt,P}$ = 4364 Hz), 18.4 (d, $^2J_{P,P}$ = 7, $^1J_{Pt,P}$ = 3409 Hz) ppm. 12: Off-white powder, m.p. 225−226 °C (dec.). ^1H NMR (400 MHz, $CDCl_3$): δ = 1.20−1.40 (m, 9 H), 1.52−1.68 (m, 6 H), 1.94 (br. s, 3 H), 2.21 (br. s, 6 H), 7.14 (t, *J* = 7.0 Hz, 12 H), 7.23 (t, *J* = 7.0 Hz, 6 H), 7.44−7.49 (m, 12 H) ppm. ^{31}P NMR (162 MHz,$CDCl_3$): δ = 22.9 (s, $^1J_{Pt,P}$ = 2925 Hz) ppm. FAB MS (*m*-nitrobenzyl alcohol): *m*/*z* = 989 [M^+ + 1], 931, 853. $C_{51}H_{54}P_2PtS_2$ (988.14): calcd. C 61.99, H, 5.51; found C 62.00, H 5.62.

Reaction of Tetrathiolane 2,3-Dioxide 5 with 4

Equimolar Amount of 4: Compound **4** (20.7 mg, 0.0277 mmol) was added to a solution of **5** (10.1 mg, 0.0277 mmol) in toluene (1 mL) at −20 °C under argon. The mixture was stirred for 1 h at this temperature and the solvent was then evaporated to dryness. The residue was subjected to column chromatography (silica gel, CH_2Cl_2/Et_2O, 5:1) to give a mixture of thioketone **14** and the (1*R**,3*R**)- and (1*R**,3*S**)-dithiirane 1-oxides **15**, and the S_2O complex **10** (13.8 mg, 0.62 molar equiv.). The mixture of **14** and **15** was further subjected to HPLC (silica gel, CH_2Cl_2/hexane 1:1) to give the thioketone **14** (1.4 mg, 0.21 molar equiv.), (1*R**,3*R**)-dithiirane 1-oxide [**(1*R**,3*R**)-15**; 1.9 mg, 0.24 molar equiv.], and (1*R**,3*S**)-dithiirane 1-oxide [**(1*R**,3*S**)-15**; 2.0 mg, 0.25 molar equiv.].

Two Molar Equivalents of 4: Tetrathiolane **9** (10 mg, 0.031 mmol) was oxidized with four molar equivalents of DMD (0.102 M, 1.2 mL, 0.123 mmol) in dichloromethane (1.5 mL) for 1 h at −20 °C. The solvent was removed under reduced pressure below −20 °C, and the resulting tetrathiolane 2,3-dioxide **5** was used without further purification. The 2,3-dioxide **5** was dissolved in toluene (2 mL) at −20 °C, and the solution was treated with a solution of **4** (45 mg, 0.060 mmol) in toluene (2 mL) at this temperature. The solution turned immediately from colorless to deep yellow and was stirred for 10 min at −20 °C. Removal of the solvent under reduced pressure gave an orange residue, the ^{31}P NMR integral ratio of which indicated the formation of the thioketone complex **13**, $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}SO)]$ (**16**), the S_2O complex **10**, and the *S*-oxides of **12**[31] in the molar ratio of 26:13:29:32, along with $Ph_3P{=}O$ and $Ph_3P{=}S$. The molar ratio was obtained based on the ^{31}P NMR integral ratio. The *S*-oxides of **12** are considered to be formed by reactions of dithiirane 1-oxides **15** with **4**.[31] The binuclear platinum complex **16** could not isolated in this experiment because it was not eluted from the silica-gel column.

Reaction of the S_2O Complex 10 with 4: A solution of **4** (21.7 mg, 0.029 mmol) in toluene (1.5 mL) was added at 0 °C to a solution of **10** (23.2 mg, 0.029 mmol) in toluene (1.5 mL) under argon. The mixture was stirred for 1 h at 0 °C, and the solution was concentrated to ca. one-fourth of its original volume under reduced pressure. Diethyl ether was added to precipitate the product, and the resulting precipitates were collected by filtration to give 47.7 mg (0.71 molar equiv.) of $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}SO)]$ (**16**).

16: Yellow powder, m.p. 179 °C (dec.). ^1H NMR (400 MHz, $CDCl_3$): δ = 6.97−7.02 (m, 24 H), 7.11−7.18 (m, 12 H), 7.29−7.34 (m, 12 H), 7.47−7.52 (m, 12 H) ppm. ^{31}P NMR ($CDCl_3$, 162 MHz): δ = 21.0 (m, $^1J_{Pt,P}$ = 3394 Hz), 21.8 (m, $^1J_{Pt,P}$ = 2427 Hz) ppm. IR (KBr): $\tilde{\nu}$ = 1095 cm^{-1}. ESI MS: *m*/*z* = 1519.2 [M^+ + 1]. $C_{72}H_{60}OP_4Pt_2S_2$ (1519.44): calcd. C 56.91, H 3.98; found C 56.13, H 3.94.

Reaction of Pentathiane 3-Oxide 6 with 4: A solution of **4** (84 mg, 0.113 mmol) in toluene (12 mL) was added over 15 min to a solution of **6** (18 mg, 0.056 mmol) in toluene (2 mL) at −15 °C. The solvent was removed under reduced pressure, and the residue was subjected to column chromatography (silica gel, $CHCl_3$ and then CH_2Cl_2/Et_2O 4:1) to give $[(t\text{Bu})(\text{Ph})CS_3]Pt(PPh_3)_2$ (**17**; 46 mg, 0.85 molar equiv.) and the S_2O complex **10** (31.3 mg, 0.70 molar equiv.).

17: Yellow crystals, m.p. 143−147 °C (dec.) ($CHCl_3$/EtOH). ^1H NMR ($CDCl_3$, 400 MHz): δ = 1.11 (s, 9 H), 6.95−7.01 (m, 6 H),

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

7.03−7.09 (m, 6 H), 7.14−7.19 (m, 8 H), 7.26−7.38 (m, 7 H), 7.48−7.54 (m, 6 H), 8.08−8.11 (m, 2 H) ppm. ^{31}P NMR (162 MHz, $CDCl_3$): δ = 18.5 (d, $^2J_{P,P}$ = 23, $^1J_{Pt,P}$ = 2754 Hz), 22.9 (d, $^2J_{P,P}$ = 23, $^1J_{Pt,P}$ = 3057 Hz) ppm. $C_{47}H_{44}P_2PtS_3{\cdot}2CHCl_3$ ($C_{49}H_{46}Cl_6P_2PtS_3$; 1200.80): calcd. C 49.01, H 3.86; found C 49.06, H 3.75.

Reaction of Tetrathiolane 9 with 4: Compound **4** (6.1 mg, 0.0081 mmol) was added at room temperature to a solution of **9** (2.7 mg, 0.0081 mmol) in benzene (2 mL). The yellow mixture was stirred for 15 min at room temperature, and the solvent was removed under reduced pressure. The ^{31}P NMR spectrum of the residue indicated the formation of the dithiolato complex **12**, the thioketone complex **13**, and a compound assigned tentatively to the S_2 complex **18** (δ = 22.7 ppm, $^1J_{Pt,P}$ = 3939 Hz) in the molar ratio of 32:57:11.

Thermal Decomposition of 16. In $CDCl_3$: A solution of **16** (10 mg, 0.0065 mmol) in $CDCl_3$ (4 mL) under argon was heated at 50 °C for 1.5 h. The ^{31}P NMR spectrum of an aliquot taken from the mixture indicated the formation of the S_2O complex **10**, the S_2O_2 complex **20** (δ = 6.4, $^1J_{Pt,P}$ = 4019 Hz), [$(PPh_3)_2PtCl_2$] (δ = 14.9, $^1J_{Pt,P}$ = 3672 Hz), **16**, $Ph_3P{=}S$ (δ = 44.0 ppm), and $Ph_3P{=}O$ (δ = 29.8 ppm) in the molar ratio of 33:11:21:11:14:11.

In Benzene in the Presence of Thioketone 14: A solution of **16** (23 mg, 0.015 mmol) and **14** (3.6 mg, 0.015 mmol) in benzene (4.5 mL) was heated at 50 °C for 4 h under argon, and then the solvent was removed under reduced pressure. The ^{31}P NMR spectrum of the residue indicated the formation of the thioketone complex **13**, the S_2O complex **10**, and the S_2O_2 complex **20** in the molar ratio of 50:43:7. The residue was subjected to column chromatography (silica gel, CH_2Cl_2/Et_2O, 5:1) to give a mixture of **14** and **13** (14 mg), and **10** (7.4 mg, 0.61 molar equiv.). The S_2O_2 complex **20** was not eluted from the silica-gel column. The molar ratio of **14** and **13** was 31:69, giving calculated yields of 0.0042 mmol (0.28 molar equiv.) and 0.010 mmol (0.66 molar equiv.), respectively.

When a solution of **16** (10 mg, 0.0065 mmol) in benzene (1.5 mL) was heated at 50 °C, 1.0 mg of unidentifiable precipitates (ESI-MS: $m/2z$ = 999.5) were collected by filtration.

Photolysis of 16: A solution of **16** in $CDCl_3$ in an NMR tube was irradiated with a high-pressure Hg lamp through a Pylex filter in an ice-water bath for 1 h. The ^{31}P NMR spectrum showed the formation of the S_2O_2 complex **20**, [$(PPh_3)_2PtCl_2$], $Ph_3P{=}O$, and $Ph_3P{=}S$ in the molar ratio of 19:24:40:16. The signals due to the S_2O complex **10** were not observed (it was verified by a controlled experiment that **10** barely decomposed under the conditions).

Acknowledgments

We are grateful to Dr. Hideki Saito (Saitama University) for kind discussion on the X-ray analysis of **10**. This work was supported by a Grant-in-Aid for Scientific Research (No. 12440174) from the Ministry of Education, Culture, Sports, Science and Technology, Japan.

Pyrazolylboratozinc Complexes of Nucleosides and Nucleoside Analogues[‡]

Dirk Badura[a] and Heinrich Vahrenkamp*[a]

Keywords: Zinc / Nucleosides / Bioinorganic chemistry / N ligands

Attachment of deprotonated nucleosides or of alkylated nucleobases, as their analogues, to zinc was achieved by condensation reactions between TpZn-OH complexes and nucleobase derivatives. Pyrazolylboratozinc complexes with derivatives of uracil, thymine, guanine, xanthine and hypoxanthine were obtained and characterized by structure determination. In the uracil, thymine, guanine and hypoxanthine derivatives, zinc is bound to the nitrogen atom which bears the proton in the nucleoside. In the xanthine derivatives all three possible bonding modes are realized.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The success of cisplatin as a drug has triggered a plethora of studies on the interactions of metal ions with nucleic acids, nucleotides and their constituents.[2−4] Among these, the number of those related to zinc is relatively small. Yet it is known that zinc affects the various structures of DNA,[5] of chromatin[6] and of ribosomes,[7] as well as impeding the melting of DNA[8,9] and facilitating the recombination of the double helix.[10] Furthermore zinc ions have structural and functional roles in nucleic acid-binding retroviruses,[11] in t-RNA, DNA, and RNA polymerases,[3,11] endonucleases,[13] cytidine and adenosine deaminases,[13] aspartate transcarbamoylase,[11] and dihydroorotase.[14]

The small-molecule chemistry of zinc related to nucleotides, nucleobases and models thereof has evolved in recent years. Lippert[15] and Dubler[16] pioneered the studies of zinc-nucleobase interactions. Sigel[3,17] and Marzilli[18,19] made the leading contributions to zinc-nucleotide chemistry. Our own contributions to this field describe the interactions of nucleic acid constituents and analogues thereof with pyrazolylboratozinc units.[1,20,21]

The basis of the work reported here are our observations with nucleobases[1,21] and with drug substances, some of which are derivatives of the nucleobases.[22−26] All the substances investigated are nitrogen heterocycles with rather acidic NH functions. This was favourable as it facilitated the synthesis of pyrazolylboratozinc substrate (TpZn-X) complexes by a condensation reaction between TpZn-OH and the NH heterocycle HX. It was, however, unfavourable in terms of modelling zinc-nucleotide interactions, as the most acidic NH functions in the nucleobases are often those whose nitrogen is attached to the sugar moiety in the nucleotides. Due to this the nucleobases were attached to the TpZn unit by that nitrogen atom which is not available for attachment in DNA, RNA and their constituents.

To overcome this disadvantage we resorted to nucleobases which are alkylated at the nitrogen atom to which the sugar moiety would be attached. This paper describes the pyrazolylboratozinc complexes derived from such nucleoside analogues. The alkylated nucleobases represent uridine, thymidine, guanosine and xanthosine. A genuine nucleoside inosine (i.e. glycosylated hypoxanthine) was included in order to complement our previous studies with uridine and xanthosine.[21] The nucleobases were reacted with the pyrazolylborate-Zn-OH complexes **1a** and **1b**.

1b

Results and Discussion

Uracil and Thymine

1-Methyluracil and 1-methylthymine were chosen as the simplest nucleoside analogues. Although their NH functions, flanked by two carbonyl groups, are quite acidic, their reactions with TpZn-OH were not straightforward. It turned out that the reaction products **2** and **3** are very moisture sensitive, easily reverting to the starting materials. Pure **2** and **3** were finally obtained after removing water

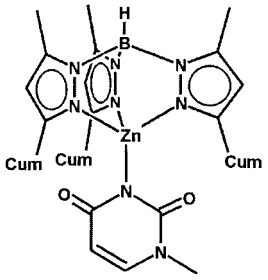
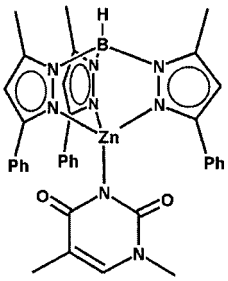
from the reaction mixture by running the reactions in a Soxhlet extractor filled with molecular sieves.

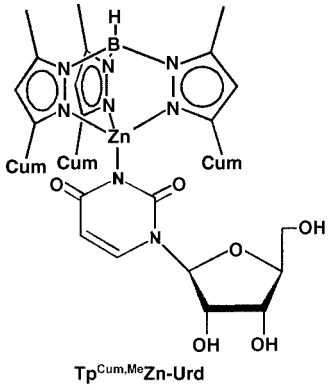


2



3

The structural assignment of **2** and **3** rests on the structure determination of **2** (see below). The spectroscopic data support the statement that all zinc complexes of 1-alkylated uracil and thymine derivatives have the nucleobase attached to zinc in the same way, i.e. via the N3 atom. The main feature is the position of the highest energy ν(CO) band in the IR spectrum. It is observed in the 1640−1670 cm^{-1} range here as well as in N_3O-tripod[27] and [12]ane-N_4 zinc complexes.[28] Its position is higher than that of the anionic 1-alkylated nucleobases, thereby excluding coordination via the oxygen atom, as this would lower the ν(CO) value. The structure determination of **2** and the similarity of all the spectroscopic data also confirm our previous structural assignment of the uridine $Tp^{Cum,Me}$Zn-Urd complex.[21]



$Tp^{Cum,Me}$Zn-Urd

Figure 1 shows the molecular structure of **2**. Notable features are the complete embedding of the nucleobase in the $Tp^{Cum,Me}$ ligand-pocket, the typically short[1,20,21] Zn−N3 bond, the non-existence of Zn−O interactions and the 10° angle between the Zn−N3 bond and the least-squares plane of the heterocycle. Unlike most other TpZn-nucleobase complexes[1,20,21] this one does not dimerize in the solid state via hydrogen bonding, as it does not contain NH or OH units.

Cytosine and Adenine

N1-alkylated cytosine and N9-alkylated adenine derivatives were found to be unsuitable for reactions with TpZn-OH. We had already observed that cytosine itself is not acidic enough for such a reaction while adenine is.[20] 9-Alkylated adenine has no additional heterocyclic (i.e. acidic) NH functions.

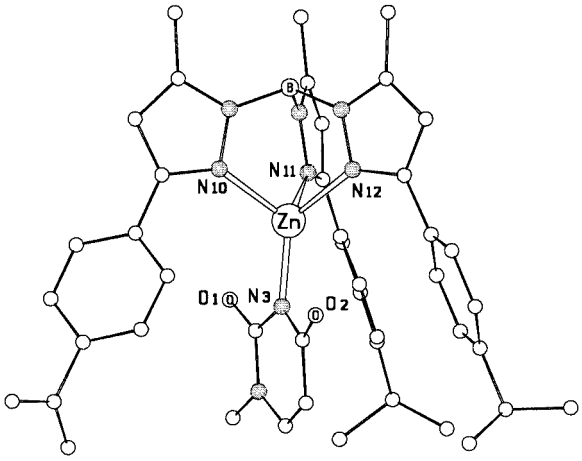


Figure 1. Molecular structure of **2**; relevant atomic distances (Å): Zn−N3 1.930(3), Zn−N10 2.034(3), Zn−N11 2.100(3), Zn−N12 2.049(3), Zn···O1 2.914(5), Zn···O2 3.086(5)

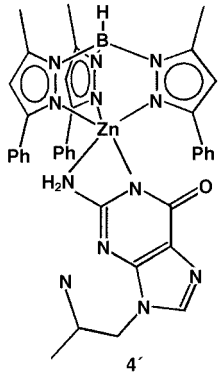
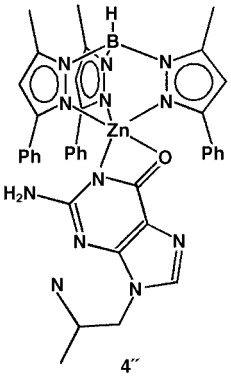
Guanine

The coordination chemistry of guanine is not well developed, and like others we have not been able to prepare zinc-guanine complexes.[20] Guanosine and 9-alkylated guanine derivatives, however, bind to zinc via N7 as uncharged molecules.[29−32] We tried to prepare a TpZn complex of anionic guanosine by reacting guanosine with **1a** and **1b** or the corresponding TpZn-H complexes. We failed, however, to separate the resulting product mixtures.

These problems did not exist when resorting to 9-isobutylguanine as a guanosine analogue. By reaction with $Tp^{Ph,Me}$Zn-H the expected complex **4** was obtained. Compound **4** seems to exist as two isomers **4′** and **4′′**. Precipitation from benzene by addition of heptane yielded **4′** as very thin needles which are not suitable for structure determination. Slow recrystallization of raw **4** or of **4′** from benzene/heptane yielded **4′′** as well-shaped crystals which were used for X-ray analysis. Based on this and on the spectroscopic evidence (see below) we assign the two isomers as follows:



4′



4′′

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The molecular structure of **4′′** is shown in Figure 2. The nucleobase is attached to zinc as a bidentate ligand via N1 and the adjacent carbonyl oxygen, forming a four-membered chelate ring. Such a bonding mode is very rare for metal-nucleobase interactions. It has not been observed before with zinc, but it occurs in zinc complexes of α-pyridone,[33,34] and we have described related N,S chelate complexes of 6-methylthiouracil and 6-mercaptopurine.[21] The Zn−O and Zn−N1 bond lengths show that both interactions are strong, i.e. zinc is genuinely five-coordinate. However, the coordination geometry of zinc cannot be described as the transition from trigonal bipyramidal to square pyramidal.[35] It seems more appropriate to assume that N1 and O1 share the single coordination position of a ligand X in the TpZn-X complexes, like the two oxygen atoms of a symmetrically bidentate carboxylate ligand in TpM-carboxylate complexes.[35] Apart from this peculiar situation, the nitrogen atom which bonds to zinc (N1), is a typical, yet not the only possible, donor atom in other metal complexes of anionic guanosine derivatives.

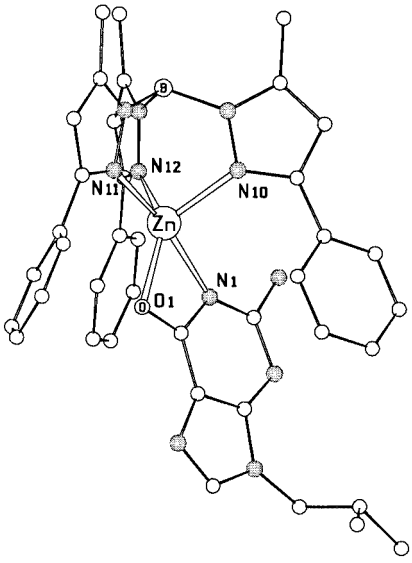


Figure 2. Molecular structure of **4′′**; relevant bond lengths (Å) and angles (°): Zn−O1 2.061(2), Zn−N1 2.182(3), Zn−N10 2.097(3), Zn−N11 2.103(3), Zn−N12 2.084(3), O1−Zn−N1 62.96(9)

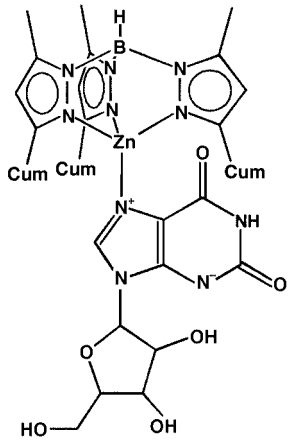
In the solid state, complex **4′′** forms dimers across an inversion center by two symmetrically equivalent hydrogen bonds between the NH_2 group and N3. This is different from all other such dimer structures of TpZn-nucleobase complexes,[1,20,21] but it is the common type of self-association for guanosine and its derivatives.[40]

The solution NMR spectra of **4′** and **4′′** are identical, indicating a rapid equilibrium between their two structures or possibly a third structure, e.g. one with a monodentate attachment of the nucleobase via N1. The IR spectra of **4′** and **4′′** in KBr show small, yet significant, differences. These concern the vibrational modes of the C=O and NH_2 units. In free 9-isobutyguanine ν(CO) and δ(NH_2) appear as strong bands at 1688 and 1631 cm^{-1}, respectively. Zinc complexes of uncharged 9-alkylguanines show very little shifts for these two band positions. Complex **4′** has its ν(CO)band at 1692 cm^{-1} (i.e. unshifted) and its δ(NH_2) band at 1611 cm^{-1} (i.e. shifted to lower wavenumbers). Complex **4′′** shows no typical ν(CO) band and its δ(NH_2) band at 1638 cm^{-1} (i.e. unshifted). This indicates that in **4′′** the CO function is involved in the zinc bonding , as proved by the structure determination. Likewise in **4′** the NH_2 group seems to act as a donor. Taking into account that N1 is most probably the main donor for zinc in both isomers, this leads to the structural assignment given above for **4′**, again with a four-membered chelate ring.

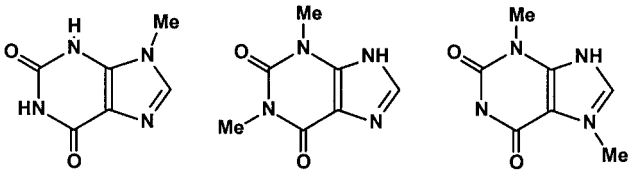
Xanthine

The xanthine-derived nucleoside xanthosine has already been incorporated in a TpZn complex, the structure of which (with zinc attachment at N7) was assigned as follows:[21]



$Tp^{Cum,Me}$Zn-Xao

The nucleobase xanthine with three NH functions permits various N-alkylations, allowing us to probe the variation of its metal binding properties. The simplest xanthosine analogue is 9-methylxanthine, while some of the other methylated xanthines are well-known purine alkaloids. For example, caffeine (1,3,7-trimethylxanthine), theophylline (1,3-dimethylxanthine) and theobromine (3,7-dimethylxanthine) are the stimulating ingredients of coffee, tea, and cocoa, respectively. Amongst these, 9-methylxanthine, theophylline and theobromine were chosen for this investigation.

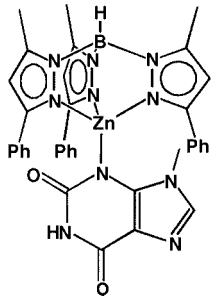


9-methylxanthine theophylline theobromine

9-Methylxanthine and **1a** yielded **5**. The NMR spectrum of **5** indicates that the attachment of the nucleobase to the zinc is different from that in the xanthosinate complex (see

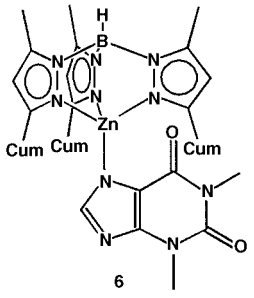
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

above). The strongest indicator is the C8-H signal at δ = 6.92 ppm, representing an upfield shift of ca. 1 ppm relative to free 9-methylxanthine. However, in all TpZn complexes of purine bases which are coordinated to zinc via N7 or N9, the C8-H resonance experiences an upfield shift of ca. 2 ppm due to the location of C8-H inside the pocket between the three phenyl groups of the Tp ligand.[1,20,21] Thus, while the C8-H proton resonance excludes N7 coordination, the N9-methyl resonance speaks against N1 coordination and favours N3 coordination. The upfield shift for this resonance, relative to that of free 9-methylxanthine, is ca. 1 ppm, which is typical for methyl groups in the Tp ligand pocket, while for N1 coordination the methyl group would point away from the Tp ligand and experience only little shielding from it. Thus the most likely structure for **5** is the following:



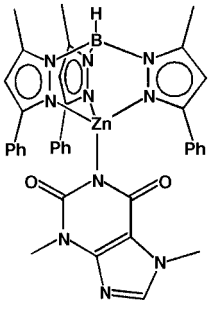
5

Anionic theophylline has been well-investigated as a ligand, showing a pronounced preference to coordinate via N7.[41,42] This was reproduced here with the complex, **6**, resulting from **1b** and theophylline. Again, NMR spectroscopic data allow a reliable structural assignment. While the 2 ppm upfield shift of the C8-H resonance indicates coordination via N7 or N9, the proton resonances of the two methyl groups make the assignment clear: the N3-methyl resonance is shifted upfield by 0.3 ppm and that of the N1-methyl group by 0.9 ppm. This places the N1-methyl group deeper into the Tp ligand pocket, which calls for attachment of theophylline to zinc via N7. Confirmation of this structural assignment also comes from the structure determination of the related $Tp^{Ph,Me}$Zn complex of 1-methyl-3-isobutylxanthine.[43]



6

In anionic theobromine N1 and N9 are available for coordination to zinc. This was tested by the formation of **7** from **1a** and theobromine. In the NMR spectrum of **7** the C8-H resonance is shifted upfield by only 0.3 ppm relative to free theobromine. Thus a coordination via N9 is unlikely, but the 0.5 ppm upfield shifts for both N-methyl resonances favour coordination via N1.



7

The assignment was confirmed by the structure determination of **7** (Figure 3). There are two independent molecules of **7** in the asymmetric unit, differing in the orientation of the purine base in the $Tp^{Ph,Me}$ ligand-pocket, but not in the relevant intramolecular bonding distances and angles. The theobrominate ligand is monodentate, and the two carbonyl functions flanking N1 are not within bonding range of the zinc ion. Correspondingly the Zn−N1 bond is quite short. As two of the three nitrogen atoms of theobromine pointing outward from the TpZn unit are methylated, there exists no possibility for the dimerization of **7** by means of hydrogen bonds. In all these respects complex **7** is unique, as no metal complex with N1-bound theobromine has been reported so far.

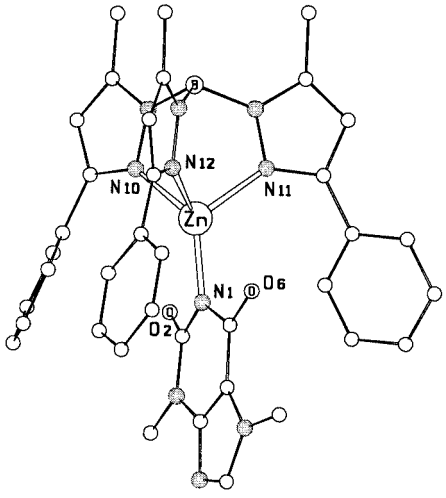


Figure 3. Molecular structure of **7** (one of the two independent molecules in the asymmetric unit); relevant atomic distances (average values, Å): Zn−N1 1.905(3), Zn−N10 2.065(4), Zn−N11 2.030(4), Zn−N12 2.010(4), Zn···O2 2.913(5), Zn···O6 2.943(5)

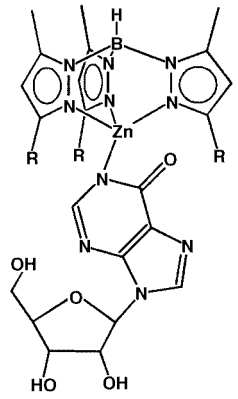
In all the zinc complexes of xanthine derivatives described here, the nucleobase has two or three nitrogen atoms available for zinc coordination (four in free xanthine). Xanthine, xanthosine and theophylline use N7, 9-methylxanthine uses N3, and theobromine uses N1. We see no consistent interpretation of this in the steric or electronic environment of the xanthine derivatives themselves. There-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fore we think that secondary interactions like base pairing or π-stacking favour the observed constitutions.

Hypoxanthine

The nucleoside of hypoxanthine is inosine. It reacted cleanly with **1a** and **1b**, producing complexes **8a** and **8b** of which **8a** could be subjected to a structure determination. Having achieved this, it was no longer necessary to resort to alkylated hypoxanthine derivatives as inosine analogues.



8a: R = Ph, **8b:** R = Cum

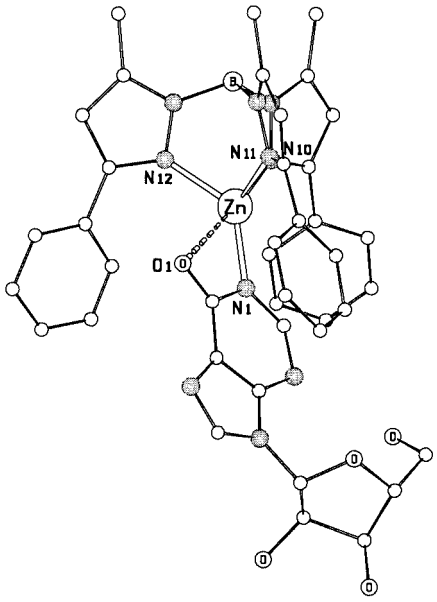


Figure 4. Molecular structure of **8a** (conformer **8a.4**); relevant bond lengths (average values, Å): Zn−N1 1.968(8), Zn−O1 2.528(8), Zn−N10 2.059(8), Zn−N11 2.031(8), Zn−N12 2.019(8)

The structure determination of **8a** was plagued by the fact that the asymmetric unit contains four independent complex units, i.e. the conformational freedom of the molecules is displayed even in the solid state. Even though enantiomerically pure D-inosine is present, its orientation in the Tp ligand-pocket yields two conformers, each of which is obtained with two different conformations of the sugar moiety. Although this generates a large amount of structural data, the essential part of the structures, i.e. the interaction between the zinc ion and the anionic nucleobase, varies very little.

In **8a** the nucleobase binds to zinc via N1, which is the nitrogen bearing the proton in neutral inosine. The negative charge in anionic inosine is presumed to rest on N1, N3 and mostly O6.[41,44] This makes O6 a potential donor atom, as is observed in the structure of **8a** by clearly noticeable Zn···O interactions (2.53−2.76 Å), creating a four-membered chelate ring. These Zn···O interactions are intermediate between the very weak ones in **2** and the very strong ones in **4′′**. Accordingly the ν(CO) IR bands for the coordinating carbonyl functions appear at 1670 cm^{-1} for **2** and at 1632 cm^{-1} for **8a**, but are absent from the IR spectrum of **4′′**. For this reason it is not appropriate to consider zinc as five-coordinate in **2** and **8a**, which is also reflected by the fact that the Zn−N1 bond in **8a** is close to the trigonal axis of the TpZn unit. There seems to be a relation, however, between the strengths of the Zn−N(nucleobase) and the Zn−O(nucleobase) interactions: in **2** and **7**, where the the Zn−O interactions are very weak, Zn−N is very short; in **8a**, where the Zn−O interactions are intermediate, it is elongated; and in **4′′**, where the Zn−O interactions are strong, Zn−N is unusually long.

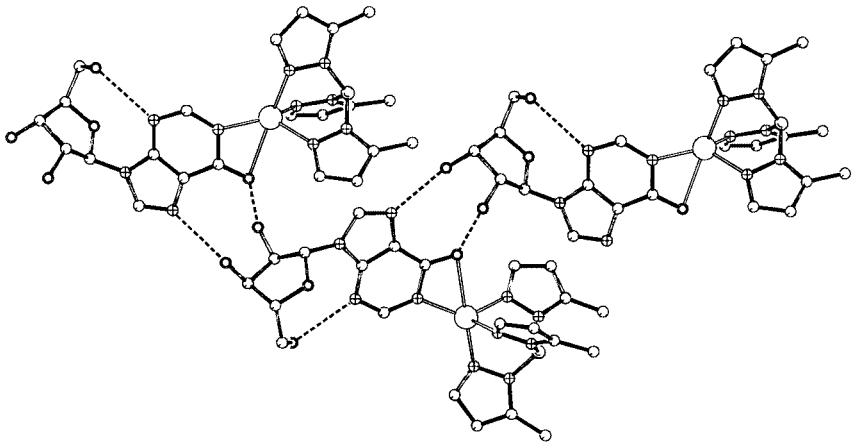

Figure 5. Hydrogen-bonding network for the conformer **4** of complex **8a**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

We are not aware of any other zinc complexes of anionic hypoxanthine or inosine. There is a bis(methylmercury) complex of inosinate which has mercury attached at N1 and N7.[45] Inosinemonophosphate also coordinates to zinc via N7.[46]

Like in the other compounds described here, the zinc ion in **8a** is not necessarily attached to the point of highest electron density in the nucleobase. One factor supporting the observed zinc-nucleobase interaction is certainly the additional bonding interaction with the carbonyl oxygen. In addition, like many other of these zinc complexes **8a** displays various kinds of hydrogen bonding which may contribute significantly to the overall stability. Each of the four individual conformers of **8a** is linked to its symmetry-related neighbours by one or two hydrogen bonds such that infinite chains result. Figure 5 displays this for the conformer **8a.4**, for which the linking consists of hydrogen bonds between the 2′-OH group and the carbonyl oxygen as well as between the 3′-OH group and N7.

Conclusions

This study brings our investigation on pyrazolylboratozinc complexes of nucleobases, nucleosides and analogues thereof to completion. Of the nine nucleobases applied[20] only guanine evaded zinc complexation. Of the four nucleosides used, three (uridine, xanthosine, inosine) could be attached to zinc. The alkylated nucleobases filled the gaps. In addition, a small number of nucleotide analogues[21] and of sugar phosphates[47] were included.

In all cases the advantage of encapsulating pyrazolylborate ligands, i.e. the limitation of the coordination space at the zinc ion, could be exploited. In all but a few cases the nucleobase-derived substrates are attached to zinc in a monodentate fashion, thereby showing their preferred donor site which is always located at a nitrogen atom. The other advantage of the Tp ligands, i.e. the preference for monoanionic coligands, which results in the formation of uncharged (and hence easily isolable) zinc complexes, could also be put to use.

The latter aspect requires, however, all the nucleobase-derived coligands to be anionic. This limits their selection to those which have at least one NH or OH function in their uncharged forms. It also means that the nitrogen atom that binds to zinc is not necessarily the one which was deprotonated. Moreover, it also means that in the free nucleobases "unnatural" coordination to zinc can occur via that nitrogen atom which bears the sugar moiety in the nucleosides; we found that this is actually the preferred bonding mode.

In the nucleosides and nucleoside analogues which are the subject of this paper "natural" binding to zinc must occur. In the pyrimidine-derived nucleobases (substituted uracil and thymine) there is only one possible donor atom, N3, which is used. In all the other (purine-derived) nucleobase derivatives there are three or more possible nitrogen donors. We have observed that the choice of the actual donor site cannot be predicted from the acid/base, electron density, or from the geometrical properties of the substrates. Instead additional bonding interactions seem to control the zinc-substrate connectivity. Thus in **4** and **8** the coordination of a carbonyl oxygen to zinc, in other cases hydrogen-bonding patterns, and possibly in all cases, π-stacking between the nucleobases of adjacent molecules or between the nucleobases and the phenyl substituents of the Tp ligands offer major contributions to the overall stability and hence to the choice of the zinc-binding nitrogen donor.

Conversely, according to the specific modes of attachment, the zinc ions can exert different kinds of influence on the electronic nature and hence the reactivity of the bound substrates. This in turn might be of use for an understanding of the modes of action of the various zinc enzymes along the metabolic pathways of the nucleobases, the nucleosides and the nucleotides.

Experimental Section

General: Reactions were performed under a nitrogen atmosphere in anhydrous solvents. The TpZn-OH complexes were prepared as described.[48,49] All other starting materials were obtained commercially. The analytical equipment was as described previously.[50]

Complex 2: A solution of **1b** (207 mg, 0.30 mmol) and 1-methyluracil (45 mg, 0.36 mmol) in 160 mL of benzene was refluxed for 3 days in a Soxhlet extractor filled with 4 Å molecular sieves. After reducing in vacuo to 40 mL and cooling to 4 °C a precipitate of unused starting materials was formed. After filtration the solution was evaporated to dryness. The residue was dissolved in a minimum amount of benzene which was layered with heptane. Within one week 128 mg (53%) of **2** had separated as colourless crystals. M.p. 211 °C. $C_{44}H_{51}BN_8O_2Zn$ (800.14): calcd. C 66.05, H 6.42, N 14.00; found C 66.11, H 6.16, N 13.70. IR (KBr): $\tilde{\nu}$ = 2547 cm^{-1} (m, BH), 1646 (vs, CO). ^1H NMR ($CDCl_3$): δ = 1.19 [d, *J* = 6.9 Hz, 18 H, Me(*i*Pr)], 2.51 [s, 9 H, Me(pz)], 2.57 (s, 3 H, MeN), 2.84 [sept, *J* = 6.9 Hz, 3 H, CH(*i*Pr)], 5.04 (d, *J* = 7.5 Hz, 1 H, C5H), 6.12 [s, 3 H, CH(pz)], 6.52 (d, *J* = 7.5 Hz, 1 H, C6H), 7.06 (d, *J* = 8.1 Hz, 6 H, Ph), 7.45 (d, *J* = 8.1 Hz, 6 H, Ph) ppm.

Complex 3: Like **2**, from **1a** (400 mg, 0.73 mmol) and 1-methylthymine (102 mg, 0.73 mmol). Yield: 386 mg (77%) of **3** as colourless crystals; m.p. 257 °C (dec.). $C_{36}H_{35}BN_8O_2Zn$ (687.93): calcd. C 62.86, H 5.13, N 16.29; found C 62.65, H 5.28, N 16.35. IR (KBr): $\tilde{\nu}$ = 2544 cm^{-1} (w, BH), 1655 (vs, CO). ^1H NMR ($CDCl_3$): δ = 1.41 (d, *J* = 1.1 Hz, 3 H, C5-Me), 2.53 [s, 9 H, Me(pz)], 2.63 (s, 3 H, NMe), 6.16 [s, 3 H, H(pz)], 6.43 (d, *J* = 1.1 Hz, 1 H, C6H), 7.16 (m, 9 H, Ph), 7.55 (m, 6 H, Ph) ppm.

Complex 4: $Tp^{Ph,Me}$Zn-H (133 mg, 0.24 mmol) and 9-isobutylguanine (50 mg, 0.24 mmol) in 30 mL of dichloromethane were stirred for 24 h. The solvent was removed in vacuo, the residue dissolved in 15 mL of benzene, filtered and layered with heptane. Within a short time a fluffy precipitate was formed, followed slowly by the growth of small evenly shaped crystals. After 2 days the heterogeneous mixture was separated by vigorous stirring and decanting of the solution in which the fluffy precipitate was suspended. The remaining crystals were washed with a small amount of heptane and dried in vacuo. 95 mg (45%) of **4′′·1.5C$_6$H$_6$** remained as colourless crystals. M.p. 203 °C. $C_{39}H_{40}BN_{11}OZn{\cdot}1.5C_6H_6$ (755.02 + 117.17): calcd. C 66.10, H 5.66, N 17.67; found C 65.53, H 5.68, N 17.77. IR (KBr): $\tilde{\nu}$ = 3471 cm^{-1} (s, NH), 2533 (m, BH), 1638

(s, CO). ^{1}H NMR ($CDCl_3$): δ = 0.87 [d, J = 6.8 Hz, 6 H, Me(*i*Bu)], 2.05 [m, 1 H, CH(*i*Bu)], 2.56 [s, 9 H, Me(pz)], 3.31 (s, 2 H, NH_2), 3.60 [d, J = 7.2 Hz, 2 H, CH_2(*i*Bu)], 6.21 [s, 3 H, H(pz)], 6.99−7.17 (m, 9 H, Ph), 7.30 (s, 1 H, C8H), 7.34 (s, 9 H, C_6H_6), 7.60 (d, J = 6.8 Hz, 6 H, Ph) ppm.

The decanted suspension was filtered and the precipitate dried in vacuo, leaving behind 33 mg (18%) of **4′** as colourless needles. M.p. 216 °C. $C_{39}H_{40}BN_{11}OZn$ (755.02): calcd. C 62.04, H 5.34, N 20.41; found C 61.87, H 5.64, N 20.27. IR (KBr): $\tilde{\nu}$ = 3414 cm^{-1} (m, NH_2), 2548 (w, BH), 1692 (s, CO). ^{1}H NMR ($CDCl_3$): identical to the spectrum of **4′′**.

Complex 5: Complex **1a** (28.5 mg, 0.05 mmol) and 9-methylxanthine (8.4 mg, 0.05 mmol) in 10 mL of dichloromethane were stirred for 2 days. The solvent was removed in vacuo and the residue dissolved in 8 mL of benzene and 2 mL of dichloromethane. Slow evaporation yielded 18 mg (50%) of **5** which, after drying in vacuo, was isolated as a colourless powder. M.p. 158 °C. $C_{36}H_{33}BN_{10}O_2Zn$ (713.92): calcd. C 60.57, H 4.66, N 19.62; found C 60.17, H 5.01, N 18.50. IR (KBr): $\tilde{\nu}$ = 2550 cm^{-1} (m, BH), 1673 (vs, CO). ^{1}H NMR ($CDCl_3$): δ = 2.54 (s, 3 H, NMe), 2.58 [s, 9 H, Me(pz)], 6.23 [s, 3 H, H(pz)], 6.92 (s, 1 H, C8H), 7.12 (m, 9 H, Ph), 7.46 (m, 6 H, Ph), 7.71 (s, 1 H, N3H) ppm.

Complex 6: Complex **1b** (200 mg, 0.29 mmol) and theophylline·H_2O (58 mg, 0.29 mmol) in 50 mL of dichloromethane were stirred for 36 h. After filtration the volume was reduced to 10 mL in vacuo. Cooling to 4 °C yielded colourless crystals. The solvent was decanted and the crystals dried in vacuo, leaving behind 125 mg (50%) of **6** as a colourless powder. M.p. 241 °C. $C_{46}H_{53}BN_{10}O_2Zn$ (854.19): calcd. C 64.68, H 6.25, N 16.40; found C 64.48, H 6.24, N 16.29. IR (KBr): $\tilde{\nu}$ = 2540 cm^{-1} (m, BH), 1698 (s, CO). ^{1}H NMR ($CDCl_3$): δ = 1.12 [d, J = 7.0 Hz, 18 H, Me(-*i*Pr)], 2.55 [s, 9 H, Me(pz)], 2.63 (s, 3 H, NMe), 2.75 [sept, J = 7.0 Hz, 3 H, CH(*i*Pr)], 3.37 (s, 3 H, NMe), 6.04 (s, 1 H, C8H), 6.14 [s, 3, H(pz)], 6.91 (d, J = 8.0 Hz, 6 H, Ph), 7.20 (d, J = 8.0 Hz, 6 H, Ph) ppm.

Complex 7: A solution of **1a** (213 mg, 0.38 mmol) in 20 mL of dichloromethane was added to a suspension of theobromine·3H_2O (86 mg, 0.37 mmol) in 30 mL of methanol. After stirring for 12 h and filtration, the solution was evaporated to 30 mL. Upon cooling to 4 °C a fine precipitate of impure product was formed. This was filtered off and the filtrate evaporated to 10 mL. Further cooling to 4 °C yielded 156 mg (58%) of **7** as colourless crystals. M.p. 244 °C. $C_{37}H_{35}BN_{10}O_2Zn$ (727.95): calcd. C 61.05, H 4.85, N 19.24; found C 60.93, H 5.07, N 18.98. IR (KBr): $\tilde{\nu}$ = 2547 cm^{-1} (m, BH), 1655s, 1632 (vs, CO). ^{1}H NMR ($CDCl_3$): δ = 2.54 [s, 9 H, Me(pz)], 3.00 (s, 3 H, NMe), 3.52 (s, 3 H, NMe), 6.17 [s, 3 H, H(pz)], 7.10 (m, 9 H, Ph), 7.22 (s, 1 H, C8H), 7.56 (m, 6 H, Ph) ppm.

Complex 8a: A suspension of inosine (150 mg, 0.56 mmol) in 30 mL of methanol was treated with a solution of **1a** (316 mg, 0.56 mmol) in 40 mL of dichloromethane. After stirring for 12 h and filtration, the solution was evaporated to 20 mL. Cooling to 4 °C yielded colourless crystals. The solution was decanted and the residue dried in vacuo, leaving behind 325 mg (71%) of **8a** as colourless crystals. M.p. 320 °C (dec.). $C_{40}H_{39}BN_{10}O_5Zn$ (816.01): calcd. C 58.88, H 4.82, N 17.16; found C 58.66, H 4.81, N 17.28. IR (KBr): $\tilde{\nu}$ = 3274 cm^{-1} (broad OH), 2546 (m, BH), 1632 (vs, CO). ^{1}H NMR ([D_6]DMSO, assignments by COSY): δ = 2.58 [s, 9 H, Me(pz)], 3.49−3.72 (m, 2 H, C5′H_2), 3.95 (m, 1 H, C4′H), 4.11 (m, 1 H, C3′H), 4.45 (m, 1 H, C2′H), 5.16 (d, J = 4.8 Hz, 1 H, O3′H), 5.21 (d, J = 6.1 Hz, 1 H, O5′H), 5.36 (d, J = 6.4 Hz, 1 H, O2′H), 5.74 (d, J = 6.0 Hz, 1 H, C1′H), 6.09 (s, 1 H, C2H), 6.44 [s, 3 H, H(pz)], 7.11 (m, 9 H, Ph), 7.41 (m, 6 H, Ph), 7.96 (s, 1 H, C8H) ppm.

Complex 8b: Like **8a**, from inosine (32 mg, 0.31 mmol) and **1b** (212 mg, 0.31 mmol). Yield: 240 mg (83%) of **8b** as colourless needles. M.p. 206 °C. $C_{49}H_{57}BN_{10}O_5Zn$ (942.25): calcd. C 62.46, H

6.10, N 14.87; found C 61.90, H 6.01, N 14.49. IR (KBr): $\tilde{\nu}$ = 3430 cm^{-1} (broad, OH), 2542 (m, BH), 1639 (vs, CO). ^1H NMR ([D_6]DMSO, assignments by COSY): δ = 1.02 [d, J = 6.9 Hz, 18 H, Me(*i*Pr)], 2.56 [s, 9 H, Me(pz)], 2.69 [sept, J = 6.9 Hz, 3 H, CH(*i*Pr)], 3.46−3.70 (m, 2 H, C5′H_2), 3.90 (m, 1 H, C4′H), 4.09 (m, 1 H, C3′H), 4.37 (m, 1 H, C2′H), 5.13 (m, 2 H, O3′H and O5′H), 5.25 (d, J = 6.1 Hz, 1 H, O2′H), 5.68 (d, J = 5.0 Hz, 1 H, C1′H), 6.12 (s, 1 H, C2H), 6.39 [s, 3 H, H(pz)], 6.94 (d, J = 8.1 Hz, 6 H, Ph), 7.33 (d, J = 8.1 Hz, 6 H, Ph), 7.97 (s, 1 H, C8H) ppm.

Structure Determinations:[51] Crystals were obtained as described in the Exp. Sect.. Diffraction data were recorded at 180 K (**7**) and at room temp. (**2, 4′′, 8a**) on a Nonius CAD4 (**2**) or a Bruker Smart CCD diffractometer (**4′′, 7, 8a**). Empirical absorption corrections were applied for **4′′, 7** and **8a**. The structures were solved with direct methods and refined anisotropically with the SHELX program suite.[52] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5 times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_0 - F_c|/\Sigma F_o$ and $wR_2 = [\Sigma[w(F_0^2 - F_c^2)^2]-\Sigma[w(F_0^2)^2]]^{1/2}$. Drawings were produced with SCHAKAL.[53] Table 1 lists the crystallographic data.

Chain-Like Tetra-, Penta- and Heptanuclear Cyanide-Bridged Complexes by Attachment of Organometallic Cyanides to M_2, M_3 and M_5 Units

Tianlu Sheng,[a] Ralf Appelt,[a] Virginie Comte,[a] and Heinrich Vahrenkamp*[a]

Keywords: Cyanides / Polynuclear complexes / Metal-metal interactions / Electrochemistry

Attachment of the "ligands" [Cp(dppe)Fe-CN], [Cp(PPh_3)$_2$-Ru-CN], [Cp(CO)$_2$Fe-CN] and [(CO)$_5$M-CN]$^-$, (where M = Cr, Mo, W) to the polymetallic centres [$Ru_2(OAc)_4$]$^+$, [$Co_3(dpa)_4$]$^{2+}$ and [$Ni_5(tdpa)_4$]$^{2+}$ yielded two tetra-, three penta- and five heptanuclear complexes with chain-like linear arrangements of the metal ions and the bridging cyanide ligands, as proved by the structure determination of [$Ni_5(tdpa)_4${Cp(dppe)$_2$Fe-CN}$_2$](PF_6)$_2$. IR and CV data show that the Ru_2, Co_3 and Ni_5 centres of these complexes withdraw electron density from the external organometallic units. This prevents electronic interactions between the two terminal metal ions, yet allows multistep one- and two-electron redox processes.

Introduction

Molecular wires, comprised of arrays of metal atoms surrounded by ligands as insulators, are attractive as conducting leads in nanoscale devices, with possible applications ranging from electrical connections to light harvesting antennas.[1−3] One approach to the design of such wires is the lining up of metals and bridging ligands up to infinite arrays, as was successfully applied to metal-cyanide combinations.[3−5] The other approach is direct linking of the metal atoms along the chain, as applied successfully in the Krogmann salts.[6]

Well-defined molecular species of this kind, with nanoscale dimensions, have not been prepared yet. The longest (M-CN)$_x$ chain which has been crystallographically characterised contains seven manganese atoms.[7] Likewise, the longest chain-like array with metal-metal bonds is formed from seven chromium atoms.[8] Like others,[5] we are involved in attempts to stretch these limits.

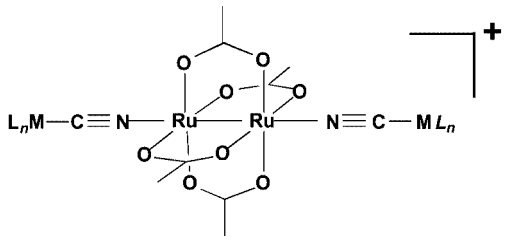
Our contributions to this field have so far consisted in the synthesis and investigation of (M-CN)$_x$ arrays.[9−14] We were able to show that there exist electronic interactions between terminal metals as far as 12 Å apart[9] and that a 90° angle in a chain interrupts such interactions.[11] We also observed the drawback that with increasing length the (M-CN)$_x$ chains become fragile, showing a tendency for dismutation with formation of shorter fragments.

Following on from here, it seemed favourable to us to combine the advantages of the cyanometal building blocks (i.e. a large variability) with those of the metal-metal bonded chains (i.e. rigidity due to their rigid ligand environment). This paper reports on some combinations of Ru_2, Co_3 and Ni_5 chains with terminal organometallic cyanides. Other than us[15] only the group of Kühn has prepared related complexes based on [$Re_2(OAc)_4$][16] and [$Mo_2(OAc)_4$] units.[17]

Results and Discussion

Derivatives of [$Ru_2(OAc)_4$]$^+$

The [$Ru_2(OAc)_4$]$^+$ unit is a mixed-valence species containing Ru^{II} and Ru^{III}. This is promising in terms of redox chemistry, particularly when combined with the redox chemistry of cyanide-linked metal complex units. We therefore attached the organometallic cyanides [Cp(dppe)Fe-CN] and [Cp(PPh_3)$_2$Ru-CN] to this core by reacting them with [$Ru_2(OAc)_4(THF)_2$]BF_4. The complex cations **1a** and **1b** were obtained as tetrafluoroborate salts.



1a: L_nM = Cp(dppe)Fe **1b:** L_nM = Cp(PPh_3)$_2$Ru

Confirmation of the identity of complexes **1a** and **1b** was obtained independently by an X-ray analysis of **1b** as a hexafluoroantimonate salt.[15] Information on their electronic nature can be drawn from the ν(CN) values in their

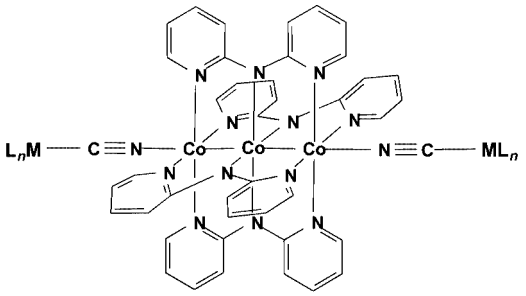
IR spectra. The corresponding bands (2059 cm^{-1} for **1a** and 2061 cm^{-1} for **1b**) are lower by 3 and 10 cm^{-1}, respectively, than those in the free L_nM-CN "ligands". Previously, we observed that ν(CN) is raised in similar situations, reflecting the kinematic effect, i.e. the increased energy for the CN vibration due to the attachment of CN^- to two metal centres.[11−13] However, for dinuclear CN-bridged complexes we had also observed that ν(CN) can be lowered when the metal centre attached at the N terminus is strongly electron-withdrawing.[18] In those cases the electron withdrawal is compensated by increased M→C π-back-donation from the other metal centre, which populates antibonding orbitals and lowers the strength of the C−N bond. Complexes **1** seem to represent an intermediate situation, where the kinematic effect and the back-bonding effect are virtually identical. The important conclusion from this is that the Ru_2 core is an electron sink which may impede electronic interactions between the two terminal metal centres.

This is also evident from the electrochemical investigation of **1a** and **1b**. The electrochemical response of the Ru_2 core of these complexes is poor, as is that of the parent complexes $[Ru_2Cl(RCOO)_4]$,[19] showing only an irreversible reduction around −0.4 V (in CH_2Cl_2 vs. Ag/AgCl). The oxidative waves assigned to the organometallic cyanides occur at +0.67 V for **1a** and +1.02 V for **1b**. Both these values are 0.2 V higher than those of the free organometallic cyanides. This confirms the electron withdrawal by the Ru_2 core, which, by means of the π-back-donation, extends to the terminal metal centres. The electrochemical waves have the characteristics of reversible one-electron transfers. Together with the notion that there is no splitting of the redox waves, this indicates that there is no electronic interaction between the two terminal iron or ruthenium atoms. The same observation was made by Kühn for the related complexes with Re_2 and Mo_2 cores.[16,17]

Derivatives of $[Co_3(dpa)_4]^{2+}$

Complexes with metal chains stabilized by sawtooth-like pyridylamide ligands were introduced by Peng.[8,20,21] To start with we chose the best-investigated example with the shortest chain length, i.e. the cobalt(II) complex.[22,23] The reactions between $[Co_3(dpa)_4]Cl_2$ and the cyanometal complexes [Cp(dppe)Fe-CN], $[Cp(PPh_3)_2Ru$-CN] and Na-$[(CO)_5Cr$-CN] were straightforward and yielded the pentanuclear complexes **2a**−**c**. Complexes **2a** and **2b** are dications and were isolated as hexafluoroantimonate salts. Complex **2c** is neutral.



2a: L_nM = Cp(dppe)Fe **2b:** L_nM = $Cp(PPh_3)_2Ru$ **2c:** L_nM = $(CO)_5Cr$

Complexes **2a**−**c** could not be obtained in the form of crystals suitable for X-ray analysis, yet their identity is evident from their spectra and their redox behaviour. The ν(CN) band-positions of **2a** and **2b** (2055 and 2057 cm^{-1}) are virtually identical to those of **1a** and **1b**. The slight lowering of the ν(CN) values relative to those of the free organometallic cyanides leads to the same conclusions as above: the $[Co_3(dpa)_4]^{2+}$ core, just like the $[Ru_2(OAc)_4]^+$ core, seems to be a rather strong electron acceptor. The fact that the ν(CN) band of **2c** (2120 cm^{-1}) is raised by 17 cm^{-1} with respect to that of free $[(CO)_5Cr$-$CN]^-$ is not in contradiction with this conclusion: upon formation of the pentanuclear complex the negative charge of $[(CO)_5Cr$-$CN]^-$ disappears, hence the strong Cr→C π-back-donation is diminished and this results in a strengthening of the C−N bond.

The electrochemical behaviour of complexes **2** underlines the strong electron-acceptor properties of their $[Co_3(dpa)_4]^{2+}$ cores (see Table 1 and Figure 1). The first oxidative wave corresponds to a one-electron oxidation of the Co_3 unit. The second wave represents the transfer of two electrons, one each from the two terminal metal atoms. Relative to free $[Co_3(dpa)_4(CH_3CN)_2]^{2+}$ the Co_3 core in complexes **2** is easier to oxidize by 0.1−0.2 V, reflecting the electron donation from the organometallic cyanides, typically strongest from the anionic $[(CO)_5Cr$-$CN]^-$. In turn, the terminal metal units are more difficult to oxidize by roughly 0.4 V, in comparison to the free organometallic cyanides. This is about twice as much as in complexes **1**, indicating that the Co_3 unit is a stronger electron acceptor than the Ru_2 unit. As above, the redox wave for the organometallic cyanides is not split into two components, again indicat-

ing that the central polymetallic unit interrupts electronic communication between the two terminal metal atoms.

The electronic spectra of complexes **2** (for details see Exp. Sect.) are very similar to those of the Co_3 parent compounds $[Co_3(dpa)_4]Cl_2$ and $[Co_3(dpa)_4(CH_3CN)_2](PF_6)_2$.[22,23] Very strong absorptions in the near UV and one strong absorption in the visible range can be assigned to π-π* and MLCT transitions, and very weak absorptions in the NIR to d-d transitions of the Co^{II} ions. Complexes **2** show no additional features other than a slight intensification of the NIR bands. The positions of the NIR bands of **2a** and **2b** make it clear that they are not MMCT bands representing electron transfer from the outer metal centres to the Co_3 core: the prominent band for the Ru complex **2b** at 1248 nm occurs at lower energy by 26 nm than the corresponding band for the Fe complex **2a** at 1222 nm. Yet $[Cp(PPh_3)_2Ru\text{-}CN]$ is much more difficult to oxidize than [Cp(dppe)Fe-CN] (see Table 1). Hence these band positions only reflect the influence of the terminal organometallic units on the electronic structure of the Co_3 core.

The reversible redox steps in the cyclic voltammograms indicate that complexes **2** should be suitable for chemical oxidations. This was probed for **2a**. Addition of one equivalent of magic blue $[(4\text{-}Br\text{-}C_6H_4)_3N^+$ as the SbF_6 salt, $E_{1/2} = +1.0$ V[24]] produced a change of colour and spectra, addition of two further equivalents produced another. The resulting complex cations which we assign as **2a′** and **2a′′** were stable enough to be investigated in solution, but we failed to isolate them as pure complex salts.

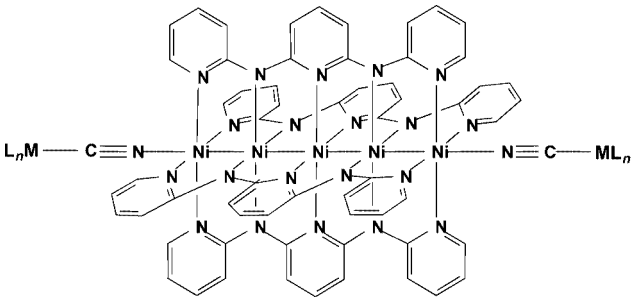
$[Cp(dppe)Fe\text{-}CN\text{-}Co_3(dpa)_4\text{-}NC\text{-}Fe(dppe)Cp]^y$

2a: $y = 2+$, **2a′**: $y = 3+$, **2a"**: $y = 5+$

The ν(CN) bands in the IR spectra of **2a**, **2a′** and **2a′′** occur at 2057, 2047 and 2134 cm^{-1}, respectively, in CH_2Cl_2 solution. The changes are in agreement with the structural and electronic assignments given above. The decrease from **2a** to **2a′** reflects the increased charge on the Co_3 core and hence its increased electron withdrawal. The sharp rise from **2a′** to **2a′′** reflects the positive charges on the two terminal Cp(dppe)Fe units, which dramatically reduces their ability for M→C π-back-donation. In the electronic spectrum of **2a′** (for details see Exp. Sect.) two new bands of medium intensity occur in the far visible and near IR range. In the electronic spectrum of **2a′′** these two new bands are shifted to lower energies. New bands of similar position and intensity were also observed upon one-electron oxidation of $[Co_3(dpa)_4]Cl_2$.[25] The simplest interpretation is that they are due to MMCT transitions within the $Co^{II}_2Co^{III}$ core. There is no obvious relation in terms of MMCT with the terminal [FeCp(dppe)] units, other than the band shift upon changing their oxidation state. Thus, similar to the situation with the $[Ru_2(OAc)_4]$-derived complexes, neither the electrochemical behaviour nor the electronic spectroscopy of complexes **2** indicate any electron transfer behaviour, be it between the two terminal metal units or between one of these units and the trimetal core.

Derivatives of $[Ni_5(tpda)_4]^{2+}$

The starting material for our heptanuclear complexes, $[Ni_5Cl_2(tpda)_4]$, was also described for the first time by Peng.[20] After conversion to its more reactive form, $[Ni_5(tpda)_4(CH_3CN)_2]^{2+}$, by reaction with $AgBF_4$ in acetonitrile,[26] it could be reacted with [Cp(dppe)Fe-CN], $[Cp(PPh_3)_2Ru\text{-}CN]$, $[Cp(CO)_2Fe\text{-}CN]$, $Na[(CO)_5Mo\text{-}CN]$ and $Na[(CO)_5W\text{-}CN]$. Complexes **3a**−**e** resulted in moderate yields. They were isolated as deeply coloured crystalline hexafluorophosphate salts (**3a**, **3b**, **3c**) or neutral complexes (**3d**, **3e**).



3a: $L_nM = Cp(dppe)Fe$ **3b:** $L_nM = Cp(PPh_3)_2Ru$ **3c:** $L_nM = Cp(CO)_2Fe$

3d: $L_nM = (CO)_5Mo$ **3e:** $L_nM = (CO)_5W$

Crystals of **3a** were chosen for a representative structure determination (see Figure 2). The complex cation has internal symmetry, with the central nickel atom being located on a twofold axis. The central molecular axis of **3a** which is comprised of 11 atoms (5 Ni, 2 Fe, 2 CN) is almost perfectly linear, with the strongest bending occurring typically at the nitrogen atom of the bridging cyanide (172°). The helical nature of the $[Ni_5(tdpa)_4]$ core, due to the wrapping of the tdpa ligands, and the uneven distribution of Ni−Ni distances along the Ni_5 chain closely correspond to those in the parent complexes, $[Ni_5Cl_2(tpda)_4]$[20] and $[Ni_5(tpda)_4(CH_3CN)_2](PF_6)_2$.[26] The geometry of the [Cp(dppe)Fe-CN] "ligands" compares well with that in related di- and trinuclear complexes.[9−14,18] Neither the Fe−C nor the C−N distances in all the cyanide-bridged complexes derived from [Cp(dppe)Fe-CN] vary so much as to draw reliable conclusions on the amount of Fe→C π-back-donation. Thus, the structural data of such oligometallic complexes yield no information about the net electron withdrawal from the terminal organometallic cyanides to the central M_2, M_3 or M_5 core. The two iron atoms in **3a** are 19.4 Å apart, which is the longest distance between such terminal redox centres in cyanide-bridged complexes observed so far.

As for complexes **1** and **2**, the IR data of complexes **3** yield unambiguous information on the net electron withdrawal from the terminal organometallic cyanides into the Ni_5 core. Table 2 shows that this is the same as in **1** and **2** for **3a** and **3b** [slight lowering of ν(CN)] as well as for **3d** and **3e** [slight increase of ν(CN)]. Complex **3c** shows a large increase in ν(CN) as compared to free $[Cp(CO)_2Fe\text{-}CN]$. This clearly supports the notion that in all the other complexes described here, it is the M→C π-back-donation

Table 2. ν(CN) Data of complexes **3** and reference compounds

	Complex	Free L_nM-CN
3a	2062	2062
3b	2067	2072
3c	2141	2106
3d	2116	2107
3e	2120	2111

which provides the electron flow from the terminal metal units to the M_n complex cores: $[Cp(CO)_2Fe\text{-}CN]$ is quite electron-poor compared to [Cp(dppe)Fe-CN] (its redox potential is more than 1 V higher), and hence it can provide much less electron density for π-back-donation. Thus, the kinematic effect is the decisive influence on ν(CN) of **3c**, resulting in a rather high ν(CN) value.

The redox behaviour of complexes **3a**−**c** is mostly that of their Ni_5 core (see Table 3). The reference complex $[Ni_5(tdpa)_4]^{2+}$ undergoes a reversible one-electron oxidation and can be isolated in the form of $[Ni_5(tdpa)_4]^{3+}$ compounds.[27] As we found for $[Ni_5(tdpa)_4(CH_3CN)_2]^{2+}$, there are two further irreversible oxidation steps. Complexes **3a**−**c** also show these three redox steps, albeit in ill-resolved, yet reversible, cyclic voltammograms. Figure 3 shows this in the case of **3a**, which is the only complex **3** that also displays the redox wave for the organometallic cyanide.

In the cyclic voltammogram of **3a** the redox wave assigned as $E_{1/2}(2)$ is twice as high and hence must be associated with the oxidation of the two [FeCp(dppe)] units present. If this is so, then **3a** compares favourably with **2a**: in both cases the redox potential of the organometallic cyanide is raised by 0.2−0.3 V while that of the Co_3 or Ni_5 core is lowered by ca. 0.2 V. This clearly reproduces the conclusions on the net flow of electron density drawn from the IR data. Complexes **3b** and **3c** do not give such a clear indication of the electronic situation. Their organometallic cyanides are more difficult to oxidize. This results in a lesser effect on the first redox potential of the Ni_5 unit and hides their redox waves in the cyclic voltammograms. Again, as before for **1a** and **2a**, there is no splitting of the redox wave due to the [FeCp(dppe)] unit in **3a**. Furthermore, attempts at chemical one-electron oxidation of **3a** (which was shown to be possible for the parent Ni_5 complex[27]) were not successful.

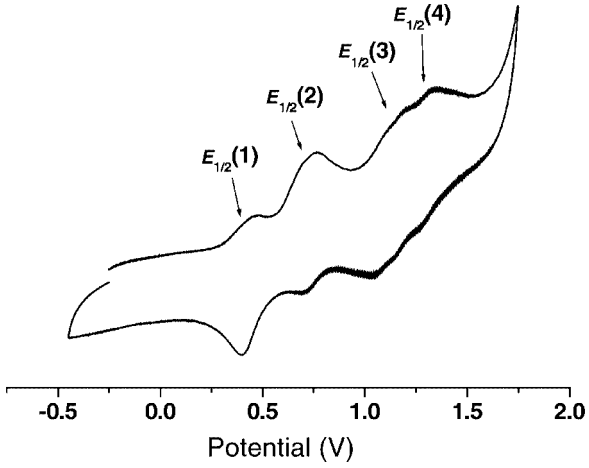

Figure 3. Cyclic voltammogram of **3a** (in CH_2Cl_2, potentials vs. Ag/AgCl)

Table 3. Cyclovoltammetric data (in CH_2Cl_2, potentials in V vs. Ag/AgCl) for complexes **3** and the Ni_5 reference compound

	$E_{1/2}(1)$	$E_{1/2}(2)$	$E_{1/2}(3)$	$E_{1/2}(4)$
3a	0.44	0.72	1.11	1.31
3b	---	0.67	1.10	1.28
3c	---	0.68	1.08	1.26
$[Ni_5(tpda)_4(CH_3CN)_2](PF_6)_2$		0.68	0.94(irr)	1.29(irr)

The UV/Vis spectra of complexes **3** (for details see Exp. Sect.) only show the features of their Ni_5 core. The absorptions due to the organometallic cyanides are completely hidden. There are intense π-π* and MLCT transitions up to about 400 nm and weak d-d bands in the 500−700 nm range.[26] Upon one-electron oxidation of $[Ni_5Cl_2(tpda)_4]$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

MMCT bands show up in the NIR.[27] The spectra of complexes **3** show no features of this kind which might be attributed to a MMCT from the electron-rich organometllic units to the electron-poor Ni_5 core. Actually the spectrum of **3a**, which, due to its easily oxidizable [FeCp(dppe)] constituents, should be most suitable for such a MMCT, is virtually superimposable to that of $[Ni_5(tpda)_4Cl_2]$.

Conclusions

The concept of constructing cyanide-bridged extended arrays of metal ions by linking organometallic cyanides to chain-like polymetallic units was applied successfully. Tetra-, penta- and heptanuclear complexes based on Ru_2, Co_3 and Ni_5 cores were obtained. The pronounced electron-acceptor properties of the core units result in a stable attachment of the terminal cyanometal constituents. The structure determination of **3a** with an almost perfectly linear Fe-CN-Ni_5-NC-Fe array and an Fe−Fe distance of 19.4 Å has confirmed the longest distance between two such Cp(dppe)Fe-CN units yet.

The spectroscopic data of the new complexes have shown uniformly that their Ru_2, Co_3 and Ni_5 cores are electron sinks. They withdraw electron density from the terminal organometallic units via the CN bridges, yet not to an extent that optically induced MMCT occurs. For all three complex types the first oxidative process converts one of the metal ions in the core from the M^{II} to the M^{III} state. This further increases the electron-sink properties of the core units. As a result any possible MMCT between the two terminal organometallic units is interrupted, and MMCT occurs either within the core units or from one of the terminal units into the core.

One goal of this work, i.e. finding electronic communication between the terminal units in complexes with longer chain lengths, could not be achieved. Both the electron-sink properties of the core units and the failure to observe split redox waves for [FeCp(dppe)] and related units prevented this. It has been achieved in much longer chains with electronically more balanced (e.g. polyacetylide) chains,[28] leaving the challenge to find similarly suitable chains in cyanide-bridged systems.

Experimental Section

General: The general experimental and measuring techniques are given in ref.[11]. $[Ru_2(OAc)_4(THF)_2]BF_4$,[29] $[Co_3(dpa)_4]Cl_2$,[22] $[Ni_5(tpda)_4(CH_3CN)_2](BF_4)_2$,[26] [Cp(dppe)Fe-CN],[30] $[Cp(PPh_3)_2$-Ru-CN],[30] $[Cp(CO)_2$Fe-CN][31] and Na[$(CO)_5$M-CN] with M = Cr, Mo, W[32] were prepared according to the published procedures.

1a: [Cp(dppe)Fe-CN] (30 mg, 0.06 mmol) was added with stirring to a solution of $[Ru_2(OAc)_4(THF)_2]BF_4$ (20 mg, 0.03 mmol) in 10 mL of THF. After 2 h the solvent was removed in vacuo and the residue dissolved in 10 mL of dichloromethane. Layering with hexane led, within a few days, to the separation of 25 mg (50%) of **1a** as blue-green crystals. M.p. 330 °C (dec.). $C_{72}H_{70}BF_4Fe_2N_2O_8P_4Ru_2$ (1615.89): calcd. C 53.52, H 4.37, N 1.73; found C 52.91, H 4.28, N 1.64.

1b: Like **1a** from $[Cp(PPh_3)_2$Ru-CN] (170 mg, 0.20 mmol) and $[Ru_2(OAc)_4(THF)_2]BF_4$ (80 mg, 0.10 mmol). Yield 100 mg (50%) of **1b** as red-brown crystals. M.p. 174 °C. $C_{92}H_{82}BF_4N_2O_8P_4Ru_4 \cdot 2CH_2Cl_2$ (1958.65 + 169.87): calcd. C 53.04, H 4.07, N 1.32; found C 52.81, H 4.04, N 1.13.

2a: A mixture of $[Co_3(dpa)_4]Cl_2$ (102 mg, 0.09 mmol) and [Cp(dppe)Fe-CN] (101 mg, 0.19 mmol) in 40 mL of ethanol and 20 mL of dichloromethane was treated with $NaSbF_6$ (48 mg, 0.19 mmol) and stirred for 1 h. After filtration the solvents were removed in vacuo. The residue was extracted with 20 mL of dichloromethane and the extract layered with 60 mL of hexane. Within a few days 135 mg (60%) of **2a** had separated as brown crystals. M.p. 223 °C. $C_{104}H_{90}Co_3F_{12}Fe_2N_{14}P_4Sb_2$ (2419.81): calcd. C 51.62, H 3.75, N 8.10; found C 51.07, H 3.57, N 7.93. UV/Vis (CH_2Cl_2): λ (ε) = 404sh (19000), 430sh (10500), 460sh (2100), 560 (3600), 1222 nm (240).

2b: Like **2a** from $[Co_3(dpa)_4]Cl_2$ (85 mg, 0.08 mmol), $[Cp(PPh_3)_2$Ru-CN] (114 mg, 0.16 mmol) and $NaSbF_6$ (41 mg, 0.16 mmol). Yield 92 mg (43%) of **2b** as brown crystals. M.p. 240 °C. $C_{124}H_{102}Co_3F_{12}N_{14}P_4Ru_2Sb_2$ (2762.57): calcd. C 53.91, H 3.72, N 7.10; found C 53.93, H 2.78, N 7.20. UV/Vis (CH_2Cl_2): λ (ε) = 396sh (17000), 452sh (5800), 512sh (1500), 526 (2800), 1248 nm (190).

2c: Like **2a** from $[Co_3(dpa)_4]Cl_2$ (79 mg, 0.07 mmol) and Na-[$(CO)_5$Cr-CN] (35 mg, 0.15 mmol) in 50 mL of ethanol. Yield 50 mg (57%) of **2c** as a red powder. M.p. 184 °C. $C_{52}H_{32}Co_3Cr_2N_{14}O_{10}$ (1293.70): calcd. C 48.28, H 2.49, N 15.16; found C 48.05, H 2.43, N 14.10. UV/Vis (CH_2Cl_2): λ (ε) = 394 (13500), 458sh (5200), 510sh (1550), 558 (2830), 1194 nm (300).

Chemical Oxidation of 2a: A 0.1 M solution of $[(4\text{-Br-}C_6H_4)_3N]$-$SbF_6$ [24] in CH_2Cl_2 was added dropwise with stirring to a 0.1 M solution of **2a** in CH_2Cl_2. IR spectroscopy indicated the formation of **2a′** after addition of one molar equivalent and the formation of **2a′′** after the addition of two further molar equivalents, as evident from their ν(CN) bands at 2047 and 2134 cm^{-1}, respectively. UV/Vis data: **2a′**: λ (ε) = 424 (8300), 582sh (3050), 712 (6900), 1096 (2300); **2a′′**: λ(ε) = 432 (10300), 546 (3200), 714 (3400), 1180 (1800), 1420 nm (1300).

3a: A solution of $[Ni_5Cl_2(tpda)_4]$ (42 mg, 0.03 mmol) and $AgBF_4$ (12 mg, 0.06 mmol) in 20 mL of dichloromethane and 4 mL of acetonitrile was stirred for 1 h. After removal of the solvents in vacuo the residue was extracted with 10 mL of dichloromethane and the extract filtered off. [Cp(dppe)Fe-CN] (33 mg, 0.06 mmol) was added to this solution. After 4 h of stirring, NH_4PF_6 (12 mg, 0.07 mmol) and 1 mL of methanol were added. After 10 min of stirring the solution was filtered off. Slow diffusion of diethyl ether into this solution yielded, within one week, 48 mg (63%) of **3a** as black crystals. M.p. 340 °C (dec.). These crystals, containing dichloromethane and methanol, were taken as such for the structure determination. Pumping in vacuo converted them into a solvent-free powder. $C_{124}H_{102}F_{12}Fe_2N_{22}Ni_5P_6$ (2719.28): calcd. C 54.77, H 3.78, N 11.33; found C 54.23, H 4.07, N 11.04. UV/Vis (CH_2Cl_2): λ (ε) = 368 (9400), 472 (640), 596 nm (880).

3b: Like **3a** from $[Ni_5(tpda)_4Cl_2]$ (56 mg, 0.04 mmol), $AgBF_4$ (16 mg, 0.08 mmol), $[Cp(PPh_3)_2$Ru-CN] (57 mg, 0.08 mmol) and NH_4PF_6 (15 mg, 0.09 mmol). Yield 32 mg (25%) of **3b** as black crystals. M.p. 320 °C (dec.). $C_{144}H_{114}F_{12}N_{22}Ni_5P_6Ru_2 \cdot CH_2Cl_2$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(3070.11 + 84.93): calcd. C 55.34, H 3.72, N 9.79; found C 55.41, H 4.25, N 9.79. UV/Vis (CH_2Cl_2): λ (ε) = 364 (6800), 388 (6000), 482 (680), 536 (790), 600 nm (980).

3c: Like **3b** with [Cp(CO)$_2$Fe-CN] (16 mg, 0.08 mmol). Yield 31 mg (38%) of **3c** as black crystals. M.p. 340 °C (dec.). $C_{76}H_{54}F_{12}Fe_2N_{22}Ni_5O_4P_2$ (2034.48): calcd. C 44.87, H 2.68, N 15.15; found C 44.77, H 2.58, N 15.04. UV/Vis (CH_2Cl_2): λ (ε) = 360 (5100), 388 (4300), 492 (700), 548 (760), 606 nm (820).

3d: Like **3a** from [$Ni_5(tpda)_4Cl_2$] (56 mg, 0.04 mmol), $AgBF_4$ (16 mg, 0.08 mmol) and Na[(CO)$_5$Mo-CN] (23 mg, 0.08 mmol), without addition of NH_4PF_6. Yield 15 mg (20%) of **3d** as black crystals. M.p. 340 °C (dec.). $C_{72}H_{44}Mo_2N_{22}Ni_5O_{10}\cdot 0.5CH_2Cl_2$ (1870.64 +42.47): calcd. C 45.71, H 2.38, N 16.18; found C 45.53, H 2.49, N 15.53. UV/Vis (CH_2Cl_2): λ (ε) = 366 (2500), 376 (2300), 470 (170), 536 (200), 588 nm (250).

3e: Like **3d** with Na[(CO)$_5$W-CN] (30 mg, 0.08 mmol). Yield 11 mg (12%) of **3e** as black crystals. M.p. 340 °C (dec.). $C_{72}H_{44}N_{22}Ni_5O_{10}W_2\cdot 2CH_2Cl_2$ (2038.43 + 169.87): calcd. C 40.25, H 2.19, N 13.95; found C 40.56, H 2.32, N 13.80. UV/Vis (CH_2Cl_2): λ (ε) = 356 (10700), 394 (8700), 474 (1900), 534 (2400), 590 nm (2900).

Structure Determination:[33] The crystal of **3a** was taken directly from the reaction solution. Diffraction data were recorded at room temperature on a Bruker Smart CCD diffractometer and subjected to an empirical absorption correction. The structure was solved with direct methods and refined anisotropically with the SHELX program suite.[34] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5 times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL.[35] Table 4 lists the crystallographic data.

Coenzyme B_{12} Model Studies − Kinetics of Axial Ligation of Alkylcobalt Complexes Containing a Tridentate Amino-Oximate Ligand

Basam M. Alzoubi,[a] Mohamed S. A. Hamza,[a] Alessandro Felluga,[c] Lucio Randaccio,[c] Giovanni Tauzher,[c] and Rudi van Eldik*[a]

Keywords: Ligand substitution / Cobalt / Kinetics / Mechanism / Enzymes / High-pressure chemistry

The ligand-substitution reaction of $[RCo(LNHpy)(HLNHpy)]^+$ by cyanide was studied in methanol as a solvent, where R = Et (**1**), Me (**2**), CF_3CH_2 (**3**), and bridging CH_2 (**4**), HLNHpy = 2-(2-pyridylethyl)amino-3-butanone oxime and $LNHpy^-$ is its conjugate base. The second-order rate constants for the substitution of the 2-pyridylethyl moiety in $[RCo(LNHpy)(HLNHpy)]^+$ by cyanide were found to be 19.1, 0.25, $2.2\cdot10^{-2}$, and $1.7\cdot10^{-2}$ $M^{-1}\cdot s^{-1}$ for R = Et, Me, CF_3CH_2, and bridging CH_2, respectively. From the temperature- and pressure-dependence studies of the substitution reaction, the activation parameters ($\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, $\Delta V^{\ddagger}$) for the reaction of $[RCo(LNHpy)(HLNHpy)]^+$ with cyanide in methanol were found to be, for R = Et: 69±2 kJ·mol^{-1}, +11±7 J·K^{-1} mol^{-1}, +9.6±0.3 cm^3·mol^{-1}; R = Me: 86±4 kJ·mol^{-1}, +31±15 J·K^{-1}·mol^{-1}, +4.3±0.2 cm^3·mol^{-1}; R = CF_3CH_2: 73±3 kJ·mol^{-1}, −33±10 J·K^{-1}·mol^{-1}, +8.7±0.2 cm^3·mol^{-1}; R = bridging CH_2: 80±1 kJ·mol^{-1}, −13±3 J·K^{-1}·mol^{-1}, +5.4±0.1 cm^3·mol^{-1}, respectively. Based on the reported rate and activation parameters, the mechanism of the ligand-substitution reaction varies between a limiting dissociative and a dissociative interchange type of mechanism depending on the σ-donor and steric effects of the alkyl group.

Introduction

The discovery of coenzyme B_{12} and the increasing amount of information on its biochemical role[1,2] has led to great efforts in the synthesis and study of model organocobalt complexes with a coordination sphere as similar as possible to that of the corrin ring. Much work has been carried out on organocobalt B_{12} model complexes to achieve a deeper understanding of the behaviour of coenzyme B_{12} by studying *cis* and *trans* effects which significantly influence the physical and chemical properties of vitamin B_{12} and its chemical models.[3−6] The nature of the alkyl group in the axial position has an effect on the Co−C and $Co-N_{(axial)}$ bond lengths, where the latter increase with increasing donor properties of the σ-donor ligand and are significantly influenced by the nature of the equatorial ligand.[7−9] The reaction of cyanide with different alkylcobalamines (RCb1, where R = CF_3, CF_3CH_2, CF_2H, Me, and CH_2Br) showed that the nature of the alkyl group has an influence on the thermodynamic stability constants, as well as on the rate constants of the substitution reactions of the axial ligand *trans* to the alkyl group.[10]

In order to obtain further insight into these reactions, a class of organocobalt complexes *trans*-$[(R)Co(LNHpy)(HLNHpy)]ClO_4$, where HLNHpy is the tridentate ligand 2-(2-pyridyethyl)amino-3-butanone oxime and LNHpy is its conjugated base, were synthesized.[5,11] The alkyl group R was Me, Et, CF_3CH_2, or the intramolecular bridging CH_2 group as shown in Figure 1. The geometry of these compounds is reminiscent of the lariat-type ligands previously reported,[3,12] since they contain a potentially quinquedentate ligand forming an equatorial chelating system bearing a pendant pyridyl group axially coordinated to the cobalt atom. The structural features of these complexes allow better modeling of the displacement of 5,6-dimethylbenzimidazole in coenzyme B_{12} than any other model so far studied. It is further of interest that the geometry of the N−Co−C unit in the Me derivative [Co−C = 1.971(7) Å, Co−N = 2.159(5) Å] is much closer to that of MeCbl [Co−C = 1.979(4) Å, Co−N = 2.162(4) Å] than of any other previously proposed B_{12} model complex.[5]

Ligand-substitution reactions of vitamin B_{12} and its model complexes in general follow a dissociative (I_d or D) type of mechanism.[13−15] In the case of the coenzyme, however, evidence was originally reported for an associative substitution mode, which was later corrected to result from the combination of a rapid substitution of dimethylbenzimi-

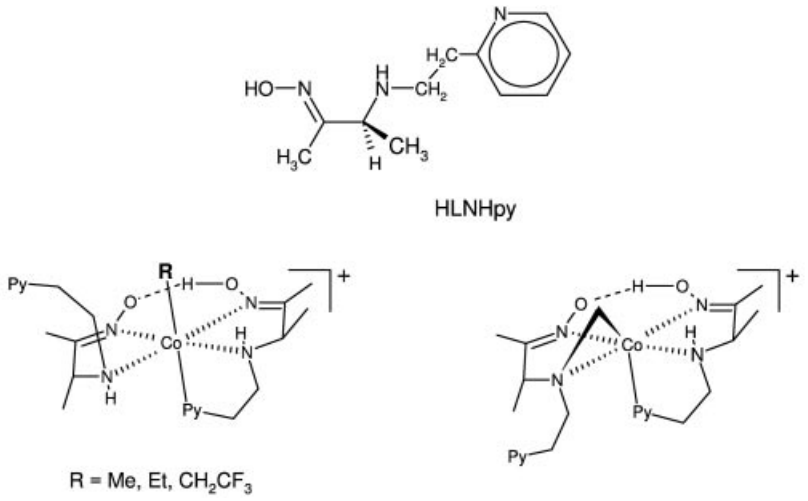

Figure 1. Structures of HLNHpy, which is the tridentate ligand 2-(2-pyridyethyl)amino-3-butanone oxime, and of *trans*-[(R)Co(LNHpy)(HLNHpy)]$^+$, where R = Et, Me, CF_3CH_2, and bridging CH_2

dazole and subsequent water-assisted heterolysis of the cobalt−carbon (adenosyl) bond.[16,17] Ligand-substitution reactions of different cobalamins (R = CF_3, CN^-, $NCCH_2$) with cyanide have been studied,[10,18] and it was found that CN^- substitutes the 5,6-dimethylbenzimidazole (DMBz) moiety in all cases. The activation parameters were interpreted in terms of a limiting D mechanism.

Kinetic and mechanistic studies on the substitution behaviour of alkyl derivatives of bis(dimethylglyoximate)-cobalt(III) complexes have been performed extensively.[19−33] Most of these studies have been aimed to asses the role of the σ-bonded alkyl group to Co^{III} in affecting the axial substitution rates in the *trans* position. Typical reactions that have been studied can be represented by Equations (1) and (2), where DH represents the monoanion of dimethylglyoxime, R is an alkyl group, and L and L^I are neutral bases.

$$\textit{trans}\text{-}[RCo(DH)_2H_2O] + L \rightarrow \textit{trans}\text{-}[RCo(DH)_2L] + H_2O \quad (1)$$

$$\textit{trans}\text{-}[RCo(DH)_2L] + L^I \rightarrow \textit{trans}\text{-}[RCo(DH)_2L^I] + L \quad (2)$$

In the present study, we investigated the ligand-substitution reactions of *trans*-[(R)Co^{III}(LNHpy)(HLNHpy)]$^+$, where R = Et, Me, CF_3CH_2, and bridging CH_2. These reactions were studied as a function of entering nucleophile concentration, temperature, and pressure in order to elucidate the reasons for the observed lability and the intimate mechanisms of these reactions.

Results and Discussion

The kinetics of the reaction of complexes of the type *trans*-[(R)Co(LNHpy)(HLNHpy)]$^+$, R = Et (**1**), Me (**2**) and CF_3CH_2 (**3**), with CN^- were studied in methanol. Cyanide was used as the entering nucleophile, since other less-strong nucleophiles are known to be incapable of replacing any of the axial ligands in these complexes. The reaction of the complex[11] *trans*-[(CH_2)Co(LNHpy)(HLNpy)]$^+$ (**4**) with CN^- was also studied. Complex **4** was characterized to involve a $-CH_2-$ group that forms a three-membered metallacycle,[34,35] in which the other two members are the Co atom and the equatorial nitrogen donor. Complexes containing this type of metallacycle are quite rare[34,35] and scarcely studied. In view of the unusual geometry of this complex, it seemed to be of interest to examine its kinetic properties with reference to the reactivity of the *trans* position with respect to the bridging $-CH_2-$ fragment.

Reaction of *trans*-[(R)Co(LNHpy)(HLNHpy)]$^+$ with Cyanide

R = Et

The UV/Vis spectrum of *trans*-[(Et)Co(LNHpy)-(HLNHpy)]$^+$ shows two bands at 368 and 464 nm (376 and 207 $M^{-1}\cdot cm^{-1}$, respectively) in methanol at 25.0 °C. The substitution reaction of *trans*-[(Et)Co(LNHpy)-(HLNHpy)]$^+$ occurs by displacement of the axial 2-pyridylethyl ligand by cyanide, which is positioned *trans* to the ethyl group. The product is light-sensitive, suggesting the presence of the alkyl group in the axial position. The product spectrum has a single band at 452 nm (137 $M^{-1}\cdot cm^{-1}$) with a shoulder at 338 nm (441 $M^{-1}\cdot cm^{-1}$); good isosbestic points at 334 and 360 nm were observed during the reaction.

Figure 2 presents a plot of k_{obs} versus [CN^-] for the reaction of $2.5\cdot10^{-3}$ M *trans*-[(Et)Co(LNHpy)(HLNHpy)]$^+$ with cyanide (0.025−0.20 M) at I = 0.5 M (CF_3SO_3Li) in methanol at 25.0 °C. The linear plot has a negligible intercept, indicating that the back reaction does not contribute significantly and that no parallel reaction takes place. The second-order rate constant for the substitution of 2-pyridylethyl by

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

CN^- was found to be 19.1±0.2 $M^{-1}s^{-1}$ at 25.0 °C. This behaviour can be expressed by the rate law given in Equation (3).

$$k_{obs} = k_a [CN^-] \quad (3)$$

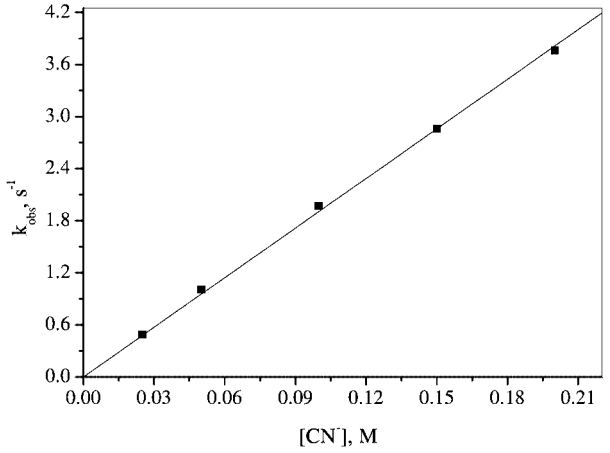

Figure 2. Plot of k_{obs} versus [CN^-] for the reaction of *trans*-[(Et)Co(LNHpy)(HLNHpy)]$^+$ with cyanide in methanol; experimental conditions: [Co^{III}] = $1\cdot10^{-3}$ M, I = 0.5 M, T = 25.0 °C

The reaction was also studied as a function of temperature and pressure, for which the results are reported in Tables 1 and 2. A plot of ln k_a versus pressure gives a good linear relationship as shown in Figure 3. The activation parameters ($\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, $\Delta V^{\ddagger}$) were found to be 69±2 kJ·mol^{-1}, 11±7 J K^{-1}·mol^{-1} and 9.6±0.3 cm^3·mol^{-1}, respectively. Based on the reported rate and activation parameters, the ligand-substitution reaction of the complex *trans*-[(Et)Co(LNHpy)(HLNHpy)]$^+$ with cyanide follows a dissociative mechanism as presented in reaction [Equation (4)].

(4)

R = Me, CF_3CH_2, and Bridging CH_2

The UV/Vis spectra of *trans*-[(R)Co(LNHpy)-(HLNHpy)]$^+$ show two bands at 362 and 452 nm (466 and 330 $M^{-1}\cdot cm^{-1}$, respectively) for R = Me, one band at 462 nm (187 $M^{-1}\cdot cm^{-1}$) with a shoulder at 364 nm (256 $M^{-1}\cdot cm^{-1}$) for R = CF_3CH_2, and a single band at 400 nm (509 $M^{-1}\cdot cm^{-1}$) with a shoulder at 472 nm (303 $M^{-1}\cdot cm^{-1}$) for R = bridging CH_2 in methanol at 25.0 °C. The ligand-substitution reactions of *trans*-[(R)Co(LNHpy)-(HLNHpy)]$^+$ occurrs by displacement of the axial 2-pyridylethyl ligand, which is located *trans* to the alkyl group, by cyanide. Good isosbestic points at 361 and 328 nm for R = Me, at 364 nm for R = CF_3CH_2, and at 362 and 398 nm for R = bridging CH_2, were obtained upon mixing the complex with cyanide. The UV/Vis spectra of the products show a band at 450 nm (274 $M^{-1}\cdot cm^{-1}$) with a shoulder at 340 nm (554 $M^{-1}\cdot cm^{-1}$) for R = Me, one band at 452 nm (132 $M^{-1}\cdot cm^{-1}$) for R = CF_3CH_2, and one band at 476 nm (233 $M^{-1}\cdot cm^{-1}$) with a shoulder at 372 nm (692 $M^{-1}\cdot cm^{-1}$) for R = bridging CH_2.

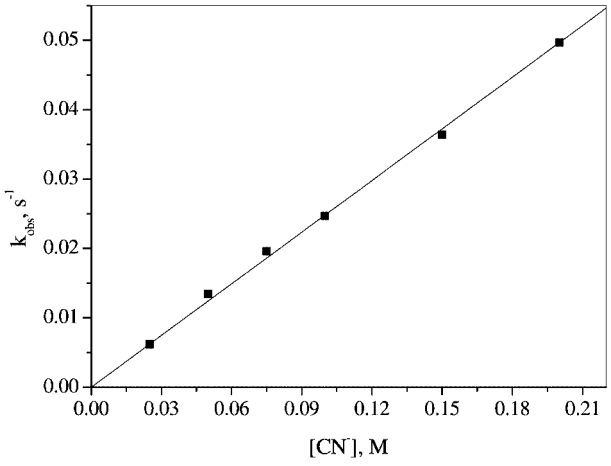

Figure 4. Plot of k_{obs} versus [CN^-] for the reaction of *trans*-[(Me)Co(LNHpy)(HLNHpy)]$^+$ with cyanide in methanol; experimental conditions: [Co^{III}] = $2.5\cdot10^{-4}$ M, I = 0.5 M, T = 25.0 °C

Figures 4, 5, and 6 report plots of k_{obs} versus [CN^-] for the reaction of *trans*-[(R)Co(LNHpy)(HLNHpy)]$^+$ with cyanide (0.025−0.20 M) at I = 0.5 M (CF_3SO_3Li) in methanol at 25.0 °C. The linear plots have negligible intercepts, indicating that the back reaction does not contribute significantly and that no parallel reaction takes place. The second-order rate constants for the substitution of 2-pyridylethyl by CN^- were found to be 0.25±0.01, $(2.3\pm0.1)\cdot10^{-2}$, and $(1.6\pm0.1)\cdot10^{-2}$ $M^{-1}\cdot s^{-1}$ for R = Me, CH_2CF_3 and bridging CH_2, respectively, at 25.0 °C. This behaviour can be expressed by a rate law similar to that given in Equation (3).

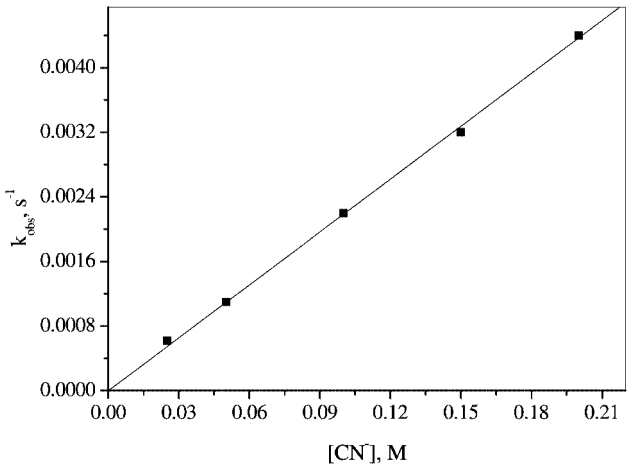

Figure 5. Plot of k_{obs} versus [CN^-] for the reaction of *trans*-[(CF_3CH_2)Co-(LNHpy)(HLNHpy)]$^+$ with cyanide in methanol; experimental conditions: [Co^{III}] = $1\cdot10^{-3}$ M, I = 0.5 M, T = 25.0 °C

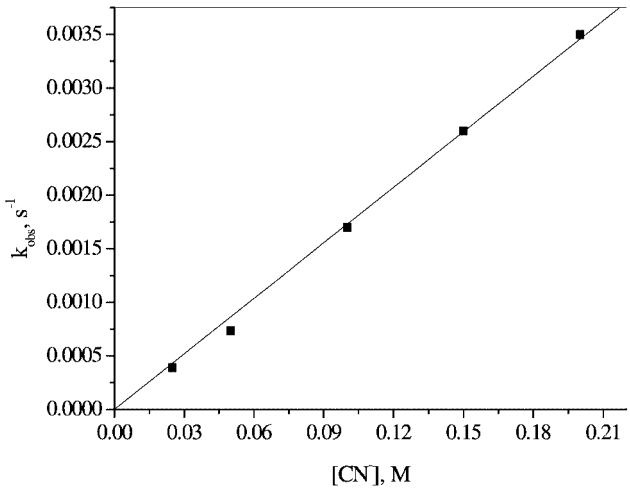

Figure 6. Plot of k_{obs} versus [CN^-] for the reaction of *trans*-[(CH_2)Co(LNHpy)(HLNHpy)]$^+$ with cyanide in methanol; experimental conditions: [Co^{III}] = $2.5\cdot10^{-3}$ M, I = 0.5 M, T = 25.0 °C

The reactions were studied as a function of temperature and pressure, for which the results are reported in Tables 1 and 2. Plots of lnk_a versus pressure gave good linear relationships as shown in Figure 3. The activation parameters ($\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, $\Delta V^{\ddagger}$) were found to be 86±4 kJ·mol^{-1}, +31±15 J·K^{-1}·mol^{-1}, and +4.3±0.2 cm^3·mol^{-1} for R = Me; 73±3 kJ·mol^{-1}, −33±10 J·K^{-1}·mol^{-1}, and +8.7±0.2 cm^3·mol^{-1} for R = CF_3CH_2; and 80±1 kJ·mol^{-1}, −13±3 J·K^{-1}·mol^{-1}, and +5.4±0.1 cm^3·mol^{-1} for R = bridging CH_2, respectively. Based on the reported rate and activation parameters, it is reasonable to suggest that ligand substitution in the complexes *trans*-[(R)Co(LNHpy)(HLNHpy)]$^+$ proceeds by a dissociative interchange (I_d) mechanism.

Overall Mechanistic Comparison

It is interesting to compare the structural and solution properties of complexes **1**−**3** with those of the corresponding alkylcobaloximes. It has been shown that in the latter

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

series, the $Co-N_{(axial)}$ distance increases with the σ-donor property of R. Thus, the order of increasing $Co-N_{(axial)}$ distance is: CF_3CH_2 (2.041 Å) < Me (2.068 Å) < Et (2.081 Å).[36] There is also a defined trend in the rate constant of the axial ligation for a given incoming base. In all the studied cases, it was found that the rate constants increase on increasing the σ-donor strength of the R alkyl group.[19−33,37] By way of example, some data for the axial ligation of a series of alkyl(aqua)cobaloximes by the neutral dimethoxyethylamine base are summarized in Table 3. These data show that the ground-state *trans* influence of a given R group parallels the kinetic *trans* effect of the same group, both effects being controlled by the electronic properties of R. Similarly to that observed in the alkylcobaloximes, it has been shown that the electronic properties of the R group affect the $Co-N_{(axial)}$ bond lengths and control the *trans* influence and *trans* effect in some other complexes with tetradentate chelating systems such as the alkyl derivatives[33,36] of the type $[RCo(DO)(DOH)pnH_2O]^+$ {where (DO)(DOH)pn = N^2,$N^{2\prime}$-propanediylbis(2,3-butanedione) 2-imine 3-oxime} and alkylrhodoximes.[38,39]

Table 3. Second-order rate constants for the reaction *trans*-$[(R)Co(DH)_2H_2O]$ + DEA → *trans*-$[(R)Co(DH)_2DEA]$ + H_2O

R[21]	σ*	*k* at 25 °C, $M^{-1}\cdot s^{-1}$
Et	−0.10	81±6
Me	0.00	5.1±0.2
CF_3CH_2	+0.99	$(2.7\pm0.1)\cdot10^{-2}$

Contrary to the cobaloximes, there is no definite trend in the observed $Co-N_{(axial)}$ distances along the series **1**−**3**. In this series the distances are 2.160(6), 2.158(5), and 2.168(5) Å for the CF_3CH_2, Me (mean value of two structurally independent molecules) and Et derivatives, respectively.[5] The difference in the $Co-N_{(axial)}$ distances between the Me and Et derivatives, although smaller than that found in the corresponding alkylcobaloximes, is in agreement with the donating properties of the R groups. However, a shorter $Co-N_{(axial)}$ distance with respect to that observed would be expected for **3**, due to the poorer donor ability of CF_3CH_2. This apparent anomaly can be explained on the basis of the structural features of complexes **1**−**3**, and of the different steric properties of the R groups considered. In particular, it is observed that the flexibility of the ethylene chain bearing the coordinated pyridyl group allows the axial pyridyl residue to rotate around the $Co-N_{(pyridyl)}$ bond. There is clear evidence that the orientation of the pyridyl moiety appreciably influences the length of the $Co-N_{(axial)}$ bond, so that by varying the R group, the trend in the *trans* influence is modified with respect to that expected on the basis of the donating properties of R.

These conformational changes have been observed not only in complexes **1**−**3**, but also in some other alkylcobalt chelates.[3,12,40,41] Hence the $Co-N_{(axial)}$ distances found in complexes **1**−**3** are a result of a compromise between the energies involved either in the torsion or in the stretching of the $Co-N_{(axial)}$ bond.[5] This leads to the conclusion that for compounds **1**−**3** any attempt to correlate the electronic properties of the R group with the ground state *trans* influence, has to be considered as of little use.

The second-order rate constants for substitution of 2-pyridylethyl by cyanide were found to be 19.1, 0.25, $2.2\cdot10^{-2}$, and $1.7\cdot10^{-2}$ $M^{-1}\cdot s^{-1}$ at 25 °C for the series of complexes *trans*-$[(R)Co(LNHpy)(HLNHpy)]^+$, where R = Et, Me, CF_3CH_2, and CH_2, respectively. It seems that this trend reflects the σ-donor properties of R. However, significant differences are observed in the transmission of effects of R when the series **1**−**3** are compared with the corresponding cobaloximes. A comparison of the rate constant ratios Et/Me and CF_3CH_2/Me for cobaloximes and for the series **1**−**3** can illustrate these differences. From the data for the second-order rate constants of complexes **1**−**3** and the data reported in Table 3, these ratios are 15.9 and $5.3\cdot10^{-3}$ for cobaloximes and 76.4 and $88.0\cdot10^{-3}$ for complexes **1**−**3**. From this it follows that in reference to the Me derivatives, the ligation rates in both Et and CF_3CH_2 derivatives are greatly enhanced in **2** and **3** with respect to the corresponding cobaloximes. By assuming that in the latter compounds the effect of R is mainly an electronic one, it can be deduced that steric effects play an important role in affecting the reaction rates also for **1**−**3**. Structural data show that, according to the bending angle (a) values,[42−45] bending away from the neutral base L between the two DH units is significantly smaller than that of the Schiff-base complexes and range between 0 and 3°; the bending angles in complexes **1**−**3**[5] range between 8 and 16°. This is probably due to the higher flexibility of the equatorial system in complexes **1**−**3** with respect to the $Co(DH)_2$ moiety. The increased level of flexibility in the latter compounds can be ascribed to the presence of only one O−H···O bridge (vs. two present in cobaloximes) and to the less-extensive electronic delocalization over the equatorial plane (two conjugated C=N bond vs. four conjugated C=N bond in cobaloximes). Based on the above argument it may be inferred that in approaching the transition state, the bending of the equatorial ligand toward the pyridyl group is permissible and that this contributes to the extension of the $Co-N_{(pyridyl)}$ bond. It is reasonable to expect that these steric effects will be more pronounced in complexes having relatively bulky R groups such as Et and CF_3CH_2.

The activation volume data reported in Table 2 suggest an increasing dissociative character of the ligand-substitution process on going along the series Me < CF_3CH_2 < Et. This order does not reflect the donating properties of R. As suggested above, this order has to be largely ascribed to steric effects. Probably in the case of the large value found for the Et derivative, both electronic and steric effects contribute. By way of comparison, we reported $\Delta V^{\ddagger}$ values for the ligation of cysteine to *trans*-$[(R)Co(DH)_2H_2O]$, where DH = dimethylglyoximate anion for R = CF_3CH_2, Ph, and CH_2Ph, of 0±1, +4.9±0.3, and +5.9±0.4 $cm^3\cdot mol^{-1}$, respectively.[46] The sequence CF_3CH_2 < Ph < CH_2Ph is as expected and corresponds to an increase in the dissociative character of the process with increasing donor properties of R.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The reaction of cyanide with different alkycobalamines (RCbl, where R = CF_3, CF_3CH_2, CF_2H, Me, and CH_2Br) was studied, and it was found that the nature of the alkyl group has a strong influence on the thermodynamic stability constants as well as the rate constants for the substitution reactions of the axial ligand *trans* to the alkyl group.[10] It was found that Co−N and Co−C bond lengths increase in the RCbl series in the order $H_2O < CN < CF_3 < CF_2H <$ Me < adenosyl.[47−50] The second-order rate constants for RCbl with CN^- were found to be 1.1 (25 °C), 217 (10 °C), 483 (5 °C), and $1{\cdot}10^3$ $M^{-1}{\cdot}s^{-1}$ (5 °C), for X= CN^-, CF_3, $NCCH_2$, and CF_2H, respectively.[18] The kinetic *trans* effect was found to decrease in the order *n*Pr ≥ adenosyl ≥ Me ≥ $CF_3CH_2 > CF_2H > NCCH_2 > CF_3 > CN^-$.

The relatively slow reaction rate of complex **4** is consistent with the short $Co-N_{(pyridyl)}$ bond[11] [2.118(3) Å], and the $\Delta V^{\ddagger}$ value suggests an $Co-N_{(pyridyl)}$ bond extension in the transition state similar to that of the Me derivative. Therefore, this complex exhibits no special kinetic properties. Perhaps the only relevant point is the presence of the $-CH_2-$ arm, which imparts a greater rigidity to the system, so that in this case the steric effects become less important.

On the basis of the activation parameters presented in Tables 1 and 2, it is reasonable to conclude that the ligand-substitution reactions of *trans*-$[(R)Co(LNHpy)(HLNHpy)]^+$ with cyanide, where R = Et, Me, CF_3CH_2, and bridging CH_2, follow a dissociative mechanism whose nature can vary from limiting dissociative to a dissociative interchange (I_d) mechanism, depending on the σ-donor and steric properties of the alkyl group, as discussed in detail above. It may be concluded, that the complexes studied here are more suitable than the cobaloximes to examine the influence of steric effects, which have up to now been disregarded in the study of model compounds for coenzyme B_{12}.

Experimental Section

Materials: All chemicals were of analytical reagent grade and used as received. Sodium cyanide was purchased from Merck and lithium trifluoromethanesulfonate from Aldrich. *trans*-$[(R)Co(LNHpy)(HLNHpy)]ClO_4$ (R = Me, Et, CF_3CH_2) were prepared by reduction of *trans*-$[Co(LNHpy)(HLNHpy)](ClO_4)_2$ by $NaBH_4$ and addition of alkyl iodide under nitrogen. The remaining complex *trans*-$[(CH_2)Co(LNHpy)(HLNHpy)]ClO_4$ was prepared by treating *trans*-$[(ClCH_2)Co(LNHpy)(HLNHpy)]ClO_4$ with NaOH. The complexes were characterised by elemental analysis and NMR spectroscopy, and the results were in agreement with those reported in the literatures.[5,11] All preparations and measurements were carried out in the dark since alkylcobaloximes are light-sensitive.

Instrumentation: UV/Vis spectra were recorded with Shimadzu UV-2101 and Hewlett Packard 8452A spectrophotometers. Kinetic measurements were carried out with the Shimadzu instrument. Measurements at elevated pressures (up to 150 MPa) were carried out using the Shimadzu spectrophotometer equipped with a home-made high-pressure unit for slow reactions,[51] and a high-pressure stopped-flow unit for fast reactions.[52] Kinetic data were analyzed with the OLIS KINFIT program. The standard deviations reported for the experimental data were estimated using the ORIGIN program. All instruments were thermostatted to the desired temperature (±0.1 °C). Kinetic measurements were carried out under pseudo-first-order conditions, i.e. the ligand concentration was in at least a 10-fold excess.

Cyclotetrapeptide Complexes of Nickel(II) and Palladium(II) by Template Synthesis from Dipeptide Esters with Functionalized Side Chains − Crystal Structure of [(*cyclo*-Gly-β-Ala-Gly-β-Ala-4H$^+$)Cu](PPN)$_2$[‡]

Jan Schapp,[a] Katharina Haas,[a] Karlheinz Sünkel,[a] and Wolfgang Beck*[a]

Dedicated to Professor Dieter Seebach on the occasion of his 65th birthday

Keywords: Peptides / Nickel / Palladium / Copper

The cyclocondensations of dipeptide esters [Gly-L-Asp(OMe)$_2$, Gly-L-Glu(OMe)$_2$, L-AspOMe-β-AlaOMe, β-Ala-L-Lys(ω-*N*-Boc,OMe), β-Ala-L-Orn(ω-*N*-Boc,OMe)] at nickel(II), palladium(II), and copper(II) templates give dianionic square-planar complexes of deprotonated cyclotetrapeptides that contain functional groups in the side chains. The complexes with 14- or 16-membered rings were isolated as [Ph$_3$PNPPh$_3$]$^+$ salts. Hydrolysis of {[*cyclo*-Gly-Asp(OMe)-Gly-Asp(OMe)-4H$^+$]Pd}$^{2-}$ affords the tetraanionic complex [{*cyclo*-Gly-Asp(O$^-$)-Gly-Asp(O$^-$)-4H$^+$}Pd]$^{4-}$(Li$^+$)$_2$(PNP$^+$)$_2$. The crystal structure of [(*cyclo*-Gly-β-Ala-Gly-β-Ala-4H$^+$)Cu](PPN)$_2$ is also reported.

Introduction

Biologically active natural cyclic tetrapeptides[2] are promising candidates for new anticancer agents.[3] Seebach et al. have pioneered studies on the synthesis, structure, and biological activity of *cyclo*-β-tetrapeptides.[2,4] Although some cyclotetrapeptides are difficult to synthesize,[2,4,5,6] our facile route from non-activated peptide esters on metal centres[7,8] involves the cyclocondensation of dipeptide esters at metal templates (Cu^{2+}, Ni^{2+}, Pd^{2+}) and requires neither a protecting nor an activating group or a coupling agent. Also, high dilution of the reaction mixture is not necessary. With half sandwich tripeptide ester ruthenium complexes cyclization to cyclotripeptides has been observed.[9] Current interest in the metal complexes of cyclic peptides includes the functionalization of biomolecules,[10] complexes with marine natural products,[11] their structure,[12] in "molecular engineering",[13] as selective ligands,[14] as models for metal enzymes,[8,11,12,15] and as precursors for polyazamacrocyclic complexes.[1,16] Cyclopeptide complexes may be suitable diagnostic and therapeutic tools.[17] For example, linear peptides have been cyclized using conventional methods and their metal complexes may find use for scintigraphy and radiotherapy.[18] These applications seem to require water-soluble complexes and, therefore, we aimed to synthesize cyclotetrapeptide complexes that contain functional groups in the ligands. Seebach and co-workers have reported a series of linear and cyclic β-oligopeptides with functionalized polar side chains derived from serine, aspartic and glutamic acids.[19] We also report here the crystal structure of [Cu(*cyclo*-Gly-β-Ala-Gly-β-Ala-4H$^+$)](PPN)$_2$.

Results and Discussion

1. Cyclotetrapeptide Complexes with Aspartic and Glutamic Acid Units

The hydrochlorides of dipeptide dimethyl esters from aspartic acid and glycine react with Na_2PdCl_4 and $NiCl_2$ in the presence of NaOMe to give the dianionic complexes **1** and **2**, which have been isolated as their PPN$^+$ salts (**1a**, **2**) [PPN$^+$ = bis(triphenylphosphoranylidene)ammonium] in good yields. Similarly, [Gly-L-Glu(OMe)$_2$] and Na_2PdCl_4 gave the cyclotetrapeptide complex **3**. The dipeptide of β-alanine and aspartic acid affords complexes **4** and **5**.

Condensation of [Gly-L-Asp(OMe)$_2$] and [L-Asp(OMe)-β-AlaOMe] at the metal centre could lead to either 12- or 14-membered chelate rings. The less strained C_2-symmetric 14-membered ring is probably formed; a 12-membered chelate from Gly-L-AlaOMe was obtained only in low yield.[7] Recently it was demonstrated that 13-membered cyclic tetrapeptides are easier to synthesize from linear tetrapeptides, and are more stable and conformationally more homogeneous, than are 14-membered rings, which have unfavorable strain.[20]

The ester groups of complex **1** were hydrolyzed to give the tetraanionic palladium complex in **6**. For possible use in diagnostics and radiotherapy [17,18] the water-soluble sodium salts **1b** and **7** were prepared by the addition of water to a mixture of H-Gly-Asp(OMe)$_2$, NaOMe, and metal salt. The structures of complexes **1b** and **7** were verified by 2D NMR techniques. In one preparation of **7** the sodium compound $Na(OH_2)_4[O_2CCH_2CHC(O)NHCH_2C(O)NH]_2$ was obtained, as a by-product containing the (3,6-dioxopiperazine-2-yl)acetate anion, from [Gly-L-Asp(OMe)$_2$] by cyclocondensation of the amino group of the glycine component and the α-CO_2Me group of the aspartic acid component in the dipeptide. This product was characterized by X-ray crystallography [21] after recrystallization from water.

The mass spectra (FAB) show peaks for [M^{2-} + H^+] (m/z = 475 (**1**), 427 (**2**), 455 (**4**), 503 (**3**, **5**). An ESI spectrum of **6** exhibits peaks, among others, at m/z = 447 [M^{4-} + $3H^+$], 984 [M^{4-} + PPN^+ + $2H^+$] and 453 [M^{4-} + Li^+ + $2H^+$].

In the IR spectra characteristic signals appear for the ester groups (**1**: 1735 cm^{-1}; **4**, **5**: 1725 cm^{-1}) and for the carboxylate group in **6** at 1677 and 1665 cm^{-1}.

Two amide I absorptions of **1**−**5** appear at 1590 and 1570 cm^{-1}.

The nickel complex **2** undergoes stepwise and selective hydroxylation at the α-carbon atom of the glycine units with oxygen in air.[8] This reaction is related to the copper enzyme peptidylglycine α-hydroxylating monooxygenase (PHM), which catalyzes the stereospecific hydroxylation of the α-C atom of the terminal glycine unit of a peptide.[22]

The ^{1}H NMR spectra (Tables 1 and 2) of compound **1** show only one signal for the two COOMe groups of the cyclotetrapeptide, while for **2**−**5** there are two singlets in a 1:1 ratio. Concomitantly, the glycine-containing complexes **2** and **3** show two AB sets for the glycine CH_2 protons, whereas **1**, and the hydrolyzed carboxylate derivatives **6** and **7**, have only one such set. Therefore compounds **1**, **6**, and **7** have a C_2 symmetry, while **2**−**5** have only C_1 symmetry, but for all compounds there exsists only one conformation of the cyclotetrapeptide unit. [Some weaker signals (< 10% intensities compared with the main signals) in all spectra indicate other, minor, cyclopeptide conformations.] Careful analysis of the AB parts of the glycine moieties of **1**−**3** and **6**, **7** (using the program WinDNMR) shows that the two CH_2 protons generally have quite different environments ($\Delta\delta > 0.20$ ppm), except for both glycine chelates in **3** and one in **2** (Table 1).

Table 1. ^{1}H NMR data (glycyl protons) of **1**−**3**, **6**, **7**

Compound	δ ($H_{A/B}$) [ppm]	J_{AB} [Hz]	Δδ (H_A/H_B)
1a	4.085/ 3.837	−19	0.248
2	3.725/ 3.477	−19	0.248
	3.588/ 3.534	−19	0.054
3	3.961/ 3.873	−19	0.088
	3.890/ 3.741	−19	0.149
6	4.120/ 3.863	−18	0.257
7	4.052/ 3.835	−18	0.217

Table 2. ^{1}H NMR data (aspartyl protons) of **1**, **2**, **6**, **7**

Compound	δ (H_A)	δ (H_B)	δ (H_X)	J_{AB}	J_{AX}	J_{BX}
1a	2.692	2.528	4.427	−15.7	4.7	4.6
2	2.696	2.639	4.014	−14	6	6
	2.454	2.489	4.122	−16.3	6	3
6	2.730	2.507	4.359	−15	4	4
7	2.673	2.692	4.136	−17	10.3	1.7

The ^{13}C NMR spectra of all compounds confirm the given interpretations, although good-quality spectra could not always be obtained.

2. Cyclopeptide Complexes with Lysine and Ornithine Units

The dipeptide esters β-Ala-L-Lys(ω-NBoc)OMe and β-Ala-L-Orn(ω-NBoc)OMe afforded, with Na_2PdCl_4 or $NiCl_2$, compounds **8**−**10**. Treatment of **9** with a solution of hydrogen chloride in methanol furnished the free cyclopeptide **11**, which was easily separated due to its low solubility in methanol. Finally, the Boc protecting group can be cleaved by trifluoroacetic acid.

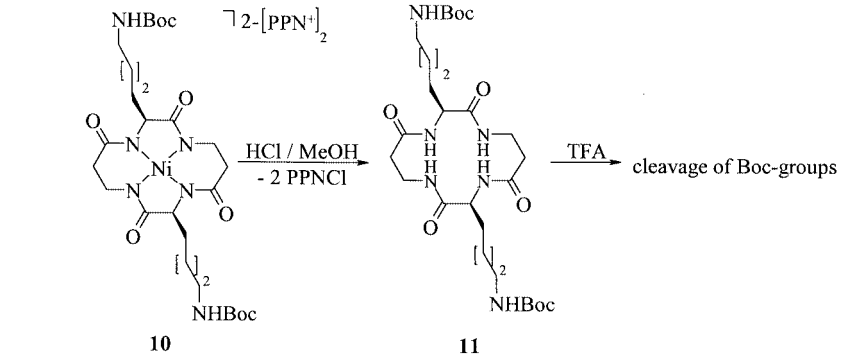
3. Crystal and Molecular Structure of [(*cyclo*-Gly-β-Ala-Gly-β-Ala-4H$^+$)Cu(PPN)$_2$ (12)

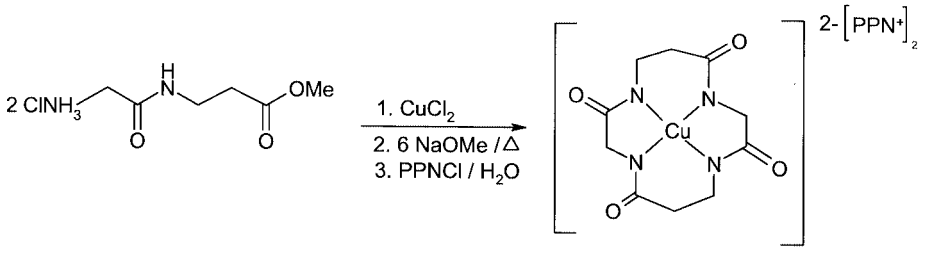
The crystal structure of the palladium complex [Pd(*cyclo*-Gly-β-Ala-Gly-β-Ala-4H$^+$)](PPN)$_2$ has been reported.[7] Crystals of the copper complex **12**, formed from Gly-β-Ala-OMe at the Cu^{2+} ion,[7] were obtained from acetonitrile solution, but as they quickly became opaque when taken out of the mother liquor the structure was determined at 266 K. Even so, the crystals decayed slowly, approximately 12% over the course of the measurement. The structure refinement yielded an average composition of the crystal as **12**·MeOH·2MeCN·6H_2O, with the methanol solvent disordered over two positions and two of the water molecules disordered over three positions.

The program VOID revealed that without the solvents the crystal structure contains large voids, making up for nearly 25% of the cell volume. The structure can be described as a sheet structure with alternating cation and anion layers parallel to the *ab* plane. Within the anion sheets, the anions are connected to a one-dimensional polymer in the (0 1 0) direction via a complex system of hydrogen bonds involving the amide oxygens and the water and methanol OH functions. A side view of the undulating sheets thus formed is given in Figure 1. The acetonitrile molecules are situated between the PPN cations, with their molecular axes almost parallel to the *z*-direction and their methyl groups pointing towards the neighbouring anion layers, excluding any hydrogen bond interactions of the nitrile nitrogens with the anion H-bond system.

The molecular structure (Figure 2) requires only a few comments on the complex anion. Due to crystal decomposition and other common difficulties in describing structures containing so many water molecules, the geometrical parameters have rather high standard deviations. Nonetheless, the copper ion clearly has a square-planar coordination with the four deprotonated amide nitrogens [the σ(plane)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim





12

parameter is 0.123 Å, with Cu1 0.032(6) Å out of that plane]. There are no further ligands attached to the copper, and no intermolecular contacts within 4.0 Å of the copper. The average copper−nitrogen distance of 1.928 Å is normal for a deprotonated amide nitrogen, and the long C−O and short C−N distances of the amide group suggest a strong contribution of the O−C=N form. Table 3 gives the important geometrical parameters of **12** along with those of other copper complexes of 1,4,8,11-tetraazacyclotetradecanes with 0, 1, and 2 oxo groups in the ligand backbone and the corresponding parameters of the Pd^{II} analogue of **12**.[7]

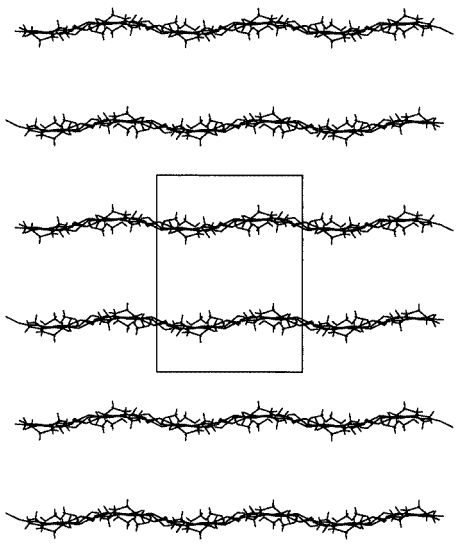


Figure 1. Packing of the anion sheets in the crystal of **12**

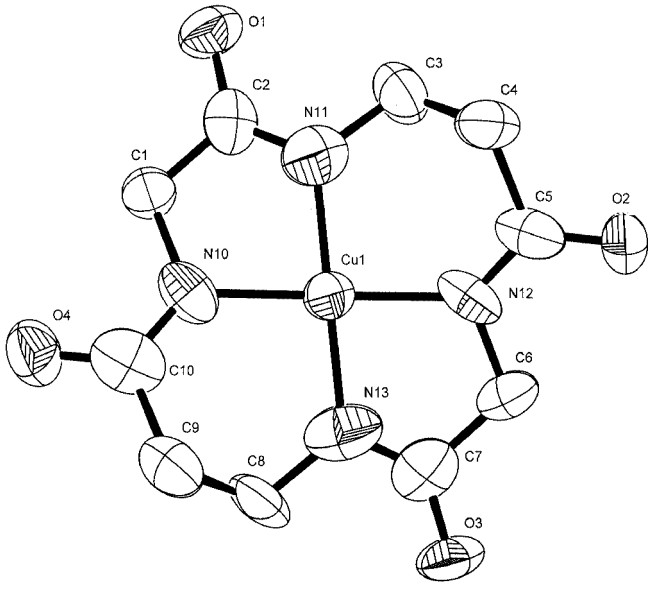

Figure 2. Molecular structures of the dianion of **12** in the crystal

Conclusion

Cyclotetrapeptides containing functional groups are accessible from the corresponding dipeptide esters by template synthesis at nickel(II) and palladium(II) centres. This is a very facile method in comparison to conventional procedures.

Experimental Section

General Method for the Preparation of 1−10 (except for 1b, 6, 7): A methanolic sodium methoxide solution (6 mmol) was added dropwise to a mixture of the dipeptide ester hydrochloride (2 mmol) and metal salt (Na_2PdCl_4 or $NiCl_2{\cdot}6H_2O$, 1 mmol) dissolved in methanol (40 mL). The resultant solution was then heated to 65 °C for 24 h, after which [PPN]Cl (2 mmol) was added. Upon addition of water, the products **1−9** were obtained as crystalline solids.

{*cyclo*-[(Gly-L-Asp(OMe)-Gly-L-Asp(OMe)-4H$^+$]Pd}(PPN)$_2$ (1a): Colorless crystalline needles, yield: 1004 mg (58%). $C_{86}H_{76}N_6O_8P_4Pd{\cdot}10H_2O$ (1730.42): calcd. C 59.64, H 6.47, N 4.85; found C 59.61, H 5.54, N 4.76. ^{1}H NMR (CD_3OD, 400 MHz, ppm): δ = 3.634 (OCH_3). ^{13}C NMR (CD_3OD, 100 MHz, ppm): δ = 44.0, 52.4, 55.7, 57.9, 170.8, 174.3, 181.0. MS (FAB−): *m*/*z* = 475 [M^{2-} + H^+], 1012 [M^{2-} + PPN^+], 415 [M^{2-} + H^+ − ($HCOOCH_3$)]. IR (KBr): ν(OH) 3436 vs (H_2O), ν(C=O) 1735 s (COOMe), 1578vs, 1557 vs (amide-I).

{*cyclo*-[(Gly-L-Asp(OMe)-Gly-L-Asp(OMe)-4H$^+$]Pd}Na$_2$ (1b): A solution of NaOMe (6 mmol) in methanol (1.5 mL) was added dropwise to a solution of H-Gly-Asp(OMe)$_2$ (508 mg, 2 mmol) and Na_2PdCl_4 (284 mg, 0.97 mmol) in methanol (40 mL) − whereby the light yellow solution became colorless. The reaction mixture was then boiled under reflux for 48 h (60 °C). After removal of the solvent in vacuo the residue was dissolved in water (5 mL) and purified by HPLC (stationary C-18 reversed phase, mobile phase 100% of water). Colorless needles, yield: 402 mg (66%). $C_{14}H_{16}N_4Na_2O_8Pd{\cdot}6H_2O$ (628.52): calcd. C 26.73, H 4.46, N 8.91; found C 26.38, H 4.33, N 8.83. IR (KBr, cm^{-1}): ν(OH) 3436 vs (H_2O), ν(C=O), 1726 s (COOMe), 1598 vs, 1552 vs (amide-I). ^{1}H NMR (CD_3OD, 400 MHz, ppm): δ = 3.694 (OCH_3). ^{13}C NMR (100 MHz, CD_3OD, ppm): δ = 43.1, 52.6, 55.8, 57.7, 171.1, 174.7, 181.4. MS (FAB−/mNBA): *m*/*z* = 475 [M^{2-} + H^+], 497 [M^{2-} + Na^+].

{*cyclo*-[Gly-L-Asp(OMe)-Gly-L-Asp(OMe)-4H$^+$]Ni}(PPN)$_2$ (2): Yellow crystalline needles, yield: 950 mg (59%). $C_{86}H_{76}N_6NiO_8P_4{\cdot}6H_2O$ (1610.71): calcd. C 64.07, H 5.46, N 5.22; found C 63.91, H 5.49, N 5.15. ICP-AES (Ni, 231.60) calcd. Ni 3.64; Ni 4.16. ^{1}H NMR (CD_3OD; 400 MHz, ppm): δ = 3.667, 3.663 (OCH_3). ^{13}C NMR (CD_3OD, 100 MHz, ppm): δ = 38.7, 42.1, 52.0, 52.4, 53.0, 54.5, 57.5, 61.3, 171.7, 173.4, 174.7, 178.9; 180.1, 181.9. MS (FAB−): *m*/*z* = 427 [M^{2-} + H^+], 964 [M^{2-} + PPN^+], 367 [M^{2-} + H^+ − (HCOOMe)]. IR (KBr, cm^{-1}): ν(OH) 3428 vs (H_2O), ν(C=O) 1730s (COOMe), 1592 vs, 1581 vs, 1567 vs (amide-I).

{*cyclo*-[Gly-L-Glu(OMe)-Gly-L-Glu(OMe)-4H$^+$]Pd}(PPN)$_2$ (3): Colorless crystalline needles, yield: 1073 mg (61%). $C_{88}H_{80}N_6O_8P_4Pd{\cdot}10H_2O$ (1758.42): calcd. C 60.05, H 5.69, N 4.78; found C 60.18, H 5.69, N 4.74. ICP-AES (Pd, 340.46) calcd. Pd 6.05; Pd 6.24. ^{1}H NMR (CD_3OD, 400 MHz, ppm): δ = 3.613, 3.597 (OCH_3); δ (glutamyl res.) = 4.14 m/4.04 m (2 × H_X), 2.64 m/2.47 m/ 2.30 m/ 2.14 m/ 2.00 m/ 1.86 m (2 × H_{ABCD}). ^{13}C NMR (CD_3OD, 100 MHz, ppm): δ = 28.0, 30.0, 31.5, 34.3, 51.8, 51.9, 53.1, 59.4, 60.9, 65.3, 175.9, 176.4, 179.3, 179.8, 181.6, 184.4. MS (FAB−): *m*/*z* = 503 [M^{2-} + H^+], 443 [M^{2-} + H^+ − HCOOMe]. IR (KBr, cm^{-1}): ν(OH) 3436 vs (H_2O), ν(C=O) 1726 s (COOMe), 1590 vs, 1568 vs, 1557 vs (amide-I).

{*cyclo*-[Gly-L-Asp-Gly-L-Asp-6H$^+$]Pd}Li$_2$(PPN)$_2$ (6): A mixture of **1a** (173 mg, 0.1 mmol) and LiOH (10 mg, 0.4 mmol) were dissolved in CH_3CN (10 mL). After the addition of H_2O (2 mL) the mixture was heated to 65 °C for 24 h. Colorless crystalline needles of **6** were then obtained following the addition of water. Yield: 115 mg (67%). $C_{84}H_{70}Li_2N_4O_8PdP_4 \cdot 10H_2O$ (1714.42): MS (ESI−): *m*/*z* = 447 [$M^{4-} + 3H^+$], 453 [$M^{4-} + Li^+ + 2H^+$], 984 [$M^{4-} + PPN^+ + 2H^+$], 1074 [$M^{4-} + PPN^+ + 5\ H_2O + 2H^+$], 1521 [$M^{4-} + 2\ PPN^+ + H^+$], 1611 [$M^{4-} + 5\ H_2O + 2\ PPN^+ + H^+$], 1701 [$M^{4-} + 10\ H_2O + 2\ PPN^+ + H^+$]. IR (KBr, cm^{-1}): ν(OH) 3377 vs (H_2O), ν(C=O) 1677 s, 1665 s (COOLi), 1570 vs (amide-I), 1438 s, 1415 cm^{-1} (COOLi).

{*cyclo*-[Gly-L-Asp-Gly-L-Asp-4H$^+$]Ni}Na$_2$ (7): A solution of NaOMe (6 mmol) in methanol (1.5 mL) was added dropwise to a solution of H-Gly-Asp(OMe)$_2$ (508 mg, 2 mmol) and $NiCl_2 \cdot 6H_2O$ (238 mg, 1 mmol) in methanol (40 mL), whereupon the light yellow solution became colorless. The reaction mixture was then boiled under reflux (60 °C) for 48 h. After removal of the solvent the residue was dissolved in water (5 mL) and purified by HPLC (stationary C-18 reversed phase, mobile phase 100% of water). Yellow needles, yield: 287 mg (60%). $C_{12}H_{12}N_4Na_2NiO_8 \cdot 2H_2O$ (478.69): calcd. C 30.08, H 3.34, N 11.70; found C 30.56, H 4.21, N 11.20. IR (KBr): ν(OH) 3429 vs (H_2O), ν(C=O), 1687 s, 1661 s (COOH), 1597 vs (amide-I), 1463 s, 1421 cm^{-1} (COOH). ^{13}C NMR (CD_3OD, 67 MHz, ppm): δ = 41.5, 45.6, 54.2, 168.6, 171.1, 177.3. MS (ESI−): *m*/*z* = 365 [$M^{2-} - 2CO_2 + 2H_2O + H^+$].

{*cyclo*-[β-Ala-L-Orn(ω-NHBoc)-β-Ala-L-Orn(ω-NHBoc)-4H$^+$]Pd}-(PPN)$_2$ (8): MS (FAB−): *m*/*z* = 673 [$M^{2-} + H^+$], 691 [$M^{2-} + H^+ + H_2O$], 709 [$M^{2-} + H^+ + 2H_2O$], 1097 [$M^{2-} + PPN^+ - 2\cdot(CH_3)_3C$].

{*cyclo*-[β-Ala-L-Lys(ω-NHBoc)-β-Ala-L-Lys(ω-NHBoc)-4H$^+$]Pd}-(PPN)$_2$ (9): Colorless powder, yield: 1150 mg (61%). $C_{100}H_{106}N_8O_8P_4Pd \cdot 6H_2O$ (1884.42): calcd. C 63.68, H 6.26, N 5.94; found C 63.26, H 6.09, N 6.17. MS (FAB−): *m*/*z* = 701 [$M^{2-} + H^+$]. IR (KBr): ν(OH) 3414 vs (H_2O), ν(C=O) 1699 s (amide-I), 1588 vs (amide-I), 1567 vs (amide-I), 1548 vs (amide-I), ν(NH) 1628 s (amide-II).

{*cyclo*-[β-Ala-L-Lys(ω-NHBoc)-β-Ala-L-Lys(ω-NHBoc)-4H$^+$]Ni}-(PPN)$_2$ (10): Yellow powder, yield: 1131 mg (62%). $C_{100}H_{106}N_8NiO_8P_4 \cdot 3CH_3OH$ (1824.72): calcd. C 65.76, H 5.81, N 6.13; found C 68.70, H 6.13, N 5.13. ^{13}C NMR (CD_3OD, ppm): δ = 20.0, 28.6, 30.7, 26.0, 36.8, 37.5, 38.8, 61.5, 155.5, 172.1, 178.5. MS (FAB−): *m*/*z* = 653 [$M^{2-} + H^+$].

***cyclo*-[β-Ala-L-Lys(ω-NHBoc)-β-Ala-L-Lys(ω-NHBoc)] (11):** Colorless powder, yield: 270 mg (90%). $C_{28}H_{50}N_6O_8$ (598.74): calcd. C 56.12, H 8.35, N 14.03; found C 55.77, H 8.43, N 13.94. MS (FAB+): *m*/*z* = 600 [$M + H^+$]; 500 [$M + 2H^+ - (COO\mathit{t}Bu^+)$], 400 [$M + 3H^+ - 2\cdot(COO\mathit{t}Bu^+)$]. IR (KBr, cm^{-1}): ν(OH) 3318 vs (H_2O), ν(C=O) 1689 s (amide-I), 1648 vs (amide-I), ν(NH) 1538 s (amide-II).

[*cyclo*-(Gly-β-Ala-Gly-β-Ala-4H$^+$)Cu](PPN)$_2$ (12): A solution of MeONa (6 mmol) in methanol was added dropwise to a mixture of Gly-β-AlaOMe·HCl (425 mg, 2 mmol) and $CuCl_2 \cdot 2H_2O$ (170 mg, 1 mmol) in methanol (40 mL), whereupon the initial green solution turned deep blue and NaCl was precipitated. The reaction mixture was then boiled under reflux for 24 h, filtered and the filtrate concentrated to 5 mL in vacuo. [Ph_3PNPPh_3]Cl (2 mmol) was then added. After the addition of water (100 mL), bronze-like plates of the cyclopeptide copper complexes were obtained, recrystallized from MeOH/H_2O, and dried in vacuo. Yield: 535 mg (37%). IR (KBr): $\tilde{\nu}$ = 1575, 1542 cm^{-1}. MS (FAB−, mNBA): *m*/*z* (%) = 316 (100) [$M^{2-} + H^+$], 853 (3) [$M^{2-}PPN^+$]. $C_{82}H_{72}CuN_6O_4P_4 \cdot 3H_2O$ (1447.0): calcd. C 68.00, H 5.39, N 5.81; found C 68.04, H 5.40, N 5.09.

Crystal Structure Determination of 12: An orange-brown block crystal was grown from acetonitrile solution and placed with a small amount of mother liquor inside a glass capillary that was sealed and transferred to a SYNTEX R3/Siemens P4 diffractometer equipped with a low-temperature measurement device, LT-1. The temperature was adjusted to −7 °C. As the LT-1 prevented the measurement of a psi-scan, no semi-empirical absorption correction could be applied. The data were processed with the Siemens XSCANS software, and the structure was solved with SHELXS-86 and refined with SHELXL-97.[23]

The refinement for the PPN cations and the complex anion as well as for the two acetonitrile and four of the water solvent molecules presented no difficulties, but that of the disordered methanol and two water molecules was less straightforward. The methanol was refined with a fixed C−O distance of 1.38 Å and common isotropic thermal parameters for each of the disordered carbon and oxygen positions and the sum of the s.o.f.s was fixed to 1.0. Three relatively weak peaks were found in the difference Fourier synthesis and assigned to the oxygen atoms of disordered water molecules. First, a common "reasonable" isotropic thermal parameter U of 0.09 was assigned to these atoms and the site occupancies were refined. This procedure led to approximate s.o.f.s of 0.7, 0.75 and 0.55, which were fixed afterwards on these values, since they added, reasonably, to an integer (2). With these fixed s.o.f.s the thermal parameters of the three oxygen atoms were refined freely isotropic. Geometrical analyses were performed with the program package WinGX v.1.64.04, the graphics were produced by the programs PLUTO and ORTEP3 for Windows, which are part of the WinGX suite.[24] CCDC-191607 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Long-Lived MLCT Excited States-Ru^{II} Complexes with a Helical Bis-Phen Ligand

Christine Goze,[a] Jean-Claude Chambron,[a][‡] Valérie Heitz,*[a] Didier Pomeranc,[a] Xavier J. Salom-Roig,[a] Jean-Pierre Sauvage,*[a] Angeles Farrán Morales,[b] and Francesco Barigelletti*[b]

Keywords: Luminescence / N ligands / Photochemistry / Ruthenium

The synthesis of a new Ru^{II} complex [Ru(**L$_1$**)(4,7-dpphen)]$^{2+}$, bearing a tetradentate bis-1,10-phenanthroline ligand **L$_1$**, is described. X-ray crystal structure analysis shows that the tetradentate ligand **L$_1$** coils around the metal and occupies both axial and two of the equatorial positions of the complex. ^{1}H NMR studies clearly indicate that the complex has C_2 symmetry in solution. The room temperature luminescence properties of [Ru(**L$_1$**)(4,7-dpphen)]$^{2+}$ have been studied, as have those of the related complex [Ru(**L$_2$**)(4,4′-dmbp)]$^{2+}$. For both complexes, the luminescence quantum yields and lifetimes are three to ten times higher than those of [Ru(bpy)$_3$]$^{2+}$. These unusual results are explained by the geometrical constraints imposed by the tetradentate ligands **L$_1$** and **L$_2$** in their respective complexes, resulting in an effective decoupling between the ^{3}MLCT and ^{3}MC excited states.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

[Ru(bipy)$_3$]$^{2+}$ (bipy = 2,2′-bipyridine) continues to be the most popular transition metal complex in the field of photochemistry and electron transfer.[1] A huge number of derivatives have been prepared and studied by numerous groups with the improvement of the photochemical properties of Ru-polypyridine complexes in mind, in view of their utilisation in, for instance, molecular photovoltaics and the chemical conversion of light energy.[2,3] In fact, the photochemical stability, the thermal stability of the reduced and oxidized states, the energy levels of the singlet and triplet MLCT states, the emission quantum yield, the ^{3}MLCT excited state lifetime, and the redox properties of the ground and excited states are important parameters that can, to a large extent, be controlled by the structural features of the chelates.[1,4] We now report that, through the use of tetradentate bis-1,10-phenanthroline ligands, which impose a helical geometry to the system in a strictly controlled fashion, the obtained ruthenium(II) complexes display unusually long-lived excited states. This behaviour is probably due to a cage-like effect for the employed tetradentate ligands rather than to electronic delocalisation in their frame systems.

Results and Discussion

The synthesis of [Ru**L$_1$**(4,7-dpphen)](PF$_6$)$_2$ is described in Figure 1 (4,7-dpphen represents 4,7-diphenyl-1,10-phenanthroline, as shown in Figure 2). This complex contains the 1,4-phenylenebis(7-bromo-1,10-phenanthroline) ligand **L$_1$**, which was synthesized from 7-*p*-bromophenyl-4-methyl-1,10-phenanthroline (**1**). At first, **1** was obtained through a Skraup reaction between 4-methyl-8-aminoquinoline[5,6] and *p*-bromophenyl β-chloroethyl ketone[7] in sulfuric acid in the presence of arsenic pentoxide, in 71% yield.[8] Subsequent treatment of **1** with LDA at −70 °C, followed by addition of α,α′-dibromo-*p*-xylene at −40 °C, afforded **L$_1$** in 7% yield, which is quite low in comparison with a similar reaction producing **L$_2$** in 88% yield.[5,6] This may be due to lower stability of the carbanion of **1**.

Coordination of ligand **L$_1$** on the ruthenium centre was achieved under high-dilution conditions in refluxing dichloroethane with use of [Ru(CH$_3$CN)$_4$Cl$_2$] as precursor complex, as described by von Zelewsky and co-workers.[9] The intermediate complex, [Ru**L$_1$**Cl$_2$], formed during the reaction, was treated directly with 4,7-dpphen in a refluxing mixture of water and ethanol. After anion exchange with an aqueous solution of KPF$_6$ and separation by column chromatography, the complex [Ru**L$_1$**(4,7-dpphen)](PF$_6$)$_2$

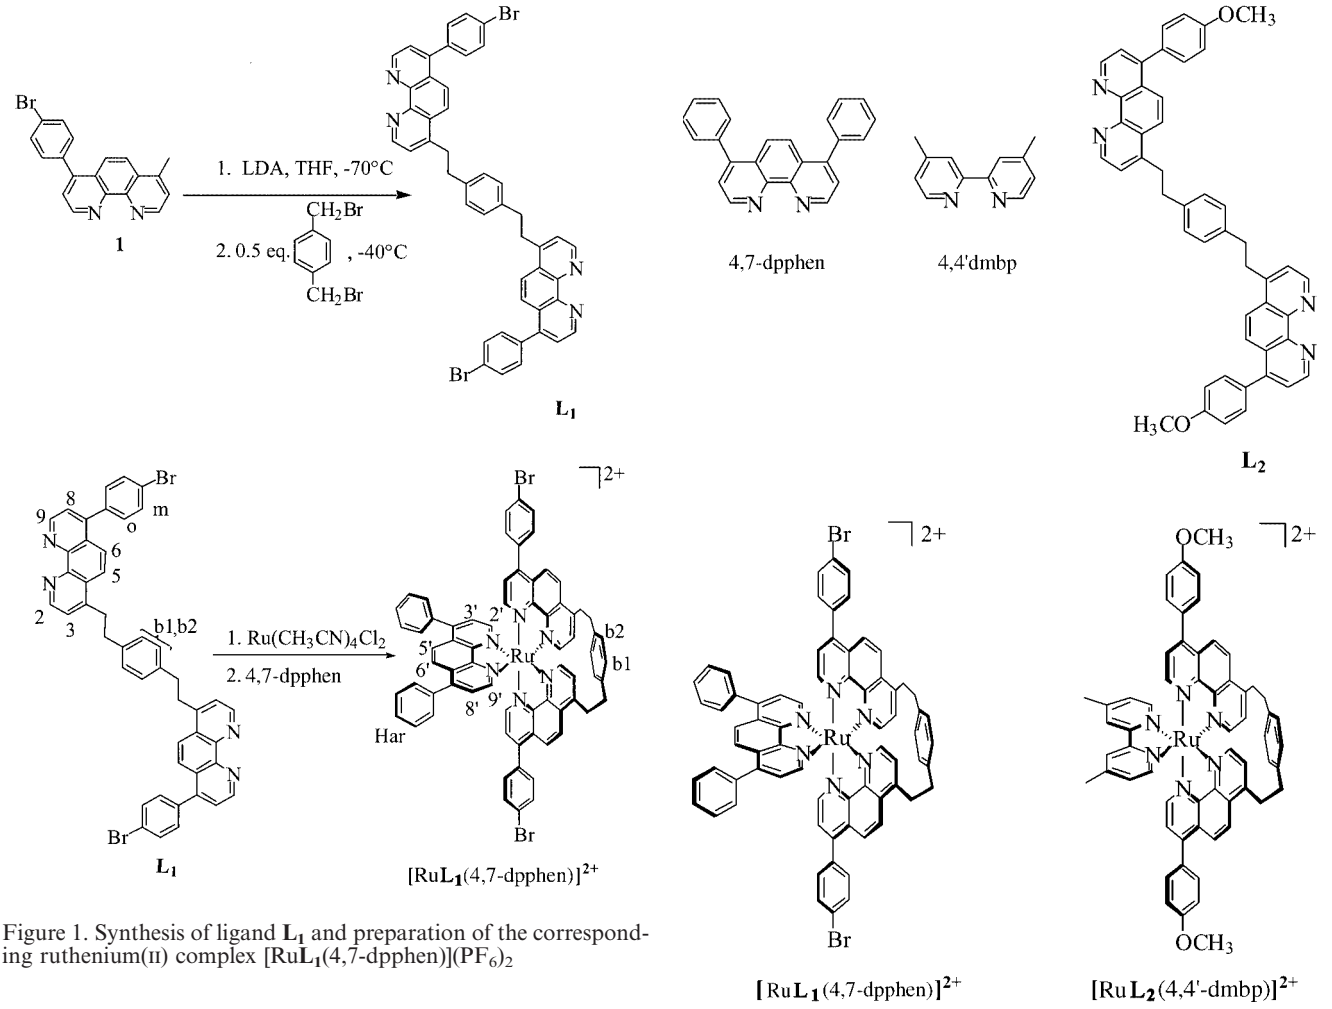

Figure 1. Synthesis of ligand $\mathbf{L_1}$ and preparation of the corresponding ruthenium(II) complex [Ru$\mathbf{L_1}$(4,7-dpphen)](PF$_6$)$_2$

Figure 2. Chemical formulae of the ligands and the complexes studied

was isolated in 44% yield. The C_2 symmetry of the complex in solution is clearly shown by analysis of its ^{1}H NMR spectrum (Figure 3). Protons H^2 and H^9 and protons H^{b1} and H^{b2} of ligand $\mathbf{L_1}$ are particularly sensitive to geometric and electronic changes on going from the free ligand $\mathbf{L_1}$ to the Ru-coordinated ligand $\mathbf{L_1}$ in [Ru$\mathbf{L_1}$(4,7-dpphen)](PF$_6$)$_2$, as shown in Figure 3. Protons H^{b1} and H^{b2}, homotopic in $\mathbf{L_1}$ (singlet at δ = 7.13 ppm), become diastereotopic in the C_2 symmetric complex [Ru$\mathbf{L_1}$(4,7-dpphen)](PF$_6$)$_2$, appearing as a pair of doublets [δ(H^{b1}) = 6.67 ppm, δ(H^{b2}) = 6.32 ppm]). In the non-coordinated ligand $\mathbf{L_1}$, protons H^2 and H^9 have low-field chemical shifts typical of protons located α to the nitrogen atom of a free 1,10-phenanthroline [δ(H^2) = 9.04 ppm and δ(H^9) = 9.19 ppm]. These protons are shifted upfield in the complex [δ(H^2) = 7.39 ppm and δ(H^9) = 7.99 ppm], since coiling of the ligand around the ruthenium centre places H^2 in the shielding field of the other phenanthroline of $\mathbf{L_1}$ and H^9 in that of the ancillary ligand 4,7-dpphen.

The X-ray crystal structure of the complex [Ru$\mathbf{L_1}$(4,7-dpphen)](PF$_6$)$_2$ was solved (Figure 4).[10] The complex crystallises in the monoclinic $P12/n1$ space group, with two molecules in the unit cell. The structure clearly shows that the axial and two equatorial positions are occupied by the nitrogen atoms of the ligand $\mathbf{L_1}$ and that the remaining equatorial positions are occupied by the 4,7-dpphen ligand. The Ru−N distances range between 2.057(9) Å and 2.076(9) Å. This structure is close to that of the complex [Ru$\mathbf{L_2}$(4,4′-dmbp)](PF$_6$)$_2$,[5] but with less distortion from linearity. The angle Br(1)−Ru−Br(2) is 174.6(9)°, as compared with 169.9(7)° for O−Ru−O. The distance Br(1)···Br(2) is 21.86(8) Å.

The synthesis of the ruthenium complex [Ru$\mathbf{L_2}$(4,4′-dmbp)](PF$_6$)$_2$ has been described previously.[5,6] This complex contains a bis-1,10-phenanthroline ligand $\mathbf{L_2}$, functionalized with a *p*-anisyl group on each position 7 of the phenanthroline unit (Figure 2), and differs from the former mainly in the nature of the ancillary ligand [4,4′-dimethyl-2,2′-bipyridine (4,4′-dmbp)].

Figure 5 shows the absorption spectra ($1\cdot10^{-5}$ M, acetonitrile) of the investigated complexes containing the tetradentate ligands $\mathbf{L_1}$ and $\mathbf{L_2}$; for purposes of comparison, the spectrum of [Ru(bpy)$_3$](PF$_6$)$_2$ is also shown.

For the [Ru$\mathbf{L_2}$(4,4′-dmbp)](PF$_6$)$_2$ and [Ru$\mathbf{L_1}$(4,7-dpphen)](PF$_6$)$_2$ complexes, the lowest-lying ^{1}MLCT band maxima fall at slightly lower energies − 458 and 460 nm, respectively − than that of the reference complex [Ru-

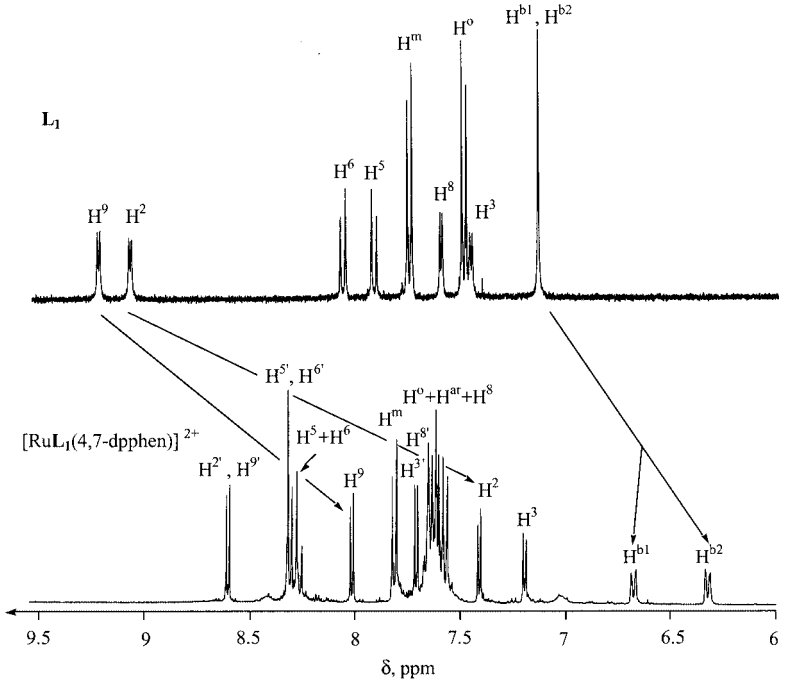

Figure 3. 400 MHz ^{1}H NMR spectra (low field region, CD_2Cl_2) of ligand $\mathbf{L_1}$ and complex [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$

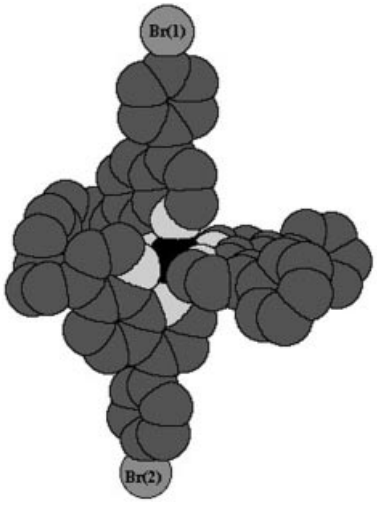

Figure 4. X-ray crystal structure of [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$

$(bpy)_3](PF_6)_2$ (452 nm). The absorption intensities at the MLCT band maxima are $\varepsilon = 20300$ and 20600 $M^{-1}\cdot cm^{-1}$, respectively, and hence about 40% higher than that of the reference complex ($\varepsilon = 14300$ $M^{-1}\cdot cm^{-1}$). This is an effect due to the "transfer term" for the promoted electron,[11−13] the average displacement of which during the MLCT transition is larger than that occurring in the case of $[Ru(bpy)_3]^{2+}$. The MLCT absorption features for [Ru$\mathbf{L_2}$(4,4′-dmbp)]$(PF_6)_2$ and [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$ thus suggest that the MLCT transitions in the visible region probably involve the extended frames of the $\mathbf{L_2}$ and $\mathbf{L_1}$ ligands, respectively {and also of the ligand 4,7-dpphen in the case of [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$}.

An observation of interest relates to the presence of intense absorption bands appearing at 310−320 nm for [Ru$\mathbf{L_2}$(4,4′-dmbp)]$(PF_6)_2$ and [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$, but not exhibited by $[Ru(bpy)_3](PF_6)_2$ (see Figure 5). This is a spectral region in which ^{1}MC (d-d) transitions are expected for Ru^{II}-polypyridine complexes.[1] This type of transition is Laporte-forbidden, and its extinction coefficient is estimated $\varepsilon \approx 10^2$ $M^{-1}\cdot cm^{-1}$ for $[Ru(bpy)_3]^{2+}$.[14] The fact that for [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$ and − even more so − for [Ru$\mathbf{L_2}$(4,4′-dmbp)]$(PF_6)_2$, the forbidden nature of the transition appears to be substantially lifted may be associated with permanent or transient distortions of the octahedral environment around the metal centre; the X-ray results (see above) are consistent with this interpretation. Finally, the absorption features in the 280−290 nm spectral portion are ^{1}LC in nature and are probably attributable to the ligand subunits directly coordinated to the metal centre,[1] as shown by the fact that their intensities are similar; see Figure 5.

Room temperature luminescence properties of [Ru$\mathbf{L_2}$(4,4′-dmbp)]$(PF_6)_2$ and [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$, obtained in degassed acetonitrile, are illustrated in Table 1; for purposes of comparison, luminescence results for $[Ru(bpy)_3](PF_6)_2$ are also listed.

The room temperature luminescence profiles (shown in the inset of Figure 5), the band peaks and the lifetime values are consistent with a ^{3}MLCT nature for the lowest-lying level of the investigated Ru-polypyridine luminophores. The band maxima of [Ru$\mathbf{L_2}$(4,4′-dmbp)]$(PF_6)_2$ and [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$ are slightly lower in energy than that of $[Ru(bpy)_3](PF_6)_2$, consistently with the absorption results. The relevant observation here is that, for the two complexes containing the tetradentate ligands $\mathbf{L_1}$ and $\mathbf{L_2}$, the lumi-

[a] $k_r = \varphi / \tau$. [b] $k_{nr} = (1 - \varphi)/\tau$.

nescence quantum yields (Φ) and lifetimes (τ) are three to ten times larger than those for [Ru(bpy)$_3$]$(PF_6)_2$. In these complexes, this happens because the non-radiative transitions (as quantified by the appropriate rate constant k_{nr}; see Table 1), known to govern the luminescence properties in the Ru-polypyridine complexes,[1,4] appear to be substantially depressed. Below we briefly discuss possible reasons for this behaviour.

With regard to the nature of the non-radiative processes deactivating the ^{3}MLCT luminescent level in Ru-polypyridine complexes, three main issues can be considered. These are: (i) the effect of the electronic delocalisation in the ligand system,[13,15,16] (ii) the effect of the energy gap law (regarding the direct ^{3}MLCT-to-GS transition),[17,18] and (iii) the thermal accessibility from the luminescent ^{3}MLCT level of a higher-lying ^{3}MC state, an effective doorway both to photochemistry (ligand release) and to fast, non-radiative deactivation (because of the strong ^{3}MC-GS coupling).[1] Given the extended ligand systems of $\mathbf{L_1}$ and $\mathbf{L_2}$, and also of 4,7-dpphen, we have addressed the role of electronic delocalisation, point (i), in detail. The extent of delocalisation is related to the displacement of the potential energy curve for the luminescent MLCT excited state with respect to the curve for the ground state (GS) (i.e., a high degree of delocalisation is accompanied by a small displacement). Analysis of the luminescence profiles affords the displacement parameter, the Huang−Rys electron-vibrational coupling constants pertinent to average frequencies (S_M) of ligand origin, $\hbar\omega_M = 1350$ cm^{-1}, corresponding to the vibrational progression exhibited by the low-temperature luminescence spectra.[15,16] The results of the vibronic analysis on the corrected luminescence profiles (on an energy scale, spectra obtained in frozen solvent at 77 K) are illustrated in Figure 6 and summarized in Table 2.

While for complexes containing highly delocalised ligand systems, such as dipyrido-phenazine,[19] pyrimidine-substituted terpyridine (tpy)[20] or back-to-back bis-tpy,[13] this type of vibronic analysis provides S_M values of between 0.2 and 0.5, for [Ru$\mathbf{L_2}$(4,4′-dmbp)]$(PF_6)_2$ and [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$ we find $S_M = 0.75$ and 0.78 (Table 2). These values are not greatly different from that for [Ru(bpy)$_3$]$(PF_6)_2$ ($S_M = 0.92$) taken as a prototype of a complex in which the ligand system is not greatly delocalised. The vibronic analysis does not therefore support delocalisation

	E_{00}, cm^{-1} [a]	S_M [b]
[Ru$\mathbf{L_2}$(4,4′-dmbp)]$(PF_6)_2$	16680	0.78
[Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$	16540	0.75
[Ru(bpy)$_3$]$(PF_6)_2$	17250	0.92

[a] Energy of the luminescent level (0−0 transition). [b] Huang−Rys factor for frequencies of ligand origin, $\hbar\omega_M$ = 1350 cm^{-1}.

in the ligands as a crucial factor for explaining the quite different luminescence features of [Ru$\mathbf{L_2}$(4,4′-dmbp)]$(PF_6)_2$ and [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$, in comparison with the case of [Ru(bpy)$_3$]$(PF_6)_2$. Effects related to point (ii) above (energy-gap law)[17,18] would also be expected to be of limited importance, given that the luminescent levels are not too apart from one another in energy (Table 2). In conclusion, we point to the fact that the tetradentate $\mathbf{L_1}$ and $\mathbf{L_2}$ ligands contain two bidentate subunits linked together. Literature examples exist in which constraints against elongation of the Ru−N bonds (inhibiting ligand release as a consequence of extreme elongation) can result in a sort of cage-like effect; this type of restrictions can originate from physical interactions, as found within zeolite frameworks, for instance,[21] or can be imposed at the molecular level by linking the coordinating bpy units together, thus yielding caged or hemi-caged complexes.[22] For the luminescent levels of both the [Ru$\mathbf{L_2}$(4,4′-dmbp)]$(PF_6)_2$ and the [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$ complexes, the reduced role of the non-radiative relaxation is probably related to such a cage-type effect, due to coordination of the tetradentate $\mathbf{L_1}$ and $\mathbf{L_2}$ ligands.

In conclusion, we have been able to show that the use of a bis-phen ligand, displaying geometrically constraining properties with respect to the coordination sphere of the complexed ruthenium(II) centre, produces effective decoupling between the ^{3}MLCT and the ^{3}MC excited states. This effect results in remarkably long-lived ^{3}MLCT excited states for the corresponding ruthenium(II)-tris(diimine) complexes.

Experimental Section

Materials: Starting materials were from commercial sources and were used as received. THF was distilled from sodium/benzophenone prior to use. Reactions performed under an atmosphere of argon used standard Schlenk techniques. [Ru$(CH_3CN)_4Cl_2$] was prepared according to the literature procedure.[9]

Physical Measurements: ^{1}H NMR: Bruker WP200SY (2OOMHz) and Bruker AM (400 MHz) instruments; the reported chemical shifts are referenced to Me_4Si as an internal standard. Mass spectroscopic data were obtained on a ZAB-HF (FAB) spectrometer with a nitrobenzyl alcohol matrix.

7-(*p*-Bromophenyl)-4-methyl-1,10-phenanthroline (1): A mixture of 4-methylquinolin-8-ylamine (1.5 g, 9.5 mmol), arsenic acid (5.65 g, 13.3 mmol), and phosphoric acid (15 mL) was heated at 100 °C. *p*-Bromophenyl-β-chloroethylketone[7] (3.28 g, 13.3 mmol) was added over a period of 1 h at such a rate that the temperature did not exceed 120 °C. After the addition the temperature was raised to 140 °C for 2 hours. After cooling, the mixture was poured onto ice and the resulting solution was neutralised with aqueous sodium hydroxide (30%), resulting in the precipitation of a brown solid. The mixture was left at 0 °C overnight. The precipitate was extracted several times with boiling toluene, the combined solutions were dried with $MgSO_4$, and the solvent was evaporated. The crude product was chromatographed on silica, eluted with hexane/ethyl acetate (50:50), with a gradient to ethyl acetate/methanol (99:1), yielding **1** as a pale brown solid (2.34 g, 71%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.78 (s, 3 H, CH_3), 7.42 (d, ^3J = 8.12 Hz, 2 H, H^m), 7.49 (d, ^3J = 4.42 Hz, 1 H, H^3), 7.53 (d, ^3J = 4.42 Hz, 1 H, H^8), 7.70 (d, ^3J = 8.12 Hz, 2 H, H^o), 7.86 (d, ^3J = 9.34 Hz, 1 H, H^5), 7.97 (d, ^3J = 9.36 Hz, 1 H, H^6), 9.07 (d, ^3J = 4.42 Hz, 1 H, H^2), 9.22 (d, ^3J = 4.42 Hz, 1 H, H^9) ppm. FAB-MS: *m*/*z* = 349.4 [M + H]$^+$.

$\mathbf{L_1}$: Diisopropylamine (0.162 mL, 1.15 mmol) was dissolved in THF (4 mL) under argon. *n*-Butyllithium (1.5 M, 0.764 mL) was added at 0 °C, and the mixture was stirred at 0 °C for 1 h. Compound **1** (400 mg, 1.15 mmol) was dissolved in THF (10 mL) under argon and transferred by cannula at −40 °C to the freshly prepared LDA solution. The solution instantly turned dark red and was stirred for 1 hour at −70 °C and for 1/2 h at −40 °C. α,α′-Dibromo-*p*-xylene (151.2 mg, 0.057 mmol) was dissolved in THF (5 mL) under argon and transferred to the reaction mixture at −40 °C by cannula. The mixture was stirred at room temperature overnight, during which the dark red solution turned pale brown. The solution was poured into water and extracted with dichloromethane. The combined organic phases were washed with ethanol in order to remove the oligomers and chromatographed on alumina, eluted with dichloromethane with a gradient to dichloromethane/methanol (98:2), to yield $\mathbf{L_1}$ as a brown solid (32 mg, 7%). ^{1}H

NMR (400 MHz, CD_2Cl_2): δ = 3.09 (m, 4 H, CH_2), 3.42 (m, 4 H, CH_2), 7.13 (s, 4 H, H^{b1}+H^{b2}), 7.44 (d, ^3J = 4.20 Hz, 2 H, H^3), 7.47 (d, ^3J = 8.25 Hz, 4 H, H^o), 7.58 (d, ^3J = 4.39 Hz, 2 H, H^8), 7.73 (d, ^3J = 8.22 Hz, 4 H, H^m), 7.90 (d, ^3J = 9.37 Hz, 2 H, H^5), 8.05 (d, ^3J = 9.43 Hz, 2 H, H^6), 9.04 (d, ^3J = 4.32 Hz, 2 H, H^2), 9.19 (d, ^3J = 4.35 Hz, 2 H, H^9) ppm. FAB MS: *m*/*z* = 801 [M + H]$^+$.

[RuL_1(4,7-dpphen)]$(PF_6)_2$: Compound $\mathbf{L_1}$ (50 mg, 0.062 mmol) was dissolved in 1,2-dichloroethane (15 mL) under argon. Freshly prepared [Ru$(CH_3CN)_4Cl_2$] (21 mg, 0.062 mmol) was dissolved in 1,2-dichloroethane (15 mL) under argon. The two solutions were simultaneously added dropwise to refluxing 1,2-dichloroethane (800 mL) at a rate of 5 mL/h. After completion of the addition, the dark violet mixture was heated at reflux for two more hours, and allowed to cool overnight. The solvent was evaporated, and the resulting dark violet solid was dissolved in a mixture of ethanol/water (8 mL/1 mL) under argon. 4,7-Diphenylphenanthroline (4,7-dpphen, 20.6 mg, 0.062 mmol) was then added, and the reaction mixture was heated for 4 h, during which the solution turned orange-red. After the mixture had cooled, the ethanol was evaporated and the product was precipitated with a saturated aqueous solution of potassium hexafluorophosphate. The resulting precipitate was filtered under vacuum and chromatographed on silica, eluting with a gradient of dichloromethane/methanol, from 100:0 to 90:10. The complex [Ru$\mathbf{L_1}$(4,7-dpphen)]$(PF_6)_2$ was obtained as an orange solid (41 mg, 44%). TLC: one spot, R_f = 0.62 (CH_2Cl_2/MeOH, 8:2). ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 3.11 (m, 2 H, CH_2), 3.28 (m, 2 H, CH_2), 3.42 (m, 2 H, CH_2), 3.94 (m, 2 H, CH_2), 6.32 (dd, ^3J = 7.95, ^4J = 1.6 Hz, 2 H, H^{b2}), 6.67 (dd, ^3J = 8.07, ^4J = 1.72 Hz, 2 H, H^{b1}), 7.18 (d, ^3J = 5.36 Hz, 2 H, H^3), 7.39 (d, ^3J = 5.4 Hz, 2 H, H^2), 7.55 (d, ^3J = 8.52 Hz, 4 H, H^o), 7.59 (d, ^3J = 5.5 Hz, 2 H, H^8), 7.61 (m, 10 H, H^{ar}), 7.68 (d, ^3J = 5.52 Hz, 2 H, $H^{3',8'}$), 7.79 (d, ^3J = 8.52 Hz, 4 H, H^m), 7.99 (d, ^3J = 5.4 Hz, 2 H, H^9), 8.24 (d, ^3J = 9.32 Hz, 2 H, H^5), 8.28 (d, ^3J = 9.2 Hz, 2 H, H^6), 8.29 (s, 2 H, $H^{5',6'}$), 8.57 (d, ^3J = 5.52 Hz, 2 H, $H^{2',9'}$) ppm. FAB MS: *m*/*z* = 1379.1 [M − PF_6^-]$^+$, 1234.2 [M − 2PF_6^- + e$^-$]$^+$, 617.6 [M − 2PF_6^-]$^{2+}$/2.

Optical Spectroscopy: Absorption spectra were recorded with a Perkin−Elmer Lambda 9 spectrophotometer in dilute (10^{-5} M) acetonitrile solutions. Luminescence experiments were performed in pump-freeze-thaw degassed acetonitrile at room temperature and at 77 K (liquid nitrogen temperature, samples were in capillary tubes immersed in a quartz finger Dewar).

Luminescence spectra were obtained with a Spex Fluorolog II spectrofluorimeter equipped with a Hamamatsu R928 phototube. Uncorrected luminescence band maxima are used throughout the text unless otherwise stated; in order to determine luminescence quantum yields and to perform the vibronic analyses (see below) of luminescence intensity profiles, we employed corrected luminescence spectra on an energy scale (cm^{-1}). The corrected spectra were obtained either by use of a correction curve provided by the supplier or by employment of a calibrated 45-W quartz-halogen tungsten filament lamp (Optronic Laboratories) as a standard for the correction of the phototube response. Luminescence quantum yields Φ_s were obtained according to Equation (1),[23] where *s* and *r* stand for sample and reference standard, respectively, A is the absorbance (taken ≤ 0.1) at the selected excitation wavelength, and n is the refractive index of the solvent. [Ru$(bpy)_3$]Cl_2 was chosen as a reference standard ($\Phi = 2.8\cdot10^{-2}$ in air-equilibrated water).[24] The experimental uncertainty in the band maximum for absorption and luminescence spectra is 2 nm; that for luminescence quantum yield is 20%. Luminescence lifetimes were obtained with an IBH single-photon-counting apparatus (N_2 lamp, excitation at 337 nm). The uncertainty in the evaluated lifetimes is 8%.

$$\frac{\Phi_s}{\Phi_r} = \frac{A_r n_s^2 (area)_s}{A_s n_r^2 (area)_r} \quad (1)$$

Vibronic band intensities of the luminescence spectra on an energy scale (cm^{-1}) were analysed according to a fitting procedure proposed by Meyer and co-workers.[25,26] For the luminescence spectra obtained at 77 K we used a two-mode analysis according to the following expression [Equation (2)]:

$$I(\bar{\nu}) = \sum_{v_M=0}^{\infty}\sum_{v_L=0}^{\infty}\left(\frac{\bar{\nu}_{00} - v_M\bar{\nu} - v_L\bar{\nu}}{\bar{\nu}_{00}}\right)^3\left(\frac{S_M^{v_M}}{v_M!}\right)\times \left(\frac{S_L^{v_L}}{v_M!}\right)\exp\left[-(4\ln 2)\left(\frac{\bar{\nu} - \bar{\nu}_{00} - v_M\bar{\nu} - v_L\bar{\nu}}{\bar{\nu}_{1/2}}\right)^2\right] \quad (2)$$

where $I(\bar{\nu})$ is the luminescence intensity profile, $\bar{\nu}_\infty$ is the energy of the 0−0 transition (hereafter indicated as E_∞), *v* are vibrational quantum numbers, *M* and *L* are labels for average and low frequency modes, taken as $\hbar\omega_M$ = 1350 cm^{-1} and $\hbar\omega_M$ = 400 cm^{-1}, respectively, S_M and S_L are displacement parameters along the indicated vibrational modes, and $\bar{\nu}_{1/2}$ is the bandwidth at half maximum (fwhm) of the vibronic line.

Acknowledgments

$P_8O_{12}\cdot 2BH_3$ – The Borane Adduct of a New Molecular Phosphorus Oxide

Akbar Tellenbach,[a] and M. Jansen*[a]

Keywords: Phosphorus / Phosphorus oxides / Boranes / Cage compounds / Dimerization

$P_4O_6\cdot BH_3$, which readily forms from P_4O_6 and $Me_2S\cdot BH_3$ in a stoichiometric reaction, dimerizes spontaneously at –30 °C in a concentrated toluene solution resulting in the crystallization of $P_8O_{12}\cdot 2BH_3$ (**1**). The synthesis of **1** represents the first selective interconnection of molecular phosphorus chalcogenides leading to the formation of a new, flexible P_8O_{12} cage. The thermodynamic driving force for the dimerization reaction results from a gain of enthalpy due to enhanced P–O double-bond contributions and a relief of angular strain. In terms of kinetics, the behavior of $P_4O_6\cdot BH_3$, differing from that of other P_4O_6 derivatives, is caused by the low π-donor ability of BH_3 provoking a Michaelis–Arbuzov-like reactivity at the adjacent phosphorus atom and thus inducing cage opening. **1** was characterized by means of X-ray diffractometry (powder, single crystal), NMR spectroscopy (solution, solid), IR spectroscopy, Raman spectroscopy, and mass spectrometry. Mass spectrometric investigations suggest considerable BH_3 abstraction as well as an enhanced stability of $P_8O_{12}\cdot BH_3$ and P_8O_{12}, compared to **1**.

Introduction

The chemical behavior of P_4O_6, a molecular phosphorus oxide having an adamantane-like birdcage structure, seems to be rather ambivalent. On the one hand P_4O_6 reacts readily with electrophilic compounds resulting in the attachment of terminal atoms or groups to phosphorus atoms of the cage. The electrophilic addition gives rise to the formation of chalcogen derivatives P_4O_n ($n = 7-10$),[1−6] $P_4O_6S_n$ ($n = 1-4$),[7−10] $P_4O_6Se_n$ ($n = 1-4$),[11−14] and transition metal complexes like $P_4O_6[Ni(CO)_3]_n$ ($n = 1-4$),[15,16] $P_4O_6[Fe(CO)_4]_n$ ($n = 1-4$),[17,18] and $P_4O_6[M(CO)_5]$ (M = Cr, Mo, W).[19] On the other hand, ring-opening reactions are much more difficult to control and normally lead to complete degradation of the framework.[20−22] Among the few selective cage-opening reactions, known so far, there is the formation of P_4O_6NR (R = organic groups) by nitrene insertion and rearrangement of the cage structure, resulting in an adamantane-like P_4O_5N unit.[23−25] Although quantum chemical calculations for P_4O_6X (X = O, S, H^+, F^+, Cl^+, N^-)[26] indicate a strong dependence of the P−O cage bond lengths on the electronegativity of terminal atoms attached to the phosphorus atom, very similar geometrical parameters have been found for the P_4O_6 cages of P_4O_7,[2,3] P_4O_6S,[7] P_4O_6Se,[11] and $P_4O_6Fe(CO)_4$.[18] Up to now, this observation and the different behavior of P_4O_6NR in comparison with P_4O_6X (e.g. X = O, S, Se, etc.) are not completely understood.

In contrast to chalcogen atoms, the electrophilic addition of BH_3 is expected to affect the cage bonds in a different manner due to the reduced π-donor abilities of boron. For this reason we have tried to synthesize and characterize borane complexes of P_4O_6, the constitutions of which were previously studied by ^{31}P NMR spectra of solutions.[27−29] Thus far, a detailed investigation of these compounds in a pure state failed because of their high sensitivity and instability. During our recent attempts in crystallizing dissolved $P_4O_6\cdot BH_3$, we have achieved the first selective dimerization of phosphorus chalcogenides. The obtained product, $P_8O_{12}\cdot 2BH_3$ (**1**), is the bis(borane) adduct of a new molecular phosphorus oxide P_8O_{12}.[30]

Results and Discussion

Synthesis and Thermal Properties

Depending on the relative quantities, P_4O_6 readily forms $P_4O_6\cdot nBH_3$ ($n = 1-3$) when reacting with gaseous diborane in organic solvents at room temperature.[28,29] The reaction takes place in a sequential manner with the successive coordination of one, two, and three BH_3 groups. The chemical shifts, coupling constants, and splitting patterns, observed in ^{31}P NMR spectra, clearly indicate boron atoms being attached to phosphorus atoms.[28,29] If pure liquid P_4O_6 is used, electrophilic addition stops at the stage of $P_4O_6\cdot 2BH_3$ due to crystallization.[27] For practical reasons, we have chosen $Me_2S\cdot BH_3$ as a reagent. The first equivalent of $Me_2S\cdot BH_3$ reacts completely within an hour, giving mainly $P_4O_6\cdot BH_3$ with small amounts of $P_4O_6\cdot 2BH_3$, P_4O_7, P_4, and some residual P_4O_6. $Me_2S\cdot BH_3$ is less effective than B_2H_6. Thus, $P_4O_6\cdot BH_3$ and $P_4O_6\cdot 2BH_3$ are generated in a 1:2.5

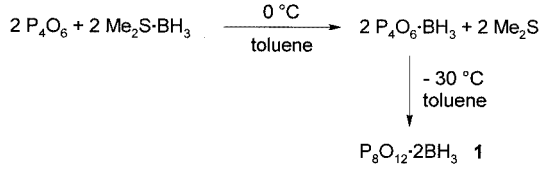
ratio without any $P_4O_6 \cdot 3BH_3$, even if 4 equiv. of $Me_2S \cdot BH_3$ are applied. The NMR spectroscopic data of these compounds (see Exp. Sect.) are in good agreement with those described earlier.[28] After removing Me_2S and storing a highly concentrated solution of $P_4O_6 \cdot BH_3$ in toluene at −30 °C for a period of three months, cuboid crystals were recovered. Crystal structure determination, ^{31}P NMR spectroscopy, and mass spectrometry (see below) demonstrate that the crystallization product does not consist of the expected $P_4O_6 \cdot BH_3$, but of the corresponding dimer $P_8O_{12} \cdot 2BH_3$, (Scheme 1).



Scheme 1. Reaction scheme of the formation of **1**

Under standard conditions, **1** forms a colorless solid, which is extremely sensitive to humidity as well as to nucleophilic or protic reagents. Furthermore, **1** is highly explosive, when exposed to any kind of pressure, traces of pure water or ethanol. Upon heating the solid above 70 °C for some hours, decomposition occurs, with the color turning yellow, orange, and finally red. According to the results of temperature-dependent powder diffractometry (Guinier−Simon technique), crystalline BPO_4 (tetragonal) is generated above 230 °C. As is to be expected, the thermal decomposition is irreversible. Apart from a slight mass loss of about 4%, thermal analyses by DTA and TGA do not show any well-defined effect below 250 °C. In solution (toluene, xylene, CH_2Cl_2) **1** slowly decomposes furnishing a mixture of **1**, $P_4O_6 \cdot BH_3$, P_4O_6, and some P_4O_7. At room temperature the monomer/dimer ratio climbs to 1:1 within 18 h. Furthermore, the solution mainly contains entire molecules of **1**, even on heating at 70 °C for 2 h. On the other hand, $P_8O_{12} \cdot 2BH_3$ is stable at −30 °C both, as a solid and in solution.

Crystal Structure Determination

The powder diffraction pattern of **1** (Figure 1; Table 1) has been indexed based on an orthorhombic unit cell (Table 2). The crystal structure has been determined and refined using single-crystal X-ray methods. The crystal data are summarized in Table 2. A powder diffraction pattern, which has been calculated on the basis of the single-crystal data, is in good agreement with the observed one (Figure 1).

The crystal structure consists of $P_8O_{12} \cdot 2BH_3$ molecular units. As shown in Figure 2, two bicyclic $P_4O_5 \cdot BH_3$ subunits are connected by O1 and O7 in a way, such that the BH_3 groups are pointing in opposite directions (head−tail linkage). Thus, $P_8O_{12} \cdot 2BH_3$ represents the bis(borane) complex of a new molecular phosphorus oxide P_8O_{12}, which is the dimer of the well-known P_4O_6. In recent investigations concerning the dimerization tendency of molecular phosphorus oxides, we have been able to confirm the existence of ligand-free P_8O_{12} by means of ^{31}P NMR spectroscopy (P_8O_{12} has been mentioned before by Meisel and co-workers,[31] but neither experimental evidence nor analytical data were presented). Due to packing effects the point symmetry C_{2h}, expected for free $P_8O_{12} \cdot 2BH_3$ molecules, is reduced to C_1 in the crystalline solid. As a consequence, the two bicyclic $P_4O_5 \cdot BH_3$ units are folded and slightly twisted against each other (folding along the O1−O7 axis with torsion angles of 151° for P1−O1−O7−P5 and 164° for P4−O7−O1−P8; twisting along the O4−O10 axis; see Figure 2).

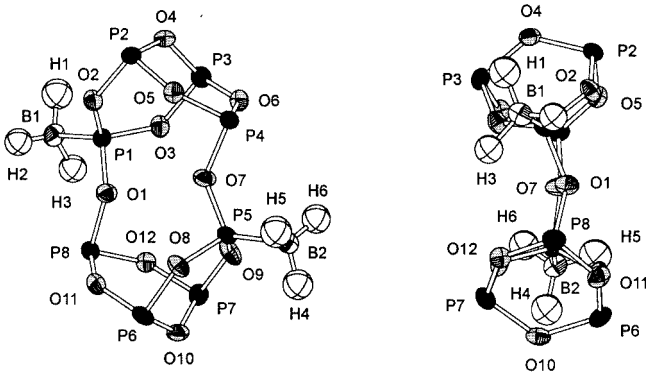

Figure 2. Molecular structure of **1** (two views; ellipsoids for 50% probability)

As there are no other phosphorus compounds known that have a similar structure, we are restricted to comparing the geometric parameters of **1** with those of P_4O_6X (X = O, S, Se) and $(RO)_3P{\cdot}BH_3$ (R = organic groups). The P−O bond lengths, varying between 157.8 and 167.1 pm, indicate pronounced P−O double-bond contributions [P−O (calculated): 176 pm;[32] P=O: 145.0 pm in P_4O_7,[3] 145.5 pm in P_4O_8 [4]] and may be subdivided into three types: P(B)−O_P^{III}, P^{III}−$O_{P(B)}$, and P^{III}−O_P^{III}, with P(B) and P^{III} being phosphorus atoms in the unit O_3PB and O_3P, respectively. The corresponding bond lengths reflect a characteristic distortion of the phosphorus−oxygen framework, which is already known from P_4O_6X (Table 3; X = O, S, Se) and is apparently induced by the electrophilic addition to the P_4O_6 cage. Thus, starting from the respective four-fold-coordinated phosphorus atom, the P−O bonds display an alternating contraction and elongation compared to the corresponding length in P_4O_6 (P−O: 165.3 pm[33]). But in the case of **1**, the distorting effect spreads out from two centers (P1 and P5) across a larger network. As mentioned in the introduction, the degree of this distortion so far seems to be rather independent of the nature of the terminal atom attached to the phosphorus atom. In this regard, the significant contraction of all P−O bonds by about 1 or 2 pm, as determined for **1**, is remarkable (Table 3). According to quantum chemical calculations,[26] the P(X)−O_P^{III} bonds are elongated, as the positive polarization of P(X) decreases, which on its part depends on the electron-withdrawing character of the attached element X. In contrast to these findings, boron generates significantly shorter P−O bonds than the more electronegative elements oxygen, sulfur, and selenium. A possible explanation for this observation may be seen in the fact that, contrary to chalcogen atoms, BH_3 groups are σ-acceptors with strongly reduced π-donor capabilities. A small degree of π-back donation by BH_3 was postulated very early in the investigations of the bonding in $PF_3{\cdot}BH_3$ [34,35] and $CO{\cdot}BH_3$.[34,36] More recent theoretical studies including natural energy decomposition analyses seem to confirm the effect of hyperconjugation for $CO{\cdot}BH_3$ [37,38] and $PF_3{\cdot}BH_3$.[39,40] On the other hand, it has to be stated that hyperconjugation is not mentioned in some of the respective treatments[41] and experimental evidence for it can hardly be provided. Anyway, the efficiency of π-back donation should be smaller for BH_3 than for chalcogen atoms leading, in the case of **1**, to an enhanced positive polarization of P(X). Another special feature of **1** arises from the head−tail linkage in combination with the alternation of contracted and stretched P−O bonds. As a result, both $P_4O_5{\cdot}BH_3$ units are connected by extremely asym-

Table 3. Mean bond lengths [pm] and mean bond angles [°] for **1**, P_4O_7, P_4O_6S, and P_4O_6Se; X = B, O, S, Se; P(X) = P in unit O_3PX; P^{III} = P in unit O_3P

metrical P−O−P bridges, containing the longest and the two shortest P−O bonds in the molecule (167.1, 158.0, and 157.8 pm, respectively). These bridges are arranged in a way that favors a symmetrical cleavage of the molecule. In fact, this is what we have observed in both, solution (^{31}P NMR spectra) and gas phase (mass spectra).

The O−P−O bond angles ranging from 95.3 to 104.7° tend to be about 4° smaller at the P^{III} than at the P(X) atom (Table 3). The mean bond angles for O−P−O and X−P−O are nearly identical to those in P_4O_6X (Table 3), whereas the mean values for P−O−P are substantially larger [about 5° for P^{III}−O−P^{III} and about 9° for P(X)−O−P^{III}]. Both, contraction of P−O bonds and widening of P−O−P bond angles, are consistent with assuming an increased double-bond character. These π-interactions are promoted by a reduction of ring strain upon dimerization, and balance the positive polarization of the P(B) atom at the same time.

The geometric parameters within the $O_3P{\cdot}BH_3$ unit of **1** correspond quite well with the values obtained for borane complexes of organic phosphites $(RO)_3P{\cdot}BH_3$.[42−45] The P−B mean bond length of 187.0 pm, especially, is in line with assuming a pure single bond. Due to the difficulties in accurately localizing hydrogen positions by X-ray diffraction methods, the B−H bond lengths and bond angles vary significantly (mean values for B−H: 109.8 pm; P−B−H: 103.5°). However, the H−B−H mean bond angle of 114.7° is exactly the average value of 109.4 and 120°, encountered for tetrahedral and trigonal-planar coordination of the boron center, respectively. The intermolecular atomic distances are in the range as expected for van der Waals interactions.

NMR Spectroscopy

In our previous investigations on phosphorus oxides and their derivatives, NMR spectroscopy turned out to be a useful tool, sometimes providing essential insights otherwise not accessible.[46−48] For **1** the isotropic signals of nearly all eight crystallographically independent phosphorus atoms can be resolved in the ^{31}P MAS NMR spectrum (Figure 3).

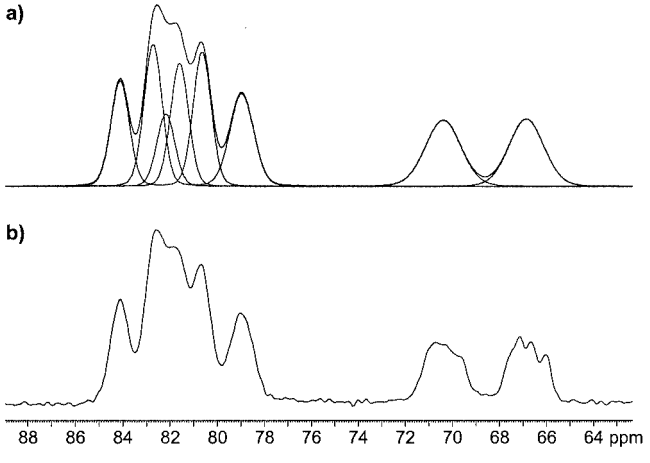

Figure 3. Isotropic signals of the ^{31}P MAS NMR spectrum of **1**; simulated with deconvolution (a; see Table 4) and observed (b)

Table 4. Simulation parameters for the isotropic ^{31}P MAS NMR signals of **1** (see Figure 3)

δ [ppm]	Amplitude	Line width [Hz]	Intensity [%]
66.9	73.5	279.6	13.4
70.4	72.1	286.2	13.5
79.0	101.0	190.4	12.6
80.7	146.9	145.8	14.0
81.6	134.6	145.4	12.9
82.2	79.0	145.8	7.6
82.8	155.2	145.8	14.9
84.2	115.1	145.7	11.1

A simulation using the individual chemical shifts given in Table 4 is in good agreement with the observed spectrum (Figure 3). By means of cross polarization from ^{1}H onto ^{31}P spins the signals at δ = 66.9 and 70.4 ppm could be assigned to the BH_3-bearing phosphorus atoms P1 and P5. This is in accordance with additional broadening and splitting of these signals due to coupling with ^{11}B nuclei having a quadrupole moment. Thus, the other six signals can be attributed to the P2, P3, P4, P6, P7, and P8 atoms. A further assignment to individual atoms has not been attempted. An explanation for the low signal intensity at δ = 82.2 ppm cannot be given. The isotropic chemical shifts of the BH_3 groups of **1**, observed in ^{1}H and ^{11}B MAS NMR spectra, are δ = 0.88 and −39.6 ppm, respectively, and match quite well with the values of $P_4O_6{\cdot}BH_3$ (δ = 0.6 and −40 ppm[29]).

The NMR spectra of **1**, in solution, are in accordance with molecules exhibiting C_{2h} symmetry. This observation might be understood by assuming a flexible P_8O_{12} framework allowing fast internal motion in solution, and adaptation to packing requirements in the solid phase. In the case of fluctuations being faster than the time-scale of the NMR spectroscopic experiments, a time-averaged state of the molecule is recorded instead of an individual conformer. As a consequence, the P1 and P5 atoms appear as chemically equivalent, but magnetically inequivalent nuclei. The same holds for P4 and P8 and for P2, P3, P6, and P7, respectively giving an AA′BB′B′′B′′′XX′ spin system. Therefore, a set of three signals is obtained in the ^{31}P NMR spectrum (Figure 4). P1 and P5 give rise to a signal appearing as a diffuse hump at δ = 71.5 ppm due to the quadrupole moment of the boron atom and complicated spin-spin coupling with hydrogen, boron, and trivalent phosphorus

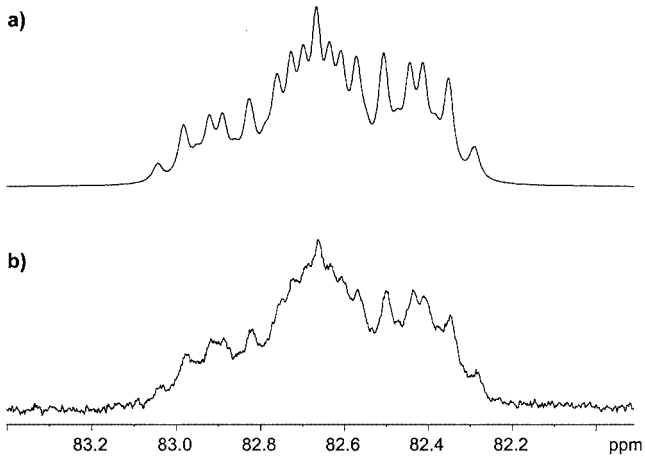

Figure 5. Splitting pattern for P_A in the ^{31}P NMR spectrum of dissolved **1**; simulated (a; see Table 5) and observed at −20 °C (b)

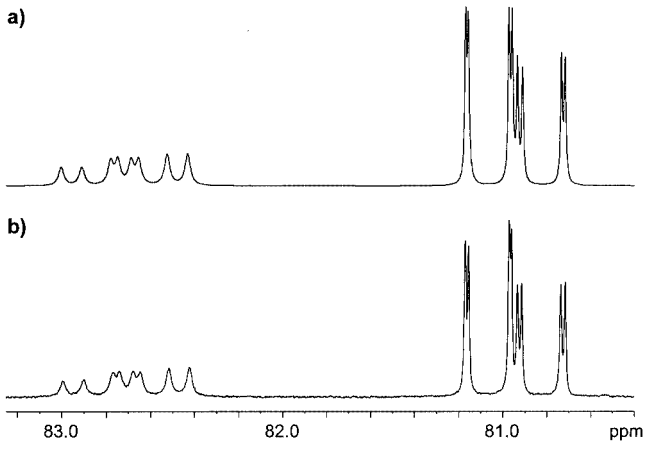

Figure 6. Splitting patterns for P_A and P_B in the $^{31}P\{^1H\}$ NMR spectrum of dissolved **1**; simulated (a; see Table 5) and observed at −20 °C (b)

atoms. The best resolution for the splitting pattern of the broad signal at δ = 83.7 ppm has been obtained at −20 °C for the temperature-dependent measurements (Figure 5; the displacement of the signal is caused by the general temperature dependence of chemical shifts). The corresponding $^{31}P\{^1H\}$ NMR signal (Figure 6) indicates pronounced ^{31}P-^1H coupling, whereas the other signals remain unchanged. The splitting patterns for both NMR spectra can be explained and simulated in full detail using the parameters summarized in Table 5 (Figures 5 and 6). The assignments are consistent with homonuclear decoupling experiments and an intensity ratio of 1:2:1 for the signals of P_A, P_B, and P_X, respectively.

In line with increased P−O double-bond contributions as discussed above, a considerable upfield shift is to be expected for the ^{31}P NMR signals of **1** in comparison with its monomeric counterpart $P_4O_6{\cdot}BH_3$ (the upfield shifts for the BH_3-bearing and for the trivalent phosphorus atoms are about 20 and 40 ppm, respectively; see Exp. Sect.). Among molecular phosphorus oxides and their derivatives only the trivalent phosphorus atoms of $P_4O_6X_3$ (X = O, S, Se; also mixed) exhibit chemical shifts in this region. Surprisingly, the coupling constants are nearly unaffected by the change in bonding situation. Thus, the coupling constants within the bicyclic $P_4O_5{\cdot}BH_3$ unit ($^2J_{AB}$ = 29.2; $^2J_{BX}$ = 24.0 Hz) are of the same order as the $^2J_{P,P}$ values, found for $P_4O_6{\cdot}BH_3$ (27.7 Hz) and $P_4O_6{\cdot}2BH_3$ (24.5 Hz). The weak coupling across P1−O1−P8 and P4−O7−P5 ($^2J_{AX}$ = 11.4 Hz) reflects the flexible linkage between the $P_4O_5{\cdot}BH_3$ subunits. The additional quadruplet splitting of the P_A signal, observed in the ^{31}P NMR spectrum (Figure 5), may be considered as either $^4J_{AH}$ or $^6J_{AH}$. Having the flexible linkages in mind, coupling along the rigid $P_4O_5{\cdot}BH_3$ units ($^6J_{AH}$) seems to be more favorable.

Vibrational Spectroscopy

On dimerization, the molecular symmetry of $P_4O_6{\cdot}BH_3$ (C_{3v}) is reduced to at least C_{2h}, leading to the splitting of vibrational modes of the *E* representation. Moreover, the distortion of the P_8O_{12} cage in the crystalline solid provokes a further symmetry reduction to C_1, which is confirmed by the violation of the mutual exclusion rule normally holding for centrosymmetric molecules. Thus, absorptions at 431, 655, 666, 757, 1119, 2343, and 2363 cm^{-1} are observed in both, IR and Raman spectra (Figure 7; Table 6). As expected, the spectra are very similar to those of P_4O_6 [49] and P_4O_7,[3] for which strong bands around 950 cm^{-1} in the IR spectrum (broad) and around 620 cm^{-1} in the Raman spectrum (sharp) are quite characteristic. The vibrational frequencies of **1** are shifted by up to 20 cm^{-1} compared to

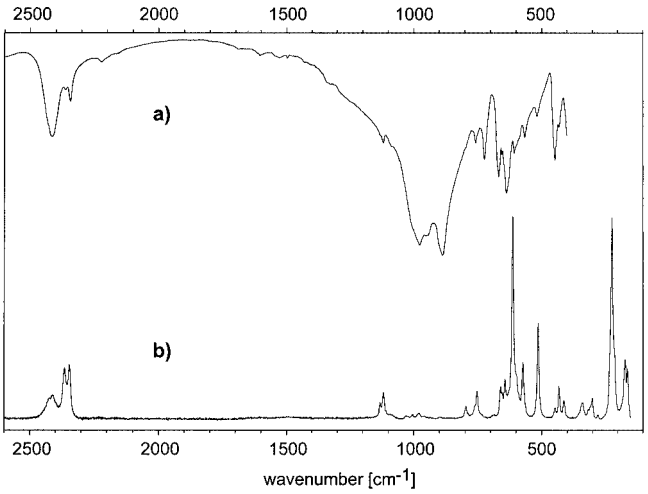

Figure 7. IR (a) and Raman (b) spectrum of solid **1**

those of P_4O_6 and P_4O_7 (Table 6). As cage vibrations are always mixed with motions of the terminally bonded groups, which is different for P_4O_7 and **1**, reliable conclusions concerning the nature of the P−O cage bonds cannot be drawn from the comparison of individual frequencies at a first glance. The four absorptions ranging from 2340 to 2430 cm^{-1} may be attributed to symmetric and antisymmetric B−H stretching modes and agree with data of compounds containing similar P−BH_3 groups.[42,50] The region in which ν(P−B) modes are observed for $R_3P{\cdot}BH_3$ (R = H, Me, Cl),[50] is between 560 and 585 cm^{-1}. Pronounced bands at 565 and 574 cm^{-1} are obtained in the IR and Raman spectra of **1** and are not significant in the spectra of P_4O_6 and P_4O_7. Therefore, assigning them as ν(P−B) seems to be reasonable.

Mass Spectrometry

Some instructive conclusions can be drawn about the nature of the P_8O_{12} cage from mass spectrometry. The corresponding data for **1** are given in the Exp. Sect. Boron-containing species are easily identified by their characteristic isotope patterns, which are modified by consecutive hydrogen abstraction from BH_3 groups. In contrast to the molecular ions almost not being detected at all, peaks with intensities around 13% are observed in the EI mass spectrum at 100 °C arising from P_8O_{12} and $P_8O_{12}{\cdot}BH_3$. MS/MS experiments could not be used to decide whether the corresponding BH_3 abstraction occurs before ionization or afterwards, due to the low intensity of the molecular ion peak. Nevertheless, the differing peak intensities for P_8O_{12}-containing species suggest an enhanced stability for P_8O_{12} and $P_8O_{12}{\cdot}BH_3$ ions. In addition, the three P_8O_{12}-containing species show different fragmentation behaviors. Thus, the P_8O_{12} cage of **1** is cleaved symmetrically yielding mainly P_4O_6 and $P_4O_6{\cdot}BH_3$ [MS (EI, 40 °C): *m/z* = 220 and 233, respectively; Exp. Sect.), whereas for $P_8O_{12}{\cdot}BH_3$ the cleavage takes place asymmetrically (MS of $P_8O_{12}{\cdot}BH_3^+$; Exp. Sect.), resulting in an enhanced formation of $P_4O_7{\cdot}BH_2^+$ in the EI mass spectrum of **1** at 100 °C (*m/z* = 249; Exp. Sect.). For $P_8O_{12}^+$ both, symmetrical and asymmetrical cleavage, occur to the same extent generating $P_4O_5^+$ and $P_4O_6^+$ (MS of $P_8O_{12}^+$; Exp. Sect.). The increased stability of P_8O_{12} and $P_8O_{12}{\cdot}BH_3$ compared to **1** is supported by further observations. Because Chemical Ionization (CI) is less destructive than Electron Impact (EI), the cleavage of $P_8O_{12}{\cdot}BH_3$ is drastically reduced, whereas that of **1** is boosted (cf. peak intensity ratio of *m/z* = 233 and 249 for MS (EI, 100 °C) and MS (CI, 100 °C); Exp. Sect.). In the absence of collision gas no cleavage is detected at all for $P_8O_{12}^+$, even at 100 °C. Both, the different stabilities and fragmentation patterns may be fully understood from the results of the crystal structure determination. Due to the formation of asymmetrical P1−O−P8 and P4−O−P5

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bridges, the complexation of borane groups at P1 and P5 destabilizes the P_8O_{12} cage of **1** and induces symmetrical cleavage. On the other hand, in P_8O_{12} the two bicyclic P_4O_5 units are connected by symmetrical P−O−P bridges stabilizing the framework and permitting symmetrical as well as asymmetrical cleavage, at the same time. Finally, $P_8O_{12}{\cdot}BH_3$ is destabilized by only one asymmetrical P−O−P linkage. These results encourage further investigations aiming at the synthesis of dimeric phosphorus oxides. Selective BH_3 abstraction cannot be accomplished by thermal degradation, for example by heating solid **1** for some days at 90 °C. The decomposition product thus obtained is an amorphous orange solid, which is insoluble in toluene.

Conclusion

The thermodynamic driving force of the dimerization of $P_4O_6{\cdot}BH_3$ consists in a gain of enthalpy due to additional P−O double-bond contributions within the P_8O_{12} cage. These are promoted by a relief of angular strain and are in line with contracted P−O bonds (about 20 pm per P_4O_6 unit), enlarged P−O−P bond angles, and enhanced electronic shielding of phosphorus nuclei in **1**. At low temperatures, the benefit in enthalpy compensates for the loss in entropy, associated with dimerization. As the solubility of dimeric species is lower than that of $P_4O_6{\cdot}BH_3$, **1** is continuously removed from the solution through crystallization. As a result, the solved $P_4O_6{\cdot}BH_3$ dimerizes selectively in a kinetically controlled reaction in the absence of nucleophilic reagents. The poor π-donor property of BH_3 is responsible for the different reactivity of $P_4O_6{\cdot}BH_3$, compared to other P_4O_6 derivatives. The additional double-bond contributions within P(B)−O, balancing the positive polarization at the fourfold-coordinated phosphorus atom P(B) at the expense of the adjacent $P^{III}-O_{P(B)}$ bonds, strongly favor the fission of one of the destabilized $P^{III}-O_{P(B)}$ bonds. In this respect, the behavior of the $H_3B-P(OP)_3$ group would be very similar to that of alkylated phosphites $[R'-P(OR)_3]^+$, which are immediately cleaved in the well-known Michaelis−Arbuzov reaction[51−53] yielding organic phosphonates $R'-PO(OR)_2$. If the resulting polarities are taken into account, intermolecular recombination of the dangling P−O bonds create molecules having exactly the constitution observed for **1** (head−tail linkage). But, of course, a concerted mechanism via a four-membered P−O−P−O ring including two intact $P_4O_6{\cdot}BH_3$ units is also a reasonable alternative. This type of ring-opening reaction is considered as one possible pathway for the cationic polymerization of cyclosiloxanes.[54] In any case, the electrophilic addition of BH_3 seems to be associated with kinetic activation of the P_4O_6 cage.

Experimental Section

General: Synthesis of **1** as well as all sample preparations were carried out under inert conditions (argon) either in a glass apparatus or in a glove box. P_4O_6 (Hoechst) was purified by distillation at 50 °C under reduced pressure into a cooling trap. Toluene was heated under reflux over P_4O_{10} and freshly distilled prior to use. $Me_2S{\cdot}BH_3$ was commercially available (Strem Chemicals; about 5% excess of Me_2S).

Synthesis: $Me_2S{\cdot}BH_3$ (0.47 mL, 0.38 g, 4.96 mmol) was added dropwise to a solution of P_4O_6 (1.2 g, 5.46 mmol) in toluene (1.0 mL) at 0 °C while stirring. The clear colorless solution was stirred at 0 °C for a further 2 h and Me_2S was subsequently removed in vacuo at −10 °C over 4 min. At this stage the solution contained mainly $P_4O_6{\cdot}BH_3$ with small amounts of P_4O_6, $P_4O_6{\cdot}2BH_3$, P_4O_7, and P_4. After storage for three months at −30 °C the almost solidified solution was warmed up to room temperature. Clear colorless crystals of **1**, which were up to 1 mm in size and cuboid in shape, initially remained undissolved. The crystals were separated from the mother liquor at 0 °C and dried in vacuo at room temperature for 5 h giving pure **1** (yield: ca. 0.38 g, 0.82 mmol, 30%). The reproducibility of the crystallization strongly depends on temperature and concentration. The best results were obtained for concentrations ranging from 1.25 to 1.43 mg of P_4O_6 per mL of toluene (after removal of Me_2S and some solvent in vacuo).

Caution: Solid $P_8O_{12}{\cdot}2BH_3$ is highly explosive when exposed to any kind of mechanical stress, even under inert conditions at −80 °C (friction- and shock-sensitive). Contact with pure water or ethanol causes violent decomposition. We recommend that the solid should be neither handled in sealed glass vessels nor in large amounts (maximum 1.5 g). Under argon, loose crumbs can be ground without danger, if portions less than 100 mg are used. For disposal, **1** is covered with aromatic solvents and carefully decomposed by adding ethanol in small portions (formation of H_2).

Crystal Structure Analysis: A cuboid crystal with dimensions given in Table 2 was picked up by a mounted CryoLoop (Hampton Research) using an inert immersion oil (Hampton Research) and then measured at −90 °C using a SMART 1000 diffractometer with CCD detector and graphite monochromator (Bruker AXS). Absorption corrections based on symmetry-equivalent and redundant reflections (SADABS); structure solution by direct methods (SHELXS-97[55]); structure refinement according to full-matrix least-squares procedures against F^2 (SHELXL-97[56]); hydrogen atoms refined freely (isotropic); display of molecular structure by DIAMOND.[57] Further details of the crystal structure investigation may be obtained from Table 2 and from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany [Fax: (internat.) + 49-7247/808-666; E-mail: crysdata@fiz-karlsruhe.de], on quoting the depository number CSD-411904 and the names of the authors.

Powder Diffractometry: Stadi P diffractometer (Stoe & Cie); Debye−Scherrer geometry; Ge single crystal (111) as monochromator; $\lambda(\text{Cu-}K_{\alpha 1}) = 154.0598$ pm; **1** was ground in a glove box and sealed in a capillary (Hilgenberg) with 0.2 mm in diameter; after zero point correction on the basis of silicon as external standard and baseline correction profile fitting was performed by FULLPROF98[58] using least-squares procedures; refinement results are given in Table 1 (reflection positions) and Table 2 (lattice parameters).

NMR Spectroscopy: Solutions: 300 MHz spectrometer (Avance DPX 300 SB; Bruker); 121.50 MHz (^{31}P), 96.29 MHz (^{11}B); in toluene; [D_6]benzene or [D_8]toluene as lock solvents; glass tubes (Wilmad) were sealed; simulation by WINDAISY.[59] Solid: 400 MHz spectrometer (Avance DSX 400 WB; Bruker); 2.5 mm CP MAS

Modulation of the Communication between Redox Centers in a Tris(ferrocene)-tren Ligand by Complexation of Lanthanide Ions

Marie Heitzmann,[a,d] Jean-Claude Moutet,*[a,d] Jacques Pécaut,[b,d] Olivier Reynes,[a,d] Guy Royal,*[a,d] Eric Saint-Aman,[a,d] and Guy Serratrice[c,d]

Keywords: Sandwich complexes / Electrostatic interactions / Electrochemistry / Lanthanides

The tripodal ligand L built on the tren platform and bearing three chemically equivalent ferrocene units was prepared and characterized. Electrochemical investigations indicate that electrostatic communication occurs between the three ferrocene groups in L, which leads to the observation of two distinct voltammetric waves. The electrochemical communication between the three ferrocene moieties is disrupted in 1:1 ($L:M^{3+}$) type complexes formed between L and Y^{3+} or Eu^{3+} metal cations and their electrochemical response tends towards that of a single three-independent-electrons oxidation wave. Modulation of the electrochemical properties of L in the presence of lanthanide ions might be exploited with a view to their electrochemical sensing in organic and aqueous media.

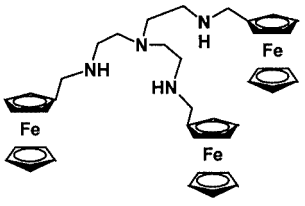
Introduction

Macromolecular systems containing multiple redox active centers have been the subject of numerous studies due to their intriguing electrical and redox properties, and their potential use as functional nanostructured materials.[1−3] In particular, structures such as linked metallocenes,[3−7] metallodendrimers,[6,8,9] or polymers containing metallocenes[2,10,11] may present remarkable intramolecular electrostatic communication throughout the redox active sites due to their spatial proximity. An interesting feature of the multi-redox systems is that the extent of communication between the redox centers can be controlled and modulated in several ways, including protonation or alkylation of the compounds,[4−7,12] or changes in solvent polarity[5,13] and supporting electrolyte composition.[14] Here, we report how the degree of electrostatic communication between three chemically equivalent redox centers in the tren-based tris(ferrocene) ligand L is deeply changed upon complexation of the secondary nitrogen bridging atoms by Eu^{3+} and Y^{3+} ions.

Moreover, important applications in sensors are envisaged for multi-redox molecules and macromolecular systems, with the opportunity of coupling the interactions of analyte-redox material into transducible responses.[15−17] We demonstrate that the very simple redox receptor L might be used for the electrochemical detection and titration of lanthanide ions (Eu^{3+} and Y^{3+} which is considered as a pseudo lanthanide), through the modification of the interactions between the redox active groups that occurs in the presence of these guests metal cations.



L

Results and Discussion

The homotrimetallic ligand L used in this study is based on the tripodal tetramine tren, namely the tris(2-aminoethyl)amine, which is a well-known ligand for metal cations[18] and an excellent platform on which to build sensing devices. For example, a redox-responsive receptor[19] for

halide anions and fluorescent sensors[20−22] for the recognition of anions, transition metals or protons have been developed by linking cobaltocenium[19] and photoactive fragments[20−22] to the tren unit.

Synthesis and Characterization of L

The tripodal receptor L was readily synthesized in a two-step procedure. Reaction of the tris(2-aminoethyl)amine with three equivalents of ferrocenecarboxaldehyde in biphasic media (water/diethyl ether) allows the precipitation of the trisimine intermediate, which is further reduced with sodium borohydride to produce L as an oily solid. Crystals of the protonated form of L could be obtained from a solution containing L along with ten equivalents of HCl_{aq}. It has to be noted that the solid state of the hydrochloride form of L is highly unstable and fuses rapidly when manipulated at room temperature. This results in a poor quality crystal. However, the data collection (Table 3) undoubtedly reveals a triply-protonated molecular structure, LH_3^{3+}, $3Cl^-$, depicted in Figure 1.

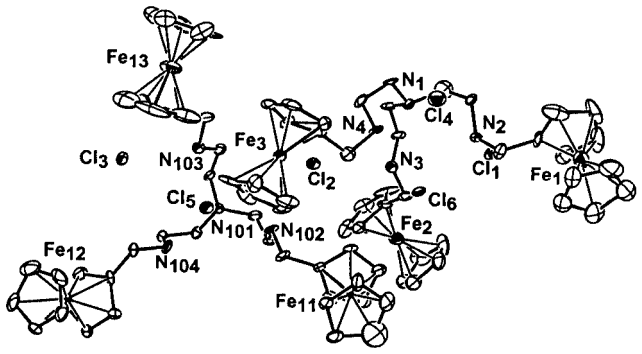

Figure 1. X-ray structure of the two entities of LH_3^{3+}, $3Cl^-$. Hydrogen atoms and solvent molecules are omitted for clarity. Hydrogen bonds lengths [Å]: Cl(1)···H−N(2), 2.31; Cl(6)···H−N(2), 2.26; Cl(2)···H−N(3), 2.27; Cl(6)···H−N(3), 2.27; Cl(4)···H−N(4), 2.20; Cl(6)···H−N(4), 2.27; Cl(2)···H−N(102), 2.20; Cl(5)···H−N(102), 2.24; Cl(3)···H−N(103), 2.21; Cl(5)···H−N(103), 2.22; Cl(1)#···H−N(104), 2.24; Cl(5)···H−N(104), 2.23 [symmetry transformation: # $-x+1$, $y-1/2$, $-z+3/2$; d(N−H) = 0.92 Å]

The X-ray structure determination shows that LH_3^{3+}, $3Cl^-$ crystallizes in the $P2_12_12_1$ space group of the orthorhombic system, revealing two independent molecular entities. These two entities display very close crystallographic data. The molecular structure, formulated as $[C_{39}H_{51}Fe_3N_4]Cl_3{\cdot}2CH_3CN{\cdot}C_2H_5CO_2CH_3{\cdot}H_2O$, consists of a tricationic LH_3^{3+}, three Cl^- counterions and four disordered solvent molecules (two acetonitrile molecules, one ethyl acetate, and one water molecule). The three metallocene units are located on the same side of the bridging nitrogen atom; the three iron centers in L are separated by ca. 11 Å and the distance between the iron center of a metallocene unit and its bridging secondary nitrogen is ca. 4.4 Å. The three chloride anions are closer to the secondary nitrogen atoms [N(2−4)···Cl distances of ca. 3.1 Å) than to the tertiary nitrogen, N(1)···Cl ranging between 3.73 and 4.43 Å. Cl(5) and Cl(6) are located inside the tren cavities, defined by N(101−104) and N(1−4), respectively, suggesting that these chloride anions are complexed by L via three convergent N−H···Cl hydrogen bonds (the distances between Cl(6) and N(2−4) are close to 3.1 Å). On the contrary, Cl(3) and Cl(4) interact only with HN(103) and HN(4), respectively. Finally, when referring to the two entities, Cl(1) bridges HN(2) and HN(104) (from an entity in a symmetrical position) and Cl(2) bridges HN(3) and HN(102).

Complexation Studies

Potentiometric titration studies and electrospray-mass spectra (ES-MS) experiments were first used to investigate the complexation of L by lanthanide ions.

Potentiometric Titration

The protonation constants of L and the stability constants of the corresponding Eu^{3+} and Y^{3+} complexes were calculated using the HYPERQUAD program,[23,24] from potentiometric titration curves obtained in a CH_3OH/H_2O solution (3:1, v:v) containing 0.1 M tetra-*n*-butylammonium perchlorate (TBAP). Three pK_a values (9.37, 8.13, and 6.47 at 25 °C) were measured for L. The species LH_4^{4+} could not be reached, its pK_a being too low to be observed. In agreement with the results of Fabbrizzi et al.,[21] based on other tren derivatives, the three protons in LH_3^{3+} are bound to the secondary amino groups. Protonation of the sole secondary amino groups is corroborated by the crystallographic data of the hydrochloride form of L showing that *(i)* LH_3^{3+}, $3Cl^-$ was obtained in the presence of a large excess of HCl and *(ii)* the Cl^- ions are closer to the secondary amino groups than to the apical nitrogen atom. As already observed for alkylated-tren derivatives, the pK_a's are lower than those of the tren parent.[25,26] Stability constants of the complexes formed between L and the Y^{3+} or Eu^{3+} cations were then determined at a molar ratio of 1:1 (L/M^{3+}). Measurements were made in the 2.5 to 7 pH range, the precipitation of hydroxylated species being observed above pH 7−8. The best fit of the data was obtained by considering only the 1:1 species (LM) and $[LM(OH)_2]$ and yielded log$K$(LM) = 9.17(0.05) and 9.48(0.05) with $K(LM) = [LM]/[M][L]$, log$K$(LM{OH}$_2$) = 13.50(0.05) and 13.00(0.05) with $K(LM\{OH\}_2) = [LM]/[LM(OH)_2][H^+]^2$, for the LEu and LY complexes, respectively. Coordination numbers for lanthanide or yttrium (which is often treated as a "pseudo-lanthanide") trivalent cations are typically between seven and ten,[27] and only four coordination sites can be afforded by the amino groups in L. It can thus be assumed that counterions and/or solvent molecules are also coordinated to the metal center in LEu and LY complexes.

ES-MS Qualitative Speciation

The binding of the Eu^{3+}, Y^{3+}, La^{3+}, and Sm^{3+} cations by L was studied by electrospray-mass spectrometry. Solutions of complexes were prepared by mixing equimolar solutions (1 mg·mL^{-1}) of L and the nitrate salt of a given metal cation in acetonitrile:water (1:1, v:v). In all cases, only one kind of complex was detected (Figure 2 and Table 1).

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

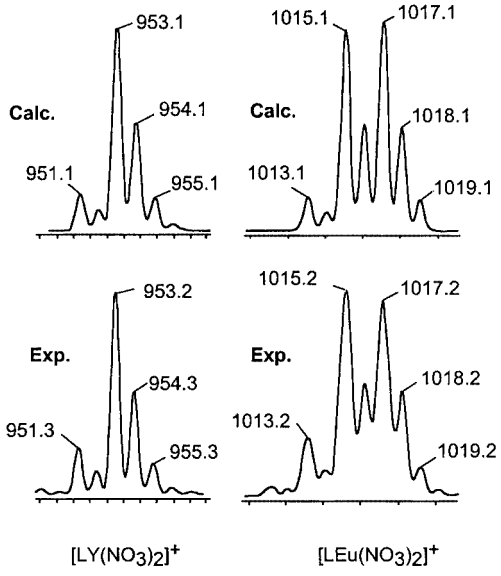

Figure 2. Calculated and experimental ES-MS spectra of $[LY(NO_3)_2]^+$ and $[LEu(NO_3)_2]^+$

Table 1. Electrospray-mass spectroscopic data (*m*/*z*) for L + M^{3+} 1:1 complexes (M = Eu, Y, Sm, La)

Species	Eu^{3+}	Y^{3+}	Sm^{3+}	La^{3+}
$[LM(NO_3)_2]^+$	1017.2	953.2	1016.2	1003.3
$[LM(NO_3)_3]^+$	1079.2	1015.2	1078.3	1065.3

All the isotopic peaks are separated by 1.0 *m*/*z* unit, revealing a charge state of +1 for the corresponding ions. Calculated spectra (Figure 2) show unambiguously that these signals correspond to the $[LM(NO_3)_2]^+$complexes, i.e. a 1:1 (L/M^{3+}) stoichiometry is observed, two nitrate anions being coordinated to the metal center. Interestingly, a second and smaller signal {10% in intensity compared with the signal of $[LM(NO_3)_2]^+$} corresponding to the complex $[LM(NO_3)_3]^+$ was also observed from the mass spectra. It can be assumed that the positive charge of this last species is provided by oxidation of one ferrocene unit of the complex under our experimental conditions. Spectra showing the same features were also obtained starting from isolated LY and LEu complexes.

Electrochemical Results

Electrochemical Behavior of Free L

The electrochemical behavior of the free receptor L was investigated by cyclic voltammetry (CV) and differential pulse voltammetry (DPV) in methanol containing 0.1 M tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte. In weakly polar solvents such as CH_2Cl_2, the poor solubility of the electrogenerated compounds was responsible for adsorption phenomena and led to the observation of complex voltammograms. CV experiments revealed the presence of two partially overlapping waves at $E_{1/2}$ = +25 mV and +135 mV, with ΔE_p = 90 mV in both cases. Two peaks at +30 mV and +140 mV were observed by DPV (Table 2). The three ferrocene groups in L being chemically equivalent, this behavior (observation of two distinguishable signals) can be attributed to interactions occurring between the three redox centers. Indeed, a separation $\Delta E°$ of $(RT/F)\ln 2^3$, i.e. 57 mV, between the first and third electron transfer is expected in a molecule with three completely non-interacting equivalent redox centers,[28,29] leading to the observation of a voltammetric curve with the shape of a single-electron transfer reaction (one CV wave with $\Delta E_p \approx 60$ mV, and a single peak by differential pulse voltammetry). In contrast, significant electronic or electrostatic communication between these three redox centers should lead to larger $\Delta E°$ values and, therefore, to the observation of multiple CV waves.[29,30] The degree of communication between the three ferrocene groups in L was evaluated via the determination of the three formal potentials $E°^1$, $E°^2$, and $E°^3$, corresponding to the successive oxidations of the three ferrocene subunits (Scheme 1).

Table 2. Electrochemical data for free L, LH_3^{3+}, LEu, and LY complexes

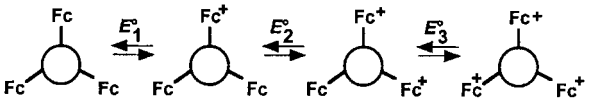

Scheme 1. Schematic representation of the three oxidation steps of L

The experimental voltammograms were fitted to digitally simulated voltammograms using the ESP software.[31] Results are depicted in Figure 3(A) and the three formal potentials evaluated from the optimization of the fitting analysis are given in Table 2. ΔE° values of ca. 70 mV between two consecutive redox systems (i.e. $E^{\circ 2} - E^{\circ 1}$ and $E^{\circ 3} - E^{\circ 2}$) were found. These results are in accordance with those already reported for bis[5] and tris[13] ferrocenyl compounds that showed significant communication between the redox centers and were characterized by two distinguishable voltammetric waves.

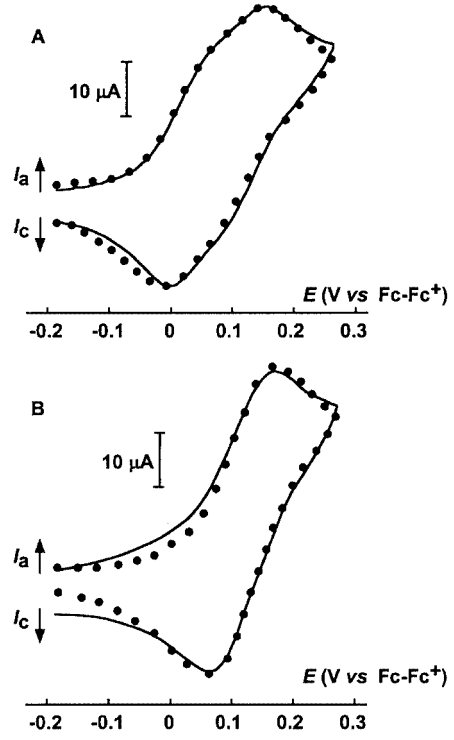

Figure 3. Experimental (continuous line) and best-fit simulated (dotted line) cyclic voltammograms of (A) 1 mM free L and (B) 1 mM LEu complex in CH_3OH containing 0.1 M TBAP; sweep rate 0.1 $V \cdot s^{-1}$

Since the three ferrocene groups in L are relatively far one from one another and separated by simple bonds, electronic communication through the bonds could not be invoked. Thus, it is reasonable to deduce that there are electrostatic interactions occurring between the electrogenerated positive charge of the first ferricinium group and the lone pair of a nitrogen atom connected to a second ferrocene group, the latter being more difficult to oxidize. In the same way, the third ferrocene group is oxidized at a higher potential than the second one. This hypothesis will be further discussed in the following paragraph.

Electrochemical Behavior of the Eu^{3+} and Y^{3+} Complexes of L

The same electrochemical experiments were conducted starting from chloride or nitrate salts of the isolated LEu and LY complexes. Results are summarized in Table 2. Both complexes exhibit one quasi-reversible CV wave [see for example Figure 3(B), for LEu] at $E_{1/2}$ = 144 (ΔE_p = 92 mV) and 148 mV (ΔE_p = 102 mV), and one DPV peak at E_p = 140 and 150 mV for LEu and LY complexes, respectively. These observations reveal a strong decrease in the communication between the three redox active units. The metallocene moieties of the complexed L therefore exhibit a more independent electrochemical behavior and the shape of the resulting voltammograms tends towards that of a single three-independent-electrons oxidation wave.

As mentioned previously, the determination of the three formal potentials E° corresponding to the three successive oxidations of the ferrocene groups in the complexes was performed by fitting simulated voltammograms to experimental CV curves. The data are summarized in Table 2. Firstly, due to electrostatic repulsion effects arising between the bound metal cation and the positive charge on the electrooxidized ferrocenyl unit, these potentials are logically shifted to more positive values as compared to those measured for the free receptor. Moreover, the three successive oxidations in both complexes are separated by ca. 30 mV and the separation between the first and the third redox events ($E^{\circ 3} - E^{\circ 1}$) is 59 mV, showing that the communication between the three ferrocene units is almost fully cancelled upon metallation of the receptor. The strong decrease in the interactions is thus a direct consequence of the complexation of L by metal ions through the secondary nitrogen atoms, and this result confirms that the lone pairs of the secondary amines are involved in the communication between the ferrocene groups in L.

In order to further confirm the above hypothesis, CV and DPV experiments were conducted on L in acidic media. Addition of $HClO_4$ in a solution of L led to the emergence of a single DPV peak at E_p = 175 mV and of a unique CV wave at $E_{1/2}$ = 180 mV (ΔE_p = 140 mV). These observations clearly indicate a strong decrease in the interactions between the three iron centers upon protonation of L, in accordance with that already observed with others nitrogen-bridged polyferrocenes.[4−7,12] Moreover, as in the metallic complexes, the average apparent potential for the first oxidation of the ferrocene centers is shifted to more positive values upon protonation of L. The potential shift is due to the electron-withdrawing effect induced by the introduction of positive charges on the bridging nitrogen atoms. Unfortunately, owing to complex voltammograms due to adsorption phenomena the potentials for the three electron transfers in LH_3^{3+} could not be accurately evaluated using electrochemical simulation. However, the potential shift for the first oxidation of L ($E^{\circ 1}$) induced by its protonation can be roughly evaluated to ca. +160 mV. This value is in agree-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ment with the results of Plenio et al.[32] who studied a number of ferrocene-nitrogen compounds and their protonated forms. They found a linear relationship between the inverse Fe−N distance (provided by X-ray data) and the shift of the potential of the ferrocene-ferricinium couple observed upon protonation of the neutral compounds. In particular, a shift of +190 mV was found for an iron-ammonium distance equal to 4.56 Å,[32] that is similar to the 4.4 Å Fe−N distance in LH_3^{3+} (Figure 1).

Electrochemical Behavior of L_1 after Addition of Increasing Amounts of Eu^{3+} or Y^{3+} Cations

We took advantage of the disruption of the communication in L upon complexation to investigate the sensing properties of this redox receptor towards lanthanide cations. Electrochemical experiments were carried out by DPV in CH_3OH solution containing 0.1 M TBAP. Results are illustrated in Figure 4. The addition of increasing amounts of Eu^{3+} or Y^{3+} cations (as nitrate or chloride salts) in a solution of L causes the linear growth of the intensity of the second DPV peak, along with the decrease of that for the first one. It must be pointed out that such evolution is observed because the electrochemical signal due to the lanthanide complex (140 and 150 mV for LEu and LY respectively) is very close to the second redox event in free L (E_{p2} = 140 mV). The first peak disappears and the second one reaches full development when one molar equivalent of metal salt has been added. This result is in keeping with ES-MS and potentiometric titration experiments and confirms the 1:1 binding mode between L and Eu^{3+} or Y^{3+} ions. Moreover, it has to be noted that a very slight precipitate was observed in the solution following the addition of a small amount of metal cation (ca. 0.1 molar equivalent), accompanied by a slight decrease in the intensity of the electrochemical signals. This precipitate disappeared when more metal cation was added. The intermediate formation of an insoluble complex, most likely an oligomeric assembly, at a low M^{3+}-to-L ratio could explained these observations.

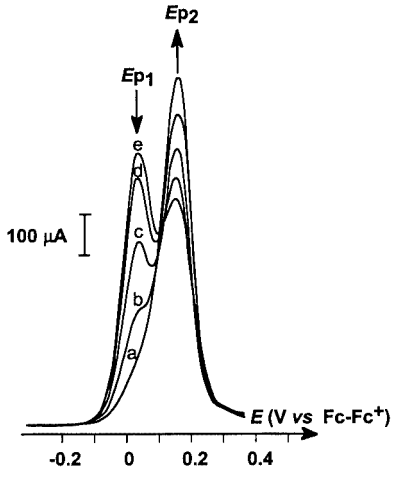

Figure 4. DPV curves for L (1 mM in CH_3OH +0.1 M TBAP) in the presence of increasing amounts of Eu^{3+} cations: Eu^{3+}/L = 0.1 (a), 0.25 (b), 0.5 (c), 0.75 (d) and 1 (e); sweep rate 0.01 $V{\cdot}s^{-1}$; pulse height 25 mV; step time 0.2 s

Analysis of the intensities of the two DPV peaks allowed us to draw amperometric titration curves (Figure 5), which clearly show the linear growth above 0.2 equivalent of the second DPV peak and the linear decrease of the first one upon addition of increasing amounts of trivalent cation. The same experiments were conducted in a CH_3OH/H_2O mixture (3:1, v:v) containing 0.1 M TBAP or $LiClO_4$. No major changes were observed, i.e. the same amperometric calibration curves were obtained, indicating that the electrochemical response of L towards lanthanide ions is not affected by the presence of water.

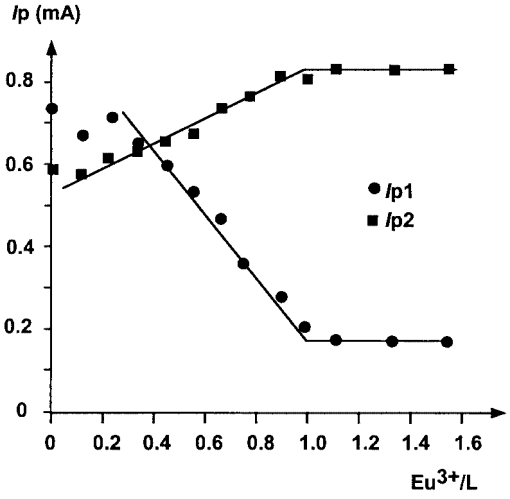

Figure 5. Amperometric titration curves: evolution of the DPV peak currents as a function of the Eu^{3+}-to-L ratio (see Figure 4)

Conclusion

The three chemically equivalent ferrocene subunits in L show a significant degree of electrostatic communication, which is responsible for the observation of two distinct electrochemical signals. These interactions are severely disrupted upon complexation of this tren-based ligand by lanthanide ions to form 1:1 (L:M) complexes. This leads to the observation of a unique voltammetric wave. Changes in the redox features of L in the presence of lanthanide ions can thus be exploited to detect and sense these guest species. Although a number of redox-active receptors able to electrochemically sense metal cations have been described previously,[33−35] to the best of our knowledge, L is the first example of a multi-redox ligand allowing an amperometric titration of metal cations in organic and aqueous media, via a large decrease in the communication between the redox active sites upon complexation.

Experimental Section

General Remarks: Hydrated metal ions (chloride or nitrate salts) were obtained from Aldrich. All compounds were of reagent grade and were used without further purification. Methanol (SDS, 99%,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

purex analytical grade) was used as received. Tetra-*n*-butylammonium perchlorate (TBAP) was purchased from Fluka and dried under vacuum at 80 °C for 3 days. ^{1}H and ^{13}C NMR spectroscopic experiments were conducted at 22 °C on a Bruker AC250 spectrometer using the solvent deuterium signal as internal reference. FAB (positive mode) mass spectra were recorded with an AEI Kratos MS 50 spectrometer fitted with an Ion Tech Ltd. gun and using *m*-nitrobenzyl alcohol as a matrix. ES-MS spectra were recorded on a Micromass Quattro mass spectrometer, equipped with an electrospray source. The temperature was set at 80 °C. The electrospray probe (capillary) voltage was optimized in the range 3.5−5 kV for positive ion electrospray. The sample cone voltage was set within the range 40−200 V. Complexes in solution [1 mg·mL^{-1} in CH_3CN/H_2O (3:1, v:v)] were infused in CH_3CN containing 0.01% HCOOH, through a fused silica tubing, using a syringe pump at a flow rate in the range 5−10 μL·min^{-1}. Potentiometric titrations were performed at 25 °C and the solutions were prepared in CH_3OH/H_2O (3:1, v:v). The ionic strength was fixed at I = 0.1 M with TBAP. An automatic titrator system (DMS, 716 Titrino Metrohm) equipped with a combined glass electrode and connected to an IBM Aptiva microcomputer was used. The electrodes were calibrated to read pH according to the classical method.[36] The ligand and its metal(III) complex of ca. 0.001 M were titrated with standardized 0.025 M NaOH at 25 °C. Argon was bubbled through the solutions to exclude CO_2 and O_2. A NaOH solution was standardized against potassium hydrogenphtalate. Carbonate content was checked by Gran's method. The titration data were refined by the non-linear least-squares refinement program HYPERQUAD[23,24] to determine the stability constants. The values of the stability constants are the mean values calculated from three titrations.

Electrochemical Studies: Experiments were conducted in a conventional three-electrode cell using an EGG PAR model 273 potentiostat, at 20 °C under an argon atmosphere. The Ag|10 mM $AgNO_3$ + 0.1 M TBAP in CH_3CN was used as a reference electrode. The potential of the regular Fc/Fc^+ redox couple used as an internal standard was 0.130 V under our experimental conditions. The working electrode consisted of a platinum disk (5 mm diameter) polished with 2 μm diamond paste. DPV curves were recorded at a 10 mV·s^{-1} scan rate with pulse height of 25 mV and a step time of 0.2 s. Electrochemical simulations and best fitting of experimental data were performed by the Electrochemical Simulations Package [ESP software, version 2.4, by Dr. Carlo Nervi (nervi@lem.ch.unito.it)]. The common approximation, which considers that formal potentials and half-wave potentials are identical, was applied.[30] The electrochemical parameters used for the digital simulation are: α = 0.5, k^0 = 0.02 cm·s^{-1}, and D = 10^{-5} cm^2·s^{-1}, α and k^0 being respectively the transfer coefficients and the heterogeneous transfer constant of the corresponding electrochemical reactions and D being the diffusion coefficient of the species. These values were assumed to be constant for all the systems studied since a slight modification of these parameters does not significantly affect the results.

Synthesis of L: Tris(2-aminoethyl)amine (0.5 g, 3.42 mmol) were dissolved in water (15 mL). A solution of ferrocenecarboxaldehyde (2.2 g; 3 × 3.42 mmol) in diethyl ether (15 mL) was then added and the biphasic solution was stirred vigorously in a sealed vessel for 12 hours. The orange precipitate was then filtered off, washed with diethyl ether (5 × 10 mL), and dried under vacuum. The trisimine intermediate was obtained in 95% yield (2.44 g). ^{1}H NMR (250 MHz, CD_3OD): δ = 2.73 (t, 6 H, N-CH_2CH$_2$-), 3.18 (t, 6 H, N-CH$_2$CH_2-), 4.07 (s, 15 H, Fc), 4.32 (m, 6 H, Fc), 4.51 (m, 6 H, Fc), 8.01 (s, 3 H, *H*C=N) ppm. ^{13}C NMR (250 MHz, CD_3OD): δ = 57.98, 61.58, 71.51, 71.90, 73.56, 82.16, 167.44 ppm. FAB-MS, *m/z*: 735 [M + H]$^+$. UV/vis, λ_{max} (ε/M^{-1}·cm^{-1}): 326 (6700), 455 nm (1300). $C_{39}H_{42}Fe_3N_4$, H_2O (752.32): calcd. C 62.26, H 5.89, N 7.45; found C 62.37, H 5.87, N 7.71.

Trisimine (500 mg) was dissolved in CH_3OH (50 mL) after which $NaBH_4$ (100 mg) was slowly added. The solution was then stirred for 4 hours. CH_3OH was removed by distillation, the residue was dissolved in H_2O (100 mL) and extracted with CH_2Cl_2 (3 × 30 mL). The organic phases were washed with water (2 × 10 mL), dried with $MgSO_4$, and the solvents evaporated to give the expected compound as a brown oil. Yield 93%. (470 mg). ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.90 (br. s, 3H N*H*), 2.50 (t, 6 H, N-CH_2CH$_2$-), 2.61 (t, 6 H, N-CH$_2$CH_2-), 3.45 (s, 6 H, Fc-CH_2) 4.08−4.16 (m, 27 H, Fc) ppm. ^{13}C NMR (250 MHz, $CDCl_3$): δ = 47.17, 49.05, 54.32, 67.79, 68.40, 68.62, 86.42 ppm. FAB-MS, *m/z*: 741 [M + H]$^+$. UV/Vis λ_{max} (ε/M^{-1}·cm^{-1}): 323 (440), 436 nm (370). $C_{39}H_{48}Fe_3N_4$ (740.36): calcd. C 63.27, H 6.53, N 7.57; found C 62.55, H 6.64, N 7.53.

LEu and LY Complexes: The LEu and LY complexes were isolated by mixing L and one equivalent of metal cation (as chloride or nitrate salts) in CH_3OH. The solution was stirred for one hour and the complexes were precipitated as a yellow powder upon addition of diethyl ether. Complexes were characterized by ES-MS measurements (see the text). No reproducible elemental analysis could be obtained and crystals suitable for X-ray studies could not be grown, due to hygroscopic properties

X-ray Crystallographic Study: Crystals of the hydrochloride form of L (LH_3^{3+}, 3Cl$^-$) were obtained by slow diffusion of diethyl ether into a solution of L with ten equivalents of HCl_{aq} in ethyl acetate/acetonitrile. Due to its instability, the crystal was mounted on the X-ray diffractometer and its structure determined at low temperature (143 K). Diffraction data (Table 3) were collected with a SMART CCD diffractometer (Mo-K_α radiation, graphite-monochromator, λ = 0.71073 Å). Intensity data were corrected for Lorentz polarization effects and absorption. Structure solution and refinement were performed with the SHELXTL package. Hydrogen

Pd^{II}, Zn^{II} and Ag^{I} Complexes of Tetrakis(*N*-7-azaindolyl)benzene: Variation of Bonding Modes, Extended Structures and Luminescence

Datong Song[a] and Suning Wang*[a]

Keywords: N ligands / Coordination modes / Palladium / Zinc / Silver / Luminescence

Pd^{II}, Ag^{I} and Zn^{II} complexes of tetrakis(7-azaindolyl)benzene (ttab), $[(PdCl_2)_2(ttab)]$ (**1**), $[(ZnCl_2)_2(ttab)]$ (**2**), $[Ag(NO_3)]_2$-(ttab) (**3a**) and $[Ag(NO_3)(DMSO)]_2(ttab)$ (**3b**) were synthesized and fully characterized by NMR spectroscopy, single-crystal X-ray diffraction and elemental analyses. The ttab ligand in these complexes displays two different bonding modes. In the Pd^{II} and Zn^{II} complexes, the ttab ligand chelates to the metal center via two *ortho* 7-azaindolyl groups (the *ortho* mode). In contrast, in the Ag^{I} complex, it chelates to the Ag^{I} ion via two *meta* 7-azaindolyl groups (the *meta* mode). In the solid state, molecules of **1** and **2** form grid-like extended structures that host solvent molecules such as DMSO and CH_2Cl_2. Compound **3a** appears to be a coordination polymer and can be converted into compound **3b** when dissolved in DMSO. A hydrogen bonded complex $[Zn(O_2CCF_3)_2(H_2O)_2](ttab)$ (**4**), which displays an unusual hydrogen bonded helical chain structure in the solid state, was also characterized. Except for compound **1**, these new compounds all emit blue light when irradiated by UV radiation.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Luminescent transition metal complexes are of great interest because of their potential application in chemical optical sensors, photosensitization and electroluminescent devices.[1,2] We have previously demonstrated that Pt^{II} and Pd^{II} complexes of 7-azaindole based organic ligands can emit green and orange light, either in frozen solutions or in the solid state, when irradiated by UV light.[2f,3a] In addition to luminescent properties, the coordination chemistry displayed by transition metal complexes of the 7-azaindole-based ligands is also interesting. As we reported previously, the coordination mode displayed by ligands involving 7-azaindolyl groups varies drastically according to the geometry of the ligand. For example, as shown in Scheme 1, the 1,3-bis(7-azaindolyl)benzene ligand has been found to bind to Pd^{II} or Pt^{II} centers as a tridentate NCN-type ligand through cyclometallation[3] (bonding mode **A**). In contrast, the 1,2-bis(7-azaindolyl)benzene ligand usually acts as a bidentate chelate ligand through the two 7-azaindolyl groups (bonding mode **B** in Scheme 1).[3b] The 1,3,5-tris(7-azaindolyl)benzene ligand, on the other hand, uses two of the 7-azaindolyl groups to chelate to the metal center with the NCN type of binding similar to that in **A**, and uses the remaining 7-azaindolyl group as a bridging ligand to form a trinuclear complex (**C**).[2f] Recently we reported the synthesis of the new ligand 1,2,4,5-tetrakis(7-azaindolyl)benzene (ttab),[4] which is a bright blue luminescent emitter. The organoplatinum complexes of ttab have been found to display unusual structural features and chemical reactivity.[4] In the previously reported organoplatinum complexes, the ttab ligand chelates to the Pt^{II} center in the *ortho* bonding mode (**D**) as shown in Scheme 1. Further investigation revealed that the ttab ligand also displays a second bonding mode (**E**), the *meta* mode. The third bonding mode (**F**), the cyclometallation mode, was not observed for the ttab ligand.

The metal ion and the ligands surrounding the metal ion appear to play a key role in the bonding mode of the ttab ligand. We report herein the results of our investigation on Pd^{II}, Ag^{I} and Zn^{II} complexes of the ttab ligand.

Results and Discussion

Syntheses of Complexes

The ttab ligand reacts readily with K_2PdCl_4 and $ZnCl_2$ in solution to afford complexes $[(PdCl_2)_2(ttab)]$ (**1**) and $[(ZnCl_2)_2(ttab)]$ (**2**), respectively, in nearly quantitative yields. When ttab was reacted with $AgNO_3$, we obtained a white solid of **3a**, which displays blue luminescence at ambient temperature and is insoluble in most organic solvents. Based on elemental analysis results, **3a** has the formula $[Ag(NO_3)]_2(ttab)$. Compound **3a** can be dissolved in DMSO under sonication to form a dinuclear complex $[Ag(NO_3)(DMSO)]_2(ttab)$ (**3b**), in which the DMSO molecules coordinate to the Ag^{I} center through the oxygen atom, as

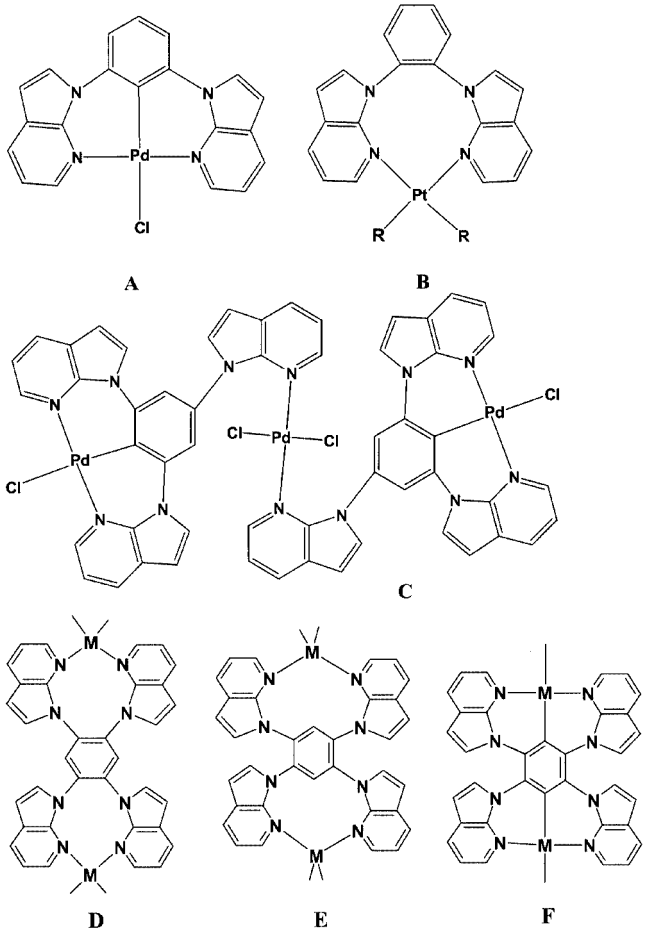

Scheme 1

confirmed by X-ray diffraction analysis. Anhydrous $ZnCl_2$ reacts with ttab in a THF solution, resulting in a blue luminescent white solid of **2**. Attempts to synthesize the complex $[Zn(O_2CCF_3)_2]_2$(ttab) by reacting $Zn(O_2CCF_3)_2$ hydrate with ttab were unsuccessful. Every attempt led to the isolation of crystals of $[Zn(O_2CCF_3)_2(H_2O)_2]$(ttab) (**4**), where the $Zn(O_2CCF_3)_2(H_2O)_2$ molecule is not coordinated to the ttab ligand but hydrogen bonded with the ttab ligand in the crystal lattice as confirmed by the X-ray diffraction study. The structures of ttab, **1**, **2**, **3b** and **4** were determined by X-ray diffraction analyses. Selected bond lengths and angles for **1**, **2**, **3b** and **4** are provided in Table 1.

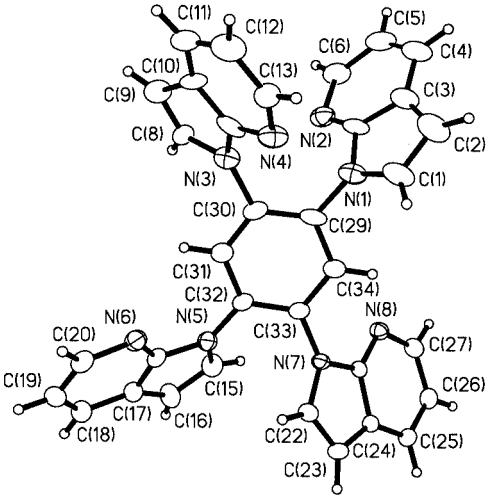

Figure 1. A diagram showing the structure of one of the independent ttab molecules in the crystal lattice with labeling schemes

Structures of ttab and of the Complexes

There are 1.5 independent molecules in each asymmetric unit of the crystal lattice of ttab, with one of the ttab molecules being located at the inversion center of symmetry. The structure of one of the independent molecules in the crystal lattice of ttab is shown in Figure 1. The ttab ligand has a non-planar structure. The 7-azaindolyl groups do not have significant conjugation with the central benzene ring as indicated by the dihedral angle between the central benzene plane and the 7-azaindolyl plane that ranges from 46.6° to 76.7°. Unlike 1,2-bis(7-azaindolyl)benzene or 1,3-bis(7-azaindolyl)benzene, which have only one way of chelating to the metal center, ttab has four nitrogen donor atoms available, which can chelate to the metal center either with two *ortho* 7-azaindole moieties (*ortho* fashion, **D**) or with two *meta* 7-azaindole moieties (*meta* fashion, **E**). In addition, it is conceivable that the ttab ligand could also form cyclometallated complexes (**F**), especially with the Pd^{II}

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and Pt^{II} centers, in the same manner as 1,3-bis(7-azaindolyl)benzene and 1,3,5-tris(7-azaindolyl)benzene, as shown in Scheme 1. However, despite our repeated attempts to react Pd^{II} and Pt^{II} ions with ttab under various conditions, no cyclometallated products were obtained. For the Pd^{II} ion, the *ortho* chelated complex **1** was isolated, instead.

The structure of **1**, as shown in Figure 2, has a crystallographically imposed inversion center of symmetry. Each Pd^{II} ion in **1** is chelated by two *ortho* 7-azaindolyl groups via the nitrogen atoms, resulting in a dinuclear complex. Each Pd^{II} center adopts a typical square-planar geometry, with the two nitrogen donor atoms *cis* to each other and two chloride ligands *trans* to each nitrogen atom. The Pd−N and Pd−Cl bonds in **1** show typical bond lengths with averages of 2.027(4) Å and 2.2876(14) Å, respectively, which are close to those reported previously.[2f,3a] The four 7-azaindolyl planes are nearly perpendicular to the central benzene ring as indicated by the dihedral angles between the 7-azaindolyl plane and the benzene ring (100.2° and 102.6°, respectively). The central benzene ring of the ttab ligand is "sandwiched" midway between the two $PdCl_2N_2$ planes. The $PdCl_2N_2$ plane is approximately parallel to the central benzene plane as indicated by the dihedral angle of 25.5° between these two planes. The separation distance between the two Pd^{II} centers in **1** is 6.660(2) Å. As a result, the distance between the center of the benzene ring and the Pd atom is 3.33(1) Å. The shortest contact distances between the Pd atom and the carbon atoms of the benzene ring are 2.99(1) Å [Pd(1)−C(16)] and 3.01(1) Å [Pd(1)−C(15)]. These distances are considerably shorter than the sum (≈3.22 Å) of the van der Waals radii of Pd and C, indicating the presence of some interactions between the Pd atom and the benzene ring. The structure of **1** resembles that of $[(PtR_2)_2(ttab)]$, where R equals methyl or

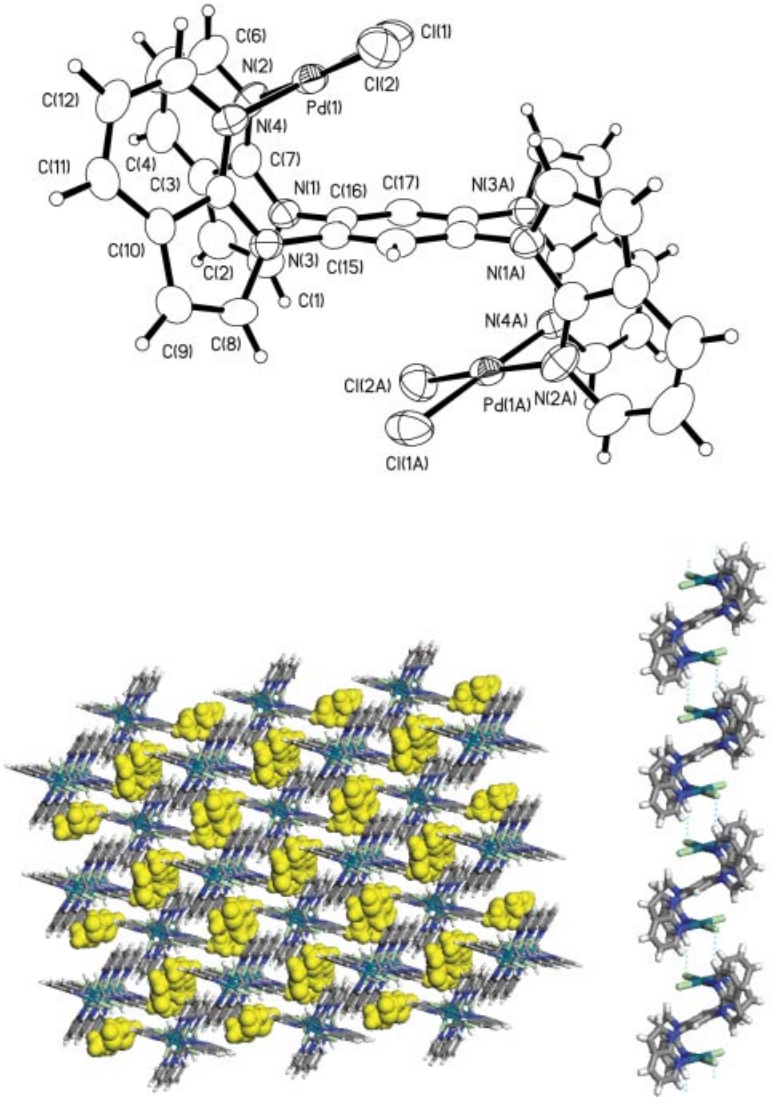

Figure 2. Top: a diagram showing the structure of **1** with labeling schemes; bottom, right: the hydrogen bond-linked 1D column; left: unit cell packing diagram viewed down the 1D column, the DMSO solvent molecules are shown using space-filling models

phenyl, reported previously, where substantial interactions between the Pt atom and the central benzene ring were also observed.[4]

Molecules of **1** stack along the *b* axis as shown in Figure 2. There are weak intermolecular hydrogen bonding interactions between the chloride ligands and the protons on the 7-azaindole rings of the neighboring molecules [Cl(1)···C(13) = 3.62 Å, Cl(2)···C(6) = 3.70 Å], leading to the formation of a 1D column. The shortest intermolecular Pd···Pd distance along the 1D column is 4.800(2) Å. The void space between the 1D columns forms extended channels in the crystal lattice. DMSO solvent molecules are located in these channels, as shown in Figure 2. There are hydrogen bonding interactions between the oxygen atom of the DMSO molecule and a proton on the central phenyl ring of the ttab ligand as indicated by the O···C distance of 3.10 Å. Crystals of **1** are stable at ambient temperature and no loss of DMSO solvent molecules was observed, as evident by the elemental analysis results.

Earlier we postulated that a "sandwich" structure similar to **1** is only possible for metal ions that have a square-planar geometry,[4] based on the assumption that if the metal ion has a tetrahedral geometry, it would bring the ligands bound to the metal center into close contact with the central benzene ring of the ttab ligand and as a result, the *ortho* coordination mode would not be possible. To prove this postulation, we examined the structure of **2**. As shown in Figure 3, the molecule of **2** has a crystallographically imposed inversion center. One surprising finding is that the ttab ligand adopts the *ortho* coordination mode with the Zn^{II} ion in the same manner as that observed in **1**. The common coordination geometry for a four-coordinate Zn^{II} ion is tetrahedral. The *ortho* bonding mode displayed by the ttab ligand in **2** is therefore totally unexpected. Each Zn^{II} center in **2** has a distorted tetrahedral geometry, with two nitrogen donor atoms from the ttab ligand occupying two coordination sites and two chloride ligands occupying the other two sites. The bond angles of N(2)−Zn(1)−N(4), N(2)−Zn(1)−Cl(1), and N(4)−Zn(1)−Cl(1), which are 97.2(3)°, 116.7(2) °, and 123.9(3) °, respectively, deviate significantly from a typical tetrahedral geometry. To minimize steric interactions between the chloride ligand Cl(1) and the central phenyl ring of the ttab ligand, the Zn(1)−Cl(1) bond is almost parallel to the central phenyl ring of ttab. The Zn(1)−Zn(1A) separation distance is 7.538(2) Å, much longer than the Pd(1)−Pd(1A) distance in **1**. The distance between Cl(1) and the center of the central phenyl ring of ttab is 3.19 Å. The distances between the Cl(1) atom and C(15), C(16), C(17) atoms of the phenyl ring are in the range of 3.42 to 3.50 Å, much shorter than the corresponding Cl−C separation distances in **1** [the shortest Cl−C distance in **1**, 3.76 Å, is between Cl(1) and C(16)]. The Zn(1)−Cl(2) bond is considerably longer than the Zn(1)−Cl(1) bond (by 0.05 Å). The Zn−N and Zn−Cl bond lengths in **2** [av. 2.060(9) Å and 2.221(3)Å, respectively] are typical.[5] The orientation of the 7-azaindolyl groups in **2** is similar to their orientation in **1**, with the dihedral angles between the 7-azaindolyl planes and the central benzene plane being 82.7° and 82.4°, respectively. However, the bond angles of C(7)−N(2)−Zn(1) [131.1(8)°] and C(14)−N(4)−Zn(1) [129.4(7)°] are considerably larger than the corresponding ones in **1** [C(7)−N(2)−Pd(1) = 123.7(4)°, C(14)−N(4)−Pd(1) = 124.0(3)°]. The geometry distortion around the metal ions and the nitrogen donor atoms in **2** is clearly a consequence of steric interactions between the chloride ligands and the central phenyl group. Nonetheless, the structure of **2** demonstrates that the *ortho* bonding mode is possible and favorable for a tetrahedrally coordinated Zn^{II} ion. In solution, only one set of chemical shifts for the ttab ligand was observed in the ^1H NMR spectrum of **2**. Therefore, we believe that only one bonding mode, most likely the *ortho* mode, exists in solution for complex **2**. In coordinating solvents such as DMSO, the $ZnCl_2$ units appear to dissociate from the ttab ligand as indicated by the ^1H NMR spectrum of **2** in [D_6]DMSO, which is exactly identical to that of the free ttab ligand in [D_6]DMSO. We believe that the DMSO solvent molecules are coordinated to the $ZnCl_2$ unit in solution, replacing the nitrogen donor atoms of the ttab ligand and resulting in the dissociation of the complex **2**.

In the crystal lattice, molecules of **2** (Figure 3) form one-dimensional chains through intermolecular hydrogen bonding interactions between the chloride ligands of one molecule and the protons on the 7-azaindole rings of the neighboring molecules in a similar manner as observed in **1**. The intermolecular Cl(1)···C(2′) separation distance is 3.67 Å. An interesting feature is that the 1D columns of **2** are arranged in such a way that rhombohedral-shaped channels are formed. Disordered CH_2Cl_2 solvent molecules occupy these channels. The crystals of **2** lose the trapped solvent molecules rapidly at ambient temperature, causing the collapse of the crystal lattice. The structure of the dinuclear silver complex **3b** is shown in Figure 4. In contrast to the structures of **1** and **2**, the ttab ligand in **3b** adopts the *meta* bonding mode. The molecule of **3b** has a crystallographically imposed center of inversion symmetry. Each Ag^{I} ion is coordinated to two 7-azaindolyl groups at the 1,3 positions of the ttab ligand. The Ag^{I} center is also coordinated to two oxygen atoms, one from the DMSO molecule and the other from a disordered nitrate anion. Coordination to a metal center via the oxygen atom of the DMSO ligand has previously been observed.[6] The bond angles around the Ag(1) atom range from 80.9(8) to 136.3(2)°. The geometry of the Ag(1) center can therefore be best described as a highly distorted tetrahedron. The dihedral angles between the 7-azaindolyl plane and the central benzene ring are 123.7° and 115.9°, respectively, much greater than those of **1** and **2**. The preference for the "*meta*" bonding mode shown by the ttab ligand in **3b** could be attributed to the relative bulkiness of the DMSO and NO_3^- ligands compared to the chloride ligands. The *meta* mode appears to minimize the interactions between the oxygen donor ligands and the central phenyl ring as well as satisfy the geometric preference of the Ag(1) ion. The distance between the two Ag(1) centers in **3b** is 6.594(2) Å, similar to the Pd−Pd distance observed in **1**. The distances between the

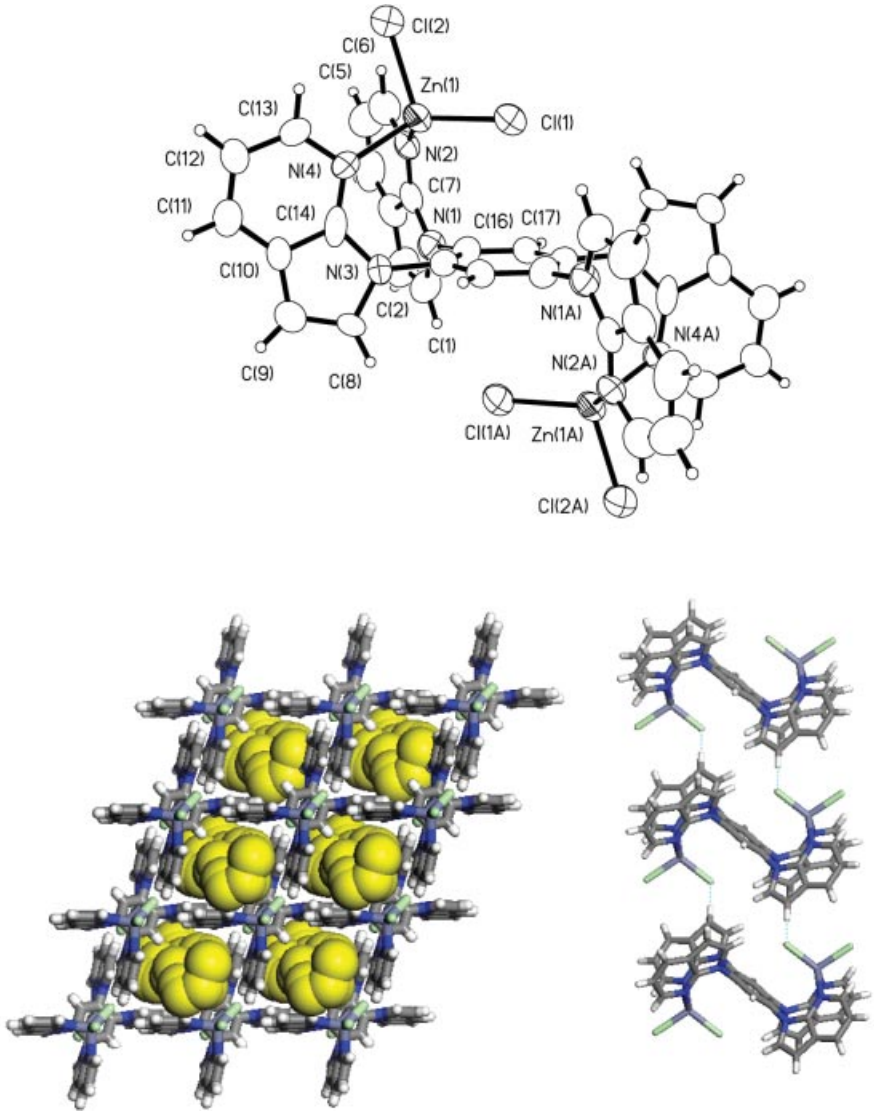

Figure 3. Top: a diagram showing the structure of **2** with labeling schemes; bottom, right: the hydrogen bond-linked 1D column; left: unit cell packing diagram viewed down from the 1D column, the disordered CH_2Cl_2 solvent molecules are shown using space-filling models

Ag(1) center and the carbon atoms C(15), C(16) and C(17) of the central phenyl ring, which are 3.20 Å, 2.72 Å and 3.17 Å, respectively, are either close to or less than the van der Waals contact distance of Ag−C (literature C−Ag bond length: ≈2.58 Å).[7b] Therefore, some weak bonding interactions between the Ag centers and the central phenyl ring appear to be present. The Ag(1)−O(1) and Ag(1)−O(3A) bond lengths are similar to those reported previously.[7]

The extended structure of **3b** is shown in Figure 4. Each molecule of **3b** is bonded to four neighboring molecules through hydrogen bonding between the oxygen atom of the nitrate ion and a proton (H14′) on the 7-azaindole ring of the neighboring molecule, as indicated by the O(4)···C(12′) distance of 3.33 Å, to form a two-dimensional layered network. In the crystal lattice, these layers stack on top of one another in an *ABAB* fashion, with toluene molecules filling the gaps. Compound **3b** slowly loses the DMSO ligands and reverts back to **3a** upon standing at ambient temperature. Due to the poor solubility of **3a**, NMR and X-ray diffraction experiments could not be carried out. Based on the poor solubility, the elemental analysis and the structure of **3b**, we believe that **3a** is likely to be a one-dimensional coordination polymer, where the nitrate anions function as bridging ligands, linking the dinuclear silver units together (in a similar way as that observed in **3b)** to form a coordination polymer chain.

Because the *meta* structure displayed by complex **3b** appears to be the consequence of the relatively large ligands DMSO and nitrate, we decided to examine the reaction of $Zn(O_2CCF_3)_2$ with the ttab ligand, anticipating a *meta* structure similar to that of **3b**. However, surprisingly, the product we isolated does not contain any coordination bonds between the Zn^{II} ion and the ttab ligand. Instead, the ttab ligand and the $Zn(O_2CCF_3)_2(H_2O)_2$ molecule located in the crystal lattice are linked together via hydrogen bonds, as shown in Figure 5. The H_2O ligands are from the starting material. Repeated efforts to synthesize the water-

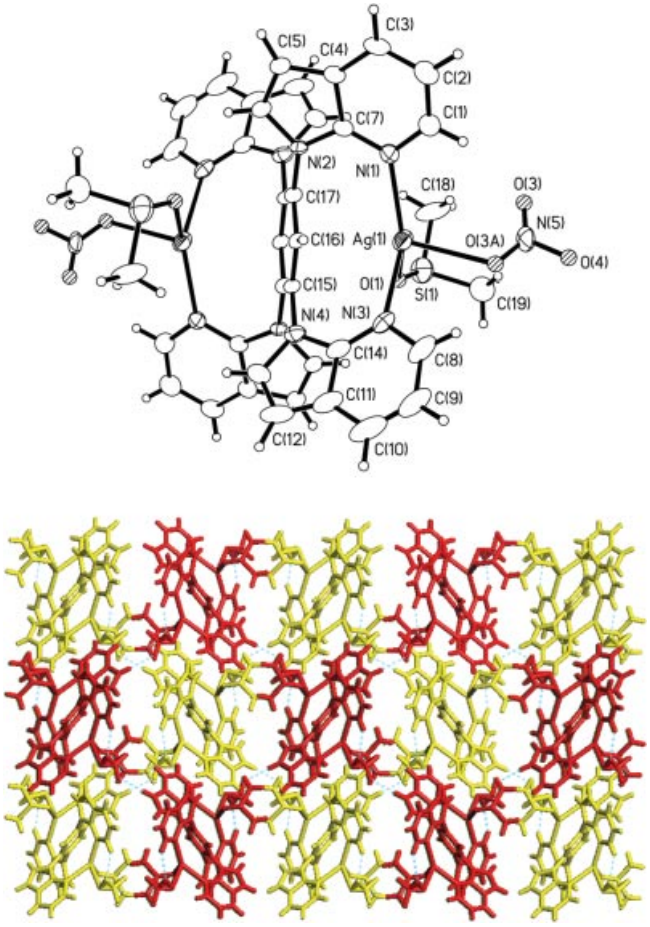

Figure 4. Top: a diagram showing the structure of **3b** with labeling schemes; for clarity, the oxygen atoms on DMSO and the NO_3^- are shown as ideal spheres; one of the disordered oxygen atoms [O(4A)] is not shown; bottom: unit cell diagram showing two layers (red and yellow) of hydrogen bond-linked 2D sheets

free complex $[Zn(O_2CCF_3)_2]_2$(ttab) were unsuccessful. Despite the poor quality of the crystal of **4**, the crystal data established unambiguously that the Zn^{II} ion is coordinated to two trifluoroacetate ligands and two H_2O ligands with an irregular geometry: four normal Zn−O bonds and two long Zn−O bonds [Zn(1)−O(2) = 2.557(16) Å, Zn(1)−O(4) = 2.467(16) Å]. The four non-coordinating nitrogen atoms of the ttab ligands form hydrogen bonds with the coordinated H_2O ligands. The N(8) and N(6) atoms are hydrogen-bonded to the O(6) atom while the N(2) and N(4) atoms are bonded to the O(5A) atom from a neighboring $Zn(O_2CCF_3)_2(H_2O)_2$ group, as indicated by the distances of O(5A)···N(2), 2.73(2) Å; O(5A)···N(4), 2.74(2) Å; O(6)···N(6), 2.70(2) Å; O(6)···N(8), 2.71(2) Å. The $[Zn(O_2CCF_3)_2(H_2O)_2]$ unit therefore functions as a linker for the ttab ligands through hydrogen bonds, leading to the formation of an unusual hydrogen-bond linked 1D chain (Figure 5). Extended structures involving metal complexes and organic molecules linked by hydrogen bonds have been reported previously.[8] One important feature of **4** is that the hydrogen-bonded 1D chains are helical and rotate in the same direction in the crystal lattice, resulting in the formation of a chiral lattice as shown in Figure 5. Interestingly, the hydrogen-bonding interactions between the zinc(II) complex and the ttab molecule are apparently retained in non-coordinating solvents such as CH_2Cl_2, as confirmed by the ^1H NMR study, which shows that the chemical shifts of the ttab molecule in **4** are drastically different from those of the free ttab molecule. In coordinating solvents such as DMSO, the NMR spectrum of **4** is identical to that of the free ttab ligand, indicating the Zn^{II} complex is no longer interacting with the ttab ligand through hydrogen bonds. It is very likely that the DMSO molecules coordinate to the Zn^{II} center and saturate the coordination sphere of the Zn^{II} ion, which may or may not lead to the replacement of the H_2O ligands at the zinc center. Due to the presence of an excess of DMSO molecules, the H_2O ligands are very likely to form hydrogen bonds with the DMSO solvent molecules instead of the ttab molecule, thus resulting in the free ligand-like behavior of the ttab molecule in DMSO. Toluene solvent molecules were also found in the lattice of **4** (one toluene per molecule of **4**), which do not escape from the crystal lattice at ambient temperature, as indicated by elemental analysis results.

Luminescent Properties

When irradiated by UV light, ttab emits a bright blue light both in solution and in the solid state. The emission maximum of ttab in a CH_2Cl_2 solution is at 377 nm when the concentration of the solution is approximately 10^{-4} M, while at high concentrations a significant red shift is observed (e.g. 0.10 M solution, emission maximum at approximately 463 nm), which can be attributed to intermolecular interactions or excimer emission. Compound **1** shows no detectable luminescence in solution or in the solid state, attributable to the quenching by the Pd^{II} ion. Compound **2** is blue luminescent in solution and in the solid state (λ_{max} = 380 nm). Compound **3a** is blue luminescent in the solid state with the emission maximum at 432 nm. The substantial red shift of the emission band of **3a**, compared to that of free ttab in solution, is clearly caused by intermolecular interactions in the solid state. Due to the insolubility of **3a** in most solvents, no spectrum was recorded in solution. Compound **3b** does not display any significant luminescence in the solid state, weak blue luminescence from **3b** in solution was observed (λ_{max} = 375 nm). The emission spectra of ttab, **2**, **3a**, **3b** and **4** are shown in Figure 6. The emission maximum of **2** (375 nm) in a CH_2Cl_2 solution (approx. 10^{-4} M) is essentially the same as that of the free ligand ttab. The emission bands of **2** and **3b** in solution at the same concentration resemble that of the free ttab ligand in solution, indicating that they are all ttab-based emissions. However, the intensity of the emission bands of **2** and **3b** is much weaker than that of the free ttab under the same conditions, indicating that the Zn^{II} ion and the Ag^{I} ion partially quench the emission from the ttab ligand. Compound **4** displays blue luminescence in solution. However, the emission spectrum of **4** recorded in CH_2Cl_2 is blue-shifted by about 20 nm, compared to that of the free ttab ligand recorded under the same conditions. Furthermore, the emis-

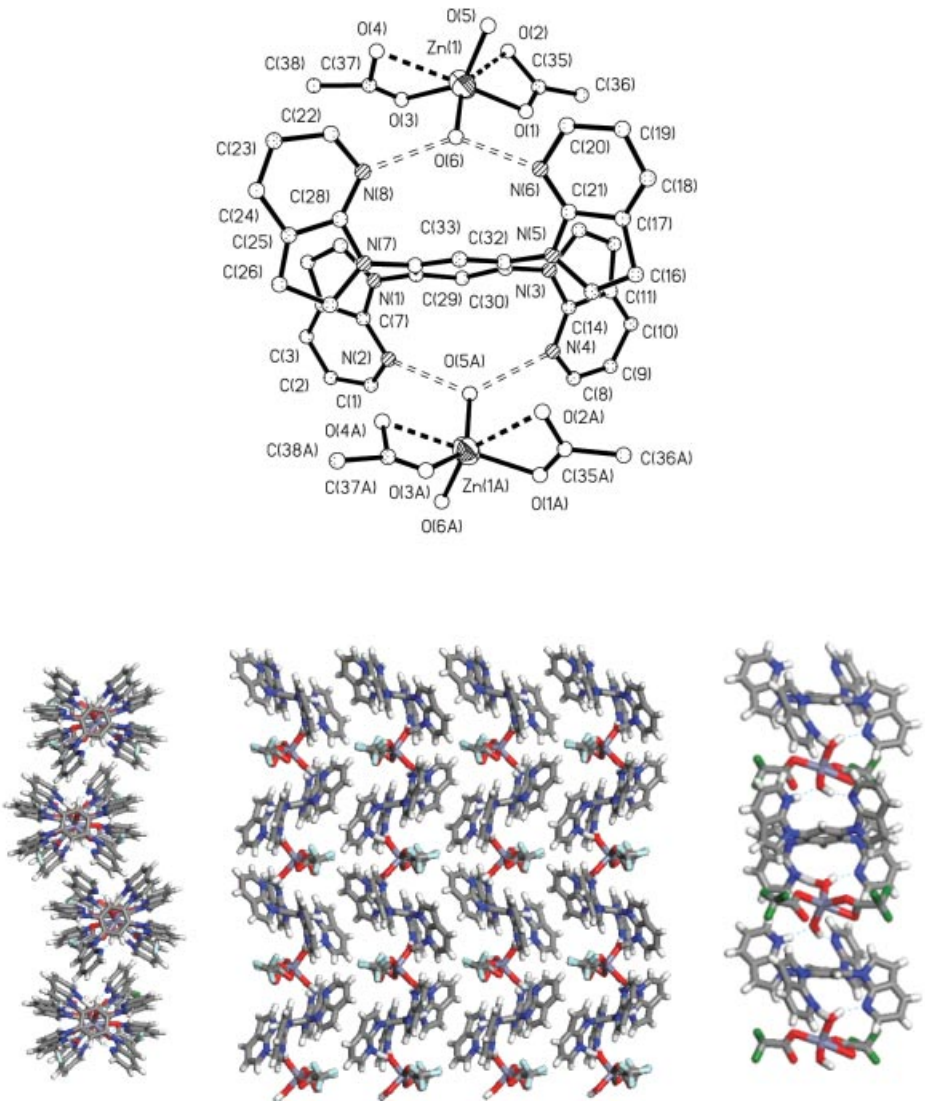

Figure 5. Top: a diagram showing the structure of **4** with labeling schemes (a second $[Zn(O_2CCF_3)_2(H_2O)_2]$ unit from a neighboring molecule is also shown to demonstrate the hydrogen bond pattern.); for clarity, the disordered fluorine atoms are omitted and all atoms except zinc are shown as ideal spheres; bottom, right: the hydrogen bond linked 1D chain; left: the view projected down the 1D chain; middle: the packing of the 1D chains in the lattice

sion intensity of **4** is about 1% of the intensity of the free ttab ligand. These experimental observations provide further support for the presence of hydrogen-bonding interactions between the $[Zn(O_2CCF_3)_2(H_2O)_2]$ group and the ttab ligand in solution. This appears to partially quench the emission of the ttab ligand.

In summary, both the *meta* and *ortho* coordination modes of the ttab ligand were established. The cyclometallated bonding mode was not observed for the ttab ligand. Both the coordination geometry of the metal ion and the nature of the surrounding ligands appear to influence the bonding mode of the ttab ligand. The unusual extended structures displayed by the complexes of the ttab ligand and its hydrogen-bonded compound were demonstrated. The fact that these extended structures have the tendency to host solvent molecules makes these compounds potentially useful for applications in host-guest chemistry. The Pd^{II} ion appears to be capable of completely quenching the lumi-

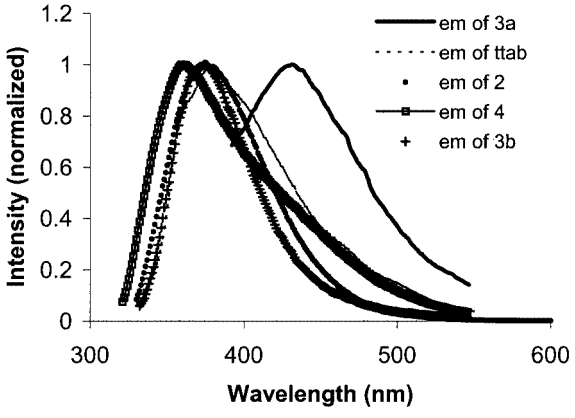

Figure 6. The emission spectra of ttab (1.0×10^{-4} M, CH_2Cl_2), **2** (1.0×10^{-4} M, CH_2Cl_2), **3a** (solid), **3b** (1.0×10^{-4} M, DMSO) and **4** (1.0×10^{-4} M, CH_2Cl_2)

nescence of the ttab ligand while the Zn^{II} and Ag^{I} ions partially quench the emission of the ttab ligand. Hydrogen-bonding interactions also lead to the significant quenching of the ttab luminescence. The sensitivity of the ttab luminescence toward various metal ions and hydrogen-bonding interactions makes it potentially useful as a fluorescent sensor for certain metal ions and molecules, which are being investigated in our laboratory.

Experimental Section

All the starting materials were purchased from Aldrich Chemical Co. THF was dried by refluxing over sodium and was freshly distilled prior to use. All the other reagent-grade solvents were used without further purification. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker Advance 300 or 500 MHz spectrometer. Excitation and emission spectra were recorded on a Photon Technologies International QuantaMaster Model 2 spectrometer. Elemental analyses were performed by Canadian Microanalytical Service, Ltd, Delta, British Columbia.

Synthesis of $[(PdCl_2)_2(ttab)]$ (1): A solution of ttab (0.20 mmol, 0.108 g) in 20 mL of CH_3CN was added to a solution of K_2PdCl_4 (0.40 mmol, 0.130 g) in a minimum amount of water. The mixture was stirred at room temperature for 0.5 h, and the yellow precipitate was collected by filtration and washed with CH_3OH and diethyl ether. Recrystallization of the crude product from DMSO yielded orange crystals of **1** (0.204 g 97%). ^{1}H NMR (500 MHz, [D$_6$]DMSO, 25 °C): δ = 8.93 (d, *J* = 5.0 Hz, 4 H, 7-aza), 8.17 (s, 2 H, phenyl), 8.14 (d, *J* = 7.0 Hz, 4 H, 7-aza), 7.70 (d, *J* = 3.5 Hz, 4 H, 7-aza), 7.29 (dd, *J* = 7.0, *J* = 5.0, 4 H, 7-aza), 6.76 (d, *J* = 3.5 Hz, 4 H, 7-aza) ppm. ^{13}C NMR: δ = 147.4, 145.6, 137.7, 136.7, 132.3, 131.3, 122.3, 117.7, 103.4 ppm. $C_{34}H_{22}Cl_4N_8Pd_2{\cdot}2DMSO$ (1053.52): calcd. C 43.32, H 3.25, N 10.64; found C 42.85, H 3.20, N 10.48.

Synthesis of $[(ZnCl_2)_2(ttab)]$ (2): Anhydrous $ZnCl_2$ (0.054 g, 0.4 mmol) and ttab (0.108 g, 0.2 mmol) were mixed in 20 mL of THF and stirred overnight under nitrogen. The white precipitate formed was collected by decanting the solution, it was washed with THF and dried under vacuum to afford a white powder of **2** (0.148 g, 91%). ^{1}H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 9.14 (dd, *J* = 5.5, *J* = 1.5 Hz, 4 H, 7-aza), 8.16 (dd, *J* = 8.0, *J* = 1.5 Hz, 4 H, 7-aza), 7.74 (d, *J* = 4.0 Hz, 4 H, 7-aza), 7.55 (s, 2 H, phenyl), 7.30 (dd, *J* = 8.0, *J* = 5.5 Hz, 4 H, 7-aza), 6.72 (d, *J* = 4.0 Hz, 4 H, 7-aza) ppm. ^{13}C NMR (CD_2Cl_2, 25 °C): δ = 147.9, 145.2, 139.3, 136.1, 134.3, 131.7, 124.7, 117.5, 104.1 ppm. $C_{34}H_{22}Cl_4N_8Zn_2{\cdot}0.5CH_2Cl_2$ (857.66): calcd. C 48.32, H 2.70, N 13.07; found C 48.56, H 2.73, N 13.02.

Synthesis of $[Ag_2(NO_3)_2(ttab)]_n$ (3a): A solution of $AgNO_3$ (0.50 mmol, 0.085 g) in 5 mL of H_2O was layered on top of a solution of ttab (0.10 mmol, 0.0542 g) in 5 mL of CH_2Cl_2. After 12 days standing at ambient temperature, the white precipitate formed was collected and washed with H_2O, ethanol and then CH_2Cl_2, and dried under vacuum to afford **3a** (0.064 g, 73%). Compound **3a** is not soluble in non-coordinating solvents. As a result, NMR spectra were not recorded. $C_{34}H_{22}Ag_2N_{10}O_6$ (882.32): calcd. C 46.28, H 2.51, N 15.87; found C 46.91, H 2.65, N 15.75.

Synthesis of $[Ag_2(NO_3)_2(ttab)(DMSO)_2]$ (3b): Upon dissolution in DMSO under sonication, **3a** was converted into **3b** quantitatively. ^{1}H NMR (300 MHz, DMSO, 25 °C): δ = 8.50 (s, 2 H, phenyl), 8.24 (d, *J* = 4.5 Hz, 4 H, 7-aza), 8.08 (d, *J* = 7.5 Hz, 4 H, 7-aza), 7.24 (dd, *J* = 7.8, *J* = 4.8 Hz, 4 H, 7-aza), 7.10 (d, *J* = 3.0 Hz, 4 H, 7-aza), 6.52 (d, *J* = 3.6 Hz, 4 H, 7-aza) ppm. ^{13}C NMR: δ = 146.6, 143.6, 132.4, 129.7, 128.6, 128.1, 121.3, 117.0, 102.2 ppm. The CHN analysis results for **3b** are identical to those of **3a**, due to the loss of DMSO ligands prior to the analysis.

Synthesis of $[Zn(O_2CCF_3)_2(H_2O)_2]$(ttab) (4): $Zn(CF_3COO)_2 \cdot 3H_2O$ (0.079 g, 0.23 mmol) and ttab (0.070 g, 0.13 mmol) were dissolved in 20 mL of THF at ambient temperature. Slow diffusion of toluene into the solution afforded colorless crystals of **4**. (0.114 g, 91%). ^1H NMR (300 MHz, CD_2Cl_2, 25 °C): δ = 8.49 (br. s, 4 H, H_2O), 8.17 (s, 2 H, phenyl), 8.10 (d, J = 4.2 Hz, 4 H, 7-aza), 7.25 (m, 8 H, 7-aza), 7.11 (d, J = 3.6 Hz, 4 H, 7-aza), 6.56 (d, J = 3.6 Hz, 4 H, 7-aza) ppm. For comparison purposes, the ttab free ligand ^1H NMR spectroscopic data are also included here (CD_2Cl_2, 25 °C): δ = 8.25 (s, 2 H, phenyl), 8.16 (dd, ^3J = 5.0, ^4J = 1.5 Hz, 4 H, 7-aza), 7.85 (dd, ^3J = 7.5, ^4J = 1.5 Hz, 4 H, 7-aza), 7.05 (dd, $^3J_1$ = 7.5, $^3J_2$ = 5.0 Hz, 4 H, 7-aza), 6.98 (d, ^3J = 3.5 Hz, 4 H, 7-aza), 6.37 (d, ^3J = 3.5 Hz, 4 H, 7-aza) ppm. $C_{38}H_{26}F_6N_8O_6Zn \cdot C_7H_8$ (962.20): calcd. C 56.17, H 3.56, N 11.65; found C 55.94, H 3.44, N 11.98.

X-ray Crystallographic Analysis: Single crystals of ttab were obtained by slow diffusion of hexanes into a CH_2Cl_2 solution. Single crystals of **1** were obtained from a saturated DMSO solution. Single crystals of **2** were obtained from a CH_2Cl_2 solution. Single crystals of **3b** were obtained by slow diffusion of toluene and ethanol into a DMSO solution. Single crystals of **4** were obtained from a toluene/THF solution. All crystals were mounted on glass fibers. All data were collected on a Bruker P4 X-ray diffractometer with a SMART CCD 1000 detector, with monochromated Mo-K_α radiation, operating at 50 kV, 30 mA and ambient temperature. No significant decay was observed during the data collection. Data were processed on a Pentium PC using Bruker Axs Windows NT SHELXTL software package (version 5.10).[9] Neutral atom scattering factors were taken from Cromer and Waber.[10] Empirical absorption correction was applied to all crystals. The crystals of ttab and **2** belong to the triclinic space group $P\bar{1}$. The crystals of **1** and **3b** belong to the monoclinic space groups $P2_1/n$ and $P2_1/c$, respectively. The crystals of **4** belong to the orthorhombic space group $Pca2_1$. All structures were solved by direct methods. DMSO molecules were located in the lattice of **1** (2 DMSO per molecule of **1**). Disordered CH_2Cl_2 molecules were located in the lattice of **2** (4 CH_2Cl_2 per molecule of **2**). Toluene molecules were located in the lattice of **3b** and **4** (2 toluene per molecule of **3b**, 1 toluene per molecule of **4**). There are 1.5 independent molecules in the asymmetric unit of ttab. The disordered nitrate ions of **3b** and the CH_2Cl_2 molecules that co-crystallized with **2** were modeled successfully. All non-hydrogen atoms in **1**−**3b** were refined anisotropically except for the disordered nitrate ion, the co-crystallized toluene and CH_2Cl_2 molecules. The quality of the crystals of **4** is poor and partially twin. The CF_3 groups in **4** are all disordered. As a result, not all non-hydrogen atoms in **4** can be refined anisotropically. The positions of the hydrogen atoms were calculated and their contributions in structural factor calculations were included. The crystal data are summarized in Table 2. (The crystal data for the free ttab ligand are provided in the supporting information).

CCDC-213370 (**1**), -213371 (**3b**), -213372 (**4**), and -213374 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information Available (see footnote on the first page of this article): A complete drawing of compound **3b** and the excitation and emission spectra.

Syntheses, Structures, and Properties of Two-Dimensional Honeycomb Networks from the Assembly of the Tripodal Ligand 2,4,6-Tris[4-(imidazol-1-ylmethyl)phenyl]-1,3,5-triazine with Metal Salts

Shuang-Yi Wan,[a] Yi-Zhi Li,[a] Taka-aki Okamura,[b] Jian Fan,[a] Wei-Yin Sun,*[a] and Norikazu Ueyama[b]

Keywords: Tripodal ligands / Zinc / Nickel / Supramolecular chemistry / Organic-inorganic hybrid composites

Two novel coordination networks, $[Zn_2(timpt)_2(\mu\text{-}OH)](NO_3)_3$ (**1**) and $[Ni_2(timpt)_2(H_2O)_2(SO_4)_2]\cdot 0.5H_2O$ (**2**) were obtained by assembly of 2,4,6-tris[4-(imidazol-1-ylmethyl)phenyl]-1,3,5-triazine (timpt) with the corresponding metal salts. The X-ray single-crystal diffraction analysis reveals that complex **1** possesses μ-OH-bridged dinuclear zinc(II) subunits (Zn_2OH) and each timpt ligand connects three metal atoms to form a two-dimensional (2D) honeycomb network structure, in which each independent sheet contains two sublayers. While in the case of complex **2**, the nickel(II) atom is coordinated by N atoms of timpt, O atoms of sulfate anions and water molecules to give a 2D honeycomb network. The luminescence properties of timpt, **1** and **2** in the solid state were investigated at room temperature. The maximum emission wavelength of **1** is red-shifted by 17 nm compared with that of timpt. While complex **2** showed an emission with remarkably reduced intensity under the same conditions. The results imply that the metal ions have great influence on the structure and properties of the complexes.

Introduction

Employing multidentate organic ligands and suitable metal salts to construct supramolecular architectures has been a major strategy in recent years.[1] Metal-organic frameworks (MOFs) with specific topologies such as cage-like structures, honeycomb and interpenetrating networks have been obtained by self-assembly of suitable metal salts with rigid or flexible tripodal ligands, for example 1,3,5-tricyanobenzene,[2] 1,3,5-tris(4-ethynylbenzonitrile)benzene,[3] 2,4,6-tris(4-pyridyl)-1,3,5-triazine,[4] 1,3,5-benzenetricarboxylate,[5] 1,3,5-benzenetribenzoate,[6] 1,3,5-tris(pyrazol-1-ylmethyl)-2,4,6-triethylbenzene,[7] 1,3,5-tris(4-pyridylmethyl)benzene,[8] 1,3,5-tris(benzimidazol-1-ylmethyl)-2,4,6-trimethylbenzene.[9] In contrast to the rigid tripodal ligands with little or no conformational changes when they interact with metal salts, the flexible tripodal ligands have much more possible coordination modes than the rigid ones due to their flexibility and low symmetry, since the flexible ligands can adopt different conformations according to the geometric needs of different metal ions. Accordingly, we designed and synthesized a series of flexible tripodal ligands with aromatic core rings as spacers and systematically investigated their assembly reactions with metal salts.[10] Most recently, we prepared a novel nanometer-sized tripodal ligand 2,4,6-tris[4-(imidazol-1-ylmethyl)phenyl]-1,3,5-triazine (timpt) which reacted with $Pb(NO_3)_2$ to give a two-dimensional (2D) 4.8^2 network with threefold interpenetrations.[11] We report herein two novel 2D honeycomb coordination polymers $[Zn_2(timpt)_2(\mu\text{-}OH)](NO_3)_3$ (**1**) and $[Ni(timpt)_2(H_2O)_2(SO_4)_2]\cdot 0.5H_2O$ (**2**) obtained by solvothermal reactions of timpt with $Zn(NO_3)_2\cdot 6H_2O$ and $Ni(SO_4)_2\cdot 7H_2O$, respectively.

Results and Discussion

Crystal Structure Description

The structures of complexes **1** and **2** were determined by X-ray crystallography. The crystal and data collection parameters are summarized in Table 3 and selected bond lengths and angles are listed in Table 1.

Crystal Structure of 1

The complex crystallizes in rhombohedral space group of $R\bar{3}c$ and all the zinc(II) atoms have a tetrahedral coordination geometry with an N_3O donor set as illustrated in Figure 1. The three N atoms are from the imidazole groups

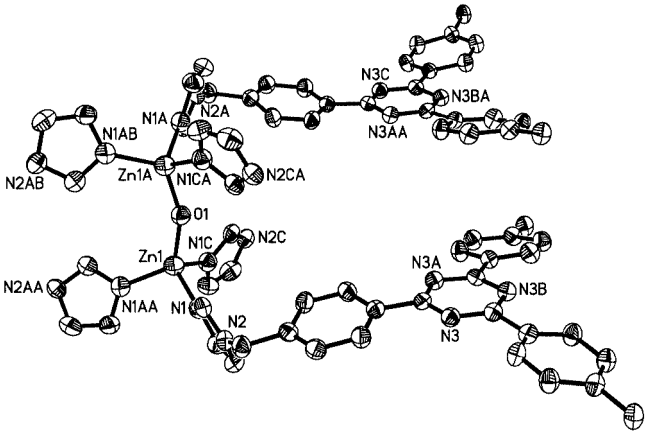

Figure 1. The coordination environment of Zn^{II} in **1**; thermal ellipsoids are drawn at 30% probability; the carbon atoms are unlabelled and hydrogen atoms are omitted for clarity

of three different timpt ligands with the Zn−N bond lengths of 2.001(3) Å. The fourth site was completed by an O atom from a hydroxy group which connects another zinc(II) atom to form a μ-hydroxy bridge. The Zn−O bond length is 1.874(2) Å which is slightly shorter than the Zn−O distances in the reported hydroxy-bridged zinc(II) complexes.[12] The Zn−O-Zn bond angle is 156.7° and the Zn···Zn distance is 3.67 Å, which are within the ranges of the reported Zn−O−Zn angles and Zn···Zn separations in the hydroxy-bridged zinc(II) complexes.[12] The N−Zn−N and N−Zn−O bond angles are ranging from 106.95(11) to 104.3(2)°, which are close to the ideal tetrahedral angle of 109.5°.

Each timpt ligand coordinated to three different zinc(II) atoms to form an equilateral triangle with an edge length (Zn···Zn separation) of 17.57 Å. Such units repeated along the *ab* plane to generate an infinite 2D honeycomb network as shown in Figure 2 (part a). It is noteworthy that two such networks are bridged by hydroxy groups through the Zn−O coordination bonds to form an independent layer (Figure 2, b). Namely, every independent 2D layer in complex **1** contains two sublayers which are connected by the hydroxy bridges. This is, to the best of our knowledge, the first example of 2D honeycomb networks in which each independent layer contains two sublayers linked by μ-hydroxy bridges through the M−O(H)−M (M represents the metal ion) bonds. Disordered nitrate anions are located between the two sublayers of an independent layer and held there by O(1B)−H(1AB)···O(3) (NO_3^-) with an O(1B)···O(3) distance of 3.269(12) Å and C−H···O (NO_3^-) hydrogen bonds with C···O distances of 3.381(15) and 3.398(11) Å (Figure 3, a). The 2D independent layers are closely stacked with each other and connected by the NO_3^- anions through the C−H···O hydrogen bond with C···O distance of 3.212(8) Å to produce a 3D framework as exhibited in Figure 3 (part b). The hydrogen-bonding data are summarized in Table 2.

In addition to the hydrogen bonds as mentioned above, there are weak π−π interactions between the benzene rings of the timpt ligands. The two benzene rings from two different ligands are nearly parallel with a dihedral angle of 2.2° and a centroid-to-centroid distance of 4.28 Å. The two tri-

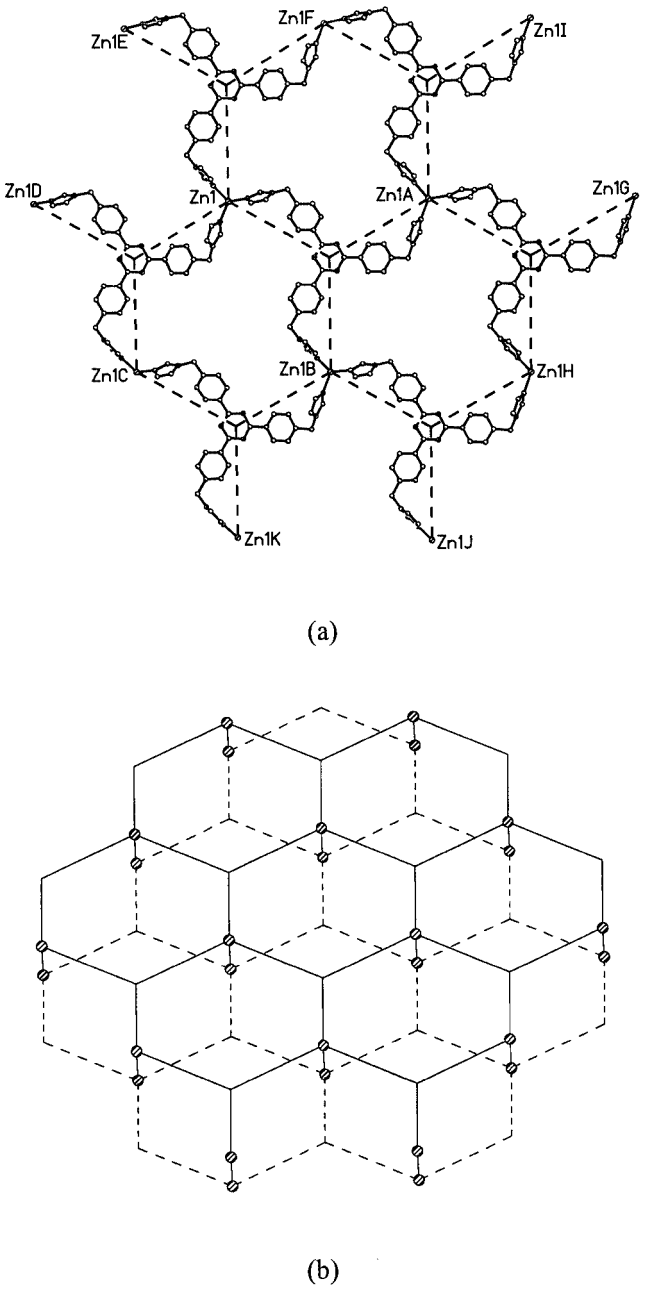

Figure 2. (a) The perspective view of the 2D cationic sublayer with the honeycomb structure (dashed lines) in the *ab* plane; (b) schematic drawing of 2D honeycomb network in which the timpt ligands are represented by three spokes radiating from a point and Zn centers by circles; the hydroxy bridges (Zn−O−Zn) are represented by solid lines; the solid and dashed lines refer to timpt ligands of each sublayer

azine rings of the two ligands of the neighboring sublayers of the two different layers adopt a face-to-face conformation and are strictly parallel to each other with a centroid-to-centroid distance of 3.44 Å, indicating the presence of π−π stacking interactions (Figure 4). The hydrogen bonding and π−π interactions as well as Zn−O−Zn bridges may play an important role in stabilizing the layered structures in the titled complex.

Crystal Structure of 2

In contrast to the tetrahedral coordination geometry of the zinc(II) atom in complex **1**, nickel(II) atoms usually adopt octahedral geometry when they interact with N-donor ligands. Thus, the reaction of timpt with nickel(II) sulfate was carried out and complex **2** was obtained. From the X-ray analysis, it is interesting that there are two kinds of Ni^{II} atoms with different coordination environments: the Ni(1) atom is six-coordinate with a distorted octahedral geometry while the Ni(2) atom is five-coordinate with a distorted trigonal-bipyramidal geometry as shown in Figure 5. The Ni1 atom lies in the plane defined by the O(1), O(2), N(22), and N(112) atoms since the deviation of Ni(1) from this plane is 0.08 Å. Three of the six sites of Ni(1) are coordinated by three N atoms of imidazole groups from three different timpt ligands with Ni−N bond lengths varying from 2.033(5) to 2.078(4) Å (Table 1), and the remaining three sites are occupied by O atoms from a monodentate sulfate anion and two water molecules. The Ni(2) atom lies above the plane of the O(21), N(122), and N(132) atoms by 0.23 Å. The three sites of Ni(2) are coordinated by three imidazole-group N atoms with Ni−N bond lengths ranging from 1.978(5) to 2.024(4) Å, while the additional two sites are completed by two O atoms of a sulfate anion in a bidentate mode.

An infinite 2D honeycomb network sheet of **2** is achieved by the coordination of the timpt ligands to Ni^{II} atoms as shown in Figure 6. The triangles formed by three Ni^{II} atoms connected by one timpt ligand are non-equilateral which are different from those observed in complex **1**. Furthermore, there are two kinds of triangles in **2**: one is formed by two five-coordinate Ni atoms and one six-coordinate Ni^{II} atom with the edge lengths of 19.85, 19.52, and 16.47 Å, respectively, e.g. Ni(2), Ni(2B), and Ni(1B) in Figure 6; another one is formed by one five-coordinate Ni^{II} atom and two six-coordinate Ni^{II} atoms [e.g. Ni(2B), Ni(1A), and Ni(1C) in Figure 6] with the edge lengths of 19.19, 19.11, and 16.47 Å, respectively. Disordered water molecules are located in the voids between the adjacent sheets through C−H···O hydrogen bonds (Table 2). The 2D honeycomb sheets are linked through the C−H···O (coordinated water molecules and sulfate anions) hydrogen-bonding interactions to form a 3D structure (Figure 7).

Face-to-face π−π interactions were found between the triazine rings of the two layers since the two triazine ring planes are strictly parallel to each other with a centroid-to-centroid distance of 3.86 Å. In addition, π−π interactions are also found between the triazine rings and the benzene rings of two adjacent layers. The dihedral angle between them is 11.8° and the centroid-to-centroid separation is 3.88 Å (Figure S1 in Supporting Information, see footnote on page 1 of this article).

Although both complexes **1** and **2** have the honeycomb network structures, there are distinct differences between these two complexes. First, they crystallize in different crystal systems with **1** in rhombohedral $R\bar{3}c$ and **2** in triclinic $P\bar{1}$. Another important difference is that each independent layer in **1** contains two sublayers which feature the honey-

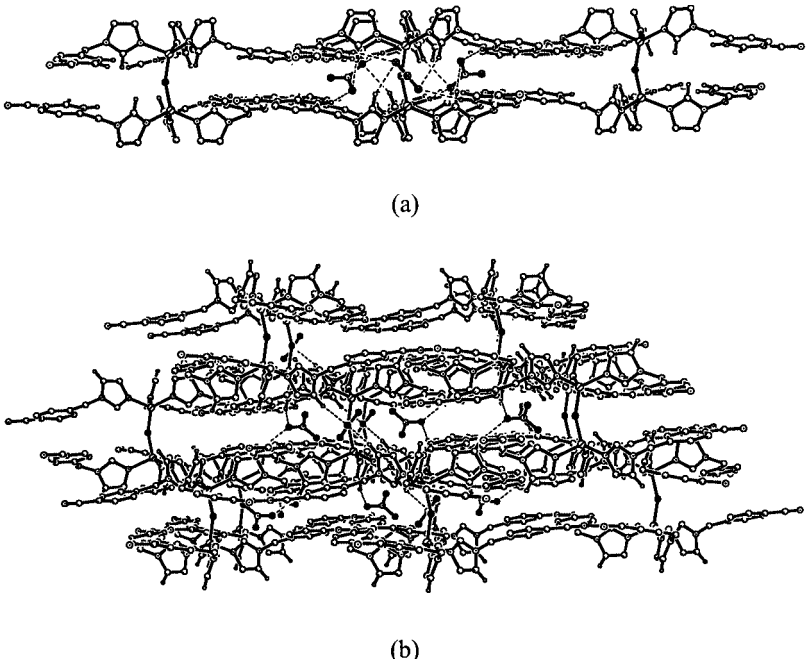

Figure 3. (a) View of an independent layer with nitrate anions located within the layer through hydrogen bonds (dashed lines); (b) crystal packing diagram of **1**; the two adjacent independent layers are connected by nitrate anions through hydrogen-bonding interactions

comb structures and are connected by hydroxy bridges, while **2** contains no sublayers. Furthermore, the conformations of the timpt ligand in **1** and **2** are obviously different. In complex **1**, the dihedral angle between the central triazine ring plane and the benzene ring plane is 12.6°. While the one between the terminal imidazole ring plane and the benzene ring plane is 109.4°, indicating a near perpendicular orientation of the imidazole ring plane to the benzene ring plane (Figure 2, a). The plane defined by three coordinated imidazolyl N atoms of one timpt ligand is parallel to the triazine ring plane with a separation of 1.35 Å. In the previously reported metal complexes of 1,3,5-tris(imidazol-1-ylmethyl)-2,4,6-trimethylbenzene (timtb) with *cis*,*cis*,*cis* conformation, the distance between the plane defined by three coordinated imidazolyl N atoms and the central benzene ring plane is ca. 3.1 Å.[10f,10g] Therefore, the conformation of timpt in **1** is a propeller-type rather than *cis*,*cis*,*cis* or *cis*,*trans*,*trans* as observed in complexes of timtb (Scheme 1).[10] In complex **2**, the three coordinated imidazolyl N atoms of the timpt ligand are at both sides of the central triazine ring plane and the dihedral angles between the plane defined by the three N atoms and the triazine ring plane are 16.9 and 19.8°, respectively, since there are two kinds of timpt ligand in **2** as mentioned above. This causes the backbone of complex **2** to be different from that of **1**. In addition, the vacancies between the two sublayers in **1** are occupied by nitrate anions, while in the case of **2**, the sulfate anions are coordinated with the Ni^{II} atoms and the voids between the 2D layers are filled with disordered lattice water molecules.

In the reported 2D coordination polymers with honeycomb structures, rigid tripodal ligands, e.g., 1,3,5-tricyanobenzene or 1,3,5-benzenetricarboxylate, enclosing an angle of 120° were used to link the linear metal centers.[2,5] In our previously reported honeycomb complexes, the flexible tripodal ligand timtb with the *cis*,*cis*,*cis* conformation, connected three six-coordinate metal centers to direct the formation of the 2D honeycomb network.[10f] However, in the present case, the metal atom in **1** is four-coordinate with three sites occupied by three N atoms from three ligands and the fourth site finished by a hydroxy O atom. If the Zn−O−Zn units are considered as one metal center M, then the metal center M is six-coordinate and the backbone of **1** is identical with those of the complexes with honeycomb structures reported previously.[10f] However, the backbone of **2** is different from **1** and other reported complexes with timtb ligand.[10f]

Luminescent Properties

The photoluminescence studies of timpt, **1** and **2** in the solid state under the same conditions showed that, although the maximum-excitation wavelengths of the complexes **1** and **2** are the same as that of the timpt ligand at 396 nm, the maximum emission wavelength of **1** is red-shifted by 17 nm from 443 to 460 nm compared with that of the ligand, accompanied by an increase of luminescent intensity (Figure 8). However, the maximum-emission wavelength of **2** is red-shifted by 25 nm from 443 to 468 nm relative to that of the ligand, accompanied by a greatly decreased luminescent intensity. The red shift of emission maxima

Conclusion

The present study evidences that flexible tripodal ligands are efficient in constructing novel coordination networks with metal salts. The nanometer-sized flexible tripodal ligand timpt, using its imidazolyl N atoms, coordinates to metal atoms to form 2D coordination polymers with honeycomb network structures. In the zinc(II) complex **1**, each independent layer has two sublayers which are linked by hydroxy bridges through Zn−O coordination bonds. The emission maximum of timpt is red-shifted and the intensity is enhanced by coordination of timpt with zinc(II) nitrate. While in the case of the Ni^{II} complex of timpt (**2**), the luminescent intensity was remarkably reduced compared with that of timpt. The results show that the metal ions have great influence on the structure and properties of the timpt complexes.

Experimental Section

General: The timpt ligand was synthesized as described previously.[11] All the chemicals were of reagent grade and used as received without further purification. C, H, and N analyses were carried out with a Perkin−Elmer 240C elemental analyzer at the analysis center of Nanjing University. Luminescence spectra for the solid samples were recorded with a Hitachi 850 fluorescence spectrophotometer at room temperature (25 °C). TGA measurement was performed with a simultaneous SDT 2960 thermal analyzer under nitrogen with a heating rate of 10 °C·min^{-1}.

Synthesis of $[Zn_2(timpt)_2(\mu\text{-}OH)](NO_3)_3$ (1): The complex was prepared by solvothermal reaction. The timpt ligand (61.9 mg, 0.11 mmol) was added to a water/ethanol (6:1, v/v) solution (14 mL) of $Zn(NO_3)_2{\cdot}6H_2O$ (46.0 mg, 0.15 mmol). After stirring at room temperature for ca. 15 min, the reaction mixture was transferred to an autoclave and kept at 150 °C for 3 d. Light yellow cubic crystals (50.2 mg) were obtained in 62% yield (based on ligand) after cooling the autoclave. $C_{66}H_{55}N_{21}O_{10}Zn_2$ (1433.05): calcd. C 55.32, H 3.87, N 20.52; found C 55.49, H 3.82, N 20.55.

Synthesis of $[Ni_2(timpt)_2(H_2O)_2(SO_4)_2]{\cdot}0.5H_2O$ (2): Complex **2** was synthesized in a similar manner to that of **1**. The timpt ligand (28.3 mg, 0.052 mmol) was added to a water/ethanol (6:1, v/v) solu-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion (14 mL) of $NiSO_4 \cdot 7H_2O$ (15.7 mg, 0.056 mmol). After stirring at room temperature for ca. 15 min, the reaction mixture was placed in an autoclave and kept at 150 °C for 1 d. Green plate crystals (23.0 mg) were obtained in 61% yield (based on ligand) after cooling the autoclave. $C_{66}H_{59}N_{18}Ni_2O_{10.5}S_2$ (1453.81): calcd. C 54.53, H 4.09 N 17.34; found C 54.57, H 4.17, N 17.31. TGA data of **2** show that the weight loss of 3.06% between 10 and 90 °C corresponds to the loss of 2.5 water molecules per molecule of **2** (calcd. 3.10%). No further weight loss was observed from 90 to 310 °C.

X-ray Crystal Structure Analysis for Complexes 1 and 2: Data collection for **1** (Table 3) was performed with a Smart Apex CCD diffractometer at 293 K, using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). The structure was solved by direct methods with SHELXTL and refined by full-matrix least-squares calculations. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated geometrically. The O1 atom of the hydroxy ion is disordered in three positions [O(1), O(1A), and O(1B)], each assigned 1/3 site occupancy. The O(2) and O(3) atoms of the nitrate anion are disordered in two positions, each with 1/2 site occupancy. The intensity data for complex **2** (Table 3) were collected with a Rigaku RAXIS-RAPID Imaging Plate diffractometer at 200 K, using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). The structure was solved by direct method with SIR92, and expanded with Fourier techniques. All data were refined anisotropically by full-matrix least-squares calculations for non-hydrogen atoms. The hydrogen atoms were generated geometrically except those of water molecules. CCDC-201837 (**1**) and -201838 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Theoretical Search for Anions Possessing Large Electron Binding Energies

Monika Sobczyk,[a] Agnieszka Sawicka,[a,b] and Piotr Skurski*[a,b]

Keywords: Anions / Superhalogens / Electron-binding energy

The vertical electron detachment energies (VDE) of several anions were calculated at the OVGF level with 6-311++G(d) basis sets. The negatively charged species studied were chosen based on the observation that the largest electron binding energies for such systems are expected to be found for the anions whose neutral parents are polynuclear superhalogens. The largest vertical electron binding energy of 12.63 eV was found for $Ta_3F_{16}^-$, and this is the largest excess electron binding energy of a molecular system reported in the literature thus far. Moreover, the VDEs of 12.63 and 12.20 eV calculated for $Ta_3F_{16}^-$ and $As_3F_{16}^-$, respectively, exceed the upper limit for the excess electron binding energy (thought to be 12 eV). Several other anions were also found [at the OVGF/6-311++G(d) level] to possess very large VDEs (i.e. $Al_2Br_7^-$: 7.08 eV, $Al_2Cl_7^-$: 7.75 eV, $Al_2F_7^-$: 11.16 eV, $P_2F_{11}^-$: 10.95 eV, $V_2F_{11}^-$: 10.98 eV, $As_2F_{11}^-$: 11.43 eV, and $Ta_2F_{11}^-$: 11.84 eV).

1. Introduction

The electron affinities of molecules are of interest not only in areas where gas-phase ions are encountered (e.g. negative-ion analytical mass spectrometry, gas-phase radiation chemistry, and electron capture detector gas chromatography), but also in the much wider field of condensed-phase chemistry.[1] Since molecular systems exhibiting extreme characteristics are of particular interest from both theoretical and practical points of view, the molecules possessing large electron affinities (EA) have been extensively studied in the past, primarily by Gutsev and Boldyrev.

It is well-known that halogen atoms possess the highest electron affinities among the elements (fluorine 3.40 eV, chlorine 3.62 eV).[2] However, the EA of a polyatomic system may exceed the 3.62 eV limit due to collective effects. Such species are of great importance in chemistry since they can be used for the oxidation of counterpart systems with relatively high ionisation potentials (such as O_2, Xe) and allow the synthesis of unusual chemical compounds (e.g. those involving noble gases atoms). In addition, molecules possessing high electron affinities are widely used in the production of organic super-conductors.[3,4]

Such species have been attracting the attention of chemists since the early 60's; however, the term *superhalogens* for these species was proposed by Gutsev and Boldyrev as late as 1981. Further, they introduced a simple formula for one class of these compounds, MX_{k+1}, where M is a main group or transition metal atom, X is a halogen atom, and k is the maximal formal valence of the atom M.[5] This work was of great importance since Gutsev and Boldyrev not only provided theoretically estimated electron binding energies of superhalogen-based anions, but they also explained the reason for the increase in the vertical electron detachment energy (VDE) of MX_{k+1}^- relative to X^-. These reasons include: (i) the delocalisation of the extra electron over $k+1$ halogen atoms instead of one only, (ii) the non-bonding character of the highest occupied molecular orbital (HOMO), (iii) the coordination of the X^- anion to the electropositive ion M^{k+} (electrostatic effect), and (iv) the stabilising electron relaxation and correlation effects.[5]

Since the early 80's many other theoretical studies have been undertaken to estimate the VDEs of various anions having superhalogens as their neutral parents (see refs.[6–9] and references cited therein). Major progress was made in 1999 in the investigations involving superhalogen systems due to the joined theoretical and experimental studies. This resulted in an excellent report comprising the first experimental photoelectron spectra of superhalogens (measured by Wang's group), together with theoretical interpretations provided by Boldyrev and Simons.[10] In particular, the photoelectron spectra of the anions MX_2^- (where M = Li, Na, and X = Cl, Br, I) have been obtained and assigned on the basis of ab initio outer valence Green function (OVGF) calculations. An excellent agreement between experimentally and theoretically estimated values of VDEs has been achieved, and all the anions have been proven to be superhalogen–based species since their electron binding energies were found to be greater than 3.62 eV (see ref.[10] for details).

Recently, Schaefer's group studied the electron affinities of arsenic fluorides AsF_n (n = 1–6), from which they deduced that the AsF_6^- anion has a very large vertical elec-

tron detachment energy (VDE = 7.95−10.54 eV, depending on the density functional method used).[9]

It should be noted that although there are many theoretical results for superhalogen anions available, most were obtained in the 80's when computational resources limited the level of the calculations. In particular, early discrete−variational X_a-method (DV-X_a) calculations led to underestimated values of the VDEs of many superhalogen anions. However, it should be stated that the main goal of these investigations was to prove that such species indeed exhibit extremely large electron binding energies, rather than to provide precise vertical detachment energies.[5,6]

The problem of estimating the maximum possible electron binding energy for a molecular system was raised by Gutsev and Boldyrev in the 80's.[6] Naturally, these two authors began their theoretical search for the species possessing extremely large VDE values by investigating the superhalogen anions. From their experience in examining such negatively charged molecules, they concluded that the anion should contain the maximum possible number of fluorine atoms as ligands. This issue has also been discussed by Kalcher and Sax,[12] who investigated the relationship between the EA of a molecule M and the ionisation potential (IP) of the same molecule. On the basis of the observation that the IP of a given molecule always exceeds its own EA, and that the IPs of some molecules (such as fluorides like CF_4, SiF_4, SF_6, etc.) are found to be in the range 15−17 eV, they concluded that the EA value in that range (i.e. 15−17 eV) should be considered as the upper limit for the electron affinity characterising the neutral molecular system. However, Kalcher and Sax admitted that neither theoretical nor experimental evidence could be provided for such high values.[12] In fact, this idea had been proposed earlier by Gutsev and Boldyrev who based their analysis on the anionic daughters of the MF_6 superhalogens in which the extra electron resides in a nonbonding orbital which is delocalised over all F ligands.[6,13] These authors observed that the EAs of such systems depend primarily on the F_k ligand framework (rather than the nature of the transition metal centre), and estimated that the maximum EA (EA_{max}) for $k = 2$ is 5.5 eV, $EA_{max} = 6.5$ eV for $k = 6$, and that the limiting EA value (i.e. for $k = \infty$) is 10−12 eV.[13]

The estimate of the maximum value possible for the EA, made originally by Gutsev and Boldyrev, is of great importance for studying the properties of the chemical species in general, and for designing novel super-conductors in particular. However, it should be stressed that despite determining the 12 eV limit, there is no evidence that any of the known (reliable) EA values approaches this ultimate theoretical value. In particular, the early calculations (using discrete-variational X_a-method) performed on As_2F_{11} and P_2F_{11} resulted in an EA of 8.6 eV (for both cases).[6] To the best of our knowledge, the only known VDE that approaches the 12 eV limit is that estimated by Boldyrev and Simons[14] for TeF_7^- (11.9 eV); however, it corresponds to the result calculated at the Koopmans' Theorem (KT)[15] level, which is not very accurate.[16]

In this paper we present the results of our theoretical search for anions that possess extremely large (i.e. approaching the 12 eV limit or above) electron binding energies. While performing our search, we followed the very interesting and valuable suggestions on designing such species described by Gutsev and Boldyrev,[6] which, in fact, allowed us to find the anions that exhibit such large VDEs. In particular, we focused our studies on the various polynuclear superhalogen anions, for which we calculated VDE values that may possibly be accurate.

2. Methods

Since our main goal was to calculate the vertical electron detachment energies for several anions, we limited our geometry optimization calculations to the closed-shell anionic species for which we also obtained harmonic vibrational frequencies at their minimum energy structures. For this purpose we applied the Hartree−Fock Self-Consistent Field method (SCF). Since the SCF method does not include electron correlation effects, we decided to test if this affects the equilibrium geometries of the anions studied. Therefore, for two cases (i.e. $Al_2F_7^-$ and $Al_2Cl_7^-$) we performed geometry optimization calculations (followed by the calculations of harmonic vibrational frequencies) at the second-order Møller−Plesset (MP2) perturbational level. We concluded that the equilibrium structures obtained with the SCF method are very similar to those calculated at the MP2 level (the average differences in bond lengths and valence angles did not exceed 0.2 Å and 0.5 deg, respectively). Since the possible inaccuracies in our vertical electron detachment energies (caused by using the SCF rather than MP2 geometries) was considered to be most important, we verified that our best VDE estimates (i.e. calculated with the outer valence Green function method) for $Al_2F_7^-$ and $Al_2Cl_7^-$ differ by less than 0.05 eV (which corresponds to 1% of the total VDE value) when obtained using the SCF and MP2 equilibrium anionic structures. Therefore, we concluded that using the SCF rather than MP2 geometries does not cause any significant errors in the systems studied in this work.

In order to obtain reliable vertical electron detachment energies of the superhalogen anions, a more accurate treatment of the data is required, thus we decided to perform both *direct* and *indirect* calculations of the electron binding energies. A *direct* scheme was based on applying the outer valence Green function (OVGF) method,[17,18] while the latter (*indirect*) approach involved subtracting the anion energies from those of the neutral species (both calculated at the same level of theory). In the *indirect* approach, we used the MP2 perturbational method. The core electrons were frozen when treating the electron correlation.

We applied the 6-311++G(d) basis sets[19,20] for the calculations of the equilibrium geometries and harmonic frequencies, and for estimating the vertical electron detachment energies at various levels, since analogous basis sets have recently been used for the BeX_3^- superhalogen anions

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(X = F, Cl, Br), which have provided reliable VDEs for these species.[21] However, it is important to note that applying the OVGF method with the 6-311++G(3df) basis sets would most likely provide better vertical electron detachment energies [as described in ref.[10] for LiX_2^- and NaX_2^- (X = F, Cl, Br, I), and in ref.[21] for BeX_3^- (X = F, Cl, Br)], since the OVGF/6-311++G(3df) treatment was found to produce an excellent agreement between such calculated and experimentally measured VDEs. Since the species studied in this work are relatively large (i.e. containing up to 19 heavy atoms) we had to employ the 6-311++G(d) basis set rather than the 6-311++G(3df) basis set. On the basis of our previous results [obtained for the BeX_3^- superhalogen anions (X = F, Cl, Br)],[21] we expect our final VDEs to be underestimated by less than 0.2 eV (which corresponds to ca. 1−2% of the vertical electron detachment energies).

All calculations were performed with the GAUSSIAN98 program[22] on Intel Pentium IV computers and an SGI Origin2000 numerical server.

3. Results

The theoretical and experimental results involving the superhalogen anions available in the literature relate mostly to *mononuclear systems* (i.e. those involving one central atom and several halogen ligands).[5−14,21] As we stated in Section 1, the mononuclear anionic system most likely possessing the largest vertical electron detachment energy that has been found thus far is TeF_7^-, for which the VDE of 11.9 eV was estimated (at the KT level) by Boldyrev and Simons.[14] Since the VDE of the superhalogen anion increases with the number of halogen ligands involved, one could explore this route in order to search for systems that maximise the VDE. However, one should recall that the TeF_7^- anion contains seven halogen atoms, and it is clear that attempts to search for another mononuclear anion involving larger number of ligands would be extremely difficult due to central atom valence saturation and topological limitations. Moreover, it has been shown that mononuclear species containing larger number of ligands, such as MnF_8^- or TcF_8^-, possess VDEs that are actually *smaller* than those of the anions MX_6^- or MX_7^- (the VDE values for MnF_8^- and TcF_8^- were found to be 6.7 and 5.8 eV, respectively).[6] Therefore, it seemed natural to examine whether the polynuclear superhalogen anions could exist as (geometrically and electronically) stable species since this would provide more than one central atom and hence would greatly increase the maximum number of halogen atoms in the system. This idea had been originally investigated as early as in 1987 by Gutsev and Boldyrev.[6] They proposed a few polynuclear superhalogen anions and estimated their VDEs.

The polynuclear superhalogen anions proposed by Gutsev and Boldyrev involved phosphorus, aluminium, arsenic, and vanadium as the central atoms and fluorine atoms as the ligands. On the basis of the DV-X_a calculations, they estimated the following electron binding energies: 8.6 eV

(for $P_2F_{11}^-$), 7.5 eV (for $Al_2F_7^-$), 8.6 eV (for $As_2F_{11}^-$), and 8.0 eV (for $V_2F_{11}^-$).[6] Moreover, Gutsev and Boldyrev concluded that exploring the polynuclear superhalogen species is a promising way of searching for systems with the maximum VDE value. Therefore, we decided to take a closer look at such species to examine whether VDE values that exceed the 12 eV limit (see Section 1) could be found.

3.1. Dinuclear Superhalogen Anions

We begin our discussion with the superhalogen anions that possess two central atoms and consider a few species that have been proposed earlier by Gutsev and Boldyrev (the VDEs of these species could not be estimated accurately in the past due to the rather limited computer resources available at the time).[6] In addition, we examine other ligands of $Al_2X_7^-$, such as chlorine and bromine, to verify (or confirm) whether F ligands indeed lead to the largest vertical electron detachment energies.

3.1.1. Equilibrium Geometries

The parameters defining the geometries corresponding to the minima on the potential energy surfaces for $Al_2F_7^-$, $Al_2Cl_7^-$, $Al_2Br_7^-$, $P_2F_{11}^-$, $V_2F_{11}^-$, $As_2F_{11}^-$, and $Ta_2F_{11}^-$ are presented in Table 1, and the equilibrium structures are depicted in Figure 1. In each case, the two central atoms (M) are linked via a halogen atom (X), and the M−X−M bond could be linear (as in $Al_2F_7^-$, $V_2F_{11}^-$, $As_2F_{11}^-$, and $Ta_2F_{11}^-$), quasi-linear (as in $P_2F_{11}^-$) or bent (as in $Al_2Cl_7^-$ and $Al_2Br_7^-$) (see Figure 1).

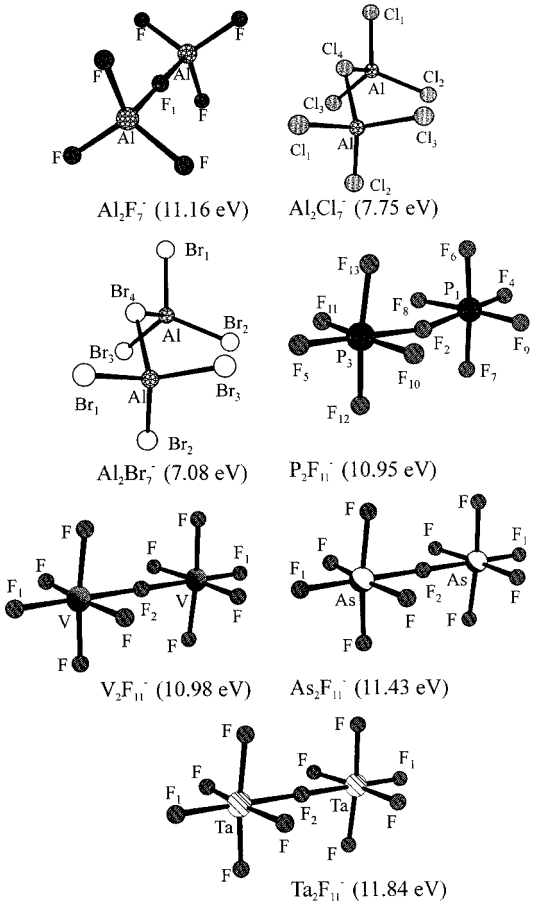

Figure 1. The SCF/6-311++G(d) equilibrium structures of the dinuclear superhalogen anions studied in this work. The corresponding OVGF/6-311++G(d) vertical electron detachment energies are given in parenthesis

The Al−F bond lengths in the $-AlF_3$ units in $Al_2F_7^-$ are shorter (by 0.1 Å) than the Al−F distances in the −Al−F−Al− fragment that serves as a bridge between the two subunits in this superhalogen anion. A similar observation can be made in the case of other dinuclear anions containing Al as the central atoms (see Table 1). Specifically, in the case of $Al_2Cl_7^-$ (and $Al_2Br_7^-$), the Al−Cl (Al−Br) bond lengths in the $-AlCl_3$ ($-AlBr_3$) units are shorter by ca. 0.2 Å than the Al−Cl (Al−Br) distances in the −Al−Cl−Al− (−Al−Br−Al−) fragment.

The P−F bonds in the $-PF_5$ subunits of the quasi-linear $P_2F_{11}^-$ structure are also shorter (by ca. 0.25 Å) than the P−F distances in the −P−F−P− fragment (see Table 1). An analogous situation can be observed in the case of all other dinuclear anions (i.e. $V_2F_{11}^-$, $As_2F_{11}^-$, and $Ta_2F_{11}^-$). The V−F bonds in the $-VF_5$ subunits of the $V_2F_{11}^-$ structure are shorter by ca. 0.2 Å than those in the −V−F−V− fragment connecting the two central atoms (see Table 1). A similar elongation (by ca. 0.2 Å) of the M−X distance is observed in $As_2F_{11}^-$ and $Ta_2F_{11}^-$ (see Table 1).

Since the corresponding harmonic vibrational frequencies for all the dinuclear superhalogen anions studied are positive (see Table 2), we conclude that each of these anionic structures is a true minimum on the potential energy surface, and this indicates the geometrical stability of such a system.

3.1.2. Vertical Electron Detachment Energies

The VDEs of all the dinuclear superhalogen anions studied in this work [calculated at the OVGF and MP2 levels with the 6-311++G(d) basis sets] are presented in Table 1. The second-order MP vertical electron detachment energies are usually smaller than those calculated at the OVGF level. This is consistent with the fact that the OVGF method approximately corresponds to the third-order perturbational treatment. Moreover, the largest discrepancies between MP2 and OVGF results were found for the superhalogens anion which had fluorine atoms as ligands.[21] This is also the case for the dinuclear superhalogen anions studied in this work (see Table 1). Therefore, we prefer to use the OVGF values in our discussion (given in this Section) since the OVGF treatment[23] has proven to produce a much better agreement between the calculated and experimentally determined electron binding energies of such species.[21]

Our results obtained for $Al_2X_7^-$ anions (X = F, Cl, Br) support the observation established earlier by others that species with fluorine ligands tend to have the largest VDE values (see Table 1). Indeed, the VDE calculated for $Al_2F_7^-$ is 11.16 eV, while those obtained for the analogous species with chlorine and bromine ligands are smaller (7.75 and 7.08 eV for $Al_2Cl_7^-$ and $Al_2Br_7^-$, respectively). To support this finding we calculated the vertical electron binding energies for mononuclear octahedral superhalogen anions hav-

ing phosphorus as a central atom. The results shown in Tables 3 and 4 indicate that the VDE of PF_6^- is relatively large (9.4 eV) and decreases when the F ligands are replaced with Cl or Br ligands. In addition, our earlier results obtained for BeX_3^- (X = F, Cl, Br),[21] as well as the results obtained by others,[5–7] support this conclusion. Hence, we decided not to calculate the electron binding energies for other species containing either Cl or Br ligands, since it can be predicted that such anions would have smaller VDEs than the corresponding species containing fluorine atoms as the ligands.

One should also notice that the VDE of $Al_2F_7^-$ calculated at the OVGF/6-311++G(d) level differs significantly from the electron binding energy determined by Gutsev and Boldyrev (7.5 eV).[6] We believe that our OVGF value of 11.16 eV, even if slightly overestimated, is much closer to the true vertical electron detachment energy of this anion. The VDE calculated for the $P_2F_{11}^-$ superhalogen anion (10.95 eV) is slightly smaller than that of $Al_2F_7^-$ (see Table 1). On the basis of the discussion given in the preceding paragraphs, we do not expect the VDE to increase when the fluorine atoms in $P_2F_{11}^-$ are replaced by other halogen atoms. However, we have verified that replacing the phosphorus atoms (the central atoms) by other elements, such as V, As, or Ta, may lead to larger electron binding energies. In particular, the VDE for the superhalogen anion $V_2F_{11}^-$ [calculated at the OVGF/6-311++G(d) level] approaches the value of 11 eV (10.98 eV, see Table 1), while the vertical electron detachment energy of $As_2F_{11}^-$ is even larger and equals to 11.43 eV. The largest VDE for a dinuclear superhalogen anion was found for $Ta_2F_{11}^-$ (11.84 eV). We considered this finding to be promising because the VDE of dinuclear $Ta_2F_{11}^-$ (11.84 eV) approaches the value of 12 eV (which is supposed to be the VDE limit according to the recent studies[6,12,13]), and one could expect the VDE to increase when a third central atom is added. Therefore, we now move on to the discussion of the vertical electron detachment energies of the superhalogen anions containing three central atoms.

3.2. Trinuclear Superhalogen Anions

3.2.1. Equilibrium Geometries

Although our original intention was to determine the vertical electron binding energies for four trinuclear superhalogen anions $M_3F_{16}^-$ (where M = P, V, As, Ta), the VDEs of only two trinuclear species were determined. In the case of the two species $P_3F_{16}^-$ and $V_3F_{16}^-$, whose geometrical stability we initially assumed, it was not possible to find any structures corresponding to local minima on the potential energy surface. Instead, the geometry optimisations led to fragmentation of these two systems. Therefore, we concluded that neither $P_3F_{16}^-$ nor $V_3F_{16}^-$ was geometrically stable, and hence decided to focus on two trinuclear species, $As_3F_{16}^-$ and $Ta_3F_{16}^-$.

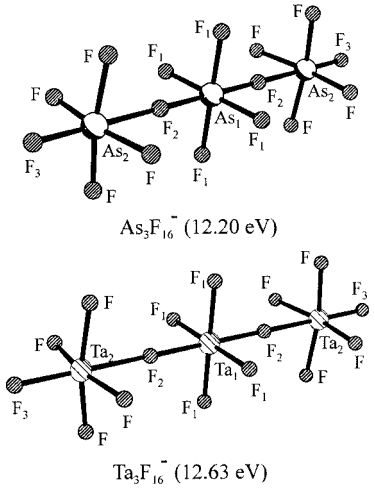

Figure 2. The SCF/6-311++G(d) equilibrium structures of the trinuclear superhalogen anions studied in this work. The corresponding OVGF/6-311++G(d) vertical electron detachment energies are given in parenthesis

The equilibrium structures of $As_3F_{16}^-$ and $Ta_3F_{16}^-$ are depicted in Figure 2 and the corresponding parameters defining these geometries are given in Table 5. Since the harmonic vibrational frequencies calculated for these structures are positive (see Table 6), we conclude that each of these trinuclear superhalogen anions is a true minimum on the potential energy surface. This indicates the geometrical stability of such a system.

In $As_3F_{16}^-$ and $Ta_3F_{16}^-$, the central atoms (M) are linked via fluorine atoms and the M−F−M bonds are linear (see Figure 2 and Table 5). The As−F bonds in the As−F−As−F−As linking fragment in $As_3F_{16}^-$ are longer (by ca. 0.1−0.3 Å) than those in which only two atoms (i.e. one As and one F atom) are involved. A similar situation can be observed in $Ta_3F_{16}^-$, where the Ta−F distances in the Ta−F−Ta−F−Ta linking fragment are longer (by ca. 0.1−0.3 Å) than those that involve only two atoms (see Table 5).

Both the $As_3F_{16}^-$ and $Ta_3F_{16}^-$ equilibrium structures possess relatively high symmetry (D_{4h}), and each of these

species can be viewed as three quasi-octahedral MF_6 systems (M = As, Ta) linked together by two bridging fluorine atoms.

3.2.2. Vertical Electron Detachment Energies

The vertical electron detachment energies for the two trinuclear superhalogen anions studied in this work [calculated at the OVGF and MP2 levels with the 6-311++G(d) basis sets] are presented in Table 5. As in the preceding Section (related to dinuclear species), we use the OVGF values whilst discussing the VDEs of $As_3F_{16}^-$ and $Ta_3F_{16}^-$.

We expected the VDEs of the $As_3F_{16}^-$ and $Ta_3F_{16}^-$ anions to be larger than the VDEs calculated for the corresponding dinuclear species (i.e. $As_2F_{11}^-$ and $Ta_2F_{11}^-$) because the excess negative charge can be delocalized over a larger number of electronegative ligands in the trinuclear superhalogen anions. Indeed, the VDE calculated for $As_3F_{16}^-$ (12.20 eV) is larger by 0.77 eV than the VDE of $As_2F_{11}^-$, and the VDE obtained for $Ta_3F_{16}^-$ (12.63 eV) is greater (by 0.79 eV) than that of $Ta_2F_{11}^-$ (see Tables 1 and 5). Hence, in both cases, the VDE of the superhalogen anion increases by ca. 0.8 eV when another central atom (of the same type) and the proper number of fluorine ligands is added to the parent structure.

We believe that our VDE values that exceed the 12 eV limit by 0.2−0.6 eV, found for the two negatively charged systems $As_3F_{16}^-$ and $Ta_3F_{16}^-$ may be approaching the largest possible VDE values because: (i) the largest known vertical electron detachment energies described in the literature thus far are those calculated by Boldyrev and Simons for TeF_7^- (11.9 eV),[14] and those obtained (also theoretically) by Schaefer's group for AsF_6^- (10.5 eV),[11] and (ii) the limit for the maximum possible excess electron binding energy is thought to be about 12 eV.[12,13] Although the extremely large VDE (12.63 eV) calculated by us for $Ta_3F_{16}^-$ seems to be the largest excess electron binding energy reported in the literature thus far, we believe the maximum possible VDE value has not yet been achieved. In addition, we conclude that the upper limit for the electron affinity characterising the neutral molecular system is in fact higher than 12 eV, and it seems likely it might be larger than 13 eV, as suggested by Gutsev and Boldyrev in the 80′s.[24] Therefore, we believe that the negatively charged system that has the maximum vertical electron detachment energy is yet to be found and we consider such species (i.e. those possessing extremely large VDEs) as systems of great importance in chemistry.

4. Summary

The vertical electron detachment energies of several polynuclear superhalogen anions were calculated at the OVGF/6-311++G(d) level. The largest vertical electron binding energy of 12.63 eV was found for $Ta_3F_{16}^-$, and it is recognised as the largest excess electron binding energy of a molecular system reported in the literature thus far. Since the VDE of 12.63 eV (found for $Ta_3F_{16}^-$) exceeds the upper VDE limit that was thought to be 12 eV, it is proposed that the largest possible excess electron binding energy of a molecular system be reconsidered. Several other anions were also found [at the OVGF/6-311++G(d) level] to have very large VDEs (i.e. $Al_2Br_7^-$: 7.08 eV, $Al_2Cl_7^-$: 7.75 eV, $Al_2F_7^-$: 11.16 eV, $P_2F_{11}^-$: 10.95 eV, $V_2F_{11}^-$: 10.98 eV, $As_2F_{11}^-$: 11.43 eV, $Ta_2F_{11}^-$: 11.84 eV, and $As_3F_{16}^-$: 12.20 eV).

Structures of the Octahedral Persulfuranes H_4SF_2, H_2SF_4, Me_2SH_4 and Me_2SF_4, and Activation Enthalpies for Their *cis*/*trans* Isomerization[‡]

Yana Steudel[a] and Ralf Steudel*[a]

Keywords: Hypercoordinate molecules / Ab initio calculations / Transition states / Isomerism / Sulfur / Fluorides

Eight hypothetical persulfurane molecules of the type X_2SY_4 (X, Y = H, F, Me) have been studied by ab initio MO calculations at the G3(MP2) level of theory. Depending on the substituents either the *cis* or the *trans* isomers of these octahedral molecules are most stable. While H_4SF_2 is most stable as the *cis* isomer, the global minimum structures of H_2SF_4, Me_2SH_4, and Me_2SF_4 are the *trans* isomers. The enthalpy differences between the corresponding isomers are in the range 7–53 kJ·mol^{-1}. The transition states for the intramolecular *cis* ⇌ *trans* isomerization have been located in all cases. Starting from the global minimum geometries the activation enthalpies ($\Delta H^{\#}_{298}$) for this isomerization are in the range 199–263 kJ·mol^{-1}, indicating rather rigid structures. Therefore, it should be possible to isolate both isomers at low to moderate temperatures.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The persulfurane SF_6 is not only an important industrial product[2] but also one of the most-investigated molecules as far as the bonding properties of so-called hypervalent or hypercoordinate molecules are concerned.[3] Numerous derivatives of the types RSF_5 and R_2SF_4 are known[4,5] but the most simple examples, HSF_5 and H_2SF_4, have never been prepared. While HSF_5 has been investigated by ab initio MO calculations,[6,7] the related molecules H_2SF_4 and H_4SF_2 have not yet been studied at all. We have used these species as model compounds to determine the activation energies for the mutual isomerization of the *cis* and *trans* isomers of octahedral persulfuranes for the first time. To further study the influence of the substituents on these energies the methyl-substituted species Me_2SH_4 and Me_2SF_4 were also included in this investigation. These molecules are also hypothetical species. A theoretical treatment of Me_2SF_4 (at the HF/3-21G* level of theory) has been published before,[8] but no structural data were given and only *trans*-Me_2SF_4 was considered. The formation of Me_2SF_4 from Me_2SF_2 and F_2 was shown to be exothermic.

Calculations

Standard ab initio MO calculations were performed using the Gaussian 98 series of programs.[9] The energies of various equilibrium structures and transition states were examined at the G3(MP2) level of theory.[10] In brief, the G3(MP2) method is a composite procedure which provides an accurate approximation, to a high level of theory, at QCISD(T)/GTMP2LARGE//MP2(full)/6-31G(d), with the incorporation of zero-point energy (ZPE) [calculated from HF/6-31G(d) vibrational wavenumbers, scaled by 0.8929] and higher level corrections. It has been shown before that this theoretical method is suitable for hypercoordinate molecules: The reaction enthalpy for the formation of SF_6 from F_2 and SF_4 was obtained as −439.1 kJ·mol^{-1} at 0 K,[1] whereas from the best available experimental enthalpies of formation of these compounds[11] the reaction enthalpy is calculated as −450±20 kJ·mol^{-1} at 0 K. In the case of the hypervalent SF_6 molecule the related G2(MP2) method − using the same geometry calculation as in G3(MP2) − reproduced the very accurately known experimental enthalpy of formation within 7.5 kJ·mol^{-1}.[11]

For all investigated molecules a charge-density analysis, at the MP2(full)/6-31G(d) level, was performed using the natural bond orbital (NBO) approach.[12] NBO atomic charges of small molecules have recently been demonstrated to agree well with experimental values obtained from X-ray diffraction data.[13] Unless otherwise noted, all relative energies reported in this publication are given as ΔH^{o}_{298} and correspond to the G3(MP2) level, while structural parameters were obtained at the MP2(full)/6-31G(d) level. Since *trans*-Me_2SF_4 (**4a**) does not represent a minimum at the HF/6-31G(d) level of theory, for the calculation of G3MP2 enthalpies and Gibbs energies of **4a**, **4b**, and **TS4** the ZPE and the entropy values obtained from the frequency calculation at the MP2(full)/6-31G(d) level of theory were used.

The transition states obtained were characterized by one imaginary vibrational wavenumber whereas the wavenumbers of the structures of minimal energy were all real. The intrinsic reaction coordinates were calculated at the HF/6-31G* level.[14]

Results and Discussion

Sulfur Hydride Fluorides

The possible isomers of H_4SF_2 (**1**) and H_2SF_4 (**2**) are shown in Figure 1, which also gives the internuclear distances; bond angles are listed in Table 1. The two *trans* isomers are of D_{4h} symmetry with all bond angles either 90° or 180°. The *cis* isomers are of C_{2v} symmetry.

Unexpectedly, the *cis* isomer of H_4SF_2 (**1a**) and the *trans* isomer of H_2SF_4 (**2a**) represent the global minimum structures. The *trans* isomer of H_4SF_2 (**1b**) is 53 kJ·mol^{-1} and the *cis* isomer of H_2SF_4 (**2b**) is 37 kJ·mol^{-1} less stable than the most stable structures **1a** and **2a**, respectively. The origin of these differing stabilities is not evident from the molecular structures. The NBO charges of the sulfur atoms (in atomic units) are +1.29 in **1a**, +1.45 in **1b**, +2.12 in **2a** and +2.13 in **2b**. For comparison, for the octahedral SF_6 molecule we found a charge of +2.85 at the sulfur atom at the same level of theory. It appears that the higher the fluorine content the smaller is the NBO charge on the F atoms (**1a**: −0.62, **1b**: −0.60, **2a**: −0.55, **2b**: −0.53, SF_6: −0.475).

The SH and SF internuclear distances given in Figure 1 show an interesting pattern. As a reference value the SF

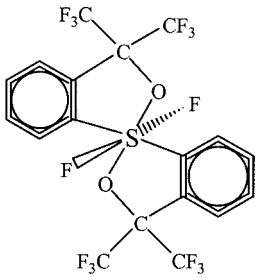
bond length of SF_6 was calculated as 159.3 pm, 3.6 pm (2.2%) longer than the experimental value of 155.7 pm.[15] In **1a** through **2b** the SF distances range from 162.3 to 167.8 pm. With decreasing fluorine content all bonds in the molecules shown in Figure 1 increase substantially in length. Comparing the two pairs of isomers of identical composition (**1a**/**1b** and **2a**/**2b**) one notices that the SH bonds are shortest and the SF bonds are longest in the global minimum structures but the sum of all bond lengths is practically identical in each pair of compounds.

Previous authors have discussed the possibility of so-called *cis*- and *trans*-effects in HSF_5 and related molecules.[6,7] Such effects can partly be seen in the structures investigated in this work as judged from the bond length variation. For the fluorine atoms of H_4SF_2 it is more favorable for them to be *cis* to each other, as in **1a**, while the hydrogen atoms do not show any preference for either *cis* or *trans* positions to each other or to the F atoms. However, the structure of the H_2SF_4 isomer **2b**, with practically identical SH and SF bonds (as judged by the internuclear distances), seemingly rules out any *trans* effect.

The structure of *cis*-H_4SF_2 (**1a**) demonstrates that the formal space requirement of the SH bonds is larger than that of the SF bonds, as expected from the much lower electronegativity of H compared to F. Thus, the H3−S−H4 angle is 171° and the two SH bonds are bent towards the fluorine atoms (see Figure 1). Of course, this effect can also be interpreted as a sign of attractive interactions between the two positively charged hydrogen atoms H3 and H4 (+0.015) and the negatively charged fluorine atoms (−0.62). The hydrogens *trans* to the fluorine atoms (H1 and H2) are slightly negatively charged (−0.04).

The transition states for the *cis*/*trans* isomerization, and vice versa, have been located on the potential energy hypersurfaces; their structures are also shown in Figure 1 (**TS1** and **TS2**). For the *cis* → *trans* isomerization **1a** → **1b** via **TS1** an activation enthalpy of 263 kJ·mol^{-1} is needed ($\Delta G^{\#}_{298}$ = 265 kJ·mol^{-1}). The *trans* → *cis* isomerization **2a** → **2b** via **TS2** requires an activation enthalpy of 199 kJ·mol^{-1} ($\Delta G^{\#}_{298}$ = 196 kJ·mol^{-1}). To the best of our knowledge, neither experimental nor theoretical activation energies for the *cis*/*trans* isomerization of octahedral persulfuranes have been published before, excepting our own recent work on $SF_4(CN)_2$.[1] The data obtained in the present investigation indicate that these molecules are rather rigid, in sharp contrast to the well-known fluxionality of sulfuranes of the type SX_4: in the case of SF_4 the barrier for pseudorotation is only $\Delta H^{\#}_{298}$ = 47 kJ·mol^{-1}.[16] In the case of the persulfurane **A** no *cis*/*trans* isomerization was observed within 254 h at 238 °C under basic conditions. However, the compound isomerized rapidly after addition of a catalytic amount of SbF_5, which cleaved one of the SF bonds, generating a cationic five-coordinate intermediate.[17]

The two transition states **TS1** and **TS2** are of C_2 symmetry and may be regarded as distorted trigonal-prismatic structures. During the isomerization of **1** the F−S−F bond



A

angle changes from 89.4° in **1a** via 140.6° in **TS1** to 180° in **1b**. Similarly, the H−S−H bond angle of **2** decreases from 180° in **2a** via 131.6° in **TS2** to 96.4° in **2b**. The latter value, together with the other bond angles of **2b**, demonstrates once more that the formal space requirement of the SH bonds is larger than that of the SF bonds in these molecules (in **2b** all F−S−F angles are smaller than 90°). This finding is in agreement with the expectations from the VSEPR model of molecular structures[18] but in contrast to the size of the atoms.

The bond length variations during the isomerization processes are most interesting. For example, the SF bond lengths of H_4SF_2 increase from 167.8 pm in **1a** to 182.8 pm in **TS1** and then decrease to 164.9 pm in **1b**. The SH bonds are much less affected: they change from 135.7/136.3 pm in **1a** via 134.4/137.1 pm in **TS1** to 137.7 pm in **1b**. The corresponding transformation **2a** → **2b** takes the SF bond lengths from 162.8 pm in **2a** via 165.8/170.8 pm in **TS2** to 162.2/162.3 pm in **2b** while the SH bonds change simultaneously only from 133.0 via 133.2 to 133.9 pm. The NBO charges on the sulfur atoms in these transition state structures are slightly lower than in the *cis* and *trans* isomers (**TS1**: +1.18; **TS2**: +2.07).

Dimethyl Sulfur Tetrahydride and Tetrafluoride

The *cis* and *trans* isomers of Me_2SH_4 and Me_2SF_4 are shown in Figure 2. The geometrical data are presented in Table 2 (bond lengths) and Table 3 (bond angles).

The *trans* isomer of Me_2SH_4 (**3a**) is of C_{2h} symmetry and is more stable than the *cis* form **3b**, which is of C_s symmetry, by 7 kJ·mol^{-1}. The transition state **TS3** for the *trans*→*cis* isomerization is also shown in Figure 2. The activation enthalpy of 236 kJ·mol^{-1} ($\Delta G^{\#}_{298}$ = 246 kJ·mol^{-1}) is of the same order of magnitude as in the case of the other octahedral molecules studied here and in our recent work on the isomers of $SF_4(CN)_2$.[1] The *trans* isomer of Me_2SF_4 (**4a**; C_{2v} symmetry) is 31 kJ·mol^{-1} more stable than the *cis* isomer **4b** ($\Delta G°_{298}$ =38 kJ·mol^{-1}); the transition state for this isomerization (**TS4**; see Figure 2) is 238 kJ·mol^{-1} higher in energy than the *trans* isomer ($\Delta G^{\#}_{298}$ = 252 kJ·mol^{-1}).

The geometry of *trans*-Me_2SH_4 (**3a**) is highly symmetrical (C_{2h}) and all bond angles at the sulfur atom are either 90° or 180°. The atomic charges of this molecule are as follows: S +0.90, C −0.69, H1−H4 −0.14, methyl-H +0.17. Although the electronegativities of sulfur and carbon are usually believed to be more or less identical,[19] and that of

H(F)1−S−H(F)2:	90.0	89.3	89.0	88.8	136.7	133.9

hydrogen considerably smaller, our calculated NBO charges show a different picture: The carbon atoms of **3a** are negative, sulfur and the methyl H atoms are positive and the four hydrogen atoms linked directly to the central atom are negatively charged. It has been noted before[19] that the electronegativity of hydrogen is not a constant value and, in general, most electronegativity data are derived from non-hypervalent molecules and may not apply to atoms in species of the type investigated in this work.

The geometry of *trans*-Me_2SF_4 (**4a**) is much less symmetrical (C_{2v}) than that of **3a** although the bond angles at the sulfur atom deviate from the ideal values of 90° and 180° by only 1.0−3.4° (Table 2). The atomic charges of **4a** are as follows: S +2.48, C −0.80, F −0.61, H +0.26. Surprisingly, both the sulfur atom in **4a** is more negative than in H_2SF_4 (**2a**: +2.12) and the two carbon atoms are more negative than in **3a** (−0.69), although one would expect the opposite from the well-known inductive effects of the four fluorine atoms and two methyl groups, respectively. Evidently, the electron-donating properties of methyl groups known from organic chemistry are not active in hypervalent sulfur compounds.

The methyl groups of **3a** and **4a** can be rotated separately about the C−S axis without much change in energy. Scans

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

over 75° in steps of 5° with optimization of all other parameters resulted in absolute energies which differed by less than 0.02 kJ·mol^{-1}.

We now turn to the structures of the less stable isomers. The geometry of *cis*-Me_2SH_4 (**3b**) is of C_2 symmetry with a C−S−C bond angle of 91.7°. As far as possible, the methyl groups are staggered with respect to the hydrogen atoms of the SH_4 group. Thus, the pairwise equivalent torsion angles H8−C1−S−H1/H7−C2−S−H3 are 48.9°, H5−C2−S−H4/H10−C1−S−H2 are +19° and H9−C1−S−H3/H6−C2−S−H1 are −11°. The torsion angles H8−C1−S−C4/H7−C2−S−C1 are −43°. The geometry of *cis*-Me_2SF_4 (**4b**) is also of C_2 symmetry but the orientation of the methyl groups is different since there are evidently attractive non-bonding H···F interactions as a result of the opposite charges on these atoms (H atoms: +0.19−0.22; F atoms: −0.55±0.01). For example, the two pairs of symmetry-related distances H2···F3 and H4···F1 (235 pm) as well as H3···F2 and H5···F4 (233 pm) are shorter than the van der Waals distance of 260 pm between hydrogen and fluorine atoms. The corresponding torsion angles H2−C1−S−F3 and H4−C2−S−F1 are −1° and the C−S−C angle of **4b** is 97.3°.

The transition states **TS3** and **TS4** are of C_1 symmetry but both geometries are very close to C_2 symmetry, the small deviation from the higher symmetry being caused by the methyl groups. The C−S−C angles are 133.3° in **TS3** and 130.6° in **TS4**. The NBO charges of the sulfur atoms are +0.91 in **TS3** and +2.23 in **TS4**. As a result of these differing charges, the C−S bond lengths are considerably longer in **TS3** (187.8 pm) than in **TS4** (181.4 pm), a situation very similar to the one in the stable isomers **3a,b** and **4a,b**.

Summary

We have shown that the most stable structures of several persulfuranes of the type X_2SY_4 (X = H, Me, F; Y = H, F) are in agreement with the predictions made by the VSEPR model. All molecules are approximately octahedral, and the relative stability of the *cis* and *trans* isomers depends on the substituents. An unusual charge distribution has been discovered in these molecules by an NBO analysis. Starting from the most stable of the two isomers, the intramolecular *cis* ⇌ *trans* isomerization is possible only if an activation barrier of $\Delta H^{\#}_{298} \geq 200$ kJ·mol^{-1} can be overcome. Therefore, it should be possible to prepare both isomers separately. The geometries of the transition state structures are all very similar and correspond approximately to a distorted trigonal prism with the sulfur atom at the center.

Density Functional Study of the Complexation Reaction of $Sn(CH_3)_3X$ (X = F, Cl, Br and I) with Halide Anions

Frank De Proft,[a] Ricardo Vivas-Reyes,[a] Monique Biesemans,[b] Rudolph Willem,[b] Jan M. L. Martin,[c] and Paul Geerlings*[a]

Keywords: Tin / Halides / HSAB / Density functional calculations / NMR spectroscopy

The Lewis acid-base reaction between $Sn(CH_3)_3X$ and Y^- (with X, Y = F, Cl, Br and I) has been studied using quantum chemical calculations. Complexation energies were calculated at the Density Functional Theory (DFT) level and rationalized on the basis of a local application of the hard and soft acids and bases principle. It was observed that smaller differences in the local softness of the interacting sites in the Lewis acid and base correspond to stronger interactions. Moreover, the calculated sequences in complexation energies can be reproduced using equations containing chemical concepts introduced within the framework of conceptual density functional theory and rooted in the hard and soft acids and bases principle and referring only to the reactants. A method of treating the electronegativity and softness of the halide anions is presented based on a Taylor expansion of the electronegativity of the neutral halogens and the softness-polarizability proportionality. Experimental evidence for the calculated sequences was gathered from measured ^{117}Sn chemical shifts and ^1J (^{13}C-$^{119/117}Sn$) coupling constant changes upon complexation.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

It is well-known that four-coordinate Sn^{IV} compounds bearing electronegative groups react with nucleophiles to form pentacoordinate stannate complexes through expansion of the coordination sphere.[1] An example is the following Lewis acid-base reaction

$$Sn(CH_3)_3X + Y^- \rightarrow Sn(CH_3)_3XY^- \quad (a)$$

where both X and Y are halogens. A detailed and systematic theoretical and experimental analysis of this reaction has not yet been provided. Tudela and co-workers[2] performed experimental and theoretical studies on tri- and tetrahalodiorganostannate salts and studied, inter alia, their complexation reactions. In their studies, they considered the following reactions:

$$SnR_2X_2 + X^- \rightarrow SnR_2X_3^- \quad (b)$$

$$SnR_2X_3^- + X^- \rightarrow SnR_2X_4^{2-} \quad (c)$$

with R being an alkyl group (more specifically Me or Et) and X being F, Cl, Br or I. They concluded,[2] from computations at the Hartree−Fock level, that the formation of the pentacoordinate anions is an exothermic process, while the formation of the octahedral compounds is endothermic, these compounds thus being unstable in the gas phase. They also confirmed that the exothermicity of reaction (b) increased with the electronegativity of the halogen X.

In the present combined theoretical and experimental study, DFT calculations have been performed for the energetics of reaction (a), in order to gain insight into the nature of the tin atom in these interactions. As such, the resultant sequences were assessed on the basis of predictions resulting from the application of the hard and soft acids and bases principle,[3] using reactivity descriptors defined within the framework of conceptual density functional theory.[4] These descriptors, such as the chemical potential,[5] the electronegativity,[5,6] chemical hardness and softness,[7,8] Fukui functions,[9] local softness[8,10] and hardness[11] have been used quite exhaustively among others and by our group for the study of general Lewis acid-base reactions and have proven to be valuable in the interpretation of observed differences in reactivity.[4f,12]

High level ab-initio computational studies on tin compounds are still relatively scarce[13] as are the interpretations of observations in tin chemistry using the above mentioned reactivity indices.[14−16] Recently, our group has contributed significantly to this area, computing ^{119}Sn chemical shifts using Gauge-Including Atomic Orbitals and interpreting them via group electronegativities and hardness,[14] studying

the interaction of the tin nanocluster $[(RSn)_{12}O_{14}(OH)_6]^{2+}$ with negatively charged and neutral nucleophiles[15] and investigating the simultaneous complexation of a Sn containing crown ether compound with positive and negative ions.[16]

Experimentally, it is well-known that ^{117}Sn NMR spectroscopic data are useful for assessing the complexation of R_3SnX compounds with nucleophiles and halide anions, since this gives rise to low frequency changes in the $^{119(117)}$Sn chemical shifts as well as increasing the magnitude of the $^1J(^{13}C\text{-}^{119/117}Sn)$ coupling constants reflecting increases in the percentage of s character of the hybridized atomic orbitals of the tin upon change from four- to five-coordination.[17,18] For the sake of comparison of the calculations and in the context of our long standing interest in NMR studies on Sn compounds,[19] experimental ^{117}Sn chemical shifts δ as well as $^1J(^{13}C\text{-}^{117}Sn)$ coupling constants are provided for equilibrium mixtures of reaction (1) for X = Cl, Br and Y = F, Cl, Br and I. To the best of our knowledge, such a systematic and internally consistent NMR study of these systems has not yet been published.

The combined theoretical and experimental data provide insight into the Lewis acidity of tin compounds, place the tin element in the context matter of hard or soft character and provide, via a number of reactivity descriptors, the rationalization of its behavior in reaction (a).

Theory, Computational and Experimental Details

All molecular systems were optimized at the B3LYP level[20] using the cc-pVTZ basis set for C and H,[21] the aug-cc-pVTZ basis set for F, Cl and Br,[22] the SDB-cc-pVTZ for Sn and the aug-SDB-cc-pVTZ for I[23] using Gaussian 98.[24]

On the carbon and hydrogen atoms, the standard Dunning cc-pVTZ (correlation consistent polarized valence triple zeta[21]) basis set was used, while on the F, Cl, and Br halides, the diffuse-function augmented version of the same basis sets (aug-cc-pVTZ[22]) was employed. For the heavier tin and iodine atoms, we employed regular and diffuse-function augmented versions, respectively, of the SDB-cc-pVTZ basis set,[23] which is a valence basis set of cc-pVTZ quality optimized for use with a large-core (46-electron) Stuttgart−Dresden relativistic effective core potential.[25]

Since the 4d orbitals of free tin are energetically quite close to the valence s orbitals of the halides (particularly the 2s of fluorine), it could not be taken for granted that the large −core RECPs would be sufficient. In order to ascertain that this was indeed the case, we repeated our calculations for $Sn(CH_3)_3F$ and $Sn(CH_3)\ F^-$ with a small-core (28-electron) ECP on tin.[26] The accompanying basis set was developed for the purpose of this work as follows: (a) a 28s23p17d well-tempered basis set[27] was placed on Sn, the inner 28 electrons replaced by the RECP, and an SCF calculation carried out; (b) all primitives contributing less than 0.0001 to any atomic orbital were deleted, leaving an 18s15p11d basis set; (c) this "pruned' basis set was contracted based on the SCF orbitals; (d) the 2nd through 5th outermost s and p primitives were expanded, as were the four othermost d primitives; (e) additional d and f functions were optimized at the CISD level, correlating valence electrons only; (f) in order to accommodate angular correlation from the (4d) orbital, additional (2f1 g) functions were optimized for the difference between the valence+(4d) and valence CISD correlation energies. The use of this small core basis set yielded, for these two systems, only minor differences in geometry and complexation energy. When the small core ECP on Sn was used, the Sn−F distance in the $Sn(CH_3)_3F_2^-$ complex was 2.103 Å. Upon using the large core ECP this distance changes by less than 1 mÅ. The complexation energies using the large and small core Sn ECP amount to −52.1 and −50.7 kcal/mol respectively. As a result, the large core ECP on Sn was used throughout this study.

Anions of the type $Sn(CH_3)_3X_2^-$ show a trigonal-bipyramidal geometry with the methyl groups (average distance Sn−C = 2.17 Å) in the equatorial position. The average Sn−X bond lengths decrease in the order Sn−I (2.98 Å) > Sn−Br (2.77 Å) > Sn−Cl (2.61 Å) > Sn−F (2.09 Å). The Cartesian coordinates of all geometries are available in the supplementary material. All structures were confirmed to be minima by vibrational frequency calculations. DFT complexation energies, enthalpies and free energies were computed on this basis. In view of the extent of the basis set used and the conceptual difficulties arising from the use of effective core potentials, no correction for the basis set superposition error has been included.

In order to judge the effect of the solvent, the free energies of solvation of the Lewis acid-base complexes were estimated using the PCM model.[28]

As stated in the introduction, in addition to the generally accepted computational advantages of density functional theory, it has also been a source for the introduction of chemical concepts readily known by chemists but in most cases defined only on an empirical basis. Also several principles, such as Sanderson's principle of electronegativity equalization and Pearson's hard and soft acids and bases and maximum hardness principles have received theoretical justification. The complexation energy sequences of reaction (a) were rationalized using a local version of the hard and soft acids and bases principle. This principle, introduced by Pearson in the 1960s, states that hard acids prefer to bond to hard bases and soft acids to soft bases.[3] This principle and related chemical concepts have received theoretical justification within the framework of conceptual density functional theory. It can be adopted locally as follows: consider the interaction between a site k in a Lewis acid and a site l in the Lewis base. Application of the local HSAB principle would imply that the interaction between these sites will be favorable when the difference in their local softness is small, as was shown by Gazquez et al.[29] and elaborated among others by our group.[12,30] The local softness[10] can be obtained as described in Equation (1)

$$s(\mathbf{r}) = Sf(\mathbf{r}) \quad (1)$$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

where S is the global softness of the system[8] and $f(\boldsymbol{r})$ the so-called Fukui function,[9] a frontier MO reactivity index defined as the derivative of the electron density of the system with respect to the number of electrons at a constant external (i.e. due to the nuclei) potential:

$$f(\boldsymbol{r}) = \left(\frac{\partial \rho(\boldsymbol{r})}{\partial N}\right)_v \tag{2}$$

Due to the discontinuity of $\rho(\boldsymbol{r})$ with respect to N, left and right derivatives have to be associated with Equation (2):

$$f^-(\boldsymbol{r}) = \left(\frac{\partial \rho(\boldsymbol{r})}{\partial N}\right)^-_v \tag{3}$$

$$f^+(\boldsymbol{r}) = \left(\frac{\partial \rho(\boldsymbol{r})}{\partial N}\right)^+_v \tag{4}$$

corresponding to the cases of electrophilic and nucleophilic attacks, respectively. In the present contribution, the so-called condensed Fukui functions[31] were calculated as described in Equation (5) and (6), where $N_k(N + 1)$, $N_k(N)$ and $N_k(N - 1)$ are the number of electrons on atom k in the $N + 1$, N and N - 1 electron system.

$$f_k^-(\boldsymbol{r}) \approx N_k(N) - N_k(N-1) \tag{5}$$

$$f_k^+(\boldsymbol{r}) \approx N_k(N+1) - N_k(N) \tag{6}$$

The condensed local softnesses are then obtained by multiplying the appropriate Fukui function with the global softnesses, approximated as described in Equation (7), where IE and EA are the vertical ionization energies and electron affinities respectively.

$$S \approx \frac{1}{IE - EA} \tag{7}$$

In a final stage, the complexation energy was calculated using Equation (8) derived within the framework of the hard and soft acids and bases principle,[29] which was already applied successfully in the past.[32] This equation results from a decomposition of the interaction energy of two systems A and B into two terms: the first term, ΔE_v, representing the energy change at constant external potential and corresponding to the charge transfer process between A and B at constant external potential, and the second term, an energy change, equivalent to a reshuffling of the charge distribution at constant chemical potential ΔE_μ, :

$$(\Delta E_{int})_{AB} = -\frac{1}{2}\left(\frac{(\mu_A - \mu_B)^2}{S_A + S_B}\right)(S_A S_B) - \frac{1}{2}\left(\frac{\lambda}{S_A + S_B}\right) \tag{8}$$

In this expression μ is the chemical potential of A and B.

The chemical potential μ has been calculated using Equation (9).

$$\mu = \left(\frac{\partial E}{\partial N}\right)_v \approx \frac{IE + EA}{2} \tag{9}$$

The parameter λ has been shown to be proportional to an effective number of valence electrons involved in the interaction between A and B. Pal and co-workers have recently defined the parameter λ as the change in the electronic densities of the system before and after the interaction process.[32c,32d,32e] In this work however, the choice was made to set this parameter equal to 0.5, in accordance with previous studies by Gazquez and Mendez[29a] and our group.[32b] This methodology avoids the evaluation of λ using information about the electronic structure of the product and thus enhances the predictive ability of the method.

If the interaction on A is localized on an atomic site k, Equation (8) changes to Equation (10), where $f_{A,k}$ is the Fukui function value of the site k of system A.

$$(\Delta E_{int})_{Ak,B} = -\frac{1}{2}\left(\frac{(\mu_A - \mu_B)^2}{S_A f_{A,k} + S_B}\right)(S_A f_{A,k} S_B) - \frac{1}{2}\left(\frac{\lambda}{S_A f_{A,k} + S_B}\right) \tag{10}$$

In the evaluation of the condensed Fukui functions and local softnesses, NPA charges[33] were used showing less basis set dependence than the Mulliken[34] type charges[35] and avoiding certain difficulties associated with electrostatic potential based charges[36] for atoms buried withing the molecule.[37]

The trend in DFT complexation energies was compared with experimental data. It is well-known that the ^{119}Sn or ^{117}Sn resonance shifts to lower frequency when the tin nucleus extends its coordination.[17] Typically a difference of 150−200 ppm is noticed when going from coordination 4 to 5.[17] At the same time the $^1J(^{13}C\text{-}^{119/117}Sn)$ coupling constant increases by 100−150 Hz.[17,18] Both parameters are useful for detecting complexation in the reaction of $Sn(CH_3)_3X$ with halide anions. Thus standard 1D ^1H-decoupled ^{117}Sn spectra were recorded with a Bruker Avance 250 spectrometer. Solutions of $Sn(CH_3)_3Cl$ and $Sn(CH_3)_3Br$ in $CDCl_3$ were mixed with equimolar amounts of $(CH_3CH_2CH_2CH_2)_4NY$ (Y = F, Cl, Br, I). For two of the salts (Y = Br and I) more aliquots were added in order to perform a titration experiment from which the association constant K_{ass} for the complex formation could be determined by fitting the experimental chemical shift to Equation (18) (vide infra) using a two parameter ($K_{ass}^{-1} = K_{diss}$, δ_{bound}) non-linear regression as implemented with SigmaPlot 2000 software (Jandel Scientific).

Results and Discussion

The DFT reaction energies, enthalpies and free energies of reaction (1) for X or Y = F, Cl, Br and I can be found

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 1. Hybrid HF-DFT complexation energies ΔE, enthalpies ΔH (298.18 K) and free energies ΔG (298.15 K) for the reaction $Sn(CH_3)_3X + Y^- \rightarrow Sn(CH_3)_3XY^-$ with X, Y = F, Cl, Br and I. Also listed are the PCM free energies of solvation ΔG_s of the Lewis acid-base complexes $Sn(CH_3)_3XY^-$. All values are in kcal/mol

(X, Y)	ΔE	ΔH	ΔG	ΔG_s
(F,F)	−52.1	−52.3	−45.8	−35.0

(I,I)	−19.5	−19.7	−12.3	−24.9

in Table 1. Also given in this table are the free energies of solvation of the acid-base complexes estimated using the PCM model. As can be seen, the values of ΔE, ΔH and ΔG are all negative, implying that the formation of the products from the starting compounds is an energetically favourable process which is also exergonic in all cases. Moreover, one can make the following general conclusions: for a given halogen X in the Lewis acid, the complexation energies become less negative when going from F^- to I^-. For a given Lewis base Y^-, the complexation energies become more negative going from $Sn(CH_3)_3F$ to $Sn(CH_3)_3I$. As such, the complexation energy of $Sn(CH_3)_3I$ with F^- is the most negative. This indicates that the Sn atom in these Lewis acids preferably interacts with the hardest anion (F^-) in the series of nucleophiles and that a complexation with the softest anion (I^-) is always the least favourable. From the application of the HSAB principle, it can be concluded that the Sn atom is essentially hard in these compounds, in line with our previous work on the $[(RSn)_{12}O_{14}(OH)_6]^{2+}$ nanocluster and the Sn containing crown ether compounds.[15,16] The free energies of solvation become more negative with decreasing size of the Lewis acid-base complex, in line with a simple Born-type[38] model. The ΔG_s values follow the same trends as the ΔG values so that, although there is a very large contribution of ΔG_s to the energy of association in solution, the trends are almost identical as in the gas phase (vide infra).

In order to gain more insight into the trends of the gas-phase complexation energies, they were interpreted within the framework of the HSAB principle, using the method of "softness matching", introduced and applied in many of our previous papers.[30] As the interaction occurs between the electrophilic Sn atom in the trimethyltinhalides and the nucleophilic halide ion, the most favorable interaction should take place when the difference of the local softnesses on both of these atoms is the smallest.

The difficulty lies however in the determination of the softness, both global and local, of the halide anions. It has been suggested repeatedly[39] that in order to estimate the relative ordering of the hardness of anions, the hardness of the corresponding uncharged radicals can be used, that is, the hardnesses of F^-, Cl^-, Br^- and I^- should have the same ordering as those of F, Cl, Br and I. However, now absolute hardness values are needed, since these can now be compared with those of the Lewis acids for which the usual approach can be adopted. Furthermore, the values of the electronegativities of the halide anions are also unknown. However, they can in principle be estimated from a Taylor series expansion of the electronegativity with respect to the charge q on the atom.[4a] Indeed :

$$\chi(q) \approx \chi^0 + 2\eta^0 q \tag{11}$$

where χ^0 and η^0 are the electronegativity and hardness of the corresponding uncharged system. Since for an anion $q = -1$, this equation can be rewritten as shown in Equation (12), indicating that the electronegativity of the anion $[\chi(-1)]$ is the difference of the electronegativity χ^0 and twice the hardness η^0 of the corresponding neutral atom..

$$\chi(-1) \approx \chi^0 - 2\eta^0 \tag{12}$$

Table 2. Polarizabilities of Y [α (Y)] and Y^- [α (Y^-)] (au), together with their hardnesses η (Y) and η (Y^-) (eV). Also given are the condensed local softnesses s_{Y^-} of the bases Y^- (The condensed Fukui functions are all equal to 1) and the electronegativities of Y χ(Y) (eV)

Atom (Y)	α (Y)	α (Y^-)	η (Y)	η (Y^-)	s_{Y^-}	χ(Y)
F	3.57	8.85	7.11	2.86	4.75	10.64
Cl	14.82	28.78	4.70	2.42	5.62	8.38
Br	21.43	41.97	4.20	2.14	6.35	7.75
I	32.81	56.68	3.65	2.11	6.44	6.94

These values can also be found in Table 2. As can be seen, this leads in most cases to very small and even negative estimates of the electronegativity of the anion. As a result, the electronegativities of these anions were set equal to zero in this work.

The next problem consists of estimating the absolute hardness of the anions. In order to deal with this problem, the following approach was adopted. It has been proposed several times[40] that the global softness is proportional to the polarizability of the system. We then assumed that the ratio of the global softness values of the neutral halogen atom and the halide anion is equal to the ratio of their polarizabilities as described in Equation (13) so that an estimate of the global softness of Y^- can be obtained as demonstrated in Equation (14).

$$\frac{S_{Y^-}}{S_Y} \approx \frac{\alpha_{Y^-}}{\alpha_Y} \tag{13}$$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$S_{Y^-} \approx \frac{\alpha_{Y^-}}{\alpha_Y} S_Y \tag{14}$$

The hardness of the halide ions Y^- (= $1/(2S_{Y^-})$) obtained in this way which are, to the best of our knowledge, the first absolute, theoretically evaluated, numerical gas phase values, are given in Table 2, together with the polarizability and the hardness of the corresponding neutral halogens and the polarizabilities of the halide anions. As can be seen by comparison with the global hardness values of the Lewis acids $Sn(CH_3)_3X$ given in Table 3, these anions are all softer than the Lewis acids. Moreover, as stated many times in the literature,[39] the hardness sequence is $\eta(F^-) > \eta(Cl^-) > \eta(Br^-) > \eta(I^-)$.

Table 3. Chemical potential μ (eV), hardness η (eV) and polarizabilities α (au) of the Lewis acids considered in this work. Also given are the condensed Fukui functions, local softness and charges on the Sn atom, all in au

Lewis acid	μ	η	α	f^+_{Sn}	s^+_{Sn}	q_{Sn}
$Sn(CH_3)_3F$	−4.30	5.71	74.3	0.24	0.57	2.19
$Sn(CH_3)_3Cl$	−4.23	5.47	90.5	0.25	0.61	1.91
$Sn(CH_3)_3Br$	−4.22	5.24	99.7	0.29	0.75	1.82
$Sn(CH_3)_3I$	−4.13	4.93	114.9	0.36	1.00	1.71

The condensed local softnesses for the Lewis acids and bases are given in Table 2 and 3. As can be seen with the use of Figure 1, the principle of softness matching (i.e. looking for the smallest softness difference between the acceptor atom in the Lewis acid and the donor atom in the Lewis base) perfectly explains the two above mentioned sequences for the complexation energies. From Figure 1, it can be seen that all the Lewis acids are harder than the Lewis bases and since F^- is the hardest Lewis base, the smallest local softness difference always occurs with F^-. Furthermore, since the softness of the Sn atom in $Sn(CH_3)_3I$ is the highest, the complexation energies of this compound with the halide ions are more negative than for the other $Sn(CH_3)_3X$ compounds. In the next step, the complexation energies were correlated with the absolute value of the softness difference between the Sn atom and the Lewis base as shown in Equation (15).

$$\Delta s = \left| s^+_{Sn} - s^-_{Y^-} \right| \tag{15}$$

From the HSAB principle, it can be inferred that the smaller the value of this difference, the more negative the complexation energy should be. This can indeed be deduced from Figure 2, where the correlation is shown ($r^2 = 0.91$).

In a final step, the complexation energies, as determined from Equation (10) were correlated with the DFT values from Table 1. This correlation ($r^2 = 0.94$) is depicted in Figure 3. As stated in Section 2, the parameter λ, which is proportional to the effective number of valence electrons part-

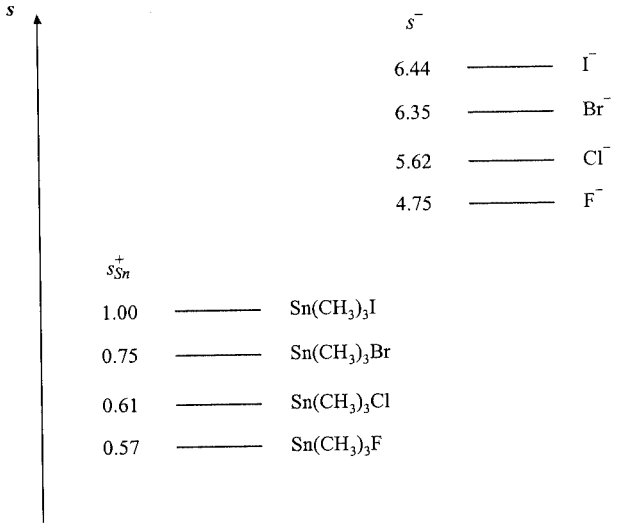

Figure 1. Relative ordering of the local softness of the Sn atom in the $Sn(CH_3)_3X$ compounds and the halide anions. All values are in au

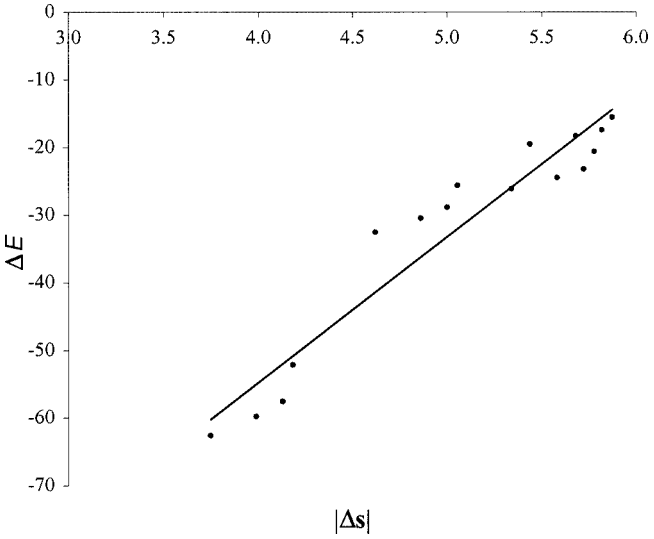

Figure 2. Correlation of the softness difference (au), defined in Equation (15) with the ab-initio complexation energies (kcal/mol)

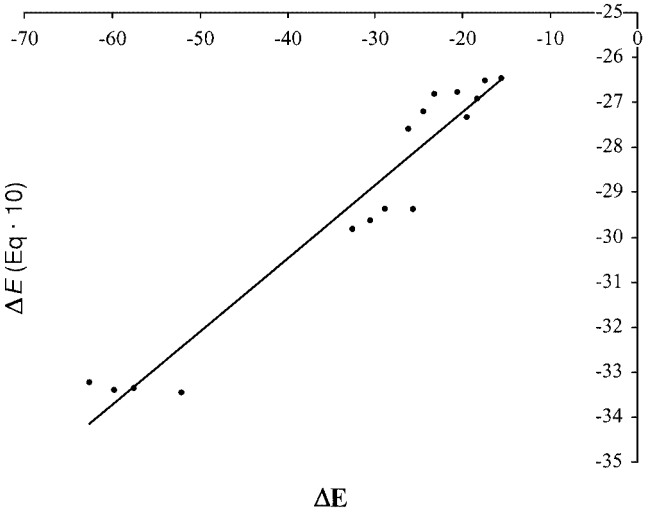

Figure 3. Correlation of the complexation energies (kcal/mol), as calculated from Equation (10) with the ab-initio complexation energies (kcal/mol).

icipating in the interaction, was arbitrarily set to 0.5. With this value, the second term in Equation (10) is dominant and accounts for 77 (X,Y = I) to 88% (X,Y = F) of the total interaction energy. Moreover, the correlation coefficient r^2 does not drop below 0.9 when λ is varied between 0.3 and 1.0. This is again a fine example of the usefulness of the concepts introduced within the framework of conceptual DFT. The correct trends in complexation energies can be recovered from equations involving properties only associated with the reagents.

The Lewis acidities of the tin compounds have also been analyzed by considering the charge of the tin atoms in the different compounds, given in Table 3. Assuming that a more positive tin reflects a higher Lewis acidity, the charge sequence shown in Table 3 should also reflect the acidity sequence.

$Sn(CH_3)_3F > Sn(CH_3)_3Cl \approx Sn(CH_3)_3Br \approx Sn(CH_3)_3I$

This trend is however the reverse of that seen in the computed complexation energies. Moreover, it can be deduced from Table 3 that electronegativity differences apparently do not strongly affect the charge on the tin atom. This leads to the conclusion that the interaction of the tin halides with halide ions is essentially orbitally controlled and not charge controlled. Indeed, when using the concept of softness matching, one considers the reaction to be orbitally controlled, whereas in the case of hard-hard interactions, charge control is implied. It has been argued recently by Chattaraj[41] that the maximum Fukui function (or local softness) site is the best for the frontier-controlled soft-soft reactions whereas for the charge-controlled hard-hard interactions the preferred site is associated with the maximum net charge and not necessarily the minimum Fukui function.

Our results for the relative Lewis acidities of $Sn(CH_3)_3F$, $Sn(CH_3)_3Cl$, $Sn(CH_3)_3Br$ and $Sn(CH_3)_3I$ are in line with the findings of Frenking et al.[42] They have shown that for the Lewis acids BX_3 (with X = F, Cl, Br and I), the hydride affinity increases from BF_3 to BI_3, although the p(π) population is higher in BI_3 than in BF_3. Moreover, they demonstrated that the electronic structure of the Lewis acid alone is not sufficient to determine the affinity toward a nucleophile.

^{117}Sn chemical shifts and $^1J(^{13}C\text{-}^{117}Sn)$ coupling constants for $Sn(CH_3)_3Cl$ and $Sn(CH_3)_3Br$ mixed with an equimolar amount of $(CH_3CH_2CH_2CH_2)_4N^+X^-$ are summarized in Table 4. As the anion exchange is fast on the ^{117}Sn NMR timescale the experimental chemical shifts and $^1J(^{13}C\text{-}^{117}Sn)$ coupling constants are weighted averages of free and complexed species and as such reflect the amount of complexation or, indirectly, the association constant of the formed complex. The NMR measurements show, for a given halogen X, a difference in chemical shift and $^1J(^{13}C\text{-}^{117}Sn)$ coupling constant between the uncomplexed and complexed species that decreases along the series F > Cl > Br > I in accordance with the calculated complexation energies. Since however the difference in chemical shift is not only dependent on the strength of the formed complex but also influenced by the nature of the complexing halide,

Table 4. ^{117}Sn chemical shifts and $^1J(^{13}C\text{-}^{117}Sn)$ coupling constants for compounds $(CH_3)_3SnCl$ and $(CH_3)_3SnBr$ in $CDCl_3$ before and after addition of an equimolar amount of $(CH_3CH_2CH_2CH_2)_4NX$; Δδ refers to the difference in chemical shift between the complexed and uncomplexed species

X	$Sn(CH_3)_3Cl$ δ (ppm)	Δδ	$^1J(^{13}C\text{-}^{117}Sn)$ (Hz)	$Sn(CH_3)_3Br$ δ (ppm)	Δδ	$^1J(^{13}C\text{-}^{117}Sn)$ (Hz)
–	170.7	–	360	137.1	–	345
F	−41.4	212.1	530	−34.1	171.2	515
Cl	−24.0	194.7	496	−8.2	145.3	474
Br	−12.1	182.8	480	7.7	129.4	454
I	47.5	123.2	430	22.1	115.0	437

a more elaborate ^{117}Sn NMR titration experiment was performed for two of the salts, in order to determine the association constants in an independent way.[43] The dependence of the ^{117}Sn chemical shift on the concentration of complexed species is given by the Equation (16), where $\delta_{obsd.}$ is the ^{117}Sn chemical shift of the fast exchanging triorganotin compound observed for a given analytical concentration $[Y^-]_0$, whereas δ_{bound} and δ_{free} are the ^{117}Sn chemical shifts of the complexed and free R_3SnX respectively.

$$(\delta_{obs} - \delta_{free}) = \frac{[R_3SnXY^-]_e}{[R_3SnX]_0}(\delta_{bound} - \delta_{free}) \quad (16)$$

The actual equilibrium concentration of the adduct $[R_3SnXY^-]_e$ in solution obeys Equation (17) with $C = [R_3SnX]_0 + [Y^-]_0$, where, in both equations, $[R_3SnX]_0$ represents the analytical concentration of the trimethyltin halide under consideration.

$$[R_3SnXY^-]_e = \frac{1}{2}\left\{\left(C + K_{ass}^{-1}\right) - \sqrt{\left(C + K_{ass}^{-1}\right)^2 - 4[R_3SnX]_0[Y^-]_0}\right\} \quad (17)$$

Substituting Equation (17) into Equation (16) and solving $\delta_{obsd.}$ gives Equation (18)

$$\delta_{obs} = \delta_{free} + \frac{(\delta_{bound} - \delta_{free})\left\{\left(C + K_{ass}^{-1}\right) - \sqrt{\left(C + K_{ass}^{-1}\right)^2 - 4[R_3SnX]_0[Y^-]_0}\right\}}{2[R_3SnX]_0} \quad (18)$$

By fitting $\delta_{obsd.}$ to Equation (18) using a non-linear regression the parameters $K_{ass}^{-1} = K_{diss}$ and δ_{bound} were obtained. These data are summarized in Table 5. From this

Table 5. Dissociation constants of the complexes $(CH_3)_3SnClY^-$ and $(CH_3)_3SnBrY^-$ in $CDCl_3$ solution, obtained by fitting ^{117}Sn chemical shifts to Equation (18)

X	$Sn(CH_3)_3Cl$	$Sn(CH_3)_3Br$
I^-	$(8 \pm 2) \times 10^{-2}$	$(9 \pm 2) \times 10^{-2}$
Br^-	$(1.3 \pm 0.4) \times 10^{-2}$	$(3.1 \pm 0.1) \times 10^{-2}$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

table it is again clear that Br^- forms more stable complexes than I^- for a given $(CH_3)_3SnX$ in accordance with our earlier statement and the calculated complexation energies. Comparison of the dissociation constants of $(CH_3)_3SnCl$ for both complexing anions with those of $(CH_3)_3SnBr$ indicate that the first one has slightly higher association constants than the latter one, whereas the calculations predict the reverse order. However for both the calculated complexation energies and the experimentally obtained association constants the differences between the two are rather small. From the experimentally determined association constants, it can indeed be deduced that the difference in complexation free energy between $(CH_3)_3SnCl$ and $(CH_3)_3SnBr$ amounts to 0.51 and 0.07 kcal/mol upon complexation with Br^- or I^- respectively, which is well below what is considered to be chemically accurate in quantum chemical computations. Moreover, the computed free energy differences for these compounds are also below 1 kcal/mol. The addition of the free energies of solvation of the Lewis acid-base complexes, computed using the PCM model, to the gas phase free energies of complexation in the case of the reaction of $Sn(CH_3)_3Cl$ and $Sn(CH_3)_3Br$ with Br^- reverses the gas phase trend in agreement with the solution phase dissociation constants. In the case of the complexation of $Sn(CH_3)_3Cl$ and $Sn(CH_3)_3Br$ with I^- however, the reversal is not achieved. The difference between the gas phase and solution phase free energies however being reduced to around 0.4 kcal/mol.

The $^1J(^{13}C\text{-}^{117}Sn)$ coupling constants in Table 4, being weighted averages of those in the free and complexed species, reflect the geometry of the formed complexes. These data indeed depend on the percentage of s character in the Sn−C bond and thus the trigonal bipyramidal character of the resultant compound. Inspection of the data indicate that the highest values are found after complexation with F^-, followed by Cl^-, Br^- and finally I^-, again in accordance with the calculated complexation energies.

Conclusions

A combined theoretical and experimental NMR study of the complexation reaction between $Sn(CH_3)_3X$ and a halide ion Y^- (X, Y = F^-,Cl^-,Br^-, and I^-) has been carried out.

For a given Lewis acid, the ab-initio complexation energy becomes more negative upon going from F^- to I^-. For a given Lewis base, $Sn(CH_3)_3I$ is always found to give the most negative interaction energies. It was shown that complexation energies become more negative when the softness difference between the acceptor atom in the Lewis acid and the donor atom in the Lewis base becomes smaller, in agreement with the hard and soft acids and bases principle. Moreover, a quantitative agreement of the DFT complexation energies and an expression, derived within the framework of conceptual density functional theory, has been put forward. In this way, high level ab-initio computed complexation energies of medium sized tin compounds, combined with the first ab-initio evaluation of halide anion hardness, have provided insight into the ordering of the Lewis acidities of these compounds and in the interpretation of the strength of the Lewis acid-Lewis base interaction in terms of the HSAB principle in a parameter free context. Both experimentally measured ^{117}Sn chemical shifts and $^1J(^{13}C\text{-}^{119}Sn)$ coupling constants for the $Sn(CH_3)_3Cl$ and $Sn(CH_3)_3Br$ compounds confirm the computed complexation energy ordering $F^- > Cl^- > Br^- > I^-$. In addition, association constants of these two Lewis acids with Br^- and I^- have been calculated and lead to the same conclusion.

Stable Platinum(0) Catalysts for Catalytic Hydrosilylation of Styrene and Synthesis of [Pt(Ar-bian)(η^2-alkene)] Complexes

Jeroen W. Sprengers,[a] Michiel de Greef,[a] Marcel A. Duin,[a] and Cornelis J. Elsevier*[a]

Keywords: Platinum / Hydrosilylations / N ligands / Homogeneous catalysis / Alkene ligands

The use of alkenes and bidentate N-ligands in the platinum(0)-catalyzed hydrosilylation of styrene with triethylsilane has been evaluated. A number of bidentate N-ligands, phen, bpy, dafo, and phenyl-bian, were tested at various reaction temperatures using in situ formed catalysts with [Pt(nbe)$_3$] as a precursor. The main conclusions are: (i) ligands, such as phen, which form stable platinum(0) complexes, give lower catalytic activities compared to the ligands which form less stable complexes; (ii) a small ligand effect is observed with dafo and phenyl-bian compared to [Pt(nbe)$_3$], the precursor complex, displaying the lability of these ligands. The complex [Pt(nbe)$_3$], that only has labile alkene ligands, is an active catalyst at low temperatures. At higher temperatures, the catalyst is no longer stable and a decrease in yield is observed. Several novel complexes have been synthesized: [Pt(*m*,*m*-(CF$_3$)$_2$-C$_6$H$_3$-bian)(tcne)], [Pt(*m*,*m*-(CF$_3$)$_2$-C$_6$H$_3$-bian)(ma)], [Pt(*p*-MeO-C$_6$H$_4$-bian)(ma)], [Pt(*p*-MeO-C$_6$H$_4$-bian)(dmfu)] and [Pt(phenyl-bian)(dmfu)]. Whereas the two [Pt(Ar-bian)(ma)] complexes are intrinsically more active than the two [Pt(Ar-bian)(dmfu)] complexes, the latter are much more stable, i.e. the nature of the alkene in these complexes is an important factor in determining their catalytic behavior. Compared to [Pt(Me-nq)(nbe)$_2$], the two [Pt(Ar-bian)(dmfu)] complexes are much more stable resulting in significantly higher overall yields.

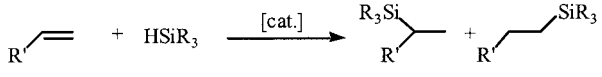
1. Introduction

The catalytic hydrosilylation of unsaturated compounds, such as alkenes, alkynes, ketones, and imines, is one of the most elegant methods for the synthesis of organosilicon compounds [Equation (1)].[1] The use of organosilicon compounds as reagents and synthons for the construction of natural products has become a powerful tool in synthesis. In addition to its use in laboratory syntheses, the hydrosilylation reaction is used in many ways in the industrial manufacture of silicon polymers, for example for the curing and modification of polyorganosiloxanes and the modification of unsaturated polymers.



(1)

Since the first report on catalyzed hydrosilylation in 1947 by Sommer et al.,[2] many efforts have been made to develop optimized catalytic systems. By now, numerous transition metal based catalysts have been reported for hydrosilylation, including metals of groups 8, 9, and 10. Platinum catalysts, especially, are very active in the hydrosilylation of unsaturated carbon−carbon bonds. The Speier catalyst,[3] H_2PtCl_6 dissolved in 2-propanol, and the Karstedt catalyst,[4] H_2PtCl_6 dissolved in tetramethyldivinyldisiloxane [(CH$_2$=CHSiMe$_2$)$_2$O], are frequently used.

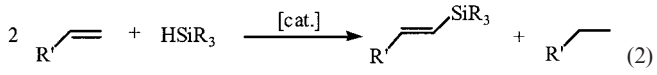
However, a problem associated with these platinum catalysts is their very limited stability when exposed to hydrosilylation conditions; rapid formation of platinum colloids, that are catalytically not active, takes place. The preparative scope of Speier's catalyst is further restricted by its long and variable induction period. The nature of the catalytically active species, homogeneous vs. heterogeneous, has been questioned in the literature for a long time.[5] Recently, it has become clear that the type of platinum compound that would generate the highest activity is one in which formation of a single platinum(0) atom and concomitant loss of ligands is facile.[5] It has been observed that the Karstedt catalyst contains preponderantly [Pt$_2$(CH$_2$=CHSiMe$_2$)$_2$O]$_3$, a platinum(0) complex containing one bridging tetramethyldivinyldisiloxane ligand.[6] A widely accepted mechanism for hydrosilylation of alkenes is the Chalk−Harrod mechanism which consists of oxidative addition of a hydrosilane, insertion of an alkene into the metal−hydride bond, and reductive coupling of the alkyl and silyl fragments.[7]

Osborn et al.[8] published a series of platinum(0) complexes with the general formula [Pt(η^2-alkene)(η^4-CH$_2$=CHSiMe$_2$)$_2$O]. When naphthoquinones were used as the co-

[a] Institute of Molecular Chemistry, Coordination and Organometallic Chemistry, Universiteit van Amsterdam, Nieuwe Achtergracht 166, 1018 WV Amsterdam, The Netherlands
Fax: (internat.) + 31-20/5256456
E-mail: elsevier@science.uva.nl

ordinating alkene, highly active catalysts were obtained. Markó et al.[9] used platinum(0) catalysts with N-heterocyclic carbenes as ligands. These catalysts were less active than the Karstedt catalyst, but side-reactions, such as isomerization and dehydrogenative silylation, were significantly suppressed. Also our group used some N-heterocyclic carbene ligands which yielded outstanding catalysts.[10]

Hydrosilylation of alkenes is often accompanied by side-reactions such as isomerization and dehydrogenative silylation. The latter can be of interest, because it produces vinylsilanes, which are very useful synthetic reagents in synthesis [Equation (2)].



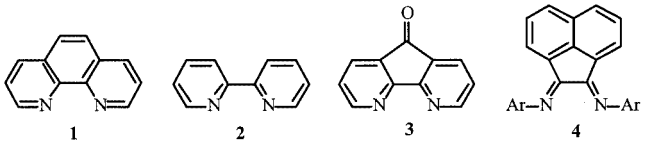
(2)

Of course, it would be desirable to have catalysts that are selective either to hydrosilylation or to dehydrogenative silylation. For instance, the catalysts $[Ru_3(CO)_{12}]$[11] and $[Fe_3(CO)_{12}]$[12] are known to be very selective towards dehydrogenative silylation of several alkenes, which is also true for rhodium(I)[13] and palladium(II) catalysts[14] when employing an excess of styrene relative to the hydrosilane or a more steric hydrosilane. Also platinum(0) catalysts can give rise to a certain extent of dehydrogenative silylation,[15,16] for which the Chalk−Harrod mechanism does not account. Therefore, other mechanisms have been proposed to explain this reaction. Characteristically, these mechanisms feature the formation of an olefin-hydride complex, arising from β-hydride elimination of a β-silylalkyl intermediate [Equation (3)]. Dissociation of the *trans*-vinylsilane yields a metal hydride complex, which is responsible for the hydrogenated product. This dissociation of the vinylsilane is favored by a high styrene concentration and by using more steric hydrosilanes.

As mentioned before, many of the known platinum(0) catalysts suffer from deactivation. For instance, Steffanut et al.[8] observed decomposition of [Pt(η^2-2-methylnaphthoquinone)(η^4-CH_2=$CHSiMe_2$)$_2$O] at temperatures higher than 20 °C. Moreover, alkene/hydrosilane ratios of two were used in their experiments, which contributes to a significantly higher catalyst stability. It would be desirable to use an alkene/hydrosilane ratio of one, but then more stable catalysts are definitely required. Thus, further manipulation of the coordination sphere of the metal center will be indispensable in order to obtain an active catalyst that is stable under the reaction conditions.

We have been interested in the use of bidentate N-ligands, especially bidentate N-ligands, for several catalytic and stoichiometric transition metal mediated carbon−element coupling reactions and for the stereoselective *cis*-hydrogenation of alkynes.[17−22] These ligands are known to stabilize platinum(0) compounds when coordinated in a bidentate manner,[23−24] yet readily give rise to free coordination sites due to their hemilability.[25−26]

An effective catalyst for hydrogenation or hydrosilylation requires a low coordination number and valence. Hence, hydrosilylation should proceed effectively for those late transition metal compounds that can readily vacate two or more coordination sites, in order to accommodate substrates, yet is able to stabilize the complex in its resting state by re-coordination of the hemilabile donor atom. In this respect, platinum based precatalysts combining a labile alkene with a hemilabile, bidentate N-ligand, specifically 1,10-phenanthroline (**1**) (phen), 2,2′-bipyridyl (**2**) (bpy), 4,5-diazafluoren-9-one (**3**) (dafo), and bis(arylimino)acenaphtene (**4**) (Ar-bian), seem to be very promising indeed for platinum(0)-catalyzed hydrosilylation.



In this paper, the use of bidentate N-ligands, as ligands for Pt-catalyzed hydrosilylation of styrene with triethylsilane, is reported. The performance and stability of several in situ prepared systems, obtained from [Pt(2-norbornene)$_3$], [Pt(nbe)$_3$], with appropriate bidentate N-ligands, has been evaluated and compared with several novel [Pt(Ar-bian)(η^2-alkene)] complexes.

2. Results and Discussion

Bidentate N-Ligands as Ligands in the Hydrosilylation of Styrene by Triethylsilane

First, the platinum(0) complex [Pt(nbe)$_3$][27] was used as a precursor for the hydrosilylation of styrene with triethylsilane yielding products **I** and **II** (Scheme 1). The hydrosilylation of styrene is always accompanied by dehydrogenative silylation, yielding products **III** and **IV**. Throughout, ethylbenzene (**IV**) was always formed in the same amount as the unsaturated silyl product (**III**) by subsequent hydrogenation of styrene. Since the nbe ligands readily dissociate from platinum, active, coordinately unsaturated platinum(0) species are readily obtained.

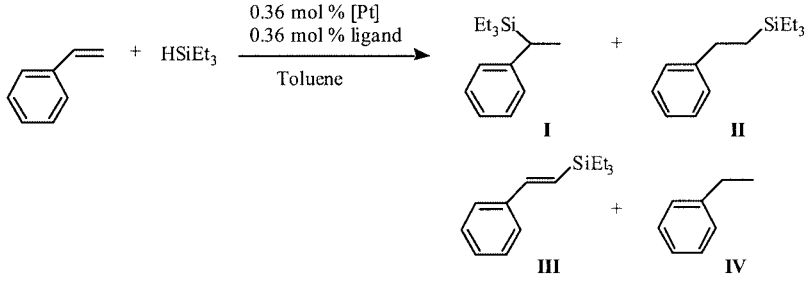

Scheme 1. Hydrosilylation and dehydrogenative silylation of styrene with triethylsilane

The bidentate N-ligands are expected to coordinate to platinum immediately upon their addition, prior to the start of catalysis. Thus influencing the activity and stability of the hydrosilylation reaction. Liedtke et al.[28] also used $[Pt(nbe)_3]$ as a precursor in their hydrosilylation reactions with certain phosphiranes as ligands. These experiments were performed at different temperatures and at a styrene/hydrosilane ratio of 2.8. For comparison, 2-methylnaphthoquinone (Me-nq), Osborn's ligand,[8] and bis(diphenylphosphanyl)ethane (dppe), a strongly coordinating ligand, which results in a platinum complex with low activity,[29] were also tested in this catalytic system. The results of these catalytic hydrosilylations have been collected in Table 1.

Table 1. Hydrosilylation of styrene with triethylsilane

Entry	Ligand[a]	Temp. [°C]	Yield [%][b]	Selectivity [%][c] **I/II/III**

		50	–	–
		100	5.1	3.5:67.2:29.3

[a] 0.36 mol % of catalyst, styrene/triethylsilane ratio 2.8, toluene. [b] Combined GC yield, after 2 h, of products **I**, **II**, and **III** using *n*-decane as the internal standard. [c] Product **IV** was always observed in the same amount as product **III**, therefore the amount of **IV** has been omitted.

It is clear that the precursor complex $[Pt(nbe)_3]$ is an active catalyst at 30 °C, but that it progressively loses its activity at higher temperatures due to deactivation of the catalyst (Entry 1). Addition of 1 equiv. of Me-nq to $[Pt(nbe)_3]$ (Entry 2) gives results that are similar to those of $[Pt(nbe)_3]$: the same trend in deactivation at higher temperatures is observed and only a small increase in the yield of product **I** relative to the other products was observed. So, Me-nq is not able to act as a stabilizing ligand at higher temperatures.[8] Furthermore, the use of Me-nq does not lead to a higher yield at 30 °C compared to $[Pt(nbe)_3]$ itself, which generates highly active platinum species. This observation is in agreement with the common view that single unsaturated platinum(0) atoms are highly active hydrosilylation catalysts.[5,8]

A completely different catalytic behavior is observed when 1,10-phenanthroline (phen) is used as the ligand (Entry 3). In this case, hydrosilylation only takes place at a very slow rate at 100 °C. Apparently, phen forms a very stable platinum(0) complex. This idea is supported by the fact that no significant catalyst deactivation was observed, even when running this reaction at 100 °C for 24 h, which resulted in a total yield (**I** + **II** + **III**) of 81%. The relative amount of dehydrogenative silylation has increased using phen, which can be explained by invoking the strong bidentate coordination of phen to the Pt center, favoring the dissociation of the *trans*-vinylsilane.

When bpy is used in the hydrosilylation (Entry 4), the yield obtained increases when going from 30 to 50 °C due to the increased lability of bpy with temperature. The low yield observed at 100 °C is caused by the deactivation of the catalyst at this temperature. The selectivity (**I/II/III**) obtained with this ligand changes significantly with temperature and differs from the selectivity obtained in Entries 1 and 3. Furthermore, bpy shows an increased amount of dehydrogenative silylation compared to $[Pt(nbe)_3]$, but not to the same degree as phen. This can be understood from differences in the fluxional behavior of phen and bpy: by its rigidity, phen forms complexes more readily than bpy, but bpy is more flexible and can easily adapt to the η^1-coordinate structure.

The ligand dafo (Entry 5) shows a behavior completely different from phen and bpy. Only a very small decrease in yield and the same selectivity compared to $[Pt(nbe)_3]$ is observed. These results indicate that dafo coordinates relatively weakly, in a bidentate fashion, to the platinum(0) atom, which is most likely due to the larger bite angle of this ligand (about 82°) compared to phen and bpy (about 77°). Indeed, Klein et al.[26] have previously observed an enhanced aptitude for dissociation of one of the donor atoms of dafo in platinum(0) and palladium(0) complexes,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

due to the reduced overlap between relevant metal and ligand orbitals caused by the larger bite angle. Also dimeric palladium(II) complexes have already been synthesized with dafo as a bridging ligand.[30]

Although phenyl-bian (Entry 6) possesses a bite angle similar to phen and bpy (about 77°), the catalytic results obtained with this ligand differ completely from that of phen and bpy. In fact, almost the same yield and selectivity were obtained as observed for dafo. Similarly to dafo, phenyl-bian displays a significant lability. Although platinum(0) or palladium(0) complexes in which the Ar-bian ligands act as monodentate ligands are not known, several palladium(II) complexes containing monodentate Ar-bian ligands are known.[25,31] These studies have shown that rigid bidentate N-ligands are more prone to hemilabile behavior than the more flexible ones. Assuming partial dissociation of Ar-bian in such cases may explain the observed selectivity for phenyl-bian.

Results obtained for dppe (Entry 7) again demonstrate that this bidentate phosphane ligand forms a stable chelate with platinum(0), resulting in zero activity at 30 and 50 °C and only a very low activity at 100 °C. Triphenylphosphane was also tested once in the hydrosilylation at 30 °C. After 2 h, a total yield of only 8.5% was obtained with a selectivity of 3.0:73.0:24.0 (**I/II/III**).

As mentioned before, the selectivities of platinum catalysts depend strongly on the styrene/triethylsilane ratio. For example, applying a styrene/triethylsilane ratio of 0.5 using [Pt(nbe)$_3$] as the catalyst yielded a selectivity (**I/II/III**) of 2.0:90.0:8.0. However, when a styrene/triethylsilane ratio of 6.4 was used, an enormous increase in dehydrogenative silylation was observed: 37% of product **III** was obtained. This observation supports the idea[13,14] that the dissociation of the vinylsilane is favored by a higher styrene concentration [Equation (3)]. Comparing our selectivities obtained with already reported catalysts is not straightforward since the conditions applied can have a significant influence. For example, Skoda-Földes et al.[29] obtained 12.3% of **III** with $PtCl_2$ as a catalyst and using a styrene/triethylsilane ratio of 1.0 in the hydrosilylation of styrene with triethylsilane. Employing 2.8 equiv. of styrene, we obtained 31.0% of product **III** using [Pt(nbe)$_3$] as the catalyst. However, when using a styrene/triethylsilane ratio of 1.0 with this catalyst, product **III** was observed in only 11.0%, which is almost similar to the result obtained by Skoda-Földes et al. with $PtCl_2$. Also, Dötz et al.[15] and Caseri and Pregosin[16] obtained considerable amounts of product **III** in this reaction, using [Pt(η^2-2-methylnaphthoquinone)(η^4-CH_2=$CHSiMe_2$)$_2$O] and *trans*-[$PtCl_2$(PhCH=CH_2)$_2$] as the catalyst, respectively.

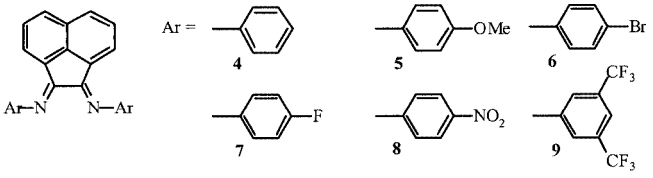
The activities of our catalysts are influenced by several reaction conditions; temperature was already discussed, but the styrene concentration also influences the reaction significantly. In general, a higher styrene concentration contributes to a higher stability of the catalyst. Consequently, when [Pt(nbe)$_3$] was used as a catalyst using a styrene/triethylsilane ratio of 1.0, a yield of only 32% was obtained after 2 h, which is rather low when compared to the 91.9% yield using a styrene/triethylsilane ratio of 2.8 (Table 1, Entry 1). However, when the reaction using a styrene/triethylsilane ratio of 1.0 was repeated, but now without 20 mL of toluene as the solvent, an increase in yield was also observed: from 32 to 88%. Caseri and Pregosin[16] reported that [Pt(styrene)$_3$] was more active than *trans*-[$PtCl_2$(PhCH=CH_2)$_2$] and that this complex did not show an induction period. From our results, we can say that [Pt(nbe)$_3$] also generates highly active platinum(0) species, probably similar to [Pt(styrene)$_3$][16] although we did not check if this complex is formed during catalysis.

The lability of the phenyl-bian ligand was studied in more detail by substituting the aryl groups of this ligand. Thus, ligands **4**−**9** were synthesized and tested in the catalytic hydrosilylation of styrene with triethylsilane at 30 °C. The results are collected in Table 2.

Table 2. Hydrosilylation of styrene with triethylsilane using Ar-bian ligands

Entry	Ligand[a]	Yield [%][b]	Selectivity [%][c] **I/II/III**
1	**4**	86.0	2.0:67.5:30.5
2	**5**	84.7	2.0:67.5:30.5
3	**6**	87.0	2.0:67.0:31.0
4	**7**	91.0	2.0:67.5:30.5
5	**8**	90.1	2.0:66.5:31.5
6	**9**	90.0	2.0:67.5:30.5

[a] 0.36 mol % of catalyst, styrene/triethylsilane ratio 2.8, toluene, 30 °C. [b] Combined GC yield, after 2 h, of products **I**, **II**, and **III** using *n*-decane as the internal standard. [c] Product **IV** was always observed in the same amount as product **III**, therefore the amount of **IV** has been omitted.



It is immediately evident from Table 2 that substitution of the Ar-bian ligands has no significant influence on the selectivity of the hydrosilylation. There seems to be a relation between the yield and the inductive effect of the *para* substituents on the aryl groups of the Ar-bian ligand, as increasing yields are observed with decreasing electron-donating ability. This can be explained by the fact that electron-donating substituents increase the basicity of the Ar-bian ligand, resulting in more stable platinum(0) complexes. As a consequence, the lowest yield is obtained for *p*-MeO-C_6H_4-bian (Entry 2), but the differences are small.

Synthesis of [Pt(Ar-bian)(η^2-alkene)] Complexes

When obtaining the catalysts in situ, there may be competition for the substrate, due to the relatively large amount (2−3 equiv.) of alkene liberated upon reaction of [Pt(nbe)$_3$] with the bidentate N-ligand (Scheme 2). On the other hand, the Ar-bian ligands are also labile. Therefore, we were inter-

Scheme 2. Synthesis of [Pt(Ar-bian)(η^2-alkene)] complexes

ested in comparing our hitherto obtained results with experiments employing predefined [Pt(Ar-bian)(η^2-alkene)] complexes as catalyst precursors in the hydrosilylation of styrene with triethylsilane. The stability of these complexes will depend on the nature of the Ar-bian ligand as well as of the alkene. Electron-donating substituents on the Ar-bian ligand, concomitant with the use of electron-poor alkenes is expected to increase the stability of complexes of this type. Van Asselt et al.[24] already synthesized several [Pt(Ar-bian)(η^2-alkene)] complexes. By employing *p*-Me-C_6H_4-bian and *o*,*o*′-*i*Pr_2-bian with fumaronitrile (fn), maleic anhydride (ma), and tetracyanoethylene (tcne) as coordinating alkenes, stable complexes were obtained starting from [Pt$(dba)_2$]. However, complexes with the less electron-poor dimethyl fumarate (dmfu) could not be obtained by using this method, which includes heating in THF at 45 °C for 16 h. Since our aim was the synthesis of several new complexes with alkenes like dmfu, which at the same time have Ar-bian ligands containing electron-withdrawing substituents, such as *m*,*m*-$(CF_3)_2$-C_6H_3-bian, we selected [Pt$(nbe)_3$] instead of [Pt$(dba)_2$] as the precursor, allowing milder reaction conditions.[23,32,33] First, the synthesis of various platinum(0) complexes of type [Pt(*m*,*m*-$(CF_3)_2$-C_6H_3-bian)(η^2-alkene)] was addressed by treating [Pt$(nbe)_3$] with stoichiometric amounts of the ligands. Attempts to prepare [Pt(*m*,*m*-$(CF_3)_2$-C_6H_3-bian)(dmfu)] were not successful. Allowing equimolar amounts of [Pt$(nbe)_3$], *m*,*m*-$(CF_3)_2$-C_6H_3-bian, and dmfu to react in tetrahydrofuran at room temperature led to the formation of mixtures of starting materials and reaction products. Similar results were obtained when diethyl ether instead of tetrahydrofuran was used as a solvent. In both cases, purification of the reaction product was troublesome due to its complete solubility in most common organic solvents. ^{1}H NMR spectroscopy of the crude reaction product suggested that ligand substitution had not been complete: large amounts of uncomplexed *m*,*m*-$(CF_3)_2$-C_6H_3-bian were present. Using [Pt$(cod)_2$] as starting material, [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(dmfu)] could not be obtained either.

Initial attempts to prepare [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(ma)] by adding [Pt$(nbe)_3$] to a dilute solution of equimolar amounts of *m*,*m*-$(CF_3)_2$-C_6H_3-bian and maleic anhydride in tetrahydrofuran were in vain. Similar to the case of [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(dmfu)], purification of the reaction product was tedious and ^{1}H NMR spectroscopy suggested incomplete ligand substitution. Better results were obtained, when *m*,*m*-$(CF_3)_2$-C_6H_3-bian was added to an ice cold concentrated solution of ma and [Pt$(nbe)_3$]. After washing the crude reaction product with pentane, [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(ma)] readily precipitated from the combined organic extract and was obtained as a pure compound.

Similarly, the synthesis of [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(tcne)] was straightforward and proceeded as expected. In order to probe the influence of electronic effects on the synthesis of platinum(0) complexes of type [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(η^2-alkene)], it was attempted to use electron-rich instead of electron-deficient alkenes. Thus, synthesis of [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(trimethylvinylsilane)] was attempted by stirring equimolar amounts of [Pt$(nbe)_3$], *m*,*m*-$(CF_3)_2$-C_6H_3-bian, and trimethylvinylsilane in tetrahydrofuran. Although nearly all of the starting materials had reacted after 4 h of stirring at room temperature, at least six different reaction products were formed as was evident from TLC and no efforts were made to further purify the crude reaction product.

Next, in order to study the influence of electronic effects on the synthesis of platinum(0) complexes of type [Pt(Ar-bian)(η^2-alkene)] and also on their catalytic hydrosilylation behavior, the synthesis of various platinum(0) complexes of type [Pt(*p*-MeO-C_6H_4-bian)(η^2-alkene)] was addressed. As opposed to the synthesis of [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(dmfu)], the synthesis of [Pt(*p*-MeO-C_6H_4-bian)(dmfu)] was successful and yielded the desired reaction product in excellent yield. Likewise, the synthesis of [Pt(*p*-MeO-C_6H_4-bian)(ma)] was straightforward, but the synthesis of [Pt(*p*-MeO-C_6H_4-bian)(acrylonitrile)] was more troublesome. Although TLC revealed that all of the starting materials had reacted after 2 h of stirring at room temperature, it was not possible to unambiguously characterize the residue obtained after washing the crude reaction mixture with diethyl ether/pentane. Finally, the complex [Pt(phenyl-bian)(dmfu)] was also synthesized in good yield using the same procedure.

Synthesis of [Pt(dafo)(dmfu)], [Pt(dafo)(ma)], and [Pt(dafo)(tcne)] was also addressed, but these attempts were not successful. Adding dafo to a concentrated solution of [Pt$(nbe)_3$] and 1.20 equiv. of dmfu in tetrahydrofuran did not result in the formation of [Pt(dafo)(dmfu)] after overnight stirring at reflux. None of the starting dafo had re-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

acted, as was evident from ^{1}H NMR spectroscopy. Likewise, the synthesis of [Pt(dafo)(ma)] and [Pt(dafo)(tcne)] did not succeed. In the latter cases a slight amount of complexed dafo was observed by ^{1}H NMR spectroscopy, but the yields remained very low, in keeping with the weak ligating properties of dafo.

Hydrosilylation of Styrene by Triethylsilane Catalyzed by [Pt(Ar-bian)(η^2-alkene)] Complexes

In order to study the catalytic behavior of platinum(0) complexes of type [Pt(Ar-bian)(η^2-alkene)], [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(ma)], [Pt(*p*-MeO-C_6H_4-bian)(ma)], [Pt(*p*-MeO-C_6H_4-bian)(dmfu)], and [Pt(C_6H_5-bian)(dmfu)] were tested as catalysts in the hydrosilylation of styrene by triethylsilane, applying a styrene/triethylsilane ratio of only 1.0. The complex [Pt(Me-nq)$(nbe)_2$], an active hydrosilylation catalyst,[8] was also tested. The yields of the combined silyl products against time are shown in Figure 1.

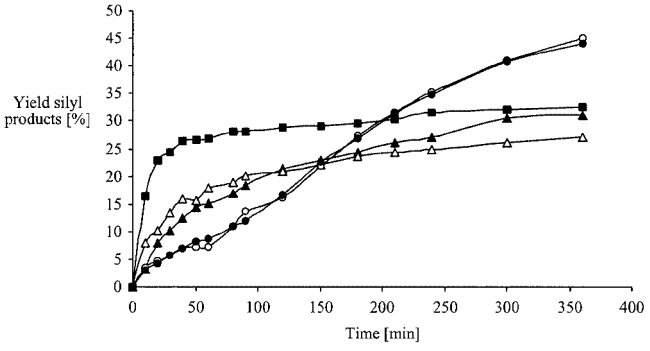

Figure 1. Hydrosilylation of styrene by triethylsilane catalyzed by [Pt(*m*,*m*-$(CF_3)_2$-C_6H_3-bian)(ma)] (open triangles), [Pt(*p*-MeO-C_6H_4-bian)(ma)] (filled triangles), [Pt(*p*-MeO-C_6H_4-bian)(dmfu)] (open circles), [Pt(C_6H_5-bian)(dmfu)] (filled circles), and [Pt(Me-nq)$(nbe)_2$] (filled squares); conditions: 0.36 mol % of catalyst, styrene/triethylsilane ratio 1.0, toluene, 30 °C; yield is the combined GC yield after 2 h of products **I**, **II**, and **III** using *n*-decane as the internal standard

From these results, it is obvious that the nature of the coordinated alkene determines the catalytic behavior of the complexes. [Pt(*p*-MeO-C_6H_4-bian)(dmfu)] and [Pt(C_6H_5-bian)(dmfu)] show an almost completely identical catalytic activity and stability. The complexes [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(ma)] and [Pt(*p*-MeO-C_6H_4-bian)(ma)] give different results compared to the two dmfu complexes: they show a higher initial activity, but decompose faster, resulting in a lower overall yield. From the synthetic experiments (see above), it is known that electron-donating substituents on the Ar-bian ligand increase the stability of the complex. However, for the two maleic anhydride complexes only a small difference in catalytic behavior is observed. In the beginning of the reaction, [Pt(*p*-MeO-C_6H_4-bian)(ma)] is slightly less active than [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(ma)], but is slightly more stable. [Pt(Me-nq)$(nbe)_2$] is a very active catalyst, but decomposition of the catalyst starts immediately after addition of triethylsilane. After 6 h, a yield of 32.5% was obtained with [Pt(Me-nq)$(nbe)_2$], which is almost similar to [Pt{*m*,*m*-$(CF_3)_2$-C_6H_3-bian}(ma)] (27.1%) and [Pt(*p*-MeO-C_6H_4-bian)(ma)] (31.1%). Although [Pt(*p*-MeO-C_6H_4-bian)(dmfu)] and [Pt(C_6H_5-bian)(dmfu)] are less active catalysts, there stability resulted in higher overall yields of 41.1% and 44.9%, respectively, after 6 h with the catalysts still being active after this time. After 24 h, a yield of 65% was obtained for [Pt(*p*-MeO-C_6H_4-bian)(dmfu)].

For all complexes, compound **II** was observed as the major product (85−87%) along with a minor amount of compound **I** (about 2%). The dehydrogenative silylation product **III** was observed in about 11−13% yield. The selectivities obtained with these catalysts were constant in time. The decreased amount of dehydrogenative silylation, compared to the reactions with in situ prepared catalysts, is caused by the lower styrene concentration compared to the other experiments, since a styrene/triethylsilane ratio of 1.0 instead of 2.8 was employed. As discussed before, the selectivities obtained are quite similar to those obtained using $PtCl_2$ as the catalyst.[29] $PtCl_2$, in fact every platinum(II) or platinum(IV) catalyst, is deemed to be reduced to a platinum(0) species. The reduction process, often of variable duration, causes the frequently observed induction periods for these catalysts.[3a] For example, using [$PtCl_2$(PhCH=$CH_2)_2$] as a catalyst, Caseri and Pregosin showed that the hydrosilylation of styrene proceeded by reduction of the Pt^{II} complex to [Pt(styrene)$_3$] with concomitant formation of 2 equiv. of R_3SiCl and 1 equiv. of ethylbenzene.[37] From Figure 1 it becomes quite obvious that our [Pt(Ar-bian)(η^2-alkene)] complexes do not suffer from an induction period; the hydrosilylation reactions start immediately after addition of the substrates. This behavior is in agreement with that observed for other platinum(0) catalysts.[8−10,16]

Since the palladium complexes [Pd(Ar-bian)(η^2-alkene)] are versatile catalysts for the selective hydrogenation of alkynes to (*Z*)-alkenes,[21] we also tested [Pd(*p*-MeO-C_6H_4-bian)(dmfu)] as a hydrosilylation catalyst and compared its catalytic behavior with its platinum analogue. However, it appears that this compound does not catalyze the hydrosilylation reaction at all: the complex immediately decomposed under hydrosilylation conditions in both THF and toluene at 30 °C.

Conclusion

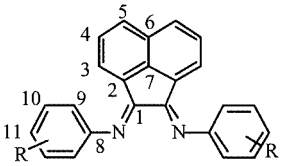
In conclusion, several bidentate N-ligands have been evaluated in the hydrosilylation of styrene with triethylsilane at different temperatures, using in situ formed catalysts with [Pt(nbe)$_3$] as a precursor. In general, the ligands which form more stable platinum(0) complexes result in a lower catalytic activity and somewhat more dehydrogenative silylation compared to the ligands which form less stable complexes. Consequently, the precursor complex, [Pt(nbe)$_3$] itself, which has only labile alkene ligands, is an active catalyst at 30 °C and at a styrene to triethylsilane ratio of 2.8. At higher temperatures, the catalyst is no longer stable and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a decrease in yield is observed when the temperature is increased. The complex [Pt(Me-nq)(nbe)$_2$], does not give significantly higher yields. Common bidentate ligands such as phen and dppe form stable complexes, resulting in no or very low hydrosilylation activity. However, for the ligands dafo and phenyl-bian, a small ligand effect is observed. Substituting the aryl groups of phenyl-bian ligand does not influence the catalysis significantly. By studying the behavior of various [Pt(Ar-bian)(alkene)] complexes, it has become clear that the nature of the alkene ligand in these complexes determines its catalytic behavior; the [Pt(Ar-bian)(ma)] complexes are intrinsically slightly more active than the two [Pt(Ar-bian)(dmfu)] complexes, however, the [Pt(Ar-bian)(dmfu)] complexes result in much more stable catalysts. The fact that the different Ar-bian ligands do not have a major influence on the catalytic behavior of the complexes demonstrates the lability of these bidentate ligands compared to several alkenes. Importantly, compared to [Pt(Me-nq)(nbe)$_2$], the two [Pt(Ar-bian)(dmfu)] complexes show an intrinsically lower activity, but are at the same time much more stable, resulting in significantly higher overall yields under similar conditions. We are at present investigating the use of alkenes as ligands in the platinum(0)-catalyzed hydrosilylation in more detail.

Experimental Section

General Remarks: All experiments were carried out by using standard Schlenk techniques under dry nitrogen. The solvents were dried according to standard procedures and distilled before use. Quantitative gas liquid chromatography (GLC) analyses were carried out with a Varian 3300 apparatus equipped with a semicapillary column (J&W, DB 5, 30 m × 1 μm) with *n*-decane as internal standard. Elemental analyses were carried out by Kolbe, Mikroanalytisches Laboratorium, Mülheim a. d. Ruhr, Germany. ^{1}H, ^{13}C, and ^{19}F NMR spectra were recorded at 300.1, 75.5, and 282.4 MHz, respectively, with a Varian Mercury 300 and with a Varian Inova 500 spectrometer at 499.8 and 125.7 MHz, respectively. Chemical shift values are in ppm relative to external TMS or Cl_3CF with high frequency shifts signed as positive. Abbreviations used are s = singlet, d = doublet, pst = peudotriplet, m = multiplet; multiplicity, number of protons and coupling constants (Hz) in parentheses. Triethylsilane (Acros), *n*-decane (Acros), dimethyl fumarate (Merck), tetracyanoethylene (Fluka), 1,10-phenanthroline (Aldrich), 2,2′-dipyridyl (Aldrich), triphenylphosphane (Aldrich), bis(diphenylphosphanyl)ethane (Strem), 2-methyl-2,4-naphthoquinone (Aldrich), acenaphthenequinone (Aldrich), and 4-fluoroaniline (Janssen Chimica) were used as received. Styrene (Acros) was purified by flash chromatography on alumina immediately prior to use. Maleic anhydride (EGA) was recrystallized from dichloromethane. [Pt(nbe)$_3$],[27] [Pd(*p*-MeO-C$_6$H$_4$-bian)(DMFU)],[24] phenyl-bian,[34] *p*-MeO-C$_6$H$_4$-bian,[34] *p*-Br-C$_6$H$_4$-bian,[34] *p*-NO$_2$-C$_6$H$_4$-bian,[35] and *m*,*m*-(CF$_3$)$_2$-C$_6$H$_3$-bian[35] were synthesized according to published procedures. 4.5-Diazafluoren-9-one[36] was synthesized according to the literature, but was additionally purified using column chromatography [silica, MeOH/dichloromethane (5:95)].



Bis(4-fluorophenylimino)acenaphthene (*p*-F-C$_6$H$_4$-bian, 7): The ligand was prepared analogous to the method described in the literature[36] for that of acenaphthenequinone and 4-fluoroaniline and was obtained as an orange solid. Yield: 1.81 g, 75%. ^{1}H NMR (300.1 MHz, $CDCl_3$): δ = 6.94 (d, ^3J = 7.14 Hz, 2 H, 3-H), 7.10 (m, 4 H, 9-H), 7.18 (m, 4 H, 10-H), 7.42 (pst, ^3J = 7.42 Hz, 2 H, 4-H), 7.93 (d, ^3J = 7.14 Hz, 2 H, 5-H) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 116.52 (d, $^2J_{F,C}$ = 22.57 Hz, C-10), 119.95 (d, $^3J_{F,C}$ = 8.06 Hz, C-9), 124.10 (C-3), 127.91 (C-4), 128.48 (C-2), 129.46 (C-5), 131.47 (C-6), 142.03 (C-7), 147.71 (C-8), 160.28 (d, $^1J_{F,C}$ = 243.46 Hz, C-11), 162.00 (C-1) ppm. ^{19}F NMR (282.4 MHz, $CDCl_3$): δ = −119.31 ppm.

(σ-*N*,σ-*N*′-Bis{3,5-bis(trifluoromethyl)phenylimino}acenaphthene)-(η^{2}maleic anhydride)platinum(0) (10a): THF (2.5 mL) was added to maleic anhydride (127.0 mg, 275 μmol). The colorless solution was cooled to 0 °C, after which [Pt(nbe)$_3$] (119.5 mg, 250 μmol) was added. The solution was stirred at 0 °C for 15 min, after which *m*,*m*-(CF$_3$)$_2$-C$_6$H$_3$-bian (164.9 mg, 273 μmol) was added. Stirring was continued at 0 °C for 45 min, followed by the heating of the reaction mixture to room temperature. The orange solution was concentrated to dryness and the residue dissolved in 2 mL of dichloromethane. Pentane (20 mL) was added to the solution, after which a dark precipitate formed. The solvent was removed via a syringe and the solid was washed with pentane (4 × 20 mL) and dried in vacuo. The isolated dark purple powder was analyzed by NMR spectroscopy and appeared to be a mixture of reaction products. However, upon standing, a dark solid had precipitated from the combined organic extract. The precipitate was washed with pentane (8 × 10 mL) and dried in vacuo, after which **10a** was obtained as a dark purple powder. Yield: 96.5 mg, 43.0%. ^{1}H NMR (499.8 MHz, CD_2Cl_2): δ = 3.76 (s, $J_{Pt\text{-}H}$ = 89.84 Hz, 2 H, ma), 7.49 (d, ^3J = 7.32 Hz, 2 H, 3-H), 7.63 (pst, ^3J = 7.70 Hz, 2 H, 4-H), 8.10 (s, 2 H, 11-H), 8.21 (s, 4 H, 9-H), 8.38 (d, ^3J = 8.24 Hz, 2 H, 5-H) ppm. No ^{13}C NMR spectrum was recorded due to the low solubility and stability of the complex. ^{19}F NMR (282.4 MHz, CD_2Cl_2): δ = −63.35 ppm. $C_{32}H_{14}F_{12}N_2O_3Pt$ (897.52): calcd. C 42.82, H 1.57, N 3.12; found C 42.67, H 1.63, N 3.04.

(σ-*N*,σ-*N*′-Bis{3,5-bis(trifluoromethyl)phenylimino}acenaphthene)(η^2-tetracyanoethene)platinum(0) (10b): THF (20 mL) was added to *m*,*m*-(CF$_3$)$_2$-C$_6$H$_3$-bian (121 mg, 200 μmol), and tetracyanoethene (26.3 mg, 205 μmol). [Pt(nbe)$_3$] (92.1 mg, 193 μmol) was added to this mixture, and the solution changed color from bright orange to deep red. The mixture was stirred for 4 h at room temperature, after which the reaction was complete as was evident from TLC. The solvent was removed in vacuo and the residue washed with diethyl ether (3 × 2 mL) to afford **10b** as an orange solid. Yield: 151 mg, 81.6%. ^{1}H NMR (499.8 MHz, [D$_6$]acetone): δ = 7.80 (d, ^3J = 7.33 Hz, 2 H, 3-H), 7.85 (pst, ^3J = 7.81 Hz, 2 H, 4-H), 8.38 (s, 2 H, 11-H), 8.52 (s, 4 H, 9-H), 8.58 (d, ^3J = 8.06 Hz, 2 H, 5-H) ppm. ^{13}C NMR (125.7 MHz, [D$_6$]acetone): δ = 115.07 (CN), 123.92 (q, $^1J_{F,C}$ = 272.68 Hz, CF_3), 124.08 (C-9), 124.35 (C3), 125.84 (C-2), 126.78 (C-4), 130.77 (C-5), 133.18 (C-6), 134.44 (q, $^2J_{F,C}$ = 33.94 Hz, C-10), 134.45 (C-11), 149.69 (C-8), 150.07 (C-7), 176.67 (C-1) ppm. ^{19}F NMR (282.4 MHz, [D$_6$]acetone): δ = −63.57 ppm. $C_{34}H_{12}F_{12}N_6Pt$ (927.56): calcd. C 44.03, H 1.30, N 9.06; found C 44.11, H 1.36, N 9.13.

(σ-*N*,σ-*N*′-Bis{4-methoxyphenylimino}acenaphthene)(η²-maleic anhydride)platinum(0) (11a): THF (3.5 mL) was added to *p*-MeO-C_6H_4-bian (107.3 mg, 273 μmol), and maleic anhydride (27.2 mg, 277 μmol). [Pt(nbe)$_3$] (120 mg, 251 μmol) was added to this solution after which the solution changed color from deep red to dark green. The mixture was stirred at room temperature for 60 min, and the solvent was removed in vacuo. The dark residue was washed with diethyl ether (3 × 3 mL), dried, dissolved in 5 mL of dichloromethane, and filtered through Celite Hyflo. Pentane (20 mL) was added to the filtrate followed by the formation of a dark precipitate. The solid was washed with pentane (4 × 10 mL) and dried in vacuo, after which **11a** was obtained as a brown red solid. Yield: 98.3 mg, 57.3%. ^{1}H NMR (499.8 MHz, CD_2Cl_2): δ = 3.55 (s, J_{Pt-H} = 84.46 Hz, 2 H, ma), 3.93 (s, 6 H, MeO), 7.09 (d, ^3J = 9.03 Hz, 4 H, 9-H), 7.48 (pst, ^3J = 7.81 Hz, 2 H, 4-H), 7.63−7.71 (m, 6 H, 3-H and 10-H), 8.17 (d, ^3J = 8.06 Hz, 2 H, 5-H) ppm. ^{13}C NMR (125.7 MHz, CD_2Cl_2): δ = 25.97 (ma), 55.81 (MeO), 114.45 (C-10), 123.39 (C-9), 124.97 (C-3), 127.30 (C-2), 128.94 (C-4), 130.41 (C-5), 132.19 (C-6), 141.26 (C-8), 145.50 (C-7), 160.47 (C-11), 168.64 (C-1), 174.51 (ma) ppm. $C_{30}H_{22}N_2O_5Pt$ (685.58): calcd. C 52.56, H 3.23, N 4.09; found C 52.48, H 3.20, N 3.99.

(σ-*N*,σ-*N*′-Bis{4-methoxyphenylimino}acenaphthene)(η²-dimethyl fumarate)platinum(0) (11c): THF (20 mL) was added to *p*-MeO-C_6H_4-bian (78 mg, 199 μmol) and dimethyl fumarate (31.0 mg, 215 μmol). The solution changed color from deep red to dark green upon addition of [Pt(nbe)$_3$] (120 mg, 251 μmol). The mixture was stirred at room temperature for 90 min, after which the reaction was complete as was evident from TLC. The solvent was removed in vacuo and the dark brown residue washed with diethyl ether (2 × 3 mL) and dissolved in 5 mL of dichloromethane. The dark brown solution was filtered through Celite Hyflo and the filtrate concentrated to dryness in vacuo. The desired reaction product **11c** was obtained as a dark brown solid. Yield: 137 mg; 94.0%. ^{1}H NMR (300.1 MHz, CD_2Cl_2): δ = 3.40 (s, 6 H, dmfu), 3.72 (s, J_{Pt-H} = 91.22 Hz, 2 H, dmfu), 3.98 (s, 6 H, MeO), 7.49 (d, ^3J = 7.42 Hz, 2 H, 3-H), 7.63 (pst, ^3J = 7.70 Hz, 2 H, 4-H), 8.10 (s, 2 H, 10-H), 8.21 (s, 4 H, 9-H), 8.14 (d, ^3J = 8.24 Hz, 2 H, 5-H) ppm. ^{13}C NMR (125.7 MHz, CD_2Cl_2): δ = 27.29 (dmfu), 50.57 (dmfu), 56.17 (MeO), 115.07 (C-10), 123.54 (C-9), 125.72 (C-3), 129.21 (C-2), 130.11 (C-4), 130.71 (C-5), 133.43 (C-6), 134.04 (C-8), 142.62 (C-7), 160.92 (C-11), 168.93 (C-1), 176.45 (dmfu) ppm. $C_{32}H_{28}N_2O_6Pt$ (731.65): calcd. C 52.53, H 3.86, N 3.83; found C 52.34, H 3.76, N 3.95.

(σ-*N*,σ-*N*′-Bis{phenylimino}acenaphthene)(η²-dimethyl fumarate)-platinum(0) (12c): [Pt(nbe)$_3$] (0.92 g, 1.93 mmol), C_6H_5-bian (0.70 g, 2.11 mmol) and dimethyl fumarate (0.31 g, 2.15 mmol) were dissolved in THF (20 mL). The color of the solution changed to dark green immediately. The mixture was stirred at room temperature for 60 min and the solution was filtered through Celite Hyflo. The filtrate was concentrated to dryness in vacuo and was washed with a 50-mL pentane/diethyl ether (1:1) mixture and 2 × 50 mL of pentane. The desired reaction product **12c** was obtained as a dark green solid. Yield: 1.04 g; 80.0%. ^{1}H NMR (300.1 MHz, CD_2Cl_2): δ = 3.33 (s, 6 H, dmfu), 3.71 (s, J_{Pt-H} = 93.15 Hz, 2 H, dmfu), 7.46−7.53 (m, 6 H, 3-H + 4-H + 11-H), 7.60 (m, 8 H, 9-H + 10-H), 8.21 (d, ^3J = 5.50 Hz, 1 H, 5-H), 8.23 (d, ^3J = 5.50 Hz, 1 H, 5-H) ppm. ^{13}C NMR (125.7 MHz, CD_2Cl_2): δ = 27.93 (dmfu), 50.96 (dmfu), 122.87 (C-9), 123.76 (C-3), 128.30 (C-2), 128.62 (C-4), 129.87 (C-11), 130.16 (C-10), 130.43 (C-5), 132.7 (C-6), 145.85 (C-7), 149.19 (C-8), 169.65 (C-1), 176.47 (dmfu) ppm. $C_{30}H_{24}N_2O_4Pt$ (671.60): calcd. C 53.65, H 3.60, N 4.17; found C 53.88, H 3.74, N 4.08.

General Procedure for the Hydrosilylation of Styrene with Triethylsilane: A two-necked Schlenk tube equipped with a septum, a reflux condenser and a stirring bar was charged with the appropriate platinum complex (0.022 mmol) and, in the case of the in situ prepared catalysts, 1 equiv. of ligand. The Schlenk tube was evacuated and filled with nitrogen three times. Then toluene (20 mL), styrene (6.16 mmol or 17.24 mmol), *n*-decane (3.08 mmol), and triethylsilane (6.16 mmol) were added, in this order, in quick succession from syringes through the septum. The reactor was immediately immersed in an oil bath, which was kept at the required reaction temperature. Samples were taken periodically for GC analyses. Products were characterized using NMR spectroscopy and GC-MS.

Acknowledgments

The research has been performed within the National Research School Combination Catalysis (project number: 2000-14), which is gratefully acknowledged for financial support. We thank M. W. van Laren for synthesizing [Pd(*p*-MeO-C_6H_4-bian)(dmfu)].

Synthesis, Structure and Magnetic Properties of a New Iron Arsenate, $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$, with a Layer Structure

Sandip Chakrabarti,[a] Swapan K. Pati,[b] Mark A. Green,[c] and Srinivasan Natarajan*[a]

Keywords: Iron / Arsenic / Solvothermal synthesis / N ligands

The reaction of $FeCl_3 \cdot 6H_2O$, H_3AsO_4, HF and 1,4-bis(3-aminopropyl)piperazine under solvothermal conditions gives rise to a new iron arsenate, $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ (**I**) with a layered structure. The cell parameters are monoclinic, space group = $P2_1/n$ (no.14), M = 1143.08, a = 9.6320(3), b = 8.3598(3), c = 10.7794(1) Å, β = 115.036(1)°, V = 786.42(4) Å^3, Z = 4, R_1 = 0.0492, wR_2 = 0.1227 [1114 observed reflections with $I > 2\sigma(I)$]. The connectivity between $FeO_3F_2(OH)$ octahedra and $HAsO_4$ tetrahedra forms a secondary building unit (SBU) of the type SBU-4. The SBU-4 units are linked together to form a layer structure with apertures formed by 8-T atoms (T = Fe, As). The amine molecules are disordered and occupy the inter-lamellar region. To the best of our knowledge, **I** is the first example of an iron arsenate structure formed from only one type of secondary building unit, SBU-4. A dimer model has been used to describe the magnetic behavior.

Introduction

The synthesis, structure and properties of metal phosphates prepared in the presence of organic amines has been intensely researched during the last two decades.[1] Of these, the transition metal phosphates are interesting due to the variations in the oxidation state and coordination preferences of the transition element. Thus, a large number of iron phosphates with novel structures have been prepared and characterized.[2,3] Most of these iron phosphates have been prepared by employing hydrothermal methods. In some cases HF was used as the mineralizer, which also becomes part of the structure by linking the metal centers.[2−4] It is interesting to note that the use of HF produced a number of novel phosphate frameworks that do not generally form in the fluoride-free medium.

Though arsenic belongs to the same group as phosphorous, little work has been carried out on arsenate-based framework structures. It is likely that the larger size of the As^{5+} cation (0.335 Å) compared to the P^{5+} cation (0.17 Å)[5] would lead to the formation of completely different structures. In addition, a comparison of the pK_a values of H_3PO_4 and H_3AsO_4 also gives an idea about the relative ease of removal of protons. Thus for H_3PO_4, pK_{a1}, pK_{a2} and pK_{a3} are 2.12, 7.21 and 12.32, respectively, while for H_3AsO_4, pK_{a1}, pK_{a2} and pK_{a3} are 2.3, 6.9 and 11.5, respectively. This probably indicates that arsonic acid is somewhat weaker than phosphoric acid. The research in arsenate-based framework compounds are beginning to emerge, but is limited possibly due to the toxicity associated with arsenic and its relative inability to form extended networks. The intense investigations by many researchers during the last decade or so have given rise to new arsenates of different compositions and structures. Thus, arsenates of aluminum,[6,7] gallium,[8−10] molybdenum,[11,12] vanadium,[13−18] iron[19−24] and zinc[25−27] have been prepared and their structures reported in the literature. In order to expand the family of known arsenate framework structures, we have been investigating the formation of iron arsenates in the presence of structure-directing organic amine molecules. In this paper, we report the hydrothermal synthesis, crystal structure and spectroscopic and magnetic properties of a new iron(III) arsenate prepared in the presence of 1,4-bis(3-aminopropyl)piperazine (AP-PIP) cations, $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ (**I**). This compound possesses a layer structure formed entirely by the linking between only one type of secondary building units (SBU-4),[28,29] which to the best of our knowledge is the first example of an iron arsenate formed with organic cations.

Results and Discussion

The structure consists of macroanionic layers of $[\{FeF(OH)(HAsO_4)\}_4]^{4-}$ formed by the linking of FeO_4-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200300237

F(OH) octahedra and $AsO_3(OH)$ tetrahedra. The AP-PIP cations are located in the inter-lamellar region. The asymmetric unit of the layer is shown in Figure 1. There is only one crystallographically distinct Fe and As atom in the asymmetric unit. The Fe atom is octahedrally coordinated by four O and two F atoms with Fe−O/F bond lengths in the range 1.884(6)−2.049(5) Å (av. 1.9842 Å). The octahedral O/F−Fe−O/F bond angles are in the range 77.6(2)−176.3(3)° (av. 106.3°). The iron atom is linked to the arsenic atom by three Fe−O−As bonds, two Fe−F−Fe bonds and one terminal -OH group. The As atom also has three As−O−Fe bonds and one terminal As−O bond. The As atom is tetrahedrally coordinated by oxygen atoms with an average As−O distance of 1.6873 Å and O−As−O bond angle of 109.4°. Using the Brown−Altermatt formalism[30] for the bond length/bond valence relationship for Fe−O and As−O, bond-order sums for the cations and anions were calculated (Table 1). The calculated bond-order sums for both cations and anions are in agreement with the formal oxidation states of +3, +5 and −2 for Fe, As and O atoms respectively.

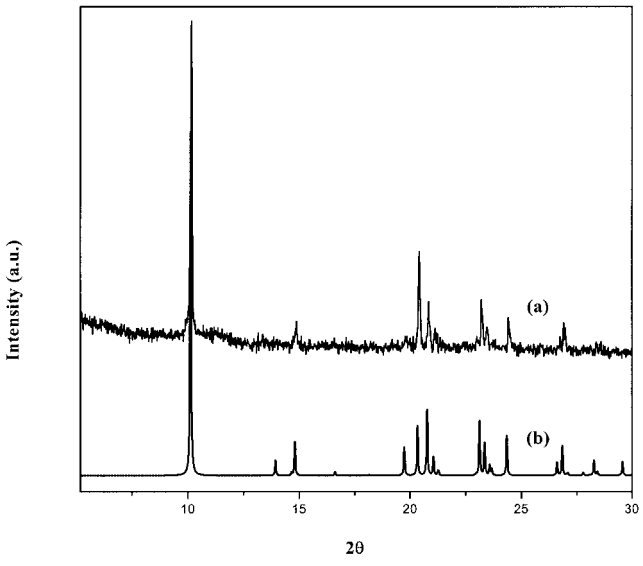

Figure 1. ORTEP diagram of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ showing the atoms that constitute the layer; thermal ellipsoids are given at 50% probability

The inset of Figure 2 shows the $\{FeF(OH)(HAsO_4)\}^-$ segment of the structure. As can be seen, two $FeO_3F_2(OH)$ distorted octahedra share a common edge. These dimeric units are connected by AsO_4 groups in a doubly bridging fashion. The AsO_4 units also act as a terminal ligand to the neighboring $FeO_3F_2(OH)$ octahedra. Thus, each AsO_4 unit is linked to three $FeO_3F_2(OH)$ octahedra, its fourth vertex being free and pointing into the inter-lamellar region. Similarly, each $FeO_3F_2(OH)$ octahedron links with three AsO_4 tetrahedra and connects to another Fe through the edge, with the remaining vertex, which is an -OH group, pointing into the interlayer region. The $(Fe_2F_2)^{4+}$ core and the two AsO_4 units linking it in a chelating fashion is identical to the secondary building unit SBU-4, formulated by Ferey.[28,29] Similar building units and connectivity have also been observed in A-frame compounds.[31] The SBU-4 units are linked through their corners forming an extended layered structure (Figure 2). The arrangement of layers in the *ab* plane is shown in Figure 3. As can be seen there are

interactions between the layers through the terminal Fe−OH bonds.

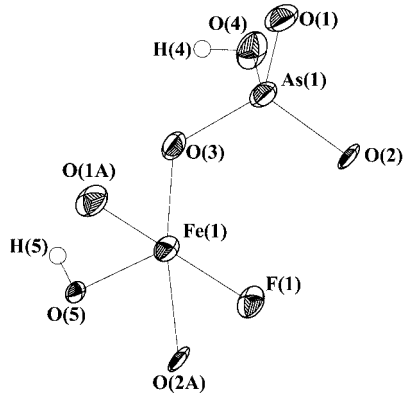

Figure 3. Polyhedral view of the structure of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ in the *ac* plane showing the arrangement of layers; the amine molecules are not shown for clarity; dotted lines represent possible hydrogen bond interactions

The concept of secondary building units for the description of framework structures is common in pure tetrahedral aluminosilicate and phosphate structures.[32] Recently, many secondary building units have been identified and proposed for the description of octahedral-tetrahedral frameworks.[28,29] Though many secondary building units have been identified to describe the structure of an octahedral-tetrahedral framework solid, the assembly of only one type of secondary building unit is rare. To the best of our knowledge, $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ (**I**) is the first example possessing only the SBU-4 units, though similar layers formed by SBU-4 units are known for vanadium arsenate.[15] Similar building units of the type described here have also been observed earlier in a gallium phosphate, $[C_6N_2H_{14}][Ga_3(OH)F_3(PO_4)(HPO_4)_2]\cdot 0.5H_2O$.[33]

The variable-temperature magnetic susceptibility measurements of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ (**I**) were carried out on a powdered sample in the range from 4 to 300 K. Plots of the χ_m versus T is shown in Figure 4 and the inset shows the χ^{-1} versus temperature plot. The molar magnetic susceptibility increases with decreasing temperature and reaches a sharp maximum around 20 K. If T is reduced further, the susceptibility decreases very sharply. This sharp exponential decrease of magnetic susceptibility corresponds to a finite spin-gap in the system. In general, for a system with a spin-gap at low temperature, the susceptibility obeys a form given by χ (low-T) = $A\exp(-\Delta/T)/T^{\zeta}$, where A and ζ are constants and Δ represents the magnetic gap.[34,35] By fitting the experimental data at low temperature with this form of χ, we obtain a gap of about 8.1 K (with A = 2.5, and ζ = 0.6). On the other hand, the high temperature susceptibility data fits with the Curie−Weiss form χ(high-T) = C/(T-θ), with θ = −31 K and C = 16.424. High temperature χ of this form fits well with the experimental data (χ_m) up to a temperature of about 65 K.

A closer look at the magnetic lattice suggests that within the Fe_2F_2 dimers, the magnetic super-exchange is very strong, while the Fe_2F_2 dimers interact with the neighboring dimers through the AsO_4 bridges by weak super-exchange interactions. The Fe−F−Fe bond angle of 102.4° seems to favor ferromagnetic interactions, while those between the dimers through arsenate with the Fe−O−As bond angles of 128.67° favor anti-ferromagnetic interactions, according to the Goodenough rules.[36] Using the Heisenberg model for two S = 5/2 spins (dimer), the magnetic energy levels can be written as E_S = -J/2[$S(S + 1) - 35/2$] with S values 0,1,2,3,4 and 5. The magnetic susceptibility can be defined as $\chi = g^2\mu_B{}^2[\langle M^2\rangle - \langle M\rangle^2]/K_BT$, where $[\langle M\rangle^2 - \langle M\rangle^2]$ is the fluctuation in magnetization, M. For an antiferromagnet in the absence of magnetic field, the average

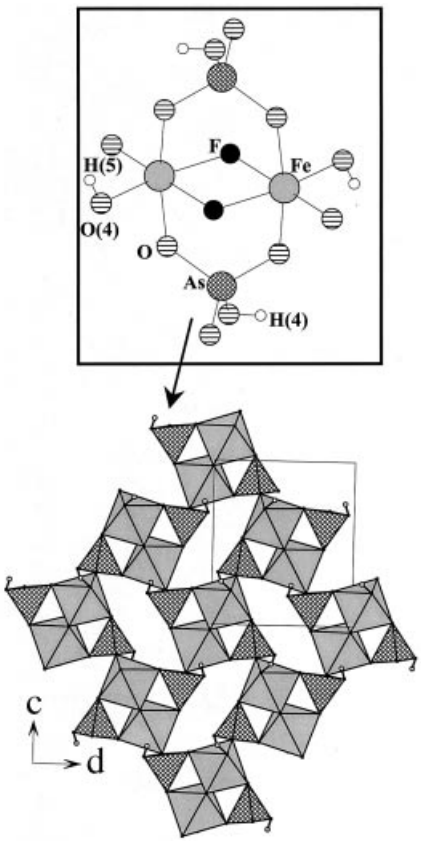

Figure 4. Thermal variation of the experimental magnetic susceptibility (χ) of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$; the solid line is a fit using the exponential form (see text); the Inset shows the variation of inverse magnetic susceptibility (χ^{-1}) with temperature; the Curie−Weiss fit is shown as dotted lines

magnetization, <M>, vanishes. Thus the magnetic susceptibility for the dimer can be written as $\chi_{dimer} = g^2\mu_B{}^2/K_BT[\Sigma_S\{S(S+1)\exp(E_S/K_BT)\}/\Sigma_S\exp(E_S/K_BT)]$, $S = 0,1,2,3,4$ and 5. In Figure 5 we have fitted this dimer susceptibility with the experimental χ_mT, varying the exchange constant, J, and the Lande factor, g. The best fit is obtained with $g = 2.01$ and $J = -12$ K. The same $\chi_{dimer}T$ formula with fitted J and g values is used to calculate the effective magnetic moment. The effective magnetic moment (μ_{eff}) appears to compare well with the presence of iron in the +3 state. Note that the dimer model cannot adequately reproduce the experimental data over all the temperatures. The lowest magnetic gap is 12 K (−J) from the dimer model, while the fit of the low temperature χ_m gives a gap of about 8.1 K (Δ). This discrepancy can be attributed to the neglect of inter-dimer exchange interactions in the dimer model. More work is clearly necessary to understand the significance of inter-dimer exchange interactions in two-dimensional systems.

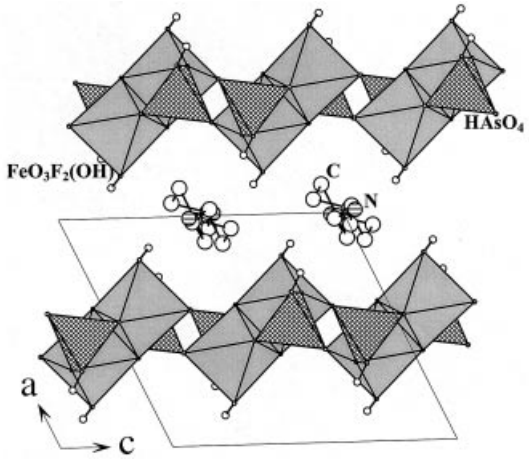

Figure 5. The variation of the χT as a function of temperature for $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$; the inset shows the variation of $\mu_{eff.}$ as a function of temperature; the solid line in both the cases shows the dimer-model fit to the experimental data

Conclusions

In conclusion, a new layered Fe^{III} arsenate, $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$, has been prepared in the presence of 1,4-bis(3-aminopropyl)piperazine by employing hydrothermal methods. The formation of the layered structure based purely on only one type of building unit (SBU-4) and its assembly through their corners are noteworthy structural features. Our continuing investigations clearly reveal that the chemistry of inorganic compounds possessing octahedral-tetrahedral building units is rich and many more novel structures are likely to be discovered. We are currently pursuing this theme.

Experimental Section

Synthesis and Initial Characterization

Solvothermal reactions were carried out under autogenous pressure in PTFE-lined stainless steel acid digestion bombs. For the preparation of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ (**I**) a mixture of iron chloride hexahydrate $[FeCl_3{\cdot}6H_2O]$ (0.1487 g), arsonic acid (0.6248 g), AP-PIP (0.441 g), HF (48%, 0.12 mL), water (4 mL) and *n*-hexanol (2 mL) were taken in the ratio 1:8:4:6:400:29. The mixture was homogenized at room temperature for 30 min and heated

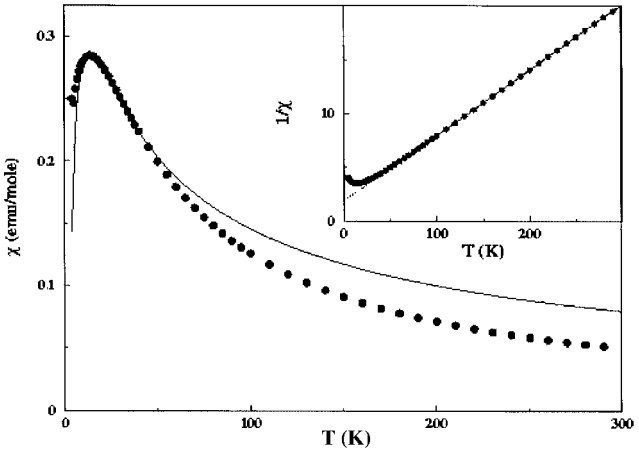

Figure 6. Powder XRD pattern of $[C_{10}N_4H_{28}]$-$[\{FeF(OH)(HAsO_4)\}_4]$ (a) experimental (Cu $K\alpha$) and (b) simulated

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at 150 °C for 72 h. The initial pH of the reaction mixture was about 2 and there was no appreciable change in the pH after the reaction. The resulting product, a crop of colorless plate-like crystals, was filtered, washed with water, and dried at room temperature [yield = 70% based on Fe]. A microanalysis of this phase by energy-dispersive X-ray fluorescence indicated the presence of As and Fe in a 1:1 ratio. $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ (1131.07): calcd. C 10.6, H 3.18, N 4.95; found C 10.1, H 3.01, N 4.89. A chemical analysis also confirmed the presence of fluorine (calcd. 6.65%; found 6.5%).[37]

The product contained a single crystalline phase as judged by a comparison of the powder pattern with the pattern simulated from the atomic coordinates obtained from the single crystal structure analysis (Figure 6). A least-squares fit of the powder XRD (Cu *Kα* radiation) lines, using the *hkl* indices garnered from single-crystal data, gave the following cell: a = 9.5941(3), b = 8.3335(4), c = 10.7420(4) Å, β = 114.99(3)°. The cell parameters are in good agreement with those determined from the single crystal XRD.
Thermogravimetric analysis (TGA) of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ (**I**) was carried out under N_2 (flow rate = 50 mL/min) in the range between 25 and 700 °C (heating rate = 10 °C/min) (Figure 7). A small initial weight loss of about 2% observed in the region 25−200 °C, probably corresponds to the loss of some adsorbed water on the surface of the sample. Similar initial weight losses have been encountered in many solids with open-framework structures. The TGA shows a sharp weight loss in the region 250−300 °C followed by a tail up to 600 °C. The total weight loss of 57% corresponds very well with the loss of the amine, fluoride, the condensation of the -OH groups and the partial removal of As_2O_5 (calcd. 57.5%). The powder XRD showed the resulting decomposed powder to be amorphous.

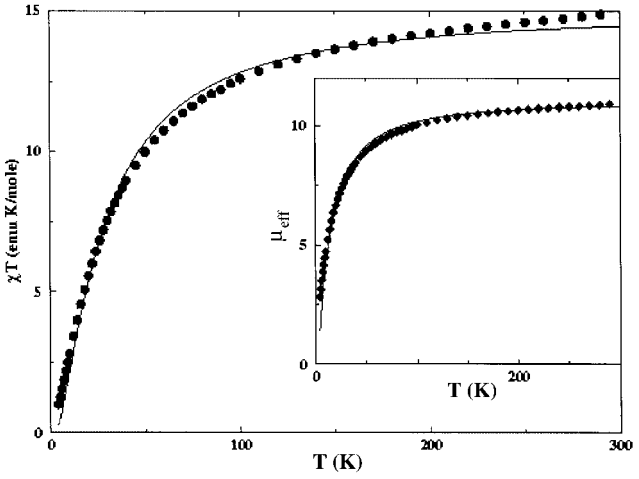

Figure 7. Thermogravimetric analysis (TGA) of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$

Infrared (IR) spectra of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ (**I**) was recorded in the range 400−4000 cm^{-1} using the KBr pellet method. The IR spectra showed typical peaks with absorption bands for N−H, C−H and O−H bending and stretching vibrations: ν_s(OH) = 3426 cm^{-1} (vb), ν_s(NH) = 2873 (w), $\delta_s(NH_2)$ = 1619 cm^{-1} (s) and 1524 (s) cm^{-1}, $\delta(N^+\text{-}CH_2$ asym. drift) = 1480 cm^{-1} (m), ν_s(C−N) = 843 cm^{-1} (s), $\rho_r(CH_2)$ = 767 cm^{-1} (m), $\nu(NH_2^+)$ = 2373 cm^{-1} (m) and ν(C−C) = 1058 cm^{-1} (w).

Single-Crystal Structure Determination

A suitable colorless single crystal was carefully selected under a polarizing microscope and glued to a thin glass fiber with cyanoacrylate (superglue) adhesive. Crystal structure determination by X-ray diffraction was performed on a Siemens SMART-CCD diffractometer equipped with a normal focus, 2.4 kW sealed tube X-ray source (Mo-K_α radiation, λ = 0.71073Å) operating at 40 kV and 40 mA. A hemisphere of intensity data was collected at room temperature in 1321 frames with ω scans (width of 0.30° and exposure time of 20 s per frame) in the 2θ range 3 to 46.5°. Pertinent experimental details for the structure determination of $[C_{10}N_4H_{28}][\{FeF(OH)(HAsO_4)\}_4]$ (**I**) are presented in Table 2.

V (Å^3)	786.42(4)
Z	4
D_{calcd} (g cm^{-3})	2.378
μ (mm^{-1})	6.093
R indexes [$I > 2\sigma(I)$]	R_1 = 0.0497;[a] wR_2 = 0.1238[b]
R (all data)	R_1 = 0.0729; wR_2 = 0.1366

[a] $R_1 = \Sigma||F_0| - |F_c||/\Sigma|F_0|$. [b] $wR_2 = \{\Sigma[w(F_0^2 - F_c^2)^2]/\Sigma[w(F_0^2)^2]\}^{1/2}$. $w = 1/[\sigma^2(F_0)^2 + (aP)^2 + bP]$, $P = [\max.(F_0^2,0) + 2(F_c)^2]/3$, where a = 0.0738 and b = 0.0.

An absorption correction based on symmetry equivalent reflections was applied using the SADABS program (maximum and minimum effective transmission: 1.000000, 0.639708).[38] Other effects, such as absorption by the glass fiber, were simultaneously corrected. The structures were solved by direct methods and in each case, a sufficient fragment of the structure was revealed (As, Fe and O) to enable the remainder of the non-hydrogen atoms to be located from difference Fourier maps and the refinements to proceed to $R <$ 10%. Fluorine atoms, identified by chemical analysis, were localized after consideration of thermal motion parameters and bond valence calculations.[30] The amine molecule was disordered and a model was established based on the observed positions of the various peaks in the difference Fourier map, resulting in shorter C−C distances and angles. Geometric constraints on the bond lengths have been used to keep the molecule in position during the refinement cycles. The disorder of the amine molecule also precluded the anisotropic refinement of the C and N atoms. No hydrogen atoms corresponding to the amine molecules were found in the difference Fourier map and hence were not included. The hydrogen atoms attached to the oxygen atoms [O(4) and O(5)] were placed and held in the riding mode during the refinement cycles. The last cycles of refinement included atomic positions for all the atoms, anisotropic thermal parameters for all non-hydrogen framework atoms, isotropic thermal parameters for all the hydrogen atoms attached to the oxygen atoms. Full-matrix least-squares refinement against $|F^2|$ was carried out using the SHELXTL-PLUS[39] suite of programs. Details of the final refinement are given in Table 2. The selected bond lengths and angles are given in Table 1. CCDC-204836 contains the supplementary crystallographic data for this paper. Synthesis and Characterization of Oxorhenium and Oxotechnetium Complexes with a Novel Tetradentate N_3O Bifunctional Agent

Maria Papachristou,[a] Ioannis Pirmettis,[a] Theodora Siatra-Papastaikoudi,[b] Maria Pelecanou,[c] Charalambos Tsoukalas,[a] Catherine P. Raptopoulou,[d] Aris Terzis,[d] Efstratios Chiotellis,[e] and Minas Papadopoulos*[a]

Keywords: Rhenium / Technetium / N,O ligands / Radiopharmaceuticals

The novel tetradentate N_3O bifunctional agent 3-hydroxy-4-[2-(2′-pyridinecarboxamido)acetylamino]benzoic acid (**1**), reacts with $[Bu_4N][ReOCl_4]$ or $[Bu_4N][^{99g}TcOCl_4]$ in EtOH resulting in neutral and stable oxorhenium **2** or oxotechnetium-99 g **3** complexes. Both complexes were characterized by elemental analysis, IR, ^1H and ^{13}C NMR spectroscopy. X-ray analysis of **2** showed that the rhenium atom is pentacoordinate presenting a distorted square-pyramidal coordination geometry. The analogous oxotechnetium-99m complex **4** was also prepared quantitatively by the reaction of ligand **1** with $Na^{99m}TcO_4$ in isotonic saline using tin chloride as reducing agent. Its identity was established by chromatographic comparison to the oxorhenium **2** and oxotechnetium **3** complexes.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Technetium belongs to Group 7 of the Periodic Table and its chemistry has been explored extensively over the past years primarily because of the importance of the radioisotope ^{99m}Tc in the field of diagnostic nuclear medicine.[1,2] Rhenium, which also belongs to Group 7, exhibits similar chemical properties to technetium and is often used as a nonradioactive alternative to working with technetium radionuclides.[2] Furthermore, the β-emitting radionuclides ^{186}Re ($t_{1/2}$ = 90 h) and ^{188}Re ($t_{1/2}$ = 17 h) are of great interest to nuclear medicine as they possess physical and nuclear properties favourable for use in systemic radiotherapy.[3] In fact, ^{99m}Tc and $^{186/188}Re$ can be considered to be a matched pair for imaging and therapy.

The bifunctional strategy for the development of technetium and rhenium radiopharmaceuticals has become the most widely used method for producing well-defined technetium- and rhenium-labelled receptor ligands capable of highly specific in vivo localization in target tissues.[4] In this strategy a bifunctional coupling agent (BFCA) is used for the chelation of the radionuclide (^{99m}Tc or ^{188}Re) and the conjugation of the receptor ligand. An ideal BFCA is one which is able to form stable and inert ^{99m}Tc or ^{188}Re complexes in high yield at low concentration without the formation of isomers.

In this work, we report the synthesis and characterization of the new BFCA 3-hydroxy-4-[2-(2′-pyridinecarboxamido)acetylamino]benzoic acid and of the corresponding oxorhenium(v) and oxotechnetium(v) complexes. Studies at tracer level using ^{99m}Tc are also reported. This ligand is designed with the purpose of chelating to oxorhenium and oxotechnetium with an N_3O donor system involving the pyridine nitrogen, the amide nitrogens and the phenolate oxygen. For coupling to the target molecule, the carboxyl group is selected since many biomolecules contain amino groups available for formation of amide bonds. Furthermore, this ligand system does not lead to formation of *syn-anti* isomers.

Results and Discussion

Condensation of ethyl 4-amino-3-hydroxybenzoate, N-Boc-glycine and 2-carboxypyridine in the presence of DCC resulted in the novel tetradentate ligand 3-hydroxy-4-[2-(2′-pyridinecarboxamido)acetylamino]benzoic acid (**1**; Scheme 1).[5] The product was purified by flash column chromatography and characterized by elemental analysis, ^1H and ^{13}C NMR spectroscopy (Table 1 and Figure 1).

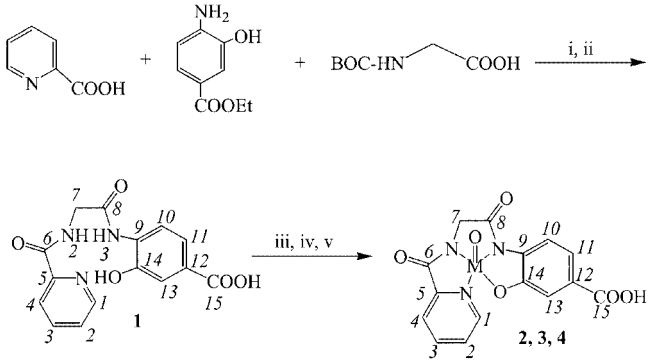

Scheme 1. Synthesis of ligand and complexes studied: (i) DCC, THF, 25 °C, 4 h; (ii) $NaHCO_3$, CH_3COOH (yield 42%); (iii) M= Re, $[Bu_4N][ReOCl_4]$ for **2**; (iv) M=^{99g}Tc, $[Bu_4N][^{99g}TcOCl_4]$ for **3**; (v) M=^{99m}Tc, $Na^{99m}TcO_4$, $SnCl_2$ for **4**

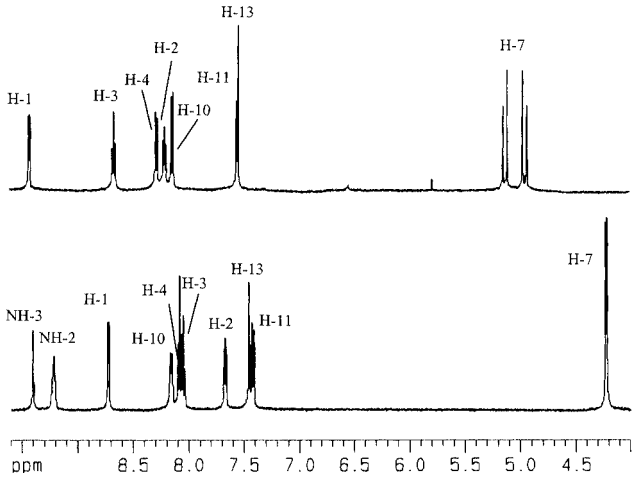

Figure 1. ^{1}H NMR spectra of ligand **1** (bottom) and complex **3** (top) in $[D_6]$DMSO (range 9.60−4.00 ppm) at 25 °C

The oxorhenium complex **2** was prepared by reacting ligand **1** with the $[Bu_4N][ReOCl_4]$ precursor in EtOH (Scheme 1). A similar reaction was employed for the preparation of the oxotechnetium complex **3** using $[Bu_4N][^{99g}TcOCl_4]$ as a precursor. Complexes **2** and **3** were characterized by elemental analysis, IR, UV/Vis, ^{1}H and ^{13}C NMR spectroscopy (Table 1 and Figure 1). Complex **2** was also characterized by X-ray crystallography. Both complexes are soluble in DMSO, slightly soluble in dichloromethane, methanol and ethanol and insoluble in water. They are stable in the solid state as well as in organic solvents (for a period of months), as shown by HPLC and NMR spectroscopy. Their stability is not affected by the presence of air or moisture.

The IR spectra of the complexes show characteristic peaks at 981 cm^{-1} and 972 cm^{-1} that can be attributed to oxorhenium and oxotechnetium bond stretches respectively.[6] The Re=O stretch in **2** is higher than the Tc=O stretch in **3**. This shift to higher frequencies of the Re=O compared to Tc=O complex has been attributed to the greater orbital overlap of the 5d orbitals of rhenium as compared to the 4d orbitals of technetium.[7] The electronic absorption spectra of the oxorhenium and oxotechnetium complexes were determined upon HPLC analysis by using a photodiode array detector. The UV/Vis spectrum of complex **2** is characterized by an intense band at 380 nm, while the UV/Vis spectra of the oxotechnetium complex **3** is characterized by an intense band at 480 nm.

An ORTEP diagram of complex **2** is given in Figure 2. Selected distances and angles are listed in Table 2. The coordination geometry about the metal is distorted square pyramidal with the pyridine nitrogen, the two amide nitrogens and the phenolate oxygen of the tetradendate ligand occupying the equatorial plane and the oxo group directed in the apical position. The carboxylate group of the tetradentate ligand remains uncoordinated. Rhenium lies 0.76 Å out of the equatorial plane toward the oxo group. The angles between the opposite atoms of the equatorial plane severely deviate from the ideal value of 180° [N(1)−Re−N(3) = 135.3(3)°, N(2)−Re−O(3) = 134.7(3)°]. Inspection of the shape-determining angles about the metal

Table 1. ^{1}H and ^{13}C NMR chemical shifts (ppm) for ligand **1** and complexes **2** and **3** in $[D_6]$DMSO at 25 °C; the numbering used is shown in Scheme 1 and is according to the crystallographic structure of Figure 2

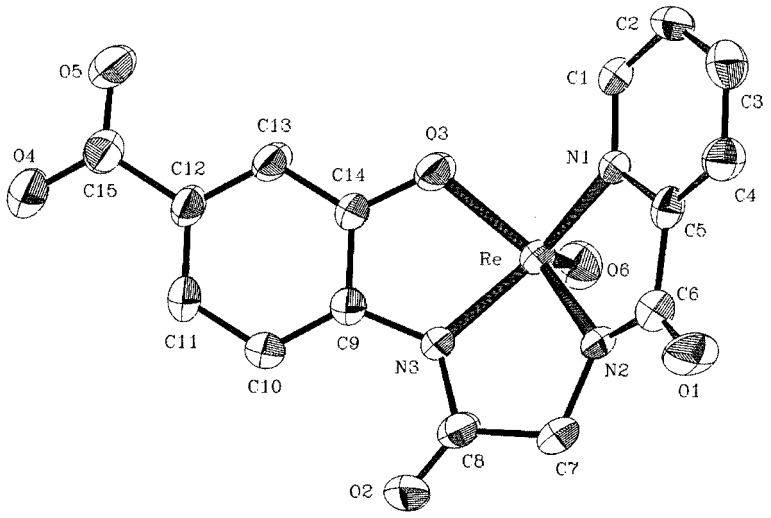

Figure 2. ORTEP diagram of **2** with 50% probability thermal ellipsoids showing the atomic labelling scheme

according to the analysis of Addison et al.[8] gives a value of 0.01 for the trigonality index, τ. The Re−N_{amide} bond lengths are 1.965(6) Å while the Re−$N_{pyridine}$ bond length is slightly longer at 2.076(6) Å. The Re−O_{oxo} and the Re−$O_{phenolate}$ bond lengths are 1.685(6) and 1.962(5) Å respectively. These values are in agreement with those found in analogous pentacoordinate oxorhenium complexes.[9] However, the Re−$N_{pyridine}$ and the Re−$O_{phenolate}$ bond lengths are shorter than heptacoordinated oxorhenium complexes with similar donor centers.[10] The two five-membered rings in the coordination sphere, i.e. those defined by Re−N2−C7−C8−N3 and Re−N3−C9−C14−O3 adopt the stable envelope configuration, with the metal being 0.53 and 0.35 Å, respectively, out of the mean plane of the remaining four atoms. On the contrary, the five-membered ring defined by Re−N1−C5−C6−N2 is planar, with C5 having the largest displacement of 0.028 Å out of the best mean plane.

Table 2. Selected bond lengths (Å) and angles (°) for complex **2**

Distances (Å)			
Re−O(6)	1.685(6)	Re−N(2)	1.965(6)
Re−O(3)	1.962(5)	Re−N(3)	1.965(6)
Re−N(1)	2.076(6)		
Angles (°)			
O(6)−Re−O(3)	112.9(3)	N(3)−Re−N(2)	79.1(3)
O(6)−Re−N(3)	113.1(3)	O(6)−Re−N(1)	111.3(3)
O(3)−Re−N(3)	80.4(2)	O(3)−Re−N(1)	87.8(2)
O(6)−Re−N(2)	112.2(3)	N(3)−Re−N(1)	135.3(3)
O(3)−Re−N(2)	134.7(3)	N(2)−Re−N(1)	79.4(2)

The two amide functions of the tetradentate ligand are planar, as indicated by the values of the ω_1 (C-C-*N*-C), ω_2 (O-C-*N*-M) and ω_3 (O-C-*N*-C) torsion angles and the values of the parameters τ [$(\omega_1 + \omega_2)/2(|\omega_1 - \omega_2| < \pi)$], χ_N [$(\omega_2 - \omega_3 + \pi)$mod2π] and χ_C [$(\omega_1 - \omega_3 + \pi)$mod2π], where τ is the approximate measure of the angles between the nitrogen and carbonyl carbon π orbitals and χ_N and χ_C describe the out-of-plane bending at the amide nitrogen and at the amide carbon respectively.[11] The torsion angles for the one amide group are: ω_1 = C5−C6−N2−C7 = −165.47°, ω_2 = O1−C6−N2−Re = 173.14° and ω_3 = O1−C6−N2−C7 = 11.32° thus, the calculated parameters are τ = 3.84°, χ_N = −18.18° and χ_C = 3.21°. For the second amide function these angles are: ω_1 = C7−C8−N3−C9 = −158.85°, ω_2 = O2−C8−N3−Re = −167.91° and ω_3 = O2−C8−N3−C9 = 22.33° thus, the calculated parameters are τ = −163.38°, χ_N = −10.24° and χ_C = −1.18°.

The short interatomic distance between the carboxylate oxygens O(4)···O(5′) (1 − *x*, 1 − *y*, −*z*) = 2.603 Å belonging to adjacent molecules is probably indicative of a hydrogen bonding interaction, although the hydrogen atom was not located in the difference map.

The synthesis of the complex was successfully transferred at tracer level (^{99m}Tc). Ligand **1** reacted with $Na^{99m}TcO_4$ in isotonic saline using tin chloride as reducing agent (Scheme 1) to give the oxotechnetium-99m complex **4**. The radiochemical purity of the reaction mixture was checked by HPLC and the radioactivity of the major peak was more than 85%, while the recovery of radioactivity from the column was quantitative. The characterization of complex **4** was accomplished by chromatographic comparison (HPLC) to the analogous oxorhenium (**2**) and oxotechnetium-99 g (**3**) complexes adopting parallel radiometric and photometric detection. Thus, by co-injection of the respective ^{99m}Tc and Re/^{99g}Tc complexes, identical retention times were obtained revealing the structural analogy of the three complexes (Figure 3).

In conclusion, the novel tetradentate ligand 3-hydroxy-4-[2-(2′-pyridinecarboxamido)acetylamino]benzoic acid (**1**) was synthesized and successfully used for the synthesis of stable and neutral complexes with rhenium and technetium at carrier (Re/^{99g}Tc) and at tracer level (^{99m}Tc). The carboxyl group does not coordinate to the metal and thus it

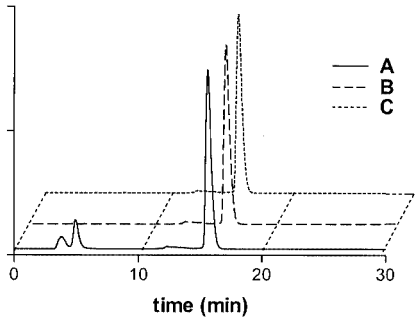

Figure 3. Comparative reverse-phase HPLC chromatograms: **A** (radiometric detection): reaction mixture from the preparation at tracer level (^{99m}Tc), complex **4** (t_R: 15.58 min, 85%); **B** (UV recording at 254 nm): complex **2** (t_R: 15.04 min); **C** (UV recording at 254 nm): complex **3** (t_R: 15.34 min)

could be used for the conjugation of the receptor ligand to develop target-specific radiopharmaceuticals for diagnosis and therapy.

Experimental Section

Caution!!! Technetium-99 g is a weak β-emitter (0.292 MeV) with a half life of 2.12×10^5 years. All manipulations of solutions and solids were carried out in a laboratory approved for the handling of low-level radioisotopes. Normal safety procedures were followed at all times to prevent contamination.

IR spectra were recorded as KBr pellets in the range 4000−500 cm^{-1} on a Perkin−Elmer 1600 FT-IR spectrophotometer. NMR spectra were recorded in [D_6]DMSO, at 25 °C on a Bruker 500 MHz Avance DRX spectrometer using TMS as internal standard. Chemical shift assignments were based on a series of 2D homo- and heteronuclear correlation spectra. Elemental analyses were performed on a Perkin−Elmer 2400/II automated analyser. ^{99g}Tc was purchased as ammonium pertechnetate from the Oak Ridge National Laboratory. The impure black solid was purified prior to use by overnight treatment with hydrogen peroxide and ammonium hydroxide in methanol. Evaporation of the solvent gave ammonium pertechnetate as a white powder. $Na^{99m}TcO_4$ was obtained in isotonic saline as commercial ^{99}Mo/^{99m}Tc generator eluate (Cis International). The precursors [Bu_4N][$ReOCl_4$] and [Bu_4N][$^{99g}TcOCl_4$] were synthesized by literature methods.[12,13] Ethyl 4-amino-3-hydroxybenzoate was prepared by refluxing 4-amino-3-hydroxybenzoic acid in EtOH in the presence of HCl. All laboratory chemicals were reagent grade.

High performance liquid chromatography (HPLC) analysis was performed on a Waters 600E Chromatography System coupled to both a Waters 991 photodiode array detector (UV trace for ^{99g}Tc, Re and ligands) and a GABI gamma detector from Raytest (γ trace for ^{99m}Tc). Separations were achieved on a Techsil C18 (10 μm, 250 mm × 4 mm) column eluted with a binary gradient system at a 1.0 mL/min flow rate. Mobile phase A was water containing 0.1% trifluoroacetic acid while mobile phase B was methanol. The elution profile was: 0 min 5% B followed by a linear gradient to 70% in 8 min; this composition was held for another 12 min. Prior to each injection the column was washed with 95% B for 5 min and re-equilibrated by applying the initial conditions (5% B) for 15 min.

NMR spectroscopic data for **1**, **2** and **3** are given in Table 1.

Synthesis of Ligand 1: A solution in THF (40 mL) of ethyl 4-amino-3-hydroxybenzoate (1.81 g, 0.01 mol), N-Boc-glycine (1.75 g, 0.01 mol), 2-carboxypyridine (1.23 g, 0.01 mol) and *N*,*N*′-dicyclohexylcarbodiimide (2.48 g, 0.012 mol) was stirred at room temperature for 4 hours. The insoluble urea was removed by filtration, the solvent was replaced by ethyl acetate and the solution was washed with dilute acetic acid and aqueous sodium hydrogencarbonate. The solvent was removed and the product was purified by flash column chromatography (silica gel 60, $CHCl_3$/MeOH/CH_3COOH, 77:15:8). Yield 42%. $C_{15}H_{13}N_3O_5$ (315.28): calcd. C 57.14, H 4.16, N 13.33; found C 57.07, H 4.22, N 13.17.

Synthesis of Oxorhenium Complex 2: A solution of ligand **1** (40 mg, 0.1 mmol) in MeOH (3 mL) was added to a solution of [Bu_4N][$ReOCl_4$] (58.6 mg, 0.1 mmol) in MeOH (15 mL). The reaction mixture was refluxed for 1 h. After cooling to room temperature the reaction mixture was diluted with CH_2Cl_2 and then washed with water. The organic layer was collected and dried over $MgSO_4$. The volume of the solution was reduced and then 5 mL of MeOH was added. Slow evaporation of the solvents at room temperature afforded the product as red crystals. Recrystallization from CH_2Cl_2/MeOH afforded crystals of **2** suitable for X-ray crystallography. Yield: 50%; R_f (SiO_2, CH_2Cl_2): 0.5; HPLC retention time: 15.04 min. FT-IR (KBr): $\tilde{\nu}$ = 981 cm^{-1} (Re=O). UV/Vis: λ_{max} = 229 nm, 271, 380. $C_{15}H_{10}N_3O_6Re$ (514.46): calcd. C 35.02, H 1.96, N 8.17; found C 34.95, H 1.94, N 8.04.

Synthesis of Oxotechnetium-99g Complex 3: A solution of **1** (40 mg, 0.1 mmol) in MeOH (2 mL) was added to a solution of [Bu_4N][$^{99g}TcOCl_4$] (50 mg, 0.1 mmol) in MeOH (10 mL) and the mixture was stirred at room temperature for 1 h. Upon standing, a brown solid precipitated that was collected and washed with Et_2O. Yield: 40%; R_f (SiO_2,CH_2Cl_2): 0.5; HPLC retention time: 15.34 min. FT-IR (KBr): $\tilde{\nu}$ = 972 cm^{-1} (Tc=O). UV/Vis: λ_{max} = 229 nm, 265, 480. $C_{15}H_{10}N_3O_6Tc$ (427.16): calcd. C 42.18, H 2.36, N 9.84; found C 42.08, H 2.29, N 9.73.

Synthesis of Oxotechnetium-99m Complex 4: Ligand **1** (0.5 mg in 100 μL saline solution) and $Na^{99m}TcO_4$ (40 mCi in 600 μL saline solution) were added to a vial containing a 0.1 M solution of sodium citrate (100 μL). A fresh solution of $SnCl_2$ in EtOH (20 μg, 20 μL) was subsequently added and the mixture was left to react at room temperature for 15 min. The pH was then brought to 7.0 and the reaction was analysed by HPLC. HPLC retention time: 15.58 min. Labelling yield >85%. The identity of the ^{99m}Tc complex was established by comparative HPLC studies using samples of the well-characterized corresponding oxorhenium and oxotechnetium complexes as references.

X-ray Crystal Structure Determination: A red crystal of **2** with approximate dimensions 0.04 × 0.20 × 0.40 mm was mounted in air. Diffraction measurements were made on a Crystal Logic Dual Goniometer diffractometer using graphite monochromated Mo-K_α radiation. Complete crystal data and parameters for data collection and refinement are listed in Table 3. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11 < 2\theta < 23°$.

Intensity data were recorded using the θ-2θ scan method. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarization and ψ-scan absorption corrections were applied using the Crystal Logic software.

V (Å^3)	1498(2)
Z	4
ρ (Mg·m^{-3})	2.281
T (°C)	25
λ (Mo-K_α) (Å)	0.71073
μ (mm^{-1})	8.151
F(000)	976
$2\theta_{max}$ (°)	50
Index ranges	$-11 \le h \le 8$, $-25 \le k \le 0$, $0 \le l \le 9$
No. of reflections collected	2682
No. of indep. refls./ Rint	2519/0.0303
Data with $I > 2\sigma(I)$	2184
$(\Delta/\sigma)_{max}$	0.041
GOF (on F^2)	1.089
$R1$[a]	0.0376
$wR2$[b]	0.0947
Residuals (e·Å^{-3})	0.798/−0.403

[a] $R1 = \Sigma(|F_o| - |F_c|)/\Sigma(|F_o|)$. [b] $wR2 = \{\Sigma[w[(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

The structure was solved by direct methods using SHELXS-86[14] and refined by full-matrix least-squares techniques on F^2 with SHELXL-93.[15] All hydrogen atoms (except that of the carboxylate group which was not included in the refinement) were located by difference maps and their positions were refined isotropically. All non-hydrogen atoms were refined anisotropically.

CCDC-208922 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows the crystal structure of lithium bis[benzoyl-$W(CO)_5$][μ_2-hydrogen] (orange: tungsten; red: oxygen; blue: lithium; grey: carbon), a new class of hydrogen-bridged organometallic complexes exhibiting strong, charge-assisted hydrogen bonds between anionic metal–acyl moieties in Fischer-type carbene precursors. The novel cation-exchange procedure used here could find application in future organometallic crystal engineering studies involving carbonylmetal fragments. Details are discussed in the article by H. G. Raubenheimer et al. on p. 3861 ff. *Dedicated to E. O. Fischer on the occasion of his 85th birthday*

Investigating Actinyl Oxo Cations by X-ray Absorption Spectroscopy

Christophe Den Auwer,*[a] Eric Simoni,[b] Steven Conradson,[c] and Charles Madic[d]

Keywords: Actinides / Oxo ligands / XANES / EXAFS

Early actinide elements (from U to Am) have the ability to form linear *trans*-dioxo complexes with formal valence of the actinide being equal to (V) or (VI). For instance, the ubiquity of the uranyl cation in uranium aqueous chemistry is the basis for its very important industrial and environmental concerns. As a result, the physical chemistry of the actinyl moieties has been the subject of constantly growing investigations. Among all the spectroscopic probes, X-ray absorption spectroscopy is a particularly useful element and energy-selective technique. This article reviews the investigation of molecular actinyl complexes using both XANES and EXAFS tools. The absorption edge features have long been used to characterize the frontier orbitals of the absorbing atom. In the case of actinide cations, the L_{III} edge, located in the hard X-ray region, provides a useful fingerprint of the cation polyhedron. Tentatively, simple molecular orbital considerations together with full multiple scattering simulation codes have provided significant interpretations of the edge features. Various examples involving a distortion of the actinyl coordination sphere, starting from the aqueous species are given. Complementary structural data can be obtained in the EXAFS region of the absorption spectrum. In the literature, such molecular systems have been well documented from uranyl aqueous chemistry to neptunyl or plutonyl coordination complexes with oxygen donor ligands. Furthermore, complexation mechanisms upon absorption onto mineral surfaces have been increasingly investigated over the past few years. Overall, contribution of the XAS technique to a better understanding of the actinide bonding is demonstrated from various examples of the literature and the authors' data. Importance of the simulation codes in order to better describe the absorption features is also strongly underlined.

1. Introduction

Due to their incomplete 5f and 6d electronic subshells, the actinide elements present some unusual physical and chemical properties. Moreover, the very large atomic numbers of the actinides are also responsible for very important relativistic effects, among which the scalar effect is at the origin of the so-called lanthanidic and actinidic contraction. As a consequence, the elements from the first half of the actinide series exhibit a large number of stable or metastable formal oxidation states ranking from (III) to (VII), de

Dr. Christophe Den Auwer (top, left) has completed his PhD in 1996 at the chemistry department of McGill University (Canada) and the LURE synchrotron center of Paris XI University (France). He his now a staff scientist at CEA Marcoule in charge of synchrotron radiation studies and molecular radiochemistry. Since 1997, he has been involved in the synchrotron radiation studies of a joint CNRS/CEA/EDF/ANDRA research cluster about the investigation of the physical-chemical properties of actinide elements in solution. His research interests include the electronic and structural investigation of molecular actinide and transition metal species. He has particularly focused on the use of X-ray absorption techniques using synchrotron radiation in order to probe the metal−ligand bond.

Prof. Eric Simoni (top, right) is in charge of the radiochemistry graduate studies at Paris XI University/IPN. He has completed his PhD in the Institute of Nuclear Physics of Paris XI University in 1988. He has been working in the field of the electronic structure of actinides in condensed matter and specialized in optical spectroscopy. He is now involved in the mechanistic understanding of radionuclide transport in the environment related to nuclear waste disposal and environmental contamination, using several spectroscopic techniques such as photoelectron spectroscopy (XPS), time resolved laser induced fluorescence (TRLIF) and X-ray absorption spectroscopy (XAS).

Dr. Steven Conradson (bottom, left) is a project leader in the Materials Science and Technology Division at Los Alamos National Laboratory. Beginning in 1988, he has led a major program in synchrotron X-ray studies of actinides including both X-ray absorption and scatteringmethods, determining speciation in studies of both the environmental and fundamental chemistry of actinides as well as characterizing the local structure in actinide-containing solids. His current interests beyond these include the extension of local structure and lattice distortions into the origins, attributes, and implications of nanoscale heterogeneity in crystalline materials.

Prof. Charles Madic (bottom, right) presented his PhD in 1975 at the Paris VI University, France. His PhD, concerning the solvent extraction of transuranium elements from nitric acid solutions by synergistic mixture of extractants was prepared at the Fontenay-aux-Roses Nuclear Research Center of the CEA and Paris VI University. He became a Professor at the National Institute for Training Nuclear Techniques in 1988 and Director of research at the CEA in 1995. At the beginning of the 1990s, he was nominated as French delegate at the Nuclear Science Committee of the NEA (OECD). His field of interest in research concerns the chemistry of actinide elements in relation with the reprocessing of nuclear spent fuels and the treatment of nuclear wastes. Since the beginning of the 1990s, he is in charge of research programs in these fields financed by the European Commission.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

pending on the atomic number. The question of delocalized vs. localized behavior of the 5f electrons still remains a critical issue to be addressed from both experimental and theoretical points of view. For that purpose, comparisons between the properties of actinides and lanthanides or even transition metals is often a common way to study these elements, although the radial extension of the 5f wavefunctions is larger than those of the 4f wavefunctions. Consequently, the actinides behave either as itinerant d transition-like systems or as localized lanthanide-like systems.[1] Indeed, americium ($5f^7 7s^2$) is considered the first actinide in the series to exhibit rare-earth-like behavior. From the structural point of view and due to their sizeable ionic radii, the actinides exhibit a wide variety of coordination numbers and therefore, both the molecular and solid-state chemistry of these elements have been extensively investigated. According to the relatively large ionic radii, these coordination numbers are rather high (6 to 12).

From both electronic and structural points of view, investigations of actinide compounds have been performed using several different techniques such as X-ray or neutron scattering, optical and vibrational spectroscopy, NMR and Mössbauer spectroscopy. Most of this work, originating from the early 1940s has dealt with condensed matter. As one of the numerous fields of investigation, the actinide electronic structure exemplifies the specificity of the 5f orbitals. In this framework, fluorescence emission lifetime, oscillator strength measurements and Zeeman effects have been widely studied and compared with corresponding lanthanide data such as those of Nd^{3+}, Eu^{3+} and Er^{3+} in the same host material.[2−5] These studies have dealt mainly with the crystal-field parameters, the wavefunctions and the associated 5f-5f transition probabilities,[6,7] the 5f-6d energy gap[8−17] (experimental values compared to ab initio DV-Xα calculations) and the energy transfers between lanthanide and actinide ions.[18] The delocalization of the 5f electrons has mainly been investigated by Mössbauer spectroscopy (mainly on the Np element), which is an efficient tool for measuring hyperfine interactions and thus to study the electronic configuration of actinides bound in solids.[19−30] many of the actinide intermetallic compounds (monopnictides and monochalcogenides) present 5f-electron behavior analogous to the 4f electrons (NpSb, NpAs, ...) but could show itinerant behavior as for the 3d electrons ($NpCo_2Si_2$, Usb, UP, ...).[31−39]

Since the mid 1970s, X-ray absorption spectroscopy (XAS) has become widely recognized as an element-specific and non-destructive structure and electronic probe. It is of particular interest when the system under investigation is lacking crystallographic order (as in glasses, solutions or gases) and precludes the use of X-ray or neutron diffraction as the preferred structural probe. NMR and Mössbauer spectroscopy are also restricted to the use of adequate nuclei. Although the applications of XAS to material or biological sciences, for instance, have been extensive since the 1980s, its use for actinide systems is relatively recent. This is mainly due to three reasons as pointed out by Karim and co-workers in 1980:[40] the need for high-energy X-ray beams as a result of the high atomic numbers of the actinides, the lack of either reliable computed electronic parameters or model compounds and the safety requirements associated with high radioactivity of most of these elements. Despite these difficulties, XAS has now been largely applied to the structural and electronic understanding of actinide materials, as summarized by P. G. Allen or S. D. Conradson in their 1997[41] and 1998[42] reviews. See also refs.[43,44] and references herein for a larger discussion on the use of XAS in coordination or environmental chemistry.

In this article, we report on the use of the XAS technique to investigate the coordination chemistry of actinyl cations. Indeed, this technique has revealed itself as one of the unique tools for addressing the characterization of the heavy cation coordination sphere in solution or in amorphous materials. We do not intend to fully describe the theory and practice of XAS as well as the physical-chemical properties of the actinyl adducts as many books and review articles have dealt with the subject extensively.[45−49] Only a brief overview is given.

XAS is a spectroscopic technique based on the informative modulations of the X-ray absorption cross section. The electronic transitions driving the absorption cross section obey the Fermi−Golden rule in its dipolar approximation, where $i>$ is the initial state wave function of eigenvalue E_i, $|f>$ is the final state wave function of eigenvalue E_f, $\varepsilon \cdot r$ is the interaction hamiltonian in the dipolar approximation and $h\omega$ is the energy of the incoming photon [Equation (1)].

$$\mu \propto \sum_f \left|\langle i|\varepsilon . r|f\rangle\right|^2 \delta\left(E_i + \hbar\omega - E_f\right) \quad (1)$$

Because of the δ function, no quantum transition can occur before the incident photon energy $h\omega$ is at least equal to the energy of the LUMO or partially vacant authorized orbital. The dipolar transition operator results in the following transition rules for the absorption process: $\Delta L = \pm 1$; $\Delta J = 0, \pm 1$ (where L is the angular momentum term and J is the LS coupling term).

It is then convenient to divide the absorption process into two parts, depending on the incident photon energy. Above the threshold (X-ray absorption near edge structure, XANES), the photoelectron is trapped inside the absorber potential barrier and it is promoted to vacant or partially vacant bound states. As the kinetic energy of the photoelectron increases, transitions outside the potential barrier can occur towards the continuum states of the system. From ca. 100 eV above the absorption edge to ca. 1000 eV (extended X-ray absorption fine structure, EXAFS), modulations of the absorption coefficient are driven by the interference between the outgoing wave function associated with the photoelectron and the backscattered ones. The EXAFS signal χ is given as the ratio between the absorption cross section μ and the atomic absorption function μ_0 [Equation (2)].

$$\mu = \mu_0(1 + \chi) \quad (2)$$

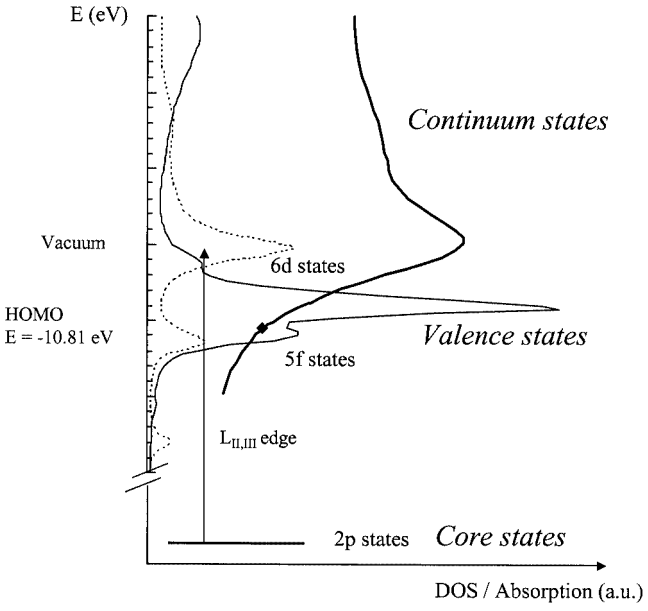

Figure 1. Schematic transitions involved in the L_{III} edge of uranyl moiety; both density of states (DOS) and absorption edge have been calculated with Feff8.1 code[50]

Figure 1 shows a schematic representation of the absorption process in the case of the L_{III} edge of UO_2^{2+}. In the primary channel picture, the $L_{II,III}$ edge corresponds to a $2p^6_{1/2,3/2}$-$nd^m \rightarrow 2p^5_{1/2,3/2}$-$nd^{m+1}$ transition (for the actinides, the first partially available d orbital is the 6d one). The threshold energy, the d and f Density of States (DOS) and the absorption spectrum have been calculated using Feff8.1 code.[50] Above the threshold, transitions occur towards the first allowed empty orbitals (6d) of uranium. Above the ionization potential (vacuum level), transitions occur towards the continuum states of the molecule.

Because most of the actinide complexes (from uranium to americium) with oxidation states higher than (IV) contain the actinyl AnO_2^{n+} ($n = 1, 2$) moieties, they are of technological and environmental importance.[41,43,51–53] Furthermore, the ubiquity of the uranyl cation in the geosphere, due to its remarkable stability, makes it one of the most extensively investigated cations within the actinide family.

The major characteristic of actinyl cations is the occurrence of quasi-linear O–An–O units with a short An–O multiple bond and a bond length ranging from 1.7 to 1.9 Å depending on the cation. This characteristic is also specific to the actinide family as only one analogue (the osmyl cation OsO_2^{2+}) is known in the d block.[54] This is good evidence of the bonding particularity that involves significant participation of the 5f orbitals in the HOMO of the AnO_2^{n+} unit. As a matter of fact, the bent structure of molecular ThO_2 versus the linear one has been the subject of numerous theoretical works questioning the extent of the 5f and 6d participation in the bonding molecular orbitals involving the two oxygen atoms.[55–59] This discussion is, however, beyond the scope of this paper as the authors would like to emphasize the role of XAS in understanding the physicochemical properties of actinyl cations.

2. Working with Actinide Elements

Although one of the major advantages of XAS is the ability to tune the absorption edge for a given element, most of the actinyl studies have dealt with L_{III} and more rarely L_I edges. Reasons for this limitation are mainly technical, as explained in the following.

The high specific radioactivity of most of the actinide elements impinges strong experimental limitations in order to comply with the safety regulations. Although dedicated research nuclear laboratories possess the experimental specific setup, this is often not the case of traditional beam line hutches at the synchrotron. Therefore, either the sample holder itself must be adequately shielded or the beam line hutch must be specifically designed. Lately, the design of dedicated beam lines at the synchrotron with appropriate shielding and/or radiation equipment has been a major improvement in the acquisition of data on actinide elements.[60–63] However, when available, the use of a specific low active radioisotope such as the uranium-238 natural isotope (^{238}U has a specific activity of $3.4 \cdot 10^{-7}$ $Ci \cdot g^{-1}$ that does not require any specific shielding) is always the preferred method. Because the X-ray beam must be transmitted through the shielding barriers, the most conveniently accessible absorption edges of the actinide series are the L edges located in the hard X-ray region from ca. 17000 to 25000 eV from U to Cf. This energy range allows successive shielding of the sample with negligible absorption of the photon beam (typically, layers of polymer or beryllium windows are used to confine the sample). Among the L edges, the L_{III} edge is very sensitive to the polyhedron structure because of the presence of strong multiple scattering contributions, as will be developed in the course of the next sections. The edge resolution is, however, limited by the short core hole life-time (giving a width of typically 7 eV at the L_{III} edge of uranium[64]). Lower energy studies at the M, N or O edges present a better edge resolution because of the larger core hole life-time and allows the 5f orbitals to be probed through the allowed dipolar transition. However, to date, these studies are scarce, given the technical difficulties in shielding the sample in the soft X-ray region. General considerations related to the manipulation of radionuclides at the synchrotron sources have been summarized in the Proceeding of the 2nd Euroconference and NEA Workhop on Speciation, Techniques and Facilities for Radioactive Materials at Synchrotron Light Sources.[61]

Another crucial issue of XAS analysis is obtaining reliable electronic model parameters [phase $\Phi(\theta, k, R) = 2kR + \varphi$, amplitude $f(\theta, k, R)$, electron mean free path $\lambda(k)$ and inelastic losses S_0^2]. Two ways of evaluating the electronic parameters are either to calculate it or to extract it from a model compound that is of known structure (i.e. the absorber to neighbor distance R and the number of neighbors

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

N are known) and chemically close to the material under study. On the one hand the use of experimental model compounds is the preferred method in order to obtain reliable electronic parameters. However, the difficulty in obtaining three-dimensional structures from single crystals of actinide elements is responsible for the scarcity of adequate model compounds. This statement should be tempered in the case of thorium and uranium adducts since many crystallographic data are available for these two elements. On the other hand, XAS simulation codes have become accessible for 5f elements and can be used to calculate the electronic parameters on the basis of assumed atomic coordinates.[50] In that case, several methods have been used: extrapolation from known uranium or thorium structures;[65] extrapolation from corresponding isostructural lanthanide compounds;[66] comparison with simple molecular clusters based on either quantum chemical or molecular dynamics considerations.[67] Over the past few years, the Feff code (versions 7 and 8) has been extensively tested for the actinide elements as will be reported on in the following sections. In the field of absorption edge simulation, major developments have included the implementation of self-consistent fully relativistic potential calculations based on Dirac−Hara atomic calculations and full multiple scattering treatment of the photoelectron.[68,69]

3. Actinide XANES and Electronic Structure

Near-edge spectroscopy has long been used as a fingerprint of the absorbing atom coordination geometry and electronic state. Because at low kinetic energy the photoelectron mean free path increases dramatically, the structural component of XANES can be viewed as an extension of the EXAFS energy region, given that high-order multiple scattering paths are dominant. Many works have aimed at simulating and better understanding the information included in the edge features. Depending on the relative proportion of delocalization in the valence states or electronic correlation within the final state, so-called multiple scattering or multiplet approaches have been developed.[70] Such quantitative approaches in the hard X-ray region have long been applied to spin state or local symmetry studies of transition or lanthanide metal series. On the other hand, a limited number of studies have been devoted to actinide elements, most of which deal with oxide, halide or intermetallic solid-state materials.[68,69,71−76] At the molecular level, only a few papers have addressed the simulation of actinide L edges with a multiple scattering approach.[77,78] In that framework, Ankudinov et al.[68,69] have published an extensive comparison between the series of Pu hydrates and simulations with the Feff code. Other studies have addressed this issue using both phenomenological and computational approaches.[77,78] There is still some controversy as to whether the edge features, depending on their energy (or position in the XANES spectrum) must be interpreted in terms of transitions to bound, semi-bound or continuum states. Within the absorber potential barrier, the electron is trapped above the energy threshold and both multiple scattering or molecular orbital pictures can be used as they should reflect the same underlying phenomena when electronic correlations are negligible.[79] Whether or not part of the edge features must be considered as transitions to bound states or to continuum states depends on the work function of the system. It is well known for instance that pre-edge features of the transition metal K edges can be treated as transitions to bound states made up of the hybridized unoccupied or partially occupied d states.[80−82] In the case of the L_{III} edges of the actinide elements, it has been suggested that the multiple scattering picture is more suitable to explain the edge features[69] since mixed bound-continuum states are believed to dominate the white line (WL) shape and intensity. In contrast, the L_{III} edges of the lanthanide ions exhibit a very sharp, intense and often featureless WL.[71] In the one-electron picture, this high WL ratio reflects the transition to the narrow 5d states compared to the more diffused 6d states. Additional broadening by the core hole life-time must also be taken into account as it increases with atomic number *Z*.[64,72,74] In Figure 2, the broad and intense WL, A, is typical for the actinyl L_{III} edge, from uranium to americium. Figure 2 compares the full multiple scattering (FMS) simulation of the uranyl L_{III} edge to the atomic absorption spectrum (absorption edge calculated as if the absorption atom was isolated) using the Feff-8.1 code (simulation parameters are described in ref.[83]). Calculations have been carried out on a pentagonal bipyramid cluster using self-consistency methods and muffin tin potentials, but without taking into account any sol-

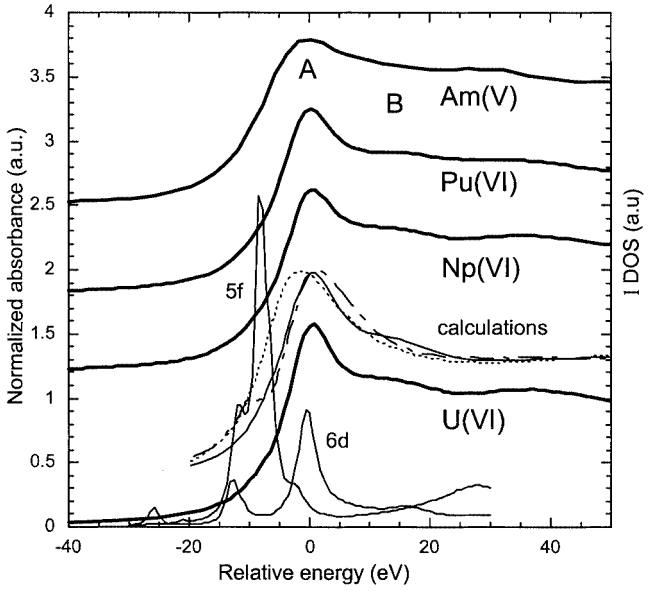

Figure 2. Experimental L_{III} edges of UO_2^{2+} (solution in perchloric acid[84]), NpO_2^{2+} (solution in perchloric acid), PuO_2^{2+} [solution of $PuO_2(NO_3)_2TBP_2$ in TBP[85]] and AmO_2^{+} [solid $K_3AmO_2(CO_3)_2$ [86]] (—); calculations (Feff-8.1) are compared to the experimental uranium edge: FMS (—), single scattering (− −) and atomic absorption (----); the $l = 2$ and $l = 3$ projected DOS is also displayed on the same relative energy scale; all the experimental spectra have been shifted in energy with respect to the calculated uranium pentagonal bipyramid edge maximum

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

vent effects. In addition, the *l* projected density of states (DOS) calculated with the same potentials but with no core hole, for $l = 2$ and 3, are shown on the same relative energy scale. The interpretation of A originating from a 2p to mixed 6d-continuum state transition (as the primary channel $\Delta l = +1$ of the Golden Rule) is in agreement with the 6d DOS. The similarity between the experimental WL and the atomic absorption background confirms the partial atomic character of the WL. Note that in the molecular picture, the 6d state should split under the crystal field energy (D_{5h} symmetry) but this splitting is not observed here. At about 15 eV above the WL maximum, feature B is clearly reproduced by the FMS calculation but not by the atomic absorption spectrum. A similar calculation using a single scattering approach does not account for B either. The identification of the multiple scattering (MS) paths in the FMS calculation shows that B originates from the multiple scattering paths along the *trans*-dioxo cation for both AnO_2^+ and AnO_2^{2+} moieties. This attribution of B in terms of MS contributions was previously demonstrated by Templeton[87] and Petiau[72] using polarized XAS.

Relative position of the edge is also informative as an increase in the central atom partial charge leads to a stabilization of the electronic core levels (because of the decrease in the screening effect) and a destabilization of the valence levels. If the WL is mainly of atomic-like character (as the L_{III} edge of the lanthanide for instance), the net result, everything else being equal, is a shift of the absorption edge towards higher energies as the central atom partial charge increases. Although the partial charge is often correlated to the formal oxidation state, this simplification can be misleading when different ligands yield different charge transfers between the ligands and the metal cation for a given oxidation state. This interpretation can be partially used for instance to explain the breakdown of the linear increase in edge energy (taken at the inflexion point) from An^{IV} to An^{V} [88] as a diminution in the difference of the An charge associated with the presence of covalent bonding within the *trans*-dioxo unit. More often, the absorption edge is not of pure atomic character and this leads to a mixing of both electronic and geometrical effects. This is a common ambiguity in XANES analysis as a change in the central atom oxidation state is often correlated to a change in coordination sphere. The following two examples illustrate this difficulty.

Firstly, we consider the series of Ba_2ZnAnO_6 perovskite solid-state compounds (An = U, Np, Pu) in which the actinide formal oxidation state is (VI) as in the actinyl hydrate. In these compounds, the actinide cation has been shown to be mainly ionic with an octahedral environment of 6 oxygen atoms at 2.09 Å,[89] in contrast with the rod-like structure of the actinyl cation. XANES spectra exhibit both an edge energy shift and a shape modification compared to the aqua species.[83,90] Although the edge feature can be explained in terms of transitions to the t_{2g} and e_g 6d states in an O_h symmetry, multiple scattering interpretation has also been used successfully.[83,91] In Figure 3, the *l* projected DOS calculations (Feff-8.1) of the 6d orbital matches the XANES

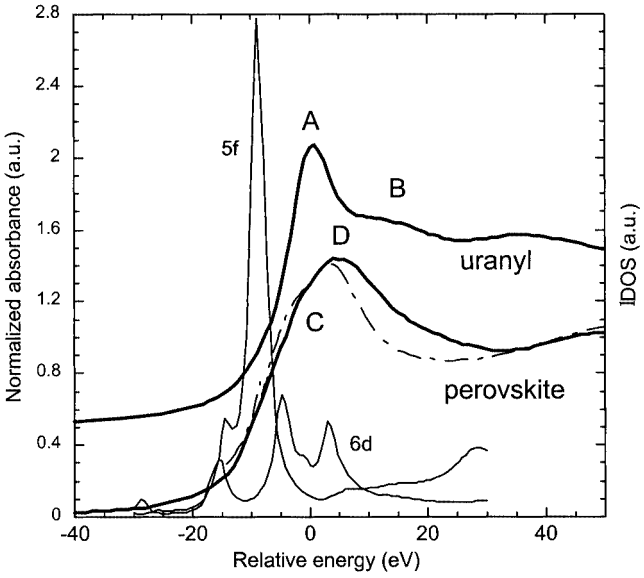

Figure 3. Experimental L_{III} edges of U^{VI} in perchloric acid and solid-state Ba_2ZnUO_6 (—) compared to FMS calculation (Feff-8.1[83]) of Ba_2ZnUO_6 (– – –); both experimental spectra have been shifted in the same relative energy scale with respect to the calculated uranium

features in terms of $t_{2g}-e_g$ splitting. The splitting energy (8 eV) is in relative agreement with previous calculations on UO_8^{13-}, AmO_8^{13-} and CmO_8^{13-} clusters (ca. 5 eV).[92] However, attribution of C and D to transitions to bound 6d states depends on the position of the ionization potential. The present calculation places the vacuum level just above C feature, meaning that D would be better described as a mixed bound−continuum state. In the MS picture, path analysis at the edge energy reveals that the low energy shoulder can be attributed to constructive interference from triangular paths within the octahedron. The high energy shift of the edge maxima from UO_2^{2+} (A) to Ba_2ZnUO_6 (D) (ca. 5 eV) would be in agreement with an increase of the uranium partial charge from uranyl to perovskite. However, attribution of D as the formal WL maximum is doubtful and the symmetry change from D_{5h} to O_h makes difficult the energy comparison with respect to the edge maximum. Also, there is a low energy shift of the inflexion point of ca. 2 eV from uranyl to perovskite, in contradiction with the above explanation. These simplistic interpretations lack a quantitative evaluation of the symmetry effect compared to the electronic effect, both effects being highly related. The energy threshold calculated by Feff-8.1 in both cases shows an increase of 1.14 eV from uranyl to perovskite and places the position of the threshold at the bottom of the absorption edge. Although this increase seems small compared to the calculation accuracy (1−2 eV [68]) it is in agreement with a significant decrease of the charge transfer (from 0.69 for uranyl to 0.35 for perovskite) calculated with the same code. At the M_v edge (3d−5f dipolar transition), the very intense WL ratio of Figure 4 reflects the more localized character of the 5f orbitals compared to the 6d ones, as well has the magnitude of the core hole attraction.[72] MS contributions

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are therefore expected to be relatively weak and comparison of the WL full width at half maximum (FWHM) should reflect the trend in the 5f relative localization. Although small, the reduction of the FWHM from uranyl to perovskite (from 9.1 to 6.9 eV) agrees with the previous interpretations accounting for an increase of the uranium ionic character. Simulation of the M_V edge using a cluster based on the crystallographic structure of $UO_2(NO_3)_2{\cdot}6H_2O$ also suggests that the WL, E, is mainly driven by the final state density. Features F and G have been described in the literature [72,74] as a satellite peak (F), as an MS *trans*-dioxo contribution (G). Other authors have also observed these features in U^{VI} complexes but did not attribute it.[93] The absence of feature F in the simulation backs the interpretation of this shoulder as a multielectronic process that cannot be reproduced by the MS-based simulation code. Also, path analysis shows that G is driven by the presence of the *trans*-dioxo group and H originates from the contributions of the equatorial atoms.

As a second example, we consider the $Np^{VI}O_2^{2+}$ cation in basic and acidic solutions. In the first case, the Np atom is surrounded by 2 axial oxygen atoms at 1.82 Å and 4 equatorial oxygen atoms at 2.21 Å [94] and in the second case by 2 axial oxygen atoms at 1.75 Å and 5 equatorial oxygen atoms at 2.41 Å.[60] Both L_{III} edge spectra are compared in Figure 5 (a). From acidic to basic, they exhibit in one hand a broadening of WL A and on the other hand a shift to lower energy (-1 ± 0.5 eV for the inflexion point; -0.7 ± 0.2 eV for the WL maximum). In order to quantify the experimental changes in the edge shape and position, two series of simulations with Feff-8.1 code have been undertaken using similar parameters as those used in the case of aqueous uranyl.[84] Starting from a pentagonal bipyramid structure with the structural parameters in acidic solution, the coordination sphere has been distorted towards the structural parameters of the basic solution. Note that the symmetry is frozen at the D_{5h} point group and that neither the hydrogen atoms nor the solvent water molecules have been included in the cluster. In process I, the axial bonds have been elongated from 1.75 to 1.82 Å, the equatorial bonds being kept fixed at 2.41 Å; in process II, the equatorial bonds have been shortened from 2.41 to 2.21 Å, the axial bonds being kept fixed at 1.82 Å. The L_{III} edge simulations are compared to the experimental spectra in Figure 5 (a). The broadening of the WL from acidic to basic medium is qualitatively reproduced by the simulation. Figure 5 (b) presents the second derivative spectra calculated from the edges. Figure 5 (c) reports the first and second derivative zero points as well as the position of B shoulder. In process I, the elongation of the axial bond results in a shift of B towards A, in agreement with the relation $\Delta E{\cdot}R^2 = \text{cst}$,[72,95,96] as shown in Figure 5 (c). At the same time, both inflexion point and A are shifted to lower energy, demonstrating the sensitivity of the edge position to the coordination sphere distortion. In process II, the shortening of the equatorial distances interferes very little with the position of B, while the inflexion point and A are shifted similarly as in process I. The net result at the end of process II is an energy shift between the simulation and the experimental spectrum relative to the basic medium (Figure 5, a,b). The lower energy position of the experimental spectrum could be explained as a charge effect as the negative charge of the hydroxy ions have not been taken into account in the simulation. A higher electronic density around the neptunium atom is in agreement with a low energy shift, as observed here.

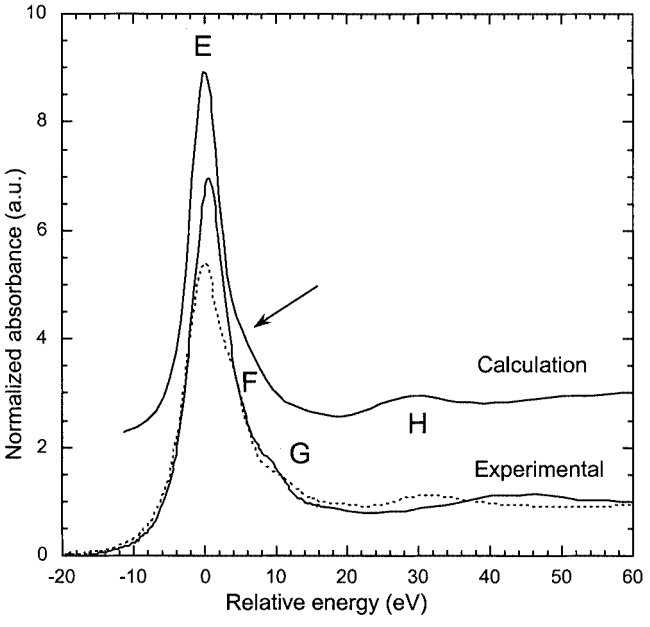

Figure 4. Experimental M_V edges of Ba_2ZnUO_6 (----) and $UO_2(NO_3)_2{\cdot}6H_2O$ (—) compared to the simulated M_V edge of $UO_2(NO_3)_2{\cdot}6H_2O$ (—);[83] all spectra have been shifted in the same relative energy scale with respect to the calculated uranium $UO_2(NO_3)_2{\cdot}6H_2O$ edge maximum

4. XAS, a Probe for Actinyl Complexes

4.1. Aqueous Actinyl Cations

The speciation of the actinyl cations in aqueous electrolytes shows a strong pH dependence and can also be affected by the presence of complexing ligands.

Although many studies have concentrated on the redox equilibrium behavior of the actinyl ions, fewer are reported on the actinide coordination sphere characterization. Lately, these data have also been complemented by quantum chemical calculations as to support the experimental results [67,97–100]. Generally speaking and in noncomplexing electrolytes, the hydrated cations can be written as $AnO_2^{n+}{\cdot}mH_2O$ (n = 1, 2) below the pH of hydrolysis and $AnO_2(OH)_{m'}^{2-m'}$ in alkaline solution. The coordination polyhedron of the actinide atom can be described as a bipyramid with the axial *trans*-dioxo atoms in the apical position and equatorial coordination geometry from trigonal to hexagonal. In acidic media, both formal oxidation states (V) and (VI) have been reported with U, Np, Pu and Am cations. As an example, the L_{III} edges of UO_2^{2+}/aq.,[84] NpO_2^{2+}/aq., PuO_2^{2+} [101] and AmO_2^{+} [86] are compared in Figure 2. All spectra are similar with a strong white line (A)

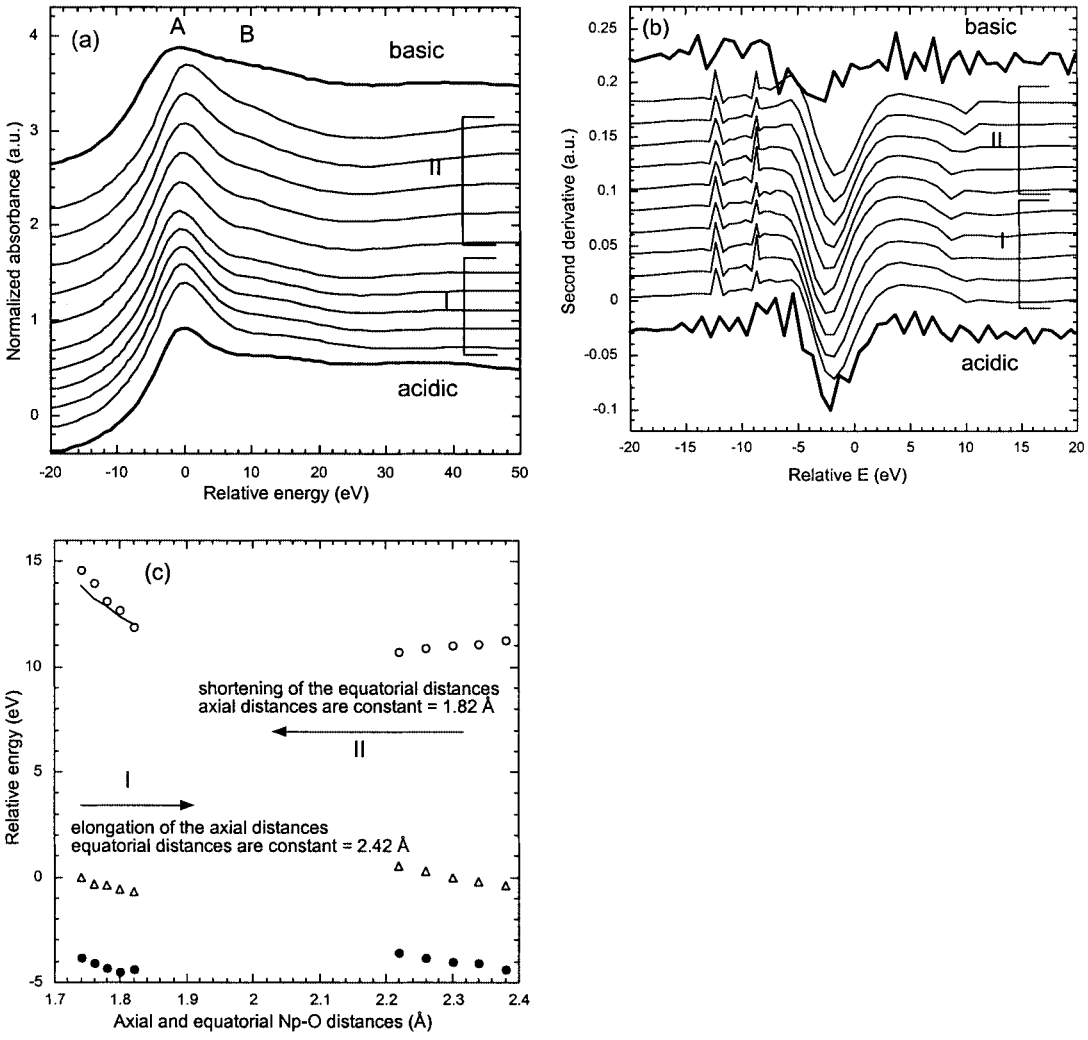

Figure 5. (a) Experimental (—) and simulated (—) L_{III} edges of $Np^{VI}O_2^{2+}$ in basic (TMA-OH) and acidic ($HClO_4$) solutions; simulations (Feff-8.1) have been carried out starting from the acidic structural parameters by successive elongation of the two apical oxygen atoms by 0.02-Å steps (process I) and by further successive shortening of the five equatorial oxygen atoms by 0.02-Å steps (process II); (b) second derivatives of the experimental (—) and simulated (—) edges; in (a) and (b) experimental and simulated spectra have been shifted in the same relative energy scale with respect to the edge maximum of the experimental acidic spectrum; (c) energy position of the simulated edge inflexion point (filled circles), maximum (triangles) and shoulder (empty circles) as a function of the axial and equatorial distances (process I and process II); the straight line (—) represents the correlation $\Delta E \cdot R^2$ = cst

and a shoulder (B) at about 15 eV above the WL maximum. Note that the relative smaller intensity of the WL in the case of the Am compound is due to the lower resolution of the beam line used to record the spectrum.

In order to address the structure of the aqueous ions, EXAFS data on aqueous actinyl ions have been well documented in the literature. Figure 6 (a,b,c) present an overview of the published data for U, Np and Pu, including the author's results. Agreement within the axial (not shown) and equatorial distances is usually satisfactory. On the contrary, it is well known that one of the major limitation of the XAS technique is the accurate determination of all the amplitude terms because they are significantly correlated. Many of the structural determinations reported in Figure 6 have used a fixed number of neighbors for the equatorial coordination shell. When floating, the parameter uncertainty is close to 20% due to amplitude transferability and experimental accuracy. This means in the case of actinyl ions that the equatorial shell is defined within plus or minus one oxygen atom.

Np and Pu are notable among the actinides for having the largest number of accessible valences, up to valence (VII). The valence (VII) state was first reported in the Russian literature[112−114] under alkaline conditions although detailed studies about the precise coordination sphere remain scarce. Due to its greatest stability for the (VII) state within the actinide family, neptunium has been the subject of most of the investigations. Recently, a few groups have provided a much more complete characterization of Np^{VII} complexes, both in the solid state and alkaline solution.[91,94,115−117] In the solid state, current XAFS[91] and single-crystal diffraction studies support the original Russian results, finding the tetraoxo configuration in the highly alkaline solutions (> 4 M OH^-) that stabilize this

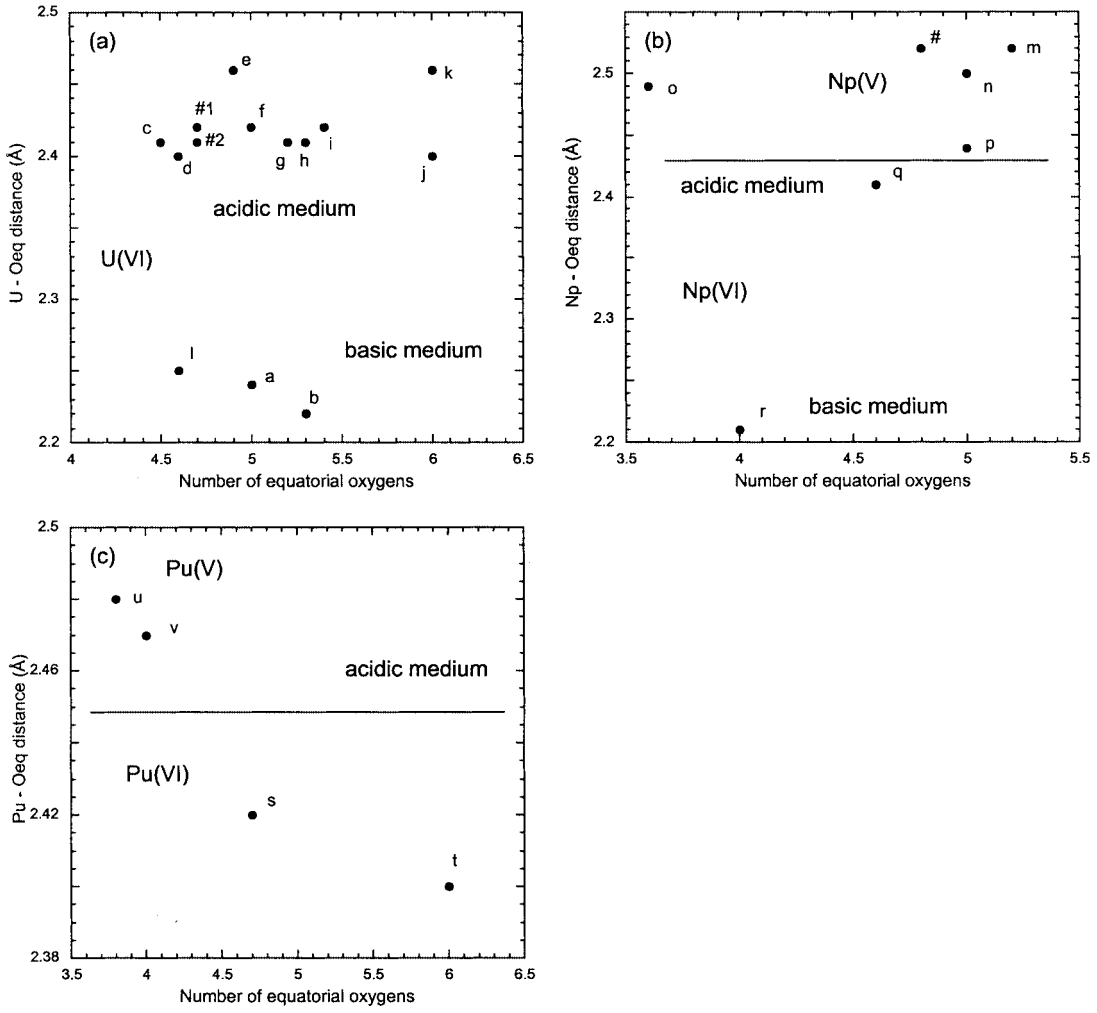

Figure 6. Actinide−oxygen equatorial distances [Å] and number of neighbors as reported from the literature: (a) uranium: a[100] − b,c[102] − d[99] − e,i[103] − f[104] − g[67] − h[105] − j[106] − k[107] − l[108] − # this work (#1 in 0.1 M $HClO_4$; #2 in 0.1 M HNO_3); (b) neptunium: the horizontal line represents the border between the Np^V/Np^{VI} domains: m[109] − n[105] − o,q[60] − p[110] − r[94] − # this work (0.01 M in $HClO_4$); (c) plutonium: the horizontal line represents the border between the Pu^V/Pu^{VI} domains; s,u[111] − t,v[42]

high oxidation state and in crystals of $Co(NH_3)_6NpO_4(OH)_2{\cdot}2H_2O$ grown from this medium. In this compound, the four Np=O oxo bonds expand to 1.85−1.90 Å, ca. 0.05 Å longer than in dioxo compounds, and the pair of *trans*-hydroxo ligands are also found at a longer 2.35−2.40 Å distance. This radical change in geometry produces a comparable change in the XANES, as shown in Figure 7. In these tetraoxo complexes the inverted ratio of short to long An−O bonds results in a shift in the relative amplitudes of the two principal features typical of the XANES of $An^{V,VI}$ with their two different An−O distances. The lower energy peak, A, corresponding to the white line in the spectra of $An^{V,VI}$ complexes decreases in intensity slightly while the higher energy feature, B, that typically occurs as a shoulder on this peak increases by a larger amount. This results in a spectrum with two resolved peaks of comparable amplitude. The separation between these features by ca. 10 eV is quite close to the energy between the peak and shoulder in the spectra of dioxo materials. This result corroborates the importance of the nearest neighbor distances as the primary origin and determinant of these two spectral features. Relative to Np^{VI} complexes, an increase in the edge energy of 1−2 eV (smaller relative to carbonato complexes, larger for hydroxo) occurs, consistent with a higher charge on the Np but also demonstrating that the incremental charge is, as expected, less than found in the oxidation from (V) to (VI). As a possible explanation, the combination of high oxidation state and OH^- donor properties promotes a higher degree of covalency and a lower charge on the central Np.

This scenario is complicated in solution, however, as observation of both dioxo and tetraoxo complexes under conditions identical to those used to prepare the tetraoxo crystals have been reported [94,115,116] by using the XAS technique. Although the Np−O distances are similar to those in Np^{VI} hydroxo complexes, the energies of the absorption edges of these samples are higher than those of Np^{VI} and close to those of the Np^{VII} tetraoxo compounds, consistent with Np^{VII} (Figure 7). However, both close inspection and curve-fits of the EXAFS indicate the presence of a small

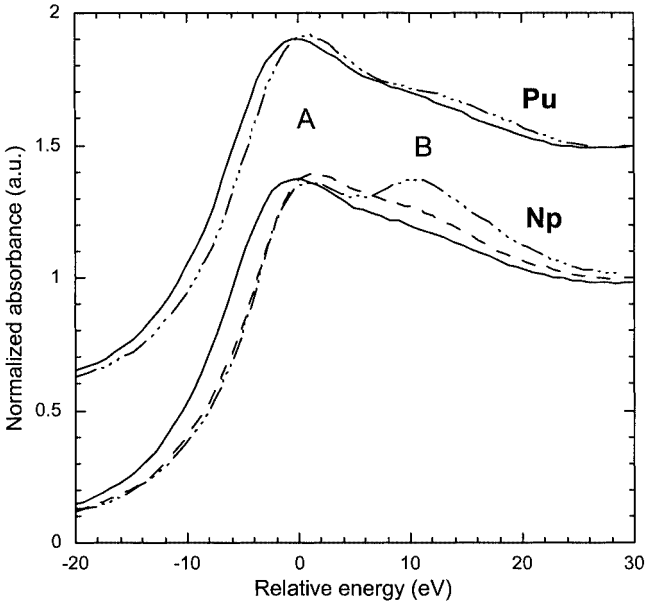

Figure 7. Experimental L_{III} edges showing both dioxo (VI) and (VII) and tetraoxo (VII) signatures of Np and Pu cations;[118] plain line spectra (—) represent the Np, Pu cations at oxidation state (VI) (in concentrated sodium hydroxide); dotted line spectra represent the Np, Pu cations at oxidation state (VII): dioxo Np^{VII} (– –) (in concentrated sodium hydroxide), tetraoxo Np^{VII} (–···–···) [in $Co(NH_3)_6NpO_4(OH)_2{\cdot}2H_2O$] and dioxo Pu^{VII} (–···–···) (in concentrated sodium hydroxide); spectra have been shifted in ordinates and energy calibrated with respect to the edge maximum of the Np^{VI} spectrum

amount of CO_3^{2-} in addition to the OH^-, so that these actually exhibit mixed hydroxy/carbonato coordination. Curve-fits show a larger number of O at the shorter Np–OH distance, which suggests an increase in number of equatorial ligands to five. The presence of strongly bound carbonate would be expected to disrupt the formation of the tetraoxo complex, resulting in the more typical dioxo geometry. This result, therefore, also demonstrates that the balance between the two geometries is delicate so that Np^{VII} is stable in both conformations, even while displaying a slight preference for the tetraoxo configuration. As would be expected from the correlation between the geometry and XANES features, the shape of the XANES of these compounds are quite similar to those of the Np^{VI} hydroxide materials, with a single peak broadened on the high energy side as the separation between the peak and shoulder decrease. The only unique signature of the Np^{VII} state is thus the somewhat higher energy of the edge. A full discussion about this issue is to be published in ref.[118] Recently, these findings have been corroborated to the Pu^{VII} system. The reversible, electrochemical production of soluble Pu^{VII} in highly alkaline media results in a dioxo complex with very slightly contracted bond lengths (0.01–0.02 Å) relative to the original Pu^{VI} starting material and a 1 eV increase in the energy of the absorption edge. At least under the conditions used in this experiment,[118] the number or order of the equatorial ligands was shown by the EXAFS to be altered in the Pu^{VII} product. No sign of CO_3^{2-} ligation is seen in the EXAFS, but only of OH^- ligation, showing that the fine balance between tetra- and dioxo configurations tips toward the latter for Pu. The Pu–O distances are also very similar between the (VI) starting material and oxidized (VII) state. Therefore, the principal effect of the higher valence on the XANES is, similarly, a 1-eV increase in the edge energy.

Studies including a variation of the electrolyte have shown that the counterion may enter the equatorial coordination sphere. Although it is usually accepted that perchlorate ions never coordinate the cation in aqueous solutions,[99] other counterions like F^-, Cl^-, CO_3^{2-} or SO_4^{2-} may form inner-sphere complexes, depending on the anion ionic strength. In the case of Cl^-/NpO_2^+ or UO_2^{2+}, it leads to a decrease of the hydration number and an increase in the Np,U–O equatorial distances as a maximum of 1.0 Cl^- (Np) or 2.6 Cl^- (U) enter the coordination sphere.[105] Similar behavior has been reported for PuO_2^{2+} with replacement of hydration water molecules with chloride ligands.[119] In the case of F^-/UO_2^{2+}, a combined EXAFS and quantum chemistry study[67] has shown that $UO_2F_n(H_2O)_{5-n}^{2-n}$ ($n = 3-5$) complexes can form within a pentagonal bipyramid geometry. Because of its ubiquity in ground water systems, carbonate ions have been extensively studied, revealing complex equilibria in solution.[120–125] Sulfate ions in binary or ternary systems have also been investigated.[126]

4.2. Coordination of Actinyl Cations with Oxygen Donor Ligands

Both steric and electronic ability of the actinide oxo cations to accept donor ligands in the equatorial plane has been at the origin of numerous coordination chemistry species.[49] As mentioned in the introduction of this article, both environmental and nuclear fuel applications of actinyl coordination chemistry have yielded a significant quantity of literature data. Most of it illustrates the use of XAS for the study of short range interactions in the solvent phase or as a complementary technique to X-ray diffraction measurements. Among the coordinating ligands of interest, oxygen donor (mono-, bi- or polydentate) ligands have been predominantly investigated. Hydroxy, carboxylate, phosphate or ether functions are often the functional groups used as donor agent in the actinyl equatorial plane.

For instance, various liquid alkyl phosphate ligands have been the subject of structural variation studies within the actinyl series from uranyl to plutonyl.[85,127] In comparison, the humic acids contain several of the above functional oxygen groups and are indeed among the most complex natural systems. Donor sites are therefore difficult to identify and alternate strategies as complexation by synthetic identified functional groups as xylose, phenylalanine or glycine are needed in order to understand the complex formation.[128] Comparison between the natural and synthetic humic acids has revealed no severe discrepancies, showing that the carboxylate groups act predominantly as monodentate ligands.[127,129] Similarly, natural wood-degradation processes lead to possible complexation by either hydroxybenzoic acids or phenols.[130] Under acidic conditions, the carboxylic

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

group coordinates in a bidentate mode to the uranyl cation, where under basic conditions the phenolic OH functions are the coordinating ones. Biological systems as cells have also been investigated recently. For instance, complexation of uranyl[131] and plutonyl[111] by *Bacillus sphaericus* has shown that the actinyl ion is coordinated to organophosphate groups.

Because of the relatively large atomic number of the phosphorus atom compared to C, N and H and because of the pseudo linear binding mode of the M−O=P group (M = metal), alkyl phosphates can be easily identified using EXAFS spectroscopy. Figure 8 shows the experimental and calculated EXAFS spectra and corresponding FT of solid-state compound $UO_2(NO_3)_2(TiBP)_2$ (TiBP = triisobutyl phosphate). Calculated spectra have been carried out with Feff-7 code based on the crystal structure of the compound at 77 K.[132] In this structure, the uranyl equatorial plane is filled with two bidentate nitrate ions and two monodentate phosphate ligands, the uranium atom being located on a center of symmetry. Deconvolution of the FT modulus in *n* moduli corresponding to *n* backscattering paths can be misleading if no phase is taken into account. Overall, assignment of the FT peaks in terms of backscatters is helpful, although it should be kept in mind that doing so, constructive and destructive interference are neglected. In Figure 8, the 11 paths represent the most intense backscattering process of the photoelectron. Path description is provided below with relative amplitude with respect to the one of the most intense path (a).

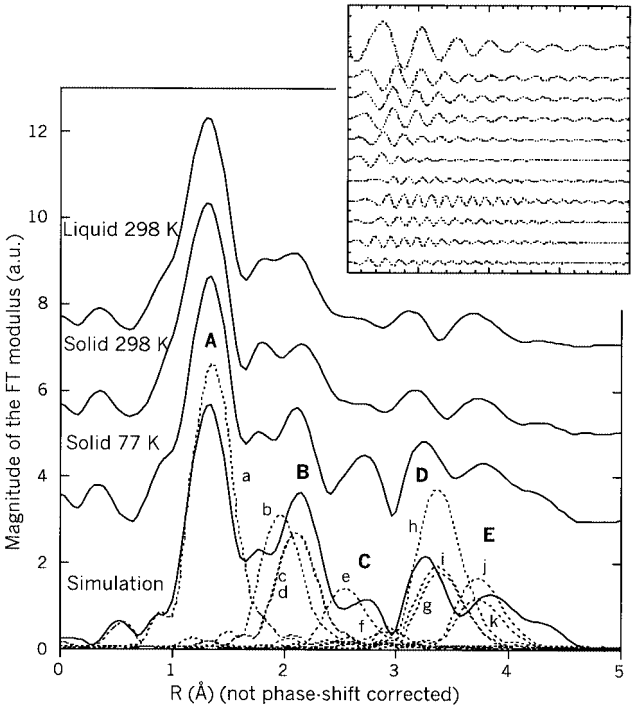

Figure 8. FT (moduli) of the EXAFS spectra of $UO_2(NO_3)_2(TBP)_2$ in TBP solution, solid-state $UO_2(NO_3)_2(TiBP)_2$ (298 K) and $UO_2(NO_3)_2(TiBP)_2$ (77 K);[85] calculated spectrum (Feff-7) of $UO_2(NO_3)_2(TiBP)_2$ is compared with moduli of each back-scattering path a to k; insert: EXAFS oscillations of each back-scattering path

Some of these paths are out of phase within each other as shown in the EXAFS spectra, leading to complex structures in the FT modulus between 2.5 and 4.5 Å (not phase-shift-corrected). For instance, peaks C and D can be mainly attributed to the two nitrogen atoms of the nitrate groups and to the phosphorus atoms of the equatorial ligands. In reality, paths e, f, g, h and i interfere. Peak E originates in a simpler way from the centrifugal oxygen atoms of the two nitrate groups. On the basis of such a path analysis, modifications of the multiple scattering amplitude factors can be used to trace deviations from linear tricenter atomic arrangements. This is the case here with the quasi linear U−O=P bonds. The quadratic dumping of the 4-leg multiple scattering path amplitude as well as the phase shift when the bond angle decreases can be used to extract bond angle information.[85]

On Figure 8, comparison is made with the FT of both solid-state $UO_2(NO_3)_2(TiBP)_2$ at 298 K and $UO_2(NO_3)_2(TBP)_2$ (TBP = tributyl phosphate) in TBP solution at 298 K. Both liquid and solid-state complexes analyzed at room temperature exhibit the same FT, in particular in the multiple-scattering 2.5−4.5-Å region. However, discrepancies with the same solid-state complex analyzed at 77 K indicate that the conformation of the uranyl coordination sphere is temperature-dependent. Decrease of the Debye−Waller factors upon temperature drop may also account for differences on the FT although data fitting has not shown any significant trend in this particular case.[85] The best fit results exhibit a nonsignificant expansion (+ 0.01 Å) of the equatorial U−O bond lengths from 77 to 298 K. At the same temperature, the solid-state and solution complexes are similar from the EXAFS point of view with 2 axial O at 1.77 Å, 2 equatorial O(phosphate) at 2.40

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Å and 4 equatorial O(nitrate) at 2.54 Å. From U to Pu, no significant evolution of the coordination sphere can be observed. The slight coordination sphere contraction of ca. 0.03 Å upon atomic number increase can be attributed to the actinidic contraction, a direct effect of the relativistic character of the 5f electrons.[101]

Monoamide and Malonamides are also oxygen donor monodentate ligands and bind in a similar way to the uranyl equatorial plane. Few solid-state crystal structures have been published[133,134] with nitrate ligands. In Figure 9 (a,b), comparison between solid-state $UO_2(NO_3)_2(TiBP)_2$ [85] and $UO_2(NO_3)_2(DBDMBA)_2$ (*N*,*N*-dibutyl-dimethylbutaramide)[135] complexes shows minor differences. In the multiple scattering regime, peaks C, D and E are present with modulations compared to $UO_2(NO_3)_2(TiBP)_2$ because of differences in backscattering phases and amplitudes. The coordinating carboxy group plays an equivalent role as the phosphorus one, and paths g, h and i apply to peak D with a carbon atom replacing the phosphate one. Similarly with phosphate coordination, comparison between solid state and solution, both at room temperature, shows no significant difference. However, at high acidity (above ca. 5 M), protonation of the malonamide occurs and direct binding to the uranyl is inhibited.[136] Such complexes are known as ion-pairs in which outer-sphere interactions between the actinyl and the malonamide occur. Such structural modification causes dramatic changes in the EXAFS spectra as shown in Figure 9 (a,b). Symmetrization of the equatorial plane by introducing 3 bidentate nitrate ions causes a large increase in peak B of the FT. Peak D decreases in amplitude and is shifted toward smaller distances. In the absence of any U−O=C MS paths, it originates exclusively from axial oxygen atoms (path f). Overall, the U−O(nitrate) distances decrease from 2.52 Å in the inner-sphere complex to 2.48 Å in the outer-sphere complex and this contraction is explained in terms of reduced steric hindrance in the outer-sphere complex. The U−O(axial) distance is unchanged at 1.77 Å.

4.3. Actinyl Uptake from Mineral Surfaces

Actinyl interactions with mineral surfaces is of very important environmental impact, as stressed in the introduction of this article. Among the questions that XAS has addressed are inner- versus outer-sphere complexation, formation of polynuclear precipitates, and mono- vs. polydentate surface binding modes. Such data are the prerequisite to further model the interactions between the heavy metal ions and the mineral surfaces in aqueous medium. Although one of the drawbacks of the technique is to average the signal over all the possible species, tentative site-by-site data analysis has been successfully undertaken. Some of the more recent studies[84,137−140] exemplify this method, considering a topological approach between the cation coordination sphere and the surface. Such data have to be compared to the coordination processes to natural substances as humic acids, as described in the previous paragraph. The uranium cation has been the most extensively studied because of its ubiquity in the geosphere and the absence of radiological concerns[106,140−152]. However, recent work has also been devoted to thorium[138] or neptunium.[109,139] Many mineral substrates have been use, based on their occurrence in the geosphere: goethite (FeOOH), muscovite $[KAl_2(AlSi_3O_{10})(F,OH)_2]$, mackinawite (FeS),[139,144] hematite (Fe_2O_3),[137,141] ferrihydrite ($Fe_2O_3H_2O$),[150] montmorillonite $[(Na,Ca)(Al,Mg)_6(Si_4O_{10})_3(OH)_6n(H_2O)]$,[107,153] zircon ($ZrSiO_4$),[154] zirconium diphosphate (ZrP_2O_7),[142] titania (TiO_2),[84] silica,[151,155] alumina (Al_2O_3)[140] etc. In most cases, intricate binary or ternary complexes are formed between the oxo cation, the surface and the solution counterions or water molecules. Note that for all these systems the species involved in the interface chemical reactions are difficult to measure due to their low

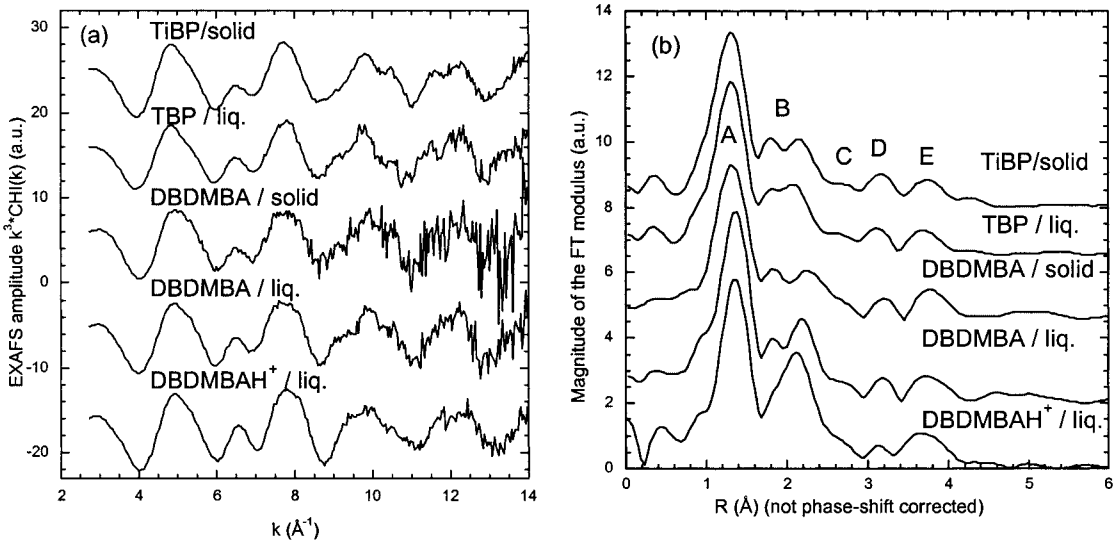

Figure 9. EXAFS spectra of solid-state compound $UO_2(NO_3)_2(TiBP)_2$, $UO_2(NO_3)_2(TBP)_2$ in TBP solution,[85] solid-state $UO_2(NO_3)_2(DBDMBA)_2$, $UO_2(NO_3)_2(DBDMBA)_2$ and $UO_2(NO_3)_3^-DBDMBAH^+$ in DBDMBA;.[135] all spectra were recorded at 298 K; (a) raw EXAFS oscillations and (b) corresponding modulus of the Fourier transform

concentration on the solid surface. Participation of the counterion to the surface complex depends on its chelating ability under the sorption conditions.

The redox chemistry of uranium in aqueous solution is predominantly governed by the +VI oxidation state (the +VI/+IV potential with respect to the standard electrode is equal to 0.27 V). As a consequence, no reduction to the +IV oxidation state is expected upon sorption under atmospheric conditions as confirmed by the invariance of the uranium L_{III} edges observed in most of the above references. Similarly, the +V oxidation state is conserved when NpO_2^+ is sorbed onto goethite (FeOOH).[109] Conversely, when mackinawite (FeS) is used as a substrate, reduction of Np^V to Np^{IV} has been observed.[139] The authors have observed a similar behavior when PuO_2^{2+} is sorbed onto thorine (ThO_2): reduction of the plutonium oxidation state from +VI to +IV occurs. This phenomenon is not explained to date. Indeed, no redox reaction can occur between the plutonium species and the tetravalent thorium as it appears with iron substrates. The physico-chemical parameters at the solid/solution interface such as pH, redox potential, structure of the water molecules, may be different than those in the bulk solution, which could change drastically the radionuclide's chemical properties at the interface. Therefore, careful investigation of the microscopic properties of this interface should be carried out. In Figure 10, examples of EXAFS spectra of UO_2^{2+}/H_2O/substrate (substrate = $LaPO_4$, ZrP_2O_7 and TiO_2)/surface complexes are presented. Table 1 summarizes the structural parameters (the first uranium coordination sphere) of surface complexes published in the literature. Confirming the XANES results, the uranyl entity is conserved in all cases. When complexing counterions are present, such as carbonate anions, ternary inner-sphere complexes can be formed with the surface and the counterion.[137,141,151] The final stoichiometry often depends on the sorption conditions (pH, concentration in the solution). In presence of perchlorate ions, no inner-sphere complex with the counterion has been published to date. On the average, the equatorial uranium coordination number ranges from 5 to 6 as in aqueous uranyl. When a two-shell fit of the equatorial oxygen atoms is performed, a shorter bond length is observed between the uranium atom and the surface than between the uranium atom and the outer oxygen atoms (carbonate oxygen atoms,[137] water oxygen atoms[84,142,151,154–156]). For example, the Fourier transform of the EXAFS spectrum, corresponding to the U^{VI}/ZrP_2O_7 system, exhibits two equatorial oxygen atoms contributions and another one arising from the phosphorus atoms. The $U-O_{surf.}$ (2.33 Å) and U–P (3.60 Å) distances and the $O_{surf.}-P-O_{surf.}$ (110°) and P–O–P (150°) angles indicate clearly that the two oxygen atoms on the surface (associated to the shorter bond length) cannot belong to only one P_2O_7 surface group, but to two different ones.[142] A similar structural investigation has been carried out with the same metal ion on the $LaPO_4$ substrate. One phosphorus atom has been found at 2.74 Å. In that case, according to the bond lengths $U-O_{surf.}$ (2.31 Å) and P–O (at 1.50 Å in the PO_4 group), the $U-O_{surf.}-P$ angle is around 90°. Consequently, if the two oxygen atoms ($U-O_{surf.}$ at 2.31 Å) belong to the same PO_4 surface group, the $O_{surf.}-P-O_{surf.}$ angle should be around 114°, which is a reasonable value for the PO_4 tetrahedron. Therefore, it is assumed that the uranyl ion is complexed with only one PO_4 surface group. Moreover, as the phosphorus atom is at only 2.74 Å from the uranium atom, this indicates that there is no water molecule layer between the sorbed uranyl ion and the surface and thus that this ion is sorbed as an inner-sphere complex.[156] Nevertheless, the data from Waite et al.[150] seem to contradict this kind of interpretation with a reverse order of the distances. EXAFS studies have been performed on totally different substrates such as montmorillonite clay as well. By comparing the EXAFS data for uranyl ions in solution and sorbed onto this clay, it has been possible to distinguish different sorption mechanisms depending on the pH value of the suspension. For instance, for a pH value equal to 5, the EXAFS spectrum of loaded uranyl is identical to the one corresponding to the uranyl ions in solution, which demonstrates that these ions are sorbed as an outer-sphere complex onto the ion-exchange interlayer site of the clay.[106]

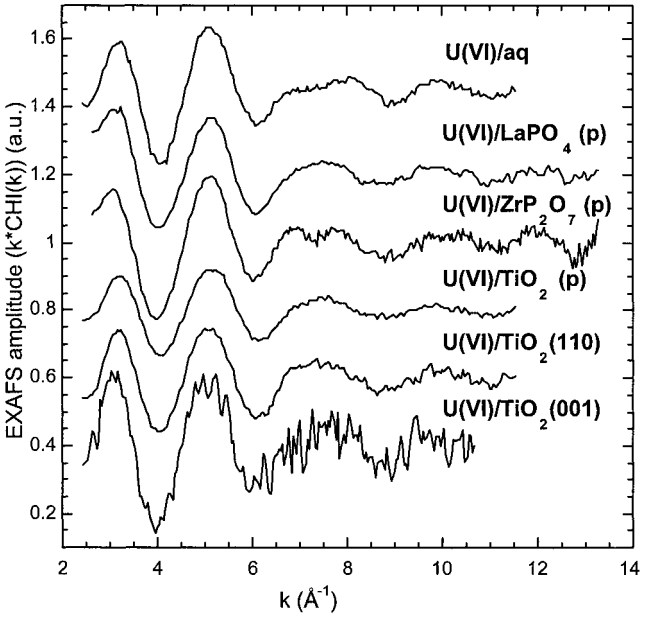

Figure 10. Raw EXAFS spectra of uranyl uptake from polycrystalline $LaPO_4$, ZrP_2O_7, TiO_2 powders[84,142,156] and single crystal of the (110) and (001) planes of TiO_2;[84] the spectrum of starting uranyl solution in perchloric acid is also displayed

As demonstrated by the growing number of sorption/XAS references, the use of polycrystalline substrates is essential to pin down the sorption mechanisms. Site-by-site interpretation of the sorption sites has even been attempted.[137,157] However, in order to better describe these surface sites, the use of crystallographic plane substrates allows a real site-by-site investigation of the surface complexes.[147,148] In the case of the uranyl oxo cation, advantage of the linear polarization of the synchrotron light has been taken in order to seek the uranyl rod orientation on the surface. Such experiment is known as Grazing Incidence

U^{VI}/montmorillonite[d]	*2.0(−)* O −1.79(1)	5.4(8) O −2.43(1)		[155]
U^{VI}/silica	*2.0(−)* O −1.78(1)	3.0(9) O −2.46(3)	2.1(6) O −2.28(2)	[155]

[a] Details about sorption conditions are given in the corresponding reference. In case of varying parameters such as pH or stock solution concentration, only one result is reported in the Table. [b] Distinction between surface-bonded and outer oxygen atoms is provided when a two-shell fit is provided. [c] Numbers in *italic* correspond to fixed or linked variables. [d] Outer-sphere complex.

XAS (GXAS) and its application to actinide chemistry is relatively new.[84,143] In a general sense, GXAS is based on the variation of the apparent number of neighbors with the angle between the electric field and the chemical bond.[158] Figure 11 shows the calculated effect of polarization on the sorption orientation of UO_2^{2+} onto the (011) plane of rutile. The modulations of feature B associated with the *trans*-dioxo unit are monitored by the angle between the O=U=O bond vector and the electric field vector: maximum intensity when both vectors are collinear, minimum intensity when both vectors are normal to each other. In comparison with the calculation, the parallel and perpendicular experimental measurements exhibit a slight decrease of feature B.[84] The small difference between the two measurements suggests that the uranyl rod sorbs quasi parallel to the surface, deviation from ideality being attributed to surface defects.[159]

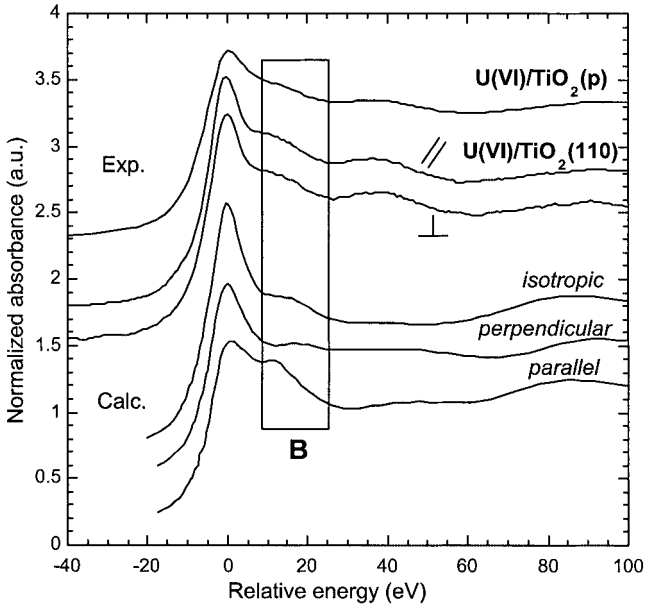

Figure 11. Uranium L_{III} edge experimental spectra of U^{VI}/TiO_2(p) and U^{VI}/TiO_2(110); U^{VI}/TiO_2(p) corresponds to an isotropic measurement; U^{VI}/TiO_2(110) has been measured with the electric field vector ε parallel (∥) and perpendicular (⊥) to the (110) surface;[84] comparison with uranium L_{III} edge simulated spectra (Feff-8.1) of $UO_2(O)_5^{2+}$ and $UO_2(O)_5$ cluster onto the TiO_2 (110) surface in the parallel and perpendicular configuration of the oxo cation bond vector with respect to ε ; for clarity, spectra have been shifted in ordinates and energy calibrated with respect to the edge maximum

EXAFS data analysis of the uranyl sorbed onto the (110) plane shows a splitting of the equatorial U−O bond lengths between U−O(surface) and U−O(out). Two possible sorption sites are available for bidentate complexation on the (110) surface: shared-edge distorted TiO_6 polyhedra and shared-summit polyhedra. Both sites are present in the surface complexes in proportions that are unknown from data analysis. Figure 12 shows a schematic representation of the surface complex in the case of the shared-edge sorption site of the (110) surface. The structural parameters are similar to the one obtained from uranyl sorption on polycrystalline

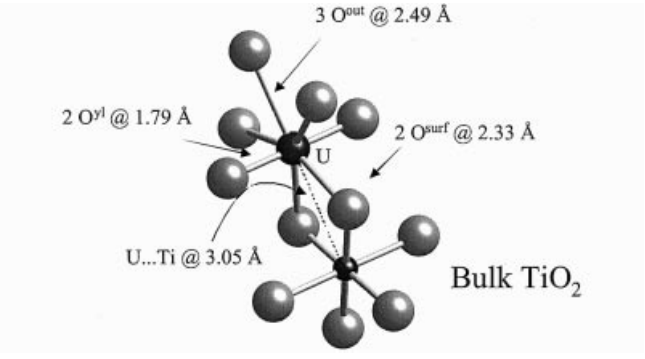

Figure 12. From EXAFS data analysis, schematic representation of the uranyl surface complex on the (110) surface of TiO_2; only the shared-edge site is represented[84]

rutile (Table 1). The shortening of the U−O equatorial bond from 2.42 Å for aqueous uranyl to 2.32 Å for U−O(surface) suggests an increase in covalency of the U−O(surface) bond. This would not be surprising, taking into account the lack of coordination for the rutile surface oxygen atoms and the possibility of charge delocalization along the surface.

5. Summary

This overview on structural and electronic aspects of actinide molecular chemistry, although limited, has hopefully demonstrated the advantages of XAS for such chemical systems. Since the actinide elements are electron-rich cations from high atomic numbers, they bear remarkable chemical properties, from the availability of many stable oxidation states to the formation of large coordination polyhedra. Such properties demonstrate the richness of the actinyl chemistry; they also underline the intricacy of working with actinide cations.

Two major issues have been schematically addressed in this article. The first one deals with acute understanding of the actinyl electronic properties. Clearly the XAS probe by itself will not fully describe the electronic valence states of the molecule and a palette of complementary techniques and calculations must be employed. Coupling simulation codes to experimental results is also essential. In that sense, the selection of various transition channels from core spectroscopy to higher primary quantum numbers is a unique tool based on the tinability of the synchrotron radiation. Photoelectron or photoemission spectroscopy are examples of electronic probes based also on the interaction of a photon with the electronic cloud. In all cases, the key approximations that must be made for simulation purposes are driven by the final state. Although the relative qualitative evolution of the features driven by the absorption processes in homogeneous series of complexes is most often understood, absolute qualitative values are much more difficult to obtain. One of the major difficulties lies in the evaluation of the structural and electronic contributions to the absorption edge, both being highly related. In that sense, increased accuracy in the calculation results, such as Fermi levels, should be particularly helpful. The development of full multiple scattering codes can be considered as one of the major milestones in the field, although progresses must be carried out in the definition of the scattering potentials.

The second issue deals with the high energy part of the absorption process, where modulations of the absorption coefficient is related to the spatial arrangement around the absorbing atom. Although the single backscattering processes describe adequately the first coordination sphere, they are of limited information beyond this shell and multiple scattering processes must be taken into account. Accurate geometrical information can also be drawn from the multiple scattering paths as their phases and amplitudes are affected by the relative bond angles and distances. Finally, coupling with quantum chemistry is essential in order to validate or favor one of the geometrical models deduced from the EXAFS data. One of the major difficulties to be pointed out occurs when several species or conformations are present. This is a common case in solution coordination chemistry when either labile complexes or low equilibrium constants are encountered. As a result, the data analysis accuracy is limited by an increasing number of fitting parameters.

From speciation to simulation, XAS has proven to be one of the useful probes for actinyl chemistry. As suggested in this article, limitation of XAS data analysis to phenomenological aspects is often restrictive and coupling with calculation codes should help to quantify the links between absorption processes and electronic properties.

Acknowledgments

This research was mainly carried out at the Laboratoire d'Utilisation du Rayonnement Electromagnétique (Orsay, France) a national user facility operated by CEA/CNRS/MR and the Stanford Synchrotron Radiation Laboratory (Stanford, USA), a national user facility operated by Stanford University on behalf of the U.S. Department of Energy, Office of Basic Energy Sciences. The authors are particularly grateful to the beam line scientists and health physicists of LURE for their constant help, support and advice. They would like also to acknowledge the beam line scientists of SSRL and health physicists supported by the Seaborg Institute at LANL. Many fruitful discussions with J. J. Rehr, A. Ankudinov and C. Cartier dit Moulin played an important part in this work and the authors would like to thank them for their help. This work has been financially supported by CEA/DEN, PRACTIS (France) and by DOE OBES Division of Chemical Sciences under Contract W-7405 (USA).

Lithium [Bis{benzoyl-$W(CO)_5$}(μ_2-hydrogen)] − A Charge-Assisted H^+-Bridged Organometallic Complex Prepared by Selective Li^+ Ion Replacement

Matthias W. Esterhuysen[a] and Helgard G. Raubenheimer*[a]

Dedicated to E. O. Fischer on the occasion of his 85th birthday

Keywords: Lithium / Tungsten / Hydrogen bonds / Crystal engineering / Carbene complexes / Self-assembly

Efficient syntheses and isolation procedures of two closely related benzoyl–$W(CO)_5$ compounds, [{Li(diglyme)}{Ph(O)-$CW(CO)_5$}] (**1**) and [$Li(diglyme)_2$][(μ_2-H){Ph(O)$CW(CO)_5$}$_2$] (**2**) are reported. The empirical formulae of **1** and **2** differ only in that the latter contains half the number of Li^+ ions, with the balance of cations replaced by protons through an acidic silica gel filtration procedure. X-ray structural investigations of both compounds revealed a self-assembled polymeric Li^+-bridged structure for **1**, and a strikingly dissimilar H^+-bridged structure for **2**, thereby emphasising the important influences of strong, charge-assisted hydrogen bonds on solid-state structures. Possible implications of this novel route to charge-assisted hydrogen bonds for crystal engineering are discussed.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Hydrogen bonding effects are essential in crystal engineering.[1] Recent advances in organometallic crystal engineering, especially by the group of Braga and Grepioni, have exhibited the versatility of hydrogen bonds in the "construction" of extended organometallic structures.[2] Variation of the non-covalently bonded ligand components in the crystals may then ultimately enable chemists to "tune" the crystal so that aspects of transition metal coordination chemistry (e.g. variable valence, oxidation, and spin states of the metal atoms) are incorporated in the crystals.[2] Organometallic crystal engineering studies are presently focused mainly on the use of functionalised ferrocenes, and other sandwich compounds, in forming crystals with extended structures.[2] Carboxylic acid and 1,3-cyclohexanedione functionalities in these compounds are, furthermore, the preferred vehicles for introducing hydrogen bonds, which ultimately produce the extended structures of molecules in the crystals.[2] Strong, charge-assisted O−H···O^- hydrogen bonds − valuable tools for crystal engineers − are generally obtained by partial deprotonation of acidic moieties (typically carboxylic acids) in the crystals and significantly strengthen the extended structures.[3] These short hydrogen bonds, as they occur in homonuclear molecule−ion associates, AHA^- (A = anion base, e.g. carboxylate anion), have been subject to intensive theoretical and experimental investigations and, also, much debate.[4]

Transition metal−acyl complexes are an extremely important class of organometallic compounds; they feature in many homogeneous catalytic processes, especially ones involving carbon monoxide,[5] and have hence been the subject of many reactivity and theoretical studies.[6] Transition metal−acyl complexes are also useful models for key catalytic intermediates in heterogeneous catalytic processes,[7] such as the Fischer−Tropsch process, where Fe-surface alkyl and acyl species play an important role in the formation of oxygenates (mainly formates, alcohols, and ketones).[8] Anionic transition metal−acyl complexes are, furthermore, important water-soluble intermediates in many synthetic routes to useful organometallic compounds, including Fischer's classical, and Semmelhack's more recent, methods to prepare carbene complexes.[9] Both routes involve the formation of anionic metal−acyl species that, upon oxygen alkylation/protonation, yield a wide variety of carbene complexes. Even though hydrogen bonding and cation coordination to metallo-acyl oxygen atoms in hydroxycarbene[10] and metal−acyl[11] complexes is well known, no examples of such complexes with extended solid state structures have been described.

We report here the isolation and structural characterisation of the widely employed organometallic reaction intermediate [Li(diglyme){Ph(O)$CW(CO)_5$}] (**1**), as a diglyme stabilised Li^+ salt, and the closely related H^+-bridged organometallic compound [$Li(diglyme)_2$][(μ_2-H){Ph(O)-$CW(CO)_5$}$_2$] (**2**) − both prepared from identical reaction mixtures. In the solid state, complex **1** exhibits a linear polymeric structure of Li^+-ion-bridged Ph(O)$CW(CO)_5^-$ ions

[a] Department of Chemistry, University of Stellenbosch, Private Bag X1, 7602 Matieland, South Africa
E-mail: hgr@sun.ac.za

in which the Li^+ ions coordinate to the acyl oxygen atom and a carbonyl oxygen atom of a neighbouring $Ph(O)CW(CO)_5^-$ ion. A strong, charge-assisted hydrogen bond in **2** bridges two $Ph(O)CW(CO)_5^-$ ions in the solid state structure. The remaining positive charge in **2** is provided by a Li^+ ion, indicating that only one Li^+ ion was selectively replaced during the filtration/protonation procedure executed on the common reaction mixture. In both compounds 1 mol equiv. of diglyme (diethylene glycol dimethyl ether) is incorporated to stabilise the Li^+ ion and it is, furthermore, thought to be imperative to the efficient selective protonation that affords **2**.

Results and Discussion

Synthesis and Isolation of Benzoyl−$W(CO)_5$ Complexes, Their Crystal Structures, IR Spectra, and NMR Spectra

The anionic benzoyl−$W(CO)_5$ complexes, **1** and **2**, were synthesized in the same manner as the first step of the synthesis of the Fischer-type carbene complex [Ph(OR)C=$W(CO)_5$], i.e. by dropwise addition of 1.2 mol equiv. PhLi to a suspension of $W(CO)_6$ in Et_2O at room temperature.[9a] However, instead of alkylating the so-formed Li[Ph(O)-$CW(CO)_5$], **1** and **2** were prepared using slightly modified procedures (Scheme 1). Complex **1** was isolated in high yield [78%, based on $W(CO)_6$] as bright-red crystals, suitable for X-ray crystallographic analysis, by the addition of 1 mol equiv. diglyme to the reaction mixture and subsequent crystallisation from a diethyl ether/*n*-pentane mixture. Complex **2** was prepared similarly, except that the red reaction mixture was carefully filtered through cooled (0 °C) acidic silica gel (10−15 cm, Ø 4 cm) before crystallisation from a diethyl ether/*n*-pentane mixture to afford bright-red crystals of **2**, suitable for X-ray crystallographic analysis, in moderate yields [69%, based on $W(CO)_6$]. Et_2O was used to elute the mixture from which **2** crystallised as a slow-moving red band from the silica gel. This procedure is closely related to the synthesis of hydroxycarbene complexes, as originally reported by Fischer et al.[12]

Removal of half the Li^+ ions from the reaction mixture by proton exchange upon filtration through silica gel, so that **2** may crystallise, is closely linked to the amount of diglyme present in the reaction mixture. The Li^+ ions in the reaction mixture have to be strongly solvated to pass through the silica gel during the filtration procedure. As only one mol equivalent of diglyme is added to the reaction mixture, and two diglyme molecules are required to solvate each Li^+ ion (as in the crystal structure of **2**, Figure 3), exactly half the Li^+ ions remain in solution after chromatography. The other half are immobilised on the silica gel and, to balance the charge, are replaced by mobile protons. Et_2O solvent molecules do not solvate Li^+ ions strongly enough to facilitate their efficient mobilisation through silica gel.

Low-temperature crystal and molecular structures of **1** (173 K) and **2** (173 K) (Figure 1 and Figure 3) were determined by X-ray diffraction. The structure of **1** clearly shows a $Ph(O)CW(CO)_5^-$ ion interacting with a Li^+ ion through its acyl moiety. Li^+-coordination to the oxygen atom of the CO ligand *trans* to the benzoyl group [O(3)] in neighbouring anions results in infinite zig-zag chains of alternating $Ph(O)CW(CO)_5^-$ and Li^+ ions along the *a* axis of the unit cell of **1** (Figure 2). The remaining coordination positions on the Li^+ ion are occupied by a diglyme molecule, coordinating to the cation through all three of its ether oxygen atoms. The coordination mode of the five-coordinate Li^+ ion is best described as distorted square pyramidal, with O(3) at the apex. O(5) lies on the underside of the square pyramid, beyond bonding distance [O(5)−Li = 3.506(4) Å],

Scheme 1

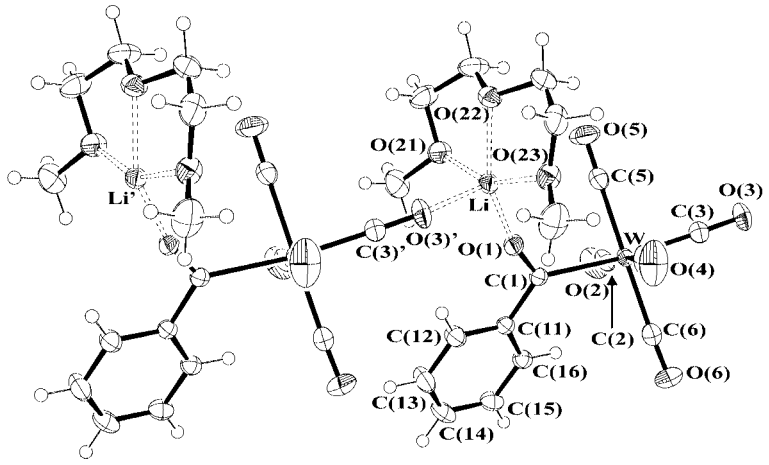

Figure 1. ORTEP[13] plot of **1** (two asymmetric units, 50% probability ellipsoids), showing the atomic numbering scheme and the polymeric structure observed in the crystal; selected bond lengths [Å] and angles [°]: W−C(1) 2.283(2), O(1)−C(1) 1.239(2), C(1)−C(11) 1.523(3), O(1)−Li 1.875(4), O(3)−Li 2.071(4), O(5)−Li 3.506(4), O(21)−Li 2.095(4), O(22)−Li 2.083(4), O(23)−Li 2.070(4), W−C(2) 2.026(2), W−C(3) 1.981(2), W−C(4) 2.047(2), W−C(5) 2.048(2), W−C(6) 2.024(3), C(2)−O(2) 1.150(3), C(3)−O(3) 1.164(3), C(4)−O(4) 1.136(3), C(5)−O(5) 1.137(3), C(6)−O(6) 1.143(3), C(1)−W−C(3) 171.8(1), C(2)−W−C(4) 175.0(1), C(5)−W−C(6) 179.5(1), W−C(1)−O(1) 119.9(2), W−C(1)−C(11) 126.6(1), O(1)−C(1)−C(11) 113.5(2), O(1)−Li−O(3)′ 105.2(2), O(1)−Li−O(21) 95.8(2), O(1)−Li−O(22) 150.5(2), O(1)−Li−O(23) 102.4(2), O(21)−Li−O(23) 154.1(2), O(3)′−Li−O(21) 95.6(2), O(3)′−Li−O(22) 104.1(2), O(3)′−Li−O(23) 97.3(2), W−C(2)−O(2) 178.8(2), W−C(3)−O(3) 178.3(2), W−C(4)−O(4) 178.0(3), W−C(5)−O(5) 179.2(2), W−C(6)−O(6) 177.5(2), O(1)−C(1)−C(11)−C(12) 8.9(3), C(5)−W−C(1)−O(1) 34.7(2)

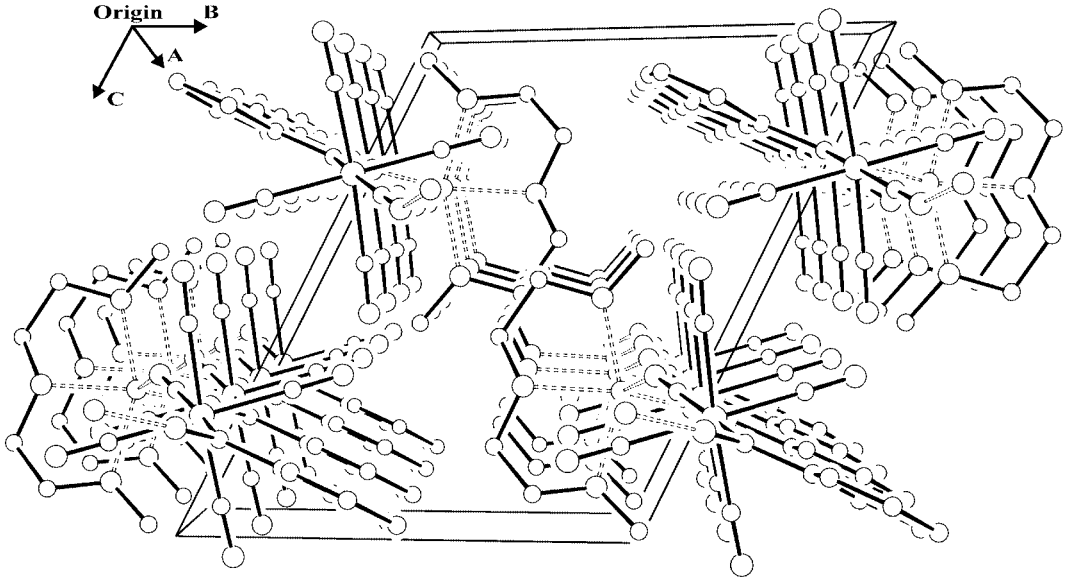

Figure 2. Packing diagram of **1**, viewed along the *a* axis, showing the extended structure of linked molecules (hydrogen atoms are omitted for clarity)

but sterically preventing the diglyme molecule from assuming a coordination mode that is closer to trigonal bipyramidal.

Interestingly the Li−O separations in the structure of **1** vary: Li to the diglyme oxygen atoms and to the CO ligand, O(3) are slightly shorter than in comparable five-coordinate Li[diglyme] structures [average of these four Li−O separations = 2.080(4) Å],[14] but the Li−acyl oxygen separation is still ca. 0.2 Å shorter than this [Li−O(1) = 1.875(4) Å]. In the absence of any obvious steric reasons, this difference within **1** indicates a much stronger electronic interaction between the Li^+ ion and O(1) than with other oxygen atoms.

The W−C(1) and C(1)−O(1) bond lengths [2.283(2) and 1.239(2) Å] in **1** are consistent with a small amount of charge delocalisation from the tungsten to the oxygen atom, due to Li^+-acyl coordination. Pure zero-valent tungsten W−C(sp^2) single bonds are usually slightly longer [≈ 2.31 Å][15] whereas uncoordinated acyl C=O double bonds are usually slightly shorter [≈ 1.21 Å].[16] An O(1)−C(1)−C(11)−C(12) torsion angle of 8.9(3)° describes the orientation of the phenyl ring toward the acyl moiety. The sp^2 hybridisation of C(1) is confirmed by its, within experimental error, flat bonding geometry [the greatest deviation from the least-squares plane through W, C(1), O(1),

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and C(11) is 0.004(2) Å for C(1)]. A C(5)−W−C(1)−O(1) torsion angle of 34.7(2)° describes how the benzoyl ligand is rotated relative to the $W(CO)_4$ coordination plane. Distortion of the $W(CO)_4$ coordination plane from planarity, due to bonding of the benzoyl ligand, is described by deviations from planarity from the least-squares plane through W, C(2), C(4), C(5) and C(6) of −0.0253(9), 0.0477(11), −0.0472(11), −0.0334(11), and −0.0362(12) Å respectively, and, furthermore, concurs with the relatively intense and infrared active B_1 absorption mode in the carbonyl region of the IR spectrum of **1** (see below).

In the crystal, asymmetric units of **1** pack in infinite polymeric chains, as described above, along the *a* axis of the unit cell in the triclinic centrosymmetric space group, $P\bar{1}$ (Figure 2). No significant intermolecular interactions, other than the intramolecular Li^+-bridges, are observed in the crystal structure of **1**. The highly ordered polymeric chain structure found for **1** might be partly responsible for the low crystal mosaicity [0.464(1)°] in the crystal selected for the X-ray diffraction study. It is noteworthy that this crystal yielded excellent diffraction data and that hence a very well-determined crystal structure was obtained for **1** [$R_1(I > 2\sigma I) = 1.38\%$].

Although lithium alkyl/aryl pentacarbonyl chromates/molybdates/tungstates are common organometallic intermediates in the synthesis of many alkyl/aryl alkoxy Fischer-type carbene complexes, the crystal structure of **1** appears to be the first example of this commonly employed organometallic Li^+-salt. The structure of a complicated lithium−(μ^2-benzoyl)-1,10-bis(diphenylphosphanyl)-(1,4,7,10-tetraoxadecane)$Mo(CO)_3$ complex, specifically designed to trap this Li^+ metallo−acyl species, has, however, been reported.[11a]

The crystal and molecular structure of **2** (Figure 3), although possessing a very similar empirical formula to **1** and containing the same metal carbonyl moieties, exhibits a completely different molecular arrangement. The structure of **2**, which is formally also a rare example of a hydrogen bond stabilised Fischer-type hydroxycarbene complex, clearly shows a Li^+ ion coordinated to two diglyme molecules, and two $Ph(O)CW(CO)_5^-$ ions linked via a strong, negative charge-assisted hydrogen bond between their acyl oxygen atoms. The striking difference in structure between **1** and **2** is down to the different interaction patterns of the cations. Protons, unlike Li^+ ions, are sufficiently stabilised in a two-coordinate hydrogen-bonded system while Li^+ ions can easily accommodate up to eight oxygen donor species and are rarely stabilised by less than four neutral oxygen donor atoms in the solid state.[17] Replacing half the Li^+ ions in solution thus allows the Li^+ ion to very efficiently coordinate to two diglyme molecules, whereas the strongly hydrogen-bonded proton in **2** is situated between two acyl groups of separate $Ph(O)CW(CO)_5^-$ ions.

The W−C(1) bond in **2** is slightly shorter than in **1** [W−C(1) = 2.238(5) Å in **2** vs. 2.284(2) Å in **1**] while the C(1)−O(1) bond in **2** is slightly longer [C(1)−O(1) = 1.276(6) Å in **2** vs. 1.239(2) Å in **1**]. These changes indicate a slight shift in electron density from the $W(CO)_5$ fragment

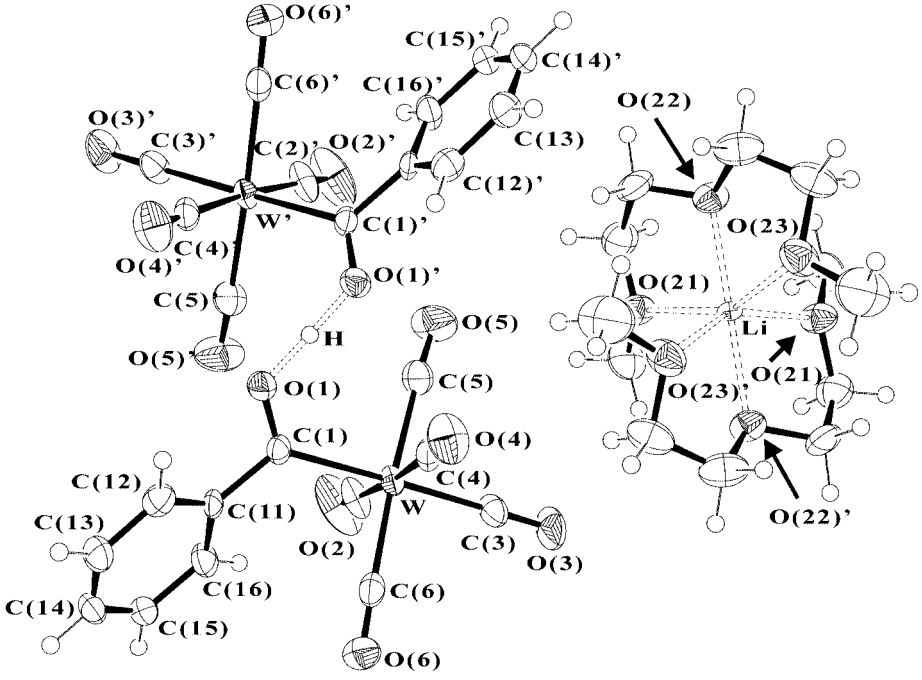

Figure 3. ORTEP[13] plot of **2** (two asymmetric units, 50% probability) showing the numbering scheme and charge-assisted hydrogen-bonding interactions observed in the crystal; selected bond lengths [A] and angles[°]: W−C(1) 2.237(5), O(1)−H 1.233(12), O(1)−C(1) 1.277(6), C(1)−C(11) 1.505(7), O(1)−O(1)′ 2.442(6), W−C(2) 2.015(7), W−C(3) 1.996(6), W−C(4) 2.025(6), W−C(5) 2.044(6), W−C(6) 2.028(6), O(21)−Li 2.170(8), O(22)−Li 2.075(3), O(23)−Li 2.169(9), O(2)−C(2) 1.152(8), O(3)−C(3) 1.147(6), O(4)−C(4) 1.136(7), O(5)−C(5) 1.149(6), O(6)−C(6) 1.155(6), O(1)−H−O(1)′ 164.5(3), C(1)−W−C(3) 173.9(2), C(2)−W−C(4) 176.1(3), C(5)−W−C(6) 174.7(2), W−C(1)−O(1) 125.1(3), W−C(1)−C(11) 123.9(3), O(1)−C(1)−C(11) 110.7(4), W−C(2)−O(2) 176.4(5), W−C(3)−O(3) 178.5(6), W−C(4)−O(4) 178.5(5), W−C(5)−O(5) 175.2(5), W−C(6)−O(6) 177.4(5), O(21)−Li−O(23) 150.7(2), O(22)−Li−O(22)′ 167.8(6), C(5)−W−C(1)−O(1) 35.9(5), O(1)−C(1)−C(11)−C(12) 29.2(6)

to the acyl oxygen atom from **1** to **2** and suggest a stronger bonding interaction between the proton and the acyl oxygen atoms in **2** than between the Li^+ ion and the acyl oxygen atom in **1**. The O···O separation in **2** is very short [2.442(6) Å], showing that the hydrogen bond is indeed strong.[2] The position of the proton could be reliably determined and refined from the difference Fourier map and is, as expected in a hydrogen-bonding situation that involves identical anionic moieties, evenly spaced between the metallo-acyl oxygen atoms [O(1)−H = 1.232(11) Å].[18] The bridging hydrogen atom is, furthermore, situated on a crystallographic twofold rotation axis that lies parallel to the *c* axis of the unit cell and relates the anions in the formula unit to one another. Braga suggests that strong inter-anionic hydrogen bonds could be the result of a residual negative charge residing on the oxygen donor atoms.[2] In **2** this is clearly not the case. The bulk of the negative charge in anionic metallo-acyl metal carbonyl species is expected to be on the strongly electron-withdrawing $M(CO)_n$ fragments, as the W−C(1) and C(1)−O(1) bond orders and IR data, discussed below, of **1** and **2** reflect. Although some increase in the W−C(1) bond order and reduction of the C(1)−O(1) bond is seen upon hydrogen bonding in **2** (compared to **1**), the observed bond lengths and $\tilde{\nu}$(CO) absorption bands of **2** still suggest large amounts of negative charge delocalised onto the $W(CO)_5$ fragment. In [$(CO)_5$W=C(OEt)Ph], in which some delocalisation of negative charge to the $W(CO)_5$ fragment is also present, these separations are 2.195 and 1.299 Å.[19] These observations suggest that the hydrogen bonding interactions observed in **2** are the result of classical hydrogen bonds and do not involve residual negative charge on the oxygen atom.[4d,20]

The Li^+ ion in **2** also resides on the twofold rotation axis in this space group, indicating that the Li(diglyme)$_2$ coordination possesses twofold symmetry. The crystallographic asymmetric unit of **2** thus consists of a single $Ph(O)CW(CO)_5^-$ ion hydrogen-bonded to a bridging proton, and one diglyme molecule coordinated to a shared Li^+ ion. Interestingly the hydrogen-bonded proton does not lie linearly between the metallo-acyl oxygen atoms [O(1)−H−O(1)′ = 164.5(3)°]; this measurement is not biased by the proton's crystallographically special position. The O(1)−H−O(1)′ angle depends on the unique coordinate of the proton along the *c* axis of the unit cell, which is free to change during the structure refinement. The reason for this kink in the hydrogen bond is not entirely clear. Similar kinks in hydrogen bonding interactions have, however, been reported between other anionic organometallic fragments and have been linked to weakening of the hydrogen bonding interaction, especially once the O−H−O angle exceeds 165°.[18,20]

An O(1)−C(1)−C(11)−C(12) torsion angle of 29.2(6)° describes the orientation of the phenyl ring toward the acyl moiety. Curiously, the sp^2 hybridisation of C(1) is somewhat more distorted from trigonal planar geometry than in **1**, possibly due to steric considerations [the respective deviations from the least-squares plane through W, C(1), O(1), and C(11) are 0.012(1), −0.044(4), 0.018(2), and 0.015(1) Å]. A C(5)−W−C(1)−O(1) torsion angle of 35.9(5)° is similar to that in **1**, and describes how the benzoyl ligand is rotated on the $W(CO)_4$ coordination plane. Distortion of the $W(CO)_4$ coordination plane from planarity, due to bonding of the benzoyl ligand, is also more than in **1**, and is described by deviations from planarity from the least-squares plane through W, C(2), C(4), C(5), and C(6) of −0.013(2), −0.057(3), −0.054(3), −0.063(3), and −0.061(3) Å, respectively. Coordination of the Li^+ ion to the six ether oxygen atoms of the two diglyme molecules in **2** is best described as a distorted, yet symmetrical, octa-

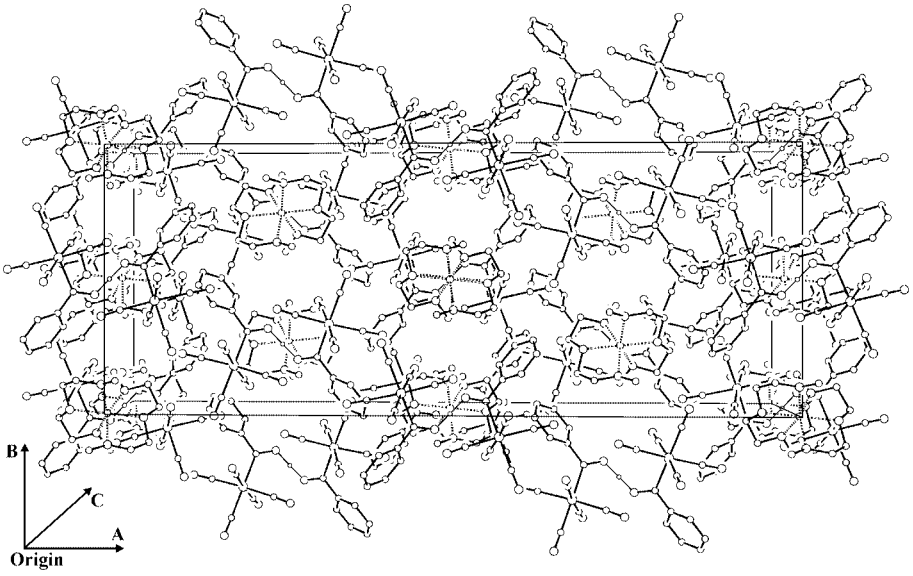

Figure 4. Packing diagram of **2**, viewed along the *c* axis of the unit cell, showing the packing arrangement of the dimeric H^+-bridged units in the crystal (all H atoms, except the bridging proton, have been omitted for clarity)

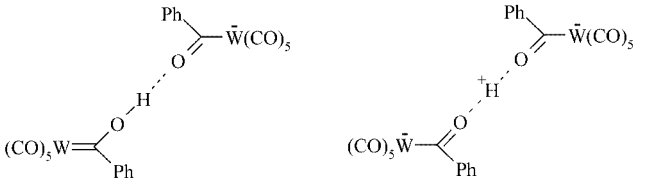
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hedron with O(22) and its symmetry equivalent, O(22)′ occupying the axial positions. The Li−O separations in this arrangement are normal.[21]

In the crystal, **2** packs in the unusual orthorhombic and non-centrosymmetric face-centred space group, *Fdd*2. A view along the *c* axis of the unit cell (Figure 4) shows how eight hydrogen-bonded molecules (16 asymmetric units) pack in the unit cell with the bridging protons and Li^+ ions situated on the eight twofold rotation axes parallel to the *c* axis in this space group. No other significant intermolecular interactions were observed for **2**.

The crystal structures of hydroxycarbene complexes exhibit characteristic hydrogen bonding interactions involving the hydroxyl hydrogen atom. Of the 20 reported structures in the Cambridge Crystallographic Database[22] that can formally be regarded as hydroxycarbene complexes, 17 exhibit intramolecular hydrogen bonds [10c,23] while the remaining three exhibit intermolecular hydrogen bonds (two with $CF_3SO_3^-$ ions and one with an acetonitrile solvent molecule).[10a,10b,24] Consequently, the OH hydrogen atoms in hydroxycarbene complexes, without consideration of their spectroscopic or thermodynamic characteristics, are weakly linked to what is a pseudo metallo-acyl oxygen atom, and require further stabilisation through hydrogen bonding interactions. This interpretation is supported by the significant double bond character of the C(carb)−O bond in hydroxycarbene complexes (average C−O separation = 1.290 Å). The only neutron diffraction study of a hydroxycarbene complex, furthermore, reports a long O−H separation [1.142 Å].[10c] Hydroxycarbene complexes would therefore perhaps be better described as ion-paired [metallo−acyl][H] complexes, exhibiting hydrogen bonding interactions between acyl-oxygen atoms and a second donor atom, rather than complexes with a formal oxygen−hydrogen bond.

This approach enables a more accurate description of the hydrogen bonding interactions found in **2** as no classical donor−acceptor definitions are applicable. The hydrogen-bonded structure in **2** can thus be described as an anionic homonuclear molecule−ion associate of two $Ph(O)CW(CO)_5^-$ ions interacting with a proton, thus forming the strong, charge-assisted hydrogen-bonded complex found in the crystal (Scheme 2). Similar centred O···H···O hydrogen bonds have been described as quasi-covalent.[4d] Comparable μ_2-hydrogen-bonded structures have been reported for anionic organometallic cyanide complexes $[(CO)_5Cr\{C{\equiv}N{\cdots}H{\cdots}N{\equiv}C\}Cr(CO)_5]^-$ and



Classical donor-acceptor H-bond model of **2**

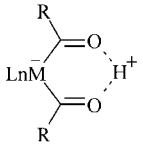
Scheme 2

$[(CO)_5Cr\{C{\equiv}N{\cdots}H{\cdots}N{\equiv}C\}FeCp(dppe)]$ [18] as well as for several carboxylate-functionalised sandwich compounds,[2,3] but not for complexes with metallo-acyl ligands.

Furthermore, of the 17 crystal structures of hydroxycarbene complexes that exhibit intramolecular hydrogen bonds, all but three [23j,23k,23l] contain two metallo-acyl moieties on a single metal atom involved in the hydrogen bonding interaction. This arrangement, forming six-membered metallacyclic rings (Scheme 3), is thus particularly favoured.



Scheme 3

The hydrogen bonding arrangement found in the crystal structure of **2** is similar to those described above (between two metallo-acyl groups), except that the metallo-acyl moieties involved in the hydrogen bonding interaction are on separate metal centres and, therefore, form a pseudo-linear hydrogen bonding arrangement. The structure of **2**, although novel, is thus not completely unexpected. Moreover, the structural characteristics of anionic metal−acyl complexes exhibited in the current structures, together with their general physical properties (e.g. stability, water solubility), firmly places them in the realm of suitable candidates for building blocks in organometallic crystal engineering. The selective introduction of a strong, charge-assisted hydrogen bonding interaction by selective Li^+ ion replacement in complex **2** may, furthermore, be a valuable tool to crystal engineers.

The infrared (IR) spectra of **1** and **2** were recorded as KBr pellets. The $\tilde{\nu}$(CO) absorption peaks for the CO ligands in both complexes exhibit the typical pattern of $A_1^{(1)}$, $A_1^{(2)}$, B_1, and E vibrational modes for molecules of the type $[M(CO)_5L]$ and are practically identical. The only clear deduction from the CO ligand stretching frequencies of **1** and **2** is that the metal atoms in these compounds are electron rich relative to other reported $[W(CO)_5L]$ complexes.[25] Comparison of the acyl C=O stretching frequencies [1517 cm^{-1} (**1**) and 1510 cm^{-1} (**2**)] is more fruitful. The 7 cm^{-1} lower C=O stretching frequency in **2** indicates that this bond is slightly more reduced in **2**, suggesting better interaction of the metallo-acyl anions with the proton in **2** than with the Li^+ ion in **1**, and corresponds to the results described by the crystal structures. The $\tilde{\nu}$(OH) frequency in **2** could, unfortunately, not be assigned reliably.

The IR spectrum of **1** was measured in CH_2Cl_2 solution. Dissolution of **1** causes a large change in the stretching frequency of the acyl vibrational mode (89 cm^{-1} "blue shift"). The $A_1^{(2)}$ vibration, assigned to the stretching frequency of the CO ligand trans to the metallo-acyl moiety, is unfortunately barely observable as a narrow shoulder on the intense E absorption peak in the solution IR spectrum of **1**, but is nevertheless shifted to higher energy (≈ 10−15 cm^{-1}).

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

These shifts strongly suggest that the clear interactions in the solid state of the Li^+ ions with the metallo acyl group, as well as with the CO ligand *trans* to the metallo acyl bond on a neighbouring anion, do not persist in dichloromethane solution. No interaction with Li^+ ions translates to less loss of electrons from the oxygen atoms in the groups that interact with the cation in the solid state and translates to stronger C≡O and C=O bonds in these groups.

The solution IR spectrum of **2** (CH_2Cl_2) is dominated by an extremely broad, intense and unresolved absorption band at ca. 1900 cm^{-1}. This is probably because, upon dissolution, **2** reverts, according to NMR spectroscopic data (discussed below), to a 50/50 mixture of Li[Ph(O)CW(CO)$_5$] and [Ph(OH)C=W(CO)$_5$] from whence it crystallised, and thus gives an IR spectrum for both compounds with broad, overlapping absorption bands. The ν(CO) for the acyl groups in this mixture as well as the ν(OH) absorption could, unfortunately, not be assigned reliably.

The ^1H and $^{13}C\{^1H\}$ NMR spectra of **1** are identical to the reported values,[12b] whereas the spectra of **2** contain partly overlapping resonances of both **1** and [Ph(OH)C=W(CO)$_5$]. For both compounds additional NMR resonances, representing 1 mol equiv. of diglyme, were also present. These resonances appear as a singlet at δ = 3.42 (6 H, OCH_3) and two triplet signals at δ = 3.77 and 3.66 ppm ($^3J_{H,H} \approx 5$ Hz, 4 H each), representing two sets of unique CH_2 groups in the diglyme molecule. In the $^{13}C\{^1H\}$ NMR spectra of **1** and **2** the resonances corresponding to diglyme appear at δ = 59.0, 70.7, and 72.2.

Experimental Section

General: All reactions and manipulations were carried out under a dry argon atmosphere using standard Schlenk and vacuum-line techniques. Et_2O was dried and purified by conventional methods and was freshly distilled under argon shortly before use. Melting points were measured with a Büchi 535 melting point determination apparatus and are uncorrected. NMR spectra were recorded on a Varian INOVA 600 spectrometer (^1H, 600 MHz; $^{13}C\{^1H\}$, 151 MHz; $^{31}P\{^1H\}$, 243 MHz) at 25 °C. NMR chemical shifts are reported in ppm relative to the ^1H and ^{13}C residue of the deuterated solvents. IR spectra were recorded on a Perkin−Elmer 1600 Series FTIR spectrometer. Elemental analyses were performed on a Fisons CHNS elemental analyser 1108. PhLi was prepared and standardised according to standard procedures. Diglyme and $W(CO)_6$ were purchased from Aldrich and used without purification.

Preparation of 1 and 2: PhLi (1.2 equiv., 0.6 mL, 1.6 M solution in Et_2O) was added dropwise to a suspension of $W(CO)_6$ (282 mg, 0.8 mmol) suspended in dry, degassed Et_2O (30 mL) over 30 min, and the resultant red reaction mixture was stirred for a further 1 h. Diglyme (1 equiv., 110 mg) was then added. To prepare crystals of **1** the volume of this mixture was reduced in vacuo to ca. 15 mL, carefully layered with an equal amount of *n*-pentane and cooled to −20 °C. $C_{18}H_{19}LiO_9W$ (570.13): calcd. found C 37.8, H 3.40, O 25.4. m.p. 76 °C. IR (KBr): ν(CO) = 2049 cm^{-1} (m, $A_1^{(1)}$), 1968 cm^{-1} (w, B_1), 1895 cm^{-1} (vs, E), 1885 cm^{-1} (m, sh, $A_1^{(2)}$), 1517 cm^{-1} (m, C=O). IR (CH_2Cl_2): ν(CO) = 2050 cm^{-1} (m, $A_1^{(1)}$), 1975 cm^{-1} (w, B_1), 1908 cm^{-1} (vs, E), ≈ 1895−1900 cm^{-1} (m, sh, $A_1^{(2)}$), 1606 cm^{-1} (m, C=O).

Crystals of **2** were prepared by filtering the red reaction mixture through acidic silica gel (10−15 cm, Ø 4 cm), using additional Et_2O to elute the red complex from the column. The volume of the elute was then reduced in vacuo to ≈ 15 mL, which was then carefully layered with an equal amount of *n*-pentane and cooled to −20 °C. $C_{36}H_{39}LiO_{18}W_2$ (1134.32): calcd. C 38.1, H 3.47, O 25.4; found C 38.0, H 3.40, O 25.5. m.p. 68 °C (decomp.). IR (KBr): ν(CO) 2049 cm^{-1} (m, $A_1^{(1)}$), 1968 cm^{-1} (w, B_1), 1904 cm^{-1} (vs, E), 1885 cm^{-1} (m, sh, $A_1^{(2)}$), 1510 cm^{-1} (m, C=O).

X-ray Crystallographic Analysis of 1 and 2: Suitable crystals of **1** and **2** were selected and mounted on glass fibres. Low temperature (173 K) diffraction data were collected for both crystals on a Nonius−Kappa CCD diffractometer,[26] equipped with an Oxford Cryostream cooling apparatus, using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). A summary of the diffraction data is given in Table 1. Data sets for both crystals were scaled, reduced and corrected for Lorenz and polarisation effects using DENZO-SMN.[27] Both structures were solved by the interpretation of Patterson syntheses (SHELX-97),[28] which produced the positions of the metal atoms. The structures were completed by full-matrix least-squares calculations (SHELXL-97)[28] on F^2 and anisotropic thermal motion was allowed for all the non-hydrogen atoms during the final cycles of refinement. The space group in **2** is non-centrosymmetric; the Flack test[29] suggested the presence of a racemic twin and subsequent refinement revealed a racemic twin ratio of 0.886:0.114. Although the positions of most of the hydrogen atoms in **1** and **2** could be located from the difference Fourier map, all the hydrogen atoms situated on the phenyl rings were placed in idealised positions with their thermal parameters fixed at 1.2 times the equivalent isotropic displacement parameters of their parent atoms. The position of the bridging hydrogen atom in **2** could be reliably located from the difference Fourier map and refined isotropically. CCDC-211587 (**1**) and -211588 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank Dr. John Bacsa for the collection of the X-ray data.

Keywords: Molybdenum / N ligands / Mesoporous materials / Supported catalysts / Epoxidations

The dioxomolybdenum(VI) complex $[MoO_2Cl_2(L\text{-}L)]$, containing the bidentate 1,4-diazabutadiene ligand RN=C(Ph)–C(Ph)=NR [R = $(CH_2)_3Si(OEt)_3$], was immobilised in the ordered mesoporous silica MCM-41 by carrying out a grafting reaction in dichloromethane. The grafted material (3.3 wt.-% Mo) was tested as a catalyst for the epoxidation of cyclooctene with *tert*-butyl hydroperoxide (TBHP) at 55 °C. Selectivity to the epoxide was very high and the observed kinetic profile was similar to that of the complex $[MoO_2Cl_2(L\text{-}L)]$ in the homogeneous phase. On recycling several times, some activity was lost from the first to second runs, but thereafter stabilised. Tethered complexes of this type were also prepared by a stepwise approach. The mesoporous silicas MCM-41 and MCM-48 were first treated with a toluene solution of the ligand L-L under reflux. Before isolating the grafted materials, the silylating agent Me_3SiCl was added to remove the residual Si–OH groups on the surface of the mesoporous materials. Oxomolybdenum species were subsequently introduced into the ligand-silicas by pore volume impregnation of a solution of the complex $[MoO_2Cl_2(THF)_2]$ in CH_2Cl_2 at room temperature. The modified materials have been characterised by powder X-ray diffraction, N_2 adsorption, and solid-state MAS NMR (^{13}C, ^{29}Si). Despite having lower metal loadings (1 wt.-% Mo), the materials exhibited similar catalytic activities for the epoxidation of cyclooctene to that of the modified MCM-41 with 3.3 wt.-% of Mo. However, selectivities to the epoxide were lower. The MCM supported catalysts have also been tested for the epoxidation of cyclododecene and α-pinene with TBHP.

Introduction

High-valent d^0 transition metal complexes, such as Mo^{VI}, V^V, and Ti^{IV}, are effective catalysts for the selective epoxidation of olefins by alkyl hydroperoxides (ROOH).[1] In particular, Mo^{VI} complexes of the type $[MoO(O_2)_2(L^1)(L^2)]$ and $[MoO_2X_2(L^1)(L^2)]$ (X = Cl, Br, CH_3), with different combinations of base ligands L^1 and L^2, have been experimentally characterised and tested as catalysts for epoxidation reactions, usually employing *tert*-butyl hydroperoxide (TBHP) as the mono-oxygen source.[2,3] It is ever more accepted that alkyl peroxides activate these complexes by an intermediate η^2-coordination of the peroxidic agent to the Lewis acidic metal centre.[4] Important properties, such as the solubility of the complex and the Lewis acidity of the metal centre, can be fine-tuned by variation of either X or L.

Despite the good results obtained for oxomolybdenum(VI) complexes in homogeneous catalysis, increasing attention is being paid to heterogeneous catalysts since these can be easily separated from a reaction mixture and recycled, which is of significant industrial interest. The immobilisation of transition metal catalysts, for example on an inorganic support,[5] may also eliminate other problems associated with homogeneous catalysis, such as dimerisation of the active complex or auto-oxidation. One approach is to use support materials modified with Lewis base ligands. Sherrington and co-workers reported that polymer-supported molybdenum(VI) complexes are active and recyclable catalysts for olefin epoxidation with TBHP.[6] For inorganic supports, a general strategy is to use functional alkoxy silanes. Corma et al. have prepared dioxomolybdenum(VI) complexes with chiral ligands derived from (2*S*,4*R*)-4-hydroxyproline.[7] The complexes bearing a $Si(OEt)_3$ group were heterogenised to a modified USY-zeolite by covalent bonding.

Micelle-templated silicas as catalyst supports for transition metal catalysts have been extensively studied over the last decade,[5] and are often more effective than amorphous silica.[8] This is probably due to the unique combination of a high surface area, allowing a good dispersion of active sites, with an ordered mesoporous structure, allowing selective catalysis in a constrained environment. Jia and Thiel modified the ordered mesoporous silica MCM-41 with a bidentate pyrazolylpyridine ligand and prepared a coval-

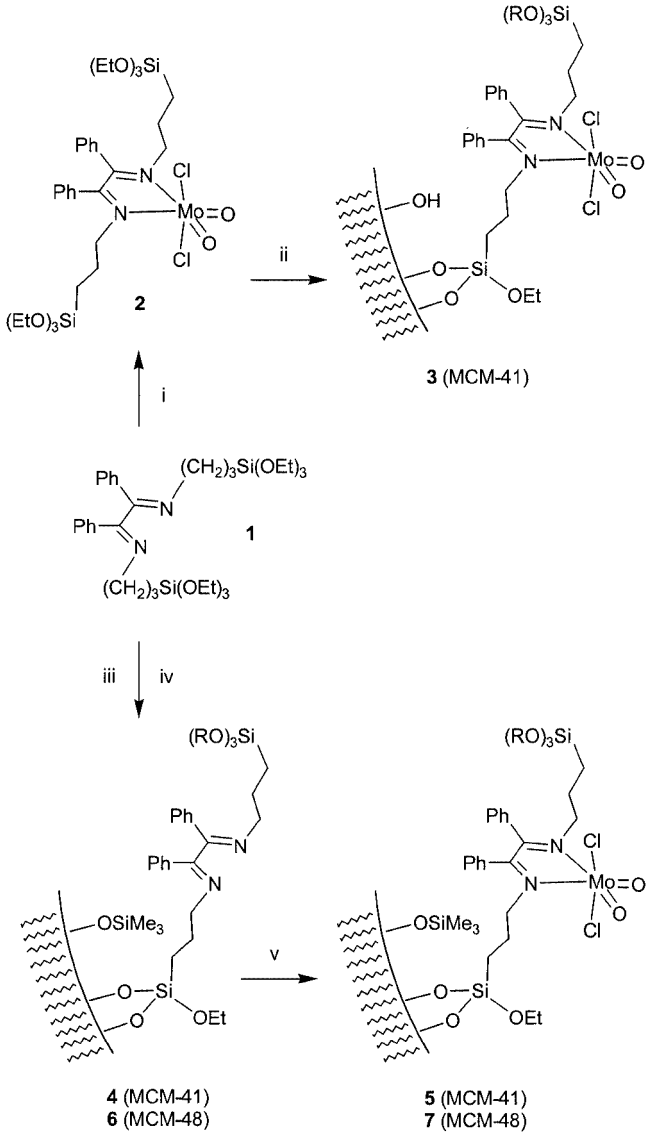
ently anchored complex of the type $[MoO(O_2)_2(L\text{-}L)]$.[9] The hybrid system was highly active and truly heterogeneous for liquid-phase epoxidation of cyclooctene with TBHP as the oxygen source. The molybdenum(VI) complexes $[MoO_2Cl_2(L^1)(L^2)]$ have also been immobilised in MCM-41 derivatised with monodentate nitrile and bidentate bipyridyl ligands.[10] Unfortunately, they are unstable towards molybdenum leaching, which accounts for their nearly complete loss of activity in a second reaction cycle. The high molybdenum loadings resulted in weakly adsorbed Mo dimeric species that were easily extracted during the oxidative transformations.

In the present work, we have attempted to prepare more stable heterogeneous olefin epoxidation catalysts by immobilisation of dioxomolybdenum(VI) complexes in the ordered mesoporous silicas MCM-41 and MCM-48 functionalised with a bidentate 1,4-diazabutadiene ligand.

Results and Discussion

The supported catalysts were prepared from MCM-41 and MCM-48 materials (Scheme 1). First, the triethoxysilyl ligand RN=C(Ph)−C(Ph)=NR (**1**) [R = $(CH_2)_3Si(OEt)_3$] was prepared by the reaction of benzil $[C_6H_5(CO)(CO)C_6H_5]$ with two equivalents of (3-aminopropyl)triethoxysilane. Treatment of the solvent adduct $[MoO_2Cl_2(THF)_2]$ with one equivalent of the ligand **1** gave the complex $[MoO_2Cl_2(L\text{-}L)]$ (**2**) in good yield. Such complexes, with bidentate substituted 1,4-diazabutadiene ligands L-L (RN=CR′−CR′=NR), are active, stable homogeneous catalysts for the epoxidation of olefins using TBHP.[3b] Treatment of MCM-41 with a solution of complex **2** in dichloromethane gave a modified material **3** containing approximately 3.3 wt.-% Mo (0.34 mmol·g^{-1}). The solid-state ^{13}C CP MAS NMR spectrum of **3** was similar to that of **2** except for less intense peaks corresponding to the OEt groups (δ = 58.4 and 18.3), due to the grafting on MCM-41. Tethered complexes of this type were also prepared by an alternative stepwise approach. MCM-41 and MCM-48 were first treated with a toluene solution of **1** under reflux. Before isolating the grafted materials, the silylating agent Me_3SiCl was added to remove the residual Si−OH groups on the surface of the mesoporous materials, which could be unfavourable for the catalytic reaction.[9] Trimethylsilylation may also render the surface more hydrophobic and improve stability against moisture and mechanical compression. Oxomolybdenum species were subsequently introduced into the ligand-silicas **4** (MCM-41) and **6** (MCM-48) by pore volume impregnation of a solution of the dioxomolybdenum(VI) complex $[MoO_2Cl_2(THF)_2]$ in CH_2Cl_2 at room temperature. Elemental analysis indicated metal loadings of 1.0 wt.-% (0.10 mmol·g^{-1}) for **5** (MCM-41) and 1.4 wt.-% (0.14 mmol·g^{-1}) for **7** (MCM-48).

The solid-state ^{13}C CP MAS NMR spectra of the ligand-silicas **4** and **6**, and the derivatised materials **5** and **7**, were similar to those of the grafted material **3**, confirming the presence of surface-bound 1,4-diazabutadiene groups. An



Scheme 1. Reagents: i, THF, $[MoO_2Cl_2(THF)_2]$; ii, CH_2Cl_2, MCM-41; iii, toluene, MCM-41 or MCM-48; iv, Me_3SiCl; v, CH_2Cl_2, $[MoO_2Cl_2(THF)_2]$

additional peak at about δ = −0.5 was attributed to $(-O)_3Si-O-SiMe_3$ species. The solid-state ^{29}Si MAS NMR spectra of the grafted materials **3**−**7** provide direct evidence for the incorporation of the covalently anchored organic system. Figure 1 shows the ^{29}Si MAS and CP MAS NMR spectra for pristine calcined MCM-41, the ligand-silica **4**, and the derivatised material **5**. Similar results were obtained for the corresponding MCM-48 materials. Unmodified MCM-41 displays two broad convoluted resonances in the ^{29}Si CP MAS NMR spectrum at δ = −110.7 and −100.9, assigned to Q^4 and Q^3 species of the silica framework, respectively [$Q^n = Si(OSi)_n(OH)_{4-n}$]. A weak shoulder is also observed at δ = −91.0 for the Q^2 species. The Q^3 sites are associated with the single silanols Si−OH (including hydrogen-bonded silanols), and the Q^2 sites correspond to the geminal silanols. Grafting of the triethoxysilane ligand **1** and Me_3SiCl into MCM-41 reduces

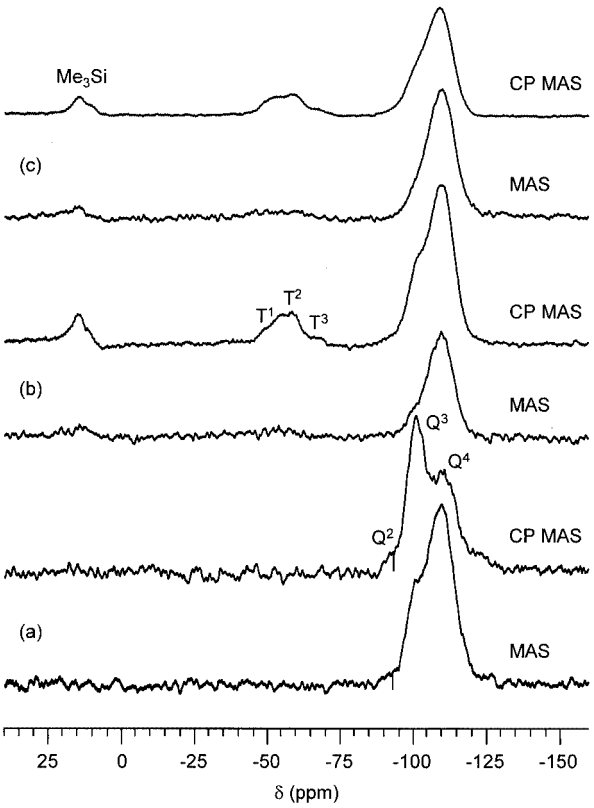

Figure 1. ^{29}Si MAS and CP MAS NMR spectra of (a) MCM-41, (b) MCM-41-L/Me_3SiCl (**4**), and (c) MCM-41-L/Me_3SiCl/MoO_2Cl_2 (**5**)

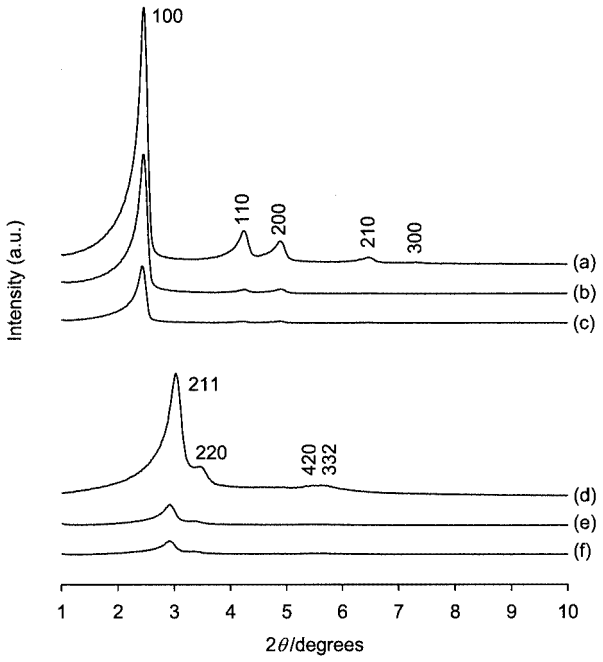

Figure 2. Powder XRD patterns of (a) MCM-41, (b) MCM-41-L/Me_3SiCl (**4**), (c) MCM-41-L/Me_3SiCl/MoO_2Cl_2 (**5**), (d) MCM-48, (e) MCM-48-L/Me_3SiCl (**6**), and (f) MCM-48-L/Me_3SiCl/MoO_2Cl_2 (**7**)

the Q^3 and Q^2 resonances and, concomitantly, increases the Q^4 resonance. This is consistent with esterification of the isolated silanol groups by nucleophilic substitution at the silicon atom in the organic compounds. The ^{29}Si CP MAS NMR spectrum of **4** reveals unchanged Q^3 silicon atoms. These might be hydrogen-bonded surface silanols, $(SiO)_3Si-OH-OH-Si(SiO)_3$, which are unreactive to silylating agents.[11] The ^{29}Si CP MAS NMR spectra of **4** and **6** also display two signals at $\delta = -50.0$ and -58.5, assigned to T^1 and T^2 organosilica species, respectively [$T^m = R.Si(OSi)_m(OEt)_{3-m}$]. A weak, broad signal at $\delta = -67.5$ is assigned to a T^3 environment, and a sharp peak at about $\delta = 14.0$ to the silicon nuclei of the Me_3Si groups. Reaction of the ligand-silicas **4** and **6** with the complex $[MoO_2Cl_2(THF)_2]$ does not measurably change the ^{29}Si MAS and CP MAS NMR spectra (Figure 1).

The powder XRD patterns of the pristine calcined MCM-41 and MCM-48 starting materials agree with reported patterns, indicating well-ordered materials (Figure 2).[12,13] Several distinct Bragg peaks are observed in the range $2\theta = 2-8°$, which can be indexed to different *hkl* reflections. MCM-41 is indexed on a hexagonal unit cell (using the strongest reflection, d_{100}, $a = 2d_{100}/\sqrt{3} = 41.4$ Å) and MCM-48 on a cubic unit cell (using the strongest reflection, d_{211}, $a = d_{211}\sqrt{6} = 71.5$ Å). Upon grafting with the triethoxysilyl ligand **1** and Me_3SiCl, several distinct Bragg peaks are still observed, indicating retention of the long-range hexagonal and cubic symmetries (Figure 2). A significant attenuation of the XRD peak intensities is not interpreted as a loss of order, but to a likely reduction in the X-ray scattering contrast between the silica walls and pore-filling material.[14] Reaction of the ligand-silicas **4** and **6** with the complex $[MoO_2Cl_2(THF)_2]$ does not change the powder XRD patterns significantly. There is a further slight reduction of peak intensities, for the reason outlined above. A similar result was obtained after reaction of the complex $[MoO_2Cl_2(THF)_2]$ with MCM-41 functionalised with bipyridyl groups.[10b]

The pristine MCM solids show reversible type IV N_2 adsorption−desorption isotherms, typical of mesoporous solids (pore width between 2 and 50 nm, according to IUPAC).[15] The step corresponding to capillary condensation in the primary mesopores appears in the relative pressure ranges 0.3−0.4 and 0.15−0.27 for unmodified MCM-41 and MCM-48, respectively, and is less pronounced for the latter (Figure 3). The specific surface area and total pore volume of the pristine MCM materials are greater than 940 $m^2 \cdot g^{-1}$ and 0.7 $cm^3 \cdot g^{-1}$, respectively (Table 1). The isotherms of the functionalised MCM samples show a lower N_2 uptake, pointing to a decrease in the specific surface area and pore volume. This effect is more pronounced for the trimethylsilylated samples **5** and **7**, for which S_{BET} decreased more than 33% and V_p decreased more than 56%. The height of the capillary condensation step and the p/p_0 coordinate of the inflection point decreases significantly, indicating changes in pore size distribution due to grafting of the internal silica surface with the molybdenum species and, for **5** and **7**, with Me_3SiCl.[10b,16,17] This is confirmed by comparing the pore size distributions (PSD) of the pristine and modified MCM materials (Figure 3). Upon surface

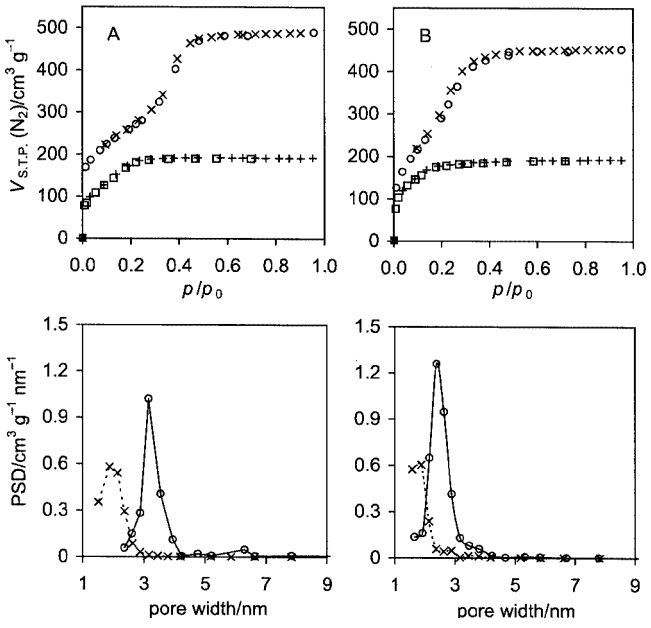

Figure 3. Nitrogen isotherms at 77 K of pristine MCM-41 (A) and MCM-48 (B) [(O) adsorption; (×) desorption], and surface-grafted **5** (A) and **7** (B) [(□) adsorption; (+) desorption]. Pore size distribution curves are also shown for the pristine (—) and surface-grafted materials (- - -)

grafting, the PSDs shift towards smaller pore sizes and the peaks become lower, indicating decreased uniformity of the pores.

The catalytic performance of complex **2** was studied for the epoxidation of cyclooctene with TBHP at 55 °C (1% molar ratio of complex/cyclooctene). After one hour the turnover frequency (TOF) was 18 mmol g^{-1}_{cat} h^{-1} and after 24 h the selectivity to cyclooctene oxide was 96% at 56% conversion (Table 2). The activity of **2** is similar to that reported under identical reaction conditions for other (dichloro)dioxomolybdenum(VI) catalysts bearing 1,4-diazabutadiene ligands without aromatic substituents.[3b] Despite using excess of oxidant with respect to the substrate, cyclooctene conversion at 24 h is still far from quantitative. In these catalysts the molybdenum centre acts as a Lewis acid, thereby decreasing the electron density in the coordinated TBHP molecule and promoting nucleophilic attack of the olefin on the O−O bond.[4b] The formation of *tert*-butyl alcohol during epoxidation may contribute to the decay in the reaction rate since it may act as a competitive inhibitor for the attack of TBHP at the Mo centre.[4b,10a,18] Conversely, although the complex bears relatively stable chelating nitrogen ligands,[3b,3c] the pendant triethoxysilyl groups may furnish less reactive dimers/oligomers, thus accounting for catalyst deactivation during epoxidation.

As described above, complex **2** was grafted onto the surface of MCM-41 to give the supported catalyst **3** at a metal loading of approximately 3.3 wt.-% Mo. The catalytic results obtained in the presence of **3** are similar to those obtained in homogeneous phase for complex **2** (Table 2, Figure 4). The corresponding kinetic curves are alike, suggesting a similar reaction mechanism. The reaction rate decreases after 7 h reaching a maximum conversion of 65% after 24 h (Table 2). Such retardation may result from the competitive reaction of the active Mo complex with *tert*-butyl alcohol, as in the homogeneous phase, and/or catalyst deactivation. The stability of catalyst **3** was studied by reusing the recovered solid in three consecutive reaction cycles. Before each reuse the solid was separated from the reaction solution, thoroughly washed with dichloromethane and dried at 60 °C. The catalytic activity decreased from the first to the second run, but afterwards tended to remain constant (Table 2, Figure 4). Probably, weakly adsorbed molybdenum complexes that were not efficiently solvent extracted after the grafting reaction were leached to the reaction solution. The catalyst stability was further investigated by reusing **3** in a fourth reaction cycle. After 2 h, the catalyst was separated at the reaction temperature and the solution was stirred for another 4 h. Cyclooctene conversion remained practically unchanged and molybdenum was not detected in the reaction solution by ICP-AES. Furthermore, the FTIR spectra of the solids recorded before and after catalysis showed no major changes. These results suggest that catalyst **3** is fairly stable and that catalysis is, in principle, heterogeneous.

The modified materials **5** and **7** were also tested as catalysts for the epoxidation of cyclooctene with TBHP at 55 °C. Considering the initial activities, the epoxidation of cyclooctene in the presence of **5** is slightly faster than for **7** (TOF = 6.7 and 5.9 mmol·g^{-1}_{cat}·h^{-1}, respectively), despite the lower molybdenum content of the former. However, at 24 h, both catalysts give approximately 63% conversion (Table 2). Overall, the kinetic profiles for **5** and **7** are similar (Figure 5). The difference in initial activities may be due, in part, to different internal diffusion rates during the initial unsteady operation as a result of the different channel structures of the mesoporous hosts. MCM-41 consists of an

hexagonal arrangement of cylindrical pores, whereas MCM-48 possesses a three-dimensional gyroid-type pore structure. Despite the lower Mo loadings of catalysts **5** and **7** in comparison to **3**, they are more active initially (Table 2). Trimethylsilyation of MCM-41 and MCM-48 makes the surface more hydrophobic, thereby enhancing the adsorption of the olefin, and concomitantly reducing the adsorption of polar *tert*-butyl alcohol, making the Mo centres more available for the attack of TBHP. For catalysts **5** and **7** the selectivity to cyclooctene oxide is lower than for **3** and the complex **2**. This is unexpected since the adsorption of the polar epoxide should be less favourable on a more hydrophobic surface. Probably, trace amounts of HCl, which remained inside the MCM materials after silylation, are responsible for the ring opening reaction. In fact, selectivity to 1,2-cyclooctanediol decreases in recycling runs (Table 2). The stability of **5** and **7** was studied in a similar fashion to that of **3**. The Mo loading after three reaction cycles is at least 99% of the original value, as ascertained by ICP-AES. The main loss of catalytic activity is observed from the first to the second run, but the activity then tends to remain constant, similar to that observed for **3** (Table 2, Figure 4). The leaching of some weakly adsorbed molybdenum complexes present in the fresh catalyst may account for the initial loss of activity.

The MCM catalysts **3**, **5**, and **7** were also tested for the epoxidation of cyclododecene and α-pinene with TBHP at 55 °C (Figure 6). For each catalyst, olefin conversion at 24 h decreases in the order: cyclooctene (Cy8=) > cyclododecene (Cy12=) > α-pinene. Cyclododecene oxidation yields exclusively the corresponding epoxide (Cy12 oxide). A higher conversion is achieved with **3** (60% at 24 h) than with **5** and **7**, which may be due to the faster diffusion of the bulky substrate molecules inside the wider pores of **3**. For α-pinene oxidation, less than 2.5% α-pinene oxide is yielded at 24 h. The main reaction product is campholenic aldehyde (< 6% yield), which is an intermediate for sandalwood fragrance santalol and may be formed by the Lewis acid catalysed rearrangement of α-pinene oxide.[18,19]

Conclusions

The prepared supported catalysts reported here are active for the epoxidation of olefins using TBHP as the oxidant.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

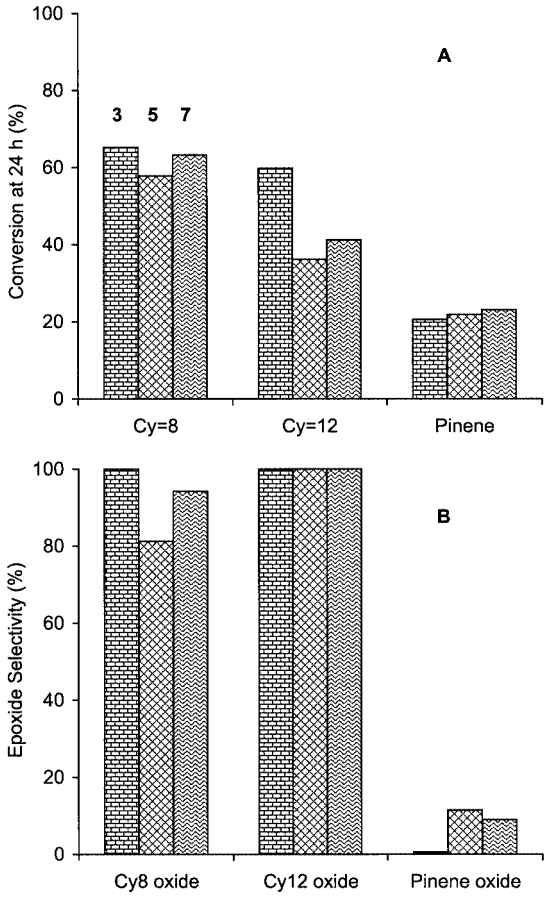

Figure 6. Conversion of cyclooctene (Cy8=), cyclododecene (Cy12=) and α-pinene (A) and selectivity towards the epoxide (B) observed for **3** (bricks), **5** (diamonds) or **7** (waves), at 24 h

Some activity is lost from the first to second runs, but thereafter the solids can be recycled without significant loss of activity. Tests indicate that the recycled solids operate as true heterogeneous catalysts. Previously, 2,2′-bipyridine was covalently grafted to MCM-41 and the resulting MoO_2Cl_2 supported material used as an epoxidation catalyst.[10b] However, most of the observed activity was due to leached molybdenum species in solution. Better results have been obtained here by using the 1,4-diazabutadiene ligand bearing triethoxysilyl groups. Future studies will centre on the use of this chelating ligand to immobilise other transition metal homogeneous catalysts.

Experimental Section

Material and Methods: Starting materials were obtained from commercial sources and used as received. All preparations and manipulations were carried out using standard Schlenk techniques under nitrogen. Solvents were dried by standard procedures (THF, hexane, and diethyl ether with Na/benzophenone ketyl; CH_2Cl_2 with CaH_2), distilled under nitrogen and kept over 4 Å molecular sieves. The solvent adduct $[MoO_2Cl_2(THF)_2]$ was prepared as described previously.[20]

Microanalyses were performed at the University of Aveiro. Powder XRD data were collected on a Phillips X'pert diffractometer using Cu-K_α radiation filtered by Ni. Nitrogen adsorption−desorption isotherms were measured at 77 K, using a gravimetric adsorption apparatus equipped with a CI electronic MK2−M5 microbalance and an Edwards Barocel pressure sensor. Before the measurements the MCM silicas were outgassed at 450 °C and the modified materials at 140 °C (to minimise destruction of the functionalities) and maintained at that temperature overnight to a residual pressure of ca. 10^{-4} mbar. The texture parameters, BET specific surface area (S_{BET}) and specific total pore volume (micropore plus mesopore, V_P), were estimated from the adsorption isotherm data. The pore size distribution curves (PSD − differential volume adsorbed with respect to the differential pore size per unit mass vs. pore width) were computed from the desorption branch of the experimental isotherms, using a method based on the area of the pore walls.[15,21] Assuming open cylindrical pores with radius r_p and zero contact angle and correcting for the thickness of the layer already adsorbed, r_p can be calculated by summing the Kelvin radius and the statistical average thickness (t, calculated using the Halsey equation) of the adsorbed layer.

IR spectra in transmission mode were measured with a Mattson Mod 7000 FTIR spectrometer using KBr pellets. Raman spectra were recorded on a Bruker RFS 100/S FT Raman spectrometer using a 1064 nm excitation of the Nd/YAG laser. ^1H and ^{13}C solution NMR spectra were obtained with a Bruker AMX-300 spectrometer. ^{29}Si and ^{13}C solid-state NMR spectra were recorded at 79.49 and 100.62 MHz, respectively, on a (9.4 T) Bruker Avance 400P spectrometer. ^{29}Si MAS NMR spectra were recorded with 40° pulses, spinning rates 5.0−5.5 kHz, and 60 s recycle delays. ^{29}Si CP MAS NMR spectra were recorded with 5.5 μs ^1H 90° pulses, 8 ms contact time, a spinning rate of 4.5 kHz, and 4 s recycle delays. ^{13}C CP MAS NMR spectra were recorded with a 4.5 μs ^1H 90° pulse, 2 ms contact time, a spinning rate of 8 kHz, and 4 s recycle delays. Chemical shifts are quoted in ppm from TMS. ^{13}C spectra were also recorded in the solid state at 125.76 MHz on a Bruker Avance 500 spectrometer.

MCM-41 and MCM-48: Purely siliceous MCM-41 was synthesised as described previously using $[(C_{14}H_{29})N(CH_3)_3]Br$ ($C_{14}TMABr$) as the templating agent.[10b] MCM-48 was crystallised from a gel with the molar composition SiO_2:0.26Na_2O:60H_2O:0.8$C_{16}TMABr$. Specifically, a solution of tetraethyl orthosilicate (17.36 g, 0.083 mol) in H_2O (30 mL) was added slowly to a vigorously stirred solution of $[(C_{16}H_{33})N(CH_3)_3]Br$ (24.05 g, 0.066 mol) in H_2O (40 mL). A solution of NaOH (1.76 g, 0.044 mol) in water (20 mL) was then added and the resulting mixture was stirred for 30 min and then autoclaved at 110 °C for 2 days in Teflon-lined stainless steel reaction vessels. The solid product was recovered by filtration, washed with hot water and air-dried at 30 °C. Calcination at 540 °C for 6 h then removed the surfactant template. Before the grafting experiments with MCM-41 and MCM-48, physisorbed water was removed from the calcined materials by heating at 180 °C in vacuo (10^{-2} Pa) for 2 h.

Ph-DAB-$(CH_2)_3Si(OEt)_3$ (1): A solution of (3-aminopropyl)triethoxysilane (2.85 g, 12.9 mmol) in THF (10 mL) was added to a solution of benzil (1.35 g, 6.4 mmol) in THF, followed by 4 Å molecular sieves (1.6 mm pellets, 0.6 g) and a catalytic amount of $ZnCl_2$. After 12 h at 50 °C the solution was filtered , and the resultant residue rinsed with THF and the filtrate evaporated in vacuo to give the product as a pale yellow oil (3.98 g) in 84.7% yield. IR (KBr): $\tilde{\nu}$ = 3062 (m), 2973 (vs), 2926 (vs), 2885 (vs), 1674 (vs), 1626 (s), 1595 (s), 1579 (s), 1448 (s), 1390 (s), 1318 (m), 1294 (m), 1281 (m), 1220 (s), 1166 (vs), 1102 (vs), 1062 (vs), 957 (vs), 792 (s), 776 (s), 724 (m), 696 (s), 623 (m) cm^{-1}. ^1H NMR (300.13 MHz,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$CDCl_3$, 25 °C, TMS): δ = 0.60−0.68 (m, 4 H, $SiCH_2$), 1.15−1.24 (m, 18 H, OCH_2CH_3), 1.76−1.86 (m, 4 H, $CH_2CH_2CH_2$), 3.40−3.44 (t, 4 H, NCH_2), 3.73−3.84 (m, 12 H, OCH_2CH_3), 7.32−7.50 (m, 5 H, Ph), 7.57−7.75 (m, 3 H, Ph), 7.88−7.93 (m, 2 H, Ph) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, 25 °C, TMS): δ = 8.0 ($SiCH_2$), 18.3 (OCH_2CH_3), 24.3 ($CH_2CH_2CH_2$), 56.4 (CH_2N=C), 58.1 (OCH_2CH_3), 127.2, 128.6, 129.1 (Ph), 166.3 (CH_2N=*C*) ppm. ^{29}Si NMR (59.62 MHz, $CDCl_3$, 25 °C, TMS): δ = −52.90 ppm. $C_{32}H_{52}N_2O_6Si_2$ (616.99): calcd. C 62.30, H 8.50, N 4.54; found C 62.00, H 8.41, N 4.28.

MoO_2Cl_2[Ph-DAB-$(CH_2)_3Si(OEt)_3$] (2): A solution of $MoO_2Cl_2(THF)_2$ (0.25 g, 0.75 mmol) in THF (10 mL) was treated with 1 equivalent of the ligand **1** in THF (5 mL). The resulting turbid solution was stirred for a further 30 min at room temperature. The solvent was then evaporated, and the resultant solid product washed with hexane and dried in vacuo. Yield: 0.47 g, 76%. IR (KBr): $\tilde{\nu}$ = 2973 (s), 1681 (s), 1674 (vs), 1594 (s), 1491 (m), 1449 (s), 1306 (m), 1230 (m), 1077 (vs), 1047 (vs), 984 (s), 943 (vs), 915 (vs), 879 (s), 774 (m), 703 (m), 684 (m), 643 (m) cm^{-1}. ^{13}C CP MAS NMR: δ = 9.6 ($SiCH_2$), 18.3 (OCH_2CH_3), 21.7 ($CH_2CH_2CH_2$), 55.0 (CH_2N=C), 58.4 (OCH_2CH_3), 128.8 (Ph), 167.5 (CH_2N=*C*) ppm. ^{29}Si MAS NMR: δ = −54.4 ppm. $C_{32}H_{52}Cl_2MoN_2O_8Si_2$ (816.90): calcd. C 46.99, H 6.65, N 3.42; found C 46.56, H 6.29, N 3.38.

MCM-41/MoO_2Cl_2[Ph-DAB-$(CH_2)_3Si(OEt)_3$] (3): A solution of **2** (0.40 g, 0.49 mmol) in CH_2Cl_2 (10 mL) was added to a suspension of MCM-41 (1.0 g) in CH_2Cl_2 (15 mL) and the mixture stirred at room temperature for 24 h. The solution was then filtered and the so-obtained pale blue powder washed repeatedly with CH_2Cl_2 (4 × 20 mL), before drying in vacuo at room temperature for several hours. IR (KBr): $\tilde{\nu}$ = 1633 (m), 1596 (w), 1450 (m), 1384 (w), 1230 (sh), 1078 (vs), 954 (m), 914 (sh), 798 (m), 568 (m), 455 (s) cm^{-1}. ^{13}C CP MAS NMR: δ = 8.7, 15.6, 21.1, 53.2, 58.8, 128.7, 131.7, 136.6, 137.9 ppm. ^{29}Si MAS NMR: δ = −50.4, −56.2, −102.6 (Q^3), −108.0 (Q^4) ppm. Elemental analysis found C 8.50, N 0.49, H 0.90, Mo 3.3.

MCM-41-L/Me_3SiCl (4): A solution of the ligand **1** (0.66 g, 1.07 mmol) in toluene (5 mL) was added to a suspension of MCM-41 (1.0 g) in toluene (10 mL) and the mixture heated at 100 °C for 9 h. After cooling to ambient temperature, Me_3SiCl (5 mL) was added and the mixture stirred at room temperature for a further 24 h. The resultant solid was then filtered off and washed twice with acetone (2 × 20 mL), twice with CH_2Cl_2 (2 × 15 mL), and dried in vacuo at 100 °C for 3 h. Selected FT Raman: $\tilde{\nu}$ = 3069 (m), 2961 (m), 2904 (s), 1600 (s), 1552 (w), 1452 (m), 1415 (w), 1028 (w), 1001 (s), 617 (m) cm^{-1}. ^{13}C CP MAS NMR: δ = −0.5 (Me_3SiO−), 8.4 ($SiCH_2$), 16.4, 20.8, 24.9, 57.8, 127.6 (phenyl-C) ppm. ^{29}Si MAS NMR: δ = 14.5 (bd), −53.8 (bd), −109.5 ppm. ^{29}Si CP MAS NMR: δ = 13.8 (Me_3SiO−), −54.0 (T^1), −58.5 (T^2), −67.5 (T^3), −102.0 (sh, Q^3), −108.8 (sh, Q^4) ppm. Elemental analysis found C 16.24, N 1.34, H 2.33.

MCM-41-L/Me_3SiCl/MoO_2Cl_2 (5): A solution of $MoO_2Cl_2(THF)_2$ (0.52 g, 1.5 mmol) in CH_2Cl_2 (5 mL) was added to a suspension of the ligand-silica **4** (1.0 g) in CH_2Cl_2 (10 mL) and the mixture stirred overnight at room temperature. The resultant solid was then filtered off and washed with CH_2Cl_2 (4 × 20 mL), and dried in vacuo at room temperature for 3 h. Selected FT Raman: $\tilde{\nu}$ = 3069 (m), 2962 (m), 2904 (s), 1602 (m), 1001 (m) cm^{-1}. ^{13}C CP MAS NMR: δ = −0.3 (Me_3SiO−), 9.3 ($SiCH_2$), 20.8, 25.0, 57.9, 128.5 (phenyl-C). ^{29}Si MAS NMR: δ = 14.6, −55.0 (bd), −110.0 ppm. ^{29}Si CP MAS NMR: δ = 14.4 (Me_3SiO−), −54.0 (T^1), −58.0 (T^2), −67.5 (T^3), −108.9 (sh, Q^4) ppm. Elemental analysis found C 10.94, N 1.25, H 2.63, Mo 1.0.

MCM-48-L/Me_3SiCl (6): A solution of the ligand **1** (0.71 g, 1.15 mmol) in toluene (5 mL) was added to a suspension of MCM-48 (1.15 g) in toluene (10 mL) and the mixture heated at 100 °C for 9 h. After cooling to ambient temperature, Me_3SiCl (5 mL) was added and the mixture stirred at room temperature for a further 24 h. The so-obtained solid was then filtered off and washed twice with acetone (2 × 20 mL), twice with CH_2Cl_2 (2 × 15 mL), and dried in vacuo at 100 °C for 3 h. Selected FT Raman: $\tilde{\nu}$ = 3068 (s), 2971 (m), 2932 (s), 2901 (s), 1599 (s), 1550 (w), 1452 (m), 1414 (w), 1028 (w), 1001 (s), 617 (m) cm^{-1}. ^{13}C CP MAS NMR: δ = −0.3 (Me_3SiO−), 9.3 ($SiCH_2$), 17.0, 20.8, 58.9, 128.2 (phenyl-C) ppm. ^{29}Si MAS NMR: δ = −109.6 ppm. ^{29}Si CP MAS NMR: δ = 13.9 (Me_3SiO−), −50.0 (T^1), −58.4 (T^2), −67.5 (T^3), −101.9 (Q^3), −109.4 (Q^4) ppm. Elemental analysis found C 13.38, N 1.30, H 2.33.

MCM-48-L/Me_3SiCl/MoO_2Cl_2 (7): A solution of $MoO_2Cl_2(THF)_2$ (0.52 g, 1.5 mmol) in CH_2Cl_2 (5 mL) was added to a suspension of the ligand-silica **6** (1.0 g) in CH_2Cl_2 (10 mL) and the mixture stirred overnight at room temperature. The resultant solid was then filtered off and washed with CH_2Cl_2 (4 × 20 mL), and dried in vacuo at room temperature for 3 h. Selected FT Raman: $\tilde{\nu}$ = 3066 (m), 2962 (m), 2903 (s), 1598 (m), 1001 (m) cm^{-1}. ^{13}C CP MAS NMR: δ = 0.7 (Me_3SiO−), 8.7 ($SiCH_2$), 17.5, 20.7, 58.9, 128.7 (phenyl-C), 184.4 ppm. ^{29}Si MAS NMR: δ = 14.8, −55.0 (bd), −108.7 ppm. ^{29}Si CP MAS NMR: δ = 14.7 (Me_3SiO−), −54.7 (T^1), −59.4 (T^2), −67.5 (T^3), −108.7 (Q^4) ppm. Elemental analysis found C 10.94, N 1.30, H 2.63, Mo 1.4.

Catalysis: The liquid-phase epoxidation of cyclooctene was carried out at 55 °C under air in a micro reaction vessel equipped with a magnetic stirrer, which was loaded with complex (0.073 mmol) or MCM-catalyst (175 mg), olefin (7.3 mmol) and TBHP (11 mmol, 5.5 M in decane). Samples were withdrawn periodically and analysed using a gas chromatograph (Varian 3800) equipped with a capillary column (SPB-5, 20 m × 0.25 mm × 0.25 μm) and a flame ionisation detector. Undecane was used as internal standard added after the reaction.

Acknowledgments

The authors are grateful to FCT, POCTI, and FEDER for financial support (Project PCTI/1999/QUI/32889). CN thanks the University of Aveiro and the FCT for research grants. Paula Brandão and Cláudia Morais are acknowledged for assistance with the NMR experiments.

The 2,6-bis(diphenylphosphanylsulfide)phosphinine (**1**) reacts with water to afford a 1,2-dihydrophosphinine oxide **5** featuring a P–H bond. Reaction of **5** with one equivalent of $[Pd(COD)Cl_2]$ yields the SPS pincer-based complex **6** with a P(OH) λ^5-phosphinine central ligand. Complex **6** has been structurally characterized. Two possible mechanisms account for the formation of **5**: an intramolecular P–H to P–Pd metathesis or one based on the P=O to POH equilibrium. Methanol, ethanol or diethylamine also react with **1** to afford the corresponding P(H)(OMe) **7**, P(H)(OEt) **8**, and P(H)(NEt_2) **9** λ^5-phosphinines. No definitive mechanism for the formation of **7**–**9** can be proposed since no intermediates were detected in situ by ^{31}P NMR spectroscopy. However, DFT calculations (at the B3LYP 6-311+G(d,p) level of theory) suggest that the conversion of 1,2-dihydrophosphinines into λ^5-phosphinines is not viable because it involves a high activation energy. Like **5**, λ^5-phosphinines **7** and **8** react with $[Pd(COD)Cl_2]$ to afford the expected palladium complexes **10** and **11**. An alternative method relies on the reactivity of nucleophiles with a SPS pincer-based complex **2** featuring a P–Cl bond. (–)-Menthol and lithium diethylamide react with **2** to yield the expected P-OMen **13** and P-NEt_2 **14** complexes. Both complexes have been structurally characterized. Bromonickel **18** and chloroplatinum **19** complexes of the SPS ligand, featuring a P–Br or P–Cl bond, have also been prepared by reacting **1** with $[NiBr_2(DME)]$ and $[Pt(COD)Cl_2]$, respectively. Like their palladium congener, both species react with ethanol to afford the corresponding P–OEt derivatives **20** [M = Ni] and **21** [M = Pt]. *n*Butyl derivatives of these SPS ligands also bind to Ni–Br (complex **22**) and Pt–Cl (complex **23**) fragments. Both complexes were straightforwardly prepared by reacting anion **3**, resulting from the reaction of *n*BuLi with **1**, with the $[NiBr_2(DME)]$ and $[Pt(COD)Cl_2]$ precursors. The chloride ligand is readily substituted by acetonitrile in complexes **4**, **11**, **20**, and **21** upon treatment with $AgBF_4$ in dichloromethane. Reaction of AgOTf with the palladium complex **4** affords complex **28** via substitution of the chloride ligand by TfO^-. The X-ray crystal structures of the dimethyl-λ^5 derivative **29** of **1**, and that of its P-OMe anion **30**, have been recorded. Anion **30** can be regarded as a phosphanyl-substituted pentadienyl anion. DFT calculations and a charge decomposition analysis (CDA) show that the phosphorus atom in these SPS-pincer structures is a classical tertiary phosphane ligand in terms of donation and acceptance.

Introduction

The last decade has seen considerable interest in the synthesis and use of pincer ligands in coordination chemistry and catalysis, largely due to their particular backbone that allows not only the meridional encapsulation of transition metals but also the fine tuning of their coordination behavior and electronic capacity by varying the central or ancillary ligands. This area, pioneered by Shaw,[1] has been thoroughly reviewed recently.[2−4] Though early studies mainly focused on the ubiquitous PCP systems, polyheteroatomic-based pincer ligands featuring N, O, P, and S atoms have attracted increasing attention because multiple combinations can be used to build mixed systems.[5−7] Sulfur-based ligands are particularly appealing since they can also be employed in the elaboration of synthetic models of enzymes.[8] Mainly, four types of sulfur ligands are used: classical thioethers,[9−12] thiolates,[13,14] sulfoxides,[15] in which coordination occurs through the remaining lone pair at sulfur, and phosphane sulfides.[16,17] The latter, though not yet employed in pincer type structures, have found an interesting application in the rhodium-catalyzed carbonylation of methanol when incorporated in a mixed P−P=S bidentate ligand.[18,19]

Conversely, phosphane derivatives (probably the most studied ligands) have essentially been used as peripheral binding sites in pincer systems. This clearly results from their tetrahedral geometry that precludes the elaboration of planar rigid-backbones when the phosphorus atom is the central ligand. Therefore, the building of pincer systems incorporating a planar phosphorus atom as central binding site is an interesting challenge. Besides their structural interest, such systems exhibit very peculiar electronic properties that markedly differ from those of classical phosphanes and

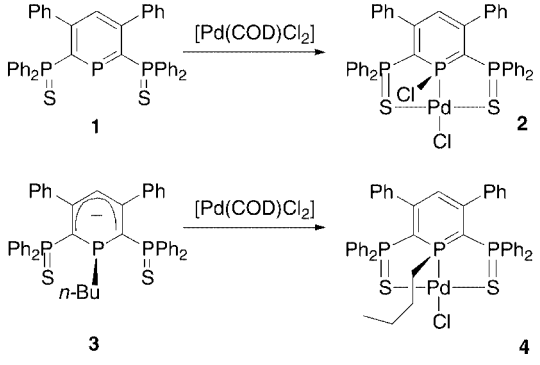
nitrogen analogs. Indeed, phosphorus in multiple bonds essentially behaves as a relatively poor σ-donor ligand but displays a powerful π-accepting capacity.[20] Very different systems, incorporating phosphaalkene (P analogs of alkenes) or heterocycles, can be anticipated but, in practice, only aromatic phosphorus heterocycles are sufficiently stable.

We thus recently launched a program aimed at incorporating phosphinines (phosphorus analogs of pyridines) in pincer-type structures. Our initial work focused on the synthesis of mixed S-P-S ligands featuring a phosphinine as central unit and two phosphane sulfides as ancillary ligands. Such systems proved to be easily available in large amounts by sulfurization of the corresponding 2,6-bis(diphenylphosphanyl)-λ^3-phosphinines. However, the highly electropositive phosphorus atoms are particularly reactive towards nucleophilic attack. Thus the reaction of ligand **1** with [Pd(COD)Cl_2] afforded a complex **2** featuring a central (λ^5-σ^4) pentavalent tetracoordinate phosphorus atom.[21] This new type of palladium complex, which can be derivatized by nucleophilic displacement of the chlorine atom at phosphorus, is particularly stable. Recently, we devised a much more rational approach to these complexes through the reaction of 1-*R*-1-*P*-phosphahexadienyl anions with [Pd(COD)Cl_2]. Thus, anion **3**, which is readily obtained by reacting *n*BuLi with phosphinine **1**, reacted with [Pd(COD)Cl_2] to afford complex **4** (Scheme 1). The latter proved to be particularly active (TON up to 10000) in the Miyaura-catalyzed cross-coupling process that allows the synthesis of aromatic boronic esters from halo aromatic and dialkoxyboranes.[22]

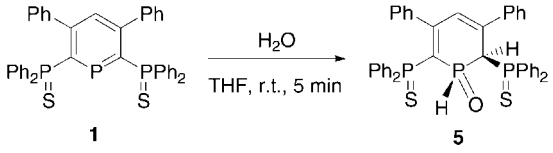


Scheme 1

As this chemistry might be extended to other metal centers, we aimed to expand the synthesis of this new type of phosphorus ligand and their applications in coordination chemistry and catalysis. We report here the synthesis of group 10 metal complexes. Different synthetic methodologies, the X-ray structures of some complexes as well as a preliminary theoretical study of their electronic properties are reported.

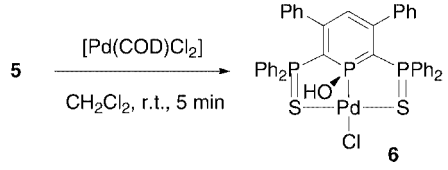
Results and Discussion

Two routes that exploit the high electrophilicity of the phosphorus atom in **1** have already been designed for the synthesis of these SPS palladium complexes. In exploring the reactivity of **1** toward nucleophiles, we found that reaction with water readily afforded the 1,2-dihydrophosphinine oxide **5** (Scheme 2). This is a common transformation for non-kinetically stabilized phosphaalkenes, but not, usually, for λ^3 -phosphinines in which the P=C double bond is thermodynamically stabilized.[23,24] However, the presence of strong acceptor groups at the α position of phosphorus (C2 and C6) sometimes provokes a significant dearomatization of the ring.[25] Interestingly, only one diastereomer of **5** was formed. The mechanism leading to **5** is discussed below.



Scheme 2

The structure of **5**, fully characterized by NMR spectroscopy and elemental analysis, was confirmed by an X-ray crystal structure study. It shows no particular features and is not presented here.[26] Interestingly, **5** could also be used as a source of [Pd(SPSOH)Cl] (**6**) [SPS = $C_5H(Ph_2PS)_2P$] upon reaction with [Pd(COD)Cl_2] (Scheme 3).



Scheme 3

Complex **6** was characterized by ^{31}P and ^{1}H NMR as well as by elemental data but was too insoluble to be characterized by ^{13}C NMR spectroscopy. Fortunately, suitable crystals for an X-ray crystal analysis could be grown by diffusing hexanes into a chloroform solution of the complex. A view of one molecule of **6** and the most significant metric parameters (Figure 1), and crystal data and structural refinement details (Table 6), are presented here. Complex **6** adopts a distorted planar geometry around the palladium atom and the two sulfides act as ancillary ligands. The most interesting data are the internal metric parameters within the SPS ligand. As previously noted for the *n*Bu derivative **4**, the phosphorus atom and the C3 carbon atom escape from the plane defined by the C1−C2−C4 and C5 atoms by 19.0° and 4.8°, respectively, to yield a boat-like conformation. Though the pyramidality of the phosphorus atom (316.5°) compares with that of classical tertiary phosphanes, the P−C1 [1.757(4) Å] and P−C5 [1.767(4) Å] bond lengths are very short. At first sight, these data suggest that the ylidic character of the λ^5-phosphinine has been pre-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

served upon coordination. Another intriguing piece of data is the bond lengths within the two ancillary P=S ligands. Indeed, whereas the two external P−C bond lengths [e.g. P3−C5 = 1.776(4) Å] are also very short compared to classical P−C single bonds, the two P=S bonds are lengthened [e.g. P2−S1 = 2.039(2) Å] compared with classical uncoordinated and coordinated phosphane sulfides. For example, in [Pd(R_3P=S)] complexes the P=S bond length usually falls between 1.9823(17), 2.0089(18) and 2.0237(9) Å.[27−29] The concomitant lengthening of this P−S bond with the shortening of the external P−C bond suggests there is delocalization within the unsaturated ligand backbone. Theoretical calculations to clarify this point will be presented below. The structure of **6** shows no other particular features.

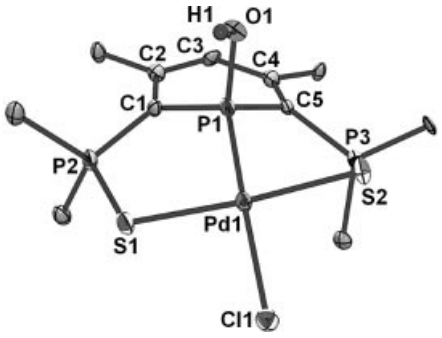


Figure 1. ORTEP view of complex **6**. Atoms are drawn as 50% thermal ellipsoids. Phenyl groups are omitted for clarity. The numbering is arbitrary and different from that used in the NMR spectroscopic data. Selected bond lengths [Å]: P1−C1 1.757(4), C1−C2 1.420(5), C2−C3 1.391(5), C3−C4 1.407(5), C4−C5 1.384(5), C5−P1 1.767(4), P1−O1.597(4), P2−C1, 1.759(4), P2−S1 2.039(2), P3−C5 1.776(4), P3−S2 2.1018(2), P1−Pd1 2.186(1), S1−Pd1 2.310(1), S2−Pd1 2.353(1), Pd1−Cl1 2.405(1); selected bond and dihedral angles [°]: C1−P1−C5 102.7(2), P1−C1−C2 117.5(3), C1−C2−C3 122.2(4), C2−C3−C4 125.2(4), C3−C4−C5 122.6(4), C4−C5−P1 119.3(3), P1−Pd1−Cl1 174.66(4), S1−Pd1−S2 174.67(4), (mean plane C1−C2−C4−C5)−P1 19.0, (mean plane C1−C2−C4−C5)−C3 4.8. Σangles at P1 316.5

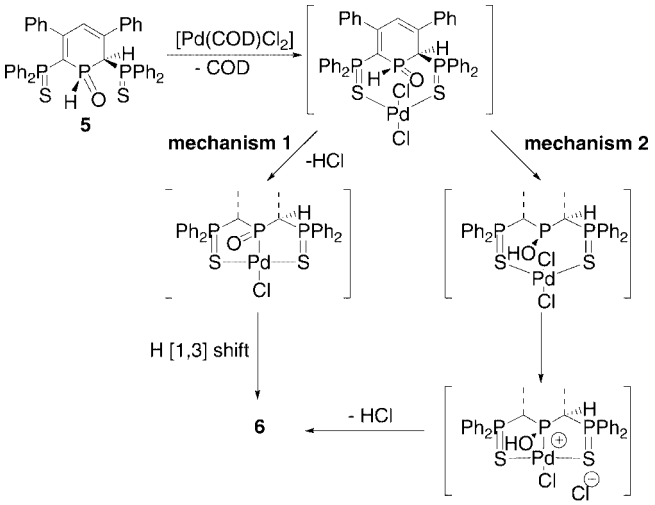
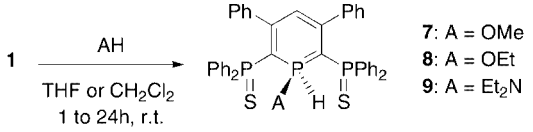
It is relatively difficult to propose a definitive mechanism to account for the formation of **6** from **5**. Indeed, ^{31}P NMR monitoring of the reaction revealed only signals corresponding to **5** and **6**. Two possible mechanisms leading to **6** can be proposed, both of which are promoted by the initial displacement of the COD ligand by the two ancillary phosphane sulfide groups to yield an intermediary $PdCl_2$ complex. In the first mechanism, the close proximity of the P−H and Pd−Cl bond leads to dehydrochlorination to yield HCl and a metallated 1,2-dihydrophosphinine oxide; the last step can be regarded as a (1,3) shift of hydrogen from the C2 carbon atom to the P=O bond (Scheme 4). The second mechanism relies on the phosphane oxide−hydroxyphosphane tautomerism. Thus, displacement of one chloride ligand by the phosphorus atom lone pair would yield a cationic complex that could further undergo a dehydrochlorination. Such metal-promoted P=O to POH or P=S to P−SH rearrangements have been used to prepare palladium-phosphinous or palladium phosphinothious acid complexes, and in C−P coupling.[30−32]



Scheme 4

Compound **1** also reacted with primary alcohols and secondary amines to afford the corresponding λ^5-phosphinines that formally result from the insertion of the phosphorus atom lone pair into the A−H bond (A = RO or R_2N). Whereas the reactions with methanol and ethanol to give **7** and **8** are rather slow and need excess ROH to go to completion, diethylamine readily reacts with **1** to form compound **9**. These derivatives are the first examples of λ^5-phosphinines featuring a P−H bond.[22,33] Both compounds were fully characterized by NMR and mass spectroscopy, as well as by elemental analysis for **7** (Scheme 5). Only primary alcohols react with **1** and additional experiments with menthol and phenol led to the recovery of **1**, even under forcing conditions (heating, high concentration of reagents). In ^{31}P NMR, the formation of **7**, **8**, and **9** was evidenced by the presence of two magnetically equivalent PPh_2S groups. The presence of a P−H bond was definitively established in the ^{1}H NMR spectrum by a strong ^1J(P-H) coupling constant (619.0 Hz in **7**, 613.0 Hz in **8** and 545.0 Hz in **9**).

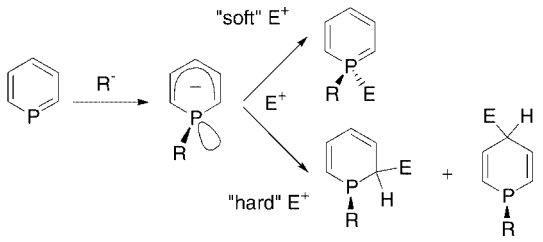


Scheme 5

The formation of λ^5-phosphinines by the direct condensation of alcohols and amines with phosphinines is unprecedented and emphasizes the reactivity of **1**. In most of the several synthetic approaches towards λ^5-phosphinines they are obtained directly by trapping the 1-R-1-*P*-phosphahexadienyl anions with electrophiles. Indeed, these anions are ambident and display two sites of attack, the lone pair at phosphorus and the Cα and Cγ carbon atoms of the carbocyclic backbone. "Soft electrophiles" (MeI for example) react at the phosphorus atom whereas "hard electro-

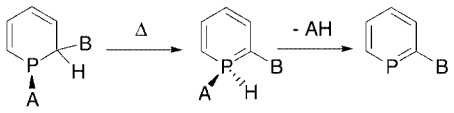
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

philes'' (such as H^+) tend to react at the anionic part of the ring to afford 1,2-dihydrophosphinines.[34−36] This is probably why λ^5-phosphinines featuring a PH bond have never been synthesized before (Scheme 6).



Scheme 6

However, λ^5-phosphinines are supposed intermediates in the thermolysis of 1,2-dihydrophosphinines to produce phosphinines. This transformation, which involves a (1,2) shift of the R group from the Cα carbon atom to phosphorus (Scheme 7) followed by an elimination of AH, usually occurs at high temperature and is well documented.[34,37]



Scheme 7

Though no intermediates could be detected during our experiments, we first supposed that the reaction of MeOH and Et_2NH initially produces transient 1,2-dihydrophosphinines that can further isomerize to yield the corresponding λ^5 derivatives. No theoretical data are available on this isomerization. To clarify this point, DFT calculations were carried out using the combination of the B3LYP functional with the 6-311+G(d,p) basis set. We first focused on the rearrangement of Cα-unsubstituted compounds derived from the parent phosphinine (compounds **Ia**, **b**, **c**, **d**). The relative energies show that the 1,2-dihydro derivative are the most stable isomers (Table 1). Substitution of alkyl groups by OMe or NH_2 groups tends to reduce the energetic difference. This is in good agreement with previous theoretical calculations, which showed that the introduction of an electronegative atom on phosphorus slightly increases the aromaticity of the ring by negative hyperconjugation.[38] However, whatever the substituent at phosphorus, conversions of the 1,2-dihydrophosphinines into the corresponding λ^5-compounds (**IIa**, **b**, **c**, **d**) require a high activation energy (E_A) (from 50.442 kcal/mol for R = OMe to 66.393 kcal/mol for R = H) (Scheme 8). To assess the influence of the substitution pattern of the ring, calculations were performed on a model compound featuring two PPH_2S at the α-positions and a methoxy group at phosphorus. However, as in Cα-unsubstituted derivatives, a high activation barrier (44.848 kcal/mol) is required to form the corresponding λ^5-phosphinine (Scheme 9).

Table 1. Relative energies (ZPE corrected) in kcal/mol of model compounds **I**, **II**, and their corresponding **TS**

I		TS		II

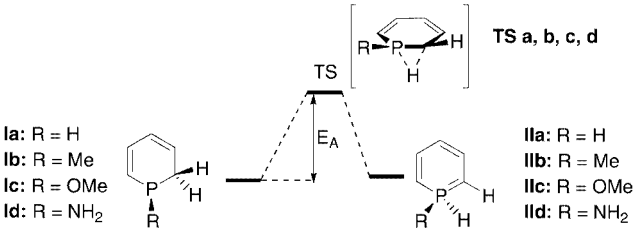
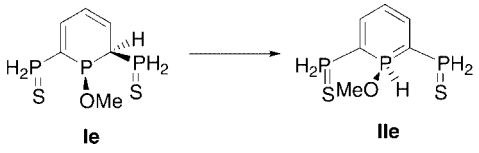
Id	0	TSd	+57.760	IId	+6.874
Ie	0	TSe	+44.848	IIe	+0.245

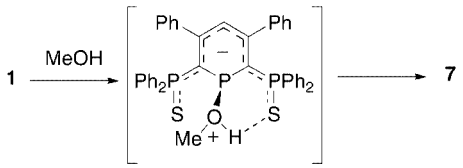


Scheme 8



Scheme 9

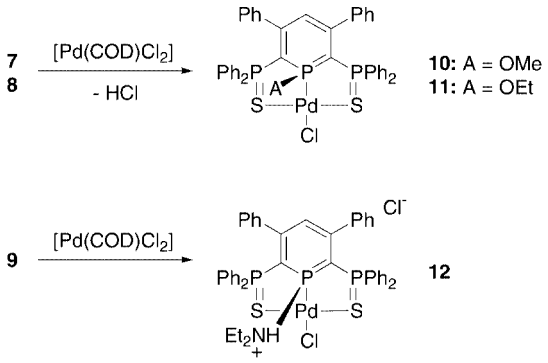
This short theoretical investigation clearly shows that the introduction of two diphosphanylsulfide groups at the Cα position of phosphorus does not significantly modify the reaction pathway. Therefore, at this stage, no definitive mechanism can be proposed. However, we believe that this transformation is promoted by an initial attack of the oxygen or nitrogen atom at the phosphorus, the two ancillary PPh_2S groups assisting, in a second step, the transfer of H^+ to phosphorus (Scheme 10). Further calculations to localize a possible transition state as well as a complete study on the transformation of λ^5 and dihydrophosphinines into phosphinines are currently underway and will be reported in due course. Very probably, a similar mechanism takes place between **1** and H_2O in the formation of **5** via a transient λ^5-phosphinine. Indeed, λ^5-phosphinines featuring a P−OH group rapidly isomerize to the corresponding 1,2-dihydrophosphinine oxide derivatives.[39]



Scheme 10

Interestingly, compounds **7**, **8** can also be used as precursors for the synthesis of P-alkoxy-substituted PdCl complexes. Thus when **7**, **8** were treated with $[Pd(COD)Cl_2]$ in THF at room temperature, complexes **10** and **11** were cle-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

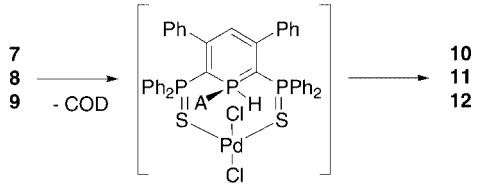


Scheme 11

anly formed in good yields (Scheme 11). Complex **10** has previously been obtained by a nucleophilic substitution of the P−Cl complex. Complex **10** and **11** were identified by NMR techniques and elemental analyses.

The synthesis of an amino derivative proved to be much more difficult to handle because of the concomitant release of HCl. For example, reaction of **9** with $[Pd(COD)Cl_2]$ in THF at room temperature afforded the poorly soluble salt **12**. The formulation of **12** was established on the basis of its ^1H NMR spectrum, which reveals an acidic proton at $\delta(CD_3COCD_3) = 9.25$ ppm, and elemental analyses. The formation of **12** could not be prevented even in the presence of a large excess of diethylamine as HCl scavenger.

Since no intermediates could be detected in ^{31}P NMR spectroscopy during the synthesis of **10** and **11**, no definitive mechanism can be proposed. However, a mechanism close to that proposed for the synthesis of complex **6** seems plausible. In a first step, the COD ligand is displaced from palladium by the two ancillary sulfide ligands and an elimination of HCl takes place to form the P−Pd bond (Scheme 12).



Scheme 12

Alkoxy complexes can also be obtained by the classical route that relies on the displacement of the Cl atom from phosphorus by ROH in complex **2**. Thus, complex **13** was easily obtained by treating (−)-menthol with **2** in dichloromethane at room temperature. The formation of **13** was evidenced by an ABC spin system pattern in ^{31}P NMR spectrum − a result of the chiral group introduced at phosphorus, which renders the two ancillary PPh_2S substituents magnetically non-equivalent (see Exp. Sect.). The formulation of **13** was confirmed by an X-ray structural study. A view of one molecule of **13** and the most significant metric

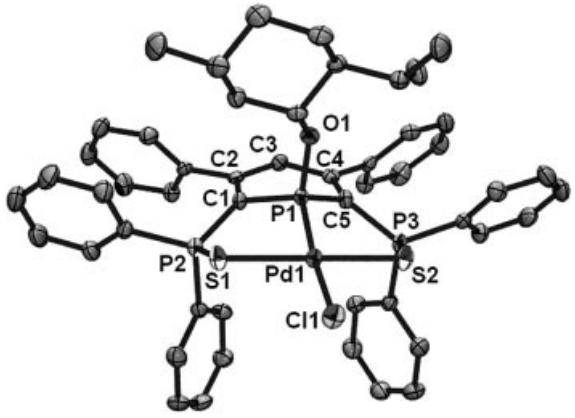


Figure 2. ORTEP view of complex **13**. Atoms are drawn as 50% thermal ellipsoids. C4−C2−C1−P1 20.0, C1−C5−C4−C3 5.2, (mean plane C1−C2−C4−C5)−P1 20.9, (mean plane C1−C2−C4−C5)−C3 5.5. Σangles at P1 313.3

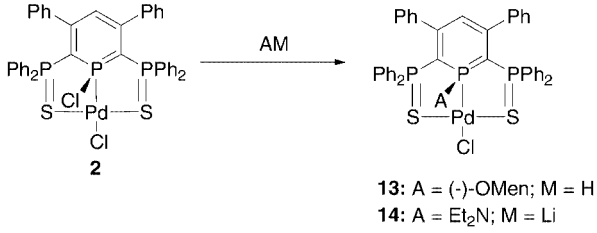
parameters (Figure 2), and crystal data and structural refinement details (Table 6), are given. This route was also efficient for the synthesis of the amino derivative **14**. Reaction of Et_2NLi with **2** in THF at low temperature cleanly afforded **14** which was recovered as a yellow solid in nearly quantitative yield (Scheme 13).



Scheme 13

The structure of **14** was confirmed by an X-ray analysis. An ORTEP view of one molecule of **14** (Figure 3), and crystal data and structural refinement details (Table 7), are given. The structure of **14** does not significantly differ from that of **5**. The two internal P−C bond lengths [P1−C1 1.756(2) Å and P1−C5 1.763(2) Å] as well as the external ones [C1−P2 1.766(2) Å and C5−P3 1.762(2) Å] are also short, and the two P−S bond lengths [P2−S1 2.029(1) Å and P3−S2 2.033(1) Å] are long.

Our investigations on potential precursors of these palladium(II) complexes have yielded another approach to P-alkyl derivatives. Reaction of anion **15** with C_2Cl_6 afforded the λ^5-phosphinine **16** featuring a P−Cl bond (Scheme 14). This compound, isolated as a moisture-sensitive solid, was successfully characterized by NMR and mass spectroscopy.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

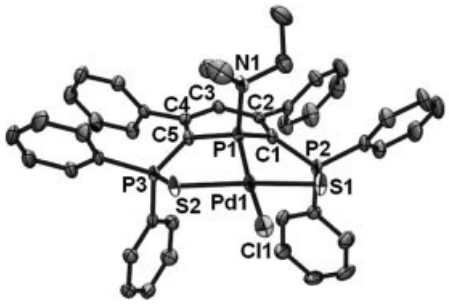


Figure 3. ORTEP view of complex **14**. Atoms are drawn as 50% thermal ellipsoids. Σangles at P1 314.1

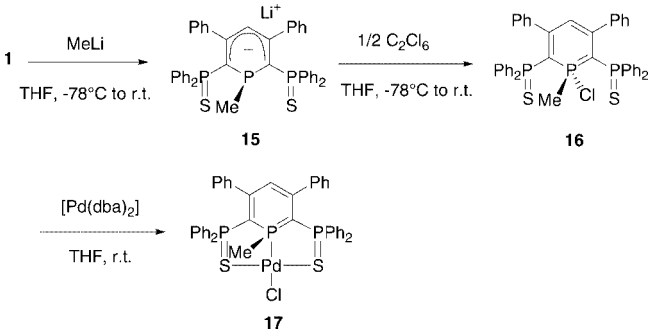
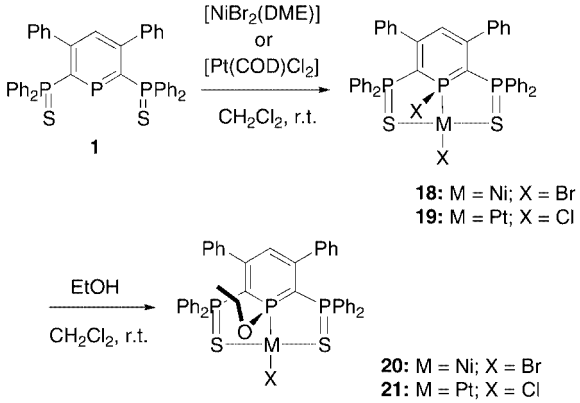


Scheme 14

Interestingly, **16** reacts with the [Pd(dba)$_2$] complex to form complex **17** (Scheme 14), which can be rationalized following a classical mechanism that involves the insertion of palladium into the P−Cl bond of **16**. Practically, this route is probably less straightforward than the direct reaction of anion **15** with [Pd(COD)Cl$_2$]. (Scheme 1) However, it shows that zerovalent metal centers can readily be inserted into the P−Cl bond of λ^5-phosphinines. This strategy could be particularly useful when divalent metal precursors are not available.

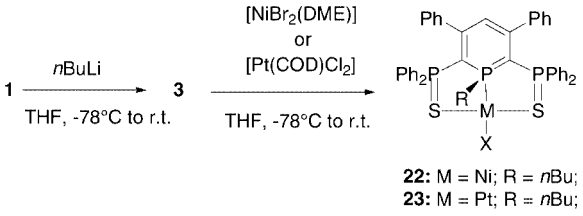
We wished to extend our several methods devised to introduce any substituent at the phosphorus to nickel and platinum(II) derivatives. All the approaches developed with palladium complexes have not yet been systematically explored. The original method involving the displacement of a chloride atom from the metal to the phosphorus atom could be duplicated with nickel and platinum using [NiBr$_2$(DME)] (DME = dimethoxyethane) and [Pt(COD)Cl$_2$] as starting precursors. Both reactions took place in dichloromethane at room temperature to afford



Scheme 15

complexes **18** and **19** respectively (Scheme 15). The P−Br **18** and P−Cl **19** derivatives, which are moisture sensitive, were characterized by ^{31}P NMR spectroscopy and by X-ray diffraction studies. However their structures, which are similar to that of the Pd−Cl complex **2**, are not reported here. As with the palladium derivative the P−Br and P−Cl bonds are sufficiently reactive to undergo nucleophilic substitution. Thus, reaction of EtOH with **18** and **19** cleanly afforded complexes **20** and **21**, respectively, which were fully characterized by NMR and mass spectroscopy as well by elemental analysis. Under standard conditions, intermediates **18** and **19** need not be isolated (Scheme 15).

Nickel and platinum complexes of alkyl derivatives were also prepared using the anionic approach. Phosphinine **1** reacted with *n*BuLi in THF at low temperature to produce anion **3** which was subsequently treated with [NiBr$_2$(DME)] and [Pt(COD)Cl$_2$] to yield complexes **22** and **23**, respectively (Scheme 16). The NMR spectroscopic data of **22** and **23** are comparable to those of their palladium analog **4**.



Scheme 16

Complex **22** was structurally characterized. An ORTEP view of one molecule of **22** and the most significant metric parameters (Figure 4), and crystal data and structural refinement details (Table 7), are presented here. These data reveal that replacement of palladium by nickel does not significantly modify the λ^5-phosphinine backbone, and the same trends are observed. The P−C bonds (external and internal) are short and the P−S bonds are slightly lengthened. The two angles between the C1−C2−C4−C5 plane and the phosphorus atom (21.05°) and the C3 carbon (4.7°)

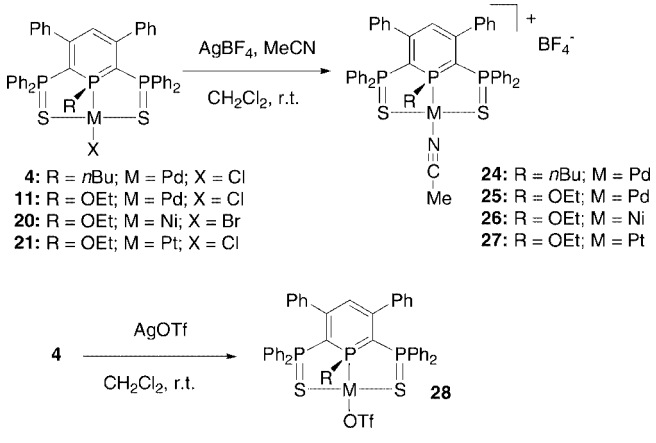
atom also compare with those of **5**, **13** and **14** as well as the pyramidality of the phosphorus atom.

Finally, a preliminary study of the reactivity of the halogen ligand in these complexes showed that the chloride (Pd and Pt) or bromide ligand (Ni) is easily abstracted upon reaction with $AgBF_4$ in dichloromethane at room temperature in the presence of acetonitrile (Scheme 17). Four cationic complexes **24**−**27** were thus obtained and fully characterized by NMR techniques and elemental analyses. Interestingly, reaction of the palladium complex **4** with AgOTf furnished the neutral complex **28**. Its formulation was unambiguously established on the basis of NMR spectroscopic data and elemental analysis.

Having developed several new synthetic pathways to these d^8 metal complexes, we turned our attention to the electronic structure of the SPS pincer ligands. As noted earlier, some X-ray structural data suggest that electronic delocalization occurs within the ligand. To establish a significant structural comparison, three compounds were crystallized and submitted to X-ray crystal structure analysis, the phosphinine precursor **1**, the free anionic ligand **15** and the λ^5-dimethylphosphinine **29**. Phosphinine **1** was easily crystallized by diffusion of hexanes into a solution of **1** in CH_2Cl_2. An ORTEP view of one molecule of **1** and the most relevant metric parameters (Figure 5), and crystal data and structural refinement details (Table 5), are presented.



Scheme 17

Compound **29** was prepared conventionally with the subsequent trapping of anion **15** with methyl iodide. As explained above, in good agreement with literature data, the alkylation takes place exclusively at the phosphorus atom lone pair to yield **29** in very good yields (Scheme 18). The formulation of **29** was easily established on the basis of NMR spectroscopic data and combustion analysis. Suitable crystals were obtained by diffusion of hexanes into a solution of **29** in $CDCl_3$. An ORTEP view of one molecule of **29** and the most significant metric parameters (Figure 6), and crystal data and structural refinement details (Table 5), are given.

The crystallization of an anionic derivative of **1** proved to be much more difficult. To draw a precise comparison with the dimethyl-λ^5-phosphinine **29**, the crystallization of anion **15** was attempted. However, whatever the experimental conditions used (solvent, temperature, presence or absence of cryptand) no suitable crystals could be grown. However, crystallization of the methoxy-substituted species **30** gave more satisfying results. Anion **30** was readily prepared by reacting 3 equivalents of MeONa with **1** in THF at room temperature (Scheme 19). Suitable crystals of this anion were obtained upon crystallization with the (2.2.2) cryptand. An ORTEP view of one molecule of **30** and the most relevant bond lengths and bond angles (Figure 7), and crystal data and structural refinement details (Table 5), are presented.

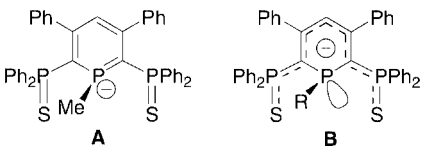
The structural data of **1**, **29**, and **30** provide interesting information. The structure of ligand **1** is relatively classical and compares with those of other λ^3-phosphinines. The two internal P=C bond lengths and the C−C bond lengths within the ring fall in the usual range and the ring is planar. The two sulfide groups point towards the back of the molecule to minimize the electronic repulsion between the lone pair at phosphorus and that of sulfur atoms (Figure 5). Of most interest is the external P−C bond lengths [C1−P2 1.826(2) Å and C5−P3 1.835(2) Å], which compare with those of classical P−C single bonds. Moreover, the P=S bond lengths [P2−S1 1.956(1) Å and P3−S2 1.953(1) Å] are normal. Transformation of **1** into **29** obviously induces important distortions and the phosphorus atom now escapes, by 23.15°, from the C1−C2−C4 and C5 plane. While the ylidic structure of the ring is evidenced by a small lengthening of the internal P−C bonds, the two external ones are slightly shortened [1.789(2) Å and 1.792(2) Å], suggesting that a delocalization occurs. However, this delocalization is probably weak and does not extend to the two P=S bonds due to the orientation of the two phosphane-sulfides groups, which are not coplanar with the unsaturated part of the ring. This effect is also apparent in **30**, which consists of two discrete units of the anionic ligand and [Na(2.2.2)]. Though the substituent at phosphorus is different (Me in **29**, OMe in **30**), the introduction of the charge significantly modifies the hybridization state of the phosphorus atom. Thus, in **30** the two internal P−C bond lengths [1.802(4) Å and 1.791(5) Å] have lost their ylidic character and this anion can be considered as a simple phosphanyl-substituted pentadienyl anion.[40] Note also that, as in **29**, the two external P−C bond lengths [1.794(5) Å and 1.770(4) Å] are also quite short.

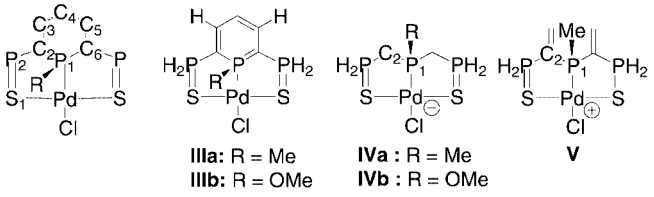
These data do not obviously compare with those of the Pd and Ni complexes, and it is relatively difficult to establish whether the ligand behaves as an anionic λ^4-phosphinine (form A) or as a classical tertiary phosphane (form B). The short internal P−C bond lengths suggest that the ylidic structure of the phosphinine has been restored upon complexation but, conversely, the relatively long P−S bonds and short external P−C connections point to delocalization within the unsaturated part of the ligand (form B) (Scheme 20).



Scheme 20

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Reasonably, one may propose that both forms can contribute to the bonding, the respective contributions being determined by the nature of the metal centre and its formal oxidation state. Lacking a wide range of complexes and X-ray structures, it seems premature to propose a definitive model to rationalize the bonding in these complexes. A preliminary theoretical study aimed at evaluating the electronic capacity of the ligand in these group 10 complexes was thus undertaken. Optimizations were carried out on the two model complexes **IIIa**, **b** featuring a methyl group and a methoxy group at phosphorus, respectively (Scheme 21). The ligand substitution scheme was simplified to save computation time, and phenyl groups of the phosphane sulfide substituents, as well as those located on the phosphinine ring, were replaced by hydrogen atoms (Scheme 21).



Scheme 21

Various functional and basis sets were tested. The best compromise, in terms of computation time and accuracy of structural data, was a combination of the B3LYP functional with a mixed basis set composed of the 6-31G* basis set for C, H, O, P, S and Cl atoms and the effective core potentials (ECP) of Hay and Wadt for Pd. The most significant bond lengths and bond angles of **IIIa**, **b** (Table 2) show an acceptable fit between theoretical and experimental parameters. Thus, the same trend is seen for P−C (internal and external) and P−S bond lengths. For example in **IIIa**, the internal P−C bonds (1.796 Å) are close to that in the *n*Bu derivative [1.762(7) Å] whose structure was previously reported. In **IIIb**, the external P−C bonds are shortened (1.774 Å *vs* 1.778(3) Å in **13**) and the P−S bonds are lengthened (2.049 Å vs. 2.033(2) Å in **13**). The only discrepancies arise from the P−Pd and S−Pd bond lengths and from the dihedral angle measuring the out-of-plane distortion of the phosphorus atom. Indeed, P−Pd and S−Pd bond lengths are overestimated and the out-of-plane distortion is underestimated in the theoretical structures. However, modification of the basis set for Pd (all electron-basis sets, other ECP, diffuse functions) or phosphorus and sulfur (diffuse functions) did not significantly improve data.

An analysis of natural charge (NBO method) reveals that, in **IIIa**, **b**, the phosphorus atom bears a significant positive charge and that the α (C2 and C6) and γ (C4) carbon atoms are negatively charged (Table 3). Conversely, the β (C3 and C5) carbon atoms are positively charged. This charge distribution is relatively equivalent to that observed in λ^5-phosphinines (see for example data for **IIe**). However, a relatively similar charge distribution is observed in the phosphane-based complexes **IVa**, **b** and **V**. These data also suggest that the P−Pd bond is slightly more polarized in **IIIa**, **b** than in **IVa**, **b** and **V**, but these differences are not very significant. Care must be taken in drawing rapid conclusion from charge distributions, especially in transition metal complexes.

To determine which form (A or B) is preponderant in the bonding to the metal, a charge decomposition analysis was carried out using the CDA program developed by Frenking and coll. Such analysis has proved to be very useful in estimating the ratio between donation and back-donation for ligands following the classical Dewar−Chatt−Duncansson (DCD) model. Further explanations about the method, the terms used in these calculations and their relevance are given in the theoretical section. Complexes **IIIa**, **b** were compared to the virtual cationic complexes **IVa**, **b**, and **V** featuring a tertiary phosphane as central ligand and two peripheral phosphane sulfide groups. Complex **V** only differs from **IVa** by the presence of two exocyclic CH_2 groups which mimic the unsaturated backbone of the phosphinine ring.

The results of the CDA analysis are presented in Table 4. A first important remark concerns the residual term (Δ) which allows one to consider the interaction in terms of donor−acceptor behavior. All of the complexes exhibit a low (Δ) value, indicating that their bonding to Pd can be described following the DCD model. The second interesting point concerns the $b/(d+b)$ value which reflects the percentage of π-acceptance. The similarity of these values clearly indicates that the central phosphorus atom in **IIIa**, **b** (15.19 and 19.23%) exhibits electronic properties that are close to

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 4. Charge decomposition analysis of complexes **IIIa**, **b**, **IVa**, **b**, and **V**

	IIIa	IIIb	IVa	IVb	V
d[a]	1.089	0.844	0.855	0.935	0.863
b[b]	0.195	0.201	0.171	0.160	0.147
d/b	5.58	4.20	5.00	5.843	5.87
$b/(d+b)$	15.19	19.23	16.66	14.62	14.55
r[c]	−0.397	−0.076	0.069	−0.092	−0.093
Δ	−0.008	−0.005	−0.001	0.025	0.004

those of classical tertiary phosphane complexes **IV** and **V** (between 14.55 and 16.66%). Note that the exocyclic double bonds in **V** do not significantly modify the electronic capacity of the ligand. Overall, we therefore propose that, at least in the case of d^8 palladium complexes, the delocalized form B is probably preponderant.

Conclusion

We have presented several unusual routes towards λ^5-phosphinines derivatives of the 2,6-bis(diphenylphosphanyl)phosphinine. Easy access towards previously unknown P−H derivatives and a straightforward preparation of a P−Cl derivative have also been devised. Additionally, new synthetic approaches towards SPS-λ^5 phosphinine group 10 metal complexes have been developed using either these P−H, P−Cl derivatives or a 1,2-dihydrophosphinine oxide. Most of these routes should be operative with other metal halides. Structural data as well as a preliminary theoretical investigation suggests that a delocalization takes place within the carbocyclic part of the ligand but that the central phosphorus atom behaves as a classical tertiary phosphane. Further studies will now focus on the catalytic properties of the group 10 complexes and on a systematic investigation of the coordinative properties of SPS based-ligands. A detailed theoretical study of their electronic properties will be reported elsewhere.

Experimental Section

General Remarks: All reactions were routinely performed under an inert atmosphere of argon or nitrogen using Schlenk and glove-box techniques and dry deoxygenated solvents. Dry THF and hexanes were obtained by distillation from Na/benzophenone and dry diethyl ether from $CaCl_2$ and then NaH and dry CH_2Cl_2 from P_2O_5. Acetonitrile (99.5% purity) was purchased from SDS and used without further purification. $CDCl_3$ was dried over P_2O_5, and stored on 4Å Linde molecular sieves. CD_2Cl_2, [D_8]THF, and [D_6]acetone were used as purchased and stored in the glove-box. Nuclear magnetic resonance spectra were recorded on a Bruker AC-200 SY spectrometer operating at 300.0 MHz for ^{1}H, 75.5 MHz for ^{13}C and 121.5 MHz for ^{31}P. Solvent peaks were used as internal reference relative to Me_4Si for ^{1}H and ^{13}C chemical shifts (ppm); ^{31}P chemical shifts are relative to an 85% H_3PO_4 external reference. Coupling constants are given in Hertz. The following abbreviations are used: s, singlet; d, doublet; t, triplet; q, quadruplet; p, pentuplet; m, multiplet; v, virtual; b, broad. Mass spectra were obtained at 70 eV with a HP 5989B spectrometer coupled to a HP 5980 chromatograph by the direct inlet method. Elemental analyses were performed by the "Service d′analyse du CNRS", at Gif sur Yvette, France. Phosphinine **1** and complex **2**,[21] anion **3** and complex **4**,[22] [Ni(dme)Br_2],[41] [Pd(COD)Cl_2],[42] [Pd(dba)$_2$],[43] and [Pt(COD)Cl_2][44] were prepared according to reported procedures.

Phosphinine 1: Suitable crystals for X-ray structure analysis were grown by diffusion of hexanes into a solution of **1** in CH_2Cl_2.

Phosphane Oxide 5: Water (0.1 ml) was added to a solution of **1** (370 mg, 0.54 mmol) in THF (20 mL). The reaction was then stirred for 5 min at room temperature and the solvent was removed under vacuum. The solid was washed with diethyl ether (2 × 5 mL) and, after drying, **5** was recovered as a yellow powder. Suitable crystals for X-ray structure analysis were grown from a diffusion of hexanes into a solution of **5** in CH_2Cl_2.Yield: 97%, 366 mg. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 5.05 [ABB′X, td, ^2J(H-P_A) = ^2J(H-P_B) = 16.6, ^3J(H−H) = 2.1, 1 H, H^2], 6.55 (ABB′X, m, ΣJ= 9, 1 H, H^4), 6.74 [dd, ^1J(H-P_A) = 580, ^3J(H−H) = 2.7, 1 H, PH], 6.82−8.20 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 43.5 (m, C^2H), 119.9 (m, C^6), 127.7−133.4 (m, C^4H, CH and C of Ph), 137.4 (ABB′X, m, ΣJ= 20, $C^{5\ or\ 3}$), 140.5 (ABB′X, m, ΣJ= 21, $C^{3\ or\ 5}$), 163.4 [d, ^3J(C-P_A) = 3.7, C of Ph] ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = 4.22 [ABB′, dd, ^2J(P_A-P_B) = 35.3, ^2J(P_A-$P_{B'}$) = 17.0, P_AH], 36.47 [ABB′, d, ^2J(P_A-P_B) = 35.3, P_BPh$_2$], 38.92 [ABB′, d, ^2J(P_A-$P_{B'}$) = 17.0, $P_{B'}$Ph$_2$] ppm. MS (EI): m/z = 682 [M^+ − (H_2O)]. $C_{41}H_{33}OP_3S_2$ (698.75): calcd. C 70.47, H 4.76; found C 70.03, H 4.34.

Complex 6: A solution of [Pd(COD)Cl_2] (155 mg, 0.54 mmol) and **5** (380 mg, 0.54 mmol) in CH_2Cl_2 (10 mL) was stirred for 2 h at room temperature. After removing the solvent under vacuum, the resultant yellow solid was washed with hexanes (3 × 5 mL) and dried. Suitable crystals for an X-ray structure analysis were grown from a diffusion of hexanes into a solution of $CDCl_3$. Yield: 83%, 376 mg. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 5.83 (m, 1 H, H^4), 6.60−7.60 (m, 30 H, CH of Ph) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = 54.36 [AB_2, d, ^2J(P_A-P_B) = 105.7, P_BPh$_2$], 90.10 [AB_2, t, ^2J(P_A-P_B) = 105.7, P_A] ppm. Complex **6** was too insoluble to a give a satisfactory ^{13}C NMR spectrum. $C_{41}H_{32}ClOP_3PdS_2$ (839.62): calcd. C 58.65, H 3.84; found C 58.28, H 3.47.

λ^5-Phosphinine 7: A solution of **1** (100 mg, 0.15 mmol) and methanol (200 μL, 4.9 mmol) in THF (5 mL) was stirred for 24 h at 40 °C. After removing the solvent under vacuum, the resultant yellow solid was washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). After drying, **7** was recovered as a yellow powder in 73% (78 mg) yield. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 3.38 (d, $^3J_{H-P}$ = 13.8, 3 H, CH_3), 5.7 [td, ^4J(H-P_B) = 3.8, ^4J(H-P_A) = 1.7, 1 H, H^4], 7.56 [dt, ^1J(H-P_A) = 619.0, ^3J(H-P_B) = 1.9, 1 H, PH], 6.80−7.76 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 49.5 (br. s, CH_3), 80.7 (m, $C^{2,6}$), 116.3 (m, C^4H), 125.8−133.5 (m, CH and C of Ph), 140.5 [m, ΣJ(C-P) = 20.7, $C^{3,5}$], 156.4 (s, C of Ph) ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 27.57 [AB_2, t, ^2J(P_A-P_B) = 43.7, P_A], 39.46 [AB_2, d, ^2J(P_A-P_B) = 43.7, P_B] ppm. MS (EI): m/z = 682 [M^+ − (MeOH)]. $C_{42}H_{35}OP_3S_2$ (712.78): calcd. C 70.77, H 4.95; found C 70.31, H 4.44.

λ^5-Phosphinine 8: A solution of **1** (550 mg, 0.8 mmol) and ethanol (200 μL, 3.4 mmol) in THF (5 mL) was stirred for 24 h at 40 °C. After removing the solvent under vacuum, the resultant solid was

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). After drying, **8** was recovered as a yellow powder in 78% (433 mg) yield. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.26 [t, ^3J(H−H) = 7.2, 3 H, CH_3], 3.90 [dq, ^3J(H−H) = ^3J(H-P_A) = 7.2, 2 H, CH_2], 5.72 [t, ^4J(H-P_B) = 7.2, 1 H, H^4], 6.84−7.76 (m, 30 H, CH of Ph), 7.73 [d, ^1J(H-P_A) = 613.0, 1 H, PH] ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 15.1 [d, ^3J(C-P_A) = 16.0, CH_3], 63.3 [d, ^2J(C-P_A) = 6.9, CH_2O], 81.7 [ddd, ^1J(C-P_A) = 101.2, ^1J(C-P_B) = 80.5, ^3J(C-$P_{B'}$) = 4.6, $C^{2,6}$], 117.2 (m, C^4H), 127.1−132.2 (m, CH of Ph), 133.5 [dd, ^1J(C-P_B) = 11.5, ^3J(C-P_A) = 3.5, C of Ph], 134.7 [dd, ^1J(C-P_B) = 13.8, ^3J(C-P_A) = 3.4, of Ph], 141.5 [dt, ^2J(C-P_A) = 11.5, ^2J(C-P_B) = ^4J(C-$P_{B'}$) = 3.4, $C^{3,5}$], 156.3 (s, C of Ph) ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 25.87 [AB_2X, t, ^2J(P_A-P_B) = 43.1, P_A], 39.46 [AB_2, d, ^2J(P_A-P_B) = 43.1, P_B] ppm. MS (EI): *m*/*z* = 682 [M^+ − (EtOH)]. $C_{43}H_{37}OP_3S_2$ (726.81): calcd. C 71.06, H 5.13; found C 70.67, H 4.82.

λ^5-Phosphinine 9: A solution of **1** (100 mg, 0.15 mmol) and diethylamine (200 μL, 1.9 mmol) in CH_2Cl_2 (5 mL) was stirred for 15 min at room temperature. After removing the solvent under vacuum, the so-obtained yellow solid was washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). After drying, **9** (98 mg) was recovered as a yellow powder in 87% yield. ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 1.14 [t, ^3J(H−H) = 6.9, 6 H, CH_3], 2.92 [q, ^3J(H−H) = 6.9, 4 H, CH_2], 5.59 [t, ^3J(H-P_B) = 4.6, 1 H, H^4], 7.29 [dt, ^1J(H-P_A) = 545.0, ^1J(H-P_B) = 2.0, 1 H, PH], 6.76−7.72 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 10.9 (s, CH_3), 41.5 [d, ^2J(C-P_A) = 19.6, CH_2], 87.6 (m, $C^{2,6}$), 113.9 [d, ^4J(C-P_A) = 13.6, C^4H], 122.6−131.1 (m, CH of Ph), 134.5 [d, ^1J(C-P_B) = 84.1, C of Ph], 135.2 [d, ^1J(C-P_B) = 86.8, C of Ph], 141.4 (m, $C^{3,5}$), 155.5 (m, Cq de C_6H_5) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 298 K): δ = −0.31 [AB_2, t, ^2J(P_A-P_B) = 50.6, P_A], 37.36 [AB_2, d, ^2J(P_A-P_B) = 50.6, P_B] ppm. MS (EI): *m*/*z* = 682 [M^+ − ($NHEt_2$)]. $C_{45}H_{42}NP_3S_2$ (753.88): calcd. C 71.69, H 5.62; found C 41.26, H 5.17.

Complex 10: A mixture of [Pd(COD)Cl_2] (28 mg, 0.1 mmol) and **7** (71 mg, 0.1 mmol) in THF (10 mL) was stirred for 1 h at room temperature. After removing the solvent under vacuum, the resultant solid was washed first with hexanes (3 × 2 mL) then with diethyl ether (3 × 2 mL). After drying, **10** (78 mg) was recovered as a yellow solid in 92% yield. For characterization see ref.[21]

Complex 11: A mixture of [Pd(COD)Cl_2] (28 mg, 0.1 mmol) and **8** (71 mg, 0.1 mmol) in THF (10 mL) was stirred for 1 h at room temperature. After removing the solvent under vacuum, the so-obtained solid was washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). After drying, **11** (76 mg) was recovered as a yellow powder in 78% yield. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.20 [t, ^3J(H−H) = 7.0, 3 H, CH_3], 4.30 [dq, ^2J(H-P_A) = 9, ^4J(H−H) = 7, 2 H, CH_2], 5.47 [t, ^3J(H-P_B) = 7.0, 1 H, H^4], 6.68−7.89 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 17.6 (m, CH_3), 66.0 [d, ^2J(C-P_A) = 4.6, CH_2], 95.9 [ddd, ^1J(C-P_A) = 91, ^1J(C-P_B) = 66.3, ^3J(C-$P_{B'}$) = 7.7, $C^{2,6}$], 116.1 [q, ^4J(C-P_A) = ^4J(C-P_B) = 12.2, C^4H], 128.8−129.9 (m, CH of Ph), 131.7 [dd, ^1J(C-P_B) = 84.3, ^3J(C-P_A) = 8.5, C of Ph], 132.8 [dd, ^1J(C-P_B) = 37.2, ^3J(C-P_A) = 3.8, C of Ph], 133.2−133.8 (m, CH of Ph), 141.5 [dt, ^2J(C-P_A) = 9.2, ^2J(C-P_B) = ^4J(C-$P_{B'}$) = 3.5, $C^{3,5}$], 155.5 [d, ^3J(C-P_A) = 2.3, C of Ph] ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 52.20 [AB_2, d, ^2J(P_A-P_B) = 103.0, P_B], 96.24 [AB_2, t, ^2J(P_A-P_B) = 103.0, P_A] ppm. $C_{43}H_{36}ClOP_3PdS_2$ (867.67): calcd. C 59.52, H 4.18; found C 59.14, H 3.79.

Pd Complex 12: A mixture of [Pd(COD)Cl_2] (37.9 mg, 0.13 mmol) and λ^5-phosphinine **9** (100 mg, 0.13 mmol) in CH_2Cl_2 (5 mL) was stirred for 30 min at room temperature. The so-obtained yellow precipitate was washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). After drying, complex **12** (114 mg) was recovered as a yellow solid in 90% yield . ^{1}H NMR (300 MHz, [D_6]acetone, 298 K): δ = 1.27 [t, $^3J_{H,H}$ = 6.3, 6 H, CH_3], 2.95 [dq, ^3J(H-P_A) = ^3J(H−H) = 6.3, 4 H, CH_2], 5.84 [dt, ^3J(H-P_A) = ^3J(H-P_B) = 3.5, 1 H, H^4], 6.66−7.70 (m, 30 H, CH of Ph), 9.25 (br. s, 1 H, NH) ppm. ^{31}P NMR (121.5 MHz, CH_2Cl_2, 298 K): δ = 49.32 [AB_2, d, ^2J(P_A-P_B) = 100.1, P_BPh_2], 82.18 [AB_2, t, ^2J(P_A-P_B) = 100.1, P_A]. **12** was too insoluble to give a satisfactory ^{13}C NMR spectrum. $C_{45}H_{42}Cl_2NP_3PdS_2$ (931.20): calcd. C 58.04, H 4.55; found C 57.91, H 4.37.

Pd Complex 13: A mixture of **1** (300 mg, 0.44 mmol) and [Pd(COD)Cl_2] (125 mg, 0.44 mmol) in CH_2Cl_2 (10 mL) was stirred for 15 min at room temperature. Menthol (6.9 mg, 0.44 mmol) was then added to the solution, which was stirred for a further hour at room temperature and then filtered through celite. After evaporation of the solvent, the resultant solid was washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). After drying, complex **13** was recovered as a yellow solid. Suitable crystals for X-ray structure analysis were grown by diffusion of hexanes into a solution of **13** in CH_2Cl_2. Yield 94%, 404 mg. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 0.75 [d, ^3J(H−H) = 7.1, 3 H, CH_3], 0.87 [d, ^3J(H−H) = 6.2, 3 H, CH_3], 0.95 [d, ^3J(H−H) = 6.8, 3 H, CH_3], 1.08−1.75 (m, 8 H, CH and CH_2), 2.57 [d, ^2J(H−H) = 13.4, 1 H, CH_2], 4.78−4.87 (m, 1 H, OMen), 5.65 [t, ^4J(H-P_B) = 4.3, 1 H, H^4], 6.64−7.60 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 16.7 (s, CH_3), 20.4 (s, CH_3), 21.2 (s, CH_3), 22.4 (s, CH_2), 24.4 (s, CH), 31.3 (s, CH), 33.6 (s, CH_2), 44.2 (s, CH_2), 48.9 [d, ^3J(C-P_A) = 6.6, O−CH−CH], 77.2 [d, ^1J(C-P_A) = 6.4, O-CH], 116.6 [AB_2X, q, ^4J(C-P_A) = ^4J(C-P_B) = 10.7, C^4H], 127.0−128.2 (m, CH of Ph), 130.1 [dd, ^1J(C-P_B) = 83.3, ^3J(C-P_A) = 7.6, C of Ph], 130.4 [dd, ^1J(C-P_B) = 84.3, ^3J(C-P_A) = 7.2, C of Ph], 131.2−132.1 (m, CH of Ph), 139.2 (m, $C^{3,5}$), 155.8 (br. s, C of Ph), 156.4 (br. s, C of Ph). C^2 and C^6 not observed. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 47.67 [ABB′, d, ^2J(P_A-P_B) = 111.3, P_B], 49.89 [ABB′, d, ^2J(P_A-$P_{B'}$) = 104.1, $P_{B'}$], 88.24 [ABB′, dd, ^2J(P_A-P_B) = 111.3, ^2J(P_A-$P_{B'}$) = 104.1, P_A] ppm. $C_{51}H_{50}ClONP_3PdS_2$ (977.87): calcd. C 62.64, H 5.15; found C 62.19, H 4.84.

Pd Complex 14: A mixture of **1** (100 mg, 0.15 mmol) and [Pd(COD)Cl_2] (42 mg, 0.15 mmol) in THF (5 mL) was stirred for 15 min at room temperature. In a glove-box, Et_2NLi (15 mg, 0.19 mmol) was added to the solution which was then stirred for 30 min at room temperature. The solvent was subsequently removed under vacuum and the resultant solid washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). After evaporation of the solvent, the resulting solid was dissolved in CH_2Cl_2 and filtered through celite. After drying, complex **14** was recovered as a yellow solid. Suitable crystals for X-ray structure analysis were grown by diffusion of hexanes into a solution of CH_2Cl_2. Yield: 89%, 132 mg. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.14 [t, ^3J(H−H) = 7.1, 6 H, CH_3], 4.30 [dq, ^3J(H-P_A) = 11.3, ^4J(H−H) = 7.1, 4 H, CH_2], 5.45 [t, ^4J(H-P_B) = 4.9, H^4], 6.71−7.52 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 11.1 (s, CH_3), 42.1 (m, CH_2), 89.1 [ddd, ^1J(C-P_A) = 89.0, ^1J(C-P_B) = 64.3, ^3J(C-$P_{B'}$) = 7.6, $C^{2,6}$], 115.0 [td, ^4J(C-P_B) = 10.3, ^4J(C-P_A) = 2.9, C^4H], 127.6−128.8 (m, CH of Ph), 131.6 [dd, ^1J(C-P_B) = 78.9, ^3J(C-P_A) = 5.4, C of Ph], 132.4 [dd, ^1J(C-P_B) = 84.3, ^3J(C-P_A) = 5.7, C of Ph], 132.1−132.7 (m, C of Ph), 141.5 [m,

Σ^2J(C-P) = 14.8, $C^{3,5}$], 155.5 (m, C of Ph) ppm. ^{31}P NMR (121.5 MHz, CH_2Cl_2, 298 K): δ = 51.77 [AB_2, d, $^2J(P_A\text{-}P_B)$ = 100.0, P_B], 66.46 [AB_2, t, $^2J(P_A\text{-}P_B)$ = 100.0, P_A] ppm. $C_{45}H_{41}ClNP_3PdS_2$ (894.74): calcd. C 60.41, H 4.62; found C 59.96, H 4.13.

Anion 15: A solution of MeLi in Et_2O (1.8 mL, C = 0.16 M, 0.29 mmol) was added by syringe into a solution of **1** (200 mg, 0.29 mmol) in THF (10 mL) at −78 °C. The solution was then warmed to room temperature and stirred for 20 min. After drying, **15** (206 mg) was recovered as a red solid in 100% yield. ^{1}H NMR (300 MHz, [D$_8$]THF, 298 K): δ = 0.99 [d, $^2J(H\text{-}P_A)$ = 3.4, 3 H, CH_3], 5.13 [t, $^4J(H\text{-}P_B)$ = 4.8, 1 H, H^4], 6.53−7.57 (m, 30 H, CH of Ph) ppm. ^{31}P NMR (121.5 MHz, [D$_8$]THF, 298 K): δ = 45.87 [AB_2, d, $^2J(P_A\text{-}P_B)$ = 155.5, P_B], −65.70 [AB_2, t, $^2J(P_A\text{-}P_B)$ = 155.5, P_AMe].

λ^5-Phosphinine 16: A solution of MeLi in Et_2O (1.8 mL, C = 0.16 M, 0.29 mmol) was added by syringe into a solution of **1** (200 mg, 0.29 mmol) in THF (10 mL) at −78 °C. The solution was then warmed to room temperature and stirred for 20 min. Complete formation of **15** was checked by ^{31}P NMR spectroscopy. After cooling at −78 °C, C_2Cl_6 (69 mg, 0.29 mmol) was added and the resultant solution was warmed to room temperature and stirred for a further 20 min. After removing the solvent, the solid was washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). The so-obtained solid was then dissolved in CH_2Cl_2 and filtered through celite. After drying, **16** (201 mg) was recovered as a yellow solid in 95% yield. ^{1}H NMR (300 MHz, [D$_8$]THF, 298 K): δ = 2.04 [d, $^2J(H\text{-}P_A)$ = 15.1, 3 H, CH_3], 6.16 [vq, $^4J(H\text{-}P_B)$ = $^4J(H\text{-}P_B)$ = 4.1, 1 H, H^4], 6.97−8.15 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, [D$_8$]THF, 298 K): δ = 18.6 [d, $^1J(C\text{-}P_A)$ = 67.3, CH_3], 83.8 [dd, $^1J(C\text{-}P_A)$ = 90.9, $^1J(C\text{-}P_B)$ = 83.1, $^3J(C\text{-}P_{B'})$ = 3.2, $C^{2,6}$], 117.7 [dt, $^3J(C\text{-}P_A)$ = 27.8, $^3J(C\text{-}P_B)$ = 9.0, C^4H], 128.5−138.7 (m, C and CH of Ph), 143.5 [m, ΣJ(C-P) = 18.3, $C^{3,5}$], 157.6 [d, ^3J(C-P) = 5.3, C of Ph] ppm. ^{31}P NMR (121.5 MHz, [D$_8$]THF, 298 K): δ = 65.62 [AB_2, t, $^2J(P_A\text{-}P_B)$ = 42.5, P_A], 35.16 [AB_2, d, $^2J(P_A\text{-}P_B)$ = 42.5, P_B] ppm. MS (EI): m/z = 732 [M$^+$]. **16** was too moisture sensitive to give satisfactory elemental data.

Pd Complex 17: A mixture of [Pd(dba)$_2$] (79 mg, 0.14 mmol) and **16** (100 mg, 0.14 mmol) in CH_2Cl_2 (5 mL) was stirred for 30 min at room temperature. After evaporation of the solvent, the resultant solid was washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). After drying, **17** (108 mg) was recovered as a brown powder in 92% yield. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.88 [d, $^2J(H\text{-}P_A)$ = 9.6, 3 H, CH_3], 5.42 [t, $^4J(H\text{-}P_B)$ = 4.4, 1 H, H^4], 6.61−7.47 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 24.3 (m, CH_3), 74.2 [dd, $^1J(C\text{-}P_A)$ = 97.4, $^1J(C\text{-}P_B)$ = 53.0, $C^{2,6}$], 117.7 [m, ΣJ(C-P) = 36.5, C^4H], 127.6−132.5 (m, C and CH of Ph), 141.5 [m, ΣJ(C-P) = 23.1, $C^{3,5}$], 158.9 (s, C of Ph) ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 49.44 [AB_2, m, $^2J(P_A\text{-}P_B)$ = 35.0, P_A], 50.44 [AB_2, m, $^2J(P_A\text{-}P_B)$ = 35.0, P_B] ppm. $C_{42}H_{34}ClP_3PdS_2$ (837.65): calcd. C 60.22, H 4.09; found C 59.83, H 3.86.

Ni Complex 18: A mixture of [Ni(dme)Br$_2$] (136 mg, 0.44 mmol) and **1** (300 mg, 0.44 mmol) in CH_2Cl_2 (10 mL) was stirred for 1 h at 40 °C. After evaporation of the solvent, the resulting solid was washed with hexanes (3 × 2 mL) and, after drying, complex **18** (384 mg) was then recovered as a brown powder in 97% yield. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 55.92 [AB_2, d, $^2J(P_A\text{-}P_B)$ = 137.4, P_BPh_2], 98.52 [AB_2, t, $^2J(P_A\text{-}P_B)$ = 137.4, P_A]. Complex **18** was too moisture sensitive to give satisfactory elemental data.

Pt Complex 19: A mixture of [Pt(COD)Cl$_2$] (165 mg, 0.44 mmol) and **1** (300 mg, 0.44 mmol) in CH_2Cl_2 (10 mL) was stirred for 15 min at room temperature. After evaporation of the solvent, the resulting solid was washed with hexanes (3 × 2 mL) and then dried to afford complex **19** (400 mg) as a yellow powder in 96% yield. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 47.99 [AB_2, d, $^2J(P_A\text{-}P_B)$ = 109.1, P_B], 67.10 [AB_2M, td, $^1J(P_A\text{-Pt})$ = 3860.3, $^2J(P_A\text{-}P_B)$ = 109.1, P_A].

Ni Complex 20: A solution of [Ni(dme)Br$_2$] (136 mg, 0.44 mmol) and **1** (300 mg, 0.44 mmol) in CH_2Cl_2 (10 mL) was stirred for 30 min at room temperature and then ethanol (200 μL, 3.4 mmol) was added. After stirring for 15 min at room temperature, the solvent was removed under vacuum and the resulting solid was washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). After drying, complex **20** (365 mg) was recovered as a brown powder in 96% yield. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.27 [d, $^3J(H\text{−}H)$ = 7.0, CH_3], 4.52 [AB_2X, dq, $^3J(H\text{−}H)$ = $^3J(H\text{-}P_A)$ = 7.2, 2 H, CH_2], 6.73−7.82 (m, 31 H, H^4 and CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 16.4 [d, $^3J(C\text{-}P_A)$ = 8.0, CH_3], 65.4 [d, $^2J(C\text{-}P_A)$ = 4.0, CH_2], 95.9 [m, ΣJ(C-P) = 158.1, $C^{2,6}$], 114.8 [q, $^3J(C\text{-}P_A)$ = $^3J(C\text{-}P_B)$ = 10.1, C^4H], 127.6−132.5 (m, C and CH of Ph), 140.9 [p, $^2J(C\text{-}P_A)$ = $^2J(C\text{-}P_B)$ = $^4J(C\text{-}P_{B'})$ = 3.4, $C^{3,5}$], 154.4 (s, C of Ph) ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 58.26 [AB_2, d, $^2J(P_A\text{-}P_B)$ = 123.9, P_B], 104.57 [AB_2, t, $^2J(P_A\text{-}P_B)$ = 123.9, P_A] ppm. $C_{43}H_{36}BrNiOP_3S_2$ (864.40): calcd. C 59.75, H 4.20; found C 59.29, H 3.80.

Pt Complex 21: A solution of [Pt(COD)Cl$_2$] (165 mg, 0.44 mmol) and **1** (300 mg, 0.44 mmol) in CH_2Cl_2 (10 mL) was stirred for 15 min at room temperature and ethanol (200 μL, 3.4 mmol) was then added. After stirring for a further 15 min at room temperature, the solvent was removed under vacuum and the resulting solid was washed first with hexanes (3 × 2 mL) and then with diethyl ether (3 × 2 mL). After drying, complex **21** (400 mg) was recovered as a yellow powder in 95% yield. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.38 [d, $^3J(H\text{−}H)$ = 7.0, CH_3], 4.31 [dq, $^3J(H\text{-}P_A)$ = 9.0, $^3J(H\text{−}H)$ = 7.0, 2 H, CH_2], 5.66 [dt, $^4J(H\text{-}P_B)$ = 4.8, $^4J(H\text{-}P_A)$ = 0.8, 1 H, H^4], 6.69−7.67 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 16.6 [d, $^3J(C\text{-}P_A)$ = 7.3, CH_3], 62.7 [d, $^2J(C\text{-}P_A)$ = 5.0, CH_2], 88.8 [ddd, $^1J(C\text{-}P_A)$ = 92.6, $^1J(C\text{-}P_B)$ = 80.0, $^3J(C\text{-}P_{B'})$ = 5.0, $C^{2,6}$], 116.3 [q, $^4J(C\text{-}P_A)$ = $^4J(C\text{-}P_B)$ = 12.8, C^4H], 127.6−128.8 (m, CH of Ph), 130.7 [dd, $^1J(C\text{-}P_B)$ = 83.9, $^3J(C\text{-}P_A)$ = 5.7, C of Ph], 131.5 [dd, $^1J(C\text{-}P_B)$ = 86.6, $^3J(C\text{-}P_A)$ = 3.4, C of Ph], 132−132.8 (m, C of Ph), 140.5 [dt, $^2J(C\text{-}P_A)$ = 8.3, $^2J(C\text{-}P_B)$ = $^4J(C\text{-}P_{B'})$ = 2.9, $C^{3,5}$], 155.5 (s, C of Ph) ppm. ^{31}P NMR (121.5 MHz, CD_2Cl_2, 298 K): δ = 48.86 [AB_2M, d, $^2J(P_A\text{-}P_B)$ = 98.5, P_B], 65.47 [AB_2M, t, $^1J(P_A\text{-Pt})$ = 3640.0, $^2J(P_A\text{-}P_B)$ = 98.5, P_A] ppm. $C_{43}H_{36}ClOP_3PtS_2$ (956.33): calcd. C 54.00, H 3.79; found C 53.64, H 3.48.

Ni Complex 22: A solution of *n*BuLi in hexanes (0.275 mL, C = 1.6 M, 0.44 mmol) was added by syringe into a solution of **1** (300 mg, 0.44 mmol) in THF (10 mL) at −78 °C. The resultant solution was then warmed to room temperature and stirred for 20 min. Complete formation of **3** was checked by ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 45.80 [AB_2, d, ^2J(P-P) = 156.0, P_BPh_2], −66.20 [AB_2, t, $^2J(P_A\text{-}P_B)$ = 156.0, P_A-*n*Bu]. After cooling at −78 °C, [Ni(dme)Br$_2$] (136 mg, 0.44 mmol) was added and the solution was warmed to room temperature and stirred for 15 min. The solvent was then removed and the resulting solid was dissolved in CH_2Cl_2 (8 mL) and filtered through celite. After evaporating the solvent under vacuum, the solid was washed several times with hexanes (3 × 2 mL) and diethyl ether (3 × 2 mL). After drying, **22** was recovered as a

brown solid. Suitable crystals for X-ray structure analysis were grown from a diffusion of hexanes into a solution of CH_2Cl_2. Yield: 91%, 350 mg. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 0.97 [t, ^3J(H-H) = 7.2, 3 H, CH_3], 1.53 (m, 2 H, CH_2), 2.00 (br. s, 4 H, CH_2), 5.38 [t, ^4J(H-P_B) = 4.2, 1 H, H^4], 6.62−7.44 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 12.8 (s, CH_3), 23.2 [d, ^3J(C-P_A) = 13.7, CH_2], 25.2 (s, CH_2), 38.9 [d, ^1J(C-P_A) = 25.7, CH_2], 72.5 (m, $C^{2,6}$), 118.6 (m, C^4H), 126.7−132.0 (m, CH and C of C_6H_5), 139.4 [d, ^2J(C-P_A) = 6.8, $C^{3,5}$], 158.1 (s, C of C_6H_5) ppm. ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 57.34−63.09 (m, AB_2) ppm. $C_{45}H_{40}BrNiP_3S_2$ (876.45): calcd. C 61.67, H 4.60; found C 61.31, H 4.24.

Pt Complex 23: A solution of *n*BuLi in hexanes (0.275 mL, C = 1.6 M, 0.44 mmol) was added by syringe into a solution of **1** (300 mg, 0.44 mmol) in THF (10 mL) at −78 °C. The resultant solution was then warmed to room temperature and stirred for 20 min. Complete formation of **3** was checked by ^{31}P NMR spectroscopy. After cooling at −78 °C, [Pt(COD)Cl_2] (165 mg, 0.44 mmol) was added and the solution was warmed to room temperature and stirred for 15 min. The solvent was then evaporated and the resulting solid was dissolved in CH_2Cl_2 (8 mL) and filtered through celite. After removing the solvent under vacuum, the solid was washed several times with hexanes (3 × 2 mL) and diethyl ether (3 × 2 mL), and, after drying, **23** (392 mg) was recovered as a yellow solid in 92% yield. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.1−2.22 (m, 9 H, CH_3 and CH_2), 5.60 [br. d, ^4J(H-P_A) = 2.4, 1 H, H^4], 6.70−7.70 (m, 30 H, CH of C_6H_5) ppm. ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 21.52 [AB_2M, td, ^2J(P_A-Pt) = 3030.6, ^2J(P_A-P_B) = 81.0, P_A], 46.95 [AB_2M, d, ^2J(P_A-P_B) = 87.0, P_B]. **24** was too insoluble in common solvents to give a satisfactory ^{13}C NMR spectrum. $C_{45}H_{40}ClP_3PtS_2$ (968.38): calcd. C 55.81, H 4.16; found C 55.43, H 3.75.

Pd Complex 24: Acetonitrile (50 μL, 0.96 mmol) was added to a mixture of **4** (150 mg, 0.17 mmol) and $AgBF_4$ (37 mg, 0.19 mmol) in CH_2Cl_2 (5 mL). The resultant solution was stirred for 15 min at room temperature and was then filtered through celite. After drying, **24** (140 mg) was recovered as an orange powder in 85% yield. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.05 [t, ^3J(H−H) = 7.3, 3 H, CH_3 of *n*Bu], 1.62 [qt, ^3J(H−H) = 14.6, ^3J(H−H) = 7.3, CH_2], 2.03 (m, 2 H, CH_2), 2.26 (m, 2 H, CH_2), 2.23 (s, 3 H, CH_3 of CH_3CN), 2.44 (m, 2 H, CH_2), 5.60 [t, ^4J(H-P_B) = 5.1, 1 H, H^4], 6.69−7.89 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 8.6 (s, CH_3 of CH_3CN), 13.4 (s, CH_3 of *n*Bu), 23.5 [d, ^3J(C-P_A) = 17.2, CH_2], 25.7 [d, ^2J(C-P_A) = 15.7, CH_2], 45.2 [d, ^1J(C-P_A) = 38.2, CH_2], 71.5 (m, $C^{2,6}$), 119.3 (m, C^4H), 126.2 [d, ^2J(C-P_A) = 25.5, C of CH_3CN], 125.2−134.5 (m, CH and C of Ph), 138.4 [ABB′X, dt, ^2J(C-P_A) = ^2J(C-P_B) = 9.0, ^4J(C-$P_{B'}$) = 3.1, $C^{3,6}$], 163 (m, C of Ph) ppm. ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 49.72 [AB_2, d, ^2J(P_A-P_B) = 69.6, P_BPh_2], 64.61 [AB_2, t, ^2J(P_A-P_B) = 69.6, P_A] ppm. $C_{47}H_{43}BF_4NP_3PdS_2$ (972.13): calcd. C 58.07, H 4.46; found C 57.67, H 4.02.

Pd Complex 25: Acetonitrile (50 μL, 0.96 mmol) was added to a mixture of **11** (148 mg, 0.17 mmol) and $AgBF_4$ (37 mg, 0.19 mmol) in CH_2Cl_2 (5 mL). After stirring for 15 min at room temperature, the solution was filtered through celite. After drying, **25** (155 mg) was recovered as an orange powder in 95% yield. ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.35 [t, ^3J(H−H) = 7.0, 3 H, CH_3 of EtO], 2.20 (s, 3 H, CH_3 of CH_3CN), 4.22 [dq, ^3J(H-P_A) = 1.2, ^3J(H−H) = 7.0, 2 H, CH_2], 5.71 [t, ^4J(H-P_B) = 4.9, 1 H, H^4], 6.69−7.79 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 2.3 (s, CH_3), 16.2 [d, ^3J(C-P_A) = 8.6, CH_3], 66.9 [d, ^2J(C-P_A) = 8.1, CH_2], 91.6 [ddd, ^1J(C-P_A) = 93.2, ^1J(C-P_B) = 71.0, ^3J(C-$P_{B'}$) = 7.7, $C^{2,6}$], 117.1 [q, ^4J(C-P_A) = ^4J(C-P_B) = 12.2, C^4H], 121.2 (br. s, C of CH_3CN), 127.8 [dd, ^1J(C-P_B) = 84.7, ^3J(C-P_A) = 7.4, C of Ph], 128.1 [ABX, d, ^1J(C-P_B) = 86.6, C of Ph], 128.1−134.8 (m, CH of Ph), 139.0 [dt, ^2J(C-P_A) = 9.1, ^2J(C-P_B) = ^4J(C-$P_{B'}$) = 3.5, $C^{3,5}$], 160.5 (s, C of Ph) ppm. ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 49.03 [AB_2, d, ^2J(P_A-P_B) = 85.5, P_B], 87.81 [AB_2, t, ^2J(P_A-P_B) = 85.5, P_A] ppm. $C_{45}H_{39}BF_4NOP_3PdS_2$ (960.08): calcd. C 56.30, H 4.09; found C 55.84, H 3.75.

Ni Complex 26: Acetonitrile (50 μL, 0.96 mmol) was added to a mixture of **20** (138 mg, 0.16 mmol) and $AgBF_4$ (37 mg, 0.19 mmol) in CH_2Cl_2 (5 mL), and the resultant solution was stirred for 15 min at room temperature. The solution was then filtered through celite and, after drying, **26** was recovered as a brown powder (yield: 92%, 134 mg). ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.20 (br. s, 3 H, CH_3 of Et), 2.30 (br. s, 3 H, CH_3 of CH_3CN), 4.15 (br. s, 2 H, CH_2), 5.60 (br. s, 1 H, H^4), 6.40−7.80 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 7.8 (s, CH_3 of CH_3CN), 15.7 [s, ^3J(C-P_A) = 8, CH_3 of Et], 64.6 [d, ^2J(C-P_A) = 6.9, CH_2], 91.9 (m, $C^{2,6}$), 115.1 [q, ^4J(C-P_A) = ^4J(C-P_B) = 9.8, C^4H], 127.19−132.4 (m, CH and C of Ph and C of CH_3CN), 139.0 [dt, ^4J(C-P_B) = 8, ^2J(C-P_A) = ^2J(C-P_B) = 4, $C^{3,5}$], 156.5 (s, C of Ph) ppm. ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 55.22 [AB_2, d, ^2J(P_A-P_B) = 106.3, P_B], 88.79 [AB_2, t, ^2J(P_A-P_B) = 106.3, P_A] ppm. $C_{45}H_{39}BF_4NNiOP_3S_2$ (912.35): calcd. C 59.24, H 4.31; found C 58.79, H 3.92.

Pt Complex 27: Acetonitrile (50 μL, 0.96 mmol) was added to a mixture of **21** (153 mg, 0.16 mmol) and $AgBF_4$ (37 mg, 0.19 mmol) in CH_2Cl_2 (5 mL). After stirring for 15 min at room temperature, the solution was filtered through celite. After drying, **27** was recovered as a yellow powder (yield: 93%, 156 mg). ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.49 [t, ^3J(H−H) = 7.0, 3 H, CH_3 of Et], 2.37 (s, 3 H, CH_3 of CH_3CN), 4.15 [p, ^3J(H-P_B) = ^3J(H−H) = 7.0, 2 H, CH_2], 5.97 [t, ^4J(H-P_B) = 5.1, 1 H, H^4], 6.75−7.82 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 3.5 (s, CH_3), 16.5 [d, ^3J(C-P_A) = 7.5, CH_3], 65 [d, ^2J(C-P_A) = 9.8, CH_2], 84.5 [ddd, ^1J(C-P_A) = 96.8, ^1J(C-P_B) = 87.2, ^3J(C-$P_{B'}$) = 5.6, $C^{2,6}$], 118.5 [q, ^4J(C-P_A) = ^4J(C-P_B) = 2.1, C^4H], 125.0 [d, ^2J(C-P_A) = 21.4, C of CH_3CN], 127 [dd, ^1J(C-P_B) = 91.0, ^3J(C-P_A) = 4.1, C of Ph], 128 [dd, ^1J(C-P_B) = 95.7, ^3J(C-P_A) = 3.7, C of Ph], 128.1−134.8 (m, CH of Ph), 139 (m, $C^{3,5}$), 160.5 (s, C of Ph) ppm. ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 48.92 [AB_2M, d, ^2J(P_A-P_B) = 80.4, P_B], 54.60 [AB_2M, ptt, ^1J(P_A-Pt) = 3592.9, ^2J(P_A-P_B) = 75.2, P_A] ppm. $C_{45}H_{39}BF_4NOP_3PtS_2$ (1048.73): calcd. C 51.54, H 3.75; found C 51.29, H 3.24.

Pd Complex 28: A mixture of **4** (97 mg, 0.11 mmol) and AgOTf (37 mg, 0.19 mmol) was stirred in CH_2Cl_2 (3 mL) for 15 min at room temperature and filtered through celite. After drying, **28** was recovered as a red powder (yield: 87%, 95 mg). ^{1}H NMR (300 MHz, CD_2Cl_2, 298 K): δ = 1.05 [t, ^3J(H−H) = 6.9, 3 H, CH_3], 1.62 [qt, ^3J(H−H) = 6.9, ^3J(H−H) = 13.8, CH_2], 1.92−2.06 (m, 2 H, CH_2), 2.19−2.31 (m, 2 H, CH_2), 5.50 [t, ^4J(H-P_B) = 4.7, 1 H, H^4], 6.68−7.56 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 13.9 (s, CH_3 of *n*Bu), 23.5 [d, ^3J(C-P_A) = 2.6, CH_2], 25.5 [d, ^2J(C-P_A) = 2.6, CH_2], 38.3 (m, CH_2), 71.6 (m, $C^{2,6}$), 118.6 [q, ^4J(C-P_A) = ^4J(C-P_B) = 10.6, C^4H], 127.7−128.8 (m, CH of Ph), 131.1 [dd, ^1J(C-P_B) = 83.8, ^3J(C-P_A) = 8.3, C of Ph], 131.9−133.0 (m, CH of Ph), 139.6 (m, $C^{3,5}$), 159.5 ppm (m, C of Ph), CF_3 not observed. ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 49.47 [AB_2, d, ^2J(P_A-P_B) = 84.4, P_B], 56.05 [AB_2,

t, $^2J(P_A\text{-}P_B)$ = 84.4, P_A] ppm. $C_{46}H_{40}F_3O_3P_3PdS_3$ (993.34): calcd. C 55.62, H 4.06; found C 55.43, H 3.86.

λ⁵-Dimethylphosphinine 29: A solution of MeLi in hexanes (275 μL, *C* = 1.6 M, 0.44 mmol) was added by syringe into a solution of **1** (300 mg, 0.44 mmol) in THF (10 mL) at −78 °C. The resultant solution was then warmed to room temperature and stirred for 20 min. Complete formation of **15** was checked by ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 44.83 [AB_2, d, $^2J(P_A\text{-}P_B)$ = 156.7, P_B], −66.52 [AB_2, t, $^2J(P_A\text{-}P_B)$ = 156.7, P_A]. After cooling at −78 °C, MeI (50 μL, 0.80 mmol) was added and the solution was warmed to room temperature and stirred for 15 min. The solvent was then evaporated and the resulting solid was dissolved in CH_2Cl_2 (8 mL) and filtered through celite. After removing the solvent under vacuum, the solid was washed several times with hexanes (3 × 2 mL) and then diethyl ether (3 × 2 mL). After drying, **29** was recovered as an orange powder. Suitable crystals for X-ray structure analysis were grown by diffusion of hexanes into a solution of $CDCl_3$.Yield: 89%, 278 mg. ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = 1.64 [d, $^2J(P_A-H)$ = 13.4, 6 H, CH_3], 5.34 [t, $^4J(H\text{-}P_B)$ = 4.8, 1 H, H^4], 6.71−7.81 (m, 30 H, CH of Ph) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K): δ = 12.2 [d, $^1J(C\text{-}P_A)$ = 58.4, CH_3], 67.0 [ddd, $^1J(C\text{-}P_A)$ = 88.8, $^1J(C\text{-}P_B)$ = 76.9, $^3J(C\text{-}P_{B'})$ = 2.9, $C^{2,6}$], 118.5 [m, ΣJ(C-P) = 42.8, C^4H], 127.6−131.9 (m, CH of Ph), 136.5 [dd, $^1J(C\text{-}P_B)$ = 85.4, $^3J(C\text{-}P_A)$ = 2.5, C of Ph], 142.8 [ddd, $^2J(C\text{-}P_A)$ = 10.9, $^2J(C\text{-}P_B)$ = 6.9, $^4J(C\text{-}P_{B'})$ = 3.3,$C^{3,5}$], 157.8 (s, C of Ph) ppm. ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 20.77 [AB_2, t, $^2J(P_A\text{-}P_B)$ = 41.1, P_A], 37.44 [AB_2, d, $^2J(P_A\text{-}P_B)$ = 41.1, P_B] ppm. MS (EI): *m*/*z* = 712 [M^+]. $C_{43}H_{37}P_3S_3$ (710.81): calcd. C 72.66 H, 5.25; found C 72.28 H, 4.91.

Anion 30: In a glove-box, a mixture of **1** (150 mg, 0.22 mmol) and MeONa (36 mg, 0.66 mmol) in THF (5 mL) was stirred for 15 min. After drying, **30** was recovered as a yellow powder. Suitable crystals for X-ray structure analysis were grown from a diffusion of hexanes into a solution of THF. ^{31}P NMR (121.5 MHz, THF, 298 K): δ = 44.60 [AB_2, d, $^2J(P_A\text{-}P_B)$ = 153.2, P_B], 66.55 [AB_2, dd, $^2J(P_A\text{-}P_B)$ = 148.4, P_A] ppm. **30** was too moisture sensitive to give satisfactory elemental data.

X-ray Crystallographic Study: Crystals of compounds **1** (Table 5), **5**, **6**, **13** (Table 6), **14**, **22** (Table 7), **29** and **30** (Table 5) suitable for X-ray diffraction were obtained by slow diffusion of hexanes into a CH_2Cl_2 solution for **1**, **5**, **13**, **14**, **22**, into a $CDCl_3$ solution for **6**, **29**, and into a THF solution for **30**. Data were collected at 150.0(1) K on a Nonius Kappa CCD diffractometer using a Mo-*K*α (λ = 0.71070 Å) X-ray source and a graphite monochromator. All data were measured using phi and omega scans. Experimental details are described in tables 1, 3 and 4. The crystal structures were solved using SIR 97[45] and Shelxl-97.[46] ORTEP drawings were made using ORTEP III for Windows.[47] CCDC-210894 to 210900 and 210982 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Theoretical Methods: The calculations were performed with the GAUSSIAN 98 series of programs.[48] The geometries of compounds I and II were optimized using the gradient-corrected

density functional theory (DFT) utilizing Becke's three-parameter hybrid method B3LYP.[49,50] The standard 6-311+G(d,p) basis set was used for all atoms (C, H, P, O, N, and S). Harmonic frequencies were calculated at the same level of theory to characterize the stationary points and to determine the zero-point energies (ZPE). Intrinsic reaction coordinates calculations (IRC) were performed to ensure that the transition states found for the (1,2) hydrogen-shift actually connect the two products. Final energies were optimized, including ZPE energies scaled by the empirical factor of 0.9806. All optimized structures reported here have only positive eigenvalues of the Hessian matrix, i.e. they are minima on the potential energy surface. Optimizations of complexes **III**, **IV**, and **V** were also carried out with the hybrid B3LYP functional. The basis set is identical to that used by Frenking and co-workers in many studies.[51] The basis set, which is known as "Basis set II", incorporates the Hay−Wadt small-core relativistic effective core potential[52] and double-ζ valence basis set (441/2111/31) in conjunction with the all-electron 6-31G(d) basis sets for the main-group elements, H, C, O, P, S, Cl.

Inspection of ligand-to-metal donor−acceptor interactions were performed by charge-decomposition analysis (CDA).[53] In the CDA method the (canonical, natural, or Kohn Sham) molecular orbitals of the complex are expressed in terms of MOs of appropriately chosen fragments. In the cases studied the Kohn−Shan orbitals of the B3LYP/II calculations are formed in the CDA procedure as a linear combination of the MOs of the SPS anionic ligand and those of the remaining cationic fragment $[PdCl]^+$ for complexes **IIIa**, **b**. The same method was used to analyze complexes **IVa**, **b**, and **V**, but the two fragments are the neutral ligand $[RP(CH_2PH_2S)_2]$, and the cationic fragment $[PdCl]^+$. In both cases, the ligands and the metal fragments were computed in the geometry of the complex. The orbital contributions are divided into four parts: (i) the mixing of the occupied MOs of the ligand and the unoccupied MOs of the metal fragment. This value (denoted *d*) represents the donation ligand → [metal fragment]; (ii) the mixing of the unoccupied MOs of the ligand and the occupied MOs of the metal fragment. This value (denoted *b*) accounts for the back donation [metal fragment] → ligand; (iii) the mixing of the occupied MOs of the ligand and the occupied MOs of the metal fragment. This term (denoted *r*), which describes the repulsive polarization ligand ⇄ [metal fragment], is negative because electronic charge is removed from the overlapping area of the occupied orbitals; (iv) the residual term (Δ) which results from the mixing of the unoccupied MOs of the two respective fragments. Usually this term is very close to zero for closed-shell interactions. This value constitutes an important probe to determine whether the bonding studied can be really classified as a donor−acceptor interaction following the Dewar−Chatt−Duncansson model. Important deviations from $\Delta = 0$ imply that the bond studied is more conventionally described as a normal covalent bond between two open shell fragments. A more detailed presentation of the CDA method and the interpretation of the results can be found in the literature.[53] CDA calculations were performed with the program CDA version 2.1.[54] These calculations were also performed with the Gaussian-98 program. The charge distributions in the optimized structures were calculated with the NBO partitioning scheme.[55]

Supporting Information Available: ORTEP drawing of compound **5** and geometrical parameters of theoretical structure of **Ia-Ie**, **TSa-TSd**, **IIa−IIe**, **IIIa**, **IIIb**, **IVa**, **IVb**, and **V**.

Synthesis, Characterisation of (Arene)tricarbonylchromium Complexes Linked to Cationic Fe and Ru Derivatives and Studies of First Hyperpolarisabilities by Hyper-Rayleigh Scattering

Maria Helena Garcia,*[a,b] Sophie Royer,[b] Maria Paula Robalo,*[b,c] Alberto Romão Dias,[b] Jean-Philippe Tranchier,[d] René Chavignon,[d] Damien Prim,[d] Audrey Auffrant,[d] Françoise Rose-Munch,[d] Eric Rose,*[d] Jacqueline Vaissermann,[e] André Persoons,[f] and Inge Asselberghs[f]

Keywords: Chromium / Iron / Ruthenium / Non-linear optics / Arene ligands / Carbonyl ligands / Hyperpolarisability

In order to investigate the non-linear optical properties, in particular second-order effects of binuclear organometallic complexes, a series of new cationic binuclear [MCp(DPPE)N≡C–(spacer)–C≡C–$C_6H_5Cr(CO)_3$]$^+$[PF_6]$^-$ compounds and mononuclear precursors [N≡C–(spacer)–C≡C–$C_6H_5Cr(CO)_3$] have been synthesised [where M = Fe^{II} or Ru^{II}; Cp = η^5-C_5H_5 and spacer = phenyl ring (C_6H_4), thiophene, (C_4H_2S), or bithiophene ($C_4H_2S)_2$]. The Fe or Ru organometallic π-donor fragments were linked by an extended π system to the acceptor $Cr(CO)_3$ fragment. The effect of π back-donation involving the second Fe or Ru metal centre and the π* orbitals of the N≡C-coordinated group, was probed by the $\nu_{(N\equiv C)}$ stretching bands on the IR spectra and also by NMR spectroscopic data. The planarity, largely due to the π-electron resonance, found on the solid state structure of the mononuclear complex [N≡C–C_6H_5–C≡C–(η^6-C_6H_5)$Cr(CO)_3$] (**1Cr**) determined by X-ray diffraction [monoclinic system, $P2_1/c$ space group, with a = 10.326(2) Å, b = 13.209(5) Å, c = 11.799(2) Å and Z = 4] emphasises the electronic effect of this building block. The significant values of first hyperpolarisability β determined by hyper-Rayleigh scattering (HRS) indicate that the Fe containing compounds were more efficient on second-order non-linear optical properties than the ruthenium analogues and the parent mononuclear chromium compounds.

Introduction

Over the past decade a pattern has emerged for the design of organometallic materials with large second-order optical non-linearities, in which the molecules have important changes of dipole moments between ground and excited states and large transition dipole moments.[1] Using this molecular criteria, organometallic and coordination chemists have synthesised compounds possessing very intense metal-to-ligand and ligand-to-metal charge transfer bands in the UV/Visible spectrum, which showed very large molecular hyperpolarisabilities.[2] The use of organometallic polarising groups in dipole structures has been of growing interest in the search for new molecular materials for non-linear optics, and various binuclear compounds have been published in the literature presenting significant values of first hyperpolarisabilities β. Representative examples are the ferrocenyl derivatives where the best reported β values are found for bimetallic compounds possessing an (η^5-thiophene)$Mn(CO)_3$,[3] a group 6 pentacarbonyl,[4] or an η^7-cycloheptatrienyltricarbonylchromium[5] as the acceptor moieties. Also indenyl or cyclopentadienylruthenium(II) donor moieties and group 6 pentacarbonyl or pentaminaruthenium(III) acceptor partners have been used successfully as building blocks for the synthesis of bimetallic non-linear optical (NLO) active systems.[6]

Our approach to the synthesis of bimetallic molecules for NLO purposes, was based on the use of the fragment

$[M(\eta^5\text{-}C_5H_5)(P\text{-}P)]^+$ (M = Fe^{II} or Ru^{II} and P-P = diphosphane) as a π-donor building block, bridged through a π-delocalised system to the auxochrome $[\eta^6\text{-}(benzene)\text{-}Cr(CO)_3]$. The amphoteric nature has been studied in monometallic compounds.[7] The π-donor ability of the Ru^{II}/Fe^{II} fragments and the high values found for the quadratic hyperpolarisabilities of some monometallic molecules based on these moieties, have been explained on the basis of π back-donation towards the π* empty orbitals of −N≡C− and −C≡C− functional groups.[8,9]

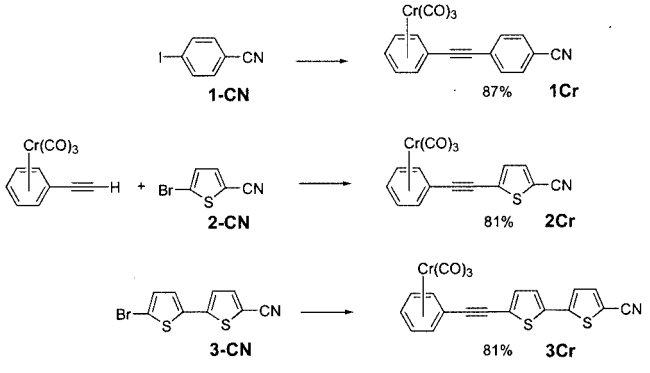
The interest surrounding the use of these $[M(\eta^5\text{-}C_5H_5)(P\text{-}P)]^+$ fragments as building blocks also comes from their cationic nature, where the contribution for the alignment of the chromophores in the solid state can be of potential interest for macroscopic NLO properties, as found for $[Fe(\eta^5\text{-}C_5H_5)\{(R)\text{-prophos}\}(p\text{-}NCC_6H_4NO_2)][PF_6]$ ($\beta = 545\cdot10^{-30}$ esu)[10].

In the present work based on donor−spacer−acceptor structures, besides the exploitation of two donor fragments based on Ru^{II} and Fe^{II} centres, we have studied different spacers, using conjugated π systems containing the benzene ring and alternatively one or two thiophene rings.

Results and Discussion

Preparation of the Mononuclear Chromium $[\{N\equiv C-(spacer)-C\equiv C-\eta^6\text{-}C_6H_5\}Cr(CO)_3]$ Complexes 1Cr, 2Cr, and 3Cr

Mononuclear chromium complexes of the general formula $[\{N\equiv C-(spacer)-C\equiv C-\eta^6\text{-}C_6H_5\}Cr(CO)_3]$, where the spacer is a phenyl ring $-C_6H_4$ (**1Cr**), a thiophene ring $-C_4H_2S$ (**2Cr**) or two thiophene rings $(C_4H_2S)_2$ (**3Cr**) were obtained[11] by a Sonogashira palladium-catalysed cross-coupling reaction[12] between the (η^6-phenyl)ethynyltricarbonylchromium complex and various bromo, iodo arenes substituted by a nitrile group, **1-CN**, **2-CN**, and **3-CN** as depicted in Scheme 1. The free ligands **1**−**3** were synthesised analogously by the palladium copper catalysed coupling of iodonitrile aromatics **1-CN**, **2-CN**, and **3-CN** and phenylacetylene, see Experim. Section.



Scheme 1. Sonogashira-coupling reactions

Preparation of the Bimetallic Iron/Chromium and Ruthenium/Chromium Derivatives

$[FeCp(DPPE)\{N\equiv C-(spacer)-C\equiv C-\eta^6\text{-}C_6H_5\}Cr(CO)_3][PF_6]$ [Cp = $\eta^5\text{-}C_5H_5$; spacer = C_6H_4: **1FeCr**, C_4H_2S (thiophene): **2FeCr**, and $(C_4H_2S)_2$ (bithiophene): **3FeCr**] were prepared following the general procedure of iodide abstraction of the parent compound [FeCp(DPPE)I] by the use of $TlPF_6$, in the presence of a slight excess of the corresponding chromophores,[13] which in the present case were the mononuclear chromium complexes **1Cr**, **2Cr**, and **3Cr** described above. The reactions were carried out in dichloromethane by stirring at room temperature for several hours, and were followed by thin layer chromatography (TLC). After workup, orange reddish crystalline compounds were obtained in a yield of ca. 90%.

$[RuCp(DPPE)\{N\equiv C-(spacer)-C\equiv C-\eta^6\text{-}C_6H_5\}Cr(CO)_3][PF_6]$ [DPPE = 1,2-diphenylphosphanyl ethane; with the spacer as C_6H_4: **1RuCr**, C_4H_2S (thiophene): **2RuCr**, and $(C_4H_2S)_2$ (bithiophene): **3RuCr**], were prepared following the same general procedure of halide abstraction, by precipitation of TlCl from the parent compound [RuCp(DPPE)Cl], with $TlPF_6$ in the presence of a slight excess of the corresponding chromophores $[\{N\equiv C-(spacer)-C\equiv C-\eta^6\text{-}C_6H_5\}Cr(CO)_3]$ (compounds **1Cr**, **2Cr**, and **3Cr**) in dichloromethane.[14] Depending on the chromium derivative, the reactions were carried out at room temperature or refluxed for several hours. The evolution of the reactions was followed by TLC, as in the case of the iron analogues. After workup orange crystalline compounds were obtained in a yield of ca. 70%.

Characterisation of the New Mono 1Cr, 2Cr, and 3Cr and Binuclear 1FeCr−3FeCr and 1RuCr−3RuCr Compounds

All the new compounds are fairly stable towards oxidation in air and to moisture, but the ruthenium bithiophene derivative $[RuCp(DPPE)\{N\equiv C-2\text{-}(5\text{-}C_4H_2S)_2-C\equiv C-\eta^6\text{-}C_6H_5\}Cr(CO)_3][PF_6]$ (**3RuCr**) turned out to be light-sensitive. Analytical data, IR spectroscopy, and ^1H, ^{31}P, and ^{13}C NMR spectroscopy support the formulations. For the cationic binuclear complexes, the molar conductivities of 10^{-3} M solutions in acetone, in the range 101−115 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$, are consistent with values reported for 1:1 electrolytes.[15]

IR Spectroscopic Studies

Two well resolved CO stretching modes in accordance with the symmetry C_{3v} are observed from IR measurements on solutions of chromium tricarbonyl arene complexes. The wavenumber of the CO modes is known to reflect the effect of a substituent on the coordinated aromatic ring. For example the complex of anisole presents two bands at 1978.9 and 1908.9 in isooctane whereas the complex of methylbenzoate shows two bands at 1992.5 and 1929.2, which have to be compared with the values of 1984.3 and 1916.5 for $[C_6H_6Cr(CO)_3]$.[16a] Thus an electron donating group significantly decreases the IR resonance. The two bands relative to the ν(C≡O) are in the range 1985−1898 cm^{-1} for the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mononuclear complexes and in the range 1969−1888 cm^{-1} for the dinuclear complexes. Coordination of **1Cr** with Fe and Ru give the dinuclear complexes **1FeCr** and **1RuCr** which present resonances at lower frequencies: up to −17 cm^{-1} is in good agreement with π back-bonding from the other metal. This effect is also observed for complexes **2FeCr** and **2RuCr**. As for complexes **3FeCr** and **3RuCr**, the spectra exhibit a small decrease of the E mode but an unexpected although small increase of the A1 mode, Table 1.

Table 1. Selected IR data (KBr)

	ν CN (cm^{-1})	ν CO (cm^{-1})
1	2218	–
1Cr	2222	1985−1902
1FeCr	2216	1969−1900
1RuCr	2227	1968−1890
2	2220	–
2Cr	2214	1972−1915
2FeCr	2197	1969−1890
2RuCr	2216	1969−1892
3	2220	–
3Cr	2212	1957−1898
3FeCr	2197	1965−1888
3RuCr	2212	1966−1889

The ν(N≡C) IR analysis of mononuclear complexes **1Cr**, **2Cr**, **3Cr** shows the presence of the characteristic nitrile band in the range 2212 to 2222 cm^{-1}. For the binuclear derivatives, typical IR bands confirm the presence of the cyclopentadienyl ligand (≈ 3060 cm^{-1}), the $[PF_6]^-$ anion (840 and 545 cm^{-1}), the characteristic band of the coordinated nitrile ν(N≡C) in the range 2197 to 2227 cm^{-1}. Comparison of ν(N≡C) upon coordination of the chromium mononuclear complexes to iron or ruthenium centres, reveals a negative shift −6 to −17 cm^{-1} for the iron binuclear compounds indicating the existence of π back-bonding from the metal to the N≡C group, Table 1. The unexpected slight positive shifts, +5 cm^{-1} for **1RuCr**, +2 cm^{-1} for **2RuCr**, and no shift for **3RuCr**, observed for the corresponding ruthenium atom which are less effective π donors than the iron derivatives, can also be correlated with a weaker π back-donation effect, since normal σ coordination leads to significant positive shifts on ν(N≡C) (up to +80 cm^{-1}). The present results for terminal nitrile coordination are in good agreement with our earlier reports dealing with iron and ruthenium related monometallic compounds.[13,14]

NMR Spectroscopic Studies

^1H NMR spectroscopic data of arenetricarbonylchromium complexes **1Cr**, **2Cr**, **3Cr** are presented together with the corresponding data for the free aromatic ligands and the binuclear iron **1FeCr**−**3FeCr** and ruthenium **1RuCr**−**3RuCr** complexes in Tables 2, 3, and 4. The complexation of the benzene ring to the chromiumtricarbonyl moiety in complexes **1Cr**, **2Cr**, **3Cr** was easily identified due to the characteristic upfield shift to the region 5.3−5.6 ppm.[16b] The protons of the free arene give rise to different sets of signals and multiplicity in the region 7.2−7.5 ppm. We took into account that in the case of diphenyl acetylene, the protons H^2 and H^6 resonated at the highest frequency and the protons H^3, H^5, and H^4 resonated almost at the same frequency (increment H_{ortho} = +0.19, increment H_{meta} = +0.02 and increment H_{para} = +0.00). It is worth noting that in the case of tricarbonylchromiumarene complexes, the differences in the chemical shifts between the *meta* and the *ortho* protons: $\delta(H^3) - \delta(H^2)$ can give an idea as to the effect of the substituent and about the conformation of the tripod in solution with respect to the arene ring.[17a−17g] By using the classical equation $\delta(H^3) - \delta(H^2) = (2x - 1)\cdot\Delta\delta_{max}$[17g] we calculated the percentage of the conformation eclipsing the substituted

aromatic carbons. Thus we obtained populations x of 38, 40, and 36% for complexes **1Cr**, **2Cr**, and **3Cr** respectively, Tables 2−4, in good agreement with the almost staggered conformation found in the solid state, Figure 1.

Analysis of the ^{1}H NMR spectroscopic data of the iron binuclear complex [FeCp(DPPE)(N≡C−C_6H_4−C≡C−η^6-C_6H_5)Cr(CO)$_3$][PF_6] (**1FeCr**), and its ruthenium analogue [RuCp(DPPE)(N≡C−C_6H_4−C≡C−η^6-C_6H_5)Cr(CO)$_3$][PF_6] (**1RuCr**), Table 2, shows a shielding $\delta_{1Cr} - \delta_{1FeCr} = 1.18$ and $\delta_{1Cr} - \delta_{1RuCr} = 1.11$ ppm, respectively, for protons $H_{11,13}$, placed at the *ortho* position relative to the N≡C functional group with respect to the mononuclear complex **1Cr**. Such shielding could be in good agreement with the π back-donation from the other metal already suggested by the $\Delta\nu_{(N\equiv C)}$ found for both compounds, and also with the results earlier reported for other monocyclopentadienylruthenium/iron mononuclear compounds containing benzonitrile ligands as chromophores.[13,14] This is better proved by the fact that the $H_{2,6}$ protons even farther from the Fe and the Ru residues resonate at slightly lower frequencies for **1FeCr**−**3FeCr** and **1RuCr**−**3RuCr** with respect to the mononuclear complex **1Cr**−**3Cr**, the anisotropy of the Cp and the phenyl groups of the phosphane ligand being unable to interfere at this distance. This indicated a weak electron donating ability of the −CC−C_6H_4−CNFeCp(DPPE) residue; indeed, it is well reported that the protons of C_6H_5R−Cr(CO)$_3$ (R = electron donating group) resonate at lower frequencies than the protons of C_6H_6−Cr(CO)$_3$.[16b]

In a similar manner the analysis of Tables 3 and 4, for compounds containing one and two thiophene units, reveals a shielding of 0.86 ppm ($\delta_{2Cr} - \delta_{2FeCr}$) and 0.72 ppm ($\delta_{2Cr} - \delta_{2RuCr}$) for protons H^{11} (*ortho* to the NC group) with respect to the mononuclear complex **2Cr** and smaller shieldings for the adjacent H^{10} protons. Similar shielding values were also found for the equivalent protons H^{14} and H^{15} of the bithiophene containing compounds. Nevertheless this shift effect is barely felt on the H^{11} proton of the second thiophene ring where only the small shielding values of ca. 0.15 ppm were observed for H^{11}. The chemical shifts of the $H^{2,6}$ protons of complexes **2FeCr**,**3FeCr** and **2RuCr**,**3RuCr** resonate at lower frequencies with respect to the mononuclear complexes **2Cr**,**3Cr** but the shielding is small.

Selected ^{13}C NMR spectroscopic data of mononuclear complexes are reported in Table 5. The carbon resonances of the C^1 to C^4 atoms (complexed phenyl rings of **1Cr**, **2Cr**,

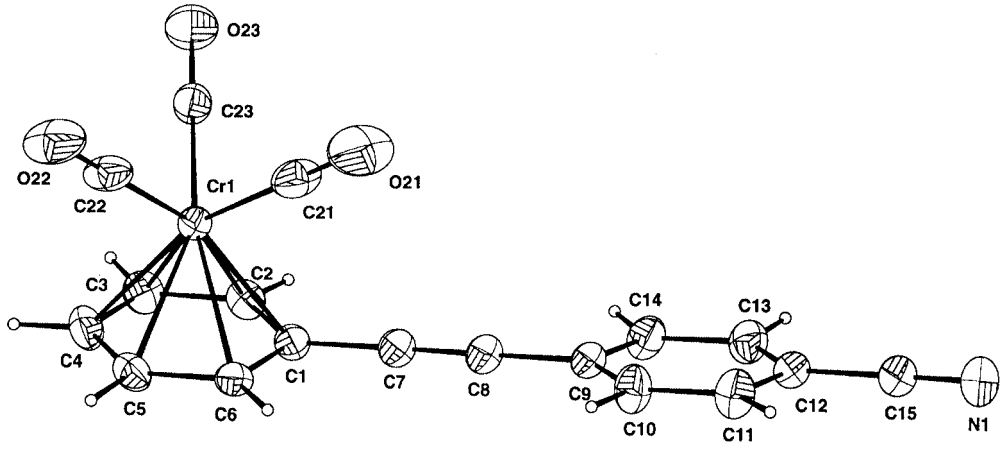

Figure 1. ORTEP diagram and atomic numbering scheme of the molecular structure of complex **1Cr** including a view along the Cr-ring axis. Thermal ellipsoids are presented at the 30% probability level

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3Cr) are assigned by CH correlation spectroscopy. They are shifted to lower frequency in the region 88−96 ppm. It is worth calculating the complexing chemical shifts (CCS)[18,19] of these carbons. Indeed the shifts due to the complexation are characteristic of each carbon, this is also true for the resonances of the alkyne carbon atoms C^7 and C^8. Thus the quaternary carbon C^1 is shifted by 32.8±0.4 ppm, the carbons C^2, C^3, and C^4 are shielded by 35.6±0.1, 36.3±0.3, and 36.7±0.1 ppm, respectively. The carbon C^7 is shielded by 3.5±0.5 ppm whereas the carbon C^8 is deshielded by 1.0±0.1 ppm. The carbonyl carbon resonances of complexes **1Cr**, **2Cr**, and **3Cr** appeared almost at the same frequency δ = 231.8 ppm for **1Cr** and **2Cr**, δ = 231.9 ppm for **3Cr**.

The ^{13}C NMR spectra of the binuclear compounds reveal a deshielding of up to ca. 7.5 ppm of the carbon atom of the NC group, as expected. The ^{31}P NMR spectra of the Fe/Cr and Ru/Cr binuclear compounds display one singlet relative to the dppe coligand at δ ≈ 97 ppm for the Fe derivatives and at δ ≈ 79 ppm for the Ru analogues, at about the same chemical shifts found for other related compounds.[14] The signal relative to the PF_6^- counterion is placed for all the compounds at δ ≈ −143 ppm as a septet.

X-ray Structural Determination of [(N≡C−C_6H_4−C≡C−η^6-C_6H_5)Cr(CO)$_3$]

Information on [(N≡C−C_6H_4−C≡C−η^6-C_6H_5)Cr(CO)$_3$] (**1Cr**) and conformation of the solid state could be obtained from the X-ray crystal analysis, Table 6. Suitable crystals were obtained by crystallisation of complex **1Cr** in a mixture of diethyl ether and petroleum ether. The structure represented in Figure 1 shows an almost staggered conformation of the Cr(CO)$_3$ tripod with respect to the carbon atoms of the aromatic ring, with the Cr−C^{21} bond rotating 23° away from the alkynyl substituent.

The C^7≡C^8 triple bond: 1.196(3) Å is slightly longer than those observed in two relevant examples in the literature

Table 6. Selected interatomic distances (Å) for **1Cr**

1Cr	
C1−C2	1.398(4)
C2−C3	1.406(3)
C3−C4	1.391(4)
C4−C5	1.407(4)
C5−C6	1.397(3)
C6−C1	1.427(3)
C7−C8	1.196(3)

Cr−C4	2.215(2)
Cr−C5	2.220(2)
Cr−C6	2.216(2)

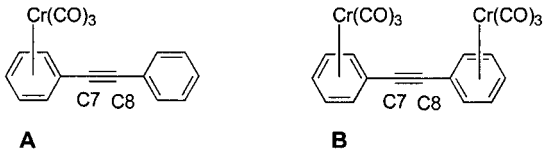

Figure 2. Complexes **A**[18] and **B**[19]

shown in Figure 2. 1.167 Å for C^7≡C^8 in complex **A**,[18] 1.188(5) Å for complex **B**.[19] The slight elongation observed for the C^7≡C^8 triple bond in our compound [(N≡C−C_6H_4−C≡C−η^6-C_6H_5)Cr(CO)$_3$] when compared with complex **B** [with two Cr(CO)$_3$ tripods attached to the phenyl rings] shows that the effect of the N≡C group can be compared with the effect of the Cr(CO)$_3$ acceptor group.

The C^{15}−N bond length of 1.113 Å in **1Cr** should be compared with a similar value of 1.114 Å described in the case of a nitrile coordinated to a cationic Ru(Cp)(PPh$_3$)$_2$ fragment: [CpFeC_5H_4−CH=CH−*p*-C_6H_4−CN−Ru(Cp)(PPh$_3$)$_2$].[2c] These values seem similar but with the nature of the phosphanes being different it is hard to compare the back-donation of the metal in these mono and dinuclear complexes.

The deviation from co-planarity of the complexed and uncomplexed phenyl rings in **1Cr** is small (10°) whereas the corresponding dihedral angle in complex **A** is 50.9° (in complex **B** this deviation is small: 3°). It would be interesting to evaluate the preservation of the planarity in the spacer in the binuclear compounds. Nevertheless, attempts of growing suitable single crystals for this purpose have been unsuccessful so far.

UV/Visible Studies

The UV/Vis electronic spectra of the aromatic free ligands **1**−**3**, the new monometallic **1Cr**−**3Cr** and the bimetallic **1FeCr**−**3FeCr** and **1RuCr**−**3RuCr** compounds were studied in acetone and chloroform solutions, in order to characterise the absorption bands and to obtain some idea of their hyperpolarisabilities, Table 7.

The spectra of the aromatic free ligands **1**−**3** displayed one intense π-π* intraligand absorption band (ILCT) in the region 317 to 370 nm.

The spectra of the monometallic complexes **1Cr**−**3Cr** in chloroform solutions, were characterised by two bands, one at ca. 425 nm and the other one in the region 300−360 nm. The first band was assigned to a metal-to-ligand charge transfer (MLCT) transition originating due to the charge transition from the chromium centre to the π- and σ-bound ligands. Although spectroscopic and theoretical studies[20,21] predict the existence of two bands for the dominant excitations d_π-to-2π*(CO) and d_π-to-π*(arene) in [(η^6-C_6H_6)Cr(CO)$_3$] related compounds, only one band was clearly observed in the present studies. A similar situation was also reported by other authors for related complexes, namely alkynyl and the alkenyltricarbonylchromium derivative.[7c] The second and more intense absorption band, predicted for the π-π* intraligand transitions (ILCT),[20] was

found in the range 300–360 nm, in agreement with the electronic spectra of the aromatic free ligands **1**–**3**.

The spectra of the bimetallic compounds (chloroform solution) showed the expected MLCT (at ca. 430 nm) and ILCT (in the range 320–400 nm) bands attributed to the monometallic parent [{N≡C–(spacer)–C≡C–η^6-C_6H}-$Cr(CO)_3$] complexes. The MLCT band was found to be insensitive to the polarity of the solvent, when chloroform was replaced by acetone, suggesting that there is no significant variation of polarity between the fundamental and the excited states, while the ILCT band showed some solvochromicity. In addition to these bands, a third band emerged in the electronic spectra of some of the binuclear complexes, namely **1FeCr** (348 nm) and **2FeCr** (374 nm), and it was attributed to a new metal-to-ligand charge transfer band involving the iron centre. The characterisation of this new band as a MLCT transition centred at the iron fragment, was supported by our previous studies in other related mononuclear iron compounds and explained by π back-donation involving d_π-π*(N≡C) orbitals.[8,22]

In Figure 3, the electronic spectrum of the binuclear compound **2FeCr** is compared with the spectrum of the parent mononuclear compound **2Cr** in chloroform. The arrow in the figure points indicates this new Fe centred MLCT band, clearly absent in the spectrum of the mononuclear parent compound.

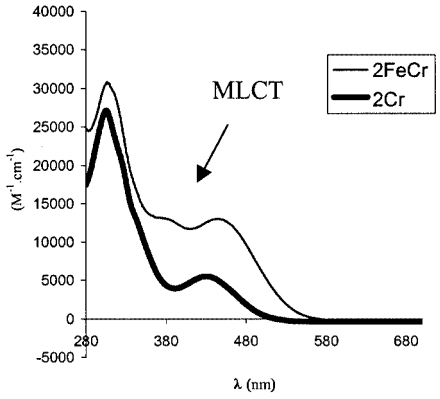

Figure 3. UV/Vis. Electronic spectra of **2FeCr**, showing a weak MLCT band, and **2Cr**

Interestingly, the **3FeCr** showed only one very broad and intense band (chloroform solution), centred at 398 nm, with the shape suggesting the overlap of the observed bands for **1FeCr** and **2FeCr**. The complexity of this band was corroborated by the optical spectrum of this compound in acetone, where two peaks seem to emerge clearly from that broad band.

The general characteristic of the electronic spectra of the studied set of binuclear complexes was a comparative increase of the intensity of the MLCT (Cr centred) and ILCT absorption to the corresponding mononuclear chromium derivatives. This effect was more pronounced on the ILCT band and particularly for ruthenium derivatives. In addition, the existence of a new MLCT, centred on the second metal, clearly observed in the binuclear iron derivatives and located in the same direction of the strengthened ILCT transition, might be the origin of the higher hyperpolarisabilities found for the binuclear derivatives, discussed below.

Nonlinear Optical Studies

The dynamic first hyperpolarisabilities β of the new complexes were measured in chloroform using the HRS technique[23–25] with a 1064 nm Nd:YAG laser fundamental. Results are presented in Table 8. The applicability of the two-level model to these types of chromium tricarbonyl arene derivatives has been questioned.[20] For the push-pull extended organic π-system chromophores func-

tionalised with the $Cr(CO)_3$ group, this model has been applied based on the assumption that the major contribution to the hyperpolarisabilities arises from the ILCT transition occurring along the chromophore molecular axis.[7c] The additional MLCT band centred at the second metal (Fe^{II} or Ru^{II}) fragment due to an enhanced back-donation to the π* nitrile group, found clearly for the iron binuclear derivatives, and the evidence found in the IR and ^1H NMR spectroscopic data, for its existence in the ruthenium analogues, strongly suggests that the two-level approximation should not be applied in this case and therefore the corresponding static hyperpolarisabilities β_0 were not calculated. Moreover, the similarity in the positions of the charge-transfer bands would result in approximately identical resonance enhancement for all the complexes.

The β values found for compounds [{N≡C−(spacer)−C≡C−η⁶-C_6H_5}$Cr(CO)_3$] (28−88 $\times 10^{-30}$ esu), where N≡C− is an acceptor group, are similar to those reported in the literature for compounds of the same general formula, namely [$Cr(\eta^6$-$C_6H_5R)(CO)_3$] with R= −C≡C−C_6H_4R' or −C(H)=C(H)−C_6H_4R' (R′ = NMe_2, NO_2), corroborating that the chromium tricarbonyl arene fragment is amphoteric with respect to its electronic behaviour.[7] Indeed, electron donating or electron withdrawing behaviour in NLO chromophores depends on the electronic nature of the far end group of the chromophore.[7c] In addition, the substitution of the phenyl spacer **1Cr** by a thiophene spacer **2Cr** causes a twofold increase in the β value, probably due to the reduced aromaticity of the thiophene. The introduction of the second thiophene unity **3Cr** also enhances the hyperpolarisability, as expected due to the increase of the conjugation length.

The experimental β values measured for all the binuclear compounds studied (Table 8) showed that the best values of β were obtained for the Fe binuclear derivatives **2FeCr** and **3FeCr**, 170 and 197 $\times 10^{-30}$ esu, respectively. These values are relatively higher than those of the precursor mononuclear compounds **2Cr** ($59 \cdot 10^{-30}$ esu) and **3Cr** ($88 \cdot 10^{-30}$ esu). The ruthenium series **1RuCr**, **2RuCr**, and **3RuCr** showed lower β values relative to the iron series, as would be expected from our previous studies on similar systems[8] and in accordance with the better donor role of the iron fragment. Comparison of the different spacers follow the same trend observed for the corresponding mononuclear chromium complexes. The β values obtained can be compared with other β values of organometallic congeners described in the literature[1b,2i,5,7c] and with the $31 \cdot 10^{-30}$ esu β value in the case of the prototypical "push-pull" chromophore (*Z*)-1-ferrocenyl-2-(4-nitrophenyl)ethylene complex[2m] which has an SHG efficiency 62 times that of urea.

The comparison of the β values of mono and binuclear compounds studied in the present work show relatively higher values for the binuclear derivatives. These results might be expected by the higher intensity of the ILCT transitions observed in the optical spectra of the binuclear compounds and the existence of a second MLCT band (iron/ruthenium centred) in the axis of the chromophore, due to d_π-π*(N≡C) π back-donation. It is important to note that the direction of the ILCT transition is reversed when the binuclear compounds are formed. In fact, the N≡C ending group, in the chromium mononuclear compounds [{N≡C−(spacer)−C≡C−η⁶-C_6H}$Cr(CO)_3$], plays the role of acceptor while the chromiumtricarbonylarene fragment acts as the donor group (see Figure 4, a). However, the coordination of this N≡C group to a second metal (Fe/Ru) makes it behave as a π* acceptor relatively to this new metal centre. Thus, in the binuclear complexes, the new ending group [MCp(DPPE)(N≡C)−]$^+$ acts as a π donor while the chromiumtricarbonyl fragment now behaves as an acceptor (see Figure 4, b). These results are in good agreement with the electronically amphoteric character reported for the chromium tricarbonyl arene fragment in analogous compounds of general structure [{R−(spacer)−C≡C−η⁶-C_6H}$Cr(CO)_3$] where R is the donor NMe_2 or the acceptor NO_2.[7c]

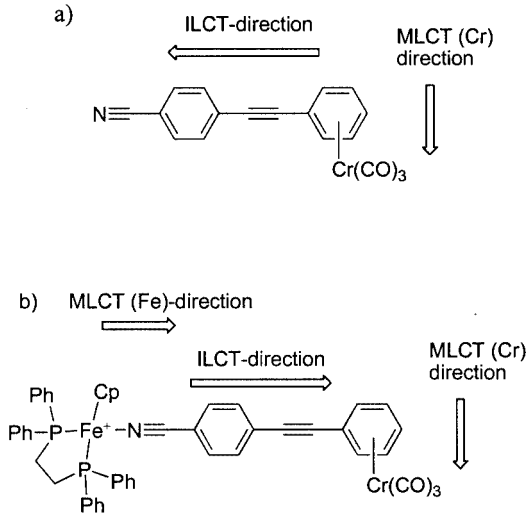

Figure 4. Ground state dipole vectors of chromium mononuclear complexes compared with the corresponding binuclear complexes. The direction of the ILCT contribution in the binuclear complexes is reversed, due to the role of the new ending group [MCp(DPPE)(N≡C−)]$^+$

Conclusion

The synthesis of nitrile ligands linked to tricarbonyl (η⁶-arene)chromium complexes [{N≡C−(spacer)−C≡C−η⁶-C_6H_5}$Cr(CO)_3$] by conjugated spacers is performed by reacting aromatic bromo or iodo nitrile derivatives with tricarbonyl chromium complexed phenylacetylene using the Sonogashira-coupling reaction. Characterisation of these mononuclear complexes obtained and the corresponding dinuclear [M{N≡C−(spacer)−C≡C−η⁶-C_6H_5}$Cr(CO)_3$] complexes M = Fe(dppe)Cp, Ru(dppe)Cp has been studied using ^1H, ^{13}C, IR, and UV/Vis spectroscopy and in the case of one of them by X-ray crystallography. Measurements of the dynamic first hyperpolarisabilities (β) by HRS, showed significant higher values for the binuclear derivatives when

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compared with the corresponding monometallic parent compounds. This enhancement of β observed upon coordination of the [{N≡C−(spacer)−C≡C−η^6-C_6H_5}Cr(CO)$_3$] ligand complex to a second iron(II) or ruthenium(II) metal centre can be explained by the significant enhancement observed for the molar absorptivity of the ILCT band relative to the nitrile chromophore and the synergic effect of a new MLCT band originating due to π back-bonding from the second metal towards the nitrile functional group.

Experimental Section

General Procedures: All the experiments were carried out under vacuum or nitrogen atmosphere using standard Schlenk techniques, and solvents were dried following published methods.[26] [Cr(η^6-C_6H_5−C≡CH)(CO)$_3$] was easily prepared as reported recently.[18] Chlorobenzene tricarbonylchromium complex was prepared according to literature procedures.[27] The halo nitrile aromatics **1-CN**−**3-CN** are commercially available or prepared using standard literature procedures.[28] The synthesis of some new chromium derivatives was recently published in a preliminary communication.[11] Fe(η^5-C_5H_5)(dppe)(I)][22] and [Ru(η^5-C_5H_5)(dppe)(Cl)][29,30] were prepared according to the procedures described in the literature. IR spectra were recorded in KBr pellets on a Perkin−Elmer 683 spectrophotometer; only significant bands are cited. ^{1}H, ^{13}C, and ^{31}P NMR spectra were recorded in $CDCl_3$ on a Varian Unity 300 spectrometer at probe temperature. The UV/Vis spectra were taken on a Perkin−Elmer λ9 UV/Vis/Nir spectrophotometer. Elemental analysis of mononuclear compounds were performed by "le service de Microanalyses" (Université Pierre et Marie Curie). Binuclear compounds were analysed at Laboratório de Análises, Instituto Superior Técnico, using a Fisons Instruments EA1108 system. Data acquisition, integration, and handling were performed using a PC with the software package Eager-200 (Carlo Erba Instruments). Melting points were obtained on a Reichert Thermovar. The molar condutivities of 10^{-3} mol·L^{-1} solutions of the complexes in acetone were recorded with a Schott CGB55 Konduktometer. The ^{1}H ([D]chloroform) and ^{13}C ([D]chloroform) chemical shifts are reported in parts per million downfield from internal Me_4Si and the ^{31}P NMR spectra are reported downfield from external 85% H_3PO_4 ([D]chloroform). Spectral assignments follow the numbering scheme shown in Tables 2−4.

Synthesis of the Free Ligands 1, 2, and 3: The free ligands were synthesised in a similar manner to the chromium complexes (see below) by the palladium copper catalysed coupling of the aromatic iodonitriles **1-CN**, **2-CN**, and **3-CN** and phenylacetylene.

N≡C−(C_6H_4)−C≡C−C_6H_5 (1): 54% yield. IR: see Table 1. ^{1}H NMR: see Table 2. ^{13}C NMR: see Table 5 and 127.2 (C^9), 131.0 (C^{10},C^{14}), 131.0 (C^{11},C^{13}), 110.4 (C^{12}), 117.5 (C^{15}), (UV/Vis, see Table 7).

N≡C−2-(5-C_4H_2S)−C≡C−C_6H_5 (2): 49% yield. IR: see Table 1. ^{1}H NMR: see Table 3. ^{13}C NMR: see Table 5 and 129.7 (C^9), 130.4 (C^{10}), 136.2 (C^{11}), 108.8 (C^{12}), 112.6 (C^{13}).

General Procedure for the Synthesis of Chromium Mononuclear Complexes

[{N≡C−(C_6H_4)−C≡C−η^6-C_6H_5}Cr(CO)$_3$] (1Cr): (η^6-Phenyl)-ethynyltricarbonylchromium complex (171 mg, 0.71 mmol), [$PdCl_2(PPh_3)_2$] (25 mg, 0.035 mmol), CuI (7 mg, 0.035 mmol), and *p*-iodobenzonitrile (158 mg, 0.69 mmol) were placed in a bicol under unit atmosphere and dried in vacuo for 30 min. NEt_3 (5 mL) and anhydrous THF (10 mL) were then added and the mixture was immediately heated to reflux for 3 h. After cooling at room temperature, the suspension was filtered, washed with Et_2O (3 × 20 mL) and the solvents were removed under reduced pressure. The residue was chromatographed on silica gel (diethyl ether/ petroleum ether 96:4 to 80:20) to afford **1Cr** (210 mg) in 87% yield as an orange solid. m.p. 168 °C (dec). IR: see Table 1. ^{1}H NMR: see Table 2. ^{13}C NMR: see Table 5 and 126.8 (C^9), 132.2 (C^{10},C^{14}), 132.5 (C^{11},C^{13}), 112.4 (C^{12}), 118.4 (C^{15}), 231.6 (CO) ppm. $C_{18}H_9CrNO_3$ (339.3): calcd. C 63.72, H 2.65, N 4.13; found C 63.13, H 2.84, N 3.96.

[{N≡C−2-(5-C_4H_2S)−C≡C−η^6-C_6H_5}Cr(CO)$_3$] (2Cr): (η^6-Phenyl)ethynyltricarbonylchromium complex (119 mg, 5 mmol), [$PdCl_2(PPh_3)_2$] (175 mg, 0.25 mmol), 2-bromocyanothiophene (6.05 g, 25 mmol), and NEt_3 (30 mL) were added together in a bicol under N_2. The mixture was heated for 3 h. By using the same procedures complex **2Cr** was obtained in 81% (1.38 g) as an orange solid. m.p. 140 °C (dec). IR (KBr): see Table 1. ^{1}H NMR: see Table 3. ^{13}C NMR: see Table 5 and 129.2 (C^9), 132.9 (C^{10}), 137.4 (C^{11}), 111.1 (C^{12}), 113.6 (C^{13}), 231.8 (CO) ppm. $C_{16}H_7CrNO_3S$: calcd. C 55.65, H 2.02, N 4.05; found C 55.43, H 2.21, N 3.92.

[{N≡C−2-(5-C_4H_2S)$_2$−C≡C−η^6-C_6H_5}Cr(CO)$_3$] (3Cr):[11] 81% yield; m.p. 141 °C (dec). IR: see Table 1. ^{1}H NMR: see Table 4. ^{13}C NMR: see Table 5, and 134.2 (C^9), 125.9 (C^{10}), 132.7 (C^{11}), 143.4 (C^{12}), 123.1 (C^{13}), 124.2 (C^{14}), 138.4 (C^{15}), 112.2 (C^{16}), 114.2 (C^{17}), 231.9 (CO) ppm.

General Procedure for the Synthesis of the Bimetallic Iron/Chromium Derivatives

[FeCp(dppe){N≡C−(spacer)−C≡C−C_6H_5}Cr(CO)$_3$][PF_6]: A slight excess of the adequate amount of chromium chromophore [{N≡C−(arene)−C≡C−C_6H_5}Cr(CO)$_3$] (1.1 mmol) and $TlPF_6$ (1.1 mmol) was added to a solution of the [CpFe(dppe)(I)] (1 mmol) in dichloromethane (25 ml) followed by stirring, at room temperature, for 3 h in the case of [{N≡C−(C_6H_4)−C≡C−η^6-C_6H_5}Cr(CO)$_3$] and 18 h for the thiophene derivatives. The evolution of these reactions was followed by TLC (thin layer chromatography). A colour change was observed from brown to red with simultaneous precipitation of thallium iodide.

After filtration, the solution was evaporated under vacuum to dryness and washed several times with diethyl ether to remove the excess of chromium [{N≡C−(arene)−C≡C−C_6H_5}Cr(CO)$_3$] starting material. The residue was recrystallised from dichloromethane/ diethyl ether.

[FeCp(dppe)(N≡C−C_6H_4−C≡C−C_6H_5)Cr(CO)$_3$][PF_6] (1FeCr): 90% yield, red-orange, m.p. 128−130 °C. IR: see Table 1. ^{1}H NMR: see Table 2. ^{13}C NMR: δ = 79.8 (η^5-C_5H_5), 88.3 (C^1), 95.1 (C^2,C^6), 91.3 (C^3,C^4,C^5), 90.1 (C^7), 87.6 (C^8), 126.5 (C^9), 132.7 (C^{10},C^{14}), 131.6 (C^{11},C^{13}), 112.0 (C^{12}), 110.9 (C^{15}), 231.9 (CO) ppm. ^{31}P NMR: δ = 97.59 (s, dppe), −143.69 (hept, PF_6) ppm. $C_{49}H_{38}CrF_6FeNO_3P_3$·1/2($C_2H_5)_2$O: calcd. C 58.64, H 3.80, N 1.39; found C 59.8, H 3.70, N 1.47. Molar conductance: 113.7 cm^{-1}·mol^{-1}·Ω^{-1}.

[FeCp(dppe){N≡C−2-(5-C_4H_2S)−C≡C−C_6H_5}Cr(CO)$_3$][PF_6] (2FeCr): 86% yield, red, m.p. 130−132 °C. IR: see Table 1. ^{1}H

[RuCp(dppe){N≡C−2-(5-C_4H_2S)$_2$−C≡C−C_6H_5}Cr(CO)$_3$][PF_6] (3RuCr): Light-sensitivity prevented complete characterisation by elemental analysis. NMR samples were prepared in the dark. 70% yield; orange-brownish; m.p. 94−97 °C. IR: see Table 1. ^1H NMR: see Table 4. ^{13}C NMR: δ = 82.5 (η^5-C_5H_5), 89.2 (C^1), 94.7 (C^2, C^6), 91.1 (C^3, C^4, C^5), 82.0 (C^8), 134.8 (C^9), 133.1 (C^{10}), 131.5 (C^{11}), 130.7 (C^{14}), 138.3 (C^{15}), 124.1 (C^{16}), 106.7 (C^{17}); 231.8 (CO) ppm. ^{31}P NMR: δ = 79.66 (s, dppe), −143.61 (hept, PF_6) ppm. * Located under a broad signal.

Crystal Structure of 1Cr: [(CO)$_3$Cr($C_{15}H_9N$)], M = 339.27, μ = 0.735 mm^{-1}, ρ = 1.46 $g\cdot cm^{-3}$, monoclinic, $P2_1/c$, Z = 4, a = 10.326(2), b = 13.209(5), c = 11.799(2) Å, β = 106.61(2)°, V = 1542.3(7) $Å^3$, from 25 reflections (27.6°< 2θ < 28.4°). Cell dimensions and intensities were measured at 295 K on a Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). ω/2θ scans, two standard reflections measured every hour showed no significant variation.1° < θ < 28° (0 < h < 13, 0 < k < 17, −15 < l < 14), 4085 measured reflections, 3715 unique reflections of which 2590 were observed [$F_o^2 > 3\sigma(F_o^2)$]; R_{int}= 0.03 for equivalent reflections. Data were corrected for Lorentz and polarisation effects. The structure was solved by direct methods using SHELXS,[31] all other calculations used CRYSTALS.[32] Atomic scattering factors and anomalous dispersion terms were taken from the literature.[33] Full-matrix least-squares refinement based on F and a Chebychev weighting scheme gave final values R = 0.0399, wR= 0.0508, and s = 1.05 for 209 variables and 2590 contributing reflections. The maximum shift/esd on the last cycle was 1.75. Non-hydrogen atoms were anisotropically refined. Hydrogen atoms were located on a difference Fourier map; they were allocated an overall isotropic thermal parameter. The final difference electron density map showed a maximum of 0.42 and a minimum of −0.30 $e\cdot Å^{-3}$.

Hyper-Rayleigh Scattering: Details of the HRS experiment have been discussed previously.[20] A Q-switched Nd: YAG laser emitting at 1064 nm was used to obtain the incident light. A reference value of $23\cdot 10^{-30}$ esu[23] for 4-nitroaniline in chloroform was used to calculate the hyperpolarisability of the compounds by the external reference method. Solutions for measurements until 10^{-4} M depending on the nature of the complex under study, the low concentration being necessary to minimise absorptive losses. One-dimensional hyperpolarisability is assumed, i.e. $\beta_{1064} = \beta_{333}$, and a relative error of ±10% is estimated.

Supplementary Material: Crystallographic data for the structural analysis of compound [Cr(η^6-C_6H_5−C≡C−C_6H_4C≡N)(CO)$_3$] (excluding structure factors) have been deposited in the Cambridge data base. CCDC-147256 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Mono- and Dinuclear Complexes of a Flexible Schiff Base Ligand − Crystal Structures of a Bishelicate and Two Acentric Monohelicates

Jesús Sanmartín,*[a] Ana M. García-Deibe,[a] Manuel R. Bermejo,[a] Fernando Novio,[a] Debora Navarro,[a] and Matilde Fondo[a]

Keywords: Helical structures / N ligands / Schiff bases / Supramolecular chemistry / Transition metals

Neutral Ni^{II}, Pd^{II}, Cu^{II}, Ag^{I}, Zn^{II}, Cd^{II}, and Pb^{II} complexes of *N*,*N*′-bis(2-tosylaminobenzylidene)-1,4-diaminobutane (H_2SB) have been prepared. The Schiff base seems to exist in a helically coiled state around nickel, copper and zinc ions, but not in $Pd(SB)\cdot 3H_2O\cdot MeCN$, $Ag_2(SB)\cdot 2H_2O$, $Cd(SB)\cdot 3H_2O$, and $Pb(SB)\cdot 3H_2O$, the metal ions of which seem to show planar geometries. The determination of the absolute structures of $Cu(SB)\cdot MeCN$ and $Zn(SB)\cdot 2MeCN$, which crystallise as non-centrosymmetric racemic compounds, shows that these metal(II) ions assume distorted tetrahedral coordination geometries involving the four N atoms of the dianionic ligand. X-ray structural characterisation also shows that this ligand behaves as a $N_2{+}N_2$ donor in the [4+4] bishelicate $Ni_2(SB)_2\cdot 5MeCN$. Secondary interactions between metal centres and one of the O atoms of each tosyl group are detected in these three crystal structures, being especially intense in the dimeric one.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Among other reasons, helical metal complexes[1−4] have attracted physicists' and chemists' attention due to their potential optical activity.[5] As achiral ligands are unable to induce predetermined chirality, helicates crystallise as racemic compounds or as mechanical mixtures of enantiopure crystals (racemic mixtures or conglomerates).[6−7] Of these two types of crystalline racemates, conglomerates are far easier to resolve, but much rarer.

The obtaining of non-centrosymmetric inorganic materials with nonlinear optical properties is undoubtedly a challenge in chemistry.[8] Since the inverse of a left-handed helix is a right-handed one, a helical compound may crystallise with an inversion centre if both types of handedness appear in a crystal. Thus, with achiral ligands, the heterochiral interaction required to form racemic compounds takes place in centrosymmetric space groups, the overwhelming majority, whereas the minority homochiral crystallisation required to obtain conglomerates exclusively occurs in non-centrosymmetric space groups.

We have recently reported the crystal structures of the two compounds $Zn_2(SB^1)_2\cdot 1.5H_2O\cdot MeCN$[9] (a typical racemic compound) and Λ-$Zn(SB^2)\cdot H_2O$,[10] which homochirally crystallises as a conglomerate. Despite the intrinsic similarities between these two symmetric *N*-tosyl-substituted Schiff bases, which contain $(CH_2)_3$ and $CH_2CH(OH)CH_2$ groups, respectively, as spacers (Scheme 1), their behaviour in their corresponding helical Zn^{II} complexes is either binucleating ($N_2{+}N_2$ donor) or mononucleating (N_4 donor), respectively. Another ligand with a three-membered spacer, although a more rigid one, in the form of H_2SB^3 (Scheme 1), only yielded racemic monohelicates.[11]

In an effort to understand the behaviour of this type of helical thread, we wished to explore how the higher flexibility of a $(CH_2)_4$ spacer might influence the coordination behaviour and spatial arrangement of the potential helicand H_2SB ("S" arranged, for a classic bisbidentate conduct, in Scheme 1) in several main group and transition (first and second row) metal complexes.

Results and Discussion

Mass and IR Spectroscopic Data

The mass spectra of these complexes exhibit medium- to high-intensity signals, with satisfactory isotopic profiles, attributable to $[M(SB) + H]^+$ species, as expected for mononuclear and monomeric compounds. This kind of species is more in accordance with a solvated nature than with coordinating behaviour of the water molecules present in these complexes. With respect to the ESI MS spectrum of the Ag^{I} complex, a group of peaks assignable to $[Ag_2(SB) + H]^+$ species could be notable, since it seems to corroborate the $Ag_2(SB)\cdot 2H_2O$ formula found by elemental analysis.

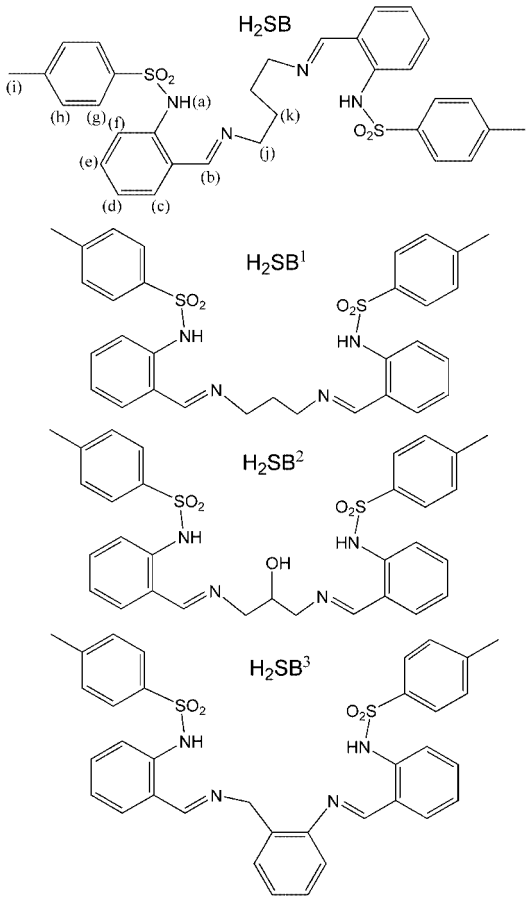
Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.



Scheme 1. Schematic representation of the *N*-tosyl-substituted Schiff bases H_2SB^1, H_2SB^2, H_2SB^3, and H_2SB (with labelling scheme for ^1H NMR studies)

It may also be worth mentioning that no peaks with intensities higher than 4% can be detected in the spectra of these complexes in those regions in which dimeric species could appear, even in the case of the dimeric Ni^{II} complex. This prevents the use of the ESI-MS technique to determine whether these complexes are of the type M(SB) or $M_2(SB)_2$.

The IR spectra of these complexes contain absorptions consistent with the presence of the N_4 donor ligand. The CN stretching frequencies show shifts to lower wavenumber values with respect to those observed for the free ligand.[12] The slight shifts of the ν(C=N) bands to lower wavenumber (in the 1−15 cm^{-1} range) contrasts with the substantial shifts observed for the ν(C−N) stretching frequencies (30−45 cm^{-1}). These facts, together with the absence of the ν(N−H) band, are in agreement with double deprotonation of the ligand, as well as with the participation of both the amide and imine N atoms in the coordination to the metal centres.[9−12]

Other bands attributable to $\nu_{as}(SO_2)$ and $\nu_s(SO_2)$ vibration modes also experience significant decreases in their frequencies. This behaviour could be a sign of interaction between the metal centre and the O atoms belonging to the tosyl groups.

Single-Crystal X-ray Diffraction Studies

Cu(SB)·MeCN and Zn(SB)·2MeCN

Slow evaporation of saturated acetonitrile solutions of $Cu(SB)\cdot 4H_2O$ and $Zn(SB)\cdot H_2O$ yielded brown and yellow X-ray-quality crystals of Cu(SB)·MeCN and Zn(SB)·2MeCN, respectively. The crystallographic analyses reveal that in both asymmetric units, a solvated acetonitrile molecule (with 0.5 and 1 occupancy sites, respectively) coexists with half a molecule of the symmetric helical complex M(SB) (M= Cu or Zn), the metal ion of which is situated on a twofold axis positioned along *z*. The whole complex molecules can be generated by the same symmetry operation (−*x*, −*y*, *z*). All the atoms so generated have been labelled with $^{\#1}$.

Although both helical enantiomers (Λ and Δ) are present in the unit cell, only the molecular structure of the single-stranded helix corresponding to Λ-Cu(SB) is represented in Figure 1, whereas Δ-Zn(SB) is shown in Figure 2, with the atom labelling schemes used in Table 1. This table lists the most significant bond lengths and angles.

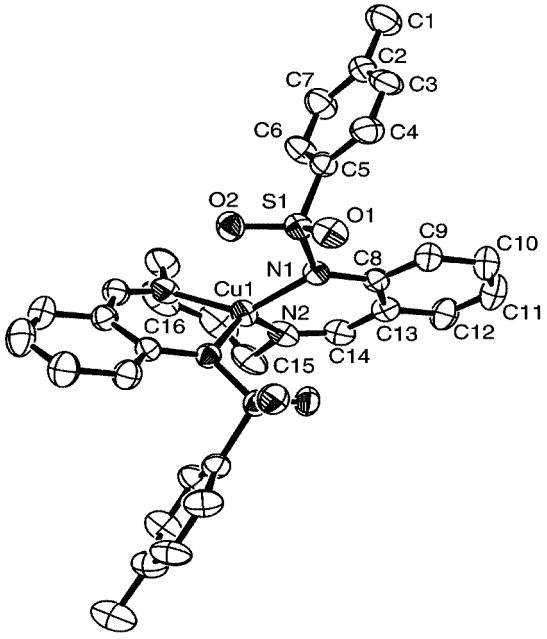


Figure 1. ORTEP view of Λ-Cu(SB), contained in the Cu(SB)·MeCN unit cell; symmetry transformations used to generate equivalent atoms: $^{\#1}$ −*x*, −*y*, *z*

The ions in both complexes are symmetrically tetra-coordinated to the four N atoms of the Schiff base, with bond lengths in the ranges typical for this sort of complex. Both coordination environments can be regarded as distorted tetrahedra, especially that corresponding to the Cu^{II} ion, in that the dihedral angles between the two N−M−N terminal planes (θ) are 65.79(14)° and 73.31(7)° for the Cu^{II} and Zn^{II} complexes, respectively. Moreover, one of the O atoms of each tosyl group [O(2) and $O(2)^{\#1}$] is weakly interacting with the Cu^{II} and Zn^{II} ions, although these M···O distances (ca. 2.8 Å) are too long to be viewed as true coordinated bonds. The $S(1)\cdots S(1)^{\#1}$ distance (about

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

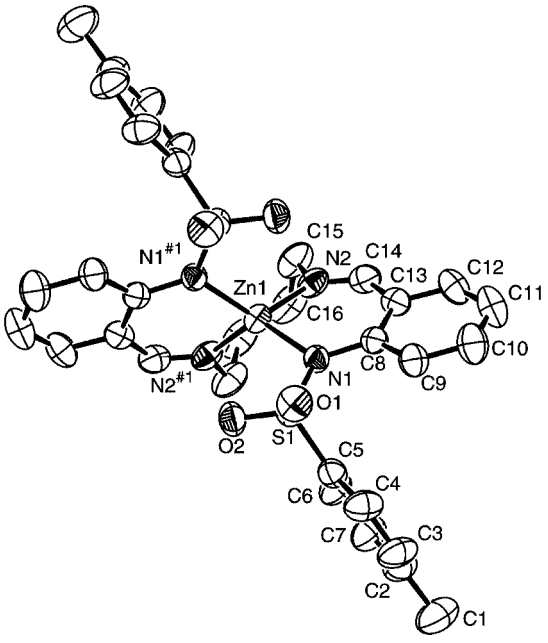

Figure 2. ORTEP view of Δ-Zn(SB), contained in the Zn(SB)·2MeCN unit cell; symmetry transformations used to generate equivalent atoms: #1 $-x, -y, z$

4.34 and 4.62 Å for the copper and zinc complex, respectively) could in both cases be regarded as a rough estimate of the pitch.[3] As also occurs in other related monohelicates,[9−12] if we consider the whole ligand, the wrapping angle would exceed 360°.

The chemical species concerned here, Cu(SB)·MeCN and Zn(SB)·2MeCN, are intrinsically chiral due to their helicity, crystallising in the non-centrosymmetric space group *Fdd*2 of the orthorhombic system, belonging to the *mm*2 crystal class. Although this class is not qualified as chiral or enantiomorphic, it does present a polar axis direction (z),[13] which means that the unit-cell origin may be arbitrarily placed along this axis. In these cases, the values found for the Flack parameter[14] [0.03(19) and 0.021(11) for the Cu^{II} and Zn^{II} complexes, respectively] determine a correct absolute structure, as well as a closely coincident orientation of the structure with respect to the polar axis, more than the enantiopurity or racemic twinning evaluation related with homochiral crystals.

Both crystal packings, which we can see in Figure 3 for Zn(SB)·2MeCN, are based on feeble C−H···O, C−H/π and π-π stacking interactions. They clearly show both types of helical molecules, with right- and left-handedness (Δ and Λ enantiomers, respectively) arranged on infinite sheets parallel to their C faces, indicative of their non-linearity. This heterochiral crystallisation satisfactorily explains the lack of global optical activity exhibited by crystalline samples of these racemic compounds in acetonitrile solution.

$Ni_2(SB)_2$·5MeCN

This crystal structure shows the double helical assembly of this neutral dinuclear Ni^{II} complex (Figure 4), in which the ligand assumes a N_2+N_2 bisbidentate coordinating behaviour. As is the case for many other homotopic double-stranded helicates, this one crystallises as a racemate in the most frequently occurring space group for metallohelicates: the centrosymmetric $C2/c$.[3] The X-ray structural characterisation reveals that its asymmetric unit contains half the bishelicate, with a crystallographically imposed twofold symmetry, which allows the other half molecule to be generated by use of the symmetry operation $-x, y, -z + 1/2$. All the atoms related in this way have been denoted with #1. Additionally, two and a half molecules of solvated acetonitrile are also present, with some disorder, in the asymmetric unit.

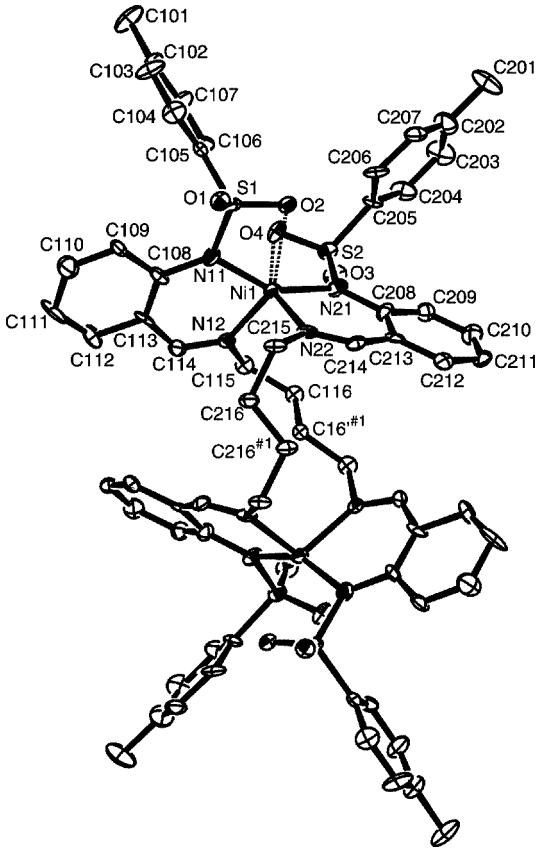

Figure 4. ORTEP view of Δ,Δ-$Ni_2(SB)_2$ contained in the $Ni_2(SB)_2$·5MeCN unit cell, with the secondary Ni···O interactions shown as dotted lines; symmetry transformations used to generate equivalent atoms: $^{\#1}$ $-x, y, -z + 1/2$

The [4 +4] bishelical nature of $Ni_2(SB)_2$·5MeCN is not common for dinuclear Ni^{II} complexes with bisbidentate ligands, which mostly give rise to [6 + 6] triple-stranded helicates.[3−4,15] However, so far the X-ray evidence available indicates, this sort of *N*-tosyl-substituted ligand only yields four coordinate complexes, both in double-stranded helicates[9,16] and monohelicates.[9−12] This even occurs with metal ions that characteristically display pseudooctahedral geometries, such as Mn^{II} or Fe^{II}, in that they exhibit unfamiliar tetrahedral geometries with H_2SB^3.[11]

The explanation for this low coordination number may lie in the bulky tosyl groups. On one hand, they appear to exert such substantial steric hindrance as apparently to avoid the presence of exogenous coordinating groups, solvent molecules or additional ligand units suitable for achieving an actual hexa-coordination. On the other hand, this uncommon tetra-coordination of the Ni^{II} ions may be easier to understand if we also consider that significant secondary Ni···O interactions (ca. 2.5 Å) exist between the Ni^{II} ion and an O atom of each adjacent tosyl group [O(2) and O(4)]. As a result, each N_4 pseudotetrahedral Ni^{II} environment (Figure 4) suffers a substantial seesaw-shaped distortion that the value of θ (ca. 80.15°) does not reveal at first sight, but the N−Ni−N angles do (Table 1). Although these minor M···O contacts are typical of metal complexes containing this type of *N*-tosyl-substituted Schiff-base ligand,[9−12,16] it could be worthy of mention that these interactions seem to be significantly shorter when the ligand behaves as N_2+N_2-bisbidentate (about 2.5 Å),[9,16] than as merely N_4-tetradentate (usually about 2.8 Å),[9−12] as in the preceding Cu^{II} and Zn^{II} complexes (vide supra).

The bishelical arrangement of $Ni_2(SB)_2$·5MeCN with metal coordination environments that could be also regarded as severely distorted N_4O_2 pseudooctahedral (Figure 4), therefore seems to be more appropriate than simple mononucleating N_4 donor behaviour for satisfying the stereochemical requirements of Ni^{II} (preferably octahedral). This tendency of Ni^{II} to achieve a pseudooctahedral coordination through secondary Ni···O contacts had also been indicated for some mesohelicates containing bisbidentate ligands designed to provide tetrahedral coordination environments.[17] Something similar also occurred in the case of $Ni_2(SB^1)_2$·MeCN,[16] whereas the rigid H_2SB^3 (Scheme 1), designed to be N_4-mononucleating, is able to impose a distorted tetrahedral geometry, though also exhibiting Ni···O interactions (2.5 and 2.8 Å).[11] In contrast, a simple N_4-compartment can adequately fulfil the tetrahedral coordination preferences of Cu^{II} ions. Unlike Cu^{II} and Ni^{II}, the spherical Zn^{II} ions (d^{10}) allow both monohelicates to be obtained, with H_2SB, H_2SB^2 [10] or H_2SB^3, and also a bishelicate,[9] when interacting with H_2SB^1 (Scheme 1). Hence, while the spacer length has a significant influence on the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stereochemistry of some types of helicates,[18] it does not appear to be a crucial factor for providing single- or double-stranded helicates with *N*-tosyl-substituted Schiff bases.

Ideally, homotopic helicates should give rise to palindromic helices; this means with constant pitch,[3] as occurs in $Ni_2(SB^1)_2$·MeCN,[16] in which both $(SB^1)^{2-}$ threads are similarly arranged, the centroids of their benzylidene groups being at about 10 Å. In principle, the ligand array in $Ni_2(SB)_2$·5MeCN could appear similar to that, even also showing a minor and a major groove. However, a thorough inspection allows it to be established that the higher flexibility of SB^{2-} seems to tolerate a clear disparity of both helical strands, with substantially different arrangements (Figure 5). Thus, we can see that the C101−C101$^{\#1}$ ligand strand (shaded in Figure 5) seems more stretched than the C201−C201$^{\#1}$ one, which shows a pronounced folding. Hence, the theoretical pitch must be longer for the first one. In fact, the distances between their benzylidene centroids are about 10.9 and 8.6 Å, respectively. Although the two coilings are fairly different, their assembly, lacking significant intra- or intermolecular π-π or C−H/π interactions, produces a symmetric, even crystallographically, homotopic double-helix.[3] Consequently, their also different wrapping angles could compensate for their differences, and result in an intramolecular Ni···Ni distance of about 6.8 Å. This is only slightly longer than that reported for $Ni_2(SB^1)_2$·MeCN (6.2 Å).[16] Similitude in the intramolecular M···M distances with $(CH_2)_2$ and $(CH_2)_3$ bridging groups has also been observed for some [6+6] Fe^{II} bishelicates.[19]

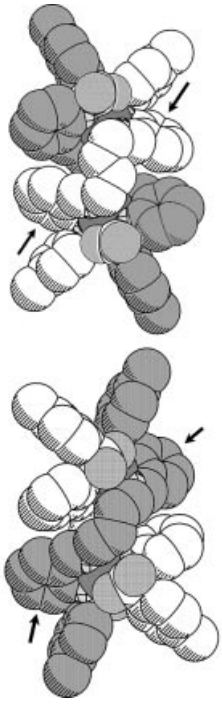

Figure 5. Two opposite views of a compact ball scheme for $Ni_2(SB)_2$·5MeCN with the helical axis parallel to left margin; the more stretched ligand strand (C101−C101$^{\#1}$) is shaded; the intramolecular distances between those ring centroids signed by arrows are: 8.6 Å (top) and 10.9 Å (bottom)

Finally, the C−N distances found confirm those observed in the IR spectroscopy section. Thus, the $C{=}N_{imine}$ and $C\text{-}N_{imine}$ distances show values similar to those reported for the free ligand,[12] whereas the $C\text{-}N_{amide}$ distances are significantly longer. The M−N distances (Table 1) are in the usual range reported for Ni^{II}, Cu^{II}, and Zn^{II} complexes containing N_{amide} and N_{imine} donor atoms.[9−12,16,20] As was also suggested by the IR techniques, M···O interactions seem to affect the S−O bonds, since these are slightly longer than those found for the free ligand.[12]

^{1}H NMR Studies

Zn(SB)·H$_2$O

In order to investigate the solution behaviour of Zn(SB)·H_2O, we have studied its ^{1}H NMR spectra in $CDCl_3$ at temperatures ranging between 323 and 218 K (deposited as Electronic Supporting Information, see footnote on the first page of this article). From these results, and in view of the ligand symmetry, the observation of two signals each for H_j and H_k (Scheme 1), must be a consequence of the diastereotopic natures of the geminal protons of each methylene group. This is consistent with a helical arrangement,[21] as also occurred in the solid state. Since both methylene protons are non-equivalent even at 323 K, Zn(SB)·H_2O seems to preserve its helical conformation in chloroform solution on the NMR timescale, which is also indicative of a strong coordination of the N atoms to the metal centre. On the basis of the kinetic stability of this complex, the results obtained at room temperature can be used as a diagnostic probe for helicity.

Both COSY and NOESY experiments at room temperature in chloroform, acetonitrile or dimethyl sulfoxide solutions allow a full assignment of the ^{1}H NMR signals (see Experim. Section). They clearly show AB spin behaviour of the methylene protons on the NMR timescale, since those protons situated near to equatorial positions with respect to the C(15)N(2)C(14) or C(15$^{\#1}$)N(2$^{\#1}$)C(14$^{\#1}$) planes, H_{jeq} and H_{keq}, are observed at higher field than those situated close to axial positions (H_{jax} and H_{kax}).

A NOESY experiment (Figure 6) shows coupling of H_b with H_c and H_{jeq} (but not with H_{jax}), as well as between H_g and H_f. Consequently, these intramolecular H···H distances should be lower than ca. 3.1 Å in solution. The X-ray crystal studies determined that the H_b···H_c, H_b···H_{jeq} and H_g···H_f distances in the solid state are in the 2.2−2.7 Å range, whereas H_b···H_{jax} is higher (3.1 Å). These facts seem to indicate that the spatial arrangement of the helical ligand in the zinc complex is analogous, both in the solid state and in solution (even in a coordinating solvent such as dmso).

Pb(SB)·3H$_2$O

A NOESY experiment was a key element in the full assignment of the proton signals (deposited as Electronic Supporting Information). Since the H_b and H_i signals are two clear references in the spectrum, the H_i-H_h, H_b-H_c and H_b-H_j couplings allow the unequivocal identification

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

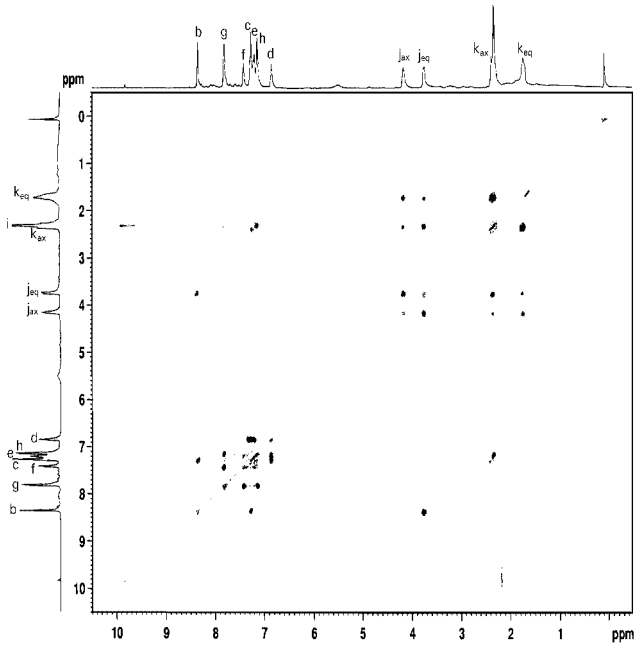

Figure 6. NOESY experiment for $Zn(SB)\cdot H_2O$ in $CDCl_3$ at 300 K

of H_h, H_c, and H_j, respectively. Similarly, the H_c-H_d, H_d-H_e, and H_e-H_f couplings provide evidence of the H_d, H_e, H_f, and H_g positions, whilst the absence of coupling between H_g and H_f seems to indicate that the spatial arrangement of the tosyl groups, with respect to benzylidene rings, is not equivalent to that observed in $Zn(SB)\cdot H_2O$.

The experiment mentioned also shows the enantiotopic nature of the geminal protons in each methylene group on the NMR timescale at room temperature. This could rule out a helical arrangement of SB^{2-} in this complex. Although the observation of one signal each for H_j and H_k (in $[D_6]$DMSO or Cl_3CD at room temperature) could be due to a fast exchange between helical and non-helical arrangements of SB^{2-} in the Pb^{II} complex, a series of ^1H NMR spectra in the 323−218 K range reveals the kinetic stability of this complex in chloroform solution, even at high temperatures.

Pd(SB)·3H₂O·MeCN, Ag₂(SB)·2H₂O and Cd(SB)·3H₂O

The diamagnetism of the Pd^{II} complex attests to the electronic pairing in the d_{xz}, d_{yz}, d_z^2, and d_{xy} orbitals, which is consistent with a square planar symmetry for a d^8 ion. Both the spectra of the Pd^{II} and Cd^{II} complexes display only one signal each for H_j and H_k, as would be expected for a planar arrangement of SB^{2-}. NOESY experiments in $[D_6]$DMSO at room temperature allow a rigorous assignment of the ^1H NMR signals for these complexes (see Experim. Section).

The diamagnetism shown by $Ag_2(SB)\cdot 2H_2O$ attests to the presence of Ag^I ions and consequently the inability of the ligand to stabilise Ag^{II} even under strongly oxidising conditions (10 V). As in previous cases, the observation of only one signal each for H_j and H_k at room temperature (Electronic Supplementary Material) is indicative of a non-helical arrangement of SB^{2-} in this complex. Its anomalous stoichiometry and the ligand versatility allows the postulation that the ligand could behave as bisbinucleating, so it could act as a bridge between the two Ag^I ions.

Diffuse Reflectance and Magnetism

The diffuse reflectance spectrum of $Ni_2(SB)_2\cdot 2H_2O$ is characterised by a medium intensity broad band around 680 nm, which is attributed to a *d-d* transition expected for d^8 ions in tetrahedral fields.[22] In the spectrum of $Cu(SB)\cdot 4H_2O$, the only absorption attributable to a *d-d* transition is observed at about 460 nm, which is also consistent with a tetrahedral geometry.[23]

The magnetic moment for the Ni^{II} dimer at room temperature (3.0 BM per mol of Ni^{2+}) is quite low for a tetrahedral compound. This could be caused by a considerable distortion from the ideal geometry, resulting in a fall in the orbital contribution to this value.[24] In fact, we have found a similar value (3.3 BM per mol of Ni^{2+}) for $Ni_2(SB^1)_2\cdot MeCN$,[16] in which the ligand, helical arrangement and the Ni···Ni distance (ca. 6.2 Å) are not very different from those observed for $Ni_2(SB)_2\cdot 2H_2O$. No coupling interactions between the two Ni^{2+} ions are to be expected, because these are quite far apart (ca. 6.8 Å) and the ligands seem incapable of transmitting any interaction. Finally, a μ value at room temperature (2.1 BM) in the narrow range expected for a magnetically dilute tetrahedral compound arises from the magnetic susceptibility measurements for $Cu(SB)\cdot 4H_2O$.

Conclusions

The studied N_4 donor ligand displays a helical arrangement around those ions corresponding to the fourth period − Ni^{II}, Cu^{II}, and Zn^{II} − but it appears planar around Pd^{II}, Ag^I, Cd^{II}, and Pb^{II} ions, belonging to the fifth and sixth periods. Ionic radii thus seem to play a relevant role in the stereochemistry. Similarly, and in view of the secondary M···O interactions, a predilection for pseudooctahedral rather than distorted tetrahedral environments could be responsible for the obtaining of double-stranded Ni^{II} helicates, instead of monohelicates, with *N*-tosyl-substituted Schiff bases containing a pure alkyl chain of three or four members as spacer. Both Cu^{II} and Zn^{II} ions assume distorted tetrahedral coordination geometries involving the four N atoms of the dianionic ligand in their monohelicates, whereas the ligand behaves as a N_2+N_2 donor in $Ag_2(SB)\cdot 2H_2O$ and $Ni_2(SB)_2\cdot 5MeCN$.

The studied $(CH_2)_4$ spacer between the two 2-tosylaminobenzylidene units has not given rise to homochiral crystals of $Ni_2(SB)_2\cdot 5MeCN$, $Cu(SB)\cdot MeCN$, or $Zn(SB)\cdot 2MeCN$. However the last two crystallise in an acentric space group with a polar axis, forming alternative sheets of the two helical enantiomers (Λ and Δ), which is unusual for helical racemic compounds.

Experimental Section

General: Elemental analyses were performed on a Carlo−Erba EA 1108 analyser. NMR spectra were recorded on a Bruker DRX 500 spectrometer in $CDCl_3$, CD_3CN, or [D_6]DMSO as solvents. Infrared spectra were recorded as KBr pellets on a Bio-Rad FTS 135 spectrophotometer in the 4000−600 cm^{-1} range. Electrospray mass spectra were recorded on a LC/MSD Hewlett−Packard 1100 spectrometer with DMSO and methanol with formic acid (2%) as solvent. The FAB mass spectrum was recorded on a Micromass Autospec spectrometer, with *m*-nitrobenzyl alcohol as matrix. Diffuse reflectance spectra were recorded on a Perkin−Elmer Lambda 9 spectrophotometer. Magnetic susceptibility measurements were performed on pulverised samples at room temperature with a Sherwood Scientific magnetic susceptibility balance.

Syntheses: Chemicals of the highest commercial grade available (Aldrich) were used as received. *N*,*N*′-Bis(2-tosylaminobenzylidene)-1,4-diaminobutane (H_2SB) was prepared[12] by condensation of 2-(tosylamino)benzaldehyde[25] with 1,4-diaminobutane. Complexes, except for Pd(SB)·3H_2O·MeCN, were obtained by an electrochemical method,[9−12,22] in which a metal anode was oxidised in an acetonitrile solution of H_2SB. The preparation of Zn(SB)·H_2O is outlined below. The cell can be summarised as:
$Zn_{(+)}|H_2SB + NMe_4ClO_{4(MeCN)}|Pt_{(-)}$.

Caution: *Although no problem has been encountered in this work, all perchlorate compounds are potentially explosive, and should be handled in small quantities and with great care!*

An acetonitrile solution (80 cm^3) of H_2SB (100 mg, 0.166 mmol), containing about 30 mg of tetramethylammonium perchlorate, was electrolysed for 1 h 45′, with use of a 5 mA current intensity and an initial voltage of 16 V. Filtration and concentration of the resulting solution yielded a solid that was washed with diethyl ether and dried in vacuo. The ligand amount, current intensity and electrolysis time were identical for all the complexes. Initial voltages were in the 8−16 V range.

Pd(SB)·3H_2O·MeCN was obtained by heating of a methanol solution containing H_2SB, NaOH, and $Pd(AcO)_2$ in 1:2:1 molar ratio at reflux for 6 hours. Filtration of the resulting suspension yielded a solid that was washed with diethyl ether and dried in vacuo. The reaction end was determined by TLC.

$Ni_2(SB)_2$·2H_2O: Green solid. Yield 81%. M.p. > 320 °C. $C_{64}H_{68}N_8Ni_2O_{10}S_4$ (1354.91): calcd. C 56.7, H 5.1, N 8.3, S, 9.5; found C 56.7, H 5.3, N 8.5, S 9.2. IR (KBr): $\tilde{\nu}$ = 3440 (br., O−H), 1626 (s, C=N), 1301 (s, C−N), 1260, 1134 (s, SO_2) cm^{-1}. FAB-MS: *m*/*z* (%) = 659.0 (55%) [Ni(SB) + H]$^+$; μ (300 K): 6.0 B.M. UV/Vis (solid): λ_{max} (nm) = 680 [m, $^3T_1(P)\leftarrow{}^3T_1(F)$].

Pd(SB)·3H_2O·MeCN: Brown solid. Yield 82%. M.p. 260 °C. $C_{34}H_{41}N_5O_7PdS_2$ (802.27): calcd. C 51.9, H 4.9, N 7.5, S 8.6; found C 51.6, H 4.7, N 7.7, S 8.3. IR (KBr): $\tilde{\nu}$= 3441 (br., O−H), 1632 (s, C=N), 1294 (s, C−N), 1242, 1143 (s, SO_2) cm^{-1}. ESI-MS (100 V): *m*/*z* (%) = 707.0 (100) [Pb(SB) + H]$^+$. ^{1}H NMR (500 MHz, [D_6]DMSO): δ = 1.58 (m, 4 H, H_k), 1.88 (m, 4 H, H_j), 2.07 (s, 6 H, H_i), 7.10 (m, 14 H, H_c+H_d+H_e+H_g+H_h), 7.20 (d, 2 H, H_f), 7.65 (s, 2 H, H_b) ppm.

Cu(SB)·4H_2O: Brown solid. Yield 87%. M.p. 250 °C. $C_{32}H_{40}CuN_4O_8S_2$ (736.36): calcd. C 52.2, H 5.5, N 7.6, S, 8.7; found C 52.7, H 5.3, N 7.8, S 8.7. Single-Crystal X-ray Diffraction Studies

Cu(SB)·MeCN and Zn(SB)·2MeCN: Diffraction intensity data were collected at room temperature on a Bruker SMART CCD-1000 diffractometer with use of graphite-monochromatised Mo-K_α radiation (λ = 0.71073 Å). Absorption correction was carried out from equivalents with the aid of the SADABS program.[26] The structures were solved by direct methods and refined by full-matrix, least-squares based on F^2, with the aid of SHELX-97 software.[27] All non-hydrogen atoms were anisotropically refined. Hydrogen atoms were included at geometrically calculated positions with thermal parameters derived from the parent atoms. Table 2 provides a summary of crystal data, data collection and refinement parameters. Molecular graphics are represented by Ortep-3 for Windows, RasWin, and Platon.[28]

$Ni_2(SB)_2$·5MeCN: Several green needle crystals from different recrystallisation attempts of $Ni_2(SB)_2$·2H_2O were measured at 120 K, showing poor diffracting behaviour. This could be the result of extensive solvation and disorder,[3] as several low-quality refinements indicated. For the best data set that could be obtained, the measured crystal proved to be a two-component twin [twin ratio: 0.719(5)], arising from a rotation of −179.94° around the vector normal to (1 0 0) in the reciprocal space. The twin law was used to process the data with the aid of the GEMINI program.[29] The structure was solved with the help of DIRDIF[30] and then treated as in the two previous cases. The C atoms of one of the methylene

Synthesis, Crystal Structure, and Optical Properties of a New Molecular Complex of C_{60} with a Covalently Linked $(Fe^{III}TPP)_2O$ Dimer

Aleksey L. Litvinov,[a] Dmitri V. Konarev,[a] Andrey Yu. Kovalevsky,[b] Alexander N. Lapshin,[a] Evgeniya I. Yudanova,[a] Natalia V. Drichko,[c] Philip Coppens,[b] and Rimma N. Lyubovskaya*[a]

Keywords: Fullerenes / Porphyrinoids / Crystal engineering / Solid-state structures / UV/Vis spectroscopy

A new molecular complex of C_{60} with covalently linked μ-oxo dimer $(Fe^{III}TPP)_2O$ are (TPP = tetraphenylporphyrin) was obtained. The complex has a neutral ground state and is formed mainly by van der Waals forces. The X-ray analysis of the crystal structure of the complex showed it to have isolated packing of fullerenes in which each fullerene molecule is embraced in a pocket built by porphyrins. Optical properties and EPR behavior of the complex are described.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Fullerenes form complexes with aromatic hydrocarbons, amines, substituted tetrathiafulvalenes, metallocenes, porphyrins, and metalloporphyrins.[1−6] The latter family of complexes is of great interest because of their promising photoactive properties.[7] Metalloporphyrins can be used to develop neutral and ionic multi-component systems[8,9] and to determine the molecular structure of endohedral[10] and chemically modified fullerenes.[6] Different chemically modified porphyrins in which two porphyrin moieties bonded by one (''jaw'' porphyrins[11]) or two bridged chains (cyclic dimers[12]) have been used to prepare complexes with fullerenes. These molecules have a high affinity for fullerenes.[11,12]

Additionally to monomeric and chemically modified porphyrins, covalently linked dimers of metal-containing porphyrins with different bridging atoms (O,[13] N,[14] and C[15]) are also promising components for the development of photoactive complexes with fullerenes. It has been shown that, on photoexcitation with a 441.6 nm laser, $(Fe^{III}TPP)_2O$ undergoes photodisproportionation to the oxoferryl species Fe^{IV}=O(TPP) and five-coordinate, high-spin Fe^{II}-TPP(L).[16]

The present work reports for the first time the synthesis, crystal structure, and optical properties of the C_{60} complex, $(Fe^{III}TPP)_2O{\cdot}C_{60}$ (**1**), with a covalently linked μ-oxo-bis[5,10,15,20-tetraphenylporphyrinatoiron(III)] dimer.

Results and Discussion

X-ray diffraction[17] shows that **1** has a 1:1 solid-state stoichiometry $[(Fe^{III}TPP)_2O{:}C_{60}]$. The crystal is a racemic twin with two equal components [the Flack parameter[18] is 0.50(2)].

In the crystal, the $(Fe^{III}TPP)_2O$ and C_{60} molecules alternate in chains along the crystallographic *c* axis (Figure 1, a). The chains are positioned so that each C_{60} molecule is surrounded only by $(Fe^{III}TPP)_2O$ moieties; their are no inter-fullerene contacts. Because of this, $(Fe^{III}TPP)_2O$ forms a three-dimensional supramolecular network (Figure 1, b) through shortened H(Ph)···H′(Ph) (2.20−2.28 Å) and H(Ph)···C′(Ph) (2.72−2.86 Å) contacts. Each fullerene molecule is found in a pocket built by two porphyrin moieties from one chain and the phenyl substituents of four porphyrins from the adjacent chains. The phenyl substituents form short van der Waals contacts with fullerenes, with C(Ph)···C(C_{60}) distances in the 3.235−3.358 Å range.

The bond lengths and angles of $(Fe^{III}TPP)_2O$ in **1** are similar to those of the parent compound[13] (Table 1). The Fe−O−Fe moiety is bent, with an Fe1−O−Fe2 bond angle of 173.7(2)°. Four nitrogen atoms form an almost perfect plane. The Fe1 and Fe2 atoms are displaced from their planes by 0.46 and 0.47 Å, respectively, in the direction of the μ-oxo group. The porphyrin rings are strongly distorted and have a saddle-like conformation. Moreover, the por-

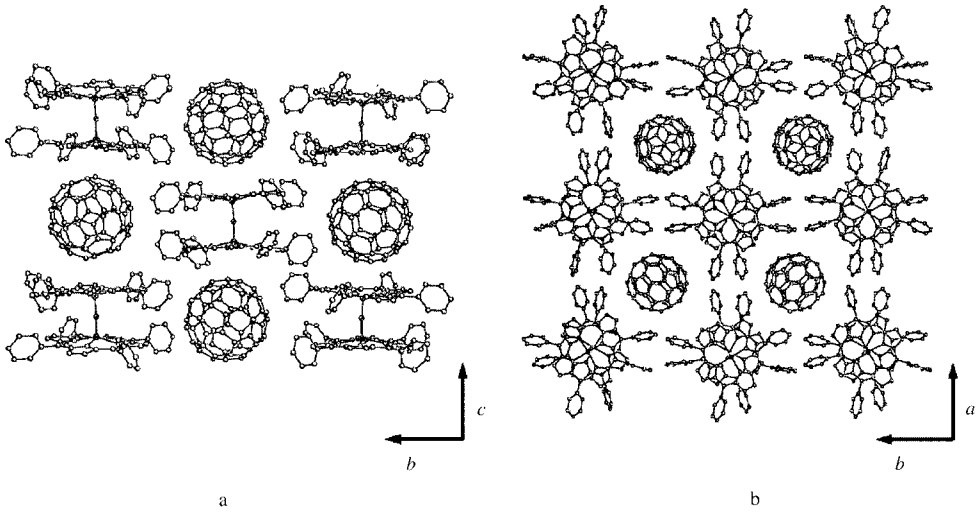

Figure 1. Projections of the crystal structure of **1** along the *bc* (a) and *ab* (b) planes

Table 1. Bond lengths and angles for parent $(Fe^{III}TPP)_2O$ and for the $(Fe^{III}TPP)_2O$ moieties in **1**

Compound	Fe1−O	Fe2−O	Fe1−Fe2	Fe1−Ct	Fe2−Ct	Fe1−O−Fe2	Torsion angle N−Fe−Fe′−N′
$[Fe^{III}TPP]_2O$[13]	1.763	1.763	3.522	0.54	0.54	174.5(1)°	35.4°
$[Fe^{III}TPP]_2O{\cdot}C_{60}$	1.745	1.771	3.511	0.47	0.46	173.7(2)°	29.7°

phyrin rings are rotated about the Fe−O−Fe moiety (the least torsion angle N−Fe1−Fe2−N′ is 29.7°).

The iron atoms of $(Fe^{III}TPP)_2O$ are located on the other side of the porphyrin macrocycle from the fullerene. Because of this the Fe···C(C_{60}) contacts of 3.239−3.513 Å are rather long compared to those in fullerene complexes with other metal-containing porphyrins (2.57−3.12 Å[5,6,8,19]). In addition to the Fe···C_{60} contacts (Figure 2), the porphyrins form shortened contacts with fullerenes through nitrogen [the N(TPP)···C(C_{60}) contacts are 3.081−3.186 Å] and carbon atoms [the C(TPP)···C(C_{60}) contacts are 3.244−3.425 Å]. For comparison, the sum of the van der Waals radii of two C atoms is 3.42 Å and that of a C and an N atom is 3.21 Å.[20]

Two complexes of C_{60} with Fe^{III} porphyrinates have been structurally characterized (Table 2). Provided the absence of an axial ligand at $Fe^{III}TPP$, a shortened Fe···C(C_{60}) contact of 2.56 Å is observed in $Fe^{III}TPP{\cdot}[B(C_6F_5)_4]{\cdot}C_{60}{\cdot}2.5C_6H_4Cl_2$ ($C_6H_4Cl_2$ = 1,2-dichlorobenzene),[19] while because of the presence of chlorine in octaethylporphyrinatoiron(III) chloride ($Fe^{III}ClOEP$), these contacts are much longer (3.20 Å[6]) in $Fe^{III}ClOEP{\cdot}C_{60}{\cdot}CHCl_3$. In **1** the Fe···$C_{60}$ contacts are close to those in the C_{60} complex with $Fe^{III}ClOEP$. The van der Waals N(TPP)···C(C_{60}) and C(TPP)···C(C_{60}) contacts have similar values in all three complexes (Table 2). It should be noted that the C_{60} molecules in **1** and in the C_{60} complex with $Fe^{III}TPP{\cdot}[B(C_6F_5)_4]$[19] are isolated, while in the C_{60} complex with $Fe^{III}ClOEP$ one observes one-dimensional zig-zag chains from C_{60}.[6]

The IR spectrum of **1** is a superposition of those of the individual components, namely C_{60} and $(Fe^{III}TPP)_2O$. The band for the $F_{1u}(4)$ vibration of C_{60}, which is most sensitive to charge transfer to the C_{60} molecule, is observed at 1427

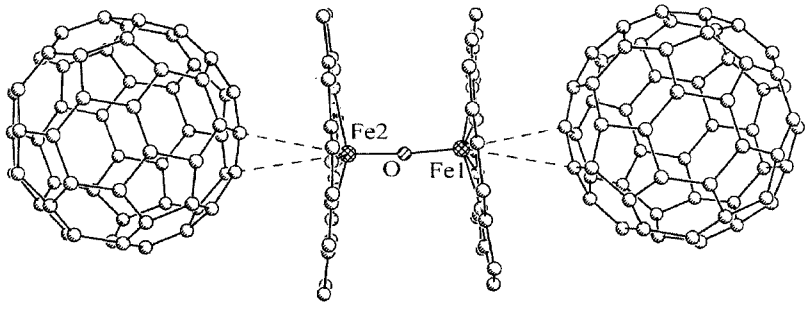

Figure 2. Mutual arrangement of $(Fe^{III}TPP)_2O$ and C_{60} molecules in **1**; phenyl substituents of $(Fe^{III}TPP)_2O$ are not shown

Table 2. Structural data for C_{60} complexes with Fe^{III}-containing porphyrins

Complex	C_{60} order	$C_{60}\cdots C_{60}$ centre to center	Fe···Fe	Fe···C(C_{60})	N···C(C_{60})	C(porphyrin)···C(C_{60})
$Fe^{III}ClOEP\cdot C_{60}\cdot CHCl_3$[6]	–	9.94	8.079	3.204–3.371	3.020–3.208	3.237–3.336
$Fe^{III}TPP\cdot[B(C_6F_5)_4]\cdot C_{60}\cdot 2.5C_6H_4Cl_2$[19]	–	14.43	11.684	2.570–3.413	3.018–3.448	3.263–3.421
$(Fe^{III}TPP)_2O\cdot C_{60}$	+	14.20	3.511	3.239–3.513	3.090–3.247	3.245

cm^{-1} in **1**, and is similar to that in the parent fullerene (1429 cm^{-1}), indicating no noticeable charge transfer. The absorption bands of $(Fe^{III}TPP)_2O$ are slightly shifted in **1** (up to 4 cm^{-1}) relative to the parent porphyrin.

The Vis-NIR reflectance spectra of a single crystal of **1** were measured in two perpendicular polarizations with maximal anisotropy of reflectivity from the most developed face of the crystal ($E\|c$ and $E\perp c$). The corresponding absorption spectra in both polarizations (Figure 3) show strong bands attributed to the dipole-allowed electronic transitions in the fullerene: $h_u\rightarrow h_g$ and $g_g,h_g\rightarrow t_{1u}$ at 270 and 343 nm for $E\perp c$, and 272 and 335 nm for $E\|c$. The $E\perp c$ spectrum also shows strong bands attributed to the absorption of $(Fe^{III}TPP)_2O$, at 417 and 579 nm, with a shoulder at 615 nm. These bands are red shifted (up to 10 nm) relative to the parent metalloporphyrin indicating a slight change in its initial geometry. In the structure of **1** the $(Fe^{II}TPP)_2O$ and fullerene molecules alternate in the stacks directed parallel to the crystallographic *c* axis, the planes of the porphyrin macrocycles of $(Fe^{III}TPP)_2O$ being perpendicular to the *c* axis. Consequently, with polarization perpendicular to the porphyrin planes ($E\|c$), the absorption bands of $(Fe^{III}TPP)_2O$ are absent. A similar anisotropy was observed in the spectrum of $Co^{II}TPP\cdot C_{60}\cdot 0.5CS_2$.[5] Thus, the absorption spectrum of the complex is a superposition of those of the parent molecules, indicating a neutral ground state in **1**.

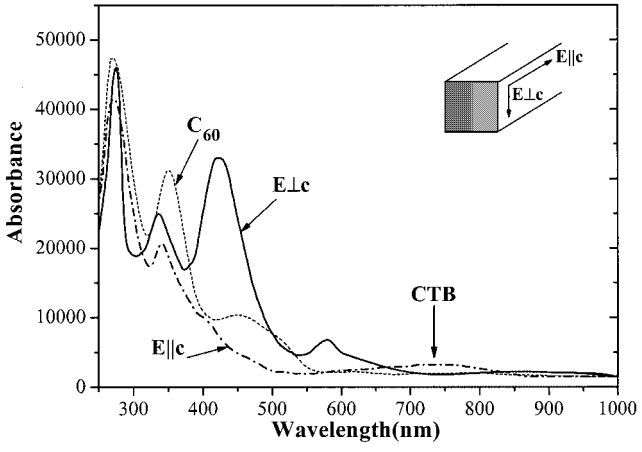

Figure 3. The UV/Visible absorption spectra of a single crystal of **1** for two polarizations of light ($E\|c$ and $E\perp c$)

It should be noted that the bands of dipole-allowed transitions of the fullerene ($h_u\rightarrow h_g$ and $g_g,h_g\rightarrow t_{1u}$) in the spectrum of the complex are narrower than those in the spectrum of a pure fullerene crystal and are shifted to higher frequencies. In $E\|c$ polarization, the position of the band $g_g,h_g\rightarrow t_{1u}$ is close to that of the parent C_{60} molecule (335 nm). The absorption band of C_{60} at 450 nm is also absent in the spectrum of the complex (Figure 3). Previously,[21] this band was attributed to intermolecular electron transfer between the adjacent C_{60} molecules. Indeed, the isolation of fullerene molecules from each other by the $(Fe^{III}TPP)_2O$ ones in **1** results in the absence of the band at 450 nm.

An additional weak absorption is observed in the visible range with a maximum at 720 nm in $E\perp c$ polarization. This band is also present in the isotropic spectrum of **1** in a KBr matrix and could be evidence of photoinduced charge transfer from $(Fe^{III}TPP)_2O$ to C_{60}. The position of this band is close to that in C_{60} complexes with (tetraphenylporphyrin)cobalt(II): $Co^{II}TPP\cdot C_{60}\cdot 0.5CS_2$ (750 nm)[5] and tetrakis(*p*-methoxyphenyl)porphyrincobalt(II): $Co^{II}TMPP\cdot(C_{60})_2\cdot 3C_7H_8$ (820 nm).[8] The position of a charge-transfer band (CTB) in a series of complexes with one acceptor is dependent on the ionization potentials of the donors. The ionization potential of $(Fe^{III}TPP)_2O$ is not known. However, metal-containing tetraphenylporphyrins have similar ionization potentials ($Fe^{III}TPPCl$: 6.1±0.2 eV; $Co^{II}TPP$: 6.1±0.2 eV; $Cu^{II}TPP$: 6.2±0.2 eV; $Mn^{III}TPP$: 6.0±0.2 eV[22]) that can be evidence of a close position of CTB in the complexes with C_{60}.

The EPR behavior of **1** is close to that of parent $(Fe^{III}TPP)_2O$. EPR signals were not observed at room temperature, whereas upon lowering the temperature down to 77 K, EPR signals with $g = 5.7$ and $\Delta H_{pp} = 200$ G appeared in both compounds. The *g* factor of the signal is characteristic of a square-planar complex of Fe^{III} with a high-spin $3d^5$ configuration. A strong exchange interaction between Fe^{III} in the dimer results in the absence of EPR signals at room temperature. However, the temperature decrease seems to cause a freezing of the state with the dihedral N–Fe–Fe′–N angle differing slightly from 180° between the porphyrin planes and results in the appearance of a weak EPR signal.[23] The similarity of the EPR spectra of **1** and $(Fe^{III}TPP)_2O$ indicates the absence of Fe^{III} coordination to fullerene and the changes in $(Fe^{III}TPP)_2O$ geometry in the complex with C_{60}, in agreement with the data of the X-ray analysis. A similar phenomenon was observed earlier for a C_{60} complex of $Fe^{III}ClTPP$, which also has an EPR spectrum similar to that of starting $Fe^{III}ClTPP$.[5] It seems that Fe^{III} is shifted from the porphyrin plane to oxygen in **1** as well as to chlorine in $Fe^{III}ClTPP$ that hinders the Fe^{III} coordination to C_{60}.

Conclusion

A new complex of C_{60} with $(Fe^{III}TPP)_2O$ has been synthesized. The complex has a neutral ground state and is formed mainly by van der Waals forces. The neutral ground state and the occurrence of a charge-transfer band in **1** provides for possible photoinduced charge transfer in the complex.

Experimental Section

General Remarks: The IR spectra of the powdered samples pressed in KBr pellets (1:400) were registered with a Perkin−Elmer 1725X spectrophotometer in the 400−7000 cm^{-1} range. Electronic absorption spectra were registered with a Perkin−Elmer Lambda 19 UV/Vis-NIR spectrophotometer in the 220−3000 nm range (KBr pellet, 1:2000). Polarized reflectance spectra of the single crystals were recorded with a microspectroreflectometer equipped with a UV/Vis microscope in the 260−1000 nm range at room temperature. The spectra were measured from one crystal face in two orthogonal directions with the maximal reflectance anisotropy, their orientation relative to the crystal axis was done based on the positions of the polarized absorption bands of the $(Fe^{III}TPP)_2O$ molecule. The absorption spectra were derived from the reflectance ones by the Kramers−Kronig transformation. EPR spectra were registered with a Radiopan SE/X 2547 spectrometer.

$(Fe^{III}TPP)_2O·C_{60}$ (1): Crystals of **1** were obtained by slow evaporation of the solvent from a toluene solution containing 20 mg of C_{60} and 38 mg of $(Fe^{III}TPP)_2O$[24] (1:1 molar ratio) under argon during a week (yield 18 mg, 90%). The composition of the complex was determined by X-ray diffraction on a single crystal.

X-ray Crystallographic Study: X-ray diffraction data for **1**[17] were collected at 90(1) K using a Bruker SMART1000 CCD diffractometer with a rotating anode source (Mo-K_α radiation, λ = 0.71073 Å), and equipped with an Oxford Cryosystems nitrogen gas-flow apparatus. The data were collected by the rotation method with a 0.3° frame-width (ω scan) and 40 sec exposure time per frame. Four sets of data (600 frames in each set) were collected, nominally covering half of the reciprocal space. The data were integrated, scaled, sorted and averaged using the SMART software package.[25] The structure was solved by the Patterson method using SHELXTL NT Version 5.10.[26] The structure was refined by full-matrix least-squares against F^2.

Non-hydrogen atoms were refined in the anisotropic approximation. Anisotropic thermal parameters of several carbon atoms were restrained to behave isotropically. Positions of hydrogen atoms were refined using the "riding" model with $U_{iso} = 1.2U_{eq}$.

Stepwise Assembly of Mixed Metal Dinuclear Carbonyl Complexes

Katja Heinze*[a] and Volker Jacob[a]

Keywords: Heterometallic complexes / Isocyanide ligands / Bridging ligands / Isomers / Group 6 elements

The one-pot/three-step solution synthesis of a library of nine directional, dinuclear mixed-metal complexes composed of different metal-carbonyl units (M = Cr, Mo, W) and a bifunctional bridging isocyanide Schiff-base ligand is described. The well-defined metal sequence in these complexes with Cr, Mo, and W in two positions can be determined post-synthesis by a combination of spectroscopic methods.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

One-dimensional materials are interesting with respect to their exceptional physical and chemical,[1−3] such as photophysical or electrochemical properties.[4] However, the synthesis of metal-containing chain complexes with defined chain lengths is difficult to achieve. An elegant approach to overcome the problem of obtaining mixtures of complexes with different chain lengths is the design and synthesis of special ligands which allow for only one definite chain length. This approach has been used, for example, in the synthesis of oligo-α-pyridylamino ligands which form string complexes with two, three, four, five, and seven metal centres depending on the length of the ligand.[5−8] The problem is thus transferred to organic synthesis of the ligand while metal incorporation is subject to self-organisation processes. A particular drawback of this approach is the need to synthesise special ligands for each chain length and the limited control over the metal sequence within the chain, as usually only homometallic complexes are obtained.

The construction of oligonuclear metal complexes may also be achieved by the stepwise connection of stable metal complexes through covalent bonds using a protection/deprotection strategy which has been successfully applied, for example, to defined ferrocene oligomers[9,10] and oligo-porphyrin systems.[11−14]

A similar, albeit more difficult, approach is the controlled stepwise assembly of building blocks through coordinative bonds. Such a procedure should allow the synthesis of complexes with any desired chain length controlled by the number of repetition cycles. Repeated complex activation and subsequent addition of a metal-bridging ligand fragment to a starting complex has been employed for the synthesis of oligonuclear ruthenium−pyrazine complexes.[15] Sequential protection/deprotection of a potential coordination site of a coordinated ligand has allowed a step-by-step synthesis of oligonuclear ruthenium and osmium polypyridine complexes.[16] Redox activation has been used to construct oligomeric iron/platinum complexes by a stepwise procedure.[17]

The repeated alternate addition of metal complex fragments and bridging ligands would be a procedure which allows full control over chain length, metal, and ligand sequence within the backbone. An important prerequisite for this method is the kinetic stability of the metal−ligand bonds within the chain so that undesired self-organisation processes, which would ultimately lead to the thermodynamically most stable species (e.g. scrambled metals, oligomer mixtures, or polymers), are suppressed.

The stepwise solution synthesis and characterisation of nine dinuclear chain complexes composed of different metal−carbonyl units (M = Cr, Mo, W) and a bifunctional bridging isocyanide Schiff-base ligand is the subject of this contribution.

Results and Discussion

Inert metal−ligand bonds are required for the stepwise controlled synthesis of multinuclear metal chain complexes. The coordinative bond between isocyanides and M^0 carbonyl complexes (M = Cr, Mo, W) is kinetically stable so that ligand-exchange processes are prevented.[18−20] Consequently, a suitable bridging ligand with an isocyano group is used in the assembly of dinuclear metal complexes.

The bridging Schiff-base ligand (4-isocyanophenyl)pyridine-2-ylmethylenamine C≡N−(N∩N′) is accessible by a two-step procedure starting from 1,4-diaminobenzene (Scheme 1). Transformation of one amino group into the desired isocyano group gives 4-isocyanophenylamine in rather poor yields according to the literature.[21] Optimis-

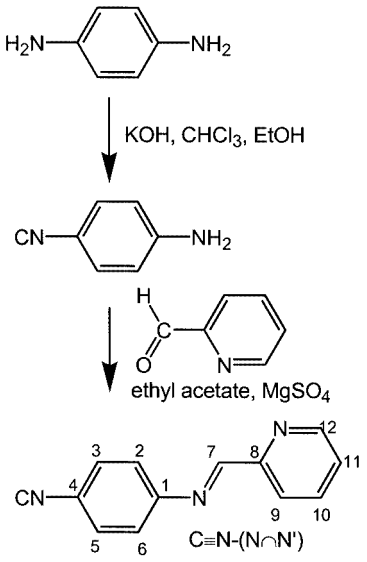
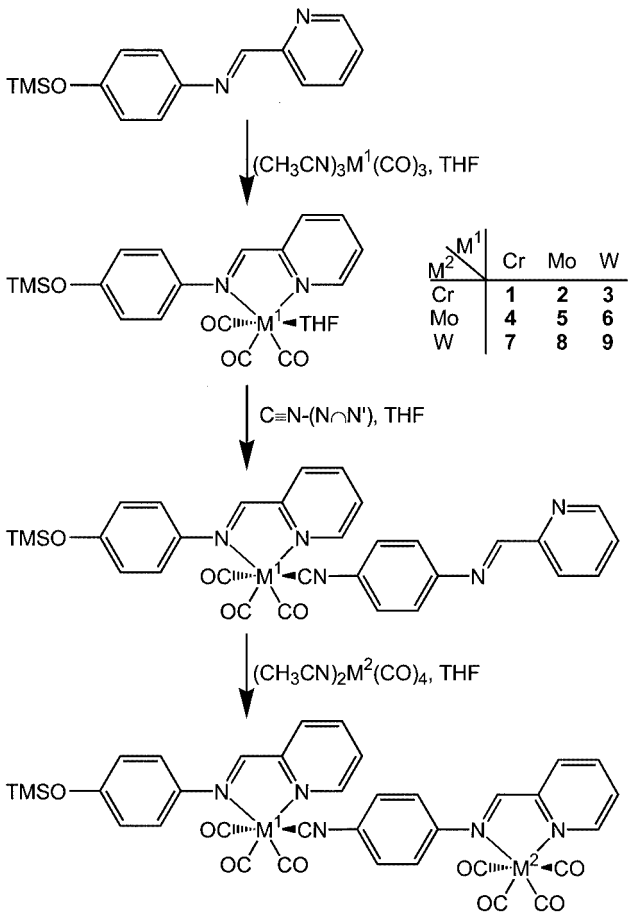


Scheme 1

ation of the purification increased the yield to 45% (see Exp. Sect.). Schiff-base condensation of the remaining amino group with pyridine-2-carbaldehyde affords the desired ligand C≡N−(N∩N′) (Scheme 1). C≡N−(N∩N′) can act as bridging ligand between two M^0-carbonyl units through i) the chelating Schiff-base moiety, and ii) the isocyano group.

The trimethylsilyloxy-substituted analogous Schiff-base ligand TMSO−(N∩N′)[18] was used as the starting point for the synthesis of dinuclear complexes. TMSO−(N∩N′) reacts with one equivalent of $[(CH_3CN)_3M^1(CO)_3]$ (M^1 = Cr, Mo, W) in THF at ambient temperature to give the reactive intermediate complexes [TMSO−(N∩N′)-$M^1(CO)_3$thf] (Scheme 2).[18] The labile solvent molecule can be displaced by the isocyanide ligand C≡N−(N∩N′) to afford green stable intermediate isocyanide complexes [TMSO−(N∩N′)$M^1(CO)_3$C≡N−(N∩N′)] (Scheme 2). The potentially chelating Schiff-base site of the coordinated C≡N−(N∩N′) ligand is finally coordinated to an $M^2(CO)_4$ fragment by reaction with $[(CH_3CN)_2M^2(CO)_4]$ (M^1 = Cr, Mo, W) yielding the dinuclear complexes [TMSO−(N∩N′)$M^1(CO)_3$C≡N−(N∩N′)$M^2(CO)_4$] **1**−**9** with the metals Cr, Mo, and W in defined positions of M^1 and M^2 (Scheme 2). This reaction sequence may be performed as a one-pot procedure — isolation of the intermediate complexes is unnecessary — provided that exact stoichiometric conditions are fulfilled. Otherwise, side products such as [X−(N∩N′)$M^{1,2}(CO)_4$], [X−(N∩N′)$M^{1,2}(CO)_3$C≡N−(N∩N′)V (X = OTMS, CN) are obtained in larger amounts which have to be removed by chromatography. The reactions can easily be monitored by IR spectroscopy due to the characteristic IR absorption bands of the intermediate complexes (Table 1).

Formation of the intermediate complexes [TMSO−(N∩N′)$M^1(CO)_3$thf] is shown by the appearance of two absorption bands in the ν_{CO} region (Table 1). Coordination of the isocyanide ligand C≡N−(N∩N′) replaces



Scheme 2

these two bands with a new set of three ν_{CO} bands plus one ν_{CN} band (Table 1, cf.[18,19,20]). A further proof for isocyanide coordination is the shift of the ν_{CN} signal by about 50 cm^{-1} to lower energy than the signal of the free ligand C≡N−(N∩N′) (ν_{CN} = 2127 cm^{-1}). This shift is also observed in the IR spectra of the dinuclear complexes **1**−**9** (Table 2). Introduction of the $M^2(CO)_4$ fragment causes additional ν_{CO} bands to appear (Table 2) so that the IR spectra of the dinuclear complexes **1**−**9** can be described as a superposition of the IR spectra of the corresponding mononuclear isocyanide tricarbonyl complex [TMSO−(N∩N′)$M^1(CO)_3$C≡N−(N∩N′)] and the tetra-

The ^{1}H NMR spectra of the complexes **1**−**9** show broad and overlapping multiplets in the aromatic region (see Exp. Section) and are thus not particularly informative. Only the signals for the imine protons (chemical shift range δ = 8.4−8.9 ppm) are clearly assignable (Table 3). A closer inspection reveals that imine protons of the tungsten complexes resonate at δ ≥ 8.84 ppm while imine protons of the chromium and molybdenum complexes resonate at higher fields with δ ≤ 8.62 ppm in THF. ^{13}C NMR spectra could not be obtained due to the low solubility of the complexes.

Table 3. ^{1}H NMR chemical shifts of imine protons of complexes **1**−**9** in CD_2Cl_2

	8.47	8.58	8.51
W	8.54	8.51	8.90
	8.87	8.84	8.87

In the UV/Vis spectra of complexes **1**−**9** one or two MLCT absorption bands are observed in the range 524−666 nm (Table 4). The low-energy absorption is due to the (N∩N′)$M^1(CO)_3$ chromophore, while the high-energy absorption arises from the (N∩N′)$M^2(CO)_4$ chromophore.[18−20,22−24] Like the IR spectra the UV/Vis spectra can be interpreted as a superposition of spectra of the individual chromophores, as shown for the ditungsten complex **9** in Figure 2. These observations demonstrate that, in each case, the two metal fragments of the dinuclear system behave as mechanically (IR) and electronically (UV/Vis) independent units, which appears reasonable in view of the large metal−metal distance of around 10 Å (estimated on model calculations) and the flexible orientation of the $M^2(CO)_4$ fragment with respect to the $M^1(CO)_3$ moiety.

Table 4. UV/Vis spectroscopic data of complexes **1**−**9** in THF (λ_{max} in nm; ε in $M^{-1}cm^{-1}$)

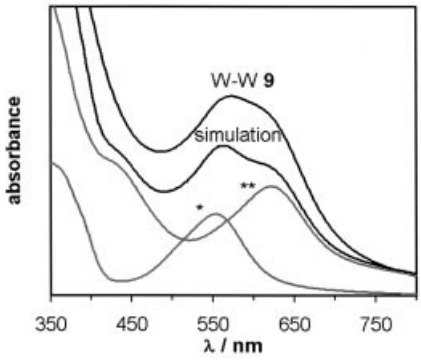

Figure 2. UV/Vis spectrum of the dinuclear complex **9** and spectra of the corresponding mononuclear complexes [HO−(N∩N′)-$W(CO)_4$] (*)[20] and [TMSO−(N∩N′)$W(CO)_3$C≡N−(N∩N′)] (**) in THF

As additional proof for the dinuclear nature of the complexes in solution, and to exclude a simple mixture of mononuclear complexes, the molecular masses of complexes **1**−**9** have been determined by osmometry (see Exp. Sect.). In all cases the results agree with the expected mass within experimental error. This also shows that the complexes remain stable in solution without dissociation, i.e. the metal−isocyanide bond remains intact.

The dinuclear species were further characterised by FAB mass spectroscopy (see Exp. Sect.). Peaks corresponding to

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ions of the dinuclear complexes and to fragments with loss of one to seven carbon monoxide ligands but with an intact {TMSO−(N∩N′)M^1C≡N−(N∩N′)M^2} backbone substantiate the above findings.

The cyclic voltammograms of complexes **1**−**9** in CH_2Cl_2/($n$$Bu_4N$)($PF_6$) show only irreversible and quasireversible oxidation waves, probably due to the loss of carbon monoxide upon oxidation. This behaviour has already been observed for the corresponding mononuclear complexes.[18−20]

With all these spectroscopic data at hand we tried to answer the following question: Is it possible to determine ("read") the metal sequence in these dinuclear complexes without any prior knowledge of the synthetic protocol used? In other words, can these nine complexes be distinguished with respect to their spectral properties? A closer inspection of the IR, ^{1}H NMR, and UV/Vis spectra of the complexes **1**−**9** reveals distinct differences between the individual complexes (Tables 2−4).

The IR spectra give three criteria:

(i) $\tilde{\nu}_{CN} \geq 2075$ cm^{-1} indicates M^1 = Mo (complex **2** or **8**)

(ii) $\tilde{\nu}_{CO,tetra} \geq 2012$ cm^{-1} indicates M^2 = Mo (complex **4** or **6**)

(iii) both (i) and (ii) indicates M^1 = M^2 = Mo (complex **5**)

The ^{1}H NMR spectra give two criteria:

(iv) one $\delta_{H(Imin)} \geq 8.84$ indicates M^1 = W or M^2 = W (**3**, **6**, **7**, or **8**)

(v) two $\delta_{H(Imin)} \geq 8.84$ indicates M^1 = M^2 = W (complex **9**)

Criteria (iii) and (v) completely assign complexes **5** and **9**. Taking (i), (ii), and (iv) together complexes **2**, **8**, **4**, and **6** can be unambiguously assigned. For example, (i) and (iv) together indicates complex **8**. Combining IR and ^{1}H NMR spectroscopy all complexes except the isomeric pair **3**/**7** can be unambiguously assigned.

The Cr/W isomers **3** and **7** can be distinguished on the basis of their UV/Vis spectra: the difference of λ_{max} for the MLCT absorption maxima of the individual chromophores in the dinuclear species is almost twice as large for complex **7** as for complex **3** (estimated on the basis of the absorption bands of corresponding mononuclear complexes[18−20]) so that for complex **7** a broad absorption with a low-energy shoulder is observed while complex **3** displays only one comparatively sharp band (Figure 3).

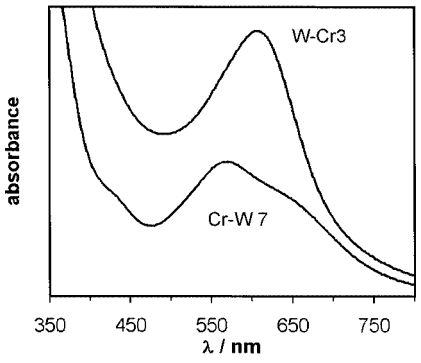

Figure 3. UV/Vis spectra of the dinuclear Cr/W complexes **3** and **7**

On the basis of IR (determination of molybdenum content and position), NMR (determination of tungsten content), and UV/Vis (discrimination between **3** and **7**) spectroscopy the metal positions in all nine dinuclear complexes **1**−**9** can be unambiguously determined.

Conclusion

Dinuclear directional complexes with well-defined metal sequences have been prepared in solution and characterised. However, low yields and lengthy purification renders this solution synthesis unsuitable for trinuclear and higher chain complexes which could be obtained by repeated chain growth cycles with [$(CH_3CN)_3M(CO)_3$] and C≡N−(N∩N′). Currently a new method for the stepwise assembly of tri- and oligonuclear complexes on a solid phase is being developed.[18,25,26]

The metal sequence of nine dinuclear complexes with Cr, Mo, and W in two possible positions can be determined using a combination of standard spectroscopic techniques. It should be possible to extend the sequence determination to "sequencing" or "readout" of oligonuclear complexes if the simulation technique based on spectra of mononuclear complexes is used in combination with chemometric methods such as, for example, principal component analysis (PCA) or partial least-squares (PLS).[29] As the spectroscopic determination of the chromium content is rather indirect a two letter code with molybdenum and tungsten as the basis might be advisable in larger chain complexes. The preparation and characterisation of oligonuclear complexes built from molybdenum and tungsten fragments is currently underway.[26]

Experimental Section

Unless noted otherwise, all manipulations were carried out under argon by means of standard Schlenk techniques. All solvents were dried by standard methods and distilled under argon prior to use. All other reagents were used as received from commercial sources. NMR: Bruker Avance DPX 200 at 200.15 MHz (^{1}H), 50.323 MHz (^{13}C) at 303 K; chemical shifts (δ) in ppm with respect to residual solvent peaks as internal standards: $CDCl_3$ (^{1}H: δ = 7.24; ^{13}C: δ = 77.0 ppm), [D_8]THF (^{1}H: δ = 1.73, 3.58; ^{13}C: δ = 25.5, 67.7), CD_2Cl_2 (^{1}H: δ = 5.32; ^{13}C: δ = 53.8 ppm). IR spectra were recorded on a BioRad Excalibur FTS 3000 spectrometer using CaF_2 cells or CsI disks. UV/Vis/NIR spectra were recorded on a Perkin−Elmer Lambda 19, 0.2 cm cells (Hellma, suprasil). Mass spectra were recorded on a Finnigan MAT 8400 spectrometer. Elemental analyses were performed by the microanalytical laboratory of the Organic Chemistry Department, University of Heidelberg. Molecular weight determinations in THF: Knauer vapour-pressure osmometer No. 7311100000, calibration with benzil.

The ligand TMSO−(N∩N′) was prepared according to the literature procedure.[18] The acetonitrile complexes were prepared from [(cycloheptatriene)$M(CO)_3$] and [(norbonadiene)$M(CO)_4$],[27,28] respectively, by reaction with CH_3CN (M = Cr, Mo, W).

4-Isocyanophenylamine:[21] 1,4-Diaminobenzene (0.28 mol, 30 g) was suspended in ethanol (120 mL) and chloroform (400 mL). A

solution of KOH (200 g) in water (800 mL) was carefully added and the mixture was refluxed for 2.5 h. The organic layer was separated and the residue was extracted twice with dichloromethane. The combined organic phases were washed with water and dried with $MgSO_4$. After evaporation of the solvent the residue was purified by flash chromatography (Alox, diethyl ether, $R_f = 0.5$) giving the product as yellow needles. Yield: 15 g (0.13 mol, 45%). $C_7H_6N_2$ (118.1): calcd. C 71.17, H 5.12, N 23.71; found C 71.11, H 5.12, N 23.52. MS (EI): *m/z* (intensity [%], fragment) = 118 (100) [M^+], 91 (33) [M^+ − HCN]. IR ($CHCl_3$): $\tilde{\nu}$ = 2129 (s, CN), 3410 cm^{-1} (br., NH). IR (CsI): $\tilde{\nu}$ = 2129 (s, CN), 3460 cm^{-1} (s, NH). ^1H NMR ($CDCl_3$): δ = 3.79 (br., 2 H, NH_2), 6.62 (d, 2 H, $H^{2,6}$, $^3J_{H,H}$ = 8.5 Hz), 7.17 (d, 2 H, $H^{3,5}$, $^3J_{H,H}$ = 8.5 Hz) ppm. ^{13}C NMR ($CDCl_3$): δ = 115.2 (s, $C^{2,6}$), 128.0 (s, $C^{3,5}$), 147.8 (s, C^1), C^4 and *C*N not observed ppm.

(4-Isocyanophenyl)pyridine-2-ylmethyleneamine C≡N−(N∩N′): A mixture of 4-Isocyanophenylamine (34.6 mmol, 4.08 g), pyridine-2-carbaldehyde (52.3 mmol, 5 mL), $MgSO_4$ (5 g), and ethyl acetate (80 mL) was heated under reflux for 6 h. The resulting brown suspension was filtered and the orange solution was evaporated to dryness. After recrystallisation from acetone/diethyl ether the brown solid was dried in vacuo for 4 days. Yield 5.5 g (26.5 mmol, 77%). $C_{13}H_9N_3$ (20.7.2)·0.25 H_2O: calcd. C 73.74, H 4.52, N 19.85; found C 73.89, H 4.49, N 19.62. m.p. 84−85 °C. MS(EI): *m/z* (intensity [%], fragment) = 207 (31) [M^+], 179 (M^+ − HCN, − H), 79 (100) [$C_5H_5N^+$]. HR-MS(EI): Calcd. for $C_{13}H_9N_3$: 207.07965; found 207.07663. IR (CH_2Cl_2): $\tilde{\nu}$ = 2127 cm^{-1} (s, CN). IR (CsI): $\tilde{\nu}$ = 2131 cm^{-1} (s, CN). ^1H NMR ([D$_8$]THF): δ = 7.39 (d, 2 H, $H^{2,6}$, $^3J_{H,H}$ = 8.6 Hz), 7.45−7.49 (m, 1 H, H^{11}), 7.55 (d, 2 H, $H^{3,5}$, $^3J_{H,H}$ = 8.6 Hz), 7.90 (dvt, 1 H, H^{10}, *J* = 7.8, *J* = 1.2 Hz), 8.26 (d, 1 H, H^9, *J* = 7.8 Hz), 8.62 (s, 1 H, H^7), 8.72 (d, 1 H, H^{12}, *J* = 4.8 Hz) ppm. ^{13}C NMR ([D$_8$]THF): δ = 121.5 (s, C^9), 122.5 (s, $C^{2,6}$), 125.8 (s, C^{11}), 127.7 (s, $C^{3,5}$), 136.7 (s, C^{10}), 150.0 (s, C^1), 150.2 (s, C^{12}), 152.4 (s, C^4), 155.1 (s, C^8), 163.2 ppm (s, C^7), *C*N not observed. All signals were assigned on the basis of DEPT, CH-COSY, and NOESY experiments. The conformation in solution is *transoid* as no cross peak between H^7 and H^9 is observed in the NOESY spectrum.

Complexes 1−9: All glassware was passivated with $(CH_3)_3SiCl$ before use. [$(CH_3CN)_3M^1(CO)_3$] (1 mmol) was treated with TMSO−(N∩N′) (270 mg, 1 mmol) in 40 mL of THF and the solution was stirred until IR control (see Table 1) indicated complete formation of [TMSO−(N∩N′)M(CO)$_3$thf] (at least 15 min). C≡N−(N∩N′) (207 mg, 1 mmol) was added as a solid and the solution turned green immediately. IR control indicated complete formation of [TMSO−(N∩N′)M^1(CO)$_3$C≡N−(N∩N′)] after 10 min (see Table 1). A solution of [$(CH_3CN)_2M^2(CO)_4$] (1 mmol) in THF (10 mL) was then added. The reaction mixture turned black and was stirred for 30 min. Celite was added and the solution was evaporated to dryness. The dark residue was chromatographed on silica gel (*T* = 0 °C; Et_2O, purple fraction; THF, dark-blue fraction, product complex). The THF fraction was concentrated and layered with petroleum ether (40/60). The black precipitate was collected and dried in vacuo. Yields: 20−55% (0.2−0.55 mmol).

[TMSO−(N∩N′)Cr(CO)$_3$C≡N−(N∩N′)Cr(CO)$_4$] (1): $C_{35}H_{27}Cr_2N_5O_8Si$ (777.7): calcd. C 54.05, H 3.50, N 9.01; found C 53.22, H 3.62, N 9.58. Molecular mass found: 765. MS(FAB): *m/z* (intensity [%], fragment) = 777 (17) [M^+], 693 (100) [M^+ − 3CO], 581 (94) [M^+ − 7CO]. ^1H NMR (CD_2Cl_2): δ = 0.38 (s, 9 H, SiCH_3), 7.0 (br. s, 2 H), 7.2−7.6 (m, 8 H), 7.9 (br. s, 4 H), 8.48 (s, 1 H), 8.54 (s, 1 H), 9.29 (br. s, 1 H), 9.39 (br. s, 1 H) ppm. IR (CsI): $\tilde{\nu}$ = 1832, 1908, 2009 (CO), 2082 (CN) cm^{-1}.

[TMSO−(N∩N′)Mo(CO)$_3$C≡N−(N∩N′)Cr(CO)$_4$] (2): $C_{35}H_{27}CrMoN_5O_8Si$ (821.7): calcd. C 51.16, H 3.31, N 8.52; found C 50.74, H 3.38, N 8.97. Molecular mass found: 846. MS(FAB): *m/z* (intensity [%], fragment) = 823 (15) [M^+], 711 (100) [M^+ − 4CO], 683 (58) [M^+ − 5CO], 627 (40) [M^+ −5 CO]. ^1H NMR (CD_2Cl_2): δ = 0.38 (s, 9 H, SiCH_3), 7.02 (d, *J* = 8.0 Hz, 2 H), 7.2−7.6 (m, 8 H), 7.8−8.0 (m, 4 H), 8.49 (s, 1 H), 8.62 (s, 1 H), 9.2−9.4 (br. s, 2 H) ppm. IR (CsI): $\tilde{\nu}$ = 1832, 1911, 2010 (CO), 2084 (CN) cm^{-1}.

[TMSO−(N∩N′)W(CO)$_3$C≡N−(N∩N′)Cr(CO)$_4$] (3): $C_{35}H_{27}CrN_5O_8SiW$ (909.6): calcd. C 46.22, H 2.99, N 7.70; found C 46.32, H 3.47, N 8.02. Molecular mass found: 917. MS(FAB): *m/z* (intensity [%], fragment) = 908 (100) [M^+], 797 (66) [M^+ − 4CO]. ^1H NMR (CD_2Cl_2): δ = 0.38 (s, 9 H, SiCH_3), 7.0 (m, 2 H), 7.3−7.5 (m, 8 H), 7.93 (br. s, 4 H), 8.48 (s, 1 H), 8.90 (s, 1 H), 9.27 (br. s, 1 H), 9.38 (br. s, 1 H) ppm. IR (CsI): $\tilde{\nu}$ = 1828, 1907, 2008 (CO), 2080 (CN) cm^{-1}.

[TMSO−(N∩N′)Cr(CO)$_3$C≡N−(N∩N′)Mo(CO)$_4$] (4): $C_{35}H_{27}CrMoN_5O_8Si$ (821.7): calcd. C 51.16, H 3.31, N 8.52; found C 50.73, H 3.40, N 8.68. Molecular mass found: 806. MS(FAB): *m/z* (intensity [%], fragment) = 739 (36) [M^+ − 3CO], 711 (94) [M^+ − 4CO]. ^1H NMR (CD_2Cl_2): δ = 0.31 (s, 9 H, SiCH_3), 6.94 (d, *J* = 8.0 Hz, 2 H), 7.3−7.6 (m, 8 H), 7.9−8.0 (m, 4 H), 8.42 (s, 1 H), 8.47 (s, 1 H), 9.1−9.3 (m, 2 H) ppm. IR (CsI): $\tilde{\nu}$ = 1837, 1912, 2012 (CO), 2082 (CN) cm^{-1}.

[TMSO−(N∩N′)Mo(CO)$_3$C≡N−(N∩N′)Mo(CO)$_4$] (5): $C_{35}H_{27}Mo_2N_5O_8Si$ (865.6): calcd. C 48.57, H 3.14, N 8.09; found C 48.31, H 3.28, N 8.91. Molecular mass found: 841. MS(FAB): *m/z* (intensity [%], fragment) = 866 (67) [M^+], 782 (67) [M^+ − 3CO], 670 (100) [M^+ − 7CO]. ^1H NMR (CD_2Cl_2): δ = 0.38 (s, 9 H, SiCH_3), 7.0 (d, *J* = 8.4 Hz, 2 H), 7.34 (d, *J* = 8.4 Hz, 2 H), 7.5−7.7 (m, 6 H), 7.9−8.0 (m, 4 H), 8.58 (s, 1 H), 8.61 (s, 1 H), 9.22 (d, *J* = 3.7 Hz, 1 H), 9.28 (br. s, 1 H) ppm. IR (CsI): $\tilde{\nu}$ = 1830, 1911, 2016 (CO), 2084 (CN) cm^{-1}.

[TMSO−(N∩N′)W(CO)$_3$C≡N−(N∩N′)Mo(CO)$_4$] (6): $C_{35}H_{27}MoN_5O_8SiW$ (953.5): calcd. C 44.09, H 2.85, N 7.35; found C 43.34, H 3.22, N 8.01. Molecular mass found: 967. MS(FAB): *m/z* (intensity [%], fragment) = 955 (17) [M^+], 927 (71) [M^+ − CO], 915 (100) [M^+ − 5CO]. ^1H NMR (CD_2Cl_2): δ = 0.31 (s, 9 H, SiCH_3), 6.95 (d, *J* = 8.0 Hz, 2 H), 7.22 (d, *J* = 8.0 Hz, 2 H), 7.5−7.7 (m, 6 H), 7.9−8.0 (m, 4 H), 8.51 (s, 1 H), 8.83 (s, 1 H), 9.12 (br. s, 1 H), 9.31 (br. s, 1 H) ppm. IR (CsI): $\tilde{\nu}$ = 1829, 1907, 2016 (CO), 2077 (CN) cm^{-1}.

[TMSO−(N∩N′)Cr(CO)$_3$C≡N−(N∩N′)W(CO)$_4$] (7): $C_{35}H_{27}CrN_5O_8SiW$ (909.6): calcd. C 46.22, H 2.99, N 7.70; found C 45.41, H 3.29, N 7.88. Molecular mass found: 937. Lacunary Wells−Dawson Sandwich Complexes − Synthesis, Characterization, and Stability Studies of Multi-Iron Species

Israel Martyr Mbomekalle,[a] Bineta Keita,[a] Louis Nadjo,*[a] Wade A. Neiwert,[b] Lei Zhang,[b] Kenneth I. Hardcastle,[b] Craig L. Hill,[b] and Travis M. Anderson[b]

Keywords: Polyoxometalates / Sandwich complexes / Iron / Manganese

Reaction of α-$Na_{12}(As_2W_{15}O_{56})$ with Fe^{II} in 1 M NaCl solution followed by air oxidation yields αααα-$H_2Na_{14}[(NaOH_2)_2Fe^{III}_2(As_2W_{15}O_{56})_2]$ (Na**2**), the arsenic analogue of the divacant lacunary sandwich, αααα-$H_2Na_{14}[(NaOH_2)_2Fe^{III}_2(P_2W_{15}O_{56})_2]$ (Na**1**). This complex (Na**2**) consists of a Na_2Fe_2 central unit sandwiched between two B-α-$As_2W_{15}O_{56}^{12-}$ moieties. Both Na**1** and Na**2** react with one equivalent of Fe^{III} to give ααβα-$Na_{14}[(NaOH_2)(Fe^{III}OH_2)(Fe^{III})_2(X_2W_{15}O_{56})_2]$, where X = P (Na**3**) or As (Na**4**), or two equivalents of Mn^{II} to give αββα-$Na_{14}[(Mn^{II}OH_2)_2(Fe^{III})_2(X_2W_{15}O_{56})_2]$, where X = P (Na**5**) or As (Na**6**). A single-crystal X-ray diffraction analysis of Na**5** has been carried out [a = 13.5387(8) Å, b = 13.9327(9) Å, c = 21.3347(13) Å, α = 92.921(1) °, β = 94.367(1) °, γ = 118.154(1) °, triclinic, $P\bar{1}$, $R1$ = 5.49%, based on 24662 independent reflections], which revealed a Mn_2Fe_2 central unit sandwiched between two B-α-$P_2W_{15}O_{56}^{12-}$ units. All of the new complexes have been characterized by FTIR spectroscopy, UV/Visible spectroscopy, elemental analyses, and cyclic voltammetry, and they are all stable for at least 24 h over a wide pH range (0–7), except for Na**4**, which is unstable below pH 2.

Introduction

Polyoxometalates (POMs for convenience) and their transition metal substituted derivatives (TMSPs) are a versatile and robust group of metal−oxygen anionic clusters with applications in catalysis, medicine, and materials science.[1−3] Among known POM structural types, sandwich complexes are the largest class of TMSPs. There are five major families of sandwich POMs (Figure 1), four of which are derived from trivacant Keggin structures ($XW_9O_{34}^{n-}$ or $XW_9O_{33}^{n-}$, where X = Fe^{III}, Co^{II}, Cu^{II}, Zn^{II}, Si^{IV}, P^{V}, As^{III}, As^{V}, Sb^{III}, Bi^{III}, Se^{IV}, or Te^{IV}),[4−8] and the fifth consists of the Wells−Dawson-derived structures.[8−21] These complexes are composed of a central M_4O_{16} unit encapsulated by two B-α-$X_2W_{15}O_{56}^{12-}$ (X = P^{V} or As^{V}) trivacant POMs. The structural properties of sandwich compounds derived from B-α-$P_2W_{15}O_{56}^{12-}$ are among the most well known because they are more amenable to NMR studies (such as ^{31}P NMR) than are the analogous Keggin (i.e. B-α-$XW_9O_{34}^{n-}$) and arsenic-containing Wells−Dawson species (i.e. B-α-$As_2W_{15}O_{56}^{12-}$).[8,16,18]

Recently we reported the new sandwich complex αααα-$H_2Na_{14}[(NaOH_2)_2(Fe^{III})_2(P_2W_{15}O_{56})_2]$ (Na**1**), which differs from conventional B-type Keggin and Wells−Dawson species;[14] X-ray structure analysis reveals only two d-electron metals reside in the central unit,[22] and the other positions are occupied by two weakly bound and labile seven-coordinate Na^+ ions that can readily exchange with a number

of d-electron-containing metals, including Fe^{III}, Co^{II}, Cu^{II}, and Ni^{II}.[23]

We now report the first arsenic analogue of Na**1**, αααα-$Na_{16}[(NaOH_2)_2(Fe^{III})_2(As_2W_{15}O_{56})_2]$ (Na**2**), which is of considerable interest because the replacement of P with As in other sandwich-type complexes can greatly enhance catalytic activity for the H_2O_2-based epoxidation of alkenes without adversely affecting selectivity.[21,24] Both Na**1** and Na**2** react with a single equivalent of Fe^{III} to produce ααβα-$Na_{14}[(NaOH_2)(Fe^{III}OH_2)(Fe^{III})_2(X_2W_{15}O_{56})_2]$, where X = P (Na**3**)[16] or As (Na**4**), respectively.[25] Na**1** and Na**2** also react with two equivalents of Mn^{II} to yield new mixed-metal sandwich complexes, αββα-$Na_{14}[(Mn^{II}OH_2)_2(Fe^{III})_2(X_2W_{15}O_{56})_2]$, where X = P (Na**5**) or As (Na**6**). The four new complexes reported here (Na**2**, Na**4**, Na**5**, and Na**6**) have all been characterized by FTIR spectroscopy, UV/Visible spectroscopy, elemental analyses, and cyclic voltammetry. Complexes Na**2**, Na**4**, and Na**5** have also been characterized by X-ray crystallography.

Results and Discussion

Syntheses: The reaction of α-$Na_{12}(As_2W_{15}O_{56})$ with Fe^{II} in 1 M NaCl solution followed by air oxidation yields αααα-$H_2Na_{14}[(NaOH_2)_2Fe^{III}_2(As_2W_{15}O_{56})_2]$ (Na**2**), the arsenic analogue of the divacant lacunary sandwich, αααα-$H_2Na_{14}[(NaOH_2)_2Fe^{III}_2(P_2W_{15}O_{56})_2]$ (Na**1**). The synthesis of Na**2** is similar to Na**1** with two important exceptions.[14] First, the trivacant precursor α-$Na_{12}(As_2W_{15}O_{56})$ was used instead of α-$Na_{12}(P_2W_{15}O_{56})$. Second, the metastable dark green complex $Na_{16}[(Fe^{II}OH_2)_2Fe^{II}_2(As_2W_{15}O_{56})_2]$ was crystallized at 4 °C rather than at 10 °C.

Both Na**1** and Na**2** react with a single equivalent of Fe^{III} in water or in dilute NaCl to produce ααβα-$Na_{14}[(NaOH_2)(Fe^{III}OH_2)(Fe^{III})_2(X_2W_{15}O_{56})_2]$, where X = P (Na**3**)[16] or As (Na**4**), respectively.[26] Complexes Na**3** and Na**4** may also be isolated via fractional crystallization (≈ 48−70% yield for Na**4** and Na**3**, respectively) as byproducts in the synthesis of Na**1** and Na**2** {via the air-sensitive $Na_{16}[(Fe^{II}OH_2)_2Fe^{II}_2(X_2W_{15}O_{56})_2]$, where X = P^V or As^V, precursor}. Na**1** and Na**2** may also react with other d-electron-containing metals to yield mixed-metal sandwich complexes. Specifically, Na**1** and Na**2** react with 2.0 equivalents of Mn^{II} to yield αββα-$Na_{14}[(Mn^{II}OH_2)_2(Fe^{III})_2(X_2W_{15}O_{56})_2]$, where X = P (Na**5**) or As (Na**6**). ^{31}P NMR analysis of Na**5** suggests the reaction proceeds to 100% product (one peak for the symmetry-equivalent distal P atoms at δ = −11.9 ppm), although isolated yields of the arsenic analogue, Na**6**, were significantly higher than for the phosphorus analogue, Na**5** (84% versus 10% for Na**6** and Na**5**, respectively).

Crystallographic Studies: The X-ray structure of Na**2** reveals that only two Fe^{III} atoms are present in the innermost positions of the central tetrameric unit (Figure 2, A). The other two positions are occupied by two weakly-bound six-coordinate Na atoms. Each Na atom is coordinated to three oxygen atoms from one B-α-$As_2W_{15}O_{56}^{12-}$ moiety, two oxygen atoms from the other B-α-$As_2W_{15}O_{56}^{12-}$ moiety, and by a weakly-bound terminal water molecule. This complex is nearly isostructural to Na**1**, except that the As−O bond lengths in Na**2** are slightly longer than the analogous P−O bond lengths in Na**1**.[14] Disorder in the W_3O_{13} triad containing W1, W2, and W3 (rotation by 60 °) and of the Na counter cations and solvent water molecules prevented anisotropic refinement of all atoms (for details see data deposited in the crystal data base).

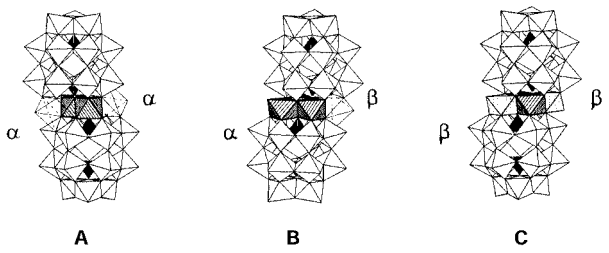

Figure 2. Polyhedral representations of the new Wells−Dawson sandwich complexes. **A:** Na**1** or Na**2** (W atoms are white, P or As atoms are black, Fe atoms are striped) **B:** Na**3** or Na**4** **C:** Na**5** or Na**6** (Mn atoms are gray). The central junctions are labeled α or β, and the central hexacoordinate Na atoms are shown for clarity.

An X-ray crystallographic analysis was also performed on the triferric arsenic complex, Na**4** (Figure 2, B). However, the crystals of this complex were of poorer quality than the analogous phosphorus complex, Na**3**.[16] While the structure of Na**4** was well determined and isostructural with the phosphorus complex, Na**3**, a poor refinement arose from the significant disorder of both a 60 ° rotation of the two W_3O_{13} triads containing W1, W2, and W3 and W28, W29, and W30 and the external Na1 and Fe1 positions in the $NaFe_3$ central unit (see crystal data base for additional details).[27]

An X-ray crystallographic analysis of the new mixed-metal sandwich POM, Na**5** (Table 1, Figure 2, C) shows that two Mn^{II} atoms have replaced the two Na^+ atoms of the

central unit of Na**1**. Each Mn^{II} atom is ligated by three oxygen atoms from one B-α-$P_2W_{15}O_{56}^{12-}$ unit, two oxygen atoms from the other B-α-$P_2W_{15}O_{56}^{12-}$ unit, and a terminal water ligand. Bond valence sum calculations from the X-ray crystal structure of Na**5** give an average oxidation state of 2.07 ± 0.02 for the two Mn atoms and 2.94 ± 0.02 for the two Fe atoms.[28] Crystals suitable for a complete X-ray crystallographic analysis could not be grown for the arsenic analogue (Na**6**).[29]

Stability Measurements: Unlike the Keggin-derived complexes which show a well-defined peak in their spectra, the UV/Visible spectra of the Wells−Dawson-derived species are usually more complex (with several broad absorptions). The complexes studied here exhibit spectra with different extinction coefficients and different peak wavelengths. Specifically, for a given pH, the spectra for Na**1**, Na**3**, and Na**5** show two main absorption bands around 220−250 nm and 340−360 nm, respectively. The same trends were observed for the As derivatives, Na**2**, Na**4**, and Na**6**. Thus, the stability of the oxidized forms of the complexes (Na**2**, Na**4**, Na**5**, and Na**6**), as a function of pH (0−7) and time (1 to 24 h), can be monitored by their UV/Visible spectra. Each experiment lasted 24 h, which is longer than necessary for complete electrochemical characterization of the complexes, but is relevant for long-lasting or preparative scale catalytic and electrocatalytic processes. All of the reported complexes (Na**2**, Na**4**, Na**5**, and Na**6**) are stable from pH 0 to 7 over a 24 hour period except for Na**4**, which is unstable below pH 2.

In additional stability tests on the reduced forms of the complexes, which are of interest for both catalytic and electrocatalytic processes, the Fe^{III} centers were exhaustively reduced to Fe^{II} by controlled potential coulometry and then reoxidized to the ferric state. The stability was monitored by cyclic voltammetry, recorded before and after the forward and backward electrolysis reaction. The data suggest that the Fe^{II} state within the complexes is stabilized by the two Mn^{II} centers (Na**5** and Na**6**). In contrast, electrolyses in pH < 4 media show that the Fe^{II} forms are unstable within Na**1** and Na**2** in the absence of Mn^{II}.

Electrochemistry: Cyclic voltammetry of the sandwich complexes, in a pH 3 sulfate medium (0.5 M Na_2SO_4 and H_2SO_4), afforded voltammograms of the arsenic complexes Na**2** and Na**4** that are similar to their corresponding phosphorus analogues.[15,20] However, the waves of the arsenic-containing species (Na**2** and Na**4**) are at slightly more positive potentials than for phosphorus-containing complexes (Na**1** and Na**3**).[24] Table 2 compares specifically the peak potential locations for the Fe waves and for the Mn waves (the Fe centers are arbitrarily numbered 1, 2, and 3 for clarity). The representative cyclic voltammograms in Figure 3 show in superposition the patterns for Na**1** and Na**5** (Figure 3, A) as well as Na**2** and Na**6** (Figure 3, B). As expected, only Na**5** and Na**6** show an oxidation process attributable to the overall four-electron oxidation of the Mn centers. The associated reduction patterns are composite and partially feature the characteristic shape of surface adsorbed species.

Table 2. Peak potential (V vs. SCE) for Fe waves E_{pc} (reduction) and the Mn wave (oxidation) determined by cyclic voltammetry at pH 3.00 (0.5 M Na_2SO_4 + H_2SO_4) for the new complexes. Scan rate: 10 $mV \cdot s^{-1}$, working electrode: glassy carbon

The Fe and W waves are well separated in all of these complexes and the number of Fe waves observed for each complex corresponds exactly to that known from the stoichiometry of the relevant molecules.[15] Similar behavior has been observed for αββα-$Na_{12}[(Fe^{III}OH_2)_2(Fe^{III})_2(As_2W_{15}O_{56})_2]$.[20] Here again, controlled potential coulometry confirms that the exhaustive reduction of each Fe center consumes one electron per molecule. Also noteworthy is the observation that the first Fe wave of Na**4** is at a more positive potential than all other Fe waves present

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the series (Table 2). The Mn^{II} in Na**5** and Na**6** also modifies the characteristics of the Fe waves, which are at slightly more positive potentials than for the divacant lacunary precursors Na**1** and Na**2**. Tentatively, and with the assumption of minimal variation in other electronic properties between the two complexes, this change might be attributable to differences in the overall negative charge of the complexes, which decreases from 16 (in Na**1** and Na**2**) to 14 (in Na**5** and Na**6**), thus rendering the Mn-containing complexes easier to reduce than their precursors. The magnitude of this difference, however, might be modulated by the acid−base properties of the reduced forms of these complexes. In short, as expected, Na**5** and Na**6** behave much like saturated sandwich-type derivatives while Na**1** and Na**2** are more lacunary. These observations are similar to those described by Pope and Chorghade for Sn-substituted monovacant POM complexes.[30] Sn^{II} is too large for the octahedral vacancy and the corresponding substituted derivatives behave much like the lacunary precursor complexes. In contrast, Sn^{IV} fits in the vacancy much better, and its derivatives behave very similarly to the saturated complexes.

Conclusions

The new divacant, lacunary arsenic-containing sandwich-type complex, Na**2**, synthesized here is isostructural with its phosphorus analogue, Na**1**. Both complexes react with one equivalent of Fe^{III} to yield triferric sandwich-type complexes, $\alpha\alpha\beta\alpha$-$Na_{14}[(NaOH_2)(Fe^{III}OH_2)(Fe^{III})_2(X_2W_{15}O_{56})_2]$, where X = P (Na**3**) or As (Na**4**). Na**1** and Na**2** also react with two equivalents of Mn^{II} to produce new mixed-metal sandwich-type complexes. All of the new complexes are stable for at least 24 h over the wide pH range 0−7, except for Na**4**, which is not stable below pH 2. This stability is remarkable and in sharp contrast with many other TMSPs. Typically within the Wells−Dawson family, the saturated compounds (formula $X_2W_{18}O_{62}^{6-}$, where X = P^V or As^V) are stable in mostly acidic media while their monosubstituted derivatives (formula $X_2MW_{17}O_{61}^{n-}$, where X = P^V or As^V and M = first row transition metal cation) require a higher pH. The wide stability seen here is an important prerequisite for substantial catalytic and electrocatalytic processes and may be a key parameter in preparing new effective catalysts.

Experimental Section

General Methods and Materials: α-$Na_{12}(As_2W_{15}O_{56})$, α-$Na_{12}(P_2W_{15}O_{56})$, Na**1**, and Na**3** were obtained by published procedures, and their purity was confirmed by IR, cyclic voltammetry, and ^{31}P NMR [except α-$Na_{12}(As_2W_{15}O_{56})$].[14,16−18,31] Elemental analyses of As, Fe, Mn, Na, P, and W were performed by Kanti Labs (Mississauga, Canada). Infrared spectra were recorded with a Perkin−Elmer Spectrum One and Nicolet 510 FT-IR instruments. All electrochemical measurements were performed with an EG and G 273A apparatus under computer control (M270 software). Potentials are quoted against a saturated calomel electrode (SCE). ^{31}P NMR measurements were made with a Varian INOVA 400 MHz spectrometer, and peaks were referenced to 85% H_3PO_4. Thermal analyses were performed with an ISI TGA 1000 and used to confirm the number of water molecules per POM.

X-ray Crystallography: Suitable crystals of Na**2**, Na**4**, and Na**5** were coated with Paratone N oil, suspended on a small fiber loop and placed in a cooled nitrogen stream at 100 K on a Bruker D8 SMART APEX CCD sealed tube diffractometer with graphite-monochromated Mo-K_α (0.71073 Å) radiation. A sphere of data was measured using a series of combinations of φ and ω scans with 10 s frame exposures and 0.3° frame widths. Data collection, indexing, and initial cell refinements were handled using SMART software.[32] Frame integration and final cell refinements were carried out using SAINT software.[33] The final cell parameters were determined from least-squares refinement. The SADABS program was used for absorption corrections.[34] The structures were solved by Direct Methods and difference Fourier techniques.[35] All atoms were refined anisotropically, except where noted (see data deposited in the crystal structure data base). The scattering factors and anomalous dispersion corrections were taken from the International Tables for X-ray Crystallography.[36] Additional details for Na**5** (Table 1) and polyhedral representations of Na**2**, Na**4**, and Na**5** (Figure 2) are given here (see crystallographic details for Na**2** and Na**4** and additional refinement information for Na**2**, Na**4**, and Na**5** deposited in the data base). Further details of the crystal structure investigations may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany on quoting depository numbers CSD-380223 (Na**2**), -380224 (Na**4**), and -380225 (Na**5**).

Synthesis of $\alpha\alpha\alpha\alpha$-$H_2Na_{14}[(NaOH_2)_2Fe_2^{III}(As_2W_{15}O_{56})_2]\cdot 54H_2O$ (Na2) and $\alpha\alpha\beta\alpha$-$Na_{14}(NaOH_2)(Fe^{III}OH_2)Fe_2^{III}(As_2W_{15}O_{56})_2]\cdot 55H_2O$ (Na4): α-$Na_{12}(As_2W_{15}O_{56})$ (22.3 g, 5 mmol) was slowly added, with stirring, to a solution of $FeCl_2\cdot 4H_2O$ (1.96 g, 9.86 mmol) dissolved in NaCl solution (120 mL, 1 M). The resulting dark green solution was heated to 65 °C for 15 min, filtered hot, and cooled to 4 °C overnight. The crystals that formed were redissolved in deionized water (120 mL) and oxidized in air for one week at ambient temperature. A yellow-brown precipitate of Fe_2O_3 (determined by elemental analysis) was removed daily by filtration. NaCl (6 g) was then added, and the resultant additional yellow-brown precipitate was again filtered off. After 2−3 days, 2.56 g (yield 11%) of large, light-yellow crystals were collected and recrystallized from 0.5 M NaCl. IR (2% KBr pellet, 1000−400 cm^{-1}): $\tilde{\nu}$ = 947 (s), 871 (s), 831 (m), 724 (s), 519 (m), and 494 (w). $H_{114}As_4Fe_2Na_{16}O_{168}W_{30}$ (9097.5): calcd. Na 4.04, As 3.29, Fe 1.23, W 60.63; found Na 4.23, As 3.36, Fe 1.31, W 60.00. The filtrate was concentrated to approximately 70% of its original volume, and, after 2 days, 11 g (yield 48%) of a light yellow precipitate was collected by filtration. The precipitate was redissolved in 0.5 M NaCl to give diffraction-quality crystals. IR (2% KBr pellet, 1000−400 cm^{-1}): $\tilde{\nu}$ = 953 (s), 871 (s), 836 (m), 730 (s), 523 (m), and 494 (w). $H_{114}As_4Fe_3Na_{14}W_{30}O_{169}$ (9123.4): calcd. As 3.28, Fe 1.84, Na 3.53, W 60.45; found As 3.34, Fe 2.10, Na 3.85, W 59.60.

Synthesis of $\alpha\beta\beta\alpha$-$Na_{14}[(Mn^{II}OH_2)_2Fe_2^{III}(P_2W_{15}O_{56})_2]\cdot 8H_2O$ (Na5): $MnCl_2\cdot 4H_2O$ (1.38 g, 7 mmol) was slowly added to Na**1** (6.4 g, 0.7 mmol)[18] dissolved in a minimal amount of 0.5 M NaCl (pH adjusted to about 2 by 1 M NaOH). The initial light yellow-green solution turned dark red, and was then heated to 60 °C for 10 min. After 7−8 days, brown crystals formed (0.56 g, yield 10%). IR (2% KBr pellet, 1300−400 cm^{-1}): $\tilde{\nu}$ = 1085 (s), 1060 (w, sh), 1014 (w, sh), 941 (s), 918 (w), 890 (m), 816 (m), 776 (m), 734 (w) and 522

[22] αααα is used in the Wells−Dawson sandwich-type structural formulas to indicate the connectivity for the first cap-belt junction, the first and second belt-central M_4 junctions, and the second belt-cap junctions, respectively.
[23] In addition, the junctions between each trivacant POM and the central tetrameric unit in Na**1** (and Na**2**) differ from those in all previously known sandwich-type POMs derived from Wells−Dawson and B-Keggin units. For more information on α- and β-junctions in Wells−Dawson sandwich-type structures, see ref.[16]

[25] It is unclear whether Na**3** and Na**4** can be considered monovacant lacunary species. Studies are now underway to react these complexes with other d-electron-containing metals (such as Cu^{II}, Mn^{II}, and Co^{II}) and will be reported in due course.
[26] Complexes Na**3** and Na**4** may be isolated during the synthesis of Na**1** and Na**2** via metastable tetraferrous intermediates and separated via fractional crystallization. Na**3** and Na**4** are also formed by adding one equivalent of Fe^{III} to a solution of Na**1** or Na**2**, respectively [$FeCl_3\cdot 6H_2O$ (0.049 g) was dissolved in water (10 mL) and added dropwise to Na**1** or Na**2** (20 mL 9 mM) with stirring and heating to 55 °C for about 15 min]. The former method is preferable due to higher yields.
[27] Bond valence sum calculations from the X-ray structures of Na**2** and Na**4** yield average Fe oxidation states of 3.00 ± 0.02 and 3.04 ± 0.02, respectively.[28]

Syntheses, Structure and Magnetic Properties of the First $\mu_{1,5}$-Dicyanamido-Bridged Dinuclear Compounds $[Ni(\mu_{1,5}\text{-dca})(dca)(dpt)]_2$ and $[Ni(\mu_{1,5}\text{-dca})(dca)(medpt)]_2$

Keywords: N ligands / Bridging ligands / Nickel / Magnetic properties

The first structural determination of dinuclear compounds with $\mu_{1,5}$-dicyanamide [dca, $N(CN)_2^-$] as bridging ligand has been achieved with the products of formula $[Ni(\mu_{1,5}\text{-dca})(dca)(dpt)]_2$ (**1**) and $[Ni(\mu_{1,5}\text{-dca})(dca)(medpt)]_2$ (**2**) [dpt = bis(3-aminopropyl)amine and medpt = bis(3-aminopropyl)methylamine]. The X-ray diffraction analysis reveals dinuclear compounds with double $\mu_{1,5}$-dicyanamide bridges. The nickel atoms are hexacoordinate. The small differences in the terminal ligand (dpt or medpt) create a drastic change in the magnetic behaviour: the susceptibility measurements of **1** show weak antiferromagnetic coupling ($J = -1.2$ cm^{-1}, $g = 2.29$) whereas those of **2** show ferromagnetic coupling ($J = 0.7$ cm^{-1}, $g = 2.17$). The related compound (μ-terephthalato)$[Ni(dca)(dpt)(H_2O)]_2$ (**3**) is also described. The X-ray diffraction analysis reveals a dinuclear terephthalato-bridged Ni^{II} compound with terminal dca ligands. The susceptibility measurements of **3** indicate weak antiferromagnetic coupling: $J = -0.3$ cm^{-1}, $g = 2.13$.

Introduction

The dicyanamide ligand [dca, $N(CN)_2^-$] has been extensively used during the last few years to generate a wide variety of polynuclear compounds of different topologies and magnetic properties: 3-D compounds of general formula $[M(dca)_2]$ which order magnetically as weak ferro- or antiferromagnets[1−5] and low-dimensional systems (2D or 1D) with general formula $[M(L)_x(dca)_2]_n$ showing weak antiferromagnetic coupling have been obtained.[5−14] Another way of synthesising 3D systems with general formula $[M(L)(dca)_2]$ is by using ancillary ligands such as pyrazine, 4,4′-bipyridine, pyrimidine and 2,2′-bipyrimidine in addition to the dicyanamido ligand.[15−21] The $[M(L)(dca)_2]$ (L = pyrazine) compound exhibits long-range magnetic-ordering below 2.53(2) K.[19] Surprisingly, structurally described dinuclear dca compounds are rare: as far as we know, no dinuclear compounds with $\mu_{1,5}$-dicyanamide bridging ligands have been reported to date. Following our work in this field, we report in this paper the synthesis and magnetostructural characterisation of the first dinuclear $\mu_{1,5}$-dca derivatives with formula $[Ni(\mu_{1,5}\text{-dca})(dca)(dpt)]_2$ (**1**) and $[Ni(\mu_{1,5}\text{-dca})(dca)(medpt)]_2$ (**2**) with double dca bridges.

Alternating chains can be obtained by using two different bridging ligands. We have used this strategy successfully with azido and oxalate.[22,23] Similar attempts using dca and oxalate were unsuccessful, but in an attempt to obtain a mixed dca-terephthalato Ni^{II} chain the dinuclear compound (μ-terephthalato)$[Ni(dca)(dpt)(H_2O)]_2$ (**3**) was obtained. Here the terephthalato anion acts as a bridging ligand between two nickel atoms, whereas the dca anions act as terminal ligands. Susceptibility measurements indicate weak antiferromagnetic coupling for **1** and **3**, while for **2** weak ferromagnetic coupling is shown. The ferromagnetic coupling in low dimensional polynuclear compounds with $\mu_{1,5}$-dicyanamide bridging ligands is rare: it has been found in the sheet-like polymer of formula $[Cu(\mu_{1,5}\text{-dca})_2(phen)]_n$ and has been attributed to a case of accidental orthogonality between the magnetic orbitals.[24]

Results and Discussion

Crystal Structures

$[Ni(\mu_{1,5}\text{-dca})(dca)(dpt)]_2$ (1)

A labelled ORTEP plot of the structure of $[Ni(\mu_{1,5}\text{-dca})(dca)(dpt)]_2$ (**1**) is shown in Figure 1. Selected bond lengths and angles are reported in Table 1. The structure of the compound consists of dinuclear units of nickel atoms bridged by means of double end-to-end dicyanamide bridges. Each nickel atom is hexacoordinate, with a coordination polyhedron close to octahedral. Hexacoordination is achieved by means of three N atoms belonging to the dpt ligand in a *mer* disposition, two N atoms from the bridging dicyanamide ligands, and one N atom from the terminal dicyanamide ligand. The Ni−N distances are in the range 2.082(5) −2.217(3) Å. Bond angles related to the dicyanamide bridging ligands are Ni(1)−N(7)−C(9) and Ni(1)−N(9)−C(10) of 157.4(3)° and 155.3(3)°, respectively, with a central C(10)−N(8)−C(9) angle of 117.0(3)°. The intradimer Ni−Ni distance is 7.270(3) Å.

$[Ni(\mu_{1,5}\text{-dca})(dca)(medpt)]_2$ (2)

A labelled ORTEP plot of the structure of $[Ni(\mu_{1,5}\text{-dca})(dca)(medpt)]_2$ (**2**) is shown in Figure 2. Selected bond lengths and angles are reported in Table 2. The crystal structure of complex **2** is similar to **1**: dinuclear units of nickel atoms bridged by means of double end-to-end dicyanamide bridges. The Ni−N distances are in the range 2.071(3)−2.176(3) Å. Bond angles related to the dicyanamide bridging ligands are Ni−N(4)−C(8) and Ni−N(5)−C(9) of 165.1(3)° and 151.2(3)°, respectively, with a central C(8)−N(8)−C(9) angle of 122.2(4)°. The Ni−Ni intradimer distance is 7.520(3) Å. The same Ni−Ni intradimer distance is 0.25 Å shorter in **1** due to a lower central NCN(dicyanamide) angle [117.0(3)°]. For comparative purposes, the intermetallic separation inside the dinuclear unit in **2** is about 0.2 Å longer than the values detected in polymeric networks. In fact, in three topologically different structures the distance between Ni ions bridged by two dca ligands ranges from 7.310 to 7.364 Å, as documented in a layered framework, in a ladder-like 1D polymer,[25] and in a molecular tube-like structure.[26]

(μ-terephthalato)[Ni(dca)(dpt)(H_2O)]$_2$ (3)

A labelled ORTEP plot of the structure of (μ-terephthalato)[Ni(dca)(dpt)(H_2O)]$_2$ is shown in Figure 3. The structure of the compound consists of dinuclear units in which the nickel atoms are bridged by the terephthalato ligand. Each nickel atom is hexacoordinate, with a coordination polyhedron close to octahedral. Hexacoordination is achieved by means of three N atoms belonging to the dpt ligand, one oxygen atom from the monodentate carboxylato ligand, one oxygen atom from the water molecule and, finally, one N atom from the terminal dicyanamido ligand. The bond lengths to the nickel atom are in the range 2.062(7)−2.097(6) Å except the relatively long Ni−O(water) of 2.186(5) Å. The bond angles related to the dicyanamido ligand are in the normal range for this ligand [Ni−N(4)−C(7) = 168.3(10)°], with a central C(7)−N(5)−C(8) angle of 121.4(10)°. The Ni···Ni intradinuclear distance is 11.379(10) Å (Table 3).

Magnetic Properties

A plot of $\chi_M \cdot T$ vs. T for **1** in the temperature range 245−2 K is shown in Figure 4. The overall behaviour of **1** corresponds to an antiferromagnetically coupled system. $\chi_M \cdot T$ has a practically constant value of 2.59 $cm^3 \cdot K \cdot mol^{-1}$ in the range 245−60 K. In the 60 −2 K range, $\chi_M \cdot T$ decreases quickly, reaching 1.19 $cm^3 \cdot K \cdot mol^{-1}$ at 2 K. The magnetic data of **1**, in agreement with its dinuclear structure, were analysed by means of an analytical expression based on the Hamiltonian $H = -J S_1 S_2$ for local spin values $S = 1$. The best fit parameters were $J = -1.2(1)$ cm^{-1} and $g = 2.29(1)$ (Figure 4). Alternatively, the magnetic data of **1** were analysed by considering a non-coupled Ni^{II} mononuclear compound by using an equation[27] that considers only non-interacting $S = 1$ ions in the presence of a single ion anisotropy. The best fit is given by the parameters $D = -10.9(1)$ cm^{-1} and $g = 2.16(1)$. The reliability factors are similar in both cases: 1.5×10^{-4} and 9.8×10^{-4}, respectively. Compound **1** can be considered, according to these data, as a practically non-coupled Ni^{II} compound.

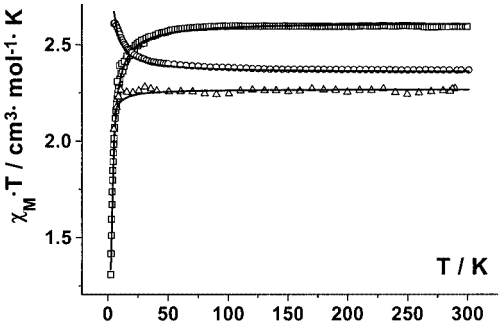

Figure 4. Plot of $\chi_M \cdot T$ vs. T for compounds [Ni($\mu_{1,5}$-dca)(dca)(dpt)]$_2$ (**1**) (open squares), [Ni($\mu_{1,5}$-dca)(dca)(Medpt)]$_2$ (**2**) (open circles) and (μ-terephthalato)[Ni(dca)(dpt)(H_2O)]$_2$ (**3**) (open up triangles); the solid line shows the best fit of the data (see text)

A plot of $\chi_M \cdot T$ vs. T for **2** in the temperature range 300−5 K is shown in Figure 4. The overall behaviour of **2** corresponds to a ferromagnetically coupled system. $\chi_M \cdot T$ has a value of 2.37 $cm^3 \cdot K \cdot mol^{-1}$ at room temperature and increases as the temperature decreases, reaching 2.61 $cm^3 \cdot K \cdot mol^{-1}$ at 5 K. The increase of the $\chi_M \cdot T$ product when T decreases is a clear evidence of a positive J value more important than the ZFS contribution. The magnetic data of **2**, in accordance with its dinuclear structure, were analysed by means of an analytical expression based on the Hamiltonian $H = -J S_1 S_2$ for local spin values $S = 1$. The best fit parameters were $J = 0.7(1)$ cm^{-1} and $g = 2.17(1)$ (Figure 4). In a previous work[10] we concluded from extended Hückel MO calculations that the dicyanamide $\mu_{1,5}$ bridge possesses two superexchange pathways: t_{2g}-π_y-t_{2g} and e_g-σ-e_g. The t_{2g}-π_y-t_{2g} pathway leads always to weak antiferromagnetically coupled systems, but in cases where this pathway is not active (d^8 and d^9 ions) there exists the possibility of accidental orthogonality via the e_g-σ-e_g pathway for M−N−C(dicyanamide) angles around 160°. The positive J value found in **2** is the first experimental evidence of the above proposal in a dinuclear compound.

A plot of $\chi_M \cdot T$ vs. T for **3** in the temperature range 300−5 K is shown in Figure 4. The overall behaviour of **3** corresponds to an antiferromagnetically coupled system. χ_M·T has a practically constant value of 2.26 $cm^3 \cdot K \cdot mol^{-1}$ in the range 300−15 K. In the 15−5 K range, $\chi_M \cdot T$ decreases, reaching 2.06 $cm^3 \cdot K \cdot mol^{-1}$ at 5 K. The magnetic

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

data of **3**, in accordance with its dinuclear structure, were analysed by means of an analytical expression based on the Hamiltonian $H = -J S_1 S_2$ for local spin values $S = 1$. The best-fit parameters were $J = -0.3(1)$ cm^{-1} and $g = 2.13(1)$ (Figure 4). The very weak J value for **3** is in accordance with the previously published experimental data and MO calculations which conclude that the terephthalate bridge is not a suitable bridging unit to mediate significant exchange coupling.[28]

Experimental Section

[Ni(μ$_{1,5}$-dca)(dca)(dpt)]$_2$ (1): Na[N(CN)$_2$] (13.6 mmol in 30 mL of water), $(C_2H_5)_4NCl\cdot H_2O$ (13.6 mmol in 30 mL of water) and, drop by drop, dpt (6.8 mmol in 10 mL of water) were added successively to a stirred solution of $Ni(NO_3)_2\cdot 6H_2O$ (6.8 mmol in 50 mL of water). Finally a mixture of isophthalic acid (6.8 mmol in 30 mL of water) and NaOH (13.6 mmol in 15 mL of water) was added. The resulting blue solution was left to stand in the air. Blue crystals of **1** suitable for X-ray determination were formed over two weeks. $C_{20}H_{34}N_{18}Ni_2$ (644.0): calcd. C 37.3, H 5.3, N 39.1; found C 37.4, H 5.5, N 39.5.

[Ni(μ$_{1,5}$-dca)(dca)(medpt)]$_2$ (2): Bis(3-aminopropyl)methylamine (Medpt; 1 mmol) was added dropwise to an aqueous solution (10 mL) of $Ni(ClO_4)_2\cdot 6H_2O$ (1 mmol) with constant stirring. A solution of Na[N(CN)$_2$] (2 mmol of) in water (10 mL) was added and a bluish-violet precipitate formed immediately. The reaction mixture was stirred for 30 min and then filtered. After a few days deep bluish-violet single crystals of complex 2 suitable for X-ray diffraction were obtained from the filtrate. $C_{22}H_{38}N_{18}Ni_2$ (672.1): calcd. C 38.28, H 5.66, N 37.49; found C 38.42, H 5.37, N 37.91.

(μ-Terephthalato)[Ni(dca)(dpt)(H$_2$O)]$_2$ (3): Sodium terephthalate (0.723 g, 3.4 mmol in 20 mL of water), Na[N(CN)$_2$] (0.612 g in 20 mL of water), $(C_2H_5)_4NCl\cdot H_2O$ (1.262 g, 6.9 mmol in 20 mL of water) and dpt (0.451 g in 10 mL of water) were added successively to a stirred solution of $Ni(NO_3)_2\cdot 6H_2O$ (1 g, 3.4 mmol) in 30 mL of water. The resulting blue solution was left to stand in the air. Blue crystals of **4** suitable for X-ray determination were formed over ten days. $C_{10}H_{18}N_{10}Ni$ (337.0): calcd. C 34.2, H 5.1, N 23.8; found C 33.9, H 5.3, N 23.7.

Spectral and Magnetic Measurements: Magnetic susceptibility measurements were carried out for **1** and **2** on polycrystalline samples with a SQUID apparatus working in the range 2−300 K for **1** and 5−300 K for **2** in a magnetic field of 0.5 T. Magnetic susceptibility measurements in the temperature range 4−300 K were carried out for **3** on polycrystalline samples with a pendulum-type magnetometer (MANICS DSM8) equipped with a helium continuous-flow cryostat and a Bruker B E15 electromagnet. The magnetic field was approx. 1.5 T. Diamagnetic corrections were estimated from Pascal tables.

Crystal-Structure Determination: The X-ray single-crystal data for **1** and [**3**] were collected on an Enraf−Nonius CAD4 four-circle diffractometer. Crystal size: 0.1 × 0.1 × 0.2 [0.1 × 0.1 × 0.2] mm. The crystallographic data, conditions used for the intensity data collection, and some features of the structure refinement are listed in Table 4. Graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) with the ω/2θ technique was used to collect the data sets for **1** and **3**. The accurate unit-cell parameters were determined from automatic centring of 25 reflections, $12 < \theta < 21°$, [25 reflections, $12 < \theta < 21°$] and refined by least-squares methods. 4147 [4740] Reflections were collected in the range $2.67° < \theta < 31.96$ [$2.16° < \theta < 30.15°$]. 1878 [1758] reflections were assumed as observed applying the condition $I > 2\sigma(I)$. Corrections were applied for Lorentz-polarization effects, and for intensity decay during data reduction processing. The structures were solved by direct methods, using the SHELXS[29] computer program, and refined by full-matrix least-squares methods with the SHELXL-97[30] computer program using 4147 [4740] reflections (very negative intensities were not assumed). The function minimised was $\Sigma w| |F_o|^2 - |F_c|^2|^2$, where $w = |\sigma^2(I) + (0.0196\ P)^2|^{-1}$ and $P = (|F_o|^2 + 2|F_c|^2)/3$ for **1** and $w = |\sigma^2(I)|^{-1}$ for **3**. $P = (|F_o|^2 + 2|F_c|^2)/3$. f, f' and f'' were taken from the International Tables of X-ray Crystallography.[31]

For compound **1** sixteen hydrogen atoms were computed and refined, by using a riding model, with an isotropic temperature factor equal to 1.2-times the equivalent temperature factor of the atom to which they are linked. For **3** all H atoms were computed and refined, using a riding model, with an isotropic temperature factor equal to 1.2-times the equivalent temperature factor of the atom to which are linked. Number of refined parameters: 202 [199]. Maximum and minimum peaks in the final difference synthesis: 0.537 and −0.500 e·Å^{-3} [0.536 and −0.497 e·Å^{-3}]. Significant bond parameters are given in Tables 1 and 3, respectively. For compound **2** data collection was carried at 293(3) K using Mo-K_α radiation (λ = 0.71073 Å) on a Nonius DIP-1030H system (30 frames exposure time of 15 min with a rotation of 6° about , detector being at a distance of 90 mm from the crystal). Crystal size 0.35 × 0.35 × 0.40 mm. Cell refinement, indexing and scaling of the data set were carried out using Mosflm and Scala.[32] 191 Parameters and 4746 reflections, 2880 unique of which 2545 with $I > 2\sigma(I)$. The structure was solved by Patterson and Fourier analyses and refined by the full-matrix least-squares method based on F^2 with all observed reflections.[33] All the calculations were performed using the WinGX System, Ver 1.64.[34] Maximum and minimum peaks in the final difference synthesis: 0.543 and −0.511 e·Å^{-3}. Selected bond parameters are given in Table 2.

Table 4. Crystal data and structure refinement for [Ni(μ$_{1,5}$-dca)(dca)(dpt)]$_2$ (**1**), [Ni(μ$_{1,5}$-dca)(dca)(medpt)]$_2$ (**2**), and (μ-terephthalato)[Ni(dca)(dpt)(H$_2$O)]$_2$ (**3**)

Synthesis and Conformational Studies of a Chiral Octadentate Ligand Derived from (*R*)-1,1′-Binaphthyl-2,2′-diamine and its Dinuclear Zinc(II) and Nickel(II) Complexes

Maria Chiara Mimmi,[a] Michele Gullotti,*[a] Laura Santagostini,[a] Roberto Pagliarin,[b] Luca De Gioia,[c] Enrico Monzani,[d] and Luigi Casella[d]

Keywords: N ligands / Zinc / Chirality / Conformational analysis / Nickel

The synthesis of the octadentate ligand (*R*)-(–)-*N*,*N*′-dimethyl-*N*,*N*′-bis{3-[bis(1-methyl-2-benzimidazolylmethyl)]-aminopropyl}-1,1′-binaphthyl-2,2′-diamine (**L**), containing a central 1,1′-binaphthalenediamine core connected to two aminobis(benzimidazole) arms by flexible trimethylene carbon chains, and its dinuclear complexes $[Zn_2\mathbf{L}](ClO_4)_4$ and $[Ni_2\mathbf{L}](ClO_4)_4$ is reported. The structural features of the free ligand and the metal complexes have been investigated by NMR, UV/Visible, CD, and computational methods, including simulated annealing-molecular mechanics and semiempirical PM3 calculations. The preferred conformation of the free ligand is characterized by a relatively small dihedral angle of about 75° between the two naphthyl rings, which is imposed by favorable stacking interactions between benzimidazole rings from different arms. In the dinuclear zinc(II) complex each metal ion is pseudotetrahedral and bound to three N donors of one aminobis(benzimidazole) arm and one N donor of the binaphthalenediamine residue. Coordination of the benzimidazole groups to the metal ions prevents the stacking interactions seen in the free ligand and, consequently, the dihedral angle between the naphthyl groups increases to the more usual ca. 90°. In the dinuclear nickel(II) complex, the ligand still provides four nitrogen donors to each metal centers, but the stereochemical preference of the nickel(II) ions imposes a ligand field of tetragonal symmetry, with pseudo-octahedral metal centers, and this occurs with pronounced flattening of the dihedral angle between the naphthyl groups. The change in conformation, from **L** to $[Zn_2\mathbf{L}]^{4+}$ to $[Ni_2\mathbf{L}]^{4+}$, of the critical 1,1′-binaphthalenediamine residue is clearly indicated by CD spectra.

Introduction

Polydentate ligands carrying nitrogen donor atoms have been extensively used in the biomimetic chemistry of metal enzymes, particularly those depending on copper and associated with oxidative processes, which typically contain dinuclear or trinuclear metal centers.[1] Surprisingly, though, few of the various ligands studied contain chiral centers. This is partly because of the difficulties encountered in synthesizing such polyfunctional molecules, as illustrated by our attempt to prepare biomimetic ligands containing L-histidine residues.[2] Nonetheless, chiral centers add a new dimension and open up interesting perspectives for synthetic active site analogues of metal enzymes, such as the possibility to perform asymmetric transformations.

We have, in particular, studied various copper complexes with polyamino-polybenzimidazole ligands to simulate structural and functional properties of dioxygen-activating copper enzymes.[3] Suitable dinucleating ligands usually contain a set of six nitrogen donors to be evenly distributed between the metal ions, whereas for trinuclear complexes the ligand must bind the metal ions with a total of eight nitrogen donors. A simple way to introduce a chiral moiety into the ligand scaffold is to use the 1,1′-binaphthalene residue. Chiral complexes of 1,1′-binaphthyl ligands have been extensively used in asymmetric catalysis; the complexes of 1,1′-bis(2-naphthol) (BINOL) and 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthalene (BINAP)[4,5] are recent examples. In addition, the chiroptical properties and the conformations of 2,2′-homosubstituted 1,1′-binaphthyl derivatives have been studied in detail,[6,7] and useful correlations between CD spectra and solution conformation for these C_2-symmetric chromophores are available. We therefore designed the new chiral ligand **L**, in which an (*R*)-(+)-1,1′-

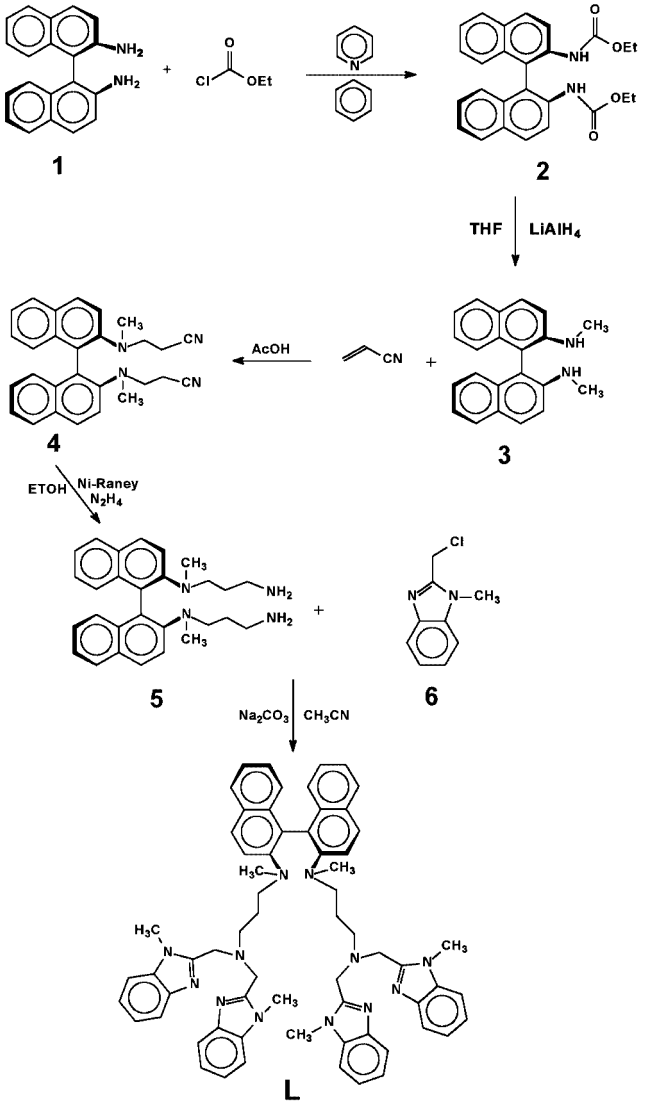
binaphthyl-2,2′-diamine residue acts as the spacer between two chelating arms containing tridentate aminobis(benzimidazole) donors (Scheme 1), and recently reported briefly that dinuclear and trinuclear copper(II) complexes derived from this ligand perform stereoselective catalytic oxidation of optically active diphenolic substrates.[8] We report here full synthetic details for the preparation of **L** and the conformational characterization of this new ligand and the corresponding dinuclear zinc(II) and nickel(II) complexes.



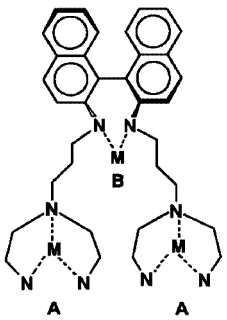
Scheme 1. Synthetic route for the preparation of ligand **L**

Results and Discussion

Synthesis

A particular challenge in the synthetic route to octadentate ligand **L** (Scheme 1) is to maintain an intact chiral moiety throughout the various reactions. To obtain a symmetric ligand containing a single arm attached to each nitrogen atom of the (*R*)-1,1′-binaphthyl-2,2′-diamine residue, compound **1** was initially derivatized with a double Benson-type monomethylation,[9] which gave the corresponding dicarbamate **2** in excellent yield (> 95%). The subsequent reduction using lithium aluminium hydride in anhydrous THF was also highly effective, since the *N*,*N*′-dimethyldiamine derivative **3** was isolated in high overall yield (> 70%). The diamine was then subjected to a Michael-type alkylation with acrylonitrile. This reaction was investigated under several conditions to avoid monoalkylation and/or oligomerization of the reagent. A good yield of the dialkylated compound proved difficult, but operating under nitrogen, and using acrylonitrile as solvent and a large excess of glacial acetic acid,[10] we obtained the dialkylated product **4** in > 80% yield. The pure compound was obtained by flash chromatography in 52% yield. The dicyano functionalities were reduced successfully to primary amines by reaction with Raney nickel and hydrazine hydrate in ethanol solution, and the resulting compound **5** was obtained in good yield (> 70%). Other reducing agents such as lithium aluminium hydride or sodium borohydride gave much poorer yields and formed by-products. Finally, the ligand **L** was obtained by condensation of an excess 2-(chloromethyl)-1-methylbenzimidazole, **6**,[11] with the diamine **5**. The use of *N*-methylated benzimidazoles increased the chemical stability of the resulting metal complexes in the oxidative reactions studied by us.[8]

The distribution of nitrogen donors of the ligand may allow one to obtain trinuclear metal complexes containing two equivalent metal coordination sites (**A**) within the tridentate units consisting of the aminobis(benzimidazole) residues and a third metal site at the binaphthalenediamine residue (**B**) (Scheme 2). This arrangement is adopted by the complex $[Cu_3\mathbf{L}]^{6+}$,[8] and reproduces the type of donor atom distribution among the metal centers in the trinuclear cluster of multicopper oxidases.[12] When the ligand **L** is used in a dinuclear complex several possibilities exist, according to the characteristics and stereochemical preferences of the metal ions, and the two sites may even result in non-equivalent coordination types. Since copper(II) is stereochemically flexible and a pair of Cu^{II} ions in close proximity can undergo electronic coupling interactions, unraveling the coordination environment of the two copper ions in $[Cu_2\mathbf{L}]^{4+}$ in solution[8] is difficult. The simplest situation occurs when the eight donor atoms of **L** are evenly distributed within the two metal ions (Scheme 3); a favored situation when the metal centers can adopt a tetrahedral geometry. Therefore, we anticipate that this structural ar-



Scheme 2. Proposed structure for the trinuclear complexes of **L**

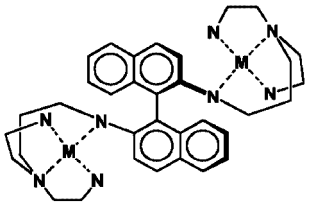
rangement will be present in the dinuclear zinc(II) complex $[Zn_2L]^{4+}$; the diamagnetism of this metal ion is also useful since it enables a thorough investigation in solution by NMR spectroscopy. Only the dinuclear complex was isolated when we attempted to obtain a trinuclear zinc(II) complex, even upon reacting **L** with a large excess of Zn^{2+} at such high temperatures as boiling DMF, indicating that zinc(II) behaves differently from copper(II) in binding to **L**. This suggests that the binaphthalene-diamine nitrogen donors in the dinuclear complex $[Zn_2L]^{4+}$ cannot be made available for binding a third metal ion. The investigation has been extended to the dinuclear nickel(II) complex $[Ni_2L]^{4+}$, since the structural preferences of nickel(II) differ from those of zinc(II) and, in general, are relatively easy to assess on spectroscopic grounds. To this end, the spectral characteristics of $[Ni_2L]^{4+}$ were compared with those of the mononuclear nickel(II) complex with the ligand *N*,*N*-bis[(2-*N*-methylbenzimidazol-2-yl)ethyl]benzylamine (**BzB**),[13] which essentially reproduces the tridentate donor set provided by the aminobis(benzimidazole) units present in each arm of **L**.



Scheme 3. Proposed structure for dinuclear complexes of **L** with metal ions in a tetrahedral geometry

NMR Experiments

Deuterated acetone was chosen as solvent for comparative NMR experiments between **L** and the zinc(II) complex because both compounds are sufficiently soluble in it, and the best peak resolution was obtained. The assignment of the ^1H and ^{13}C signals of **L** (Table 1) was based on the expected chemical shifts and *J*-coupling patterns, and was confirmed by two-dimensional NMR experiments (Figure 1). An unambiguous assignment of the particularly challenging aromatic resonances of the binaphthyl and benzimidazole residues was obtained from the combination of ^1H-^{13}C HMQC, ^1H-^1H COSY, DEPT135, and ^1H-^{13}C HMBC spectra. With an ^1H-^{13}C HMQC experiment all the direct connections between protons and carbons could be detected. Long-range correlation with the known methyl protons **g** allowed the assignment of the quaternary carbon **8** resonance; then proton **e** could be recognized by correlations with carbons **8** and **10**. Signals belonging to the benzimidazole residues could be assigned from the long-range correlation between carbon **16** and protons **k** and **l**. Similarly, long-range correlations among protons and quaternary carbons, combined with the ^1H-^1H COSY spectrum, led to the identification of all the aromatic signals.

The assignment of protons **g**, **k**, and **l**, respectively, correlated with carbons **11**, **15**, and **17**, is consistent with the signal intensities and with the analysis of the DEPT135 spectrum. Due to the chirality of the compound, the three pairs of geminal protons **h**, **h′**, **i**, **i′**, **j**, **j′** give rise to three pairs of multiplets. Despite the overlap of signals **g** and **h′**, the analysis of the ^1H-^{13}C HMQC spectrum clearly showed the correlation of protons **h** and **h′** to the same carbon. The diastereotopic proton pairs **i**, **i′**, **j**, **j′** are connected in the same fashion to carbons **13** and **14**. Interestingly, the geminal protons **k** exhibit a singlet peak.

The NMR spectra of **L** are strongly affected by the coordination of Zn^{2+} ions. When Zn^{2+} is added to the solution of **L** in a 1:1 stoichiometry, several isomeric species are formed, because the metal ion can bind in different coordination modes, and this gives a proton NMR spectrum dominated by broad, poorly defined envelopes as the result of many superimposed resonances. The addition of Zn^{2+} to the ligand in a 2:1 stoichiometry removes the coordinative vacancies and gives the dinuclear complex $[Zn_2L]^{4+}$ consisting of a single species. In the ^1H NMR spectrum, the broad envelopes are replaced by well-resolved peaks. Compared with the spectrum of the ligand, several signals undergo apparent splittings and many of them are shifted either downfield or upfield. Thus, the full assignment of the signals required the combination of one- and two-dimensional spectra (Figure 2). For the ^1H and ^{13}C NMR spectra

of the zinc complex (Table 2), as with **L**, the long-range correlations among protons and quaternary carbons combined with the $^1H-^1H$ COSY spectrum led to the identification of the signals of binaphthyl and benzimidazole residues. Analysis of the spectra of the cation $[Zn_2L]^{4+}$ gave many clues about the coordination mode of the Zn^{2+} ions, which is consistent with the computed structure of the complex (see below).

In general, the coordination of metal ions makes the ligand more rigid: consequently, in the complex $[Zn_2L]^{4+}$ there is no rapid exchange of nuclei and the signals of the methyl-benzimidazoles residues are split into two sets of resonances. As reported by Quiroz-Castro et al.,[14] the shift to higher frequencies of the **k** and **q** methylene groups indicates that the tertiary amine nitrogen atom is bonded to the metal center. The coordination of each Zn^{2+} ion with two benzimidazole *N*-donors is consistent with the downfield shift of the resonances of protons **m**, **n**, (at δ = 7.78, 7.35 ppm) and **s**, **t**, (7.90, 7.29) when compared with the corresponding protons **m** and **n** of the free ligand (at δ = 7.47, 7.26 ppm). Conversely, protons **o**, **p**, **u**, **v** undergo highfield shifts that can be explained by considering the computed structure of the complex. In fact, coordination of Zn^{2+} brings the aromatic protons **m**, **n**, **s**, **t** to an outer position with respect to the core of the molecule, while protons **o**, **p**, **u**, **v** occupy an inner position, where they are shielded by the aromatic binaphthyl residue.

The coordination of each Zn^{2+} ion to one naphthylamino nitrogen donor is shown by the downfield shift of all the ^1H signals of the naphthyl residue, with the strongest effect on proton **d** ($\Delta\delta = +0.34$, with respect to the free ligand), and on carbon **8** ($\Delta\delta = +1.2$). Interestingly, the two naphthylamine fragments still give a unique set of signals as for the free ligand: probably, the mobility of the molecule averages the signals in the dinuclear complex. Finally, the aliphatic chain with the carbon skeleton indicated as **12**, **13**, **14** undergoes some important modifications: strong positive shielding effects are observed on carbon **12** ($\Delta\delta = -3.5$ ppm) and on **h** and **h′** multiplets ($\Delta\delta = -0.66$ and -0.61 ppm, respectively), as well as on **j** and **j′** multiplets (-0.65 and -0.56, respectively), while a slight positive shielding effect occurs on carbon **13** ($\Delta\delta = -0.3$ ppm) and on **i** and **i′** multiplets (-0.47 and -0.33, respectively), and a deshielding effect is observed on carbon **14** ($+2.8$). The Δδ between geminal protons of these groups increases; the strongest effect is for the **i**, **i′** multiplets (Δδ of $+0.33$). The reported values arise from the opposing effects of coordination to a metal ion and interaction with the positive shielding zone of the binaphthalene and benzimidazole rings.

The proton NMR spectra of both $[Ni_2L]^{4+}$ and $[Ni(\mathbf{BzB})]^{2+}$ exhibit paramagnetically shifted resonances up to about 90 ppm (Figure 3). This precludes the metal centers having a four-coordinate, square-planar coordination environment as this would result in a diamagnetic species. The broad peaks downfield indicate an orbitally nondegenerate ground state, with excited states well separated in energy, for both complexes. This can occur with six-coordinate (pseudo-octahedral) or five-coordinate (both TBP and SP) nickel(II) complexes. By contrast, pseudo-tetrahedral nickel(II) complexes exhibit sharper NMR resonances due to fast electronic relaxation caused by the low energy excited states originating from the orbitally degenerate $^3T_1$ ground state of a pure tetrahedral symmetry.[15] Furthermore, in pseudo-tetrahedral nickel(II) complexes, the dipolar and spin polarization contributions to the paramagnetic shift generates both downfield and upfield shifts in the NMR resonances. The spectrum of $[Ni(\mathbf{BzB})]^{2+}$ exhibits sharper NMR lines than that of $[Ni_2L]^{4+}$, and also some upfield signals. The whole spectrum resembles those of five-coordinate, trigonal bipyramidal, nickel(II) complexes,[16] in which an unpaired electron in the equatorial plane accounts for the moderately intense spin-polarization and dipolar contributions. The donor groups for nickel(II) in $[Ni(\mathbf{BzB})]^{2+}$ are the two benzimidazoles, the central amine and two solvent molecules, as in structurally characterized copper(II) complexes with related aminobis(benzimidazole) ligands.[17] On the other hand, the NMR spectrum of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

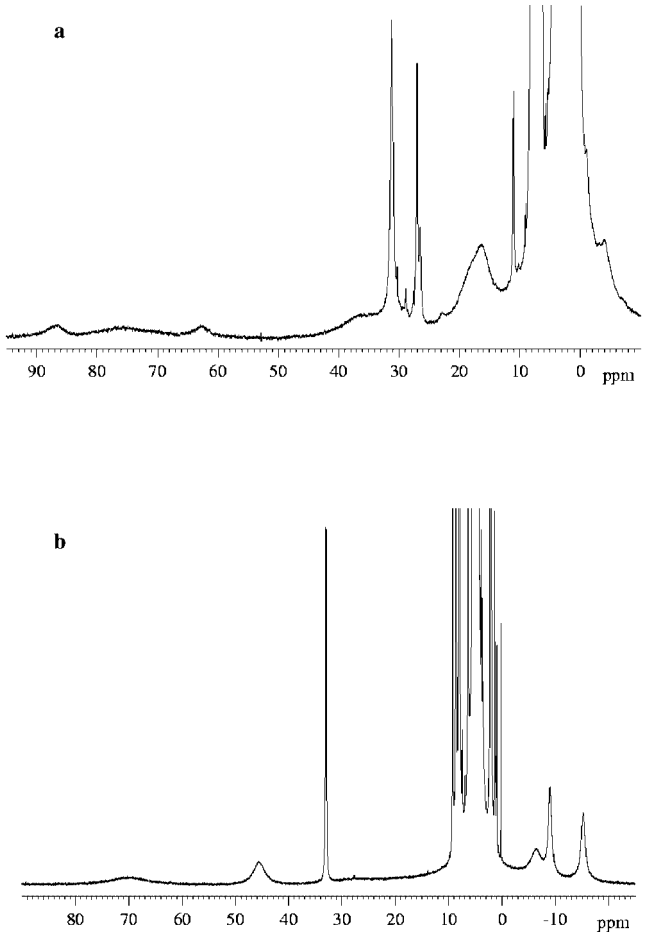

Figure 3. Paramagnetic NMR spectra recorded in [D_6]acetone solution at 25 °C of (a) $[Ni_2\mathbf{L}]^{4+}$ and (b) $[Ni(\mathbf{BzB})]^{2+}$ complexes

$[Ni_2\mathbf{L}]^{4+}$ shows essentially downfield shifts, indicating that the Fermi-contact is the predominant contribution to the paramagnetic NMR shifts. This situation is characteristic for electron configurations with a nondegenerate ground state, with unpaired electrons in σ-type d orbitals, as it occurs in six-coordinate, pseudo-octahedral or tetragonally distorted nickel(II) complexes.[15] The difference in metal coordination environment observed for $[Ni_2\mathbf{L}]^{4+}$ with respect to $[Ni(\mathbf{BzB})]^{2+}$ clearly arises from the additional binding of the binaphthalenediamine nitrogen donors in the former complex, which provide the tetragonal equatorial field for each metal ion.

Optical and CD Spectroscopy

The electronic spectrum of **L** consists of transitions associated with both the 1,1′-binaphthyl and the benzimidazole chromophores. The former is mostly responsible for the absorptions at 305 and 258 nm, and the latter for the multicomponent bands at 286, 278, and 271 nm, while both chromophores contribute to the band at 352 nm and the intense absorption at highest energy.[7a,11] The CD spectrum of **L** is dominated by the features of the (*R*)-1,1′-binaphthyl moiety (Figure 4), and from a comparison with the pattern of CD bands of (*R*)-*N*,*N*,*N*′,*N*′-tetramethyl-[1,1′-binaphthalene]-2,2′-diamine[7a] the replacement of a methyl group of each NMe_2 residue of the latter compound with the methylene chain carrying the aminobis(benzimidazole) arm in **L** clearly maintains the *cisoid* conformation (M helicity) of the naphthalene rings. This arrangement is determined by the steric hindrance between the amino substituents and the naphthyl group, which prevents their coplanar disposition maximizing conjugation of the nitrogen lone pair with the naphthalene ring.[7a]

In addition to the CD bands attributable to the binaphthyl chromophore, the CD spectrum of **L** displays a clearly defined positive peak at 248 nm (inset of Figure 4). This corresponds to a distinctive CD feature detected, or deduced from the CD lineshape, at 240 nm in the spectra of chain-bridged (*R*)-1,1′-binaphthyl derivatives.[7b] The latter feature, attributed to an inter-naphthalenic CT transition, witnesses that the dihedral angle between the naphthalene rings of the chromophore reduces to significantly below 90°.[7b] This unexpected arrangement for **L** is confirmed by the minimum energy conformation of the ligand resulting from the computations described below.

The CD spectrum of $[Zn_2\mathbf{L}]^{4+}$ is qualitatively similar to, though appreciably less intense than, that of the free ligand (Figure 4). Clearly, the M chirality of the (*R*)-1,1′-binaphthyl chromophore is maintained in the complex, but the spectrum lacks the distinctive positive CD peak at 248 nm which is present in the spectrum of **L**. This suggests that in the complex the dihedral angle between the naphthalene rings must increase to around 90°, which typically characterizes the conformation of unstrained 1,1′-binaphthyl chromophores.[7b] The decrease in intensity of the CD couplet, from **L** to $[Zn_2\mathbf{L}]^{4+}$, agrees with the increase in dihedral angle between the naphthalene rings.[6] The change in conformation undergone by the ligand on metal binding must be associated with the fact that the amino groups linked to the naphthalene rings are now involved in the coordination to the metal centers.

The reduction in CD amplitude of the exciton coupled binaphthalene transitions in the 210−230 nm range becomes drastic for the $[Ni_2\mathbf{L}]^{4+}$complex (Figure 4). Here, the ligand conformation must meet the coordination requirements of the metal ions, which tend to arrange the four nitrogen donor atoms in a nearly coplanar disposition. This apparently imposes a marked flattening of the dihedral angle between the naphthalene planes, as indicated by the much weaker intensity of the CD couplet.[6,7b] Also for $[Ni_2\mathbf{L}]^{4+}$ the CD spectrum has a positive peak in the 245 nm range, but the assignment to an intraligand transition is less certain, because LMCT transitions involving the Ni^{II} ions may occur in the same wavelength range. The optical and CD spectra of the $[Ni_2\mathbf{L}]^{4+}$complex exhibit additional weak absorptions in the visible region, which can be assigned to LF transitions. The reduced molar absorptivity observed in this range excludes pseudo-tetrahedral coordination, in agreement with the NMR spectrum of the complex. The LF spectrum (λ_{max} at 566 and 980 nm) is con-

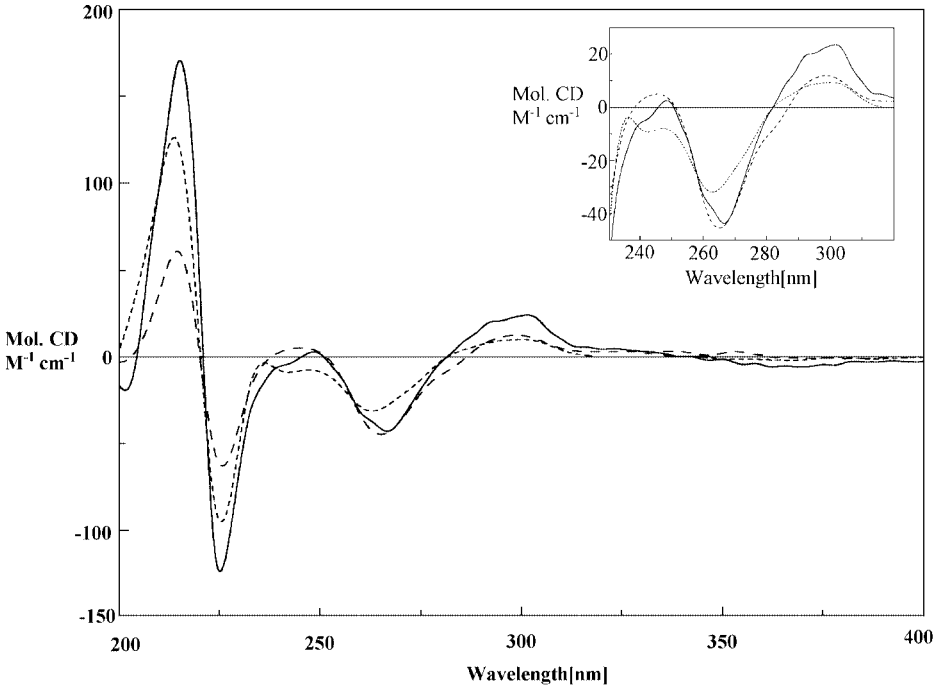

Figure 4. Circular dichroism spectra in CH_3CN solution of (—) **L**, (- - - -) $[Zn_2L]^{4+}$, and (– – –) $[Ni_2L]^{4+}$

sistent with six-coordinate, pseudo-octahedral metal centers,[18] which generally exhibit three absorption bands in the range 300−1200 nm. In the present case, the LF band at highest energy is clearly buried under the strong intraligand bands of **L**. The LF spectrum of $[Ni(\mathbf{BzB})]^{2+}$ contains absorptions of low intensity at 605, 920 and 1020 nm, which are consistent with a five-coordinate species and agree with the characteristics of the NMR spectrum. However, the optical spectrum cannot distinguish between trigonal bipyramidal and square-pyramidal configuration, due to the relatively high number of energy terms of the nickel(II) ion produced by even small geometric distortions from regular geometries.[19]

Computational Studies

Being unable to obtain crystals suitable for X-ray investigations, the structures of the ligand **L** and the binuclear complex $[Zn_2L]^{4+}$, for which the conformational preferences deduced from CD are more reliable, were investigated by simulated annealing (SA) molecular mechanics (MM) and semiempirical calculations (see Exp. Sect.). The best structures obtained are shown in Figure 5. In **L** the benzimidazole rings from different arms are involved in favorable stacking interactions and this forces the dihedral angle θ defining the conformation of the 1,1′-binaphthyl group to close to 75° (Figure 5, a). A very similar arrangement is observed in all the most stable **L** structures obtained by the computational procedure (θ = 77±4°). In the binuclear complex $[Zn_2L]^{4+}$ the benzimidazole rings are involved in Zn coordination. Both metal ions are in a slightly distorted tetrahedral environment, characterized by bond lengths ranging from 2.02 (Zn-*N*-benzimidazole) to 2.16 Å (Zn-*N*-binaphthyl). As a consequence of metal coordination, the benzimidazole rings fold around the two metal ions (Figure 5, b), which does not allow the stacking interactions observed in **L**, and relaxes the dihedral angle defining the conformation of the 1,1′-binaphthyl group to close to 90° (θ = 91±3°). In addition, the steric constraints imposed by the nitrogen ligand result in a distorted tetrahedral coordination geometry, suggesting that an extra ligand could bind to the metal forming a trigonal bipyramidal complex. To investigate this possibility we added a water molecule to the metal coordination environment and optimized the structure using semiempirical calculations. It turns out that a water molecule can bind (albeit weakly) to the metal center without affecting significantly the spatial disposition of the nitrogen ligands (data not shown). However, the slightly unfavourable reaction energy associated with its binding (0.2 kcal mol^{-1}) and the relatively long computed Zn−O distance (2.43 Å) indicate that it is more appropriate to consider the water molecule as only solvating the metal ion. Computed models of the $[Ni_2L]^{4+}$complex could not be investigated because the electronic structure of the metal ion

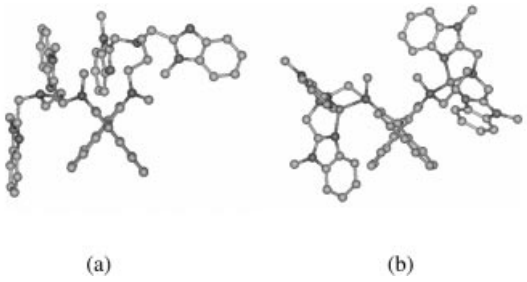

Figure 5. Best structures for **L** (a) and $[Zn_2L]^{4+}$ (b) as obtained by the combined SA-MM + PM3 procedure. Hydrogen atoms not shown for clarity

precluded reliable results with MM and semiempirical methods.

Conclusion

We have shown that (*R*)-1,1′-binaphthyl-2,2′-diamine provides a useful starting point for the synthesis of polyfunctional chiral ligands. The conformational features of the octadentate ligand **L** markedly change when it folds around the metal ions in the dinuclear zinc(II) and nickel(II) complexes. The spectroscopic and CD features of these complexes are consistent with the adoption of pseudo-tetrahedral structures for the zinc(II) centers and pseudo-octahedral structures for the nickel(II) centers. The stereochemical arrangement of the critical binaphthalenediamine portion of the molecule carrying the chiral unit can be clearly assessed on the basis of the CD spectra.

Experimental Section

Materials and Physical Methods: All reagents and solvents were obtained from commercial sources and used without further purification. The ligand *N*,*N*-bis[(2-*N*-methylbenzimidazol-2-yl)ethyl]-benzylamine (**BzB**) was synthesized according to a published procedure,[13] while the corresponding nickel(II) complex was prepared in situ by mixing equimolar amounts of the ligand and nickel(II) salt. Tetrahydrofuran was dried by refluxing and distilling from metallic sodium. Elemental analyses were performed at the microanalytical laboratory of the Chemistry Department in Milan. Optical rotations were obtained from a Perkin−Elmer 241 polarimeter at 25 °C using a quartz cell of 10 cm path length. Optical spectra were obtained with HP 8452A and 8453 diode array spectrophotometers. MS spectra were obtained from a VG 7070 EQ spectrometer. Circular dichroism (CD) spectra were recorded with Jasco J-500 or J-710 spectropolarimeters, using quartz cells of 0.01−2 cm path length. ^{1}H and ^{13}C NMR spectra were recorded with Bruker AC 300 or Bruker AVANCE 400 spectrometers operating at 7.03 and 9.37 T, respectively. For solubility reasons, comparative NMR studies of **L** and $[Zn_2\mathbf{L}](ClO_4)_4$ were performed on CD_3COCD_3 solutions. A concentrated solution of the complex was obtained by mixing solutions of the ligand **L** and $Zn(ClO_4)_2{\cdot}7H_2O$ in [D_6]acetone and stirring for a few min in the NMR tube. The paramagnetic NMR spectra of $[Ni_2\mathbf{L}]^{4+}$ and $[Ni(\mathbf{BzB})]^{2+}$ complexes were recorded in the same solvent at 25 °C; the spectral width was increased to 50000 Hz and the pulse length reduced to 3 μs.

Ligand Synthesis. (*R*)-(+)-*N*,*N*′-(Ethoxycarbonyl)-1,1′-binaphthyl-2,2′-diamine (2): Compound **2** was prepared in accordance with Benson et al.[9] Commercial (*R*)-(+)-1,1′-binaphthyl-2,2′-diamine, **1**, (2.0 g, 7.19 mmol) was dissolved in benzene (25 mL) and pyridine (5 mL, 62.14 mmol) under N_2 and cooled to 0 °C. A solution of ethyl chloroformate (1.8 mL, 18.89 mmol) in benzene (5 mL) was then added dropwise during 15 min. The mixture was subsequently warmed to room temperature and stirred for 2 h. The reaction, followed by TLC (silica gel) using light petroleum/ethyl acetate (8:2, v:v) as eluent, was then quenched by the addition of 2 N KOH (40 mL); the organic layer was separated, and the aqueous layer was extracted with benzene (3 × 20 mL). The organic layers were dried with Na_2SO_4 and the solvent was removed by rotary evaporation. After drying, a slightly pink powder was obtained, with sufficient purity for the subsequent reaction (yield 97%). $[\alpha]_D^{20}$ = +86.68 ($c = 4.28{\cdot}10^{-3}$, $CHCl_3$). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 1.18 (t, $J_{H,H}$ = 7.1 Hz, 6 H, CH_3), 4.1 (q, $J_{H,H}$ = 7.1 Hz, 4 H, CH_2), 6.28 (br., 2 H, NH), 6.98 (d, $J_{H,H}$ = 8.5 Hz, 2 H, CH), 7.24−7.30 (m, 2 H, CH), 7.41−7.46 (m, 2 H, CH), 7.94 (d, $J_{H,H}$ = 8.1 Hz, 2 H, CH), 8.08 (d, $J_{H,H}$ = 9.1 Hz, 2 H, CH), 8.57 (d, $J_{H,H}$ = 9.1 Hz, 2 H, CH) ppm.^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, TMS): δ = 14.7, 61.8, 117.8, 119.7, 125.2, 125.5, 127.7, 128.7, 130.7, 131.0, 132.9, 135.7, 154.0 ppm.

(*R*)-(+)-*N*,*N*′-Dimethyl-1,1′-binaphthyl-2,2′-diamine (3): $LiAlH_4$ (2.65 g, 69.83 mmol) was suspended in dry THF (40 mL) under N_2, and cooled to 0 °C. The dicarbamate **2** (2.71 g, 6.33 mmol) dissolved in dry THF (15 mL) was then slowly added via addition funnel, and the mixture was warmed and then refluxed for 24 h. The reaction was followed by TLC (silica gel) using light petroleum/ethyl acetate (8:2, v:v) as eluent. After cooling to room temperature, excess $LiAlH_4$ was quenched with MeOH (2 mL), NaOH 15% (2 mL), and finally water (2 mL). The resultant gray precipitate was filtered off through Celite and washed with diethyl ether. The filtrate and washings were combined and the solvent was removed by rotary evaporation under vacuum, giving a pale yellow solid. The crude compound was purified by silica gel flash chromatography using light petroleum/ethyl acetate (8:2, v:v) as eluent, furnishing a white compound in 72% yield. $[\alpha]_D^{20}$ = +182.82 ($c = 4.08{\cdot}10^{-3}$, $CHCl_3$). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 2.84 (s, 6 H, CH_3), 6.96−7.00 (m, 2 H, CH), 7.14−7.23 (m, 4 H, CH), 7.27 (d, $J_{H,H}$ = 8.9 Hz, 2 H, CH), 7.79−7.84 (m, 2 H, CH), 7.93 (d, $J_{H,H}$ = 8.9 Hz, 2 H, CH) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, TMS): δ = 32.1, 113.1, 114.5, 122.8, 124.4, 127.5, 128.6, 130.5, 134.3, 145.6 ppm. MS (70 eV, EI): *m*/*z* (%) = 312 (100) $[M]^+$.

(*R*)-(−)-*N*,*N*′-Dimethyl-*N*,*N*′-[bis(2-cyanoethyl)]-1,1′-binaphthyl-2,2′-diamine (4): Glacial acetic acid (7 mL, 12.24 mmol) was added to compound **3** (1.5 g, 4.80 mmol) dissolved in acrylonitrile (35 mL). The resulting mixture was then heated to reflux whilst stirring in a nitrogen atmosphere for 72 h. Some signs of polymerization were evident on heating, and the initial yellow solution turned brown. The reaction was followed by TLC (silica gel) using light petroleum/ethyl acetate (8:2, v:v) as eluent. Excess acrylonitrile was removed by rotary evaporation and the remaining residue was extracted with aqueous Na_2CO_3 and CH_2Cl_2. The organic layer was anhydrified with Na_2SO_4. After filtration, the solvent was removed by rotary evaporation to give a brown, oily product. Silica gel flash chromatography using light petroleum/ethyl acetate (8:2, v:v) as eluent afforded a light yellow product in 52% yield. $[\alpha]_D^{20}$ = −173.48 ($c = 6.60{\cdot}10^{-3}$, $CHCl_3$). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 1.46−1.70 (m, 4 H, CN-CH_2-CH_2-N), 2.80 (s, 6 H, CH_3), 2.80−2.89 (m, 4 H, CN-CH_2-CH_2-N), 7.12 (d, $J_{H,H}$ = 8.5 Hz, 2 H, CH), 7.23−7.29 (m, 2 H, CH), 7.38−7.43 (m, 2 H, CH), 7.55 (d, $J_{H,H}$ = 8.9 Hz, 2 H, CH), 7.90 (d, $J_{H,H}$ = 8.1 Hz, 2 H, CH), 7.98 (d, $J_{H,H}$ = 8.9 Hz, 2 H, CH) ppm. ^{13}C (75.5 MHz, $CDCl_3$, 25 °C, TMS) δ = 16.6, 41.2, 53.1, 118.9, 121.6, 125.4, 126.1, 127.6, 128.6, 129.9, 130.1, 131.2, 134.7, 148.9 ppm. MS (70 eV, EI): *m*/*z* (%) = 418 (100) $[M]^+$.

(*R*)-(−)-*N*,*N*′-Dimethyl-*N*,*N*′-bis[(3-aminopropyl)]-1,1′-binaphthyl-2,2′-diamine (5): Compound **4** (600 mg, 1.43 mmol) was dissolved in EtOH (30 mL) by heating to 60 °C. A water suspension of Ni-Raney (12 g) and $N_2H_4{\cdot}H_2O$ (8 mL, 257 mmol) was added and the mixture maintained at 60 °C. After 3 h, complete nitrile consumption was evident by TLC (silica gel); excess Ni-Raney was removed by filtration through Celite and the solvent distilled off under vacuum. The remaining residue was purified by silica gel flash chromatography eluting with CH_2Cl_2/*i*PrOH (60:40, v:v) and an increasing

amount of concentrated NH_3 (0 to 7%). A light yellow oil was obtained in > 70% yield. $[\alpha]_D^{20} = -95.11$ ($c = 1.00 \cdot 10^{-2}$, $CHCl_3$). ^1H NMR (300 MHz, $CDCl_3$, 25 °C, TMS) δ = 0.85−0.95 (m, 2 H, CH_2-CH_2-CH_2), 1.16−1.27 (m, 2 H, CH_2-CH_2-CH_2), 1.82−1.94 (m, 4 H, CH_2), 2.52−2.64 (m, 4 H, CH_2), 2.64 (s, 6 H, CH_3), 7.09−7.22 (m, 4 H, CH), 7.26−7.36 (m, 2 H, CH), 7.53 (d, $J_{H,H}$ = 8.3 Hz, 2 H, CH), 7.83−7.93 (m, 4 H, CH) ppm. ^{13}C NMR (75.5 MHz, [$CDCl_3$, 25 °C, TMS): δ = 32.0, 40.4, 40.8, 56.0, 121.9, 124.6, 126.6, 126.9, 128.5, 129.1, 131.0, 135.1, 151.2 ppm. MS (FAB): *m*/*z* (%) = 428 (100) $[M+1]^+$.

(*R*)-(−)-*N*,*N*′-Dimethyl-*N*,*N*′-bis{3-[bis(1-methyl-2-benzimidazolylmethyl)]aminopropyl}-1,1′-binaphthyl-2,2′-diamine (L): (*R*)-(−)-*N*,*N*′-Dimethyl-*N*,*N*′-bis[(3-aminopropyl)]-1,1′-binaphthyl-2,2′-diamine (**5**, 332.5 mg, 0.78 mmol) was dissolved in anhydrous acetonitrile (40 mL). 2-(Chloromethyl)-1-methylbenzimidazole (**6**)[11] (365.7 mg, 3.45 mmol) and dry sodium carbonate were then added and the stirred mixture was boiled under reflux for 6 h under N_2. The reaction was followed by TLC (silica gel) using CH_2Cl_2/MeOH (9:1, v:v), as eluent. The mixture was then cooled to room temperature and the so-obtained precipitate filtered off; it consisted of product and inorganic salts and thus was treated with $CHCl_3$ and filtered again. The combined filtrates were finally dried under vacuum to afford a yellow powder in 65% yield. $C_{64}H_{66}N_{12}\cdot 1.5CHCl_3$ (1182.34): calcd. (%) C 66.53, H 5.80, N 14.22; found C 66.41, H 5.90, N 14.21. $[\alpha]_D^{20} = -87.40$ ($c = 5.00 \cdot 10^{-3}$, $CHCl_3$). ^1H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.70−0.90 (m, 2 H, CH_2-CH_2-CH_2-N), 1.00−1.30 (m, 2 H, CH_2-CH_2-CH_2-N), 1.45−1.65 (m, 4 H, CH_2-CH_2-CH_2), 2.10−2.37 (m, 4 H, CH_2-*N*-binaphthyl), 2.37 (s, 6 H, CH_3-*N*-binaphthyl), 3.45 (s, 12 H, CH_3-*N*-benzimidazole), 3.51−3.64 (d, 8 H, CH_2-benzimidazole), 6.98−7.13 (m, 4 H, CH), 7.20−7.26 (m, 16 H, CH), 7.65−7.72 (m, 8 H, CH) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, TMS): δ = 24.1, 30.1, 40.1, 51.2, 52.2, 55.5, 109.4, 113.7, 120.0, 121.4, 122.4, 123.1, 124.3, 126.4, 126.5, 128.0, 128.6, 129.1, 129.6, 130.5, 134.6, 136.4, 142.4, 150.7, 151.7 ppm. MS (FAB): *m*/*z* (%) = 1003 (100) $[M+1]^+$. UV/Vis (CH_3CN): λ_{max} (ε) = 208 (239000), 258 (71000), 271 sh (54400), 278 sh (43500), 286 (32400), 305 sh (11900), 352 nm (6300 $mol^{-1}\cdot dm^3\cdot cm^{-1}$). CD ($CH_3CN$): λ_{max} (Δε) = 214 (+169.8), 225 (−124.5), 240 sh (−3.8), 248 (+2.7), 260 sh (−36.1), 266 (−44.7), 301 (+23.2), 368 nm (−5.9 $mol^{-1}\cdot dm^3\cdot cm^{-1}$).

Caution! *1,1′-Binaphthyl-2,2′-diamine derivatives are not stable in solution; after a few hours a deeper color orange is observed. These compounds should be kept dry and protected from light.*

Synthesis of the Metal Complexes. $[Zn_2L](ClO_4)_4$: A methanolic solution of $Zn(ClO_4)_2\cdot 7H_2O$ (0.038 mmol) (4 mL) was added dropwise to a solution of the ligand **L** (0.019 mmol) in $CHCl_3$/MeOH (1:5, v:v) (20 mL). The mixture was stirred for 3 h at room temperature, and then the solvent was removed by rotary evaporation. The residue was washed with a little water, filtered, and dried under vacuum. Elemental analysis for $C_{64}H_{66}Cl_4N_{12}O_{16}Zn_2$ (1530.14): calcd. (%) C 50.20, H 4.31, N 10.98; found C 50.33, H 4.41, N 10.95. UV/Vis (CH_3CN): λ_{max} (ε) = 220 sh (99000), 254 (46300), 264 (44400), 272 (43000), 280 (37200), 300 sh (10500), 350 nm (3000 $mol^{-1}\cdot dm^3\cdot cm^{-1}$). CD ($CH_3CN$): λ_{max} (Δε) = 213 (+122.5), 225 (−95.1), 240 sh (−8.2), 263 (−31.9), 298 (+9.3), 365 nm (−2.8 $mol^{-1}\cdot dm^3\cdot cm^{-1}$).

$[Ni_2L](ClO_4)_4\cdot 2H_2O$: This compound was prepared in a similar way as for the zinc complex, but using $Ni(ClO_4)_2\cdot 6H_2O$ as metal salt. A pale green precipitate was obtained after addition of the metal salt to the ligand solution. The complex was separated by centrifugation, washed several times with MeOH, and dried under vacuum. Elemental analysis for $C_{64}H_{66}Cl_4N_{12}Ni_2O_{16}\cdot 2H_2O$ (1552.77): calcd. (%) C 49.50, H 4.54, N 10.83; found C 49.22, H 4.63, N 10.78. UV/Vis (CH_3CN): λ_{max} (ε) = 222 sh (97800), 260 (67500), 272 (56800), 282 (42600), 304 (15300), 356 (5400), 566 (8), 980 nm (2 $mol^{-1}\cdot dm^3\cdot cm^{-1}$). CD ($CH_3CN$): λ_{max} (Δε) = 214 (+61.0), 225 (−63.2), 245 (+4.72), 265 (−45.8), 278 sh (−13.0), 298 (+11.7), 331 sh (+1.9), 373 (−2.6), 583 nm (−0.1 $mol^{-1}\cdot dm^3\cdot cm^{-1}$).

Caution! *Perchlorate complexes with organic ligands are potentially explosive and should be handled with great care. Only small amounts of material should be prepared. We had no problems working with the small amounts of perchlorate complex described here.*

Molecular Modelling: The structures of the ligand and the corresponding dinuclear zinc(II) complex were derived as follows. Starting structures were submitted to SA calculations carried out in vacuo over 200 ps, starting from 10 K, heating the system to 500 K in 80 ps, and then cooling it to 10 K in 110 ps. The time step was set to 1 fs. The final structures were optimized by MM calculations, using the conjugate gradient algorithm and requiring that the residual gradient of energy did not exceed 0.01 $kcal\cdot mol^{-1}\cdot Å^{-1}$. SA and MM calculations were carried out using the Universal Force Field.[20] This cycle was repeated 50 times both for the ligand and the dinuclear zinc(II) complex. The families of structures generated were clustered according to RMSD and ranked by relative energies. The conformers within 10 $kJ\cdot mol^{-1}$ above the computed global minimum conformation were further optimized by semiempirical calculations using the PM3 method.[21] All calculations were performed on a Silicon Graphics Indigo workstation using the software packages InsightII and Cerius2 [Biosym/MSI 9685, Scranton Road, San Diego, CA, USA].
